We will not dwell further on the events that led to the abandonment of the idea of transuranics in favor of nuclear fission,[4–6] nor shall we describe how *McMillan* and *Abelson*[7] eventually found element 93, neptunium, among the irradiation products of uranium with neutrons. It was identified as a β^--emitter with a half-life of 2.3 d but with chemical properties completely different from what was expected. Instead of eka-rhenium, an element closely related to uranium had been found. Nor shall we describe in much detail how, step by step, further elements were synthesized and identified.[8–10] From 1944 onwards this was pursued systematically according to the concept of 14 actinoid elements, formulated by *Seaborg*.[11] The basis of the idea is that an inner electron shell is being filled (5f subshell[12]) as in the case of the 14 lanthanoid elements (4f subshell). Today the elements thorium to uranium are placed in the rows under the main part of the periodic table (Fig. 2); this arrangement emphasizes the similarities between lanthanoid and actinoid elements.

What we shall do is to start again with eka-rhenium, which has the atomic number 107 in today's periodic table, i.e. with the element with which studies on the synthesis of new elements started at the heavy-ion-accelerator UNILAC (UNIversal Linear ACcelerator) designed by *Schmelzer*.[13] We shall report on the elements 107, 108, 109 and 110, and on the search for "superheavy" elements near 114. And we shall also look at the possibilities of extending the periodic system beyond today's limits: what can we

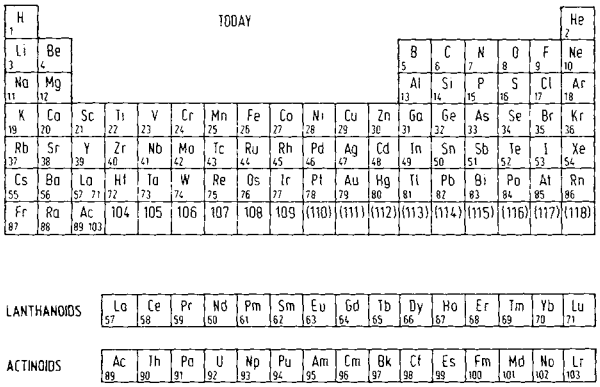

Fig. 2. The periodic table of the elements today. The atomic numbers of unknown elements are given in brackets.

expect with regard to the stability of even heavier atomic nuclei and the possibilities of their production?

2. Stability of the Heaviest Atomic Nuclei

A first impression of the stability of the heaviest nuclei can be obtained from Figure 3.[14] Starting with uranium, the half-lives of the longest-lived isotopes are shown as a function of their atomic number. The half-lives are shown separately for the two decay modes which are important here; α-decay (emission of helium-4 nuclei) and spontaneous fission into two fragments. Despite some fluctuations, the trend is obvious: for both decay modes the half-lives decrease exponentially with increasing atomic number, the respective slopes being different, however. For the lighter elements α-decay is by far the faster process. The

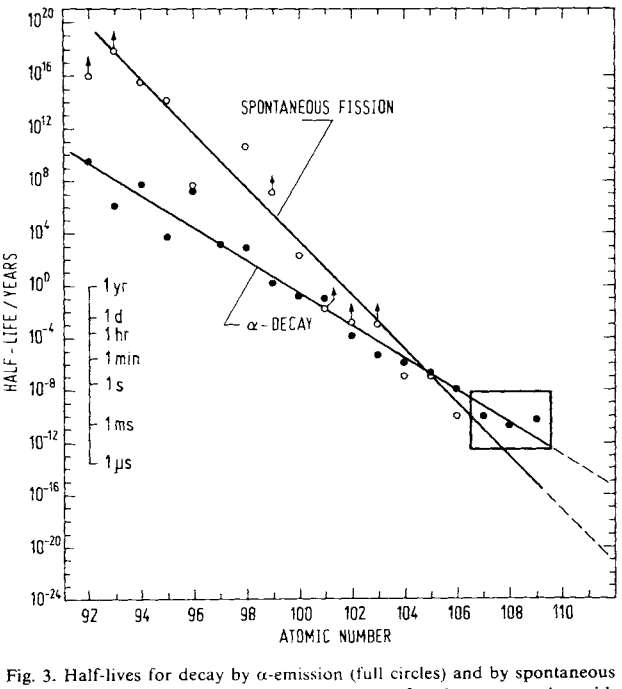

Fig. 3. Half-lives for decay by α-emission (full circles) and by spontaneous fission (open circles) versus the atomic number for elements starting with uranium [14]. The values for the most long-lived isotope for each element are given. The new elements reported on here are contained in a rectangle.

heavier the elements become, the stronger is the competition by spontaneous fission. If we ignore the elements 107 to 109, and just look at the situation as it was ten years ago, spontaneous fission would be expected to become the dominating decay mode near element 106. Close to element 115 the life-time of the nuclei would be as small as the period of their zero-point vibrations. This would be the end of the periodic table, because nuclear stability would cease to exist. This consequence was already noted in the first theoretical interpretations of nuclear fission[15, 16] based on the liquid-drop model of atomic nuclei.

Even today the liquid-drop model is still a strong conceptual basis for describing nuclear stability, or, in other words, for describing the binding energy of nuclei. The binding energy is the difference between the actual mass of a nucleus and the total mass of its constituents, the neutrons and protons. This is the amount of energy that would be released if the respective number of protons and neutrons were united to form a nucleus. The upper part of Figure 4 shows the various contributions to the binding energy within the framework of the liquid-drop model. For better comparison of the relative stability the energy is given in terms of binding energy per nucleon.

"surface energy" diminishes the binding energy, especially for light nuclei. In this case the binding energy decreases to about 8 MeV per nucleon. The binding energy decreases to this value also in the case of heavier nuclei, albeit for a different reason, namely because of the coulomb repulsion between the protons. The nuclear force increases only linearly with the proton number Z, whereas the "coulomb energy" increases quadratically. This effect is diluted for heavy nuclei because they contain up to 1.5 times more neutrons than protons which reduces the charge density. On the other hand, an increasing difference between the neutron and proton numbers results in a loss of binding energy ("asymmetry energy") due to a quantum mechanical effect. Thus, there is also a limit on the neutron excess. The binding energy per nucleon is finally the sum of all these contributions and has a maximum near the mass number 50. The region of most stable nuclei is near iron and nickel. This result is very important for the formation of the chemical elements in the cosmos by nuclear processes inside stars.

If one compares the experimental binding energies with the values calculated from the liquid-drop model, striking deviations are found for certain proton and neutron num-

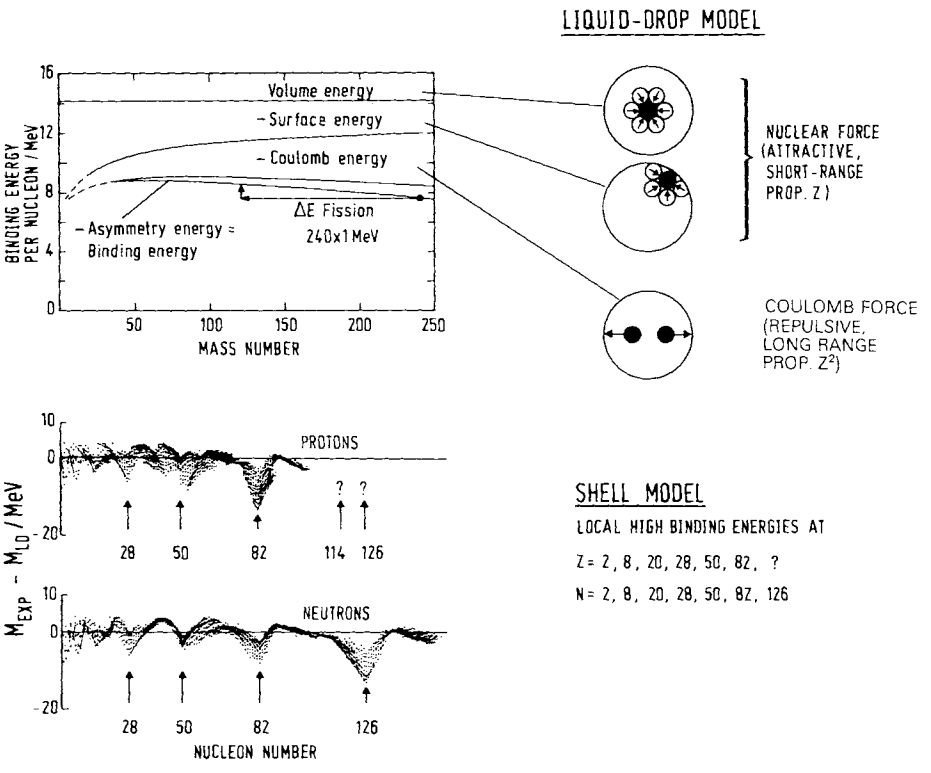

Fig. 4. Binding energy of nuclei according to the liquid-drop model of atomic nuclei and the influence of the shell structure. Top: the different components of the liquid-drop model in the binding energy per nucleon are shown as a function of mass number (after [17]). Starting with a constant volume energy, the surface, coulomb, and asymmetry energies are successively subtracted. Bottom: the difference between experimental nuclear masses and theoretical values obtained from the liquid-drop model are shown. Large differences occur at the "magic" proton and neutron numbers where nuclear shells are filled and strongly bound nuclei are found [18].

According to the liquid-drop model there are two large counteracting forces inside nuclei; the short-range, attractive nuclear force between the nucleons, and the long-range, repulsive coulomb force which acts only between protons. Each nucleon inside the nucleus interacts with the same number of nucleons via the nuclear force, and therefore adds a constant contribution to the binding energy. This "volume energy" is a constant of about 14 MeV per nucleon. The nucleons at the surface, however, have fewer neighbors, and contribute less to the binding energy; this

bers: the nuclei in certain vicinities are more stable than expected. The lower part of Figure 4 shows such a comparison on the basis of nuclear masses. This local stability is a consequence of nuclei being quantum-mechanical. Nuclei must also be viewed as an ensemble of nucleons with individual orbital and intrinsic angular momenta, as becomes evident in their nuclear spin. This recognition leads to a completely different kind of nuclear model, the shell model, in which certain nuclear properties are attributed to the motion of individual nucleons in a mean potential pro-

vided by all the other nucleons. The resulting nuclear energy levels can only be occupied by limited numbers of nucleons, as is also the case in electron shells, and when energetically favorable levels are exactly filled one obtains a gain in binding energy, the shell energy. For protons as well as for neutrons the nuclear shells contain the same "magic" numbers of nucleons: 2, 8, 20, 28, 50 and 82. In the case of neutrons there is an additional, experimentally verified, shell at neutron number 126; whether there is a corresponding proton shell will be discussed below. It can arise that both a proton and a neutron shell is filled for some nuclei; these doubly magic nuclei are characterized by an extremely high stability. One example is lead-208 with 82 protons and 126 neutrons.

The liquid-drop model demonstrates that the heaviest nuclei are unstable toward nuclear fission; *Meitner* and *Frisch*[19] realized this fact shortly after the discovery of nuclear fission. The binding energy per nucleon for a nucleus with 240 nucleons is about 1 MeV ($=1\times10^6$ eV) smaller than that for a nucleus with just 120 nucleons (see upper part of Fig. 4). This means that if nuclei in the uranium region undergo fission into two fragments of the same size approximately $2\times120\times1=240$ MeV of energy should be released, quite close to the observed value of 207 MeV.[20]

The liquid-drop model also explains why, in spite of this enormous energy release, such heavy nuclei still exist instead of promptly undergoing fission. The model assumes nuclei to be spherical objects in order to minimize the loss of binding energy at the surface. During the lead-up to fission, nuclei must elongate. This requires some energy input because the surface tension counteracts the elongation. Only beyond a certain deformation does the repulsive coulomb force start to dominate over the attractive nuclear force; then the way to fission is free. The activation energy for fission, i.e. the fission barrier, is around 6 MeV in the uranium region. This energy is quite small if compared to the total binding energy of about 1900 MeV or even the energy release from fission of about 200 MeV. The influence of the fission barrier is, however, very strong; uranium-238, e.g., has a half-life of 8×10^{15} years against spontaneous fission, i.e. fission without some external energy input. Spontaneous fission is a tunneling process through the fission barrier, analogous to the tunneling of α-particles through the coulomb barrier. According to the liquid-drop model, the fission barriers decrease as the nuclear charge increases and eventually disappear near element 110.[21] Very heavy nuclei are somewhat elongated instead of being spherical and their barriers are more complicated than expected on the basis of the liquid-drop model, but this does not change the general trend just outlined.

The shell structure of nuclei, however, might cause a drastic change in this trend. Closed nuclear shells stabilize shapes of high symmetry, such as the spherical one, against deformation. As a result, fission barriers appear even in cases where none should be expected from the liquid-drop model. *Myers* and *Swiatecki*[21] were the first to show that these shell-induced barriers can be even higher than the liquid-drop barriers in the uranium region.

The problem is now to find the next shell closure for protons. First it was assumed that in analogy to the neutron shell 126 element 126 should be "magic". This was too far away from the heaviest known elements to seriously consider a synthesis. The situation changed dramatically when, in 1967, *Meldner* showed[22] that such an analogy is not valid. The next proton shell is expected to be closed at element 114 and the next neutron shell for neutron number 184.[21,22] It seemed that a synthesis might be feasible for elements near 114. Moreover, very high fission barriers were expected,[23] and, in turn, extremely long half-lives. Thus, it was speculated that such "superheavy" elements could exist even in nature. This triggered off the publication of a multitude of theoretical papers on the nuclear properties, electronic structure, and chemical properties of these elements, and, of course, the search for such elements in nature and the first attempts at their synthesis. A review published in 1975[25] cited no less than 329 publications. More recent reviews can be found in Refs. [26, 27] and reviews of the heaviest elements recently synthesized in Refs. [28–31]. The somewhat exotic and exaggered name "superheavy elements" was adopted in the course of earlier speculations[24] about the existence of even much heavier nuclei.

Let us now have look at the nuclear landscape shown in Figure 5.[32] In the plane we find the two coordinates atomic number Z and neutron number N which define the location of each atomic nucleus. The third, vertical coordinate is the stability, measured in terms of binding energy per nucleon. In order to clarify the global trend, only nuclei with a half-life of more than one second are shown. If all nuclei were shown, the "beaches" would extend a little more into the "sea of instability", and the small "waterway" between the lead-mountain and the uranium-island would disappear.

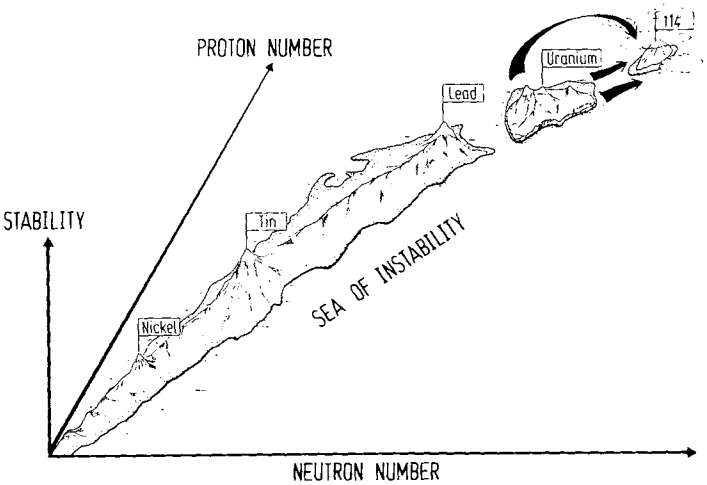

Fig. 5. The nuclear landscape. The nuclear stability measured by the binding energy per nucleon is shown as a function of neutron number N and proton number Z. Only nuclei with a half-live of more than one second are included [32].

The nuclear world of Figure 5 looks like an elongated mountain ridge slightly bent towards the neutron axis reflecting the liquid-drop character of nuclei. On top of this we have the shell effects which create mountains and valleys, the doubly magic nuclei being the highest peaks. The island of superheavy nuclei remains hidden behind the

clouds, as we shall discuss later. It should be noted, however, that this landscape would be a lot poorer if the delicate balance between nuclear and coulomb forces were to deviate a little, a few percent, in one direction or the other. The build-up of complex nuclei from hydrogen by nuclear reactions inside stars would have already terminated at very light nuclei, at deuterium or helium-2.[33]

3. Synthesis of the Heaviest Elements

There are two ways of approaching the synthesis of new elements; they are represented by arrows in Figure 5. One might gain a new piece of land, element by element, or one might try to jump to the island of superheavy elements in one big step. In either case the yield is expected to be very small, and therefore the synthesis has to start with elements which can still be obtained in weighable amounts. It turns out that einsteinium ($Z=99$) is the heaviest potential target material; the isotope einsteinium-254 with 276 d half-life can be produced in microgram quantities. The reaction partner must always be a heavy ion, in order to provide a reasonable number of protons in one step.

One should choose the reaction partners such that the sum of their proton numbers equals the proton number of the element to be synthesized. If one succeeds in fusing the two nuclei the task is, in principle, accomplished. This concept has been a great success in the synthesis of the heaviest elements. Starting with element 102, all the new elements were first made by this method.[9, 10, 29, 31]

Such a fusion of two nuclei is shown in Figure 6 for the example of element 107. Chromium-54, the projectile nucleus, is delivered by an accelerator, and bismuth-209 serves as target nucleus. The comparatively small projectile collides with the larger target nucleus, and forms an excited, rotating collision-complex. After some time the projectile is swallowed by the target, the reaction partners lose their previous identities and an excited "compound nucleus" (107)-263 is formed. The energy released is distributed statistically over all the nucleons. It is removed by prompt emission of one or more neutrons, and by further deexcitation via γ-rays. The final nucleus, here (107)-262, has the desired proton number and a neutron number which is one unit lower than that in the compound nucleus. This evaporation residue is now in its ground state and its further transformation proceeds on a much longer time scale via radioactive decay.

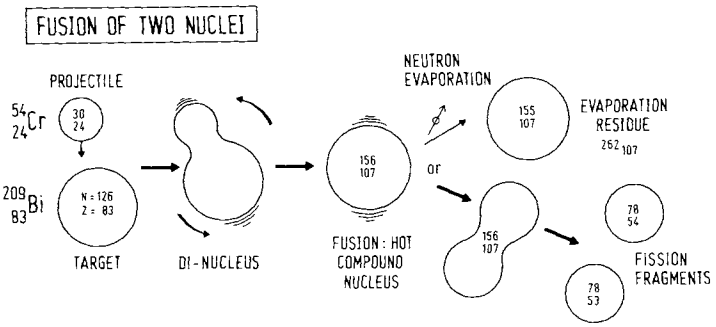

Fig. 6. Scheme of the synthesis of heavy nuclei by nuclear fusion, for the case of element 107 by fusion of bismuth-209 with chromium-54.

This sequence of events, however, occurs very rarely. It is much more likely, about 100 times on average, that the fragile compound nucleus undergoes fission decay rather than that a neutron evaporates. Suppose four evaporation steps are needed for deexcitation, then the survival probability of the evaporation residue reduces down to $1:10^8$. This explains why such compound nuclei should be produced in a cold state with as little excitation energy as possible. On the other hand, the projectile needs a certain minimum kinetic energy in order to establish contact with the target nucleus. This minimum energy is, of course, given by the coulomb repulsion between the two reaction partners. Part of it will be needed to counteract the loss of binding energy, but there always remains some excitation energy, the amount of which strongly depends on the system.

It should be noted that the proton number of the detected reaction product does not necessarily equal the total proton number of the two partners. The fusion reaction can either be incomplete or the primary fusion products may evaporate protons or decay radioactively. An unambiguous experimental identification of the proton number of the reaction products is clearly necessary.

After some early abortive attempts to synthesize superheavy elements via fusion reactions the search was made for other possible synthetic routes. Such an alternative was provided by the UNILAC, because it was the first machine capable of accelerating all elements up to uranium with kinetic energies high enough to induce nuclear reactions with any element up to uranium.

Thus, it became possible to transfer many nucleons during the collision of two very heavy nuclei like uranium-238 (see Fig. 7). Because the coulomb repulsion between the

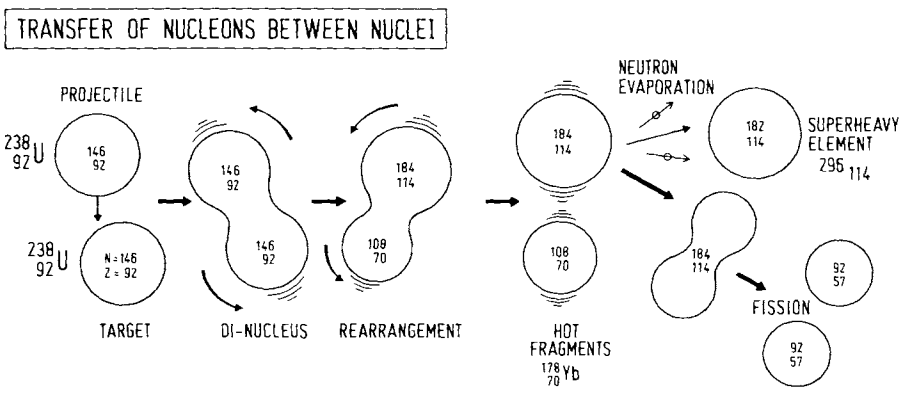

Fig. 7. Scheme of the synthesis of heavy nuclei by nucleon transfer during the collision of heavy nuclei, in this case two uranium-238 nuclei.

reaction partners is very high, the nuclei only touch each other, forming a dinucleus rather than a compound nucleus. The rotating dinucleus separates again after about 10^{-20} s, usually into nuclei similar to the initial ones. Occasionally it may happen that a large number of nucleons diffuse in one direction within the dinucleus, or, in other words, one half of the dinucleus grows at the expense of the other. In extreme cases (transfer of 22 protons within the uranium-uranium dinucleus) this could result in the formation of a superheavy nucleus, the remaining half shrinking down to a light nucleus (ytterbium in this case). Such complementary light nuclei indeed emerge from the reaction, indicating that a large nucleon transfer has taken place. But again most of the newly formed superheavy nuclei undergo prompt fission, because diffusion of nucleons also heats up the product nuclei. It is important to note that the excitation energy of the superheavy nuclei is broadly distributed, in contrast to the case of fusion reactions where it is well defined. One may hope, therefore, to obtain a sufficiently large number of nuclei with low excitation energy.

4. Separation and Detection of Heaviest Nuclei

Irrespective of how the synthesis of the heaviest elements proceeds, they are always formed in extremely small amounts. The number of detected atoms, N, is given by:

$$N = \sigma N_t N_p \varepsilon$$

where σ is the production cross section for the nucleus formed, N_t the number of target atoms per cm^2, N_p the dose of projectile nuclei, and ε the efficiency of the detection method. As an example, let us take values of $N_t = 2 \times 10^{18}$ atoms/cm^2 (i.e. 1 mg/cm^2 target thickness), $\varepsilon = 0.2$, and a dose of 1×10^{18} projectiles per day (or 1×10^{13} per s) which is typical for the UNILAC. If the cross section is of the order of $\sigma = 1 \times 10^{-35}$ cm^2, then each day only four atoms would be detected. The example cross section implies that a surviving heavy nucleus is produced in about 1 out of 10^{11} nuclear collisions.

This ratio cannot be greatly improved as the cross sections are well defined physical quantities. Larger amounts of target material do not help, because the reactions take place only in a very small depth zone of the target. Neither can the projectile dose be increased very much because the targets are subject to radiation and temperature damage, and also because the neutron-rich nuclei needed as projectiles are available only in very limited amounts. One therefore has to accept the small number of atoms produced. To make things worse, they have to be isolated from a huge surplus of target and projectile atoms and from radioactive products of concurrent nuclear reactions. Present day experimental techniques have reached such a high standard that the production of a few atoms per day is already sufficient for the detection of new elements.

An additional experimental problem is the life-time of the nuclei to be detected. For element 107 and those immediately after it is of the order of milliseconds. This is too short for chemical separations, even though the field of fast chemical separation techniques is quite advanced.[34] Only with physical methods may one hope to be successful. For the superheavy elements with their supposedly much longer half-lives, chemical separation techniques might again be applicable.

The following concept emerged for the experiments to be carried out at UNILAC: in order to proceed step by step to heavier elements, *Armbruster, Münzenberg* et al. built a physical separation apparatus at the Gesellschaft für Schwerionenforschung (GSI), namely the velocity filter SHIP.[35] The search for superheavy elements was initiated using simple techniques, and then continued also with the use of chemical methods.[36] The latter were mainly worked out and applied by a group of nuclear chemists from the University of Mainz and from GSI.

4.1. Physical Methods

The velocity filter SHIP is shown schematically in Figure 8. The apparatus, 11 m long, separates the slow evaporation residues flying out of the target from the faster projectiles and also to a large extent from products of competing reactions. The targets are mounted on a rotating wheel in order to minimize the heat deposited by the beam spot. After leaving the target the beams of projectiles and products are focussed by magnetic lenses and are separated from each other during traversal of a number of electric and magnetic fields. The reaction products are again focussed and implanted in solid-state detectors. One of the decay modes of the new elements is α-decay which serves to connect them genetically with known nuclei.

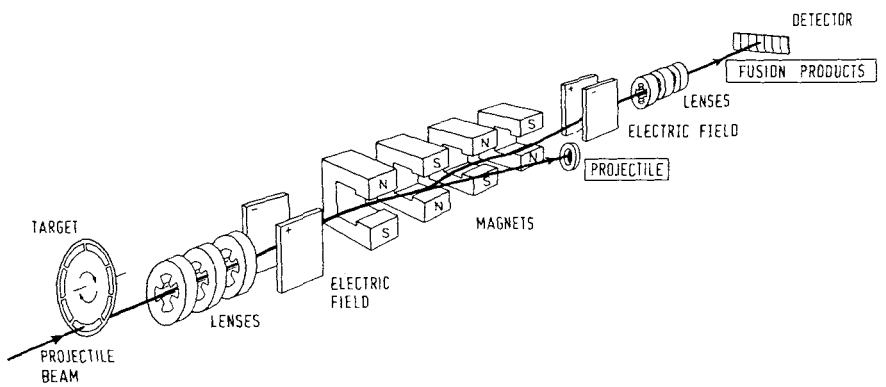

Fig. 8. Schematic diagram of the velocity filter SHIP that separates fusion products from the projectile beam by a combination of electric and magnetic fields (after [30]).

Figure 9 outlines this procedure. In collisions of bismuth-209 with chromium-54 one finds nuclei with a half-life of 4.7 ms that emit an α-particle of 10.38 MeV energy, leading to three known α-emitters—(105)-258, lawrencium-254 and mendelevium-250. Since the first α-emitting nucleus must have 2 protons and 4 nucleons more than (105)-258, the nucleus in question can only be element 107 with mass number 262. This technique was brought to such a high standard by the SHIP group[37] that even very small numbers of nuclei can be detected. This is achieved with a solid-state detector following the velocity filter that measures the arrival time and position of an incoming atom. Taking the arrival as the time reference, the decay mode—α-decay or spontaneous fission—the energy, and the time of the subsequent decay processes are registered. This decay must, of course, occur at the place where the atom initially hit the detector. All this information gives the decay history of the primary atom (this will be explained in another example in Section 5). The minimum half-life required is of the order of microseconds, corresponding to the time-of-flight through the apparatus.

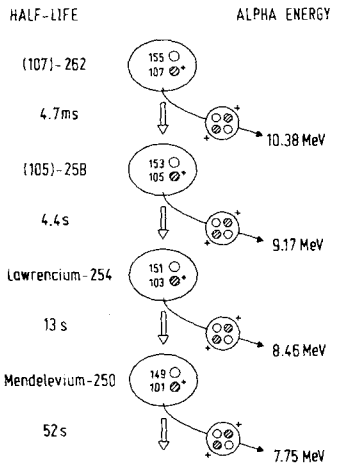

Fig. 9. Detection scheme for a new element, e.g. element 107, via its α-decay leading to a chain of known radioactive nuclei.

Another possible way[38] to identify new elements via subsequent α-decay chains is, instead of detecting the short-lived daughter-nuclei just described, to detect a long-lived member late in the decay chain after chemical isolation. It is necessary, however, to ensure that this member of the chain cannot be formed in any other way than that which would involve the synthesis of the new element.

The method of using spontaneous fission as the characteristic decay mode of new elements is applied by the group of *Flerov* and *Oganessian*, who work at the heavy ion cyclotron of the Joint Institute for Nuclear Research in Dubna. They use a very simple technique[39] which is outlined schematically in Figure 10. It covers half-lives down to milliseconds. The target material, e.g. bismuth metal, is attached to the surface of a rotating, cooled drum. The beam hits the target material along a tangent. The drum is surrounded by a fixed ring of mica foils. If a new isotope is formed in the target and decays by spontaneous fission, then its fragments are emitted from the rotating drum and hit the mica. This damages the solid, and after the experiment these damaged areas can be enlarged by chemical etching to form tracks. Once the rotational velocity of the drum is chosen properly, the number of tracks along the mica will decrease continuously. From this decrease one can calculate the isotope's half-life for spontaneous fission, as is shown at the bottom of Figure 10.

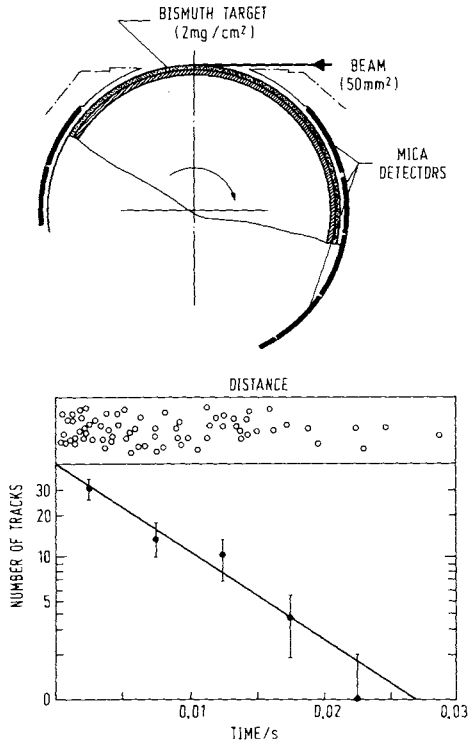

Fig. 10. Top: Apparatus for the detection of short-lived spontaneous-fission isotopes with a rotating drum and mica detectors [40]. Bottom: Positions of the etched fission-fragment tracks on a sheet of mica, and the resulting decay curve for the nuclide (104)-256 with 8 ms half-life produced on bombardment of lead-208 with titanium-50 [39].

This procedure, however, does not allow a direct identification of the nuclear charge and mass numbers. Each fission fragment, wherever it may come from, produces the same kind of track. One cannot rule out a priori the production of spontaneously fissioning actinoid isotopes by transfer reactions which occur along with the desired fusion reaction.[41] Thus, in order to unambiguously identify an element, additional information is needed. The Dubna group relies mainly on some characteristics of the nuclear reaction used for production. If one compares the results from several projectile-target combinations, where only one of them can lead to the sought after new element (whereas all the others have fewer protons) the new activity must only appear with the proper combination. Also, for each reaction in question, the production rate depends in a characteristic way on the projectile energy. And, finally, one can make use of differences in the spatial distribution; fusion products leave the target in a cone which is narrower than that for products from transfer reactions.

There is controversy[42,43] as to which criteria need to be fulfilled in order to identify a new element by spontaneous

fission. This is the reason for the ongoing debate[31,44] about the priority of the discovery of some of the heaviest elements, especially the elements 104 and 105.

When searching for the island of superheavy elements, the problem of element identification is especially critical because one can no longer expect α-decay chains leading to known nuclei. In the world of Figure 5, each chain will sooner or later end in the sea of instability, viz. the region of spontaneous fission, without ever reaching beaches of known territory. It is quite likely, however, that the fission of superheavy nuclei will result in unusually high fragment energies and a large number of neutrons.[45] Such unusual events of spontaneous fission might be the first hints of superheavy nuclei. But again one needs additional proofs, e.g. the requirement that the spontaneously fissioning nuclei behave chemically like superheavy elements.

4.2. Chemical Methods

Which chemical properties can be expected for the heaviest elements and which ones can be used for their separation? If one naively extends the periodic table, as in Figure 2, then element 112 is placed below mercury and element 114 below lead. And indeed, quantum-mechanical calculations justify this continuation.[46] The predicted electronic structures of the atomic ground states of the related elements are very similar. For element 112 one expects the valence electrons to be in the $7s^2$ state, in analogy to $6s^2$ for mercury, and for element 114 in the $7s^27p_{1/2}^2$ state, in analogy to $6s^26p_{1/2}^2$ for lead. The same is true for the neighboring elements. For element 118 the $7p_{3/2}$ state would be filled, and the next noble gas configuration reached. Based on this kind of reasoning many chemical and physical properties of superheavy elements and their respective compounds were extrapolated by using systematic trends.[47] As an example, Figure 11 shows the extrapolation of the evaporation enthalpies[48] indicating, for example, that element 114 should be fairly volatile.

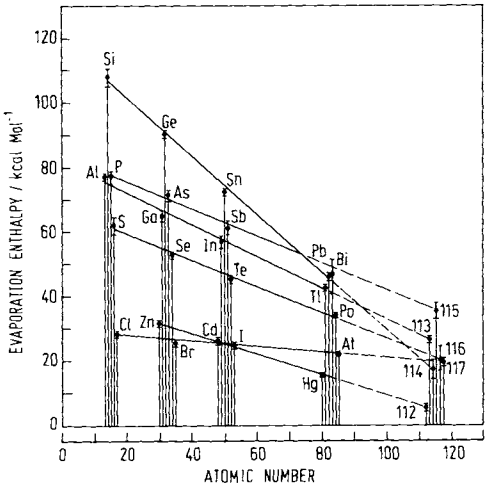

Fig. 11. Extrapolation of evaporation enthalpies for the elements 112 to 117 [48].

On the other hand, the chemical properties of these elements might deviate from such systematic trends.[49] Due to their high orbital velocity, the outermost electrons experience a relativistic mass increase and, in turn, a stronger binding. Therefore, the $7s^2$ subshell in element 112 and the $7p_{1/2}^2$ subshell in element 114 could be stabilized like complete electron shells. These elements would then be chemically inert and highly volatile, perhaps even gaseous at room temperature. For the neighboring elements low oxidation states would dominate. Relativistic effects could thus become obvious in the test tube. Because of the small production rates and the short half-lives there are as yet few studies of the chemistry of the heaviest elements which extend to element 105. The information thus far available has been collected in several review articles.[50-52] In those and in very recent studies of elements 103[53-56] and 105,[57] large relativistic effects have not yet been observed.

The validity of extrapolating macroscopic properties cannot be taken for granted in experiments with only a few atoms of superheavy elements. The chemical behavior at such low concentrations could well be different from that of macroscopic amounts. Even amounts that are usually considered very small are still huge in comparison to those dealt with here: 1 pg (10^{-12} g) of lead still contains 3×10^9 atoms! The chemistry at lowest concentrations has long been an attractive area of research in radiochemistry.[58] Recent theoretical[59] and empirical[60,61] studies have shown that even for very small amounts one can expect normal behavior. Of course, some macroscopic properties like the melting point and density cannot be determined with a few atoms.

The methods used to chemically separate superheavy elements should not be very specific at first. On the contrary, since the region of highest nuclear stability can only be estimated, it is advisible to separate as many superheavy elements as possible in one experiment.[26] If spontaneous fission is used as the method of detection, one only needs to remove any actinoid element contamination because these elements also decay by spontaneous fission. Lighter homologues of superheavy elements, such as mercury or lead, are no problem in this respect. If this kind of group-separation should give any indication of the presence of superheavy elements, then more specific separation methods would have to be employed in a subsequent experiment.

Three types of group separations are shown in Figure 12. Extrapolations of evaporation enthalpies, like those in Figure 11, indicate that the elements 112 to 118 should be volatile at temperatures around 1000 °C;[48,47] this is the

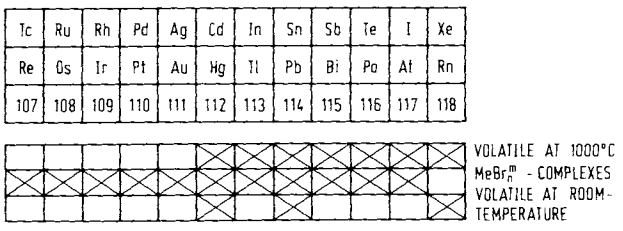

Fig. 12. Detection scheme for superheavy elements with three different chemical separations. Elements which should be volatile at 1000 °C are indicated by crosses in the upper line, in the middle line those which should form negatively charged bromide complexes with hydrobromic acid are indicated, and in the lower line those which might already be volatile at room temperature. To facilitate comparison, a section of the periodic system is also depicted.

group of "lead-like" superheavy elements. For the non-volatile "platinum-like" elements 107 to 111 one can apply a separation based on ion-exchange which makes use of the expected formation of negatively charged bromide complexes;[62] this separation should also include the elements 112 to 117. Finally, the elements 112 and 114 together with 118 might be "radon-like", i.e. volatile at room temperature.[49]

If one is searching for long-lived superheavy nuclei, it is possible to combine several different "off-line" separation techniques.[63] In this case, either the targets or metal foils used to collect reaction products emitted from the target are chemically processed after the irradiation. The different chemical fractions are finally measured with extremely sensitive detectors for spontaneous fission events.

A schematic diagram of such a detector[64] is shown in Figure 13. It detects the two fission fragments, records their respective kinetic energies, and the number of neutrons emitted from the fragments. It will clearly identify events with high kinetic energy and neutron number. Thin samples are placed between two solid-state detectors in order to observe the fission fragments that are emitted in opposite directions. Six samples can be measured simultaneously in different solid-state detectors. The neutrons are first slowed down in paraffin, and are then detected in a ring of 30 helium-3 filled counters. To give an impression of the size of the detector, the length and the diameter of the paraffin cylinder are 130 and 65 cm, respectively. In order to suppress the cosmic-ray background, shielding counters are put above and below the detector. In addition the whole system is placed underground. If the detector is operated to register only events which consist of both fission fragments and neutrons, the background is less than one event per month.

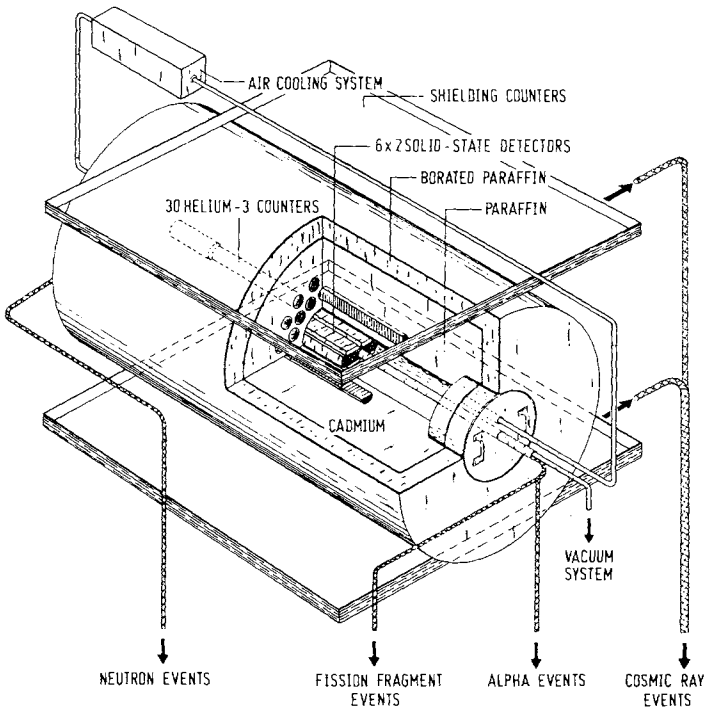

Fig. 13. Schematic drawing of a highly sensitive detection system for superheavy nuclei by simultaneous observation of fission fragments with solid-state detectors and of fission neutrons with helium-3 counters [64].

For an "on-line"chemical process the transport of the reaction products, the chemical separation and the subsequent measurement all take place continuously during the irradiation. The main features are depicted in Figure 14 for

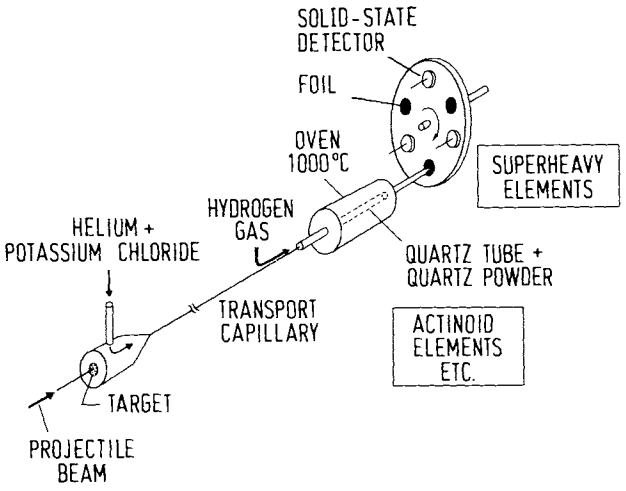

Fig. 14. Chemical on-line separation and subsequent measurement with a wheel system of lead-like superheavy elements by volatilization at 1000°C [36] (after [65]).

the example of lead-like elements.[36] The beam of projectiles hits a thin target and kicks the reaction products into a chamber where they are slowed down in helium. The helium gas contains minute amounts of small potassium chloride particles. The reaction products become attached to these aerosols and are transported at high velocity through a capillary to the separation and detection device, usually many meters away in a low background area. During the transport, hydrogen is added to serve as a reducing agent. Lead-like elements are thus stabilized in elemental form. The stream of gas passes a tube filled with quartz powder at a temperature of 1000°C where less-volatile species, especially the undesired actinoid elements, are adsorbed. Any volatile superheavy elements, however, pass through the tube and are deposited on thin cooled metal foils. These foils are mounted on a rotating wheel that positions the foils successively between pairs of solid-state detectors to detect fission fragments and α-particles. The efficiency of the method is continuously monitored by measuring short-lived α-emitters of homologous elements such as polonium and lead that are formed in side reactions. This technique is able to detect nuclei with half-lives down to a few seconds.

The platinum-like elements, after being attached to aerosols, are also transported with the gas stream. The aerosols are then dissolved in hydrobromic acid and transferred to a cation exchange column. The actinoids are adsorbed as cationic species whereas the negatively charged bromide complexes of the superheavy elements and their homologues pass through the column. Solid samples are prepared subsequently by evaporating the eluates.[36] All essential steps are computer-controlled, e.g. the switching on and off of the sampling processes, the preparation and addition of different solutions for elution, and the conditioning of the columns for the next separation. One column is

used for a separation, while at the same time another one undergoes conditioning.[66] In this way the discontinuous column chromatography becomes "quasi on-line". The limit of detectable half-lives is of the order of several minutes.

Radon-like elements are transported by a gas stream without aerosols and are fed through a column filled with quartz powder at 1000°C to filter out less volatile components. The volatile elements are condensed on the surface of a cooled solar cell which is facing a solid-state detector. Spontaneous fission events are registered by simultaneously detecting fragments in both detectors.[67] It is again possible to cover half-lives down to the order of seconds.

5. The Heaviest Elements

All elements at the end of the periodic table up to element 106 were first produced from heavy actinoid nuclei by fusion with light projectiles; e.g. element 106 by fusion of californium-249 and oxygen-18.[68] The compound nucleus is highly excited, as evidenced by the emission of four neutrons:

$$^{249}_{98}\mathrm{Cf} + {}^{18}_{8}\mathrm{O} \longrightarrow {}^{263}106 + 4\,{}^{1}_{0}\mathrm{n}$$

Usually a shorthand notation is used for nuclear reactions where the projectile and ejecta are written in parentheses:

$$^{249}_{98}\mathrm{Cf}({}^{18}_{8}\mathrm{O}, 4\mathrm{n})\,{}^{263}106$$

This large excitation energy dramatically reduces the survival probability of the evaporation residues, as was already explained in Section 3. For the synthesis of even heavier elements a technique suggested by *Oganessian*[69,70] turned out to be essential. He proposed the use of target nuclei with closed nuclear shells, such as lead-208 or bismuth-209. A large fraction of the energy deposited by the projectile has to be used for breaking the shells, preventing it from being turned into excitation energy. This cold fusion was demonstrated for the first time in reactions such as

$$^{208}_{82}\mathrm{Pb}({}^{40}_{18}\mathrm{Ar}, 2\mathrm{n})\,{}^{246}_{100}\mathrm{Fm}$$

which led to previously known nuclei.[69-72] Sometimes it is even possible to keep the excitation energy of the compound nucleus so low that it is insufficient to evaporate a neutron, and only γ-rays are emitted instead:[38]

$$^{208}_{82}\mathrm{Pb}({}^{50}_{22}\mathrm{Ti}, \gamma)\,{}^{258}104$$

The SHIP group has systematically investigated cold fusion in the region of known heavy nuclei.[28,73] These studies led also to a characterization of the decay chains to be genetically connected to the new elements produced later. It became clear, however, that very neutron-rich projectiles like chromium-54, iron-58 and nickel-64 are needed for the synthesis of new elements. These isotopes have natural abundances of only a few percent or even less. They therefore have to be enriched by electromagnetic isotope separators, a costly process.

5.1. Element 107

The first synthesis of a new element at UNILAC was accomplished in 1981, when *Münzenberg* et al.[74] obtained element 107 by fusion of bismuth-209 and chromium-54, as outlined schematically in Figure 6. A previously unknown α-emitter of 4.7 ms half-life and 10.38 MeV α-energy could be connected to the decay chain shown in Figure 9. The reaction is thus

$$^{209}_{83}\mathrm{Bi}({}^{54}_{24}\mathrm{Cr}, \mathrm{n})\,{}^{262}107$$

Within three days of beam time a total of five correlated decay chains were found, all starting with this new α-emitter. One of these chains, together with the lifetimes τ of the individual nuclei in the intermediate steps, is shown in Figure 15. The lifetimes may differ from the average values; however, the width of this deviation is well defined by statistical laws. The resulting errors in the average lifetimes will, of course, be large if only a few nuclei are observed. From the lifetime of 12.6 ms of the initial nucleus (107)-262 in Figure 15 one formally obtains a half-life

$$T_{1/2} = (\ln 2)\,\tau = 0.693 \times 12.6 = 8.7 \text{ ms}.$$

This agrees well with the mean half-life of 8.2 ± 2.2 ms resulting from later experiments.[75,76] Figure 15 shows a case in which mendelevium-250 decayed via electron capture into the α-emitter 30-min fermium-250, and not by α-decay as indicated in the scheme of Figure 9. Up to now 14 decay chains of this isotope have been observed (Table 1).

Table 1. The heaviest elements discovered at the heavy-ion accelerator UNILAC.

Atomic number Z	Mass number	Half-life	α-Decay energy [MeV]	Synthesis reaction	Number of atoms observed	Time of discovery	Ref. for discovery
107	262	8.2 ± 2.2 ms	10.38, 10.24	$^{209}_{83}\mathrm{Bi}(^{54}_{24}\mathrm{Cr}, \mathrm{n})$	14	February 1981	[74]
		106 ± 30 ms	10.01, 9.91, 9.74		15		
	261	$9.0^{+4.4}_{-2.3}$ ms	10.39, 10.10, 10.03	$^{209}_{83}\mathrm{Bi}(^{54}_{24}\mathrm{Cr}, 2\mathrm{n})$	9		
108	265	$1.8^{+2.2}_{-0.7}$ ms	10.36	$^{208}_{82}\mathrm{Pb}(^{58}_{26}\mathrm{Fe}, \mathrm{n})$	3	March 1984	[83]
	264	76^{+364}_{-36} µs	11.0 [a]	$^{207}_{82}\mathrm{Pb}(^{58}_{26}\mathrm{Fe}, \mathrm{n})$	1		
109	266	$3.4^{+6.1}_{-1.3}$ ms	11.10	$^{209}_{83}\mathrm{Bi}(^{58}_{26}\mathrm{Fe}, \mathrm{n})$	3	August 1982	[87]

[a] The α-decay energy was estimated from the measured half-life using the known relationship between these quantities.

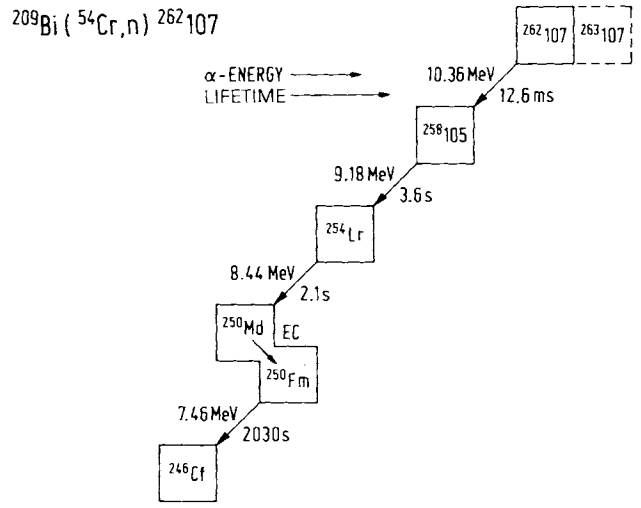

Fig. 15. The first detection of element 107: one of the observed α-decay chains from the irradiation of bismuth-209 with chromium-54 [74]. EC = electron capture.

During later experiments at SHIP[75,76] an additional group of α-decays of element 107 was discovered in 15 correlated decay chains; such a group had already been suspected to occur in this reaction.[74] The decay chain also belongs to mass number 262, but starts with a half-life of 106 ± 30 ms and a complex α-energy spectrum (see Table 1). This phenomenon is called nuclear isomerism, i.e. there are two nuclei of the same mass number but with different binding energy and decay properties. The 8-ms activity is the metastable isomeric state, and the 106-ms activity is the ground state of (107)-262.

The existence of these nuclei with mass number 262 was confirmed in Dubna[38] by detecting 1.5-d californium-246, the nucleus at the end of the decay chain in Figure 15. Californium was chemically isolated after bombardment of bismuth-209 with chromium-54. The lower part of Figure 16 shows the α-spectrum of the californium fraction. The presence of californium-246 is statistically quite well determined.

A second isotope of element 107 with mass number 261 was produced at UNILAC with the same projectile-target combination at somewhat higher projectile energy. Three decay chains were observed,[75] and could be connected via α-decay with the known nucleus 1.4-s (105)-257 and its respective decay chain.[77] The reaction is

$$^{209}_{83}\mathrm{Bi}(^{54}_{24}\mathrm{Cr},2n)^{261}107$$

The nuclide has a half-life of $9.0^{+4.4}_{-2.3}$ ms,[76] and a complex α-energy spectrum (see Table 1). No spontaneous fission events have been observed along with the nine α-decay events known up to now.[76] *Oganessian* et al.[78] claim to have detected this isotope as early as 1976 in the same reaction via spontaneous fission, but with a half-life of 1 to 2 ms. In the meantime the half-life of the spontaneous fission activity has been corrected to $2.8^{+2.1}_{-1.1}$ ms,[79] still considerably shorter than the value found at UNILAC. For this spontaneously fissioning nuclide the Dubna group calculated a production cross section of about 1×10^{-34} cm^2.[78] The SHIP group, on the other hand, concludes that because spontaneous fission has not been observed in their experiments, the production cross section must be at least ten times lower.[76] Thus, the existence of this fission activity has not been confirmed by the SHIP group.

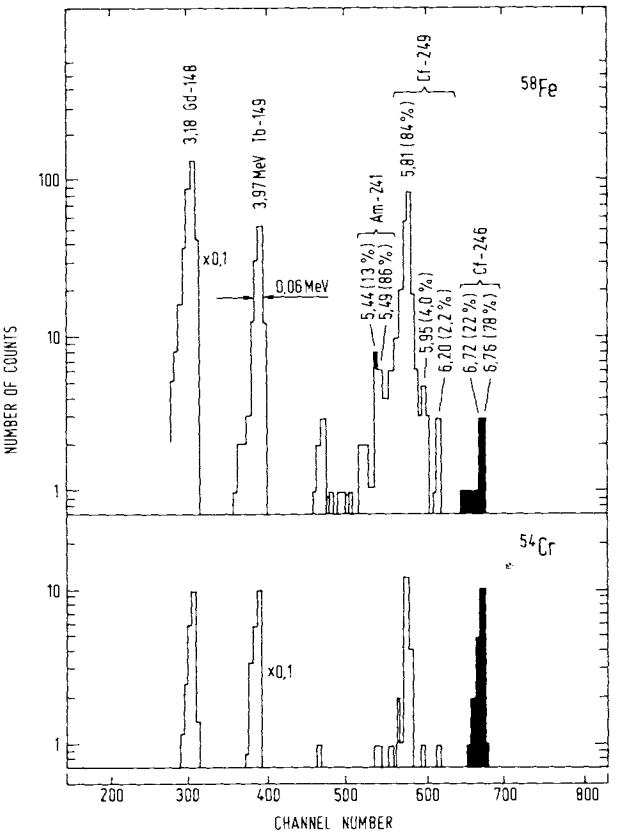

Fig. 16. Indirect evidence for the formation of elements 107 (bottom) and 109 (top) in a chemically isolated californium fraction after the irradiation of bismuth-209 with chromium-54 (107) and iron-58 (109), respectively. The heavy elements were identified via 1.5-d californium-246 produced late in the α-decay chains. The characteristic α-peak of californium-246 is shown in black. The remaining peaks are α-emitters used for calibration (after [38]).

Table 1 summarizes our present knowledge about the isotopes of element 107, including results of the most recent experiment carried out by the SHIP group.[76] A total number of 38 atoms has been observed, 13 of which were correlated with the decay products lawrencium-253 and -254 ($Z = 103$). The most recent summary by the Dubna group[31] no longer contains the isotope with mass 260 which was included earlier.[80] A search for neutron-rich isotopes of element 107 such as (107)-266, which might have half-lives of the order of minutes,[81] was carried out during the bombardment of einsteinium-254 with oxygen-16, albeit without success.[82]

To summarize: element 107 was first identified unambiguously by the SHIP group.[74] They succeeded in detecting the α-decay of isotope 262 into previously known nuclei. The earlier assignment of a 1–2 ms spontaneous fission activity to the isotope 261 by the Dubna group[78] seems less justified.

5.2. Element 108

Münzenberg et al.[83,84] have been able to detect three atoms of the isotope 265 of element 108, again via α-decay chains, two of which are depicted in Figure 17. The reaction for the synthesis is

$^{208}_{82}Pb(^{58}_{26}Fe,n)^{265}108$

The half-life of (108)-265 is 1.8 ms with an α-decay energy of 10.36 MeV (see Table 1). Figure 17 again demonstrates the statistical fluctuations of the measured lifetimes as compared to the mean values. It also shows that if the α-particles are sometimes emitted towards the surface of the detector (i.e. "escape"), only a fraction of their energy is detected. This fraction is around 1 MeV, and it is not specific at all. The observation of an α-decay and the lifetime are, however, still unambiguous. The existence of the nucleus (108)-265 was confirmed in the same reaction by the radiochemical detection of a long-lived end product of the decay chain, the 20-d einsteinium-253.[38]

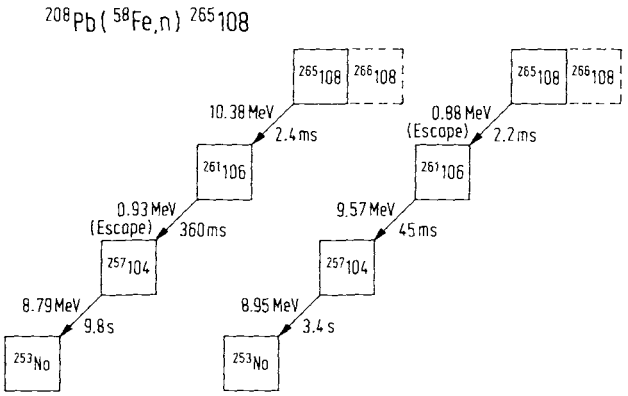

Fig. 17. Discovery of element 108: α-decay chains of two nuclei of the isotope 265 formed by fusion of lead-208 with iron-58 (after [83]).

Taking the reaction of lead-208 with iron-58 as an example, we shall describe what the original data look like when they are obtained during the detection of new elements with SHIP. Figure 18a shows the complete α-spectrum measured in a detector at the end of SHIP, without any selection criteria. The spectra in (b)–(e) have been subjected to boundary conditions: the α-decay must first be correlated in space and time with the implantation of a heavy nucleus (b); this nucleus must have a mass between 235 and 295 (c), and successive α-decays must originate from it (d, e). The first generation of α-decays is shown in (d), the second and third in (e). The heaviest nuclei searched for become recognizable in part (b), constitute the only remaining events in (c), and are identified unambiguously in (d) and (e) as members of a decay chain starting with the new element (d).

A second isotope of element 108 with mass 264 and half-life 0.08 ms (Table 1) was produced at UNILAC by fusion of lead-207 with iron-58;[85,84] we shall discuss it in Section 7. There is some evidence for a third isotope of mass 263, but the half-life is still unknown.[86]

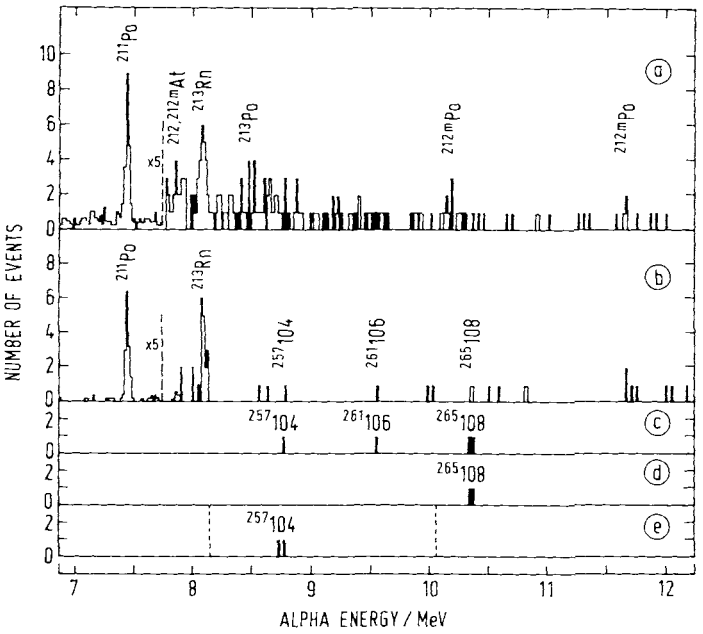

Fig. 18. α-Spectra observed from products of the bombardment of lead-208 with iron-58: (a) spectra taken between the beam pulses of the UNILAC; (b) α-decays that are connected with the implantation of a heavy nucleus; (c) α-decays connected with nuclei of mass 235 to 295; (d, e) correlated α-decays starting with the new element (d) and its known decay products (e) (after [84]).

5.3. Element 109

The periodic table presently ends at element 109. In 1982, during a ten day long bombardment of bismuth-209 with iron-58, *Münzenberg* et al.[87] succeeded in detecting one single decay chain, depicted in Figure 19. It connects a new α-emitter with a decay chain already known from the synthesis of element 107. Thus, the synthesis was carried out via the reaction

$^{209}_{83}Bi(^{58}_{26}Fe,n)^{266}109$

This nucleus decayed with a lifetime of 5.0 ms corresponding to a half-life of $3.5^{+16.6}_{-1.6}$ ms, and with 11.10 MeV α-energy into the isotope 262 of element 107. The following nuclide (105)-258 did not decay via α-emission but rather by electron capture (EC), which occurs with 33% probability; the resulting isotope (104)-258 decayed via

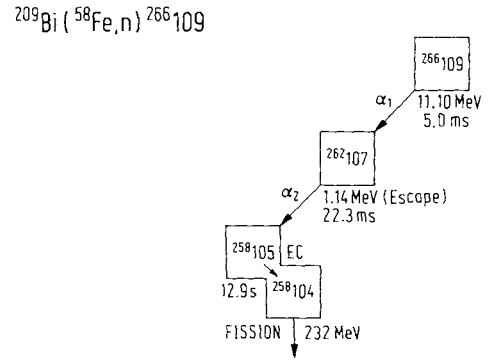

Fig. 19. Discovery of element 109. A single α-decay chain of mass number 266 was observed in the irradiation of bismuth-209 with iron-58 (after [88]).

spontaneous fission. In a very careful analysis of this single event *Münzenberg* et al.[88] were able to demonstrate that it is significant. The analysis involved additional information, for example the approximate mass number calculated from the time-of-flight, the systematics of α-decay energies, and possible side reactions. In a second experiment performed in February 1988 the SHIP group found a second atom of element 109 with almost the same lifetime which was correlated with the following successive nuclei:[89]

$$^{266}109 \xrightarrow{\alpha} {}^{262}107 \xrightarrow{\alpha} {}^{258}105 \xrightarrow{\alpha} {}^{254}_{103}\mathrm{Lr} \xrightarrow{EC} {}^{254}104 \xrightarrow{\alpha} {}^{250}_{102}\mathrm{No}.$$

In addition, a third decay chain of (109)-266 was observed in which the first member was not, however, detected.

This discovery is corroborated by *Oganessian* et al.,[38] who radiochemically detected a long-lived end product of the α-decay chain, the 1.5-d californium-246 which was already observed in the production of element 107. The α-spectrum of the chemically isolated californium fraction is shown in the upper part of Figure 16. The peak at 6.75 MeV, characteristic of the californium isotope, contains seven events.

5.4. Attempts to Synthesize Element 110

It seemed natural to extend this successful concept one step further, to element 110, and to try to fuse lead-208 with nickel-64:

$$^{208}_{82}\mathrm{Pb}(^{62}_{28}\mathrm{Ni}, 1\text{-}2n)^{271,270}110$$

The search for this element with SHIP in an experiment lasting 11 days, again using the α-correlation technique as detection method, remained unsuccessful; no event was observed with a cross-section limit of 5×10^{-36} cm^2.[90,91] Nor has it been possible in Dubna to fuse bismuth-209 and cobalt-59 to form element 110 or to fuse bismuth-209 and nickel-64 to form element 111. In these experiments it was again intended to identify the new elements by long-lived members of possible decay chains.[38]

The difficulties encountered in these experiments become obvious from Figure 20. The production cross-section of the heaviest nuclei by cold fusion is seen to decrease rapidly with increasing atomic number by about a factor of three per element step. For element 110 a value between 10^{-35} and 10^{-36} cm^2 is extrapolated that is just at the limit of present experimental techniques. It is still not completely hopeless to discover element 110 in the way just described, but a beam time of the order of two months would be required.

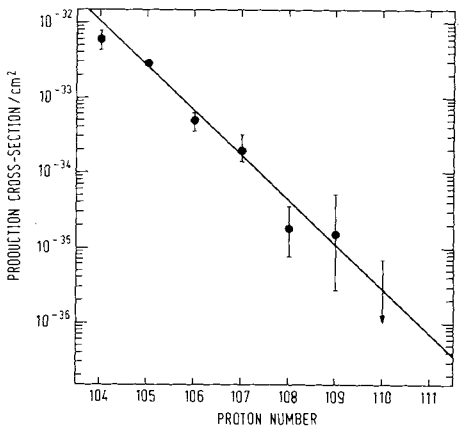

Fig. 20. Production cross sections of the heaviest elements by cold fusion versus the proton number (after [91]).

From systematic studies of the fusion of heavy nuclei[28,73] and from theoretical work[92,93] one realizes that the fusion process becomes increasingly difficult with increasing mass and charge of the nuclei involved. It is no longer sufficient for fusion to establish some contact between the nuclei at the coulomb barrier. Rather, the contact has to be strong enough for the attractive nuclear force to dominate over the coulomb force. This requires a higher projectile energy or an "extra push" that increases the excitation energy of the compound nucleus and, as a result, drastically diminishes its survival probability against spontaneous fission.

This hindrance is less severe when a small projectile nucleus and a larger target nucleus are used than in the case of cold fusion with lead or bismuth targets. The smaller projectile nucleus is more likely to be absorbed by the much larger target nucleus. The disadvantage, however, is that since one no longer starts with shell-stabilized target nuclei the excitation energy of the compound nucleus is higher, even if fusion takes place at the coulomb barrier. Nevertheless, according to this concept suggested by *Flerov*,[40] element 110 might be more likely to survive than if the synthesis had started with lead. However, the systematic trend of production cross sections for "warm fusion" speaks against this possibility.[73]

Among many possible combinations one may choose argon-40 as the projectile and a uranium isotope as target, e.g.:

$$^{235}_{92}\mathrm{U}(^{40}_{18}\mathrm{Ar}, 3n)^{272}110$$

As in the case of the other heaviest elements one still remains in an area where some local stability is expected; more will be said about this in Section 7. None the less, the search[90,94] for characteristic decay chains of element 110 with SHIP in the above reaction remained unsuccessful down to a cross-section limit of 8×10^{-36} cm^2. Negative results were also obtained in radiochemical experiments[95] in the case of reactions of argon-40 with uranium-233, -235, and -238.

In contrast *Oganessian* et al.[96,97] found a spontaneously fissioning isotope of about 8 ms half-life in irradiations of thorium-232 with calcium-44, and of uranium-236 with argon-40. Both reactions lead to the same compound nucleus of element 110 with mass number 276. In the argon plus uranium reaction 16 fission tracks were found, corresponding to a production cross-section of 1×10^{-35} cm^2. The observed activity might be due to the well known spontaneous fission isomer of americium-242 ($Z=95$) with 14 ms half-life, because the close neighbor, the 0.8-ms spontaneous fission isomer of americium-240, is known to be produced with a large cross section. *Oganessian* et al.[97] believe, however, that the americium-242 isomer can be excluded on grounds of additional experiments, and they

"are inclined" to ascribe the observed activity to the decay of a nucleus of element 110. It remains an open question as to whether this can be corroborated.

5.5. The Names

No names have yet been suggested for the new elements 107, 108, and 109. Some reluctance is prevalent, because there have been controversies about the discovery of some transactinoid elements resulting in different names in the East and West, kurchatovium and rutherfordium for element 104, and nielsbohrium and hahnium for element 105. It is desirable at first to come to an agreement on how to judge the results of such experiments at the limits of technology. In order at least to come to temporarily agreed names and element symbols, e.g. for registrary purposes and literature searches, the International Union of Pure and Applied Chemistry decided some years ago to name future elements according to their atomic number.[98] With unabashed optimism a nomenclature was developed for elements up to 999.[98,99] Element 107 is called unnilseptium, with symbol Uns, element 108 unniloctium (Uno), element 109 unnilennium (Une), and element 110 ununnilium (Uun). One may very well question the usefulness of such a scheme. As far as can be seen at the moment it will only be necessary to find names for a few more elements anyway, and discussions about the priority of discoveries cannot be avoided either.

6. Superheavy Elements

When trying to synthesize superheavy elements by fusion, even the choice of the reaction system is a problem. This is obvious from Figure 21, which shows schematically the upper end of the chart of nuclides. The heaviest known nuclei are found in the lower left-hand corner, marked by squares, while the island of superheavy elements is represented in the upper right-hand corner by the hatched area. The island results from theoretical estimates of the half-lives of all competing decay modes, viz. α-decay, β-decay, and spontaneous fission. Rather than showing all its details, we indicate the island by a contour line which connects all nuclei with a one microsecond half-life. This is about the shortest detectable half-life. Depending on how the theoretical calculations are carried out, different landscapes will be obtained. The results of two such studies are shown in Figure 21; one predicts a broad beach extending to the west,[100] the other a steep cliff in just the same area.[101] Both calculations expect the longest half-life, i.e. 10^9 years[100] or 10^5 years,[101] respectively, for element 110 with neutron number 184, and not for the magic atomic number 114. The reason is that α-decay should be dominant near $Z = 114$, and is not reduced as much by shell closures as spontaneous fission.

Figure 21 shows that with respect to the proton number the heaviest known nuclei are already up to the island, but the neutron number is still far away from it. Superheavy nuclei are predicted to be extremely neutron-rich and even fusion of the most neutron-rich projectile and target nuclei barely reaches the north-western shore of the island. This is indicated by parachutes in Figure 21 which stand for the compound nuclei resulting from fusion of the neutron-rich calcium-48 and the neutron-rich nuclei plutonium-244, curium-248, and einsteinium-254.

One can, of course, quite optimistically rely on a shallow western shore which can be reached by projectile-target combinations more readily available. A large number of such syntheses had already been performed before the construction of the UNILAC was completed. A review published in 1979[102] quotes 16 different combinations, and by 1982 the number had increased to 22.[26] The list includes systems ranging from calcium-48 plus thorium-232 with the compound nucleus (110)-280 up to krypton-84 plus uranium-238 with the compound nucleus (128)-322. None of these fusion experiments has been successful, even though positive results have been reported from time to time. None of the positive results could ever be confirmed. Therefore, when heavy projectiles became available at UNILAC, another type of reaction was preferred: nucleon transfer between very heavy nuclei. We shall discuss these experiments later, and instead concentrate on the most recent attempts at synthesis via fusion.

6.1. Attempted Synthesis by Nuclear Fusion

Among the three combinations depicted in Figure 21, the reaction of calcium-48 with curium-248 seems to be the

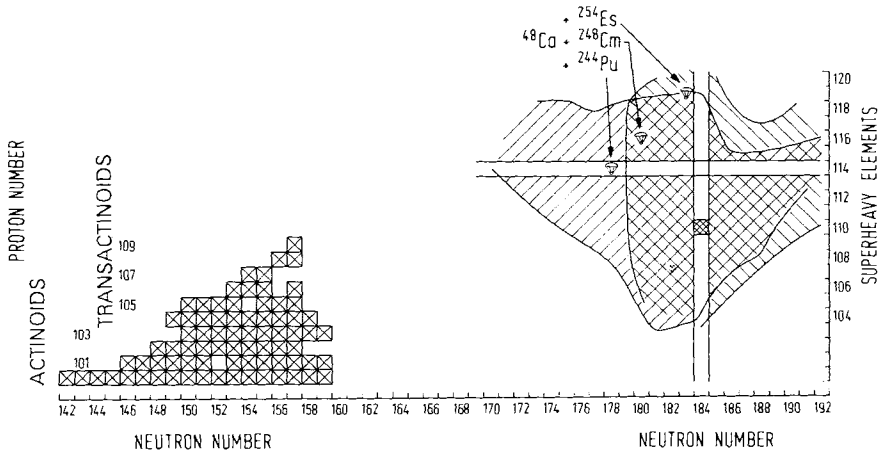

Fig. 21. Upper end of the present chart of nuclides and two predicted versions of the island of superheavy elements [100, 101], enclosed in contour lines corresponding to a half-life of 1 μs (see text).

most promising one. This results in a compound nucleus with 116 protons and 180 neutrons, not far from the closed proton and neutron shells. With plutonium-244 one would reach the proton shell 114 exactly, and with einsteinium-254 one would get closer to the neutron shell 184, but the other nuclear shell in both cases would be further away. Curium-248, with a 3.4×10^5 years half-life, is produced in milligram quantities from lighter actinoids by neutron capture in the high-flux reactor at Oak Ridge. Calcium-48, a stable isotope with 0.19% abundance in natural calcium, is produced in nearly pure form by electromagnetic isotope separators. As early as 1977/78 scientists from the Lawrence Berkeley Laboratory and the Lawrence Livermore Laboratory[103-106] as well as from the Joint Institute for Nuclear Research[107] tried to produce superheavy elements with this reaction at the respective heavy-ion accelerators at Berkeley and Dubna. However, the experiments were not successful.

In these experiments it had been assumed that an "extra-push", i.e. some additional projectile energy, is needed in order to fuse these two nuclei. A number of later experimental and theoretical studies raised doubts as to whether an "extra push" was really necessary. Therefore, it was decided to try again to fuse these nuclei, this time under very gentle conditions close to the coulomb barrier. Even in this case, 20 MeV of excitation energy remains in the compound nucleus. This is quite a large value considering the fragility of these nuclei. This new series of experiments were carried out in collaboration by scientists from GSI Darmstadt, the Lawrence Berkeley Laboratory, the University of Mainz, the Los Alamos National Laboratory, and the Universities of Berne and Göttingen using the heavy ion accelerators at Darmstadt and Berkeley. Making use of the whole repertoire of physical and chemical separation and detection methods, they intended to cover a region of half-lives as large as possible with highest sensitivity.[108]

This search for superheavy elements, probably the most elaborate one, also ended without clear evidence of their existence. The quantity used to describe such negative results is the upper limit of the production cross-section of the sought after nuclei that is compatible with the negative result. Its value depends on the half-life; neither the very short-lived nuclei can be detected (because they already decay before being separated) nor the very long-lived ones (because they do not decay in appreciable amounts during the limited time of measurement). Between these extremes the detection limit is independent of the half-life. Thus the production cross-section limits, depicted as a function of the half-life, have a trapezoidal shape, as in Figure 22. For the sake of clarity the cross-section limits are replaced in Figure 22 by an equivalent quantity, viz. the probability for superheavy nuclei to be formed in a collision between the reaction partners. This probability is at most $1:10^{10}$ for 14 orders of magnitude in half-life. Even lower values result for half-lives of the order of weeks and months. The formation of superheavy nuclei is excluded in the hatched area, i.e. for half-lives ranging from several microseconds to several years at most a few nuclei per day could have been produced.

A more correct description of the results is given in Figure 23, which shows the regions of half-lives in which different methods are sensitive. Very short-lived nuclei would have been detected by the velocity filter SHIP at GSI (curve 2), and the gas-filled fragment-separator SASSY at Berkeley (1). Chemical on-line methods were sensitive to lead- and radon-like (3, 4) as well as platinum-like (5) elements with medium half-lives. Off-line separations in combination with highly sensitive detector arrays were used to search for long-lived nuclei in the radon (6), platinum (7), and lead fractions (8).

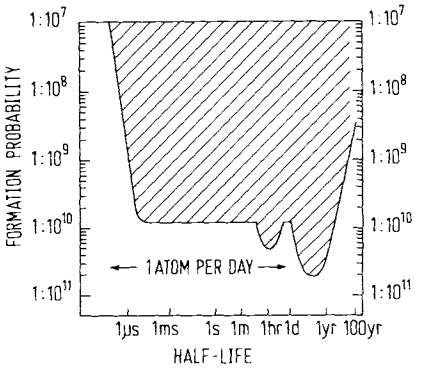

Fig. 22. Results from a search for superheavy elements in the reaction of calcium-48 with curium-248. As a function of the half-life the upper limit for the formation probability per collision is depicted which is still compatible with a negative result; the hatched area is ruled out by the experiments. The diagram is actually made up from several parts shown individually in Figure 23 (from [65]).

Another reaction indicated in Figure 21 was recently carried out in Berkeley, the fusion of calcium-48 with einsteinium-254.[109] The experiments were again negative with a cross-section limit of 3×10^{-31} cm^2 for half-lives ranging from one day to several months. Future experiments with better sensitivity are feasible if the current pro-

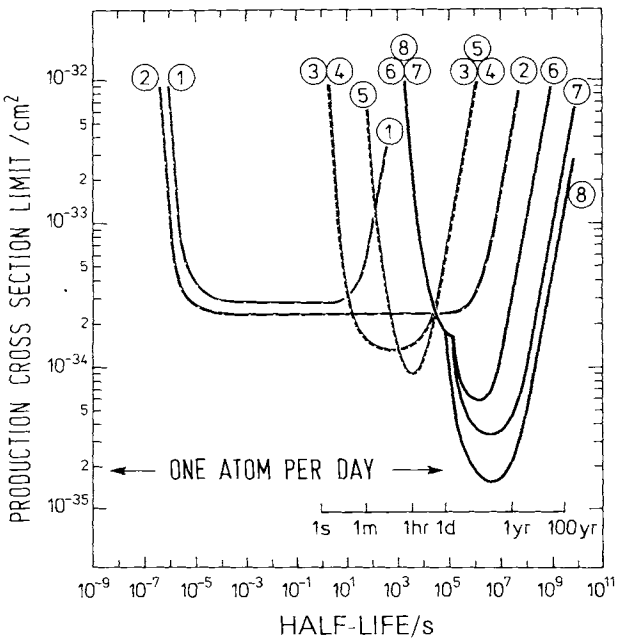

Fig. 23. Results from a search for superheavy elements in the reaction of calcium-48 with curium-248. The upper limits of production cross-sections determined with different separation techniques are shown as a function of the half-life. The results were obtained with fragment separators (curves 1 and 2), chemical on-line (3-5) and chemical off-line separations sensitive to lead- (3, 8), platinum- (5, 7), and radon-like (4, 6) elements (after [108]).

duction rate of einsteinium-254 of several micrograms per year is increased by one order of magnitude. Such an increase has been proposed[110] for a number of scientific reasons.

6.2. Attempts to Synthesize by Nucleon Transfer

The typical spectrum of products resulting from a fusion reaction is quite well known, in contrast to products from nucleon transfer between heavy nuclei. Questions of whether a broad or a narrow spectrum of product nuclei is formed and whether the excitation energy of these nuclei is distributed sharply or not have to be verified experimentally and interpreted by theoretical models.[111]

The first reaction to be studied at UNILAC was that of xenon-136 with uranium-238. In this reaction the Dubna group had observed a spontaneous fission activity with 150 d half-life[112, 113] which they attributed to a superheavy element.[113] This activity could not be found at UNILAC.[114]

A more attractive case, of course, was the reaction between two uranium-238 nuclei, the study of which was only possible with the UNILAC. The question was, what would happen in reactions between the heaviest naturally occurring nuclei. The first radiochemical studies[115] of the uranium-uranium reaction were encouraging; nuclei beyond uranium being formed. The respective yields, however, decrease strongly with increasing atomic number because the nuclei tend to be more and more fissile. On the other hand, the occurrence of complementary nuclei near element 70 indicated (see Fig. 7) that the proton transfer in the collision complex is large enough to produce superheavy elements with the appreciable cross section of 10^{-28} cm^2. It remained open, however, whether their survival probability was sufficiently large.

During the first experiments to detect superheavy elements in the uranium-uranium reaction the reaction products were measured without separation from other products. They were either implanted in solid-state detectors[116, 117] or transported to the detector system by a carrier gas[118–120] or by a wheel.[121, 122] In these cases the detection threshold was limited by the background of α- and spontaneous fission decay of the actinoids. More sensitive measurements were performed with radiochemical off-line methods[121] that separated the actinoids. These experiments were complemented by on-line measurements of radon-like products.[67] All these attempts had negative results. The respective cross-section limits are depicted in Figure 24.

Two different ideas prompted further experiments. The reaction of uranium-238 as projectile and curium-248 as target was studied[123] because transfer towards superheavy nuclei should be more favorable when starting with a heavier target. This was shown in the build-up of heavy actinoids.[124] The reaction between uranium-238 and lead-208 was also studied[125] because the structural properties of the reaction partners might favor the transfer. These experiments were unsuccessful, too. The cross-section limit for the uranium-curium reaction was 4×10^{-35} cm^2 for lead-, platinum-, and radon-like elements with half-lives between several days and years, and 1×10^{-33} cm^2 for radon-like elements with half-lives of several minutes to hours. For the uranium-lead reaction the corresponding limits are 1×10^{-33} cm^2 for half-lives of milliseconds to days and one order of magnitude lower for half-lives of some hours to years.

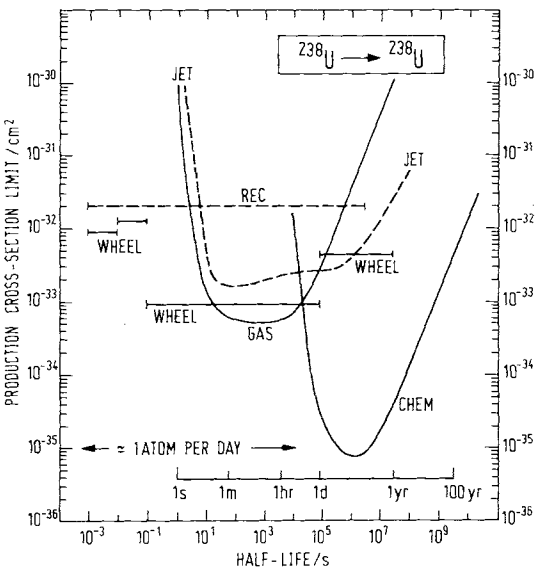

Fig. 24. Results from a search for superheavy elements in the reaction of uranium-238 with uranium-238. Upper limits of the production cross-sections as a function of half-life, measured after implantation of the unseparated reaction products into solid-state detectors ("rec") [116, 117], after transport of the products by a gas jet ("jet") [118–120] or a wheel ("wheel") [121] to the detectors, after chemical on-line separation of radon-like elements ("gas") [67], and after off-line separation of lead-, platinum-, and radon-like elements ("chem") [121] (after [67]).

7. Perspectives

The nuclei at the end of the periodic table decay differently from what would be expected from Figure 3. Spontaneous fission does not tend to dominate in the rectangular, new region; α-decay remains the dominant decay process. This is even true for nuclei with even numbers of protons and neutrons. In this case spontaneous fission competes most favorably with α-decay, whereas for odd numbers of protons or neutrons the unpaired nucleon slows down spontaneous fission by orders of magnitude more than α-decay. Such α-emitters with even proton and neutron numbers, like the heaviest one, the isotope 264 of element 108,[84, 85] are especially informative, because their most energetic α-transition ends in the ground state of the resulting daughter nucleus. From the decay energies one can therefore calculate the binding energies of the successively decaying nuclei of a whole decay chain, and derive the corresponding nuclear masses. These masses allow the calculation of the shell energies from which one can deduce the fission barriers shown in Figure 25.[84, 30] These barriers have the unexpectedly large values of 6 to 7 MeV over the whole range from element 92 to 108, whereas the liquid-drop model predicts their continuous decrease to vanishingly small values. More recent theoretical calculations are able to reproduce the barrier heights deduced from experiment, as is obvious in Figure 25. These barriers are caused

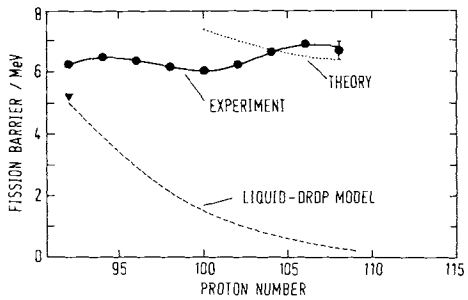

Fig. 25. Fission barriers of heavy nuclei with $N-Z=48$ as a function of proton number. Dots: values obtained from experimentally determined nuclear masses. Dotted line: calculated theoretical values. Dashed line: barrier heights expected from the liquid-drop model (after [30]).

by shell effects in non-spherical, slightly elongated nuclei.[127, 128]

The heaviest known nuclei are only able to exist because of the strong stabilization against fission, which corresponds to 18 orders of magnitude in half-life for element 108.[73] If the attribute "superheavy" means that an element exists only by virtue of the stabilizing effect of nuclear shells and not the requirement to be spherical, as is expected for element 114, then the superheavy elements have already been found; *Armbruster* has stressed this point.[28, 73] The idea that superheavy, shell-stabilized nuclei do not necessarily have to be spherical but might be deformed was already formulated by *Bohr* in 1974;[129] shell closures would then occur for different nucleon numbers, in regions more easily accessible to experiments.

The nuclear landscape, as it should look according to the most recent theoretical studies,[81, 126–128, 130] is shown in Figure 26. The "microscopic" contribution to the binding energy is represented by contour lines. The numbers in the figure give these values in MeV for the respective contour lines. This contribution is due to the nuclear structure and causes the stabilization. The heaviest known nuclei are again shown as squared boxes near the lower left-hand corner. Nuclei above the dashed line cannot exist because they promptly emit a proton. Nuclei above the dotted line should not exist according to the liquid-drop model, because they do not have any fission barriers. Nuclei that may exist due to shell stabilization fall between these two lines. Taking into account that for detection the lifetime has to be longer than microseconds, the barrier height has

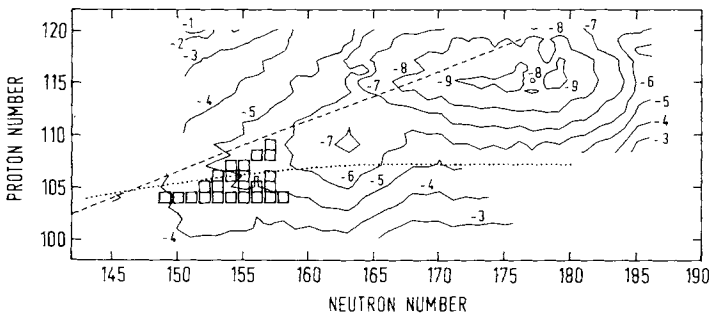

Fig. 26. Predicted shell correction energies of heavy and superheavy nuclei [130]. Nuclei with the same shell correction (given in MeV) are connected by contour lines. Known nuclei are marked as squares. Above the dashed line prompt emission of protons is expected. The dotted curve indicates the limit for spontaneous fission from the liquid-drop model. No nuclei should exist above this line according to this model (after [30]).

to be at least 4 MeV.[73] Thus, the elements 107 to 109 reported here owe their existence only to these shell-induced fission barriers.

The landscape looks much different now than in Figure 21. It has been changed by the experimental results of recent years and the refined theoretical calculations that they stimulated. The center of the island of spherical nuclei is located around the region of largest microscopic corrections of more than 8 MeV. The elements 114 to 116 are still at the center, but now with the lower neutron numbers of 171 to 179. From the center a ridge develops towards the south-west, exactly in the direction of the heaviest known nuclei. It includes a little peak around element 109 and neutron number 163.[130, 126, 128] In this local region half-lives of, e.g., 40 ms for (110)-272, an α-emitter, are estimated,[127] or even of some hours for the spontaneous-fission isotope (106)-268.[81] However, it is possible that, due to a special kind of fission, spontaneous fission is more dominant in this region. This special fission process is observed in the region of element 100, fermium,[131, 132] and might be present also for heavier nuclei.[133] It occurs faster than usual fission and involves a compact form of the fissioning nucleus rather than the usual elongated one. Similarly, the resulting fragments are spherical rather than deformed.

The fusion of calcium-48 with curium-248 results in a compound nucleus of 116 protons and 180 neutrons, which, after some neutrons have evaporated, is quite close to the center of the newly determined island of spherical superheavy nuclei. From there, α-decay chains should start with half-lives of milliseconds to minutes,[127] which eventually reach the area of spontaneous fission near element 110.[81] The fact that these decay chains could not be found, even though the prediction about the island's location is more favorable now, most likely means that fusion is already strongly hindered. Some recent theoretical[93] and experimental[134] studies point in that direction, too.

It should be possible to reach the region of local stability near neutron number 163 by fusion of easily accessible nuclei. One might use, for example, the reactions of argon-40 with uranium isotopes. As already discussed in Section 5.4, results of such experiments are still ambiguous.

The stability of the heaviest nuclei is still a topic with open problems but it does not seem to be a major obstacle to further extension of the periodic table. The syntheses are much more of a problem. The general trend of an increasing hindrance to fusion with increasing masses of the nuclei involved is well established. For the individual case, however, the situation is less transparent, in spite of the systematic experiments carried out at UNILAC[28, 73] and theoretical studies.[92, 93] First of all, the onset of hindrance depends on the nuclear charge and mass numbers of projectile and target, reflecting the opposing effects of attractive and repulsive forces. A second complication comes from the nuclear structure of the reaction partners. Its influence is not easy to predict for the systems of interest here. What has been learned from lighter systems that are quite easy to study does not necessarily apply to these heavy systems.

The over all situation is represented in Figure 27 (after *Armbruster*).[28] The proton numbers of target Z_T and pro-

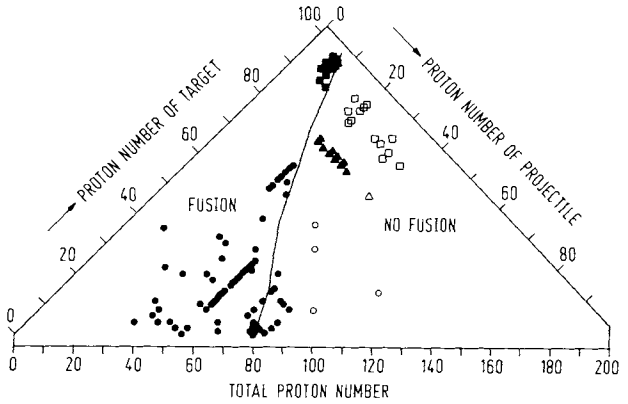

Fig. 27. Fusion reactions for different target-projectile combinations, after [28, 30]. The proton numbers of target and projectile are given on the tilted axes, the sum of both, i.e. the proton number of the compound nucleus, on the bottom axis. Full symbols: fusion was observed via evaporation residues. Empty symbols: fusion was not observed. With combinations to the right of the solid line (calculated from a macroscopic model [93]) an "extra push" should be needed.

jectile Z_p are given on the skewed axes and the sum of both, the proton number of the compound nucleus, is shown on the horizontal axis. Each projectile-target combination is represented by a full symbol if fusion has been detected via evaporation residues and by an empty symbol if none has been observed. Reactions with lead as target are shown as triangles, those with actinoids as squares. Let us take the compound nucleus thorium, $Z_p + Z_T = 90$, as an example. In the vertical direction one finds the different target-projectile combinations: the ones between nuclei of about the same size with Z_p and Z_T from 40 to 50 are in the lower part, the more asymmetric combinations with Z_p and Z_T around 20 and 70 in the upper part. Up to about thorium it seems that any combination of nuclei results in fusion. Beyond it, for example for fermium ($Z = 100$), only asymmetric systems are successful, either with lead or with actinoids as a target (see upper corner in Fig. 27). Fusion finally ends around element 109.

The prediction of the "extra push" model for the limits of fusion is shown by the theoretically derived solid line.[93] It describes the general situation but certainly not the details. Syntheses starting with lead or bismuth (triangles in Fig. 27) work much better than expected. The closed shells are helpful for two reasons: the resulting compound nuclei have a very low excitation energy and the extra push is obviously reduced or not needed at all.[73] It is necessary to shed more light on the remaining mysteries of the fusion hindrance in order to clarify whether it can be circumvented for the purpose of producing even heavier elements, the stability of which may well be high.

Recently, an aspect of cosmic dimensions was added to the speculations about superheavy elements. Figure 28 shows the chart of nuclides as viewed by some elementary particle theorists.[135, 136] The lower left-hand corner shows a conventional chart of nuclides, somewhat mutilated at its upper end. In the upper right one sees an island of stability, the neutron stars, with mass and "atomic" numbers around 10^{57} and 10^{55}, respectively. "Nuclides" with even higher masses are unstable against gravitational collapse leading to black holes. In the middle region one finds the

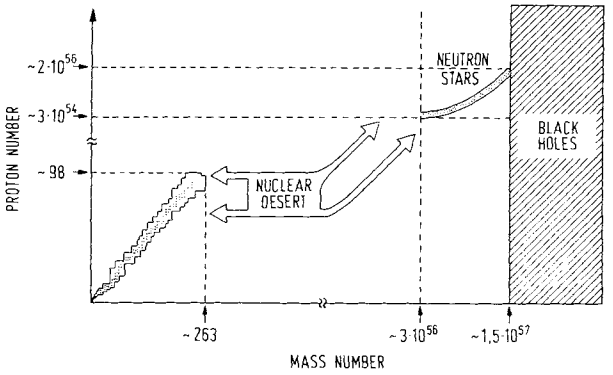

Fig. 28. All-inclusive chart of the nuclides, hopefully incomplete in the nuclear desert region [135].

nuclear desert. It might, however, not be completely empty. Conventional nuclei consist of protons and neutrons. These are, in turn, made up of three quarks each. The proton contains two "up" quarks with charge + 2/3 and one "down" quark with − 1/3. The neutron contains one "up" and two "down" quarks. More massive quarks probably existed only in the very early times of our universe. It is still possible, however, that the "strange" quark, either during these early times or after having been produced later in the course of some high energy processes, formed larger aggregates together with the "up" and "down" quarks. These multi-quark aggregates might constitute the true ground state of nuclear matter,[137, 135] and thus might still be present today. They are candiates for being part of the "dark matter" which fills the universe.[137, 135] The radii of these lumps of "strange" matter may be between 10^{-15} and 10^{3} m.[135, 137] Different methods can be used to search for these lumps in natural samples.[135, 137] At UNILAC this is done by backscattering of very heavy ions like uranium.[138, 139] Superheavy elements as messengers of strange matter—what a perspective!

To arrive at the results and ideas presented here many scientists worked together in friendship and competition. Their names can be found in the references. Christoph Schmelzer contributed to all these subjects, not only by the design and the construction of the UNILAC, but also by his steady encouragement of the "Nuclear Alchemists". Thanks are due to Helmut Ahrens, Peter Armbruster, Hans-Otto Denschlag, Heinz Gäggeler, Jens Volker Kratz, Klaus Lützenkirchen, Gottfried Münzenberg, Matthias Schädel and Norbert Trautmann for their critical reading of the manuscript.

Donor-Acceptor-Substituted Cyclic π-Electron Systems—Probes for Theories and Building Blocks for New Materials

By Rudolf Gompper* and Hans-Ulrich Wagner

Donor and acceptor substituents stabilize (4n)π-electron systems and destabilize those with (4n+2)π electrons. The same is true for the transition states of pericyclic reactions, which explains the appearance of dipolar intermediates in symmetry-allowed cycloadditions and sigmatropic rearrangements. Donor-acceptor-substituted semibullvalenes undergo rapid Cope rearrangement, as do tetraazabarbaralanes. In contrast, tetraazasemibullvalenes cannot be isolated, since the isomeric tetrazocines always result. The usefulness of the donor-acceptor concept in preparative chemistry is demonstrated by numerous stable cyclic (4n)π-electron systems, like donor-acceptor-substituted cyclobutadienes, tetraaminobenzene, and *p*-benzoquinone dications, benzodiazepinyl anions, and donor-acceptor-substituted cyclopentadienyl cations and their heteroatom-containing analogues. The new compounds are of interest in the fields of organic metals and ferromagnets, nonlinear optics, and dyestuffs, among others.

1. Introduction

The special properties of cyclic π-electron systems, well known to everybody from time immemorial, have always been attracting to chemists. For the chemist it is also routine to include donor and acceptor effects in planning syntheses. The concepts of aromaticity and donor-acceptor effect can be traced back to *Kekulé*'s benzene formula (1865)[1] and beyond and to *Witt*'s theory of chromophores and auxochromic groups (1876).[2,3] Though these ideas have been used successfully for over 100 years, their heuristic power and interpretative potential remain unexhausted. As regards the donor-acceptor concept, there are so many examples that only a few can be mentioned here: capto-dative-substituted radicals[4] (merostabilization:[5] the concept of capto-dative stabilization has been disputed[5c]), the use of donor-acceptor molecules in nonlinear optics (NLO),[6-9] TICT compounds (TICT=twisted intramolecular charge transfer),[10] and the allopolarization principle that describes the regioselectivity of ambident ions.[11]

The continuing topicality of aromaticity is to some extent surprising, since even today aromaticity has no generally applicable or accepted definition.[12-14] Indeed, quite a few chemists are extremely skeptical of the usefulness of this concept. *Heilbronner*,[15] for example, has stated that "aromaticity is not an observable property ... and it is not even a concept which, in my experience, has proved very useful". *Binsch*[16] gave an instructive article the title "Aromaticity—an Exercise in Chemical Futility".

Nevertheless, there has been an unbroken chain of remarkable results up to the present day. Clearly, an intuitive grasp of the phenomenon of "aromaticity" is very fruitful for the chemist. From a theoretical point of view, aromaticity is a complex phenomenon, and its usefulness as a concept can only be maintained by applying aromaticity criteria to precisely defined areas.[17-19] In spite of the skepticism towards aromaticity, new "aromaticities" have constantly been put forward (homoaromaticity,[20,21] bicycloaromaticity,[22] Y-aromaticity,[23-25] "4n+2 interstitial electron rule",[19] "in-plane aromaticity",[26,27] "trefoil aromaticity"[28,29]) and the transition states of pericyclic reactions have also been included.[30-32] On the other hand, questions as fundamental as the D_{6h} symmetry of benzene[33] and the driving force of double-bond delocalization in the "aromatic" sextet[34-40] are still open or, at least, the classical answers have been called into question (if the symmetrical hexagonal structure of benzene is driven by the σ framework alone, the π system favoring a localized structure, the π-electron delocalization energy can no longer be a criterion for the empirical resonance energy[40]). Significantly, VB theory is once again gaining importance in this field.[41-44]

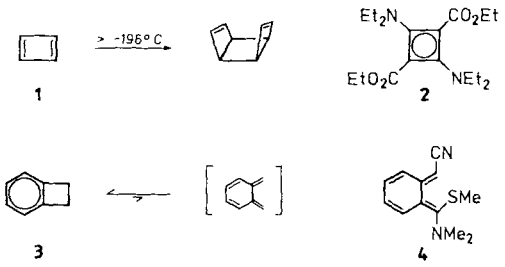
In view of the many studies on the theoretical background of aromaticity on one hand and the great significance of substituents for the course of aromatic substitutions on the other, it is amazing that the influence of substituents on aromaticity has not been systematically studied. Substituents have only been discussed in connection with the stabilization of heterocycles (topological charge stabilization[45,46]) and of a few special π systems (tetra-*tert*-butylcyclobutadiene,[47] tri-*tert*-butylazete,[48] pentalenes[49,50] such as 1,3-bis(dimethylamino)-2-azapentalene,[51] and 4,8-bis(dimethylamino)- or 1,3,5,7-tetra-*tert*-butyl-*s*-indacene[52,53]) and with distortion (Mills-Nixon effect[54]) or bending of the benzene ring.[55,56a] It is obvious that any unsymmetrical distortion of annulenes will lead to a loss of frontier orbital degeneracy. The principal distinction between the orbital schemes of aromatic and antiaromatic compounds on one hand and polyenes on the other disappears, and the question arises which "character" substituted polyenes possess. Particularly strong substituent effects are to be expected with acceptor groups (A) like NO_2, CN, COR, SO_2R, with donor groups (Do) like NR_2, SR, OR, and with combinations of A and Do. The following discussion will pursue this question and, on the basis

[*] Prof. Dr. R. Gompper, Dr. H.-U. Wagner
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (FRG)

of synthesized compounds, will explain the usefulness of the concepts arising from it.

1.1. Donor-Acceptor-Substituted Polyenes

The dramatic influence exerted by donor-acceptor groups on the properties of cyclopolyenes can best be demonstrated with cyclobutadiene **1**.[56b] Although it is rectangular[57-63] (valence tautomerism[64]) and therefore no longer fully antiaromatic, **1** is extremely unstable and can only be detected in a matrix below −196 °C. Diethyl 2,4-bis(diethylamino)cyclobutadiene-1,3-dicarboxylate **2**,[65-70] by contrast, forms yellow crystals (m.p. 56 °C), has four equal-length ring C–C bonds corresponding to a low tendency towards second-order bond fixation ("λ_{max}" = 1.24; see below), and only dimerizes above 120 °C to a red cyclooctatetraene. (1,3-Bis(diethylamino)-2,4-bis(phenylthio)cyclobutadiene[71] and tris(dimethylamino)azete[72] can also be synthesized.)



Only on heating to > 150 °C do cyclobutabenzenes **3** (cf. Refs. [73, 74]) show noticeable valence tautomerization to *o*-quinodimethanes, which can be trapped with dienophiles. The aromaticity of the annelated benzene ring hence hinders ring opening of the cyclobutene system. Donor-acceptor-substituted *o*-quinodimethanes[75] like **4**, however, show no tendency at all to dimerize or polymerize, nor any tendency to rearrange into cyclobutabenzenes.

Clearly, donor-acceptor groups reduce both the antiaromatic destabilization of **1** and the aromatic stabilization of the benzene system in **3**. Therefore, (4n+2)π cyclopolyenes are generally made more weakly aromatic by donor-acceptor substituents, while (4n)π cyclopolyenes become more weakly antiaromatic and may even become "aromatic". As explained above, the classification of cyclopolyenes as aromatic, nonaromatic, and antiaromatic depends on what criteria are used; it must be "defined"[15] each time what "aromaticity" means. As a basis, the Hückel rule (antiaromaticity[76]) is used almost exclusively and, in addition, despite their problematic nature, the following criteria:

Resonance energy (Hückel,[77] DRE,[13,79-81] TRE,[82] PMO[78b,c])
NMR data (diatropism, paratropism)[83-85] (problems with homotropylium cations[86])
Bond alternation,[53,87,88] bond order[89,90]
HOMO-LUMO gap[91-93] (LUMO vs. $E^{red.}_{1/2}$, cf. Ref. [94])

How do the above experiments with cyclobutadienes and cyclobutabenzenes relate to these criteria? Predictions from resonance energy are frequently problematic, particularly with polycyclic compounds (see pentalenes, Section 2.4). More dependable results can generally be obtained from the HOMO-LUMO gap. Cyclopolyenes with (4n+2)π electrons have larger HOMO-LUMO gaps than the corresponding polyenes; in cyclopolyenes with (4n)π electrons, degenerate frontier orbitals (SOMOs) are present (cf. Ref. [91]). How do donor-acceptor substituents affect the HOMO-LUMO gap in these π-electron systems? From Figure 1 it can be seen that donor and acceptor groups reduce the HOMO-LUMO gap of 2β in benzene to 1β in a 1,4-A_2-2,5-Do_2-benzene, which, according to this model, is therefore more weakly aromatic than benzene. The corresponding substituents increase the HOMO-LUMO gap of cyclobutadiene from 0β to the same value as for the substituted benzene, 1β. Resonance energies give a similar picture. A 1,3-A_2-2,4-Do_2-cyclobutadiene is therefore just as "aromatic" as an analogously substituted benzene derivative. The values in Figure 1 support the experimental results, and the following rule may be defined: *Donor-acceptor substituents destabilize (4n+2)π-electron systems and can stabilize (4n)π-electron systems to such an extent that they acquire aromatic properties.*

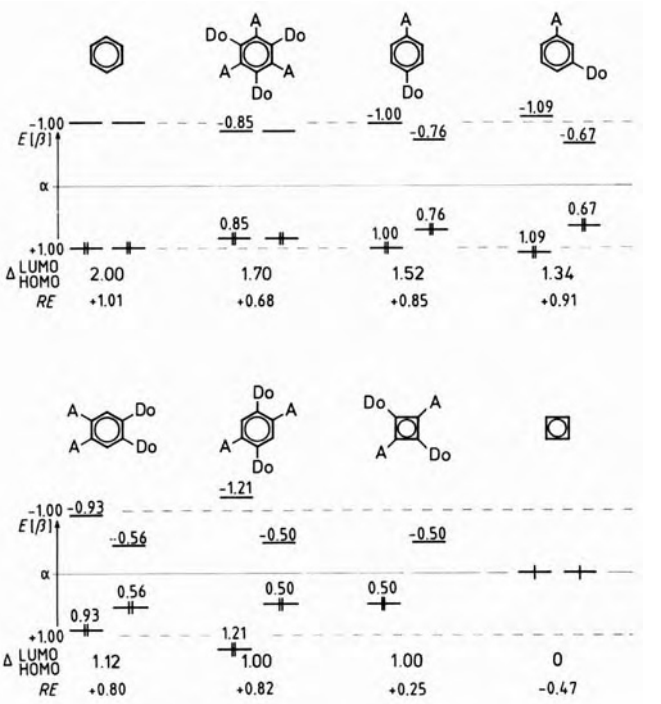


Fig. 1. HOMO-LUMO gaps [β] and resonance energies *RE* [β] of donor-acceptor-substituted benzene and cyclobutadiene derivatives (HMO)

$RE = E_\pi(\text{ring}) - E_\pi(\text{polyene})$
$\alpha_x = \alpha_c + h_x\beta_{cc}$, $h_A = -1.5$, $h_{D_o} = +1.5$

The same conclusion is reached if the relative HOMO-LUMO gaps $\Delta\Delta E$ are considered,[95] i.e., the difference in energy between the HOMO-LUMO gaps of the cyclopolyenes on one hand and the corresponding polyenes on the other (Figs. 2 and 3). The numerical value of $\Delta\Delta E$ is diminished by donor substituents in cations and by acceptor substituents in anions (Fig. 2), leading to a weakening of the aromaticity of 2π and 6π systems ($\Delta\Delta E$ positive) and to a weakening of the antiaromaticity of 4π systems

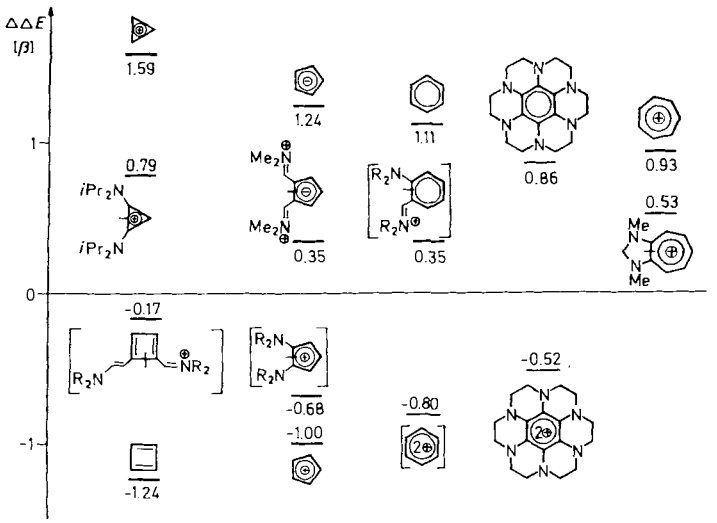

Fig. 2. Influence of donor or acceptor groups on the relative HOMO-LUMO gap $\Delta\Delta E$ [β] (HMO) of cyclic π systems.

$\Delta\Delta E = \Delta E_{\text{HOMO-LUMO(ring)}} - \Delta E_{\text{HOMO-LUMO(polyene)}}$

($\Delta\Delta E$ negative). However, when $\Delta\Delta E$ is used instead of $\Delta E_{\text{HOMO-LUMO(ring)}}$, the (4n)$\pi$ systems still remain in the antiaromatic region. This is also true of systems with donor *and* acceptor substituents (Fig. 3). With an identical acceptor group, the numerical value of $\Delta\Delta E$ falls with donors

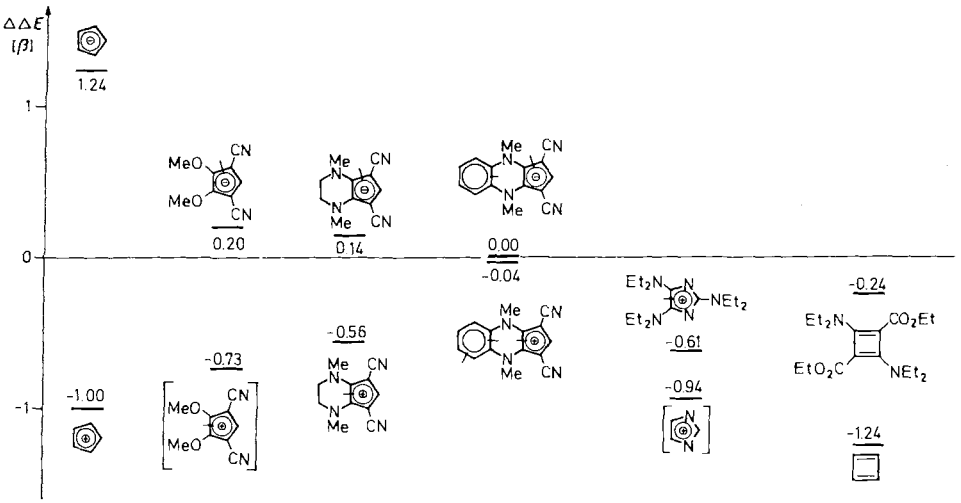

Fig. 3. Influence of donor *and* acceptor groups on the relative HOMO-LUMO gap $\Delta\Delta E$ [β] (HMO) of cyclic π systems.

$\Delta\Delta E = \Delta E_{\text{HOMO-LUMO(ring)}} - \Delta E_{\text{HOMO-LUMO(polyene)}}$

of increasing strength. It is remarkable that the cyclopentadienyl cation is stabilized to the same extent by two amino and two cyano groups ($\Delta\Delta E = -1.00 \Rightarrow -0.56$) as by two amino groups ($\Delta\Delta E = -1.00 \Rightarrow -0.68$). The benzoannelated diamino(dicyano)cyclopentadiene system, for example, demonstrates particularly clearly how the charcteristics of these opposing π-electron systems converge under the influence of donor-acceptor substituents. The 6π anion is destabilized, the 4π anion is stabilized.

1.2. Transition States

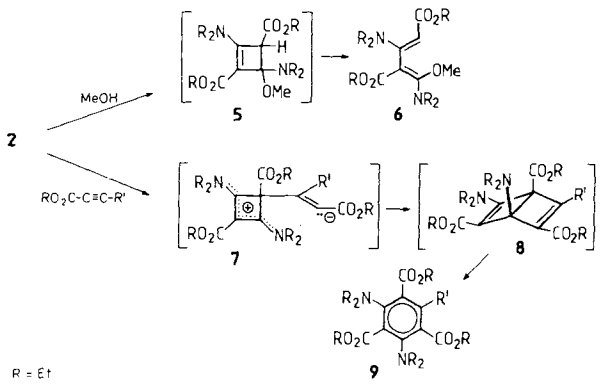
Donor-acceptor substituents should influence the transition states of pericyclic reactions just as they do the ground states of cyclopolyenes. In reactions which, according to the Woodward-Hoffmann rules,[30] are symmetry-forbidden as one-step processes[96] (antiaromatic transition states),[31,32] *this symmetry-prohibition can be circumvented by using polar reactants in two-step reactions involving 1,4-dipolar intermediates.*[97] It should be possible for such two-step reactions to take place in one step, however, if substitution with sufficiently strong donor and acceptor groups gives the transition states aromatic character and thereby reduces the activation energies. (Interpretation by configuration interaction;[98] the possibility of SET processes in [2+2][99-101] and [4+2] cycloadditions[102-107] can be only briefly mentioned here.) In polar [2+2] cycloadditions, for example, **2** would be the model for the transition state. On the other hand, symmetry-allowed one-step reactions should be slower under the influence of donor-acceptor groups, and two-step reactions with dipolar intermediates should gain in significance. The transition state for the Cope rearrangement of a 2-acceptor-5-donor-substituted 2,5-hexadiene, for example, is comparable with a 1-A-4-Do-benzene, which is more weakly aromatic than benzene (see Fig. 1).

The donor-acceptor effect can be illustrated in pericyclic reactions with numerous examples (reaction rates, isolation and trapping of dipolar intermediates). Several of these will now be discussed.

1.2.1 Electrocyclic Reactions

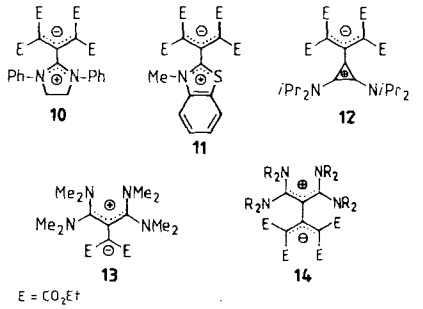
Reaction of **2** with methanol yields butadiene **6** rather than cyclobutene **5**,[108a] apparently because **5** is unstable as a result of donor-acceptor substitution (see also Ref.

[109]). The reaction of **2** with acetylenes, via the 1,4-dipole **7**, does not afford the Do-A-substituted Dewar benzenes **8**, but the benzene derivatives **9**,[108b] even at low temperature. The symmetry-forbidden rearrangement of **8** to **9** is hence greatly accelerated by Do-A substituents.



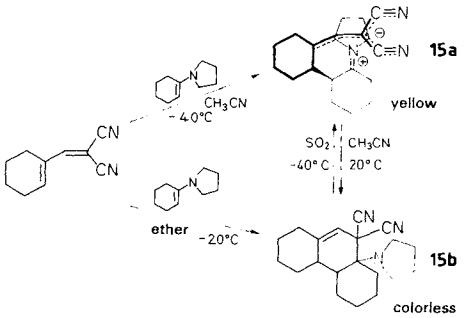
1.2.2. [2+1] Cycloadditions; Stable Non-Kekulé Systems

Singlet carbenes add to olefins stereospecifically.[110] However, if electron-poor allenes like tetraethyl allenetetracarboxylate are reacted with nucleophilic carbenes, the products are not cyclopropanes, but stable, crystalline 1,3-dipoles **10–12**.[111] An analogous compound **13** is obtained if the electron-rich tetrakis(dimethylamino)allene is combined with diazomalonic ester.[112] Compounds **10–13** can also be viewed as stable trimethylenemethanes; if trimethylenemethanes, as 4π-electron systems, are classified as antiaromatic, the stabilization of destabilized π systems is seen again. Finally, combination of electron-poor and electron-rich allenes gives the crystalline tetramethyleneethane derivative **14**.[113] Compounds **10–14** are of interest because, among other things, they are stable examples of non-Kekulé systems.



1.2.3. [4+2] Cycloadditions

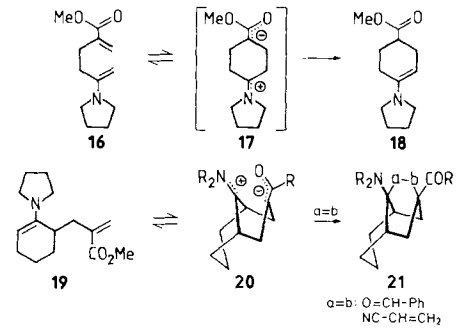
The mechanism of the Diels-Alder reaction still arouses discussion.[114] Reactions of oppositely polarized components take place very quickly, and dipolar intermediates can be detected. The reaction of cyclohexenylmethylenemalonodinitrile with 1-(1-cyclohexenyl)pyrrolidine at room temperature gives the colorless Diels-Alder cycloadduct **15b**, but at −40 °C the crystalline, yellow, 1,6-dipole **15a** is obtained, which is converted into **15b** on warming.



In liquid sulfur dioxide, even at −40 °C, **15b** is transformed into **15a**.[66,115] (Two-step polar Diels-Alder reactions have also been observed with other dienes[116] and heterodienes.[117–121])

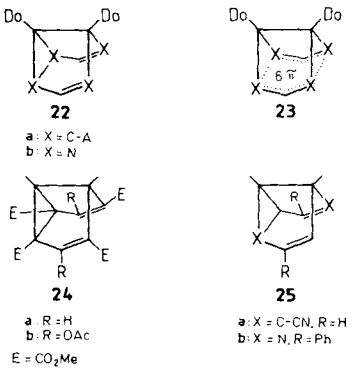
1.2.4 [3,3]-Sigmatropic Rearrangements (the Semibullvalene Problem; Tetrazocines; Tetraazabarbaralanes)

Just as with the Diels-Alder reaction, the question of the concertedness of the Cope rearrangement of "normal" 1,5-hexadienes still remains open.[122] Cope and hetero-Cope rearrangements of 2-donor-5-acceptor-substituted 1,5-(hetero)dienes like **16** and **19**, for example, proceed extremely rapidly, and 1,4-dipoles (**17**, **20**) can be detected.[123–129] Dipole **17**, which is in equilibrium with **16**, eventually affords **18** by prototropism, and **20** can be trapped with benzaldehyde or acrylonitrile to give the tricyclic compound **21**.[123] (Two-step [2,3]-sigmatropic rearrangements are also known.[130,131]) The formation of 1,4-dipoles could be caused by a slowing of the one-step Cope rearrangement

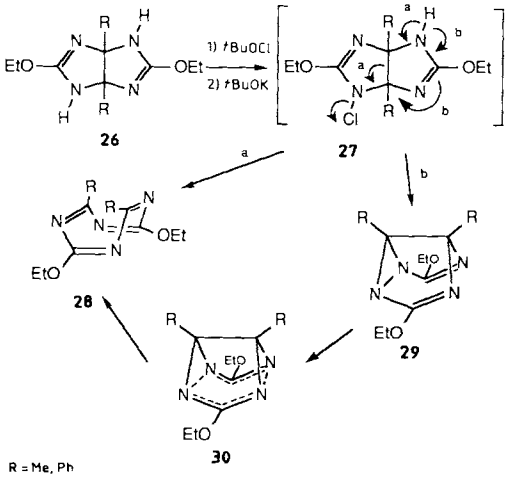


(higher activation energy due to the weaker aromaticity of the transition state) and an acceleration of the two-step reaction (stabilization of the transition state leading to the 1,4-dipole).

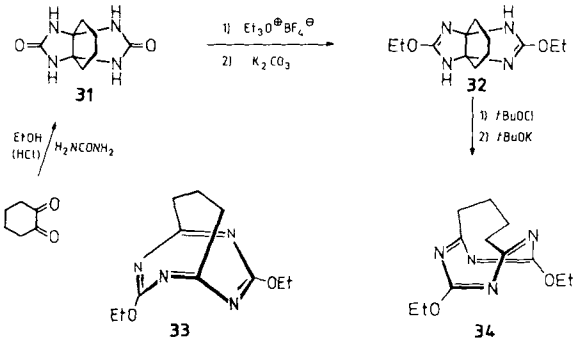
Cope rearrangement of semibullvalenes proceeds extremely rapidly.[132] According to *Dewar* et al.[133] and *Hoffmann* et al.[134] 1,5-didonor-2,4,6,8-tetraacceptor-substituted semibullvalenes **22** could have a bishomoaromatic ground state **23**. Till now, such systems have been sought in vain (**24a**,[135] **24b**,[136,137] **25a**,[138] **25b**,[139]). There could be two reasons for this. Either the rearrangement of the donor-acceptor-substituted semibullvalenes studied so far does not go through a bishomoaromatic ground state or it is not stabilized sufficiently for the reasons outlined above. Possibly, the substituents used (Do, CH_3; A, 4 CO_2R, 2 CN, 2 ring N) were not "strong" enough.



Since synthesis of semibullvalene-2,4,6,8-tetracarbonitriles[140] has not yet been possible, we have attempted to produce the electronically equivalent 2,4,6,8-tetraazasemibullvalenes **22b**. Oxidation of the bisimidates **26** of the glycouril series does not, however, lead to tetraazasemibullvalenes **29**, but to the tetrazocines **28**.[141] Either the tetraazasemibullvalenes **29** and the bishomoarenes **30** are both destabilized relative to the "nonaromatic" tetrazocines (the X-ray crystal structure shows a boat form, as for cyclooctatetraene) and rearrange rapidly to **28** (path b), or a fragmentation of **27** occurs (path a). 1,5-Dimethyl-3,7-diphenyl-2,6-diazasemibullvalene also rearranges to 2,6-dimethyl-4,8-diphenyl-1,5-diazocine, though only at 90 °C.[142]

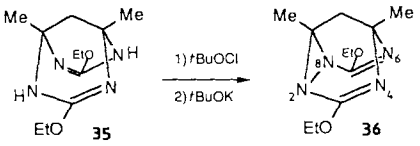


To prevent conversion to tetrazocines, 3a,6a-bridged-glycourils such as **31** were synthesized (cf. cyclooctatetraenes containing $(CH_2)_n$ bridges between the 1,3-,[143a] 1,4-,[143b] and 1,5-positions[143c]) and transformed into **32**, which were then oxidized. However, tetrazocines[144] were produced here too[143] (e.g., **34** and **33**, prepared from an analogue of **31**). This is all the more astonishing since, although **33** is a derivative of bicyclo[3.3.3]undec-1-ene and is therefore counted as a member of the "isolable" bridgehead olefins,[145,146] it is the only "anti-Bredt" bridgehead imine isolated to date, apart from 2-azabicyclo[3.3.1]non-1-ene[147] (cf. Ref. [148]). The synthesis of 1,5-bridged cyclooctatetraenes with five, six, or ten methylene groups in



the bridge[143c] was only possible on heating the corresponding semibullvalenes to 500–521 °C.

If **29** (and **30**) are inherently unstable, then the 2,4,6,8-tetraazabarbaralanes ought also to be so, at least in part. 2,6-Diphenylbarbaralanes and 2,6-barbaralanedicarbonitriles have localized double bonds and undergo faster Cope rearrangement than the parent compound.[149–151] (Substituents at C-3,7 have a moderate rate effect;[152–154] in the crystal, though not in solution, a 9-phosphoniobarbaralane is nearest to a bishomaromatic state.[155]) The tetraazabarbaralanes **36** can be synthesized from **35** by the same procedure as **28, 33,** and **34**.[158] Compound **35** itself is available from the corresponding urea derivative.[156,157]



The X-ray crystal structure of **36** shows a large difference between the N2–N8 (158 pm) and N4–N6 (236 pm) distances, in accord with the given formula. However, the N2–N8 distance is significantly greater than the N–N distance in diaziridines[159–161] (145.3–150.6 pm), and is comparable with that in highly substituted 1,2-bis(*p*-bromo-α,α-dimethylbenzyl)diaziridinone[162] (160.1 pm). The NMR spectra establish that **36** in solution also has a localized structure, for which the Cope rearrangement becomes fast between 25 and −60 °C. A variable-temperature NMR study showed that **36** rearranges more slowly (!) ($\Delta G^{\ddagger}_{210} = 38.9$ kJ mol^{-1}) than barbaralane ($\Delta G^{\ddagger}_{200} = 31.5$ kJ mol^{-1}).[153] This can be rationalized by assuming a bishomoaromatic transition state in the rearrangement of **36**, resembling 3,6-diethoxy-1,2,4,5-tetrazine and therefore, according to Figure 1, being less aromatic than a benzene-like transition state. In the rearrangement of 2,6-barbaralanedicarbonitrile, however, the transition state may have a diallyl structure (cf. Ref. [153]).

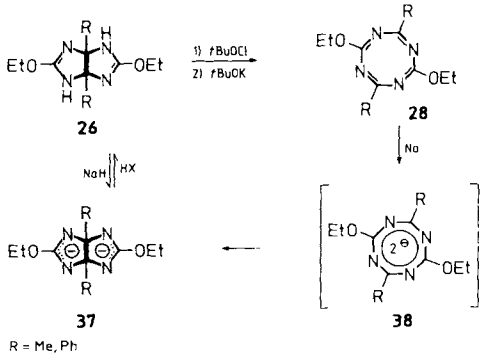
2. Novel Donor-Acceptor-Substituted Aromatic Compounds

Of all compounds synthesized recently by us and other groups, the ones that will be presented are primarily

those examples of 8π- and 4π-electron systems which demonstrate the stabilization and double-bond delocalization effects of donor-acceptor substituents on one hand, and particular characteristics of the substances on the other (color, oxidizability or reducibility, electrical conductivity).

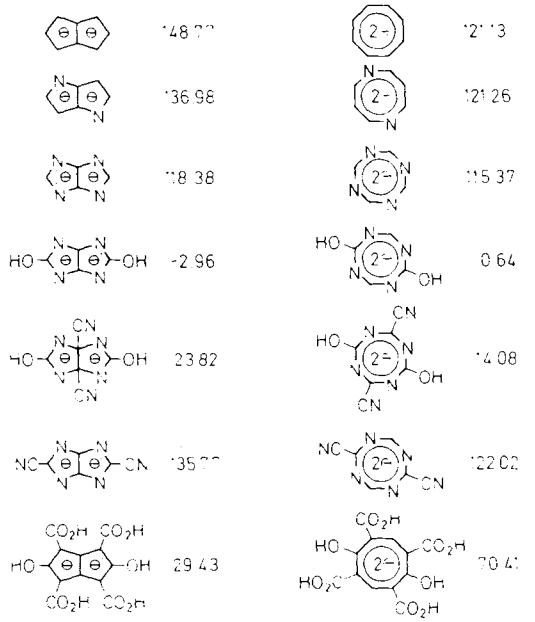
2.1. Ten π Electrons in an Eight-Membered Ring

Cyclooctatetraene (8π, nonplanar) can be reduced to its aromatic dianion (10π, planar);[163-165] azocines[166,167] and diazocines[142] behave similarly. Surprisingly, however, tetrazocines **28** do not afford the monocyclic dianions **38**, but the bicyclic dianions **37**, which can also be obtained from **26** with strong base.[144] This appears to contradict the observed ring-opening of the dianionic bicyclo[3.3.0]octadienediide.[168] In fact, when the energies of dianionic (diaza/tetraaza)bicyclo[3.3.0]octadienediides are compared with those of (diaza/tetraaza)cyclooctatetraenediides, using calculated heats of formation (Table 1), the monocyclic dianions are found to be more favored. In donor-acceptor-substituted systems, however, the balance swings to the side of the bicyclic dianions. While **37** can be viewed as a bishomoantiaromatic[22] 8π-electron system, it is doubtful whether homoaromaticity plays any role at all in carbanions.[169] The formation of **37** rather than **38** demonstrates particularly clearly how a (4n)π system can be stabilized at the expense of a (4n+2)π system by donor-acceptor groups.



26 **28** **37** **38**

Table 1. Heats of formation [kcal mol^{-1}] of bicyclic and isomeric monocyclic dianions (MNDO).

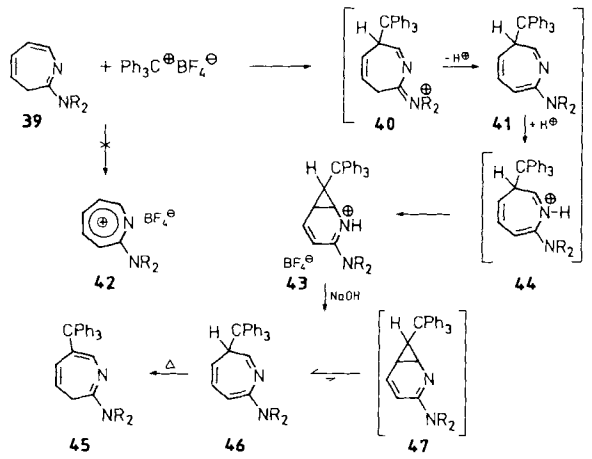


2.2. Six π Electrons in a Seven-Membered Ring (Azatropylium Ions)

Like benzene and pyridine, the tropylium ion and the azatropylium ion are a pair of Hückel-aromatic 6π-electron systems. However, while for pyridine and benzene the effect of aza-substitution on the calculated heats of formation is negligible ($\Delta\Delta H_f = -0.1$ kcal mol^{-1}) (MNDO),

$\Delta H_f^0 = H_f(\text{PhCH=NPh}) - H_f(\text{PhCH=CHPh}) = 7.6$ kcal mol^{-1}
$\Delta\Delta H_f = H_f(\text{AzaAr}) - H_f(\text{Ar}) - 7.6$

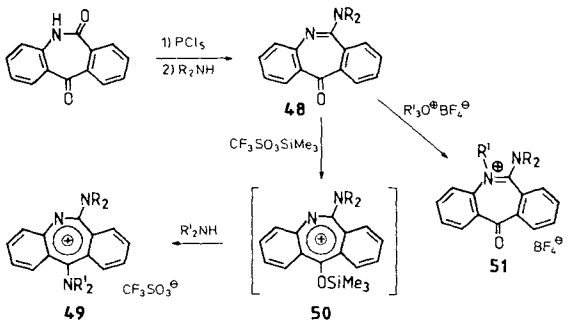
the azatropylium ion proves to be significantly less stable than the tropylium ion ($\Delta\Delta H_f = 10.7$ kcal mol^{-1}). In view of its "aromatic" electron sextet, it is nonetheless surprising that it has not yet been possible to synthesize any azatropylium salts. An attempt to oxidize 2-amino-3*H*-azepines **39** to 2-aminoazatropylium salts **42** with trityl tetrafluoroborate, where the destabilizing influence of the ring N atom ought to be (over)compensated for by the donor group, led to salts **43** of 2-azanorcaradienes **47**, the first salts of this type[170] (3-azanorcaradienes, see Ref. [171]). Obviously, this occurs by initial electrophilic addition to give **40**, followed by deprotonation (→**41**), reprotonation (→**44**), and electrocyclization to yield **43**. Treating **43** with alkali gives **47**, which suffers ring-opening to **46**, and on warming affords the 6-substituted 2-amino-3*H*-azepines **45**. The more electron-rich 2-dialkylamino-6-methylthio-3*H*-azepines cannot be dehydrogenated to azatropylium salts either.[170]



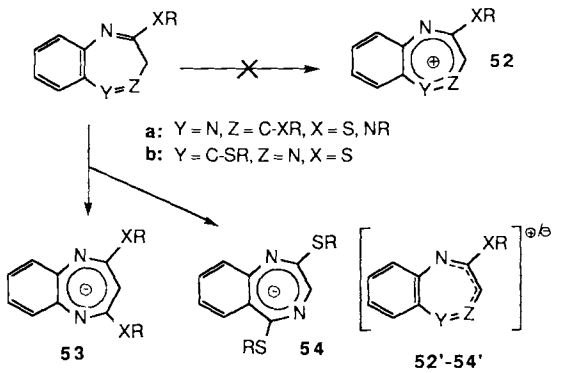
39 **40** **41** **42** **43** **44** **45** **46** **47**

The first derivatives of azatropylium salts have now been synthesized[174] via aminodibenzoazatropones **48** from morphanthridinediones.[172,173] The electronic differences between the tropones and **48** can be seen in the fact

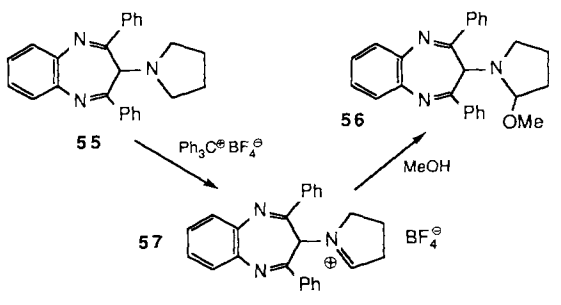
that unlike tropones, **48** are not *O*-alkylated, but can be *N*-alkylated to form **51**. Compound **48** can only be converted into the red salt **50** with trimethylsilyl triflate; this is then transformed in situ into the stable orange salt **49**.



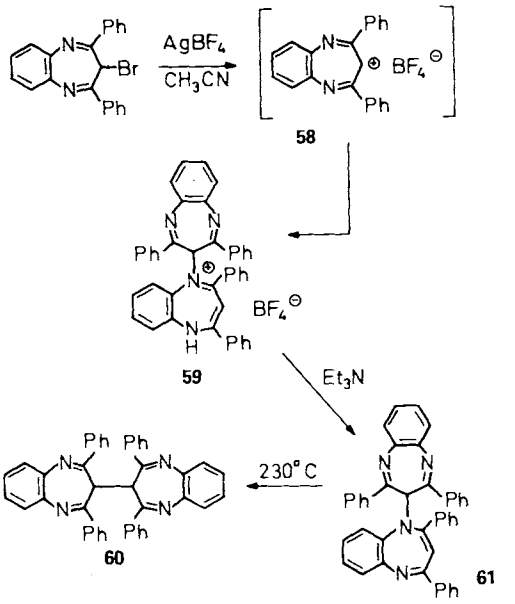
Only by severely changing the azatropylium system by annelation of two benzene rings is it possible to obtain stable derivatives. Just as for the compound types mentioned above, the Hückel rule is no help here. As yet, benzodiazepinium ions of type **52** have not been obtained



either,[175,176] though, as 6(10)π-electron systems combined with donor substituents (SR, NR_2), they ought to be sufficiently stabilized. The low tendency to form **52** is probably connected with the high contribution of resonance structure **52'**, and is illustrated by the observation that on reaction of **55** it is not the seven-membered ring but the five-

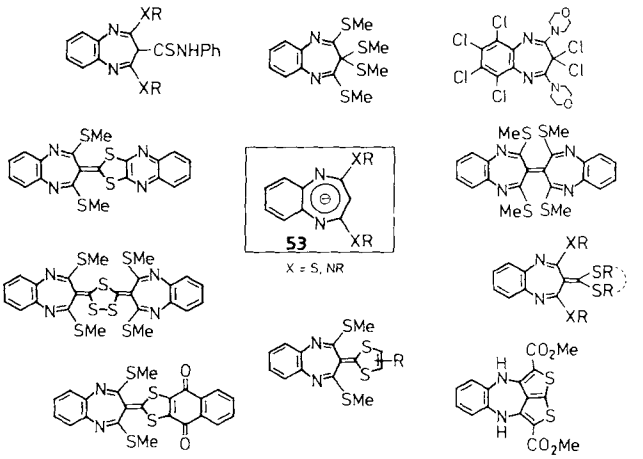


membered ring that is dehydrogenated to give **57**, which yields **56**.[175] The reaction of silver tetrafluoroborate and 2,4-diphenyl-3-bromo-1,5-benzodiazepine, which gives the red salt **59**,[175] might involve the benzodiazepinium ion **58** as an intermediate, but other mechanisms are also conceivable. Salt **59** can be deprotonated to give the yellow *N,C*-bis(benzodiazepine) **61**, which on heating affords the *C,C* dimer **60**.



2.3. Eight π Electrons in a Seven-Membered Ring

While azepinium and benzodiazepinium ions have not yet been detected, 8π-[176] and 12π-electron anions[174,175,177] have been produced for the two classes of compounds, respectively (cf. carbon analogues[178-182]). The anions **53**[175,177] and **54**[174] are easy to synthesize and undergo numerous reactions. In solution, the lithium salts of **54**, R = alkyl, and **53**, RX = alkylthio, are purple and red, respectively, and therefore probably have strongly ionic character. Compounds **53**, RX = dialkylamino, with lithium as counterion, are colorless and are therefore likely to be covalent species. Compounds **53** and **54**, whose stabilities can be ascribed to resonance structures **53'** and **54'**, react at C-3 with electrophiles to form novel sesquifulvalenes and heptafulvalenes, among other products (Scheme 1).

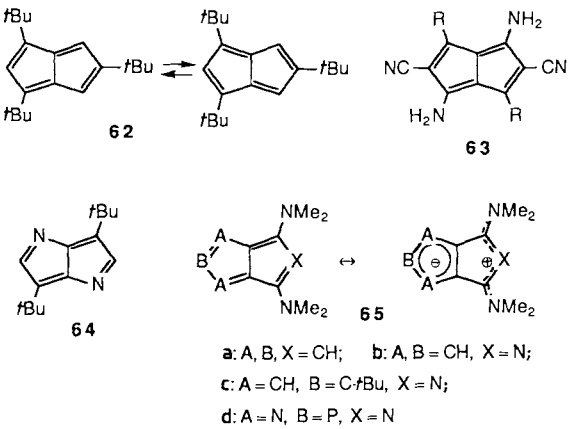


Scheme 1. Reactions of 1,5-benzodiazepinyl anions **53** with electrophiles.

2.4 Eight π Electrons in a 5/5-Ring System ((2,5-Diaza)pentalenes) and Twelve π Electrons in a 5/6/5-Ring System (2,6-Diaza-*s*-indacenes)

2.4.1. *Donor-Substituted 2,5-Diazapentalenes*

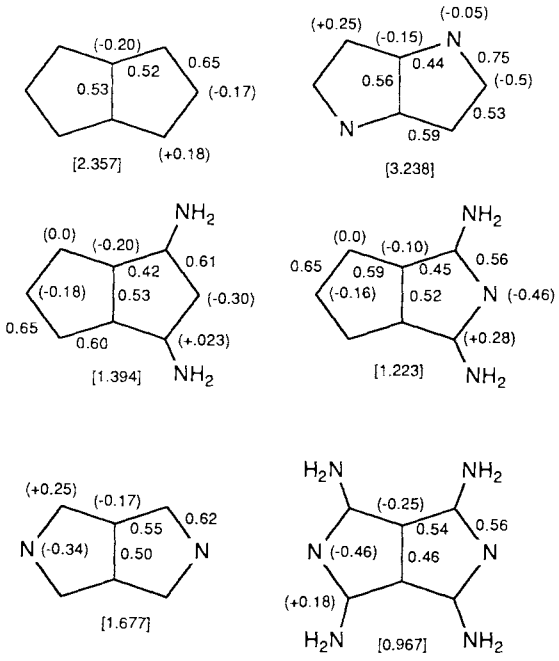
As planar analogues of the nonplanar cyclooctatetraene, pentalenes are usually classified as antiaromatic.[78c, 183–187] However, use of sterically demanding groups makes it possible to obtain stable pentalenes like **62** and to prove that these are compounds showing bond alternation, which undergo rapid valence tautomerization.[51, 188] With aza- and diazapentalenes,[82, 187] the destabilizing effect can become smaller.[49, 50] The diazapentalene **64**, described as "electronically pure",[189] (cf. Ref. [190]) is clearly a localized system and therefore actually nonaromatic[189] (incidentally, alkyl substituents are in no way electronically "pure", i.e., without influence, as is shown, for example, by the orientation effect in aromatic electrophilic substitution, by Hammett constants, and by the structural discussion on *s*-indacene,[52, 53] where *tert*-butyl groups are not treated differently from amino groups). Bond localization also seems

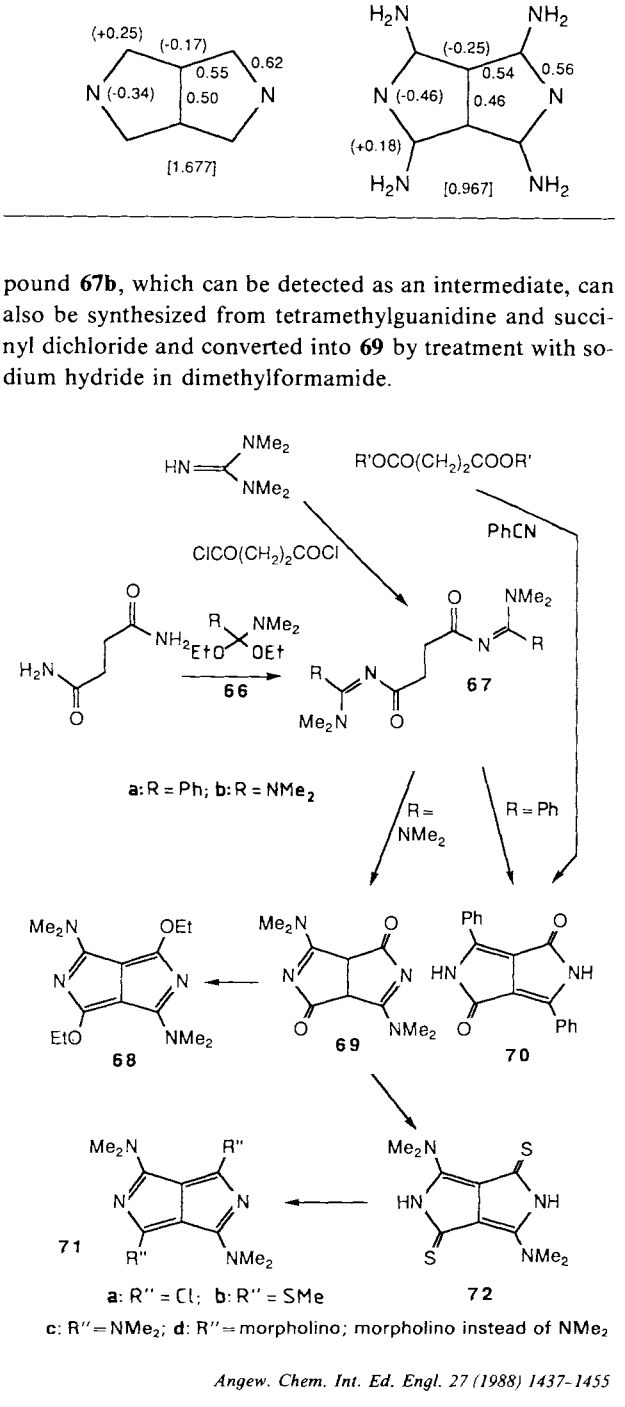


dominant in **65b,c**,[51] while **65a**[51] and **65d**[191] are best characterized by dipolar resonance structures. The bond localization in **62** agrees with the bond-localization parameter "λ_{max}" calculated according to *Binsch* and *Heilbronner*'s method[53, 87, 88] (see Table 2), while that of **64** agrees with the calculated bond orders; by calculation, **65a–c** should show approximately the same bonding situation. 1,3,4,6-Tetraamino-, 2,5-diaza-, and especially 1,3,4,6-tetraamino-2,5-diazapentalene have "λ_{max}" values which fall below the critical value. This, and the larger HOMO–LUMO gap, leads one to expect 1,3,4,6-Do_4-2,5-A_2-substituted pentalenes to be aromatically stabilized and to show a delocalized π-bond system (cf. also Refs. [49, 50]). At this point the interesting Do-A-substituted pentalene derivatives **63**, R = alkyl or phenyl,[192] should also be mentioned.

The reaction of succinamide with the amidoacetals **66** is, along with the reaction of succinic acid and aromatic nitriles[193] (cf. also Ref. [194]), a simple method of producing diones such as **70**,[195] which are of great interest, not least as pigments.[193] With **66b** one obtains the colorless compound **69**[196] in high yield. In contrast to the red **70**, compound **69** does not exist in the enamine form. Compound **67b**, which can be detected as an intermediate, can also be synthesized from tetramethylguanidine and succinyl dichloride and converted into **69** by treatment with sodium hydride in dimethylformamide.

Table 2. Calculated substituent effects on double-bond delocalization in (aza)pentalenes ($\lambda_{crit} \approx 1.7$). Numbers on the bonds, π bond order; numbers in parentheses, π charge; numbers in square brackets, "λ_{max}".





From **70** and the dithione derived from it,[195,197a] one can synthesize bis(trimethylsiloxy)- and bis(alkylthio)-2,5-diazapentalenes, respectively.[175] Compound **69** is the starting material for 1,3,4,6-tetradonor-2,5-diazapentalenes. Using triethyloxonium tetrafluoroborate one obtains **68**; with Lawesson's reagent **72** is obtained; **72** gives **71b**, which yields **71c** upon treatment with dimethylamine at 140 °C. Phosphorus oxychloride gives **71a**, from which **71d** can be obtained. The high thermal stability of these crystalline compounds dramatically demonstrates the effectiveness of the donor-acceptor effect (cf. Table 2). The 1,3,4,6-tetraamino-2,5-diazapentalenes **71c,d** are especially interesting from a theoretical point of view. They allow an investigation of the question of whether **71** has a localized (C_{2v} symmetry) or delocalized structure (D_{2h} symmetry).

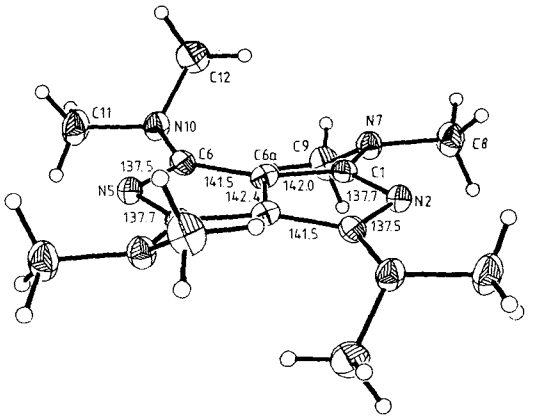


Fig. 4. Crystal structure of **71c** (ORTEP).

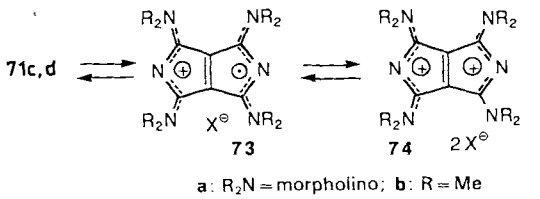
X-ray analysis of **71c** (Fig. 4) reveals double-bond delocalization, as required by theory (as to the question of equilibrium structure, stabilized transition state or disorder in the crystal, cf. Ref. [197b]). Compounds **71c,d** must therefore be described as "aromatic Hückel antiarenes", since they show neither strong first-order bond fixation nor strong second-order bond fixation.[87,88] (If the expression "electronic purity"[189] is adopted, then the "electronically impure" Hückel antiarenes **71c,d** represent delocalized cyclopolyenes, i.e., arenes, while the "electronically pure" Hückel antiarenes **63** and **64** are localized cyclopolyenes and therefore nonaromatic compounds.)

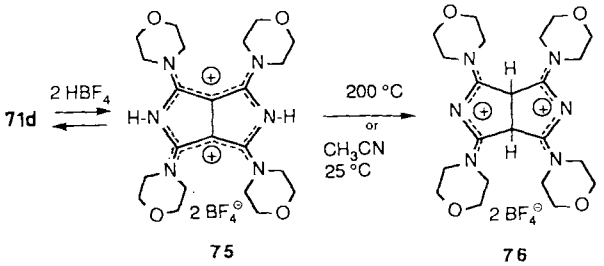
Compounds **68** and **71** provide examples of reversible multistep redox systems (formation of radical anions and radical cations (cf., e.g., **73**), dianions and dications (cf., e.g., **74**)). The salt **74a**, X = BF_4, can be obtained as reddish-purple crystals on a preparative scale by reaction of **71d** with trityl tetrafluoroborate in dichloromethane; **73a**, X = BF_4, which is bluish-purple in acetonitrile solution, arises by combination of **71d** and **74a**, X = BF_4.

With **74**, dications of pentalene have been isolated and characterized for the first time. Though the synthesis of a hexachloropentalenediylium bis(hexachloroantimonate) has been reported,[198] its structure was not proved. Dications of dibenzopentalene have been generated in solution and characterized by NMR spectroscopy,[199] and the radical cation of 1,3,5-tri-*tert*-butylpentalene, stable up to −77 °C, has also only been obtained in solution.[200,201]

The use of tetradonor-substituted diazapentalenes now makes possible the synthesis of an entire series of stable, crystalline pentalene dication salts. The Wiberg bond index[202] for C3a-C6a in **74** is 1.852, which corresponds almost to a CC double bond, as in the given formula (π charges: C-1, +0.35; C-3a, +0.09; N-2, −0.46). The 6π system formed by oxidation of **71c,d** is therefore converted from a delocalized into a localized structure by first-order bond fixation.



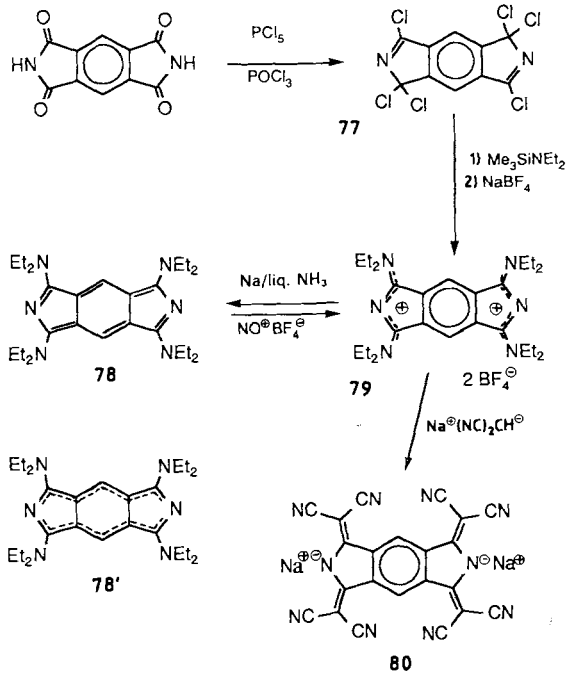
a: R_2N = morpholino; b: R = Me



Tetradonor-substituted-2,5-diazapentalenes are quite strong bases (pK_a1, pK_a2 (in 50% EtOH): **71c**, 6.40, 10.35; **71d**, 4.28, 8.63). It is interesting to note that **71c** is as basic as 1,8-bis(dimethylamino)naphthalene (pK_a = 10.40 (in H_2O, pK_a = 12.34[203,204])), but 1,3-bis(dimethylamino)-2-azapentalene **65b**[205,206] is a markedly weaker base (pK_a = 6.82). Protonation of **71c,d** does not take place on the dialkylamino groups as in "proton sponge", though, but on the ring N atoms. Reaction of tetrafluoroboric acid etherate with **71d** in dichloromethane leads to the yellow NH salt **75**, which decomposes to the colorless CH salt **76** either thermally or on standing in acetonitrile solution.

2.4.2. *1,3,5,7-Tetraamino-2,6-diaza-s-indacenes*

In **76**, two azaallylium or azavinamidinium units are connected by a CC single bond, while in **74** it is a CC double bond that links the two. The analogous yellow dicationic salt **79**,[207] which has a benzene ring as the linking unit, is obtained by reaction of the hexachloro compound **77**, which is available from pyromellitimide, with diethyl(trimethylsilyl)amine. (A structure corresponding to **79** has been calculated for the dication of *s*-indacene.[208a]) Like **74**, though at a more negative potential, **79** can be reversibly electrochemically reduced to **78** via a stable radical cation. If the reduction is carried out with sodium in liquid ammonia, then **78** can be isolated as air-sensitive violet crystals. X-ray analysis (Fig. 5) shows that **78** has a delocalized structure corresponding to **78'**, though, like **71c** it belongs to the Hückel antiarenes. The predictions arising from "λ_{max}" and *RE* (*s*-indacene, 1.57,[53,88] 1.145; 2,6-diaza-*s*-indacene, 1.36, 1.341; 1,3,5,7-tetraamino-*s*-indacene, 1.18, 1.151; 1,3,5,7-tetraamino-2,6-diaza-*s*-inda-



cene, 1.22, 1.367) of increasing delocalization and stabilization of *s*-indacene by donor and acceptor groups are therefore fulfilled. These had already proved to be correct with the compounds synthesized by *Hafner* et al. (4,8-bis(dimethylamino)-*s*-indacene,[51,53] 1,3,5,7-tetra-*tert*-butyl-*s*-indacene[52,53]). Hexamethyl 4,8-dihydroxy-*s*-indacene-1,2,3,5,6,7-hexacarboxylate[208b] is also a stable compound. Compound **79** is the phenyl analogue of **74** and **78'** is the quinodimethane homologue of **71c,d**.

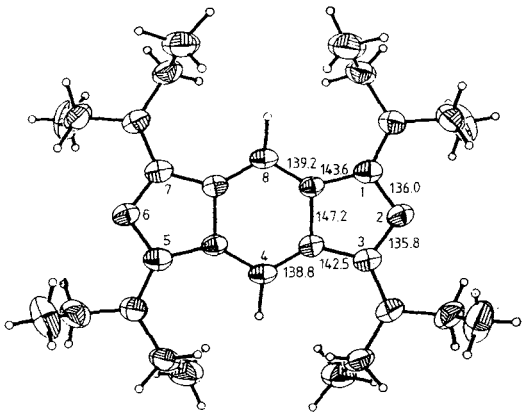


Fig. 5. Crystal structure of **78** (ORTEP).

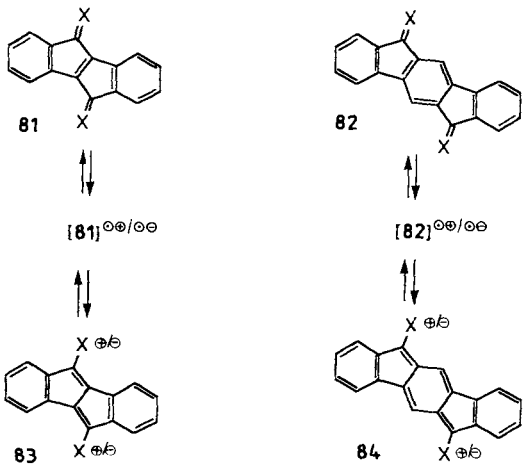
Compounds **76** and **79** readily react with nucleophiles. The formation of the dianionic salt **80** is remarkable; it reacts with **79** to form a red dicationic dianionic salt containing a small proportion of radical ions. Compounds **79** and **78** combine to form a radical cation (λ_{max}(THF) = 795, 875 nm).

It is worth noting that the transformation of **78'** (λ_{max}(benzene) = 614 nm) to **79** (λ_{max}(CH_2Cl_2) = 440 nm) is associated with a strong hypsochromic shift, while that of **71d** (λ_{max}(C_6H_6) = 483 nm) to **74a** (λ_{max}(CH_3CN) = 520 nm) shows a bathochromic shift.

2.4.3. Derivatives of Dibenzopentalenes

In contrast to pentalenes, dibenzo[*a,e*]pentalene[209] and its 1,9-dimethyl[210] and 1,9-dichloro derivatives[211] are thermally stable. Dications and dianions of dibenzo[*a,e*]pentalene can be obtained[199,212] from the parent compound by oxidation and reduction, respectively, or by metalation of 1,9-dihydrobenzo[*a,e*]pentalene **80**, X = H_2.[211] The ability of the dibenzopentalene system to form both a stable 14π dication and a stable 18π dianion is reflected in the properties of the electron-rich dihydrobenzopentalene derivatives **81a**, and the corresponding electron-poor compounds **81b**, X = N–CN,[213] $C(CN)_2$.[214] From **81b**, X = $C(CN)_2$, and **81a**, X = 2-(3-methylbenzthiazolylidene), for example, a complex is formed that has high electrical conductivity (σ = 0.74 S cm^{-1}, as a powder). By the same routes used for **81** the "phenylogous" dibenzopentalene derivatives **82** can be synthesized,[213,218] from 6,12-dihydroindene[1,2-*b*]fluorene[215] or the corresponding dione.[216,217] Compounds **81** and **82** can both be reversibly oxidized or reduced via radical cations/anions to give the dications/dianions **83** and **84**, respectively. De-

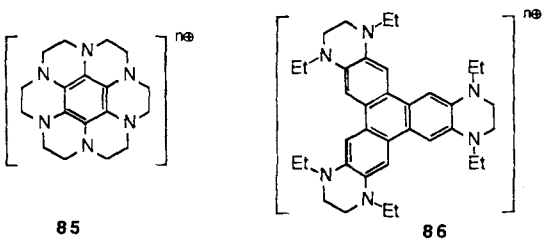


pending on the oxidant, one obtains, for example, colored crystalline bis(tetracyano-*p*-quinodimethides) or bis(tetrafluoroborates) of **83a** and **84a**.

2.5. Four π Electrons in a Six-Membered Ring (Benzene and Quinone Dications)

The benzene dication, the simplest Hückel antiaromatic[219–221] carbodication, has to date only been detected by mass spectrometry.[222] Naturally, with increasing donor strength, substituted benzene derivatives are more easily oxidized.[223,224] The hexachlorobenzene dication can be detected spectroscopically at 77 K[225] (the hexamethyl benzene dication has a pentagonal-pyramidal structure[226,227]). As materials for ferromagnets,[228–231] these unstable compounds are of as little use as the colorless quinone diiminium salts.[232] A system with a triplet ground state is required,[228–231] or one in which the triplet state is easily accessible from the singlet ground state.[231]

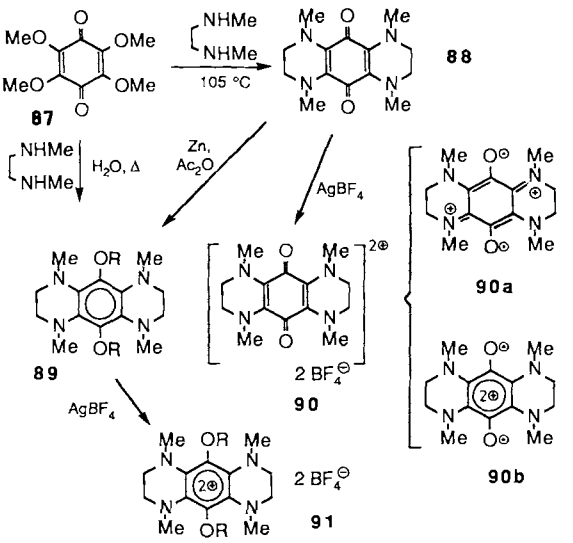
The hexaaminobenzene derivative **85a**[224] and the hexaaminotriphenylene derivative **86a**[233,234] can be easily oxidized to the stable dications **85b** ($RE = +0.14\beta$!) and **86b**, respectively. These have a triplet ground state in solution and are therefore a priori of special interest as materials for organic ferromagnets.



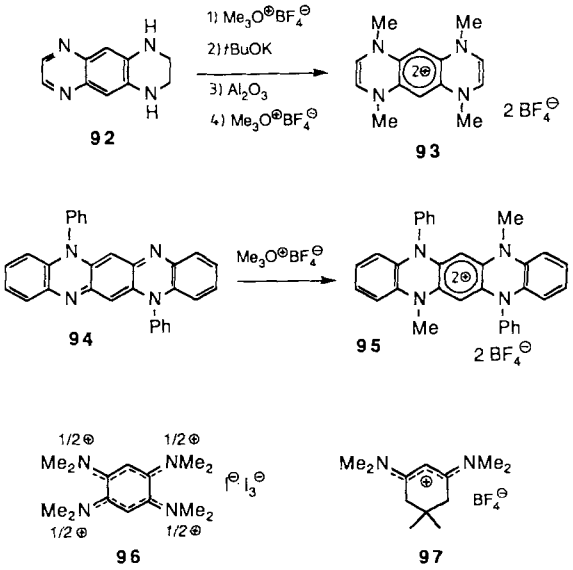
85 **86**

a: n = 0; **b**: n = 2

Tetraaminohydroquinone derivatives **89** are structurally very similar to the hexaaminobenzene derivative **85a**. They are obtained by reductive acetylation (**89**, R = Ac) of decahydro-1,4,6,9-tetramethylpyrazino[2,3-*g*]quinoxaline-5,10-dione **88**, or by reaction of tetramethoxy-*p*-benzoquinone **87** and dimethylethylenediamine (**89**, R = Me).[235,236] They are converted into the blue benzene dicationic salts **91** with silver or nitrosyl tetrafluoroborate ($\lambda_{max}(CH_3CN) = 631$ and 680 nm, respectively). Interestingly, the donor effect of four amino groups is sufficient to cause "umpolung" of the *p*-benzoquinone system; both **88** and **89** can be oxidized to the violet dicationic salt **90** ($\lambda_{max}(CF_3COOH) = 588$ nm), either electrochemically, at very similar potentials, or with silver tetrafluoroborate (the product of oxidation of tetrakis(dimethylamino)-*p*-benzoquinone is reported to be a radical cation[237]). The mesomeric structures **90a** and **90b** emphasize the benzenedicationic nature of **90** and its relationship to **91**.



Further derivatives of tetraaminobenzene dications can be synthesized from pyrazino[2,3-*g*]quinoxalines such as **92** and quinoxalino[2,3-*b*]phenazines such as **94**. By alkylation of **92**[238] one arrives at the green, orange-yellow-fluorescing dicationic salt **93**[236] ($\lambda_{max}(CF_3COOH) = 572$ nm), whose long-wavelength absorption maximum is bathochromically shifted relative to that of **91**. Methylation of **94**[239] with trimethyloxonium tetrafluoroborate in nitromethane affords the green dicationic salt **95**[236] ($\lambda_{max}(CH_3CN) = 639$ nm; salts of this type have been reported in a patent,[240] without synthetic details; a bis(*N*-methylsulfate) of **94**, Me instead of Ph, is also known[241]). The salt **95** is reduced by naphthalenesodium to a radical cation, which can be isolated as a green-black tetrafluoroborate ($\lambda_{max}(CH_3CN) \approx 900$ nm). The radical cation is also formed when the electronic spectrum of **95** is recorded in DMF ($\lambda_{max} = 910$ nm).



92 **93** **94** **95** **96** **97**

The dicationic salt **96** is produced from 1,2,4,5-tetrakis(dimethylamino)benzene and iodine.[242] X-ray structural analysis shows that in **96** the two vinamidinium units are linked by what are almost single bonds, possibly because of steric hindrance. In **91**, **93**, and **95** a similar distortion of the central ring is either impossible or only possible to a reduced extent, because of the additional rings. However, the length of the CC bonds in the central ring does not appear to have a great influence on the electronic state of the dications, since the chemical shifts of the vinamidinium proton signals in **96** ($\delta = 5.85$) and **93** ($\delta = 5.96$) are not significantly different from those in **97** ($\delta = 5.484$).[243] Only in **95** ($\delta = 6.32$) does one see a stronger downfield shift, in agreement with the calculated charge density (HMO charge densities: **95**, −0.141; **93**, −0.159; **97**, −0.163). In their color, too, **91**, **93**, **95**, and **96** (blue to green) do not differ fundamentally from one another.

2.6. Four π Electrons in a Five-Membered Ring ((Aza)cyclopentadienyl Cations)

Initially, cyclopentadienyl cations were only obtained in solution; the cyclopentadienyl cation and its pentachloro derivative have triplet ground states,[228] while the pentaphenyl and pentakis(*p*-methoxyphenyl) derivatives[228,244] have singlet ground states and a low-lying triplet state. One way of generating cyclopentadienylium salts, which are also of interest in the production of organic ferromagnets, among other things,[228-231] is shown by the donor-acceptor

effect (cf. Figs. 1 and 2). The HMO charge densities point in the same direction (Fig. 6). In the framework of this model one sees no destabilization of the π system on moving from the allyl cation to the 2-azaallyl cation, because of the greater electronegativity of the N atom; in the 2-azavinamidinium cation the N atom has a stabilizing effect (cf. electron-gas model[245-247]). Because of the positive charge on all the ring atoms of the cyclopropenylium and tropylium ions, an N atom in these positions destabilizes the π-electron system. With the corresponding diamino derivatives this effect is smaller or not present at all. While the azacyclopentadienyl cation is, naturally, destabilized relative to the cyclopentadienyl cation, with the diaminoazacyclopentadienyl cation one observes a dramatic stabilization. It should be stressed that as yet the "aromatic" azacyclopropenylium and azatropylium salts could not be synthesized (cf. Section 2.2), but that the "antiaromatic" (aza)cyclopentadienylium salts have been prepared!

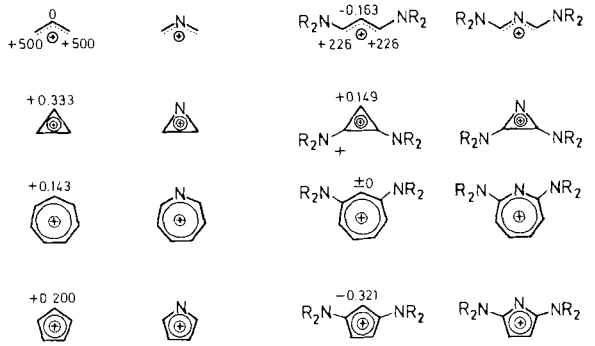


Fig. 6. HMO charge densities of systems with allylic cation structure.

The relationship between color and structure in the compounds synthesized to date is given in Figure 7. The long-wavelength absorption maxima are hypsochromically shifted proportionally to the increases in the HOMO-LUMO gap of the parent compounds.

The compounds presented in Figure 7, and related ones, can basically all be synthesized by (1) substitution or (2) dehydrogenation processes.

(1) Reaction of **101a**,[248] **100b**,[249] or **101b**,[250] with dialkyl(trimethylsilyl)amines gives the red azacyclopentadienylium salts **99**,[251] the benzo analogues **102b**,[252] and the yellow 1,3-diazacyclopentadienylium salt **103**.[252] Like **98** and **102a**[254] (accessible from **100a**[253]), these are stable, crystalline compounds. (Anilino and amino derivatives of type **102** are also known,[255-257] as are several other indenylium salts;[258-261] cf. also solvolyses with indenylium cation intermediates.[262,263])

A variant of this method is to synthesize enaminoketone **105b** from **105a**[264] or by other routes,[265] and from it to obtain thioketone **105c**[266] (2-phenyl derivatives[267,268]). By alkylation of **105b,c** one arrives at **104**, and from this one eventually obtains **102a**[266] (DMAP = 4-dimethylaminopyridine).

(2) The 1,3-diazacyclopentadienylium salt **107**, the phenyl analogue of **103** and structurally related to **98**, has been synthesized by dehydrogenation of imidazole **106**.[269] By

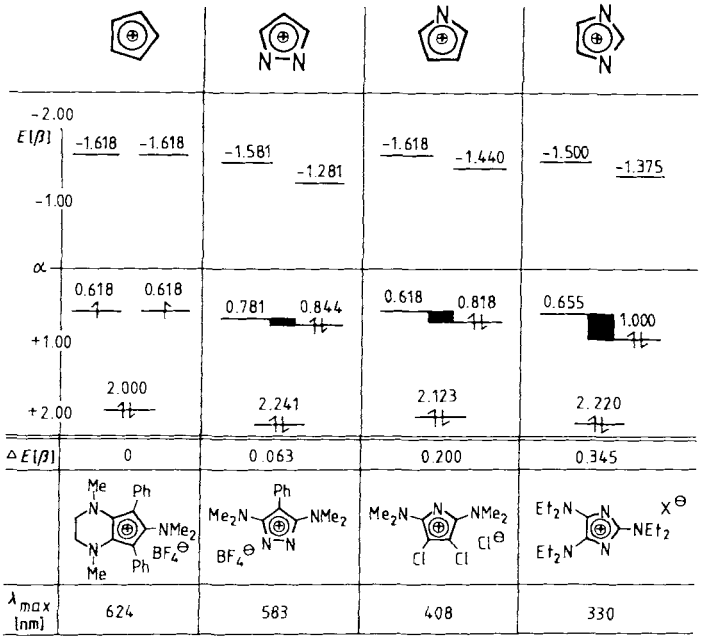

Fig. 7. HOMO-LUMO gaps (HMO) of (aza)cyclopentadienyl cations, and long-wavelength absorption maxima of several typcial (aza)cyclopentadienylium salts.

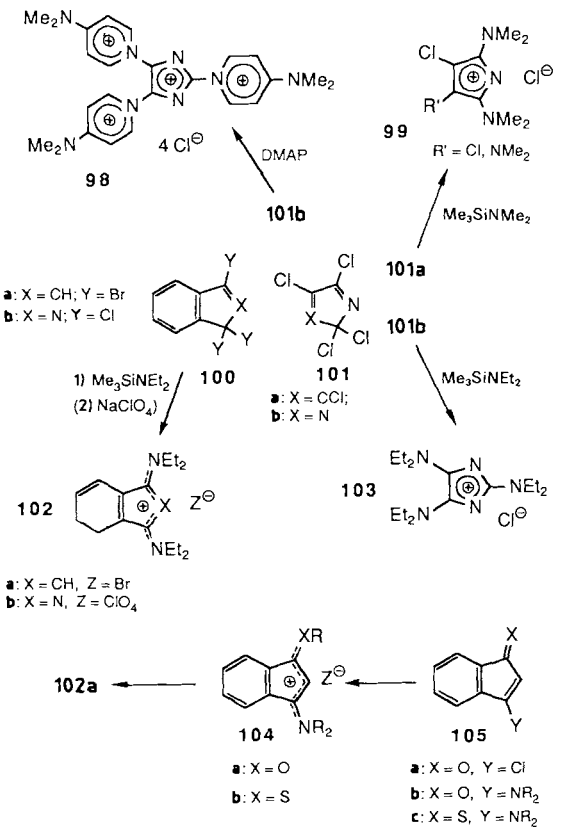
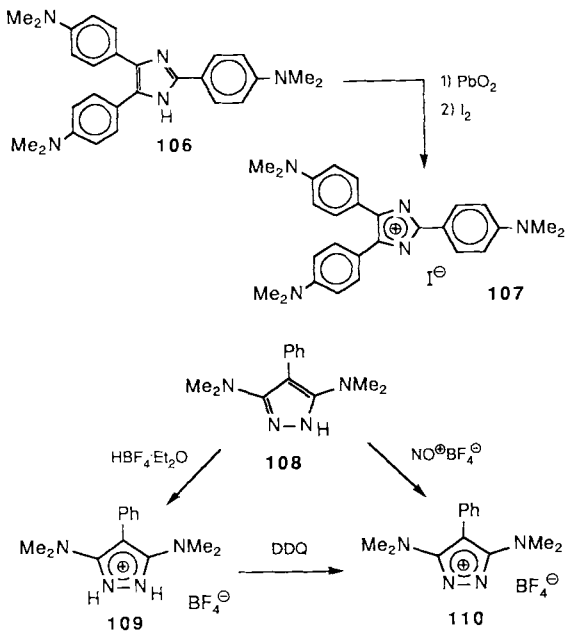
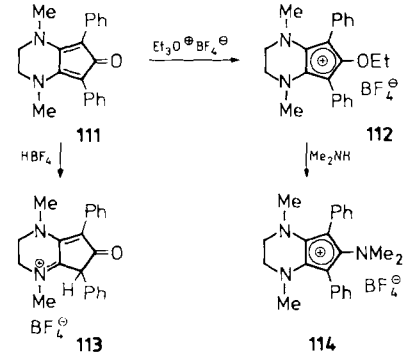


the same principle, it has been possible to obtain 1,2-diazacyclopentadienylium salts **110** by dehydrogenation of **108** or **109**[270] (as to the parent compound, cf. Ref. [271]). The difference in color between the colorless 6π system **109** and the blue 4π system **110** is striking.

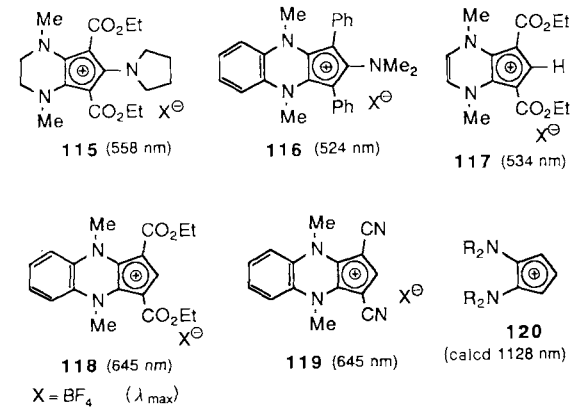
These two routes can be used for the synthesis of numerous thermally stable, crystalline cyclopentadienylium salts.



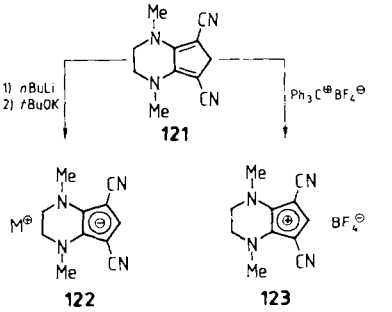
For example, condensation of diphenylcyclopentanetrione with *N,N'*-dimethylethylenediamine yields the stable, red diaminocyclopentanedienone **111**. Whereas protonation of this leads to **113**, reacting it with triethyloxonium tetrafluoroborate gives the green ethoxydiaminocyclopentadienyl salt **112** in quantitative yield ($\lambda_{max}(Ac_2O) = 735$ nm).



Further reaction with secondary amines affords crystalline blue triaminocyclopentadienylium salts like **114** ($\lambda_{max}(CHCl_3) = 624$ nm).[271] By the same principle, one can obtain cyclopentadienylium salts **115–118**.[272] The dependence of the long-wavelength absorption maxima on substituents agrees with MO calculations.



Analogously to the synthesis of **111**, the donor-acceptor-substituted cyclopentadiene **121** is obtained by condensation of dioxocyclopentanedicarbonitrile with *N,N'*-dimethylethylenediamine.[95,273] If one assumes that the effects of the donor and acceptor groups cancel each other out, then the compound ought to behave almost like a normal cyclopentadiene. This is indeed the case, permitting formation of the yellow **122** and the synthesis of numerous fulvenes and fulvalenes,[95,273] whose UV/VIS spectra display a bathochromic shift of 60–100 nm relative to those of the corresponding non-Do-A-substituted compounds. The peculiarity of **121**, however, is that it can be easily converted not only into the salt **122** of a 6π-electron anion, but also to the stable, crystalline, deep-green salt **123** of a 4π-electron cation;[95,273] **119** is another compound of this type.[95] The fact that **122** and **123** are both stable, despite belonging to different π-electron categories, shows the consequence of the donor–acceptor effect particularly graphically. In contrast to the cyclopentadienyl cation ($RE = -0.23\beta$), the cation of **123** has a positive resonance energy ($RE = +0.11\beta$ (HMO)).



The UV/VIS spectra of all donor-acceptor-substituted cyclopentadienediylium salts show very long-wavelength absorption maxima, with medium extinction coefficients ($\log \varepsilon \approx 3$). So far **123** is the record holder, with $\lambda_{max} = 810$ nm, and thereby comes very close to the value calculated for the as yet unknown **120**.[274–277]

Cyclopentadienylium salts **117–119**, **122**, and **123** are most suitable for examining the question of the ring-current effect in stable anti-Hückel systems with positive *RE*. Figure 9 reveals that the donor-acceptor-substituted anions **122**, **124**, **125**, and **127**, the aminocyclopentadiene imine **126** and the cation **119** all fall on regression line for aromatic compounds ($\delta(^1H) = 10.4 q_{N\mu} + 7.59$; $r = 0.988$), produced by plotting $\delta(^1H)$ values against calculated charge densities. (For a detailed discussion of other regressions,[278–284] see Ref. [95].) They can therefore be classified as arenes.

In contrast to this, and above all to the position of **119**, one finds a large upfield shift with cation **123**. From the difference in the net π charge at C-6 between **122** and **123**, a charge-induced shift $\Delta\delta_q = 3.45$ ppm can be calculated, which is significantly larger than that found ($\Delta\delta = 2.10$ ppm). Though the paratropic shift for **123** ($\Delta\delta_p = \Delta\delta_q - \Delta\delta = 1.35$ ppm) is smaller than that for the benzocycloheptenyl anion ($\Delta\delta_p = 3.7$–6.8 pm, relative to the corresponding cation[285]), it is comparable to that observed for tri-*tert*-butylcyclobutadiene ($\Delta\delta_p = 1.04$ ppm, relative to cyclopentadiene[286]) and for **63**, R = alkyl or phenyl ($\Delta\delta_p = 1.10$–1.64 ppm, relative to 1,2-dihydropentalene).[287] According to NMR criteria (paratropism) and

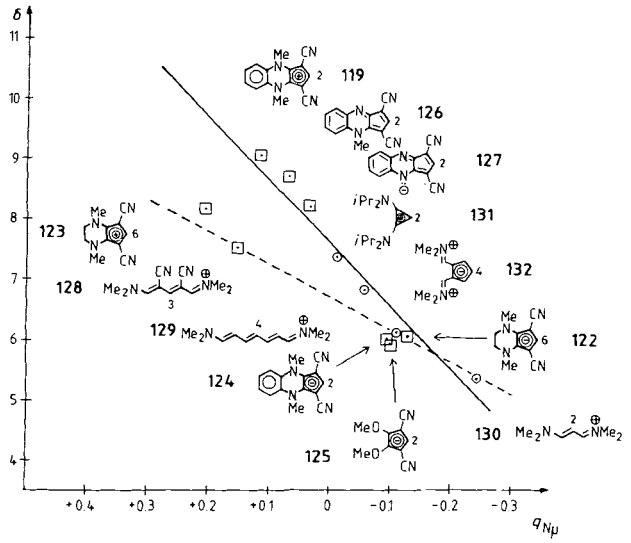


Fig. 8. Chemical shifts $\delta(^1H)$ of the protons in the five-membered ring of donor-acceptor-substituted cyclopentadiene derivatives and related cyanine systems, relative to the calculated net π charges $q_{N\mu}$(PPP). Solid line, aromatic systems; broken line, cyanine systems. ⊡ and ⊙ mean systems with Do or A and systems with Do and A, respectively.

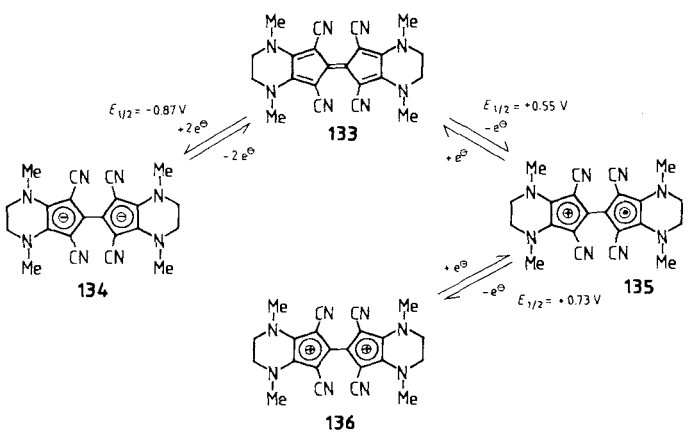
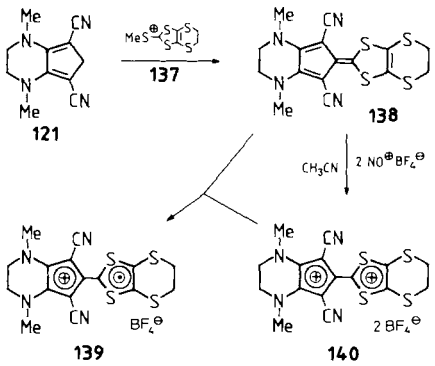
$\Delta\Delta E_{\text{HOMO-LUMO}}$ (cf. Fig. 3), **123** is classified, then, as antiaromatic (cf. Refs. [288, 289]). According to *RE*, however, it is aromatic (cf. the difference between absolute and relative antiaromaticity.[78b])

In addition to the regression line for aromatic systems, Figure 8 shows that for cyanines ($\delta(^1H) = 5.36q_{N\mu} + 6.69$; cf. also Ref. [290]). The open-chain compound **129** ($(\lambda_{max}(CH_3CN) = 389$ nm),[95] a model compound for **123**, fits in here. Accordingly, **123** can also be viewed as a cyanine salt without a ring-current effect, though in view of the positions of the open-chain cyanines **129** and **130**, and of the cyclic **131**[291] and **132**,[292,293] this appears problematic. The enormous color difference between **123** and **128** ($\Delta\lambda_{max}(CH_3CN) = 421$ nm) must also be taken into account. It is also informative that the cyanine salts **131** and **132** fit in best as (4n+2)π systems and are therefore quite distinct from the (4n)π system **123**.

The great stability of **123** is proved in the reversible formation of dication **136**[95] from the fulvalene **133**[273] (cyclic voltammetry; 10^{-3} M, 0.1 M $KPtF_6$ in acetonitrile). It is noteworthy that in the oxidation the stable radical cation **135** appears first, while on reduction only dianion **134** can be detected.

Although **135** has not yet been successfully isolated, the related dicationic salt **140**[95] has been made





($\lambda_{max}(H_2SO_4) = 724$ nm). The salt **140** is obtained by oxidation of fulvalene **138** ($\lambda_{max}(DMF) = 500$ nm), synthesized from **121** and **137**. If one combines **138** and **140**, the radical cation salt **139** is formed ($\lambda_{max}(CF_3COOH) = 819$ nm).

3. Applications and Prospects

Above, all, this review has aimed to show that antiaromatic compounds and antiaromatic transition states can be stabilized by donor-acceptor groups. Knowledge of the properties of donor-acceptor-substituted cyclic π-electron systems naturally does not allow statements to be made about the properties of the parent compounds. Indeed, the very aim of donor-acceptor substitution is to obtain compounds that do *not* have the same characteristics as the parent compounds. This means that in the main the novel π systems have properties that are not determined by the outer-shell π electrons in the classical sense of "(4n)π = unstable, (4n+2)π = stable". Typically, donor-acceptor substitution causes a benzene-like delocalization of the ring electrons of (4n)π systems, while that of (4n+2)π systems brings about a localization to a certain extent (cf. crystal structures of *p*-nitroaniline,[294] *N,N*-dimethyl-*p*-nitroaniline,[295] *p*-nitrophenol,[296] and other benzene derivatives (cf. Ref. [297])). We therefore suggest extending the traditional classification of cyclic π systems as aromatic and antiaromatic with the class of "aromatic (4n)π systems":

Aromatic systems ("stable")
(4n+2)π electrons
$RE > 0$
diatropic
$\Delta E_{\text{HOMO-LUMO}} > 0$
$\Delta\Delta E = \Delta E_{\text{HOMO-LUMO(ring)}} - \Delta E_{\text{HOMO-LUMO(polyene)}} > 0$
weak bond fixation
Antiaromatic systems ("unstable")
(4N)π electrons
$RE < 0$
paratropic
$\Delta E_{\text{HOMO-LUMO}} = 0$
$\Delta\Delta E = \Delta E_{\text{HOMO-LUMO(ring)}} - \Delta E_{\text{HOMO LUMO(polyene)}} < 0$
strong bond fixation (⇒ nonaromatic system)
Aromatic (4n)π systems ("stable")
(4n)π electrons
$RE > 0$
paratropic
$\Delta E_{\text{HOMO-LUMO}} > 0$
$\Delta\Delta E = \Delta E_{\text{HOMO-LUMO(ring)}} - \Delta E_{\text{HOMO LUMO(polyene)}} > 0$
weak bond fixation

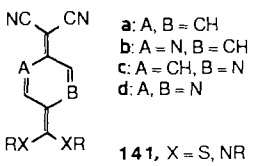
Scheme 2. Proposed classification of cyclic π systems.

One can, of course, have different opinions on whether a (4n)π system that satisfies significant criteria for aromaticity (low tendency towards bond fixation, relatively large HOMO-LUMO gap) should be termed "aromatic". (*Heilbronner*:[15] "'Aromaticity', if to be used at all, should be a purely structural concept. We should define certain molecules as 'aromatic', depending on the formal aspects of their structure." *Binsch*:[88] "A conjugated π-electron system is called aromatic if it shows neither strong first-order nor second-order double-bond fixation. ... Whether [this criterion] is an important one or not will have to be decided by the experimentalist."). However, since the aromaticity criteria presented at the beginning are routinely used with the traditional π systems, including the substituted ones, donor-acceptor-substituted cyclic π systems should not be made an exception.

By use of the donor-acceptor effect, classes of compounds whose members could previously only be generated at very low temperature or as very strongly hindered derivatives have become accessible, and indeed relatively easily so. Where can one generally make use of these Do-A-substituted cyclic π systems? With the change in HOMO-LUMO gap by donor-acceptor substitution there is a possibility of constructing new chromophores (cf. Refs. [3, 247]). Since the novel species are commonly electron-rich or electron-poor π systems, they have the ability to become radical cations or anions, dications or dianions. With this, new substances can be synthesized that, among other things, are suitable in the field of "organic metals" and related areas of application (cf. Ref. [298]). In this respect one should recall that the electrical conductivity of organic donor-acceptor complexes has been traced back to a "migration of aromaticity" within molecular stacks.[299] Despite its not being generally accepted,[300,301] this model offers the synthetic chemist some guidelines.

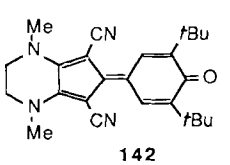
Many of the compounds described are disc-shaped and carry substituents that could be provided with long-chain alkyl groups. Liquid-crystalline (discotic) mesophases (cf. Ref. [302]) and monolayers should therefore also form.

The above discussions were limited to aromatic and antiaromatic systems. If the above question as to the character of substituted cyclopolyenes is to be fully answered, then nonaromatic systems (fulvenes, fulvalenes, quinones, quinone methides, quinodimethanes) and all those compounds whose aromaticity can be seen only in polar resonance structures (cyclopropenone, tropone, etc.; (pseudo)oxohydrocarbons, radialenes) must be considered. *p*-Quinodimethanes **141**,[303-305] for example, have a strongly polar character, and, as has been demonstrated with materials based on **141a**, they are therefore predestined for nonlinear optics.[306] Quinone methides like **142** (synthesized from **123**),[307] are also of interest in this area.



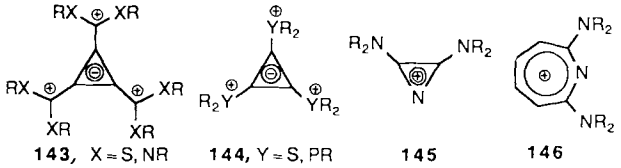
a: A, B = CH
b: A = N, B = CH
c: A = CH, B = N
d: A, B = N

141, X = S, NR



142

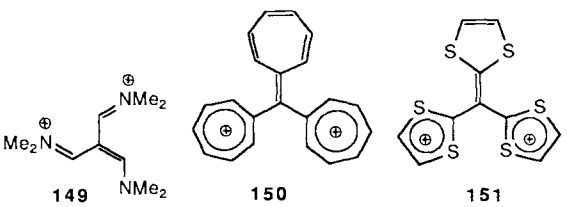
Acceptor and donor groups should make it possible to synthesize several cyclic π systems which until now have been unknown or have only been detected as reactive intermediates—e.g., the cyclopropenyl anion derivatives **143** and **144**, the azacyclopropenylium salts **145** (cf. attempted syntheses[308,309]), and the azatropylium salts **146**.



143, X = S, NR **144**, Y = S, PR **145** **146**

Antiaromatic compounds, which till recently have been a curiosity, are now gaining increasingly more interest in the search for organic ferromagnets.[228-231] In this area non-Kekulé systems like trimethylenemethane[310] and tetramethyleneethane[311,312] also have a role to play, because of their triplet ground state. One possibility for stabilizing trimethylenemethane with donor and acceptor groups has been outlined in **10**–**13**. Another could be the oxidation of Y-aromatic dianions of type **147a** ($n=2^{\ominus}$)[15-17,313,314] or **147d** ($n=2^{\ominus}$), if it were possible to suppress ring closure to methylenecyclopropanes.[266,315] This could especially be the case with **147c** ($n=2^{\ominus}$) or **147d** ($n=2^{\ominus}$). But even the reduction of Y-shaped dications of type **147b,c** ($n=2^{\oplus}$) (cf. Ref. [316]) could lead to (stable?) trimethylenemethanes **147** ($n=2^{\odot}$). A closer investigation of **147** ($n=2^{\oplus}$) would also be of interest because of the fact that no (Y-aromatic) stabilization has been found for the parent compound or for the alkyl and phenyl derivatives.[317] Trihydroxy derivatives have, however, been detected,[317] and the salts of **149**,[318] **150**,[319] and **151**[320] are stable compounds (cyclic voltammetry of derivatives of **151** reveals two reversible reduction waves).

	a	b	c	d	e
R'	CN	NR_2	SR	CN	=X (X = O, $C(CN)_2$)
R"	CN	NR_2	SR	NR_2	

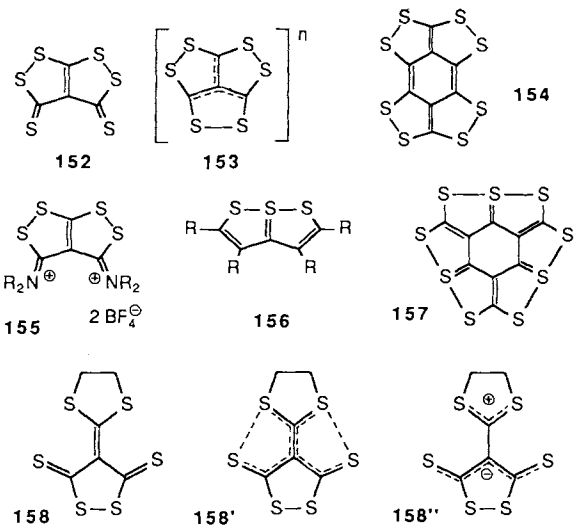


149 **150** **151**

The [3]radialenes **148** are also synthetic targets with respect to organic metals and ferromagnets. Compound **148a** ($n=2^{\ominus}$)[321] is known (heteroderivatives, cf. Refs. [322-327]) and can be oxidized to the diamagnetic(!)[328] **148a** ($n=1^{\odot\ominus}$). Compound **148e** (X = O, $n=0,2^{\ominus}$)[329,330] is also known. Compound **148e**

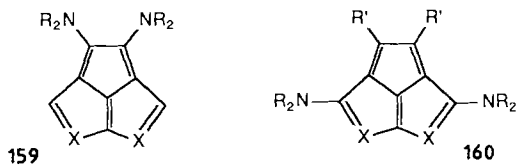
($X=C(CN)_2$) would, of course, be interesting as a tetracyanoquinodimethane (TCNQ) analogue; so too would the [3]radiaalenes **148b,c** (n=0) as electron-rich systems, and compounds **148d** as "neutral" systems.

Compounds like **152** and **154** are further precursors of trimethylenemethane.[300,331] The neighboring CS double bonds are reminiscent of the bonding in 1,6,6a-λ^4-trithiapentalenes **156**[332] and in **157**,[333,334] which can be viewed as a "sulfur-coated" [6]radialene or benzene. Compound **152** can be seen as a precursor of **153** ($n=2^{\odot}$),[300] which, as a trimethylenemethane derivative, should have a triplet ground state and therefore must be considered in the production of "ferromagnetic organic metals" (FOM).[230] Radical anions **153** ($n=1^{\odot\oplus}/1^{\odot\ominus}$) and dications or dianions **153** ($n=2^{\oplus}/2^{\ominus}$) would also be interesting.[300] Though it has not yet been possible to synthesize **152**, the closely related salts **155** have been made.[335]



An interesting variant of structure type **153** is compound **158**. Based on the nonbonded S-S distances it can be regarded, in accordance with formula **158'**, as a "trimethylenemethane imbedded in a pseudo-1,2-dithiolo[5,4-*c*]-[1,2]dithiole, (4n+2) π-electron, milieu" or as "heteroaromatic trimethylenemethane".[336] However, the dipolar structure **158"** has to be considered as well.

Acepentalene, which is structurally related to **153**, has also not yet been synthesized.[337,338] The unfavorable electronic structure of the parent compound (two SOMOs) would no longer be present in **159** and **160** and, therefore, such compounds may be synthesizable.



X = CR, N, C-CN, C-CR=$NR_2^{\oplus}$; R' = R, CN

By varying the donor and acceptor groups, donor-acceptor-substituted cyclic π systems can be synthesized whose electron donating/accepting properties are suitable for the application concerned. It does not need to be mentioned that such substituent effects have always been used with success in the past, and it is not only in this respect that the boundary between classical aromatic chemistry and the Do-A π systems described here is a fluid one.

This article has had to omit discussion of many workers results which have contributed significantly to progress in this area. We express our thanks both to them and to those workers mentioned in the references for their commitment. The Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie earn special thanks for their generous support of this research over many years.

Ketenimine Complexes from Carbene Complexes and Isocyanides: Versatile Building Blocks for Carbocycles and N-Heterocycles

New Synthetic Methods (74)

By Rudolf Aumann*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 70th birthday

Ketenimine complexes are readily available in great variety by reaction of isocyanides with carbene complexes. They have proven to be useful building blocks in new synthetic approaches to carbocyclic and *N*-heterocyclic four-, five-, and six-membered rings. The reactions involve new metal-induced bond formation patterns of the ketenimine ligands, which can be influenced across a wide range by varying the following five parameters: the metal, the ligands, and the three substituents on the N=C=C unit.

1. Introduction

The potential of classical synthetic methods involving typically "organic" reactivity patterns and selectivities can be considerably extended by including metal complexes as "non-classical" building blocks. Almost any functional group can be bonded to metal residues, thereby changing its reactivity completely. In this article this will be exemplified by the ketenimines:[**] we shall see how the reactivity[1] of these compounds is altered on complexation and how

Table 1. Coordination of N=C=C units to one-, two-, and four-electron acceptors in mono- and binuclear complexes.

Coordination type		L_nM	R^1	R, R	Ref.
Mononuclear complexes					
type A $\eta^2(C=N)$		$[V(C_5H_5)_2]$	Ph	Me Me	[4]
		$[Fe(CO)_2\{P(OMe)_3\}_2]$	*p*-tolyl	Ph Ph	[5]
		$[Ni(CN\,tBu)_2]$	*t*Bu	CN CN	[6]
		$[U(C_5H_5)_3]$	*cyclo*-C_6H_{11}	$=CH-PPh_2Me$	[7]
type B $\eta^2(C=C)$		$[Fe(CO)_3]$	*cyclo*-C_6H_{11}	$C(CO_2Me)=CH_2$ OMe	[8]
		$[Fe(CO)_2(C_5H_5)]^{\oplus}$	H	H H	[9]
		$[OsCl(PPh_3)_2NO]$	*p*-tolyl	H H	[10]
type C $\eta^1(N)$		$[Cr(CO)_5]$	*cyclo*-C_6H_{11}	Me	[11]
type D $\sigma(N)$ (1-aza-allenyl)		$[SnEt_3]$		Et CN	[12]
		$[Fe(CO)_2(C_5H_5)]$		$C(CN)_2CH_2Ph$ CN	[13]
		$[Ir(tcne)CO(PPh_3)_2]$ [a]		$CH(CN)_2$ CN	[14]
type E $\sigma(C)$ (3-aza-allenyl)		$[Mn(CO)_2(C_5H_5)]^{\oplus}$	*t*Bu	Ph	[15]
		$[Re(CO)_2(C_5H_5)]^{\oplus}$	*t*Bu	Me	[16]

[**] According to IUPAC rules ketenimines should be called 1-alkenylideneamines; however, the term "ketenimines" continues to be used in Chemical Abstracts.

ketenimine complexes can be used as versatile synthetic building blocks.

The preparative usefulness of new reagents highly depends on their ready availability. In the present case carbene complexes[2] and isocyanides[3] form a broad base of starting materials for the generation of ketenimine complexes. We shall commence by discussing different bonding modes in these compounds.

2. Classification of Ketenimine Complexes

At least eight types of complex can be derived from ketenimines: their characteristic features are collected in Table 1. The complexation with *two-electron* acceptors L_nM can occur laterally (side-on) via the C=N or C=C π bonds or terminally (end-on) via the nitrogen lone pair (types A–C). Electron-rich metal residues and electron-withdrawing substituents on the ketenimine appear to favor the coordination via π bonds (types A and B); in such cases the ligand is considerably bent. The CN bond in complexes of type A has the length of a single bond, and the ν(N=C=C) band in the IR spectrum undergoes a bathochromic shift (Table 2). Electron-poor metal residues can be coordinated via the nitrogen lone pair (type C): in such cases the N=C=C skeleton remains almost linear, and the interatomic distances are scarcely changed from those in the free ketenimine. However, there is a great change in reactivity on complexation of the ketenimine to give complexes of type C (see Sections 4–7). Bonding between the N=C=C unit and *one-electron* acceptors L_nM (types D–F) can occur via nitrogen, via the terminal carbon, or via a side chain, and the properties of these σ complexes differ considerably from those of the π complexes. The π,σ complexes of type G are of particular interest: in these the originally orthogonal π system of the ligand is "decoupled", so that one π-allyl bond and one σ bond to a *four-electron* acceptor can be formed. In complexes of type H, also π,σ complexes, the C=C bond remains free.

Table 2. Some structural and IR-spectroscopic parameters for ketenimine complexes of type A (see Table 1; the complexes listed therein are denoted here only by giving the metal).

M	∢ N–C–C [°]	d(C–N) [pm]	d(C–C) [pm]	$\tilde{\nu}$(NCC) [cm^{-1}] [a]
V [4]	140.5(8)	137.1(9)	132.0(9)	1670
Fe [5]	137.6(15)	134.4(21)	138.3(23)	
Ni [6]	144.2(4)	124.5(4)	138.6(5)	1710
U [7]	122.(2)	139.(4)	133.(3)	

[a] In free ketenimines at ca. 2050–2000 cm^{-1}.

It may be dangerous to draw conclusions as to the reactivity of complexes merely on the basis of their structures, since this would completely disregard the transition states of the reactions. Nevertheless, one can predict to a first approximation that all the various types of complexes (A–H) will react differently from each other. The reactivity of a given substrate can be modified gradually and over a wide range by complexing it in different ways. The reactions of ketenimine complexes show no similarity with those of free ketenimines; the complexation causes complete "umpolung".

3. Preparation of Ketenimine Complexes

Ketenimine complexes with different substitution patterns and their *N*- or *C*-metalated or *N*-alkylated derivatives can be most efficiently prepared by C=C coupling reactions within the ligand sphere of transition metals: e.g., by reacting carbene[11,19] or carbyne[15,16] complexes with isocyanides or by treating isocyanide complexes with carbene sources (e.g., diazoalkanes).[6] Other methods of preparation include electrophilically induced σ/π rearrangements of α-cyanoalkyl ligands,[9] insertions of cyanoolefins into M–H or M–C bonds,[12–14] oxidative addition of α-chloroenamines (or suitable precursors thereof)[20] to carbonyl metalates, and the introduction of tricyanomethanide ligands.[21] In only a few cases have ketenimine complexes been prepared directly by complexation of free ketenimines.[5,18]

3.1. Addition of Isocyanides to Carbene Complexes

Carbene complexes **1** add one equivalent of an isocyanide **2** to give ketenimine complexes **3** via a 1,2-insertion of the N≡C bond into the M=C bond[11,19] [Eq. (1)].

$$[L_nM{=}CXR] + R^1{-}\overset{\oplus}{N}{\equiv}\overset{\ominus}{C}: \rightarrow [L_nM(R^1N{=}C{=}CXR)] \qquad (1)$$

1 **2** **3**

X = O-alkyl,[11,19] S-alkyl,[26] $N{=}CR_2$,[27] PR_3[7]

R, R^1 = alkyl, aryl, alkenyl, akynyl

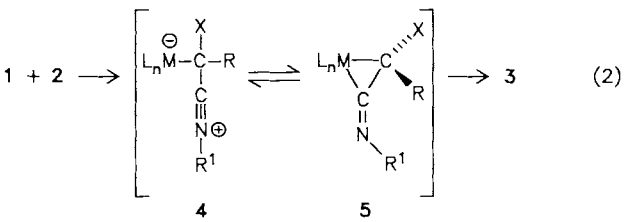
M = Cr,[11] Mo,[22] W,[23] Mn,[24] Fe,[25] Os,[10] Th,[17] U[7]

L = CO, PR_3, η^5-$CH_3C_5H_4$, η^5-C_5H_5

Of particular interest for synthetic applications are functionalized ketenimine complexes **3**: these are obtainable in great variety from heterocarbene complexes **1**[7,11,19,26,27] and are generally reacted further in situ.

The insertion of isocyanides into M=C bonds is not metal-specific: complexes **3** with M = V,[4] Cr,[11c] Fe,[5,8] Ni,[6] Os,[10] Th,[17] and U[7] have been characterized crystallographically.

The coupling of isocyanides with carbene ligands probably occurs in several steps via ylide complexes **4**[28] and/or (with charge neutralization) via metallacyclopropanes **5** [Eq. (2)].[29]



(2)

The isocyanide undergoes addition to the carbene carbon directly, instead of first coordinating to the metal atom. This is suggested by the observation that chromium complexes **7**, with carbene and isocyanide ligands in a *cis* arrangement, are stable under the reaction conditions.[27,30] Complexes **7** can be prepared[27] from **6** via the standard procedure[11a] [Eq. (3)] and, when heated under CO, give

neither ketenimine complexes nor products derived therefrom.[31]

$$[(R^1\text{–NC})Cr(CO)_5] \xrightarrow[2.\ [Et_3O]BF_4]{1.\ C_6H_5Li} [cis\text{-}(CO)_4Cr(R^1\text{–NC})\{C(OEt)C_6H_5\}] \quad (3)$$

(6) (7)

$R^1 = CH_3$, *cyclo*-C_6H_{11}

The reaction sequence shown in Equation (2) for *chromium* is not general: thus, in the case of *nickel* [Eq. (4)], the coupling of carbene and isocyanide ligands to give ketenimine ligands occurs readily[6] when the external carbene source diazomalodinitrile **10** is allowed to react with the isocyanide complex **9**. Complex **11** was detected as an intermediate in this reaction.[32]

$$[(R^1\text{–NC})_4Ni] + N_2C(CN)_2 \rightarrow [(R^1\text{–NC})_3Ni\{N_2C(CN)_2\}] \rightarrow [(R^1\text{–NC})_2Ni\{R^1\text{–N=C=C(CN)}_2\}] \quad (4)$$

9 **10** **11** **12**

$R^1 = t\text{-}C_4H_9$

On the other hand, it is possible to construct *palladium* ketenimine complexes catalytically from isocyanides **2**, allyl bromides **13**, and triethylamine [Eq. (5)].[33] The catalysis involves the *N*-substituted alkenimidoyl complexes **15** as intermediates (**15**, $R = CH_3$, H, has been isolated[33,34]), probably formed by insertion of R^1–NC into a Pd-C σ bond; however, coupling via Pd=C bonds cannot be excluded.

$$R^1\text{–NC} + BrCH_2\text{–CH=CHR} + Et_3N \xrightarrow{[PdCl_4]^{2\ominus}} R^1\text{–N=C=CH–CH=CHR} + [Et_3NH]Br \quad (5)$$

2 **13** **14**

$R^1 = cyclo\text{-}C_6H_{11}$, C_6H_5, $p\text{-}NO_2\text{–}C_6H_4$

$[(R^1\text{–NC})ClM\text{–}C(=NR)CH_2\text{–CH=CHR}]$ **15**, M = Pd

Coupling reactions of (metal-free) carbenes (dichloro-, diphenyl-, dimethoxycarbonylcarbene) with isocyanides to give ketenimines are also known.[35]

3.2. Addition of Isocyanides to Metal Carbyne Complexes

Isocyanides undergo insertion not only into M–C[3b] and M=C bonds (see Section 3.1) but also into M≡C bonds: for example, the carbyne complex **16** adds R^1–NC to give the keteniminyl complex **17**[15,16] [Eq. (6)].

$$[L_nM{\equiv}C(C_6H_5)]X + R^1\text{–NC} \longrightarrow \left[\begin{array}{l} H_5C_6 \\ L_nM \end{array}\!\!>\!\!=\!\!=\!\!N\text{–}R^1\right]^{\oplus} X^{\ominus} \quad (6)$$

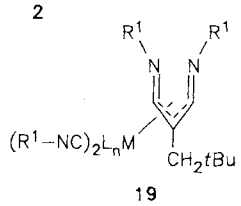
16 **2** **17**

$L_nM = [Mn(CO)_2(C_5H_5)]$, $X = BCl_4^{\ominus}$, $R^1 = t\text{-}C_4H_9$

Complexes of type **17** generally undergo further isocyanide insertions into the (M–C) σ bond: thus, **18** adds a total of four molecules of **2** to give the η^3-1,5-diazapentatrienyl complex **19**[36] [Eq. (7)], two molecules being inserted into the M≡C bond.

$$[\,|P(OMe)_3|_2L_nM{\equiv}CCH_2t\text{Bu}] + 4\ R^1\text{–NC} \longrightarrow \longrightarrow$$

18 **2**



(7)

19

L_nM = $[Mo(C_5H_5)]$, $[W(C_5H_5)]$; R^1 = 2,6-xylyl

3.3. Electrophilically Induced σ,π Rearrangements

Protonation of the cyanomethyl complex **20** leads, via σ,π rearrangement, to a cationic complex **21**[9] of the simplest ketenimine [Eq. (8)]; while the free ketenimine is not stable,[37] the π complex **21** bearing the electron-rich $[Fe(CO)_2(C_5H_5)]$ residue is stable.[38a,b]

$$[L_nM\text{–}CH_2\text{–}C{\equiv}N] + H^{\oplus} \rightarrow [L_nM(H_2C{=}C{=}NH)]^{\oplus} \quad (8)$$

20 **21**

$L_nM = [Fe(CO)_2(C_5H_5)]$

3.4. Complexation of Ketenimines

The formation of ketenimine complexes by direct complexation of ketenimines is problematic, since both ketenimines and ketenimine complexes are very prone to undergo condensation reactions, so that unwanted secondary reactions often occur. The few exceptions known include the complexation of **23a,b** with vanadocene **22** to give mononuclear **24** [Eq. (9)][4] and of **23c** with (photochemically generated) coordinatively unsaturated **25** to give binuclear **26** [Eq. (10)].[4]

$$L_nM + R^1N{=}C{=}CR_2 \rightarrow [L_nM(R^1N{=}C{=}CR_2)] \quad (9)$$

22 **23a,b** **24a**, 91%; **b**, 87%

$L_nM = [V(C_5H_5)_2]$; $R^1 = C_6H_5$

$$(L_nM)_2 + \textbf{23c} \rightarrow [(L_nM)_2(R^1N{=}C{=}CR_2)] \quad (10)$$

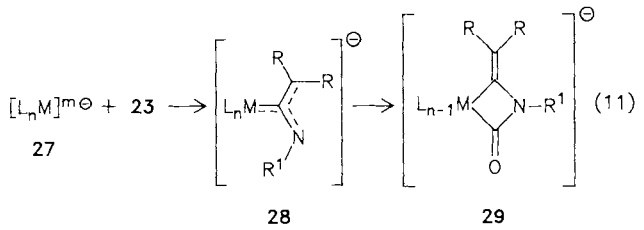
25 **26**

$L_nM = [Mo(CO)_2(C_5H_5)]$

a, $R = C_6H_5$; **b**, $R = CH_3$; **c**, $R = p\text{-}CH_3\text{–}C_6H_4$

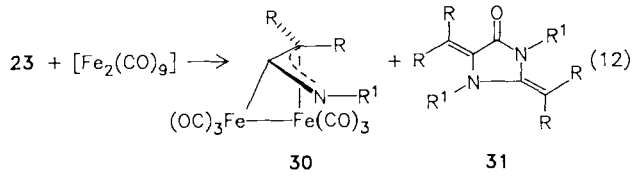
In contrast to neutral metal residues, metal carbonylates cleanly form adducts **28**, which subsequently isomerize to stable metallaazetidinones **29**[39] [Eq. (11)].

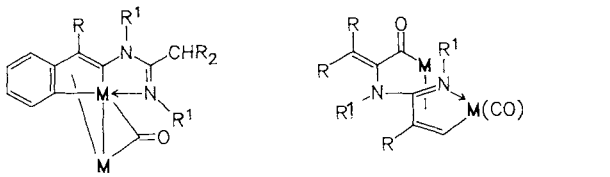
Metal carbonyls react much less cleanly with **23** than do the carbonylates: thus, $[Fe_2(CO)_9]$ gives binuclear azaallyl complexes **30**[18] as well as imidazolidinones **31**[18b] formed by coupling of two ketenimine units with cyclocar-



$[L_nM]^{m\ominus}$ = $[Cr(CO)_5]^{2\ominus}$, $[Re(CO)_5]^{\ominus}$

bonylation [Eq. (12)]. Compound **23a** also gave a ferraindene **32**, while **23b** yielded the azaferrole **33**, which is structurally related to **31**.

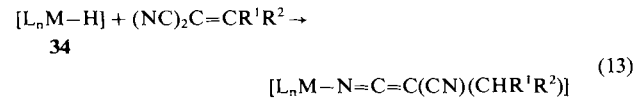




32, M = $[Fe(CO)_2]$
R = R^1 = C_6H_5

33, M = $[Fe(CO)_2]$
R = CH_3; R^1 = C_6H_5

Complexes **32** and **33** are apparently formed by intra- or intermolecular transfer of hydrogen atoms with the participation of M–H bonds. In this connection, 1,4-additions of metal hydrides **34** to cyanoethylene are of interest; these lead to 1-azaallenyl complexes **35** [Eq. (13)].



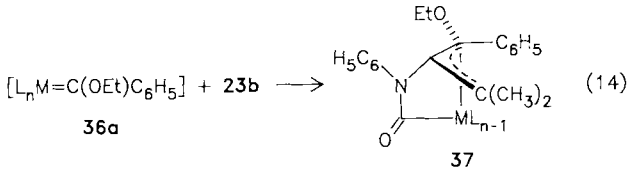
L_nM	R^1	R^2	Ref.
$[Ir(CO)_2(PPh_3)_2]$	CN	CN	[14]
$[Fe(CO)_2(C_5H_5)]$	CN	CN	[13]
$[Sn(n\text{-}C_4H_9)_3]$	H	CH_3	[12]

The ketenimine **23b** undergoes a novel type of addition to the M=C bond of **36** (Table 3) to give the π, σ complex

Table 3. L_nM groups in **36a–e** and the compounds obtained therefrom.

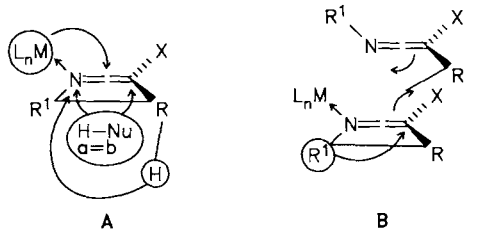
a	b	c	d	e
$[Fe(CO)_4]$	$[W(CO)_5]$	$[Mo(CO)_5]$	$[Cr(CO)_5]$	$[Mn(CO)_2(CH_3C_5H_4)]$

37[40] [Eq. (14)]. This reaction has a parallel in the addition of allenes to carbene complexes to give trimethylenemethane complexes.[41]



4. Simple Addition and Isomerization Reactions of Ketenimines

The typical reactivity patterns[1] of metal-free ketenimines are completely changed on complexation. The reactivities of ketenimine complexes can be varied across a wide range by means of five parameters (R, R^1, X, M, L). We shall first discuss some typical transformations at the N=C=C skeleton of chromium, molybdenum, tungsten, manganese, and iron complexes and shall then proceed to reactions also involving substituents R, R^1, and X. These "basic reactions", **A** and **B**, are listed in Scheme 1. Either the metal residue L_nM undergoes a shift to the central carbon atom (formation of an aminocarbene unit, Sections 4.1.1–4.1.3 and 4.2.1) or the coordination at nitrogen is preserved (Sections 4.2.2, 4.3, and 4.4).

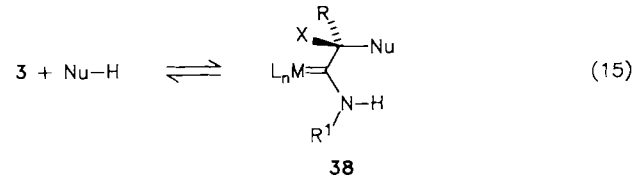


Scheme 1. Principal conversions of ketenimine complexes involving either 1,2-shift of the metal residue (**A**) or retention of coordination via nitrogen (**B**).

4.1. 1,3-Additions to the N=C=C Skeleton

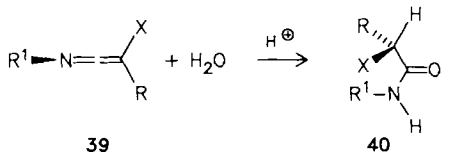
4.1.1. Additions of Protic Nucleophiles

In contrast to metal-free ketenimines, ketenimine complexes **3** react like 1,3-dipoles, the metal undergoing a shift to the central carbon of the N=C=C unit: the products are aminocarbene complexes **38**. The "reactivity umpolung" of ketenimine ligands by the metal residue permits addition of protic nucleophiles to the terminal carbon atom [Eq. (15)][25,26,31] of the ketenimine ligand. In contrast, me-



Nu–H = R'O–H, R'S–H, R'_2N–H
L_nM = $[Cr(CO)_5]$, $[Mo(CO)_5]$, $[W(CO)_5]$, $[Mn(CO)_2(CH_3C_5H_4)]$, $[Fe(CO)_4]$

tal-free ketenimines add protic nucleophiles to the central carbon atom; for example, **39** gives amides **40** on treatment with water [Eq. (16)]. Ketenimine complexes **3**, on

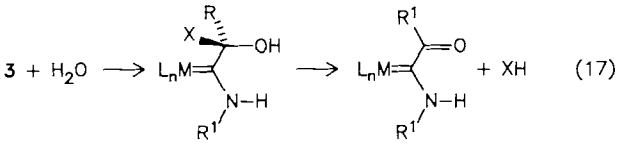


(16)

39 40

$R = C_6H_5$, CH_3, $CH{=}CH{-}C_6H_5$; $R^1 = cyclo\text{-}C_6H_{11}$; X = OEt

the other hand, give aminocarbene or acylaminocarbene complexes **41** or **42** [Eq. (17)].

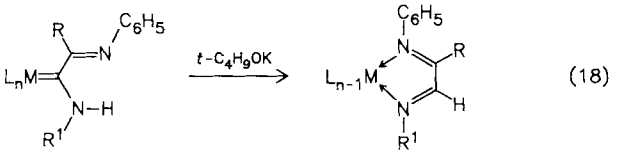


(17)

41 42

$L_nM = [Cr(CO)_5]$, $[Mo(CO)_5]$, $[W(CO)_5]$, $[Mn(CO)_2(CH_3C_5H_4)]$, $[Fe(CO)_4]$

The addition of nucleophiles Nu-H to **3** is reversible: thus, in the case of bulky substrates (e.g., $t\text{-}C_4H_9SH$) the ketenimine complexes are re-formed when the aminocarbene complexes are heated.[42] The isomerization reaction of aminocarbene complexes via a 1,2-N/C hydrogen shift to give aldimine complexes competes with this reverse reaction;[42] for example, the condensation product **43** from **3** and aniline undergoes thermal rearrangement to **44** [Eq. (18)], the rearrangement being catalyzed by bases such as $t\text{-}C_4H_9OK$ in THF. The net reaction **3**→→→**44** corresponds to a metal-induced 1,2-addition of Nu-H to the C=C bond of the ketenimine ligand (followed by loss of XH) and thus exhibits the reverse regiochemistry to that observed in corresponding additions to metal-free **39** [Eq. (16)].



(18)

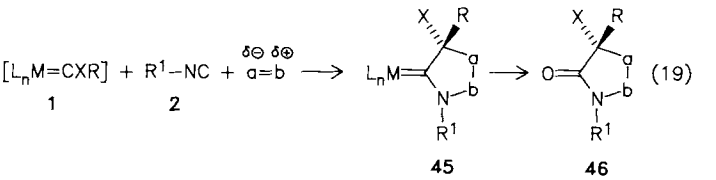
43 44

$L_nM = [W(CO)_5]$, $R = C_6H_5$, $R^1 = cyclo\text{-}C_6H_{11}$

Since ketenimine complexes can be formed by addition of isocyanides to carbene complexes on the one hand and undergo conversion to (amino)carbene complexes via addition of Nu-H on the other, it should be possible to build up carbon chains in a stepwise manner by applying this principle.

4.1.2. [3+2] Cycloadditions

The 1,3-dipolar properties of **3** make possible [3+2] cycloadditions of polarized double bonds, e.g., of aldehydes or isocyanates, to give oxazolidine or imidazolidine complexes **45a** or **45b**, respectively [Eq. (19)]. These conversions can be readily carried out under mild conditions as three-component reactions without isolation of the intermediate ketenimine complexes;[23,31,43] however, the addition is greatly slowed by the presence of bulky substituents. Oxidative decomposition of **45b** ($R' = cyclo\text{-}C_6H_{11}$) with $KMnO_4/Fe(NO_3)_3$ yielded the previously inaccessible 5-ethoxyhydantoins **46b**.



(19)

1 2 45 46

$L_nM = [W(CO)_5]$[23, 43], $[Mn(CO)_2(CH_3C_5H_4)]$[31]

$R = CH_3$, C_6H_5; X = OEt

$R^1 =$ $cyclo\text{-}C_6H_{11}$, CH_3, $CH_2C_6H_5$

a=b: **a**, O=CHR';[31, 43] **b**, R'N=CO;[23] **c**, R'N=CNR';[31, 42] **d**, S=CS;[31] **e**, S=CNR'[31]

4.1.3. [3+1] Cycloadditions

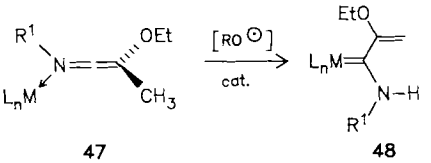
The tendency of ketenimine complexes to form aminocarbene complexes permits [3+1] cycloadditions of **3** with isocyanides (see Sections 5.2 and 5.3) or vinylidene ligands (see Section 6.1) to give four-membered heterocyclic rings.

4.2. Isomerizations

Ketenimine complexes are thermally labile and may isomerize under certain conditions to aminocarbene or nitrile complexes.

4.2.1. Ketenimine/Aminocarbene Rearrangements

C-Alkylketenimine complexes **47** rearrange readily via 1,4-C/N hydrogen shifts to give the alkenylaminocarbene complexes **48**[11a] [Eq. (20)]. The reaction can be induced



(20)

47 48

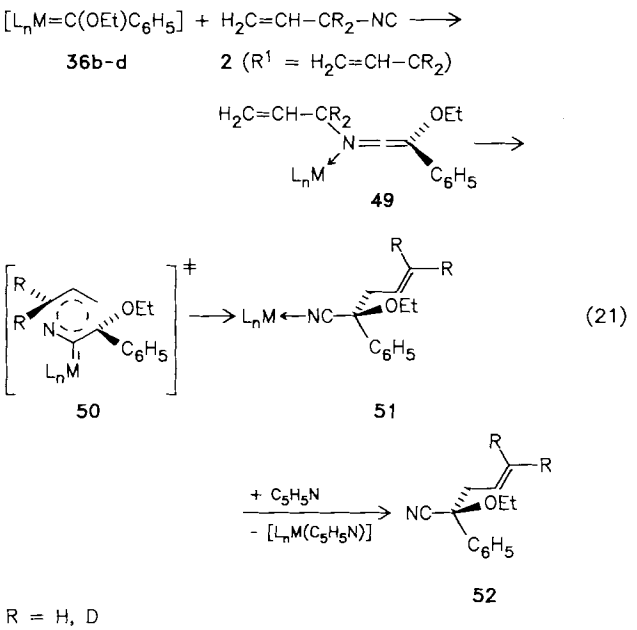
$L_nM = [Cr(CO)_5]$, $[W(CO)_5]$

by air or traces of peroxide and is weakly exothermic. The 1,4-C/N shift of the allylic hydrogen probably occurs via a chain mechanism (e.g., via a radical cation).

4.2.2. Ketenimine/Nitrile Rearrangements

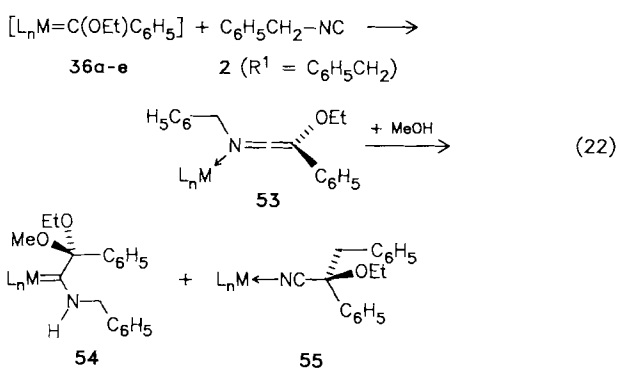
The isomerization of ketenimines to nitriles via a 1,3-N/C shift of R^1 from nitrogen to the terminal carbon of the N=C=C unit can be favored or hindered by complexation, depending on L_nM. Thus NH ketenimines ($R^1 = H$) are unstable in the free form, but can be stabilized in the iron complex **21** (Section 3.3).[9] However, *N*-allyl, **49**,[44] and *N*-benzylketenimine complexes, **53**,[31] of Cr, Mo, and W isomerize even at 0 °C to nitrile complexes **51** and **55**,

respectively [Eqs. (21) and (22)]. The rearrangement takes place within the ligand sphere and is probably favored by a metal-induced bending of the N=C=C unit. Complex **53e** (M = Mn; see also Table 3) is stable for several hours at 80 °C and isomerizes at a measurable rate only above 100 °C,[31] while **53c** (M = Mo) isomerizes rapidly even at 0 °C. The N/C shift of the allyl group exhibits the regiochemistry of a [3,3] shift (as shown by deuterium labeling). Since the nitrile ligands of **51** (and **55**) can be readily substituted by pyridine, thermolabile chiral olefins **52** can be obtained in this sequence [Eq. (21)].



(21)

If **36** (Table 3) is allowed to react with benzyl isocyanide **2**, $R^1 = CH_2C_6H_5$, at 20 °C in the presence of methanol, a mixture of the isomerization and addition products **55** and **54** is obtained [Eq. (22)]. Isomerization dominates in the case of the molybdenum complex **53c**, while for the tungsten (**53b**), manganese (**53e**), and iron (**53a**) complexes



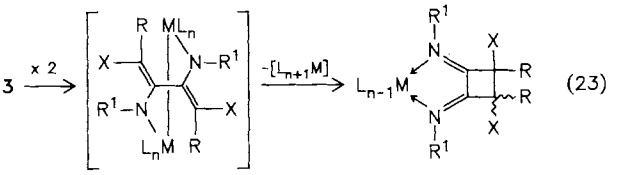
(22)

a	> 95	:	1
b	> 95	:	1
c	1	:	10
d	1	:	3
e	> 95	:	3

practically only addition to **54** is observed. This change in reactivity has a parallel in a change of the coordination mode of the ketenimine ligands in **53**. The chromium complex **53d** is coordinated via the lone pair on nitrogen. The manganese complexes **53e** exist in solution[24] as η^2(C=C) complexes of type B (Table 1)].[31]

4.3. [2+2] Dimerization of Ketenimine Ligands

Ketenimine complexes **3** (M = Cr, Mo, W) dimerize on warming, possibly via an intermediate **56**, to give $[M(CO)_6]$ and 1,2-bis(imino)cyclobutane complexes **57** [Eq. (23)].



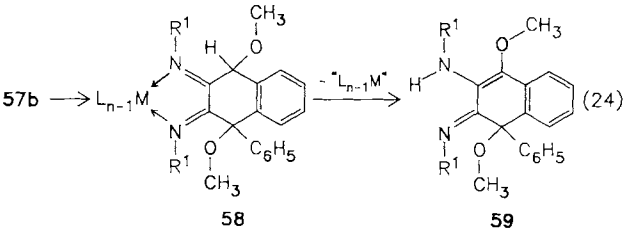
(23)

L_nM = $[Cr(CO)_5]$, $[Mo(CO)_5]$, $[W(CO)_5]$; X = OCH_3
R: a, CH_3; b, C_6H_5; c, $C_{10}H_7$; d, C_4H_4S
R^1 = CH_3, *cyclo*-C_6H_{11}, t-C_4H_9

The dimerization of the ketenimine ligands leads solely to symmetrical [2+2] adducts.[45] The carbocyclic four-membered ring in **57** is formed from four C_1 units (carbenes, isocyanides) via a template-induced coupling. Treatment of **57** with hydroxylamine leads to bis(hydroximino)cyclobutanes.[45]

4.4. Template-Directed Expansion of Four-Membered to Six-Membered Rings

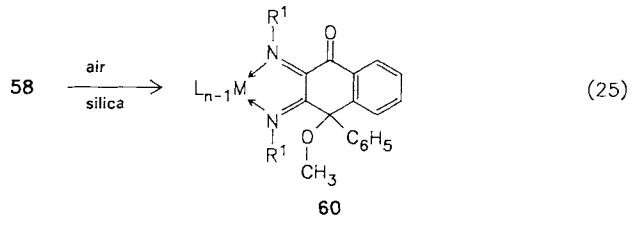
1,2-Bis(imino)cyclobutane complexes **57** with R = aryl are thermally labile and isomerize on warming to bis(imino)tetrahydronaphthalene complexes **58**;[45b] the four-membered ring undergoes an expansion to a six-membered ring in which the aryl group participates [Eq. (24)]. The



(24)

isomerization occurs within the ligand sphere of the metal complex and is stereoselective, the chirality transfer being ca. 80%.

Complexes **58** decompose above 100 °C to dihydronaphthalenes **59**; the latter are available directly from carbene complexes and isocyanides without isolation of intermediates in a one-pot procedure.[45] Complex **58** adsorbed on silica is rapidly oxidized by air to give the ketone complex **60** and other products [Eq. (25)].[22]

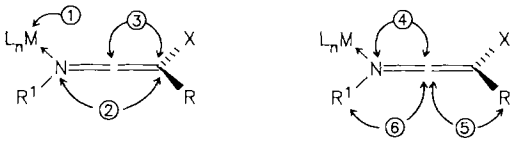


(25)

5. Addition of Isocyanides to Ketenimine Complexes

Both carbene complexes **1** and ketenimine complexes **3** add to isocyanides **2**, and the relative rates of the addition processes determine whether 1:1, 1:2, 1:3, or 1:4 adducts between **1** and **2** are formed. An analysis of the many possibilities leads to the identification of the following six basic reaction patterns (Scheme 2):

① addition of isocyanides to the metal with displacement of ketenimine ligands
② [3+1] cycloaddition of isocyanides to the ketenimine ligand from the side opposite to the metal
③ [2+2] cycloaddition of isocyanides to the C=C bonds of ketenimine ligands from the metal side
④ [2+1+1] cycloaddition of two isocyanide molecules to N=C bonds of ketenimine ligands
⑤ [4+1] cycloaddition of isocyanides to *C*-aryl-substituted ketenimine ligands with *ortho*-substitution at the aryl residue
⑥ [4+1] cycloaddition of isocyanide to *N*-aryl-substituted ketenimine ligands with *ortho*-substitution at the aryl residue



Scheme 2. Addition of isocyanides to ketenimine complexes.

5.1. Addition of Isocyanides to the Metal

Ketenimines **39** can be displaced from **3** by isocyanides: this is true in particular for bulky ketenimines (R^1 = *cyclo*-C_6H_{11}, *t*-C_4H_9), for which reactions involving addition to the ligand (see Sections 5.2–5.5) to give nonlinear C–N–R^1 bonds become difficult for steric reasons.[11b,24,31] Instead of isocyanides, other aprotic nucleophiles (**61**) may be used [Eq. (26)]: for example, ketenimine **39** is obtained simply and readily by treating carbene complex **1** with isocyanide **2** in the aprotic nucleophilic solvent acetonitrile.

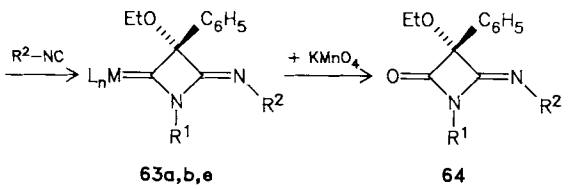
$$[L_nM(R^1N{=}C{=}CXR)] + Nu \rightarrow [L_nM(Nu)] + R^1N{=}C{=}CXR \quad (26)$$
3 **61** **39**

R^1 = *cyclo*-C_6H_{11}, *t*-C_4H_9; X = OEt
L_nM = [Cr(CO)$_5$], [Mo(CO)$_5$], [W(CO)$_5$], [Mn($CH_3C_5H_4$)(CO)$_2$]
Nu = $P(C_6H_5)_3$, C_5H_5N, CH_3CN, *cyclo*-$C_6H_{11}NC$, *t*-C_4H_9NC

5.2. [3+1] and [2+2] Cycloadditions

The construction of four-membered *N*-heterocycles from isocyanides[46] and carbene complexes is also of interest for synthetic purposes. This reaction occurs in a particularly uniform manner with carbene complexes of iron:[25] thus, **36a** (Table 3) adds two equivalents of **2** even in the cold to give 4-iminoazetidinylidene complexes **63a** [Eq. (27), Table 4]. Compound **36e** similarly gives the manganese complex **63e**. Since in the case of **36e** the isocyanide reacts more slowly with the intermediate ketenimine complex **62** than in the case of **36a**, **62e** can be isolated. It is thus possible to incorporate two *different* isocyanides into the four-membered ring of **63**. However, this reaction is limited by the fact that bulky isocyanides cause a ligand displacement in the ketenimine complex **62e**; in addition, an unwanted side reaction to give **65** [Eq. (28)] is observed. In the case of the tungsten complex **36b**, four-membered rings (**63b**) are formed only in low yields, with the exception of the addition of alkenyl isocyanides.[47]

$$[L_nM{=}C(OEt)C_6H_5] + R^1{-}NC \rightarrow [L_nM\{R^1N{=}C{=}C(OEt)C_6H_5\}]$$
36a,b,e **2** **62a,b,e**



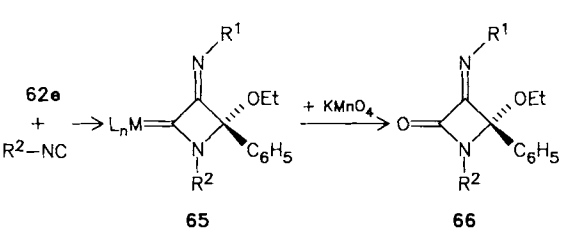
(27)

Table 4. Yields of **63** in reactions (27). See also Table 3.

63	R^1, R^2	Yield [%]	R^1, R^2	Yield [%]
a	*cyclo*-C_6H_{11}	77	CH_3	94
	C_6H_5	76	$CH_2C_6H_5$	80
b	$CH{=}CH_2$	20	$CH{=}CHCH_3$	31
e	CH_3	30	C_6H_5	67

β-Lactams **64** can be obtained by oxidative decomposition of **63** in the two-phase system ether/water: practically no side reactions are observed.[24]

The reaction of **36** with **2** is influenced by the reaction conditions as well as by the nature of the reaction partners: thus, on careful warming of the reaction mixture, the manganese complex **36e** and methyl or phenyl isocyanide preferably form 4-iminoazetidinylidene complexes **63e**, while rapid warming gives the 3-iminoazetidinylidene complex **65** as the main product [Eq. (28)].[24] Thermal isomerization of **63e** to **65** (via metathesis) can be excluded, as shown by control experiments: thus, the two complexes are formed in competition. If **63b** and **65** are

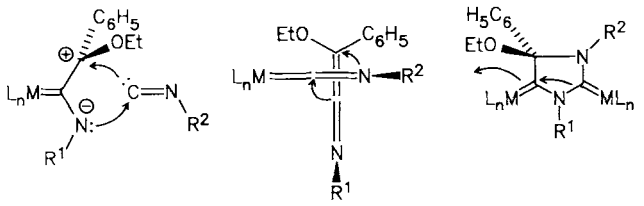


(28)

R^1, R^2 = CH_3, C_6H_5

each constructed from two different isocyanides R^1–NC and R^2–NC, it can be shown that R^2–NC has attacked the ketenimine ligand from the side opposite to the metal in one case and from the metal side in the other.

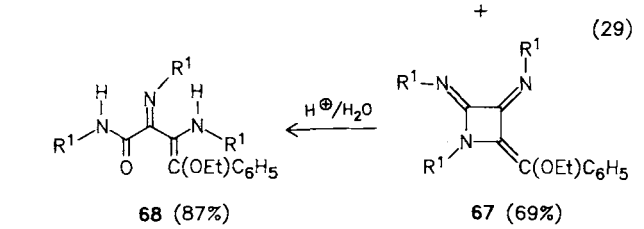
The processes leading to **63** and **65** can be regarded as [3+1] and [2+2] cycloadditions, respectively (**C** and **B**). We assume that in the formation of **65** the ketenimine ligand is first substituted by isocyanide; this is followed by addition of the electron-rich double bond of the ketenimine to the isocyanide ligand. An alternative possibility would be a [3+2] cycloaddition to give **E**, followed by ring contraction with elimination of L_nM.



C D E

5.3. [2+1+1] Cycloaddition of Two Isocyanides

A further possibility for the synthesis of azetidines from carbene complexes and isocyanides is shown in Equation (29). The reaction of **36d** with four equivalents of *p*-nitrophenyl isocyanide **2**, R^1=*p*-NO_2–C_6H_4, gives the 2,3-bis(imino)azetidine **67** in metal-free form via [2+1+1] cycloaddition of **2** to an intermediate ketenimine complex. The acid hydrolysis of **67** occurs cleanly to give a 3-butenamide **68**; the C_4 skeleton of this molecule is built up from one carbene and three isoycanide carbons.[48]



$[L_nM{=}C(OEt)C_6H_5]$ + 4 R^1–NC ⟶ $[L_nM(R^1{-}NC)]$

36d 2 (R^1 = *p*-NO_2–C_6H_4)

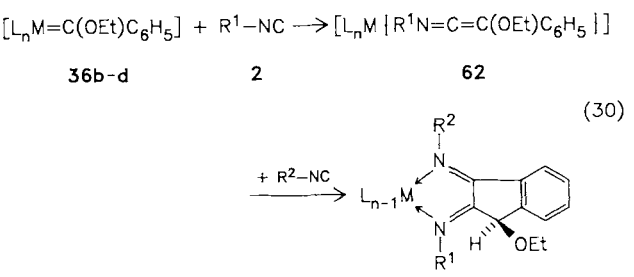
+

68 (87%) **67** (69%) (29)

5.4. [4+1] Cycloadditions to Give Indanes

Ketenimine complexes of Cr, Mo, and W react differently with isocyanides than do those of Mn or Fe, substituents on the N=C=C skeleton often being involved in the reactions. Arylcarbene complexes of Cr, Mo, and W add two equivalents of methyl or benzyl isocyanide via a cyclization involving *ortho* attack at the *C*-aryl residue to give deep blue 1,2-bis(imino)indane complexes **69** [Eq. (30)]. The reaction takes place in a stepwise manner via a *C*-arylketenimine complex **62** (from **36** and R^1–NC). This complex adds R^2–NC in the sense of a [4+1] cycloaddition involving the annelation of a carbocyclic five-membered ring to the aryl residue.[22]

The five-membered ring annelation to arenes occurs in a regiospecific manner; 1- and 2-naphthyl- or 1- and 2-thienylcarbene complexes give only the angularly annelated isomers.[22]



$[L_nM{=}C(OEt)C_6H_5]$ + R^1–NC ⟶ $[L_nM\{R^1N{=}C{=}C(OEt)C_6H_5\}]$

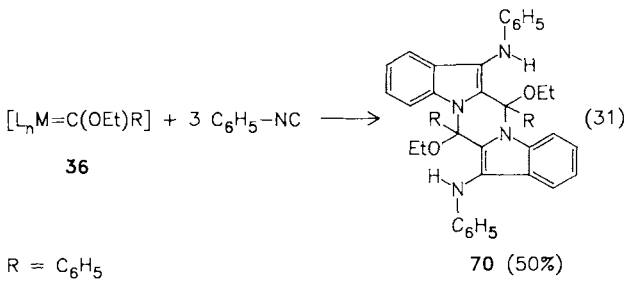
36b-d **2** **62**

+ R^2–NC ⟶ $L_{n-1}M$ **69** (30)

R^1, R^2 = CH_3, $CH_2C_6H_5$

5.5. [4+1] Cycloadditions to Give Indoles

Not only *C*-aryl- but also *N*-arylketenimine complexes of Cr, Mo, and W form [4+1] cycloadducts with further isocyanide. Since *N*-aryl groups are considerably more reactive than *C*-aryl groups, the reaction products are indoles rather than indanes. The reaction is regiospecific and can be varied in a number of ways.[43,48] In contrast to the synthesis of bis(imino)indane complexes, the preparation of indoles requires three equivalents of isocyanide: the second equivalent is required for the construction of the indole ring from the ketenimine complex, the third for its displacement from the metal. With three equivalents of aryl isocyanide, **36** forms 2-alkylidene-3*H*-indoles, which dimerize to pyrazinodiindoles **70** [Eq. (31)].

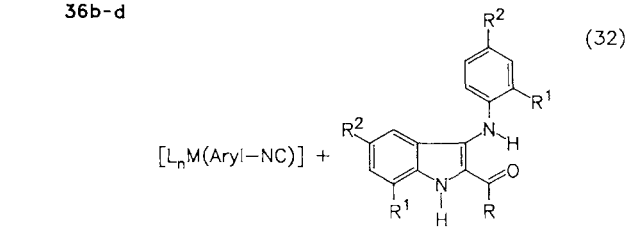


$[L_nM{=}C(OEt)R]$ + 3 C_6H_5–NC ⟶

36

R = C_6H_5 **70** (50%) (31)

The indole synthesis [Eq. (31)] is capable of considerable variation: thus, in the presence of water, **36b-d** react with aryl isocyanides in a three-component reaction to give 3-amino-2-aroylindoles **71**, which are obtained only with difficulty by other routes [Eq. (32), Table 5].[48]



$[L_nM{=}C(OEt)C_6H_5]$ + 3 Aryl–NC + H_2O ⟶

36b-d

$[L_nM(Aryl{-}NC)]$ + **71** (32)

Aryl = 2,4-$R^1R^2C_6H_3$

Table 5. Yields of **71**, R = C_6H_5, in reaction (32) for various aryl residues 2,4-$R^1R^2C_6H_3$. Complex **36d** was employed.

R_1	R^2	Yield of **71** [%]
H	H	72
H	CH_3	59
H	NO_2	—
H	OCH_3	58
OCH_3	H	66

The indole synthesis is possible only when electron-rich aryl isocyanides are used. Electron-poor aryl isocyanides form azetidines (see Section 5.4), since in this case the *ortho* attack at the aromatic ring required for the formation of the indole is unfavored.

6. Addition of Alkynes to Ketenimine Complexes

Three-component reactions of carbene complexes with isocyanides and alkynes afford a great variety of products: as examples we shall consider reactions with 1-alkynes and ynamines.

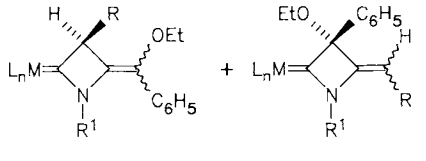
6.1. 1-Alkynes

Complex **62b** and 1-alkynes **72** (R = C_6H_5, $Si(CH_3)_3$, CH_2OCH_3, OC_2H_5) give the azetidinylidene complexes **73** and **74** [Eq. (33), Table 6]. In **73** the C_2 unit of the alkyne residue is on the same side as the metal, in **74** on the side opposite to the metal.[49] This suggests that these products are formed from vinylidene units via [2+2] or [3+1] cycloadditions, just as in the case of the corresponding four-membered ring ligands built up from isostructural isocyanides [cf. Eqs. (27) and (28)]; the vinylidene complexes are formed by isomerization of 1-alkyne complexes.

The reactions of 1-alkynes with ketenimine complexes can, as expected, be influenced by the metal. The tungsten complex **62b** forms only four-membered ring heterocycles

$[L_nM\{R^1N{=}C{=}C(OEt)C_6H_5\}]$ + HC≡C–R ⟶

62b **72**



(33)

73 **74**

R^1 = *cyclo*-C_6H_{11}

Table 6. Yields of **73** and **74** in reactions (33).

C_6H_5	28	[1:12]	—
$Si(CH_3)_3$	[a]		[a]
CH_2OCH_3	18	[1:2]	—
H	13	[2:3]	10

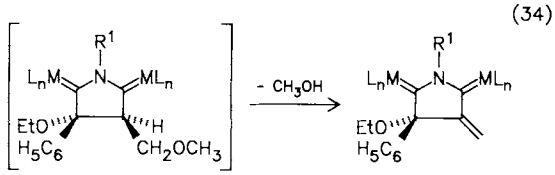
[a] Not isolated.

via [2+2] and [3+1] cycloadditions [Eq. (33)], while the electron-rich manganese complex **62e** yields five-membered ring heterocycles **76** via [3+2] cycloadditions[31] [Eq. (34)], presumably with **75** as an intermediate.

$[L_nM\{R^1N{=}C{=}C(OEt)C_6H_5\}]$ + HC≡C–CH_2OCH_3 ⟶

62e **72** (R = CH_2OCH_3)

(34)



75 **76**

R^1 = CH_3

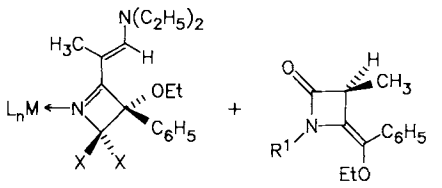
6.2. Ynamines

The addition of an electron-rich ynamine **77** to **62b,d** unexpectedly yields 2,3-dihydroazete complexes **78** [Eq. (35)].[50] In this case the four-membered ring is built up from three(!) atoms of the isocyanide used to synthesize **62** and a carbene carbon of the starting material **36**. An α-H in R^1 is transferred to the C=C unit of **77**. In addition, "normal" [2+2] cycloaddition products are formed: these are hydrolyzed to azetidinones **79** during chromatographic workup.

$[L_nM\{R^1N{=}C{=}C(OEt)C_6H_5\}]$ + H_3C–C≡C–$N(C_2H_5)_2$ ⟶

62b,d **77**

(35)



78 **79**

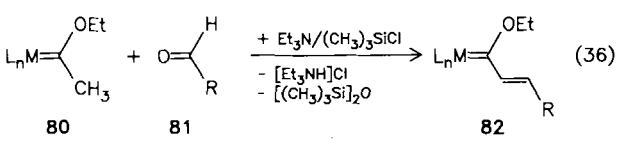
L_nM	R^1	X, X
$[Cr(CO)_5]$	CH_3	H, H
$[W(CO)_5]$	*cyclo*-C_6H_{11}	$(CH_2)_5$

7. Cyclizations with *N*- and *C*-Alkenylketenimine Complexes and Synthesis of *C*-Alkylidenaminoketenimine Complexes

Since ketenimine complexes can be formed from **1** and **2** under very mild, neutral conditions, our procedure is also suitable for the synthesis of thermolabile and reactive compounds such as *N*-alkenylketenimine complexes **100** [Eq. (43)] or *C*-alkenylketenimine complexes **86** [Eq. (38)] as well as *C*-alkylidenaminoketenimine complexes **102** [Eq. (44)].

The carbene complexes **82**[51] and **85**[52] required as starting materials can be prepared in a particularly simple manner by a base-catalyzed condensation[53] of the (CH-

acid) methylcarbene complex **80** with aldehydes **81** in the presence of chlorotrimethylsilane [Eq. (36), yield 50–70%] or of the aminocarbene complex **83** with acid chlorides **84**[59] [Eq. (37), yield 70–90%].

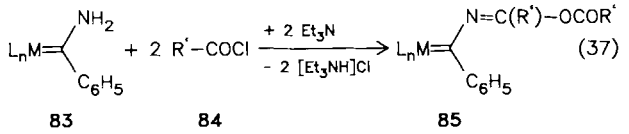


(36)

80 **81** **82**

L_nM = $[Cr(CO)_5]$

R = C_6H_5, *trans*-CH=CH–C_6H_5, *o*-$(CH_3)_3SiO$–C_6H_4, *o*-HO–C_6H_4, 2-thienyl, 2-furyl, 2-pyrrolyl



(37)

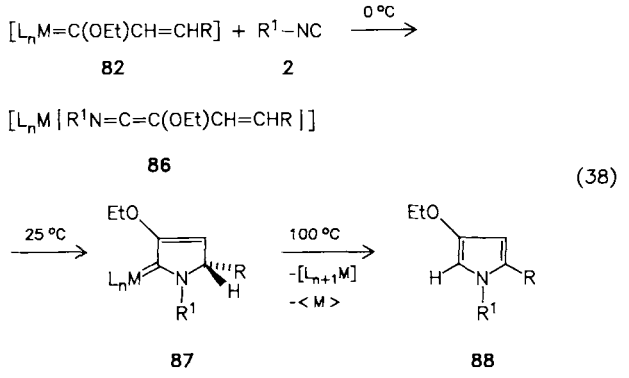
83 **84** **85**

L_nM = $[Cr(CO)_5]$; R' = C_6H_5, $C(CH_3)_3$

7.1. Pyrroles and δ-Carbolines

C-Alkenylketenimine complexes **86** of Cr, Mo, W (R^1 = alkyl,[54] alkenyl,[31] aryl[11c]) are well suited for cyclizations owing to their many double bonds. These reactions can occur both inter- and intramolecularly.

Thus, the *N*-cyclohexyl-substituted Cr complex **86** (L_nM = $[Cr(CO)_5]$) isomerizes spontaneously at 25 °C to the dihydropyrrolylidene complex **87** [Eq. (38)], the metal resi-



(38)

82 **2**

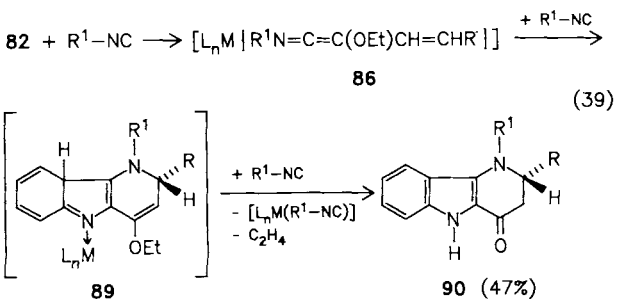
86

87 **88**

R = C_6H_5, *trans*-CH=CH–C_6H_5; R^1 = *cyclo*-C_6H_{11}

due undergoing a shift from nitrogen to the neighboring carbon. Complex **87** decomposes on warming via a hydrogen shift and elimination of the metal residue to give the ethoxypyrrole **88**; the latter can also be obtained directly without the isolation of organometallic intermediates by warming a 1:1 mixture of **82** and cyclohexyl isocyanide to 100 °C.[54]

Multiple cyclizations to partially hydrogenated δ-carbolinones **90**[11c] were observed when **82** was treated with three equivalents of an aryl isocyanide [Eq. (39)]. Organometallic intermediates of type **89** were isolated during a pyrrole synthesis which occurred in an analogous manner

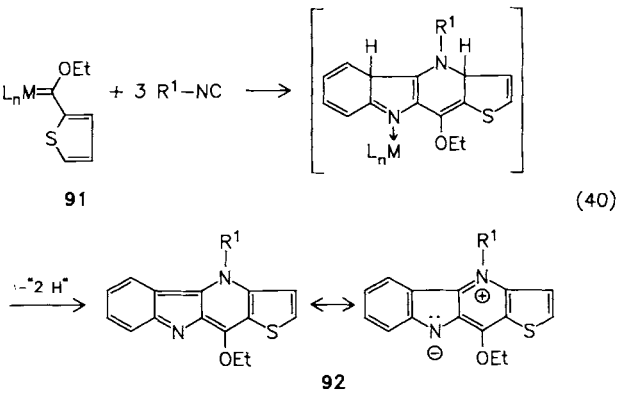


(39)

86 **89** **90** (47%)

R = C_6H_5, $CH{=}CHC_6H_5$; R^1 = C_6H_5

(see Section 7.4). The synthesis of δ-carbolines [Eq. (40)] starting from the particularly reactive thienylcarbene complex **91** leads spontaneously to the tetracyclic molecule **92**.[11c]



(40)

91 **92**

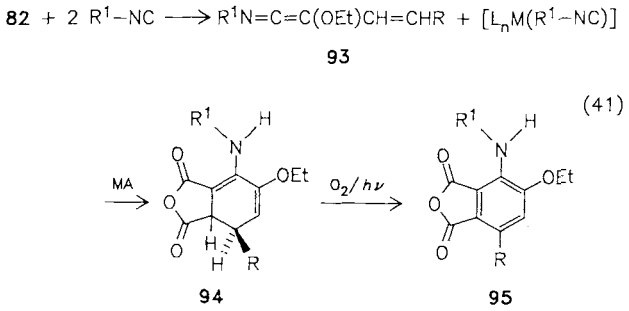
L_nM = $[Mo(CO)_5]$, R^1 = C_6H_5

7.2. [4+2] Cycloadditions with *C*-Alkenylketenimines

The reactions of **86** are strongly influenced not only by the metal residue L_nM but also by R^1, i.e., by the isocyanide used in the preparation of the complex. In the series M = Cr, Mo, W the intramolecular cyclization of the *N*-cyclohexyl-substituted Cr complex to give **87** is a borderline case. Since, in principle, competing reactions are possible which are influenced in a subtle manner by the spatial requirements of the substituents on nitrogen, the cyclization to the pyrrolylidene complex of type **87** "loses out" for both primary and tertiary isocyanides, with different results in each case. Only in the case of the ketenimine complex which is derived from (secondary) cyclohexyl isocyanide are the subsequent intermolecular reactions with isocyanides so slow (cf. Section 7.3) that time is available for the cyclization.

The bonding of the ketenimine ligand to the metal becomes weaker as the size of R^1 increases; i.e., it can be more easily replaced by other ligands. Therefore, the complete reaction of carbene complexes with tertiary isocyanides generally requires two equivalents of isocyanide. In this way it is possible to obtain ketenimines in a preparatively simple manner, to isolate them, or, as illustrated in reaction (41), to capture them with a third component: thus, the three-component reaction of **82** with two equivalents of *tert*-butyl isocyanide in the presence of maleic anhydride (MA) gives the adduct **94**. The latter is rapidly

oxidized in solution in the presence of air and light to the aminoethoxyphthalic anhydride **95** [Eq. (41)].[54,55]

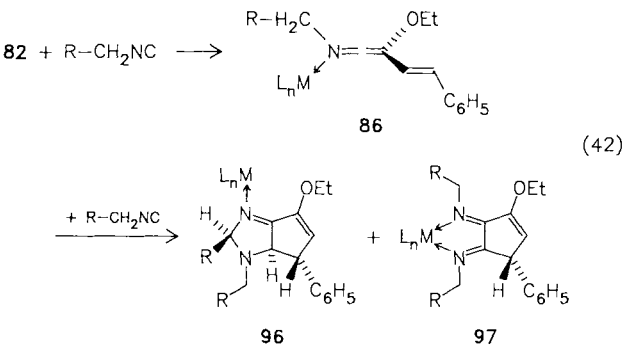


(41)

R = C_6H_5, R^1 = t-C_4H_9

7.3. [4 + 1] Cycloadditions with *C*-Alkenylketenimine Complexes

Alkenylcarbene complexes **82** of Cr, Mo, and W react with methyl isocyanide or primary isocyanides in a 2:1 ratio. In contrast to the reactions of bulky isocyanides, the second isocyanide is here added to the intermediate ketenimine ligand [Eq. (42)].[54,56]



(42)

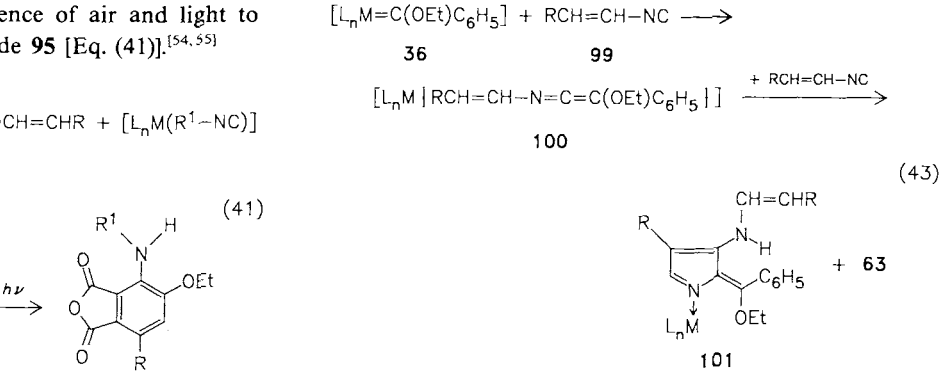
Table 7. Yields and product distributions in reactions (42). L_nM = [Cr(CO)$_5$].

R	Yield [%]	**96:97**
H	42	1:2
C_6H_5	46	> 10:1
CH_2=CH	10 [cf. Eq. (21)]	> 50:1

Complexes **96** and **97** (Table 7) are formed by [4 + 1] cycloaddition of the isocyanide to **86** from the side opposite to the metal and from the metal side, respectively, in multistep processes and, in the first case, additionally via insertion into an α-CH bond (see Section 6.2[57,58]).

7.4. [4 + 1] and [3 + 1] Cycloadditions with *N*-Alkenylketenimine Complexes

Carbene complexes **36** of Cr, Mo, and W add alkenyl isocyanides **99** to give *N*-alkenylketenimine complexes **100**, from which it is possible by means of competing reactions with further **99** to prepare the 1-azafulvene complexes **101** via [4 + 1] cycloaddition or the 2-azetidinylidene complexes **63** via [3 + 1] cycloaddition [Eq. (43), Table 8]. Complexes **101** are hydrolyzed to 3-amino-2-benzoylpyrroles [cf. Eq. (32)] and give a pyrrolopyridine on thermolysis.[47]



(43)

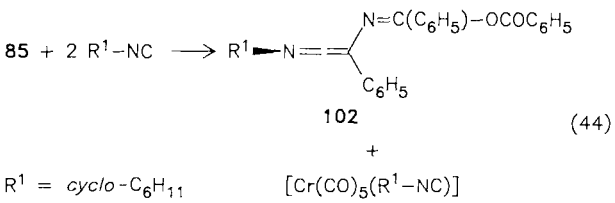
Table 8. Yields and product distributions in reactions (43). L_nM = [W(CO)$_5$] (**36b**).

R	Yield [%]	**101:63b**
H	80	3:1
CH_3 [a]	93	2:1

[a] *cis*-**99** : *trans*-**99** = 10:1.

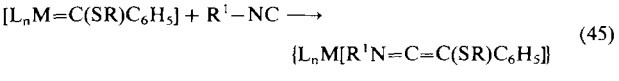
7.5. *C*-Alkylidenamino and *C*-Mercaptoketenimines

Not only alkoxy- but also mercapto- and aminocarbene complexes can be cleanly converted into ketenimine complexes by means of our procedure. The aminocarbene complex **85** (R' = C_6H_5) gives the alkylidenamino-substituted ketenimine **102**[27] with two equivalents of cyclohexyl isocyanide [Eq. (44)], while the mercaptocarbene



(44)

complexes **103** give ketenimine complexes **104** which are coordinated via sulfur[26] [Eq. (45)].



(45)

L_nM = [W(CO)$_5$]; R, R^1 = *cyclo*-C_6H_{11}, t-C_4H_9

8. Future Prospects

The use of metal complexes in organic synthesis offers a vast potential for novel "umpolung" reactions and possibilities for "nonclassical" construction of synthetic building blocks via template reactions. Our knowledge of procedures for the preparation of ketenimine complexes from carbene complexes, together with an extrapolation of previously analyzed reaction patterns of these compounds, opens numerous possibilities for their application in synthesis which—as a further advantage—involve only relatively simple procedures; we have taken care to adjust our

procedures to fit the capabilities of a conventionally equipped synthetic laboratory.

It would appear to be of importance to carry out systematic studies involving various metals and ligands and asymmetric syntheses via induced chirality, as well as to transfer the results obtained for stoichiometric reactions to catalytic processes.

Our work has been supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk and the Fonds der Chemischen Industrie. The development of the synthetic procedures described here required careful sorties into virtually unexplored territory. Exact predictions on the basis of known reactions were hardly possible: instead, our reactions were discovered on the basis of critical and creative analytical-strategic reflections and discussion at the laboratory bench and were then developed into synthetic procedures. I thank my co-workers whose names are mentioned in the list of references for their efforts and their enthusiasm for their research topics.

High-Resolution Solid-State ^{13}C-NMR Spectroscopy of Polymers

New Analytical Methods (37)

By Rüdiger Voelkel*

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

Until a few years ago, solid-state nuclear resonance yielded spectra containing broad lines only. Meanwhile, CP/MAS-NMR spectroscopy has provided a method which gives narrow nuclear resonance lines from a solid-state specimen as well. Using this technique, it is now possible to produce spectra of "rare" nuclei (^{13}C, ^{29}Si, ^{15}N etc.) which are resolved in terms of chemical structure. The analytical capabilities of NMR spectroscopy can be applied to the solid state: it may be that it is necessary to identify compounds in the solid state because, for example, a solvent would alter the coordination sphere, or that it is desired to monitor chemical reactions in the solid state, for example the baking of an enamel. Where a substance in the solid state is concerned, high-resolution ^{13}C-NMR spectroscopy provides not only information about the chemical structure, but also about the solid state itself. To mention just a few examples, information on the conformation, crystal structure and molecular dynamics, as well as molecular miscibility is given. This opens up a broad spectrum of applications, from a statement concerning the crystal modification of an active substance in ready-to-use pharmaceutical preparations, e.g. tablets, to the question of whether two polymers are miscible with one another at a molecular level.

1. Introduction

Since the introduction of the CP/MAS (*c*ross *p*olarization, *m*agic *a*ngle *s*pinning) ^{13}C-NMR experiment in its present form[1] as a combination of dipolar decoupling,[2] sample rotation at the magic angle[3] and cross polarization,[4] a number of articles[5] and monographs[6] presenting an introduction to the method have been published, as well as articles providing an overview of individual areas of application, e.g. polymers,[7] carbohydrates[8] and biopolymers.[9]

CP/MAS-NMR spectroscopy opens up the possibility of obtaining, even from a substance in the solid state, ^{13}C-NMR spectra, the signals of which can be correlated with chemical structures. The resolution of individual signals can be useful in two ways on the one hand, solid-state NMR spectroscopy can be used in direct analogy with solution NMR spectroscopy as an analytical tool for the investigation of compounds which have low solubility or are insoluble. On the other hand, it is also possible to make a number of statements regarding the physics of the solid substance. In both cases, the correlation of individual signals with chemical structural elements is an indispensible prerequisite. Accordingly, Section 2 deals initially with the question of the line width, and, in connection with the generation of the signals, quantifiability is also discussed. In Section 3, relating to analytical applications, consideration is given only to insoluble polymers. Attention centers on reaction resins, which otherwise are analytically accessible only with difficulty on account of their cross-linked nature. They are however of great technical importance, for example as matrix materials in composites.

In the second part (Sections 4 and 5) a number of physical applications are presented, which are less familiar to chemists accustomed to NMR spectroscopy in solution. One of the strengths of solid-state NMR spectroscopy is that it provides information on questions of conformation, crystal modification, molecular dynamics, and molecular adjacency. An understanding of the physical behavior of the sample is essential in order to take advantage of the unique possibilities offered by solid-state NMR spectroscopy: for example, selectivity with respect to certain components is also useful in the case of analytical applications.

The present article is limited to the one-dimensional methods which have already become well-established in practice. Very promising additional possibilities offered by two-dimensional NMR experiments will be dealt with separately by *B. Blumich* and *H. W. Spiess*.[10]

2. Line Width, Quantifiability

When reference is made to "magic angle spinning" NMR spectroscopy, what is almost always meant is the combination of *c*ross *p*olarization (CP), the actual rotation of the sample at the magic angle of 54.7° (MAS) and dipolar decoupling (DD) of the ^{1}H nuclei from the observed ^{13}C nucleus. With rigid solid substances only the combination of all three experimental "tricks" makes it possible and practicable to record spectra of rare nuclei (most commonly ^{13}C) resolved in terms of chemical structure.

Magic angle spinning, however, imposes the most stringent requirements on the experimental procedure, and makes the most striking contribution to the narrowing of the lines. The effect of MAS can be seen particularly well in the case of pure polyacetylene with only one chemical environment of the ^{13}C nuclei (Fig. 1). When the sample is

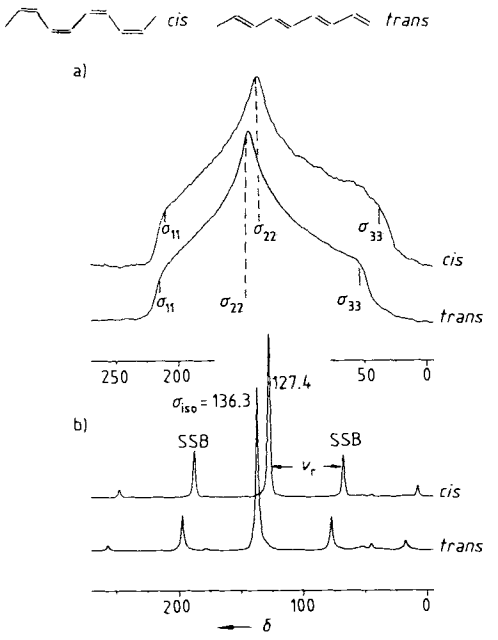

Fig. 1. Solid-state ^{13}C-NMR spectra of *cis*- and *trans*-polyacetylene. a) Stationary powder sample. The spectrum scans the entire range of the chemical shift. b) With sample rotation (ν_r = 4500 Hz) at the magic angle. A narrow line is obtained at the isotropic value of the chemical shift, and spinning sidebands (SSB) are spaced at intervals of ν_r (all spectra cross polarized with 3 ms, dipolar decoupled with ν_{1H} = 50 kHz, each 20000 recordings at intervals of 2 s).

stationary, a powder spectrum is measured, which sweeps over the entire range of the chemical shift. The principal values σ_{ii} of the chemical shift tensor can be obtained by matching of the theoretical spectrum.[6a, 11a] However, if the sample were rotated at speeds of rotation which are large in relation to the width of the powder spectrum (in Hz), the result obtained would be only one sharp line at the isotropic value of the chemical shift, the position of which is different for the *cis* and *trans* isomers of polyacetylene.

When the sample is rotated more slowly, spinning sidebands (SSB) occur, in addition to the isotropic signal, at a spacing corresponding to the frequency of rotation (in Fig. 1, 4500 Hz). The chemical shift tensor can be reconstructed from the intensity of these sidebands.[11b,c] If the recording is synchronized stepwise with the rotor position in a two-dimensional measurement, the sideband intensity gives the orientation distribution of anisotropic samples.[10, 12] In the event of interfering superpositions of the spinning sidebands with other signals, it is possible to suppress the sidebands by appropriate sequences of pulses.[13] When such suppression is applied, the signal intensities are often distorted to a great extent. Except in the case of extremely broad signals, for example when examining coal or charged, electrically conductive polymers, another measurement at a different speed of rotation frequently proves to be more advantageous.

With regard to the use of MAS-^{13}C-NMR spectroscopy as an analytical tool, especially for compounds which have low solubility or are insoluble, two questions are of prime importance: the question of the attainable resolution, i.e. the line widths which can be obtained in comparison with the range of the chemical shift (^{13}C: approximately 200 ppm), and the question of the quantifiability of the spectra.

2.1. Line Width

In solid-state NMR spectra the line widths are usually 10–100 times greater than those of solution NMR spectra. The attainable line width of 10–100 Hz at 7T for rigid, crystalline solid substances is determined, on the one hand, by susceptibility variations and by dipolar interactions which are not entirely averaged out. On the other hand, effects which are typical of solid substances frequently limit the resolution which can be attained.[14] Errors in the setting of the magic angle play virtually no part, provided that adjustment is carried out using KBr[15] and double-bearing rotors are used.

When several molecules are situated at non-equivalent positions within a crystal, or if the symmetry of the crystal is less than that of the molecule, molecular positions which are equivalent to one another in solution can lead to several signals in the solid state. In the case of small differences in shift, a broadening of the signal may result[16] (Fig. 2). Similarly, the freezing-in of conformations in the solid substance leads to the non-equivalence of signals. Such a conformational effect on the solid-state spectrum has been described both in the case of peptides[17] and also in the case of synthetic polymers.[18, 44]

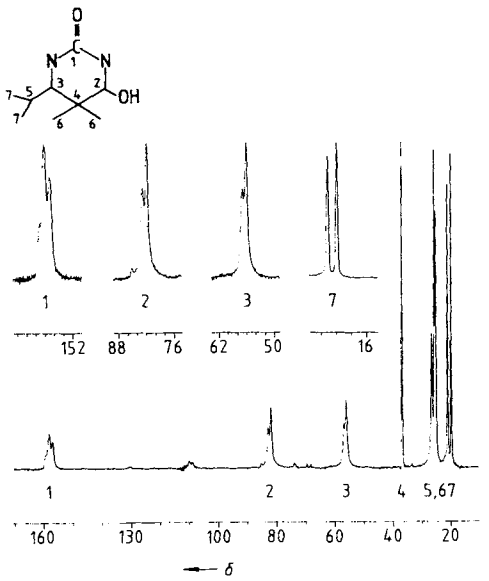

Fig. 2. Effect of the crystal structure on the solid-state NMR spectrum (for the example of a urea derivative). Two molecules in non-equivalent positions lead to a doubling of the signals (each 1000 recordings at intervals of 6 s, CP 2 ms, $\nu_{1H} = \nu_{1C}$ = 50 kHz, ν_r = 3650 Hz).

Conformation and, to a lesser extent, packing, are variables which contribute to the determination of the line position. This frequently results in complications when interpreting the solid-state NMR spectra of crystalline samples with respect to chemical structures; on the other hand, the influence of conformation and packing enables the spectroscopist to distinguish various modifications of chemi-

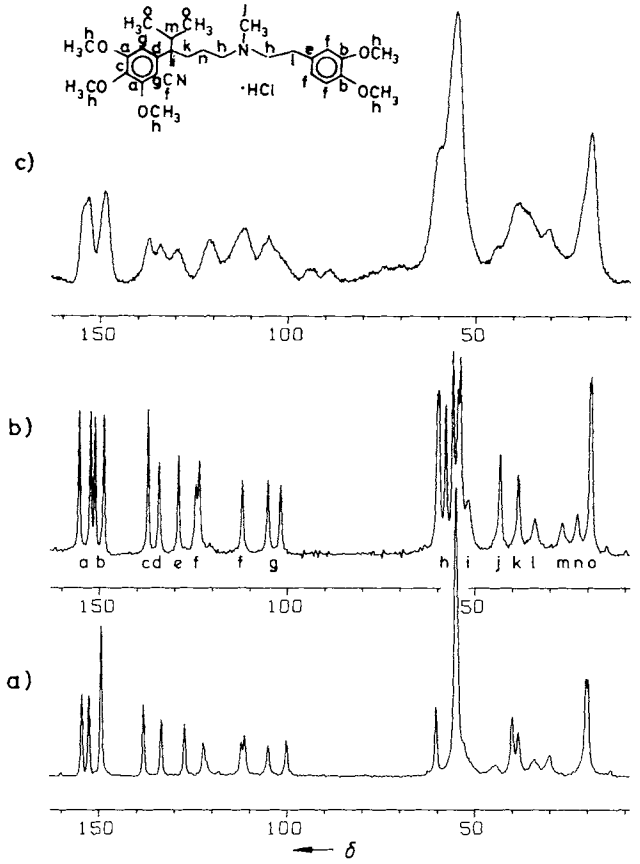

Fig. 3. Effect of crystal modification and crystallinity on the solid-state NMR spectrum of an amine hydrochloride. a) Crystallization from 2-propanol/diisopropyl ether. b) Recrystallized from ethyl acetate. Attention is drawn to the non-equivalence within the positions a, b, g and h and the modification effect (compare (a) with (b)). c) Amorphous sample (quenched from the melt). Conformational and packing disorder leads to broad signals ((a) and (b) each 2000 recordings plus 3000 recordings added with inverted 1st order SSB [13a], in order to suppress the sidebands, $\nu_r = 4500$ Hz, CP 2 ms, $\nu_{1H} = \nu_{1C} = 50$ kHz; c) 4000 recordings at intervals of 2 s, CP 2 ms, without SSB suppression).

cally identical compounds (Fig. 3). Under conditions of increasing temperature, e.g. by interconversion of conformers[19] or tautomerism,[20] there may be a dynamic exchange between signals which are distinguishable in the solid-state NMR spectrum. Whenever the atoms undergoing exchange with one another differ in chemical shift by a few ppm at the most, slow dynamic processes with a lifetime in the region of 10^{-4} s can be investigated by line shape analysis.

Below the glass-transition temperature the conformational and packing disorder leads to relatively broad lines for amorphous samples. Line widths between 100 and 500 Hz (Fig. 3c) are typical at 75 MHz (^{13}C). Accordingly, differing tacticities in polymers can only be measured in the solid state if they result in differing conformations in the crystal[21] or if the formation of hydrogen bonds is restricted to a specific tacticity.[22]

In the case of elastomers having a glass-transition point below room temperature, the modulation of the C-H dipole coupling due to motion plays a part in determining the line width.[14,20,23] Indeed, if the frequency of the jump process and that of the decoupling field (usually $\omega_{1H}/2\pi \simeq 50$ kHz) are comparable, the suppression of the dipolar coupling becomes inefficient; the natural line width of ^{13}C-NMR signals (T_2) due to relaxation via the C-H dipolar interaction then limits the resolution attainable.[24] Figure 4 shows an appropriate example: in this case, a spin-lock frequency in the median kHz range was employed. The maximum line width is therefore to be expected at approximately 30 K above the glass-transition temperature (in the case of poly(butyl acrylate) $T_G = -46$ °C) (cf. Section 5.3). The agreement between the decoupling frequency ω_{1H} and the jump frequency of the motion leads to line broadening. There is also a broadening due to modulation of the resonance frequency on account of the anisotropy of the chemical shift, if the mobility is comparable with the rotor frequency (in most cases, approximately 4000 Hz).[14a]

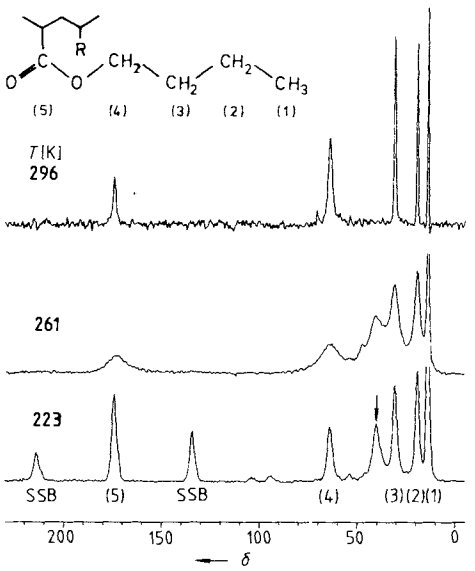

Fig. 4. Effect of the molecular dynamics on the CP/MAS-NMR spectrum of polybutyl acrylate. If the frequency of the molecular dynamics is comparable with the strength of the decoupling field ($\omega_{1H}/(2\pi) = 50$ kHz), a line broadening results ($T = 261$ K). In contrast to $T = 296$ K, there are spinning sidebands at $T = 223$ K. Attention is drawn to the absence of the signal from the chain (arrow in the spectrum at $T = 223$ K, $\delta \approx 40$) at $T = 296$ K.

When measurements are taken far above the glass transition, which is the case with rubbers even at room temperature, the dipolar interaction is to a large extent averaged out by the high molecular mobility, so that very narrow lines are measured even without dipolar decoupling.[6c,24,25] On account of the small line widths of rubbers, it is possible to determine the microstructure of elastomers and elastomeric copolymers even in the solid state. Even the scalar ^{13}C-^{1}H coupling was resolved in a two-dimensional experiment in the case of polyisoprene.[26]

2.2. Quantifiability

The ^{13}C-NMR signal in solid-state NMR spectroscopy is enhanced by cross polarization,[4] a transfer of magnetization from ^{1}H to ^{13}C in a double resonance experiment. In order to achieve the transfer of magnetization, a Hartmann-Hahn contact is at present almost always used, i.e., the simultaneous application of two radio-frequency fields

in resonance with ^{13}C and ^{1}H respectively with the same frequency of the nuclei in the rotating coordinate system. Other cross polarization techniques[4b, 27] are not considered in the text which follows. The reason for using cross polarization for enhancing the ^{13}C signal resides, on the one hand, in the ratio of the gyromagnetic ratios $\gamma_H/\gamma_C \simeq 4$. Additionally the maximum permissible repetition rate with cross polarization is determined by the very much faster relaxation of the ^{1}H and not by the ^{13}C; in favorable circumstances it is possible to achieve an enhancement factor of up to 20 in the signal-to-noise ratio. This is why cross polarization is frequently a necessary prerequisite for the practical feasibility of MAS-^{13}C-NMR spectroscopy. Among polymers, the elastomers are an exception—measurements are made far above the glass-transition temperature and excitation takes place directly by a 90° pulse with the resonant frequency of the ^{13}C nuclei.

Signal enhancement by cross polarization implies that the signal intensities are influenced by the kinetics of this transfer of magnetization[6a, 28] and are not a priori quantitative. Figure 5 shows the growth of the magnetization for

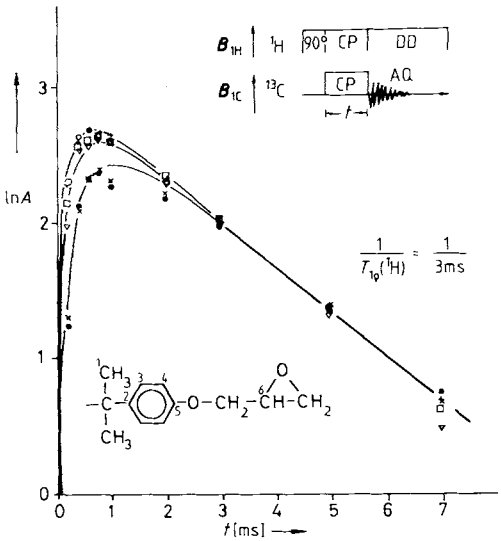

Fig. 5. Rise of the ^{13}C-NMR signal during cross polarization, for the example of an epoxy resin of bisphenol-A diglycidyl ether and diaminodiphenylmethane (0.172 epoxide units/bisphenol-A unit). The individual positions in the molecule have an individual time of build-up (cf. Table 1). In the case of long contact times, the signal amplitude declines with the common time constant $T_{1\rho}(^{1}H)$ (4000 recordings in each instance, at intervals of 2 s, $\nu_r = 3850$ Hz, $\nu_{1C} = \nu_{1H} = 50$ kHz). AQ = acquisition time of the FID, □ C1, ● C2, + C3, ○ C4, × C5, ▽ C6.

the various positions in a hardened epoxy resin. The mechanism which couples the ^{13}C nuclei to the ^{1}H "reservoir" is the dipole-dipole interaction. On account of its $1/r^6$ dependence upon the spacing r between ^{13}C and ^{1}H, the signal build-up for the various resonance lines takes place at differing speeds: quaternary C nuclei without ^{1}H nuclei within bonding distance cross-polarize in the Hartmann-Hahn contact[4] more slowly than H-substituted C nuclei. Where methyl groups are present, the dipolar interaction is reduced by the rotation about the ternary axis, so that a CH_3 group behaves in a similar way to a CH group (cf. Fig. 5). In the case of single-phase systems with adequate dipole-dipole interaction between the protons the signal intensity $M(t)$ passes through a maximum and then falls off exponentially with increasing contact time t. The time constant $T_{1\rho}(^{1}H)$ of the decay is common to all C atoms [Eq. (a)-(d)].[6a, 7b, 28]

$$M(t) = M_0 \lambda^{-1} \left\{1 - \exp\left(-\frac{\lambda t}{T_{CH}}\right)\right\} \exp\left(-\frac{t}{T_{1\rho}(^{1}H)}\right) \quad (a)$$

$$M(t) = M_0 \lambda^{-1} f(t) \quad (b)$$

where

$$\lambda = 1 + \frac{T_{CH}}{T_{1\rho}(^{13}C)} - \frac{T_{CH}}{T_{1\rho}(^{1}H)} \quad (c)$$

and

$$f(t) = \exp\left(-\frac{t}{T_{1\rho}(^{1}H)}\right) - \exp\left[-t\left(\frac{1}{T_{CH}} + \frac{1}{T_{1\rho}(^{13}C)}\right)\right] \quad (d)$$

In order to treat the protons as a spin reservoir with a single spin temperature, the derivation of equation (a) is based on a strong homonuclear H-H dipole interaction, i.e. a short proton relaxation time $T_2(^{1}H)$. Equation (a) describes the rise of the ^{13}C magnetization with a time constant $\lambda^{-1} T_{CH}$, during the contact of the ^{13}C nuclei with the ^{1}H reservoir which in the "locked" condition is cold with regard to the spin temperature. Superimposed on the rise of the ^{13}C magnetization, there is a contrary process: the "heating" of the proton reservoir, i.e. reduction of the proton magnetization, due to the relaxation of the protons in the rotating coordinate system with the time constant $T_{1\rho}(^{1}H)$. As a result of the reduction of the proton magnetization during the double resonance experiment, the maximum ^{13}C magnetization attainable in the cross polarization experiment also falls to $M_0 \lambda^{-1} \exp(-t/T_{1\rho}(^{1}H))$. For large radio-frequency field strengths, $M_0 = \gamma_H/\gamma_C M_{eq}$, i.e. the theoretically attainable ^{13}C magnetization M_0 amounts to approximately four times the equilibrium magnetization M_{eq} in the external field B_0. As already mentioned, an even more significant gain in the signal-to-noise ratio is observed in cross polarization, because the repetition rate of the experiment is not determined by the longitudinal relaxation of the ^{13}C nuclei but by the very much more rapid relaxation of the protons.

In the quantitative evaluation of the spectra,[7b] magnetizations of the various positions in the molecule which are generated with a fixed contact time t are compared. The scaling of M_0 is different for the individual positions; the relaxation time in the rotating coordinate system, $T_{1\rho}(^{13}C)$, and the cross polarization constant T_{CH} are both individual quantities for the various positions in the molecule [see equations (a) and (c)]. $T_{1\rho}(^{1}H)$ is determined from the gradient $1/T_{1\rho}(^{1}H)$ of the straight line at long contact times in a logarithmic plot of the signal amplitudes, assuming $T_{1\rho}(^{1}H) \gg T_{CH}$ (Fig. 5). The initial part of the curve is analyzed according to equation (d) in order to obtain $1/T_{CH} + 1/T_{1\rho}(^{13}C)$ (Table 1). $T_{1\rho}(^{13}C)$ can be measured in a separate experiment (cf. Section 5.2). $T_{1\rho}(^{1}H)$, T_{CH} and $T_{1\rho}(^{13}C)$ are used to compute the scaling factors λ [Eq. (c)] and $f(t)$ [Eq. (d)]; finally, $\lambda/f(t)$ gives the factor by which the measured intensity according to equation (b) must be multiplied in order to guarantee a "correct" count of the spins (Table 2).

Table 1. Dynamics of the cross polarization in the case of an epoxy resin [cf. Fig. 5 and Eq. (a)-(d)]. The time constant for the transfer of magnetization, T_{CH}, can be determined from the rise of the signal amplitudes A at the commencement of the C-H contact in Figure 5 (time constant in column (2)). $T_{1\rho}(^{13}C)$ must be obtained from a separate experiment. $T_{1\rho}(^{1}H)$ is obtained from the graph in Figure 5 for long contact times. The scaling λ for the various signals is computed from T_{CH}, $T_{1\rho}(^{13}C)$ and $T_{1\rho}(^{1}H)$ in accordance with equation (c).

C nucleus	$\frac{1}{T_{CH}}+\frac{1}{T_{1\rho}(^{13}C)}$ [a] $[ms^{-1}]$	$\frac{1}{T_{1\rho}(^{13}C)}$ [b] $[ms^{-1}]$	$\frac{1}{T_{CH}}$ $[ms^{-1}]$	$\frac{T_{CH}}{T_{1\rho}(^{13}C)}$	$\frac{T_{CH}}{T_{1\rho}(^{1}H)}$ [c]	λ

[a] With $\nu_{1C}=\nu_{1H}=62.5$ kHz, $\nu_r=3850$ Hz. [b] With $\nu_{1C}=30$ kHz (separate measurement). [c] $T_{1\rho}(^{1}H)=3$ ms.

Table 2. Falsification of the signal intensities by cross polarization. The magnetization M_0 corresponding to a true "spin counting" is falsified by a factor of $f(t)/\lambda$ on account of the cross polarization dynamics [Eq. (b)]. The smaller the difference in $f((t)/\lambda$ for the individual positions in the molecule, the better is the reproduction of the quantitative conditions in the spectrum. $f(t)$ was computed for two contact times t ($t=1$ ms and $t=2$ ms respectively) using equation (d) and the experimental times derived from Table 1. λ was taken from Table 1. The values in column 7 and the renormalized values (column 8) show that quantitativity is satisfied to an accuracy of $\pm 5\%$ for $t=2$ ms ($0.95 \le f(t)/\lambda < 1.05$).

C nucleus (Fig. 5)	λ [a]	$t=1$ ms			$t=2$ ms		
		$f(t)$ [b]	$\frac{f(t)}{\lambda}$	$\left(\frac{f(t)}{\lambda}\right)_{norm}$ [c]	$f(t)$ [b]	$\frac{f(t)}{\lambda}$	$\left(\frac{f(t)}{\lambda}\right)_{norm}$ [c]

[a] From Table 1. [b] Calculated according to equation (d) with the values from Table 1 for $t=1$ and 2 ms. [c] For easier comparison scaled to $f(t)/\lambda=1$ for CH_3 (C1).

As $T_{CH}/T_{1\rho}(^{13}C) \le 0.1$ and $T_{CH} \gg T_{1\rho}(^{1}H)$, the scaling factor λ differs for the individual positions in the epoxy resin only to a slight extent (cf. Table 1, $0.85 < \lambda \approx 1.0$). If the value of T_{CH} is short in comparison with $T_{1\rho}(^{13}C)$ and $T_{1\rho}(^{1}H)$, at least approximately quantitative cross polarization spectra are recorded, even without measurement of the cross polarization dynamics, as already described in the literature.[7b] However, it is necessary to ensure adequately long contact times, $t > 3T_{CH}$. The second term in $f(t)$ [Eq. (d)], which is dependent upon the C position, then approximates to the value zero and thus $f(t)$ becomes almost unitary (Table 2, $t=2$ ms $0.48 \le f(t) \le 0.52$). As the value of $T_{1\rho}(^{1}H)$ is unitary, too, as a result of spin diffusion, the first term in equation (d) is a constant for all positions in the molecule.

The condition of a contact time t which is long in comparison with the cross polarization constant T_{CH}, $t \ge 3T_{CH}$, clearly means that, for the sake of quantifiability, a measurement on the rising branch of the ^{13}C magnetization should be avoided (cf. Fig. 5). The price which is paid is a deterioration in the signal-to-noise ratio (cf. $f(t)/\lambda$ in Table 2 for $t=1$ and 2 ms; the magnetization of CH_3 (C1), for example falls from $0.71M_0$ to $0.54M_0$, i.e. to 2/3). On the other hand, the distortion of the signal intensities $f(t)/\lambda$ as compared with the true intensity ratios is very small at $t=2$ ms (Table 2, column 8, $\pm 5\%$).

To be able to evaluate quantitatively, measurements close to the $T_{1\rho}$ minima should be avoided. It is also true that the line widths increase close to $[T_{1\rho}(^{13}C)]_{min}$ (cf. Sections 2.1 and 5.3) and that close to $[T_{1\rho}(^{1}H)]_{min}$ the signal amplitudes decline strongly [Eq. (a)].

To sum up, then, sufficiently long contact times (≥ 2 ms) give spectra of homogeneous samples which are, as a rule, at least approximately quantitative, even without laborious normalization. It is not necessary to measure the cross polarization dynamics or to use calibration samples. An exception is systems which are strongly heterogeneous in terms of dynamics, e.g. polymeric glasses modified for high impact strength. In this case a quantitative comparison of the rubber and matrix signals is not permissible. The problem of quantifiability of partially crystalline samples has been investigated in detail with polyethylene as a model compound.[29]

3. Reaction Plastics

The application of high-resolution solid-state ^{13}C-NMR spectroscopy to insoluble polymer networks[7h] is, in particular, of industrial interest, since such cross-linked polymers participate in a multiplicity of processes which are important at the industrial level. Examples are, to mention just a few, the baking of enamels, controlled thermal decomposition in the production of carbon fibers, adhesion and coating processes, and especially the curing of resins.

Investigations, in addition to those on resins based on furfuryl alcohol[30] and polydiacetylene[31] as well as end-capped polyimides,[32] have principally been carried out on methacrylate-based resins,[33] urea/formaldehyde condensates[43] as well as phenolic[35] and epoxy resins.[7b, 19, 36]

In the case of the dimethacrylates, the investigations were aimed at the determination of the residual double

bonds[33c,d] and at the part played by the melamine/formaldehyde adduct, which is added in most cases. The hardening[33a,b] is essentially determined by the reaction of the hydroxymethyl groups of the melamine/formaldehyde. The extent to which it is possible to make statements concerning the number of hydroxymethyl radicals by means of solid-state NMR spectroscopy is shown by Figure 6. A

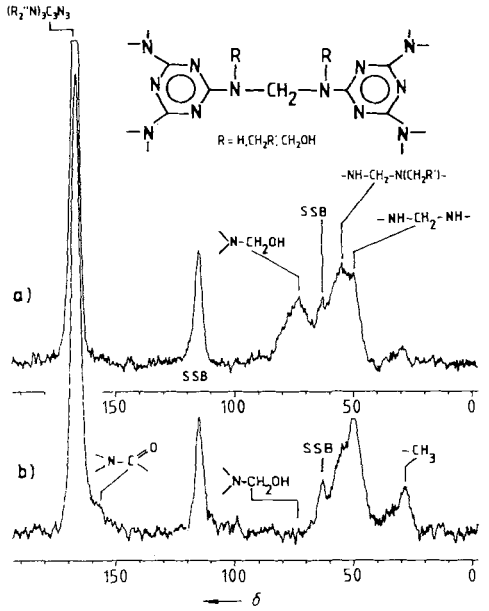

Fig. 6. Heat treatment of a melamine/formaldehyde condensate. a) After 2 h at 200 °C, a large number of hydroxymethyl groups is still present ($\delta \approx 70$). b) After 24 h at 240 °C, no CH_2OH groups can be detected any longer, but there are signs of degradation (CH_3 and $>N-CO-$); 1000 recordings in each instance, waiting time 2 s, $\nu_r = 3900$ Hz).

pure melamine/formaldehyde condensate (a foam) was used. At the end of the foaming process, there are initially considerable proportions of $N-CH_2OH$ functions, which can, however, be virtually entirely eliminated by subsequent tempering. A similar behavior is shown by urea/formaldehyde condensates.[34] It is important that tempering should not be excessive, since this would not only lead to oxidative decomposition, but also to the formation of methyl groups because of undesired reactions (Fig. 6). Both effects have also been observed in the case of phenolic resins, in spite of the different starting materials used.[35a] In order to monitor the hardening of phenolic resins and the formation of methylene bridges from the hydroxymethyl radicals, the contact time for the transfer of magnetization from ^1H to ^{13}C was varied. With the aid of model substances, suitable conditions of measurement for a quantitative determination of the ratio of methylene bridges to aromatic rings were found[35b] (cf. Section 2.2 with regard to quantitative evaluation).

Even at a very early stage, epoxy resins were investigated in detail using MAS-NMR spectroscopy;[36a,7b] such resins have great technological importance as matrix resins for composite materials consisting of polymer and carbon fibers embedded therein for strengthening. The epoxy resins are made from two components, which may be, for example, a bifunctional resin (diepoxide) and a diamine as tetrafunctional hardener. The network structure present in the finished articles (and thus also the mechanical properties) is critically dependent upon the final conversion obtained during curing. In the MAS-^{13}C-NMR spectrum (Fig. 7) measured for the cured resin, the individual signals can be correlated with the different chemical structures.[36b] The possibilities described in the literature with regard to solid-state NMR spectroscopy in the investigation of epoxy resins have recently been reviewed.[36c]

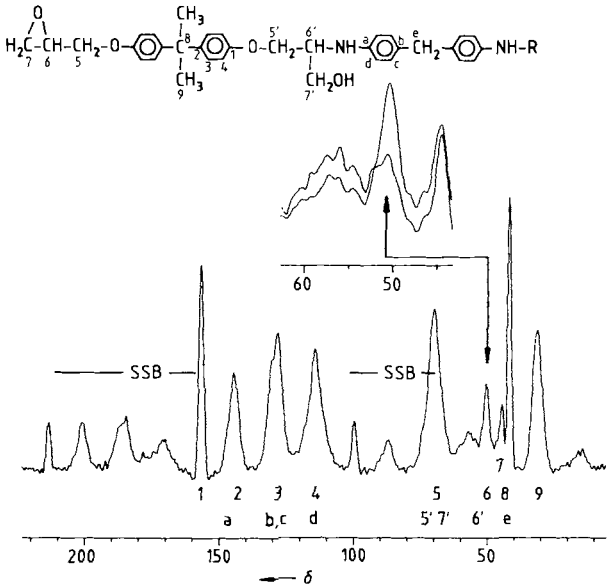

Fig. 7. Solid-state ^{13}C-NMR spectrum of an epoxy resin based on the diglycidyl ether of bisphenol-A (DGEBA), cured with 4,4'-diaminodiphenylmethane (DDM). By evaluating the epoxide signal (arrow, signal 6, $\delta = 53.7$) the epoxide content can be measured to an accuracy of approximately ± 0.04 epoxide units/bisphenol-A unit and the curing conversion can be determined. The figure shows the spectrum of the starting mixture containing 0.64 epoxide units/bisphenol-A unit and a partially cured sample containing 0.42 epoxide units/bisphenol-A unit. The signals 1 or 9 are suitable for internal standardization. They are not affected by superposition of DDM (4000 recordings in each instance, 2 s, $\nu_r = 4300$ Hz, CP 2 ms).

In epoxy resins too, the line width of the signals is essentially based on an inhomogeneous broadening, which arises as a result of a distribution of the values of the isotropic chemical shift on account of the differing conformations.[7b] In the case of the aromatic carbons *ortho* to the ether bond in bisphenol-A, at a low temperature a signal doubling was resolved. At room temperature and above, these two signals coalesce as a result of "chemical" exchange of the two *ortho* carbons by 180° ring flips. The correlation time of this movement was determined from investigations of the line shape and compared with mechanical relaxation data.[19]

Particular importance is ascribed to the question of the quantifiability of the spectra when it is desired to measure the curing conversion by means of NMR spectroscopy. One possibility consists in investigating the dynamics of the cross polarization[7b] and thus arriving at scaling factors for the areas of the individual signals (including sidebands) (cf. Section 2.2). Because of the necessity to evaluate areas, this process is, however, relatively inaccurate.

A more reliable and simpler method is the evaluation of the signal amplitudes of the solid-state NMR spectra of model substances (e.g. oligomers of the diglycidyl ether of bisphenol-A). If the model substances are soluble, it is possible to determine the epoxide content in solution and to plot calibration curves of the signal amplitude against the epoxide content. For this purpose, the signal of the central carbon (C6) in the glycidyl radical ($\delta = 53.7$, Fig. 7) is, for example, normalized internally with reference to another signal of bisphenol-A, e.g. to that of C9 ($\delta = 35.2$).

For a predetermined measurement condition, the residual epoxide content and thus an upper limit for the conversion can be determined by means of such a calibration line from the signal amplitude of the epoxide. Residual epoxide contents of up to approximately 1 epoxide/20 bisphenol-A are measurable and can be correlated with the curing conditions.

If cross-linkable thermoplastic materials are employed as matrix materials, it is possible to utilize the advantage of the thermoplastic processability and storage stability, without having to accept the sensitivity of non-crosslinking thermoplastic materials, for example, to solvents. Figure 8 shows the spectrum of such a cross-linking thermoplastic material based on aromatic thioether ether sulfones. After tempering at 350 °C, the homopolymer shows only a relatively small shift in peak intensity from $\delta > 130$ to $\delta < 125$, which is in accord with a partial neutralization of the pure *para*-substitution of the aromatic compounds by opening and reforming the thioether linkages. On the other hand, under the same temperature conditions a copolymer with bisphenol-A units (Fig. 8b) shows a drastic change of the spectrum (Fig. 8a). After 24 h at 350 °C, the spectrum still consists of the starting material spectrum only to the extent of a proportion of 50% in terms of area. In 12 h, the signals of the central propylidene unit in bisphenol-A ($\delta = 29$ and 41.6) fall to 60% of the initial intensity; after 24 h only 25% is still present, which demonstrates the direct participation of the comonomer in the cross-linking. In the case of a thermal cross-linking under the very drastic conditions chosen here, a multiplicity of in some cases very similar structures are produced. Accordingly, the difference spectrum between product and starting material (Fig. 8c) also shows only broad ^{13}C-NMR signals. However, this is not a weakness of MAS-NMR spectroscopy caused by the method itself, but a consequence of the fact that an unspecific reaction cannot generate a specific spectrum.

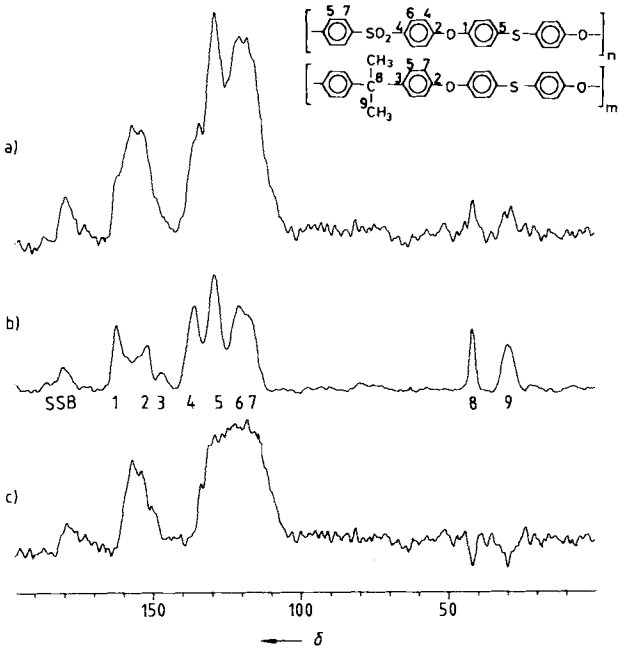

Fig. 8. Solid-state ^{13}C-NMR spectra of a cross-linking thermoplastic material consisting of a copolymer of poly(thioether ether) and poly(thioether ether sulfone). a) Spectrum after 24 h at 350 °C. b) Educt spectrum. c) Difference spectrum a–b. The spectrum a consists only to the extent of 50% of the educt signals. The signals (8 and 9) of the propylidene unit in bisphenol-A are reduced to 25%, which demonstrates participation of this unit in the cross-linking mechanism. The newly formed structures are non-unitary, as is evident from the difference spectrum showing poor resolution (at the bottom in the figure). (The sidebands have been eliminated mathematically.)

4. Physical Influences

A number of physical properties of the solid substance either influence the line position and line shape or determine the relaxation behavior of the nuclei (Table 3).

Table 3. Physical effects in CP/MAS-NMR spectra and their possible applications for the characterization of solid substances.

Effect on	by	Information on
Line position	conformation, packing	crystal structure, polymorphism, partial crystallinity
	coordination	catalysis
	chemical exchange	molecular dynamics, tautomerism, conformational transformations
Relaxation	spin dynamics, spin diffusion	amorphous components, high-impact modifier, block copolymers and graft content from relaxation time-selective spectra
	adjacency	polymer blends, plasticizers, antioxidants, heterogeneous systems
	molecular dynamics	block copolymers, additives, polymer mixtures, glass transitions, mechanical properties

It is precisely the physical influence on the spectra which broadens the range of application of CP/MAS-NMR spectroscopy considerably beyond the purely analytical application: as a result of the conformational effect on the *line position*, it is possible to obtain information concerning the conformation in the solid substance, and modifications and crystalline or amorphous components also become indirectly distinguishable (sections 4.1 and 4.2).

The combination of high resolution with *relaxation time measurements* gives, on account of the resolution of signals of individual positions of a molecule, very detailed information, at the local, molecular level, concerning the dynamics (Section 5) and the molecular adjacency relationships which are present (Section 4.4). However, the relaxation behavior may also be utilized with advantage for analytical applications, in order to achieve selectivity of the spectrum with respect to specified components in the case of heterogenous samples. Depending upon the selection of the experimental parameters, a determination is made in

terms of crystalline or amorphous material (Section 4.2), or in terms of the elastomer component or matrix (Section 4.3).

4.1. Conformation, Modification, Amorphous Components

The conformation plays an important part with regard to the line position in solid-state NMR spectra: two methylene signals are observed at a spacing of 8.7 ppm ($\delta = 39.6$ and 48.3 respectively) as a result of conformational nonequivalence in syndiotactic polypropylene[21] as a consequence of a γ-*gauche* effect.[37,38] In one half of the methylene groups, two γ-carbon atoms are present in the *gauche* (*g*) conformation, while in the other half both γ-carbons occupy the *trans* conformation. The conformation of isotactic polypropylene is distinct, in turn, from that of the syndiotactic polymer and gives a methylene signal at $\delta = 44.5$.[21,39] This is, besides polyvinyl alcohol,[22] one of the few examples where differing tacticities can be discerned in the solid-state NMR spectrum.

The methylene groups of the α- and γ-modifications of polypivolactone should be mentioned as a further example of a signal doubling as a result of conformational nonequivalence.[40]

Very much more frequent than the creation of two different conformations of otherwise equivalent positions of a molecule in the same crystal is the formation of differing conformations in polymorphism.

The modifications can then be detected because of the conformational effect on the chemical shift (see Fig. 3). Examples from the field of polymers are polybutylene terephthalate with a *gtg* conformation in the α form and *ttt* conformation in the β form,[41] α- and γ-polypivolactone (2_1 helix) in comparison with β-polypivolactone (planar zig-zag conformation)[40] and peptides (α-helix vs. γ-sheet).[17b,42] In the case of isotactic poly(1-butene), the various modifications differ only in the dihedral angle of the *gt* conformation, which is, however, sufficient for their identification by means of NMR spectroscopy.[39,43]

While in the above-cited cases the conformation and thus an *intra*molecular effect is responsible for the ability of NMR spectroscopy to distinguish the modifications, in other cases the conformations are the same and the modifications vary only in the nature of the packing of the polymer chains in the crystal. However, the *inter*molecular effect of the packing leads only to small differences in the signal position: $\Delta\delta = 0.8$ ppm between the α- and the β-modification of isotactic polypropylene[39] and 1.4 ppm between orthorhombic and monoclinic polyethylene.[29b]

In α-olefins of greater chain length (e.g. poly[(*S*)-3,7-dimethyl-1-octene]), the side chain is in rapid movement even in the solid state, and the carbon atoms of the side chain from C5 onwards are conformationally disordered.[44] Thus, the situation is very similar to that in the case of partially crystalline polymers, where the conformation, packing and mobility of the crystalline component differ from those of the amorphous component, which has appropriate consequences for the NMR spectrum: in addition to a sharper signal from the crystalline regions, there is a broader signal, frequently shifted in its position, from the chains in the amorphous region. This was first observed in polyethylene;[45] there have meanwhile been further examples, e.g. polyethylene terephthalate,[46] *trans*-polybutadiene,[47] polymethylene oxide[48] and polyethylene oxide.[14a,49]

In polyethylene (see Fig. 9a), the signal of the amorphous regions is shifted by 2.3 ppm upfield.[18b,45,50] The reason for this is the proportion of *gauche* conformations, which can be estimated from this difference in shift at approximately 1/3. By using cycloalkanes as model substances,[18a,51] an attempt was made to obtain information on the conformation of the folds contained in the amorphous covering layers of polyethylene single crystals.[18b] In this case, the problem resides principally in the low proportion by mass of the folds in the entire sample and thus the poor signal-to-noise ratio of the corresponding signals. On the other hand, with regard to solution-crystallized *trans*-polybutadiene it is known that, in spite of the restriction due to the adjacent re-entry of the chains, the folds of the chains adopt the same conformation as in entirely amorphous samples.[47]

4.2. Partial Crystallinity

In order to separate the signals from the crystalline and amorphous component respectively, use is frequently made of the very much shorter longitudinal relaxation time $T_1(^{13}C)$ of the amorphous regions.[52] In the case of direct ^{13}C-NMR signal generation using 90° pulses, short waiting times preferentially emphasize the signal originating from the amorphous regions (cf. Figs. 9a and 9b). The physical cause of the shorter $T_1^{am}(^{13}C)$ is the higher spectral density in the MHz range due to fluctuating fields on account of the higher molecular mobility. Since the transport of mag-

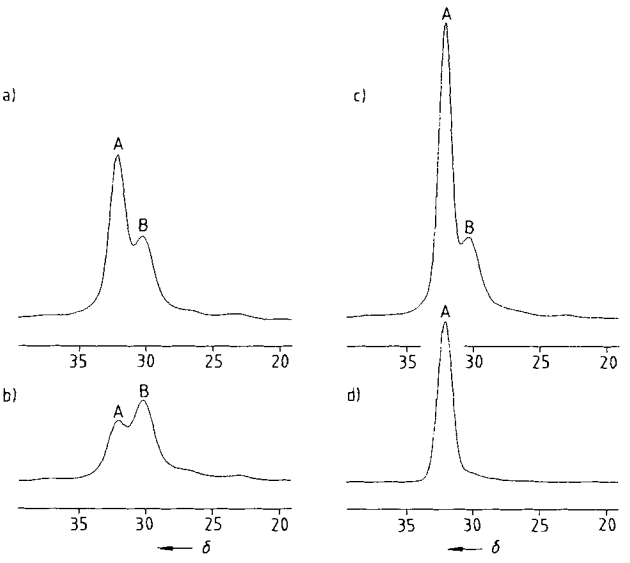

Fig. 9. Effect of conditions of measurement on the spectrum of polyethylene [56]. The conformational difference between the crystalline (all-*trans*) and the amorphous modification (*trans/gauche*) leads to the separated signals A and B ($\Delta\delta = 2.3$ ppm). a) 90° excitation, 800 s waiting time reproduces the correct intensities. b) 90° excitation, 4 s waiting time gives preference to the amorphous signal. c) CP contact (1 ms) gives preference to the crystalline signal. d) "Spin locking" of the protons (20 ms) before cross-polarization gives only the signal of the crystalline components. Scaling to the same amplitudes of B (a–c) and A (a, d).

netization through spin diffusion for ^{13}C nuclei at natural abundance is very slow as a result of the high degree of isotopic dilution, the $T_1^{am}(^{13}C)$ is determined by the high-frequency components of the local molecular dynamics: along the side chain of an ethylene-1-octene copolymer, the value of $T_1(^{13}C)$ rises on account of the increasing mobility.[53] Thus, in the stricter sense, $T_1(^{13}C)$ is not a phase property. Nevertheless, in appropriate systems a selectivity of the spectrum with respect to mobile (= amorphous) and rigid (= crystalline) components can be achieved as a result of the very much more rapid relaxation of the ^{13}C nuclei in the mobile component.

Whilst the mobile components are preferentially recorded in a rapidly repeated 90° pulse experiment, conversely in the case of polarization transfer from ^1H to ^{13}C with short contact times the signal of the crystalline component (cf. Figs. 9a and 9c) is maintained at an intensified level. The increased molecular mobility in the amorphous substance partially averages out the dipole-dipole interaction necessary for the transfer of magnetization from ^1H to ^{13}C, and leads to slower transfer rates $1/T_{CH}$ for the mobile (amorphous) components. Both in the case of selection via the more rapid longitudinal relaxation $T_1^{am}(^{13}C)$ of the mobile components and also in the case of selection of the rigid components via a short cross polarization contact (shorter T_{CH} in the rigid component), use is made of the molecular dynamics in order to make the distinction. The same applies to $T_{1\rho}(^{13}C)$, the relaxation time of the ^{13}C nuclei in the rotating coordinate system, which is likewise a quantity that is local at the molecular level and is determined by the dynamics in the median kHz range (cf. Section 5.2). Nevertheless, in rigid systems, $T_{1\rho}(^{13}C)$ is shortened by spin-spin processes, so that $T_{1\rho}^{am}(^{13}C) \gg T_{1\rho}^{cryst}(^{13}C)$ is applicable.[52a,54]

In cases where the association of rigid with crystalline and mobile with amorphous does not apply, the relaxation behavior of the protons must be used for selection. Spin diffusion between the protons leads to a volume averaging of the polarization state (cf. Section 4.4). Thus, for example, the question of the distribution of the ethyl branches over the two phases of semi-crystalline polyethylene was investigated by a $T_{1\rho}(^1H)$-NMR experiment[52a,56,57] preceding the cross-polarization as pre-contact delay[55] (Fig. 9d). Since ethyl side chains within the crystalline regions are certainly to be regarded as mobile, on account of their defect property in comparison with the crystallized main chain of the polyethylene, in this case a selection by means of the local molecular mobility, i.e. the relaxation of the ^{13}C nuclei, would lead to erroneous results.

4.3. Elastomer Components

The very much more rapid longitudinal relaxation of rubber components in a sample consisting of several components frequently permits the spectrum of the elastomer components to be selectively recorded without special preparation of the samples, by means of 90 degree ^{13}C pulses.

In order to achieve decoupling of the residual dipolar interaction between ^1H and ^{13}C, it is sufficient to provide a "low power decoupling" (LPD) similar to that employed in NMR of solutions, since the dipolar interaction is to a large extent averaged out just by the high molecular mobility and the sample rotation at the magic angle.[50]

In this way, investigations were carried out not only on the homopolymers[58] but also, for example, on a polypropylene grafted with butadiene, in order to determine quantitatively the proportion of grafts.[59] Even in the case of segmented copolymers consisting of poly(tetramethylene terephthalate) hard segments and poly(tetramethyleneoxy-terephthalate) soft segments

(Hytrel®)

only the soft phase is recorded at 90° ^{13}C excitation and low power decoupling.[60] The same applies to poly(acrylonitrile-butadiene-styrene) block copolymers (ABS), in which case the spectrum is selectively measured for the butadiene blocks, for which the glass transition temperature is far below room temperature.[61] In the case of polybutadiene, the resolution is so good that a sequence analysis of the microstructure is possible as far as triads. In the case of ABS, cross polarization and dipolar decoupling give, as a complement to the 90°-LPD measurement, the spectrum of the styrene-acrylonitrile blocks. In analogous terms, Figure 10 shows two spectra of a poly(styrene-butadiene-isoprene) block copolymer.

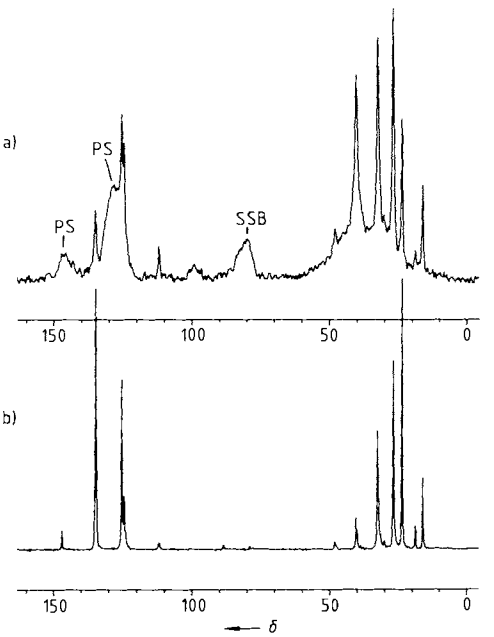

Fig. 10. Solid-state ^{13}C-NMR spectra of a poly(styrene-butadiene-isoprene) rubber. a) CP 2 ms gives the polystyrene signal PS (17%) (20000 recordings FIDs broadened by 30 Hz with exponential multiplication). b) Polyisoprene component, measured with 90°-τ-180°-τ-AQ, $\tau = 2.9$ ms (6000 recordings, waiting time 0.1 s, low power decoupling (LPD), inverse gating).

Figure 11 also follows the idea of the selective recording of the soft phase by a 90°-LPD experiment, in this case with the investigation of an unsaturated polyester resin (UP resin) which is toughened by rubber particles. The detection of a rubber in such a matrix, which is also frequently filled

with glass fibers, confronts other techniques with particular problems: the matrix is insoluble and double bonds are invariably present in a UP resin on account of incomplete conversion.

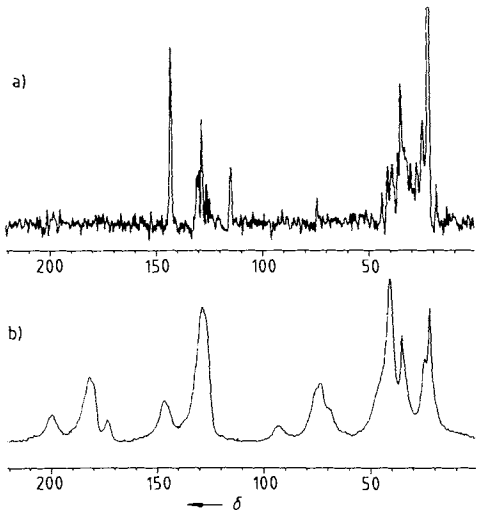

Fig. 11. Detection of 5% rubber (poly(styrene-butadiene) with 20% styrene) in a matrix consisting of unsaturated polyester (adipic acid/neopentyl glycol/maleic acid/styrene). a) Rubber signal (90000 recordings as in Fig. 10b, $\tau = 2.5$ ms, waiting time 0.5 s). Attention is drawn to the high 1,2 linkage content (signals at $\delta = 142.7$ an 114.6). Only CH_3 groups of the matrix ($\delta = 21.8$) are included in the recording. b) Matrix signals (CP 1 ms, 4000 recordings, dipolar (DD) decoupled with $\nu_{1H} = 50$ kHz).

MAS-NMR not only detects the rubber (in the present case 5% by weight), but also permits statements concerning the chemical structure of the rubber employed (a polybutadiene with a considerable proportion of 1,2 linkages).

If the proportions of the soft phase amount to a few percent only, rapid 90° excitation and low power decoupling are frequently not sufficient to suppress the matrix signal entirely. Accordingly, in the examples given (Figs. 10 and 11), use was additionally made of the fact that under the condition of weak decoupling the signals of the soft phase are very much narrower (longer T_2) than those of the hard phase: a 180° pulse of the ^{13}C nuclei within the longer free induction decay of the rubber component refocuses only the signals of the rubber, whereas the broad signals from the matrix are already irreversibly relaxed. Thus, even in the case of difficult samples, what is obtained is the rubber signal without the broad matrix and blank signal background (Fig. 11).

Rubbers are usually measured by direct 90° excitation of the ^{13}C nuclei, since cross polarization is based on dipole–dipole interaction and is therefore of low effectiveness, on account of the high molecular mobility. Nevertheless, cross polarization represents an alternative of interest even for pure elastomers: by variation of the mismatch of the Hartmann-Hahn condition ($\gamma_C \boldsymbol{B}_{1C} \neq \gamma_H \boldsymbol{B}_{1H}$) or alteration of the speed of rotation of the rotor, statements can be made on the degree of cross-linking of the rubber.[62]

4.4. Molecular Neighborhood: Blends

While the ^{13}C relaxation times $T_1(^{13}C)$, $T_{1\rho}(^{13}C)$ and T_{CH} are quantities which are individual to each position in the molecule, in the $T_{1\rho}$ of the *protons* there is a volume property averaged over a distance of approximately 2 nm.[63] The cause of this spatial averaging of $T_{1\rho}(^1H)$ is the small mean distance between the ^1H nuclei, since ^1H is an abundant nucleus, in contrast to the "rare" nucleus ^{13}C. As a result of the spatial closeness of the protons to one another, an exchange of spin energy of the individual protons within the transverse relaxation time $T_2(^1H)$ takes place, i.e. in rigid systems within less than 0.1 ms.

The residual ^1H magnetization at the end of the spin-lock time in the $T_{1\rho}(^1H)$-NMR experiment is not measured directly. Instead, a polarization transfer $^1H \rightarrow {}^{13}C$ is undertaken and the ^1H magnetization is detected indirectly via the ^{13}C-NMR signal (Fig. 12).

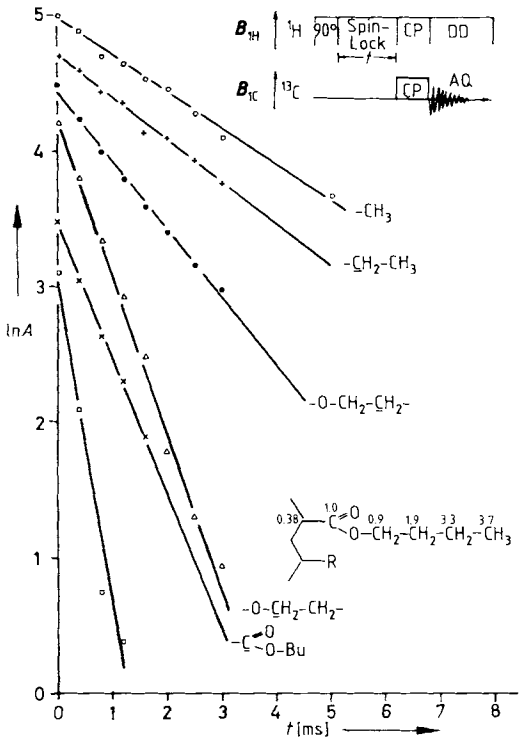

Fig. 12. Indirect measurement of $T_{1\rho}(^1H)$ of the protons of solid polybutyl acrylate via the ^{13}C-NMR spectrum (298 K). The proton magnetization is "locked" after 90° excitation for a variable time t in the radio-frequency field, and the remaining magnetization is detected by cross polarization with a fixed contact time. At room temperature, the T_2 of the protons is too long to produce a common $T_{1\rho}(^1H)$ by spin diffusion; individual values of $T_{1\rho}(^1H)$ [ms] in the formula (10240 recordings in each instance, CP 1 ms, ordinates arbitrarily shifted, $\nu_C = 3000$ Hz, $\nu_{1H} = 50$ kHz, D_2(contact time, already given as CP 1 ms) = 1 ms). □ measured values for skeleton C atoms.

This process appears at first sight to be awkward and of little advantage, since the experiment becomes more complicated on account of the indirect detection of the ^1H magnetization. Moreover, there is a loss by a factor exceeding 1000 in the signal-to-noise ratio. However, the benefit of the indirect detection of the $T_{1\rho}$ of the protons via ^{13}C resides in that this process combines the high resolution of the MAS-^{13}C-NMR spectrum with a volume property, namely $T_{1\rho}(^1H)$. In view of the fact that the remaining ^1H magnetization is detected at the end of a specified ^1H spin-lock time via the signal amplitude of a ^{13}C-NMR signal, which is to be correlated with a quite specific

chemical structure, the $T_{1\rho}(^1H)$ can be interrogated in the environment of this structure.[64] If, for example, a blend of two polymers A and B is present, which differ in their solid-state ^{13}C-NMR spectra, the $T_{1\rho}(^1H)$ can be separately determined in the environment of molecules of type A and B respectively by evaluation of the signals from A and B respectively. If there is molecular miscibility of A with B in the sense of a spacing of less than 2 nm, what is expected is a common $T_{1\rho}^{AB}(^1H)$, or otherwise, depending upon the $T_{1\rho}(^1H)$ of the homopolymers, two separate $T_{1\rho}^{A}(^1H)$ and $T_{1\rho}^{B}(^1H)$ values. This process was employed in the first instance with blends of polystyrene and polyphenylene oxide[65] and later with polystyrene/polyvinyl methyl ether[66] and polyvinylidene fluoride/polymethyl methacrylate.[67]

Two different measurement processes are possible for the measurement of $T_{1\rho}(^1H)$ via ^{13}C.[55,65b] The more frequently employed pulse program varies the length of the CP contact and determines the $T_{1\rho}(^1H)$ from the ^{13}C-NMR signal amplitudes for long contact times[65b] (cf. Fig. 5). The advantage is that it is possible to determine the magnetization transfer rate $1/T_{CH}$ with short contact times by the same measurement program. However, the evaluation presupposes $T_{CH} < T_{1\rho}(^{13}C) \ll T_{1\rho}(^1H)$ and moreover the beginning of the $T_{1\rho}(^1H)$ curve is absent. During the spin lock time the ^1H and the ^{13}C nuclei are irradiated simultaneously, so that the sample head has to cope with a relatively high power. As an alternative to the $T_{1\rho}(^1H)$ measurement via variable length of the contact time, it is possible in the first instance to carry out the ^1H spin-lock experiment, and only at the end of the ^1H spin-lock time to cross-polarize with a fixed contact time as usual.[55] The latter process (Fig. 12) was used, which avoids the disadvantages mentioned above and is more reliable in terms of evaluation. Last but not least this procedure permits the selective recording of a specified phase by means of a suitable contact time in the case of heterogeneous systems.

A system which is of interest for such investigations with regard to molecular miscibility comprises dispersions, made into films, obtained by emulsion copolymerization. This may be, for example, a butyl acrylate/acrylic acid copolymer, which was produced by emulsion polymerization. Such films from emulsions are spatially heterogeneous with one phase predominantly containing the hydrophobic building block (in this case the butyl acrylate), and other regions which principally consist of a polymer of the hydrophilic monomer (in this case, acrylic acid). The question of how sharp the separation is, i.e. to what extent, for example, the acrylic acid is also present in the phase rich in butyl acrylate, can be investigated by such $T_{1\rho}(^1H)$ measurements. What is important is to select the correct temperature for the measurement: in the case of elastomers such as, for example, polybutyl acrylate ($T_G = -46\,^\circ C$), at room temperature the proton line width under MAS conditions amounts to only approximately 150 Hz. The proton-proton dipolar interaction is averaged out by the molecular mobility to such an extent that an individual $T_{1\rho}(^1H)$ is measured for the protons at each position in the butyl radical of the polybutyl acrylate homopolymer (see values [ms] quoted in the structural formula in Fig. 12). As is expected, the ^1H line width increases rapidly with decreasing measurement temperature. At $-25\,^\circ C$ it reaches approximately 13 kHz, and thus leads to a common $T_{1\rho}(^1H)$ (Fig. 13). When acrylic acid is incorporated as co-

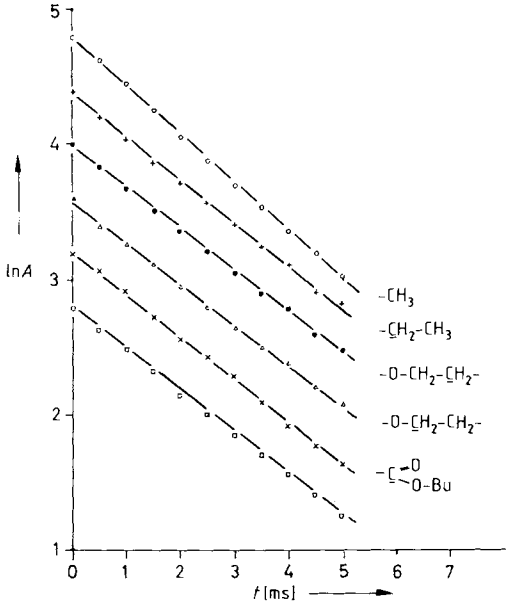

Fig. 13. $T_{1\rho}(^1H)$ via ^{13}C in a dispersion made into a film (emulsion copolymer consisting of 85% butyl acrylate (BA) and 15% acrylic acid (AA)). At 248 K, spin diffusion leads to a unitary $T_{1\rho}(^1H)$ for all protons (768 recordings in each instance, otherwise conditions as in Fig. 12). □ measured values for skeleton C atoms.

monomer into the phase rich in polybutyl acrylate, the glass transition temperature should rise in comparison with the homopolymer consisting of polybutyl acrylate. This is why a temperature of $-25\,^\circ C$ satisfies the requirements with regard to adequate spin diffusion for the copolymer as well. Therefore $T_{1\rho}(^1H)$ is a volume property. The evaluation of the signal amplitudes as a function of the proton spin lock time is, in fact, purely exponential and gives a unitary $T_{1\rho}(^1H)$ for all signals. This $T_{1\rho}(^1H)$ is between the values for the homopolymers polybutyl acrylate and polyacrylic acid respectively, and shows that acrylic acid and butyl acrylate in the phase rich in butyl acrylate are present alongside one another at a spacing of less than 10 Å (Fig. 14).

On the other hand, a non-exponential decline of the signal amplitude in the $T_{1\rho}(^1H)$-NMR experiment cannot be taken as unambiguous evidence leading to the opposite conclusion as to a multiphase system.[68]

In addition to the $T_{1\rho}(^1H)$ measurement via ^{13}C, there are certain other CP/MAS NMR techniques for detecting molecular adjacency. These include the intermolecular magnetization transfer from a molecule containing ^1H to a deuterium-containing polymer. However, this presupposes the availability of a corresponding deuterium-containing polymer, and is accordingly a process which is not suitable for the investigation of commercial products. But it can certainly answer questions concerning the fundamental understanding of, for example, the functioning of block copolymers as compatibility promotors in blends. Thus, the formation of a mixture of the styrene block from a

poly(styrene-butadiene) block copolymer with the surrounding styrene matrix was demonstrated,[69] but also block copolymers of polyether/polyester segments[70] and the miscibility of polystyrene with polymethyl methacrylate or polyvinyl methyl ether[71] were investigated. Furthermore, the compatibility of low-molecular-weight additives with the polymer matrix and selective interactions of these additives with functional groups of the polymer are detectable by intermolecular cross polarization, as has been demonstrated for a photoconductive compound in a polycarbonate matrix[72] and a plasticizer in PMMA.[70]

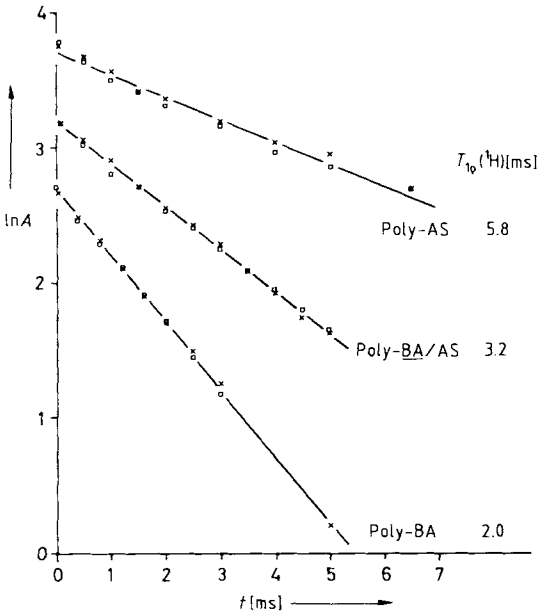

Fig. 14. $T_{1\rho}(^1H)$ via ^{13}C of polyacrylates for the detection of molecular adjacency. The emulsion copolymer, made into a film, consisting of BA/AA (85/15% by weight) shows a $T_{1\rho}(^1H)$ between the corresponding values for the homopolymers (P-BA/AA: 3.2 ms, P-BA: 2.0 ms, P-AA: 5.8 ms). The phase rich in butyl acrylate contains polymerized acrylic acid at the molecular level (presumably as comonomer) (conditions of measurement as in Fig. 13). × –COO–, □ skeleton C atoms.

Instead of using the $1/r^3$ dependence of the C–H dipolar interaction upon the C–H spacing r for the detection of adjacency by intermolecular cross polarization, it is possible to use the dipolar interaction with a nucleus, e.g. ^{19}F, which, in contrast to ^1H, is not decoupled, in order to demonstrate adjacency: this is true of suitable systems, as has been proved for a number of polyvinylidene(PVF_2) blends. In the event of miscibility, the adjacency of ^{19}F nuclei broadens the ^{13}C-NMR signal of the admixed components at ^{13}C–^{19}F spacings of ca. 0.1 nm, in such a manner that the ^{13}C nuclei adjacent to the ^{19}F nuclei are no longer recorded in the MAS-NMR experiment and a reduction of the signal intensities results, as has been shown for PVF_2/PMMA and other PVF_2 blends.[67a,73]

Finally, in order to demonstrate adjacency, it is possible to use the homonuclear dipole–dipole interaction and to measure directly the residual protons in an (almost) deuterated matrix. If a ^1H-containing polymer is admixed, only isolated ^1H nuclei are measured as sharp lines, and their intensity evaluated.[74] Whilst here, as a result of the deuteration, ^1H becomes the "rare" nucleus, ^{13}C can conversely also be abundant, as a result of ^{13}C enrichment, so that intermolecular spin diffusion from the ^{13}C-labeled molecule (e.g. a plasticizer) to the unlabeled neighbor (the polymer) becomes possible.[75] If both components are ^{13}C-labeled, as in the case of a polyethylene terephthalate/polycarbonate mixture,[76] it is finally possible for spin diffusion between the ^{13}C nuclei to be used for the investigation of blends in the same way as in the case of ^1H multipulse MAS-NMR experiments.[77]

5. Molecular Dynamics

Relaxation time measurements under CP/MAS conditions give individual ^{13}C-relaxation times for the positions in the molecule which are resolved in the spectrum.[64] This gives rise to the hope that it will be possible to investigate the molecular dynamics of the pertinent group in this way.

5.1. Longitudinal Relaxation Time $T_1(^{13}C)$

Measurements[78] of the longitudinal relaxation time $T_1(^{13}C)$ are used to detect motions with a spectral density in the region of the Larmor frequency, i.e. in the MHz range. In the case of polymers in the glassy state, by reason of this high frequency, it is frequently a methyl group which determines the relaxation behavior, in the event that such a group is present: the dipole field which is generated by the protons of the rapidly rotating methyl group contributes most strongly to the fluctuations in the range of high frequencies at the location of the neighboring ^{13}C nuclei, although the effectiveness of the dipole field for the relaxation decreases strongly with the distance r ($\sim 1/r^6$). In polymethyl methacrylate, the α-CH_3 group, for which room temperature is above the T_1 minimum,[79a] determines the T_1 behavior of the polymer chain as well.[79b] The mobility of the polymer chain does not contribute to the spectral density in the MHz range, so that, even when the glass point is exceeded, the effects on the T_1 value of the carbon atoms in the chain are small.[79c] For the same reason, plasticizer effects in the case of PMMA[79b] are not detectable via $T_1(^{13}C)$, in contrast to polycarbonate.[80] However, in the case of PMMA,[81a] just as in the case of polyethylene oxide,[81b] T_1 can be employed for the selective recording of the amorphous component (see Section 4.2).

When elastomers are analyzed, individual $T_1(^{13}C)$ relaxation times can also be measured using a stationary sample. The position of the $T_1(^{13}C)$ minimum in the case of a stationary measurement but with variable temperature is dependent upon the content of 1,2 linkages, in the case of polybutadiene. If it is borne in mind that the T_1 minimum occurs at correlation times which correspond to the Larmor frequency, then good agreement is found between the temperature of the T_1 minimum and the glass point of the samples.[82] Stationary investigations were likewise carried out above the glass point on polyterephthalic acid esters and polysuccinic acid esters respectively.[83]

5.2. Relaxation in the Rotating Coordinate System, $T_{1\rho}(^{13}C)$

A matter of particular interest for the investigation of polymers is the relaxation time in the rotating coordinate system, $T_{1\rho}(^{13}C)$[64] (Fig. 15). The amplitude of the radio-

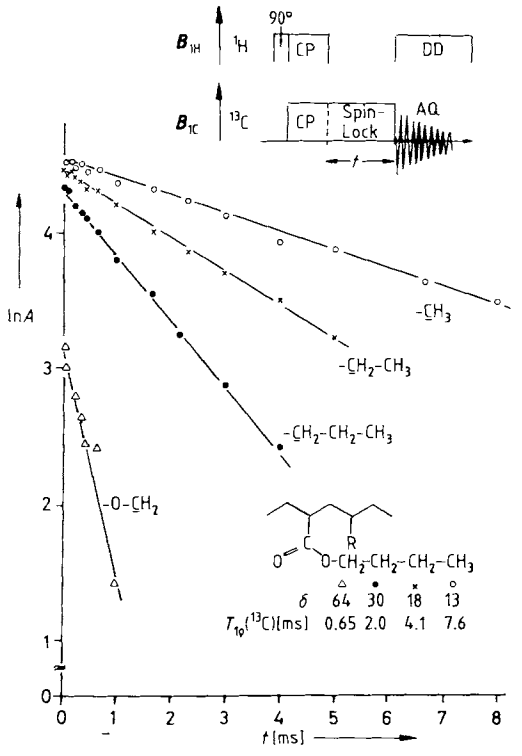

Fig. 15. $T_{1\rho}^{*}(^{13}C)$ of polybutyl acrylate at 283 K. The usual generation of the signal via a CP contact is followed by a "spin locking" of the ^{13}C nuclei for a variable time t. The plot of the signal amplitudes as a function of t gives, as a reciprocal of the gradients of the straight lines, individual relaxation times $T_{1\rho}(^{13}C)$ for the various positions in the molecule (768 recordings in each instance, CP 0.75 ms, $\nu_r = 3000$ Hz, $\nu_{1C} = 25$ kHz.

frequency field which is applied during the relaxation and which is parallel to the magnetization determines the frequency $\nu_{1C} = \omega_{1C}/(2\pi)$ of the spins within the rotating coordinate system. Molecular motions having a spectral component at this frequency are of crucial importance for the relaxation. In the case of the conventional radio-frequency field strengths, this is 25 kHz–75 kHz. Now, the median kHz range is of particular interest in the case of polymers, since the mechanical properties are also governed by the molecular dynamics in this frequency range.

The interpretation of $T_{1\rho}(^{13}C)$ data, however, is complicated by the fact that the relaxation in the rotating coordinate system is caused by the fluctuating dipole fields of the protons.

This fluctuation can arise on account of changes of the C–H bond vector $\boldsymbol{r}$, e.g. a change of direction in the case of the rotational diffusion of a methine group. This phenomenon (i.e. the change of $\boldsymbol{r}$) is referred to as spin-lattice relaxation, and it is possible to draw conclusions as to the molecular dynamics from $T_{1\rho}(^{13}C)$. However, the measured $T_{1\rho}^{*}(^{13}C)$ [Eq. (e)] consists of two possible components, the spin-lattice $T_{1\rho}(^{13}C)$ just mentioned and a possible spin-spin contribution T_{CH}^{D}.[14b,28,54,64]

$$\frac{1}{T_{1\rho}^{*}(^{13}C)} = \frac{1}{T_{1\rho}(^{13}C)} + \frac{1}{T_{CH}^{D}} \qquad \text{(e)}$$

It is indeed possible for fluctuating dipole fields to be generated not only by molecular dynamics but also by a change of the spin state of the proton adjacent to the ^{13}C nucleus. In this case, the dipole field at the location of the ^{13}C nucleus changes, without a change of the space coordinates of the molecule being associated with this. Thus, relaxation due to such spin-spin processes does not give any information on the molecular dynamics. Before measured $T_{1\rho}^{*}(^{13}C)$ values can be interpreted in terms of molecular dynamics, it must be certain that the spin-spin relaxation time $T_{CH}^{D} \gg T_{1\rho}(^{13}C)$, i.e. the spin-lattice relaxation $T_{1\rho}(^{13}C)$ determines the measured $T_{1\rho}^{*}$.[84a] T_{CH}^{D} can be measured separately.[28,84b] It becomes evident that the condition $T_{CH}^{D} \gg T_{1\rho}(^{13}C)$ in the case of amorphous polymers is also satisfied in the glassy state, as is the case for plastic crystals at room temperature. In amorphous polymers, the measured $T_{1\rho}^{*}(^{13}C)$ is predominantly ($\approx 80\%$) determined by spin-lattice processes, and may thus be interpreted in terms of molecular dynamics.[54b] Polystyrene, polymethyl methacrylate and polyphenylene oxide, as well as polyethylene terephthalate and polycarbonate, may serve as examples.[28,54b,64,84b] However, when rigid polymers with strongly coupled protons are analyzed, and particularly when crystalline samples are used, spin-spin relaxation is predominant, as for example in the case of polyethylene[54a] and polyoxymethylene.[28] Besides the homopolymers, investigations were also carried out on poly(ether-ester) block copolymers[85] and anti-plasticizer effects on polycarbonate.[86] Measurements on polypropylene with variable measurement temperatures[87] do indeed indicate spin-lattice processes determining the relaxation at a low temperature, in which connection, however, the movement of the CH_3 groups contributes to relaxation. For this reason, statements concerning the dynamics of the main chain were not possible. Relaxation due to the rotation of the CH_3 groups is likewise found in PMMA.[88] Furthermore, a cured epoxy resin was investigated over a broad temperature range, and the relaxation was at least predominantly ascribed to spin-lattice processes.[89] Apparently a very broad correlation time distribution is present, since $T_{1\rho}(^{13}C)$ hardly varied at all with the temperature.

Figure 16 shows an example with a marked $T_{1\rho}(^{13}C)$ minimum, as is expected for spin-lattice-determined $T_{1\rho}(^{13}C)$. On account of the measurement frequency of 25 kHz, the minimum is situated approximately 30 K above the glass point ($T_G = -46\,^{\circ}C$). In the case of copolymerization of the butyl acrylate with acrylic acid, the position of the minimum is shifted by approximately 10 K (Fig. 17); a value of 9 K was measured by differential scanning calorimetry.

With an adequate radio-frequency field strength a clear dominance on the part of spin-lattice processes can be expected, particularly in the vicinity of the $T_{1\rho}^{*}$ minimum. This dominance also extends into the temperature range above the minimum provided that the rotational diffusion is not excessively anisotropic.[54a] This likewise applies below the minimum, at least for the quaternary carbons which are less strongly coupled to ^1H and for methyl

groups, both of which show an appropriately marked $T^*_{1\rho}(^{13}C)$ minimum (Fig. 16). At the minimum, the correlation time τ of the motion causing the minimum can be inferred from $\omega_{1C}\tau = 1$. The depth of the minimum is determined by the magnitude of the second moment, modulated by the variation of the C–H dipolar interaction.[14b, 54a] Accordingly, the expectation for all CH_2 groups is the same $[T^*_{1\rho}(^{13}C)]_{min}$ and that for quaternary C is a longer $[T^*_{1\rho}(^{13}C)]_{min}$, as, in fact, is verified (Fig. 16). The large

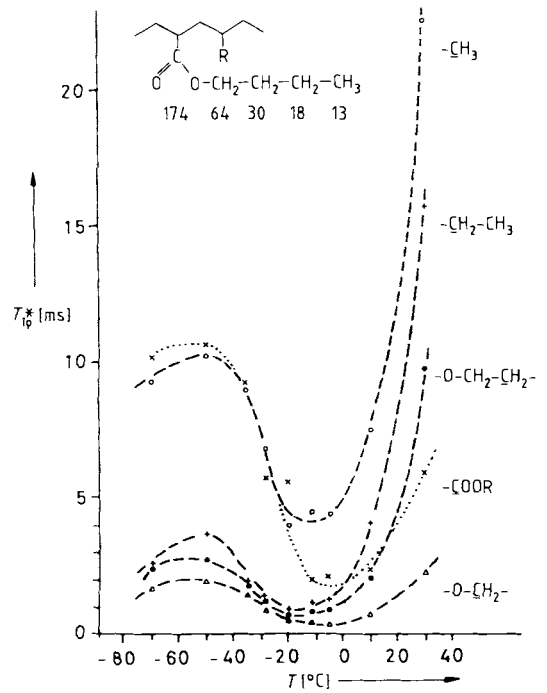

Fig. 16. $T^*_{1\rho}(^{13}C)$ of polybutyl acrylate as a function of temperature. At the minimum, the correlation time $\tau = 1/(2\pi\nu_{1C})$ of the motion ($\tau = 6.4$ µs) is obtained from the "spin lock" frequency ν_{1C}. As a result of the frequency of $\nu_{1C} = 25$ kHz, the position of the minimum is shifted by approximately 30 K above the glass-transition temperature. $\nu_r = 3000$ Hz.

long $T^*_{1\rho}(^{13}C)$ of the CH_3 groups at the minimum is due to the rotation which is still present about the ternary axis, and corresponds to the finding that the cross-polarization behavior of CH_3 groups is also rather similar to that of CH groups (cf. Fig. 5 and the $1/T_{CH}$ value in Table 1).

In the copolymer of butyl acrylate with 10% by weight of acrylic acid, all butyl positions have a minimum of the same depth as in the homopolymer. On the other hand, the position of the minimum is shifted by 10 K towards a higher temperature. An exception with regard to the magnitude of $[T^*_{1\rho}(^{13}C)]_{min}$ is the C nucleus of the carboxy group, whose $[T^*_{1\rho}(^{13}C)]_{min}$ rises from approximately 2 ms (homopolymer) to 3.2 ms in the copolymer (Fig. 17). A broader distribution of the correlation times can be ruled out as a possible reason, since the shape of the $T^*_{1\rho}(^{13}C)$/temperature curve is, in the case of the copolymer, the same as in the case of the homopolymer. There remains a greater anisotropy of the motion as a possible cause, presumably on account of hydrogen bonds between the ester and acid radicals.

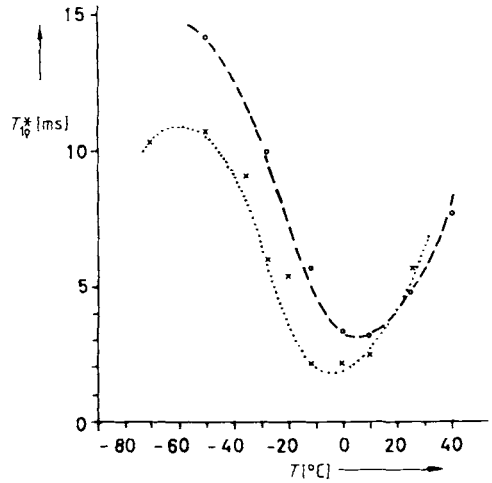

Fig. 17. $T^*_{1\rho}(^{13}C)$ of the BA-carboxy group of the BA-homopolymer (×) and of a copolymer (○) consisting of BA/AA (85/15% by weight). In the copolymer, the position of the minimum is shifted by approximately 10 K, corresponding to the rise in the glass transition temperature. The greater $T^*_{1\rho}(^{13}C)$ at the minimum in the case of the copolymer is presumably due to a higher degree of anisotropy of the carboxy group motion due to hydrogen bonds.

5.3. Transverse Relaxation $T_2(^{13}C)$

The transverse relaxation rate $[T_2(^{13}C)]^{-1}$ is affected by the spectral density at the frequency ω_{1H} of the protons in the rotating coordinate system under the influence of the decoupling field. If no other effects determine the line width $\Delta\nu_C$ of the ^{13}C-NMR signal, then $\Delta\nu_C \sim 1/T_2(^{13}C)$ is applicable, and $\Delta\nu_C$ passes through a maximum when the stochastic dynamics possesses the same frequency as the coherent decoupling. In the event of equality of frequency, the latter becomes inefficient.[23] In CP/MAS-NMR spectroscopy, the Hartmann-Hahn condition[4a] $\omega_{1C} = \omega_{1H}$ is usually satisfied for the purpose of cross polarization, and the angular frequency in the radio-frequency field is equal for ^1H and ^{13}C (Section 2.2). In the $T_{1\rho}(^{13}C)$-NMR experiment, the spectral density is detected at ω_{1C} (cf. Section 5.2). $T_2(^{13}C)$ (or the line width $\Delta\nu_C$ of the ^{13}C-NMR signal) is determined by the spectral density at ω_{1H}. Thus, for $\omega_{1C} = \omega_{1H}$ in CP/MAS-NMR experiments, both $T_{1\rho}(^{13}C)$ and also $T_2(^{13}C)$ are affected by the same spectral density.[20] Accordingly, the line width of the ^{13}C-NMR signal should pass through a maximum at the $T_{1\rho}(^{13}C)$ minimum, if the molecular dynamics determine the two quantities. This is in fact the case for polybutyl acrylate (compare Fig. 16 with Fig. 4).

As the measurement of relaxation times only permits statements on the spectral density at the measurement frequency no information on the geometry of the movement can be obtained for isotropic samples. If, for example, we add a plasticizer to polystyrene,[90] no distinction can be made as to whether the reduction of the $T_{1\rho}(^{13}C)$ is based on a change in the frequency of the motion or its amplitude. Only processes which utilize the anisotropy of a magnetic interaction permit statements on the geometry of the motion. They include the two-dimensional methods[10] of the "dipolar rotational spin-echo"[91] and of the "chemical exchange"[92] under MAS conditions. The "dipolar rotational spin-echo" experiment is based on the dipolar inter-

action of a C–H pair, in which connection the homonuclear interaction of the protons with one another must be suppressed by multiple-pulse sequences. Investigations were carried out principally on polycarbonate[91b] and polystyrene.[91c] The selectivity with respect to a specified position in the molecule is achieved, in the case of the "dipolar rotational spin-echo", by MAS-NMR spectroscopy via the chemical shift. In contrast to this, for the evaluation of powder spectra of stationary samples[93] it is necessary to have ^{13}C-labeled substances, i.e. the selectivity is obtained by a preparative route, as in the case of deuteron-NMR spectroscopy.

In two-dimensional exchange spectroscopy[92] information on jump angles and correlation times is obtained from the anisotropy of the chemical shift. The possibilities offered by this process regarding the investigation of slow motions[10] with correlation times τ_c in the range $T_1 > \tau_c > 1$ ms have been demonstrated with reference to the example of polyoxymethylene.[92b]

6. Summary and Outlook

The recording of solid-state ^{13}C-CP/MAS-NMR spectra is now no longer a problem; however, when measurement at variable temperature is concerned, this statement is only partly true. If we have sufficient prior knowledge of the sample, the chemical structures in the compounds which exhibit low solubility or are insoluble are accessible by means of this technique. When dealing with partially crystalline samples, familiarity with the particular solid-state effects on the spectrum is required. Where soluble compounds are concerned and where chemical analysis only is involved, recourse will also be had in future to NMR spectroscopy in solution, since the line widths achievable in solution are smaller by more than an order of magnitude.

Quite apart from the analytical application in the case of insoluble samples, the strength of solid-state CP/MAS NMR spectroscopy becomes clear in two areas: it becomes evident in the techniques for correlating chemical shifts (= chemical structure) with the relaxation behavior (= dynamics, adjacency). By this means, it is possible to make very detailed statements on the dynamics of individual positions in the molecule. A second strength resides in the possible selectivity which in the case of heterogeneous samples can be achieved by utilizing the relaxation behavior. Simply by selecting the measurement conditions, i.e. without sample preparation, it is possible to investigate selectively the chemical structure, molecular dynamics and possibly the orientation of a specified component of the sample. It is precisely this selectivity which is of great advantage in connection with the frequently very complex composition of industrial products.

By way of analogy with NMR spectroscopy in solution, future development gives rise to the expectation of a diversification from ^{13}C nuclei to other nuclei; even at the present time, ^{29}Si is playing an important part in certain areas of research, and there is increasing interest in ^{15}N. In specific cases outside the field of pure analysis, solid-state ^{1}H-NMR spectra could also be used to an increasing extent. Both the recording of ^{15}N-NMR spectra and also increasing utilization of variable temperature measurements, relaxation time measurements and a greater range of 2-D NMR experiments in the solid state will result in an increasing measurement time requirement for solid-state NMR spectroscopy.

Two-dimensional solid-state NMR spectroscopy[10] is still at the start of its development. In this instance, additional information is to be expected in the future concerning molecular structure, e.g. bond lengths, concerning molecular dynamics, such as the nature and time scale of motions, and concerning molecular order.

Phosphaalkynes—Syntheses, Reactions, Coordination Behavior**

New Synthetic Methods (73)

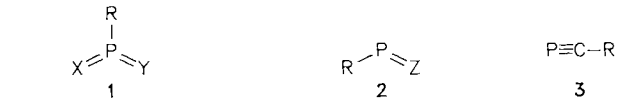
By Manfred Regitz* and Paul Binger

Organophosphorus compounds have been applied in two ways in chemical synthesis. They can either be used as a reagent in a step of the synthesis (for example, in the Wittig reaction) or they can be incorporated directly into the target molecule. This second application, in particular, has expanded greatly in the last few years with the preparation of low-coordination phosphorus compounds. These include the phosphaalkynes, which are of great interest to organic and inorganic chemists. Phosphaalkynes have been employed in the synthesis of heterocyclic compounds, phosphaarenes and their valence isomers, and polycyclic compounds. Further applications have been the use of phosphaalkynes as new ligand systems in complex chemistry and their cyclooligomerization with organometallic reagents. While the chemical properties of phosphaalkynes have little in common with those of nitriles, they are in many ways very similar to those of the isoelectronic acetylenes.

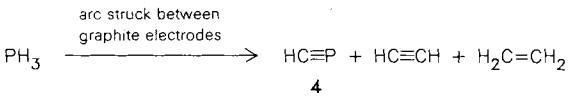
1. Introduction

Whoever believed that the development of organophosphorus chemistry was temporarily coming to a close with the synthesis of classical compounds, such as derivatives of phosphoric acid in the widest sense or phosphane oxides, has had to reconsider that opinion. The barrier presented by the double bond rule[1]—generally valid until the 1960s—which states that stable (p-p) π multiple bonds should not be formed between, for example, phosphorus and elements of the first period, can now be regarded as finally breached. The synthesis of the first compounds of trivalent phosphorus containing PC double bonds, such as the phosphamethinecyanine cations[2] and the phosphabenzenes (λ^3-phosphinines)[3], paved the way for the comprehensive chemistry of low-coordinate phosphorus compounds that we know today.[4]

In the last fifteen years it has proved possible to produce and trap derivatives of five-valent tricoordinate phosphorus (**1**)[5] and also to stabilize them sufficiently by the incorporation of bulky groups to be able to isolate them.[6] Milestones in this development are compounds with $\lambda^3\sigma^2$ phosphorus (**2**),[7] which in the case of $Z = CR_2$ (phosphaalkenes) are also to be regarded as forming a bridge to organic chemistry.



Finally, at the beginning of this decade, the first stable phosphaalkynes (alkylidynephosphanes) **3** were isolated.[8,9] These compounds, which were soon recognized as valuable materials for synthesis, are the central theme of this review. Interestingly, the parent compound of this series, phosphaacetylene **4**, was prepared as long ago as 1961 by *Gier*[10] from phosphane in a rotating arc struck between graphite electrodes; the product was quenched in a cold trap, purified by rapid gas chromatography, and finally characterized by IR spectroscopy.



Naturally, attempts have also been made to prepare and isolate phosphaalkynes with $\lambda^5\sigma^3$ phosphorus (**6a**). Such compounds can also be described as ylids **6b** and they can even be regarded as phosphinocarbenes **6c**. They are apparently only short-lived and have not been isolated. An ab initio study has demonstrated the importance of the contribution of the zwitterionic canonical structure **6b**.[11] This structure also provides the best explanation for the known trapping reactions. *Appel* et al.[12] have postulated that a species of type **6** is an intermediate in the conversion of methylenephosphoranes to methylenephosphanes.

[**] Phosphorus Compounds with Unusual Coordination, Part 30. Part 29: [119].

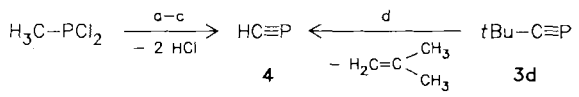
The photolytic or thermal elimination of N_2 from phosphinodiazoalkanes **5**[13,14] results in the formation of short-lived intermediates which can be trapped[15] by 1,2 addition by, for example, chlorotrimethylsilane (→ **7**)[13] or dimethylamine (→ **8**).[13] A further indication of the zwitterionic character of **6** is found in the dimerization of **5** to give $1\lambda^5,3\lambda^5$-diphosphete derivatives **9**,[14,16] which is not accompanied by any of the olefin formation that is characteristic of carbenes. If the residue R in **6** is a phosphoryl group, a P→P oxygen shift takes place before the dimerization to **9** occurs.[14] The O-shift has also been found in other phosphinocarbenes with PO or CO groups.[17]

2. Synthesis

β-Elimination is the method of choice for preparing phosphaalkynes.[18] In the case of the rather unstable phosphaacetylene **4** and simple substituted phosphaalkynes, only flash pyrolysis is successful.

2.1. Short-Lived Phosphaalkynes

Nowadays the historical procedure of *Gier*[10] to prepare HC≡P **4** has been superseded by flash pyrolysis of dichloro(methyl)phosphane at 900–1100°C. The hydrogen chloride produced at the same time has to be removed by basic adsorption materials[19–22] because it interferes with trapping reactions and also reverses the process of formation. Although the latter problem does not arise when **4** is prepared by the elimination of isobutylene from **3d**,[22] this advantage is outweighed by the low yield (ca. 10% conversion to **3d**, as opposed to ca. 30% from $MePCl_2$) and by the effort required to synthesize **3d**.

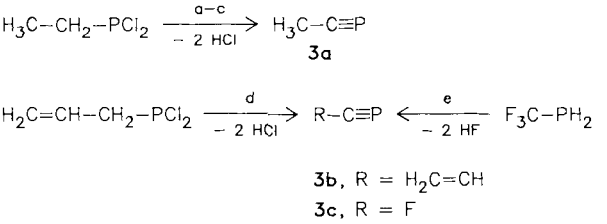


a) 1000°C/0.02 torr, KOH at −78°C [19]. b) 900°C/10^{-3} torr, 1,3,5-tricyclohexyl(hexahydro)-*s*-triazine at 20°C [21]. c) 1100°C/4×10^{-5} torr, KOH/K_2CO_3 at −78°C [22]. d) 950°C/5×10^{-4} mbar.

Phosphaacetylene **4** can be stored as a colorless solid at < −124°C; above this temperature it "polymerizes". The monomer and fresh "polymer" are pyrophoric in air.[10] An NMR sample dissolved in toluene is unchanged after two weeks at −70°C. When the sample is warmed up, one of the products is white phosphorus.[22] Under reduced pressure **4** can even be kept at room temperature.[23] It has been shown that HC≡P is also found in space.[24,25] The physical properties of phosphaacetylene **4** have been investigated thoroughly. Selected physical data for **4** are collected in Table 1.

HC≡N has a much smaller carbon-heteroatom bond length (1.155 Å) than **4**. On the other hand, it has a much larger dipole moment ($\mu = 2.957$ D),[29] which is oriented in the opposite direction to that of HC≡P because of the different charge distribution.[30] The ionization potential of phosphaacetylene is lower than that of hydrogen cyanide but its π/n separation is much larger.[31]

In analogy to **4**, 1-phospha-1-propyne (ethylidynephosphane, **3a**) is obtained from dichloroethylphosphane.[21,32,33] The phosphaalkyne can be separated from the HCl gas either by trapping the former in a cold trap or by reacting the latter with a base.[21,33] If it is intended to use the phosphaalkyne in a synthesis, it is best to add triethylamine directly to the pyrolysis mixture and to filter off the ammonium salt formed with a G1 frit.[33] Some physical data for **3a** are given in Table 1.



a) 900°C/0.03 torr, **3a** is trapped in a cold trap at −120°C [32]. b) 750°C/10^{-3} torr, 1,3,5-tricyclohexyl(hexahydro)-*s*-triazine at 20°C [21]. c) 500–700°C (temperature gradient in the oven)/10^{-4} torr, triethylamine [33]. d) 1000°C/0.03–0.06 torr [35]. e) 0.03 torr, KOH [39, 40].

Vinylphosphaacetylene (2-propenylidynephosphane), **3b** has been produced by an analogous HCl elimination and characterized by microwave spectroscopy.[35,37,38]

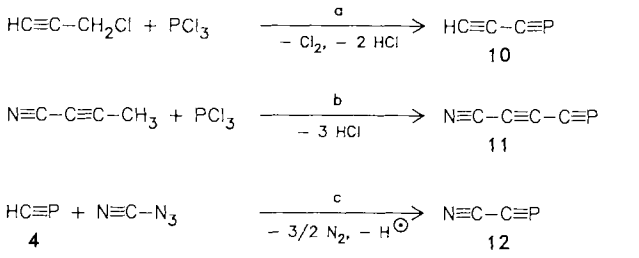
In contrast to the previous cases, the elimination of hydrogen fluoride from trifluoromethylphosphane initiated by potassium hydroxide (here the groups to be eliminated have the opposite orientation to the examples already discussed) proceeds even at room temperature. It has been proved that 2,2-difluoro-1-phosphaethene is an intermediate, which, on longer contact with the base, is completely converted into **3c**.[39,40] The product was identified by photoelectron spectroscopy (the first three ionization potentials are 10.57, 13.55, and 17.63 eV)[39] as well as by IR (CP stretch, 1671 cm^{-1})[41,42] and microwave spectroscopy.[43]

Table 1. Some physical properties of HC≡P **4** and Me–C≡P **3a**.

	HC≡P	Ref.	Me–C≡P	Ref.
CP-bond length	1.5421(5) Å	[26]	1.5438(4) Å	[34]
dipole moment	0.39 D	[26]	1.499 D	[34]
1st ionization potential (π MO)	10.79 eV	[27]	9.89 eV	[35]
2nd ionization potential (n_σ MO)	12.86 eV	[27]	12.19 eV	[35]
IR stretch	1278.3 cm^{-1}	[10, 28]	1558.7 cm^{-1}	[36]
NMR(CD_2Cl_2, −80°C, δ) ^1H	2.90	[21, 22] [a]	2.20	[21] [c]
^{13}C	158.0	[21] [b]	170.8	[21] [d]
^{31}P	−32	[21, 22] [a]	−60	[21] [c]

[a] $^2J(P,H) = 44.0$ Hz. [b] $^1J(P,C) = 56.0$ Hz. [c] $^3J(P,H) = 15.0$ Hz. [d] $^1J(P,C) = 49.0$ Hz.

Finally, phosphaalkynes are now known containing acetylene and nitrile groups so placed that they can conjugate with the phosphaalkyne group. They are obtained by copyrolysis or by substitution.



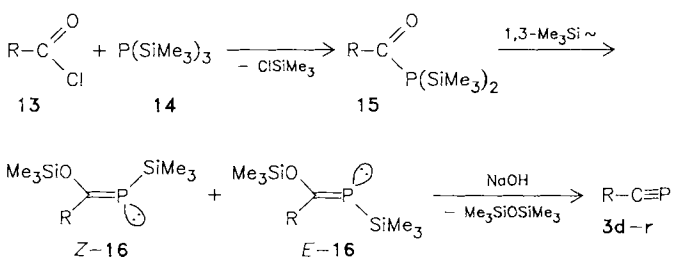
a) 1100°C/0.03–0.06 torr. b) 1100°C/0.08 torr. c) 700°C.

For example, the flash pyrolysis of propargyl chloride and phosphorus trichloride produces 1-phospha-1,3-butadiyne **10** ($\mu = 0.745$ D).[38,44] The heteropolyyne **11** ($\mu = 4.3$–4.5 D)[45] can be prepared similarly. Lastly, the hydrogen of HC≡P **4** can be replaced by cyanide radicals by passing **4** and cyanazide together through a pyrolysis oven: the product **12** ($\mu = 3.44$ D) has been identified by microwave spectroscopy.[46]

2.2. Kinetically Stable Phosphaalkynes

tert-Butylphosphaacetylene **3d** has played a decisive role in the synthesis of kinetically stable phosphaalkynes. Its reactivity has been investigated more thoroughly than that of any other compound with a PC triple bond. The synthesis published by *Becker* et al. in 1981[8,47] (**13c** → **15c** → **16c** → **3d**) was later generalized (see Table 2), above all by significant developments in the step in which hexamethyldisiloxane is eliminated (**16** → **3**) to form the phosphaalkyne.[48,49]

The starting material for the phosphaalkyne synthesis is the silyl phosphane **14**,[50] which can be readily obtained from white phosphorus, sodium/potassium alloy, and chlorotrimethylsilane. Compound **14** has often been replaced successfully by the more reactive lithium bis(trimethylsilyl)phosphide·2THF (**14**, Li instead of a $SiMe_3$ group).[51] The acyl phosphides **15** formed in the first step by reaction of acyl chlorides **13** with **14** can be detected,[52,53] but they generally rearrange rapidly by a 1,3-



shift of a trimethylsilyl group to the oxygen atom of the acyl group to form the phosphaalkenes **16**, the *Z* isomer of which usually predominates.[52,53] The configuration of **16** apparently has no influence upon the subsequent elimination step (→ **3d**–**r**). However, it has proved to be decisive for the general application of this elimination step in synthesis that it should take place at high temperature without solvent and that the phosphaalkyne together with the silyl ether should be removed rapidly from the reaction vessel.[48,49,54] Information relating to specific examples is either given below or is to be found in the footnotes to Table 2.

Phosphaalkynes having tertiary substituents, such as **3d**–**j**, have an unusually high thermal stability. Those with secondary substituents or a neopentyl residue, such as **3k**–**p**, also survive the temperatures of the elimination steps, but the yields clearly suffer. At room temperature they tend to "oligomerize". Substitution with a phenyl group[58] (see below) produces a rather unstable phosphaalkyne. Methyl (→ **3r**)[55] or *tert*-butyl (→ **3q**)[57] substituents in the 2-, 4-, and 6-positions of the phenyl ring improve the kinetic stability decisively.

It was reported recently that the elimination step **16a** → **3d** can also be carried out with the aid of diiron nonacarbonyl;[59] it is immaterial whether one starts with the *Z*- or the *E*-phosphaalkene. These isomers can be prepared selectively when **13d** is reacted with lithium bis(trimethylsilyl)phosphide·2THF either at +20°C (→ *Z*-**16d**) or at −78°C (→ *E*-**16d**).[59] The elimination step **16** → **3** can also be carried out with tetrabutyl ammonium fluoride,[53] as was shown for the preparation of **3i**. Finally, one can do without additives entirely, as in the preparation of **3j**[56] and **3q**.[57]

Phosphaalkynes have been well characterized by their ^{31}P and ^{13}C chemical shifts and their $^{1}J_{P,C}$ coupling constants (see Table 2). Aromatic substituents (**3q**,**r**) cause a marked shift of the phosphorus resonance to lower field. The structure of **3d** in the gas phase has been studied in detail by electron diffraction and by microwave spectroscopy (P≡C = 1.536(2) Å)[60] and the ionization potentials have been determined (first IP = 9.7 eV, second IP = 11.45 eV) and compared with those of other phosphaalkynes.[31,61]

The stabilities of the precursor and of the product limit the extent to which this method of synthesizing phosphaalkynes can be applied. A further limitation is shown by the attempt to prepare the bis(phosphaalkyne) **18**.

Thus, when dimethylmalonyl dichloride is treated with two equivalents of lithium bis(trimethylsilyl)phosphide,[51] the bis(phosphaalkyne) **18** is not formed. Instead, an intramolecular [2 + 2] cycloaddition occurs to afford 2,3-diphosphabicyclo[2.1.0]pentane **19**.[62]

The elimination of chlorotrimethylsilane from suitably substituted phosphaalkenes **20** by flash pyrolysis can also be used to form PC triple bonds. Phenylphosphaacetylene **3s**[58,63] and trimethylsilylphosphaacetylene **3t**[9] have been prepared in this way.

Their half-lives (**3s**, $\tau/2$ (0°C) = 7 min; **3t**, $\tau/2$ (20°C) = 50 min) indicate that their stabilities lie between those of the short-lived phosphaalkynes on the one hand and the kinetically stabilized ones on the other.

Finally, a variant should be mentioned which permits acyl chlorides to be converted into phosphaalkynes using lithium phosphide (DME complex).[64] The primary prod-

Table 2. Kinetically stabilized phosphaalkynes **3d–r** prepared by the elimination of hexamethyldisiloxane from phosphaalkenes **16d–r**. NMR data (C_6D_6, J in Hz). DEG = diethylene glycol; DME = 1,2-dimethoxyethane.

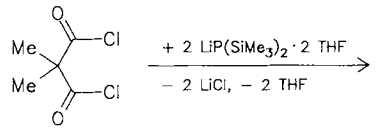
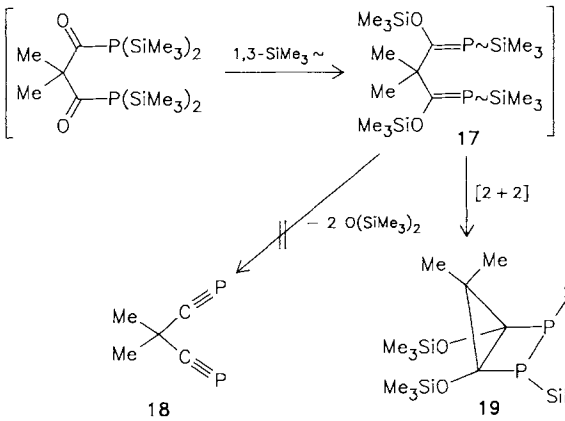
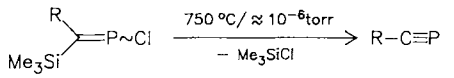
[a] Stable at 20°C, but the complete removal of hexamethylsiloxane has not yet been achieved. This is of no significance for further reactions. [b] Measured in $CDCl_3$. [c] Stored at −30°C. [d] Mixed with hexamethyldisiloxane; stored at −30°C. [e] The modest yield is partly the result of the competing formation of a 2,3-diphospha-1,3-butadiene.



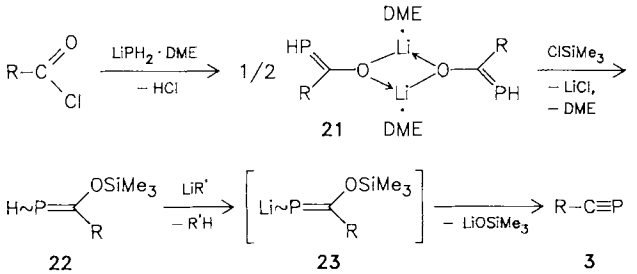




20a: R = Ph **3s**: R = Ph
20b: R = Me_3Si **3t**: R = Me_3Si

3s: ^{31}P NMR (solvent not reported), $\delta = -32$; ^{13}C NMR (CD_2Cl_2), $\delta = 164.9$ ($^1J(P,C) = 48.3$ Hz) [59]. **3t**: ^{31}P NMR (solvent not reported), $\delta = 96$; ^{13}C NMR (solvent not reported), $\delta = 201.4$ ($^1J(P,C) = 13.9$ Hz) [9].

ucts of the reaction are the dimeric "lithium monoacylphosphides" **21**, which afford the phosphaalkenes **22** upon silylation. The reaction sequence is completed by lithiation and the spontaneous elimination of lithium triethylsilanolate (**22** → **23** → **3**).[65]



Although the experimental details of this reaction sequence have not been reported and its versatility is unknown, it is difficult to see any advantage it may have over the corresponding reaction of acyl chlorides **13** with tris(trimethylsilyl)phosphane **14**.

3. Reactions

3.1. 1,2 Additions

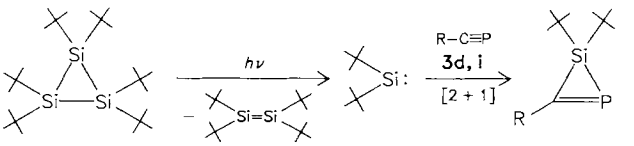
The 1,2 addition of HCl to the triple bond of a phosphaalkyne is as old as the discovery of phosphaacetylene **4** itself.[10] Dichloro(methyl)phosphane is produced, reflecting the Pauling electronegativities of carbon (2.5) and phosphorus (2.1)[66] and the charge distribution in phosphaacetylene.[67] HCl has been found to add to 1-phospha-1-propyne **3a** in the same orientation.[32] In the case of 2-phenyl-1-phosphaacetylene **3s** it is assumed that first a stereospecific *cis* addition of hydrogen chloride occurs, followed by addition of a second equivalent in the same orientation to form benzyldichlorophosphane.[58] A similar sequence is also known for the silylated phosphaalkyne **3t**.[9]

The addition of halogens to **3d** has been investigated. First, a mixture of *cis/trans*-1,2-dihalophosphaalkenes is produced, followed by saturation of the double bond. Finally, the PC bond is cleaved by a third equivalent of the halogen.[47,68]

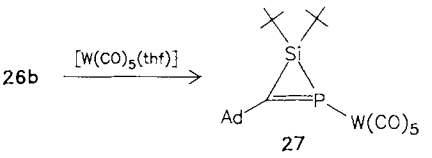
The 1,2 addition of boron tribromide and tin tetrabromide to **3d** is also known. The product is a mixture of *E/Z*-isomeric phosphaalkenes, in which the phosphorus atom is halogen-substituted and the boron or tin residue is bonded to carbon.[68]

3.2. [2+1] Cycloaddition

Attempts to add carbenes such as dichloro-, chloro(phenyl)-, or diphenylcarbene to the phosphaacetylene **3d** have not yet succeeded. The Simmons-Smith reaction has also produced no concrete results.[69] However, when the silanediyl (silylane) **25** is produced photolytically from the cyclotrisilane **24** in the presence of the phosphaacetylenes **3d** or **3i**, the phosphasilirenes **26a** or **26b**, respectively, are isolated without difficulty.[70]



24 **25** **26a**, R = *t*Bu; **26b**, R = Ad



27

26a: ^{31}P NMR (C_6D_6), $\delta = 274.0$. **26b**: ^{31}P NMR (C_6D_6), $\delta = 272.6$. Ad = 1-adamantyl.

When $[W(CO)_5 \cdot (thf)]$ reacts with **26b**, the tungsten complex **27** is obtained, the crystal structure of which reveals that the PC bond distance is 1.686 Å,[70] a typical value for phosphaalkenes.

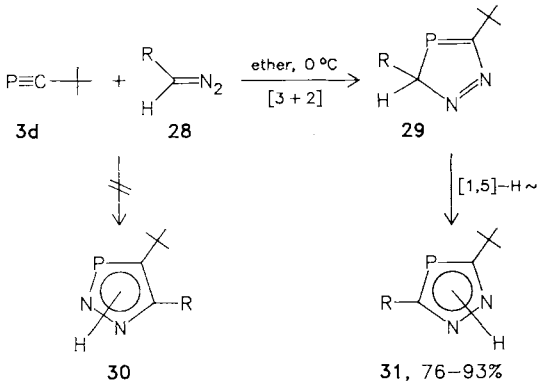
3.3. [3+2] Cycloadditions

Chemists have only relatively recently become interested in phospholes with further heteroatoms in the ring.[71,72] These compounds are playing a significant role in the development of the chemistry of compounds of low-coordinate phosphorus. Like alkynes, phosphaalkynes have a marked potential for undergoing cycloaddition reactions[49,73,74] and, in view of the variety of 1,3-dipoles avail-

able, they widen the scope of the phosphole synthesis enormously.

3.3.1. 1H-1,2,4-Diazaphospholes

Detailed investigations have been carried out on cycloaddition reactions of **3d** with diazomethane **28a** itself and with its alkyl-, aryl-, acyl-, phosphoryl-, and silyl-substituted derivatives **28b–i**. All these reactions proceed regioselectively in the first stage to give 3*H*-1,2,4-diazaphospholes **29a–i**. The orientation of the dipole is in agreement with the electronegativities of carbon and phosphorus[66] and with the calculated charge distribution in unsubstituted phosphaacetylene **4**.[67] Steric influences do not oppose the mode of reaction favored by electronic factors. Only **29f** can be detected in the NMR spectrum; this compound, like the other primary products, rapidly undergoes an H-shift to form an aromatic ring (**31a–h**). In the case of **29i** the silyl shift is more rapid, giving an *N*-silylated diazaphosphole (**31i**: Me_3Si instead of H, R = H). Regioisomers of type **30** are not present within the limits of detection of ^{31}P NMR spectroscopy.[54,73,74]



3d 28 29

30 31, 76–93%

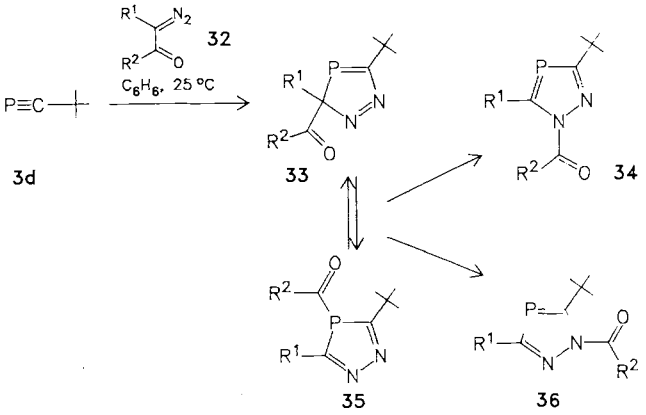
a, R = H; b, R = Me; c, R = Ph; d, R = *t*Bu; e, R = CO_2*t*Bu
f, R = CO_2Me; g, R = PhCO; h, R = Ph_2PO; i, R = Me_3Si

31: ^{31}P NMR ($CDCl_3$), δ = 67.6–110.8.

The kinetically stabilized phosphaalkynes **3e,f**,[55] **3g, h**,[48] and **3i**[53] react in a similar fashion with diazomethane **28a**. It should be pointed out that the short-lived parent compound HC≡P **4** can also be converted in this way into 1,2,4-diazaphosphole.[22] Its reaction with **28e** is the only cycloaddition of this type known which does not proceed regiospecifically (**31e** : **30e** (H instead of *t*Bu) = 6 : 1).[22] 1-Phosphapropyne **3a**, the stability of which is similar to that of **4**, adds diazo compounds with the usual orientation of the dipole.[33]

α-Diazoketones **32a–c**, which, unlike **28**, have no diazomethyl hydrogen, react with **3d** to give mixtures of *N*-acylated 1,2,4-diazaphospholes, **34a–c**/**36a–c** in which the isomers **34** dominate (≥85%). They can be separated from the other components.[54]

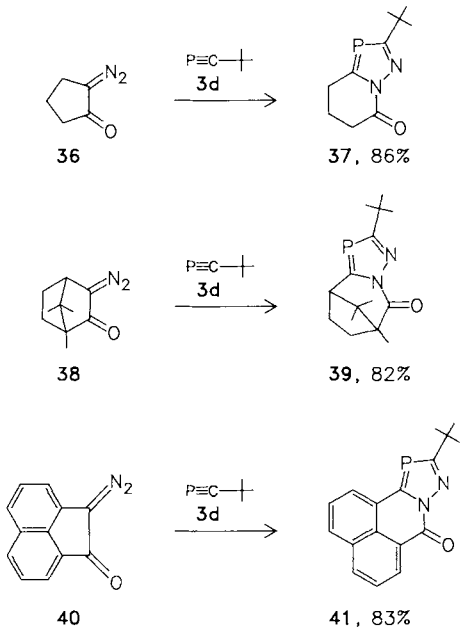
The reaction **3d** + **32a–c** has been monitored by ^{31}P NMR spectroscopy. The 4*H*-1,2,4-diazaphosphole isomers **35a–c** were thereby detected as intermediates (δ = 37.0–54.8) preceding the acyl shift to the ring nitrogen atom (→ **34**, **36**). The rapid [1,5]-sigmatropic shift (to phosphorus in the first instance) precludes any chance of the primary products **33a–c** being detected.[54] Phosphoryl-substituted diazo compounds (**32**, R^2PO instead of R^2CO) react in the same way with **3d**;[54] sigmatropic phosphoryl shifts are known in pyrazoles.[75,76]



3d 33 34 35 36

a, $R^1 = R^2$ = Me; b, R^1 = Me, R^2 = Ph; c, $R^1 = R^2$ = Ph

The vast range of applications of this synthetic principle can be recognized from the formation of the annelated *N*-acyl-1,2,4-diazaphospholes **37**, **39**, and **41** from **3d** and the cyclic α-diazoketones **36**, **38**, and **40**, respectively (all reactions carried out in benzene at 25 °C).[54,73]



36 37, 86%

38 39, 82%

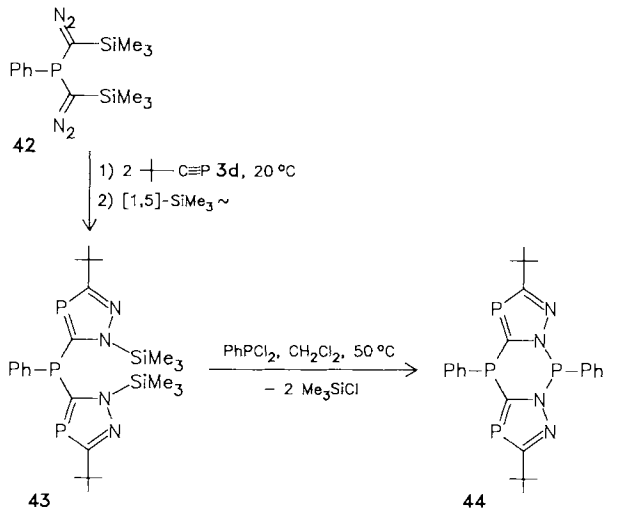
40 41, 83%

37: ^{31}P NMR (C_6D_6), δ = 95.9. **38**: ^{31}P NMR ($CDCl_3$), δ = 90.5. **41**: ^{31}P NMR ($CDCl_3$), δ = 98.2.

In analogy to **33**, the spirocyclic compounds are formed first, followed by the kinetically determined acyl shift to the phosphorus atom, after which the thermodynamically stable isomers are finally produced.[54]

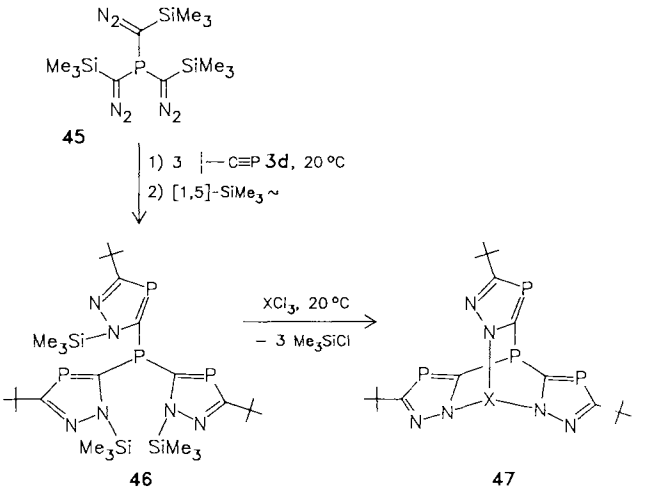
Cycloaddition reactions of bis[diazo(trimethylsilyl)-methyl]phosphanes **42**[77] and tris[diazo(trimethylsilyl)-methyl]phosphane **45**[77] with the phosphaalkyne **3d** are the starting point of a highly promising synthesis of complicated molecules with numerous heteroatoms. Thus, **42**—easily prepared from dichloro(phenyl)phosphane and two

equivalents of diazo(trimethylsilyl)methyllithium—adds smoothly to **3d** in the usual orientation with subsequent trimethylsilyl shift to afford bis(1,2,4-diazaphospholyl)phosphane **43**.



Condensation with additional dichloro(phenyl)phosphane and elimination of chlorotrimethylsilane gives **44**.[77] Analogous reactions with tetrachlorosilane result in the formation of a spirocyclic silicon compound.[77]

The rather unstable compound **45**, which is obtained from phosphorus trichloride and diazo(trimethylsilyl)methyllithium, adds **3d** in a molar ratio of 1 : 3 and undergoes the usual silyl shift to yield tris(1,2,4-diazaphospholyl)phosphane **46**. Cyclocondensation with the trichlorides of phosphorus, arsenic, or antimony, or with trichloro(methyl)silane or -germane in ether or CH_2Cl_2 provides an easy route to the heteroatom-substituted barrelenes **47a–e**.[77]



a, X = P; b, X = As; c, X = Sb; d, X = MeSi; e, X = MeGe

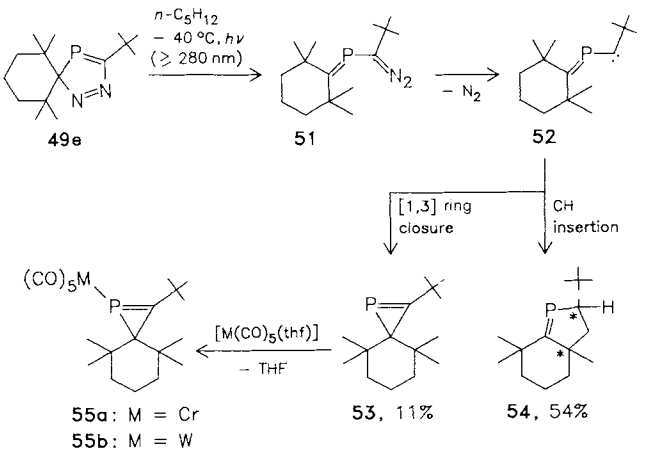
3.3.2. 3H-1,2,4-Diazaphospholes

The previous section showed that the 3*H*-1,2,4-diazaphospholes obtained as the primary products of reaction between diazo compounds and phosphaalkynes become aromatic by rapid sigmatropic shifts of hydrogen as well as acyl, phosphoryl, or silyl groups. The potential access to the chemistry of phosphavinylcarbenes by photochemical elimination of N_2 is thereby lost unless the shift of the substituent is prevented, for example, by cycloaddition of dialkyl-substituted diazo compounds.[78]

	a	b	c	d	e	f	g	h
R	*t*Bu	*t*Bu	*t*Bu	*t*Bu	*t*Bu		*i*Pr	CH_2-*t*Bu
R^1	*t*Bu	*t*Bu	*i*Pr			*t*Bu	*t*Bu	*t*Bu
R^2	*t*Bu	Me	*i*Pr			*t*Bu	*t*Bu	*t*Bu

This approach allows the 3*H*-1,2,4-diazaphospholes **49a–c** and **49e–h** (yields 92–100%; ^{31}P NMR, $\delta = 263$–304) to be obtained as colorless to pale yellow oils when **3d**, **g**, **k**, **l** are treated with diazo compounds of type **48** at low temperature.[49,69,79–81] The cycloadduct **49d** cannot be prepared in this way since even at −40 °C a sigmatropic alkyl migration occurs, giving the 4*H*-1,2,4-diazaphosphole **50d**.[80] All other 3*H*-diazaphospholes **49** also undergo the same R^1 shift (→ **50**) on standing in chloroform at 25 °C (yield 82–100%; ^{31}P NMR ($CDCl_3$), $\delta = 38$–58).[69,79–81] That this rearrangement is promoted by all the substituents being bulky can be concluded indirectly from the fact that **49b** does not rearrange even when distilled.[79] 4*H*-1,2,4-Diazaphospholes such as **50a,f,g** with a *tert*-butyl group in the 4-position lose the *tert*-butyl group R^1 as isobutylene on heating, forming heterocycles of type **31**.[79,80]

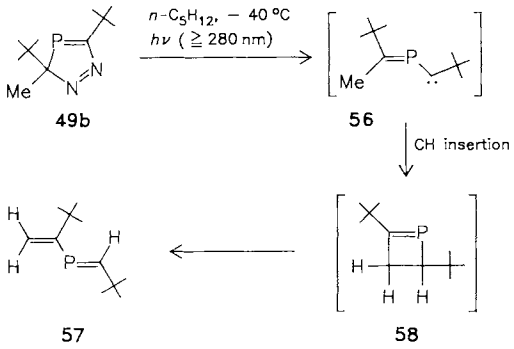
Therefore, to convert 3*H*-1,2,4-diazaphospholes **49** into phosphavinylcarbenes, one can irradiate **49e**, for example, at −40 °C, upon which ring opening to the diazo isomer **51** first occurs,[82] followed by the elimination of nitrogen to afford the desired carbene **52**. At this point different reactions can occur: CH insertion gives the phosphacyclopen-



tene **54** and 1,3 ring closure forms the 2*H*-phosphirene **53**, the first phosphacyclopropene with a PC double bond.[81]

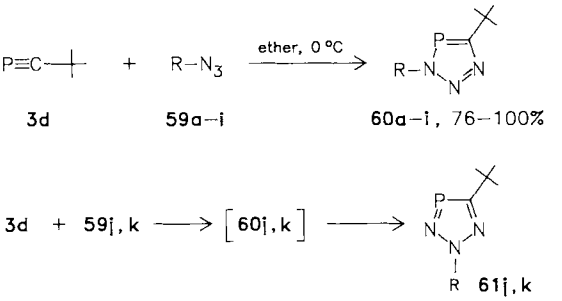
To remove any last doubts about the constitution of **53**—the phosphorus resonance at $\delta = 71.7$ ($CDCl_3$) lies to rather high field (compare, for example, the phosphasilirenes **26a** and **26b**)—the metal complexes **55a** and **55b** were prepared and the structure of the tungsten derivative **55b** was confirmed by X-ray crystallography. The P=C bond length is 1.634(4) Å, shorter than the corresponding bonds in the tungsten complex **27**[70] or in open-chain phosphaalkenes bound in metal complexes.[83,84]

The photolysis of other 3*H*-1,2,4-diazaphospholes such as **49a**[79] and **49f-h**[80] affords the phosphaalkenes corresponding to **54** in high yield (63–81%; ^{31}P ($CDCl_3$), $\delta = 250$–263). However, when **49b** is irradiated the rearrangement proceeds differently. While the carbene is formed as before (→**56**), the CH insertion occurs at the methyl and not at the *tert*-butyl group. The first isolable product is the 2-phospha-1,3-butadiene **57**, which results from the electrocyclic ring opening of the insertion product **58**.[85] The same sequence of reactions can be achieved with **49c**.[69]



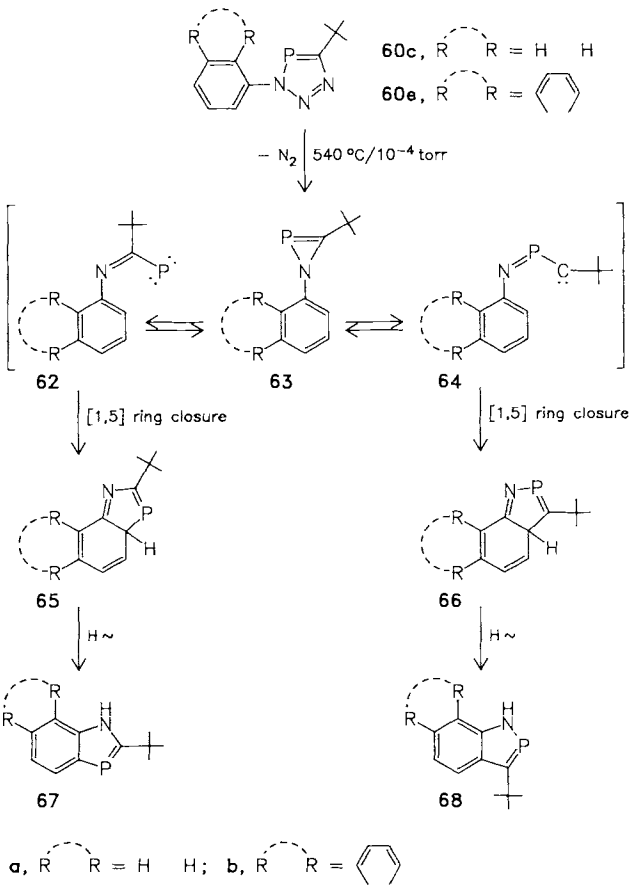
3.3.3. 3*H*-1,2,3,4-Triazaphospholes

3*H*-1,2,3,4-Triazaphospholes were first prepared in 1984 by the 1,3-dipolar cycloaddition of azides to phosphaalkynes.[73,74] Thus, **59a-i** add regiospecifically to **3d** in the same orientation as the isoelectronic diazo compounds (see Sections 3.3.1 and 3.3.2) to afford the 3*H*-1,2,3,4-triazaphospholes **60a-i**.[85] These compounds show no tendency towards a substituent shift of the type found for **60**→**61**. This is observed only when **3d** is treated with trimethylsilyl azide **59j** or hydroazoic acid, which produces **61j** or **61k**, respectively.[85]



a, R = Me; **b**, R = *t*Bu; **c**, R = Ph; **d**, R = 4-EtO_2C-C_6H_4; **e**, R = 1-naphthyl; **f**, R = $CH{=}CH_2$; **g**, R = CO_2Me; **h**, R = CH_2CN; **i**, R = CH_2SiMe_3; **j**, R = $SiMe_3$; **k**, R = H

60a-i: ^{31}P NMR ($CDCl_3$; **60d**, **e**, C_6D_6), $\delta = 161.8$–180.7.



^{31}P NMR ($CDCl_3$): **67a**, $\delta = 66.3$; **67b**, $\delta = 74.4$; **68a**, $\delta = 210.3$; **68b**, $\delta = 180.1$.

Azide additions are not limited to **3d**: adducts of methyl azide of type **60** are known for the parent compound **4**,[22] as well as for the phosphaalkynes **3e,f**,[55] **3g,h**,[48] **3i**,[53] **3k,l**,[48] **3m-p**,[55] and **3r**.[55]

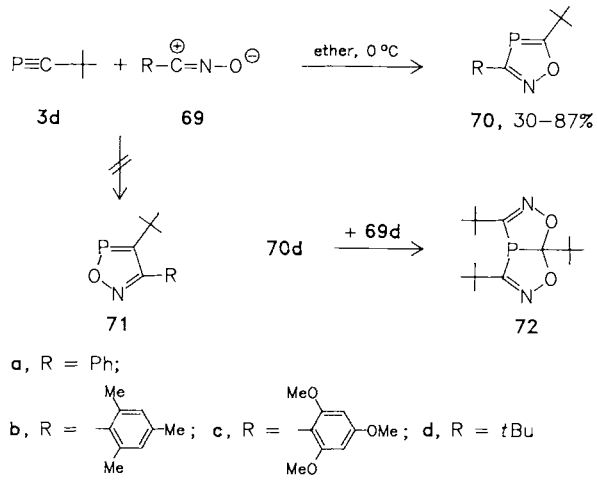
The 3*H*-1,2,3,4-triazaphospholes have an extraordinary thermal stability and lose nitrogen only during flash pyrolysis. Model reactions with **60c** and **60e** give mixtures of isomers of benzoannelated azaphospholes **67a/68a** (95%, 1:4) and **67b/68b** (99%, 1:3).[85]

This result can be interpreted as arising from competing phosphanediyl and carbene reactions, where the azaphosphirenes can react in two different ways (**60**→**63**⇄**62** or **64**). A [1,5] electrocyclization[86] of the intermediate with the electron-deficient (six-electron) phosphorus atom (**62**→**65**, **64**→**66**) and subsequent H-shift gives the products **67** and **68**.[85] Analogous reaction sequences are known for styryl-[87] and aryliminocarbenes.[88]

3.3.4. 1,2,4-Oxazaphospholes

Intuitively one would expect that 1,2,5-oxazaphospholes **71** would be formed when nitrile oxides **69** undergo addi-

tion with phosphaalkynes, if only because of the proverbial oxygen affinity of phosphorus. The process **3d** + **69** actually proceeds specifically in the opposite sense, affording **70**.[73,89] No doubt this is more favorable on steric grounds. Other phosphaalkynes, such as **3e**,**f**,[55] **3g**,**h**,[48] **3i**,[53] **3k**,**l**,[48] and **3r**,[55] show the same orientation when [3+2] cycloadditions occur with nitrile oxides.

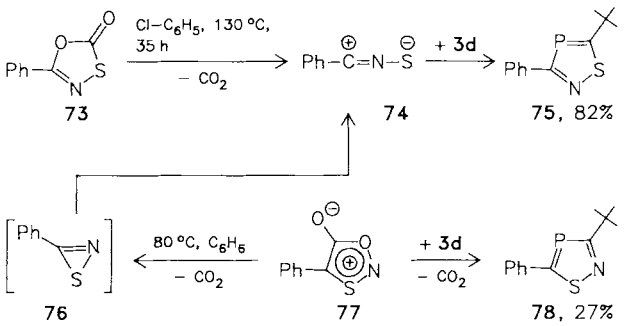


70a–c: ^{31}P NMR ($CDCl_3$; **70a**, C_6D_6), δ = 66.8–81.9.

Despite the steric bulk of its substituents, the PC double bond of **70d** is so reactive that it takes up a further mole of the dipole **69d** to give the heterobicyclic compound **72**.[89] A corresponding reaction of **3d** with 4-chlorophenylnitrile oxide is also known.[74] The trapping reaction of HC≡P **4** with **69a** also is a 1:2 addition.[22]

3.3.5. 1,2,4-Thiazaphospholes

Phenylnitrile sulfide **74**, produced by thermal cycloelimination of carbon dioxide from the oxathiazolone **73**,[90] adds to **3d** in the same orientation as nitrile oxides and affords the thiazaphosphole **75**.[89] To our knowledge, compounds of this type were previously unknown.



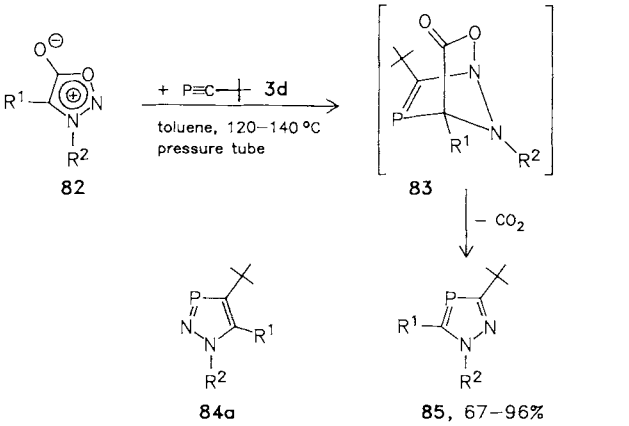
Surprisingly, **75** is also produced when the mesoionic oxathiazolylium-5-olate **77**[91] is heated with **3d** in benzene, although the yield is only 3%. The major product of the cycloaddition, which is accompanied by CO_2 elimination, is the isomer **78**.[92] A possible interpretation of the formation of the unusual thiazaphosphole **75** is that, to a small extent, **77** forms the thiazirine **76**, which, in turn, is transformed into the nitrile sulfide **74**; this then adds **3d** in the normal way.

3.3.6. N-Substituted 1,2,4- and 1,2,3-Diazaphospholes

Nitrilimine dipoles such as **79a** and **79b** do not react regiospecifically with **3d**. In both cases, the product ratios **80a** : **81a** and **80b** : **81b** determined by ^{31}P NMR spectroscopy are 98 : 2. The difference between the chemical shifts (^{31}P NMR ($CDCl_3$): **80a**,**b**, δ = 86.7, 91.9; **81a**,**b**, δ = 224.4, 218.5) is so large that the compounds can be assigned unambiguously.[89] Although **81a** and **81b** can be enriched by fractional crystallization, they cannot be obtained pure. In the reaction **3d** + **79c**, no regioisomer **81c** could be found by ^{31}P NMR spectroscopy.[89]

	R^1	R^2	**80** : **81**	Yield **80** + **81** [%]
a	Ph	Me	90 : 2	85
b	Me	Ph	98 : 2	55
c	Ph	Ph	100 : 0	72

Diazaphospholes closely related structurally to **80**, differing only in that the *N*-substituent is on the other nitrogen atom, can be obtained by the reaction of **3d** with sydnones **82a–e**. Primary products of the type **83** could not be detected; the products **85a–e** were isolated directly.[92] Only in the reaction **3d** + **82a** is a mixture of regioisomers formed (**85a**/**84a** in the ratio 87 : 13, determined by ^{31}P NMR spectroscopy). Attempts to separate the isomers by MPLC led to decomposition of **84a**.[92]

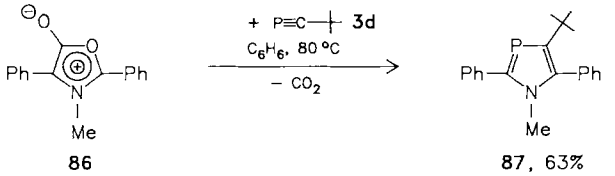


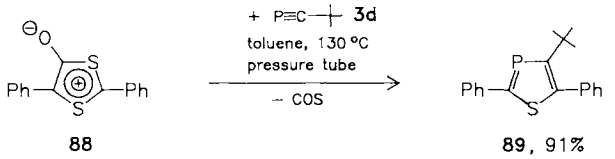
a, R^1 = H, R^2 = Me; **b**, R^1 = H, R^2 = Ph; **c**, R^1 = R^2 = Me; **d**, R^1 = Me, R^2 = Ph; **e**, R^1 = Ph, R^2 = Me

As a general principle, diazaphospholes of type **85** can also be obtained by lithiation of 1*H*-diazaphospholes **31** and subsequent alkylation.[54]

3.3.7. 1,3-Aza- and 1,3-Thiaphospholes

The munchnone **86** is much more reactive towards **3d** than the sydnones **82**. The product is the 1,3-azaphosphole **87**;[92] the first representatives of this type of compound have only recently been prepared.[93,94] Phosphaacetylene **4** also reacts smoothly with **86** to give 1-methyl-2,5-diphenyl-1,3-azaphosphole (**87**, H instead of *t*Bu): the addition reaction and CO_2 elimination take place as the ice bath warms up.[22]



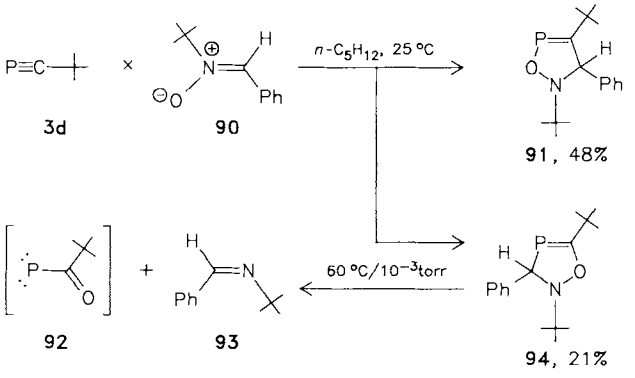


87: ^{31}P NMR ($CDCl_3$), $\delta = 96.6$. **89**: ^{31}P NMR ($CDCl_3$), $\delta = 220.6$.

One can obtain a derivative of the previously little known 1,3-thiaphosphole system when **3d** is treated with the 1,3-dithiolylium-4-olate **88** under more drastic conditions.[95] The phosphorus resonance of the product, **89**, is found at remarkably low field.[92]

3.3.8. Dihydro-1,2,4- and Dihydro-1,2,5-oxazaphospholes

In comparison with the reaction **3d** + **79** → **80** + **81**, a further loss of regiospecificity is found when the nitrone **90** reacts with **3d**. After workup by chromatography, the dihydrooxazaphospholes **91** and **94** are obtained in the ratio ≈ 2 : 1.[79]



91: ^{31}P NMR ($CDCl_3$), $\delta = 260.1$. **94**: ^{31}P NMR ($CDCl_3$), $\delta = 130.2$.

A first attempt to separate the mixture of regioisomers by distillation in a kugelrohr apparatus caused decomposition of **94** by [3 + 2] cycloreversion—although not the reverse of its reaction of formation. The Schiff base **93** was identified unambiguously, but the fate of the pivaloyl phosphanediyl (phosphinidene) **92** is uncertain.[79]

3.4. [4 + 2] Cycloadditions

Most of the phosphaalkenes that have been synthesized are open-chained.[4a,7b] However, Diels–Alder reactions with phosphaalkynes open up numerous possibilities of exploring the chemistry of mono- and polycyclic compounds with a PC double bond. Compounds of these kinds were previously unknown.

3.4.1. The Valence Isomers of Phosphinines

Phosphinines (phosphabenzenes) are a class of heteroarenes that have been investigated thoroughly.[96] There have been no reports on their valence isomers such as Dewar-phosphinines, phosphaprismanes, or phosphabenzvalenes. In just the same way that the pair of reactants "cyclobutadiene/acetylene" has allowed access to the chemistry of the valence isomers of benzene,[97] the problem of the synthesis of valence-isomeric phosphabenzenes can be solved by using phosphaalkynes and the same cyclic 1,3-dienes.[49]

1- and 2-Dewar-Phosphinines: When the kinetically stabilized cyclobutadienes **95a** and **95b** are treated with the phosphaalkynes **3d,g,i,k,l**, the reaction is regioselective (only the reaction **95a** + **3i** is regiospecific), affording the 2-Dewar-phosphinines **96** (≥ 85%) and **97** (≤ 15%) (Table 3).[98]

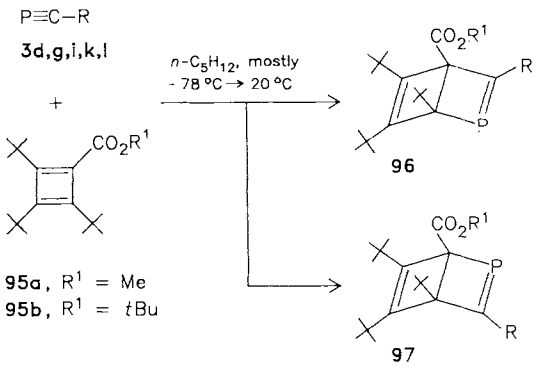


Table 3. Regioisomeric 2-Dewar-phosphinines **96**, **97** prepared from phosphaalkynes **3** and cyclobutadienes **95**. ^{31}P NMR (C_6D_6).

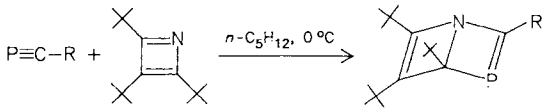
	R [a]	R^1	**96** : **97**	$\delta(^{31}P)$
3d + **95a** → **96a**	*t*Bu	Me	96 : 4	315
3g + **95a** → **96b**	C_7H_{13}	Me	98 : 2	315
3i + **95a** → **96c**	Ad	Me	100 : 0	314
3k + **95a** → **96d**	*i*Pr	Me	97 : 3	312
3l + **95a** → **96e**	CH_2–*t*Bu	Me	93 : 7	314
3d + **95b** → **96f**	*t*Bu	*t*Bu	85 : 15	316
3g + **95b** → **96g**	C_7H_{13}	*t*Bu	85 : 15	316
3i + **95b** → **96h**	Ad	*t*Bu	85 : 15	317

[a] C_7H_{13} = 1-methylcyclohexyl; Ad = 1-adamantyl.

The reaction is therefore mainly kinetically controlled (→ **96**), as can also be recognized in the appreciable increase in the proportion of **97** formed in going from **95a** to

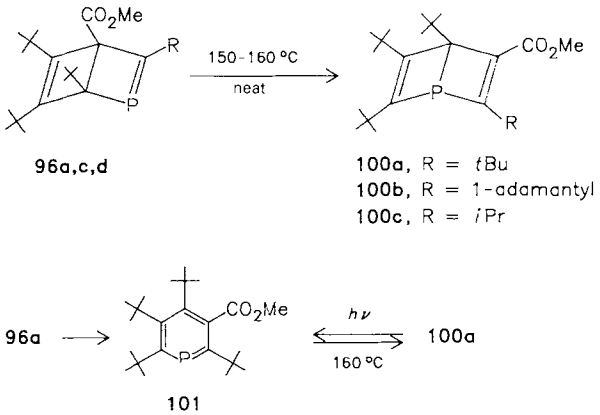
95b.[98] X-ray crystallographic data are available for **96c** (length of the PC double bond: 1.68(1) Å).[98] Typical of all phosphabicyclic compounds of type **96** is the narrow range of their ^{31}P resonances ($\delta = 312$–317); the phosphorus signals of the isomers **97** are found at higher field ($\delta = 285$–300).[98]

Unsubstituted bicyclobutadiene—liberated from its corresponding iron tricarbonyl complex by oxidation[99]—also adds **3d**, but the bicyclic primary product isomerizes spontaneously to the 2-*tert*-butylphosphinine **113d**.[79] Similarly, the recently prepared azete **98**[100] undergoes a Diels–Alder reaction with **3d** and **3l**: this reaction also proceeds under kinetic control and affords the Dewar isomers of the 1,3-azaphosphinines **99a** and **99b**.[101, 102]



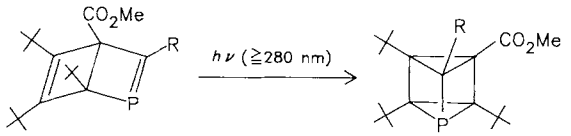
3d,l **98** **99a**, R = *t*Bu; **99b**, R = CH_2–*t*Bu

When the 2-Dewar-phosphinines **96a,c,d** are heated they isomerize to the 1-phosphabicyclic compounds **100a–c**.[79, 103–105] The change from $\lambda^3\sigma^2$ phosphorus to $\lambda^3\sigma^3$ phosphorus is accompanied by a striking shift of the ^{31}P resonance to higher field (**96**, see Table 3; **100** ($CDCl_3$), $\delta = -19$ to -25). One can reasonably assume that the 1-isomers **100** are thermodynamically more stable than the 2-isomers **96**. The intermediates in the isomerization are probably λ^3-phosphinines, at least as far as the process **96a** → **100a** is concerned. Evidence for this comes from the isomerization of the 1-Dewar-phosphinine **100a** (≥ 280 nm, $CHCl_3$, 25 °C): it isomerizes on irradiation to the heteroarene **101**, which as expected reverts to **100a** on heating to 160 °C.[103]



This electrocyclic reaction is at first glance surprising. The explanation is certainly of steric nature: as a result of the accumulation of bulky groups, **101** is no longer planar. Its crystal structure shows that it has a twisted boat conformation with angles at the bow and the stern of 33.7 and 17.9, respectively.[106] The phosphinine **101** has the most distorted structure in a 6π system yet known, except for fused-ring and bridging systems.

Phosphaprismane and Phosphabenzvalene: When the 2-Dewar-phosphinines **96a,c–e** are irradiated in pentane or $CDCl_3$, they undergo relatively fast intramolecular [2+2] cycloadditions to afford the phosphaprismanes **102a–d**.[79, 103–105] This is followed by the photochemical isomerization to the phosphabenzvalenes **105** and **106**: thus, as soon as the concentration of phosphaprismane has peaked, the photolysis must be stopped and the products worked up. This limits the yields that can be achieved (see Table 4).



96a, c–e **102a–d**

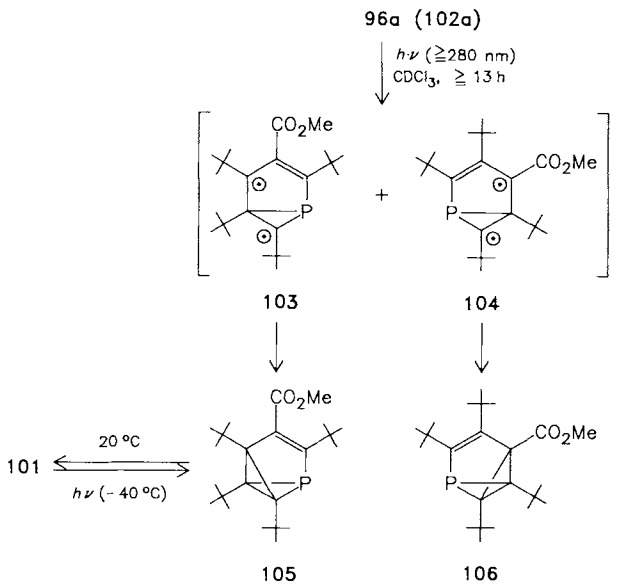
Table 4. Phosphaprismanes **102** prepared from 2-Dewar-phosphinines **96**. ^{31}P NMR ($CDCl_3$).

	R [a]	*t* [b]	Yield [%]	$\delta(^{31}P)$	Ref.
96a → **102a**	*t*Bu	4 h	40	−130.2	[103]
96c → **102b**	Ad	30 min	59	−133.0	[104]
96d → **102c**	*i*Pr	45 min	63	−128.4	[79]
96e → **102d**	CH_2–*t*Bu	45 min	70	−101.3	[105]

[a] Ad = 1-adamantyl. [b] Reaction time.

The incorporation of the $\lambda^3\sigma^2$ phosphorus into the phosphirane ring of the tetracyclic compound **102** is associated with an enormous high-field shift of the ^{31}P resonance (compare the values in Tables 3 and 4).

When the 2-Dewar-phosphinine **96a** (or the phosphaprismane **102a**) is subjected to extended photolysis, a further isomerization takes place, yielding the phosphabenzvalenes **105** and **106**. Compound **106** is thermally stable and can be isolated. However, even at room temperature, **105** rearranges to the phosphinine **101**.[103]

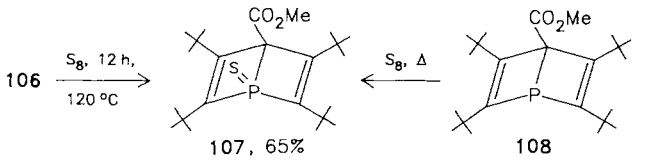


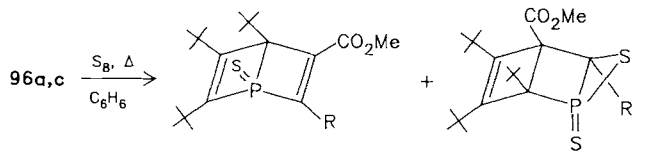
105: ^{31}P NMR ($CDCl_3$), $\delta = -89.8$. **106**: ^{31}P NMR ($CDCl_3$), $\delta = -83.3$.

That this reaction pathway is correct emerges partly from the photochemical retroisomerization of the phosphabenzene **101** to phosphabenzvalene **105** at −40 °C and partly from the reversal of the isomerization at room temperature. Furthermore, it is completely consistent with the

detection by ^{31}P NMR spectroscopy of the phosphabenzvalene **105** (together with **106**) when **96a** is photolyzed at low temperature.[103] The biradicals **103** and **104** are presumed intermediates in the phosphaprismane/phosphabenzvalene isomerization.[103] Stable phosphabenzvalenes corresponding to **106** are also formed during the extended photolysis of **96d** and **96e**.[79]

Oxidation Reactions of Valence Isomers of Phosphinine: When the stable phosphabenzvalene **106** is heated with sulfur, the bicyclic phosphane sulfide **107** is formed, the structure of which has been confirmed by X-ray crystallography.[103] The assumption that the isomerization **106** → **108** precedes the oxidation is inconsistent with the fact that this step only occurs at much higher temperature (160°C as opposed to 120°C). Thus, the formation of **107** by oxidation of **108** with sulfur allows no conclusions to be drawn regarding the mechanism. It seems more plausible that **106** is first oxidized to the corresponding sulfide, which, in turn, gives the bicyclic compound **107**.[79]





109a: R = *t*Bu, 10%
109b: R = 1-Ad, 9%

110a, R = *t*Bu, 66%
110b, R = 1-Ad, 79%

107: ^{31}P NMR ($CDCl_3$), $\delta = 39.3$.

The oxidation of the 2-Dewar-phosphinines **96a** and **96c** with sulfur is more complicated; various products are formed. The 1-Dewar-phosphinine sulfides **109a** and **109b** are side products, while the main reaction is the incorporation of two equivalents of sulfur without rearrangement of the skeleton, giving the thiaphosphirane sulfides **110a** and **110b**.[104] There are no difficulties in interpreting the mechanism of the latter reaction. The structure of **110b** has been confirmed by X-ray crystallography.[104, 107]

The conversion of **96** to **109** is most easily understood if one assumes that a phosphinine sulfide (**101**, P=S instead of P) is first formed, which then undergoes an electrocyclic ring closure.[104]

3.4.2. New Phosphinines

Phosphinines with $\lambda^3\sigma^2$ phosphorus are mostly synthesized from pyrylium salts and one PH_3 equivalent.[96] New and versatile synthetic possibilities are opened up by the Diels–Alder reaction of phosphaalkynes with cyclic 1,3-dienes that have an easily eliminated group connecting C-1 and C-4.[49] Although all the reactions require rather high temperatures, the phosphaalkyne **3d** survives them without problem.

	a	b	c	d	e	f
R^1	Ph	Pr	H	H	Ph	H
R^2	Ph		Me	H	H	R^3	Ph		Me	H	Ph	
R^4	Ph	Pr	H	H	H	Et
X						
Yield [%]	92	93	61	91	48	54
δ (^{31}P)($CDCl_3$)	202	266	187	202	187	187

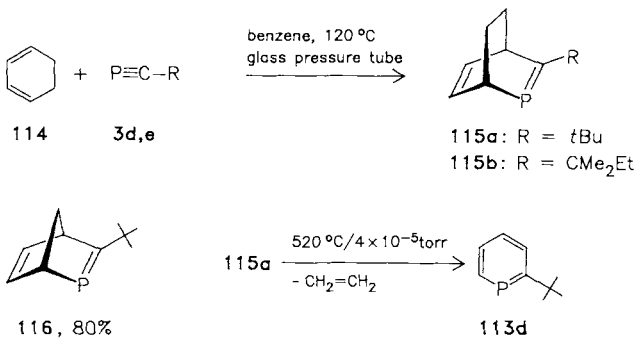
Suitable reactants include cyclopentadienones (**111a,b**; CO elimination) and the phosphole sulfide **111c** (Ph–P(=S) elimination)[108] as well as a α-pyrones (**111d–f**; elimination of CO_2). In all cases the yields of phosphinines (**113a**,[109] **113b**,[110] **113c,d**,[109] **113e,f**[110]) are good to very good. The bicyclic intermediates **112a–f** cannot, of course, be detected under these drastic reaction conditions.

Highly reactive phosphaacetylene **4** reacts with **111a**, even as the cooling bath warms up, to give 2,3,4,5-tetraphenyl-λ^3-phosphinine.[111] The Diels–Alder route can also be used to prepare 1,3λ^3-azaphosphinines from **3d** or **3i** and 2-trifluoromethyl-1,3-oxazin-6-one.[112]

3.4.3. Polycyclic Phosphorus Compounds

Bi-, tri-, and tetracyclic compounds containing three-valent two- or three-coordinate phosphorus can also be obtained by cycloaddition processes involving phosphaalkynes. It is important that, in contrast to **111**, the 1,3-dienes employed should have no easily eliminated "X" group.

Bicyclic Compounds: Apart from the reactions of cyclobutadienes such as **95a,b**, [4+2] cycloadditions with homologous cycloalka-1,3-dienes offer good chances of preparing 2-phosphabicyclic compounds with methano or ethano bridges. The 2-phosphabicyclo[2.2.2]octa-2,5-dienes **115a** and **115b**, prepared from **114** and the phosphaalkynes **3d**[109] and **3e**,[113] are thermally so stable that they can be purified by distillation. On the other hand, the 2-phosphabicycloheptadiene **116**, prepared from cyclopentadiene and **3d**, can only be handled in solution (ether, 20°C); attempts to isolate it led to its oligomerization.



115a: ^{31}P NMR ($CDCl_3$), $\delta = 226$. **115b**: ^{31}P NMR (C_6D_6), $\delta = 232$. **116**: ^{31}P NMR (C_6D_6), $\delta = 246$.

Flash pyrolysis of **115a** causes it to undergo a retro-Diels-Alder reaction. However, this is not the reverse of the reaction of formation, but involves the elimination of ethylene and the formation of the phosphabenzene **113d**.[109]

Phosphabarrelenes with $\lambda^3\sigma^3$ phosphorus are quite well known,[114] but those with a phosphaalkene unit still unknown. Attempts to synthesize a compound of this class by [4+2] cycloaddition of hexafluoro-2-butyne to 3-methyl-2-phosphanaphthalene failed, because the benzobarrelene, which is presumably formed initially, decomposed to 2,3-bis(trifluoromethyl)naphthalene and the phosphaalkyne **3a**.[115]

	R^1	R	Yield [%]	$\delta(^{31}P)$ ($CDCl_3$)
a	H	*t*-Bu	91	230
b	H	1-Ad	65	234
c	Me	*t*-Bu	87	246
d	Ph	*t*-Bu	28	235

In contrast, no difficulties are encountered in the Diels-Alder reaction of anthracene and its 9-substituted derivatives **117** with the phosphaalkynes **3d** and **3i**; this reaction gives the barrelenes **118a–d** containing low-coordinate phosphorus.[116]

Tricyclic Compounds: The result of the reaction of the phosphaalkyne **3d** with acyclic 1,3-dienes **119a–d** is unexpected in that tricyclooctenes **122a–d** containing one diphosphirane unit are formed, irrespective of the ratio of the reactants. The dienophile and the diene react in the ratio 2:1. The structure of the products is based upon the X-ray analysis of **122a**. The high-field chemical shifts of both phosphorus nuclei in the ^{31}P NMR spectra of **122** reflect the conversion of the phosphorus from $\lambda^3\sigma^1$ to $\lambda^3\sigma^3$.[117]

The mechanism of the formation of the tricyclic compound can be understood as involving an initial Diels-Alder reaction **119** + **3d** → **120** followed by the ene reaction **120** + **3d** → **121**, which has not previously been observed

	R^1	R^2	R^3	R^4	Yield [%]	$\delta(^{31}P)$ P-1 / P-7
a	H	H	H	H	90	−190 / −195 [a]
b	H	H	Me	H	85	−166 / −202 [a]
c	H	Me	Me	H	86	−166 / −211 [b]
d	H	H	H	Me	66	−174 / −176 [b]

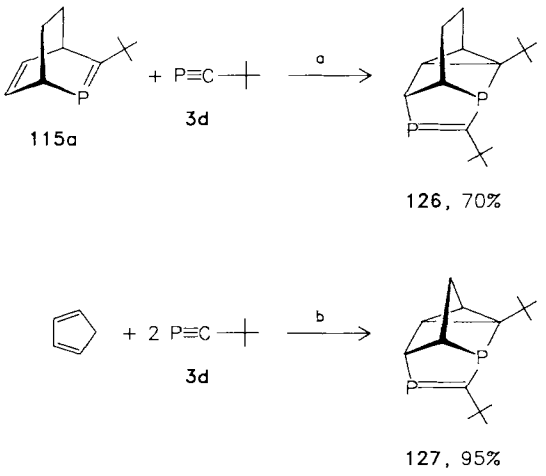
[a] In C_6D_6. [b] In $CDCl_3$.

for phosphaalkynes (see Section 3.5). Finally, the intramolecular [4+2] cycloaddition **121** → **122** takes place. The first step is not regiospecific: with 1,3-butadienes **119b** and **119d**, in addition to the major products **122b** and **122d**, respectively, side products are obtained in which the order of the substituents R^1 to R^4 is reversed. On the other hand, the subsequent ene reaction always proceeds with the formation of a PP bond.[117]

	R^1	R^2	Yield [%]	$\delta(^{31}P)$ ($CDCl_3$)
a	H	H	90	−234
b	CH_2–CH=CH–CH_2		33	−197
c	Me	Me	60	−192
d	CH_2–CH_2–CH_2		46	−205

These conclusions on the sequence of reactions are confirmed by the reaction of the cyclohexa-1,4-dienes **123a–d** with **3d** under similar conditions to yield the phosphatricyclooctenes **125a–d**, although in this case, too, the product of the ene reaction (**124**) cannot be detected directly. However, as seen from the composition of the products formed, the ene reaction must be highly specific.[117]

Tetracyclic Compounds (Homo-Diels-Alder Reaction): Homo-Diels-Alder reactions in the chemistry of carbon compounds are, by comparison with the Diels-Alder reac-



a) C_6H_6, 140°C/5 bar. b) Ether, 180°C/5 bar. **126**: ^{31}P NMR (C_6D_6), $\delta = -16, 316$. **127**: ^{31}P NMR (C_6D_6), $\delta = 5, 322$.

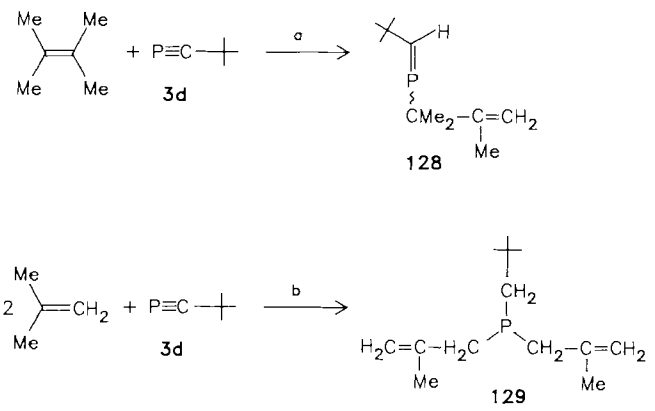
tion itself, a rarity.[118] However, they expand enormously the methods available for preparing phosphorus-containing tetracyclic compounds.

Thus, when the phosphaalkyne **3d** is heated with **115a**, it adds regiospecifically to form the tetracyclic compound **126**. Three- and two-coordinate phosphorus can be identified unambiguously from the high- and low-field chemical shifts in the ^{31}P NMR spectrum.[119] This diphosphatetracyclodecene **126** has ultimately been built up from cyclohexa-1,3-diene **114** and two equivalents of **3d**. A corresponding sequence of reactions has been achieved with cyclopentadiene and **3d**, leading to the formation of **127**.[119]

3.5. The Ene Reaction

Ene reactions with phosphaalkynes have previously been postulated to provide a plausible explanation of the reaction of **119** with **3d** (molar ratio 1:2) to give **122** and of **123** with **3d** to give **125**.[117] This suggested that this type of reaction should be attempted with phosphaalkynes directly.

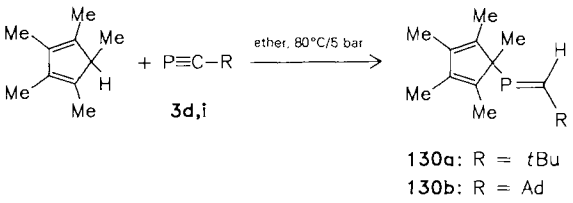
This has been achieved with 2,3-dimethyl-2-butene and **3d** and leads to the formation of the kinetically stabilized phosphaalkene **128**.[117] This addition reaction can also be carried out with isobutene and **3d**. Indeed, it occurs not once but twice, first on **3d** and then on the phosphaalkene



a) C_6H_6, 130°C, pressure vessel. b) 120°C, pressure tube.

formed as an intermediate, yielding the phosphane **129**.[117]

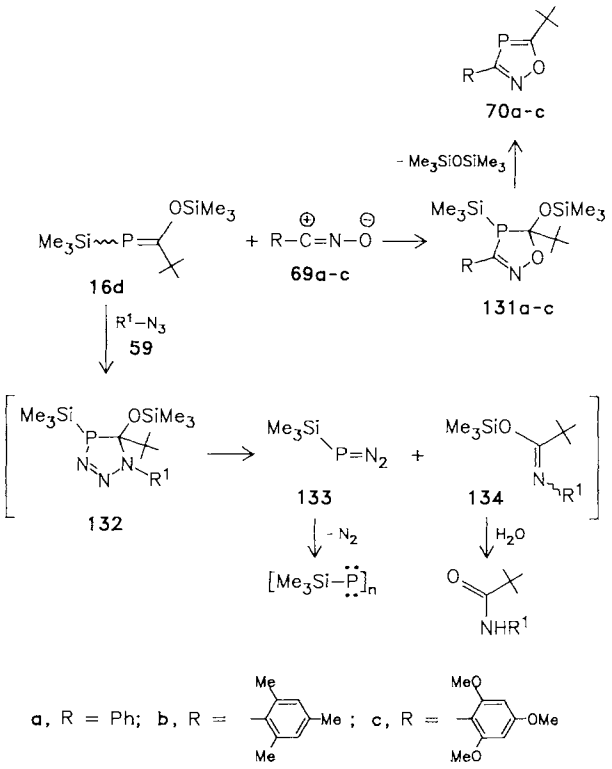
A particularly fascinating reaction is observed between 1,2,3,4,5-pentamethylcyclopentadiene and the phosphaalkynes **3d** and **3i**, where the Diels–Alder reaction is completely suppressed in favor of the ene products **130a** and **130b**, respectively.[119] The room temperature ^1H NMR



spectrum of **130a** shows only one resonance for the 15 methyl hydrogen atoms, which can only be interpreted as meaning that the phosphaalkene unit undergoes a rapid degenerate [1,5]-sigmatropic shift. On cooling the sample, the coalescence temperature is reached at ca. −40°C, and at −70°C three signals are observed, as expected for a nonfluctuating system **130a** ($\delta = 1.27$, 1.77, and 1.85, ratio 3:6:6).[119]

3.6. Synthetic Equivalents of Phosphaalkynes

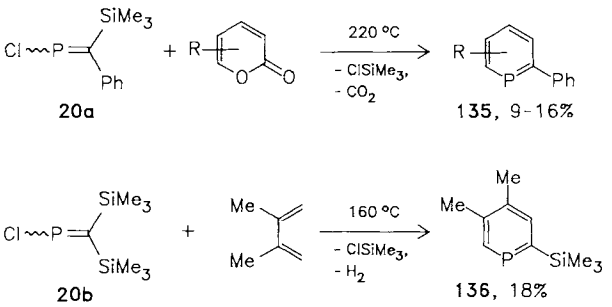
Phosphaalkynes in cycloaddition processes can be replaced by their phosphaalkene precursors. Thus, the nitrile oxides **69a–c** add to the phosphaalkene **16d** in ether or pentane at 25°C to give the corresponding dihydro-1,2,4-oxazaphospholes **131**, which then eliminate hexamethyldisiloxane either spontaneously (**131a,b**) or catalyzed by sodium hydroxide (**131c**) to aromatize to **70a–c**.[120] Compounds **70a–c** can also be prepared directly from **3d** and the same dipoles (see Section 3.3.4). 1*H*-1,2,4-Diazaphos-



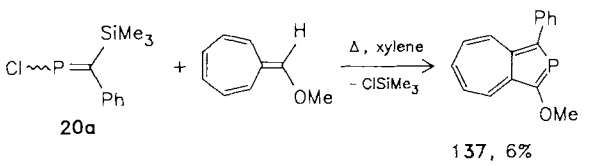
pholes with phenyl or trimethylsilyl substituents in the 5-position can be prepared similarly by the reaction of the phosphaalkenes **20a** and **20b** with diazomethyl compounds. In this case the elimination of chlorotrimethylsilane is responsible for the formation of the heteroarenes.[22, 121, 122]

Limitations to this method become obvious when the orientations of the dipoles of the phosphaalkene and phosphaalkyne are no longer identical. For example, reaction of **16d** with azides **59** (at −15 to +25°C in ether) does not give 3*H*-1,2,3,4-triazaphosphole **60**, since the orientation of the dipole is reversed in the primary step (see Section 3.3.3). The regioisomeric adducts **132** undergo rapid cycloreversion to the phosphazide **133** (which is thermally unstable and decomposes) and the imidoesters **134** (which hydrolyze during the workup).[120]

Phosphaalkenes with groups that can be eliminated are also used for the synthesis of phosphinines. Thus, the phosphinine **135** is obtained from **20a** and pyrone in the presence of potassium fluoride and 18-crown-6 at very high temperature.[123] When **20b** reacts with 2,3-dimethyl-1,3-butadiene in *o*-dichlorobenzene at room temperature, the first product is the usual Diels–Alder adduct. To effect its aromatization to **136**, however, similarly drastic conditions are required as for the reaction just discussed.[122]



In the synthesis of the first phosphaazulene **137**, the phosphaalkene **20a** was taken as the equivalent of Ph–C≡P **3s**. The decisive step is an [8+2] cycloaddition with methoxyheptafulvene, which is followed by the elimination of chloromethylsilane and hydrogen to afford **137**.[124] For both the cycloadditions with **20a** it cannot be excluded a priori that the products are formed in part or entirely from the phosphaalkyne **3s** that has formed in the reaction mixture (see Section 2.2). Both reactions also require the addition of [18]crown-6.

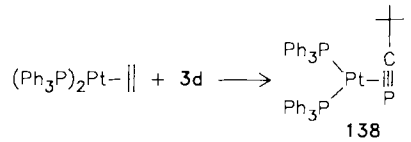


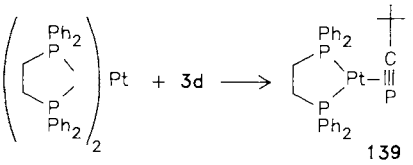
3.7. Metal Complexes

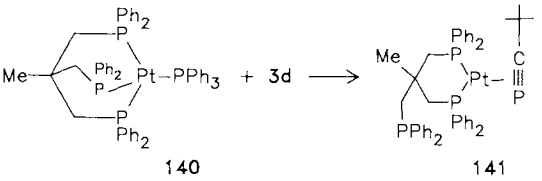
The reactions discussed above show that phosphaalkynes are much more closely related to acetylenes than to nitriles. Their photoelectron spectroscopic properties[31, 61] suggest that they should be good ligands in metal complexes.[61] In principle, they could act as two-, four-, or six-electron donors. Side-on, end-on, and bridging coordination are conceivable and all have been realized. In practice, the thermally stable *t*BuC≡P **3d** has nearly always been chosen as the ligand.

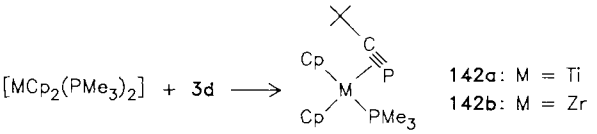
3.7.1. Side-on Coordination

Mononuclear complexes with η^2-bonded phosphaalkynes have been prepared with platinum, titanium, and zirconium as the central metal. Thus, the complexes **138**, **139**, and **141** can be prepared from **3d** and ethenebis(triphenylphosphane)platinum,[125] [Pt(diphos)$_2$],[126] and the complex **140**, respectively.[127] Replacement of a phosphane ligand in the corresponding bis(trimethylphosphane) compounds by **3d** affords the titanium and zirconium complexes **142a** and **142b**.[128]







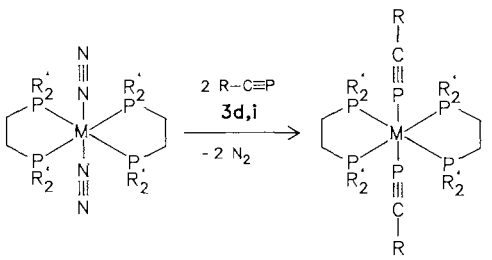


The side-on coordination of the phosphaalkyne in complexes **138**[125] and **142a**[129] has been confirmed by X-ray crystallography. Characteristic of both compounds is the lengthening of the PC bond from 1.54 Å in **3d** when not coordinated to 1.672 Å (**138**) and 1.636 Å (**142a**) when complexed.

3.7.2. End-on Coordination

Until recently, end-on coordination of phosphaalkynes by the nonbonding electron pair on the phosphorus atom was unknown. Apparently, this mode of bonding is found only when η^2-bonding cannot occur for steric reasons.

The only known examples are the compounds **144a–c**, where the end-on-bound N_2 ligands in the dinitrogen complexes **143a** and **143b** have been replaced by the phosphaalkynes **3d** and **3i** to form 2:1 complexes.[130] A mixed complex has also been synthesized by exchange of just one dinitrogen ligand (**143**, M = Mo, R′ = C_6H_4–Cl(4), *t*Bu–C≡P instead of one N≡N).[130]



143a: M = Mo, R' = Et
143b: M = W, R' = Ph

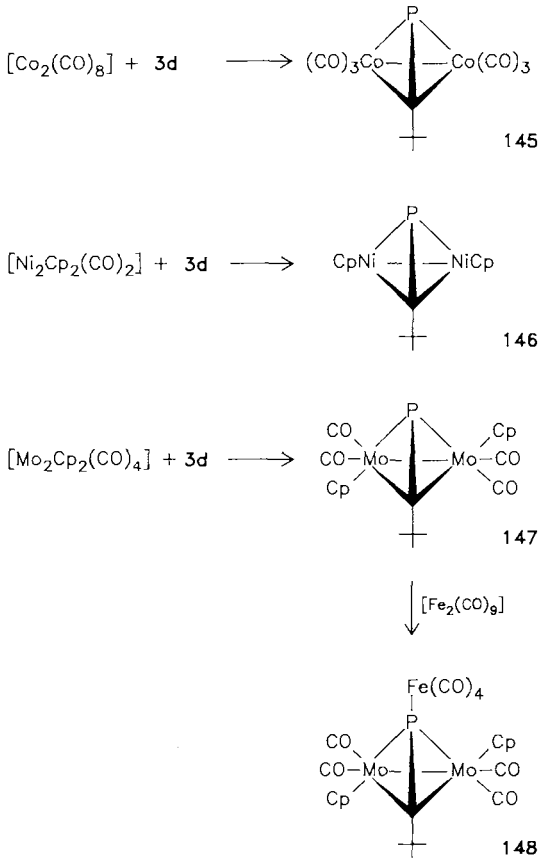
144a: M = Mo, R = *t*Bu, R' = Et
144b: M = Mo, R = 1-Ad, R' = Et
144c: M = W, R = *t*Bu, R' = Ph

The crystal structure of **144b** is characterized by a linear chain of seven atoms, C-C-P-Mo-P-C-C, which includes the two phosphaalkyne ligands in *trans* positions. The PC bond length of 1.520 Å in **144b** is shorter than in "free" **3d** and in the side-on complexes **138** and **142a** (see Section 3.7.1).

3.7.3. Bridging Coordination

Several dinuclear metal carbonyl complexes that form tetrahedral bimetallic complexes with η^2,η^2-coordinated alkynes[131] behave in an analogous fashion with the phosphaalkyne **3d**. The dinuclear complexes **145**,[125,132] **146**,[133] and **147**,[132,134] all of which have a tetrahedrane skeleton, were thereby obtained.

The crystal structure of **147** reveals that the PC bond length is not typical of a single bond (≈1.82–1.87 Å); the bond distance of 1.719 Å falls more in the range expected for a double bond.[134] In the complexes **145**, **146**, and **147** the phosphorus atom can coordinate to a second metal complex fragment using its nonbonding electron pair. Thus, treatment of the dimolybdenum complex **147** with $[Fe_2(CO)_9]$ leads to the formation of compound **148**,[135] in which the phosphaalkyne acts as a six-electron donor. Similar displacement reactions can be carried out such that moieties with tungsten,[132] platinum, or palladium[136] as the central atom can be coordinated to the phosphorus atom of **147**. The coordination number of the phosphorus atom in the dicobalt complex **145** can be increased in the same way.[132,137]



145

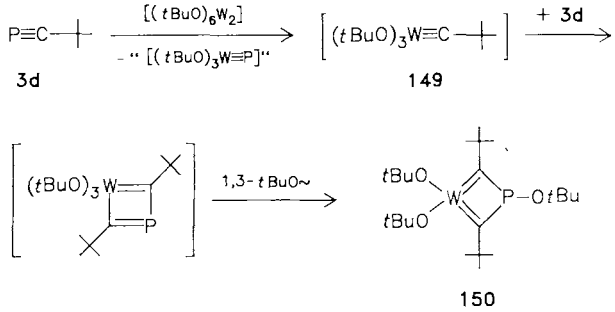
146

147

148

Instead of a phosphaalkyne as a four-electron donor, one can take its synthetic equivalents to prepare dicobalt complexes that have a tetrahedrane structure. Thus, the reaction of $[Co_2(CO)_4]$ with dichloro(dichloromethyl)phosphanes ($RCCl_2-PCl_2$, R = Me, Ph, $SiMe_3$) proceeds with dehalogenation to give complexes of the type **145** (R instead of *t*Bu) in rather low yields.[137]

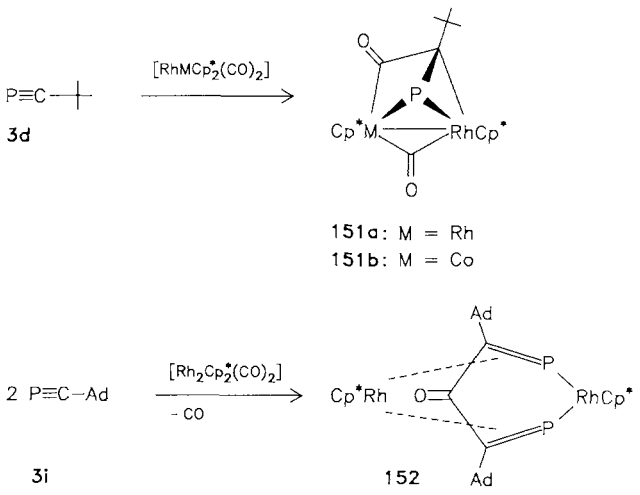
In contrast to $[Mo_2Cp_2(CO)_4]$, the initial reaction of hexa-*tert*-butoxyditungsten (which also has a metal–metal triple bond) with **3d** is a metathesis to afford the intermediate **149**.



3d **149** **150**

Cycloaddition of the phosphaalkyne **3d** to the tungsten–carbon triple bond is held to account for the formation of a further intermediate with antiaromatic character. This gives the stable final product **150** by a 1,3 shift of a *tert*-butoxy residue from tungsten to phosphorus.[47,68]

When the CO-bridged metal complex $[RhMCp^*_2(CO)_2]$ (M = Rh, Co) is treated with the phosphaalkyne **3d**, the



3d

151a: M = Rh
151b: M = Co

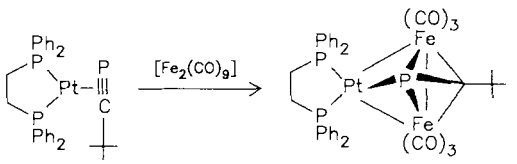
3i **152**

$Cp^* = (\eta^5\text{-}C_5Me_5)$

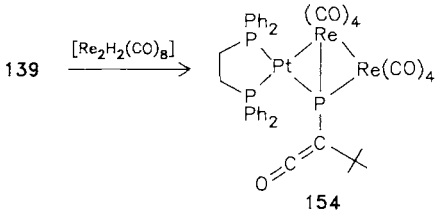
products are not, as might have been expected, complexes with a tetrahedrane structure. Instead, the compounds **151a**[134] and **151b**[138] are formed. As with the corresponding reactions of alkynes,[139] the addition of the phosphorus atom of the phosphaalkyne to the Rh–Rh or Rh–Co double bond is accompanied by insertion of the phosphaalkyne carbon into one of the Rh–CO bonds. The second carbonyl group remains as a bridging ligand.

If an excess of the phosphaalkyne **3i** reacts with $[Rh_2Cp^*_2(CO)_4]$, then, in addition to **151a** (Ad instead of *t*Bu), the complex **152** is formed, which contains the previously unknown ligand unit P=CR–C(=O)–CR=P. According to the crystal structure analysis, the P–C distance is 1.783 Å.[138] In this case, too, the formation of this complex has its parallel in the chemistry of alkynes.[140]

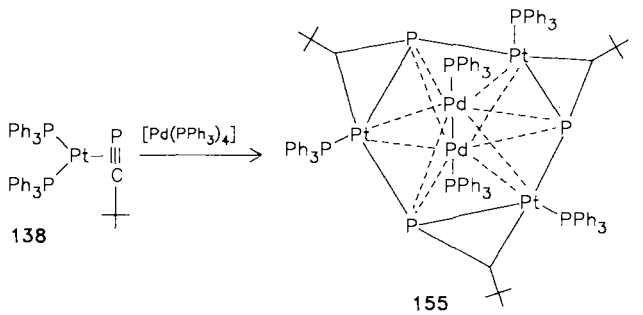
Metal complexes with bridging phosphaalkyne ligands can also be obtained from the side-on complexes mentioned at the beginning of this section. An example is the trinuclear cluster compound **153** formed from **139** and $[Fe_2(CO)_9]$.[126] The X-ray crystallographic study of **153** shows that each metal atom is bound to all the others.[126]



139 153



154



138 155

A new and unusual result is obtained when **139** is treated with $[Re_2H_2(CO)_8]$: the phosphanediyl complex **154** is formed in a low yield (10%).[141] The critical step in incorporating the originally η^2-coordinated phosphaalkyne into the phosphanediyl ligand in the product, in which it is bound to all three metal atoms, is the coupling of CO with the carbon atom of the phosphaalkyne.

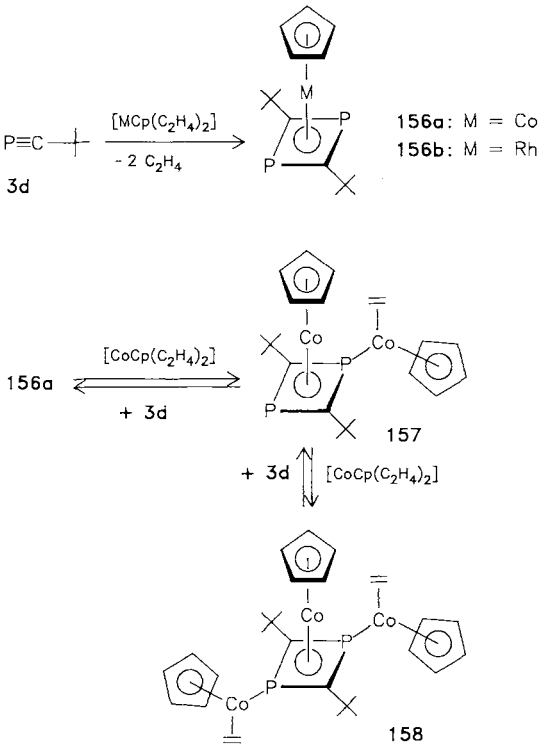
Finally, the cluster compound **155**, prepared from **138** and $[Pd(PPh_3)_4]$, should be mentioned: this compound contains five metal atoms.[142] Both palladium atoms take up axial sites (bond length: 2.679 Å), while the platinum atoms are found in equatorial positions. The three phosphaalkyne units each bridge two platinum atoms; they are η^2-coordinated to one of these platinum atoms, the other forming a σ bond with the nonbonding electron pair of the phosphorus.

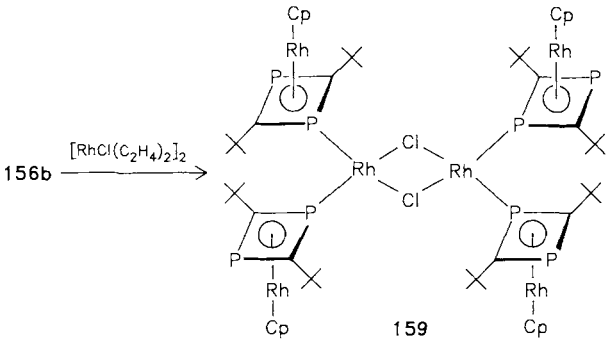
3.7.4. Cycloaddition in the Coordination Sphere of Metal Atoms

In the previous sections it was shown that in metal complexes phosphaalkynes can act as two-, four-, or six-electron ligands. However, until recently it was not known whether they can be cyclooligomerized in the coordination sphere of suitable metals. This has now been achieved, once again most notably with the phosphaacetylene **3d**, which undergoes di- and trimerization to give new ligand systems.

Complexes of Cyclic Dimers: The cyclodimerization of the phosphaalkyne **3d** was achieved by drawing upon experience gained in the cyclooligomerization of acetylenes with $[CoCp(C_2H_4)_2]$.[143] The reaction, carried out in ether/pentane at $-30°C$, is regiospecific and affords η^5-cyclopentadienyl(η^4-1,3-diphosphacyclobutadiene)cobalt **156a** (67%).[144–146] If the relative amount of $[CoCp(C_2H_4)_2]$ is increased significantly, then **156a** reacts further to produce the di- and trinuclear complexes **157** and **158**, respectively. The cobalt ligands σ-bound to phosphorus can be removed again by adding **3d** to produce **156a**.[145, 146]

$[RhCp(C_2H_4)_2]$ can also be used to cyclodimerize **3d** (→ **156b**), but the yield is unconvincing.[144] The formation of compounds containing two and three rhodium complex fragments (**157** and **158**, Rh instead of Co) is not observed. However, **156b** can be converted with $[RhCl(C_2H_4)_2]_2$ into the hexarhodium complex **159** by a similar substitution process.[147]

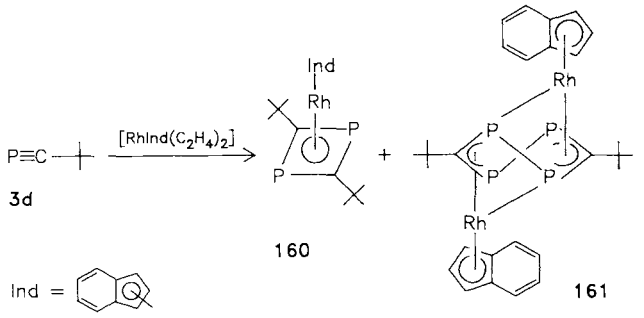




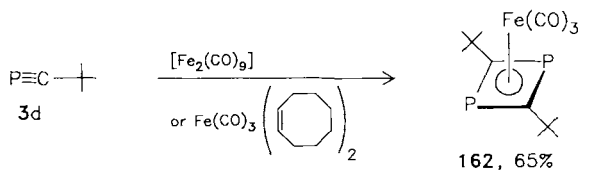
Cyclodimerization with the bis(ethene)pentamethylcyclopentadienyl complexes of cobalt, rhodium, and iridium[144] appears to have no advantages over the reaction **3d** → **156a**.

Whereas the indenyl complex $[CoInd(C_2H_4)_2]$ reacts with **3d** and **3k** to form the expected 1,3-diphosphacyclobutadiene complexes of type **156** in the normal way,[145,146] the corresponding reaction with $[RhInd(C_2H_4)_2]$ is unusual.

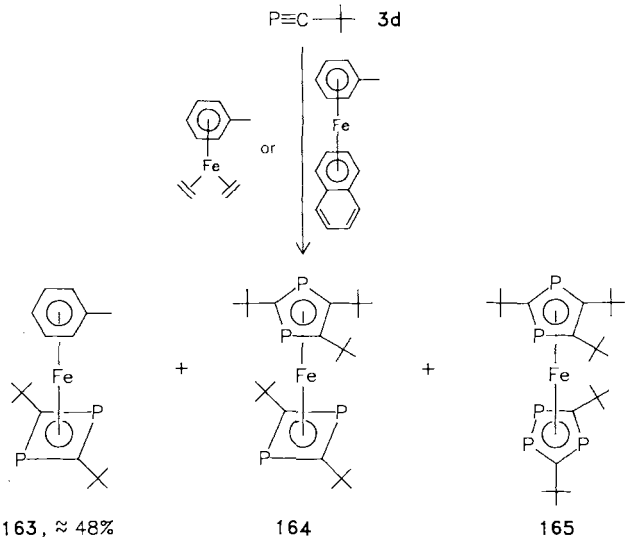
Although in this case, too, the dimer complex **160** is formed, a second product, a dinuclear complex with the structure **161**, is isolated.[148] According to the X-ray crystallographic analysis, the six-membered ring is somewhat distorted. The *t*Bu–C fragments that have apparently been "lost" turn up as di-*tert*-butylacetylene. It is presumed that steric interactions prevent further $MInd(C_2H_4)_2$ ligands from binding to η^4-diphosphacyclobutadiene(η^5-indenyl)cobalt and -rhodium complexes in the same way as in **157** and **158**.[146]



The tricarbonyliron complexes have a special significance in the chemistry of cyclobutadienes because the antiarene can be liberated from them in various ways.[149] The corresponding iron complex of 2,4-di-*tert*-butyl-1,3-diphosphacyclobutadiene (**162**, 65%) is obtained by the cyclodimerization of **3d** with diiron nonacarbonyl at 100°C or with tricarbonylbis(cyclooctene)iron at only −30°C.[150]

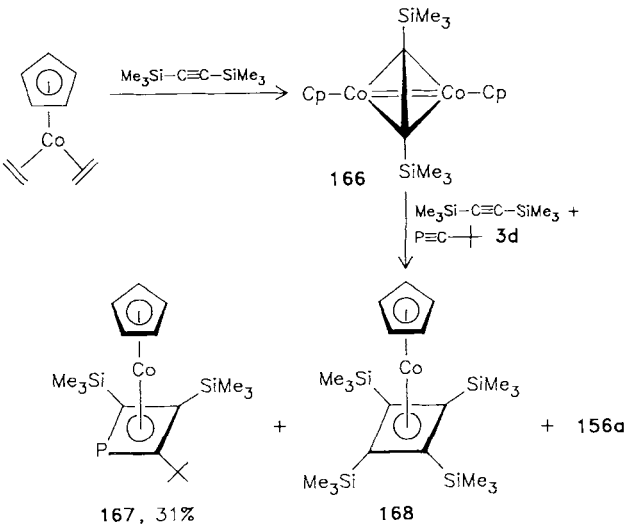


By contrast, the reaction of **3d** with bis(ethene)(toluene)iron and 1-methylnaphthalene(toluene)iron is somewhat more complicated.[151] In both cases the major product is the 1,3-diphosphacyclobutadieneiron complex **163**, but, in addition, a mixture of the two new sandwich complexes **164** and **165** is formed.[152] Although the presence of di- and triphosphacyclopentadienyl ligands in these two complexes must mean that **3d** has been cleaved in a metathetical reaction, no mechanistic studies have yet been carried out on this reaction.[153] It should be mentioned that the 3,5-di-*tert*-butyl-1,2,4-triphosphacyclopentadienide ligand in **165** can be isolated as the lithium salt (with three moles of coordinated 1,2-dimethoxyethane) if the phosphaalkyne precursor **16d**, used to prepare **3d**, is treated with $LiP(SiMe_3)_2 \cdot 2THF$.[47,68]



Attempts to codimerize **3d** and 2-butyne using $[CoInd(C_2H_4)_2]$ failed because the triple bond systems react independently of one another: the phosphaalkyne dimerizes to the 1,3-diphosphacyclobutadiene complexes of type **156**, while the alkyne trimerizes to hexamethylbenzene, probably via η^6-hexamethylbenzene(η^5-indenyl)cobalt.[146]

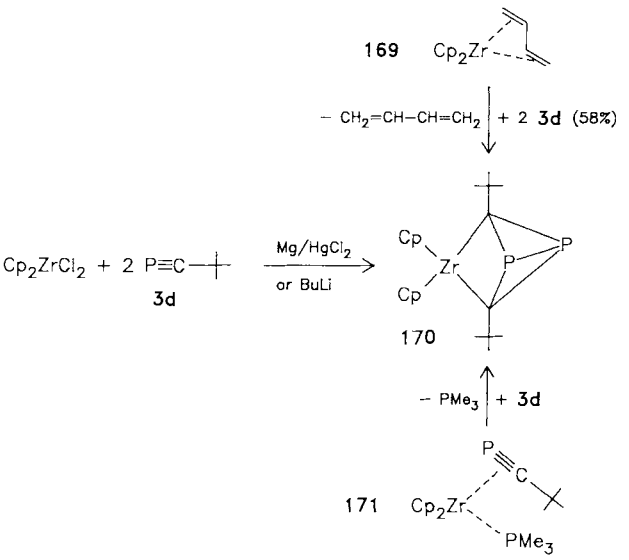
On the other hand, the codimerization experiment with the sterically demanding bis(trimethylsilyl)acetylene (which apparently cannot trimerize because it is too bulky), $[CoCp(C_2H_4)_2]$, and **3d** succeeded. In addition to the desired phosphacyclobutadiene complex **167**, the "pure"



dimer complexes **168** and **156a** are formed.[154] One must assume that the dinuclear cobalt complex **166** is formed first[143,155] and that this then reacts with the molecules containing triple bonds to form the products.

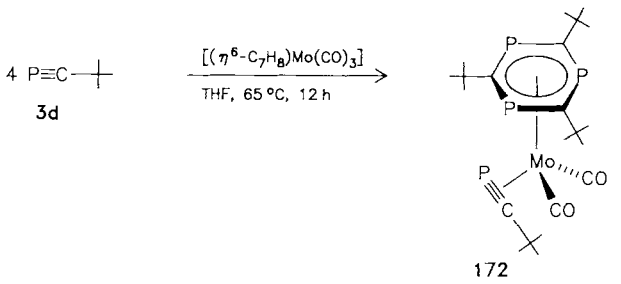
Some of the spectroscopic and structural properties of the 1,3-diphosphacyclobutadiene complexes are illustrated by the data for **156a** and **160** (Co instead of Rh). The crystal structure analysis of **160** (Co instead of Rh) shows that the bonding relationships correspond to those of metal cyclobutadiene complexes.[149] The delocalization of the electrons in the four-membered ring can be seen from the equidistant PC bond distances (1.797 Å)[146] (see also Ref. [144]). The signals in the ^{31}P NMR spectrum are observed at $\delta = 38.1$ and 38.0, respectively.[146] The ions $M^{\oplus} - P_2$ and $M^{\oplus} - t\text{Bu}-\text{C}\equiv\text{C}-t\text{Bu}$ are particularly prominent following fragmentation induced by electron collision.[146] It is not clear whether they are formed after **156a** and **160** (Co instead of Rh) isomerize to tetrahedrane-like compounds or complexes similar to **170**.

A completely new type of phosphaalkyne dimerization is encountered when $[ZrCp_2Cl_2]$ is treated with **3d** in the presence of magnesium or butyllithium. Presumably, it starts with the coordinatively unsaturated zirconocene Cp_2Zr. The product is the 1,3-diphosphabicyclo[1.1.0]butane complex **170** (53 and 26% yields, respectively).[156] The corresponding hafnium compound is obtained under similar conditions in only a low yield (7%).[128]



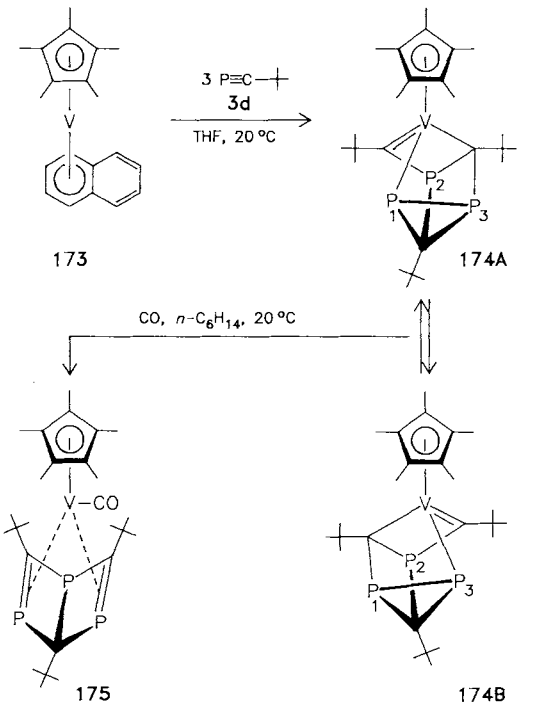
Complex **170** can also be prepared from the complexes **169** and **171**, which contain the Cp_2Zr^{II} fragment, by displacement of the ligands and incorporation of two equivalents of **3d**.[156,128] The crystal structure indicates that the PP bond is relatively short (2.147 Å) and that there is no interaction between Zr and the phosphorus atoms (2.906 and 2.909 Å. respectively).[156] Interestingly, there are no parallels here with the chemistry of the alkynes, which form metallacyclopentadienes, not bicyclic dimeric complexes.[157]

Complexes of Cyclic Trimers: It is well known that the preferred reaction of alkynes on transition-metal centers is the trimerization to benzene derivatives.[158] Since the chemistry of alkynes, including complex chemistry, is with few exceptions, astoundingly similar to that of phosphaalkynes, it would seem quite possible to trimerize the heteroalkynes to 1,3,5-triphosphabenzenes. However, this was not achieved, as one might have expected, on the classical catalysts involving Co^{I}, Ni^{0}, or Ni^{II} and Pd^{0} compounds, but on derivatives of metals of the vanadium and chromium groups.



When tricarbonyl(η^6-cycloheptatrienyl)molybdenum is heated with **3d** in tetrahydrofuran, the heteroarene complex **172** is formed.[159] The structure has been assigned on the basis of high-resolution mass spectroscopy and ^{31}P NMR spectroscopy ($\delta = +25.2$, -228.2, intensity ratio 3 : 1).

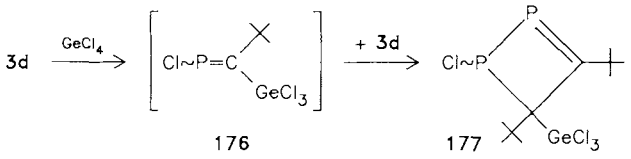
At the same time, **3d** was successfully cyclotrimerized in the coordination sphere of vanadium.[160] The primary product of the reaction with the arene complex **173**[161] at room temperature is the 14-electron trimer complex **174**, the structure of which has been confirmed by X-ray crystallography.[160] However, only one signal is observed for P-1 and P-3 in the ^{31}P NMR spectrum at room temperature ($\delta = -58.2$ at 20°C). On cooling the sample, this signal splits into two resonances ($\delta = +140.4$ and -234.4 at -100°C) and the chemical shift of P-2 remains constant ($\delta = -130.9$). A valence isomerization **174A** ⇄ **174B** must therefore be taking place.



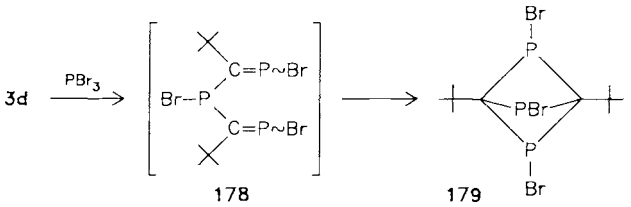
Treatment of **174** with carbon monoxide results in binding of CO to vanadium and rearrangement of the trimer skeleton. The product, **175**, is the first example of a complex containing a Dewar 1,3,5-triphosphabenzene bound to a metal (crystal structure).[160]

3.7.5. *Further Aspects*

It has already been mentioned that the halides of the main-group elements undergo 1,2-addition on the PC triple bond (see Section 3.1). The same is basically true of the reaction of germanium tetrachloride and phosphorus tribromide with **3d**, but in both cases the phosphaalkenes formed initially (**176** and **178**, respectively) undergo further reactions.[47,68]

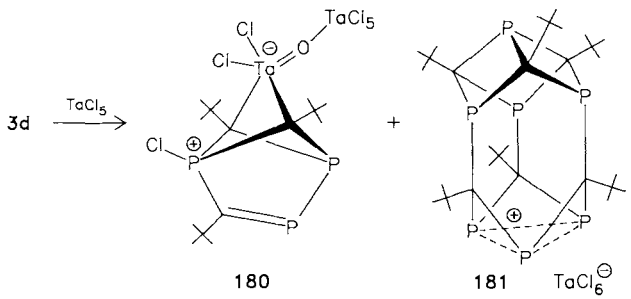


176 177



178 179

A further equivalent of **3d** adds to **176** in a [2+2] process to form the substituted 1,2-diphospha-2-cyclobutene **177**.[68] It appears certain that **177** does not undergo the electrocyclic ring-opening reaction to form the vinyldiphosphene for energetic reasons. The 1,4-bis(phosphaalkenyl)phosphane **178** isomerizes with conversion of the $\lambda^3\sigma^2$ phosphorus to $\lambda^3\sigma^3$, yielding the triphosphabicyclo[1.1.1]pentane **179**.[47,68] Tungsten hexachloride and molybdenum pentachloride react with **3d** in an unusual manner in that the PC triple bond of the phosphaalkyne is cleaved with the formation of the ("phosphorus-free") di-*tert*-butylacetylene complexes of tetravalent tungsten[47,68,162] and trivalent molybdenum,[47,68,163] in which the remaining available coordination sites are occupied by the solvent (Cl_3PO).



180 181

On the other hand, the reaction of **3d** with tantalum pentachloride takes a completely different course. The major product is the chlorophosphonium oxotantalate **180**, the zwitterionic structure of which incorporates three *t*BuCP units.[47,68] Its structure and that of the side product **181** have been confirmed by X-ray analysis. The latter contains six phosphaalkyne molecules and has triphosphatrishomocyclopropenylium character.[47,68]

4. Prospects

There can be no doubt that entry into the chemistry of the phosphaalkynes has been achieved. The behavior of the heteroalkyne in 1,2 additions, 1,3-dipolar additions, and Diels–Alder reactions, as well as its fixation to metal centers, is now known in outline. However, by comparison with the synthetic potential of the acetylenes, many questions remain unanswered. While almost all the reactions that have been carried out to date have involved kinetically stabilized phosphaalkynes (i.e., those with bulky substituents), in the future greater attention will have to be paid to the more short-lived members of this class of compounds. The introduction of donor and acceptor substituents, which has been neglected, will allow conclusions to be reached on the mechanisms of the reactions. The behavior of phosphaalkynes as ligands awaits a more thorough investigation. The same can be said of their oligomerization, which promises more unexpected results. There is almost nothing known about the $\lambda^5\sigma^3$-phosphaalkynes mentioned in the introduction. One does not need to be a prophet to predict surprises in this particular field.

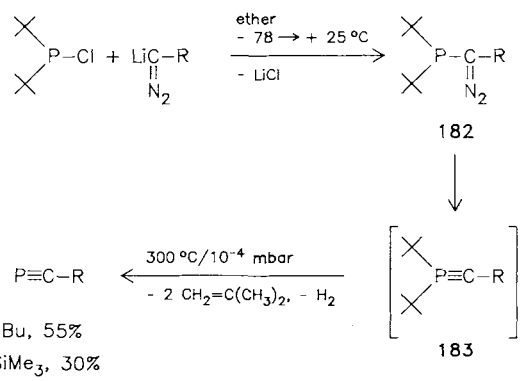
5. Addendum

The rapid rate of development in the chemistry of phosphaalkynes is reflected in the appearence of important results during the period between the submission of the manuscript of this review and the preparation of the galley proofs. This justifies an update.

5.1. Synthesis

A new synthesis of λ^3-phosphaalkynes has been reported, starting with phosphino-diazo compounds, which, as discussed in Section 1, are also suitable for preparing λ^5-phosphaalkynes (**5**→**6**). A necessary condition for the preparation of phosphaalkynes of type **3** is that the phosphorus atom should have substituents that can be eliminated.

When lithiated diazomethyl compounds are subjected to electrophilic diazoalkane substitution[164] with di-*tert*-bu-

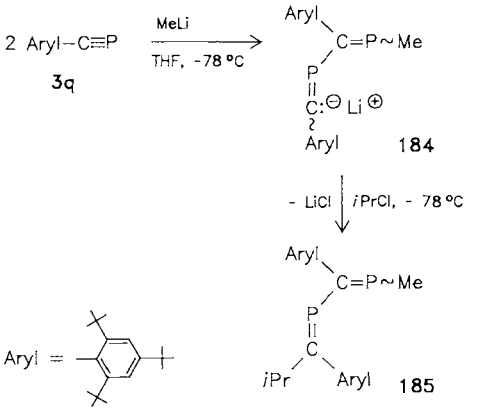


3d: R = *t*Bu, 55%
3t: R = $SiMe_3$, 30%

tyl(chloro)phosphane, the thermally rather stable (diazomethyl)phosphane **182** is formed.[165] The flash pyrolysis of this compound was originally carried out with the intention of isolating kinetically stabilized λ^5-phosphaalkynes **183**. This failed since even at moderate temperatures abstraction of isobutylene and hydrogen occurs to afford the λ^3-phosphaalkynes **3d** and **3t**.[165]

5.2. 1,2 Additions

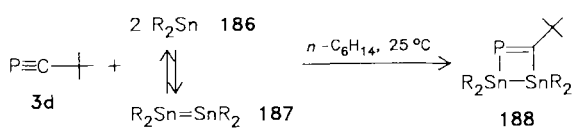
Although the addition reactions of hydrogen halides, boron tribromide, and tin tetrabromide to phosphaalkynes (see Section 3.1) reveal the polarization of the PC triple bond, they are of no preparative value. A 1,2 addition of more promise as regards synthetic application is the reaction of **3q** with methyllithium, the result of which is dependent upon the ratio of the reactants.



After hydrolysis, the 1:1 reaction yields, as expected, 2,4,6-tri-*tert*-butylbenzylidene(methyl)phosphane (i.e., a phosphaalkene).[166] On the other hand, when the same reaction is carried out in the ratio 2:1, the methyllithium adduct formed initially reacts with the "excess" **3q** to afford the lithium derivative **184**. This can be alkylated with isopropyl chloride to give the 1,3-diphospha-1,3-diene **185**.[166]

5.3. [2+1], [2+2], and [2+3] Cycloaddition

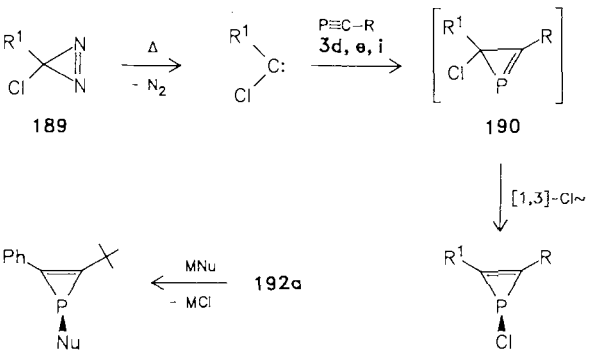
The potential of cycloaddition reactions of phosphaalkynes towards electron-deficient species has recently been expanded most significantly. The germanediyl (germylene) $Ge[CH(SiMe_3)_2]_2$ adds smoothly to **3d**, analogously to the previously known reaction of the Si analogues (see Section 3.2), to afford the corresponding phosphagermirene (**26a**, $Ge[CH(SiMe_3)_2]_2$ instead of $SitBu_2$, 80%). The P–C bond distance has been determined by X-ray crystallography to be 1.661(11) Å.[167]



R = $CH(SiMe_3)_2$

It might be anticipated that **3d** would react analogously with the stannanediyl (stannylidene) **186**, which is presumably in equilibrium with the corresponding distannene **187**, at least in solution.[168] However, instead of a [2+1] cycloaddition, a [2+2] cycloaddition occurs, forming the phosphadistannacyclobutene **188**.[169] The P=C bond distance [1.697(15) Å] is in agreement with the suggested structure.[169]

The addition of carbenes to phosphaalkynes **3** opens up completely new perspectives. While diazo compounds are unsuitable as precursors for the carbenes because they undergo rapid 1,3-dipolar cycloaddition with the triple bond (see Sections 3.3.1 and 3.3.2), the cycloisomeric diazirines serve the purpose.



191a: Nu = N_3
191b: Nu = $C(=N_2)SiMe_3$

192a: R = *t*Bu, R^1 = Ph, 63%
192b: R = CMe_2Et, R^1 = OPh, 26%
192c: R = 1-Ad, R^1 = Ph, 24%

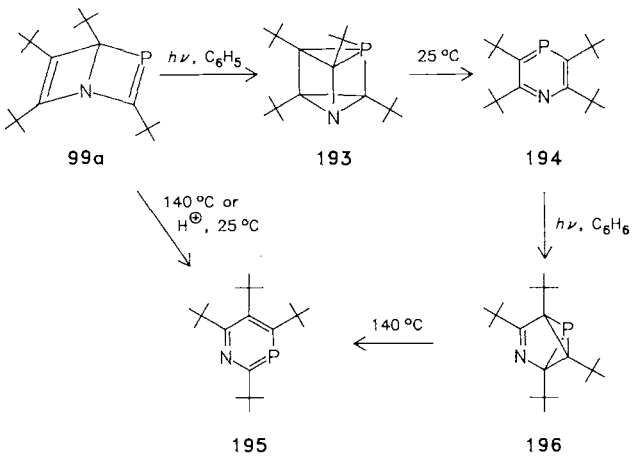
If one warms the chlorine-substituted diazirines **189** in an excess of **3d**, **3e**, or **3i**, the carbenes formed in the initial reaction undergo [2+1] cycloaddition to yield the 2*H*-phosphirenes **190**, which, however, cannot be isolated. Instead one obtains the 1*H* isomers **192a–c**, which are formed by a [1,3] chlorine shift and which are obviously more stable than the isomers with a PC double bond.[170] Presumably the chlorine substituent does not lie in the plane of the three-membered ring, since possible aromatic character would then be lost.[171]

Nucleophilic exchange of halogen allows numerous variations on the substitution at phosphorus to be achieved. Thus, **192a** can be converted into the 1-azido-1*H*-phosphirene **191a** by treating it with trimethylsilyl azide in $CDCl_3$ at room temperature. With lithiated diazo(trimethylsilyl)methane (ether, −78 °C) one obtains **191b** just as smoothly.[170]

The cycloaddition of $[Ph-C^{\ominus}=N-CH^{\ominus}-p-C_6H_4-NO_2]$, a nitrilylidene, to the phosphaalkynes **3d,e,i** has now been achieved. The reaction is regiospecific and involves a [1,5] H-shift to the ring nitrogen atom: it is a useful complement to the synthesis of the 1,3-azaphosphole from **3d** and the munchnone **86** (see Section 3.3.7). Finally, the unusual 1,5-substituent shift in 3*H*-1,2,4-diazaphospholes (see Section 3.3.2) from the sp^3-hybridized carbon atom to the neighboring phosphorus atom has been confirmed by X-ray crystallographic analysis of **50** ($R^1 = R^2 = Ph$, R = *t*Bu).[173]

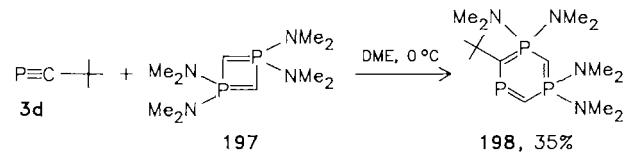
5.4. [4+2] Cycloaddition

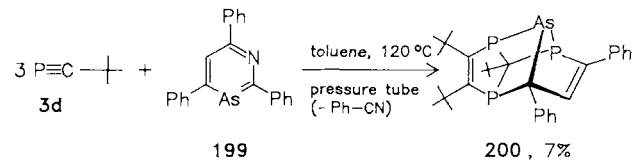
1,3-Azaphosphinines are readily obtained from 1,3-oxazinylium(3-azapyrylium) salts by O/P exchange with tris(trimethylsilyl)phosphane **14**,[174] but very little is known about their classical valence isomers, which can be prepared starting from the Dewar isomer **99a**[175] (see Section 3.4.1).



Photolysis of **99a** leads first to azaphosphaprismane **193**, which is thermally considerably less stable than aza-[176] and phosphaprismane[103] and isomerizes to the 1,4-azaphosphinine **194** even at room temperature. Photochemical excitation of **194** leads to the first azaphosphabenzvalene **196**, which is thermally very stable indeed.[175] Only on heating to 140°C does it isomerize further to the heteroarene and this proceeds not by re-forming **194** but by producing the 1,3-azaphosphinine **195**. The latter can also be prepared directly from the Dewar isomer **99a** by heating it or by carrying out the acid-catalyzed isomerization at room temperature.[175]

The 1,3,5-triphosphabenzene **198** with two λ^5,σ^4-phosphorus atoms and one λ^3,σ^2-phosphorus atom is formed directly from **3d** and the $1\lambda^5,3\lambda^4$-diphosphete **197**,[177] but the Dewar isomer that must have been formed initially in the reaction cannot be detected.

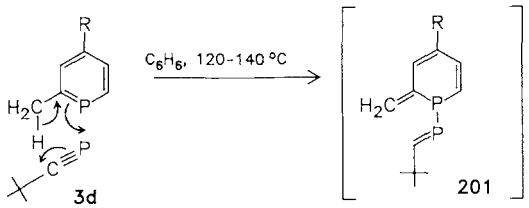


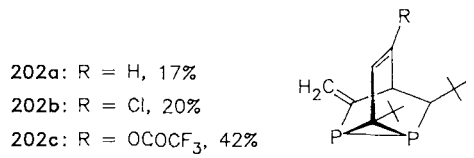


The formation of the triphosphaarsatetracyclodecadiene **200** by the reaction of the 1,3-azarsinine **199** with **3d** in the molar ratio 1:3 also occurs with an initial [4+2] cycloaddition step at the 1,4 positions of the heteroarene. This is followed by the cycloelimination of benzonitrile[178] to form the 1,3-phosphaarsinine which then gives the final product (→ **200**).[178]

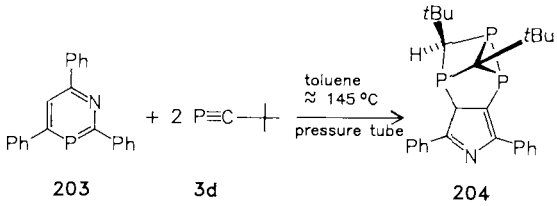
5.5. The Ene Reaction

The ene reaction of the phosphaalkyne **3d** is the decisive factor in the formation of the diphospha- and monophosphatricyclooctenes **122** and **125** (see Section 3.4.3). Their direct preparation with pentamethylcyclopentadiene (→ **130**; Section 3.5) suggests that 2-methylphosphinine should also be a suitable enophile. The reaction with **3d** provides experimental confirmation of this: the products of the ene reaction formed first (**201**) subsequently undergo an intramolecular Diels–Alder reaction to give the diphosphatricyclooctenes **202a–c**.[113]





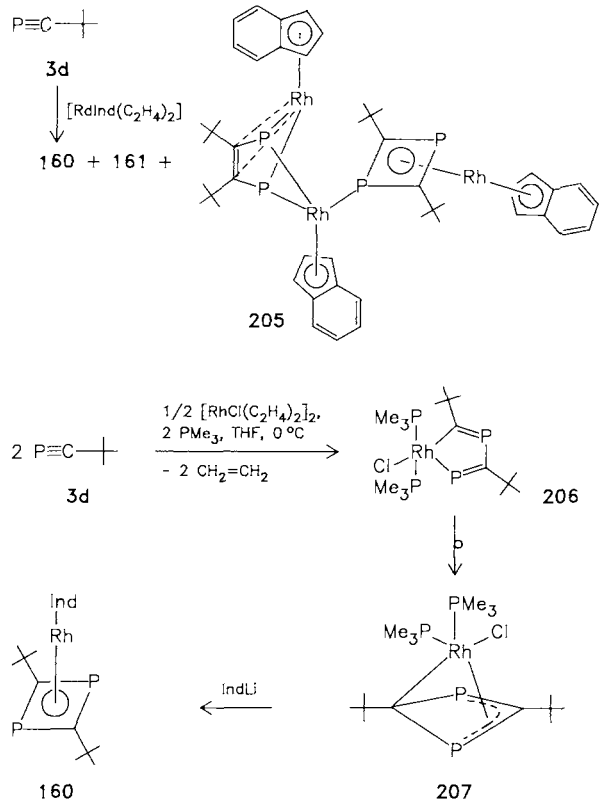
Finally, the formation of the azatriphosphatetracyclodecadiene **204** from the 1,3-azaphosphinine **203** and **3d** in a molar ratios of 1:2 should be mentioned.[179] Once again, the decisive step in the formation of the diphosphirane unit is an ene reaction. In this way the second equivalent of **3d** is incorporated into the molecule to afford **204**.[179]



5.6. Metal Complexes

The structure of the third product of the reaction of **3d** with [RhInd(C_2H_2)] (the others are **160** and **161**; see Section 3.7.4)[148] has been established by X-ray crystallography to be the unusual trinuclear complex **205** incorporating four phosphaalkyne units.[128]

A further way of forming rhodium-complexes of 1,3-diphosphacyclobutadiene (see Section 3.7.4) begins with the treatment of **3d** with dimeric bis(ethylene)rhodium chloride in the presence of trimethylphosphane. The product is the first diphospharhodacyclopentadiene **206** to have been isolated and characterized by X-ray crystallography.[180] At room temperature it isomerizes slowly to **207**, in which the four-membered ring has considerable η^1,η^3 character.[180]

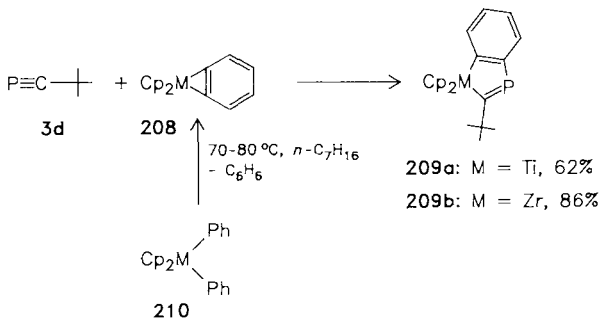


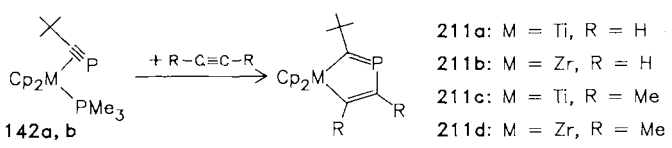
Reaction of **207** with indenyllithium leads to the formation of the 1,3-diphosphacyclobutadiene complex **160** described earlier.[180] This result supports the assumption that 2,4-diphosphametallacyclopentadienes are generally the intermediates in the cyclodimerization of phosphaalkynes.

1-Phospha-3-metallacyclopentadienes of type **209** and **211** with titanium and zirconium as the ring metal atom can be readily prepared by two methods.

The first method is to heat the diphenylmetallocenes **210** (M = Ti or Zr) with **3d**, which affords the derivatives **209** in good yields.[181] It is reasonable to suppose that the attack of the phosphaalkyne is preceded by the formation of the dehydrobenzene complex **208**.

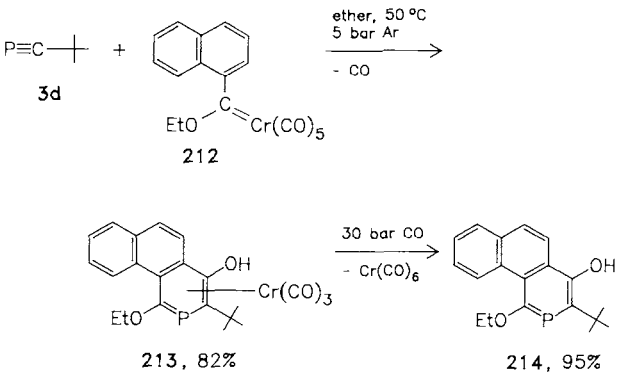
The second method is to treat the complexes **142a,b**, which have side-on-coordinated **3d**, with alkynes. With





acetylene itself the displacement of the trimethylphosphane ligand and the formation of the ring (→ **211a,b**) occurs at 0 °C, while with 2-butyne the products (→ **211c,d**) are formed only after warming to 60 °C.[128]

The cyclotrimerization reaction between two molecules of **3d** and the complex-bound carbon monoxide in $[(\eta^5\text{-}C_5H_5)_2Ti(CO)_2]$ was reported recently. The product is a diphosphatricyclo[2.1.0.0^{2,5}]pentane (**170**, O=C instead of Cp_2Zr).[182]



Another example of the similarity in the behavior of alkynes and phosphaalkynes is found in the annelation of carbene ligands. When the chromium carbene complex **212** reacts with **3d**, the functionalized phosphaphenanthrene complex **213** is isolated in high yield.[183]

The metal-free heteroarene **214** can be liberated by treating **213** with carbon monoxide.[183]

The results of our own work cited here came from research generously supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, the Fonds der Chemischen Industrie, and the State of Rheinland-Pfalz. We would also like to express our thanks to our co-workers whose work has been reviewed here. Their enthusiasm has contributed greatly to the development of phosphaalkyne chemistry.

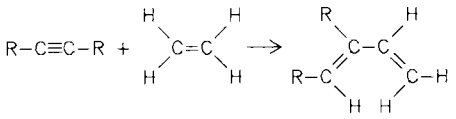
Acid-Catalyzed Alkyne/Alkene Coupling at Re^{III} Centers**

By *Wolfgang A. Herrmann,* Roland A. Fischer,* and *Eberhardt Herdtweck*

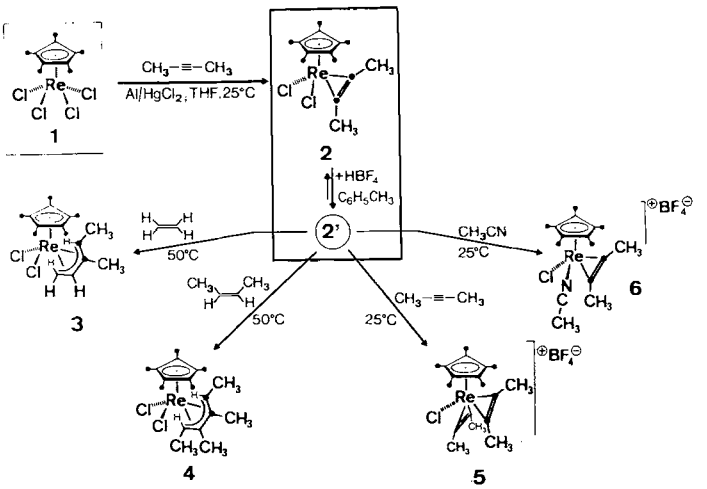
Dedicated to Professor Ernst Otto Fischer on the occasion of his 70th birthday

Whereas the oligomerizations of ethylene and acetylene provide model examples for the effectiveness of organotransition metal catalysts in the chemical industry,[1] the CC coupling of alkenes and alkynes in stoichiometric or catalytic cocyclizations has gained importance only in preparative organic chemistry.[2] The majority of the previously known coupling reactions of these classes of compounds at metal centers preferentially yield metallacyclopentenes, but seldom the tautomeric 1,3-dienes.[3] We report here on a model organometallic system for the synthetic reaction depicted in Scheme 1, which, at the same time, demonstrates differences in reactivity of the analogous d^2-Ta^{III} and d^4-Re^{III} complexes.



Scheme 1.

Starting from the organorhenium(v) complex **1**, π-alkyne derivatives such as the 2-butyne complex **2**,[4] are accessible via reductive routes in accordance with Scheme 2. Like its Ta^{III} analogues $[(\eta^5\text{-}C_5Me_5)Ta(\eta^2\text{-}RCCR)Cl_2]$, **2** is inert towards ethylene or excess alkyne even under drastic conditions. Only the Ta^{III} complex of unsubstituted acetylene, $[(\eta^5\text{-}C_5Me_5)Ta(\eta^2\text{-}HCCH)Cl_2]$, adds ethylene in toluene solution, and only then at 80°C, forming the corresponding metallacyclopentene $[(\eta^5\text{-}C_5Me_5)Ta(CH{=}CH{-}CH_2CH_2)Cl_2]$.[5]



Scheme 2.

When, however, the light-yellow solution of **2** in toluene is treated with a catalytic amount of tetrafluoroboric acid, and ethylene is then fed into the mixture, a color change to wine-red is observed within minutes. Chromatographic work-up of the crude product affords the red, air-stable compound **3** in 80% yield whose analytical and spectroscopic data are consistent with a Re^{III} complex of (*E*)-3-methyl-1,3-pentadiene.[6]

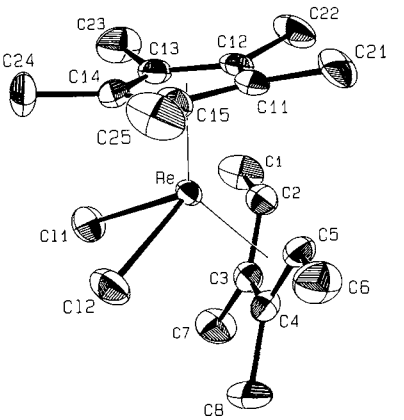


Fig. 1. Molecular structure (ORTEP) of the (*E,E*)-3,4-dimethyl-2,4-hexadiene complex **4** in the crystal. The thermal ellipsoids correspond to the 50% probability level. Selected bond lengths [pm] and angles [°]: Re-Cl1 244.1(1), Re-Cl2 243.8(1), Re-C2 222.0(3), Re-C3 236.4(3), Re-C4 235.5(3), Re-C5 222.1(3), C2-C3 143.8(4), C3-C4 139.6(4), C4-C5 144.0(4); Cl1-Re-Cl2 79.83(3). The dihedral angle between the Re-C2-C5 and C1-C8 planes is 95.8(1)°. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-52936, the names of the authors, and the full journal citation.

Apparently the methyl-substituted butadiene ligand is formed from ethylene and the 2-butyne attached to the metal of **2** by CC coupling with H-migration. **3** can also be prepared by reductive dehalogenation of the Re^V compound **1** with $HgCl_2$-activated Al-granules in the presence of *cis/trans*-3-methyl-1,3-pentadiene. Although the constitution of **3** could be confirmed by a single crystal X-ray

[**] Multiple Bonds between Main Group Elements and Transition Metals, Part 56. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 55: J. K. Felixberger, J. G. Kuchler, E. Herdtweck, R. A. Paciello, W. A. Herrmann, *Angew. Chem. 100* (1988) 975; *Angew. Chem. Int. Ed. Engl. 27* (1988) 946.

structure analysis, because of a disorder of the chiral molecule in the crystal the analogous symmetrical derivative **4** was synthesized and characterized by its structural chemistry (Fig. 1).[6, 7]

The atoms C2–C5 of the 1,3-diene ligand lie, as also their methyl substituents, in one plane; the distances between them are almost identical, with a mean value of 142.5(4) pm. C2 and C5 are noticeably closer to the metal (220.0(3) and 222.1(3) pm, respectively) than C3 and C4 (236.4(3) and 235.5(3) pm, respectively). **4** cannot be described as a metalla-3-cyclopentene; the compound rather corresponds to a η^4-*s-cis*-1,3-diene complex.[8] The different Re–C distances, which lead to an unsymmetrical diene coordination, are presumably a result of steric interactions of the butadiene ligand with the $[(\eta^5\text{-}C_5Me_5)ReCl_2]$ fragment. This would also explain the preferred *supine* position of the ligand over the prone arrangement.[8] Moreover, no configurational stability can be observed NMR spectroscopically in solution. The selectivity with which exclusively (*E,E*)-3,4-dimethyl-2,4-hexadiene is formed at the Re[11] center, is certainly also governed by the steric demand of the pentamethylcyclopentadienyl ligand, which should determine the preferred position of the methyl groups on the atoms C2 and C5.

As expected, if an unsymmetrical olefin such as propene instead of ethylene is used as reaction partner, a ca. 1:1 mixture of two positional isomers is obtained with the CH_3 group originating from the propene molecule appearing either on C4 or on C5.

In the presence of equimolar amounts of acid, **2** also reacts with alkynes or nitriles at room temperature in toluene solution. CC coupling to form metallacyclopentadiene derivatives, however, does not occur. Rather, the complex salts **5** and **6**, respectively, whose formation does not occur without addition of acid, are obtained in quantitative yield according to Scheme 2. When **2** is allowed to react in a competition experiment with excess 2-butyne and ethylene in the presence of traces of acid, formation of the 1,3-diene does not occur. Rather, some **5**, the amount of which corresponds to the acid used, is obtained along with unchanged **2**.

The assumption of a protonation of the alkyne complex **2** appears to be meaningful for the action of the activating acid. A novel example for this is provided by the protonation of the Rh^I complex $[(\eta^5\text{-}C_5H_5)Rh(\eta^2\text{-}RCCR)(PiPr_3)]$; migration of a proton from the metal atom to the alkyne ligand results in σ-vinyl intermediates, which are amenable to further reactions.[9] However, no NMR spectroscopic evidence could be obtained for an H atom attached to metal or to vinyl ligands upon reaction of mineral acids with **2**.

Although the mechanisms of the reactions depicted in Scheme 2 have not been clarified and the reactive intermediate **2'**, in particular, has not yet been identified, the *intramolecular* character of the formation of the butadiene from free olefin and acetylene fixed to metal can be considered as established. Labeling experiments indicated, for example, that no deuterium is incorporated in the 1,3-diene complex on using deuterated acids in [D8]toluene. As expected, completely substituted olefins, e.g. 2,3-dimethyl-2-butene, do not react with **2**, whereas 2-methyl-2-butene, with one less methyl group, leads to complexes of type **3** and **4**. It can be concluded therefore that the H-migration with formation of the 1,3-diene system provides the driving force behind the described coupling reaction.[3] Since such an H-migration is not possible when acetonitrile and 2-butyne are used as reaction partners with **2**, this also explains the other type of reaction course to **5** and **6**, respectively.

Experimental

4: A solution of **2** (200 mg, 0.5 mmol) in toluene (50 mL) was heated to 50 °C and treated with a catalytic amount of HBF_4 in diethyl ether. A vigorous stream of dry *cis*-2-butene was then fed through the yellow solution. Within 5 min a color change to wine red was observed. After ca. 15 min the solvent was removed under vacuum. The red residue was chromatographed at 15 °C on a column charged with silylated silica gel/*n*-hexane (30 cm × 1 cm). **4** was then eluted as a red zone with methylene chloride/*n*-hexane (10:3). Recrystallization from *n*-hexane/methylene chloride (1:1) afforded 190 mg (75%) of analytically pure **4** as red, thin, transparent crystalline platelets. Decomp. 226 °C. **3** can be synthesized analogously from **2**.

5: A solution of **2** (200 mg, 0.5 mmol) in toluene (50 mL) was treated with 0.1 mL of 2-butyne. 0.1 mL of an HBF_4 solution in diethyl ether (c = 7.2 mmol/mL) was then added to the reaction solution with vigorous stirring. Yellow droplets immediately separated out. The mixture was stirred for a further 30 min and all volatiles then removed under vacuum. The residue was repeatedly washed with diethyl ether and recrystallized several times from *n*-hexane/methylene chloride (1:2). Yield 235 mg (85%) of analytical pure **5** as orange-yellow needles. Decomp. 188 °C.

Diastereospecific Gas/Solid Additions with Cholesterol Derivatives**

By *Gerd Kaupp** and *Christine Seep*

Gas/solid additions are very simple, mild, and economical procedures. They often allow the selective synthesis of highly reactive compounds;[1] however, pronounced stereoselectivities have only seldom been observed.[1,2] We have now found that cholesterol and some of its esters exhibit gas/solid reactivity and undergo diastereospecific additions even as crystalline powders.

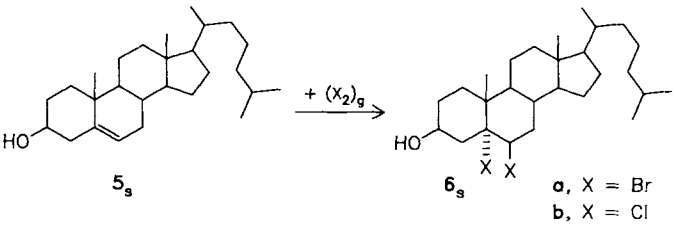
Owing to its cholesteric liquid-crystalline phase, cholesteryl oleate **1** has found wide application.[3] When crystalline **1** (**1**$_s$) is allowed to react at -30 to $-20°C$ for 10 h with gaseous hydrogen bromide in excess, the HBr adds regio- and diastereospecifically to give **2** (100%, m.p. 58–59 °C, $[\alpha]_D^{20} = +0.7$, $\tilde{\nu}_{CBr} = 669$ cm^{-1}), without the crystal melting.

Crystalline cholesteryl acetate **3**$_s$ reacts more slowly with gaseous HBr (1 bar, $-30°C$, 6 d). The known 5α-bromide **4**[4] (100%, $[\alpha]_D^{20} = +2.3$, $\tilde{\nu}_{CBr} = 669$ cm^{-1}) is obtained regio- and diastereospecifically. These reactions are very easy to carry out. In solution (e.g., dichloromethane), both reactions yield, in addition to **2** and **4**, respectively, an appreciable amount of side products, even if every attempt is made to exclude water.

Surprisingly, the gases HCl and HI (1 bar, -30 to $+25°C$) do not react at all with **1**$_s$ or **3**$_s$—apart from changes in the color of the crystal to pale yellow or to reddish brown—and cholesteryl stearate is not even attacked by the especially effective HBr. These findings show that, instead of the reaction enthalpies, specific crystal effects are presumably the crucial criterion in determining the gas/solid reactivity. This is even true when the gases can penetrate into the crystal, as shown by the change in color without chemical reaction.[5]

The gas/solid addition of bromine to cholesterol **5** (1 : 1 ratio of the reactants, 25 °C, 2 h) also proceeds quantitatively and diastereospecifically to give the thermodynamically less favored 5α,6β-dibromide **6a**[4,6] ($[\alpha]_D^{20} = -52$, $\tilde{\nu}_{CBr} = 566$, 591, 616 cm^{-1}). Thus, without stabilization by acetic acid of crystallization, this compound is now accessible in a form that can be stored for weeks at room temperature. It is a welcome starting material for mild and economical gas/solid reactions with reactive gases such as NH_3, CH_3NH_2, HI, and CH_3SH.[7]

The reaction of chlorine gas with **5**$_s$ (1 : 1 to 2 : 1, <0.2 bar, $-50°C$, 5 h) exhibits little regioselectivity but is diastereospecific with respect to the proportion of addition at the 5,6-positions, which maintains the steroid framework. Thus, only the 5α,6β-dichloride **6b**[4] can be isolated (after preparative thin layer chromatography: 34%, $[\alpha]_D^{20} = -32$, $\tilde{\nu}_{CCl} = 656$ cm^{-1}).[8] At higher temperatures (above $-30°C$), the reaction becomes appreciably slower owing to partial melting, since this protects the crystal from further contact with the gas. In this case, the gas/solid technique appears to offer little advantage over conventional chlorination.



The configurations of the products **2**, **4**, **6a**, and **6b** are supported[9] by the optical rotations (see Ref. [4] and references cited therein) and by characteristic CCl(CBr) vibrational frequencies.[4,10]

The products **2**, **4**, and **6**, easily and economically obtained by the gas/solid technique under mild conditions, are interesting intermediates for further reactions in solution.

Experimental Procedure

Commercially available **5** (Aldrich or Fluka) contains water of crystallization (^{1}H NMR detection) and is purified by sublimation in vacuo (5×10^{-4} torr, bath temperature 140 °C). The X-ray powder diagrams before and after sublimation are nearly identical. However, the FT-IR difference spectra show weak new bands in the fingerprint region ($\tilde{\nu}$ = 1262, 1100, 1027, and 806 cm^{-1}) for the sublimed cholesterol. The cholesteryl esters **1** (m.p. 44.5 °C) and **3** (m.p. 116.5 °C) (Aldrich) did not require further purification. $[\alpha]_D^{20}$ values in $CHCl_3$; IR spectra in KBr.

A 500-mL round-bottom flask containing 1.0–3.0 g of powdered **1**, **3**, or **5** was evacuated (5×10^{-4} torr). At the temperature given in the text, the gas was passed through a vacuum line fitted with a pressure relief valve or the reaction vessel was connected via a vacuum line with a reservoir containing the calculated amount of gas, the reaction assembly being protected from sunlight. After the required reaction time, the excess gas was pumped off. The crystals were mixed and a representative sample was taken for ^{1}H NMR analysis. The finely crystalline products can be reacted further without initial purification. They can be recrystallized from CH_3OH or CCl_4.

[4] C. W. Shoppee, M. E. H. Howden, R. Lack, *J. Chem. Soc. 1960*, 4874.
[5] This is shown even more clearly when **5**, is treated with gaseous HCl (at −20 to +25 °C, yellow-green, later brown-orange) or HI (at −20 to +25 °C, beige, later red-brown; after pumping off the gas, colorless; after exposure to air, initially dark green, then anthracite-colored). In neither case does a chemical reaction take place (^{1}H NMR in $CDCl_3$).
[6] In syntheses carried out in solution, this isomer has to be protected from mutarotation to the 5β,6α isomer by crystallization with 1 mole equivalent of acetic acid: *Org. Synth. Collect. Vol. 4* (1965) 195 (cf. D. H. R. Barton, E. Miller, *J. Am. Chem. Soc. 72* (1950) 1066). The optical rotation in [4] is given as $[\alpha]_D^{20} = -44$. In solution the value slowly decreases owing to mutarotation.
[7] These reagents, available as gases, react in the usual manner with crystals of **6a**.
[8] Further 5,6-dichlorides of **5** cannot be detected, even before chromatographic purification, although the 5α,6α isomer is known to be stable (no mutarotation) [S. P. J. Maas, J. G. De Heus, *Recl. Trav. Chim. Pays-Bas 77* (1958) 531; [10]] and, in the case of the dibromide, the 5β,6α form is more stable than **6a**. In the reactions competing with 5,6-addition, the steroid framework undergoes rearrangement according to the ^{1}H NMR spectrum. The exact constitution of the rearrangement products, however, could not yet be determined.
[9] Further data supporting the constitution and purity were provided by elemental analyses, mass spectroscopy, and ^{1}H NMR spectroscopy at high field strengths (300 MHz).

$[Ni_9(\mu_4\text{-}As)_6(PPh_3)_5Cl_3]$, a Cubic Body-centered Ni_9-Cluster**

By *Dieter Fenske,* Kurt Merzweiler,* and *Johannes Ohmer*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 70th birthday

Phosphane complexes of electron-rich transition-metal halides react with $E(SiMe_3)_2$ (E = S, Se, Te) and $RP(SiMe_3)_2$ (R = Ph, Me, Et) with formation of Me_3SiCl and mixtures of metal-rich clusters. For example, reaction

$[Co_4(PPh_4)(PPh_3)_4]$ **1** $[Ni_8(PPh)_6(PPh_3)_4]$ **2**

$[Ni_8(PPh)_6Cl_4(PPh_3)_4]$ **3**

of $[MCl_2(PPh_3)_2]$ (M = Co, Ni) with $PhP(SiMe_3)_2$ affords the clusters **1–3** in very high yields.

The clusters contain Co_4-tetrahedra or distorted cubic Ni_8-polyhedra whose faces are capped by PPh ligands.[1]

The analogous reaction of $[CoCl_2(PPh_3)_2]$ with $PhAs(SiMe_3)_2$, on the other hand, leads to formation of the complex $[Co_4(\mu_3\text{-}As)_3(\mu_3,\eta^3\text{-}As_3)(PPh_3)_4]$ **4**, via a redox reaction in which all As–C bonds of $PhAs(SiMe_3)_2$ are cleaved.[2]

We have now investigated the reaction of $[NiCl_2(PPh_3)_2]$ with $PhAs(SiMe_3)_2$ [Eq. (a)]. A rapid dissolution of the normally sparingly soluble $[NiCl_2(PPh_3)_2]$ is observed in THF; a crystalline mixture of various clusters and small amounts of metallic nickel separate out from the brown solution.[3] Crystals of **5** and **6** (yield: 50% referred to Ni) are obtained on treatment of the precipitate with $1,2\text{-}C_2H_4Cl_2$ and subsequent covering of the solution with hexane.

$$[NiCl_2(PPh_3)_2] \xrightarrow{PhAs(SiMe_3)_2} [Ni_9(\mu_4\text{-}As)_6(PPh_3)_5Cl_3] + [Ni_9(\mu_4\text{-}As)_6(PPh_3)_6Cl_2] \quad \text{(a)}$$

5 **6**

Derivatives of **5** are obtained in an analogous way from $[NiCl_2(PR_3)_2]$ ($R = C_2H_5$, C_6H_{11}). The IR spectra of **5** and **6** are almost identical with the spectrum of $[NiCl_2(PPh_3)_2]$ above $\tilde{\nu}$ = 400 cm^{-1}, and the recording of NMR spectra is problematic owing to the sparing solubility and paramagnetic behavior of **5**. According to crystal structure analyses **5** and **6** contain the same cluster skeleton.[4] However, an accurate determination of the structure of **6** is not possible because of a disorder of the PPh_3 ligands and the co-crystallizing $C_2H_4Cl_2$ molecules. **5** (Fig. 1) contains a cubic Ni_8 cluster (Ni1–Ni8), with a further Ni atom (Ni9) located in its center. The distances between the Ni atoms of the cube

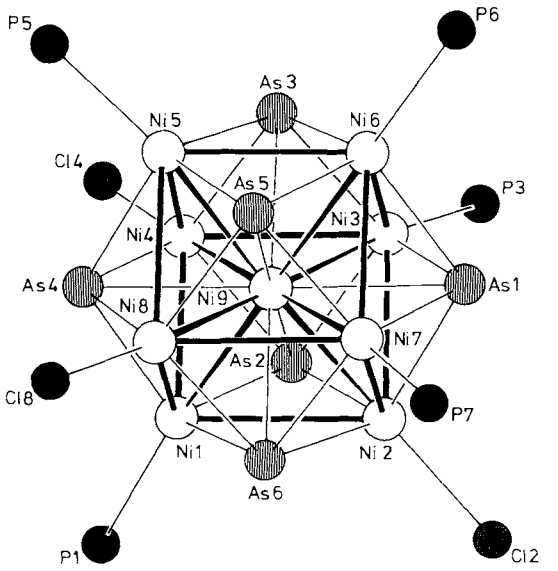

Fig. 1. Molecular structure of **5** (without phenyl groups) in the crystal. Important bond lengths [pm] and angles [°] (±0.1°): Ni-Ni (in the Ni_8 cube) 276.9–284.6(5), Ni-Ni9 238.2–248.4(6), Ni(1–8)-As 229.8–235.0(5), Ni9-As 261.0–264.1(6), Ni-Cl 216.5–218.1(7), Ni-P 217.7–222.9(9); Ni-Ni-Ni (in the Ni_8 cube) 87.0–92.4, Ni-Ni9-Ni 69.8–71.2, 108.6–110.2, 178.4–179.7, Ni-As-Ni 72.6–75.1, 115.9–119.1, Ni(1–8)-As-Ni9 57.0–59.6.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

(277–285 pm) are about 40 pm longer than the distances to the central Ni9 (238–248 pm).

The bonds from Ni9 to the Ni atoms bound to $Cl^{\ominus}$ (Ni2, Ni4, Ni8) are significantly longer (245–248 pm) than the other Ni–Ni bonds (238–242 pm). The distances in the Ni_8 cube of **5** also differ markedly from the values (251–269 pm) found for Ni_8 clusters without an interstitial Ni atom.[1,5] Ni1–Ni8 are coordinated in a distorted tetrahedral fashion to three μ_4-As ligands and one $Cl^{\ominus}$ ligand (Ni2, Ni4, Ni8) or to three μ_4-As ligands and the P atom of a PPh_3 group (Ni1, Ni3, Ni5, Ni6, Ni7). The Ni(1–8)–As bonds (230–235 pm) are only about 30 pm shorter than the distance between Ni9 and the μ_4-As bridges (261–264 pm).

If the μ_4-As ligands are regarded as 3e donors and PPh_3 and $Cl^{\ominus}$ as 2e donors, then **5** and **6** contain 121 and 122 valence electrons, respectively, in remarkable agreement with the number of valence electrons (122) expected according to the 18-electron rule, although this provides no conclusive evidence for the Ni–Ni two-center bonds in the Ni_9 skeleton. An electron counting rule was developed by *Mingos*[6] for clusters with interstitial metal atoms; the number of valence electrons in closest packed metal clusters should be $12n_s + \Delta i$ (n_s = number of metal atoms at the cluster surface, Δi = electron number dependent upon cluster type and central atom). For cubic body centered metal clusters of Au, Rh, and Pt, Δi is 18 or 24. Assuming similar bonding situations in the Ni_9 clusters, **5** and **6** should contain either 114 or 120 valence electrons. The actual number of valence electrons in **5** and **6** show that this rule does not always apply. Other authors have already reported on compounds which contain a section of the cubic body-centered metal structure; examples are $[Rh_{14}(CO)_{25}]^{4\ominus}$, $[Rh_{14}(CO)_{26}]^{2\ominus}$, and $[Au_9(PPh_3)_8]^{n\oplus}$[7,8] ($n = 1, 3$).

[3] Procedure: A suspension of $[NiCl_2(PPh_3)_2]$ (8 g, 12.2 mmol) in THF (100 mL) was treated with a solution of $PhAs(SiMe_3)_2$ (5.5 g, 18.5 mmol) in THF (20 mL). After 4 d, 2.5 g of a fine crystalline precipitate were recovered by filtration. Treatment of the precipitate with 100 mL of $C_2H_4Cl_2$ led to dissolution of about 1.6 g of **5** + **6**. After covering with a layer of hexane, black crystals of **5** and **6** separated at the interface.

[4] Siemens AED II, ω-scan (profile analysis), empirical absorption correction, Patterson methods, Ni, As, P, Cl refined anisotropically. **5** crystallizes with four molecules $C_2H_4Cl_2$ per formula unit: space group $P\bar{1}$, lattice constants (210 K): $a = 1440.7(6)$, $b = 1616.6(8)$, $c = 2473.1(10)$ pm, $\alpha = 99.63(4)$, $\beta = 96.96(4)$, $\gamma = 109.72(4)°$; $Z = 2$, $\mu(Mo_{K\alpha}) = 41.1$ cm^{-1}; $2\theta \leq 48°$, 15700 reflections, 8174 with $I > 2\sigma(I)$. Ph refined as rigid group (C–C: 139.5 pm), $R_1 = 0.083$, $R_2 = 0.079$. **6** crystallizes with 16 molecules of $C_2H_4Cl_2$ and two molecules of THF per formula unit; space group C_m; lattice constants (180 K): $a = 2361.8(12)$, $b = 2262.9(11)$, $c = 1611.9(8)$ pm, $\beta = 94.50(4)°$; $Z = 2$, $\mu(Mo_{K\alpha}) = 41.1$ cm^{-1}; $2\theta \leq 52°$, 8878 reflections, 3876 with $I > 2\sigma(I)$. Owing to a disorder of the PPh_3 groups and the $C_2H_4Cl_2$ molecules only the structure of the cluster could be refined; $R_1 = 0.14$, $R_2 = 0.13$. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53110, the names of the authors and the journal citation.

Organobimetallic Mg–Pd Complexes as Intermediates in the Formation of Amorphous $MgPdC_xH_y$ from $Mg(C_2H_5)_2$ and $[Pd(\eta^3\text{-}C_3H_5)_2]$**

By *Borislav Bogdanović*,* *Sara C. Huckett*, *Ursula Wilczok*, and *Anna Rufińska*

Intermetallic compounds are usually prepared by metallurgical methods,[1] although metal-organic chemical vapor deposition has become increasingly important.[2] We recently described[3] the synthesis of amorphous Mg-based intermetallic compounds and their hydrides and carbides under mild conditions ($T \leq 25°C$) in organic solvents from catalytically prepared magnesium hydride[4] or from magnesium alkyls and bis(allyl)metal compounds. We report here the formation of amorphous $MgPdC_xH_y$ **3** ($x = 0.4$–0.8, $y = 0.4$–2.3) from $Mg(C_2H_5)_2$ **1** and $[Pd(\eta^3\text{-}C_3H_5)_2]$ **2** and the identification of intermediate organobimetallic complexes.

The reaction of **1** with **2** (molar ratio 2:1, 25°C) proceeds as shown in Equation (a) (neglecting the C and H in **3**).

$$\underset{\mathbf{1}}{\tfrac{3}{2}Mg(C_2H_5)_2} + \underset{\mathbf{2}}{[Pd(\eta^3\text{-}C_3H_5)_2]} \xrightarrow{THF} \underset{\mathbf{3}}{MgPdC_xH_y} + 2\,H_2C{=}CH_2 + H_2C{=}CHCH_3 + C_2H_6 + \underset{\mathbf{4}}{\tfrac{1}{2}Mg(\eta^1\text{-}C_3H_5)_2} \quad (a)$$

No reflections were observed in the X-ray powder pattern of the black, pyrophoric **3** (crystalline MgPd[5] and $Mg_{0.9}Pd_{1.1}$[5b,6] are known); the same result was obtained even after annealing **3** (650°C, 72 h). Further, **3** does not react with H_2 (20–400°C, normal H_2 pressure), suggesting that substantial amounts of free, finely divided Mg or Pd are not present in the sample.[7] Therefore, **3** is probably a new amorphous Mg–Pd carbide which, in contrast to the analogous amorphous $MgNiC_xH_y$[3a] ($x = 1.2$–1.8, $y = 2.3$–3.4), does not transform into crystalline intermetallic compounds and carbides upon annealing. A more detailed description of the properties of **3** will be presented elsewhere.[8] Efforts are currently being made to learn more about the structure of **3**.

[†] ^1H NMR spectroscopy.

[**] This work was supported by the North Atlantic Treaty Organization under a Grant awarded to *S. C. H.* (1987). We gratefully acknowledge Dr. *R. Mynott*, *B. Gabor*, and *S. Zöcklein* for obtaining and interpreting the ^{13}C NMR data, as well as *R. Ettl* and *G. Schroth* for their contributions in obtaining and analyzing the ^1H NMR data.

To elucidate the pathway(s) leading to the formation of **3**, the reaction [Eq. (a)] was begun at −78 °C in [D_8]THF. After 2 h this led to precipitation of a white solid which redissolved upon warming to −55 °C. ^{1}H NMR spectra were obtained at several temperatures (Fig. 1).[9] The spectrum at −60 °C shows that **5** is formed via transfer of an ethyl group from **1** to **2** and an $\eta^3 \rightarrow \eta^1$ rearrangement of the Pd-allyl group [see Eq. (b)]. The ^{1}H NMR shift differences for H16 and H18[10] are small and an overlap of the peaks for H15 and H17 is observed, but the ^{13}C NMR spectrum[11] clearly shows the distinction between Mg-ethyl groups in **5**[11] and **1**.[12] Precedence for the formation of $MgR^{\oplus}$ ions from MgR_2[13] exists. The ^{13}C NMR chemical shifts and coupling constants for the Pd ligands in **5** are also consistent with the proposed structure. Similar shifts are found for the analogous $[(\eta^3\text{-}C_3H_5)(\eta^1\text{-}C_3H_5)NiCH_3]Li(thf)_4$[14] and $[(\eta^3\text{-}C_3H_5)(\eta^1\text{-}C_3H_5)PdCH_3]Li(thf)_4$.[15]

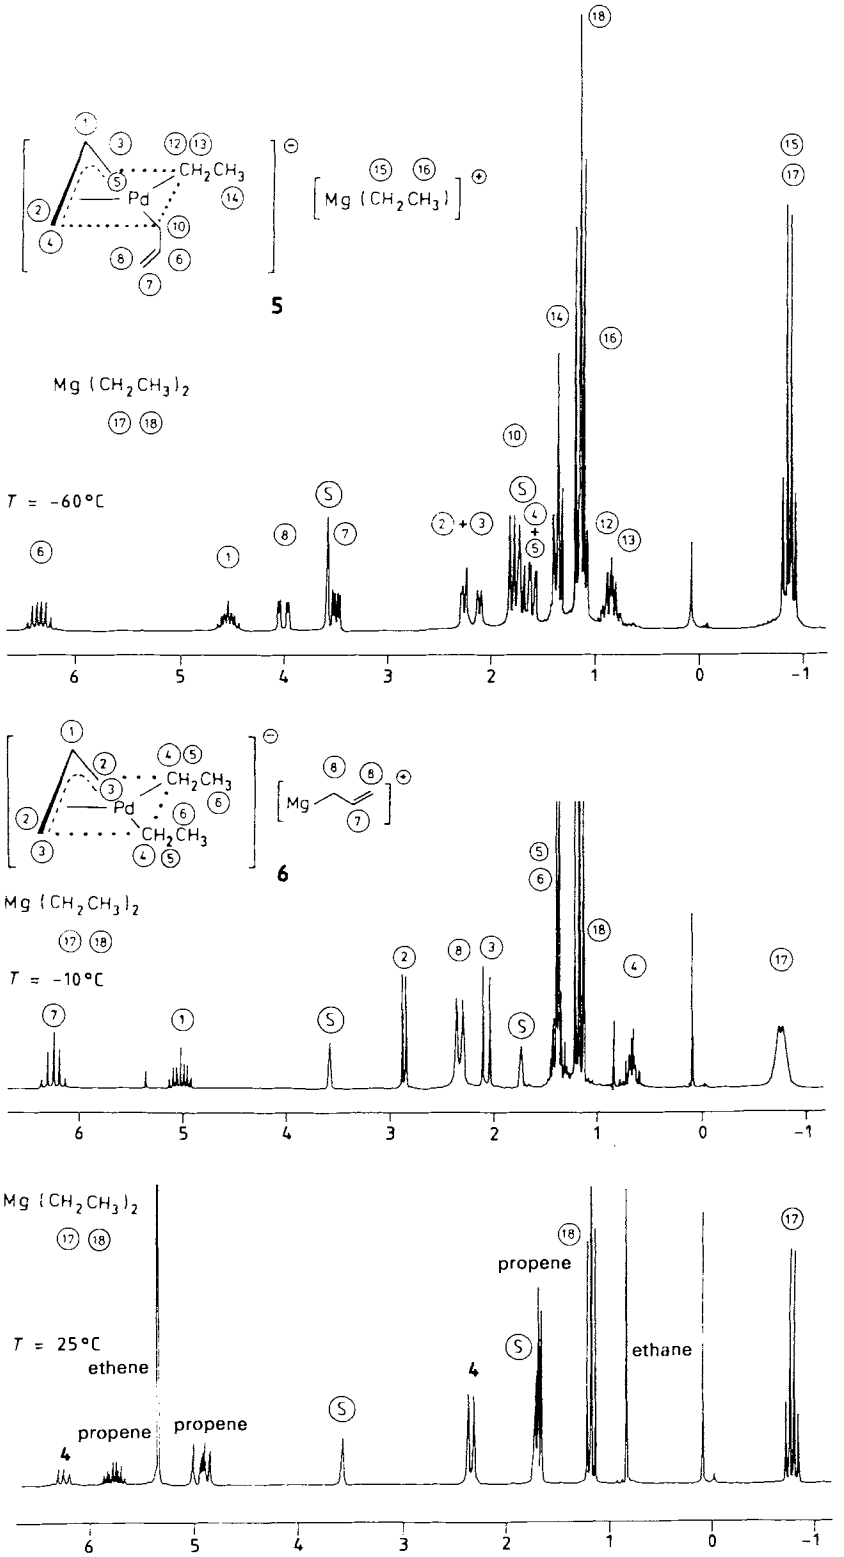

Fig. 1. Variable-temperature ^{1}H NMR spectra of the reaction mixture of **1** and **2** in [D_8]THF (S).

At $-10\,^{\circ}C$ resonances corresponding to **6** are observed as a result of transfer of a second ethyl group to Pd and an allyl group to Mg [Eq. (b)]. The ^1H NMR (η^1-C_3H_5) reso-

$$\mathbf{1} + \mathbf{2} \xrightleftharpoons{-60\,^{\circ}C} \underset{\mathbf{5}}{[(\eta^3\text{-}C_3H_5)(\eta^1\text{-}C_3H_5)(C_2H_5)Pd]^{\ominus}Mg(C_2H_5)^{\oplus}} \xrightleftharpoons{-10\,^{\circ}C} \underset{\mathbf{6}}{[(\eta^3\text{-}C_3H_5)(C_2H_5)_2Pd]^{\ominus}Mg(\eta^1\text{-}C_3H_5)^{\oplus}} \quad (b)$$

nances for **6** are similar to those for **4**[16] but also to those reported for $[CpCo(\eta^3\text{-}C_3H_5)Mg(\eta^1\text{-}C_3H_5)(thf)_2]$.[17] However, the broadness of the terminal ^{13}C NMR resonances[11] precludes definitive assignments for the Mg-allyl ligand in **6**. At 25 °C the only signals in the ^1H NMR spectrum (Fig. 1) are those of **4**,[16] ethene, propene, ethane, and excess **1**.

Intermediates **5** and **6** are shown in Figure 1 and Equation (b) as ionic; however, the presence of a bridging alkyl group or a covalent Pd–Mg bond cannot be ruled out on the basis of the NMR data. Of the known Mg–transition-metal complexes,[10, 17, 18] the following have been shown to contain Mg–transition-metal bonds by X-ray structure determination:

$[Cp(diphos)FeMgBr]\cdot 3\,THF$,[18e] $diphos = (Ph_2P{-}CH_2{-})_2$
$[Cp(C_2H_4)(C_6H_5)CoMgBr](tmeda)$
$[Cp(\eta^3\text{-}C_3H_5)CoMgBr]\cdot 2\,THF$[17]
$[(tmeda)MgCH_3(\mu\text{-}CH_3)Ni(C_2H_4)_2]$[10, 18k]

The stoichiometry of reaction (a) requires, however, that prior to the decomposition of **6** the exchange of an allyl and ethyl group between **6** and excess **1** to produce a third intermediate, presumably **7** [Eq. (c)], should occur. The

$$\mathbf{6} + \tfrac{1}{2}\,\mathbf{1} \longrightarrow \underset{\mathbf{7}}{[(\eta^3\text{-}C_3H_5)(C_2H_5)_2Pd]^{\ominus}Mg(C_2H_5)^{\oplus}} + \tfrac{1}{2}\,\mathbf{4} \quad (c)$$

broadening of the Mg–ethyl resonances observed in both the ^1H and ^{13}C NMR spectra at $-10\,^{\circ}C$ could support this proposal.

Decomposition of **7** via β-hydrogen and reductive[19] elimination [Eq. (d)] would produce **3**, ethene, propene,

$$\mathbf{7} \longrightarrow \mathbf{3} + 2\,H_2C{=}CH_2 + H_2C{=}CHCH_3 + C_2H_6 \quad (d)$$

and ethane in the molar ratio 1 : 2 : 1 : 1 as was experimentally observed. Examples of reductive elimination of hydrocarbons from binuclear organometallic compounds to produce transition-metal complexes have been reported.[20]

Further information concerning intermediates **5** and **6**, and their modes of decomposition was obtained by reacting **1** and **2** (molar ratio 1 : 1, $-78\,^{\circ}C$, THF) and isolating the resulting white solid. The extremely air- and temperature-sensitive solid was shown, on the basis of Mg and Pd elemental analysis, to be a 1 : 1 complex of **1** and **2** with 6 moles of THF per mole of complex (i.e., **5** or **6**). Once isolated, the complex is no longer soluble at $-60\,^{\circ}C$; therefore, a stirred suspension of the solid in $[D_8]$THF was warmed to $-25\,^{\circ}C$, and ^1H NMR spectra were recorded at -30, -10, and 25 °C. At $-30\,^{\circ}C$ broad resonances were observed; however, at $-10\,^{\circ}C$ the resonances corresponding to **6** were present, suggesting that **5** was initially present and was converted into **6** by increasing the temperature of the solution. In contrast to spectra obtained with an excess of **1** present, resonances corresponding to **2** were observed in the spectra at -30 and $-10\,^{\circ}C$. At 25 °C only signals corresponding to ethene, propene, and ethane were observed.

The decomposition of **6** would be expected to produce ethene and propene [Eq. (e)] but not ethane, as observed in

$$\mathbf{6} \longrightarrow \mathbf{3} + 2\,H_2C{=}CH_2 + 2\,H_2C{=}CHCH_3 \quad (e)$$

the ^1H NMR spectrum. However, larger-scale reactions of 1 : 1 molar ratios of **1** and **2** under various conditions (Table 1) were consistent with this observation. Production of ethane can be explained by assuming that the decomposition takes place partially as shown in Equation (f).

$$\mathbf{6} \longrightarrow \tfrac{2}{3}\,\mathbf{3} + \tfrac{4}{3}\,H_2C{=}CH_2 + \tfrac{2}{3}\,H_2C{=}CHCH_3 + \tfrac{2}{3}\,C_2H_6 + \tfrac{1}{3}\,\mathbf{4} + \tfrac{1}{3}\,\mathbf{2} \quad (f)$$

Table 1. Yields of gaseous products [a] and **3** from reaction of **1** and **2**.

Experiment	Yields [%] $H_2C{=}CH_2$	$H_2C{=}CHCH_3$	C_2H_6	**3**
1 [b]	1.8	1.6	0.40	84.2
2 [c]	1.9	1.4	0.55	89.9
3 [d]	1.8	1.6	0.40	86.0

[a] mol gas/mol Mg. [b] Isolated $\mathbf{5}\cdot 6\,THF$ decomposed by warming from -78 to 25 °C in THF. [c] **1** and **2** (molar ratio 1 : 1) reacted at $-78\,^{\circ}C$ to form the white solid which was then decomposed in situ by warming to 25 °C. [d] Reaction of **1** and **2** (molar ratio 1 : 1) at 25 °C.

The yields of the gases and **3** (Table 1) are in agreement with those calculated for simultaneous decomposition via Equations (e) and (f) to the extent of approximately 60 and 40%, respectively. The decomposition of **6** via Equation (f) probably occurs, owing to the reversibility of Equation (b), by reaction of **6** with small amounts of **1** to produce **7**, which can subsequently decompose as shown in Equation (d). The presence of **1** and **2** in the ^1H NMR spectrum of the isolated **5** supports this proposed pathway. The partial decomposition of **6** via Equation (f) in the absence of excess **1** suggests that reductive elimination of ethane from **6** is more favorable than that of propene. This parallels the decreasing order of reactivity towards reductive elimination from $[(Ph_3P)_2Pt(H)R]$ complexes (R): Ph > C_2H_5 > CH_3 > $CH_2{=}CHCH_2$.[21]

These results are, to our knowledge, the first observations of discrete organobimetallic complexes which undergo reductive elimination to produce intermetallic compounds or intermetallic carbides as reaction products.

Experimental Procedure

All manipulations were performed in air- and water-free solvents under Ar. All ^1H and ^{13}C NMR spectra were referenced to $[D_8]$THF.

3: **2** (5.68 g, 30.2 mmol) in THF (40 mL) was added dropwise to a stirred solution of **1** (5.51 g, 66.8 mmol) in THF (30 mL) over 45 min. The gases evolved from the reaction were collected in a gas buret and quantitatively analyzed by mass spectrometry. After 18 h the THF and remaining gaseous products were removed in vacuo (0.1 mbar) into -78 and $-196\,^{\circ}C$ traps, respectively. The GC analysis of the THF from the $-78\,^{\circ}C$ trap showed that it only contained trace amounts of propene (<0.05%). The $-196\,^{\circ}C$ trap gases were also subjected to MS analysis. THF was added to the black residue remaining in the reaction flask and the solution stirred for 12 h. The resulting black solid was collected by filtration, washed with THF and pen-

tane, and dried under high vacuum. Yield: 3.91 g (93.1%). Elemental analysis: Pd 76.29%, Mg 17.58%, C 4.93%, H 1.11% ($PdMg_{1.01}C_{0.57}H_{1.54}$).

5: **1** (0.71 g, 8.61 mmol) and **2** (1.65 g, 8.60 mmol) were dissolved in THF (20 mL) in separate flasks; the solutions were cooled to −78°C and then combined. After stirring for 24 h, the resulting white solid was filtered at −78°C, washed with THF and pentane, and dried under high vacuum at −78°C. Elemental analyses: calculated for **5**·6THF, Pd 15.12%, Mg 3.45%, C 58.02%, H 9.76%; found, Pd 14.69%, Mg 3.54%, C 48.11%, H 8.38%. Low-temperature elemental analysis performed by Dornis & Kolbe, Mülheim a. d. Ruhr (FRG). Intermediate **5** used for the decomposition experiment (Table 1) was prepared analogously.

Host-Guest Bonding of Oxoanions to Guanidinium Anchor Groups**

By *Gerhard Müller, Jürgen Riede,* and *Franz Peter Schmidtchen**

Our concept for the construction of synthetic, selective host molecules by linear coupling of recognition functions[1,2] requires, inter alia, the most specific anchor groups possible for the anionic substructures of the guest. This suggests adaptation of the recognition principle of many biogenic hosts which preferentially utilize the interaction between the guanidinium function of arginyl side chains and carboxylate or phosphate groups[3] (Scheme 1a). On the basis of this bonding pattern of the natural receptors, for which theoretical calculations also confirm a high stability,[4] we designed the abiotic binding groups shown in Scheme 1b for oxoanions, for these should essentially fulfill the following requirements: by the binding of the guanidine structure in an essentially strain-free bicyclic compound, host-guest complexation should lead, as in the case of the natural prototypes, not only to a topologically unmistakable complex structure but, at the same time, orientation and spacing of the guest should be defined within narrow limits by the host without having to resort to molecular inclusion in a macrocyclic host. The substituents on the α,α′-C atoms should provide for the covalent coupling of further bonding groups and be utilizable for the anchoring of the host to a solid support; the stereogenicity of these ring positions should force the guest into a fixed dissymmetric environment. The combined effect of several bonding functions ought to make the desired enantioselective recognition of the substrate possible. We present here

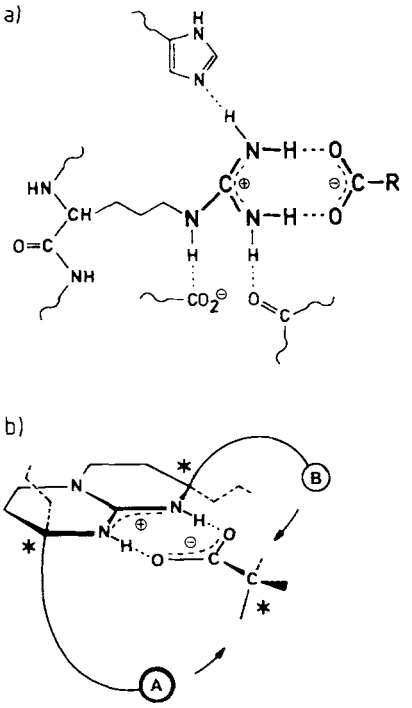
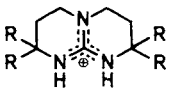


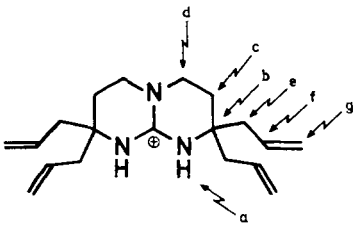
Scheme 1.

NMR spectroscopic and crystallographic proof that the symmetrically substituted guanidinium salts **1**–**3** fulfill the premise of this concept, the binding of oxoanions analogously to that found in natural products (Scheme 1b).



1, R = CH_3
2, R = CH_2-CH=CH_2
3, R = CH_2-CH_2-CH_2-OH

The construction of the characteristic hydrogen-bonding pattern in the course of the host-guest complexation with anions ought to be easily observed if the host does not already contain this structural element. Therefore, the readily crystallizable tetraphenylborates of **1** and **2**[5] and of the hydroxypropyl derivative accessible from **2** by hydroboration and oxidation were suitable for investigations with the aid of NMR spectroscopy. The salts are readily soluble in dipolar solvents (acetonitrile, nitromethane) and their NMR signals do not show any concentration dependence. Even the addition of tetrabutylammonium perchlorate ($TBAClO_4$) has no influence on the signal positions. If, however, a solution of **2** · BPh_4 in CD_3CN is titrated with TBA·*p*-nitrobenzoate in the same solvent, significant shifts of all resonances are observed in the ^{1}H-NMR spectrum (Fig. 1). Especially drastic is the down-field shift of the NH signal ($\Delta\delta > 5$ ppm). Apart from slight changes in the region of the strongly coupled olefinic protons no new signals appear in the spectrum. This picture is to be expected for a host-guest system in which host and complex show the same symmetry elements on time average and rapid guest exchange leads to concentration-weighted signal positions. The shape of the titration curve shows a distinct 1 : 1 stoichiometry of the host-guest interaction, but only a lower limit for the complex stability ($K_{diss} < 10^{-4}$ M) can be estimated under these conditions. Even the ^{1}H-resonances of the *p*-nitrobenzoate are shifted a small amount ($\Delta\delta < 0.03$ ppm) to higher field, whereby the four-line AB system degenerates into almost a singlet. Like the proton signals, the ^{13}C- (see Fig. 1) and ^{15}N-resonances[6] of the bicyclic guanidinium ion **2** are also shifted. Especially striking is that large shifts are observed only for the signals of the molecular hemispheres which are constitutively or spatially in the neighborhood of the guanidinium NH. The host-guest complexation must therefore occur at this substructure of the host, although we have not succeeded in demonstrating a homonuclear intermolecular nuclear Overhauser effect between **2** and *p*-nitrobenzoate.



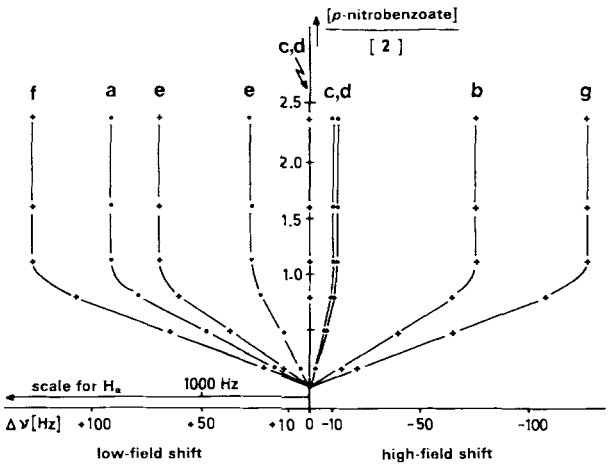


Fig. 1. NMR titration (360 MHz ^{1}H = ●; 90 MHz ^{13}C = +) of **2** · BPh_4 (0.05 M) with TBA·*p*-nitrobenzoate in CD_3CN.

In a similar way as for the described carboxylate, NMR signal shifts are also found with $H_2PO_4^\ominus$ or $Cl^\ominus$ as guest anions. Since qualitatively the same effects are observed, the site of binding of the guest is undoubtedly the same in all cases. Even the hydroxy functions in the side chains of **3** do not decisively alter the mode of binding of an oxoanion to the guanidinium fragment. Only the distinctly smaller overall shift of the NH signal, in particular, gives an indication that additional hydrogen bridges of the carboxylate to the side chains weaken the interaction between the guanidinium fragment and the anion.

In the weaker solvating solvent $CDCl_3$ the free rotation of the allyl substituents of **2** · BPh_4 is hindered, so that the methylene protons show an ABX coupling pattern. Addition of *p*-nitrobenzoate simplifies this to an A_2X system, thus confirming the large flexibility of the host in the host-guest complex. Moreover, even more pronounced line shifts are observed in the ^{1}H-NMR spectrum in this solvent, and also a small hypsochromic shift of the long wavelength UV absorption bands of the guest now accompanies the host-guest bonding. According to *Benesi* and *Hildebrand* the dissociation constant of the host-guest complex can be determined as $K_{diss} = 7 \times 10^{-6}$ M. This extraordinary stability of the ion-pairing between two monovalent ions likewise indicates a special complex structure.

Direct observation of the host-guest configuration was made possible by the determination of the crystal structure of **3**·acetate.[7] It confirms the symmetric bonding pattern of the acetate ions via two H-bridges to both N-atoms of the guanidinium counterion (Fig. 2). The guanidinium fragment is, to a very good approximation coplanar with the acetate ion and the H-bridge system; this can be regarded as an indication of considerable stability of the observed host-guest interaction. The short N2...O01 distance (2.850(5) Å) also indicates that the H-bridges are strong. Moreover, there is a further connection between host and guest via two of the side chains of **3** by two further H-bridges O1-HO1...O01'' (O1...O01'' 2.733(5) Å) to acetate O-atoms. Particularly remarkable is the fact that, at least in the crystal, this connection is not intramolecular but links the cation-anion pair **3**·acetate into polymer strands (Fig. 2).

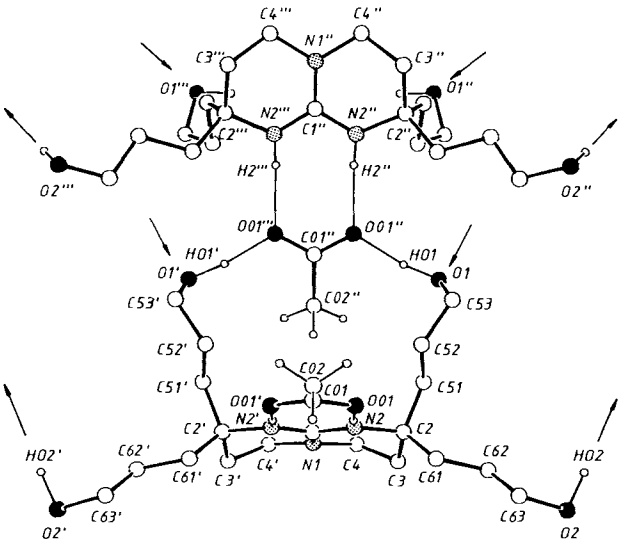

Fig. 2. Section of the crystal structure of **3**·acetate (ORTEP, atoms with arbitrary radii, only N- and O-bonded H atoms are shown). The molecular moiety **3**·acetate has crystallographic mirror symmetry, the mirror plane contains the atoms N1, C1, C01 and C02. The illustrated strands (**3**·acetate)$_x$ are generated by a crystallographic glide plane (a) and connected with one another by four H-bridges per **3**·acetate (O2-HO2...O1*/O2*-HO2*...O1; indicated by arrows) via inversion centers.—Important bond lengths [Å] and angles [°]: N1-C1 1.333(7), N2-C1 1.338(5), C01-C02 1.497(8), C01-O01 1.258(4); N1-C1-N2 121.4(3), N2-C1-N2' 117.2(5), C02-C01-O01 118.5(3), O01-C01-O01' 123.1(6). H-bridges: N2-H2···O01 0.88(4)/1.97(4), O1-HO1···O01'' (−0.5+x,y,2.5−z) 1.08/1.66, O2-HO2···O1* (−x,1−y,2−z) 1.20/1.70.

Since these H-bridges are shorter they must be even stronger than those between acetate ion and guanidinium fragment, which is consistent with the NMR observations. The two remaining side chains surprisingly do not participate in the host-guest interaction, but couple the strands together by H-bonding with the hydroxy O-atoms O1* of neighboring guanidinium ions **3**, so that all NH- and OH-functions participate in H-bonding in the crystal.

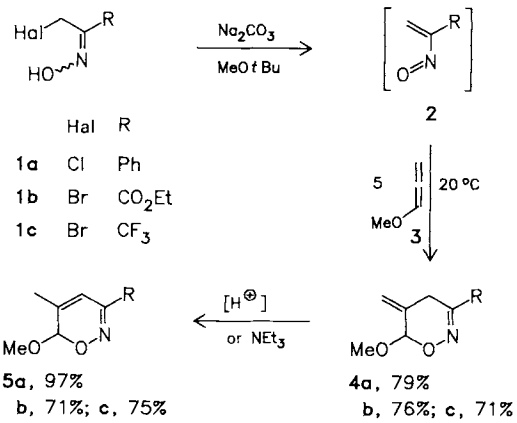
Methoxyallenes as Components in Diels–Alder Reactions with Inverse Electron Demand: Synthesis of 6*H*-1,2-Oxazines**

By *Reinhold Zimmer* and *Hans-Ulrich Reissig**

During the last few years acceptor-substituted allenes have been used for various pericyclic reactions.[1] In contrast, electron-rich allenes, some of which are much more readily accessible, have hardly been employed at all. Herein we report on Diels–Alder reactions with inverse electron demand[2] involving various methoxyallenes.

The nitrosoalkenes **2**, generated in situ from α-halo oximes **1** and sodium carbonate (Scheme 1),[3] add smoothly to methoxyallene **3**[4] (five equivalents). Of the four conceivable regioisomeric cycloadducts, only the heterocycles **4** containing an *exo*-methylene group at C-5 are formed, as



Scheme 1. Synthesis of 6*H*-1,2-oxazines **4** and **5**. The yields given are based on **1** or **4**, respectively.

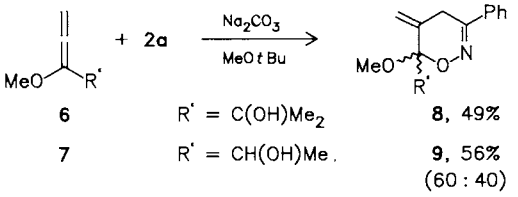
expected in view of the electronic properties of the reaction partners.[5] Conjugation of the exocyclic double bond may be achieved by treatment with bases or, more quickly, under acid catalysis. The 6*H*-1,2-oxazines **5** are thereby obtained in good yields.

Since **3** can be easily substituted at C-1 by deprotonation and subsequent reaction with electrophiles,[6] it is also possible to synthesize 1,2-oxazine derivatives containing two substituents in the 6-position. Whereas the addition of **2** to 1-alkylated methoxyallenes affords only moderate yields (e.g., 30% yield of 1-methyl-1-methoxyallene and **2a**), the sterically encumbered hydroxylated allenes **6** and **7** give the functionalized heterocycles **8** and **9**, respectively, with reasonable efficiency. A moderate diastereoselectivity (60:40) was found in the cycloaddition of **2a** to **7** to give **9**. The products **8** and **9** can also be transformed into the conjugated systems **5** by treatment with base.



1,2-Oxazines are compounds of little explored but readily apparent synthetic potential.[7] We therefore investigated transformations of the heterocycles **5**. Oxidation of **5a** with pyridinium chlorochromate (PCC) affords the 1,2-oxazin-6-one **10**;[8] treatment with $BF_3 \cdot OEt_2$/allyltrimethylsilane results in C–C bond formation to give **11**. This reaction, like the reduction with triethylsilane in the presence of the Lewis acid $BF_3 \cdot OEt_2$ to give **12**, probably proceeds via the intermediacy of an azapyrylium ion.[9] Reaction of **5a** with aluminum amalgam[7a] gives the pyrrole derivative **13**.[10] These reactions point to the diverse possible reactions of 6*H*-1,2-oxazines. Table 1 contains relevant physical data of characteristic compounds.

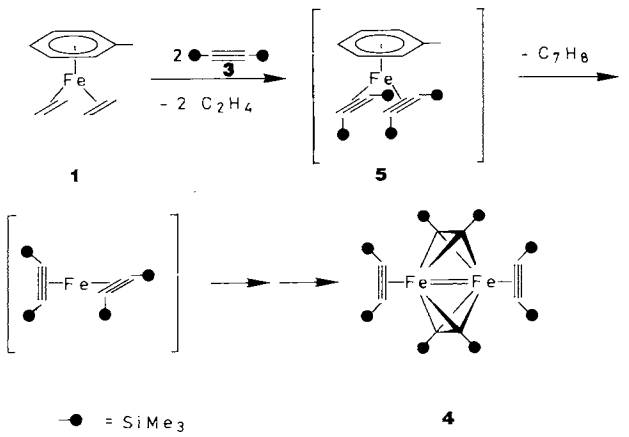
[**] Reactive π-Complexes of the Electron-rich Transition Metals, Part 7. This work was supported by the Stiftung Volkswagenwerk. Part 6: [1].

lyl)ethyne]diplatinum,[2] which, according to its spectra, has a dimetallatetrahedrane structure. Since such clusters are of considerable importance as intermediates in the catalytic and stoichiometric reactions of alkynes with transition metals, there has been no lack of attempts to synthesize further complexes of this type. Among other methods, metal-atom chemistry has been employed[3] and, especially in the case of iron, has afforded unexpected results. Thus, the cocondensation of iron atoms with butyne-2 yielded decamethylferrocene[4] and the corresponding reaction with bis(trimethylsilyl)ethyne gave a product of variable composition ($[Fe\{(SiMe_3)_2C_2\}_x]$, $x = 1.8$–4.0).[5]

The reaction of the reactive iron complexes **1** and **2**, readily accessible by a metal-atom reaction, with alkynes results in catalytic cyclotrimerization. This is not the case, however, for bis(trimethylsilyl)ethyne **3**.[1] When a mixture consisting of **3** and either **1** or **2** is allowed to stand *with-*

$[Fe(\eta^2\text{-}C_2H_4)_2(\eta^6\text{-PhMe})]$ **1**[6]
$[Fe(\eta^4\text{-1-Me-}C_{10}H_7)(\eta^6\text{-PhMe})]$ **2**[7]

out agitation at room temperature for several days, **4** (tetrakis[bis(trimethylsilyl)ethyne]diiron) crystallizes as large, analytically pure, lustrous black crystals, containing, as the sole impurity, 0.1 to maximally 0.3% of metallic iron.



The yield lies between 70 and 98%, independent of which of the reaction components is used in excess. Compound **4** is only sparingly soluble in the conventional polar and nonpolar solvents at room temperature and, as a solid, only slightly air-sensitive. To remove the traces of metallic iron, **4** is dissolved in a large volume of toluene at 80 °C, the solution is stirred in the presence of pieces of ferrite, and the suspension is then filtered. Compound **4** crystallizes from the filtrate at 20 °C. The ^1H NMR spectrum of **4** shows two singlets at $\delta = 0.3$ and -0.2 in a ratio of 1 : 1. The low solubility of **4** prevented the recording of a ^{13}C NMR spectrum.

The nearly quantitative formation of **4** by reaction of **1** or **2** with **3** is easily explained if the bis(alkyne)-(toluene)iron **5** is assumed as an intermediate.

Normally, compounds of type **5** rearrange to ferrols,[1] a reaction pathway that is blocked in the case of **3** as alkyne ligand owing to the large substituents. If, instead, the toluene ligand is lost, a bis(alkyne)iron is formed which formally dimerizes via at least one further intermediate. The existence of a further intermediate is shown by a trapping experiment with trimethyl phosphite, which, at -20 to 0 °C, affords the paramagnetic binuclear complex **6** in good yields; the structure of **6** has not yet been established. Neither **5** nor **4** can be considered as a direct precursor of **6**, since **5** reacts with trimethyl phosphite to

$[Fe_2\{(Me_3Si)_2C_2\}_3\{P(OMe)_3\}_2]$ **6**[1]

give tris(trimethylphosphite)(bis(trimethylsilyl)ethyne)-iron[1] and **4** reacts with trimethyl phosphite only above 80 °C and then to afford only low yields of **6**. In contrast to many other binuclear complexes containing metal-metal multiple bonds,[8] **4** has so far proved to be quite resistant to reaction.

Complex **4** was characterized by a crystal structure analysis[9] (Fig. 1). The cluster framework can be described as two edge-sharing tetrahedra in which the iron atoms define

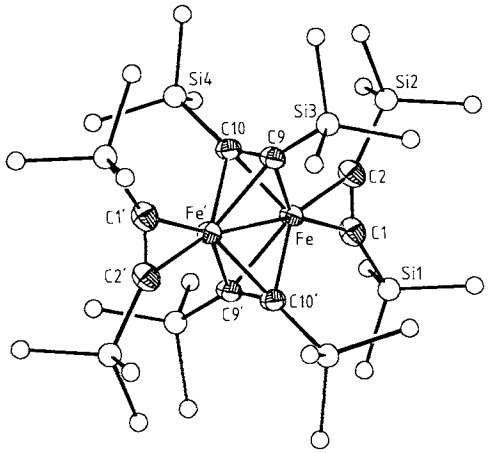


Fig. 1. Molecular structure of **4**. Selected bond lengths [Å] and angles [°]: Fe-Fe' 2..465(1), Fe-C1 and Fe-C2 1.972(2), Fe-C9 2.078(2), Fe-C9' 2.079(2), Fe-C10 2.076(2), Fe-C10' 2.082(2), C1-C2 1.288(3), C9-C10 1.314(3); C1-C2-Si2 141.8(2), C2-C1-Si1 141.4(2), C9-C10-Si4 149.8(1), C10-C9-Si3 149.6(1).

the shared edge. Accordingly, the bridging carbon atoms C9, C10, C9', and C10' define a rectangle lying perpendicular to the edge Fe-Fe'. The axes C1-C2 and C1'-C2' of the terminal alkyne ligands lie perpendicular to the axes C9-C10 and C9'-C10'. The Fe-Fe' distance lies in the range expected for localized single bonds;[10] however, the presence of a single bond is contradicted by the diamagnetism of the cluster, which has 32 valence electrons if one assumes that the terminal $(Me_3Si)_2C_2$ provide four π-electrons.

In terms of structure and electron count, **4** is closely related to the clusters $[(\mu\text{-}t\text{Bu}_2C_2)_2Fe_2(CO)_4]$[11] and [(μ-3,3,6,6-$Me_4$-1-thiacyclohept-4-yne)$_2Fe_2(CO)_4$].[12] In those two cases, the short Fe-Fe distance (2.215 and 2.225 Å, respectively), corresponds to a double bond. Owing to its diamagnetism, **4** should also have a double bond which, compared with those in carbonyl clusters, is lengthened by about 10%. Its length is similar to that determined for μ-hexamethylbenzenebis(cyclopentadienyliron) (2.424 Å).[13]

Comparison of the results presented here with the little information available on the cocondensation product formed between iron atoms and **3**[5] indicates that, in that case, too, a large part of the product consists of **4**, which, owing to its sparing solubility, could not be separated from the side products. The contrasting high selectivity and high yields of the reaction of **1** or **2** with **3** documents the value of multistep syntheses based on an effective cocondensation reaction. Complex **4** was formed here in a total of three reaction steps:

① iron atoms + toluene ⟶ bis(toluene)iron

② bis(toluene)iron + ethene ⟶ **1**[6]

or

② bis(toluene)iron + 1-methylnaphthalene ⟶ **2**

③ **1** (**2**) + **3** ⟶ **4**

The yields via the three steps are 30–50% based on the iron vaporized.

Partially Reversible Intercalation of Ferrocene in a Zeolite-like Host Lattice Consisting of $Fe(CN)_6$ and Me_3Sn Units**

By *Peter Brandt, Abdul K. Brimah,* and *R. Dieter Fischer**

Dedicated to Professor Ernst Otto Fischer on the occasion of his 70th birthday

While the existence of highly symmetric 3D networks of the general type

$[M(\mu\text{-}CN\text{-}A\text{-}NC)_3]_\infty$ **1**

1, composed of exclusively linear $\dashv M-C\equiv N\rightarrow A\leftarrow N\equiv C\vdash_\infty$ chains ("super Prussian blue" analogues), has not been established with certainty,[1] 3D coordination polymers of a similar composition but with chains bent at the N atom have been known for some time (e.g., M = Co and A = Ag, H[2]).

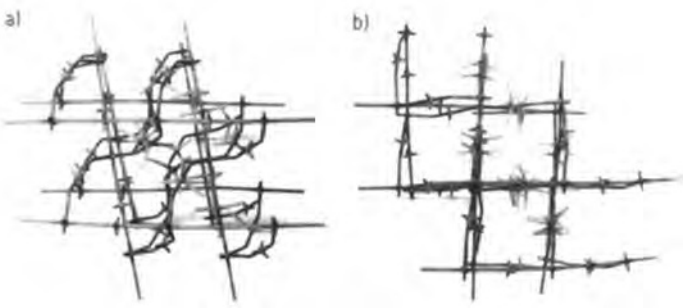

Fig. 1. Minit model (section) of the lattice structure of **1a**. a) View in the direction of "closest" packing. b) View in the direction of parallel channels.

Interestingly, in the recently described compound **1a**, M = Co, A = Me_3Sn, up to one-third of the $\dashv Co-C\equiv N\rightarrow Sn\leftarrow N\equiv C\vdash_\infty$ chains are linear.[1] Although the structure of **1a** (Fig. 1) cannot give rise to a density as low as that of its hypothetical isomer composed of exclusively linear chains, the lattice of **1a** displays strictly parallel channels extending in one direction with nearly square cross sections (Fig. 1b). Their maximum size is ca. 6.8×6.8 Å^2 since the positions of the methyl groups are not rigidly fixed, and the inclusion of, e.g., ferrocene molecules (ca. 4.4×3.3 Å^2[3]) may therefore be expected.

Actually, simple grinding of the orange-yellow, slightly wetted (H_2O) **1b**, M = Fe,[4] with ferrocene (Cp_2Fe) results in quantitative formation of the deep blue and, like **1**, paramagnetic[5] ferrocenium intercalate **2**[6] [Eq. (a)].

$$[(Me_3Sn)_3Fe^{III}(CN)_6]_\infty + Cp_2Fe^{II} \longrightarrow [Cp_2Fe^{III}(Me_3Sn)_3Fe^{II}(CN)_6]_\infty \quad \text{(a)}$$

1b → **2**

The likewise rapid formation of blue **2** from the starting materials spatially separated by a **1a** pellet[7,8] demonstrates a high diffusion rate of the guest species in **1a**, too,[9] in accordance with the earlier X-ray analysis.

In addition to some vibrational bands diagnostic of the ferrocenium ion, the ν_{CN} absorptions characteristic of distorted $[Fe^{II}(CN)_6]$ octahedra and the $(\nu_{SnC})_{as}$ band, the IR spectrum[10] of **2** shows, e.g., the medium-intense $\delta_{Fe^{II}C}$ band at 600 cm^{-1}[18] which is absent in the spectra of **1a** and **1b**. The ^{57}Fe Mössbauer spectrum[11] displays the singlets of the newly formed $[Fe^{II}(CN)_6]^{4\ominus}$ unit and of the $[Cp_2Fe^{III}]^{\oplus}$ ion, while the doublet of the $[Fe^{III}(CN)_6]^{3\ominus}$ unit of **1b** is absent.

The spectroscopic data confirm that the solid-state reaction of Cp_2Fe with **1b** is—in contrast to that with, e.g., tetracyanoethylene[12]—a genuine redox reaction. At moderately high temperatures (80–160 °C) under high vacuum, it is, nevertheless, possible to sublime off about half of the incorporated Cp_2Fe. In the IR spectrum of the black powder (**3**) of empirical formula $Fe_{0.4}(Me_3Sn)_3Fe(CN)_6$ remaining after exhaustive sublimation,[13] all $[Cp_2Fe^{III}]^{\oplus}$ bands are absent, while the other absorption regions in the spectrum of **3** do not differ notably from those of **2**.[10]

Apart from a singlet due to the presumably diamagnetic $[Fe^{II}(CN)_6]^{4\ominus}$ structural unit, the ^{57}Fe Mössbauer spectrum of **3**[11] shows a new, broad doublet, which, owing to its isomeric shift and the relatively high paramagnetism of **3**[5] (based on the concentration of incorporated iron), may be

best ascribed to high-spin Fe^{II} ions. The elemental analysis and the black "color" of **3**, as well as an optimal calculated fit of the Mössbauer spectrum, do not rule out that **3** is an intercalate of both Fe^{II} and Fe^{III} (**3′**/**3″**) ions [Eq. (b)].

The X-ray powder patterns of microcrystalline **2** and **3** are very similar; however they differ markedly from those of compounds **1a** and **1b**.

Whereas many examples of an intercalation of metallocenes in inorganic layer-structure compounds are known,[14] little information is available on the inclusion of Cp_2Fe into "classical zeolites.[15] A major goal of such experiments is to obtain, after replacement of the organic ligands in the intercalated complex, iron/zeolite intercalates that are likely to exhibit optimal catalytic activity. The readily accessible iron-ion intercalate **3** described here, as well as analogous products containing other metal ions,[16] could be an interesting alternative to metal-ion intercalates based on zeolites or $AlPO_4$.[17]

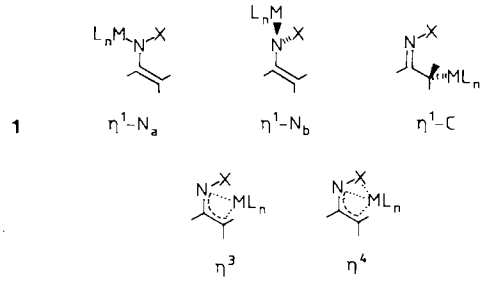
Structure of a Chiral Lithium Azaenolate: Monomeric, Intramolecular Chelated Lithio-2-acetylnaphthalene-SAMP-hydrazone**

By *Dieter Enders,* Gerhard Bachstädter, Kenneth A. M. Kremer, Michael Marsch, Klaus Harms,* and *Gernot Boche**

In the form of metalated alkylideneamines, oximes, oxime ethers, hydrazones and their heterocyclic analogues, "1-azaallyl anions" (metalloenamines, alkylideneamine anions, azaenolates) **1** have gained increasing importance in synthetic chemistry over the past 15 years.[1] In particular, the fact that practically complete asymmetric inductions can be achieved with chiral azaallylmetal reagents **1**[1–3] has prompted numerous experimental[1–3] and theoretical[4] investigations of the structure of these compounds and their selective reactions with electrophiles. Thereby, η^1-N_a-, η^1-N_b-, η^1-C-, and η^3- and η^4-structures have been discussed (Scheme 1).



Scheme 1. Possible structures of 1-azaallyl anions 1.

Although it has recently been possible to gain insights into the bonding behavior of some 1-azaallylmetal com-

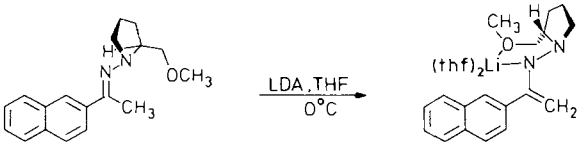
pounds by X-ray structure analyses,[5-12] of more particular importance are X-ray structure investigations on synthetically useful chiral azaenolates.[1-3] In the following communication we report on the crystal structure of an enantiomerically pure lithium azaenolate. Deprotonation of 2-acetylnaphthalene-SAMP-hydrazone (*S*)-**2** with lithium



(*S*)-**2** (*S*)-**3**

diisopropylamide (LDA) in tetrahydrofuran at 0°C affords the lithio-SAMP-hydrazone (*S*)-**3**, which crystallizes in the form of ruby-red crystals as monomeric, intramolecularly chelated (*S*)-**3** · 2 THF[13,14] (Fig. 1).[15]

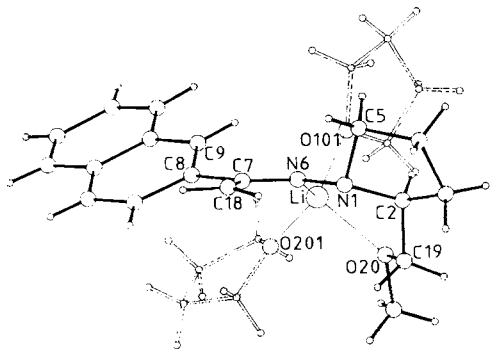


Fig. 1. Crystal structure of (*S*)-**3** · 2 THF [18]. Important bond lengths [pm] and angles [°]: C18-C7 137.2(2), C7-N6 136.9(2), N6-N1 145.0(2), N6-Li 195.8(3), O20-Li 200.4(3), O201-Li 198.2(3), O101-Li 198.9(3), C7-C8 149.4(3),; C18-C7-N6 129.0(2), C7-N6-N1 110.0(1), N1-N6-Li 118.8(1), C7-N6-Li 127.6(1), C18-C7-N6-Li 157.73(0.31), C18-C7-N6-N1 −0.52(0.41), C7-N6-N1-C5 −87.85(0.27), C7-N6-N1-C2 163.64(0.22), C18-C7-C8-C9 149.60(0.29).

(*S*)-**3** · 2 THF contains an almost planar N1-N6-C7-C18 array (torsion angle −0.52(0.41)°), in which, in analogy to enamine structures,[19] the N–N bond is synperiplanar to the CC "double bond" (C7-C18) (C18-C7-N6 129.0(2); C7-N6-N1 110.0(1)°). The C7–C18 bond (137.2(2) pm) is somewhat longer than the CC double bond in enamines (134 pm[19]), whereas the N6–C7 bond (136.9(2) pm) is somewhat shorter than the CN bond in enamines (138–142 pm[19]).

The sum of the angles at N6 is 356.4°, indicating only a slight pyramidalization and thus a relatively high sp^2 character at N6.[20] Accordingly, a favorable overlapping of the lone pair on N6 with the π electrons of the CC "double bond" and thus a pronounced delocalization in the azaallyl moiety is possible, consistent with the results of earlier NMR spectroscopic measurements.[21] It can be concluded from the C18–C7–C8–C9 torsion angle of 149.60(0.29)° that the naphthyl moiety on C7 is inclined at an angle of ca. 30° to the azaallyl plane.

As can be seen from the schematic side view of (*S*)-**3** · 2 THF (Fig. 2), the N6–Li axis is inclined downwards at an angle of 17.5(4)° relative to the azaallyl plane due to the intramolecular chelation by the methoxy group (the lithium atom lies 59(4) pm below the azaallyl plane). At the same time the pyrrolidine ring is bent upwards from the azaallyl plane (C7–N6–N1–C5 −81.85(0.27)°). The structure of (*S*)-**3** · 2 THF in the crystal shows the hitherto postulated intramolecular methoxy-chelation of the lithium ion and the (*Z*)-configuration at C7–N6 (*syn* effect).[22] The structure in solution could be similar, since according to cryoscopic measurements in tetrahydrofuran—i.e. under the standard conditions of asymmetric induction—and according to ^{1}H-NMR spectroscopic investigations (*S*)-**3** · 2 THF is likewise present as monomer.[14,23] Moreover, the "puckered" η^1-N_a structure with "lone pair"(N6)–π(CC) overlapping found here (see Scheme 1 and Figs. 1 and 2), as also the η^1-N_b structure (σ(NLi)–π(CC) overlapping[2]) postulated for lithiated oxazolines, is consistent with the proposed metallo-retentive S_E2'-front mechanism for asymmetric electrophilic substitutions at chiral azaenolates.[2,23-25]

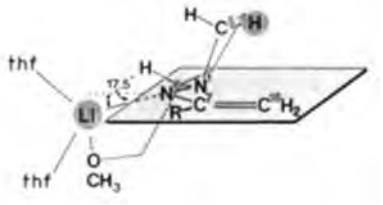

Fig. 2. "Side view" of (*S*)-**3** · 2 THF (schematic). R = 2-naphthyl.

[13] As alternative to the earlier procedure, which led to crystals that were unsuitable (twinning) for an X-ray structure analysis [14], the following method was used: An LDA solution, prepared from 2.5 mL of THF, 0.2 g (1.9 mmol) of diisopropylamine and 1.4 mL (2.2 mmol) of *n*-butyllithium (1.6 M in *n*-hexane) was treated dropwise under argon at 0°C with a solution of (*S*)-**2** [m.p. 62.63°C, $[\alpha]_D^{25} = +1041$ ($c = 1$, $CHCl_3$) (0.51 g, 1.8 mmol)]. The blood-red solution was stirred for 4 h at 0°C and than allowed to stand for 1 h at −78°C. Finally, the reaction product was crystallized out overnight at −18°C.

[25] As in the case of chiral oxazolines [2], a previously undiscussed, cooperative effect must also be taken into consideration in lithiated SAMP- and RAMP-hydrazones, namely the steric hindrance of an electrophilic attack at C18 from above by the C5 methylene group of the pyrrolidine ring (see Fig. 2). Accordingly, a sterically more demanding hydrazine auxiliary in this molecular region (two methyl groups on C5) shows, in preliminary experiments, an even more pronounced diastereofacial selectivity: D. Enders, G. Bachstädter, unpublished work.

On the Structure of the Cation $N_2H_7^{\oplus}$ with an N–H···N Hydrogen Bond in the Monoammonia Adduct of Ammonium Iodide**

By *Hans Joachim Berthold,* Wolfgang Preibsch,* and *Elke Vonholdt*

The cation $N_2H_7^{\oplus}$, which has the structure $[H_3N{-}H\cdots NH_3]^{\oplus}$, has only been detected so far in the gas phase by mass spectrometry and IR spectroscopy.[1-5] The energy of the hydrogen bond is ca. 104 kJ mol^{-1}.[1,2] By X-ray studies of powders and single crystals of $NH_4I \cdot NH_3$, we found that the unit cell of this compound contains the cation $N_2H_7^{\oplus}$. This afforded us the opportunity to investigate, for the first time, the structure of the cation in the solid state and to compare the results with those of calculations on the interaction $NH_4^{\oplus}\cdots NH_3$.

Owing to the great importance of the hydrogen bond in every field of chemistry and to the significance of the mechanism of proton transfer in biological processes for systems containing hydrogen bonds, interactions of the type $H_3O^{\ominus}\cdots H_2O$, $NH_4^{\oplus}\cdots NH_3$, $NH_4^{\oplus}\cdots H_2O$, etc. have been the subject of intensive theoretical investigation in recent years. The focus of interest in these studies has been on the bonding energy in the cationic complexes, the equilibrium distance (O–O, N–N, N–O, etc.), and the shape of the potential curve in both the equilibrium state and the transition state.[6-16]

The structure of the cation $H_5O_2^{\oplus}$ in crystalline compounds has been known for a long time—$[H_2O{-}H\cdots OH_2]^{\oplus}$[17-25]—so that the results of calculations carried out on this cation can be checked in detail. By contrast, reliable structural data for the cation $N_2H_7^{\oplus}$ are still lacking. The N–N equilibrium distances determined for the cation in the gas phase were calculated to be 250 to 296 pm, depending on the parameters and assumptions used in the ab initio calculations. Correspondingly large are the variations in the bonding energies (93–151 kJ mol^{-1}) as well as in the potential barriers in the equilibrium state (15–65 kJ mol^{-1}) and in the transition state for the transfer of the proton to the second minimum (6–31 kJ mol^{-1}). The proton transfer is associated with a contraction of the cation; all calculations were in close agreement as to the N–N distance in the transition state (258–259 pm).[7,11,13]

Assuming C_{3v} symmetry and a staggered conformation of the two NH_3 groups (all HNH angles 109.5°), *Scheiner* and *Harding*[13] calculated for the equilibrium distance (273.1 pm) a bonding energy of 130 kJ mol^{-1} and a potential barrier between the two minima (for fixed N positions) of 15.9 kJ mol^{-1}. In the transition state the barrier amounts to only 8.8 kJ mol^{-1}. The structural data are presented in Figure 1.

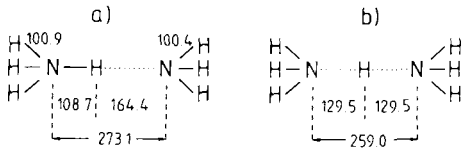

Fig. 1. Calculated distances [pm] in the $N_2H_7^{\oplus}$ cation according to *Scheiner* and *Harding* [13]. a) Equilibrium state. b) Transition state.

We have now been able to show that, owing to the interaction $NH_4^{\oplus}\cdots NH_3$, the cation $N_2H_7^{\oplus}$ is present in the crystalline monoammonia adduct of ammonium iodide $NH_4I \cdot NH_3$.

$NH_4I \cdot NH_3$ can be prepared according to the procedure of *Lindenberg*[26] by treatment of NH_4I at 298 K with gaseous NH_3 ($p = 195$ torr). *Lindenberg* determined a tetragonal unit cell ($Z = 4$) by powder diffractometry, but a structure determination was not carried out.[27,28]

X-ray investigations of powders of $NH_4I \cdot NH_3$—prepared at NH_3 pressures of between 350 and 450 torr—showed that the compound crystallizes in the cubic space group $Pm3m$ ($Z = 1$) at 298 K. Preliminary intensity calculations indicated the existence of the cation $N_2H_7^{\oplus}$ in the crystal.[29] The single-crystal X-ray structure analysis, carried out recently, confirmed these earlier results.

By using the refined positional parameters for nitrogen, one obtains an N–N distance of 269(5) pm. This value is somewhat smaller than the distance (273.1 pm) calculated by *Scheiner* and *Harding*[13] and clearly indicates a strong interaction between the $NH_4^{\oplus}$ ion and the NH_3 molecule in $NH_4I \cdot NH_3$. The assumption of the formation of the cation $N_2H_7^{\oplus}$ containing a hydrogen bond thus appears to be justified.

The cubic symmetry of the structure is the consequence of orientational disorder of the cation, whose center of gravity lies in ½½½ on a time average and whose N–H···N axis in the various unit cells points statistically in the direction of one of the three cubic crystallographic axes. Further, there is a positional disorder of the terminal H atoms around the threefold axes of $NH_4^{\oplus}$ and NH_3.

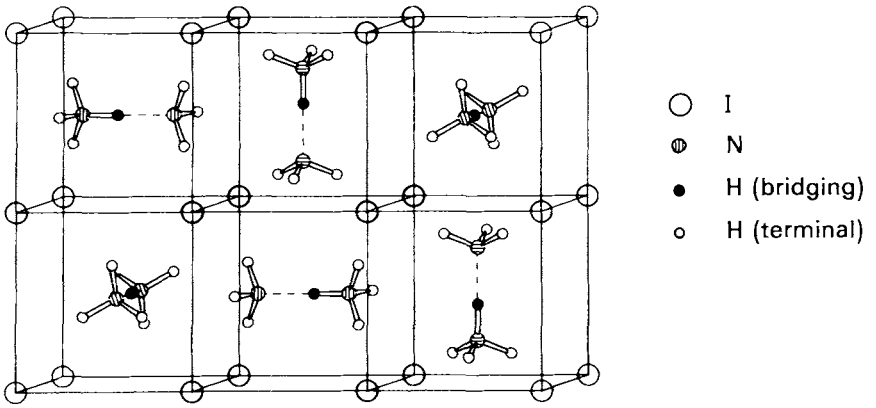

Fig. 2. Section of the structure of $NH_4I \cdot NH_3$ (298 K) containing six unit cells, assuming an arbitrarily specified transient order; cf. text.

Figure 2 shows a section of the structure of $NH_4I \cdot NH_3$ at 298 K assuming an arbitrary transient order. It shows the three orientations of the cation that are adopted statistically. The fact that the H atoms in the hydrogen bond can occupy two different positions has been taken into consideration for the six cations shown. Owing to the low potential barrier for proton transfer, exchange between the two minima is almost unhindered.[7]

Upon cooling $NH_4I \cdot NH_3$, three new phases appear, which are characterized by increasing order. In the tetragonal phase (ca. 203–230 K), the cation displays only a two-dimensional orientational disorder in the *xy* plane. In the orthorhombic phase (ca. 143–203 K), the cations are presumably ordered in the *xy* plane. Below ca. 143 K, a phase with a complex diffraction diagram appears which could not be indexed. We assume that, in this phase, the terminal H atoms occupy ordered equilibrium positions. The deuterated compound $ND_4I \cdot ND_3$ has the same cubic structure as $NH_4I \cdot NH_3$ at 298 K. However, upon cooling, direct transformation to the orthorhombic phase occurs at ca. 237 K and an unknown phase is formed at ca. 147 K. Further details on the structure of the cation—particularly in the phase that is stable at very low temperatures—should be provided by neutron diffraction studies, which are in progress.

Investigations of $NH_4I \cdot NH_3$ and $ND_4I \cdot ND_3$ in the various phases (including partially deuterated samples) by laser Raman spectroscopy, as well as by neutron scattering experiments on the two compounds at 5–298 K, have confirmed the strong interaction $NH_4^{\oplus} \cdots NH_3$ and $ND_4^{\oplus} \cdots ND_3$.

Experimental Procedure

$NH_4I \cdot NH_3$: Cubic phase: $a = 512.9(3)$ pm (298 K), space group *Pm3m*, $Z = 1$. Three-dimensional intensity data were obtained by measurement of a single crystal of $NH_4I \cdot NH_3$ contained in a capillary by means of a four-circle diffractometer (Stoe Siemens AED2) with $Mo_{K\alpha}$ radiation (graphite monochromator): 2051 reflections, $2\theta(\max) = 51°$). After data reduction, 44 unique reflections were available for the least-squares refinement (program: SHELX 76). Iodine occupies the position 1a (000); the two nitrogen atoms are distributed statistically at the positions 6*f* (x 1/2 1/2, occupation factor 1/3, $x = 0.238(5)$). $R = 1.9\%$, $R_w = 1.7\%$, and $R_G = 1.9\%$, N–N distance 269(5) pm; tetragonal phase: $a = 525(1)$, $c = 485(1)$ pm (220 K), space group *P4/mmm*, $Z = 1$; orthorhombic phase: $a = 751(1)$, $b = 743(1)$, $c = 479(1)$ pm (202 K), $Z = 2$ (C-centered).

$ND_4I \cdot ND_3$: Cubic phase: $a = 513.3(7)$ pm (298 K), space group *Pm3m*, $Z = 1$; orthorhombic phase: $a = 759(1)$, $b = 745(1)$, $c = 478(1)$ pm (233 K), $Z = 2$ (C-centered).

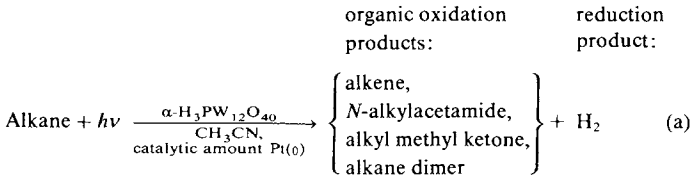
Selective Photochemical Dehydrogenation of Saturated Hydrocarbons with Quantum Yields Approaching Unity**

By *Roman F. Renneke* and *Craig L. Hill**

The development of systems for the effective and selective catalytic functionalization of alkanes continues to be a topic of intense research interest. The activation and/or functionalization of alkanes by organometallic complexes,[1] metalloporphyrin-based systems,[2] electrophilic species,[3] the Gif and Gif-Orsay systems,[4] photosensitized Hg vapor,[5] and polyoxometalates[6, 7] continue to evolve rapidly. Our group recently developed both thermal[6] and photochemical[7] systems for the selective functionalization of unactivated hydrocarbons based on early-transition-metal polyoxometalate derivatives, for these complexes are not only thermodynamically resistant to oxidative degradation, but also soluble, experimentally tractable, and amenable to extensive synthetic modification. The initial research on polyoxometalate-based photochemical alkane functionalization involved primarily an in-depth examination of the reactions of α-$H_3PW_{12}O_{40}$ and related polyoxotungstate compounds of T_d symmetry [Eq. (a)].



(a)

These systems exhibit moderate to high selectivities with respect to production of organic products, operate best with mid UV light, and use only 10% of the incident radiation for the formation of the products shown in Equation (a); greater than 90% is lost in radiationless processes. Three processes sum to the net reaction in Equation (a): absorption of light by polyoxometalate, P [Eq. (b)]; oxidation of the alkane by the polyoxometalate excited state, P*, with production of reduced polyoxometalate, P_r [Eq. (c)]; and a thermal reoxidation of P_r by H_2 evolution [Eq. (d)].[7]

$$P + h\nu \longrightarrow P^* \quad (b)$$

$$P^* + \text{alkane} \longrightarrow P_r + \text{alkene and other products} + 2H^{\oplus} \quad (c)$$

$$P_r + 2H^{\oplus} \longrightarrow P + H_2 \quad (d)$$

We report here the remarkable effect of acid on the catalytic photochemical functionalization of alkanes by polyoxometalates and the development of a new system based on two types of oxidatively resistant species, decatungstate and strong mineral acids, that utilizes near UV and visible light ($\lambda > 360$ nm) and results in the selective dehydrogenation of alkanes with quantum yields approaching unity.

Table 1 summarizes the results from several alkane photochemical dehydrogenation reactions by representative polyoxometalates present in free acid ($H^{\oplus}$), $NH_4^{\oplus}$, or n-$Bu_4N^{\oplus}$($Q^{\oplus}$) forms. The quantum yields are specifically defined here as the number of electrons in the reduced polyoxometalate product divided by the number of photons absorbed by that polyoxometalate. All reactions were run using 3.3 mM polyoxometalate and 0.45 M alkane substrate in acetronitrile contained in quartz cuvettes under an Ar atmosphere at 25°C. The light for all reactions was from a 1000-W Xe lamp filtered through infrared and UV/VIS cut-off filters ($\lambda > 360$ nm) for determination of organic products, or filtered through a 320-nm interference filter (peak width at half height = 9.6 nm, transmission maximum at 320 nm = 21%) for determination of the quantum yields. All measurements of the quantum yields were conducted under optically dense conditions (> 99% of the incident light was absorbed by the systems). The cyclooctane and cyclohexane reactions with decatungstate, both in the presence and absence of acid, showed product distributions that were independent of the light intensity and the wavelength of irradiation; a 320-nm interference filter and 295-, 320-, 360-, and 395-nm cut-off filters were all used in the latter experiments. For the acidified decatungstate reactions, irradiation even at the tail end of the absorption envelope (395-nm cut-off filter) results in the reasonably fast functionalization of alkanes. This light, although substantially lower in energy and hence potentially more selective than that often used in photochemical reactions (e.g., Hg light/quartz vessel; $\lambda > 190$ nm), is nevertheless adequate to produce the excited states of polyoxometalates that are kinetically competent to oxidize even saturated hydrocarbons! None of the acids at the concentrations given in Table 1 produced any detectable decomposition of $[W_{10}O_{32}]^{4\ominus}$ over the time period of the experiments (5–30 min), although some of these acids in higher concentrations produced appreciable decomposition of the complex

Table 1. Quantum yields for production of the reduced polyoxometalate in homogeneous photooxidation of alkanes by polyoxometalates [a].

Reaction	System [b]	Alkane	Φ [c]
(1)	α-$H_3PW_{12}O_{40}$/no acid	cyclooctane	0.08
(2)	α-$H_3PW_{12}O_{40}$/TFA	cyclooctane	0.12
(3)	α-$H_3PW_{12}O_{40}$/H_2SO_4(0.82 M)	cyclooctane	0.12
(4)	α-$Q_3PW_{12}O_{40}$/no acid	cyclooctane	0.02
(5)	α-$Q_3PW_{12}O_{40}$/TFA	cyclooctane	0.02
(6)	α-$Q_3PW_{12}O_{40}$/H_2SO_4 (0.82 M)	cyclooctane	0.10

(8)	α-$H_3PMo_{12}O_{40}$/TFA	cyclooctane	0.02
(9)	α-$Q_3PMo_{12}O_{40}$/no acid	cyclooctane	0.002
(10)	α-$Q_3PMo_{12}O_{40}$/TFA	cyclooctane	0.004
(11)	$(NH_4)_6P_2W_{18}O_{62}$/no acid	cyclooctane	0.01
(12)	$(NH_4)_6P_2W_{18}O_{62}$/TFA	cyclooctane	0.03
(13)	$Q_2W_6O_{19}$/no acid	cyclooctane	0.01
(14)	$Q_2W_6O_{19}$/TFA	cyclooctane	0.06
(15)	$Q_4W_{10}O_{32}$/no acid	cyclooctane	0.14
(16)	$Q_4W_{10}O_{32}$/TFA	cyclooctane	1.0
(17)	$Q_4W_{10}O_{32}$/H_3PO_4 (0.82 M) [d]	cyclooctane	0.8
(18)	$Q_4W_{10}O_{32}$/HCl (0.026 M)	cyclooctane	1.0
(19)	$Q_4W_{10}O_{32}$/H_2SO_4 (0.82 M)	cyclooctane	1.0
(20)	$Q_4W_{10}O_{32}$/CF_3SO_3H (0.026 M)	cyclooctane	1.1
(21)	$Q_4W_{10}O_{32}$/$HClO_4$ (0.026 M) [d]	cyclooctane	1.1
(22)	$Q_4W_{10}O_{32}$/no acid	cyclohexane	0.02
(23)	$Q_4W_{10}O_{32}$/TFA	cyclohexane	0.53
(24)	$Q_4W_{10}O_{32}$/no acid	n-octane	0.03
(25)	$Q_4W_{10}O_{32}$/TFA	n-octane	0.45
(26)	$Q_4W_{10}O_{32}$/no acid	2,2-dimethylbutane	0.01
(27)	$Q_4W_{10}O_{32}$/TFA	2,2-dimethylbutane	0.29
(28)	$Q_4W_{10}O_{32}$/no acid	2,3-dimethylbutane	0.03
(29)	$Q_4W_{10}O_{32}$/TFA	2,3-dimethylbutane	0.49

[a] Reaction conditions given in text. [b] Q in all cases is tetra-n-butylammonium cation; TFA = trifluoroacetic acid; acid concentrations given in parenthesis after name of acid; [TFA] = 0.82 M in all TFA-containing reactions. [c] Quantum yields defined in text. [d] H_3PO_4 and $HClO_4$ were 85% and 70% aqueous solutions, respectively.

after several hours. Although the presence of trifluoroacetic acid (TFA) increased the ability of $[W_{10}O_{32}]^{4\ominus}$ to oxidize both $nBu_4N^{\oplus}$ and the acetonitrile solvent in alkane-free control reactions, no products resulting from the photooxidation of either of these species were observed in the presence of alkane (0.45 M), for any of the reactions in Table 1, with the exception of reactions 26 and 27 involving 2,2-dimethylbutane.

The presence of the strong acids greatly accelerates the rates for the photoredox process [Eq. (c)]. The rates of photoreduced polyoxotungstate reoxidation [Eq. (d)] are negligible compared to the rate of photochemical polyoxotungstate reduction both in the presence and absence of acids. The acid-containing reactions in Table 1, along with the nonacidified reactions, then, are effectively stoichiometric based on the complex. Addition of the hydrogen-evolution catalyst RuO_2, however, causes reaction (d) to proceed rapidly and the overall photochemical dehydrogenation reactions become catalytic, proceeding at rates of over 15 turnovers of $[W_{10}O_{32}]^{4\ominus}$ per hour (conditions: 3.3 mM $[W_{10}O_{32}]^{4\ominus}$, cyclooctane substrate, 320-nm cut-filter). Additional alkane oxidation products are formed in some cases.

The data in Table 1 indicate that both polytungstates and polymolybdates of several different structures present in different salt forms are all active for the photochemical dehydrogenation of alkanes. The data in Table 1 and gas-chromatographic analyses of the organic product distributions of the reactions indicate that the presence of the moderate to strong acids TFA, H_3PO_4, HCl, H_2SO_4, CF_3SO_3H, and $HClO_4$ increases the rate of formation of alkane oxidation products and the selectivity for production of alkenes at the expense of the other products shown in Equation (a). In most of the acid-containing reactions, the alkene (or isomeric alkenes) are the only detectable alkane oxidation products, although in some cases, additional unidentified oxidation products are formed in low yields. For most of the cyclooctane reactions in Table 1, cyclooctane oxidation products represent at least 80% of the total oxidation products based on the concentration of P_r. For the optimally effective and stable $Q_4W_{10}O_{32}$/TFA system, the ratio of detected alkane oxidation products to P_r is 0.55 for the cyclohexane and 0.82 for the cyclooctane reactions. For most of the other alkanes, this ratio lies between these values. Also for this system, *cis*-cyclooctene, cyclohexene, the isomeric *n*-octenes, and 2,3-dimethyl-2-butene are the only detectable alkane oxidation products resulting from reaction of cyclooctane, cyclohexane, *n*-octane, and 2,3-dimethylbutane, respectively [reactions 16, 23, 25, and 29 in Table 1; see also Eq. (e)].

$$[HW_{10}O_{32}]^{3\ominus} + h\nu + \text{alkane} \longrightarrow [HW_{10}O_{32}]^{5\ominus} + 2\,H^{\oplus} + \text{alkene} \quad \text{(e)}$$

The $Q_4W_{10}O_{32}$/strong acid systems display quantum yields for the photoreduction of this polyoxotungstate complex by cyclooctane on the order of 1 (reactions 16 and 18–21). These are the highest quantum yields, by a good margin, for any polyoxometalate-based photochemical process. Since Equation (e) is endothermic in the dark (80–125 kJ mol^{-1}), depending on the alkane used, $Q_4W_{10}O_{32}$/acid/acetonitrile/alkane also represent truly efficient homogeneous systems for the conversion of light into chemical energy.

Absorption spectra, redox titrations, and quantum yields as a function of [acid]/$[Q_4W_{10}O_{32}]$ ratio establish that, for Equation (e) the form of the reduced $[W_{10}O_{32}]^{n\ominus}$ moiety is the monoprotonated two-electron reduced species, $[HW_{10}O_{32}]^{5\ominus}$.[8] The rate of production of $[HW_{10}O_{32}]^{5\ominus}$ is first order in light intensity and first order in both alkane and $H^{\oplus}$ at low concentrations of these species, but tends toward zero order in both at higher concentrations of each. Optically dense conditions render the rate effectively independent of the concentration of the catalyst, $[W_{10}O_{32}]^{4\ominus}$, because all incident light is being absorbed by the complex. Both the protonated and deprotonated forms of $[W_{10}O_{32}]^{4\ominus}$ are capable of photooxidizing alkane.

Slow Tautomerization in a Rhenium–Oxo–Hydroxide Complex**

By *Torsten K. G. Erikson* and *James M. Mayer**

Metal–oxo ("yl") groups play a critical role in a variety of metal-mediated transformations, from stoichiometric reactions to heterogeneous catalysis and enzymatic processes.[1] The reactivity of the metal–oxygen multiple bond ranges from very low (e.g., the vanadyl ion $VO^{2\oplus}$[2]) to exceptionally high (cf. the "ferryl" unit believed to be the active site in cytochrome P-450 enzymes[3]). Despite much interest in the chemistry of metal–oxo species, few elementary steps involving metal–oxo groups have been examined in detail. We describe here our studies of one of the simplest reactions of a metal–oxo group, degenerate proton transfer between oxo and hydroxide ligands. We have prepared the rhenium–oxo–hydroxide complex **3** and observed that proton transfer from the hydroxide to the oxo ligand occurs very slowly, requiring more than 24 h at ambient temperatures to reach equilibrium.

The rhenium–oxo–hydroxide complex **3** is formed quantitatively (by NMR) on reaction of the ethoxide or

[*] Prof. J. M. Mayer, T. K. G. Erikson

[**] Low-Valent Metal–Oxo Compounds, Part 6. This work was supported by Research Corporation, Chevron Research Co., the National Science Foundation, and the Petroleum Research Fund. Part 5: [4].

methylamide derivatives (**1**, **2**)[4] with one equivalent of water [Eq. (a)].

$$[Re(O)X(MeC{\equiv}CMe)_2] + H_2O \longrightarrow [Re(O)(OH)(MeC{\equiv}CMe)_2] + HX \quad (a)$$

1, X = OEt
2, X = NHMe

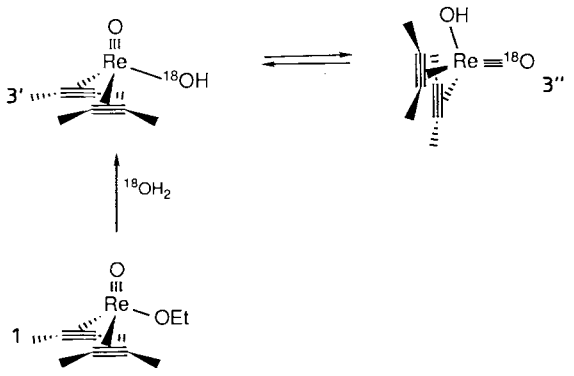
3

This type of ligand exchange reaction occurs readily in this system: for instance, the ethoxide in **1** is displaced by alcohols, ammonia, acetic acid, or H_2S.[4] Complex **3** reacts with acetic acid to give the rhenium acetate complex $[Re(O)(O_2CCH_3)(MeC{\equiv}CMe)_2]$[5] and water; with phenol an equilibrium mixture of **3** and $[Re(O)OPh(MeC{\equiv}CMe)_2]$ is observed.[4] Preparation of **3** from **2** is particularly useful because the methylamine byproduct evaporates readily, leaving a pure benzene solution of **3**. Although **3** is readily generated in solution, it has not been isolated because of its high solubility (even in pentane at $-80\,^{\circ}C$) and because concentration of solutions of **3** results in condensation to form the μ-oxo complex **4**.[6]

$[\{Re(O)(MeC{\equiv}CMe)_2\}_2(\mu\text{-}O)]$ **4**

The NMR, IR, and mass spectra of **3**[7] are very similar to those of analogous alkoxide,[4] halide,[5] and alkyl[8] derivatives. Therefore, these compounds undoubtedly have the pseudo-tetrahedral structure established by X-ray crystal structure analysis for the phenoxide, iodide, and ethyl derivatives. The assignments of the Re≡O and Re–OH stretching frequencies at 971 and 587 cm^{-1} is supported by their shift on ^{18}O labeling to 920 and 558 cm^{-1} ($\tilde{\nu}_{Re\text{-}OD} = 573\ cm^{-1}$). The sharp O–H stretch at 3607 cm^{-1} (O-D, 2660 cm^{-1}) in the solution IR spectrum indicates that **3** is not hydrogen-bonded in benzene solution. Complex **3** is not deprotonated by dimethylamine or by "proton sponge" (1,8-bis(dimethylamino)naphthalene) in benzene solution; reaction of **3** with stronger bases such as LiO*t*Bu or MeLi results in rapid decomposition.

Addition of one equivalent of $H_2{}^{18}O$ to solutions of **1** or **2** yields the oxo–hydroxide complex **3′** with the ^{18}O label predominantly in the hydroxide position (Scheme 1). The



Scheme 1.

position of the ^{18}O is easily monitored by IR spectroscopy. Over 1.5 d at ambient temperatures in a solution IR cell (NaCl windows) the label gradually becomes evenly distributed between the oxo and hydroxide positions. The IR spectra suggest a first-order approach to equilibrium, with a half-life of roughly 11 h, although precise kinetic studies were hampered by a lack of reproducibility and by catalysis of the reaction by stirring in a Pyrex flask. The observed rate does not appear to depend on whether **3** was formed from **1** or from **2** and is not strongly affected by the presence or absence of stoichiometric ethanol or methylamine, or catalytic amounts of benzoic acid or "proton sponge". However, addition of even trace quantities of trifluoromethanesulfonic acid results in complete equilibration of the ^{18}O label before an initial spectrum can be taken. The acid catalysis probably occurs via protonation of the oxo ligand of **2** to give a symmetrical bis-hydroxide complex; trifluoromethanesulfonic acid has been shown to protonate the oxo ligand of the related ethyl complex $[Re(O)Et(MeC{\equiv}CMe)_2]$.[8]

The observation of slow tautomerization in **3** is surprising, because the reaction is essentially a proton transfer between oxygen bases. Proton transfer among oxygens is usually fast because the addition of a proton to an oxygen lone pair does not cause a substantial change in structure.[9] For example, the tautomerization of carboxylic acids, which are formally analogous to **3**, is very facile. In **3**, however, transfer of the proton from the hydroxide to the oxo group is accompanied by a large change in structure and bonding because it involves the rhenium–oxygen multiple bond, which is quite different from an organic carbonyl group.

The rhenium–oxo bond in **3** is best described as a triple bond, following the theoretical study of the iodide derivative[5] (compare $\tilde{\nu}(Re{\equiv}O) = 971$, 975 cm^{-1} for $[Re(O)X(MeC{\equiv}CMe)_2]$, X = OH, I). The rhenium–oxygen bonding causes the acetylene ligands to lie perpendicular to the Re≡O bond, with a sizable barrier to acetylene rotation.[5] Tautomerization of **3** therefore requires movement of the acetylene ligands (see **3″** in Scheme 1); this movement is probably in large part responsible for the significant activation barrier to and hence the slow rate of proton transfer. The substantial change in rhenium–oxygen bond lengths on proton transfer (ca. 0.25 Å based on Re≡O 1.712(13), Re–OPh 1.966(14) Å in the structure of the phenoxide complex[4]) should also be contribute to the barrier.

Slow proton transfer between oxygen or nitrogen atoms has been observed in other systems[10] where a π-bonding orbital is the proton-accepting site: for instance, reactions involving the vanadyl oxo group[11] or proton transfer among imido, amido, and amine ligands in a tungsten complex.[12] In sum, tautomerization of **3** is slow because the proton transfers not to an oxygen lone pair but to a rhenium–oxygen π-bonding orbital, so proton motion is coupled to dramatic changes in bonding and structure.

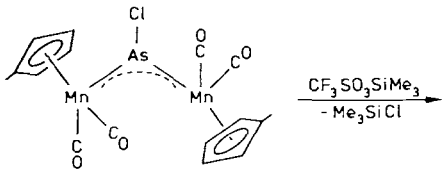
Linear Twofold Coordination of Arsenic in $[Cp'(CO)_2Mn{=}As{=}Mn(CO)_2Cp']^{\oplus}$**

By *Albert Strube, Gottfried Huttner,** and *Laszlo Zsolnai*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 70th birthday

Linear μ_2-coordination in the case of the heavier elements of the fourth[1] and sixth[2] main groups was first demonstrated a few years ago by *E. Weiss* et al.[1a] and *L. Sacconi* et al.[2a] Corresponding examples for the fifth main group have so far never been described. Herein we report on the dimanganese complex **2** (Cp′ = η^5-MeC_5H_4), the first compound of a new, unusual class of substances.

An entry to complexes of this kind appeared to be opened up with the availability of $[(L_nM)_2EHal]$[3] (E = P,[4] As,[5] Sb,[6] Bi[7]); however, all attempts to cleave halogen from such potential precursors with $AlCl_3$,[8] $BHal_3$,[9] $TlPF_6$[10] or $AgPF_6$[11], with formation of $[(L_nM)_2E]^{\oplus}$, were unsuccessful. We have now found a reagent, namely $CF_3SO_3SiMe_3$, which reacts smoothly with **1** to give **2** [Eq. (a)].



1

Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

2 is a dark-brown, crystalline solid, which is sensitive to hydrolysis but can be stored for weeks under inert gas at 20°C; its brown CH_2Cl_2 solution, however, reacts with trace amounts of moisture.

The $\tilde{\nu}_{CO}$ bands of **2** are shifted about 40 cm^{-1} to larger wave numbers compared to those of **1** [IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] for **2**: 2037 s, 2006 vs, 1983 s, 1951 m; for **1**: 1994 s, 1951 vs, 1928 s, 1912 sh] thus indicating the positive charge of the organometal ion.

The ^{1}H-NMR signals of **2** are correspondingly shifted downfield relative to those of **1** [^{1}H-NMR ($CDCl_3$, 293 K): δ for **2**: 1.97 (s, 6H), 4.93 (m, 4H), 5.32 (m, 4H); for **1**: 1.89 (s, 6H), 4.60 (m, 4H), 4.94 (m, 4H)].

It follows from the electronic spectra that the bonds in **1** and **2** must be described in terms of different Mn–As–Mn π-systems:[12,13] the wavelength for the ππ* transition in the case of **2** is considerably shorter than in the case of **1** [UV (CH_2Cl_2): λ [nm] (ε [L mol^{-1} cm^{-1}][14]) for **2**: 380 (13000); for **1**: 512 (14000)]. An X-ray structure analysis of **2** was rendered difficult by the disorder of the $CF_3SO_3^{\ominus}$ ion; the linear arrangement of the Mn–As–Mn unit in **2** was, however, established beyond all doubt. Better results were obtained in the case of **3** (Cp* = η^5-Me_5C_5)[15] (Fig. 1).

$[Cp^*(CO)_2Mn{=}As{=}Mn(CO)_2Cp^*]BF_4$ **3**

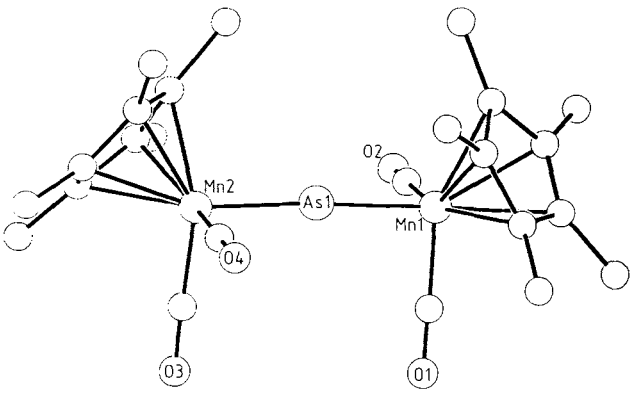

Fig. 1. Crystal structure of **3**: d_{MnAs} = 214.2(2), 215.1(2) pm; MnAsMn = 176.3(1)°; torsion angle Z1Mn1Mn2Z2 = 88.5° (Z1, Z2: midpoints of Cp*).

The cations in **2** and **3** are isoelectronic with the compounds with linear coordinated elements of the fourth[1] and sixth[2] main groups. Thus, the Mn–As distances are very short (Fig. 1), distinctly shorter than the Mn–As bonds in arsanediyl complexes,[3,12] which are shortened in any case by π-interaction (cf. $[Cp(CO)_2Mn]_2AsCl$, d_{MnAs} = 222.3 pm[9]). The {$L(CO)_2Mn$} fragments (L = Cp′, Cp*) in **2** and **3** are twisted through about 90° referred to the Mn–As–Mn axis, as is required for formulation of the cations as allene analogues.[13]

Experimental

All experiments were carried out under argon with anhydrous solvents. ^{1}H-NMR: Bruker AC200; IR: Perkin-Elmer 983G; UV/VIS: Perkin-Elmer Lambda 9; m.p. not corrected.

1 was prepared by a method analogous to that for $[(\eta^5\text{-}C_5H_5)(CO)_2Mn]_2AsCl$ [9].

2: A stirred solution of **1** (180 mg, 0.37 mmol) in CH_2Cl_2 (17 mL) was treated at 20°C with 0.23 mL (283 mg, 1.27 mmol) of $CF_3SO_3SiMe_3$ (the deep-red solution turned pale red within 1 min). After three hours' stirring, all volatile components were removed under high vacuum at 20°C. The oily, brown residue became solid after repeated washing with *n*-pentane and drying in a

high vacuum. Crystallization at −80°C from 6 mL of CH_2Cl_2/Et_2O (3/1) gave analytically pure crystals of **2** (m.p. 73°C); yield: 155 mg (69% referred to **1**); correct C,H,F,S analysis for $C_{17}H_{14}AsF_3Mn_2O_7S$.

3: ^{1}H-NMR ($CDCl_3$, 293 K): $\delta = 2.01$ (s, 30H); correct C,H,F analysis for $C_{24}H_{30}AsBF_4Mn_2O_4$.

[14] The ε values quoted are only lower limits because of the instability of the compounds.

[15] X-ray structure analysis of **3**: $a = 1325.8(9)$, $b = 1458.7(8)$, $c = 1562.1(9)$ pm, $\beta = 113.17(4)°$, space group $P2_1/c$, $Z = 4$. The $BF_4^\ominus$ tetrahedron showed a rotational disorder which could be modeled by a rigid $BF_4^\ominus$ tetrahedron with appropriate temperature factors. Solution and refinement of the structure [Program system SHELX 76 and SHELX 86 (G. Sheldrick, Universität Göttingen)] led to $R_1 = 0.091$, $R_2 = 0.074$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53 186, the names of the authors, and the journal citation.

A Morphology-Selective Copper Organosol**

By *Andrew C. Curtis, Daniel G. Duff, Peter P. Edwards,* David A. Jefferson, Brian F. G. Johnson,* Angus I. Kirkland,* and *Andrew S. Wallace*

There is continuing interest in colloidal metal particles, especially those which are important in commercial catalytic processes. However, while it has recently been demonstrated[1,2] that conventional chemical routes provide samples which are just as suitable for structural studies as those prepared by vacuum evaporation[3] or impregnation/reduction[4] methods, total control over particle morphology in both routes has proved difficult to achieve. In this communication we wish to report the preparation of a polymer-protected copper organosol in which a high percentage of the particles exhibit a single well-defined morphology within a relatively narrow particle-size range.

A solution of copper(II) acetate in acetonitrile was reduced with hydrazine hydrate under an inert atmosphere at 80°C under reflux, in the presence of poly(vinyl-2-pyrrolidone) as a stabilizing agent, to yield a deep red copper sol. This sol, which exhibited no appreciable Tyndall effect, was subsequently transferred to a controlled-argon-atmosphere glove box for all further manipulations. Under these conditions the sol was indefinitely stable against aggregation. A typical optical spectrum of this copper sol is illustrated in Figure 1 (curve I). The peak maximum at 575 nm was in good agreement with that predicted by the theory of *Mie*,[5] and the extinction coefficient at the peak maximum, $\varepsilon_{max} = 2803$ mol^{-1} dm^3 cm^{-1}, was more than an order of magnitude larger than that of the original copper(II) acetate solution ($\varepsilon_{max} = 111$ mol^{-1} dm^3 cm^{-1} at ca. 668 nm). If the sols prepared as described above were subject to limited air exposure, they were observed to become progressively paler. The peak in the optical spectrum, however, remained at 575 nm, although the extinction coefficient decreased as shown by curves II to VII in Figure 1.

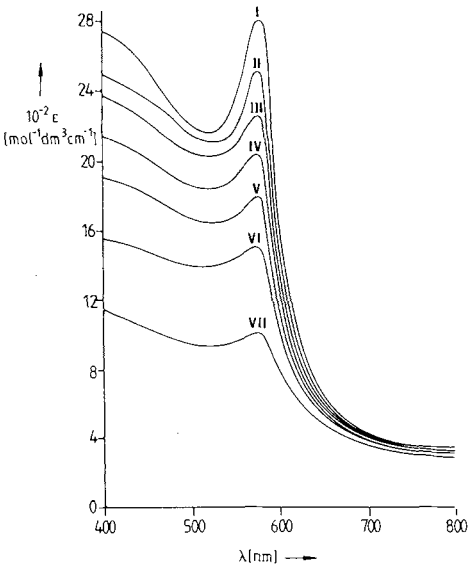

Fig. 1. The optical spectrum of the sol with a peak maximum at $\lambda_{max} = 575$ nm (curve I) together with the changes in optical spectra on limited oxidation (curves II to VII).

Low-resolution transmission electron microscopy (TEM) indicated large numbers of particles with approximately hexagonal outlines, referred to hereafter as "hexagons". Among these particles, the majority exhibited almost perfect hexagonal outlines, although a significant minority possessed an approximately truncated trigonal outline. These "hexagons" were generally of low contrast with no internal features visible (Fig. 2), and if the specimen was tilted with respect to the electron beam, the hexagonal outline of these particles was observed to foreshorten (Fig.

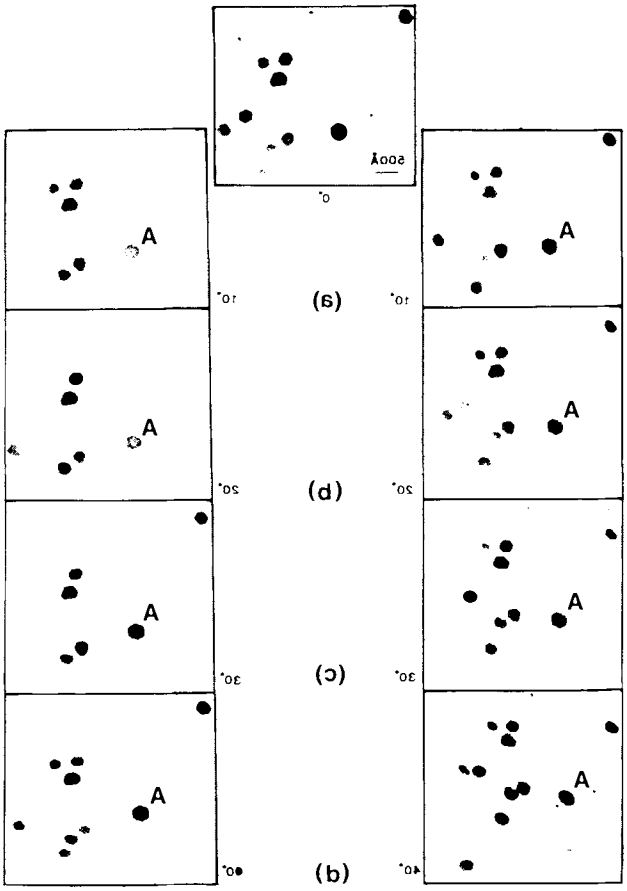

Fig. 2. Typical low-magnification TEMs of the sol recorded at different specimen tilts. The outline of the particle marked A clearly foreshortens as the specimen tilt is increased. a) ±10°. b) ±20°. c) ±30°. d) ±40°.

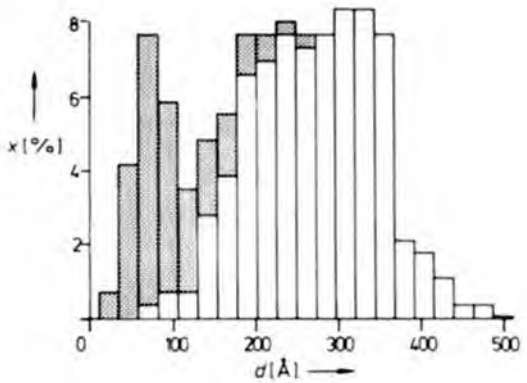

Fig. 3. The measured size distribution for the sol, with the unshaded areas representing the "hexagons" and the shaded areas the elliptical particles. For the whole system the mean particle diameter is 226 Å and $C_v = 45\%$.

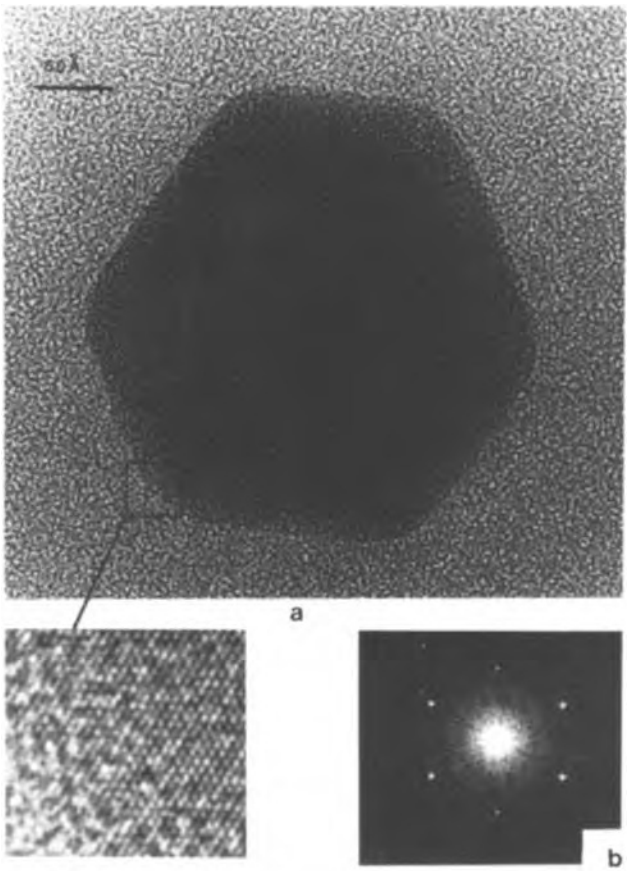

Fig. 4. a) A high-resolution image of a platelet in a ⟨111⟩ orientation showing two sets of {110} fringes across the entire platelet. b) Optical diffractogram from the image of Fig. 4a.

2a–d). This suggested a platelike morphology, with the effect being clearly illustrated for the particle marked A in Figure 2, the outline of which becomes noticeably narrower as the specimen tilt is increased. Measurement of diffraction contrast images recorded at differing amounts of specimen tilt gives an average aspect ratio of 0.2 for the "hexagons" subject to the errors in the measurement[6, 7] imposed by variations in objective-lens defocus, specimen height, and residual astigmatism with the degree of tilt. The remaining particles in the system were observed to be approximately elliptical in projection, and many of these exhibited striped diffraction contrast indicative of parallel twinning.[2]

Detailed analysis of the low-resolution micrographs (Fig. 2a) showed that the "hexagons", with a mean edge-to-edge diameter of 270 Å and a coefficient of variation C_v of 28% ($C_v = \sigma/d \times 100$, where σ is the standard deviation of the measured diameters and d is the mean particle diameter), represented ca. 75% of the particles present. The elliptical particles, with an equivalent circle diameter of ca. 100 Å and a C_v of 50% accounted for the remainder (Fig. 3).

High-resolution examination showed that, if suitably oriented, particles displayed faint fringes across the entire plane of the platelets (Fig. 4a), these having a spacing of 2.56 Å and an interplanar angle of 60°. Optical diffractometry (Fig. 4b) from recorded images confirmed that such particles were in ⟨111⟩ orientations and that the fringes corresponded to formally forbidden {110} diffraction maxima. These can arise in one of three ways: (1) as a result of the particle possessing a number of close-packed layers which is not a multiple of three, therefore breaking the systematic absence condition of the bulk metal; (2) as a result of non-zero Laue zone effects[8, 9] due to the extreme thinness of the crystals; (3) because of twins/stacking faults parallel to the platelet surface. The latter can be expected to reinforce the effects of the first two factors. In the light of recent studies of gold and silver platelets, where stacking faults have been observed directly using the profile imaging tech-

nique,[8, 10] it would appear likely that similar features are present in the copper platelets. Whereas some platelets in ⟨110⟩ orientations can inevitably be found in partially aggregated gold and silver sols, similar studies in the case of the copper "hexagons" have as yet proved impossible as a result of difficulties encountered in attempting to aggregate this sol. Neither solvent evaporation nor addition of a miscible "non-solvent" for the polymer (e.g., diethyl ether) succeeded in providing suitably aggregated samples, the latter process causing the solution to become turbid. TEM of this solution revealed a large proportion of particles to be well separated with some clumps of particles embedded in a dense polymer matrix. Even within these groups the particle surfaces were never in contact, and although some of the hexagons contained therein were possibly in ⟨110⟩ orientations, the polymer rendered them unsuitable for high-resolution examination as a result of extensive carbon contamination arising from polymer degradation.

Platelets of copper in colloidal solution have not previously been reported. However, flat platelets of colloidal gold are well known from sols formed under slow-growth conditions.[11, 12] Although their formation has been attributed to growth via raftlike aggregation of nuclei,[13] they are conventionally thought to arise from selective growth on non-{111} faces on a nucleus without radial twins. This has been explained in terms of the Kossel–Stranski theory of face-selective development of crystals,[14] possibly reinforced by proton adsorption on {111} surfaces inhibiting growth in the normal direction.[15] In gold sols platelets are usually accompanied by numbers of large decahedral and icosahedral MTPs (multiply twinned particles).[1, 11] These develop under slow-growth conditions from small MTPs into near-perfect decahedral and icosahedral forms enclosed by {111} faces with little or no Wulff-faceting,[16] by analogy with platelet formation. Their absence in this sol suggests that the nuclei are of standard close-packed form. In previously reported copper sols prepared in methanol[2] MTPs, although present, were considerably less frequent than in typical gold and silver colloids. Indeed, EXAFS of very small copper clusters in argon[17] shows fcc-based cubeoctahedral structures for clusters containing as few as 13 atoms, whereas icosahedra and icosahedral MTPs are calculated to be the minimum energy forms for very small particles.[18–20] The slower rate of growth in the present sol relative to the sols in methanol may be due to the formation of a stable copper(I) intermediate, probably the colorless tetrakis(acetonitrile) copper(I) complex[21] in this case. The formation of this stable intermediate is probably the cause of the smaller number of nuclei (and hence the larger particles) and the kinetically controlled growth forms exhibited by these sols. Another possibility is that a face-selective reaction involving the cross-linking of the polymer by acetonitrile may hinder the diffusion of reagents to the {111} planes.

As previously mentioned, evaporation of the solvent under an inert atmosphere by heating did not induce particle aggregation and an associated color change from red to green, in contrast to unprotected copper organosols,[2] and the sol, even if dried completely, could always be redispersed. If the sol was heated after drying for 30 minutes, however, a red film formed which was insoluble in methanol, ethanol, 1-propanol, 2-propanol, tetrahydrofuran, water, and acetonitrile.

TEM of the insoluble film revealed the presence of both circular and rounded hexagonal particles, most of which exhibited no diffraction or strain contrast. A typical micrograph of this film is shown in Figure 5a, from which it has been possible to measure the size distribution illustrated in Figure 5b, corresponding to an overall mean particle size of 231 Å with a C_v of 45%. Comparison of the size distributions of Figure 3 and 5b clearly indicates that the rounded particles showing no internal diffraction or strain contrast are derived from the "hexagons" in the sol.

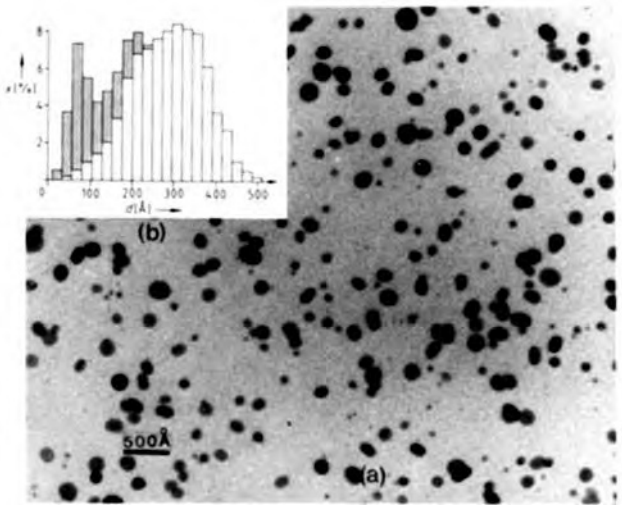

Fig. 5. a) Low-resolution TEM of the insoluble red film clearly indicating the absence of any interparticle contact. b) Measured size distribution of the particles in this film with the unshaded areas representing the "hexagons" (mean particle diameter = 248 Å, $C_v = 32\%$) and the shaded areas the eliptical particles (mean particle diameter = 97 Å, $C_v = 49\%$).

If the solvent was similarly removed via evaporation under vacuum, a red solid was again formed which was redispersible in all the solvents in which the previously described heat-treated film was insoluble. TEM indicated no particle aggregation even when this solid was redispersed in any of these solvents and repeatedly dried under vacuum. If, however, the system redispersed in these various other solvents was heat-treated as before, an insoluble red film again resulted.

The formation of this intractable red film after heating and removal of the solvent is attributed to cross-linking of the loops and tails of the polymer surrounding the copper particles. A similar reaction indeed occurs in the absence of copper particles. The resistance of the sol to particle aggregation and interparticle contact can be explained by cross-linking of the polymer at the metal surface, possibly catalyzed by the metal. This would be expected to result in highly effective steric stabilization which can account for the redispersible nature of the red solids, as well as the inability of the miscible non-solvents to induce interparticle contact. The precise nature of the cross-linking reaction is uncertain, although it should be noted that the presence of acetonitrile appears essential to this and hence towards the high degree of stabilization against aggregation.

Experimental Procedure

Copper(II) acetate monohydrate (25.5 mg, 0.128 mmol) and poly(vinyl-2-pyrrolidone) (average molecular weight = 40000; 158 mg, 1.423 mmol monomer units) were dissolved in freshly distilled, deoxygenated acetonitrile (100 mL). This solution was heated at 80 °C under reflux in a nitrogen atmosphere; on addition of a solution of hydrazine hydrate in deoxygenated acetonitrile, a deep red sol of zero-valent copper particles formed via a colorless intermediate which persisted for a period of ca. 2 min. Initial characterization of the copper sol by optical spectroscopy was performed using a Pye Unicam SP8800 UV/VIS spectrophotometer with the sol contained in 1-cm stoppered quartz cells.

Low-resolution transmission electron microscopy (TEM) of these samples was performed using a JEOL JEM-200CX electron microscope operating at 200 kV and fitted with a standard double-tilt side-entry goniometer allowing specimen tilts of ±45° about two orthogonal axes with respect to the incident electron beam. Subsequent high-resolution electron-microscopic (HREM) examination was carried out using our modified JEOL JEM-200CX electron microscope [22], thus permitting structural characterization at an interpretable point resolution of 1.95 Å. For such high-resolution studies care was taken to correct illumination-system misalignments and objective-lens astigmatism prior to recording micrographs at electron-optical magnifications of either ca. 450000× or ca. 690000×.

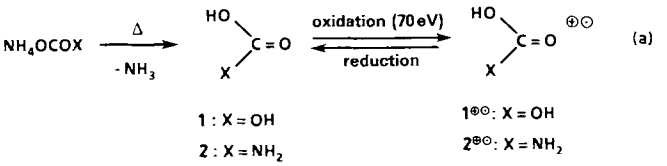
Generation and Characterization of Sulfurous Acid (H_2SO_3) and of Its Radical Cation as Stable Species in the Gas Phase**

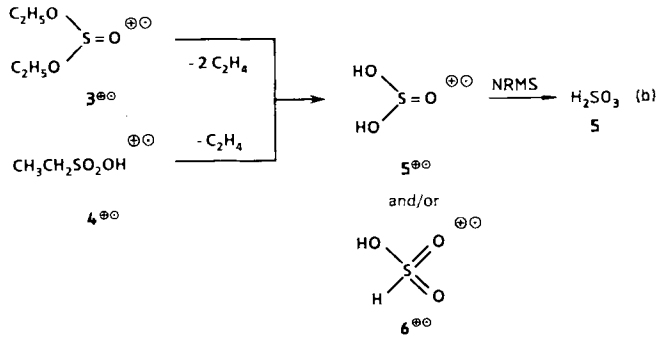
By *Detlev Sülzle, Marjon Verhoeven, Johan K. Terlouw,* and *Helmut Schwarz**

Dedicated to Professor Geo Dijkstra on the occasion of his 65th birthday

Sulfurous acid, H_2SO_3, has in common with carbonic acid **1** and carbamic acid **2** (X = NH_2), that general textbook knowledge takes it to be nonexistent in the free state.[1] Recently we were able to show[2] that this instability is determined only by the environment and is not an inherent property of the molecules: This we achieved by generating the molecules **1** and **2** by thermolysis of ammonium hydrogen carbonate and ammonium carbamate, respectively [Eqn. (a)] and showing them to be stable in the gas phase. **1** and **2** could be oxidized by electron impact ionization (70 eV) to the likewise stable radical cations $\mathbf{1}^{\oplus\odot}$ and $\mathbf{2}^{\oplus\odot}$, respectively, whose neutralization was accomplished under the conditions of neutralization reionization mass spectrometry (NRMS).[3] The obvious route to sulfurous acid, namely via removal of NH_3 from ammonium hydrogen sulfite by thermolysis, is thwarted by the fact that anhydrous NH_4HSO_3 is unknown. (Drying of $MHSO_3$ salts (M = metal) usually produces disulfites.[1a,b])



On the other hand, both the radical cation of sulfurous acid $\mathbf{5}^{\oplus\odot}$ and the neutral molecule **5** are easily generated in the gas phase by dissociative ionization (70 eV) of diethyl sulfite **3** or ethanesulfonic acid **4** [Eqn. (b)]. Reduction of $\mathbf{5}^{\oplus\odot}$ in an NRMS experiment affords sulfurous acid **5**. The experimental finding is substantiated by ab initio calculations (HF/6-31G*//6-31G*).



First, however, it has to be established whether the $(H_2,S,O_3)^{\oplus\odot}$ ions *m/z* 82, generated from **3** or **4**, exist in the form $\mathbf{5}^{\oplus\odot}$ or $\mathbf{6}^{\oplus\odot}$. Both upon unimolecular as well as collision-induced decomposition, the mass selected *m/z* 82 ions (MSMS-experiment) overwhelmingly split off $OH^{\odot}$ (*m/z* 82→*m/z* 65). This can be considered indicative of the presence of $\mathbf{5}^{\oplus\odot}$, as simple thermochemical considerations based on literature data compellingly lead to the conclusion that the reaction $\mathbf{5}^{\oplus\odot} \rightarrow HOSO^{\oplus} + OH^{\odot}$ is the favored fragmentation over all conceivable decomposition processes of $\mathbf{5}^{\oplus\odot}$. For $\mathbf{6}^{\oplus\odot}$ the situation is less clear; since not all thermochemical data (e.g. ΔH_f^0 of $HSO_2^{\oplus}$) are reliably known it cannot be established in the case of $\mathbf{6}^{\oplus\odot}$ whether the loss of $OH^{\odot}$ is favored or whether other modes of dissociation such as the loss of H_2O are more important.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the Fondsgesellschaft von Freunden der Technischen Universität Berlin e.V.

The following experiment provides a clear decision in favor of $5^{\oplus\odot}$ [Eqn. (c)]: if **4a** generates the isotopomer $\mathbf{5a}^{\oplus\odot}$ loss of both $OH^{\odot}$ *and* $OD^{\odot}$ will be observed in MSMS-experiments; should $\mathbf{6a}^{\oplus\odot}$ be generated, then (provided the isomers are separated by considerable barriers) elimination of $OD^{\odot}$ would occur exclusively. The assumption of a barrier preventing the rapid equilibration $\mathbf{5a}^{\oplus\odot} \rightleftharpoons \mathbf{6a}^{\oplus}$ is justified: ab initio MO calculations[4] (UHF 6-31G*//6-31G*+ZPVE) indicate that $5^{\oplus\odot}$ is 37.3 kcal/mol more stable than $6^{\oplus\odot}$ but that the barrier against the conversion $6^{\oplus\odot} \rightarrow 5^{\oplus\odot}$ is 44.5 kcal/mol.

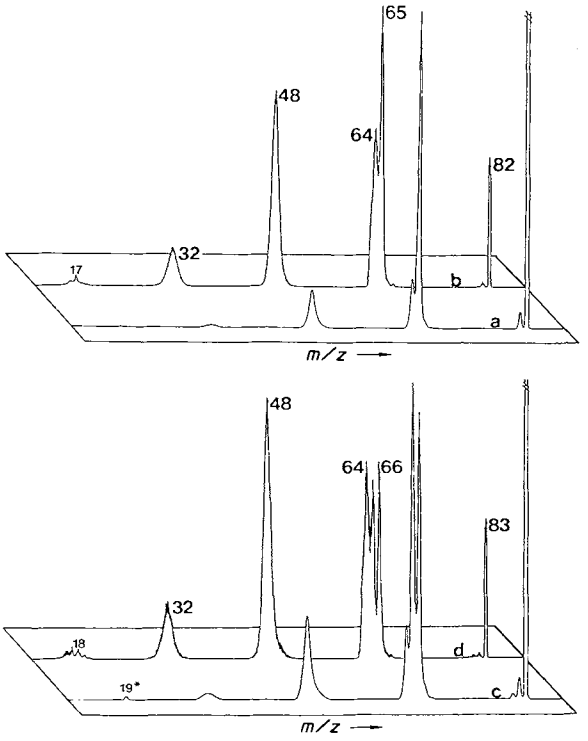

Fig. 1. CA and NR mass spectra (Xe/O_2) of $H_2SO_3^{\oplus\odot}$ (precursor **4**) and $HDSO_3^{\oplus\odot}$ (precursor **4a**). a) CA of $H_2SO_3^{\oplus\odot}$. b) NR of $H_2SO_3^{\oplus\odot}$. c) CA of $HDSO_3^{\oplus\odot}$. d) NR of $HDSO_3^{\oplus\odot}$. The spectra were recorded on VG-Instruments mass spectrometers of types ZAB-2F (Utrecht), and ZAB-HF-3F (Berlin) under the conditions given in Refs. [2, 3b].

The experimental result (Fig. 1c) is unambiguous. Under collisional activation (CA) conditions both *m/z* 65 (loss of $OD^{\odot}$) and *m/z* 66 (loss of $OH^{\odot}$) occur, so the dissociative ionization of **4a** generates the radical cation of sulfurous acid $\mathbf{5a}^{\oplus\odot}$.[5] Since the ions $H_2SO_3^{\oplus\odot}$ generated from **3** and from **4** are identical in all mass spectrometric properties it must be concluded that the double elimination of ethylene from diethyl sulfite **3** also leads to $5^{\oplus\odot}$ and not to $6^{\oplus\odot}$.[6]

In the neutralization-reionization experiments carried out on $5^{\oplus\odot}$ and $\mathbf{5a}^{\oplus\odot}$ the spectra given in Figures 1b and 1d, respectively, are obtained; they do not require any detailed interpretation. The "survivor" signals at *m/z* 82 and *m/z* 83 tell us that neutrals with lifetimes of $t > 10^{-5}$ s are generated upon neutralization of $5^{\oplus\odot}$ and $\mathbf{5a}^{\oplus\odot}$.[7] The isotope effect mentioned in Ref. [5] also favors the loss of $OH^{\odot}$ over that of $OD^{\odot}$ in the NRMS experiment. That, once again, the neutral molecule **6** does not come into consideration is clear not only from the competitive loss of $OH^{\odot}/OD^{\odot}$ but also from MO calculations (RHF/6-31G*//6-31G*+ZPVE). According to these calculations **6** is 16.8 kcal/mol less stable than sulfurous acid **5**, and the transition structure TS **5/6** is 88.0 kcal/mol more energetic than **5**.

Summary: Sulfurous acid **5** and its radical cation $5^{\oplus\odot}$ are stable in the gas phase. The "nonexistence" of H_2SO_3 in solution does not reflect an intrinsic instability but, as also in the cases of carbonic acid and carbamic acid, is the result of bimolecular reactions.

[4] Stationary products were considered to indicate unambiguously minima or transition structures (TS). Geometrical data are available upon request. The $\langle S^2 \rangle$ values, whose deviation from the expected value $\langle S^2 \rangle = 0.75$ may be considered a measure for UHF calculations, are 0.76 for $5^{\oplus\odot}$, 0.76 for $6^{\oplus\odot}$ and 0.84 for the transition structure TS $5^{\oplus\odot}/6^{\oplus\odot}$.

[5] The ratio of the signals for *m/z* 65 to *m/z* 66 is not a straightforward indication for the isotope effect in the elimination of $OD^{\odot}$ and $OH^{\odot}$. The reasons for this are: 1) The deuterium substitution in **4a** amounts at most to 50%, and 2) *m/z* 83 is not isotopically pure but is a mixture of $\mathbf{5a}^{\oplus\odot}$ (H, D, S, O_3)$^{\oplus\odot}$ and $(H_3,S,O_3)^{\oplus}$. $H_3SO_3^{\oplus}$ results from the loss of C_2H_4 from protonated **4**. Semiquantitative corrections indicate that 30 to 40% of the signal at *m/z* 65 can be traced back to an elimination of H_2O from $H_3SO_3^{\oplus}$. If this is taken into consideration then an isotope effect $k_{OH}/k_{OD} = 1.4$ is obtained for the decomposition of $\mathbf{5a}^{\oplus\odot}$.

[6] It remains to be seen whether the hydrogen transfers involved in the reaction $3^{\oplus\odot} \rightarrow 5^{\oplus\odot} + 2C_2H_4$ occur via a four-centered or a six-centered mechanism. This could only be resolved by a double isotope labeling experiment. This aspect, however interesting in itself, has no bearing upon the question of the generation of $5^{\oplus\odot}$ or $6^{\oplus\odot}$.

[7] It must be pointed out that neutralization of $H_3SO_3^{\oplus}$ does not generate detectable amounts of $H_3SO_3^{\oplus}$ with a lifetime of $t > 10^{-5}$ s. The question whether this is the result of an inherent instability of $H_3SO_3^{\oplus}$ or, more probably, whether $H_3SO_3^{\oplus}$ has a short half-life when generated in a highly excited state upon vertical neutralization remains open. Here, the only fact of importance is that the *m/z* 83 signal in Figure 1d is not due to $H_3SO_3^{\oplus}$.

The SF_5-Unit as Steric Protecting Group; Synthesis and Structure of $F_5S-C{\equiv}SF_3$**

By *Rolf Gerhardt, Thomas Grelbig, Jürgen Buschmann, Peter Luger,* and *Konrad Seppelt**

Surprisingly, the bonding angle at the central carbon atom of $F_3C-C{\equiv}SF_3$[1a] is 171.5(2.0)° in the solid state,[1b] and, in the gaseous state, it is even smaller: 155.0(3.0)°.[2] Ab initio calculations[2–4] with inclusion of configurational interaction showed that the molecule tolerates bending to 140° without any mentionable resistance, and that the energy minimum possibly does not lie at 180°.[2] In view of this unusual behavior it appeared worthwhile synthesizing

at least one further compound containing a sulfur-carbon triple bond in order to establish whether the non-linearity of $F_3C-C\equiv SF_3$ is a special case or not.[5] However, the necessity for steric and presumably also electronic stabilization of the sulfur-carbon triple bond drastically limits the number of possible stable compounds of the type $R-C\equiv SF_3$. Herein we describe the synthesis of $F_5S-C\equiv SF_3$ and its crystal structure analysis at $-168\,^{\circ}C$.

Since the $C\equiv SF_3$-group was meant to be formed in a final step from a CH_2-SF_5-group, the synthesis required a compound bearing two SF_5 groups on one carbon atom. This could be obtained by twofold addition of SF_5Cl to 1,1-difluoroethene (Scheme 1). The addition of SF_5Cl—corresponding to the radical mechanism—is regiospecific both times.[6, 7]

$$H_2C{=}CF_2 + SF_5Cl \xrightarrow{h\nu} F_5S{-}CH_2{-}CF_2Cl\ [8] \xrightarrow[-HCl]{KOH}$$
$$F_5S{-}CH{=}CF_2\ [8] \xrightarrow{SF_5Cl,\ h\nu} (SF_5)_2CH{-}CF_2Cl \xrightarrow[-HCl]{KOH}$$
$$(SF_5)_2C{=}CF_2 \xrightarrow[-HF]{H_2O} (SF_5)_2CH{-}COF \xrightarrow[-HF]{H_2O}$$
$$(SF_5)_2CH{-}COOH \xrightarrow[-CO_2]{} F_5S{-}CH_2{-}SF_5 \xrightarrow[-2HF]{KOH,\ 80^{\circ}} F_5S{-}C\equiv SF_3$$

Scheme 1. Synthesis of $F_5S-C\equiv SF_3$.

The intermediate product $(SF_5)_2CH-CF_2Cl$ is present in the form of two conformers, even above room temperature. This is undoubtedly a result of hindrance of rotation by the two rigid, square-pyramidal SF_5 groups. The energy profile of the rotation about the C–C bond can be derived from the temperature-dependence of the NMR spectra (Fig. 1).

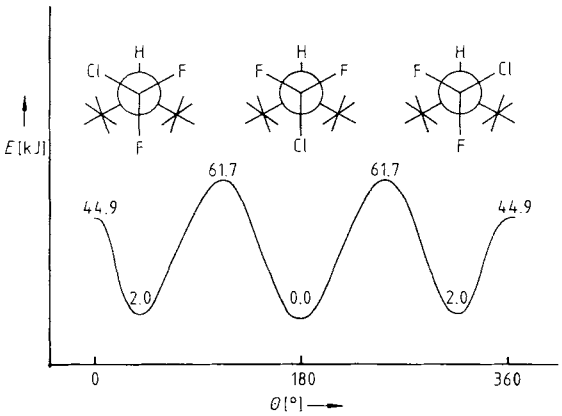

Fig. 1. Energy profile of the rotation about the C–C bond in $(SF_5)_2CH-CF_2Cl$. The energies were calculated according to known methods from the temperature-dependent ^{19}F-NMR spectra [9].

In certain cases hydrolyses of 1,1-difluoroethenes are known;[10] acid fluoride and acid can then be isolated as intermediates. The decisive step of the synthesis according to Scheme 1 is the double elimination of HF from $F_5S-CH_2-SF_5$ to give $F_5S-C\equiv SF_3$. $F_4S{=}C{=}SF_4$ is (unfortunately) not observed. Pentafluorothiomethylidine sulfur trifluoride is a colorless liquid, which is already volatile at $-78\,^{\circ}C$ in vacuo; it decomposes slowly above this temperature, and rapidly at room temperature, to give as yet unknown compounds. The existence of the compound was confirmed by the usual physical methods, especially ^{19}F-NMR spectroscopy. Noteworthy here is that the resonance of the four equatorial F atoms of the SF_5 group appear at lower field than the resonance of the axial F atom. This phenomenon was hitherto observed in F_5S-C compounds only in the case of acetylenes $F_5S-C\equiv C-X$. It is explained in terms of the opposing influence on axial and equatorial fluorine atoms by the anisotropic cylindrical triple bond.[11]

Investigation of the crystal structure of the compound, which melts at $-130\,^{\circ}C$, revealed an arrangement of the molecule on a threefold crystallographic axis with resulting disorder of the SF_5 group (Fig. 2).[12] Nevertheless, the molecule is clearly recognizable. An extremely short S–C distance of 139.2(4) pm is observed for the triple bond, which contrasts with the C–S single bond length of 168.2(4) pm in the same molecule.

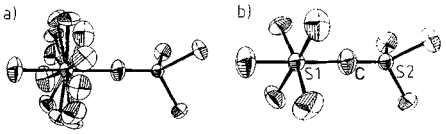

Fig. 2. Crystal structure of $F_5S-C\equiv SF_3$ at $-168\,^{\circ}C$. a) Threefold rotational symmetric disordered model. Vibration ellipsoids at the 20% probability level. b) One molecule; ellipsoids at the 30% probability level. Bond lengths [pm] and angles [°]: S1-C 168.2(4), S2-C 139.2(4), S2-F 153.4(3); S1-C1-S2 180, F-S1-F 93.5(1), C-S2-F 122.7(2).

In complete constrast to $F_3C-C\equiv SF_3$, $F_5S-C\equiv SF_3$ is linear. The exact 180° angle at the carbon atom is prescribed by the crystal symmetry. A deviation from linearity would give rise to a threefold disorder of the carbon atom and of the axial fluorine atom. A quantitative evaluation of the thermal parameters of both atoms shows that their mean vibration amplitudes ($\bar{u} = \sqrt{u}$) are only 8 and 11 pm greater than those of the sulfur atoms, respectively. This gives deviations from linearity of, at the most, 3–4°.

Unfortunately, the disorder of the SF_5 moiety limits the quality of the crystal structure determination to such an extent that it is not suitable for accurate statements about the electron density distribution—despite accurate intensity measurements, a five- to six-fold redundancy in determination for the measured data, and a very good R value. Nevertheless, in a density difference chart, an expanded disk-like electron-density plateau is seen perpendicular to the bond direction. Its maximum is located not quite centrally between C and S but somewhat nearer to the C atom. Exact details are not recognizable.

The question of whether the linearity is caused by the SF_5 groups, or is a result of the packing forces in the lattice, remains unanswered. An answer is not furthcoming by vapor phase structure investigations (electron diffraction, microwave spectroscopy, matrix IR spectroscopy). This is very difficult because of the size of the molecule.

Experimental

$(SF_5)_2CH-CF_2Cl$: A mixture of 0.2 mol of $F_5S-CH{=}CF_2$, 0.23 mol of SF_5Cl and 400 g of $C_2F_4Cl_2$ was irradiated at $-30\,^{\circ}C$ with a Hg high-pressure lamp for 2 d. After spinning band distillation $(SF_5)_2CH-CF_2Cl$ was obtained as a colorless liquid in 30% yield, b.p. 56°C/130 mbar.—^1H-NMR ($-80\,^{\circ}C$): $\delta = 5.7$. ^{19}F-NMR ($-80\,^{\circ}C$): $\delta = 80$–82 (SF), -35.4 (CF_2 of the symmetric conformer), -34.1 and -51.2 ($^2J_{FF} = 200.0$ Hz, CF_2 of the asymmetric conformer): IR (gas): strong bands at $\tilde{\nu} = 1281, 1173, 1149, 1113, 1042, 976, 932, 876, 857, 818, 769, 684, 615, 592\ cm^{-1}$; MS: m/z 317 ($[M-Cl]^{\oplus}$, 21% referred to $SF_3^{\oplus}$ = 100%) and numerous lighter fragments.

$(SF_5)_2C{=}CF_2$: $(SF_5)_2CH-CF_2Cl$ (30 mmol) was allowed to react with an excess of KOH pellets at room temperature. All compounds volatile in vacuum were distilled with a spinning band column. $(SF_5)_2C{=}CF_2$ was obtained as a colorless liquid in 80% yield, b.p. 88°C.—^{19}F-NMR: $\delta = 72.3$ (SF_{ax}), 74.9 (SF_{eq}), -54.8 (CF_2); IR (gas): strong bands at $\tilde{\nu} = 1706, 1667, 1337, 956, 928, 879, 857, 804, 696, 621, 595\ cm^{-1}$; MS: m/z 316 ($M^{\oplus}$, 18% referred to $SF_3^{\oplus}$ = 100%) and numerous lighter fragments.

$F_5S-CH_2-SF_5$: A solution of $(SF_5)_2C{=}CF_2$ in an excess of water/tetraglyme (bis(2-(2-methoxylethoxy)ethyl)ether) was stirred for several days in a closed

system at room temperature. After vacuum distillation for quick separation of tetraglyme and most of the water the volatiles were distilled on a spinning band column. $F_5S-CH_2-SF_5$ was obtained in 70% yield as a colorless liquid, b.p. 67°C.—^{1}H-NMR: $\delta = 5.5$; ^{19}F-NMR: $\delta = 73.4$ (SF_{ax}), 69.2 (SF_{eq}); IR (gas): strong bands at $\tilde{\nu} = 934$, 863, 752, 655, 598 cm^{-1}; MS: m/z 249 ($[M-F]^{\oplus}$, 11% referred to $SF_5^{\oplus} = 100\%$) and lighter fragments.

$F_5S-C\equiv SF_3$: $F_5S-CH_2-SF_5$ was passed, in amounts of 1-3 g, through a glass tube filled with KOH at 80°C. The reaction products were frozen out with liquid nitrogen. NMR mointoring revealed completion of the reaction. $F_5S-C=SF_5$ was obtained as colorless gas in ca. 30% yield, m.p. −130°C, b.p. above room temperature (extrapolated).—^{19}F-NMR: AB_4C_3 spectrum, $\delta_A = 75.9$, $\delta_B = 96.9$, $\delta_C = 61.3$, $J_{AB} = 154$, $J_{BC} = 22$ Hz; IR (gas): strong bands at $\tilde{\nu} = 1717$ ($\nu_{C=S}$), 1150, 926, 897, 784, 692, 610, 564 cm^{-1}; MS: m/z 227.9306 ($M^{\oplus}$); calcd. for $CS_2F_8^{\oplus}$: 227.9314.

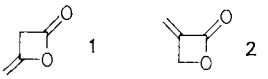
α-Methylene-β-lactone, a Novel Heterocyclic Ring System via Deoxygenation of α-Methylene-β-peroxylactones with Triphenylphosphane**

By *Waldemar Adam,* Ludwig Hasemann,* and *Frank Prechtl*

Aldolketene dimers, 4-methyleneoxetan-2-ones **1**, belong to a well established heterocyclic ring system that is readily accessible by dimerization of aldehydic ketenes.[1] Surprisingly, however, no examples of the isomeric 3-methyleneoxetan-2-ones **2** have thus far been reported. This is especially puzzling in view of the high degree of functionality contained in this as yet unknown heterocyclic ring system, which should lend itself to diversified synthetic utilization.



For example, besides the usual electrophilic sites of the carbonyl and oxetane carbon atoms contained in β-lactones, Michael-type additions of nucleophiles and radicals at the methylene carbon atom are feasible and offer attractive possibilities for preparative purposes. Moreover, the carboxy-activated exomethylene double bond should serve as reactive dienophile, while the α,β-unsaturated carbonyl moiety promises potential as heterodiene for [4+2] cycloadditions. Finally, on thermolysis the 4-methyleneoxetan-2-ones **1** suffer retrocleavage to aldoketenes, while in the case of 3-methyleneoxetan-2-ones **2** decarboxylation to allenes is expected; thus, such α-methylene-β-lactones could represent allene equivalents.

We have already shown that trivalent phosphorus nucleophiles are effective reagents for the deoxygenation of cyclic peroxides. Thus, the β-peroxy lactones **3** afford the β-lactones **4**[2] and the malonyl peroxides **5** the anhydrides **6**[3] on treatment with triphenylphosphane. It was, therefore, anticipated that the recently discovered α-methylene-β-peroxylactones **8**[4] should constitute convenient precursors for the desired α-methylene-β-lactones **9** under these reaction conditions. That this is indeed the case is demonstrated by reaction (a), which now provides a convenient entry to the versatile 3-methyleneoxetan-2-ones **9**.

7 8 9

a, R = Me; b, R = Et; c, R = *i*Pr

The methacrylic acid derivatives **7a–c** were prepared by Wittig-Horner reaction of α-bromopropionic acid with the corresponding aldehydes.[5] The photosensitized oxygenation of **7** was carried out in chloroform at −5 to 0°C with tetraphenylporphine as sensitizer, and afforded the hydroperoxy acrylic acids as ene products essentially quantitatively. These were cyclized with catalytic amounts of concentrated sulfuric acid to the α-methylene-β-peroxylactones **8a–c** in 70, 57 and 50% yields, respectively. Satisfactory elemental analyses, appropriate spectral data (IR, ^{1}H- and ^{13}C-NMR, MS), and peroxide tests support the structure assignments for the peroxides **8**, of which the methyl derivative **8a** was already known.[4]

The oxygen extrusion from **8** was achieved with equimolar amounts of triphenylphosphane in chloroform at

$-40\,^{\circ}C$. Slow warm-up to room temperature, column chromatographic work-up (silica gel flash chromatography, elution with a 10:1:1 mixture of dichloromethane, petroleum ether (30–50 °C) and diethyl ether), and Kugelrohr distillation (bath temperature 45 °C at 0.1 torr) afforded the α-methylene-β-lactones **9a–c** in 27, 48 and 40% yields, respectively, as pale yellow liquids with a pungent odor. Satisfactory elemental composition (**9a** exact mass by mass spectrometry and **9b**, **c** combustion analyses) and appropriate spectral data (IR; ^{1}H- and ^{13}C-NMR, MS) substantiate the proposed 3-methyleneoxetan-2-one structures for **9**. Significant in this context is that the position of the IR absorption of the exo −C=C− bond in **8** and **9** remained essentially constant at $\tilde{\nu}=1700$–$1710\ cm^{-1}$, while the carbonyl stretching frequency underwent the expected hypsochromic shift from $\tilde{\nu}=1790$–$1795\ cm^{-1}$ in **8** to $\tilde{\nu}=1820$–$1825\ cm^{-1}$ in **9**.

As anticipated, preliminary results of reactions with **9** reveal that the α-methylene-β-lactones are highly reactive. For example, **9a** reacts as dienophile nearly quantitatively with cyclopentadiene, yielding a diastereomeric mixture of [4+2]-cycloadducts. At elevated temperatures (ca. 60 °C), this highly activated heterocyclic ring system readily polymerizes. The chemistry of these potentially useful building blocks should be of general interest. In view of the high genotoxicity of the analogous α-methylene-γ-butyrolactones, which are naturally occurring biologically active compounds,[6] the potential carcinogenic behavior of this novel class of heterocyclics should be checked.

$$K(R^1)E^1\text{–}E^1(R^1)K + Cl_2E^2R^2 \longrightarrow \underset{R^1E^1\text{—}E^1R^1}{\overset{R^2}{\overset{E^2}{\triangle}}} + 2\ KCl \qquad (a)$$

R^1, R^2 = *t*Bu; E^1, E^2 = P, As

Herein we report on an alternative route to diphosphaarsiranes **B** and phosphadiarsiranes **C** and on the X-ray structure analysis of the substituted diphosphaarsirane **4**. Contrary to other findings,[6] 2,4,6-tBu$_3$C$_6$H$_2$AsCl$_2$ **2**, the required reactant, is readily formed from 2,4,6-tBu$_3$C$_6$H$_2$Li and $AsCl_3$ in THF/hexane.

The bis(trimethylsilyl)phosphidoiron complex **1**[7] reacts with **2** in THF at 0 °C [Eq. (b)] to give the red-violet diphosphaarsirane **4** (10% yield), which can be separated from the orange phosphadiarsirane **5** (5% yield) and the diphosphadiarsetane **6** (27% yield) by fractional crystallization. Further, the presence of the P=As complex **3** in the reaction solution can be shown by ^{31}P NMR spectroscopy ($\delta=765.7$, s); it could not be isolated, however.

Synthesis and Molecular Structure of the Diphosphaarsirane [{[(η^5-C$_5$Me$_5$)(CO)$_2$Fe]P}$_2$AsC$_6$H$_2$*t*Bu$_3$]**

By *Lothar Weber,* Dagmar Bungardt, Uwe Sonnenberg,* and *Roland Boese*

The study of small rings is currently a focus of interest in inorganic chemistry.[1] In the last few years, for example, *Baudler* et al. have explored the ring systems **A**–**D**.[2–5] In general, the compounds were synthesized by cyclocondensation [Eq. (a)].

On the other hand, treatment of the reaction solution with [((*Z*)-C_8H_{14})Cr(CO)$_5$][8] in excess prior to workup allows complex **7** to be isolated in 32% yield [Eq. (c)]. Since **6** is formed here in 31% yield, it is probably not produced by dimerization of **3**. In these experiments it was also possible to isolate chromatographically the previously unknown diarsene **8** (2% yield).

The constitutions and configurations of **4**–**8** were established from the elemental analyses and the spectroscopic data. Doublets at $\delta=6.4$ and 40.6 ($^1J(PP)=227$ Hz) in the ^{31}P NMR spectrum of **4** as well as two ^{1}H NMR signals for the protons of the C_5Me_5 ligands are in agreement only with the relative *trans* orientation of the substituents on the P atoms and rule out more highly symmetric structures.

The ^{31}P NMR spectra of the heterocycles **5** and **6** show singlets at $\delta=24.3$ and 87.7, respectively, whereas the ^{31}P NMR resonance of **7** ($\delta=616.3$) is markedly shifted upfield relative to **3** ($\Delta\delta(^{31}P)=-149.4$ ppm). The ν(CO) region in the IR spectrum of **7** features seven sharp bands, which, with respect to position and

[+] Present address:
Fakultät für Chemie der Universität
Postfach 8640, D-4800 Bielefeld (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and BASF AG, Ludwigshafen (FRG).

intensity, are identical with those observed for the complex $[\{(C_5Me_5)(CO)_2Fe\}P\{Cr(CO)_5\}=PAryl]$[9] and the complex $[\{(C_5Me_5)CO)_2Fe\}As\{Cr(CO)_5\}=PAryl]$,[10] thus indicating a similar σ-donor/π-acceptor relationship of the ligands $[\{(C_5Me_5)(CO)_2Fe\}E^1=E^2Aryl]$ (E^1, E^2 = P, As) toward the $Cr(CO)_5$ group. In the mass spectra (EI) of **4** and **5**, the peaks with the largest *m/z* value correspond to the molecular ions, whereas the molecular ion peak of **6** was not observed under comparable conditions. In the FD mass spectrum of **6**, the molecular ion of **3** produces the peak of greatest intensity. An additional signal at *m/z* = 918 (37%) is assigned to **5**. The facile fragmentation of **6** to **3** and **5** is possibly due to the very bulky substituents.

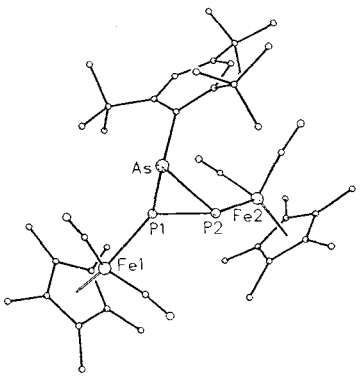

Fig. 1. Molecular structure of **4**. Selected bond lengths [Å] and angles [°]: As-P1 2.316(1), As-P2 2.350(2), P1-P2 2.207(2), As-C 2.010(6), Fe1-P1 2.373(2), Fe2-P2 2.326(2); P1-As-P2 56.5(1), As-P1-P2 62.5(1), As-P2-P1 61.0(1), P1-As-C 105.8(1), P2-As-C 104.5(2), As-P1-Fe1 110.5(1), P2-P1-Fe1 117.1(1), As-P2-Fe2 124.6(1), P1-P2-Fe2 105.3(1).

The X-ray structure analysis of **4** is of particular importance[11] since there is little available structural information on molecules containing As–P bonds[12] and such data are fully lacking for As–P three-membered rings. The basic framework of the molecule consists of an AsP_2 triangle in which the As–P2 bond (2.350(2) Å), with the substituents in *cis* orientation, is slightly lengthened compared with the As–P1 bond (2.316(1) Å). The P–P bond lengths (2.207(2) Å) correspond to the normal value.[13] As expected, the endocyclic angle at the As atom (56.5(1)°) is smaller than those at the phosphorus centers (61.0(1)° and 62.5(1)°).

The $[(\eta^5\text{-}C_5Me_5)(CO)_2Fe]$ groups on P1 and P2 are oriented in a *trans* fashion. The steric bulk of the substituents on the AsP_2 framework results in markedly increased exocyclic bond angles at P1 (110.5°, 117.1°) and P2 (124.6°, 105.3°).

Experimental procedure

NMR spectra recorded in C_6D_6 at 22°C; ^1H NMR, 200 MHz; IR spectra recorded in cyclopentane.

2: A 2.5 M solution of *n*-butyllithium in hexane (23 mL) was added dropwise to a solution of 1-bromo-2,4,6-tri-*tert*-butylbenzene (18.1 g, 55.6 mmol) in THF (250 mL). After stirring for 1 h at −50°C, the reaction mixture was cooled to −70°C and treated dropwise with $AsCl_3$ (4.7 mL, 55.6 mmol). The green reaction solution was evaporated to dryness (−30°C) and the residue was dissolved in *n*-pentane (150 mL), the resulting solution filtered, and the filtrate concentrated until the onset of crystallization. Colorless crystalline needles formed at −28°C and were recrystallized from *n*-pentane. Yield 5.3 g (24%) **2**. ^1H NMR: δ = 1.15 (s, 9H, *p*-*t*Bu), 1.51 (s, 18H, *o*-*t*Bu), 7.44 (s, 2H, aryl). EI-MS: *m/z* 390 ($M^{\oplus}$).

4–**6**: A solution of **1** (1.40 g, 3.30 mmol) [7] in THF (30 mL) at 0°C was treated with **2** (1.29 g, 3.30 mmol), resulting in a spontaneous change in color from red-brown to dark green. The reaction mixture was stirred for an additional 5 min at 20°C and then evaporated to dryness. The solution of the residue in 20 mL of ether afforded red-violet crystals of **4** at −28°C (0.14 g, 10%). ^1H NMR: δ = 1.39 (s, 9H, *p*-*t*Bu), 1.53 (s, 15H, C_5Me_5), 1.67 (s, 15H, C_5Me_5), 1.98 (s, 18H, *o*-*t*Bu), 7.35 (s, 2H, aryl). $^{31}P\{^1H\}$ NMR (AB spectrum): δ_A = 6.4 (P1), δ_B = 40.6 (P2), *J*(AB) = 227 Hz. IR (CO): $\tilde{\nu}$ = 1994 (m), 1988 (s), 1948 (s), 1945 (s) cm^{-1}. EI-MS: *m/z* 876 ($M^{\oplus}$). On concentration of the mother liquor to ca. 15 mL, 0.07 g (5%) of **5**, m.p. 157°C (dec.), was obtained. ^1H NMR: δ = 1.36 (s, 18H, *p*-*t*Bu), 1.58 (s, 15H, C_5Me_5), 1.65 (s, 36H, *o*-*t*Bu), 7.26 (s, 4H, aryl). $^{31}P\{^1H\}$ NMR: δ = 24.2 (s); IR (CO): $\tilde{\nu}$ = 1992 (vs), 1980 (w), 1949 (vs), 1939 (w) cm^{-1}. EI-MS: *m/z* 917 ($M^{\oplus}$). The green mother liquor was concentrated to ca. 5 mL and allowed to stand overnight at −28°C, thereby affording 0.54 g (27%) of dark green crystals of **6**, m.p. 133°C (dec.). ^1H NMR: δ = 1.36 (s, 18H, *p*-*t*Bu), 2.10 (s, 18H, *o*-*t*Bu), 7.36 (AB spectrum, J_{AB} = 2 Hz, 2H, aryl), 7.55 (AB spectrum, J_{AB} = 2 Hz, 2H, aryl). $^{31}P\{^1H\}$ NMR: δ = 87.7 (s); IR (CO): $\tilde{\nu}$ = 1983 (vs), 1947 (s), 1931 (m) cm^{-1}. FD-MS: *m/z* 598 ($[(\eta^5\text{-}C_5Me_5)(CO)_2Fe\text{–}P{=}As\text{–}Aryl]^{\oplus}$, 100%).

7: After a reaction time of 5 min, the solution of **1** (3.14 g, 7.40 mmol) and **2** (2.90 g, 7.40 mmol) in THF (50 mL) was treated with 80 mL of a photochemically freshly prepared solution of $[((Z)\text{-}C_8H_{14})Cr(CO)_5]$ (10.00 mmol) in hexane. After stirring for 1 h at 20°C, the reaction solution was evaporated to dryness and the solid residue was chromatographed (Al_2O_3 Woelm TSC); column, *d* = 5 cm, *l* = 25 cm). Elution with petroleum ether gave an orange zone containing 0.05 g of **8** (2%). Subsequent elution with a mixture of petroleum ether and ether (5 : 1) gave a dark green zone, from which 1.36 g (31%) of **6** could be isolated. A red fraction followed which contained 1.88 g (32%) of red **7**, m.p. 184°C (dec.). ^1H NMR: δ = 1.38 (s, 9H, *p*-*t*Bu), 1.47 (s, 15H, C_5Me_5), 1.71 (s, 18H, *o*-*t*Bu), 7.65 (s, 2H, aryl). $^{31}P\{^1H\}$ NMR: δ = 616.3 (s). IR: $\tilde{\nu}$ = 2061 (s), 1986 (w), 1946 (vs), 1938 (s), 1925 (s) [Cr(CO)], 2018 (s), 1973 (s) cm^{-1} [Fe(CO)]. Carbon as Leaving Group—Stereochemistry of Nucleophilic Substitution

By *Wolfgang Kirmse** and *Klaus Zander*

Dedicated to Professor Günther Snatzke on the occasion of his 60th birthday

Grob's cationic fragmentation[1] can be regarded as the reverse of electrophilic addition to alkenes or—referred to

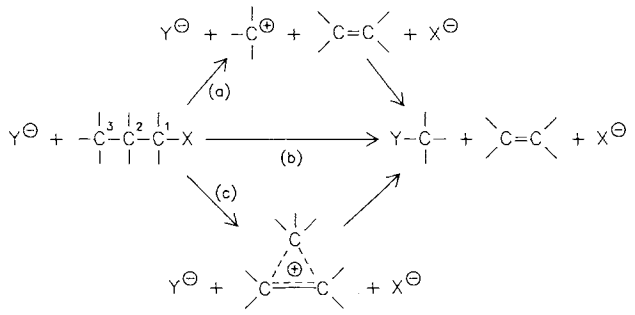
Fakultät für Chemie der Universität
Postfach 102148, D-4630 Bochum 1 (FRG)

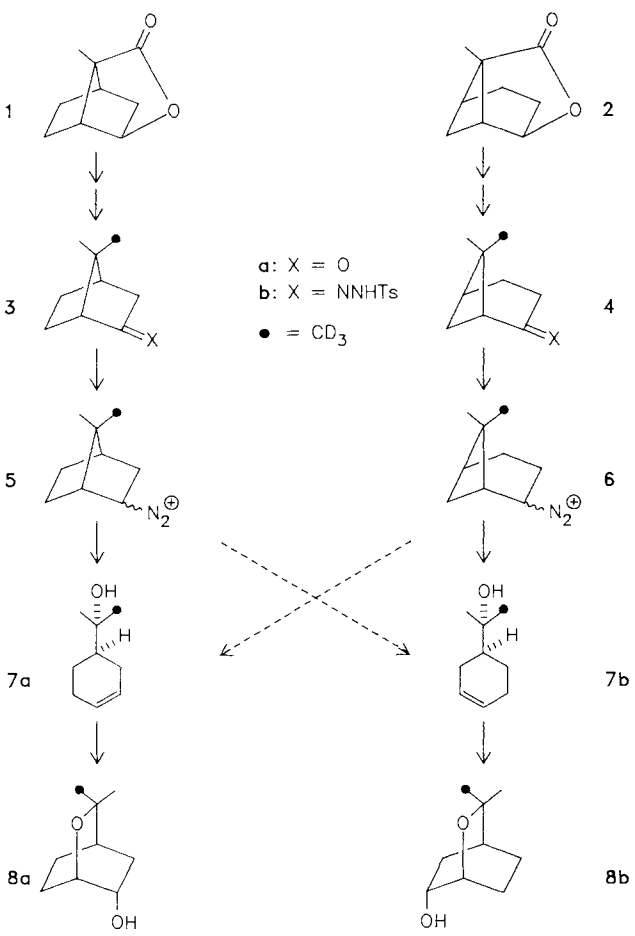
C-3—as nucleophilic substitution. Whereas an antiperiplanar arrangement of the C-X and C-2-C-3 bonds is known to be a prerequisite for many fragmentations,[1] the stereochemistry at C-3 has, to our knowledge, not yet been investigated. Frequently, the fragmentation is supported by donor substituents (NR_2, OR) on C-3; it then leads to planar, resonance-stabilized fragment ions (route a in Scheme 1). Our studies are concerned with bicyclic educts whose fragmentation is promoted by the release of ring strain.



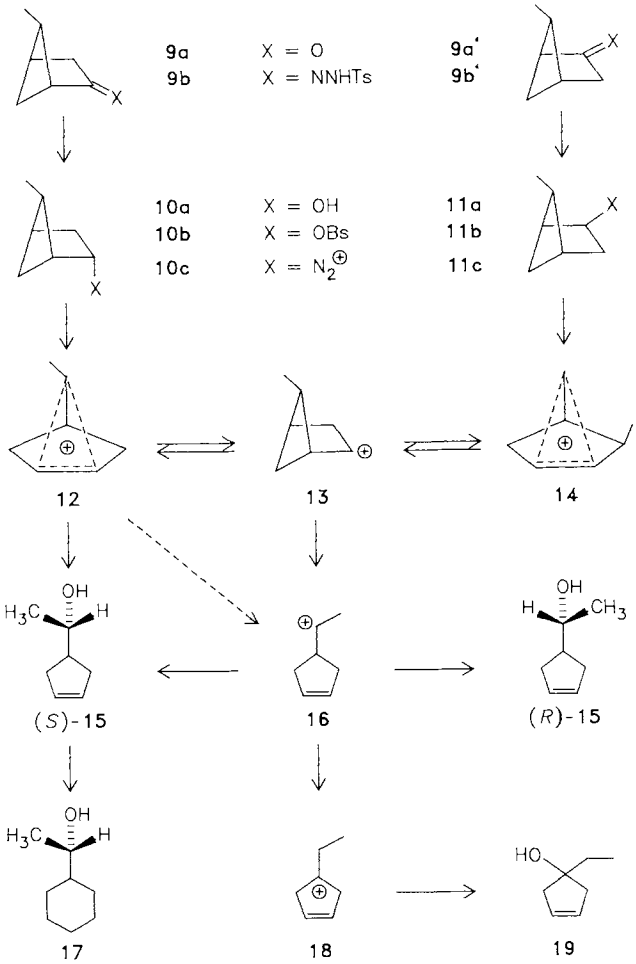
Scheme 1.

In the bicyclo[2.2.1]heptane[2-4] and bicyclo[3.1.1]heptane series,[5] fragmentation takes place only with a peralkylated carbon atom as electrofugal group and with *endo*(*trans*) position of X. Suitably labeled starting compounds for our studies were obtainable from the known lactones **1**[6] and **2**[7] by stepwise reduction[8] with $LiAlD_4$ (Scheme 2). The diazonium ions **5** and **6**, (*exo,endo* mixtures, only the *endo*-diazonium ions fragment[2-5]) were generated from the tosylhydrazones **3b/4b** of the ketones **3a/4a**, respectively, by irradiation in aqueous sodium hydroxide. The ring-opening product **7** (9% from **3b**, 15% from **4b**) shows separate signals in its ^{1}H-NMR spectrum (400 MHz) for the diastereotopic methyl groups ($\delta = 1.12$ and 1.13), the intensities of which give the amounts of **7a** and **7b**, respectively. For the determination of the configuration, **7** was converted by epoxidation and base-induced ring-closure into **8**, whose methyl groups ($\delta = 1.10$ and 1.28) can be assigned by NOE measurements. **3b** preferentially affords **7a**, **4b** preferentially **7b**; both starting compounds chiefly react with inversion (Table 1).

The increased ring strain of the bicyclo[2.1.1]hexane skeleton facilitates fragmentations also with a secondary carbon atom as electrofugal group.[9] Reduction of the racemic ketone **9**[9,10] with fermenting yeast yielded the alcohols **10a** ($ee = 98\%$)[11] and **11a** ($ee = 66\%$) in the ratio 1.2 : 1 (Scheme 3). Reoxidation of **10a** and **11a** afforded enantiomeric ketones; the (1*R*,4*R*,5*R*)-configuration was assigned to the dextrorotatory ketone **9a** on the grounds of its positive circular dichroism.[12] Irradiations of the tosylhydrazone **9b** in aqueous sodium hydroxide and solvolysis of the brosylates **10b** and **11b** in acetone/water (3 : 2, 110 °C, 18 h) furnished product mixtures from which the ring-opening product **15** was separated; its configuration was determined by ring expansion (1. dibromocarbene; 2. hydrogenation) to the known (+)-(*S*)-**17**.[13] The configuration of the brosylate not only influences the yield of **15**



Scheme 2.



Scheme 3.

Table 1. Stereochemistry of the fragmentations.

Starting compound	Product	Inversion : Retention
3b	**7**	81 : 19
4b	**7**	75 : 25
9b	**15**	88 : 12
10b	**15**	93 : 7
11b	**15**	79 : 21

(**10b**: 36%, **11b**: 9%), but also its enantiomeric purity (Table 1).[11] A 1:1 mixture of the epimeric diazonium ions (**10c**, *ent*-**11c**) is expected from the tosylhydrazone **9b**; the results (18% **15**) lie between those for **10b** and **11b**. **15** is always formed with pronounced inversion (Table 1).

The substitution reactions of the methylbicyclo-[2.1.1]hexane derivatives indicate the participation of bridged (e.g. **12** and **14**) and open carbocations (e.g. **13**).[9] The transformation **14** ⇄ **12** via **13** is probably the reason for the (inefficient) fragmentation of **11b**, despite the "wrong" position of the OBs group. The ring-opening with inversion to (*S*)-**15** can be ascribed to the bridged ion (π-complex) **12**, whereas racemic **15** is formed from **16**. Evidence for the occurrence of **16** is provided by the H-shift **16** → **18**, which leads to the tertiary alcohol **19**. The amount of **19** formed in the fragmentation reactions is, however, markedly smaller than in the direct generation of **16**. That **12** can be formed directly from **10b** but only indirectly (via **13**) from **11b** would explain the differences in yield and enantiomeric purity of **15** from the two processes.

The ring opening **5/6** → **7** can be formulated in an analogous way, whereby a 7-bridged norbornyl cation[14] is formed instead of **12**. The predominant but incomplete inversion indicates that the fragmentations investigated here are limiting cases of nucleophilic substitution. Such borderline cases (e.g. solvolyses of secondary alkylsulfonates) have been explained in terms of a competition between or "blending" of the mechanistic extremes (e.g. S_N1/S_N2).[15] In our opinion the observed stereoselectivity is best explained in terms of a competition of the fragmentation routes (a) and (c) in Scheme 1.[16]

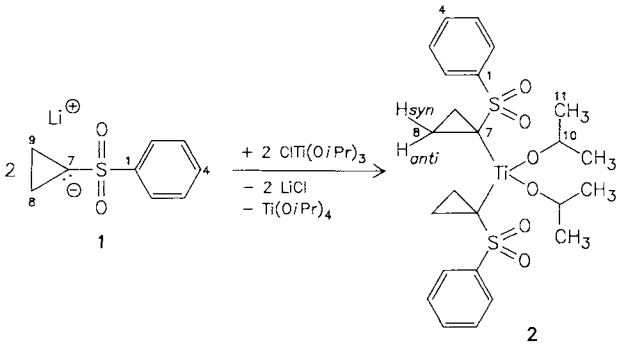
[16] We consider a participation of the completely concerted route (b) in Scheme 1 as unlikely. The contribution of (b) should increase with increasing ring strain (**5/6**) and with poorer leaving groups (**10b/10c**) and should increase the stereoselectivity. This was not observed.

Synthesis and Structure of [*cyclo*-C_3H_4–$SO_2Ph]_2Ti[OCH(CH_3)_2]_2$, a *C*-Titanated "α-Sulfonyl Carbanion"**

By *Hans-Joachim Gais,* Jürgen Vollhardt, Hans J. Lindner,* and *Helmut Paulus*

The titanation of heteroatom- or resonance-stabilized "carbanions" is a valuable instrument for control of selectivity.[1,2] However, little is known on the structures[3] of the titanium compounds formed.[1,2,4] Our investigations on the reactivity of titanated sulfones[2b] led us, therefore, to investigate their structure.[5]

Herein we report on the synthesis, crystal structure analysis, and characterization by NMR spectroscopy of the titanium compound **2**, which was generated from (phenylsulfonyl)cyclopropyllithium **1** and chlorotriisopropoxytitanium by Li–Ti exchange and crystallized from *n*-hexane. Crystalline **2** is stable at room temperature if protected from air and moisture.



1 2

According to the crystal structure analysis,[6] **2** is a true diorganotitanium compound containing two enantiomeric (phenylsulfonyl)cyclopropyl moieties and displaying normal Ti–C distances (average value 2.177 Å) and short Ti–O*i*Pr bonds (average value 1.763 Å) (Fig. 1). Noteworthy is the observation that one O atom of each sulfonyl group is coordinated to the Ti atom, thereby extending the coordination number of the metal atom to 6. Evidence for the existence of the two O–S–C–Ti chelate rings and thus for

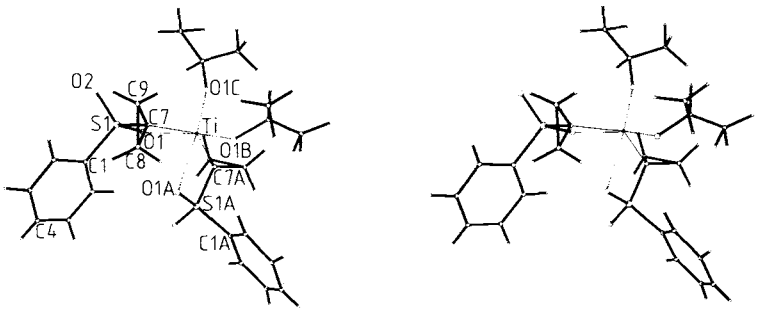

Fig. 1. Stereoview of the molecular structure of **2**. Selected distances [Å] and angles [°]: Ti-C7 2.181(3), Ti-C7A 2.174(4), C7-S1 1.725(4), C7A-S1A 1.719(4), C1-S1 1.779(4), C1A-S1A 1.759(4), S1-O1 1.476(2), S1-O2 1.445(3), C7-C8 1.503(5), C7-C9 1.497(6), C8-C9 1.466(6), Ti-O1B 1.771(3), Ti-O1C 1.755(2), Ti-O1 2.315(3), Ti-O1A 2.243(2); O1B-Ti-O1C 102.6(1), C7-Ti-C7A 139.7(1), Ti-C7-S1 95.9(2), Ti-C7A-S1A 95.0(2), Ti-C7-C8 124.7(3), Ti-C7-C9 135.3(3), C7-Ti-O1-S1 3.2, C7A-Ti-O1A-S1A 3.8, O1-S1-C7-C8 −133.8, O1-S1-C7-C9 156.6, O2-S1-C7-C8 101.2, O2-S1-C7-C9 31.6.

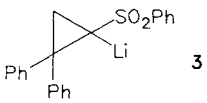
the binding of the titanium atom via a C *and* an O atom to the deprotonated sulfone is provided by the Ti-O1/O1A distances (average value 2.279 Å), the dihedral angles C-Ti-O-S (average value 3.5°), the conformation around C7-S1, the bond angles Ti-C-S (average value 95.4°), and the distortion of the tetrahedral coordination geometry at the Ti atom. The greater length of the S1-O1 bond compared with the S1-O2 bond also fits this description. For dilithiosulfones,[7] lithiosulfoximines,[8] and a phenylsulfonyl-substituted Sb ylide,[9] similar chelate rings were found in the crystal. The bond between the "carbanionic" C atom and the sulfonyl group in **2**, 1.722 Å (average value), is significantly longer than that (1.676(7) Å) in **3**,[10a] which, remarkably in contrast to other alkali-metal sulfones,[10b,c] exhibits a C-Li bond and a Li-C-S-O chelate ring in the crystal; **2** also does not have the C_α-S conformation of **3** required for an $n_C-\sigma^*_{SPh}$ interaction.[10b]



3

Table 1. ^1H and ^{13}C NMR data of **1** and **2** [a].

1: ^1H NMR (60 MHz, [D$_8$]THF, 25°C, 0.2 M, [D$_7$H]THF: δ(β-H) = 1.72): δ = 0.42 (d, ^2J(C7,8/9-H) = 2.0 Hz; 8-H, 9-H), 7.2 (m; 2-H, 6-H), 7.5 (m; 3-H, 4-H, 5-H); 400 MHz: δ = 0.43 (br. s; 8-H, 9-H), 7.33 (m; 3-H, 4-H, 5-H), 7.63 (m; 2-H, 6-H). ^{13}C NMR (100 MHz, [D$_8$]THF, 25°C, 0.2 M, [D$_8$]THF: δ(β-C) = 25.2): δ = 7.6 (s, ^{1+2}J(C7,C8/9) ≤ 1.4 Hz; C8, C9) [b], 28.5 (br. s, C7), 129.0, 128.1 (C2, C6, C3, C5), 130.2 (C4), 139.8 (br. s; C1) [c]

2: ^1H NMR (400 MHz, [D$_6$]benzene, 25°C, 0.3 M, [D$_5$H]benzene: δ = 7.16): δ = 1.24 (d, J = 6 Hz; 11-H), 1.27 (m; 8-H$_{anti}$, 9-H$_{anti}$) [d], 1.58 (m; 8-H$_{syn}$, 9-H$_{syn}$) [d], 4.86 (sept., J = 6 Hz; 10-H), 6.98 (m; 3-H, 4-H, 5-H), 8.25 (m; 2-H, 6-H). ^1H NMR (400 MHz, [D$_8$]THF, 25°C, 0.3 M, [D$_7$H]THF: δ(β-H) = 1.72): δ = 1.06 (m; 8-H$_{syn}$, 9-H$_{syn}$) [d], 1.29 (d, J = 6 Hz; 11-H), 1.43 (m; 8-H$_{anti}$, 9-H$_{anti}$) [d], 4.90 (sept., J = 6 Hz; 10-H), 7.50 (m; 3-H, 5-H), 7.60 (m; 4-H), 8.07 (m; 2-H, 6-H). ^{13}C-NMR (20 MHz, [D$_6$]benzene, 25°C, 0.3 M, [D$_6$]benzene: δ = 128.0): δ = 16.9 (C8, C9), 26.0 (C11), 52.4 (C7), 80.4 (C10), 128.63, 128.69 (C2, C6, C3, C5), 132.7 (C4), 140.5 (C1)

[a] *cyclo*-$C_3H_5SO_2Ph$: ^1H NMR (250 MHz, $CDCl_3$, TMS): δ = 1.04 (m, 8-H$_{anti}$, 9-H$_{anti}$), 1.36 (m, 8-H$_{syn}$, 9-H$_{syn}$), 2.48 (tt, J = 7.8, 4.3 Hz; 7-H), 7.57 (m; 3-H, 5-H), 7.65 (m; 4-H), 7.91 (m; 2-H, 6-H). ^{13}C NMR (100 MHz, $CDCl_3$, TMS): δ = 6.0 (C8, C9), 32.9 (C7), 127.6 (C2, C6), 129.3 (C3, C5), 133.4 (C4), 140.8 (C1). [b] For (1-trimethylsilylcyclopropyl)phenylsulfone and cyclopropylphenylsulfone, on the other hand, ^{1+2}J(C7,8/9) = 6.0 and 10.5 Hz, respectively. [c] Measured for [^{13}C,^{6}Li]-**1**. [d] AA'XX' system.

The ^1H and ^{13}C NMR spectroscopic data of **2** (Table 1) show that it, too, exists in solution as an organotitanium compound. Evidence is provided by the chemical shift of δ = 52.4 for the cyclopropyl C atom bearing the Ti atom and the diastereotopism of the cyclopropyl H atoms 8-H$_{syn}$/9-H$_{syn}$ and 8-H$_{anti}$/9-H$_{anti}$ manifested by the signals at δ = 1.06 and 1.43. In the ^{13}C NMR spectrum of the lithiosulfone **1**, on the other hand, the signal of the "carbanionic" C atom is found at δ = 28.5; no ^1J(^{13}C,^{6}Li) coupling is apparent down to −110°C and, owing to rapid (on the NMR time scale) inversion of this C atom and rotation of the SO_2Ph group,[11] only a broad signal at δ = 0.43 is found for the four cyclopropyl H atoms in the 400-MHz ^1H NMR spectrum (Table 1). The downfield shift of the signal for C7 upon exchange of lithium for titanium with formation of a C-Ti bond (**1** → **2**) is in agreement with expectations.[1a,4,12]

The lithium and titanium species **1** and **2**, respectively, differ markedly in their reactivity. Whereas **1** reacts rapidly with methyl iodide at −35°C in THF to give (1-methylcyclopropyl)phenylsulfone[14] (97%), **2** is not methylated under these conditions. Workup of **2** with CF_3COOD affords a C7-deuterated cyclopropylphenylsulfone. We made similar findings with other titanated sulfones.[2b] The existence of a titanium species **2** in solution with O-Ti bonds, but no C-Ti bonds, would be in poor agreement with the available spectroscopic and chemical findings.

Experimental Procedure

Cyclopropylphenylsulfone (632 mg, 3.47 mmol) was dissolved in 15 mL of water- and oxygen-free ether and treated at −80°C with 2.1 mL of a 1.67 M solution of *n*BuLi in *n*-hexane. The resulting suspension of **1** [15] was warmed to room temperature (RT) and then added dropwise to a solution of $ClTi(OiPr)_3$ (905 mg, 3.47 mmol) in 10 mL of water- and oxygen-free ether at −50°C. Upon warming to RT, dissolution takes place followed a short time later by precipitation of LiCl. After 1 h at RT, the reaction solution was filtered, the solvent was removed, and the residue was dissolved in 25 mL of water- and oxygen-free *n*-hexane by warming to 60°C. The hot solution was filtered and the filtrate cooled to 6°C, affording, after 5 h, **2** (630 mg, 69%) as colorless crystals.

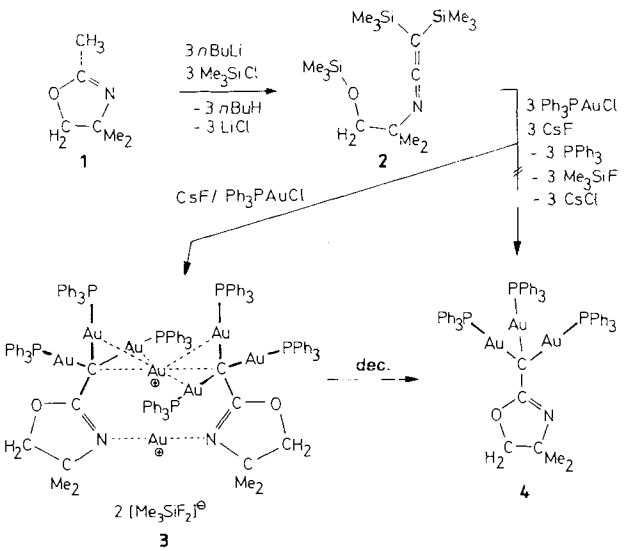
Use of the CH Acidity of 2,4,4-Trimethyl-4,5-dihydrooxazole to Synthesize Triauriomethanes and Novel Gold Clusters**

By *Franz Scherbaum, Brigitte Huber, Gerhard Müller,* and *Hubert Schmidbaur**

Gold forms numerous organometallic compounds, those with discrete Au–C σ bonds dominating by far. However, π complexes of this element are rare and usually of low stability.[1] In this respect, gold shows similarities to the organometallic chemistry of the neighboring elements mercury and thallium.[2] A unique feature of organometallic compounds of gold, on the other hand, is the existence of surprisingly strong bonding interactions between two-coordinate gold atoms with a d^{10} electron configuration. In the case of *intra*molecular bonding forces between polynuclear compounds, for example, certain conformations are favored.[3] For mononuclear gold complexes or polynuclear analogues having an unfavorable relative arrangement of the metal atoms, *inter*molecular interactions occur.[4] These as yet poorly understood phenomena, which are at least in part due to relativistic effects, should become particularly pronounced when many gold atoms are bonded to one common center. For this reason, we have attempted, inter alia,[5] to synthesize polyauriomethanes whose structures and properties could provide further insight into the nature and consequences of secondary Au···Au interactions.

Polyauriomethanes are formed particularly readily from substrates containing CH-acidic groups.[6] For instance, the only *tri*auriomethane so far known is derived from ylide-forming phosphonium salts.[7] Accordingly, we have now succeeded in generating a triauriomethane derivative by exploiting the CH acidity of 2-methyl-4,5-dihydrooxazoles.[8] However, the new product, generated in a very unusual way (Scheme 1), exhibited a surprisingly high acceptor strength for further Au^I ions, which led to the formation of a novel cluster containing exclusively metal atoms in the oxidation state +I.

The synthesis starts from 2,4,4-trimethyl-4,5-dihydrooxazole **1**: Trilithiation followed by derivatization with chlorotrimethylsilane gives the open-chain, triply silylated ketenimine **2** (Scheme 1). Without further purification, **2** can react with four equivalents of triphenylphosphanegold(I) chloride in hexamethylphosphoric triamide (HMPT) at 20°C in the presence of cesium fluoride to give the yellow-orange gold cluster **3** in nearly quantitative yield. The analytical and spectroscopic data of the product corresponded in no way to those expected for **4**. In solution, however, **3** decomposes to **4**, thereby indicating that **4** is a component of **3**.



Scheme 1.

The X-ray structure analysis[9] of **3** allowed not only the elucidation of the structure of the cluster cation, but also revealed the presence of the likewise unexpected trimethyldifluorosilicate anions. Although this anionic species has been described,[10] it is difficult to characterize spectroscopically owing to rapid exchange processes.

The cation possesses a crystallographic twofold axis (through the gold atoms Au4 and Au5, Fig. 1). The central

C atom of each moiety (C1, C1′) was originally the methyl C atom of the dihydrooxazole (in position 2). The heterocycle, which is opened in going to **2**, is once again closed in the course of the polyauration. Apparently, the molecules **4**, thereby formed, efficiently bind further Au^I ions. In this process, the formation of a bridge (N3-Au4-N3′) involving the two N atoms of the dihydrooxazole rings and an Au^I ion is less surprising than the unprecedented binding of an Au^I ion, Au5, to the triangles defined by C1-Au1-Au3 and C1′-Au1′-Au3′. The $RC(AuL)_3$ molecule thus proves to be "aurophilic".[12]

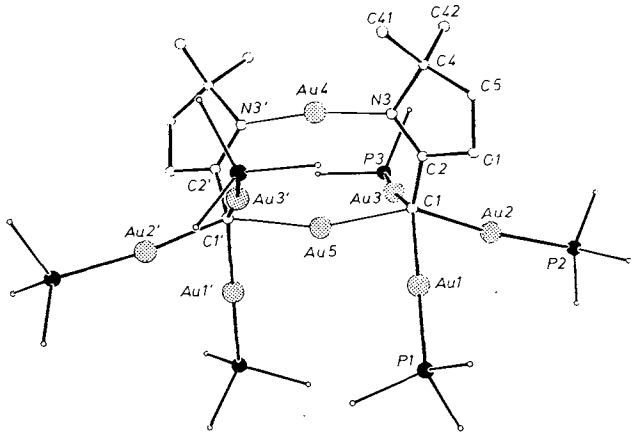

Fig. 1. Molecular structure of the dicationic gold cluster **3** (ORTEP, arbitrary radii). A twofold axis through Au4 and Au5 lies in the plane of the paper. Only the C_{ipso} atoms of the phenyl groups are shown. Selected bond lengths [Å] and angles [°]: C1-Au1 2.12(1), C1-Au2 2.16(1), C1-Au3 2.12(1), C1-Au5 2.22(1), N3-Au4 1.99(1), Au1-P1 2.265(5), Au2-P2 2.273(5), Au3-P3 2.259(4), C1-C2 1.50(2); C2-C1-Au1 117.7(9), C2-C1-Au2 106.8(9), C2-C1-Au3 111.2(8), C2-C1-Au5 109.6(9), Au1-C1-Au2 83.3(4), Au2-C1-Au3 83.1(5), Au3-C1-Au5 80.2(4), Au5-C1-Au1 83.6(4), C1-Au5-C1′ 161.9(6), N3-Au4-N3′ 170.3(7).

The carbon atom C1 (C1′) in **3** is bonded to C2 (C2′) and, in addition, to four gold atoms, which form a four-sided polygon of roughly equal edge length: Au1-Au2 2.839(1), Au2-Au3 2.839(1), Au3-Au5 2.799(1), Au5-Au1 2.893(1) Å. Thus, the pentacoordinated atoms C1 and C1′ have a tetragonal-pyramidal environment; Au5 is the common corner of the two pyramids. The planes through the gold atoms Au1, Au2, Au3, Au5, and Au1′, Au2′, Au3′, Au5 form an angle of 73.2°. The Au4–Au5 distance (2.811(1) Å) is also short; thus, all eight Au atoms are components of a single cluster. C1, C2, N3, Au4, N3′, C2′, C1′, and Au5 thereby form a slightly twisted eight-membered ring system (angle formed by the planes Au4,N3,C2,C1,Au5/Au4,N3′,C2′,C1′,Au5 = 17.5°) having a transannular Au···Au contact distance, as is typical of many binuclear gold(I) complexes.[11]

The gold atoms Au1–Au3 bear phosphorus atoms lying on the line defined by the C1–Au bonds; the ^{31}P NMR spectra show that, even in solution, these phosphorus atoms are not equivalent. The ABC spin system can be simulated. In agreement with the C_2 symmetry, the H atoms on C5, as well as the methyl groups on C4, are diastereotopic (^1H and ^{13}C NMR). The phenyl groups give rise to three sets of ^{13}C NMR signals. These findings prove that the double Au^I bridging of the two moieties **4** to give **3** is also occurs in solution and is not affected by solvation.

In the crystal, the counterions $[(CH_3)_3SiF_2]^{\ominus}$ display a nearly trigonal-bipyramidal structure with the fluorine atoms in axial positions. In solution, only singlets are observed in the ^1H, ^{13}C, and ^{19}F NMR spectra owing to rapid $F^{\ominus}$ exchange. The crystals of **3** contain, in addition, CH_2Cl_2 and (strongly disordered) diethyl ether molecules. Both are also revealed upon dissolution by NMR spectroscopy.

It is remarkable that formation of **3** occurs in the presence of the triphenylphosphane released from Ph_3PAuCl. Therefore, binding of the phosphane ligand is suppressed not only by the N atoms of the dihydrooxazole but also by the σ framework of the triauriomethane **4**, which also functions, unexpectedly, as a donor. This phenomenon demonstrates the high formation tendency of the cluster.

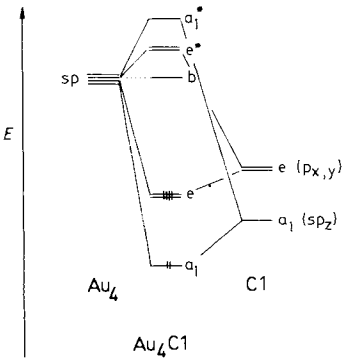

Fig. 2. MO scheme describing the bonding in the tetragonal pyramids around the atoms C1 and C1′ in **3** (idealized point group C_{4v}; only one sp hybrid orbital of each gold atom and the orbitals p_x and p_y of C1 are shown).

The MO description of the bonding in the $C2C1Au_4$ structural unit offers no difficulties. On the contrary, it is amazing that, in the point group C_{4v} according to the scheme shown in Figure 2, the linear combination of the frontier orbitals of the atoms involved gives rise to exactly three binding cluster orbitals, which can be filled with the six available electrons. Here, the four Au atoms, as well as the C1 atom, were assumed to be sp hybridized, which corresponds well to the actual geometry in the two tetragonal pyramids in **3**.

Experimental Procedure

2: **1** (8.73 g, 77.2 mmol) was dissolved in diethyl ether (75 mL) and treated at −55 °C with a solution of *n*-butyllithium (77.4 mmol) in *n*-hexane. The solution was stirred for 30 min, Me_3SiCl (8.4 g, 77.3 mmol) was then added, and the resulting mixture was stirred for 2 h at −45 to −20 °C. The same silylation procedure was repeated with two more equivalents of the same reagents. The reaction was allowed to proceed for 10 h at −20 to +10 °C; 100 mL of hydrochloric acid was then added at 0 °C (pH = 2), the two-phase mixture was separated, and the aqueous phase was extracted with 2 × 50 mL of ether. Drying of the combined organic extracts over sodium carbonate and removal of all volatiles in vacuo afforded **2** as a colorless oil. IR (neat): $\tilde{\nu}$ = 2002 cm^{-1} (C=C=N). ^1H NMR (C_6D_6): δ = 0.08 (s, 9H; $SiMe_3$), 0.19 (s, 18H; $SiMe_3$), 1.23 (s, 6H; CMe_2), 3.38 (s, 2H; CH_2). ^{13}C NMR (C_6D_6): δ = −0.46 (Me_3SiO), 1.29 (s; Me_3SiC), 25.61 (s; Me_2C), 59.39 (s; CMe_2), 71.39 (s; CO), 169.18 (s; C=N). The ^1H-coupled spectrum gave the expected multiplicities. ^{29}Si NMR (C_6D_6): δ = −1.83 (s, 1Si; SiO), 17.86 (s, 2Si; Si_2C).

3: CsF (2.5 g, 16.5 mmol, excess) was added to a solution of Ph_3PAuCl (1.50 g, 3.03 mmol) in 40 mL of HMPT. Compound **2** (0.25 g, 0.76 mmol) in 20 mL of HMPT was added to the resulting suspension with stirring. The reaction mixture was stirred for 3 d at 22 °C under nitrogen in the dark; it was then filtered and the filtrate was diluted with 60 mL of benzene. Addition of 300 mL of pentane resulted in precipitation of a yellow product, which was collected by filtration, crystallized from CH_2Cl_2/Et_2O, washed with pentane, and dried in vacuo. Yield 1.31 g (96.2%) **3**, dec. 134–136 °C. ^1H NMR (CD_3CN): δ = 0.27, 1.31 (s, each 3H; Me_2C), 3.68, 4.22 (each 1H, AB, $J(HH)$ = 8.79 Hz; CH_2), 6.8–7.8 (m, 45H; Ph), −0.18 (s; Me_3Si), 1.08, 3.37 (t and q, J = 6.95 Hz; Et_2O). ^{13}C NMR (CD_3CN): δ = 27.88, 29.89 (s; Me_2C), 66.11, 81.33, 187.10 (s, C6, C5, and C4); C3 is not observed owing to overlap of other signals; three sets of Ph resonances; Me_3Si, broadened by

exchange. ^{31}P NMR (CD_3CN): $\delta = 28.50, 28.55, 29.97$ (ABC, $J(PP) = 4.4$ Hz). FAB MS: m/z 1684.7 for the dication of **3**.

"Aurophilicity" as a Consequence of Relativistic Effects: The Hexakis(triphenylphosphaneaurio)methane Dication $[(Ph_3PAu)_6C]^{2\oplus}$**

By *Franz Scherbaum, Andreas Grohmann, Brigitte Huber, Carl Krüger,* and *Hubert Schmidbaur**

Recent work on polyauriomethanes[1-3] has revealed that the highly aurated compounds containing two or more gold atoms on one and the same carbon atom readily bond further gold(I) units $LAu^{\oplus}$ (L = R_3P), a property termed aurophilicity. The coordination number of the polyauriated C atoms is thereby increased beyond 4, so that, for example, tetragonal-pyramidal structures with close Au···Au contacts are formed. Based on local C_{4v} symmetry, a simple MO scheme for the cations $[RC(AuL)_4]^{\oplus}$ shows full occupation of the bonding orbitals, which well explains, at least qualitatively, the unexpected formation tendency of such systems.[2] The resulting bonds, directed toward the C atom, are complemented by contributions from Au···Au interactions, which, owing to relativistic effects, can be ascribed in part to the d^{10} systems.[4] Our investigation of this novel phenomenon has led us to seek synthetic routes to the first *tetraauriomethane*, which, because of its presumably still greater aurophilicity, would make it possible to prepare even more highly coordinated auriomethanes.

In analogy to relevant work on related mercuriomethanes,[5,6] we selected tetrakis(dimethoxyboryl)methane as our starting material.[5] This readily accessible precursor reacts with Ph_3PAuCl in tetrahydrofuran in the presence of CsF in excess within one day at room temperature to give a yellow-red suspension. After filtration and addition of benzene to the filtrate, a stable, colorless, crystalline substance can be isolated in high yields. The product is insoluble in diethyl ether, pentane, and benzene, but dissolves in di- and trichloromethane as well as in hexamethylphosphoric triamide to afford dilute solutions. Both the solid and the solutions are hardly sensitive toward air, but they are very hygroscopic.[7]

$\{^1H\}^{31}P$ NMR spectra of such solutions (CD_2Cl_2, $-60°C$) display a single signal, the position of which is largely temperature independent ($\delta = 27.73$). The $\{^1H\}^{13}C$ NMR spectrum displays one set of signals, indicating that the phenyl groups are equivalent. The resonances of C_{ipso}, C_{ortho}, and C_{meta} can be interpreted by simulation as $AA'A''X$ spin systems (A = P, X = C). C_{para} appears as a singlet. A slight temperature dependence (-60 to $+30°C$) does not lead to significant changes, but only affects the signal width and resolution. Further, a weak-intensity quartet is found ($\delta = 49.1$, $J(CF) = 4.4$ Hz), which can be assigned to the anion $[F_3BOCH_3]^{\ominus}$.[8] This corresponds to a quartet in the ^{11}B NMR spectrum ($\delta = -17.8$, $J(BF) = 14.2$ Hz) and to a broad singlet ($\delta = 3.20$) in the ^1H NMR spectrum. Two ^1H NMR multiplets at $\delta = 6.75$–7.10 and 7.10–7.52 can once again be assigned to the equivalent phenyl groups.

The substance is diamagnetic. In the mass spectrometric ionization (FAB), the heaviest ions detected are $[(Ph_3PAu)_6C]^{2\oplus}$ and the *mono*cation (m/z 1383.9 and 2767.8, respectively), which, together with the spectroscopic data and the values of the elemental analysis, support the formulation shown in Equation (a) for the reaction course:

$$C[B(OCH_3)_2]_4 + 6\,Ph_3PAuCl + 6\,CsF \longrightarrow 6\,CsCl + 2\,B(OCH_3)_3 + [(Ph_3PAu)_6C]^{2\oplus}[CH_3OBF_3]_2^{\ominus} \quad (a)$$

Despite much effort, it was not possible to detect the presumed carbon atom in the center of the proposed gold cluster by NMR spectroscopy. The X-ray structure analysis,[9] however, removed any doubts as to the structure. The investigation revealed the presence of an only slightly distorted octahedron of gold atoms, the crystallographic inversion center of which is occupied by a carbon atom (Fig. 1). A Ph_3P ligand is attached to each of the gold atoms, so that the Au(I) centers are each bonded classically (sp hybrids) in a linear fashion to one phosphorus atom and to the central carbon atom. The Au–P distances (average value 2.271 Å) are in good agreement with the values ex-

pected from the coordination chemistry of univalent, two-coordinate gold.[10]

The bonding between the central atom of the cluster and the six metal atoms can be described (not taking into consideration, initially, the closed-shell d^{10} states) by a simple MO diagram (Fig. 2; cf. also Ref. [11]). The scheme shows that, for the local symmetry O_h, four strongly bonding states (a_{1g} and t_{1u}) result from the six σ orbitals of the Au atoms (simplified: sp hybrids) and the s and p orbitals of the C atom. These four orbitals can just be fully occupied by the eight available electrons (diamagnetic singlet ground state). An e_g state remains as the LUMO. The gap between t_{1u} and e_g is so large that the compound does not absorb in the visible region. The six medium-length Au–C

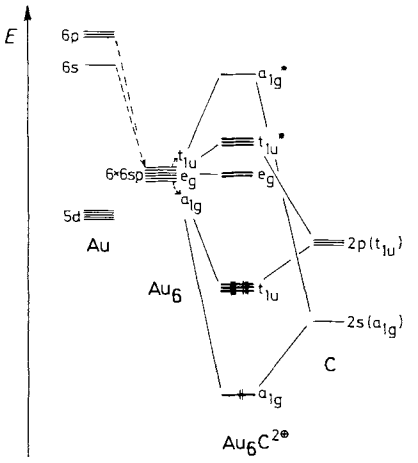

Fig. 2. MO diagram of the Au_6C framework in the cation $[(Ph_3PAu)_6C]^{2\oplus}$ not taking into consideration the d/s/p(Au,C) interactions: local symmetry O_h; s and p orbitals of the central C atom (right); the six sp hybrid orbitals of the metal atoms (left) are appreciably lowered by relativistic s contraction and almost attain the level of the d^{10} states. The six P atoms are bonded via electron-pair bonds formed from the other six sp(Au) hybrid orbitals, which leads to the radial arrangement of the C1–Au–P bonds (see Fig. 1).

bonds (2.124 Å) can be assigned a formal bond order of 2/3.[10] The reduction in energy due to overlap of the C and Au orbitals is improved considerably by the lowering of the energy levels of these orbitals by relativistic contraction.[12]

The average value (3.003 Å) of the Au···Au contacts along the edges of the octahedron lies in the range of those usually found for numerous polynuclear gold complexes.[13] The lowering in energy resulting here mainly from d^{10}–d^{10} interactions was recently estimated from a binuclear model to be ca. 6–8 kcal mol^{-1}, the first such experimental determination.[14] Even if this amount must be reduced in the cluster owing to polycoordination of each metal atom (four nearest Au neighbors), the twelve edges of the cluster give rise to a considerable lowering in energy upon aggregation, which explains quite well the aurophilicity of the tetraauriomethanes $C(AuL)_4$ toward $LAu^{\oplus}$.

In the long series of reported clusters containing low-valent gold atoms (having an average oxidation state between 0 and +I), there is one example[15] in which six gold atoms form an octahedron, which, however, is supposedly *not occupied at the center:* namely, $[\{(p\text{-}MeC_6H_4)_3PAu\}_6][B(C_6H_5)_4]_2$. This cluster is of interest because the synthesis, carried out only once and affording a minimal yield, could not be repeated[16, 17] and because its geometry could not be fitted into the overall scheme of noble-metal clusters: For $(LAu)_6^{2\oplus}$ aggregates, the structure is predicted to be an edge-sharing double tetrahedron, which, in other cases, was indeed found.[18] An analysis of the X-ray data of the tolylphosphane complex mentioned above showed that its dication not only has nearly the same crystal dimensions as the title compound but also exhibits appreciable residual electron density at the center of the octahedron. This finding indicates that the structure of this compound most probably is also a C-centered octahedron, the formation of which is presumably due to C-contributing impurities. Thus, the chemistry of *homo*atomic gold clusters, which are still only accessible by somewhat alchemistic methods, would have one less "exception". At the same time, a new class of carbido clusters is emerging; these compounds may be prepared directly in high yield by exploiting what is known about the aurophilicity of polyauriomethanes. Following a suggestion made by *King*,[19] they have already been given a name, at least for *metal*-centered coinage-metal clusters, namely, "porcupine compounds", which is a good choice indeed (see Fig. 1).

Finally, it should be noted that ab initio calculations for $(CLi_6)^{2\oplus}$ gave a "local" energy minimum for O_h symmetry but no absolute thermodynamic stability. The binding of $Li^{\oplus}$ to $(CLi_5)^{\oplus}$ is thus endothermic,[20] and mass spectrometric studies have only shown $(CLi_5)^{\oplus}$.[20, 21] The molecule CLi_6, on the other hand, was shown to exhibit "global" stability.[22]

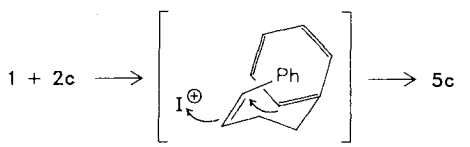
Iodine-Induced Stereoselective Carbocyclizations: A New Method for the Synthesis of Cyclohexane and Cyclohexene Derivatives**

By *José Barluenga,* José M. González, Pedro J. Campos,* and *Gregorio Asensio*

Intramolecular cyclization of unsaturated systems is of theoretical and synthetic interest and has attracted considerable attention,[1] especially those processes dealing with biomimetic reactions of polyenes.[2] Different electrophiles have been tested for C–C bond formation in reactions leading to ring closure.[1–3] Reactions involving bromine-containing reagents, and following biosynthetic pathways,[4] have been presented.[5] Nevertheless, little attention has been paid to iodine-induced carbocyclizations and only a few examples of limited application are known.[6] The current importance of carbocyclizations stimulated us to search for a methodology based on iodine electrophiles.

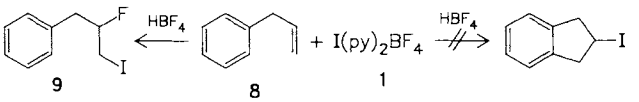
Recently, we described the preparation of $I(py)_2BF_4$ **1** and its reactivity towards olefins in the presence of several nucleophiles, including aromatic compounds.[7] We now report a diastereoselective and high-yield intramolecular reaction for six-membered-ring construction initiated by **1**. Simple protonation of **1** takes place in dry dichloromethane at −90°C, using HBF_4 or CF_3SO_3H to neutralize the pyridine; the addition of the appropriate arene–olefin or olefin–olefin system to the **1**/acid solution readily promotes C–C bond formation (see Table 1).[8]

The excellent yields of isolated products and the diastereoselectivity obtained in these reactions, as well as the purity of the crude reaction mixture, are noteworthy. These features, along with the low reaction temperature and the known versatility of the iodine atom in functional group exchange, are relevant advantages of this reaction, in comparison with other carbocyclizations promoted by electrophiles. This iodine-promoted carbocyclization could be initiated by interaction of the iodine cation with a C–C double or triple bond. The regio- and stereochemistry found can be explained by assuming a chairlike transition state for the reaction, in agreement with the Stork–Eschenmoser postulate[1] (see Scheme 1).



Scheme 1.

All attempts to carry out iodine-induced carbocyclization of allylbenzene were unsuccessful and led to the exclusive formation of a fluorinated product **9** (see Scheme 2),[9] irrespectively of the reaction temperature (−90°C to 20°C).



Scheme 2.

Baldwin's rules for ring closure[10] account for the striking control observed in these carbocyclizations. According to these rules, the favored reactions leading to six-membered rings can be characterized as 6-*exo-trig*, 6-*endo-trig*, or 6-*endo-dig* ring closures. On the other hand, ring construction from allylbenzene should involve a 5-*endo-trig* closure, and hence would be a disfavored process.

This is the first general intramolecular iodine-induced carbocyclization reaction. The availability of the unsaturated starting materials and the suitability of the resulting products as synthetic building blocks are also noteworthy. In fact, **7b** is a highly versatile synthon, which allows a simple entry into C4-functionalized cyclohexenes by io-

Cyclobis(paraquat-*p*-phenylene). A Tetracationic Multipurpose Receptor

By *Barbara Odell, Mark V. Reddington, Alexandra M. Z. Slawin, Neil Spencer, J. Fraser Stoddart,** and *David J. Williams*

Recently, we reported[1] on cyclophane-like molecular receptors, such as bisparaphenylene-34-crown-10 **1**, which contains π-electron-rich hydroquinone units for face-to-face complexation (Fig. 1) with paraquat **2**, a π-electron-deficient dication. These observations led us to propose that it might be possible to reverse constitutionally the roles of the receptor and the substrate and so bind a π-electron-rich diphenol ether, such as 1,4-dimethoxybenzene **3a**, inside a tetracationic molecular receptor (Fig. 1). Such a receptor is the tetracation cyclobis(paraquat-*p*-phenylene) **4** which incorporates two π-electron-deficient paraquat residues connected in a phane-like manner by means of two *para*-phenylene groups.[2] Here, we describe (i) the synthesis of **4** as its tetrakis(hexafluorophosphate) **4** · 4 PF_6, (ii) its X-ray structural characterization as the acetonitrile solvate **4** · 4 PF_6 · 3 MeCN, (iii) the UV and ^{1}H-NMR spectroscopic evidence for 1 : 1 complex formation (a) between **4** · 4 PF_6 and 1,2-, 1,3-, and 1,4-dimethoxybenzene **3a/3b/3c** in acetonitrile (CD_3CN) and (b) between **4** · 4 Cl and 1,4-dihydroxybenzene **6** in water (D_2O),[3] and (iv) the results of molecular and semiempirical quantum mechanical calculations on **4** and on **4** · 2 MeCN.

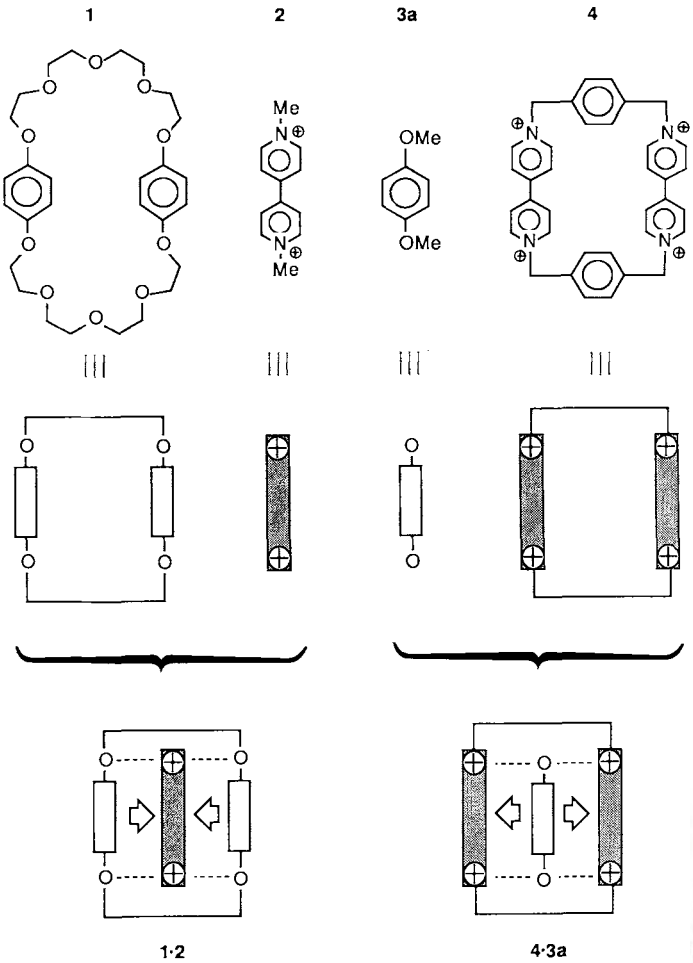

Fig. 1. Schematic representation of the basis for the proposal that the cyclobis(paraquat-*p*-phenylene) **4** should act as a tetracationic receptor for 1,4-dimethoxybenzene **3a**.

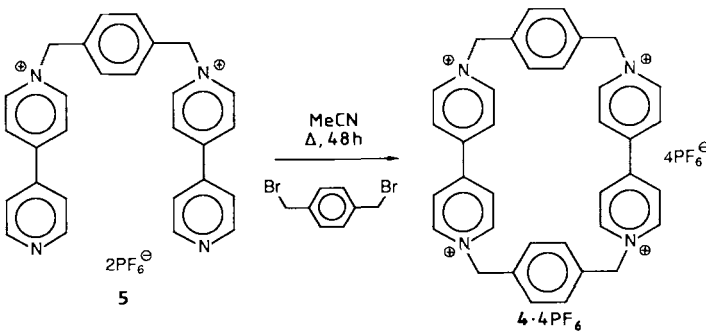
The procedure (cf. Ref. [2]) employed for the preparation of $4 \cdot 4PF_6$ starting from the bis(pyridinium) salt **5** and 1,4-bis(bromomethyl)benzene is outlined in Scheme 1. $4 \cdot 4PF_6$ is soluble in MeCN and $MeNO_2$, sparingly soluble in Me_2CO, and insoluble in Et_2O, $CHCl_3$, MeOH, and H_2O. Exchanging the counterion to afford (Scheme 1) the tetrachloride $4 \cdot 4Cl$ confers aqueous solubility (cf. Refs. [1] and [2]) upon the tetracation **4** but renders it insoluble in Me_2CO, MeCN, and $MeNO_2$. Thus, simply by altering the nature of the counterion the receptor properties of **4** can be investigated in *both aqueous and non-aqueous media*, as well as in the solid state.



Scheme 1.

An X-ray structural analysis[4] of $4 \cdot 4PF_6 \cdot 3MeCN$[5] shows (Fig. 2, top) that **4** adopts a rigid centrosymmetric rectangular box-like conformation with the two paraquat units forming the longer sides and the two *para*-xylylene residues, the shorter ones. There is a 19° twist angle between the two pyridinium rings of each paraquat unit: in addition, there are deformations of both the paraquat and *para*-xylylene components producing a bowing of the sides of the cyclophane. Thus, the strain within the molecule is relieved by out-of-plane bending of the six aromatic rings and is distributed throughout the macrocycle with the maximum deviations associated with the exocyclic C-CH_2 bonds emanating from the *para*-phenylene residues: these bonds subtend an angle of 14° with respect to each other whilst the two $N^{\oplus}$-CH_2 bonds associated with the paraquat units subtend an angle of 23°. There is also a concomitant reduction in the macrocyclic valence angles at C7 and C14 [108.3(7)° and 108.5(7)°, respectively, instead of ca. 111°]. The overall dimensions of the macrocycle are 10.3 Å between the centroids of the two *para*-phenylene rings and 6.8 Å between C1 and C18.[6] Inspection of the space-filling representation (Fig. 2, bottom) shows there to be a significant free pathway through the center of the macrocycle. Furthermore, each macrocyclic ring is stacked almost directly above its neighbor in adjacent unit cells in the crys-

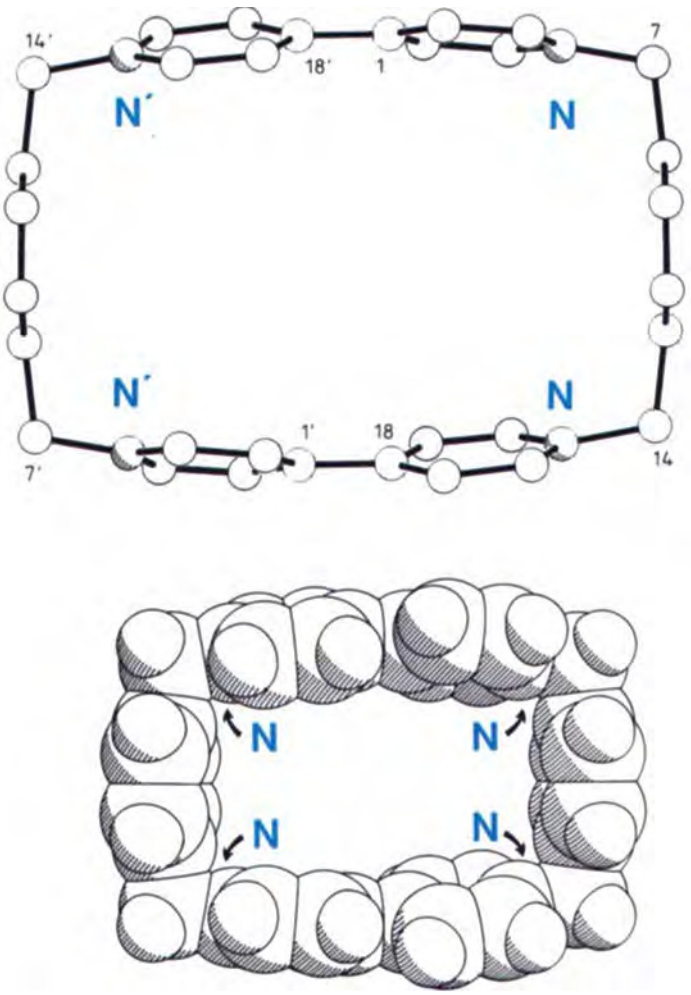


Fig. 2. Top: Structure of **4** in the crystal. Crystal data for $4 \cdot 4PF_6 \cdot 3MeCN$: monoclinic, $a = 10.805(1)$, $b = 19.819(2)$, $c = 14.027(2)$ Å, $\beta = 109.36(1)°$, $V = 2834$ Å^3, space group $P2_1/n$, $Z = 2$ (the molecule is disposed about a center of symmetry), $\rho = 1.43$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 23$ cm^{-1}, 2027 independent observed reflections with $[|F_o| > 3\sigma(|F_o|)$, $\theta \leq 50°]$, $R = 0.100$, $R_w = 0.087$. Bottom: Space-filling representation of the structure of **4**.

tallographic *a* direction: the small off-set is a result of the unit cell β angle. The region between unit-cell translated tetracations is occupied by four $PF_6^{\ominus}$ counterions and two MeCN molecules arranged in the form of a torus. The gross structure (Fig. 3) has continuous parallel open channels bounded by alternatively-charged entities. Measurements of the dimensions of the free pathways within these channels show these to be large enough to accommodate a wide range of different substrates. In this case, in the solid state, part of this void is filled by a MeCN molecule in two centrosymmetrically-related partial occupancy sites.

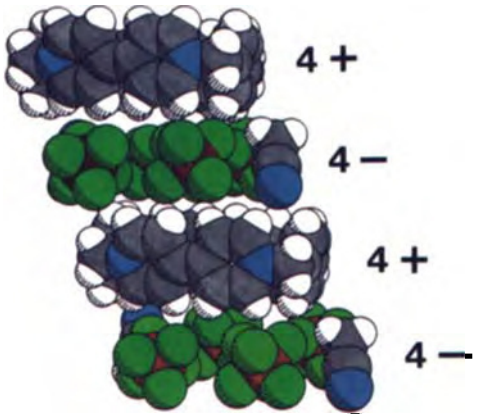

Fig. 3. Space-filling representation of alternately-charged entities of $4 \cdot 4PF_6 \cdot 3MeCN$ in the solid state (H = white, C = gray, N = blue, P = brown, F = green).

A significant result of semiempirical quantum mechanical calculations, based on the X-ray coordinates of **4** and using AM1[6] in conjunction with the program VSSPOT[7] (VSS approximation), which treats the charge distribution as having arisen from ZDO-type valence quantum mechanical calculations and approximates the nuclear charge attraction integrals in terms of spherically-symmetric functions, is to highlight (Fig. 4) the existence of regions of relatively more positive electrostatic potential lining the interior of the two paraquat components of the cyclophane. This anisotropic distribution of molecular electrostatic potential, associated with the paraquat residues, may be a consequence of the bowing distortions in the tetracation as a whole.

Addition of equimolar proportions of any of the isomeric dimethoxybenzenes, **3a**, **3b**, or **3c**, to $4 \cdot 4PF_6$ in CD_3CN results instantaneously in the formation of red or orange colored solutions (cf. Table 1),[8] suggesting that the π-electron-rich aromatic ethers are entering the cavity of **4** and experiencing stabilizing charge transfer interactions with the π-electron-deficient bipyridinium rings of **4**. This proposal is supported by ^{1}H-NMR spectroscopic studies on the 1:1 complexes (0.01–0.03 M) in CD_3CN solution: although, relative to spectra recorded for the free receptor and the substrates, the chemical shift changes ($\Delta\delta$) experienced by protons in the receptor are small ($\Delta\delta < 0.1$ ppm), those observed[9] for protons in **3a**, **3b**, and **3c** are appreciable ($\Delta\delta = -0.10$ to -0.91 ppm). When 0.5 molar equivalents of **3a** was added to a 0.01 M solution of $4 \cdot 4Cl$ in D_2O, the $\Delta\delta$ values were even more dramatic (-0.47 to -2.99 ppm for the methoxyl and aromatic protons, respectively, in **3a**) and, in this case, the chemical shift changes observed[10] for some of the protons in **4** were not insignificant. By employing (Table 1) the charge transfer band as a quantitative spectroscopic probe and subjecting the data to

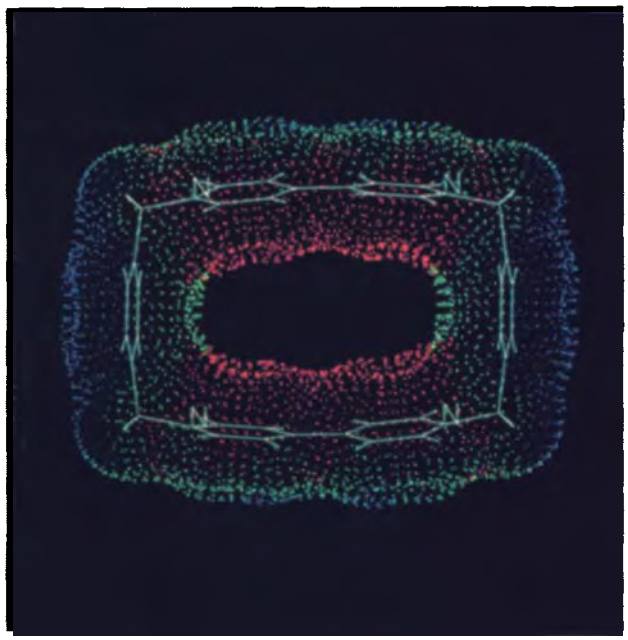

Fig. 4. The molecular electrostatic potential for **4** computed on a Connolly (QCPE Program No. 429) surface (red = positive, green = neutral, blue = negative).

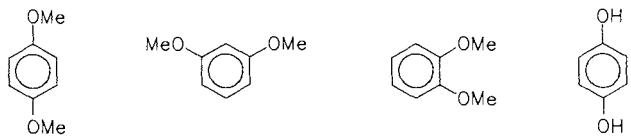

3a 3b 3c 6

a modified[11] Benesi-Hildebrand treatment[12] using experimental procedures recommended[13] for weak complex formation, 1:1 stoichiometries were established in MeCN solution for $4 \cdot 4PF_6 \cdot$ **3a**, $4 \cdot 4PF_6 \cdot$ **3b**, and $4 \cdot 4PF_6 \cdot$ **3c** with K_a values of 17.0, 8.0, and 8.1 M^{-1}, respectively. When the ^{1}H-NMR spectrum of $4 \cdot 4Cl \cdot$ **6** is recorded in D_2O, $\Delta\delta$ values of appreciable magnitude were noted[10] for some of the protons in **4**, whereas all the protons in **6** underwent rapid H/D exchange.[14]

Although many cyclophane hosts have been described[15] in the literature during the last decade, the new cyclobis(paraquat-*p*-phenylene) **4** offers novel design features of both a steric and electronic nature which give it considerable promise as a tetracationic multipurpose receptor.

Table 1. UV/VIS Spectroscopic data for complexes formed between the dimethoxybenzenes **3** and $4 \cdot PF_6$ in MeCN at 25°C [a].

Substrate	CT band λ_{max} (nm)	CT band $\varepsilon_{\lambda max}$ [b]	Substrate concentration [b] [M]	K_a [c] [M^{-1}]	$-\Delta G^0$ [kcal mol^{-1}]
3a	478	631	0.023–0.230	17.0 ± 0.5	1.68 ± 0.01
3b	484	392	0.023–0.450	8.0 ± 0.3	1.23 ± 0.02
3c	462	1025	0.034–0.454	8.1 ± 0.2	1.24 ± 0.01

[a] MeCN was distilled from P_2O_5 and then degassed. [b] The receptor concentration was held constant at 2.27×10^{-3} M and the substrate concentrations were varied accordingly to ensure that UV/VIS absorption data were obtained in those regions of the 'saturation curve' where errors are minimal, see ref. [11]. Since the UV/VIS spectrum of $4 \cdot 4PF_6$ in MeCN changes slowly with time, the substrates were added immediately after the spectrum for the receptor had been recorded, recognizing the need to correct for a very weak absorption ($\varepsilon_{\lambda max} \cong 30$) for the receptor in the 460–500 nm region. [c] The K_a values were obtained from the 'non-reciprocal format' modification described in Ref. [9] for expressing a Benesi-Hildebrand plot (see Ref. [10]) as well as establishing the 1:1 stoichiometry of the complex.

Experimental

4·4 PF_6: 1,4-Bis(bromoethyl)benzene (520 mg, 1.96 mmol) and **5** (1.20 g, 1.98 mmol) were dissolved in dry MeCN (300 mL) and the solution was heated under reflux for 24 h. A further quantity (200 mg, 0.76 mmol) of the dibromide was added to the reaction mixture and heating was continued for another 24 h. The yellow precipitate which formed was filtered off, dried, and subjected to chromatography [SiO_2 : MeOH/H_2O/satd. aq. NH_4Cl (6 : 3 : 1)] to afford a solid residue containing **4** as its tetrahalide after evaporation of the solvents under vacuum. This crude product was dissolved in the minimum volume of H_2O and a concentrated aqueous solution of NH_4PF_6 was added until no further precipitation was observed. The precipitate was filtered off, washed (H_2O), and recrystallized from Me_2CO/H_2O to give **4**·4 PF_6 (271 mg, 12%, assuming the salt is not solvated) as white needle-like crystals, decomp. >275 °C (It should be noted that these crystals become bluish-green on standing in the open laboratory during a few hours.)—FAB-MS: m/z = 955 ($[M-PF_6]^{\oplus}$); ^{1}H-NMR (CD_3CN): δ = 5.74 (s), 7.52 (s), 8.16 (d), 8.86 (d) with all signals having equal intensities (8H); ^{13}C-NMR (CD_3CN): δ = 65.7, 128.3, 131.4, 137.0, 146.2, 150.4.

4·4Cl: The pure tetrachloride **4**·4Cl was isolated as a precipitate from a solution of **4**·4 PF_6 in $MeNO_2$ after addition of an excess of Et_4NCl dissolved in $MeNO_2$ and careful washing of the precipitate with $MeNO_2$.

[2] The systematic name for the tetracation cyclobis(paraquat-*p*-phenylene) is 5,12,19,26-tetraazoniaheptacyclo[24.2.2.2^{2,5}.2^{7,10}.2^{12,15}.2^{16,19}.2^{21,24}]tetraconta-1(28),2,4,7,9,12,14,16,18,21,23,26,29,31,33,35,37,39-octadecaene. The syntheses of the constitutionally isomeric derivatives containing (a) two *ortho*-, (b) two *meta*-, and (c) one *ortho*- and one *meta*-phenylene ring(s) have already been reported (W. Geuder, S. Hünig, A. Suchy, *Angew. Chem. 95* (1983) 501; *Angew. Chem. Int. Ed. Engl. 22* (1983) 489; *Tetrahedron 42* (1986) 1665. Although these tetracations were characterized as their tetrabromides and tetrakis(hexafluorophosphates), there is no report in these publications of them forming inclusion complexes. However, after our communication had been submitted for publication, we received from Professor *Hünig* a copy of a communication (M. Buhner, W. Geuder, W.-K. Gries, S. Hünig, M. Koch, T. Poll, *Angew. Chem. 100* (1988) 1611; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1553) in which the ability of a number of different tetracationic macrocycles (containing two paraquat units connected in a phane-like manner by means of bridges incorporating different aromatic residues) to form inclusion complexes with a range of neutral guests is described.

[3] Interestingly, it proved impossible to dissolve more than 0.5 molar equivalents of 1,4-dimethoxybenzene (**3c**) in a 0.01 M solution of **4**·4Cl in D_2O.

[4] Nicolet R3m diffractometer, ω-scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structure was solved by direct methods and refined anisotropically. Further details of the crystal structure investigation can be obtained from the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation for this communication.

[5] Single crystals, suitable for X-ray crystallography, were grown by vapor diffusion of iPr_2O into a solution of **4**·4 PF_6 (3 mg) in MeCN (1.5 mL). Change of the crystallization solvent from MeCN to $MeNO_2$ results in exchange of the acetonitrile molecules in the interleaving tori by nitromethane molecules without any noticeable perturbation of the extended channel structure. Crystal data for **4**·4 PF_6·2 $MeNO_2$·H_2O: monoclinic, a = 10.478(2), b = 20.152(4), c = 13.757(3) Å, β = 106.45(2)°, V = 2786 Å^3, space group $P2_1/n$, Z = 2 (the molecule is disposed about a center of symmetry), ρ = 1.48 g cm^{-3}, $\mu(Cu_{K\alpha})$ = 24 cm^{-1}, 2847 independent observed reflections [($|F_o| > 3\sigma|F_o|$), $\theta \leq 55°$], R = 0.089, R_w = 0.091. The H_2O molecule lies within the channels in two centrosymmetrically-related partial occupancy sites.

[6] Force field calculations using AMBER (P. A. Kollman, S. J. Weiner, D. T. Nguyen, D. A. Case, *J. Comput. Chem. 1* (1986) 230) and semiempirical quantum mechanical calculations, using AM1 (QCPE Program No. 506) (M. J. S. Dewar, E. G. Zoebisch, E. F. Healy, J. J. P. Stewart, *J. Am. Chem. Soc. 107* (1985) 3902) to encompass the residual charges required for modeling electrostatic interactions, predict a gross conformation for **4** that is in close accord (cyclophane dimensions, 10.3 × 7.2 Å, cf. 10.3 × 6.8 Å) with that observed by X-ray crystallography. Furthermore, these studies have demonstrated that there are two regions within the cyclophane that constitute favorable binding sites for MeCN molecules in accord, once again, with the X-ray structural observations.

[14] In the absence of **4**·4Cl, the singlet resonance (δ = 6.72) for the aromatic ring protons of hydroquinone **6** can be detected in the ^{1}H-NMR spectrum recorded in D_2O. The catalysis of H/D exchange by **4**·4Cl is presently under investigation. The observation recalls the enhanced H/D exchange of the aromatic ring protons vicinal to the hydroxyl groups in 2,6- and 2,7-dihydroxynaphthalene when these two diols are dissolved in D_2O/DCl containing either a large macrobicyclic hexamine incorporating two triphenylethane bridgeheads (J. Franke, F. Vögtle, *Angew. Chem. 97* (1985) 224; *Angew. Chem. Int. Ed. Engl. 24* (1985) 219) or macrocyclic hexamides with side-arms containing pyridine units (F. Vögtle, W. M. Muller, *Angew. Chem. 96* (1984) 711; *Angew. Chem. Int. Ed. Engl. 23* (1984) 712).

Isostructural, Alternately-Charged Receptor Stacks. The Inclusion Complexes of Hydroquinone and Catechol Dimethyl Ethers with Cyclobis(paraquat-*p*-phenylene)**

By *Peter R. Ashton, Barbara Odell, Mark V. Reddington, Alexandra M. Z. Slawin, J. Fraser Stoddart,** and *David J. Williams*

Spectroscopic studies in solution[1] have provided evidence for the formation of 1 : 1 complexes between the cyclobis(paraquat-*p*-phenylene) tetracation **4**[2] and the constitutionally isomeric dimethoxybenzenes **3a**, **3b**, and **3c**. Here, we describe solid state structures of the 1 : 1 complexes formed between **4**·4 PF_6·2MeCN and (a) hydro-

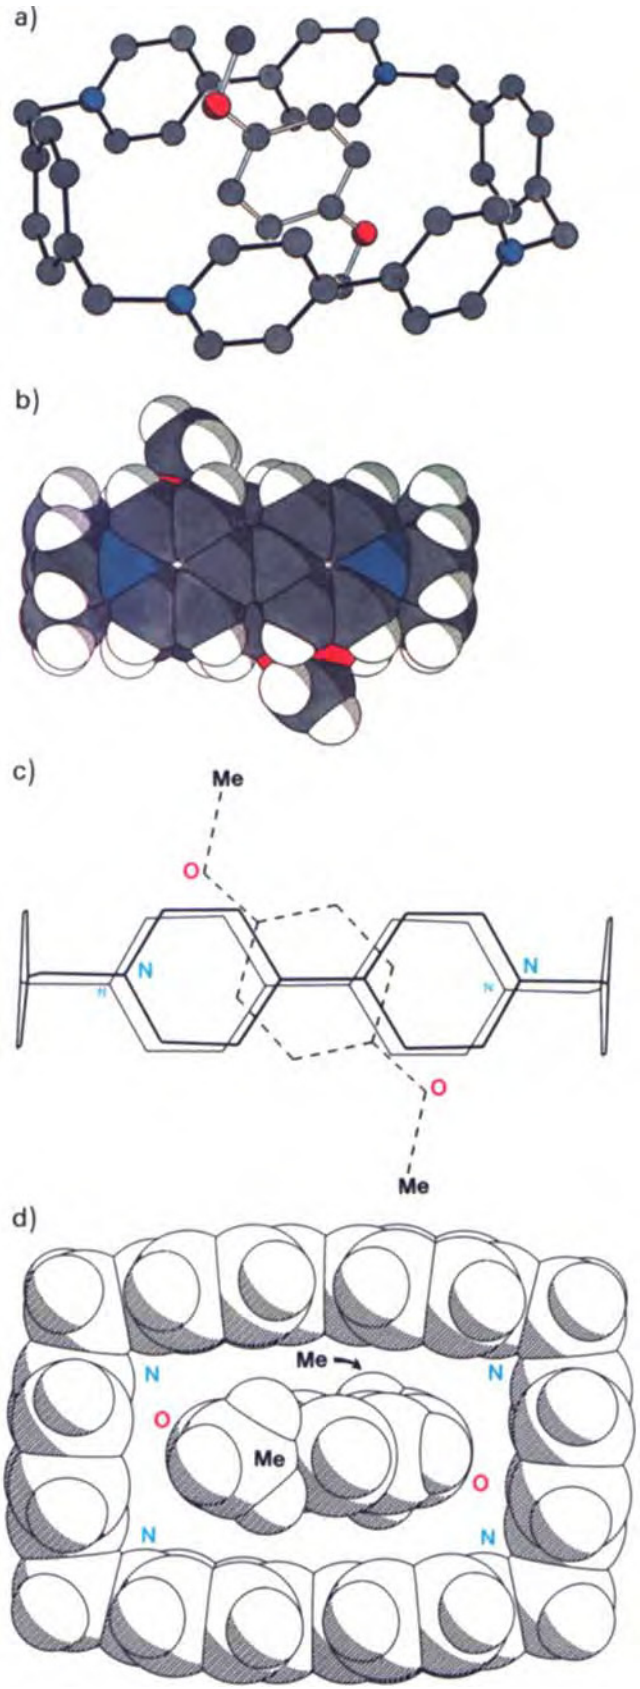

Fig. 1. a) Structure of **4**·**3a** in the crystal. Crystal data: monoclinic, $a = 10.948(4)$, $b = 19.869(8)$, $c = 13.886(6)$ Å, $\beta = 110.55(3)°$, $V = 2828$ Å^3, space group $P2_1/n$, $Z = 2$ (the molecule is disposed about a center of symmetry, $\rho = 1.45$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 23$ cm^{-1}, 2935 independent observed reflections with ($|F_o| > 3\sigma(|F_o|$, $2\theta \leq 116°$), $R = 0.101$, $R_w = 0.110$. b/c) Space-filling and skeletal representation of **4**·**3a** viewed normal to the plane of **3a** showing the degree of envelopment of **3a** by **4**. d) Space-filling representation of **4**·**3a** viewed perpendicular to the mean plane of the cyclophane (H = white, C = gray, N = blue).

quinone dimethyl ether **3a** and (b) catechol dimethyl ether **3c**.

A striking feature of both complexes is the distinctive red color of the crystals: this indicates the retention, in the solid state, of the charge transfer (CT) interaction observed[1] in solution. Preliminary X-ray measurements showed that both complexes have the same space group, and virtually identical unit cell dimensions to those observed[1] for **4**·4 PF_6·3 MeCN.

The X-ray structure analysis[3] of **4**·4 PF_6·2 MeCN·**3a** shows (Fig. 1a) that the neutral hydroquinone dimethyl ether molecule is inserted through the center of the centrosymmetric tetracationic macrocyclic receptor **4** with the methyl groups of the methoxy substituents protruding above and below the rims of **4** (Fig. 1b/c). The gross structure of the **4**·4 PF_6·2 MeCN receptor is essentially the same as that observed previously[1] in the absence of **3a**. The overall dimensions of the rigid macrocyclic ring of **4** are virtually unchanged on complexation with **3a**. Likewise, the degree of bowing of the sides of the cyclophane is the same with the C–CH_2 bonds emanating from the *para*-phenylene units subtending an angle of 13° and the $N^{\oplus}$–CH_2 bonds associated with the paraquat units subtending an angle of 24°. The only significant change in the conformation of **4** on complexation with **3a** is a noticeable reduction (Fig. 1d) in the twist angle between the two pyridinium rings from 19° to 4°. This demonstrates the ability of **4** to flex so as to accommodate the π-electron-rich substrate **3a** within its π-electron-deficient cavity: this stereoelectronically-induced fit[4] does not, however, perturb the overall channel structure of the alternately-charged receptor stack. The relative arrangements of the four interleaving $PF_6^{\ominus}$ ions and two MeCN molecules is unchanged (Fig. 2) from that observed previously.[1] These are sandwiched in fixed positions between the upper and lower rims of adjacently-stacked tetracations, indicating a strong degree of stabilizing pole-pole and pole-dipole interactions.

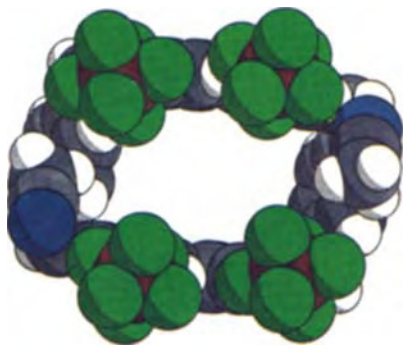

Fig. 2. Space-filling representation of part of the continuous stacked channel structure formed by **4** with the toroidal arrangement of the four $PF_6^{\ominus}$ ions and two MeCN molecules uppermost (H = white, C = gray, N = blue, P = brown, F = green).

The X-ray structural analysis[3] of **4**·4 PF_6·2 MeCN·**3c** shows (Fig. 3) that the neutral catechol dimethyl ether molecule is also included within the cavity of the tetracationic receptor **4**. However, unlike **3a**, which was positioned at about the center of symmetry within **4**, **3c** is disordered about this point.[5] As a consequence the catechol rings protrude significantly above and below the rims of **4**, though the external oxygen atoms of the methoxyl groups

Fig. 3. Skeletal representation of **4**·**3c** viewed approximately normal to the mean plane of **3c** showing the disordered arrangement of **3c** about the center of symmetry within **4** and the degree of protrusion of **3c** above and below the torus of **4**. One molecule of **3c** is highlighted in red and the other in blue. Crystal data: monoclinic, $a = 11.076(3)$, $b = 19.805(9)$, $c = 13.962(5)$ Å, $\beta = 111.57(2)°$, $V = 2848$ Å^3, space group $P2_1/n$, $Z = 2$ (the molecule is disposed about a center of symmetry), $\rho = 1.44$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 23$ cm^{-1}, 3281 independent observed reflections with ($|F_o| > 3\sigma(|F_o|)$, $2\theta \leq 116°$), $R = 0.097$, $R_w = 0.110$.

occupy positions similar to those of the hydroquinone dimethyl ether in **4**·**3a** (Fig. 1c). A fortuitous consequence of this disordered arrangement[4] is an indication of the potential ability of **4** to complex with 1,5-dimethoxynaphthalene and related substrates.

Molecular mechanics geometry calculations using the AMBER force field,[6] together with atomic charges obtained using the AM1 SCF-MO procedure,[7] result in (Fig. 4) a predicted geometry of complexation for **4**·**3a** that is

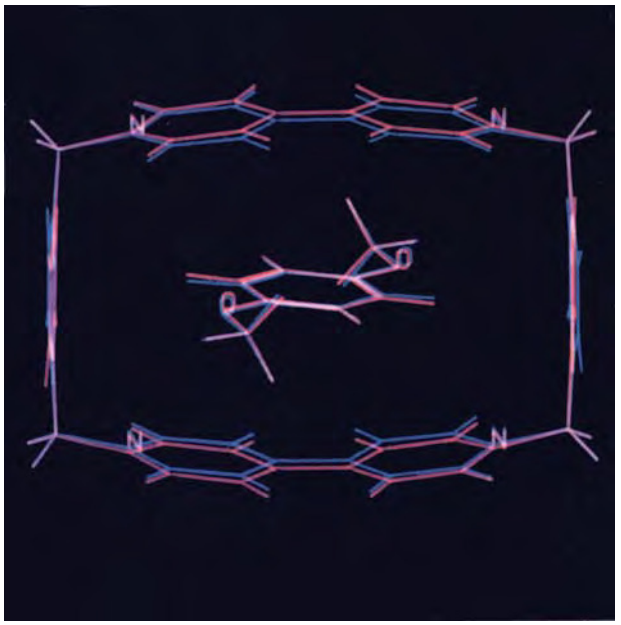

Fig. 4. Comparison of the calculated structure (red) of **4a**·**3a** with that (blue) obtained by X-ray crystallography.

almost identical with that observed in the X-ray crystal structure.

The majority of the cyclophane hosts already described[8] in the literature are just as likely to form clathrates in which the substrate molecules are accommodated between host molecules in the crystal lattice as they are to form complexes of the cavity inclusion type. By contrast, **4**·4 PF_6·2 MeCN appears, possibly as a result of the unique steric characteristics and electronic properties of **4**, to offer the exciting reality of an inexpensive synthetic receptor which is probably quite versatile in its substrate acceptance. Another fascinating feature of **4** is its propensity to form a channel structure in the crystalline state in which the rigid tetracations form an alternating charged stack cemented together electrostatically with *four* $PF_6^{\ominus}$ counterions and also *two* neutral MeCN molecules, irrespective of the nature of the substrate occupying the preorganized cavity of **4**. This type of crystal packing is characteristic of many of the inclusion complexes formed by the cyclodextrins[9] where intermolecular hydrogen bonding can stabilize stacks of these rigid naturally-occurring receptor molecules. Like the cyclodextrins, **4**·4 PF_6·2 MeCN can form inclusion complexes with a wide variety of substrates, some (e.g. **3c**) of which can diffuse out of and into the polar molecular chimneys of the receptor, producing the anticipated color changes under appropriate conditions[10] of temperature and pressure. The tantalizing prospect of a new class of inclusion compounds possessing 'zeolitic' characteristics and comprised of organic and inorganic ions and capable of including neutral organic molecules looms over the horizon.[11] The weak complexation exhibited by **4** in solution has important implications for its potential use in catalysis.

Experimental

4·4 PF_6·2 MeCN·**3a** and **4**·4 PF_6·2 MeCN·**3c**: In separate experiments, equimolar amounts (1 mg) of **3a** or **3c** were added to solutions of **4**·4 PF_6 (9 mg) in MeCN (0.7 mL). Crystals, suitable for X-ray crystallography, of **4**·4 PF_6·2 MeCN·**3a** and **4**·4 PF_6·2 MeCN·**3c**, were obtained from the deep-red solutions by vapor diffusion with iPr_2O. An attempt to determine the melting point of **4**·4 PF_6·2 MeCN·**3a** resulted in the following sequence of events: (i) during 5 min, the transparent crystals darkened and became opaque over the temperature range 87–92 °C, and then (ii) after raising the temperature for a further 10 min to 145 °C, the crystals gradually began to lose their color until (iii) this decoloration was complete after the temperature had been increased to 173 °C during 15 min before finally (iv) the crystals decomposed at > 275 °C. An attempt to determine the melting-point of **4**·4 PF_6·2 MeCN·**3c** resulted in the following sequence of events: (i) the transparent crystals darkened and became opaque at ca. 90 °C, and then (ii) over the temperature range 90–110 °C, the crystals gradually lost their red color during 8 min and became white before finally (iii) the crystals behaved in a manner reminiscent [1] of **4**·4 PF_6, i.e. they decomposed > 275 °C. In a separate experiment, **4**·4 PF_6·2 MeCN·**3c** (9 mg) was subjected to gradual heating under high vacuum (0.03 torr): at ca. 100 °C, the red color disappeared and subsequent ^{1}H-NMR spectroscopic analysis revealed only the presence of **4**·4 PF_6. When fresh clear crystals (14 mg) of **4**·4 PF_6 were immersed in **3c** for several days they gradually assumed a deep-red color: isolation after 14 days, followed by ^{1}H-NMR spectroscopy showed that **4**·4 PF_6 and **3c** were present in the ratio 1 : 1.

[10] The conditions under which catechol dimethyl ether (**3c**) will diffuse out of **4**·4 PF_6·2 MeCN·**3c** and into **4**·4 PF_6·2 MeCN are described in the *Experimental* section. The ease of diffusion of **3c** relative to that of hydroquinol dimethyl ether (**3a**) reflects (i) the observed disorder of **3c** in **4**·4 PF_6·2 MeCN·**3c** in the solid state and (ii) the relatively low K_a value (8.1 M^{-1}) for 1:1 complex formation between **3c** and **4**·4 PF_6 in MeCN solution. It is also interesting that, even although FABMS has proved to be a highly successful technique for the detection of noncovalently bonded complexes (i) between crown ethers and metal cations (R. A. W. Johnstone, M. E. Rose, *J. Chem. Soc. Chem. Commun. 1983*, 1286; R. A. W. Johnstone, I. A. S. Lewis, M. E. Rose, *Tetrahedron 39* (1983) 1597; P. D. Beer, *J. Chem. Soc. Chem. Commun. 1985*, 1115; D. W. Anderson, P. R. Ashton, R. M. Black, D. A. Leigh, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, *J. Chem. Soc. Chem. Commun. 1988*, 904), organic (B. L. Allwood, N. Spencer, H. Shahriari-Zavareh, J. F. Stoddart, D. J. Williams, *J. Chem. Soc. Chem. Commun. 1987*, 1064; P. R. Ashton, A. M. Z. Slawin, N. Spencer, J. F. Stoddart, D. J. Williams, *J. Chem. Soc. Chem. Commun. 1987*, 1066), and metalloorganic substrates (B. L. Allwood, H. M. Colquhoun, S. M. Doughty, F. H. Kohnke, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, R. Zarzycki, *J. Chem. Soc. Chem. Commun. 1987*, 1054; D. R. Alston, A. M. Z. Slawin, J. F. Stoddart, R. Zarzycki, *Angew. Chem. 99* (1987) 698; *Angew. Chem. Int. Ed. Engl. 26* (1987) 693), and (ii) between methylated cyclodextrins (P. R. Ashton, J. F. Stoddart, R. Zarzycki, *Tetrahedron Lett. 29* (1988) 2103) and organic ammonium salts, organometallic cations, and neutral metalloorganic complexes, all attempts, using a variety of different conditions, to obtain evidence for complex formation between either **3a** or **3c** and **4**·4 PF_6 were fruitless. When samples were run from a sulpholane-3-nitrobenzyl alcohol (3:1 v/v) matrix on a stainless steel probe, using a primary atom beam Xe^0 (8 keV) on a Kratos MS80RF mass spectrometer coupled to a DS55 data system, only evidence for the parent receptor $[M-PF_6]^{\oplus}$ ion at m/z 955 [1] was obtained. Considering that, with crown ethers K_a values (in organic solvents) of 10^3–10^7 M^{-1}, and with methylated cyclodextrins K_a values (in water) of ca. 10^3 have been measured for 1:1 complexes, it is hardly surprising that, in the case of **3a**·**4** and **3c**·**4**, where K_a values (in acetonitrile) of ca. 10 have been obtained, detection of complexed positive ions by FABMS is not revealed: this observation is entirely consistent with very weak complexation and lends support to the view that the technique is a reliable one for at least the semiquantitative evaluation of complexation strengths.

[11] In exhibiting clathration and inclusion simultaneously, the solid state structures of **4**·4 PF_6·2 MeCN·**3a** and **4**·4 PF_6·2 MeCN·**3c** have analogies with the recently reported [S. G. Bott, A. W. Coleman, J. L. Atwood, *J. Am. Chem. Soc. 110* (1988) 610] crystal structure of $[NH_4]_6$-[calix[4]arylsulfonate][$MeOSO_3$]·$(H_2O)_2$.

A Novel Type of Cationic Host Molecules with π-Acceptor Properties**

By *Manfred Bühner, Wolfram Geuder, Willi-Kurt Gries, Siegfried Hünig,* Michael Koch,* and *Thomas Poll*

Dedicated to Professor Friedrich Cramer on the occasion of his 65th birthday

The positive charges of macrocyclic onium host compounds have been used for two purposes: for the bonding of anions in host molecules[1,2] and to make macrocyclic compounds water-soluble; they can then take up lipophilic guests (such as chloroform, durene, naphthalene derivatives and polynuclear arenes as well as even cycloaliphatics like *trans*-1,4-cyclohexanediol and adamantanol) in their hydrophilic cavity in aqueous solution.[3,4]

Since most cationic host molecules are tailored for a multisided clasping of the guest,[1-3] the complex stability in the case of suitable host-guest complementarity is mainly determined by van der Waals, electrostatic, and hydrohobic interactions.[4] Aromatic guest molecules can, in addition, be more tightly bound by electron donor-acceptor (EDA) effects (polarization and electrostatic interactions). The weak donor properties of the alkyl-substituted benzene and/or anisole units of the known host compounds with passable topology do not suffice, however, to form charge transfer (CT) complexes even with strong acceptor guests.[3] Only when dibenzo[30–34]crown ethers are used as host for 2,2′- and 4,4′-bipyridinium ions are complexes with CT stabilization formed.[5] Bipyridinium ions are such strong π-acceptors that CT-complexes are even formed from **5** (with Me instead of $PhCH_2$ however) and hydroquinone,[6] *p*-phenylenediamine[7] or polynuclear arenes.[7]

Reversing the roles of host and guest we now present as host molecules the tetracations **1** and **2** in which two 4,4′-bipyridinium and 1,2-bis(4-pyridinium)ethene moieties, respectively, are so parallely arranged that they can embrace flat guest molecules in a sandwich-like fashion. **1** and **2** should form CT as well EDA complexes with π-donor guest compounds.

The following variations of the hosts have been examined:

1) π-System: different lengths (**1**, **2**).
2) Bridges X: a) same length but different flexibilities (**b**/**c**, *vide infra*); b) different lengths (**b**,**c** compared to **d**).

As reference substances we used the tetracationic cyclophanes **1a** and **2a**, the singly bridged derivatives **3a**[8]–**3d** and **4a**–**4d**, as well as the dicationic systems **5** and **6**.

The new onium compounds were synthesized according to a previously used scheme.[8-10] The dibromides **7a**–**7d** were first allowed to react with 4,4′-bipyridine and 1,2-bis(4-pyridinio)ethene, respectively, in acetonitrile to give the salts **8** and **9** (35–96%), which, upon reaction with further **7a**–**7d** in nitromethane furnished **1** and **2** respective-

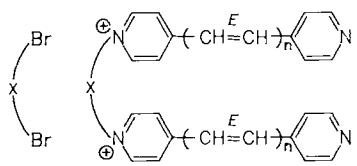
ly, or with benzyl bromide **3** and **4**, respectively, in almost quantitative yields. The required dilution conditions are determined by the low solubility of the intermediary trications **8** and **9**. Nevertheless, polymers must be separated



7a-d 8, n = 0; 9, n = 1

chromatographically. The synthesis of **1** and **2** frequently succeeds in a single-pot process from the bases and **7**. The yield increases thereby in the case of **1d** from 3-5% to 16% if phenanthrene is present in excess. This appears to be the first template effect of a hydrocarbon.[11]

The cations **1**-**6** have been isolated and characterized as PF_6-salts which are sparingly soluble in water.[12] Treatment of their solutions with tetrabutylammonium chloride leads to separation of the corresponding chlorides,[8] which we employed as the most readily soluble salts in water and methanol for the present studies.

The formation of complexes and especially of host-guest compounds of the cations **1**-**6** was tested as follows:

1. Detection of complex formation: Since all cations **1**-**6** are firmly retained on silica gel, the complex formation can be compared by thin-layer chromatography with a large number of UV-detectable arenes. The strength of the host-guest bond can thus be measured by the percentage lowering of the R_f value, referred to as the selectivity S.[13] According to Table 1 structurally very different pyridinium derivatives and almost all donors form adducts which are also identifiable by their typical CT absorptions (pale yellow to orange). Whereas the open-chain di- and tetracations **6** and **4d** hardly differ in their bonding ability, in the case of the cyclic tetracation **2a** with a small cavity the acceptor strength is frequently diminished. On the other hand, **2b**-**2d** and **1d**, as cyclophane hosts, bind some donors very strongly. **2b** and **2c** apparently have the most

Table 1. Thin-layer chromatographically determined selectivities $S=(1-R_f)/R_f^0\times 100$ (%) of various quaternary salts towards the donors **10**-**19** (silica gel, $MeOH/H_2O = 9:1$, $c = 1.7\times10^{-3}$ mol L^{-1}; **6**: $c = 6.7\times10^{-3}$ mol L^{-1}).

Donor		**6**	**4d**	**2a**	**2b**	**2c**	**2d**	**1d**
10		4	6	0	16	19	10	10
11		6	7	1	15	20	11	15
12		4	9	4	24	26	13	18
13		0	2	2	6	5	4	4
14		2	5	6	28	24	7	7
15		2	6	7	31	28	7	7
16		6	10	4	15	24	20	11
17		1	4	3	6	5	3	5
18		5	9	9	52	25	16	10
19		1	5	3	7	4	23	4

favorable dimensions for the majority of donors (**10**-**12**, **14**-**16**, **18**) whereas **2d** has too wide a bridge for some donors (**10**-**12**, **14**, **15**, **18**) and **1d** too short a π-acceptor system for some others (**16**, **18**, **19**). The large cavity of **2d** is of advantage only in the case of the particularly expanded donor **19**. Remarkable is the minimal binding of the monosubstituted naphthalenes **13** and **17** compared to the disubstituted derivatives **14**, **15**, and **18**.

2. Stoichiometry of the complex: By variation of the concentration ratio in CD_3OD/D_2O (3:1) of 2,7-dihydroxynaphthalene **15** as donor and the cationic acceptors **5**, **6** (reference compound), **3a**, **3d** (open-chain) and **2b**-**2d** (cyclic), the stoichiometry of the complex can be determined (Job's method[14]) from the change of the chemical shift of ^{1}H-NMR signals and from the change in extinction of the CT bands (**2b**-**2d** + **15**: $\lambda_{max} = 420$ nm). In all cases a 1:1 ratio is found. This suggests the accommodation of **15** in the cavity of **2b**-**2d** and a scissor-like clasping of the donor by **3a** and **3d**. An analogous behavior is assumed

for a tetracation in which the bipyridinium ions of **3d** are replaced by 2,7-diazapyrenium moieties.[15]

3. Association constants: Evaluation of ^{1}H-NMR titrations with **15** according to *Benesi* and *Hildebrand*[16] or *Scatchard*[17] gives the following association constants K (L mol^{-1}): **5**: 1.5±0.1; **6**: 2.1±0.3; **3a**: 2.3±0.6; **3d**: 2.7±0.5; **1d**: 3.5±1.2; **2d**: 13±3.3 (CD_3OD/D_2O 3:1; RT). From UV titrations the following were calculated: **6**: 9.1±0.1; **2b**: 95±5.8; **2c**: 46±4.9; **2d**: 20±0.1 (CH_3OH/H_2O 3:1; RT). In the case of the NMR and UV spectroscopically determined values, those for the cationic cyclophanes **2b**–**2d** are outstanding. As is often observed, the association constants in organic solvents are relatively small with narrow margins of variation.[2,3]

To find out the effects of water, the association constants for the systems **2b**–**2d**/anthracene **10**, phenanthrene **11** and pyrene **12** were estimated by solid/liquid extraction.[18] With $K = 10^5$–10^6 L mol^{-1}[19] they reach stabilities that have previously been achieved only with tetracationic hosts bearing outward directing ionic centers.[3]

4. Transport reactions in a triple-compartment stirrer system:[20] The tetracations transport arenes dissolved in hexane through water to a second hexane phase at different rates. From a comparison of solutions with tetracations and a carrier-free solution of the same ionic strength ($PhCH_2NEt_3Cl$) transport rates can be calculated as described previously,[21] the relative values of which (referred to **2a**) are listed in Table 2. The π-interactions between the arenes and the reference system **6**, the cyclic tetracation with too small a cavity (**2a**), and the open-chain cation **4d** suffice no longer for complexation. Obviously the accommodation in the cavities of **1d** or **2b**–**2d** is necessary for the transport of the hydrocarbons. The bond strength increases in the series anthracene, phenanthrene, pyrene, and decreases markedly for perylene, which is obviously too large for all cavities. Expansion of the cavity by the diphenylmethane bridges in **2d** has a destabilizing effect on all host-guest complexes, an effect which should have importance for the synthesis of intercalation compounds for nucleic acids.[15,22]

Table 2. Acceleration factors F, referred to **2a**, for the transport of arenes by carriers dissolved in water between two hexane phases (triple compartment system [20], 20°C, cf. text).

Arene	Carrier						
	1d	**2a**	**2b**	**2c**	**2d**	**4d**	**6**
Anthracene **10**	2	1	13	17	2	0.5	0.1
Phenanthrene **11**	6	1	16	39	3	—	—
Pyrene **12**	9	1	41	63	10	1.5	—
Perylene	1	1	4	3	3	0.6	0.4

5. Structure of the complex: Using **12** as example it can be shown that the required complementarity of the cavity of the host molecule is achievable in two ways: When solutions of **1b**, **2c** and **1d** in D_2O are treated with pyrene, only the ^{1}H-NMR spectrum of the solution of **1b** remains unchanged after brief sonication, whereas in the case of **2c** and **1d** the signals of the pyrene are observed. Since the bridges **b** and **c** keep the pyridinium units at the same distance of ca. 750 pm[23] the acceptor unit (including CH_2 groups) in **1b** must be too short (1020 pm); extension by a vinyl group to ca. 1230 pm provides an adequately sized cavity. This can, however, also be realized if the shorter acceptor system **1** is retained and a maximum cavity length of 1810 pm is provided by the longer bridge **d** (1020 pm) which is bent in the middle.

Upon accommodation of pyrene **12** the solutions of **2c** and **1d** become yellowish. This is due to a broadening of the long-wavelength absorption bands of **2c** (λ_{max} = 313, 322, 340 (sh) nm) and **1d** (λ_{max} = 256 nm) out to the visible range. In **1d**·pyrene, the typical pyrene absorption bands are not masked by those of the host. They are shifted, as in other host-guest complexes,[3] to longer wavelengths (324 nm and 341 nm). Also in these complexes the donor strength of the pyrene does not suffice for a CT interaction.

The opposing influence of the π-systems manifests itself ^{1}H-NMR spectroscopically in characteristic $\Delta\delta$ values (Table 3). The sandwich-like inclusion of pyrene **12** leads, in contrast to the stronger spherical inclusion,[3,24] to the signal of the apical H^2-atoms experiencing the largest upfield shift. Also the stronger influence of the pyridinium H-atoms in **2c** compared to those in **1d** is plausible.

Simulation of the energies (with optimized geometry) of pyrene **12** (49 kJ mol^{-1}), **1b** (179), **1d** (190), **2c** (234) and of their host-guest complexes with the aid of MM2 force field calculations[23] gives the following overall picture, which, however, takes neither EDA- and hydrophobic interactions nor entropic effects into account: For the host **1b**, which does not accomodate **12** in the cavity, the equilibrium host + guest ⇄ host·guest (382) in the case of longitudinal incorporation of the guest is completely on the lefthand side ($\Delta H = +154$ kJ mol^{-1}).

In the cases of lateral insertion of **12** in **1b**, ΔH is calculated to be -60 kJ mol^{-1}; however the overlapping of the π systems is then substantially smaller, so that the hydrophobic interactions cannot be fully exploited. In contrast, the complexes **1d**·**12** ($\Delta H = -58$ kJ mol^{-1}) and **2c**·**12** ($\Delta H = -77$ kJ mol^{-1} are already strongly favored according to the interactions taken into account by the MM2 program.

The models of the host-guest compounds **2c**·**12** and **1d**·**12** (Fig. 1) generated according to the calculations also clearly indicate that a smaller complexation constant can

Table 3. ^{1}H-NMR shifts $\Delta\delta$ of host and guest protons upon formation of the complexes **1d**·pyrene and **2c**·pyrene in D_2O [a]. Ar = aryl.

[a] 200 MHz, $c_{host} = 1.4 \times 10^{-2}$ mol L^{-1} (**1d**); 3.4×10^{-4} mol L^{-1} (**2c**). After 15 minutes ultrasonic treatment with excess pyrene, the filtered solution was measured. +$\Delta\delta$ = high-field shift **2c** and **1d** are present at least up to 0.1 mol L^{-1} as molecular dispersion (^{1}H-NMR). [b] Comparative value in [D_4]methanol (δ = 3.5): δ = 8.38 (d, $J_{1,2}$ = 7.3 Hz; 1-H), 8.19 (t, $J_{1,2}$ = 1.3 Hz; 2-H), 8.27 (s; 4-H). [c] Signals cannot be assigned with certainty.

be expected in the second case. The structure of the host molecules remains virtually unchanged during the adduct formation.

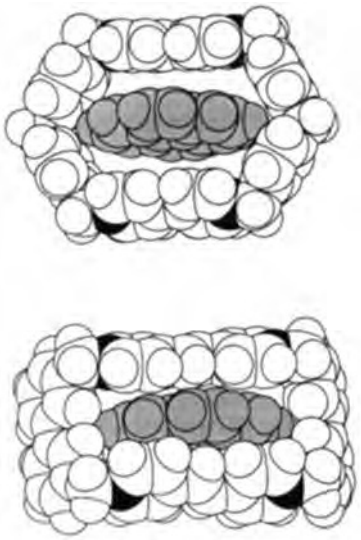

Fig. 1. Top: Space-filling model (SCHAKAL program) according to the optimized geometries [23] of the host-guest molecule **2c**·pyrene. Bottom: Space-filling model (SCHAKAL program) according to the optimized geometries [23] of the host-guest molecule **1d**·pyrene.

The examples given here show that arenes are bound by cationic hosts when these are stabilized in the sandwich-like structure of the host-guest complex by strong EDA and/or CT interactions and the otherwise usual factors. It is then unnecessary for the host cavity to be completely enveloped and the charge centers to lie on the periphery.[2,3] As reported in the preceding communications, *J. F. Stoddart* et al. have synthesized a tetracation of type **1** with two *p*-xylylene bridges by the method described here and have characterized host-guest compounds containing dimethoxybenzenes.[25]

Gas Chromatographic Separation of Enantiomeric Olefins**

By *Jens Ehlers, Wilfried A. König,* Sabine Lutz, Gerhard Wenz,* and *Heindirk tom Dieck**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

The enantiomeric excess in catalytic reactions of olefinic substrates is often very difficult to determine, because mixtures of substances can form and the optical rotations of many compounds are not known. Since, in addition, the synthesis of diastereomers frequently poses problems, the enantioselectivity in some cases cannot be determined at all or only with great difficulty.

We were able to show that optically active 1,4-diaza-1,3-dienes (dad = $R^1N{=}CR'{-}CR''{=}NR^2$) in catalytically active fragments "(dad)Fe" catalyze the enantioselective coupling of dienes to give cyclodimers.[1] The reaction of ethene with 1,3-dienes and norbornadiene may also be achieved under mild conditions. For example, (*Z*)-3-methyl-1,4-hexadiene **1** is obtained by reaction of (*E*)-1,3-pentadiene and ethene. Similary, norbornadiene gives *endo*-3-vinylnortricyclane **2**, which has also been obtained with cobalt catalysts.[2] By using chiral dad cocatalysts, op-

[**] Diazadienes as Controlling Ligands in Homogeneous Catalysis, Part 16. Part 15: H. tom Dieck, M. Mallien, R. Diercks, *J. Mol. Cat.*, in press. Part 14: M. Mallien, E. T. K. Haupt, H. tom Dieck, *Angew. Chem. 100* (1988) 1091; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1062.

tically active products are obtained. The enantiomeric excess and the configuration of the major isomer were determined for **1** by hydrogenation and comparison of the optical rotation with that of independently synthesized, optically pure 3-methylhexane **3**—a relatively involved procedure.[3,4] In the case of **2**, the vinyl group was transformed into an aldehyde function (**4**) by oxidation with *m*-chloroperbenzoic acid and cleavage with periodic acid, and the aldehyde was then converted into the aldehyde-SAMP hydrazone **5**.[5] The *ee* value of **5** could be determined from the OCH_3 signal in the ^1H NMR spectrum.

König et al. recently introduced new α- and β-cyclodextrin phases as chiral stationary phases for capillary gas chromatography[6] to separate a variety of enantiomers at temperatures up to at least 210°C. The enantiomeric separation of the aldehyde **4** was achieved on heptakis(2,3,6-tri-*O*-*n*-pentyl)-β-cyclodextrin as a stationary phase.

Surprisingly, it was also possible to separate easily the olefins **1** (Fig. 1) and **2** into their enantiomers. The results (Table 1) are in good agreement with the enantiomeric excesses determined by chemical methods. There have only been scattered reports on the chromatographic separation of chiral olefins.[7]

Table 1. Enantiomeric yields and absolute configuration of the major isomer of catalysis products separated by gas chromatography.

Product	*ee* [%] (configuration)	$[\alpha s]_D^{20}$ [a] (c [g mL^{-1}])	Controlling ligand [b]
1	37 (*S*)	−34.8 (0.1)	2	20 (?)	−12.6 (neat)	6	31 (*S*)	−12.0 (0.8)	7	34 (?)	[c]	
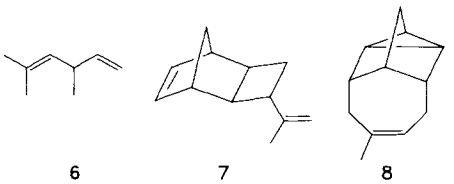
[a] **1** in CH_2Cl_2, **6** in Et_2O. [b] *o*-py = 2-pyridyl; R = (1*R*,2*S*,5*R*)-menthyl. [c] Not determined.

In further experiments, we were able to show that 3,5-dimethyl-1,4-hexadiene **6**,[4] obtained from ethene and 2-methyl-1,3-pentadiene on an optically active catalyst, could be resolved into enantiomers on this phase (Fig. 1). Finally, two products of the iron-catalyzed addition of isoprene to norbornadiene (**7** and **8**) were investigated. The *exo* adduct **7** is separated (Table 1), the 1,6 *endo* adduct is



6 7 8

not. The latter finding might be due to the spherical shape of the molecule or the absence of a sterically easily accessible double bond.

The possibility of separating many chiral olefins by gas chromatography will undoubtedly encourage the optimization of enantioselective homogeneously catalyzed reactions.

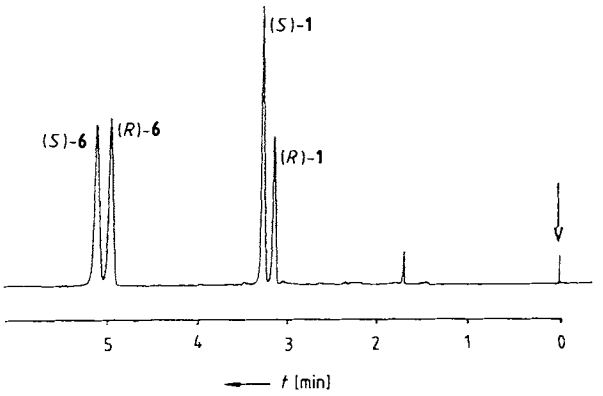


Fig. 1. Gas-chromatographic separation of the chiral olefins **1** and **6** (42-m perpentyl-β-CD column, 25°C, 1 bar H_2, head-space injection).

Experimental Procedure

1 was obtained from (*E*)-1,3-pentadiene and ethene in excess (carried out in a glass ampoule, 50 bar counter pressure in an autoclave) in the presence of 1 mol% of "(dad)Fe" [1] at room temperature. ^1H NMR (360 MHz, $CDCl_3$): $\delta = 5.75$ (dddd), 5.43 (dq), 5.22 (ddq), 4.97 (ddd), 4.89 (ddd), 3.45 (ddq), 1.61 (dd), 1.05 (d). Hydrogenation of **1** on Pd/C gave 3-methylhexane **3**. Optically pure (*R*)-(−)-3-methylhexane was obtained from (*S*)-(−)-citronellol by a similar procedure to that in [3]: it was transformed into the olefin by tosylation and $LiAlH_4$ reduction. (*S*)-4-Methylhexanal, obtained by oxidation of this olefin with *m*-chloroperbenzoic acid and cleavage with periodic acid, was reduced to (*R*)-(−)-**3** by Wolff-Kishner reduction: $[\alpha]_D^{20} = -6.8$ ($c = 0.1$ in Et_2O) [4]. From the gas-chromatographic separation and the *ee* value of **1**, we calculated a value of +6.5 for (*S*)-(+)-**3** ($c = 0.1$ in CH_2Cl_2).

2: Synthesized from norbornadiene and ethene in analogy to **1**. ^{13}C NMR (90.5 MHz, $CDCl_3$): $\delta = 139.33$, 114.46, 48.28, 34.29, 34.17, 29.13, 14.19, 11.28, 9.54. MS (70 eV): *m/z* 120 (23%, $M^{\oplus}$), 105 (80), 92 (100), 91 (96), 79 (89), 77 (49), 66 (68).

4: IR: $\tilde{\nu} = 1760$ cm^{-1} (C=O); ^1H NMR (360 MHz, $CDCl_3$): $\delta = 9.64$ ($^3J = 2.3$ Hz, CHO). MS (70 eV): *m/z* 122 (25%, $M^{\oplus}$), 93 (57), 91 (97), 79 (25), 78 (74), 77 (100), 66 (38). Isothermal gas-chromatographic separation at 50°C (in CH_2Cl_2).

5: Synthesis from **4** following the procedure in [5]. ^1H NMR (360 MHz, $CDCl_3$): $\delta = 3.394$, 3.390 (OCH_3). MS (70 eV): *m/z* 234 (3%, $M^{\oplus}$), 189 (100), 118 (21), 93 (16), 91 (32), 77 (20), 70 (30). *ee* from the NMR spectrum 20%.

6: Synthesis from 2-methyl-1,3-pentadiene in analogy to **1**. ^{13}C NMR (90.5 MHz, $CDCl_3$): $\delta = 149.4$, 130.9, 128.6, 111.7, 36.5, 25.7, 20.6, 17.8. ^1H NMR (360 MHz, $CDCl_3$): $\delta = 5.76$ (ddd), 4.96 (dqq), 4.95 (dd), 4.88 (dd), 3.04 (ddq), 1.69 (d), 1.62 (d), 1.03 (d). MS (70 eV): *m/z* 110 (36%, $M^{\oplus}$), 95 (100), 67 (64), 55 (37), 53 (14), 41 (37), 39 (29). Synthesis of **7** and **8** from norbornadiene and isoprene; purification by preparative GC and separation of isodimers.

7: ^{13}C NMR (90.5 MHz, $CDCl_3$): $\delta = 148.8$, 135.8, 135.0, 107.4, 44.4, 44.1, 42.3, 40.6, 40.4, 33.3, 24.9, 20.5. MS (70 eV): *m/z* 160 (5%, $M^{\oplus}$), 94 (58), 93 (46), 92 (52), 91 (83), 79 (100), 66 (65), 39 (30). Temperature-programmed gas-chromatographic separation: $T_0 = 50$°C, *T* increase 2°/min, in CH_2Cl_2, retention times ca. 26 and 26.2 min.

8: ^{13}C NMR (90.5 MHz, $CDCl_3$): $\delta = 134.9$, 121.4, 41.2, 40.9, 40.6, 35.4, 29.7, 27.5, 13.7, 10.6. MS (70 eV): *m/z* 160 (16%, $M^{\oplus}$), 94 (30), 91 (52), 81 (23), 80 (100), 79 (71), 77 (29), 39 (29).

Reaction of Tropone with a Homopyrrole. The Result of a Computer-Assisted Search for Unique Chemical Reactions**

By *Dietmar Forstmeyer, Johannes Bauer, Eric Fontain, Rainer Herges, Rudolf Herrmann,* and *Ivar Ugi**

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

The computer-assisted discovery of novel molecules and reactions is especially challenging with regard to the use of computers in chemistry. The computer program IGOR (Interactive Generation of Organic Reactions) first described by *Bauer* and *Ugi* in 1982[1] is based on the theory of ***B/E*** and ***R*** matrices (the matrices ***B*** and ***E*** describe the chemical constitution of starting materials and products, respectively; the matrix ***R*** corresponds to the electron shift scheme of the reaction)[2] and can generate any desired molecules and chemical reactions with a reaction generator.[3,4] From the theory of the ***B/E*** and ***R*** matrices a hierarchical classification of chemical reactions can also be derived,[5] which enables the degree of novelty of a unique reaction to be determined.[6,7] In the search for reactions with a high degree of novelty the irreducible matrix $\boldsymbol{R}^{C}_{10,10}$ of the resonance of $10\pi_e$-arenes was incorporated into IGOR2, a modified PC-adaptable FORTRAN 77 version of IGOR.

$$\boldsymbol{R}^{C}_{10,10} = \begin{pmatrix} 0 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ -1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & -1 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 \end{pmatrix}$$

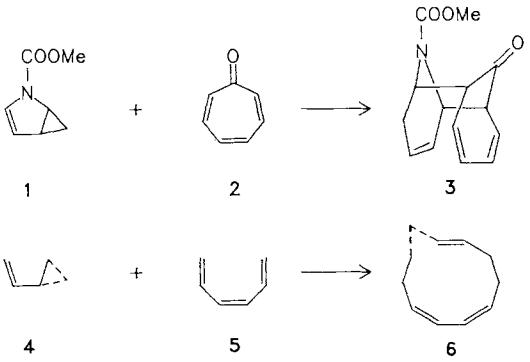
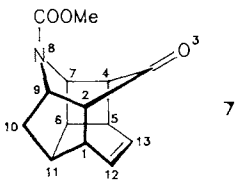
One of the results (***B***, ***E***) of the IGOR 2 analysis of ***R***, the reaction **1** + **2** → **3**, corresponds to the unique basic reaction[3] **4** + **5** → **6**.



The homopyrrole **1** was already found to be a suitable homodiene component in cycloadditions.[8,9] Tropone **2** was chosen as triene component. On attempting to obtain **3** by reaction of **1** with **2**, however, **7** was formed (as racemate), as follows from the NMR data (Table 1) and the X-ray structure analysis.[10] All C atoms of the cage molecule **7** are constitutionally non-equivalent.[11]



7

Table 1. NMR spectroscopic and mass spectrometric data of **7**.

^{1}H NMR [a] ($CDCl_3$, 360 MHz, TMS): δ = 1.92 (s, 2H; H^{10}), 2.18 (m, 1H; H^{11}), 2.95 (m, 1H; H^1), 3.05 (m, 1H; H^6), 3.15 (m, 1H; H^5), 3.23 (m, 1H; H^2), 3.45 (m, 1H; H^4), 3.65 (s, 3H; OCH_3), 4.77 (m, 1H; H^7), 4.88 (m, 1H; H^9), 6.15 (t, 1H, $J_{13,12}$ = 7.9 Hz; H13), 6.31 (t, 1H, $J_{12,13}$ = 7.9 Hz; H12)

[a] Assignment of signals by means of NOE difference measurements.

When **1** and **2** as starting compounds and **7** as product are fed into the recently implemented program RAIN,[3,12] a reaction network is obtained which contains two further reaction pathways besides that of **1** + **2** → **3** → **7**, namely: **1** + **2** → **8** → **7** and **1** + **2** → **9** → **7**. The first step in the formation of **7**, however, is probably an *endo*-[4 + 6]-addition of the homodiene **1** to the triene **2** to give **3**, since the reactions via **8** and **9** include steps that are forbidden under thermal conditions.[13]

The reason for the relatively high reactivity of **1** as homodiene (compared to other vinylcyclopropane systems) can be deduced from an analysis of the frontier orbitals

(Fig. 1). For vinylcyclopropanes, **1** has an energetically high-lying "Walsh orbital" in the three-membered ring, which, together with the π-system of the double bond has suitable symmetry for interaction with the LUMO of **2**.[14] The *endo*-addition is preferred over the *exo*-addition, presumably on steric grounds (hindrance by the methoxycarbonyl group in **1**).

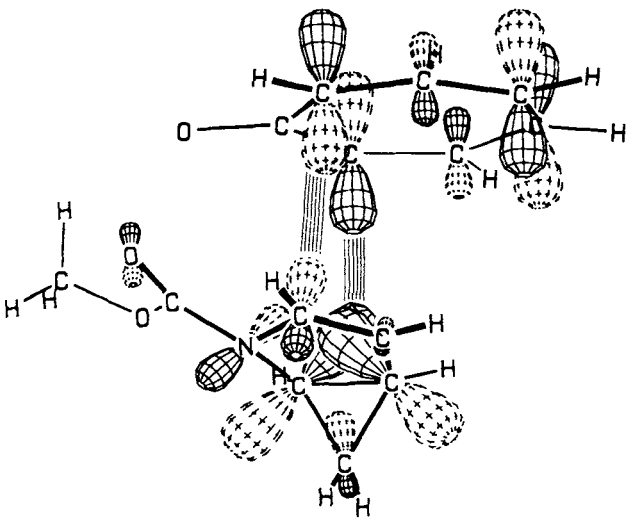

Fig. 1. Interaction of the LUMO of tropone with the second highest occupied MO of homopyrrole.

According to *Houk* and *Woodward*,[15] 2,5-dimethyl-3,4-diphenylcyclopentadione and tropone form a [4+6]-cycloadduct. The product is present in the *exo*-configuration; at elevated temperatures it rearranges by intramolecular Diels–Alder reaction into a cage compound. The structure of the hypothetical [4+6]-adduct **3** was calculated using the semiempirical method AM1.[16] The molecular geometry obtained after optimization of all parameters (Fig. 2) shows that the diene unit and the double bond of **3** are fixed by the molecular skeleton in an arrangement that is favorable for the subsequent Diels–Alder reaction leading to **7**.

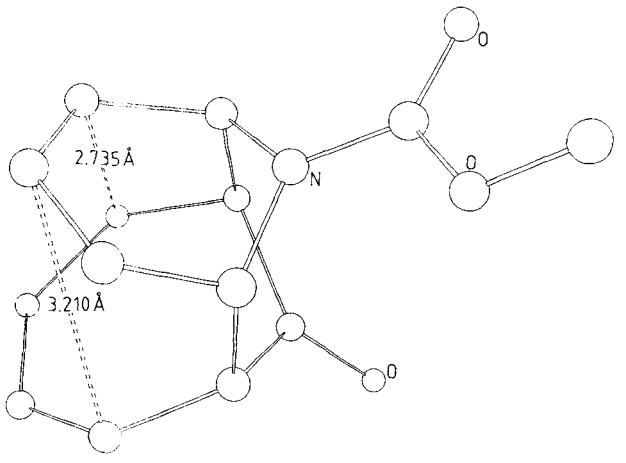

Fig. 2. The structure of the [4+6]-adduct **3** calculated by AM1.

Experimental

7: *N*-methoxycarbonyl-1-aza[3.1.0]bicyclohex-3-ene **1** (0.66 g, 4.7 mmol) was treated with 0.5 g (4.7 mmol) of **2** at 180°C in the absence of solvent. The reaction product was recrystallized from toluene. Yield: 92%; m.p. 173–174°C.

First Structure Analysis and Photoelectron Spectroscopic Investigation of an Azete and an Azete–Cobalt Complex**

By *Martin Ledermann, Manfred Regitz,* Klaus Angermund, Paul Binger, Carl Krüger, Richard Mynott, Rolf Gleiter,* and *Isabella Hyla-Kryspin*

Dedicated to Professor Robert Carrié on the occasion of his 60th birthday

In contrast to cyclobutadienes,[1] no crystal structure investigations of azetes (azacyclobutadienes) have hitherto been described in the literature. The synthesis of **3**,[2] the first kinetically stabilized azete, provided us with the chance of studying the influence of the ring nitrogen atom on the structure of the molecule. However, because of a phase transformation at −75°C, the crystal structure anal-

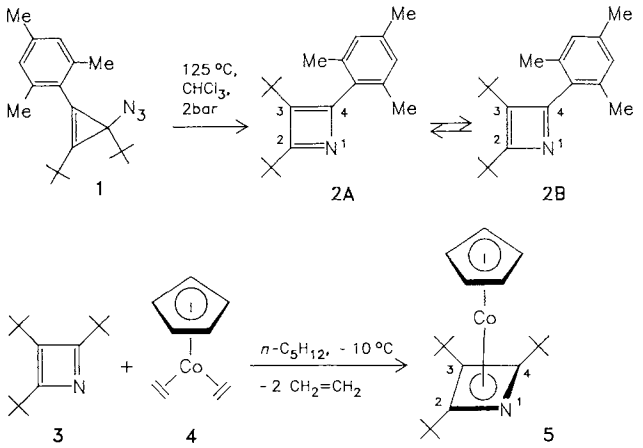
[**] Antiaromatics, Part 25. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Stiftung Volkswagenwerk.—Part 24: U. Hees, U.-J. Vogelbacher, G. Michels, M. Regitz, *Tetrahedron 44* (1988), in press.

ysis of **3** (m.p. 37°C) could only be carried out above this temperature and the results were unsatisfactory due to disorder effects in the region of the methyl groups. In order to acquire accurate information about the azete structures we have now prepared and investigated the unequally substituted antiaromatic heterocycle **2** and the cobalt complex **5**.

The novel azete **2** is formed in analogy to the synthesis of **3** by thermolysis of the cyclopropenyl azide **1**[3] in a pressure Schlenk tube in the form of extremely oxygen-sensitive, reddish-brown crystals (80%, m.p. 59°C, from pentane at −78°C). The ring expansion is highly selective; there is no NMR evidence for the formation of the isomeric 2,4-di-*tert*-butyl-3-mesitylazete.



The complex **5** is obtained as light-brown crystals (79%, m.p. 117°C, from pentane at −78°C)[5] on reaction of **3**[2] with cyclopentadienylbis(ethylene)cobalt **4**;[4] **5** is the first metal complex of an azete.[6]

The crystal structure analysis of the azete **2** (Fig. 1, top) clearly shows that the antiaromatic compound crystallizes as the valence isomer **2A**. The four-membered ring has a planar, distorted rectangular structure with long C2–C3 and N–C1 single bonds (1.59(1) and 1.58(1) Å, resp.);[7] the lengths of the C1–C2 and N–C3 double bonds, on the other hand, are normal. Steric interaction of the mesityl moiety with the neighboring *t*Bu group leads to an interplanar angle of 70° between the two rings, so that a π-interaction with the four-membered ring is almost impossible (see also the photoelectron (PE) spectrum). The bulky ring substituents are responsible for the, in part relatively large, widening of the exocyclic angles C2–C1–C4, C3–C2–C13, and C2–C3–C17.

On comparing these findings with the structural data of kinetically stabilized cyclobutadienes,[1] one finds several parallels to the methyl tri-*tert*-butylcyclobutadienecarboxylates with regard to four-membered ring geometry, the angle of the plane of the substituent relative to the ring, and the steric effects on the exocyclic bond angles.[9] This close relationship also manifests itself on comparing the first band in the He(I)-PE spectrum of this cyclobutadiene with that of **3**.[10]

The ^{13}C-NMR spectrum of **2** measured at 40°C (75.5 MHz, [D$_8$]toluene) shows three sharp singlet signals for the four-membered ring (δ = 200.9, 141.2, 151.2).[11] These largely temperature-independent resonances[12] can be assigned to the carbon atoms C2, C3, and C4 of the valence isomer **2A**, which is also present in the crystalline state. A valence isomer equilibrium **2A** ⇄ **2B** is thus, other than in the case of **3**,[2] not detectable; the isomer **2B** participates at best to the extent of 5%. The signals were assigned with the help of a 2D-^{13}C,^{1}H-correlated spectrum (optimized for long-range couplings $^{n}J_{(C,H)}$), on the basis of estimations of the chemical shifts and by a comparison of the signal position of the azomethine carbon atom C-2 with the signals in the low-temperature spectrum of **3**.

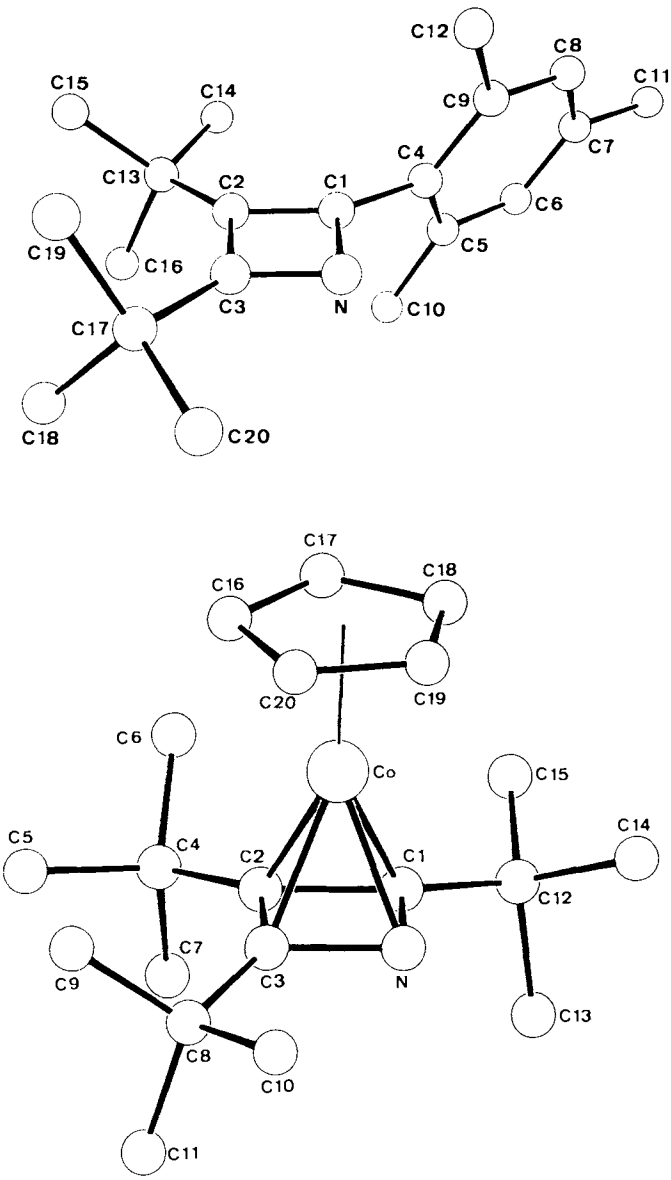


Fig. 1. Top: Molecular structure of **2**. $C_{20}H_{29}N$: $P2_1/c$, a = 14.256(3), b = 8.222(1), c = 16.078(4) Å, β = 93.06(2)°, T = 20°C, Z = 4, ρ_{calcd} = 1.00 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 0.53 cm^{-1}. Enraf-Nonius diffractometer CAD-4; 4686 measured reflections, averaged to 424, 1043 observed ($I \geq 2\sigma(I)$): R = 0.076, R_w = 0.071 ($w = 1/\sigma^2(F_0)$) for 190 parameters [8]. Enraf-Nonius diffractometer CAD-4; 25564 measured reflections, averaged to 11622 (R_{ave} = 0.06), 4516 observed ($I \geq 2\sigma(I)$): R = 0.046, R_w = 0.040 ($w = 1/\sigma^2(F_0)$) for 327 parameters [8]. Selected bond lengths [Å] and angles [°]: N-Co 1.958(2), C2-Co 2.027(2), C3-Co 1.958(2), C1-Co 1.960(2), N-C3 1.433(2), N-C1 1.424(3), C2-C3 1.462(3), C2-C1 1.478(3), N-C3-C2 92.8(2), N-C1-C2 92.5(2), C3-C2-C1 85.8(2), C3-N-C1 88.9(1).

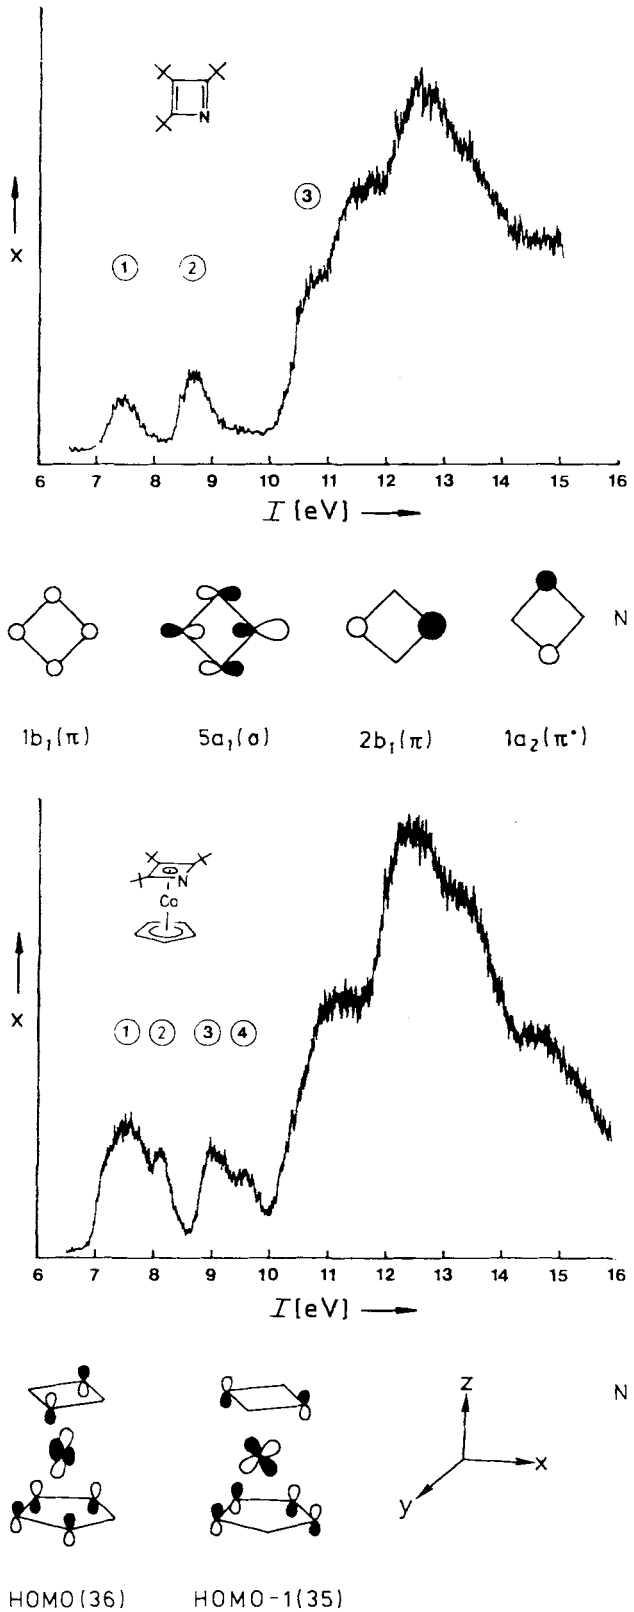

Fig. 2. PE spectra of **3** (top) and **5** (bottom). x = count rate. The MOs associated with the bands are given below the two spectra.

The comparison of the PE spectra of **2** and **3** shows that the position and shape of the bands involving the outer valence electrons are very similar.[10] This is best explained in terms of the interaction between the mesityl and azete moieties being very weak. The PE spectrum of **3** (Fig. 2, top) shows two bands in the outer valency range (① and ②), which we assign to the ionization from the two MOs $2b_1(\pi)$ and $5a_1(\sigma)$ (see below). The ionization energy for $1b_1(\pi)$ is, according to the PE spectrum, 10.7 eV (band ③). Comparison of the PE ionization energies with the results of MO calculations (semiempirical and ab initio methods[13]) confirms this.

Table 1. Orbital sequence of **5**, Me instead of *t*Bu, calculated according to the INDO method.

MO	ε_i [eV]	% Co	% L	% Cp	MO type
36	− 8.74	8	37	55	Cp(π), L($1a_2$), dxz, dyz
35	− 9.02	3	51	46	L($2b_1$), Cp(π), dxz, dyz
34	−10.70	40	45	15	L($1b_1$), dz^2, dxz, dyz
33	−11.25	47	35	18	d_{z^2}, dxz, dyz, L($1b_1$), Cp(π)
32	−11.40	34	26	40	Co(π), dxz, dyz
31	−11.62	22	61	17	L($5a_1$), dxz, dxy, dyz, dz^2
30	−11.96	88	8	4	dx^2-y^2
29	−12.10	80	13	7	dxy

The crystal structure analysis of the cobalt complex **5** (Fig. 1, bottom) reveals that the bond lengths in the planar four-membered ring become much more similar as a result of electron delocalization (1.478(3)) and 1.462(3) Å for C–C and 1.424(3) and 1.433(2) Å for N–C). The distances of N, Cl, and C3 to the metal atom are almost equal, only the C2–Co distance is somewhat longer. The coplanarity of the two rings (interplanar angle: 2°) indicates an analogous situation in the case of the Co–C cyclopentadiene distances. The bonds of the quaternary *t*Bu–C atoms C4, C8 and C12 to the azete C atoms are bent out of the plane of the four-membered ring away from the Co atom by 9°, 10° and 11°, respectively.[14]

According to INDO calculations[15] the two highest occupied MOs of the cyclopentadienyl(trimethylazete) cobalt complex (**5**, Me instead of *t*Bu) can be described as linear combinations of the $1a_2(\pi^*)$ and $2b_1(\pi)$ of the azete with the CpCo fragment (see Fig. 2, bottom and Table 1). As a result of this interaction the electron density in the four-membered ring of **5** is increased compared to **3**. This explains why the bond lengths in the ring in **5** are found to approach one another. In the PE spectrum of **5** (Fig. 2, bottom), the ionizations from the two HOMOs are superposed by other bands which we ascribe to ionizations from MOs that are strongly localized at the metal.[16]

4-Iodo-1,3,5,7-tetramethyl-1,3,5,7-tetraaza-4λ⁵-phosphaspiro[3.3]heptane-2,6-dione: Synthesis and Crystal Structure of the First Iodophosphorane**

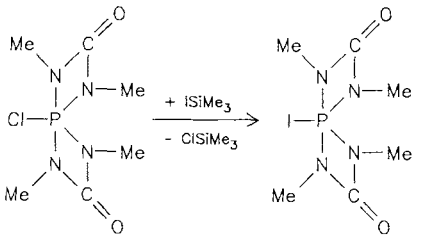
By *Johannes Breker, Peter G. Jones, Dietmar Stalke,* and *Reinhard Schmutzler**

Dedicated to Professor Ernst Otto Fischer on the occassion of his 70th birthday

The earlier described iodine-phosphorus compounds containing phosphorus in the oxidation state 5 have been shown by electrical conductivity measurements[1,2] to be phosphonium iodides with tetracoordinated phosphorus. A report on a stable iodophosphorane formed by oxidation of triethyl phosphite with iodine[3] has meanwhile been retracted.[4] The crystal structure analysis[5] of a 1:1 adduct obtained on reaction of tri-*tert*-butylphosphane with iodine revealed a linear arrangement of the P–I–I structural unit with tetracoordinated phosphorus. This geometry represents a structural alternative to the earlier postulated[2,6] undissociated precursor R_3PI_2 of phosphonium iodides $R_3PI^{\oplus}I^{\ominus}$. Here we describe the synthesis of the first λ^5P iodophosphorane. The postulated pentacoordination of the P atom was confirmed by an X-ray structure analysis.

The phosphorane **1**, whose Cl atom has already been exchanged for other substituents,[7,8] is a readily accessible compound containing a pentacoordinated P atom. Indeed, the synthesis of the iodophosphorane **2** from **1** was accomplished by Cl/I exchange with $ISiMe_3$[9] in benzene.

Crystals of **2**[10] (correct elemental analysis), which are pale yellow at −30 °C, are pale brown at room temperature. The ^{31}P NMR signal of the iodophosphorane **2** (δ = −119.1) is markedly shifted upfield compared with that of **1**; this is in agreement with the findings reported



for iodo- and chlorophosphanes.[11] Because of the rapid exchange of the axial and equatorial positions on the NMR time scale at room temperature (pseudorotation), only one doublet is observed for the ^{1}H and ^{13}C resonances of the methyl groups. The positions of the signals in the ^{1}H and ^{13}C NMR spectra are similar to those for the chloro derivative **1**.[7]

The structure of **2** was determined by X-ray structure analysis.[12] The molecule (Fig. 1, Table 1) displays the distorted trigonal-bipyramidal geometry typical of related phosphoranes.[7] As expected, the axial bonds P-N2 (176(1) pm) and P-N4 (175(1) pm) are longer than the equatorial

bonds P-N1 (167(1) pm) and P-N3 (168(1) pm). To the best of our knowledge, there is no reference value against which to compare the P–I bond length (245.8(3) pm).

The decision whether the P atom is coordinated in a trigonal-bipyramidal (in the ideal case, D_{3h}) or square-pyramidal (C_{4v}) fashion can be made on the basis of the following considerations: (1) The sum of the squared deviations (relative to the ideal values) of all angles at the P atom[13] is $\Sigma\Delta^2(D_{3h}) = 1105$ and $\Sigma\Delta^2(C_{4v}) = 1387$, respectively, and thus does not permit a clear distinction. (2) However, the four-membered rings have N–P–N angles that must deviate considerably from the ideal value of 90°. (3) The P–N bond lengths can be unambiguously distinguished as axial (long) and equatorial (short). The P coordination should therefore be classified as trigonal-bipyramidal. The dihedral angle between axial and equatorial planes (defined by P, I, N2, N4 and P, I, N1, N3, respectively) is 77°.

The synthesis of the F and Br analogues of **1**, as well as of a pseudohalogen derivative (CN), was also accomplished, along with the corresponding structure determinations.[14]

Experimental Procedure

1 (6.22 g, 26 mmol) was dissolved in benzene (60 mL) in a Schlenk tube protected from light, and iodotrimethylsilane (15.4 g, 78.2 mmol) was added to the stirred solution at 0°C. After complete conversion of **1** (4 d), the brown solution was removed by pipette from the dark brown solid residue. The benzene was removed in vacuo and the resulting residue was dissolved in 30 mL of toluene. Insoluble solid matter was filtered off and the solution was kept at 0°C. The solution was subsequently separated by pipette from a reddish oil that had formed. Addition of 30 mL of methylcyclohexane to this solution at 0°C resulted in the formation of brown crystals, which were freed of an accompanying red oil by washing with methylcyclohexane. The crude product was stirred with copper powder in 20 mL of toluene to form a suspension, which, after 15 min, was filtered. Compound **2** crystallized from the filtrate within a few days at −30°C. The crystals were dried at 10^{-2} torr. Yield 2.0 g (23%), decomposition > 50°C.

Coordination of H_2 and O_2 to $[OsHCl(CO)(PiPr_3)_2]$: A Catalytically Active $M(\eta^2\text{-}H_2)$ Complex**

By *Miguel A. Esteruelas, Eduardo Sola, Luis A. Oro,* Uwe Meyer,* and *Helmut Werner**

Dedicated to Professor Ernst Otto Fischer on the occasion of his 70th birthday

The binding of small (diatomic) molecules to transition-metal centers is regarded as the key step in many homogeneously catalyzed processes.[1] Numerous examples of the coordination of O_2 to the central atom of metal complexes[2] are known, and compounds of the type $[(M(O_2)L_n]$ are not only of interest as intermediates in catalytic oxidations but also have long attracted attention as O_2 reservoirs.[3] However, the isolation and structural characterization of the first $M(H_2)$ complex containing side-on-bonded H_2 ligands was only accomplished a few years ago.[4] To the best of our knowledge, up to now no compound has been described which coordinates H_2 as well as O_2 without the subsequent occurrence of spontaneous reduction or oxidation with cleavage of the E_2 bond.

Two years ago we reported[5] that complex **1**, containing presumably square-pyramidally pentacoordinated os-

$[OsHCl(CO)(PiPr_3)_2]$ **1**

mium, is formed in nearly quantitative yield (96%) upon reaction of osmium trichloride with triisopropylphosphane in methanol. At room temperature, it adds Lewis bases L that are not too bulky, such as CO, PMe_3, $P(OMe)_3$, $H_2C{=}CHX$ (X = CN, COMe, CO_2Me) to form octahedral compounds $[OsHCl(CO)L(PiPr_3)_2]$.[5] Alkynes (C_2H_2, PhC_2H) undergo insertion into the Os–H bond.[6] In the presence of $NaBH_4$ or KOH, moreover, **1** is catalytically active and promotes hydrogen transfer from 2-propanol to ketones (acetophenone, cyclohexanone) and to phenylacetylene.[7]

In continuation of the catalytic studies, we have now found that, under normal conditions (25°C, 1 bar) in benzene, **1** also reacts with H_2 and O_2. In both cases, the initially red benzene solution rapidly turns colorless. In addition to the well-resolved hydride signal at $\delta = -7.90$ (**1**, δ(in C_6D_6) = −31.92 (t, $J(PH) = 14$ Hz; [OsH])),[5] the ^1H NMR spectrum of **2**,[8] recorded under H_2 atmosphere, exhibits a relatively broad resonance at $\delta = -1.30$ ($\omega_{1/2} = 13$ Hz), which is characteristic of η^2-bonded H_2 ligands.[4b,9,10] Integration of the two signals gives an intensity ratio of 1:2. The IR spectrum of a benzene solution of **2** shows a strong absorption for the CO stretching vibration at 1913 cm^{-1}, which, as expected, is shifted by ca. 25 cm^{-1} to higher wavenumbers compared with that of **1**. Upon removal of the H_2 atmosphere, **2** is slowly transformed back into the starting complex **1**—this reaction is very fast under vacuum.

Even *traces* of oxygen result in displacement of H_2 from **2** to give **3**, which is also formed upon stirring a suspension of **1** in 2-propanol exposed to air or under oxygen atmosphere.[11] The dioxygen ligand is very strongly bound, a fact reflected not only in the stability of **3** under high vacuum but also in the spectroscopic data (e.g., lowering of the O–O stretching absorption to 862 cm^{-1}). The *trans* position of the O_2 relative to the hydride ligand, a very good σ donor, is probably responsible for this strong binding.[2] An η^2-O_2 complex of osmium(0) was first described by *Roper* et al.[12] and one of osmium(II) having a composition similar to that of **3** was first synthesized by *Moers* et al.[13]

At room temperature, **2** does not rearrange to the isomeric trishydridoosmium(IV) compound **4**.[14] Only upon

$[OsH_3Cl(CO)(PiPr_3)_2]$ **4**

warming to about 40°C does exchange of the hydrido and H_2 ligands of **2** occur, along with re-formation of **1**. This process is revealed in the broadening of the corresponding signals in the ^1H NMR spectrum. Theoretical studies have indicated[15] that the presence of good donor ligands at an electron-rich metal center promotes charge transfer (i.e., backbonding) from M to the σ^* orbital of H_2 and thus favors cleavage of the H_2 molecule with the formation of two M–H bonds. We assume that the CO and Cl ligands in **2** largely compensate for the electron donation from the phosphane ligands, so that, at room temperature, detectable formation of $[OsH_3Cl(CO)(PiPr_3)_2]$ does not occur. Transformation of the $Os(\eta^2\text{-}H_2)$ unit to an OsH_2 unit might also be suppressed by steric hindrance due to the bulky $PiPr_3$ groups.[16]

Complex **2** is also a catalyst—or, more likely, a catalytic precursor. Whereas **1** does not react with styrene, cyclohexene, cyclohexa-1,4-diene, or benzylideneacetone under the conditions given in Table 1, addition of the respective substrate to a solution of **2** results, in part, in very rapid reaction. The rate v depends on the solvent (for styrene, $v[C_6H_6] < v[1,2\text{-}C_2H_4Cl_2] < v[i\text{PrOH}]$) and on the olefin (in *i*PrOH, benzylideneacetone < cyclohexene < styrene). Phenylacetylene is selectively reduced to styrene, and benzylideneacetone to benzylacetone; for cyclohexa-1,4-diene and diphenylacetylene (preferential formation of (*Z*)-stilbene), on the other hand, the selectivity is rather low. Kinetic investigations indicate[17] that a trishydrido(alkene)osmium or trishydrido(alkyne)osmium complex, respectively, occurs as intermediate, which, via an insertion reaction, gives an alkyl or vinyl species. In contrast to **2**, the Kubas compounds $[M(\eta^2\text{-}H_2)(CO)_3(PR_3)_2]$ (M = Mo, W; $PR_3 = PiPr_3$, $P(cyclo\text{-}C_6H_{11})_3$, $PiPr(cyclo\text{-}C_6H_{11})_2$) are inactive in the catalytic hydrogenation of ethylene,[16] which might be due to a kinetic barrier to formation of the intermediate $[MH_2(C_2H_4)(CO)_{4-n}(PR_3)_n]$ (n = 1, 2).

Table 1. Catalytic hydrogenations with **2** [a].

Substrate Su [b]	Solvent	t [min]	mol SuH_2 / mol **2**	Product SuH_2 [c]
Styrene	C_6H_6	120	56.0	Ethylbenzene
Styrene	$1,2\text{-}C_2H_4Cl_2$	120	80.0	Ethylbenzene
Styrene	*i*PrOH	5	100.0	Ethylbenzene
Cyclohexene	$1,2\text{-}C_2H_4Cl_2$	15	51.0	Cyclohexane
Cyclohexene	*i*PrOH	15	68.0	Cyclohexane
Cyclohexa-1,4-diene	*i*PrOH	5	42.0	Cyclohexane
			50.0	Cyclohexene
			6.5	Cyclohexa-1,3-diene
		120	57.0	Benzylacetone
Benzylideneacetone	C_6H_6		1.0	4-Phenylbutan-2-ol
		120	81.0	Benzylacetone
Benzylideneacetone	*i*PrOH		1.5	4-Phenylbutan-2-ol

The Art of Scientific Writing. From Student Reports to Professional Publications in Chemistry and Related Fields. By *H. F. Ebel, C. Bliefert,* and *W. E. Russey.* VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1987. xix, 493 pp., hard cover, DM 98.00.—ISBN 3-527-26469-8; 0-89573-495-8; paperback, DM 48.00.—ISBN 3-527-26677-1; 0-89573-645-4

American English has become the international language of science in the last 40 years. Scientists who desire international recognition must publish in English. The book under consideration, a substantially expanded translation of an German forerunner, makes due recognition of this development.

"The Art of Scientific Writing" is best characterized as a handbook or guide, designed to help the scientist with all aspects of writing and publishing. Although the book mainly addresses chemists, other scientists would also find it quite useful, unless they expect to find information specific to their own field.

An important aspect of the book is that it is itself designed to serve as an example of the techniques and guidelines presented. As a result, for example, it is extensively cross referenced and indexed. However, the too frequent use of substantive footnotes often hinders the easy flow of the text. One of the book's strongest points is its superb documentation.

The work is divided into two parts, followed by 11 appendixes, a section for references and further reading, and an index. Part 1 describes all forms of scientific writing. The first two chapters (56 pages), on laboratory notebooks, laboratory reports, research reports, and theses, are written for students, except for the short discussion of grant reports and proposals. The rest of the book chiefly addresses the needs of professional chemists. This presents a problem. As the authors themselves point out (p. 122), fundamentally different approaches are required for a student textbook or for a book whose "reader is expected to be a busy specialist". Indeed, the first two chapters have the character of a college textbook (unfortunately, not a very good one), whereas the rest of the book has the quality of a well-written monograph. Chapters 3 and 4 (91 pages) contain a highly informative description of the different types of journals and books, and of the process involved in their publication. These chapters and much of the rest of the book are written by authors with extensive knowledge and experience in publishing.

Part 2 covers the technical aspects of preparing scientific publications. Chapter 5 (17 pages) deals with the production of the manuscript and its transformation into the finished product. The use and advantages of word processors are discussed, as well as such technical questions as paper, format, and proofreading. Chapter 6 (31 pages), a description of chemical nomenclature, is something of an enigma. Although I found the treatment interesting, and obviously written by an expert, it is much too brief to teach the reader this incredibly difficult subject. In a shortened form this chapter could serve as an appendix, but I would much prefer that it be expanded and made into a book of its own. Chapter 7 (29 pages) is also a digression, this time into the subject of quantities, units, and numbers. It would certainly make a good addition to a modern general chemistry textbook. The reader seeking comprehensive information on this subject should consult the IUPAC "Green Book" (*Quantities, Units and Symbols in Physical Chemistry,* Blackwell, Oxford 1988) or "The ACS Style Guide" (edited by *Janet S. Dodd,* American Chemical Society, Washington 1986). Chapters 8 to 10 (62 pages) return to the technical aspects of the publishing process, providing a detailed treatment of equations, formulas, figures, and tables. My only criticism here is that in the coverage of stencils only those products of VCH Publishers are described. Chapter 11 (44 pages), after briefly discussing personal literature card files (or databases), gives a thorough treatment of literature citation.

The appendixes (104 pages) range from short chapters (oral presentations, English grammar and style, copyrights and publishing agreements, an overview of the chemical literature, preparation of an index, ISSN and ISBN) to supplementary tables (journal abbreviations, other common abbreviations, proofreader's marks, recommended citation forms, and quantities, units, and constants).

A discussion of "The Art of Scientific Writing" would not be complete without a comparison with the most authoritative book for chemists on this subject, namely "The ACS Style Guide" mentioned earlier. In short, the two books are more complementary than competitive. Almost half of the "Style Guide" is devoted to grammar, style, and usage. "The Art of Scientific Writing", on the other hand, contains a detailed description of the publishing process, both for books and journals. The "Style Guide" presents guidelines specific to ACS publications, whereas the present book attempts to address the needs of authors internationally, and largely succeeds.

This book will be of service to chemists and especially to chemistry editors and should also be in every technical library.

Experimental Design: A Chemometric Approach. By *S. N. Deming* and *S. L. Morgan.* Elsevier, Amsterdam 1987. xiii, 275 pp., bound, HFl 225.00.—ISBN 0-444-42734-1

Good planning is half the battle! It is beyond question that scientific curiosity and researchers' intuition have led to many important discoveries. However, it is also indisputable that rationally planned experiments are essential in a scientific investigation with specific objectives.

What does the term "experimental design" mean? The best interpretation is that it is the art of planning an investigation. *Stanley N. Deming* and *Stephen L. Morgan* teach this skill in what is, it must be said at the outset, on the whole a very good book—good because it is so different from other books on this theme. It succeeds in the aim of providing a simple introduction to planning scientific experiments and dealing with the problems which arise. Mathematical statistics does not occupy a central position in the book, but is instead developed naturally alongside the main theme, where it is essential to understanding the treatment and carrying it forward.

The two introductory chapters pose the questions: what is a system? how is the system under investigation influenced by the input variables and conditions? what are

the responses which result as the output from the system, and how can the relationship between the input variables and the resulting output be described? Following a short account of the basic concepts of statistics (Chapter 3), the next four chapters deal in turn with developing a model (Chapter 4. One experiment), linear regression analysis (Chapter 5. Two experiments), testing hypotheses (Chapter 6), and the variance-covariance matrix (Chapter 7). The chapters which follow lead into the central theme of the book, the statistical design of experiments. Taking the case of three experiments as an example, linear models and second order models are treated (Chapter 8), then the analysis of variance (Chapter 9), followed by an example in which the pH dependence of the activity of an enzyme is determined from a series of ten experiments (Chapter 10). Chapter 11 discusses for the first time cases in which a system is influenced by several factors, and introduces standard experimental schemes (e.g. 2^n factorial schemes). Following Chapter 12, which deals with randomized block schemes, we suddenly reach the end of the book. Did the authors tire of their task? Or did they feel that, in a book which is based on courses given to college and university students, the reader should not be expected to go further than the classes to which they lectured? Special experimental schemes, such as the Latin square, the Greek-Latin square and the Youden square are explained briefly in the exercises of Chapter 12; other methods, such as simplex procedures or Plackett-Burman designs are only mentioned, with an invitation to the reader to look these up in the literature and critically evaluate them.

In marked contrast to the quality of the text (and indeed of the price), the publishers show a noticeable lack of care. Perhaps only a pedant would be troubled by the fact that from p. 150 onwards the sub-headings suddenly become larger. The description of a minimum as a maximum in Fig. 2.6 is also not a very serious matter. However, the fact that under the initial letter L in the key-word index one finds only entries with the letter M cannot be allowed to pass. The publishers have not even considered it necessary to insert a page listing corrections. If one is looking for the key-word "Latin square", for example, there are several possibilities: look in the contents list (nothing there), look under "Square design" (nothing), thumb through the pages of the book (a hit on p. 250), or look under "Experimental designs, Latin square" (hit).

This book is recommended as an introduction to the statistical design of experiments. Readers who already have some knowledge of this field should follow the advice of the authors and consult other monographs.

Variety in Coordination Modes of Ligands in Metal Complexes. By *S. Kawaguchi*. Springer, Berlin 1988. ix, 123 pp., bound, DM 128.00.—ISBN 3-540-18305-1

Nearly all ligands can occur in metal complexes in several different bonding situations. To write a comprehensive monograph on this subject is a scarcely manageable task. Even the book reviewed here is not such a work, despite the hopes raised by its title. The author has selected a few examples and discussed them in order of the number of atoms in the ligands, under the headings: Monoatomic Ligands (H), Diatomic Ligands (CO, N_2), Triatomic Ligands ($SCN^{\ominus}$) and Polyatomic Ligands (β-diketones). Whether or not this choice of examples is representative or rational is an open question; however, the reader of a monograph is entitled to expect that he will be offered a balanced overview of the topic covered. Regrettably that is not the case here.

The book begins with a short introduction to the classification of ligands (with an incorrect formula for EDTA even on the first page), and the phenomenon of linkage isomerism. Here it already becomes apparent that the author has not thought sufficiently about which group of readers he is aiming at: a commonplace statement such as "When a ligand connects two or more metal atoms, it is called a bridging ligand" is given equal weight alongside a detailed discussion on the formation of $[Co(NH_3)_5ONO]^{2\oplus}$. The second chapter (Monoatomic Ligands), which is devoted to the hydrido ligand, gives a similarly inconsistent impression. A discussion of the possible types of bonding (terminal or bridging) is followed by sections on synthesis and characterization. The information given here is anything but complete. Although some M–H vibrational frequencies and ^1H NMR data are included, the treatment of ^{31}P NMR spectroscopy is limited to the laconic comment "... also helpful". In discussing structures the author, for some obscure reason, limits himself to trigonal-prismatic, octahedral and pentagonal-bipyramidal examples, leaving the reader unaware of the existence of square-planar, trigonal-bipyramidal and many other types of structures. The sections on hydrogen-bridged complexes contain essentially nothing more than a mention of the structures. There follows a chapter on the reactions of hydrido-complexes, beginning with a list of Brønsted acidities and a discussion of some typical reactions. The chapter concludes with an excursion into homogeneous catalytic hydrogenation using rhodium complexes (who would expect this in a book with the above title?); here, though, one learns nothing more than can be found in the standard textbooks. For example, there is a section on "Asymmetric Hydrogenation" which consists of only ten lines of text, three formulas and five literature references.

The third chapter (Diatomic Ligands) likewise contains less than is promised. After listing the types of bonding for carbon monoxide, the chapter continues by describing only structures in which the oxygen atom of the CO group is coordinated to a metal. This is apparently intended as an introduction to the section on "CO Cleavage and Reduction", which, in a mere two pages, contains only a somewhat naive description of the Fischer-Tropsch synthesis and of CO reduction at $[Fe_4(CO)_{13}]^{2\ominus}$; it therefore cannot in any way claim to be a full account of the topic. The section on N_2 complexes appears to be rather more complete, although here there is less material to be covered.

The fourth chapter (Triatomic Ligands) begins with a discussion of the structures of $SCN^{\ominus}$-bridged complexes. A page and a half is devoted to the IR spectroscopy of these compounds; other spectroscopic methods receive only a bare mention and no literature references. The discussion of terminal thiocyanate complexes (with N or S bonding) allows the author to digress into the HSAB concept, which is probably already quite familiar to the average reader of such a monograph.

The final chapter (Polyatomic Ligands), which stands out impressively from the preceding parts of the book in the standard of treatment and information content, is essentially a reprint of an article by the author on this topic, which appeared in *Coordination Chemistry Reviews*. Here the reader learns that in addition to the usual β-dionate chelates there exist many other types of complexes which contain a β-diketone, as the neutral molecule, as monoden-

tate ligands (O or C bonded), as bridging ligands, as allyl-type η^3-ligands, or in a wide variety of ways as dianions. The structures, spectroscopic properties and reactions are discussed in detail, and published work up to 1985 is covered, with occasional references to more recent papers.

On balance, this book contains much less than its all-embracing title suggests. Half of the costly space (DM 1.00 per page!) is taken up by information which one can find equally well or better in standard textbooks. The claim to completeness is only justified in the case of the overview of β-diketone complexes, but that is already available in every well stocked library.

Two-Dimensional NMR Spectroscopy. (Methods in Stereochemical Analysis. Vol. 9.) Edited by *W. R. Croasmun* and *R. M. K. Carlson*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1987. 511 pp., bound, DM 210.00.—ISBN 3-527-26528-7/0-89573-308-0

During the last decade nuclear magnetic resonance (NMR) has become one of the main spectroscopic tools in research laboratories for structural analysis of biological and chemical compounds. Several factors have contributed to the increase in popularity of NMR. The construction of high-field NMR magnets and the use of modern computers in NMR spectrometers were a prerequisite. However, the major advances came from the development of the two-dimensional (2D) NMR method by *Ernst* and coworkers, and the sequencial assignment strategy for proteins by *Wüthrich* and coworkers. The rapid growth of the NMR field has led to impressive scientific results, published initially in scientific journals. In addition, in the past two years a number of good books on various subjects and at various levels have been published. For expert NMR spectroscopists, for example, there appeared the texts of *Ernst* et al. ("Principles of Nuclear Magnetic Resonance in One and Two Dimensions", Clarendon 1987) and *Wüthrich* ("NMR of Proteins and Nucleic Acids", Wiley-Interscience 1986), while for students a number of suitable NMR textbooks have been published in England (*R. K. Harris* and *A. E. Derome*, or *J. K. M. Sanders* and *B. K. Hunter*). Any new book explaining 2D NMR techniques faces the difficult task of having to compete with these publications.

Croasmun and *Carlson*, researchers at two large industrial laboratories, have edited a new volume of the "Methods in Stereochemical Analysis" series, which is devoted entirely to 2D NMR and contains contributions from various authors. The book is aimed at chemists and biochemists who are not NMR spectroscopists, but who may want to apply 2D NMR to their field of interest. However, it is doubtful whether this volume is really attractive for readers other than researchers who already use NMR techniques. It is certainly not recommended as a general introduction to 2D NMR, for which purpose the books mentioned previously are much more suitable. Nevertheless, the volume contains a number of reviews which are certainly worthwhile reading. *Horst Kessler*'s group have reviewed their extensive 2D NMR studies of the cyclic peptide Cyclosporin A, and compare various experimental techniques for assigning the resonances and extracting *J*-coupling parameters from 2D spectra. In another fine chapter, *David Kearns* describes the internal motions in DNA and their effects on the relaxation parameters as measured by NMR, and summarizes his 2D NMR studies of simple-sequence DNAs such as poly(dA-dT)·poly(dA-dT). *Janusz Dubrowski* reviews the application of 2D NMR in the structural analysis of oligosaccharides, and demonstrates the usefulness of NMR in this area. Furthermore, the book contains three chapters on the use of 2D techniques in studies of natural products. *William Croasmun* and *Robert Carlson* have written a chapter on steroid structure analysis by 2D NMR, *Gary Martin* has done the same for coal-derived heterocyclics, terpenoids and alkaloids, while *Peter Rinaldi* compares the characterization of an intermediate in the organic synthesis of spatol using several different high- and low-field 2D NMR experiments.

However, the outstanding chapter, and also the longest (more than 150 pages), on the experimental aspects of 2D NMR, is written by *William Hull*. This chapter gives a clear treatise on good 2D practice, and an insight into many 2D pulse sequences and their phase cycles. It is by virtue of this chapter that I would recommend keeping the book beside your 2D NMR spectrometer (even if it isn't a Bruker). Unfortunately, the book is dated, which is not very harmful for the last mentioned contribution, but more so for the other chapters on research topics, since NMR has developed very rapidly in the last few years. Most references do not extend beyond 1985 or the start of 1986, and it is rather unfortunate that the publisher was unable to bring it out at the end of 1986 or early 1987. In general, the book is rather specialized; it will probably find its way into major university libraries or research institutes.

Rolf Boelens [NB 900 IE]
Department of Organic Chemistry
University of Utrecht (Netherlands)

Silicon Reagents in Organic Synthesis. (Series: Best Synthetic Methods.) By *E. Colvin*. Academic Press, New York 1988. xxii, 147 pp., bound, £ 27.00.—ISBN 0-12-182560-4

A report on the new series "Best Synthetic Methods" has already appeared.[*] The fourth volume has now been published; this is quite a slim one with 140 pages of text, dealing with silicon as a key element in organic syntheses. The author, *E. Colvin*, has already set standards in this field several years ago with his excellent monograph "Silicon in Organic Synthesis" (Butterworth, London 1981).

The present volume follows the well proven division of the subject that was used in the previous work. A general introduction to the chemistry of silicon compounds is followed by representative examples of the various compound classes and types of reactions (e.g., vinylsilanes, allylsilanes, silyl anions, silyl enol ethers, the Peterson olefination, etc.). The lists of relevant review articles and the inclusion of information about suppliers of organosilicon intermediates are very useful features; however, both of these are treated from an English-speaking viewpoint, so that, for example, the Houben-Weyl volume on silicon is missing from the list of publications.

The treatment of individual compound classes includes, in addition to detailed schemes showing syntheses and reactivity, very useful experimental details for carrying out many of the typical transformations; each chapter ends with a list of literature references. The last chapter con-

[*] See *Angew. Chem. Int. Ed. Engl. 26* (1987) 593.

tains a list of those compounds and syntheses for which more detailed experimental information can be found in other compilations (e.g., "Organic Syntheses"). However, it would have been more sensible to incorporate this information into the appropriate earlier chapters.

The question is, who are the readers most likely to benefit from this comparatively inexpensive little book? It is true that, in thumbing through the book, one picks up the occasional stimulus or new idea, but beginners will certainly gain a better understanding from the older monographs. On the other hand, those already experienced in this field will already have their own compilations of experimental methods, and therefore the main feature of this series—the more or less detailed descriptions of syntheses—will scarcely be a useful additional resource for this group either. An element-oriented methods collection of this type is really of little help in searching out the *best method* for a problem in synthesis. "*Best Synthetic Procedures*" would perhaps be a less misleading title for the whole series.

Mechanisms of Photophysical Processes and Photochemical Reactions in Polymers. By *J. F. Rabek*. Wiley, Chichester 1987. xix, 756 pp., bound, £ 99.00.—ISBN 0-471-91180-1

In a total of 750 pages this book covers the most important findings of photochemistry and photophysics in polymer systems up to 1984 inclusive, and according to its author it is suitable both for polymer scientists and for advanced students who have some familiarity with or interest in this field.

The contents are arranged systematically, beginning with an introductory summary of the most important basic facts and concepts of photophysics, followed by an account of the relationships that are specific to energy transfer and excimer and/or exciplex formation in polymers, and of luminescence methods in polymer analysis. The remaining three-quarters of the book deals with various aspects of photochemistry in relation to polymers, together with a brief section on photochromic polymers. The individual topics covered are photoinitiation and photopolymerization (ca. 185 pages), polymer photodegradation and light stabilizers for polymers (ca. 170 pages), and the more applications-orientated topics of photoresists, photopolymer-coated printing plates, and the use of polymers in solar energy utilization (altogether ca. 90 pages).

Those chapters that deal with photochemical topics, making up more than half of the book, give an excellent up-to-date survey of current knowledge in this field. All the chapters and sections that are concerned more with photophysical aspects are, in comparison, too brief to cover these topics adequately, and consequently do not really justify the book's title; here, and also in the treatment of photochromicity, the importance of some of the key research contributions is not sufficiently brought out, and in some cases they are not referred to at all, or are cited incorrectly.

The book assumes that the reader has, in addition to a sound basic knowledge of the chemistry and physics of polymers, a grounding in the essentials of photochemistry and photophysics, and it is consequently not really suitable for those without a minimum of previous knowledge. Taken as a whole, however, the book is to be recommended, especially for the wealth of literature references which it contains, and for the generally good treatment of this field of importance to polymer science and technology.

Materials Federations—The State of Play

Editorial Essay

By Robert W. Cahn*

In May of this year, the Federation of Materials Institutes (of the United Kingdom) gave the press the news of its impending creation. The Institute of Ceramics, the Institute of Metals and the Plastics and Rubber Institute announced the formation, on June 1, of the new Federation.

The beginnings of the new federation lie two years in the past: the Institute of Ceramics and the Plastics and Rubber Institute, both British professional bodies, federated in November 1986. This decision represented, in the words of one of the senior officers concerned, 'a natural meeting of minds.' Earlier this year the Institute of Metals, London, decided to join the new federation, and soon afterwards the creation of the new body was announced to the world. What lies behind this innocuous news item?

A dignified contest has been in progress for many years between the drive to mark the emergence of the new superdiscipline of Materials Science and Engineering (MSE) by the creation of corresponding professional institutes, and the equally strong urge to strengthen the existing sectional bodies in the traditional fields of metallurgy, ceramics and polymers, as well as the newer fields of electronic materials, composites, solid-state chemistry, and others.

Probably the earliest manifestation of the MSE lobby's activity was the formation, in 1963, of the (British) Materials Science Club. The initiative stemmed from the late Mr. *Leslie Holliday* of the Institute of Chemical Engineers and several colleagues in the same Institute. At its apogee, this Club had several hundred members: it was always administered from within one of the British industrial companies to which its members belonged, first Shell and subsequently other bodies in the chemical engineering field—it never reached the dignity of a fulltime secretariat—and it held frequent meetings focused on industrial applications of various fields of MSE. The Club never sought to appropriate the other functions of a professional body and in particular it never tried to arrogate to itself the role of a professional qualifying body. This role may seem surprising to some readers outside the U.K. ... but in that country, the right to put letters such as F.I.M., F.R.I.C. or F.I.P.—or 'Chartered Engineer' or 'Chartered Physicist'—after one's name has always been highly prized and has

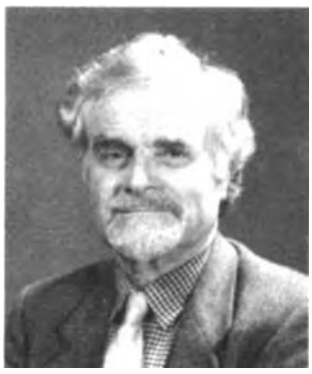
always enhanced the holder's chance of securing a good post in industry—though it rarely influenced academic appointment committees! Some four years ago, the Materials Science Club, which had fallen on hard times, applied to amalgamate with the Metals Society, itself soon to become part of the Institute of Metals, and thereupon became one of its 'activity groups'. Existing members who were not metallurgists—the majority—were invited to join the Institute of Metals on favorable terms, but few accepted this offer, and the Materials Science Club, having fulfilled what was expected of it, is now to all intents and purposes dead.

The history of this pioneering Club illustrates a tendency which, rightly or wrongly, worries many materials scientists and engineers (let us call them MSEists) who are not primarily metallurgists. They have for some years perceived the large national metallurgical bodies as being engaged in a ruthless takeover campaign for the world's MSEists. Where Britain is concerned, the evidence for this worry is not strong: The Materials Science Club takeover, though it seemed innocuous enough, perturbed some; and the Institute's research journals, which had been entitled *Metal Science* and *Metals Technology*, were conflated to form *Materials Science and Technology*. The Institute of Metals sought to persuade ceramists, composite and polymer people to publish in its revamped periodical; when they did (as one eminent polymer specialist declared to the writer) they might receive no requests at all for reprints, which of course served as clear evidence that their papers had been read by few of those at whom they had been directed. The Institute of Metals certainly made it clear to the world that it wished to broaden its field of activities, after long years when much of its membership fiercely resisted any such broadening. The Institute may be forgiven if it feels aggrieved that, when at length it has reacted positively to this long-standing pressure, it has encountered a strongly negative reaction from some of its sister institutions! This is certainly unfortunate ... but, as we shall see below, this is probably a defensive response to the buccaneering activities of one of the American metallurgical societies.

Another body which has been in existence for some years in Britain is the Materials Forum, which owes its existence to the initiative of the (British) Institution of Mechanical Engineers and, more specifically, to the advocacy of a distinguished mechanical engineer, *Sir Hugh Ford*. The Materials Forum is intended to be a materials users' representative body. This body seeks to cover a wider range of engineering materials, and also to play a political (lobbying) role. By no means all British MSEists would accord the Metals Forum such a central position, and indeed would consider its claims as yet further evidence of metallurgical hubris!

America is another matter altogether. There are two major metallurgical bodies in the U.S.: The Metallurgical Society (TMS) of the American Institute of Mining, Metallurgical and Petroleum Engineers, and the American Society for Metals. The former has always maintained a decent reticence vis-à-vis its sister societies, but the ASM has recently gone unashamedly on the warpath. It has rechristened itself 'ASM International ... a Society for Materials', it has opened an ASM-Europe office, has created ASM 'chapters' in Benelux and Finland and has sought to create similar chapters (in some cases involving attempted takeovers of existing bodies) in countries such as India. This activity (which in the business world would be called an attempt at hostile takeovers) has not gone unnoticed and in this writer's view may have played a significant role in promoting the federation initiatives such as that between the ceramics and polymer bodies in Britain two years ago. Following that particular initiative, the Institute of Metals felt bound to become involved, which showed an impressive capacity for taking a long-term view.

The ASM action, and the subsequent actions in Europe, were no doubt partly a response to the runaway success of the (American) Materials Research Society, formed in the early seventies by a group of industrial materials physicists and, to a lesser extent, chemists who were frustrated by the lack of interest of the American Physical Society and American Chemical Society, at that time, in their concerns. The MRS, which now has more than 6000 members, has excited considerable suspicion and even hostility among some metallurgists in America and is perceived as a threat to the viability of the metallurgical societies by some of their members. While a European clone has recently started operations—the E-MRS or European Materials



Prof. Robert W. Cahn was for many years Professor of Materials Science at the University of Sussex, UK, following that with a shorter period as Professor of Physical Metallurgy at the University of Paris-Sud. He is now retired, and attached to the Department of Materials Science and Metallurgy at Cambridge University, in the capacity of Senior Associate, and continuing to do research. His researches have been in various aspects of physical metallurgy, including ordered alloys, recrystallization of deformed metals, twinning and rapid solidification. He has been active for many years as an editor and correspondent: jointly with others, he created the Journal of Nuclear Materials and the Journal of Materials Science, has edited three editions of a text on Physical Metallurgy, has for 16 years edited a monograph series for the Cambridge University Press, has been materials science correspondent for 'Nature' for 20 years, is a principal editor of the new Journal of Materials Research and has embarked on a new editing venture, a series of 18 texts in MSE, for the publishers of 'Advanced Materials'.

ADVANCED MATERIALS

Research Society—it is at far too early a stage to be a serious threat to existing European bodies, but nevertheless the evidence is that it is already viewed with alarm.

Even before the Federation of Materials Institutes—to give it its formal name—began operations in Britain, other defensive initiatives had been seen in Europe. About five years ago, the various national polymer societies of Europe formed a European Polymer Federation, and last year, under the presidency of a distinguished Dutch ceramist, Dr. *R. Metselaar*, the ceramics societies of Europe formed the European Ceramic Society (in fact, though not in name, a federation) which is soon to hold its first international conference. This ceramics initiative apparently owed much to the discreet support offered by the American Ceramic Society, which wished to see a strong Europe-wide activity in ceramics (perhaps to counter what it may have perceived as metallurgical presumption!) Until this year the metallurgical bodies of Europe had not yet federated in any shape or form, although for some years their administrators have met regularly to prevent timetable conflicts with respect to their various national conferences. Indeed, such efforts to avoid timetable conflicts constitute one of the more basic objectives of European federations. However, as this editorial is being revised for press, an invitation is being circulated to a conference, entitled Euromat '89 and sponsored by a Federation of European Materials Societies! On closer examination, their brandnew Federation consists of the national metallurgical bodies of Britain, France and Germany, with the Swiss Society of Materials Technology for seasoning. The administrative seat is in Germany, so the initiative presumably stemmed from the Deutsche Gesellschaft für Metallkunde. Once again, metallurgical hubris has prevailed ... the latest Federation claim to represent all materials, not just metals!

Inaugural party, or ... wearing many hats

Reverting to the recently formed (British) Federation of Materials Institutes, this body is now taking active steps to enlarge its scope. Negotiations with the recently formed British Composites Society are at an advanced stage; there have been preliminary contacts with the Institute of Textiles and with other bodies. The Federation is strongly placed financially. Its administrative headquarters will soon move to the premises of the Plastics and Rubber Institute in London, and *Sir Geoffrey Ford*, the recently retired Secretary of the Institute of Metals, has already taken over as Secretary of the new Federation. The Chairman is *Sir John Collyear*, an industrialist who was Chairman of a Committee which, in 1985, was charged by the British Government with formulating a "Programme for the Wider Application of New and Improved Materials and Processes". (Their excellent report, like so many others in the materials field, led to no action whatsoever.) The Council will include, inter alios, the Presidents of the constituent societies. The aims of the new Federation are announced as being to "coordinate the activities of professional bodies and learned societies involved in the science, engineering and applications of materials in order to provide unbroken coverage of the entire field; improve services to members, to industry, and to the whole materials community; and to promote a wider understanding of engineered materials." The only possible response to that is: Amen!

Even more to the point is the following forthright assertion: "The three founding societies ... see as their ultimate aim the formation of a single Institute of Materials in the UK." This is undoubtedly difficult to achieve; the Institute of Metals will be the first to concede this, in view of its long years of effort directed, successfully in the end, to its mergers, first with the Iron and Steel Institute and then with the Institution of Metallurgists (which last was largely a professional qualifying body). One should not forget the trauma suffered by the Institute of Physics in London, many years ago, when it engineered its merger with the Physical Society; a very eminent physicist was reported as saying, in a moment of exasperation, that he supposed his Nobel Prize had really been awarded for his role in forcing through the merger!—Nevertheless, for the first time the objective of creating a materials institute in a European country has been announced, not unrealistically by a single existing body but rather by a federation of several such bodies: one can only hope that the creation of the metallurgically biased Federation of European Materials Societies will not interfere with the objective of eventually creating a British Institute of Materials.

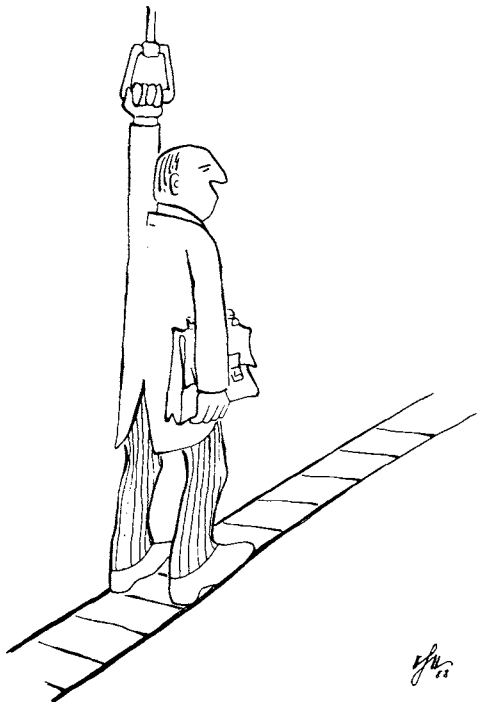
An interesting question is the future relation between the international discipline-based European federations such

as those in the ceramics and polymer fields (and possibly a future metallurgical one), and the trans-disciplinary single-nation federation represented by the new body. It seems that no initiatives have yet been seen in other European countries to establish trans-disciplinary federations or societies in these countries. Perhaps we face a competition between single-nation trans-disciplinary bodies and international single-disciplinary bodies. One possibility, idealistic no doubt, is that the projected British Institute of Materials will actually come into existence and act as a template for a large European Institute of the same kind. That will certainly work better than the Federation of European Materials (i.e. Metals) Societies! A genuine European Materials Institute is certainly quite some years ahead and—who knows?—by then the European Materials Research Society, at present still a fairly modest enterprise, may have taken off as successfully as its American progenitor.

There have been suggestions in the foregoing that metallurgical bodies fear the MRS and that non-metallurgical bodies fear the metallurgists—perhaps more than they fear the MRS. The fear, so far as can be assessed, seems to be that the existing, traditional functions of the many bodies involved—the organizing and publishing of conferences, the holding of short discussion meetings, the publication of learned periodicals and news-filled house journals, the pleasant activity of formal dinners and (possibly the most important psychologically) the behind-the-scenes influencing of ministers and prime-ministerial science advisers—that all these varied activities are at risk from predators of one kind or another. The response of the ASM has been to undertake preemptive strikes across the world, and this is really rather odd, taking into consideration the fact that bodies such as the ASM have no shareholders to clamor for more profits. It is hard to see what benefit is achieved, for such a society, in growing beyond a certain size and income. Indeed, the MRS, ASM and AIME alike have all grown to a size which makes their meetings somewhat uncomfortable as social occasions. The most curious aspect of the situation, perhaps, is that the MRS has to be regarded, for the present, as a sleeping giant so far as political influence goes. It is so busy running and publishing specialized symposia, publishing one of the best house journals in the business and getting its new learned periodical off the ground, that it has not found time or inclination to lobby members of Congress for funds and to bend the ears of the President's Science Advisor or of the beleaguered minions of the National Science Foundation. That may change, of course—voices are beginning to be raised inside the MRS in favor of a higher political profile—but for the moment there are many smaller bodies which are far more active politically, for weal or woe. So perhaps the widespread apprehension is premature. There exists, in fact, a primarily politically oriented body, the Federation of Materials Societies (of the U.S.A.), founded in 1972. It is run from a small office in Washington, and unites twelve societies (in metallurgy, ceramics, engineering and chemistry ... i.e. polymers, electronics and crystal growth; The Materials Research Society is not a member). It organizes impressive, biennial conferences devoted primarily to policy issues, and through these seeks to influence the Administration and Congress. The Executive Director is an expert in public relations. The participants in the conferences are mostly research directors and other policy makers. The technical papers are surveys, not research reports. One wonders whether one of the European federations will go this way ... targeted on the Brussels bureaucrats!

One other consideration warrants careful thought. As stated, the Institute of Metals has sought to broaden the scope of its technical journal, and encountered some difficulty in doing so. Presumably, its partners in the new British Federation will now press it to leave ceramics to the ceramists, polymers to the polymer scientists and composites to the compositeers. If and when the Federation is replaced by a (national) Institute of Materials, that will be the time to go for a broad materials journal. But, in the view of the writer (who is an editor of long and varied experience) this will only work if the old journals close down and an entirely new journal, under entirely new management, starts up. Journals are like the Old Man of Siam:

There was an old man of Siam
Who said: "I perceive that I am
A creature that moves
In predestinate grooves,
Not a car, not a bus, but a tram."



"... not a car, not a bus, but a tram"

Within a year or two of the creation of a new journal, its scope and readership become set in stone (or grooves), and therafter extensions of either, however sincerely sought, become ever more difficult. The MRS started its new journal after the Society had become established in the eye of the technical public, and was thus able to aim immediately at a wide scope and readership; even so, it has had difficulties to overcome ... a tendency by readers to suspect the new journal of electronic favoritism, and problems in extending readership across the Atlantic. It has scored with a striking innovation, however: it may well be the first learned periodical (as distinct from house journal) to be distributed free to all members who pay their modest membership subscriptions. There is undoubtedly much to learn, on this side of the Atlantic, from the MRS's new *Journal of Materials Research*.

For better or worse, Europe has embarked on a new route marked with much promise and numerous difficulties: it will be next to impossible to stop at a halfway point, and we may all expect to witness a rapid succession of mergers, federations and recreations. Good luck ... bonne chance ... zum Wohle!

New Donors for Molecular Organic (Super)Conductors and Ferromagnets**

Organic Metals
Organic Ferromagnets
Charge-Transfer Complexes
1,3-Dithiol-2-ylidene Donors

By Zen-ichi Yoshida* and Toyonari Sugimoto

1. Introduction

Synthetic chemistry has in the past been directed towards "structural" synthesis, in which compounds of known structure (e.g. natural products) or structure designed new systems (e.g. novel π systems) are the synthetic targets. This sort of chemistry will continue to be important in the future. However, "functional" synthesis, directed towards synthesizing organic compounds with novel functions, has recently started to emerge as a very important new field of chemistry, which will make valuable contributions to creating new advanced materials. Since we have already succeeded in creating an excellent new molecular energy storage system ("DONAC") based on our concept, in this review we shall discuss experiments aimed at synthesizing organic compounds with interesting electrical or magnetic properties.

The discovery in the early 1970's that single crystals of a tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ) charge-transfer (CT) complex showed metal-like electrical conductivity[1] marked an epoch in a new area of chemistry and physics. The energetic investigations that followed led in 1980 to another big discovery, that of the first organic superconductor, $(TMTSF)_2PF_6$, where TMTSF is tetramethyltetraselenafulvalene. This has a critical temperature T_c of 0.9 K under a pressure of 12 kbar.[2] Looking back on the brilliant history of organic conducting materials, one recognizes that two organic molecules originally synthesized for their structural interest as novel π-electron systems, TTF[3] and TCNQ,[4] played a crucial role in this new scientific field. From this viewpoint it can be said that organic and organometallic syntheses, which have yielded a number of promising organic molecules used to prepare interesting and useful organic materials, provide a springboard for new developments in this field.[5] However, the electrical, magnetic and optical properties of organic solids arise from special types of interactions between several organic constituents in ways that are as yet little understood. Therefore, in addition to the preparation of organic compounds that show promise as such constituent molecules, there is an urgent need to develop guiding concepts regarding the problem of crystal growth, to bring a deeper understanding of the properties of organic solids.

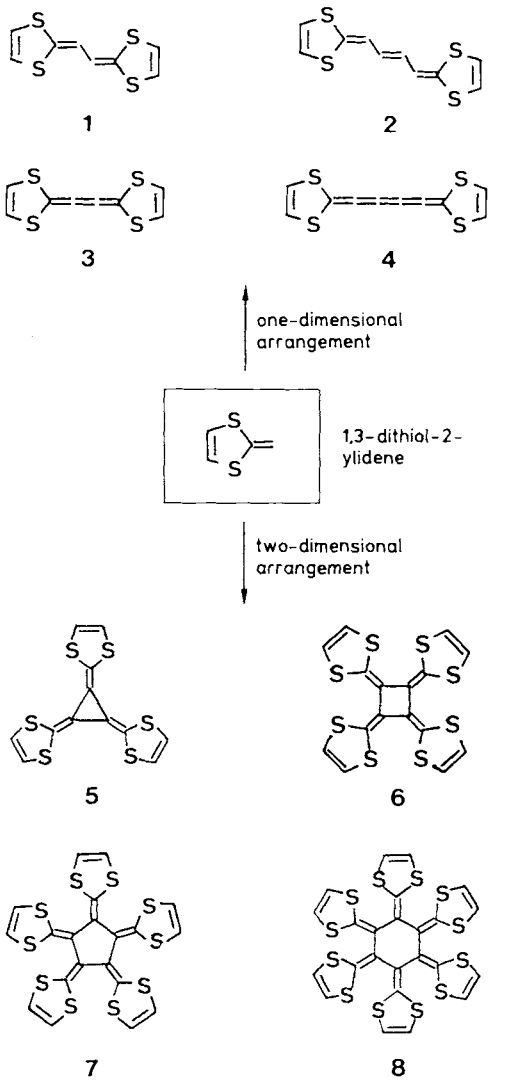
[*] Prof. Dr. Z. Yoshida, Dr. T. Sugimoto
Department of Synthetic Chemistry, Kyoto University
Yoshida, Kyoto 606 (Japan)

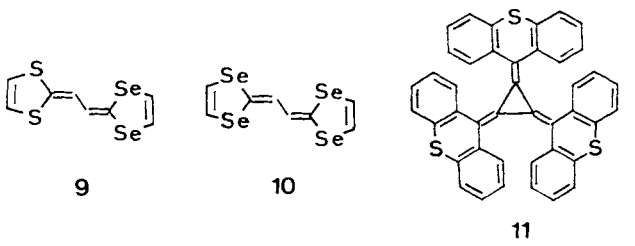
[**] The authors thank the Grants-in-Aid for Scientific Research on Priority Areas, New Functionality Materials—Design, Preparation and Control, the Ministry of Education, Science and Culture, Japan (Grant No. 62604004) for financial support. Discussions with Prof. *N. Kasai*, Dr. *Y. Kai*, Dr. *T. Kobayashi*, Dr. *H. Anzai*, Dr. *J. Yamauchi* and *Y. Misaki* are highly appreciated.

At present the usual course is to synthesize suitable organic compounds and investigate the properties of organic solids made up of these constituents, in the hope of discovering improved or novel effects. With many different systems under investigation it is likely that now and again someone will be lucky enough to make a new discovery. Our research on the design of new 1,3-dithiol-2-ylidene electron donors, with the aim of preparing molecular organic conductors and ferromagnetic materials, must be viewed in this context.

2. New 1,3-Dithiol-2-ylidene Electron Donors

In the early 1970's metallic conductivity was observed for two organic solids, consisting of the chloride salt of TTF[6] and the CT complex formed by TTF with TCNQ.[2] This discovery not only destroyed the belief hitherto held that "all organic compounds are electrically insulating", but also encouraged chemists to synthesize other such "organic metals", and hopefully even "organic superconductors", with physical properties that had previously been observed only in some metals and alloys. The electron donors so far used to prepare organic metals and superconductors are virtually limited to TTF and its chalcogen (Se and Te) analogs, TSF and TTeF. It appears that if high-T_c organic superconductors are ultimately to be achieved, new donors with skeletal structures different from that of TTF will be needed. Based on this view, research has begun on synthesizing new types of donors, in the belief that this will lead to the preparation of organic conductors and superconductors with properties superior to those hitherto obtained. The donors synthesized for this purpose are ethanediylidene-2,2'-bis(1,3-dithiole) **1**,[7] 2-butene-1,4-diylidene-2,2'-bis(1,3-dithiole) **2**,[8] ethenediylidene-2,2'-bis(1,3-dithiole) **3**,[9] butatrienediylidene-2,2'-bis(1,3-dithiole) **4**,[9] and [3]-,[10] [4]-,[11] [5]-,[12] and [6]-radialenes[13] substituted with 1,3-dithiole **5**–**8**. Among the compounds **1**–**4**, which have structures containing two or four sp^2 or sp carbon atoms between two 1,3-dithioles, **1** and **2** and their alkyl- and aryl-substituted derivatives were readily synthesized, but **3** and **4** could not be isolated owing to their extreme instability. In addition, two derivatives of **1** substituted with two or four selenium atoms in place of the corresponding sulfur atoms (ethanediylidene-2-(1,3-dithiole)-2'-(1,3-diselenole) **9**[14] and ethanediylidene-2,2'-bis(1,3-diselenole) **10**[14]) were prepared by the same method as for **1**. These new donors apparently have a one-dimensional arrangement of two 1,3-dithiol-2-ylidene moieties which differs from that in TTF. On the other hand, **5**–**8** have a two-dimensional arrangement of three, four, five, and six of the same moieties, respectively, if it is assumed that their molecular structures are completely planar. The X-ray structure analyses indicated instead a three-dimensional arrangement for **6**, **7** and **8**. A high degree of planarity is expected for **5**, but unfortunately this compound has not yet been prepared. Instead, [3]-radialene substituted with a sterically bulky, but still electron-donating, thioxanthenyl group in place of the 1,3-dithiole group **11** was prepared. In spite of considerable efforts, single crystals suitable for X-ray structure analysis have not yet been obtained.





3. Redox Behavior

Data on redox potentials, especially the first (E_1) and second (E_2) values for donors, is very important in designing organic materials with interesting and useful physical

properties such as electrical conductivity and ferromagnetism. Table 1 summarizes the redox potentials of the new donors. Except for **8**, where the central six-membered ring is in the chair form, and **11** the other donors have either smaller or similar E_1 values compared with that for TTF ($E_1 = +0.34$ V and $E_2 = +0.71$ V vs. Ag/AgCl in CH_2Cl_2). However, results from cyclic voltammetry indicate that **3**, **4** and **8** (twisted-boat form of the central six-membered ring) are undesirable donors by reason of extreme instability of the neutral species and radical cations for **3** and **4**, and of the dication for **8**. Eventually, the remaining six new 1,3-dithiol-2-ylidene systems might meet our expectations as promising donors. Brief information is given on the redox behavior of each donor. As is observed for TTF, two consecutive one-electron redox processes also occur for **1**, **9**, **10** and **11**. It should be noted that the second redox process can proceed at a lower potential than that of TTF, indicating that in the radical cation and dication states of these donors the on-site Coulomb repulsion is greatly reduced. For **2** and **6** the first and second one-electron redox processes occur simultaneously, although the subsequent electrochemically irreversible third and fourth ones are observed for the latter donor. Very interestingly, **7** exhibits only one redox process involving four-electron migration in one step. These unique types of redox behavior can reasonably be interpreted by considering that their conformations change so drastically as to increase the conjugation of the whole π electron system, as the oxidation proceeds. From consideration of the redox potentials these new donors show great promise for the preparation of organic conductors, and also of organic ferromagnets. However, the design of these new donors is lacking in another important respect, i.e. the stacking of the donor molecules. All the new donors have conformations that are far from planar, as is shown by their X-ray structure analyses and by spectroscopy. It is hoped that the donors can adopt molecular conformations sufficiently planar to allow close stacking in the form of CT complexes and radical cation salts.

4. New Organic Metals

The six new electron donor compounds that have been successfully prepared were used to investigate the formation of CT complexes with familiar acceptors, and of radical cation salts. All the donors gave CT complexes with TCNQ, tetrafluoro-substituted TCNQ, and 2,3-dicyano-5,6-dichloro-*p*-benzoquinone (DDQ). Comparatively high electrical conductivities (3×10^{-2} to 8×10^{-1} S cm^{-1}) in the form of compressed pellets at room temperature were observed for **1**·TCNQ, $\mathbf{9}_2(TCNQ)_3$, $\mathbf{10}_2(TCNQ)_3$, **2**·TCNQ, and **6**·$(TCNQ)_2$.[15] Attempts were made to obtain their CT complexes as single crystals, but this was successful only for **1**·TCNQ. The electrical conductivity of a **1**·TCNQ single crystal at 300 K was 16 S cm^{-1}, and the value gradually increased as the temperature was reduced from 300 to 200 K, reaching a maximum of 23 S cm^{-1}. This change of electrical conductivity with temperature implies that the crystals have metallic properties in this temperature range. However, at 200 K a metal-to-insulator phase transition occurred, and below this temperature semiconductor type behavior was observed. Thus, the **1**·TCNQ single crystal does not behave as a metal at low temperatures, much less as a superconductor.

Radical cation salts were prepared from the donor compounds using electrochemical crystallization. Here again single crystals were not easily obtained. Only the PF_6 and ClO_4 salts of the radical cation of a tetrabenzo-substituted derivative of **6** were obtained as single crystals of very small size.[16] The electrical conductivity at room temperature was ca. 1 S cm^{-1}, and unfortunately showed a temperature dependence characteristic of a semiconductor. Judging from the results obtained so far on the new 1,3-dithiol-2-ylidene donors, it appears that the nonplanar conformations of the new donors have an undesirable effect on the stacking of donor molecules in the CT complexes and radical cation salts. This situation was not unexpected from the outset. However, this difficult problem might be solved by introducing a suitable substituent group so as to give stronger intermolecular interaction, and/or by urgent synthesis of the planar molecule **5**, which appeared most promising in our first donor design considerations.

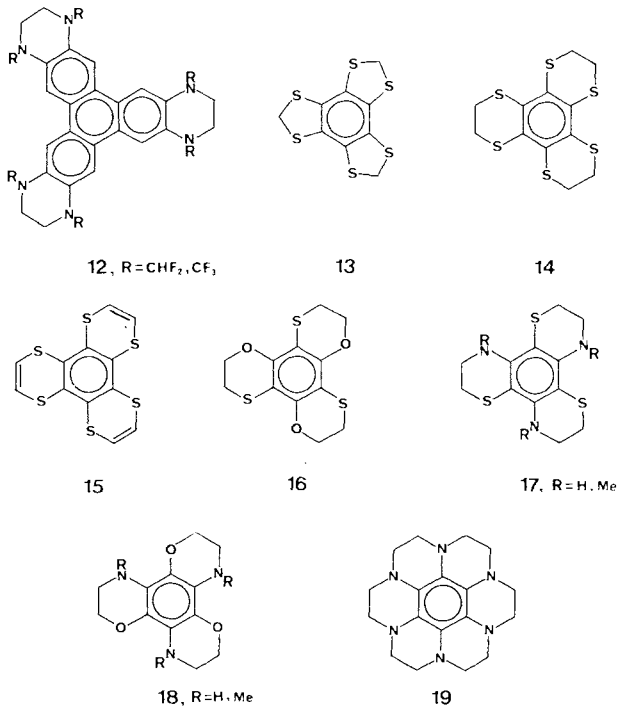
5. Molecular Organic Ferromagnets

In contrast to the considerable developments that have occurred in organic materials with electrical conductivity, and especially superconductivity, ferromagnetism, another very important and useful physical property, has not yet been achieved in organic materials. Ferromagnetism is a special state of complete spin alignment throughout the bulk. Several theoretical models have already been proposed for achieving a linear-chain ferromagnetic coupling in an organic solid. The most attractive of these are two models proposed by *McConnell*, based respectively on Heitler–London spin exchange between positive spin den-

sity on one radical and negative spin density on another,[17] and on configurational mixing of a virtual triplet excited state with the ground state for a chain of alternating radical cation donors and radical anion acceptors,[18] and a ferromagnetic superexchange model proposed by *Soos*.[19] Very recently, *Miller* et al. have developed an extended *McConnell* model leading to the spin alignment throughout the bulk that is necessary for bulk ferromagnetism.[20]

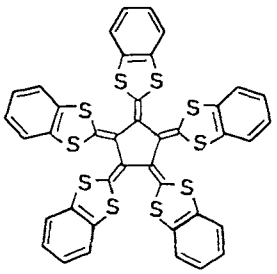
Guided by the theoretical background, current experimental programs are very actively concentrated in two directions, starting from polymeric systems and molecular solids respectively. For the latter types of organic ferromagnets with which we are concerned, particularly those based on CT solids, the second McConnell model can serve as a reliable initial guide. To give ferromagnetic behavior the donor or acceptor component needs to occupy at least one pair of degenerate highest occupied (HO) or lowest unoccupied (LU) molecular orbitals (MOs). This situation appears very often in d and f orbitals of transition metals, but very rarely in organic molecules, except for the case where there is an odd-fold axis of symmetry. *Breslow*[21] and *Miller* et al.[20] are continuing their efforts to prepare organic ferromagnets based on a mixed stack of CT complexes of a donor and an acceptor as above. On the other hand, *Torrance* et al.[22] and *Wudl* et al.[23] are investigating the possibility of organic ferromagnets in a stack of either all donors or all acceptors, as commonly found in electrically conducting radical ion salts.

Until now all the attempts have been limited to the CT complexes and radical cation salts of organic donors with C_3 or higher symmetry. Such donors are hexaazatritetralin **12**,[24] hexakis(alkylthio)benzenes **13**, **14** and **15**,[25] tris(ethyleneoxythio)benzene **16**,[25] tris(ethyleneaminothio)benzene **17**,[26] tris(ethyleneoxyamino)benzene **18**,[26] and hexaazaoctadecahydro-coronene **19**,[26] as shown below. Of these, the last donor is very attractive by virtue of its high symmetry and very low redox potentials (−0.771 V, −0.285 V, +0.178 V and +0.556 V vs. Ag/0.01 M $AgNO_3$, CH_3CN, 25 °C). Detailed investigations have been carried out on **12** and **19**. Unfortunately their CT complexes and radical cation salts, whose magnetic susceptibilities were examined as a function of temperature, were antiferromagnetic, not ferromagnetic. The dications of their donors generated in solution are ground state triplets, and the CT complex and radical cation salts have 1:1 stoichiometry of donor and acceptor components. These facts appear to fulfil the requirements of *McConnell*'s second model. However the actual situation turns out to be otherwise. A possible reason is that the molecular symmetry of the donor is reduced by Jahn-Teller distortion in the solid environment.



Our group is currently investigating the preparation of molecular organic ferromagnets by using electron-donating odd-numbered [n]-radialenes, which have a pair of degenerate HOMOs of comparatively high energy, assuming that the molecular symmetry is C_n or higher. With this assumption the radialenes are a pentabenzosubstituted derivative of **7** (**20**) and **11**. Compound **11** did not form a

20



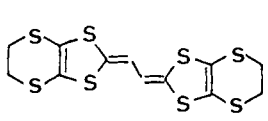
CT complex with any of the usual acceptors. This might be due to the high first redox potential and large steric hindrance of this donor. In addition, the dication generated chemically or electrochemically in solution was not a ground-state triplet, but a thermally accessible triplet.[10] On the other hand, **20** formed CT complexes with comparatively strong acceptors such as DDQ.[12b] We have investigated the magnetic properties of the CT complex of **20** with DDQ, whose composition was **20**:DDQ = 1:2, in contrast to the 1:1 ionic CT pair expected theoretically for the CT ferromagnet. The temperature change of the paramagnetic susceptibility of the **20**·$(DDQ)_2$ solid followed a Curie-Weiss law, and the Weiss constant was ca. −2 K. In the EPR spectrum at room temperature (298 K) the half-field (triplet state) resonance signal also appeared. The temperature change of the signal intensity in the range 298 to 4.5 K followed a Curie law, indicating involvement of a ground-state triplet in the solid. Both these results lead to the conclusion that $\mathbf{20}^{2\oplus}$ is a ground-state triplet which undergoes a weak antiferromagnetic interaction with two

ADVANCED MATERIALS

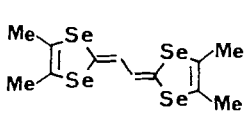
$DDQ^{\odot\ominus}$ radical ions in the CT solid. In contrast to the difficulty in achieving linear-chain ferromagnetic coupling in a purely molecular organic solid, a ferromagnetic organometallic molecular CT solid, decamethylferrocenium tetracyanoethylide, was very recently prepared.[27] Also for CT complexes of decamethylferrocene with DDQ,[28] and with hexacyanobutadiene,[29] linear-chain ferromagnetic coupling was observed, although a bulk ferromagnetic material was not achieved. In these complexes two spins which occupy a pair of degenerate HOMOs (d orbitals of the iron atom) are forced into a parallel orientation by their strong exchange interaction. This lowest excited state, formed via virtual CT between the ferrocene radical cation and the tetracyanoethylene radical anion, induces the triplet to be the ground state by admixing each other, resulting in stabilization of ferromagnetic coupling for this complex. In a pure organic donor with s and p orbitals such a lowest excited triplet state can arise only accidentally or from intrinsic π-orbital degeneracies, which are easily broken by Jahn-Teller distortion.

6. Prospects

The pace of research on organic conductors and superconductors has lost some of its impetus since the discovery of high-T_c ceramic superconductors. Nevertheless, it must be emphasized that research on organic (super)conductors needs to be actively pursued with the aim of preparing organic superconductors with higher T_c and elucidating the detailed mechanisms of superconductivity. Research on organic ferromagnetic materials is still in its infancy. Further development of these two research topics, especially on molecular organic (super)conductors and ferromagnets, depends ultimately on the synthesis of reliable organic donors, as this short review makes clear. To the best of our belief, the 1,3-dithiol-2-ylidene systems are still promising as donors for the preparation of the two types of organic materials, despite the fact that the six donor compounds investigated have not yet led to either organic superconductors or ferromagnetic materials. With regard to organic superconductors we are now investigating two new donors, a bis(ethylenedithio)-substituted derivative of **1** (**21**), and a tetramethyl-substituted derivative of **10** (**22**), which are the ethanediylidene analogs of the well-known bis-



21



22

23

(ethylenedithio)-TTF and TMTSF, many of whose radical cation salts are superconductors. With regard to organic ferromagnets, **5** and its benzo-substituted derivative are the prospective donor compounds whose preparation is now our most urgent objective. These resemble hexa(dimethylamino)trimethylenecyclopropane **23**, which has been proposed by *Miller* et al. as a most promising donor. Also, the 1:1 CT complexes of **20** with appropriate acceptors might exhibit favorable magnetic properties, if $\mathbf{20}^{2\oplus}$ retains its ground state triplet in the complexes, as is the case in the $\mathbf{20}\cdot(DDQ)_2$ complex. We believe there is a good prospect that a new organic superconductor and/or a first purely organic ferromagnet will emerge from these newly designed 1,3-dithiol-2-ylidene donors.

Beryllium Crystals for Neutron Monochromators

Since the introduction of neutron diffraction for the investigation of condensed systems, beryllium has been known as the most efficient material for thermal neutron monochromators. Additionally, a great demand has grown in recent years for beryllium single crystals as X-ray monochromators. Compared to the common neutron monochromator materials such as copper, silicon and niobium, beryllium crystals yield a distinctly higher intensity of the monochromated neutron beam. In most cases high reflectivity of the monochromator is not demanded for a distinct wavelength only, but for a small wavelength range. Therefore, the monochromator crystals should have a uniform distribution of dislocations, the so-called mosaic spread, throughout the bulk.

For a long time no single crystals of a sufficient size and with the desired mosaic spread were available because of difficulties in crystal growth.[1] Using a double ellipsoid mirror furnace, developed at the Crystallographic Institute of the University of Freiburg,[2] *Jönsson* succeeded in growing a small crystal by crucible-free zone melting.[3] Encouraged by this success, several neutron scattering laboratories joined the collaborative team formed by the Institute Laue-Langevin, Grenoble, and the Max Planck Institute for Metals Research, Stuttgart, in 1984.[4] In 1987 the Rheinisch-Westfälische Technische Hochschule Aachen also joined in this project.

A double and a triple ellipsoid mirror furnace were constructed, using designs developed in the universities of Freiburg and Stuttgart.[2,5] The growth conditions, described and discussed in deteil recently,[4], were steadily improved. In particular it became necessary to incorporate a complex purification process to radically reduce the high beryllium oxide content which interferes with crystal growth.

At present, crystals of 15 to 17 mm in diameter and 50 to 70 mm in length can be grown. Their quality is checked by Laue transmission photographs, by X-ray, γ-ray and neutron diffraction, and by neutron topography. Figure 1 shows a typical series of neutron rocking curves for different crystal lengths. Plastic deformation techniques are now being studied in order to obtain the desired mosaic spread of 15′ to 30′. The construction of the first beryllium monochromator, using some thirty beryllium crystals, will soon be achieved.

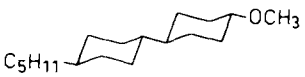
ADVANCED MATERIALS

Liquid Crystals in Variable Friction Devices

Although the first thermotropic liquid crystalline compound was discovered in 1888 by *Reinitzer*, it was not until almost 80 years later that the phenomenon of an ordered fluid found its first application in electrooptical displays. The ability to switch the orientation of molecules between transparent electrodes is nowadays exploited for displays in wrist watches, pocket calculators, data screens and pocket TV's.[1] The anisotropic physical properties of liquid crystalline materials depend on chemical structure and molecular order. Compounds with rod-shaped molecules can form nematic, different types of smectic (A to I), and also cholesteric including the so-called blue phases, depending on the detailed intermolecular interactions. In the course of the rapid developments in the physics and chemistry of liquid crystals in the last 20 years, it appears to have been overlooked that transitions between such phases, or between the isotropic phase and a liquid crystalline phase, have an enormous potential in mechanical engineering applications. These transitions can be brought about by changes of temperature or pressure. At the Hannover Messe Industrie 1988, a water-cooled brake was presented which exploited the drastic change in effective viscosity which accompanies the transition at 29 °C from a nematic to a smectic B phase[2] in *trans,trans*-4-methoxy-4′-pentylbicyclohexane.[3] The rate of conversion of mechanical to thermal energy in such a brake depends on the appropriate heat-transfer coefficients, the thermal conductivities of the materials involved, and the temperature of the coolant.



At the 12th International Liquid Crystals Confererence held in Freiburg, 15–19 August 1988, some measurements of the change of torque in such a device as it changes its function from a plain bearing to an effective brake were reported.[4] Figure 1 shows schematically a lubricated bearing of given clearance tempered with water. The axle is rotated by a motor with constant speed. The torque M in Nm is the momentum of friction transmitted from the axle to the bearing. Figure 2 gives its dependence on the reciproke temperature for compound **1** as lubricant in the region of mixed friction.

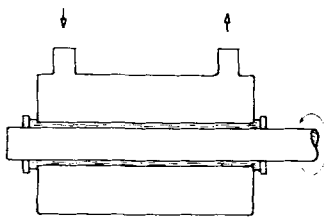


Fig. 1. Scheme of a lubricated axle rotating in a tempered bearing; the form of the lubrication layer corresponds to fully hydrodynamic conditions [5].

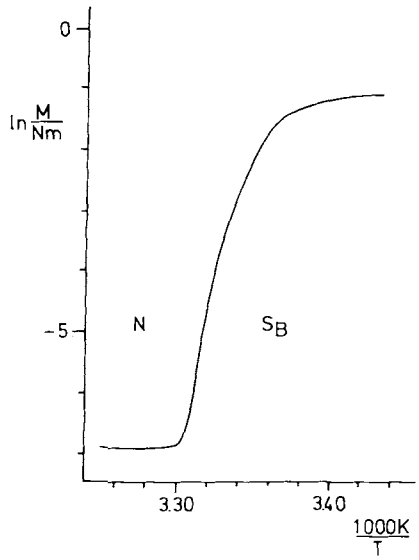

Fig. 2. Plot of the friction moment M transmitted by an axle rotating with constant speed with **1** as lubricant vs. $1/T$; N = nematic, S_B = smectic B phase.

The application of this principle in clutches, valves and hydraulic devices, as well as in bearings in which the effective viscosity of the lubricant can be adjusted to the rotating speed of the axle using two or more Stribeck curves,[5] was also suggested. In this way, "intelligent lubricants" should make it possible to construct bearings with less abrasion and less energy loss. The fast and reversible transition between phases of quite different effective viscosity also suggests new ways of designing mechanical components.

The basis for the understanding of friction in bearings under pure hydrodynamic conditions is given by the Reynold's differential equation. Although this has not been completely solved, the behavior is adequately understood for the case of isotropic lubricants, also including the case of mixed friction.[5] The description of friction in ordered fluids, taking into account the coefficients in the viscosity tensor (5 independent coefficients for the nematic phase, and many more for a smectic phase depending on its symmetry) is a formidable task. The measurements reported demonstrate that the orientation at the surfaces of the materials making up the device has a great influence on the frictional torque.

The phase transition is most easily brought about by changes of temperature. The use of Peltier elements seems to be of particular interest for low power devices. For many types of devices it would be useful to have high viscosities at high temperatures and low viscosities at low temperatures, i.e. the opposite of the usual situation. Leaving aside the possibility in principle of using liquid crystals with re-entrant phases,[6] there is no solution to this problem under isobaric conditions. In these cases phase transitions induced by changes of pressure are a possibility. At constant temperature the more highly ordered phase appears at higher pressure.[7] Thus, changes in effective viscosity can be expected at pressures much lower than those used with transmission fluids and oils, e.g. in gear-transmissions.[8] Unfortunately, kinetic data on transitions between the isotropic phase and a smectic phase, or between a nematic phase and a smectic phase, are not yet available. From isobaric microscopic observations it can be estimated that in compounds such as 4,4'-dialkylbiphenyls the molecular rearrangement will take place within a small fraction of a second at room temperature.

To be applicable in engineering many tribological conditions must be fulfilled. Obviously the compounds tested so far wet metals very well. There are many compounds of low molecular weight that are apparently resistant to hydrolysis and oxidation by air at not too high temperatures. A lucky circumstance is the fact that many stable and relatively easily synthesized compounds have an S_B phase, a highly ordered phase within the smectic layers. The occurrence of such a phase was undesirable in compounds synthesized for electrooptical displays. One can predict that, because of the low molecular weight, the resistance to molecular cleavage by shear forces should be good. The role of cavitation forces in highly stressed layers needs to be investigated by long-term tests. The point to be careful about seems to be the presence of organic impurities in the friction layer, which can cause a shift of the transition temperature.

Conference Reports

Liquid Crystals Centenary

The 12th International Liquid Crystals Conference, held in Freiburg, FRG, on 15-19 August 1988, was attended by over 700 scientists from 31 countries; it is especially noteworthy that these included delegates from the German Democratic Republic and other eastern block countries. The conference, which was sponsored this time by the Deutsche Bunsen-Gesellschaft für Physikalische Chemie, is one of a series that began in 1965 in Kent, Ohio, USA; it is held bienially, the preceding one having been in Berkeley, California. One of the reasons for holding this year's conference in the Federal Republic of Germany is that the discovery of liquid crystals by *Friedrich Reinitzer* took place there 100 years ago. German scientists in Karlsruhe, Freiburg and Halle/Saale became closely involved in further studies of this fourth state of aggregation of matter, whose existence did not at first go unchallenged.

The scientific program of the conference included eight plenary lectures (45 min), 17 invited lectures (30 min), 58 short contributions (15 min), and 420 poster presentations. Apart from the plenary lectures, the meeting was divided into two parallel sessions covering the following main topics:

1. Synthesis and molecular properties (SY)
2. Polymer liquid crystals (PO)
3. Lyotropic liquid crystals (LY)
4. Chiral liquid crystals, blue phases (CH)
5. Ferroelectric liquid crystals (FE)
6. Applications (AP)
7. Surfaces and interfaces (SU)
8. Phase structure and transitions (PH)
9. Molecular dynamics and molecular theory (DY)
10. Instabilities, defects and fluctuations (IN)
11. Nonlinear optics in liquid crystals (NO)

During the course of the twelve conferences held since 1965 the number of scientific contributions has grown in an approximately linear fashion (Fig. 1). The Scientific

ADVANCED MATERIALS

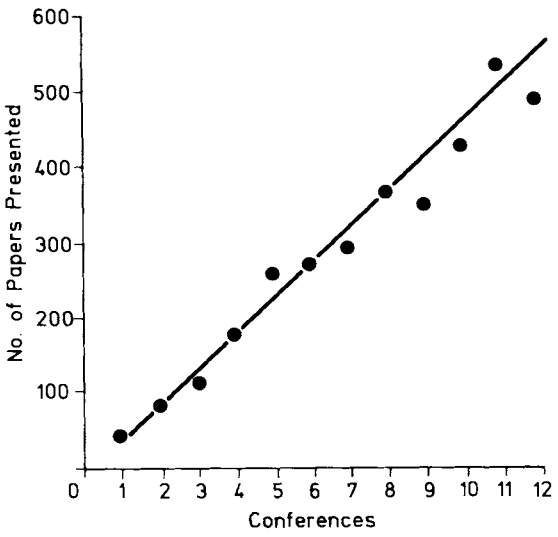

Fig. 1. Total number of papers presented at the International Liquid Crystals Conferences.

Committee of the Freiburg conference applied exacting standards to the papers submitted, and found it necessary to reject about 100 papers to maintain the required high level of scientific quality.

The 100th anniversary of the discovery of liquid crystals was acknowledged in a *historical session* with additional plenary lectures on the history of liquid crystals by *H. Kelker* (Frankfurt) and *H. Sackmann* (Halle/Saale), and in an exhibition entitled "100 Years of Liquid Crystal Research", prepared by *H. Kelker, G. Baur* and *M. Schadt*.

The conference's principal organizers were *G. Meier* of the Fraunhofer-Institut IAF, Freiburg (Conference Chairman), *H. Stegemeyer* of the University of Paderborn (Chairman of the Scientific Committee), *G. Baur* of the Fraunhofer-Institut IAF, Freiburg (Chairman of the Organizing Committee), and *H. Kelker* of the University of Frankfurt/Main (Treasurer).

Session SY was concerned with the synthesis of new types of liquid crystalline materials, and the relationship between molecular structure and physical chemical behavior. The main objective of these investigations is to develop materials with greater "intelligence" for applications in liquid crystal display devices, an area in which there are increasingly stringent demands from applications engineers with regard to switching by electric fields, image resolution, and information storage density. The contributions here emphasized the special importance not only of substances which contain polar and chiral groups and form ferroelectric liquid crystalline phases, but also of classical nematogenic compounds with high multiplexing capability.

Session PO was devoted to the chemistry of *polymer liquid crystals*. The number of groups working in this field and the volume of publications continue to grow, and closer contacts between these groups and those working on low molecular weight liquid crystals proved again very fruitful scientifically at this conference. The upward trend in research on polymer liquid crystals is clearly seen from the large increase in the numbers of papers on this topic over the last five conferences (Fig. 2, ×). While polymers

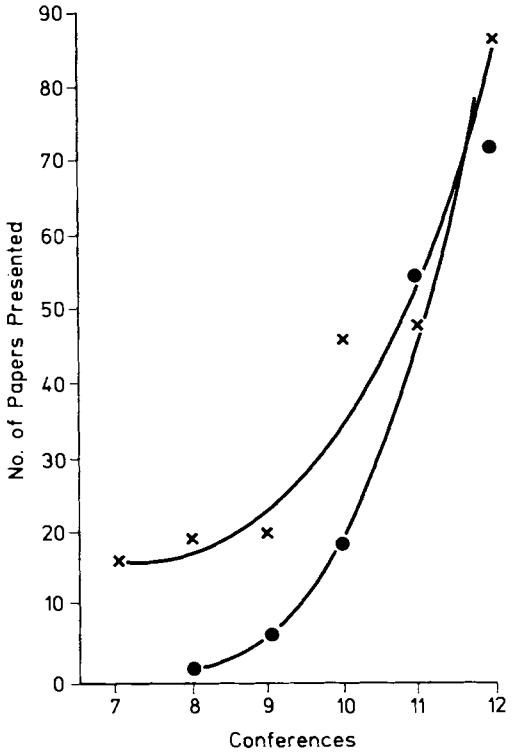

Fig. 2. Number of papers presented on polymer liquid crystals (×) and ferroelectric liquid crystals (●).

with main chain liquid crystalline behavior have for some time had an established place in applications, e.g. in the manufacture of high tensile strength fibers, the prospect of a technical breakthrough for liquid crystalline side chain polymers is only just emerging. The results reported at the conference suggest that we may expect this to occur in the area of thin films made from high molecular weight liquid crystals frozen in a glassy phase, and having special optical and dielectric properties; these could be used as ultra-high density data storage media. Another area where significant progress can be seen is the development of ferroelectric liquid crystalline polymers.

In *Session LY* the Scientific Committe aimed to direct special attention to *lyotropic liquid crystals* as an area with potential for further development. Liquid crystals of this type, which occur especially in aqueous solutions of surface active substances, have been studied with regard to their structures and their relationship to classical liquid crystals. As lyotropic liquid crystals have an important role in biological systems such as membranes and cell tissues, there is increasing research activity on this topic, which deserves a greater input of resources than in the past.

Nearly all the papers in *Session CH* were concerned with the *blue phases* observed in some *cholesterogenic liquid crystals*, perhaps still at present no more than a scientific

curiosity, but now attracting increasing attention, both experimentally and theoretically. Studies are in progress aimed at discovering how nature, starting from disordered systems of optically active molecules, builds up highly ordered cubic lattice structures in phases of extremely high chirality, with the result that one even observes liquid single crystals; studies have been made of the distortion of such single crystals in applied electric fields. These studies have led to the discovery of a number of distinct blue phases that are only stable in the presence of an electric field, and whose structures are in some cases still a subject of controversy.

Session FE was of particular importance, being devoted to the highly topical theme of *ferroelectric liquid crystals*. From the materials standpoint the preparation of these types of liquid crystals had already been covered in Session SY, and this session was therefore concerned mainly with physical processes in an applied electric field. In an electric field these ferroelectric systems can be switched between two stable states, and by suitably immobilizing these on surfaces in thin cells (up to 2 μm) they can be preserved after the field is removed. The switching times in these processes are extremely short, resulting in switching that is several orders of magnitude faster than can be achieved using nematic phases. It may therefore be possible to use these materials to make faster optical information storage devices, which accounts for the enormous interest shown by applications engineers. Because of this overwhelming interest in applications, the physics of dynamic field effects in ferroelectric liquid crystals has unfortunately been rather neglected. The conference illustrated that much basic research still remains to be done in order to elucidate, for example, the detailed mechanism of switching between the bistable states, and how molecular structural features such as chirality and polarity influence the spontaneous polarization. This area of ferroelectric materials is now clearly emerging as an important direction in liquid crystal research, as is evident from Figure 2 (●) which also shows the growth in the numbers of scientific contributions on this theme over the last five conferences.

In *Session AP, applications* were the theme. Improvements in the LC display devices which have now been in common use for some years are aimed at increasing the information storage density,and improving switching times and multiplexing capability. Important developments here are supertwist cells and active matrix displays. Developments in LCD technology now in progress in Japan, making it possible to produce TV screens with a higher information density, were especially impressive.

The papers in *Session SU* dealt with surface and interface effects in liquid crystals. The binding of liquid crystal molecules on surfaces prepared by vapor plating with inorganic materials or coating with amphiphilic monolayers was described. These techniques, and orientation effects on liquid crystals near to interfaces, also attracted much attention from applications engineers, since such processes are very important in the formation of ultrathin LCD films. Liquid crystal structures at free surfaces were also discussed, including the use of nonlinear optical effects to investigate these systems. The theoretical treatment of smectic layer structures consisting of only a few molecular layers requires an entirely new approach in contrast to the bulk behavior.

Session PH was mainly concerned with theories of *phase transitions* between polymorphic liquid crystal phases, and with experimental testing of such theories. The discussions included insights into the detailed topology of smectic layer structures (e.g. sub-types of the classical S_A phase); multicritical behavior and new types of phase structures were also discussed.

In *Session DY* the *dynamic behavior* of liquid crystals was discussed. An interesting aspect of this was the flow properties of liquid crystals, which one needs to know in order to understand the reorientation processes that occur during switching in a field. Molecular dynamics in monomeric, and more especially polymeric, liquid crystals have also been intensively studied; by using nuclear spin methods it has been possible to study the dynamic behavior of individual molecular segments. This has led to a deeper understanding of motional and relaxation processes in the different liquid crystal phases, the earlier considerations based on rigid rod-like molecules having been shown to be insufficiently detailed for this.

The papers in *Session IN* were again of predominantly theoretical interest, being concerned with *instabilities, defects and fluctuations* in liquid crystals. In this case, however, the results based on considerations of electrohydrodynamic instabilities have also turned out to have practical implications, since it is only thus that a deeper understanding of some of the long familiar processes involved in the switching of liquid crystals is now emerging.

Session NO was arranged by the Scientific Committee to allow a discussion of problems in *nonlinear optics* of liquid crystals. This was the smallest of the sessions, with only seven poster contributions, though by no means least in importance. It became evident that more efforts of research groups should be directed to this field. First of all, a number of problems related to the materials must be solved. Nevertheless, the possibility of using liquid crystalline components in integrated optics where nonlinear optical effects are important is now beginning to emerge.

In summary one can conclude from the results reported at this conference that polymeric liquid crystals, lyotropic systems and ferroelectrics are especially important topics for future research, with corresponding implications for applications technology, in some cases with a direct bearing on applications. The conference papers will be published in *Liquid Crystals* 5 early in 1989.

ADVANCED MATERIALS

Synthetic Metals—Coming of Age But Still Controversial

The "International Conference on Science and Technology of Synthetic Metals" (ICSM '88) was held from 26 June to 2 July 1988 in Santa Fe, New Mexico, USA. It was attended by more than 550 physicists, chemists and materials scientists, more than half of whom came from Europe and Japan. There were over 700 contributions—lectures and posters—in four parallel sessions. The conference, organized by *M. Aldissi* from the Los Alamos National Laboratory, was primarily concerned with experimental and theoretical aspects of low dimensional conductors. Since the discovery of the first conducting polymer, more than ten years ago, there has been a growing interest in organic conducting materials. The main purpose of these investigations is the synthesis and study of new materials which combine the electrical properties of semiconductors or metals with the mechanical properties of polymers or other compounds. These have, in addition, the advantage that their properties can be tuned through molecular engineering, leading to well defined chemical structures.

The program of the conference covered the following areas: conducting crystals, conducting polymers, organic and high-T_c superconductors, organic ferromagnets, and materials with nonlinear optical properties. In contrast to the latest three ISCM meetings in Les Arcs (1982), Abano Terme (1984) and Kyoto (1986), the interest was focused on applications of conducting polymers. More than fifty presentations dealt with applications and many participants came from industry; however, only one or two products have been introduced to the market.

The meeting started with three plenary lectures: *V. J. Emery* (Brookheaven National Lab., Upton, USA) talked about the relationship between organic and high-T_c superconductors, and made a critical comparison of the mechanisms of superconductivity in both materials. It was hoped that the knowledge gained recently in the high-T_c ceramics field would help to improve organic superconductors as well. *K. Bechgaard* (Copenhagen, Denmark) reported on new molecular metals based on various heterocyclic donors. *H. Shirakawa* (Univ. of Tsukuba, Japan) chose as his topic polyacetylene with high conductivity (up to 22000 S cm^{-1}), high density and good mechanical strength. He stressed the importance of synthesizing polyacetylene films with very long conjugated segments and highly oriented polymer chains free of chemical defects. This can be achieved by a special treatment of the catalyst such as ageing and solvent evaporation prior to the polymerization process. Unfortunately, the chemical stability toward autoxidation could not be improved.

Three different types of polymers dominated the conducting polymers sessions: polyacetylene, polyaniline and substituted conducting polymers, especially substituted polyheterocycles (polypyrroles and polythiophenes) and poly-*p*-phenylenevinylenes. Substituents improve the solubility and processability of these materials. Nevertheless, a more accurate characterization of the polymers with respect to structural details, molecular weights etc. was not achieved.

Of particular interest in this area were talks dealing with composites or blends of conducting polymers and insulating matrix polymers. Such materials combine the intrinsic conductivity of the polyconjugated system and the mechanical properties of the matrix polymer.

M. F. Rubner (MIT, Cambridge, USA), *S. Tripathy* (Lowell Univ., USA) and *T. A. Skotheim* (Brookhaven National Lab., Upton, USA) presented results on conducting thin films of substituted polypyrroles and polythiophenes, which were made using the Langmuir-Blodgett technique. Such conducting thin films are of interest for developing molecular electronics.

Another polymer which received particular attention was polyaniline. Despite the fact that the conduction mechanism and the exact structure of this polymer are still a matter of controversy, as a large number of contributions proved, the first example of a commercial application of a conducting polymer in energy storage was reported by *T. Nakayima* (Bridgestone Corp., Tokyo, Japan). He described a rechargeable battery, developed in a joint project by Bridgestone and Seiko, which consisted of a polyaniline cathode and a lithium/aluminium alloy anode. Such a battery is used as a back-up power source for integrated circuit memories, or as an energy store for clocks with solar cells. That conducting polymers are promising materials for energy storage was also demonstrated in the subsequent talks by *M. Mizumoto* (Hitachi Ltd, Hitachi-she, Japan), *E. M. Genies* (Centre d'etudes Nucleaires, Grenoble, France) and *L. W. Shacklette* (Allied Signal Inc., Morristown, USA).

Polyacetylene again attracted a lot of interest, particularly because its conductivity has been improved significantly; the value of about 10^5 S cm^{-1} that has recently been reported by *Naarmann* et al. (BASF, Ludwigshafen, FRG) is almost equal to that of copper. Several other authors reported conductivity values of more than 10^4 S cm^{-1} in oxidized and highly oriented samples of polyacetylene [*T. Schimmel* (Univ. of Bayreuth, FRG), *M. Galtier* (Univ. of Montpellier, France); *Y. W. Park* (Seoul National Univ., Korea) and *J. Chiang* (UC Santa Barbara, USA)]. The improvement in the conductivity is achieved by a further development of the Shirakawa technique of acetylene polymerization using different solvent and polymerization conditions. This procedure probably leads to a more uniform catalyst with a smaller number of different

reactive species. Nevertheless, a complete understanding of the structural parameters and nature of the charge carriers and their mobility is still lacking.

An increasing number of contributions—compared with the Kyoto meeting two years ago—dealt with the possibility of using polymers with conjugated backbones in semiconductor devices [*F. Garnier* (Lab. Photochimie Solaire, Thiais, France), *R. H. Friend* (Cavendish Laboratory, Cambridge, UK) and *H. Koezuda* (Mitsubishi Electric Corp., Japan)]. The idea of an all-plastic electronic device constructed from semiconducting polymers is challenging. In these presentations it was shown that such devices work in principle, but up to now either the charge carrier mobility and/or the long term stability of the device is not sufficient compared to conventional inorganic semiconductors.

Next to polymers, the synthesis, structure and theory of superconducting low molecular weight crystals were covered in many contributions. The most promising candidates as organic superconductors are various BEDT-TTF radical salts; the onset of superconductivity has been measured at about 10 K at ambient pressure! Although this temperature is not very high compared to the values of the new high-T_c ceramics, the steady increase in the transition temperature and the more detailed knowledge of the structure encourage further investigations of these new organic materials.

A variety of social events such as receptions and excursions to places of interest near Santa Fe provided a relaxing diversion from the intense scientific program (up to 13 hours per day). The large number of lectures and poster presentations made it difficult to attend contributions in different fields. The shortness of the lectures (15 or 25 minutes plus five minutes for discussion) led to the situation that in some cases the results of one research project were reported in different lectures and poster presentations. It would be better to restrict the number of oral contributions in order to keep track of the progress made in the different fields. For reasons of clarity a combination of longer plenary lectures and short communications would be preferred.

The contributions to the ICSM '88 will be published in "Synthetic Metals" before the end of this year. The next ICSM meeting will be held in 1990 in Tübingen (FRG) and will be organized by *M. Hanack* (Univ. Tübingen, FRG) and *S. Roth* (Max Planck Institute for Solid State Research, Stuttgart, FRG).

Mainz (FRG)

Surface and Colloid Science

The 6th International Conference on Surface and Colloid Science (6-ICSCS) was held on June 5–10, 1988 in Hakone, Japan, organized by the Division of Colloid and Surface Chemistry of the Chemical Society of Japan. Surface and colloid science has made rapid progress in recent years, due to the development of completely new experimental techniques and the industrial needs arising from the introduction of advanced technologies. Studies of amphiphilic substances are being pursued alongside research on organized molecular assemblies in solutions and at interfaces. Rapid progress is being made in investigating solid surfaces using the experimental techniques of high-vacuum physics, leading to many new results related to catalysis and chemical and photochemical reactions at surfaces. Biosurfaces and biocolloids are important research topics in the context of the recent upsurge in biological science. The preparation of fine particles and of concentrated dispersions are important topics in relation both to new industrial applications and to pure research, e.g. the direct measurement of interparticle forces.

Nearly 800 participants from 25 countries throughout the world came together for the 6-ICSCS, and 530 papers and poster presentations made up the five sessions: 1) Organized Molecular Assemblies in Solution, 2) Organized Molecular Assemblies at Interfaces, 3) Solid Surfaces and Catalysis, 4) Biomembranes and Biocolloids, and 5) Fine particles and Dispersed Systems. In addition to exchanging information on fundamental aspects of surface and colloid science and their applications to advanced materials, participants were able to enjoy the beautiful scenery of Mt. Fuji.

Six plenary lectures were presented on the mornings of Monday and Wednesday. In the first of these, *E. Matijević* (Potsdam, NY, USA) discussed "Colloidal Science of Ceramic Powders", pointing out that the properties and processing of ceramic materials are strongly influenced by the nature of the powders from which they are made. With the help of many beautiful electron micrographs he showed that a large number of dispersions can now be obtained with uniform particles, ranging in size from several μm to several nm, in a variety of shapes including spheres, rods, ellipsoids, cubes, platelets, discs, etc.

K. Shinoda (Yokohama, Japan) lectured on "Conceptual Advances in Organized Solutions: a Milestone in the Physical Chemistry of Biological Organization", and described the ideal organized solution.

J. M. Thomas (London, England) gave a lecture entitled "Colloidal Metals: Past, Present and Future", starting from the beautifully colored colloidal gold prepared by *Michael Faraday* in 1856, and incorporating some material from his Christmas Lecture last winter. He reviewed newly developed technologies that can be used to determine the structure of metal colloids, and presented a variety of new results on the structure of colloidal metals, alloys, oxides, etc., and their application to catalysts.

G. A. Somorjai (Berkeley, CA, USA) lectured on "The Molecular Surface Science of Organic Monolayers", focussing on studies of alkanes and arenes adsorbed on flat metal surfaces of low Miller index as models for catalyst surfaces. The studies employed a combination of new surface science techniques including surface crystallography by low energy electron diffraction (LEED), high resolution electron energy loss spectroscopy (HREELS), and scanning tunneling microscopy (STM), as well as second harmonic and sum frequency generation using non-linear laser optics, and scanning atomic force microscopy (AFM).

Other plenary lectures were on "Measurements and Relation between the Static and Dynamic Interaction between Surfaces Separated by Thin Liquid and Polymer Films", by *J. N. Israelachvili* (Santa Barbara, CA, USA) and "Forces between Colloidal Particles and Phase Equilibria", by *H. Wennerström* (Lund, Sweden).

42 invited lectures were also presented. Of these, eight were described as invited general lectures, presenting selected topics from the latest Japanese technology. They were "Mass Spectrometric Analysis of Gas Molecule Adsorption on Solids", by *T. Kurabayashi* et al. (Tohoku University, Sendai), "Advanced Conducting and Superconducting Organic Materials", by *H. Inokuchi* (Institute of Molecular Science, Okazaki), "Chemical and Physical Properties of Oxide Superconductors", by *K. Kitazawa* et al. (University of Tokyo), "Preparation of Monodisperse Particles of Precious Metals and their Applications for Electronics", by *Y. Zeniya* et al. (Tanaka Matthey K. K., Kanagawa), "Preparation of Stable Ultrafine Emulsions", by *H. Nakajima* (Shisheido Co., Yokohama), "New Applications of Polystyrene Sulfonate Dispersant for Coal-Water Mixture and other Uses", by *K. Ohbu* et al. (Lion Corp., Tokyo), "Properties and Applications of Amino-acid-based Surfactants", by *M. Takehara* (Ajinomoto Co., Kawasaki), and "Principles of Production and Stability Assurances of Liposomes", by *S. Hirota* et al. (Daiichi Seiyaku Co., Tokyo).

The success of the conference confirmed the importance of continuous exchange of information. The next international conference is to be held in France in 1991. In association with 6-ICSCS, five pre- and post-conference symposia were held in Japan. These were the Kyushu Symposium on Surfactant Solutions and Interfaces (June 2–3), the Tsukuba Pre-conference Congress on Dispersed Systems and Biocolloids (June 3–4), Fuji Post-conference Symposium on Current Problems and Possibilities for the Future of Organized Molecular Assemblies at Interfaces (June 10–12), Symposium on Solid Surface Phenomena (June 11), and International Symposium on Adsorption (June 13–15). They were also very successful.

Call for Short Communications · Call for Short Communications · Call for Short Communications

ADVANCED MATERIALS from now on welcomes short communications from all over the world, from academia and from industry, from chemists, physicists and materials scientists, provided they are in keeping with the program outlined in the editorial published in May. Authors who are interested in submitting short communications (up to six pages of double-spaced manuscript together with an appropriate number of figures and/or formulas) should prepare their manuscripts in accordance with the "Notice to Authors" of Angewandte Chemie reproduced in the January issue of the journal following the list of contents; upon request, a copy can be obtained from the editorial office:

Conference Calendar

December 1988

7 **Polymers for Life Science Applications**
London (United Kingdom)
Contact: Dr. M. D. Purbrick, Kodak. Ltd. Research Div., Headstone Drive, Harrow, Middlesex HA1 ATY, UK

7-8 **Materials Science and Eng. Towards the 21st Century,**
4th Israel Mater. Eng. Conf.
Beer-Sheva (Israel)
Contact: Peltours-Conventions, The Secretariat, 4th Israel Mater. Eng. Conf., P.O. Box 394, 61003 Tel-Aviv, Israel

7-9 **Ceramics for Environmental Protection,**
1st Int. Symp.
(ENVICERAM '88)
Köln (Fed. Rep. Germany)
Contact: G. von Landsberg, Deutscher Wirtschaftsdienst, Marienburger Straße 22, D-5000 Köln 51, FRG

8-16 **Semiconductor Materials,**
Int. Conf.
New Delhi (India)
Contact: Prof. P. C. Mathur, Univ. of New Delhi, Dept. of Physics, Delhi 110007, India

11-14 **Electron Devices,**
Int. Mtg.
San Francisco (USA)
Contact: M. Widekehr, c/o Courtesy Assoc. Inc., 655 15th St. NW, Suite 3000, Washington, DC 20005, USA

12-17 **Advances in Holography and Speckle Phenomenon and their Industrial Applications,**
Int. Workshop
Madras (India)
Contact: Prof. R. S. Sirohi, Indian Inst. of Technol., Physics Dept., Madras 600036, India

14-16 **SIMCER 7/ZIRCONIA 88**
7th Int. Symp. on Ceramics
Bologna (Italy)
Contact: Centro Ceramico, Via Martelli, 26, I-43138 Bologna, Italy

15-16 **Amorphous and Crystalline Silicon Carbide and Related Materials,**
Int. Conf.
Santa Clara (USA)
Contact: Prof. M. Rahman, Dept. of Electrical Eng. and Computer Sci., Univ. of Santa Clara, Santa Clara, CA 95050, USA

19-21 **Biosensors,**
Winter Mtg.
London (United Kingdom)
Contact: Prof. D. Chapman, Royal Free Hospital, School of Medicine, Rowland Hill St., London NW3, UK

20-22 **Solid State Physics,**
Annu. Conf.
Nottingham (United Kingdom)
Contact: Inst. of Physics, 47 Belgrave Sq., London SW1X 8QX, UK

January 1989

2-7 **Solid State Physics,**
2nd Int. Symp.
Kandy (Sri Lanka)
Contact: The Coordinator, Conf. Div., Inst. of Fundamental Studies, Hantana Rd., Kandy, Sri Lanka

11-13 **Superconductivity Applications,**
2nd. Annu. Int. Convention (SC '89)
San Francisco (USA)
Contact: Superconductor Applications Assoc., 24781 Camino Villa Ave., El Toro, CA 92630, USA

15-18 **Composites and Advanced Ceramics,**
13th Annu. Conf.
Cocoa Beach (USA)
Contact: The American Ceramic Soc., 757 Brooksedge Plaza Dr., Westerville, OH 43081-6136, USA

15-20 **Optics, Electro-Optics, and Laser Applications in Sci. and Eng.,**
Symp. and Exhibition
Los Angeles (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham, WA 98227, USA

23-24 **Commercial Applications of Superconductivity,**
2nd Annu. Cambridge Conf.
Boston (USA)
Contact: World Tech. Press, 1 Kendall Sq., Suite 2200, Cambridge, MA 02139, USA

31-3 **Polymer,**
17th Australian Symp.
Brisbane (Australien)
Contact: Dr. D. J. T. Hill, Chem. Dept., Univ. of Queensland, Brisbane 4067, Australia

31-3 **Sintering of Multiphase Metal and Ceramic Systems**
Int. Conf.
New Delhi (India)
Contact: G. S. Upadhyaya, Convener ICSMC '89, Dept. of Metallurgical Eng., Indian Inst. of Technol., Kanpur 208 016, India

February 1989

2-4 **Nonlinear Guided Wave Phenomena: Physics and Applications,**
Top. Mtg.
Houston (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

5-9 **Biomedical Polymers,**
Int. Symp.
Perth (Australia)
Contact: Secretary, W. A. Polymer Group, Royal Australian Chemical Inst., 125 Hay St., Perth, W. A. 6000, Australia

6-10 **Composites,**
SPI Inst. Annu. Conf.
Dallas (USA)
Contact: Composites Inst., SPI, 355 Lexington Ave., New York, NY 10017, USA

6–9 **Optical Fiber Communication,**
IEEE-LEOS-OSA Conf.
(OFC '89 and IGWO '89)
Houston (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl., NW Washington, DC 20036, USA

7–9 **Physics and Chemistry of Semiconductor Interfaces (PCSI-6)**
Bozeman (USA)
Contact: G. J. Lapeyre, Physics Dept., Montana State Univ., Bozeman, MT 59717, USA

12–15 **High-Resolution Optical Fourier Transform Spectrometry and Noninvasive Assessment of Visual Systems,**
Top. Mtgs.
Santa Fe (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

19–22 **Adhesion,**
12th. Annu. Mtg.
Hilton Head Island (USA)
Contact: D. Hunston, NBS, Polym. Div., Gaithersburg, MD 20899, USA

21–24 **Recent Advances in Drug Delivery**
Salt Lake City (USA)
Contact: K. Knutson, Univ. of Utath, Dept. of Pharmaceutics, CCCD, 421 Wakara Way, Suite 318, Salt Lake City, UT 84108, USA

21–26 **Optical Fibers and their Applications,**
5th Symp.
Warsaw (Poland)
Contact: R. S. Romaniuk, IPI Warsaw Univ. of Technol., Nowowiepska 15–19, PL-00-665, Warsaw, Poland

26–3 **Microlithography,**
Symp. and Exhibition (Micro '89)
Santa Clara (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham, WA 98227, USA

27–1 **Microphysics of Surfaces, Beams and Adsorbates,**
3rd Top. Mtg.
Salt Lake City (USA)
Contact: R. B. Hall, Exxon Research & Eng., Rt. 22E, Annandale, NJ 08801, USA

27–3 **Superconductivity,**
Gordon Conf.
West Coast (USA)
Contact: A. Sleight, E. I. Du Pont de Nemours, Experimental Station 356/301, Wilmington, DE 19898, USA

27–3 **High-Temperature Superconducting Oxides: Processing & Related Properties,**
TMS Annu. Mtg.
Las Vegas (USA)
Contact: M. Karl, The Metallurgical Soc., 420 Commonwealth Drive, Warrendale, PA 15086, USA

March 1989

1–3 **Technical Ceramics,**
2nd Int. Congr. and Exhibition (Techkeram 2)
Wiesbaden (Fed. Rep. Germany)
Contact: Demat Exposition Managing, P.O. Box 110611, D-6000 Frankfurt, FRG

5–10 **Liquid Crystals,**
6th Eur. Winter Conf.
Schladming (Austria)
Contact: P. Laggner, Inst. für Röntgenfeinstrukturforschung of the Austrian Academy of Sci., Steyrergasse 17, A-8010 Graz, Austria

6–8 **Lithium Battery Technology & Applications,**
4th Int. Seminar
Deerfield Beach (USA)
Contact: S. P. Wolsky, Ansum Enterprises Inc., 950 De Soto Rd., Suite 3B, Boca Raton, FL 33432, USA

6–9 **Condensed Matter Division**
9th Gen. Conf.
Nice (France)
Contact: Dr. F. Raymond CNRS-Bât. 3, rue Albert Einstein, F-06560 Valbonne, France

6–9 **Advanced Materials**
MRS Industry-Univ. Conf.
Denver (USA)
Contact: Dr. Fred Smith, Adv. Mater. Inst., Colorado School of Mines, 1500 Illinois, Golden, CO 80401, USA

6–10 **Quantum Wells for Optics and Optoelectronics; Picosecond Electronics and Optoelectronics,**
Top. Mtg.
Salt Lake City (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

8–9 **Molecular Chemistry of Solid-State Electronics**
London (United Kingdom)
Contact: The Royal Society, 6 Carlton House Terrace, London SW 1Y 5AG, UK

9–11 **Makromolekulares Kolloquium**
Freiburg (Fed. Rep. Germany)
Contact: Prof. H. Finkelmann, Inst. für Makromol. Chemie der Univ., Stefan-Meier-Str. 31, D-7800 Freiburg, FRG

11–14 **Surface Finishing '89**
Brighton (United Kingdom)
Contact: Inst. of Metal Finishing, Exeter House, 48 Holloway Head, Birmingham B1 1NQ, UK

12–14 **High-Tech-Materials and Finishing**
Berlin
Contact: Technik + Kommunikation-Verlag GmbH, Ritterfelddamm 82 h + i, D-1000 Berlin 22

12–25 **Diffusion in Materials,**
NATO Adv. Study Inst.
Aussois (France)
Contact: A. L. Laskar, Phys. and Astron. Dept., Clemson Univ., Clemson, SC 29631, USA

13–14 **Regio Macro II**
Basel (Switzerland)
Contact: Prof. M. Mutter, Inst. für Org. Chem., Univ. Basel, St. Johanns-Ring 19, CH-4056 Basel, Switzerland

15–17 **Intelligent Materials,**
Int. Workshop
Ibaraki (Japan)
Contact: T. Kurino, The Soc. of Nontraditional Technol., Toranomon Kotohira-Kaikan Bldg. 3F, 1-2-8 Toranomon, Minato-ku, Tokyo 105, Japan

20-22 **Mechanical Properties of Materials at High Rates of Strain,** 4th Int. Conf.
Oxford (United Kingdom)
Contact: J. Harding, Eng. Sci. Dept., Univ. of Oxford, Parks Rd., Oxford OX1 3PJ, UK

20-22 **Refractory Metals and Silicides**
Eur. Workshop
Houthalen (Belgium)
Contact: R. De Keersmaecker, IMBE, Kapeldreef 75, B-3030 Leuven, Belgium

20-23 **Surface Science,**
Interdisciplinary Conf.
Liverpool (United Kingdom)
Contact: P. Weightman, Liverpool Univ., Oliver Lodge Lab., Oxford St., P.O. Box 147, Liverpool L69 3BX, UK

28-31 **Aluminum-Lithium**
5th Int. Conf.
Williamsburg (USA)
Contact: Al-Li-V, School of Eng. and Applied Sci., Thornton Hall, Univ. of Virginia, Charlottesville, VA 22901, USA

29-31 **Neutron and X-Ray Scattering: Complementary Techniques**
Canterbury (United Kingdom)
Contact: Dr. R. J. Newport, Univ. of Kent, Physics Dept., Canterbury, Kent CT2 7NR, UK

30-31 **Colorado Microelectronics**
Colorado Springs (USA)
Contact: CMC '89 Conf. Secretary, Microelectronics Research Lab., Univ. of Colorado, Colorado Springs, CO 80933-7150, USA

30-10 **Frontiers of Laser Spectroscopy of Gases,**
NATO Adv. Study Inst.
Vimelro (Portugal)
Contact: J. M. Hollas, Dept. of Chemistry, Univ. of Reading, Reading RG6 2AD, UK

30-14 **High-T_c Superconductors,**
Exp. Workshop
Miramare (Italy)
Contact: Int. Ctr. for Theoretical Physics, P.O. Box 586, I-34100 Trieste, Italy

April 1989

1-6 **Superconductivity,**
2nd World Congr.
Houston (USA)
Contact: R. D. Kane, World Congr. on Superconductivity, P.O. Box 27805, Houston, TX 77227-7805, USA

3-5 **Modern Practice in Stress and Vibration Analysis**
Liverpool (United Kingdom)
Contact: Meetings Officer, Inst. of Physics, 47 Belgrave Sq., London SW1X 8QX, UK

3-6 **Low Energy Ion Beams,**
5th Conf.
Guildford (United Kingdom)
Contact: Meeting Officer, Inst. of Physics, 47 Belgrave Sq., London SWIX 8QX, UK

3-7 **Copolymerization and Copolymers in Dispersed Media**
Lyon (France)
Contact: I. Guillot/C. Pichot, Lab. des Materiaux Organiques, BP 24, F-69390 Vernaison, France

3-7 **High Temperature Materials '89**
Gaithersburg (USA)
Contact: J. W. Hastie, National Bureau of Standards, Gaithersburg, MD 20899, USA

6-7 **Modeling in Crystal Growth from the Melt,**
NATO Workshop
Parma (Italy)
Contact: G. Müller, Inst. für Werkstoffwissenschaften 6, Martensstraße 7, D-8520 Erlangen, FRG

10-12 **Bayreuther Polymer Symp.,** (BPS '89)
Bayreuth (Fed. Rep. Germany)
Contact: BPS '89, Lehrstuhl Makromolekulare Chemie II, Univ. Bayreuth, Postfach 101251, D-8580 Bayreuth, FRG

10-13 **Microscopy of Semiconducting Materials,**
MRS 6th Oxford Conf.
Oxford (United Kingdom)
Contact: Administrator, Royal Microscopy Soc., 37/38 St. Clements, Oxford OX4 1AJ, UK

Under the Surface of the Chemical Article**

By Roald Hoffmann*

You open an issue of a modern chemical periodical, say the important German *Angewandte Chemie*[1] or the *Journal of the American Chemical Society*, and what do you see? Riches upon riches: reports of new discoveries, marvelous molecules, unmakeable, unthinkable yesterday—made today, reproducibly, with ease. The chemist reads of the incredible properties of novel high-temperature superconductors, organic ferromagnets, and supercritical solvents. New techniques of measurement, quickly equipped with acronyms—EXAFS, INEPT, COCONOESY—allow you to puzzle out the structure of what you make more expeditiously. Information just *flows*. No matter if it's in German, if it's in English. It's chemistry—communicated, exciting, alive.

Let's, however, take another perspective. To the pages of the same journal turns a humanist, a perceptive, intelligent observer who has grappled with *Shakespeare, Pushkin, Joyce*, and *Paul Celan*. I have in mind a person who is interested in what is being written, and also in how and why it is written. My observer notes in the journal short articles, a page to ten pages in length. She notes an abundance of references, trappings familiar to literary scholars, but perhaps in greater density (number of references per line text) than in scholarly texts in the humanities. She sees a large proportion of the printed page devoted to drawings. Often these seem to be pictures of molecules, yet they are curiously iconic, lacking complete atom designations. The chemist's representations are not isometric projections, nor real perspective drawings, yet they are partially three-dimensional.

My curious observer reads the text, perhaps defocusing from the jargon, perhaps penetrating it with the help of a chemist friend. She notes a ritual form. The first sentences often begin: "The structure, bonding and spectroscopy of molecules of type X have been subjects of intense interest.[a-z]" There is general use of the third person and a passive voice. She finds few overtly expressed personal motivations, and few accounts of historical development. Here and there in the neutered language she glimpses stated claims of achievement or priority—"a novel metabolite", "the first synthesis", "a general strategy", "parameter-free calculations". On studying many papers she finds a mind-deadening similarity. Nevertheless, easy to spot in some of the articles, she also sees style—a distinctive, connected scientific/written/graphic way of looking at the chemical universe.

I want to take a look, now not hiding behind this observer, at the language of my science, as it is expressed in the essential written record, the chemical journal article. I will argue that much more goes on in that article than one imagines at first sight; that what goes on is a kind of dialectical struggle between what a chemist imagines should be said (the paradigm, the normative) and what he or she must say to convince others of his or her argument or achievement. That struggle endows the most innocent-looking article with a lot of suppressed tension. To reveal that tension, I will claim, is not at all a sign of weakness or

[*] Prof. R. Hoffmann
Department of Chemistry, Cornell University
Ithaca, NY 14853 (USA)

[**] This article is derived from the text of a lecture I presented at the Chemiedozententagung in Mainz on March 14, 1988. At a special session of that meeting the 100th anniversary of *Angewandte Chemie* was celebrated.

irrationality, but a recognition of the deep humanity of the creative act in science.

The Scientific Article: A Brief History

There was chemistry before the chemical journal. It was described in books, in pamphlets or broadsides, in letters to secretaries of scientific societies. These societies, for instance the Royal Society in London, chartered in 1662, played a critical role in the dissemination of scientific knowledge. Periodicals published by these societies helped to develop the particular combination of careful measurement and mathematization that shaped the successful new science of the time.[2]

The scientific articles of the period are a curious mixture of personal observation and discussion, with motivation, method, and history often given firsthand. Polemics abound. Cogent arguments for the beginning of a codification of the style of the scientific article in France and England in the 17th century have been given by *Shapin*,[3a] *Dear*,[3b] and *Holmes*.[3c] I think the form of the chemical article rigidified finally in the 1830s and 1840s and that Germany was the scene of the hardening. The formative struggle was between the founders of modern German chemistry—people such as *Justus von Liebig*—and the *Naturphilosophen*. In that particular period the latter group might be represented by *Goethe*'s followers, but their like was present elsewhere in Europe even earlier, in the eighteenth century. The Natural Philosophers had well-formed notions, all-embracing theories, of how Nature should behave, but did not deign to get their hands dirty to find out what Nature actually did. Or they tried to fit Nature to their peculiar philosophical or poetic framework, not caring about what our senses and their extension, our instruments, said. The early 19th century scientific article evolved to counter the pernicious influence of the Natural Philosophers. The ideal report of scientific investigation should deal with the facts (often labeled explicitly or implicitly as truth; more on this later). The facts had to be believable independent of the identity of the person presenting them. It followed that they should be presented unemotionally (so in the third person) and with no prejudgment of structure or causality (therefore the agentless or passive voice).

The fruits of this model reportage were immense. An emphasis on experimental facts stressed the reproducible.

211. Fr. Goldmann: Ueber Derivate des Anthranols.

(Vorgetragen vom Hrn. Professor Liebermann.)

In einer früheren Mittheilung[1]) habe ich über die Einwirkung von Brom auf Anthranol berichtet und ein dabei entstehendes Dibromsubstitutionsproduct als analog dem Anthrachinondichlorid von Thörner und Zincke bezeichnet. Die Bildung des Anthrachinondichlorides war hiernach bei der Einwirkung von Chlor auf Anthranol zu erwarten.

Anthrachinondichlorid, Dichloranthron, $C_6H_4\langle{}^{CO}_{CCl_2}\rangle C_6H_4$

In eine kalte concentrirte Lösung von Anthranol in Chloroform wurde während etwa 20 Minuten trockenes Chlorgas geleitet, wobei die Lösung auf Zimmertemperatur erhalten wurde. Nach beendeter Reaction, bei der reichliche Chlorwasserstoffentwicklung stattfand, wurde das Chloroform auf dem Wasserbade verjagt, der Rückstand mit heissem Ligroïn ausgezogen und das in Lösung gegangene Product aus einer heissen Mischung von Benzol und Ligroïn umkrystallisirt.

Die Substanz wird so in Form von wasserklaren dünnen Prismen erhalten. Dieselben schmelzen bei 132–134°.

Die Verbindung ist in Benzol, Schwefelkohlenstoff, Chloroform sehr leicht, in kaltem Ligroïn oder Aether ziemlich schwer löslich. Aus der Schwefelkohlenstofflösung erhält man die Substanz beim Verdunsten in schönen wasserklaren Krystallen.

	Gefunden		Ber. für $C_{14}H_8OCl_2$
C	64.62	—	64.12 pCt.
H	3.25	—	3.05 »
Cl	—	26.96	26.72 »

Durch Kochen mit Eisessig oder Alkohol wird die Verbindung vollständig in Anthrachinon übergeführt. Die Chloratome müssen daher in der Mittelkohlenstoffgruppe sich befinden. Die Verbindung ist hiernach und nach ihren Eigenschaften mit dem Anthrachinondichlorid, welches Thörner und Zincke[2]) bei der Einwirkung von Chlor auf o-Tolylphenylketon erhielten, indentisch.

[1]) Diese Berichte XX, 2436.
[2]) Diese Berichte X, 1480.

Aus dem Anthranol entsteht sie nach der Gleichung:

$$C_6H_4\langle{}^{C(OH)}_{CH}\rangle C_6H_4 + 2Cl_2 = C_6H_4\langle{}^{CO}_{CCl_2}\rangle C_6H_4 + 2HCl.$$

Hr. Privatdozent Dr. A. Fock hatte die Güte, mir über die Krystallform des aus Schwefelkohlenstoff auskrystallisirten Anthrachinondichlorides Folgendes mitzutheilen:

Die Krystalle sind monosymmetrisch:

$$a : b : c = 0.7973 : 1 : 0.6262.$$
$$\beta = 72^\circ 48'.$$

Beobachtete Formen:

$$m = \infty P (110),\ c = 0 P (001),\ p = -P (111).$$

Die Krystalle bilden schwach gelblich gefärbte dünne Prismen, die Basis tritt nur an einzelnen Individuen und zwar ganz untergeordnet auf.

	Beob.	Berechnet
$m : m = 110 : \bar{1}10$	$= 74^\circ 36'$	—
$m : c = 110 : 001$	$= 76^\circ 24'$	—
$p : c = 111 : 001$	$= 37^\circ 54'$	—
$p : p = 111 : \bar{1}11$	$= 45^\circ 30'$	$45^\circ 2'$
$p : m = 111 : 110$	$= 38^\circ 38'$	$38^\circ 30'$
$p : m = 111 : \bar{1}10$	$=$ —	$71^\circ 25'$

Spaltbarkeit nicht beobachtet.

Auch das analoge Anthrachinondibromid hat Hr. Dr. Fock zu messen die Güte gehabt, wobei er folgende Resultate erhielt:

Die Krystalle sind monosymmetrisch:

$$a : b : c = 1.5009 : 1 : 1.4708.$$
$$\beta = 70^\circ 43'.$$

Beobachtete Formen:

$$c = 0 P (001),\ p = -P (111),\ o = +P (\bar{1}11),$$
$$q = {}^1/_2 \breve{P}\infty (012),\ w = +2\breve{P}2 (\bar{1}21).$$

Schwach gelblich gefärbte Krystalle von 1—4 mm Grösse und recht verschiedenartiger Ausbildung. Meistens herrschen die Flächen der vorderen Pyramide p und der Basis vor, während die übrigen nur ganz untergeordnet ausgebildet sind. Bisweilen sind die Flächen der Pyramide w grösser ausgebildet und zwar theilweise nur einseitig, so dass die Krystalle eine ganz verzerrte Ausbildung erhalten.

Fig. 1. The first two pages of a typical article from 1888 [4].

The conciseness of the German language seemed ideally suited to the developing paradigm. Cadres of chemists were trained. The development of the dyestuff industry that followed in England and Germany is a particularly well studied manifestation of the industrial application of the new, organized chemistry.

The scientific article acquired in this period a canonical or ritual form. In Figure 1, I reproduce part of a typical article of that period.[4,5] Note most of the features of a modern article—references, experimental part, discussion, diagrams. All that's lacking is the acknowledgment thanking the Deutsche Forschungsgemeinschaft or the National Science Foundation.

In Figure 2, a contemporary article, we approach the present. This particular contribution, an important one by *O. J. Scherer* and *T. Brück*[6] reports a remarkable ferrocene-type system in which one cyclopentadienyl ring has been replaced by P_5. The work is novel and significant, but I want to focus on the mode of presentation rather than the content. How does this article differ from one published a hundred years ago? The dominant language has changed, for interesting geopolitical reasons, to English.[7] Yet it seems to me that there is not much change in the construction or tone of the chemical article. Oh, marvelous, totally new things are reported. Measurements that took a lifetime are made in a millisecond. Molecules unthinkable a cen-

[(η^5-P_5)Fe(η^5-C_5Me_5)], a Pentaphosphaferrocene Derivative**

By *Otto J. Scherer** and *Thomas Brück*

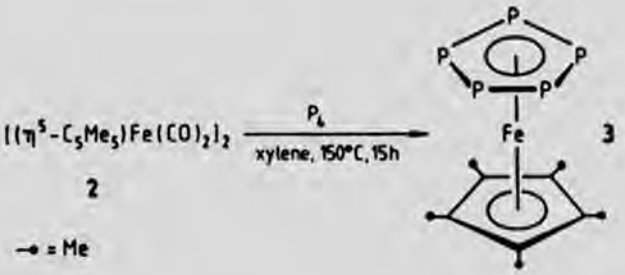
After having demonstrated that *cyclo*-P_5 could be stabilized as bridging ligand in the mixed-valence triple-decker complex **1**,[1] we then attempted to realize the classical

[(η^5-C_5Me_5)Cr(μ,η^5-P_5)Cr(η^5-C_5Me_5)]

1

sandwich coordination of this ligand (cyclo-$P_5^\ominus$ as 6π electron donor). Success was achieved upon cothermolysis of **2** with white phosphorus.

Pentamethylpentaphosphaferrocene **3** forms sublimable, green crystals which can be handled in the presence of air and which begin to melt (with partial sublimation and slight decomposition) at 270°C when heated in a sealed tube. **3** is very soluble in dichloromethane, readily soluble in benzene and toluene, and moderately soluble in pentane.



In the ^{1}H-NMR spectrum (200 MHz, 293 K, C_6D_6, TMS int.) of **3** a sharp singlet is observed at $\delta = 1.08$ which is shifted 0.6 ppm upfield compared to that of decamethylferrocene [(η^5-C_5Me_5)$_2$Fe] **4**.[3] In comparison to the ^{13}C{^{1}H}-NMR signals of **4**,[2,3] those of **3**[2] are shifted slightly downfield. The ^{31}P{^{1}H}-NMR signal shows a continuous downfield shift within the series triple-decker **1** ($\delta = -290.5$[1]), monophosphaferrocene [(η^5-C_5H_5)Fe(η^5-PC_4H_4)] **5** ($\delta = -67.5$[4]), **3** (81.01 MHz, C_6D_6, 85% H_3PO_4 ext., $\delta = 153.0$ (s)), and Li(P_5) ($\delta = 470$[5]). In the mass spectrum,[2] the most intense peak is the molecular peak of **3**, followed by the peak for $M^\oplus - P_2$. So far, all attempts to prepare a single crystal suitable enough for an X-ray structure analysis have failed, both by sublimation as well as recrystallization. *cyclo*-$P_5^\ominus$ is probably formed from $P_3^\ominus$ and P_2.[6]

Experimental

A mixture of **2** [7] (980 mg, 2.3 mmol) and P_4 (1500 mg, 12.1 mmol) in xylene (80 mL) was stirred under reflux for 15 h and the insoluble material removed by filtration on a D3 frit and extracted three times with 80 mL each of CH_2Cl_2 (393 mg of residue after drying under high vacuum). The solvent was removed from the combined extracts under oil-pump vacuum. After three extractions with 50 mL each of pentane there remained 726 mg of a brown solid whose composition could not be unequivocally established. After removal of the solvent from the green extracts (oil-pump vacuum), the residue remaining behind was sublimed. At 60°C/0.01 torr, excess phosphorus was removed; between 90° and 110°C, green needles sublimed on the wall of the glass vessel. Recrystallization from pentane furnished 175 mg of **3** (yield 11%). Correct elemental analysis.

Fig. 2. A contemporary article [6].

tury ago are easily made, in a flash revealing their identity to knowledgeable us. All communicated, with better graphics and computer typesetting, in a flashier journal, printed probably on poorer paper. But essentially in the same form. Is that good, is that bad?

Well, I think both. The periodical-article system of transmitting knowledge has worked remarkably well for two centuries or more. But I think there are real dangers (to which I will return) implicit in its current canonical form. My primary concern is what is really going on in the writing and reading of a scientific article, which is much more than just communication of facts. To set the stage for a discussion of the journal article, I need to say something about what I think science, chemistry in particular, is.

A Personal View of Chemistry

No one else's than my own, and others will see it in a different way:[8]

1. Science is the acquisition of knowledge about the world

That sense is clear in the etymology of the English word, or in the German *Wissenschaft* or *Naturwissenschaft*. Note that "truth" doesn't enter explicitly into that etymology. To be sure, reproducibility, verifiability, reliability, which are essential to any scientific enterprise, depend on *honest* measurement. Scientists would like to think that they acquire truth (morally and ethically valued) and not just knowledge (quite neutral; recall the tree of knowledge of good and evil in Genesis). But I would warn my colleagues that to purvey to the world at large the image of scientists as seekers of truth, rather than reliable knowledge,[9] is dangerous. It makes us out as priests, with the attendant hazards. I suspect much of the exaggerated interest of the public in the rare cases of fraud in science bears some similarity to the prurient interest of the world at large in the moral failings of priests and ministers. I think we gain knowledge, and do that as truthfully as possible.

2. Science is part discovery, part creation

I take discovery in the sense of revealing some perhaps obscured laws of nature, creation in the sense of making new things. In describing their work most scientists will stress the discovery metaphor, while most artists will emphasize creation. Well, I think much of what we do in science is creation. Especially so in chemisty. The synthesis of molecules not present on earth before is clear evidence of this. Synthesis is a marvelous congeries of discovery and creation that brings chemistry close to the arts—and to engineering.[10]

3. Science is done by human beings and their tools

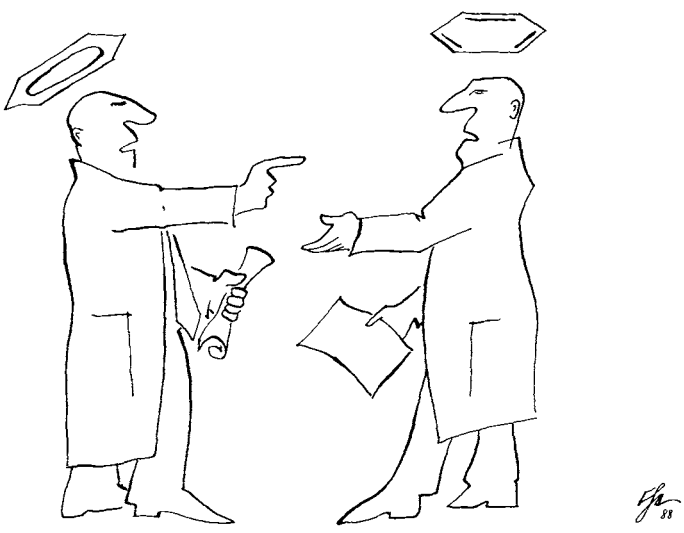
Which means that it is done by fallible human beings. The driving forces for acquiring knowledge are, to be sure, curiosity and altruism, rational motives. But creation is just as surely rooted in the irrational, in the dark, murky waters of the psyche, where fears, power, sex, childhood traumas swim in all their hidden, mysterious movements. And spur us on. To follow *Pushkin*'s *Mozart and Salieri* or its modern reincarnation in *Peter Shaffer*'s play *Amadeus* and the movie based on it: Angelic music (read chemistry) is brought into this world by such crass vessels. Not only do character and deep-down motivations not matter—their "unsavory" side may well be the driving force of the creative act.

4. Science proceeds in part by the rules

The modern model of the scientific method, associated in this century perhaps with the name of *Karl Popper*, begins with measurable, reproducible observations. One then forms alternative hypotheses or models, explaining these observations. Finally, with the aid of further experiments or reliable theory, the hypotheses are culled, eliminated one by one, until the one most likely to be right remains. Sometimes it works this way,[11] though rather interestingly this happens mostly with everyday and not ground-breaking science. But does the model apply to a modern synthesis of an unnatural molecule, for instance dodecahedrane, a beautiful $C_{20}H_{20}$ molecule shaped like its name? Or the development of the technique of nuclear magnetic resonance, equally useful to chemists seeking the arrangement of atoms in space and to a physician looking for a brain tumor?

5. Science depends on argument

"Argument" has several meanings—it could be taken as a simple process of reasoning, a statement of fact; the word also may mean disagreement, the confrontation of opposites. I would argue that both senses are essential to science: dispassionate logical reasoning *and* impassioned conviction that one (model, theory, measurement) is right and another is wrong. I feel that scientific creativity is rooted in the inner tension, within one and the same person, of knowing that he or she is right and knowing that



that conviction has to be proven to others' satisfaction. By a journal article.

6. *As a system, science works*

Individual scientists struggle to acquire knowledge, and in their struggle they are driven by many complex motivations. Because researchers are human, they are subject not only to inaccuracy, but sometimes prejudice. Remarkably, the error and prejudice of individual chemists does not matter to the progress of chemistry. Chemistry as a science, the collective activity of the half-million people in the world who are chemists, advances despite mistakes by individual chemists.[12] The science has self-correcting features in abundance: the most important one is that the more interesting the observation or theory, the more likely it is to be checked by someone else. Often for entirely the "wrong" reasons—driven by plain disbelief arising from the conviction that the initial observation must be wrong. It doesn't matter why an individual chemist repeats a critical synthesis, or tries an alternative theory. Chemistry progresses.

And yet, that a chemist *try* to prove someone else's mechanism wrong, or to make a molecule first, does matter. For without the human impulse nothing would get accomplished. It's a curious creation, this science of ours—an incredibly sturdy, exciting, and useful system of knowledge built by imperfect people, and depending for progress on their imperfection.

7. *Chemistry is the science of molecules*

Need I say more? There are limitations to the definition, but molecules, from diatomics to carbonic anhydrase and $YBa_2Cu_3O_{7-x}$ are our business. They're also big business—there are 10^{11} kilograms of sulfuric acid made per year around the world, and more pounds of ammonia than there are human beings.

8. *Chemistry is not reducible to physics*

Reductionism is something we've been saddled with for two centures. By the term I mean the setting up of a hierarchical ordering of the sciences: social sciences, biology, chemistry, physics, and a corollary definition of understanding in one science as a reduction to the next, deeper level.[13] My feeling is that scientists buy this as an ideology, but it does not represent the reality of productive work in any science, and the idea is dangerous. I'll come back to the dangers later. What I think happens in reality is that from every activity of human beings there evolves a set of objects, questions and concepts. We might call these categories. Understanding may be defined vertically, in a reductionist way, but also horizontally, in terms of the concepts and questions of that science. Most of the useful concepts of chemistry (for the chemist: aromaticity, the concept of a functional group, steric effects, and strain) are imprecise. When reduced to physics they tend to disappear.[14] But with them marvelous chemistry has been—is—wrought.

What Really Goes on in a Chemical Paper

One could proceed and list other points of view on science and chemistry, but for me these suffice to begin a discussion of the chemical article and what transpires in it.

On the face of it the article purports to be a communication of facts, perhaps a discussion, always dispassionate and rational, of alternative mechanisms or theories, and a more or less convincing choice between them. Or the demonstration of a new measurement technique, a new theory. And, remarkably, the article works. An experimental procedure detailed in *Angewandte Chemie* in German or English can be reproduced (actually how easily it can be reproduced is another story[15]) by someone with a rudimentary knowledge of either language, working in Okazaki or Krasnoyarsk. This underlying feature of potential or real reproducibility is to me the ultimate proof that science is reliable knowledge.[16]

But in so many ways there is more than meets the eye in the scientific article. I see in it the following themes, many of which are also described and analyzed in a much deeper way in a remarkable forthcoming book by *David Locke, Science as Writing*.[17]

Art

The chemical article is an artistic creation. Let me expand on what might be viewed as a radical exaggeration. What is art? Many things to many people. One aspect of art is aesthetic, another that it engenders an emotional response. In still another attempt to frame an elusive definition of that life-enhancing human activity, I will say that art is the seeking of the essence of some aspect of nature or of some emotion, by a human being. Art is constructed, human and patently unnatural.

What is written in a scientific periodical is not a true and faithful representation (if such a thing were possible) of what transpired. It is not a laboratory notebook, and one knows that that notebook in turn is only a partially reliable guide to what took place. It is a more or less (one wishes more) carefully constructed, man- or woman-made *text*. Most of the obstacles that were in the way of the synthesis or the building of the spectrometer have been excised from the text. Those that remain serve the rhetorical purpose (no weaker just because it's suppressed) of making us think better of the author. The obstacles that are overcome highlight the success story.

The chemical article is a man-made, constructed abstraction of a chemical activity. If one is lucky, it creates an emotional or aesthetic response in its readers.

Is there something to be ashamed of in acknowledging that our communications are not perfect mirrors, but in substantial part literary texts? I don't think so. In fact, I think that there is something exquisitely beautiful about our texts. These "messages that abandon", to paraphrase *Jacques Derrida*,[18] indeed leave us, are flown to careful readers in every country in the world. There they are read, in their original language, and understood; there they give pleasure *and*, at the same time, they can be turned into

chemical reactions, real new things. It would be incredible, were it not happening thousands of times each day.

History

One of the oft cited distinguishing features of science, relative to the arts, is the more overt sense of chronology in science. It is made explicit in the copious use of references. But is it real history, or a prettified version?

A leading chemical style guide of my time admonished: "... one approach which is to be avoided is narration of the whole chronology of work on a problem. The full story of a research may include an initial wrong guess, a false clue, a misinterpretation of directions, a fortuitous circumstance; such details possibly may have entertainment value in a talk on the research, but they are probably out of place in a formal paper. A paper should present, as directly as possible, the objective of the work, the results, and the conclusions; the chance happenings along the way are of little consequence in the permanent record."[19]

I am in favor of conciseness, an economy of statement. But the advice of this style guide, if followed, leads to real crimes against the humanity of the scientist. In order to present a sanitized, paradigmatic account of a chemical study, one suppresses many of the truly creative acts. Among these are the "fortuitous circumstance"—all of the elements of serendipity, of creative intuition at work.[20]

Taken in another way, the above prescription for good scientific style demonstrates very clearly that the chemical article is *not* a true representation of what transpired or was learned, but a constructed text.

Language

Scientists think that what they say is not influenced by the language they use, meaning both the national language (German, French, Chinese) and the words within that language. They think that the words employed, providing they're well-defined, are just representations of an underlying material reality which they, the scientists, have discovered or mathematicized. Because the words are faithful representations of that reality they should be perfectly translatable, into any language.

That position *is* defensible—as soon as the synthesis of the new high-temperature superconductor $YBa_2Cu_3O_{7-x}$ was described, it *was* reproduced, in a hundred laboratories around the globe.

But the real situation is more complex. In another sense words are all we have. And the words we have, in any language, are ill-defined, ambiguous. A dictionary is a deeply circular device—just try and see how quickly a chain of definitions closes upon itself. Reasoning and argument, so essential to communication in science, proceed in words. The more contentious the argument, the simpler and more charged the words.[21]

How does a chemist get out of this? Perhaps by realizing what some of our colleagues in linguistics and literary criticism learned over the last century.[22] The word is a sign, a piece of code. It signifies something, to be sure, but what it signifies must be decoded or interpreted by the reader. If two readers have different decoding mechanisms, then they will get different readings, different meanings. The reason that chemistry works around the world, so that BASF can build a plant in Germany or Brazil and expect it to work, is that chemists have in their education been taught the same set of signs.

I think this accounts in part for what *Carl Friedrich von Weizsäcker* noted in a perceptive article on "The Language of Physics":[23] If one examines a physics (read chemistry) research lecture in detail one finds it to be full of imprecise statements, incomplete sentences, halts, etc. The seminar is usually given extemporaneously, without notes, whereas humanists most often read a text verbatim. The language of physics or chemistry lectures is often imprecise. Yet chemists understand those presentations (well, at least some do). The reason is that the science lecturer invokes a code, a shared set of common knowledge. He or she doesn't have to complete a sentence—most everyone knows what is meant halfway through that sentence.

Graphics

The semiotics of chemistry is most apparent in the structures of molecules that grace most every page of a chemical journal, that identify at a glance a paper as chemical.[24,25] The given, just over a century old, is that the structure of a molecule matters. It's not only what the atomic constituents are. It's also how the component atoms are connected up, how they are arranged in three-dimensional space, and how easily they move from their preferred equilibrium positions. The structure of a molecule, by which I mean the disposition in space of nuclei and electrons, both the static equilibrium structure and its dynamics, determines every physical, chemical, and ultimately biological property of the molecule.

It is crucial for chemists to communicate three-dimensional structural information to each other. The media for that communication are two-dimensional—a sheet of paper, a screen. So one immediately encounters the problem of representation.

Actually that problem is already there. What is a ball-and-stick model of a molecule? Is that reality? Of course not. The model is just one representation of the equilibrium positions of the nuclei, with some further assumptions about bonding. An instructive videotape from the laboratory of *F. P. Brooks, Jr.* at the University of North Carolina is entitled "What Does a Protein Look Like?" It shows 40 different representations (recalling to my mind the woodcut suite of *Hokusai* entitled "36 Views of Mt. Fuji") of one and the same enzyme, superoxide dismutase—a "ball-and-stick" model, a "space-filling" model, the electrostatic field experienced by a probe charge near the molecule, and so on.[26]

Let me return to the communication problem. Chemists are impelled to communicate three-dimensional information in two dimensions. But they're not *talented* at that. Young people are not selected or select themselves to be chemists on the basis of their artistic ability.

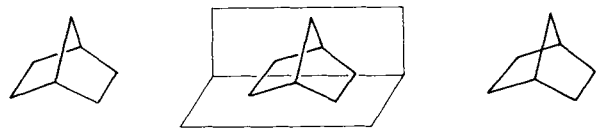
So people are required to do what they're not talented at. That's one definition of life! Chemists cope, by the expedient of inventing a code for communicating three-di-

mensional structure. *And* they train people in that code. The various elements of that code are known to chemists as Fischer or Newman projections, or as the wedge-dash representation. A molecule of ethane, C_2H_6, is represented in two possible geometries, **1** and **2**.

1 **2**

Note another piece of code: carbon is that vertex of the graph which has four lines to it, but it's not labeled C. There are hydrogens at the ends of the lines. They're also not labeled. The notation is simple: a solid line is in the plane of the paper, a wedge in front, a dashed line in back. Saying that may be enough to make these structures rise from the page for some people, but the neural networks that control representation are effectively etched in, for life, when one handles (in human hands, not in a computer) a ball-and-stick model of the molecule while looking at this picture.

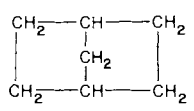
It's fascinating to see the chemical structures floating on the page of every journal and to realize that from such minimal information people can actually *see* molecules in their mind's eyes. The clues to three-dimensionality are minimal. The molecules do float, and you're usually discouraged from putting in a reference set of planes to help you see them (**3** vs. **4**).



3 **4** **5**

Some chemists rely so much on the code that they don't draw **3** but **5**. What's the difference? One line "crossed" instead of "broken". What a trivial clue to three-dimensional reconstruction, that one part of a molecule is behind another one, is given in **3**, absent in **5**! The person who draws **5** is making many assumptions about his audience. I bet he or she hardly thinks about that.

The policies of journals, their economic limitations, and the available technology put constraints not only on what is printed but also on how we *think* about molecules. Take norbornane, C_7H_{12}, molecule **3**. Until about 1950 no journal in the world was prepared to typeset this structure as **3**. Instead you saw it in the journal as **6**. Now everyone



6

knew, since 1874, that carbon was tetrahedral, meaning that the four bonds to it were formed along the four directions radiating out from the center of a tetrahedron to its vertices. You can see this geometry in the two carbon atoms of structures **1** and **2**. Molecular models were available or could be relatively easily built. Yet I suspect that the image or icon of norbornane that a typical chemist had in his mind around 1925 was **6** and not **3**. He was conditioned by what he saw in a journal or textbook—an image. He was moved to act, in synthesizing a derivative of this molecule, for instance, by that unrealistic image.

Maybe it's not that different from the way we approach romance in our lives, equipped with a piecewise reliable set of images from novels and movies.

Style

Every manual of scientific writing I've seen exhorts you to use an impersonal, agentless, superrational style. Please give us the facts, gentlemen, and just the facts! Still style rears its head.

My papers are recognizable in a journal just by the proportion of the space given to graphical material, or the way I "line" my orbitals. *R. B. Woodward*'s papers were recognizable in the (constructed) elegance of their scientific storyline, and in the matching elegance, the cadence of his words. I can read a paper by *Jack Dunitz*, by *Rolf Huisgen*, *Rudolf Hoppe*, or *Bill Doering* and hear their voices in these papers just as surely as I hear the voice of *A. R. Ammons*, a great American poet, or of *Bertolt Brecht*, a German one, when I see their work on a printed page.

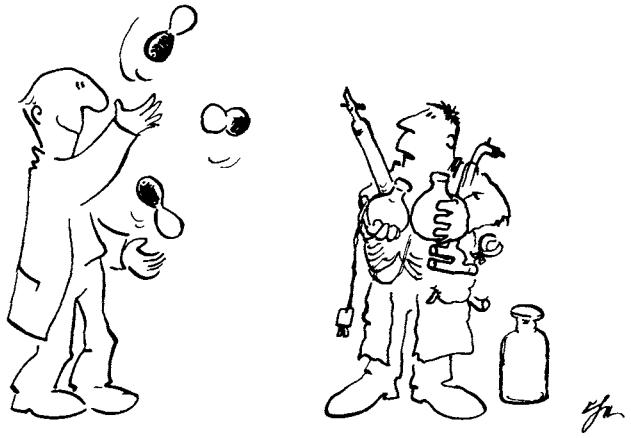
It is in the nature of creative human beings to have a style. Why should I write my theory the way *Bill Goddard*, a theorist I admire, does, anymore than you expect *Karlheinz Stockhausen* and *Pierre Boulez* to write piano pieces that sound alike?

Dialectical Struggles

A nice, even-toned, scientific article may hide strong emotional undercurrents, rhetorical maneuvering, and claims of power. One has already been mentioned—the desire to convince, to scream "I'm right, all of you are wrong", clashing with the established rules of civility supposedly governing scholarly behavior. Where this balance is struck depends on the individual.

Another dialogue that is unvoiced is between experiment and theory. There is nothing special about the love-hate relationship between experimentalists and theorists in chemisty. You can substitute "writer" and "critic" and talk about literature, or find the analogous characteristics in economics. The lines of the relationship are easily caricatured—experimentalists think theorists are unrealistic, build castles in the sky. Yet they need the frameworks of understanding that theorists provide. Theorists may distrust experiments, wish that people would do that missing experiment, but where would the theorists be without any contact with reality?

An amusing manifestation of the feelings about this issue is to be found in the occasionally extended quasi-theoretical discussion sections of experimental papers. These



sections in part contain a true search for understanding, but in part what goes on in them is an attempt to use the accepted reductionist ideal (with its exaggerated hailing of the more mathematical)—so as to impress one's colleagues. On the other side, I often put more references to experimental work in my theoretical papers than I should, because I'm trying to "buy credibility time" from my experimental audience. If I show experimental chemists that I know of their work, perhaps they'll give me a little time, listen to my wild speculations.

Another struggle, related, is between pure and applied chemistry. It's interesting to reflect that this separation also may have had its roots in Germany in the mid-nineteenth century; it seems to this observer that in the other chemical power of that time, Britain, the distinction was less congealed. Quite typical in a pure chemical paper is a reaching out after some justification in terms of industrial use. But at the same time there is a falling back, an unwillingness to deal with the often unruly, tremendously complicated world of, say, industrial catalysis. And in industrial settings there is a reaching after academic credentials (quite typical, for instance, of the leaders of chemical industry in Germany).

The Id Will Out

I use the subject word in the psychoanalytical sense, referring to the complex of instinctive desires and terrors that inhabit the collective unconscious. On one hand, these irrational impulses, sex and aggression figuring most prominently, are our dark side. On the other hand, they provide the motive force for creative activity.[27]

The irrational seems to be effectively suppressed in the written scientific word. But of course scientists are human, no matter how much they might pretend in their articles that they are not. Their inner illogical forces push out. Where? If you don't allow them in the light of day, on the printed page, then they will creep out or explode in the night, where things are hidden, and no one can see how nasty you are. I refer, of course, to the anonymous refereeing process, and the incredible irrational responses unleashed in it by perfectly good and otherwise rational scientists. You have to let go sometime ...

I actually think that what saves the chemical article from dullness is that its language comes under stress. We are trying to communicate things that perhaps cannot be expressed in words but require other signs—structures, equations, graphs. And we are trying hard to eliminate emotion from what we say. Which is impossible. So the words we use occasionally become supercharged with the tension of everything that's *not* being said.

. . .

So, many things go on in a scientific article. I will spare you the charts that I've seen hanging in many laboratories, that translate shop-worn phrases into what they really mean. Like "A regime of slow cooling over a period of four weeks produced a 90% yield of black crystals of...", meaning "I went on vacation and forgot to wash out the flask. When I came back ..." And so on.

I want to return to the complexity of deciding what is truth in the scientific process. In a recent article, *Harald Weinrich*[28] describes the classic paper of *Watson* and *Crick* on the structure of DNA in *Nature* in 1953. It is succinct, beautifully reasoned, elegant. *David Locke,* in his book, analyzes the rhetorical structure and the use of irony in the same paper.[17] I think most readers were immediately convinced that the Watson and Crick model was the truth, that this was the way it had to be. And so it is (with some minor variation on hydrogen-bonding schemes in unusual forms of DNA). The Watson and Crick model was and is right. One needs little more.

But then in 1968 *Watson* writes a book, *The Double Helix,* in which he tells the story of how it really happened. Of course, it's a self-centered story, and not kind or fair to *Rosalind Franklin* and others. *Watson*'s story is much like one of the four views of an event in *Akira Kurosawa*'s masterful film *Rashomon.* It needs other views, which some historians have provided. But there is no question that *Watson*'s account is vibrant, full of life. It tells us how he saw the truth, and I think it's a great book.

So (and here I follow *Weinrich*) what *is* the truth: Is it the 1953 paper of *Watson* and *Crick*, or is it the 1968 book by *Watson*? Does the latter diminish the former? It bears reflection.

What Is to Be Done?

I have tried to deconstruct, to borrow some language from critical theory, the scientific article, ossified in its present form for over a hundred years. I think I could have done this better with a specific text before me, but then I would have run the danger of libel suits or loss of friendship. And it is in the nature of human beings to be unable to criticize, truly, deeply, their own work. So I can't do it to myself. But I'm sure every chemist knows some superb example of what I allude to, especially in the work of one of his less favorite scientists.

The deconstruction is done by me not with malice, but with care. I love this molecular science. I love its richness, and the underlying simplicity, but most of all the rich, life-giving variety and connection of all of chemistry. Let me give you an example in Figure 3. I see C_2 in a carbon arc and in the tail of Halley's Comet.[29a] I see it in acetylene, ethylene, and ethane. I see it in the lovely molecular complexes of *P. Wolczanski,*[29b] *M. I. Bruce,*[29c] and *G. Lon-*

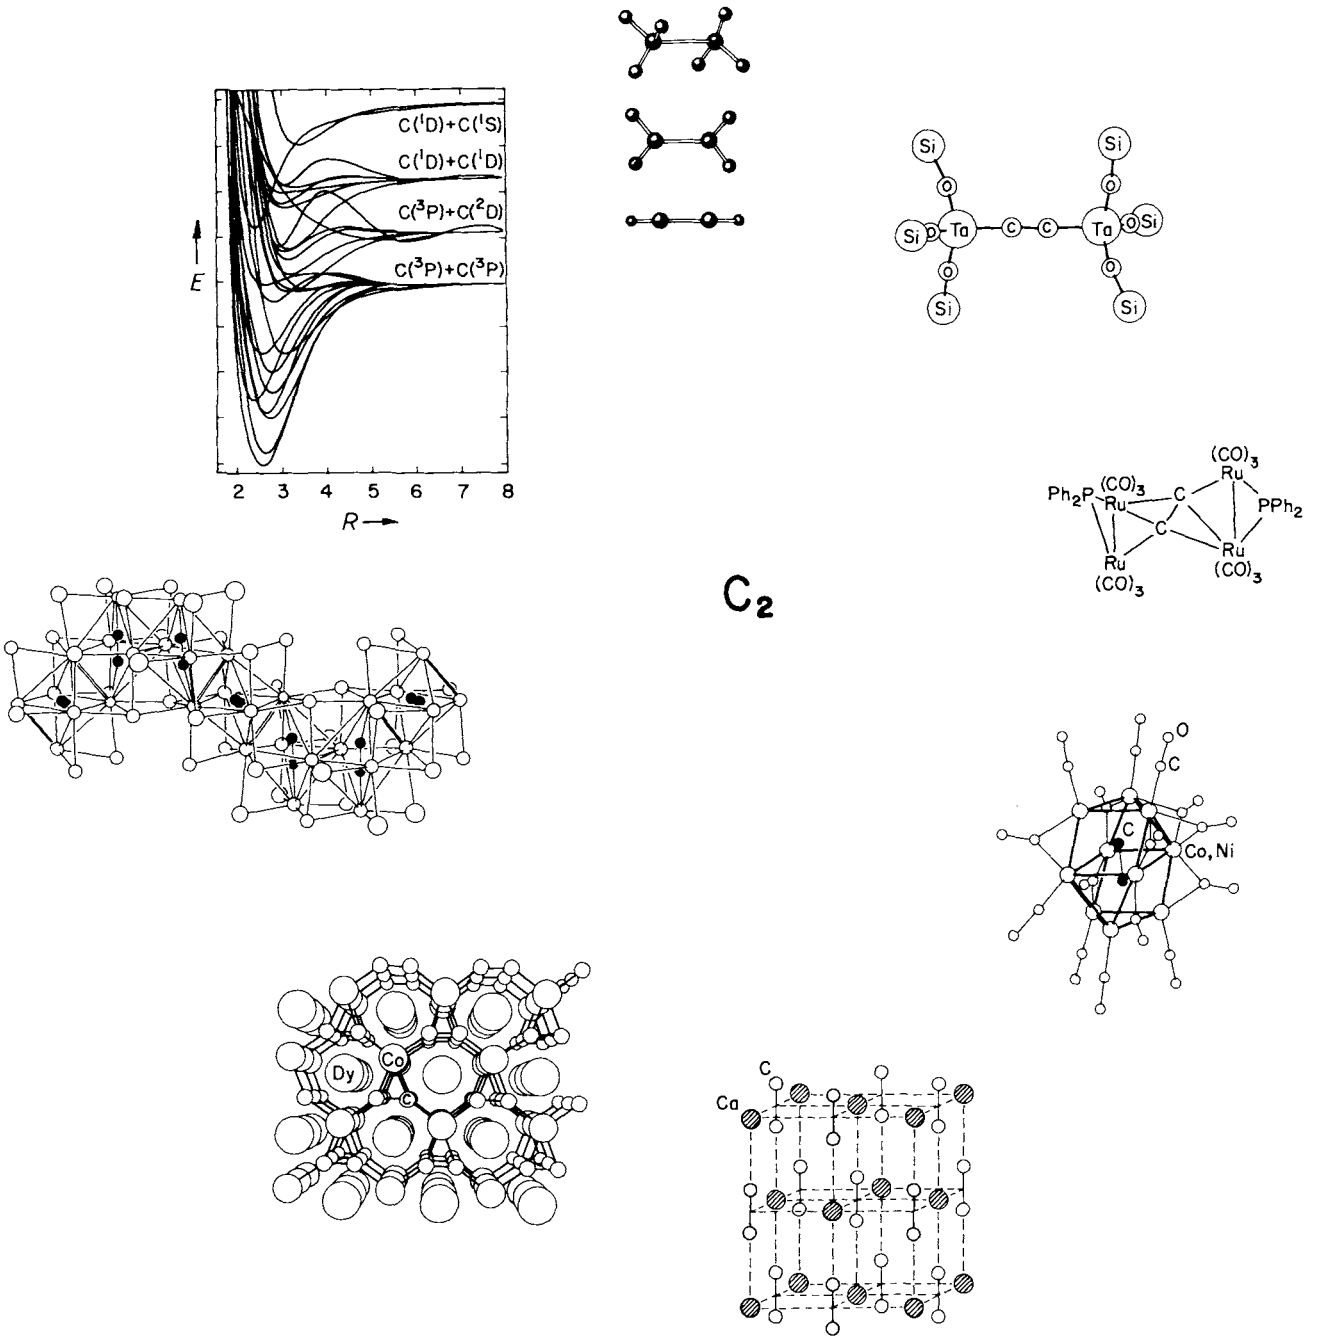


Fig. 3. Some of the ways in which C_2 finds its way in this world. Clockwise from 10:30: a) some calculated potential energy curves for diatomic C_2 [29a]; b) ethane, ethylene, acetylene; c) a dinuclear tantalum complex of C_2 [29b]; d) Ru_4C_2 cluster [29c]; e) C_2 inside a Co_3Ni_7 cluster [29d]; f) calcium carbide; g) $DyCoC_2$ [29e]; h) $Gd_{12}C_6I_{17}$ [29f].

goni[29d] and their co-workers, shown in Figure 3. I see it in CaC_2, in *W. Jeitschko*'s[29e] and *A. Simon*'s[29f] and their co-workers' rare-earth carbides. It's staggering!

I know that that richness was created by human beings. So I'm unhappy to see their humanity suppressed in the way they express themselves in print. I also think that there are some real dangers in the present intellectual stance of scientists and in their ritual mode of communication.

Here are the dangers as I perceive them. Acceptance of a facile reductionist philosophy, a vertical mode of understanding appropriated as the *only* mode of understanding, creates a gap between us and our friends in the arts and humanities. They know very well that there isn't only one way of "understanding" or dealing with the death of a parent, or a political election, or a woodcut by *Ernst Ludwig Kirchner*. The world out there is refractory to reduction, and if we insist that it must be reducible, all that we do is to put ourselves into a nice box. The box is the small class of problems that are susceptible to a reductionist understanding.

A second danger, more specific to the scientific article, is that by dehumanizing our mode of communication, by removing emotion, motivation, the occasionally irrational, we may have in fact done much more than chase away the

Natural Philosophers. That we've accomplished, to be sure. But 150 years down the line what we have created is a mechanical, ritualized product that 3×10^5 times per year propagates the notion that scientists are dry and insensitive, that they respond only to wriggles in a spectrum. The public at large types us by the nature of our product. How can it do otherwise when we do not make a sufficient effort to explain to the public what it is that we really do in our jargon-barricaded world?

What is to be done? I would argue for a general humanization of the publication process. Let's relax those strictures, editorial or self-imposed, on portraying in words, in a primary scientific paper, motivation, whether personal and scientific, emotion, historicity, even some of the irrational. So what if it takes a little more space? We *can* keep up with the chemical literature, and tell the mass of hack work from what is truly innovative, without much trouble as it is. The humanizing words will not mislead; they may actually encourage us to read more carefully the substance of what is said. I would plead for a valuation and teaching of style, in the written and spoken language of one's own country, as well as in English. I think chemistry has much to gain from reviving the personal, the emotional, the stylistic core of the struggle to discover and create the molecular world.

The Chemistry of Amino Imino Boranes

By Heinrich Nöth*

Dicoordinated boron compounds can no longer be considered as "exotic" species in boron chemistry: this is proved by the extensive chemistry of bis(dialkylamino)boron(1+) ions, alkylidene boranes, and imino boranes. The latter are characterized by high reactivity and chemical versatility. A special position is taken by amino imino boranes, whose chemistry is reported here. The presence of an amino group enhances the reactivity of imino boranes on the one hand and increases their kinetic stability on the other. New types of diamino boranes accessible via amino imino boranes often undergo intramolecular ring closure. These heterocycles are well suited to generate new types of cations of boron. Cycloaddition reactions using amino imino boranes open up a new heterocyclic chemistry of boron. The chemistry of *N*-functional amino imino boranes, which is still its infancy, shows much promise.

1. Introduction

Among the elements of the second period, boron is unique in attaining coordination numbers greater than 4. Many metal borides,[1] but particularly polyboranes, carboranes, and metallaboranes,[2] display this topology, which is explained in terms of multicenter bonding by theories of chemical bonding.[3] This exceptional position, however, should not blind one to the fact that boron is tricoordinate in most of its compounds, corresponding to its three valence electrons, or tetracoordinate due to the four valence orbitals with which a boron atom can contribute to bonding.

Will it be possible to realize even lower coordination numbers? A first answer to this question is provided by gas-phase studies: several physical methods have allowed the detection of boroxanes X–B=O,[4] borthianes X–B=S,[5] and borselenanes X–B=Se.[6] These linear, highly reactive molecules have been prepared so far only in the gas phase. The latter two types of molecules contradict *Goubeau*'s rules for systems containing multiple bonds;[7] these boron compounds polymerize or decompose in the condensed phase. To prevent polymerization, their kinetic stabilization is necessary. It is impossible to predict, however, whether this can be achieved by steric effects alone or only with electronic assistance. As has been demonstrated in recent years by the rapidly developing chemistry of dicoordinated boron compounds, both concepts for stabilization are valid.

Of the classes of compounds known so far, the boroxanes,[4,8] the imino boranes,[9] the bis(dialkylamino)boron(1+) ions,[10] and the alkylidene boranes,[11] *Paetzold* et al. have investigated diorgano imino boranes R–B≡N–R′ particularly extensively. These compounds not only are isoelectronic with diorgano acetylenes but also exhibit similar chemical behavior. It is well known that introduction of an amino group enhances and modifies the reactivity of the CC triple bond of alkynes.[12] This status report asks the question whether this holds also for amino imino boranes, which are isoelectronic with ynamines.[12]

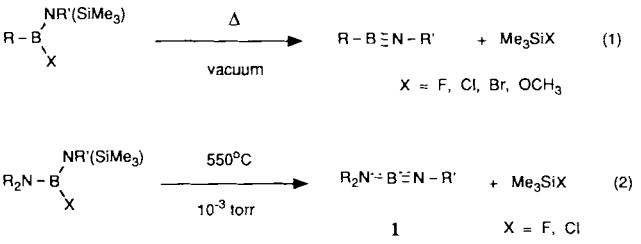
2. Synthesis

Among possible synthetic strategies for amino imino boranes, elimination reactions play an important role. Such reactions can be divided into four general categories:

a) thermal elimination of stable molecules from suitable borane precursors,
b) thermally induced ring-opening of cyclic systems,
c) rearrangement reactions,
d) chemically induced elimination reactions.

2.1. Thermally Induced Elimination

Paetzold et al.[9] have developed the vacuum gas-phase pyrolysis of (trimethylsilylamino)boron halides [Eq. (1)] into an effective method of generating imino boranes R–B≡N–R′.[*] This process can also be used in the synthesis of amino imino boranes, as shown in Equation (2). *tert*-Butylimino(2,2,6,6-tetramethylpiperidino)borane **1a** — the first amino imino borane to be isolated and fully characterized — was obtained in high yield via this pathway as a



colorless liquid.[13,14] Further examples are listed in Table 1. The limits of this method have certainly not been fully explored. It remains to be tested, for example, whether the

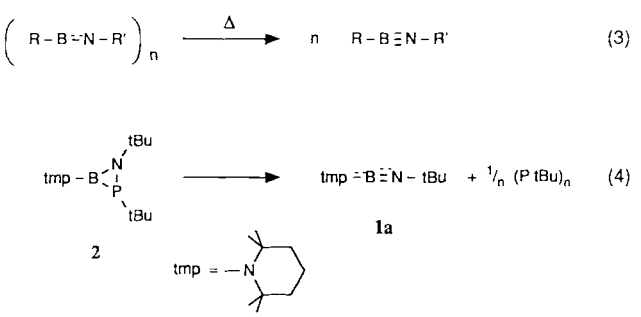
[*] Formal charges in valence formulas are not indicated here, nor will they be used in this work. This is in accord with the notation suggested by *Paetzold* [9].

species $Me_2N{=}B{\equiv}N{-}tBu$, an electronically stabilized compound, can be isolated and characterized.

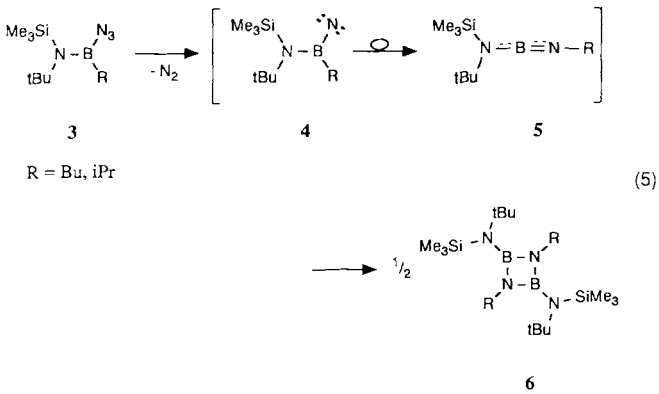
2.2. Thermal Ring-Opening of Cyclic Systems

The conceivable thermal decomposition of borazines (1,3,5,2,4,6-triazatriborinanes) and 1,3,2,4-diazadiboretidines into their monomeric imino borane units via gas-phase pyrolysis according to Equation (3) has not yet been achieved. However, that this possibility represents a realistic synthetic pathway for amino imino boranes can be seen from the recently discovered thermal decomposition (ca. 100°C) of the azaphosphaboriridine **2**.[8] The three-membered heterocycle thus serves as a source of the amino imino borane **1a**. However, since **2** was synthesized from **1a** in two steps, the reaction represented in Equation (4) would only be of preparative interest if precursors of type **2** become more readily accessible by a different route.



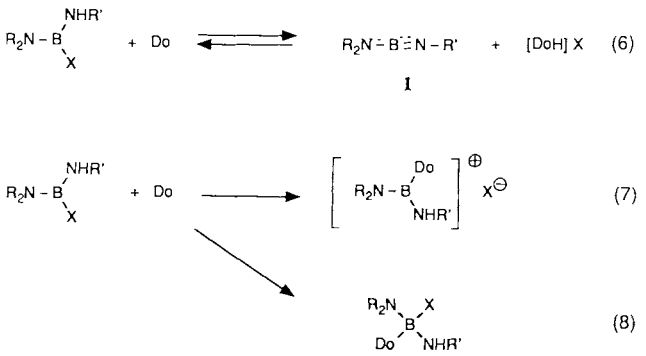
2.3. Rearrangement Reactions

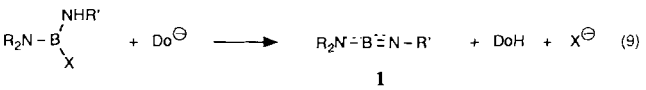
Imino boranes $R{-}B{\equiv}N{-}R'$ result from the pyrolysis of azido diorgano boranes. The intermediate is assumed to be a boryl-substituted nitrene $RR'B\ddot{N}$, which then rearranges to the imino borane.[9] The decomposition of the amino azido borane **3** at 400°C does not allow detection of either the nitrene **4** or the amino imino borane **5**, since the rearrangement of **4** to **5** and the dimerization of **5** to the corresponding diazadiboretidine **6** occur extremely rapidly.[15] Apparently, owing to their relatively low steric bulk, the alkyl substituents R (butyl, isopropyl) do not protect the amino imino borane **5** effectively from undergoing dimerization; even the derivative **1b** (see Table 1; **1b** ≡ **5**, R = *t*Bu) dimerizes, albeit slowly, to yield **6**.[16]



2.4. Dehydrohalogenation Reactions

In principle, amino boranes $RB(NR'E)X$ and diamino boranes $R_2NB(NR'E)X$ should be suitable starting materials for the synthesis of amino imino boranes if the elimination of EX can occur at a relatively low temperature. This requires the presence of weak NE bonds (E = electrophilic group) and relatively weak BX bonds (X = nucleophilic group). On the other hand, a strong EX bond will favor the elimination thermodynamically. These are difficult requirements to meet; however, in the diamino borane $tmpB[NtBu(SiPh_2Cl)]Cl$ they are partially fulfilled.[19] For EX = HF, HCl (and, in exceptional cases, HBr) strong bases Do make the dehydrohalogenation from diamino halo boranes $R_2NB(NHR')X$ possible, as shown in Equation (6). The competing substitution reaction (7) and/or addition reaction (8) must be suppressed. Neutral bases such as trimethylamine, pyridine, DBU, and 1,8-bis(dimethylamino)naphthalene are not suitable for dehydrohalogenation of $tmpB(NHtBu)X$ (X = F, Cl, Br). However, strong anionic bases $Do^{\ominus}$ well serve this purpose since these give rise to weakly protic compounds DoH (e.g., hydrocarbons, amines). These latter substances must, of course, be inert towards the amino imino boranes.





Whereas *n*-butyllithium mostly leads to substitution of the halogen atom, *tert*-butyllithium reacts at least partly via dehydrohalogenation.[16,20] With triphenylmethylpotassium, the elimination occurs at temperatures as low as −50°C; however, separation problems prevent the general application of this method.[16] The best reagents for the dehydrohalogenation according to Equation (9) are bulky alkali-metal amides MNR_2.[16,20,21] Of the compounds lithium tetramethylpiperidide, lithium *tert*-butyl(isopropyl)amide; lithium or sodium bis(trimethylsilyl)amide, and lithium *tert*-butyl(trimethylsilyl)amide, the latter has proved to be the most useful: it is a strong base (base 1 in

Table 1) and the amine (DoH) formed in the course of reaction (9) is relatively volatile. Furthermore, the steric bulk of the resulting amine prohibits further reaction with the amino imino borane formed. All compounds **1** in Table 1, except for **1c** and **1d**, were synthesized according to Equation (9). From Table 1 it should be clear that only amino imino boranes containing bulky substituents, that is, kinetically stabilized derivatives, can be synthesized according to this method.

Table 1. Amino imino boranes **1**, their ^{11}B chemical shifts, and their ^{11}B≡N stretching frequencies. Method of synthesis: **1a**, according to Section 2.1, 2.2, or 2.4; **1b** according to Section 2.1 or 2.4; **1c** and **1d** according to Section 2.1; **1e** to **1y** according to Section 2.4 [a].

3. Physical and Structural Characterization

Paetzold and co-workers, using both physical and theoretical methods, have thoroughly studied diorgano imino boranes R−B≡N−R′, and they have established the triple-bond character of the BN bond.[9] The data on amino imino boranes **1**, summarized in Table 1, allow one to study substituent effects.

3.1. Infrared Spectra

The ^{11}BN absorption in H−B≡N−H is found at 2009 cm^{-1},[22] that of *t*Bu−B≡N−*t*Bu at 1785 cm^{-1}.[23] This shift to longer wavelength is caused by coupling of $\nu(^{11}BN)$ with the ^{11}BC and NC stretching vibration.[23] The ^{11}BN force constants of the two molecules (13.14 and 12.79 Nm^{-1}, respectively) do not differ significantly.

In all amino imino boranes a prominent band is found in the region between 2000 and 1900 cm^{-1}, accompanied by a less intense, higher frequency band; these bands are assignable to $\nu(^{11}BN)$ and $\nu(^{10}BN)$, respectively. It is readily seen from the data in Table 1 that the imino substituents R have a much stronger influence on the position of this band than the amino substituents R. This band, assignable to the B≡N stretching vibration, is observed at 1990 cm^{-1} for both **1a** and **1f**, that is, closer to the frequency (2009 cm^{-1}) characteristic of H−B≡N−H (for comparison, the band for *t*Bu−B≡N−*t*Bu is found at 1785 cm^{-1}). This arises from the coupling of $\nu(B(NR_2))$ with $\nu(B{\equiv}N)$. The introduction of a Me_3Si group (**1d**) in place of a *t*Bu group (**1a**) shifts the frequency of the observed band by only 68 cm^{-1}. This allows the cautious conclusion that altering the substituent on the amino nitrogen has only a small effect on the position of the B≡N band, in contrast to substitution at the imino nitrogen.

In Figure 1 the observed ^{11}B≡N frequencies are plotted versus calculated bond indices *P*(BN), obtained by the CNDO method for $H_2N{=}B{\cong}N{-}R'$ as model compound.[20] The almost linear relation implies that $\nu(^{11}B{\equiv}N)$—and therefore the strength of the BN bond—is primarily influenced by the inductive effect of the imino substituents.

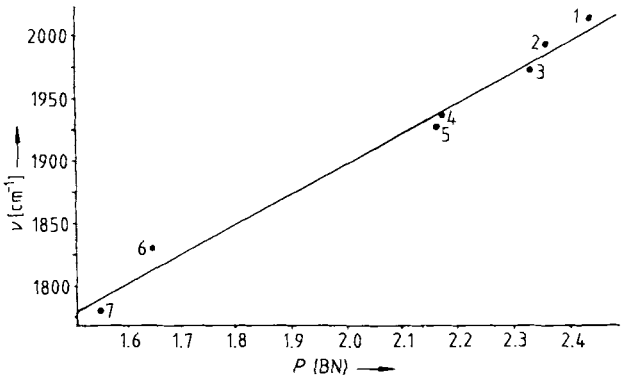

Fig. 1. Correlation of the $\nu(B{\equiv}N)$ frequency of the amino imino boranes **1** with the calculated bond indices *P*(BN) for $H_2N{=}B{\cong}N{-}R'$ as model compound. The linear dependence excludes any significant π-bonding effects involving the imino substituent. In No. 3 the influence of the $B(NH_2)_2$ group (calculated) or of the diazaborolidinyl group (found) must also be mostly inductive in nature as a result of the electronic saturation of the boron atom via π-interaction with the NH_2 groups or N ring atoms, respectively. Bzl = benzyl.

3.2. ^{11}B Nuclear Magnetic Resonance Spectra

The ^{11}B chemical shifts of the amino imino boranes **1** show the same tendencies as the $^{11}B{\equiv}N$ stretching frequencies. $\delta(^{11}B)$ is only slightly influenced by solvents ($\Delta\delta = \pm 1$ ppm), not even by pyridine; this finding provides a clear indication that the boron center in **1** is both electronically and sterically shielded.

Since the magnetic shielding of the ^{11}B nucleus in boron compounds increases with increasing coordination number,[24] the observed strong shielding in the amino imino boranes comes at first as a surprise. However, the same also holds true for acetylenic C atoms. Since the paramagnetic term of the shielding plays a significant role in the shielding of alkyne ^{13}C nuclei, it is understandable that the correlation found for the borane derivatives between $\delta(^{11}B)$ and π-electron density[25a,b] cannot be true for either the imino boranes[9] or the amino imino boranes. The empirical correlation between $\delta(^{11}B)$ and $\delta(^{13}C)$ values for isoelectronic systems with tricoordinate boron and carbon[25c] can surprisingly also be used satisfactorily to estimate $\delta(^{13}C)$ and $\delta(^{11}B)$ of alkynes and imino boranes, respectively. As indicated in Figure 2, a linear correlation

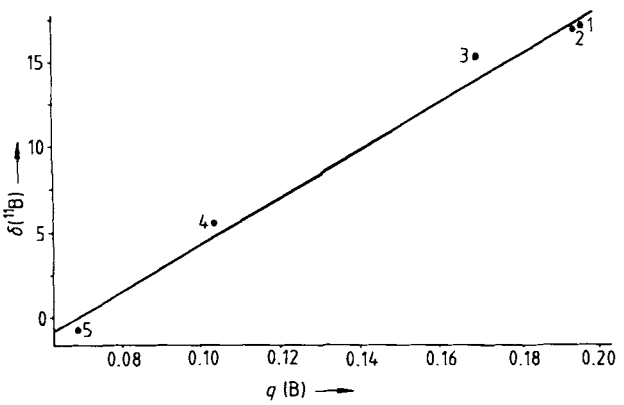

Fig. 2. Correlation of $\delta(^{11}B)$ values of amino imino boranes with calculated net charges q(B) at the boron atoms. Since $\delta(^{11}B)$ and $\delta(^{13}C)$ of comparable imino boranes and acetylenes are related via $\delta(^{11}B) = 0.393\,\delta(^{13}C) - 30.73$ [25c], the screening constants of both nuclei are influenced analogously.

also exists between $\delta(^{11}B)$ values of the amino imino boranes studied and the net charge q(B) at the boron atoms.

3.3. Theoretical Studies

According to ab initio calculations, the parent imino borane, H–B≡N–H, possesses the symmetry of the point group $C_{\infty v}$[26,27] and a calculated BN bond length of 127 pm[24] or 123 pm.[27] For the dimethyl derivative, Me–B≡N–Me, the point group C_{3v} and a BN bond length of 119 pm have been determined by MNDO/1 calculations.[28] By analogy to the corresponding acetylenes, the HOMO of the imino borane is a degenerate BN π orbital; however, in contrast to acetylenes, imino boranes possess dipole moments due to the differing electronegativities of boron and nitrogen. Therefore, the atomic dipoles of the HB and HN bonds or the CB and CN bonds no longer compensate. However, the calculated dipole moments are small: 0.86 D for H–B≡N–H[27] and 0.14 D for Me–B≡N–Me.[28]

Answers to the questions how substituents at the B atom influence bonding in imino boranes (cf. entry 1 in Table 2) and what effects the substituents have on the net charge at the boron atom can be found in Table 2, which contains data obtained from STO-3G calculations.[14,29] According to these results, a fluorine substituent increases the positive charge at the boron atom and, at the same time, slightly weakens the B≡N bond (entry 2). In the parent (entry 3) amino imino borane, H_2N–B=N–H, a relatively large partial charge is also found at the boron atom, whereas the introduction of a methyl group at the boron atom significantly decreases this charge (entry 4). A methyl group at the imino nitrogen is electron-donating (cf. entries 1 and 7), whereas the BH_2 group (entry 5) and even more so the BF_2 group (entry 6) reduce the electron density at the boron atom. The reason for this is less an inductive effect than a BN π interaction with the substituent. In contrast, an *N*-bonded amino group enhances the charge density at the boron atom.

Table 2. BN bond lengths d, π-bond orders $p_{\mu\nu}$, and net charges q(B) at the boron atom for several B- and N-substituted imino boranes calculated according to STO-3G. The π-bond order is defined as $p_{\mu\nu} = \sum_i n_i C_{\mu i} C_{\nu i} S_{\mu\nu}$, where C are the orbital coefficients and S represents the overlap matrix of the atoms μ and ν [29]. n is the number of electrons [29].

Entry		d(BN) [pm]	$p_{\mu\nu}$	q(B)
1	H–B≡N–H	119.6	0.759	0.291
2	F–B≡N–H	119.9	0.744	0.478
3	H_2N–B=N–H	120.1	0.746	0.454
4	Me–B≡N–H	119.7	0.757	0.362
5	H–B≡N–BH_2	121.7	0.719	0.321
6	H–B≡N–BF_2	121.3	0.729	0.315
7	H–B≡N–Me	119.7	0.754	0.267
8	H_2N–B=N–Me	120.3	0.741	0.437

As an estimate of the reactivity towards nucleophiles and electrophiles, one can use the HOMO-LUMO separation. Values for a series of typical BN compounds are given in Figure 3. As can be seen, bis(amino)boron cations can be labeled as strong electrophiles, whereas amino imino boranes should possess nucleophilic character.[14] As will be demonstrated below, amino imino boranes can indeed be described as electron-rich systems.

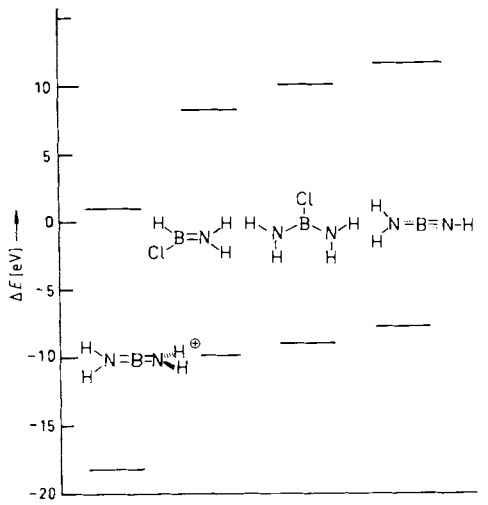

Fig. 3. HOMO-LUMO separations ΔE for a series of typical BN compounds. Included in the formulas are the calculated BN bond orders. All HOMOs and LUMOs are π type; the N atoms of the amino group are sp^2-hybridized. For the cation, the data are valid for a molecule possessing D_{2d} symmetry.

3.4. Direct Structural Information

The high BN bond order of imino boranes, which was inferred from the vibrational spectra and theoretical studies, has been verified by results of X-ray crystal structure determinations. The BN bond length for the compound *t*Bu–B≡N–*t*Bu, found to be 125.8 pm,[27] cannot be used as a relative measure for the BN triple bond lengths because of disorder phenomena. A better experimental standard is provided by $(Me_3Si)_3Si$–B≡N–*t*Bu, for which a BN bond length of 122.1 pm was determined.[30] What influence does an amino group have on the imino group? 2,2,6,6-Tetramethylpiperidino[(2,4,6-tri-*tert*-butylphenyl)imino]borane **1i** crystallizes orthorhombically with two molecules per asymmetric unit cell. The average B≡N distance is 125 pm, the average BN distance to the tmp group 138 pm. The latter distance corresponds to the BN bond length found in monoamino boranes. In spite of the numerical agreement, this value cannot represent the same degree of multiple bonding, since the boron atom in monoamino boranes is tricoordinate whereas in amino imino boranes the boron atom is only dicoordinate. Since the covalent radius of a boron atom is 7 pm larger than that of a carbon atom but that of nitrogen is 5 pm smaller, BN compounds should have somewhat longer BN bonds than the CC distance in comparable isosteric analogues. The BN lengths observed are, however, almost always longer than those of the carbon analogues, a result of the polarity of the BN bond. It must be added, however, that it is difficult to justify the choice of a standard bond length for a BN single bond. Should one choose the BN bond length in H_3B–NH_3 or that found in the cubic form of boron nitride? The latter choice makes more sense.

Amino imino boranes **1** can be described with the use of resonance structures (**A**–**C**), whereby the boron atom in structures **A** and **B** possesses a formal negative charge. The simplest representation for amino imino boranes is the one that has been used in this work, R_2N=B≡N–R′.

$$R_2\ddot{N}\text{–}B{\equiv}N\text{–}R' \longleftrightarrow R_2N{=}B{=}\ddot{N}\text{–}R' \longleftrightarrow R_2\ddot{N}\text{–}B{=}\ddot{N}\text{–}R'$$

A **B** **C**

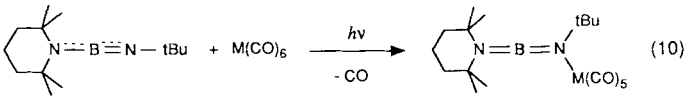
1

4. Reactions of Amino Imino Boranes

The chemistry of amino imino boranes should reflect the unsaturated character of the BN triple bond; in this respect, it should be similar to that of imino boranes R–B≡N–R′.[9] Thus, addition and insertion reactions as well as cycloaddition reactions are to be expected. Furthermore, the amino group opens up additional reaction possibilities.

4.1. Addition Reactions at the Imino Nitrogen

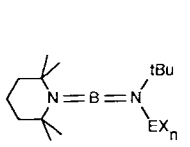
The simplest imaginable reaction of amino imino boranes is coordination via the imino nitrogen in a simple Lewis acid–base reaction. Particularly well suited are transition-metal carbonyl fragments as Lewis acids. $Cr(CO)_6$ and $W(CO)_6$ react with **1a** to give the pentacarbonyl complexes **7**.[33] The X-ray crystal structure of the chromium complex confirms the allene-like structure. It contains two BN bonds of different length (129.5(6) pm to the NC(Cr) group, 136.8(6) pm to the NC_2 group).



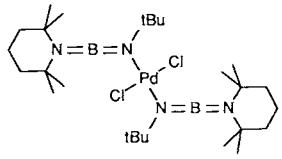
(10)

1a **7**

It is also possible to isolate 1 : 1 adducts **8** when suitable Lewis-acidic metal halides are used—e.g., $AlCl_3$, $AlBr_3$, $GaCl_3$,[34] HgI_2,[35] or $PdCl_2$[36] (see also Section 4.5.1). $PdCl_2$ adds two molecules of **1a** to form **9**. The amino imino borane units in **9** are almost perpendicular to the $PdCl_2N_2$ plane. The two BN bond lengths are 132 and 135 pm and are thus somewhat more balanced than in **7**.



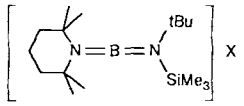
8



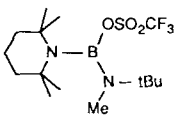
9

The addition of carbenium ions at the imino nitrogen of **1a** has not yet been successful. In contrast, the addition of the trimethylsilyl cation is known. The reaction of trimethylsilyl iodide or triflate with **1a** leads cleanly to the boron(1+) salts **10**. The weak nucleophilicity of the anion is important for the stability of the product; however, the steric bulk of the Me_3Si group also plays a role: methyl triflate reacts with **1a** forming the diaminoboryl triflate **11**[37] as the insertion product.

These reactions are typical of amino imino boranes, owing to the stabilization of the diaminoboron(1+) stage, the formation of which is not possible using imino boranes



10



11

R–B≡N–R′. Analogous reactions involving amino alkynes are unknown to our knowledge.[12]

4.2. Reactions with Protic Compounds

The polar imino borane group in amino imino boranes **1** undergoes a rapid and straightforward reaction with protic compounds HY with insertion into the HY bond according to Equation (11). However, carrying out the reaction under

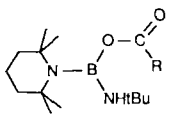
(11)

1

controlled reaction conditions or stoichiometry is usually required since an excess of the reagent results in most cases in cleavage of BN bonds.

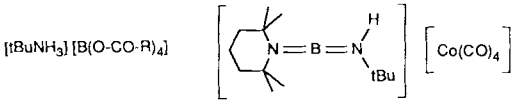
4.2.1. Reactions with Acids

Hydrogen chloride[38] and trifluoromethanesulfonic acid[37] react with amino imino boranes in a 1:1 molar ratio according to Equation (11) to give the corresponding diamino(chloro)- or diamino(trifluoromethylsulfonyloxy)boranes. Compound **1b** reacts similarly with HCl.[15] An excess of HY results in cleavage of BN bonds, partly in ways which are difficult to define. Analogous reactions have been found for carboxylic acids, which react with **1a** in the first reaction step to yield monomeric acyloxy(*tert*-butylamino)tetramethylpiperidinoboranes **12**. Excess carboxylic acid leads eventually to the tetracarboxylatoborates **13**.[39]



12

R = CH_3, CF_3

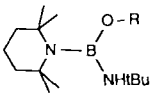


13 14

Mechanistically, all of these reactions proceed via the *tert*-butylamino(tetramethylpiperidino)boron(1+) ion, as shown by the reaction of tetracarbonylhydridocobalt[36] with **1a** in a 1:1 ratio to give the thermally unstable salt **14**. The weakly nucleophilic, bulky cobaltate ion fails to attack the boron center of the cation to form the corresponding insertion product.

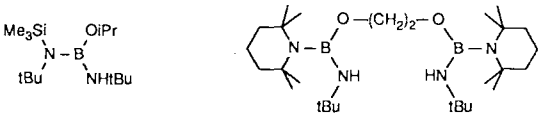
4.2.2. Reactions with Alcohols, Thiols, Amines, and Phosphanes

In contrast to the undefined nature of the hydrolysis products of amino imino boranes, **1a** reacts as a model system with alcohols in a rapid reaction to yield the alkoxy(diamino)boranes **15**.[39] Failure of this reaction has only been found in the case of extremely bulky alcohols such as 2,4,6-tri-*tert*-butylphenol. Compound **16** can be prepared from **1b** and isopropyl alcohol.[15]



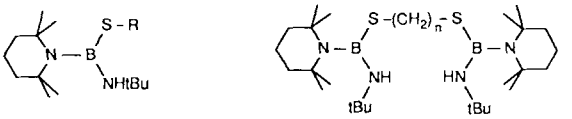
15

R = Me, iPr, tBu, Ph, 2,4,6-$tBu_3C_6H_2$



16 17

Whereas alkoxy(dimethylamino)boranes decompose during distillation into $B(OR)_3$ and $B(NMe_2)_3$,[40] the compounds **15** and **16** remain stable. The same holds true for the product **17**, which is obtained from the reaction between **1a** and glycol.[41]



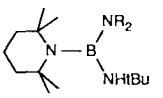
18 19

R = tBu, Ph n = 2, 3

Hydrogen sulfide is rapidly taken up by **1a**; however, the suspected reaction product **18**, R = H, characterized by a ^{11}B NMR signal at $\delta = 37.7$ decomposes very rapidly.[42] In contrast to this behavior, thiols[39,41] and α,ω-dithiols yield stable, distillable compounds **18** and **19**. Thus, in these cases, the equilibrium for the reaction (12)

(12)

lies far to the right. This is in marked contrast to the boranes with R = Me, Et.[43]



20

NR_2 = NH_2, NH iPr, NH tBu, NHPh, NMe_2, pyrrolidino, 1-pyrrolyl, 1-imidazolyl, NH-NMe_2, NMe-NHMe

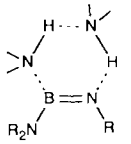
21 22

By addition of ammonia, amines, or hydrazines to **1a**,[39] the triamino boranes **20** become accessible, which contain three different amino groups. Compound **1b** behaves similarly.[15] In addition, no ligand exchange reactions occur, a consequence of the "steric overloading" of the molecules. For the same reason, the pyrazolylborane derivative **22**[39] fails to dimerize. Compound **21** is formed by addition of $Me_3SiNHiPr$ to **1a**.[19]

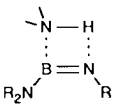
Diethylamine, bis(trimethylsilyl)amine, *tert*-butyl(trimethylsilyl)amine, and 2,2,6,6-tetramethylpiperidine fail to react with **1a** for steric reasons. This is the essential prerequisite for the success of dehydrohalogenation reactions [Eq. (9)], in which the anions of these amines have been used successfully.

That the rate of amination of **1a** is more dependent on the steric bulk and less on the basicity (or the nucleophilicity) of the amines involved is indicated by the qualitatively determined series $NH_3 > NH_2R > NHR_2$. Compared with aniline (100% reaction in 30 min), phenylphosphane reacts only very slowly with **1a** (50% reaction in 24 h) to give tmp–B(PHPh)–NH*t*Bu.[42]

All reactions of **1a** with protic compounds occur regiospecifically with protonation of the imino nitrogen atom only. Mechanistically, the reactions of **1a** with amines could proceed via an attack of the nitrogen atom at the boron center. However, since $\delta(^{11}B)$ of **1a** is not significantly influenced by pyridine, such a reaction path seems



23

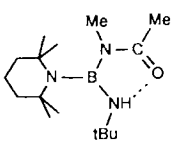


24

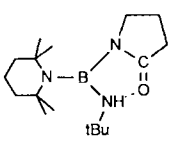
highly unlikely. The latent electrophilic nature of the boron atom in amino imino boranes is increased significantly, however, upon protonation of the imino nitrogen. The protonation step could be induced by hydrogen bonding between the amino imino borane and the amine or the alcohol. *Paetzold*[9] has suggested a cyclic transition state **23**. However, the alternative **24** cannot be excluded.

4.2.3. Reactions with Carboxylic Acid Amides

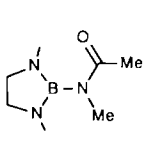
N-Methylacetamide reacts rapidly and quantitatively with **1a** to give the *N*-acyl-substituted triamino boranes **25**. The formation of the *O*-isomer is ruled out by the NMR spectra (^1H, ^{11}B, ^{13}C, ^{14}N).[44] 2-Pyrrolidone behaves analogously as a cyclic carboxylic acid amide, affording **26**.[45] Both **25** and **26** correspond to the *N*-methylacetamido borane **27** described by *Meller* et al.[46]



25



26

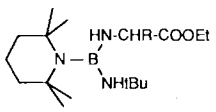


27

The question whether the acetamides react with **1a** in their amide or their imide form remains open.[44] The BO bond would be thermodynamically more favorable; evidently, the resonance-stabilized form of the acid amide determines the course of the reaction.

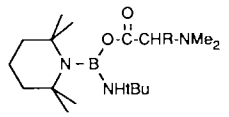
4.2.4. Reactions with Amino Acids and Their Derivatives

Compound **1a** is extremely well suited to borate amino acids under very mild conditions.[47] In this way **1a** dramatically differs from the isoelectronic ynamines, which cause the condensation of amino acids.[12]



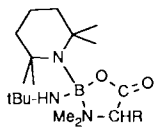
28

R = H, Me, $CHMe_2$, CH_2CHMe_2



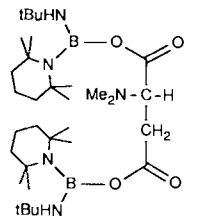
29

R = H, Me, $CHMe_2$, CH_2CHMe_2



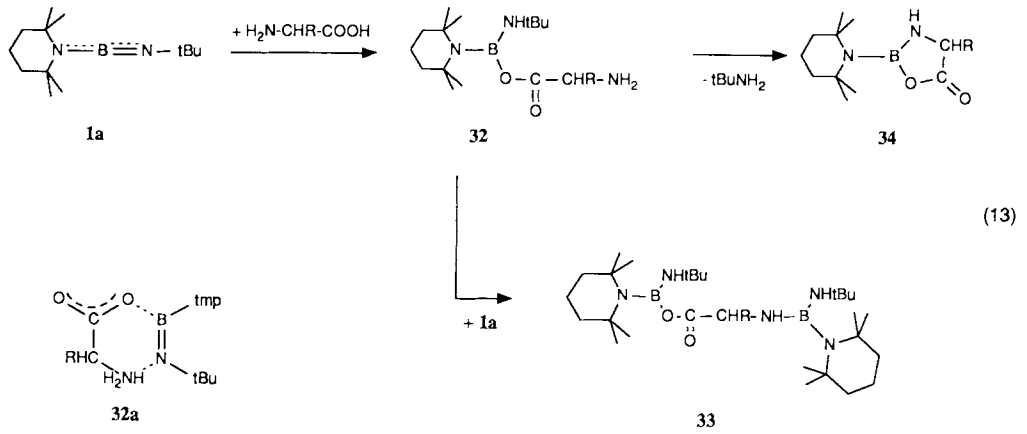
30

Amino acid esters behave like amines in the presence of **1a**: triamino boranes of type **28** are obtained in yields of up to 85%. NMR spectra indicate an *anti* conformation of the HNCH group, which is probably sterically induced. *O*-Borylated amino acid derivatives **29** are obtained from the *N,N*-dimethylamino acids. ^{11}B nuclear resonance data rule out the possibility that ring closure to **30** has occurred.[47] Furthermore, no formation of borates of the type $[B(OCO{-}CHR{-}NMe_2)_4]^{\ominus}$ is observed, in marked contrast to the reaction of **1a** with carboxylic acids. This is presumably due to the heterogeneous reaction conditions used for the synthesis of **29**; i.e., **1a** is always present in excess. Compound **1a** fails to differentiate between the two carboxylic acid functions of *N,N*-dimethyl-L-aspartic acid. A single reaction product **31** is obtained.



31

Based on these results, one could expect that in free amino acids both the carboxylic acid and the amino function would react with **1a**. In fact, however, there is a competition between such a double borylation to yield **33** and an amine elimination which leads to **34** [Eq. (13)]. The monoboration product **32** could serve as a common intermediate in these reactions.[47]



(13)

Table 3. Product distribution [mol %] between the borylation products **33** and **34** formed by reaction of amino acids with **1a**.

Amino acid	33	34
Glycine	100	–
L-Alanine	50	50
L-Valine	20	80
L-Leucine	35	65
L-Isoleucine	5	95
L-Phenylalanine	20	80

The product distribution **33/34** is controlled by the steric demand of the organic group R, as the data in Table 3 indicate. This is best seen by comparing the results for L-leucine and L-isoleucine.

We postulate that the formation of **32** results from proton transfer from the zwitterionic structure of the amino acid to the imino nitrogen, as shown in **32a**. Attack of the carboxylate moiety at the boron atom leads to **32**. Increasing bulkiness of the amino group hinders the second boration step to **33**. This allows the intramolecular condensation to the oxazaborolidinone derivative **34**, whose almost planar five-membered ring structure has been confirmed by an X-ray analysis.[47]

4.3. Boration Reactions

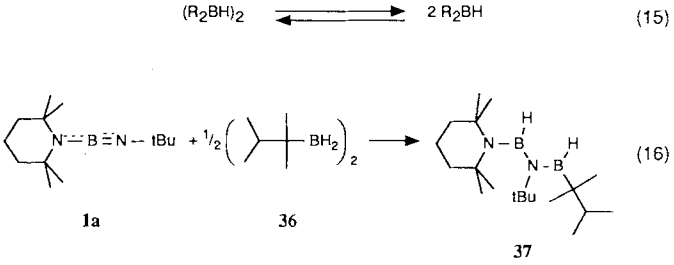
Lewis-acidic boron compounds correspond in many ways to protic acids. For instance, alkynes not only add hydrogen halides[12] but also borane derivatives. The boration of acetylenes proceeds stereospecifically, yielding *cis*-alkenylboranes.[48] No stereospecific boration of the B≡N bond has so far been detected owing to the smaller rotational barrier of the B=N bond present in amino boranes as compared with the C=C bond in alkenes, but this reaction allows an easy synthesis of new, even *B*-functionalized, diborylamines, as shown by *Paetzold*.[9] Using amino imino boranes, one obtains diborylamines, the isoelectronic analogues of butadiene—a formalism which is valid structurally only in part.[49]

4.3.1. Hydroboration Reactions

The use of diorgano boranes (or their dimers) instead of diborane allows a better control of the regiospecificity of the hydroboration of unsaturated CC systems.[48] This problem is invalid with amino imino boranes because the mode of addition and therefore the regiospecificity is predetermined by the polarity of the BN bond. The relative inertness of the BC bond is the prerequisite for the regiospecific hydroboration of amino imino boranes by diorgano boranes (or their dimers) according to Equation (14). Compound **1a** reacts with dicyclohexyl- and disiamylborane and with 9-borabicyclo[3.3.1]nonane at ambient temperature to yield amino-substituted diborylamines of type **35**.[50] The rate of reaction with these hydrides increases in this sequence of compounds approximately in the ratio 1 : 12 : 48. This is surprising insofar as the sterically least hindered diorgano borane, namely, dicyclohexylborane, hydroborates *most slowly*.

(14)

This gradation in reactivity is, however, easily explained by taking the equilibrium (15) into account; i.e., the hydroboration rate is determined by the equilibrium concentration of the monomeric diorgano borane. The higher the value of ν(BHB), the stronger is the hydrogen bond, the smaller the equilibrium concentration of the monomer, and the slower the hydroboration. This corresponds to the experimental facts for the three dimeric diorgano boranes investigated.[50] It becomes clear under this presumption why dithexyldiborane **36** hydroborates the amino imino borane **1a** according to Equation (16) very slowly to give **37**. Only one of the two hydridic hydrogens of the RBH_2 units in dithexyldiborane is used in the hydroboration of **1a**.[50]

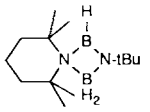


(15)

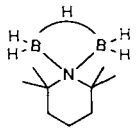
(16)

In contrast to the examples cited above, a more complex pattern of reactivity during the hydroboration of **1a** is ob-

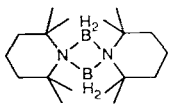
served with either diborane or $BH_3 \cdot THF$.[50,51] Under carefully controlled reaction conditions, **38** is the principal product. The coordinatively unsaturated $N-BH_2$ group first formed is saturated by coordination to the N atom of the tmp group. Compound **38**, however, is not very stable thermally. Thus, its $tmpBH_2$ component is trapped by "BH_3" as the μ-aminodiborane derivative **39**. In addition, **40** is produced, along with the borazine $(HBNtBu)_3$.[14,51]



38



39

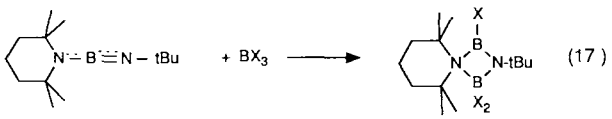


40

Use of $H_3B \cdot SMe_2$ reduces the concentration of free BH_3 to such an extent that **38** becomes the main product (>80%); i.e., the relatively small amount of rapidly accessible BH_3 results in suppression of subsequent and side reactions.[50]

4.3.2. *Haloboration Reactions*

The boron trihalides BF_3,[14] BCl_3, and BBr_3[21] haloborate **1a** according to Equation (17) to give compounds **41**. Instead of BBr_3, the adduct $BBr_3 \cdot SMe_2$ can also be used.[50] The bonding between the two tetracoordinated ring atoms in **41** is weak as shown by the long BN bond



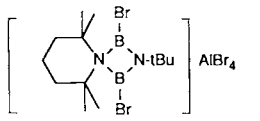
1a **41**

X = F, Cl, Br, (17)

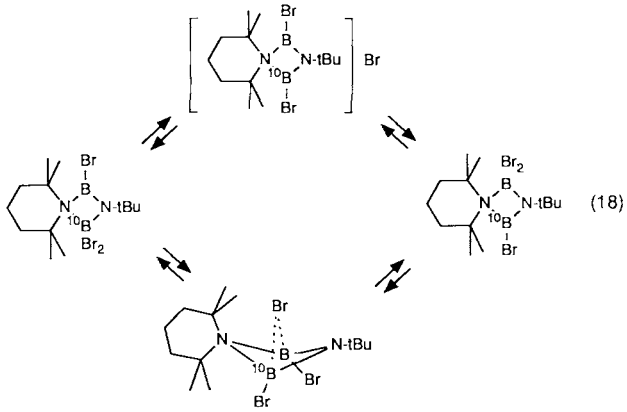
(172(1) pm) of the bromine derivative.[21] By means of $AlBr_3$, a bromide ion may be removed from **41** (X = Br) to produce the salt **42**. A single ^{11}B NMR signal at $\delta = 36.8$ shows the chemical equivalence of the two boron atoms.[52] When $^{10}BBr_3$ is used for the bromoboration of **1a**, the intensities of the two boron NMR signals of **41** (X = Br) in both the ^{11}B NMR spectrum and the ^{10}B NMR spectrum are equal. This corresponds to an equilibrium (18). Whether the bromine migration occurs by a dissociative step or via a Br-bridge across a folded four-membered ring has not yet been definitely established. MNDO calculations favor the intramolecular process.[50]

In contrast to **1a**, a fluoroboration product **43** is obtained in the reaction of **1g** with BF_3. It contains only tricoordinated boron atoms ($\delta(^{11}B) = 26.7, 18.7$).[44] This result is intelligible by assuming a *cis* attack of BF_3 and a sterically determined high rotational barrier at the central BN bond.

From **1a** and methylboron dichloride, the compound type **44** forms exclusively;[52] this finding was corroborated by an X-ray structure analysis.[14] In contrast, phenylboron dichloride and dibromide yield mixtures of the isomers **44** and **45** (R = Ph, X = Cl, Br).[51] It seems, therefore, that



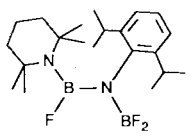
42



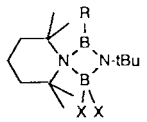
(18)

organoboration is faster than the haloboration. By using $^{10}MeBBr_2$ it has been shown[50] that haloboration occurs exclusively, because the methyl group remains at the ^{10}B atom. Therefore, in **45** (R = Me, X = Br) a bromine atom must migrate until it is finally held tightly by the more acidic BBr group. However, in boiling hexane the methyl group becomes mobile.

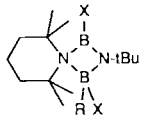
That two isomers appear for R = Ph and X = Cl (**44** : **45** = 3 : 1) can be explained by the stronger Lewis-acidic character of the $PhBN_2$ group as compared with the $MeBN_2$ group. Practically only a single isomer **45** ($\delta(^{11}B) = 31.0, 8.5$) results if $PhBBr_2$ is employed. In the case of $tBuBBr_2$, the bulky *t*Bu group prohibits an intramolecular saturation of the bromoboration product **46** ($\delta(^{11}B) = 38.7, 26.0$).[50]



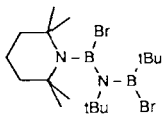
43



44

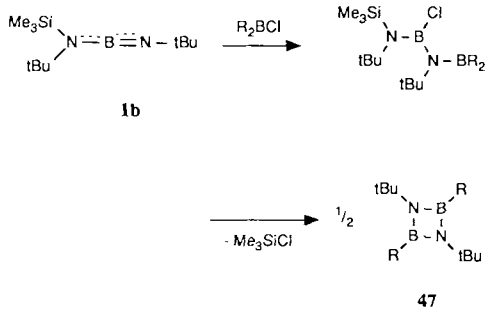


45



46

Imino boranes R−B≡N−R′ are chloroborated by dialkylboron chlorides R''_2BCl (R″ = *i*Pr, *n*Bu, *t*Bu) to yield diborylamines of type $R''_2B-NR'(Cl)$.[9] The amino group present in amino imino boranes opens up an additional reaction channel. According to Equation (19), the expected chloroboration product is formed with **1b** at low temperature: However, the chloroboration product easily decomposes with elimination of Me_3SiCl, forming the diazadi-



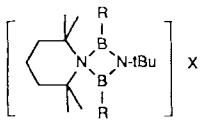
1b

47

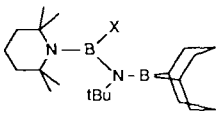
(19)

boretidine **47**, whose structure was established by X-ray analysis, as the final product.[15]

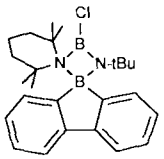
In contrast, salts of type **48** arise from **1a** and diorgano boron halides. In solution, **48** (R = Et, X = Cl) exists in equilibrium with the "simple" chloroboration product tmp–BCl–N*t*Bu–BEt_2.[50] Following the arguments put forward by *Eisch* et al.,[53] derived from results obtained by studying the boration of alkynes, we have to regard the chloroboration products of amino imino boranes as the kinetically controlled reaction products, whereas the organoboration products (or their cyclic isomers **48**) would be the thermodynamically controlled compounds.



48



49



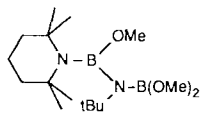
50

If one suppresses the migration of organo groups from diorgano boron halides by incorporating the boron atom into a ring system (e.g., by reaction of **1a** with 9-borabicyclo[3.3.1]non-9-yl chloride, bromide, or triflate, then the diborylamines **49** are obtained. On the other hand, 9-chloro-9-borafluorene furnishes the spirocyclic compound **50**,[50] because the boron atom in the planar five-membered ring is more acidic.

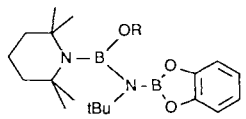
4.3.3. Alkoxy- and Alkylthioboration

Trimethyl borate, $B(OMe)_3$, reacts with **1a** readily to yield the methoxyboration product **51**. Only one methoxy group is transferred. Compound **51** distills undecomposed. $B(OPh)_3$ behaves similarly. With 2-methoxy and 2-butoxy-1,3,2-benzodioxaborole, **1a** undergoes alkoxyboration to give **52** exclusively, and 2-methylthio-1,3,2-dithiaborolane reacts, also regiospecifically, to give **53**.[50]

Still more interesting is the reaction of $B(OMe)_3$ with **1b**. Smooth methoxyboration at −40 °C according to Equation (20) is followed by elimination of Me_3SiOMe. Instead

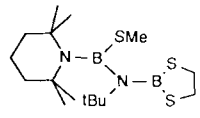


51



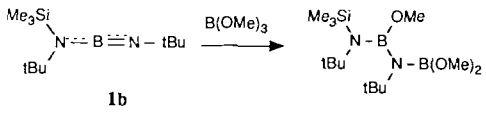
52

R = Me, Bu



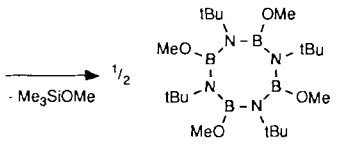
53

of a diazadiboretidine, its dimer, the crystalline tetraazatetraborocane **54**, is thereby formed.[20]



1b

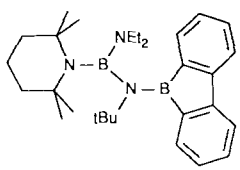
(20)



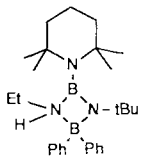
54

4.3.4. Aminoboration

Tris(dimethylamino)borane does not react with **1a**, even under reflux conditions. It does not attack at the imino nitrogen atom for electronic and steric reasons. The same holds for $MeB(NMe_2)_2$ and Ph_2BNEt_2. However, 9-dimethylamino-9-borafluorene aminoborates **1a** to yield **55**, because the planar 9-borafluorenyl group is sterically less demanding than the Ph_2B group. That steric requirements are responsible in addition to Lewis acidity—the two factors naturally go together—for a successful aminoboration is demonstrated by the smooth reaction of **1a** with Ph_2B–NHEt to yield **56**, whose structure was established by X-ray methods.[50] Thus, the amino boranes are more reactive towards amino imino boranes **1** than towards imino boranes R–B≡N–R′,[9] since the latter are only aminoborated by the more acidic hydroxyamino boranes R'_2B–N($SiMe_3$)$OSiMe_3$.[9,54]



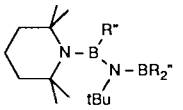
55



56

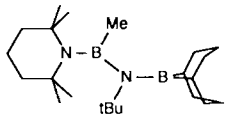
4.3.5. *Organoboration Reactions*

Whereas the organoboration of imino boranes $R-B{\equiv}N-R'$ by trialkyl boranes BR_3'' leads to pentaorganodiborylamines $RR''B-NR'-BR_2''$, amino-substituted diborylamines of type **57** are formed when amino imino boranes such as **1a** are employed. The rate of the organoboration is primarily controlled by the steric requirement of the organo groups R'': the relative rates for R'' = Me, Ph, Bu, *i*Pr are approximately 1 : 16 : 24 : 336.[50]



57

R = Me, Bu, iPr, Ph

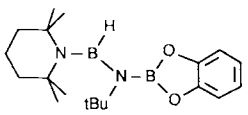


58

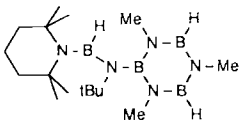
The organoboration of **1a** with 9-methyl-9-borabicyclo[3.3.1]nonane furnishes the methylboration product **58** exclusively; i.e., the insertion of **1a** into a BC bond of the ring is suppressed. Compounds **1b,c** readily react with BEt_3 in a similar fashion.[15,17]

4.3.6. *Competing Boration Reactions*

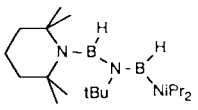
As shown in Section 4.3.5, an organo group bound to boron is not inert towards the attack of an imino borane. However, in most cases the imino borane undergoes insertion into the more polar BX bond.[55] By studying boration reactions with mixed boranes RBX_2 or BX_2Y, useful information regarding the relative migratory aptitude of the substituents R and X or Y and X are obtained.



59



60

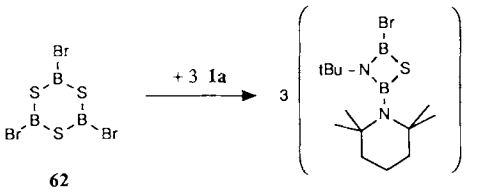


61

Benzodioxaborole serves as a selective hydroboration reagent. It hydroborates **1a** specifically to produce **59**.[56] This is true also for bis(dimethylamino)borane and 1,3-dimethyl-1,3,2-diazaborolidine as well as for 1,3,5-trimethylborazine, which yields **60**.[50] Of the three BN compounds cited, $(Me_2N)_2BH$ reacts most slowly whereas the other two species hydroborate **1a** even at ambient temperature. This underlines again the influence of the acidity of the borane on the reaction rate.

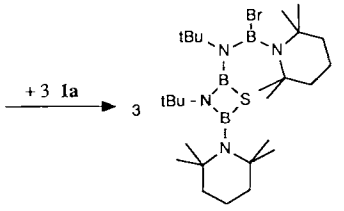
Compound **61** is formed from **1a** and monomeric iPr_2NBH_2.[20] The amino imino borane **1a** is therefore much more reactive than alkynes, which react at the BH bond of alkoxy or amino boranes only at elevated temperature and pressure.[57] Regarding the migratory aptitude one finds H > OR and H > NR_2.

The reaction of diethoxyboron chloride with **1a** proceeds even at −50 °C. It leads to a mixture of isomers consisting of the ethoxy- and chloroboration products.[50] However, a specific chloroboration is achieved in the reaction of **1a** with 2-chloro-1,3,2-benzodioxaborolane.[50] Only chloroboration is observed when 2-chloro-1,3,2-dithiaborolane reacts with **1a**, in spite of the presence of the labile BS bond. The reaction of **1a** with tribromoborthiine **62** deviates from this simple reaction scheme: the product is the 1,3,2,4-thiazadiboretidine derivative **63**, whose formation can be imagined to occur via an intermediate product [Eq. (21)], which, in turn, bromoborates **1a** to give **63**.[58]



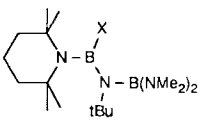
62

(21)



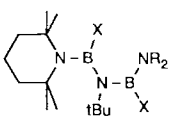
63

Diamino boron halides and amino boron dihalides react with **1a** with haloboration only. Compound types **64** and **65** are formed with $(Me_2N)_2BCl$, $(Me_2N)_2BBr$, and 2-chloro-1,3-dimethyl-1,3,2-diazaborolidine (not shown),[50] and with Me_2NBCl_2, Me_2NBBr_2, Et_2NBCl_2,[50] Et_2NBBr_2,[58] iPr_2NBCl_2,[50] iPr_2NBBr_2,[58] and $tmpBCl_2$,[18] respectively. $tmpBF_2$ will not react with **1a** to give a fluoroboration product.[50] Provided that the R_2N group is small ($R_2N = Me_2N$, X = Cl, Br), then **66** is observed in solution besides **65**.[50] Structure **66** will probably dominate for these compounds in the solid state, whereas they are present as type **65** in solution.



64

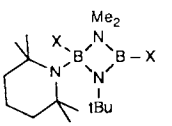
X = Cl, Br



65

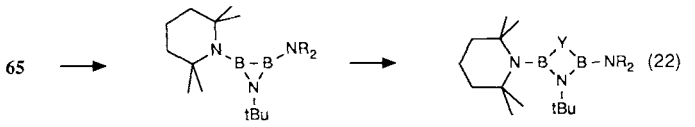
X = Cl, Br

$R_2N = Et_2N$, iPr_2N, tmp



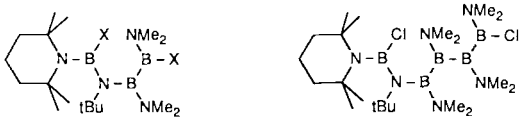
66

The haloboration products **65** react with alkali metals to yield azadiboriridines **67**.[58-60] These heterocycles, in turn, readily undergo oxidative ring expansion[58] with sulfur or selenium to give **68** [Eq. (22)].



67 **68** Y = S, Se

Of the two boron–halogen bonds in dichloro- and dibromo(dimethylamino)diborane $B_2(NMe_2)X_2$, only one is involved in the haloboration of **1a**. Both products **69** show no tendency to undergo an intramolecular BN coordination. This holds also for the chloroboration product **70**, which was also characterized by an X-ray structure analysis.[58]



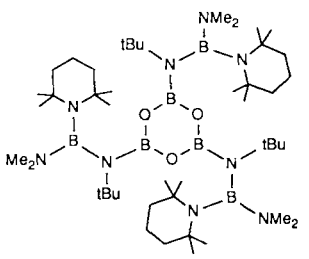
69 X = Cl, Br **70**

The rate of chloroboration of **1a** decreases as the steric shielding at the boron–halogen group increases:

$B_2(NMe_2)_2Br_2 < B_2(NMe_2)_2Cl_2$ and
$B_2(NMe_2)_2X_2 < B_4(NMe_2)_4X_2$ (X = Br, Cl).[58]

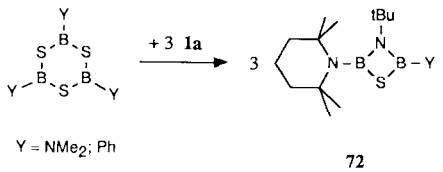
*t*Bu(Me$_2$N)BB(NMe$_2$)Cl is inert towards **1a**.

The instability of simple alkoxy amino boranes and alkylthio amino boranes excludes an investigation of the relative migration of the RO/R$_2$N and RS/R$_2$N groups, respectively. Instead, one has to investigate stable ring systems. 2-Dimethylamino-1,3,2-dioxa- and 2-dimethylamino-1,3,2-dithiaborolanes act as specific aminoboration reagents toward **1a**.[50] Of these two compounds, the more acidic and more electrophilic sulfur species reacts substantially faster.



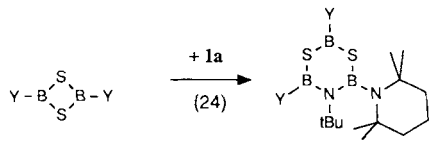
71

Tris(dimethylamino)boroxine also proved to be an aminoboration reagent. Irrespective of the molar ratio, the boroxine **71** is obtained by reaction with **1a**.[19] Tris(dimethylamino)borthiine is attacked by **1a** not at the BN bonds but rather at the ring BS bonds. Ring degradation leads to the thiazadiboretidine **72** according to Equation (23); i.e., the six-membered borthiine ring will be broken down by

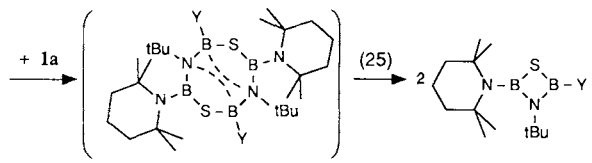


Y = NMe$_2$; Ph **72** (23)

loss of X–B=S fragments. The exact course of this borthiine degradation is still unknown. Possibly, insertion of **1a** into the ring of the borthiine with ring expansion to an eight-membered ring occurs; **72** then cleaves off with formation of **73**. The latter reacts with **1a** with thioboration, giving **74**.[58] Its further reaction to **72** is shown in Equation (25). It should also be mentioned, however, that **1a** inserts into the BN bond of the cluster compound **75** to give **76**,[58] indicating that in this case the BN bond is more reactive than the BS bond. The reactivity pattern of the system **75** differs, however, owing to the sulfonium character of its sulfur atoms, from the aminoborthiine $(R_2NBS)_3$

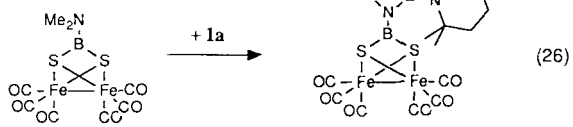


73 Y = NMe$_2$, NEt$_2$ **74** (24)



72 (25)

discussed above. While exocyclic BN bonds are more reactive than ring BO bonds in the case of amino boroxines, the same does not hold generally for systems with exocyclic BN and endocyclic BS bonds.

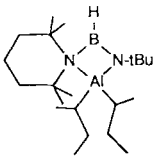


75 **76** (26)

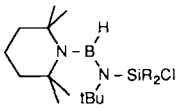
One may state as a rule, however, that the BO, BS, and BN bonds of 1,3,2-dioxaborolanes, 1,3,2-dithiaborolanes, and 1,3,2-diazaborolidines are inert against an attack of **1a** because both the 2-methyl and 2-phenyl derivatives of these heteroycles react with **1a** exclusively by organoboration.[50] Therefore, the insertion of the B≡N unit into BY ring bonds to produce seven-membered rings is not realized.

4.4. Hydrometalation Reactions

Hydroboration is a special case of hydrometalation.[61] Since alkenes and alkynes are readily hydroaluminated by diisobutylalane, it is not surprising that the B≡N bond of the amino imino borane **1a** is also reduced by this reagent. The oily compound **77**, containing a tetracoordinated Al atom ($\delta(^{27}Al) = 109$),[50] is formed regiospecifically.



77

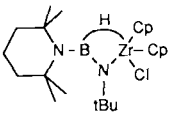


78

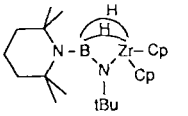
R = Me, Cl

Whereas in most cases the hydrosilylation of alkenes or alkynes requires a catalyst, the hydrosilylation of **1a** needs only a sufficiently acidic Si center. Me_3SiH does not add to **1a** either in the presence of a radical initiator or of a hydrosilylation catalyst. However, reactions with Me_2SiHCl and $SiHCl_3$ to give **78** occur even at ambient temperature without a catalyst. The possible chlorosilylation (see Section 4.5.2), which could compete with the hydrosilylation, does not occur. Chlorosilylation is thermodynamically favored by 55 kJ mol^{-1} over hydrosilylation;[36] even statistically, the chlorosilylation should be dominant at least in the case of $SiHCl_3$. Since a strong Lewis acidity of the silane is a prerequisite for the success of the reaction, one can conclude that hydrogen transfer occurs anionically. Under this assumption, the better polarizability of the hydrogen atom explains the kinetically controlled formation of **78**. Accordingly, the hydrometalation of amino imino boranes should occur more readily the more polar the hydrogen-metal bond. Me_3GeH will not react with **1a**; however, Me_3SnH and Bu_3SnH yield the hydrostannation products (SnR_3 instead of SiR_2Cl) analogous to **78**; these are thermally labile liquids which destannylate during distillation.

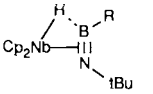
Compound **1a** is also hydrometalated by transition-metal hydrides such as Cp_2TiH,[36] Cp_2ZrH_2, and Cp_2ZrHCl.[56] Compound **79** is a hydride-bridged species according to its X-ray structure. Spectroscopic data (^{11}B NMR, IR) prove the presence of a double hydride bridge for **80**. The hydride bridge in **79** is exceptional insofar as a tricoordinated boron atom is involved. Such a hydrido bridge is only weakly indicated (d(B–H) = 137(3) pm) in



79



80



81

R = N(SiMe$_3$) tBu, tBu

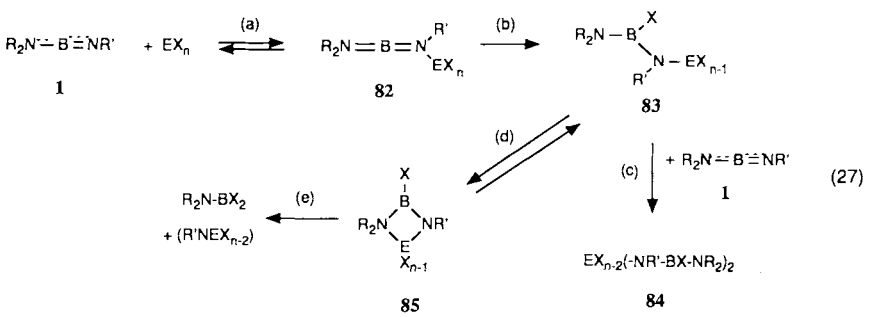
compounds **81**, which are formed by reaction of Cp_2NbH_3 with **1b** or tBu–B≡N–tBu whereby elemental hydrogen is lost. The most remarkable structural part of **81** is the side-on coordination of the imino borane unit.[62]

4.5. Halometalation Reactions

Covalent element halides EX_n react readily with amino imino boranes. Depending on their Lewis acidity, the polarity of the element halogen bond, the steric bulk of the amino imino borane fragment, and the halogen atom, as well as the Lewis-acidic character of the resulting $N-EX_{n-1}$ group, the reaction (27) stops at one of the stages **82**–**85**.[63] For these reactions **1a** and **1g** were used as model compounds.

4.5.1. Adduct Formation and Equilibria

The Lewis acidity of the attacking element halides determines the position of the equilibrium (27a). Me_3SiCl, Me_3SiBr,[14] Ph_3SiCl,[19] Me_3GeCl, Me_2GeBr_2,[36] Me_3SnCl, Me_3SnBr,[14] $CpTiCl_3$, Cp_2TiCl_2, Cp_2ZrCl_2, and Ph_3PAuCl[36] do not react with **1a**. Analogously, **1g** is not attacked by Me_3SiCl, Me_3SiBr, Me_3SiN_3, Me_3SiCN, $EtSiCl_3$,[19] $HgBr_2$, HgI_2, CuCl, $RhCl_3$, VCl_3, or $MnCl_2$.[64] However, **1g**, *like* **1a**, adds $AlCl_3$, $AlBr_3$, and $GaCl_3$[64] to produce compounds of type **82**, and this is also true for AsI_3, SbI_3, and $BiCl_3$.[65] This type is also formed by the action of **1a** on $SnCl_2$, Me_2SnCl_2, Me_2SnBr_2, $SnBr_4$,[36] AsI_3, $SbBr_3$, SbI_3, $BiCl_3$,[65] $TiBr_4$, $ZrCl_4$, and $PdCl_2 \cdot 2\,PhCN$.[36] The Lewis acids $SnCl_2$, Me_2SnCl_2, and Me_2SnBr_2 are only loosely coordinated to **1a**, as reflected in the solution equilibrium (27a). This can be shown by a decreased intensity of the characteristic IR band of **1a** at 990 cm^{-1} or by molecular weight determinations. Thus, **1a** · Me_2SnCl_2 in benzene at 0°C is dissociated to the



(27)

extent of 61% in a 0.001 M solution. Adduct **1a** · Me_2SnBr_2 in toluene at −78 °C is present as a stable adduct of type **82** according to ^1H and ^{13}C NMR spectra, and the $^2J(^{119}Sn^1H)$ coupling constant of 81 Hz indicates pentacoordinated Sn.[66] At 57 °C, however, the complex is totally dissociated into its components.

Compound **1g** is sterically more demanding than **1a**. This explains why the former will not react with HgI_2 and $HgBr_2$, in contrast to **1a**, nor with TiI_4 or $TiCl_3$.[44]

4.5.2. Insertion Reactions

If less polar covalent element halides are employed, halometalation to give compounds of type **83** dominates. Borylamino-substituted element halides **83** are thereby formed, mostly in a straightforward manner. These compounds are of high potential precursors in the synthesis of heterocycles which cannot be obtained by other routes.

Borylamino-substituted silanes of type **83** result from **1a** and SiF_4, $SiCl_4$, $MeSiCl_3$,[36] Me_2SiCl_2, $EtSiCl_3$, Me_2SiCl_2, Ph_2SiCl_2, Si_2Cl_6,[19] and $SiBr_4$.[36] Double insertion to give the compound type **84** occurs only with SiF_4.[36] However, Si_2Cl_6 also reacts with a second mole of **1a**, the second $SiCl_3$ group being converted into an $SiCl_2NtBu-BCl(tmp)$ group.

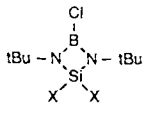
Compound **1g** is also subject to halosilylation. Insertions to produce the compound type **83** occur with $SiCl_4$, $SiBr_4$, $PhSiCl_3$, Ph_2SiCl_2, and Si_2Cl_6.[50,64] Double insertion into the SiCl bonds of these chlorosilanes has not been achieved.

The structure of the insertion product **1g** · Ph_2SiCl_2 was established by X-ray methods. In solution this compound dissociates in part into Ph_2SiCl_2 and **1g**.[19] This chlorosilane elimination occurs at the lowest temperature so far observed. If this compound and similar material were made available by a different route in high yield, then one would have excellent sources for amino imino boranes at hand.

Chlorosilylation has also been observed for **1c**, with Me_2SiCl_2 and $EtMeSiCl_2$, as well as for **1b** with $SiCl_4$ and Me_2SiCl_2. The latter products eliminate Me_3SiCl in chloroform solution with condensation to diazasilaboretidines **86**.[67]

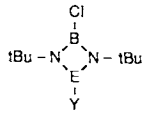
Halogermylation and halostannylation, respectively, of **1a** and **1g** to the compound type **83** is achieved with $GeCl_4$ or $MeSnCl_3$.[36,64] The same holds for **1b** and $GeCl_4$, Me_2GeCl_2, and $SnCl_4$. The products are stable in $CHCl_3$ solution, in contrast to the chlorosilylation products. However, they decompose on heating.[67]

Borylamino-substituted phosphorus(III), arsenic(III), antimony(III), and sulfur compounds are formed in the reactions of **1a,b,g** with PCl_3, PBr_3, AsF_3, $AsCl_3$, $AsBr_3$, SbF_3, $SbCl_3$, SCl_2, and S_2Cl_2.[41,65,67] Many of these are not very stable. Thus, $tmp-BF-NtBu-AsF_2$ decomposes readily at ambient temperature according to Equation (27d) into $tmpBF_2$ and the diazadiarsetidine $(tBuNAsF)_2$.[65] Although the structures of these insertion products **84** are uniquely established by their NMR spectra in solution, some of them may represent more likely the compound type **85** in the solid state. Proof for this statement is provided by the X-ray structures of $tmp-NtBu-ECl_2$ (E = As, Sb).[65] The coordinative EN bond is more pronounced for the antimony compound due to the stronger acceptor strength of the antimony moiety.



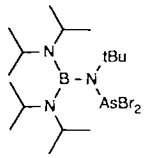
86

X = Cl, Me



87

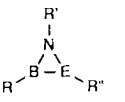
E = P, As, Sb
Y = Cl, Et, tBu, Ph



88

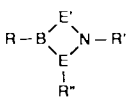
The product of type **83** obtained at −30 °C from **1b** and $AsCl_3$ is unstable at ambient temperature and decomposes with elimination of Me_3SiCl.[67] Reactions of **1b** with PCl_3, $AsCl_3$, or $SbCl_3$ in $CHCl_3$ lead directly to the four-membered heterocycles **87** instead of compounds of type **83**.[67]

The chemospecific insertion of the B≡N bond of **1a,c,g** into the element halogen bond of $MePCl_2$,[44,67] iPr_2PCl,[20,68] $PhPCl_2$,[44] $MeAsCl_2$,[67] and $tBuAsCl_2$[44] to give diamino boranes **83** can be understood in terms of the low chemical reactivity of the respective element carbon bonds. This chemoselectivity remains, astonishingly, in the reactions of **1a,g** with $(MeO)_2PCl$ or with 2-fluoro-1,3,2-benzodioxaarsolane and -stibolane.[44] While the products formed from **1a** and Me_2NPCl_2 are unaccounted for,[44] chloroarsenation occurs exclusively in the reaction of iPr_2NAsCl_2 with **1b**. However, the primary insertion product **88** rearranges subsequently.[67] $EtPCl_2$, $tBuPCl_2$, and Et_2NPCl_2 do not give interceptable chlorophosphorylation products; only the heterocycles **87**[67] can be isolated.



89

E	P	Si	Si	P
R''	*i*Pr	Me_2	MeEt	N*i*Pr



90

E	PPh	AsPh	PPh	AsPh
E'	$SiMe_2$	$SiMe_2$	B(N*i*Pr$_2$)	B(N*i*Pr$_2$)

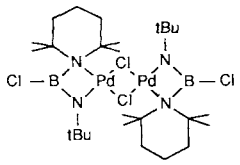
Many of the insertion compounds **83** mentioned can be dehalogenated to produce the three-membered heterocycles **89** or, via nucleophilic substitution reactions, the four-membered heterocycles **90**. From this point of view these compounds are valuable synthons.[67,68]

4.5.3. Intramolecular Stabilization

Halotitanation of the B≡N bond of **1g** is observed when $TiCl_4$, $TiBr_4$, and Me_2NTiCl_3 are used.[19] TiF_4 reacts very slowly in boiling hexane beyond the stage **83** with elimination of $tmpBF_2$.[19,64] In contrast, the insertion product of $TiCl_4$ and **1a** stabilizes itself as a compound of type **85**. The same is true for the products obtained from **1a** and $SnCl_4$, $NbCl_5$, $TaCl_5$, and $PdCl_2 \cdot 2\,PhCN$.[36]

The ^{13}C NMR spectra of compounds **85** are characterized by a substantial low-field shift ($\Delta\delta$ = 10–20 ppm) of

the C atoms bound to the nitrogen atom of the tmp group. In the case of the tin compounds, the ^{119}Sn resonance lies in the range for pentacoordinated tin.[66] Finally, this mode of bonding is proved by an X-ray structure determination of the centrosymmetric insertion product **91**.[36,63]

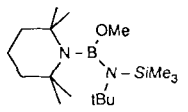


91

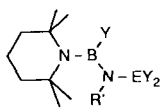
The intramolecular stabilization requires acidic metal centers and substituents offering little steric hindrance, as provided by chlorides and the amino imino borane **1a**. It is conceivable that the compound type **85** cannot form in reactions of silicon, phosphorus, and arsenic halides with imino boranes R–B≡N–R′, reactions recently investigated extensively by *Paetzold* et al.[67]

4.6. Aminometalation and Alkoxymetalation Reactions

The acceptor character of the central atom E decreases in the series E–Hal, E–OR, E–NR_2 due to the decreasing bond polarity as well as the increasing steric shielding. For that reason the insertion of **1a**, for example, into the element nitrogen bond of a covalent amide should be more difficult than insertion into an element-halide bond. Since, except for Me_3SiI, trimethylsilyl halides will not react with **1a**, it is surprising to find that Me_3SiOMe adds readily at ambient temperature to give **92**. It is conceivable that the greater nucleophilicity of the MeO group as compared with the halogen plays a decisive role.[19]



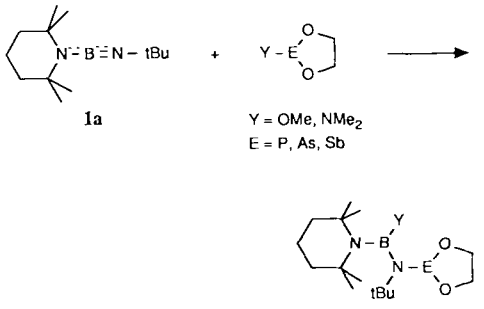
92



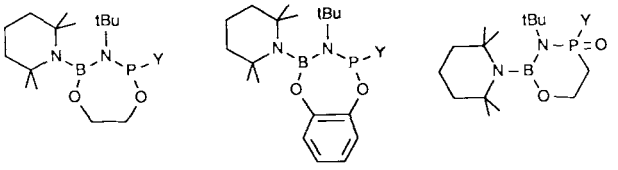
93

E	As	As	Sb	Sb
Y	OMe	NMe_2	OMe	NMe_2

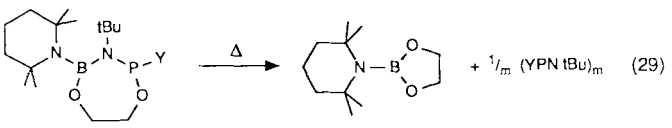
$P(OMe)_3$, $P(NMe_2)_3$, and $Sb(SMe)_3$ do not react with **1a**, in contrast to $As(OMe)_3$, $Sb(OMe)_3$, $As(NMe_2)_3$, and $Sb(NMe_2)_3$.[44] Borylated amides **93** of arsenic and antimony are obtained. Compound **1g** behaves analogously. In this case, however, an aminoarsenation with $As(NMe_2)_3$ is also possible.[44] The enhanced electrophilicity of phosphorus, arsenic, and antimony in 1,3,2-dioxaphospholane, -arsolane, and -stibolane derivatives allows reactions according to Equation (28) to occur. The same holds for the corresponding benzodioxa compounds. In each case it is the exocyclic bond that will be broken. However, in the case of the 2-halo and 2-methyl derivatives of dioxaphospholane and benzodioxaphosphole, the PO ring bond is more reactive, resulting in a ring expansion to the seven-membered heterocycles **94** and **95**.[44] Arbusov rearrangement to **96** is not observed, either on heating or in the presence of carbenium ions.[44] This reaction cannot compete with the ring contraction to the 1,3,2-dioxaborolane **97** [Eq. (29)].[44]



1a Y = OMe, NMe_2; E = P, As, Sb (28)



94 Y = Me, F, Cl, Br **95** **96**



94 **97** (29)

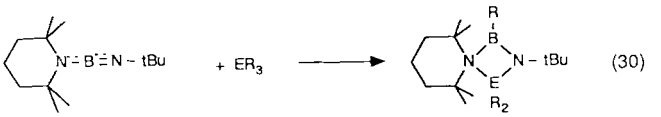
In reactions of **1a** with 2-chloro-1,3,2-dibenzodioxarsole and -stibole, only benzoannelated compounds of type **97** are observed besides AsN and SbN heterocycles.[44] The formation of the benzodioxaborole is explained by an intramolecular ring contraction of the seven-membered rings of type **95**. Finally, it is worth mentioning that **1a** is aminostannylated by Me_3SnNEt_2.[20]

4.7. Azidation Reactions

Boryl azides, R_2BN_3, and trimethylsilyl azide react with imino boranes by azidation of the boron atom. A [2+3] cycloadduct is formed as a byproduct.[69] The latter is not observed at all in the reaction of Bu_2BN_3 or Me_3SiN_3 with **1b**[15] or of Me_3SiN_3 with either **1a** or **1g**.[19,36,69]

4.8. Organometalation Reactions

The organoboration of amino imino boranes is matched by organoalumination, -gallation, and -indation according to Equation (30). These reactions are successful in hexane



1a E = Al, Ga, In; R = Me, Et, Ph; Me, Et, Ph; Ph **98** (30)

solution by using either the associated compounds $(ER_3)_n$ or the ether adduct $AlEt_3 \cdot OEt_2$.[50] An acid-base product can be expected in the first step of the reaction. However, only the compounds **98**, having a cyclic structure as evidenced by ^{13}C and ^{27}Al (for E = Al) NMR spectra, are observed.

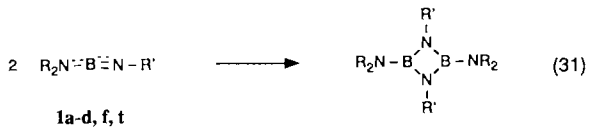
$SnMe_4$ will not methylstannylate **1a**.[50] This failure is due to the low Lewis acidity of this organometallic compound.

4.9. Cycloaddition Reactions

Contrary to alkynes and ynamines,[12] no high activation energy or enhancement by a catalyst is generally necessary for the oligomerization of imino boranes in spite of the fact that some compounds act catalytically.[9] The reason lies in the polarity of the BN bond. Depending on the steric bulk of the organo groups R and R′ of imino boranes R−B≡N−R′, these stabilize themselves by undergoing transformation to the cyclodimeric diazadiboretidines, the cyclotrimeric borazines, or "Dewar-borazines", to the cyclotetrameric tetraza-2,4,6,8,1,3,5,7-tetraborocanes, or to polymeric imino boranes, as has been shown by *Paetzold*[9] in fundamental studies.

4.9.1. Dimerization of Amino Imino Boranes

The oligomerization of amino imino boranes **1** has been limited so far to a monotonous dimerization to diazadiboretidines **99** as shown in Equation (31);[14,17,20,21] imino boranes R−B≡N−R′ behave differently. The X-ray structure analysis of the two diazadiboretidines **99a**[38] and **99f**[19] shows that these possess a planar, slightly diamond-shaped B_2N_2 four-membered ring (cf. Ref. [9]). The BNC_2 planes of the planar-coordinated amino nitrogens are oriented almost perpendicular to the ring B_2N_2 plane (for the substituents of **1** and **99** see Table 1).



(31)

The rate of dimerization of the amino imino boranes is sterically controlled. While pure, liquid **1a** remains monomeric for only a few hours,[21] the likewise liquid **1m** remains monomeric even after several months.[19] While the initiation of the dimerization of **1h** requires about 100°C, it is suppressed for **1i**.[14] However, **1d** dimerizes within a few minutes.[20] Dimerization is detectable in liquid **1f** only after two days,[16] whereas it is spontaneous for **1c**.[17] This is convincing evidence that amino imino boranes are kinetically stabilized by bulky substituents.

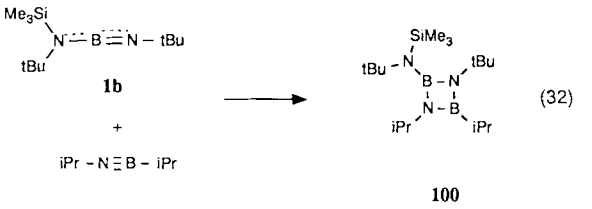
Total energies, calculated for molecules with optimized geometries, show that the diazadiboretidine model molecules gain substantially in stability ($E_{stab.}$) as compared to the amino imino borane precursors (cf. Table 4).[14] Accordingly, the amino imino boranes possess a higher thermodynamic tendency to dimerize than the imino boranes R−B≡N−R′.

Table 4. Gain in stability, $E_{stab.} = E_{total,\,dimer} - 2E_{total,\,monomer}$ [kJ mol^{-1}], of some model amino imino boranes (type **1**) by dimerization to diazadiboretidines (type **99**).

H−B≡N−H −386	F−B≡N−H −499	H_2N−B≡N−H −495
Me−B≡N−H −300	H−B≡N−Me −245	H−B≡N−NH_2 −286

According to STO-3G calculations, the dimerization of imino boranes is a thermally allowed one-step process,[14,20] which is forbidden for the isoelectronic carbon counterparts.[70] A nonconcerted two-step process of the dimerization of imino boranes can be excluded on the basis of MNDO calculations.[14,20] The following activation energies E_A [kJ mol^{-1}] for the dimerization of amino imino boranes have been obtained from calculated potential plots: H−B≡N−H 96.3, Me−B≡N−Me 146.5, Me−B≡N−SiH_3 134, H_2N−B≡N−Me 121.[20]

The second-order rate for the dimerization of **1a**, as demanded by Equation (31), is observed experimentally. The rate depends slightly on the solvent. Thus, the dimerization rate for **1a** at 20°C is about twice as fast in toluene as in CCl_4.[71]



(32)

Codimerization of **1b** succeeds with the reactive imino borane *i*Pr−B≡N−*i*Pr; i.e., the cycloaddition of two different imino boranes is achieved according to Equation (32) to give the asymmetrically substituted diazadiboretidine **100**.[15]

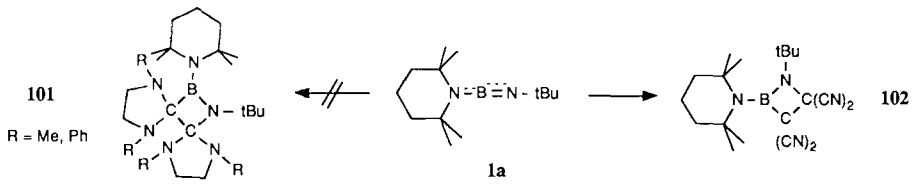
4.9.2. [2+1] Cycloaddition Reactions

[2+1] cycloaddition reactions of amino imino boranes should make three-membered ring systems available. However, diphenylcarbene, generated from diphenyldiazomethane, did not react with **1a**. Since methylene, prepared from diazomethane, also did not react with **1a** to produce an azaboriridine, but instead yielded only polymethylene, the reason for the failure of the reaction with diphenylcarbene cannot be steric in nature.[36]

Dodecamethylcyclohexasilane yields dimethylsilanediyl photochemically,[72] which reacts, in turn, with **1a**. However, the separation of the various reaction products has not yet been possible.[36] On the other hand, dimethylgermanediyl, generated from 7-germanorbornadienes according to *Neumann* et al.,[73] does not react with **1a**.[36]

4.9.3. [2+2] Cycloaddition Reactions

With Olefins and Alkynes: It is well known that concerted [2+2] cycloaddition reactions of carbon systems are thermally forbidden but photochemically allowed.[70] This

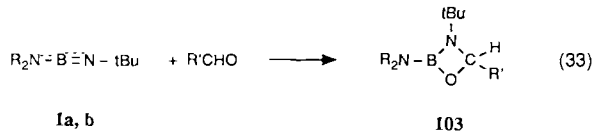


does not apply strictly for the isoelectronic BN bonding systems due to their lower symmetry. However, the polarity of the BN bond may favor multistep reactions.

Electron-rich 2,2'-biimidazolidinylidene derivatives do not react with **1a** at 70°C to produce **101**, in contrast to the electron-deficient tetracyanoethylene, which cycloadds within a few minutes to give the 1,2-azaboretidine **102**. Its four-membered ring is planar according to its X-ray structure,[36] in contrast to isoelectronic cyclobutenes. Not only the ring CC bond (159 pm) but also the ring BC bond (171 pm) of **102** is longer than standard single bond distances. The ring BN bond length (141 pm) indicates double-bond character.

Nonactivated alkynes such as acetylene and diphenylacetylene, but also methoxyacetylene, produce no [2+2] cycloadducts with **1a**. However, they accelerate its dimerization slightly.[36] Reaction with dihydrobenzene, generated from 1-bromo-2-fluorobenzene and magnesium,[74] leads to no defined product.[36] Also, hexafluorobutyne does not undergo cycloaddition with **1a**, in contrast to dimethyl acetylenedicarboxylate which prefers, however, a different reaction path (see Section 4.9.6).

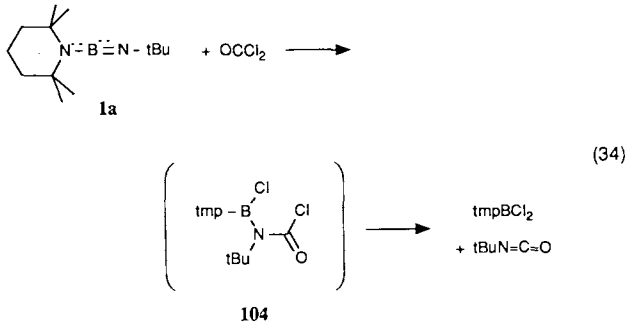
With Carbonyl Compounds: Paetzold et al. (cf. Ref. [9]) observed that imino boranes R–B≡N–R′ react with aldehydes and ketones to produce oxazaboretidines, whereas ketones having an enolizable proton provide access to aminovinyloxy boranes RB(NHR′)OCR″=CR‴₂. This reaction mode [see Eq. (33)] holds also for the amino imino



1a → **103**: R_2N = tmp, R′ = H
1b → **103**: R_2N = *t*Bu(Me₃Si)N,
R′ = Ph, MeCH=CH, CH_2=CMe

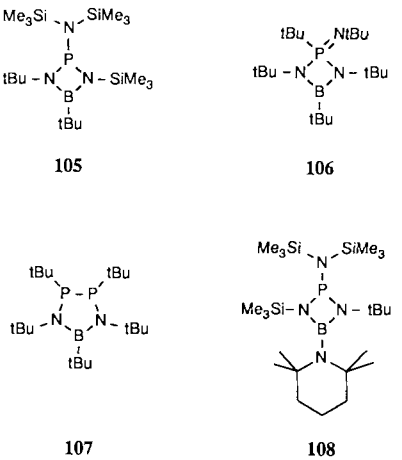
borane **1b**, which reacts with aldehydes to afford high yields of the heterocycles **103**.[15] Crotonaldehyde and 2-methylacrylaldehyde, therefore, do not react as 1,4-dipolar systems. Formaldehyde cleanly furnishes in its reaction with **1a** the distillable [2+2] cycloadduct.[36]

Benzophenone is unreactive towards **1a**, and acetone only reacts at 57°C to generate, via its enolic form, tmp–B(NH*t*Bu)OC(Me)=CH_2.[36] Phosgene reacts readily even at low temperature according to Equation (34). However, distillative workup produces tmpBCl_2, which most likely is formed via the product **104**.[36] Therefore, the chlorine transfer dominates the cycloaddition in this case, presumably because the RN–C(O)Cl group is well stabilized by resonance.



With Iminoalkenes: As shown in Section 4.2.2, amino boranes react rapidly with NH functional groups. In order to observe [2+2] cycloaddition with imino alkenes, which are well known from imino borane chemistry,[9] a reaction with HN=CR_2 compounds, as well as with imine–enamine tautomeric azomethines, is therefore prohibited. In analogy to benzophenone, MeN=CPh_2 and **1a** do not react to give a diazaborolidine.[36]

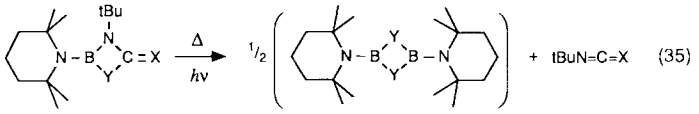
With Iminophosphanes: The [2+2] cycloaddition of *t*Bu–B≡N–*t*Bu with the amino imino phosphane $(Me_3Si)_2N$–P=N–$SiMe_3$ proceeds regioselectively to give the 1,3,2,4-diazaphosphaboretidine **105**.[75] Reaction of *t*Bu–N=P–*t*Bu with *t*Bu–B≡N–*t*Bu occurs, however, approximately in a molar ratio of 1.5 : 1. The heterocycle **106** is thereby formed as the oxidation product and the diazadiphosphaborolidine **107** as the reduction product.[76]



The cycloaddition of **1a** with $(Me_3Si)_2N$–P=N–$SiMe_3$ proceeds rapidly and regiospecifically yielding the heterocycle **108**, whose ^{11}B and ^{31}P atoms are very well shielded in comparison with those of 1,3,2,4-diazadiboretidines and 1,3,2,4-diazadiphosphetidines, indicating transannular interactions.[36]

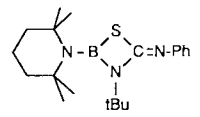
With Allenes: The heterocumulenes CO_2, COS, CS_2, and CSe_2 cycloadd to **1a**, rapidly producing the four-mem-

bered rings **109**. It is interesting to note that COS yields exclusively the 1,3,2-thiazaborolidin-4-one (**109**, X = O, Y = S); i.e., the thermodynamically preferred C=O bond remains intact. On heating, the heterocycles **109** decompose with cycloreversion according to Equation (35), producing the diboretanes **110**.[77]

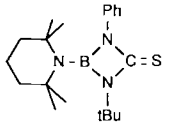


109 **110** (35)

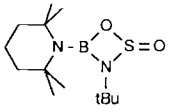
[2+2] cycloadducts of **1a** with MeN=C=O, *t*BuN=C=O, and dicyclohexylcarbodiimide extend the range of new four-membered heterocycles of boron.[36] When phenyl isothiocyanate and **1a** are allowed to react, a 7:3 mixture of isomers consisting of **111** and **112** results.[36] In contrast, $Ph_3P{=}C{=}PPh_3$ proved to be unreactive.[36]



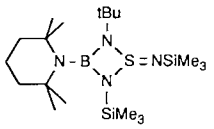
111



112

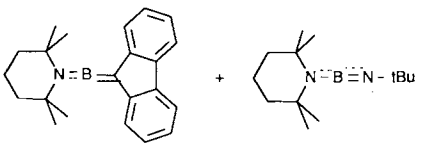


113

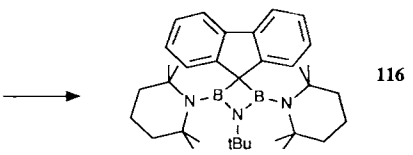


114

In addition, SO_2[41] and $S(NSiMe_3)_2$,[20] bent heteroallenes, react quickly with **1a** to give the two cycloadducts **113** and **114**. The former decomposes at about 200°C into $(tmpBO)_2$ and $(tmpBO)_3$.[41] A cycloaddition between **1a** and $S(NtBu)_2$ is prevented on steric grounds.[41]



115 **1a**

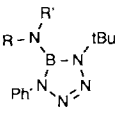


116

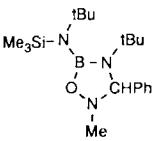
The amino alkylidene borane **115** counts also as a heteroallene. Its cycloaddition with **1a** makes the nonplanar 1,2,4-azadiboretidine **116** available, as also shown by X-ray crystallography. The nonplanarity of the ring indicates strong 1,3-transannular interactions.[78]

4.9.4. [2+3] Cycloaddition Reactions

In contrast to Me_3SiN_3, which azidosilylates **1a** and **1b**—explainable by nucleophilic attack of the imino nitrogen on the silicon atom—phenyl azide reacts as a 1,3 dipole with **1b**,**c**, producing the dihydrotetrazaboroles



117

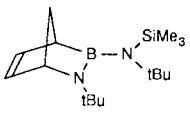


118

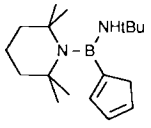
117.[15,17] *N*-Methylbenzylideneamine *N*-oxide analogously leads to the 1,2,4,5-oxadiazaborolidine **118**.[15]

4.9.5. [4+2] Cycloaddition Reactions

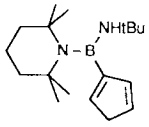
The imino borane $C_6F_5{-}B{\equiv}N{-}tBu$ reacts as a dienophile with cyclopentadiene to give a Diels–Alder adduct.[79] Compound **1b** should yield, in analogy, the compound **119**.[15] However, no such adduct has been obtained from **1a**; instead, a mixture of isomers **120/121** is formed, whereby the structural assignment required ^{11}B-decoupled ^{13}C NMR spectra.[36] That cyclopentadiene acts only as a protic species towards amino imino boranes has been established meanwhile also for the product obtained from this diene and **1b**,**c**.[17]



119



120

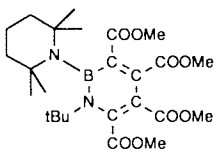


121

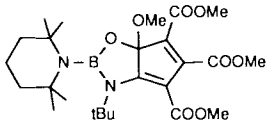
No [4+2] cycloaddition takes place between **1a** and 1,1-dimethyl-2,3,4,5-tetraphenylgermole or -stannole or between **1a** and 2,5-dimethylfuran.[36]

4.9.6. Reactions with Dimethyl Acetylenedicarboxylate

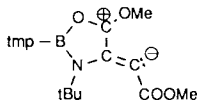
Alkynes R–C≡C–H are in most cases too weakly acidic to react with amino imino boranes with CH insertion. Also, their CC triple bond is not reactive towards these compounds. Methyl propiolate provides an exception: it protonates **1a** to give $tmpB(NHtBu){-}C{\equiv}C{-}C(O)OMe$. In contrast, dimethyl acetylenedicarboxylate reacts with **1a** in a 2:1 molar ratio. The NMR data of the product could be interpreted in terms of an azaborabenzene **122**.[63] However, an X-ray structure analysis definitely showed a bicyclic structure **123**.[36] Therefore, the amino imino borane attacks with its imino nitrogen atom at one of the alkyne carbon atoms. A second molecule of the ester adds in a more rapid second step to the 1,3-dipolar intermediate **124** to produce **123**.



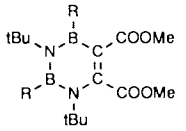
122



123



124



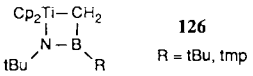
125

R = Me, Et

An analogous reaction is unknown for imino boranes R–B≡N–*t*Bu, but their dimers add dimethyl acetylenedicarboxylate in a molar ratio of 1 : 1 to give a diazadiborabenzene derivative **125** which is not planar.[80]

4.10. Reactions with Organotransition-Metal Compounds

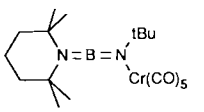
The imino borane *t*Bu–B≡N–*t*Bu[81] and the amino imino borane **1a**[82] add to electron-deficient carbene complexes of titanium by [2+2] cycloaddition, giving the metallacycles **126**. In contrast to the hafnium complex, compounds **126** are not susceptible to cycloreversion, thereby opening up an elegant route to alkylidene boranes $R_2N-B=CR_2$.[83]



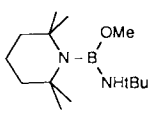
126

R = tBu, tmp

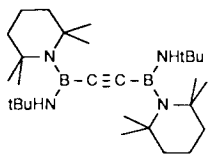
In contrast, the electron-rich Fischer carbene complex [$(CO)_5Cr=C(OMe)Me$] reacts with **1a** approximately in a molar ratio of 4 : 1. The products **127**–**129** are formed in this process, and a vinylidene complex [$(CO)_5Cr=C=CH_2$] is discussed as an intermediate. Some of the postulated reaction steps have been verified by deuterium labeling.[82]



127

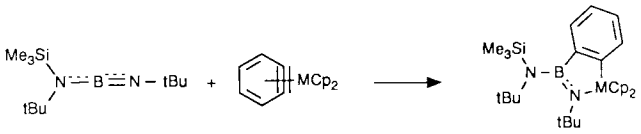


128



129

How enormous a variability can be unraveled by studying the chemistry of amino imino boranes with organometallic compounds is convincingly demonstrated by the reaction of **1b** with dehydrobenzene complexes: azaborametallaindanes **130** result with **1b**. The titanium compound shows an almost planar five-membered ring.[84] Alkynes interact in a similar fashion with the dehydrobenzene complex.[85]



1b

130

M = Ti, Zr

4.11. Reactions with Strong Bases

The steric and electronic shielding of the boron atom in amino imino boranes prevents proton-inactive neutral bases, such as ether, tetrahydrofuran, or pyridine, from adding to **1a**. However, **1b** reacts readily with strong anionic bases such as MeLi, BuLi, and *t*BuLi to yield *N*-lithio bis(amino) boranes *t*Bu(Me_3Si)NBR(NLi*t*Bu), whose Li atom can be complexed by tetramethylethylenediamine without opening the original NLi bond.[87] Analogous reactions have been observed between **1a** and Grignard compounds. We are dealing again, in principle, with insertion reactions (i.e., an organolithiation of the imino borane bond). It remains at present an open question whether the carbanion attacks the boron atom or the lithium atom the imino nitrogen.

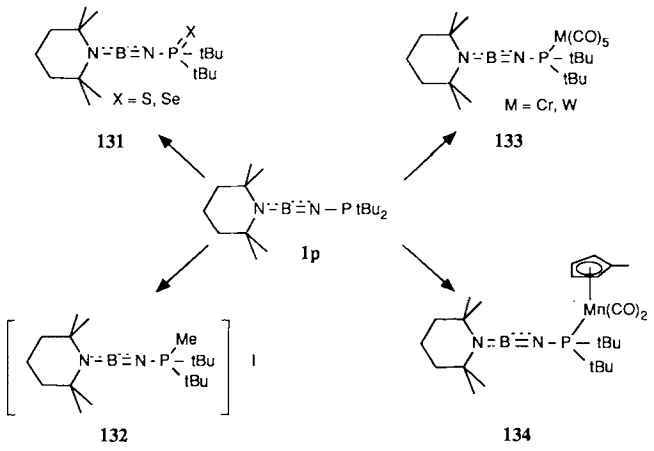
However, the reaction of RLi with an amino imino borane does not always follow the path just outlined, because *t*BuLi cleaves the tmp group of **1a**. The diazadiboretidine (*t*Bu–N=B–*t*Bu)$_2$ results,[14] an indication that either the reaction conditions or the steric crowding will influence the course of the reaction.

4.12. Reactions at the Imino Substituent

N-functionalized imino boranes open up new reaction channels similar to *B*-functionalization. The chemistry of *N*-functional amino imino boranes has not yet been well investigated except for the di-*tert*-butylphosphane derivative **1p**. As a phosphane derivative, **1p** readily adds sulfur or selenium at its P atom to give the compounds **131**. The oxidation of the phosphorus atom influences the shielding at the boron nucleus only slightly. $\delta(^{31}P)$ is now found in the region typical of the $R_2NP(S)tBu$ group. The position of the $\nu(B\equiv N)$ band reveals that the oxidation brings about a weakening of the BN triple bond, because there is a shift by 55 cm^{-1} to longer wavelengths for X = S and by 95 cm^{-1} for X = Se.[20]

Methyl iodide transforms **1p** ($\nu(B\equiv N) = 1935$ cm^{-1}) into the phosphonium salt **132**, whose $\nu(B\equiv N)$ band lies at 1870 cm^{-1}, a 65-cm^{-1} shift to longer wavelength as compared with the starting material.

Of the various reaction possibilities which are available for a metal carbonyl fragment—side-on coordination of the BN triple bond, addition to the imino nitrogen, dimerization and complexation, and *P*-coordination—only the latter occurs for $Cr(CO)_5$, $W(CO)_5$, and $MeCpMn(CO)_2$ (cf. **133** and **134**).[20] Thus, the P atom dominates as the



coordination center over the imino nitrogen, thereby demonstrating the validity of the HSAB concept. Addition of the metal carbonyl fragment causes $\nu(B{\equiv}N)$ to shift by 5–25 cm^{-1} to longer wavelengths and consequently changes the amino imino borane bonding system much less than the methylation to the salt **132**.

According to MNDO/CNDO calculation (see Table 5) on the model compound $H_2N{-}B{\equiv}N{-}PMe_2$, neither the addition of sulfur to phosphorus nor the phosphonium salt formation influences the BN bond order of the $H_2N{-}B$ group significantly, but the salt formation weakens the BN triple bond considerably and strengthens the PN bond. The net positive charge at the boron is increased. Consequently, **133** and **134** should be attacked electrophilically at the boron atom.

Table 5. Calculated bond enthalpies ΔH [kJ mol^{-1}], dipole moments μ [D], total bond orders P, net charges q at the B atom and imino N atom, and HOMO-LUMO energy differences ΔE [eV] for three phosphorus-containing amino imino boranes $H_2N{-}B{\equiv}N{-}X$.

X	ΔH	μ	P		q		ΔE

5. Concluding Remarks

The developing chemistry of imino boranes in general[9] and of the amino imino boranes in particular has not only substantiated former speculations that they may appear as intermediates in the synthesis of boron heterocycles, especially borazines.[87] As unsaturated systems, even the kinetically stabilized members exhibit high reactivity and a versatile chemisty which allows access to new classes of compounds. In addition, it emerges that they will be suitable for the boration of biochemically interesting molecules, which, in turn, may be useful for the development of new reagents and compounds for neutron therapy.[88]

Amino imino boranes **1** enhance the chemical versatility of imino boranes considerably due to allene-type intermediates and new coordination possibilities. The amino group may adopt the function of a protecting group if it is possible to remove it from the reaction product, thus generating new reactive centers. This function will not be fulfilled by the 2,2,6,6-tetramethylpiperidino group; the $Me_3Si(t\text{Bu})N$ group is a much better candidate in this respect. The Me_2N group would possibly be ideal, but it will most likely not augment the kinetic stabilization of amino imino boranes.

From the point of view of a preparative chemist, the amino- and the imino-functional amino imino boranes should become particularly attractive in the near future, especially with regard to the synthesis of small rings and for chemical vapor deposition (CVD) processes.

The present report contains many results so far available only in the form of doctoral theses. It is hoped that these will become more readily accessible in the near future. The following co-workers have contributed to the development of the field in our laboratories: G. Geisberger, P. Kölle, D. Männig, Ch. K. Narula, K. Neukirchinger, E. Salzbrenner, M. Schwartz, B. Stoeber, E. Striedl, W. Rattay, and S. Weber. I would like to express my sincere thanks for their engagement, interest, and careful work and for many inspiring discussions. Also, I wish to thank my colleague, Prof. Dr. P. Paetzold, Technische Universität Aachen, for helpful cooperation. Without additional financial support we would not have been able to investigate the chemistry of amino imino boranes so comprehensively: we therefore thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, BASF Aktiengesellschaft and, last but not least, Chemetall GmbH for supporting our research.

[31] This problem has been discussed recently also by *P. Paetzold* (see [9]). He recommends the following bond lengths: $\geqslant$B–N$\leqslant$ 158 pm, $>$B=N$<$ 141 pm, –B≡N– 126 pm.
[32] The notion "addition" is used for the formation of Lewis acid-base adducts; i.e., the boron atom remains dicoordinated. In insertion reactions both the boron and the nitrogen atoms of the imino borane become tricoordinated.

[55] A decision whether kinetic or thermodynamic product control prevails is difficult to make because, although BX bonds are opened in boration reactions, a new BX bond is formed; however, the strength of the BN bond decreases in the order monoamino, diamino, triamino boranes [56]. The observed effect should be larger in amino boranes with very bulky substituents than in the thermochemically investigated series of dimethylamino chloro boranes.

Structure and Reactivity of Lithium Enolates. From Pinacolone to Selective *C*-Alkylations of Peptides. Difficulties and Opportunities Afforded by Complex Structures

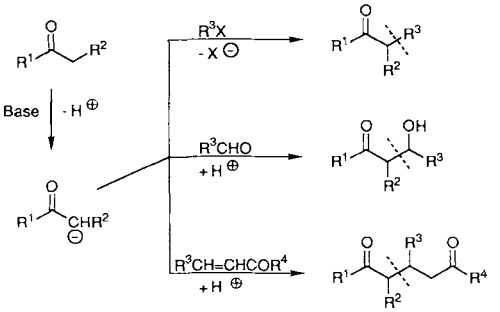
By Dieter Seebach*

The chemistry of lithium enolates is used to demonstrate that complex structures held together by noncovalent bonds ("supramolecules") may dramatically influence the result of seemingly simple standard reactions of organic synthesis. Detailed structural data have been obtained by crystallographic investigations of numerous Li enolates and analogous derivatives. The most remarkable features of these structures are aggregation to give dimers, tetramers, and higher oligomers, complexation of the metal centers by solvent molecules and chelating ligands, and hydrogen-bond formation of weak acids such as secondary amines with the anionoid part of the enolates. The presence in nonpolar solvents of the same supramolecules has been established by NMR-spectroscopic, by osmometric, and by calorimetric measurements. The structures and the order of magnitude of the interactions have also been reproduced by ab-initio calculations. Most importantly, supramolecules may be product-forming species in synthetic reactions of Li enolates. A knowledge of the complex structures of Li enolates also improves our understanding of their reactivity. Thus, simple procedures have been developed to avoid complications caused by secondary amines, formed concomitantly with Li enolates by the common methods. Mixtures of achiral Li enolates and chiral Li amides can give rise to enantioselective reactions. Solubilization by LiX is observed, especially of multiply lithiated compounds. This effect is exploited for alkylations of N-methylglycine (sarcosine) CH_2 groups in open-chain oligopeptides. Thus, the cyclic undecapeptide cyclosporine, a potent immunosuppressant, is converted into a THF-soluble hexalithio derivative (without epimerization of stereogenic centers) and alkylated by a variety of electrophiles in the presence of either excess lithiumdiisopropyl amide or of up to 30 equivalents of lithium chloride. Depending on the nature of the LiX additive, a new stereogenic center of (*R*) or (*S*) configuration is created in the peptide chain by this process. A structure-activity correlation in the series of cyclosporine derivatives thus available is discussed.

Nowadays, the molecular program of
chemistry has arrived at its successful termination.
H. Primas, ETH Zürich (1982)

1. Introduction—from α-Carbonyl Carbanions to Metal Enolates

Carbon-carbon bond formation in α-carbonyl positions is one of the most important processes for elaboration of carbon skeletons ("backbone of organic synthesis"). From the very beginning,[1] the variety of reactions of this type carried out under alkaline conditions was described as involving enolates which were drawn with the negative charge on carbon, pragmatically so, because that is where they react (Scheme 1). This notation continued to be used, especially in teaching, even when these reactions were no longer carried out in aqueous or other protic media, where solvent-separated "free" ions occur, and even though one realized that the negative charge is located on the more electronegative oxygen atom. The decisive role of the metal was appreciated when silyl enol ethers ("silyl enolates") were discovered for synthetic purposes[2]—they can be activated[3,4] by transmetalation or by treatment with fluoride ion, and they combine with electrophiles in reactions mediated by Lewis acids—and when the correlation between the configuration of the Li, B, Mg, and Sn[11] enolate double bond and the steric course of aldol additions[5-7] and other reactions[8] was disclosed.[9,10] Most of these reactions are



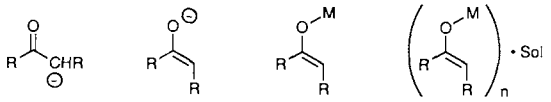
Scheme 1. Three classical reactions of carbonyl compounds: α-alkylation, aldol addition, and Michael addition.

[*] Prof. Dr. D. Seebach
Laboratorium für Organische Chemie der
Eidgenössischen Technischen Hochschule
ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich (Switzerland)

performed in nonpolar solvents (hydrocarbons, chlorohydrocarbons, open-chain or cyclic ethers, amines),[11] preferably at low temperatures, i.e., under conditions disfavoring the formation of ions, the separation of charges.[12-14]

While the important role of the metal in aldol additions quickly became part of synthetic planning, another property of the polar alkali and alkaline-earth enolates remained the "esoteric science" of only a few specialists: *the aggregation to higher-order structures.* It was known that potassium *tert*-butoxide is tetrameric in the solid state and in the gas phase[15] and that alkali enolates, even of β-diketones, form dimeric aggregates in the crystalline state.[16-18] It was concluded from ebullioscopic measurements[19] and from NMR spectra[20,21] that Li and Na enolates and phenolates are dimeric or tetrameric[22] in nonpolar solvents.[11] It is especially in the footnotes of early synthetic papers where one finds speculative suggestions that such enolate aggregates may be influential in product formation. In contrast, it has been well known for almost 30 years that aggregates of organolithium compounds with carbon–lithium bonds *may be* the product-forming species.[23,24] References are found in a classical monograph on the structure and reactivity of alkali and alkaline-earth metal derivatives[25] and in more recent books[26-36] and review articles (general,[37-41] NMR spectroscopy,[42-46] crystal structure analysis[47-53]).

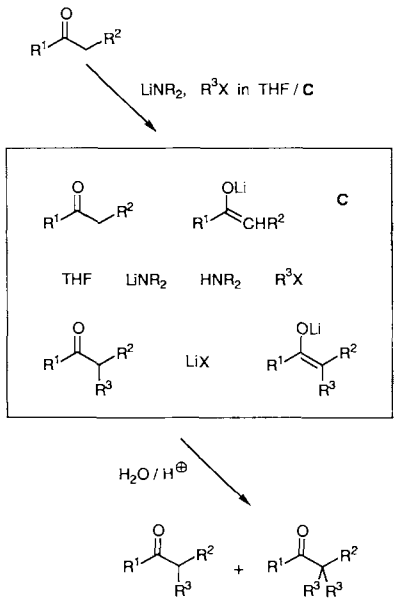
In this article we describe results of the past decade which not only increased our knowledge of Li enolates[53] but also enlarged the scope of these most important reagents and their nitrogen analogues, which are widely applied in research laboratories as well as in industrial development and production of drugs, pesticides, and fine chemicals. The choice of examples to be discussed is necessarily influenced by the personal experiences of the author and his collaborators: by making structural investigations on synthetically relevant reagents we try to reduce frustration originating from the fact that part of our group keeps discovering highly selective transformations which we do not understand at all.[54-57] Thus, the route of the sorcerer's apprentice is described, as indicated by the sequence of formulae in Scheme 2.



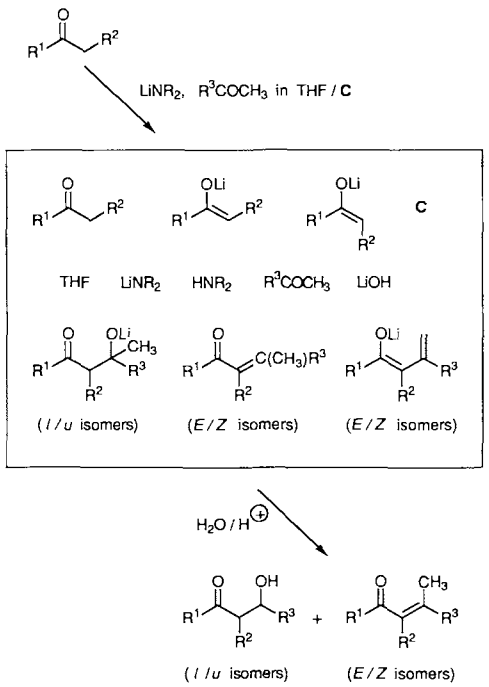
Scheme 2. From the deprotonated carbonyl derivative, via the metal enolate (M = metal), to aggregates, solvated and complexed by additives ("supramolecules" [58]). Sol = solvent molecules (ligands) in the coordination sphere of the metal.

2. The Complex World of Li Enolates—in Crystals and in Solution

Today's standard method of doing enolate reactions involves deprotonation of carbonyl compounds by lithium amide bases, for instance, lithium diisopropylamide (LDA),[59] tetramethylpiperidide (LTMP),[60] or hexamethyldisilazanide (LHMDS)[61] in THF, possibly in the presence of a cosolvent[8,62-65] or of a complexing agent.[26,52,66] The enolate solution thus obtained is combined with an electrophile. For CC bond formation this is usually an alkyl halide (Scheme 3) or a carbonyl compound (aldehyde/ketone,[67] Scheme 4). During these procedures, mixtures of the species shown inside the boxes of Schemes 3 and 4 are present. Since the first crystal structure analyses of ketone Li enolate aggregates[68] in 1981, numerous aggregates and complexes between these species have been isolated as single crystals suitable for X-ray analysis and/or have been



Scheme 3. Components which may coexist in a reaction mixture under the normal alkylation conditions of carbonyl compounds. **C** should be taken to represent an additive [cosolvent, complexing agent, e.g., hexamethylphosphoric triamide (HMPT) [62], "*N,N'*-dimethylpropyleneurea" (1,3-dimethyltetrahydropyrimidin-2(1*H*)-one, DMPU) [63], *N,N,N',N'*-tetramethylethylenediamine (TMEDA) [26], *N,N,N'*-trimethylethylenediamine (TriMEDA) [66], pentamethyldiethylenetriamine (PMDET) [26], dimethoxyethane (DME)].



Scheme 4. Components that may occur in an aldol reaction performed with an enolate generated by R_2NLi. **C** is an additive (see caption to Scheme 3).

detected in solution. Thermochemical data were collected and force-field calculations, as well as quantum-mechanical "investigations", were performed. This will form the subject of the following sections, before we turn to the question of whether these complex structures are involved in product-forming steps.[69]

2.1. Li enolates and "Ingredients" in the Crystalline State

... la virtùe della geometria esser il più potente strumento d'ogni altro per acuir l'ingegnio e disporlo al perfettamente discorrere e specolare.[*]
Galileo Galilei

All crystalline Li enolates for which an X-ray structure analysis has been successfully performed so far are dimeric, tetrameric, or hexameric aggregates, the degree of aggregation depending less upon the particular enolate structure than upon solvent and added complexing or chelating agents (Figs. 1–12). Dimers tend to be favored in the presence of ethylenediamines and tetramers with ethers such as THF; a hexamer was crystallized from a non-donor hydrocarbon solvent. Lithium enolates of pinacolone (3,3-dimethyl-2-butanone, Figs. 1–3) and its derivatives (Figs. 7, 8, 10) prevail among the structures solved, for obvious reasons (high stability, only one enolate possible).

Lithium enolates of esters are unstable even in the crystalline state, due to their decomposition to ketenes and alkoxides.[72,73] Special techniques are required for the generation and isolation of suitable single crystals at low temperatures[51,67c,87] (Figs. 4 and 13). Amide enolates are much more stable (Figs. 5 and 6, compare the leaving groups $LiNR_2$ and LiOR). Again, dimeric and tetrameric aggregates are present in the crystals of these Li enolates containing additional heteroatoms. Other components of the mixtures present during generation and during reactions of Li enolates with electrophiles have been crystallized and successfully subjected to X-ray crystal structure analysis in recent years. Oligomeric aggregates of Li amides (Fig. 9, dimer), of an aldolate (Fig. 7, tetramer), and of a dienolate (Fig. 8, dimer) were found, the Li atoms of which are solvated by the oxygens of ethers (Figs. 2, 6, 9) or carbonyl compounds (Fig. 7, 8, 11), by the oxygens of HMPT (Fig. 12), or by the nitrogens of secondary or tertiary amines (Figs. 3–5). The formation of aggregates, $[(LiX)_n]$, is not limited to identical components; mixed aggregates $[(LiX)_n(LiY)_m]$ may also be formed from different components, for instance, the complex skeleton assembled from LDA and a siloxy-substituted Li enolate (Fig. 10).

Since lithium is *usually* tetracoordinated, it is possible—with due care—to deduce the degree of aggregation of Li enolates, alkoxides, phenolates,[90] and their nitrogen analogues from the stoichiometric composition of isolated samples. In order to achieve tetracoordination, one, two, or three "external" ligand atoms are present per lithium in a tetramer, dimer, or monomer, respectively. The ratios given in Table 1 confirm that aggregation of LiX in the crystalline state is a general phenomenon, also by this criterion. Furthermore, inspection of Table 1 reveals that lithiated nitriles (Li ketene imines) and iminoesters (Li enamides) are also aggregated, which was confirmed by crystal structure analysis:[98] see Table 2 and Figures 14 and 15, showing a lithio "bis-lactim ether" (reagent for enantioselective amino acid synthesis[99,100]) and the HMPT-solvated lithio malononitrile, respectively.

The structures of sodium, magnesium, aluminum, and zinc enolates (Figs. 16–19) exemplify the fact that aggregation is by no means a peculiarity of Li derivatives, but is a general phenomenon in polar metal enolates.[115]

Many a crystallographer and inorganic chemist does not quite share the excitement of us organic chemists about the structures described here; these colleagues live with the fact that aggregates and clusters are "ubiquitous all over the periodic table".[115] For synthetic organic chemists[116]

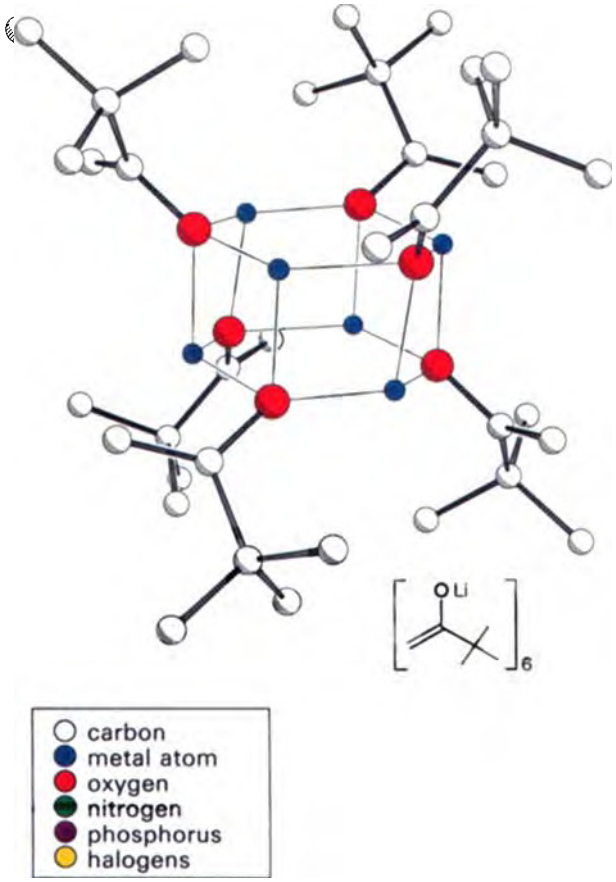


Fig. 1. Hexameric lithium enolate derived from pinacolone (enolate generated with LDA in heptane) [70, 71]. The crystal does not contain any solvent. The Li atoms are only threefold coordinated. Three square units of dimers are assembled in a hexagonal prism. A threefold axis runs perpendicularly to the hexagonal basis plane. The coordinates are stored in the *Cambridge Structural Database (CSD)* under the code CUYVOH. Here, and in all other illustrated structures (Figs. 1–12, 14–20, 23, 25, as well as the structures in [115]), the atoms are color-coded according to the key shown above. Other, non-carbon atoms are signified by their chemical symbol. The first coordination sphere of the metals is represented throughout by thin connection lines—for clarity, the neutral ligands or solvent molecules are not drawn to the same scale—while the anionic ligands are emphasized by bolder connection lines and larger spheres for the atoms.

[*] ... whoever has a grasp of geometry is capable of understanding this world.

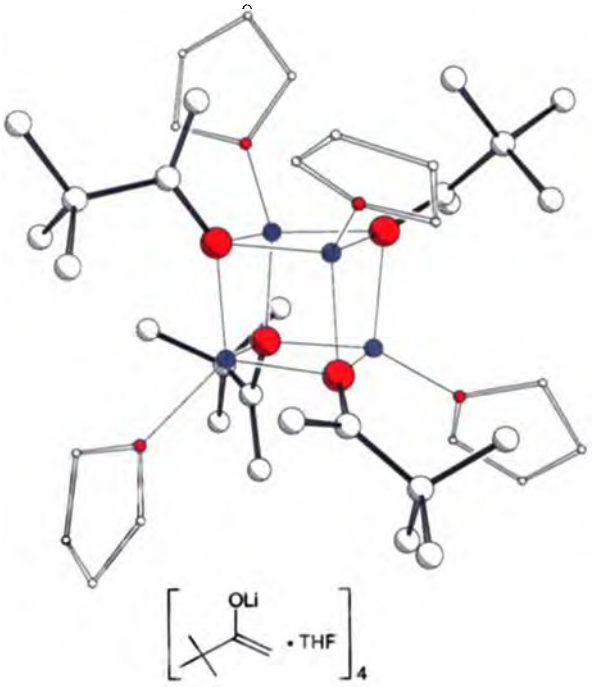

Fig. 2. Tetrameric Li enolate of pinacolone, crystallized from tetrahydrofuran. An almost perfect cube of four Li and four O atoms is surrounded by a "shell" of organic units—the enolate carbon skeleton and the THF molecules. The Li atoms are each surrounded by three enolate oxygens and one THF oxygen, so that a distorted tetrahedral coordination sphere results [68] (*CSD*: BEDYOY). The structure of the analogously arranged cyclopentanone-derived Li enolate is described in the same publication [68]; the corresponding coordinates are deposited under the *CSD* code BEDYUE.

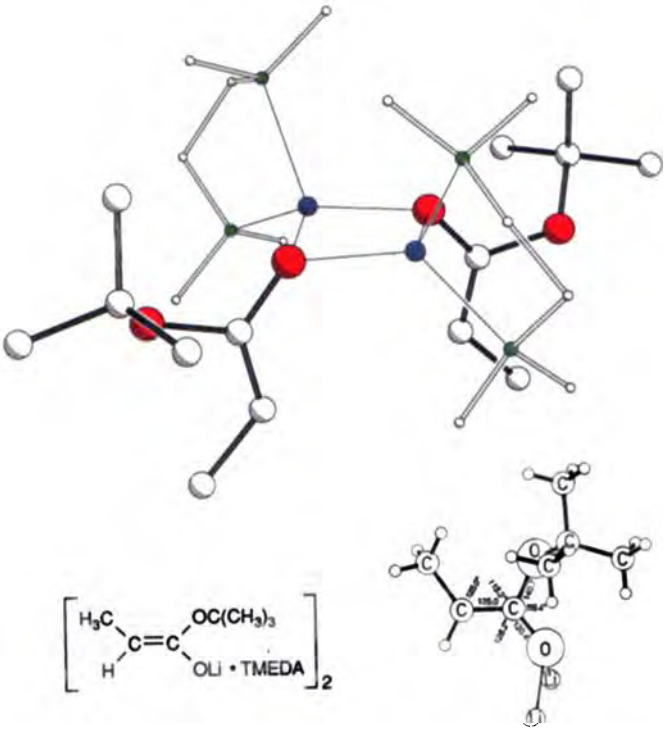

Fig. 4. Dimeric lithium (*Z*)-enolate of *tert*-butyl propionate, crystallized in the presence of TMEDA. The two enolate units are *cis* to each other on the LiOLiO four-membered ring through the center of which runs a C_2 axis of the dimeric aggregate. Even in the crystal, the ester enolate is unstable above −30°C. Its decomposition to a ketene [72, 73] and lithium *tert*-butoxide is perhaps indicated by the different C-O bond lengths (141 vs. 130 pm) and C=C−O bond angles (ca. 115 vs. 128°) at the trigonal O-substituted center of the double bond [73]. The *tert*-butyl group stands nearly perpendicular to the enolate plane (*CSD*: DEDXEP).

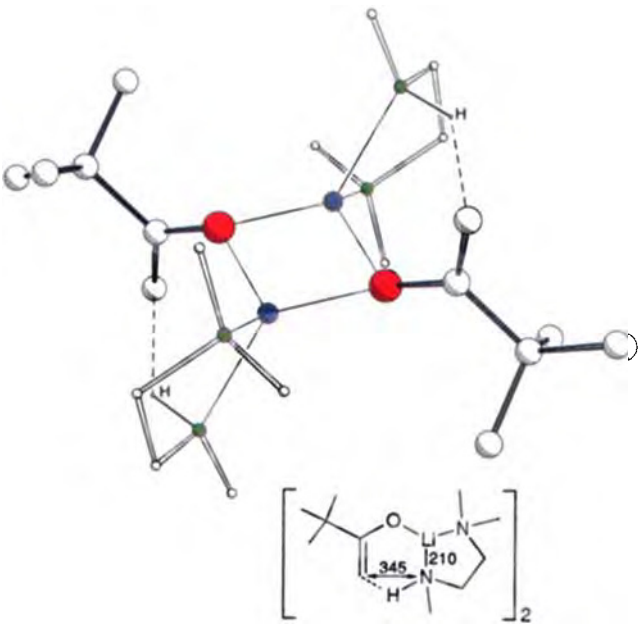

Fig. 3. Dimeric Li enolate of pinacolone crystallized in the presence of TriMEDA [66]. The nitrogens of the bidentate chelate ligand and two enolate oxygen atoms form a pseudo-tetrahedral arrangement around the Li atom. The distance between the NH hydrogen of the secondary amino group and the terminal C atom of the enolate double bond amounts to ca. 260 pm. The plane in which the atoms H···C=C lie forms an angle of ca. 60°C with that of the double bond. In the center of the LiOLiO quadrangle, there is a center of symmetry (*CSD*: DETRAV) [66], i.e., the enolate units are *trans* to each other (like the TriMEDA complex in Fig. 5 and the dienolate in Fig. 8, but unlike the dimers "solvated" with TMEDA or THF in Figs. 4 and 6).

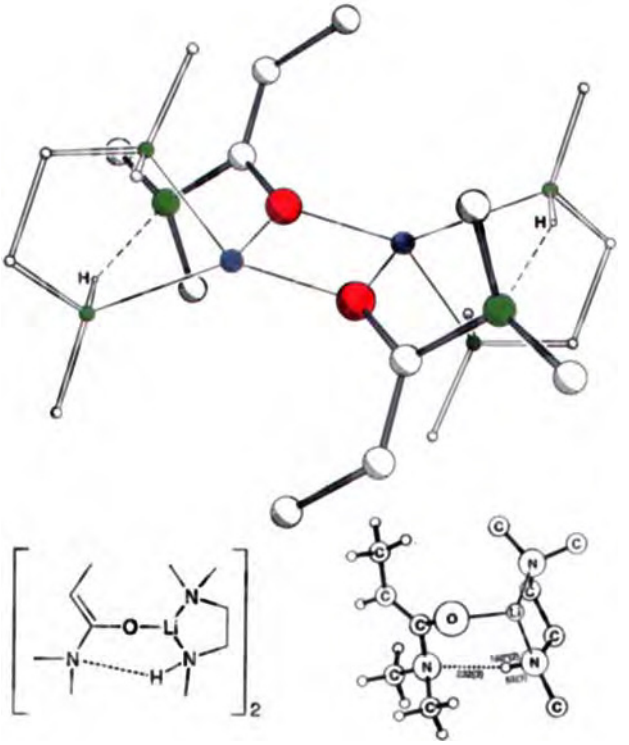

Fig. 5. *N,N*-Dimethylpropionamide lithium (*Z*)-enolate dimer, crystallized with TriMEDA. The center of the LiOLiO quadrangle is a center of inversion in the aggregate. The dimethylamino group of the enolate is like that in enamines [74], but much more strongly pyramidalized; the H atom of the secondary amino group lies in the direction of the virtual electron pair on this enamine nitrogen (lengths of hydrogen bonds, see [75, 76]) (*CSD*: DETPUN) [66].

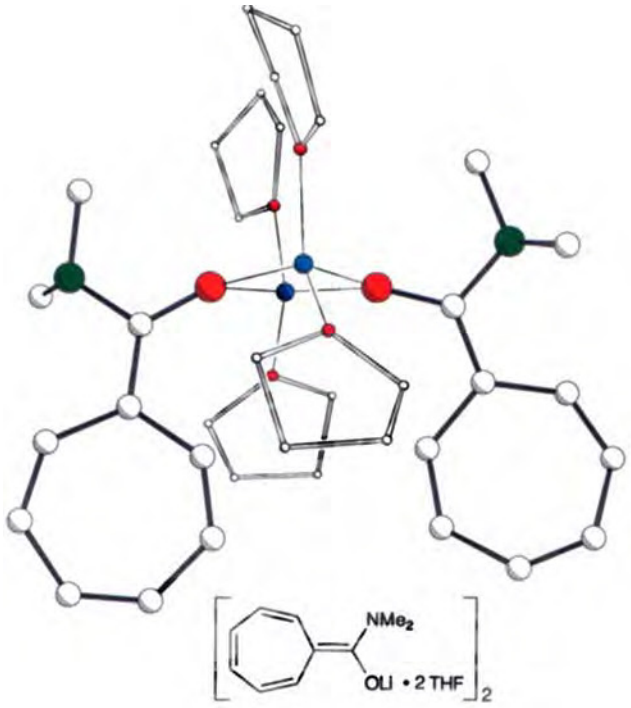

Fig. 6. Dimeric lithium enolate of *N,N*-dimethylcycloheptatrienecarboxamide, crystallized from THF [77]. As in the dimeric Li enolates of esters (Fig. 4), the enolate units are *cis* to each other at the LiOLiO quadrangle (with a C_2 axis through the ring center). THF molecules occupy quasi-axial and quasi-equatorial positions at the Li atoms of the folded four-membered ring (puckering angle between OLiO planes 68.6°, between the LiOLi planes 47.3°). The extended π systems do not participate in the complexation of the Li atoms. The Me_2N groups are turned out of the π plane, and the nitrogen is pyramidal (Δ = 36.5 pm) as in the propionamide enolate of Fig. 5.

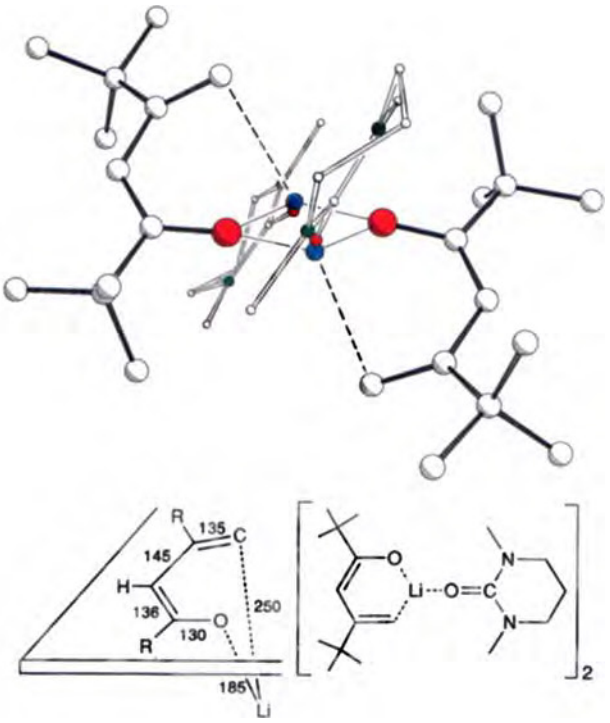

Fig. 8. Dimeric lithium (*Z*)-dienolate of 2,2,5,6,6-pentamethylhept-4-en-3-one (the product of aldol condensation between two pinacolone molecules), crystallized in the presence of DMPU [79]. The carbonyl oxygens of the cyclic urea and the terminal C atom of the dienolate (LiC bond distance 250 pm; cf. that in trityllithium, 223 pm [80]), as well as two oxygen atoms of the LiOLiO ring, surround the Li atom in the centrosymmetric dimeric aggregate (*CSD*: DIXWIQ).

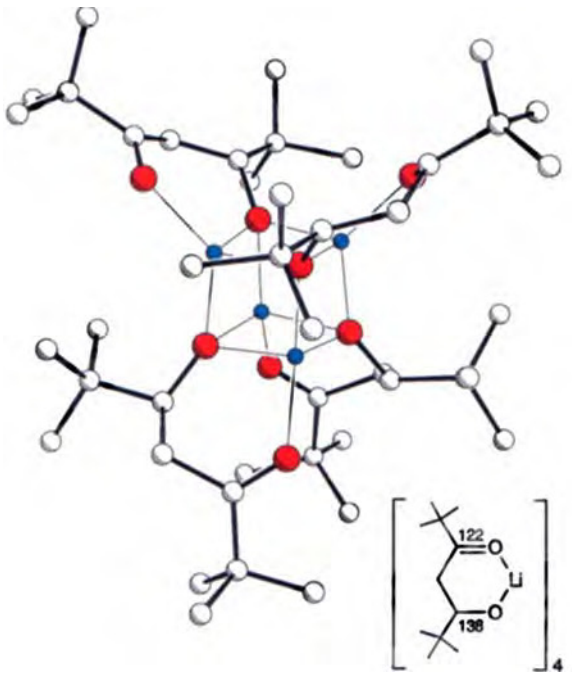

Fig. 7. Tetrameric aggregate of the Li aldolate from pinacolone and pivalaldehyde [78]. The negatively charged alkoxide oxygens and four Li atoms form a distorted cube (LiO distances 191–195 pm). The carbonyl oxygens of the aldolates are bonded to the Li atoms from outside (LiO distance 197 pm), as in other cases with the oxygen atoms of the solvent or nitrogen atoms of the ethylenediamine unit. In this arrangement, four "external" six-membered rings are formed, fused to alternating edges of the cube. The tetramer crystallized from pentane (*CSD*: DEWBIQ).

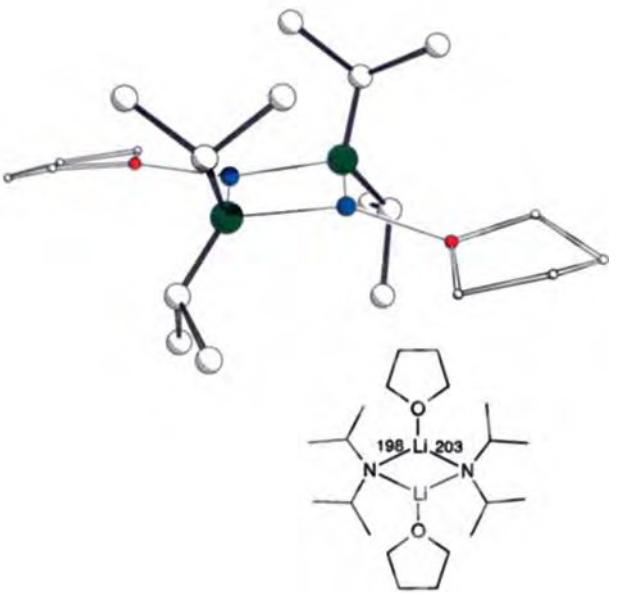

Fig. 9. Dimeric lithium diisopropylamide, obtained from THF [$(LDA)_2 \cdot (THF)_2$] [81]. The methyl groups of the isopropyl units point inwards, i.e., towards the LiNLiN four-membered ring. The Li atoms are each threefold coordinated as in other lithium amides (steric hindrance?). Additional $LiNR_2$ structures (monomer, four-membered ring dimer, six-membered ring trimer, and eight-membered ring tetramer) are shown in a review article on Li structures [47]; among these are also found lithium tetramethylpiperidide and hexamethyldisilazanide. (For more recent structure determinations of lithium anilide derivatives, see [82–84].)

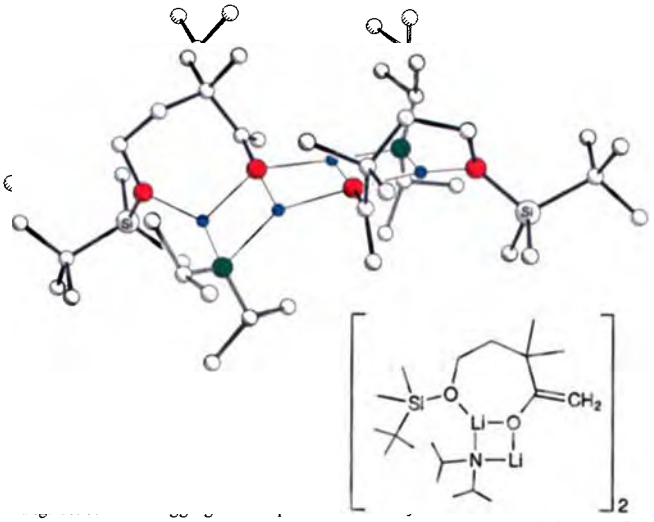

(from a methyl ketone, 5-(*tert*-butyldimethylsiloxy-3,3-dimethylpentan-2-one) and LDA. Three LiXLiY four-membered rings are fused to form a step-like structure. The siloxy oxygen serves as an "external" ligand to Li [85].

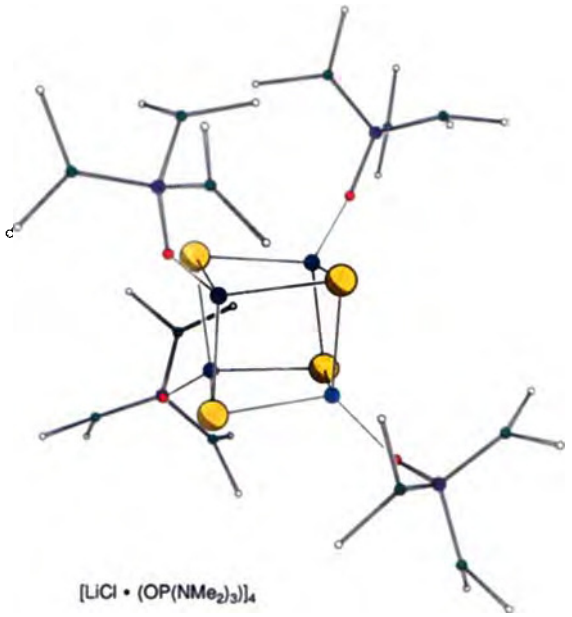

Fig. 12. Lithium chloride tetramer with four HMPT molecules, which are bonded to lithium via oxygen (from an "utterly fortuitous in situ preparation in high yield" involving $LiNCBu_2$, HMPT, $AlCl_3$ (1:1:0.3) in hexane/ether) [86] (*CSD*: CAWSIC). (For additional crystal structures with HMPT as "solvating ligand", see the review in [47], cf. also Fig. 15.)

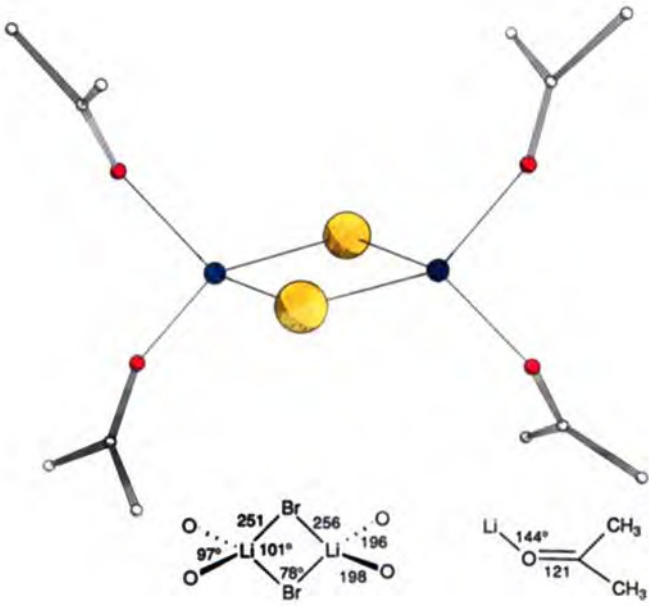

lithium atoms form a rhombus with acute angles at the bromine atoms. As in the case of protonated carbonyl compounds, the bond angle at oxygen is less than 180° in this complex between a ketone and LiBr (*CSD*: DECXEO 01). (See also the other adducts involving alkali-metal derivatives and carbonyl compounds in Figs. 7, 8, and 16 and in Tables 1, 2, 4, and 7 as well as the discussions in [79] and in Sections 2.3, 3, and 4.)

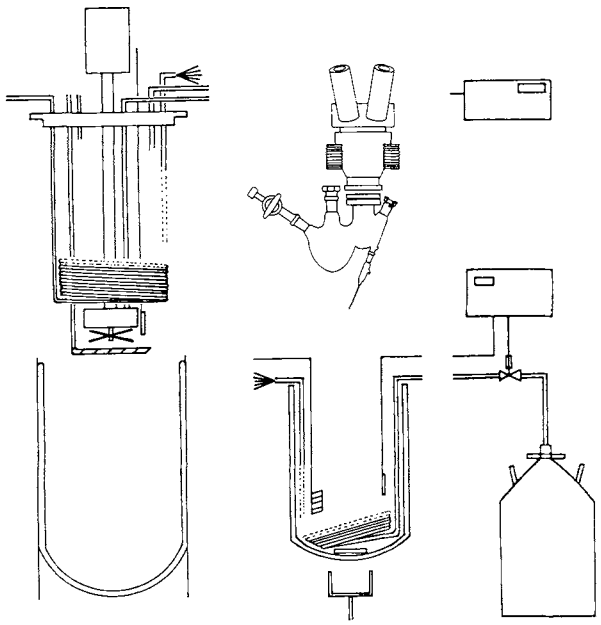

Fig. 13. Apparatus for the preparation of single crystals at low temperatures under inert atmosphere following the procedure in [67c, 73]. In this way, crystals of the ester enolates [73] (Fig. 4) and of a very unstable lithiated allyl thioether [87] were obtained; cf. also the X-ray structure analyses of aliphatic carbocation derivatives [88, 89] and the review article cited above [51].

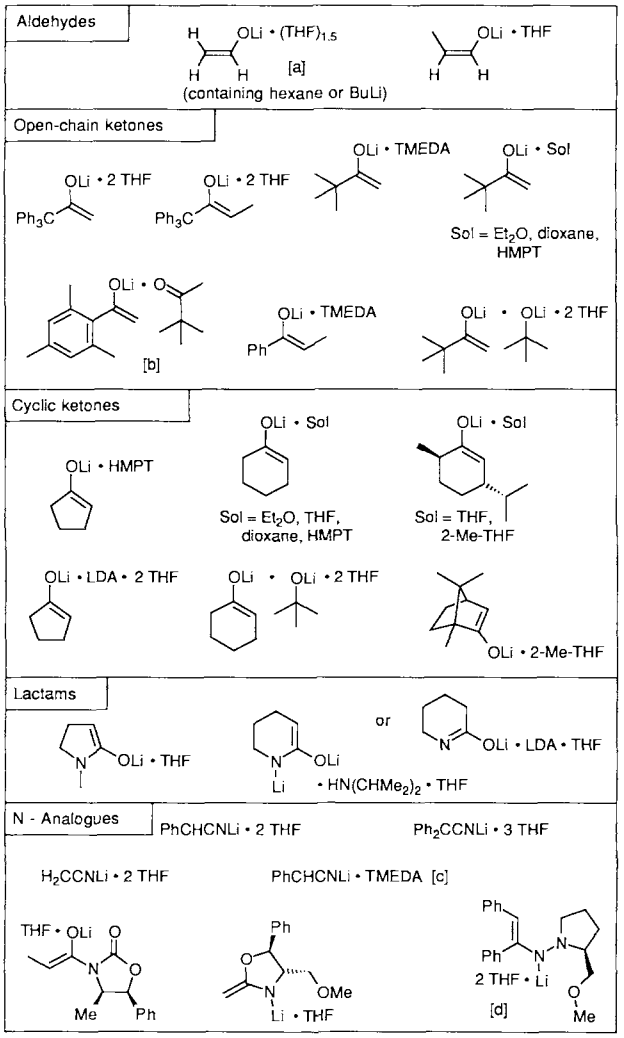
these structures are of enormous importance for the following reasons: (1) With an accuracy provided only by X-ray crystal structure analysis, we finally have structural parameters of the reactive intermediates used in the most important CC bond-forming synthetic methods. (2) Applications of the structure-reactivity correlation principle[117–124] lead to conclusions about mechanistic details of the reactions of these species, and these conclusions become more and more reliable with an increasing number of structures. (3) The less stable these species are, the more their structures hint at their reactivity; reaction trajectories can be read from distortions of the molecules as they occur in the crystalline state.[73,87–89] (4) Finally, knowing the rich complexity of the reagents involved, we can use these structures to reconsider and discuss in a more systematic way the jumble of excellent preparative results, useful recipes, and procedures.

Before doing so, the results of structural investigations of Li enolates in solution will be briefly discussed.

Table 1. Composition of crystalline samples of Li enolates and nitrogen analogues. The samples were obtained in the course of attempted preparations of single crystals for X-ray structure analysis. The solvent content was determined, after drying the crystals under high vacuum, by addition of excess CD_3COOD in an NMR tube and integration of appropriate signals in the resulting spectra [91-94]; for further examples see [66].



[a] Beautiful looking crystals separated from THF to which BuLi/hexane had been added [95]. Unfortunately, the crystals are not suitable for X-ray crystal structure analysis. [b] Compare with the Na enolate solvated by pinacolone (Fig. 16). [c] In the meantime, the dimeric Li phenylacetonitrile-TMEDA complex solvated by one molecule of benzene per aggregate unit was isolated and successfully subjected to X-ray crystal structure analysis [96]. [d] For the crystal structure of the Li enehydrazide of the hydrazone obtained from 2-naphthyl methyl ketone and *N*-aminoprolinol methyl ether, see [97] (monomeric, with two THF oxygens and the oxygen of the prolinol ether unit surrounding the Li atom).

Table 2. Schematic representation of some crystal structures of N-analogues of Li enolates. The PLUTO plots of two further structures of this type are shown in Figures 14 and 15 (see also a review article [47] covering the literature up to the beginning of 1984).

	Li enamide of the product formed from cyclohexanone and aniline [102]
	Polymeric Li enehydrazide of the product formed from 1,1-dimethylhydrazine and cyclohexanone [102]
	Dimeric Li enehydrazide of the product formed from 1,1-dimethylhydrazine and 1-oxocyclohexanecarboxylate. The compound contains two "very different" Li atoms [101a] (cf. Fig. 14)
	Dimeric Li ketenimide formed from phenylacetonitrile and TMEDA. A molecule of "crystal benzene"[96, 98] is present (for "simple" Li imides see [103-105])
	Section of the polymeric structure of the Li nitronate of phenylnitromethane $[PhCH{=}NO_2Li \cdot EtOH]_n$ [106]

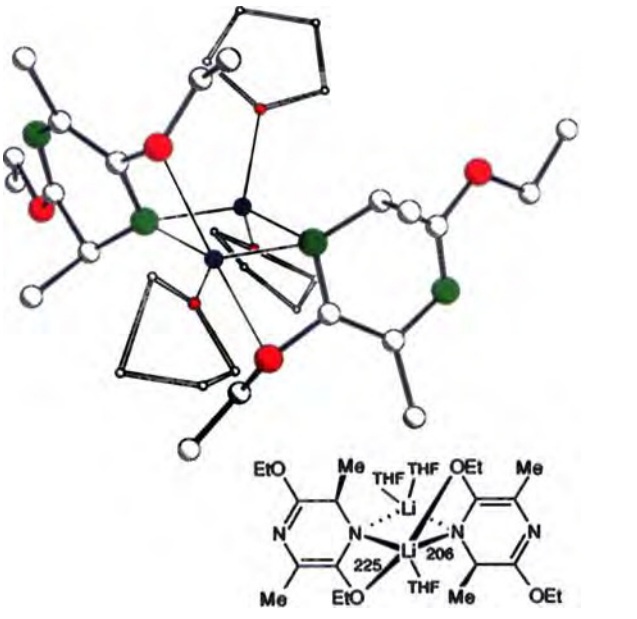


Fig. 14. Dimeric aggregate of the lithium bis-lactim ether derived from alanine [107] (*CSD*: CIFBOI). The two lithium atoms have very different environments; if the Li-Li neighborhood is not included, one Li atom is fivefold coordinated, the other fourfold. In this way, the diastereotopic faces of the dihydropyrazine ring are differentiated more strongly than by the methyl group at the stereogenic center (cf. the structure of the lithiated oxocyclohexanecarboxylic acid derivative in Table 2).

2.2. Li Enolate Structures in Solution—Not Simple Either!

2.2.1. Osmometric Measurements—Colligative Properties

From effects which ideally depend upon the number of particles per volume, the average molecular weight can be calculated, in the present case the degree of aggregation of Li enolates in solution. Ebullioscopy, vapor pressure osmometry, differential vapor pressure barometry, and cryoscopy applied to enolate solutions thus led to aggregation numbers between 1.0 and 4.0 (in certain cases several hundred), depending upon the type of enolate, the solvent,

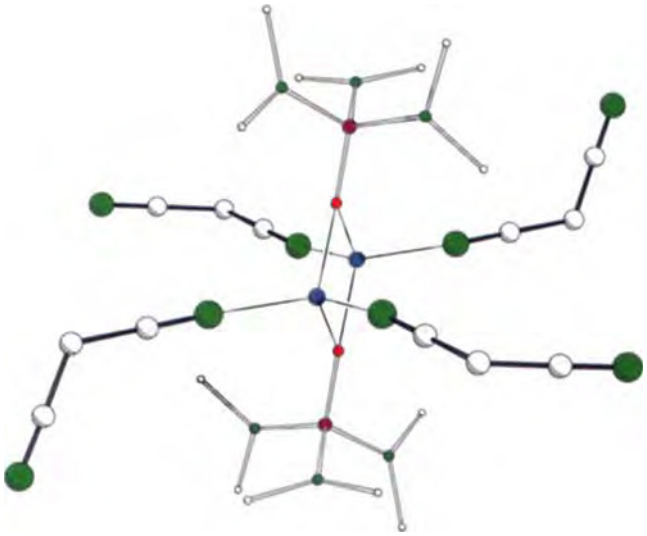

Fig. 15. Section of the polymeric structure of lithiated malononitrile $[LiCH(CN)_2 \cdot HMPT]_n$, which crystallized from a mixture of HMPT, hexane, and THF [108]. It is striking that the LiXLiX four-membered ring is not built up from the heteroatoms of the counterion (here the nitrogen) with the Li atoms, as usual, but from the oxygens of the HMPT. The nitrogen atoms of the dicyanomethanide lie "outside" of the aggregate. In the LiCl structure of Fig. 12, the HMPT oxygens are "outside". (Compare the structures in Fig. 12 and in Fig. 15 with a possible interpretation [69] of the HMPT effect on enolate reactions given in 1981, when there was no structural information about HMPT complexes. See also Scheme 9.)

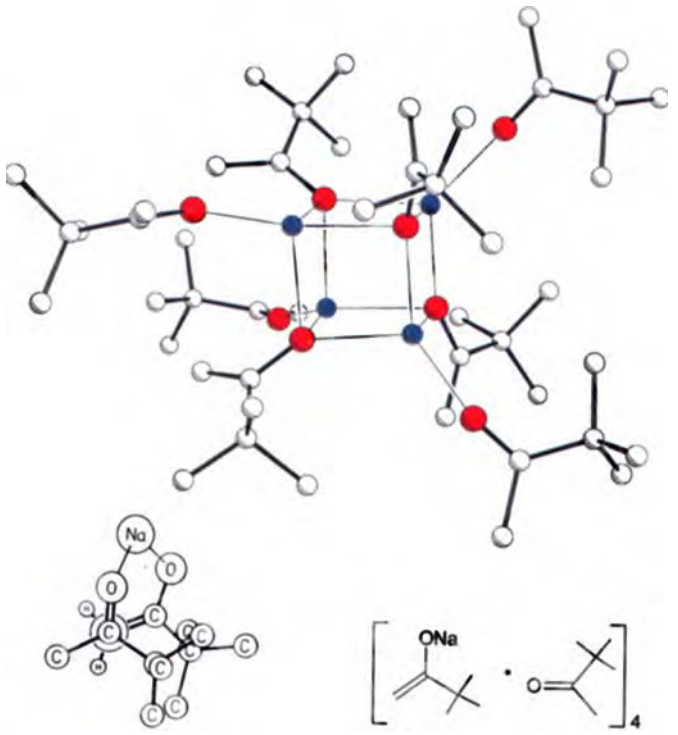

Fig. 16. Tetrameric sodium enolate of pinacolone, with pinacolone as "solvate molecule" (*CSD*: DIPSAW) [71]. A section shows that the planes of the π systems of the enolate and the ketone (bound together by the sodium) are more or less parallel, as they would have to be in a reaction between the electrophilic carbonyl carbon and the nucleophilic enolate one (separation distance 380 pm). The structure of the hexameric pinacolone K enolate solvated with THF, $[t\mathrm{BuC(OK)CH_2} \cdot \mathrm{THF}]_6$, is described in the same publication (*CSD*: DIPSEA). A complete collection of the structures of Na, K, Rb, and Cs organometallic compounds was published in 1987 [48].

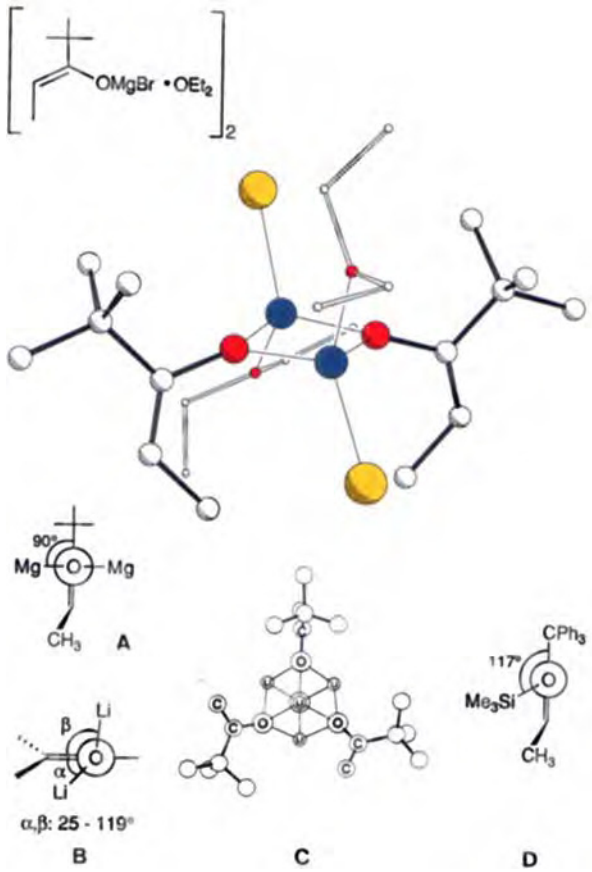

Fig. 17. Dimeric bromomagnesium (*Z*)-enolate of *tert*-butyl ethyl ketone (2,2-dimethylpentan-3-one), crystallized from diethyl ether (*CSD*: DILPUJ) [109]. The plane of the MgOMgO four-membered ring and that containing the enolate double bond are more or less perpendicular to each other (A). In the Li enolate dimers, the Li atoms lie outside the plane of the double bonds (Figs. 3-6) with very different LiOC=C torsion angles (B). In the tetramer (Fig. 2), however, a lithium atom does lie in the plane of the enolate (C). In a crystalline silyl enol ether (*CSD*: DIWXOW), the Si-O bond forms an angle of 117° with the plane of the enolate double bond [110a] (D).

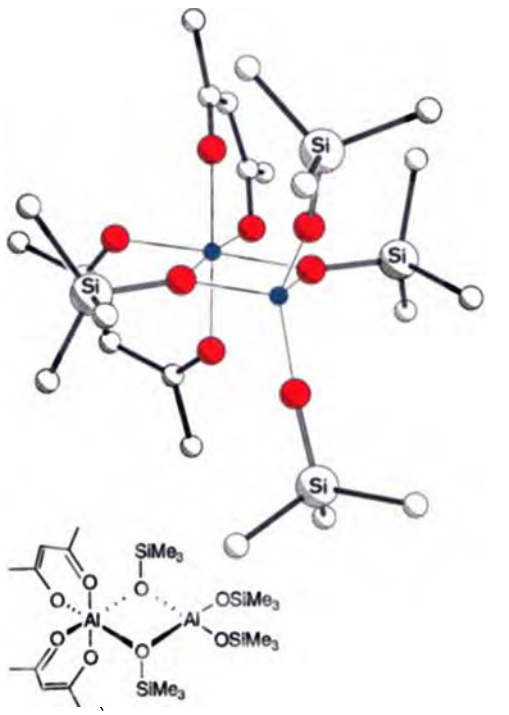

Fig. 18. Crystal structure of $[Al(OSiMe_3)_2(acac)]_2$, with two very different aluminum atoms (*CSD*: CIRMOF) [111]. In the opinion of the authors, the unexpectedly complex structure of these kinds of Al derivatives has to be borne in mind when considering their application as catalysts and as precursors of ceramic materials!

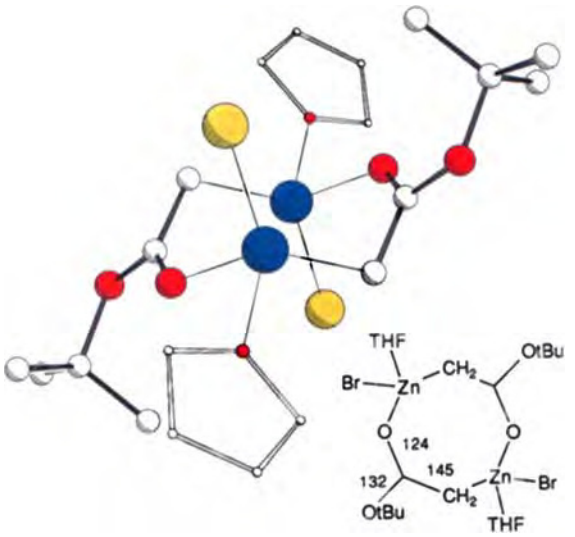

Fig. 19. Crystal structure of a Reformatsky reagent, $[BrZnCH_2COO(tBu)\cdot THF]_2$, crystallized from THF (*CSD*: BUDKAM) [112]. Two each of Zn, CH_2, C(O-*t*Bu), and O form an eight-membered ring. Each Zn bears a Br and a THF as substituents. In contrast to the alkali and Mg enolates, where the metal atoms are always bound to oxygens, the Zn atom here is simultaneously attached to the CH_2 group of one unit and the CO group of the other (see also the C-C and C-O bond lengths of the eight-membered ring). A discussion on the structures of cyclopropane and aziridine carboxylic ester enolates in which α-metallocarbonyl derivatives may also be present instead of the usual metal enolates can be found in [113, 114]. It is noteworthy that the Zn is σ-coordinated to oxygen, but π-coordinated to carbon (torsion angle Zn-O-C-O 164°, Zn-C-C-O −83°, respectively).

and the temperature.[22, 25, 27, 30, 94, 125, 126] Since many Li enolate reactions are preferentially carried out at dry-ice temperature in THF, the melting-point depressions measured[94] in this solvent (m.p. −107 °C) are especially "realistic". Of the numerous measurements only one will be referred to here: the Li enolate of cyclopentanone, which crystallizes as a tetramer from THF (see Fig. 2[68]), gives an aggregation number of 2.6–2.8 in THF solution at −107 °C, corresponding to a tetramer/dimer mixture of ca. 1:2. Vapor pressure measurements at higher temperature indicate that Li phenolates are largely tetrameric in ether solvents[127] (with polar organometallic compounds the entropy term may be such that larger aggregates—fewer solvent molecules bonded per Li—prevail at higher temperature and smaller ones at lower temperature[42c]).

2.2.2. *NMR Spectroscopy—More Detail*

By definition (*W. Wundt* and *W. Ostwald*) it is not possible to obtain information about the structure of aggregates in solution from colligative effects. Today's method of choice for studying solution structures is NMR spectroscopy. With the modern techniques (2D, 3D[128–131]) proximity between *nonbonded nuclei* (nuclear Overhauser effects) is detected, relaxation times are measured, quadrupole resonance spectra are obtained, dynamic processes are studied at very low temperatures, and the sensitivity is increased by isotopic labeling (^6Li, ^{13}C, ^{15}N, ^{17}O). All of this has provided a vast amount of detailed information about the species present in solution and the equilibria between them.[132] With *C*-metalated, "true" organolithium compounds the direct $^6Li,^{13}C$ coupling is the most valuable source of information about bonding between these two nuclei, about aggregation and the lifetime of aggregates (the multiplicity of the ^{13}C signals reveals the number of Li atoms bonded to the observed carbon[133]). Corresponding $^6Li,^{15}N$ coupling was used most recently for the determination of $LiNR_2$ aggregation in weakly polar solvents.[101b, 132b, 132c, 134, 135] There are no reports about Li,O coupling in enolates and phenolates; the investigation of Li enolates in solution by NMR spectroscopy is more difficult. So far, we owe the measurements in this area essentially to a single research group.[21, 22, 127, 136–140] From elaborate studies, especially of isobutyrophenone Li enolate and of Li phenolates, rather stable representatives of this type of species, many structural details have been deduced. Not only was the equilibrium between dimeric and tetrameric aggregates discovered, but also the presence of mixed aggregates between Li enolates or phenolates and LiBr, LiCl, and $LiClO_4$ in solution (all of this work has been carefully described; for an early review article on structure and reactivity of Li enolates see Ref. [22]). From hitherto unpublished ^1H and ^{13}C NMR measurements of the Li (*Z*)-enolate of propiophenone in THF, the following conclusions were drawn:[141] (1) There is an equilibrium between dimers and tetramers. (2) The dimer, but not the tetramer, forms a mixed aggregate with LDA. (3) Complexes between the Li enolate and diisopropylamine are formed; most likely these are more stable with the tetramer than with the dimer. (4) Addition of HMPT does not destroy the dimeric and tetrameric aggregates. (5) Mixed aggregates are formed upon addition of LiCl to the Li enolate solution. Also from NMR measurements, it is known that the parent compound, the Li enolate of acetaldehyde, is tetrameric in THF solution[142] (cf. Table 1 and Section 3), and that dimeric aggregates and mixed aggregates with LiBr exist in solutions of lithium amides.[101b, 102b, 132b, 132c, 143]

2.2.3. *ate Complexes—Also of Li Enolates?*

In the early fifties, *Wittig* interpreted the fact that organolithium compounds self-associate as arising from the formation of "autocomplexes"[144a] ("triple ions"). He ranked the dimeric phenyllithium in ether as $[Ph_2Li]Li$ in a series with the complexes $[Ph_3Be]Li$ and $[Ph_4B]Li$. Subsequently, such species were called *ate* complexes,[144b] by analogy with *onium* salts (cf. $[Me_4N]Cl$). When the first X-ray crystal structure analyses of Li,C and Li,O compounds appeared, it was realized that ate complexes form especially in those cases in which different metal cations or different anions are involved. In both the crystal[145, 146] (Fig. 20) and in solution[21] organolithium compounds with lithium halides were shown to be present as mixed aggregates rather than ate complexes, the formation of the latter being accompanied by charge separation.[150] Under these circumstances it is questionable whether ate complexes are present in solutions of Li enolates under the usual conditions, i.e., in nonpolar solvents and at low temperatures. Indeed, the only Li enolates for which ate complex-type structures have been detected are derived from β-dicarbonyl compounds (e.g., acetylacetone, acetoacetic esters; see the examples in Refs. [22, 47]). Some recent examples of Li ate complexes are collected in Table 3; cryptands and HMPT seem to favor their formation.

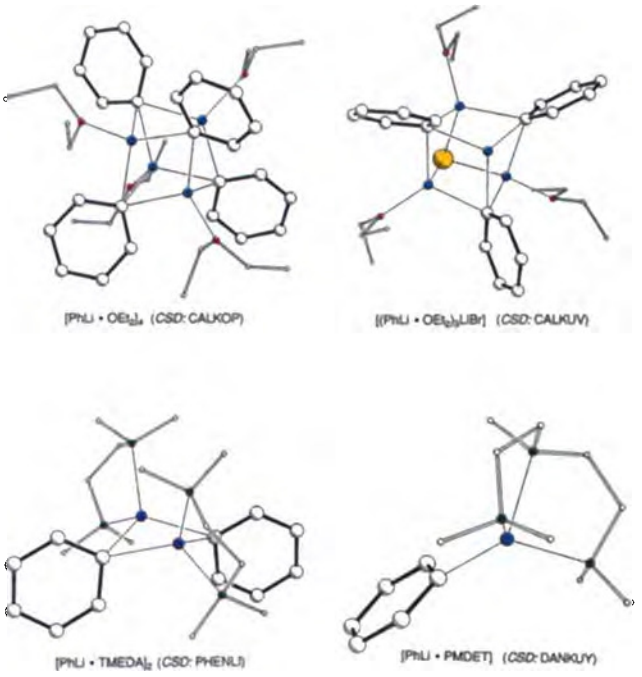

Fig. 20. Four different forms of phenyllithium in the crystalline state. From ether, a tetrameric aggregate crystallizes; in its center there are two "intertwined" tetrahedra, a larger one of four carbons and a smaller one of four lithiums [145]. In the presence of LiBr, a mixed tetrameric aggregate of three PhLi and one LiBr was crystallized from ether; three of the four Li atoms are complexed by ether oxygens, the fourth one, diagonally across the cube from the bromide, is not [145]. With TMEDA, a dimeric aggregate crystallizes [147], with PMDET a monomer was isolated [148] (for recent papers on PhLi structures in solution see Ref. [42a, 94, 149]). Until now, the "de-aggregation" of Li derivatives by addition of the tridentate PMDET has hardly been used by preparative organic chemists as a simple means of avoiding complications caused by aggregation.

Table 3. Some Li ate complexes detected in the solid state and in solution. In the examples chosen, oxygen-, nitrogen-, or carbon-centered anionic ligands are present.

Li ate complex ("triple ion")	*Method*	*Ref.*
	NMR	[151]

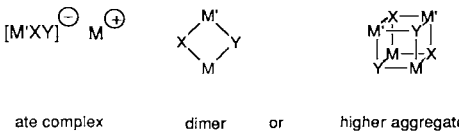
 (C-Li-C linear, C,Li: 216-220 pm)	X - ray crystal structure	[152]
	X - ray crystal structure	[153]

There are mixtures of bases (see Scheme 5) which exhibit properties drastically different from those of the components. It is not clear at this point[158] whether this is due to ate complexes or to dimeric, tetrameric, or even higher-order aggregates.

NaOR / NaR "complexes" [154]

$NaNH_2$ / NaOR "complex bases" [155]

KO*t*Bu / LiBu "super bases" [156,157]



Scheme 5. Mixtures of bases may cause rate enhancements of deprotonations or eliminations in THF by several orders of magnitude as compared to the individual components.

2.3. Thermodynamic Data

Some thermodynamic data relevant to our discussion are listed in Tables 4–6. Again, many more measurements have been performed with Li,C than with Li,O derivatives.[22–53, 150] The most simple model for explaining the formation of aggregates may be to assume that it is caused by charge attraction. Lithium may be considered a small sphere of high positive charge density. In a Li enolate dimer each Li is "neutralized" by two counterions (and vice versa), and in a tetramer, by three (cf. the Madelung energy stabilization in an ionic crystal lattice). The large solvation energy of $Li^{\oplus}$ (interestingly, it is 7 kcal mol^{-1} more with NH_3 than with H_2O) is a consequence of the high charge density, and so is the exothermicity of LiX dimerization—the first step in formation of an ionic inorganic crystal lattice (Table 4).

The heats of deprotonation of carbonyl compounds by Li amides and of formation of an aldolate from Li enolate and aldehyde were measured only very recently (Table 5). The latter reaction is exothermic by 18 kcal mol^{-1} in THF and by 30 kcal mol^{-1} in cyclohexane (the calculated average bond energy change is $\Delta mBE = -19.4$ kcal mol^{-1}, i.e., the difference between a CC double and two CC single bonds).

The contributions of charge neutralization and complexation of the Li atoms by oxygens is clearly evident from these calorimetric measurements. Some of the reactions are so highly exothermic that their transition states should be more similar to the starting material than to the product (cf. the more selective deprotonations by LHMDS with the smaller heat of reaction!).

Some properties of Li enolates, such as the equilibrium ratios between regioisomers and between *E*/*Z* isomers (cf.

[a] pK_a (DMSO scale [165]) of pinacolone, 27.7; of dipivaloylmethane, 15.4. [b] Other ketones and 1,3-dicarbonyl compounds give similar values under the same conditions: cyclohexanone, −34.9; dimethyl malonate, −52.5 kcal mol^{-1}. [c] Under these conditions, enthalpies for the deprotonation (ΔH_{dep} of phenylethanol [$PhCH(OH)CH_3$] and of ephedrine derivatives [$PhCH(OH)CH(CH_3)NR_2$] are between −18.7 and −20.6 kcal mol^{-1}, thus, there is no indication of (OLi···N) chelation (see, however, Refs. [166–169]).

the correlation between enolate and product configuration in aldol and other addition reactions[5–10, 72a, 173, 174]), are collected in Table 6.

3. Computational Studies of Formation and Reactions of Li Enolates—Contributions from Force-Field Calculations and Quantum Mechanics

In view of the availability of more and more powerful (super) computers, and of ab-initio[175] and force-field programs with an increasing number of improved parameters,[176] it is not surprising to see that almost all of the renowned research groups in this area of theoretical chemistry have contributed calculations of ground-state and transition-state geometries of Li and other polar metal enolates and of their reactions. It is impossible to do justice to this work in these pages and it is hoped that the accompanying Tables 7 and 8 and Figure 21 may suffice for the presentation of some of the results.

The examples in Table 7 and Figure 21 show that very large supramolecular structures have become subject to computational studies. These confirm the decisive role of solvation in the structures of polar Li derivatives; reasonable results, i.e., compatibility with experimental parameters, are frequently not obtained unless Li is given a solvent shell or is "removed" from an intramolecular chelating heteroatom by fixing the geometry otherwise (see the Li dienolate and the dioxanone Li enolate in entries 4 and 5, respectively, of Table 7). Table 8 contains the results of modeling, MNDO, and ab-initio calculations of reaction coordinates involving enolates. The layman certainly has cause to marvel at the ability of theory to reach conclusions about the structures of extremely complex arrangements of atoms, including those of higher periods such as zinc.

With the calculations, we have gone on to the gas phase in which minimum-energy structures may deviate from those in solution even more noticeably than in the crystalline state. It is evident that computations have become so

Table 6. Rotational barriers in Li enolates and relative stabilities of isomeric Li enolates as determined by equilibrium studies under various conditions.

powerful that solvent molecules can also be included. It is to be expected that discrepancies between calculated and observed values will eventually vanish. So far, theory has reproduced experimental results in this area. As far as I know, there is no instance of an organometallic reaction mechanism being put forward solely on the basis of calculation which was not first proposed, prior to calculation, on grounds of structural investigations in the solid or liquid phase,[199] or on the basis of preparative results, or of chemical intuition.

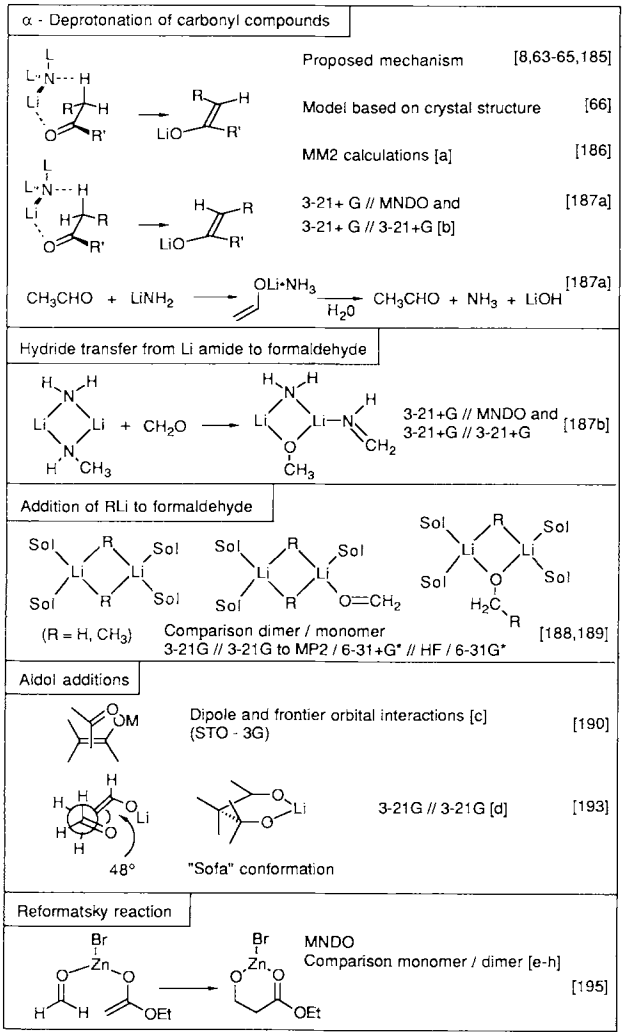
4. Reactions of Li Enolates—Supramolecules as Product-Forming Species

The behavior and properties of any organized system arise not only from its parts but also from the manner in which they are arranged.[200]

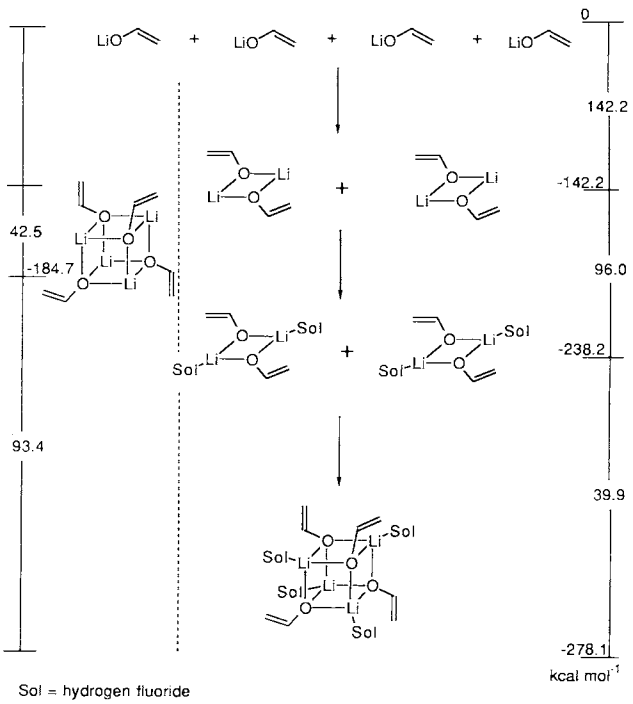
The fact that Li enolates are found to be more or less aggregated in solution and crystals does not, of course, tell us anything about the actual reactive species, at this point. As with Li,C derivatives,[24,25] it is not at all easy to furnish proof for the participation of aggregates in product-forming steps. Elaborate kinetic measurements of fast reactions of air-sensitive compounds at low temperature are necessary. NMR spectroscopy is the method of choice, and it was used early on, in a masterly manner,[21,137,138,201] to demonstrate that Li enolate aggregates *may* be directly involved in reactions, rather than being the pre-equilibrium precursors of monomeric reactants: the degree of aggregation and the presence of Li salts were clearly correlated with ratios of isomeric products formed (e.g., *C*- vs. *O*-alkylation of Li enolates[21,137,138]), the conclusion being that "ion-pair aggregates are the true reactants".[137] Dimeric aggregates turn out to be more reactive than tetrameric ones, according to these measurements.[138]

A new dimension of mechanistic details was made accessible by a new NMR technique, the method of rapid injection (RINMR):[202,203] reactants are quickly mixed in an NMR tube—also possible at very low temperatures—and the first spectrum can be taken after a few milliseconds.[204-206] This allows one to see different species, as well as transient ones, disappearing and appearing in the reaction mixture. Thereby, it was found[141] that the reac-

Table 8. Calculations on various nucleophilic additions to carbonyl groups, including the aldol addition of Li enolates and the Reformatsky reaction.



[a] Calculations without consideration of experimental results. [b] The protonation of the enolate-ammonia complex was also calculated (cf. the discussion in Section 3.1 (R_2NH effect)). [c] Compare the model of "unsuccessful cycloaddition" [191], earlier comments on the significance of HOMO-LUMO interaction [192], the chelate model [5, 12], and the general topological rules for coupling of trigonal centers following the Bürgi–Dunitz trajectory,[13,14] see also: D. Seebach, V. Prelog, *Angew. Chem. 94* (1982) 696-702; *Angew. Chem. Int. Ed. Engl. 21* (1982) 654-660. [d] For MNDO calculations of the aldol addition of *E*/*Z*-isomeric boron enolates to aldehydes, see Ref. [194]. [e] According to this calculation, reactions starting from the dimeric Reformatsky reagent, as present in the crystal (Fig. 19), have an activation energy at least 15 kcal mol^{-1} higher than those with the monomeric reagent. [f] According to the calculation, a reaction starting from the α-Zn-ester (*C*-metalated enolate), a formal [3,1]-sigmatropic rearrangement, has a higher activation barrier (by ca. 15 kcal mol^{-1}). [g] A general comparison of aldol addition and other reactions of metal derivatives in nonpolar solvents with pericyclic processes (Woodward-Hoffmann type) is certainly apparent [102c, 195]. The present example would have to be called a [3,3]-sigmatropic rearrangement [196], a metallo-oxa-Claisen, or a metallo-dioxa-Cope reaction [197]. However, considering the involvement of strongly polar (ionic?) bonds and, more importantly, the presence of an element of the higher periods (Zn), this comparison should be regarded as a formalism. [h] According to the formalism proposed by *Baldwin* [198], a metal-atom-involving aldol addition between the two trigonal carbon atoms of the carbonyl and the enolate double bond may be regarded as an "allowed bis-(*6-endo-trig*) process". On the other hand, the 1,3-shift mentioned in footnote [f] would be a "forbidden (*4-endo-trig*) process"!



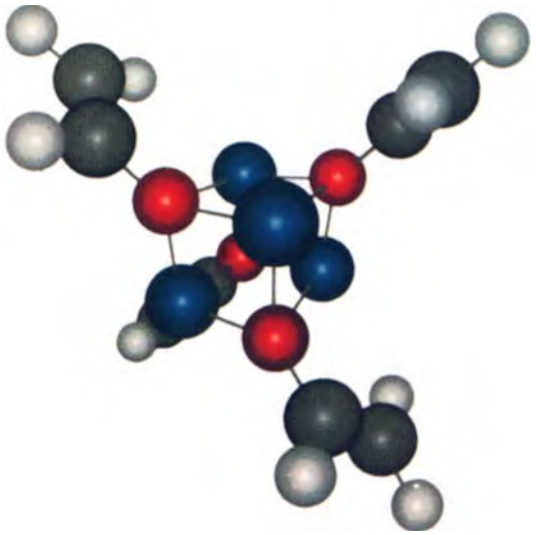


Fig. 21. Calculated (ab-initio 3-21G) aggregation and solvation enthalpies of the Li enolates of acetaldehyde (cf. Table 1) with HF as solvent molecule (Sol) [184]. According to this calculation, 33.5 kcal mol^{-1} of energy is liberated upon complexation of two additional solvent molecules to the dimer $[(EnOLi)_2Sol_2 \rightarrow (EnOLi_2) \cdot Sol_4]$ (En = CH_2=CH); therefore, without consideration of the entropy effect [42c], the difference in the stability between the dimer and the tetramer would be 27 kcal mol^{-1}, the latter being more stable. In THF, this difference is found to be significantly smaller: one often observes both species coexisting (see also Section 2.2). The color picture of the tetramer was generated from the calculated coordinates with the program *MacModel* [184].

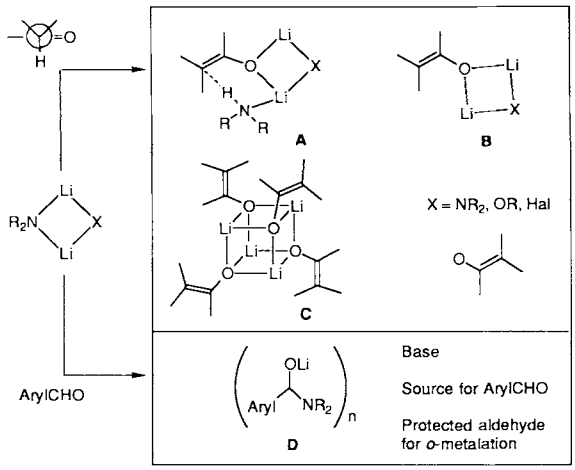
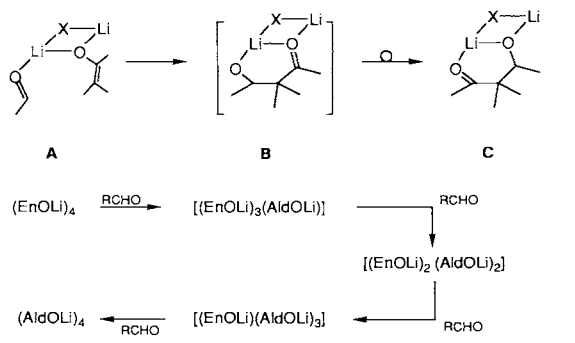
tion of a dimeric Li enolate aggregate with an added aldehyde is much faster than its regeneration from the equilibrium with the tetrameric aggregate. The higher reactivity of the dimer may be attributed to less steric hindrance and more negative charge density, the enolate moiety being "neutralized" by two, rather than three, Li counterions; a monomeric Li enolate would be expected to be even more reactive,[207] and an ate complex should exhibit further increased reactivity (enolate "neutralized" by only 1/2 Li!).[208,209]

It is much easier for the chemist dealing with synthetic and preparative aspects of Li enolate reactions to demonstrate that complex structures rather than a simple reagent

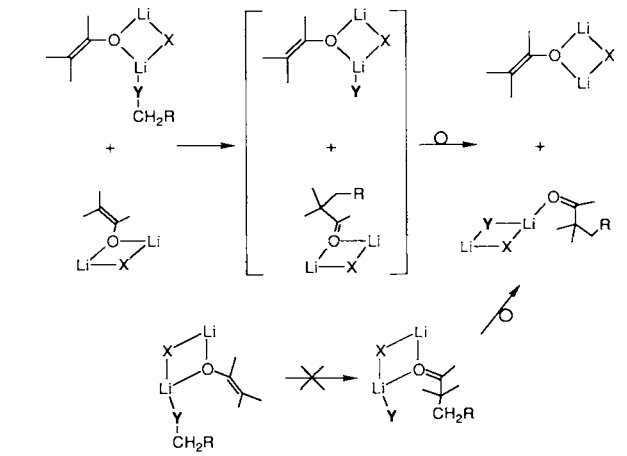
molecule *must* be responsible for an observed result. On the other hand, he or she has very little choice but to speculate exactly which species did it! Little fantasy is required to imagine what a wealth of complications can be caused by aggregations and complexations in processes as fundamental as deprotonation of a carbonyl compound (Scheme 6), aldol addition (Scheme 7), alkylation in the α-position of a carbonyl group (Scheme 8), with (Scheme 9) or without addition of a polar aprotic cosolvent.[216] An almost confusing situation results[217] in which a great variety of structurally different Li enolates of different reactivity may arise in the course of a simple transformation such as the reaction of an enolate with an electrophile[218]—a nightmare for the synthetic chemist, just like the one a crystallographer may experience, who, by pushing the wrong button, generates the chaos shown in Figure 22 instead of a beautiful three-dimensional representation of a structure. After all, it is surprising how well we fared with the simple model, how forgiving the Li enolates are! In the following sections I will describe results to show not only how we might reduce but also how we might exploit the complexity we gained. Once again, it must be emphasized



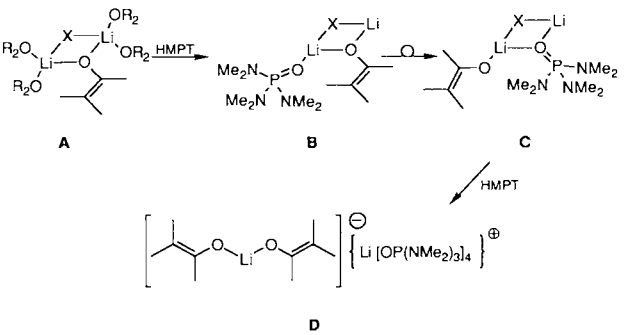
Scheme 6. Reaction of a carbonyl compound with LDA or with an LDA/Li halide or Li alkoxide mixture (cf. the structures in Figs. 2-4, 9, 10). **A**: Dimeric Li enolate or mixed aggregate complexed with a secondary amine. **B**: Pure or mixed aggregate from two LiX units. **C**: Tetrameric aggregate. **D**: Adducts of Li amides with nonenolizable, aromatic aldehydes [210-212].



Scheme 7. Possible reactions of Li enolate aggregates with an aldehyde (cf. structures in Figs. 2, 7, 16). In the process of C-C bond formation, complex **A** is converted, through adduct **B** with the negative oxygen in an "outer position", into the aldolate **C**. The reaction of a Li enolate tetramer $(EnOLi)_4$ may take place over four steps to give the aldolate tetramer! (Cf. the structure in Fig. 7.)



Scheme 8. Formulation of a reaction between two Li enolate aggregates and an alkyl halide to give an α-alkylated ketone and Li halide (cf. the structures in Figs. 11, 20). Because the alkylation of Li enolates occurs with inversion at the alkylating C atom [213], it should not be able to take place in an "intrasupramolecular" ("intraaggregate") fashion (linear S_N2 transition state!) [214].



Scheme 9. Structures that may be formed from a Li enolate by addition of HMPT with enhancement or alteration of reactivity as compared to nonpolar solvent systems. The enolate unit in **A** (enolate inside, cf. Figs. 3-6) can attain increased charge density through complexation of the Li with an HMPT oxygen (**B**), the enolate O atom being still "neutralized" by two $Li^{\oplus}$ (cf. the tetrameric LiCl with HMPT complexation in Fig. 12). Through reorganization, the HMPT oxygen may become part of the aggregate nucleus (**C**), the enolate oxygen outside being "neutralized" only by one $Li^{\oplus}$, which should increase the nucleophilicity/basicity (cf. Fig. 15). In the ate complex **D** (cf. Table 3), the enolate would be even more activated. Very much the same effects are observed with the nonmutagenic cyclic urea DMPU as with HMPT (see Fig. 8 and Ref. [63]) [215].

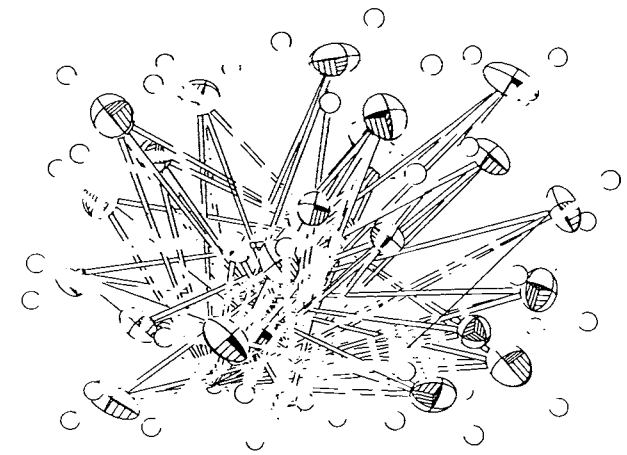


Fig. 22. Unsuccessful ORTEP plot, due to erroneous data input, of the structure of the TriMEDA-complexed amide enolate shown in Fig. 5.

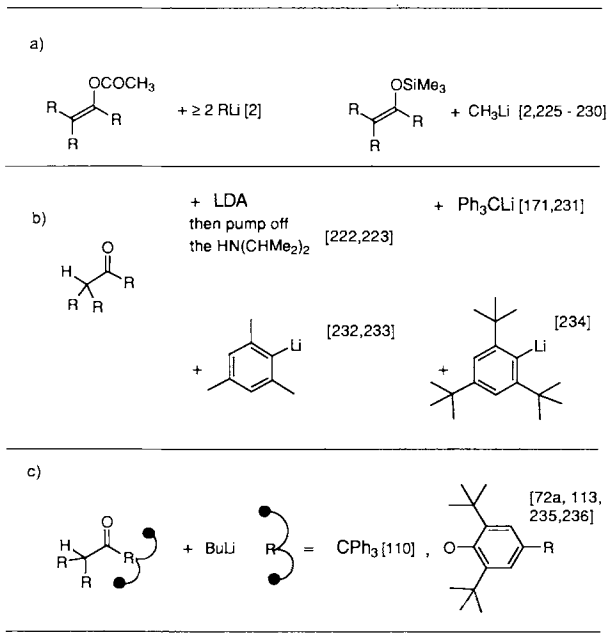
that other polar organometallic compounds behave similarly, so that the discussion of Li enolates will lead to quite general conclusions.[219,220]

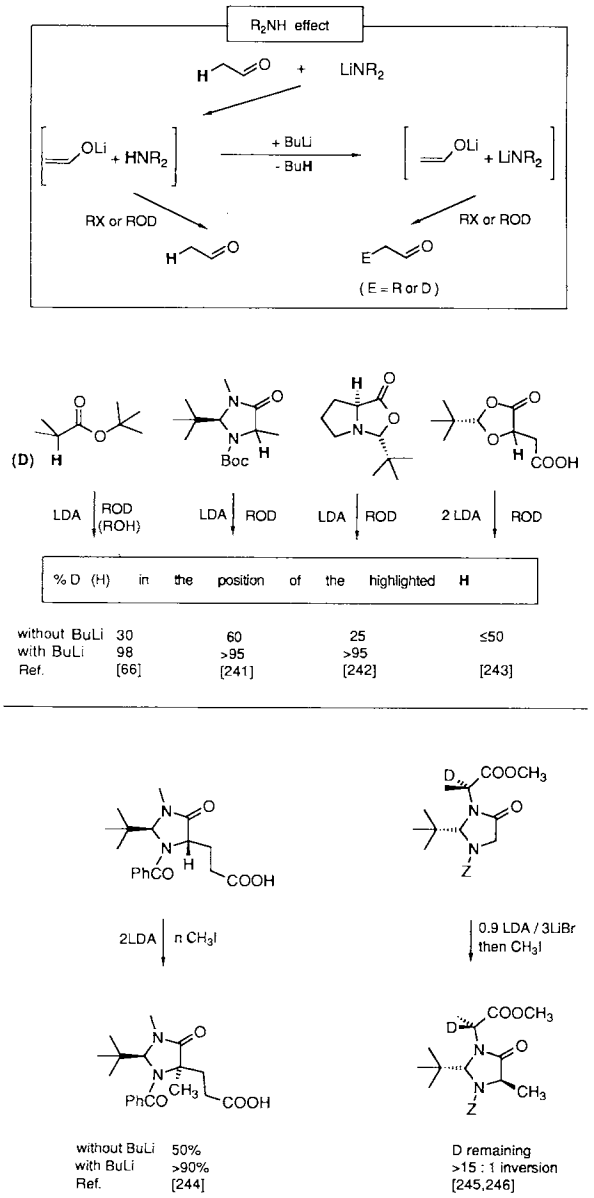
4.1. The Effect of Secondary Amines

It has been known since the beginning of the LDA era[59,221] that the secondary amine concomitantly generated with the Li enolate from a carbonyl compound and LDA *may* have an effect upon the reactivity of the enolate.[67b,222-224] In many reactions with electrophiles the amine-free Li enolate solution gives better results; examples for the generation of amine-free solutions are given in Scheme 10—note that some of these methods are "pre-LDA"!



Scheme 10. Generation of amine-free Li enolate solutions. a) From enol esters and silyl enol ethers. b) From carbonyl derivatives and LDA (pumping off the secondary amine formed), or with sterically hindered, and therefore regioselective, organolithium compounds (with formation of a hydrocarbon). c) From a compound having a sterically hindered, but electronically effective [237] carbonyl group, with butyllithium [238].

Recently, a number of cases have come to light in which totally unexpected results were obtained with Li enolate reactions in the presence of secondary amines, mostly diisopropylamine: Addition of deuterating or alkylating reagents (DX and RX, respectively) does not furnish the desired α-deuterio or α-alkyl carbonyl compound, but a more or less completely α-protonated product, i.e., starting material, and it was shown that the proton stems from the secondary amine.[239] The expected products are often isolated in high yields if butyllithium is added prior to the electrophiles. The amine as a proton source for much too weak bases was observed especially with substrates having more than one acidic proton (effect of the "hidden proton").[240] The general effect is pictured in Scheme 11, which also contains some examples from the recent literature. Obviously, the complexes that we have discovered in crystals[66] (Figs. 3, 5) are also present in solution, and are much more stable than anticipated. Under quenching conditions the "intra-supramolecular" proton transfer from the diisopropylamine to the Li enolate, which are linked together by Li-N complexation and hydrogen bonding,[247,248] competes successfully with the expected intermolecular attack of the electrophile.[249] Formally, huge isotope effects occur in such deuterolysis experiments

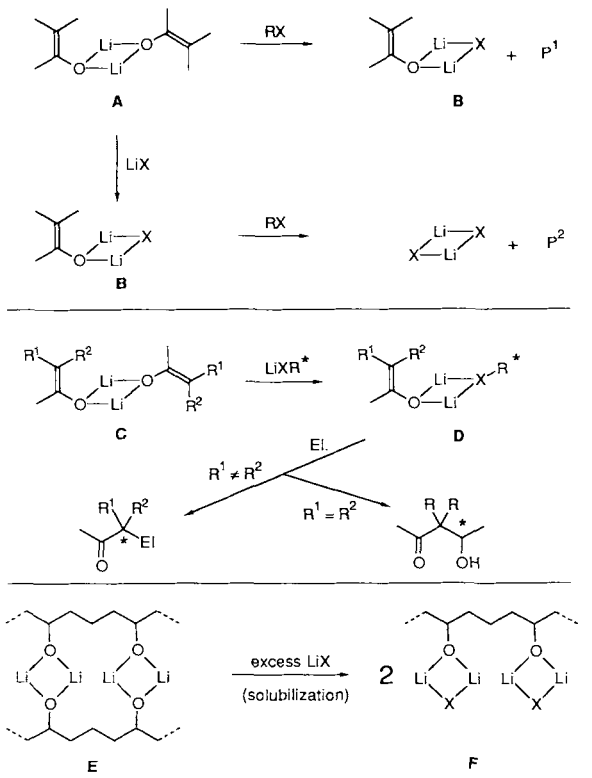


Scheme 11. Reactions of Li enolate-diisopropylamine complexes (in THF). *Top:* In the enolate-amine complex, a (partial) reprotonation occurs under the influence of the electrophile; by removal of the amine with BuLi, the yield of the desired product may be improved. *Middle:* Examples of deuterolyses; only after removal of the NH proton is a good deuterium incorporation achieved; a control experiment with the deuterated precursor and hydrolysis gives a complementary result (D replaced by H only after treatment of the enolate-DNR_2 with BuLi). *Bottom:* Examples for methylation of LDA-generated enolates with iodomethane. *Left:* Only after removal of the R_2NH proton is a high yield of the α-methylglutamic acid derivative obtained. *Right:* The deuterated imidazolidinone derived from glycylalanine is epimerized and alkylated, without loss or scrambling of deuterium over the two α-carbonyl positions, by treatment with LDA/LiBr (LDA alone does not cause a clean conversion, see Section 4.3) and CH_3I (with acetic acid instead of CH_3I as an electrophile, the starting material is recovered without loss of the D and without epimerization!).

when the Li enolate/amine solution in THF is added dropwise to a many thousandfold excess of perdeuteroacetic acid. The "internal return" of the originally removed proton is reminiscent of an effect termed *conducted-tour mechanism* coined many years ago by *Cram* to characterize the stereochemical course of certain ion-pair reactions,[250-252] and of proton-transfer mechanisms[253,254] discussed for active sites of enzymes (cf. serine proteases[255]).

Treatment of an LDA-generated enolate with BuLi is, of course, a drastic cure for removal of the villainous NH proton. Since an LDA/enolate mixture is formed, the product will be exposed to the base LDA; furthermore, an enolate results which may have quite different properties as compared to the original one, due to the presence of LDA (see Section 4.2). This is why the methods collected in Scheme 10 for the generation of amine- and amide-free Li enolate solutions should be kept in mind. To avoid many a complication, the use of sterically more hindered Li amides such as lithium *tert*-butyl(1,1,3,3-tetramethylbutyl)amide (also called LOBA ≡ *l*ithium-*tert*-*o*ctyl-*tert*-*b*utyl-*a*mide[65]) or of the less basic, but also less highly aggregated, disilazanides[256] (LHMDS, KHMDS; cf. the heats of deprotonation in Table 5), producing the poorer complexing $HN(SiMe_3)_2$ in the deprotonation step, is recommended.

The complexes of Li enolates and secondary amines dealt with here are probably also involved in some of the processes discussed in the following section, when achiral enolates are generated by chiral Li amides.



Scheme 12. Addition of LiX to an enolate solution could lead to formation of a mixed aggregate (**A** → **B**), and therefore change the product ratio P^1/P^2. A chiral additive puts an achiral enolate in a chiral environment (**C** → **D**), which may lead to the formation of enantiomerically enriched products. The LiX addition can have a solubilizing effect with a polylithiated derivative (**E** → **F**).

4.2. The LiX Effect in Li Enolate Reactions

Gedanken ohne Inhalt sind leer,
Anschauungen ohne Begriffe sind blind.[*]
Immanuel Kant

If the result of Li enolate reactions, carried out under the usual conditions in nonpolar solvents and at low temperatures, does depend upon the complex processes indicated in Schemes 6-8, then we not only need to worry about the secondary amine being a component of the mixture (Section 4.1); the formation of mixed aggregates may cause the following additional phenomena:

(1) The properties of Li amides used for deprotonations might be influenced by LiX additives, especially with more complex substrates.

(2) An enolate may exhibit different reactivity at the beginning ("pure" aggregate) and at the end ("mixed" aggregate with the LiX formed) of a reaction.

(3) The mode of addition and large excesses of one reactant in small-scale runs may strongly influence the results.

(4) LiX additives that are not part of the stoichiometric equation may decisively change the properties of an enolate.

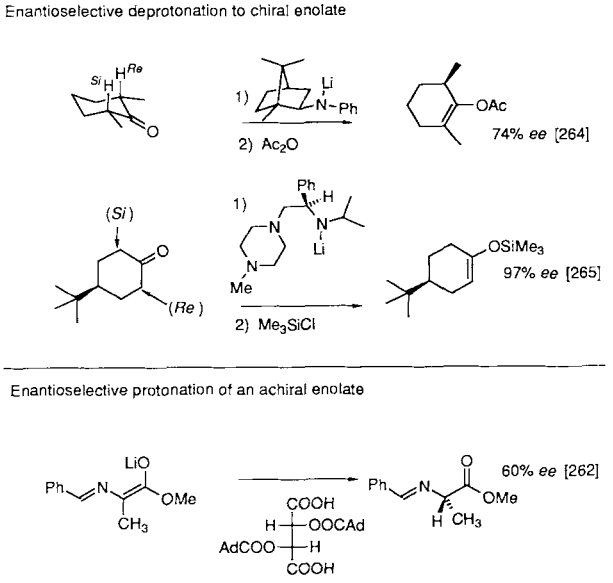
In the three parts of Scheme 12 these effects are exemplified. *Firstly*, a Li enolate dimer may be converted into a mixed dimer by addition of LiX, which is formed in alkylations by alkyl halides or sulfonates. Assuming that the dimeric enolate gives rise to one product, the mixed aggregate of Li enolate and LiX another one; in the absence of interaggregate exchange, this would lead to formation of the two products in a 1 : 1 ratio. On the other hand, addition of excess LiX could convert all of the "pure" into the "mixed" aggregate so that a single product would be formed. *Secondly*, addition of a chiral Li derivative LiXR* to the dimer of an achiral Li enolate should give a chiral mixed aggregate, the enolate component of which has diastereotopic faces or, depending upon the substitution pattern of its double bond, can differentiate enantiotopic faces of a reactant. *Thirdly* (bottom part of Scheme 12), a polylithiated, self-aggregated compound (insoluble) may be converted into a mixed aggregate with added LiX and thus be solubilized (a kind of cross-linking is disrupted).

Of course, the LiX effect as sketched here is oversimplified, perhaps in a single-minded way: especially when added in large amounts, Li halides, thiolates, alkoxides, enolates, and amides will also change the medium itself,[257] rendering it more polar ("salt effect").[150] In addition, formation of ionized species[258] (ate complexes, ion pairs) will be more likely even at low temperatures. Still, the concept of mixed-aggregate formation turned out to be extremely fruitful in the course of our own work, some of which will be outlined in the following sections.

[*] Thoughts without content are empty, intuitions without concepts blind. *Critique of Pure Reason*. Edited and translated by W. Schwarz, Scientia Verlag, Aalen 1982, p. 29.

4.3. Achiral Enolates for the Preparation of Enantiomerically Enriched Products—Making a Virtue of Necessity

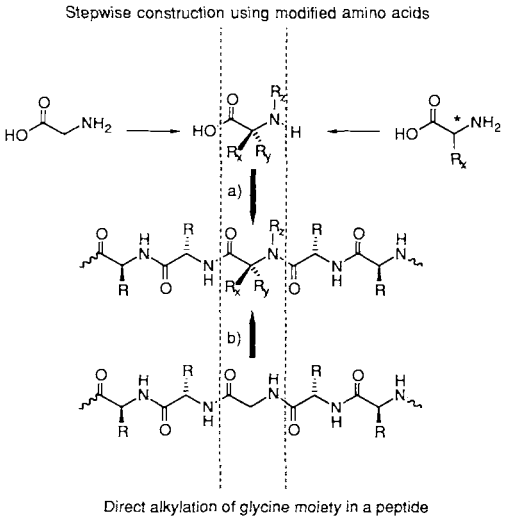
In Section 4.1, methods of avoiding the problems caused by the complexation of Li enolates with secondary amines were discussed. Here, we turn our attention to potentially very useful transformations which depend on the complexation between Li enolate and Li amide. For an enantioselective reaction, instead of coupling an enolate with a chiral auxiliary covalently, which requires a cleavage later on, the components are joined through a complexation, an interaction which is simply broken during aqueous workup! Just like in a chiral solvent,[259, 260] two achiral reactants, such as an enolate and an aldehyde, may thus be coupled to give enantiomerically enriched products (Scheme 12, middle). This procedure is fundamentally different from the use of a chiral Li amide[261] for enantioselective deprotonations or of a chiral acid for protonations[262, 263] (Scheme 13). A number of examples are collected in Table 9. As can be seen, metals other than Li can be employed. Chiral alkoxides are less effective than amides. Usually a Li enolate/$LiNR^*_2$ ratio of 1:3 gives rise to the highest enantiomer excesses.[278] Most of the chiral Li amides used are prepared from 1-phenylethyl amine or from amino acids and are thus readily available. Since there is very little structural information (Fig. 10) about complexes of Li amides with Li enolates, all attempts toward interpretations of these results are highly speculative, and we refrain from reproducing them here.



Scheme 13. Enantioselective protonations/deprotonations involving Li enolates. The chiral reagent (base or acid) selectively attacks enantiotopic groups or faces [266–268]. (With the protonations, the R_2NH effect discussed in Section 4.1 may be involved as well; with the deprotonations, the LiX effect may be operative—carefully excluded only in one case [264, 269].)

5. Alkylations of Sarcosine Units in Peptides—from Expectation to Surprise

What we learned about structure and reactivity of Li enolates was found to be successfully applicable to a seemingly unrelated project. For several years now, our group has been engaged in the development of new methods for the preparation of nonproteinogenic amino acids.[56, 100] These are required for incorporation into peptides whose biological properties are to be modified.[279] Normally, a separate synthesis is necessary for every peptide analogue [Scheme 14, route (a)]. A method by which a glycine unit in a given oligopeptide could be converted into other amino acid moieties by direct *C*-alkylation would not only be much more efficient; it would no doubt provide valuable information about the influence of chirality centers of neighboring amino acid units on the formation of a new stereogenic center in an open-chain peptide[280] [Scheme 14, route (b)].



Scheme 14. Synthesis of modified peptides. a) By stepwise construction from the appropriately modified amino acid building blocks. b) Elaboration of an amino acid by introduction of side chains; many analogous derivatives could thus be obtained from a common precursor peptide.

The notion of generating an enolate in a peptide chain seems to be absurd:

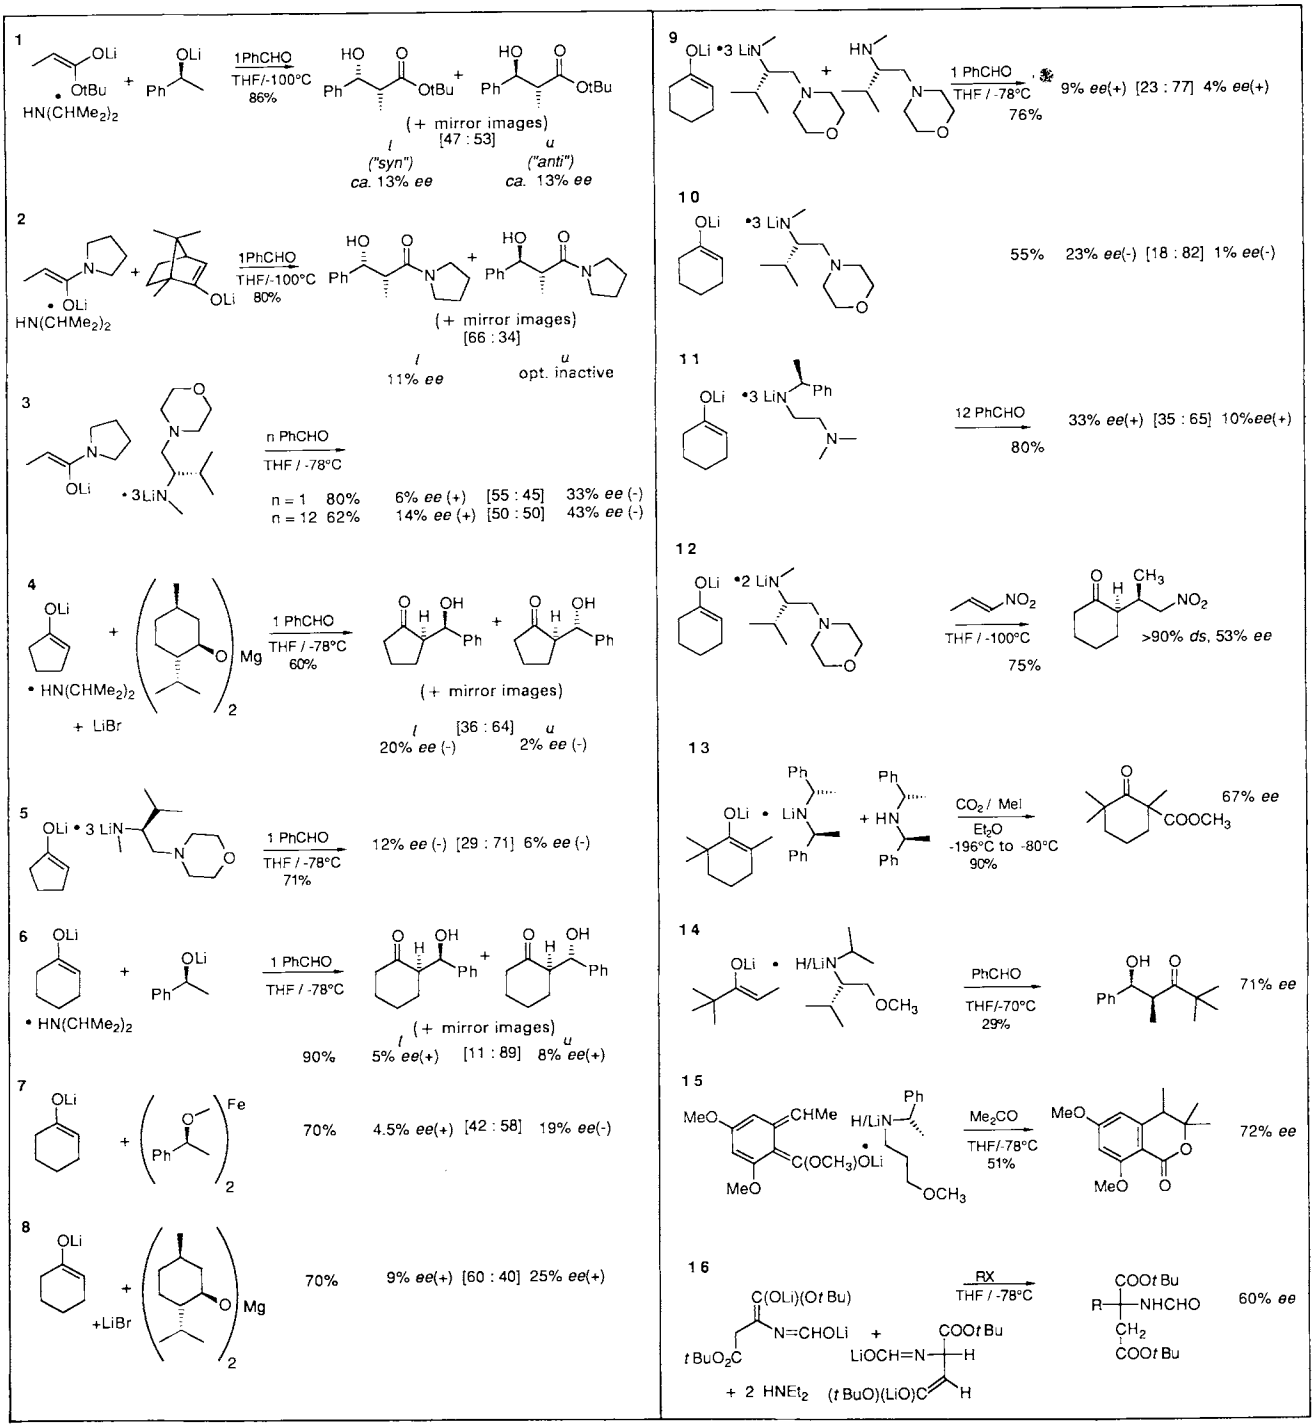
Firstly, there is an acidic amide NH hydrogen ($pK_a < 20$) per amino acid unit to be removed before the CH_2 group of a glycine moiety can be deprotonated (there are even more acidic hydrogens in side-chain functionalized amino acids).

Secondly, strongly basic conditions are bound to be applied for such a CH deprotonation under which epimerizations of stereogenic centers might occur (in an n-oligopeptide a maximum of 2^n different diastereoisomers could be formed!).

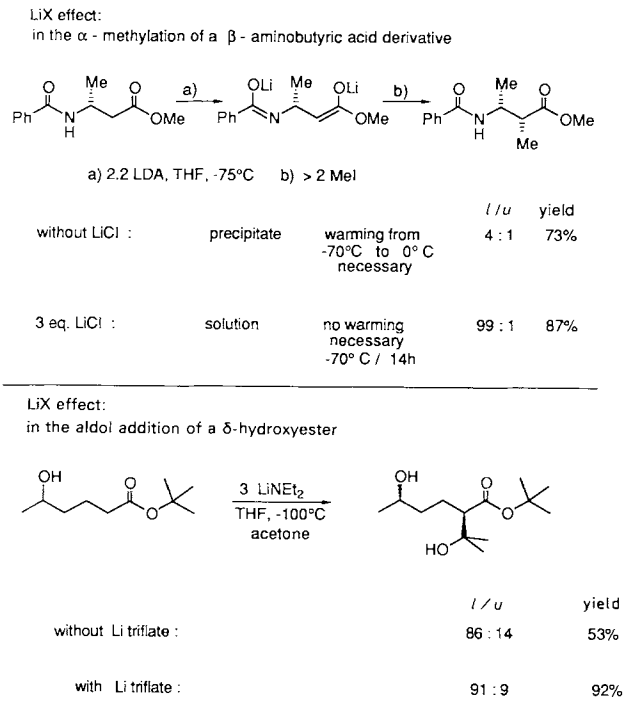
Thirdly, it is usually necessary to generate Li enolates in an aprotic medium at low temperatures, conditions in which an oligopeptide itself, and even more so a polylithiated one, might be expected to have little solubility.

At the outset of our investigations in this area, we did not entertain such reflections; rather, a gifted young chemist[281] did a bold and careful experiment with an already rather large oligopeptide. For reasons of systematization, let us start with the simple cases, reversing the order of events.

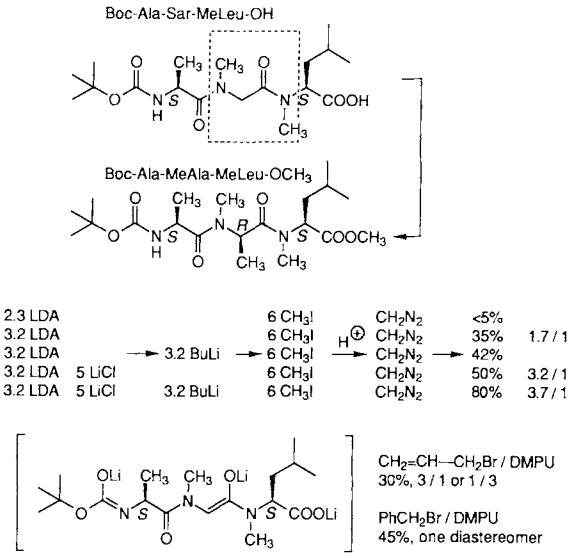
Table 9. Enantioselective aldol additions, Michael additions to a nitroolefin, carboxylation, and alkylation of achiral enolates in the presence of chiral lithium alkoxides or amides. The examples 1–12 and 16 are taken from our own work [53, 91–93, 270–273], whereas we owe the results in entries 13 [274], 14 [275], and 15 [276] to research done by others. Enolate solutions free of amine were obtained either by addition of BuLi to enolates generated with $LiNR_2^1$ or by use of the silyl enol ether/methyllithium procedure. The configurations shown and the enantiomer ratios given were determined by NMR spectroscopy or with chiral HPLC columns [277].



Two nonpeptide examples pictured in Scheme 15 may be used to demonstrate the LiX effect. The (*R*)-*N*-benzoyl-3-aminobutyrate shown in the upper part of Scheme 15 can be alkylated through a dilithium derivative in the 2-position.[41i, 282] At dry-ice temperature the reaction mixture in THF is heterogeneous; warming is necessary to complete the reaction with iodomethane. In contrast, the reaction takes place in homogeneous solution if LiCl[285] is added, with greatly improved result! Other Li salts such as LiBr, $LiClO_4$, $LiOSO_2R$ have similar effects (cf. the lower part[283] of Scheme 15).



Scheme 15. LiX effect on the generation and behavior of two dilithium derivatives [41i, 282, 283]. In the case of the *N*-benzoyl β-amino acid ester the reagent to be alkylated is rendered soluble by addition of LiCl [41i]. In both cases, yields and stereoselectivities are increased. (C=C and C=N configurations here, in Schemes 16-21, and in Fig. 24 are drawn arbitrarily! [284].)



Scheme 16. Diastereoselective alkylations of the sarcosine unit in a Boc-protected tripeptide [286]. For the allylation and benzylation reactions, the cosolvent DMPU [63] had to be added to afford the yields shown.

5.1. Open-Chain Tri-, Tetra-, and Hexapeptides

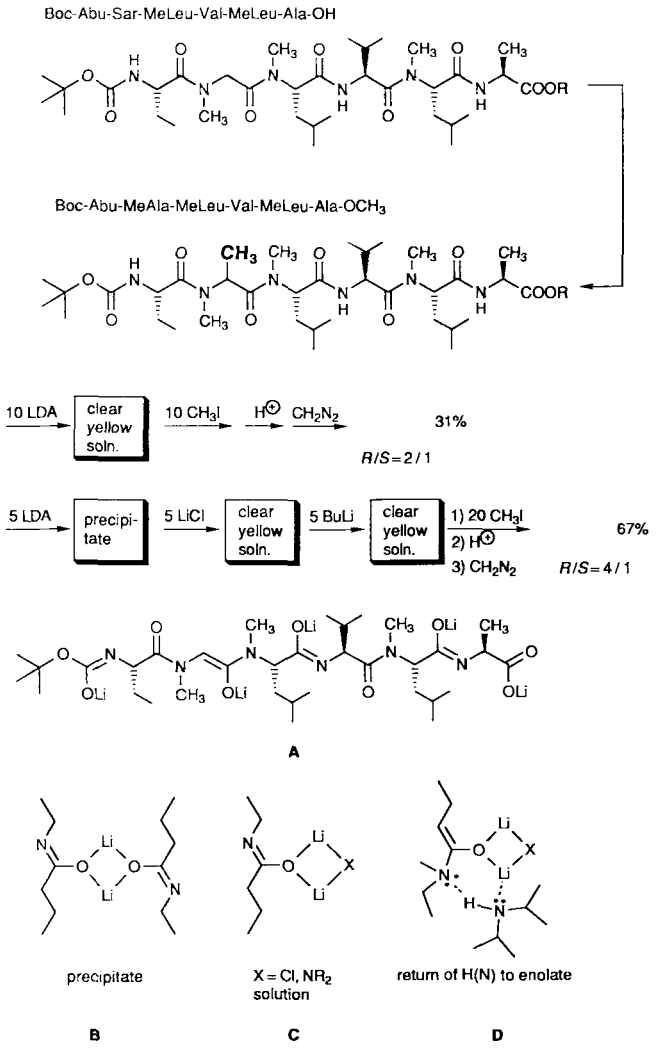
For *C*-alkylations of open-chain peptides we first chose those containing (1) a sarcosine (*N*-methylglycine) substructure (shown in Scheme 16, sarcosine = *N*-methylglycine), (2) a Boc-protected amino end group (Boc = *tert*-butoxycarbonyl), and (3) a nonprotected carboxylic acid end group. Upon mixing of such peptides with the prerequisite number of equivalents of LDA, a more or less dense precipitate is formed. An enolate at the methylglycine (sarcosine) component of the tripeptide shown in Scheme 16 must arise when slightly more than three equivalents of LDA is added, because subsequent addition of iodomethane furnishes a new tripeptide with *N*-methylalanine at the former sarcosine position.

Removal of the diisopropylamine with butyllithium (cf. Section 4.1) led to marginal improvement of the yield, but addition of LiCl *and* BuLi (after LDA deprotonation) led to the isolation of the new peptide in 80% yield. More importantly, the reaction is diastereoselective (*R*-MeAla/*S*-MeAla almost 4 : 1), and it occurs without epimerization at the two stereogenic centers which were present in the starting material! The configuration was proved by comparison with authentic samples.[286-288]

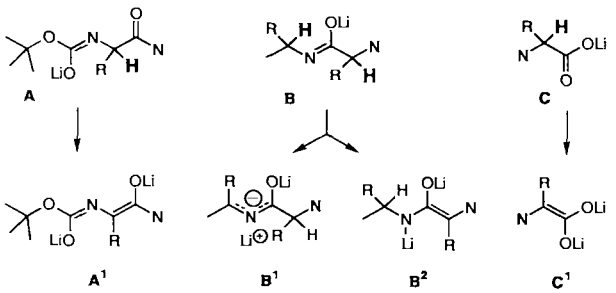
Likewise, with the hexapeptide depicted in Scheme 17, containing four acidic OH and NH hydrogens besides a sarcosine CH_2 group, a precipitate is formed upon addition of the stoichiometric amount of LDA. Twice the calculated amount of LDA[289] or LiCl[285] causes the solid to dissolve.[290] A homogeneous, nonviscous, slightly yellow THF solution results, readily stirred at dry-ice temperature, and typical of polylithiated compounds under these conditions. Methylation again produces, in yields ranging from 30 to 67%, a new *N*-methylalanine unit in the peptide chain, the yield increasing in the presence of LiCl and with diisopropylamine deprotonation by BuLi.[285] Again, the reaction is diastereoselective, with the *R* configuration at the newly created stereogenic center prevailing (by comparison with authentic samples[288]). The hexalithio hexapeptide that ought to give rise to the observed product is shown at the bottom of Scheme 17.

Inspection of the *formulae* in Schemes 16 and 17 reveals that the peptides used have two characteristic features in common: (1) adjacent to each and every stereogenic center a deprotonation has occurred, rendering a certain protection from further deprotonation, i.e., from epimerization (see Scheme 18); (2) the peptides employed carry aliphatic side chains and are thus lipophilic, which should increase the solubility of their Li derivatives in the nonpolar THF. Had these properties been found to be essential for successful application of the above alkylation procedure, the method would be rather limited. The following two examples show that this is not the case.

The Boc-protected alanyl-glycyl-glycyl-glycine was selected as an example of an especially hydrophilic oligopeptide which, in fact, can hardly be retrieved from water. This also led to the discovery of a quite different LiX effect. As evident from the data in Scheme 19, the peptide, which itself is very insoluble in THF at room temperature, and LiCl form an extremely soluble complex. Furthermore, addition of five equivalents of LDA neither causes precipitation nor decomposition; hydrolysis leads to recovery of the peptide in optically active form. The possibility of carrying out reactions with the solutions thus obtained is currently being investigated. While the great solubility of peptide-LiCl complexes in an organic solvent is very surprising, the fact that anhydrous crystalline adducts

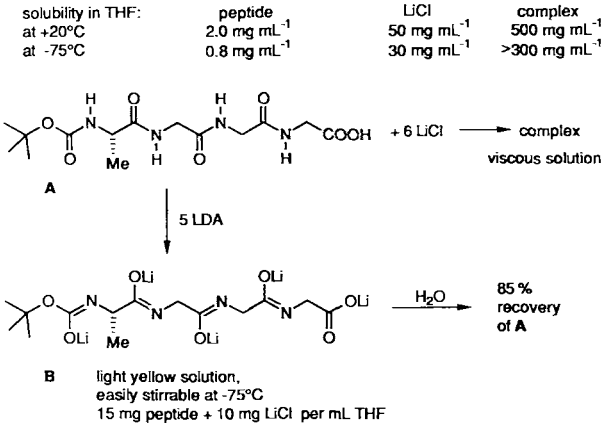


Scheme 17. Fivefold deprotonation of a Boc-protected hexapeptide (consisting of three *N*-methyl and three normal amino acid building blocks) by LDA and diastereoselective methylation at a sarcosine unit [285]. The yields shown were recorded after simple column chromatography and refer to the sum of the two epimers [2-(*R*-MeAla) and 2-(*S*-MeAla)]; the configurations at the other stereogenic centers are the same as in the starting material. **A**, pentalithium derivative; **B**, aggregates of **A**, poorly soluble; **C**, solubilization with LDA or LiCl, probably by formation of mixed aggregates (cf. Figs. 10, 20); **D**, complexation with diisopropylamine results in "reprotonation", i.e., lower yields without subsequent BuLi "treatment" (cf. Fig. 5 and Section 4.1).



Scheme 18. Deprotonation of the carboxylic acid, carbamate, and amide groups of Boc-peptides, as applied to the reactions shown in Schemes 16 and 17, results in protection of the adjacent stereogenic center from epimerization. The highlighted hydrogens are less acidic in these structures than those in which a neighboring anionoid group is absent. The generation of doubly lithiated systems $\mathbf{A}^1$, $\mathbf{B}^1$, $\mathbf{B}^2$, and $\mathbf{C}^1$ from the respective precursors **A**, **B**, and **C** is indeed possible, as shown with simple molecules [126, 248, 291–293], but demands harsher conditions. (Protection of carbonyl groups against metal hydride reduction, and against addition of MeLi, by directed Li enolate formation in di- and tricarbonyl compounds has been well known for a long time [294, 295].

of Li salts with peptides may separate from aqueous solutions has been known since the beginning of this century (*Pfeiffer*'s "Neutralsalzverbindungen der Polypeptide und Eiweisskörper"[298]).[299] Furthermore, the solubilization in water of a protein antigen by addition of LiBr is described in a patent.[300] Some amide, peptide, and urea complexes of Li salts have been subjected to X-ray crystal structure analysis;[301] one such structure is shown in Figure 23.[303]



Scheme 19. Enormous increase in the solubility of a 1:6 mixture of Boc-Ala-Gly-Gly-Gly-OH and anhydrous LiCl in THF compared to that of the components. After removal of the solvent (5 h/10^{-3} torr/20°C), a solid residue is left which contains peptide, LiCl, and THF in the ratio 1:6:2.5. Adding five equivalents of LDA to the mixture of **A** and LiCl, at −75°C, produces a clear solution which probably contains the pentalithio derivative **B** [296, 297].

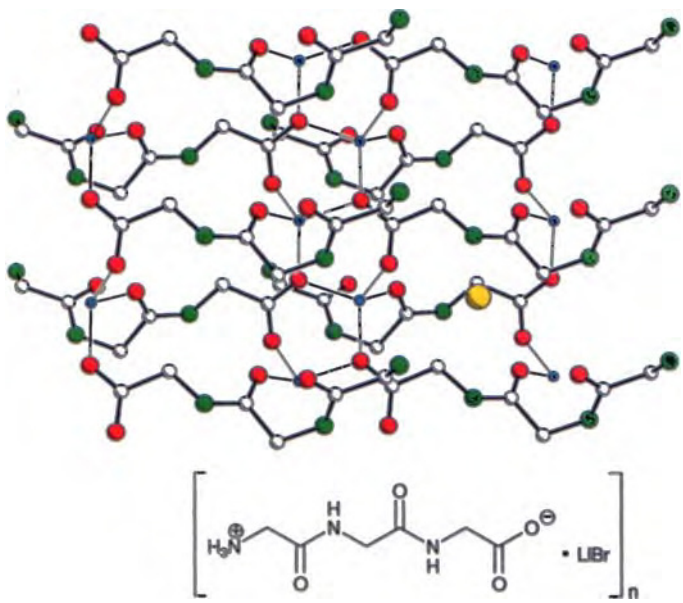


Fig. 23. Crystal structure of the LiBr complex of glycyl-glycyl-glycine [302] (section of the polymeric arrangement; *CSD*: GLYLIB). Cf. the LiX complexes with amides in Table 4, and the structures in Figs. 8, 11, and 16. The "addition ability" of Li salts toward amino acids decreases in the following series: Li > Na > K and I > Br > Cl (after *Pfeiffer*) [299].

5.2. Cyclosporine A

Nescire quaedam magna pars est sapientiae[304][*]

So far, the largest peptide in which we have been able to alkylate a sarcosine unit is cyclosporine A (CyA)[305,306] and some of its analogues.[307-311] CyA contains a series of amino acid moieties which are not protected against epimerization in the way indicated in Scheme 18. CyA is a novel immunosuppressive drug,[312] the discovery and use of which is as important as skilled surgery for the recent rapid developments in organ transplantations. CyA is a cyclic undecapeptide containing seven *N*-methyl amino acids (Fig. 24), four of which are adjacent to each other

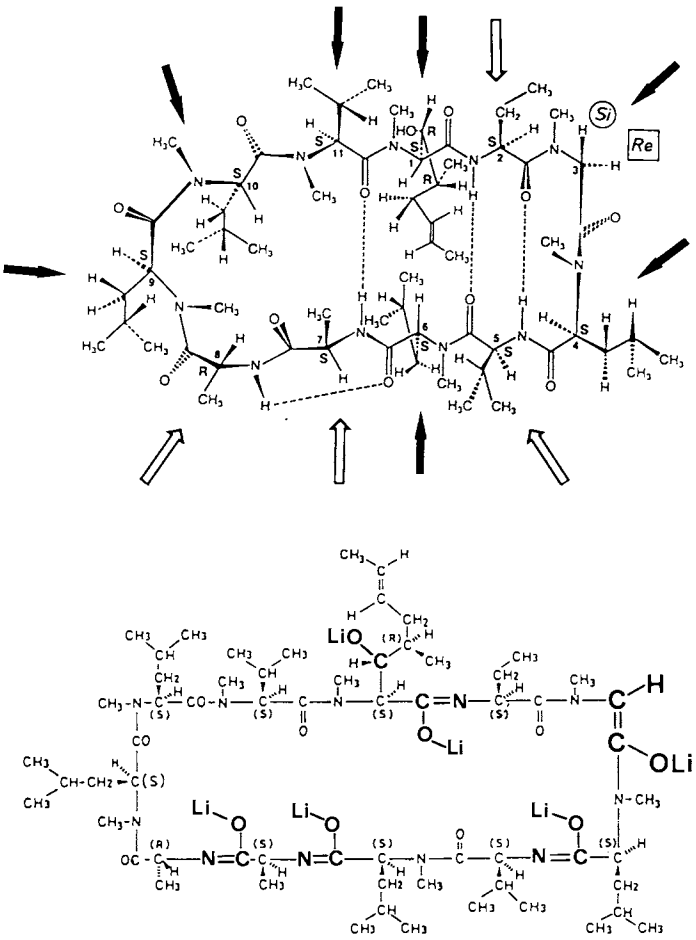

Fig. 24. Cyclosporine A (top) and the hexalithio derivative (bottom). The seven *N*-methyl amino acid building blocks are indicated by solid arrows, the four normal ones by open arrows. The conformation of CyA is identical in the crystal [306] and in solution [130a, 313], except for the orientation of the side chains of amino acids No. 1 and No. 11. There is no structural information available for the Li derivative (*E/Z* configuration at CC and CN double bonds is drawn arbitrarily). The Li derivative exists in THF solution in the presence of diisopropylamine, or LDA, or of LiCl, or mixtures of all three. The yellow solution (≥ 20 g L^{-1}), generated at -75°C, can be warmed up to $+20$°C without decomposition, at least for a short period of time.

(Nos. 9, 10, 11, 1). The amino acid No. 3 is sarcosine, which is followed by another *N*-methyl amino acid, MeLeu. CyA is highly lipophilic and insoluble in water due to the aliphatic side chains and the presence of transannular hydrogen bonds between opposite NH and CO groups in the pleated-sheet-type part of the molecule. In organic solvents CyA exhibits extremely high solubility (>600 mg mL^{-1} in THF at room temperature and >300 mg mL^{-1} at -75°C), and with LiCl a complex is formed, as evidenced gravimetrically or NMR spectroscopically[314] (cf. the LiBr complex of the cyclic decapeptide antamanide in Fig. 25).

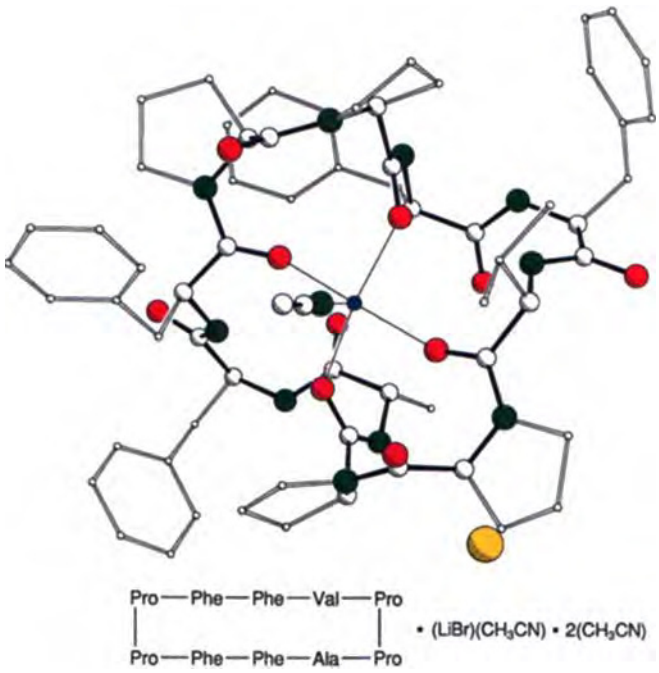

Fig. 25. LiBr complex of antamanide, *cyclo*(Val-Pro-Pro-Ala-Phe-Phe-Pro-Pro-Phe-Phe), crystallized from acetonitrile (*CSD*: ANTAML 10) [315]. The four carbonyl oxygens bound to Li form the base of a nearly square pyramid, with the acetonitrile nitrogen at the apex. The cyclic decapeptide originates from the green death cup mushroom *(Amanita phalloides)* [316]. There are two additional molecules of CH_3CN per cyclic peptide in the crystal.

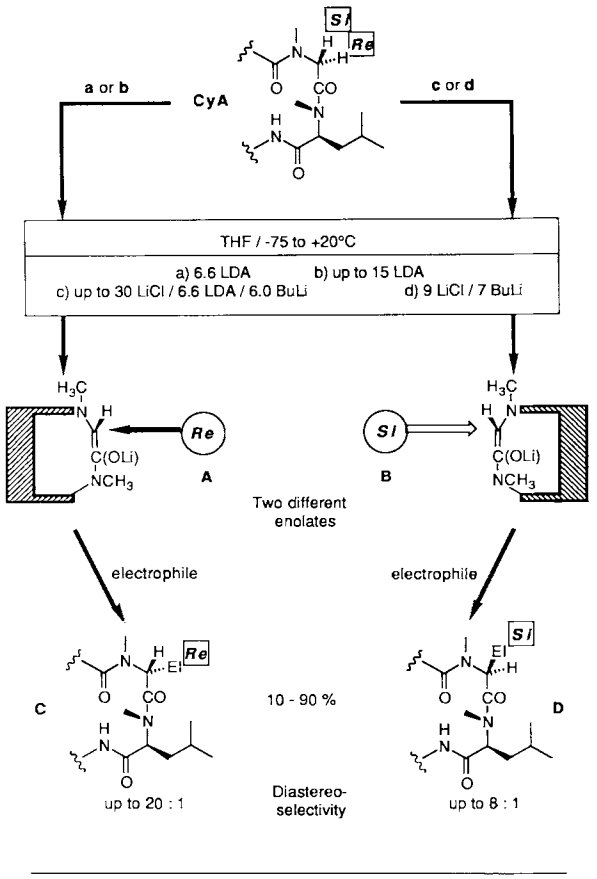
When treated with the required number of equivalents of LDA (≥ 6) in THF, CyA is deprotonated at the sarcosine unit to give a Li enolate without destruction of the peptide ring. Reactions with electrophiles give derivatives with substituents in the former sarcosine position.[281, 285, 286, 289, 314, 317] With CyA and LDA alone a precipitate or a viscous mixture, which may solidify as a gel, results at -78°C. If an amount of LDA exceeding the six equivalents required (for removal of one OH, one CH_2, and four NH protons) is added (up to 15 equivalents), a clear, yellow, readily stirred solution is obtained, quenching of which with water leads to the recovery of more than 90% CyA. Epimerizations are observed only to a very small extent, and they do indeed occur mainly at the amino acids Nos. 9, 10, and 11, those lacking the protection discussed above. Simple column chromatography readily frees CyA from the impurities thus generated. With electrophiles other than water, products of substitution of the diastereotopic *Re* hydrogen ($\leq 90\%$ *ds*) in the sarcosine unit (Sar^3)

[*] Not knowing is the essence of wisdom.

are formed in yields ranging from 10 to 50%, with a large amount of unreacted CyA being recovered. Some of the substituents that were introduced into CyA by this procedure are indicated in Scheme 20.



El = D, CH_3, $CH_2CH{=}CH_2$, $CH_2COO(t\,Bu)$, CH_2OH, $CH(OH)Ph$, $COOCH_3$, F, SCH_3

Scheme 20. Alkylation of CyA on the sarcosine unit via the Li enolate shown in Fig. 24 [317]. Depending on the conditions of deprotonation either an enolate **A** is generated that is preferentially attacked from the *Re* side, or an enolate **B** with *Si* selectivity (see the products **C** and **D**, respectively) [318]. The highest yields were recorded under "amine-free, LiCl conditions" [c and d], and the best selectivities under the "LDA conditions" [a and b]. CD_3CO_2D, MeI, alkyl bromides, aldehydes, CO_2/CH_2N_2, $FClO_3$, and disulfides were used in excess as electrophiles. The products **C** and **D** can be separated by flash chromatography and isolated in pure form.

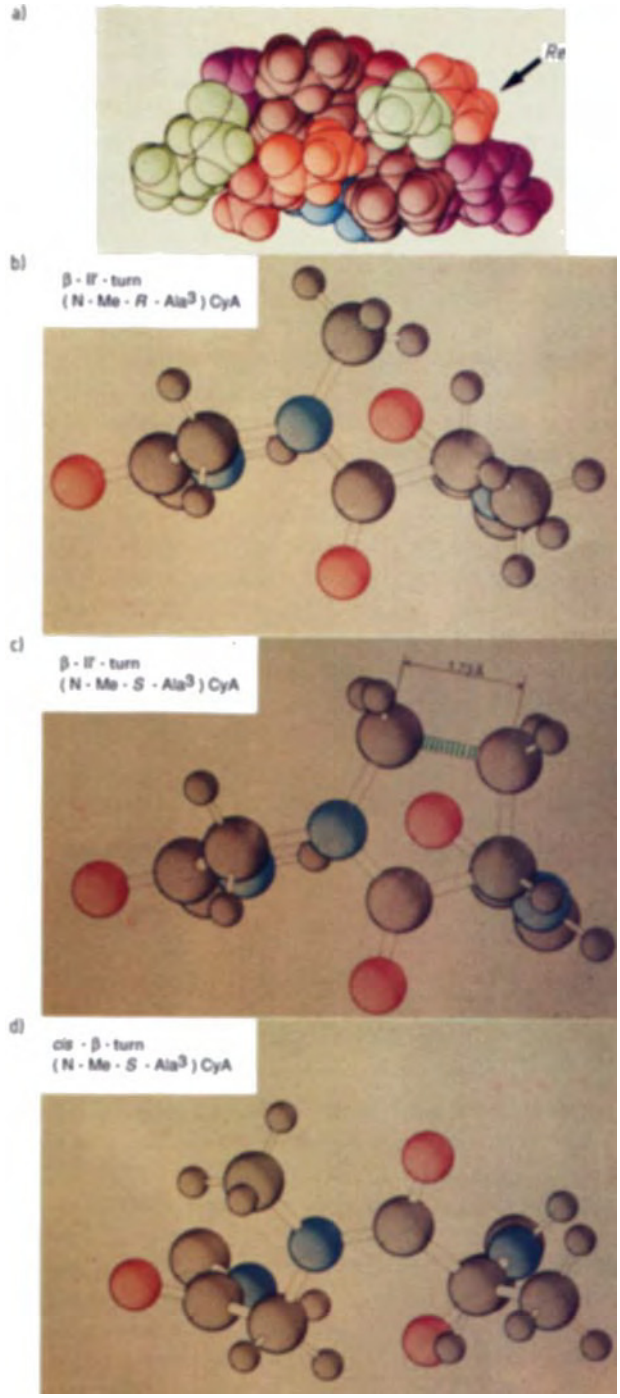


Fig. 26. Space-filling model of CyA generated with the data of the structure analysis, and ball-and-stick model of the partial structure around the β-turn at which the stereoselective alkylation through a Li enolate occurs (Fig. 24, Scheme 20). a) Overview, in which the *Re* hydrogen on sarcosine is emphasized; the *Si* hydrogen and the neighboring NCH_3 group are quasi-1,3-diaxial to each other as viewed by the reader. b) H(*Re*) substituted by CH_3, no steric hindrance [the NMR spectra of CyA and (*N*-Me-(*R*)-Ala^3)CyA are superimposable over wide regions]. c) H(*Si*) substituted by CH_3, strong penetration of van der Waals radii of the two CH_3 groups in maintaining the β-II'-turn. d) Equatorial (*Si*)-CH_3 group in a *cis* β-turn, with formation of a *cisoid* peptide bond [the NMR spectra of the (*R*) and (*S*) derivatives differ greatly].

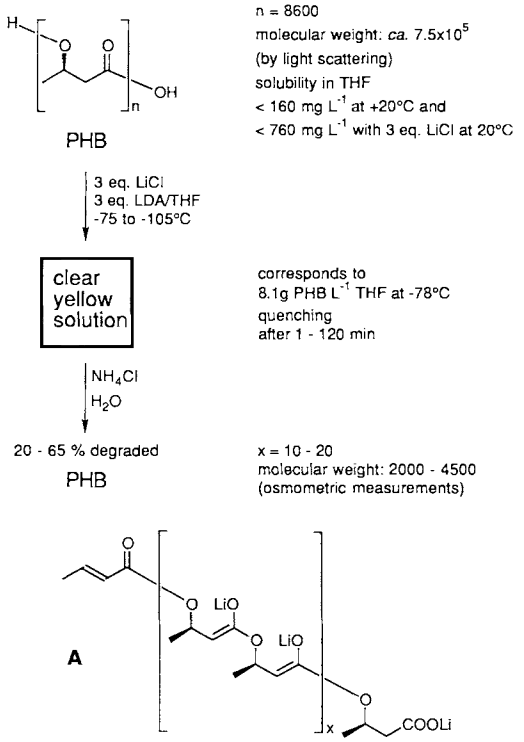
We were overjoyed that the products derived from replacement of the diastereotopic *Si* hydrogen can also be obtained selectively; yields of over 90% may be obtained if the deprotonation of CyA by LDA is carried out in the presence of large amounts of LiCl (up to 30 equivalents), and if the diisopropylamine is removed by BuLi addition. We do not know whether the enolates generated under the two different sets of conditions are configurationally different (*E*/*Z* on C=N and/or C=C) or whether they differ only by different LiX effects exerted by LDA and LiCl. At any rate, the *Re* face of the enolate double bond must be hindered in one case, the *Si* face in the other, by the arrangement of the macrocyclic ring (see Scheme 20).

The pure products are readily isolated by medium-pressure chromatography on SiO_2. Miraculously, CyA ($M_r = 1202$) and the two diastereomeric products of methylation [N-Me-(*R*)-Ala^3)CyA and (N-Me-(*S*)-Ala^3)CyA,

$M_r = 1216$] clearly separate on a simple analytical silica gel thin-layer plate![319] (The structural assignment of the two methyl derivatives was arrived at by comparison of the NMR spectra with those of authentic samples.[287,288])

Cleavages of the CyA peptide backbone or alkylations of amino acids other than the sarcosine occur only to a very small extent. Upon treatment of CyA with BuLi in the presence of LiCl (Scheme 20, d) appreciable amounts of a butyl ketone may be isolated, if desired, which results from attack at the carbonyl group of amino acid No. 9 (an "unprotected" site!).

The biological activity of the products thus available follows a simple rule: derivatives with substituents in the *Re* position still have immunosuppressive properties comparable to CyA, those substituted in the *Si* position do not. The reason for this is obvious from modeling as shown in Figure 26; the *Re* hydrogen of the sarcosine in CyA occupies a quasi-equatorial position, the *Si* hydrogen a quasi-axial one; introduction of a substituent into the latter position imposes such severe steric hindrance by van der Waals overlap with the NCH_3 group of the adjacent amino acid that the peptide chain must adopt a different conformation, causing the shape of the entire molecule to change.



Scheme 21. Deprotonating solubilization and partial degradation of poly-[(*R*)-3-hydroxybutyrate], PHB, with LDA/LiCl in THF at low temperature. The solubilities described for PHB in THF are upper limits, which have been extrapolated from experiments in volumes of much less than 1 L. The upper limit of the solubility accessible by addition of LDA/LiCl was not investigated. The enolate could also decompose by α-elimination [72] (lithium oxybutyrate end group) instead of β-elimination (crotonate terminal group). There is no indication of a direct attack by LDA on the ester carbonyl groups of the polymer (aminolysis, resulting in formation of carboxamide end groups).

6. Outlook—on to Even More Complex Systems

An experiment is in progress
but it is uncertain
if we are in control
or just observers
Roald Hoffmann[320]

Encouraged by the solubilization of polylithiated organic compounds, such as peptides, by addition of inorganic Li salts, we also investigated other systems. We found, for instance, that when a suspension of the biopolymer PHB (polyhydroxybutyrate, $M_r = 7.5 \times 10^5$), which itself is totally insoluble both in water and THF, was treated with excess LDA in the presence of LiCl at low temperature, a clear, slightly yellow THF solution was obtained. Subsequent quenching with water leads to recovery of up to 65% of a polymer of lower molecular weight (Scheme 21).[321,322] The fact that decomposition of the polyester polyenolate does not take place all the way to the monomer (Li crotonate), but that an unexpectedly long-lived species containing ca. 30 units persists, suggests the answer must have something to do with the structure of this species—which we do not know.[323]

Our excursion into the world of Li enolate aggregate structures and the quest for proof of their involvement in product-forming steps did not only furnish important new knowledge, but led us continuously back to the laboratory. There, we have arrived at systems of a complexity with which we could not have hoped to cope at the outset; they exhibit reactivities which we observe with pleasure and with excitement, but which we again do not understand.

Lesson: Even the synthetic organic chemist must consider very complex structures, supramolecules in *Lehn*'s terminology, in his everyday work. I have nothing to add to the statement of *Lord Todd*:[324]

> Apart from consideration of the hydrogen bond, we organic chemists have really paid little attention to linkages other than the purely covalent. I believe that it will be the duty of organic chemists in the future to study the weak non-bonding interactions which are of enormous importance in the large natural macromolecules. Such studies will lead to a new blossoming of organic chemistry in the future.
>

[67] Special precautions have to be taken in synthesizing 1,3-dicarbonyl compounds via lithium enolates to avoid double addition. a) A well-known method especially applied to synthesizing methyl ketones is the use of Li carboxylates as acylating agents. Review article: M. J. Jorgenson, *Org. React. 18* (1970) 1–97. b) The acylation succeeds directly with acid chlorides by (inverse) addition of Li enolates at very low temperatures, even with 3-nitropropanoyl and 4-nitrobutanoyl chloride: D. Seebach, T. Weller, G. Protschuk, A. K. Beck, M. S. Hoekstra, *Helv. Chim. Acta 64* (1981) 716. c) Review article on "Synthese bei Temperaturen unter −80°C": D. Seebach, A. Hidber, *Chimia 37* (1983) 449–462. d) A trick that avoids complications is the reaction of the enolate with acyl cyanides, which at first results in cyanohydrin derivatives: S. Hünig, R. Schaller, *Angew. Chem. 94* (1982) 1–15; *Angew. Chem. Int. Ed. Engl. 21* (1982) 36–49 (review). L. N. Mander, S. P. Sethi, *Tetrahedron Lett. 24* (1983) 5425.

[73] D. Seebach, R. Amstutz, T. Laube, W. B. Schweizer, J. D. Dunitz, *J. Am. Chem. Soc. 107* (1985) 5403. The structures of the *tert*-butyl 2-methylpropionate lithium enolate (dimer with TMEDA; *CSD*: DEDXIT) and of the tetrameric methyl 3,3-dimethylbutyrate lithium (*Z*)-enolate solvated by four THF molecules (*CSD*: DEDXOZ) are described in the same paper. It is striking that in all dimeric ester and amide enolates with THF and TMEDA as ligands to Li, the two enolate units are on the same side of the OLiOLi quadrangle, as if it were a bisected cube in which the enolates are necessarily *cis* to each other.

[116] It might be appropriate at this point to mention that, in the discussion of structures, we draw formulae and use a language not according to the usual conventions in organic chemistry but rather according to those in crystallography. A line between two atoms thereby does not correspond to an electron pair but indicates that their distance is smaller than the sum of the van der Waals' radii. Here, we do not observe the octet rule; otherwise we would have to add a ⊕ charge to all the oxygens of the THF molecules bound to Li. We also speak of an X atom not of a $Li^{\oplus}$ cation or an $RO^{\ominus}$ anion! (See also the remarks in the caption of Fig. 1.)

[133] a) As the following details of the ^{13}C NMR spectra (A^1 and A^2) show, the content of dimeric aggregate increases by cooling a solution of butyllithium (THF), and dynamic processes that "smear out" the ^{6}Li, ^{13}C coupling at −70°C are frozen out at −90°C, so that the coupling of two ^{6}Li($I=1$) with the neighboring ^{13}C atom can be recognized from the quintet splitting [42a, c]. b) Mixed aggregates $(R^1Li \cdot n\,R^2Li)_m$ are formed by addition of Bu^6Li to a solution of ^{6}Li,^{13}C-labeled lithium phenylacetylide: the pure acetylide dimer (B^1) first equilibrates with the mixed dimer (B^2) and, after addition of 6 equiv. of BuLi, only the mixed tetramer (B^3) is present: R. Hässig, D. Seebach, *Helv. Chim. Acta 66* (1983) 2269.

[143] This footnote must be sufficient for the remark that the N-analogues of the Li enolates also form aggregates, mixed aggregates, and all the complex arrangements in solution, as has been shown especially by *Collum* and his group [101, 102, 132]. Higher alkali metals can also be present within complex structures in solution (see also the discussion about ate complexes in Section 2.2.3). In the pK_a determination of cesium ion pair acidities in THF (Streitwieser scale) aggregation effects also occur: M. J. Kaufman, A. Streitwieser, Jr., *J. Am. Chem. Soc. 109* (1987) 6092.

[206] By this method the rate of equilibration [204, 205] between dimeric and tetrameric BuLi in THF (cf. [42a,c, 133]) was measured at -60 to $-85\,^{\circ}C$ as well as that of the reaction of butyllithium with oxygen [204], with cyclopentadiene, and with benzaldehyde [205]. Most important findings: no indication of monomeric BuLi down to concentrations of 10^{-4} M; $(BuLi)_2$ as well as the mixed aggregate $[Bu_2(BuO)_2Li_4]$ react about ten times faster with PhCHO than does $(BuLi)_4$; the alkoxide $PhCH(OLi)C_4H_9$, formed from BuLi and PhCHO, adds to benzaldehyde to give the alkoxide of a hemiacetal (cf. Scheme 6 and references cited there). See also the RINMR measurement of the addition of Grignard compounds to alkoxy ketones [166].

[207] In the case of Li enehydrazide it was concluded from kinetic measurements of the alkylation that the monomeric species forms product, not the aggregate, though the latter is the predominant species in solution [102c].

[208] See Schemes 5 and 9, Table 3, and Section 2.2.3.

[209] A "free" anion (not neutralized by *any* Li) must of course be even more reactive. A "fairly free" carbanion was recently proposed as the product-forming species from results obtained for Sn/Mg exchange processes in the reaction of Me_3Sn-substituted aryl bromides: H. J. R. de Boer, O. S. Akkerman, F. Bickelhaupt, *Angew. Chem. 100* (1988) 735; *Angew. Chem. Int. Ed. Engl. 27* (1988) 687.

[210] a) $LiNR_2$ adducts to aromatic aldehydes for *ortho*-metalations: U. Michael, S. Gronowitz, *Acta Chem. Scand. 22* (1968) 1353; D. L. Comins, J. D. Brown, *Tetrahedron Lett. 22* (1981) 4213; D. L. Comins, J. D. Brown, N. B. Mantlo, *ibid. 23* (1982) 3979; b) $LiNR_2$ adducts to aromatic aldehydes for aminative alkylations and reductive aminative coupling with low-valent titanium: D. Seebach, M. Schiess, *Helv. Chim. Acta 65* (1982) 2598; D. Seebach, A. K. Beck, M. Schiess, L. Widler, A. Wonnacott, *Pure Appl. Chem. 55* (1983) 1807–1822; D. Seebach, C. Betschart, M. Schiess, *Helv. Chim. Acta 67* (1984) 1593; C. Betschart, D. Seebach, *ibid. 70* (1987) 2215.

[211] $LiNR_2$ and LiOR adducts [*t*BuOCH(OLi)R] to nonenolizable aldehydes as bases and precursors for the in-situ liberation of an aldehyde: D. Seebach, T. Weber, *Tetrahedron Lett. 24* (1983) 3315; *Helv. Chim. Acta 67* (1984) 1650.

[214] L. Tenud, S. Farooq, J. Seibl, A. Eschenmoser, *Helv. Chim. Acta 53* (1970) 2059.

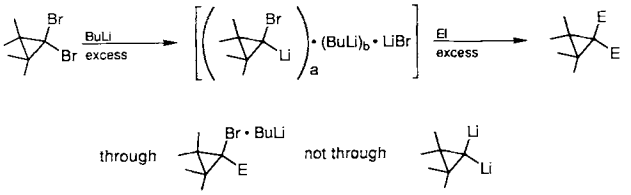
[215] See also the amide complexes in Table 4, urea and amide complexes of Li in crystals [47], and the discussion about LiX effects on peptides in Section 5.

[216] Most of the reaction paths via aggregates shown in Schemes 6–9 had been proposed by us already in 1981 and 1983 [53, 69]; only the complexity, not the principle, is changed if the reaction is formulated for tetrameric aggregates instead of dimeric ones as done here.

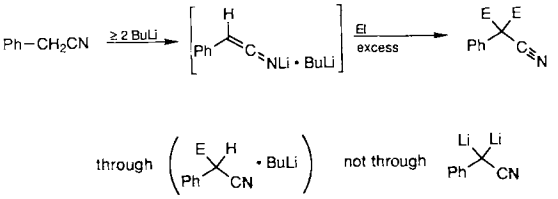
[217] The scenario is even extended if one considers that single-electron transfers (SET) become more probable with increasing degree of aggregation of polar organometallic compounds; a supramolecule can more likely donate an electron (as in the present case), or accept one, than one of its components, because the resulting charge deficiency is distributed over a larger area (higher lying HOMO, lower LUMO). Accordingly, for example, it was recently proved that the tendency of single-electron transfer to occur from a Li amide strongly increases with its degree of aggregation (P. Renaud, M. A. Fox, *J. Am. Chem. Soc. 110* (1988) 5702). An SET mechanism with participation of the aggregate (Fig. 14) was also proposed [56] to explain the reversal of stereoselectivity of reactions of the Li enamides of diketopiperazine-bislactim ethers when going from "normal" electrophiles [99] to C_2Cl_6 (U. Schöllkopf, H.-J. Neubauer, M. Hauptreif, *Angew. Chem. 97* (1985) 1065; *Angew. Chem. Int. Ed. Engl. 24* (1985) 1066).

[218] In the case of participation of aggregates in product-forming steps, different results are possible depending on the use of the respective enolates as racemic mixtures (which can form diastereomeric aggregates) or of enantiomerically pure reagents! Compare the nonlinear dependence of the product *ee* values in numerous enantioselective reactions on the enantiomeric purity of the reagents used. Several examples can be found in the following references: [53]; A. Horeau, *Tetrahedron Lett. 1969*, 3121; C. Agami, C. Puchot, H. Sevestre, *ibid. 27* (1986) 1501; C. Puchot, O. Samuel, E. Dunach, S. Zhao, C. Agami, H. B. Kagan, *J. Am. Chem. Soc. 108* (1986) 2353; Review on *Kinetic Resolution*, H. B. Kagan, J. C. Fiaud, *Top. Stereochem. 18* (1988) 249.

[219] Two "aggregate effects" may prove this. a) In the reaction of *gem*-dibromocyclopropane with an excess of butyllithium and subsequent addition of an excess of electrophile, products of double substitution



are formed which originally was seen as proof for the occurrence of *gem*-dilithiocyclopropanes. These species, however, could not be detected by NMR spectroscopy of ^{6}Li- and ^{13}C-labeled samples. It turns out that a mixture of bromolithium carbenoid and BuLi is present instead. The added electrophiles react faster with the carbenoid than with BuLi, and "interaggregate" Br/Li exchange leads to the observed result. See flow chart (R. Dammann, *Dissertation Nr. 6277*, ETH Zürich 1978). b) In the reaction of phenylacetonitrile with 2 BuLi (see structure



in Table 2) it is not a dilithium derivative that is responsible for the formation of double substituted products, but a fast "interaggregative" proton transfer during addition of electrophile (P. J. Crowley, M. R. Leach, O. Meth-Cohn, B. J. Wakefield, *Tetrahedron Lett. 27* (1986) 2909). c) Cf. also the discussion in: P. Beak, T. J. Musick, C. Chen, *J. Am. Chem. Soc. 110* (1988) 3538.

[220] Representations from publications by *Schlosser* show what has been concluded from kinetic measurements of the HCl elimination with potassium alkoxides: "Alcoholate Clusters ("Aggregates") and Their Role in Alkyne-Forming Elimination Reaction." M. Schlosser, T. D. An, *Angew. Chem. 93* (1981) 1114; *Angew. Chem. Int. Ed. Engl. 20* (1981) 1039; M. Schlosser, C. Tarchini, T. D. An, R. Ruzziconi, P. J. Bauer, *ibid. 93* (1981) 1116 and *20* (1981) 1041, respectively.

[238] P. Beak, D. B. Reitz, *Chem. Rev. 78* (1978) 275–316; P. Beak, W. J. Zajdel, D. B. Reitz, *ibid. 84* (1984) 471–523.
[239] In this case alkylated diisopropylamine can be formed under conditions, under which pure diisopropylamine would not be alkylated (−80°C, in THF); thus, one must conclude that the amine is activated by the Li enolate for the alkylation to the tertiary amine! (See [244].)
[240] a) The effect of the "hidden proton" has been observed in substrates with several acidic sites also in the absence of secondary amines; see, e.g., the results of protonation of Schiff bases of penicillamine benzyl esters: R. A. Firestone, N. Schelechow, D. B. R. Johnston, B. G. Christensen, *Tetrahedron Lett. 1972*, 375; R. A. Firestone, N. S. Maciejewicz, R. W. Ratcliffe, B. G. Christensen, *J. Org. Chem. 39* (1974) 437; R. A. Firestone, B. G. Christensen, *J. Chem. Soc. Chem. Commun. 1976*, 288. b) Doubly deprotonated species—bis(enolates)—can be more stable than the corresponding simply deprotonated ones; see the following newer papers and the references cited therein: K. G. Bilyard, P. J. Garratt, R. Hunter, E. Lete, *J. Org. Chem. 47* (1982) 4731; K. Furuta, A. Misumi, A. Mori, N. Ikeda, H. Yamamoto, *Tetrahedron Lett. 25* (1984) 669. Solvation and chelation (see Tables 4,5) can invert the normal order of acidity: S. M. Bachrach, *J. Am. Chem. Soc. 108* (1986) 6406. But also here, as a warning, we must point to the intraaggregate effects mentioned in [219].

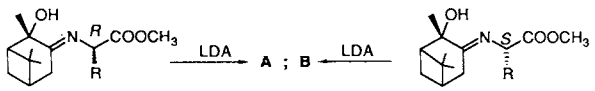
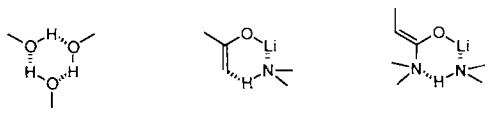
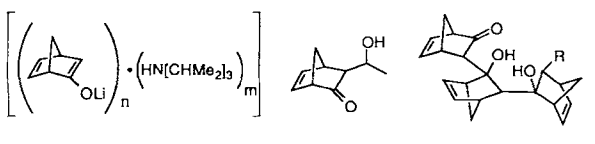
[246] Cf. the protonations and alkylations of Schiff base enolates formed from amino acids and hydroxypinanone; under otherwise identical conditions, the epimeric precursors give rise to two enolates, **A** and **B**, that behave very differently (both should have the (*E*) configuration of the enolate double bond!); A. El Achqar, M.-L. Roumestant, P. Viallefont, *Tetrahedron Lett. 29* (1988) 2441.



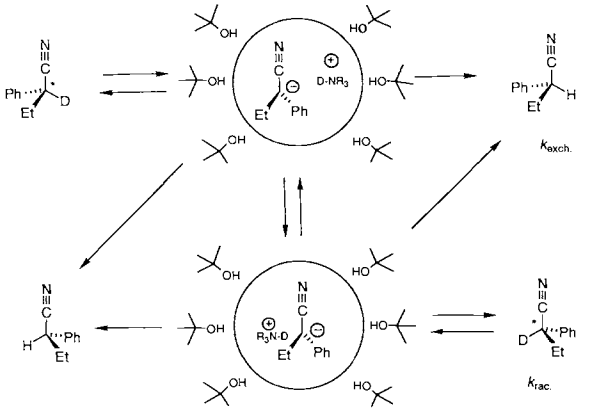
[247] Cf. the cooperative hydrogen bonds [76] in many biologically important structures in which, for example, three hydrogen bonds are arranged in a cyclic array, **A**, with the complexes **B** and **C** (Figs. 3, 5, Table 2). Here, as there, the bond strength is greater than anticipated from simple O···HO, N···HN or πC···HN hydrogen bonds. Much stronger are hydrogen bonds between ions, and between ions and neutral molecules, see [250, 251, 252c].



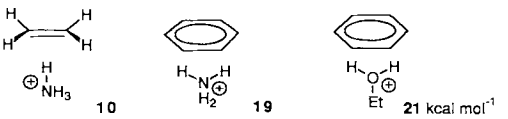
[248] The effect of the complexation of Li carboxylate (or the [RR'C=CO_2Li]Li derivative) with the secondary amine and the return of the proton in attempted deuterations of doubly metalated toluic acids as well as aliphatic or alicyclic carboxylic acids was already discussed at the beginning of the 1970s: P. L. Creger, *J. Am. Chem. Soc. 92* (1970) 1396; P. E. Pfeffer, L. S. Silbert, J. M. Chirinko, Jr., *J. Org. Chem. 37* (1972) 451.
[249] Reports on the observation of such effects in carbonyl additions, which occur much faster than nucleophilic substitutions, are not known to us. The enolate **A** generated with LDA, e.g., adds smoothly to acetaldehyde to give the expected product **B** (84%), while with CH_3I a 3:1 product **C**, R = CH_3, is generated in ca. 50% yield, which was attributed to the existence of tetrameric aggregates [183].



[250] D. J. Cram: *Fundamentals of Carbanion Chemistry*, Academic Press, New York 1965. In spite of the protic medium, the rate of racemization ($k_{rac.}$) is greater than that of the D/H exchange ($k_{exch.}$) via an ion pair. The formulae show the "conducted tour mechanism" (*Cram*), $k_{rac.}:k_{exch.} = 20:1$. Cf. also: A.-M. Weidler, G. Bergson, *Act. Chem. Scand. 18* (1964) 1487; K. Bott, *Tetrahedron Lett. 1965*, 4569.



[251] There are very strong hydrogen bonds formed between ammonium or oxonium ions and π systems: C. A. Deakyne, M. Meot-Ner (Mautner), *J. Am. Chem. Soc. 107* (1985) 474 (measurements and ab-initio calcula-



tions), cf. also [257]. Hydrogen bonds between an amine NH and the fluorenyl carbanion: S. Buchholz, K. Harms, M. Marsch, W. Massa, G. Boche, *Angew. Chem. 101* (1989) No. 1; *Angew. Chem. Int. Ed. Engl. 28* (1989) No. 1. Intramolecular hydrogen bonds between an OH group and an indenyl carbanion: P. Ahlberg, B. Johnsson, I. McEwen, M. Rönnqvist, *J. Chem. Soc. Chem. Commun. 1986*, 1500.

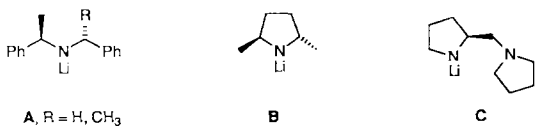
Acta 65* (1982) 1101; T. M. Williams, R. Crumbie, H. S. Mosher, *J. Org. Chem. 50* (1985) 91; M. Eyer, D. Seebach, *J. Am. Chem. Soc. 107* (1985) 3601; U. Brändli, M. Eyer, D. Seebach, *Chem. Ber. 119* (1986) 575.

[268] Further enantiooselective deprotonations have been performed, e.g., with the bases **A**–**C** (see also Table 9 and N. S. Simpkins, lecture held at the Society of Chemical Industry Symposium "Chirality Recognition in Synthesis", London, March 17, 1988). For **A**, see [261, 263, 264] and



A, R = H, CH_3 **B** **C**

J. A. Marshall, J. Lebreton, *Tetrahedron Lett. 28* (1987) 3323; *J. Am. Chem. Soc. 110* (1988) 2925; L. Duhamel, A. Ravard, J.-C. Plaquevent, D. Davoust, *Tetrahedron Lett. 28* (1987) 5517; For **B** see [26]; For **C**, see M. Asami, *Chem. Lett. 1984*, 829; *Tetrahedron Lett. 26* (1985) 5803; M. Asami, H.Kirihara, *Chem. Lett. 1987*, 389; S. K. Hendrie, J. Leonhard, *Tetrahedron 43* (1987) 3289.

[269] When the precursor of the achiral enolate is a mixture of enantiomers and a chiral base is used for the deprotonation, a kinetic resolution may be responsible for the optical activity of the product; this has to be considered especially in cases of yields below 50%, see for example: M. B. Eleveld, H. Hogeveen, *Tetrahedron Lett. 27* (1986) 631, and review article cited in [218].

[270] M. Simpson, *Diplomarbeit*, ETH Zürich 1982.

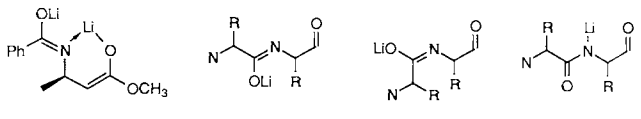
[284] The configuration of the CC and CN double bond of the enolate drawn in Scheme 15 is, as with all deprotonated peptides in this section (Schemes 15–19 and 24), chosen arbitrarily (or better, by the "technique of illustration"). There are no structural investigations of such species known to us. There is probably no doubt about the position of the Li at the more electronegative heteroatom oxygen (**A**–**C** vs. **D**). Of the four possible geometric isomers of the butyric acid derivative, **A** seems to be especially "attractive". Besides the *Z* isomer **B**, the *E* isomer **C** may be also considered for the lithiated peptides. See also entry 16 in Table 9.



A (*E*,*E*) **B** (*Z*) **C** (*E*) **D**

[285] The first experiments on solubilization and alkylation of polylithiated open-chain peptides in the presence of LiCl have been performed in our laboratory by *S. Shoda* (Postdoctoral fellow at the ETH Zürich 1984–1986).

Two-Dimensional Solid-State NMR Spectroscopy: New Possibilities for the Investigation of the Structure and Dynamics of Solid Polymers

New Analytical Methods (38)

By Bernhard Blümich and Hans Wolfgang Spiess*

Dedicated to Professor Dr. Helmut Dörfel on the occasion of his 60th birthday

NMR spectroscopy is an effective method not only for examining liquid samples but also for characterizing molecular structure, order and dynamics in amorphous and ordered solids. Recent developments in the area of solid-state NMR spectroscopy span from model-dependent studies of conventional one-dimensional spectra to the more definitive two-dimensional (2D) spectra which provide more specific information. For example, with 2D-NMR spectroscopy it is possible to determine the orientational distribution functions of molecular segments in drawn polymers and to distinguish different mechanisms of complex molecular motions. Following an introduction to basic NMR spectroscopy, an overview of the current state-of-the-art of 2D methods in solid-state NMR spectroscopy is presented and demonstrated with selected examples.

1. Introduction

Polymeric materials are valued not only for their light weight and low production costs, but also for their diversity of physical properties. For these reasons polymers are increasingly replacing conventional materials and constitute essential components of new technologies. The exceptional mechanical, electrical, optical and transport properties of polymers are ultimately determined by the structure and organization of the macromolecules.

A classical example of the relationship between molecular organization and macroscopic properties is the partial crystallinity of polymers such as polyethylene.[1] In the crystalline regions the polymer chains are highly ordered and immobile. These regions give the plastic material its mechanical strength. In the amorphous layers, however, the polymer chains are mainly disordered and mobile. These regions allow plastic deformation of the material.

The precise characterization of molecular order and dynamics is consequently an important prerequisite for understanding the macroscopic properties of polymer materials. The achievement of this goal is very important but also very difficult, since the macromolecules of synthetic polymers possess an enormous number of internal degrees of freedom. Therefore, there are numerous possible molecular motions with characteristic times of about 10^{-11} s to minutes.[1a] Solid polymers often occur in the glassy state. Even in this amorphous state, however, it is possible to establish molecular order in the polymers by controlled deformation, macroscopic orientation of the polymer chains or preferential packing of the macromolecules.[1b] Solid-state NMR spectroscopy[2-6] offers new possibilities for polymer characterization and has repeatedly proven itself useful in recent years in this area.[7-16]

The main advantage of NMR spectroscopy is its high selectivity. For instance, the individual functional groups of a macromolecule can be distinguished in a ^{13}C-NMR spectrum because of their different chemical shifts. However, the necessary spectral resolution in solids can only be achieved by mechanically rotating the sample at the "magic" angle of 54.7° relative to the magnetic field (MAS: *M*agic *A*ngle *S*pinning).[17,18] In addition, the sensitivity of ^{13}C-NMR spectroscopy can be significantly increased by means of cross polarization (CP: *C*ross *P*olarization).[19]

The signal intensities observed in a CP/MAS-^{13}C-NMR spectrum depend on various spin relaxation times.[3,4] These reflect the mobility of the respective functional groups in the solid state. On the basis of these differences, one can successfully examine molecular structure and dynamics with relatively simple 1D-NMR methods, as described in a review article by *R. Voelkel*.[20]

Selectivity can also be achieved by isotope labeling, whereby the ^{2}H-NMR spectroscopy of selectively deuterated solids has become a standard procedure.[13-16] Exploiting the differences in relaxation time and using suitable pulse sequences, molecular motions can be investigated in the entire range of interest (10^{-11} to ca. 100 s) by using relatively simple 1D-NMR methods. The orientational distribution functions of macromolecules in partially ordered polymers can likewise be exactly assessed.

One-dimensional solid-state NMR spectroscopy already provides highly selective information and is therefore used on a routine basis nowadays. Nonetheless, this method often fails to sufficiently characterize molecular structure, order and dynamics in solid polymers, because the data analysis is based on model concepts and different models cannot always be unequivocally differentiated. It is not surprising then, that 2D-NMR spectroscopy, which has proven most effective for elucidating the structure of biomolecules in solution, is now being used to gain this information.[21,22]

The present article is therefore concerned with 2D solid-state NMR spectroscopy. Although this procedure is more complicated than 1D-NMR, considerably more informa-

[*] Prof. Dr. H. W. Spiess, Priv. Doz. Dr. B. Blümich
Max-Planck-Institut für Polymerforschung
Postfach 3148, D-6500 Mainz (FRG)

tion can be acquired by its application. For example, a 2D spectrum allows one to either correlate various molecular properties or molecular states at different times,[23-28] or to separate different molecular properties.[29-33] The following section (Section 2) covers the basics of solid-state NMR spectroscopy which are necessary for understanding these new techniques. Section 3 then presents a systematic overview of 2D-NMR methods for the investigation of solids. Sections 4 and 5, respectively, cover molecular motion and molecular order, which are especially relevant for an understanding of solid polymers. These sections provide a more detailed account of new 2D-NMR experiments. In this way, we not only hope to provide detailed information to those readers who are already acquainted with modern NMR spectroscopy, but also to show the layman the potential of these new methods.

2. Basic Solid-State NMR Spectroscopy

Molecules are less mobile in the solid state than in the liquid state. Therefore, a number of anisotropic (orientation dependent) interactions occur in the solid state, whereas in the liquid state these interactions are averaged by fast molecular motions.[2-6] The three most important interactions are listed as follows:

1) The *magnetic dipole-dipole coupling* of two nuclei: One hereby distinguishes between the homonuclear dipole-dipole coupling of like nuclei (e.g. ^{1}H) and the heteronuclear dipole-dipole coupling of different nuclei (e.g. ^{1}H and ^{13}C). In the case of ^{1}H, each nucleus couples with many other nuclei which causes wide structureless bands in the spectrum.
2) The *electric quadrupole coupling* of nuclei with a spin $I > 1/2$; such nuclei possess a quadrupole moment which couples to the electric field gradient at the site of the nucleus.
3) The *magnetic shielding* of the nucleus by the surrounding electrons is also anisotropic. In liquids, the time average of this interaction is seen as the chemical shift, while dipole-dipole and quadrupole coupling are averaged to zero by the molecular motion.

The quadrupole coupling generally dominates in solids for nuclei with a spin $I > 1/2$. Although the quadrupole coupling is small for ^{2}H, in hydrocarbons it leads to spectra typically having a line width of 250 kHz. The homonuclear dipole-dipole coupling between ^{1}H results in line widths up to 100 kHz, whereas the heteronuclear dipole-dipole coupling between ^{1}H and ^{13}C yields line widths up to 50 kHz. These values are independent of the Larmor frequency, while the frequency shifts due to the anisotropy of the magnetic shielding are proportional to the static magnetic field $\boldsymbol{B}_0$ and are therefore proportional to the Larmor frequency. At an anisotropy of the chemical shift of 200 ppm, a typical value for hydrocarbons with π-bonds,[3,4,34] the ^{13}C-NMR spectrum has a line width of 15 kHz at a field strength of 7 T.

Because of the anisotropy of the interactions, in solids the NMR frequency depends on the orientation of the molecules in the magnetic field. Consequently, for many years narrow signals which shift in a characteristic way on rotating the sample were observed only with single crystals. However, powders can also furnish spectra with narrow signals if the orientation-dependent terms of the nuclear interactions are eliminated during the measurement by:

1) *Heteronuclear decoupling*[2,3,35,36] especially of ^{1}H and ^{13}C through irradiation at the ^{1}H resonance frequency;
2) *Rotation of the sample at the magic angle*;[3,4-6,17]
3) *Homonuclear decoupling*,[2,3,37,38] in particular of ^{1}H-^{1}H by pulsed irradiation at the ^{1}H resonance frequency (multi-pulse methods for selective averaging).

2.1. Orientation Dependence of the NMR Frequency

The orientation-dependent nuclear-spin interactions introduced here are described by second-rank tensors. The angular dependence of the NMR frequency is then given by the following equation:[2-4]

$$\Omega = \Omega_0 + \tfrac{1}{2}\Delta(3\cos^2\theta - 1 - \eta\sin^2\theta\cos 2\phi). \quad (1)$$

Ω_0 denotes the Larmor frequency including the part of the isotropic chemical shift, Δ is the coupling constant, and the asymmetry parameter $0 \le \eta \le 1$ represents the deviation from axial symmetry around the principal Z axis of the coupling tensor; the polar coordinates θ and ϕ describe the orientation of the magnetic field $\boldsymbol{B}_0$ in the principal axes system of the tensor. The principal axes system for the generally dominating intramolecular contributions is determined by the local symmetry of the molecule in the vicinity of the nucleus under study. Some especially significant examples for ^{13}C- and ^{2}H-NMR spectroscopy are illustrated in Figure 1. The NMR spectrum for a particular molecular orientation is shown in the middle. The powder spectrum, obtained as a superposition of the spectra for all orientations, is displayed on the right-hand side.

The anisotropic interactions are partially or totally averaged in the presence of fast molecular motions with correlation times $\tau_c \ll \Delta^{-1}$. Nevertheless, the tensorial character of the coupling is maintained and is characterized by $\bar{\Delta}$ and $\bar{\eta}$.[4] Equation (2) then applies for the resonance frequency:

$$\Omega = \Omega_0 + \tfrac{1}{2}\bar{\Delta}(3\cos^2\theta' - 1 - \bar{\eta}\sin^2\theta'\cos 2\phi), \quad (2)$$

whereby θ' and ϕ' represent the polar angles of $\boldsymbol{B}_0$ in the principal axes system of the averaged tensor. Hereby, deviations of the axial symmetry can occur. This means that $\bar{\eta} \neq 0$, although $\eta = 0$.[13] For motions with cubic symmetry, such as tetrahedral jumps which occur in crystalline hexamethylenetetramine,[39] and consequently also for isotropic reorientations, the anisotropic coupling vanishes, so that $\bar{\Delta} = 0$.

2.2. Rotation at the Magic Angle: MAS

If a sample is rotated with angular velocity $\Omega_R > \Delta$ (Fig. 2) about an axis which is inclined at an angle of Φ with respect to the magnetic field $\boldsymbol{B}_0$, then the orientation-de-

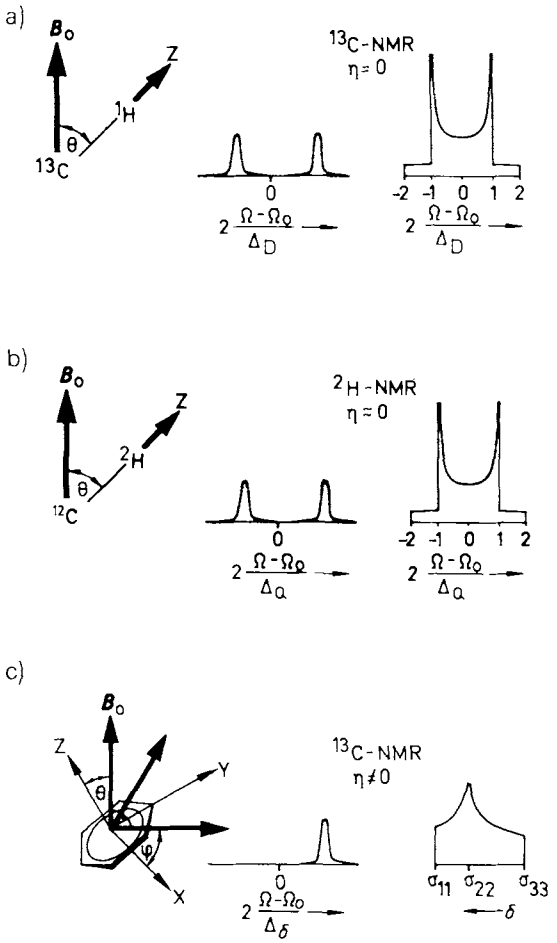

Fig. 1. Anisotropic interactions in the solid state which make the NMR frequency dependent on the molecular orientation: a) dipole-dipole coupling between ^{1}H and ^{13}C. Because the total spin amounts to $I=1$, the ^{13}C-NMR spectrum is made up of two signals, the separation of which is dependent on the orientational angle θ. b) Quadrupole coupling of the ^{2}H nucleus with the electrical field gradient of the C-^{2}H bond. Because the ^{2}H nucleus possesses a spin $I=1$, the NMR spectrum looks similar to that of the dipole-dipole coupling between ^{1}H and ^{13}C. c) Anisotropic magnetic shielding of the ^{13}C nuclei. Because ^{13}C has a spin of 1/2, only one NMR signal is observed.

pendent nuclear-spin interactions are scaled by a factor of $\frac{1}{2}(3\cos^2\Phi-1)$.[3,17] For the magic angle of $\Phi=54.7°$, the anisotropic interaction averages to zero. This applies, however, only under the condition, that the rotation frequency Ω_R is considerably larger than the coupling constant Δ. This prerequisite can still be met for the anisotropy of the magnetic shielding at rotation frequencies of up to 20 kHz which can be currently attained. Therefore, MAS-^{13}C-NMR spectroscopy together with high-power proton decoupling has become a routine method for measuring highly resolved spectra of solids[36] as shown in Figure 2d with dimethyl sulfone as an example.

By rapid MAS, the wide solid-state resonances are narrowed to small lines (see Figs. 2c and 2d). One simultaneously gains signal intensity thereby shortening the measurement time from hours to minutes. Such MAS-NMR spectra are comparable to NMR spectra of liquids, even though they exhibit lower resolution.[20] However, because the information about the anisotropic coupling is lost, the carrier of information regarding molecular order and dynamics is lost as well (see Sections 4 and 5).

On the other hand, for slower sample rotations ($\Omega_R<\Delta$), one observes rotational sidebands separated by multiples of Ω_R from the center line at the isotropic chemical shift (Fig. 2e). The sideband spectrum covers the same frequency range as the spectrum of the static sample (Fig. 2c), so that information about the anisotropic coupling is basically retained.[40,41] Sideband spectra of ^{13}C nuclei with different isotropic chemical shifts are shifted accordingly and therefore can be resolved.

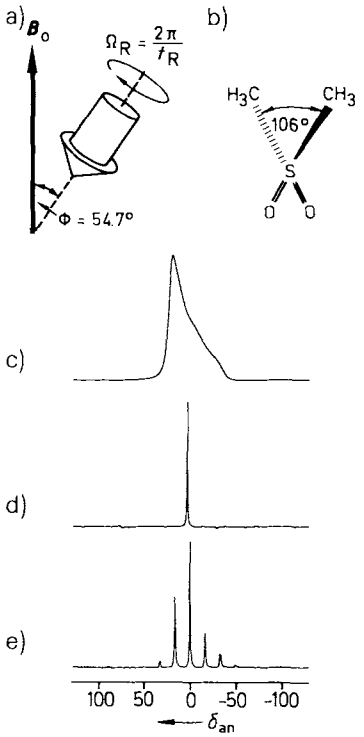

Fig. 2. Sample geometry during rotation at the magic angle a) and proton decoupled ^{13}C-NMR spectra of dimethyl sulfone b) at room temperature, c) static sample, d) fast sample rotation at $\Omega_R=5000$ Hz and e) slow sample rotation at 1000 Hz.

If rotational sidebands are unwanted, they can be suppressed by means of the so-called TOSS method (TOSS: *T*otal *S*uppression of *S*idebands) (Fig. 3).[42-46] Application of 180° pulses causes the sidebands to cancel during the detection period. The TOSS method demonstrates that averaging processes are possible not only by manipulating the sample in the spacial dimension (rotation at the magic angle), but also by manipulating the sample in the spin di-

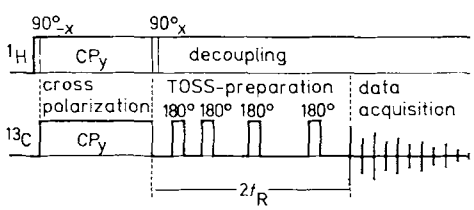

Fig. 3. Excitation scheme for TOSS and cross polarization. By means of cross polarization, transverse magnetization is transferred from the protons to the ^{13}C nuclei (see Figure 4 and caption). In order to prevent cross-polarization effects during the TOSS pulses, the transverse proton magnetization is rotated back to the z-direction by a 90° pulse at the beginning of the TOSS preparation period [47].

mension (rotation of the nuclear moments by radio-frequency pulses, selective averaging). The TOSS procedure, however, is problematic for analytical applications,[20] because the intensities of the center lines deviate from their theoretical values. As was recently shown, the TOSS method can, nonetheless, be used to detect ultra-slow molecular motions.[48]

2.3. Cross Polarization

With pulse spectroscopy the signal-to-noise ratio depends on the spin-lattice relaxation time[4] and on the degree of nuclear magnetization which can be achieved. Both of these parameters are unfavorable for ^{13}C nuclei, because the relaxation times are longer than those of ^{1}H nuclei, and the natural abundance of ^{13}C amounts to only 1%. However, by using the cross polarization technique illustrated in Figure 4, these disadvantages can be circumvented by transferring magnetization from ^{1}H to ^{13}C.[18,49,50]

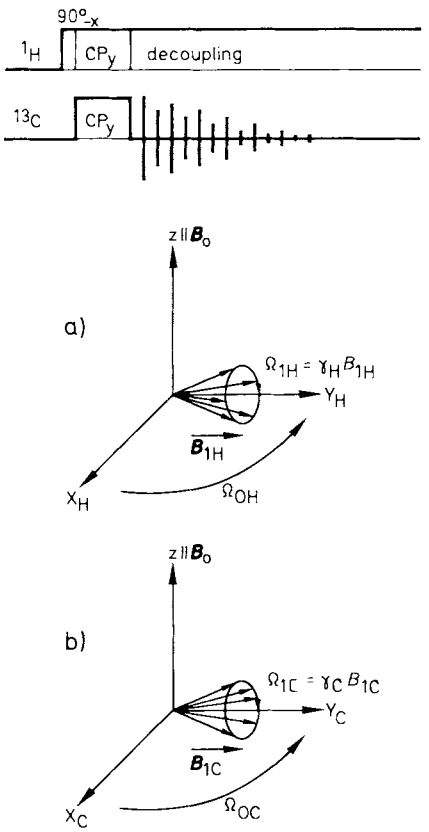

Fig. 4. Cross polarization: Transfer of magnetization from ^{1}H to ^{13}C. ^{1}H- and ^{13}C-nuclear spins precess around their respective transverse magnetic fields. For details see text.

Transverse ^{1}H-magnetization is generated by a 90° pulse. After the pulse, the phase of the ^{1}H transmitter is shifted by 90°, causing the magnetic field $\boldsymbol{B}_{1H}$ of the ^{1}H transmitter to lie parallel to the transverse ^{1}H magnetization. Therefore, in the coordinate system, which rotates with the Larmor frequency Ω_{0H}, the ^{1}H nuclear spins precess with a frequency $\gamma_H B_{1H} = \Omega_{1H}$ (Figure 4a) around the $\boldsymbol{B}_{1H}$ field. During this period, the carbon spins are likewise irradiated with a radio-frequency magnetic field $\boldsymbol{B}_{1C}$. The amplitude is selected in such a way as to fulfill the Hartmann-Hahn condition (Fig. 4b),[19] so that $\gamma_C B_{1C} = \Omega_{1C} = \Omega_{1H} = \gamma_H B_{1H}$. In the coordinate system, which rotates with the Larmor frequency Ω_{0C}, the ^{13}C spins then precess around the $\boldsymbol{B}_{1C}$ field with the same frequency as the ^{1}H spins do around the $\boldsymbol{B}_{1H}$ field. Because of the ^{1}H-^{13}C dipole-dipole interaction, the magnetization of the highly polarized ^{1}H nuclei can then be transferred to the unpolarized ^{13}C nuclei.[19] As a result of this cross polarization, the ^{13}C nuclei can be polarized by a factor of up to 4 higher than by their spin-lattice relaxation. Furthermore, the repetition rate of the cross polarization is now determined by the spin-lattice relaxation of ^{1}H, which is typically shorter than that of ^{13}C.

In practice, all the phases of the radio frequency fields are cyclically varied to reduce the degradation of the ^{13}C-NMR signal by relaxation effects and pulse distortions. The phase cycle for the cross-polarization sequence is compiled in Table 1 for one phase of the ^{1}H-cross-polarization field (Y). It is extended to the other phases by means of cyclic permutation.

Table 1. Phase cycle for cross polarization.

90° (^{1}H)	CP (^{1}H)	CP (^{13}C)	Receiver
X	Y	X	X
X	Y	Y	Y
X	Y	−X	−X
X	Y	−Y	−Y
−X	Y	X	−X
−X	Y	Y	−Y
−X	Y	−X	X
−X	Y	−Y	Y

To simplify complicated sideband spectra, the cross-polarization technique can be varied, so that either protonated or unprotonated carbons alone are polarized.[51,52] This type of selectivity is reached on the basis of variations in the dipole-dipole coupling between ^{1}H and ^{13}C in different functional groups such as $-CH_3$, $=CH_2$, $\equiv CH$ and $-COO^{\ominus}$. Some polarization schemes are summarized in Figure 5. In Figure 5a the cross-polarization time (1–5 ms) is selected such that all ^{13}C positions are polarized. At shorter cross-polarization times (50 μs, Fig. 5b), only protonated nuclei with strong dipole-dipole couplings are polarized. The process according to Figure 5c leads to the complementary spectrum: first all C atoms are polarized. Thereafter, the proton decoupling is turned off for a period of $t_d \approx 100$ μs (gated decoupling). Because of the dipole-dipole coupling, the transverse magnetization of the protonated C atoms is destroyed faster during t_d than that of the unprotonated C atoms, the signals of which therefore dominate during the detection period. To avoid phase errors, the data acquisition starts only after the resulting ^{13}C magnetization has been refocussed by a 180° pulse to the beginning of a rotor period $t_R = 2\pi/\Omega_R$.[32]

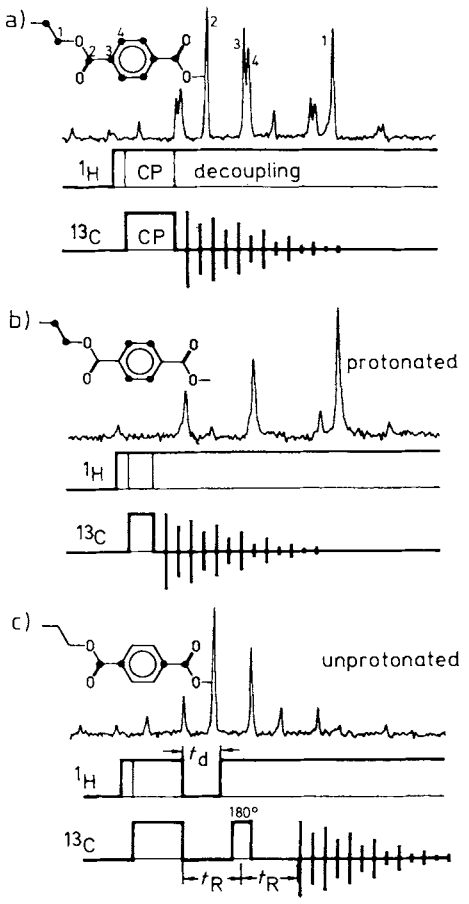

Fig. 5. The selectivity of different cross polarization schemes is illustrated on polyethylene terephthalate at room temperature at a sample rotation frequency of $\Omega_R/2\pi = 4090$ Hz. a) Polarization of protonated and unprotonated ^{13}C nuclei. b) Polarization of protonated ^{13}C nuclei. c) Polarization of unprotonated ^{13}C nuclei.

3. Review of Two-Dimensional Solid-State NMR Spectroscopy

3.1. Basics

The time scheme of two-dimensional, solid-state NMR spectroscopy (Fig. 6) is identical with that of high-resolution 2D-NMR spectroscopy of liquids.[21-24] The nuclear spin system is first brought into a well-defined initial state during the *preparation period*. During this time, spin-lattice relaxation typically occurs followed by a 90° pulse or cross polarization (Section 2.3). During the following *evolution period* t_1, the spin system develops under the influence of various nuclear spin interactions (Section 2.1). In conventional 1D-NMR spectroscopy, the nuclear signal is recorded during the time t_1, and the spectrum is produced after Fourier transformation. In 2D-NMR spectroscopy, however, the state of the spin system after a certain time t_1 is generally altered abruptly by at least one further radio-frequency pulse. The resonance signal is then recorded during a subsequent *detection period* (t_2). Afterwards, the entire experiment is repeated with an incremented evolution time t_1, whereby the initial state of the nuclear spin system during the detection period at $t_2 = 0$ changes accordingly. The 2D-NMR spectrum is produced by two successive Fourier transformations after t_2 and t_1.

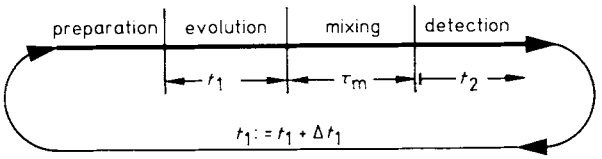

Fig. 6. Timing diagram of two-dimensional-NMR spectroscopy. During the detection period t_2 transverse magnetization is measured, the history of which is determined by the preparation period and the evolution period t_1 and by the fixed mixing time τ_m, respectively. Data acquisition is repeated after incrementing the evolution period.

As explained in Section 2, the interactions which influence a nuclear spin during the preparation period, the evolution time t_1 or the detection time t_2, can be manipulated in many ways such as by homo- or heteronuclear decoupling, through MAS or by polarization transfer. Finally, a fixed mixing period of duration τ_m can be introduced between the evolution and detection times (Fig. 6), during which the nuclear magnetization is mixed between different resonances. This occurs, for example, during chemical reactions and chemical exchange. In solids, the nuclear spin interactions are also anisotropic, so all feasible molecular orientations must be considered. Correlations, which associate different interactions with particular nuclear positions or which indicate the exchange of molecular groups or orientations due to dynamic processes, are marked by cross peaks. In all, there are a large number of 2D-NMR methods which can be utilized for the study of molecular structure, order, and dynamics. In Section 3.2 a systematic overview of the various types of solid-state 2D-NMR spectroscopy is presented.

3.2. The State-of-the-Art

In order to simplify the summary of the numerous 2D-NMR techniques, the various methods are compiled in two tables. Table 2 concerns static samples, whereas Table 3 deals with rotating samples, i.e. MAS-NMR spectroscopy. The rows and columns a–j contain the nuclear spin interactions which determine the NMR frequencies on both axes of the 2D-NMR spectra and take effect during the evolution time t_1 and the detection time t_2. The isotopic chemical shift is given by δ_{iso}, whereas J denotes the indirect hetero- or homonuclear spin-spin coupling,[2-6] R the relaxation effects, δ_{an} the anisotropy of the magnetic shielding (chemical shift), D_{II} the homonuclear dipole-dipole coupling, D_{IS} the heteronuclear dipole-dipole coupling, Q the quadrupole coupling, and ϕ the sample orientation at the beginning of data collection. The upper triangle refers to crystals and ordered samples, and the lower triangle to amorphous and powdered samples.

The entries S, D, O specify the suitability of the particular method for studying molecular structure (S), molecular dynamics (D) or molecular order (O).

All experiments having a mixing time are labeled with D. These include exchange experiments as well as spin-diffusion experiments, whereby the latter essentially yield information about structure. The term "exchange" denotes frequency exchange caused by either chemical reactions or

molecular reorientation. The correlation of different, isotropic chemical shifts is sufficient for detecting chemical exchange. However, in order to detect molecular reorientation, an isotropic interaction must be present. Many of the correlation experiments denoted with S can in principle also be applied for examining molecular dynamics. A particular method is labeled with D only in cases in which such applications have been experimentally demonstrated.

Rows and columns of the tables are marked with small letters (a–j) which refer to the corresponding literature references. Two examples are presented to demonstrate how the tables should be used. The 2D-^{2}H-exchange experiment for detecting ultra-slow molecular motions described later in Section 4 is found in Table 2 in the lower triangle under the heading iiD, since a static isotropic sample is measured, the quadrupole coupling is detected during the evolution and detection times, and because molecular dynamics are investigated. The MAS method used to determine molecular order and which is described further in Section 5 is accordingly found in Table 3 under ejO, since the sample rotates and is ordered. Furthermore, one frequency axis corresponds to the magnetic shielding (chemical shift), and the other corresponds to the mechanical sample rotation.

The particular techniques applied during the various experiments are not specified in the tables, for this would be beyond the scope of this article. For NMR specialists, however, the relevant publications are cited: multi-pulse methods for homonuclear decoupling,[2, 53, 56, 60–63, 69, 71, 93, 94, 97–99, 107, 110, 111, 118, 119, 124] and for scaling of the chemical shift[97, 103, 106, 125] multiquantum NMR spectroscopy,[54, 65, 126] switching of the spinning axis,[92, 101, 102, 107, 127] discrete sample reorientations,[57, 73] rotor synchronization of the excitation sequence,[30–33, 41, 101, 104, 107, 108, 121, 122, 124] dynamic nuclear polarization,[74] overtone excitation and

detection,[55] and the reduction of the effective magnetic field by nutation in the B_1 field,[55,67,80–83] switching of the B_0 field,[79] or by zero-field NMR spectroscopy.[78,84,128]

On the diagonals of Tables 2 and 3, the 2D-NMR methods appear, in which an interaction is correlated with itself. The other experiments correlate various interactions with each other which, with the exception of the sample orientation ϕ, correspond to local fields that influence the NMR frequency. As proposed by *J. S. Waugh*, such experiments are named "separated local field" (SLF) experiments,[61] although this name is frequently used only to signify the correlation of the heteronuclear dipole-dipole coupling with the anisotropic chemical shift.

For a number of 2D solid-state NMR experiments, the information about the anisotropy of the nuclear spin interactions is deliberately dispensed with by selecting samples with extremely high molecular mobility, or by examining highly-ordered samples or crystals. In other cases, the respective information is discarded by averaging the anisotropy by means of multi-pulse or MAS techniques. With regard to their informational value, these methods are comparable with the 2D-NMR techniques known in the high-resolution NMR spectroscopy of liquids. They are found in Tables 2 and 3 in the rows and columns labeled a–d.

On the other hand, all 2D-NMR experiments based on the anisotropy of nuclear spin interactions are typical solid-state methods. For example, these include the SLF experiments, which can be used to study the relation of the a priori unknown principal axes system of a ^{13}C chemical shift tensor with the C–H bond axes, from which information about structure and dynamics can be obtained.[76] Other typical solid-state techniques involve experiments with a mixing time for longitudinal magnetization components, by which the molecular reorientations can be followed (see Section 4).[25]

The methodological development of 2D solid-state NMR spectroscopy is in no way complete. This is demonstrated by the fact that many of the fields in Tables 2 and 3 are still open. There are several reasons for this. For example, solid-state NMR signals are currently still too broad for resolving the *J*-coupling between light nuclei such as ^1H, ^{13}C, ^{15}N etc.; MAS-NMR spectroscopy of quadrupolar nuclei will only be extensively used when the rotation velocity can be raised to 100 kHz.[129] Moreover, it has only recently been recognized that MAS-NMR spectroscopy of partially ordered samples can yield useful structural information.[30]

In order not only to demonstrate the effectiveness of 2D solid-state NMR spectroscopy but also to show how complex these methods can be, a few representative experiments are briefly introduced in Sections 3.3–3.7.

3.3. Correlation of Dipole-Dipole Coupling and Chemical Shift

In such a correlation one frequency axis of the spectrum depicts the local field of the homo- or heteronuclear dipole-dipole coupling D_{11} or D_{1S}. The other axis denotes the isotropic[55,106,107] (δ_{iso}) or isotropic and anisotropic chemical shift ($\delta_{iso}+\delta_{an}$), via which the local dipolar spectra can be assigned to the corresponding chemical structure (see Tables 2 and 3).

This has been the subject of numerous studies, most of which, however, deal with heteronuclear dipole-dipole coupling; very few concern homonuclear dipole-dipole coupling.[58,74,123,195] Crystals[55,58–60,62,63,71] and highly ordered samples[61] were examined without sample rotation, because the necessary resolution of the chemical shift is already achieved by the molecular orientation. For disordered static samples isotope labeling is necessary.[74,75,76]

To illustrate dipolar SLF-NMR spectroscopy, Figure 7[61] shows the ^{13}C-NMR spectrum of highly-ordered polyethylene and the corresponding excitation sequence. During the evolution period homonuclear decoupling is applied to the protons by a multi-pulse sequence, so that only the heteronuclear coupling between the protons and ^{13}C is effective. The orientation of the dipolar coupling tensors can be determined from the dipolar splitting measured in the 2D-NMR spectrum for different molecular orientations. Furthermore, the position of the chemical shift tensor can be ascertained from the form of the spectrum. Consequently, with this method one obtains precise informa-

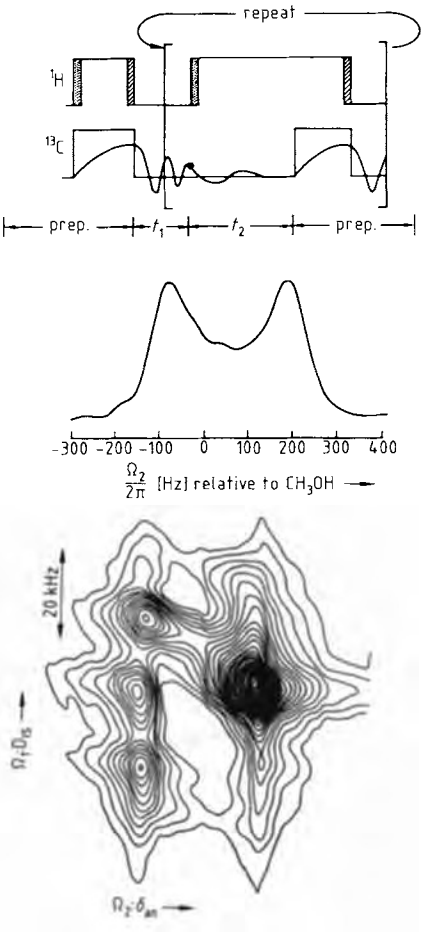

Fig. 7. Excitation sequence (above), 1D-^{13}C spectrum (middle) and 2D SLF-^{13}C-NMR spectrum (below) of highly oriented polyethylene with the draw direction perpendicular to the magnetic field. The hatched pulses are $\pi/2$ pulses phase-shifted by 90° to lock the proton magnetization during cross polarization and decoupling. The protons were homonuclearly decoupled during the evolution period t_1. The axes of the 2D-NMR spectrum denote the anisotropic chemical shift δ_{an} of the ^{13}C nuclei (horizontal) and the heteronuclear dipole-dipole coupling D_{1S} (vertical).

tion about bond angles and orientations of the various structural elements which can be distinguished on the chemical shift axis.

Besides obtaining detailed information about molecular structure, one can also examine molecular motion via a line shape analysis.[6] However, there are only a few experimental examples of this, because complicated model-dependent simulations are necessary to quantitatively analyze dipolar line shapes.[77, 107, 124] For instance the powder ^{13}C-NMR spectra of calcium formate, measured as a function of the dipolar coupling between ^{13}C and ^{1}H, cannot be explained without the assumption of molecular motion.[77] More exact and less model-dependent information about molecular dynamics can be expected from methods which correlate the local fields after a mixing time through an exchange of magnetization components (see Section 4).[71]

For disordered samples MAS must be applied in order to increase resolution (see Section 2.2).[41, 105–111, 123, 124] To exemplify this, Figure 8 depicts the excitation sequence

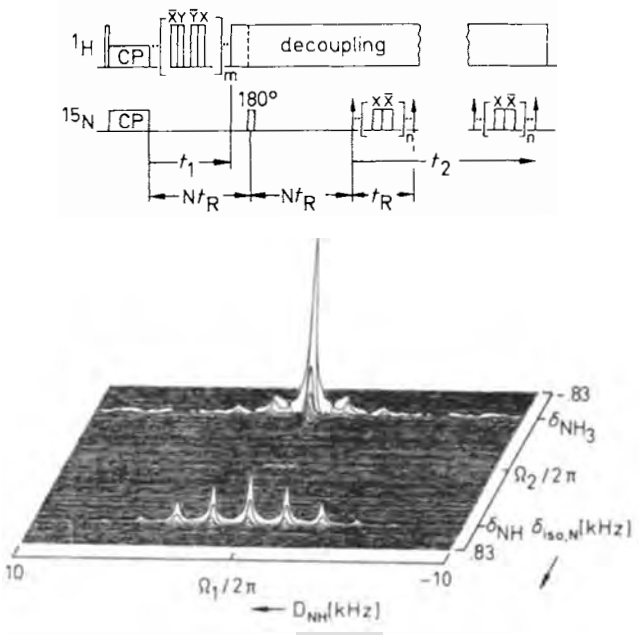

Fig. 8. Pulse sequence of the dipolar SLF-^{15}N-NMR spectrum of Gly-Gly·HCl·H_2O. Evolution time and detection time were synchronized with the rotor period. During the detection period the chemical shift was scaled by 50%.

and the SLF-^{15}N-NMR spectrum of the dipeptide Gly-Gly·HCl·H_2O.[106] During the evolution period, the protons are subject to homonuclear decoupling, and ^{15}N nuclear magnetization is subsequently focused with a 180° pulse at the beginning of a rotor period t_R (see also Fig. 5c). During t_1 the homonuclear dipole-dipole coupling dominates. Afterwards, the nitrogen is completely decoupled from the protons until data acquisition begins at the echo maximum at $t_1 = 0$. The echo is therefore modulated by the heteronuclear dipole-dipole coupling. In order to avoid rotational sidebands, only one data point per rotor period is recorded during the detection period. Because the spectral width is then limited by the rotor frequency, the chemical shift is scaled by a multi-pulse sequence.[125]

In the spectrum shown in Figure 8 the rotational sideband spectra of the dipole-dipole coupling between ^{15}N and ^{1}H nuclei, which are separated from each other on the vertical axis by the isotropic chemical shifts of the ^{15}NH- and the $^{15}NH_3$ resonances, appear parallel to the horizontal axis. In this way the strength of the dipole-dipole coupling tensors can be determined in polycrystalline and amorphous materials. Consequently, the N-H- (or C-H-) bond lengths can be determined. If the strength of the dipole-dipole coupling is known, then information about the molecular dynamics can be derived from the signal shape, as *Schaefer* et al. demonstrated in a related experiment on polystyrene and polycarbonate.[124]

For unprotonated C atoms, the dipole-dipole coupling to the nearest ^{1}H nuclei is often so weak that no dipolar rotational sidebands occur. The SASS (*S*witching-*A*ngle *S*ample *S*pinning) technique is suitable for examining such weak local fields.[107] During the evolution period, the rotor axis is inclined to the magnetic field at an angle different from the magic angle.[127] Between the evolution period and detection period, the rotor axis is turned back to the magic angle. A narrower powder spectrum is obtained in this way and is correlated with the high-resolution chemical shift.[101] By means of such spectra, for example, the bond lengths and angles of such enclosure compounds as the clathrates of β-quinone–methanol and of urea and *trans*-4-octene were determined.[107]

3.4. Heteronuclear Correlation Spectroscopy

Solid-state techniques have been developed which deliver information similar to two-dimensional methods in the high-resolution NMR spectroscopy of liquids. An example of this is the heteronuclear correlation experiment,[56, 93, 94] in which the chemical shifts of an abundant nucleus, e.g. ^{1}H, are correlated with the shifts of rare nuclei such as ^{13}C coupled to ^{1}H. Because of the higher resolution that is often associated with the rare nucleus, the spectrum of the abundant nucleus can then be more easily assigned to the chemical structure.

This is demonstrated in Figure 9 by the heteronuclear correlation spectrum of threonine and the corresponding excitation sequence.[93] The axes of the spectrum show the isotropic chemical shifts of ^{13}C and ^{1}H, while the signals indicate which nuclei are coupled by the heteronuclear dipole-dipole interaction. The homonuclear dipole-dipole interaction of the protons is suppressed during the evolution period by a multi-pulse sequence (BLEW-12,[130]) such that the cross peaks only occur between neighboring heteronuclei. At the same time ^{13}C and ^{1}H are heteronuclearly decoupled by another multi-pulse sequence (WALTZ-8[131]). During the detection period, the ^{13}C nuclei are decoupled from the protons by strong continuous irradiation of the protons. In this way, each type of nucleus becomes isolated from the other during the evolution and detection periods. Sample rotation at the magic angle reduces the anisotropic contributions of the nuclear spin interactions, so that finally only isotropic chemical shifts are correlated with each other.

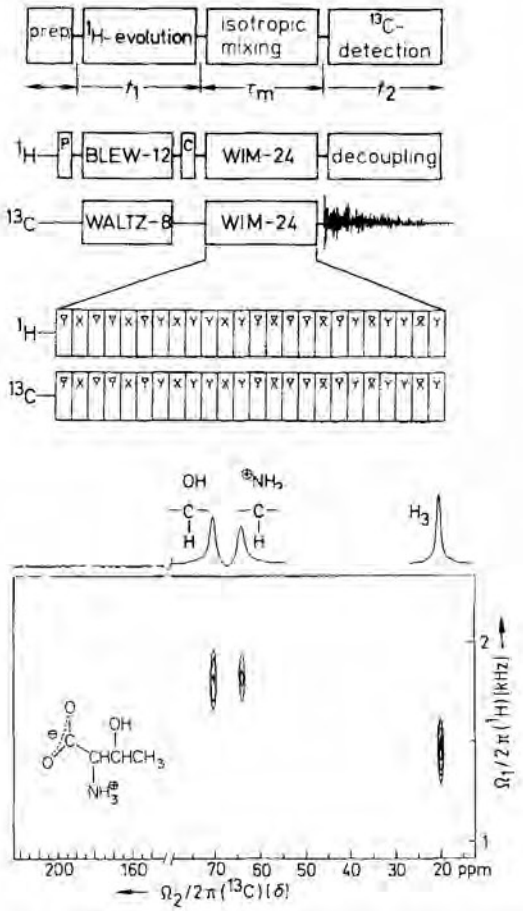

Fig. 9. Excitation sequence and resulting heteronuclear correlation spectrum for threonine with sample rotation at the magic angle. BLEW-12 [130] and WALTZ-8 [131] are multi-pulse sequences for homo- and heteronuclear decoupling. The WIM-24 pulse sequence (WIM, *W*indowless *I*sotropic *M*ixing) causes an isotropic magnetization transfer from ^{1}H to ^{13}C.

The mixing period τ_m amounts to an integral multiple of the rotor period t_R. b) and c) ^{13}C-exchange spectra of the crystalline fraction of polyoxymethylene. b) No exchange; measurement time 13 h. c) Cross signals caused by molecular reorientation; measurement time 37 h.

3.5. MAS-^{13}C-NMR Spectroscopy for the Investigation of Molecular Reorientation in Powdered and Amorphous Samples

MAS-^{13}C-NMR spectroscopy is increasingly becoming an important method for studying molecular reorientational processes, since the sensitivity of the MAS method is higher than that of static methods and the samples need not be isotopically labeled. Nevertheless, because of the typical asymmetric chemical shift tensors, the resulting exchange spectra cannot be as directly interpreted as can the ^{2}H-exchange spectra described in Section 4, where the coupling tensors are approximately axially asymmetric.[24–28]

Figure 10 depicts the pulse sequence and exchange spectra of the crystalline parts of polyoxymethylene at different mixing times.[122] A diagonal spectrum is obtained at short mixing times (Fig. 10b). At long mixing times, the rotation of the polymer chain in the solid state leads to off-diagonal cross peaks (Fig. 10c). In order to rule out artifacts, the mixing time τ_m must be a multiple of the rotor period.[122] By analyzing the pattern of the cross peaks, the geometry of the dynamic process can be ascertained. The spectra in Figure 10 are explained by a rotation of the helix by $\pm 200°$ together with a translation. By varying the mixing time, the correlation time of the process can be determined; by varying the temperature, the activation energy, in this case 80 kcal/mol, can also be determined.[122]

3.6. Spin Diffusion for the Characterization of Polymer Mixtures

In the exchange experiment,[23] not only chemical exchange and molecular reorientation can be detected in solids, but also spin diffusion can be measured at longer mixing times.[69, 70, 72, 87–89, 95, 116–118] Spin diffusion can be understood as an energy-conserving flip-flop process between two dipolar coupled nuclear spins. Because the dipole-dipole coupling in the MAS method with typical rotor frequencies under 10 kHz cannot be completely averaged, spin diffusion occurs also during MAS-NMR of disordered materials. Grain boundaries and the walls between domains differing in composition hinder the spin diffusion. As a result, the heterogeneity of polymer mixtures and other amorphous materials can be determined by 2D-diffusion spectroscopy.[88, 95, 96, 118]

In order to observe diffusion between ^{13}C nuclear spins, the sample must be enriched in ^{13}C. Otherwise spin diffu-

sion would be very weak, because of the low natural abundance of the nuclei.[69,89,90,95] Although the spin diffusion of protons is strong, the resolution necessary to differentiate the various proton chemical shifts can be attained only with extensive experimental effort, that is with homonuclear decoupling and rotation at the magic angle.

Figure 11 depicts the pulse sequence and experimental spectra of ^{1}H-spin-diffusion measurements for two different mixtures of polystyrene and poly(vinyl methyl ether).[118] In the 1D-^{1}H-NMR spectrum (Fig. 11b), the signals of the aromatic hydrogen positions of polystyrene are clearly separated from those of the OCH_3 and OCH groups of poly(vinyl methyl ether). The mixture precipitated from chloroform shows no cross peaks between the signals of the aromatic and the OCH_3 and OCH protons (Fig. 11c). The mixture precipitated from toluene, on the other hand, additionally yields the corresponding cross peaks. These indicate spin diffusion between the components of the mixture and prove that the macromolecules in the material precipitated from toluene are intimately mixed on the molecular level, whereas those in the material precipitated from chloroform are not.

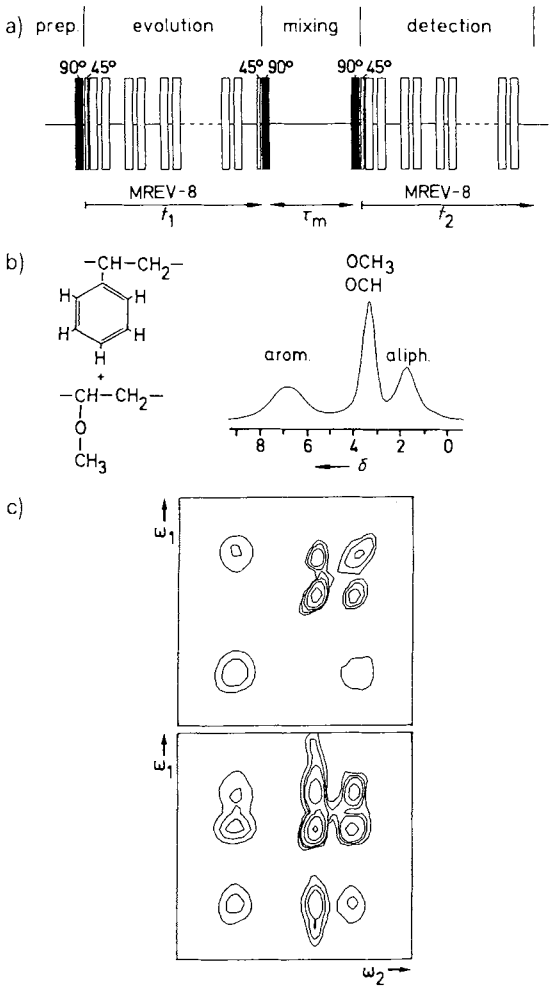

Fig. 11. a) Pulse sequence for 2D-spin diffusion experiments. b)–d) Spectra of polymer mixtures of polystyrene and poly(vinyl methyl ether). Spectral resolution is obtained through homonuclear multiple-pulse decoupling during the evolution and detection periods combined with MAS. Cross peaks between both components were only observed for the mixture precipitated from toluene (d) and not for the mixture precipitated from chloroform (c).

3.7. Variation of the Effective Magnetic Field

In the case of powder samples the NMR spectra of nuclei with quadrupole moments are generally difficult to observe with pulse methods because of their width. For non-integral spins, a 2D nutation experiment was devised which incorporates high resolution and high sensitivity.[55,67,80–83,132] The nuclear spins precess around the B_1 field during the evolution period, and the free induction decay in the B_0 field occurs during the detection period. In the resulting 2D-NMR spectrum, the spectrum of the nuclei in the low B_1 field is correlated with that in the high B_0 field. The low field yields high resolution due to the reduced angular dependence of the anisotropic nuclear-spin interactions. The high field, on the other hand, raises the sensitivity of detection. Related techniques are 2D Zeeman quadrupole-resonance spectroscopy[65] and zero-field NMR spectroscopy.[78,84,128,133,134] With the latter method, evolution occurs in the magnetic field-free space, and the detection takes place in the high magnetic field B_0. Because no preferred orientation exists for the spins in the absence of a magnetic field, sharp signals are observed for powders and amorphous samples. In zero-field NMR spectroscopy, the sample is either moved in and out of the B_0 magnetic field, or the magnetic field itself is cycled.[134] With two-dimensional zero-field NMR spectroscopy,[74,84] one hopes to be able to determine internuclear distances in powders and amorphous materials by means of the dipole-dipole coupling, similar to 2D-NOE-NMR spectroscopy in the liquid phase,[21,135] which forms the basis for the determination of the structure of proteins in solution.

4. Molecular Motion: 2D-Exchange Spectroscopy

With 2D-exchange spectroscopy, changes in the resonance frequency can be detected with high accuracy if they occur during a mixing period which is longer than the evolution period and shorter than the longitudinal relaxation time T_1. Consequently, this method is especially suitable for the detection of very slow dynamic processes in the range of 10^{-3} to ca. 100 s.

For anisotropic coupling with axial symmetry, e.g. ^{2}H quadrupole coupling (Fig. 1), one obtains in powder spectra exchange signal patterns with extremely simple geometry which supply immediate information about the type and rate of the dynamic process. 2D-^{2}H-exchange spectroscopy therefore makes possible the model-free determination of the angle at which a selectively deuterated group rotates during the mixing period τ_m.[25] This is presently not possible with any other method. Therefore, a more detailed account of this method will be presented here.

The study of molecular reorientation processes by the ^{2}H-alignment procedure has already established itself as one initial step toward 2D solid-state spectroscopy.[13,14] In this experiment the echo stimulated by three radio-frequency pulses analogous to the time scheme of 2D-NMR spectroscopy (Fig. 6) is observed. The echo senses a quadrupolar state of order of the ^{2}H nuclear spin which is termed "alignment".[16] In the case of molecular reorienta-

tion during the mixing period τ_m, the observed spins precess during t_2 with a different frequency than during t_1 after the first pulse. As a consequence of this, the echo amplitude is reduced.

Nevertheless, one cannot immediately deduce the motion from the resulting spectra obtained through Fourier transformation of the echo decay. Information is lacking about which molecular orientations during t_1 have been transformed into which orientations during t_2. Equation (1) denotes the various molecular orientations θ in the frequency dimension of the NMR spectrum. In order to study the molecular reorientation from an angle θ_1 at a time t_1 to an angle θ_2 at a time t_2, the NMR spectrum measured at t_1 must be correlated to the NMR spectrum measured at t_2. This is exactly the information which is delivered by the corresponding 2D-NMR spectrum,[28] which therefore represents a two-time distribution function.[28]

4.1. Experimental Aspects

2D-^{2}H exchange spectroscopy, which is especially informative regarding the measurement of very slow molecular motions, will be used to illustrate how 2D-NMR experiments are performed.[27] In the corresponding excitation sequence (see Fig. 6), the various time periods are separated by radio-frequency pulses. The magnetization decays between the pulses in free precession (Fig. 12). The initial

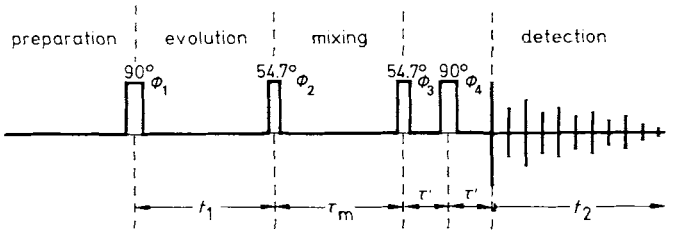

Fig. 12. Pulse sequence for 2D-^{2}H-exchange-NMR spectroscopy. The pulse lengths are selected such that the same heights result for the stimulated and the alignment echo in the absence of longitudinal relaxation processes, despite different spin states during the mixing time τ_m [27]. τ' = refocusing time.

pulse produces transverse magnetization. During the subsequent evolution period t_1, each magnetization component builds up a particular phase which is determined by its precession frequency. The second pulse induces longitudinal magnetization and spin alignment, the amplitudes of which correspond to the real part (cosine) or the imaginary part (sine) of the preceding transverse magnetization. The remaining transverse magnetization decays to zero during the mixing period, and the quadrupole coupling of the nuclear spin can alter by molecular reorientation. After the third pulse, the generally much more slowly relaxing longitudinal magnetization and the spin alignment are again transformed into measurable transverse magnetization. With regard to molecular reorientation during the mixing period, the precession frequencies of the affected magnetization components have changed, allowing the various frequencies in the evolution and detection periods to be correlated with each other.

In order to circumvent the dead time of the receiver, data is first collected after refocussing by a fourth pulse.[136] In order to obtain 2D-NMR spectra in absorption the sine and the cosine components of the transverse magnetization, which precesses during the evolution period, have to be measured.[137, 138] This is achieved in two separate experiments. The alignment echo of a nucleus with spin $I=1$ is formed from the sine component, whereas the stimulated echo is formed from the cosine component. On the assumption that the carrier frequency lies exactly in the middle of the ^{2}H-NMR spectrum and disregarding relaxation, one measures the following signals [(3a) and (3b)]:

$$\text{stimulated echo: } \langle \mathrm{cis}(\Omega_1 t_1) \cdot \cos(\Omega_2 t_2) \rangle \tag{3a}$$

$$\text{alignment echo: } \langle \sin(\Omega_1 t_1) \cdot \sin(\Omega_2 t_2) \rangle \tag{3b}$$

The symbols Ω_1 and Ω_2 denote the resonance frequencies of a nucleus in the evolution and in the detection phases, respectively, and the symbol $\langle \cdots \rangle$ denotes the summation over all magnetization components. With regard to the orientation dependence of the resonance frequencies [Eq. (1)], Equations (3a) and (3b) define two correlation functions of the different molecular orientations θ_1 and θ_2, whereby, however, only even powers of the angles are correlated with each other.

Both functions are measured with the pulse sequence shown in Figure 12 but with different phases. The respective minimal phase cycles necessary to eliminate artifacts are listed in Table 4. The complete phase cycle results whenever the phases ϕ_1 and ϕ_3 in Table 4 are varied independently of each other. The total measurement time typically amounts to one day.

Table 4. Phase cycles for the cosine and the sine correlation function. For the definition of ϕ_1–ϕ_4 see Figure 18.

Cosine: Stimulated echo					*Sine: Alignment echo*				
ϕ_1	ϕ_2	ϕ_3	ϕ_4	Receiver	ϕ_1	ϕ_2	ϕ_3	ϕ_4	Receiver
+Y	+Y	+Y	+X	+X	+Y	+X	+X	+X	+X
+Y	+Y	+Y	−X	+X	+Y	+X	+X	−X	+X
+Y	−Y	+Y	+X	−X	+Y	−X	+X	+X	−X
+Y	−Y	+Y	−X	−X	+Y	−X	+X	−X	−X

The matrices of the time data and the resulting 2D-NMR spectrum should be symmetrical to the main diagonal, because of the equivalence of the evolution period and the detection period. Pulse width effects, however, generally lead to asymmetrical measured data. Consequently, the two-dimensional time function must be interpolated to symmetrical time values before the 2D-Fourier transformation. Since the required interpolation routines are currently lacking in commercial spectrometer software, the data is processed on an external computer.[27]

In ^{13}C-exchange spectroscopy, experiment and data processing are conducted accordingly. As opposed to the ^{2}H nucleus with $I=1$, ^{13}C has a spin $I=1/2$, so that only one spectroscopic transition is observed. Therefore, no alignment state exists, and the sine and cosine correlation

functions are both measured with the stimulated echo [Eqs. (3c) and (3d)].

$$\langle \cos(\Omega_1 t_1) \cdot \exp\{i\Omega_2 t_2\} \rangle \tag{3c}$$

$$\langle \sin(\Omega_1 t_1) \cdot \exp\{i\Omega_2 t_2\} \rangle \tag{3d}$$

Pulse sequence and phase cycle correspond to Figure 12 and Table 4; however, the 54.7° pulses are replaced by 90° pulses, and the fourth pulse is a 180° pulse. In order to increase the ^{13}C nuclear polarization, the initial pulse is replaced by a cross-polarization sequence.

4.2. Theory

Instead of isolated cross peaks as seen in the 2D-exchange spectra of liquids and crystals, the exchange signals in the 2D-NMR spectra of powders are broad spectra which can stretch over the entire frequency range of the powder spectrum. However, they contain singularities. For a molecular jump reorientation of a particular angle θ_s which, for example, can be fixed by the molecular geometry, these singularities yield defined geometrical patterns. The patterns for aliphatic deuterons with an asymmetry parameter $\eta \approx 0$ appear as straight lines parallel to the frequency axes (thick lines in Fig. 13) and as one ellipse for

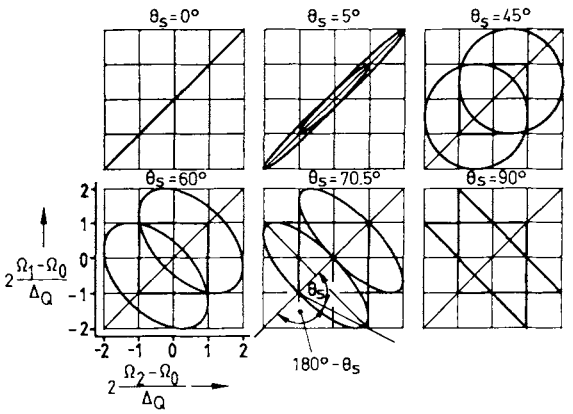

Fig. 13. Exchange singularities for ^2H powder spectra with an axially symmetrical, quadrupole coupling tensor at various molecular reorientational angles θ_s. For the case $\theta_s = 70.5°$, the jump angle is marked for illustration.

each spectroscopic transition.[25] For extrapolation of the lines: $-1 \leq 2(\Omega_{1,2} - \Omega_0)/\Delta \leq 3\sin^2\theta_s - 1$. The ellipses are characterized for all initial orientations θ of the magnetization components by the Equations (4). These are parameter representations of two spheres which are centered at the coordinates $\Omega_{1,2} - \Omega_0 = \pm\frac{1}{2}\Delta$. The molecular reorientation angle θ_s appears as the phase difference $2\theta_s$ in the coordinates of the singularities, the patterns of which in this way resemble Lissajous figures.

$$\Omega_1 - \Omega_0 = \pm\tfrac{1}{2}\Delta(3\cos^2\theta - 1) = \pm\tfrac{1}{4}\Delta(1 + 3\cos 2\theta) \tag{4a}$$

$$\Omega_2 - \Omega_0 = \pm\tfrac{1}{2}\Delta(3\cos^2(\theta \pm \theta_s) - 1) = \pm\tfrac{1}{4}\Delta(1 + 3\cos 2(\theta \pm \theta_s)) \tag{4b}$$

The ratio of the half-axes b and a of an ellipse yields the reorientation angle θ_s according to Equation (5). Since the magnitude of the tangent function appears in Equation (5), the jump angles θ_s and $180° - \theta_s$ lead to identical ellipses.

$$b/a = |\tan(\theta_s)|. \tag{5}$$

Whenever more than one jump angle is involved in a motional mechanism, the corresponding number of ellipses is observed in the ^2H-exchange spectrum. The exchange spectra of diffuse motions can be understood as superimpositions of the spectra for an infinite number of jump angles.[28] Consequently, no more sharp contours appear in the 2D-exchange spectrum. For an isotropic rotational diffusion, Figure 14 shows calculated exchange spectra for different ratios of mixing time τ_m and correlation time τ_c. For each spectrum the angular distribution of a particular molecular orientation is also depicted according to the solution obtained from the isotropic rotational diffusion equation. If the mixing time is $\tau_m = 0$, no reorientation can occur. The angular distribution is sharp, and the exchange spectrum incorporates the conventional 1D-^2H NMR spectrum along the diagonal. The angular distribution as well as the signal along the diagonal of the exchange spectrum "flow apart" with increasing mixing time. In the final state ($\tau_m/\tau_c = 10$), an isotropic angular distribution is obtained, and the 2D-NMR spectrum extends over the entire frequency range. The only singularities now ob-

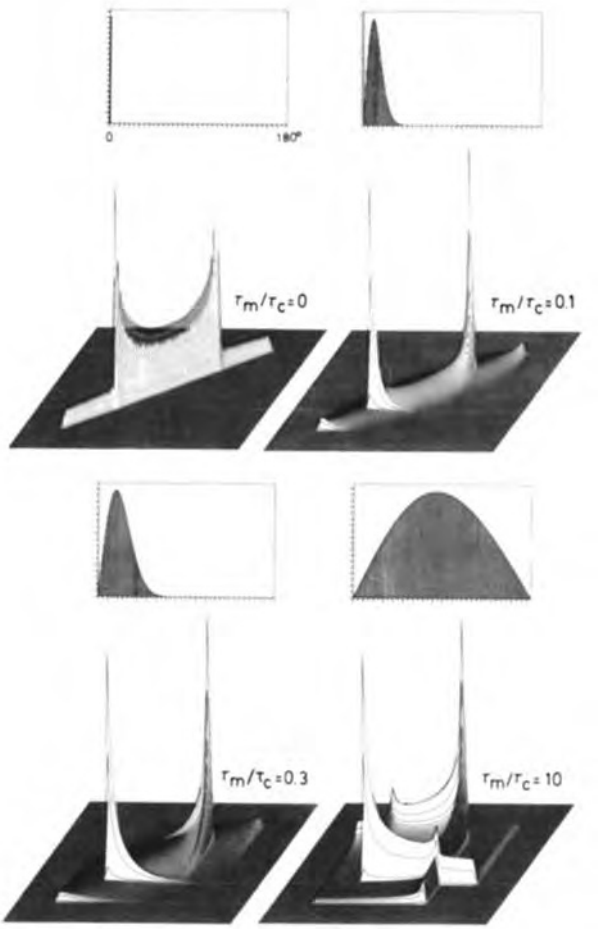

Fig. 14. Calculated ^2H-exchange spectra for isotropic rotational diffusion with correlation time τ_c and different mixing times τ_m in the 2D-NMR experiment. The form of the 2D-NMR spectrum directly reflects the evolution of the angular distribution of a given molecular orientation (plotted above the spectra).

served are sharp ridges parallel to the frequency axes. They stem from the 1D singularities of the diagonal spectrum and exhibit the form of a 1D powder spectrum for a single transition. These singularities also occur during jump reorientation, and can serve as an indication of molecular motion whenever the quality of the measured data is poor. Apparent cross peaks at the cross-over points of these exchange singularities are observed as a result of a superposition of the signals.

4.3. Applications

Figure 15 shows the 2D-^{2}H-exchange spectrum of dimethyl sulfone at 310 K[25] as an example of molecular reorientation through discrete jumps. The mixing time was 3 ms and therefore was longer than the correlation time $\tau_c \approx 1$ ms of the motion. The evolution and detection periods were each scanned in 256 steps at intervals of 1 μs. The refocussing time τ' amounted to 25 μs. At the measurement temperature, the methyl groups rotate so rapidly about their respective C_3 axes that in the case of the methyl deuterons an axially symmetric quadrupole coupling tensor results with its principal axis lying along the S–C bond axis. From the geometry of the elliptical exchange singularities, one can directly read off the jump angle as 106°. The negative signals on the subdiagonal can be explained by different relaxation of longitudinal magnetization and alignment states during the mixing time.

Whereas the jump angle can be directly ascertained from the geometry of the ellipse with a goniometer (see Fig. 13), a numerical analysis of the signal form is necessary for motional processes involving diffusion. As an example, Figure 16 exhibits the experimental and the calcu-

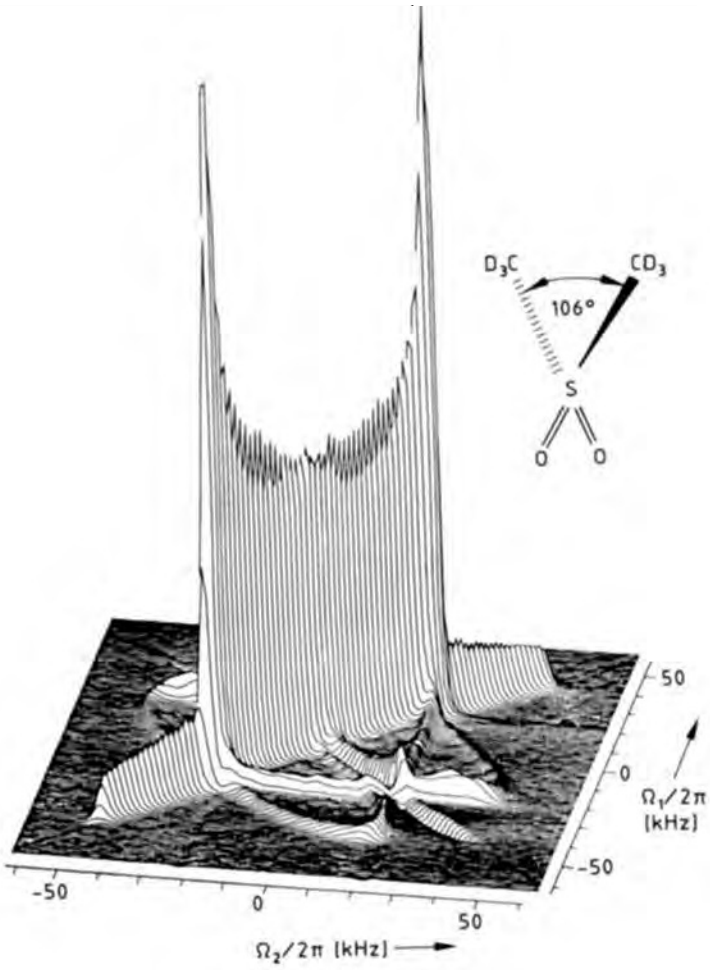

Fig. 15. ^{2}H-exchange spectrum of dimethyl sulfone.

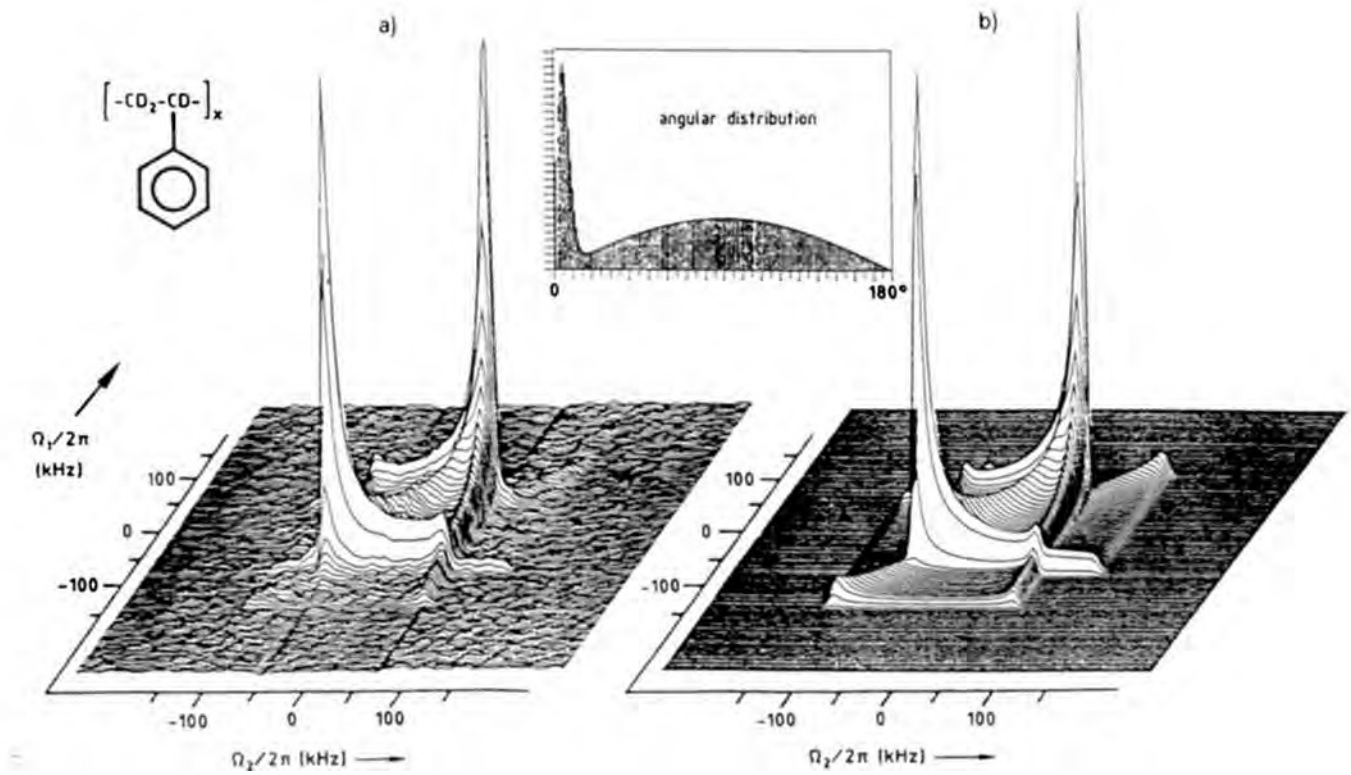

Fig. 16. ^{2}H-exchange spectra of chain-deuterated polystyrene. The analysis (b) of the experimental data (a) points towards a faster and a slower diffusive motion of the chain.

lated spectrum of the chain motion of polystyrene.[28] The experimental spectrum (Fig. 16a) was measured at about 25 °C above the glass transition temperature with a mixing time of 12 ms. The broadened signal nearby the diagonal indicates diffusive chain motion (cf. Fig. 15). The spectrum could be simulated by assuming both a rapid and a slow rotational diffusion process (Fig. 16b).

Both examples demonstrate that reorientational jumps at well-defined angles can be clearly differentiated from rotational diffusion in 2D-^{2}H exchange spectra. From the exchange spectra of aliphatic deuterons, the jump angle can be determined directly without model assumptions from the excentricity of the elliptical exchange singularities [Eq. (5)].

For an asymmetric coupling tensor such as the anisotropic magnetic shielding in ^{13}C-NMR spectroscopy, the geometrical form of the exchange singularities is affected by the asymmetry parameter η.[76,85] ^{13}C-exchange spectroscopy was recently used in an experiment to detect the previously suggested collective motion of phenyl and carbonate groups in bisphenol-A polycarbonate.[90,140] No exchange could be detected at room temperature in a sample enriched with up to 99% ^{13}C at the carbonate group even with a mixing time of $\tau_m = 10$ ms. Noticeable changes of the signal form first resulted at a mixing time of $\tau_m = 2$ s. The experimental spectrum in Figure 17 shows a line broadening which infers a diffusive process.[90] The comparably long mixing time and the temperature independence of the exchange process can be explained by spin diffusion. In fact, the 2D spectrum can be simulated by merely considering spin diffusion (Fig. 17b).[90,141] A significant reorientation of the polymer chain cannot therefore occur, even within a mixing period of 2 s.

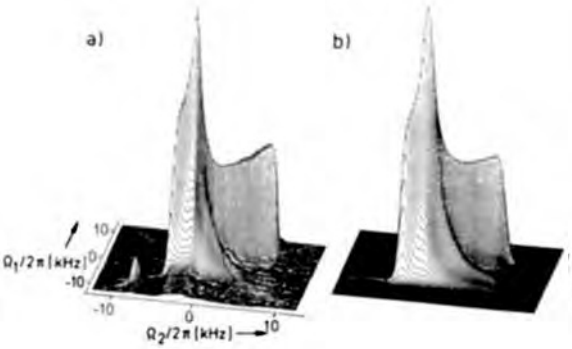

Fig. 17. a) 2D-^{13}C-exchange spectrum of bisphenol-A polycarbonate. $\tau_m = 2$ s, $T = 298$ K. b) The calculated spectrum for spin diffusion and a correlation time of $\tau_c = \tau_m$.

5. Molecular Order: MAS-NMR Spectroscopy with Rotor Synchronization

There are various methods for determining the degree of molecular order. Birefringence or IR dichroism measurements only yield the second moment of the orientational distribution function without differentiation of molecular structural elements. The complete orientational distribution can be obtained, however, from X-ray and neutron-scattering data as well from solid-state NMR spectroscopy.[142,143] Moreover, the selectivity of NMR spectroscopy makes it possible to ascertain the orientational distribution of several functional groups of the monomer unit. Consequently, for partially ordered polymers the chain alignment as well as the respective conformation can be studied in the ordered state. MAS-^{13}C-NMR spectroscopy is especially useful here, because it is applicable for practically all synthetic polymers and biopolymers. The 2D-NMR method described below for determining molecular order is therefore well suited for routine applications.[30,31]

A macroscopically oriented sample is packed in a rotor in such a way that its preferential ordering axis is not parallel to the rotor axis. Liquid crystalline polymers can often be magnetically oriented in the rotor and then cooled down below the glass transition temperature for the measurement. Fibers are glued parallel together into layers which are stacked in the rotor. In order to balance the rotor, remaining empty spaces are filled with a mixture of KBr and talcum which has approximately the same density as the sample.

Because of the dependence of the resonance frequency on orientation [Eq. (1)], the MAS-^{13}C-NMR spectrum of an oriented sample depends on the rotor position at the beginning of the measurement.[41] The degree of orientation of the sample is probed by conducting several measurements for different rotor phases.[30,31] Figure 18 shows the

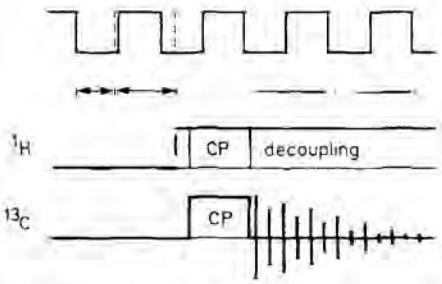

Fig. 18. Timing diagram of rotor-synchronized 2D MAS-NMR spectroscopy for the investigation of molecular order.

course of the measurement with time.[30] The rotor position is determined from the signal which is produced in commercial spectrometers to count the rotor frequency. By means of the pulse program software, the negative slope of the rotor signal is probed to trigger the beginning of the measurement. A fixed time delay t_0, which sets the phase in the Ω_1-direction, is followed by the evolution period t_1, which is varied from experiment to experiment in 16 equidistant steps within one rotor period. Cross polarization and detection of the ^{13}C-NMR signal subsequently occur after the evolution period.

The sidebands in the Ω_1 direction are denoted by $\pm$M, those in the Ω_2 dimension by $\pm$N. The intensities I of the sidebands obey a simple symmetry relationship (6) described below which can be employed to control the measurement results.[31]

$$I_{M,N} = I_{-M,N-M} \qquad (6)$$

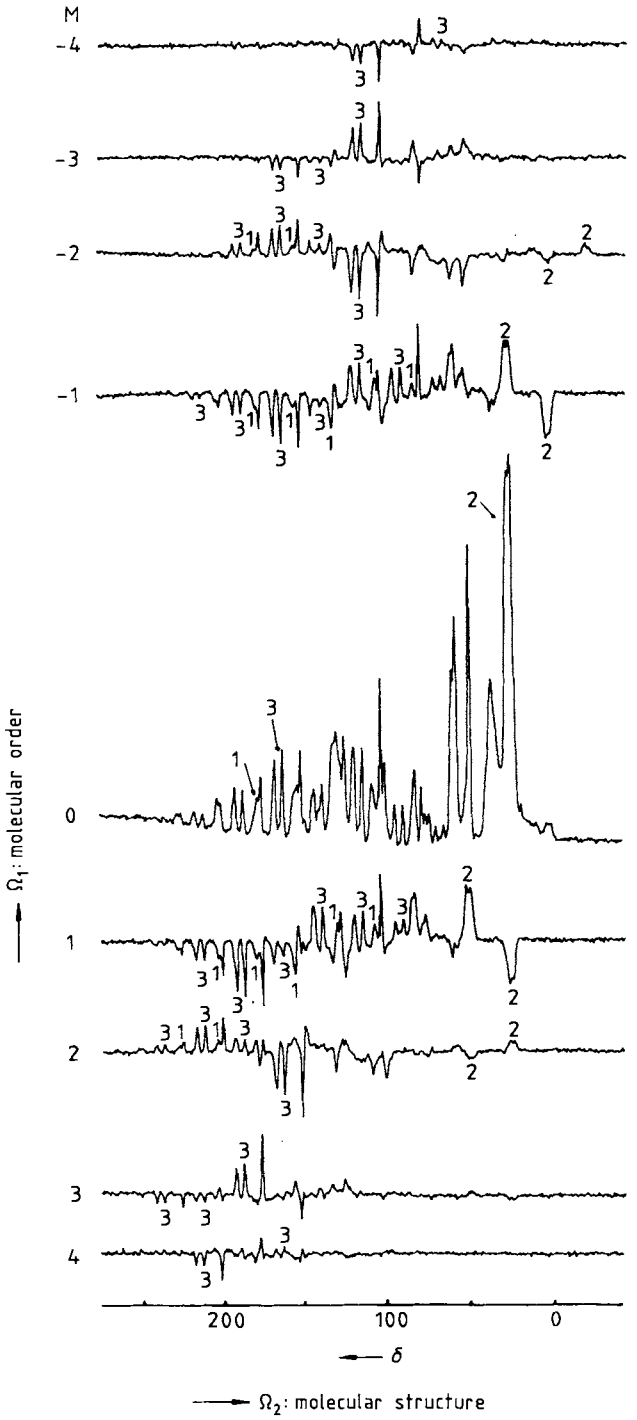

Fig. 19. 2D MAS-^{13}C-NMR spectrum of a liquid-crystalline polyacrylate (molecular structure in Fig. 20). The signals of the carbon atom of the acrylic group (**1**), the spacer (**2**) and the mesogenic group **3** are marked. Only the isotropic chemical shifts are identified in the spectrum with M = 0.

Figure 19[32] shows the significant lines of the 2D MAS-^{13}C-NMR spectrum of a liquid crystalline polyacrylate in the frozen smectic phase. **1** denotes the signals of the acrylic carbon close to the chain, **2** the signals of the spacer, and **3** the signals of the mesogenic groups (see Fig. 20 regarding the molecular structure).[32] The spectrum in the row labeled by M = 0 is the center band spectrum which is also observed when the sample is macroscopically disordered. But the rows labeled by $M \neq 0$ contain signals only if the sample is macroscopically ordered. The higher the degree of order, the higher is the value of M for which significant signals in the corresponding sideband spectrum are still observed. The orientational distributions for all magnetically distinguishable structural elements can be gained from the sideband intensities. In general the following applies: in the calculation of the sideband spectrum of the order $\pm M$, at least the Mth moment of the orientational distribution function[142-147] is required,[31] whereby, however, odd moments, are inaccessible. Thus, according to Figure 14, at least the fourth moment is still significant in the orientational distribution function of the mesogenic group **3** (see the following section).

5.2. Determination of the Orientational Distribution from 2D MAS-NMR Spectra

The analysis of MAS sideband spectra requires appropriate numerical resources.[40] This holds true especially for 2D-MAS sideband spectra. The basics of the method developed for the analysis[31] will therefore be outlined in the following.

For simplification, only uniaxially ordered samples which can be characterized by a one-dimensional orientational distribution are considered. The orientational distribution function is expanded into a series of Legendre polynomials $P_l(\cos\beta)$ [Eq. (7)],[143,144] where the P_{l00} are the moments of the orientational distribution function and β is the angle between the molecular axis and the direction of order of the sample. The P_{l00} are defined by the averages $\langle P_l \rangle$ of the Legendre polynomials [Eq. (8)]. The average over P_2 is *Saupe*'s order parameter S,[145] [Eq. (9)]. In Eq. (9), $\langle \cdots \rangle$ signifies the average over the orientational distribution function.

$$P(\beta) = \sum_{l=0}^{\infty} P_{l00} P_l(\cos\beta), \tag{7}$$

$$\langle P_l \rangle = \langle P_l(\cos\beta) \rangle = \frac{8\pi^2}{2l+1} P_{l00} \tag{8}$$

$$\langle P_2 \rangle = S = \tfrac{1}{2}\langle 3\cos^2\beta - 1 \rangle, \tag{9}$$

Corresponding to the series expansion of the orientational distribution function, the 2D MAS-NMR spectrum $S(\Omega_1,\Omega_2)$ is expanded into a series of 2D subspectra $S_l(\Omega_1,\Omega_2)$, from which the moments of the distribution function P_{l00} [Eq. (8)] are directly obtained via Equation (10),

$$S(\Omega_1,\Omega_2) = \sum_{l=0}^{\infty} \langle P_l \rangle S_l(\Omega_1,\Omega_2). \tag{10}$$

The subspectra $S_l(\Omega_1,\Omega_2)$ must be calculated once for each respective ^{13}C position. The subsequent data fitting for determination of $\langle P_l \rangle$ is no longer numerically complicated.[31] The method can be extended in a straightforward fashion for studying macroscopically or microscopically biaxial samples.[31,141]

5.3. Applications

The 2D MAS-^{13}C-NMR experiment was first tested on highly oriented polyethylene[30] and has since been applied to various other oriented polymers. For example, the degree of order S as the function of the draw ratio was measured on drawn polycarbonate. The result correlates well with X-ray data,[147] showing, that this NMR method is suitable for ascertaining small degrees of order ($\langle P_2 \rangle < 0.2$). Furthermore, microscopic biaxiality could be determined for commercial polyethylene terephthalate fibers.[31]

Application of the technique to liquid-crystalline polymers frozen in the mesophase is particularly interesting, because orientational distributions of various widths can be observed for different structural elements. Figure 20 shows the result of an evaluation of the sideband spectra of the liquid-crystalline side-chain polymer displayed in Figure 19.[32] The respective, orientational distribution functions for the carbon atoms **1** (acryl group), **2** (spacer) and **3** (mesogenic group) were calculated by means of the subspectral analysis. The C atoms of the polymer chain do not show any preferential orientation. The acrylic carboxyl group, however, shows a noticeable orientation of the side chain. The orientation increases at the spacer, but no order gradient for its different CH_2 groups was observed. The highest order was found for the mesogenic group. Consideration of the 8th moment of the orientational distribution function for the mesogenic group carbon was necessary in the analysis of the measured sideband spectra in Figure 19.

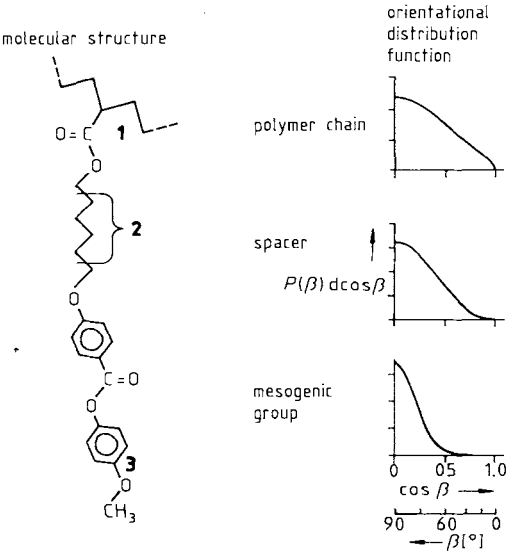

Fig. 20. Orientational distribution functions of different structural elements of polyacrylate. For the definition of $P(\beta)$ see Equation (7).

This example shows, that even complicated spectra can be handled with the 2D MAS-^{13}C-NMR method. Such spectra can also be simplified with the pulse sequences depicted in Figure 5, with which the signals of the protonated or the unprotonated ^{13}C nuclei can be suppressed. Other than in the case of ^{2}H-NMR spectroscopy, isotope labeling is not necessary. The measurement itself only takes 16 times longer than the measurement of a conventional solid-state ^{13}C-NMR spectrum, because generally only 16 rows are necessary in the additional dimension due to the limited number of possible sidebands. These properties therefore make this method especially interesting for applications with commercial products.

6. Summary and Outlook

Solid-state NMR spectroscopy differs considerably from the high-resolution NMR spectroscopy of liquids. The difference results from the numerous orientation-dependent spin interactions which affect the NMR spectrum of solids. The intensity of the interactions and the resulting width of the spectra necessitate more powerful equipment and more complicated experimental procedures. Consequently, only the simple, one-dimensional MAS technique is currently employed on a routine basis.

For studying solid polymers ^{2}H-NMR spectroscopy[13, 14] and MAS-^{13}C-NMR spectroscopy[6-12] are especially relevant. ^{2}H-NMR spectroscopy has proven useful through the quantitative evaluation of results with respect to models of molecular motion, time scales of dynamic processes and orientational distribution functions. Unlike ^{2}H-NMR spectroscopy MAS-^{13}C-NMR spectroscopy does not require isotope labeling. Because of the broad range of chemical shifts, various structural elements can be assessed with only one measurement. The anisotropic magnetic shielding (chemical shift) as well as the dipole-dipole coupling to the protons can be used as a source of information about molecular order and molecular dynamics. The sensitivity of ^{13}C-NMR spectroscopy is considerably increased by the MAS method, since the spectral intensity is focussed in narrow rotational sidebands and is no longer distributed over a wide powder spectrum.

With 2D-NMR spectroscopy one obtains information about chemical structure, molecular motion and molecular order in solids. The study of the chemical structure of polymers is especially interesting whenever the respective materials are insoluble, for the molecular structures of dissolved substances can be determined quite easily. The questions about molecular order and type and rate of molecular motion are particularly relevant. 2D solid-state NMR spectroscopy is more effective in obtaining answers to these questions than the experimentally more simple 1D-NMR methods. Whereas there are currently many 2D-NMR methods available for studying dynamical processes, there is only one such technique[30-33] for examining molecular order, and that is based on the rotor synchronized acquisition of MAS-^{13}C-NMR spectra.

The presently known 2D-NMR methods correlate molecular structure and dynamics or structure and order. Multi-dimensional techniques which correlate the molecular order with molecular motion are still lacking. The TOSS experiment combined with a mixing period, however, is a start in this direction.[48]

For practical purposes 2D-NMR methods are particularly interesting which allow: 1) simple sample preparation, 2) uncomplicated experimentation, and 3) the quantification of measurements. Consequently, ^{13}C-NMR spectroscopy takes the lead with regard to applications to or-

ganic solids. The number of high frequency pulses can be used as a criterium for the straightforwardness of an experiment. In this respect, the exchange experiment and the 2D-MAS experiment with rotor synchronization are simple experiments. Quantitative, largely model-independent data can likewise be obtained from the corresponding 2D-NMR spectra. Although the spin-diffusion experiment for examining the compatibility of macromolecules in polymer mixtures provides highly interesting information for the polymer chemist, it demands multi-pulse excitation as well as sample rotation at the magic angle.[118] Currently, only a few laboratories have access to these techniques.

The previously cited 2D-NMR methods make it possible to correlate various molecular parameters with one another. On the other hand, 2D-NMR spectroscopy also allows one to correlate the NMR spectrum directly with macroscopic properties of the sample. In this respect, totally new possibilities are emerging to probe the fundamental questions about the relationship between molecular structure and material properties of polymers. For example, if the sample is stressed during the mixing period by a jump in temperature,[149] voltage, pressure, mechanical rotation or electrical fields, its relaxation into the new state of molecular equilibrium can be traced with NMR on a molecular scale. This has recently been demonstrated in an experiment focussing on the rotational viscosity of liquid-crystalline polymers.[150]

A number of colleagues in the NMR group at the Max-Planck-Institut für Polymerforschung were considerably involved in the 2D-NMR research work cited in Sections 4 and 5. We would especially like to thank Dr. C. Boeffel, Dr. G. Harbison, Mr. S. Kaufmann, Dr. C. Schmidt and Mr. S. Wefing. We are likewise grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their continuing support of our work.

Uniform Heterogeneous Catalysts: The Role of Solid-State Chemistry in their Development and Design**

By John M. Thomas*

Heterogeneous catalysts are generally assumed to be multiphasic and multicomponent; many of them are, and this is one of the reasons why disentangling the factors that govern their mode of action is so difficult. But there is a large class of heterogeneous catalysts where the solid is monophasic and where the activity may be envisaged as being dispersed in a spatially uniform fashion throughout its bulk. This is true both of zeolites and many other microporous catalysts on the one hand, and of certain mixed metal oxides, where the non-stoichiometry is inextricably mingled with the catalysis, on the other. By recognizing this broad classification numerous operational advantages follow: the performance of existing catalysts and the design of those yet to be prepared can be placed on a rational footing; moreover, the myriad techniques of solid-state chemistry and physics, often regarded as inapplicable to the subtle and special problems of surface chemistry, are seen to be of direct relevance as probes for the structure and properties of proven uniform heterogeneous catalysts as well as for the synthesis and development of new ones. This review, which draws analogies with and lessons from the chemistry of enzyme catalysts, focuses largely on the catalytic conversions of hydrocarbons over zeolites, clays, microporous $AlPO_4$ and a wide range of metal oxides.

1. Setting the Scene: What is a Uniform Heterogeneous Catalyst?

Every chemist knows that there is a large class of heterogeneous catalyst the function of which is to accelerate chemical conversion at *the exterior surface* of the solid. As an undergraduate, the chemist learns that, in the catalytic synthesis of ammonia from H_2 and N_2, for example, or in the Fischer-Tropsch conversion of mixtures of H_2 and CO to hydrocarbons and alcohols, the seat of reaction is the surface of metallic iron and the surface of metallic cobalt respectively. And these surfaces, on the atomic scale, are thought to look like the enlarged view of a precious opal, shown in Figure 1. Many other familiar catalytic reactions fall into this category (Table 1); and it follows that the detailed chemistry of the exterior surfaces holds the key to the deeper understanding of the intricacies of this class of catalyst. It is far less widely appreciated that there is an equally large class of heterogeneous catalysts where all, or nearly all, *atoms in the bulk* of the solid either participate directly or are implicated indirectly in the crucial catalytic act. Prominent examples are the zeolites,[1-6] certain clays[7-12] and pillared clays.[13-17] A large number of oxides,[18-24] including those listed in Table 1, also falls into this category.

In zeolites, and other related microporous solids[25-29] such as those derived from crystalline low density $AlPO_4$ and metal-substituted (in the framework) variants of $AlPO_4$ and $(Si_xAl_yP_z)O_2$, all bulk atoms are, at one and the same time, surface atoms in that they are accessible to gaseous reactants capable of entering the apertures (3 to 8 Å) of their cages and channels. Likewise, in layered aluminosilicate (clay) catalysts, the active sites are situated in ac-

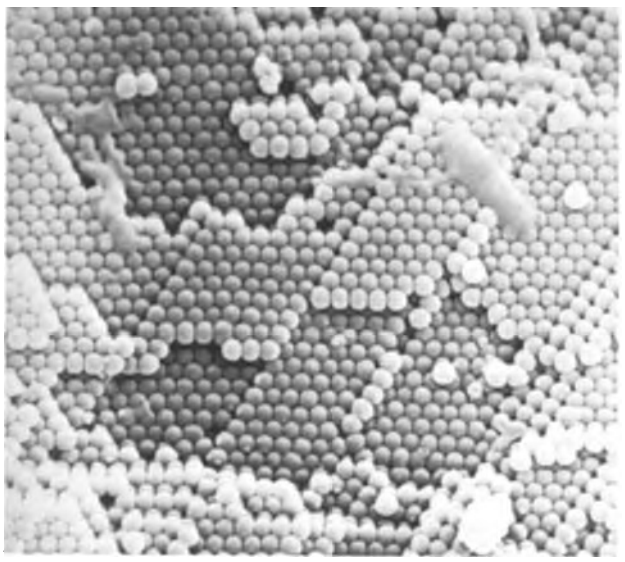

Fig. 1. The surface of a metallic catalyst, when suitably enlarged, is thought to look like this surface of an opal examined by scanning electron microscopy. Picture each spherical particle of silica to be an atom; and note the monatomic steps (terraces), the kinks in the steps and the tendency for some atoms to exist individually, as pairs or as two-dimensional clusters of twelve or more bound to the underlying structure. Antiphase boundaries, vacancies and even impurity (rogue) species are also present. The SiO_2 particles have a diameter of 5000 Å. Micrograph taken by *J. V. Sanders*.

[**] Based, in part, on the Hund-Klemm Lecture given at the Max Planck Institute for Solid State Research, Stuttgart (20 May 1987), and on seminars given at the Institute of Fundamental Chemistry, Kyoto (14 June, 1988), the Fritz Haber Institute of the Max-Planck-Gesellschaft, Berlin (12 March 1987), and the University of California, Berkeley (19 April 1988).

Table 1. Two classes of heterogeneous catalysts.

Composition of Catalyst	Reaction Catalyzed	Whether Already Commercial (C) or Demonstrated on Laboratory Scale (L)
Category 1: Spatially non-uniform distribution of active sites, often of different kinds and consisting of multiple phases		
Cobalt and other transition-metals on a variety of supports (Fischer-Tropsch Reaction)	$CO + H_2 \longrightarrow \begin{cases} C_nH_{2n+2} \\ C_nH_{2n} \\ C_nH_{2n+1}OH \end{cases}$	C
Copper on ZnO/Al_2O_3 (ICI Methanol Synthesis)	$CO + 2H_2 \longrightarrow CH_3OH$	C
Nickel on Al_2O_3 (methanation reaction)	$CO + H_2 \longrightarrow CH_4$	C
Iron with traces of Al, Si, K (Haber Process)	$N_2 + 3H_2 \longrightarrow 2NH_3$	C
Rhodium (and platinum and palladium) on cerium oxide and cordierite (Auto exhaust catalyst)	$CO + NO \longrightarrow CO_2 + N_2$ $C_xH_y + O_2 \longrightarrow CO_2 + H_2O$ $CO + O_2 \longrightarrow CO_2$	C
Palladium on Al_2O_3	$CH_4 \xrightarrow{[O]} CH_3OH$	C
Silver powder	$CH_3OH \xrightarrow{[O]} HCHO$	C
Silver on Al_2O_3 + chloride	$C_2H_4 \xrightarrow{[O]} H_2\overbrace{C-O-C}H_2$	C
Tungsten oxide on silica (Olefin Metathesis)	$R^1R^2C=CH_2 + R^3R^4C=CH_2 \longrightarrow C_2H_4 + R^1R^2C=CR^3R^4$	C
Category 2: Spatially uniform distribution of structurally equivalent active sites in a monophasic solid		
Zeolite ZSM-5 ($H^\oplus$ form) (Ethyl benzene formation) (Mobil-Badger process)	$C_6H_6 + C_2H_4 \longrightarrow C_6H_5C_2H_5$	C
ZSM-23 or theta-1 (Zeolites in $H^\oplus$ form)	Alkylation of Benzene	L
SAPO-5 (or 11) (Silicon aluminum phosphate)	Methanol to olefin conversion	L
ZSM-5 ($H^\oplus$ form)	Methanol to petrol (gasoline) conversion	C
$La^{3\oplus}$ exchanged zeolite Y	Cracking and Hydrocracking of gas oil	C
Zeolite rho (or ZSM-5) ($H^\oplus$ forms)	$NH_3 + CH_3OH \longrightarrow HN(CH_3)_2$	L
Zeolite ZSM-5 ($H^\oplus$ form) Xylene isomerization and toluene disproportionation	Synthesis of *para*-xylene	C
$Al^{3\oplus}$-exchanged montmorillonite and pillared clay	Production of *tert*-butylmethyl ether from MeOH and 2-methylpropene	L
Ti-silicalite	Synthesis of hydroquinone from phenol and H_2O_2	C
Ti-silicalite	Synthesis of propene oxide from propene and H_2O_2	L
Bi_2MoO_6 (or $Bi_2Mo_2O_9$ or $Bi_2Mo_3O_{12}$)	Selective oxidation of propene to acrolein Selective ammoxidation of propene to acrylonitrile	C
$Ba_2Bi_{2-x}La_xO_{6-y}$	Selective oxidation of propene to 1,5 hexene and benzene	L

cessible, interlamellar regions. And in pillared clays the active (acid) sites drape the walls of the pillar, the initial function of which is to enhance the utility of the catalyst by, inter alia, enlarging the separation of the layers and keeping them apart.

Those ternary oxides that are efficient selective oxidation catalysts of hydrocarbons such as propylene—and the bismuth molybdenum oxides as well as the calcium manganates[24] and other perovskites[30] are in this class—entail *sacrificial loss of oxygen*. Experiments[22] using isotopically labelled reactants or solid catalysts reveal beyond doubt that structural oxygen is released from the catalyst, thereby converting it—at least temporarily—to a non-stoichiometric oxide. The gaseous oxygen present as one of the reactants is then taken up by the catalyst, thus making good its anion deficiency. The cycle repeats itself for as long as the catalyst is active. The idea that this was how certain selective oxidation catalysts worked was first clearly enunciated in 1954 by *Mars* and *van Krevelen*.[18]

It is to be noted that, both for the zeolites and pillared clays on the one hand, and the oxide catalysts capable of sacrificial loss of structural oxygen on the other, *the bulk of the solid is of central importance in the catalysis*. Moreover, as we shall show below, in the zeolitic catalysts the special (active) sites situated within the bulk (and at the surface) of the solid are distributed in a spatially uniform fash-

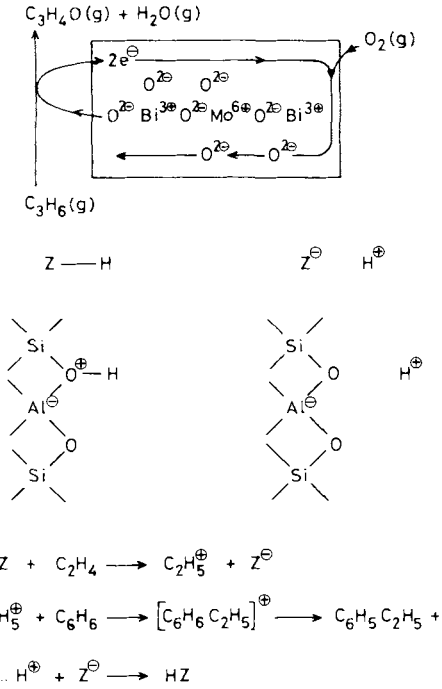

Fig. 2. Top: Certain oxides (e.g. Bi_2MoO_9, $Bi_2Mo_2O_9$, $Bi_2Mo_3O_{12}$) release their structural oxygen to the hydrocarbon that is being selectively oxidized (e.g. propene to acrolein). But they can also assimilate oxygen from the gas phase. They are, effectively, flexible carriers of oxygen. Bottom: Zeolites in their protonic form (see Section 2), represented HZ, likewise may be regarded as carriers of protons. The proton assimilated by ethene in reaction 1 is jettisoned in 2 at the instant preceding catalytic formation of ethyl benzene in a ZSM-5 (or other) zeolite catalyst.

ion.[31] All these active sites are accessible to the reactants. In the sacrificial oxide catalyst, again we see that the bulk atoms are crucial, in that *all* the oxygen ions participate in the turmoil of events—loss, gain and migration (Fig. 2)—involved in the overall catalysis. It follows, therefore, that, since *any* oxygen ion in the solid can, through migration, appear at the surface and be removed by the oxidizable hydrocarbon, these oxide catalysts may also be legitimately termed uniform; there is, again, a spatial uniformity in the arrangement of the species within the solid implicated in the catalysis.

We can now appreciate the essential differences between metal, alloy and other examples of heterogeneous catalysis belonging to category 1 in Table 1 on the one hand, and those that belong to category 2 on the other. Category 1 catalysts have reactions restricted to their exterior surface and there is a substantial body of experimental evidence that only a small fraction of that exterior surface is involved in the catalytic act. Such surfaces are catalytically non-uniform. In category 2 catalysts, however, the chemical conversions entail participation of atoms uniformly distributed within the bulk of the solid.

1.1. Pointers from Enzyme Catalysis and Organometallic Chemistry

It is relevant to cite here the kinship that exists between category 2 catalysts, as defined above, and biological (enzyme) catalysts. Ever since the classic work of *Phillips*[33] in this laboratory on the mode of action of lysozyme, it has been recognized that enzymes generally have active sites which consist of pockets, or clefts, the lining of which contain the key set of amino acids, in the right sequence and conformation, required to 'process' the substrate (i.e. the reactant species). Each molecule of an enzyme is itself a massive entity possessing a well-defined, three-dimensional structure. In a crystal or quasi-crystalline assembly of an enzyme the active sites are arranged in a spatially uniform fashion.[34] It is precisely because this is so that, with the aid of X-ray crystallography, we know so much, and in considerable atomic detail, about the nature of the active center in many enzymes. The very uniformity of the enzyme lends itself to the elucidation of its three-dimensional structure by X-ray diffractometry (and, more recently, by NMR spectroscopy). Nowadays, with site-selective mutagenesis, the constituent amino acids of the lining of the active center can be delicately modified.[35] X-ray techniques then reveal the subtle changes wrought upon the active site and the catalytic consequences—changes in activity and selectivity—can be assessed by standard tests of the performance of the enzyme. The key point here is that, because the catalyst is structurally uniform, the three-dimensional structure deduced from X-ray crystallography immediately clarifies mechanistic and other features associated with the catalytic action (Fig. 3).

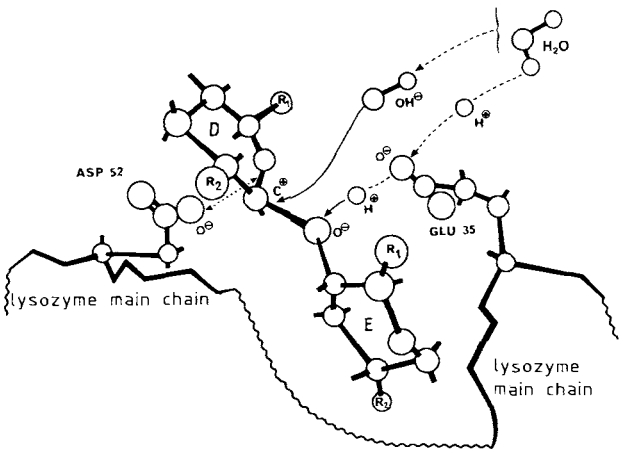

Fig. 3. Outline of the mechanism of the catalysis of a polysaccharide hydrolysis by lysozyme. This was deduced from the classic X-ray study of *Phillips* [33].

As a result of the enormous progress achieved recently in two-dimensional crystallography[37,38] (based mainly on low-energy electron diffraction, LEED) it might be thought that our knowledge of the mode of action of category 1 catalysts is now comparable to that of the mode of action of enzymes. After all, there have been dramatic steps forward taken in arriving at the nature of the structures formed at metal surfaces known to be active catalysts. A brief selection of some of the two-dimensional metal-organic structures that have come to light recently[39] is shown in Figure 4. Almost all of these structures have their analogues in the three-dimensional solid states of organometallic compounds.[39] Despite this remarkable insight into the atomic structure of the two-dimensional entities formed at the exterior surfaces of metal and alloy catalysts,

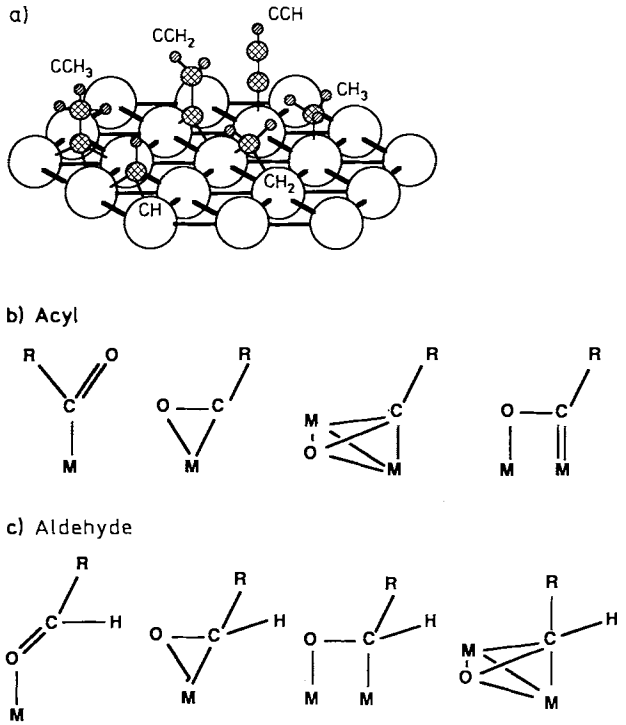

Fig. 4. A selection of some of the structures adapted by small hydrocarbon fragments and other molecules adsorbed at the surfaces of metal catalysts.

comparatively little has been gained so far as enhancing our knowledge of the mode of operation of heterogeneous catalysts in category 1 is concerned. And the reason for this state of affairs is because, as *Somorjai* et al.,[37] *Yates* et al.[40] and others[39] have shown, these surface structures (or the chemisorbed phase) are simply spectator species—they are not crucially involved in the key catalytic act. To know the structure of the predominant surface phase is of little value if that phase plays only a secondary or no role—other than rendering the surface more non-uniform—in catalytic events. So, even though recent progress in surface science has brought us to the stage where we can characterize the structural details of two-dimensional phases and learn that they mirror the bonding patterns that abound in the rich diversity of organometallic compounds, this is not enough to bring us to the ultimate frontier for category 1 catalysts. Only a mere fraction of the surface—and possibly[37] also a small fraction of the sub-surface atoms—is thought to be involved in the catalysis. It is the structure of transitory complexes formed at these sites that is crucial; and present day surface techniques are not yet good enough to determine such structures.[41]

The situation is different for category 2 catalysts, which, from now on, we shall call uniform heterogeneous catalysts. Here, because bulk structure is a quintessential, determinative feature of the catalytic act, a knowledge of that structure permits both an atomic interpretation of the catalysis and, at the same time, points the way to the design of new catalysts. This is precisely what has already been achieved in the realm of enzymatic reactions, as may be gleaned from the recent work of *Fersht, Blow* and others.[35] Analogues of enzymes, built up, for example, from cyclodextrins have been shown by *Bender, Breslow, Lehn* and *Tabushi* and their coworkers to be capable of mimicking the catalytic performance of enzymes. These catalysts are however homogeneous and lie outside the scope of this review.[36]

Although it is a salutary situation that a knowledge of the three-dimensional bulk structure of uniform heterogeneous catalysts holds the key to deeper understanding of their mode of action and for the design of superior ones, it must be emphasized that seldom is it possible to prepare single crystals of the numerous individual solid catalysts that fall into this category suitable for conventional X-ray study. (This situation often plagues the enzyme and protein crystallographer who spends much time in endeavoring to grow good quality crystals.) In the vast majority of cases these uniform, inorganic catalysts are polycrystalline phases which may or may not be catalytically active. Fortunately, several techniques,[4,42] used singly or in combination, have been developed to cope with the determination of the structure of materials in polycrystalline states (Table 2). Some of these techniques have recently been adapted to cope with structure determination under in situ conditions. Since enzymatic reactions take place around room temperature, X-ray and other techniques can be reasonably modified to work under in situ, generally in vitro, conditions. Heterogeneous reactions with uniform catalysts, however, almost invariably take place at elevated temperatures and often under high pressure. Devising suitable in situ techniques for structure determination is, therefore, no mean task. But encouraging progress has been made. Even so, just as with homogeneous gas-phase reactions probing transition states at the femtosecond level is inordinately difficult. About the only prospect currently in sight for the temporal resolution of surface processes utilizes sum-frequency generation.[43]

Table 2. Techniques used singly or in combination for structural elucidation of poylcrystalline catalysts [a].

High resolution electron microscopy
Electron, X-ray and neutron diffraction
Rietveld powder profile analysis
High-resolution, multinuclear, solid-state NMR spectroscopy
Extended X-ray absorption fine structure (EXAFS)
Differential anomalous X-ray diffraction

[a] Some of these, along with other techniques like neutron-inelastic scattering or diffuse reflectance infra-red (Fourier-transform) spectroscopic techniques, may be used under in situ conditions.

2. Uniform Zeolitic Catalysts

By virtue of their structure, crystallinity and variable stoichiometry, zeolitic catalysts have sharply defined pore-size distributions, high and adjustable acidity (see below), very high surface areas (typically 600 $m^2 g^{-1}$), the majority of which (ca. 90%) is, depending upon crystal size, internal and accessible through apertures of well-defined dimensions. They also have good thermal stability (e.g. they can survive heat treatments in air up to 1000°C, the precise temperature being dependent upon the composition of the zeolitic framework).

Catalytic activity in zeolites may be of at least two distinct kinds: the one based on their Brønsted acidity[1-6] (which serves, for example, to generate carbocations in intrazeolitic cavities and channels); the other on transition-metal cations,[6,44-47] which, in the microenvironment of the interior of the zeolite, can facilitate various kinds of redox reactions. We concentrate here on the first of these. (There are other catalytic uses to which zeolites are put. For example, finely-divided platinum group metals may be dispersed in zero-valent state more or less uniformly throughout the interior of the zeolite, thereby making it a bifunctional catalyst, in which 'acid' reactions proceed at one set of uniformly distributed sites and hydrogenation-dehydrogenation as well as bond-shift reactions proceed at the distributed metal particles.[47] We shall not pursue further discussions of these bifunctional catalysts, partly because, upon continued use, there is a tendency for the dispersed metals to aggregate and become non-uniformly distributed).

One of the root causes of the Brønsted acidity of a zeolite which confers upon it its catalytic activity is the mere existence of a heteroatom (Al, Ga, B, Fe etc.) in a silica framework.[3] The situation that exists in the zeolitic catalyst known as ZSM-5 is summarized in Figure 5.[48] The hydrogen atom bonded to the oxygen adjacent to the tetrahedrally incorporated aluminum (or gallium, etc.) has a propensity to free itself as a proton, thereby leaving a macroanionic framework. Evidence from IR spectroscopy substantiates this picture, and corroborative evidence comes from high-resolution solid-state ^{27}Al NMR spectroscopy[3,49] and other probes which monitor the concentration of tetrahedrally-coordinated aluminum. The catalytic activity of a range of ZSM-5 samples containing different quantities of a particular heteroatom in the silica framework of ZSM-5 is shown in Figure 5a left. The first-order rate coefficient for the cracking of *n*-hexane is known to be a good measure of the (Brønsted) catalytic activity of the solid. *Haag* et al.[3] have in particular shown that the catalytic activity per Al atom in the unit-cell remains constant over large concentrations of this, uniformly distributed "active site". The microporosity, viewed (Fig. 5b) in projection along the [010] axis, is clearly apparent.

Another source of detachable protons that make zeolites such good Brønsted acid catalysts is a strongly polarizing cation which can be inserted into certain intrazeolitic cavities. Thus, uniformly distributed (by cation-exchange) ions such as $La^{3\oplus}$ or $Ca^{2\oplus}$ will, because they facilitate hydrolysis, yield more-or-less free protons [Equation (a)]. At low temperatures the liberated proton would be expected to attach itself to a framework oxygen as symbolized in Figure 5c, whereas at elevated temperatures it would be quasi-free.

$$La(OH_2)^{3\oplus} + \text{Zeolite} \longrightarrow La(OH)^{2\oplus} + \text{Zeolite-H}^{\oplus} \qquad \text{(a)}$$

Acid catalysis by zeolites, as well as being used for the cracking and isomerization of hydrocarbons is also the basis of several useful syntheses like the production, on an industrial scale, of ethylbenzene (Figures 2 and 6). Such are the dimensions of the pores of ZSM-5 that shape-selectivity (see Figure 6 bottom) is conferred upon the catalytic

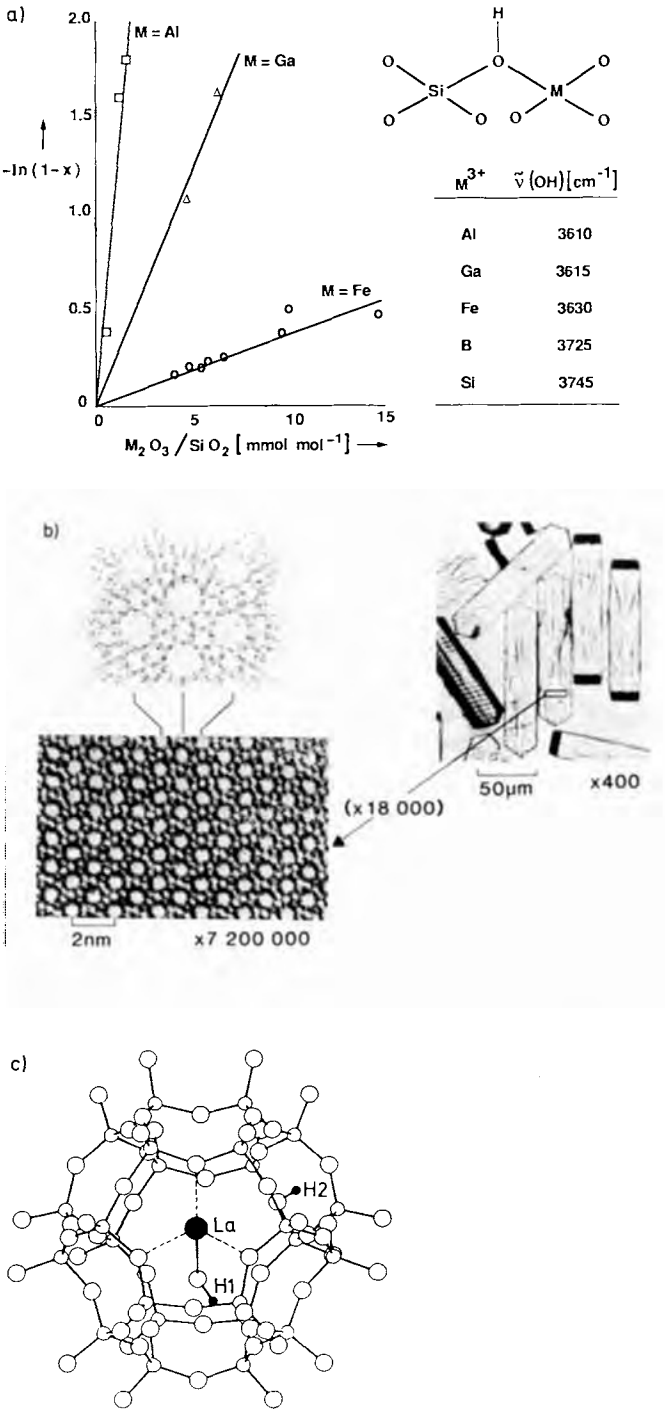

Fig. 5. a) Pentasils, of which ZSM-5 is the archetype, are good catalysts for the thermal cracking of *n*-hexane. There is a correlation between catalytic activity and the acidity of the OH group attached to heteroatom M [48]. b) Structure of ZSM-5 viewed in projection along the straight channels of diameter ca. 5.5 Å. The electron micrograph (bottom left) is taken of the area shown in the optical micrograph (top right). c) The catalytically active site in $La^{3\oplus}$-exchanged zeolite Y consists of a proton (H2) which, although bound to the framework oxygen at 5 K, is mobile at higher temperatures.

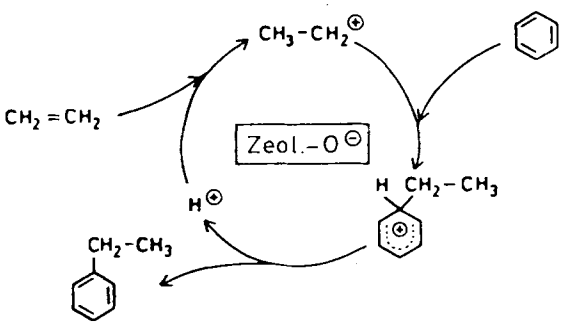
action of this uniform heterogeneous catalyst, thereby leading to the highly efficient generation of mono-ethylbenzene from benzene and ethene. This is the essence of the Mobil-Badger process. It has many advantages in comparison with the traditional Friedel-Crafts process previously preferred for the production of ethylbenzene, espe-

cially in regard to the high selectivity for the mono substituted product.

Redox catalysis on an industrial scale entailing the conversion of phenol to hydroquinone and of propylene to propylene oxide also uses a uniform heterogeneous catalyst of the ZSM-5 type.[50] To be sure, the framework is predominantly SiO_2 but some $Ti^{4\oplus}$ ions are incorporated; and these are thought to be the active sites. The mechanism of the conversion has not been fully clarified, but $>Ti=O$ linkages, embedded uniformly in the framework are implicated.[50]



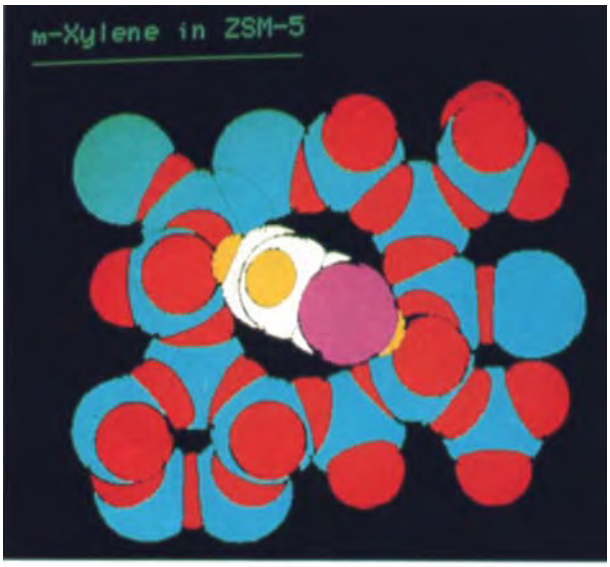


Fig. 6. Top: Mechanism of the proton catalyzed alkylation of arenes. Ethene and benzene yield ethyl benzene over ZSM-5. It is easier for *para*-xylene (bottom), more difficult for *meta*-xylene (middle), to diffuse through a ZSM-5 catalyst.

The kinship between zeolitic and enzymatic catalysts is underlined when one recognizes the importance of shape-selectivity in the chemistry of zeolites. Not only are certain reactants favored—because they possess the requisite dimensions to gain access into the internal area of the zeolite (where the majority of the active sites reside)—but certain products are also preferentially released from within the interior of the catalyst according to their ability to diffuse out. Diffusivities of enzymes and zeolites are directly governed by molecular size and shape. Table 1 shows those reactions where shape-selective catalysis is at work.

The application of various characterizing techniques, including some of those enumerated in Table 2, leads to the conclusion that the active sites—the locus of detachable protons—are uniformly distributed throughout the bulk. One especially powerful method of structural elucidation of polycrystalline zeolitic catalysts is the so-called Rietveld powder profile method.[51,52] This is a refinement procedure, in which a model structure can be tested, and quantitative values of bond lengths and bond angles determined, from profile analysis of the diffractogram (either X-ray or neutron). Using deuterated $La^{3\oplus}$-exchanged zeolite Y catalysts, such as those employed for the cracking of hydrocarbons, the nature of the active site in the catalyst was determined by *Eddy, Cheetham* and *Thomas*.[53] At temperatures below ca. 20 K the location of loosely bound protons attached to framework oxygens could be determined. At higher temperatures (above 300 K), in line with expectation, the proton is mobile and migrates rather freely over the framework; the proton associated with the OH group anchored to the $La^{3\ominus}$ could also be readily located (Fig. 5c).

One expects that, in due course, with the development of in situ structural techniques for the study of zeolitic catalysts, progress comparable to that already achieved by the molecular biologists in elucidating metal catalyzed reactions might be accomplished. Take, for example, the work of *Brown* et al.[54] They examined by single-crystal X-ray studies the manner in which Pb^{II} ions catalytically depolymerize RNA. Using yeast tRNA they showed that site-specific cleavage can be brought about by the action of Pb^{II}. Since single-crystals of yeast tRNA soaked in Pb^{II} acetate (at pH 5.0) and containing the complex formed between the catalyst and the reactant yield good X-ray data, it was possible, by difference Fourier analysis, to deduce the structure of the Pb^{II}-tRNA reaction center (Fig. 7). These workers also observed, again by difference Fourier analysis, sugar-phosphate strand scission between the residues labelled 17 and 18 in crystals of the yeast tRNA soaked in dilute Pb^{II} solutions at pH 7.4 where the catalysis is marked. At pH 5.0 the catalysis is essentially zero. *Brown* et al.,[54] therefore, succeeded in arriving, just as *Phillips* did with lysozyme,[33] at a picture of the reactants and products of the cleavage reaction, and this, in turn, led to their proposed mechanism.

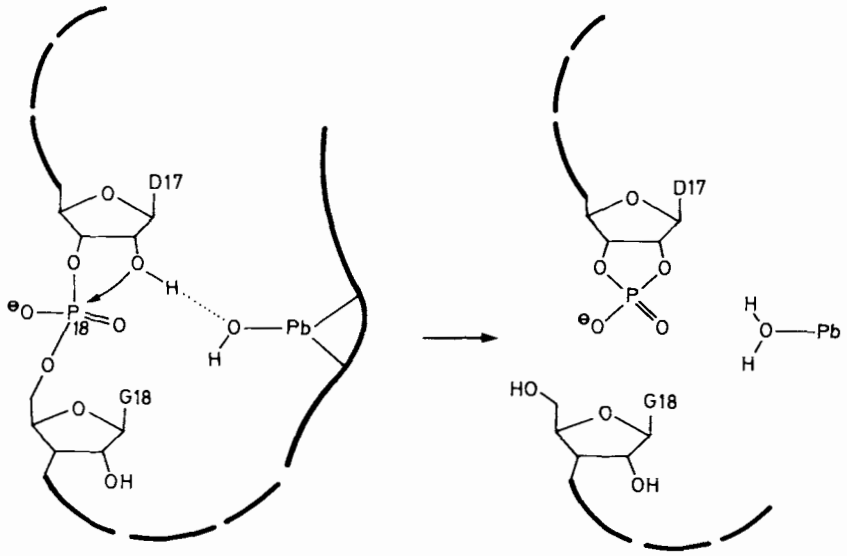

Fig. 7. X-ray diffraction studies yield the mechanistic outlines of the Pb^{II}-catalyzed cleavage of the sugar-phosphate backbone in tRNA.

In the uniform heterogeneous catalysis prominently displayed by zeolites it is unlikely that much success will come from single-crystal X-ray studies since zeolitic catalysts tend to be microcrystalline. But Rietveld powder methods may provide the necessary routes.

2.1. Designing New Zeolitic Catalysts

Very many (some seventy) distinct zeolitic structure-types are known, and numerous recipes are available for the hydrothermal or other more or less demanding syntheses of monophasic, microcrystalline catalysts. Ease of preparation of a zeolitic catalyst, mundane as it may seem as one of the attributes of this class of solid, is as important a factor as any in determining the widespread use of zeolites in industrial catalysis. Faujasite, for example, is a very rare mineral: it occurs in only a few geological locations, and in minute amounts, but its synthetic analogues, zeolites X and Y (Fig. 8) are very easily prepared from solutions of silicates and aluminates. To convert an as-prepared faujasitic zeolite into its acid form capable of exerting its influence as a Brønsted catalyst involves either cation substitution, in which $Ca^{2\oplus}$, $Mg^{2\oplus}$ or $La^{3\oplus}$ ions (capable of causing hydrolysis of bound water) are introduced into the intrazeolitic cavities, or the preparation of the $NH_4^{\oplus}$ exchanged form followed by heating (to drive off the ammonia). Alternatively the synthesis can be effected in the presence of $La^{3\oplus}$ or other polarizing ions. In each case uniform heterogeneous catalysts, in the sense defined earlier, are produced.

The framework composition of some zeolites, especially faujasitic ones, can be changed from the extremes of low-silica to high-silica contents (i.e. from Si/Al ratios of 1.0, which is the lower ratio for zeolite X, through to 1.5 to 3.0 (zeolite Y) and beyond to well above 100). This may be accomplished in several ways. One procedure involves treatment with gaseous $SiCl_4$, another with solutions of $(NH_4)_2SiF_6$. Moreover, after the Si/Al ratio has been greatly increased by such treatment, it is possible[55] to re-aluminate in a rather delicate fashion so as to favor one particular framework environment for the aluminum re-inserted into the framework. This strategem promises a route to fine-tune catalytic performance for a given structural type of zeolite. High resolution solid-state ^{29}Si MAS-NMR spectroscopy[49] is an invaluable tool for monitoring the framework composition, especially the loss and preferential gain of Si (Fig. 9).

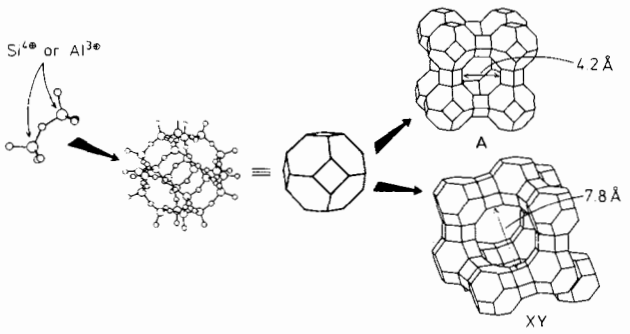

Fig. 8. Schematic illustration of how the structures of zeolites X, Y and A are built up from corner-sharing tetrahedron TO_4 (T = Si and Al).

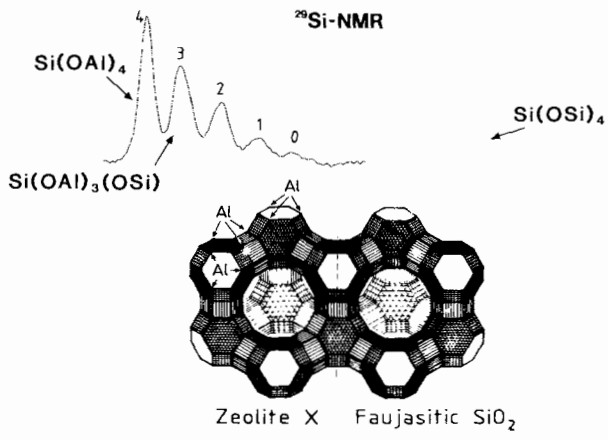

Fig. 9. Crystalline faujasitic silica (right) may be prepared from zeolite X or Y (left) by treatment with $SiCl_4$. The ^{29}Si MAS-NMR spectrum of the product shows one peak corresponding to one type of silicon site in the monophasic silica.

In the numerous zeolitic solids that are known there are several well-defined so-called secondary building units (Fig. 10).[56] Faujasitic zeolites are built up of a combination of β-cages (i.e. truncated octahedra which are synonymous with the tetradecahedron) and double six rings (D6R). The β-cages are arranged as in the diamond lattice.

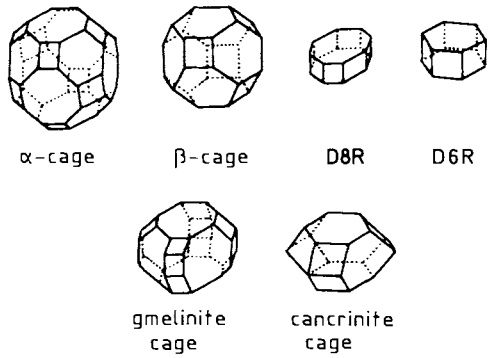

Fig. 10. A selection, presented as polyhedral analogues (compare Fig. 8), of the so-called secondary building units from which many of the more common zeolites are constituted. (D8R and D6R refer to double-eight and double-six rings, respectively.)

But just as lonsdaleite (a rare mineral and polymorph of carbon) is a variant of diamond where ABAB rather than ABCABC stacking exists so also is it possible to conceive of similar polymorphic forms of faujasite in the world of zeolitic catalysts. Indeed, knowing the ease with which irregular as well as regular stacking sequences occur in zeolitic solids,[32,57,58] the distinction between polymorphism and polytopism tends to vanish. In this connection, it is noteworthy that high-resolution electron microscopy (HREM) has brought to light hitherto unsuspected subtleties and patterns in the internal structure of zeolites.[58,59] And, significantly, HREM has led to the discovery of two new zeolitic frameworks closely related to faujasite. Thus two related[60] frameworks tend to intergrow (as many closely related solids do[32]) and the resulting solid is a well-known catalyst and sorbent, zeolite beta.

HREM has recently brought to light another[61] novel zeolitic structure termed ECR-1. It has been shown by a combination of solid-state structure-probing techniques to be a recurrent intergrowth of strips of two naturally occuring minerals, mordenite and mazzite (see Fig. 11). It has recently been realized[62] on the basis of both computed energy and other principles of the stacking of layers that other variants of this solid, labelled DF-1 and shown in Figure 12, are possible. It is not yet clear whether ECR-1, which has been isolated and characterized, and DF-1, which at present is known only as a theoretically possible structure, have any potential as catalysts.

Intergrowths, of a more or less random nature, depending upon the precise conditions of preparation of the catalyst, can occur[57,63] in the so-called pentasil zeolites of which ZSM-5, shown in Figure 5, and a closely-related analogue, ZSM-11 are prominent members (Fig. 13). Such intergrowths lead to quite significant catalytic consequences. We shall illustrate this point by recalling the Mobil synthesis of petrol (gasoline) from methanol using a

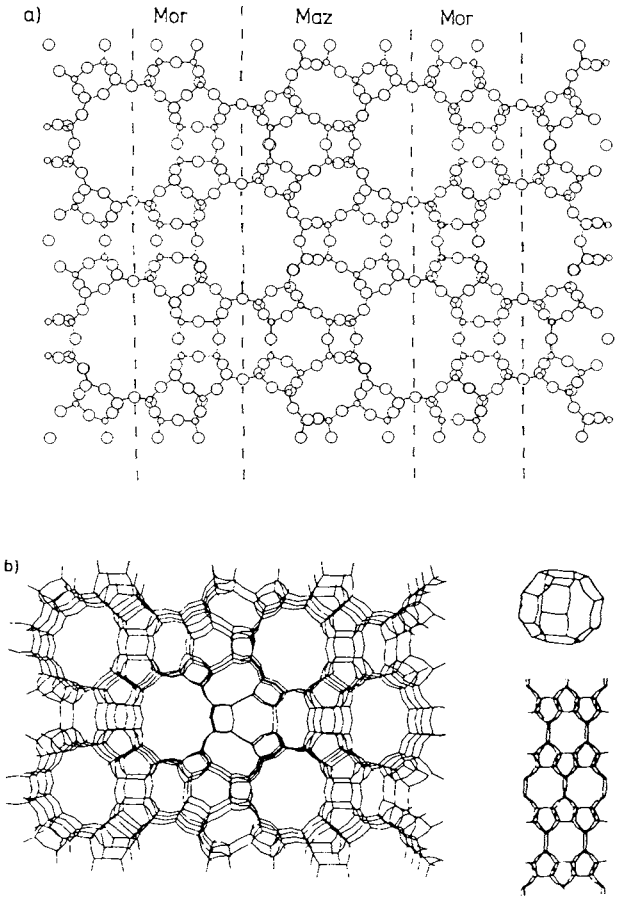

Fig. 11. a) Projection of the ECR-1 zeolite structure along the *a*-axis showing the component sheets of mordenite (Mor) and mazzite (Maz). Large spheres denote oxygen atoms, small ones T-atoms (Si and Al). b) Perspective view of the ECR-1 framework (left). The top right inset shows the gmelinite cage as observed in mazzite, the bottom right inset shows a layer of the mordenite structure.

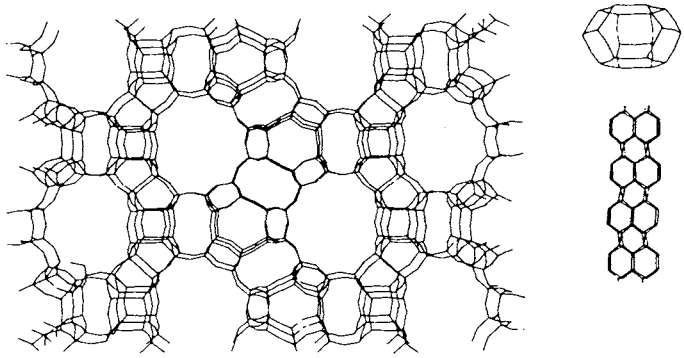

Fig. 12. Left: Perspective view of the framework of the theoretically predicted [62] new zeolite DF-1. The top right inset shows the cancrinite cage and the bottom right inset the layer of four-, five- and six-rings which is found in DF-1.

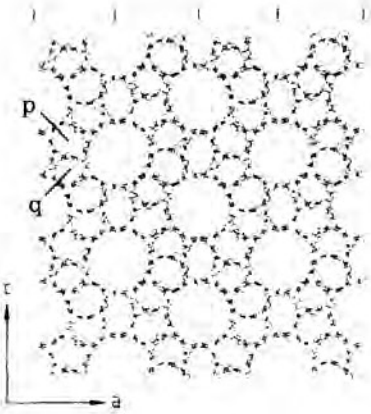
ZSM-5 catalyst. In this synthesis a distribution of aromatic products, typified by that shown in Figure 14, is observed. In practice, however, product distribution curves of this kind are found to vary quite appreciably from one preparation of ZSM-5 to another. Moreover, with ZSM-11, the carbon number for the peak as well as the distribution curve itself shifts to higher values, compared with the re-



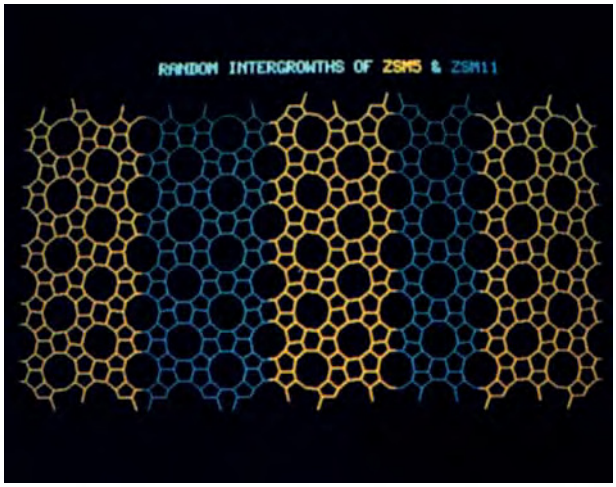


Fig. 13. Top: ZSM-11 is closely related to ZSM-5 (compare with Fig. 5b); bottom: intergrowths, drawn schematically in color here, of the two are known to exist. (The symbol i denotes inversion; p and q refer to the larger and smaller 5-membered rings, respectively.)

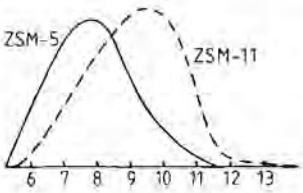

sults for ZSM-5. It is not difficult to appreciate why this is so. There are in ZSM-11 two kinds of cavities created by the intersecting channels. One cavity has a volume about 1.6 times that of the other, the volume and shape of which is exactly the same as the single type of cavity found in ZSM-5. The shape and size of these cavities crucially govern the maximum dimension attainable in the transition-state when the alkylcarbenium ions, formed from methanol, are established inside the zeolite catalysts.[64,65] The shift of the distribution curve to higher values is therefore explicable in terms of the subtleties of the mode of operation of shape-selective catalysts. And the reason why preparations of ZSM-5 exhibit variability in catalytic performance vis-a-vis product distributions is attributable to the fact that intergrowths of ZSM-11 (present to a variable degree) occur within the ZSM-5. Proof of the occurrence of intergrowths has been presented previously and is seen in the high-resolution micrograph that constitutes Figure 15.

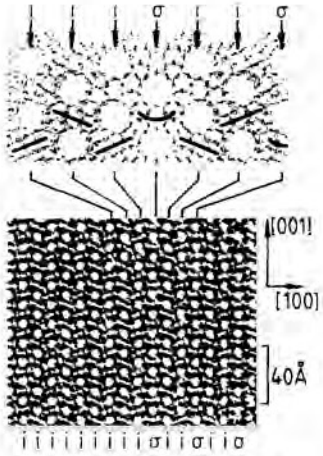

Fig. 15. High-resolution electron micrograph of a typical ZSM-5/ZSM-11 catalyst which contains some intergrowths at the sub-unit-cell level. In perfectly ordered ZSM-11 one sheet (on (100)) is related to its predecessor by a mirror (σ) relation, whereas in ZSM-5 successive sheets are related by inversion (i).

The preparation and characterization of new zeolites has rapidly gained pace in recent years, largely because of the arrival of a range of powerful new techniques for identifying and determining their structures.[42] Moreover, some techniques, notably multinuclear NMR spectroscopy as well as IR, laser Raman and other spectroscopic procedures are applicable to solutions and gels so that information can be gleaned about the role of organic templates in governing the formation of cages and other secondary building units in the evolution of the precursor state prior to crystallization. It is premature, at this stage, to draw too many firm conclusions. But already it has become apparent that many of the originally introduced templates—such as the tetraethylammonium ion (for the preparation of zeolite beta) or bis-(2-hydroxyethyl)-dimethyl-ammonium ion in sodium aluminate-sodium silicate solutions (for the preparation of ECR-1)—tend not to remain intact during the course of synthesis. More work needs to be done to clarify the role of templates, to assess the importance of Ostwald ripening, and other related processes before one can envisage reaching the state of designing a new zeolite, de novo.

One of the most fascinating aspects of crystalline microporous solids, of which zeolites and the aluminum phosphates described below are prominent subsets, is the great variety of framework types that are already known to exist, and the even larger range that is theoretically possible. Much work has been done in the enumeration of possible, as yet hypothetical structures. This follows on from the pioneering studies of *Wells*[66] who was among the first to deal systematically with the analysis of three-dimensional nets and polyhedra in relation to inorganic structures based on four-cornered, three-dimensional topologies.[67]

In such analyses, the tetrahedral junctions (or nodes) of the nets represent the Si (or Al, Ga, B etc.) so-called 'T' atoms of the zeolite, and the linkages between nodes are, in reality, oxygen bridges represented for convenience as straight lines.

2.2. Designing New $AlPO_4$-Based Molecular Sieves

In the last six years, thanks largely to the efforts of *Wilson, Lok, Flanigen* et al., many new types of open framework structures have been brought to light. Most of these have trivalent aluminum and pentavalent phosphorus as the principal occupants of the tetrahedral site, with other elements (such as Li, Be, Mg, B, Si and As) also capable of being incorporated into the tetrahedrally-bonded framework. Aluminum phosphate, either in its pure state (designated ALPO), or as the metal-aluminum phosphate (where the metal (M) can also be Li, Fe, Mn, Co, Zn and Ni) and metal-silicon aluminum phosphates (MAPO and MAPSO respectively) may take up some of the structures previously identified among the zeolitic aluminosilicates (faujasite, chabazite, sodalite, erionite, zeolite rho etc.), but quite often they adopt structures that are novel. These materials are synthesized by the use of organic amines as templates. Typical templates for generating large-pore variants are the tetrapropylammonium ion and tri-*n*-propylamine which favor the production of a hitherto unknown channel structure termed ALPO-5 (Fig. 16 left). The effective pore diameter is ca. 8 Å, comparable to that in the aluminosilicate faujasitic structure (zeolite Y), which also has twelve tetrahedral sites circumscribing the aperture. Recently, *Davis* et al.[68] have described eighteen-numbered rings in a new ALPO structure, termed VPI-5, that is believed to be a reamed out version of ALPO-5 (Fig. 16 right). The pore diameters in VPI-5 are 12 to 13 Å.

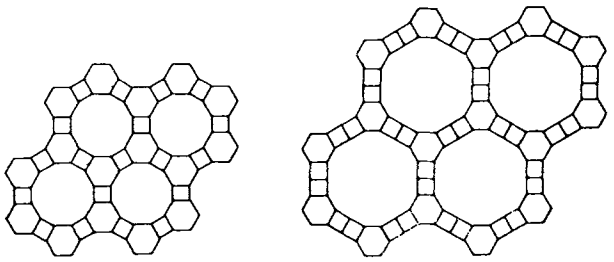

Fig. 16. Schematic structural projection drawing of the new molecular series known as ALPO-5 (left) and VPI-5 (right).

Intermediate-pore-diameter ALPOs, SAPOs, MAPOs and MASPOs (i.e. with apertures of from ca. 6 Å) are favored with amines such as di-*n*-propylamine, and small-pore analogues (diameters of ca. 4 Å) using either isopropylamine, piperidine or quinuclidine. Very small pore ALPOs (ca. 3 Å diameter) tend to be favored using tetramethylammonium ions in the mother liquid from which the ALPO is produced.

As yet, the full potential of these new, crystalline $AlPO_4$-based solids as uniform heterogeneous catalysts has not been adequately explored. The SAPOs are exceptionally good in converting methanol to olefines (with no aromatics);[69] and others are quite promising, as may be assessed from Table 3 which lists the pseudo first-order rate coefficients, for *n*-butane cracking over the corresponding molecular sieve.

Table 3. Typical catalytic performance, expressed as first-order rate coefficients, k_A for the cracking of *n*-butane over $ALPO_4$-based molecular sieves at 400°C [27].

Catalyst	k_A	Catalyst	k_A
AlPO-5	0.05	CoAPO-36	11
CoAPO-5	0.4	CoAPO-34	3.7
MnAPO-5	1.2	MnAPO-34	ca. 4.0
SAPO-5	ca. 0.2	BeAPSO-34	7.6

More will undoubtedly be heard about the variety of other uniform heterogeneous catalysts that may be derived from the $AlPO_4$-based molecular sieves, especially in the light of *Rabo*'s recent work.[69] It is interesting to observe that framework structures (such as ALPO-5) which were not known among the previously reported, and extensively researched (prior to 1988) family of aluminosilicate zeolites, have subsequently been prepared in their all-silica forms. Starting from the all-silica molecular sieve, SSZ-24, recently described by *Van Norstrand* et al.,[70] SAPO-5, in which some substitution of Si by tetrahedral Al and P atoms occurs, has also been prepared. With the aid of the technique of re-alumination,[55] and the recently derived method[50] of introducing Ti into open framework structures, enormous scope now exists for the design and synthesis of both $AlPO_4$- and SiO_2-based uniform catalysts into which delicately minute amounts of Al, Ti and other catalytically potent elements (such as Ga used for dehydrocyclization) may be introduced. Owing to fundamental differences in bonding we cannot expect *all* the SiO_2 structures exhibited to be repeated in the ALPO or SAPO series and vice versa. Geometric arguments take no account of the relative strengths and lengths of T-O bonds or of the magnitude of T-O-T angles. Aluminosilicate zeolites have T-O distances which fall in the range 1.58 to 1.78 Å and most of the T-O-T angles in the range 126 to 170°. The structures of aluminosilicate zeolites with angles close to these limits tend to be rather fragile, and the same arguments, but based on different values for (Al, P, M)-O distances and (Al, P, M)-O-(Al, P, M) angles, apply to new $AlPO_4$-based molecular sieve catalysts. It is interesting to note that, despite strenuous efforts, it seems that no one has yet prepared the ALPO analogues of the pentasils (ZSM-5, ZSM-11 and intergrowths) described by *Kokotailo* and *Meier*.[71]

The report by *Davis* et al.[68] describing VPI-5 which has pore apertures significantly larger than those hitherto found for aluminosilicate zeolites prompts speculation as to which other large-pore structures are feasible. Geometrically, and taking into account known structural patterns (combinations of secondary and tertiary building units), numerous large-pore structures may be proposed, like that shown[72] in Figure 17. Imaginative synthetic inorganic chemistry may lead, via an adroit choice of templates, to

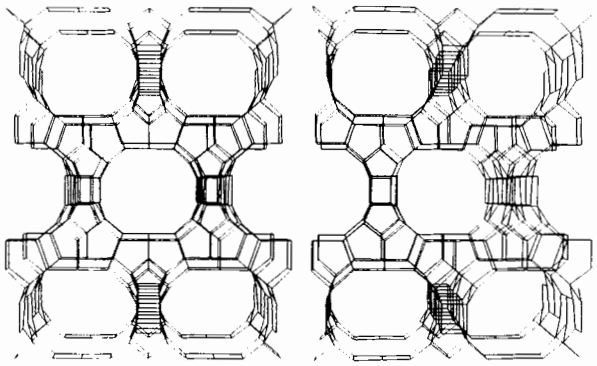

Fig. 17. One of the many possible large-pore crystalline molecular sieve catalysts (after *Akporiaye* [72]). Here there are channels intermediate in diameter between those of zeolite beta and VPI-5.

the synthesis of structures such as these. What would be helpful in this regard is sound theoretical guidance based on estimates of the relative lattice energies. In that fashion[62,73] specific structures with less intrinsic metastability, could be selected as preferred targets for synthesis. It must not be forgotten, however, that kinetic and other means of stabilization which the synthetic chemist routinely harnesses could lead to the preferential isolation of less rather than more stable structures. It must also be emphasized that isolating a new large-pore zeolitic solid is not synonymous with designing a new catalyst. The root cause of Brønsted acidity (see Fig. 5) lies in the immediate environment of the uniformly distributed heteroatom. Quantum-chemical and other arguments[74–77] show that the specific architectural detail plays a critical role in governing the detachability of protons loosely bound to the framework.

3. Uniform Clay Catalysts and their Pillared Variants

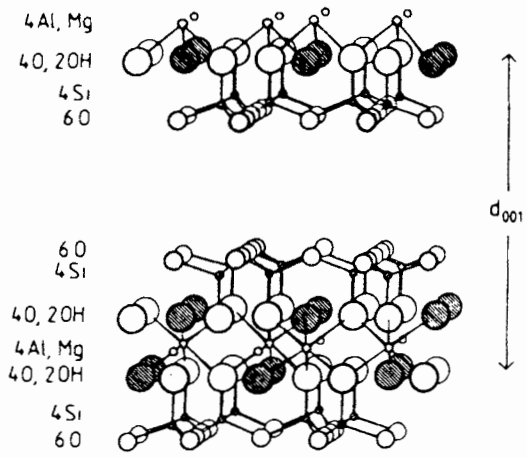
Many members of the clay mineral family exhibit powerful catalytic properties, especially after being subjected to slight changes of composition or structure. The catalytically significant centers reside, and are uniformly distributed, in the interlamellar spaces of these two-dimensional aluminosilicates. So far as acid catalysis is concerned, these centers are either the quasi-free protons generated by hydrolysis of cations such as $Al^{3\oplus}$ or $Cr^{3\oplus}$ introduced by ion-exchange, or the weak Brønsted acidic centers that are attached to interlamellar macrocations (such as the Keggin ion $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7\oplus}$), additional functions of which are to enhance the separation of the component sheets, to increase the surface area and to improve the thermal stability of the original clay. When the clay is used as a redox catalyst, transition-metal or other, including organometallic, cations are inserted by various chemical means[78]—either by ion-exchange of the naturally occuring or synthetic clay or during the course of synthesis—into the interlamellar region. Again there is every reason to believe that these ions, which are the catalytically active centers, are arranged in a spatially uniform fashion in the available interlamellar space.

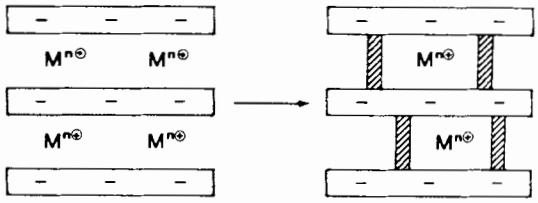
The sheet silicates of principal interest for present purposes (i.e. montmorillonites and hectorites) have edge-sharing octahedral layers ($M(O,OH)_6$ where M is typically Al, Mg, Fe, Na, Li, etc.) flanked on either side by corner-sharing tetrahedral (SiO_4 or occasionally $(Si,Al)O_4$) layers. The octahedral and the tetrahedral layers may be partially substituted by ions of lower valency (e.g. $Mg^{2\oplus}$ or $Li^{\oplus}$ in the former and $Al^{3\oplus}$ or $Fe^{3\oplus}$ in the latter case). This confers a negative charge upon the layers and this charge is balanced by interlamellar, exchangable cations, which are often $Na^{\oplus}$ or $Ca^{2\oplus}$ in naturally occurring clays. The idealized formula of three currently used clay catalysts are:

$(Na, \frac{1}{2}Ca)_x(Si_8)^{IV}(Al_{4-x}, Mg_x)^{VI}O_{20}(OH)_4 \cdot nH_2O$ montmorillonite

$(Na, \frac{1}{2}Ca)_x(Si_8)^{IV}(Mg_{6-x}, Li_x)^{VI}O_{20}(OH)_4 \cdot nH_2O$ hectorite

$(Na, \frac{1}{2}Ca)_x(Si_{8-z}Al_z)^{IV}(Al_4)^{VI}O_{20}(OH)_4 \cdot nH_2O$ beidellite





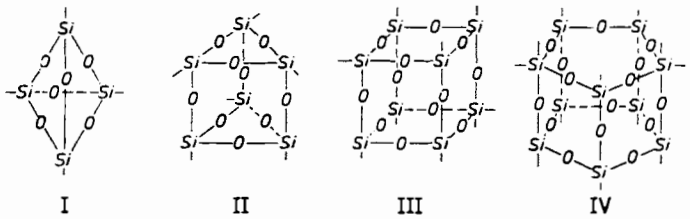


Fig. 18. Top: Schematic illustration of the structure of montmorillonite. Middle: Illustration of how a clay mineral (typically montmorillonite or beidellite) is converted into its pillared form. Bottom: Siliceous pillars (vertical hatched regions of the drawing above can have repeat units such as those shown (I to IV).

where *IV* and *VI* refer to the tetrahedrally and octahedrally cordinated ions. Figure 18 top illustrates the disposition of the constituent atoms in montmorillonite prior to ion-exchange; Figure 18 middle shows schematically, and 18 bottom in atomic detail, what is achieved in the process of pillaring. There is considerable evidence[79] for believing that the pillars are formed from the 'Al_{13}' Keggin ions and composed predominantly of pencils of alumina, the surface of which has more or less uniformly exchanged acid groups. It is possible to introduce totally siliceous (SiO_2) pillars by an ingenious[80] organo-silicon route using sesquisiloxanes. As expected, siliceous pillars possess hardly any Brønsted acidity, but other cations of catalytic significance can be accommodated uniformly elsewhere in the interlamellar space which is enlarged by the presence of the silica pillars. Ammonium ions[81] and transition-metal chelates[82] have also been used as pillaring cations, but the thermal stability of the resulting pillared clay is inadequate for general catalytic purposes. Other polycations include those of zirconium,[83] titanium,[84] iron,[85] chromium[86] as well as various of the ever-popular aluminum.[17,87,88] Alumina-crated silica pillars have also been successfully introduced. The best pillared clays for catalytic purposes have[17,74] surface areas of 200 to 500 $m^2\,g^{-1}$, pore volume of 0.15 to 0.20 mL g^{-1}, and layer spacings of 16 to 20 Å, which is the consequence of an expansion of 6 to 10 Å of the interlamellar distance of the starting material.

Synthetic hectorites, first produced by the LaPorte Company in England and subsequently named laponite, may also be prepared as fluoro derivatives, which are more thermally stable than their hydroxy analogues. Laponites are not sufficiently crystalline to yield precise X-ray structural data. Recently, large crystalline specimens of the sodium tetrasilicic mica (designated TSM) have been produced by Topy Industries, Japan. This material is a fluoro derivative and has the formula $NaMg_{2.5}Si_4O_{10}F_2$. In the as-prepared state it possesses no Brønsted acidity.

A selection of the reactions that are catalyzed by clay-based solids is shown in Table 4. These are acid (proton)-catalyzed reactions of the type illustrated mechanistically in Figure 19. Other non-acid catalyzed reactions which have been explored by *Morikawa* et al.,[78] are represented by the selection shown in Figure 20. Further details about the optimal conditions and mechanistic features of these reactions have been given elsewhere.[4,90,96] Briefly, proton-catalyzed conversions, similar to those that occur with uniform zeolitic catalyst, take place within the interlamellar spaces.

Table 4. A selection of organic reactions catalyzed by clays. [9–12, 95, 96]

Cracking and hydrocracking of hydrocarbons
Dehydration of alkanols, with the formation of ethers, alkenes, and naphthenes
Isomerizations, alkylations, and cyclizations
Conversion of primary amines to secondary ones
Dimerizations, oligomerizations, and polymerizations
Oxidations and reductions
Hydration, alkylation, and acylation of alkenes to form alkanols, ethers, and esters
Hydrogen exchange and hydrodesulfurizations
Decarboxylations and lactonizations
Polycondensations (e.g., peptides from amino acids)

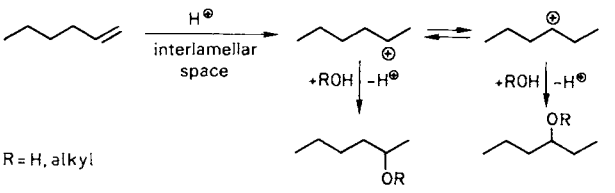

Fig. 19. The interlamellar regions of certain clays function as uniform acidic heterogeneous catalysts for the production of alcohols and ethers from alkenes [9, 96].

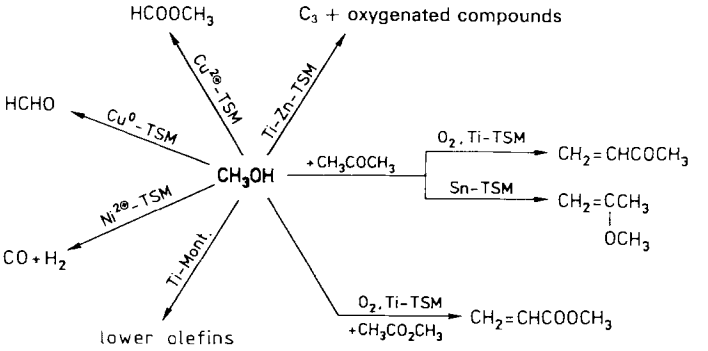

Fig. 20. A selection of non-acid-catalyzed reactions of metal-substituted clays [78].

3.1. Prospects for Designing More Effective Clay Catalysts

We have already seen that synthesizing the fluoro analogues of naturally occurring clays improves their thermal stability (compare fluorohectorite with ordinary hectorite) and that fluorotetrasilicic mica (FTSM) can be prepared in such good states of crystallinity and swellability (after intercalation) that they are amenable to single-crystal X-ray structural analysis. We also note that there are already a number of alternatives for introducing thin pillars into the interlamellar region, thereby enhancing the all-round catalytic performance of the clay.

Further scope exists for designing better clay catalysts. Thus, $Li^{\oplus}$ ions may be diffused into the octahedral sublattice of certain montmorillonite clays, leading to a reduction in the density of negative charge on the individual layers.[97] This in turn reduces the cation-exchange capacity of the clay catalyst and, if it were subsequently pillared, one would expect the pillar separation distance to increase (see Figure 18 middle).

Another strategem for structural variation is suggested by recent Chinese work on rectorite clays, which are interstratified at the unit-cell level and consist of thin sheets of mica in a more or less regularly spaced matrix of a swellable montmorillonite clay. Pillaring of such interstratified material leads to a more thermally resistant product than those derived from other clays. The challenge now is to devise inorganic syntheses so as to generate the best possible combination and sequence of interstratified aluminosilicates. In this connection, beidellite, which bears its surplus negative charge in the tetrahedral rather than the octahedral sub-lattice,[14,15] may have advantages over montmorillonite in view of the ostensible ease of 'keying' Keg-

gin-like cations to the sheets, thereby strengthening the binding of the pillar to the sheet. Further scope also exists in chemically derivatizing the cylindrical surfaces of the pillars with well-defined, accessibly and uniformly arranged 'active sites'.

All these design features, if successful, would lead to two-dimensional analogues of solids but with substantially enlarged pore-apertures (> 15 Å). Amongst other things such hosts, with polyvalent cations capable of hydrolyzing water, such as $La^{3\oplus}$ or $Al^{3\oplus}$, would be suitable for the catalytic cracking and hydrocracking of molecules a good deal larger than those that can be so processed by $La^{3\oplus}$-exchanged faujasitic zeolites.

4. Uniform Oxide Catalysts

Whereas in uniform zeolitic catalysts there are discrete active sites, such as framework $Al^{3\oplus}$ ions in the aluminosilicate framework or extra-framework $La^{3\oplus}$ ions with their associated protons loosely bound to the framework, in the oxide catalysts that concern us here the situation is quite different. In this type of uniform heterogeneous catalyst all the oxygen of the structure is potentially implicated in the catalytic oxidation: the reactant combines with, and removes, the oxygen situated at the surface of the solid, but the sacrificial loss of oxygen is made good by assimilation of gaseous oxygen into the solid allowed by its conversion to oxide ions and the migration of the latter throughout the bulk catalyst. During this kind of catalysis the oxide is rendered non-stoichiometric (oxygen deficient), the extent and nature of which is governed by the prevailing conditions.

Several industrially important processes[98, 100] utilize uniform heterogeneous oxide catalysts, the best known being the ammoxidation of propylene to acrylonitrile and its oxidation to acrolein (over bismuth molybdates). But there are many other laboratory-scale reactions where it has been established that such oxide catalysts function in the sacrificial manner described above. Oxide catalysts of this kind also figure eminently in certain electrocatalytic processes,[101, 102] such as the oxidation of methane, and in autoemission exhaust systems.[103] There are doubtless many other oxidation processes which use oxide catalysts of one kind or another where it has not yet been confirmed that structural oxygen is implicated.

4.1. Fluorites and Perovskites as Uniform Catalysts

What is it that enables some oxides to release their structural oxygen reversibly so as to form grossly non-stoichiometric intermediates and thereby to function as efficient oxidation catalysts? Why, for example, are perovskite-based structures so prominent among this category of catalyst? We do not, as yet, know the answer to these questions; but accumulated chemical experience teaches us to use analogies between different types of perovskite and other structures, so that some progress can be made in the search for more efficient and specific catalysts.

One of the key attributes of a desired new uniform oxide catalyst is its ability to sustain gross non-stoichiometry. The solid-state chemist knows that it is no easy task to predict which oxide structures are favorable in this regard. Thus TiO_2 in the form of rutile, but not in the form of either of the other two principal polymorphs anatase and brookite (which are quite similar to rutile in the coordinates of the $Ti^{4\oplus}$ ion) is easily rendered grossly non-stoichiometric (e.g. TiO_x, $1.5 < x < 2.0$). MgO, which has the rock salt structure, is incapable of housing high concentrations of point defects, whereas in solid solutions of MnO and MgO that also have the rock salt structure, a substantial fraction of the oxygen atoms can be removed without changing the structure. Again, with oxides of the AO_2 type, those that crystallize with the fluorite structure, provided the A cation is capable of variable valency, can often be rendered grossly non-stoichiometric; yttrium-stabilized zirconia, for example, has many anion vacancies, a typical example being $Zr_{0.83}Y_{0.17}O_{1.915}$. For structures such as ABO_3, those that have the pyroxene or wollastonite structure seem incapable of being rendered non-stoichiometric by loss of oxygen, whereas in the perovskite structure (Fig. 21), they can be accommodated in non-stoichiometric forms. In addition to the requirements of valency, it seems that the structure's elastic properties are crucial in governing ease of formation of high concentrations of point defects and especially of planar faults. But the whole question of non-stoichiometry in binary and ternary metal oxides is a complicated one, and even the broad outline of the determinative principles are not yet clear.

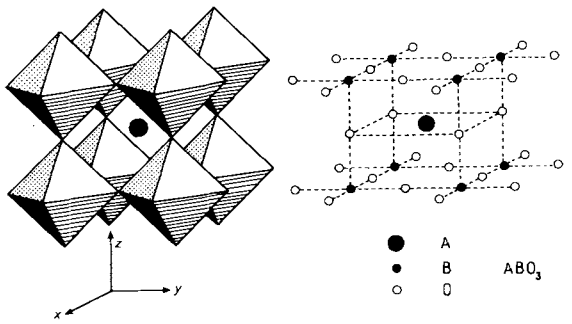

Fig. 21. Two schematic representations of the idealized perovskite ($CaTiO_3$) structure. The B site in ABO_3 is octahedrally coordinated to oxygen.

4.2. Bismuth Molybdates and Calcium Manganates

Experiments that use[22, 104] isotopic labelling as well as secondary ion mass spectrometry (SIMS) point unmistakenly to the participation of bulk oxygen, which migrates to the seat of a reaction at the surface of the oxide catalyst and is made good by dissolution and subsequent compensatory reduction of gaseous oxygen. This is true of the bismuth molybdates,[98–100] of which the α- ($Bi_2Mo_3O_{12}$), β- ($Bi_2Mo_2O_9$) and γ-phases (Bi_2MoO_6) are the best known, in the selective oxidation and ammoxidation of alkenes. The first step in each of these selective oxidations is the abstraction of hydrogen from the alkene at a bismuth center to produce allylic intermediates (π-complex). This intermediate then forms a σ-bonded complex and finally a second hydrogen is abstracted (Fig. 22). Mechanistic details of these conversions are described elsewhere.[98, 99]

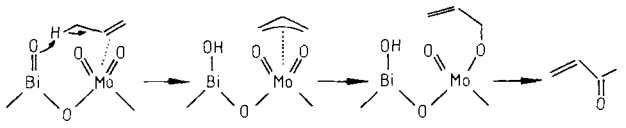

Fig. 22. The selective oxidation of propene over a bismuth molybdate catalyst proceeds via an allylic intermediate complex.

For a long while the broadly similar catalytic performance of the α-, β- and γ-phases was difficult to reconcile with the seemingly quite different crystallographic structures of the respective phases. (The α-phase, $Bi_2Mo_3O_{12}$, has been described as a defect scheelite structure. Scheelite itself ($CaWO_4$) has ABO_4 repeat units in which the A cation is eight-coordinated by oxygen and the B cation is hexavalent and present as discrete BO_4 tetrahedra. The α-phase can be regarded as a structure containing one cation vacancy (□) for every two $Bi^{3\oplus}$ ions and may be written as $Bi_{2/3}\square_{1/3}MoO_4$. The β-phase, $Bi_2Mo_2O_9$, has a defect fluorite structure, the $Bi^{3\oplus}$ being in eight-fold coordination and again there are distorted MoO_4 tetrahedra. Below about 570 °C the structure of the γ-phase, Bi_2MoO_6, is that of the rare mineral koechlinite, where there are alternating sheets of $Bi_2O_2^{2\ominus}$ and $MoO_4^{2\ominus}$, the latter being composed of corner-sharing MoO_6 octahedra.) With such variety in crystal structure, and in particular in the coordination of the hexavalent Mo, it was puzzling that the catalytic performance of all three phases was so similar. Recent work[105] using electron diffraction and high-resolution electron microscopy, has shown that these ostensibly different bismuth molybdates—as well as others—can all be considered as defect fluorites (Fig. 23–25). The α-phase may readily be regarded as a defect fluorite structure if one allows for small displacements of some of the oxygens.

Recognizing that essentially all of the catalytically active bismuth molybdates possess the same kind of fluorite based structure—like δ-Bi_2O_3 itself, which may be written as $Bi_{2/3}O_{3/2}\square_{1/2}$, where ◘ now stands for an oxygen vacancy—it is not surprising in broad terms that the catalytic performance of the respective phases are so comparable. But this conclusion does presuppose that the surfaces of all these catalysts are also comparable structurally. It is not certain how different the surfaces of these solids are, in their active catalytic state, from those of the bulk solids. Compositional changes under operating conditions can certainly be expected.[106]

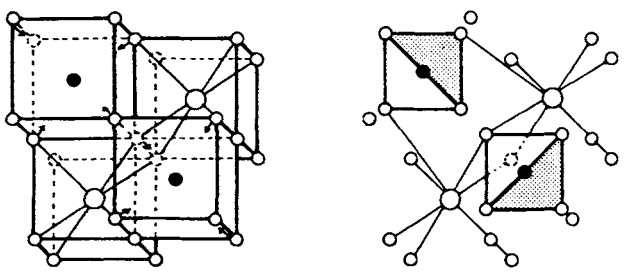

Fig. 23. Modification of a single fluorite-like unit cell, containing two bismuth and two molybdenum atoms (left) to produce two MoO^4 tetrahedra, schematically shown right. Movement of oxygen atoms in the left picture is indicated by arrows [105].

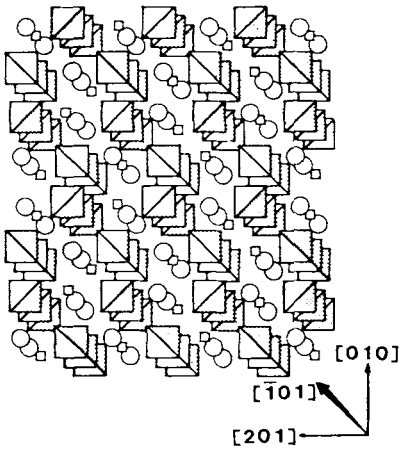

Fig. 24. Schematic clinographic projections of the $Bi_2Mo_3O_{12}$ structure, viewed down [$\bar{1}$01] axis, showing the two fluorite-like axes down which bismuth and molybdenum atoms do not superimpose. Vacant bismuth sites are denoted by □.

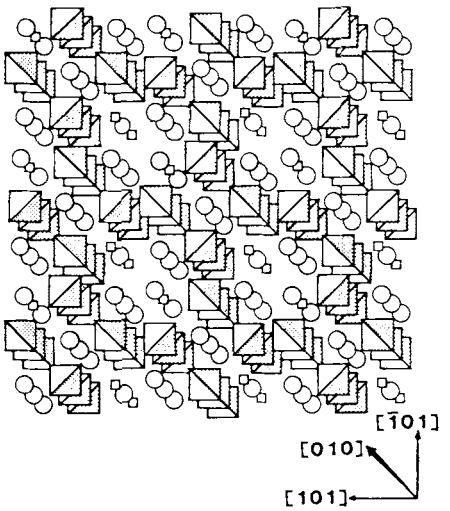

Fig. 25. Clinographic projection of the structure of $Bi_2Mo_2O_9$, viewed down [010] axis.

Bismuth molybdate catalysts are not always based on the defect fluorite structure. When some of the Mo is replaced by hexavalent W, forming a solid of stoichiometry $Bi_2(Mo,W)_{12}O_{35}$ a totally novel structure (established by HREM) is formed[107, 108] (Fig. 26). Here there are interleaved layers of bismuth oxide and mixed Mo-W oxides. In the latter, which are six corner-sharing octahedra in height, there are both corner-sharing and edge-sharing $(Mo,W)O_6$ octahedra parallel to the layers. Along the layers, at regular intervals, are crystallographic shear (CS) planes at which, locally, corner-sharing is replaced by edge-sharing of the $(Mo,W)O_6$ units. The presence of these CS planes modifies the stoichiometry of the six octahedra wide layers from $(Mo,W)O_3$ to $(Mo,W)_2O_5$; and the stoichiometry of the bismuth oxide, cationic layer, from Bi_2O_2 (which is what it is in koechlinite) to Bi_2O_3. It is very likely that numerous other structures of bismuth oxide-based selective oxidation catalysts are built up on these general principles: variable composition can be adapted by varying the thickness of the corner- and edge-sharing of the oxide layers and also by changing the spacing of the shear

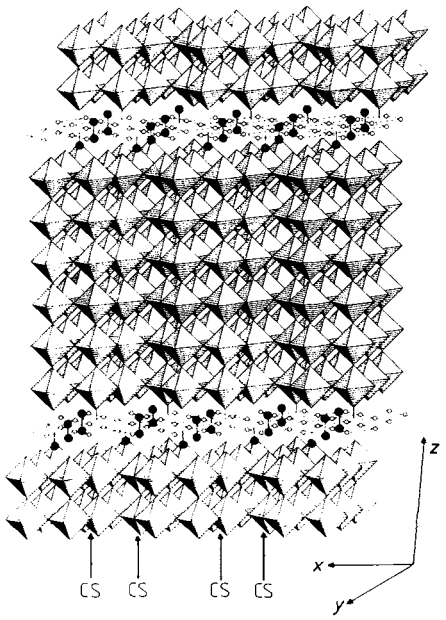

Fig. 26. This hitherto unknown structure for the uniform selective oxidation catalyst $Bi_2(Mo,W)_{12}O_{35}$ was deduced from high-resolution electron microscopic imaging and related techniques [107, 108]. The crystallographic shear (CS) planes (see text) are perpendicular to the sheets of bismuth oxide.

planes. It is possible that, during the course of a particular catalytic reaction, given the lability of compositional oxygen, that the spacings of CS planes, and the accompanying composition of the $Bi_2O_2^{2\oplus}/Bi_2O_3$ layer, may undergo dynamic change.

Many metal oxides ABO_3 possessing the perovskite structure ($CaTiO_3$) have been known to exhibit promising catalytic properties.[103] One such oxide, $CaMnO_3$, selectively oxidizes[24] propene to benzene and 2-methyl propene to *para*-xylene. In so doing the solid itself is converted into more or less grossly non-stoichiometric products, $CaMnO_{3-x}$, where x is, typically, 0.20 or 0.25. Many other perovskites display similar properties; and although not all perovskitic solids of formula ABO_{3-x} are catalytically active, it is well-known that many of them can be converted relatively easily, by progressive removal of oxygen, to the stage $ABO_{2.5}$ without disrupting the structural integrity—apart from creating oxygen vacancies—of the perovskite. $CaFeO_{2.5}$ for example,[109] the product of reduction of the ferrite, $CaFeO_3$, is made up of stacks of alternate layers of FeO_6 octahedra and FeO_4 tetrahedra. This structure corresponds to that of the naturally occurring mineral brownmillerite. Variants of this structure have been reported by *Bando* et al.[110] in $Ca_4YFe_5O_{13}$ and by *Alario-Franco* et al.[111] in $Ca_2LaFe_3O_8$ and $Ca_xLa_{1-x}FeO_{3-y}$.

For intermediate phases between perovskite-like ABO_3 and brownmillerite-like $ABO_{2.5}$, *Grenier* et al.[112] argued that there were $n-1$ perovskite-like layers of BO_6 octahedra alternating with one layer of BO_4 tetrahedra. Such structures undoubtedly exist for certain kinds of transition-metal ions B. For $CaMnO_3$, however, *Reller* and others[24, 113] have shown that square-pyramidal (MnO_5) entities—similar to those in $Na_4Mn_2O_5$ as was first reported by *Brachtil* and *Hoppe*[114]—are produced in ordered states with progressive reduction of the $CaMnO_3$ to its grossly non-stoichiometric forms. The essence of the conversion from $CaMnO_3$ to $CaMnO_{2.5}$ is symbolized in Figure 27.

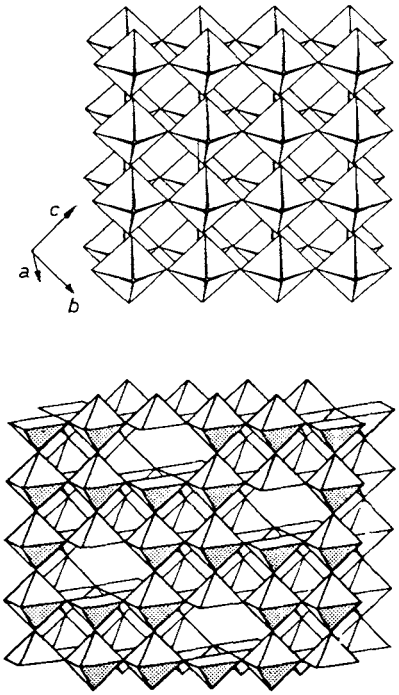

Fig. 27. Top: The ReO_3-type structure shown here has corner-sharing (MO_6) octahedra, which are also present, along with the A atoms at the center of a cube of such octahedra, in the perovskite structure (see Fig. 21). Bottom: When the uniform heterogeneous catalyst $CaMnO_3$ is used in the selective oxidation of propene it can be converted to non-stoichiometric variants, one of which is shown here (for simplicity without the $Ca^{2\oplus}$ ions). Oxygen removal from the solid converts MO_6 octahedra to MO_5 square pyramids [113].

Ideally, the way to explore precisely which ordered, non-stoichiometric phases of ABO_{3-x} are the most catalytically active and selective, and at the same time to test the ease with which oxygen is released and regained by the active catalyst, is to employ an in-situ crystallographic method of study. In principle, transmission electron microscopy is capable of uncovering such information. But it is not easy to perform the necessary experiment in the appropriate microscope hot-stage. Sensible progress can, however, be made by ex situ studies combining selected-area electron diffraction, high-resolution imaging and optical diffractometry. (All of these are essentially 'bulk' methods, but since we are dealing with uniform heterogeneous catalysts they are perfectly valid probes.)

Reller et al.[24] have arrived at the structural character of five distinct, grossly non-stoichiometric solids: $CaMnO_{2.88}$, $CaMnO_{2.75}$, $CaMnO_{2.667}$, $CaMnO_{2.556}$ and $CaMnO_{2.5}$. And although oxygen migration within these solids was not studied, the subtlety of the adapted structure *for a given composition* could be ascertained. For $CaMnO_{2.5}$, for example, five distinct structures were discovered differing in their superlattice character one from the other. Schematic drawings of two of these are shown in Figure 28. (Note the presence of the square-pyramidal MnO_5 units, formed by loss of oxygen from MnO_6 octahedra.)

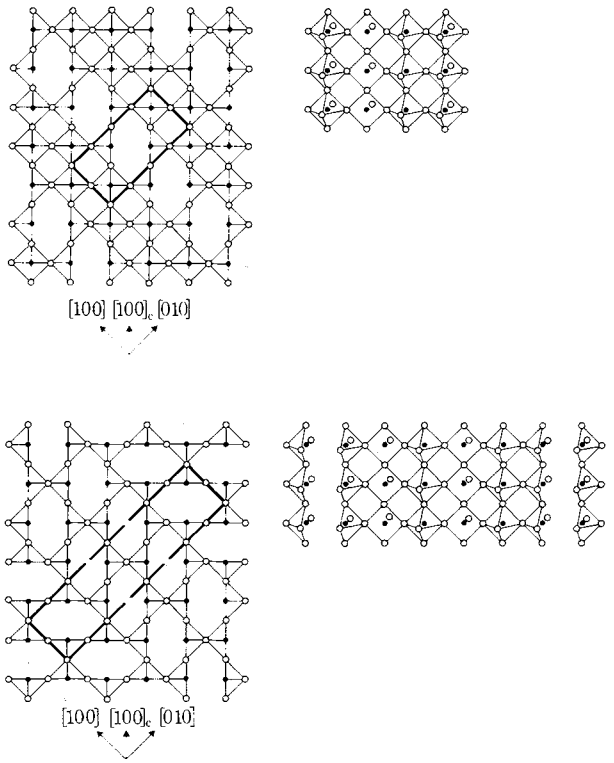

Fig. 28. Top: Schematic drawing of one of the many structures taken up by the uniform oxidation catalyst $CaMnO_{2.5}$. There is a supermesh, shown in thick outline, of $2\sqrt{2} \times \sqrt{2}$ times the parent one and rotated by 45°. Bottom: Another structure found by *Reller* et al. [113] for the $CaMnO_{2.5}$ catalyst. Here the supermesh, also rotated, is $4\sqrt{2} \times \sqrt{2}$. In both drawings small dotted circles denote location of the $Ca^{2\oplus}$ ions in the parent perovskite structure.

There are other perovskites[115, 116] which exhibit catalytic properties (see Table 1) in the oxidation of hydrocarbons. $Ba_2Bi_2LaO_6$ and its non-stoichiometric (oxygen deficient) variants ($Ba_2Bi_{2-x}La_xO_{6-y}$) are one set of examples. The recently discovered high-T_c superconductors $YBa_2Cu_3O_{7-\delta}$ ($0 \leqslant \delta \leqslant 1$) are another. It is not yet established whether, as in the bismuth molybdates, sacrificial loss of oxygen is a cardinal feature of the catalysis. But it is quite clear[117] that there can be facile loss and gain of oxygen into structures such as $YBa_2Cu_3O_{7-\delta}$ at the low temperatures required for catalysis freely to proceed. A new family[118] of related metallic oxides, derived from perovskite by loss of oxygen (e.g. $La_4BaCu_5O_{13}$—see Fig. 29),

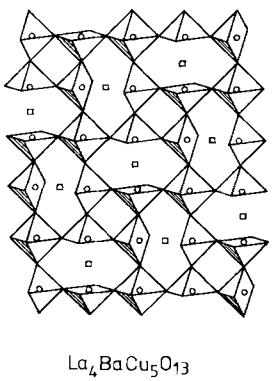

Fig. 29. Schematic representation of the recently reported [118] metallic oxide which is replete with ordered vacancies (compare Fig. 27 bottom).

can also be rendered grossly non-stoichiometric. But little is known as yet of the chemical properties of these fascinating complex oxides. They are, however, likely to function as oxidation catalysts, just as $YBa_2Cu_3O_{7-\delta}$ catalyze the following reactions:

$$CO + \tfrac{1}{2}O_2 \longrightarrow CO_2$$

$$2\,NO \longrightarrow N_2 + O_2$$

$$C_6H_5CH_3 \xrightarrow[O_2]{NH_3} C_6H_5CN$$

On the basis of work done by *Jacobson* et al.[115, 116] who studied the ease of generating non-stoichiometric perovskites as a function of the cation constituents, it is clear that much scope exists to fine-tune the performance of new uniform, selective oxidation catalysts. They studied perovskites of composition $A_2BB'O_6$ in which the initial (stoichiometric) structure shows B-cation order when there were large differences in charges and radii of B and B'. This happens in Ba_2LaBiO_6 for example. They found that on increasing x in the series $Ba_2Bi_{2-x}La_xO_{6-y}$ ($0 \leqslant x \leqslant 1$) more severe reducing conditions were required to reduce the $Bi^{5\oplus}$ ions completely. They concluded that removal of oxygen from this structure is relatively easy from Bi^{V}-O-La^{III} and Bi^{V}-O-Bi^{III} structural units, and that cation disorder increases the probability of occurrence of Bi^{V}-O-Bi^{III} linkages. This family of non-stoichiometric uniform oxides are good heterogeneous catalysts for the oxidation of propene to benzene and 2-methyl propene to *para*-xylene.

4.3. Aurivillius, Sillén and Related Structures

The discovery[105] that at least six of the bismuth molybdate phases are based on the defect fluorite structure prompted *Zhou* et al.[119–121] to re-investigate the structural principles displayed by so-called solid solutions in other systems, notably Bi_2O_3-WO_3, Bi_2O_3-Nb_2O_5, Bi_2O_3-V_2O_5 and Bi_2O_3-Ta_2O_5. The full potential of the catalytic performance of these solids remains to be explored; but at least some of them exhibit catalytic activity, both thermal and photo-induced.[122] Their structures, which have been the subject of systematic investigation by combined electron diffraction and electron microscopy, are quite remarkable, and the salient features are summarized in Figure 30. Depending upon the precise compositional range and the pair of metals involved, the 'solid solutions' are found to take up large superlattices based on fluorite, or pyrochlore, or perovskite, and two other phases. One of these has the well-known Aurivillius structure (which is a regular interleaving of $Bi_2O_2^{2\oplus}$ and anionic perovskitic layers), the other is a unit-cell-level hybrid of pyrochlore and perovskite subunits.

Recently, layered bismuth oxyhalides belonging to the large class of structures first identified by Sillén,[123] such as $MBi_3O_4X_2$ (M = Na, K ..., X = F, Cl, Br) have been found[124] to be promising hydrocarbon oxidation catalysts. Their structures are shown in Figure 31. It is not yet known whether these solids are genuinely uniform heterogeneous oxide catalysts, but they have been shown[125] to lose oxygen rather freely during contact with one or more hydro-

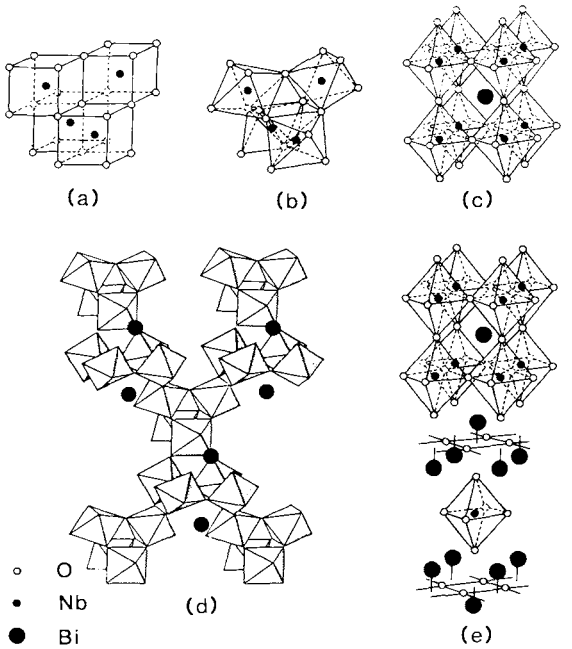

Fig. 30. Depending upon the precise composition, the so-called solid solutions formed between Bi_2O_3 and oxides such as Nb_2O_5, V_2O_5 etc. take up well-defined superstructures based on fluorite (a), pyrochlore (b), perovskite (c), half perovskite-half pyrochlore (d) and the Aurivillius structure (e) (see text) [119, 121].

carbon reactants. Several novel structures, including unit-cell-level intergrowth structures formed from an Aurivillius and Sillén phase end-member (general formula $(Bi_2O_2)^{2\oplus}Cl^{\ominus}(Bi_2O_2)^{2\oplus}(A_{n-1}BO_{3n+1})$ where the A and B cations are two- and six-coordinated respectively as in a perovskite), can be formed[126] and these, as well as others,[127] show some promise as oxidation catalysts.

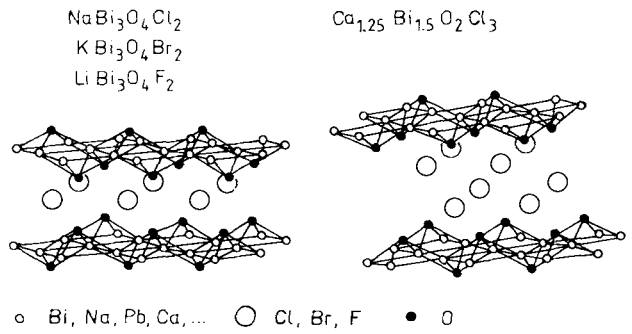

Fig. 31. Examples of the Sillén-type structures taken up by certain layered bismuth oxychlorides which are [124] promising hydrocarbon oxidation catalysts.

5. Epilogue

Many seemingly widely different types of heterogeneous catalysts, encompassing a variety of structures and compositions, are seen to belong to the same family, the key characterizing feature of individual members of which is their spatial uniformity. Apart from its practical convenience, this classification, by uniting a large number of distinct materials, reinforces the role that the design and synthesis of new solids in general can play in formulating and preparing new heterogeneous catalysts in particular. It also demonstrates the applicability of most of the structural techniques of solid-state chemistry to the central problems associated with the characterization of the growing class of inorganic catalysts, many of which already figure eminently in processes conducted on the industrial scale (see Table 1).

As tends to happen with all classifications, distinctions sometimes become blurred. With zeolitic catalysts, for example, there are two situations under which it is no longer true that all the active sites are uniformly distributed throughout their bulk. First, some of the active elements of the framework (e.g. $Al^{3\oplus}$ in the tetrahedral macroanion) may be partially leached out into intra-zeolitic cavities. Such detrital aluminous material may itself be catalytically significant. Often this is quite uniformly distributed but not invariably so. Second, when platinum or other noble metal species are atomically or very finely (ca. 5 Å diameter) distributed inside a zeolite so as to confer upon the catalyst the bifunctional character, it is found that the minute particles of platinum, initially uniformly distributed, tend to accrete, sinter and grow. The resulting catalyst may still retain its uniformity so far as its Brønsted acidity is concerned, but with respect to the platinum it now develops features more akin to category 1 (see Table 1) catalysts. Likewise, with clay and pillared clay catalysts, when they collapse, as sometimes occurs on extended use, they are no longer uniform and only their exterior surfaces are catalytically active, again resembling materials in category 1. With oxides it is occasionally found that, even at the outset, the sacrificial loss of oxygen and its subsequent replenishment is restricted to the exterior surface—the entire bulk of the oxide is not implicated. Additionally, some oxide catalysts which undoubtedly operate via sacrificial loss of structural oxygen, exhibit superior performance when in contact with a second or third solid component, usually an oxide. Under these circumstances it is no longer adequate to talk of uniform heterogeneous catalysts. With selective hydrogenation catalysts like the well known copper chromite system,[128] where uniformly distributed platinum particles serve as gateways for the release of hydrogen held as in a reservoir within the bronze, it may also be profitable to place this type of "reverse spillover"[128, 129] catalyst into category 2. And it may well transpire that very finely divided metallic catalysts of colloidal dimension may also be best regarded as spatially uniform in the sense defined here.

In the main, however, the merits of identifying the existence of uniform heterogeneous catalysts are considerable both on practical and other grounds. One particular advantage of recognizing the importance of the structure of the entire solid catalyst, not merely that of its surface, is that the chemist has at his disposal a wide sweep of new routes for the preparation of new catalysts. Since many of these have to be produced as metastable solids the elegant variations of structure pioneered for metal oxides by *Magneli*,[130] who first prepared the hexagonal tungsten bronze form of WO_3 (Fig. 32 which should be compared with Figure 27 top) may be implemented in the realm of the sacrificial metal oxides just as they have been already in the zeolites and the aluminum phosphates. In this regard, the

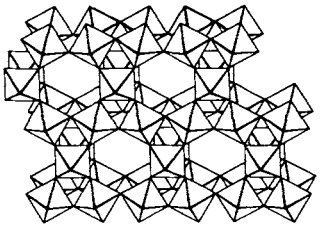

Fig. 32. Structure of hexagonal WO_3 showing one-dimensional tunnels [130].

set of 'soft' chemical principles—termed 'chimie douce' by their French originators, *Rouxel, Livage* and *Figlarz*[131-133] and already widely exploited by others[134-139] in other contexts—have a role to play in the production of new uniform heterogeneous catalysts.

Another important advantage of recognizing the bulk, solid-state chemical essence of uniform catalysts is that new powerful conceptual advances[140,141] in the use of equipotential and minimum potential surfaces for the deeper understanding of chemical properties can be readily applied to this class of heterogeneous catalysts.

[31] This is not to imply that the solid catalyst is totally free of coherent intergrowths of various kinds [32] or of zoning or other structural defects. Rather, we use the term uniform in the sense that, within a given microregion of the catalyst, the active sites are present uniformly throughout that spatially specified region.

[41] There are *very* few techniques that are suited to probe transition state characteristics in chemical kinetics. When one talks of a time-resolved experiments it is reckoned to be a great achievement if nanosecond time-scales are reached. But this is still some five orders of magnitude too slow for tracking the fundamental dynamics of chemical change. Only very recently has femtosecond real-time dynamics been reached [M. J. Rosker, T. S. Rose, A. H. Zewail, *Chem. Phys. Lett. 146* (1988) 175; M. J. Rosker, M. Dantus, A. H. Zewail, *Science (Washington) 241* (1988) 1200] in simple, gas-phase reactions. With this temporal discrimination the potential energy surfaces of the transition-state can be explored.

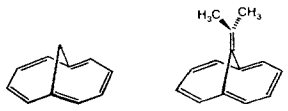
1,6-Methano[10]annulene Dianion, a Paratropic 12π-Electron Dianion with a C_{10} Perimeter**

By *Dietmar Schmalz* and *Harald Günther**

Dedicated to Professor Fabian Gerson on the occasion of his 60th birthday

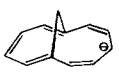
The synthesis of 1,6-methano[10]annulene **1** by *Vogel* and *Roth*,[1] which marked the beginning of the chemistry of bridged annulenes with acene perimeters, is clearly a milestone of modern arene chemistry. Since then, numerous investigations of the physical and chemical properties of **1** have confirmed the interesting bonding situation in this hydrocarbon.[2] However, its reduction to the dianion $\mathbf{1}^{2\ominus}$ has not yet been reported. Only the derivative **2**, modified at the bridge, could be transformed into the ionic system $\mathbf{2}^{2\ominus}$ by reaction with metallic lithium.[3] The ^{1}H NMR spectrum, however, shows only a relatively small upfield shift of 2–3 ppm for the perimeter protons and therefore $\mathbf{2}^{2\ominus}$ is only weakly paratropic.[4]



1 **2**

Results recently obtained for dilithium naphthalene $\mathbf{3}^{2\ominus}$[5] suggested that the reduction of **1** might also be possible under identical conditions. Indeed, reaction of **1** and lithium sand in [D$_8$]THF at −80 °C with vigorous vibration afforded the dark brown solution of a species that, according to its NMR spectroscopic data, is unambiguously characterized as the dilithium salt of $\mathbf{1}^{2\ominus}$ (Fig. 1, Table 1).

The reductive transformation of the diamagnetic 10π-electron system of **1**[6] into the paramagnetic 12π-electron system of $\mathbf{1}^{2\ominus}$ results in the expected[4,7] shifts of the ^{1}H NMR signals and in ^{1}H NMR data similar to that observed for bridged [14]annulene dianions[3] and the 12π-electron monoanion bicyclo[5.4.1]dodecapentaenide **4**.[8]



4

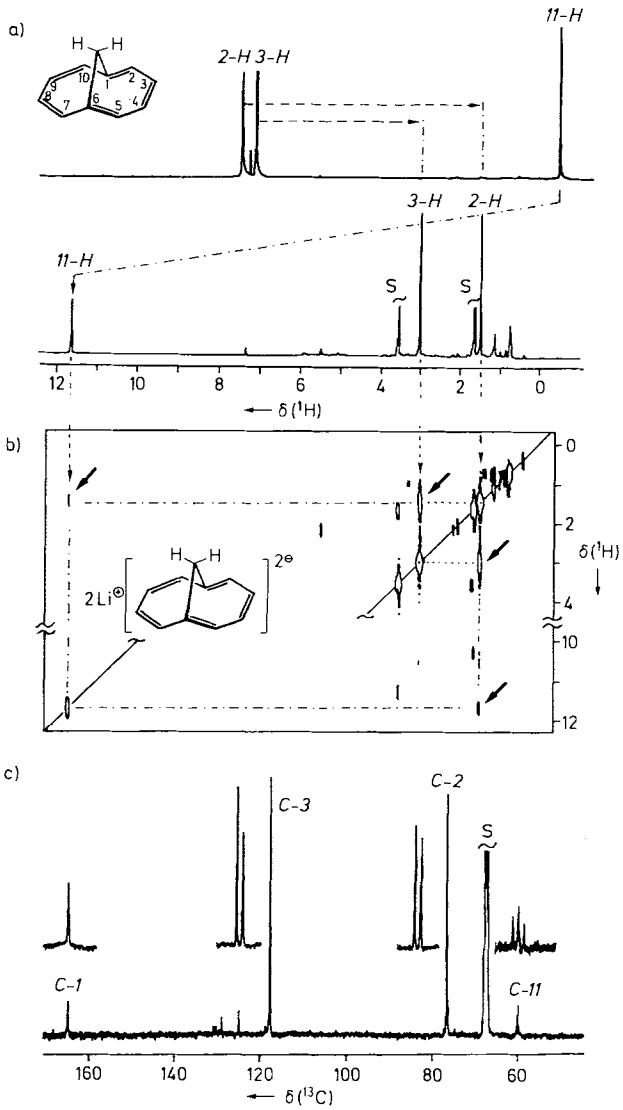


Fig. 1. a) 400-MHz ^{1}H NMR spectra of **1** ($CDCl_3$) and 2 $Li^{\oplus}/\mathbf{1}^{2\ominus}$ ([D$_8$]THF). b) COSY-45 [9b] spectrum of 2 $Li^{\oplus}/\mathbf{1}^{2\ominus}$ (cross signals marked with arrows). c) 100-MHz ^{13}C NMR spectrum of 2 $Li^{\oplus}/\mathbf{1}^{2\ominus}$ with the multiplets of the ^{1}H-coupled spectrum. S = solvent signal, X = unknown product. $T = -80$ °C.

Table 1. ^{1}H and ^{13}C NMR data [δ relative to TMS] for **1**, $\mathbf{1}^{2\ominus}$, and $\mathbf{3}^{2\ominus}$ [a].

	1	$\mathbf{1}^{2\ominus}$	$\mathbf{3}^{2\ominus}$	Δδ [ppm] $\mathbf{1}^{2\ominus}-\mathbf{1}$	Δδ [ppm] $\mathbf{3}^{2\ominus}-\mathbf{3}$
δ(2,5,7,10-H)	7.27	1.59	1.27	− 5.68	− 6.43
δ(3,4,8,9-H)	6.95	3.07	3.09	− 3.88	− 4.25

[a] Naphthalene is numbered unsystematically in accordance with **1**.

The protons in the methano bridge of the dianion $\mathbf{1}^{2\ominus}$ are shifted about 12 ppm downfield compared with those of **1**, whereas the perimeter protons are strongly shielded.

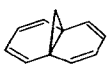
[**] This work was supported by the Fonds der Chemischen Industrie.

Assignment of the signals was only possible by means of a two-dimensional COSY experiment,[9] since cross peaks between scalar-coupled protons appear even when, as in this case, the coupling in the 1D NMR spectrum is not resolved.[10] To determine the long-range coupling between the protons in the bridge and those at C-2,5,7,10, which is crucial for signal assignment, the successful pulse sequence with a fixed time interval (50 ms in this case) before and after the second 90° pulse was employed.[9b] As shown in Figure 1b, there is a cross peak between the 11-H signal and the high-field signal at $\delta = 1.59$, which is therefore assigned to the perimeter protons 2,5,7,10-H in α-positions.

High-field shifts are also observed for the ^{13}C resonances of C-2,5,7,10 and C-3,4,8,9, whereas C-11 and C-1,6 are strongly deshielded. The signal assignment in this case was achieved via a 2D $^{13}C,^{1}H$ shift correlation,[11] the results of which were corroborated by the multiplicities in the ^{1}H-coupled ^{13}C NMR spectrum (Fig. 1c).

Whereas the low-field shift of the C-11 signal can be ascribed in part to a paramagnetic ring-current effect,[12] the strong deshielding of C-1,6 must be due to a partial positive charge at these positions in the dianion. Positive charges at bridgehead positions have also been found for the dianions of bridged [14]annulenes.[3] This finding, along with the other NMR parameters of $\mathbf{1}^{2\ominus}$, shows striking parallels to the data of $\mathbf{3}^{2\ominus}$, so that the two systems presumably have very similar charge distributions. This is also expected in terms of HMO theory, since the lowest unoccupied π molecular orbitals of **1** and **3**, which are essentially responsible for the charge distribution in the dianions, are practically identical.[5, 13]

The $^{1}J(^{13}C,^{1}H)$ coupling at C-11 (136 Hz), which is appreciably smaller than the corresponding coupling in **1** (142 Hz),[6] as well as the low-field position of the C-1,6 resonance, prove, moreover, that $\mathbf{1}^{2\ominus}$ cannot be formulated as the dianion of the bisnorcaradiene **5**.[12, 14] As in



5

the case of naphthalene,[5, 15] reduction of **1** to the dianion should lead to an increase in the distance between the quaternary C atoms. Further, the unresolved $^{3}J(^{1}H,^{1}H)$ coupling between 2-H and 3-H[16] indicates that $\mathbf{1}^{2\ominus}$, like **4**,[8] is strongly distorted from planarity owing to folding of the C2–C5 and C7–C10 fragments.

The chemical structural proof of $\mathbf{1}^{2\ominus}$ is based on the oxidation by air, which affords the hydrocarbon **1** in 88% yield. Dianion $\mathbf{1}^{2\ominus}$ exhibits remarkable thermal stability. At room temperature, the ^{1}H NMR signals disappear only after about 20 h, that is, when the solvent THF undergoes partial decomposition by reaction with residual lithium metal.

Titanium(0) Arene Complexes: Synthesis and X-ray Crystal Structure of $[(\eta^6\text{-}C_{10}H_8)Ti\{t\text{BuSi}(CH_2PMe_2)_3\}]$**

By *Thomas G. Gardner* and *Gregory S. Girolami**

Arene complexes of titanium are exceedingly uncommon, and only two principal classes of such species are known: titanium(II) complexes of stoichiometry $[(arene)TiX_2]$[1–4] and titanium(0) sandwich complexes $[(arene)_2Ti^0]$.[5–8] The sandwich compounds are important examples of molecules that, at present, can best be made by metal-vapor techniques, although it has been postulated that reductive carbonylation of titanium halides by naphthalenesodium yields titanium(0) naphthalene intermediates that subsequently undergo irreversible substitution by carbon monoxide.[9] We wish to report here the isolation, characterization, and X-ray crystal structure of the unique titanium(0) naphthalene complex $[(\eta^6\text{-}C_{10}H_8)Ti(trimpsi)]$ **1**, where trimpsi is the tripod phosphane $t\text{BuSi}(CH_2PMe_2)_3$. This 16-electron species exhibits a folding of the naphthalene ring that is indicative of partial diene–diyl bonding and strong metal-to-ligand δ backbonding.

Reductive carbonylation of $[TiCl_3(trimpsi)(thf)]$ by naphthalenesodium gives the titanium(0) carbonyl $[(trimpsi)Ti(CO)_4]$.[10] In the absence of carbon monoxide, the reduction results in a deep red-purple solution in tetrahydrofuran, from which the naphthalene complex $[(\eta^6\text{-}C_{10}H_8)Ti(trimpsi)]$ **1** may be obtained.

$$[TiCl_3(trimpsi)(thf)] + 3\,C_{10}H_8Na \longrightarrow [(\eta^6\text{-}C_{10}H_8)Ti(trimpsi)] + 3\,NaCl + 2\,C_{10}H_8$$

1

Compound **1** is a deep red-purple crystalline solid which is very air-sensitive, but thermally stable at room temperature in solution or as a solid. Unlike the known

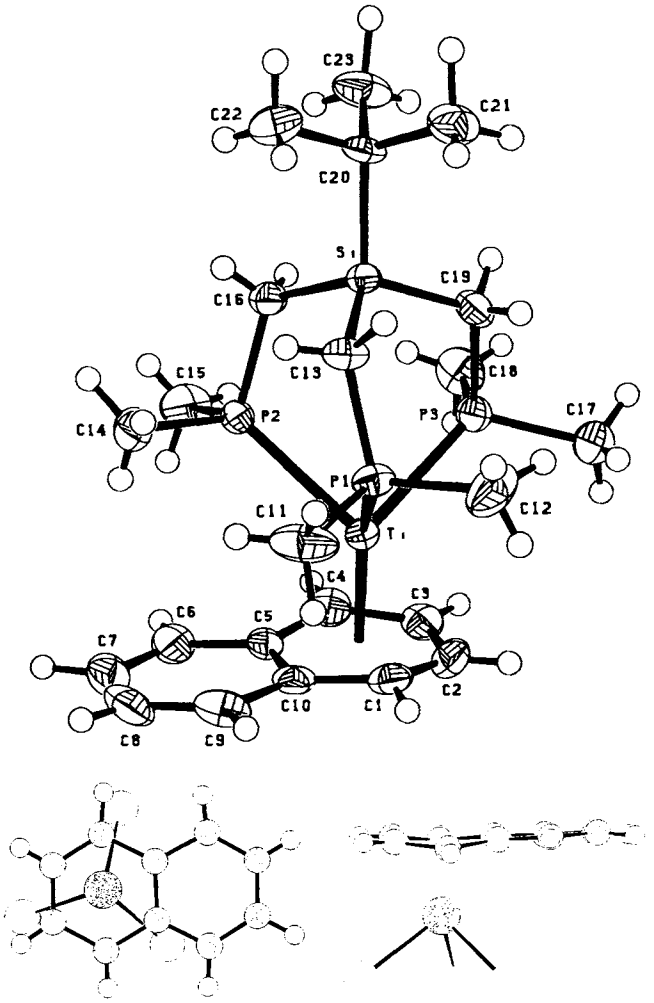

Fig. 1. Top: Molecular structure of $[(\eta^6\text{-}C_{10}H_8)Ti(trimpsi)]$ **1**. Important bond distances [Å] and angles [°]: Ti-P1 2.532(2), Ti-P2 2.552(2), Ti-P3 2.523(2), Ti-C^n 1.833(1), Ti-C1 2.236(7), Ti-C2 2.303(8), Ti-C3 2.296(8), Ti-C4 2.244(7), Ti-C5 2.417(6), Ti-C10 2.390(7), Ti···Si 3.921(2), C1-C2 1.39(1), C2-C3 1.37(1), C3-C4 1.45(1), C4-C5 1.43(1), C5-C10 1.424(9), C5-C6 1.41(1), C6-C7 1.36(1), C7-C8 1.35(1), C8-C9 1.37(1), C9-C10 1.44(1), C10-C1 1.44(1); P1-Ti-P2 86.73(6), P1-Ti-P3 88.03(7), P2-Ti-P3 88.30(6), Si···Ti-C^n 177.73, P1-Ti-C^n 128.98(6), P2-Ti-C^n 124.64(6), P3-Ti-C^n 126.97(7). Bottom left: Relative orientation of the phosphane and naphthalene ligands. Important torsion angles [°]: P1-Ti-C^n-C1 16.1(6), P2-Ti-C^n-C5 13.3(5), P3-Ti-C^n-C3 10.1(6). Bottom right: Edge-on view of the conformation of the naphthalene ligand. The coordinated ring is folded 12.4° from planarity. For clarity, only the phosphorus atoms of the trimpsi ligand have been included.

bis-arene titanium(0) complexes,[5] compound **1** is apparently paramagnetic and no peaks ascribable to coordinated naphthalene or trimpsi were present in ^{1}H NMR spectra in $[D_{14}]$methylcyclohexane or other solvents under a variety of conditions. Treatment of **1** with CO rapidly yields the previously described[10] titanium(0) tetracarbonyl [(trimpsi)Ti(CO)$_4$].

The molecular structure of **1** is shown in Figure 1.[11] The overall geometry can be described as a three-leg piano stool, with the P-Ti-P angles being essentially equal and averaging 87.7°. A view down the Ti···Si vector (Fig. 1, bottom left) shows the orientation of the three phosphane ligands in relation to the naphthalene ring. The mean P-Ti-C^n-C torsion angle (C^n = centroid) is 13(1)°, which is about halfway between an eclipsed and a staggered conformation. Interestingly, a similar twist of 19(1)° is seen in $[(\eta^6\text{-naphthalene})Cr(CO)_3]$,[12] whereas the related complexes $[(\eta^6\text{-anthracene})Cr(CO)_3]$ and $[(\eta^6\text{-phenanthrene})Cr(CO)_3]$ are rigorously staggered with torsion angles of 30°.[13,14]

Figure 1, bottom right, shows an edge-on view of the naphthalene ligand. The coordinated naphthalene ring is folded about the C1-C4 vector with a dihedral angle of 12.4°. The noncomplexed ring, by comparison, is accurately planar. The folding of the π-bound ring causes the Ti-C distances to fall into three groups: C1 and C4 are closest at a mean Ti-C distance of 2.24(1) Å and C2 and C3 are at a medium distance of 2.30(1) Å, while C5 and C10 are most distant at 2.40(1) Å. This contrasts sharply with the structure of $[(C_6H_6)_2Ti]$, which has planar benzene rings and essentially equal Ti-C distances of 2.217-2.247(8) Å.[8] It is not uncommon for fused-ring arene ligands to have unequal M-C distances, with the longest being to the shared C-C bond; examples of this are seen in $[(naphthalene)Cr(CO)_3]$, $[(anthracene)Cr(CO)_3]$, and $[(phenanthrene)Cr(CO)_3]$; however, the π-bound rings in these chromium complexes are not deformed from planarity.[12-14] The bis-arene complex $[(\eta^6\text{-naphthalene})_2Cr]$ also possesses essentially planar naphthalene rings.[15]

The folding of the naphthalene ring can be thought of in terms of partial diene-diyl bonding character. This is consistent with strong metal-to-ligand δ back-bonding[16] from a filled Ti $d_{x^2-y^2}$ orbital into the LUMO of naphthalene, a B_{2g} orbital[17] that has large contributions from C1 and C4, smaller contributions from C2 and C3, and no contribution from C5 or C10. In this context, it is interesting to note that the "σ" Ti-C1 and Ti-C4 distances are comparable to that of 2.217(2) Å in the titanium *alkyl* complex $[TiMe_2(dmpe)_2]$.[18] The strong donor ability of the (trimpsi)Ti unit has been previously established from the low $\tilde{\nu}_{CO}$ IR stretching frequencies and strongly deshielded ^{13}C chemical shifts of $[Ti(CO)_4(trimpsi)]$.[10] The strong metal-to-ligand back-bonding and diene-diyl distortion of the arene ring is similar to the bonding in several electron-rich butadiene complexes of group 4 elements, in which an ene-diyl bonding mode is observed.[19,20] The dihedral angle of 12.4° in **1** is much smaller than the dihedral angles of 25° to 43° in authentic η^4-arene complexes of early-transition-metals, in which hexahapto coordination would exceed an 18-electron configuration.[21,22] Interestingly, a dihedral angle of 14.5° was noted in the X-ray crystal structure of the naphthalene dianion in $[Li(tmeda)]_2C_{10}H_8$ (tmeda = *N,N,N',N'*-tetramethylethylenediamine).[23] The folding of the naphthalene ring in **1** is not the result of steric repulsions with the methyl groups of the phosphane ligand: the closest van der Waals contact between the trimpsi ligand and the free ring of the naphthalene ligand is 3.04 Å (H14b···C7).

The average Ti-P distance of 2.536 Å in **1** is close to the 2.545-2.633-Å range observed for titanium(0) phosphane carbonyls (e.g., $[Ti(CO)_4(trimpsi)]$,[10] $[Ti(CO)_3(dmpe)_2]$,[24] and $[Ti(CO)_2(PF_3)(dmpe)_2]$[25]); in fact, all titanium-phosphane distances fall in the range 2.58 ± 0.07 Å, irrespective of oxidation state, spin state, or coordination number. The Ti-C^n distance of 1.833(1) Å is slightly longer than in $[(C_6H_6)_2Ti]$ (1.736 Å),[8] and the Si···Ti-C^n angle of 177.7° is essentially linear.

The complex $[(\eta^6\text{-}C_{10}H_8)Ti(trimpsi)]$ **1** has been shown to possess unusually strong metal-to-ligand back bonding into a naphthalene δ-acceptor orbital that causes a folding of the naphthalene ring. Additionally, **1** is a useful intermediate in the synthesis of other titanium(0) complexes such as $[Ti(CO)_4(trimpsi)]$.

Experimental Procedure

To a stirred solution of [$TiCl_3$(trimpsi)(thf)] (3.90 g, 7.27 mmol) in tetrahydrofuran (50 mL) at −78 °C was added naphthalenesodium (150 mL, 0.145 M in THF, 21.8 mmol). A red-purple solution formed immediately. The solution was warmed to room temperature slowly, and the solvent was removed in vacuum. The excess naphthalene was removed by sublimation in vacuum at 25 °C. The dark purple residue was extracted with diethyl ether (5 × 200 mL), and the combined extracts were concentrated to 200 mL and cooled to −20 °C to give dark purple crystals of **1**. Yield: 1.4 g (40%); m.p. 196–204 °C. Correct elemental analysis (C,H,Ti).

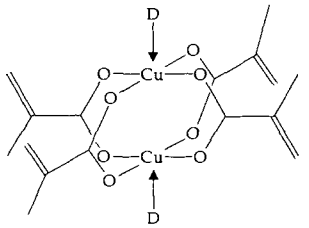
Metal-Ion-Selective Exchange Resins by Matrix Imprint with Methacrylates

By *Wilhelm Kuchen** and *Jürgen Schram*

Various attempts have been made to increase the ion selectivity of exchange resins by carrying out cross-linking polymerization of monomeric or oligomeric complex-forming compounds in the presence of metal ions. A template effect should lead to preferential binding of the respective ions by the resin.[1] Similar results have already been achieved for the separation of racemates on polymers having chiral cavities.[2]

We have now succeeded in increasing the selectivity by cross-linking copolymerization of well-defined metal complexes containing polymerizable ligands. According to our concept, removal of the metal ions from the resin with suitable eluants should leave the arrangement of binding groups intact, which are thus tailored for subsequent binding of the type of ion used to prepare the resin.[3]

Herein we report on the application of this principle to copper(II) methacrylates $Cu_2L_4 \cdot 2D$, $L = H_2C{=}C(CH_3)CO_2^{\ominus}$ (**1**, $D = H_2O$; **2**, D = pyridine; **3**, D = 4-vinylpyridine (vpy)). The results we obtained with the complexes ML_2 ($M = Zn^{2\oplus}$, $Cd^{2\oplus}$, $Pb^{2\oplus}$) and $[M_4OL_6]$ ($M = Zn^{2\oplus}$, $Pb^{2\oplus}$) are discussed in Ref. [4a] and corresponding experiments with metal acrylates are described in Ref. [4b].



$Cu_2L_4 \cdot 2D$
1-3

The macroporous resins $\mathbf{1}_H$-$\mathbf{3}_H$ (specific surface ca. 400 m^2 g^{-1}), readily wetted by water, were prepared from the copper complexes **1**-**3** by radical polymerization (precipitation polymerization in an ampoule; initiator azodiisobutyronitrile, AIBN) in the presence of an inert solvent (porogen), in this case benzene/methanol, with ethylene glycol dimethacrylate (EGDMA) as cross-linking agent. After polymerization, the resins were ground, a suitable particle size was separated out (0.8–0.2 mm), and the solvent was completely removed by drying in vacuo. Small amounts of nonpolymerized components could be removed by washing with methanol.

For comparison, we similarly prepared the "blind resins" $\mathbf{1}_B$ and $\mathbf{3}_B$, which contain the same number of polymerizable ligands (introduced into the reaction as ammonium salts NH_4L and as a mixture of NH_4L and vpy, respectively), whose distribution in the matrix, however, is purely random.

The electronic excitation spectra (measured in reemission) of the green or blue copper-containing resins do not differ significantly from the spectra of the corresponding complexes **1**-**3**. Therefore, it is safe to assume that the arrangements of the ligands around $Cu^{2\oplus}$ in the starting complexes **1**-**3** and in the resins $\mathbf{1}_H$-$\mathbf{3}_H$ are the same. To investigate the exchange behavior of the resins, they were first converted into the ammonium form by treatment with an NH_3/NH_4Cl solution (1 M in both components); in this way, all metal ions accessible to the eluant were removed from the resin as their ammine complexes (ca. 60–70% of the metal ions used in preparing the resin).

The effective loading capacity—that is, the maximum amount of metal ion that a specified amount of resin can carry under given conditions—was then determined by the batch procedure (shaking the resin with a solution of the metal salt).

Comparison of the values in Table 1 shows that the copper-imprinted resins $\mathbf{1}_H$-$\mathbf{3}_H$ exhibit an increased effective capacity for $Cu^{2\oplus}$. Upon loading, the resins bind ca. 30–40% of the amount of metal ion used in their preparation.

[*] Prof. Dr. W. Kuchen, Dr. J. Schram
Institut für Anorganische Chemie und Strukturchemie der Universität
Universitätsstrasse 1, D-4000 Düsseldorf 1 (FRG)

Table 1. Effective capacity [μmol/g resin] of "copper-imprinted" resins and of the corresponding blind resins with respect to various cations $M^{2\oplus}$. Determined by the batch procedure (25°C, 2.5 h), solution 4.08×10^{-3} M in $M^{2\oplus} \triangleq 200$ μmol $M^{2\oplus}$ per gram of resin, pH 4.7 (acetic acid/acetate buffer).

Resin	$Zn^{2\oplus}$	$Cd^{2\oplus}$	$Pb^{2\oplus}$	$Cu^{2\oplus}$
$\mathbf{1}_H$	10.3	7.4	15.5	45
$\mathbf{2}_H$	9.7	7.8	15.2	49
$\mathbf{1}_B$	4.6	4.6	16.5	12.5
$\mathbf{3}_H$	12.4	5.7	6.7	52
$\mathbf{3}_B$	3.2	4.1	12.6	30

Moreover, their capacity does not change after repeated cycles of loading and elution.

If the resins are simultaneously exposed to two kinds of metal ion in identical concentrations, one binds preferentially to the resin. The selectivity coefficients k[5] can be obtained from the equilibrium (a) according to Equation (b).

$$M1_{resin} + M2_{solution} \rightleftharpoons M2_{resin} + M1_{solution} \quad (a)$$

$$k = \frac{[M2]_{resin}[M1]_{solution}}{[M1]_{resin}[M2]_{solution}} \quad (b)$$

The blind resins $\mathbf{1}_B$ and $\mathbf{3}_B$ also exhibit a certain degree of metal-ion selectivity, owing to the different strengths of interaction of the metal ions with the randomly distributed binding groups, which are not arranged for specific metal binding. Thus, comparison of the k values of the imprinted resins with those of the blind resins allows a rough determination of the effect of imprinting on selectivity. As a measure of the selectivity due to imprinting, a relative selectivity coefficient k' [Eq. (c)] can be defined.

$$k' = \frac{k_{resin,\,imprinted}}{k_{blind\,resin}} \quad (c)$$

As shown in Table 2, $k' \gg 1$ for copper. Thus, the $Cu^{2\oplus}$ selectivity of the imprinted resins is markedly higher than that of the blind resins.

Table 2. Competitive loading of M1 ($Cu^{2\oplus}$) and M2 by copper-imprinted resins and blind resins. Batch procedure (25°C, 2.5 h), solution 2.04×10^{-3} M in M1 and M2 ≙ 100 μmol M1 and M2 per gram of resin, pH 4.7 (acetic acid/acetate buffer).

	Cd	23	2.8	10.4	—
	Pb	19	9.8	2.2	—

Although the effective capacity of the imprinted resins (not optimized in our experiments!) is still small, these resins are capable of selectively removing $Cu^{2\oplus}$ from very dilute solutions, as shown by the following experiment: With a column (300 mm × 14 mm) containing $\mathbf{3}_H$ (10 g), it was possible to remove ca. 70% of the copper ions from 25 L of a solution containing 2×10^{-5} M each of $Cu^{2\oplus}$, $Pb^{2\oplus}$, $Cd^{2\oplus}$, and $Zn^{2\oplus}$ at pH 4.8 (rate of elution 15 mL min^{-1}), whereas the other ions passed almost completely through the column. Further, this method allowed $Cu^{2\oplus}$ ions to be removed from waste water to below the limits of detection (differential pulse inverse voltammetry). The copper ions remained in a very narrow zone in the upper part of the column as revealed by the intense color of the upper column layer. Since the copper could be eluted from this zone with only a small amount of eluant, highly concentrated solutions could be obtained. The resins described here thus allow the removal and concentration of copper from highly dilute solutions.

Since, in the meantime, we have also succeeded in increasing considerably the selectivity of resins by using other metal complexes, the principle described here offers an interesting alternative procedure for preparing ion-selective exchange resins.

Experimental Procedure

Tetrakis(μ-methacrylato-*O*,*O*')bis[aquacopper(II)] **1** (M = 503.4): A mixture of basic copper carbonate (10.1 g, 45.2 mmol) and methacrylic acid (16.0 g, 186 mmol) in methanol (50 mL) was first stirred for 24 h at room temperature and then heated for 5 h at reflux. After addition of an additional 150 mL of methanol, the reaction mixture was heated for a short period to boiling and then filtered, and the filtrate was allowed to stand for ca. 12 h at −20°C. During this time, blue needles separated out; these were recrystallized from methanol. Yield 11 g (48%); decomposition at ca. 196–198°C; M = 483 (osmometry in methanol); $\mu_{eff} = 1.35\mu_B$ (298 K); λ_{max}(reemission) = 722, 364 nm.

2 and **3**: **1** (10.0 g, 19.9 mmol) in methanol (200 mL) was allowed to react at reflux with pyridine (4.0 g, 50.0 mmol) or with 4-vinylpyridine (5.2 g, 50.0 mmol). The product, which precipitated within ca. 12 h at −20°C, was recrystallized from benzene.

Tetrakis(μ-methacrylato-*O*,*O*')bis[(pyridine)copper(II)] **2** (M = 625.6): 9.6 g green needles (77%); decomposition at ca. 183–184°C; M = 614 (osmometry in benzene); $\mu_{eff} = 1.39\mu_B$ (298 K); λ_{max}(reemission) = 749, 384 nm.

Tetrakis(μ-methacrylato-*O*,*O*')bis[(4-vinylpyridine)copper(II)] **3** (M = 677.7): 9.9 g green needles (73%); decomposition at ca. 187–189°C; M = 689 (osmometry in benzene). $\mu_{eff} = 1.45\mu_B$ (298 K); λ_{max}(reemission) = 746, 386 nm.

A crystal structure analysis of **3** was carried out [6a, b]. The resins were prepared according to the method given in [2b] (see Table 3).

Table 3. Composition of the polymerization mixtures [a].

Resin	Imprinting complex [g]	Solvent [g]	
		MeOH	Benzene
$\mathbf{1}_H$	1.485 **1**	20	20
$\mathbf{2}_H$	1.846 **2**	—	40
$\mathbf{1}_B$	1.217 NH_4L	20	20
$\mathbf{3}_H$	2.000 **3**	—	40
$\mathbf{3}_B$	1.217/0.615 NH_4L/vpy	20	20

[a] In each case, 40 g of EGDMA was used as cross-linking agent and 0.200 g of AIBN as initiator.

Protecting-Group-Dependent Stability of Intersaccharide Bonds— Synthesis of a Fucosyl-Chitobiose Glycopeptide**

By *Horst Kunz** and *Carlo Unverzagt*

Tumor cells exhibit an increased metabolism of fucose compared with normal cells and, as a consequence, a higher degree of fucosylation of their cell-membrane glycoproteins.[1] Glycoproteins fucosylated on the oligosaccharide side chains are therefore of interest as potential tumor-associated cell-membrane antigens.[2] A characteristic coupling site for the fucose residue in *N*-glycoproteins is O-6 of the asparagine-linked glucosamine unit of the chitobiose portion of the core region (structure **1**). We report here the synthesis of glycopeptides that contain structural element **1** and are partial sequences of a viral envelope protein.

GlcNAcβ1→4GlcNAcβ1→Asn

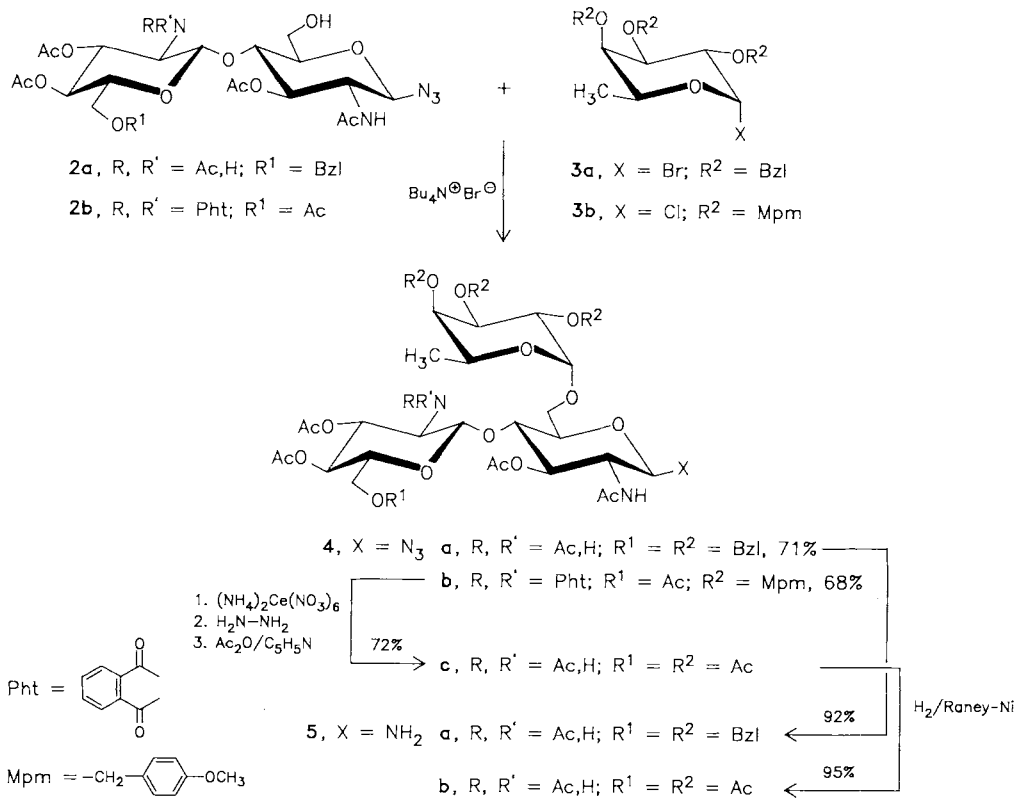
↑
Fucα1 **1**

To construct the fucosyl-chitobiose trisaccharide unit **1**, the fucosyl donor **3** is linked in an α-glycosidic fashion by the in-situ anomerization procedure,[3] to chitobiosyl azide **2**,[4] containing a free hydroxyl group at position 6. Here, the fucosyl donor **3** must be protected by non-neighboring-group-participating blocking functions (Scheme 1).

The coupling is carried out most easily with the benzyl-protected fucosyl bromide **3a**. The usual hydrogenation on platinum catalysts[5] cannot be used to reduce the azido function of the trisaccharide azide **4a** so obtained, since it would result in cleavage of the benzyl ether bonds. We achieved a selective hydrogenation to give the trisaccharide **5a** by using neutral (!) washed Raney nickel.

To synthesize the protected fucosylated chitobiosylasparagine building block **7a** (see Scheme 2), **5a** was linked, in the presence of ethyl 2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ),[6] to *N*-allyloxycarbonyl(Aloc)aspartic acid *tert*-butyl ester.[7]

The Aloc group can be removed from the complex trisaccharide-asparagine conjugate in a selective and practically quantitative fashion by palladium(0)-catalyzed allyl group transfer to dimedone as weakly basic acceptor.[7] In this process, all other protecting groups, as well as the *O*- and *N*-glycosidic bonds, remain completely intact. Subsequent condensation of the selectively deprotected trisaccharide-asparagine ester **8a** with the *N*-protected dipeptide **9** affords the fully protected trisaccharide-tripeptide **11a**, a partial structure of turkey ovomucoid.[8] Upon attempted selective cleavage of the *tert*-butyl ester bond of **11a** with



Scheme 1. Synthesis of the fucosyl-chitobiose trisaccharide unit in **1**. Bzl = Ph–CH_2.

trifluoroacetic acid for later immunological evaluation, complete cleavage of the fucoside bond occurred.

This discouraging result, obtained at the end of the multistep synthesis, reveals the inherent sensitivity of complex

glycopeptides and shows what problems have to be foreseen and taken into consideration, even at the planning stage, in attempting the synthesis of complex glycoconjugates. We ascribe the sensitivity of the fucoside bond to the ether-type protecting groups in this monosaccharide building block.

We therefore developed a new concept for the synthesis of fucosyl-chitobiose asparagine derivatives of type **1**, which makes accessible compounds containing exclusively acyl (preferentially acyl = acetyl) protecting groups in the saccharide portion. To link the fucose in an α-glycosidic fashion to the chitobiosyl azide **2b**, the (*p*-methoxyphenyl)methyl(Mpm)-protected fucosyl donor **3b**[10] is employed according to the in-situ anomerization principle[4] (see Scheme 1). By oxidation with ammonium ceric nitrate,[9] the Mpm groups can be removed selectively from the trisaccharide azide **4b**. Subsequent hydrazinolysis removes the Pht group. The functional groups liberated in these reactions are then acetylated. The azide **4c** thus obtained in good yields is reduced to the corresponding trisaccharide amine **5b**, as already discussed for **4a**. Condensation with **6** gives the trisaccharide-asparagine conjugate **7b**, which bears exclusively acetyl protecting groups in the carbohydrate portion (Scheme 2).

Pd^0-catalyzed cleavage removes the Aloc group, again in a selective and effective fashion, from the product of this multistep synthesis, **7b**. Reaction of the *N*-deprotected trisaccharide-asparagine ester **8b** with the Aloc-dipeptide **10** gives, in high yield, the trisaccharide tripeptide **11b**. This glycoconjugate, in turn, is treated with trifluoroacetic acid for the subsequent *C*-terminal chain extension or for binding to a carrier. This cleavage of the *tert*-butyl ester bond is complete after 2 h at room temperature, without accompanying cleavage of the α-fucoside bond. The selectively *C*-terminal-deprotected trisaccharide tripeptide **12** is isolated in practically quantitative yield.

The fucoside bond is markedly more labile toward acid than the corresponding galactoside bond.[12] The contrasting behavior of the trisaccharide tripeptides **11a** and **11b** toward trifluoroacetic acid clearly reveals a strong effect of the *O*-protecting groups in the fucose portion on the acid stability of this bond. We ascribe the stabilizing effect of the *O*-acetyl groups in **11b** on the intersaccharide bond to the fact that the carbonyl oxygen atoms of the acyl protecting groups in this and in analogous glycoconjugates are protonated. Coulomb repulsion hinders further protonation of the intersaccharide and the ring oxygen atoms and therefore prevents saccharide cleavage. Thus, the acetyl groups not only protect the hydroxyl functions of the fucose residue but also protect an especially sensitive structural element to which they are not directly bonded: the intersaccharide bond. This effect is of great practical im-

portance for developing and carrying out syntheses of such complex, sensitive glycopeptides, since it defines the conditions under which the efficient *tert*-butyl protecting groups can be employed in the synthesis of polyfunctional glycoconjugates. It also explains the observed stability of serine and threonine glycopeptides[13] and the remarkable stability of the intersaccharide bond in chitobiosyl *N*-glycopeptides, even toward strong acids.[14]

The *C*-terminal-deprotected glycopeptide **12** was linked with the tripeptide ester **13** to give the trisaccharide hexapeptide **14**.[15] Compound **14** is the first fucose-containing trisaccharide glycopeptide to be obtained by both *N*- and *C*-terminal deprotection and corresponds to a partial structure of the linking region of the envelope protein of a leukemia virus.[16]

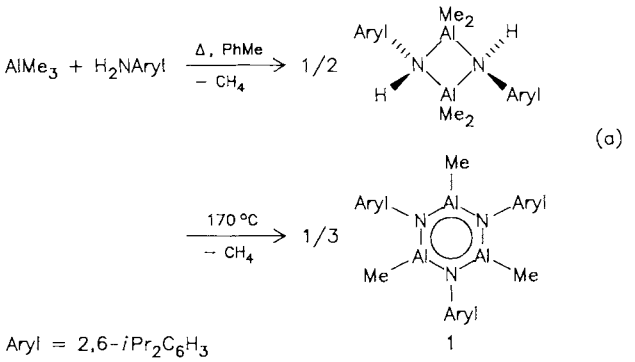
Synthesis and Structure of [MeAlN(2,6-*i*Pr$_2$C$_6$H$_3$)]$_3$: An Aluminum-Nitrogen Analogue of Borazine**

By *Krista M. Waggoner, Håkon Hope* and *Philip P. Power**

The poly(*N*-alkyliminoalanes), $(RAlNR')_n$, constitute an interesting class of aluminum-nitrogen compounds.[1] They are most notable for the variety and novelty of structures that they can adopt. Typically these are of a three-dimensional type involving an Al–N framework wherein both the Al and N atoms are four coordinate. The simplest structure involves a regular Al_4N_4 cubane framework as in $(PhAlNPh)_4$.[2] However, $(RAlNR')_n$ compounds with higher degrees of aggregation, up to n = 16, have been reported and the structures are known for such compounds where n = 4, 6, 7, 8, and R and R' = a variety of alkyl, aryl and hydrogen substituents.[1] To date, however, no aggregates involving n values less than 4 have been described. The lower $(RAlNR')_n$ compounds, where n = 1, 2 or 3 are of interest because they imply the presence of Al–N multiple bonds, as in the monomer RAlNR', or the potentially aromatic ring systems such as $(RAlNR')_3$. We now report the first example of a trimeric iminoalane. This is the title compound [MeAlN(2,6-*i*Pr$_2$C$_6$H$_3$)]$_3$ **1** which has been characterized by X-ray crystallography and ^1H- and ^{27}Al-NMR spectroscopy.

The compound **1** was synthesized, in high yield, as colorless crystals via a two stage elimination reaction between $AlMe_3$ and 2,6-*i*Pr$_2$C$_6$H$_3$NH$_2$ [Eq. (a)].



The crystal structure of **1**[3] is illustrated in Figure 1. It consists of a central planar six-membered ring of alternating Al and N atoms with an average Al–N bond length of 1.78 Å. The C atoms bonded to Al or N are coplanar with

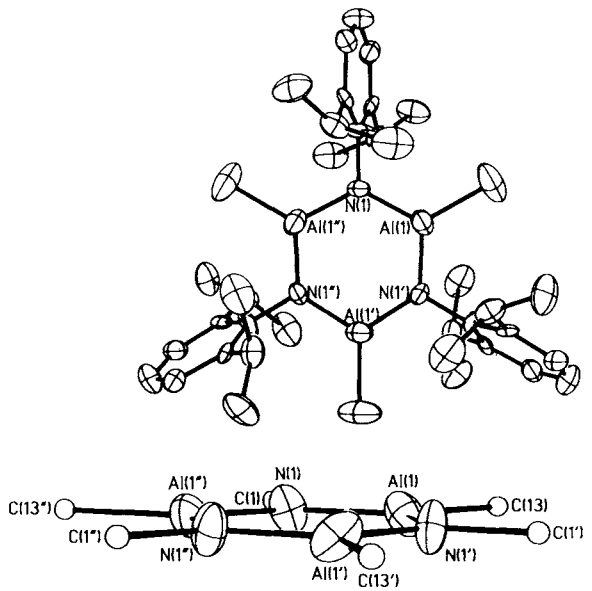


Fig. 1. Two views of the crystal structure of one of the molecules of **1** (H atoms omitted for clarity). Selected bond distances [Å] and angles [°]. Al(1)–N(1) 1.782(4), Al(1)–C(13) 1.978(15), N(1)–C(1) 1.442(14); N(1)–Al(1)–N(1') 115.3(5), Al(1)–N(1)–Al(1') 124.7(5). The dihedral angle between the Al_3N_3 and C(1) rings is 75.2°.

Department of Chemistry, University of California
Davis, California 95616 (USA)

[**] This work was supported by the National Science Foundation. We also thank *R. A. Bartlett* and Dr. *M. M. Olmstead* for helpful discussions and experimental assistance.

the central ring. The Al–N distance may be compared with the Al–N bond lengths found in the higher polyiminoalanes which generally range from 1.89–1.96 Å.[1] Since the latter distances invariably involve four-coordinate Al and N centers, a bond-shortening is to be expected in the case of **1**. Unfortunately, very few compounds with bonding between three-coordinate aluminum and nitrogen centers are available for comparison. An exception is $Al[N(SiMe_3)_2]_3$,[4] which was reported to have an Al–N bond length of 1.78 Å. Clearly more structural data regarding Al–N bonding will be needed to assess more accurately the amount of bond-shortening in **1**.

The ^{1}H-NMR spectrum of **1** confirms the X-ray crystallographically determined composition, since the ratio of Al–Me groups to aryl groups is 1 : 1. The ^{27}Al-NMR spectrum reveals a broad singlet at $\delta = 168$ ($\nu_{1/2} = 8800$ Hz), which is shifted slightly downfield compared to the signals generally observed for three-dimensional polyiminoalanes.[5] These ^{27}Al-NMR data are consistent with the lower coordination number and the asymmetry of the aluminum center in **1**.

The title compound **1** bears an obvious isoelectronic resemblance to the recently synthesized boraphosphabenzenes $(RBPR')_3$.[6,7] It is notable, however, that the Al–N bonds are considerably shorter than the B–P (1.84 Å) distances. The much greater ionic character of the Al–N pair may account for part of this difference. It is also noteworthy that **1** is an aluminum counterpart of a substituted borazine.[8] However, **1** appears to be much more reactive and is instantly decomposed by traces of air or moisture.

Although the equivalence and shortness of the Al–N bonds support delocalization, the possible aromatic nature of **1** remains an open question. In the case of the related B_3P_3 rings there is some ^{1}H NMR spectroscopic evidence which supports the presence of a ring current.[7] The ^{1}H-NMR spectrum of **1**, however, appears to display no unusual shifts which could be attributed to a ring current. Preliminary calculations[9] on both the B_3P_3 and Al_3N_3 rings indicate extensive delocalization. However, more firm conclusions await the synthesis and characterization of a range of Al_3N_3 ring systems.

Experimental Procedure

A 2.0 M solution of $AlMe_3$ (13 mL, 26 mmol) in toluene was added dropwise, under anaerobic and anhydrous conditions, to a solution of 2,6-diisopropylaniline (4.9 mL, 26 mmol) in toluene (50 mL) at room temperature. The mixture was then heated under reflux for 20 h. Concentration under reduced pressure to ca. 20 mL afforded colorless crystals of $[Me_2AlNH(2,6\text{-}iPr_2C_6H_3)]_2$ (yield: 4.8 g, 10.3 mmol, 79%; m.p. = 135 °C). Heating $[Me_2AlNH(2,6\text{-}iPr_2C_6H_3)]_2$ at 170 °C resulted in frothing due to evolution of CH_4. After ca. 10 minutes gas evolution ceased and the reaction mixture resolidified to give **1** in essentially quantitative yield; m.p. = 272 °C. Crystals for X-ray structural characterization were grown from hexane. 300 MHz ^{1}H-NMR (C_6D_6): $\delta = 6.94$ (m; aryl-H), 3.38 (sept.; CH), 1.18 (d, $J = 9$ Hz; $CH(CH_3)_2$), −0.38 (Al–CH_3).

Novel Anionic Aryl Complexes of Rh^{III}: $[Rh(C_6F_5)_5]^{2\ominus}$ and $[Rh(C_6F_5)_4(CO)_2]^{\ominus}$**

By *María P. García,* Luis A. Oro,* and *Fernando J. Lahoz*

Anionic transition-metal complexes have received considerable attention due to their reactivity towards organic molecules as well as their utility in the preparation of homo- and heteronuclear transition-metal clusters.[1,2] Compounds containing π-acceptor ligands such as PR_3, $P(OR)_3$, and AsR_3 are the most numerous and the most stable of all alkyl and aryl complexes of transition metals. As far as we know, it has been possible to prepare rhodium complexes containing exclusively one, two, or three aryl or alkyl groups by transmetalation reactions (for instance, $[RhMe_3(PMe_3)_3]$[3]). When the starting compounds do not contain ancillary π-acceptor ligands, the arylation can progress even to the formation of anionic transition-metal complexes.[4] Although the pentahaloaryl complexes are more stable than their unsubstituted aryl analogues, complexes with this sort of group are rather scarce.[5]

These considerations prompted us to study the arylation of rhodium compounds without group V ligands by reaction with an excess of LiC_6F_5, in order to obtain anionic aryl derivatives.

Reaction of **1** with an excess of LiC_6F_5 (ratio 1 : 8) leads to a solution containing the arylated anion $[Rh(C_6F_5)_5]^{2\ominus}$, which can be crystallized as **2** by addition of a salt of a bulky cation. Complex **2**, the first anionic homoleptic

$$[RhCl_3(SC_4H_8)_3] + 5\,LiC_6F_5 \xrightarrow[-3\,SC_4H_8]{-3\,LiCl} Li_2[Rh(C_6F_5)_5]$$

1

$$\xrightarrow[-2\,LiCl]{2[P(CH_2Ph)Ph_3]Cl} [P(CH_2Ph)Ph_3]_2[Rh(C_6F_5)_5]$$

2

Rh^{III} complex, does not react with PPh_3, pyridine, or $P(OMe)_3$; it reacts immediately with CO in CH_2Cl_2, at room temperature, giving a pale yellow solution ($\tilde{\nu}(CO) = 2065$ cm^{-1}). The spectroscopic data (IR and ^{19}F NMR) of the solid obtained after workup indicate that it is a mixture of compound **2** and a new product, presumably **3** (^{19}F NMR

$[P(CH_2Ph)Ph_3]_2[Rh(C_6F_5)_5(CO)]$ **3**

spectrum in [D$_6$]acetone, new signals at $\delta = -105.7$ (*o*-F), -167.9 (*m*- and *p*-F)). This compound is probably an intermediate of a carbonylation process, since prolonged treatment of **2** with CO, in CH_2Cl_2 (or THF) at refluxing tem-

[**] This work was supported by C.A.I.C.Y.T. (Spain).

perature, leads to a new species with a CO stretching frequency at 2100 cm^{-1}. The solution becomes colorless and the white crystalline solid obtained was identified as **4**. A similar carbonylation reaction has been reported by *Foster* et al.[6] for $[RhBr_5(CO)]^{2\ominus}$.

trans-$[P(CH_2Ph)Ph_3][Rh(C_6F_5)_4(CO)_2]$ **4**

Surprisingly, complex **4** (being a Rh^{III} derivative) can be prepared by arylation of a Rh^{I} compound, $[RhCl(CO)_2]_2$, with LiC_6F_5 in the presence of BrC_6F_5 (see *Experimental Procedure*). If BrC_6F_5 is not present, the reaction gives an oily mixture from which we have not been able to isolate any solid product. Since $[RhCl(CO)_2]_2$ does not react with BrC_6F_5 under the same reaction conditions, the formation of the anion of **4** probably takes place through an intermediate anion *cis*-$[RhR_2(CO)_2]^{\ominus}$[6] followed by oxidative addition of BrC_6F_5 to the Rh^{I} species; finally, by further reaction with LiC_6F_5, the bromine atom is replaced by a C_6F_5 group.

The arylation of $[RhCl(CO)(PPh_3)]_2$ with LiC_6F_5 produces yellow crystals identified as the rhodium(I) complex **5**. The structures of compounds **2** and **4**, determined by

trans-$[Rh(C_6F_5)(CO)(PPh_3)_2]$ **5**

single-crystal X-ray diffraction studies[7] are shown in Figures 1 and 2, respectively. In the solid state, the anion of **2**, $[Rh(C_6F_5)_5]^{2\ominus}$, has a square-pyramidal geometric arrangement with the rhodium atom slightly above (0.222(3) Å) the plane of the four basal C_6F_5 groups, while in solution, at room temperature, the ^{19}F NMR shows that all the C_6F_5 groups are equivalent. The anion $[Rh(C_6F_5)_4(CO)_2]^{\ominus}$ exhibits a clear octahedral structure with the CO groups in mutually *trans* positions. Interestingly, both Rh–CO distances are 1.93(1) Å, slightly longer than those reported in the structurally related complex $[RhI_4(CO)_2]^{\ominus}$.[6]

All the complexes prepared are solids which can be handled in air or in solution for long periods without evident decomposition.

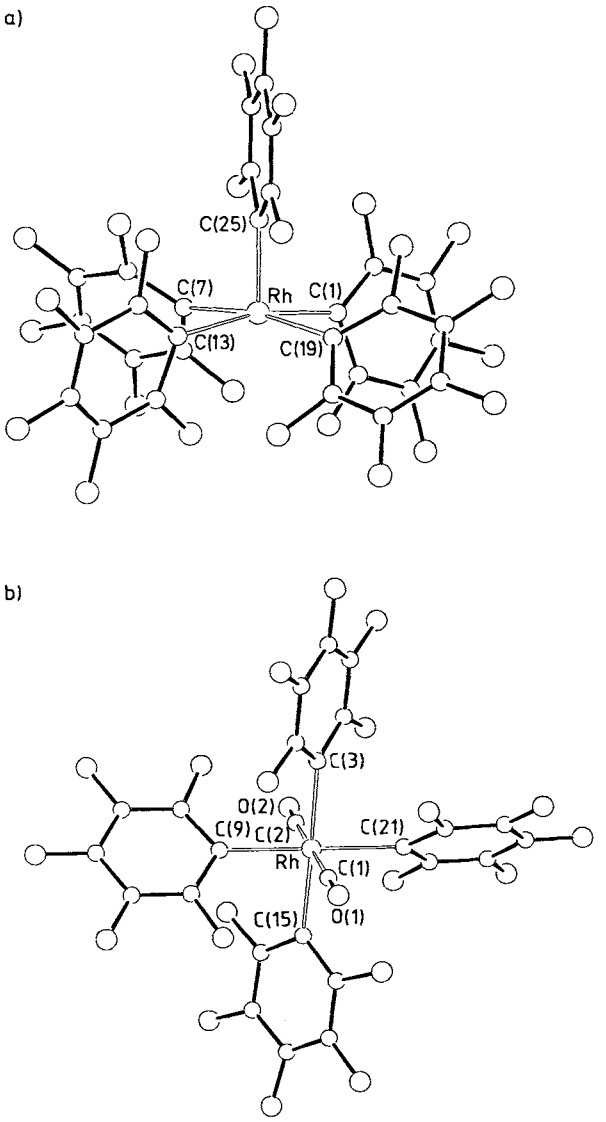

Fig. 1. Molecular structures of the anions of **2** and **4**. Selected bond lengths [Å] and angles [°]: a) **2**: Rh-C(1) 2.13(1), Rh-C(7) 2.12(1), Rh-C(13) 2.09(1), Rh-C(19) 2.12(1), Rh-C(25) 1.97(1); C(1)-Rh-C(7) 95.7(4), C(1)-Rh-C(13) 166.8(4), C(1)-Rh-C(25) 97.3(4). b) **4**: Rh-C(1) 1.93(1), Rh-C(2) 1.93(1), Rh-C(3) 2.12(1), Rh-C(9) 2.13(1), Rh-C(15) 2.13(1), Rh-C(21) 2.12(1); C(1)-Rh-C(2) 179.3(4), C(3)-Rh-C(15) 178.1(4), C(9)-Rh-C(21) 179.3(4).

Experimental Procedure

1: A suspension of commercial $RhCl_3 \cdot x H_2O$ (0.5 g) in $CHCl_3$ (10 mL) was treated with SC_4H_8 (1 mL) and 96% ethanol (20 mL). The mixture was stirred for two days at room temperature. A yellow-orange suspension was formed. Partial evaporation of the solvent and addition of diethyl ether gave a yellow-orange solid in almost quantitative yield. Correct elemental analysis for **1**.

2: To a solution of LiC_6F_5 (1.47 g, 8.44 mmol) in dry diethyl ether (30 mL) at −78 °C was added **1** (0.5 g, 1.06 mmol), and the mixture was stirred for 3 h at room temperature, hydrolyzed with aqueous ether, and then evaporated to dryness. The residue was treated with dichloromethane/acetone (20/30 mL) and filtered through $MgSO_4$-silica. Evaporation of the filtrate to ca. 10 mL and addition of $[P(CH_2Ph)Ph_3]Cl$ (0.9 g, 2.3 mmol) in 2-propanol (30 mL) led, after partial evaporation, to **2** (yellow crystalline solid; 1.40 g, 80% yield). Correct elemental analysis. NMR spectra in [D$_6$]acetone: 188-MHz ^{19}F NMR (standard $CFCl_3$): $\delta = -116.6$ (*o*-F), −168.7 (*m*- and *p*-F); 81-MHz $^{31}P\{^1H\}$ NMR: $\delta = 24.54$.

4: This complex has been prepared by two methods: a) Bubbling CO for 90 min through a solution of complex **2** (0.200 g, 0.12 mmol) in CH_2Cl_2 (or THF) at refluxing temperature gave a colorless solution. Partial evaporation of the solvent and addition of hexane gave 0.11 g of a white solid (75% yield). b) To a mixture of LiC_6F_5 (2.32 g, 12.0 mmol) and BrC_6F_5 (0.3 mL, 2.36 mmol) in diethyl ether (40 mL) at −78 °C, $[RhCl(CO)_2]_2$ (0.45 g, 2.3 mmol) was added. The reaction mixture was allowed to reach room temperature, stirred for 4 h, hydrolyzed with aqueous diethyl ether and then evaporated to dryness. The residue was extracted with dichloromethane/acetone (15/20 mL) and filtered through $MgSO_4$-silica. Evaporation of the filtrate to ca. 10 mL and addition of $[P(CH_2Ph)Ph_3]Cl$ (1 g, 2.58 mmol) in 2-propanol (30 mL) led, after partial evaporation, to a white solid (**4**; 1.9 g, 72% yield). Spectroscopic data: IR (CH_2Cl_2): $\tilde{\nu}(CO) = 2100\ cm^{-1}$; 88 MHz ^{19}F NMR ([D$_6$]acetone): $\delta = -107.1$ (*o*-F), −161.3 (*p*-F), −163.0 (*m*-F).

5: Starting compounds: $[RhCl(CO)(PPh_3)]_2$ and LiC_6F_5, ratio 1 : 4.5. The synthesis was carried out as reported for **2**. Before addition of the salt, a yellow solid separated out with diethyl ether (40% yield). Complex **5** was identified by its spectroscopic (IR, NMR) and analytical data and its molecular weight.

Soluble Chromium Selenides and Tellurides: Preparation and Structures of $[(C_6H_5)_4P]_3[Cr_3Te_{24}]$ and $[(C_6H_5)_4P]_3[Cr_3Se_{24}]$**

By *Walter A. Flomer, Samuel C. O'Neal, William T. Pennington, David Jeter, A. Wallace Cordes,* and *Joseph W. Kolis**

We have been interested in synthesizing soluble transition metal clusters containing heavy polychalcogen ligands in the hope that they might be used as reagents for the preparation of new materials, particularly low-dimensional compounds with unique conductive properties.[1] Several soluble binary selenidometalate clusters have been reported previously, such as $[Fe_2Se_{12}]^{2\ominus}$,[2] $[W_2Se_9]^{2\ominus}$,[3] $[W_2Se_{10}]^{2\ominus}$,[3] and $[V_2Se_{13}]^{2\ominus}$,[4] but in general the area is quite neglected compared to metal polysulfide chemistry.[5,6] The solid-state chemistry of metal tellurides has recently been reviewed.[7] We have found that Zintl ions such as $Te_2^{2\ominus}$, $Te_4^{2\ominus}$, and $Se_3^{2\ominus}$ can be extracted from potassium tellurides and selenides with dimethylformamide. They have proven to be convenient reagents for the preparation of a variety of chalcogenidometalates such as $[Cr(CO)_4Te_4]^{2\ominus}$,[8] $[MoSe_4]^{2\ominus}$,[9] and $[NbTe_{10}]^{3\ominus}$.[10] Herein, we report on the reaction of polytelluride and polyselenide solutions with chromium chloride leading to the novel clusters $[Cr_3Te_{24}]^{3\ominus}$ and $[Cr_3Se_{24}]^{3\ominus}$, which we believe to be the first soluble chromium selenides and tellurides.

The reaction of solids of nominal composition K_2Se_3 or K_2Te_2 with $CrCl_3$ in DMF under rigorously anaerobic conditions produces a brown solution in the case of tellurium and a red solution in the case of selenium. Slow addition of THF in the presence of $(C_6H_5)_4PBr$ leads to separation of black crystals [Eq. (a)].[11]

$$Cr^{3\oplus} + 2E_4^{2\ominus} \longrightarrow 1/3[Cr_3E_{24}]^{3\ominus} \qquad (a)$$

X-ray diffraction analyses revealed compounds of the composition $[(C_6H_5)_4P]_3[Cr_3Se_{24}]$ and $[(C_6H_5)_4P]_3[Cr_3Te_{24}]$. The two structures are similar, even though the compounds crystallize in different unit cells.[12] The selenide compound contains two different $[Cr_3Se_{24}]^{3\ominus}$ clusters per asymmetric unit, but the structural features of each are similar. Each compound consists of three well separated $[(C_6H_5)_4P]^{\oplus}$ ions and a cluster of the formula $[Cr_3E_{24}]^{3\ominus}$ (E = Se, Te). The trianion is a linear array of three chromium atoms which are linked by six tetrachalcogenide groups (Fig. 1, top). The two terminal chromium atoms are octahedrally coordinated by three bidentate $E_4^{2\ominus}$ ions. Each of the chalcogenide chains has one terminal atom which is μ-2, bridging one terminal metal atom and the central metal atom. The net result is three face sharing octahedra, if only the coordinated chalcogenides are considered. The overall structure is similar to that of $[(C_6H_5)P_4]_2Na[Cr_3(SCH_2CH_2O)_6]$.[13] Each compound possesses an inversion center at the central chromium atom, making these molecules two of the very few purely inorganic meso compounds. A view down the Cr_3-axis shows the overall S_6 symmetry (Fig. 1, bottom).

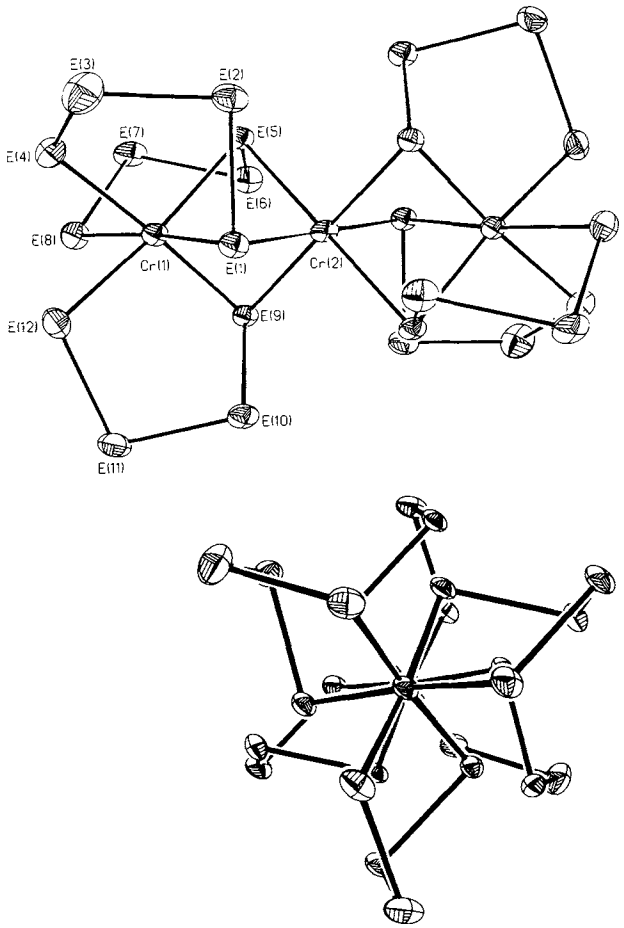

Fig. 1. Top: Side view of the $[Cr_3E_{24}]^{3\ominus}$ ion, where E = Se, Te. Bottom: End view of the $[Cr_3E_{24}]^{3\ominus}$ molecule showing the $S6$ symmetry.—Some important distances [Å] and angles [°] in the $[Cr_3Te_{24}]^{3\ominus}$ ion: Cr1–Cr2 3.41(1), Cr1–Te1 2.737(6), Cr1–Te4 2.688(8), Cr1–Te5 2.753(7), Cr1–Te8 2.684(7), Cr1–Te9 2.741(8), Cr1–Te12 2.696(7), Cr2–Te1 2.746(3), Cr2–Te5 2.735(2), Cr2–Te9 2.722(3), Te1–Te2 2.773(4), Te2–Te3 2.705(5), Te3–Te4 2.823(5), Te5–Te6 2.782(4), Te6–Te7 2.731(5), Te7–Te8 2.813(4), Te9–Te10 2.781(3), Te10–Te11 2.725(5), Te11–Te12 2.792(5); Cr1–Te1–Cr2 77.2(2), Cr1–Te5–Cr2 77.1(1), Cr1–Te9–Cr2 77.5(2), Te1–Cr1–Te4 102.5(2), Te5–Cr1–Te8 102.5(2), Te9–Cr1–Te12 101.5(2).—Some important distances [Å] and angles [°] in the $[Cr_3Se_{24}]^{3\ominus}$ ion: Cr1–Cr2 3.207, Cr1–Se1 2.529(9), Cr1–Se5 2.520(9), Cr1–Se9 2.541(9), Cr2–Se1 2.585(17), Cr2–Se4 2.476(16), Cr2–Se5 2.586(17), Cr2–Se8 s.474(17), Cr2–Se9 2.589(16), Cr2–Se12 2.450(17), Se1–Se2 2.378(13), Se2–Se3 2.317(13), Se3–Se4 2.368(15), Se5–Se6 2.367(15), Se6–Se7 2.342(13), Se7–Se8 2.364(15), Se9–Se10 2.383(14), Se10–Se11 2.332(12), Se11–Se12 2.368(13); Cr1–Se1–Cr2 77.7(4), Cr1–Se5–Cr2 77.8(4), Cr1–Se9–Cr2 77.4(4), Se1–Cr2–Se4 98.1(6), Se5–Cr2–Se8 97.5(6), Se9–Cr2–Se12 97.9(6).

The Te–Te distances average 2.767 Å compared to 2.72 Å in PhTe–TePh, while the Se–Se distances average 2.358 Å compared to 2.29 Å in PhSe–SePh.[14] The average Cr–Te distance is 2.719 Å and the average Cr–Se distance is 2.525 Å, with the *bridging* Cr–E distance being longer by about 0.1 Å in each case. They thus resemble the Cr–Te distance of 2.726 Å in $[(CO)_4CrTe_4]^{2\ominus}$[8] and the Cr–Se distance of 2.453 Å in $[\{(C_5H_5)CrNO\}_2(\mu\text{-}SePh)_2]$.[15] The Cr–Cr distances of 3.41 Å in the telluride and 3.20 Å in the two molecules of the selenide compound are substantially longer than a Cr–Cr bond. The effective magnetic moments of the selenido- and tellurido-clusters at 300°K, are 5.25 and 5.74, respectively, indicating a spin = 3/2 system with reasonably strong antiferromagnetic coupling in each case.[16]

Molecular chromium chalcogenides were hitherto unknown; however, several solid-state chromium selenides and chromium tellurides have been reported, but many of these have not been structurally characterized.[17] The binary compounds CrSe and CrTe crystallize with the NiAs-type structure.[18] A chromium telluride of composition $CrTe_3$[19] has a complicated structure consisting of octahedrally coordinated $Cr^{3\oplus}$ atoms and layers containing $Te_2^{2\ominus}$ and $Te_3^{2\ominus}$ as well as $Te^{2\ominus}$ ions. The Cr–Te and Te–Te distances in this compound resemble those in $[Cr_3Te_{24}]^{3\ominus}$.

[11] Typical procedure: A mixture of K_2Se_3 (250 mg, 0.790 mmol), $CrCl_3$ (125 mg, 0.790 mmol) and $(C_6H_5)_4PBr$ (660 mg, 1.58 mmol) is treated under argon with 20 mL of DMF. The reaction mixture is than stirred at room temperature for 1 h, filtered and the filtrate (red solution) is covered with a layer of THF (5 mL). After one week, 200 mg of large black crystals can be isolated (25% yield based on chromium). The telluride is prepared in a similar way, but a threefold excess of polytelluride is required; furthermore, a microcrystalline product usually results. It is often easier to obtain single crystals by first dissolving the appropriate amounts of telluride and phosphonium salt in DMF, and then adding $CrCl_3$. The selenide, on the other hand, readily forms large crystals upon slow addition of THF.
[12] Crystal structure data: a) $[(C_6H_5)_4P]_3[Cr_3Se_{24}]$: space group $P\bar{1}$, $a=13.971(5)$, $b=14.208(3)$, $c=25.756(5)$ Å, $\alpha=74.17(2)$, $\beta=86.04(4)$, $\gamma=84.83(2)°$, $V=4893(3)$ Å^3, $Z=2$, $\mu_{MoK\alpha}=92.25$ cm^{-1}, refined, using 2275 reflections ($2\theta\leq45°$) with $F_o^2>3\sigma(F_o^2)$, to $R=0.0833$ and $R_w=0.0967$ for 349 refined parameters, $[w=1/(\sigma^2F+0.001F^2)]$ holding all phenyl rings as rigid groups. b) $[(C_6H_5)_4P]_3[Cr_3Te_{24}]$: space group $P\bar{1}$, $a=10.749(5)$, $b=14.328(5)$, $c=20.395(5)$ Å, $\alpha=72.09(4)$, $\beta=80.87(3)$, $\gamma=73.24(4)°$, $V=2853(3)$ Å^3, $Z=1$, $\mu_{MoK\alpha}=63.65$ cm^{-1}, refined using 2978 reflections ($2\theta\leq45°$), with $F_o^2>3\sigma(F_o^2)$, to $R=0.0636$, $R_w=0.0808$. The solution of the structure of the telluride is hampered by a disordering of one of the three $(C_6H_5)_4P^{\oplus}$ counterions about an inversion center. The final refinement was based on an idealized molecule from the best fit of observed difference map peaks. Variations in the modeling of the disordered counterion, or its removal from the refinement altogether, have no effect on the structural parameters of the anion. The displacement of the phosphorus atom from the inversion center by 3.75 Å indicates that the lattice cavity is much larger than needed. The vacant space remaining may be filled by solvent molecules, however, as no suitable model for the disorder may be resolved, the presence of a solvent molecule could not be determined.—Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53331, the names of the authors, and the journal citation.

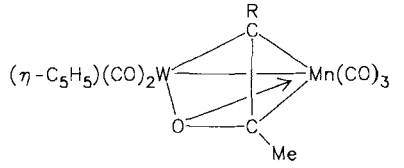
Acyl–Alkylidyne Coupling in the Synthesis of Dinuclear Complexes**

By *Ian J. Hart, John C. Jeffery, Rachel M. Lowry,* and *F. Gordon A. Stone**

The two main classes of primary products derived from Fischer-Tropsch synthesis are terminal alkenes and primary alcohols.[1] The carbide–methylene mechanism,[2] which would logically involve methylidyne fragments in an intermediate step, satisfactorily accounts for the production of terminal alkenes. However, a pathway involving incomplete reduction of CO must be responsible for the production of primary alcohols and minor oxygen-containing products such as aldehydes, ketones, carboxylic acids, and esters.[2]

One popular mechanism to account for the oxygenated products is based on 'CO insertion' into a metal–carbon bond.[3] Herein we report the first acyl–alkylidyne coupling reactions in which carbon–carbon bond formation takes place.[4] The acyl ligands are derived from alkyl migration at a mononuclear metal center. The resulting compounds have organic groups displaying unusual ligating properties.

$[W(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$ **1**, $(R = p\text{-}C_6H_4Me)$



2

The alkylidynetungsten complex **1** reacts with $[Mn(Me)(CO)_5]$ in refluxing toluene to give the MnW-complex **2** identified by its spectroscopic properties[5] and by an X-ray structure analysis (Fig. 1).[6a] The combination of the acyl and alkylidyne moieties occurs via carbon–carbon bond formation giving a bridging C(R)C(O)Me ligand. The most striking aspect of the coordination of this ligand is that it formally donates six electrons to the metal centers. The carbon C10, derived from the alkylidyne unit, bridges the W–Mn bond, whilst the carbon C9 and oxygen O9, de-

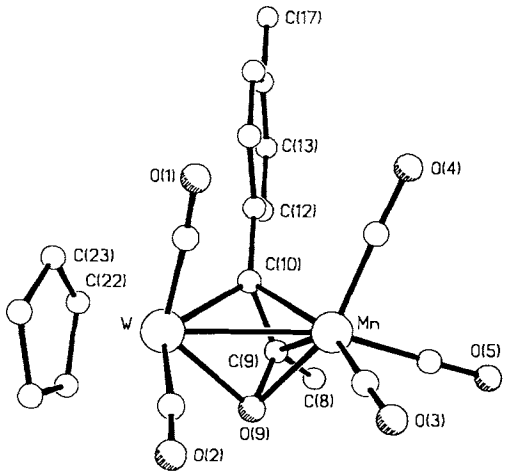

Fig. 1. Crystal structure of **2**. Selected bond lengths [Å] and angles [°]: W-Mn 2.696(1), Mn-C9 2.115(6), Mn-O9 2.043(4), W-O9 2.148(4), C9-O9 1.398(6), O9-C9-C10 105.5(4).

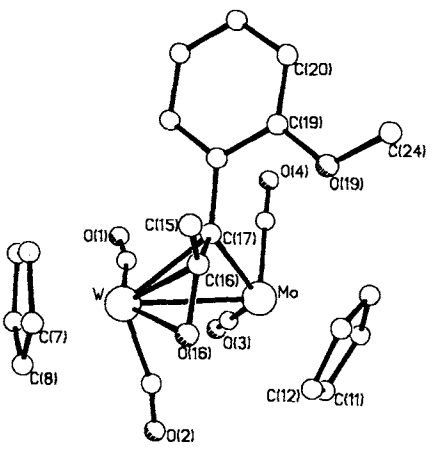

Fig. 2. Crystal structure of **3c**. Selected bond lengths [Å] and angles [°]: Mo-W 2.935(1), W-C16 2.370(4), W-O16 2.157(4), C16-O16 1.321(7), O16-C16-C17 115.9(5).

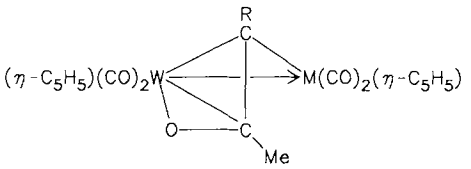
rived from the inserted CO, are bonded to the manganese and tungsten respectively. The manganese atom is also ligated by a dative bond from the oxygen O9.

This remarkable coordination gives rise to a very short W-Mn separation (2.696(1) Å), being almost 0.3 Å shorter than the only previously determined W-Mn bond length of 2.9939(8) Å.[7] This is also formally a single bond. Evidently the C(R)C(O)Me ligand constrains the two metal atoms, holding them very close indeed. Noteworthy also is the lengthening of the acyl derived C9-O9 bond to 1.398(6) Å. Previously determined uncoordinated manganese-acyl bond lengths fall in the range 1.20-1.22 Å.[8]

The mechanism whereby **2** is formed must involve migration of the manganese-ligated methyl group to a carbonyl ligand to generate a transient unsaturated species $[Mn\{C(O)Me\}(CO)_4]$ to which the W≡C triple bond of **1** can coordinate. Carbon-carbon bond formation followed by loss of CO would then lead to the observed product.



3a, M = Mo, R = p-C_6H_4Me
3b, M = W, R = p-C_6H_4Me
3c, M = Mo, R = o-C_6H_4OMe

The reaction between **1** and the complexes $[M(Me)(CO)_3(\eta\text{-}C_5H_5)]$ (M = Mo or W) under UV irradiation affords the dinuclear complexes **3a**, **b**.[9] Similarly, reaction of $[W(\equiv C\text{-}o\text{-}C_6H_4OMe)(CO)_2(\eta\text{-}C_5H_5)]$ and $[Mo(Me)(CO)_3(\eta\text{-}C_5H_5)]$ furnished **3c**, the structure of which was established by X-ray diffraction (Fig. 2).[6b] This confirmed that acyl and alkylidyne groups had again combined to give μ-C(R)C(O)Me fragments, but the mode of bonding to the dimetal centers was substantially different from that in **2**. In the compounds **3** the alkylidyne derived carbon atom again bridges the metal-metal bond but the acyl derived carbon and oxygen atoms are both bonded to the same metal center. A metal-metal donor bond allows each metal atom to conform to the 18-electron rule.

Previously, we have demonstrated the synthetic utility of the alkylidyne complex **1** in rational metal cluster syntheses.[10] We have now further shown the potential of **1** in the preparation of complexes exhibiting unusual organic ligands.[11]

Experimental Procedure

2: A solution of **1** (0.41 g, 1.0 mmol) and $[Mn(Me)(CO)_5]$ (0.21 g, 1.0 mmol) in toluene (ca. 20 mL) was refluxed under nitrogen for 4 h. The solvent was removed in vacuo, and the residue was dissolved in CH_2Cl_2 (ca. 10 mL) and chromatographed on an alumina column (2 × 10 cm) with CH_2Cl_2-light petroleum (3 : 1) as eluent. A yellow fraction was collected. After removal of solvent in vacuo, the residue was dissolved in CH_2Cl_2 (ca. 5 mL), and light petroleum (ca. 25 mL) was added. After cooling to −78 °C, and removal of supernatant liquid there remained yellow microcrystals of **2** (0.53 g, 90%).

3a: A solution of **1** (0.41 g, 1.0 mmol) and $[Mo(Me)(CO)_3(\eta\text{-}C_5H_5)]$ (0.26 g, 1.0 mmol) in light petroleum was cooled under nitrogen to 0 °C and irradiated with UV light for 12 h. The solvent was removed in vacuo and the residue was dissolved in CH_2Cl_2 (ca. 10 mL) and chromatographed on an alumina column (2 × 15 cm). Elution with CH_2Cl_2-light petroleum (4 : 1) gave a purple band, which was collected and the solvent removed in vacuo. Dissolution of the residue in CH_2Cl_2 (ca. 5 mL), addition of light petroleum (ca. 25 mL), and removal of the supernatant liquid furnished purple microcrystals of **3a** (0.32 g, 48%).

In an analogous way, compound **1** (0.41 g, 1.0 mmol) and $[W(Me)(CO)_3(\eta\text{-}C_5H_5)]$ (0.35 g, 1.0 mmol), and $[W(\equiv C\text{-}o\text{-}C_6H_4OMe)(CO)_2(\eta\text{-}C_5H_5)]$ (0.42 g, 1.0 mmol) and $[Mo(Me)(CO)_3(\eta\text{-}C_5H_5)]$ (0.26 g, 1.0 mmol), gave the complexes **3b** (0.24 g, 32%) and **3c** (0.31 g, 45%), respectively.

2,2′,7,7′-Tetrahydroxy-1,1′-binaphthyl: a Versatile Chiral Spacer for Novel Mono- and Ditopic Cyclophane Hosts with Apolar Binding Sites**

By *François Diederich,* Matthew R. Hester,* and *Mike A. Uyeki*

We recently reported on the synthesis of an optically active cyclophane host and described ^{1}H-NMR evidence for the formation of diastereomeric complexes with (*R,S*)-naproxen and its methyl ester in aqueous solution.[1] The rather low stability of these complexes was explained in force-field computational studies by a reduced degree of preorganization[2] of the apolar binding site shaped by a chiral 4-phenyl-1,2,3,4-tetrahydroisoquinoline spacer. According to the calculations, the energetically lowest host conformations did not provide sufficient cavity space for the inclusion of aromatic guests. We subsequently identified the known 2,2′,7,7-tetrahydroxy-1,1′-binaphthyl unit **1**[3] as a potentially more efficient, readily available, and versatile chiral spacer for our cyclophanes. The ditopic component has C_2-symmetry and possesses two distinctive geometric clefts. For a dihedral angle Θ about the chirality axis of 88°, the O···O distance in **1** is ca. 3.60 Å for the minor groove.[4] The minor grooves of binaphthyls shape efficient cation binding sites, as demonstrated by *Cram* et al.[5] in their impressive studies with optically active binaphthyl crown ethers. With an O···O distance of ca. 7.05 Å, the major groove in **1** is almost twice as wide and should be ideal to shape flat binding sites for arenes.[1] In this paper, we describe the synthesis of the racemates of the monotopic host **2** and the ditopic component **3** derived from **1**. Their binding properties clearly demonstrate that **1** is indeed a superior chiral spacer for cyclophanes with apolar binding sites.[6, 7]

For the synthesis of the novel hosts, it was necessary to prepare a regioselectively protected derivative of **1**. In an oxidative coupling reaction of 7-benzyloxy-2-naphthol with $Mn(acac)_3$ (acac = acetylacetonate; CH_3CN, N_2, 45°, 1 d),[8] the binaphthyl unit **4** (m.p. = 104–106 °C), protected at the major groove, was obtained in 43% yield. For the preparation of the cyclization component **7** on the way to host **2**, the binaphthol **4** was converted with α-bromo-*N,N*-diethylacetamide into the diamide **5** (m.p. = 98–100 °C, K_2CO_3, DMF, 80% yield). Deprotection at the major groove (10% Pd/C, $NH_4^{\oplus}HCOO^{\ominus}$, MeOH, N_2, 64% yield) afforded the binaphthol **6** (m.p. = 238–241 °C), which was reacted with 1,4-dichlorobutane to give **7** (m.p. = 120–121 °C, Cs_2CO_3, DMF, 79% yield). The cyclization of **7**

	R'	R"
4	$PhCH_2$	H
5	$PhCH_2$	CH_2CONEt_2
6	H	CH_2CONEt_2
7	Cl-$(CH_2)_4$	CH_2CONEt_2

8, R = H
9, R = $(CH_2)_4$-Cl

	R'	R"
10,	CH_3CO	CH_2CONEt_2
11,	CH_3CH_2	$CH_2CH_2NEt_2$

with **8**[9] led to the macrocyclic triamide **10** (colorless foam, Cs_2CO_3, DMF, 37% yield), which was reduced with $BH_3 \cdot THF$ to give the triamine **11** (m.p. = 162 °C, 65% yield). Quaternization in pure ethyl iodide followed by anion exchange (Dowex, $Cl^{\ominus}$) and recrystallization from acetone/ether furnished the target host **2** (m.p. = 207–209 °C, 87% yield) as colorless hygroscopic crystals.

For the preparation of the ditopic host **3**, the binaphthol **4** was allowed to react with pentaethyleneglycol di-*p*-toluenesulfonate to give the binaphthyl crown ether **12** (NaH, THF, N_2, 57% yield, colorless foam). The subsequent conversions followed the procedures described above. Deprotection led to the binaphthol **13** (m.p. = 190–192 °C, 69% yield), which was cyclized with the dichloride **9**[9] to give the ditopic macrocycle **14** (m.p. = 188–189 °C, 23% yield). Reduction to **15** (m.p. = 163–165 °C, 43% yield) followed by quaternization, ion exchange, and recrystallization from acetone/ether afforded the target compound **3** as colorless crystals (m.p. = 205–207 °C, dec., 75% yield).

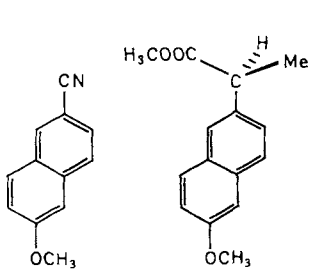
^{1}H-NMR spectroscopic studies showed the efficient inclusion complexation of ten neutral naphthalene derivatives by the hosts **2** and **3** in D_2O/[D_4]methanol (60:40). The observed large and specific complexation-induced shifts of both host and guest resonances indicated that the guests are included pseudo-axially in the apolar binding sites and, in time average, assume a similar orientation as in the cavities of the previously studied bis(diphenylmethane) hosts.[10,11] A direct comparison of the association constants for the 1:1 complexes of 6-methoxy-2-naphthonitrile (**16**), determined from ^{1}H-NMR titrations in D_2O/[D_4]methanol (60:40; T = 293 K), clearly demonstrates that the novel cyclophanes **2** (K_a = 1990 L·mol^{-1}) and **3** (K_a = 4510 L·mol^{-1}) are much better binders than the above-mentioned host shaped by a 4-phenyl-1,2,3,4-tetrahydroisoquinoline unit (K_a = 336 L·mol^{-1}).[1]



16 **17**

Only a few ditopic hosts are known for which the efficient complexation of two different guests could be unambiguously demonstrated.[12] In most of these studies, the solvent dependency of the two complexation events was very similar. However, a very different solvent dependency could be expected for the complexation of an alkali cation and a neutral naphthalene derivative at the two binding sites of **3**. We investigated the binding of potassium cations and of **16** in various D_2O/[D_4]methanol mixtures. Table 1 shows the association constants determined from

Table 1. Association constants K_a [L·mol^{-1}] and free binding enthalpies $-\Delta G^0$ [kcal·mol^{-1}] for the complexes of host **3** with $K^{\oplus}$ and **16** (T = 293 K) [13].

^{1}H-NMR titrations for the 1:1 complexes formed in the various solvent mixtures.[13] As expected, the stability of the complex of **16** markedly decreases with increasing methanol content of the solvent mixture,[7b] whereas the stability of the $K^{\oplus}$-complex markedly increases with increasing methanol content.[14] The opposite solvation characteristics of the two complexation processes are shown in Figure 1. Clearly, the host **3** constitutes a ditopic receptor

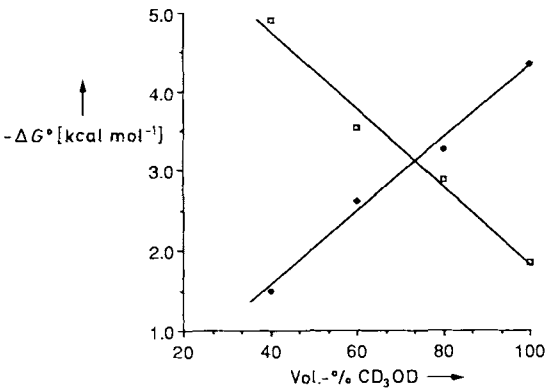

Fig. 1. Complexation of $K^{\oplus}$ (◆) and of **16** (□) by the ditopic host **3** in D_2O/[D_4]methanol mixtures.

which can be switched from an efficient binder of neutral naphthalene derivatives to an efficient binder of potassium cations by simply changing the water content of the water-methanol mixture. The formation of a 1:1:1 ($3 \cdot K^{\oplus} \cdot 16$) complex was observed in all four solvent mixtures shown in Table 1. Although specific shifts in the ^{1}H-NMR spectra[15] indicate a considerable change in the conformation of the binaphthyl unit upon complexation of a potassium cation, the complexation ability of the major groove binding site is only weakly affected by the cation binding at the minor groove. The binding of **16** by host **3** in 0.1 molar solutions of KCl in various D_2O/[D_4]methanol mixtures is only slightly weaker than the binding in the absence of KCl.

Preliminary chiral molecular recognition studies with racemic **2** and **3** show that the preparation and the study of

Advertisement pages 1707–1710

the enantiomerically pure hosts represent extremely worthwhile objectives. The methyl ester of (*S*)-naproxen **17** forms stable inclusion complexes with both hosts, and the ^{1}H-NMR spectra show significant differential shifts of the aromatic host resonances in the resulting diastereomeric complexes. As an example, the ^{1}H-NMR spectrum of a solution with $[\mathbf{17}]=[\mathbf{2}]=1.2\times10^{-3}$ mol·L^{-1} in D_2O/[D_4]methanol at an estimated degree of complexation of approx. 60% contains two signals for the binaphthyl proton 8-H which are shifted by 0.17 and 0.13 ppm, respectively, against the resonance of 8-H in the solution of pure host.

In conclusion, the results of the first binding studies with **2** and **3** show that derivatives of **1** are novel, synthetically readily available chiral spacers for cyclophanes with apolar binding sites. They are comparable in their efficiency and versatility to the diphenylmethane units which we use successfully in our host systems. We are now pursuing the optical resolution of **4** on the preparative scale as well as the preparation of the enantiomerically pure hosts **2** and **3**.

[13] The ^{1}H-NMR titrations were evaluated by a non-linear least-squares curve fitting procedure. The concentration ranges were chosen to provide approximately 20-80% complexation of the binding partner present at constant total concentration. For the determination of the stability of the complexes of **2** and **3** with guest **16**, the host concentration was continuously changed, and the resonances of the four guest protons 1-H, 3-H, 5-H, and OCH_3 were evaluated. The binding data in Table 1 are averaged data. *Example*: $[\mathbf{16}]=5\times10^{-4}$ mol·L^{-1} and $[\mathbf{3}]=3\times10^{-4}$–$5\times10^{-3}$ mol·L^{-1} in D_2O/[D_4]methanol (40:60): 1-H: $\Delta\delta_{max/obs}=1.86$, $\Delta\delta_{sat/calcd}=2.67$: $K_a=448$. 3-H: $\Delta\delta_{max/obs}=1.13$, $\Delta\delta_{sat/calcd}=1.61$: $K_a=476$. 5-H: $\Delta\delta_{max/obs}=1.01$, $\Delta\delta_{sat/calcd}=1.47$; $K_a=435$. OCH_3: $\Delta\delta_{max/obs}=0.35$, $\Delta\delta_{sat/calcd}=0.57$; $K_a=406$. $K_{a\,average}=441$ L·mol^{-1}. For the determination of the stability of the $\mathbf{3}\cdot K^{\oplus}$ complexes, the potassium cation concentration was changed and the shifts of the resonances of the host proton 8-H and the diastereotopic protons Naph-O-CH_AH_B-CH_2-O were evaluated. *Example*: $[\mathbf{3}]=5\times10^{-4}$ mol·L^{-1} and [KCl] $=5\times10^{-3}$–8×10^{-2} mol·L^{-1} in D_2O/[D_4]methanol (40:60): 8-H: $\Delta\delta_{max/obs}=0.136$, $\Delta\delta_{sat/calcd}=0.154$; $K_a=88$. CH_A: $\Delta\delta_{max/obs}=0.340$, $\Delta\delta_{sat/calcd}=0.363$; $K_a=100$. CH_B: $\Delta\delta_{max/obs}=0.263$, $\Delta\delta_{sat/calcd}=0.301$; $K_a=80$. $K_{a\,average}=89$ L·mol^{-1}.

[14] R. M. Izatt, R. E. Terry, D. P. Nelson, Y. Chan, D. J. Eatough, J. S. Bradshaw, L. D. Hansen, J. J. Christensen, *J. Am. Chem. Soc. 98* (1976) 7626.

[15] In a solution of $[\mathbf{3}]=5.0\times10^{-4}$ mol·L^{-1} and $[KCl]=8.0\times10^{-2}$ mol·L^{-1} in D_2O/[D_4]methanol (40:60, $T=293$ K) with ≈88% of the total amount of host complexed, the binaphthyl resonances of **3** are specifically shifted against the resonances observed in the solution of pure host: 8-H: $\delta=6.18$ ($\Delta\delta=+0.14$; + = upfield shift); 6-H: 6.689 (−0.06); 3-H: 7.521 (−0.12); 5-H: 7.687 (−0.12); 4-H: 7.983 (−0.14). The specific upfield shift of the signal for 8-H can be explained by a reduction of the dihedral angle Θ as a result of the complexation of a potassium cation. Such a complexation-induced conformational change could be expected on the basis of X-ray crystallographic data for binaphthyl crowns and their cation complexes; see: D. J. Cram, K. N. Trueblood, *Top. Curr. Chem. 98* (1981) 43.

A Donor-Acceptor Substituted Quinoid Pentalene

By *Toyonari Sugimoto, Akihiko Sakai, Toshiki Takahashi, Hiroshi Ando, Tatsushi Okuda, Zen-ichi Yoshida,* Yasushi Kai, Nobuko Kanehisa,* and *Nobutami Kasai**

Antiaromatic systems can be stabilized by the simultaneous presence of electron-donating (Do) and electron-withdrawing (A) substituents,[1] because the antiaromatic destabilization is reduced by participation of a push-pull type of π-electron conjugation. As a typical example, a Do_2/A_2 cyclobutadiene substituted with two diethylamino (Do) and two methoxycarbonyl (or ethoxycarbonyl) (A) groups has been realized.[2] Such a Do/A synergic effect on pentalene, the second smallest antiaromatic system (8π, n = 2 for 4nπ), has not been investigated so far, although some reports have appeared in the literature on the individual effect of Do and A groups.[3] We now wish to report on the synthesis and structure of the pentalene **1**, which is formally substituted in one of the five-membered rings by a 3,4-dicyanocyclopentadienide group ($Do^{\ominus}$) and in the other by a tetramethylamidinium group ($A^{\oplus}$).

The pentalene **1** was synthesized by a novel reaction from the calicene **2**[4] and the fulvene **3**.[5] A mixture of **2**

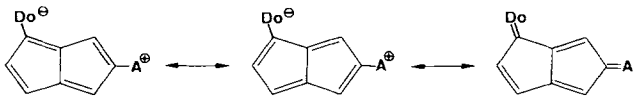
(0.1 mmol) and **3** (0.15 mmol) in anhydrous THF (10 mL) was heated under reflux for 3 h under argon. After thin-layer chromatographic separation of the crude product (silica gel, CH_2Cl_2) and recrystallization from chlorobenzene, **1** was isolated as blue-violet crystals (m.p. 220°C (dec.)) in 16% yield. The mass spectrum showed a parent peak at *m/e* 466, which corresponds to the sum of the molecular weights of **2** and **3** minus two H atoms.[6] The 400-MHz ^{1}H-NMR spectrum in CD_2Cl_2 consisted of six signals, at $\delta = 7.38$ (m, 4H), 7.20 (m, 7H), 6.64 (d, $J = 0.85$ Hz, 1H), 5.84 (d, $J = 2.20$ Hz, 1H),), and 3.10 (s, 12H). No signal appeared at about $\delta = 8$, where the proton of the seven-membered ring of 5,6-bis(*tert*-butylthio)-9-[bis(dimethylamino)methylidene]cyclopent[*e*]azulene-1,2-dicarbonitrile is observed.[7] Moreover, the coupled signals at



$\delta = 6.64$ and 5.96 appear at similar positions as those of the ring protons of **3**.[8] The presence of the 3,4-dicyanocyclopentadienyl group was inferred from the appearance of one of the two coupled signals at about $\delta = 7.20$, which is hidden by overlapping with signals of the *m*- and *p*-protons of the phenyl ring. On the other hand, the partner signal was unexpectedly observed at a fairly high field ($\delta = 5.84$).[9] There was no indication of coalescence of the two signals, even at a temperature of ca. 100°C, thus indicating a large rotation barrier around the C=C bond. These results are consistent with a quinoid-Do/A pentalene structure rather than a $Do^{\ominus}/A^{\oplus}$-pentalene structure for **1**.

For confirmation, an X-ray structure analysis was carried out (Fig. 1).[10] It follows therefrom that **1** undoubtedly has a quinoid-type pentalene structure. The central pentalene moiety is planar within a deviation of 0.02 Å for each atom. The dicyanocyclopentadienylidene moiety forms a torsional angle of 14.6° with this plane along the C1–C9 bond. The two phenyl groups and the bis(dimethylamino)methylidene moiety also deviate from the pentalene plane, forming torsional angles of 61.2°, 47.5° and 35.2° about the C2–C21, C3–C31, and C5–C14 bonds, respectively. The interatomic distances C2–C3, C4–C8, C6–C7, C1–C9, C10–C11, and C12–C13 must be regarded as equivalent to elongated double bonds, since they are significantly shorter than the other carbon–carbon bonds in **1**.[11] Preferred adoption of the Do/A-quinoid pentalene structure in spite of the presence of comparatively weak $Do^{\ominus}$ and $A^{\oplus}$ groups, clearly reflects a strong tendency to avoid antiaromatic destabilization due to the eight π-electrons. Very interestingly, this result is in marked contrast with that of a Do_2/A_2 cyclobutadiene, in which a quinoid type of structure has not apparently been recognized.[12]

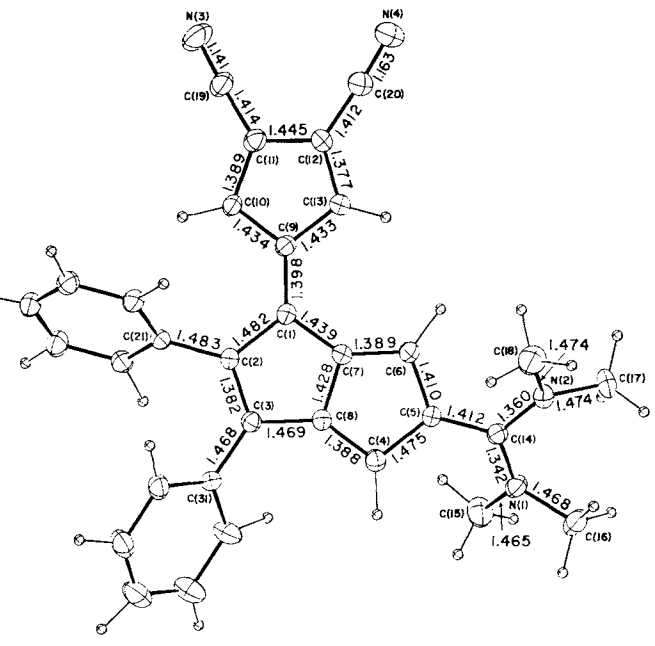


Fig. 1. Molecular Structure of **1** with selected interatomic bond distances. Thermal ellipsoids for non-hydrogen atoms are drawn at the 30% probability level. The hydrogen atoms are shown as spheres with arbitrary temperature factor of 1.0 Å^2. The standard deviations for bond distances lie between 0.007 and 0.010 Å.

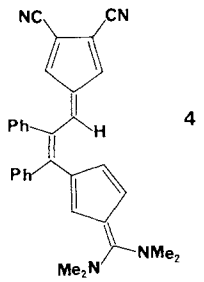

4

On the other hand, when the same reaction of **2** with **3** was carried out at room temperature, an acyclic product (**4**) was obtained in 23% yield as considerably unstable violet crystals (m.p. 140°C, decomp.) together with **1** (2% yield): *m/e* 468. ^{1}H-NMR ($CDCl_3$): $\delta = 7.48$ (s, 1H), 7.4–7.0 (m, 12H), 6.66 (s, 2H), 5.21 (s, 1H), and 3.11 (s, 12H). On exposing the CH_2Cl_2 solution of **4** to air for 4 h, **1** was obtained in 11% yield. This could be indicative of the mode of formation of **1**: possibly C-2 of **3** attacks the 5-position of **2** and then opening of the cyclopropene ring to give **4** followed by ring-closure and dehydrogenating aromatization leads to **1**.

[8] The ^{1}H-NMR spectrum of **3** in $CDCl_3$ showed two doublet signals at $\delta = 6.30$ and 6.12.

[9] The molecular structure obtained by the X-ray crystallographic analysis can also be assumed in solution. Thus, one proton on the five-membered ring is located so closely to the plane of the neighboring phenyl ring as to be susceptible to a magnetic anisotropy effect.

[10] Crystal data of **1** (Rigaku four-circle diffractometer using nickel-filtered $Cu_{K\alpha}$ radioation): $C_{32}H_{26}N_4$, $M_r = 466.6$, triclinic, space group $P\bar{1}$, $a = 12.500(1)$, $b = 11.762(1)$, $c = 9.437(1)$ Å, $\alpha = 101.51(1)$, $\beta = 107.10(1)$,

$\gamma = 89.82(1)°$, $V = 1297.2(3)$ Å^3, $\rho_{calcd} = 1.197$ g cm^{-3}, $Z = 2$, $F(000) = 492$, $\mu(Cu_{K\alpha}) = 5.2$ cm^{-1}. A total of 3253 independent reflections were collected up to $2\theta = 110°$ by the $\theta - 2\theta$ scan technique. The intensity data were corrected for the usual Lorentz and polarization effects, but an absorption correction was not applied. The structure was solved by direct methods (SHELXS-86) (G. M. Sheldrick in G. M. Sheldrick, C. Krüger, R. Goddard (Eds.): *Crystallographic Computing 3*, Oxford University Press, Oxford 1985, pp. 175–189) and refined by the full-matrix least-squares method (XRAY-76) (J. M. Stewart: *XRAY-76: Report TR-446*, University of Maryland, 1976) using 2197 observed reflections [$|F_o| > 3\sigma(F_o)$] to $R = 0.076$ and $R_w = 0.097$, including non-hydrogen atoms with anisotropic thermal parameters and hydrogen atoms with isotropic thermal parameters, where $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$, and the weighting scheme used was $w = [\sigma(F_o)^2 + 0.003(F_o)^2]^{-1}$. Further details of the crystal structure investigation can be obtained from the Director of the Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (UK), on quoting the journal citation.

[11] The X-ray crystallographically determined lengths of the single and double bonds differ even more in the case of dimethyl-4,6-di-*tert*-butylpentalene-1,2-carboxylate (B. Kitschke, H. J. Lindner, *Tetrahedron Lett. 1977*, 2511), than in the case of **1**, suggesting a partial participation of a $Do^{\oplus}/A^{\ominus}$-pentalene structure for **1**.

[12] The X-ray structure analysis indicates a nearly square-planar geometry for the central four-membered ring; H. J. Lindner, B. V. Gross, *Angew. Chem. 83* (1971) 489; *Angew. Chem. Int. Ed. Engl. 10* (1971) 490.

Synthesis, Structure and Bonding in the Donor-Acceptor Complex [*t*Bu$_2$PSe$_2$]·[PNAryl]: En Route to the P≡N Bond**

By *Edgar Niecke,* Martin Nieger, Franz Reichert,* and *Wolfgang W. Schoeller*

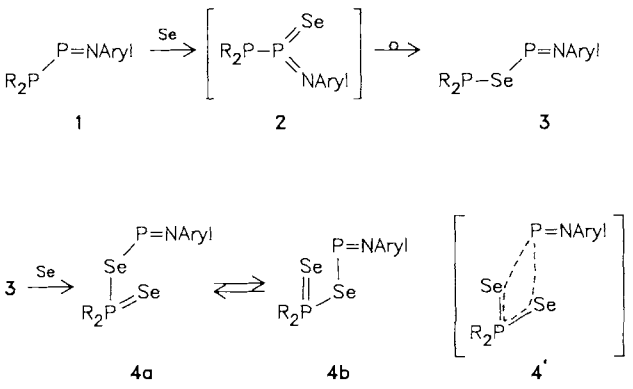
Dedicated to Professor Hans Bock on the occasion of his 60th birthday

The formal replacement of the terminal nitrogen atom in a diazonium ion[1] **A** by a phosphorus atom leads to a species **B** in which phosphorus has coordination number 1; until now phosphaalkynes **C**[2] were the only stable compounds in which phosphorus has this coordination number. We report here the synthesis of a donor-stabilized iminophosphenium ("monophosphadiazonium") ion **B** by reaction of the imino(phosphino)phosphane **1** with selenium.

$[N{\equiv}N{-}R]^{\oplus}$ **A** $[P{\equiv}N{-}R]^{\oplus}$ **B** $P{\equiv}C{-}R$ **C**

It appears likely that selenium is primarily added to the central phosphorus atom to give the selenoxophosphane **2**.[3] Subsequent selenium insertion into the P–P bond yields the imino(seleno)phosphane **3**,[4] which can be isolated in the form of reddish-brown crystals upon reaction of equimolar amounts of the starting materials. Further addition of selenium leads to a red, crystalline 1:1 "adduct" of **3** and selenium; the latter proved to be the donor-stabilized iminophosphenium ion **4** (Scheme 1).

The structures of the compounds **3** and **4** have been determined from their elemental analyses, mass spectra,[5] NMR data,[5] and, in the case of **4**, by an X-ray structure analysis. In the $^{31}P\{^1H\}$-NMR spectrum of **3** the $>P-Se-P=N-$ structural unit gives rise to two groups of signals ($\delta = 324.7$, 84.5 ppm; $J_{PP} = 212$ Hz), the ^{77}Se satellites of which ($J_{PSe} = 366$ and 202 Hz) confirm the coupling of the two phosphorus atoms via a selenium bridge. The drastic changes induced in the phosphorus spectrum by the addition of a second selenium atom ($\delta = 92$, 79 ppm; $J_{PP} = 35$ Hz), and in particular the extreme difference in the ^{31}P-^{77}Se coupling constants ($J_{PSe} = 15$ and 516 Hz), cannot be explained by the presence of classical structures with sp^2-hybridized λ^5- and λ^3-phosphorus atoms such as $>P(=Se)-Se-P=N-$ or $>P-Se-P(=Se)=N-$. These results, as well as the $^{77}Se\{^1H\}$-NMR spectrum, which shows only one set of signals at higher field, indicate a fast exchange process induced by an intramolecular nucleophilic attack of the selenoxo selenium atom at the electrophilic center of the P=N group. At a temperature of $-80°C$ the multiplet structure remains unchanged, though the "iminophosphane" phosphorus signal is shifted upfield by 25 ppm; the energy barrier for such an exchange process must therefore be very low. The solid-state ^{31}P-NMR spectrum of **4** was surprisingly almost unchanged from that in solution ($\delta = 116$ (br), $J_{PSe} = <20$ Hz; 81, $J_{PSe} = 520$ Hz), and can be interpreted in terms of a "frozen transition state" **4'**.



Scheme 1. R = *t*Bu, Aryl = 2,4,6-*t*Bu$_3$C$_6$H$_2$.

This suggested structure is confirmed by the X-ray structural analysis (Fig. 1).[6] The distorted tetrahedral coordination of the P(1) atom and the P(1)–Se(1)/Se(2) bond lengths (216–217 pm) correspond to the typical structural features of a diselenophosphinate. The P–N distance of 150 pm is considerably shorter than that found in iminophosphanes (e.g. Mes*–P=N*t*Bu: 156 pm[7]) and corresponds to that in the PN molecule (149 pm[8]). The N–N bond length in diazonium compounds (109–111 pm[8]) is also comparable with that in the N_2 molecule (110 pm[9]). The valence angle of 169° at the N atom shows it to be sp-hybridized, the deviation from the ideal angle of 180° indicating the presence of an interaction between the donor ligands and the PN bond system: in agreement with this, the P(2)–Se(1)/Se(2) bond lengths (264 and 279 pm respectively) are considerably shorter than the sum of the van der Waals radii. The electron transfer to the P(2) atom also manifests itself in the (*E*)-configuration of the PSe_2PN

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *H. Förster*, Bruker Analytische Messtechnik, Karlsruhe (FRG), for recording the solid-state NMR spectrum. Aryl = 2,4,6-*t*Bu$_3$C$_6$H$_2$.

skeleton (folding angles $\alpha = 160°$, $\beta = 125°$) (Fig. 1, bottom) and the resulting pyramidalization at P(2), which indicates stereochemical activity of the lone pair on this phosphorus atom.

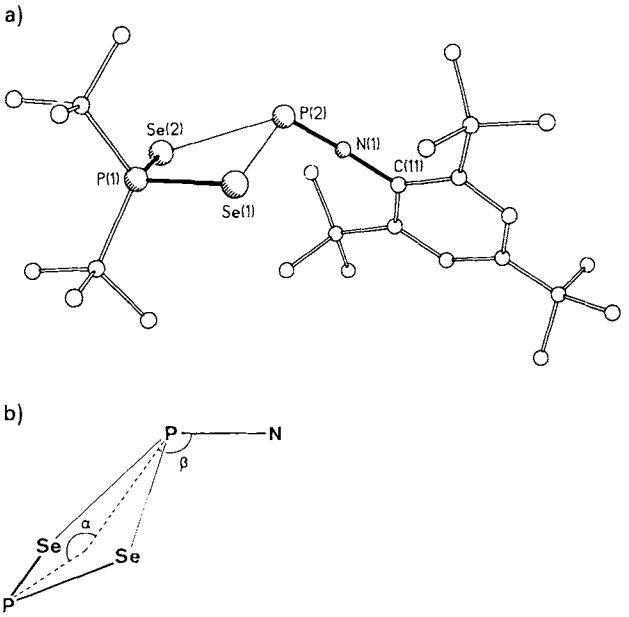

Fig. 1. a) Crystal structure of **4** (H atoms not shown); most important bond lengths [pm] and angles [°]: P(1)-Se(1) 217.0(5), P(1)-Se(2) 215.9(4), P(2)-Se(1) 263.6(5), P(2)-Se(2) 278.8(5), P(2)-N(1) 149.3(12), N(1)-C(11) 139.7(18); Se(1)-P(1)-Se(2) 108.3(2), Se(1)-P(2)-Se(2) 80.6(1), P(1)-Se(1)-P(2) 85.7(2), P(1)-Se(2)-P(2) 82.2(2), Se(1)-P(2)-N(1) 112.6(6), Se(2)-P(2)-N(1) 119.6(5), P(2)-N(1)-C(11) 169.1(11). b) Folding angles of the PSe_2PN skeleton: $\alpha = 159.8°$, $\beta = 125.6°$.

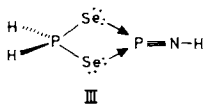
The analysis of the interactions between the frontier orbitals of the anion $[H_2PSe_2]^{\ominus}$ **I** and the cation $[H-N\equiv P]^{\oplus}$ **II** showed that electron density is transferred from the three almost degenerate doubly occupied p-MOs of the selenium atom into the π^*-MOs of the PN bond, thus leading to a weak bond between selenium and P(2). Electron transfer in the opposite direction does not occur because of the considerably greater energy difference between the HOMO of **II** and the LUMO of **I**. **I** and **II** form the donor-acceptor complex **III**. This is in accord with the results



III

of population analyses at various levels (semiempirical, ab initio).[11] The polarity of the PN bonding system in **III** is similar to that in the isolated cation **II**; both the PN molecule and **II** and **III** have a high degree of triple bond character.

Experimental

A mixture of **1** (1.4 g, 3.21 mmol) and grey selenium (253 or 507 mg; 3.21 and 6.42 mmol respectively) in 7 mL of benzene was stirred for 3 h at room temperature. The solution was filtered off and the solvent removed in vacuo. The product was purified by recrystallization from a little hexane or from 9 mL of hexane/toluene (4:3). M.p. = 156–158 °C (**3**), 170–173 °C (**4**). Yields: 1.05 g (64%) and 1.23 g (65%) respectively.

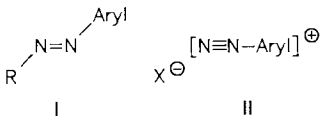
Arylimino(halogeno)phosphanes $XP{=}NC_6H_2tBu_3$ (X = Cl, Br, I) and the Iminophosphenium Tetrachloroaluminate $[P{\equiv}NC_6H_2tBu_3]^{\oplus}[AlCl_4]^{\ominus}$: the First Stable Compound with a PN Triple Bond

By *Edgar Niecke,* Martin Nieger,* and *Franz Reichert*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

The formal replacement of an alkyl group in alkyl(aryl)diazo compounds **I** by a halogen atom leads, as is well known, to the diazonium compounds **II**.[1] There have been several recent reports concerning the iminophosphanes R–P=N–Aryl analogous to **I**[2] and their carbene-like behavior, which has been demonstrated by numerous [n+1]-cycloaddition reactions.[2,3] A PN-analog of **II** was however previously unknown. We report here the synthesis and structure of the first arylimino(halogeno)phosphanes and also of an iminophosphenium ("monophosphadiazonium") ion which is obtainable from them.



I II

Surprisingly, the stable chloro(imino)phosphane **1** can be readily prepared by reaction of PCl_3 with 2,4,6-tri-*tert*-butylaniline in the presence of triethylamine. The corresponding bromo- and iodo-derivatives **2** and **3** were obtained via halogen exchange with bromo- and iodotrimethylsilane respectively.

$$PCl_3 + H_2N{-}Aryl \xrightarrow[-Et_3NHCl]{Et_3N} \underset{\mathbf{1}}{Cl{-}P{=}N{-}Aryl} \xrightarrow[-Me_3SiCl]{Me_3SiX} \underset{\mathbf{2},\ X=Br;\ \mathbf{3},\ X=I}{X{-}P{=}N{-}Aryl}$$

Aryl = 2,4,6-$tBu_3C_6H_2$

The iminophosphanes **1**–**3** are bright-red (**1**, **2**) or orange (**3**) solids which are stable under inert gas. Their structures have been determined by elemental analysis, mass and NMR spectroscopy, and, in the case of **1**, by an X-ray structural analysis. While in the corresponding *P*-alkylated iminophosphanes R–P=N–Aryl $\delta(^{31}P) = 487$–516 ppm,[2] compounds **1**–**3** show a remarkable high-field shift for the ^{31}P nucleus: $\delta = 139$ (**1**), 153 (**2**), 218 (**3**); this can be interpreted in terms of a high degree of s-character for the PN bond.[4] The molecular structure[5] (Fig. 1) confirms this suggestion: thus the angle of 155° at N(1) is significantly larger than that in the known structures of amino(imino)phosphanes and aryl(imino)phosphanes,[6] while the Cl–N–P–C skeleton has a *cis*-geometry not previously observed for iminophosphanes.[7] Both results are in agreement with the very short P–N bond (149.5 pm) and the long P–Cl bond (214 pm), which indicate a transition to the iminophosphenium ion analogous to **II**. **4** could indeed be prepared by treating **1** with aluminum trichloride, in analogy to the synthesis of aminophosphenium ions from amino(chloro)phosphanes.[8]

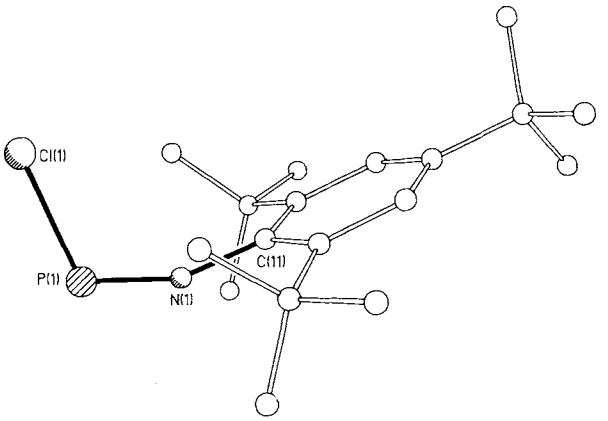


Fig. 1. Crystal structure of **1**. Important bond lengths [pm] and angles [°]: P(1)–Cl(1) 214.2(4), P(1)–N(1) 149.5(4), N(1)–C(11) 140.2(6); Cl(1)–P(1)–N(1) 112.4(2), P(1)–N(1)–C(11) 154.8(4), Cl(1), P(1), N(1) and C(11) are coplanar.

$$\mathbf{1} \xrightarrow[-[AlCl_4]^{\ominus}]{AlCl_3} [PNAryl]^{\oplus}\ \mathbf{4} \qquad Aryl = 2,4,6\text{-}tBu_3C_6H_2$$

The formation of the cation **4** is accompanied by a significant high-field shift of the ^{31}P-NMR signal; the phosphorus nucleus in the isoelectronic phosphaalkyne $P{\equiv}C{-}C_6H_2tBu_3$ is also comparatively strongly shielded.[9] The X-ray structural analysis of **4**[10] (Fig. 2) showed unequivocally that "isolated" molecular ions are present in the crystal. The bond lengths and angles in the anion are typical for tetrachloroaluminates (e.g. $KAlCl_4$: 211–214 pm[11]). With respect to Cl(1), Cl(2) and Cl′ the coordination at the P atom is distorted trigonal bipyramidal with the lone pair in an equatorial position.[12] While in **II** both N atoms are in contact with four Cl atoms,[1] in **4** there is an interaction only for the P atom; this indicates very considerable localization of the positive charge at this atom, the shortest contact (P···Cl(2) 316 pm) demonstrating that the cation originates from the iminophosphane **1**. The bonding situation in the cation, with an almost ideal hybridization of the N atom (177°) and the very short PN

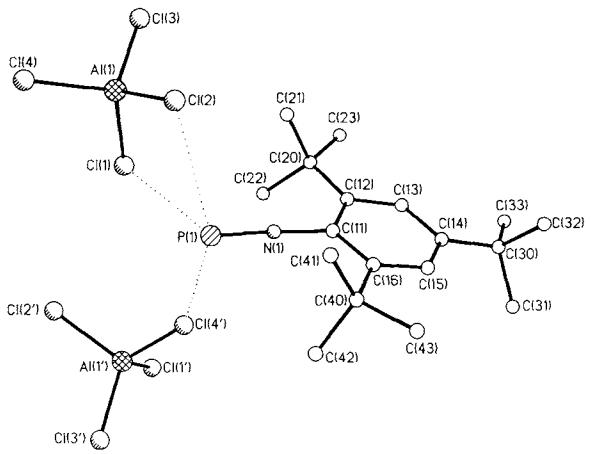

Fig. 2. Crystal structure of **4**. Important bond lengths [pm] and angles [°]: P(1)–N(1) 147.5(8), N(1)–C(11) 140.9(12), Al(1)–Cl(1) 213.2(5), Al(1)–Cl(2) 212.3(5), Al(1)–Cl(3) 210.8(5), Al(1)–Cl(4) 212.0(5), P(1)–Cl(1) 316, P(1)–Cl(2) 327, P(1)–Cl(4′) 352; P(1)–N(1)–C(11) 177.0(7).

bond (147.5 pm; $[P\equiv NH]^{\oplus}$, 147.6 pm[13]), thus corresponds to a formulation in which **4** has a very high degree of triple-bond character in the phosphorus-nitrogen bond ($[:P\equiv N-Aryl]^{\oplus}$); an SiN triple bond is also assumed for the isoelectronic arylsilaisocyanide $:Si\equiv N-Aryl$.[14]

Experimental

1: A solution of 2,4,6-tri-*tert*-butylaniline (3.70 g, 14.2 mmol) in pentane (5 mL) was treated wiith an excess of PCl_3 (113 mmol) and Et_3N (148.5 mmol): the mixture was stirred at room temperature until the reaction was complete (5 d). The amine hydrochloride formed was removed via an inverse sintered glass filter and the filtrate freed in vacuo from all volatile materials. **1** was obtained as a deep-red solid after two recrystallizations from a little *n*-hexane. Yield 3.88 g (72%); m.p. = 93–94 °C, MS: *m/z* 325 ($M^{\oplus}$, 60%), 310 ($M^{\oplus}-CH_3$, 100), 290 ($M^{\oplus}-{}^{35}Cl$, 18) and further ions; ^{31}P NMR (hexane/C_6D_6): $\delta = 138.6$; ^1H NMR (C_6D_6): $\delta = 1.3$ (s, 9H, *p*-*t*Bu), 1.5 (s, 18H, *o*-*t*Bu), 7.6 (d, $J_{HP} = 2.1$ Hz, 2H, Aryl); ^{13}C NMR (C_6D_6): $\delta = 31.0$ (d, $J_{CP} = 2.4$ Hz, *o*-CC_3), 31.6 (d, $J_{CP} = 1.0$ Hz, *p*-CC_3), 35.0 (d, $J_{CP} = 1.3$ Hz, *p*-CC_3), 35.9 (d, $J_{CP} = 1.8$ Hz, *o*-CC_3), 122.1 (d, $J_{CP} = 3.6$ Hz, PNC*C*), 138.7 (d, $J_{CP} = 40.6$ Hz, PN*C*), 139.7 (d, $J_{CP} = 10.6$ Hz, PNC*C*), 147.4 (d, $J_{CP} = 5.8$ Hz, PNCC*C*).

2, **3**: A solution of **1** (0.84 g, 4.2 mmol) in *n*-hexane (10 mL) was treated dropwise at 0 °C with an equimolar amount of Me_3SiBr or Me_3SiI respectively. After stirring for 3 h the solvent was removed in vacuo; the red (**2**) or brown (**3**) solid remaining was purified by recrystallzation from pentane/toluene (5:1). Yield 0.67 g (43%) **2**, m.p. = 79–81 °C; 0.79 g (45%) **3**, m.p. = 87–89 °C.—**2**: MS: *m/z* 369 ($M^{\oplus}$, 11%), 354 ($M^{\oplus}-CH_3$, 8), 290 ($M^{\oplus}-{}^{79}Br$, 86) and further ions; ^{31}P NMR (hexane/C_6D_6): $\delta = 153.3$; ^1H NMR (C_6D_6): $\delta = 1.3$ (s, 9H, *p*-*t*Bu), 1.5 (s, 18H, *o*-*t*Bu), 7.6 (d, $J_{HP} = 2.4$ Hz, 2H, aryl); ^{13}C NMR (C_6D_6): $\delta = 31.2$ (d, $J_{CP} = 2.2$ Hz, *o*-CC_3), 31.5 (d, $J_{CP} = 1.5$ Hz, *p*-CC_3), 35.1 (d, $J_{CP} = 1.5$ Hz, *p*-CC_3), 36.0 (d, $J_{CP} = 2.2$ Hz, *o*-CC_3), 122.2 (d, $J_{CP} = 3.7$ Hz, PNCC*C*), 139.0 (d, $J_{CP} = 42.8$ Hz, PN*C*), 139.7 (d, $J_{CP} = 11.0$ Hz, PNC*C*), 148.2 (d, $J_{CP} = 5.9$ Hz, PNCCC*C*).

3: MS: *m/z* 417 ($M^{\oplus}$, 1%), 290 ($M^{\oplus}-{}^{127}I$, 100), and further ions; ^{31}P NMR (toluene/C_6D_6): $\delta = 217.7$, ^1H NMR (C_6D_6): $\delta = 1.4$ (s, 18H, *p*-*t*Bu), 1.5 (s, 18H, *o*-*t*Bu), 7.5 (d, $J_{HP} = 2.4$ Hz, 2H, aryl); ^{13}C NMR (C_6D_6): $\delta = 31.3$ (d, $J_{CP} = 1.5$ Hz, *p*-CC_3), 31.6 (d, $J_{CP} = 2.2$ Hz, *o*-CC_3), 35.1 (d, $J_{CP} = 1.5$ Hz, *p*-CC_3), 36.2 (d, $J_{CP} = 1.5$ Hz, *o*-CC_3), 122.3 (d, $J_{CP} = 3.7$ Hz, PNCC*C*), 138.3 (d, $J_{CP} = 11.0$ Hz, PNC*C*), 140.4 (d, $J_{CP} = 50.3$ Hz, PN*C*), 148.6 (d, $J_{CP} = 5.9$ Hz, PNCCC*C*).

4: A solution of **1** (1.9 g, 5.83 mmol) in toluene (10 mL) was treated at 0 °C with 0.78 g (5.83 mmol) $AlCl_3$. After stirring for 2 h the solvent was removed. The residue was recrystallized twice from C_6H_6/CH_2Cl_2 (2:1). Yield 1.57 g (59%) pale yellow crystals. M.p. = 132–135 °C (dec.). MS: spectrum not reproducible; ^{31}P NMR (toluene/C_6D_6): $\delta = 79.3$; ^1H NMR (C_6D_6): $\delta = 1.3$ (s, 9H, *p*-*t*Bu), 1.6 (s, 18H, *o*-*t*Bu), 7.5 (d, $J_{HP} = 4.5$ Hz, 2H, aryl); ^{13}C NMR (C_6D_6): $\delta = 29.9$ (d, $J_{CP} = 1.5$ Hz, *o*-CC_3), 30.4 (s, *p*-CC_3), 35.1 (s, *p*-CC_3), 35.9 (s, *o*-CC_3), 123.3 (d, $J_{CP} = 2.9$ Hz, PNCC*C*), 153.3 (d, $J_{CP} = 5.9$, PN*C*), 153.8 (d, $J_{CP} = 5.1$ Hz, PNC*C*), 157.2 (d, $J_{CP} = 8.8$ Hz, PNCCC*C*).

Electrocatalytic Haloform Reaction: Transformation of Methyl Ketones into Methyl Esters

By *Gennady I. Nikishin,* Michail N. Elinson,* and *Irina V. Makhova*

The haloform reaction is often used for the conversion of methyl ketones into carboxylic acids or esters.[1,2] It has acquired importance primarily because of the fact that the introduction of a carboxyl group as substituent onto an aromatic ring is usually more difficult than the introduction of the acetyl group.

Methyl ketones are generally converted into carboxylic acids by halogen and sodium hydroxide.[1] Recently, sodium bromite has been found to be an effective reagent for the haloform reaction.[3] In the course of our investigations on the synthetic utility of alkali metal halides as mediators in the electrooxidation of organic compounds[4–6] we have now found the electrocatalytic variant of the haloform reaction.

The electrolysis of the methyl ketones **1** in an undivided cell in methanol in the presence of 0.35–3.00 molar equivalents of sodium bromide leads to the corresponding methyl esters **2** (Table 1).

$$\underset{\mathbf{1}}{RC(O)Me} \xrightarrow[NaBr,\ MeOH]{-e^-} \underset{\mathbf{2}}{RCOOMe}$$

Table 1. Electrooxidation of the methyl ketones **1**.

Ketone	R	[NaBr]/[**1**]	Yield [%] of **2**
1a	Ph	3.00	71
1a	Ph	1.50	74
1a	Ph	0.75	63
1a	Ph	0.35	64
1b	1-naphthyl	1.50	88
1c	$Me(CH_2)_5$	1.50	62
1d	*i*Pr	1.50	67 [a]
1e	PhCH=CH	1.50	61

[a] Determined by gas chromatography.

N. D. Zelinsky Institute of Organic Chemistry,
USSR Academy of Sciences
Leninsky Prospect 47, Moscow B-334 (USSR)

On completion of the reaction we also detected bromoform, in quantities decreasing from 0.2 to 0.05 equivalents with decreasing amount of sodium bromide used.

The mechanism suggested for the reaction is shown in Scheme 1.

anode: $6\,Br^{\ominus} \longrightarrow 3\,Br_2 + 6\,e^{\ominus}$

cathode: $6\,MeOH + 6\,e^{\ominus} \longrightarrow 6\,MeO^{\ominus} + 3\,H_2$

in solution: $RC(O)Me + 3\,Br_2 \longrightarrow RC(O)CBr_3 + 3\,H^{\oplus} + 3\,Br^{\ominus}$

$RC(O)CBr_3 + MeO^{\ominus} \longrightarrow RCOOMe + CBr_3^{\ominus}$

Scheme 1. Possible reaction mechanism of the electrocatalytic haloform reaction.

The bromoform formed in the last reaction step is further reduced at the cathode or reacts with methoxide ion. Both reactions lead to the regeneration of bromide ions. Thus the reaction proceeds catalytically, but for good yields as shown in Table 1, an excess of bromide is recommended.

Our facile and effective method has, therefore, the great advantage that sodium bromide, which is readily accessible and easy to handle, can be used instead of three molar equivalents of halogen or sodium bromite.

As shown in Table 1, not only aryl and alkyl methyl ketones but also unsaturated methyl ketones (**1e**) are converted into the corresponding methyl esters.

Under the same conditions cyclohexanone **3a** and ethyl phenyl ketone **3b** are oxidized to the α-hydroxy acetals **4a** and **4b** respectively in 75–80% yield; the reaction proceeds similarly to a previously reported reaction.[7]

$$R^1C(O)CH_2R^2 \xrightarrow[NaBr,\ MeOH]{-e^-} R^1C(OMe)_2CHOHR^2$$

3a, b **4a, b**

a, $R^1 + R^2 = -(CH_2)_4-$; **b**, $R^1 = Ph$, $R^2 = Me$

Only benzyl methyl ketone behaved differently under these conditions: it afforded **7** and, by electrochemically induced Favorskii rearrangement, the propionate **6** (yields: 40 and 50% resp.).

$$PhCH_2C(O)Me \xrightarrow[NaBr,\ MeOH]{-e^-}$$

5

$$PhCH_2CH_2COOMe + PhCHOHC(OMe)_2Me$$

6 **7**

5 : 4

Experimental

The experimental procedure is described for the example **2b**: A solution of **1b** (0.02 mol) and NaBr (0.03 mol) in methanol (20 mL) was electrolyzed in an undivided cell equipped with a Pt-anode (4.5 cm^2) and a Cu-Zn (60:40) cathode (4.5 cm^2) at 30 °C under constant current density 220 mA cm^{-2} until 8 F/mol of electricity had been used. The solvent was then removed and the reaction mixture extracted with ether, washed with water, and dried with Na_2SO_4. After distillation 3.3 g (88%) of **2b**, b.p. 93–94 °C (0.1 torr), $n_D^{21} = 1.6079$ was obtained; ^{1}H-NMR ($CDCl_3$): $\delta = 4.01$ (s, 3H, OCH_3), 7.5–8.3 (m, 7H, aryl-H) [8].

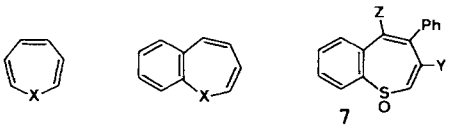
The First Transition Metal Complex of a Thiepin; Synthesis of the Thermally Labile 1-Benzothiepin 1-Oxide from 1-Benzothiepin(tricarbonyl)iron

By *Keitaro Nishino,* Sumiko Ishigami, Yutaka Tamura, Kazuko Imagawa, Yoshikazu Ikutani,* and *Ichiro Murata**

Unlike thiepin 1,1-dioxide **3**,[1] which has been isolated as a stable crystalline compound, thiepin itself **1** and its 1-oxide **2** are considered to be extremely unstable molecules.[2] On the other hand, 1-benzothiepin **4**[3,4] and its 1,1-dioxide **6**[5–7] are well characterized, but 1-benzothiepin 1-oxide **5** has not yet been synthesized. Hitherto known thiepin 1-oxides, which are confined to heavily substituted 1-benzothiepin 1-oxides such as **7a**–**7d**,[8] are thermally less stable than the corresponding 1-benzothiepins. Therefore, in view of the thermal instability of **4**



1, X = S **4**, X = S **7**
2, X = SO **5**, X = SO
3, X = SO_2 **6**, X = SO_2

a, Y = $OCOCH_3$, Z = OCH_3
b, Y = Z = OCH_3
c, Y = OCH_3, Z = $OCOCH_3$
d, Y = Z = $OCOCH_3$

($\tau_{1/2}$ at 47 °C = 58 min),[3b] synthesis of unsubstituted **5** has to be done using an appropriate precursor under mild reaction conditions. Lack of success in our previous attempts[6] to synthesize **5** by means of direct oxidation of **4** prompted us to take advantage of a transition-metal complexation strategy.[9] Thus, **4** was converted into iron tricarbonyl complex **8** in 41% yield (Scheme 1). The η^4 complexation at the thiepin ring was confirmed by the ^{1}H NMR spectrum of **8** which exhibits substantially high-field chemical shifts for H-2 and H-5 ($\delta = 3.89$ and 4.29, respectively). Complex **8** provides the first example of a thiepin–metal complex.

On oxidation with *m*-chloroperbenzoic acid (*m*CPBA), complex **8** was smoothly converted into the monoxide **9** in 98% yield as stable yellow needles. The structure of **9** was unambiguously established through its spectral data (Table 1) together with its chemical behavior. Thus, reduction of **9** with lithium aluminum hydride regenerated **8**, whereas further oxidation of **9** with *m*CPBA provided dioxide complex **10**, which was identical in all respects with an authentic sample prepared from the known 1-benzothiepin 1,1-dioxide **6**.[5,6]

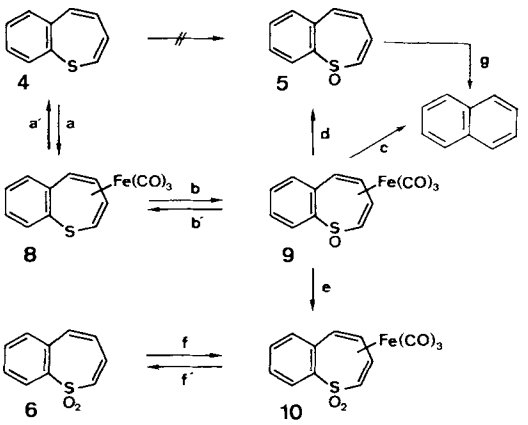

Scheme 1. Synthesis of **5** from **4** and some related reactions. a) $Fe_2(CO)_9$ (large excess) in hexane, $<15°C$, 3 d (41%). a') $Ce(NH_4)_2(NO_2)_6$ (CAN) (2.0 equiv.) in acetone, 0°C, 2 h (73%). b) *m*-chloroperbenzoic acid (*m*CPBA) (1.2 equiv.) in chloroform, −40°C, 1 h (98%). b') $LiAlH_4$ (excess) in ether/THF (1:1), −20°C, 2 h (63%). c) CAN (2.0 equiv.) in acetone, −30°C, 1 h, then −10°C, 3 h (afforded only naphthalene). d) Irradiation (400-W Hg lamp) in THF, −50°C, 1 h (afforded **5** exclusively). e) *m*CPBA (1.2 equiv.) in chloroform, −40°C, 2 h (61%). f) $Fe_2(CO)_9$ (3.0 equiv.) in THF, 40°C, 1 d (58%). f') Irradiation (400-W Hg lamp) in THF, 0°C, 2 h (76%). g) At 13°C (<1 h).

Table 1. Selected physical data for **5**, **8**, **9**, and **10** [10].

5: Pale yellow needles at −40°C; 200-MHz ^1H NMR (CD_2Cl_2) at −30°C: $\delta=6.08$ (d, 1 H, $J=9.8$ Hz, H-2), 6.38 (dd, 1 H, $J=9.8$, 5.4 Hz, H-3), 6.69 (dd, 1 H, $J=12.0$, 5.4 Hz, H-4), 7.38 (d, 1 H, $J=12.0$ Hz, H-5), 7.4–8.0 (m, 4 H, H-6,7,8,9)

8: Yellow needles, m.p. 83.0–83.5°C (from hexane); UV (cyclohexane): $\lambda_{max}(\lg\varepsilon)=276$ (4.06), 310 (sh, 3.94) nm; IR (Nujol): $\tilde{\nu}=2050$, 1982, 1977 cm^{-1}; 90-MHz ^1H NMR ($CDCl_3$): $\delta=3.89$ (dd, 1 H, $J=7.0$, 1.8 Hz, H-2), 4.29 (dd, 1 H, $J=8.1$, 0.8 Hz, H-5), 5.04 (ddd, 1 H, $J=8.1$, 4.7, 1.8 Hz, H-4), 5.24 (ddd, 1 H, $J=7.0$, 4.7, 0.8 Hz, H-3), 6.91–7.04 (m, 3 H, H-6,7,8), 7.18–7.29 (m, 1 H, H-9)

9: Yellow needles, m.p. >300°C (from benzene + hexane); UV (EtOH): $\lambda_{max}(\lg\varepsilon)=210$ (3.43), 225 (sh, 3.42), 312 (2.74) nm; IR (Nujol): $\tilde{\nu}_{CO}=2063$, 2006, 1988, $\tilde{\nu}_{SO}=1017$ cm^{-1}; 500-MHz ^1H NMR ($CDCl_3$): $\delta=3.86$ (d, 1 H, $J=8.4$ Hz, H-5), 4.03 (d, 1 H, $J=6.7$ Hz, H-2), 5.99 (dd, 1 H, $J=8.4$, 5.0 Hz, H-4), 6.10 (dd, 1 H, $J=6.7$, 5.0 Hz, H-3), 7.24–7.36 (m, 3 H, H-6,7,8), 7.48 (m, 1 H, H-9)

10: Yellow needles, m.p. 168.5–169.5°C (from benzene); UV (EtOH): $\lambda_{max}(\lg\varepsilon)=215$ (3.90), 312 (2.17) nm; IR (Nujol): $\tilde{\nu}_{CO}=2088$, 2028, 2006, $\tilde{\nu}_{SO_2}=1275$, 1120 cm^{-1}; 500-MHz ^1H NMR ($CDCl_3$): $\delta=3.84$ (dd, 1 H, $J=7.2$, 1.4 Hz, H-2), 3.95 (bd, 1 H, $J=8.4$ Hz, H-5), 5.87 (ddd, 1 H, $J=8.4$, 5.0, 1.4 Hz, H-4), 5.92 (ddd, 1 H, $J=7.2$, 5.0, 0.8 Hz, H-3), 7.28–7.34 (m, 3 H, H-6,7,8), 7.74 (m, 1 H, H-9)

In order to obtain **5** through oxidative decomplexation, **9** was treated with ceric ammonium nitrate. Monitoring of the reaction by thin layer chromatography reveals that a new polar spot appears, accompanied by a decrease in the less polar spot due to **9**. After 3 h at −10°C, however, the reaction mixture exhibited neither a polar nor a less polar spot on TLC examination. Workup of the reaction mixture afforded only naphthalene quantitatively, suggesting that the species responsible for the new polar spot might be assigned to **5**. The decomplexation can also be performed by photolysis. Irradiation of a dilute THF solution of **9** with a 400-W Hanovia lamp through quartz at −50°C resulted in the formation of **5**, which could be isolated and purified as pale yellow needles (at −40°C) through low-temperature column chromatography on silica gel (hexane) at −40°C.[10]

The first indication of its structure came from the 200-MHz ^1H NMR spectrum[11] measured at −30°C in CD_2Cl_2 which exhibited two doublets at $\delta=6.08$ (H-2) and 7.38 (H-5), two doublets of doublets at $\delta=6.38$ (H-3) and 6.69 (H-4), and an aromatic proton multiplet at $\delta=7.4$–8.0 in the ratio 1:1:1:1.2:5.5, indicating a small contamination with naphthalene. These chemical shifts are quite similar to those of 1-benzothiepin **4**. This implies no appreciable changes in electronic and geometric structures on going from **4** to its *S*-oxide **5**.[12] As expected, **5** was found to be less stable than **4** and the ^1H NMR signals due to **5** were completely replaced by those of naphthalene within 1 h at 13°C.

In view of the fact that the thermal stability of 2,3-diphenylthiirene 1-oxide was reported to be greater than that of the corresponding 1,1-dioxide,[13] it is interesting to note that 1,1-dioxide **6** is markedly more stable than 1-oxide **5**.

It is thus apparent that the thermally labile **4** and **5** can be substantially stabilized by complexation with iron tricarbonyl. Furthermore, the success in decomplexation of **9** by means of irradiation at low temperature suggests, in principle, the possibility of detecting parent thiepin **1** through its transition-metal complex by low-temperature photolysis. Efforts to achieve this goal are in progress.

Direct Michael Additions of Silyl Groups to α,β-Unsaturated β-Arylketones and an α-Benzylidenelactone with Mixtures Obtained from Copper(I) Cyanide, Butyllithium and Chlorosilanes

By *Willi Amberg* and *Dieter Seebach**

It is well known that the silyl cuprates generated in the usual way from lithiosilanes undergo 1,4-addition to α,β-unsaturated carbonyl compounds.[1,2] The prerequisite lithiosilanes are prepared from the corresponding disilanes and an alkyllithium compound (HMPA/0°C)[3] or from chlorosilanes and Li metal (THF/−8°C/36 h).[4] It is also known[5] that the primary adduct enolates formed on addi-

[*] Prof. Dr. D. Seebach, Dipl.-Chem. W. Amberg [+]

[+] Part of the projected Ph. D. thesis of W. A., ETH Zürich

tion of organocuprates[5–8] or Grignard reagents doped with Cu^{I} salts[9] to α,β-unsaturated carbonyl compounds can be trapped in situ as silyl enol ethers by carrying out the reactions in the presence of chlorosilanes.

Much to our surprise, we found that a variety of α,β-unsaturated β-arylketones (**3**) and an α-benzylidenelactone (**1**) furnish the β-silylated carbonyl derivatives **4** and **2**, respectively, when a solution of butyllithium and CuCN in THF is treated slowly at −75°C with a mixture of enone and chlorosilane (1:2), followed by low-temperature quenching with aqueous ammonia.[10]

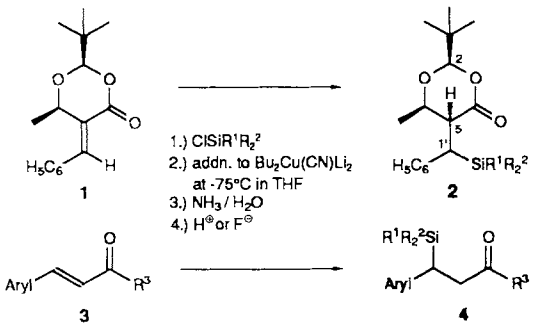

Table 1. Products **2** and **4** obtained from dioxanone **1** [11] and from the enones **3** [4-phenyl-3-buten-2-one, 1,3-diphenyl-2-propen-1-one, 3-(*p*-methoxyphenyl)-1-phenyl-2-propen-1-one] (see typical procedure). The specific rotations $[\alpha]_D^{RT}$ were measured in $CHCl_3$ (c=0.5–1.0). The IR, ^1H and ^{13}C NMR, and MS spectra as well as the elemental analyses are all in agreement with the structures shown.

	Product						
	R_1	R^2	R^3	Aryl	Yield [%]	M.p. [°C]	$[\alpha]_D^{RT}$ [°]
2a	CH_3	CH_3	—	—	81	oil	−61.5
2b	C_2H_5	C_2H_5	—	—	70	oil	−63.0
2c	t-C_4H_9	CH_3	—	—	71 [a]	92–93	−55.5
2d	C_6H_5	CH_3	—	—	52	96–97	−52.0
4a	t-C_4H_9	CH_3	CH_3	C_6H_5	68	oil	
4b	C_6H_5	CH_3	CH_3	C_6H_5	65	40–41	
4c	CH_3	CH_3	C_6H_5	C_6H_5	66	83–84	
4d	C_6H_5	CH_3	C_6H_5	C_6H_5	62	73–74	
4e	CH_3	CH_3	C_6H_5	p-$CH_3OC_6H_4$	59	92–93	
4f	C_6H_5	CH_3	C_6H_5	p-$CH_3OC_6H_4$	72	76–78	

[a] The temperature must be raised to −40°C for addition to be completed in this case.

No concomitant butyl transfer was observed with the dioxanone substrate **1**,[11] but only the reaction **1**→**2**, whereas the open-chain β-silylketones **4** were formed together with the corresponding β-butyl derivatives in the ratio 6:1–10:1 from the enones **3**.[12] The specific products prepared are listed together with some physical data in Table 1; the yields given are those obtained after *O*-desilylation of the initially formed silyl enol ethers[13] and after subsequent flash chromatographic purification.

Of the possible Michael adducts **2**, in each case only a single stereoisomer was formed with a selectivity of 92% (**2d**), 97% (**2c**) and 98% (**2a**, **b**). The chirality sense at C2 and C6 of these products must be (*R*), as in the precursor;[11] following a comparison of the coupling constants H-C5/H-C6 in the ^1H-NMR spectra with those of numerous analogous products we assign an (*R*) configuration to C5 as well.[14] The configuration of the silylated carbon C(1′) was not determined.[15]

Under the conditions described here it is possible to add a variety of silyl groups to certain Michael acceptors in a much simpler way than was possible by previously reported methods.

Typical Procedure

A suspension of 1 equiv. CuCN in dry THF (20–30 mL) was treated with 2 equiv. BuLi (1.4 M in hexane) at −75°C and the mixture warmed to −40°C under argon. To the slightly yellow solution thus obtained was added dropwise at −75°C a solution of 0.5 equiv. **1** or **3** and 1.0–1.5 equiv. $R^1R_2^2SiCl$ in THF (10–15 mL) within 1 h. A temporary dark yellow (with **1**) or deep red color (with **3**) developed. The slightly yellow solutions present after completion of addition of **1** or **3** were stirred at −75°C until the starting material was consumed (tlc analysis of withdrawn samples). Concentrated aq. NH_3 (10–30 mL for 1–10 mmolar runs) was added, and the mixture allowed to warm to +20°C, with the reaction flask open to the air. Subsequent extraction with ether (blue aq. phase), drying over $MgSO_4$ and removal of the solvent by evaporation afforded a crude mixture containing varying ratios of silylated free ketone and silylated silyl enol ether. The latter was treated as mentioned in Ref. [13] to hydrolyze the enol ethers. Flash chromatography and kugelrohr distillation, or crystallization, furnished the pure products (for yields, see Table 1).

$[V_{19}O_{41}(OH)_9]^{8\ominus}$, An Ellipsoid-Shaped Cluster Anion Belonging to the Unusual Family of V^{IV}/V^{V} Oxygen Clusters

By *Achim Müller,* Michael Penk, Erich Krickemeyer, Hartmut Bögge,* and *Heinz-Jürgen Walberg*

Although only one "larger" V^V isopolyanion, namely, $[V_{10}O_{28}]^{6\ominus}$, has been reported so far, the number of V^{IV}/V^V

[*] Prof. Dr. A. Müller, M. Penk, E. Krickemeyer, Dr. H. Bögge, H.-J. Walberg

oxygen clusters should be far greater according to our hypothesis.[1] We have now obtained the black compound **1**, which belongs to this family of clusters and have characterized it by elemental analysis, manganometric titration of V^{IV}, thermoanalysis, IR spectroscopy, magnetic measurements, and single-crystal X-ray structure analysis.[2]

$(NH_4)_8[V_{19}O_{41}(OH)_9]\cdot 11H_2O$ **1**

The anion $[V_{19}O_{41}(OH)_9]^{8\ominus}$[3] contains a large number of protons: it has the shape of an ellipsoid of approximate C_3 (or, without the central V atom, D_3) symmetry and is generated by joining 12 VO_6 octahedra (V^{IV}) and 6 VO_4 tetrahedra (V^V) as well as a central V^VO_4 unit (Fig. 1). A summation of the exponentially weighted V-O bond lengths for each V atom[4] indicates that, in the anion of **1**, all V^{IV} are in octahedral environments and all V^V are in tetrahedral environments (no example is known for V^{IV} in a tetrahedral environment). The number of V^{IV} atoms so determined is in agreement with the results of manganometric titration of V^{IV} (compare also the significant differences between $V^{IV}V^{IV}$ and $V^{IV}V^V$ separations).

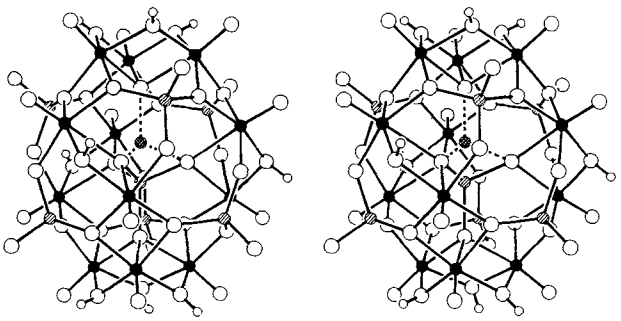

Fig. 1. Stereoprojection of the structure of the $[V_{19}O_{41}(OH)_9]^{8\ominus}$ ion in crystals of **1** (view perpendicular to the near C_3 axis; V^{IV} = black, V^V = hatched, central disordered V hatched in the first position and cross-hatched with V-O bonds drawn with broken lines in the second, O and H = white). Distances [pm] and angles [°] (central VO_4 tetrahedron and μ_3-O atom omitted; cf. text): $V^{IV}\cdots V^{IV}$ 289.6(2)-299.4(2), $V^{IV}\cdots V^V$ 330.1(2)-361.0(2), V-O_{term} 159.2(6)-162.8(6), V^{IV}-(μ_2-O(H)) 195.8(5)-202.5(5), V^{IV}-(μ_2-O) 196.0(5)-199.4(6), V^{IV}-(μ_3-O) 197.2(5)-203.1(5), V^V-(μ_2-O) 165.7(6)-168.7(5), V^V-(μ_3-O) 179.0(5)-181.9(6); O_{term}-V^{IV}-(μ-O) 95.8(2)-103.9(3), O_{term}-V^V-(μ-O) 104.7(3)-109.9(3), (μ-O)-V^{IV}-(μ-O) 82.4(2)-93.9(2), 153.0(2)-164.7(2), (μ-O)-V^V-(μ-O) 108.1(3)-114.5(2), V^{IV}-(μ_2-O)-V^V 129.5(3)-131.6(3), V^{IV}-(μ_2-O(H))-V^{IV} 111.1(3)-116.0(3), V^{IV}-(μ_3-O)-V^V 122.2(3)-143.7(3), V^{IV}-(μ_3-O)-V^{IV} 92.6(2)-96.0(2).

Within the anion are a VO_4 tetrahedron and a μ_3-O atom disordered over two lattice sites in a ratio of 1:1; the disorder could only be solved for the V atom, since the positions of the μ_3-O atoms of the two tetrahedral sites as well as those of the μ_4-O atom and the additional μ_3-O atom do not differ significantly. The 18 outer V atoms are joined by the μ_4-O atom and the 4 μ_3-O atoms in the center of the anion as well as by 12 μ_3-O and 15 μ_2-O atoms in the "outer shell". Of the latter, the nine μ_2-O atoms involved in edge-sharing of two VO_6 octahedra are protonated; the six remaining, unprotonated μ_2-O atoms each join a VO_6 with a VO_4 unit.

The V^{IV} centers are antiferromagnetically coupled ($\mu = 3.2\mu_B$ at room temperature), whereby the magnetic susceptibility continuously decreases with decreasing (measured to 160 K) temperature. Our investigations indicate that an unusually large number of "binary" mixed-valence clusters exist for vanadium; in addition, they may have different electron populations.[1] The low redox potential $V^{IV} \rightleftharpoons V^V$ may be important in this connection. Furthermore, the $V^{IV}/V^V/O$ system is of importance for understanding the technical V_2O_5 catalyst (fluid mixture of V_2O_5 and Na vanadate, in which similar clusters could be present), for which an appreciable proportion of V^{IV} has been detected by ESR spectroscopy.[5]

The class of compounds discussed here does not belong, in our opinion, to the "classical" isopolyanions, since for no other metal do isolated species exist in which the number of metal centers of different oxidation states is comparable.

Experimental Procedure

NH_4VO_3 (8.0 g, 68.4 mmol) was dissolved in H_2O (250 mL) contained in a 300-mL Erlenmeyer flask (narrow neck) at 75°C (pH 5.8). The solution was cooled to 70°C, hydrazinium sulfate (1.37 g, 10.5 mmol) was added (color change from yellow via olive green and blue-violet to dark brown), and the reaction mixture was stirred for 5 min at this temperature (the pH value increased to 7.3). The stirred mixture was then adjusted to pH 5.3-5.4 by addition of 10%-H_2SO_4 and, immediately afterward, the reaction solution (covered with a watch glass) was allowed to stand for 5 h in an oil bath (65-70°C) without stirring. The black crystals of **1** (streak color: dark brown) thereby formed were filtered from the hot solution, washed with 2-propanol and diethyl ether, dried under a stream of argon, and stored under argon. Yield: 5.0 g (2.36 mmol, 65.5%). Main adsorption bands in the IR spectrum (solid/CsI pellet): $\tilde{\nu}$ [cm^{-1}] = 970 (s, ν(V-O_{term})), 860 (s), 810 (s), 720 (s, ν_{as}(V-O-V)), 525 (m, γ(OH)).

[2] **1**: space group $P\bar{1}$; $a = 1317.3(3)$, $b = 1433.1(3)$, $c = 1602.3(3)$ pm, $\alpha = 91.16(2)$, $\beta = 93.46(2)$, $\gamma = 91.52(2)°$, $V = 3017.7 \times 10^6$ pm^3; $\mu = 28.2$ cm^{-1}; $Z = 2$; $\rho_{calcd} = 2.33$ g cm^{-3}; $R = 0.056$ for 8008 unique reflections ($F_0 > 3.92\sigma(F_0)$; Syntex $P2_1$ diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator). The water molecules and the ammonium ions are in part disordered, so that their H atoms could not be localized. All nine hydrogen positions of the VOH groups, on the other hand, were determined by high-angle refinement of the non-hydrogen atoms followed by difference Fourier synthesis with internal reflections ($2\theta \leq 40°$). Further hydrogen atoms in the anion were not found. The hydrogen parameters thus obtained were fixed in the final refinement. The powder diffraction diagram calculated from the single-crystal data is in agreement with the measured one. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53333, the names of the authors, and the journal citation.

[3] With respect to the number of protons, the formula is unambiguously established by redundant investigations (very precise N and V^{IV} analysis values), by different coordination of V^{IV} and V^V, by study of the hydrogen bond lengths, and by analysis of the V-O-V distances (cf. the procedure followed in [2]). The V^{IV}-O distances of the nine protonated and the six unprotonated μ_2-O atoms are similar, since the unprotonated μ_2-O atoms are also each involved in a markedly shorter V^V-O bond. V^{IV}-O(H)-V^{IV}: 196-203 pm; V^{IV}-O-V^V: 196-199 and 166-169 pm. Thus, the (μ_2-O)-V^{IV} distance can be lengthened both by protonation of the oxygen atom and by a (μ_2-O)-V^V bond in "close proximity" having an appreciable π-bond component. Eight H atoms display H-O distances of 77-113 pm and a V-O-H angle of 98-135°, a further H position has an "H-O" distance of 55 pm (presumably with significant error owing to the coordination of the H atom to a disordered water molecule). Of these nine H atoms, six form intermolecular hydrogen bonds to (unprotonated) terminal O atoms of other anions, whereby, as expected, the O-O distances of the (μ_2-O)-H$\cdots O_{term}$ groups are short and lie in the range 269-286 pm.

Owing to the higher electron density on the oxygen atom, the protonation of V^{IV}-O-V^{IV} centers is more reasonable than that of V^{IV}-O-V^{V} centers. Furthermore, twelve V^{IV} and six V^{V} centers can be unequivocally localized by an exponentially weighted summation of all V-O bond lengths of each V atom (cf. [4]; the bond lengths for the V^{V} atom of the central VO_4 tetrahedron deviate from those of the other V^{V} centers since they are in error owing to the disorder). The anion $[V^{IV}_{12}V^{V}_{7}O_{41}(OH)_8]^{8\ominus}$ differs from "$[V^{IV}_{6}V^{V}_{13}O_{48}(OH)]^{8\ominus}$" prepared by *Johnson* (but not published), (cf. [6, 7]), above all in the structure, the number of O and H atoms, and the V^{IV}/V^{V} ratio. Here, it is necessary to consider that *Johnson* did not determine unambiguously the number of protons and the V^{IV}/V^{V} ratio in his anion and could not account for additional electron density found in the proximity of the central V atom.

[4] For 50 structurally known compounds, it has been possible to divide the VO_n centers into V^{IV} and V^{V} centers (cf. [6]) by use of the summation $\sum_{i=1}^{n} \exp(-2.7d(V-O_i))$, which was developed based on *Pauling*'s concept of bond strength (L. Pauling, *J. Am. Chem. Soc. 69* (1947) 542).

A Novel Heterocluster with D_3-Symmetry Containing Twenty-One Core Atoms: $[As^{III}_6V^{IV}_{15}O_{42}(H_2O)]^{6\ominus}$

By *Achim Müller** and *Joachim Döring*

Arsenic-vanadium clusters with arsenic and vanadium in low oxidation states were previously unknown. The novel cluster anion reported here has an interesting structure and symmetry and exhibits cryptand properties. The brown compound $K_6[As^{III}_6V^{IV}_{15}O_{42}(H_2O)]\cdot 8H_2O$ **1** was synthesized by reduction of vanadate with hydrazinium sulfate in the presence of As^{III} and isolated as rhombohedral crystals.[1] Cluster **1** was characterized by elemental analysis (including manganometric titration and thermogravimetric determination of crystal water), vibrational spectroscopy,[2] magnetic measurements,[2] and a single-crystal X-ray structure analysis.[3]

The anion has crystallographic D_3 symmetry. It consists of 15 distorted tetragonal VO_5 pyramids and 6 trigonal AsO_3 pyramids (Fig. 1). It includes at its center a statistically disordered H_2O molecule. The 15 VO_5 pyramids are linked with one another through vertices and edges and with AsO_3 groups only through vertices. Two AsO_3 groups are joined to each other via an oxygen bridge, forming a handlelike As_2O_5 moiety.

The VO_5 pyramids can be divided into three differently linked groups. The first group includes six polyhedrons, each of which is joined through two edges and three vertices with its neighboring pyramids and through one vertex with an AsO_3 group. The second group contains six VO_5 pyramids, which are joined through three edges with other VO_5 pyramids and through two vertices with two AsO_3 groups. Finally, the third group consists of three VO_5 pyramids, which are mutually joined through two vertices and two edges with four VO_5 pyramids and through two vertices with two As_2O_5 moieties.

In the crystal lattice, the anions are joined to one another through "hydrated" potassium ions, which have a distorted octahedral coordination sphere composed of terminal oxygens of the anions and oxygen atoms of the crystal water.

V^{IV} and V^{IV}/V^{V} clusters are cryptands and tend to form spherical structures. This is shown by experience[4] as well as by quantum-chemical calculations (it is important, in this context, that the As_2O_5 groups are separated as far as possible). In the cluster anion of **1**, too, the V centers, which are antiferromagnetically coupled,[2] are localized on a spherical surface ($r = 385 \pm 15$ pm), see Ref. [4]; the As_2O_5 groups give rise to bulges.

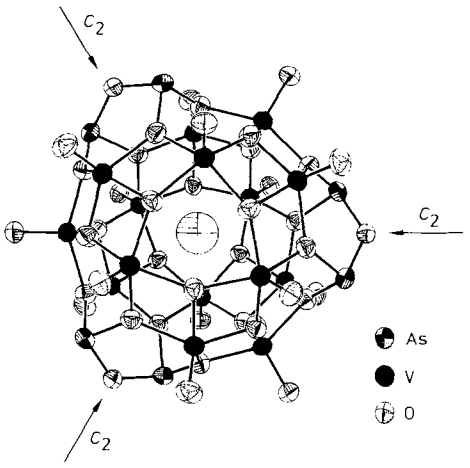

Fig. 1. Structure of the anion $[As^{III}_6V^{IV}_{15}O_{42}]^{6\ominus}$ with an interstitial, disordered H_2O molecule in the crystal of **1**: C_3 axis perpendicular to the plane of the paper. Selected bond lengths [pm]: V···V 287.0(1) to 304.9(1), V-(μ_3-O) 191.2(5) to 200.6(5), As-O 177.0(4) to 179.0(4), V-O_{term} 161.0(5) to 161.8(5); Selected bond angles [°]: O_{term}-V-(μ_3-O) 105.3(2) to 113.8(2), (μ_3-O)-V-(μ_3-O) 76.9(2) to 91.6(2) and 133.1(2) to 149.5(2), As-O-As 130.7(1), As-O-V 123.5(2) to 135.2(2), V-O-V 95.5(2) to 104.5(2) and 147.0(3) to 149.1(3).

The cluster anion of **1** may be regarded as a model for species that are formed during poisoning of the V_2O_5 catalyst (which contains V^{IV} centers) by arsenic.

Rapid Detection of Manganese Deficiency in Conifer Needles by Electron Spin Resonance Spectroscopy**

By *Peter Laggner,* Ruth Mandl, Annemarie Schuster, Monika Zechner,* and *Dieter Grill*

Manganese is an ubiquitous and important trace element in green plants[1] and is involved as a specific cofactor in the light-induced water oxidation in photosystem II.[2,3] Furthermore, green leaves and needles contain a Mn^{II} pool which takes part in the action of superoxide dismutases.[4,5] A well-documented correlation exists between manganese deficiency and reduced tree vitality.[6,7] Mn^{II} shows a strong, characteristic six-line ESR spectrum,[8,9] which can be easily distinguished from that of other paramagnetic species involved in photosynthesis. We have used this feature to develop a method for rapid screening of conifer needles for manganese deficiency. The results from a two-year screening test in Austrian forests demonstrate the diagnostic value of the method.

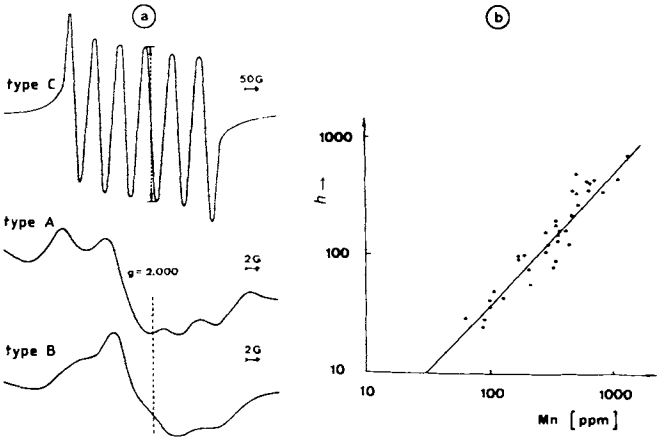

Fig. 1. a) Representative ESR spectra of spruce *(P. abies)* needles. A Varian E104-A X-band spectrometer was used for recording the spectra. The spectra were "smoothed" by hand. Typical instrument settings were: 3400 Gauss field set; scan range/100-kHz field modulation amplitude, 1000/2 Gauss (for the Mn^{II} signal), 40/2 Gauss (for signals A or B); 9.48-GHz microwave frequency; 10-mW microwave power; scan time/time constant, 2 min/0.25 s (for Mn^{II}), 4 min/4 s (for signals A or B). Needles were filled into 0.4-cm inner-diameter quartz sample tubes to a height of 3–4 cm. The net packing density achieved by gentle shaking was 0.4 ± 0.025 g cm^{-3} (mean ± S.D. for $n = 14$). Washing experiments with distilled water and metal complexing agents (EDTA) showed no interference by surface depositions. b) Double-logarithmic plot of the signal height h (arbitrary units) of type-C spectra versus total manganese concentration (of dry weight) measured by atomic absorption spectroscopy in 36 needle samples. The dots represent single determinations for any one sample. The line was determined by linear regression analysis ($r = 0.85$).

In general, the ESR spectra of spruce *(P. abies)* needles can be classified into three distinct types (Fig. 1a). Two of them, referred to by us as types A and B, have relatively weak and narrow lines and therefore require high magnification and resolution. The type-A spectrum was formerly assigned to the plastosemiquinone radical cation in photosystem II[10] but recently shown to originate more probably from a tyrosine radical;[11,12] type B is an altered form of the type-A spectrum and has possible pathological significance, since it appears for samples from visibly diseased trees.[13] Type C, a strong six-line spectrum extending over abut 500 Gauss, with a peak-to-peak separation of 95 Gauss is characteristic of motionally restricted Mn^{II}.[14,15] Figure 1b shows the correlation between the total manganese concentration in the needles and the height of the signals in the type-C spectrum. The linear regression shows an operational relationship that can be used to estimate the total manganese concentration between about 50 and 1000 ppm directly from the signal height. Between 25 and 50 ppm, the type-A spectrum becomes dominant; below about 25 ppm, the line-shape corresponds to type B.

Figure 2 shows the distribution of the spectral types as a function of manganese concentration, together with the relationship between manganese content and tree-vitality status as defined by *Kreutzer*.[6,7] With due account for the overlap between the spectral types on the one hand and between the diagnostic assignments on the other, the spectral types coincide well with the tripartite vitality scale.

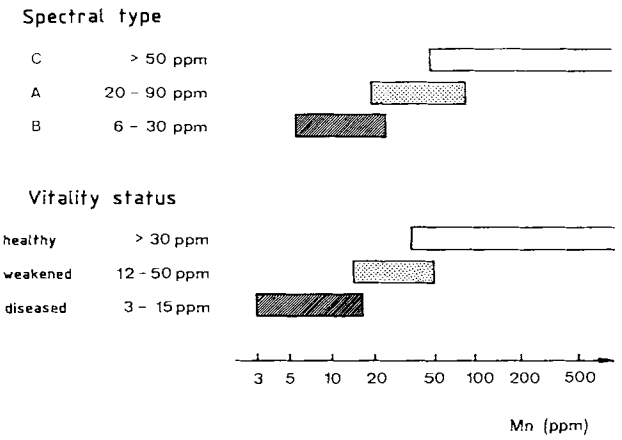

Fig. 2. Manganese concentration ranges (of dry weight) for the spectral types defined in this study (top) and for the vitality status according to *Kreutzer* [6, 7] (bottom).

The Mn^{II} ESR spectrum of photosynthetic organs is known to be light-dependent.[15,16] Since the present analysis is performed in the dark, below the threshold of such effects, they are irrelevant for the above classification. Variations in signal strength of type C do occur with the age of needles and also with the distance to the crown. These are generally in the range of less than 20% and therefore lower than the variations between trees of different vitality status. In no case did we observe a situation where, at the same time, different samples from one tree showed both type-C and type-A or -B spectra.

A representative result of a one-year monthly screening in one observation area is shown in Figure 3a. The distribution of spectral types shows that in this region, where all three vitality groups are present, the proportion of trees with no manganese deficiency (type C) remained stable,

while the number of diseased trees (type B) increased at the expense of the weakened ones (type A). At the beginning of the vegetation period, May and June, parallel measurements of the new and one-year-old needles showed generally the same spectral type. However, the new shoots gave weaker signals which can be related to their higher water content. The one-year course for a single tree is shown in Figure 3b.

The results obtained at the four observation sites in the same month of three subsequent years are shown in Figure 3c. Generally, the distributions of spectral types are in good correlation with the documented stress regions defined by the forest authorities. Thus, the high proportion of type C in region "Gruber" corresponds to its low-pollution situation, while the results in region "Au" reflect its physiologically poor environment for spruce, in an immediate urban neighborhood.

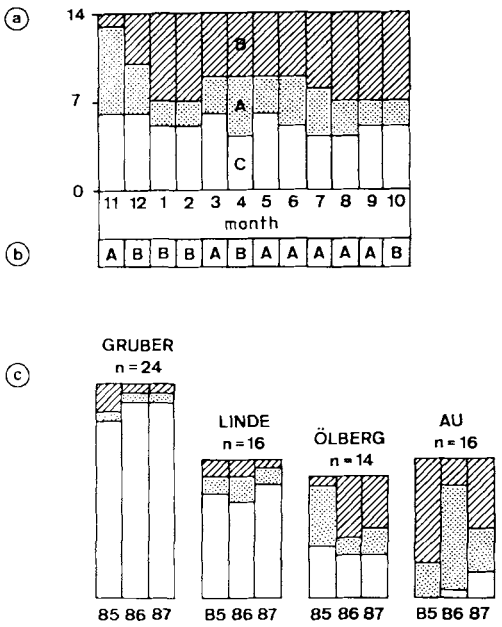

Fig. 3. a) Seasonal dependence of the spectral-type distribution in one observation area (Ölberg, 14 trees). Needles were collected from marked trees at monthly intervals from October 1985 to April 1988. The graph shows the results of a one-year screening (November 1985-October 1986). Samples were brought to the laboratory as twigs and either measured immediately or stored in a dark cold-room (2–4°C) for less than 48 h until measurement. Within this time no significant alterations in the ESR signals could be observed. b) Typical one-year course for a weakened tree, about 15 years old, growing on rock under pressure from neighboring trees in understory, showing signs of crown thinning and red-rot. c) Spectral-type distribution in four observation areas measured in November of three subsequent years (1985-1987).

Independently of the spectroscopic results, all trees in the regular observation areas were classified for risk factors by visual assessment according to established criteria. As an example, Figure 4 shows the correlation between this classification and the spectral types for the area "Ölberg". For all trees where two or more risk factors were diagnosed, severe manganese deficiency was manifest by the spectral type B. On the other hand, type-C trees invariably were of intact vitality. Spectral type A was found to correlate with trees growing in understory without visible decay symptoms. This systematic correlation pattern was also observed in all other areas of sampling. Although we cannot exclude the possibility that there exist diseased trees which do not show manganese deficiency, our present results strongly suggest that manganese deficiency as diagnosed by the absence of spectral type C is indeed a good and general indicator for tree disease.

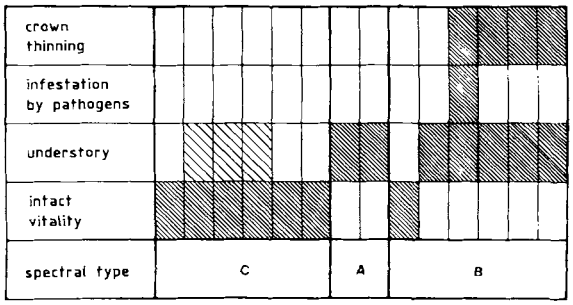

Fig. 4. Correlation between visible risk factors and spectral types for 14 trees in the area "Ölberg".

The remarkable correlation between the threshold for the appearance of a dominant Mn^{II} spectrum (type C) and apparently intact tree vitality is a fact worthy of physiological consideration. In photosystem II, Mn^{III} and Mn^{IV} are functionally involved,[2,3] as revealed by ESR spectroscopy at room temperature. This suggests that the ESR-detectable Mn^{II} is not important to photosynthetic activity. However, it was recently reported[17] that illumination of spruce needles induces changes in intensity of the Mn^{II} signal. Possibly, an excess of Mn^{II} is required to maintain redox balance in photosynthesis. Another possible function for this Mn^{II} pool may be to serve as a radical scavenger in the protection against photooxidation reactions. Of course, these two alternatives are not mutually exclusive and may well be both operative.

In order to be useful for large-scale screening, the method has to be rapid and simple. Therefore, the primary aim of the present work was not to achieve high precision in Mn determination, but to find spectroscopic criteria which can be used in a diagnostic risk assessment.

Notwithstanding the demonstrated correlation between tree vitality and spectroscopically measurable Mn^{II} content, it has to be mentioned that variations in Mn^{II} availability from the soil certainly can affect the manganese content of needles.[18] To further elucidate combined environmental effects, the presently described simple and rapid ESR method offers an attractive analytical tool.

Formation of an Oxalate-filled Cavity in a Reduced Cyclic Octanuclear Polyoxomolybdate $[(n\text{-}C_4H_9)_4N]_2[Mo_8O_{16}(OCH_3)_8(C_2O_4)]$ formed from α-$[(n\text{-}C_4H_9)_4N]_4[Mo_8O_{26}]$ and Rhodizonic Acid**

By *Qin Chen, Shuncheng Liu,* and *Jon Zubieta**

Investigations of the interactions between polyoxometalate clusters and substrate organic molecules have been prompted by the structural relationship of polyoxoanions to solid oxides.[1-4] In the specific case of polyoxomolybdate-carbonyl interactions, carbonyl insertion into a molybdenum-oxygen bond provides the common feature of the chemistry.[5-7] The syntheses of organooxomolybdates **1** with acetyl-,[5] **2** with diacetyl-,[6] and **3** with diketal-structures,[7] depending upon the choice of organic substrate, have been discussed in terms of acid-base pair binding sites and models for substrate binding on solid oxide surfaces.[8] However, the products of such molybdate-carbonyl reactions also depend intimately upon the nature of the organic precursor, as demonstrated by the isolation of the oxalatodimolybdate **4** from the reaction of the complex **5** with chloranilic acid **6** in methanol.[7] This observation suggests that ligand dissociation will occur, subsequent to carbonyl insertion, with organic residues capable of stabilizing a cationic leaving group. In order to examine the generality of carbonyl insertion coupled with ligand dissociation in polyoxomolybdate-carbonyl chemistry, we have investigated the reaction of the molybdate **5** with rhodizonic acid **7**.

$[RCHMo_4O_{15}H]^{3\ominus}$ **1**

$[HCCHMo_4O_{15}X]^{3\ominus}$ **2**

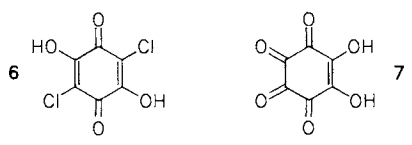
3, $C_{14}H_8$ = phenanthrenediyl

$[(n\text{-}C_4H_9)_4N]_2[Mo_2O_4Cl_4(C_2O_4)]$ **4**

α-$[(\eta\text{-}C_4H_9)_4N]_4[Mo_8O_{26}]$ **5**



6 7

The product of the reaction of **5** with **7** is a light-green, crystalline, diamagnetic species of analytical composition **8**.[9] The IR spectrum of **8** shows a band at 2930 cm^{-1} associated with the C-H stretching modes of the methoxy groups, and strong bands at 1665 cm^{-1} and 1543 cm^{-1} which are assigned to the carbonyl stretching vibrations ν(C=O) of non-equivalent carbonyl residues. The band at 972 cm^{-1} is assigned to the $\nu(Mo{=}O_t)$ stretching vibration (O_t = terminal oxo group); furthermore, the position of the absorption suggests that the molybdenum centers of the Mo^{VI} starting compound have been reduced. The band at 815 cm^{-1} establishes the presence of bridging oxo groups ($Mo\text{-}O_b\text{-}Mo$).

$[(n\text{-}C_4H_9)_4N]_2[Mo_8O_{16}(OCH_3)_8(C_2O_4)]$ **8**

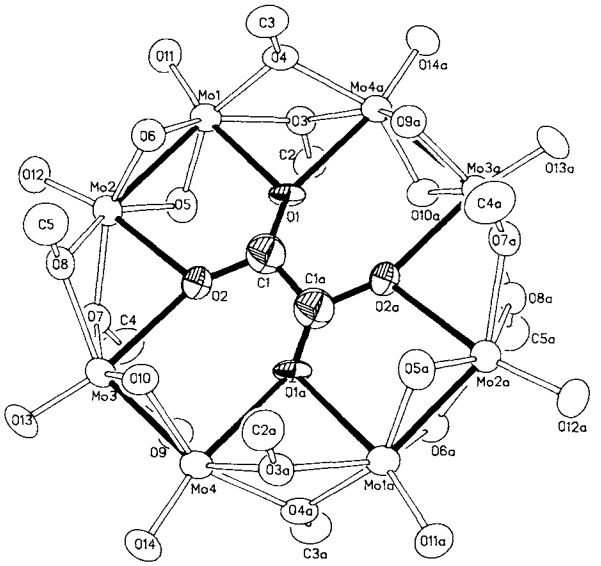


Fig. 1. Structure of the dianion $[Mo_8O_{16}(OCH_3)_8(C_2O_4)]^{2\ominus}$ of **8** in the crystal. Selected bond lengths [Å] and angles [°]: Mo1-O1, 2.367(7); Mo2-O2, 2.377(7); Mo3-O2, 2.385(8); Mo4-O1a, 2.367(7); Mo-O_t, 1.678(11) (av); Mo-O_b, 1.932(12) (av); Mo-O(methoxy), 2.106(11) (av); Mo1-Mo2, 2.582(2); Mo2-Mo3, 3.262(1); Mo3-Mo4, 2.574(2); Mo4-Mo1a, 3.312(1); C1-O1, 1.25(2); C1-O2, 1.37(2); C1-C1a, 1.43(2); O3-Mo1-O4, 71.4(3); O5-Mo1-O6, 94.3(3); O9-Mo3-O10, 94.2(3); O3a-Mo4-O4a, 71.2(3); O9-Mo4-O10, 94.5(3); Mo-O_b-Mo, 83.7(5) (av); Mo-O(methoxy)-Mo, 101.7(6) (av). Abbreviations: O_t, terminal oxo group; O_b, bridging oxo group; O(methoxy), bridging methoxy group oxygen donor.

The complex anion of compound **8** (Fig. 1)[10] consists of an octagonal array of Mo atoms, alternately bridged by two methoxy groups or two oxo groups producing a cyclic "tiara" framework $[Mo_8O_{16}(OCH_3)_8]^0$. The Mo-Mo distances display a short-long alternation around the ring (with average values of 2.578 and 3.287 Å, resp.). Each of the bonding Mo-Mo pairs is bridged by two oxo groups, while two methoxy groups bridge each of the Mo-Mo pairs with non-interacting distances. The methoxy groups

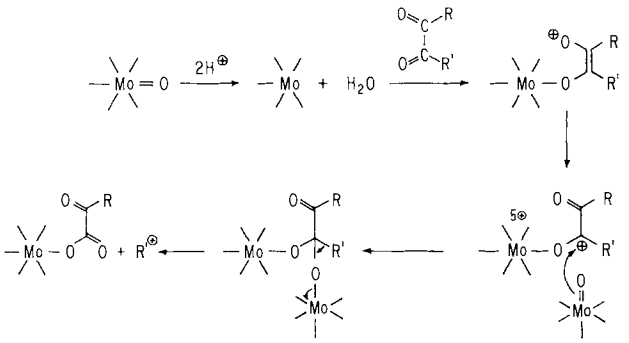
[**] This work was supported by the National Science Foundation (Grant CHE 8514634 to J. Z.).

fold out from the ring, whereas the oxo groups fold into the cavity formed by the ring. The Mo-Mo bonding distance of 2.578 Å is characteristic for Mo^{V} d^1 centers in bridged binuclear systems where a direct Mo-Mo interaction is present[11] and it accounts for the observed diamagnetism of **8** as a consequence of strong magnetic coupling.

A remarkable feature of the structure of **8** is that the cavity of the cyclic $[Mo_8O_{16}(OCH_3)_8]^0$ unit is occupied by an oxalate moiety, $[C_2O_4]^{2\ominus}$. Each oxygen of the oxalate group bridges two Mo centers with non-bonding Mo···Mo distances. The oxalate unit, the eight Mo centers and the eight terminal oxo groups form a planar $[Mo_8O_8(C_2O_4)]^{22\oplus}$ unit (maximum deviation of 0.02 Å from the best plane through all atoms). The C-O distances of the oxalate unit are distinctly non-equivalent (C1-O1, 1.25(2) Å; C1-O2, 1.37(2) Å), suggesting that the multiple bond character is localized in the C1-O1 moieties.



Scheme 1.

The synthesis of a Mo^{V}-oxalate cluster from polyoxomolybdate(VI) and rhodizonic acid precursors implies that in this instance the well-documented carbonyl insertion reaction is coupled with ligand dissociation and redox processes. Although the mechanism of this chemical transformation is not yet known in detail, the process most likely involves a succession of two-electron transfers and cationic intermediates of the type illustrated in Scheme 1. Since multicenter Mo clusters are involved in the chemistry, the formally Mo^{IV} sites produced in this sequence of electron transfer steps are in proximity to oxidized Mo^{VI} sites and rapid disproportionation is to be expected:

$$Mo^{IV}\cdots Mo^{VI} \longrightarrow Mo^{V}-Mo^{V}$$

Since the mechanism requires the formation of organic cations, the isolation of the oxalate derivative is dependent on the stability of the cationic species. Thus, whereas α-glyoxal and phenanthrenequinone yield the simple insertion products **2** and **3**, respectively, chloranilic acid **6** and rhodizonic acid **7** undergo concomitant ligand dissociation to yield the oxalate derivatives **4** and **8**, respectively. As anticipated, effective stabilization of the cationic leaving group promotes the formation of oxalato complexes. For example, di-*tert*-butylglyoxal (2,2,5,5-tetramethyl-3,4-hexanedione) reacts with the molybdate **5** to give the complex **8** in 70% yield. We are currently investigating the structural consequences of variations in the substituents of such α-diketones upon the products of the carbonyl insertion into oxometalate cores.

Reductive Oligomerization of 1,2-Di-*tert*-butyl-1,1,2,2-tetrachlorodisilane: The Tricyclo[2.2.0.$0^{2,5}$]hexasilane and Tetracyclo[3.3.0.$0^{2,7}$.$0^{3,6}$]octasilane Systems**

By *Yoshio Kabe,* Mutsumi Kuroda, Yoshihiro Honda, Osamu Yamashita, Takeshi Kawase,* and *Satoru Masamune**

Numerous recent publications are concerned with both the theoretical and synthetic aspects of strained polycycles,[1,2] for example, the bicyclo[1.1.0]tetrasilane system.[2a-e] The successful construction of this particular ring system suggests that trichlorosilanes ($RSiCl_3$) and 1,1,2,2-tetrachlorodisilanes ($RSiCl_2-SiCl_2R$) could serve, with the judicious selection of R, as precursors of hitherto unknown polycyclic systems including those represented by the molecular formula $(RSi)_{2n}$. Summarizing our initial investigations along this line, we describe below that reductive oligomerization of 1,2-di-*tert*-butyl-1,1,2,2-tetrachlorodisilane (**1**)[3] proceeded in a unique and somewhat unexpected manner to provide tricyclo[2.2.0.$0^{2,5}$]hexasilane and tetracyclo[3.3.0.$0^{2,7}$.$0^{3,6}$]octasilane derivatives.[4] The following communication will then disclose an important aspect of ^{29}Si-NMR spectroscopy displayed by these cyclic compounds.[5]

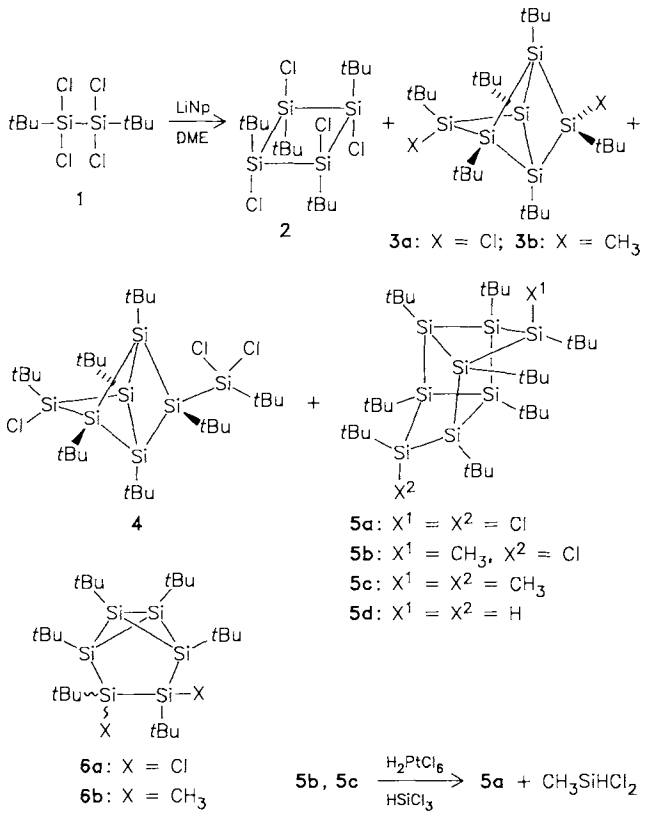
[**] The part of this work carried out at MIT was supported by the National Science Foundation (USA).

Treatment of **1** with a 1.2 M solution of naphthalenelithium (LiNp) in dimethoxyethane (DME) at −78 °C for 1 h provided sets of products which vary with the LiNp/**1** molar ratio. Typically, use of 2.5 equiv. of LiNp in the reduction followed by the usual workup (using fractional recrystallization for separation) gave rise to compounds **2** (tBu$_4$Si$_4$Cl$_4$, 8–20% yield), **3a** (tBu$_6$Si$_6$Cl$_2$, 4%), **4** (tBu$_6$Si$_6$Cl–tBuSiCl$_2$, 6%) and **5a** (tBu$_8$Si$_8$Cl$_2$, 6%). In contrast, an increase in the amount of reductant to 5 equiv. led, after silica gel chromatography, to the formation of **3b** (tBu$_6$Si$_6$Me$_2$), **5b** (tBu$_8$Si$_8$MeCl) and **5c** (tBu$_8$Si$_8$Me$_2$)[6] in a combined yield of 12%. The molecular formulas and group assignments shown in parenthesis are based on mass and ^{1}H-NMR spectral analyses (see Table 1).



In the case of **5b–d** the steric array is not confirmed.

Analysis of **2** by ^{1}H-, ^{13}C-, and ^{29}Si-NMR spectroscopy shows the presence of four-fold symmetry in the molecule. Furthermore, an X-ray analysis establishes that the *tert*-butyl groups exist in an all-*trans* orientation, as shown in **2**, but not in all-*cis* or *cis-trans-cis*-orientations.[6]

Compounds **3a** and **3b** must be tricyclic from their molecular formulas, since the absence of an SiSi double bond in either **3a** or **3b** is evident from the known spectral and chemical properties of disilenes. Each Si_6 species of **3a** and **3b** exhibits three NMR signals for its ^{29}Si nuclei and *tert*-butyl protons rather than six. This molecular symmetry requires that the structures of these compounds be expressed by those shown for **3a** and **3b** or **6a** and **6b**. The latter two structures **6a** and **6b** are clearly incompatible with the chemical behavior of compounds **3a** and **3b** as compared with the known chemistry of the bicyclo[1.1.0]tetrasilane system.[2a] This leads to the conclusion that **3a** and **3b** possess the tricyclo[2.2.0.0^{2,5}]hexasilane skeleton. Compounds **3a** and **3b** are the dichloro- and dimethyl-derivatives, respectively, **3b** being formed apparently at the expense of **3a** when a larger amount of the reductant is used with the solvent DME. It is known that silyl anions react with DME to form methyl derivatives.[9]

The structure of **4** has been established by X-ray crystallography (see Fig. 1).[10] It is likely that the precursor of **4** is **3a**. The anion derived from **3a** via reduction presumably attacks **1** with concomitant SiSi bond cleavage of **1** and elimination of a silyl anion instead of a chloride ion.

Table 1. Some physical properties of **2**, **3a**, **3b**, **4**, **5a**, **5b**, **5c** and **5d**. ^{1}H NMR (270 MHz, C_6D_6), ^{13}C NMR (67.9 MHz, C_6D_6), ^{29}Si NMR (53.7 MHz, C_6D_6).

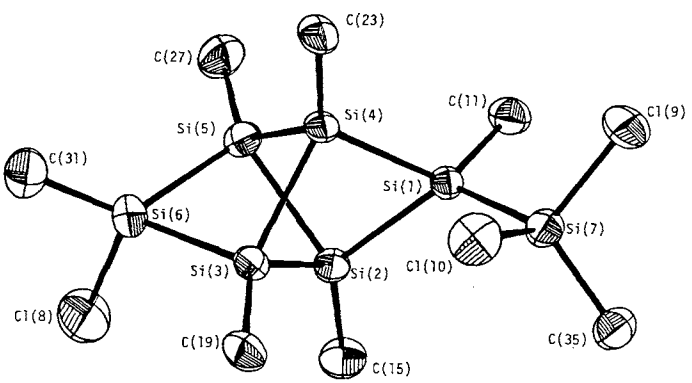

Fig. 1. Perspective ORTEP drawing of **4** showing 50% thermal ellipsoids for non-hydrogen atoms. The carbon atoms of the *tert*-butyl methyl groups have been omitted for clarity. Silicon–silicon bond distances [Å] are given below with their estimated standard deviations: Si1–Si2 2.366(2), Si1–Si4 2.370(2), Si1–Si7 2.384(2), Si2–Si3 2.364(2), Si2–Si5 2.407(2), Si3–Si4 2.392(2), Si3–Si6 2.351(2), Si4–Si5 2.389(2), Si5–Si6 2.345(2).

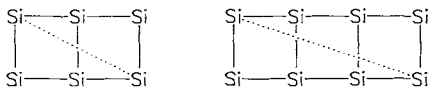

3 5

Compounds **5b** and **5c** are quantitatively converted into **5a** via Benkeser's reaction, a reaction which specifically effects the H_2PtCl_6-catalyzed Me/Cl exchange with $HSiCl_3$.[11] Treatment of **5a** with LiNp in toluene (instead of DME) provides **5d** after protolytic workup. These chemical correlations leave little doubt that compounds **5a–d** share a common Si_8 skeleton, and the molecular structure disclosed by a crystallographic analysis of **5a** (*Fig.* 2)[10] establishes the structures of all of these compounds. These structures are consistent with the symmetry displayed in the NMR spectra of these compounds (Table 1).

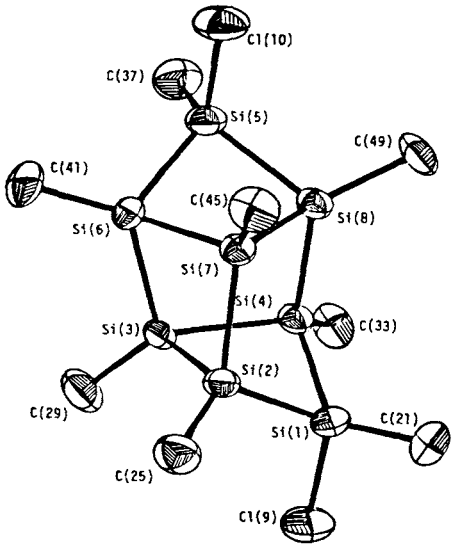

Fig. 2. Perspective ORTEP drawing of **5a** showing 50% thermal ellipsoids for non-hydrogen atoms. The carbon atoms of the *tert*-butyl methyl groups have been omitted for clarity. Since two molecules (enantiomers) are present in the asymmetric unit, two values are given for each bond distance [Å]. Each molecule contains an approximate C_2 axis, and the (approximately) equivalent bonds are paired below: Si1–Si2 2.335(2) and 2.337(2), Si5–Si6 2.335(2) and 2.342(2); Si1–Si4 2.371(2) and 2.383(2), Si5–Si8 2.370(2) and 2.371(2); Si2–Si3 2.376(2) and 2.375(2), Si6–Si7 2.378(2) and 2.377(2); Si2–Si7 2.395(2) and 2.393(2), Si3–Si6 2.393(2) and 2.397(2); Si3–Si4 2.438(2) and 2.452(2), Si7–Si8 2.447(2) and 2.445(2); Si4–Si8 2.362(2) and 2.363(2).

With the structures of the products having been established, the pathways leading to these products appear to be clarified. Of particular interest are the modes of intramolecular ring closure that are involved in the formation of the tri- and tetracyclic systems, as indicated by the dotted lines in the two skeletons **3** and **5** shown below. There was no indication that octasilacubane[12] and hexasilaprismane derivatives were present even in minute quantities among the above reduction products of **1**. It is interesting to note that the tricyclo[2.2.0.$0^{2,5}$]hexane skeleton is often exhibited by inorganic polycycles.[13]

[3] Compound **1** was prepared by $AlCl_3$-mediated Ph/Cl exchange reaction of 1,2-di-*tert*-butyl-1,1,2,2-tetraphenyldisilane, which was in turn obtained by reductive coupling of commercially available *tert*-butylchlorodiphenylsilane. We were informed that Prof. *R. West* also obtained **1** and **2** (private communication).

[4] Although (carbo)tricyclo[2.2.0.$0^{2,5}$]hexane derivatives are recorded in the literature [J. A. Uliana, *Diss. Abstr. Int. B 37(10)* (1977) 5099], the (carbo)tetracyclo[3.3.0.$0^{2,7}$.$0^{3,6}$]octane system is apparently unknown.

[6] Crystals of **2** suitable for X-ray crystallography were obtained by recrystallization from DME in a glove box. **2**: orthorhombic, space group $P2_12_12_1$, $a=13.057(2)$, $b=14.854(2)$, $c=13.698(2)$ Å, $V=2656$ Å^3, $\rho_{calcd}=1.20$ g/cm^3, $Z=4$. The structure was solved from 1433 collected independent reflections [$2\theta \leq 63°$, $|F_o| > 3\sigma(|F_o|)$] measured on a Rigaku four-circle diffractometer using $Cu_{K\alpha}$ radiation ($\lambda=1.5418$ Å). The structure was solved by direct methods (MULTAN 80) [7]. Strong diffractions of heavy atoms (Si, Cl) produced the satisfactory solution of the Si-framework, but severe disordering of *tert*-butyl groups resulted in a moderate quality of the refinement.

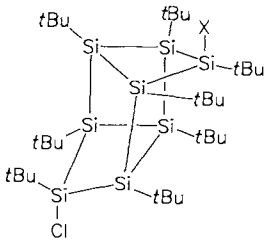
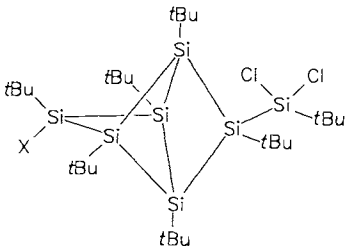
[**] The authors are grateful to the staff of JEOL Ltd. for their valuable technical assistance. The part of this work carried out at MIT was supported by the National Science Foundation (USA).

in a molecule and has found widespread use in structural elucidation of organic compounds.[1] This technique is extremely powerful when the size of ^{13}C-^{13}C one-bond coupling (^1J) is much larger than that of long-range couplings (^nJ, $n \geq 2$), which is usually the case in the acyclic and unstrained alicyclic systems thus far investigated.[2] Using the INEPT-INADEQUATE technique specifically modified for ^{29}Si nuclei,[3] we have been examining ^{29}Si-^{29}Si couplings in several cyclic compounds and wish to disclose two general trends: 1) With the decrease in ring size from six to three, $^1J_{Si,Si}$ values become smaller and $^2J_{Si,Si}$ values larger; 2) in strained polycyclic compounds such as tetracyclo[3.3.0.$0^{2,7}$.$0^{3,5}$]octasilane and tricyclo[2.2.0.$0^{2,5}$]hexasilane derivatives (**1a–b** and **2**, respectively),[4] not only are ^1J and ^2J comparable in magnitude but even two nuclei that are three and even four bonds apart and oriented in a stereochemically unique manner display a sizeable interaction.



1a, X = CH_3
1b, X = Cl



2

Very little information is available concerning the size of ^{29}Si-^{29}Si coupling constants.[5] Tables 1 and 2 list ^1J and ^nJ of several silicon compounds selected from those which have been subjected to spectral analysis (**3–7** and **1a**, **b**, resp. and **2**). The characterizations of polysilanes **3–7** appearing in Table 1 are summarized in Table 3. Compound **3**, respresenting acyclic compounds, shows ^1J values in the range 55–70 Hz, while the ^2J and ^3J values are an order of magnitude smaller (2.5–5.0 Hz). In the (relatively) strain-free six- and five-membered ring compounds **4** and **5** the ^1J values decrease slightly, but a sizeable increase in ^2J is definitely noticeable. This trend becomes pronounced with the strained systems exemplified by **6** and **7**. While ^1J values are still approximately twice as large as ^2J values in **6**, the observed ^1J for **7** is only 24.1 Hz. This increase in the magnitude of ^1J with an increase in ring size is consistent with the view that ^1J is approximately correlated with the amount of s-character of the Si orbitals participating in the ring formation.[6]

The 2D-NMR spectrum of the tetracycle **1a**[4] (Fig. 1) reveals the presence of 15 ^{29}Si-^{29}Si couplings of approximately 20 to 40 Hz. Since this system is constructed by eleven SiSi bonds, four of the 15 couplings must be long-range (^nJ). Through somewhat lengthy but logical arguments,[7] ^{29}Si signals 1–8 are assigned to the Si nuclei of compound **1a** in the manner shown in Table 2. With the completion of the spectral assignment of **1a**, that of **1b** (having a C_2 axis) readily follows. In **1b** there are three pairs of observable, significant long-range couplings of which a pair of couplings is rather small (5.8 Hz). Compound **2** also exhibits two sizeable long-range couplings demonstrated by its spectrum (Fig. 2) as there are eleven observed J's of approximately 15 to 40 Hz while only nine SiSi bonds build the framework of **2**. The most appropriate chemical shift assignments of **2** are tabulated.[7]

4: glassy solid; ^{1}H NMR: $\delta = -0.03$ (s; 6H), 0.00 (s; 3H), 0.20 (s; 3H), 0.21 (s; 6H), 0.45 (s; 6H), 0.53 (s; 6H), 1.13 (s; 9H), 7.14–7.17 (m; 3H), 7.61–7.64 (m; 2H); ^{29}Si NMR: $\delta = -42.59, -42.21, -40.33, -22.90$; MS (EI, 70 eV): m/z 452 ($M^{\oplus}$), 395 ($M^{\oplus} - t$Bu)

5: glassy solid; ^{1}H NMR: $\delta = 0.01$ (s; 6H), 0.22 (s; 6H), 0.38 (s; 6H), 0.43 (s; 6H), 1.10 (s; 9H), 7.14–7.17 (m; 3H), 7.58–7.62 (m; 2H); ^{29}Si NMR: $\delta = -43.22, -41.73, -18.50$; MS (EI, 70 eV): m/z 394 ($M^{\oplus}$), 337 ($M^{\oplus} - t$Bu)

6: m.p. (decomp.) 176°C; ^{1}H NMR: $\delta = 0.99$ (s; 9H), 1.14 (s; 9H), 1.55 (s; 18H), 6.80–7.27 (m; 12H), 7.05–8.16 (m; 8H); ^{29}Si NMR: $\delta = -8.02, 1.40, 9.11$; MS (EI, 20 eV): m/z 648 ($M^{\oplus}$), 591 ($M^{\oplus} - t$Bu)

7: m.p. (decomp.) 246°C; ^{1}H NMR: $\delta = 1.00$ (s; 9H), 1.21 (s; 18H), 7.04–7.24 (m; 7H), 7.54–7.89 (m; 4H), 8.02–8.06 (m; 4H); ^{29}Si NMR: $\delta = -37.33, -33.42$; MS (EI, 20 eV): m/z 486 ($M^{\oplus}$), 429 ($M^{\oplus} - t$Bu)

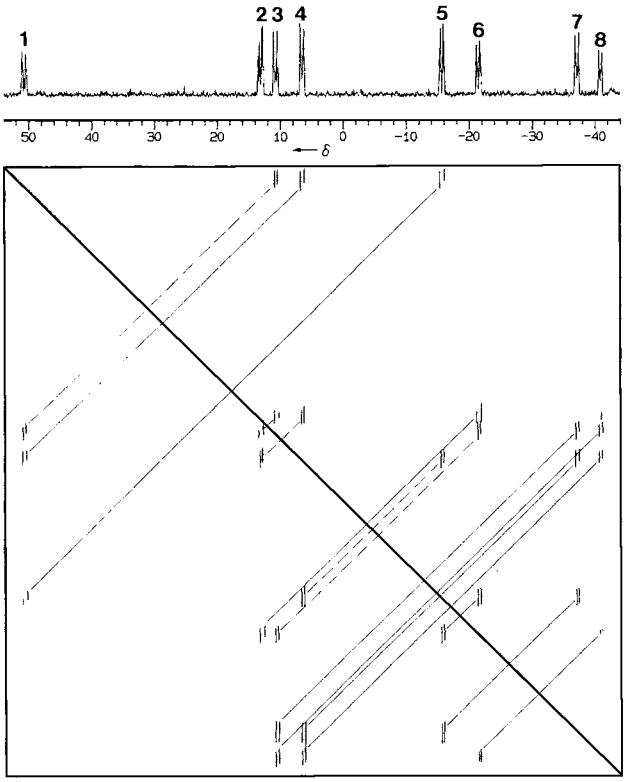

Fig. 1. 53.7-MHz ^{29}Si-^{29}Si 2D-INEPT-INADEQUATE spectrum of the tetracycle **1a** in C_6D_6 and projection of the 2D spectrum on the F_2 axis (top). Signals connected by solid lines correspond to one-bond interactions (^1J); those connected by dotted lines denote long-range couplings (^nJ).

In strained systems such as **1** and **2**, ^1J's cannot be distinguished from ^nJ's merely through the inspection of their magnitudes; in fact some ^1J's are smaller than ^nJ's. A considerable amount of information has been accumulated pertaining to long-range ^{13}C-^{13}C couplings in both unstrained and strained systems.[8,9] In comparison with the data in Tables 1 and 2, long-range ^{13}C-^{13}C and ^{29}Si-^{29}Si interactions show more or less similar trends, but, in general, the magnitude of the latter in strained systems appears more pronounced. The ^4J value in **2** is particularly noteworthy.

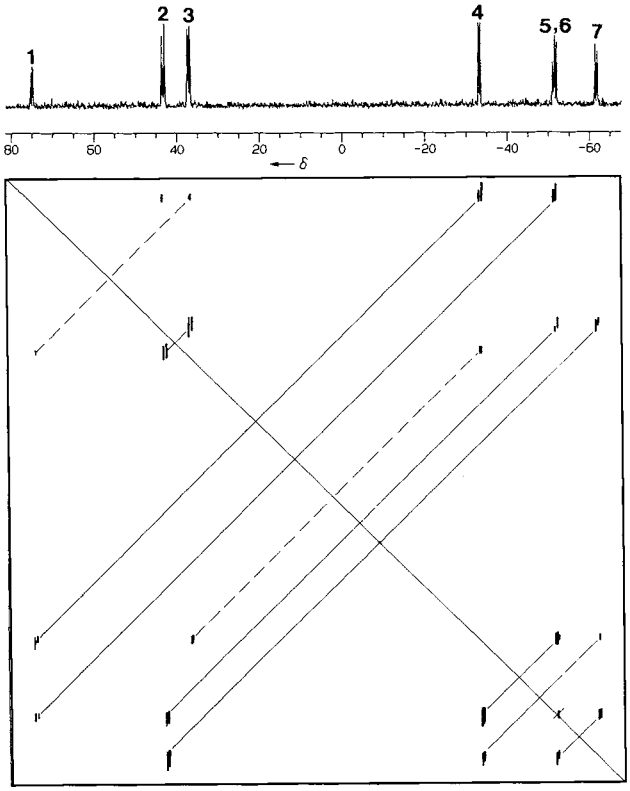

Fig. 2. 53.7-MHz ^{29}Si-^{29}Si 2D-INEPT-INADEQUATE spectrum of the tricycle **2** in $CDCl_3$ (40°C) and projection of the 2D spectrum on the F_2 axis (top). Signals connected by solid lines correspond to one-bond interactions (^1J); those connected by dotted lines denote long-range couplings (^nJ).

Linkage of Alkylidyne, Carbonyl, and Alkyne Ligands at a Tungsten Center to Form a Metallacyclopentadienone and an η^3-Oxocyclobutenyl Complex**

By *Andreas Mayr,* Ken S. Lee,* and *Bart Kahr*

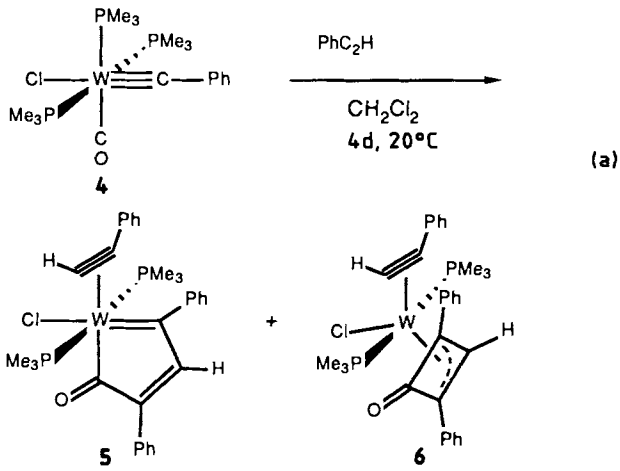
The reactivity between metal-carbon triple bonds and carbon-carbon triple bonds is complex. High-valent alkylidyne metal complexes interact with alkynes to give metallacyclobutadienes, which—depending on the system—may be activated towards alkyne metathesis,[1] insertion of a second alkyne to give cyclopentadienyl ligands,[2] or the formation of cyclopropenyl metal complexes.[3] The low-valent carbyne alkyne metal complex **1** was proposed as an intermediate in the formation of a cyclopropenyl metal complex.[4] The low-valent metal carbynes $[M(CR)Br(CO)_4]$[5] were shown to induce the polymerization of acetylenes (M = W)[6] and to give annelated phenols in reactions with α,ω-diynes (M = Cr, W).[7] We have recently described evidence for the existence of low-valent carbyne alkyne tungsten complexes of the type **2** and facile protonation to give the carbene alkyne tungsten complexes **3**.[8] Here we report the reaction of a low-valent carbyne carbonyltungsten complex with alkyne in the absence of proton sources to give a novel metallacyclopentadienone and a metal η^3-oxocyclobutenyl complex.

$[Mo(CMe)(\eta^5\text{-}C_5H_5)(PhC_2Ph)\{P(OMe)_3\}_2]$ **1**

$[W(CPh)Cl(CO)(alkyne)(PMe_3)_2]$ **2**

$[W(CHPh)Cl_2(alkyne)(PMe_3)_2]$ **3**

Reaction of **4**[9] with excess phenylacetylene (15 equiv.) in dichloromethane [Eq. (a)] generates a mixture of products from which purple complex **5** and orange complex **6** were isolated in 26 and 13% yield, respectively.[10] The molecular structure of complex **5** is shown in Figure 1.[11] The tungsten center, the former carbyne and carbonyl ligands,



and phenylacetylene combine to form a metallacyclopentadienone ring, a cyclic metal carbene. The intraring distances indicate the presence of fairly localized π bonds. The W–C(1) distance is similar to the value of the tungsten-carbon double bond (1.97(2) Å) in the related alkylidene alkyne tungsten complex **3**, alkyne = Ph_2C_2, and the W–C(8) distance may be compared to the W–CH_2CMe_3 bond length (2.258(9) Å) in **7** (dmpe = bis(dimethylphosphino)ethane).[12] The C(9)–C(30) bond length is close to the accepted value for carbon-carbon double bonds (1.34 Å) and the C(1)–C(30) as well as the C(8)–C(9) distances are in the range of C_{sp^2}–C_{sp^2} single bonds (1.48 Å). Fairly localized double bonds have also been found in the molecular structure of an organic cyclopentadienone,[13] supporting the formal analogy with the metallacyclopentadienone ring in **2**.

$[W(CCMe_3)(CHCMe_3)(CH_2CMe_3)(dmpe)]$ **7**

The η^3-oxocyclobutenyl complex **6** is formally derived from **5** by extrusion of tungsten from the metallacycle. ^{13}C

NMR resonances at $\delta = 181.2$ (CO), 59.4 ($J_{CH} = 195.8$ Hz, CH), 67.2, and 57.3 (CPh) are assigned to the carbon atoms of the oxocyclobutenyl ring. Signals at $\delta = 193.2$ ($J_{CP} = 12.5$ Hz, CPh) and 184.6 ($J_{CH} = 196.8$ Hz, $J_{CP} = 17.0$ Hz, CH) are observed for the phenylacetylene ligand.[10]

When reaction (a) was conducted with $Ph^{13}C{\equiv}CH$, the label was found to be distributed equally between the CPh groups in the metallacyclopentadienone ring of **5** and the oxocyclobutenyl ligand of **6**. Since the two CPh groups in the symmetrically substituted oxocyclobutenyl ligand[14] of **6** may exchange between equivalent sites by simple dynamic processes, we tested whether interconversion of compounds **5** and **6** may provide a mechanism for scrambling the label in complex **5**. Pure samples of **5** and **6** were heated in toluene. Compound **5** underwent conversion to **6** irreversibly. This reaction proceeds at 100 °C in about one hour, but is too slow at room temperature to account for formation of **6** in reaction (a).[15] Consequently, compounds **5** and **6** form independently in reaction (a). To account for these results we propose a mechanism involving the initial coupling of carbyne and alkyne ligands to give metallacyclobutadiene and metal cyclopropenyl intermediates. Insertion of carbon monoxide into the metallacyclobutadiene could generate the metallacyclopentadienone.[16] Insertion of carbon monoxide into a metallacyclobutene to give a metallacyclopentanone was recently reported.[17] Carbonyl insertion of the cyclopropenyl ligand may initiate formation of the oxocyclobutenyl complex. This latter type of reactivity is well established for cyclopropenyl carbonylmetal complexes.[18]

Since metal carbenes are postulated as the active species in acetylene polymerization,[6] the transformation of tungsten carbynes into tungstenacyclopentadienones represents a possible pathway for the formation of acetylene polymerization catalysts from carbonylmetal carbynes. Metallacyclopentadienones may also be considered as intermediates on the way to phenols from carbonylmetal carbynes and α,ω-diynes.[7] Insertion of a second acetylene unit into the metallacycle followed by reductive elimination would generate the organic ring system.

Structure, Magnetochemistry and Biological Relevance of $[Mn_4O_3Cl_4(OAc)_3(py)_3]$, a Complex with $S = 9/2$ Ground State**

By *Qiaoying Li, John B. Vincent, Eduardo Libby, Hsiu-Rong Chang, John C. Huffman, Peter D. W. Boyd, George Christou,** and *David N. Hendrickson**

Two to four Mn ions serve as the active site for catalyzing the oxidation of two molecules of H_2O to give one molecule of O_2 during photosynthesis.[1] Two research groups independently reported an EPR signal for the S_2 state of this site near photosystem II (PS II).[2] This signal, comprising a $g \approx 2$ feature structured with 16–19 Mn hyperfine lines and a subsequently identified $g \approx 4$ feature, was shown to be consistent with a tetranuclear $Mn_3^{III}Mn^{IV}$ site.[3] The $g \approx 2$ feature has been assigned to a low-lying $S = 1/2$ excited state, and the $g \approx 4$ feature to either the $S = 3/2$ ground state of the same $Mn_3^{III}Mn^{IV}$ site[4] or to an $S = 3/2$ state of a different conformation of this site.[5] These assignments are still matters of active discussion vis à vis detailed saturation, temperature dependence and sample history studies.

As part of our efforts to model this site, we recently reported the preparation of the first $Mn_3^{III}Mn^{IV}$ complex **1**.[6]

$(H_2Im)_2[Mn_4O_3Cl_6(HIm)(OAc)_3] \cdot 3/2\,MeCN$

1, HIm = imidazole, $H_2Im^{\oplus}$ = imidazolium cation

[**] This work was supported by the U.S. National Institutes of Health (GM 39083 and HL 13652).

The low symmetry of **1** has prevented an accurate theoretical description of its electronic structure; however, we now report the synthesis of **2**, a second complex of this type,

$[Mn_4O_3Cl_4(OAc)_3(py)_3]\cdot 3/2\,MeCN$ **2**

which has crystallographically imposed C_3 symmetry, allowing an accurate quantum mechanical description of its electronic structure to be formulated. Of specific and considerable interest and potential relevance to the S_2-state EPR signal is the finding that complex **2** has an $S=9/2$ ground state with no low-lying excited states.

$[Mn_3O(OAc)_6(py)_3](ClO_4)$ **3**

A stirred brown solution of **3** (1.74 g, 2.0 mmol) in freshly distilled MeCN (80 mL) was treated dropwise with Me_3SiCl (0.60 mL, 4.7 mmol). Overnight storage of the deep red-brown solution gave black crystals of complex **2** which were collected by filtration, washed with MeCN, and dried; yield 15–20%.[7] The complex has imposed C_3 symmetry (Fig. 1). As found for the anion of **1**, the

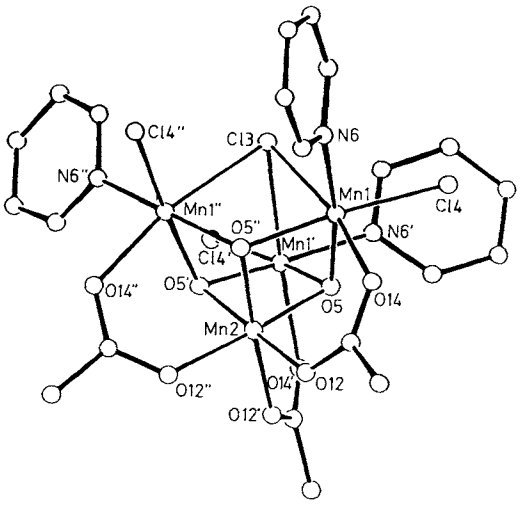

Fig. 1. Structure of complex **2** in the crystal. Selected bond distances [Å]: Mn1···Mn2, 2.815(2); Mn1···Mn1', 3.272(2); Mn1–Cl3 2.672(2); Mn1–Cl4, 2.237(2); Mn1–O5, 1.922(3); Mn1'–O5, 1.966(3); Mn1–O14, 2.146(3); Mn1–N6, 2.045(4); Mn2–O5, 1.865(3); Mn2–O12, 1.950(3). Primed and unprimed atoms are related by the threefold rotation axis.

$[Mn_4(\mu_3\text{-}O)_3(\mu_3\text{-}Cl)]^{6\oplus}$ core is best considered as an Mn_4 pyramid with the Mn^{IV} ion Mn2 at the apex; the μ_3-$Cl^{\ominus}$ ligand Cl3 bridges the basal plane, the μ_3-$O^{2\ominus}$ ions bridge each remaining face. Alternatively, the core can be considered as a severely distorted Mn_4O_3Cl cubane. Three μ-$OAc^{\ominus}$, $Cl^{\ominus}$ and py ligands complete the distorted octahedral geometry at each metal. Bridging Mn–Cl distances are appreciably longer than Mn–Cl terminal distances (2.627(2) vs. 2.237(2) Å), a point of potential relevance to the question of the possible presence of $Cl^{\ominus}$ ligands in any of the S_n states of PS II as addressed by EXAFS studies.[8]

The only available theoretical model[4] to account for the magnetic exchange interactions in a cubic $Mn_3^{III}Mn^{IV}$ model complex for the S_2-state makes the assumption that an $Mn^{III}Mn^{IV}$ pair is strongly antiferromagnetically coupled to give an $S=1/2$ state which is ferromagnetically coupled to the $Mn^{III}Mn^{III}$ pair, the latter being itself weakly antiferromagnetically coupled. The C_3 symmetry of **2** eliminates the need to make these assumptions in interpreting the solid-state magnetochemistry of **2**. As found[6] for **1**, the effective magnetic moment (μ_{eff}) per molecule of **2** increases gradually with decreasing temperature from 8.66 μ_B at 301.9 K to a maximum of 9.27 μ_B at 60.0 K, below which μ_{eff} decreases to 8.28 μ_B at 5.0 K (Fig. 2a).

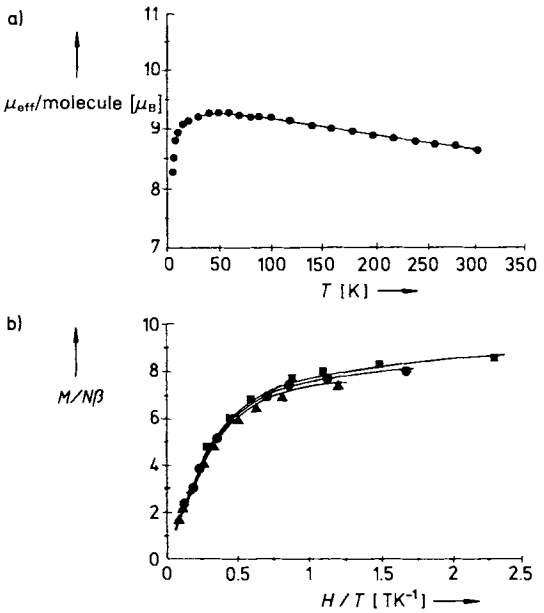

Fig. 2. a) Effective magnetic moment (μ_{eff}) per molecule as a function of the temperature T for $[Mn_4O_3Cl_4(OAc)_3(py)_3]\cdot 3/2\,CH_3CN$ at 1 T. Data are shown as points and the solid line represents the least-squares fit to the theoretical susceptibility equation with $J_1(Mn^{IV}\text{-}Mn^{III}) = -26.8\ cm^{-1}$, $J_2(Mn^{III}\text{-}Mn^{III}) = +12.1\ cm^{-1}$ and $g = 1.86$. (The data were fit only down to 30 K because the decrease in the effective moment at lower temperatures is due to zero-field splitting. To include the effects of zero-field splitting, a full matrix diagonalization procedure needs to be employed where the matrix is 500×500.) b) Plot of the molar magnetization (M) versus H/T for **2**, where H is the magnetic field in T and T is the temperature in K. Data were collected at three field strengths: ▲, 2.48 T; ●, 3.45 T; □, 4.5 T. Three isofield lines are drawn for an $S=9/2$ state with $D=0.32\ cm^{-1}$.

A Kambe vector-coupling model[9] was derived for the C_3-symmetric complex **2** by first coupling together the spin operators for the three Mn^{III} ions and then vectorially adding this to the spin operator for the Mn^{IV} ion. None of the assumptions of the previous model[4] were needed.

Three parameters were employed to least-squares fit the susceptibility data for **2** to the equation resulting from the C_3-symmetry vector-coupling model: J_1 for the three Mn^{IV}–Mn^{III} exchange interactions, J_2 for the Mn^{III}–Mn^{III} interactions, and an average g value. A systematic examination of the total parameter space (different sign combinations of J_1 and J_2, initial parameter values, etc.) showed that three sets of parameters gave reasonable fits. In the format (J_1, J_2, g) these three sets are: ($-376\ cm^{-1}$, $-94.7\ cm^{-1}$, 2.14), ($+7.4\ cm^{-1}$, $-3.6\ cm^{-1}$, 1.86) and ($-26.8\ cm^{-1}$, $+12.1\ cm^{-1}$, 1.86), the estimated standard deviations in these parameters being ±5%. Not only do these three fits deviate considerably from the view of the previous theoretical model, where J_1 is a large negative number and there is an $S=3/2$ ground state with a nearby

$S=1/2$ excited state, the three fits are each quite different. The first gives an $S=7/2$ ground state with an $S=9/2$ excited state only 9 cm^{-1} higher in energy. The second fit has an $S=9/2$ ground state and an $S=7/2$ excited state, separated by only 0.5 cm^{-1} with seven other spin states lying within 50 cm^{-1} of the ground state; whereas, the third fit has an $S=9/2$ ground state with the closest excited state being $S=7/2$ at 226 cm^{-1} above the ground state. This third fit was used for the calculation of the unbroken curve in Figure 2a.

To our surprise, magnetization data for complex **2**, collected over the temperature range 1.8 to 40 K at field values from 2.5 to 4.5 T, conclusively show an isolated $S=9/2$ ground state (Fig. 2b). This is in agreement with the third set of parameters obtained from the susceptibility data. Additional support for the isolation of this $S=9/2$ level is found in the fact that, although there are some changes and loss of resolution at elevated temperatures, the EPR spectrum of **2** (powder or glass) is readily seen at both liquid-helium and liquid-nitrogen temperatures. Such behavior would not be expected from the manifold of spin states found in the second fit.

It is likely that all the features in the glass EPR spectrum of **2** at $g \approx 2$, 6, and 9 (similar to those seen for **1**,[6]) are attributable to transitions between components of the $S=9/2$ ground state, which, as a detailed analysis of the M versus H/T data (Fig. 2b) shows, experiences an axial zero-field splitting ($D\hat{S}_z^2$) with $D=0.25$–0.35 cm^{-1}. Whether the S_2 state of PS II contains a cluster similar to that of **2** is still unclear, but the described work does suggest that the possibility that the S_2-state EPR spectral features might also arise from components of a large-spin ground state should be seriously considered. Interestingly, we have just characterized[10] a dinuclear $Mn^{II}Mn^{III}$ complex which is also ferromagnetically coupled and has an $S=9/2$ ground state (verified by M versus H/T data). The EPR spectrum for this $Mn^{II}Mn^{III}$ complex is similar to those for **1** and **2**.

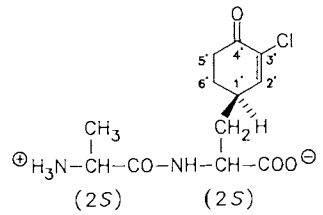
Chlorotetain from *Bacillus subtilis*, an Antifungal Dipeptide with an Unusual Chlorine-containing Amino Acid**

By *Claudius Rapp, Günther Jung,* Werner Katzer,* and *Wolfgang Loeffler*

Dedicated to Professor Theodor Wieland on the occasion of his 75th birthday

We have recently isolated new di- and tripeptides (rhizocticins A–D) from cultures of the bacterial strain *Bacillus subtilis* ATCC 6633.[1] These phosphono-containing active substances exhibit, inter alia, fungicidal properties. This inspired us to undertake a systematic search for new hydrophilic antibiotics from the genus *Bacillus subtilis*.

The antifungal activity, which was found in culture filtrates of *B. subtilis* BGSC 1E2, was competitively antagonized by di- and tri-peptides. The active compound was isolated from the culture mixture (after 84 h fermentation at 27 °C, complex culture medium) using methods suitable for the isolation of hydrophilic microbial metabolites. Thus, after removal of proteins by precipitation with alcohol and enrichment by adsorption on active charcoal, purification was carried out by gel chromatography (CM-Sephadex C-25, Sephadex G-10). The final purification of the antibiotic was performed on cellulose (yield 5 mg per liter culture filtrate). This amphoteric compound was identified as chlorotetain **1** [(*S*)-alanyl-(*S*)-3-[(*R*)-3′-chloro-4′-oxo-2′-cyclohexenyl]alanine (Ala-CCAla)], which contains the previously unknown, chlorine-containing amino acid CCAla.



1

An amino acid determination showed the presence of the components L-alanine and L-tyrosine. The determination was carried out as follows: after acid total hydrolysis (6 N HCl, 18 h, 110 °C) the resulting hydrolyzate was esterified with *n*-propanol, acylated with trifluoroacetic anhydride, $(tfa)_2O$, and analyzed by gas chromatography on Chirasil-Val.[2] The FD mass spectrum of **1** showed a peak due to $[M+H]^{\oplus}$ at m/z 289 accompanied by an isotope peak at m/z 291 (Table 1). From this mass difference of 2 and the fragment ion at m/z 253 ($[M-Cl]^{\oplus}$), the presence of chlorine in **1** could be deduced. UV and NMR spectra showed that L-tyrosine is not a natural component of **1**, but rather the decomposition product from the acid-sensitive *C*-terminal amino acid. GC-MS analysis (capillary quartz column SE 52) of the *N*-tfa-dipeptide methyl ester showed (at m/z 363) the peak of highest mass corre-

sponding to $[M-Cl]^{\oplus}$. The fragment ions at *m/z* 140 and 141 are typical for *N*-terminal alanine,[3] the presence of which was confirmed by dinitrophenylation. To explain the formation of tyrosine a six-membered ring system with a 1,4-arrangement of the peptide group and the keto-functionality is required. That the chloro-substituent occupies position 2 in the 2-cyclohexenone system was shown by the NMR chemical shifts of the olefinic proton ($\delta = 7.3$) and of the carbon atom to which it is bound ($\delta = 156.3$).[4]

The *C*-terminal amino acid contains the cyclohexenone chromophore, with an asymmetric C-atom in the 1'-position, in its side chain. Since, for steric reasons, only an equatorial position for the peptide group need be considered, only one half-chair configuration for each of the two diastereomers is conceivable, in which the 6'-CH_2 group is twisted out of the plane, either downwards [(*R*)-configuration at C-1'] or upwards [(*S*)-configuration]. The configuration at the C-1' atom was determined by measurement of the circular dichroism (Table 1). The reversed octant rule

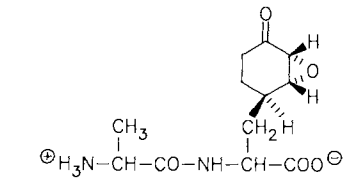
can be applied to the almost planar cyclohexenone ring system, as for α,β-epoxy- and α,β-cyclopropylketones.[5,6] According to this, the observation of a negative n,π*-Cotton effect, which in this case can be attributed to the negative contribution of the 6'-CH_2 group, requires an (*R*)-configuration.

Chlorotetain **1** is stable in aqueous solution at pH 5 at room temperature. In more strongly acidic solutions and also under alkaline conditions the biological activity rapidly decreases, particularly upon warming. It is known that amino- and amidoenones readily undergo a 1,4-addition to form 6-oxo-octahydroindoles.[7,8] A similar reactivity could well be partly responsible for the instability of **1**.

1 inhibits the growth of various fungi and, in higher concentrations, gram-positive and gram-negative bacteria. The fungi *Aspergillus fumigatus*, *Candida albicans*, and *Paecilomyces variotii* are particularly sensitive (MIC < 1 μg). **1** is the first chlorine-containing peptide to be isolated as a metabolite from *B. subtilis*. Other chlorine-containing amino acids and peptides are known to be metabolites of bacteria, fungi, plants, and sponges.[9]

The bacterial strain produces another antibiotic substance, which is structurally related to **1**. This was identified as the tetain (bacilysin)[10] (*S*)-alanyl-(*S*)-3[(*R*)-2',3'-epoxy-4'-oxocyclohexyl]alanine **2**. The *C*-terminus, which



2

was also isolated as anticapsin,[11] irreversibly inhibits the glucosamine-6-phosphate synthetase of bacteria and yeasts after intracellular hydrolysis of the dipeptide.[12,13]

Since **1** and **2** are structurally similar it is conceivable that **1** is formed from **2** during isolation. However, the fact that it was possible, prior to isolation, to correlate the biological activity with the HPLC detection via UV spectroscopy, refutes this suspicion. We were able to show that bacilysin **2** occurs relatively frequently in *Bacillus subtilis* and related species. In contrast, only one of the investigated cultures of *B. subtilis* strains, which produced bacilysin, namely *B. subtilis* BGSC 1E2, was found also to contain chlorotetain **1**. Therefore, **1** represents a new chlorine-containing secondary metabolite, which, like **2** and other oligopeptides, can enter the bacterial cell *via* the dipeptide transport system.[14]

The aromatization, which was found after the acid total hydrolysis of CCAla, is also exhibited by other peptide antibiotics containing a labile six-membered alicyclic ring. Thus aromatization of the 4-aminocyclohexadienyl system of the amiclenomycin peptides[15] with elimination of ammonia leads to the formation of L-homophenylalanine, and aromatization of the epoxide-containing six-membered ring of **2** yields L-tyrosine. Because of this tendency to form stabilized aromatic rings, the ring systems of **1** and **2** are only accessible with difficulty by chemical synthesis.

Oxidative Addition of Water to the Ru^{II} Catalyst $K[Ru^{II}(Hedta)(CO)]$: Homogeneous Catalysis of the Water-Gas Shift Reaction under Ambient Conditions

By *Mirza M. Taqui Khan,* Shivappa B. Halligudi,* and *Sumita Shukla*

The reaction of CO with H_2O to form CO_2 and H_2 [Eq. (a)] is a very important reaction[1] and is a principal method for obtaining H_2 for the Haber–Bosch synthesis of NH_3. Reaction (a), commonly referred to as the water-gas shift (WGS) reaction, is virtually the reductive decomposition of water by CO.

$$CO + H_2O \rightleftharpoons CO_2 + H_2 + 42\ kJ\ mol^{-1} \qquad (a)$$

The conventional heterogeneous catalysts for the water-gas shift reaction[2,3] consist of chromium-activated iron oxide (Fe_3O_4/Cr_2O_3) or cobalt-molybdenum oxide catalyst (CoO/MoO_2); the reaction is carried out at 400–460 °C and 200 atm of CO or CO + H_2.

Though the WGS reaction has been carried out under homogeneous catalysis,[4–10] only a few attempts have been made to perform the reaction under milder conditions (180 °C and 35 atm of CO) using metal carbonyls of the type $M(CO)_6$ (M = Fe, Cr, Mo, W, Rh, etc.) in alkaline or acidic medium. The turnover number reported[7] is 83.3 moles of CO_2/H_2 per mole of catalyst per hour.

We report here the catalysis of reaction (a) by $K[Ru^{II}(Hedta)(CO)]$ at 20–80 °C and 1–35 atm of CO. The effect of CO pressure (expressed as concentration of dissolved CO) on the rate of CO conversion into CO_2 and H_2 is shown in Figure 1. The rate v depends linearly on CO

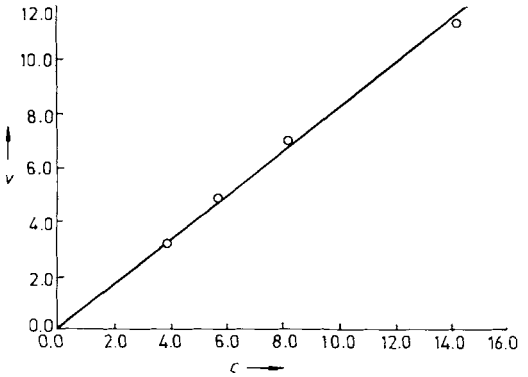

Fig. 1. Effect of concentration c [10^{-4} M] of dissolved CO on the rate v [10^{-3} M min^{-1}] of the water-gas shift reaction (1 mmol catalyst, 30 °C, 100 mL H_2O).

pressure; moreover, the rate observed at 1 atm of CO pressure ($\triangleq$ 0.00012 M concentration of dissolved CO) indicates the feasibility of the reaction even under ambient conditions. The effect of temperature on the rate of CO conversion was studied between 20 and 80 °C, as shown in the plot of $-\ln v$ versus $1/T$ in Figure 2; an activation energy E_a of 6.15 kJ mol^{-1} was found. Since the reaction is exothermic, it is not favored by higher temperatures. In fact, we observed formaldehyde formation at higher temperature (see Scheme 1). The optimum reaction conditions for the water-gas shift reaction are 50 °C and 15 atm of CO, for which the turnover number is 350 moles of CO_2/H_2 per mole of catalyst per hour.

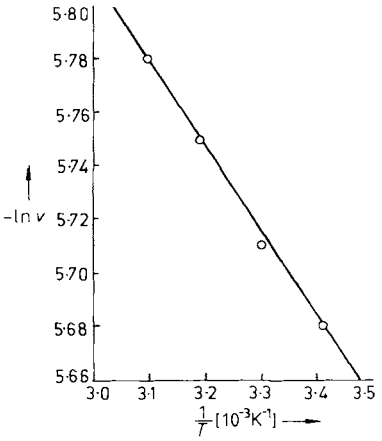

Fig. 2. Effect of temperature on the rate v of the water-gas shift reaction (1 mmol catalyst, 15 atm CO, 100 mL H_2O).

The water-gas shift reaction was also conducted at 1 atm of CO and 20 °C. A 75% conversion of CO into CO_2 and H_2 was determined after a contact time of 4 h with 3×10^{-3} M catalyst concentration. Figure 3 shows that the rate of CO conversion increases with increasing catalyst concentration for the WGS reaction conducted at 1 atm of

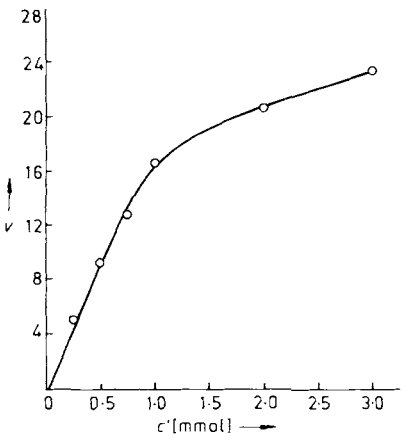

Fig. 3. Effect of catalyst concentration c' on the rate v [10^{-6} M min^{-1}] of the water-gas shift reaction at 20 °C and 1 atm of CO (100 mL H_2O).

CO and 20 °C with a contact time of 4 h. For 0.25–1.0 mmol catalyst, the reaction showed a first-order dependence on catalyst concentration. Beyond a catalyst concentration of 1.0 mmol, saturation kinetics with respect to catalyst concentration was observed. The first-order rate constant calculated in the linear range (0.25–1.0 mmol catalyst) is 1.67×10^{-2} min^{-1}. This is the first quantitative study using soluble metal complexes to catalyze the water-gas shift reaction in which it has been proved beyond doubt that the Ru^{II} catalyst species, $K[Ru^{II}(Hedta)(CO)]$, exhibits a catalytic activity far surpassing that of any known catalyst.

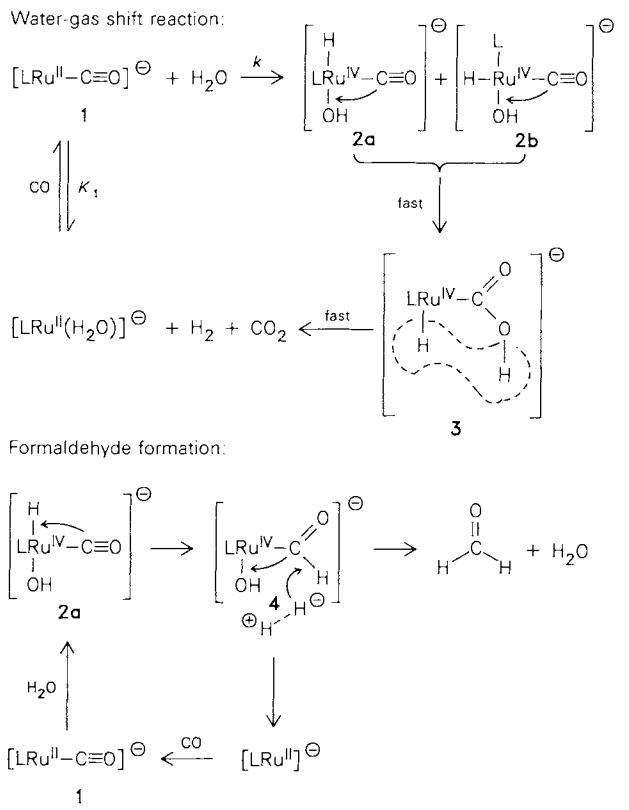
Based on the above observations a proposed mechanism for the water-gas shift reaction catalyzed by [(Ru(Hedta)(CO)]$^{\ominus}$ **1** is shown in Scheme 1.



Scheme 1. Possible reaction mechanism for homogeneous catalysis of the water-gas shift reaction by **1**. L = Hedta.

The rate-determining step of the reaction has been suggested to be the oxidative addition of H_2O to **1** to form hydrido carbonyl species **2a** and **2b**. This reaction step is supported by the ^1H NMR spectrum of the reaction solution which shows peaks at $\delta = -20.1$ and -8.1 for hydrides *trans* to OH and CO, respectively. The formation of the hydrido carbonyl complexes **2** is also supported by the UV spectrum, which has a characteristic d–d band of Ru^{IV} in the Ru^{IV} hydrido carbonyl complex at 426 nm ($\varepsilon = 65$). The differential pulse polarogram of the reaction mixture, obtained with a platinum electrode, showed a wave at $+0.4$ V (vs. Pt, $\mu = 0.1$ M $NaClO_4$) which is attributed to the Ru^{IV}/Ru^{II} redox couple. The expected Ru–H stretching frequency at 1980 cm^{-1} was not observed in the IR spectrum since this band falls in the region of the strong ligational peaks of EDTA.

Insertion of CO into the Ru^{IV}–OH bond of **2** in a fast step gives a probable η^1-formato complex **3**, which dissociates in a fast step by reductive elimination of CO_2 and H_2 to form [Ru^{II}(Hedta)(H_2O)]$^{\ominus}$. This intermediate, in turn, gives **1** on reaction with CO, thereby completing the catalytic cycle. The participation of surface hydroxyl groups in the water-gas shift reaction catalyzed by iron–chromium catalyst has recently been proposed.[10] An *O*-coordinated formato species has been suggested[10] as an intermediate, whose formation involves a change in the valence state of iron. An η^1-formato intermediate in our case seems to explain much better the enhanced catalytic activity of **1** in the reaction.

The formation of formaldehyde (Scheme 1) is explained by the insertion of CO into the Ru–H bond of **2a**. A molecule of hydrogen generated in situ attacks the resulting intermediate **4**, leading to the formation of H_2CO, H_2O, and [Ru^{II}(Hedta)]$^{\ominus}$, which is immediately transformed into species **2a** in the presence of CO and H_2O.

The values of the equilibrium constant K_1 and the rate constant k at 50° and 15 atm of CO are 11 M^{-1} and 80.0 min^{-1}, respectively, with a turnover of 350 moles of CO_2/H_2 per mole of catalyst per hour, the highest reported so far in the liquid phase water-gas shift reaction. The activation energy of the reaction was found to be 6.15 kJ mol^{-1}, which amounts to a decrease of about 188.1 kJ mol^{-1}[11] for the proposed dissociation of H_2O into $H^{\oplus}$ and $OH^{\ominus}$ in the rate-determining step. The entropy and enthalpy of activation are 2.45 e.u. and 3.35 kJ mol^{-1}, respectively.

Experimental Procedure

The water-gas shift reaction was conducted in a 300-mL stainless-steel autoclave equipped for automatic control. The reactor was charged with known quantities of catalyst, CO, and H_2O. The catalyst precursor K[Ru(Hedta)Cl]·2H_2O was prepared according to the method described elsewhere [12]. Gaseous samples withdrawn at different time intervals were analyzed by chemical gas analysis apparatus (ORSAT) and gas-liquid chromatographic (GLC) methods for CO, CO_2, and H_2. The CO used was 99.96% pure. The only solvent used was doubly distilled water. The ambient condition experiments were also conducted in a similar manner at 20°C and 1 atm of CO. The gaseous components were withdrawn after a contact time of 4 h, slowly flushed with N_2, and passed through a stirred 0.05 N KOH solution over a period of 0.5 h. The resulting solution was diluted to 100 mL by adding water and titrated against 0.025 N HCl to determine the amount of CO_2 formed during the WGS reaction. The 100-MHz ^1H NMR spectrum of the solution was recorded in D_2O (standard: sodium 3-trimethylsilylpropanesulfonate).

The Chemistry and Biochemistry of *N*-Substituted Porphyrins. By *D. K. Lavallee*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1987. x, 313 pp., bound, DM 89.00.—ISBN 3-527-266-933/0-89573-147-9

This monograph brings together in book form, for the first time, the considerable knowledge which has been accumulated during the past two decades on the chemistry of *N*-substituted porphinoids and their formation in biological systems. This survey of a particular aspect of porphin derivatives should be of interest to chemists and biochemists concerned with metalloporphyrins, heme proteins and heme biosynthesis. In accordance with the nature of this topic, the book consists of a "chemical" part and a "biochemical" part (containing four and three chapters respectively).

The first, introductory, chapter establishes the reasons for the chemical, biological, and also medical interest in *N*-substituted porphinoids.

The second chapter deals with the structures of some particular series of *N*-substituted porphinoids and compares them with those of the porphyrins. In addition to the detailed discussion of the structural effects of *N*-substitution in metal-free and metal-containing porphinoids (which includes a considerable amount of data in the form of tables, though unfortunately these are not always clearly presented and appropriately titled), an attempt is made at establishing a quantitative relationship between the bonding conditions and fundamental structural parameters such as the *N*-hybridization and π-bond order in the porphyrin ligands. Regrettably several errors in this chapter have escaped unnoticed, and adversely affect the understanding of the material.

In the third chapter, which deals at some length with the spectroscopy of *N*-substituted porphinoids, a large part of the data now available is discussed and listed in numerous (perhaps too many) tables. A strong point of this chapter is again the clear way in which the data for porphinoids are presented alongside those for the *N*-substituted porphinoids. A weakness, though, is that the important UV/VIS absorption spectra (for example) have in most cases been crudely reproduced by hand drawing. The more concise and information-packed sections on reactions and on the preparation of *N*-substituted porphinoids (Chapters 4 and 5) summarize the current state of knowledge in a clear and understandable form, and also include a short but useful collection of recipes for syntheses.

In the second, "biochemical" part of the book, Chapter 6 discusses in a lucid way the functioning of certain *N*-alkylated porphinoids as inhibitors in the enzymic incorporation of iron in the heme biosynthesis. Chapter 7 discusses the important mechanistic and structural aspects of the formation of *N*-substituted heme derivatives in the reactions of pharmacologically active substances, and of a selection of other substances (including especially "suicide" inhibitors), with Cytochrome P-450. For the reader interested in the topics covered, these two chapters provide much well-presented information.

The first part of Chapter 8 describes, as other important routes whereby *N*-substituted porphinoids are formed in biological media, the reaction of hydrazines with heme proteins, and rearrangement reactions of model compounds. The second part of the chapter is essentially a recapitulation of a part of Chapter 5.

This remarkably long work, with a total of over 300 pages, ends with a detailed author index (11 pages), and a subject index which, compared with the latter, is rather lacking in content (less than 3 pages).

The book is a comprehensive source of information on the chemistry and biochemistry of *N*-substituted porphinoids, which is nowadays recognized as an important aspect of porphinoid chemistry. Regrettably, the long-term usefulness of the work is reduced by some conspicuous weaknesses, such as the unsatisfactory layout of the text, a succession of minor errors, and some misleading comments (especially in Chapters 2 and 3). The readability of the book is also marred by a lack of clear explanations in the headings of some of the tables and in figure legends, and by the use of abbreviations that are not explained. Nevertheless, this monograph, which at present has no competitor in the field which it covers, can be well recommended for the readership mentioned at the beginning of this review.

Bernhard Kräutler [NB 911 1E]
Laboratorium für Organische Chemie
der Eidgenössischen Technischen Hochschule
Zürich (Switzerland)

Intermediate Organic Chemistry. By *J. C. Stowell*. Wiley, Chichester 1988. xv, 268 pp., bound, $ 46.50.—ISBN 0-471-09899-X

Many of the experimental and theoretical innovations developed in the last few decades, although eagerly adopted by chemists, have been slow to find a place in the major textbooks and laboratory handbooks. Examples are new spectroscopic methods, the concept of retrosynthesis, and also working methods such as on-line literature searching and molecular modeling.

Although topics such as these are very familiar to the practising chemist, the student of chemistry usually only learns of them at a late stage in his training, and often only in a fragmented way. To set out to give students a systematic description of a few of these topics which have now become so important is therefore a commendable objective. With this aim *J. C. Stowell*, in his book "Intermediate Organic Chemistry", has set out to bring together eight logically interrelated topics so as to give an overall view of organic chemistry. Following an introduction to basic nomenclature the reader is familiarized with the technique of searching the literature and with the principles of stereochemistry. This is followed by a three-part section on methods for introducing and exchanging functional groups, the formation of C—C bonds, and the concept of retrosynthesis. The chapters which follow deal with methods for elucidating reaction mechanisms, possibilities for physically influencing chemical reactions, and interdependent reactions. The book concludes with an introduction to the interpretation of NMR spectra. Exercises at the end of each chapter enable the reader to test what he has learned; unfortunately, though, he must look up the cited papers to discover the answers. Selected literature refer-

ences extending up to 1985 are provided to facilitate more advanced study.

The book is attractively printed and contains hardly any errors (one occurs in the formula for dimethylsulfoxide on page 72), although more elegant methods are available for some of the reactions given (e.g. dehydrogenation using Se, p. 84). The easily comprehensible style makes easy reading.

It is, quite understandably, not possible to treat all these topics with anything approaching completeness in 264 pages of text. Accordingly an attempt is not even made at accounting for all the facts in a logical way, nor at dealing in greater detail with the reaction schemes and rearrangements that are listed. It is perhaps on these grounds that the author has avoided giving mechanistic interpretations in the very long section on syntheses. Nevertheless, this reviewer sees the omission as a significant shortcoming, since it means that the logical conception of the subject which the author obviously sets out to promote is here disregarded, and arbitrarily selected facts and examples are substituted for a proper understanding.

Chemists nowadays are self-taught as regards their working habits. However, the work is neither a textbook nor a course book in the conventional sense: it is, in *Stowell*'s words, a novel experiment. It is an attempt to give beginners in chemistry a view of the whole scene and the interrelationships that exist; according to the introduction it should be regarded as an aid to making progress in practical organic chemistry, a bridge from basic education into the diversity of fields of more advanced chemical research.

Consequently the book is hardly suitable as a means of acquiring a thorough knowledge of the topics that are treated. Perhaps, therefore, it is just this fragmentary manner of presentation that makes the book especially suitable for students who wish to test the knowledge acquired in their studies. It can be thoroughly recommended for this purpose.

Institut für Organische Chemie
der Universität Göttingen (FRG)

Biotechnology. A Comprehensive Treatise in 8 Volumes. Series Editors: *H.-J. Rehm* and *G. Reed*. **Vol. 7a. Enzyme Technology.** Volume Editor: *J. F. Kennedy*. VCH Verlagsgesellschaft, Weinheim 1987. xii, 761 pp., bound, DM 495.00/subscription price: DM 425.00.—ISBN 3-527-25769-1

Reactions catalyzed by enzymes collectively form the foundation of biotechnology. This volume on Enzyme Technology is a very welcome addition to the mammoth task undertaken by the editors and the publisher. Incidentally, although the title says the Treatise is to have 8 volumes, the series[*] will really have 10 volumes when all the work is done.

The aim of this volume is to provide for the reader a review of the chemistry and biology of enzymes, and of how enzymes are prepared and used. In this, the authors have generally been very successful. One should not look to this volume to learn about the economics of enzyme production, or for a perspective on the historical trends in the industry or the market, or of the commercial potential of enzymes. Use or potential use of enzymes for hazardous waste treatment also could have received an emphasis. Despite this, the volume will serve as an extremely effective and comprehensive resource for any scientific worker interested in enzymes.

There are 15 chapters in all in this volume, many of them written by people who have made a good name for themselves over the years with admirable research and development contributions. Three of the chapters (numbers 1, 2 and 6) should be seen as providing the fundamentals of enzyme kinetics and molecular biology. These appear to be geared not for the uninitiated but for those who are at least somewhat familiar with the fields.

Another set of three chapters does a very good job of describing how enzymes are made via fermentation and then isolated and purified. The 146-page chapter on enzyme fermentations is in the nature of a scientific review article, as are many of the other chapters in this volume. The chapter has a good list of references spanning some 29 pages and generally has an "industrial" type outlook which helps make up for the lack of such data. Perhaps the coverage of the "fermentation engineering" aspects could have been better.

While there is some repetition in the two chapters on small scale and large scale enzyme recovery, the chapters are generally complementary. The chapters include some excellent comments which will be of great benefit to someone starting work on enzyme recovery. The perspective provided on ion-exchange chromatography is especially good. This reviewer would have liked to see a better coverage of cell separation techniques, of enzyme production economics, and of at least one flow scheme used in making any of the large volume industrial enzymes.

Two highly readable and well written chapters are on immobilized enzymes and immobilized cells. They provide a very good perspective on the types and methods available for immobilization. The authors, who have otherwise done some very good work in the field, could have elucidated why some of the approaches to immobilization have been successful on the industrial scale and why others have not. Synthetic enzymes, or the use of polymers and macrocyclic compounds to achieve "enzyme like" catalysis is the subject of another brief and readable chapter.

A chapter on the engineering aspects of enzyme reactor systems is comprehensive and well written. Here again, repetition of some of the enzyme kinetics already covered in Chapter 1 might have been avoidable.

How enzymes have been or can be used is the subject of a group of four chapters by authors several of whom have outstanding credentials. The chapter by veterans *Reed* and *Peppler* on the use of enzymes as food or animal feed processing aids shows one has to appreciate the terminology of the industry, be it baking or starch processing or brewing or dairy or wine or meat or whatever. The emphasis is on process recipes/procedures rather than on the chemistry involved. A gem here is a listing of some costs of enzyme-based processing; e.g., the cost of isomerizing 100 kg dextrose to fructose by a bacterial isomerase is 33–66 US cents. This reviewer would have liked to see more such perspectives by other authors in the volume.

Enzymes in their "free" (soluble) or immobilized form find many uses in the pharmaceutical and chemical industries and are discussed in two chapters. The use of enzymes in the making of amino acids, organic acids, antiviral compounds, coenzymes, peptides such as insulin and aspar-

[*] Cf. *Angew. Chem. Int. Ed. Engl. 26* (1987) 1057.

tame, alcohols, detergents, and antibiotics is covered in varying details.

Any volume of this type had to have a contribution by the Tanabe Seiyaku Co. team of *Chibata, Tosa* and *Sato* and it does. One of the pioneers and developers of practical scale processes based on immobilized biocatalysts, their survey chapter is most readable. Being as successful as they have been, they could have given their readers the benefit of a discussion of some of the failures; i.e., the reasons why in some of the cases the commercialization efforts did not work out. Some material on the chemical engineering of enzyme reactors, encountered earlier in the reaction engineering chapter, is repeated here, but fortunately it adds to the perspective.

The specificity of enzymes can be exploited for the analysis of scores of compounds, and the last applications chapter surveys the literature on "enzyme sensors". The author has many research achievements to his credit and could have added to the perspective by listing which of the sensors are or can be used in a practical or commercial sense, and indicating those that are commercially available.

Safety and regulatory aspects of using enzymes is the subject of a valuable chapter. Some of these aspects are also covered earlier in the chapter on the use of enzymes in food processing. There is repetition of which microorganisms produce which enzymes and the commercial food uses of enzymes. Nevertheless, the chapter adds a highly needed perspective on enzyme technology.

All in all, this volume does an excellent job of maintaining the spirit of this series. Of the 10 volumes, the first two covered the fundamentals in the field. Volumes 3 through 6b have focused on the applications of biotechnology. This volume is the first of two volumes on the core of biotechnology. We can now look forward to the next volume in the series: Gene Technology.

The Chemistry of the Semiconductor Industry. By *S. J. Moss* and *A. Ledwith*. Blackie, Glasgow and London 1987. xiv, 426 pp., bound, £ 50.00.—ISBN 0-412-01321-5

This book consists of sixteen chapters in which British and American experts from industrial, government and university laboratories describe the chemical aspects of semiconductor manufacturing and processing. Here for the first time specialists have set out to explain some of the chemistry involved in making integrated circuits, by taking a cross-section through all the relevant stages of production. They are thus able to show to what a great extent, and in how many different ways, semiconductor devices used in micro- and opto-electronics are the products of chemistry, with the background of understanding and optimization provided by solid state physics.

First the book prepares the reader by giving an overview; it is made clear that the semiconductor industry is now in a stage of rapid growth, not only in economic terms but also as regards its science and technology. In the succeeding fifteen chapters, each with its own bibliography, the different topic areas are covered in turn, in the logical sequence of their industrial application.

The first topic discussed is silicon production. The author proceeds from the extraction of raw silicon through its initial refinement to the technique of growing single crystals, and the production and conditioning of wafers. In the two chapters on III/V- and II/IV-type compound semiconductors, techniques for synthesizing these materials and growing single crystals are described; particular attention is given to the growing importance of gallium arsenide and related compounds. Next come two chapters on the deposition of thin films from the gas phase, with and without the use of a plasma, for producing epitaxial, polycrystalline or amorphous silicon films, and also thin metal films and dielectric films; kinetic aspects and technical details are also covered.

Thin epitaxial films of compound semiconductors are the main theme of the next two chapters, which are devoted to vapor phase epitaxy from organometallic compounds and to liquid phase epitaxy. Here there is a certain amount of overlapping with material covered earlier, but the large and growing importance of these techniques justifies treating them in separate chapters. Next there are chapters on photoresists and on resists for electron beam and X-ray lithography. There then comes a detailed treatment of all aspects of the use of wet etching processes in semiconductor production, in lithographic operations and in materials characterization. A short chapter is devoted to polyimides, which are being used increasingly as dielectrics and lacquers.

A chapter entitled "Molecular Electronics" gives a short survey of current research and future prospects in organic semiconductors, Langmuir–Blodgett films, and organic materials for use in integrated optics. On a related theme is a chapter which considers semiconductor junctions from a novel theoretical standpoint, not with the usual semiconductor physics approach but instead by using computer models based on the methods of the quantum chemist; for example, the models are used to describe crystal growth at the atomic level, and the incorporation of dopant atoms into silicon clusters. The final two chapters highlight the recent striking growth in the importance of plasma etching processes. The technology and mechanisms of the etching of structures in semiconductors, dielectrics, silicides and metals, and of polymer films, are described.

In nearly all cases there is a good balance between the chemical fundamentals and the technology. The current scientific and technological situation is well reviewed, and a clear distinction is made between industrial processes and laboratory procedures. Reaction equations and the kinetics and thermodynamics involved are included where these are known and are of importance, whilst those areas in which empirical knowledge does not yet have a solid scientific basis are clearly identified. The authors have consciously omitted a number of topics, such as analysis and the purification of chemicals used in the processes. Since it is often necessary in the semiconductor industry to reduce impurities to sub-ppb levels, it would have been useful to include a separate description of the techniques of purification and analysis which have been developed specially for this purpose.

The material within individual chapters of the book is clearly arranged in sub-sections, and adequately illustrated by diagrams, figures and tables. The literature references extend up to 1985 in most cases, and allow one to study topics in greater depth. Some spot checks did not reveal any incorrect citations.

The book is intended as a survey for use by scientists involved in research and development in the semiconductor and related industries. Nevertheless, it is written in language which should present little difficulty for beginners

in the field and advanced students. Only a few specialist terms are used without explanation, e.g. "latch up". The authors have succeeded in their ambitious aim of showing, by means of a sort of cross-sectional picture, the important role which chemistry plays in this rapidly developing technology. However, the reader who becomes intensively involved with a particular topic will very soon find that he must refer to the original papers or detailed monographs that are cited.

Electron Transfer Reactions in Organic Chemistry. By *L. Eberson*. Springer, Berlin 1987. xiii, 234 pp., bound, DM 128.00.—ISBN 3-540-17599-7

In recent years electron transfer (ET) has come more and more into the foreground of discussion as a component of organic reaction mechanisms. Even classical reactions such as nucleophilic aliphatic substitution and electrophilic aromatic substitution are being considered from this viewpoint. Whereas the proponents of these ideas view the whole of organic chemistry from this aspect, there are many others who are uncertain about its importance. Thanks to *Lennart Eberson* an attempt has now been made in this monograph to define the situation with regard to electron transfer in organic reactions and the limits of its applicability.

This relatively compact volume of the series "Reactivity and Structure Concepts in Organic Chemistry" begins by introducing electron transfer as a "neglected concept in organic chemistry". After defining and clarifying the concept of electron transfer (Chapter 2), which is here frequently given the unnecessarily extended description of "single electron transfer" (SET), theories of electron transfer are discussed in Chapter 3. Here, as expected, the Marcus theory, still not as well known to organic chemists as it ought to be, plays a central role. The next two chapters contain advice on the practical application of this theory, and on experimental diagnostic methods for investigating reactions thought to involve electron transfer.

I appreciate especially the great emphasis that is placed on the quantitative analysis of experimental data. It is only through careful evaluation of kinetic and thermodynamic data that a clearer view of the situation can be arrived at; for many reactions such data are not yet available. The book makes a valuable contribution by repeatedly emphasizing this point. At the same time it becomes apparent how difficult it is to obtain unambiguous evidence for the involvement of ET.

Chapters 6 to 8 describe reactions of non-metallic organic and inorganic species, reactions of organic compounds with inorganic oxidizing agents, and electron transfer processes involving exclusively organic reactants. Here again it is emphasized that in many cases much further work will be needed to establish an unambiguous picture of the mechanisms.

Chapter 9 deals with electron transfer processes induced by light or by electrodes, and Chapter 10 is concerned with the important area of ET-catalyzed reactions, which has undergone extensive development during the past two decades. Before the relatively brief account in the final chapter of applications of ET to technological synthetic processes, *Eberson*, in Chapter 11, examines the distinction between polar mechanisms and ET mechanisms. From this one recognizes how difficult it can be to draw the line between the two, and how much work still remains to be done in order that ET can be given its proper place in organic chemistry.

Although the book has been written by one of the proponents of the ET concept, care has been taken to always discuss the evidence from a critical standpoint, with a justifiable emphasis on the quantitative side, i.e. on the application of the Marcus theory. It is to be hoped that this monograph will contribute to a wider knowledge of the Marcus theory of electron transfer in organic chemistry, and will give extra impetus to this rapidly developing area of research.

For reasons of space the book does not attempt to cover ET in biological processes and in organometallic chemistry. The literature is thoroughly covered, and in some parts includes references up to 1987. The book is recommended for reading by everyone who wishes to obtain an overview of the current status of ET in organic chemistry.

Chemistry of Materials

Editorial Essay

By Leonard V. Interrante*

The association of chemical processes with the preparation and utilization of materials has its roots in the prehistory of materials technology. The fire-hardening of wooden tools and weapons by prehistoric man depended on the same basic chemical process as the current fabrication of carbon fiber by carbonization of an organic polymer fiber. The subsequent bronze and iron ages were similarly dependent on the chemical extraction of copper and iron from their ores, again reflecting the intimate association between chemical processes and materials technology.

Despite the fundamental reliance of materials processing on chemistry, the chemical profession has been slow to take up the challenges of materials technology. Perhaps as a result of this lack of strong input from chemists, the application of chemistry in materials technology has tended to be empirical in nature with an incomplete understanding of the relevant chemical processes involved.

In recent years the increasing demand for advanced materials to meet the needs of current technology has led to a reexamination of this interface between chemisty and materials science as well as an increasing recognition of the need to involve chemistry and chemical engineering more directly in the pursuit of solutions to materials-related problems.[1] The increasing interest in chemistry as a source of new materials, or as a means of processing and using known materials more effectively, is illustrated by the titles of several recent international meetings, e.g., "Better Ceramics Through Chemistry", "Molecular Design of Materials" and "Molecular Chemistry for Solid State Electronics".[2] In the United States this interest has also been reflected in increasing employment opportunities for chemists and chemical engineers in areas which were traditionally the exclusive province of other disciplines, for example, the electronic materials processing and ceramics industries.

Examples of the successful marriage of chemistry and materials science can be found in many areas of current technology. In electronics one can cite the development of chemical and biosensors using surface-modified electrodes[3] and the widespread use of polymers as dielectric materials and as radiation-sensitive resist materials.[4]

Chemistry has also played an important role in the etching and deposition of thin film electronic materials with a rapidly growing interest in plasma- and laser-assisted processing as well as in chemical vapor deposition using designed organometallic precursors.[5] The key role of chemistry in the selective addition and removal of the wide range of materials involved in the construction of a silicon integrated circuit is illustrated by the cross-sectional view of an advanced bipolar device structure in Figure 1.[6] Each of the many steps involved in the construction of this device

employs one or more chemical processes which bring into play elements of inorganic, organic and polymer chemistry.

In the area of structural and, in particular, composite materials, chemists have been called upon to produce polymeric precursors to materials such as silicon nitride and silicon carbide which can be used to prepare high temperature, high strength ceramic fibers.[7] This work extends to inorganic polymers the growing interest in rod-like organic polymers and carbon fibers as reinforcements for light weight, high strength structural composites.[8]

The current focus on chemistry as a solution to materials-related problems encompasses all of the major chemistry and chemical engineering disciplines and involves both the development of new materials and the processing of known materials. In the context of materials processing there is an increasing demand for improved methods of obtaining known materials in unusual forms such as epitaxial thin films, stable colloidal suspensions, and microporous membranes. The increasing use of sol–gel methods for the processing of ceramic powders, monoliths and films provides an illustration of the opportunities for chemistry in this area.[1,9]

A common theme in materials-related research is the interaction between materials and their environment, for example, in connection with heterogeneous catalysis, corrosion, adhesion, abrasion resistance, the design of biomaterials, chemical sensors and thin film deposition. The full understanding and control of these processes depends to a large extent on the skills of chemists and chemical engineers who are trained in areas such as surface science, analytical chemistry, chemical kinetics and thermodynamics, as well as in the theory and modeling of chemical processes on solid surfaces. On the other hand, it is clear that chemists or chemical engineers working in isolation are not likely to provide the solutions to these and the many other chemistry-related problems in materials science and technology. It is well known in industry that the greatest likelihood of success comes from an interdisciplinary approach to problems, where chemists and chemical engineers combine their knowledge with that of other scientists and engineers.

A prerequisite for effective interaction is effective communication. The scientific and technological questions posed by materials science, and their chemical implications, must be presented and discussed in a manner which is clearly understandable to all of the participants. This will require a better mechanism for communicating the results of forefront research in the area of materials science to chemists and chemical engineers. Similarly, materials scientists and technologists would benefit from increased exposure to the opportunities and advances in materials chemistry. These goals can be attained most effectively through the scientific literature, by the publication of articles which highlight and bring to the attention of the chemical and materials science communities some of the key areas of current interest in materials chemistry as well as examples of forefront research in this area.

The new Advanced Materials section of Angewandte Chemie provides an illustration of how this can be accomplished using a chemistry-related journal. The emphasis on commentary, review papers and meeting highlights in areas of current interest within materials science gives the reader an opportunity to view current work in this area from a chemical perspective.

The American Chemical Society began to explore the prospect of establishing a new primary research journal in materials chemistry in 1985. A major concern throughout this process was whether a new journal was needed, considering the proliferation of journals and the limited resources of our libraries. It was eventually decided that the need for better visibility for materials research within the chemistry community and the lack of an adequate common forum for the broad spectrum of materials chemistry

Prof. Dr. Leonard Interrante received his Ph. D. in inorganic chemistry in 1964 at the University of Illinois, Champaign-Urbana. After postdoctoral study at University College London, and several years as an assistant professor at the University of California at Berkeley, in 1968 he joined the research staff of the General Electric Research and Development Center in Schenectady, N. Y. where he conducted research in inorganic and materials chemistry. He assumed his present position as a Professor of Inorganic Chemisty at Rensselaer Polytechnic Institute in 1985. He has authored and co-authored over 75 publications in coordination chemistry, organometallic and solid state chemistry. His current research interests cover a wide range of materials-related subjects, including the synthesis and investigation of organometallic precursors to ceramic materials, chemical vapor deposition processes, and the preparation of molecular solids with novel electrical and magnetic properties. Dr. Interrante was selected as editor of the new ACS journal, Chemistry of Materials, in January 1988.

research currently in progress throughout the world required a new journal. Such a journal would highlight the role of chemistry as a source of new materials and processes for materials technology and bring together work now widely scattered throughout the literature. The recommendation that a new journal be established was subsequently approved by the ACS and the first issue is scheduled for publication in January, 1989.

From the beginning *Chemistry of Materials* was envisioned as a primary research journal which would emphasize the more chemical and fundamental aspects of materials science which underlie current and future materials technology. This journal seeks to publish the results of forefront research efforts with a molecular-level perspective at the interface of chemistry, chemical engineering and materials science. Preliminary communications and full papers, in addition to selected short reviews highlighting particular topics in materials chemistry, will be featured in its bimonthly issues.

[1] As evidence of this increasing interest in establishing better connections between chemistry, chemical engineering and materials science in the USA, several granting agencies have recently established special initiatives such as the National Science Foundation's "Materials Chemistry" initiative which are specifically directed at encouraging research at the interface between these disciplines.

Microgels—Polymers with a Special Molecular Architecture

Polymer Networks
Cross-linking
High-impact Polymers

By Markus Antonietti*

1. Introduction

The development of new polymeric systems and the improvement of their physical properties for technological applications can be brought about by two main directions of research. On the one hand, polymer properties can be adjusted by developing new monomer units: the resulting changes in local molecular properties such as rotation barriers, polarity or anisotropy are reflected in bulk polymer properties such as stiffness or flexibility, solubility, or properties associated with crystallinity. However, for obvious reasons, the scope for inventing useful "new" monomers is limited. Consequently this strategy increasingly leads to "low quantity" polymers with very special properties.

On the other hand, the properties of polymeric materials are also determined by the geometrical parameters of their macromolecules. For instance, short and long chain linear polymers have completely different properties; branched and cross-linked systems again show different behavior. Here the microscopic topology of the polymer chains and the resulting geometrical interactions, such as entanglements or even knots, are reflected in the product properties. An understanding of the relationships between these microscopic parameters and macroscopic properties helps to improve existing materials by controlling the topological structure without necessarily changing the chemical composition of the macromolecular system. These types of approaches have just started to yield quantitative relationships in polymer science. Thus, the possibilities for obtaining "new" materials (or better still, old materials with new properties) are most promising. Often small changes in reaction conditions result in different topologies and create or improve the desired property.

[*] Dr. M. Antonietti
Institut für Physikalische Chemie der Universität
Welder Weg 15, D-6500 Mainz (FRG)

This article is concerned with the second approach to improving the properties of polymeric materials; a group of polymers with a very special topology will be discussed: synthetic microgels ("μ-gels") or μ-networks. We will also focus on some of their unconventional properties and potential applications. Defining the term "μ-gel" is not a straightforward matter. It can be illustrated by means of Figure 1.

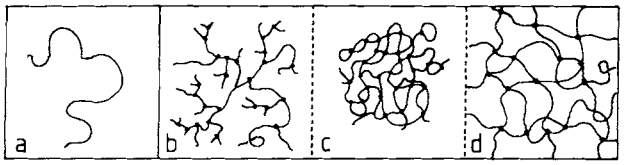

Fig. 1. Sketch showing polymer systems with different topologies: a) linear and b) branched macromolecules, c) μ-gel and d) macroscopic network.

Most commercial polymers, such as polystyrene, polyethylene or polycarbonate, have linear or slightly branched chains. Highly branched structures appear more often in the field of biopolymers, e.g. amylopectins. Networks are the oldest known "synthetic" materials: we are familiar with the properties of vulcanized "natural" rubber in daily life. μ-Gels represent structures that are intermediate between branched and macroscopically cross-linked systems. Their overall dimensions are still comparable with those of high molecular weight linear polymers. However, the internal structure of μ-gels resembles a typical network. Of course, the transition to the neighboring structures is continuous, and the definition is to some extent arbitrary. In the field of synthetic materials, μ-networks have not been extensively studied, but they are well known in biochemistry: most enzymes are linear chains cross-linked to each other by S_2 bridges or by secondary valences. Here again, special properties result from a combination of a particular geometrical arrangement with chemical functionality.

μ-Gels interestingly combine characteristics of both: being molecular structures they dissolve (networks only swell) but their conformation is nearly fixed. They can be processed like linear polymers but the final product still shows characteristic network behavior. Their solubility allows one to use the classical methods of polymer analysis in solution, enabling typical network characteristics to be identified. Therefore the objectives in studying μ-networks are twofold. First, one can study networks by modeling them with μ-gels, taking advantage of the convenience of solution characterization to examine network properties. Second, one hopes to develop a completely new group of materials with special properties. Both aspects will be illustrated in the following sections.

2. Synthesis of μ-Networks

Compared to the natural synthesis of enzymes, the possibilities available to a polymer chemist are limited. Only two routes to μ-networks are known:

1) Type A μ-gels: The addition of cross-linking agents to polymers or of multifunctional monomers to a polymerizing system usually leads to networks. According to the Ziegler dilution law, diluting the systems increases the probability of intramolecular cross-linking. This can be forced up to a threshold where no more macroscopic gelation occurs and only μ-gels are formed.[1-3]

This transition has the character of a phase transition where the critical concentration c_{crit} is given by the Flory argument:[4] internal cyclization reduces the average number of bonds to other chains below the critical value of two. Slightly below the critical concentration, structures with molecular masses $> 10^8$ g mol^{-1} are easily obtained.[1] At concentrations low compared to c_{crit} the μ-gels become smaller, until at very low concentrations only the elementary structures[3] or the "self cross-linked" molecule are formed[2,5] (molecular mass does not change upon cross-linking).

2) Type B μ-gels: μ-Gels are also obtained when the cross-linking reaction is carried out in a restricted volume, for instance in the small micelles of an emulsion,[6] or in μ-emulsion polymerization[7] of lipophilic monomers in water. Although such reaction conditions would result in macroscopic networks, the absolute molecular mass of the μ-networks is determined by the maximum micelle size, which can easily be controlled to be between 10 nm and 500 nm. This corresponds to molecular masses between 10^6 and 10^{11} g mol^{-1}.

3. Static and Dynamic Properties of μ-Gels

Type A and B μ-gels exhibit completely different properties. Cross-linking in dilution produces a lot of small loops, and, under suitable experimental conditions, a controllable proportion of dangling ends.[1,3] At the critical concentration of cross-links, type A μ-networks show an internal structure which is "self-similar". Geometrically this can be described as a "fractal", a geometrical body with a broken dimensionality. It has been proved by small angle neutron scattering measurements that this theoretical treatment fits the experimental data; a spatial dimension of $d_f = 2.5$ in the unperturbed state is obtained.[3] One can visualize a structure where the local fine structure repeats itself on a larger linear scale within the μ-network. Because type A μ-gels are still embedded in the "usual" three-dimensional space, they have a rather dense center and open up continuously towards the outer regions.

In contrast μ-networks of type B exhibit an internal structure comparable to that of macroscopic networks, except that close to the surface of the particles a higher concentration of loops is formed to ensure the molecular character. The characterization of these particles with static and dynamic light scattering reveals that the μ-gels in solution behave like nearly homogeneous swollen spheres, if the amount of cross-linking is moderate or high.[7] Where

ADVANCED MATERIALS

the amount of cross-linking is small, a transition to branched structures is observed, as mentioned above.[8] For these reasons, μ-networks of type B can be used to model the behavior of macroscopic networks. Possible perturbations due to surface contributions can be estimated by changing the absolute size of the μ-networks and thus the surface to volume ratio.

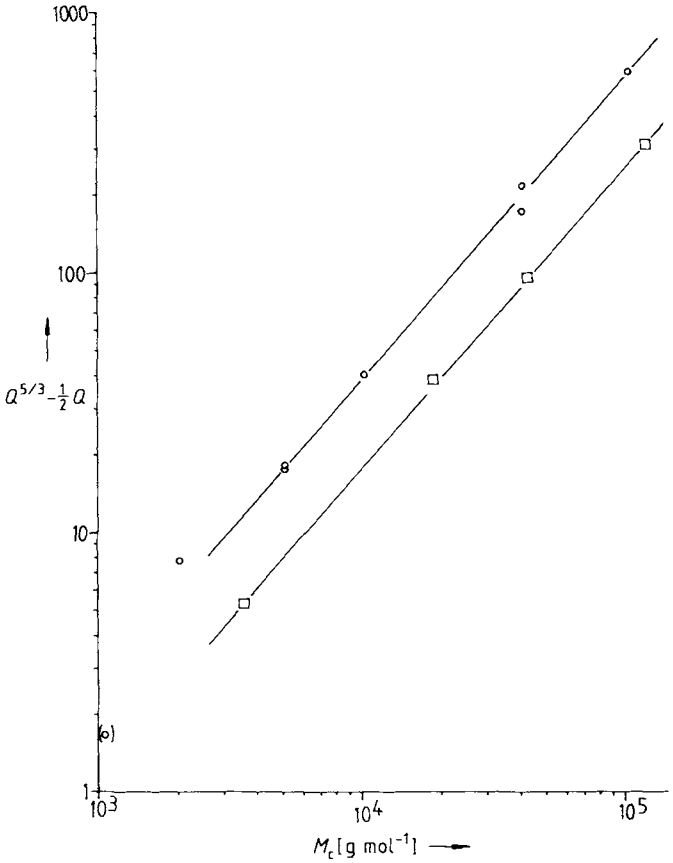

Fig. 2. Flory plot of the swelling ratio Q as a function of the chain length between two cross-links M_c; circles: styrene/*m*-diisopropenylbenzene μ-gels in toluene [7]; squares: styrene/divinylbenzene μ-gels in DMF [6].

The study of networks by substituting experiments on μ-gels is illustrated by the determination of the swelling ratio Q. Here, simple viscosity measurements replace the ambiguous swelling measurements on networks. The intrinsic viscosity $[\eta]$, a typical solution property of polymers, measures the relative increase of the viscosity of a solution per gram added polymer extrapolated to infinitesimally small polymer concentrations. According to *Einstein*, for spherical particles $[\eta]$ yields directly the average density of the swollen polymer within the sphere.[9] Since the degree of swelling of a network depends on the number of cross-links, *Flory* has derived an exact relationship between these two properties using the equations of entropy elasticity.[4] Figure 2 shows data obtained for two different network systems consisting of μ-gels.

The straight lines indicate the theoretical behavior of macroscopic networks for two different types of solvents. These measurements clearly show that type B μ-networks model the situation for all cross-linked systems. Measurements of the swelling ratio as a function of the density of cross-links, determined by intrinsic viscosity measurements, were also performed for the smallest possible μ-gels, the self-cross-linked molecules.[2] Although the treatment of the data is more complicated, the results are qualitatively in good agreement.

The situation in the case of type A μ-gels is more complicated: due to their fractal structure the swelling ratio depends only slightly on the density of cross-links, but is a function of the absolute molecular mass.[3] Although the fractal nature of type A μ-gels is more a matter for academic discussion, there are interesting implications for "real" systems. From these studies it seems likely that one can deduce certain topological knotting rules, which will lead to the understanding of internal cyclization, a typical network defect. Moreover, μ-gels offer a new way of easily determining the topological structures that result from different polymerization techniques, with regard to the degree of internal cyclization.

For characterizing the dynamic behavior of μ-gels, dynamic mechanical experiments provide the most detailed information. Here, information about both the internal, intramolecular modes of mobility and the dynamic quantities relating to the complete molecule can be obtained. In dynamic shear experiments the real and complex parts of the elastic constants (G' and G'') of the polymer are measured as a function of shear stress and frequency ω. G' describes the energy which is stored during the deformation (comparable to a spring constant) whereas G'' accounts for the viscous contribution and the energy which has been lost. From these two quantities, the complex viscosity η^* which describes the flow resistance at a certain frequency can be easily calculated.

Since we observe the response of small chain segments at high frequencies and of larger structures on a longer time scale, the data can also be interpreted as a measure of the molecular visco-elasticity as a function of a correlation

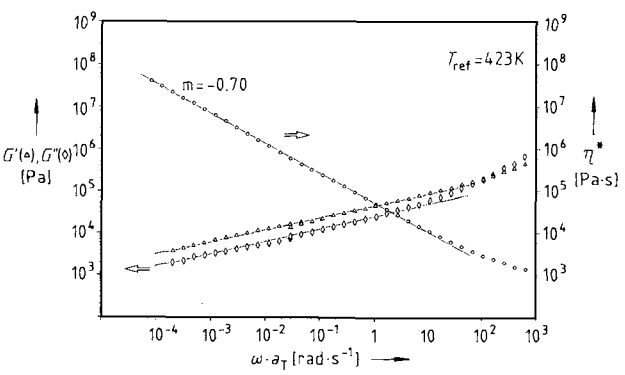

Fig. 3. Dynamic-mechanical spectrum of a type A μ-gel (material: polystyrene).

length. This length is of the same order as typical molecular substructures. For these reasons, the dynamic responses of different parts of the same polymer molecule become separated in the frequency domain.

Figure 3 shows the dynamic mechanical spectrum of a "fractal" type A μ-gel above the glass transition at a reference temperature of 150°C. In this double logarithmic plot, the elasticity varies over three orders of magnitude, while the frequency covers six decades. The resulting plots are strictly linear, with a spring constant which depends on the time scale of the mechanical perturbation.[10] Independently of frequency, a certain amount of energy is always lost (G' parallels G'').

The opposite is observed for type B μ-networks, as seen in Figure 4. Here, G' is nearly independent of frequency, as theoretically expected for an ideal macroscopic network. This is due to the fact that in the ideal case the cross-link density is uniform throughout. The plateau value in this specific sample exceeds that of linear polystyrene by a factor of two, and the mechanical loss at low frequencies is extraordinarily low for polymers. Here 98% of the stored energy can be recovered.[11]

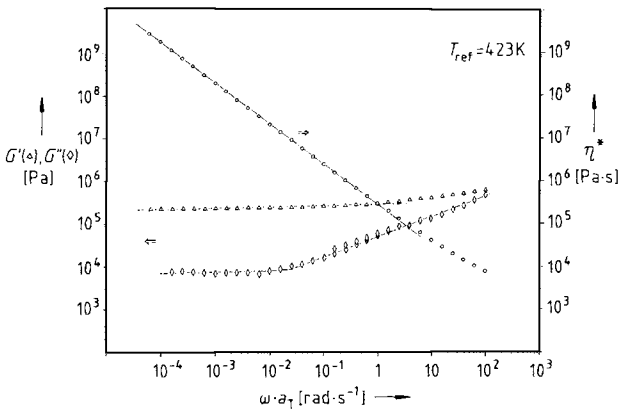

Fig. 4. Dynamic-mechanical spectrum of a type B μ-gel (material: polystyrene).

A potential application for these systems is their use as fillers for optically transparent "high impact" polymers. Here, μ-gels embedded in a matrix of linear polymer chains stabilize the whole structure by distributing the mechanical tension. Similar structuring techniques are already known, although the chemical pathway to them does not involve μ-gels.

In addition to that, one can construct composites consisting of two topologies of the same polymer. This represents a simple method of improving already existing products. Comparing Figures 3 and 4 one clearly recognizes the importance of topology in determining polymer properties: although both systems consists of the same chemical components (even molecular mass and chemical cross-linking density could be the same), a completely different macroscopic behavior can result for different topologies. Therefore, topologically structured μ-gels and networks will play a role of increasing importance since in that way the properties of any polymeric material can be varied over a wide range to fulfil the technological demands for special applications.

4. Complex Structured μ-Gels

Up to this point we have dealt with homogeneous μ-networks made of one kind of monomer and cross-linking agent. More complex molecules with μ-gel structure can easily be synthesized, and these cover a much wider range of properties and applications.

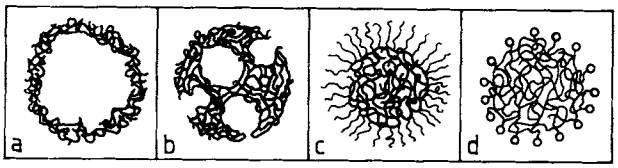

Fig. 5. Sketch showing various more complex μ-networks: a) hollow sphere μ-gel, b) macroporous μ-network, c) core-shell μ-gel, d) functionalized μ-gel where the circles indicate the centers of functionality.

Varying only structural parameters but preserving the molecular chemistry, it is possible to construct special porosities within the μ-networks (Fig. 5). The simplest case is given by the geometry of a hollow sphere, where the surface consists of cross-linked material of a controllable thickness (see Fig. 5a). Although this structure is reminiscent of vesicles prepared from special amphiphilic monomers,[13] fundamental differences exist. The hollow sphere μ-gels can be synthesized from most monomers on a larger scale, but the surface structure and the porosity are certainly far less defined. However, from a technical point of view, hollow sphere μ-gels can be used for some chemical applications which have been extensively discussed in the case of synthetic vesicles.

The second type to be discussed are macroreticular μ-networks. In simple terms, these are μ-gels with pores of different sizes. The polymerization of type B μ-gels in the presence of an ambident non-solvent leads directly to porous structures,[7] in analogy to the already known case of macroreticular networks.[14] The distinctive geometry, which is stabilized by the cross-links, results from the spinodal decomposition of the polymer and the non-solvent during the polymerization process. Materials with a continuum of pore sizes and macroscopic stability are the basis of all size exclusion chromatography techniques.[14] A study of these μ-gels by the techniques developed for simpler systems could help to provide a relationship between reaction conditions during network synthesis and the chromatographic separation properties. Such a relationship would help in designing column packings, which have hitherto been chosen more or less empirically. In this case, the step from research to a final product is small: by increasing the size of the network particles from the

nm-region to approximatey 10 μm, they can immediately be used as column packings.

In addition to these two geometrical strategies for the construction of complex μ-networks, many other possibilities exist based on varying the chemical composition of μ-gels. Just two of the most important should be mentioned. *Burchard* et al. have examined μ-gels made of two incompatible polymers, where a cross-linked core of one polymer is surrounded by a shell of grafted linear chains of the other type.[15] Light scattering techniques can be used to determine the structures of these systems, which model inner surfaces in polymer blends. Another course is being followed by *Obrecht, Seitz* and *Funke,* who have examined[15] different possibilities for synthesizing "reactive" or functionalized μ-gels. For instance, some properties of μ-networks containing vinyl, sulfate or hydroxy groups have been described.

Although the strategies applied for μ-network synthesis are still relatively crude (compared to nature), some possible goals of all these efforts are worth mentioning. The combination of a fixed, soluble structure of nanometer dimensions with a specific functionality is one possible starting point for the construction of tailor-made polymeric catalysts, mediators or phase transfer reagents. The term "artificial enzyme" in the context of this kind of research is certainly presumptuous, but functionalized μ-gels are already used as catalysts in non-aqueous media and as stabilizers in complex coatings, and that is just the beginning. Nature's concepts will increasingly be applied to synthetic materials. The development and examination of structured polymers is just one field where the patterns of nature are imitated; μ-gels are one component within this strategy.

New Organic Superconductors

BEDT-TTF Salts
2D (Super)Conductors
Charge-Transfer Complexes

By Hiroo Inokuchi*

1. Introduction

The first report of the discovery of an organic superconductor, $(TMTSF)_2PF_6$, a tetramethyltetraselenafulvalenium cation radical salt, appeared in 1980.[1] Since then, thirty different types of charge transfer complexes have been reported as organic superconductors, as summarized in Table 1.

Of the seven kinds of $(TMTSF)_2X$ superconductors, the so called Bechgaard salts, only the $ClO_4^{\ominus}$ salt becomes superconducting at ambient pressure. Though TMTSF contains selenium atoms, after the discovery of superconductivity in $(BEDT\text{-}TTF)_2ReO_4$, the first sulfur-based organic superconductor, a large part of the research into organic superconductors was devoted to the BEDT-TTF salts. The most important BEDT-TTF superconductor was β-$(BEDT\text{-}TTF)_2I_3$.[23] It was the first ambient-pressure BEDT-TTF superconductor, in addition its T_c could be increased greatly to 8 K by the application of moderate pressure; this value was the highest T_c of organic superconductors before the discovery of $(BEDT\text{-}TTF)_2Cu(NCS)_2$. Following β-$(BEDT\text{-}TTF)_2I_3$, several other BEDT-TTF iodine salts with different crystal structures, designated by the Greek letters β, γ, θ, and κ, were found to be ambient-pressure superconductors. The β-$(BEDT\text{-}TTF)_2I_3$ salt also stimulated research into salts with other linear anions, from which it has been found that $IBr_2^{\ominus}$ and $AuI_2^{\ominus}$ salts[26,27] can become superconducting.

One should also mention the unique $[M(dmit)_2]$ series; these salts are the only acceptor-based organic supercon-

Myodaiji, Okazaki 444 (Japan)

ductors known so far. The asymmetric donor DMET, which is a hybrid of TMTSF and BEDT-TTF, has been found to generate superconductors. A superconductor based on another asymmetric donor, MDT-TTF, has also been discovered (Table 1).

Table 1. Organic Superconductors.

Compounds	T_c	Ref.
$(TMTSF)_2PF_6$	1.4 K (6.5 kbar)	[1, 16]
$(TMTSF)_2AsF_6$	1.4 K (9.5 kbar)	[17]

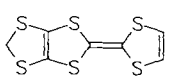
[c] MDT–TTF:

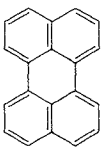


Recently, *Urayama* et al. of the Institute for Solid State Physics, University of Tokyo, discovered an ambient pressure superconductor, $(BEDT\text{-}TTF)_2Cu(NCS)_2$, BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene, with a transition temperature T_c above 10 K.[2] *Mori* and the present author, of the Institute for Molecular Science, Okazaki, have reported a novel organic superconductor, $(BEDT\text{-}TTF)_3Cl_2\cdot 2H_2O$, with an unusual molecular structure,[3] with $T_c = 2$ K at a pressure of 16 kbar.

In this article we shall review these two organic superconductors with their historical background.

2. Historical Background

Between 1925 and 1940, two groups worked on "perylene addition compounds". *Clar* et al. reported on perylene polyhalides under the title of "unpaired halides" or "anomalous halides". Their first paper[4] described the formation of dark brownish black needles by the addition of bromine to a saturated benzene solution of perylene; the needles were found to have the composition of perylene tribromide, $C_{20}H_{12}Br_3$.



perylene, $C_{20}H_{20}$

Zinke et al. published a large series of papers entitled "Studies on Perylene and its Derivatives". They reported that pulverized perylene absorbed bromine quickly and produced a greenish-black product. This product, with assigned formula $C_{20}H_{12}Br_4$, was not stable and liberated hydrogen bromide.[5]

These results were very interesting in the light of considering perylene as a fragment of graphite, and the reported electrical conductivity of graphite-lamellar compounds, now known to be graphite-intercalation compounds.[6]

In 1954 we prepared a perylene-bromine complex by *Zinke*'s method and measured its magnetic susceptibility and electrical resistivity.[7] The pressed pellets of the complex were found to have a resistivity of 8 Ωcm. The magnetic susceptibility, -61×10^{-6}, was smaller than that estimated by the additivity rule, -286×10^{-6}. This was the first report of the electrical conductivity of charge transfer complexes.

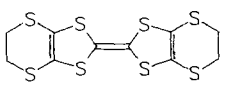
Since this discovery an enormous amount of research has been carried out to obtain novel conducting organic compounds—the so-called "conductive charge transfer complexes"—and the research field of organic semiconductors/conductors has been developed.

3. Two-dimensional conductors: BEDT-TTF complexes

The charge transfer complexes, $(TMTSF)_2X$ (X = PF_6 or AsF_6) have a metal-to-semiconductor transition at 19 and 15 K respectively at ambient pressure, while under moderate pressure these salts remain metallic, with the onset of superconductivity at 0.9 and 1.3 K, respectively. From this consideration it seemed desirable to synthesize organic metals, in which the metal-to-semiconductor transition is suppressed, so as to make new type organic superconductors and to lead to a better understanding of the requirements for them.

ADVANCED MATERIALS

The alkylthio substituted tetrathiafulvalene (TTF), BEDT-TTF **1**, a π donor, was therefore made in the hope that the chemical modification by extending the TTF moiety, with an increased polarizability, would increase the conduction band width and reduce the on-site Coulomb repulsion, resulting in a considerable enhancement of the metallic character.[8]



BEDT-TTF, 1

This character was confirmed by resistivity measurements on $(BEDT\text{-}TTF)_2ClO_4 \cdot Cl_2HCCH_2Cl$ in comparison with $(TMTTF)_2ClO_4$ (TMTTF = tetramethyl-TTF), as shown in Figure 1. As listed in Table 1, two-thirds of organic superconductors are BEDT-TTF derivatives; at present, BEDT-TTF is the most appropriate π-donor to produce organic superconductors.

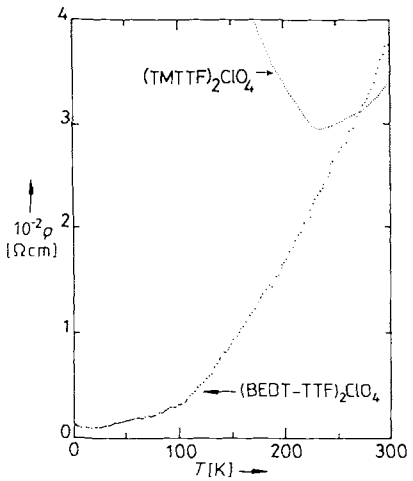


Fig. 1. Electrical resistivity ρ vs. temperature T along the elongated axis of a $(BEDT\text{-}TTF)_2ClO_4 \cdot 0.5$ 1,1,2-trichloroethane single crystal compared with that of $(TMTTF)_2ClO_4$.

4. $(BEDT\text{-}TTF)_2Cu(NCS)_2$[*]

$(BEDT\text{-}TTF)_2Cu(NCS)_2$ is the first organic superconductor with a T_c higher than 10 K under ambient pressure.[2] The preparation and crystal growth of this charge-transfer complex was carried out as follows: 30 mg of highly purified BEDT-TTF and 250 mg of purified K(18-crown-6 ether)$Cu(NCS)_2$ were placed in the anode side of an H-type reaction cell (total volume about 20 mL), and 50 mg of K(18-crown-6 ether)$Cu(NCS)_2$ were placed in the cathode side. The cell was evacuated and then filled with nitrogen. 100 mL of dried 1,1,2-trichloroethane was added, and it was stirred 15 h under inert gas. The electrolysis, using platinum wires (1–2 mm diameter), was carried out at a constant current (1 to 5 μA). Crystal growth (typical dimensions $3 \times 2 \times 0.05$ mm^3) proceeded for 5 to 14 days and the harvested crystals were washed with 1,1,2-trichloroethane, methanol and tetrahydrofuran and dried under vacuum. The crystals were stable against air and moisture.

The crystal structure of $(BEDT\text{-}TTF)_2Cu(NCS)_2$ is analogous to that of κ-$(BEDT\text{-}TTF)_2I_3$. However, the superconducting transition temperature T_c was different. In the crystal two BEDT-TTF molecules form a dimerized pair and the pairs are linked to each other by short S···S contacts almost perpendicularly, forming two-dimensional conducting sheets in the *bc*-plane. Each conducting layer is sandwiched by the insulating layers of anions along the *a*-axis.

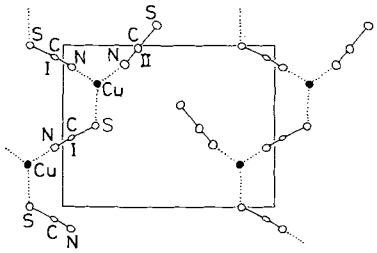

Fig. 2. Packing of $Cu(NCS)_2^{\ominus}$ anions in $(BEDT\text{-}TTF)_2Cu(NCS)_2$.

The anion $Cu(NCS)_2$ is neither symmetric nor linear, but asymmetrically bent like a boomerang. Two crystallographically independent NCS groups (I and II in Fig. 2) are almost linear. The boomerang units are arranged one after the other along the *b*-axis to form a zig-zag one-dimensional flat polymer. Three NCS groups (I, I, II) coordinate to a copper cation ($Cu^{\oplus}$) with two nitrogen atoms and one sulfur atom. Thus the polymer is represented as

$$(SCN(I)\text{–}Cu\text{–})_n$$
$$\quad\quad\quad

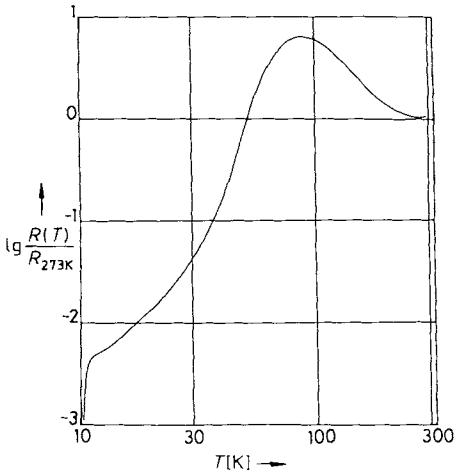

Fig. 3. Temperature dependence of electrical resistivity of (BEDT-TTF)$_2$Cu(NCS)$_2$.

ing transition at 10.4 K. The physicochemical properties, electronic structure,[9] XPS and ESR spectra,[10] thermoelectric power,[10] magnetic resistance,[9] magnetic susceptibility,[12] a.c. magnetic susceptibility, polarized reflectance spectra, anomalous NMR relaxation, tunneling spectroscopy,[13] and other properties, have already been measured. From the tunneling spectroscopy data the observed gap of 4 meV leads to a value of 4.5 for $2\Delta/kT_c$, (where $2\Delta = 4$ meV and $T_c = 10.4$ K), which is of the same order as the BCS ratio of 3.52.

5. (BEDT-TTF)$_3$Cl$_2$·2H$_2$O[*]

The chlorine salt, (BEDT-TTF)$_3$Cl$_2$·2H$_2$O, shows superconduction at 2 K under a pressure of 16 kbar.[3] An enormous number of charge-transfer complexes with halogens as acceptors have been prepared. However, no report of complex formation with chlorine has appeared so far as we know. In the case of graphite intercalation compounds, only the larger size halogens, Br_2, I_2, ICl and IBr can form intercalation compounds, and the fluorine molecule reacts directly with graphite to form insulating compounds involving F-substituted sp^3 carbon atoms.

In the structural chemistry of the BEDT-TTF salts, the discontinuity between iodine and bromine is related to the ability of iodine to form trimer anions such as $I_3^{\ominus}$. The halogen atoms Br and Cl are themselves too small to form charge-transfer complexes with BEDT-TTF, but the clusters solvated by H_2O are included in the BEDT-TTF salts. The 3:2 BEDT-TTF salts occur when the counter-anions are relatively small, e.g. as with $ClO_4^{\ominus}$ and $ReO_4^{\ominus}$. Because the Br and Cl salts have not only the same composition but also a similar donor arrangement to the salts of these tetrahedral anions, these complex anion clusters, $Br_2(H_2O)_2$ and $Cl_4(H_2O)_4$, can be regarded as rather small anions.

[*] With *T. Mori*.

The preparation of this intriguing complex, (BEDT-TTF)$_3$Cl$_2$(H$_2$O)$_2$, was also unusual: the complex was obtained by electrolysis using $[(C_2H_5)_4N]_2CoCl_4$ as electrolyte,[14] and by chlorine abstraction from the solvent CH_2Cl_2.[15] Recently the same complex was obtained by electrolysis in the presence of $[(n\text{-}C_4H_9)_4N]Cl$.

The structure of the anion, $Cl_4(H_2O)_4$, in the salt is illustrated in Figure 4. Two Cl atoms are connected to two O atoms through hydrogen bonds to form a rectangle. This unit has a close resemblance to the $Br_2(H_2O)_2$ unit in (BEDT-TTF)$_3$Br$_2$(H$_2$O)$_2$. However, in the chlorine salts additional Cl and O atoms are attached to this unit by hydrogen bonding.

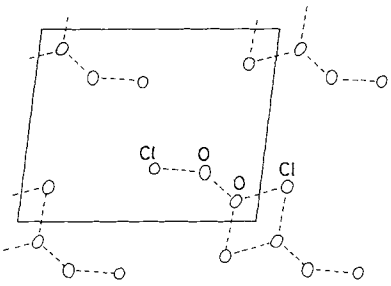

Fig. 4. Packing of $[Cl_4(H_2O)_4]^{\ominus}$ anions.

The bromine salt, (BEDT-TTF)$_3$Br$_2$(H$_2$O)$_2$, exhibits metallic conduction at room temperature, and then undergoes a metal-to-insulator transition at 185 K. On the other hand, the chlorine salt, (BEDT-TTF)$_3$Cl$_2$·2H$_2$O, has a high conductivity as a (BEDT-TTF) complex, 500 S cm^{-1} at room temperature, and is metallic down to 100 K. Although this salt undergoes a metal-to-insulator transition arund 100 K, superconductivity has been found at 2 K under a pressure of 16 kbar as mentioned above.

As can be seen from Table 1, all other organic superconductors except this chlorine salt have the 2:1 composition, irrespective of whether the conducting components are donors or acceptors, and their energy bands are quarter-filled. If the band structure is calculated by the extended Hückel approximation, the BEDT-TTF superconductors usually give comparatively simple two-dimensional metal bands. This chlorine superconductor, on the contrary, gives a semimetallic energy band.[14] This result demonstrates that neither the 2:1 composition nor a simple two-dimensional metal band is a necessary condition for organic superconductivity.

Schweitzer et al. have reviewed their excellent contributions to the field of BEDT-TTF molecular metals and superconductors.[41]

Research News

Molecular Electronics: Silicon to Soliton and Other Trends

When the British Association for the Advancement of Science (BA) first met in Oxford some one hundred and fifty years ago, only a few scientists, apart from *Faraday*, were then engaged in the new task of assembling electrical circuits. In those days, long before the age of mass production, the diameter of conducting rods was of millimeter dimension. Nowadays, with world-wide interest in the pursuit of the ultramicro-miniature, there is intense activity in the design and construction of molecular electronic devices made up of organic semiconductors, organic metals and conducting polymers which are of either organic or inorganic provenance (such as polysulfur nitride). Into the lexicon of the molecular architect a new word has been recently introduced, a "proconductor" which is the non-conducting form of a molecular entity that can also be made conducting by loss or gain of an electron by partial oxidation or reduction. Present day studies[1] which, inter alia, seek to arrive at favored molecules for memory, logic and amplification—with a view to constructing computers based, not on silicon or gallium arsenide, but on self-assembling molecules of the kind that abound in biology—focus on such problems as whether a π-conjugated molecule, a hundred Ångstrom or so in length, can serve as a proconductor or a conductor when placed between two metallic conductors. It is conceivable that the 'electronic wiring', which, it is thought, will be a characteristic of the

molecular electronic device of the future, will consist of bridges similar to those recently discussed by *Aviram* (see Fig. 1). The diameter of these 'wires' is of nanometer dimension. A diminution in diameter by a factor of 10^6 has therefore been achieved in the interval between the date of the first and most recent (September 1988 at Oxford) BA meeting.

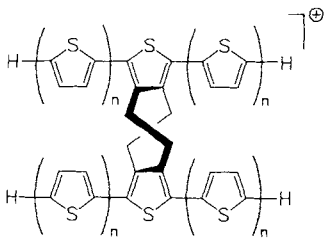

Fig. 1. A proconductor and a conductor chain connected by a σ bridge which forces the two π terminals to be at 90° to each other [1].

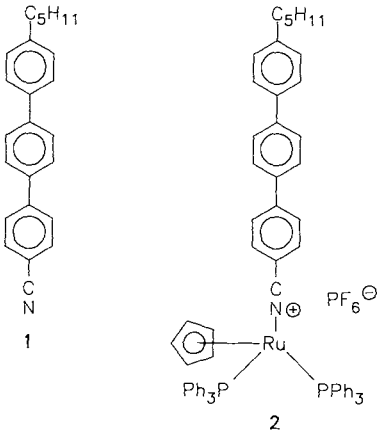
One of the numerous minisymposia held at Oxford focussed on some key aspects of molecular electronics. Present day microelectronic and opto-electronic industries rely mainly on inorganic materials. It has been clear for some time, however, that future requirements for more complex system designs predicate a renewed interest in the organic solid-state, the study of the electronic properties of which began in earnest forty years ago.[2,3] By the early seventies, these materials were seen to hold promise as sensors, protonic conductors and other useful devices.[4]

G. G. Roberts (University of Oxford and Thorn EMI plc) targeted his remarks largely on the wide scope and numerous advantages offered by carefully tailored Langmuir–Blodgett (LB) films. He demonstrated the advantages to be gained by capitalizing on the ultra-thinness and controlled, crystalline architecture of these monomolecular assemblies. That LB films may be used to generate dilute radioactive sources, magnetic monolayers and model biological membranes has been recognized quite early in their adoption as physico-chemical curiosities. What was not fully appreciated in the early days, however, was that considerable advantage could be taken of the comparative ease of preparing non-centrosymmetric, crystalline LB films. Materials with non-centrosymmetric structures exhibit pyroelectricity as well as strikingly non-linear optical behavior. *Roberts* referred in particular to work recently published[5,6] in which a novel organo-transition-metal complex had been synthesized specifically for use with the LB deposition procedure. Thus, by coordinating the liquid crystal compound **1** with $[Ru(PPh_3)_2Cp]$ forming **2**, the electron withdrawing nature of the parent molecule is greatly enhanced and, at the same time, multilayer formation, in the LB sense, is facilitated.[5] Optical second-harmonic generation yields a value for the hyperpolarizability much larger than that of most inorganic materials. Films of **2** have a pyroelectric coefficient (3×10^{-6} cm^{-2} K^{-1}) that is thought to be the largest yet reported. It is apparent from



this as well as other work by *Treadgold* et al.[7] (not presented at Oxford) that alternating LB films of polymers and merocyanine monomers (possessing large alkyl chains as quaternizing agents) are very efficient second-harmonic generators, enabling visible radiation to be generated from infrared sources. (Parenthetically, we note that it is of considerable technical and fundamental interest[8,9] that infrared–visible sum-frequency generation[10] can now be used to obtain vibrational spectra of adsorbed monolayers on metal and semiconductor surfaces).

J. White (Thorn EMI plc) dealt with the applications of liquid crystals. Although these fascinating materials have been known since the classic work in Germany in 1888, only after *G. W. Gray*'s pioneering studies at the University of Hull in the early 1970's did it become possible to produce, to order, environmentally stable liquid crystals. In the context of television displays, it is obvious that, for reasons of mass alone, the cathode ray tube cannot be a candidate for very large area (e.g. 3 m × 2 m) viewing screens. This is where it is felt that liquid crystal displays will prove advantageous, just as they have done for the currently available pocket-sized TV sets.

P. Day (Inorganic Chemistry Laboratory, Oxford and I.L.L., Grenoble) summarized the landmarks in the search for new molecular materials and superconductors. In the last few years molecular organic compounds have been discovered that not only conduct electricity like metals, but even become superconducting at low temperatures (see Fig. 2). In contrast to conventional metals, the charge-transfer salts which sometimes exhibit these properties are made from solution at room temperature by electro-crystallization. Again, in contrast to the traditional metals, the properties of 'molecular metals' are extremely sensitive to small changes in their packing arrangements. Minute alterations in the inter-molecular spacings can have profound consequences. And small chemical adjustments to the anions (e.g. the replacement of a $PF_6^\ominus$ for $ClO_4^\ominus$) in the charge-transfer salts transforms them from superconductors to normal metals or even to insulators. This is especially so for the tetrathiafulvalene derivatives. *Day* drew attention to some remarkably interesting charge-transfer

ADVANCED MATERIALS

complexes, prepared in his laboratory at Oxford, that changed from being semi- to superconducting on application of pressure. He also referred to the recent work of *Saito* et al. at the Institute of Solid State Physics, Tokyo, where an organic complex involving copper thiocyanate has a superconducting transition of 10.4 K (see review by *Inokuchi* in this issue). What is apparent from the behavior of such a material is that the rate of rise of the superconducting transition temperature (Fig. 2) is much steeper for molecular organic compounds than for the rare earth-alkaline-earth-copper oxides or their bismuth-based analogues.

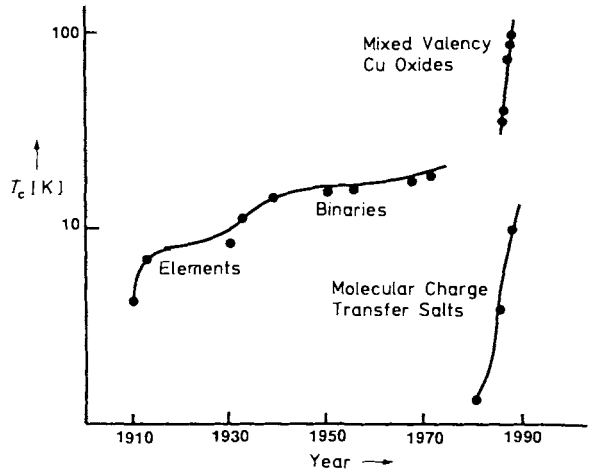


Fig. 2. The T_c history of superconductors.

H. G. Heller's presentation, based on his elegant work over the past decade at the University of Wales (first at Aberystwyth and latterly at Cardiff) was entitled 'Chameleonic chemicals'. Organic compounds that change color reversibly on exposure to light have enormous commercial potential. These thermally stable photochromic compounds can be developed for optical information storage in computers, as well as played on home video and audio equipment. By means of molecular tailoring and design, their properties can be modified so that they change color in direct sunlight and fade rapidly at room temperatures. Such compounds can be incorporated into lightweight plastic lenses which darken in sunlight and clarify under diffuse daylight. Another application lies in the security printing of banknotes, checks and other documents. By and large the chemistry of these chameleonic materials rests on the guidelines offered by the Woodward-Hoffman rules:[11] photo-stimulated, conrotatory reactions ensue freely whereas thermally-stimulated, disrotatory reactions entail overcrowding and, hence, are sluggish and unfavored.

Molecular electronics was also discussed in the Biology section of the BA meeting at Oxford, although the main emphasis was on the fundamentals of molecular recognition rather than molecular engineering. Whereas *C. R. Lowe* (Biotechnology Unit, University of Cambridge) sought to exploit the ease with which biological recognition takes place and to combine it with conventional solid-state electronics—and in so doing demonstrated how this would, inter alia, lead to effective remote sensing (especially under adverse environmental conditions) and continuous, one-line, real-time quantitative chemical or biochemical analysis—his colleague at Cambridge, *R. N. Perham* (Department of Biochemistry) ranged freely, during the course of his address, over topics such as the uncanny kinship in the architecture of the active sites in a dozen or so ostensibly quite unrelated enzymes and the role of an enzyme as an asymmetric unit. He also indicated that moving a 'recognition center' from one antibody into another was already a reality. As his was the presidential lecture of the Biology Section, he also considered other exciting areas of biochemical research: techniques are now available to enable the DNA sequence of a gene to be altered at will, thereby permitting the amino acid sequence of the encoded protein to be correspondingly changed. This testifies to the biochemists' ability directly to design protein molecules for specific, and otherwise inaccessible, purposes. *Perham* outlined how we are just beginning to acquire the ability to intervene in the elaboration of shape and form in multi-subunit, self-assembling systems.

Shortly after these minisymposia ended the 8 September issue of *Nature* appeared. In it *R. H. Friend* and his colleagues at the Cavendish Laboratory, University of Cambridge described new semiconductor devices using organic polymer diodes and transistors.[12] These devices are fashioned from polyacetylene, a conjugated polymeric semiconductor, which can readily be produced in (amorphous) thin film form, as a result of a thermally-stimulated conversion of a precursor developed at the University of Durham by *Feast* et al.[13] The devices constructed by *Friend* et al. operate in a novel way: charge is stored in localized soliton-like excitations of the polymer chain. These excitations are introduced by the presence of an adjustable surface electric charge. This is a fundamentally different method of introducing excitations from that used in devices based on silicon or gallium arsenide, where doping with controllable amounts of deliberately added impurities is the principle employed. The presence of charged solitons changes the optical properties of the hydrocarbon polymer.

The results reported by *Friend* et al. do not yet pose a threat[14] to established semiconductor technology: it must never be forgotten that the mobilities of electrons and holes in two dimensions in materials based on Si or III/V compounds, and their quantum-well variants, are phenomenally good. And, as yet, there is no organic metallic or semiconducting polymer that approaches Si in this regard. It is, therefore, arguable whether transistor devices based on organic polymers are likely to become commercial in the near future. (It is noteworthy that *Roberts* et al.[15] over a decade ago produced a p/n function based on two-dimensional LB films of anthracene. But these did not pre-

sage a growth in organic semiconductor technology). What one can reasonably expect, however, is that the elegant work of *Friend* et al. might soon lead to the development of high-performance sensors utilizing relatively cheap and easily processed organic materials.

Conference Reports

Advanced Materials— R & D Efforts in Germany

A good three years after the German Federal Ministry for Research and Technology (Bundesministerium für Forschung und Technologie, BMFT) initiated its Materials Research Program, the first Materials Research Symposium took place in Hamm/Westphalia on September 12–14, 1988. Approximately 600 scientists and engineers discussed, in plenary lectures and review papers. the current state of knowledge and techniques in materials research. Results obtained up to now in various advanced research and development projects were presented in specialist papers and posters.

Following intensive discussions with many experts, five main themes that appeared to offer a high potential for innovation had been chosen for the Materials Research Program: ceramics, powder metallurgy, metallic materials for high temperatures and specialized applications, new polymers, and composite materials. The idea of the program is to stimulate progress by setting up joint interdisciplinary research projects involving academic research institutes and industrial laboratories, with well-matched complementary work plans carefully drawn up and agreed in advance. The industrial partners contribute with about 50% of the cost of such R & D projects. Federal funding up to a total of DM 1.1 billion is to be made available over the ten-year program. The Materials Research program is being supervised on behalf of the BMFT by the Materials Research Project Group of the KFA (Nuclear Research Center), Jülich.

The DM 940 million that has been committed to the Materials Research Program up to the time of this interim review in Hamm is divided between 265 collaborative projects involving 637 research laboratories; Table 1 summarizes the distribution between topics. Of the funding provided by the BMFT, 34% has gone to academic research institutes and 66% to industrial laboratories.

Table 1. Distribution of presently committed research funds between the five main themes of the Materials Research Program (million DM).

	Ceramics	Powder metallurgy	High temperature metals	Polymers	Composites
Total budget	251	94	176	200	220
BMFT contribution	124	58	99	103	116

Ceramics

This part of the program is aimed mainly at research and development on monolithic ceramics, and also includes ceramic films. It is strongly focussed on high performance structural ceramics (engineering ceramics). At present there are very few applications for which the reliability of complex shaped ceramic engineering components under dynamic load is adequate. It should be possible to greatly improve the reliability of ceramic components by quality control during manufacture, or by structural reinforcement, helped by the expected development of more reliable non-destructive testing methods. The powders used as starting materials for the manufacture of ceramic engineering components can be synthesized by reactions in the solid state, by production from melts, or by precipitation from solutions or from gaseous phases. An example of the

many developments in progress is that by Elektroschmelzwerk Kempten (ESK) in collaboration with Kühnle, Kopp & Kausch AG (KKK) of Frankenthal and the Technical University of Braunschweig; this team is working on a new process for manufacturing turbocharger rotors from sintered silicon carbide or silicon nitride materials (SSiC, SSN and SRBSN). In particular, with Si_3N_4 rotors it has already been found that the frictional conditions at 1300 K allow peripheral velocities greater than 500 ms^{-1} to be achieved, and in tests with a SSiC rotor an operating life of 10000 km has been obtained. There are good prospects for achieving peripheral velocities of $>500\ ms^{-1}$ at 1500 K and a failure probability of less than 0.1%. However, considerable further work will be needed to achieve consistent series production with this level of quality, while also paying adequate attention to economic aspects. With the R & D work that is currently under way, ceramics research in the Federal Republic of Germany has taken a considerable step forward. However, there is likely to be an increasing need in the future for R & D work in the field of functional ceramics (including glass-ceramics and glass) with special physical properties, e.g. as regards electrical, electronic, optical or magnetic behavior.

Powder Metallurgy

Some of the topics in the powder metallurgical part of the Materials Research Program are: the reproducible manufacture of rapidly quenched powders for making alloys that are not accessible by melt metallurgy; the development of new process methods for manufacturing engineering components and semi-finished parts with, for example, spatial variations in their properties (graded structures), or with unusually high strength and toughness; the development of economical methods of production for large mechanical components. As an example, work is in progress at the Technical University of Hamburg-Harburg and at the Max Planck Institute for Metals Research, Stuttgart, in collaboration with several industrial partners, to develop high-strength aluminum alloys made by powder metallurgical techniques; with alloys of the type Al-Zn-Mg-Cu-X it was found that yield stresses as high as 750 MPa and a fatigue strength of 300 MPa could be obtained, thus giving strength properties significantly better than those of the corresponding alloys made by melt metallurgy.

Densification of powders by the direct explosive method offers an attractive means of compacting, especially for the newly developed rapidly quenched types of alloys, or for brittle materials such as ceramics or intermetallic phases. The possibilities for industrial applications of this technology are being investigated in a collaborative project between ESI GmbH, Eschborn, and Rheinmetall GmbH, Düsseldorf. The studies are based on a commendable symbiosis of theoretical calculation and experiment. The very rapid densification process, which is characterized by extremely high pressures and material velocities, was simulated using a computer program for finite element calculations. The parameters thus determined were then used in setting up experiments, and this resulted in the production of samples with 99% densification. Following the successful compaction of spherical samples, it is planned that the next stage of the project will investigate explosive densification of powders consisting of plates and of complex mechanical components such as turbine blades.

Metallic Materials for High Temperatures and Special Applications

Metallic materials continue to occupy a preferred position in high performance engineering applications, and are used in many areas of modern technology. They have high strength and toughness with good thermal conductivity, and can be economically produced and worked. The application of new metallurgical knowledge has led to improved properties with regard to strength, toughness, stability at high temperatures, and corrosion resistance, showing that the scope for continued development of metals made by melt metallurgical techniques is still far from exhausted. One factor that limits the potential applications of metallic materials is the maximum service temperature; excessive temperatures result in deterioration of the mechanical properties and corrosion resistance, and a reduction in creep strength. An example of an approach to these problems is the collaboration between the Ruhr University of Bochum and the VAW, Bonn, which is concerned with R & D work on new types of structures in Al-Li based alloys. The demand in airplane construction for materials that are ever lighter but also stronger has led to the development of Al-Li alloys with reduced density and increased tensile modulus. This allows the construction of aircrafts with significantly reduced structural masses. In these research studies the combination of new materials structures and optimized heat treatments has led to materials whose mechanical properties are superior to those of conventional cast and wrought aluminum alloys.

The overall impression is that the work on materials for high temperatures and special applications covers a wide range of topics, including both the further development of conventional high performance materials and basic studies on the potential uses of more novel materials.

New Polymers

This aspect of the program is concerned both with developing high performance polymers for use as engineering materials and with producing functional polymers with entirely novel physical properties, e.g. electrical, electronic, optical or magnetic properties. High mechanical performance in polymers may involve requirements such as stabil-

ity even at very high temperatures, or high strength while retaining good processability. Looked at in terms of theoretically attainable values, only a fraction of the potential strength properties of polymers has been used up to now. It is true that the theoretical values cannot be fully realized in practice, but there is nevertheless an enormous potential for development. Possible approaches include specifically synthesizing or otherwise forming a precisely defined molecular architecture. An example of this is a development at the Max Planck Institute for Polymer Research, Mainz, in which flexible side-chains are attached to rigid main-chains with the aim of reducing the melting temperature so as to facilitate down-stream processing, without a significant deterioration in the good mechanical properties.

Remarkable progress has been achieved in the field of functional polymers. For example, BASF in collaboration with Bayreuth University and the Max Planck Institute for Polymer Research, Mainz, has succeeded in producing polymers with intrinsic electrical conductivity similar to that of metals.

In another research project on "polymeric optical fibers", Hoechst AG, Frankfurt, has scored a notable success. Precursors for making a polymeric light-transmitting fiber have been synthesized; these have better high temperature resistance ($T_g > 130\,^{\circ}C$) and considerably lower light attenuation (20 dB km^{-1}) than conventional polymeric optical fibers made of polymethylmethacrylate (PMMA: 100 dB km^{-1}). This has been achieved by means of a hydrogen/fluorine and hydrogen/deuterium exchange in esters of acrylic and methacrylic acids. These materials make it possible to transmit signals over a distance of 1500 m without intermediate amplification, whereas the plastic optical fibers used previously have needed booster amplifiers every 100 m.

A large market in the field of short-range information technology (transmission distances under 2 km) is predicted for polymeric optical fibers, as they are more flexible than glass fibers, even with large fiber diameters, and they also offer a wider range of choice in refractive index; also the cost of a system is less owing to easier working of the material and lower manufacturing costs.

Functional polymers are likely to become especially important as a result of future advances in research. Efforts are being made to ensure close cooperation between research partners in the electronics and chemical industries.

Composite Materials

This research topic is concerned with high performance materials in which a polymeric, ceramic or metallic matrix is reinforced by the inclusion of fibers, whiskers or particles. Such materials are used in applications requiring high strength, stiffness and heat resistance with low mass.

An example of development work in this area is a project on composites based on polymer matrices, under the overall control of Volkswagen AG. This is concerned with developing economic production methods using winding and tape-laying techniques for producing motor vehicle components. A typical example is the manufacture of transmission shafts for automobiles. Here the rate of production was increased to such an extent that it is now possible to make these components with an operating cycle of less than 30 s.

Another example that may be mentioned is a joint project by the companies Didier and Kolbenschmidt to develop a composite material with a matrix of ceramic and metal. It has previously been shown that ceramic fiber reinforced metallic materials already come very close to meeting the specifications for use as pistons in automobile engines. The idea being investigated in this project is to combine the advantages of the two materials by building into the piston a fiber gradient. According to this concept the piston has a dense ceramic layer on the combustion face, with a continuous gradation of the ceramic fiber fraction along the length of the piston, from 100% at this face down to zero at the other end. The mechanical characteristics thus obtained show an improvement over those for conventional piston materials which is in some cases as much as 100%. Another very important property of materials used for pistons is the resistance to thermal shock. In this case fiber reinforcement gives an improvement of 300 to 400% in the results of temperature cycling tests.

The idea followed at Hamm of organizing the conference program with a strong interdisciplinary emphasis has proved especially successful, bringing together scientists and engineers from all branches of materials science in wide-ranging and stimulating discussions covering different disciplines. The proceedings of the symposium have been published by the Materials Research Project Group of the KFA Jülich. In addition, an overall evaluation of the results achieved compared with international developments will be published by the BMFT late in 1988.

As of January 1989, ADVANCED MATERIALS can be subscribed to separately at the annual rate of DM 178.00. Please order through your bookseller or write to VCH Verlagsgesellschaft mbH, Postfach 101161, D-6940 Weinheim, FRG. Customers in Switzerland, in the UK and in the USA should write to VCH Verlags AG, Hardstrasse 10, Postfach, CH-4020 Basel, Switzerland, VCH Publishers, Wellington Court, 8 Wellington Street, Cambridge CB1 1HW, UK, and VCH Publishers, Suite 909, 220 East 23rd Street, New York, NY 10010-4606, USA, respectively.

ADVANCED MATERIALS

Speciality Polymers

The 3rd International Conference on New Polymeric Materials, "Speciality Polymers '88", was organized by the journal *Polymer* and held from September 13–15, 1988 at Queens' College in the beautiful old university town of Cambridge, UK. About 350 participants attended to hear about the newest developments in the field, which were presented in six plenary lectures and two parallel sessions with 22 papers each, devoted to "High Performance Polymers" and "Electroactive Polymers", respectively.

In the first plenary lecture *D. T. Clark* (ICI, UK) discussed approaches to meet the development goals for high temperature performance polymers for air- and spacecraft applications: The T_g/T_m window of aromatic polyetherketones-co-sulfones can be adjusted by suitably balancing the sulfone and keto group content, with high keto content generally giving rise to high T_m, while increasing the sulfone content lowers the degree of crystallinity. The fine control of properties depends on a number of additional parameters, amongst which the sequence and isomer distribution are of major importance for the crystallization behavior and morphology, with the effective sulfone content of the interlamellar phase controlling the T_g.

From the number of papers devoted to electrically or optically active polymers, and the high innovative content of the presentations, it became clear that the bias of this session was towards polymer systems with highly sophisticated optical and/or electro-optical properties. The rich diversity of structural types of liquid-crystalline (LC) polymers, studies on their structure-property relationships, and various efforts to tailor their optical or electro-optical response for particular applications, were reviewed by *G. M. Gray* (University of Hull, UK). Taking siloxane and acrylate LC polymers as examples, it was stressed that analytically pure materials, with respect to precursor removal, molecular weight and dispersibility, are essential in order to obtain reproducible results on transition temperatures, dielectric properties, elastic constants and electro-optical response. To meet the challenge of the search for LC polymers with non-linear optical (NLO) properties, *Gray* and his coworkers have introduced a new type of LC copolymer with conventionally and laterally attached rod-like mesogens. LC side-chain polymers based on siloxanes or acrylates with birefringent, dichroic, fluorescent and NLO properties were discussed by *H. J. Coles* (University of Manchester, UK). Special consideration was given to nematic and smectic, and also ferroelectric phases, and optical effects as fast as 10^{-9} s with lateral resolution of about 10^{-6} m have been demonstrated in such systems. The kinetics of the alignment process in LC side-chain polymers can be studied by dielectric relaxation spectroscopy, as demonstrated by *G. Williams* (University of Wales, Aberystwyth, UK).

The diacetylenes, which offer a great variety of primary structures, are very promising as NLO materials and, because they can be laid down as ultrathin layers using the Langmuir-Blodgett (LB) technique, as candidates for integrated optics; accordingly they were discussed by several speakers. An alternative to LB films derived from diacetylenes, which have to be post-polymerized, are LB films from preformed polymers based on substituted acrylates with mesogenic side chains, as described by *P. Hodge* (University of Lancaster, UK). Symmetric as well as noncentrosymmetric LB multilayers can be assembled by using two or more different polymers. Second Harmonic Generation (SHG) in spin-coated PMMA films containing azo dyes was discussed by *Le Barny* (Thomson-CSF, France).

The development of "photonic computing" based on optical shutters, logic elements and storage elements requires materials with very fast (10^{-12} s) switching times, as was outlined by *R. S. Potember* (Johns Hopkins University, USA). The only processes in organic molecules that are fast enough for this purpose are electronic level jumps or polarizability changes. As an example the excitation of π-states in ladder type oligomers with an indanthrone type backbone was discussed, with the optical response varying dramatically according to the type of substitution and degree of polymerization. A final link between diacetylenes and LC materials was offered by *M. A. Schen* (National Bureau of Standards, Gaithersburg, USA), who reported on the polymerization of diacetylenes from a smectic c-phase, in which the activation energy for thermal polymerization was considerably lower than that in the crystalline phase.

The common features of electroactive polymers, and the influence of molecular or supermolecular defects on their performance as conducting, charge-storing, piezo- or pyroelectric materials were reviewed by *T. J. Lewis* (University College of North Wales, Bangor, UK). The concepts of charge transport involving localized states, tunneling structures and the influence of interfaces and phase boundaries in the solid state of conducting materials were discussed.

The contribution by *P. Kathirgamanathan* (Cookson, UK), entitled "The Future of Conducting Polymers" was expected by most of the participants to clear up some of the uncertainties in this particular field. Since the review of the present situation in conducting polymers took up all the available time, the speaker unfortunately did not reach the discussion of their future. However, the future of conducting polymers was touched on in a number of contributions, which dealt with the problems of processing such materials: *P. Smith* (University of California, Santa Barbara, USA) reported on the synthesis of polyacetylene (PA) in a polyethylene gel, from which it could be drawn into highly anisotropic fibers. *R. W. Lenz* (University of Massa-

chusetts, Amherst, USA) reported on a new route to poly(arylene-vinylenes) from polyelectrolyte precursors. Since the precursor polymers are easily soluble, they can be processed into films etc. prior to converting them thermally into conducting materials. While the "Durham route" to PA has become acknowledged as the prototype for precursor routes to conducting polymers, no such route is yet working satisfactory for poly(*p*-phenylene). *J. Feast* (University of Durham, UK) introduced a new approach via a Pd-catalyzed polycondensation of boronic acid derivatives of appropriate phenylenes, to yield side-chain substituted poly(*p*-phenylenes), which are soluble. Future prospects for the application of conducting polymers were reviewed by *J. H. Burroughes* (University of Cambridge, UK), who has succeeded in assembling a MIS-FET transistor using polyacetylene made by the Durham route.

Ionic charge transport in polymers was addressed by *S. A. Dobrowsky* (University of Leeds, UK), who has investigated *N*-substituted poly(acrylamides) as a matrix for inorganic salts to form ionically conducting polymer-salt complexes. *A. Gandini* (École Française, Paris) reviewed polymer-salt complexes with polyethyleneoxide or polypropyleneoxide networks as the matrix. In the polymer-salt complexes the glass transition behavior is found to be the dominant feature determining the ion transport properties. This seems not to be the case in polyelectrolyte glasses based on polymeric ammonium salts ("ionenes"), whose molecular dynamics and dielectric properties were compared by *G. Wegner* (Max-Planck-Institute for Polymer Research, Mainz, FRG).

It was due to the exceptionally interesting presentations that "Speciality Polymers '88" became a very successful meeting for materials scientists.

Wolfgang H. Meyer
Max-Planck-Institut für Polymerforschung
Mainz (FRG)

Call for Short Communications · Call for Short Communications · Call for Short Communications

... doesn't melt, won't dissolve, just can't be broken down — let's send it to ADVANCED MATERIALS!

ADVANCED MATERIALS from now on welcomes short communications from all over the world, from academia and from industry, from chemists, physicists and materials scientists, provided they are in keeping with the program outlined in the editorial published in May. Authors who are interested in submitting short communications (up to six pages of double-spaced manuscript together with an appropriate number of figures and/or formulas) should prepare their manuscripts in accordance with the "Notice to Authors" of Angewandte Chemie reproduced in the January issue of the journal following the list of contents; upon request, a copy can be obtained from the editorial office:

ADVANCED MATERIALS/ANGEWANDTE CHEMIE
Postfach 101161
D-6940 Weinheim
Federal Republic of Germany

Call for Short Communications · Call for Short Communications · Call for Short Communications

Conference Calendar

January 1989

15–18 **Composites and Advanced Ceramics,**
13th Annu. Conf.
Cocoa Beach (USA)
Contact: The American Ceramic Soc., 757 Brooksedge Plaza Dr., Westerville, OH 43081-6136, USA

15–20 **Optics, Electro-Optics, and Laser Applications in Sci. and Eng.,**
Symp. and Exhibition
Los Angeles (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham, WA 98227, USA

17–19 **Optical Data Storage**
Top. Mtg.
Los Angeles (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

19 **Electron Beam Testing of Integrated Circuits**
London (United Kingdom)
Contact: Meetings Officer, Inst. of Physics, 47 Belgrave Sq., London SW1X 8QX, UK

23–24 **Commercial Applications of Superconductivity,**
2nd Annu. Cambridge Conf.
Boston (USA)
Contact: World Tech. Press, 1 Kendall Sq., Suite 2200, Cambridge, MA 02139, USA

31–3 **Polymer,**
17th Australian Symp.
Brisbane (Australien)
Contact: Dr. D. J. T. Hill, Chem. Dept., Univ. of Queensland, Brisbane 4067, Australia

31–3 **Sintering of Multiphase Metal and Ceramic Systems**
Int. Conf.
New Delhi (India)
Contact: G. S. Upadhyaya, Convener ICSMC '89, Dept. of Metallurgical Eng., Indian Inst. of Technol., Kanpur 208 016, India

February 1989

2 **Silicon Molecular Beam Epitaxy**
E-MRS Spring Mtg.
Strasbourg (France)
Contact: E. Kasper, AEG-Forschungszentrum, Sedanstr. 10, D-7900 Ulm, FRG

2–4 **Nonlinear Guided Wave Phenomena: Physics and Applications,**
Top. Mtg.
Houston (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

5–9 **Biomedical Polymers,**
Int. Symp.
Perth (Australia)
Contact: Secretary, W. A. Polymer Group, Royal Australian Chemical Inst., 125 Hay St., Perth, W. A. 6000, Australia

6–10 **Composites,**
SPI Inst. Annu. Conf.
Dallas (USA)
Contact: Composites Inst., SPI, 355 Lexington Ave., New York, NY 10017, USA

6–9 **Optical Fiber Communication,**
IEEE-LEOS-OSA Conf.
(OFC '89 and IGWO '89)
Houston (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

7–9 **Physics and Chemistry of Semiconductor Interfaces (PCSI-6)**
Bozeman (USA)
Contact: G. J. Lapeyre, Physics Dept., Montana State Univ., Bozeman, MT 59717, USA

12–15 **High-Resolution Optical FT Spectrometry and Noninvasive Assessment of Visual Systems,**
Top. Mtgs.
Santa Fe (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

13–17 **Plasma Processing in Semiconductor Materials**
Bristol (United Kingdom)
Contact: Dr. S. Pringle, Dept. of Extramural Studies, The Univ., Queens Rd., Bristol BS8 1HR, UK

19–22 **Adhesion,**
12th. Annu. Mtg.
Hilton Head Island (USA)
Contact: D. Hunston, NBS, Polym. Div., Gaithersburg, MD 20899, USA

21–24 **Recent Advances in Drug Delivery**
Salt Lake City (USA)
Contact: K. Knutson, Univ. of Utath, Dept. of Pharmaceutics, CCCD, 421 Wakara Way, Suite 318, Salt Lake City, UT 84108, USA

21–26 **Optical Fibers and their Applications,**
5th Symp.
Warsaw (Poland)
Contact: R. S. Romaniuk, IPI Warsaw Univ. of Technol., Nowowiepska 15-19, PL-00-665, Warsaw, Poland

26–3 **Microlithography,**
Symp. and Exhibition (Micro '89)
Santa Clara (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham, WA 98227, USA

27–1 **Microphysics of Surfaces, Beams and Adsorbates,**
3rd Top. Mtg.
Salt Lake City (USA)
Contact: R. B. Hall, Exxon Research & Eng., Rt. 22E, Annandale, NJ 08801, USA

27–3 **Superconductivity,**
Gordon Conf.
West Coast (USA)
Contact: A. Sleight, E. I. Du Pont de Nemours, Experimental Station 356/301, Wilmington, DE 19898, USA

27-3 **High-Temperature Superconducting Oxides: Processing & Related Properties,**
TMS Annu. Mtg.
Las Vegas (USA)
Contact: M. Karl, The Metallurgical Soc., 420 Commonwealth Drive, Warrendale, PA 15086, USA

March 1989

1-3 **Technical Ceramics,**
2nd Int. Congr. and Exhibition (Techkeram 2)
Wiesbaden (Fed. Rep. Germany)
Contact: Demat Exposition Managing, P.O. Box 110611, D-6000 Frankfurt, FRG

5-10 **Liquid Crystals,**
6th Eur. Winter Conf.
Schladming (Austria)
Contact: P. Laggner, Inst. für Röntgenfeinstrukturforschung of the Austrian Academy of Sci., Steyrergasse 17, A-8010 Graz, Austria

6-8 **Crystal Structure, Microstructure and Properties of Minerals and Ceramic Materials,**
Int. Colloq.
Bochum (Fed. Rep. Germany)
Contact: Prof. O. W. Flörke, Ruhr-Univ. Bochum, Inst. für Mineralogie, P.O. Box 102148, D-4630 Bochum, FRG

6-8 **Lithium Battery Technology & Applications,**
4th Int. Seminar
Deerfield Beach (USA)
Contact: S. P. Wolsky, Ansum Enterprises Inc., 950 De Soto Rd., Suite 3B, Boca Raton, FL 33432, USA

6-9 **Condensed Matter Division**
9th Gen. Conf.
Nice (France)
Contact: Dr. F. Raymond CNRS-Bât. 3, rue Albert Einstein, F-06560 Valbonne, France

6-9 **Advanced Materials**
MRS Industry-Univ. Conf.
Denver (USA)
Contact: Dr. Fred Smith, Adv. Mater. Inst., Colorado School of Mines, 1500 Illinois, Golden, CO 80401, USA

6-10 **Quantum Wells for Optics and Optoelectronics; Picosecond Electronics and Optoelectronics,**
Top. Mtg.
Salt Lake City (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

8-9 **Molecular Chemistry of Solid-State Electronics**
London (United Kingdom)
Contact: The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG, UK

9-11 **Makromolekulares Kolloquium**
Freiburg (Fed. Rep. Germany)
Contact: Prof. H. Finkelmann, Inst. für Makromol. Chemie der Univ., Stefan-Meier-Str. 31, D-7800 Freiburg, FRG

11-14 **Surface Finishing '89**
Brighton (United Kingdom)
Contact: Inst. of Metal Finishing, Exeter House, 48 Holloway Head, Birmingham B1 1NQ, UK

12-14 **High-Tech-Materials and Finishing**
Berlin (West)
Contact: Technik + Kommunikation-Verlag GmbH, Ritterfelddamm 82 h + i, D-1000 Berlin 22

12-25 **Diffusion in Materials,**
NATO Adv. Study Inst.
Aussois (France)
Contact: A. L. Laskar, Phys. and Astron. Dept., Clemson Univ., Clemson, SC 29631, USA

13-14 **Regio Macro II**
Basel (Switzerland)
Contact: Prof. M. Mutter, Inst. für Org. Chem., Univ. Basel, St. Johanns-Ring 19, CH-4056 Basel, Switzerland

15-17 **Confocal Microscopy/3-D Image Processing in Microscopy,**
1st Int. Conf./2nd Int. Conf.
Amsterdam (Netherlands)
Contact: Bureau PAOG, Congr. Office, Tafelbergweg 25, NL-1105 BC, Amsterdam, Netherlands

15-17 **Intelligent Materials,**
Int. Workshop
Ibaraki (Japan)
Contact: T. Kurino, The Soc. of Nontraditional Technol., Toranomon Kotohira-Kaikan Bldg. 3F, 1-2-8 Toranomon, Minato-ku, Tokyo 105, Japan

20-22 **Mechanical Properties of Materials at High Rates of Strain,**
4th Int. Conf.
Oxford (United Kingdom)
Contact: J. Harding, Eng. Sci. Dept., Univ. of Oxford, Parks Rd., Oxford OX1 3PJ, UK

20-22 **Refractory Metals and Silicides**
Eur. Workshop
Houthalen (Belgium)
Contact: R. De Keersmaecker, IMBE, Kapeldreef 75, B-3030 Leuven, Belgium

20-23 **Surface Science,**
Interdisciplinary Conf.
Liverpool (United Kingdom)
Contact: P. Weightman, Liverpool Univ., Oliver Lodge Lab., Oxford St., P.O. Box 147, Liverpool L69 3BX, UK

27-31 **Aerospace Sensing,**
Tech. SPIE's Symp.
Orlando (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), Technical Program Committee, P.O. Box 10, Bellingham, WA 98227, USA

28-31 **Aluminum-Lithium**
5th Int. Conf.
Williamsburg (USA)
Contact: Al-Li-V, School of Eng. and Applied Sci., Thornton Hall, Univ. of Virginia, Charlottesville, VA 22901, USA

29-31 **Neutron and X-Ray Scattering: Complementary Techniques**
Canterbury (United Kingdom)
Contact: Dr. R. J. Newport, Univ. of Kent, Physics Dept., Canterbury, Kent CT2 7NR, UK

30-31 **Colorado Microelectronics**
Colorado Springs (USA)
Contact: CMC '89 Conf. Secretary, Microelectronics Research Lab., Univ. of Colorado, Colorado Springs, CO 80933-7150, USA

30–14 **High-T_c Superconductors,**
Exp. Workshop
Miramare (Italy)
Contact: Int. Ctr. for Theoretical Physics, P.O. Box 586, I-34100 Trieste, Italy

April 1989

1–6 **Superconductivity,**
2nd World Congr.
Houston (USA)
Contact: R. D. Kane, World Congr. on Superconductivity, P.O. Box 27805, Houston, TX 77227-7805, USA

3–5 **Modern Practice in Stress and Vibration Analysis**
Liverpool (United Kingdom)
Contact: Meetings Officer, Inst. of Physics, 47 Belgrave Sq., London SW1X 8QX, UK

3–6 **Low Energy Ion Beams,**
5th Conf.
Guildford (United Kingdom)
Contact: Meetings Officer, Inst. of Physics, 47 Belgrave Sq., London SWIX 8QX, UK

3–7 **Copolymerization and Copolymers in Dispersed Media**
Lyon (France)
Contact: I. Guillot/C. Pichot, Lab. des Materiaux Organiques, BP 24, F-69390 Vernaison, France

3–7 **High Temperature Materials '89**
Gaithersburg (USA)
Contact: J. W. Hastie, National Bureau of Standards, Gaithersburg, MD 20899, USA

4–14 **Phase Transition in Soft Condensed Matter,**
NATO Adv. Study Inst.
Geilo (Norwegen)
Contact: G. Jarret, Inst. for Energy Technol., Dept. of Physics, P.O. Box 40, N-2007 Kjeller, Norwegen

6–7 **Modeling in Crystal Growth from the Melt,**
NATO Workshop
Parma (Italy)
Contact: G. Müller, Inst. für Werkstoffwissenschaften 6, Martensstraße 7, D-8520 Erlangen, FRG

10–12 **Bayreuther Polymer Symp.,**
(BPS '89)
Bayreuth (Fed. Rep. Germany)
Contact: BPS '89, Lehrstuhl Makromolekulare Chemie II, Univ. Bayreuth, Postfach 101251, D-8580 Bayreuth, FRG

10–13 **Microscopy of Semiconducting Materials,**
MRS 6th Oxford Conf.
Oxford (United Kingdom)
Contact: Administrator, Royal Microscopy Soc., 37/38 St. Clements, Oxford OX4 1AJ, UK

11–13 **Catalysis by Well Characterized Materials**
Liverpool (United Kingdom)
Contact: Prof. R. W. Joyner, Leverhulme Ctr. for Innovative Catalysts, Univ. of Liverpool, Grove St., P.O. Box 147, Liverpool L69 3BX, UK

17–26 **Ceramics and Composite Materials,**
Spring College in Mater. Sci.
Trieste (Italy)
Contact: Int. Ctr. for Theoretical Physics, Spring College in Mater. Sci. 1989, P.O. Box 586, I-34100 Trieste, Italy

18–19 **Industrial Water-Soluble and Water-Swellable Polymers**
Manchester (United Kingdom)
Contact: The Registar (Mid-Career Training), UMIST, P.O. Box 88, Manchester M60 1QD, UK

23–28 **Nondestructive Testing,**
12th World Conf.
(WCNDT '89)
Amsterdam (Netherlands)
Contact: B. de Jong, RAI Organisatie Bureau Amsterdam bv, Europaplein 12, 1078 GZ Amsterdam, Netherlands

23–27 **American Ceramic Society,**
91st Annu. Mtg. and Expo.
Indianapolis (USA)
Contact: Dr. K. M. Nair, Electronics Dept., E.I. du Pont de Nemours Co., Inc., 3181 Buffalo Ave., Niagara Falls, NY 14302, USA

24–28 **Optical Science and Engineering,**
2nd Int. Congr.
Paris (France)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham, WA 98227, USA

24–28 **Lasers and Electro-Optics,**
LEOS-IEEE-OSA Conf.
(CLEO '89)
Baltimore (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

24–28 **MRS-Spring Mtg.**
San Diego (USA)
Contact: J. B. Ballance, MRS, 9800 McKnight Rd., Suite 327, Pittsburgh, PA 15237, USA

25–27 **Hot Isostatic Pressing of Materials**
Antwerpen (Belgium)
Contact: Hot Isostatic Pressing Conf., c/o K. VIV, Jan van Rijswijcklaan 58, B-2018 Antwerpen, Belgium

26–28 **Joining Ceramics, Glass and Metal**
3rd Int. Conf. (CGM '89)
Contact: Dtsch. Gesellsch. Metallkd., Adenauerallee 21, D-6370 Oberursel, FRG

May 1989

1–3 **Tunable Solid State Lasers,**
Top. Mtg.
North Falmouth (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

1–5 **Scanning Microscopy,**
Salt Lake City (USA)
Contact: O. Johari, Scanning Microscopy Int., P.O. Box 66507, Chicago, IL 60666, USA

4–6 **The Solid State—Dynamics and Kinetics**
Annu. Mtg. Dtsch. Bunsen-Gesellsch. für Phys. Chem.
Siegen (Fed. Rep. Germany)
Contact: Dtsch. Bunsen-Gesellsch., Carl-Bosch-Haus, Varrentrappstr. 40/42, D-6000 Frankfurt am Main 90, FRG

7–12 **High-T_c Superconductor Technologies**
175th Mtg. Electrochem. Soc.
Los Angeles (USA)
Contact: S. Raider, IBM T. J. Watson Research Ctr., P.O. Box 218, York Town Heights, NY 10598, USA

8–12 **High Temperature and Wear Resistant Materials in a World of Changing Technology**
12th Int. Plansee Seminar
Plansee (Austria)
Contact: Metallwerk Plansee, A-6600 Reutte, Austria

9–11 **Coatings and Sensors for Acoustic and Electromagnetic-Optical Applications**
Univ. Park. (USA)
Contact: V. K. Varadan, Dept. of Eng. Sci. and Mechanics, Penn. State Univ., 227 Hammond Bldg., Univ. Park, PA 16802, USA

10–11 **Polyimides**
Montpellier (France)
Contact: Prof. M. Abadie, LEMD/MAO-USTL, F-34060 Montpellier Cedex 1, France

16–19 **Modern Developments in Materials Science and Technology,**
Annu. Mtg. Dtsch. Gesellsch. Metallkd.
Karlsruhe (Fed. Rep. Germany)
Contact: Dtsch. Gesellsch. Metallkd., Adenauerallee 21, D-6370 Oberursel, FRG

22–24 **Werkstoffanalytik,**
Wien (Austria)
Contact: Prof. Dr. M. Grasserbauer, Inst. für Analytische Chem. der Tech. Univ. Wien, Getreidemarkt 9, A-1060 Wien, Austria

22–24 **Glastechnische Tagung**
Stuttgart (Fed. Rep. Germany)
Contact: Dtsch. Glastechn. Gesellsch., Mendelssohnstr. 75–77, D-6000 Frankfurt am Main, FRG

22–25 **Graphite Intercalation Compounds,**
5th Int. Symp. (ISGIC-5)
Berlin (West)
Contact: Dr. F. W. Froben, Fachbereich Physik, Freie Univ. Berlin, Arnimallee 14, D-1000 Berlin 33

24–26 **Advances in the Stabilization and Controlled Degradation of Polymers,**
11th Int. Conf.
Luzern (Switzerland)
Contact: Dr. A. V. Patsis, Inst. in Materials Sci, State Univ. of New York, New Paltz, NY 12561, USA

25–26 **Quantitative Methods in Assessment of Structural Defects**
Kansas City (USA)
Contact: A. P. Berens, Univ. of Dayton, Research Inst., 300 College Park Ave., Dayton, OH 45469, USA

29–31 **Cross-linked Polymers,**
3rd Int. Conf.
Luzern (Switzerland)
Contact: Dr. A. V. Patsis, Inst. in Materials Sci, State Univ. of New York, New Paltz, NY 12561, USA

29–2 **Molecular Beams**
Perugia (Italy)
Contact: V. Aquilanti, Univ. di Perugia, Dipt. di Chimica, I-06100 Perugia, Italy

31–2 **Applied Surface Analysis,**
11th Symp.
Cleveland (USA)
Contact: J. Grant, Research Inst., 300 College Park, Dayton, OH 45469-0001, USA

31–2 **Thermogravimmetry and Thermal Engineering,**
6th Biennial Conf.
Budapest (Hungary)
Contact: I. Benko, MATE, House of Technol. III. 318, P.O. Box 451, H-1372 Budapest, Hungary

June 1989

6–9 **Chemistry of Functional Dyes,**
Int. Symp. (ESTech '89)
Osaka (Japan)
Contact: Prof. T. Kitao, General Secretary of the Symp., Kinki Chem. Soc., Japan
1-8-4, Utsubo honmachi, Nishi-ku, Osaka 550, Japan

12–14 **Rubber,**
Int. Conf. 90 IRC Exhibition
Paris (France)
Contact: Soc. de Chimie Industrielle, 28, rue Saint-Dominique, F-75007 Paris, France

12–15 **Narrow-Gap Semiconductors and Related Materials,**
Int. Conf.
Ogunquit (USA)
Contact: D. G. Seiler, Phys. Dept., Univ. of North Texas, P.O. Box 5368, Denton, TX 76203, USA

18–21 **Colloid & Surface Science,**
63rd ACS Div. of Colloid & Surface Chem. Symp.
Seattle (USA)
Contact: J. Berg, Dept. of Chemical Eng. BF-10, Univ. of Washington, Seattle, WA 98105, USA

19–21 **SAMPE-Electronics,**
3rd Int. Conf.
Los Angeles (USA)
Contact: M. Smith, Business Director, SAMPE, P.O. Box 2459, Covina, CA 91722, USA

21–23 **Chemically Modified Surfaces,**
Midland (USA)
Contact: W. T. Collins, Dow Corning Corp., Mail Stop C41C00, Midland, MI 48686, USA

22–25 **Optics Asia '89**
Singapore (Singapore)
Contact: Asia '89, 994 Bendemeer Rd., N° 04-03, Singapore 1233, Singapore

25–30 **Solid State Sensors and Actuators (Transducers -5)/ Eurosensors III**
Montreux (Switzerland)
Contact: COMST S.A., P.O. Box 415, CH-1001 Lausanne 1, Switzerland

26–28 **Molecular Design of Functional Polymers,**
IUPAC Int. Symp.
Seoul (Korea)
Contact: IUPAC Int. Symp., c/o Polymer Soc. of Korea, Rm. 601, Hyecheon Bldg., 831 Yeoksam-dong, Kangnam-ku, Seoul 135-792, Korea

26–30 **Solid State Chemistry,**
2nd Int. Symp.
Pardubice (Czechoslovakia)
Contact: Dr. L. Koudelka, Inst. of Chem. Technol., Leninovo nam., 565, CS-53210 Pardubice, Czechoslovakia

26–30 **Supermembranes**
Trieste (Italy)
Contact: Int. Ctr. for Theoretical Physics, P.O. Box 586, I-34100 Trieste, Italy

27–28 **Polymer Latex III**
London (United Kingdom)
Contact: Miss M. Peacock, Plastics and Rubber Inst., 11 Hobart Place, London SW1W 0HL, UK

28–30 **Oxide Surfaces**
Midland (USA)
Contact: W. T. Collins, Mail Stop C41C00, Dow Corning Corp., Midland, MI 48686-0994, USA

July 1989

2–7 **Solid State Organic Materials,**
9th Int. Conf.
Como (Italy)
Contact: Centro di Cultura Scientifica, "A. Volta", Villa Olmo, Via Cantoni 1, I-22100 Como, Italy

3–6 **Conduction and Breakdown in Solid Dielectrics**
3rd Int. Conf. (ICSD '89)
Trondheim (Norway)
Contact: Prof. Sletbak, ICSD '89, The Norwegian Inst. of Technol., Sem Sælands V 13, N-7034 Trondheim, Norway

4–7 **Nonlinear and Electro-optics**
Int. Conf.
Cambridge (United Kingdom)
Contact: The Meetings Officer, The Inst. of Physics, 47 Belgrave Square, London SW1X 8QX, UK

9–14 **Zeolites,**
8th Int. Conf.
Amsterdam (Netherlands)
Contact: M. Laboushere, 792 Keizersgracht, 1017 EC, Amsterdam, The Netherlands

10–12 **Applied Organometallic Chemistry: an Entry to the New Technology**
The Pines Resort (Australia)
Contact: Dr. A. F. Masters, School of Chemistry, Univ. of Sydney, Sydney, N. S. W. 2006, Australia

10–13 **Magnetic Resonance in Polymers,**
9th Spec. Colloq. Ampere
Prague (Czechoslovakia)
Contact: P. M. M. Secretariat, c/o. Inst. of Macromol. Chem., Czech. Acad. of Sci., 16206 Prague, Czechoslovakia

10–14 **Electron Spectroscopy,**
4th Int. Conf.
Honolulu (USA)
Contact: G. E. McGuire, Microelectronics Ctr. of North Carolina, P.O. Box 12889, Research Triangle Park, NC 27709, USA

10–14 **Organic Coatings Science and Technology,**
15th Int. Conf.
Athens (Greece)
Contact: Dr. A. V. Patsis, Inst. in Materials Sci, State Univ. of New York, New Paltz, NY 12561, USA

11–14 **Numerical Analysis of Semiconductor Devices and Integrated Circuits,**
6th Int. Conf.
Dublin (Ireland)
Contact: J. J. H. Miller, Nase-Code Conf., INCA, P.O. Box 2, Dún Laoghaire, Ireland

16–21 **Catalysis,**
Eur. Conf.
Berlin (West)
Contact: Prof. G. Ertl, Fritz-Haber-Inst. der Max-Planck-Gesellsch., Faradayweg 4–6, D-1000 Berlin

17–20 **Polymer Blends**
Prague (Czechoslovakia)
Contact: P. M. M. Secretariat, c/o. Inst. of Macromol. Chem., Czech. Acad. of Sci., 16206 Prague, Czechoslovakia

18–20 **Polymer Chemistry: Aspects of Radical Polymerization**
Lancaster (United Kingdom)
Contact: Dr. J. R. Ebdon, Dept. of Chemistry, Univ. of Lancaster, Lancaster LA1 4YA, UK

18–21 **Integrated Optics and Optical Fiber Communications,**
7th Int. Conf. (IOOC-7)
Kobe (Japan)
Contact: P. W. Shumate, Jr., Bell Communications Research, 435 S St., Morristown, NJ 07960, USA

23–28 **Materials and Mechanisms of Superconductivity: High-Temperature Superconductors,**
Int. Conf. (HTSC-M^{2}S)
Stanford (USA)
Contact: Dr. T. H. Geballe, Dept. of Applied Phys., Stanford Univ., Stanford, CA 94305, USA

24–26 **Composite Structures,**
5th Int. Conf.
Paisley (United Kingdom)
Contact: Dr. I. H. Marshall, Dept. of Mechanical and Production Eng., Paisley College of Technol., High St., Paisley PA 12BE, UK

31–2 **Biologically-Engineered Polymers**
Cambridge (United Kingdom)
Contact: Royal Soc. of Chemistry, Burlington House, London W1V 0BN, UK

August 1989

2–7 **Pure and Applied Chemistry,**
32nd IUPAC Congr.
Stockholm (Sweden)
Contact: Stockholm Convention Bureau, P.O. Box 6911, S-10239 Stockholm, Sweden

13–26 **High-T_C Superconductors,**
NATO Adv. Study Inst.
Bad Windsheim (Fed. Rep. Germany)
Contact: R. Kossowsky, Applied Res. Lab., Pennsylvania State Univ., P.O. Box 30, State College, PA 16804, USA

14–17 **Shock Compression of Condensed Matter,**
APS Top. Conf.
Albuquerque (USA)
Contact: A. Roach, MS-P 915, Los Alamos Nat. Lab., Los Alamos, NM 87545, USA

20-24 **Imaging Systems – 150 Years of Photography,**
Int. Symp. (ISIS '89)
Dresden (German Dem. Rep.)
Contact: Conf. Secretary, ISIS '89, Technische Univ. Dresden, Sektion Physik, Wissenschaftsbereich Photophysik, Mommsenstr. 13, DDR-8027 Dresden, GDR

20-25 **Crystal Growth: Progress in Science and Technology,**
9th Int. Conf.
Sendai (Japan)
Contact: Prof. T. Nishinaga, Inter Group Corp., Akasaka Yamakatsu Bldg., 8-5-32, Akasaka Minato-ku, Tokyo 107, Japan

21-26 **Photochemistry,**
Int. Conf.
Beijin (People's Rep. China)
Contact: Prof. S. Wu, Inst. of Photographic Chem., Academia Sinica, Beijing, People's Rep. China

28-31 **Dynamical Processes in Excited States of Solids,**
7th Int. Conf. (DPC '89)
Athens (USA)
Contact: DPC '89, Prof. J. E. Rives, Dept. of Physics and Astronomy, Univ. of Georgia, Athens, GA 30602, USA

28-1 **Ferroelectricity,**
7th Int. Mtg. (IMF-7)
Saarbrücken (Fed. Rep. Germany)
Contact: Dr. J. Albers, Univ. des Saarlandes, Fachbereich Physik, D-6600 Saarbrücken, FRG

28-1 **Sintering,**
7th World Round Table Conf.
Herceg-Novi (Yugoslavia)
Contact: Dr. D. P. Uskoković, Serbian Academy of Sci. and Arts, Knez-Mihailova 35, 11000 Beograd, Yugoslavia

28-1 **X-Ray Optics and Microanalysis,**
12th Int. Congr.
Cracow (Poland)
Contact: S. Jasienska, Academy of Mining and Metallurgy, Inst. of Metallurgy, 30-059 Cracow, Poland

28-2 **Photochemistry for High Technology,**
Int. Summer School
Leuna-Merseburg (German Dem. Rep.)
Contact: Prof. H.-J. Timpe, Sektion Chemie, Technische Hochschule für Chemie, Leuna-Merseburg, Gensaerstr., DDR-42 Merseburg, GDR

29-2 **Innovation and Perspectives in Solid Phase Synthesis,**
Int. Symp.
Oxford (United Kingdom)
Contact: R. Epton, School of Appl. Sci., Wolverhampton Polytech., Wolverhampton WV1 1SB, UK

September 1989

4-8 **Electrically and Optically Active Polymers,**
21st Europhysics Conf.
Lodz (Poland)
Contact: Dr. J. Ulanski, Polymer Inst., Tech. Univ. of Lodz, Zwirki 36, 90-924 Lodz, Poland

4-8 **Macromolecules 89,**
Oxford (United Kingdom)
Contact: Prof. R. Epton, School of Appl. Sciences, The Polytechnic, Wulfruna St., Wolverhampton WV1 1SB, UK

4-8 **Olefin Metathesis and Polymerization,**
8th Int. Symp.
Bayreuth (Fed. Rep. Germany)
Contact: Office ISOM 8, Lab. für Anorg. Chem., Univ. Bayreuth, Postfach 101251, D-8580 Bayreuth, FRG

5-7 **Interfacial Phenomena in Composite Materials,**
Int. Conf.
Sheffield (United Kingdom)
Contact: J. Herriot, Conf. Organizer, Butterworth Scientific Ltd., P.O. Box 63, Westbury House, Bury St., Guildford, Surrey GU2 5BH, UK

5-8 **Optical, Electrical and Acoustic Properties**
Kent (United Kingdom)
Contact: M. D. Shuttleworth, Plastics and Rubber Inst., 11 Hobart Pl., London SW1W 0HL, UK

6-9 **Magnetic Materials and Applications '89**
Rimini (Italy)
Contact: I. Pareti, Local Chairman EMMA '89, Istituto Maspec CNR, Via Chiavari 18/A, 43100 Parma, Italy

10-14 **Optical Communications,**
15th Eur. Conf.
Gothenburg (Sweden)
Contact: P. A. Andrekson, Dept. of Optoelectronics, Chalmers Univ. of Technol., S-41296 Gothenburg, Sweden

11-13 **Charge Transfer in Polymeric Systems,**
RSC, Faraday Div.
Contact: Dr. J. F. Gibson, Royal Soc. of Chemistry, Burlington House, Piccadilly, London W1V 0BN, UK

11-13 **Holographic Systems, Components and Applications,**
2nd Int. Conf.
Bath (United Kingdom)
Contact: Inst. of Electronic and Radio Eng., Conf. Dept., Savoy Hill House, London WC2R 0JD, UK

11-13 **Surface Analysis Techniques and Applications**
Manchester (United Kingdom)
Contact: E. Wellingham, Conf. Secretariat, Field End House, Bude Close, Nailsea, Bristol BS19 2FQ, UK

13-15 **Microscopy,**
150th Anniversary Commemorative Mtg.
Oxford (United Kingdom)
Contact: Microscopical Soc., 37-38 St. Clements, Oxford OX4 1AJ, UK

17-22 **Defect Recognition and Image Processing in Semiconductors,**
3rd Mtg. (DRIP-3)
Yokohama (Japan)
Contact: Prof. T. Ogawa, Gakushuin Univ., Dept. of Physics, 1-5-1 Mejiro, Toshima-ku, Tokyo 171, Japan

17-22 **Optics and Optical Engineering,**
Cambridge Symp.
Cambridge (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham WA 98227, USA

AUTHOR INDEX [*Angew. Chem. Int. Ed. Engl. 27* (1988)]

The page numbers in square brackets refer to the German edition [*Angew. Chem. 100* (1988)] of Angewandte Chemie. In the case of book reviews the names of the authors are given; the corresponding GE reference can be found in the Author Index of the German Edition. AM = Advanced Materials.

ABEL, T. 944 [1006]
Adam, W. 429, 1536 [443, 1594]

SUBJECT INDEX

(page numbers in brackets indicate an erratum to the corresponding article)

(R) = Review Article (C) = Short Communication (B) = Book Review (L) = Correspondence (AM) = Advanced Materials

Ab initio calculations, Formation of dioxirane from carbonyl oxide (C) 427
— Is tetrasilatetrahedrane kinetically stable? (C) 1081
— Is the molecule BOK quasi-linear? (C) 1329
— Structure of molecular PNO, matrix isolation and ab initio calculations (C) 421
— [1,2,4]Triazolo[1,2-*a*][1,2,4]triazole-1,3,5,7(2*H*,6*H*)-tetrone (urazourazole), synthesis and structure (C) 701
γ-Acetoxylation, C_5 building blocks for terpene syntheses: γ-acetoxylation of (*E*)-2-methyl-2-butenals (C) 285
Acetylene polymerization with ylide-nickel catalysts (C) 839
Actinides, The chemistry of the actinide elements (B) 1111
Active site, Catalytic activity of enzymes altered at their active sites (R) 913
Acylations, *N*-Aryl-*O*-acylhydroxylamines: preparation by *O*-acylation or *N*→*O* transacylation and reaction with amines; model reactions for key steps connected with the carcinogenicity of aromatic amines (C) 973
Adamantanediones, Chirality solely due to the presence of an excited state (C) 975
Adamantoid compounds, The first "adamantoid" alkaline earth metal chelate complex: synthesis, structure, and reactivity (C) 851
Advanced materials—a critical view (AM) 726
— Editorial (AM) 723
Air-sensitive compounds, The manipulation of air-sensitive compounds (B) 308
Aldol reactions, Diastereo- and enantioselective aldol reactions via α-silyl ketones, asymmetric synthesis of the aggregation pheromone sitophilure (C) 581
Alkali-metal compounds, A monomeric diboryldilithiomethane with a 1,3-diboratallene structure (C) 1370
— A monomeric potassium salt of bis(trimethylsilyl)methyl phenyl sulfone and the determination of the $^1J(^{13}C,^{29}Si)$ coupling constants of Si-stabilized "carbanions" (C) 1092
— 1,2-Dilithioethane from ethylene and lithium (C) 1083
— From the dilithiooctamethylcyclotetrasilazane to the 1,3,5,7-tetraaza-2,4,6,8,9-pentasilabicyclo[3.3.1]nonane system (C) 1074
— Higher thermostability and selectivity of Köbrich reagents by transmetalation (C) 943
— Isolated, complex Zintl molecules in the gas phase (C) 1091
— Isolation and structure of $[\{fluorenone^{\odot\ominus}\}\{Na^{\oplus}(dme)_2\}]_2$ — a touchstone for radical contact ion pairs? (C) 1067
— 3-Lithio-2-(*o*-lithiophenyl)naphthalenedilithium—a tetralithio compound with σ- and π-bonded lithium atoms (C) 1182
— Novel layer structure of sodium calix[4]arenesulfonate complexes—a class of organic clay mimics? (C) 1361
— Phase transformations of lithium nitride under pressure (C) 1101
— Solid state structure of a lithium triorganostannate (C) 1381
— Structure and reactivity of lithium enolates. From pinacolone to selective *C*-alkylations of peptides. Difficulties and opportunities afforded by complex structures (R) 1624
— Structure of a chiral lithium azaenolate: monomeric, intramolecular chelated lithio-2-acetylnaphthalene-SAMP-hydrazone (C) 1522
— Synthesis and structure of $[NaTi(2,6\text{-}Me_2C_6H_3O)_4(py)]_2$: a dimeric material containing a novel phenoxide bridge (C) 1181
— Synthesis and structure of $[\{Na(tmeda)\}_3][LiPh_4]$, an organometallic complex containing two different alkali metals (C) 584
— X-ray structure investigation of 2,2-diphenyl-1-(phenylsulfonyl)cyclopropyllithium–dimethoxyethane (2/3): a sulfonyl "carbanion" having an α-C atom with a tetrahedral configuration (C) 846
Alkaloids, Synthesis of strictosidine analogues by hetero-Diels-Alder reaction and their biomimetic transformation to indole alkaloids (C) 971
Alkanes, Selective photochemical dehydrogenation of saturated hydrocarbons with quantum yields approaching unity (C) 1526
Alkynes, Acid-catalyzed alkyne/alkene coupling at Re^{III} centers (C) 1509
— Alkyne coordination to organorhenium oxides with rhenium in high oxidation states (C) 946
— Oxidative coupling of racemic and of optically active 3,6-di-*tert*-butylocta-1,4,7-triyne-3,6-diol (C) 859
— Tetrakis[bis(trimethylsilyl)ethyne]diiron (C) 1519
Aluminum compounds, New complex cations of aluminum(III) and gallium(III) (C) 277
— Synthesis and structure of $[MeAlN(2,6\text{-}iPr_2C_6H_3)]_3$: an aluminum-nitrogen analogue of borazole (C) 1699
Amines, "Proton sponges" and the geometry of hydrogen bonds: aromatic nitrogen bases with exceptional basicities (R) 865
Amino acids, Amino acid methyl esters as chiral auxiliaries in aza-Diels-Alder reactions in aqueous solution (C) 274
— A simple access to 2-substituted 3,3,3-trifluoroalanine derivatives (C) 848
— Chlorotetain from *bacillus subtilis*, an antifungal dipeptide with an unusual chlorine-containing amino acid (C) 1733
— Enantio- and diastereoselective synthesis of methyl (2*R*)-2-amino-5-oxocarboxylates from enones and bislactim-ether cuprates (C) 1194
— Enantioselective synthesis of (*R*)-*N*-Boc-1-amino-2-arylcyclopropene-1-carboxylic acid methyl ester (C) 433
— Reduction with yeast cells, the key step of an efficient synthesis of (3*S*, 4*S*)-4-amino-3-hydroxypentanoic acids (C) 426
— Synthesis and properties of N^{α}-Di-*tert*-butoxycarbonyl and N^{α}-benzyloxycarbonyl *tert*-butoxycarbonyl amino acids (C) 400
Amino imino boranes, The chemistry of amino imino boranes (R) 1603
Analytical methods, Atomic motions in molecular crystals from diffraction measurements (R) 880
— Classical light scattering from polymer solutions (B) 1221
— Gas chromatographic separation of enantiomeric olefins (C) 1556
— High-resolution solid-state ^{13}C-NMR spectroscopy of polymers (R) 1468
— Inductively coupled plasmas in analytical atomic spectrometry (B) 1387
— Multiphoton-ionization-mass spectrometry (MUPI-MS) (R) 447
— NOESY-TOCSY, an advantageous 2D NMR technique for the analysis of peptide sequences (C) 564
— Pheromones in nanogram quantities: structure determination by combined microchemical and gas chromatographic methods (R) 460
— Polymer microscopy (B) 1220
— Two-dimensional NMR spectroscopy: background and overview of the experiments (R) 490
Antibodies, An antibody-mediated redox reaction (C) 1172
Antigenes, Somatic generation of immune diversity (Nobel lecture) (R) 1028
Antimony compounds, Synthesis and structure of an azastibacubane (C) 287
— Tris(2,3-di-*tert*-butylcyclotriphosphanyl)stibane—a compound containing three P_3 rings linked by an antimony atom (C) 561
Arene complexes, Alkyne(arene)cobalt, μ-alkynebis(arenecobalt), and μ-benzylidynetris(arenecobalt) from arene/cobalt cocondensates (C) 706
— π Complexes of an amino-9-fluorenylideneborane (C) 1331
— Electron-electron/spin-spin long-range interaction as studied in the diradical dication $[Di\{bis(dimethylphosphino\text{-}\eta^6\text{-}benzene)chromium(I)\}\text{-}nickel(0)]^{++}$ (C) 414
— (Octamethyltetrasila-η^{12}-[2.2]paracyclophane)chromium — synthesis, structure, and characteristics (C) 684
— $2,4,6\text{-}Ph_3C_6H_2M$ (M = Cu, Ag), monomeric Cu^I- and Ag^I-complexes with coordination number 1 (C) 436
— Stabilization of 1,2,4,5-tetradehydrobenzene by complexation at two nickel(0) centers (C) 941
— Titanium(0)-arene complexes. Synthesis and X-ray crystal structure of $[(\eta^6\text{-}C_{10}H_8)Ti\{tBuSi(CH_2PMe_2)_3\}]$ (C) 1693
Arenes, *N*-Aryl-*O*-acylhydroxylamines: preparation by *O*-acylation or *N*→*O* transacylation and reaction with amines; model reactions for key steps connected with the carcinogenicity of aromatic amines (C) 973
— Industrielle Aromatenchemie. Rohstoffe, Verfahren, Produkte (B) 1108
— Isolation and structure of $[\{fluorenone^{\odot\ominus}\}\{Na^{\oplus}(dme)_2\}]_2$ — a touchstone for radical contact ion pairs? (C) 1067
— Methyl 4-hydroxy-5-iodo-2,3-dimethoxy-6-methylbenzoate: the aromatic fragment of calichemicin γ^1_α. Synthesis, X-ray crystallographic analysis, and properties (C) 1097
— "Proton sponges" and the geometry of hydrogen bonds: aromatic nitrogen bases with exceptional basicities (R) 865
— Strongly bent naphthalene units in [2](2,6)naphthalino[2]paracyclophane and [2](2,6)naphthalino[2]paracyclophane-1,11-diene (C) 1064
Aromaticity, A donor-acceptor substituted quinoid pentalene (C) 1711
— Biomimetic synthesis of an octavinylogous porphyrin with an aromatic [34]annulene system (C) 1170
— Bis([1,2,5]thiadiazolo)[3,4-*b*;3′,4′-*e*]pyrazine, a novel 14π-electron heterocycle with high electron affinity (C) 434
— Donor-acceptor-substituted cyclic π-electron systems—probes for theories and building blocks for new materials (R) 1437
— 1,6-Methano[10]annulenedianion, a para-

tropic 12π-electron dianion with a C_{10} perimeter (C) 1692
— Synthesis and structure of 2,7-Di-*tert*-butyldicyclopenta[*a,e*]cyclooctene (C) 1191
— 1,3,4,6-Tetraamino-2,5-diazapentalenes: delocalized antiaromatic compounds (C) 842
— Tetraoxaporphycene dication (C) 411
— Tetraoxaporphyrin dication (C) 406
— Tetraoxaporphyrinogen (tetraoxaquaterene): oxidation to the tetraoxaporphyrin dication (C) 409
— The cyclohepta[*def*]carbazolium ion (C) 585
— Tris(fluoren-9-ylidene)cyclopropane, a novel [3]radialene (C) 1080
— Tris(thioxanthen-9-ylidene)cyclopropane, and its radical cation and dication (C) 1078
Aromaticity (B) 306
Arsenic compounds, A novel heterocluster with D_3-symmetry containing twenty-one core atoms: $[As_6^{III}V_{15}^{IV}O_{42}(H_2O)]^{6\ominus}$ (C) 1721
Artificial elements, Synthesis of the heaviest chemical elements—results and perspectives (R) 1417
Aryl complexes, Novel anionic aryl complexes of Rh^{III}: $[Rh(C_6F_5)_5]^{2\ominus}$ and $[Rh(C_6F_5)_4(CO)_2]^{\ominus}$ (C) 1700
Asymmetric induction, First case of interannular, possibly electronically transmitted, asymmetric induction in an organometallic compound (C) 553
— in the [2,3] Wittig rearrangement by chiral substituents in the allyl moiety (C) 278
— Structure of a chiral lithium azaenolate: monomeric, intramolecular chelated lithio-2-acetylnaphthalene-SAMP-hydrazone (C) 1522
Asymmetric synthesis, Asymmetric induction in the replacement of diastereotopic bromine atoms by lithium atoms (C) 1176
— Diastereo- and enantioselective aldol reactions via α-silyl ketones, asymmetric synthesis of the aggregation pheromone sitophilure (C) 581
Azacyclobutadienes, Reactivity of Tri-*tert*-butylazete (C) 272
Azastibacubanes, Synthesis and structure of an azastibacubane (C) 287
Azatriphosphatetracyclodecadienes, Reaction of 1,3-azaphosphinines with 2-*tert*-butyl-1-phosphaethyne: 9-aza-2,4,6-triphosphatetracyclo[5.3.0.0^{2,4}.0^{3,6}]deca-8,10(1)-diene (C) 389
Azetes, First structure analysis and photoelectron spectroscopic investigation of an azete and an azete-cobalt complex (C) 1559
Azirines, Azirineimine as a structural unit in the side chain of a hexofuranose (C) 1075
Azoles, Nitroazoles. The *C*-nitro derivatives of five-membered *N*- and *N,O*-heterocycles (B) 985

Baeyer-Villiger oxidations, Enzymic Baeyer-Villiger oxidations by flavin-dependent monooxygenases (R) 333
Biochemistry, A synthetic heparin-like compound which still activates antithrombin III although it contains an open chain fragment instead of α-L-idopyranuronate (C) 1177
— Enzymic Baeyer-Villiger oxidations by flavin-dependent monooxygenases (R) 333
— Evidence for a folded conformation of methotrexate in solution (C) 423
— Facile reduction of 1,2-dioxetanes by thiols as potential protective measure against photochemical damage of cellular DNA (C) 429
— Flexibility and rigidity of proteins and protein-pigment complexes (R) 79
— Isoleucyl-tRNA synthetase: an enzyme with several catalytic cycles displaying variation in specificity and energy consumption (R) 773
— Oxo-bridged polyiron centers in biology and chemistry (R) 344
— Protein phosphorylation in bacteria—regulation of gene expression, transport functions, and metabolic processes (R) 1040
— Reduction with yeast cells, the key step of an efficient synthesis of (3*S*, 4*S*)-4-amino-3-hydroxypentanoic acids (C) 426
— Short, highly enantioselective synthesis of a key intermediate for the preparation of leucotriene B_4 and its 14,15-didehydro derivative (C) 1188
— Somatic generation of immune diversity (Nobel lecture) (R) 1028
— The chemistry and biochemistry of *N*-substituted porphyrins (B) 1737
— The cyclopropyl group in studies of enzyme mechanism and inhibition (R) 537
— Tumor lectinology: at the intersection of carbohydrate chemistry, biochemistry, cell biology, and oncology (R) 1267
Biogenesis, 4,6,6-Trimethyl-4-cyclohexene-1,2,3-trione, a contribution to the biogenesis of norcarotinoids (C) 695
Biohalogenation. Principles, basic roles, and applications (B) 985
Bioinorganic chemistry, Oxo-bridged polyiron centers in biology and chemistry (R) 344
Biomembranes, Molecular architecture and function of polymeric oriented systems: models for the study of organization, surface recognition, and dynamics of biomembranes (R) 113
Biomimetic syntheses, Biomimetic synthesis of an octavinylogous porphyrin with an aromatic [34]annulene system (C) 1170
— Synthesis of strictosidine analogues by hetero-Diels-Alder reaction and their biomimetic transformation to indole alkaloids (C) 971
Biomineralization, Molecular mechanisms of biomineralization in the formation of calcified shells (R) 1145
Biosensors, International workshop 1987 (B) 755
Biosynthesis, Vitamin B_{12}: experiments concerning the origin of its molecular structure (R) 5
Biotechnology, Vol. 7a: Enzyme Technology (B) 1738
Bismuth compounds, $[Cp_2Co][Bi\{Co(CO)_4\}_4]$: a paramagnetic, ten-electron, tetrahedral complex of bismuth (C) 396
— $Cs_2Bi_{10}Ca_6Cl_{12}O_{16}$: a new type of catalyst for selective oxidation derived from bismuth oxychloride (C) 1364
Boron compounds, A monomeric diboryldilithiomethane with a 1,3-diborataallene structure (C) 1370
— B_6H_{14}, a dimeric B_3H_7? (C) 262
— π Complexes of an amino-9-fluorenylideneborane (C) 1331
— Compounds with partial boron-carbon triple bonds (C) 961
— Dications based on a hydrotris(phosphonio)borate skeleton (C) 1071
— 1,3-Dihydro-1,3-diborafulvene derivatives (C) 299
— Lewis-base adducts of methyleneboranes (C) 960
— Nitrogen fixation by borabenzene (C) 295
— Novel boron-phosphorus cages with $C_4B_4P_4$ and $C_2B_4P_4$ frameworks (C) 399
— Reversible coupling and opening of a boron-carbon bond (C) 952
— Synthesis and structure of a 1,2,5,6-tetrahydro-1,2,5,6-tetraborocine (C) 926
— Synthesis and structure of $[Cp_2NbH(tBuB{\equiv}NtBu)]$, a compound with side-on coordinated iminoborane (C) 958
— Synthesis of oligomeric and polymeric monosaccharides by aldol group-transfer polymerization (C) 1158
— The chemistry of amino imino boranes (R) 1603
— The first *closo*-diphosphahexaborane $P_2B_4Cl_4$ (C) 925
Butadiene-1,4-diyl as ligand, Triple proton abstraction from a 1-methylallyl ligand on thermolysis: formation of a $Hf_3(C_4H_4)$ cluster (C) 1058
Butadiyne, Mono- and dinuclear nickel(0) complexes of butadiyne (C) 833

Cage compounds, A donor cage with bent tetrathiafulvalene moiety (C) 1377
— Functionalized, enantiomerically pure [2.1.1]-, [2.2.1]-, and [2.2.2]-triblattanes (C) 1103
— Novel boron-phosphorus cages with $C_4B_4P_4$ and $C_2B_4P_4$ frameworks (C) 399
— Reductive oligomerization of 1,2-Di-*tert*-butyl-1,1,2,2-tetrachlorodisilane: the tricyclo[2.2.0.0^{2,5}]hexasilane and tetracyclo[3.3.0.0^{2,7}.0^{3,6}]octasilane systems (C) 1725
— ^{29}Si-^{29}Si long range couplings in strained cyclic polysilanes (C) 1727
— The first *closo*-diphosphahexaborane $P_2B_4Cl_4$ (C) 925
Calcification, Molecular mechanisms of biomineralization in the formation of calcified shells (R) 1145
Calichemicins, Methyl 4-hydroxy-5-iodo-2,3-dimethoxy-6-methylbenzoate: the aromatic fragment of calichemicin $\gamma_{1\alpha}^{I}$. Synthesis, X-ray crystallographic analysis, and properties (C) 1097
Carbanions, A monomeric potassium salt of bis(trimethylsilyl)methyl phenyl sulfone and the determination of the $^{1}J(^{13}C,^{29}Si)$ coupling constants of Si-stabilized "carbanions" (C) 1092
— as intermediates in the synthesis of Grignard reagents (C) 687
— 1,2-Dilithioethane from ethylene and lithium (C) 1083
— Metal-free carbanion salts as initiators for the anionic polymerization of acrylic and methacrylic acid esters (C) 1373
— 1,6-Methano[10]annulenedianion, a paratropic 12π-electron dianion with a C_{10} perimeter (C) 1692
— Synthesis and structure of [*cyclo*-$C_3H_4{-}SO_2Ph]_2Ti[OCH(CH_3)_2]_2$, a *C*-titanated "α-sulfonyl carbanion" (C) 1540
— X-ray structure investigation of 2,2-diphenyl-1-(phenylsulfonyl)cyclopropyllithium-dimethoxyethane (2/3): a sulfonyl "carbanion" having an α-C atom with a tetrahedral configuration (C) 846
Carbene Complexes, Annelation of carbene ligands by λ^3-phosphaalkynes, an entry to functionalized phosphaarenes (C) 713
— Heterogeneous, bimetallic metathesis catalysts by reaction of Fischer-type carbene complexes with reduced Phillips catalyst (C) 275
— Ketenimine complexes from carbene complexes and isocyanides: versatile building blocks for carbocycles and N-heterocycles (R) 1456
Carbenes, Diisocyanogen (C) 936
— Formation of cycloheptatriene/norcaradiene systems in the decomposition of diaryldiazomethanes in benzene (C) 284
— 4-Oxo-2,5-cyclohexadienylidene — a carbene with a stable triplet and metastable singlet state? (C) 572
— Preparative UV-laser photochemistry: a biscarbene intermediate in the synthesis of a 5,6-dihydrodibenzo[*a,e*]cyclooctene containing a *trans*-double bond (C) 853
Carbenium ions, Inductivity and bridging in ammonium and carbenium ions (C) 714
Carbohydrates, A synthetic heparin-like compound which still activates antithrombin III although it contains an open chain fragment instead of α-L-idopyranuronate (C) 1177

— Azirineimine as a structural unit in the side chain of a hexofuranose (C) 1075
— β-Mannosides from β-glucosides by intramolecular nucleophilic substitution with inversion of configuration (C) 1086
— Protecting-group-dependent stability of intersaccharide bonds — synthesis of a fucosyl-chitobiose glycopeptide (C) 1697
— Simple synthesis of KDO α-glycosides by anomerically selective *O*-alkylation (C) 1178
— Synthesis of oligomeric and polymeric monosaccharides by aldol group-transfer polymerization (C) 1158
— Tumor lectinology: at the intersection of carbohydrate chemistry, biochemistry, cell biology, and oncology (R) 1267
Carbon-carbon linkage, Acid-catalyzed alkyne/alkene coupling at Re^{III} centers (C) 1509
— Acyl-alkylidyne coupling in the synthesis of dinuclear complexes (C) 1703
— Carbon dioxide as an alternative C_1 synthetic unit: activation by transition-metal complexes (R) 661
— Conjugated and nonconjugated cyclopentenones by a reaction cascade from methyl 6-oxo-5-phenyl-1,3,4-oxadiazine-2-carboxylate and 1,3-butadienes (C) 931
— First case of interannular, possibly electronically transmitted, asymmetric induction in an organometallic compound (C) 553
— Iodine-induced stereoselective carbocyclizations: a new method for the synthesis of cyclohexane and cyclohexene derivatives (C) 1546
— Linkage of alkylidyne, carbonyl, and alkyne ligands at a tungsten center to form a metallacyclopentadienone and an η^3-oxocyclobutenyl complex (C) 1730
— Pentadienyl, a more reactive and more strongly bound ligand than cyclopentadienyl (C) 1099
— Structure and reactivity of lithium enolates. From pinacolone to selective *C*-alkylations of peptides. Difficulties and opportunities afforded by complex structures (R) 1624
— The influence of polar and steric effects on the selectivity of the β-cleavage of alkyl radicals (C) 1168
— The reagent diphenyldiselane/Iodine: no phenylselenenyl iodide but a charge transfer complex with cyclic moieties (C) 431
Carbon compounds, Carbon—electrochemical and physicochemical properties (B) 1218
— Graphite fluorides (B) 1219
Carbon films, From carbon beams to diamond films (AM) 1203
Carbon oxides, Carbon dioxide as an alternative C_1 synthetic unit: activation by transition-metal complexes (R) 661
— C_5O_2 (1,2,3,4-pentatetraene-1,5-dione), a new oxide of carbon (C) 566
Carbonylation, Rhodium-catalyzed reductive carbonylation of methyl formate to acetaldehyde (C) 683
Carbonyl oxide, Formation of dioxirane from carbonyl oxide (C) 427
Carbonyls, Molecular organometallic chemistry on surfaces: reactivity of metal carbonyls on metal oxides (R) 1127
Carboxime (Isofulminic acid) (C) 938
Carcinogenicity, *N*-Aryl-*O*-acylhydroxylamines: preparation by *O*-acylation or *N*→*O* transacylation and reaction with amines; model reactions for key steps connected with the carcinogenicity of aromatic amines (C) 973
Carotinoids, 4,6,6-Trimethyl-4-cyclohexene-1,2,3-trione, a contribution to the biogenesis of norcarotinoids (C) 695
Catalysis, Acid-catalyzed alkyne/alkene coupling at Re^{III} centers (C) 1509
— An antibody-mediated redox reaction (C) 1172
— An introduction to chemisorption and catalysis by metals (B) 1385
— Catalyst design. Progress and perspectives (B) 592
— Catalytic fixation of nitrogen by the photocatalytic $CdS/Pt/RuO_2$ particulate system in the presence of aqueous $[Ru(Hedta)N_2]^{\ominus}$ complex (C) 923
— Catalytic isomerization of methylated 1,5-cyclooctadienes (C) 1062
— Catalytic syntheses of functionalized nitrogen heterocycles from cyanogen (C) 1372
— Contributions to organo-nickel chemistry (R) 185
— Coordination of H_2 and O_2 to $[OsHCl(CO)(PiPr_3)_2]$: a catalytically active $M(\eta^2\text{-}H_2)$ complex (C) 1563
— $Cs_2Bi_{10}Ca_6Cl_{12}O_{16}$: a new type of catalyst for selective oxidation derived from bismuth oxychloride (C) 1364
— Direct Michael additions of silyl groups to α,β-unsaturated β-arylketones and an α-benzylidenelactone with mixtures obtained from copper(I) cyanide, butyllithium and chlorosilanes (C) 1718
— Electron-transfer chain catalysis in organotransition metal chemistry (R) 643
— Enantioselective catalytic transfer-hydrogenation of α,β-unsaturated carboxylic acids with triethylammonium formate (C) 1180
— High oxidation state organometallic chemistry, a challenge—the example of rhenium (R) 1297
— Linkage of alkylidyne, carbonyl, and alkyne ligands at a tungsten center to form a metallacyclopentadienone and an η^3-oxocyclobutenyl complex (C) 1730
— Molecular organometallic chemistry on surfaces: reactivity of metal carbonyls on metal oxides (R) 1127
— Principles and applications of organotransition metal chemistry (B) 984
— Rhodium-catalyzed reductive carbonylation of methyl formate to acetaldehyde (C) 683
— Selective photochemical dehydrogenation of saturated hydrocarbons with quantum yields approaching unity (C) 1526
— Synthesis, structure and bonding of $[Cl_2Sn\{Rh(PMe_3)_3Cl\}_2]\cdot THF$, an unusual Sn^{II}-Rh^{I} adduct (C) 442
— Tris(2,2′-bipyridyl-5-sulfonic acid)rhodium(III), an improved redox catalyst for the light-induced and the electrochemically initiated enzymatic reduction of carbonyl compounds (C) 265
— Zeolites: catalysts for organic syntheses (R) 226
Catenanes, A topologically chiral [2]catenand (C) 930
Centrohexaindan, the first hydrocarbon with topologically non-planar molecular structure (C) 1192
Ceramics, Advanced materials by powder metallurgy (AM) 989
— Intelligent materials—a new frontier (AM) 1389
C—H Activation, Synthesis of octahedral hydrido(vinyl)iridium(III) complexes by C—H activation: an example of a thermodynamically favored rearrangement $[M(CHR{=}CHX)]\rightarrow[M(H)(CR{=}CHX)]$ (C) 948
Charge transfer, Electron transfer and charge transfer: twin themes in unifying the mechanisms of organic and organometallic reactions (R) 1227
Charge-transfer complexes, A conjugated bis(tetrathiafulvalene) system with tetrathia-*s*-indacene structure (C) 288
— New donors for molecular organic (super)conductors and ferromagnets (AM) 1573
— New organic superconductors (AM) 1747
— The reagent diphenyldiselane/Iodine: no phenylselenenyl iodide but a charge transfer complex with cyclic moieties (C) 431
Chelate ligands, 3- and 3,6-silylated 2-pyridinethiols: new hindered bidentate ligands and their novel silver and copper clusters (C) 1342
— A stable bis(chelate) analogue of the Creutz-Taube ion (C) 1174
— Cu^{II} and Cu^{I} coordination chemistry of a novel *O,O,Cl*-chelate ligand. Formation of a stable carbonylcopper complex (C) 580
— Elementary reactions at metal-sulfur centers: base-induced substitution of PPh_3 in $[Ru(PPh_3)_2(bmae)]$ (C) 689
— Second-sphere photochemistry and photophysics: luminescence of the $[Pt(bpy)(NH_3)_2]^{2\oplus}$-dibenzo[30]crown-10 adduct (C) 692
— The first "adamantoid" alkaline earth metal chelate complex: synthesis, structure, and reactivity (C) 851
— Transformation of open-chain thioether-dithiolato to cyclic thioether ligands by C–S bond cleavage and bond formation at ruthenium centers: synthesis of the trithiobenzo[9]crown-3 complex $[Ru(Bzo\text{-}9S3)(CO)Br_2]$ (C) 691
— Trimethylplatinum–theophylline hexamer: a novel Pt_6 heterocycle containing both Pt–N and Pt–O bonds (C) 1160
Chemical bonding, A pictorial approach to molecular bonding (B) 863
Chemical elements, Synthesis of the heaviest chemical elements—results and perspectives (R) 1417
Chemisorption, An introduction to chemisorption and catalysis by metals (B) 1385
Chemistry and language, Say it in English, please! (R) 1050
— The art of scientific writing. From student reports to professional publications in chemistry and related fields (B) 1565
— Under the surface of the chemical article (R) 1593
Chiral auxiliaries, Amino acid methyl esters as chiral auxiliaries in aza-Diels-Alder reactions in aqueous solution (C) 274
— Paraformaldehyde as possible chirality amplifier (C) 1379
— Reactivity of (*R*)-2-*tert*-butyldihydrooxazole derivatives prepared from serine and threonine: novel, versatile chiral building blocks (C) 1351
Chirality, A topologically chiral [2]catenand (C) 930
— CD spectroelectrochemistry, a method for the characterization of chiral electron transfer reagents and chiral reaction intermediates (C) 291
— Functionalized, enantiomerically pure [2.1.1]-, [2.2.1]-, and [2.2.2]-triblattanes (C) 1103
— Oxidative coupling of racemic and of optically active 3,6-di-*tert*-butylocta-1,4,7-triyne-3,6-diol (C) 859
— solely due to the presence of an excited state (C) 975
— Synthesis and crystal structure of a chiral C_3-symmetric monophosphane (C) 835
— Synthesis of optically active phosphanes via Sharpless epoxidation (C) 718
— 2,2′,7,7′-Tetrahydroxy-1,1′-binaphthyl: a versatile chiral spacer for mono- and ditopic cyclophane hosts with apolar binding sites (C) 1705
Chlorine compounds, The structures of perchloric acid, $HClO_4$, and its anhydride, Cl_2O_7 (C) 1339
Chlorotetain from *bacillus subtilis*, an antifungal dipeptide with an unusual chlorine-containing amino acid (C) 1733
Chromium compounds, Electron-electron/spin-spin long-range interaction as studied in the diradical dication [Di{bis(dime-

thylphosphino-η^6-benzene)chromium(I)}-nickel(0)]$^{++}$ (C) 414
— Heterogeneous, bimetallic metathesis catalysts by reaction of Fischer-type carbene complexes with reduced Phillips catalyst (C) 275
— (Octamethyltetrasila-η^{12}-[2.2]paracyclophane)chromium — synthesis, structure, and characteristics (C) 684
— Reactions of pentacarbonyl(trichloromethyl isocyanide)chromium (C) 1344
Circular dichroism, CD spectroelectrochemistry, a method for the characterization of chiral electron transfer reagents and chiral reaction intermediates (C) 291
— Influence of chromophore orientation on the circular dichroism of isomeric helical molecules (C) 976
— Spectroscopy with polarized light. Solute alignment by photoselection, in liquid crystals, polymers, and membranes (B) 863
Clusters, 3- and 3,6-silylated 2-pyridinethiols: new hindered bidentate ligands and their novel silver and copper clusters (C) 1342
— A new cubane cluster with the $[MoFe_3S_4]^0$ core and possible relevance to the Fe_3-centers in ferredoxins. The synthesis, structure and properties of the $[Fe_3S_4(SEt)_3Mo(CO)_3]^{3\ominus}$ anion (C) 1353
— A new type of unsaturated *triangulo* transition-metal cluster and homogeneous catalyst (C) 263
— A novel heterocluster with D_3-symmetry containing twenty-one core atoms: $[As_6^{III}V_{15}^{IV}O_{42}(H_2O)]^{6\ominus}$ (C) 1721
— A novel tetranuclear copper(I) cluster with alternate bridging halide and triazolopyrimidine ligands (C) 856
— $[Cp_2Co][Bi\{Co(CO)_4\}_4]$: a paramagnetic, ten-electron, tetrahedral complex of bismuth (C) 396
— $[Cu_8(i\text{PrPCH}_2P i\text{Pr})_2Cl_4(py)_5]$, a novel Cu^I cluster containing pentacoordinated phosphorus in μ_3-PRR′ bridges (R = *i*Pr, R′ = $CH_2P i$Pr) (C) 956
— Formation of an oxalate-filled cavity in a reduced cyclic octanuclear polyoxomolybdate $[(n\text{-}C_4H_9)_4N]_2[Mo_8O_{16}(OCH_3)_8(C_2O_4)]$ formed from α-$[(n\text{-}C_4H_9)_4N]_4[Mo_8O_{26}]$ and rhodizonic acid (C) 1724
— Formation of difluoroethyne as a ligand by coupling of two fluoromethylidyne ligands (C) 845
— New transition metal clusters with ligands from main groups five and six (R) 1277
— $[Ni_9(\mu_4\text{-As})_6(PPh_3)_5Cl_3]$, a cubic body-centered Ni_9-cluster (C) 1512
— of valence electron poor metals—structure, bonding, and properties (R) 159
— Photolytic cluster synthesis: synthesis and structure of $[\{(Ph_3P)Au\}_7Mo(CO)_3]OH$ (C) 1094
— Preparation of 2,3,4-tris(η^5-cyclopentadienyl)-1,5-diphenyl-1-phospha-2,3,4-tricobaltapentaborane(5); phenyl group migration from phosphorus to boron (C) 424
— Reaction of [NiCp(PPh$_3$)Cl] with $E(SiMe_3)_2$; the structures of $[Ni_4Se_2Cp_4]$ and $[Ni_4E_2Cp_4(PPh_3)_2]$ (E = Se, Te) (C) 965
— Real-time atomic-resolution imaging of polymorphic changes in ruthenium clusters (C) 555
— Silica-supported Fe-Pd bimetallic particles: formation from mixed-metal clusters and catalytic activity (C) 927
— Soluble chromium selenides and tellurides: preparations and structures of $[(C_6H_5)_4P]_3[Cr_3Te_{24}]$ and $[(C_6H_5)_4P]_3[Cr_3Se_{24}]$ (C) 1702
— Tetranuclear complexes as intermediates in transannular oxidative-addition reactions. Structure of the first tetrairidium linear cluster (C) 402
— Triple proton abstraction from a 1-methylallyl ligand on thermolysis: formation of a $Hf_3(C_4H_4)$ cluster (C) 1058
— $[V_{19}O_{41}(OH)_9]^{8\ominus}$, an ellipsoid-shaped species belonging to the unusual family of V^{IV}/V^V oxygen clusters (C) 1719
Coal, Chemicals from coal: new processes (B) 1385
Cobalt compounds, Alkyne(arene)cobalt, μ-alkynebis(arenecobalt), and μ-benzylidynetris(arenecobalt) from arene/cobalt cocondensates (C) 706
— Cobalt-catalyzed reactions of octamethyl-[4]-radialene and 2,5-dimethyl-2,3,4-hexatriene with ethene (C) 571
— $[Cp_2Co][Bi\{Co(CO)_4\}_4]$: a paramagnetic, ten-electron, tetrahedral complex of bismuth (C) 396
— First case of interannular, possibly electronically transmitted, asymmetric induction in an organometallic compound (C) 553
— $[\{Hg_3Co(C_4H_6NO)_6\}(NO_3)_2]_n$: a macrobicyclic bimetallic chain polymer incorporating deprotonated 2-pyrrolidone bridges (C) 261 (589)
— Photochemical reaction of $[(CO)_4Co(SiEt_3)]$ with ethylene: implications for cobaltcarbonyl-catalyzed hydrosilation of alkenes (C) 289
— Preparation of 2,3,4-tris(η^5-cyclopentadienyl)-1,5-diphenyl-1-phospha-2,3,4-tricobaltapentaborane(5); phenyl group migration from phosphorus to boron (C) 424
Cocondensations, Alkyne(arene)cobalt, μ-alkynebis(arenecobalt), and μ-benzylidynetris(arenecobalt) from arene/cobalt cocondensates (C) 706
Coenzymes, The enzymic interconversion of isobutyryl and *n*-butyrylcarba(dethia)-coenzyme A: a coenzyme-B_{12}-dependent carbon skeleton rearrangement (C) 1089
Coinage Metals, $[Au_2Ag_4L_4]^{2\ominus}$, $[Au_2Cu_4L_4]^{2\ominus}$, $[Au_3Cu_3L_4]^{2\ominus}$, $[Cu_4L_3]^{2\ominus}$, and $[Ag_9L_6]^{3\ominus}$ (L = ethane-1,2-dithiolate)—novel homoleptic complexes of the coinage metals, including the first heteronuclear metal thiolates (C) 1326
Colloidal metals, A morphology-selective copper organosol (C) 1530
Complexes with boron ligands, 1,3-Dihydro-1,3-diborafulvene derivatives (C) 299
— New complex cations of aluminum(III) and gallium(III) (C) 277
— Preparation of 2,3,4-tris(η^5-cyclopentadienyl)-1,5-diphenyl-1-phospha-2,3,4-tricobaltapentaborane(5); phenyl group migration from phosphorus to boron (C) 424
— Synthesis and structure of $[Cp_2NbH(t\text{BuB}{\equiv}N t\text{Bu})]$, a compound with side-on coordinated iminoborane (C) 958
Complexes with chalcogen ligands, New transition metal clusters with ligands from main groups five and six (R) 1277
— Reaction of [NiCp(PPh$_3$)Cl] with $E(SiMe_3)_2$; the structures of $[Ni_4Se_2Cp_4]$ and $[Ni_4E_2Cp_4(PPh_3)_2]$ (E = Se, Te) (C) 965
Complexes with hydrido ligands, Coordination of H_2 and O_2 to $[OsHCl(CO)(P i\text{Pr}_3)_2]$: a catalytically active $M(\eta^2\text{-}H_2)$ complex (C) 1563
— Mechanism of ethylene hydrogenation by the molecular hydrogen complex $[Ir(H)_2(H_2)(PMe_2Ph)_3]^{\oplus}$—characterization of intermediates (C) 1165
— Synthesis of octahedral hydrido(vinyl)iridium(III) complexes by C–H activation: an example of a thermodynamically favored rearrangement $[M(CHR{=}CHX)]{\rightarrow}[M(H)(CR{=}CHX)]$ (C) 948
— Synthesis, structure, and reactivity of $[Mn_2(\mu\text{-}H)_2(CO)_6(\mu\text{-}Ph_2PCH_2PPh_2)]$ (C) 1167
Complexes with nitrogen ligands, A novel tetranuclear copper(I) cluster with alternate bridging halide and triazolopyrimidine ligands (C) 856
— Coupling metal centers with linearly bridging, delocalized, π-bonded ligands: *p*-phenylenediimido dimolybdenum complexes (C) 569
— Helicates: tetra- and pentanuclear double helix complexes of Cu^I and poly(bipyridine) strands (C) 1095
— Stable sandwich complexes with pentamethylpyrrole ligands (C) 579
— The pentazadienide ion as a ligand in metal complexes (R) 896
— Transformation of η^1-nitrosyl to η^2-hydroxylaminyl ligands in the reduction of $[Mo(NO)_2(\text{'}S_4\text{'})]$ to $[Mo(\eta^2\text{-}NH_2O)(NO)(\text{'}S_4\text{'})]$: a model reaction for a partial step in the enzymatic $[NO_3^{\ominus}{\rightarrow}NH_3]$ conversion (C) 1164
Complexes with phosphorus ligands, $[(\eta^5\text{-}C_5Me_4Et)Rh(\mu,\eta^2\text{-}P_2)_2Rh(\eta^5\text{-}C_5Me_4Et)]$, a sandwich complex with a P_4 rectangle (C) 405
— $[Cu_8(i\text{PrPCH}_2P i\text{Pr})_2Cl_4(py)_5]$, a novel Cu^I cluster containing pentacoordinated phosphorus in μ_3-PRR′ bridges (R = *i*Pr, R′ = $CH_2P i$Pr) (C) 956
— $[Os(\eta^2\text{-PHS})(CO)_2(PPh_3)_2]$, a stable η^2-thioxophosphane(H–P=S)-metal complex (C) 302
— $P_4^{2\ominus}$ Isomers as complex ligands (C) 694
— Preparation of 2,3,4-tris(η^5-cyclopentadienyl)-1,5-diphenyl-1-phospha-2,3,4-tricobaltapentaborane(5); phenyl group migration from phosphorus to boron (C) 424
— Synthesis and molecular structure of the diphosphaarsirane $[\{[(\eta^5\text{-}C_5Me_5)(CO)_2Fe]P\}_2AsC_6H_2t\text{Bu}_3]$ (C) 1537
— Template synthesis of macrocyclic multiphosphane ligands with functional groups (C) 438
— The first diphosphaallyl system coordinated to two metal centers (C) 416
Complexes with pnictogen ligands, Linear twofold coordination of arsenic in $[Cp'(CO)_2Mn{=}As{=}Mn(CO)_2Cp']^{\oplus}$ (C) 1529
— New transition metal clusters with ligands from main groups five and six (R) 1277
— $[Ni_9(\mu_4\text{-As})_6(PPh_3)_5Cl_3]$, a cubic body-centered Ni_9-cluster (C) 1512
Complexes with sulfur ligands, A new cubane cluster with the $[MoFe_3S_4]^0$ core and possible relevance to the Fe_3-centers in ferredoxins. The synthesis, structure and properties of the $[Fe_3S_4(SEt)_3Mo(CO)_3]^{3\ominus}$ anion (C) 1353
— $[Au_2Ag_4L_4]^{2\ominus}$, $[Au_2Cu_4L_4]^{2\ominus}$, $[Au_3Cu_3L_4]^{2\ominus}$, $[Cu_4L_3]^{2\ominus}$, and $[Ag_9L_6]^{3\ominus}$ (L = ethane-1,2-dithiolate)—novel homoleptic complexes of the coinage metals, including the first heteronuclear metal thiolates (C) 1326
— $[\{Cp(CO)_2Mn\}_2SPh]^{\oplus}$, the first sulfur analogue of a phosphanediyl ("phosphinidene") complex (C) 698
— Elementary reactions at metal-sulfur centers: base-induced substitution of PPh_3 in $[Ru(PPh_3)_2(bmae)]$ (C) 689
— $[Os(\eta^2\text{-PHS})(CO)_2(PPh_3)_2]$, a stable η^2-thioxophosphane(H–P=S)-metal complex (C) 302
— Stepwise synthesis and crystal structure of tricarbonyl[pentakis(methylthio)cyclopentadienyl]manganese $[\{C_5(SMe)_5\}Mn(CO)_3]$ (C) 939
— Synthesis and structure of $[(C_5Me_5)_2Rh_2S_8]$, a dirhodium complex with unusual polysulfide bridge (C) 708
— $[TiSCl_4]^{2\ominus}$ and $[Ti_3O(S_2)_3Cl_6]^{2\ominus}$, a multinuclear complex with a structure typical for clusters (C) 293
— Transformation of open-chain thioether-

dithiolato to cyclic thioether ligands by C-S bond cleavage and bond formation at ruthenium centers: synthesis of the trithiobenzo[9]crown-3 complex [Ru(Bzo-9S3)(CO)Br_2] (C) 691
Computers, Equipotential surfaces in periodic charge distributions (C) 849
— Reaction of tropone with a homopyrrole. The result of a computer-assisted search for unique chemical reactions (C) 1558
— Structure elucidation and artificial intelligence (R) 247
Conformation, Evidence for a folded conformation of methotrexate in solution (C) 423
Conjugation, Coupling metal centers with linearly bridging, delocalized, π-bonded ligands: *p*-phenylenediimido dimolybdenum complexes (C) 569
— Synthesis and optical properties of terminally substituted conjugated polyenes (C) 281
Coordination, Alkyne coordination to organorhenium oxides with rhenium in high oxidation states (C) 946
— Cu^{II} and Cu^{I} coordination chemistry of a novel *O,O,Cl*-chelate ligand. Formation of a stable carbonylcopper complex (C) 580
— [Cu_8(*i*PrPCH_2P*i*Pr)$_2Cl_4$(py)$_5$], a novel Cu^{I} cluster containing pentacoordinated phosphorus in μ_3-PRR′ bridges (R = *i*Pr, R′ = CH_2P*i*Pr) (C) 956
— Helicates: tetra- and pentanuclear double helix complexes of Cu^{I} and poly(bipyridine) strands (C) 1095
— Hypercarbon chemistry (B) 590
— Intramolecularly stabilized organogallium compounds (C) 1077
— Linear twofold coordination of arsenic in [Cp′$(CO)_2$Mn=As=Mn$(CO)_2$Cp′]$^{\oplus}$ (C) 1529
— Naked molecule chemistry: different bonding modes of CO to FeX_2 (C) 1161
— [{$Hg_3Co(C_4H_6NO)_6$}$(NO_3)_2$]$_n$: a macrobicyclic bimetallic chain polymer incorporating deprotonated 2-pyrrolidone bridges (C) 261 (589)
— of H_2 and O_2 to [OsHCl(CO)(P*i*$Pr_3)_2$]: a catalytically active M(η^2-H_2) complex (C) 1563
— Organobimetallic Mg–Pd complexes as intermediates in the formation of amorphous $MgPdC_xH_y$ from $Mg(C_2H_5)_2$ and [Pd(η^3-$C_3H_5)_2$] (C) 1513
— 2,4,6-$Ph_3C_6H_2M$ (M = Cu, Ag), monomeric Cu^{I}- and Ag^{I}-complexes with coordination number 1 (C) 436
— Phosphane-stabilized Cu^{I} and Ag^{I} silanes (C) 1349
— Photochemical reactions of ligands in transition-metal complexes (R) 789
— Polycyclic silylamides of Ge^{II} and Sn^{II} with different structures — bis(germanediyl) versus distannate (C) 1087
— Second sphere coordination adducts of phosphane-transition metal complexes with β-cyclodextrin and its methylated derivative (C) 1184
— Stepwise synthesis and crystal structure of tricarbonyl[pentakis(methylthio)cyclopentadienyl]manganese [{C_5(SMe)$_5$}Mn$(CO)_3$] (C) 939
— Synthesis and structure of [Cp_2NbH(*t*BuB≡N*t*Bu)], a compound with side-on coordinated iminoborane (C) 958
— Synthesis and structure of [{Na(tmeda)}$_3$][$LiPh_4$], an organometallic complex containing two different alkali metals (C) 584
— The microwave spectrum and structure of the ethylene–sulfur dioxide complex (C) 1356
— The pentazadienide ion as a ligand in metal complexes (R) 896
— The surface scientist's guide to organometallic chemistry (B) 1198
— Variety in coordination modes of ligands in metal complexes (B) 1566
— X-ray structure investigation of 2,2-diphenyl-1-(phenylsulfonyl)cyclopropyllithium–dimethoxyethane (2/3): a sulfonyl "carbanion" having an α-C atom with a tetrahedral configuration (C) 846
Copper compounds, A morphology-selective copper organosol (C) 1530
— 3- and 3,6-silylated 2-pyridinethiols: new hindered bidentate ligands and their novel silver and copper clusters (C) 1342
— A novel tetranuclear copper(I) cluster with alternate bridging halide and triazolopyrimidine ligands (C) 856
— Cu^{II} and Cu^{I} coordination chemistry of a novel *O,O,Cl*-chelate ligand. Formation of a stable carbonylcopper complex (C) 580
— [Cu_8(*i*PrPCH_2P*i*Pr)$_2Cl_4$(py)$_5$], a novel Cu^{I} cluster containing pentacoordinated phosphorus in μ_3-PRR′ bridges (R = *i*Pr, R′ = CH_2P*i*Pr) (C) 956
— Helicates: tetra- and pentanuclear double helix complexes of Cu^{I} and poly(bipyridine) strands (C) 1095
— 2,4,6-$Ph_3C_6H_2M$ (M = Cu, Ag), monomeric Cu^{I}- and Ag^{I}-complexes with coordination number 1 (C) 436
— Phosphane-stabilized Cu^{I} and Ag^{I} silanes (C) 1349
— The copper salt of 2-iodo-5-methyl-*N,N′*-dicyanoquinonediimine—a radical anion salt exhibiting metallic conductivity down to low temperatures (C) 267
Corrosion, DECHEMA corrosion handbook: corrosive agents and their interaction with materials, volume 1 (B) 1407
Crown ethers, The activation of phenylmagnesium compounds by crown ethers (C) 1084
— The discovery of crown ethers (Nobel lecture) (R) 1021
Crystal structure analysis, Atomic motions in molecular crystals from diffraction measurements (R) 880
— Distorted triple-diamond structure of 3,3-bis(carboxymethyl)glutaric acid ("methanetetraacetic acid") (C) 829
— Equilibrium structure, stabilized transition state, or disorder in the crystal? Studies of the antiaromatic systems tetra-*tert*-butyl-*s*-indacene and tetra-*tert*-butylcyclobutadiene by low-temperature crystal structure analysis (C) 387
— The crystal structure of hypofluorous acid: chain formation by O–H···O hydrogen bonds (C) 392
— The fluoronium ions $H_2F^{\oplus}$ and $H_3F_2^{\oplus}$: characterization by crystal structure analysis (C) 391
— X-ray structure investigation of 2,2-diphenyl-1-(phenylsulfonyl)cyclopropyllithium–dimethoxyethane (2/3): a sulfonyl "carbanion" having an α-C atom with a tetrahedral configuration (C) 846
C_1 Synthetic units, Carbon dioxide as an alternative C_1 synthetic unit: activation by transition-metal complexes (R) 661
Cubanes, Synthesis and structure of an azastibacubane (C) 287
Cuprates, Direct Michael additions of silyl groups to α,β-unsaturated β-arylketones and an α-benzylidenelactone with mixtures obtained from copper(I) cyanide, butyllithium and chlorosilanes (C) 1718
Cyclacenes, Towards the making of [12]collarene (C) 966
Cycloadditions, Reaction of tropone with a homopyrrole. The result of a computer-assisted search for unique chemical reactions (C) 1558
— Reactivity of Tri-*tert*-butylazete (C) 272
Cyclobutabenzenes, Structures and deformation electron densities of 1,2-dihydrocyclobutabenzene and 1,2,4,5-tetrahydrodicyclobuta[*a,d*]benzene (C) 304
Cyclobutadienes, Equilibrium structure, stabilized transition state, or disorder in the crystal? Studies of the antiaromatic systems tetra-*tert*-butyl-*s*-indacene and tetra-*tert*-butylcyclobutadiene by low-temperature crystal structure analysis (C) 387
— Tetrahedrane and cyclobutadiene (R) 309
Cyclobutanones and cyclobutenones in nature and in synthesis (R) 797
Cyclobutenones, Cyclobutanones and cyclobutenones in nature and in synthesis (R) 797
Cyclodextrins increase surface tension and critical micelle concentrations of detergent solutions (C) 393
— Modified cyclodextrins—novel, highly enantioselective stationary phases for gas chromatography (C) 979
— Second sphere coordination adducts of phosphane-transition metal complexes with β-cyclodextrin and its methylated derivative (C) 1184
Cyclododecatetraenes, Synthesis of all-*cis*-1,4,7,10-cyclododecatetraene (C) 298
Cyclohepta[*def*]carbazolium ion, (C) 585
Cycloheptatrienes, Formation of cycloheptatriene/norcaradiene systems in the decomposition of diaryldiazomethanes in benzene (C) 284
Cyclohexenetriones, 4,6,6-Trimethyl-4-cyclohexene-1,2,3-trione, a contribution to the biogenesis of norcarotinoids (C) 695
Cyclooctadienes, Catalytic isomerization of methylated 1,5-cyclooctadienes (C) 1062
Cyclopentanes, Induced and non-induced diastereoselective intramolecular ene reaction of 1,6-dienes: the unusual formation of *trans*-1,2-disubstituted cyclopentanes (C) 1186
Cyclopentenones, Conjugated and nonconjugated cyclopentenones by a reaction cascade from methyl 6-oxo-5-phenyl-1,3,4-oxadiazine-2-carboxylate and 1,3-butadienes (C) 931
Cyclophanes, Complexation of neutral molecules by cyclophane hosts (R) 362
— Cyclobis(paraquat-*p*-phenylene). A tetracationic multipurpose receptor (C) 1547
— Influence of chromophore orientation on the circular dichroism of isomeric helical molecules (C) 976
— Isostructural, alternately-charged receptor stacks. The inclusion complexes of hydroquinone and catechol dimethyl ethers with cyclobis(paraquat-*p*-phenylene) (C) 1550
— Multidecker metallocenophanes (C) 701
— (Octamethyltetrasila-η^{12}-[2.2]paracyclophane)chromium — synthesis, structure, and characteristics (C) 684
— Strongly bent naphthalene units in [2](2,6)naphthalino[2]paracyclophane and [2](2,6)naphthalino[2]paracyclophane-1,11-diene (C) 1064
— Synthesis and conformational behavior of dibenzo[2.2]metaparacyclophanediene (C) 705 (1200)
— 2,2′,7,7′-Tetrahydroxy-1,1′-binaphthyl: a versatile chiral spacer for mono- and ditopic cyclophane hosts with apolar binding sites (C) 1705
Cyclophosphazenes, Synthesis and structure of [$ClV(OSiMe_3)N_2PPh_2]_2$, the first cyclodimetallaphosphazene—an eight-membered planar unsaturated heterocycle (C) 850
Cyclopropabenzenes, The structures of 1*H*-cyclopropabenzene and its 1,1-bis(triisopropylsilyl) derivative (C) 294
Cyclopropanes, The chemistry of the cyclopropyl group (B) 1199
— The cyclopropyl group in studies of enzyme mechanism and inhibition (R) 537
Cyclopropyllithium, X-ray structure investigation of 2,2-diphenyl-1-(phenylsulfonyl)cyclopropyllithium–dimethoxyethane (2/3): a sulfonyl "carbanion" having an α-C atom with a tetrahedral configuration (C) 846

Decalins, Stereoselective synthesis of *trans*-

decalins via intramolecular ene reactions; synthesis of the enantiomerically pure cadinane-sesquiterpene veticadinol (C) 703
Dehydrogenation, Selective photochemical dehydrogenation of saturated hydrocarbons with quantum yields approaching unity (C) 1526
Detergents, Cyclodextrins increase surface tension and critical micelle concentrations of detergent solutions (C) 393
— Solubilization of elemental sulfur in water by cationic and anionic surfactants (C) 1358
— Surfactants, micelles and fascinating phenomena (R) 902
Diamond-like networks, Distorted triple-diamond structure of 3,3-bis(carboxymethyl)glutaric acid ("methanetetraacetic acid") (C) 829
Diastereoselectivity, A new route to *trans*-substituted γ-lactones (C) 268
— Asymmetric induction in the replacement of diastereotopic bromine atoms by lithium atoms (C) 1176
— Diastereo- and enantioselective aldol reactions via α-silyl ketones, asymmetric synthesis of the aggregation pheromone sitophilure (C) 581
— Enantio- and diastereoselective synthesis of methyl (2*R*)-2-amino-5-oxocarboxylates from enones and bislactim-ether cuprates (C) 1194
— First case of interannular, possibly electronically transmitted, asymmetric induction in an organometallic compound (C) 553
— Induced and non-induced diastereoselective intramolecular ene reaction of 1,6-dienes: the unusual formation of *trans*-1,2-disubstituted cyclopentanes (C) 1186
— Iodine-induced stereoselective carbocyclizations: a new method for the synthesis of cyclohexane and cyclohexene derivatives (C) 1546
— Simple synthesis of KDO α-glycosides by anomerically selective *O*-alkylation (C) 1178
— Stereoselective synthesis of *trans*-decalins via intramolecular ene reactions; synthesis of the enantiomerically pure cadinane-sesquiterpene veticadinol (C) 703
Diastereospecifity, Diastereospecific gas/solid additions with cholesterol derivatives (C) 1511
1,1'-Diazaferrocene, Does a 1,1'-diazaferrocene exist? (C) 1368
Diazapentalenes, Synthesis and physical properties of 3,6-di-*tert*-butyl-1,4-diazapentalene (C) 1061
Diazocompounds, A new route to nitrile oxides via α-nitrosodiazo derivatives (C) 301
— First direct evidence for nitrile imine-diazo isomerization. Synthesis of Relatively stable *N*-silylated nitrile imines (C) 1350
— Formation of cycloheptatriene/norcaradiene systems in the decomposition of diaryldiazomethanes in benzene (C) 284
— Properties and synthesis (B) 591
Dicyclopentadienes, Blocking of the retro-Diels-Alder reaction by complex formation: [(η^5-cyclopentadienyl)(η^5-dicyclopentadienyl)iron] (C) 977
Diels-Alder reactions, Amino acid methyl esters as chiral auxiliaries in aza-Diels-Alder reactions in aqueous solution (C) 274
— Methoxyallenes as components in Diels-Alder reactions with inverse electron demand: synthesis of 6*H*-1,2-oxazines (C) 1518
Dienes, Competition of endoperoxide and hydroperoxide formation in the reaction of singlet oxygen with cyclic, conjugated dienes (C) 717
Difluoroethyne, Formation of difluoroethyne as a ligand by coupling of two fluoromethylidyne ligands (C) 845
Diheteropentalenes, A simple route to furo[3,4-*b*]furans, compounds with a new diheteropentalene system (C) 568
Dihydrocyclobutabenzenes, Structures and deformation electron densities of 1,2-dihydrocyclobutabenzene and 1,2,4,5-tetrahydrodicyclobuta[*a*,*d*]benzene (C) 304
Diisocyanogen (C) 936
α-Diketones, Tricyclo[3.1.0.$0^{2,6}$]hexanedione (the valene of *o*-benzoquinone), bicyclo[2.1.1]hexane-2,3-dione, and valenes of a quinoxaline, of phenazine, and of a benzophenazine (C) 1369
1,2-Dilithioethane from ethylene and lithium (C) 1083
Dioxetanes, Facile reduction of 1,2-dioxetanes by thiols as potential protective measure against photochemical damage of cellular DNA (C) 429
Dioxirane, Formation of dioxirane from carbonyl oxide (C) 427
1,4-Diphosphabutatriene (C) 1360
closo-Diphosphahexaboranes, The first *closo*-diphosphahexaborane $P_2B_4Cl_4$ (C) 925
Diphosphatricyclopentane, Formation of the diphosphatricyclo[2.1.0.$0^{2,5}$]pentane ring system via phosphaalkyne dimerization and carbon monoxide incorporation (C) 837
2,7-Di-*tert*-butyldicyclopenta[*a*,*e*]cyclooctene, Synthesis and structure of 2,7-Di-*tert*-butyldicyclopenta[*a*,*e*]cyclooctene (C) 1191
Donor-acceptor substitution, Donor-acceptor-substituted cyclic π-electron systems—probes for theories and building blocks for new materials (R) 1437
Dynamics, Flexibility and rigidity of proteins and protein-pigment complexes (R) 79
— of proteins and nucleic acids (B) 862
— Synthesis and conformational behavior of dibenzo[2.2]metaparacyclophanediene (C) 705 (1200)

Ecology, Natural fats and oils—renewable raw materials for the chemical industry (R) 41
Electrochemistry, Carbon—electrochemical and physicochemical properties (B) 1218
— CD spectroelectrochemistry, a method for the characterization of chiral electron transfer reagents and chiral reaction intermediates (C) 291
— Electrocatalytic haloform reaction: transformation of methyl ketones into methyl esters (C) 1716
— Electron-transfer chain catalysis in organotransition metal chemistry (R) 643
— Theoretical foundations, quantum and statistical mechanics, thermodynamics, the solid state (B) 860
— The use of light in the study of interfacial electrochemical reactions (R) 63
Electrochromism, Redox-active thieno[3,2-*b*]-thiophene as a novel, three-color electrochromic system (C) 560
Electronics industry, Fine chemicals for the electronics industry (B) 445
Electronic structure, The electronic structure and chemistry of solids (B) 719
Electron/ion transfer, From electronic/ionic conductors to superconductors: control of materials properties (AM) 1392
Electron microscopy, Real-time atomic-resolution imaging of polymorphic changes in ruthenium clusters (C) 555
Electron transfer and charge transfer: twin themes in unifying the mechanisms of organic and organometallic reactions (R) 1227
— CD spectroelectrochemistry, a method for the characterization of chiral electron transfer reagents and chiral reaction intermediates (C) 291
— Reactions in organic chemistry (B) 1740
Electron-transfer catalysis, Electron-transfer chain catalysis in organotransition metal chemistry (R) 643
Electrophoresis, Advances in electrophoresis (B) 1109
Enantiomer separation, Gas chromatographic separation of enantiomeric olefins (C) 1556
— The practice of enantiomer separation by capillary gas chromatography (B) 307
Enantioselectivity, Diastereo- and enantioselective aldol reactions via α-silyl ketones, asymmetric synthesis of the aggregation pheromone sitophilure (C) 581
— Enantio- and diastereoselective synthesis of methyl (2*R*)-2-amino-5-oxocarboxylates from enones and bislactim-ether cuprates (C) 1194
— Enantioselective catalytic transfer-hydrogenation of α,β-unsaturated carboxylic acids with triethylammonium formate (C) 1180
— Enantioselective synthesis of (*R*)-*N*-Boc-1-amino-2-arylcyclopropene-1-carboxylic acid methyl ester (C) 433
— Modified cyclodextrins—novel, highly enantioselective stationary phases for gas chromatography (C) 979
— Short, highly enantioselective synthesis of a key intermediate for the preparation of leucotriene B_4 and its 14,15-didehydro derivative (C) 1188
Endoperoxides, Competition of endoperoxide and hydroperoxide formation in the reaction of singlet oxygen with cyclic, conjugated dienes (C) 717
ENDOR spectroscopy in water: reductions and oxidations of organic compounds (C) 1069
— Isolation and structure of [(fluorenone$^{\odot\ominus}$){$Na^{\oplus}$(dme)$_2$}]$_2$ — a touchstone for radical contact ion pairs? (C) 1067
Ene reactions, Induced and non-induced diastereoselective intramolecular ene reaction of 1,6-dienes: the unusual formation of *trans*-1,2-disubstituted cyclopentanes (C) 1186
— Stereoselective synthesis of *trans*-decalins via intramolecular ene reactions; synthesis of the enantiomerically pure cadinane-sesquiterpene veticadinol (C) 703
Energy transport, Synthesis and optical properties of terminally substituted conjugated polyenes (C) 281
Environmental chemistry, Rapid detection of manganese deficiency in conifer needles by electron spin resonance spectroscopy (C) 1722
Enzyme catalysis, Catalytic activity of enzymes altered at their active sites (R) 913
— Enzyme-catalyzed synthesis of 1-deoxymannojirimycin, 1-deoxynojirimycin, and 1,4-dideoxy-1,4-imino-D-arabinitol (C) 716
— Enzymic Baeyer-Villiger oxidations by flavin-dependent monooxygenases (R) 333
— Isoleucyl-tRNA synthetase: an enzyme with several catalytic cycles displaying variation in specificity and energy consumption (R) 773
— Microbial and enzymatic processes for the production of biologically and chemically useful compounds (R) 622
— The enzymic interconversion of isobutyryl and *n*-butyrylcarba(dethia)-coenzyme A: a coenzyme-B_{12}-dependent carbon skeleton rearrangement (C) 1089
— Tris(2,2'-bipyridyl-5-sulfonic acid)rhodium(III), an improved redox catalyst for the light-induced and the electrochemically initiated enzymatic reduction of carbonyl compounds (C) 265
Enzyme chemistry, Enzymes and curvature (C) 953
— The cyclopropyl group in studies of enzyme mechanism and inhibition (R) 537
Enzyme inhibitors, Enantioselective synthesis of (*R*)-*N*-Boc-1-amino-2-arylcyclopropene-1-carboxylic acid methyl ester (C) 433

— Enzyme-catalyzed synthesis of 1-deoxymannojirimycin, 1-deoxynojirimycin, and 1,4-dideoxy-1,4-imino-D-arabinitol (C) 716
Equipotential surfaces, Enzymes and curvature (C) 953
— in periodic charge distributions (C) 849
Errata, Dinuclear complexes of gold(I) containing bridging cyclometalated arylphosphane or arylarsane ligands (E) 589
ESR spectroscopy, Rapid detection of manganese deficiency in conifer needles by electron spin resonance spectroscopy (C) 1722
— Structure, magnetochemistry and biological relevance of $[Mn_4O_3Cl_4(OAc)_3(py)_3]$, a complex with $S=9/2$ ground state (C) 1731
Ethylenedithione (C_2S_2): generation and characterization by neutralization-reionization mass spectrometry (C) 1337
Experimantal design: a chemometric approach (B) 1565

Fine chemicals for the electronics industry (B) 445
Fluorescence microscopy, Controlling the microstructure of monomolecular layers (AM) 728
Fluorine compounds, A simple access to 2-substituted 3,3,3-trifluoroalanine derivatives (C) 848
— Formation of difluoroethyne as a ligand by coupling of two fluoromethylidyne ligands (C) 845
— Graphite fluorides (B) 1219
— Novel anionic aryl complexes of Rh^{III}: $[Rh(C_6F_5)_5]^{2\ominus}$ and $[Rh(C_6F_5)_4(CO)_2]^{\ominus}$ (C) 1700
— The crystal structure of hypofluorous acid: chain formation by O—H···O hydrogen bonds (C) 392
— The fluoronium ions $H_2F^{\oplus}$ and $H_3F_2^{\oplus}$: characterization by crystal structure analysis (C) 391
— The SF_5-unit as steric protecting group; synthesis and structure of $F_5S-C\equiv SF_3$ (C) 1534
Fractals, Polymeric photoconductors—new concepts (AM) 1210
Furofurans, A simple route to furo[3,4-*b*]furans, compounds with a new diheteropentalene system (C) 568

Gallium compounds, Intramolecularly stabilized organogallium compounds (C) 1077
— New complex cations of aluminum(III) and gallium(III) (C) 277
Gas chromatography, Modified cyclodextrins—novel, highly enantioselective stationary phases for gas chromatography (C) 979
— Pheromones in nanogram quantities: structure determination by combined microchemical and gas chromatographic methods (R) 460
— The practice of enantiomer separation by capillary gas chromatography (B) 307
Gas/solid additions, Diastereospecific gas/solid additions with cholesterol derivatives (C) 1511
Genetic code, Isoleucyl-tRNA synthetase: an enzyme with several catalytic cycles displaying variation in specificity and energy consumption (R) 773
Genetic engineering, Pharmaceutical proteins (R) 207
Germanium compounds, $(Mesityl)_2Ge$(fluorenylidene)—stabilization of a Ge-C double bond by charge transfer into an aromatic system (C) 828
— Polycyclic silylamides of Ge^{II} and Sn^{II} with different structures—bis(germanediyl) versus distannate (C) 1087
Glycoconjugates, β-Mannosides from β-glucosides by intramolecular nucleophilic substitution with inversion of configuration (C) 1086
Glycopeptides, Protecting-group-dependent stability of intersaccharide bonds—synthesis of a fucosyl-chitobiose glycopeptide (C) 1697
— Solid-phase synthesis of *O*-glycopeptide sequences (C) 1365
— Solid phase synthesis of peptides and glycopeptides on polymeric supports with allylic anchor groups (C) 711
— The *p*-nitrocinnamyloxycarbonyl (noc) moiety—an acid-stable amino-protecting group removable under neutral conditions for peptide and glycopeptide synthesis (C) 1375
Gold compounds, "Aurophilicity" as a consequence of relativistic effects: the hexakis(triphenylphosphaneaurio)methane dication $[(Ph_3PAu)_6C]^{2\oplus}$ (C) 1544
— Dinuclear complexes of gold(I) containing bridging cyclometalated arylphosphane or arylarsane ligands (E) 589
— Photolytic cluster synthesis: synthesis and structure of $[\{(Ph_3P)Au\}_7Mo(CO)_3]OH$ (C) 1094
— Polyauriomethane compounds (C) 419
— Use of the CH acidity of 2,4,4-trimethyl-4,5-dihydrooxazole to synthesize triauriomethanes and novel gold clusters (C) 1542
— Weak intramolecular bonding relationships: the conformation-determining attractive interaction between gold(I) centers (C) 417
Grignard Reactions, Carbanions as intermediates in the synthesis of Grignard reagents (C) 687
— The activation of phenylmagnesium compounds by crown ethers (C) 1084
Grob fragmentation, Carbon as leaving group—stereochemistry of nucleophilic substitution (C) 1538
Guaiacolato complexes, Dinuclear vanadium(II)- and vanadium(III)-guaiacolato complexes related to vanadium-based systems for the reduction of nitrogen (C) 576

Hafnium compounds, $[M(CO)_4\{CH_3C(CH_2PMe_2)_3\}]$, M = Ti, Zr, Hf, complexes of zerovalent titanium, zirconium, and hafnium. First structural characterization of a Zr^0-carbonyl complex (C) 437
— $P_4^{2\ominus}$ Isomers as complex ligands (C) 694
— Triple proton abstraction from a 1-methylallyl ligand on thermolysis: formation of a $Hf_3(C_4H_4)$ cluster (C) 1058
Haloform reactions, Electrocatalytic haloform reaction: transformation of methyl ketones into methyl esters (C) 1716
Halogen-metal exchange, Asymmetric induction in the replacement of diastereotopic bromine atoms by lithium atoms (C) 1176
Helix, Helicates: tetra- and pentanuclear double helix complexes of Cu^I and poly(bipyridine) strands (C) 1095
— Influence of chromophore orientation on the circular dichroism of isomeric helical molecules (C) 976
— Oxidative coupling of racemic and of optically active 3,6-di-*tert*-butylocta-1,4,7-triyne-3,6-diol (C) 859
Helix inversion, How high is the activation barrier to helix inversion of 1,4,5,8-tetrasubstituted phenanthrenes? (C) 270
Heteroallenes, A monomeric diboryldilithiomethane with a 1,3-diborataallene structure (C) 1370
Heteroannulenes, Biomimetic synthesis of an octavinylogous porphyrin with an aromatic [34]annulene system (C) 1170
— Tetraoxaporphycene dication (C) 411
— Tetraoxaporphyrin dication (C) 406
— Tetraoxaporphyrinogen (tetraoxaquaterene): oxidation to the tetraoxaporphyrin dication (C) 409
Heteroarenes, Annelation of carbene ligands by λ^3-phosphaalkynes, an entry to functionalized phosphaarenes (C) 713
— 1,4-Di-*tert*-butyl-2,6-bis(trimethylsilyl)silabenzene, the first silabenzene stable in solution at −100 °C (C) 963
— Phosphaalkynes—syntheses, reactions, coordination behavior (R) 1484
— Reaction of 1,3-azaarsinines with 2-*tert*-butyl-1-phosphaethyne—2,9,10-tri-*tert*-butyl-4,6-diphenyl-1,3,8-triphospha-7-arsatetracyclo[4.4.0.$0^{2,8}$.$0^{3,7}$]deca-4,9-diene (C) 709
— Synthesis and structure of $[MeAlN(2,6\text{-}iPr_2C_6H_3)]_3$: an aluminum-nitrogen analogue of borazole (C) 1699
— Triazatrimetallabenzenes, a new class of inorganic heterocycles; synthesis and structure of $[Cp^*TaN(Cl)]_3$ (C) 1330
— Tris(thioxanthen-9-ylidene)cyclopropane, and its radical cation and dication (C) 1078
Hetero-Claisen rearrangement, Unsaturated hydrindanone derivatives from arenes by hetero-Claisen rearrangement (C) 558
Heterocycles, Addition of a distannene to a phosphaalkyne. Formation of a phosphadistannacyclobutene (C) 838
— Alkali-metal hydrogen tetraphosphides M^IHP_4—the first salts of bicyclo[1.1.0]tetraphosphane (C) 1059
— α-Methylene-β-lactone, a novel heterocyclic ring system via deoxygenation of α-methylene-β-peroxylactones with triphenylphosphane (C) 1536
— A novel tris(azo)macrobicyclic molecule—synthesis, photochemistry, and isomer separation (C) 1189
— A simple route to furo[3,4-*b*]furans, compounds with a new diheteropentalene system (C) 568
— A tetramethylene-1,4-distannacyclohexane from 3,4-dilithio-2,5-dimethyl-2,4-hexadiene and dichlorodimethylstannane: the first dimetalla[6]radialene (C) 404
— Bis([1,2,5]thiadiazolo)[3,4-*b*;3′,4′-*e*]pyrazine, a novel 14π-electron heterocycle with high electron affinity (C) 434
— Catalytic syntheses of functionalized nitrogen heterocycles from cyanogen (C) 1372
— Dications based on a hydrotris(phosphonio)borate skeleton (C) 1071
— 1,4-Diphospha-2-rhodacyclopentadiene—an isolable intermediate in the metal-induced cyclodimerization of *tert*-butylphosphaacetylene (C) 1157
— First structure analysis and photoelectron spectroscopic investigation of an azete and an azete-cobalt complex (C) 1559
— Formation of the diphosphatricyclo[2.1.0.$0^{2,5}$]pentane ring system via phosphaalkyne dimerization and carbon monoxide incorporation (C) 837
— From the dilithiooctamethylcyclotetrasilazane to the 1,3,5,7-tetraaza-2,4,6,8,9-pentasilabicyclo[3.3.1]nonane system (C) 1074
— Intramolecularly stabilized organogallium compounds (C) 1077
— 4-Iodo-1,3,5,7-tetramethyl-1,3,5,7-tetraaza-4λ^5-phosphaspiro[3.3]heptane-2,6-dione: synthesis and crystal structure of the first iodophosphorane (C) 1562
— 5-Isopropyliden-1,2-oxathiole 2-oxide by photoisomerization of 2,2-dimethyl-3(2*H*)-thiophenone 1-oxide (C) 1374
— Ketenimine complexes from carbene complexes and isocyanides: versatile building blocks for carbocycles and N-heterocycles (R) 1456
— Methoxyallenes as components in Diels-Alder reactions with inverse electron demand: synthesis of 6*H*-1,2-oxazines (C) 1518
— Nitroazoles. The *C*-nitro derivatives of five-membered *N*- and *N,O*-heterocycles (B) 985
— Phosphaalkynes—syntheses, reactions, coordination behavior (R) 1484

— Polycyclic silylamides of Ge^{II} and Sn^{II} with different structures — bis(germanediyl) versus distannate (C) 1087
— Reaction of 1,3-azaarsinines with 2-*tert*-butyl-1-phosphaethyne — 2,9,10-tri-*tert*-butyl-4,6-diphenyl-1,3,8-triphospha-7-arsatetracyclo[4.4.0.0^{2,8}.0^{3,7}]deca-4,9-diene (C) 709
— Reaction of 1,3-azaphosphinines with 2-*tert*-butyl-1-phosphaethyne: 9-aza-2,4,6-triphosphatetracyclo[5.3.0.0^{2,4}.0^{3,6}]deca-8,10(1)-diene (C) 389
— Reactivity of (*R*)-2-*tert*-butyldihydrooxazole derivatives prepared from serine and threonine: novel, versatile chiral building blocks (C) 1351
— Redox-active thieno[3,2-*b*]thiophene as a novel, three-color electrochromic system (C) 560
— Reductive oligomerization of 1,2-Di-*tert*-butyl-1,1,2,2-tetrachlorodisilane: the tricyclo[2.2.0.0^{2,5}]hexasilane and tetracyclo[3.3.0.0^{2,7}.0^{3,6}]octasilane systems (C) 1725
— Reversible coupling and opening of a boron-carbon bond (C) 952
— ^{29}Si-^{29}Si long range couplings in strained cyclic polysilanes (C) 1727
— Synthesis and molecular structure of the diphosphaarsirane [{[(η^5-C_5Me_5)(CO)$_2$Fe]P}$_2$As$C_6H_2tBu_3$] (C) 1537
— Synthesis and structure of a 1,2,5,6-tetrahydro-1,2,5,6-tetraborocine (C) 926
— Synthesis and structure of [ClV(OSiMe$_3$)N$_2$PPh$_2$]$_2$, the first cyclodimetallaphosphazene—an eight-membered planar unsaturated heterocycle (C) 850
— The chemistry of inorganic homo- and heterocycles. Vol. 1 and 2 (B) 1107
— The cyclohepta[*def*]carbazolium ion (C) 585
— The first transition metal complex of a thiepin; synthesis of thermally labile 1-benzothiepin 1-oxide from 1-benzothiepin(tricarbonyl)iron (C) 1717
— The first triphosphabicyclobutane—evidence for a 1,2,3-triphosphabutadiene (C) 957
— [1,2,4]Triazolo[1,2-*a*][1,2,4]triazole-1,3,5,7(2*H*,6*H*)-tetrone (urazourazole), synthesis and structure (C) 701
— Trimethylplatinum-theophylline hexamer: a novel Pt_6 heterocycle containing both Pt-N and Pt-O bonds (C) 1160
Hetero-Diels-Alder reactions, Amino acid methyl esters as chiral auxiliaries in aza-Diels-Alder reactions in aqueous solution (C) 274
— Reaction of 1,3-azaarsinines with 2-*tert*-butyl-1-phosphaethyne — 2,9,10-tri-*tert*-butyl-4,6-diphenyl-1,3,8-triphospha-7-arsatetracyclo[4.4.0.0^{2,8}.0^{3,7}]deca-4,9-diene (C) 709
— Synthesis of strictosidine analogues by hetero-Diels-Alder reaction and their biomimetic transformation to indole alkaloids (C) 971
Heterofulvalene, New organic superconductors (AM) 1817
Heterofulvalenes, A conjugated bis(tetrathiafulvalene) system with tetrathia-*s*-indacene structure (C) 288
— A donor cage with bent tetrathiafulvalene moiety (C) 1377
— New organic superconductors (AM) 1747
— Synthesis and structure of (ET)[Ni{SC(CN)=C(CN)S}$_2$], a radical cation salt of bis(ethylenedithio)tetrathiafulvalene (C) 699
— Tetraphosphafulvalenes (C) 950
Heterofulvenes, 1,3-Dihydro-1,3-diborafulvene derivatives (C) 299
Heterogeneous catalysis, Heterogeneous, bimetallic metathesis catalysts by reaction of Fischer-type carbene complexes with reduced Phillips catalyst (C) 275
— Methylrhenium oxides: synthesis from Re_2O_7 and catalytic activity in olefin metathesis (C) 394
— Photochemical reaction of [(CO)$_4$Co(SiEt$_3$)] with ethylene: implications for cobaltcarbonyl-catalyzed hydrosilation of alkenes (C) 289
— Silica-supported Fe-Pd bimetallic particles: formation from mixed-metal clusters and catalytic activity (C) 927
— Uniform heterogeneous catalysts: the role of solid-state chemistry in their development and design (R) 1673
Heterogeneous systems, Photochemistry in microheterogeneous systems (B) 722
Hetero-metal compounds, Silica-supported Fe-Pd bimetallic particles: formation from mixed-metal clusters and catalytic activity (C) 927
Heterometallic clusters, A Pt_2AgH_2 complex (C) 563
Heterometallic compounds, [{$Hg_3Co(C_4H_6NO)_6$}$(NO_3)_2$]$_n$: a macrobicyclic bimetallic chain polymer incorporating deprotonated 2-pyrrolidone bridges (C) 261 (589)
Heteropentalenes, Synthesis and physical properties of 3,6-di-*tert*-butyl-1,4-diazapentalene (C) 1061
— 1,3,4,6-Tetraamino-2,5-diazapentalenes: delocalized antiaromatic compounds (C) 842
Heteropolyanions, A novel heterocluster with D_3-symmetry containing twenty-one core atoms: $[As_6^{III}V_{15}^{IV}O_{42}(H_2O)]^{6\ominus}$ (C) 1721
Hexatrienes, Cobalt-catalyzed reactions of octamethyl-[4]-radialene and 2,5-dimethyl-2,3,4-hexatriene with ethene (C) 571
History of chemistry, One or several pioneers? The discovery of noble-gas compounds (R) 479
Homocycles, Catalytic isomerization of methylated 1,5-cyclooctadienes (C) 1062
— Centrohexaindan, the first hydrocarbon with topologically non-planar molecular structure (C) 1192
— Synthesis and structure of 2,7-Di-*tert*-butyldicyclopenta[*a*,*e*]cyclooctene (C) 1191
— The chemistry of inorganic homo- and heterocycles. Vol. 1 and 2 (B) 1107
— Tricyclo[3.1.0.0^{2,6}]hexanedione (the valene of *o*-benzoquinone), bicyclo[2.1.1]hexane-2,3-dione, and valenes of a quinoxaline, of phenazine, and of a benzophenazine (C) 1369
Homogeneous catalysis, Acetylene polymerization with ylide-nickel catalysts (C) 839
— A new type of unsaturated *triangulo* transition-metal cluster and homogeneous catalyst (C) 263
— Carbon dioxide as an alternative C_1 synthetic unit: activation by transition-metal complexes (R) 661
— Cobalt-catalyzed reactions of octamethyl-[4]-radialene and 2,5-dimethyl-2,3,4-hexatriene with ethene (C) 571
— Contributions to organo-nickel chemistry (R) 185
— Oxidative addition of water to the Ru^{II} catalyst K[Ru^{II}(Hedta)(CO)]: homogeneous catalysis of the water-gas shift reaction under ambient conditions (C) 1735
Host-guest chemistry, A novel type of cationic host molecules with π-acceptor properties (C) 1553
— Complexation of neutral molecules by cyclophane hosts (R) 362
— Cyclobis(paraquat-*p*-phenylene). A tetracationic multipurpose receptor (C) 1547
— Host-guest bonding of oxoanions to guanidinium anchor groups (C) 1516
— Isostructural, alternately-charged receptor stacks. The inclusion complexes of hydroquinone and catechol dimethyl ethers with cyclobis(paraquat-*p*-phenylene) (C) 1550
— Metal-ion-selective exchange resins by matrix imprint with methacrylates (C) 1695
— Modification of hydrophobic and polar interactions by charged groups in synthetic host-guest complexes (C) 1163
— The design of molecular hosts, guests, and their complexes (Nobel lecture) (R) 1009
— 2,2′,7,7′-Tetrahydroxy-1,1′-binaphthyl: a versatile chiral spacer for mono- and ditopic cyclophane hosts with apolar binding sites (C) 1705
Hydrindanones, Unsaturated hydrindanone derivatives from arenes by hetero-Claisen rearrangement (C) 558
Hydrogenation, Enantioselective catalytic transfer-hydrogenation of α,β-unsaturated carboxylic acids with triethylammonium formate (C) 1180
— Mechanism of ethylene hydrogenation by the molecular hydrogen complex [$Ir(H)_2(H_2)(PMe_2Ph)_3$]$^{\oplus}$—characterization of intermediates (C) 1165
— Reduction and hydrogenation with the system hydrocarbon/carbon (R) 679
Hydrogen bonds, On the structure of the cation $N_2H_7^{\oplus}$ with an N−H···N hydrogen bond in the monoammonia adduct of ammonium iodide (C) 1524
— "Proton sponges" and the geometry of hydrogen bonds: aromatic nitrogen bases with exceptional basicities (R) 865
— The fluoronium ions $H_2F^{\oplus}$ and $H_3F_2^{\oplus}$: characterization by crystal structure analysis (C) 391
Hydroperoxides, Competition of endoperoxide and hydroperoxide formation in the reaction of singlet oxygen with cyclic, conjugated dienes (C) 717
Hydrosilation, Photochemical reaction of [(CO)$_4$Co(SiEt$_3$)] with ethylene: implications for cobaltcarbonyl-catalyzed hydrosilation of alkenes (C) 289
Hydroxylamines, *N*-Aryl-*O*-acylhydroxylamines: preparation by *O*-acylation or *N*→*O* transacylation and reaction with amines; model reactions for key steps connected with the carcinogenicity of aromatic amines (C) 973
Hydroxylation, Kinetics and stereochemistry of the $SO_4^{\odot\ominus}$-induced hydroxylation of cyclohexenes in aqueous solution (C) 1066
Hypercarbon chemistry (B) 590
Hypofluorous acid, The crystal structure of hypofluorous acid: chain formation by O−H···O hydrogen bonds (C) 392

Iminoboranes, Synthesis and structure of [$Cp_2NbH(tBuB{\equiv}NtBu)$], a compound with side-on coordinated iminoborane (C) 958
— The chemistry of amino imino boranes (R) 1603
Iminophosphanes, Arylamino(halogeno)-phosphanes XP=N$C_6H_2tBu_3$ (X = Cl, Br, I) and the iminophosphenium tetrachloroaluminate [P≡N$C_6H_2tBu_3$]$^{\oplus}$[$AlCl_4$]$^{\ominus}$: the first stable compound with a PN triple bond (C) 1715
— Synthesis, structure and bonding in the donor-acceptor complex [tBu_2PSe_2]·[PNAryl]: en route to the P≡N bond (C) 1713
Immune system, Somatic generation of immune diversity (Nobel lecture) (R) 1028
s-Indacenes, Equilibrium structure, stabilized transition state, or disorder in the crystal? Studies of the antiaromatic systems tetra-*tert*-butyl-*s*-indacene and tetra-*tert*-butylcyclobutadiene by low-temperature crystal structure analysis (C) 387
Indoles, Transition metals in the synthesis and functionalization of indoles (R) 1113
Intelligent materials—a new frontier (AM) 1389
Intercalation, Partially reversible intercala-

tion of ferrocene in a zeolite-like host lattice consisting of $Fe(CN)_6$ and Me_3Sn units (C) 1521
Iodophosphoranes, 4-Iodo-1,3,5,7-tetramethyl-1,3,5,7-tetraaza-4λ⁵-phosphaspiro[3.3]heptane-2,6-dione: synthesis and structure of the first iodophosphorane (C) 1562
Ion beam epitaxy, From carbon beams to diamond films (AM) 1203
Ion exchange resins, Metal-ion-selective exchange resins by matrix imprint with methacrylates (C) 1695
Iridium compounds, Mechanism of ethylene hydrogenation by the molecular hydrogen complex $[Ir(H)_2(H_2)(PMe_2Ph)_3]^{\oplus}$—characterization of intermediates (C) 1165
— Synthesis of octahedral hydrido(vinyl)iridium(III) complexes by C—H activation: an example of a thermodynamically favored rearrangement $[M(CHR{=}CHX)]\rightarrow[M(H)(CR{=}CHX)]$ (C) 948
— Tetranuclear complexes as intermediates in transannular oxidative-addition reactions. Structure of the first tetrairidium linear cluster (C) 402
Iron compounds, A new cubane cluster with the $[MoFe_3S_4]^0$ core and possible relevance to the Fe_3-centers in ferredoxins. The synthesis, structure and properties of the $[Fe_3S_4(SEt)_3Mo(CO)_3]^{3\ominus}$ anion (C) 1353
— Blocking of the retro-Diels-Alder reaction by complex formation: [(η⁵-cyclopentadienyl)(η⁵-dicyclopentadienyl)iron] (C) 977
— π Complexes of an amino-9-fluorenylideneborane (C) 1331
— Does a 1,1′-diazaferrocene exist? (C) 1368
— Naked molecule chemistry: different bonding modes of CO to FeX_2 (C) 1161
— Oxo-bridged polyiron centers in biology and chemistry (R) 344
— Partially reversible intercalation of ferrocene in a zeolite-like host lattice consisting of $Fe(CN)_6$ and Me_3Sn units (C) 1521
— Short, highly enantioselective synthesis of a key intermediate for the preparation of leucotriene B_4 and its 14,15-didehydro derivative (C) 1188
— Synthesis and structure of $[(OC)_4Fe{=}Si{=}Fe(CO)_4\cdot 2(Me_2N)_3PO]$—a complex of formally zerovalent silicon (C) 583
— Tentacled iron sandwiches (C) 1347
— Tetrakis[bis(trimethylsilyl)ethyne]diiron (C) 1519
Isocyanides, Reactions of pentacarbonyl(trichloromethyl isocyanide)chromium (C) 1344
Isofulminic acid, Carboxime (Isofulminic acid) (C) 938
Isoleucyl-tRNA synthetase: an enzyme with several catalytic cycles displaying variation in specificity and energy consumption (R) 773
Isomerization, Catalytic isomerization of methylated 1,5-cyclooctadienes (C) 1062
— 5-Isopropyliden-1,2-oxathiole 2-oxide by photoisomerization of 2,2-dimethyl-3(2*H*)-thiophenone 1-oxide (C) 1374
Isopolyanions, Formation of an oxalate-filled cavity in a reduced cyclic octanuclear polyoxomolybdate $[(n\text{-}C_4H_9)_4N]_2[Mo_8O_{16}(OCH_3)_8(C_2O_4)]$ formed from α-$[(n\text{-}C_4H_9)_4N]_4[Mo_8O_{26}]$ and rhodizonic acid (C) 1724
— $[V_{19}O_{41}(OH)_9]^{8\ominus}$, an ellipsoid-shaped cluster anion belonging to the unusual family of V^{IV}/V^{V} oxygen clusters (C) 1719

Ketenimines, Ketenimine complexes from carbene complexes and isocyanides: *versatile building blocks for carbocycles* and N-heterocycles (R) 1456
Köbrich reagents, Higher thermostability and selectivity of Köbrich reagents by transmetalation (C) 943
β-Lactones, α-Methylene-β-lactone, a novel heterocyclic ring system via deoxygenation of α-methylene-β-peroxylactones with triphenylphosphane (C) 1536
γ-Lactones, A new route to *trans*-substituted γ-lactones (C) 268
Lasers in chemistry (B) 721
— Laser photochemistry at surfaces—laser-induced chemical vapor deposition and related phenomena (R) 1314
— Preparative UV-laser photochemistry: a biscarbene intermediate in the synthesis of a 5,6-dihydrodibenzo[*a*,*e*]cyclooctene containing a *trans*-double bond (C) 853
Ligand reactions, Pentadienyl, a more reactive and more strongly bound ligand than cyclopentadienyl (C) 1099
— Photochemical reactions of ligands in transition-metal complexes (R) 789
Liquid crystals—state of the art (B) 987
— Thermotropic liquid crystals (AM) 1002
Lithium nitride, Phase transformations of lithium nitride under pressure (C) 1101

Macrocycles, A novel tris(azo)macrobicyclic molecule—synthesis, photochemistry, and isomer separation (C) 1189
— A novel type of cationic host molecules with π-acceptor properties (C) 1553
— A topologically chiral [2]catenand (C) 930
— Cyclobis(paraquat-*p*-phenylene). A tetracationic multipurpose receptor (C) 1547
— $[\{Hg_3Co(C_4H_6NO)_6\}(NO_3)_2]_n$: a macrobicyclic bimetallic chain polymer incorporating deprotonated 2-pyrrolidone bridges (C) 261 (589)
— Isostructural, alternately-charged receptor stacks. The inclusion complexes of hydroquinone and catechol dimethyl ethers with cyclobis(paraquat-*p*-phenylene) (C) 1550
— Modification of hydrophobic and polar interactions by charged groups in synthetic host-guest complexes (C) 1163
— Novel layer structure of sodium calix[4]arenesulfonate complexes—a class of organic clay mimics? (C) 1361
— Supramolecular chemistry—scope and perspectives; molecules, supermolecules, and molecular devices (Nobel lecture) (R) 89
— Template synthesis of macrocyclic multiphosphane ligands with functional groups (C) 438
— The design of molecular hosts, guests, and their complexes (Nobel lecture) (R) 1009
— The discovery of crown ethers (Nobel lecture) (R) 1021

— Solid phase synthesis of peptides and glycopeptides on polymeric supports with allylic anchor groups (C) 711
— Synthesis of peptides containing (*S*)-α-methylserine (C) 858
— The *p*-nitrocinnamyloxycarbonyl (noc) moiety—an acid-stable amino-protecting group removable under neutral conditions for peptide and glycopeptide synthesis (C) 1375
Pharmaceutical proteins (R) 207
Phenanthrenes, How high is the activation barrier to helix inversion of 1,4,5,8-tetrasubstituted phenanthrenes? (C) 270
Pheromones, Diastereo- and enantioselective aldol reactions via α-silyl ketones, asymmetric synthesis of the aggregation pheromone sitophilure (C) 581
— in nanogram quantities: structure determination by combined microchemical and gas chromatographic methods (R) 460
Phosphaalkenes, 1,4-diphosphabutatriene (C) 1360
Phosphaalkynes, Annelation of carbene ligands by λ^3-phosphaalkynes, an entry to functionalized phosphaarenes (C) 713
— 1,4-Diphospha-2-rhodacyclopentadiene—an isolable intermediate in the metal-induced cyclodimerization of *tert*-butylphosphaacetylene (C) 1157
— Reaction of 1,3-azaarsinines with 2-*tert*-butyl-1-phosphaethyne — 2,9,10-tri-*tert*-butyl-4,6-diphenyl-1,3,8-triphospha-7-arsatetracyclo[4.4.0.0^{2,8}.0^{3,7}]deca-4,9-diene (C) 709
— Phosphaalkynes—syntheses, reactions, coordination behavior (R) 1484
Phosphadistannacyclobutenes, Addition of a distannene to a phosphaalkyne. Formation of a phosphadistannacyclobutene (C) 838
Phosphorus compounds, Addition of a distannene to a phosphaalkyne. Formation of a phosphadistannacyclobutene (C) 838
— A novel entry to the PC-double bond: the "phospha-Wittig" reaction (C) 1382
— Dications based on a hydrotris(phosphonio)borate skeleton (C) 1071
— Formation of the diphosphatricyclo[2.1.0.0^{2,5}]pentane ring system via phosphaalkyne dimerization and carbon monoxide incorporation (C) 837
— Novel boron-phosphorus cages with $C_4B_4P_4$ and $C_2B_4P_4$ frameworks (C) 399
— Synthesis and crystal structure of a chiral C_3-symmetric monophosphane (C) 835
— Synthesis and molecular structure of the diphosphaarsirane $[\{[(\eta^5\text{-}C_5Me_5)(CO)_2Fe]P\}_2AsC_6H_2tBu_3]$ (C) 1537
— Synthesis of optically active phosphanes via Sharpless epoxidation (C) 718
— Tetraphosphafulvalenes (C) 950
— The first *closo*-diphosphahexaborane $P_2B_4Cl_4$ (C) 925
— The first diphosphaallyl system coordinated to two metal centers (C) 416
— The first triphosphabicyclobutane—evidence for a 1,2,3-triphosphabutadiene (C) 957
Phosphorus homocycles, Alkali-metal hydrogen tetraphosphides M^IHP_4 — the first salts of bicyclo[1.1.0]tetraphosphane (C) 1059
— On the pentaphosphacyclopentadienide ion, $P_5^{\ominus}$ (C) 280
— Tris(2,3-di-*tert*-butylcyclotriphosphanyl)-stibane—a compound containing three P_3 rings linked by an antimony atom (C) 561
Phosphorus-nitrogen compounds, Arylamino(halogeno)phosphanes $XP{=}NC_6H_2tBu_3$ (X = Cl, Br, I) and the iminophosphenium tetrachloroaluminate $[P{\equiv}NC_6H_2tBu_3]^{\oplus}[AlCl_4]^{\ominus}$: the first stable compound with a PN triple bond (C) 1715
— 4-Iodo-1,3,5,7-tetramethyl-1,3,5,7-tetraaza-4λ^5-phosphaspiro[3.3]heptane-2,6-dione: synthesis and crystal structure of the first iodophosphorane (C) 1562
— Reaction of 1,3-azaphosphinines with 2-*tert*-butyl-1-phosphaethyne: 9-aza-2,4,6-triphosphatetracyclo[5.3.0.0^{2,4}.0^{3,6}]deca-8,10(1)-diene (C) 389
— Structure of molecular PNO, matrix isolation and ab initio calculations (C) 421
— Synthesis and structure of $[ClV(OSiMe_3)N_2PPh_2]_2$, the first cyclodimetallaphosphazene—an eight-membered planar unsaturated heterocycle (C) 850
— Synthesis, structure and bonding in the donor-acceptor complex $[tBu_2PSe_2]\cdot[PNAryl]$: en route to the P≡N bond (C) 1713
Phosphorylation, Protein phosphorylation in bacteria — regulation of gene expression, transport functions, and metabolic processes (R) 1040
Photochemistry, A novel tris(azo)macrobicyclic molecule—synthesis, photochemistry, and isomer separation (C) 1189
— A photolytic entry into oxepane systems (C) 1362
— Catalytic fixation of nitrogen by the pho-

tocatalytic CdS/Pt/RuO_2 particulate system in the presence of aqueous $[Ru(Hedta)N_2]^{\ominus}$ complex (C) 923
— Facile reduction of 1,2-dioxetanes by thiols as potential protective measure against photochemical damage of cellular DNA (C) 429
— in microheterogeneous systems (B) 722
— 5-Isopropyliden-1,2-oxathiole 2-oxide by photoisomerization of 2,2-dimethyl-3(2*H*)-thiophenone 1-oxide (C) 1374
— Laser photochemistry at surfaces—laser-induced chemical vapor deposition and related phenomena (R) 1314
— Mechanisms of photophysical processes and photochemical reactions in polymers (B) 1568
— Photochemical reaction of $[(CO)_4Co(SiEt_3)]$ with ethylene: implications for cobaltcarbonyl-catalyzed hydrosilation of alkenes (C) 289
— Photochemical reactions of ligands in transition-metal complexes (R) 789
— Photolytic cluster synthesis: synthesis and structure of $[\{(Ph_3P)Au\}_7Mo(CO)_3]OH$ (C) 1094
— Preparative UV-laser photochemistry: a biscarbene intermediate in the synthesis of a 5,6-dihydrodibenzo[*a,e*]cyclooctene containing a *trans*-double bond (C) 853
— Second-sphere photochemistry and photophysics: luminescence of the $[Pt(bpy)(NH_3)_2]^{2\oplus}$-dibenzo[30]crown-10 adduct (C) 692
— Selective photochemical dehydrogenation of saturated hydrocarbons with quantum yields approaching unity (C) 1526
Photoconductors, Polymeric photoconductors—new concepts (AM) 1210
Photophysics of polymers (B) 1409
Photosynthesis, Structure, magnetochemistry and biological relevance of $[Mn_4O_3Cl_4(OAc)_3(py)_3]$, a complex with $S=9/2$ ground state (C) 1731
Platinum compounds, A Pt_2AgH_2 complex (C) 563
— Trimethylplatinum-theophylline hexamer: a novel Pt_6 heterocycle containing both Pt-N and Pt-O bonds (C) 1160
Polyauriomethanes, "Aurophilicity" as a consequence of relativistic effects: the hexakis(triphenylphosphaneaurio)methane dication $[(Ph_3PAu)_6C]^{2\oplus}$ (C) 1544
— Use of the CH acidity of 2,4,4-trimethyl-4,5-dihydrooxazole to synthesize triauriomethanes and novel gold clusters (C) 1542
Polyenes, Synthesis and optical properties of terminally substituted conjugated polyenes (C) 281
— Synthesis of all-*cis*-1,4,7,10-cyclododecatetraene (C) 298
Polymerization, Acetylene polymerization with ylide-nickel catalysts (C) 839
— Metal-free carbanion salts as initiators for the anionic polymerization of acrylic and methacrylic acid esters (C) 1373
— New methods for the anionic polymerization of α-activated olefins (AM) 994
— Synthesis of oligomeric and polymeric monosaccharides by aldol group-transfer polymerization (C) 1158
— The central propellane bond as polymerizable CC single bond: poly(tricyclo-[4.2.0.0^{2,7}]octane-1,7-diyl) — a "poly([1.1.1]propellane)" (C) 296
Polymers, Classical light scattering from polymer solutions (B) 1221
— High-resolution solid-state ^{13}C-NMR spectroscopy of polymers (R) 1468
— Mechanisms of photophysical processes and photochemical reactions in polymers (B) 1568
— Microgels—polymers with a special molecular architecture (AM) 1743
— Photophysics of polymers (B) 1409
— Polymer microscopy (B) 1220
— Two-dimensional solid-state NMR spectroscopy: new possibilities for the investigation of the structure and dynamics of solid polymers (R) 1655
Porphycenes, Tetraoxaporphycene dication (C) 411
Porphyrins, Biomimetic synthesis of an octavinylogous porphyrin with an aromatic [34]annulene system (C) 1170
— Tetraoxaporphyrin dication (C) 406
— Tetraoxaporphyrinogen (tetraoxaquaterene): oxidation to the tetraoxaporphyrin dication (C) 409
— The chemistry and biochemistry of *N*-substituted porphyrins (B) 1737
Powder metallurgy, Advanced materials by powder metallurgy (AM) 989
Prismanes, Synthesis and properties of a bridged *syn*-tricyclo[4.2.0.0^{2,5}]octa-3,7-diene: formation of propella[3$_4$]prismane (C) 840
Propellanes, The central propellane bond as polymerizable CC single bond: poly(tricyclo[4.2.0.0^{2,7}]octane-1,7-diyl) — a "poly([1.1.1]propellane)" (C) 296
Propella[3$_4$]prismane, Synthesis and properties of a bridged *syn*-tricyclo[4.2.0.0^{2,5}]octa-3,7-diene: formation of propella[3$_4$]prismane (C) 840
Protecting groups, In-situ blocking of an aldehyde function by formation of (α-triphenylphosphoniumalkoxy)-titanium or -niobium complexes (C) 944
— Protecting-group-dependent stability of intersaccharide bonds — synthesis of a fucosyl-chitobiose glycopeptide (C) 1697
— Synthesis and properties of N^{α}-Di-*tert*-butoxycarbonyl and N^{α}-benzyloxycarbonyl *tert*-butoxycarbonyl amino acids (C) 400
— The *p*-nitrocinnamyloxycarbonyl (noc) moiety—an acid-stable amino-protecting group removable under neutral conditions for peptide and glycopeptide synthesis (C) 1375
— The SF_5-unit as steric protecting group; synthesis and structure of $F_5S-C\equiv SF_3$ (C) 1534
Proteins, Controlling the microstructure of monomolecular layers (AM) 728
— Dynamics of proteins and nucleic acids (B) 862
— Flexibility and rigidity of proteins and protein-pigment complexes (R) 79
— Pharmaceutical proteins (R) 207
— Practical protein chemistry—a handbook (B) 306
— Protein engineering (B) 306
— Protein engineering (B) 1110
— Protein phosphorylation in bacteria—regulation of gene expression, transport functions, and metabolic processes (R) 1040
Proton sponges and the geometry of hydrogen bonds: aromatic nitrogen bases with exceptional basicities (R) 865
Publications, The art of scientific writing. From student reports to professional publications in chemistry and related fields (B) 1565
— Under the surface of the chemical article (R) 1593
Pyrazines, Bis([1,2,5]thiadiazolo)[3,4-*b*;3′,4′-*e*]pyrazine, a novel 14π-electron heterocycle with high electron affinity (C) 434
Pyrroles, Stable sandwich complexes with pentamethylpyrrole ligands (C) 579

Quinonediimines, The copper salt of 2-iodo-5-methyl-*N,N*′-dicyanoquinonediimine—a radical anion salt exhibiting metallic conductivity down to low temperatures (C) 267

Racemization, How high is the activation barrier to helix inversion of 1,4,5,8-tetrasubstituted phenanthrenes? (C) 270
Radialenes, Cobalt-catalyzed reactions of octamethyl-[4]-radialene and 2,5-dimethyl-2,3,4-hexatriene with ethene (C) 571
— Tris(fluoren-9-ylidene)cyclopropane, a novel [3]radialene (C) 1080
— Tris(thioxanthen-9-ylidene)cyclopropane, and its radical cation and dication (C) 1078
Radiation chemistry. Principles and applications (B) 861
Radical ions, ENDOR spectroscopy in water: reductions and oxidations of organic compounds (C) 1069
— Generation and characterization of sulfurous acid (H_2SO_3) and of its radical cation as stable species in the gas phase (C) 1533
— Isolation and structure of $[(fluorenone^{\odot\ominus})\{Na^{\oplus}(dme)_2\}]_2$ — a touchstone for radical contact ion pairs? (C) 1067
— Kinetics and stereochemistry of the $SO_4^{\odot\ominus}$-induced hydroxylation of cyclohexenes in aqueous solution (C) 1066
— Synthesis and structure of $(ET)[Ni\{SC(CN)=C(CN)S\}_2]$, a radical cation salt of bis(ethylenedithio)tetrathiafulvalene (C) 699
— The copper salt of 2-iodo-5-methyl-*N,N*′-dicyanoquinonediimine—a radical anion salt exhibiting metallic conductivity down to low temperatures (C) 267
— Tris(fluoren-9-ylidene)cyclopropane, a novel [3]radialene (C) 1080
— Tris(thioxanthen-9-ylidene)cyclopropane, and its radical cation and dication (C) 1078
Radicals, The influence of polar and steric effects on the selectivity of the β-cleavage of alkyl radicals (C) 1168
Radiochemistry, Synthesis of the heaviest chemical elements—results and perspectives (R) 1417
Raw materials, Chemicals from coal: new processes (B) 1385
— Industrielle Aromatenchemie. Rohstoffe, Verfahren, Produkte (B) 1108
— Natural fats and oils—renewable raw materials for the chemical industry (R) 41
Reaction mechanisms, Acyl-alkylidyne coupling in the synthesis of dinuclear complexes (C) 1703
— Carbon as leaving group—stereochemistry of nucleophilic substitution (C) 1538
— Electron transfer and charge transfer: twin themes in unifying the mechanisms of organic and organometallic reactions (R) 1227
— Inductivity and bridging in ammonium and carbenium ions (C) 714
— Kinetics and stereochemistry of the $SO_4^{\odot\ominus}$-induced hydroxylation of cyclohexenes in aqueous solution (C) 1066
— Slow tautomerization in a rhenium-oxo-hydroxide complex (C) 1527
— The influence of polar and steric effects on the selectivity of the β-cleavage of alkyl radicals (C) 1168
Reagents, High oxidation state organometallic chemistry, a challenge—the example of rhenium (R) 1297
— Reactions of pentacarbonyl(trichloromethyl isocyanide)chromium (C) 1344
Rearrangements, The enzymic interconversion of isobutyryl and *n*-butyrylcarba(dethia)-coenzyme A: a coenzyme-B_{12}-dependent carbon skeleton rearrangement (C) 1089
Redox reactions, An antibody-mediated redox reaction (C) 1172
— ENDOR spectroscopy in water: reductions and oxidations of organic compounds (C) 1069
Reductions of epoxides, α,β-unsaturated aldehydes, and vicinal diketones with "reactive titanocene" (C) 855
— Reduction with yeast cells the key step of an efficient synthesis of (3*S*, 4*S*)-4-amino-3-hydroxypentanoic acids (C) 426
— Transformation of η^1-nitrosyl to η^2-hydroxylaminyl ligands in the reduction of $[Mo(NO)_2(S_4)]$ to $[Mo(\eta^2\text{-}NH_2O)$-

(NO)('S_4')]: a model reaction for a partial step in the enzymatic [$NO_2^{\ominus} \rightarrow NH_3$] conversion (C) 1164
Reflectance spectroscopy, The use of light in the study of interfacial electrochemical reactions (R) 63
Regioselectivity, C_5 building blocks for terpene syntheses: γ-acetoxylation of (*E*)-2-methyl-2-butenals (C) 285
Renewable raw materials, Natural fats and oils—renewable raw materials for the chemical industry (R) 41
Retro-Diels-Alder reactions, Blocking of the retro-Diels-Alder reaction by complex formation: [(η^5-cyclopentadienyl)(η^5-dicyclopentadienyl)iron] (C) 977
Rhenium compounds, Acid-catalyzed alkyne/alkene coupling at Re^{III} centers (C) 1509
— Alkyne coordination to organorhenium oxides with rhenium in high oxidation states (C) 946
— A new type of unsaturated *triangulo* transition-metal cluster and homogeneous catalyst (C) 263
— High oxidation state organometallic chemistry, a challenge—the example of rhenium (R) 1297
— Methylrhenium oxides: synthesis from Re_2O_7 and catalytic activity in olefin metathesis (C) 394
— Slow tautomerization in a rhenium-oxo-hydroxide complex (C) 1527
— Synthesis and structure of a resonance stabilized (Trimethylphosphonio)metallapropenide (C) 587
Rhodium compounds, [(η^5-C_5Me_4Et)-Rh(μ,η^2-P_2)$_2$Rh(η^5-C_5Me_4Et)], a sandwich complex with a P_4 rectangle (C) 405
— 1,4-Diphospha-2-rhodacyclopentadiene—an isolable intermediate in the metal-induced cyclodimerization of *tert*-butylphosphaacetylene (C) 1157
— Novel anionic aryl complexes of Rh^{III}: $[Rh(C_6F_5)_5]^{2\ominus}$ and $[Rh(C_6F_5)_4(CO)_2]^{\ominus}$ (C) 1700
— $P_4^{2\ominus}$ Isomers as complex ligands (C) 694
— Rhodium-catalyzed reductive carbonylation of methyl formate to acetaldehyde (C) 683
— Synthesis and structure of [$(C_5Me_5)_2Rh_2S_8$], a dirhodium complex with unusual polysulfide bridge (C) 708
— Synthesis, structure and bonding of [$Cl_2Sn\{Rh(PMe_3)_3Cl\}_2$]·THF, an unusual Sn^{II}-Rh^{I} adduct (C) 442
— Tris(2,2'-bipyridyl-5-sulfonic acid)rhodium(III), an improved redox catalyst for the light-induced and the electrochemically initiated enzymatic reduction of carbonyl compounds (C) 265
Ruthenium compounds, A stable bis(chelate) analogue of the Creutz-Taube ion (C) 1174
— Elementary reactions at metal-sulfur centers: base-induced substitution of PPh_3 in [$Ru(PPh_3)_2$(bmae)] (C) 689
— μ-Hydroxo- and μ-oxobis(μ-acetato)diruthenium complexes with weak intramolecular Ru···Ru interactions (C) 933
— Oxidative addition of water to the Ru^{II} catalyst $K[Ru^{II}$(Hedta)(CO)]: homogeneous catalysis of the water-gas shift reaction under ambient conditions (C) 1735
— Real-time atomic-resolution imaging of polymorphic changes in ruthenium clusters (C) 555
— Transformation of open-chain thioether-dithiolato to cyclic thioether ligands by C–S bond cleavage and bond formation at ruthenium centers: synthesis of the trithiobenzo[9]crown-3 complex [Ru(Bzo-9S3)(CO)Br_2] (C) 691

Sandwich complexes, [(η^5-C_5Me_4Et)Rh(μ,η^2-P_2)$_2$Rh(η^5-C_5Me_4Et)], a sandwich complex with a P_4 rectangle (C) 405
— Does a 1,1'-diazaferrocene exist? (C) 1368
— Electron-electron/spin-spin long-range interaction as studied in the diradical dication [Di{bis(dimethylphosphino-η^6-benzene)chromium(I)}-nickel(0)]$^{++}$ (C) 414
— Multidecker metallocenophanes (C) 701
— (Octamethyltetrasila-η^{12}-[2.2]paracyclophane)chromium—synthesis, structure, and characteristics (C) 684
— Partially reversible intercalation of ferrocene in a zeolite-like host lattice consisting of $Fe(CN)_6$ and Me_3Sn units (C) 1521
— Stable sandwich complexes with pentamethylpyrrole ligands (C) 579
— Tentacled iron sandwiches (C) 1347
Say it in English, please! (R) 1050
Second harmonic generation, Methyl 4-hydroxy-5-iodo-2,3-dimethoxy-6-methylbenzoate: the aromatic fragment of calichemicin γ^1_{α}. Synthesis, X-ray crystallographic analysis, and properties (C) 1097
Selenium compounds, Organoselenium chemistry (B) 444
— Selenium reagents and intermediates in organic synthesis (B) 444
— Soluble chromium selenides and tellurides: preparations and structures of [$(C_6H_5)_4P]_3[Cr_3Te_{24}$] and [$(C_6H_5)_4P]_3$-[$Cr_3Se_{24}$] (C) 1702
— The chemistry of organic selenium and tellurium compounds, Vol. 1 (B) 444
— The reagent diphenyldiselane/iodine: no phenylselenenyl iodide but a charge transfer complex with cyclic moieties (C) 431
Self organization, Helicates: tetra- and pentanuclear double helix complexes of Cu^{I} and poly(bipyridine) strands (C) 1095
— Molecular architecture and function of polymeric oriented systems: models for the study of organization, surface recognition, and dynamics of biomembranes (R) 113
Semiconductors, The chemistry of the semiconductor industry (B) 1739
Sensors, Intelligent materials—a new frontier (AM) 1389
Sesquiterpenes, Stereoselective synthesis of *trans*-decalins via intramolecular ene reactions; synthesis of the enantiomerically pure cadinane-sesquiterpene veticadinol (C) 703
Sharpless epoxidations, Synthesis of optically active phosphanes via Sharpless epoxidation (C) 718
Silanediyls, Convenient routes to Di-*tert*-butylsilanediyl: chemical, thermal and photochemical generation (C) 1355
Silicates, High-resolution solid-state NMR of silicates and zeolites (B) 1410
Silicon chemistry, Organosilicon chemistry (B) 446
Silicon compounds, Convenient routes to Di-*tert*-butylsilanediyl: chemical, thermal and photochemical generation (C) 1355
— 1,4-Di-*tert*-butyl-2,6-bis(trimethylsilyl)silabenzene, the first silabenzene stable in solution at −100 °C (C) 963
— From the dilithiooctamethylcyclotetrasilazane to the 1,3,5,7-tetraaza-2,4,6,8,9-pentasilabicyclo[3.3.1]nonane system (C) 1074
— Is tetrasilatetrahedrane kinetically stable? (C) 1081
— Phosphane-stabilized Cu^{I} and Ag^{I} silanes (C) 1349
— Polycyclic silylamides of Ge^{II} and Sn^{II} with different structures—bis(germanediyl) versus distannate (C) 1087
— Reductive oligomerization of 1,2-Di-*tert*-butyl-1,1,2,2-tetrachlorodisilane: the tricyclo[2.2.0.$0^{2,5}$]hexasilane and tetracyclo[3.3.0.$0^{2,7}$.$0^{3,6}$]octasilane systems (C) 1725
— Silicon reagents in organic synthesis (B) 1567

Tetrahydrotetraborocines, Synthesis and structure of a 1,2,5,6-tetrahydro-1,2,5,6-tetraborocine (C) 926
Tetramethylcyclohexyne, 3,3,6,6-Tetramethylcyclohexyne (C) 398
Tetramethylene-1,4-distannacyclohexanes, A tetramethylene-1,4-distannacyclohexane from 3,4-dilithio-2,5-dimethyl-2,4-hexadiene and dichlorodimethylstannane: the first dimetalla[6]radialene (C) 404
Theoretical chemistry, *Ab initio* methods in quantum chemistry, part I and part II (B) 983
— Ab-initio molecular orbital theory (B) 862
— A pictorial approach to molecular bonding (B) 863
— Donor-acceptor-substituted cyclic π-electron systems—probes for theories and building blocks for new materials (R) 1437
— Reaction of tropone with a homopyrrole. The result of a computer-assisted search for unique chemical reactions (C) 1558
Thermochromism, Inorganic thermochromism (B) 1411
Thiadiazoles, Bis([1,2,5]thiadiazolo)[3,4-*b*;3′,4′-*e*]pyrazine, a novel 14π-electron heterocycle with high electron affinity (C) 434
Thienothiophenes, Redox-active thieno[3,2-*b*]thiophene as a novel, three-color electrochromic system (C) 560
Thiepins, The first transition metal complex of a thiepin; synthesis of thermally labile 1-benzothiepin 1-oxide from 1-benzothiepin(tricarbonyl)iron (C) 1717
Thioxophosphanes, $[Os(\eta^2\text{-}PHS)(CO)_2(PPh_3)_2]$, a stable η^2-thioxophosphane (H–P=S)-metal complex (C) 302
Tin compounds, Addition of a distannene to a phosphaalkyne. Formation of a phosphadistannacyclobutene (C) 838
— A tetramethylene-1,4-distannacyclohexane from 3,4-dilithio-2,5-dimethyl-2,4-hexadiene and dichlorodimethylstannane: the first dimetalla[6]radialene (C) 404
— Polycyclic silylamides of Ge^{II} and Sn^{II} with different structures—bis(germanediyl) versus distannate (C) 1087
— Solid state structure of a lithium triorganostannate (C) 1381
— Synthesis, structure and bonding of $[Cl_2Sn\{Rh(PMe_3)_3Cl\}_2]\cdot THF$, an unusual Sn^{II}-Rh^I adduct (C) 442
— Tin in organic synthesis (B) 445
Titanium compounds, π Complexes of an amino-9-fluorenylideneborane (C) 1331
— In-situ blocking of an aldehyde function by formation of (α-triphenylphosphoniumalkoxy)-titanium or -niobium complexes (C) 944
— $[M(CO)_4\{CH_3C(CH_2PMe_2)_3\}]$, M = Ti, Zr, Hf, complexes of zerovalent titanium, zirconium, and hafnium. First structural characterization of a Zr^0-carbonyl complex (C) 437
— Pentadienyl, a more reactive and more strongly bound ligand than cyclopentadienyl (C) 1099
— Reduction of epoxides, α,β-unsaturated aldehydes, and vicinal diketones with "reactive titanocene" (C) 855
— Synthesis and structure of $[cyclo\text{-}C_3H_4\text{–}SO_2Ph]_2Ti[OCH(CH_3)_2]_2$, a *C*-titanated "α-sulfonyl carbanion" (C) 1540
— Synthesis and structure of $[NaTi(2,6\text{-}Me_2C_6H_3O)_4(py)]_2$: a dimeric material containing a novel phenoxide bridge (C) 1181
— Synthesis of TiNF and structure determination by powder diffraction using synchrotron radiation (C) 929
— $[TiSCl_4]^{2\ominus}$ and $[Ti_3O(S_2)_3Cl_6]^{2\ominus}$, a multinuclear complex with a structure typical for clusters (C) 293
— Titanium(0)-arene complexes. Synthesis and X-ray crystal structure of $[(\eta^6\text{-}C_{10}H_8)Ti\{t\text{BuSi}(CH_2PMe_2)_3\}]$ (C) 1693
Topotactic reactions, From electronic/ionic conductors to superconductors: control of materials properties (AM) 1392
Transannular oxidative-addition reactions, Tetranuclear complexes as intermediates in transannular oxidative-addition reactions. Structure of the first tetrairidium linear cluster (C) 402
Transmetalation, Higher thermostability and selectivity of Köbrich reagents by transmetalation (C) 943
Triblattanes, Functionalized, enantiomerically pure [2.1.1]-, [2.2.1]-, and [2.2.2]-triblattanes (C) 1103
Trifluoroalanines, A simple access to 2-substituted 3,3,3-trifluoroalanine derivatives (C) 848
Triketones, 4,6,6-Trimethyl-4-cyclohexene-1,2,3-trione, a contribution to the biogenesis of norcarotinoids (C) 695
Tumor lectinology: at the intersection of carbohydrate chemistry, biochemistry, cell biology, and oncology (R) 1267
Tungsten compounds, Linkage of alkylidyne, carbonyl, and alkyne ligands at a tungsten center to form a metallacyclopentadienone and an η^3-oxocyclobutenyl complex (C) 1730

Ultrathin organic films, Controlling the microstructure of monomolecular layers (AM) 728
Urazoles, [1,2,4]Triazolo[1,2-*a*][1,2,4]triazole-1,3,5,7(2*H*,6*H*)-tetrone (urazourazole), synthesis and structure (C) 701

Valenes, Tricyclo[3.1.0.0^{2,6}]hexanedione (the valene of *o*-benzoquinone), bicyclo[2.1.1]hexane-2,3-dione, and valenes of a quinoxaline, of phenazine, and of a benzophenazine (C) 1369
Vanadium compounds, A novel heterocluster with D_3-symmetry containing twenty-one core atoms: $[As_6^{III}V_{15}^{IV}O_{42}(H_2O)]^{6\ominus}$ (C) 1721
— Dinuclear vanadium(II)- and vanadium(III)-guaiacolato complexes related to vanadium-based systems for the reduction of nitrogen (C) 576
— Synthesis and structure of $[ClV(OSiMe_3)N_2PPh_2]_2$, the first cyclodimetallaphosphazene—an eight-membered planar unsaturated heterocycle (C) 850
— $[V_{19}O_{41}(OH)_9]^{8\ominus}$, an ellipsoid-shaped cluster anion belonging to the unusual family of V^{IV}/V^{V} oxygen clusters (C) 1719
Veticadinol, Stereoselective synthesis of *trans*-decalins via intramolecular ene reactions; synthesis of the enantiomerically pure cadinane-sesquiterpene veticadinol (C) 703
Viscoelasticity, Surfactants, micelles and fascinating phenomena (R) 902
Vitamin B_{12}: experiments concerning the origin of its molecular structure (R) 5

Water-gas shift reaction, Oxidative addition of water to the Ru^{II} catalyst $K[Ru^{II}(Hedta)(CO)]$: homogeneous catalysis of the water-gas shift reaction under ambient conditions (C) 1735
"Wittig reactions", A novel entry to the PC-double bond: the "phospha-Wittig" reaction (C) 1382
— Wittig reactions of unsaturated silicon compounds $\geq Si{=}Y$: isolation and structure of possible intermediates (C) 935
Wittig rearrangements, Asymmetric induction in the [2,3] Wittig rearrangement by chiral substituents in the allyl moiety (C) 278

Ylides, Acetylene polymerization with ylide-nickel catalysts (C) 839
— Synthesis and structure of a resonance stabilized (Trimethylphosphonio)metallapropenide (C) 587

Zeolites: catalysts for organic syntheses (R) 226
— High-resolution solid-state NMR of silicates and zeolites (B) 1410
— Synthesis of high-silica aluminosilicate zeolites (B) 1004
Zintl compounds, Isolated, complex Zintl molecules in the gas phase (C) 1091
— Tellurium-rich tellurides (R) 759
Zirconium compounds, $[M(CO)_4\{CH_3C(CH_2PMe_2)_3\}]$, M = Ti, Zr, Hf, complexes of zerovalent titanium, zirconium, and hafnium. First structural characterization of a Zr^0-carbonyl complex (C) 437
— $P_4^{2\ominus}$ Isomers as complex ligands (C) 694
