The basic philosophy of the series "Best Synthetic Methods" has already been discussed at some length in the review of the first three volumes.[*] To summarize briefly, it sets out to provide the practical chemist with the best preparative method for each case, giving all the details needed. This laudable aim has only been partly translated into reality in the volumes that have appeared up to now. Can the new title "Borane Reagents" turn out to be more satisfactory in this respect? The authors appear to have had their doubts about this, expressed in the preface as follows: "For a field as varied as the use of borane reagents this presents a considerable challenge, since literally hundreds of conceptually different important synthetic reactions are involved...". In order to adequately cover the large amount of material, the book has been divided into four sections. Section 1 describes how particular classes of compounds can be prepared using borane reagents, Section 2 describes reductions using boranes and complex boron hydrides, Section 3 deals with the different variants of hydroboration reactions, and Section 4 with the applications of organoboron compounds in synthesis. Sections 2 to 4 are generously furnished with laboratory recipes in the style of "Organic Syntheses". Regrettably, however, there is no tabulated survey of reaction examples, including conditions and yields.

The first impression is confusing; in common with other authors in this series *Pelter, Smith* and *Brown* have a tendency towards the encyclopedic. A critical selection, or an impartial comparison with alternative methods, which is after all the declared aim of the series, does not occur anywhere in the book. It is undeniable that synthesis without the help of hydroboration and reduction by boron hydrides is nowadays unthinkable, but is this also true of the many different CC bond-forming reactions of organoboranes? The addition reactions of allyl boron esters *(R. W. Hoffmann* and *W. R. Roush)* or of boroenolates *(S. Masamune* and *D. A. Evans)* to aldehydes have certainly extended synthetic capability in useful directions, but it remains to be seen how far this will be true of the Matteson reaction (dichloromethyllithium + alkyldialkoxyboranes) or of the "boron-Wittig" reaction. In general, though, it appears that synthetic chemists who happily use hydroboration or reduction by boron hydrides have not been so ready to use boranes for forming CC linkages, despite many efforts at making this attractive to them.

The division of the book into four sections has meant that much information has been delocalized all over the book and is hard to retrieve. For example, on page 59 one learns that alcohols can in general be prepared by oxidation of organoboron compounds using hydrogen peroxide, but to find synthetic methods for organoboranes one has to thumb through many pages before discovering the required information on pages 165ff. of Chapter 3. This chapter does not, however, include details of the oxidation; the necessary information on the conversion using hydrogen peroxide etc. does not appear until page 251, but the relevant laboratory procedure is on page 346. Thus, despite the very useful details which the book contains, it turns out to be a maze. In view of the fact that *H. C. Brown* has already publicized "his" reaction through numerous review articles and *three* books ("Hydroboration", Benjamin 1962; "Boranes in Organic Chemistry", Cornell University Press 1972; "Organic Synthesis via Boranes", Wiley 1975), the question arises whether there is a need for a further lengthy description. As the proportion of really new methods in the book is not very great, one is inclined to answer no to this question, especially since the days of generous library budgets are long past.

Carbyne Complexes. By *H. Fischer, P. Hofmann, F. R. Kreissl, R. R. Schrock, U. Schubert,* and *K. Weiss*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xviii, 235 pp., bound, DM 120.00.—ISBN 3-527-26948-7/0-89573-849-X

This volume, dedicated to Prof. *E. O. Fischer,* was issued in celebration of his 70th birthday on 10 November 1988. Five of Prof. *Fischer*'s former co-workers have contributed articles on the synthesis, molecular and electronic structure, reactivity, and catalysis of the "Fischer-type" carbyne complexes, joined by *R. R. Schrock* who (with *J. S. Murdzek*) has reviewed high oxidation state alkylidyne complexes, i.e. those of the "Schrock-type". This work, taken together with a previous dedicatory volume "Transition

[*] *Angew. Chem. Int. Ed. Engl. 26* (1987) 593.

[1] a) Alkylidynetricobalt nonacarbonyl cluster complexes: D. Seyferth, *Adv. Organometal. Chem. 14* (1976) 97-144; μ_2- and μ_3-carbyne complexes with different transition metal centers: b) F. G. A. Stone, *Angew. Chem. 96* (1984) 85-108; *Angew. Chem. Int. Ed. Engl. 23* (1984) 89-112; c) H. P. Kim, R. J. Angelici, *Adv. Organomet. Chem. 27* (1987) 51-112.

Metal Carbene Complexes" by the same five former coworkers with *K.-H. Dötz* (VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1983), serves as a remarkable tribute to the legacy of organometallic chemistry originated by Prof. *E. O. Fischer* and this students, over and above the contributions to the metallocenes and π-aromatic complexes for which *Fischer* was recognized by the 1973 Nobel Prize in Chemistry (jointly with *G. Wilkinson*).

The scope of the work under review is limited to mononuclear complexes containing the chemistry of the terminally bonded ≡CR group. As a matter of general information, it should be noted that the carbyne group is also observed in edge- or face-bridging positions in cluster complexes of dimetallic or higher nuclearity,[1a-c] reference to which is made in the introduction to the article by *P. Hofmann* (see below). The syntheses and chemical and structural properties of these polynuclear carbyne complexes are sufficiently different, however, to justify the decision to consider these outside the scope of the present volume.

The literature is covered to late 1987, starting with the report in 1973 of the first carbyne complex (E. O. Fischer, G. Kreis, C. G. Kreiter, J. Müller, G. Huttner, H. Lorenz, *Angew. Chem. 85* (1973) 618-620; *Angew. Chem. Int. Ed. Engl. 12* (1973) 564-565). The articles are preceded by a foreword by *W. A. Herrmann* describing some personal characteristics of Prof. *E. O. Fischer* and reviewing highlights of his scientific career. Among other things we learn that Prof. *Fischer* has an abiding interest in the history of art, one of the few diversions he has permitted himself in an otherwise absorbing career in science.

The first article in the volume is by *H. Fischer* on the synthesis of Fischer-type carbyne complexes of Group VI to VIII transition metals. Some 18 to 20 twenty methods are reviewed, starting from the original synthesis in which a nucleophile is abstracted from a Fischer-carbene in the reaction of its complex with a Lewis acid. Methods involving the abstraction of $O^{2\ominus}$ from acyl metallates, or conversion of other groups containing an sp^2-hybridized carbon, are also included, as are the conversions of complexes already containing an sp-hybridized carbon (such as CS or CNR).

The second article was contributed by *U. Schubert* and covers the reports of some eighty structures of carbyne complexes. Of these, 80% are of Group VI metal (Cr, Mo, or W) complexes. Only two of these, namely the complexes $Cp(CO)_2Cr{\equiv}C{-}CPh{=}CPh{-}C{\equiv}Cr(CO)_2Cp$, and $(t\mathrm{BuO})_3W{\equiv}CPh$, consist of an $L_nM{\equiv}CR$ unit for which structures of both the corresponding acetylene, $RC{\equiv}CR$, and the dinuclear metal fragment, $L_nM{\equiv}ML_n$, are known. The bond distances, $d(Cr{\equiv}C) = 170.7(2)$ pm and $d(W{\equiv}C) = 175.8(5)$ pm respectively, are those obtained by adding together one half of the M≡M and C≡C distances in the reference compounds. The M−C(carbyne) bond lengths for first row transition metals (Cr, Mn or Fe) are found in the range 165-175 pm, while whose for second or third row transition metals (Mo, W, Os or Ta) are in the range 175-190 pm; these constitute the shortest known metal-carbon distances.

The third article is by *P. Hofmann* on electronic structure. Analyses of ≡CR and various $\equiv ML_n$ fragments using the extended Hückel method are first presented. These are followed by summaries of results of calculations as they have appeared in the literature, including some based on other methods such as the Fenske-Hall SCF approximation or *ab initio* SCF-MO. The available theoretical work provides qualitatively consistent results explaining the important aspects of the chemistry of these complexes. Comparisons with experimental studies such as electronic absorption spectra and high resolution X-ray (X−X) determinations are also included.

The fourth article consists of a selected review by *F. R. Kreissl* of reactions of the Fischer-carbyne complexes. In these the carbyne carbon is generally found to be electrophilic, in contrast to that of the Schrock-alkylidynes in which the carbyne carbon is nucleophilic; the division is not rigid however, as some Fischer-carbyne complexes such as $C_5H_5(CO)_2M{\equiv}CR$ (M = Mo or W) reveal nucleophilic behavior at the carbyne carbon. The various chemical properties discussed for complexes of the general formula $X(CO)_nM{\equiv}CR$ are: substitution of X or CO, modification of the carbyne side chain at R, addition of a nucleophile or an electrophile at C, transfer of the carbyne ligand, and oxidation or reduction of the metal.

The article on high oxidation state alkylidyne complexes follows next. These are known for Nb, Ta, Mo, W, and Re, in which the metal is in its highest possible oxidation state, i.e. d^0, counting the alkylidyne as a trianion. The first such complex was the salt $[Li(dmp)][Ta(\equiv CCMe_3)(CH_2CMe_3)_3]$, obtained by removing the alkylidene α-proton in $Ta(=CHCMe_3)(CH_2CMe_3)_3$ with butyllithium in the presence of dmp (N,N′-dimethylpiperazine). The same general strategy proves successful for other metals, e.g. $W(OMe)_3Cl_3 + 6\,Me_3CCH_2MgCl$ (in diethyl ether at 0°C) → $W(\equiv CCMe_3)(CH_2CMe_3)_3$ (50% yield), or $MoO_2Cl_2 + 6\,Me_3CCH_2MgCl$ (in diethyl ether at −78°C) → $Mo(\equiv CCMe_3)(CH_2CMe_3)_3$ (ca. 35% yield). Additionally, complexes of other alkylidyne groups may be accessed through metathetical reactions with alkynes, or by reactions of alkynes (or, in a few cases, nitriles) with complexes containing metal-metal triple bonds. Schrock-type carbyne complexes have also been obtained by halogenation of Fischer-type carbyne complexes (*A. Mayr*), which results may explain the role of oxidizing co-catalysts in the olefin metathesis by Fischer-carbyne complexes (see below). Metallocyclobutadiene complexes and their role in alkyne metathesis, along with other reactions of alkylidyne complexes, are also reviewed. The structural properties ($M{\equiv}C_\alpha$ bond length and $M{-}C_\alpha{-}C_\beta$ bond angle) of some 16 d^0 alkylidyne complexes are tabulated, as are also some ^{13}C NMR data (C_α chemical shift $^2J(CP)$, where applicable) for over 250 alkylidyne complexes. The article concludes with a brief section on rhenium complexes. At Prof. *Schrock*'s invited lecture at the recent E. O. Fischer Festkolloquium in Garching, however, emphasis was placed on the growing importance of the d^0-alkylidyne chemistry of this metal.

The volume concludes with an article by *K. Weiss* reviewing the catalytic reactions of carbyne complexes. This begins with a section on alkene metathesis and ring opening polymerizations by carbyne complexes in the presence of Lewis acid co-catalysts; cationic complexes are believed to be the active catalysts. For the complex $Br(CO)_4W{\equiv}CPh$, the tautomeric 16-electron halogeno-carbene form $(CO)_4W{=}C(Br)Ph$ has been proposed (by *T. J. Katz*) to be the active form. Alkyne metathesis and alkyne polymerization are also reviewed, resulting in a small but not significant overlap with some material in the immediately preceding article.

All in all, I have found this work to be uniformly well written, well balanced in its coverage, and free of errors. I highly recommend it to every chemist interested in organometallic chemistry and the applications of organometallic compounds to catalysis. For the benefit and encourage-

ment of younger chemists, in the spirit of Prof. *E. O. Fischer* to whom this work is dedicated, I also recommend to the publishers that they should produce a paperback student edition.

From CA to CAS Online. By *H. Schulz.* VCH Verlagsgesellschaft, Weinheim 1988. xii, 227 pp., hardcover, DM 56.00.—ISBN 3-527-26866-9

The book comprises two parts; the first by *Hedda Schulz* is principally concerned with the hard copy services available from Chemical Abstracts, while the second, largely written by *H. R. Pichler,* deals with CAS Online.

After a brief introduction, the first part of the book is devoted to explaining the organization of the material within Chemical Abstracts. It starts by illustrating the differences in the information provided in abstracts of journal articles, patents, books, dissertations, etc. Unfortunately, unnecessary repetition of pointers to CA volume number and abstract number, language indicator and the like, has tended to obscure the useful guidance given here.

However, the larger part of this section of the book is devoted to illustrating (a) the indexes provided with each issue of Chemical Abstracts, (b) the volume indexes, and (c) the collective indexes. The approach is very thorough and the use of examples of searches to highlight the different informational content of the indexes is very helpful. Great emphasis is placed on the need to consult the Index Guide, which is so often overlooked even by experienced searchers.

The section ends with a brief mention of the various computer readable services produced by Chemical Abstracts and with an introduction to CAS Online. Whilst mention is made of the other hosts providing online access to Chemical Abstracts files, prominence is given to the CAS Online service, but some of the statements made are open to debate.

In Chapter 8, Mr. *Pichler* follows the elementary approach favored by *Hedda Schulz* but in this case most of the information provided is readily available in publications produced by Chemical Abstracts themselves. The "official" Chemical Abstracts guides to CAS Online are quite outstanding, being very informative and illustrated with many examples, and the availability of these, together with the excellent training and instruction manuals provided by all the Online vendors, seriously reduces the value of this part of the book.

In the last chapter an attempt has been made to compare conventional searches through hard copy with online searching, by repeating some of the searches set out in Part 1. Unfortunately, since the online part of this comparison appears to have been carried out by inexperienced searchers and no attempt has been made to check the relevance of the answers, this section adds nothing to the debate.

Thus the Fischer–Tropsch search illustrated in Part 1 using hard copy indexes was repeated online using an almost identical approach, to give 895 references from six months of Chemical Abstracts. It would have been much more interesting to see if the 71 references found immediately with the first simple strategy represented the total available from that particular volume. This would have illustrated the great advantage of online searching for such subjects, and established the cost effectiveness or otherwise of using online in preference to conventional methods.

When repeating the search for DOS, a plasticizer, the searcher misinterpreted the online search output, which showed that references were available in CAOLD, and failed to notice that the manual search had given identical results.

Recent advances in online search facilities, for example training packages such as the STN Mentor series, and front-end packages such as STN Express, have further changed the overall picture with regard to instruction books such as this.

However, whilst the book is somewhat eulogistic about CAS Online and STN, the first part by *Hedda Schulz* is sufficiently useful to make it worth consideration, especially for academic institutions with limited online facilities.

European Materials Societies

Editorial Essay

By Robert Lallement*

It is well known that many major changes in human history have coincided with the mastering of the technology of new materials, so that we read of the Stone Age, then the Bronze Age, followed by the Iron Age. Each breakthrough in materials technology has brought about a modification in the habits of men and their ways of life. Whether the changes have been good or bad is another question ... Nevertheless, it is a fact that the peoples or nations who achieved such breakthroughs usually also gained political power. This applies equally to the Hyksos, who conquered Egypt 4000 years ago through their mastery of the use of horses, metals, and war chariots, and to the nations which today have the technology for using nuclear materials.

What label can be applied to the age we now live in?—perhaps the steel and concrete age, or the plastics age? Are we now entering the era of titanium, carbon and plutonium?

The current worldwide interest in materials R & D has as its background the clear relationship that exists between technological progress and the discovery and mastering of new materials. This is not merely a passing fashion of the eighties, even though the fascination which the topic has for the media and for technical and political official bodies may sometimes appear exaggerated and irritating.

Leaving aside the materials mania, the facts which concern us as scientists are that, in the first place, advances in materials science have an essential role in the future of mankind, and secondly, the last ten or fifteen years have seen a scientific revolution in the approach to materials science. Before this, the subject was treated essentially through a *categorial* approach, with distinct sciences of ferrous materials, ceramics, plastics, etc., which were rigidly separated and did not interact very much. That approach has become less and less valid, and nowadays the optimum use of materials requires an *integrated* approach. The only effective way to prepare students and researchers for real life in our universities or laboratories is to teach them the *science of materials*, which is a cocktail of chemistry, physics, metallurgy, mechanics, and even other sciences. Our old categories are exploding and fading away:

Come teachers and searchers
Throughout the land
And keep your eyes wide open
The chance won't come again
Your old road is rapidly ageing
For the times they are a-changing.

Adapted from a song by *Bob Dylan*

The metallurgical societies, which were established according to the old categories, must adapt themselves, and these changes are already beginning. For example, the (UK) Institute of Metals has now become the Institute of Materials, the (US) Metallurgical Society is now the Minerals, Metals and Materials Society, and the Société Française de Metallurgie may soon become the Société Française de Métallurgie et des Matériaux.

Along with these trends towards increasing integration between the different aspects of materials science, we are also beginning to see moves towards growing European integration, where the long-established national scientific societies are now finding that they need to adjust to the de-

veloping European Physical Society, a Federation of European Chemical Societies, a European Polymer Federation and similar societies for other disciplines, and it seems likely that eventually we shall have a European Materials Society. At present, though, we are far from that goal. Many of the national societies in European countries are fighting for survival. They suffer financial difficulties, they sometimes find it a struggle to organize meetings that come up to the best international standards, and they compete with difficulty against the well organized US and Japanese scientific bodies.

Recognizing these problems, the Institute of Materials (IOM), Deutsche Gesellschaft für Metallkunde (DGM) and Société Française de Métallurgie (SFM) decided early in 1988 to join together and create the Federation of European Materials Societies (FEMS). I have the honor of being elected as the first acting president of FEMS. It is satisfying to report that many national bodies in Europe have responded positively to our invitation to join the Federation. We have already launched a first European Technical Conference, EUROMAT 89, to be held in Aachen in November 1989, and further European conferences are in preparation. In addition we have already signed an agreement with the Minerals, Metals and Materials Society for future collaboration. This is a significant step towards an effective and cordial relationship with the US scientific community. These and our other activities are expected to make a major contribution towards improving international communication in the world of materials science and engineering.

Dr. Robert Lallement, born in 1934, graduated from Ecole des Mines de Paris in 1955. He received a Master of Science from Caltech, Pasadena, CA in 1959 and an Ingénieur Docteur from Paris University in 1963. In 1969 he became Head of the Metallurgy and Fuel Division in the French Atomic Energy Commission (CEA); since 1982 he has been in charge of the nuclear programs in the French CEA. Dr. Lallement has been Acting Chairman of the French Metallurgical Society since 1987 and he is the first president of the Federation of European Materials Societies.

The following review articles will appear in future issues:

G. M. Whitesides, C. D. Bain: Modeling Organic Surfaces with Self-Assembled Monolayers

F. Garnier: Functionalized Conducting Polymers—Towards Intelligent Materials

D. W. McCall: Materials Issues in Electronic Systems

W. Michaeli: Material Processing—a Key Factor

B. R. Philips, D. Tanner, J. A. Fitzgerald: The Kevlar Story—An Advanced Materials Case Study

M. Salkind: Aerospace Materials Research Opportunities

D. F. Williams: Challenges in Materials for Health Care Applications

From March 1st, the editorial team of Advanced Materials will be strengthened by the appointment of Dr. Peter Gregory as Associate Editor. Peter Gregory studied chemistry at University College London, England, gaining a B.Sc. in 1983 and a Ph.D. working in the research group of Alwyn Davies in 1986. His doctoral work included a study of the radical and radical ion chemistry of polyacetylenes and other industrially utilized polymers along with research into the single electron transfer reactions of organic molecules in general. He then moved to West Germany, working for just over two years in the interdisciplinary research group of Paul Schleyer at the University of Erlangen-Nürnberg. Here he gained experience in a number of areas, ranging from spectroscopy and crystallography, through the development of high density materials, to the application of computers in chemistry. With this broad background he will help make Advanced Materials the journal which best serves the needs of the materials science community.

ADVANCED MATERIALS

Advanced Zeolite Materials Science**

By Geoffrey A. Ozin,* Alex Kuperman, and Andreas Stein

Molecular Electronics
Quantum Dots/Chains
Zeolite Electrodes, Batteries and Membranes
Nonlinear Optical Materials
Chemical Sensors
Zeolite-Polymer Composites

1. Introduction

In today's search for smaller, faster, more selective and efficient products and processes, the ability to engineer well defined spatial microarrangements of pure substances and composite materials is becoming pivotal in creating new molecular level electronic, optical and magnetic devices. One attractive method for assembling and maintaining controlled microstructures is to use solid host lattices that serve as templates within which a guest stucture of nanometer architecture can be assembled. It is the thesis of this paper that zeolites as microporous molecular electronic materials with nanometer dimension window, channel and cavity architecture represent a "New Frontier" of solid state chemistry with great opportunities for innovative research and development.

Since the first synthetic preparation of zeolites by *Barrer* in the 1940's[1] these aluminosilicate materials have been used in large quantities for hydrocarbon conversion, size/shape selective heterogeneous catalysis, gas separation and purification, as well as for ion exchange, dessication and sorbing processes.[2] Although only few zeolite compositions are used in large scale processes, the number of specifically tailored zeolite structures and modifications has increased immensely within the last decade, along with the number of publications concerning new physicochemical characterization techniques for these framework materials. In zeolite characterization X-ray and neutron diffraction, solid state magic angle spinning (MAS) NMR and FT mid and far infrared spectroscopy have proven particularly useful.[3] Combined, these methods provide comprehensive information about zeolite physicochemical properties and allow one to monitor transformations of and within the zeolite lattice.

Much zeolite research and development is still aimed at the traditional uses mentioned above. However, within the last few years considerable effort has been directed at new uses of zeolites as advanced materials. For example, in the field of solar energy conversion technology a spatially well organized molecular system is required that models photosynthetic mechanisms, thereby allowing redox reactions to proceed efficiently along desired paths. Other potential applications include zeolite electrodes and electron relays, zeolite batteries, zeolite fast ion conductors, intrazeolite semiconductors, zeolite chemical sensors, zeolite imaging and data storage materials, zeolite lasers and displays, as well as zeolite composites to form permselective membranes or thin films.

Most of the traditional and advanced applications for zeolites are based on the ability of these open crystalline structures to selectively incorporate and exchange both charged and neutral species within the void spaces and interconnecting channels on a molecular scale. In order to appreciate the unique features of zeolites it is necessary to take a brief look at their structures and compositions. Conventional zeolite structures are composed of three dimensional networks of SiO_4 and AlO_4 tetrahedra in which a unit negative charge is associated with each AlO_4 tetrahedron. This charge must be counter-balanced by a positive inorganic or organic ion. Depending on the type of connection between tetrahedral building blocks, linear or pseudo-linear channels may be formed with diameters ranging from 4.2 to 7.4 Å. In other structural types cages are formed with diameters of 6.4 to 12 Å and window sizes from 2.3 Å (6-ring) to 13 Å (18-ring). Figure 1 illustrates some typical examples of commonly encountered zeolite structures.

Isomorphous replacement of framework $Al^{3\oplus}$ and $Si^{4\oplus}$ by other elements such as $Ga^{3\oplus}$, $Ge^{4\oplus}$, $B^{3\oplus}$, $P^{5\oplus}$ as well as enrichment in framework $Si^{4\oplus}$ can be readily achieved. Most notable in this context are synthetic strategies that lead to highly or completely siliceous zeolites like ZSM-5 and silicalite as well as a new generation of molecular sieves exemplified by the aluminophosphates (ALPO's), silicoaluminophosphates (SAPO's) and their metal doped analogues denoted MAPO's and MAPSO's, where, for example, M = Li, Be, Mg, Cr, Mn, Fe, Co or Zn. The lattice of silicalite is neutral in contrast to the positively charged SAPO lattice which is negatively charged when $P^{5\oplus}$ has been partially replaced by $Si^{4\oplus}$, allowing for cation exchange. Recently a novel positively charged SAPO lattice has been synthesized in which $Al^{3\oplus}$ has been partially re-

S.* is deeply indebted to NSERC for a science graduate scholarship. Preprints of manuscripts from Professors *Tom Mallouk* and *Thomas Bein* assisted us greatly in the writing of this review paper. We also thank all our coworkers at the University of Toronto for many enlightening suggestions and discussions during the course of our research in advanced zeolite materials science.

placed by $P^{5\oplus}$, now permitting the less common mode of anion exchange.[4] The majority of the new generation molecular sieves crystallize with an encapsulated organic template, usually a charge balancing alkylammonium ion. The template can be effectively removed by controlled calcination procedures to yield the protonated analogue of the sieve which can often be subsequently ion-exchanged for other cationic guests. A wide variety of guests have been encapsulated in zeolites ranging from atoms, ions, metal clusters and salts to coordination complexes and organometallics. Until very recently this kind of inclusion chemistry has been driven mainly by the science and technology of specific molecule adsorption and diffusion, molecular sieving and chemical/catalytic transformations, usually taking advantage of restricted geometry environments.

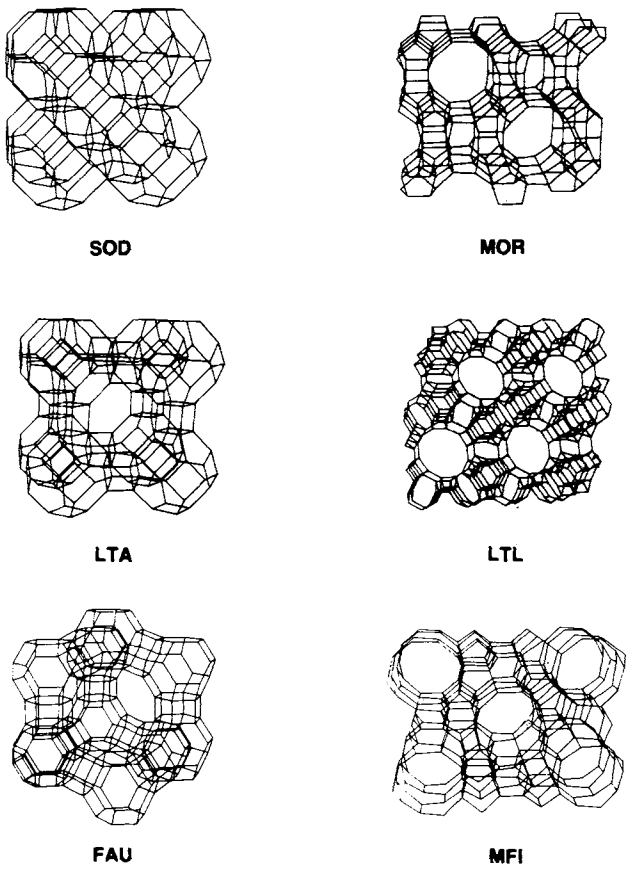

Fig. 1. Some typical zeolite structures: (SOD) sodalite, (LTA) Linde type A zeolite, (FAU) faujasite: zeolites X or Y, (MOR) mordenite, (LTL) Linde type L zeolite, and (MFI) ZSM-5 [49].

In view of the impressive range of zeolite framework structures and element substitution, rich extraframework cation modification, variety of encapsulated guests, tunable Brønsted acidity and lattice oxygen basicity, as well as the controllable hydrophobic/hydrophilic character, one can envisage that future innovations in the field will likely occur at the interface between zeolite science, solid state chemistry and molecular electronics.

2. Intrazeolitic Semiconductors

While the physical properties of materials are fairly well understood on both the molecular and bulk levels, the quantum size regime encompassing microscopically structured solids from 5 to 100 Å is the subject of much current research.[5] Particles of this size display electrical, optical and magnetic properties that are essentially independent of their chemical composition, but are related instead to their extremely small dimensions.

The tremendous present interest in ultrasmall semiconductor particles can be considered to derive from the original notion of artificially layered structures known as semiconductor superlattices, and from the exciting optical and electrical properties that such quasi-two dimensional (2D) electron systems offer. The formation of modulated chemical composition layers of this kind with a periodicity larger than the natural lattice spacing but smaller than the de Broglie wavelength of electrons of the semiconductor components, allows the realization of band gap engineering, heterojunctions, composition and doping superlattices, multiple quantum well (MQW) lasers, high electron mobility transistors, (HEMT's) non-linear optical (NLO) superlattices and optical transistors (transphasors) to name just a few applications.[6a]

Theoretical considerations have indicated that quantum size effects are significantly enhanced when the dimensionality of a quasi-2D semiconductor is further reduced. For example, strongly enhanced electron mobilities and resonant tunneling have been predicted and recently observed in the case of quantum wires and quantum boxes. Fundamental alterations in their electronic/optical properties are expected by the novel 1D and 0D quantum confinement of excitons and the modified density of states.[6b]

A major challenge in the synthesis of spatially resolved materials is the reproducible fabrication of microscopically organized semiconducting solids having quasi-1D and quasi-0D electronic/optical properties. Common methods for producing quantum microstructures include molecular beam epitaxy (MBE), metal-organic chemical vapor deposition (MOCVD), electron beam lithography and reactive ion etching.[6b, 7] As a way to avoid the minimum size limitations of electron-beam lithography, which are typically ca. 0.02 μm,[6b, 8] quantum size particles have been prepared and studied in liquid suspensions, micelles, glasses, and zeolites.[9] Host matrices like zeolites reduce the interchain and interlayer perturbation often encountered in other low dimensional solids.[10] Zeolites have an advantage over the other matrices listed, because they permit the ordered inclusion of particles with very small dimensions and a very uniform size distribution. By using zeolites of different architecture the spatial arrangement of

ADVANCED MATERIALS

the quantum size particles can be controlled and cluster growth constrained to molecular dimensions. At the same time the zeolite lattice provides a stabilizing medium because of kinetic impediments imposed on further agglomeration processes. Modification of framework charge density and electric field gradients provides extra flexibility for designed perturbation of the entrapped semiconductor characteristics (i.e. a semiconductor-support effect).

In what follows we describe some pioneering experiments aimed at producing well defined semiconductor quantum dots and semiconductor superlattices in various zeolite hosts.

3. Quantum Dots and Semiconductor Superlattices

An intriguing new avenue of advanced zeolite materials science involves the synthesis and stabilization of isolated sub-colloidal dimension intrazeolite semiconductor aggregates. As the pore filling of the zeolite is increased a percolation threshold is reached. At this point a semiconductor supercluster lattice is created by the 3D interconnection of intrazeolite quantum dots to yield materials with properties intermediate between those of discrete, "molecule-like" semiconductor clusters and bulk semiconductors. Experiments of this kind have been reported for narrow band gap semiconductors like CdS, CdSe and PbS.

Herron et al.[11, 12] have recently succeeded in incorporating semiconductor materials inside zeolites X, Y, and A. Such particles are referred to as "quantum dots" in the terminology of finely divided semiconductors. Excitons in these materials are confined in three dimensions. Due to the small size and reduced dimensionality of the occluded semiconductors, their electronic properties are altered. Absorption edge energies of confined CdS microcrystals are larger than in the bulk semiconductor,[8] so that spatial confinement of these materials allows for band gap adjustment. As the semiconductor cluster size decreases the excited-state relaxation dynamics are also influenced considerably by the host and its interface with the semiconductor.[11]

CdS particles were synthesized inside the zeolite A, X or Y framework by exposing the calcined $Cd^{2\oplus}$ ion exchanged zeolite to flowing hydrogen sulfide at 100°C. X-ray diffraction (XRD) and extended X-ray absorption fine structure (EXAFS) results revealed that discrete, cubic $(CdS)_4$ clusters (interpenetrating Cd and S tetrahedra) with a Cd-S bond length of 2.47 Å were formed strictly inside the smaller sodalite cages, where a stabilizing interaction between the cluster and framework oxygen of the double 6-rings was possible (Fig. 2). At low $Cd^{2\oplus}$ loading these clusters were isolated but formed an interconnecting extended supercluster structure as the cluster concentration increased. In this case the Cd-Cd separation between adjacent sodalite cages was ca. 6 Å, allowing for long-range interactions. It has been suggested that the supercluster was formed by a percolative process with a percolation threshold of 4 ± 1 wt%. At higher loading $(CdS)_4$ clusters must populate adjacent sodalite units. The highest CdS loading that was achieved (ca. 23 wt%) filled nearly all sodalite cages. The CdS clusters, as well as PbS clusters encapsulated in zeolites[13] were stable for at least six months in a dry, oxygen-free environment.

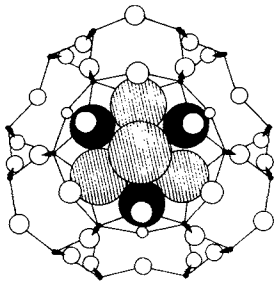

Fig. 2. Representation of the Cd_4S_4 cube inside the sodalite unit [12, 14].

Optical absorption near 290 nm characterized these ultrasmall semiconductor aggregates. Discrete $(CdS)_4$ cubes began to interconnect at higher loading densities to create a supercluster structure displaying optical absorption near 350 nm. The latter absorption is likely due to an exciton transition similar to that found in 25–30 Å colloidal CdS particles. Above the percolation threshold the absorption spectra became independent of the CdS concentration. *Wang* and *Herron*[11] studied the photoluminescence and relaxation dynamics of the superclusters. The three different emission bands observed were attributed to defect luminescence: a yellow/green band due to Cd atoms, a red band caused by sulfur vacancies, and a blue band due to shallow donors, which was probably also sulfur related. Defects like these break up the supercluster into smaller units of irregular sizes. The authors believe that the effect of the surrounding matrix on the absorption spectra of the semiconductor clusters was small, and did not alter the conclusions drawn about quantum size effects.

It has been found that partial occupancy of zeolite sites by $Cd^{2\oplus}$ produces CdS supercluster size distributions in the zeolite lattice rather than the possibly more desirable homogeneous semiconductor superlattice. Only in the case of zeolite X with the highest ion-exchange capacity, can the maximum loading of 25 wt% CdS be achieved which is close to the 27 wt% required for filling available sodalite cages. A similar investigation by *Moller* et al.[14] involved the incorporation of quantum size CdSe clusters in zeolite Y, which are of interest in the study of photosensitized electron-transfer reactions utilized for solar energy conversion and photocatalysis. A mixture of CdSe and probably helical Se chains was obtained.

The early results from these systems support the idea that semiconductor loaded zeolites have the potential to be tuned from 0D quantum dot type structures to 3D superlattice structures, the spatial arrangement and distribution of which are controlled by the templating action and framework architecture of the zeolite host.

4. Silver Sodalites: Novel, Optically Responsive, Packaged Silver Salts

β-Cages are the building blocks for several classes of zeolites. The zeolites composed exclusively of β-cages, called sodalites, have been studied mainly as model compounds for larger zeolite systems. Because of their small entrance windows (2.3 Å diameter) which block the passage of most molecules, sodalites have not been used in applications involving catalysis or gas separation. However, closer inspection leads to the realization that the sodalite lattice forms a convenient matrix for encapsulation of a variety of guests. By controlling the loading of the trapped species, it is possible to form cluster and extended supercluster structures in the quantum size regime, similar to the semiconductor superclusters described in the previous section. One important advantage of sodalites is that the lattice is comprised entirely of close-packed sodalite cages, rather than the coexisting sodalite and supercages of other zeolite hosts, thereby permitting direct or through-bond interaction between guests in *all* cages. In addition, the presence of guest-anions make sodalites unique. These can be used as internal reagents (e.g. for intra-sodalite cage redox reactions) and provide great flexibility in the composition of trapped species. By judicious selection of the anion and cation one can form packaged insulators and semiconductors as well as metals within the sodalite framework. Control of the guest-concentration in sodalites facilitates the transition above a percolation threshold (PT) from molecular type species to expanded bulk materials, as illustrated in Figure 3.

One facet of Figure 3 has recently been studied in our laboratory.[15] A range of novel silver sodalites have been synthesized. These solid state microstructures are viewed as "packaged" silver salts comprised of nanoassemblies of silver cations tetrahedrally organized with various charge balancing anions. A collection of physicochemical characterization techniques have been employed to interrogate the structure and properties of the parent silver sodalites, as well as the chemical and physical transformations of the encapsulated silver salts that relate to a number of transducer effects. An interesting question in these materials concerns intercavity communication between aggregates of the entrapped silver salt and the connection of their properties with those of the analogous bulk phase material (such as electronic transport, photoconductivity, photoaggregation and photoluminescence). Intracavity redox processes that produce encapsulated silver clusters and expanded-metal-superlattice phenomena above the PT loading level are also intriguing avenues of enquiry within the silver sodalite family of materials. In this section we will briefly describe the synthesis and characterization of a few key silver sodalites and examine their possible utilization in high resolution imaging/printing and high density data storage applications. A summary of some of the attractive features of silver sodalites in solid state chemistry is presented schematically in Figure 4.

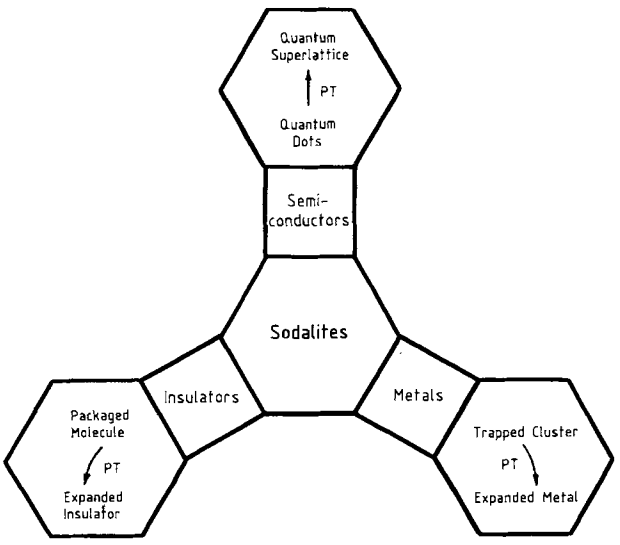

Fig. 3. Origami diagram showing the transitions between isolated and expanded insulators, semiconductors and metals that can potentially be formed within sodalites (PT = percolation threshold) [15].

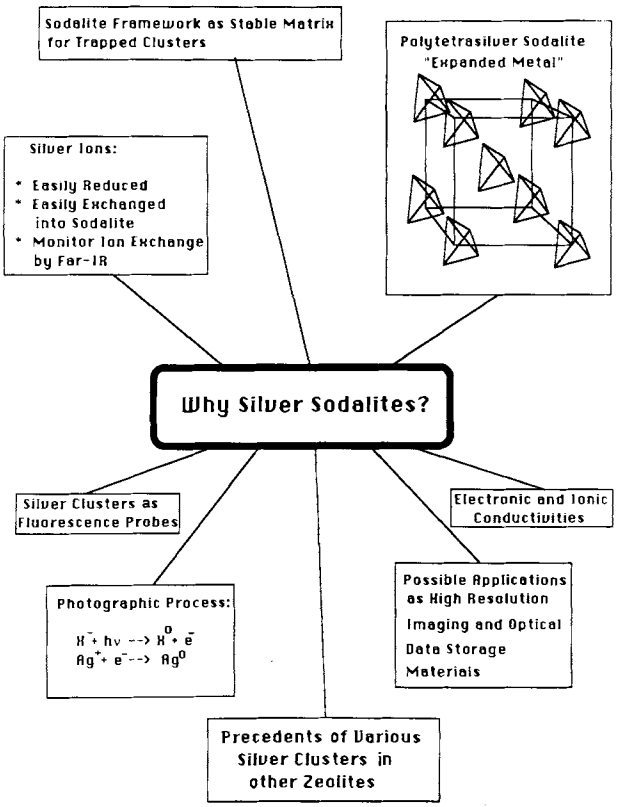

Fig. 4. Summary of the attractive features of silver sodalites in solid state chemistry [15].

ADVANCED MATERIALS

Sodalites with sodium cation guests are readily synthesized by hydrothermal reactions of silicate and aluminate sources (e.g. kaolin; or silica gel and sodium aluminate) with the appropriate anion salt in concentrated NaOH solutions. Sodium ions are exchanged for silver ions in a silver salt melt, or in some instances, in a silver salt aqueous solution. The framework structure is generally maintained after exchange, as confirmed by powder X-ray diffraction studies and mid-IR spectroscopy of the framework vibrations. The silver sodalites prepared to-date in our laboratory are listed in Table 1. The silver exchange process is conveniently monitored by the accompanying intensity changes of diagnostic sodium and silver ion translatory modes in the far-IR as well as by shifts in the frequencies of far-IR anion translations.

Table 1. Silver sodalites [15, 48].

Sodalite Type	Reason for Study
Ag, Cl–SOD	Analogues to photochromic and cathodochromic sodalites
Ag, Br–SOD	Similarities with photographic process
Ag, I–SOD	Occluded guest species are photoconductors, semiconductors, fast-ion conductors Study variation in properties down a group
Ag, S–SOD	Sensitization
Ag, Br, S–SOD	Photographic imaging
Ag, OH–SOD	Some hydroxide present in most hydrothermally prepared sodalites
Ag_6–SOD	Cages contain only three silver ions and no anion Occluded metal clusters Expanded metal Quantum size effects
Ag, CO_3–SOD	Intracage anion decomposition possible
Ag, HCO_2–SOD ≡ Ag, Fo–SOD Ag, C_2O_4–SOD ≡ Ag, Ox–SOD Ag, ClO_4–SOD Ag, SO_x–SOD	Redox switching
Na, Ag, X–SOD	Mixed cation systems to study silver concentration effects Tunable insulators /semiconductors (NaX: insulators; AgX: semiconductors, ion conductors)

Many of the silver sodalites prepared in these studies are novel materials. Interesting responses in color as well as luminescence properties were observed upon exposing several compositions to a variety of physical stimuli, including heat, light, pressure, moisture, X-rays and e-beams (Table 2). Some of the changes were reversible or semi-reversible.

The observed effects are related to the ease of silver reduction and the ability of the silver to form small clusters or expanded superclusters within the sodalite framework. In silver hydroxo-, formato- and oxalato sodalites this is facilitated by the intrazeolitic redox reactions (1)–(4). Reaction (4) can be effected both thermally and photolytically. Depending on the level of silver exchange, aggregates of the type $(Ag_nNa_{4-n})^{q\oplus}$, $n=0$ to 4, may be formed within the cages, where charge variations of q in the range $q=(4-n)$ to 4 can lead to the observed optical responses.

$$2\,Ag^{\oplus}(Z) + H_2O(Z) \longrightarrow 2\,Ag^0(Z) + 1/2\,O_2 + 2\,H^{\oplus}(Z) \quad (1)$$

$$2\,Ag^{\oplus}(Z) + OH^{\ominus}(Z) \longrightarrow 2\,Ag^0(Z) + 1/2\,O_2 + H^{\oplus}(Z) \quad (2)$$

$$2\,Ag^{\oplus}(Z) + HCO_2^{\ominus}(Z) \longrightarrow 2\,Ag^0(Z) + CO_2(Z) + H^{\oplus}(Z) \quad (3)$$

$$2\,Ag^{\oplus}(Z) + C_2O_4^{2\ominus}(Z) \longrightarrow 2\,Ag^0(Z) + 2\,CO_2 \quad (4)$$

The silver, oxalato-sodalite (Ag, Ox–SOD) system will be used as an illustrative example. The results of a full-profile Rietveld analysis of X-ray powder diffraction data for completely silver ion-exchanged Ag, Ox–SOD showed that the intracage Ag-Ag distances varied from 4.5 Å to ca. 6 Å, and intercage Ag-Ag distances from 4.5 to 4.9 Å, depending on the cage contents. These interatomic distances are too long for direct overlap of the silver orbitals but they are well within the range of through-bond interaction involving the sodalite framework. Such long range interactions would allow the formation of an expanded silver supercluster. From a unit cell size study of Na,Ag,Ox-sodalites with various silver loadings, together with transmission electron microscopy (TEM) and powder XRD data, it was determined that β-cage encapsulated $Na_n^{\oplus}Ag_{4-n}^{\oplus}$ moieties were distributed statistically throughout the sodalite lattice, in a solid-solution like manner as a function of n.

After aqueous silver exchange, Na,Ag,Ox-sodalites are white. Following thermal treatment at a temperature allowing for intrazeolite oxalate redox reaction (4), the materials

Table 2. Qualitative responses of silver sodalites to various physical stimuli [15, 48].

Barochromic:

White Ag, OH–SOD or Ag, HCO_2–SOD samples darken upon application of pressure.

Hydrochromic:

Ag, OH–SOD undergoes a reversible color change upon dehydration.

Photochromic:

Color changes and/or sample darkening can be produced by irradiation of Ag, Ox–SOD, Ag, OH–SOD, $AgCO_3$–SOD, Ag, HCO_2–SOD and sulfur-doped silver sodalites with various light sources.

Thermochromic:

Na, Ag, Ox–SOD, Ag, OH–SOD and sulfur-doped silver sodalites undergo various color changes upon heat treatment.

X-ray sensitivity:

White Ag, Ox–SOD turns yellowish green upon exposure to X-rays.

Fluorescence changes:

Heat, light and X-rays can induce Na, Ag, Ox–SOD samples to fluorescence under UV-light.

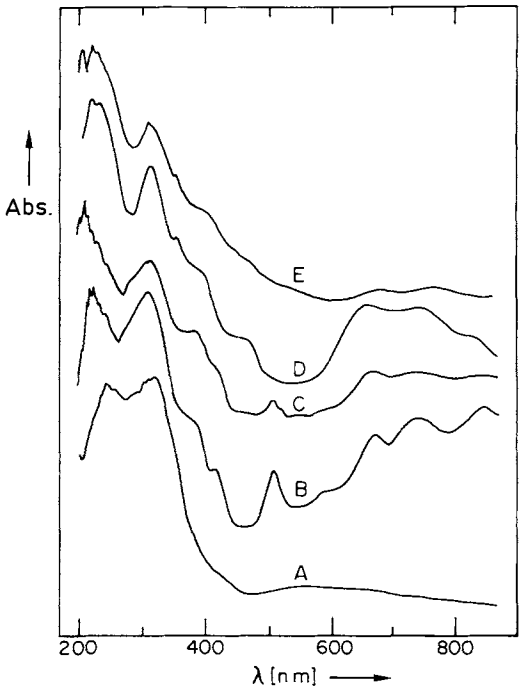

Fig. 5. UV-visible reflectance spectra of oxalato sodalites. A) Na,Ox-SOD (white); B) Na,Ag,Ox-SOD (1 Ag/unit cell), (light grey); C) Na,Ag,Ox-SOD (2 Ag/unit cell), (bluish grey); D) Ag,Ox-SOD (green); E) Ag,Ox-SOD, exposed to sunlight for four days (pale yellowish green). Samples B–E had been synthesized by $AgNO_3$-melt exchange at 230°C [15, 48].

absorb light in the UV and visible regions, the absorption spectrum depending on the silver concentration (Fig. 5). Concentration effects are also exhibited by the position of the most intense emission bands. Variations in both the identities of trapped silver clusters and the unit cell sizes could be responsible for the shifts in transition energies.

The fate of the oxalate ion during thermal treatment was followed by thermogravimetric analysis coupled with mass spectrometry (TGA-MS), mid-IR spectroscopy and powder X-ray diffraction. A comparison of the results for sodium oxalato-sodalite and silver oxalato-sodalite indicated that the reduction potential of the cation directs the reaction mechanism. While in the silver oxalate sodalite the anion is oxidized to CO_2 with concomitant reduction of the silver ions, oxalate ion decomposition in the sodium oxalate sodalite produces CO and $CO_3^{2\ominus}$, with no redox reaction occurring. In Na,Ag,Ox-sodalites the degree of silver exchange can thus be used to control not only the optical and structural properties, but also the thermal behavior of the sodalite.

Although the number of electron equivalents involved in intracavity silver ion reduction was shown to be relatively small, the alterations in silver cluster optical properties that ensue are quite spectacular. As a result, the silver sodalites lend themselves to applications in high resolution imaging and optical data storage, because the regular close-packed framework structure can trap and stabilize clusters formed inside. During a write cycle these clusters can be manipulated by the physical or chemical treatments described above (Table 2) to change their optical properties and produce a mark on the sodalite samples. The presence or absence of an optically absorbing or fluorescing mark defines a binary state. The size of the mark is affected mainly by the silver distribution, the sodalite particle size and the writing mechanism employed. The sodalite may be in the form of a self-supporting pressed disk, suspended in another material (e.g. glass or polymer), or supported on a substrate as a thin film.[15]

5. Quantum Chains

The isolation of selenium chains with controlled lengths and conformations in a zeolite host provides an interesting opportunity to probe quantum size effects in a 1D semiconductor. This type of selenium falls into the category of a "quantum chain", and may comprise a system that can exhibit discrete energy levels within the bulk semiconductor band structure with quantization of electronic properties in one dimension. One can expect isolated selenium chains to bridge the behavior between atomic/molecular forms of selenium and the bulk semiconductor trigonal form. In this regard, some interesting structure-property questions arise concerning the effects of interchain interactions, spatial restrictions and confinement on chain conformation. Selenium is of interest, because it has an intermediate electrical conductivity with a negative coefficient of resistivity in the dark. It is markedly photoconductive and has uses in, for example, photoelectric devices and xerography.

Bogomolov et al.[16] stabilized single selenium and tellurium chains in the unidimensional mordenite channels by injecting Se or Te into the zeolite from a melt under pressure or by incorporating the chalcogenide in the mordenite channels by vapor phase absorption. Isolated Se chains in mordenite channels are strongly photosensitive.[17] Results from a quantitative X-ray microprobe analysis indicated that one trigonal (helical) Se or Te chain was present in each channel with a period multiple with that of mordenite. The important question of whether the Se chains were actually *included and isolated* within the zeolite was addressed by *Tamura* et al.[17] The Se uptake (23%) in mordenite agreed with an estimate based on the assumption that the bond length of a single occluded Se chain is 2.32 Å and that the chain forms the same helical structure as in the crystalline trigonal Se. High-resolution electron micrographs of mordenite, into which Se had been inserted[10] provided further evidence of the inclusion of Se chains. This analytical technique, together with EXAFS, ^{77}Se MAS-NMR, and optical spectroscopy has provided impressive details on the distribution and form of channel confined selenium, intrachain bond length and conformational information as well as a preliminary insight into quantum size effects in one dimension. From inspection of

Figure 6a, one can determine that only one Se chain is capable of being accommodated in the large channel of mordenite. Occupied mordenite channels could be distinguished from empty channels in high resolution micrographs of Se_n/MOR (Fig. 6d). Here the white bands show white dots for the main and subsidiary channels devoid of selenium, whereas the dark bands show black main channels and white small channels. This confirms that the selenium is indeed incorporated into the large channels of mordenite.

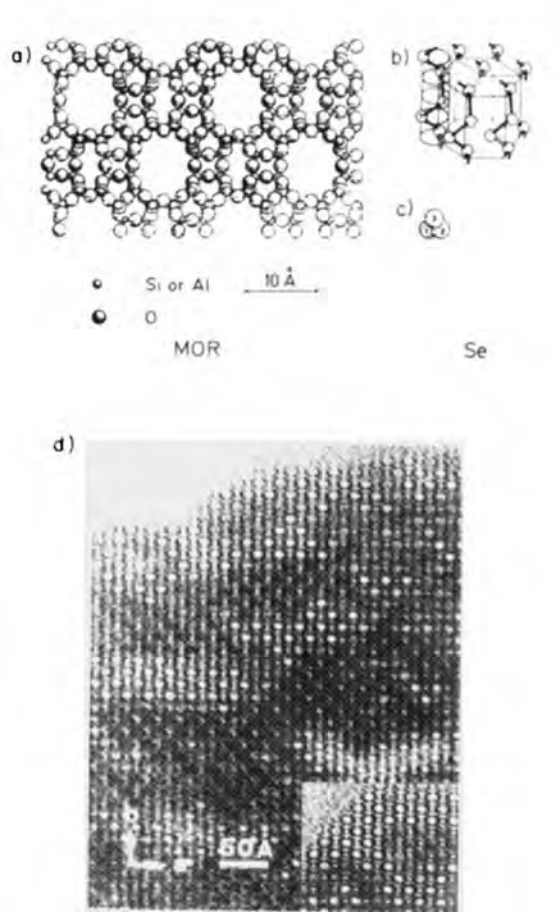

Fig. 6. a) Schematic drawing of the framework structure of mordenite (along [001]). b) The structure of crystalline Se, shown in elevation. c) A projection of the chain of Se along the *c*-axis. d) High-resolution electron micrograph of mordenite into which Se has been inserted. The regions of light contrast are seen to be indistinguishable from mordenite devoid of any guest species. At the regions of dark contrast, caused by uptake of Se the small channels are still empty as indicated by the small white dots [10].

Parise et al.[18] extended the incorporation of selenium chains to other molecular sieves, including zeolites A, X, Y, AlPO-5 and mordenite. Their study showed how the zeolite framework structure can be used to direct the growth of the occluded selenium to its various allotropes. In all samples the band gaps blue-shifted from the respective band gaps of the bulk trigonal and monoclinic forms. While only Se_8 crown rings formed inside zeolite A (band gap close to the value for monoclinic Se: Se_8 rings), helical chains predominated in the other zeolites (band gap-energy close to that for trigonal Se). In the X and Y samples the framework system was occupied by a mixture of selenium allotropes and helical chains. Mordenite and AlPO-5 resulted in the highest degree of order, having single helical chains in the 12-ring channels, with a Se-Se distance (2.34 Å) ca. 2% shorter than in crystalline trigonal Se (2.373 Å).

The particle size dependence of the band gap of semiconductor materials like ZnS, CdS, PbS is now well documented. Their optical properties have been reasonably described by the "electron-hole in a sphere" model of *Brus* and the increase in band gap follows as a result of the 3D spatial confinement of the electron-hole pair. Unlike these isotropic semiconductor particles, selenium is structurally unique in its ability to exist as helical chains and Se_8, Se_7, Se_6 puckered rings, with intraatomic chain and ring bonding being much stronger than inter-chain and inter-ring interactions. It is noteworthy that the theoretical models for size quantization effects in the optical absorption spectra of layered semiconductor colloidal particles involve modifications of the electron-in-a-cubic-box model to account for charge confinement in a rectangular box with an infinite potential barrier, which can be thinned to include the case of a single-layer 2D sheet. Thus it is likely that a different approach will be required to explain the 0.2 eV blue shift observed in the band gap of the intrazeolite Se helical chain, relative to the bulk trigonal phase. A possible contribution to the widened band gaps in the chain form arises from a reduced selenium chain length, and 1D quantum size effects. However, it is difficult to evaluate the role of chain-chain interactions on the 0.2 eV blue shift. A 0.3 eV blue shift observed in intrazeolite Se_8 appears to have its origin in the loss of ring-ring interactions. One should keep in mind that small changes in Se-Se bond lengths, together with alterations in helical pitch and dihedral angle could all contribute to the small differences observed among the optical spectra of intrazeolite selenium and their bulk analogues.

6. Molecular Wires—Conducting Polymers in Zeolites

An intriguing new direction in zeolite science focusses attention on synthetic strategies for the encapsulation of so called molecular wires", composed of "isolated" strands of conducting and semiconducting chain structures like those found in polythiazyl, polypyrrole, and polyaniline, for example, in the unidimensional channel structures of mordenite, L-zeolite and ALPO-5 hosts.

Quite often, the anisotropic electronic, magnetic and optical properties of so-called one-dimensional materials in the bulk solid phase are influenced to some degree by interchain interactions. For example, polythiazyl $(SN)_x$ is a room temperature metallic conductor, which does not un-

dergo a metal insulator Peierls distortion on cooling and, moreover, becomes superconducting at low temperatures. Tunable band filling in 1D solids is often achieved by chemical doping with electron donors or acceptors, or by electrochemical oxidation/reduction. The resulting cation/anion pair interactions are thought to play a role in the properties of the 1D material. Thus "isolated" conducting chains confined to a 1D zeolite channel provide an interesting situation for comparison with "interacting" chains in the bulk.

A recent study by *Bein* and *Enzel*[19] gives an example of the utility of zeolites in such developments. These workers allowed pyrrole (vapor and solution phase) to diffuse into Fe^{III}-containing faujasite (Y) or mordenite (M). The pyrrole polymerized within the channel system where the extraframework Fe^{III} ions served as an oxidant. The polypyrrole chains formed are expected to be 1D molecular conductors. The host pore and channel structure was anticipated to affect the polymer chain length and thus the transport properties of the molecular wires. Using the diagnostic 2.7 eV and 2.0 eV $\pi \rightarrow \pi^*$ absorptions as indicators of the degree of polymerization it was concluded that vapor phase treated $Fe^{III}Y$ contains *shorter* polypyrrole chains than those encapsulated in $Fe^{III}M$. Because of the insolubility of bulk polypyrrole, solvent extraction experiments were incapable of establishing the location (internal vs. external) of the polymerization product. However, indirect evidence provided a case for internal imbibement of the polypyrrole chain. This evidence included a) the inability to form polypyrrole in Na^{I} or Fe^{II} forms of the zeolites compared to the Fe^{III} form, b) the superior UV-visible transmission properties and narrower FT-Raman line widths of zeolite polymerized pyrrole inclusion compared to the bulk form and c) the lesser encapsulation quality of the polymer in the mordenite compared to the Y zeolite host where the former has the smaller free pore volume.

Another material of great interest for the formation of intrazeolitic molecular wires is polyaniline encapsulated in zeolite hosts. Here the possibility exists of obtaining isolated structurally defined chains whose electronic transport behavior can be switched from insulating to conducting by electrochemical oxidation and/or chemical protonation. The selection of acid versus alkali metal ion-exchanged zeolite hosts is therefore crucial in terms of synthetic strategy, details of intrazeolite polymerization, and properties of the resulting encapsulated polymer.

Polyaniline is a novel conducting polymer, salts of which have been synthesized with electrical conductivities up to $10\ \Omega^{-1}\ cm^{-1}$. In contrast to polypyrrole, which contains nitrogens as pendant groups attached to a polyacetylene like backbone, polyaniline exists with amine and imine nitrogen atoms (the relative amounts dependent on the degree of oxidation) occupying bridging positions in the backbone-structure which, furthermore, can be protonated and deprotonated by an appropriate choice of pH.[20]

Key questions are: What is the state of protonation/oxidation when aniline is polymerized and encapsulated in different zeolite host lattices, and, what are the structure-property relationships between the "isolated" polyaniline chains so formed and their connection (if any) to the bulk polyaniline analogues?

In the first study to address such questions concerning isolated polyaniline chains, the host structures examined were the sodium and Brønsted acid forms of zeolite Y and mordenite.[21] Polyaniline (PANI) was synthesized intrazeolitically via the oxidative polymerization of preloaded anilinium ion. Although ca. 30–50% extractable PANI was probably formed on the external surface, supporting evidence was given for the stabilization of polyaniline *inside* the zeolite channel system. The electronic spectrum of the various zeolite samples indicates that both the oxidized insulating (590 nm) and the conductive (800 nm) forms of PANI had been encapsulated. Polymerization appeared to be favored in the larger pore network of zeolite Y in comparison to mordenite as indicated by the red shift of the 800 nm absorption of the former relative to the latter.

Clearly these studies represent only the beginning of a large and fascinating enquiry on the synthesis, characterization and structure-property relationships of "molecular wires" comprised of isolated conducting polymeric chains in zeolite hosts. Future work will undoubtedly focus attention on other synthetic pathways to intrazeolite "molecular wires", such as electropolymerization, as well as host control over polymer chain length, definition of degree of polymerization and the intriguing question of the transport properties of "isolated" conducting chains.

7. Intrazeolite Multicomponent Electron-Transfer Chains

The utilization of zeolites in the assembly of molecular structures is demonstrated in an elegant experiment by *Mallouk* et al.[22] These workers used zeolite Y to form a molecular chain of three redox-active molecules at a reactive SnO_2 electrode surface. This self-assembly reaction overcame the great difficulty of direct synthesis. The SnO_2-covered electrode surface was allowed to react with the cationic silane (Fig. 7 top) to produce a coating a few monolayers thick. A dense single layer of zeolite particles was formed on the surface, linked to the silane coating by Si-O-Si bridges at free silanol groups. By immersing this electrode-zeolite assembly in a solution, anions and cations were incorporated at three specific ion binding sites: 1) a multiply charged anion (e.g. $[Fe(CN)_6]^{4\ominus}$) on the bridging silane; 2) a large cation (e.g. a substitution-inert metal polypyridyl complex) size-excluded on the outer zeolite surface; and 3) a small cation (e.g. cationic metallocene) that can enter the zeolite framework. The resulting structure shown in Figure 7 (bottom) was characterized electrochemically, by optical spectroscopy and by scanning elec-

ADVANCED MATERIALS

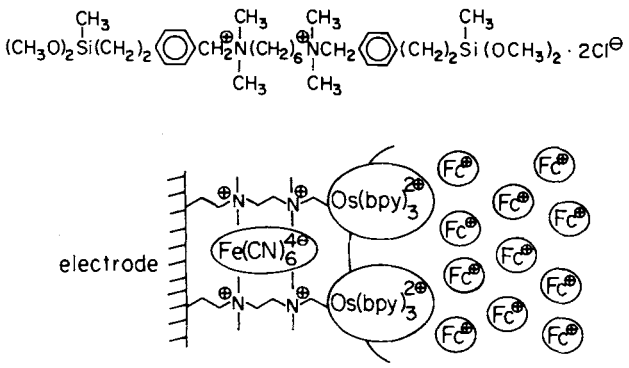

Fig. 7. Top: Cationic silane, used to functionalize the SnO_2 electrode surface before the reaction with zeolite particles. Bottom: Scheme showing the self-assembled redox chains at the zeolite Y-modified electrode. $Fc^{\oplus}$ refers to intrazeolitic cationic metallocenes. tron microscopy (SEM). The system functioned as a redox active vectorial chain only when all three components were anchored at their specific sites. Molecular microstructures of this type may serve as models for natural photosynthetic systems.

In another study *Mallouk* et al. have recently achieved long-lived light-induced charge separation in a self-assembling zeolite-based molecular triad.[23] This multicomponent system is composed of a zeolite L or Y surface-bound $RuL_3^{2\oplus}$ sensitizer, an attached $2\,DQ^{2\oplus}$ acceptor (*N,N'*-dialkyl-2,2'-bipyridinium) oriented into the open anionic structure of the zeolite and a secondary acceptor, benzylviologen ($BV^{2\oplus}$), contained within the zeolite framework (Fig. 8). Transient diffuse reflectance and luminescence lifetime measurements on this organized assembly show that intramolecular electron-transfer quenching from $Ru^{2\oplus}$ to the $2\,DQ^{2\oplus}$ moiety occurs within 5 ns or less and that the formation of the $Ru^{3\oplus}$-$BV^{\oplus}$ charge-separated state occurs in about 100 ns; this indicates that electron transfer from

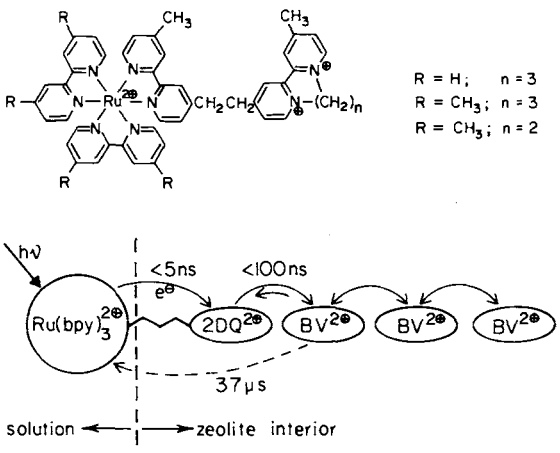

Fig. 8. Possible spatial arrangement of the $RuL_3^{2\oplus}$-$2\,DQ^{2\oplus}$ complex and $BV^{2\oplus}$ at the aqueous solution/zeolite interface. The structure of the $RuL_3^{2\oplus}$-$n\,DQ^{2\oplus}$ complex is also shown [23].

$2\,DQ^{\oplus}$ to $BV^{2\oplus}$ is complete within ≤ 100 ns. Of particular note is the long-lived nature of the $Ru^{3\oplus}$-$BV^{\oplus}$ charge-separated state, which decays via first-order kinetics with a lifetime of 37 ± 5 μs. The quantum yield for its formation is $17 \pm 5\%$.

The kind of spatial arrangement of the molecular triad shown in Figure 8 is considered to provide close contact of $BV^{2\oplus}$ contained in the zeolite with transiently formed $2\,DQ^{\oplus}$. This permits fast and efficient formation of $BV^{\oplus}$. The long lifetime of the charge-separated $Ru^{3\oplus}$-$BV^{\oplus}$ state has been attributed to a favorable spatial separation of $Ru^{3\oplus}$ and $BV^{\oplus}$ and the possibility of isoenergetic electron-exchange along the $BV^{2\oplus}$ chain depicted in Figure 8.

The work of *Mallouk* et al. has relevance to electron-transfer reactions in photosynthetic chains and light-to-chemical energy conversion systems. Of special note is the fact that the zeolite-based triad spatially resembles and behaves like the membrane-bound special pair-pheophytin-quinone triad in the reaction center of photosynthetic bacteria, which has two extremely fast forward electron-transfer steps and a long-lived charge-separated state.

8. Zeolite Electrodes—Zeolite-Modified Electrodes

Zeolites are essentially cationic conductors with the same temperature dependence typically displayed by solid ionic conductors (higher mobility of ions at higher temperature). However, some indications of partial electronic conductivity exist, for example in silver exchanged zeolite A.[24] By appropriate modifications of the zeolite composition the conductivity properties of zeolites can be altered to allow their use as solid electrolytes, membranes in ion-selective electrodes and as host structures for cathode materials in battery systems.[25]

Two types of applications exist for zeolites as part of electrode systems. In zeolite-modified electrodes the zeolite acts as a charge, size and shape selective membrane to impart a chemically specific environment for absorbed molecules at an electrode surface.[26] High product selectivities can be obtained with zeolite-modified electrodes in electrosynthetic reactions.[27] The second type, an ultramicroelectrode utilizes the zeolite framework as a matrix for intrazeolitically generated electrode components. Typically metals or metal oxides serve as electrode microstructures in and/or on the zeolite support, but organometallic or organic components, such as the polypyrrole quantum wires mentioned above can also be utilized. Organic molecular ultramicroelectrodes allow the study of conductivity and electrochemical reactivity on very small scales, as well as electrode processes at shorter times, in restricted environments and unconventional media.[26] They have potential relevance to photosynthetic systems and molecular electronics (e.g. sensors, solid state devices).

The zeolite electrode systems to be briefly described in this section include: a) encapsulated Pt_n clusters; b)

$M(bpy)_3^{2\oplus}/M(CpR)_2^{\oplus}$; c) $EDTA/MV^{2\oplus}/ZnTMPyP^{4\oplus}/Pt_n$; d) $MV^{2\oplus}/CoTMPyP^{4\oplus}$; e) $MnTMPyP^{5\oplus}$; f) composite zeolite electrodes.

An important question in all these systems is that of making electrical contacts. Some commonly used methods include 1) spring loaded contacts or coatings such as silver paint with zeolite pellets; 2) molecular attachments such as in the methylviologen-porphyrin studies described in the previous section; and 3) a method developed by *Pons* et al.[28] that avoids fixed electrical contacts altogether. The latter method consists of applying bipolar electrolytic conditions to dispersions of ultramicroelectrodes using feeder electrodes. The zeolite-supported ultramicroelectrode acts both as a mobile electrode and an electrolyte. A wide range of ultramicroelectrodes can then be accessed. This technique was applied in the study of zeolite encapsulated metal clusters for dispersion electrolyses,[26,29] as outlined below.

In practice one finds that zeolite supported platinum clusters permit dispersion electrolyses under low ionic strength conditions where microelectrodes could not function. Pt_n/zeolite Y has been shown to be a much more effective ultramicroelectrode system than $Pt_n/\gamma\text{-}Al_2O_3$ for aqueous electrolyses.[29] Control experiments showed that, although an increase in the conductivity of aqueous media did ensue from ions exchanged from the virgin zeolite, the higher ohmic background was dwarfed by the electrochemical response obtained in the presence of platinum supported in the zeolite.

Gallezot's procedures for the formation, location and sizing of Pt_n in zeolite Y were employed in the fabrication of the Pt-Y electrodes. After $[Pt(NH_3)_4]^{2\oplus}$ ion-exchange for $Na^{\oplus}$ in Na-Y, the zeolite was dried at 135°C and then heated in flowing oxygen to promote H_2O/NH_3 loss and autoreduction of Pt^{II} to Pt^0 via NH_3. The details of the activation step were crucial in determining the state and distribution of Pt_n within the zeolite microstructure. At 300°C, 6–13 Å Pt_n remained in the supercages while at 600°C, 15–20 Pt_n formed throughout the bulk of the crystal.

Typical results for the two-phase system C_6H_6/H_2O showed markedly enhanced currents at a given voltage for 1% Pt-Y (with mainly internally sited platinum), compared to 1% $Pt\text{-}Al_2O_3$, and essentially zero response for the feeder electrodes alone. The current-voltage responses of different Pt-Y loaded samples for the electrolysis of water showed that the electrolytic effectiveness followed the order: 1% Pt-Y > 5% Pt-Y > 10% Pt-Y = 1% $Pt\text{-}Al_2O_3$. Comparisons between the electrolyte response of Pt-Y samples, implied that the internally confined particles did not contribute to the electrolyses. This was rationalized by the inability to achieve electric fields high enough for bipolar electrolysis to occur on intracrystalline sited platinum particles at the voltages employed. By contrast, externally sited particles could be physically charged at the feeder electrode or via other previously charged supported platinum sites. Similar effects have been experienced for dispersion electrolysis of ferrocene/CH_3CN and a substituted ferrocene/CH_3CN too bulky to enter the Pt-Y sample, thereby supporting the proposal of externally active platinum sites in Pt-Y. In the dispersion electrolysis the zeolite support yielded a more effective material than the alumina. Based on XPS determined platinum particle sizes and associated surface areas these results suggest that the electrode processes may be affected by particle size in the submicron range.

Recently the preparation and electrochemical behavior of simple, self-assembly vectorial electron transport chains on zeolite Y modified SnO_2 electrodes have been described.[27] These involve a Y zeolite which has been ion exchanged with a tris(bipyridyl) metal complex $M(bpy)_3^{2\oplus}$ (M = Ru, Os), and a metallocene cation $M(CpR)_2^{\oplus}$ and $M(Cp)(CpR)^{\oplus}$ (M = Co, Fe; Cp = η^5-C_5H_5 and R = H, CH_3, NH_2, CO_2CH_3, $CH_2N(CH_3)_2$). Matching of the potentials of externally sited $M(bpy)_3^{2\oplus}$ and intrazeolite $M(CpR)_2^{\oplus}$ ensures facile redox reactions, an order of magnitude enhanced over the situation when $M(bpy)_3^{2\oplus}$ is absent from the system. Rapid electron-transfer cross reactions between the two complexes are proposed to explain this behavior.

Electrodes were prepared from conductive SnO_2 coated glass squares contacted to copper wire via colloidal silver paint. The electrode was dipped into a suspension containing the ion-exchanged zeolite and polystyrene in THF, and was allowed to dry in air. Scanning transmission electron microscopy and electron diffraction (STEM) experiments on freshly cleaved electrodes showed a film thickness of about 60 μm with most of the polystyrene forming a porous layer at the outer surface of the film. The metal guest was located in the ca. 1 μm zeolite particles which formed a porous compact layer tightly adhering to the SnO_2 substrate.

Reduction and oxidation peaks of the surface bound couple $Ru(bpy)_3^{2\oplus/1\oplus}/ZY/SnO_2$ occurred at −0.76 and −0.55 V vs. the saturated calomel electrode (SCE). It is interesting that the $E_{1/2}$ of this couple ($E_0 = -0.66$ V vs. SCE) was shifted about 600 mV positive of its value in polar organic solvents (−1.24 V vs. SCE), pointing to the stabilizing effect of adsorption of $Ru(bpy)_3^{1\oplus}$ relative to $Ru(bpy)_3^{2\oplus}$ on the zeolite. The quantity of charge passed in the $Ru(bpy)_3^{2\oplus}$ reduction wave indicated that only the surface $Ru(bpy)_3^{2\oplus}$ contacting the SnO_2 electrode was electrochemically accessible. In the case of a $Co(CpCH_3)_2^{1\oplus}/ZY/SnO_2$ electrode only a small fraction of the intrazeolite $Co(CpCH_3)_2^{\oplus}$ was reduced or oxidized. The $E_{1/2}$ of $Co(CpCH_3)_2^{1\oplus/0}$ also shifted to a more positive value (−0.66 V vs. SCE) compared to its solution phase value (−1.10 V vs. SCE). A tenfold increase in the height of the cathodic wave for an $Ru(bpy)_3^{2\oplus}/Co(CpCH_3)_2^{1\oplus}/ZY/SnO_2$ electrode was observed compared to the case when surface bound $Ru(bpy)_3^{2\oplus}$ was absent. Similar current enhancements were obtained for a number of substituted

ADVANCED MATERIALS

$Co(CpR)_2^{1\oplus}$ species provided that the respective $E_{1/2}$ was positive or coincident with the $Ru(bpy)_3^{2\oplus}$ wave. The mechanism shown in Figure 9a was proposed to rationalize the observation of current enhancement, where the large cathodic wave represents the reduction of bulk $Co(CpR)_2^{1\oplus}$ mediated by surface adsorbed $Ru(bpy)_3^{2\oplus}$. The observed enhanced anodic wave was ascribed to the reverse electrocatalytic reaction shown in Figure 9b. The key finding of this study is that rapid vectorial electron transfer from the electrode to the bulk materials occurs almost entirely through the $M(bpy)_3^{2\oplus}$ complex.

Experiments of this kind stimulated research on more sophisticated intrazeolite molecular electron transport chains composed of porphyrins and viologens. Two fascinating new systems will be referred to, one involving photochemical H_2 evolution via singlet-state electron-transfer quenching of zinc tetra(*N*-methyl-4-pyridyl) porphyrin cations ($ZnTMPy^{4\oplus}$) using internally platinized zeolite L particles (Fig. 10a),[30] the other involving current rectification and electron trapping by surface bound monomolecular metalloporphyrin layers on zeolite Y containing intrazeolite viologens (Fig. 10b).[31]

The first zeolite electrode concerns a metalloporphyrin-based electron-transport chain which self-assembles by virtue of ion-exchange and steric interactions with a zeolite L particle. The microstructure imposed by the zeolite permits $ZnTMPyP^{4\oplus}$ to be held in sufficient proximity to a $MV^{2\oplus}$ cation so that singlet-state electron-transfer quenching occurs on the sub-nanosecond time scale. With $EDTA^{2\ominus}$ added as a sacrificial electron donor, H_2 is evolved from water under illumination with visible light at the internal platinized zeolite L-containing $ZnTMPyP^{4\oplus}$ and $MV^{2\oplus}$. Figure 10a displays the fabrication and operating details of this compartmentalized photochemical system. The linear channels which run through zeolite L and bind $MV^{2\oplus}$ are shown as idealized hexagonal prisms. The zeolite outer surface strongly binds the $ZnTMPyP^{4\oplus}$ cation as it is size excluded from the bulk. When a more sterically hindered porphyrin replaces $ZnTMPyP^{4\oplus}$, a system results which is inactive for both H_2 evolution and singlet state quenching by $MV^{2\oplus}$. These observations are rationalized in terms of closely assembled and organized triads of molecules

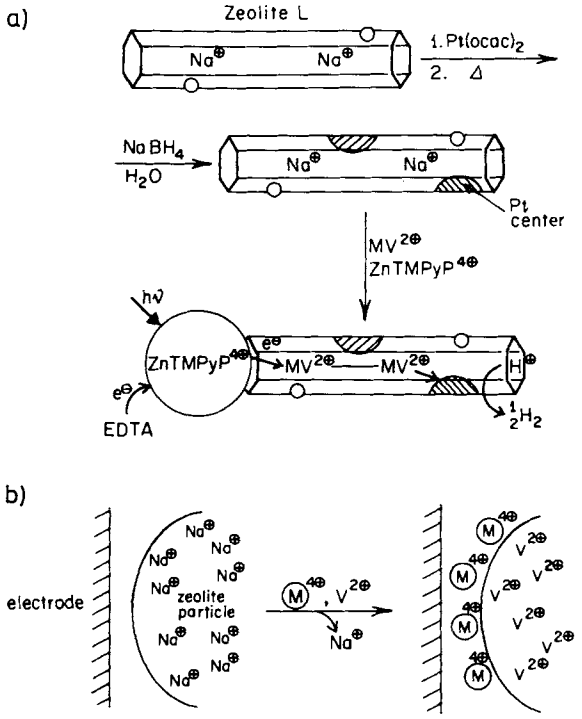

Fig. 10. a) Preparation and operation of the compartmentalized photochemical system, composed of platinized zeolite L containing $ZnTMPyP^{4\oplus}$ and $MV^{2\oplus}$ [30]. b) Preparation of metalloporphyrin/viologen($V^{2\oplus}$)-exchanged zeolite Y particles and zeolite-modified electrodes [31].

$EDTA^{2\ominus}$, $ZnTMPyP^{4\oplus}$, $MV^{2\oplus}$ located at the zeolite/solution interface.

This elegant study demonstrates that molecular level organization of electron donor, metalloporphyrin and quencher in zeolite L is feasible. Such integrated, highly ordered systems can sustain photochemical production of H_2 from water via singlet state electron transfer quenching of the porphyrin molecule. An attractive feature of the system is its self-assembly by ion-exchange from simple commercially available components. Considerable scope clearly exists for maximizing quantum yields for electron-hole separation through the clever design of more complex interfacial assemblies.

Li et al.[31] exchanged zeolite Y with viologen cations which diffused into the bulk and attached monolayers of larger cobalt or zinc porphyrin cations to the outer surface of the zeolite. The porphyrin molecules sealed the zeolite against rapid exchange of viologen molecules and facilitated the electron transfer between the encapsulated viologen ions and the surroundings of the microstructure. The porphyrin tends to remain attached to the zeolite surface because its ionic charge is high enough to avoid exchange with the ionic species of the solution, even in reduced forms of complexed metal.[32]

Another zeolite electrode system of this type was fabricated using $Mn^{III}TMPyP^{5\oplus}$ fixed onto the outer surface of zeolite Y (ZY) in contact with a controlled potential metal-

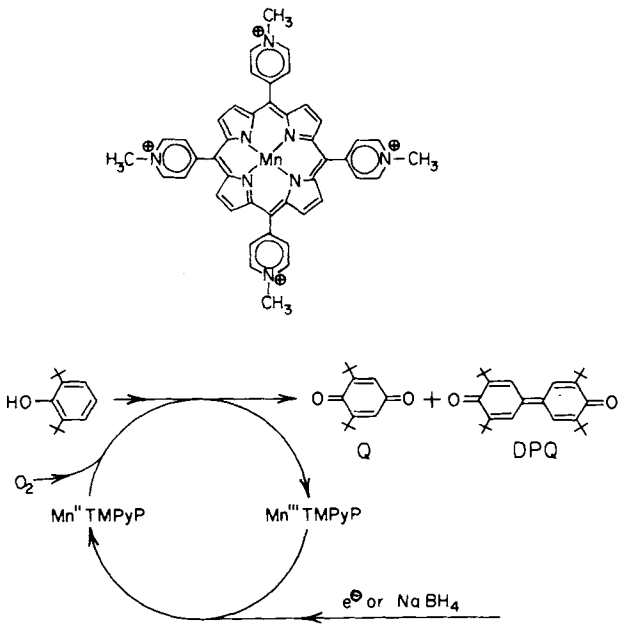

Fig. 11. Catalytic oxidation of 2,6-di-*tert*-butylphenol using a controlled potential metallic electrode (Pt grid) composed of $Mn^{III}TMPyP^{5\oplus}$ fixed onto the outer surface of zeolite Y [32].

lic electrode (Pt grid).[32] The test reaction was the oxidation of 2,6-di-*tert*-butylphenol to produce 2,6-di-*tert*-butyl-*p*-benzoquinone (Q) and diphenoquinone (DPQ). The overall catalytic process is summarized in Figure 11, where the catalytic species is $Mn^{II}TMPyP^{4\oplus}$. The study proves that $Mn^{III}TMPyP^{5\oplus}/ZY$ participates in the heterogeneous catalyzed O_2 oxidation of di-*tert*-butylphenol with quantitative conversion of the phenol to the quinone products and electrochemical regeneration of the catalyst.

The response of zeolite electrodes can be optimized by preparing a composite electrode with carbon paste. For example, *Creasy* and *Shaw*[33] constructed electrodes of methyl viologen exchanged zeolites Y and A mixed with carbon paste for the electroreduction of oxygen. The results showed that the electroreduction of oxygen by methyl viologen proceeded more efficiently upon incorporation of zeolite Y into a carbon paste electrode and that efficient mediation required the zeolite to be in close proximity to the conducting carbon particles. An optimum current was obtained when the zeolite was saturated with methylviologen.

Other zeolite composite electrodes have been formed by codepositing zeolites with organic salts or polystyrene, mixing them with conductive carbon powder or pressing them into pellets coated with doped tin oxide.[34]

9. Zeolite Solid State Batteries

In the context of advanced zeolite materials science and battery research, it is especially humbling to learn that solid state, multiple-layer zeolite batteries, having excellent high temperature (500°C) and low temperature (−78°C) operating characteristics, were developed by *Freeman* as early as 1965.[35]

The feasibility of fabricating a battery utilizing zeolite materials relates to the fact that zeolites are fairly good solid state ionic conductors with relatively small activation energies for conduction (e.g., dehydrated NaX, $\sigma(Na, 300°C) = 10^{-4}$ to $10^{-5}\ \Omega^{-1}\ cm^{-1}$). Experimentally, two types of ion motion in zeolites have been detected: a) cation jumps from site to site, b) ionic relaxation or restricted local motions of cations. These phenomena in A, X, and Y zeolites are believed to be due to cation mobility in supercages and sodalite cages. The non-monotonic ionic radius dependence of the activation energies for conduction of alkaline metal cations in faujasite has been explained in terms of a model involving coulombic interactions of the cation with the lattice and a repulsive term between cations. Some illustrative data are given in Table 3.[36]

Table 3. Activation energies [kJ mol^{-1}] for cation conduction in faujasite.

Si/Al	1.25	1.7	2.5	2.9
$Li^{\oplus}$	303	—	378	—
$Na^{\oplus}$	219	231	310	332
$K^{\oplus}$	229	226	230	271
$Rb^{\oplus}$	282	282	282	295
$Cs^{\oplus}$	232	243	—	—

Thus the activation energies tend to be larger for small cations and higher Si/Al ratios. Intercation repulsion effects appear to be responsible for the deviation of $Rb^{\oplus}$ and $Cs^{\oplus}$ from this scheme as well as the unexpected Si/Al ordering scheme. When polyvalent cations are exchanged for $Na^{\oplus}$, the activation energy for $Na^{\oplus}$ migration in the supercages, compared to the parent $Na^{\oplus}$ form decreases significantly as seen from Table 4.[36] At low $Ca^{2\oplus}$ loadings, occupancy of sodalite cages with the divalent cation is favored. Thus charge density is localized more in the sodalite cages, resulting in a decreased activation energy for $Na^{\oplus}$ migration in the supercages.

Table 4. Activation energies [kJ mol^{-1}] for cation conduction in faujasite.

Si/Al	1.25		2.5
$Ca_{42}Na_2$	247	$Ca_{26}Na_3$	172
$Ca_{40}Na_6$	192	$Ca_{22}Na_9$	163
$Ca_{35}Na_{16}$	167	$Ca_{20}Na_{15}$	180

Summarizing a large amount of conductivity data, a picture has been advanced for the motion of exchangeable cations in zeolites. It is based on the concept of highly correlated cation jumps and the idea of local cation jumps in, for example, the sodalite cages, usually from AC, DC conductivity and NMR relaxation time measurements.

With the above background material on ionic conduction of extraframework cations in zeolites, let us briefly

turn our attention to *Freeman*'s pioneering studies of zeolite batteries. Using the original notation of *Freeman* to describe a zeolite multiple layer cell composition:

$|Au|Cu^{II}X|NaX|Zn|$

one speaks of a gold catholyte contact, a copper-exchanged zeolite X catholyte, a sodium zeolite X separator and a zinc anode. The operation of the cell appears to be zinc oxidation at the anode with the liberation of electrons and concomitant reduction of Cu^{II}. This must be accompanied by the necessary ionic charge transfer of Zn^{II} liberated from the anode passing through the NaX separator lattice, to find a cation vacancy probably in the $Cu^{II}X$ lattice. Open circuit voltages for cells fabricated by pressed pellet techniques were found to be surprisingly reproducible and fell in the range 1.36–1.40 V with $Ag^{I}X$ as zeolite catholyte and calcium exchanged zeolite A (CaA) as separator, or 1.17–1.25 V with a $Hg^{II}X$ catholyte. The $|Au|Hg^{II}X|NaX|Zn|$ cell is particularly outstanding in that an appreciable current could be drawn with only a 23% drop in voltage as the load was applied.

Since most zeolites are thermally stable to at least 750 °C, zeolite cells are operable at unusually high temperatures, providing the contacts, electrodes, and intrazeolite metals are stable. In $Au|Cu^{II}X|NaX|Zn|$ an exponential increase in current with temperature is found over the range from 260 °C (3×10^{-7} A output current) to 500 °C (2.8×10^{-5} A).

The $|Au|Ag^{I}X|CaA|Mg|$ cells with magnesium anodes displayed the highest open circuit voltages obtained from single zeolite cells (1.95–2.10 V, for four different cells). It is remarkable that a $|Au|Hg^{II}X|CaA|Zn|$ cell could be operated at −78 °C with an open circuit voltage of about 1.0 V compared to 1.1 V at room temperature.

In a more recent vein, *Andersen* et al.[37] have used AC conductivity measurements on $NH_4^{\oplus}$ and $H_3O^{\oplus}$ zeolites A, X, Y and have established that $NH_4^{\oplus}$ and $H_3O^{\oplus}$ cations are mobile with conductivities dependent on the degree of hydration of the zeolite. Cell reactions have been developed for these zeolites which exploit the mobilities of the proton and ammonium ions. Cells were constructed from porous platinum blocking electrodes deposited onto pressed zeolite wafers as illustrated below:

$H_2|Pt|H_3O^{\oplus}Z|Pt|H_2$

Here the half reactions at the porous platinum electrodes involve:

$1/2\,H_2 \longrightarrow H^{\oplus} + e^{\ominus}$ anode

$H^{\oplus} + e^{\ominus} \longrightarrow 1/2\,H_2$ cathode

where the proton conductivity involves $H_3O^{\oplus}$ transfer across the solid zeolite electrolyte layer. An interesting extension of this idea involves an NH_4Z solid state electrolyte cell:

$H_2|Pt|NH_4^{\oplus}Z^{\ominus}|Pt|H_2$

where in a similar arrangement $NH_4^{\oplus}$ is gradually replaced by $H_3O^{\oplus}$ with NH_3 evolved at the cathode according to the following cell reactions:

$H_2O + 1/2\,H_2 \longrightarrow H_3O^{\oplus} + e^{\ominus}$ anode

$H_3O^{\oplus} + NH_4^{\oplus}Z \longrightarrow H_3O^{\oplus}Z + NH_4^{\oplus}$ zeolite electrolyte

$NH_4^{\oplus} + e^{\ominus} \longrightarrow NH_3 + 1/2\,H_2$ cathode

These results are quite fascinating and clearly have ramifications in advanced battery and fuel cell applications, as well as in electrochromic zeolite and molecular size/shape selective ionic-conductivity sensor elements.

Another interesting solid state zeolite cell involves the concept of utilizing dehydrated zeolite crystals as host structures for liquid and volatile electrochemically active species. *Coetzer* et al.[38] have employed this idea to investigate the performance of zeolite/iodine and zeolite/sulfur cathodes in solid state cells. For example, dehydrated sodium exchanged zeolite A (NaA) impregnated with I_2 has been used as a cathode material in a silver/I_2 solid state cell as shown in Figure 12.

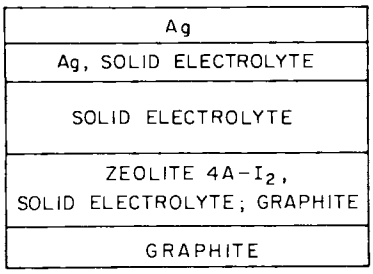

Fig. 12. A diagrammatic sketch of a Ag/zeolite 4A–I_2 cell [38].

Two quaternary amine iodide/AgI solid electrolytes, namely $Ag_{44}I_{53}(C_{11}H_{30}N_3)_3$ and $Ag_{21}I_{25}(C_9H_{24}N_2)_2$ having room temperature ionic conductivities of ca. $3 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$ are used in these cells instead of well known $Ag^{\oplus}$ conductors like $RbAg_4I_5$, as the latter is electrolytically unstable in the presence of elemental iodine. Thus it is advantageous to complex the iodine in the cathode in some way at reduced activity, as found in RbI_3, Me_4NI_5 and Me_4NI_9. The NaA/I_2 cathode is another way of achieving the goal of controlled iodine release for the cell reaction $2\,Ag + I_2 \rightarrow 2\,AgI$.

The NaA/I_2 complex used contained 38.9 wt% I_2 giving the formula $Na_{12}Al_{12}Si_{12}O_{48} \cdot 4.3\,I_2$ for the zeolite/I_2 storage cathode. A multilayer, 20 mm diameter cell construction was employed. Anode and cathode components contained finely ground electrolyte material to enhance elec-

trode-electrolyte interfacial contacts and disc binding qualities, while the cathode was mixed with finely divided graphite to enhance the electronic conductivity as the zeolites are electronic insulators.

The formation of resistive AgI ($\sigma_{25°C} \approx 10^{-4}\ \Omega^{-1}\ cm^{-1}$) as the only discharge product in the $NaA/I_2/Ag$ cell caused the internal resistance to rise and the load voltage to drop accordingly with time. This necessitates the use of relatively thin cathodes for this type of cell (cf. the Li/2-polyvinylpyridine-I_2 heart pacemaker[39]).

In summary, these results illustrate the intriguing possibility of immobilizing volatile electrochemically active species in zeolites for use as cathodes in ambient temperature cells. The immense flexibility in the choice of a zeolite host offers great opportunities for optimizing an electroactive guest molecule. One might remark on concluding this section, that it is rather surprising that the literature on zeolite batteries has been quite sparse since *Freeman*'s early pioneering work. It is expected that this situation will change rapidly as research in zeolite materials science gathers momentum in the late 1980's.

10. Optozeolite Chemical Sensors

A sensor can be defined as a small device that converts any microchange of temperature, pressure, concentration or other property into a detectable signal. The success of a chemical sensor is determined by its sensitivity and reproducible performance. The sensing element is expected to incorporate at least the following attributes: selectivity and site reversibility with respect to guest binding, fast response, small size, ruggedness, low cost, and the potential for facile integration into an automated system. With respect to sensor architecture most devices today employ a union between a selective chemireceptor and a transducer which is capable of translating the resulting physicochemical perturbation into a usable signal. Gas-sensitive metal gate semiconductor devices, chemically sensitive field effect transistors, Schottky diodes, chemiresistors and surface acoustic wave sensors represent just a few of the emerging technologies with promise in the chemical sensor field.

The concept of using zeolites as size and shape selective chemical sensors was at the basis of our research efforts to elicit from such materials an optical response such as intensity and lifetime modification due to intrusion of an adsorbate into the pore system of a zeolite. It is noteworthy that the recent patent literature mentions zeolites in applications ranging from moisture sensing,[40] oxygen monitoring,[41] and carbon monoxide detection[42] to the selective detection of ethylene, ethane and propylene.[43]

Luminescent centers housed in various zeolites were selected mainly from $Eu^{3\oplus}$, $Mn^{2\oplus}$ and $Ag^{\oplus}$ which have an extensive photochemical/photophysical solid-state literature for a range of hosts. These include single crystals, glasses, layered materials and oxide supports. Although the optical absorption and luminescence properties of certain intrazeolite metal guests are quite well understood, little is known about their excited state lifetime properties. Even less information is available on the response of these properties to specific molecule absorption and luminescence quenching in the time domain. An attractive feature of intrazeolite luminescent metal probes (ILMP's) is that one can fine-tune their optical characteristics over useful ranges of frequency and, as has been discovered recently, in time. Parameters that can be varied include the zeolite type, co-cations, Si/Al ratio and loading of the ILMP. A useful example of loading and co-cation effects stems from luminescence lifetime data obtained from the study of

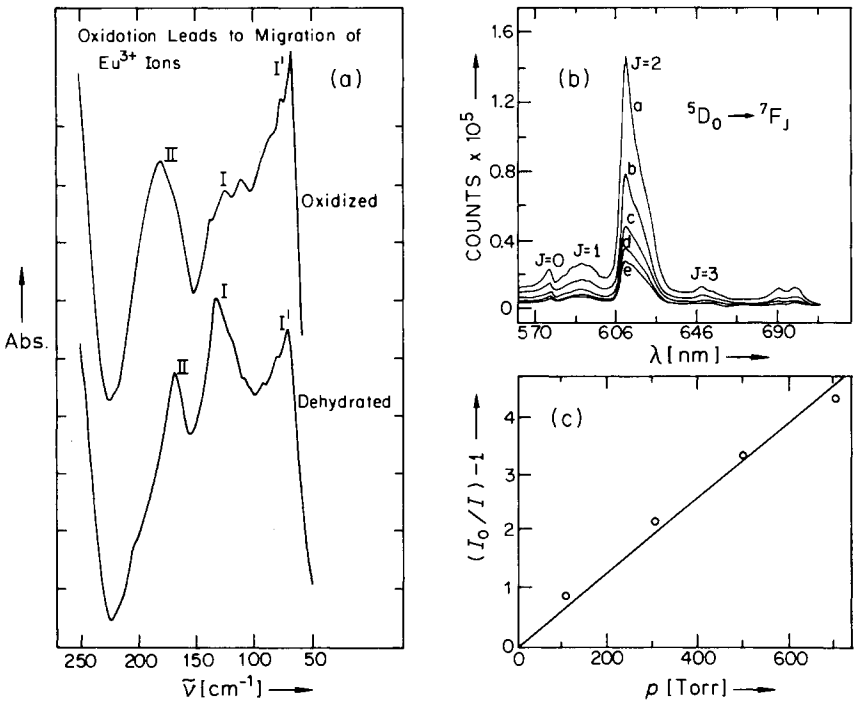

Fig. 13. a) Far infrared spectra of $Eu^{3\oplus}Y$. b) The quenching of $Eu^{3\oplus}$ luminescence at various oxygen pressures: a: vacuum, b: 105 Torr, c: 500 Torr, d: 700 Torr, e: 760 Torr. c) Stern–Volmer plot for the $J=2$ luminescence quenching depicted in b) [44].

ADVANCED MATERIALS

silver faujasites.[44a,b] The observed long-lived emissions have been associated with a spin-forbidden phosphorescence of intrazeolite $Ag_2^{\oplus}$.

The impetus for the study of $Eu^{3\oplus}$-ZY was the intrinsic very bright fluorescence of $Eu^{3\oplus}$ and the well understood luminescence spectroscopy in other solids. $Eu^{3\oplus}$ cation site locations within zeolite Y were established by far infrared spectroscopy that conveniently pinpoints cation translatory modes (Fig. 13a). The fluorescence intensity of $Eu^{3\oplus}$ was quenched upon admission of oxygen (Fig. 13b). A study of the O_2-concentration effect showed that the quenching kinetics were Stern-Volmer in nature (Fig. 13c). The lifetime decays of $Eu^{3\oplus}$-ZY also showed sensitivity to oxygen (Fig. 14). These O_2 quenching effects were found to be completely reversible at room temperature. These results demonstrate that the concept of a time-domain zeolite sensor is valid.

The sensing of NH_3 by $Eu^{3\oplus}$-ZY is noteworthy (Fig. 14b). The response was rather different to that given by O_2. While the $Eu^{3\oplus}$ $J=2$ transition decreased in intensity the $J=0$ transition was enhanced as the pressure of NH_3 was increased. The behavior was reversible upon heating the zeolite to 200°C. This is indeed a unique response. None of the adsorbates screened so far (H_2, N_2, CO, C_2H_4, O_2) produced this signature. The unusual NH_3 effect is believed to originate from a dramatic change in symmetry at the $Eu^{3\oplus}$ ion, possibly due to complexation of $Eu^{3\oplus}$ by NH_3 or the presence of $NH_4^{\oplus}$ ions formed by the interaction of NH_3 with the lattice hydroxy groups, the latter being formed from the hydrolysis of H_2O by $Eu^{3\oplus}$.[44a,b]

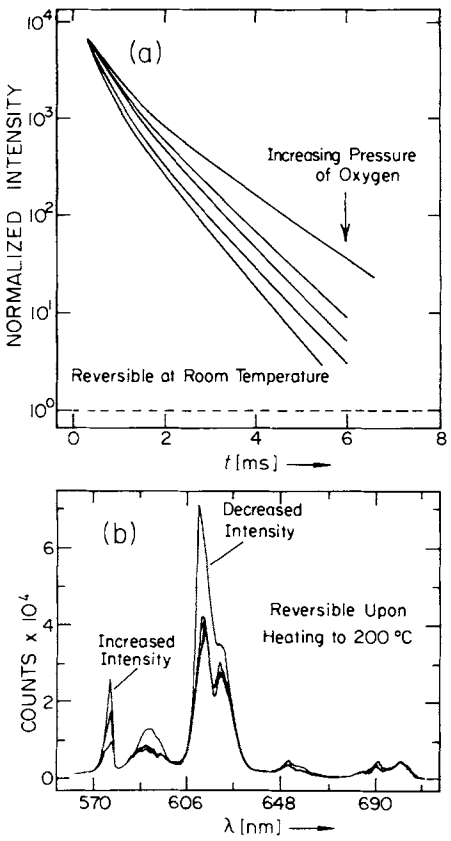

Fig. 14. a) Lifetime quenching of $Eu^{3\oplus}$-ZY luminescence by oxygen. b) The quenching of $Eu^{3\oplus}$ luminescence in zeolite X by ammonia [44].

The new generation MnAPO and MnAPSO molecular sieves provide a unique opportunity for studying the photophysical behavior of a luminescent $Mn^{2\oplus}$ framework probe. Most detailed results have been obtained so far with the MnAPSO-31 and 44 template-containing and template-free materials.[44c] Detailed EPR, steady state and time resolved optical reflectance/emission spectroscopic studies of these materials have yielded evidence for magnetic and electric dipole-coupled $Mn^{2\oplus}$ framework centers, some sites experiencing detectable interactions with neighboring template molecules.[44c]

Laser induced fluorescence studies aimed at exploring specific adsorbate quenching effects in template free MnAPSO-44 have been performed. N_2O, CO, N_2 and O_2 show reversible intensity quenching responses. Whether these are dynamic and/or static and molecule specific has yet to be quantified. It is notable that Ar, CH_4, C_3H_6 and CH_3COOCH_3 display no intensity quenching effects under similar conditions while quenching with NH_3 is irreversible. These results are encouraging as they suggest that framework metal luminescent centers might be susceptible to selective adsorbate quenching. Clearly these early studies represent just a modest beginning. Much fascinating work remains to be done in the search for a molecule size/shape discriminating optozeolite chemical sensor.

11. Tunable Non-Linear Optical Zeolites

The development of new non-linear optical (NLO) materials, which allow frequency multiplication and mixing of UV-VIS-IR radiation for laser and electrooptics applications (optical processing/computing, image analysis, switches, modulators) has recently been extended into the world of zeolites. *Cox* et al.[45] have given the first report of a non-linear optical material, fabricated by the confinement of an organic guest in an acentric zeolite host with a one-dimensional channel structure.

NLO effects are usually obtained by the polarization of a medium by an incident electric field:

$$P = \chi_1 E + \chi_2 E^2 + \chi_3 E^3 + \cdots$$

χ_1 = first order susceptibility tensor (linear optical properties, refraction, absorption); χ_2 = second order susceptibility tensor (zero for centrosymmetrical materials; non-zero values yield frequency doubling, frequency mixing effects); χ_3 = third order susceptibility tensor (non-zero for all materials, provides access to the Kerr effect, self focussing, degenerate four wave mixing, third harmonic generation).

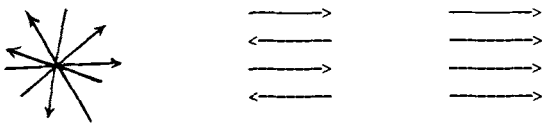
The connection of electric susceptibilities to NLO effects derives from the polarization induced by an oscillating dipole which radiates energy. The electric field associated with the radiating dipole is proportional to the polarization:

$$E_{rad} \propto P(\omega) \quad \text{or} \quad P(2\omega) \quad \text{or} \quad P(3\omega)$$

Therefore the intensity of the radiating signal is given by

$$I \propto |E_{rad}|^2$$

and for second harmonic generation



$$I(2\omega) \propto |\chi_2|^2 I^2(\omega).$$

In order to relate microscopic to macroscopic susceptibilities one considers first the molecular response to electric fields:

$$\mu = \mu_0 + \alpha E + \beta E^2 + \gamma E^2 + \cdots$$

μ_0 = permanent GS dipole moment, α = linear polarizability (2nd rank tensor, proportional to χ_1), β = second order polarizability (3rd rank tensor, proportional to χ_2), γ = third order polarizability (4th rank tensor, proportional to χ_3).

Each component molecule of a material acts as a source of non-linear polarization and so the macroscopic response is the sum of the macroscopic responses averaged over all orientations. For second harmonic generation (SHG), χ_2 must be non-zero. To achieve this objective it is mandatory that all molecular dipoles point in the same direction on average, that is:

Random	Alignment	Orientation
$\chi_2 = 0$	$\chi_2 = 0$	$\chi_2 \neq 0$

It is difficult to orient small molecules by electric or magnetic fields, because of their small dipole moments and magnetic susceptibilities. Thus it is clearly beneficial to incorporate such molecules into larger host structures to enhance orientation and alignment in addition to other properties such as mechanical stability and processibility etc. The non-centrosymmetric structural features required for SHG may be imposed on a guest species by an acentric zeolite host. In some cases synergistic sorbate-host interactions between two centric species yield a non-centrosymmetric product with very different NLO properties from either guest or host. *Cox* et al.[45] have incorporated *p*-nitroaniline (NA) and 2-methyl-*p*-nitroaniline (MNA) in zeolites Y, Omega, Mordenite and AlPO-5 in order to study changes in SHG. Note that NA has a large hyperpolarizability β but crystallizes centrosymmetrically giving $\chi_2 = 0$. To overcome the problem of relative orientation of molecules in a solid various kinds of molecular engineering approaches have been investigated, such as simple chemical modification to induce non-centrosymmetric crystallization or inclusion tuning of the organic guest by encapsulation into an acentric inorganic or organic host lattice.

NA in the centrosymmetric molecular sieves zeolite Y, Omega and Mordenite showed no SHG. For the case of NA in the acentric zeolite ALPO-5, a loading dependence of the SHG signal was observed with a maximum SHG of 630 relative to quartz at 13 wt% NA loading when all the pores were filled (Fig. 15) a magnitude *ten* times larger

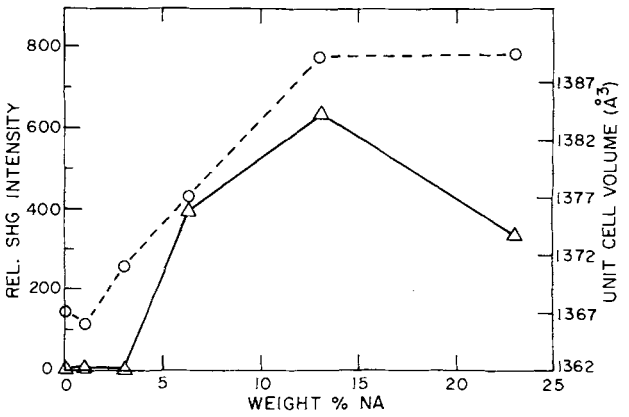


Fig. 15. *p*-Nitroaniline (NA) in ALPO-5. Loading level (weight % NA) versus SHG intensity relative to quartz (solid line) and unit cell volume in Å³ (dashed line) [45].

than that of any previously reported organic or inorganic inclusion complex. The observation of a maximum SHG at full loading implies encapsulation of NA within the pores of the ALPO-5 molecular sieve. MNA, which has a SHG by itself, loses its SHG upon inclusion in ALPO-5. The authors attributed subtle steric, symmetry and host-guest interaction effects to the ability of ALPO-5 to switch the SHG of NA on and that of MNA off. Future work concerning SHG in molecular sieves will focus attention on the effects of loading levels, other acentric hosts, host-guest interactions, and the nature of the guests.

12. Zeolite Membranes and Thin Films

In this section, a brief description will be presented of the recent development of a new generation of zeolite composite films and well-defined inorganic membrane structures that offer controlled porosity in the 10 Å range. The ultimate goal is to employ these microstructures as

ADVANCED MATERIALS

"molecular sieve" elements in chemical sensors, so that only those molecules that are able to pass through the membrane are detected at the sensor surface. The methodology employed to create such a molecule size/shape discriminating inorganic membrane structure involves the incorporation of zeolite crystals into a glass or ceramic matrix. The key objective here is to allow only passage of specific molecules through the zeolite channels while the matrix support remains impermeable.

Synthesis of the inorganic matrix derives from well established sol-gel processing technology based on the controlled hydrolysis of tetraethylorthosilicate (TEO), usually in an alcoholic solvent:

$$Si(OEt)_4 + 4\,H_2O \xrightarrow[\text{base}]{\text{acid or}} Si(OH)_4 + 4\,EtOH$$

$$n\,Si(OH)_4 \longrightarrow (SiO_2)_n + 2n\,H_2O$$

Depending on the conditions employed (pH, concentrations, temperature, solvent, etc.) condensation and polymerization of silicate species via Si-O-Si bonds can be biased towards either weakly branched "fractal" structures and microporous gels, or compact, fully polymerized colloidal particles and macroporous gels. Acid hydrolysis leads to the former, while base hydrolysis favors the latter. Incorporation of zeolite microcrystals into the sol-gel process followed by viscous sintering can provide a microcomposite thin film, composed of an impermeable silica matrix with "molecular sieving" capabilities determined by the channel architecture of the embedded zeolite.

One step in the development of thin films is the functionalization of the zeolite surface to improve the adherence properties of the zeolite on a substrate material or to use the zeolite itself as a substrate. *Bein* et al.[46] have addressed this question by studying the reactions of mono- and polyfunctional silanes (functional groups OR, Cl, NR_2, H) with zeolite Y surfaces. Although these workers were mainly interested in the possibility of anchoring molecules to the *internal* surface of zeolite pore systems, their conclusions apply similarly to the external surfaces. At moderate reaction temperatures the functional groups at the silane were lost to form bridges to the zeolite framework. As the reaction continued, Si-C bonds were broken at elevated temperatures and more highly substituted siloxane species were anchored to the zeolite framework. As expected, bridged hydroxy groups were found to be far more reactive than terminal hydroxy groups.

Early zeolite membrane experiments by *Bein* et al.[47] focussed attention on silica embedded faujasite and ZSM-5 zeolites. SEM studies revealed a fairly homogeneous dispersion of zeolite crystals in the membrane. Protrusion of single layers of zeolite crystals out of the amorphous matrix made them accessible to probe molecules adsorbing from the gas phase. This feature of these membranes is vital for sensor coatings.

The central issue of molecular access to the membrane-embedded zeolite crystals was addressed by using a surface acoustic wave device in selective adsorption experiments and mid-IR spectroscopy. A thin film of the membrane on a quartz crystal microbalance showed that in the absence of zeolite crystals, acid-catalyzed gel based films did not adsorb even nitrogen. However, gas uptake was observed when the zeolite was incorporated into the silica membrane.

In the mid-IR experiments, the Brønsted acid protons (hydroxy groups) located on the external surface of the zeolite crystals (3720–3750 cm^{-1}) were readily distinguished from internally located zeolite structural hydroxy groups (3640–3540 cm^{-1}). The gel-derived surface OH groups were characterized in the absence of zeolite by broad, weak IR bands with a sharp onset at 3750 cm^{-1} down to ca. 3200 cm^{-1}.

The key experiment involved the behavior of these differently located hydroxy groups to the adsorption of probe organic molecules whose reaction or interaction with hydroxy groups was determined by size/shape (kinetic diameter) and chemical considerations (pyridine, 5.9 Å; $(C_4H_9)_3N$, 8.1 Å; 2,2,4-trimethylpentane, 6.2 Å; NH_3, 2.6 Å; $(C_4F_9)_3N$, 10.2 Å). The results of these size/shape selective adsorption/reaction experiments provided fairly convincing evidence that, in most membranes studied, the zeolites were completely accessible from the gas phase. The membranes excluded molecules which were larger than the pore openings of the zeolite embedded in the composite. This type of microcomposite membrane is envisaged to offer great opportunities in the development of size/shape discriminating chemical sensors.

A different approach to producing thin zeolite-containing coatings used electrodeposition at a Pt or glassy carbon containing rotating disk electrode (RDE).[25] *Murray* et al. prepared the zeolite-coated RDE by spinning a Pt or glassy carbon RDE in a solution containing powdered zeolite A, Et_4NClO_4/CH_3CN and an oxidant species (1,3-dinitrobenzene, 1,4-dinitrobenzene or tetracyanoquinodimethane). A coating was formed upon repetitive scanning through the reduction waves of the oxidant. The embedded zeolite particles retained their molecular sieving properties. The coating thickness could be increased for organic oxidants by cycling through the second reduction wave and generating a dianion.

In order to use silver sodalites as optical data storage materials, *Stein*[48] embedded sodalites in a polymethylmethacrylate (PMMA) matrix and prepared thin films of the zeolite/polymer composite. This application differs from the above examples in the fact that direct access of gases or other chemicals to the zeolite is *not* required, nor even desirable. The sodalite was ground, sieved and stirred into a toluene/PMMA mixture to achieve a uniform distribution. A thin film was applied on a fused silica disk or similar support and was allowed to dry and cure at room temperature, before being treated near the glass temperature

of PMMA. The hard, highly transparent amorphous polymer PMMA was chosen because its refractive index matched that of sodalite very closely, so that light scattering was minimized. Although individual particles remained visible in many samples, greater control over the mixing and the sodalite particle size should yield fairly homogeneous films.

13. Conclusion

The unique advantages of zeolites are obvious. The stage is therefore set for some rapid and significant developments involving the synthesis, characterization and structure-property relationships of zeolite based electronic, optical, magnetic and dielectric materials. Zeolites, like any other solid state materials, have their limitations. Those specific to zeolites include pore plugging, poisoning, structural defects, the difficulties of growing large single crystals, and interfacing a zeolite device with the outside world. Many of these problems can however, be solved and are deemed to be interesting research projects.

Much of the research involving new applications for zeolite materials is still at a fairly early stage, but one can extrapolate from the present trends to make the following conjectures: the recent discovery of all-silica zeolites will pave the way to zeolite semiconductors; the marked proton conductivity of certain acid zeolites makes possible the fabrication of electrochromic zeolites; the unveiling of acentric zeolites allows the design of zeolite piezoelectric devices; the molecule size pore and channel structure of zeolites provides a novel medium in which to create ultrahigh resolution images and package and process information at high storage densities; the unidimensional channel architecture of certain zeolites permits the assembly of low dimensional zeolite conductors and the control of energy transfer and energy migration in restricted dimensions. All of this implies that innovation in zeolite materials science is likely to burgeon and flourish in the near future.

Symmetry Reduction in Solid Solutions: A New Method for Materials Design

Since 1808 Proust's Law of Definite Proportions has played a key role in the development of modern chemistry, but by focussing attention on "pure" substances it has subtly tended to discourage chemists from studying solid solutions. Recently they are rediscovering what metallurgists have long known, that solid solutions offer exceptional opportunities for tailoring the physical and chemical properties of materials.

Most chemists would probably view a molecular solid solution as the analogue of a fluid solution, envisioning a lattice of host molecules replaced at random by guest molecules. For a more detailed understanding of the system's properties they would probably consult its phase diagram. This vision suffers from two serious errors which illustrate the maxim that casual application of valid concepts can be more misleading than simple ignorance.

The first error is to assume equilibrium. Most crystals are kinetic, not thermodynamic, phenomena. The distribution of solute molecules, like a crystal's overall shape, is controlled more by the dynamics of crystal growth than by the system's equilibrium stability. Once a molecule is built into the lattice, it is usually slow to change position or orientation. Local equilibration at the solid-fluid interface is probably faster than in the bulk, but even crystal surfaces rarely display the equilibrated, symmetrical form in which the shape and area of each facet is adjusted to minimize surface free energy. The failure of crystals to equilibrate has long been recognized as important both in theory and in technology. A key factor in increasing the sensitivity of photographic emulsions was learning to influence the dynamics of silver halide crystallization so as to obtain a tabular crystal habit.

The presence of a second error in the naive view of solid solutions was recognized only quite recently. Its recognition has fundamental implications both for technology and for our understanding of crystallization. This error is the assumption that guest molecules are randomly oriented, that is, that unit cell sites which are related to one another by symmetry operations of the host's crystal space group should have equal probabilities of occupancy by guest molecules. If occupancy were random, a guest molecule would disturb local symmetry in its immediate vicinity, but the average guest population for each type of lattice site would still reflect the overall symmetry of the host. Thus bulk properties of macroscopic crystal fragments would display the same symmetry as the pure host.

Such retention of symmetry makes good thermodynamic sense, but crystals are not equilibrium systems. Twenty years ago *Kitaigorodsky* cautioned that "Formally speaking, (retention of symmetry) does not necessarily occur."[1] Nonetheless he asserted on intuitive and empirical grounds, "If a substitution of A molecules for B is possible in which the B crystal retains its symmetry, we shall find that this is the substitution that actually occurs." This point of view seemed so natural that few scientists took seriously his "formal" warning that selective substitution might destroy crystal symmetry.

In a series of publications that began last summer *Lahav* and *Leiserowitz* of the Weizmann Institute and their collaborators have challenged the assumption of symmetrical substitution.[2] On the basis of this and other recent work,[3,4] it now seems that solid solutions should routinely show lower symmetry than the pure host, and that this reduction will provide a new level of control over solid-state properties.

The Weizmann studies began with efforts to control crystal growth by inhibiting molecular deposition on particular facets through selective adsorption of additives. Additive molecules were designed so that the portion in contact with the crystal facet closely resembled the host molecule, while the portion away from the crystal surface differed in structure. Thus the additive would adsorb strongly to a chosen crystal face, become trapped within the surface layer, and by protruding prevent deposition of further layers of host molecules on that face. Deposition would continue unhindered on faces to which the additive did not adhere.

To visualize this process, consider the packing of "ducks" in Figure 1. The guest ducks have a projection be-

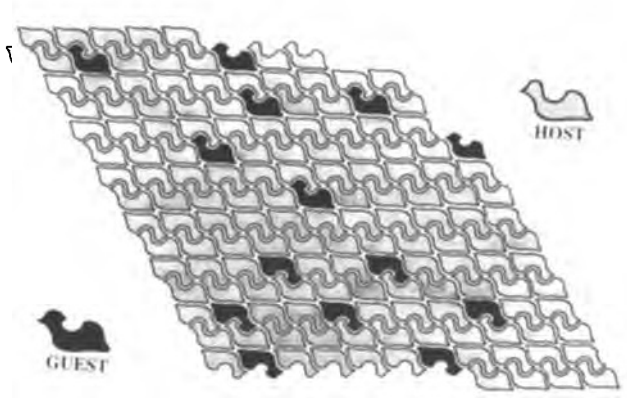

Fig. 1. Schematic solid solution of ducks with pointed heads in a *P*2 lattice of ducks with rounded heads. Note how diagonals of the crystal divide it into sectors with different symmetry properties. This shows that crystal growth nucleated at the center.

hind their heads which makes it difficult to continue deposition of host molecules in the top and bottom rows. Ultimately the head of a host duck may deform enough for it to occupy the unfavorable site where a guest's head protrudes, but the addition will be slower than normal because more energy is required.

One might imagine that the same problem would retard completion of the column at the right border of Figure 1. Here, however, the retardation would be modest, because the guest will soon leave the surface spontaneously, removing the obstacle to column growth. On the top and bottom surfaces the offending guests are locked in by a row of hosts. Many hosts would have to depart in order to allow the guest to escape, and this would take time under conditions of supersaturation. One would expect duck crystals grown in the presence of these guests to be wider than normal in comparison to their height.

In practice, appropriately chosen additives have proven useful for controlling the shape of individual crystals. They have also allowed resolution of racemic mixtures by selectively inhibiting the growth of one of the two enantiomeric crystal forms.[2e] Naturally, additives that were particularly effective in preventing crystal growth were not easily found beneath the crystal surface. Although guest molecules could sometimes be detected by spectroscopic or chromatographic techniques, their concentration was usually too low for diffraction studies that would reveal their orientation. This made it difficult to confirm a clear prediction of the proposed mechanism of growth inhibition, namely, that adsorption of additive molecules should be selective not only for certain faces, but also for certain additive orientations on those faces.

As host molecules deposit on a given face, they must assume all the symmetry-related orientations of the unit cell. At the crystal surface most bulk symmetry operations do not apply, so usually each "symmetry-related" orientation shows a different type of contact with any one crystal surface. This poses no problem for new host molecules, but for the additives some orientations will not fit to the surface. Thus only certain orientations of additive should be included through a given face, and the position of the crystal resulting from growth through that face should have lower symmetry than the pure host lattice.

In the case of Figure 1 hosts must be able to add to the top surface both head-up and head-down, but guests may add only head-up. This results in a division of the crystal into four triangular sectors, separated by diagonal lines which intersect in the region where growth began. The right and left sectors consist of molecules which were deposited through lateral faces as the crystal grew. They contain no guests, except for the one on the right border that will be rejected as the crystal continues to grow. Both top and bottom sectors include guests, but in opposite orientations. In the top all guests are oriented head-up; in the bottom, head-down. Although the crystal as a whole retains a statistical two-fold symmetry axis through its center, the top and bottom sectors considered individually have lost the axial symmetry of pure host.

Two types of diffraction studies now confirm these predictions. In both cases the additives were designed to favor high levels of incorporation and to maximize diffraction contrast. In one case, cinnamamide/thienylacrylamide, the additive differed from host only by replacement of a phenyl ring by a thienyl ring, whose sulfur provided good X-ray contrast.[2a] In the other, asparagine/aspartic acid, an NH_2 group of the host was replaced by OH, and neutron diffraction contrast was supplied by deuterating the guest molecule.[2a,b] Despite the similarity of guests to hosts, individual sectors from both solid solutions show reduction of symmetry ($P2_1/c$ to $P1$ and $P2_12_12_1$ to $P2_1$, respectively) and substantial differences in guest population among "symmetrically equivalent" sites (as much as 15% vs. 2%).

In the 99 : 1 cinnamamide/cinnamic acid system where low contrast and low additive incorporation made diffraction useless, symmetry reduction through selective incorporation was demonstrated by photochemistry.[2a,c] Although pure cinnamamide is centrosymmetric and thus achiral, unsymmetric incorporation of cinnamic acid makes opposite ends of a solid-solution crystal enantiomeric. Photocycloadducts between host and guest from one end of a crystal were optically active with enantiomeric excesses near 50% in the predicted direction. Cycloadducts from the other end of the same crystal showed the opposite stereochemistry, as expected.

Nonlinear optics may represent the most important application of symmetry lowering in solid solutions. These properties depend both on molecular features and on crystal packing. Crystals of many promising molecules have proven unsuitable because their symmetry pairs molecules in offsetting, antiparallel orientations. Cancellation can be avoided by replacing molecules in one of the orientations by additives, or by including the candidate molecule selectively as a guest in a centrosymmetric host. Second harmonic generation has now been used to demonstrate symmetry lowering in solid solutions containing as little as 0.01% guest.[2d] Solid solutions should provide a much greater number and variety of materials displaying second harmonic generation and other phenomena which require crystal polarity, such as piezo- or pyroelectricity.

Bertman and *McBride* have demonstrated another manifestation of symmetry lowering in solid solutions.[3] Host crystals of fatty acid diacyl peroxides viewed along their nominal tetragonal symmetry axes were birefringent, when they were grown so as to incorporate 5–15% of an additive. Diffraction studies on crystal segments showed complete loss of symmetry ($P4_12_12$ to $P1$). Using a polarizing microscope it was possible to trace the growth history of each crystal through differing interference colors in adjacent crystal sectors. These differences resulted from differing orientation of the polarizability tensors of guest molecules.

From one point of view this simple technique uses the additives as "indicators" to provide a new means for studying crystal growth. From another, it provides a new way to study molecular recognition by showing whether the growth site on a crystal surface can distinguish certain structural features of the additive. For example, a particular surface was shown to distinguish chlorine from iodine, but not from bromine.

If symmetry lowering in solid solutions is so general, it seems surprising that it was not recognized long ago, particularly in optical mineralogy, where solid solutions have been studied so extensively. Over the years anomalies have indeed been noted in which high symmetry minerals show division into sectors with lowered symmetry, but this phenomenon was usually attributed to strain fields or gross chemical segregation. By careful optical and X-ray studies *Allen* and *Buseck* recently established that sectoring in optically anisotropic grossular garnets is due to differing ratios of $Al^{3\oplus}$ to $Fe^{3\oplus}$ in octahedral sites which are nominally related by symmetry.[4] To explain this desymmetrization they independently postulated the type of selection during crystal growth that was proposed by *Lahav, Leiserowitz*, and their collaborators.

For all its aesthetic appeal, crystal symmetry can become a liability for designing new materials, e.g. for nonlinear optics, when it results in cancellation of desired properties between symmetry-related molecules. The generality of symmetry lowering during crystallization of solid solutions provides a promising new approach for circumventing this obstacle.

Ferroelectricity and Superconductivity

Some time ago the editor of this journal asked one of us *(H. B.)* to give, every now and then, comments on recent research news, of course, mainly concerned with materials science. Since most of the materials described in this journal are by far too complicated for basic theoretical investigations I wondered, being a theoretical physicist, what the editors really want to see in my comments. I decided that they probably want to have some founded speculations, some educated guesses, and perhaps a personal view on basic problems and ideas. Here is a first try; it is written under the impression that progress in modern materials science is mainly achieved under a broad view of various mechanical, electromagnetic or thermal properties of complex materials.

As an example, I want to discuss some theoretical considerations of the relationship between ferroelectricity and high-temperature superconductivity. This first comment is somewhat courageous as up to now there are many open questions since the pioneering ideas of *B. T. Matthias*[1] who suggested that there must be a mutual exclusion of these two properties. I don't want to give a full account of the historical aspects of the following discussion but would like to point to another paper discussing the coexistence of both effects.[2] (Experimentally, for example, it is very difficult to measure a reversable polarization in good conductors, but it seems to have been established that the superconductor GeTe is also ferroelectric.) Today we know that ferroelectricity is inherently related to the local electron–phonon coupling resulting in a soft-mode behavior for displacive ferroelectrics.[3] In recent years the late *H. Bilz* and his coworkers suggested a shell-model description of the lattice-dynamics of ferroelectrics where the main nonlinearity is locally centered at the lattice site of the chalcogen-ion (preferably oxygen) of representative ferroelectric materials.[4] The microscopic origin of the lattice instability is the nonlinear polarizability of the electron cloud around the oxygen ion, resulting in a dynamic hybridization of the corresponding p-orbitals with the orbitals of the metal-ion ("dynamic covalency").

Recently (but before the discovery of the new high-temperature superconductors), discussion of a possible connection of both phenomena was taken up again. Within the shell-model the point was stressed that a dynamic covalency induces phonon anomalies.[5] That might be thought of as the origin of both, ferroelectricity and superconductivity. Contrary to this, it was argued that pure static polar-

izabilities or static hybridizations are not favorable for these anomalies.

The spectacular discovery by *J. G. Bednorz* and *K. A. Müller*[6] of the perovskite $La_{2-x}BaCuO_4$ as a high-temperature superconductor opens up again the discussion of the relationship between ferroelectricity and superconductivity. These materials and the later ones with even higher transition temperatures (the Y-Ba-Cu-O compounds as well as the Bi-Sr-Ca-Cu-O materials), not only show structural instabilities but are also structurally closely related to many ferroelectric oxides.[7] There is even a ferroelectric-like instability in the Y-Ba-Cu-O compound at high temperatures inferred experimentally from a large dielectric constant.[8] Here it should be pointed out that in spite of the structural similarity of both compounds additional doping and other defects destroy ferroelectricity, but simultaneously are necessary ingredients for superconductivity. This may yield some kind of material recipe to construct both kinds of properties. (Obviously *K. A. Müller* is by no accident also a highly respected expert in the fields of ferroelectric materials and structural phase transitions.)

In this new class of materials one should also consider the Ba-K(Pb)-Bi-O compound[9] where Bi plays the role of the copper ion, not only allowing for a dynamic polarization of the oxygen but also giving rise to charge fluctuations at the metal site. All these facts are discussed in detail elsewhere[10] where the original shell-model is extended and compared to other models. This point of view has now been taken up by several groups and becomes more and more popular. Recently it was shown[11] that in the classical strong coupling formalism an increase in the transition temperature might occur if there is an anharmonic double-well interatomic potential. Such anharmonicities simultaneously, of course, must lead to lattice instabilities and its origin might be the dynamic covalency discussed above. In an interesting paper, *Villars* et al.[12] systematically looked for chemical trends in both high-temperature superconducting materials and high-temperature ferroelectrics. They showed that three relevant parameters, namely the averaged valence electron number, the orbital radii of the ions and the electronegativity, determine the characteristic properties of both classes of materials. All these results together indicate the possibility of a common origin of both phenomena. While in ferroelectrics the instability of the oxygen ion triggers the high macroscopic polarizability, in superconductors we deal with a metal-ion with variable valencies. This discussion, mainly originating from a lattice-dynamical point of view, can also be carried out in the context of systems with correlated electrons. In this respect, *Callaway* et al.[13] introduced their polarization induced pairing model. In an extended Hubbard system they calculated a phase diagram where, for reasonable interaction parameters, the possibility of electron pairing exists (whether this gives rise to long-range order superconductivity is still an open question). Quite recently *Varma*[14] studied a similar effect for the superconducting state resulting from an effective negative intra-atomic electron-electron interaction (especially for the Bi-ion). The origin of this negative interaction is an electron-transfer from the oxygen to the Bi-ion together with sp-hybridization. The same line of thought can be attributed to a paper by *Tesanovic* et al.[15] in which a "unified" picture of the high-temperature superconductors is presented and, in addition to the above ideas, the importance of the various anisotropic geometries of the Cu(Bi)-O arrangements are discussed in detail. With these arguments we are back at the starting point where a mutual exclusion of ferroelectricity and superconductivity was supposed to be based upon geometrical reasons. Probably it is this anisotropy which favors high-temperature superconductivity, as it is also most important for ferroelectricity.

What do we learn from this interpretation of a common origin of ferroelectricity and high-temperature superconductivity? In both cases there is the possibility of a structural instability and therefore it might be worthwhile to look for noncrystalline, that is glassy or even fractal structures[16], to further enhance the transition temperature. Furthermore, the proper choice of highly polarizable anions and valence fluctuating cations with the proper orbitals for hybridization may point to classes of other superconductors. But be cautious, this is a comment on some theoretical ideas of ferroelectricity and superconductivity. Nature might be more elegant.

Book Reviews

Zeolites, Crystal Growth, Polymers and Miscellanea

Catalysis on Zeolites. Edited by *D. Kalló* and *Kh. M. Minachev*. Akadémiai Kiadó, Budapest 1988. xi, 583 pp., bound, DM 115.00.—ISBN 963 05 4559 x

During recent decades zeolites and related molecular sieve materials have proved remarkably successful in various branches of chemistry and chemical engineering. Perhaps the most striking progress has been achieved in the application of zeolites as catalysts. Important advantages of zeolites over more conventional porous solids are their high density and strength of acid sites, the availability of numerous techniques for chemical modifications, and their thermal stability. Moreover, with the advent of molecular sieve materials, the door was opened to shape-selective catalysis, which led to a number of new catalytic processes. Today, zeolites can be tailored for a wide variety of catalytic applications. It is therefore not surprising that catalysis on zeolites is among the major research topics in almost all industrialized countries. About 15 years ago, the European socialist countries, in an attempt to coordinate and intensify their efforts in the field of zeolite catalysis, founded a coordination council, and this book is a state-of-the-art report on the achievements of this multinational cooperation.

The book contains 17 chapters written by experts from Bulgaria, Czechoslovakia, the German Democratic Republic, Hungary, Poland and the Soviet Union. About two-thirds of these chapters focus on non-catalytic aspects of zeolite science, e.g., quantum chemical studies, hydrothermal synthesis, spectroscopic characterization, and chemical procedures for modifying zeolites such as ultrastabilization and dealumination at high temperatures by gaseous reactants such as $SiCl_4$, or isomorphous substitution of silicon and aluminum by transition metals. An excellent chapter by *Wichterlová* et al. deals with the introduction of trivalent cations such as $Al^{3\oplus}$, $Fe^{3\oplus}$ and $Cr^{3\oplus}$ into zeolites, and the catalytic properties of the resulting materials. The six catalytic chapters focus around the preparation or transformation of hydrocarbons, e.g., the disproportionation of alkylaromatics, the Fischer–Tropsch synthesis, the dehydration of methanol, and the oligomerization and hydrogenation of alkenes. In one chapter the concept of hard and soft acids or bases is applied to zeolites. The final chapter reviews industrial applications of zeolites in the German Democratic Republic: catalysts were developed at Leuna for hydrocracking of vacuum gas oil, isomerization of light gasoline, isomerization of C_8-aromatics, and shape-selective hydrocracking of n-alkanes in reformer gasoline.

This is a very valuable book which contains a number of outstanding chapters prepared with great care and expertise. Among these are the chapter by *Shpiro* et al. on the application of SIMS, XPS and related spectroscopic techniques to zeolites, the chapter by *Wichterlová* et al. mentioned above, and the review by *Becker* et al. on industrial zeolite catalysts developed in the GDR, to mention only a few. The value of the book is further enhanced by the long lists of references given at the end of each chapter and the thoroughly prepared subject index.

The contributions collected in this volume also prove that the joint endeavor of the socialist countries led to a very high level of research in zeolite materials science. Given this high level, one wonders why the book pays hardly any attention to the more recent molecular sieves, i.e., zeolites of the newer generations, crystalline aluminophosphates, and materials derived from the latter, such as silicoaluminophosphates. It is also surprising that there is no chapter on the use of zeolite catalysts for the manufacture of organic intermediates containing oxygen, nitrogen, sulfur and other heteroatoms. Nevertheless, in view of the high quality of the contributions and the well-arranged layout, the book can be recommended to everybody who is involved with zeolites and zeolite-like molecular sieve materials.

Crystals in Gels and Liesegang Rings. By *H. K. Henisch*. Cambridge University Press, Cambridge 1988. xiii, 197 pp., bound, $ 35.00.—ISBN 0-521-34503-0

Although, in general, large crystals are not obtained in gels, the use of gels opens the door to the search for crystals with new and interesting optical or electronic properties. Moreover, the techniques are incomparably cheap and may lead to crystals of high perfection. Since the physical and chemical processes in gels are very complex, and inadequate understanding often results in poor crystal growth, this comprehensive review of the techniques of crystal growth in gels will be greatly appreciated.

This instructive presentation reveals the extensive practical experience of the author and his group. The book is divided into five chapters, the first four of which have already been published by the author in the monograph "Crystal Growth in Gels" (Pennsylvania State University

Press 1970), essentially in the present form. With 475 references up to 1986, the new presentation is excellently documented and completely covers the field of crystal growth in gels.

The first chapter gives a review of the early work on the growth of crystals in gels, and introduces the basic growth procedures, in which the gel is in contact with either one reagent reservoir or two separate reagent reservoirs. The operation of the techniques is instructively explained with examples of their application to various materials. Doping possibilities and difficulties that may be encountered are discussed for the first time in this book.

The second chapter deals with the preparation and properties of various gels. Their formation, structure, handling and properties, such as density and porosity, are described in great detail for silica hydrogels. A new contribution deals with the one-dimensional diffusion of one or two counter-diffusing reagents in gels. The diffusion is investigated by numerical method as a function of position and time. According to the two basic growth systems, solutions are determined for gels of finite and semi-infinite lengths with a single diffusant, and for finite gels with two species having equal diffusion coefficients. Constant or time-dependent concentrations are prescribed at the boundaries. Unfortunately the initial distributions are not mentioned.

The influence of reagent distribution on growth rate and crystal perfection is investigated in the third chapter. Growth models of crystals and the importance of diffusive transport are discussed. In addition, sophisticated growth methods and special treatments of growth systems such as reimplantation of crystals are described. In the fourth chapter nucleation and crystal growth are treated by the usual phenomenological theory and illustrated with experimental examples.

The last chapter presents the history of Liesegang rings, numerous instructive examples of Liesegang structures, and many numerical solutions on the formation and spreading of particular precipitation structures for the two basic growth systems. For the calculations the author considers diffusive transport, and assumes two conditions for precipitation, i.e., that the local concentration of the reacting species is nearly uniform, and that the reaction product concentration exceeds a critical value. The detailed presentation of numerical results for various parameters are very helpful in understanding the complex physical and chemical processes in gels. The interesting software used by the author is available for IBM-compatible personal computers. The chapter ends with two reference lists of crystals grown in gels and of growth rate measurements.

From this book the interested crystal grower can find much useful advice on the procedures of crystal growth in gels. In addition it provides the reader with simple theoretical models which are useful in understanding the basic processes such as diffusion, nucleation and crystal growth in gels. The book is easily readable and gives a full and up-to-date coverage of the literature. It will be of great interest to scientists who are involved in crystal growth or materials syntheses.

Polymer Science in the Next Decade, an International Symposium Honoring Hermann F. Mark on his 90th Birthday. Edited by *O. Vogl* and *E. W. Immergut*. Wiley, Chichester 1987. x, 284 pp., paperback, £ 90.00.—ISBN 0-471-63239-2

The above book contains the proceedings of the symposium "Polymer Science in the Next Decade", which was held in New York in 1985 to honor *Hermann F. Mark*. Subdivided into four sections, it consists of a series of short reviews on a wide variety of subjects relating to contemporary polymer science. At first one might be inclined towards the view that this is one of the numerous books put together after a symposium without much editing, and hence of rather limited use. However, closer inspection reveals that the present book is indeed an interesting contribution to the literature of polymer science. First of all, the man being honored is *Hermann F. Mark*, who can certainly be counted among the great scientists of this century. Born in 1895, he has contributed greatly to physical chemistry and to polymer science. He still continues a very active schedule of travelling and lecturing around the world. So it seems rather appropriate that on the occasion of his 90th birthday a symposium on opportunities and future trends in polymer science has taken place.

The list of speakers includes renowned names such as *Paul Flory* and *Linus Pauling*. The multitude of topics reflects modern polymeric science in a very lively fashion. The short articles are useful for gaining a first insight into the present status of certain fields. Noteworthy is the contribution of *M. F. Perutz* on the design and engineering of proteins. Another well-written review by *Katchalski-Katzir*, *Wilchek* and *Patchornik* deals with chemically active and biologically specific polymers. An article of particular interest by *F. R. Eirich* gives a very personal view on macromolecules and evolution. A number of other reviews are much shorter, but still quite useful to get an idea of present trends in polymer science. In addition to these purely scientific reviews, the book contains many personal recollections concerning *H. F. Mark* and the early days of polymer science. Both the scientific part and the more personal statements are useful for anyone who wants an overview of contemporary polymer science and how it came into being. Thus, the book is certainly recommended for libraries of departments of chemistry and biology.

Thermotropic Liquid Crystals, Fundamentals. By *G. Vertogen* und *V. A. de Jeu*. Springer-Verlag, Berlin 1988. xi, 324 pp., hard cover, DM 134.00.—ISBN 3-540-17946-1

The chemistry and physics of liquid crystals is certainly one of the most fruitful areas of modern materials science. However, despite the enormously growing literature there are only a few books available treating this subject. The classical treatise by *de Gennes* ("The Physics of Liquid Crystals", Oxford 1974) is no longer up-to-date, despite the clarity of presentation. The book by *Vertogen* and *de Jeu* aims to fill this gap. It is the clear intention of the authors to focus solely on fundamental aspects of thermotropic liquid crystals.

The book is organized in four sections. Part I is devoted to an introduction of the subject, and gives a very clear descriptive account of the various liquid crystalline phases. Here the reader finds an overview of some more recent developments, such as smectics with bond orientational order. However, other topics of interest such as discotic or polymeric liquid crystals are dealt with in a very brief manner. Part II deals with continuum theory, introduced entirely in tensor notation. Experiments relating to the orientational behavior of liquid crystals are described from a theoretical point of view in Part III. The final part outlines the present state of the theories of liquid crystalline order.

In all chapters the material is treated in a rigorous mathematical way. This makes the book rather tedious reading for the beginner, but is very useful for those who are more advanced in this field. A very thorough introduction of the Landau theory, and the treatment of molecular statistical theories starting from the theory of simple liquids, is certainly of particular interest, since it may not be found in other books. However, the choice of experimental examples has been restricted to only a few selected samples. Consequently the book is not a guide to current experimental work in this field. One wonders if a treatise on thermotropic liquid crystals can virtually omit areas such as polymer liquid crystals or discotics without being regarded as incomplete. Nevertheless, the consistent and vigorous presentation of the selected topics makes this treatise a highly useful and indispensable book for everyone working seriously in the field of liquid crystals.

Synthesis and Separations Using Functional Polymers. By *D. C. Sherrington* and *P. Hodge*. Wiley, Chichester 1988. x, 454 pp., bound, £ 52.50.—ISBN 0-471-91848-2

Coming into prominence some 25 years ago as supports for solid phase peptide synthesis, synthetic functional polymers have emerged as a class of novel materials with a multitude of applications, such as supports for biotechnology, solid phase organic synthesis, and separation techniques, as well as for several other purposes. The obvious advantages of these heterogeneous systems (ease of separation, recycling etc.) have stimulated a great deal of research interest in this area, which is evident from the many research papers and review articles on these topics. During the development of the field it became evident that the technique is far more complex than was initially thought; this warrants careful consideration of the chemical and physical properties of the polymeric supports used, and of optimizing the specific reaction conditions necessary with these systems. To apply them correctly requires a thorough understanding from the standpoints of organic chemistry (or biochemistry) and polymer chemistry.

In bringing out this volume to provide researchers with an in-depth and up-dated overview covering all these aspects, *D. C. Sherrington* and *P. Hodge* have done a commendable job with the help of a group of well-known scientists. By summarizing the published work of many leading practitioners of polymer supported chemistry, this book provides a critical review of some of the most important aspects. The present volume is a sequel to the first book on this topic ("Polymer-supported Reactions in Organic Synthesis") by the same editors, published nearly a decade ago. While some of the chapters of the earlier book have merely been updated since 1979, others are new additions.

The book is divided into eleven chapters dealing with several interesting aspects of the applications of functional polymers in chemical operations (syntheses and separations). It appears that the chapter authors were persuaded to cover the entire story instead of highlighting their own scientific accomplishments. Thus, with the exception of one chapter, a wide and balanced coverage of the specific topics has been achieved.

The book begins with a chapter by *Guyot*, which gives an authoritative and comprehensive account of the design and structural characterization of polymeric supports. Support design appears to be critically important for success in this field. The second chapter by *Hodge* provides a detailed review of the applications of functional polymers in synthetic organic chemistry. Further interesting aspects of the applications of functional polymers covered in this book include: "Polymeric Phase Transfer Catalysts" (*Tomoi* and *Ford*); "Polymeric Models of Reactive Biological Systems" (*Challa* and *van den Berg*); "Polymers in Affinity Chromatography" (*Jervis*); "Polymeric Ligands in Hydrometallurgy" (*Warshawsky*); "Polymer Bound Transition Metal Complex Catalysts" (*Garrou* and *Gates*) and "Use of Chiral Polymers for the Separation of Enantiomers" (*Pirkle* and *Mohler*), which provide valuable information on the state of the art in these research topics. Somewhat more specialized applications are dealt with in the chapters on "Design and Industrial Applications of Polymeric Acid Catalysts" (*Widdecke*), and "Properties of Polymeric Rose Bengals—Polymers as Photochemical Reagents" (*Neckers*). The last chapter of the book, "A Wider Perspective of Polymeric Supports and Reactive Polymers"

by *Sherrington*, deals with broader aspects of this field, covering new types of supports, polymeric vesicles, microcapsules, polymeric drugs, photoresists, etc. This clearly demonstrates the interdisciplinary aspects of functional polymers, and should stimulate further research interest.

One would have wished to find additional chapters on the applications of functional polymers for immobilization of enzymes and microorganisms, as well as on polymer-supported synthesis of oligonucleotides, which are likely to be some of the more rapidly expanding areas of research involving polymer supports. Nevertheless, this book serves as an excellent source of information on the applications of functional polymers. The bibliography is extensive (over 1500 citations) and up-to-date. In one particular chapter, citations are sometimes given for less accessible periodicals, even though the same results have also been published in more generally available journals. Figures and formulas are quite clear and the presentation of the book is excellent, with a colorful waterproof cover. It should find its place in all chemical libraries, and is highly recommended to all scientists working with polymeric supports, as well as to aspiring newcomers to this field. It is likely to serve as the standard monograph for some years to come.

Günter Wulff, Pradeep K. Dhal
Institut für Organische Chemie
und Makromolekulare Chemie
der Universität Düsseldorf (FRG)

Polymer Modified Textile Materials. By *J. Wypych*, Wiley, New York 1988. xiii, 317 pp., bound, £ 70.00.—ISBN 0-471-83959-0

Composites have been treated frequently in reviews and monographs; polymer-coated textile fibers, however, have been considered to a much lesser degree in the literature, although the materials and their interactions are similar. It is true that in the latter materials the polymer constitutes only a small fraction of the total mass, but it plays a key role in the often highly sophisticated applications of these textile materials.

The raw materials for coating polymers, textile materials and release papers are treated in the first chapter. In particular, solutions, emulsions/dispersions and plastisols are discussed. The second chapter deals with machines and equipment for compounding, coating, heating and finishing. Six commonly used processes, namely spreading, dipping, spraying, immersion, melt coating and lamination are treated in detail. Many photographs and diagrams of machines giving useful information are included, particularly in conjunction with examples of applications, cost analysis and ecological aspects. Production lines are described in Chapter 5, in a manner similar to that in Chapter 2, but it is incomprehensible why these two chapters were not kept together in their logical sequence.

"The scope of application of coating methods", with emphasis on end-use, type of resins, and technical demands, is discussed in Chapter 3. Topics included are consumer items, industrial uses, technical products, geotextiles and -membranes, special yarns, and PTFE-coated glass fibers. Chapter 4 describes some interesting developments, including products with advanced mechanical, thermal, and optical properties, textiles with improved dimensional stability, permeability to water and air, and special properties with regard to burning, abrasion, cleaning and ageing behavior, to give only a few examples.

Chapters 6–8 treat the rheology of the coating processes and the most important factors affecting the processes. Numerous scanning electron micrographs showing the structure of the coated materials are included. Heat and mass transfer in coating processes are discussed in relation to recent achievements of chemical engineering.

The last two chapters are concerned with toxicity (LD_{50} values, smoke production, water pollution) and waste aspects, with particular consideration of recycling and separation methods, topics which have become increasingly important.

The organization of the material in the monograph is not entirely convincing. Furthermore, the presentation is strong in some chapters and weak in others – as is to be expected for a book written by a single author and covering such a broad field. Finally, some editorial effort would certainly have improved the text.

Nevertheless, the book gives a most valuable review of the state of the art of applying polymers to textile materials to improve their properties and make them suitable for special applications.

Hartwig Höcker
Deutsches Wollforschungsinstitut
an der Technischen Hochschule Aachen (FRG)

Foams and Biliquid Foams—Aphrons. By *F. Sebba*. Wiley, Chichester 1987. vii, 236 pp., bound, £ 29.59.—ISBN 0-471-91685-4

It is not easy to assign this book to a specific category. On the one hand it is intended as a textbook on foam systems, while on the other hand it contains a number of sections which are more in the nature of popular scientific writing. The author tends very much towards a simplified style of presentation. This is certainly an advantage for readers who are not specialists in colloid chemistry. In the diagrams too one finds that only the essential relationships are outlined. The illustrations look as though they have been taken from a set of lecture notes. Furthermore the whole book makes a similar impression.

The most important of the 13 chapters have the following titles: Forces Operating at Interfaces; Thin Liquid Films; Polyhedral Gas Foams; Colloidal Gas Aphrons;

Spreading of Lenses on Water; Biliquid Foams; Polyaphrons; Applications of Polyaphrons; Invert Aphrons; Unusual Forms of Aphrons.

The Greek-derived word "aphrons" is used by the author to describe those systems which are known in general scientific usage as "concentrated emulsions". The work of *Princen* and *Lissant* and their colleagues has unfortunately been ignored, which is especially regrettable in view of the fact that modern theories on the flow behavior of foam systems originate from this group.

While the book's treatment of theoretical aspects is rather elementary, and even incomplete, the reader nevertheless finds here an extensive and hitherto unique compendium of interesting observations which the author, as an expert on this topic, has collected together. This constitutes the real worth of the book, despite some other serious shortcomings.

Gerhard Platz
Institut für Physikalische Chemie
der Universität Bayreuth (FRG)

Dispersing Powders in Liquids. By *R. D. Nelson*. Elsevier, Amsterdam 1988. xviii, 246 pp., bound, US $ 84.25.—ISBN 0-444-43004-0

This book is published as Volume 7 in the series "Handbook of Powder Technology" and comprises 245 pages, divided into eight well-arranged chapters. These describe the fundamental characteristics that play a role in the dispersion of inorganic materials in powder form. Unfortunately, certain materials of technical importance, for example synthetic silicas and carbon blacks, are not dealt with here. This is rather a pity, since these substances have very high specific surface areas which generally render them difficult to disperse. The reviewer also feels that the book lacks two chapters which would be of relevance for practical purposes—one about dispersers and one on the correct choice of mill base compositions. In the appendices the list of "liquids" includes only chemically pure solvents, but not, for instance, a selection of liquid binders, which are of technical importance in different fields of industry. This book is therefore not so much intended for experimentalists and technologists, but is more suited to the needs of readers with educational objectives, particularly since it deals with numerous basic physical principles. In this context, it is encouraging that the HLB value is also considered here; the fact that this value was established phenomenologically has often led to it being overlooked in scientific articles.

All in all, this small book is an ideal reference source for anyone who is not familiar with the problems relating to the surface science of materials in powder form.

Horst Ferch
Degussa, Hanau (FRG)

A Guide to Materials Characterization and Chemical Analysis. Edited by *J. P. Sibilia*. VCH Verlagsgesellschaft, Weinheim 1988. x, 318 pp., bound, DM 75.00.—ISBN 3-527-26867-7

This book represents a survey of state-of-the-art techniques for modern materials characterization and analysis. The book covers approximately 75 techniques that are used in characterization of chemicals, polymers, ceramics, metals and composites. The first chapter provides an introduction to how one might utilize the techniques that follow in practical problem-solving applications. Each of the following chapters describes one or more techniques, with the presentation organized according to the use of the technique, sample preparation, underlying physical and chemical principles, applications, and limitations. Due to the breadth of coverage, only a limited amount of space is devoted to each technique. However, this is adequate to introduce the technique; several references are listed after each section, providing in-depth detailed information for the reader who is interested in a more rigorous treatment.

This is a valuable book for materials laboratories and general industrial laboratories where characterization and analysis of many different substances may require several different techniques. It serves as a good review for established scientists as well as a useful resource for beginners.

Department of Chemistry
University of Houston (USA)

DECHEMA Corrosion Handbook, Vol. 2. Edited by *D. Behrens*. VCH Verlagsgesellschaft, Weinheim 1988. x, 340 pp., bound, DM 775.00.—ISBN 3-527-26653-4

The DECHEMA Corrosion Handbook—a series of at least twelve volumes is planned—is a completely new English edition of the DECHEMA Werkstoff-Tabelle.

The second volume (340 pages) describes the corrosion properties of metallic, non-metallic inorganic, and organic materials in corrosive media of aliphatic aldehydes, ammonia and ammonium hydroxide, sodium hydroxide and the underground corrosion in soil. The largest parts of this volume are devoted to sodium hydroxide (154 pages) and soil (90 pages).

Some errors of the first volume which had earlier been criticized by the reviewer have been corrected in Volume 2. As an example, some electrochemical reference systems are now mentioned in the introductory part of some chapters, but in addition to these many others are mentioned in the detailed descriptions of the corrosion behavior of the different materials. In subsequent volumes a list of all these reference systems should be included in the introduction, citing also their potentials versus the Standard Hydrogen Electrode.

In general, the clearly arranged layout of the first volume is continued in the second volume. Much valuable in-

formation concerning the corrosion behaviour of widely different materials has been carefully collected, taking into account the literature up to approximately 1985.

The first chapter, which discusses the corrosion properties in solutions of aliphatic aldehydes, contains a very well written introduction which describes the most important technical processes in which aliphatic aldehydes are used, and gives a summary of the most important corrosion problems. The different aldehydes are then described in detail, including a short summary of the corrosion problems that may arise for the given aldehyde in a given technical application. This descriptive part is more informative than the short summary table, which gives only general ratings for the different materials.

The same is true for the second chapter, which describes the corrosion behavior of materials in ammonia and ammonium hydroxide. Again, the introduction is well written, summarizing technical processes in which ammonia participates, and discussing major corrosion problems such as H-embrittlement in these solutions. The detailed description of the individual corrosion properties of the different materials is accurate and careful. In some cases, however, the electrochemical background of the corrosion process in electrolytes should have been presented more clearly, e.g. in the discussion of the activation of the corrosion process by O_2 (p. 58), or in the description of the "chemical conversion process" of the corrosion induced by O_2 (p. 55). Reference should have been made here to the electrochemical nature of the corrosion process, the O_2-reduction being the cathodic reaction.

Chapter 3 is devoted to corrosion in alkaline environments. In contrast to Chapters 1 and 2 the introduction is rather short, and presents only limited information on the technical processes in which NaOH is used, the practical corrosion problems, etc. The introduction provides some general information concerning pitting corrosion, pitting potentials and stress corrosion cracking. However, this information is rather limited, and should have been incorporated into a chapter devoted to basic corrosion mechanisms, which is missing from the Corrosion Handbook. The corrosion properties of the individual materials are discussed in great detail, with special emphasis on the corrosion of metals under conditions of stress corrosion cracking. After discussing the individual metallic, non-metallic inorganic, and organic materials, tables are presented which summarize the corrosion properties of these materials in different NaOH solutions at different temperatures, etc. These tables are quite informative to the reader. A point of criticism to the reviewer is the rather frequent statement of electrode potential without any reference system (Figs. 11, 20, 22, 23, ..., Table 11 ...). As an example, Fig. 19 shows the lifetime of an unalloyed steel in 33% NaOH as a function of the electrode potential. The result of this technically important figure is that stress corrosion cracking is observed only in a very limited potential range. However, the potential axis is given in "Volt" without any reference, and consequently the figure could be quite misleading to inexpert readers. The number of reference systems used in the Corrosion Handbook is quite large (Ag/AgCl, $Cu/CuSO_4$, Hg/HgO, SME? page 112) and these should be summarized in the introduction.

The last chapter is concerned with the underground corrosion in soil. The introduction covers about 30 pages and describes the chemical composition of different soils, their corrosivity, corrosion due to microorganisms in soil, and the possibilities for protecting metallic materials in soil, e.g. by cathodic protection. In general, this part is well written and quite informative, but the electrochemical aspects of cathodic protection could have been presented in more detail, in a better arranged and more compressed form, without repeating the same facts—e.g. the correlation between organic coating and cathodic protection—in many places throughout the text. Some techniques which are used to measure the correct protection potential—e.g. switch-off potentials—are mentioned later in this chapter, and these too should have been incorporated into the introduction. The rest of the chapter is well written and, for example, clearly shows the importance of correctly chosen organic coatings for the corrosion protection of steel pipes which are polarized cathodically.

In summary, the second volume of the DECHEMA Corrosion Handbook is a highly valuable reference book for all engineers working in the area of corrosion, provided the user has a thorough knowledge of the basic physical concepts in corrosion science.

Semiconductor Electrodes. Edited by *H. O. Finklea*. Elsevier, Amsterdam 1988. xxii, 520 pp., bound, DFl. 340.00.—ISBN 0-444-42926-3

Continuing the series "Studies in Physical and Theoretical Chemistry" (Elsevier) a new edition entitled "Semiconductor Electrodes" is now available (Vol. 55). The ten chapters by different authors are devoted to particular semiconductor electrode materials. Following a concise and well written introduction by *H. Finklea*, Chapter 2 describes the photoelectrochemistry of the large band gap oxides TiO_2 and $SrTiO_3$. A wealth of information on physical and photoelectrochemical properties is presented in this chapter. The inclusion of basic experimental aspects such as ohmic contacts, electrode preparation and sample mounting is definitely an advantage for the interested reader. Chapters 3 and 4 deal with other less intensively investigated semiconducting metal oxides (Fe_2O_3, SnO_2, In_2O_3 and WO_3). Here, too, valuable information on electrode preparation and growth methods is given, in addition to the detailed analysis of the photoelectrochemical behavior.

ADVANCED MATERIALS

In Chapter 5, Si and Ge are treated, including an important section on etching procedures which are of general relevance for those working with Si. *N. S. Lewis* and *A. B. Bocarsly* review the photoelectrode properties of these materials in aqueous and non-aqueous solutions, and include very specific topics such as derivatized surfaces (attaching mediators for improved redox activity). The following chapter on II-VI semiconductor electrodes reviews the fundamental photoelectrochemical observations on CdS, CdSe and CdTe. This chapter contains a section on thin film electrodes, including ceramic, vacuum deposited, electroplated, painted, sprayed and immersion-plated electrodes.

The next chapter treats GaP electrode behavior, and contains an interesting but somewhat speculative section on surface luminescence. Chapter 8 is a thorough and sound description of photoelectrochemical processes occurring on GaAs electrodes. Thermodynamic and kinetic aspects of electrode stability are dealt with, and expressions for the stabilization efficiency for three cases are given. Here *K. W. Frese,* Jr. also reviews CO_2 reduction at GaAs surfaces and includes data on light-to-electricity regenerative solar energy conversion. In Chapter 9 *L. F. Schneemeyer, A. Heller* and *B. Miller* review the many properties of InP electrodes. Eleven growth methods are briefly described including chemical vapor deposition, and liquid encapsulated Czochralski and molecular beam epitaxy. A short overview on solid state photovoltaic InP-based systems provides the background for the electrochemical sections that follow.

Photoanodes and -cathodes in aqueous and non-aqueous regenerative cells are thoroughly described, followed by a very intriguing section on hydrogen-evolving InP photocathodes covered by quasi-transparent metal catalysts. In addition, CO_2 and SO_2 reduction are treated. The chapter ends with a section on polycrystalline InP electrodes, including grain boundary passivation and hot carrier injection. The last chapter is devoted to the layered type transition metal dichalcogenides MoX_2 and WX_2, X = S, Se. Here *B. Scrosati* gives a thorough review of the solid state and photoelectrochemical characteristics of these materials. The section on surface morphology and its influence on the photoelectrochemistry is especially carefully written, and is followed by sections on photointercalation, behavior in non-aqueous electrolytes, and polycrystalline samples.

In summary the book contains a wealth of information on the most relevant semiconductor electrodes to date, written by some of the leading researchers in the field. There are only a few critical points to be addressed. A chapter on the intensively studied ternary chalcopyrites would have completed this volume. In addition, it would have been desirable to include also some authors from outside the United States, in accordance with the development and history of research in this area. The price of DFl. 340 appears too high for a book made by photographic reproduction.

Metallocene Carbene Complexes and Related Compounds of Titanium, Zirconium, and Hafnium

By Gerhard Erker*

The structure and reactivity spectrum of transition-metal carbene complexes has been widened significantly by the bent metallocenes of titanium, zirconium, and hafnium. Proceeding from metal carbonyls and reactive (butadiene)-, (aryne)-, or (olefin)MCp_2 complexes, many new Fischer-type metaloxycarbene complexes of Zr, Hf, V, Nb, Cr, Mo, W, Mn, Re, Fe, Ru, Os, Co, Ni, and Rh have been synthesized. The incorporation of titanocene, zirconocene, or hafnocene fragments allows new types of carbene complexes to be prepared. For the (alkylidenamido)metallocene complexes $[Cp_2M(X)(\equiv N=CRR')]$, metallocene ylides $[Cp_2M(R)(\equiv CHPPh_3)]$, and binuclear (μ-alkynyl)metallocene compounds, some metal–ligand π bonding is indicated. Metallocene complexes with metallaoxirane units, $Cp_2\overline{M-CH_2-O}$, show similar chemical behavior to that of binuclear (μ-methylene)complexes $L_n\overline{M-CH_2-M}L_n$. The methylene groups of zirconaoxirane complexes, which are derived from carbon monoxide, may be expelled as ethylene by thermally induced CC coupling. With metal hydrides, CH_2 transfer with insertion into the metal–hydride bond occurs. In one case, methylene insertion into a metal–carbon bond can even be observed. These reactions of Ti-group metallaoxiranes could be models for postulated intermediates in the Fischer–Tropsch synthesis.

1. Introduction

Carbene complexes are among the most important organometallic compounds. The discovery of heteroatom-stabilized carbene complexes $[L_nM=CR(OR)]$ by *E. O. Fischer* et al.[1] and of heteroatom-free metal alkylidene complexes $[L_nM=CR_2]$ by *R. R. Schrock* et al.[2] laid the foundation for the recognition of reactive carbene complexes as decisive intermediates for many metal-catalyzed transformations of organic substrates.[3] Carbene complexes are becoming increasingly important as reagents in organic synthesis. The nucleophilic Schrock-type carbene complexes, obtained from the early transition metals, have ylide character and have proved useful as selective Wittig reagents.[4] The CR(OR) units of Fischer-type carbene complexes are being employed very successfully as C_1 synthons in template-controlled CC-coupling sequences.[5] The $-C(=M)OR'$ unit can activate a neighboring R group, in a manner similar to that of ester groups $-C(=O)OR'$.[6] Last but not least, the carbene complexes are significant as the simplest organometallic complexes with a metal–carbon π bond.[7]

New developments have broadened considerably the preparative routes to and applications of transition-metal car-

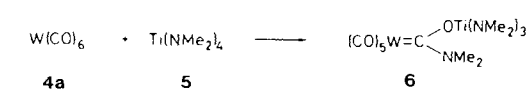
bene complexes. The bent metallocenes of group 4 transition metals[8, 9] have played an important role in this. The chemistry of titanocene, zirconocene, and hafnocene complexes has erupted with a range of new kinds of organometallic compounds that resemble the traditional mono- or multinuclear carbene complexes in their bonding properties and reactions. Consequently, the structure and reactivity spectrum of this class of compounds has been significantly widened. Selected examples illustrating these developments will be discussed in this article.

2. Synthesis and Properties of Metaloxycarbene Complexes

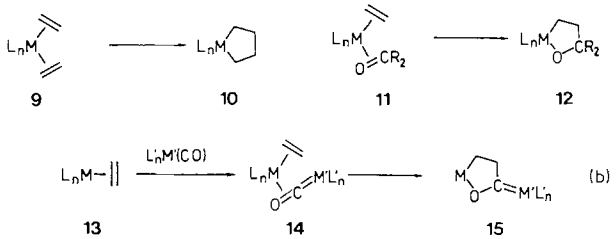


2.1. The Fischer Route

In the two-step conversion of metal carbonyls to metal carbene complexes developed by *E. O. Fischer* et al. [Eq. (a)], a carbon nucleophile is added to the M–C≡O unit of **1** in the first step to form an acylmetalate complex **2**.[1, 10] The product **3** results from further reaction with an electrophile. Organometallic compounds (e.g., from elements of the Ti group) can also function as the electrophile. As an example, the complexes $[(CO)_5Cr=C(CH_3)OTiClCp_2]$ and $[\{(CO)_5Cr=C(CH_3)O\}_2TiCp_2]$ are obtained from Cp_2TiCl_2.[11]

1 **2** **3**

This route to carbene complexes is quite general. The limits of this method are determined by the balance of reactivity at the acylmetalate intermediate **2**. On the one hand, an adequate stabilization of **2** is required, without which it would not form at all. On the other hand, the success of the second part of the reaction path can be adversely affected by overly strong localization of the negative charge at the $(CO)_nM$ group. If the intermediate **2** is too stable, it frequently resists the *O*-alkylation in the following step. Metal alkylation or reaction at another ligand affords acyl complexes rather than the desired Fischer-type carbene complex.[12] The simplest way to bypass the limitations of the Fischer synthesis would seem to be to reverse the order of the reaction steps in Equation (a). Titanium and zirconium compounds having a Lewis acidic metal center and nucleophilic ligands have proven themselves very successful as reagents for this procedure. Thus, the reaction of $[Ti(NMe_2)_4]$ **5** with $[W(CO)_6]$ **4a** affords the carbene complexes **6**. Other metal carbonyls (M = Mo, Fe, Ni) react similarly. The bis(pentamethylcyclopentadienyl)zirconium dihydride reagent **7** was used to convert metal carbonyls (M = Zr, Nb, Cr, Mo, W, Rh) into zirconiumoxycarbene complexes (e.g., **4b** → **8**). In several cases, the addition of the monomeric **7** is reversible.[13]



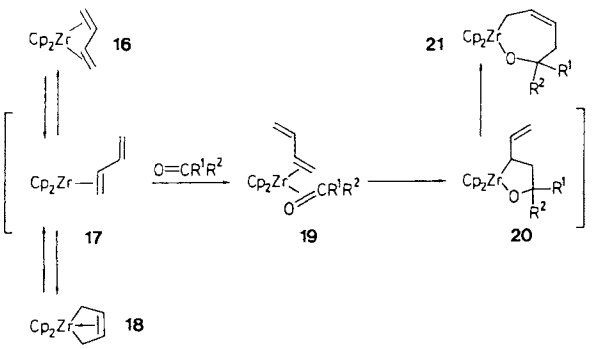
4a **5** **6**

4b **7** **8**

2.2. Synthesis of Metaloxycarbene Complexes without Nucleophilic Addition

Heteroatom-stabilized carbene complexes can be prepared by routes avoiding nucleophilic addition to metal carbonyls. Examples are the L_nM-induced cleavage of electron-rich olefins $(R_2N)_2C=C(NR_2)_2$[14] and reactions of metalate complexes, Na_2ML_n, with Vilsmeier salts, $(RClC=NR_2)^{\oplus}Cl^{\ominus}$, to give the carbene complexes $[L_nM=CR(NR_2)]$,[15] both developed by *Lappert* et al. Metal carbonyls can be converted into carbene complexes by reaction with very reactive η^2-olefin complexes of titanocene, zirconocene, or hafnocene. Although these reactions formally resemble the original reaction sequence of *E. O. Fischer*, they are probably mechanistically quite different [Eq. (b)] and complement the "classical" reaction in Equation (a). They are reminiscent of a frequently observed organometallic reaction, namely, the (presumably) concerted ring-closure of bis(olefin)metal complexes **9** to give metallacyclopentanes **10**.[16] The oxametallacyclopentanes **12** ($L_nM = Cp_2Ti$, Cp_2Zr, Cp_2Hf) are formed analogously from (η^2-ketone)(η^2-olefin)metal complexes **11**. If the side-on-coordinated organic carbonyl compound is replaced in **11** by a metal carbonyl complex, an analogous ring-closure reaction affords the metallacyclic metaloxycarbene complex **15** (**13** → **14** → **15**).

9 **10** **11** **12**

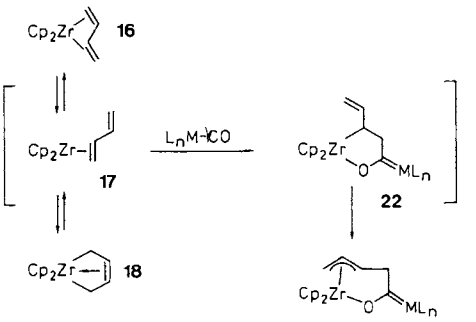


13 **14** **15**

For this reaction, the few known isolable mono(olefin)-metallocene complexes of the Ti group are obvious candidates, e.g., (ethylene)bis(η-pentamethylcyclopentadienyl)titanium or (ethylene)bis(indenyl)titanium.[17] We have used (butadiene)bis(cyclopentadienyl)zirconium and related compounds for carbene complex syntheses by Equation (b). They are available as easily accessible starting materials on a large scale.

2.2.1. Carbene Complexes from (η^4-Diene)metallocenes

(Butadiene)zirconocene exists at room temperature as two isolable isomers, (*s-trans*-η^4-butadiene)- and (*s-cis*-η^4-butadiene)zirconocene **16** and **18**, respectively.[18] The equilibration (**16**:**18** ≈ 1:1 at 25 °C; $\Delta G^{\ddagger}_{10.5\,°C}$ (**16** → **18**) = 22.7 kcal mol^{-1}) presumably occurs through the coordinatively unsaturated intermediate (η^2-butadiene)zirconocene **17**. The isomers **16** and **18** have very different reactivities.[19, 20] The (*s-cis*-η^4-diene)metallocene has metal alkyl character and adds to organic carbonyl compounds, behaving as a typical carbon nucleophile. By comparison, the CC-coupling reactions of the non-nucleophilic, coordinatively saturated (*s-trans*-η^4-diene)metallocene species proceed via the easily obtainable (η^2-diene)metallocene intermediate **17**. Surprisingly, several ketones have been shown to react faster via this reaction path (**17**) than by direct nucleophilic addi-

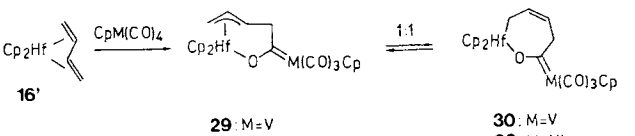


tion: under kinetic control, the only observed reaction of a **16/18** mixture with excess ketones is that of the (*s-trans*-η^4-butadiene)zirconocene. The heterocycle **21** is thereby formed via **19** and **20**. The (*s-cis*-η^4-diene)$ZrCp_2$ isomer does not react until the temperature is increased sufficiently to allow the **18** → **16** isomerization to occur.[21]

Hexacarbonylchromium reacts slowly at room temperature (12 h) with the equilibrium mixture of (*s-cis*-/*s-trans*-η^4-butadiene)zirconocene **16/18** to form the (η^3-allyl)zirconiumoxycarbene complex **23a**. Reaction of **16/18** with $Mo(CO)_6$ or $W(CO)_6$ affords the analogous **23b,c**.[22] Between −20 °C and 0 °C, the isomerization **16** ⇄ **18** is frozen out, and only the (*s-trans*-η^4-butadiene)zirconocene **16** reacts (quickly) with [$Fe(CO)_5$]. The metallacyclic (η^3-allyl)zirconiumoxycarbene complex **24a** is formed as the sole product, since the expected intermediate with (σ-allyl)metallocene structure rearranges very quickly to the more stable π-allyl form **24a**. The reaction of [$(CO)_4Fe(PPh_3)$] with the **16/18** mixture leads just as easily to the formation of the phosphane-substituted iron carbene complex **24b**.[23] Under the usual conditions of the Fischer synthesis, the *O*-alkylation step gives carbene complexes with negligible amounts of side products *only* with the use of nitrosyl ligands or very strong alkylating agents. Carbene transfer reactions (e.g., from [Cp(CO)(NO)Mo=CRPh] to photochemically generated [$Fe(CO_4)$]) represent alternative routes to simple tetracarbonyl(carbene)iron complexes.[24]

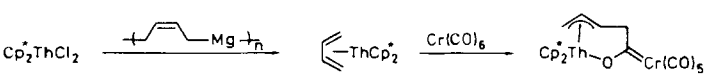
The synthesis of cobalt and rhodium carbene complexes by the route in Equation (a) requires the presence of ligands to stabilize the acylmetalate intermediate.[25,26] Carbene complexes with the (η-cyclopentadienyl)cobalt or -rhodium fragments have thus far been prepared by alternative reaction paths.[13c,15] $CpRh(CO)_2$ reacts at room temperature with the **16/18** equilibrium mixture to give the carbene complex **25a**. At lower temperatures, only the *s-trans* isomer **16** reacts.[27]

The metallacyclic (η^3-allyl)zirconiumoxycarbene complex **25b** crystallizes on cooling the $CpCo(CO)_2$/(butadiene)zirconocene reaction mixture. At room temperature in solution, a fast equilibrium between the carbene complex and the starting materials is established. In the reverse reaction with CC bond cleavage, only (*s-trans*-η^4-butadiene)zirconocene **16** is formed together with $CpCo(CO)_2$ under kinetic control. This complex then isomerizes to the *s-cis* isomer **18**. The equilibrium position between metaloxycarbene complex and starting complexes is influenced by the introduction of substituents at the Co-bound Cp ligands. The zirconiumoxycarbene complex **25c** was obtained from [(η-C_5H_4Cl)$Co(CO)_2$] by reaction with the Zr reagent. The



ML_n = $Cr(CO)_5$, $Mo(CO)_5$, $W(CO)_5$ (**23a,b,c**);
$Fe(CO)_4$, $Fe(CO)_3PPh_3$ (**24a,b**);
Rh(CO)Cp, Co(CO)Cp, Co(CO)(η-C_5H_4Cl) (**25a,b,c**);
$Ni(CO)_3$ (**26**);
$Zr(CO)Cp_2$, $Hf(CO)Cp_2$ (**27a,b**);
$V(CO)_3Cp$ (**28**)

equilibrium position for this reaction at room temperature is such that no starting materials could be detected (^1H NMR spectroscopy).[28]



The isolation of the nickel carbene complex **26** was complicated by the fast equilibrium with the reactants $Ni(CO)_4$ and (*s-trans*-η^4-butadiene)zirconocene **16**. In solution, **26** is stabilized by the presence of excess tetracarbonylnickel.[29a,b] Under the usual conditions, $Cp_2Zr(CO)_2$ and $Cp_2Hf(CO)_2$ were converted into the metaloxycarbene complexes **27a** and **27b**, respectively.[29]

Carbene complexes of vanadium are rare, although it is possible that they play an important role in vanadium-catalyzed reactions.[15a,30] Reaction of $CpV(CO)_4$ with (butadiene)zirconocene affords the vanadium carbene complex **28**. When **28** is dissolved in benzene at room temperature, equilibrium between **28** and the starting materials is established immediately (**28**: starting materials ca. 1:1 at 25 °C).[31] The equilibrium position is shifted advantageously by the use of (butadiene)hafnocene **16'**. Reaction of $CpV(CO)_4$ with **16'**[19,20] at room temperature affords the (η^3-allyl)-metaloxycarbene complex **29**. In solution, **29** does not equilibrate with the mononuclear starting materials, but instead slowly transforms into the isomeric seven-membered ring (σ-allyl)metaloxycarbene complex **30**,[31] eventually establishing an equilibrium (1:1 at 25 °C). The niobium carbene complex **31**, obtained from **16'** and $CpNb(CO)_4$ behaves analogously.[29a,32] Few heteroatom-stabilized carbene complexes of niobium have been reported[13b,d,33] thus far.

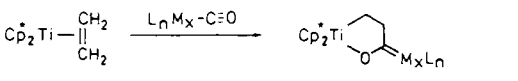
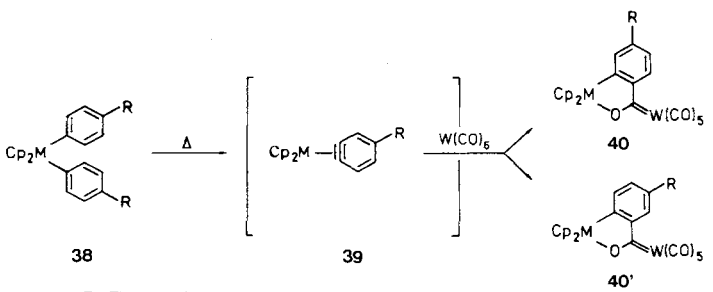
31: M=Nb
30: M=V
32: M=Nb



The very reactive η^4-diene complexes of the actinide element thorium can likewise function as reagents for carbene syntheses. (η^4-Butadiene)$ThCp_2^*$ **34** reacts at 0 °C with hexacarbonylchromium to afford the thoriumoxycarbene complex **35**. With [$Mo(CO)_6$] and [$W(CO)_6$], **34** afforded corresponding products.[34]

33 **34** **35**

2.2.2. *Carbene Complexes from (η^2-Olefin)- and (η^2-Aryne)metallocenes*



Takaya et al. used (η^2-ethylene)bis(η-pentamethylcyclopentadienyl)titanium **36** (originally reported by *Bercaw* et al.[17a]) as a reagent for carbene complex syntheses. The titaniumoxycarbene complexes **37a–c** were formed by reaction of **36** with the hexacarbonyl complexes of chromium, molybdenum, and tungsten at $-20\,^{\circ}C$. The titaniumoxycarbene complexes **37d** and **37e**, respectively, are formed analogously by addition of **36** to the carbonyl ligands of $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$. From the X-ray analysis of the rhenium carbene complex **37e**, it can be seen that the metallacyclic carbene ligand occupies the *trans* position at the binuclear metal carbonyl. Application of the Fischer synthesis [Eq. (a)] to $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$ normally affords *cis*-configurated monocarbene complexes.[10]

36

37a $M_xL_n = Cr(CO)_5$
37b $M_xL_n = Mo(CO)_5$
37c $M_xL_n = W(CO)_5$
37d $M_xL_n = trans\text{-}Mn_2(CO)_9$
37e $M_xL_n = trans\text{-}Re_2(CO)_9$

(η^2-1,2-Didehydrobenzene)zirconocene and -titanocene **39** (M = Zr, R = H and M = Ti, R = H, respectively) are easily generated by thermolysis of the diphenylmetallocenes **38**. In the absence of other reagents, they react with aromatic hydrocarbons by C–H activation, in a reversal of the reaction leading to their formation. The (aryne)metallocenes **39** add a broad palette of organic compounds having reactive π systems, with formation of five-membered benzannelated metallacycles. Thus $(C_6H_4)ZrCp_2$, thermally generated in situ at 90 °C from diphenylzirconocene, reacts with the stilbene isomers stereospecifically to give *cis*- or *trans*-1,1-bis(cyclopentadienyl)-2,3-diphenylzirconaindan.[36] Reaction between hexacarbonyltungsten and the zirconocene **38** (M = Zr, R = H) at 90 °C affords the five-membered metallacyclic benzannelated zirconiumoxycarbene complex **40**. A labeling experiment showed that this carbene complex is formed from the (aryne)metallocene intermediate **39**. Similarly, bis(*p*-tolyl)zirconocene **38** (M = Zr, R = CH_3) reacts with $W(CO)_6$ to afford the zirconiumoxycarbene complexes **40** and **40'** in the ratio 60:40. Thermally generated (η^2-aryne)titanocene also reacts with $Mo(CO)_6$ or $W(CO)_6$ immediately to afford analogous compounds.

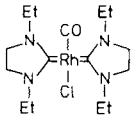
M = Zr, Ti; R = H, CH_3

2.3. Structures of Metallacyclic Zirconiumoxycarbene Complexes

There are many X-ray structural analyses of zirconiumoxycarbene complexes.[13, 22, 27, 28, 31, 37] By comparison, only a few metaloxycarbene complexes of titanium[35] or hafnium[32] have been crystallographically characterized (see Table 1). These complexes all belong to the same metallacyclic (η^3-allyl)metaloxycarbene structural type. This is true even when the equilibrium position in solution favors the σ-allyl isomer. The ZrCr and ZrW complexes **23a** and **23c**, respectively, are typical examples.[22] Both compounds exhibit an unsymmetrical Zr-bound η^3-allyl group. The bonds to the terminal allyl carbons are short and distances to C-2 and C-3 of the chain increasingly longer (**23a/23c**: Zr-C1 = 2.420(6)/2.421(14); Zr-C2 = 2.491(6)/2.497(12); Zr-C3 = 2.624(7)/2.621(15) Å). The very short carbon–oxygen bond in the carbene ligand is particularly striking. A comparison of the O–C carbonyl distances in the metallacyclic zirconiumoxycarbene complexes with those in traditional acyclic Fischer-type carbene complexes demonstrates this general effect very clearly: $d(O\text{-}C_{carbene}) = 1.254(5)$ Å for **23a** vs. 1.314(1) Å for $[H_5C_2O-C(CH_3)=Cr(CO)_5]$.[10] Together with the relatively long $M\text{–}C_{carbene}$ and Zr–O bonds, the short $O\text{–}C_{carbene}$ bond lengths clearly indicate acylmetalate character for these zirconiumoxycarbene complexes[39] (**A** ↔ **B**).

A **B**

All examples known thus far of the $[Cp_2M(X)OC\{=M'L_n\}R]$ complex type (M = Ti, Zr, Hf) have significant acyl character. Substitution of the *O*-bound alkyl group in Fischer-type carbene complexes by a very oxophilic metal complex fragment with strong σ-donor properties leads to a considerable polarization of the $[M-OC(R)=M(CO)_n]$ unit (see **B**).[39]



Fischer-type carbene complexes can be described as compounds with weak transition-metal–carbon π bonding. Experimental criteria for such π bonding include a short M=C bond, a higher activation barrier for rotation about the M=C bond axis, and a more stable preferred geometry for the $-O-C(R)=ML_n$ system. The composition of many

[a] $[M^1] = Cp_2Zr$ except for **31** (Cp_2Hf), R = C_4H_6 (π-allyl form) except for **40a** (R = C_6H_4). [b] Standard: TMS in C_6D_6. [c] Crystallographically independent units.

Fischer-type carbene complexes complicates or hinders the estimation of the M=C bond strength using such criteria. Thus, the high local symmetry of the $[M(CO)_5]$ fragment generally leads to low M–C rotational barriers in $[R'O-C(R)=M(CO)_5]$ carbene complexes.[40] *Lappert* et al. determined a Rh=C rotational barrier of $\Delta G^{\ddagger}_{55\,°C} \approx 16$ kcal mol^{-1} for the heteroatom-stabilized carbene complex **41**, for which such symmetry-related effects are negligible.[41] Similar rhodium carbene complexes have very short $Rh-C_{carbene}$ bond lengths (**42a**, 1.930(6) Å; **42b**, 1.930(11) Å). The rhodium–carbon bond in the acyclic rhodium carbene complex $[Cl_2(Et_2P)_2Rh=C(H)NMe_2]$ is considerably longer (1.961(11) Å).[42]

41

42a: X = O, $R^1 = R^2$ = Ph
42b: X = S, $R^1 = N(CO_2Et)_2$, R^2 = OEt

Although the carbene carbon in the rhodium carbene complex **25a** has only one heteroatom substituent, the $Rh-C_{carbene}$ bond length determined by X-ray diffraction (1.925(3) Å) is even shorter than those of **42a, b**. The metal carbene unit in **25a** has the geometry expected for a heteroolefin system. The four substituents O1, C12, C16 and D3 (= center of the Cp ring C17-C21; atom numbering analogous to the cobalt carbene complex **25c**, Fig. 1) are arranged coplanar with the central Rh=C unit (maximum deviation from the best plane: −0.09 Å for C12). Only one geometric isomer was found in the crystal. The bulky Cp substituent at rhodium has *Z* geometry with respect to the OZr group at the carbene carbon atom.[27] The cobalt carbene complex **25b** has an analogous structure in the crystal. The Co=C bond (1.815(4) Å) is much shorter than those in the open-chain cobalt carbene complexes $[(CO)_3(GePh_3)Co=C(C_2H_5)OC_2H_5]$ (1.913(11) Å),[25] $[Cp(PhS)Co=C(C_4H_{10}N_2)]$ (1.902(3) Å), or $[(PPh_3)(NO)(CO)Co=C(C_5H_{12}N_2)]$ (1.974(15) Å).[43] Complex **25b** also exhibits only one "double-bond isomer"

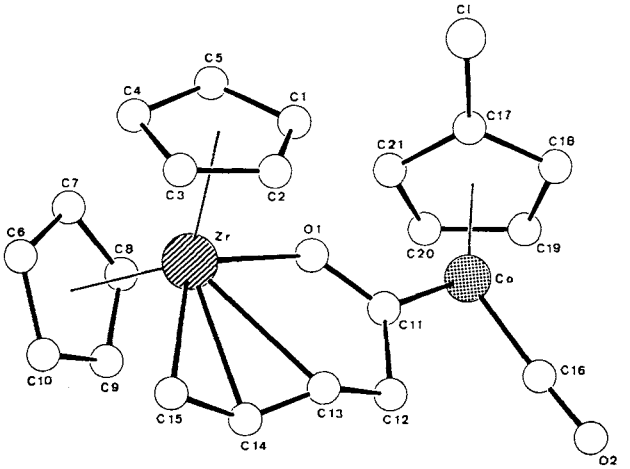

Fig. 1. Molecular structure of **25c** [28b].

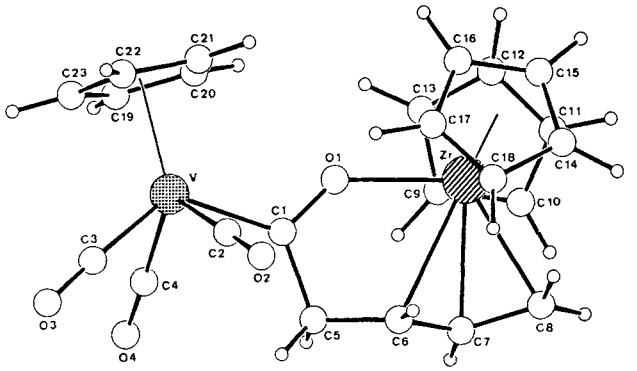

Fig. 2. Molecular structure of **28** [31].

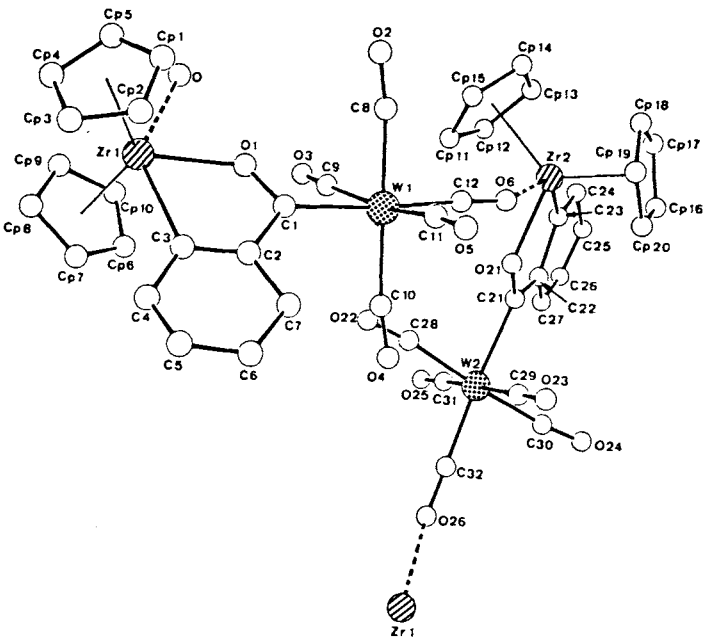
in the crystal. The CO ligand bound to Co is *E*-oriented to the OZr group at the carbene carbon.

Compound **28** is the first vanadium carbene complex for which an X-ray structural analysis was carried out (Fig. 2). The bonding in the metallacyclic ring system is typical for complexes of this type. The η^3-allyl unit is distorted in the direction of a $(\sigma,\pi$-allyl)$ZrCp_2$ structure. The C–O bond of the carbene ligand is short [d(C1-O1) = 1.270(4) Å]; thus, **28** shows considerable acylmetal complex character. The vanadium–$C_{carbene}$ bond length of 2.102(3) Å is clearly longer than $d(V-C_{CO})$ ($\approx$ 1.90 Å). For the analogous niobium carbene complex **31**, the $Nb-C_{carbene}$ distance is 2.216(6) Å.

The tungsten carbene complex **40a** also has a very short $C_{carbene}$–O bond length (1.21(2) Å) and hence significant acylmetal complex character. The peculiarity with **40a**, however, is that in the crystal it exists as an organometallic oligomer (Fig. 3). The molecular units are joined by the carbonyl group lying *trans* to the carbene ligand. The carbonyl oxygen O6 functions as a donor ligand in the oligomer, connecting one monomeric unit with the next unit through



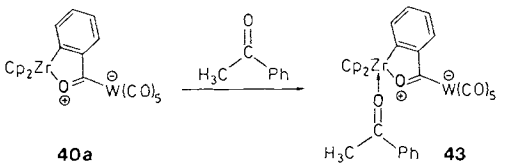


Fig. 3. Molecular structure of **40a**: the asymmetric unit with the two crystallographically independent molecules. Intermolecular interactions between Zr2 and O6 as well as Zr1 and O26 are indicated [37].

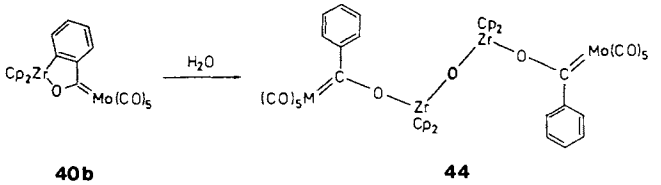
Zr. In this way, the zirconium attains an 18-electron configuration. A helical organometallic oligomeric chain is obtained from these "intermolecular" bonds, which are weak [d(Zr2-O6) = 2.49(2) Å; d(Zr1-O26) = 2.40(2) Å] compared with the Zr–O bond in the five-membered ring [d(Zr1-O1) = 2.16(2) Å].[37]



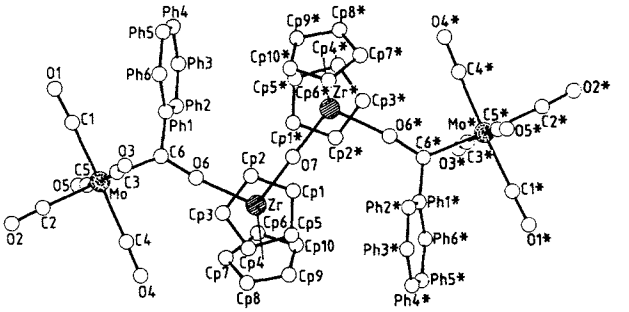
2.4. Reactivity of Metaloxycarbene Complexes

The synthesis of metaloxycarbene complexes from metallocenes is a useful extension of the classical synthesis developed by *E. O. Fischer* et al. Many reactions undergone by Fischer-type carbene complexes should also occur with the metallacyclic metaloxycarbene complexes. However, from the results thus far, it has become clear that the bonding of the electropositive early transition metal to the carbene oxygen can lead to a very specific and to some extent unexpected chemistry (e.g., of the zirconiumoxycarbene complexes).

The solid-state structure of the zirconiumoxycarbene complex **40a**, for example, is unexpected. The monomeric carbene complex unit functions as an organometallic Lewis acid in the crystal.[44] Complex **40a** even adds suitable donor ligands (e.g., methylamine) in solution. Dynamic ^{1}H NMR spectroscopy shows a fast exchange of the coordinated amine ligands with the free base in solution.[28a] Organic carbonyl compounds were added to **40a** to form 1:1 adducts: reaction with acetophenone gave complex **43** (IR: $\tilde{\nu}$(CO) = 1647 cm^{-1} vs. 1684 cm^{-1} for the free ketone[38,45]). Dynamic ^{13}C NMR spectroscopy revealed the rapid exchange of the organic carbonyl ligand [^{13}C carbonyl resonance of the bound/free acetophenone (−80 °C in CD_2Cl_2): δ = 208.4 and 198.2, respectively].

Open-chain multinuclear M−O−M-bridged bis(carbene) complexes have been obtained from the extremely moisture-sensitive metallacyclic carbene complexes and H_2O (e.g., **40b** → **44**). In the crystal, complex **44** shows an unexpected antiperiplanar arrangement of the bulky O−C(Ph)=Mo(CO)$_5$ substituents relative to the linear central (μ-oxo)bis(zirconocene) unit.[46]

The tungsten carbene complex **23c** reacts with ketones under mild conditions to give CC coupling at the η^3-allyl group. Regioselective addition of the terminal allyl carbon was observed with benzophenone, acetone, acetophenone, and pinacolone. The resulting nine-membered metallacyclic



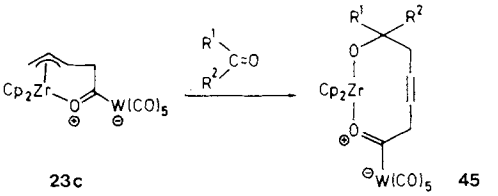


Fig. 4. Molecular structure of the bis(carbene) complex **44** [46].

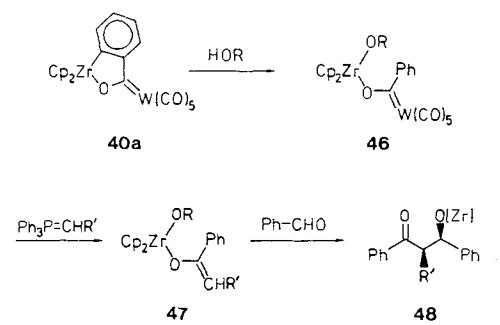
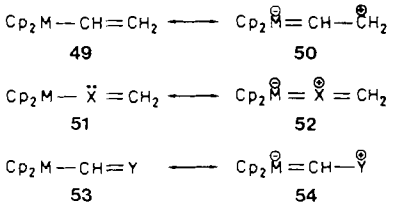


system **45** has a chiral ring conformation. When these rings were formed from prochiral ketones, diastereomeric products were observed.[47]

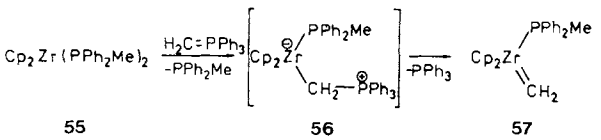
The C=ML$_n$ group in a Fischer-type carbene complex is similar to the C=O group in an organic carbonyl compound.[5,6] *Casey* et al. have shown that [(CO)$_5$W=C(Ph)OCH$_3$] reacts with non-stabilized phosphorous ylides in a reaction formally analogous to Wittig olefination (although probably different mechanistically); thus, reaction with $Ph_3P{=}CH_2$ gave $H_2C{=}C(Ph)OCH_3$ and [(CO)$_5$W(PPh$_3$)].[48]



The *ortho*-hydrogen atom very effectively shields the Zr–C σ bond in **40a** against attack by electrophiles.[36] Thus far, this bond could only be broken by protic reagents. With alcohols, one obtains (alkoxy)zirconiumoxycarbene complexes **46**. Carbene complexes with chiral auxiliaries at zirconium can be prepared in this way.

The carbene complex **46** reacts quickly with $Ph_3P{=}CH_2$ at room temperature to form the corresponding zirconium enolate **47** (R′ = H). Phosphorus ylides with only one alkyl group at the ylide carbon react in the same way.[38] This reaction can be seen as the synthetic equivalent of a Wittig olefination of a carboxylate salt—a reaction that cannot be directly realized because of the reduced carbonyl activity of carboxylate salts. The zirconium enolates obtained (**47**) react readily at room temperature with benzaldehyde in a *syn*-selective aldol reaction to give **48**.[49]

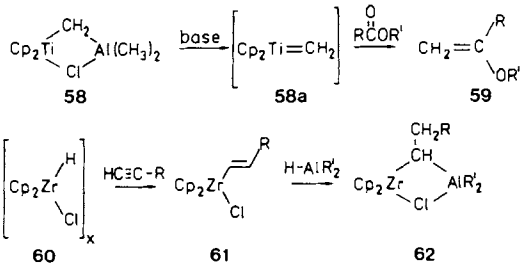
3. Complexes with Metallocene–Ligand π Bonding



The metallocene units in the carbene complexes described in the preceding Section performed important roles as auxiliaries. Their presence facilitated (or even made possible) the synthesis of the carbene complexes and to some extent modified the properties of these carbene complexes compared with ordinary Fischer-type carbene complexes. On the other hand, the central metal atom of the bent metallocene unit can itself be bound to a carbene ligand. The formation of simple alkylidene units at titanocene Cp_2Ti or zirconocene Cp_2Zr can lead to compounds with considerable M=C π-bond character.[7] In principle, complexes with $Cp_2M=L$ π-bond character can also result through combination of the metallocene unit with organic ligands capable of metal–carbon π conjugation. Thus far, no evidence for a significant π interaction exists in (σ-alkenyl)- or (σ-alkynyl)metallocene compounds.[50] It is possible that for simple mononuclear complexes **49**, the resulting charge separation is too disadvantageous (resonance structure **50**). These unfavorable effects can be decreased by the introduction of suitable heteroatoms in the α- or β positions to the metal. In a series of systems with the general formulas **51** or **53**, a considerable π character of the $Cp_2M=L$ bond was demonstrated.

49 **50** **51** **52** **53** **54**

3.1. (Alkylidene)metallocene Complexes

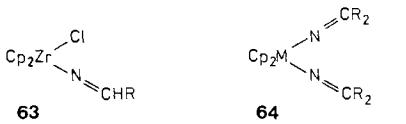


The valence orbitals of the bent metallocene that extend into the "ligand plane" can interact with the sp^2 and p orbitals of alkylidene ligands.[8] Calculations performed on model compounds attribute metallaolefin character to the $X_2Ti=CH_2$ group.[51] The $Cp_2M=CR_2$ complexes have a very electrophilic metal center. Stabilization can be achieved by occupation of the available acceptor orbital at the metal (e.g., by a phosphane). This hinders the dimerization of the (alkylidene)zirconocene to the stable 1,3-dimetallacyclobutane system. The phosphane-stabilized (carbene)zirconocene complex **57** was obtained from reaction between bis(cyclopentadienyl)bis(phosphane)zirconium(II) **55** and an ylide.[52]

55 **56** **57**

Far more significant, though, is the stabilization of the coordinatively unsaturated $Cp_2M=CHR$ unit by 1:1 complex formation with aluminum halide compounds as in **58** ("Tebbe's reagent") or **62**.[53]

The (alkylidene)metallocene complexes released from these adducts have a nucleophilic carbene carbon atom.



58 **58a** **59** **60** **61** **62**

They function as selective Wittig olefination reagents with organic carbonyl compounds (e.g., **58a** → **59**).[54] On reaction with olefins, **58a** affords metallacyclobutanes, which can form other (alkylidene)metallocene complexes by a formal [2 + 2] cycloreversion.[55]

3.2. π Conjugation in Metallocene Complexes

3.2.1. (Alkylidenamido)metallocene Complexes

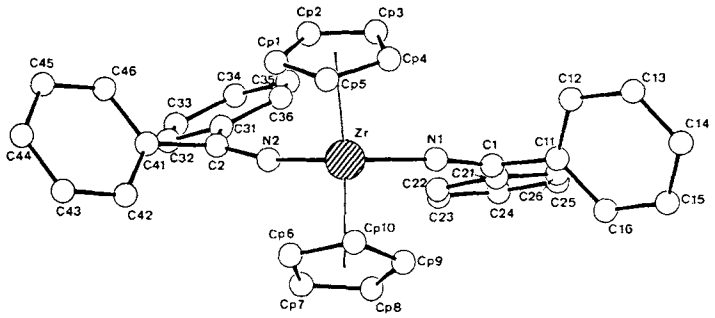
Alkylidenamido complexes $[M]-N=CR_2$ with some M–N π character have been prepared for a range of transition metals.[56] The zirconocene complexes **63** are obtained by hydrozirconation of nitriles.[57] Bis(alkylidenamido) metallocene complexes **64** are prepared from the reaction between metallocene dihalides and lithium alkylidenamides.[58] Zirconocene, generated in situ, oxidatively adds benzophenone azine in a reaction involving N–N cleavage.[59] The X-ray structure analysis of **63a** shows a nearly linear Zr–N=CHPh unit (Zr-N-C = 170.5(5)°).[57b] This compound has the shortest reported Zr–N bond thus far [d(Zr–N) = 2.013(5) Å]. Complex **63a** exhibits the stereochemical properties of a heteroallene system.[57b]

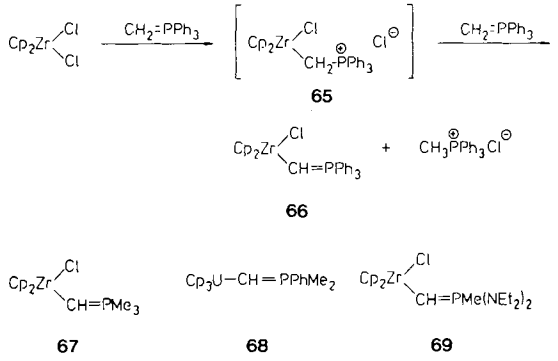
63 **63a**: R=Ph **64** **64a**: M=Zr, R=Ph

The bis(alkylidenamido) complex **64a** adopts a similar structure. The Zr–N distances (Zr-N1 = 2.058(2) Å and Zr-N2 = 2.063(2)° Å) are only slightly longer than in **63a**. The Zr-N1-C1 angle (173.7(2)°) is somewhat greater than the Zr-N2-C2 angle (164.1(2)°) and could point to an easier rearrangement to a purely σ-bound ligand in this compound. Fast equilibration between the "inward" and "outward" oriented aryl groups at the terminal carbon atoms of the alkylidene moieties in **64a** takes place in solution.[59]

3.2.2. Metallocene Ylides

Metallocene ylides **66**–**69** are examples of compounds **53** with $X=PR_3$.[60] *Kaska* et al. obtained the zirconocene ylide **66** and its hafnium analogue by reacting metallocene dichlorides with excess methylenetriphenylphosphorane.[61] Intramolecular transylidation makes metal-substituted ylides with at least one alkyl group (usually methyl) at phosphorus readily available.[62]





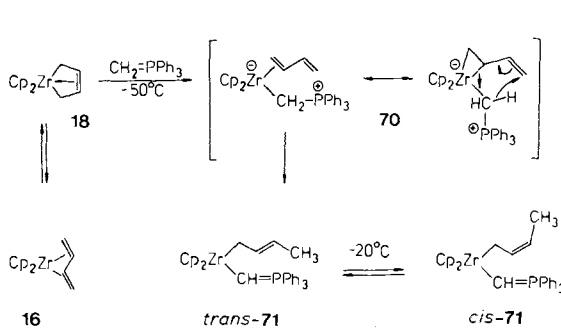


Fig. 5. Molecular structure of **64a** [59].

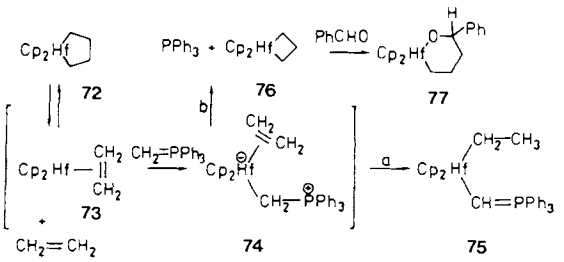
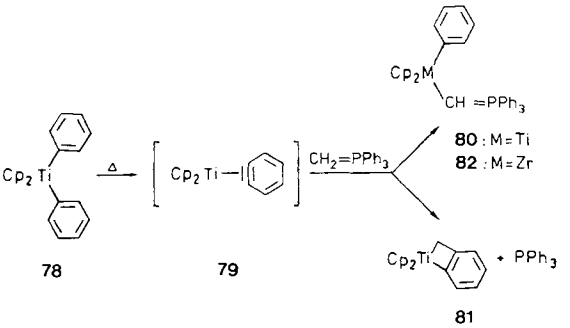


Compounds of the type $[Cp_2M(R)(CH=PPh_3)]$ (R = alkyl or aryl) can be obtained from methylenetriphenylphosphorane and (olefin)metallocene complexes in a reaction involving C–H activation and hydrogen migration.[63] From a 1:1 mixture of (*s-cis*-/*s-trans*-η^4-butadiene)hafnocene only the *s-trans* isomer reacts with the ylide under kinetic control at 0 °C. Cleavage of a C–H bond at the ylide carbon and hydrogen migration to the end of the diene chain takes place. Stereoselective formation of (*trans*-σ-2-butenyl)$Cp_2Hf(-CH=PPh_3)$ was observed. Equilibration with the *cis* isomer only occurs above 35 °C. Further stereochemical information is obtained from the reaction of the (*s-cis*-/*s-trans*-η^4-butadiene)zirconocene mixture **16/18** with $CH_2=PPh_3$. The *s-cis* isomer reacts selectively at −50 °C to give the (*trans*-σ-2-butenyl)metallocene ylide *trans*-**71**. This result possibly points to a concerted hydrogen shift in an organometallic system that occurs analogously to the homo-1,5-hydrogen shift in the purely organic methylvinylcyclopropane → hexadiene rearrangement. At −20 °C, *trans*-**71** equilibrates with *cis*-**71**.



A mixture of bis(cyclopentadienyl)zirconacyclopentane and $CH_2=PPh_3$ at room temperature affords $[Cp_2Zr(C_2H_5)(CHPPh_3)]$ after expulsion of ethylene. The

analogous reaction of (η^2-benzophenone)zirconocene gives $[Cp_2Zr(OCHPh_2)(CHPPh_3)]$. From bis(cyclopentadienyl)hafnacyclopentane **72**, (η^2-ethylene)hafnocene **73** was generated (reversibly) at 90 °C by liberation of ethylene. Intermediate **73** can react with the ylide in two different ways. Addition and intramolecular hydrogen shift affords $[Cp_2Hf(C_2H_5)(CHPPh_3)]$ **75** (path a). In a competitive reaction, transfer of the whole methylene group from the ylide to the reactive organometallic intermediate and release of a molar equivalent of triphenylphosphane gives bis(cyclopentadienyl)hafnacyclobutane **76** (path b; relative product ratios a:b ≈ 2). At elevated temperature, hafnacyclobutane **76** is stable with respect to cleavage to (methylene)hafnocene and ethylene, in contrast to the titanacyclobutane analogue. In the presence of benzaldehyde, no Wittig olefination product was observed but rather the formation of the aldehyde insertion product **77**.[64]

(η^2-1,2-Didehydrobenzene)titanocene **79**, generated thermally from diphenyltitanocene **78**, reacts with methylenetriphenylphosphorane to form the products **80** and **81** competitively (70:30 at 80 °C).[63e, 65] In contrast, (aryne)zirconocene and $CH_2=PPh_3$ afford only the zirconocene ylide **82**.

For these metallocene ylides, a clearly observable increase in carbene complex character is apparent on going from hafnium through zirconium to the titanium compound. The growing π character of the $M-C_{ylide}$ bond in the series **75**, **82**, **80** is discernible from the resonances of the CH group moving to increasingly lower field in the NMR spectra [$^1H/^{13}C$: δ = 3.72/91.6 (**75**); 5.65/106.2 (**82**); 8.78/165.2 (**80**).[63d] All metallocene ylides characterized by X-ray structure analysis have nearly coplanar arrangements of the four substituents (two Cp ligands, hydrogen, and PPh_3) at the central [M]–C_{ylide} unit (see Fig. 6). The dynamic NMR spectra (coalescence of the signals of the diastereotopic Cp ligands) showed that variation of the metal resulted in different $\Delta G^{\neq}_{rot}$ for the hindered rotation about the M–$CHPPh_3$ bond. This rotational barrier increases on going from Hf (**75**) to Zr (**82**) and then Ti (**80** (see Table 2). In addition, a clear progressive

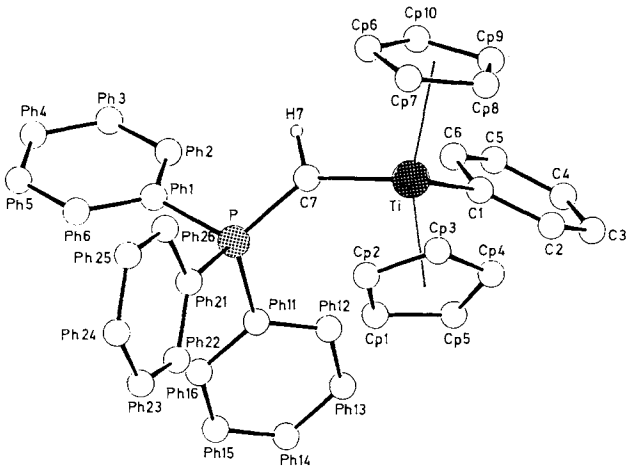


Fig. 6. Molecular structure of the titanocene ylide **80**.

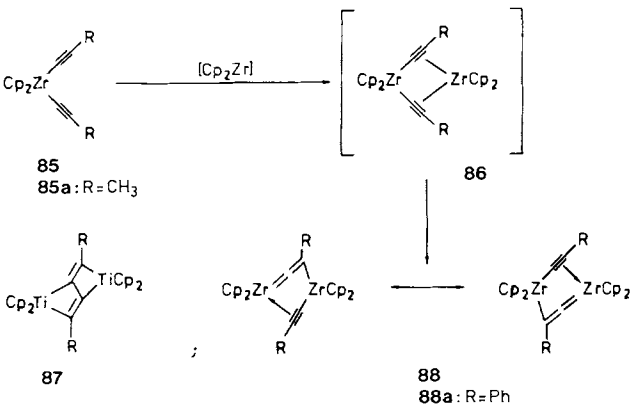
Table 2. Characteristic data for the M–C(ylide) bonds in metallocene ylides **75**, **82**, and **80** [63].

	75 (M = Hf)	**82** (M = Zr)	**80** (M = Ti)
dM–C(ylide) [Å]	2.149(6)	2.157(4)	2.033(6)
Δd [Å] [a]	0.10	0.18	0.22
$\Delta G^{\ddagger}_{rot}$ (T) [kcal mol^{-1}]	<8 (< −100 °C)	8.4 (−102 °C)	12.0 (−34 °C)

[a] Shortening of the M–C(ylide) bond owing to π interaction given relative to an adjacent M–C σ bond used as an internal standard.

shortening of the M–C_{ylide} bond length (referred to a suitable intramolecular standard) can be seen from the X-ray structure analyses of these compounds.

These data imply that the hafnium compound **75** has a comparatively small π component of the M–C_{ylide} bond; in the zirconium ylide **82** this π component is significantly greater. The titanium ylides have pronounced carbene complex character. A description of their bonding must therefore involve resonance form **54** (M = TiPh; Y = PPh_3).



This gradually changing carbene complex character is reflected in the reactivity of the metallocene ylides. Under standard conditions, the "carbene complex" **80** does not convert acetophenone, for example, into the enolate form nor reacts with carbon monoxide or benzyl isocyanide. It behaves as a coordinatively saturated compound. By contrast, the Ph_3PCH ligands of the zirconocene and, particularly, the hafnocene ylides function as carbon bases. With CO or $PhCH_2NC$, both **82** and the more reactive **75** undergo insertion exclusively into the formally stronger M–$CHPPh_3$ bond.[61, 63g]

3.2.3. π Conjugation at Binuclear (Alkynyl)metallocene Complexes

The X-ray structure analysis of the bis(propynyl)zirconocene **85a** reveals no conjugative interaction between the π systems of the σ-bound ligands and the available acceptor orbital at zirconium. The geometry of **85a** is that of a "normal" pseudo-tetrahedrally coordinated zirconium(IV) compound with a Cp–Zr–Cp angle of 132°. The linear σ-propynyl ligands subtend an angle at Zr of 103.6(1)°. The CC triple bond length is normal (1.206(4) Å). The Zr–C σ bonds to the alkynyl ligands are not shortened (2.249(3) Å).[50, 66]

The formally d^1-configurated [$Cp_2M-C\equiv CR$] complexes are different. The reaction between $(Cp_2TiCl)_2$ and $NaC\equiv CPh$ affords the binuclear diamagnetic titanium compound **87** by CC coupling of the σ-alkynyl groups to give a bridging substituted butadiene.[67] Replacement of the titanocene group by zirconocene or hafnocene gives a completely different binuclear structural type (without CC coupling) of general formula $[Cp_2M(CCR)]_2$. Thus, compound **88** was obtained by reaction of the mononuclear bis(alkynyl)metallocene complexes **85** with a zirconocene source, either [Cp_2Zr(butadiene)] or [$Cp_2Zr(CO)_2$]. Addition to give **86** is followed by rearrangement involving σ-alkynyl ligand migration to afford **88**. Hafnium analogues of **88** may be synthesized similarly.

In contrast to the mononuclear bis(alkynyl)zirconocene **85**, complex **88a** clearly shows lengthening of the C≡C bond of the alkynyl ligand (d(C1-C2) = 1.261(2) Å). The Zr–C bond is very short (2.188(2) Å) and the bond distances Zr–C1* and Zr–C2* are 2.407(2) and 2.431(2) Å, respectively. The large Zr···Zr separation (3.506(1) Å) excludes a direct metal–metal interaction.[68] These data justify a description of these diamagnetic complexes by equivalent resonance forms involving partial carbene character of the alkynyl ligands.

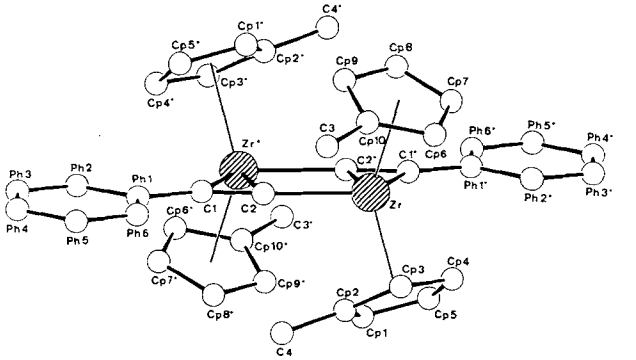


Fig. 7. Molecular structure of **88a** [68].

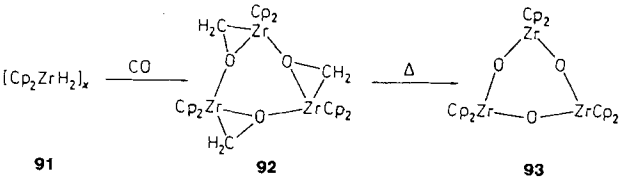
It seems, then, that metal–carbon π conjugation is significant in (alkynyl)metallocene compounds if the resulting unfavorable charge distribution can be compensated for. In the binuclear bis(alkynylmetallocene) complexes **88** this occurred by head-to-tail coupling of two identical mononuclear metallocene complex units.[69]

The X-ray structure analysis of $[Cp_2Zr(\mu\text{-}CH=CHPh)(\mu\text{-}Cl)ZrCp_2]$ also reveals a very short Zr–C distance (2.194(7) Å). A participation of the resonance form with metal carbene complex character should probably be used here to describe the structural properties of the binuclear (alkenyl)metallocene compound.[70]

4. Metallocene Compounds with a Metallaoxirane Structure

In the Fischer–Tropsch synthesis of hydrocarbons from CO and H_2, methylene groups on the surface of the active catalyst seem to play an important role. In particular, a series of simple experiments by *R. Pettit* et al. appears to confirm the original mechanistic proposal,[71] despite many other formulations of the reaction pathway.[72] These results demonstrate that, under various conditions, diazomethane can influence an active Fischer–Tropsch catalyst. Expulsion of N_2 possibly leads to the formation of a methylene complex at the catalyst surface. In the absence of hydrogen, the fast formation of ethylene as the sole product was observed. On addition of molecular hydrogen, the dimerization of methylene does not occur. Instead, CH_2 inserts into the M–H bonds formed on the surface. The growth of the alkyl chains occurs on the resulting surface-bound methyl groups. After removal of the catalyst, the product mixture of hydrocarbons was found to be very similar to that obtained from the Fischer–Tropsch synthesis. A detailed product analysis has shown that surface-bound methylene groups participate in this process both at the initiation and at the chain-growth steps. A schematic depiction is shown in Section 4.4.[73]



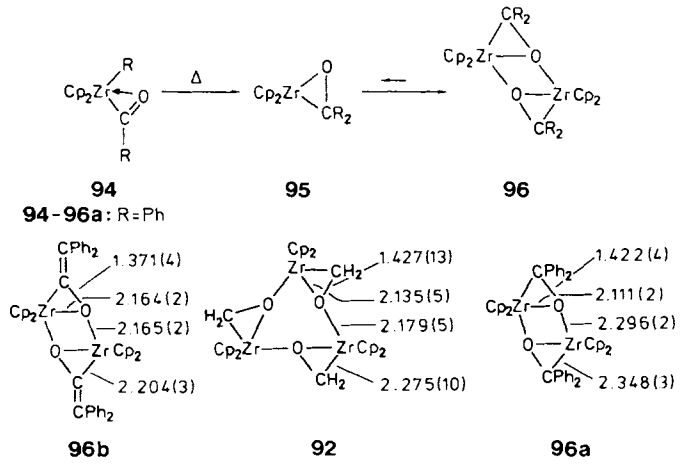
Models for this chemistry on a molecular basis have been developed. In many cases, multinuclear metal complexes with direct metal–metal bonds bridged by methylene ligands have been investigated as analogues of parts of a metal surface. Bi- and multinuclear μ-methylene complexes, "dimetallacyclopropanes", have been prepared in large numbers. A number of the reactions of these complexes show similarities to proposed steps of the Fischer–Tropsch synthesis.[74, 75] Critically, though, it has not been unambiguously established that *Pettit*'s experiments investigating parts of the Fischer–Tropsch synthesis really model the chemistry of the methylenes at the metal surface. The additional presence of a not easily reducible metal oxide (thorium oxide, zirconium oxide, titanium oxide) together with the reductive components (usually iron or cobalt) is essential for Fischer–Tropsch catalysts.[72b] Therefore, the CH_2-transforming steps might well take place at a metal oxide surface. Molecular models for this exhibit the metallaoxirane group **90** rather than the dimetallacyclopropane unit **89**.

89

90

Metallaoxiranes can be constructed stepwise by the use of hydrogen and carbon monoxide. Metallocene dihydrides can be obtained from Cp_2M precursors and H_2.[76] The reaction of $(Cp_2ZrH_2)_x$ **91** with CO affords trimeric (η^2-formaldehyde)zirconocene **92**, a compound with a metallaoxirane structure. Thermolysis of this complex leads to the expulsion of all three methylene groups and the formation of the "metal oxide" fragment $(Cp_2ZrO)_3$ **93**. This example shows that there are aspects in the chemical behavior of zirconocene-derived metallaoxiranes that are related to Fischer–Tropsch type chemistry.[77]

91 **92** **93**

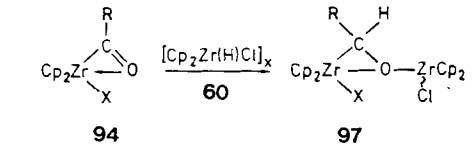


4.1. Formation of Metallaoxiranes

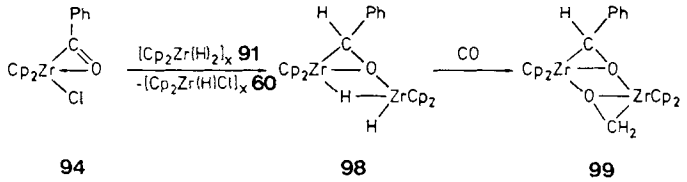
4.1.1. (η^2-Ketone)- and (η^2-Aldehyde)metallocene Complexes

Many metals from the right-hand side of the periodic table form complexes containing side-on–bonded ketone or aldehyde ligands; these complexes are obtained by reaction of a coordinatively unsaturated metal complex fragment with the organic carbonyl compounds. This method cannot usually be used for the synthesis of (η^2-ketone)- or (η^2-aldehyde)-complexes (metallaoxiranes) of titanocene, zirconocene, or hafnocene, since the resulting metallacyclic three-membered ring compounds are too reactive. They often add a further $R^1R^2C=O$ molecule very readily, followed by ring expansion via CC coupling.

Metallaoxiranes of zirconocene can be prepared from (η^2-acyl)zirconocene complexes **94**. The three-membered ring structure is formed easily by this route. Proceeding from (η^2-acetyl)zirconocene chloride, the ketene complex $[Cp_2Zr(\eta^2\text{-}O=C=CH_2)]$ (isolated as a dimer) was obtained after α-deprotonation.[78] (η^2-Ketone)metallocene complexes are frequently obtained by addition of a carbon nucleophile at the carbonyl group of an (η^2-acyl)metallocene. An existing σ-bonded alkyl or aryl group in a metal complex can be used in this way, via an intramolecular nucleophilic addition. The formation of (η^2-benzophenone)zirconocene **95a** (isolated at room temperature as the dimer **96a**) is a typical example (Scheme 1).[63f, 79]



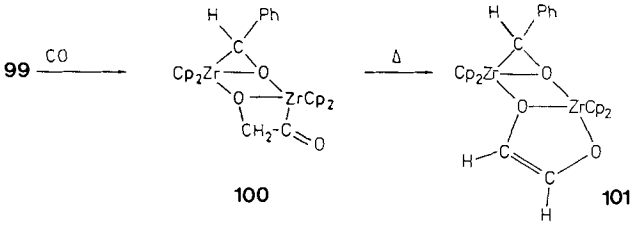
Metallaoxiranes containing the bis(cyclopentadienyl)-zirconocene fragment are characterized by oligomer formation, which occurs by coupling of the three-membered rings by bridge formation between the metallaoxirane oxygen (donor) and the metal (acceptor) in the ring plane.[80] Through this coupling, dimers or trimers with planar $(\overline{M-O-C})_n$ frameworks were obtained. The bonding between the monomeric units can be very different in strength. In the cyclodimeric (η^2-diphenylketene)zirconocene **96b**, for example, there is a central Zr_2O_2 four-membered ring with four equally short metal–oxygen distances,[78b] whereas in the cyclotrimeric (η^2-formaldehyde)zirconocene **92** the bonds between the monomers are significantly longer.[77]



Scheme 1. Formation and structural properties of (η^2-ketone)- and (η^2-aldehyde)zirconocene complexes (bond lengths in Å).

Cyclodimeric (η^2-benzophenone)zirconocene **96a** is an even more loosely bound adduct. At high temperatures a considerable amount of the monomeric metallaoxirane **95a** is present in equilibrium.[63f, 79]

Similarly, metallaoxiranes are obtained from intermolecular addition of nucleophiles to an (η^2-acyl)metallocene. (Hydrido)metallocenes have proven particularly suitable as reagents in the formation of (η^2-RCHO)MCp_2 complexes. In general, they directly afford multinuclear metallocenes with bridging $Cp_2\overline{M-O-CHR}$ units. Typical examples are the reactions of (η^2-acyl)alkyl- or (η^2-acyl)halozirconocene complexes **94** (X = alkyl or Cl) with the hydrozirconation reagent **60**, which leads to aldehyde-bridged binuclear metallaoxiranes **97**. Analogous products were isolated in most cases from further reaction, arising from **97** by rearrangement (e.g., intramolecular alkylidene shift, see Section 4.2) and/or halide/hydride ligand exchange with **60**.[81]



The synthesis of compounds with the $Cp_2\overline{M-O-CH_2}$ unit is a special case. They cannot be made using mononuclear formyl complexes of the Ti group as starting materials. (η^2-HCHO)MCp_2 complexes can, however, be obtained by direct carbonylation of several (hydrido)metallocenes. *Floriani* et al. showed in 1978 that the carbonylation of the oligomeric **60** leads to the binuclear (μ-η^1:η^2-formaldehyde)zirconocene complex **97a** (X = Cl, R = H), containing a metallaoxirane structural unit. The carbonylation of oligomeric **91** affords in a similar manner the cyclotrimeric **92** described above.[77]

An (η^2-benzaldehyde)Cp_2Zr/(η^2-formaldehyde)Cp_2Zr 1:1 adduct is obtained from (η^2-benzoyl)zirconocene chloride **94** in a reaction sequence involving hydrozirconation, Cl/H ligand exchange, and carbonylation. The binuclear intermediate, (η^2-benzaldehyde)zirconocene/dihydridozirconocene **98**, was isolated.[81]

In some cases, the methylene-bridged Zr–O unit appears to show a carbonylation chemistry similar to that of several binuclear μ-methylene complexes. Thus, **99** reacts at high temperature with CO at elevated pressure to give the insertion product **100**. Thermolysis of **100** affords the binuclear enediolate complex **101**. Starting from **98**, two molecules of carbon monoxide have thus been reductively coupled via a metallaoxirane intermediate.[81b]

The formation of enediolate complexes from metal alkyls also occurs via intermediates with metallaoxirane character (i.e., (η^2-ketone)metallocenes). Thus, exactly 1.5 molar equivalents of CO are taken up by the very reactive alkylmetallocene 1,1-bis(cyclopentadienyl)hafnacyclobutane **76** under ambient conditions. This affords compound **102** (Fig. 8), a 1:1 adduct of mono- and biscarbonylation products; in this case, the proposed intermediate, an (η^2-ketone)hafnocene, forms a complex with the enediolate before further reaction with carbon monoxide occurs.[83]

4.1.2. α-Metalated Ethers with Metallaoxirane Structures

(α-Metallocenyl)-substituted ethers exhibit three local minima on the (Cp_2MX)–CH_2OCH_3 hypersurface, similar to (η^2-acyl)metallocene complexes[84] [orientation of the CH_3OCH_2 ligands: η^1-O outside (**103**), η^2-O outside (**104a**), and η^2-O inside (**104b**)].

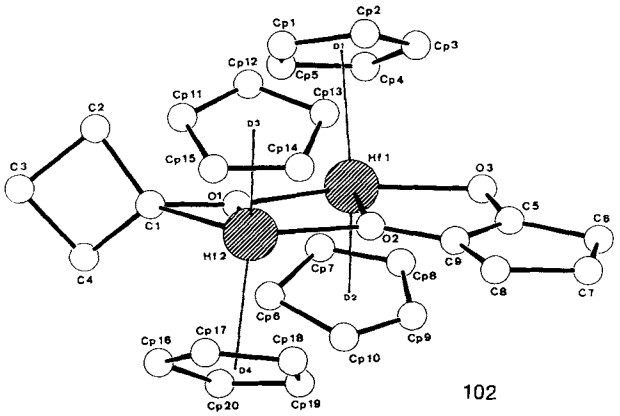


Fig. 8. Molecular structure of the (η^2-ketone)hafnocene/(enediolato)MCp_2 1:1 adduct **102**.

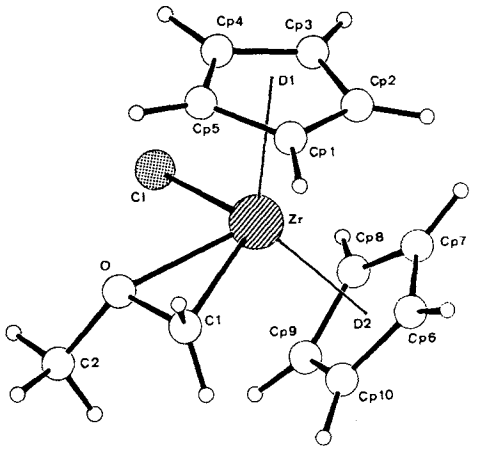

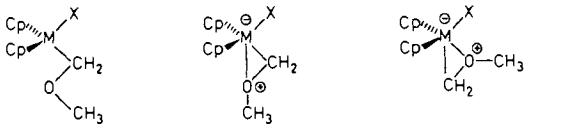

Fig. 9. Molecular structure of **106**.

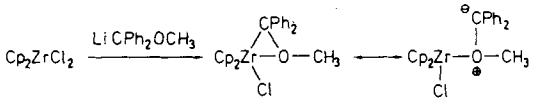
The reaction of titanocene dichloride with $ClMgCH_2OCH_3$ affords the η^1 complex **105**, having the η^1-O-outside structure. In contrast to this, the reaction of zirconocene dichloride with the same Grignard reagent gives the η^2-complex **106** with η^2-O-inside orientation [d(Zr-C1) = 2.271 (5) Å; d(Zr-O) = 2.204 (3) Å; d(C1-O) = 1.414 (6) Å] (Fig. 9).[85]

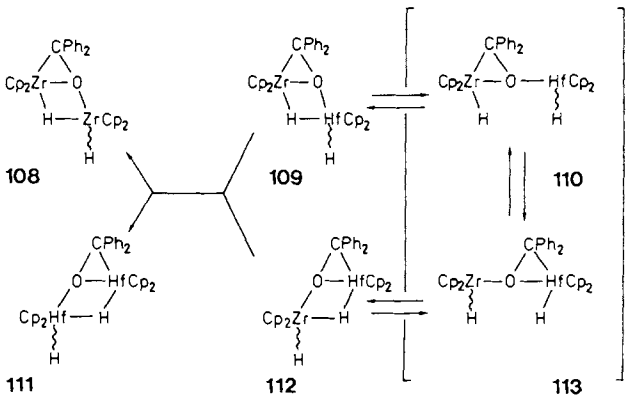


103
105: X = Cl, M = Ti

104a

104b
106: X = Cl, M = Zr

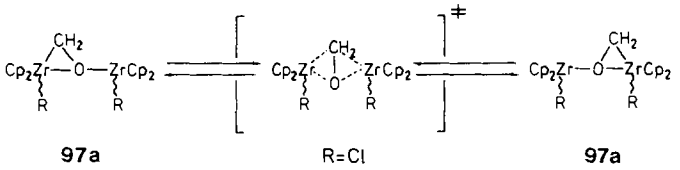
An analogous complex, **107**, is obtained by reacting Cp_2ZrCl_2 with lithiated benzhydryl methyl ether. In this case, the Zr–C bond in the three-membered ring (2.395 (6) Å) is considerably longer than the Zr–O bond (2.215 (4) Å). This can be described in terms of a contribution by the oxonium ylide resonance structure. Compounds of the type $[Cp_2\overline{Zr(X)CR_2OR}]$ can be understood as oxonium ylides internally stabilized by metallaoxirane formation.[86] The binuclear (μ-η^1:η^2-formaldehyde)zirconocene complex **97a** is a further example of this type of compound.



107

4.2. Dynamic Behavior of the Metallaoxiranes—Intramolecular Alkylidene Migration

A necessary requirement for CC coupling reactions of methylene units at the heterogeneous Fischer–Tropsch catalyst is the mobility of these groups on the surface. It is difficult to model this important dynamic property with simple molecular compounds. A larger molecular framework is required. The smallest possible segment of a metal oxide matrix at which such a migratory reaction can still occur is the M–O–M unit. (μ-η^1:η^2-O=CR'R^2)Metallocenes (e.g., **95**, **97**, and **98**; cf. Section 4.1.1) result from saturating this unit with ligands and bridging an M–O bond with an alkylidene moiety.



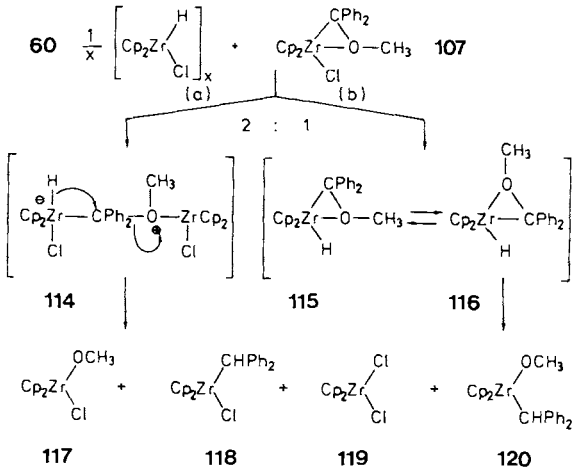
Fast, thermally induced intramolecular alkylidene shifts along the M–O–M framework are the rule with complexes containing the $\overline{Zr\text{-}CR^1R^2\text{-}O\text{-}Zr}$ group. For example, the reaction of the dimeric (η^2-benzophenone)zirconocene **96** (R = Ph) with $(Cp_2HfH_2)_x$ at room temperature affords the binuclear (μ-η^1:η^2-O=CPh$_2$) hydride-bridged Zr/Hf compound **109**. At 60 °C this complex is in equilibrium with its isomer **112**, in which the metal atoms have formally exchanged positions. Above 80 °C, subsequent statistical distribution (**108**, **109**, **111**, **112**) of metal centers is observed. The rearrangement **109** $\rightleftharpoons$ **112** requires initial opening of the hydride bridge (formation of **110**). Fast migration of the diphenylcarbene group along the Zr–O–Zr framework can then take place. Closure of the hydride bridge in the rearranged product **113** affords the isomer **112**.[63f]

108 **109** **110**

111 **112** **113**

This alkylidene migratory rearrangement occurs much faster if there is no hydride bridge at the participating metal centers that needs to be broken in the rate-determining step. This is shown by the dynamic NMR spectra of the open-chain (μ-η^1:η^2-formaldehyde)zirconocene complex **97a**. From the coalescence of the ^{1}H NMR cyclopentadienyl resonances at −140 °C, an activation barrier of $\Delta G^{\neq}_{-140\,°C} \approx$ 7 kcal mol^{-1} was estimated for the migration of the CH_2 group along the Zr–O–Zr moiety.

97a R=Cl **97a**

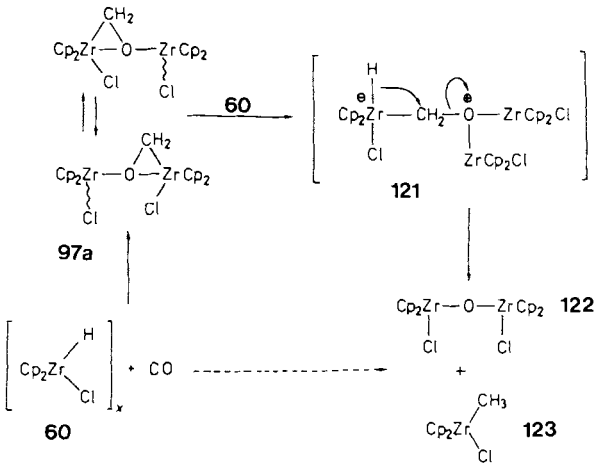


This fast automerization reaction appears to be quite general for μ-η^1:η^2-aldehyde complexes of this particular structural type (e.g., $[Cp_2\overline{ZrPh(CH_2-O)}ZrPhCp_2]$, $\Delta G^{\neq}_{-80\,°C} \approx 10$ kcal mol^{-1}; $[Cp_2\overline{ZrCl(CHMe-O)}ZrClCp_2]$, $\Delta G^{\neq}_{-8\,°C} \approx 13$ kcal mol^{-1}). Experimental studies aimed at explaining the reaction mechanism of the alkylidene migration at these binuclear metallocene complexes[81, 87] suggest a concerted "dyotropic" rearrangement.[88] Fast dyotropic

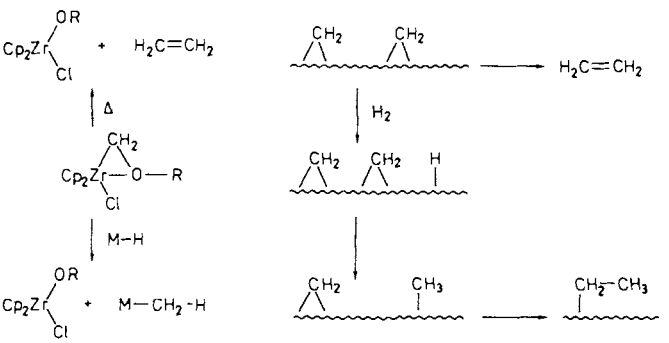
rearrangements in molecular compounds may possibly serve as models for migratory reactions on surfaces.

4.3. Alkylidene Transfer Reactions

Several metallocene complexes with metallaoxirane structural units undergo thermally induced alkylidene-coupling reactions. Thus, the compound **107** decomposes at 40 °C with formal cleavage of the diphenylcarbene moiety to give $[Cp_2Zr(Cl)OCH_3]$ and tetraphenylethylene. The methylene-bridged complex **106** is thermally more stable. It requires a temperature of ca. 200 °C to decompose to give $[Cp_2Zr(Cl)OCH_3]$ and $CH_2=CH_2$.[85]



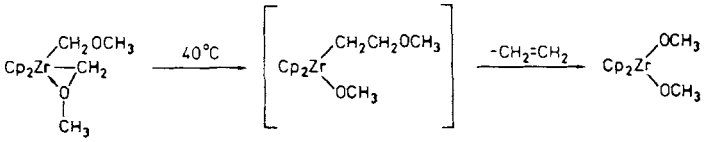
Alkylidene moieties of metallaoxiranes can be transferred to hydrido complexes and insert into the M–H bond. Thus, **107** reacts with **60** at 40 °C, transferring the CPh_2 unit to give the insertion product benzhydrylzirconocene chloride **118** and **117** [path (a)]. The nucleophilicity of the alkylidene carbon in **107** (the oxonium ylide character of this compound was confirmed by X-ray structure analysis; see Section 4.1.2) assists the formation of the intermediate **114**, which can then undergo hydride migration. The side products of this reaction, **119** and **120**, can be rationalized as resulting from intramolecular variants of this alkylidene insertion reaction occurring after Cl/H ligand exchange [path (b)].



Methylene transfer from the metallaoxirane **106** to $(Cp_2Zr(H)Cl)_x$ **60** to give methylzirconocene chloride **123** is equally facile. The binuclear complex **97a**, in which the Zr–O unit is bridged by a CH_2 group stemming from CO and H_2, also reacts in this way. At 40 °C in a slow reaction, **123** and the "metal oxide" **122** are formed very cleanly.[86a]

4.4. Do Aspects of the Chemistry of Zirconocene Metallaoxiranes Have Relevance to Fischer–Tropsch Chemistry?

As far as the formation of methylene groups from CO and H_2 at an active heterogeneous Fischer–Tropsch catalyst is concerned, the question should be answered in the negative. The surface-bound CH_2 moieties there presumably result from carbon monoxide, after dissociative adsorption and



hydrogenation of carbide intermediates.[72b] The characteristic series of reactions of the surface methylenes in Fischer–Tropsch catalysis, generally accepted after the experiments of *Pettit* et al.,[73] are reflected to some extent in the chemistry of molecular metallaoxiranes. The dimerization to give olefins and the alkylidene insertion into metal–hydride bonds are particularly noteworthy. These reactions correspond, at least formally, to two important reaction steps of methylene at the catalyst (Scheme 2).

Scheme 2. A comparison between metallaoxirane reactions (left) and proposed steps in methylene chemistry at a catalyst surface (right).

The chemistry of metallaoxiranes thus far offers no simple molecular examples modeling the C–C bond-forming steps of methylene inserting into metal–carbon bonds at the catalyst. Possibly, such a reaction step takes place during the thermally induced intramolecular formation of ethylene from **124**. Further growth of alkane chains by intermolecular CH_2 insertion in this case is prohibited by fast β-OCH_3 elimination, with release of ethylene.

The thermal decomposition of metalated thioether complexes $[Cp_2Zr(CR_2SCR')_2]$ to give $[Cp_2Zr(SR')_2]$ and $R_2C=CR_2$ may also possibly occur by this pathway.[90]

5. Outlook

Very few areas of research have so consistently produced such new and interesting results over the years as the chemistry of carbene complexes. As many examples in this article show, structural features first found with "classical" Fischer-type carbene complexes are increasingly being found for other types of organometallic compounds as well. It is expected that typical carbene complex reactions will be found for related compounds with some degree of carbene complex character. Transition-metal carbene complexes are firmly established in organic synthesis with many applications. They are now helping to make accessible experimental studies at the borderline between homogeneous and heterogeneous catalysis. Mechanistically oriented studies on the chemistry of metallaoxirane compounds as described above represent one of many possible starting points.

The work described here was carried out by a group of talented co-workers whose names appear in the list of references. To them go my particular thanks for a stimulating time working together that has given me much pleasure. Part of these results were obtained during time spent at the Max-Planck-Institut für Kohlenforschung in Mülheim a. d. Ruhr. I wish to thank Professor Dr. G. Wilke for his very generous support. I am grateful to the leaders and co-workers of many groups of the Institute for help and many stimulating discussions. Financial support from the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, the Fritz-Thyssen-Stiftung, the Stiftung Volkswagenwerk, and the Alfried Krupp von Bohlen und Halbach-Stiftung is gratefully acknowledged.

Perspectives in Photochromism: A Novel System Based on the 1,5-Electrocyclization of Heteroanalogous Pentadienyl Anions

By Heinz Dürr*

Dedicated to Professor Emanuel Vogel and Professor Klaus Hafner on the occasion of their 60th birthdays

The molecular process whereby light induces color changes in certain substances, namely photochromism, is currently a topic of active research. Many reactions—mainly monomolecular—have been reexamined in greater detail from the standpoint of photochromism. Those found to be especially suitable for such studies include *cis-trans* isomerizations, pericyclic reactions, tautomerizations and dissociations. The most important in this group are undoubtedly the electrocyclization reactions. In this paper we present spiro[fluorene-9,1'-[1,8a]-dihydroindolizine] and its bis- and tris-aza analogues as examples of a promising new system with a wide range of variability. Not only the classical uses, but also those in new fields such as frequency doubling of laser radiation, holography or molecular microcircuit chips can now be considered.

1. Introduction

Light and color—two directly interrelated concepts—have fascinated mankind since early times, with ever more novel aspects emerging. The term photochromism involves both these phenomena. The earliest scientific studies were those of *ter Meer*,[1] *Marckwald*[2a] (who was one of the first to use the expression "phototropy"[2b]), and more recently *Hirshberg*.[3] Photochromism[4] is a reversible transformation of a single chemical species between two states whose absorption spectra are recognizably different, the transformation in at least one direction being induced by electromagnetic radiation [Eq. (a)].

$$A(\lambda_1) \underset{h\nu_2,\,\Delta}{\overset{h\nu_1}{\rightleftharpoons}} B(\lambda_2) \qquad (a)$$

Species A is transformed into the higher energy form B as a result of irradiation with light. The reverse reaction to A usually occurs as a spontaneous thermal process, but may also be light-induced. Equation (a) holds true only for unimolecular reactions. More recently bimolecular photochromic systems, based on a cycloaddition or cycloreversion, have also been discovered [Eq. (b)].

$$A + B \underset{h\nu_2,\,\Delta}{\overset{h\nu_1}{\rightleftharpoons}} C \qquad (b)$$

Photochromic systems[4, 5] according to Equation (a) can be classified into several groups on the basis of the photochemically induced primary step:

1) photoreversible systems, in which the colored form B undergoes a light-induced reaction back to the form A,
2) thermoreversible systems, in which the colored form B reverts thermally to A,
3) photo- and thermoreversible systems,
4) inverse photochromic systems, in which the initial form A absorbs at the longer wavelength and form B at the shorter wavelength,
5) multiphotochromic systems, in which more than two forms undergo photochemical and/or thermochemical interconversion.

This review begins with a brief survey of the most important photochromic compounds—mainly organic. This is followed by an outline of the development of a new photochromic system based on a 1,5-electrocyclization, and the possibilities which it offers. The review finally deals with some typical applications of common photochromic materials.

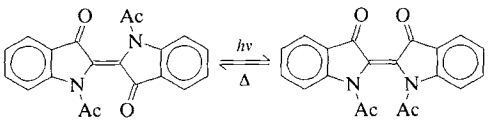
2. Common Photochromic Systems

Photochromic systems[4, 5] may be classified into six major groups according to reaction types, which are discussed in Sections 2.1 to 2.6.

2.1. Triplet-Triplet Absorption

The simplest photochromic system is one which contains molecules in the stable ground state and in a metastable, photochemically excited state. Examples are fluorescein in a boric acid matrix,[6] and picene in polymer films.[7] The triplet-triplet excitation in coronene also belongs to this class.[8]

2.2. *cis-trans* Isomerization



When the double bonds of alkenes, azomethines or azo compounds are excited either directly or via spectral sensitiz-

[*] Prof. Dr. H. Dürr

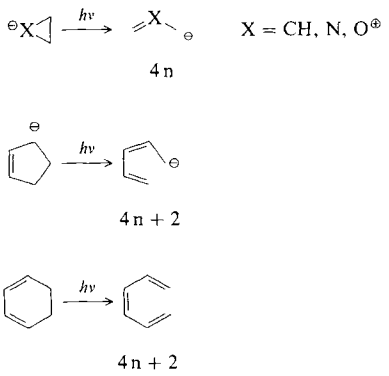
ers, a reversible *cis-trans* isomerization is observed. The two configurational isomers usually differ in the positions and intensities of their UV absorption maxima.

N,N'-disubstituted indigo derivatives such as **1** have been suggested as combined solar energy storage and conversion systems.[9, 10] Here a small proportion of the energy is stored in the *cis* isomer **2**; the greater part, however, is converted into molecular motion (Scheme 1).

1 (*trans*) **2** (*cis*)

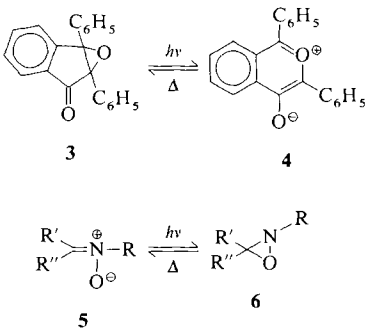


Scheme 1.

The advantages of this system lie in the absorption spectrum of **1**, which coincides very well with the photochemically active region of the solar spectrum, in the well known light fastness of indigo dyes, and in the fact that the reverse reaction **2** → **1** is strictly quantitative. Similar results have also been obtained with thioindigo derivatives.[11] A disadvantage is that in all cases the specific energy storage capacity is low owing to the high molecular weights of the indigo derivatives. The absorption maxima for the colored variants formed on irradiation of various compounds are shown in Figure 6.

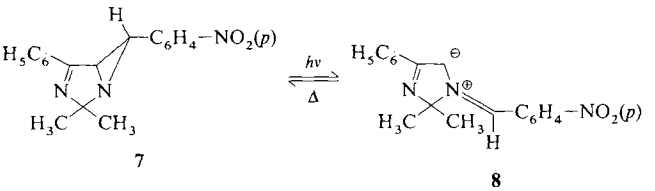
Cis-trans isomerizations also have an important role in simpler compounds such as stilbenes,[12, 13] benzylidene anilines[14a] and azobenzenes,[14b, 15] and in biological systems such as retinal in the human eye.[4] More recently so-called "photoresponsive crown ethers" have also been prepared; in these too, the light-sensitive behavior is based on *cis-trans* isomerization.[14b]

2.3. Pericyclic Reactions



Of the different classes of pericyclic reactions, the electrocyclic reactions have proved to be especially suitable as a basis for photochromic systems. Scheme 2 shows three dif-

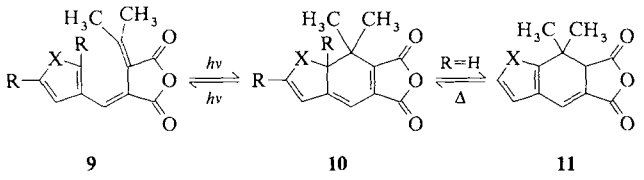
Scheme 2.



ferent types of ring-opening reactions. However, only a few of the many possible electrocyclization reactions are important.

For example, irradiation of the epoxyindanones with the general structure **3** leads to opening of the three-membered ring followed by rearrangement to give pyrylio-oxides **4**[16]. The most important representatives of this series have been studied in detail by *Ullman* et al.[17, 18] (Scheme 3).

Scheme 3.

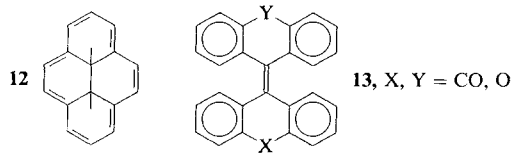


In an analogous way, the nitrones **5** can be converted by irradiation into the oxaziridines **6** (Scheme 3). These are powerful oxidizing agents, highly reactive, and in most cases cannot be isolated.[19] The reverse reaction takes place upon heating. Interesting photochromic molecules of the aziridine type have been found by *Do Minh* and *Trozzolo* et al.[20–22] These show photochromic behavior even in the crystalline state, whereas many other systems are photochromic only in solution. An especially efficient photochromic system is found in the bicyclic aziridine **7**, which undergoes a light-induced reaction according to Scheme 4 to give monocyclic **8**.[20–22]

Scheme 4.

The butadiene-cyclobutene isomerization, although extremely important from a theoretical and preparative point of view, is of no significance as a photochromic system, as the shifting absorption maxima in these derivatives are nearly all in the UV rather than in the visible region. This limitation does not, however, apply to $4n + 2$ systems (6π), whose photochromism results from the electrocyclic 1,3,5-hexatriene/1,3-cyclohexadiene interconversion. This group includes the fulgides **9**, which have been developed for specific technological uses. In this class of bis(methylene)succinic anhydride derivatives, which were first synthesized by *Stobbe*,[23b] *Heller* et al.[23a, 24–27] showed that the 1,5 hydrogen shift to structure **11**, following the photochemical valence isomerization reaction **9** → **10**, could be suppressed by substituting methyl groups in place of hydrogen atoms (Scheme 5).

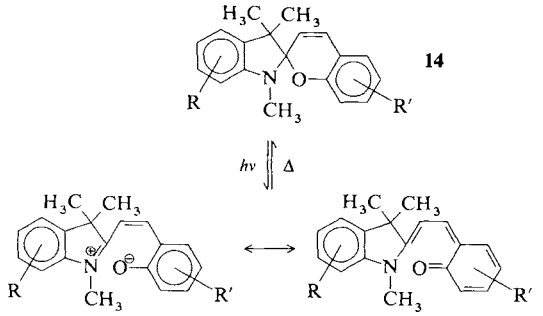
Derivatives such as Aberochrome 540 **9a** and Aberochrome 999 **9b** are used as actinometric substances in the UV and visible regions (see Section 4). The photochromic pyrene



9 **10** **11**

9a, X = O, R = CH_3 (Aberochrome 540)
9b, X = S, R = C_6H_5 (Aberochrome 999)

Scheme 5.

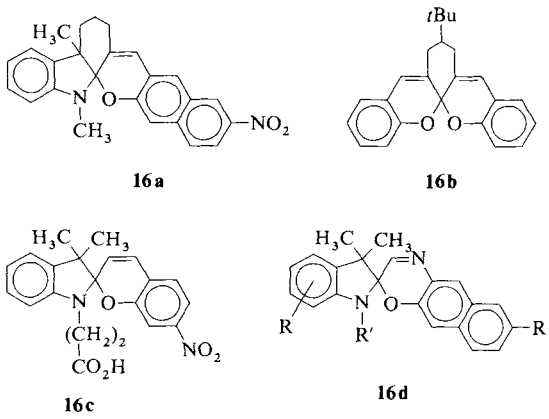


derivative **12**[28, 29] and the hexacycles **13**[30, 31] are other 6π systems which undergo analogous electrocyclic reactions (Scheme 6).

12 **13**, X, Y = CO, O

Scheme 6.

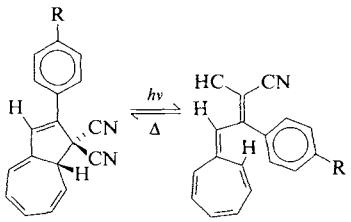
An electrocyclic $(4n + 2)$-reaction ($n = 1$) is also found in the spiropyrans **14**,[32–35] as shown in Scheme 7. UV irradi-



14 **15**

Scheme 7. R and R' can be a large number of organic groups; each ring can also contain several substituents (see Ref. [4]).

ation of the colorless spiro compounds **14** leads to cleavage of the C–O bond to give the open chain compounds **15**, which absorb strongly in the visible region. These highly interesting photochromic spiropyran derivatives have been studied very intensively,[32–49] and the literature up to 1970 is very well covered by *Brown*.[4] This system too has led to quite a number of practical applications (see Section 4).

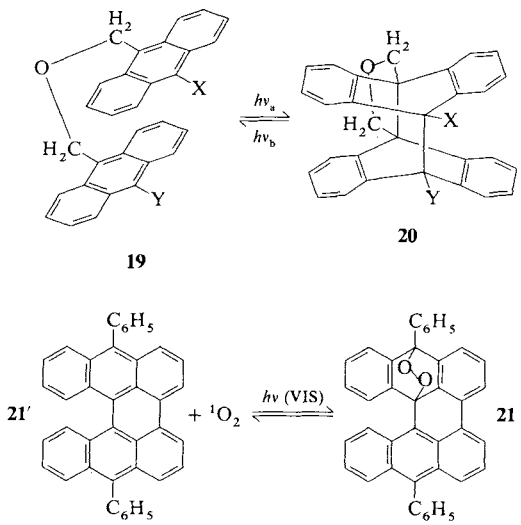


Bräuchle et al. have shown that an unstable intermediate with an orthogonally bridged structure is formed during ring-opening of spirodihydroindoles at 4.2 K.[46] Bridged compounds of this kind, such as **16a**[47] and analogues such as **16b**[48] and the spiro compounds **16c**[49a] and **16d** (Scheme 8), have been synthesized.

16c is a fatigue resistant spiropyran.[49a] According to most recent findings replacement of a CH group by N affords various spirooxazines.[49b] Another important system belonging to this class is that of the phytochromes, which have been studied by *Schaffner* and *Braslavsky* et al.; these have an important biochemical role in regulating plant growth.[49c] An electrocyclic reaction involving a $4n + 2$ π-electron ($n = 2$) system has been observed in the vinylheptafulvene derivative **18** (Scheme 9).[50]

16a **16b** **16c** **16d**

Scheme 8. Indolinospiropyrans **16**; photostable spiropyrans **16c,d.**



17 **18**

a, R = OCH_3; **b**, R = NO_2

Scheme 9. Photochromic system based on a 10π-electrocyclization.

Cycloadditions are another important class of pericyclic reactions which provide a basis for photochromic molecules. Examples are the [4 + 4] cycloadditions of "bracketed" dianthracene derivatives **19** (Scheme 10); *Bouas-Laurent* was able to demonstrate photochromic behavior in the system **19** → **20**, and to clarify the details of the reaction sequence in a series of elegant studies.[51, 52]

19 **20** **21'** **21**

	X	Y		X	Y		X	Y
a	H	H	**b**	CH_3	H	**c**	C_6H_5	H
d	Br	H	**e**	CH_3	CN	**f**	C_6H_5	CN
g	CH_3	Br	**h**	Br	Br	**i**	C_6H_5	C_6H_5

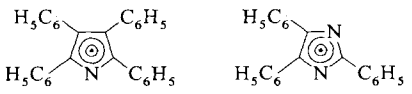
Scheme 10. Photochromic systems based on bimolecular reactions. Reaction **19** → **20**: solvent ether or methylcyclohexane, $\lambda = 335$ nm; reaction **20** → **19**: $\lambda = 254$ nm. Yield of **20a–i**: 20–90%.

Brauer et al.[53, 54] have described a cycloreversion which occurs in *endo*-peroxides such as **21** (Scheme 10). The reaction releases singlet oxygen, $^1O_2$, which then recombines reversibly with **21'**. We thus have here a bimolecular photochromic system contrasting with the intramolecular cycloaddition **19** → **20**. In the latter case, however, the effectiveness of the photocycloaddition results from the bridges between the rings.—Sigmatropic reactions do not yet appear to have been used as a basis for photochromic systems.

2.4. Tautomerization

Light-induced tautomerizations can occur in the form of prototropic rearrangements such as **22** → **23** for the case of salicylidene-anilines (Scheme 11);[55-60] similar behavior is found in 2-, 3- or 4-(salicylidenamino)pyridines.[61]

22 **23**



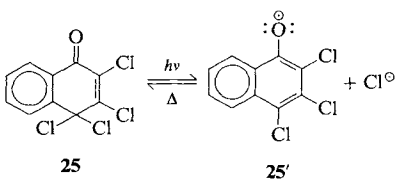
Scheme 11. R can be any group, e.g. aryl, methyl.

Such prototropic processes may be either thermally or photochemically activated. In the above example the prototropic behavior is responsible for the observed photochromism. Light-fastness of dyes is often the result of photochemically induced prototropy of this kind.

2.5. Dissociation

2.5.1. Homolytic Cleavage of Bonds

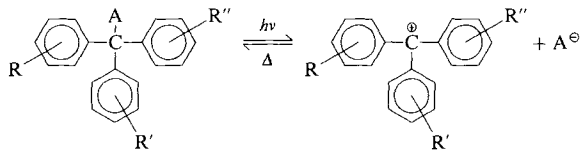
Typical examples of this type are the cleavage reactions of octaphenyl-1,1'-bipyrrolyl and of hexaphenyl-1,1'-biimidazolyl, which on exposure to light yield the colored free radicals **24a** and **24b** respectively (Scheme 12). These reactions too form the basis of a photochromic system.[62]



24a **24b**

Scheme 12.

2.5.2. Heterolytic Cleavage of Bonds



An example of this class is the loss of a Cl atom from **25**,[63] followed by recombination to give the original compound. This reaction was first formulated as in Scheme 13. More recent work[64] has shown that instead of a radical pair[63] this cleavage gives a carbenium ion.

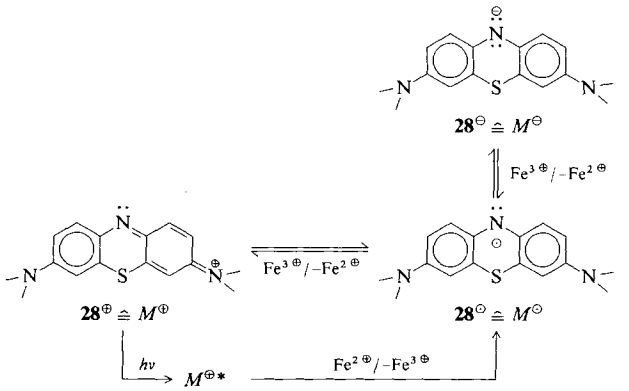
25 **25'**

Scheme 13.

The same holds true for triarylmethane derivatives **26**, whose photochromic behavior was observed as long ago as the turn of the century by *Hantzsch* et al.[65] Irradiation of the colorless (leuco) form **26** gives the strongly colored triarylmethyl cations **27**, with release of an anion $A^{\ominus}$; the thermally induced decoloration of the cation depends critically on the solvent and the anion concentration (Scheme 14).[65-67]

26 **27**

Scheme 14. R = R' = R'' = $N(CH_3)_2$; A = CN, SO_3H.



Triarylmethane derivatives whose leuco form is a spiro compound have been studied by *Gleiter* et al.[41b] In these compounds the reaction of the colored form with other anions or with the solvent, as can occur in **27**, is prevented (cf. also Ref. [68]).

2.6. Electron Transfer/Redox Photochromism

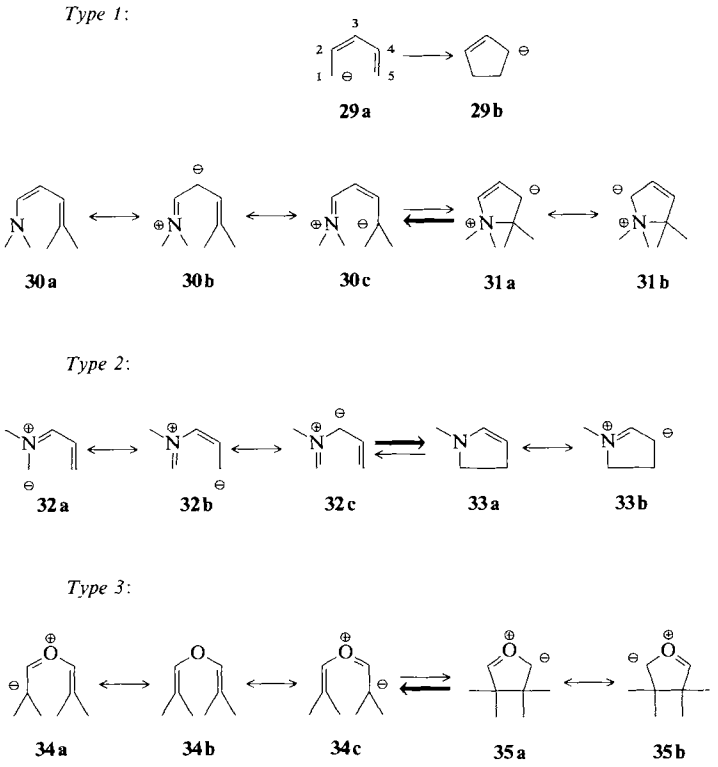
The best known photochromic system based on an electron transfer reaction is undoubtedly that of AgCl, which is decomposed by light according to Equation (c)

$$AgCl \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} Ag^0 + Cl^{\odot} \qquad (c)$$

This electron transfer reaction is of great practical importance in photochromic spectacle lenses based on silicate glass.[69] An example of a photochromic electron transfer reaction in organic chemistry is the methylene blue system which has been investigated by *Parker* (Scheme 15).[70]

Scheme 15.

3. The Development of a New Photochromic System



Pericyclic reactions, and electrocyclic reactions especially, belong to a class of rearrangements[71] which can cause photochromic behavior. The 1,5-electrocyclization reac-

tions[72, 73] of the pentadienyl anion and of its heterocyclic analogs appeared to offer attractive possibilities for this purpose.

3.1. The 1,5-Electrocyclization Reaction

The 1,5-electrocyclization reaction can in principle proceed thermally as a disrotatory process and photochemically as a conrotatory process.

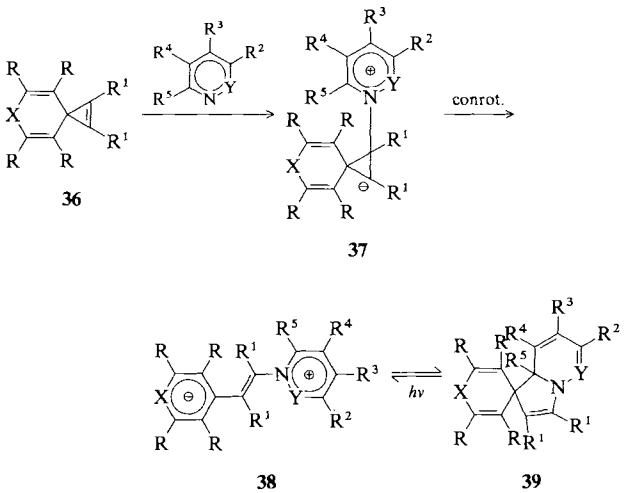
According to *Huisgen*[72] one can in addition distinguish three different cases for those hetero-analogs of the pentadienyl **29a** or cyclopentenyl anions **29b** in which a carbanion C atom is replaced "isoelectronically" by a heteroatom[72] (Scheme 16).

Scheme 16. Substituents not shown for clarity.

In type 1 (heteroatom in position 1) **30a** is a formally uncharged mesomeric structure, whereas the cyclic form **31** must be formulated as a resonance hybrid of dipolar structures. In this case, therefore, in the equilibrium **30** ⇌ **31** the ring-opened species **30** predominates. If the heteroatom is in the 2-position (type 2), an uncharged ring structure **33a** becomes possible, with the result that the equilibrium **32** ⇌ **33** is shifted towards the cyclic form **33**. In type 3 (heteroatom in the 3-position), only formula **34b** is uncharged, and the dominant species is therefore **34**, i.e. the ring-opening is favored.

If we now wish to design a photochromic system based on a 1,5-electrocyclization, the molecular structures need to be such that equilibrium mixtures are possible in each of the types 1 to 3. The individual ring-opened or cyclic systems can therefore only be allowed to have small values of ΔG_0 and $\Delta G^{\#}$. In order to synthesize tailor-made photochromic molecules one must ensure that this condition is satisfied. In the following, new systems and synthetic methods for photochromic molecules of types 1, 2 and 3 are described.

3.2. Synthetic Routes



3.2.1. *Type 1 Systems*

No photochromic systems of type 1 have so far been discovered (cf. Ref. [72]).

3.2.2. *Type 2 Systems*

Systems of type 2 can be regarded as "1,3-dipoles of allylic type".[72] The organic chemist's entire armory has been brought to bear on the study of 1,3-dipolar cycloadditions,[73] but despite this it is only quite recently that the reaction has been successfully used in an effective photochromic system.

Cyclopropene route: When spirocyclopropenes with the general structure **36**[74] are allowed to react with pyridine or pyridazine derivatives, or spiro [4a,5]dihydropyrrolo-[1,2-*b*]pyridazines, photochromic spiro[1,8-a]dihydroindolizines **39**, Y = CH, **39**, Y = N, respectively, are formed. Some representative examples of these, synthesized according to Scheme 17, are listed in Table 1.[75–77]

Scheme 17. Cyclopropene route to **38** and **39**. Solvent: CH_2Cl_2/ether, temp.: 20–25 °C, yield: 12–89% (see Table 1).

The reaction mechanism leading to the formation of **39** may be described as follows: the pyridine derivative attaches itself to the electron-deficient cyclopropene ring in **36** by nucleophilic addition. The resulting cyclopropyl anion undergoes a ring-opening to give an allyl anion, in this case the betaine derivative **38**; the process **37** → **38** is a cooperative reaction which, according to the *Woodward-Hoffmann* rules, is a conrotatory ring-opening. The betaine derivative **38** can undergo 1,5-electrocyclization to give **39**. The action of light on **39** gives **38**, and the transformation **38** ⇌ **39** thus constitutes a new photochromic system.

Compounds with a very wide range of absorption wavelengths can be synthesized using this cyclopropene route (see

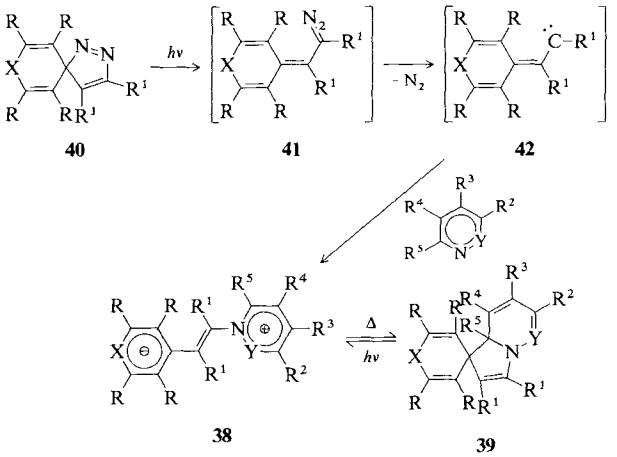


Table 1. Some data for the betaines **38** and the spiro[1,8a-dihydroindolizines] (and their N-analogues) **39**. $-R-R- = -(CH=CH)_2-$ (benzoannelation). $R^1 = CO_2CH_3$. Of the betaines, **38k** and **38s** (see Table 5) could be isolated. UV data determined at 20 °C in $CHCl_3$

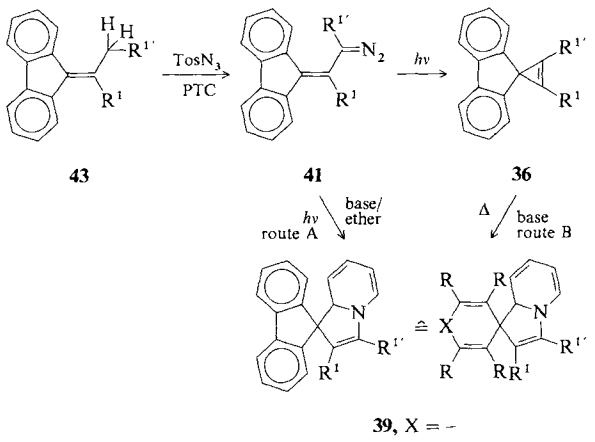
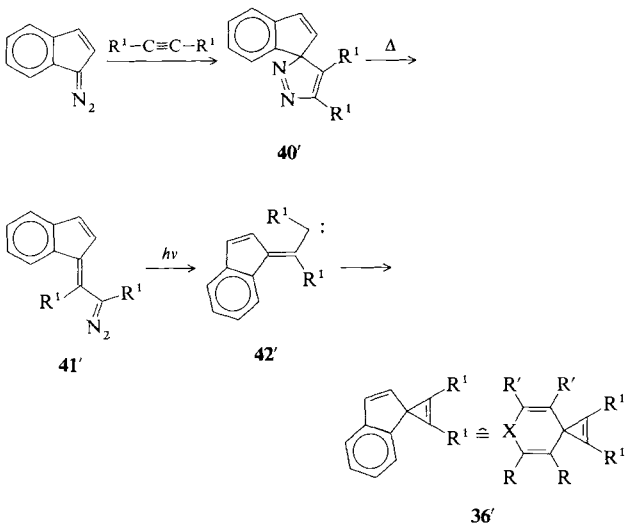
Table 1). Molecules with properties tailor-made for specific applications can be synthesized under very mild conditions in excellent yields.[74–78a] Novel materials of type **39** containing crown ether units have also been prepared.[78b]



Pyrazole route: A problem was encountered, however, when attempts were made to adapt the above synthesis to prepare CN-substituted spirodihydroindolizines. Cyano-substituted spirocyclopropenes (**36**, with $R^1 = CN$) are unknown.[79] We therefore developed an alternative method, in which the spiropyrazole derivative **40** is irradiated directly (Scheme 18). This results in ring opening with in situ formation of the diazo compound **41**, which then loses nitrogen to give the fulvenecarbene **42**. This can then react with the diazine to form a betaine **38**. Cyclization then affords the spirodihydroindolizine or the N-analogues **39**. By this route it is also possible to prepare cyano-substituted species **39**, and to obtain derivatives containing low reactivity groups, e.g. R^1 = trifluoromethyl, in considerably better yields.[75, 80]

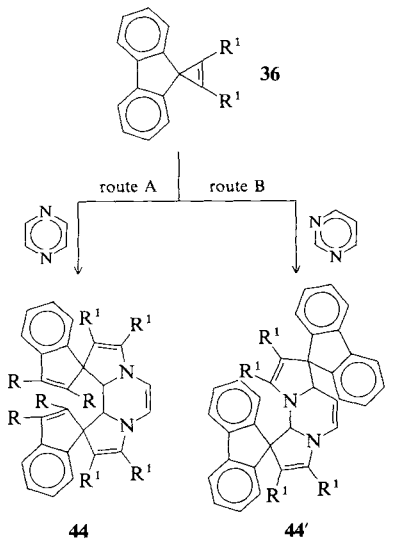
Scheme 18. Pyrazole route to **38** and **39**. $-R-R- = -(CH=CH)_2-$ (benzoannelation), R^1 = CN, CO_2CH_3 etc., X = – (zero bridge), C=O, S.

Diazo or vinylcarbene route: In both the above described methods, only symmetrical substitution at the 2,3 positions of **39** is possible, i.e., $R^1 = R^{1'}$. Since the photochromic properties of **39** are determined essentially by the double bond between C-2 and C-3 it became necessary to find a method for synthesizing asymmetrically substituted versions of **39**.



The already known fulvene derivative **43** is treated with $TosN_3$ in the presence of a phase transfer catalyst (PTC); this results in the formation of compound **41** by transfer of a diazo group[81] (Scheme 19, route B). The action of light on **41** then gives, via the vinylcarbene **42**, the spirocyclopropene derivative **36**. This reacts with suitable nucleophilic bases to give **39**. Alternatively **39** can be synthesized by direct photolysis of **41** in an ether solution of the base[82, 83a] (route A).

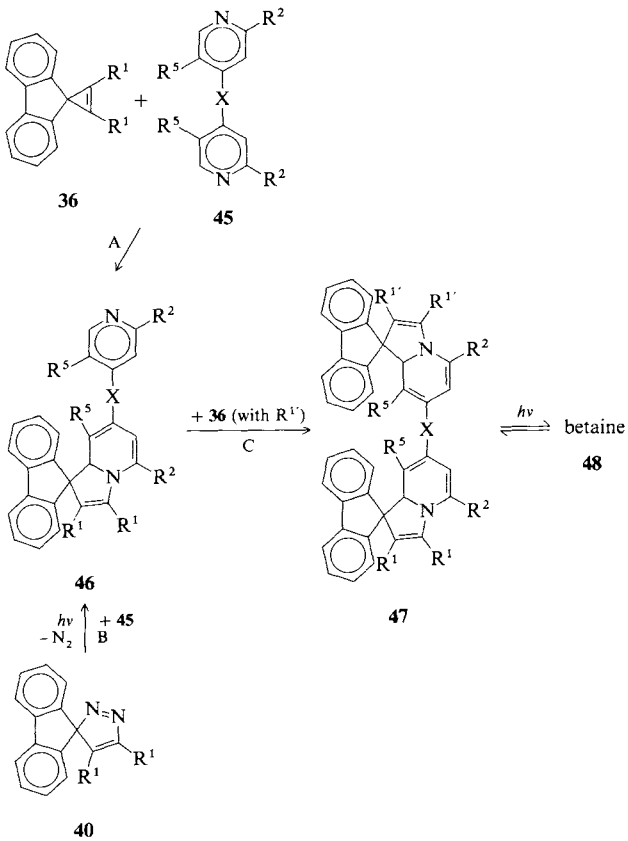
Scheme 19. Diazo- or vinylcarbene route to (**38** and) **39**. Route A: $R^1 = R^{1'} = CO_2CH_3$: yield 75%; $R^1 = CO_2CH_3$, $R^{1'}$ = CN: 12%; route B, see Table 1.



Retro-1,5-electrocyclization: Suitable spiropyrazole derivatives **40** undergo an interesting thermolysis. Thus, from the spiro[indene-1,3′-pyrrole] **40′** one obtains a vinyldiazoalkane **41′**.[82] By a route analogous to that in Scheme 19, **41** can then react to give the DHI derivative **39** (see Scheme 20) via **36′**.

Bichromophoric systems: For synthesizing bifunctional photochromic molecules (cf. also Section 1) of type 2, there are in principle two possible routes: 1) from a monofunctional unsaturated spiro compound and a bifunctional base, and 2) from a bifunctional unsaturated spiro compound and a

Scheme 20. $-R-R- = -(CH=CH)_2-$, $R' = H$, $R^1 = CO_2CH_3$ ($\equiv E$), X = – (zero bridge).



monofunctional base, the route to the bifunctional spiro compound being via either a bis(diazo) compound or a bis-alkyne.[83b]—As shown in Scheme 21, the reaction of **36** with

Scheme 21. $-R-R- = -(CH=CH)_2-$. Route A: $R^1 = CO_2CH_3$: yield 50%; $R^1 = CO_2tBu$: 30%. Route B: $R^1 = CO_2CH_3$: 24%; $R^1 = CO_2tBu$: 32%; $R^1 = COCH_3$: 28%.

pyrazine or pyrimidine (in contrast to the reaction with pyridazine derivatives) affords the very interesting bis-adducts **44** and **44'**, respectively (Route 1). However, only the compounds of type **44'** are photochromic.

If we separate the two nucleophilic centers of the azines, we have molecules of the bis(pyridine) type **45**. Reaction of such a bis-base **45** with spirocyclopropenes **36** gives first 1:1 adducts **46**. However, depending on the reaction conditions, one may also synthesize the 2:1 adduct **47** (Scheme 22, Table 2). By suitable sequencing of the individual steps of

Scheme 22. $R^1 = CO_2CH_3$, $COCH_3$ (see Table 2).

this reaction one can obtain both symmetrical and asymmetrical bichromophores[40, 84] (steps A, C or B, C).—Recently route 2, via a bis(diazo)compound, has also been realized.[84]

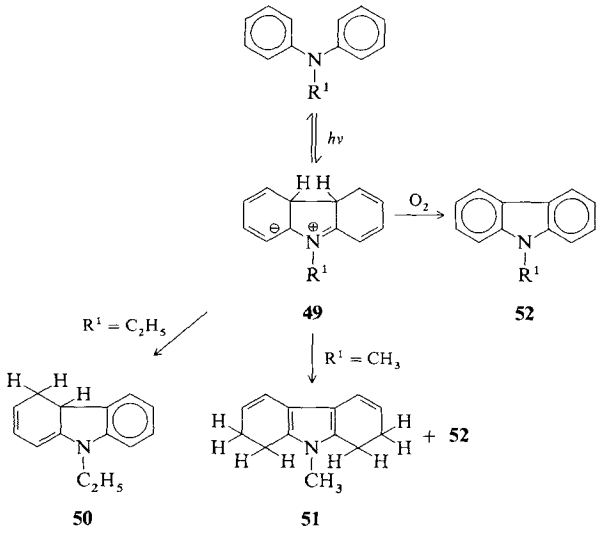


Table 2. Some data of the 2:1 adducts **47**. $E = CO_2CH_3$. UV data determined at 20 °C in CH_2Cl_2.

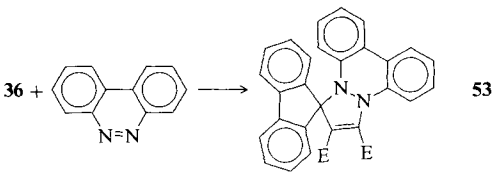
3.2.3. *Type 3 Systems*

Systems of this type have already been known for some time. However, owing to subsequent thermal reactions—mainly sigmatropic H-shifts (and possibly oxidations) at

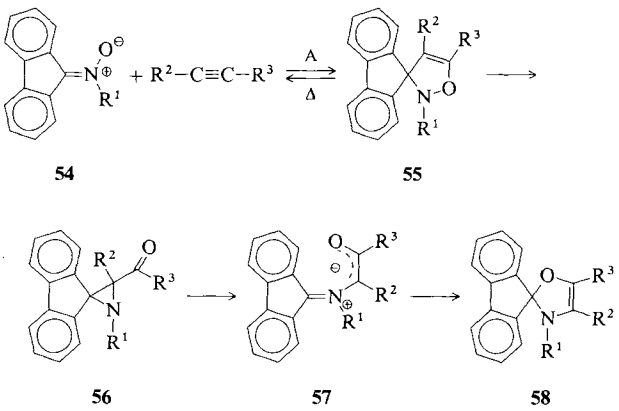


49 **52** **50** **51**

Scheme 23.

moderate or high temperatures—irreversible secondary reactions to **51** or **52** occur (Scheme 23), and the system cannot therefore be regarded as reversibly photochromic[85].

3.2.4. Mixed Systems

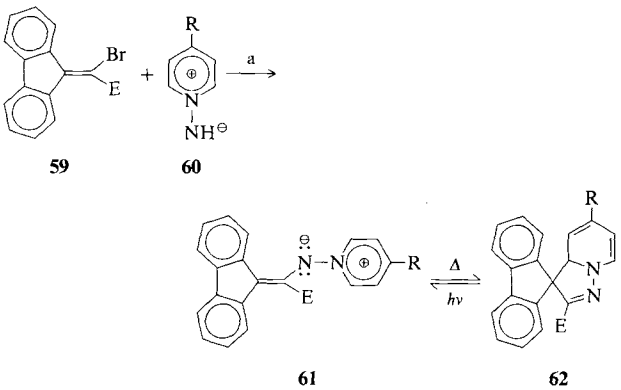


Type 1, 2 systems: If in the pyridazine derivatives, which normally give compounds **39**, one blocks the *o* or *o'* position by benzoannelation, the ring closing reaction in the betaine **38**—for example, starting from **36** and benzo[*c*]cinnoline—must proceed with the formation of a dihydropyrazoline ring rather than a dihydropyrroline ring (Scheme 24). This opens the way to an elegant route to **53**, the first type 1, 2 system.[86]

53

Scheme 24. E = CO_2CH_3.

Type 1, 2 aza-oxa systems: One expects that it should be possible to synthesize isoxazoles from nitrones and alkynes by 1,3 dipolar cycloaddition. It is in fact found that the appropriate spirodihydroisoxazolines **55** can be obtained by this method; however, these are no longer photochromic—instead they are thermochromic at moderate temperatures. At higher temperatures they are transformed irreversibly via **56** and **57** into spirodihydrooxazolines **58**[87a] (Scheme 25).



54 **55**

56 **57** **58**

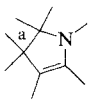
Scheme 25. 0–10 °C; $R^1 = C_6H_5$, $R^2 = R^3 = CF_3$, yield of **55**: 89%; $R^1 = C_6H_5$, $R^2 = R^3 = COCH_3$: 80%.

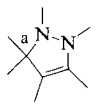
Type 2, 3 diaza systems: The 1,3 dipolar cycloaddition reaction which is so effective as a method for synthesizing five-membered rings[72] can also be used to prepare spiroheterocyclic compounds of the 2, 3 type. If a suitable substituted dibenzopentafulvene[87b] is treated with pyridine-*N*-imine **60**[88] according to Scheme 26, the corresponding

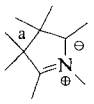
59 **60**

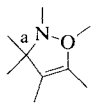
61 **62**

Scheme 26. R = H: yield 67%; R = CH_3: 30%; R = CN: 35%; E = CO_2CH_3.



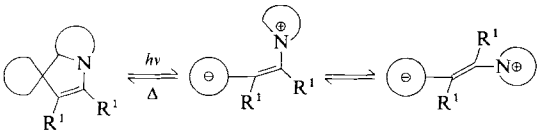






3,3a-dihydropyrazolo[1,5-*a*]pyridine **62** is formed. Compounds with the structure **62** are again photochromic, and thus constitute the first system of type 2, 3 with a dihydropyrazole ring as central unit.[40, 84, 89a]

3.3. Structure and Reactivity



Does the reaction **39** → **38** mentioned previously involve a 1,5-electrocyclization, as has been postulated for the system pentadienyl anion-cyclopentenyl anion (**29a** → **29b**)? For a better comparison, in Table 3 **39** and related compounds are reduced to the central heterocycle, which becomes closed during the 1,5-electrocyclization.

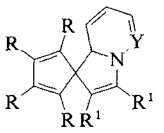
In Table 3 the σ–bonds which undergo photochemical (or in a few cases thermochemical) cleavage are marked "a". These cases differ significantly from the ring-opening of the cyclopentenyl anion, since here no anion is formed. The photoinduced products from these electroneutral five-membered heterocycles are in all cases zwitterions or betaines;

Table 3. Classification and characteristic structural features of the new photochromic systems. a: σ bond formed upon 1,5-electrocyclization (cf. also [49c]).

Cpd	Type	Central five-membered ring	Cpd	Type	Central five-membered ring
39	1, 2		**53**	1, 2	
49	3		**55**	1, 2	
			62	2, 3	

Scheme 27 shows—greatly simplified—their *E*- and *Z*-isomers. This behavior is a characteristic feature of this class of photochromic molecules, distinguishing them from the electrocyclizations of 6-atom-6π systems described previously (cf. Scheme 2).

39 *E*-**38** *Z*-**38**



Scheme 27.

3.4. UV Spectra and $t_{1/2}$ Measurements

The UV spectra of the dihydroindolizines **39**, X = CH, and dihydropyrrolo[1,2-*b*]pyridazine **39**, X = N, usually have absorption maxima in the near UV between about 360 and 410 nm. The betaines **38** produced by photochemical action absorb at about 505 to 726 nm (Table 1). Similar results are found for the bichromophoric systems **47** and the corresponding betaines **48** (381–420 nm and 575–702 nm, resp.). **39** and **47** are therefore colorless and pale yellow, respectively, while the betaines **38** and **48** all show colors which vary from red to violet or blue-green. With regard to the possible applications, the colored forms (i.e. the betaines **38** or **48**) offer a range of colors covering virtually all possible shades. The compounds **39** and **47**, on the other hand, absorb in the short wavelength region of the solar spectrum (UVA). The thermally induced reverse reaction of the betaines **38** formed from **39** can be monitored by UV spectroscopy, thus allowing one to determine the reaction rate and the half-life $t_{1/2} = \ln 2/k$ for the colored betaine form **38**.

The activation parameters for the reaction **38** → **39** can be determined from measurements at different temperatures. Table 4 shows some typical examples of results obtained from such measurements. To analyze structure-reactivity relationships for these systems we may divide the molecule **39** into three regions A, B and C as indicated in Scheme 28.

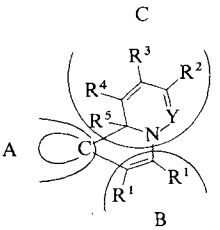


Table 4. Activation parameters for the cyclization of betaines **38** to dihydroindolizines (and N analogues) **39** (in CH_2Cl_2). –R–R– = –(CH=CH)$_2$–benzoannelation).

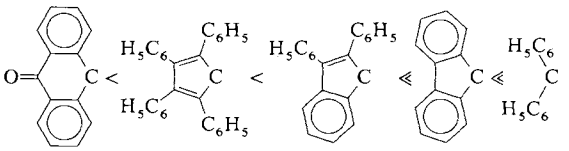
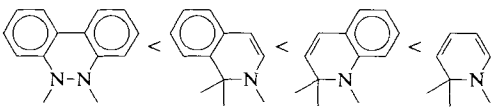


39

39	R^1	Y	$\Delta G^{\neq}$ [kcal mol^{-1}]	$\Delta H^{\neq}$ [kcal mol^{-1}]	$\Delta S^{\neq}$ [cal mol^{-1} K^{-1}]	$t_{1/2}$ [s]
a	CO_2CH_3	CH	20.1	15.9	–14.2	14.2
m	CN	CH	23.4	17.8	–18.6	16800
n	CN	N	22.4	15.3	–22.0	3375
o	CN	CCH_3	31.6	23.2	–24.9	113760

The data in Tables 1, 2 and 4 show that the half-life of the colored form **38** increases as certain changes are made in each of the three regions, as detailed below.

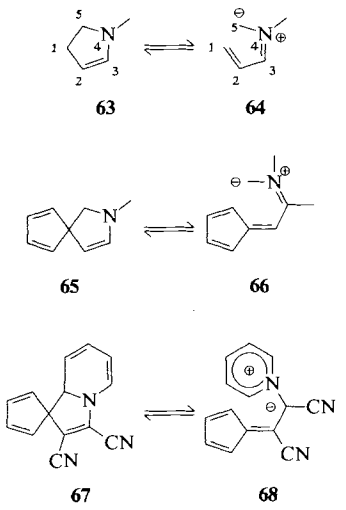


Region A:

Region B:

$$R^1 = H < CF_3 < C_6H_5CO < CH_3CO < CH_3CO_2 < CN$$

Region C:



Scheme 28. The changes quoted in the regions A, B and C stabilize the colored form **38** (i.e. increase $t_{1/2}$).

Region A: increase in $t_{1/2}$ occurs in the sequence anthronyl, tetraphenylcyclopentadienyl, indenyl, fluorenyl and finally diphenyl groups.[89b]

Region B: With regard to the substituent R^1, replacement of hydrogen by trifluoromethyl, benzoyl, acetyl, acetoxy, or cyano groups similarly reduces the energy of the colored forms and thus stabilizes them. It thus appears that the stronger the electron-withdrawing effect of the double bond, the greater is the delocalization of the negative charge, and the consequent stabilizing effect of the substituent.

Region C: The half-life of the colored form is increased on going from a tricyclic azine (benzo[*c*]cinnoline) to a bicyclic azine isoquinoline (quinoline) through to a monocyclic azine. This can be explained by the increasing degree of resonance stabilization of the betaine **38** in this sequence of structures. For R^2 to R^5 the sequence $H < CH_3 < N(CH_3)_2$ applies. $t_{1/2}$ is generally increased by substituents R^5.

Scheme 29. Equilibrium between dihydropyrroles (**63, 65, 67**) and betaines (**64, 66, 68**). Arbitrary numbering of the atoms.

These structure-reactivity relationships[90, 91] can be understood on the basis of semiempirical MINDO/3 calculations (Fig. 1).[92] For these calculations the structure **65** was chosen as the model for the closed ring form (≙ **39**), and the structure **64** for the betaine form (≙ **38**) (Scheme 29).

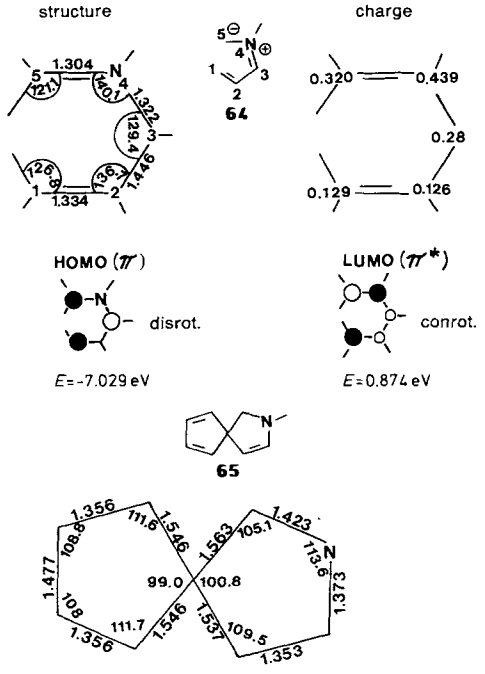


Fig. 1. Selected results of the MINDO/3 calculations on **64** (model for **38**) and **65** (model for **39**).

For the betaine **64** the following results were obtained:

1) The bond between C-2 and C-3 is to be regarded as a single bond, and all the others as double bonds (rotation about the C-2/C-3 bond therefore gives conformers).
2) The negative charges are localized preferentially on C-3 and C-5, and the positive charges mainly on the nitrogen. This means that electron acceptor substituents should have particular importance, mainly at C-3.

Analogous results are obtained from MINDO/3 calculations on more complex systems[92] of the types **67** and **68**, leading to conclusions similar to those above. The results of an X-ray structural analysis on **39** confirm the calculated geometry of the spirodihydroindolizine form **39**[91a] (Fig. 2).

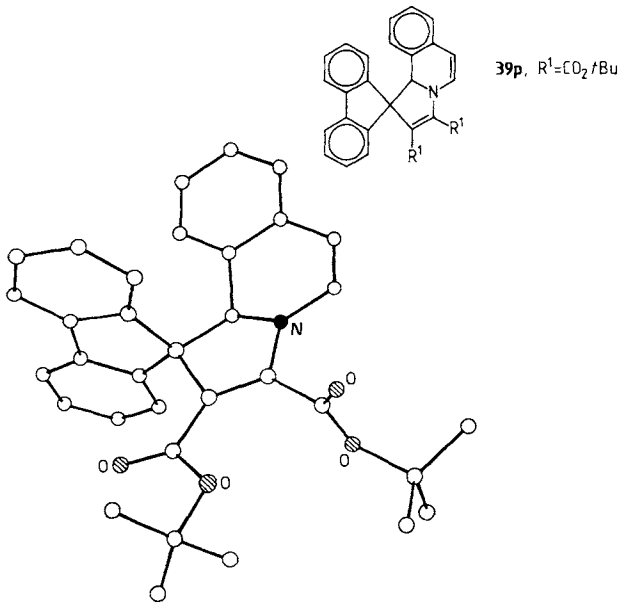

Fig. 2. Structure of **39p** in the crystal; for accurate values for bond lengths and bond angles see Ref. [91].

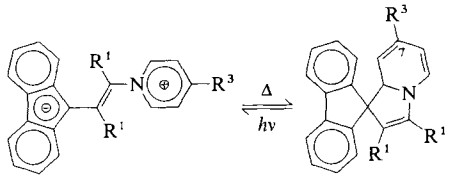
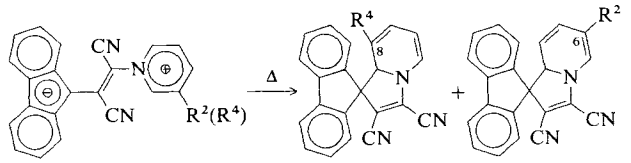


3.5. Hammett Studies of the Thermal Electrocyclization 38 → 39

In order to test the results from semi-empirical MINDO/3 calculations and to quantify electronic effects involved in the 1,5-electrocyclization **38** → **39**, LFER (= Linear Free Energy Relationship) studies were carried out. The first compounds to be investigated in this way were 7-substituted compounds **39**.

The substituents $R^1 = COOCH_3$, $COCH_3$ and CN were introduced into region B of the molecule[83, 93] (see Scheme 28). The ϱ-values obtained from a Hammett correlation of the cyclization rate constant $k_{38\rightarrow39}$ are slightly positive for the reaction R^3-**38m** → R^3-**39m**, while those for the reactions R^3-**38a** → R^3-**39a** and R^3-**38q** → R^3-**39q** are clearly negative (Fig. 3).



How can this effect be explained? Scheme 30 provides some answers. We shall consider only the partial structure α in the betaine structure; several resonating structures are conceivable.

If there is a strong electron acceptor such as CN at position 3, it is evident that a positive reaction center is present in the transition state. Strong acceptor substituents thus fa-

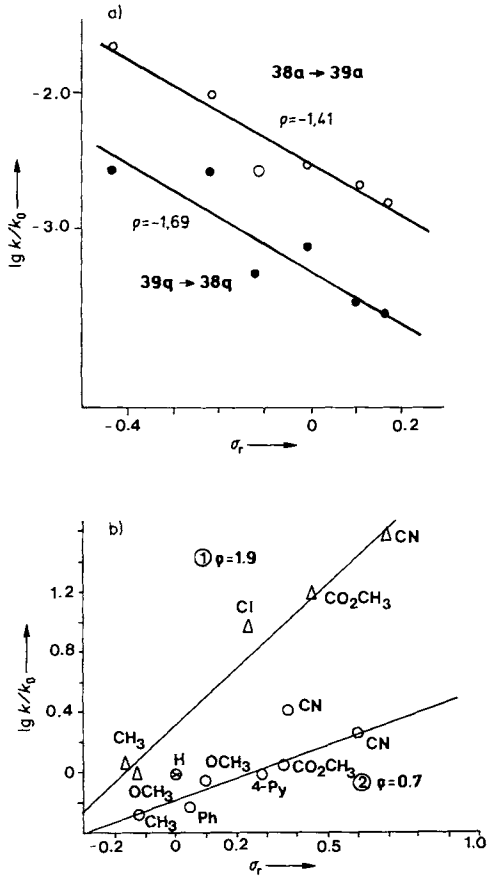
② $R^2(R^4)$-**38m** R^4-**39m** R^2-**39m**

R^3-**38m** and R^3-**39m** see R^3-**38** and R^3-**39**, R^1 = CN



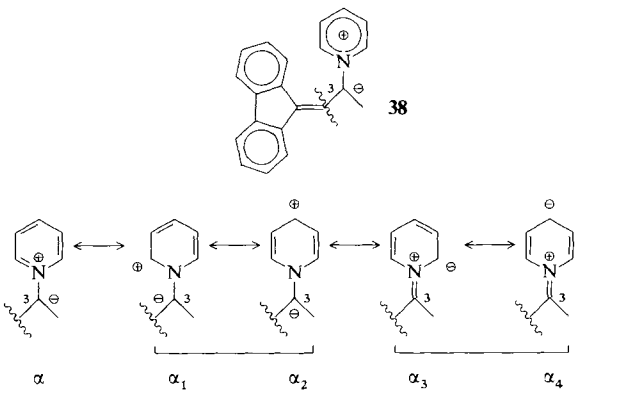


Fig. 3. Hammett correlations for the 1,5-electrocyclization of some betaines **38** to give spirodihydroindolizines **39**. a) Reactions **38a** → **39a** and **38q** → **39q** (r = 0.983 and 0.82); b) reactions of *m*- and *p*-substituted **38m** to give **39m** (r = 0.962 and 0.981, resp.).

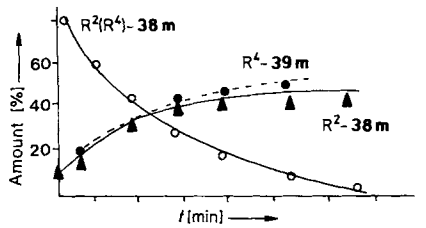
vor the nucleophilic cyclization **38** → **39**, so that structures α_1 and α_2 have the greatest weighting. If, on the other hand, position 3 is occupied by a weak electron acceptor, the reaction center in the transition state is instead more negative in nature, and in this case, therefore, the electrocyclization should be regarded as electrophilic. The corresponding data for the effects of donor or acceptor groups in region C are summarized in Figure 3 b.

Scheme 30. Partial structures of the betaines **38**, whereby the localization of the charges in the hetero-ring is explained.

3.6. Regioselectivity

If the betaine **38m** is substituted at position 6 (cf. Fig. 3), then 1,5-electrocyclization should give regioisomers of the types R^2-**39m** and R^4-**39m**. One expects intuitively that of the two regioisomers, R^2-**39m** should predominate. However, a detailed investigation (Fig. 4), gives the wholly unexpected result that the sterically less favorable regioisomer



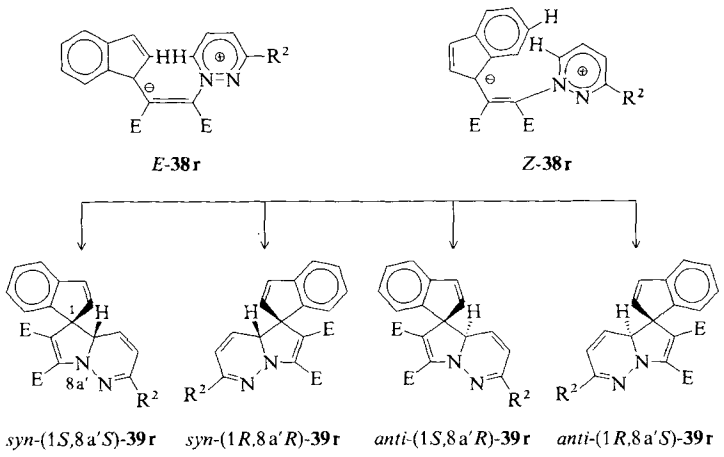


Fig. 4. Regioselectivity in the 1,5-electrocyclization of substituted betaines **38m** to the regioisomers R^4-**39m** and R^2-**39m**. The diagram is valid for $R^2 = R^4 = OCH_3$, CH_3, Cl, C_6H_5, CO_2CH_3, CN.

R^4-**39m** is formed. Moreover, in the cases where R is a donor substituent (OCH_3, CH_3, Cl) the reaction is regiospecific: in the case of the substituents C_6H_5, CO_2CH_3, and CN, the amounts of R^4-**39m** are 40, 58 and 75%, respectively.

This phenomenon is more characteristic of a pericyclic than of an ionic reaction.

3.7. Stereochemistry of the 1,5-Electrocyclization Reaction

The 1,5-electrocyclization of **39** is expected to occur photochemically as a conrotatory process and thermally as a disrotatory process (system with $(4n + 2)\pi$ electrons). Ring opening at bond "a" gives initially the *E* isomer of **38**, which can then undergo thermal conversion into the *Z* isomer. The stereochemistry of the ring closing reaction **38** → **39** can best be determined by choosing a compound that contains an asymmetrical spiro group; this results in the formation of diastereomers instead of enantiomers. For this purpose we synthesized the indenylspirene **39r**. The action of light on this molecule should give the achiral betaine **38r**. Electrocyclization of the latter should now furnish four enantiomers or two diastereomers (see Scheme 31).

E-38r *Z*-38r

syn-(1*S*,8a'*S*)-39r *syn*-(1*R*,8a'*R*)-39r *anti*-(1*S*,8a'*R*)-39r *anti*-(1*R*,8a'*S*)-39r

Scheme 31. Possible diastereomers **39r** in the 1,5-electrocyclization of **38r**, $R^2 = C_6H_5$; $E = CO_2CH_3$

According to an NMR analysis two isomer pairs were formed in the ratio 94:6. Exact analysis of the 400-MHz NOE difference spectrum showed that the *syn* diastereomeric pair had been isolated as the dominant components. The measured diastereomeric ratio also remained constant after several cycles, indicating that the reaction **38r** → **39r**, $R^2 = C_6H_5$, is *diastereoselective*.[82b] This is also true for the derivative with R^2 = styryl (*syn*:*anti* = 92:8). These results therefore demonstrate for the first time that in the 1,5-electrocyclization of a dihydropyrrole system the stereochemistry is preserved, and that the ring closing reaction **38** → **39** is therefore disrotatory.

For the 1,5-electrocyclization reaction **38** → **39** we find small values for $\Delta H^{\neq}$ and large negative values for $\Delta S^{\neq}$; depending on the substituents either electrophilic or nucleophilic cyclization can occur, and the HOMO has the correct orbital coefficients.

The reaction is regioselective and diastereoselective, and is therefore probably a pericyclic reaction.

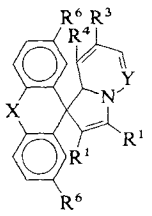
3.8. The Photochemical Reaction 39 → 38

To obtain a deeper insight into the photochemical reaction **39** → **38**, it is necessary to determine firstly its multiplicity and secondly its kinetics. To do this, however, a quantitative determination of the competing photophysical processes is first needed, and the absorption and emission spectra must be known. Table 5 gives a summary of experimental data for selected spirodihydroindolizines (and N-analogues) **39**.

From the UV spectra (see Tables 1 and 2) one can further determine the natural lifetimes, and from the fluorescence spectra the fluorescence quantum yields Φ_F (Table 6). Owing to the low fluorescence quantum yields, it is not always possible to measure the lifetimes τ of **39** directly at room temperature, but measurements can be made at 77 K (Table 6).

As Table 5 shows, the compounds **39** can be divided into three groups:

A) compounds with a C_6-spiro bridge and cyano (or ester) substituents R^1 (**39s, t**),



B) compounds with a C_5-spiro bridge and ester substituents R^1 (**39a, e, g, g(Cl$_2$), g(Br$_2$)**), and

C) compounds with a C_5-spiro bridge and cyano substituents R^1 (**39e, m, n**).

On going from group B to group A the UV absorption and fluorescence maxima undergo bathochromic shifts (i.e. to longer wavelengths). The fluorescence quantum yields are very small in all three groups. The singlet energies for groups B and C are 65–68 kcal mol^{-1}, and for group A 59–63 kcal mol^{-1}.[94]

The exact excitation energies of the compounds **39** made up of orthogonal structural units are likely to fall within region C (cf. Scheme 28). Pariser-Parr-Pople calculations[94] lend support to this assignment. It appears, therefore, that the effective chromophore in **39** may be the (aza)butadienylvinyl moiety. Intramolecular charge-transfer excitations appear less likely,[94] and the ^1A_g state from which emission occurs is not reached directly by absorption.

3.8.1. The Multiplicity of the Photochemical Reaction 39 → 38

Attempts to quench the triplet level of **39** using known quenching agents such as diacetyl or anthracene remained unsuccessful; formation of the betaine **38** was not affected at all. Another attempt had a similar result; when tetramethyl-1,2-dioxetane is decomposed thermally, triplet acetone is formed as a chemically induced species.[95, 96] If this experiment is carried out in the presence of **39**, formation of **38** via chemiexcitation is not observed. From this one must conclude that the excited state is a singlet or a fast reacting triplet which does not undergo bimolecular quenching (for details see Ref. [94]).

The determination of the quantum yield for ring opening is not a trivial problem. The general scheme can be formulated on the principle that the reaction is not only thermally but also photochemically reversible. This means that the reverse photochemical reaction (rate constant k_1) is superimposed on the reverse thermal reaction (rate constant k_2). The analysis must therefore be carried out using non-linear optimization methods (for details see Ref. [97]).

Table 6 lists the exact values. Table 7 also includes approximate values for Φ_R, determined by the classical method, neglecting the reverse thermal and photochemical reactions. The quantum yields are also wavelength-dependent (see Fig. 5). There exists as yet no simple explanation for these facts.

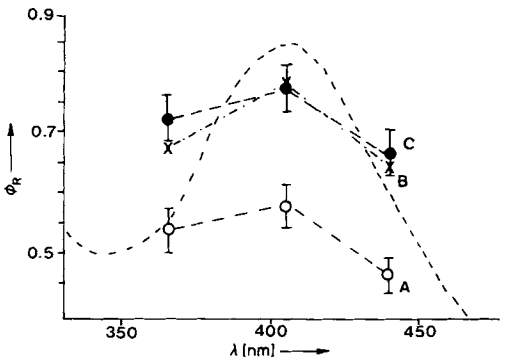

Fig. 5. Dependence of the quantum yield Φ_R on wavelength in the photoreaction of the spirodihydroindolizine **39m** to give the betaine **38m**. As derivatives of **39m** the following were used: **A**: $R^3=CH_3$; **B**: $R^3=CO_2CH_3$; **C**: $R^3=CN$ (see also Table 5).

Table 7. Reaction quantum yield Φ_R for the photoreactions **39n** → **38n** and **38n** → **39n** at 25 °C. For details see text. I_0 = intensity [Einstein s^{-1} cm^{-2}]. For substituents see Tables 1 and 5.

39n $\underset{\Phi_2}{\overset{\Phi_1}{\rightleftharpoons}}$ **38n**

4.5×10^{-11}	1.7×10^{-4}	1.11	0.02	0.81 ± 0.09	0.015 ± 0.11
8.0×10^{-10}	2.1×10^{-4}	0.86	0.002	0.87 ± 0.09	0.002 ± 0.10

[a] Uncorrected values. [b] Corrected values taking k_2 into consideration.

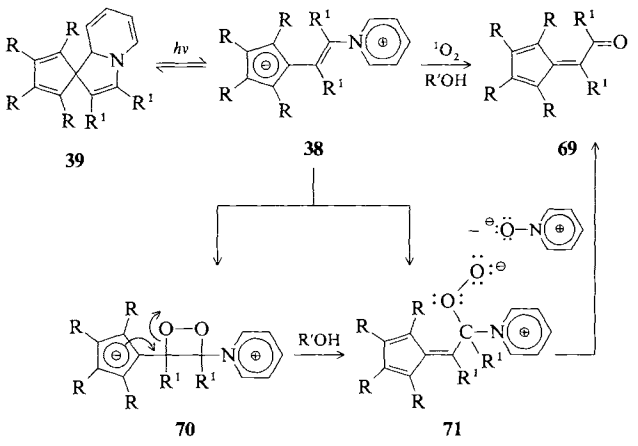
3.8.2. Kinetics

The kinetics of the photochemical ring opening can be determined from the measured data, using Equation (d):

$$\Phi_F + \Phi_R + F_{ic} + \Phi_{isc} = 1 \qquad \text{(d)}$$

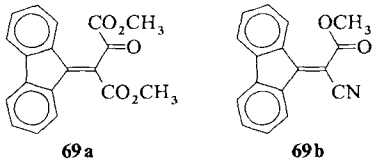
where Φ_F, Φ_R, Φ_{ic} and Φ_{isc} are the quantum yields for fluorescence, reaction, internal conversion and intersystem crossing, respectively.

Since the reaction does not proceed via the triplet state of **39**,[194] we can insert the value $\Phi_{isc} = 0$. With this assumption



the reaction rate constant k_R can now be calculated (see Table 6).

The evaluation of k_R shows that the reaction rates decrease in the series **39d** (Cl_2) > **39n** > **39u** > **39s'** > **39g** > **39d** > **39a** (for formulas see Table 5).



The conclusions reached are summarized as follows: Compounds **39** with electron-withdrawing CN groups in region B and electron-deficient dihydrodiazine groups in region C are evidently the fastest reacting systems in the photochemical reaction **39** → **38**. Laser flash photolysis studies of the kinetics of the process **39** → **38** indicate that, following the photoexcitation, the betaine **38** appears immediately in the *Z* form.[98] However, flash spectroscopic experiments on a spirotetrahydroindolizine with R^1 = benzoyl suggest the formation of an isomer which undergoes a first order conversion to the *Z* form.[99] In the chromophoric systems **47** the photochemical reaction is considerably more complex.

3.8.3. Photostability

When the spirodihydroindolizines (and *N*-analogues) **39** are irradiated with light it is found that the compounds decompose after some time. However, if oxygen is excluded by working with degassed samples, these systems are noticeably more stable. It is possible that in the presence of oxygen the betaine **38** acts as a sensitizer towards singlet oxygen. We have tried to clarify this problem by experiments in which singlet oxygen was deliberately generated, with hematoporphyrin as a sensitizer. Under these conditions the reaction of $^1O_2$ with **39** → **38** gave a base-free product, which in the case of the bis-ester **39a** was the fluorenylideneoxalacetic acid ester **69a**, and in the case of the bis-cyano compound was the cyanoacetic acid derivative **69b**. How could these products be formed? It is possible that the first stage is a photochemical ring-opening of the spirodihydroindolizine derivative **39**, with an electrocyclic reaction giving a betaine **38**. Oxygen could then add on to the betaine in a [2 + 2]cycloaddition, with formation of the dioxetane **70**. Ring opening and elimination of pyridine-*N*-oxide (identified by spectroscopy) should then give the products **69a** or **69b**. However, a possibility which now appears more likely is the direct action of $^1O_2$ on the betaine **38** to form a peroxide **71**, which then decomposes in the manner indicated, giving the appropriate product **69a** or **69b** (Scheme 32).[100a] Recently, it could be shown that the betaine **38** can indeed function as a singlet oxygen sensitizer.[100b]

product when $R^1 = CO_2CH_3$: **69a**; when R^1 = CN: **69b**

4. Possible Applications

The inherent properties of photochromic systems make them suitable for use in many different areas. Basically there are four main groups of possible applications, each making use of different special properties:

1) the control and measurement of radiation intensity,
2) visual contrast effects,
3) solar energy conversion,
4) information imaging and storage.

In the following, representative examples will be described for each of the four groups.

The physical (and chemical) characteristics which are important in applications of photochromic systems include:

- the spectral regions where absorption occurs, or the operating wavelengths
- sensitivity
- reversibility and useful life (number of cycles)
- properties as a storage medium.

The desirable properties for the application areas listed above sometimes overlap with each other to a considerable extent. Differences also arise according to whether the properties of the systems are measured in polar or non-polar solvents, or in the crystalline phase or in a polymeric matrix.

4.1. Absorption Region or Operating Wavelengths

The absorption region is subject to wide variation according to which class of materials is used. Figure 6 shows the

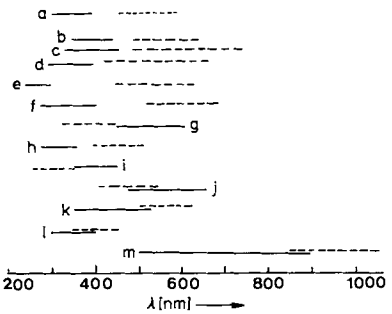

Fig. 6. Regions of the operative wavelengths of selected photochromic compounds before (——) and after (– – –) irradiation. a: fulgides (cf. **9**); b: spirodihydroindolizines (and N-analogues, cf. **39**); c: bis(spirodihydroindolizines) (cf. **47**); d: spiropyrans (cf. **14**, **16c**, **72**); e: triphenylmethane derivatives (cf. **26**); f: hexaarylbiimidazolyls (cf. **24b**); g: formazenes; h: hydrazones; i: stilbenes; j: indigoids (cf. **1**, **2**); k: azomethines (cf. **8**, **22**); l: azo compounds; m: cyanines.

absorption regions for commonly used photochromic compounds. It can be seen from the figure that in most cases the colorless form A absorbs in the near UV or visible region, while the colored form B absorbs in the range 450–600 nm. Only the bis-betaines **48** and the cyanines continue to show absorptions in the long-wave visible, or even the short-wave IR regions.[101, 102]

High extinction coefficients and conversion efficiencies are found especially for those compounds in which

- a conjugation blocking group is photolytically removed,
- a cyanine structure is formed,
- a polyene is formed,
- a charge-transfer complex is formed.

4.2. Sensitivity

The sensitivity of a photochromic system for information storage is given by the energy in joule per cm^2 of surface area which is needed to change the optical signal function (optical density (D)) by 0.1 compared with a suitable density standard. Photochromic systems are found to have maximum sensitivities of the order of $E_{max} \approx 10^{-3}$ J cm^{-2} dB^{-1}.

Semiempirical formulas exist for determining this quantity.[103] The main feature of the results is η, which depends on the position of the photochemical equilibrium and often has a value in the range 0.5–1.0.

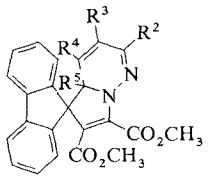
4.3. Reversibility and Useful Life (Number of Cycles)

In nearly all the areas where photochromic substances can be used, the reversibility and the useful life in cycles are among the most important properties. The useful life in cycles, Z, is essentially limited by the relative incidence of reversible (and irreversible) side reactions. The irreversible reactions are known as fatigue processes. The matrix too can cause effects which limit the life. Some typical experimentally measured values Z_{exp} for various systems are listed in Table 8.

The intensively studied spiropyran derivatives[4] show very short lifetimes of $Z_{exp} = 10^1$–10^2 cycles. The newer systems based on the spirodihydroindolizines **39**, the thymines and the fulgides (e.g. Aberochrome 540, **9a**) give Z_{exp} values of 10^3–10^4. For Aberochrome 555 **9b** and the salicylideneanilines, Z_{exp} values as high as 10^4–10^5 are found. These newer photochromic systems are of great interest because of their long useful lifes.

Molecules whose photochromism is based on triplet-triplet absorption, e.g. coronene, should in principle be capable of giving an infinite number of cycles.

Table 8. Number of cycles E_{exp} achieved experimentally for some photochromic and some non-photochemical systems.



System	Working principle	$Z_{exp.}$	Ref.
Organic photochromic systems:			
Spirodihydroindolizines (*N*-analogues) **39**	Electrocyclic (Valence tautomerization)	$>10^3$	[40, 74–80, 82–84]
Fulgides, e.g.			
Aberochrome 999 (cf. **9b**)	Valence tautomerization	$\approx 10^3$	[23–27]
Aberochrome 540 (cf. **49a**)	Valence tautomerization	10^4 to 10^5	[23–27]
Spiropyrans in polymers	Valence tautomerization	10^1 to 10^2	[4, 32–47]

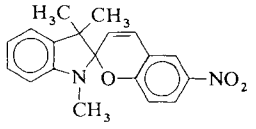
FEPC devices	Photoconductor + ferroelectric	10^{11}	[101]
Photosensitive thermoplastic films	Electrostatic process	10^2 to 10^4	[101]
MNOS-CCD storage devices	Electronic process	10^{10} to 10^{12}	[101]

4.4. Photochemical Stability



The photochemical stability (on which the potential useful life indirectly depends) can also be determined by a photochemical degradation experiment.

Table 9 gives some recent results from stability tests of this

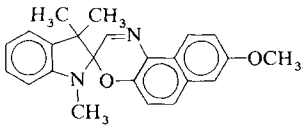


Table 9. Comparison of the photochemical stability of spirodihydroindolizine derivatives **39g, v–y** [105] and classical compounds **72** [4], **73** [49b, 108], **74** [109] of the spiropyran type. The decrease in depth of color with time (100% at $t = 0$) upon irradiation with a xenon high-pressure lamp (Sun-Test apparatus, light (irradiation) intensity 140000 Lux; on CR 39® glass, at ca. 40 °C). $t_{1/2}$ = half-life.

kind. The test conditions are in most cases those used in commercial "sun test" equipment (e.g., a high-pressure xenon lamp giving an illumination of 140000 Lux).

4.5. Information Storage Properties

Photochromic media which are to be used for display and storage applications must perform satisfactorily with regard to the properties discussed in Section 4. The operating wavelength range can nowadays be chosen to suit any specification quite accurately. Wavelengths of particular interest are those of the inexpensive He/Ne lasers ($\lambda = 633$ nm) and GaAs IR lasers ($\lambda = 830$ nm). Fast optical storage devices with rates of the order of 10^6 cycles per second are required here. For this application it will certainly be necessary to develop suitably modified versions of known photochromic systems. On the other hand, photochromic systems, as a result of their lack of graininess, have high storage densities and high image resolving power compared with AgX films. Their resolving power is in most cases about 1000 mm^{-1} [102] (see Table 10). The signal-to-noise ratio is very good.

4.6. Recent Developments

In the first group of applications, photochromic systems are used in controlling or measuring radiation intensity.

These applications make use of the change in color of photochromic materials, which is essentially caused by the action of sunlight. This property finds applications where

Table 10. Resolving powers (AV) and storage densities (D_F) of photochromic systems and other storage materials [101, 102].

System	AV [mm^{-1}]	D_F [bit cm^{-2}]

optical filters are generally used, i.e. in spectacles, optical lenses, glass used in buildings, and windshields for automobiles and aircraft (cf. Table 11).

Silver halide spectacle lenses show fatigue effects and a slow (non-linear) fading behavior when they have been in use for some time,[4, 69] and organic photochromic substances have therefore been developed for this purpose and recently introduced onto the market. Instead of the aziridines previously used for this purpose,[106] which are photochromic only in the crystalline state, spiropyrans, such as **72**[107] have been introduced as substances having suitable properties for photochromic spectacle lenses. Systems showing virtually no fatigue have been discovered in the spirooxazines, and are being marketed by the American Optical Company (**73**),[108] PPG (**74**)[109] and Rodenstock.[110] (Systems which could be suitable for this application are described in Refs. [76, 77].)

Heller et al., whose conventional types of fulgides,[23–26] being inverse photochromic systems, are unsuitable for this application, has patented a new isomeric fulgide system known as Heliochrome, which should find applications as a photoreactive material for optical lenses or spectacles.[111]

Various types of actinometers based on photochromic substances have recently come onto the market, and are used to measure radiation intensities.

Of the systems used, only a few will be mentioned here. Aberochrome 540 **9a**[23–27, 103, 112] derived from the fulgides series and Aberochrome 999, **9b**, can be used in the UV and visible regions. The *endo* peroxides of the heterocoeranthrone (Actinochrome® 238/334 and 475/610)[53, 54] (cf. also **21**), whose photochromism is based on a bimolecular photoreaction, are also employed in these spectral regions. In a similar way the spiropyran **72** is used in lithography as a simple dosimeter.

Another important area of application is that of contrast effects. In this class of applications photochromic substances are efficient as active light filters, and in the production of printing plates and printed circuits.[101, 113, 114]

The third main field of application is in solar energy con-

Table 11. Applications of photochromic materials

Control & measurement of radiation intensities	Contrast effects	Recording and storage of information
a) Optical filters – Lenses – Glasses – Cuvettes	Masks for contrast equalization in photography – Film materials	a) Imaging – Instantaneous imaging materials – Office copying materials – Microfilm – Microfilm copying materials – Sprays
Radiation protection equipment – Glasses – Spectacles – Films – Containers	Amplifying contrast in projected images – Projection screens – Projection walls	b) Digital information – Slow storage – Bulk data storage (archives etc.)
Protection from sun	Production of printing plates and circuit boards – Photoresists – Photopolymers	Holography – Storage disks – Storage films – Crystals
Protection from flash exposure, lasers etc.	Solar energy conversion	Data display systems – Display screens (image screens)
Document preservation	Energy storage	Q-switches (for lasers)
Temperature indicators		Molecular electronics
b) Actinometry, dosimetry – Actinometer – Dosimeter		

version. The need here is for photochromic systems which absorb in the visible region and have a high energy storage capacity. In these systems, however, the solar energy is stored indirectly as heat. The most favorable system of this type is quadricyclane.[115] However, the merits of this approach to research on solar energy conversion are now being questioned.[9] Storage of solar energy in other forms, namely as chemical or electrical energy, appears to have advantages.[10]

A very interesting application of photochromic systems is in the area of information recording. Two particularly important systems are the Dylux process and the perhalide process. By evaluating image-forming properties it is possible to identify materials suitable for use in photocopying and instantaneous imaging,[102] though in these applications the necessary life is only one cycle ($Z = 1$).

These techniques found a useful application in the photochromic micro-imaging (PCMI) process developed by the National Cash Register Company.[116] Microimages are now generally produced using diazo microfilm or vesicular films (polyester/diazonium salts).[117]

Photochromic substances of the fulgide type, which can be employed for information recording and in holography have also been developed by *Heller* et al.[118] Also the photochromic 2,4,5-triphenylimidazolyl dimers (cf. **24b**) can be employed as photoinitiators for producing holograms.[119]

A promising future application in the production of optical recording materials is based on the *trans-cis* isomerization of azobenzenes in a liquid crystalline medium. Azobenzene fixed covalently to glass in a nematic or cholesteric phase gives stable images with excellent resolution on exposure to light. This process has also been used for the production of holograms.[120]

An extension of this principle is the coupling of photochromic molecules—such as azobenzene,[121] spiropyrans[122] or fulgides[121]—with polymers or liquid crystalline polymers. Such combinations have been employed in holography[117] or in non-destructive optical "read-out" systems.[121–123] Nonlinear optical recording processes are based on the excitation of photochromic molecules by two-photon processes. Spiropyrans have been employed under these conditions in non-destructively operating write- and read-out systems using He/Ne lasers.[124] Photochromic spiropyrans have also found use in the production of photoresists.[125]

A new application of tailor-made molecules of the spirodihydroindole type is in frequency doubling of laser radiation. The thread-like dipolar merocyanine-type molecules become aligned in an electric field. In the presence of two electric fields the quasi-crystalline dyestuff aggregates form an excellent frequency doubler.[120] A similar system based on spirodihydroindolizine derivatives has recently been patented.[127]

An interesting potential application has been proposed in the field of molecular electronics.[128–131] By using a one-dimensional conductor ("molecular wire") of the polyacetylene type in combination with suitable molecular switches—e.g. salicylideneanilines—it should be possible to make a molecular microchip whose information storing capacity is a factor of 10^6 greater than that of conventional microchips. Such a completely new technology would make it possible to design a new generation of high performance computers with memory elements of nanometer dimensions.

5. Summary and Future Prospects

The development of new photochromic systems which involve a 1,5-electrocyclization has been described. This reaction is in principle based on the cyclization of conjugated 1,3-dipoles of the allylic type. The 1,5-electrocyclization is formally the first intermediate stage envisaged for a "1,3-dipolar (non-cooperative) cycloaddition" as described by *Huisgen*.[72] It is therefore an elegant method for synthesizing five-membered ring systems, although in the case of photochromic systems there are additional restrictions with regard to photoreversibility (and thermoreversibility).

The new photochromic systems (see also Table 3) vary widely in their properties. They provide a useful extension to the palette of homologous series of photochromic systems. In the area of basic research this reaction offers the possibility of synthesizing new photochromic substances with:

- improved photostability, and thus longer useful life (number of cycles),
- higher sensitivity, especially for information recording,
- a wider choice of operating wavelengths, especially with regard to absorption in the IR region for use with IR lasers (e.g. GaAs),
- amplification capability, i.e. with quantum yields > 1,
- functional groups which confer solubility in water.

Important objectives for future research include modifying already known systems by incorporating them physically or chemically into liquid crystals or polymers, so as to obtain improved properties for specific applications, and developing an effective molecular electronics system based on photochromic molecules to produce new VLSI (very large scale integrated) computer chips.

My thanks are due to Frau Prof. S. E. Braslavsky, MPI Mülheim and Herrn Priv. Doz. Dr. A. M. Braun, EPFL Lausanne for carefully reading the manuscript. I also thank my coworkers V. Bach, J. Besse, C. Dorweiler, H. Gross, G. Hauck, M. Herrig, M. Holderbaum, R. Johann, H. P. Jönsson, S. Kenziora, H. Kilburg, G. Klauck, J. Mosbach, T. Münzmay, V. Port, P. Scheidhauer, C. Schommer, C. Shulz, P. Spang, A. Thome and K. Zils for their involvement and enthusiasm in this project. Last but not least, my thanks are due to the Deutsche Forschungsgemeinschaft and to the Fonds der Chemischen Industrie for financial support, and to BASF for providing many chemical compounds.

Received: January 21, 1987;

Alkoxide Clusters of Molybdenum and Tungsten as Templates for Organometallic Chemistry: Comparison with Carbonyl Clusters of the Later Transition Elements

By Malcolm H. Chisholm,* David L. Clark, Mark J. Hampden-Smith, and David H. Hoffman

Dedicated to Professor Donald C. Bradley

Alkoxide and carbonyl ligands complement each other because they both behave as "π buffers" to transition metals. Alkoxides, which are π donors, stabilize early transition metals in high oxidation states by donating electrons into vacant d_π orbitals, whereas carbonyls, which are π acceptors, stabilize later transition elements in their lower oxidation states by accepting electrons from filled d_π orbitals. Both ligands readily form bridges that span M–M bonds. In solution fluxional processes that involve bridge–terminal ligand exchange are common to both alkoxide and carbonyl ligands. The fragments $[W(OR)_3]$, $[CpW(CO)_2]$, $[Co(CO)_3]$, and CH are related by the isolobal analogy. Thus the compounds $[(RO)_3W\equiv W(OR)_3]$, $[Cp(CO)_2W\equiv W(CO)_2Cp]$, hypothetical $[(CO)_3Co\equiv Co(CO)_3]$, and $HC\equiv CH$ are isolobal. Alkoxide and carbonyl cluster compounds often exhibit striking similarities with respect to substrate binding—e.g., $[W_3(\mu_3\text{-}CR)(OR')_9]$ versus $[Co_3(\mu_3\text{-}CR)(CO)_9]$ and $[W_4(C)(NMe)(O\mathit{i}Pr)_{12}]$ versus $[Fe_4(C)(CO)_{13}]$—but differ with respect to M–M bonding. The carbonyl clusters use e_g-type orbitals for M–M bonding whereas the alkoxide clusters employ t_{2g}-type orbitals. Another point of difference involves electronic saturation. In general, each metal atom in a metal carbonyl cluster has an 18-electron count; thus, activation of the cluster often requires thermal or photochemical CO expulsion or M–M bond homolysis. Alkoxide clusters, on the other hand, behave as electronically unsaturated species because the π electrons are ligand-centered and the LUMO metal-centered. Also, access to the metal centers may be sterically controlled in metal alkoxide clusters by choice of alkoxide groups whereas ancillary ligands such as tertiary phosphanes or cyclopentadienes must be introduced if steric factors are to be modified in carbonyl clusters. A comparison of the reactivity of alkynes and ethylene with dinuclear alkoxide and carbonyl compounds is presented. For the carbonyl compounds CO ligand loss is a prerequisite for substrate uptake and subsequent activation. For $[M_2(OR)_6]$ compounds (M = Mo and W) the nature of substrate uptake and activation is dependent upon the choice of M and R, leading to a more diverse chemistry.

1. Introduction

In inorganic chemistry, the term *cluster* is used to describe an assemblage of two or more metal atoms held together, at least in part, by metal–metal bonds.[1b] There may or may not be bridging ligands. Some of the earliest examples of clusters were discovered in the field of transition-metal carbonyl chemistry and within recent years giant carbonyl clusters, either neutral or bearing an overall charge, e.g,

$[Rh_{15}(CO)_{27}]^{3\ominus}$ $[Ni_{16}(CO)_{23}(C_2)_2]^{2\ominus}$ $[Pt_{19}(CO)_{22}]^{4\ominus}$ $[Pt_{38}(CO)_{44}H_x]^{2\ominus}$

where the value of x is still uncertain,[2] have attracted attention. There is also an extensive group of gold phosphane clusters[3] and, for the early transition elements, the halide complexes $[M_6Cl_{12}]^{2\oplus}$, where M = Nb and Ta, and $[M_6Cl_8]^{4\oplus}$, where M = Mo and W, each containing an octahedron of metal atoms, have been known for over 20 years.[4] More recently, the recognition of cluster subunits in inorganic solids has become an increasingly important aspect of solid-state chemistry. For instance, the lower-valent (subvalent) halides,[5] oxides,[6] and sulfides[7] of a wide variety of metals have "cluster units" that are separated from one another by bridging atoms or are fused by common metal atoms at a vertex or along a common edge or face. Examples of these types of compounds include the Chevrel phases.[7, 8]

Homoleptic metal alkoxides[9] are a well-established group of compounds having empirical formulas $[M(OR)_x]$, where x also represents the formal oxidation state of the metal, M. In general, the empirical formula is not the molecular formula because the metal strives to attain its preferred coordination number by alkoxide bridge formation. Thus, oligomeric structures, $[M(OR)_x]_n$, where n represents the de-

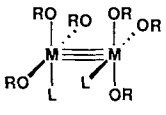
gree of oligomerization, are often found both in the solid state and in solution. The value of n is dependent on the nature of the metal and the steric properties of R. The species present in solution may not be the same as that found in the solid state and the nature of the solvent and temperature can lead to complex equilibria.

Bradley[10] formulated a structural theory for the oligomerization of metal alkoxides based on the premise that the observed structures represent a compromise of opposing forces—an enthalpic drive to form the maximum number of M–O bonds by alkoxide bridge formation and an entropic drive to minimize aggregration. In his pioneering studies, *Bradley*[11] was quick to recognize that the discrete oligomeric metal oxo alkoxides and metal oxo siloxanolates bridge the gap between polymeric alkoxides and the macromolecular solid-state structures of metal oxides and metal silicates. In all these compounds of formula $[M(OR)_x]_n$ or $[MO_a(OR)_b]_n$, however, the oligomerization involved the formation of bridges via oxo or alkoxide groups, and the term cluster is not appropriate because, as in polyoxometalate chemistry,[12] there are no metal–metal bonds.

Only within the last decade has the importance of metal–metal bonding become apparent in metal alkoxide chemistry. It was first unequivocally recognized with the structural characterization of $[Mo_2(OCH_2tBu)_6]$ **1a**, a member of an extensive class of $[Mo_2(OR)_6]$ compounds.[13] Compound **1a** adopts an ethane-like structure, **1**, rather than the common bridged dimer structure depicted by **2**. For the first time the dominant influence of a metal–metal bond was seen in the chemistry of metal alkoxides. In this instance the M–M bond is a triple bond of electronic configuration $\sigma^2\pi^4$.



1a, M = Mo, R = CH_2tBu
1b, M = W, R = tBu

2

Following the discovery of $[Mo_2(OR)_6]$ compounds, related $[W_2(OR)_6]$ compounds were isolated, often with supporting Lewis bases as in **3a** (py = pyridine).[14] The latter compounds adopt a structure depicted by **3**. Again, the unbridged M–M triple bond is retained.

3a, M≡W, R = *i*Pr, L = py

In recent years a variety of cluster alkoxides of molybdenum and tungsten have been synthesized and characterized in which alkoxide bridges and metal–metal bonds are present. A new structural relationship between metal oxides and metal alkoxides has emerged. The molecular alkoxide-supported clusters of molybdenum and tungsten contain M_xO_y cores that are analogues of the cluster subunits found in the solid-state structures of reduced metal oxides. For example, the $[W_4(OEt)_{16}]$ cluster[15] contains the same $[M_4(\mu_3\text{-}O)_2(\mu\text{-}O)_4O_{10}]$ unit found in the $[Ba_{1.14}Mo_8O_{16}]$ structure (Fig. 1).[16]

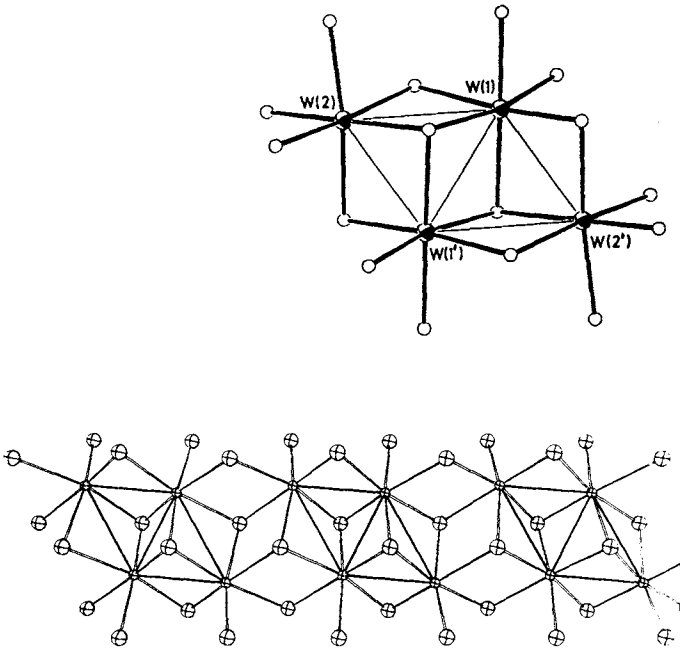


Fig. 1. The $[W_4(\mu_3\text{-}O)_2(\mu\text{-}O)_4(O)_{10}]$ unit in $[W_4(OEt)_{16}]$ (top) and a view of the similar Mo cluster linkages found in infinite chains within the solid-state structure of $[Ba_{1.14}Mo_8O_{16}]$ (bottom).

Because there are structural similarities between alkoxide clusters and reduced metal oxides, which serve as heterogeneous catalysts for a variety of reactions involving hydrocarbons and for small molecule activation, we set out to examine the organometallic chemistry of discrete molybdenum and tungsten alkoxide dimers and clusters. From our work a wide variety of dinuclear and cluster alkoxides are now known in which a hydrocarbon fragment or an atom such as H,[17] C,[18] or N[19] is attached to one or more metal atoms. As our work has progressed, we have come to recognize the similarities as well as differences between alkoxide and traditional carbonyl cluster chemistry. In this article we explore some of these relationships from the standpoint of synthesis, structure, bonding, and reactivity.

2. General Comparisons

2.1. Alkoxide and Carbonyl Ligands: Complementary Aspects of Metal–Ligand Bonding

Alkoxide and carbonyl ligands are both π buffers. The CO ligand acts as a π acceptor, stabilizing electron-rich metal atoms in their low-to-mid oxidation states. The extent of metal-to-CO ($d_\pi \rightarrow \pi^*$) back-bonding is reflected in the values of ν(CO) as, for example, in the $(t_{2g})^6$ $[M(CO)_6]^n$ ions: M = Mn, n = + 1, 2090 cm^{-1}; M = Cr, n = 0, 2000 cm^{-1}; M = V, n = − 1, 1860 cm^{-1}. Alkoxides are uninegative π donors, π^x, where $0 < x < 4$, and thus can stabilize high-oxidation-state metal centers in which vacant metal d_π orbitals are present: e.g., the d^0 metal complex $[Mo(OMe)_6]$.[20] The alkoxide ligand is electronically flexible in that π^x can vary as a function of the M–O–C angle; i.e.,

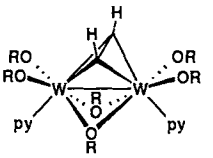
as the angle approaches 180°, x approaches 4 if the metal has available vacant d_π orbitals. The M–O–C angle is influenced by steric and electronic factors at the metal and may respond to substrate uptake or release from the metal center. Sterically demanding RO ligands will commonly have large M–O–C angles. If there are filled metal d_π orbitals, these will be raised in energy by the presence of alkoxide ancillary ligands.

Alkoxide and carbonyl ligands may take up bridging or semibridging positions and are often fluxional on the NMR time scale, showing rapid bridge–terminal exchange. The presence of bridging versus terminal OR groups does not necessarily change the total valence electron count at a metal center.

It is nearly always possible to arrive at an 18-valence-electron count for early-transition-metal alkoxide complexes by invoking d_π–p_π bonding, although it is important to note that the electrons involved in π bonding are ligand-centered. The LUMOs of metal alkoxide complexes are metal-centered (d orbitals) and therefore the compounds usually behave as coordinatively unsaturated species and are labile toward Lewis base uptake. By contrast, metal carbonyl complexes are generally coordinatively saturated and react either by nucleophilic attack on the carbon atom of a CO ligand (i.e., nucleophilic attack at the LUMO), or by initial dissociation of CO. The latter process can be induced thermally, photochemically, or by reaction with a reagent such as Me_3NO, which acts as an oxygen-atom transfer reagent generating CO_2 and either an unsaturated metal carbonyl cluster or a loosely ligated Me_3N adduct. Metal alkoxide complexes are inherently more substitutionally labile, being susceptible to both nucleophilic attack at the metal and electrophilic attack at oxygen, provided steric factors are not limiting. Dissociation of $OR^{\ominus}$ in nonpolar hydrocarbon solvents has never been established and does not present an important reaction pathway for alkoxide complexes.

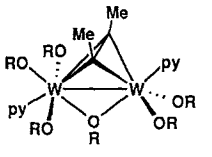
Bulky OR ligands can stabilize unusually low coordination numbers and coordinative unsaturation can be tailored for substrate selectivity in binding to the metal centers by varying R. This parallels the common use of specific PR_3 or η^5-C_5R_5 ligands to control access to the metal coordination sphere in organometallic chemistry.[21]

2.2. Isolobal Relationships



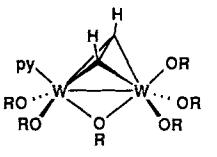
Important to the understanding of structure and reactivity patterns in organometallic chemistry has been the recognition of isolobal relationships between organometallic and organic fragments.[22] Two fragments are isolobal if the number, symmetry properties, occupation by electrons, and approximate energy of their frontier orbitals are similar. Thus methylene, CH_2, is isolobal with the 16-electron fragment $[Fe(CO)_4]$ and the trinuclear carbonyl cluster $[Fe_3(CO)_{12}]$ is an organometallic analogue of cyclopropane. Similarly, CH and $[CpM(CO)_2]$ (M = Mo, W) are isolobal, and the compounds HC≡CH, **4**, and **5**

$[Cp(CO)_2M{\equiv}M(CO)_2Cp]$ **4** $\qquad$ $[Cp(CO)_2M{\equiv}CR]$ **5**



are isolobal analogues having C≡C, M≡M, and M≡C bonds, respectively. The $[PtL_2]$ fragment is also isolobal with CH_2, and the combination of $[PtL_2]$ with either ethylene or ethyne to give $[L_2Pt(C_2H_4)]$ or $[L_2Pt(C_2H_2)]$ provides a parallel with the formation of cyclopropane and cyclopropene, respectively. Limitations to the successful combination of isolobal fragments often arise because of a mismatch of orbital energies or steric factors. It has, for example, been stated that "a mouse and an elephant are isolobal in that they both have four legs and a tail. However, they do not mate, except with themselves."[23]

It is informative to examine some isolobal relationships for alkoxide complexes and fragments of molybdenum and tungsten complexes. For example, the $[M(OR)_3]$ unit may be viewed as a 15-electron fragment if the alkoxide ligands are each counted as 4-electron donors. Thus, the compounds **1** are inorganic analogues of alkynes and are alkoxide analogues of compounds **4** (M = Mo, W).[24] Likewise, the alkylidyne compounds $[(t\mathrm{BuO})_3M{\equiv}CR]$[25,26] and **5**[27] are isolobal.



There are, however, some important differences between the alkoxide and carbonyl analogues that arise because of the different π-donor/acceptor properties of the ligands. The $[M_2(OR)_6]$ compounds can coordinate two neutral ligands to give $[M_2(OR)_6L_2]$ compounds with retention of the M≡M bond (see **3**); i.e., the $[M(OR)_3L]$ fragment is isolobal to $[M(OR)_3]$. Formation of the M–L σ bond occurs with loss of one M–OR π bond. In contrast, compounds **4** coordinate Lewis bases, L, to give M–M single-bond compounds

6, R = *i*Pr

7, R = CH_2*t*Bu

8, R = *t*Bu

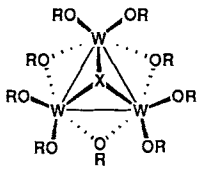
$[Cp_2M_2(CO)_4(L)_2]$. The $[CpM(CO)_2L]$ unit is a 17-electron fragment and is isolobal with the methyl radical. Similarly, whereas $[Co(CO)_3]$ is isolobal with CH and the alkyne adduct $[Co_2(CO)_6(\mu\text{-}C_2H_2)]$ is a tetrahedrane analogue formed by the combination of a hypothetical $[(CO)_3Co{\equiv}Co(CO)_3]$ unit with HC≡CH, the alkyne adducts of **1** often have supporting Lewis base ligands and bridging alkoxides (e.g., **6–8**).[28] Again, the additional coordination in the alkoxide-supported alkyne adducts reflects the electronic flexibility of the alkoxide ligands: (1) RO-to-M d_π bonding may be sacrificed in favor of σ donation from Lewis bases. (2) The facile interchange between terminal and bridging positions allows for the optimization of metal–metal and metal–ligand bonding.

2.3. Cluster Syntheses

The dinuclear complexes **1**, or their Lewis base adducts, provide useful starting materials for the assembly of trinuclear and tetranuclear compounds. The reactions bear a striking resemblance to the metal carbonyl cluster-building reactions so ably employed by *Stone* and his co-workers.[29] For example, oxo-,[30,31] imido-,[32] and alkylidyne-capped triangles[33] can be formed according to reactions (a)–(c).

Mixed-metal M_2M' clusters (M, M' = Mo, W) can be synthesized similarly.

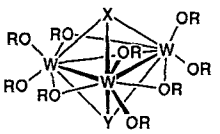
$$[M_2(OR)_6] + [MO(OR)_4] \rightarrow [M_3(\mu_3\text{-}O)(OR)_{10}] \quad (a)$$



$$[M_2(OR)_6] + [M(NH)(OR)_4] \rightarrow [M_3(\mu_3\text{-}NH)(OR)_{10}] \quad (b)$$

$$[M_2(OR)_6] + [M(CR')(OR)_3] \rightarrow [M_3(\mu_3\text{-}CR')(OR)_9] \quad (c)$$

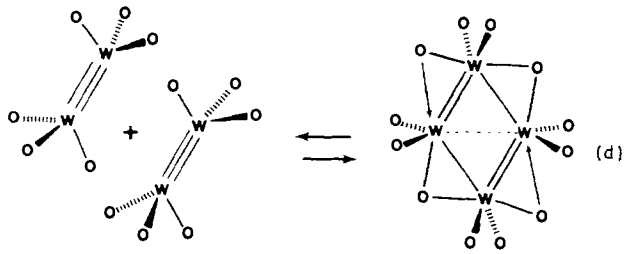
These comproportionation reactions have steric limitations based on the nature of R and, incidentally, may also be viewed as redox reactions:



$$2\,M^{III} + M^{VI} \rightarrow 3\,M^{IV}$$

The product clusters adopt geometries that have bridging alkoxide ligands as shown in **9** and **10** below.

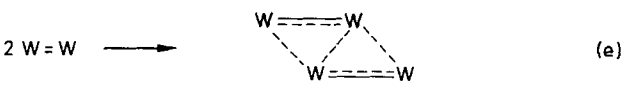
9



R = *i*Pr, CH_2*t*Bu
X = CMe, CEt, CPh

10

R = *i*Pr, CH_2*t*Bu
X = NH, O
Y = OR



It is also possible to reversibly couple $[W_2(OR)_6]$ compounds to give $[W_4(OR)_{12}]$ [Eq. (d)].[34–36]

O = OR

(d)

In other cases the reaction path leading to alkoxide cluster formation is less well defined, as in the preparation of $[W_4(OR)_{16}]$ compounds from the reactions between $[W_2(NMe_2)_6]$ and ROH (R = Et, Me).[37] The W_4 unit in the $[W_4(OR)_{16}]$ compounds can be considered, formally at least, to arise from the coupling of two $[W_2(OR)_8]$ (M≡M) units [Eq. (e)].

(e)

The formation of the unique high-oxidation-state carbide cluster $[W_4(C)(NMe)(O\mathit{i}Pr)_{12}]$ in the alcoholysis of $[W_2(NMe_2)_6]$ with 2-propanol is also not understood in terms of a detailed reaction pathway.[38] This is often the case as well in metal carbonyl cluster chemistry when carbide or nitride ligands arise. Nevertheless, there is a formula analogy between several of these alkoxide- and carbonyl-supported clusters, as, for example, in the following:

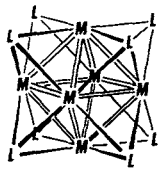
$[W_3(\mu_3\text{-}CR')(OR)_9]$ $[Co_3(\mu_3\text{-}CR)(CO)_9]$
$[M_3(\mu_3\text{-}NH)(OR)_{10}]$ $[Fe_3(\mu\text{-}NH)(CO)_{10}]$
$[W_4(C)(\mu\text{-}X)(O\mathit{i}Pr)_{12}]$ (X = O, NR) $[Fe_4(C)(CO)_{13}]$
$[W_4(O\mathit{i}Pr)_{12}]$ $[Co_4(CO)_{12}]$

3. Electronic Structure Relationships in Selected Alkoxide and Carbonyl Clusters

To start our discussion of the complementary role of alkoxide and carbonyl ligands as π buffers, we draw specific attention to the nature of the frontier orbitals of the free ligands, CO and $OR^{\ominus}$, that are used in bonding to metals. These are shown schematically in Scheme 1.

Scheme 1. Frontier orbitals of CO (left) and $RO^{\ominus}$ (right).

The $RO^{\ominus}$ ligand has a low-lying sp-hybridized σ lone pair and higher-lying oxygen p_π lone pairs. In a complex with a linear M–O–C angle the higher-lying π orbitals are degenerate, but, as this angle becomes smaller, only one orbital retains its pure p character while the other mixes with oxygen s. This mixing lowers the energy of the orbital. The CO ligand has a filled σ orbital, containing the C lone pair, and vacant π* orbitals which are degenerate.



Thus, both $RO^{\ominus}$ and CO ligands have frontier orbitals of σ and π symmetry and, by symmetry, may have similar interactions with metal atoms. The primary difference between these ligands arises from the electron occupation of the π orbitals. The vacant π* orbitals of CO are well-suited for accepting electron density from electron-rich metals, whereas the filled p_π orbitals of the $RO^{\ominus}$ ligand can donate to electron-poor metal centers. There is also an important difference in the relative energies of the σ- and π-type orbitals. The electronegativity of oxygen places the filled oxygen lone pairs well below the metal orbitals of all but the most highly oxidized metal centers whereas the π* orbitals of CO are higher in energy than metal d_π atomic orbitals. As a consequence, in metal alkoxides the metal–oxygen π bonds will be ligand-centered MOs whereas in metal carbonyls the metal–carbonyl π bonds will be primarily metal d_π in character.

In some respects the alkoxide ligand with its flexible M–O–C angle is analogous to the nitrosyl ligand;[39] the geometry of the M–N–O moiety (linear or bent) also depends on the electronic requirements of the metal center. A bent M–O–C moiety generates a lone pair, having s and p character, that is poised for alkoxide bridge formation.

3.1. $[M_6(\mu_3\text{-}L)_8L_6]^{n\ominus}$ Clusters

The central $[M_6(\mu_3\text{-}L)_8]$ core (**11**) of the $[M_6(\mu_3\text{-}L)_8L_6]^{n\ominus}$ cluster consists of an octahedron of metal atoms inscribed

within a cube of ligands that cap each triangular face. The six terminal ligands (not shown in **11**) radiate from the vertices of the M_6 octahedron. This basic cluster geometry is found for both carbonyl- and alkoxide-supported clusters—e.g., $[Mo_6(\mu_3\text{-}OMe)_8(OMe)_6]^{2\ominus}$ [40] and $[Co_6(\mu_3\text{-}CO)_8(CO)_6]^{4\ominus}$ [2]—and serves as a good starting point for comparison of the clusters.

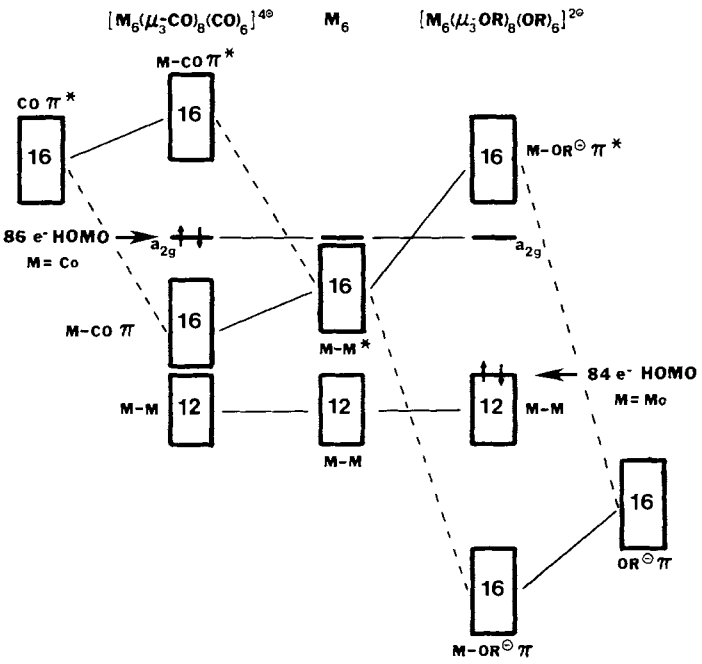
11

The bonding in these M_6 clusters has been the subject of numerous theoretical studies ranging in methodology from the d-orbital overlap model of *Cotton* and *Haas* to more sophisticated treatments employing the X_α-SW density functional technique.[41–48] Only recently, however, has interest focused on the role of π-donor versus π-acceptor ligands.[49–51]

The 30 primarily metal-d atomic orbitals of a "naked" M_6 octahedral cluster generate a manifold of thirteen metal–metal bonding MOs ($a_{1g} + a_{2u} + e_g + t_{1u} + t_{2u} + t_{2g}$) and seventeen weakly metal–metal anitbonding MOs ($a_{2g} + e_g + e_u + t_{1g} + t_{2g} + t_{1u} + t_{2u}$). The occupation of these cluster orbitals by electrons will depend on the metal. By symmetry, the interaction of ligand σ lone-pair orbitals with the M_6 cluster core will be identical for both carbonyl and alkoxide ligand sets. The six terminal ligand σ orbitals ($a_{1g} + e_g + t_{1u}$) can interact with radially directed M_6 cluster orbitals and the eight face-capping ligand σ orbitals ($a_{1g} + a_{2g} + t_{1u} + t_{2g}$) can interact with M_6 cluster orbitals derived predominantly from virtual metal s and p atomic orbitals.

The primary difference in metal–ligand bonding between carbonyl and alkoxide ligand sets arises from the nature of the π interaction of the eight face-capping ligands with the M_6 cluster core. For the eight face-capping ligands, the sixteen π orbitals ($e_g + e_u + t_{1g} + t_{2g} + t_{1u} + t_{2u}$) match the symmetry of sixteen of the seventeen weakly antibonding cluster MOs in the naked M_6 cluster. The a_{2g} M_6 cluster orbital has no symmetry match and is unaffected by interaction with the ligands. This is schematically illustrated in the interaction diagram in Figure 2, which is only meant to show in a qualitative fashion the difference in the face-capping ligand π interaction for octahedral M_6 clusters supported by carbonyl or alkoxide ligands. The blocks of M_6 cluster orbitals in the center of Figure 2 represent the number of symmetry-related cluster orbitals after taking into account the M–L σ bonding. Only the interaction of π orbitals is depicted.

For the carbonyl-supported cluster $[Co_6(\mu_3\text{-}CO)_8(CO)_6]^{4\ominus}$, the seventeen metal–metal cluster antibonding orbitals are occupied. Metal–carbonyl π back-bonding stabilizes sixteen cluster antibonding orbitals by transfer of electron density to the CO π* orbitals. As *Mingos* and *Johnston*[51] have pointed out, the removal of electron density from the cluster antibonding orbitals leads to a strengthening of the metal–metal bonding in the late-transition-metal



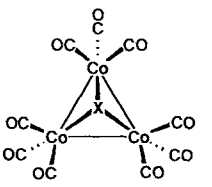


Fig. 2. Qualitative MO diagram illustrating the interaction of the sixteen π orbitals of the capping ligands with the weakly antibonding M_6 cluster MOs in $[M_6(\mu_3\text{-}L)_8L_6]$ compounds. In the center column are 12 M–M cluster bonding orbitals, 16 M–M cluster antibonding orbitals, and the noninteracting a_{2g} cluster orbital, after taking into account the M–L σ bonding. The left two columns illustrate the interaction of vacant CO π* orbitals with the 16 M–M antibonding cluster orbitals to generate an 86-electron cluster for M = Co. The right two columns illustrate the interaction of filled $OR^\ominus$ π orbitals with the 16 M–M antibonding cluster orbitals to generate an 84-electron cluster for M = Mo.

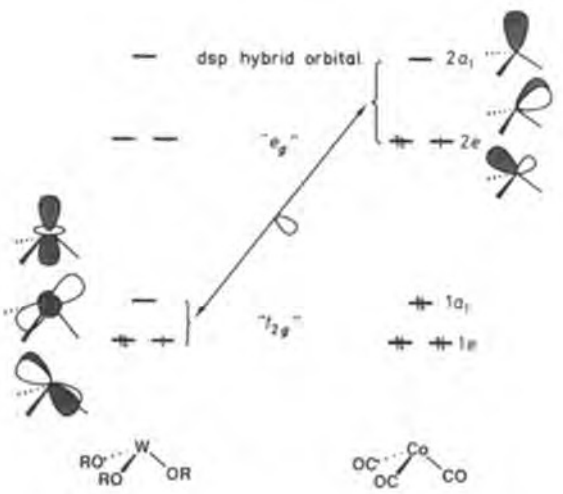

cluster. For the alkoxide-supported cluster $[Mo_6(\mu_3\text{-}OR)_8(OR)_6]^{2\ominus}$, where the corresponding cluster antibonding orbitals are empty, π donation from the alkoxide π lone-pair orbitals results in a destabilization of the cluster antibonding orbitals such that they are moved up and out of the frontier region. This effectively replaces sixteen metal–metal antibonding MOs with sixteen new ligand-based π-bonding orbitals. Finally, the difference in cluster electron count (86 electrons for $[Co_6(\mu_3\text{-}CO)_8(CO)_6]^{4\ominus}$ and 84 electrons for $[Mo_6(\mu_3\text{-}OR)_8(OR)_6]^{2\ominus}$) depends on the electron occupation of the nonbonding a_{2g} cluster MO.

3.2. Alkylidyne-Capped Clusters

Cobalt and tungsten form ethylidyne-capped clusters **12**[52–57] and **9** (X = CMe).[33] Aside from a similarity in formula, $[M_3(\mu_3\text{-}CMe)(L)_9]$, both compounds have approximate C_{3v} symmetry though the immediate coordination about the metal atoms is rather different.

12, X = CMe

Scheme 2. Frontier orbitals of the cluster fragments $W(OR)_3$ and $Co(CO)_3$.

Electronically, the clusters are related by a d^3–d^9 "hole formalism",[58] and the frontier orbitals of the ML_3 fragments that make up the clusters are isolobal (Scheme 2).

The frontier orbitals of a C_{3v} ML_3 fragment are well-known[59] and consist of low-lying $1a_1 + 1e$ orbitals, remnants of the octahedral t_{2g} set, and high-lying $2a_1 + 2e$ orbitals. The $2a_1$ orbital is a "dsp" hybrid and the 2e orbital is the remnant of the e_g octahedral set. With respect to bonding capability, the three valence electrons in a d^3 $[W(OR)_3]$ fragment formally reside in the lower $1a_1 + 1e$ orbitals, whereas in the d^9 $[Co(CO)_3]$ fragment three electrons reside in the upper $2a_1 + 2e$ set and the $1a_1$ and 1e are filled.

Orbital interaction diagrams for the combining of the $[W_3(OR)_9]^{3\oplus}$ and $[Co_3(CO)_9]^{3\oplus}$ frontier orbitals with $CMe^{3\ominus}$ are shown in Figures 3 and 4, respectively. The important metal-based fragment orbitals are drawn on the left of each interaction diagram.

Within each cluster the memory of the octahedral parentage of the ML_3 fragments persists. The C_{3v} molecular symmetry of **9** and **12** creates sets of orbitals with a and e symmetry. For the tungsten cluster the lower two sets are used in M–M and M–C alkylidyne bonding whereas for cobalt, with 24 metal-based electrons, the highest two a + e sets are used for M–M and M–C alkylidyne bonding. A similar relationship in both M–M and M–C (carbide) bonding is observed for the following cluster carbides:

$[W_4(\mu_4\text{-}C)(NMe)(O\mathit{i}Pr)_{12}]$ $[W_4(\mu_4\text{-}C)(O)(O\mathit{i}Pr)_{12}]$[18]
$[Fe_4(\mu_4\text{-}C)(CO)_{13}]$ $[Fe_4(\mu_4\text{-}C)(CO)_{12}]^{2\ominus}$[60]

One point of difference that is found in a comparison of the $M_3(\mu_3\text{-}CR)$ and $M_4(\mu_4\text{-}C)$ early- and late-transition-metal clusters arises from the different energies of the cluster frontier orbitals. Despite the higher formal oxidation state of the metal atoms in the early-transition-metal clusters, the tungsten orbitals are closer in energy to those of the carbide or alkylidyne carbon. Consequently, in the $W_4(\mu_4\text{-}C)$-containing clusters there is a significant bonding interaction between the carbon 2s atomic orbital and the metal atoms.[18] This is not observed in the $Fe_4(\mu_4\text{-}C)$ carbonyl clusters.[61, 62] For the alkylidyne-capped compounds the greater W_3-to-CR bonding manifests itself in what is tantamount to a rehybridization of the alkylidyne carbon;[58] that is, in **12** the alkylidyne carbon is essentially sp hybridized,[54–57] whereas in **9** (X = CMe) the alkylidyne carbon is sp^3 hybridized. Thus, in Figure 3, the carbon 2s character of the alkylidyne fragment orbital $3a_1$ is transferred to the $1a_1$ MO leaving the carbon $2p_z$ character entirely in the $3a_1$ MO.

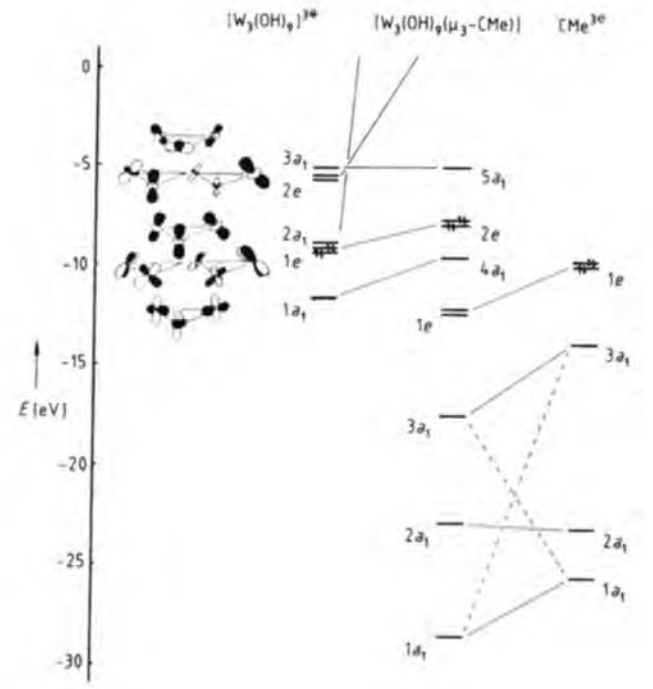

Fig. 3. An MO interaction diagram [58] showing the formation of the complex $[W_3(\mu_3\text{-}CMe)(OH)_9]$ from the fragments $[W_3(OH)_9]^{3\oplus}$ and $CMe^{3\ominus}$. The geometry of the cluster was taken from the crystal structure of **9** (X = CMe, R = *i*Pr).

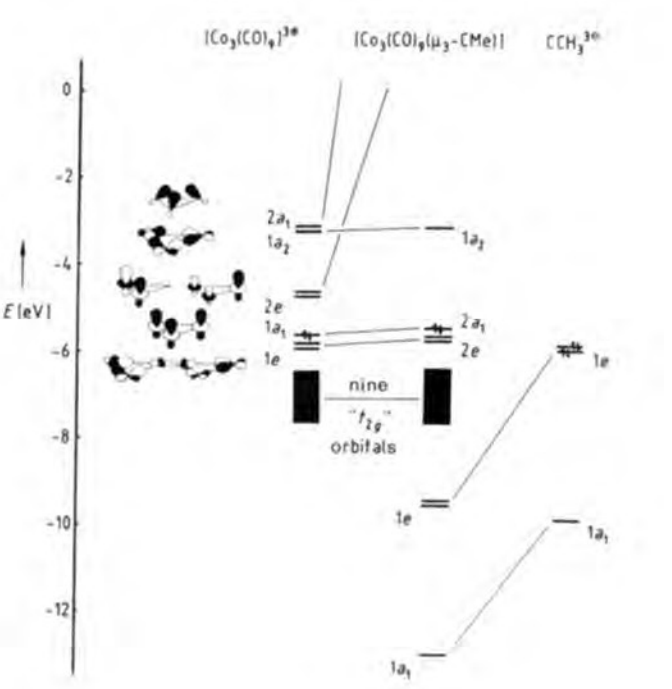

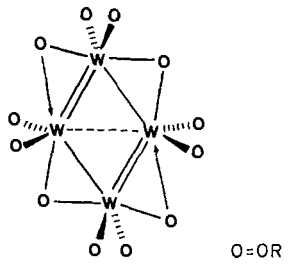

Fig. 4. An MO interaction diagram [58] showing the formation of **12** from the fragments $[Co_3(CO)_9]^{3\oplus}$ and $CMe^{3\ominus}$.

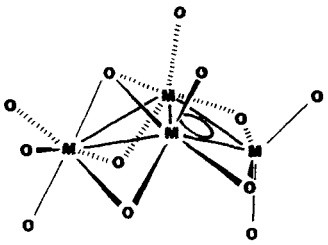


3.3. $[ML_3]_n$ Clusters

One final point of comparison between the d^3 $[M(OR)_3]$ and d^9 $[Co(CO)_3]$ fragments concerns the role of steric factors associated with the alkoxide ligands. The hypothetical molecule $[(CO)_3Co{\equiv}Co(CO)_3]$ is unstable with respect to $[Co_4(CO)_{12}]$, but $[(RO)_3M{\equiv}M(OR)_3]$ compounds can be stabilized by use of bulky R groups such as *t*Bu. As the bulk of R is decreased, the $[M_2(OR)_6]$ compounds couple to form $[M_4(OR)_{12}]$ compounds that, in contrast to $[Co_4(CO)_{12}]$, do not contain a tetrahedral M_4 core. The compounds $[W_4(OR)_{12}]$ (R = *i*Pr, cyclopentyl) adopt a distorted rhomboidal M_4 core **13** with alternating short (2.50 Å) and long (2.71 Å) M–M bonds corresponding formally to M–M double and single bonds.[34,35] This is, of course, a simplistic view and there is a significant M–M bonding interaction between the backbone tungsten atoms. The short diagonal M–M distance is 2.8 Å.

13

O=OR

14

Less sterically demanding OR ligands, such as R = CH_2*i*Pr, CH_2-cyclohexyl, CH_2-cyclopentyl, and CH_2-cyclobutyl, form $[M_4(OR)_{12}]$ compounds (M = Mo, W) with a butterfly of M atoms (**14**) in which one metal atom is octahedrally coordinated with respect to oxygen.[63]

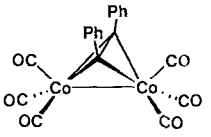
These structures illustrate an important point: In the chemistry of alkoxide clusters involving molybdenum and tungsten the importance of metal–oxygen bonding is certainly as great as that of metal–metal bonding. The observed structures reveal a subtle balance between M–O and M–M bonding within the steric constraints imposed by the specific alkoxide ligand.

4. Alkoxide Clusters—Templates for Organometallic Chemistry

The alkoxide cluster compounds of molybdenum and tungsten offer many attractive features for the development of a rich organometallic chemistry:[64,65]

1. By suitable choice of alkoxide ligand, steric access to the metal may be made substrate-selective.
2. The metal atoms behave as Lewis acidic centers and the presence of M–M bonds provides reservoirs of electrons for π-acid substrates.
3. Alkoxide ligands are electronically flexible and readily move between terminal and bridging modes. Their electron-releasing property may be tuned by variation of R. Response to substrate uptake or release may involve a change in M–O–C angle or terminal–bridge site exchange.
4. Synthetic procedures have now been established to incorporate a variety of functional groups of interest into the alkoxide clusters. Examples for such clusters are:

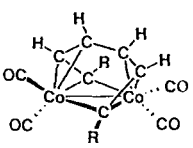
$[W_3(O)(OR)_8(R')_2]$ (R' = aryl)[66]
$[W_4(p\text{-tolyl})_2(OR)_{10}]$[66]
$[W_4(H)_2(O{i}Pr)_{14}]$[17]
$[Mo_4(N)_2(O{i}Pr)_{12}]$[19]
$[W_3(CR)(CO)_2(O{i}Pr)_9]$[67]
$[W_2(H)(CR)(\mu\text{-}C_4Me_4)(O{i}Pr)_4]$[68]



5. Unlike most organometallic systems it is not necessary to generate a reactive species by chemical or physicochemical means. For example, the fragments $[Cp^*_2M]$ (M = Ti, Zr, Hf, Mo, W), $[Co_2(CO)_6]$, [CpCo], $[PtL_2]$, and [Cp*IrL] have no known isolated existence (shelf-life)[69] and are prepared from precursor complexes, whereas the compounds **1** are isolable and have well-defined electronic structures involving metal-centered HOMOs and LUMOs.[70]

Elsewhere we have emphasized the importance of alkoxide ligands as ancillary ligands in organometallic chemistry of the early transition elements, lanthanides, and actinides.[65] We have also described in detail reactions involving $[M_2(OR)_6]$ compounds and C–O, C–C, and C–N triple bonds.[71–73] We shall restrict our discussion here to the reactions of alkynes and ethylene with $[W_2(OR)_6]$ compounds and a comparison with related reactions employing dinuclear or trinuclear carbonyl clusters.

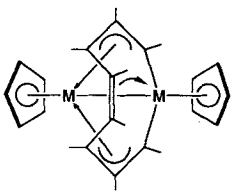
4.1. Alkyne Derivatives



As long ago as 1968 it was written: "The sticky brown soups formed in the reactions between acetylenes and metal carbonyls yield an amazing variety of complexes including many of the organometallic exotica."[74] In these reactions, η^2- and μ-alkyne complexes and products derived from alkyne–alkyne and alkyne–carbonyl coupling are observed, including η^4-cyclobutadiene, μ-metallacyclopentadiene, and cyclopentadienone complexes.

The first structural characterization of an M_2(μ-alkyne) adduct (**15**) was undertaken by *Sly*[75] and reported in 1959. Compound **15** had been prepared earlier[76] in the reaction between $[Co_2(CO)_8]$ and diphenylacetylene.

15



In 1964 *Mills* and *Robinson*[77] reported the structure of **16**. This was the first structural characterization of a product derived from the coupling of three alkynes, namely one acetylene and two tert-butylacetylene molecules, and featured a "flyover ligand".

16, R = *t*Bu

In reactions between $[Co_2(CO)_8]$ and alkynes the uptake of alkyne ligands is accompanied by loss of carbonyl ligands. Because a "μ-perpendicular" alkyne (see **15**) is a four-electron donor, two carbonyl ligands are lost, and the electron counts in $[Co_2(CO)_8]$ and compounds of type **15** are the same. Further alkyne uptake requires CO elimination unless alkyne–carbonyl coupling occurs.

The formation of **15** may be considered to arise from the formal addition of an alkyne to hypothetical $[(CO)_3Co \equiv Co(CO)_3]$. Though it is unlikely that this represents the mode of formation of compounds of type **15**, it has been shown that certain alkynes will add directly to compounds of type **4** to give related μ-perpendicular alkyne adducts, $[Cp_2(CO)_4M_2(\mu\text{-}C_2R_2)]$.[78, 79] The same compounds were first synthesized in the reactions between $[Cp(CO)_3M\text{-}M(CO)_3Cp]$ and alkynes under conditions in which carbonyl elimination was favored.[80] *Muetterties* and *Slater*[81, 82] subsequently showed that $[Cp_2(CO)_4Mo_2(\mu\text{-}C_2Et_2)]$ would react further with diethylacetylene under forcing conditions ($T > 100\,^{\circ}C$) to give, by successive elimination of carbon monoxide, $[Cp_2Mo_2(\mu\text{-}C_4Et_4)(CO)_3]$ and $[Cp_2Mo_2(\mu\text{-}C_4Et_4)(CO)]$. Finally, it is worth mentioning that compounds lacking any carbonyl ligands and containing a μ-C_8R_8 ligand derived from the coupling of four alkynes have been isolated (**17**).[83] Originally, these were isolated from

17

reactions involving alkynes and $[Cp_2Mo_2(CO)_4]$, but subsequently a high-yield synthesis from a mononuclear source was discovered.[84] This stepwise coupling of alkynes at a dimetal center is suggestive of an alkyne polymerization process. The elimination of the μ-C_xR_x ligand from the dimetal center, however, is not achieved catalytically. Because of the successive loss of CO ligands, elimination of C_xR_x would leave behind a coordinatively unsaturated and presumably highly energetic bimetallic species.

Reactions of alkynes with compounds of type **1** do not involve the elimination of alkoxide ligands. The latter act as electronic spectator ligands, but, by their steric demands, they influence greatly the course of the reaction. The bulky *t*BuO ligands prevent stable coordination of all but the least sterically demanding alkyne, C_2H_2. The compounds $[Mo_2(O\mathit{t}Bu)_6(C_2H_2)]$[85, 86] and **8**[28] have both been characterized in solution, and an X-ray crystallographic study has been carried out for **8**.[28] The C–C distance for the μ-C_2H_2 ligand in **8** is the longest reported (1.44(1) Å). This distance approaches that observed in the tetrahedral skeleton of $C_4(\mathit{t}Bu)_4$ (1.48(1) Å).[87]

A typical C–C distance for a μ-C_2R_2 ligand in carbonyl-supported dinuclear compounds is 1.34(2) Å.[88] Carbon–carbon distances determined in the proximity of heavy metal atoms, however, have estimated standard deviations in the range of one- to three-hundredths of an angstrom, which leads to problems in establishing meaningful differences in the various $M_2(\mu\text{-}C_2R_2)$-containing compounds. For this reason, we used NMR spectroscopy as a alternative probe of C–C bonding in $M_2(\mu\text{-}C_2H_2)$-containing compounds.

Table 1. C–C bond distances and ^{13}C–^{13}C coupling constants for $M_2(\mu\text{-}C_2H_2)$-containing compounds and tetra-*tert*-butyltetrahedrane.

Compound	d(C–C) [Å]	$^1J(^{13}C, ^{13}C)$ [Hz]	Ref.
$C_4(\mathit{t}Bu)_4$	1.48(1)	9.2	[87, 89]
$[W_2(O\mathit{t}Bu)_6(py)(C_2H_2)]$ **8**	1.44(1)	10.3	[28, 86]
$[W_2(O\mathit{i}Pr)_6(py)_2(C_2H_2)]$ **6**	1.39(2)	11.4	[28, 86]
$[W_2(OCH_2\mathit{t}Bu)_6(py)_2(C_2H_2)]$	1.39(2)	19.0	[28]
$[Mo_2(O\mathit{t}Bu)_6(C_2H_2)]$	–	23.2	[86]
$[Mo_2(O\mathit{i}Pr)_6(py)_2(C_2H_2)]$	1.368(6)	28.2	[101, 86]
$[Mo_2(Cp)_2(CO)_4(C_2H_2)]$	1.337(5)	43.4	[86]
$[Co_2(CO)_6(C_2H_2)]$	1.327(6)	56.0	[86][a]

[a] The distance quoted is for the closely related compound $[Co_2(CO)_4(PMe_3)_2(\mu\text{-}C_2H_2)]$: S. Aime, D. Osella, E. Giamello, G. Granozzi, *J. Organomet. Chem.* 262 (1984) C1.

The ^{13}C–^{13}C coupling constants for a number of compounds containing the μ-C_2H_2 ligand were determined by the simulation of the AA'XX' NMR spectra (^{13}C and ^1H) obtained for the μ-*C_2H_2 labeled compounds, where *C represents 90 mol% ^{13}C. As summarized in Table 1, there is an approximately inverse relationship between C–C distance and the magnitude of $^1J_{^{13}C,\,^{13}C}$. The value reported for $C_4(\mathit{t}Bu)_4$[89] is approached only by compound **8**.[28] Most importantly, the data in Table 1 reveal that the carbonyl-supported μ-perpendicular-C_2H_2 compounds have values of $^1J_{^{13}C,\,^{13}C}$ that are considerably greater than those found for the alkoxide-supported compounds. Also, for a given alkoxide ligand, the value of $^1J_{^{13}C,\,^{13}C}$ is greater for molybdenum than for tungsten complexes. From our X-ray crystallography and NMR studies we conclude that the alkoxide-supported complexes reduce coordinated alkynes more than their carbonyl analogues; i.e., the alkoxide-supported metal fragments π back-bond better.

We have investigated[86] the bonding in alkoxide- and carbonyl-supported $M_2(\mu\text{-}C_2H_2)$-containing compounds by the use of MO calculations employing the method of *Fenske* and *Hall*.[90] While the qualitative features of the bonding in the $M_2(\mu\text{-}C_2H_2)$-containing compounds are very similar for both alkoxide- and carbonyl-supported compounds, differences arise because of the relative orbital energies of the metal fragments. Despite the higher formal oxidation states of the metal atoms in the alkoxide-supported compounds, there is a more favorable match between metal d_π and C_2 π* orbitals. This is in the order of W > Mo and is assisted by the alkoxide p_π lone-pair orbitals because oxygen-to-metal p_π–d_π donation raises the energy of metal d_π electrons. The converse is true in the carbonyl-supported compounds in that d_π–π* interactions with CO lower the energy of the metal d_π orbitals.

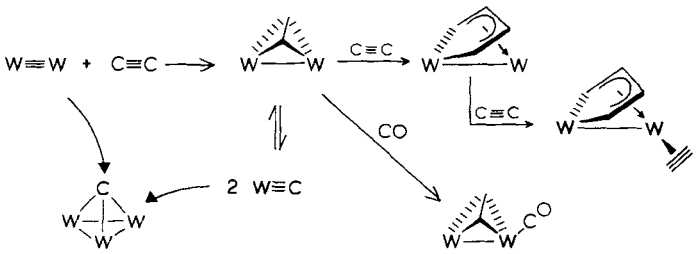
A measure of the importance of alkoxide π donation is obtained from a calculational procedure that we have termed "the frozen π orbital approach".[91] In this procedure the Mulliken populations of the μ-C_2 moiety are determined in two separate calculations, one involving only the oxygen-to-metal σ interactions and the other employing oxygen σ and π orbitals. The effect of "turning on" the oxygen p_π donation is to increase the Mulliken population of the C_2 π* orbitals. The latter provides a measure of metal-to-C_2 d_π–π* back-bonding or, equivalently, alkyne reduction.

Perhaps the most obvious indication of the ability of the dimolybdenum and ditungsten center to back-bond to π-acceptor ligands is seen in the remarkably low values of $\tilde{\nu}$(CO) observed for $[M_2(OtBu)_6(\mu\text{-CO})]$ compounds: 1670 and 1580 cm^{-1} for M = Mo and W, respectively.[92] These values reflect the back-donation order W > Mo and are well below the $\tilde{\nu}$(CO) values reported for all known μ_2-CO carbonyl-supported compounds.[93]

The unique degree of M_2-to-substrate π* bonding is also illustrated by the reactions between alkynes and **1b**, in which there is a metathesis of the W≡W and C≡C bonds [Eq. (f)].[25, 94] This reaction has been extensively studied by *Schrock* and co-workers and some of the products **18** find use as alkyne metathesis catalysts.[95, 96]

$$[(t\text{BuO})_3\text{W}\equiv\text{W}(O t\text{Bu})_3] + \text{RC}\equiv\text{CR}' \longrightarrow$$
1b

$$[(t\text{BuO})_3\text{W}\equiv\text{CR}] + [(t\text{BuO})_3\text{W}\equiv\text{CR}'] \quad \text{(f)}$$
18



A clear connection between $W_2(\mu\text{-}C_2R_2)$-containing compounds and alkylidyne compounds was first observed for **8**, which is in equilibrium with **18** (R = H).[28] The latter is not isolable but may be stabilized and crystallized as the quinuclidine adduct, **18** · quinuclidine (R = H).[94] Subsequently, evidence has been gathered for related equilibria [Eq. (g)] involving other alkoxide ligands ($OCEt_3$, O*i*Pr, OCH_2tBu) and alkynes (C_2H_2, C_2Me_2, C_2Et_2).[72, 97, 98]

$$2\,[(\text{RO})_3\text{W}\equiv\text{CR}'] \rightleftharpoons [W_2(\text{OR})_6(\mu\text{-}C_2R'_2)] \quad \text{(g)}$$

The metathesis reaction (f) may be viewed as an oxidative cleavage of the M≡M bond. In this description two metal atoms in oxidation state +3 are oxidized to oxidation state +6 and the alkyne is reduced by six electrons to give two $RC^{3\ominus}$ ligands. Similarly, equilibrium (g) may be viewed as an internal redox reaction of the type well-documented in metal–sulfur chemistry.[99]

Strong Lewis bases, when added to an equilibrium mixture of W–alkylidyne and $W_2(\mu\text{-}C_2R_2)$-containing compounds [Eq. (g)], form adducts with the alkylidyne complexes. By contrast, π-acceptor ligands, such as CO or an alkyne, react preferentially with the $W_2(\mu\text{-}C_2R_2)$ compound and draw off equlibrium (g) to the right.[97, 98] Indeed, all $[W_2(OR)_6(\mu\text{-}C_2R'_2)]$ compounds react with alkynes to give alkyne–alkyne carbon–carbon coupling.[72, 100]

A summary of the reactions between alkynes and $[W_2(OR)_6]$ compounds is shown in Scheme 3. Note that the less sterically demanding alkoxide groups O*i*Pr and OCH_2tBu allow isolation of $[W_2(OR)_6(\mu\text{-}C_4R'_4)(\eta^2\text{-}C_2R'_2)]$ compounds (R′ = Me, Et).[100] The reaction sequence is suggestive of alkyne polymerization. In practice, however, tungsten is reluctant to give up the coordinated hydrocarbon ligands, though related $[Mo_2(OR)_6]$ compounds have been found to be alkyne trimerization catalysts and $[Mo_2(OR)_6(\mu\text{-}C_2R'_2]$ and $[Mo_2(OR)_6(\mu\text{-}C_4R'_4]$ compounds have been reliably identified as intermediates in the catalytic cycle.[101] This catalytic cycle contrasts with the alkyne–alkyne coupling reactions observed at carbonyl-supported dinuclear centers.

Scheme 3. Reactions of $[W_2(OR)_6]$ with alkynes.

4.2 Ethylene Activation

The classic example of ethylene activation at a metal carbonyl cluster is the reaction of C_2H_4 with $[Os_3(CO)_{12}]$.[102] Originally, the reaction was carried out at elevated temperatures (125 °C, 1 atm C_2H_4), leading to the isolation of a μ-vinylidene complex, **19**.[103] Under these conditions no intermediates were detected. Presumably the forcing conditions were required for CO dissociation, which was followed by ethylene coordination and C–H activation. Support for this reaction scheme was found in a variety of experiments. For instance, the substitutionally labile compound **20**[104] and ethylene were found to react under much milder conditions (25 °C) to give the first example of an ethylene adduct in carbonyl cluster chemistry, **21**. The likely hydrido-vinyl intermediate **22**[105, 106] was also prepared from reactions involving "unsaturated" $[H_2Os_3(CO)_{10}]$ and ethylene[107, 108] and acetylene.[107]

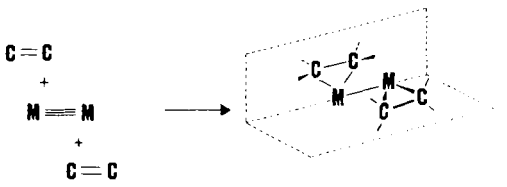
$[H_2Os_3(\mu\text{-}CCH_2)(CO)_9]$ **19**
$[Os_3(CO)_{11}(NCMe)]$ **20**
$[Os_3(\eta^2\text{-}C_2H_4)(CO)_{11}]$ **21**
$[HOs_3(\mu\text{-}CHCH_2)(CO)_9]$ **22**
$[Re_2(H)(\mu\text{-alkenyl})(CO)_8]$ **23**

The light-induced reactions between $[Re_2(CO)_{10}]$ and alkenes at 22 °C giving **23** provide excellent examples of photolytic alkene activation.[109] No intermediate was detected in the latter study, but presumably photolysis induces CO ligand expulsion, generating unsaturated species such as $[Re_2(CO)_9]$ that rapidly react with alkenes.

These reactions involving carbonyl complexes may be contrasted with our recent studies of the reactions between $[W_2(OR)_6]$ compounds and ethylene that are summarized in this article. The latter occur under mild conditions (− 78 to 0 °C, ≤ 1 atm C_2H_4) and reveal a remarkable sensitivity toward steric factors imposed by the alkoxide ligands. This is illustrated by the following experimental observations:[103] (1) $[W_2(OtBu)_6]$ **1b** and ethylene (1 atm) do not react in hydrocarbon solvents (benzene, toluene, hexane) at 22 °C; (2) $[W_2(O\text{-cyclohexyl})_6]$ and ethylene (1 atm) react slowly in hydrocarbon solvents at 22 °C to give **24** and ethane with no evidence for any intermediate; (3) $[W_2(OiPr)_6]$ and ethylene (1 atm) react in hydrocarbon solvents at 0 °C to give a "tris-ethylene adduct" **25**, which can be described *formally* as $[W_2(OiPr)_6(C_2H_4)_3]$;[110] (4) under similar conditions $[W_2(OCH_2t\text{Bu})_6]$ yields the bis-ethylene adduct **26**.[111]

$[W_2(\text{O-cylcohexyl})_6(\mu\text{-}CCH_2CH_2CH_2)]$ **24**
$[W_2(OCH_2t\text{Bu})_6(C_2H_4)_2]$ **26**

Compound **26** is formed reversibly [Eq. (h)] and there is no evidence by NMR spectroscopy for an intermediate mono-ethylene adduct $[W_2(OCH_2tBu)_6(C_2H_4)]$, which therefore must be a higher-energy species.[111]



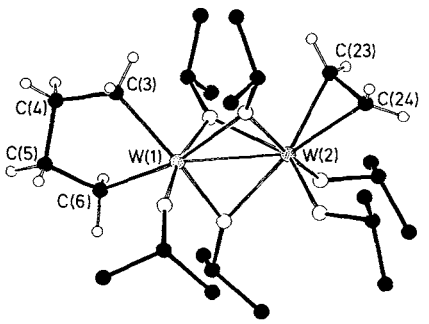
$$[W_2(OCH_2tBu)_6] + 2\,C_2H_4 \rightleftharpoons [W_2(OCH_2tBu)_6(C_2H_4)_2] \quad (h)$$
26

Although equilibrium (h) is established rapidly, it is not rapid on the NMR time scale and the ^1H and ^{13}C NMR spectra for **26** indicate that the molecule must have a virtual C_2 axis of symmetry. There are three types of OCH_2tBu ligands in the integral ratio 1:1:1 and each ligand has diastereotopic methylene protons. The proton signals for the η^2-C_2H_4 ligands represent an ABCD spin system which requires restricted rotation of the ethylene ligand about the C_2–W bond. The proton-decoupled ^{13}C NMR spectrum of **26** containing 99 mol% ^{13}C in the C_2H_4 ligand gives rise to an AB spectrum, which indicates the existence of two types of carbon atoms. The value of $^1J_{^{13}C,^{13}C}$ is 28 Hz, significantly smaller than that in ethylene (67 Hz[112]), which, together with the value of $^1J_{^{183}W,^{13}C}$ (36 Hz) suggests a significant rehybridization of the ethylene molecule upon coordination to the tungsten center. The relative intensities of the tungsten satellites due to coupling to ^{183}W, $I = 1/2$ (14.5% natural abundance), indicate that each ethylene is bound to only one tungsten atom.

Unfortunately, we have as yet been unable to obtain crystals of **26** that are suitable for an X-ray study; therefore, the detailed structure is not known. We can, however, assign a structure based on the NMR data and consideration of how a d^3–d^3 W≡W bond will interact with two C=C bonds (Scheme 4). In order for d_π-to-C_2 π^* back-bonding (W → C_2) to be effective, the C–C vectors would have to be aligned with the W–W axis. If the two WC_2 planes are at right angles, there can be a mixing of W–W π bonding and W-to-C_2 $d_\pi \rightarrow \pi^*$ back-bonding.

The $W_2(C_2)_2$ moiety shown in Scheme 4 is consistent with the observed restricted rotation about the olefin C_2-to-W axis and accounts for C_2 molecular symmetry. Based on NMR data, however, we cannot exclude the possibility of a structure in which W–W π bonding has been totally sacrificed in favor of W-to-C_2 $d_\pi \rightarrow \pi^*$ back-bonding.

One final point concerning the reversible formation of **26** that is worthy of mention arises from labeling studies employing *cis*-, *trans*-, and *gem*-$C_2H_2D_2$. The smaller gyromagnetic ratio of D ($I = 1$) leads to a simplification of the ABCD spin system because $J_{H\text{-}D} \approx 0$ Hz. Indeed, from these spectra it has been possible to extract the various H–H coupling constants and to satisfactorily simulate the ABCD spectrum of the ethylene signals associated with **26**. The coupling constants are markedly different from those of ethylene and comparable to those in phosphiranes, $RP(CH_2)_2$.[113] This supports the hypothesis that ethylene coordination to tungsten occurs with extensive rehybridization and suggests that the WC_2 moiety is best described as a metallacyclopropane. It is also significant that the spectra of the reversibly formed adducts [Eq. (h)] involving *cis*-, *trans*-, and *gem*-$C_2H_2D_2$ show no evidence of ethylene isomerization. This observation provides good evidence that both C–H bond activation and olefin metathesis reactions do no occur.



Scheme 4. Proposed structure of **26**.

In the reaction between $[W_2(OiPr)_6]$ and ethylene a "tris-ethylene" adduct is formed rapidly. This "tris-ethylene" adduct is, in fact, the dinuclear metallacyclopentane–ethylene complex **25**, which is formed reversibly [Eq. (i)].[110] There is no spectroscopic evidence that a bis-ethylene or mono-ethylene adduct is present in the equilibrium mixtures.

$$[W_2(OiPr)_6] + 3\,C_2H_4 \rightleftharpoons [W_2(OiPr)_6(CH_2)_4(\eta^2\text{-}C_2H_4)] \quad (i)$$
25

The molecular structure of **25** observed in the solid state is shown in Figure 5. Each tungsten atom is in a distorted octahedral environment if the η^2-C_2H_4 ligand is considered to occupy one coordination site. The W–W distance (2.64 Å) is intermediate between a W–W single (2.75 Å) and W–W double bond distance (2.50 Å). It is consistent with describing the $(CH_4)_4$ ligand as dianionic and the η^2-C_2H_4 ligand as either a neutral Lewis base donor or a metallacyclopropane, that is, a $C_2H_4^{2\ominus}$ ligand.

Compound **25** is fluxional in solution and shows rapid alkoxide group scrambling, presumably via a reversible opening and closing of O*i*Pr bridges. This fluxional process creates an apparent mirror plane of symmetry such that C_α is equivalent to C'_α and C_β to C'_β (Fig. 5, bottom). In addition, there is a lower-energy process that involves W–C_2 (ethylene) rotation which makes C_γ and C'_γ equivalent. Only at $-90\,^\circ C$ in [D_8]toluene are the ^1H and ^{13}C spectra consistent with the structure shown in Figure 5.

25

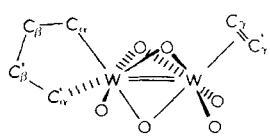


Fig. 5. Molecular structure of **25**. Top: Ball-and-stick drawing [110]. Selected bond lengths [Å]: W(1)-W(2) 2.643(1), W(1)-C(3) 2.191(12), W(1)-C(6) 2.173(12), W(2)-C(23) 2.151(11), W(2)-C(24) 2.179(12), C(23)-C(24) 1.428(17), C(3)-C(4) 1.523(17), C(4)-C(5) 1.522(20), C(5)-C(6) 1.524(18). Bottom: Schematic drawing.

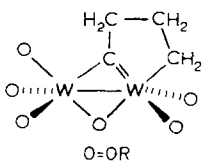
Though **25** is formed reversibly [Eq. (i)], it reacts irreversibly in solution and in the solid-state above 0 °C according to the stoichiometry shown in Equation (j) to give **27**.

$$\underset{\mathbf{25}}{} \longrightarrow \underset{\mathbf{27}}{[W_2(O\mathit{i}Pr)_6(\mu\text{-}CCH_2CH_2CH_2)]} + C_2H_6 \quad (j)$$



During studies of reaction (j) in [D_8]toluene, the formation of free ethylene and [$W_2(O\mathit{i}Pr)_6$] can be monitored by NMR spectroscopy. Reactions employing [$W_2(O\mathit{i}Pr)_6(CD_2)_4(\eta^2\text{-}C_2D_4)$] proceed to give the labeled alkylidyne-bridged compound [$W_2(O\mathit{i}Pr)_6(\mu\text{-}CCD_2CD_2CD_2)$] sufficiently slowly (because of a significant kinetic isotope effect) that [$W_4(O\mathit{i}Pr)_{12}$] can be detected in solution. The latter arises from the combination of the equilibria shown in Equations (d) and (i).

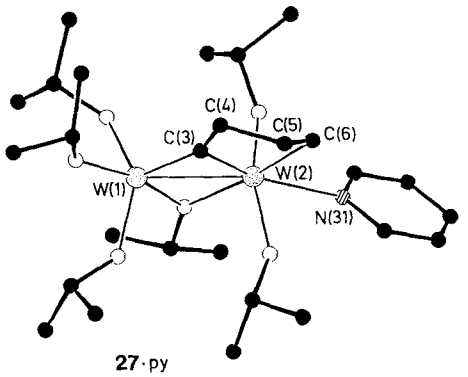
The bis-ethylene complex **26** and ethylene react further to give [$W_2(OCH_2\mathit{t}Bu)_6(\mu\text{-}CCH_2CH_2CH_2)$] and ethane but only slowly at ambient temperatures and pressure. In studies of these reactions the intermediate [$W_2(OCH_2\mathit{t}Bu)_6(CH_2)_4(\eta^2\text{-}C_2H_4)$] (structure type **25**, see Fig. 5) can be detected by NMR spectroscopy.[110]

In the reaction between [W_2(O-cyclohexyl)$_6$] and ethylene (> 3 equiv. 22 °C, [D_8]toluene or hexane), the alkylidyne-bridged compound **24** is formed, though no intermediate has been detected.[110] A similar reaction occurs for the complex containing O-cyclopentyl ligands. In this case, however, the metallacyclopentane–ethylene complex analogous to **25** can be detected by NMR spectroscopy studies.[110] The stoichiometric reaction shown in equation (k) is therefore operative for R = *i*Pr, $CH_2\mathit{t}Bu$, cyclopentyl, and cyclohexyl but not for R = *t*Bu, which fails to show any reactivity toward ethylene at 22 °C under comparable conditions.

$$[W_2(OR)_6] + 3\,C_2H_4 \longrightarrow [W_2(OR)_6(\mu\text{-}CCH_2CH_2CH_2)] + C_2H_6 \quad (k)$$

We have not as yet obtained crystals of any [$W_2(OR)_6(\mu$-$CCH_2CH_2CH_2)$] compound that are suitable for a single-crystal X-ray determination, but the 1:1 pyridine adduct **27** · py, obtained by crystallization from hexane/pyridine solvent mixtures, has been fully characterized (Fig. 6).[110] The pyridine molecule is only weakly bound, as evidenced by the long W–N bond distance (2.41 Å), and in [D_8]toluene solution the ^{13}C NMR spectra of unligated **27** and its pyridine adduct are the same except for the presence of free pyridine signals in the latter. Indeed, from NMR studies of the [$W_2(OR)_6(\mu$-$CCH_2CH_2CH_2)$] compounds, and the analogous labeled compounds derived from reactions employing $^*C_2H_4$, where *C represents 99 mol% ^{13}C, we can formulate a common structure (Scheme 5).[110, 114]

Scheme 5. Proposed structure of the alkoxide alkylidyne complexes [$W_2(OR)_6(\mu$-$CCH_2CH_2CH_2)$].



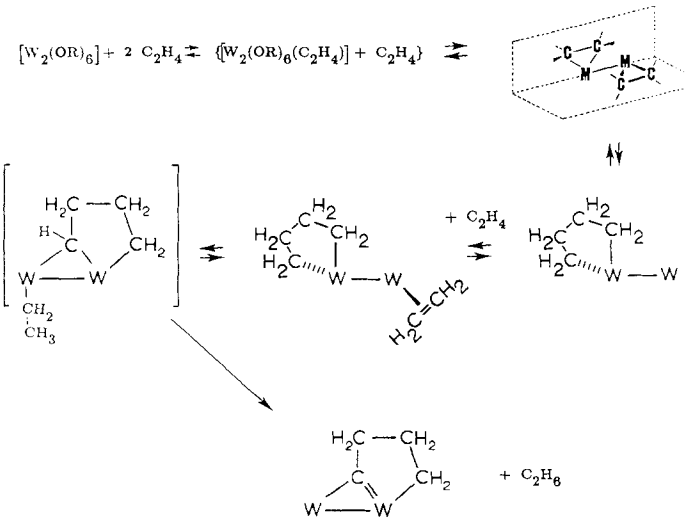


Fig. 6. A ball-and-stick drawing of the molecular structure of **27** [110]. Selected bond distances [Å]: W(1)-W(2) 2.6742(7), W(1)-C(3) 1.974(8), W(2)-C(3) 1.956(7), W(2)-C(6) 2.190(8), C(3)-C(4) 1.500(11), C(4)-C(5) 1.529(12), C(5)-C(6) 1.545(12), W(2)-N(31) 2.414(6).

Initially, we proposed[114] that the formation of the μ-$CCH_2CH_2CH_2$-containing compounds arose from a reaction sequence involving activation of a mono-ethylene adduct to give, by way of a hydrido-vinyl ligand, a μ-vinylidene ligand. This reaction path has a direct parallel with what has been observed in carbonyl dinuclear and cluster chemistry. Addition of ethylene to the μ-vinylidene ligand would then generate the μ-$CCH_2CH_2CH_2$ ligand. We can now dismiss this reaction pathway in favor of the one shown in Scheme 6.

Scheme 6. Proposed pathway for the formation of compounds having the structure shown in Scheme 5 from [$W_2(OR)_6$] and ethylene.

The intermediacy of compounds of type **25** is implicated by what we have described earlier but proof of their direct role in the formation of compounds of type **27** has come from kinetic and labeling studies.[110] What has been presented here sufficiently emphasizes the point that dinuclear alkoxides, [$W_2(OR)_6$], provide templates for C–C and C–H bond activation under mild conditions. All of the reactions described in Equations (h)–(k), which involve *reversible* ethylene binding as well as carbon–carbon and carbon–hydrogen bond activation, occur at or below room temperature.

5. Concluding Remarks

Alkoxide clusters of molybdenum and tungsten provide templates for an extensive organometallic chemistry. The choice of alkoxide ligand generates specific structural classes of clusters, which, in turn, are substrate-selective. For example, tungsten compounds of type **1** react with one equivalent of carbon monoxide to yield $[W_2(OR)_6(\mu\text{-}CO)]$ (R = *t*Bu) or $[W_4(\mu\text{-}CO)_2(OR)_{12}]$ (R = *i*Pr, CH_2tBu), whereas $[W_4(OR)_{12}]$ compounds of structural type **14** (R = CH_2iPr, CH_2-cyclopentyl, CH_2-cyclohexyl) and one equivalent of CO yield the carbido oxo cluster $[W_4(\mu_4\text{-}C)(\mu_3\text{-}O)(OR)_{12}]$.[92, 115] In contrast to carbonyl cluster chemistry, the alkoxide clusters of molybdenum and tungsten have HOMOs and LUMOs that are metal-centered and substrate activation occurs without the loss of alkoxide ligands, for instance in reactions of $[(RO)_3W\equiv W(OR)_3]$ with alkynes and ethylene. Obtaining insight into the nature of small-molecule activation by discrete alkoxide clusters promises to be an exciting endeavor.

We thank the Department of Energy, Office of Basic Sciences, Chemistry Division, for support of this work. M.H.C is indebted to all the talented co-workers cited in the references.

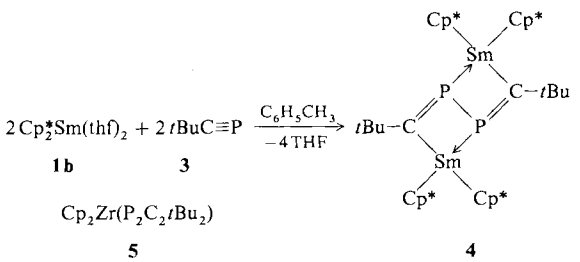
Reductive Dimerization of a Phosphaalkyne with Complexation to Samarium**



By *Anja Recknagel, Dietmar Stalke, Herbert W. Roesky* and *Frank T. Edelmann**

Of great importance for the organometallic chemistry of lanthanides in low formal oxidation states was the discovery of decamethylsamarocene **1a** by *Evans* et al.[1] Like the THF adduct **1b**, complex **1a** undergoes a number of interesting reactions;[2] for example, **2**,[3] the first dinitrogen complex of an f element was recently prepared. Noteworthy, however, is the complete absence of complexes containing phosphorus ligands.[2] Since phosphaalkynes exhibit an especially diverse reactivity toward organometallic complexes, we have investigated the reaction of 2-*tert*-butyl-1-phosphaethyne **3** with **1b**. This reaction results in reductive dimerization of the phosphaalkyne; the resulting new ligand remains coordinated to samarium.

Cp^*_2Sm **1a** $Cp^*_2Sm(thf)_2$ **1b** $[Cp^*_2Sm(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)SmCp^*_2]$ **2**

$Cp^* = (\eta^5\text{-}C_5Me_5)$

The adduct **1b**[4] reacts rapidly with the phosphaalkyne **3**[5] in toluene at room temperature, the reaction mixture displaying a striking color change from deep violet to orange-red. Recrystallization of the product from toluene affords bright red, air-sensitive crystals of composition $[Cp^*_2Sm(t\text{BuC}\equiv\text{P})]_2$ **4** (correct elemental analysis, molecular weight (EI-MS) 1042).

The ^{31}P NMR spectrum shows that the samarium complex **4** does not contain diphosphacyclobutadiene[6, 7] as ligand. The chemical shift (singlet at $\delta = -260.1$) lies in the same region as that found for the zirconium complex **5** ($\delta = -247$) recently described by *Binger* et al.[8] In that compound, $t\text{BuC}\equiv\text{P}$ is dimerized to a bent 1,3-diphosphabicyclo[1.1.0]butane. The ^1H NMR spectrum of **4** (in C_6D_6) shows a singlet for the C_5Me_5 groups ($\delta = 1.54$) and for the *tert*-butyl groups ($\delta = -2.61$). Thus, the spectroscopic data do not allow an unequivocal description of the bonding in the new ligand. The structure of **4** was therefore elucidated by X-ray structure analysis (Fig. 1),[9] which revealed a novel ligand in **4**, the dianion of a 2,3-diphosphabutadiene.

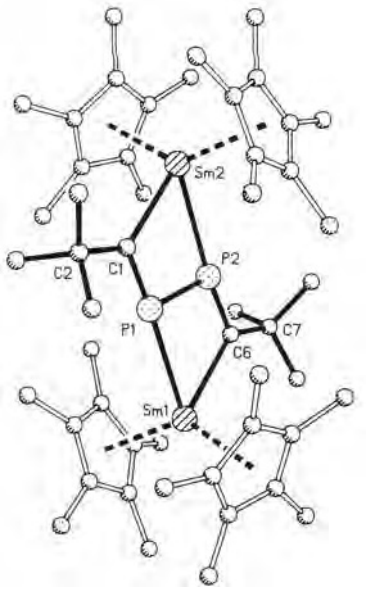


Fig. 1. Molecular structure of **1**. Selected bond lengths [pm]: Sm1-P1 295.2(2), Sm2-P2 294.5(2), Sm1-C6 255.7(6), Sm2-C1 255.6(6) (see also text).

As in the neutral species,[10] the P–C double bonds have a *trans* arrangement. The P=C bond lengths are 169.4(7) (P1-C1) and 169.8(7) (P2-C6). The P1–P2 distance of 220.7(2) is in agreement with a single bond. Each samarium bridges a phosphorus and a carbon atom. All samarium and phosphorus atoms lie in a common plane with C1, C2, C6, and C7 (largest deviation from the plane: 1.5 pm). The mean distance of the samarium atoms from the center of the Cp* ring is 247 pm.

The reductive dimerization of the phosphaalkyne is not fully surprising in view of the reduction potential of **1b**, which is similar to that of alkali metals. The result presented here should encourage the use of reactive phosphorus ligands in the organometallic chemistry of f elements.

Experimental Procedure

Compound **3** (0.4 g, 4.0 mmol) was added to a solution of **1b** (1.7 g, 3.0 mmol) in toluene (20 mL) and the reaction mixture was stirred for 12 h at room temperature. The orange-red solution was filtered and the filtrate was concentrated to ca. 10 mL and then cooled to −25 °C. After 48 h, 1.2 g (40%) of **4** was isolated as red crystals, m.p. 215 °C.

$[\{Cp(CO)_2Mn\}_2(\mu\text{-}H)]^{\ominus}$: A New, Versatile Reagent**

By *Karl Plößl, Gottfried Huttner,** and *Laszlo Zsolnai*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

The $Cp(CO)_2Mn$ fragment is one of the most versatile 16-electron species. $Cp(CO)_2Mn$ derivatives are usually obtained by substitution of weakly bound ligands L in $Cp(CO)_2MnL$ (e.g., L = THF).[1, 2] Anionic starting complexes for the formation of $Cp(CO)_2Mn$ complexes were not available previously and there have been no reports so far on the use of the recently reported anions **1**–**3** for the preparation of unusual ligands of the nitrogen group.[5]

$[Cp(CO)_2Mn]^{2\ominus}$ **1** $[Cp(CO)_2MnH]^{\ominus}$ [3] **2**

$[(MeC_5H_4)(CO)_2MnSiR_3]^{\ominus}$ [4] **3**

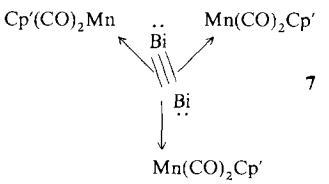
We have now found that the novel title compound **4** is a versatile reagent for carrying out this kind of chemistry. $Cp(CO)_2Mn(thf)$ reacts with $NaBH_4$ to give **4**, which could be obtained as a crystalline $[Na(crypt)]^{\oplus}$ salt.[6]

$$Cp(CO_2)Mn(thf) \xrightarrow[2)\ (crypt)]{1)\ NaBH_4} [Na(crypt)]^{\oplus}\left[Cp(CO)_2Mn(H)Mn(CO_2)Cp\right]^{\ominus}$$

4

$Cp = (\eta^5\text{-}C_5H_5)$

The anion **4** has a hydride-bridged Mn–Mn bond,[7] whereas the isoelectronic compound $[\{Cr_2(CO)_{10}\}(\mu\text{-}H)]^{\ominus}$ is "open" (i.e., without direct metal–metal contact).[8] Complex **4** reacts with halides of elements of the nitrogen group in the ways already found for $Na_2[M_2(CO)_{10}]$ (M = Cr, Mo, W).[9] Reaction of **4** with $AsCl_3$ gives the chloroarsanediyl complex **5**, which is also accessible by a different route;[10] with $SbCl_3$ the analogous antimony complex **6** is formed.[11] The non-optimized yields (**5**, 24%; **6**, 39%) are appreciably better than those obtained by previous synthetic methods (**5**, 6.6%; **6**, 18%). These syntheses and the reactions of **4** described here can be extended to its MeC_5H_4 and Me_5C_5 analogues.[12]



$$\left[Cp(CO)_2Mn(H)Mn(CO_2)Cp\right]^{\ominus} \xrightarrow{ECl_3} Cp(CO)_2Mn(Cl)(E)Mn(CO)_2Cp$$

4 **5**, E = As; **6**, E = Sb

Complex **4a**, prepared analogously to **4**, and $BiCl_3$ react to give **7**,[7] the first derivative of dibismuth coordinated side-on by three 3d L_nM fragments[13].

$$\left[Cp'(CO)_2Mn(H)Mn(CO_2)Cp'\right]^{\ominus} \xrightarrow{BiCl_3}$$

4a

7

$Cp' = (\eta^5\text{-}C_5H_4CH_3)$

Complex **7** displays the starlike structure typical of threefold side-on-coordinated Bi_2 (Fig. 1).[13] The Bi_2Mn_3 framework has D_{3h} symmetry; the arrangement of the $(MeC_5H_4)(CO)_2Mn$ fragments also approximates this symmetry (Fig. 1). The Bi–Bi distance in **7** (281.3 pm) has the value expected for side-on-coordinated Bi_2.[13] The Bi–Mn distances (289.7–295.0 pm) have a mean value of 293.2 pm. Bi–Mn distances of similar length were found previously only in sterically crowded molecules such as $Bi[Mn(CO)_5]_3$[14] (288.4–291.6 pm). This lengthening of the M–X bonds is typical of molecules of the type $(L_nM)_3X_2$ (X = Bi, Sb, As, L_nM = 16-electron fragment).[13, 15, 16]

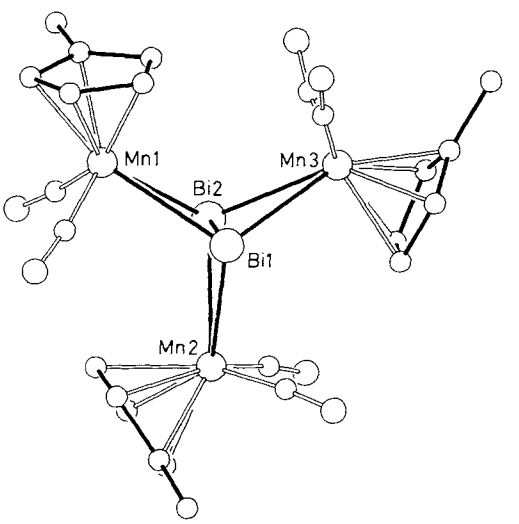


Fig. 1. Molecular structure of **7**[7].

Experimental Procedure

All reactions were performed under nitrogen with freshly prepared dried solvents. ^{1}H NMR, Bruker AC 200; IR, Perkin-Elmer 983 G; UV/VIS, Perkin-Elmer Lambda 9.

Na(crypt) · **4**: A solution of $CpMn(CO)_3$ (4.5 g, 22 mmol) in 400 mL of THF was irradiated for 3.5 h. The resulting wine-red soltion was treated with $NaBH_4$ (1 g, 26.3 mmol) and [2.2.2]cryptand (1 g, 2.6 mmol) [6] and then stirred in the dark at 25 °C for 12 h. The resulting brown suspension was filtered through 3 cm of diatomaceous earth, the filtrate was evaporated to dryness at 25 °C and 10^{-2} mbar, and the brown residue was washed with *n*-pentane until the IR spectrum no longer showed the presence of $CpMn(CO)_3$ (2.2 g of $CpMn(CO)_3$ was recovered). The red-brown powder was recrystallized from THF/*n*-pentane at − 30 C. The salts of **4** are air-sensitive to different degrees depending on the cation [17]. Yield: 2.0 g Na(crypt) · **4** (24% based on the amount of $CpMn(CO)_3$ employed, 48% based on the amount recovered). Correct C, H, N analysis; $C_{32}H_{47}Mn_2N_2NaO_{10}$ (752). IR (THF): $\tilde{\nu}_{CO}$ = 1901 (m), 1875 (vs), 1825 (vs), 1810 (m) cm^{-1}. ^{1}H NMR ([D$_6$]acetone, 293 K): δ = 4.18 (s, 10H), 3.65 (m, 24H), 2.71 (t, 12H), − 26.9 (s, br., 1H). UV/VIS (THF): λ_{max} (ε) = 405 (3090) and 508 (800) nm (L mol^{-1} cm^{-1}) [18].

7: Na · **4a** (1 g, 2.5 mmol) [12] was dissolved in 30 mL of THF · $BiCl_3$ (0.9 g, 2.9 mmol) was then added to this solution at 25 °C, resulting in foaming and the formation of a dark precipitate. The suspension was stirred for 30 min at 25 °C and then transferred directly to silylated silica gel. Chromatography on a silica gel column (30 × 1.5 cm, − 20 °C) gave a yellow forerun upon elution with *n*-pentane. Elution with CH_2Cl_2 afforded a long yellow-brown band, which, upon removing the solvent and recrystallizing the residue from 10 mL of CH_2Cl_2 at − 30 °C, gave brown needle-shaped crystals of **7**: Yield: 240 mg of **7** (15% based on $BiCl_3$). IR (CH_2Cl_2): $\tilde{\nu}_{CO}$ = 1908 (vs) and 1864 (s) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 4.38 (m), 4.3 (m) (total 12H), 2.13 (s, 9H).

[18] The given ε values are lower limits owing to the tendency of the compounds to decompose.

Chiral Building Blocks for the Synthesis of Triquinane Sesquiterpenes: Derivatives of 2-Methylbicyclo[3.3.0]octan-3-ol from Catalpol**

By *Klaus Weinges*,* *Helene Iatridou*, *Hans-Georg Stammler*, and *Johannes Weiss*

An increasing number of natural products with angular or linear triquinane carbon frameworks have been isolated in recent years and have encouraged the development of general approaches to their synthesis.[1] Because of the special biological activity often exhibited by triquinane sesquiterpenes, we are interested in synthesizing them in enantiomerically pure form. This goal can be realized by transformation of the ketoenol ether **1**[2a] to chiral compounds that display suitable structural features for the synthesis of triquinane sesquiterpenes. Compound **1** can be prepared in 93% yield from the naturally occurring catalpol according to a published procedure[2b] that has since been improved. Cuprate addition to the enone of silyl ether **2** (Scheme 1) introduces the methyl substituent at C-2, which is characteristic of a series of angular and linear triquinanes.[1]

Ramberg–Bäcklund reaction of **9** resulted in ring contraction[3] to give the pentalene derivative **10**, which was converted into 8-*tert*-butyldimethylsiloxy-2-methylbicyclo[3.3.0]octan-3-ol **11**[4] by stereoselective hydroboration. The two hydroxyl substituents at C-8 and C-3, which were selectively protected in **11** and **13**, respectively, allowed, after oxidation, a variety of alkylation reactions to be carried out at the neighboring C atoms. As in analogous compounds,[1,5] five-membered ring annelation at C1-C2 and C2-C3 gives frameworks of the angular and linear triquinanes, respectively. Furthermore, variation of the substituents at C-7[6a] or C-4[6b] offers a direct route to specific members of this class of compounds.

The C-7 geminal methyl substituents of **15**, which are introduced by a simple methylation reaction, are also found in the carbon skeletons of the antibiotically active (−)-hypnophilin[7] and (−)-coriolin **20**, which, in addition, exhibits antitumor activity.[8] Compound **15** was used to easily prepare (1*R*, 2*R*, 3*R*, 5*R*, 8*R*)-(+)-benzoyloxy-

pands the palette of available products.[2] The cyclotrimerization of alkynes on transition-metal complexes proceeds via bisalkyne complexes, which undergo C–C bond formation to give metallacyclopentadienes.[3] These products can react in two ways with an additional alkyne present in the coordination sphere of the metal: either formal insertion of the alkyne into an M–C bond to give metallacycloheptatrienes or cycloaddition to give metallabicycloheptadienes.[4] Another possibility is the direct Diels-Alder cycloaddition of the alkyne without prior coordination to the metal. This reaction is especially important when strongly activated alkynes are employed.[5]

The cyclocotrimerization of $R_2P{=}S$ cations with alkynes can only be carried out on 3d metals; this reaction is not observed for higher homologues.[6] In the case of manganese, only thiaphosphametallacyclopentadienes and -bicycloheptadienes have so far been observed as intermediates. The latter species have made accessible highly substituted thiophenes, phospholes, and their complexes, which are otherwise difficult to obtain.[2b] We have now succeeded in isolating two further intermediates which are important for understanding the mechanism of this mixed cyclotrimerization.

Reaction of $[BrMn(CO)_5]$ with $R^1_2P(S)H$ in the presence of a base leads to formation of **1**, the first (η^2-diorganothioxophosphorus)manganese complex (Scheme 1); the kinetic stabilization of **1** is due to the bulky cyclohexyl groups on the phosphorus. Smaller substituents (R^1 = Me, Et, Ph) result in immediate dimerization to give $[(OC)_4Mn(\mu\text{-}S{=}PR^1_2)]_2$. These dimers are in equilibrium with the monomers $[(OC)_4Mn(\eta^2\text{-}S{=}PR^1_2)]$, which can be trapped with alkynes.

Reaction of **1** with the acetylene dicarboxylates $R^2C{\equiv}CR^2$ in THF under mild conditions gives initially the manganacyclopentadienes **3a, b**, which then yield the manganabicycloheptadienes **6a, b**.[7] In addition, the P-isomeric metallacyclopentenes **5a, b** and, in lower yield, the P-isomeric metallacycloheptadienes **4a, b** were obtained for the first time. In contrast, **4a, b** precipitate as the main products from hexane solution; in refluxing THF, they rearrange quantitatively with loss of CO to give **6a, b.** Surprisingly, neither **4a, b** nor **6a, b** can be prepared from the P-isomeric metallacyclopentenes **5a, b** and free alkyne.

The metallabicycloheptadienes **6a, b** are thus formed via two parallel routes. Free alkyne inserts into the Mn–P bond of **1** to give **3**, which, in turn, affords **6**. Alternatively, the Mn–S bond of **1** opens—this step has been confirmed for the analogous cobalt complexes by CO addition[8]—and the resulting 16-electron species is stabilized by addition of a donor ligand L. If the coordination site is blocked by a solvent molecule L, only a small amount of **4** is formed, since a [2 + 2 + 2] cycloaddition can only occur after displacement of L by an alkyne. In noncoordinating solvents such as hexane, the 16-electron complex fragment can only be stabilized by the alkyne. Therefore, the reaction occurs much faster and the main product is **4**, which is transformed into **6** upon warming of the THF solution.

Scheme 1. R^1 = cyclohexyl, L = THF, $R^2C{\equiv}CR^2$: **a**, $R^2 = CO_2CH_3$; **b**, $R^2 = CO_2C_2H_5$. The numbering of the ring carbon atoms is for assignment of the NMR signals.

Compounds **1** and **3**–**6** were characterized by complete elemental analyses as well as by mass, IR, and NMR spectra (Table 1). In addition, X-ray crystal structures were obtained for **1** and **4a** (Fig. 1).[9]

Whereas the P–S distance in **1** is in agreement with that of other (η^2-thioxophosphorus)metal complexes,[6, 8, 10] it is considerably longer in **4a** owing to the Mn–P–S–C arrangement. The seven-membered ring of **4a** exists in boat conformation; its folding is determined by the orientation of the three planes Mn-P-C5, P-S-C5-C6 (± 14 pm), and S-C6-C7-

Experimental Procedure

1: $R^1_2P(S)H$ and $N(C_2H_5)(i\text{-}C_3H_7)_2$ (3.0 mmol each) in 50 mL of diisopropyl ether were added dropwise to a solution of $[BrMn(CO)_5]$ in 50 mL of diisopropyl ether at 60 °C. After stirring for 1 h, the solvent was removed in vacuo. The residue was suspended in 10 mL of methanol, filtered off (P4), and washed with methanol. Yield: 1.01 g (85%).

4: $R^2C{\equiv}CR^2$ (2.0 mmol) was added to a solution of **1** (0.5 mmol) in 25 mL of hexane and the resulting solution was stirred for 12 h. The precipitate was filtered off (P4), washed with hexane, and dissolved in ether. Addition of hexane resulted in precipitation of **4.** Yield: 0.238 g (70%) **4a**; 0.213 g (58%) **4b.**

3a–6a: $H_3CO_2C{\equiv}CCO_2CH_3$ (4.0 mmol) was added to a solution of **1** (1.0 mmol) in 50 mL of THF and the resulting mixture was stirred at 25 °C for 4 d. The solvent was then removed in vacuo and the crude product was purified by medium-pressure column chromatography (Merck-Lobar-Fertigsäule Gr. B LiChroprep Si 60, 40–63 μm) with petroleum ether (60–90 °C)/ethyl acetate (10/1) as eluent (cf. R_f values in Table 1). Yields: 69 mg (13%) **3a**; 27 mg (4%) **4a**; 102 mg (19%) **5a**; 182 mg (28%) **6a**.

Discovery of a D-Stereospecific Aminopeptidase and Its Use as a Catalyst in Organic Synthesis

By *Yasuhisa Asano,* Akiko Nakazawa, Yasuo Kato,* and *Kiyosi Kondo*

Enzymatic reaction has increasingly been applied to organic synthesis.[1] Several attempts have recently been reported on the in vitro synthesis of D-amino-acid–containing peptides and amides.[2] Naturally, however, these enzymatic reactions have the inevitable drawback that they are not stereospecific for substrates with D-configurations. To the best of our knowledge, there has been no report of an aminopeptidase catalyzing the stereospecific hydrolysis of D-amino-acid–containing peptides,[3] although such peptides do exist in nature.[4]

An enrichment culture technique was used for the selection of a desirable microorganism and resulted in the isolation of *Achromobacter* sp. SCRC C1-38 from a soil sample. The enzyme hydrolyzing D-alanine amide was purified about 2800-fold with a 17% yield from a cell-free extract of the bacterium. The molecular weight of the native enzyme was estimated to be approximately 122 000, with two identical subunits having molecular weights of about 59 000. Figure 1 shows a typical course of D-stereospecific hydrolysis of D,L-alanine amide to yield D-alanine. The rate of the hydrolysis

Nishi-Ohnuma 4-4-1 Sagamihara, Kanagawa 229 (Japan)

of L-alanine amide was less than 0.01% that of D-alanine amide. The identity of the D-alanine thus formed was confirmed by its isolation (correct elemental analysis: $[\alpha]_D^{20}$ −14.15 (c = 6.6, 1 N HCl)). Substrates of the enzyme included D-alanine amide (relative velocity, 100%: K_m value, 0.65 mM), glycine amide (44%, 22.3 mM), D-α-aminobutyric acid amide (30%, 18.3 mM), D-serine amide (29%, 27.0 mM), D-alanine 3-aminopentane amide (32%, 2.27 mM), D-alanine *p*-nitroanilide (96%, 0.51 mM), D-alanine methyl ester (75%), the dimer (21%, 10.2 mM), trimer (92%, 0.57 mM), and tetramer (89%, 0.32 mM) of D-alanine, D-alanylglycine (95%, 0.98 mM), D-alanylglycylglycine (45%, 0.37 mM), and D-alanyl-L-alanyl-L-alanine (100%, 0.65 mM). These results show that the enzyme has higher affinity toward peptide substrates than toward amino acid amides. The enzyme showed neither endopeptidase nor carboxypeptidase activity. When the release of amino acids from D-alanylglycylglycine was followed with time, the enzyme exhibited a mode of action typical of aminopeptidases (EC 3.4.11).[5] The effect of various compounds and metal ions on the enzyme activity indicated that the enzyme is a thiol-peptidase. Thus, we tentatively named the enzyme as "D-alanine aminopeptidase".

For enzyme-catalyzed D-stereospecific aminolysis of amino acid esters, the enzyme was immobilized by urethane prepolymer PU-6[7] and was incubated in water-saturated organic solvents (benzene, butyl acetate, 1,1,1-trichloroethane; Table 1). D-Alanine 3-aminopentane amide was quantitatively synthesized from D-alanine methyl ester and 3-aminopentane in 1 h. The catalytic activity (k_{cat}) was calculated to be as high as 7700 min^{-1}, which is several hundred to ten thousand times greater than those in α-chymotrypsin-[2a] or subtilisin[2b]-catalyzed peptide syntheses, respectively. D-Alanine 3-aminopentane amide was synthesized in 46% yield from D,L-alanine methyl ester, while no product was formed from L-alanine methyl ester. The aminolysis reaction also progressed well with D-alanine amide. The substrate specificity for the acyl donor part in this aminolysis reaction was reflected in the hydrolytic reaction. However, the substrate specificity for the nucleophile part differed: no formation of D-alanine polymer was observed when D-alanine methyl ester alone was incubated with the immobilized enzyme, but D-alanine *N*-alkylamides of *n*-butylamine, benzylamine, and neopentylamine could be synthesized in high yields.

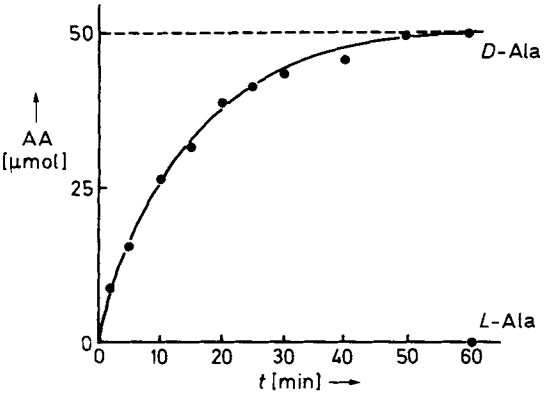

Fig. 1. Kinetic resolution of D,L-alanine amide by *Achromobacter* D-alanine aminopeptidase. *Achromobacter* sp. SCRC C1-38 was cultivated aerobically at 190 °C for 18 h in a TGY medium [8]. The enzyme was purified from cells (about 190 g wet weight) from 20 liters of culture by a procedure involving protamine sulfate treatment, ammonium sulfate fractionation, column chromatography on DEAE-Toyopearl and Butyl-Toyopearl, and gel filtration on Sephadex G-200. The activity of D-alanine aminopeptidase was routinely assayed at 30 °C by measuring the production of D-alanine from D-alanine amide, and D-alanine was determined with D-amino acid oxidase [9]. One unit of enzyme activity was defined as the amount of enzyme that catalyzed the formation of 1 μmol of D-alanine per minute. The enzyme was judged to be homogeneous based on the results of native and SDS-polyacrylamide gel electrophoresis, HPLC on a TSK Gel G-3000 SW column, and isoelectric focusing (pI = 4.2), since all of the results gave a single band or a single peak. The specific activity of the homogeneous enzyme was 596 units mg^{-1} at 30 °C and pH 8.0 with D-alanine amide as the substrate. A reaction mixture containing 0.5 mmol Tris hydrochloride (pH 8.0), 0.1 mmol D,L-alanine amide hydrochloride, and 5 units of the purified enzyme in a total volume of 5.0 mL was incubated at 30 °C. The content of L-alanine was measured with L-alanine dehydrogenase. AA = amount of amino acid.

Table 1. Aminolysis of alanine methyl ester with 3-aminopentane catalyzed by *Achromobacter* D-alanine aminopeptidase [a].

Acyl donor	Solvent	Yield [%] [b]
D-alanine methyl ester HCl	butyl acetate	98

L-alanine methyl ester HCl	butyl acetate	0
D-alanine methyl ester HCl	benzene	98
D-alanine methyl ester HCl	trichloroethane	91
D-alanine methyl ester HCl	toluene	67

[a] A reaction mixture containing PU-6-immobilized D-alanine aminopeptidase (7.5 units of partially purified enzyme of 210 units mg^{-1}), 0.1 mmol of alanine methyl ester hydrochloride, and 0.5 mmol of 3-aminopentane in water-saturated organic solvent (1 mL) was incubated at 30 °C for 1 h. [b] The yield was calibrated with chemically synthesized authentic products with ninhydrin.

The discovery of this new D-alanine aminopeptidase could bring about a new methodology in the kinetic resolution of amino acid amides, as well as in the formation of peptide bonds between racemic amino acid esters to yield D-amino acid *N*-alkylamides,[7] with extremely high D stereoselectivities.

Selenium-Catalyzed Synthesis of *S*-Alkyl Thiocarbamates from Amines, Carbon Monoxide, Sulfur, and Alkyl Halides

By *Noboru Sonoda,* Takumi Mizuno, Sinkichi Murakami, Kiyoshi Kondo, Akiya Ogawa, Ilhyong Ryu,* and *Nobuaki Kambe*

Development of synthetic reactions utilizing the characteristics of heteroatoms is of great importance. In particular, organoselenium chemistry and its synthetic applications have been growing quite rapidly.[1, 2] About ten years ago, we found a convenient method for preparing carbonyl selenide **2** by acid decomposition of amine salts of selenocarbamates (**1**) [Eq. (a)], readily available by reaction of elemental selenium with carbon monoxide and a secondary amine under mild conditions [Eq. (b)].[3]

$$\underset{\mathbf{1}}{[R^1R^2NH_2]^{\oplus}\,[R^1R^2NC(=O)Se]^{\ominus}} \xrightarrow{+\,H^{\oplus},\ -78\,^{\circ}C} Se{=}C{=}O + 2\,R^1R^2NH_2^{\oplus} \qquad (a)$$

$$\underset{\mathbf{2}}{}$$

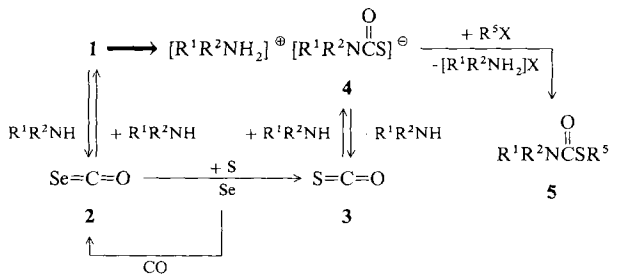
$$2\,R^1R^2NH + CO + Se \xrightarrow{20\,^{\circ}C,\ 1\ atm} \mathbf{1} \qquad (b)$$

This has enabled us to examine the properties and reactivity of **2**.[4, 5] Thus, we have discovered a facile exchange reaction of **2** with elemental sulfur [Eq. (c)]. Treatment of **2**

$$\underset{\mathbf{2}}{Se{=}C{=}O} + S \xrightarrow[-45\,^{\circ}C]{Et_3N,\ THF} \underset{\mathbf{3}}{S{=}C{=}O} + Se \qquad (c)$$

(535 mg, 5 mmol) in 5.0 mL of THF with a THF solution (5.0 mL) of elemental sulfur (160 mg, 5 mmol) and triethylamine (0.14 mL, 1 mmol)[6] over the range of -45 to 5 °C for 1 h gave carbonyl sulfide **3** (88% yield)[7] and metallic selenium.

We also observed that amine salts of selenocarbamates **1** can react with secondary amines to give a mixture of both amine salts **1** and **1'**,[8] suggesting an equilibrium with **2** as intermediate [Eq. (d)].[9] This finding and exchange reaction



$$\begin{array}{l} \xrightarrow{-\,R^1R^2NH} \\ \xleftarrow{+\,R^1R^2NH} \end{array} [R^1R^2NH_2]^{\oplus}\,[R^1R^2NC(=O)Se]^{\ominus} \quad \mathbf{1}$$

$$\mathbf{2} \qquad (d)$$

$$\begin{array}{l} \xrightarrow{+\,R^3R^4NH} \\ \xleftarrow{-\,R^3R^4NH} \end{array} [R^3R^4NH_2]^{\oplus}\,[R^3R^4NC(=O)Se]^{\ominus} \quad \mathbf{1'}$$

(c) led us to develop a new selenium-catalyzed synthesis of thiocarbamates **4** from elemental sulfur, carbon monoxide, and amines under mild conditions[10–12] (Scheme 1).

The reaction of elemental sulfur (20 mmol) with carbon monoxide (1 atm) and diethylamine (50 mmol) at ambient temperature *in the presence of a catalytic amount of selenium (10 mol%)*[14] proceeded smoothly, accompanied by carbon monoxide uptake to yield **4** ($R^1 = R^2 = Et$). Treatment of the product with methyl iodide gave *S*-methyl *N,N*-diethylthiocarbamate **5a** ($R^1 = R^2 = Et$, $R^5 = Me$) in 79

Scheme 1. Synthesis of **4** by Se–S exchange.

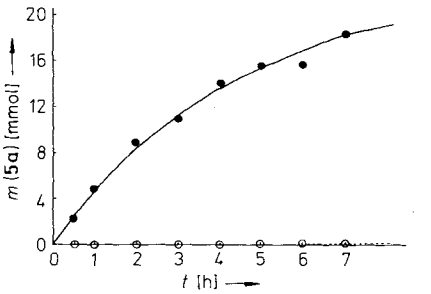


Fig. 1. Yields of **5a** versus reaction time t in the presence and absence of selenium catalyst. The solid line indicates yields of **5a** in the reaction of diethylamine (50 mmol) with carbon monoxide (1 atm) and sulfur (20 mmol) in the presence of selenium (10 mol%) at 30 °C; the dotted line shows the yields obtained without catalyst.

Table 1. Results of selenium-catalyzed synthesis of *S*-alkyl thiocarbamates **5a–i** by the route shown in Scheme 1.

Compound	R^1	R^2	R^5X	Yield [%]
5a	Et	Et	MeI	79
5b	Et	Et	$PhCH_2Br$	100
5c	Et	Et	4-Cl-C_6H_4-CH_2Cl	90
5d	*n*Pr	*n*Pr	MeI	87
5e	*n*Pr	*n*Pr	EtI	82
5f	*n*Bu	*n*Bu	MeI	87
5g	$-(CH_2)_5-$		MeI	92
5h	*n*Bu	H	MeI	69
5i	Ph	H [a]	MeI	41

[a] Triethylamine (50 mmol) and prolonged reaction time (20 h) were required.

(91)% isolated (GLC) yield. Use of a smaller amount of selenium (2.5 mol%) was also effective with prolonged reaction time (20 h) to give **5a** without decrease in the yield (85%). The yields of **5a** versus reaction time in both the presence and absence of selenium catalyst are given in Figure 1, which clearly shows the excellent catalytic activity of selenium.

A variety of *S*-alkyl thiocarbamates (**5b–i**), including the important agrochemicals **5c** and **5e**,[15] were prepared in good to excellent yields under similar reaction conditions (Table 1).

Experimental Procedure

5a: Elemental sulfur (0.32 g, 10 mmol) and selenium (79 mg, 1 mmol) were added to a THF solution (20 mL) of diethylamine (2.1 mL, 20 mmol), and the solution was vigorously stirred at 30 °C for 7 h under carbon monoxide (1 atm). After evacuation of carbon monoxide, sulfur (32 mg, 1 mmol) was added to the resulting transparent yellow solution, thereby resulting in the precipitation of metallic selenium [19]. Methyl iodide (1.0 mL, 16 mmol) was then added at 0 °C, and the mixture was stirred at room temperature for 2 h. Removal of the selenium-containing precipitate, followed by evaporation and distillation, gave **5a** in 79% yield (1.16 g) as a colorless oil; b.p. = 112 °C/14 torr (in [11a] 132.5–133.0 °C/87 torr); IR (neat): $\tilde{\nu} = 1645\ cm^{-1}$ (C=O); ^1H NMR ($CDCl_3$): $\delta = 1.17$ (t, $J = 7.1$ Hz, 6H), 2.31 (s, 3H), 3.38 (q, $J = 7.1$ Hz, 4H); MS: m/z 147 ($M^{\oplus}$). Correct C, H, N, S analysis.

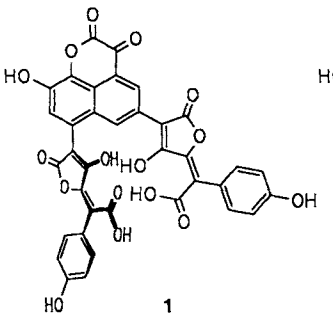
[4] For the reaction of **2** with amines, see: K. Kondo, S. Yokoyama, N. Miyoshi, S. Murai, N. Sonoda, *Angew. Chem. 91* (1979) 761; *Angew. Chem. Int. Ed. Engl. 18* (1979) 692.
[5] Compound **2** can be stored at $-30\,^{\circ}C$ in THF solution under acidic conditions for a few months and then gradually decomposes to carbon monoxide and selenium.
[6] In the absence of triethylamine, this Se–S exchange reaction was quite slow. A possible pathway is given by Equation (e).

$$2 + {}^{\ominus}S{-}S_x{-}\overset{\oplus}{N}R_3 \longrightarrow {}^{\ominus}Se{-}C{=}O \longrightarrow S{=}C{=}O + {}^{\ominus}Se{-}S_x{-}\overset{\oplus}{N}R_3 \qquad (e)$$

$$R_3\overset{\oplus}{N}{-}S_{x-1}{-}S \qquad \mathbf{3}$$



[7] Generated **3** was introduced into a THF solution of diethylamine at $-90\,^{\circ}C$, and the solution was stirred for 1 h at below $-20\,^{\circ}C$. The **4** ($R^1 = R^2 = Et$) thereby formed was esterified by methyl iodide to give **5a**. The yield of **3** was determined by GLC analysis of **5a** (88%).
[8] A THF solution of **1** ($R^1 = R^2 = Et$), prepared by reaction of diethylamine (5 mmol) and selenium (1 mmol) with carbon monoxide, and di-*n*-propylamine (5 mmol) was stirred at $20\,^{\circ}C$ for 30 min. Quenching the reaction mixture with methyl iodide (15 mmol) gave a 46:54 mixture of *Se*-methyl *N,N*-diethylselenocarbamate **6a** and *Se*-methyl *N,N*-di-*n*-propylselenocarbamate **6b**. A similar reaction of **1**, $R^1 = R^2 = n$-propyl, with diethylamine gave a 48:52 mixture of **6a** and **6b**. These results strongly suggest that an equilibrium, as shown in Equation (d) is set up.
[9] A direct nucleophilic attack of amine at the carbonyl carbon of **1** is not likely because of the steric hindrance of the alkyl group: see K. Kondo, N. Sonoda, K. Yoshida, M. Koishi, S. Tsutsumi, *Chem. Lett. 1972*, 401.
[10] Direct reaction of amines with elemental sulfur and carbon monoxide requires severe conditions (90–120 °C, 13–27 atm CO, 60–62%); see D. W. Grisley, Jr., J. A. Stephens, *J. Org. Chem. 26* (1961) 3568.
[11] For other preparative methods for *S*-alkyl thiocarbamates **5**, see a) H. Tilles, *J. Am. Chem. Soc. 81* (1959) 714; b) H. Eilingsfeld, L. Möbius, *Chem. Ber. 98* (1965) 1293; c) K. Akiba, N. Inamoto, *J. Chem. Soc. Chem. Commun. 1973*, 13; d) R. Riemschneider, *J. Am. Soc. Chem. 78* (1956) 844.
[12] The selenium-catalyzed synthesis of *S*-alkyl thiocarbamates **5** from primary amines, carbon monoxide, and organic disulfides has been reported by *P. Koch* [13].
[13] P. Koch, *Tetrahedron Lett. 1975*, 2087.
[14] The reaction without selenium catalyst under similar conditions was very sluggish and gave only a trace amount of **5a**.
[15] Compound **5c** (Benthiocarb) is an important herbicide for rice crops and is produced industrially on a large scale [16, 17]; **5e** (EPTC) possesses outstanding effectiveness and selectivity for control of annual grasses and many broadleaved weeds [11a, 18].
[16] W. Chin-Hsien, *Synthesis 1981*, 622.

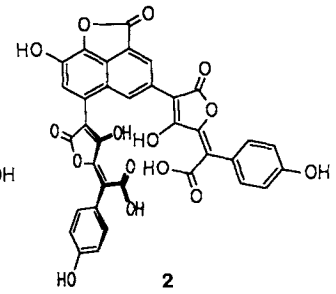
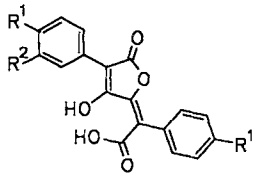
[18] H. J. Sanders, *Chem. Eng. News 59* (1981) No. 31, p. 20.
[19] Compound **1**, $R^1 = R^2 = Et$, was completely decomposed by addition of elemental sulfur, and metallic selenium was recovered. GLC analysis after addition of MeI showed that the product **5a** was pure; *Se*-methyl *N,N*-diethylselenocarbamate **6a** was not detected (< 0.01%).

Complexation of Cesium 137 by the Cap Pigments of the Bay Boletus (*Xerocomus badius*)



By *Dieter C. Aumann, Gabriele Clooth, Bert Steffan,* and *Wolfgang Steglich**

Investigations of the amount of radionuclides present in fungi after the reactor accident at Chernobyl have repeatedly shown high amounts of cesium 137 in the bay boletus (*Xerocomus badius*).[1–4] By contrast, cepe (*Boletus edulis*), a closely related edible mushroom, concentrates this radionuclide to only a small extent.



We reported earlier that the brown pileus of the bay boletus contains the unusual pulvinic acid derivatives badione A **1** and norbadione A **2**, which are absent in cepe.[5] Since **1** and **2** are present in the fungus as potassium complexes,[5–7] we examined whether these pigments play a role in the concentration of ^{137}Cs by bay boletus.

1

2

	R^1	R^2
3a	OH	H
3b	OH	OH
3c	H	H

To this end, the brown pileus of fresh bay boletus[8] was peeled off and, like the rest of the fungus, measured in a gamma spectrometer[9] (Table 1). The ratio of the specific activities gives an enrichment factor of 3.4 for ^{137}Cs in the pileus.[3] An analogous experiment with cepe gave an enrichment factor of only 0.6.

The weight ratio of pileus pigment to the rest of the fungus is very difficult to determine precisely by peeling the fruiting body. In a further experiment, therefore, the outsides of the pilei of three fresh bay boleti were carefully washed with dimethyl sulfoxide (DMSO), resulting in nearly complete dissolution of the pigment. Chromatographic purification on Sephadex LH-20 (eluant: methanol containing 5% DMSO) afforded 12 mg of a mixture of complexes **1** and **2** (according to NMR spectroscopy), which was measured in the gamma spectrometer. An enrichment factor of 87 ± 10 for ^{137}Cs in the pileus pigments was derived from the specific activity of the pigments ($11\,316 \pm 1184$ Bq/kg) and that of the "washed" fungi (130 ± 7 Bq/kg fresh weight). Interestingly, an even larger enrichment factor (138 ± 18) was obtained for the "normal" complexing metal ^{40}K.[10] This is also revealed by a comparison of the X-ray emission spectra of the pileus and the isolated pigment complex (Fig. 1).[6]

The binding of cesium to norbadione **2** is corroborated by an independent experiment using a standard solution of

Table 1. Enrichment of ^{137}Cs in the pileus of bay boletus.

	Activity: pileus A_p [Bq/kg] [a]	Activity: fruiting body A_f [Bq/kg] [a]	Enrichment factor A_p/A_f
X. badius	340 ± 50	100 ± 20	3.4 ± 0.8
B. edulis	53 ± 7	87 ± 12	0.6 ± 0.1
B. erythropus	23 ± 10	8.8 ± 3.3	2.6 ± 1.5

[a] Based on fresh weight: collected near Bonn in September 1987.

^{137}CsCl (31 Bq/100 μL). Assuming that cesium chloride is bound by **2** in a molar ratio of 1:1, 100 μL of this solution corresponds to approximately 5 mg of **2**. When 100 μL of this solution is treated with 2.5 mg of **2** and the reaction mixture is separated by column chromatography on Sephadex LH-20 (eluant: MeOH), a forerun containing 15 ± 1.7 Bq and a norbadione fraction containing 14.5 ± 1.5 Bq are obtained. The column retains 0.1 Bq. After filtration of the norbadione fraction through a column containing the cationic exchange resin Dowex 50-W X4, the radioactivity of the eluate is below the limits of detection, whereas the exchange resin now contains all the radioactivity. Thus, norbadione forms a 1:1 complex with cesium chloride,[11] which undergoes decomposition upon exposure to the strongly acidic cation exchanger.

In addition to **1** and **2**, simple pulvinic acids such as atromentic acid **3a** and xerocomic acid **3b**[12] may be responsible for binding cesium in fungi. When the complexation experiments described above are carried out with **3a** followed by chromatography on Sephadex LH-20, half of the radioactivity is found in the atromentic acid fraction. The same holds for methyl atromentate. On the other hand, the permethyl derivative of atromentic acid displays no binding of cesium chloride. When a molar equivalent of the ^{137}CsCl standard solution is added to a mixture containing molar equivalents of **2** and **3a**, all the radioactivity is found in the norbadione fraction after chromatography on Sephadex LH-20. Thus, norbadione is a much better ligand for cesium compared with simple pulvinic acids.[13] We ascribe this to the presence of two pulvinic acid chains in **1** and **2**, which, according to models, offer good spatial prerequisites for the complexation of a potassium or cesium ion. The detailed structure of the complexes, as well as the determination of the complexation constants, is the goal of further investigations.

Other mushrooms that contain pigments of the badione or norbadione type in their pilei[14] can also strongly concentrate ^{137}Cs. An example is *Boletus erythropus*,[5] which exhibits an enrichment factor of 2.6 ± 1.5 (Table 1). Surprisingly, the pileus of the American boletus *Boletus mirabilis* collected on Vancouver Island in September 1987 contains twice as much ^{137}Cs as the bay boletus fungi collected near Bonn, although no significant fall-out from Chernobyl was recorded in western Canada. Since *B. mirabilis* shows high values for ^{137}Cs and particularly low values for ^{134}Cs, the contamination in this case must have occurred earlier.[15] In an older sample of *B. erythropus* (Bonn, 1982), the amount of ^{134}Cs was below the limits of detection.

The results presented here show that bay boletus and *B. erythropus*, in contrast to cepe, contain pileus pigments that bind potassium and cesium ions absorbed from the environment by the mycelia and transported to the fruiting body. These findings explain the different enrichment factors found for these fungi.

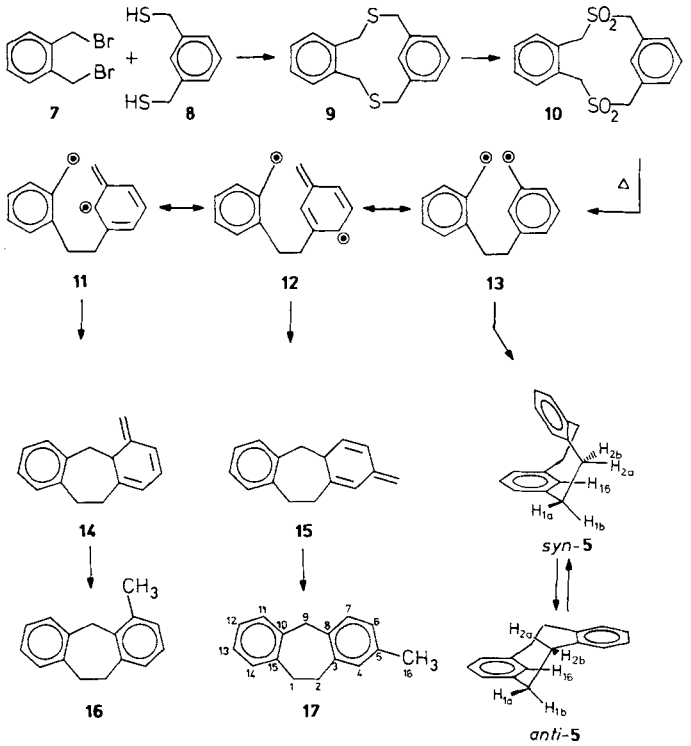
syn- and *anti*-[2.2]Orthometacyclophane **

By *Graham Bodwell, Ludger Ernst, Matthias W. Haenel,* and *Henning Hopf**

Dedicated to Professor D. J. Cram on the occasion of his 70th birthday



In [2.2]orthocyclophane **1** (tetrahydrodibenzocyclooctene) as well as in [2.2]meta- **2** and [2.2]paracyclophane **3**, the two ethano bridges connect equivalent positions of the two benzene rings. These hydrocarbons have long been known and their chemical and spectroscopic properties have been well investigated.[1] In addition to these three isomers, however, three other [2.2]cyclophanes are conceivable, whose bridges link nonequivalent carbon atoms of the benzene rings. Whereas [2.2]metaparacyclophane **4** was prepared long ago by Lewis acid–catalyzed rearrangement of **3**,[2] the synthesis of [2.2]orthoparacyclophane **6** has not yet been achieved. The route to [2,2]orthometacyclophane **5**[3] described here extends the series of available "unsymmetrical cyclophanes".[4]

1 **2** **3** **4** **5** **6**

The synthesis follows conventional routes of paracyclophane chemistry (Scheme 1).[1] Addition of a dilute solution of **7** and **8** in a 1:1 ratio in benzene to a dilute, vigorously stirred solution of sodium hydroxide (ethanol:water 4:1) afforded the dithiacyclophane **9** in 79% yield.[5] Oxidation of **9** with 30% hydrogen peroxide in the presence of 1% acetic acid yielded the expected bissulfone **10** (93%).[5]

Sulfone pyrolysis[6] at 535 °C and 10^{-2} torr gave, after column chromatography (silica gel, dichloromethane:ethyl acetate 1:1), a yellow oil (71%), which did not crystallize even after addition of pentane. Whereas the thin layer chromatogram showed only one spot, the 400-MHz ^{1}H NMR spectrum revealed that at least three products had been formed in the reaction. Although it was possible to separate analytical amounts of the product mixture by HPLC (RP-8, 7 μm, 10 × 250 mm), attempts to carry out separations on a preparative scale, as well as gas-chromatographic separation on XE-60 (strong decomposition at 180–260 °C), were

Scheme 1.

unsuccessful. Only the use of SE-30 as stationary phase (column temperature 180 °C) brought success; two fractions were obtained. The first fraction (16% of the product) contained the desired [2](1,2)[2](1,3)cyclophane **5** as a *syn*/*anti* mixture (ratio ca. 4:1),[5] as shown, in particular, by the NMR spectra (Table 1). In both isomers, the aromatic protons give rise to an AA'BB' pattern for the *ortho*-disubstituted benzene moiety and an A_2MX pattern for the *meta*-disubstituted moiety. The chemical shifts of *syn*-**5** and *anti*-**5** are characteristically different.

Except for 16-H, all aromatic protons in *syn*-**5** are more strongly shielded ($\Delta\delta$ between -0.4 and -0.7) than the corresponding protons in *anti*-**5**. This is due to the magnetic anisotropy of the opposite benzene ring.[9] However, since the rings in *syn*-**5** are not parallel to each other but rather mutually inclined (see below), 16-H lies in the deshielding region of the *ortho*-substituted ring ($\Delta\delta = +0.71$). Whereas the intraannular aromatic protons are strongly shielded in *anti*-[2.2]metacyclophanes (see **2**),[10] this is not observed in *anti*-**5**, since the aromatic rings of *anti*-**5** do not lie over each other as much as they do for double *meta* bridging.

The bridge protons in *syn*-**5** give a first-order spectrum, whose coupling constants are in good agreement with the values calculated for the torsional angles obtained from force-field calculations (MMX87[11]) (Table 1).[12] The ^{1}H NMR signals of the bridges of *anti*-**5** could not be analyzed in detail, since three of the four protons have very similar shifts according to C,H-COSY and their signals are partially overlapped by those of the main component. Striking is the strong upfield shift of 2-H_a, which extends far into the shielding region of the *meta*-substituted ring. When the measuring temperature is raised to over 100 °C (solvent: [D_6]DMSO), the ^{1}H NMR signals of the isomers of **5** are increasingly broadened; however, no coalescence of the signals is observed up to the maximum attainable temperature of 150 °C. Since the smallest frequency difference between corresponding protons is 200 Hz, the interconversion barrier (ΔG^*) must be greater than 20 kcal mol^{-1} at 150 °C. Presumably, however, the value is below 24 kcal mol^{-1}, so that

[a] 400 MHz, $CDCl_3$/TMS; $\delta(^{13}C)$ values relative to $CDCl_3$, $\delta = 77.05$. Assignments by 2D techniques [7] (H,H-COSY and its variant for long-range couplings, C,H-COSY and C,H-COLOC) and by a selective $^{13}C\{^{1}H\}$ NOE experiment [8]. [b] Calculated according to [12] using the torsional angle θ from our MMX87 calculation [11].

it does not appear reasonable to attempt a separation of the isomers at room temperature. For the "mononuclear" (3*Z*)-3,4-didehydro[6]metacyclophane, ΔG^{*} was found to be 16.5 kcal mol^{-1} for flipping of the bridge from one side of the ring to the other.[13] Thus, the replacement of the rigid *ortho*-phenylene unit of **5** by the more flexible *cis*-ethylene unit considerably facilitates the conformational transformation.

Particularly noteworthy in the ^{13}C NMR spectrum is the deshielding of C-16 in *syn*-**5** relative to the *anti* isomer. Such deshielding has also been found for C-8 in *anti*-**2**,[14] for C-11 in [5]metacyclophane,[15a] and, to a lesser extent, for C-12 in [6]metacyclophane;[15b] in the latter two compounds, the deshielding correlates with the degree of nonplanarity of the aromatic ring.[15a] Our data do not fit this picture, since we observed no deshielding of C-16 in *anti*-**5**, even though the geometries of the *meta*-substituted rings of *syn*- and *anti*-**5** are calculated to be practically identical. According to the MMX87 calculations, in both isomers C-16 is bent by 14° and C-13 by 6° toward the *exo* side from the plane formed by C-11, C-12, C-14, and C-15. To reduce the strain, the bonds C1-C2, C2-C3, and C3-C8 are lengthened, the angles C1-C2-C3 and C2-C3-C8 in the "*ortho* half" of the molecule increased, and the angles C2-C1-C15 and C1-C15-C16 in the "*meta* half" decreased compared with the normal values. The *ortho*-substituted rings are practically planar and form an angle of 54° (*syn*-**5**) and 5° (*anti*-**5**) with the plane C11-C12-C14-C15 of the *meta*-substituted ring.[16] A very small distance of 2.1 Å was calculated for the separation of 16-H and 2-H_b in *syn*-**5**. Indeed, 2-H_b does show a large nuclear Overhauser effect (16%) when the resonance of 16-H is saturated, although the geminal 2-H_a strongly competes with 16-H in the dipolar relaxation of 2-H_b. In accord with the NMR finding that *syn*-**5** predominates at equilibrium, a lower strain energy is calculated for *syn*-**5** compared with *anti*-**5** ($\Delta H = -1.75$ kcal mol^{-1}); however, this should be treated as only a rough value.

The main fraction consisted of a mixture of dibenzoannelated cycloheptadienes **16** (4%) and **17** (77%), as shown, in particular, by the NMR spectra.[5, 17] The formation of the isomeric hydrocarbons **16, 17,** and **5** can be explained most simply as proceeding via the diradicals **11**–**13**. Whereas C–C bond formation in **13** directly gives *syn*- and *anti*-**5**, compounds **16** and **17** must have been formed via **14** and **15**, respectively. Examples of the required hydrogen shift are known from the literature.[18]

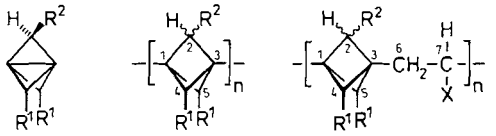
2-Pentyltricyclo[1.1.1.0^{1,3}]pentane and Its Homopolymer, a Soluble Poly([1.1.1]propellane)**



By *Klaus Opitz* and *Arnulf-Dieter Schlüter**

The [1.1.1]propellanes **1a,b** are interesting and versatile building blocks for the synthesis of homo- and copolymers

[*] Dr. A.-D. Schlüter, K. Opitz

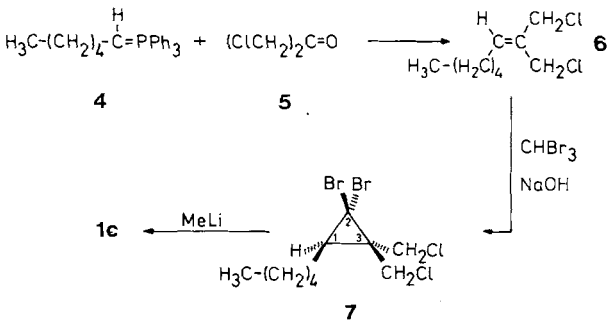
[**] We thank Prof. Dr. *G. Wegner*, Mainz, for support of this work.

having novel structures.[1] The homopolymers **2a,b**[1a-e] and the alternating 1:1 copolymers **3a,b**[1c,f] have been obtained, in some cases with high molecular weights, by both anionically initiated and spontaneous polymerization. They have a common structural feature, the highly strained bicyclo[1.1.1]pentane unit. The poly([1.1.1]propellanes) **2a,b** are rigid rods, which explains their failure to dissolve or melt, even for low degrees of polymerization ($\bar{P}_n$).



1 **2** **3**

a, $R^1=H, R^2=H$; **b**, $R^1,R^1=-(CH_2)_3-$, $R^2=H$; **c**, $R^1=H, R^2=(CH_2)_4-CH_3$

Macromolecules with rigid main chains are of theoretical and practical interest,[2] because of their tendency toward self-organization in solution on the one hand and their material properties (rigidity, tensile strength) on the other. The synthesis of soluble poly([1.1.1]propellanes) is important for the investigation and exploitation of these features. We describe here a simple synthesis of 2-pentyltricyclo[1.1.1.$0^{1,3}$]pentane **1c**[3,4] on a 5-g scale as well as its anionically initiated polymerization.[5]

We synthesized the propellane **1c** in analogy to the route used by *Szeimies* et al. to prepare the unsubstituted [1.1.1]propellane **1a**.[6] Reaction of the ylide **4**[7] with 1,3-dichloroacetone **5** yielded the olefin **6**, which, in turn, smoothly gave the dibromocarbene adduct **7**. Reaction of **7** with methyllithium afforded, after recondensation under high vacuum, compound **1c** as a solvent-free, colorless and distillable (b.p. 72 °C/12 torr, partial decomposition) liquid (20–25% based on **5**). NMR spectroscopic data for the compounds **1c**, **6**, and **7** are given in Table 1. The IR spectrum of **1c** displays a very intense absorption band at $\nu = 610\ cm^{-1}$, which is typical of small-ring propellanes;[8] exposure of **1c** to air leads to immediate disappearance of this band.

Treatment of **1c** with a small amount of a solution of *tert*-butyllithium in pentane results in an appreciable increase in viscosity. After standard workup (precipitation from toluene by addition of methanol, lyophilizing with benzene), the poly([1.1.1]propellane) **2c** was obtained as a colorless, fibrous material, along with unreacted starting material and oligomers. Polymer **2c** is soluble in toluene, as well as in chloroform, tetrahydrofuran, and petroleum ether (weight ratio **1c**:oligomer:**2c** = 1:1.3:2).

The structural assignment of the polymer **2c** is based mainly on its ^{13}C NMR spectrum (Table 1). This shows four

Table 1. ^1H ($CDCl_3$, 300 MHz) und ^{13}C NMR data ($CDCl_3$, 75 MHz) for **1c**, **2c**, **3c**, **6**, und **7**.

1c: ^1H NMR: $\delta = 2.60$ (m, 1H), 2.50 (m, 1H), 2.17 (m, 1H), 1.76 (m, 2H), 1.40–1.20 (m, 8H), 0.88 (m, 3H). ^{13}C NMR: $\delta = 91.17$ (C-2), 71.94 (C-4 or C-5), 69.24 (C-5 or C-4), 31.40, 29.29, 24.21, 22.47 (4 CH_2), 13.95 (CH_3), 5.26 (C-1,3)

2c: ^1H NMR (broad, unstructured signals, not baseline separated): $\delta = 2.12$, 1.87, 1.66, 1.55–1.05, 0.91, 0.78 (*t*Bu end group). ^{13}C NMR: $\delta = 61.7$ (C-2), 48.7 (C-4 or C-5), 44.3 (C-5 or C-4), 41.6 (C-1,3), 32.5, 29.8 (2 CH_2), 26.5 (*t*Bu end group; very low intensity) 25.3, 22.7 (2 CH_2), 14.1 (CH_3)

3c (X = CN): ^1H NMR (broad, unstructured signals, not baseline separated): $\delta = 2.46$, 2.12, 2.01, 1.88–1.15, 0.89 (CH_3). ^{13}C NMR: $\delta = 119.8$ (CN), 60.5 (very broad, C-4,5), 41.5 (C-1 or C-3), 40.4 (C-3 or C-1), 32.2 (CH_2), 29.5 (very broad, C-2), 48.5 (very broad, C-4 or C-5), 45.0 (very broad, C-4 or C-5), 28.9, 24.2, 22.5 (3 CH_2), 14.0 (CH_3)

6: ^1H NMR: $\delta = 5.75$ (t, 1H; 3-H), 4.22 (s, 2H; CH_2Cl), 4.18 (s, 2H; CH_2CL), 2.13 (dt, 2H; 4-H), 1.45–1.25 (m, 6H; 5-, 6-, 7-H), 0.88 (t, 3H; 8-H). ^{13}C NMR: $\delta = 136.67$ (C-3), 132-42 (C-2), 47.51, 39.01 (2 CH_2Cl), 31.35, 28.63, 27.88, 22.42 (4 CH_2), 13.91 (CH_3)

7: ^1H NMR: $\delta = 4.10–3.80$ (m, 4H; CH_2Cl), 1.65–1.20 (m, 9H; CH, 4 CH_2), 0.91 (t, 3H; CH_3). ^{13}C NMR: $\delta = 49.59$, 44.10 (2 CH_2 Cl), 41.45 (C-3), 40.30 (C-1 or C-2), 36.75 (C-2 or C-1), 31.39, 27.85, 27.38, 22.44 (4 CH_2), 13.94 (CH_3)

signals at $\delta = 41.59$, 44.28, 48.72, and 61.70, as expected for the monosubstituted bicyclic repeating unit (**2a**: $\delta = 39$ (C-1,3), 49 (C-2,4,5)[1c-e]). The signal of the methylene group (C-4 or C-5) at $\delta = 44.28$ consists of three lines in an intensity ratio of 1:2:1. This splitting is a possible indication that the monomer adds to the growing chain with no preferred orientation[9] and that **2c** is present as an atactic polymer. The average degree of polymerization of **2c** was determined by ^1H NMR spectroscopy from the ratio of the signal intensities of the terminal *tert*-butyl group at $\delta = 0.78$ and the methyl group of the pentyl chain at $\delta = 0.91$ to be $\bar{P}_n \approx 40$.

Preliminary investigations show that the properties of **2c** are considerably different from those of the unsubstituted polymer **2a**. For instance, **2a** is insoluble in refluxing toluene, whereas **2c**, despite the presumably higher $\bar{P}_n$ value (40[10]), dissolves completely in several organic solvents at room temperature. Unusually sharp and nearly complete weight loss is observed in thermogravimetric investigations of **2a** at 300 °C;[1e] by contrast, the polymer **2c** suffers continuous weight loss to ca. 5% of the initial weight at 300–450 °C (N_2; rate of heating 3 K/min). Pure **2c** under gentle pressure or from solution forms transparent films, which, however, exhibit only low mechanical strength. Preliminary viscosity measurements in chloroform at 25 °C gave a Staudinger index of $[\eta] = 0.34\ dLg^{-1}$ for **2c**.

The positive effect of the pentyl chain on solubility is also shown by the copolymers, which are easily prepared from the propellane **1c** and acceptor-substituted olefins. Thus, reaction of **1c** with two equivalents of acrylonitrile, without addition of an initiator, gave the alternating copolymer **3c** (X = CN), which, in contrast to the corresponding copolymer from **2a** and acrylonitrile,[1c] is readily soluble. The structure of **3c** was confirmed by spectroscopic data [Table 1; gel permeation chromatography (GPC) (*o*-dichlorobenzene; standard, polystyrene): $M_w = 530\,000$; $M_n = 176\,000$; $M_w/M_n = 3.02$; viscosity ($CHCl_3$, 20 °C): $[\eta] = 6.4\ dL\,g^{-1}$].

Experimental Procedure

1c: A solution of **7** (38 g, 0.10 mol) in 100 mL of diethyl ether was added dropwise over 30 min to 130 mL of a 1.6 M solution of methyllithium in ether (0.21 mol) at −45 °C. After stirring for 1 h at 20 °C, **1c** was condensed under vacuum (1 Pa) into a trap cooled to −30 °C (5.9 g, 43%) and then further purified by recondensation from a vessel cooled to 0 °C into a dry-ice trap (yield: 4.75 g, 34%). For smaller runs (10–15 g of **7**) the yields of **1c** can be

increased up to 60%; similar yields are obtained by adding methyllithium to **7**. Compound **1c** is storable under nitrogen at $-20\,^{\circ}C$.

6: A 1.6 M solution of *n*BuLi in hexane (310 mL) was added to hexyl(triphenyl)phosphonium chloride (215 g, 0.50 mol, Aldrich) in 1 L of diethyl ether at 20 °C. The clear, dark red solution was cooled to $-65\,^{\circ}C$ and treated over 2 h with a solution of **5** (65 g, 0.50 mol) in 1 L of ether. The resulting precipitate was filtered off under suction at low temperature, the solvent was removed, and the residue was distilled (b.p. 50 °C/0.1 Pa; yield 50–60 g, 51–61%).

7: A solution of **6** (48 g, 0.25 mol) and bromoform (80 g, 0.3 mol) in 80 mL of dichloromethane was treated at room temperature with 0.8 g of trimethyl(phenyl)ammonium chloride and 0.8 mL of ethanol. A 50% solution of sodium hydroxide (80 mL) was then added dropwise to the stirred solution. After stirring for 3 d, the reaction mixture was subjected to aqueous workup. Vacuum distillation (0.1 Pa, bath at 110 °C) afforded reusable starting material and **7** as a colorless liquid (b.p. 95 °C/0.1 Pa; yield 42 g, 46%; yield when **6** was reused, 90%).

[10] The $\bar{P}_n$ value of **2a** could not be determined [1e]; the $\bar{P}_n$ value of **2b** was estimated to be 20 [1a, b]. Presumably, $\bar{P}_n$ of **2a** is similar.

The Structures of 1,n-Bis(9-lithio-9-fluorenyl)ethane · 8 THF and -hexane · 8 THF as Models for Solvent-Separated Ion Pairs**

By *Bardo Becker, Volker Enkelmann,* and *Klaus Müllen**

The rate of an intramolecular electron transfer depends, apart from geometric factors, on the ion-pair structure of the charged π systems involved.[1–3] Thus, for the alkali-metal derivatives of various radical anions, the rate of intramolecular electron transfer is increased on going from contact ion pairs to solvent-separated ion pairs[3, 4] as well as when the counterion is arranged between the charged units.[5] Spectroscopic investigations of biselectrophoric systems in solution often provide only indirect information on the relevant structures involved in electron transfer.[3, 5] Crystal structure investigations of carbanions have been carried out mostly for salts containing heteroatom bases as ligands to promote crystallization or stabilize the salt and have revealed contact ion pairs.[6] Removal of the counterion from the carbanion has been achieved by using crown ethers,[7] tetramethylethylenediamine,[8] and ethylenediamine[9] as ligands. We have now succeeded in crystallizing the diionic systems 1,n-bis(9-lithio-9-fluorenyl)ethane and -hexane as adducts with eight THF molecules (**1** and **2**, respectively) from pure THF. Their molecular structures, which are models for solvent-separated ion pairs, show that each lithium atom is surrounded tetrahedrally by four THF molecules and that there are minimal interactions between the fluorenyl moieties.

Compound **1** was prepared by treating 1,2-di(9-fluorenyl)ethane (0.2 g, 0.56 mmol) in 40 mL of dry THF at $-20\,^{\circ}C$ with highly active lithium.[10] The dark red solution thereby obtained afforded a microcrystalline precipitate. Heating of the solution to redissolve the product and slow cooling (48 h) from 25 °C to $-25\,^{\circ}C$ yielded **1** as long red needles. The hexane analogue **2** (pale red plates) was prepared similarly.[11] When **1** (or **2**) was transferred under inert gas to an NMR tube and solvolyzed with [D_4]methanol, the relative intensities of the ^1H NMR signals revealed the presence of eight THF ligands per molecule (for ^1H and ^{13}C NMR data of **1** and **2**, see Table 1).

The crystal structures of **1** and **2** (Fig. 1)[12] display the following features: (1) The chains have all-*trans* conformation, and the fluorenyl moieties, which are planar within the

Table 1. ^1H and ^{13}C NMR chemical shifts of **1** and **2** ([D_8]THF).

limits of experimental error, lie parallel to each other. (2) In both cases, two crystallographically independent molecules are present; i.e., the asymmetric unit comprises two molecules of the type [fluorenyl$(CH_2)_{n/2}$(Li$(THF)_4$)]. Each lithium ion is surrounded by four THF molecules, the oxygen atoms of which approximate a regular tetrahedron [d(Li-O) ca. 190 pm, $\sphericalangle$ (O-Li-O) 104–114°, d(O-O) 299–317 pm, $\sphericalangle$ (O-O-O) 56.6–62.8°]. (3) No contacts smaller than the van der Waals distances are found between lithium ions and carbon centers of the fluorenyl moieties. The shortest distances d(Li-C) are 436 pm in **1** and 442 pm in **2**. (4) In the crystal lattice of **2**, the Li–Li distances (less than 1000 pm) are 756, 852, and 870 pm, the intramolecular C9–C9 distances 888 and 896 pm, and the intermolecular C9–C9 distances 770 pm. Thus, these values are of a similar magnitude as the C9–Li distances, which are between 563 and 895 pm.

A comparison with the structures of fluorenyllithium adducts[9, 13] and larger π-delocalized carbanions containing fluorenyl units[14–16] is very informative. For fluorenyllithium · 2 quinuclidine, contact ion pairs are found in which the metal lies above the plane of the π system[13] and the distance d(C9–Li) is 233 pm. The structure is explained in terms of electrostatic effects.[10, 13, 17, 18] The formation of a "solvent-separated" ion pair in the case of fluorenyllithium · 2 ethylenediamine is due to the stabilizing effect of NH hydrogen bonds to the carbanion.[9] In larger systems[14, 15] a Li center can interact with the fluorenyl moieties of two molecules to form a double-layer structure.

The salts **1** and **2** clearly differ from the cases known so far. The crowded coordination spheres of the metals, each of which is surrounded by four tetrahedrally arranged solvent molecules, prevent close Li–C contacts. Further, there are neither intra- nor intermolecular fluorenyl–fluorenyl interactions. Thus, no assignment of a carbanion to "its" counterion can be made. Instead, the Li and the C9 centers are arranged with equal separations in a quasi-ionic lattice. Since the rings in the two crystallographically different molecules are not oriented parallel to one another, no stacked structures with particularly strong Li–fluorenyl interactions in the stacking planes are found. On the contrary, comparison of Figures 1 b and 1 c reveals that a three-dimensional saltlike packing arises owing to the presence of cavities containing the Li$(THF)_4$ units next to the fluorenyl rings. Special geometric assignments (e.g., between Li$(THF)_4$ and the central cyclopentadienide ring) of the shortest Li–C distances given are not apparent.

The fluorenyllithium system is one of the best-investigated carbanion systems. The crystal structures of the derivatives **1** and **2** are good models for solvent-separated ion pairs in THF and may facilitate a deeper theoretical understanding of these species, which have been postulated mainly on the basis of spectroscopic data. Further, there is no evidence for an "aggregation" of the carbanion subunits.

[11] Under these experimental conditions, UV spectroscopic investigations [10] have revealed that **1** and **2** are present as solvent-separated ion pairs. The NMR chemical shifts of **1** and **2** (Table 1) largely correspond to those of simple fluorenyllithium systems [19]. The differences in the δH and δC values observed for **1** and **2** provide no evidence of an interaction between the fluorenyl moieties.

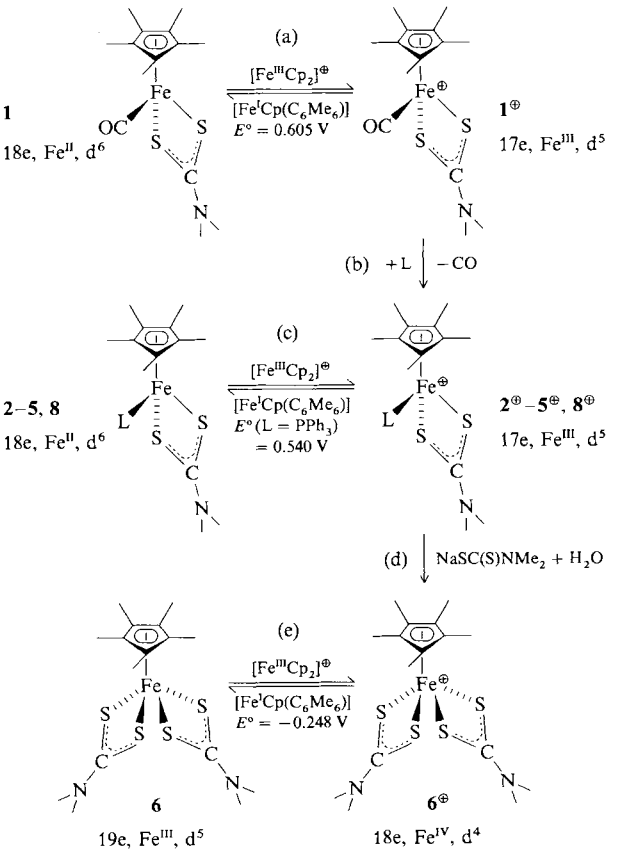
17- to 19-Electron Pentamethylcyclopentadienyl Iron Dithiocarbamate Complexes. Formation of a Cp*Fe^{IV} Complex

By *Marie-Hélène Desbois* and *Didier Astruc* *



The chemistry of inorganic and organometallic radicals[1] has attracted much attention recently because of their involvement in electron-transfer-catalyzed (ET-catalyzed) reactions[2] and energy conversion.[3] We wish to report a series of kinetically very labile but thermally stable 17e complexes of general formula **A** (Cp* = η^5-C_5Me_5; counterion $PF_6^\ominus$), their oxidation to $\mathbf{6}^\oplus$, and several new redox couples.

$[Fe^{III}Cp^*(\eta^2\text{-}SC(S)NMe_2)(L)]^\oplus$ **A**
$\mathbf{1}^\oplus$, L = CO
$\mathbf{2}^\oplus$, L = MeCN
$\mathbf{3}^\oplus$, L = Me_2CO
$\mathbf{4}^\oplus$, L = CH_2Cl_2
$\mathbf{5}^\oplus$, L = THF
$[Fe^{IV}Cp^*(\eta^2\text{-}SC(S)NMe_2)_2]^\oplus$ $\mathbf{6}^\oplus$

Oxidation of the red precursor complexes **1**[4] or $[Fe^{II}Cp^*(\eta^1\text{-}SC(S)NMe_2)(CO)_2]$ **7**[4] by one equivalent of $[FeCp_2]^\oplus$ in THF gives green $\mathbf{1}^\oplus$ and $FeCp_2$ in 85% yield each [Eq. (a)]. The new 17e complex $\mathbf{1}^\oplus$ was characterized by elemental analysis as well as by IR, ESR, and Mössbauer spectroscopy and compares with other 17e complexes of the type $[FeCp^*(L^1)(L^2)(CH_3)]^\oplus$ (L^1, L^2 = CO, phosphane).[5] It can be reduced back to **1** in 81% yield using $[Fe^ICp(C_6Me_6)]$[6] in THF [Eq. (a) in Scheme 1].

The chemistry of $\mathbf{1}^\oplus$ is of interest since this species was proposed to be an intermediate in the ET-catalyzed conversion of **7** to **1**.[7] The complex $\mathbf{1}^\oplus$ is insoluble in THF, but its CO ligand is extremely labile in polar solvents such as MeCN, Me_2CO, and CH_2Cl_2. When $\mathbf{1}^\oplus$ is dissolved in any of these solvents at 20 °C, its green color rapidly turns red, the color of $\mathbf{2}^\oplus$, $\mathbf{3}^\oplus$, and $\mathbf{4}^\oplus$, respectively, and CO evolves [Eq. (b)]. The reaction $\mathbf{1}^\oplus \rightarrow \mathbf{2}^\oplus + CO$ could be followed by visible spectroscopy at 5 °C (Fig. 1) and two isosbestic points (λ = 488 and 600 nm) were observed.

The complexes $\mathbf{2}^\oplus$–$\mathbf{4}^\oplus$ could also be characterized by their ESR spectra in solution, which are characteristic of 17e Fe^{III}

Scheme 1. The counterion is always $PF_6^\ominus$. $E°$ is given relative to the standard calomel electrode (SCE).

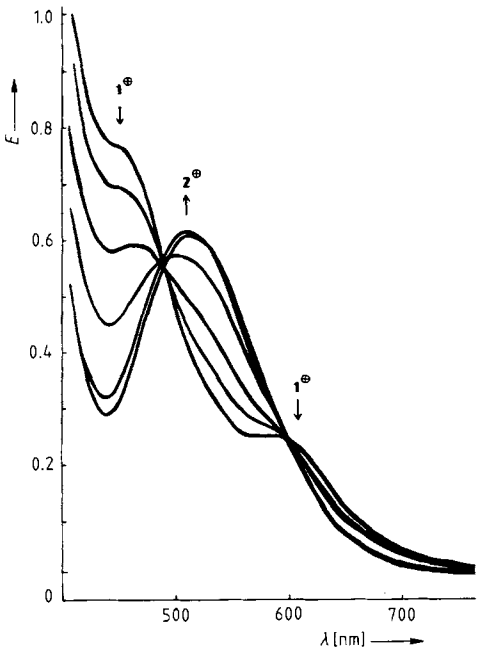

Fig. 1. Visible spectroscopy of the conversion of $\mathbf{1}^{\oplus}$ ($c = 3.2 \times 10^{-3}$ mol L^{-1}) to **2** in CH_3CN at 5 °C. E = extinction coefficient.

Table 1. Physical data for the cations $\mathbf{1}^{\oplus}$–$\mathbf{4}^{\oplus}$ and $\mathbf{6}^{\oplus}$ as $PF_6^{\ominus}$ salts.

$\mathbf{1}^{\oplus}$: Mössbauer data (mm s^{-1} vs Fe; 298 K, 77 K): $IS = 0.518$, $QS = 0.686$. IR (KBr pellet): $\tilde{\nu}$[cm^{-1}] = 2030, 1985 (CO), 1550 (CN), 1015 (CS). ESR (solid sample, 10 K): $g_1 = 2.239$, $g_2 = 2.107$, $g_3 = 2.049$; orthorhombic transition at 200 K: $g_1 = 2.237$, $g_{2,3} = 2.071$. Visible spectrum (MeCN): λ[nm] (ε [L mol^{-1} cm^{-1}]) = 584 (811), 452 (2451). Elemental analysis calcd for $C_{14}H_{21}FeNOPS_2F_6$: C 34.72, H 4.37, Fe 11.53, N 2.89; found: C 34.19, H 4.36, Fe 12.11, N 2.77.

$\mathbf{2}^{\oplus}$: Mössbauer data (mm s^{-1} vs Fe; 298 K): $IS = 0.550$, $QS = 0.620$. IR (MeCN, 298 K): $\tilde{\nu}$[cm^{-1}] = 1535 (CN), 1035 (CS). ESR (CH_3CN, 20 K): $g_1 = 2.611$, $g_2 = 2.184$, $g_3 = 2.001$. Visible spectrum (MeCN, 5 °C): λ[nm] (ε [L mol^{-1} cm^{-1}]) = 514 (1823). Elemental analysis calcd for $C_{15}H_{24}FeS_2N_2PF_6$: C 36.23, H 4.86, N 5.63; found: C 36.48, H 4.63, N 5.08

$\mathbf{3}^{\oplus}$: IR (Me_2CO, 298 K): $\tilde{\nu}$[cm^{-1}] = 1510 (CN), 1015 (CS). ESR (Me_2CO, 20 K): $g_1 = 2.453$, $g_2 = 2.035$, $g_3 = 1.995$

$\mathbf{4}^{\oplus}$: IR (CH_2Cl_2): $\tilde{\nu}$[cm^{-1}] = 1520 (CN), 1015 (CS). ESR (CH_2Cl_2, 20 K): $g_1 = 2.571$, $g_2 = 2.135$, $g_3 = 1.990$

$\mathbf{6}^{\oplus}$: ^{1}H NMR (CD_3CN, 20 °C, TMS): $\delta = 3.228$ (s, 12H; NMe), 1.279 (s, 15H; Me). ^{13}C NMR (CD_3CN): $\delta = 200.56$ (CN), 106.04 (C_5Me_5), 38.42 (NMe), 9.75 ($C_5(CH_3)_5$). IR (KBr pellet, 298 K): $\tilde{\nu}$[cm^{-1}] 1540 (CN), 1005 (CS). Mössbauer data (mm s^{-1} vs Fe 298 K, 77 K): $IS = 0.460$, $QS = 0.220$. Cyclic voltammetry (dimethylformamide, 0.1 M $nBu_4N^{\oplus}BF_4^{\ominus}$, 298 K, $v = 400$ mV s^{-1}, Pt): E°[V] vs SCE = -0.248 ($\Delta E_p = 135$ mV, $i_a/i_c = 0.89$, $\alpha = 0.67$, $D = 1.07 \times 10^{-5}$ cm^2 s^{-1}, $k_s = 4 \times 10^{-3}$ cm s^{-1}; $\Delta G^{\neq} = 5.88$ kcal mol^{-1}), -0.765 ($\Delta E_p = 210$ mV, $i_a/i_c = 0.88$, $\alpha = 0.60$, $D = 1.46 \times 10^{-5}$ cm^2 s^{-1}, $k_s = 2.3 \times 10^{-3}$ cm s^{-1}; $\Delta G^{\neq} = 5.62$ kcal mol^{-1}). Elemental analysis calcd for $C_{16}H_{27}S_4N_2FePF_6$: C 33.33, H 4.72, N 4.85; found: C 33.59, H 4.71, N 4.65

piano-stool complexes (Table 1).[5] Their IR spectra show the absence of carbonyl groups. The homogeneous reaction of $\mathbf{4}^{\oplus}$ with a CH_2Cl_2/THF mixture (3/1) slowly gives $\mathbf{5}^{\oplus}$ (4 h, 20 °C).

The 17e complexes $\mathbf{2}^{\oplus}$–$\mathbf{5}^{\oplus}$ can be reduced by [$Fe^{I}Cp(C_6Me_6)$] to **2**–**5**, which, in turn, can be reoxidized back to $\mathbf{2}^{\oplus}$–$\mathbf{5}^{\oplus}$ using $[FeCp_2]^{\oplus}$ [Eq. (c)], all the redox reactions being performed in THF at 20 °C. Reaction (b) follows pseudo-first-order kinetics and its rate depends on L ($t_{1/2}$: 57 min in CH_2Cl_2, 25 °C; 13.5 min in Me_2CO, 5 °C; 5 min in MeCN, 5 °C), suggesting an associative mechanism via the formation of 19e intermediates or transition states as the rate-limiting step. Reaction of $\mathbf{2}^{\oplus}$–$\mathbf{4}^{\oplus}$ with one equivalent of PPh_3 in situ cleanly gives the known complex $\mathbf{8}^{\oplus}$.[7]

$[Fe^{III}Cp^*(\eta^2\text{-}SC(S)NMe_2)(PPh_3)]^{\oplus}$ $\mathbf{8}^{\oplus}$

Reaction of one equivalent of $Na^{\oplus}{}^{\ominus}SC(S)NMe_2 \cdot 2\,H_2O$ with $\mathbf{1}^{\oplus}$ in CH_2Cl_2 at 20 °C gives initially the red complex $\mathbf{4}^{\oplus}$, which is transformed into the green complex $\mathbf{6}^{\oplus}$ within 1.5 h [Eq. (d)]. The complex $\mathbf{6}^{\oplus}$ crystallized in 75% yield (0.2-mmol scale) and was characterized as an 18e Fe^{IV} complex by ^{1}H and ^{13}C NMR, IR, and Mössbauer spectroscopy. The NaOH formed in this reaction was titrated by a 0.01 N solution of HCl; its amount agreed with the stoichiometry of Equation (f). Further H_2 was detected by gas chromatography. Thus water is reduced in this reaction:

$$[Fe^{III}Cp^*(SC(S)NMe_2)(L)][PF_6] + NaSC(S)NMe_2 + H_2O \rightarrow [Fe^{IV}Cp^*(SC(S)NMe_2)][PF_6] + NaOH + 1/2\,H_2 + L \quad (f)$$

$L = CO, CH_2Cl_2$

We propose that the 19e intermediate **6** is formed in reaction (f) and reduces H_2O. Cyclic voltammetry of $\mathbf{6}^{\oplus}$ shows a quasi-reversible redox system, $\mathbf{6}^{\oplus}/\mathbf{6}$, with $E^{\circ} = -0.248$ V vs SCE [Eq. (e)]. The complex $\mathbf{6}^{\oplus}$ is also formed in lower yields (30–40%) by disproportionation of the 17e complexes $\mathbf{1}^{\oplus}$–$\mathbf{5}^{\oplus}$ and $\mathbf{8}^{\oplus}$ at 20 °C in the absence of $Na^{\oplus}{}^{\ominus}SC(S)NMe_2$ but in the presence of water. Reduction of $\mathbf{6}^{\oplus}$ to **6** can be rapidly effected at 20 °C using one equivalent of [$Fe^{I}Cp(C_6Me_6)$] in THF. The birefringent purple/blue-turquoise 19e Fe^{III} complex **6** is soluble in ether and shows an ESR spectrum typical[8] of 19e Fe species (20 K, solid state: $g = 2.268$, 2.126, 2.035).

In summary, access to the 17e complexes of general formula **A** opens a route to several new redox couples for which both forms were isolated and characterized. This chemistry demonstrates the good electron-reservoir properties of the $SC(S)NMe_2$ ligand and the intermediacy of 19e species in the reactions of 17e complexes with various ligands.

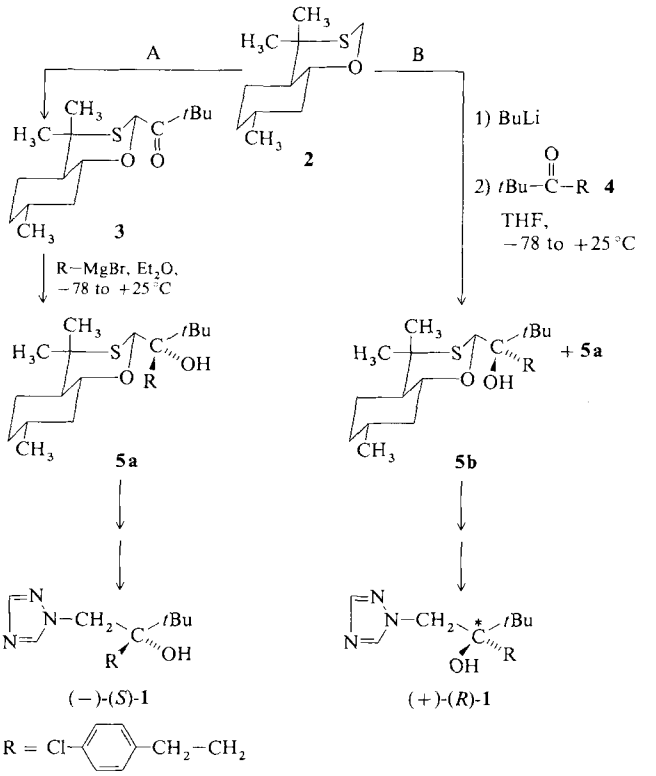
The Enantiomers of the Azole Fungicide HWG-1608—Asymmetric Synthesis of a 2-Hydroxyethyl Azole Fungicide**

By *Johannes Kaulen**

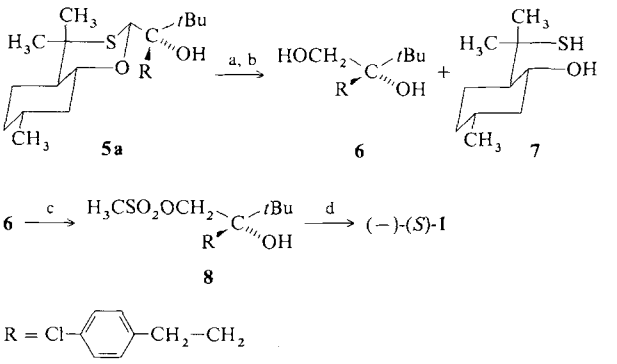
Dedicated to Professor Hans Rudolph on the occasion of his 60th birthday

The azole fungicide HWG-1608 **1** (commercial name Folicur®, Raxil®), first synthesized by *Holmwood* et al., is a new, highly effective fungicide belonging to the class of ergosterol-biosynthesis inhibitors.[1] Compound **1** has an asymmetric center and is therefore prepared commercially as a racemate. However, the pure enantiomers were required for more detailed biological and biochemical investigations. We report here the synthesis of the enantiomers of **1** via a reaction sequence in which both enantiomers can be obtained—either by asymmetric synthesis or by separation of diastereomers—using the same chiral auxiliary.



The synthesis of the enantiomers was achieved by extending the oxathiane method developed by *Eliel* et al. to azole chemistry, starting from the chiral oxathiane derivatives **2** and **3**[2] (Scheme 1), which are readily accessible from (+)-pulegone.

Grignard addition of *p*-chlorophenethylmagnesium bromide to **3** (path A) afforded **5a**,[3] the precursor of (−)-(*S*)-**1**, with excellent diastereoselectivity (*de* > 95%). Addition of lithiated **2** to the *tert*-butyl ketone **4**, an intermediate in the commercial synthesis of racemic **1**, gave primarily **5b** (*de* = 48%,[4] path B), which was surprisingly easy to separate from **5a** (SiO_2, petroleum ether:diethyl ether 5:1; R_F values: **5b**, 0.43; **5a**, 0.31). This route provided easy access to large quantities of pure **5b**, the precursor of (+)-(*R*)-**1**.[5]



The diastereoselectivity observed for path B is appreciably higher than that usually found for addition of **2** to ketones,[2a] presumably because the *tert*-butyl group is more sterically demanding than the phenethyl moiety.

Mild cleavage of the oxathiane moiety of **5a** with *N*-chlorosuccinimide (NCS)/silver nitrate[2, 6] and in situ reduction of the liberated aldehyde with $LiAlH_4$[7] affords the diol **6**. The oxathiane chiral auxiliary is thereby recovered in the form of the mercapto alcohol **7**.[2] Selective mesylation of **6** to give **8** and nucleophilic replacement of the mesyloxy group by a triazole group leads to the desired (−)-(*S*)-**1** (95% *ee*, Scheme 2). Compound **5b** reacts in a similar fashion to give (+)-(*R*)-**1**. The overall yield of (−)-(*S*)-**1** in this five-step synthesis starting from **3** is 37%.

The absolute configurations of the intermediate and end products were confirmed by X-ray structure analysis of (−)-(*S*)-**1**[1b] and support the rules established earlier by *Eliel* et al.[2a]

Scheme 1.

Scheme 2. NCS, $AgNO_3$, CH_3CN, 15 min 40–50 °C [2, 6]. b) $LiAlH_4$, Et_2O, 3 h, 35 °C [7] (85% crude yield for two steps). c) CH_3SO_2Cl, Et_3N, CH_2Cl_2, 4 h 25 °C (89% crude yield). d) Sodium salt of triazole, DMF, 6 h 120 °C, 37% overall yield from **3**.

The novel combination of the complementary paths A and B allows both enantiomers of HWG-1608 **1** to be prepared using the same chiral auxiliary. The active (−)-(*S*) enantiomer is obtained by an asymmetric synthesis, the less active (+)-(*R*) enantiomer by intervening separation of diastereomers. Thus, as exemplified by (−)-(*S*)-**1**, we have accomplished the asymmetric total synthesis of a 2-hydroxyethyl azole fungicide.[8]

Experimental Procedure

The structures of all new compounds were confirmed by ^1H NMR, IR, and mass spectra (Table 1) as well as by C, H analyses. The diastereomeric excesses were determined by capillary chromatography, HPLC, and ^1H NMR spectroscopy. The enantiomeric purity of the end products was determined by high-pressure liquid chromatography on chiral columns.

5a: A solution of **3** (31.3 g, 0.11 mol) [2a] in 200 mL of anhydrous diethyl ether was added to a solution of the Grignard reagent prepared from 4-chlorophenethyl bromide (48.3 g, 0.22 mol) in 100 mL of anhydrous diethyl ether at −78 °C. The bath was allowed to warm slowly to room temperature and the reaction mixture was then heated at reflux for 3 h. Workup was carried out by

Table 1. Characteristic spectroscopic data for the diastereomers **5a** and **5b**: ^{1}H NMR: 360 MHz ($CDCl_3$); MS: 70 eV; IR: neat (NaCl).

5a: ^{1}H NMR: δ = 0.93 (d, J = 6.7 Hz, 3H, CH_3-CH), 1.02 (s, 9H, *t*Bu); 1.29 and 1.42 (each s, each 3H, CH_3-C-CH_3); 2.75 and 3.05 (each d of t, J = 4.9, 12.8 Hz, each 1 H, $HO-C-CH_2-$), 2.06 (s, 1H, *OH*), 3.36 (d of t, J = 4.0, 10.7 Hz, 1H, $>CH-OR$), 5.29 (s, 1H, $-S-CH-O$), 7.15–7.28 (m, 4H, arom. H)

5b: ^{1}H NMR: δ = 0.92 (d, J = 6.4 Hz, 3H, CH_3-CH); 1.03 (s, 9H, *t*Bu); 1.29 and 1.44 (each s, je 3H, CH_3-C-CH_3); 2.59 and 3.09 (each d of t, J = 5.0, 13.1 Hz, each 1H, $HO-C-CH_2$); 3.37 (s, 1H, *OH*); 3.41 (d of t, J = 4.3, 10.7 Hz, 1H, $>CH-OR$); 5.05 (s, 1H, $-S-CH-O$); 7.17–7.30 (m, 4H, arom. H)

MS (identical for **5a** and **5b** ($M^{\oplus}$ absent): m/z 367 ($M^{\oplus}-t$Bu, 4%); 199 ($C_{11}H_{19}SO$, oxathiane fragment, 100%)

IR (identical for **5a** and **5b**): $\tilde{\nu}$ = 3550 cm^{-1} (OH)

pouring the reaction mixture into 200 mL of a saturated NH_4Cl solution, separating the ether phase, extracting three times with dichloromethane, and drying the combined organic phases over Na_2SO_4, then concentrating the solution in a rotary evaporator and removing low-boiling impurities in vacuo (0.1 mbar, bath temperature 140 °C). Yield: 40.2 g (86%) **5**. Ratio **5a:5b** = 97.7:2.3 (95.4% *de*). The product was used without further purification (for spectroscopic data see Table 1).

5b: A solution of butyllithium (1.98 M, 45.5 mL, 90 mmol) in hexane was added under N_2 to a solution of **2** (18.0 g, 90 mmol) [2c, d] in 100 mL of dry THF at −78 °C. The reaction mixture was warmed briefly to 0 °C and then cooled again to −78 °C. Compound **4** (20.2 g, 90 mmol) [1a] in 50 mL of dry THF was added dropwise at this temperature. The resulting reaction mixture was warmed slowly in the bath to room temperature and then stirred for 30 min at 25 °C. Workup was carried out as for **5a**. Yield: 37.6 g (98%) crude product. Ratio **5a:5b** = 26:74 (48% *de*). Chromatography on 1 kg of silica (petroleum ether:ether 5:1 as eluent) gave, as the first fraction, 20.5 g (54%) of **5b**, followed by a second fraction containing 4.04 g (18%) of **5a**, both compounds being isolated as colorless oils (for spectroscopic data see Table 1).

(−)-(*S*)-**1**: Crude **8** (27.3 g, 81.5 mmol) was stirred with the sodium salt of triazole (22.3 g, 0.24 mol, 3 equiv.) in 100 mL of dry dimethylformamide (DMF) under N_2 for 6 h at 120 °C. The DMF was removed in a rotary evaporator and the residue was dissolved in water/dichloromethane. The organic phase was separated and the aqueous phase was extracted twice with CH_2Cl_2. The combined organic phases were dried over Na_2SO_4, and concentrated in a rotary evaporator. The entire crude product was purified by chromatography on 1 kg of SiO_2 (CH_2Cl_2:MeOH 95:5 as eluent). Yield: 12.4 g (49%, 37% overall yield starting from **3**) (−)-(*S*)-**1**: $[\alpha]_D^{20} = -34.0$ (c = 1, $CHCl_3$); enantiomeric purity determined by HPLC to be ≥ 95%; spectroscopic data identical with that of racemic reference compound.

Eliel (Ed.): *Asymmetric Reactions and Processes in Chemistry, ACS Symp. Ser. 185* (1982) 37–53.

[3] The diastereomeric excess determined by capillary gas chromatography was practically independent of the solvent used (diethyl ether or THF) and of the nature of the Grignard reagent (bromide or iodide).

[4] Attempts to increase the diastereoselectivity by transmetalation (reaction of lithiated **2** with $ClTi(OiPr)_3$, $MgBr_2$, or $ZnCl_2$) were unsuccessful, since the metalated oxathianes thus formed did not add to **4**.

[5] Reversal of the order of addition of reagent and substrate (i.e., addition of *tert*-butylmagnesium bromide to **3**, with 4-chlorophenethyl instead of *t*Bu), a commonly used trick in asymmetric synthesis, did not lead to **5b**; in addition to unchanged starting material, the secondary alcohol (Grignard reduction of the ketone) was found.

[6] E. J. Corey, B. W. Erickson, *J. Org. Chem. 36* (1971) 3553.

[7] Reduction with $NaBH_4$ gave, besides **6** (20% yield), a very stable boron chelate complex containing two units of **6** as main product (40%). This complex could be isolated by chromatography, but could not be converted into **6** under mild conditions.

[8] Azole fungicides with secondary hydroxyl groups at the stereogenic center have been obtained in special cases by asymmetric reduction of ketones, cf. U. Kraatz, P. Feyen, Eur. Pat. 196504 (1986), Bayer AG; Y. Yoneyoshi, G. Gohfu, K. Mamada, T. Nishioka, Eur. Pat. 170350 (1986), Sumitomo; Y. Funaki, Y. Yoneyoshi, Y. Ishiguri, K. Izami, Eur. Pat. 175278 (1986), Sumitomo.

Synthesis, Structure, and Bonding of the Cation $[\{(C_6H_5)_3PAu\}_5C]^{\oplus}$ **

By *Franz Scherbaum, Andreas Grohmann, Gerhard Müller,* and *Hubert Schmidbaur**

The diverse observations of unexpectedly strong metal–metal interactions in polynuclear gold(I) compounds, which lead to molecular conformations with close Au···Au contacts on the one hand[1–3] and discrete Au–Au bonds on the other,[4–6] have recently focused attention especially on polyaurated organogold compounds. The aggregation of gold atoms at a single carbon atom in these compounds results in particularly striking examples of the phenomenon of "secondary" Au···Au bonding, which is only partly understood. This is above all true for the recently reported dication $[\{(C_6H_5)_3PAu\}_6C]^{2\oplus}$, in which the central C atom is surrounded octahedrally by six gold atoms.[7] Owing to their high formation tendency and stability, the salts of this dication are surprisingly easy to prepare in high yields. A polyauriomethane compound with a coordination number of 5 at the C atom is exemplified by a (triauriomethyl)oxazoline complex with a complicated structure:[8] The first coordination sphere, which is tetragonal-pyramidal, contains an organic group in addition to four gold atoms. Supported by structure analyses, plausible descriptions of the bonding in both electron-deficient species were given on the basis of simple MO diagrams. In continuation of these studies, we have now synthesized and structurally characterized a second homoleptic cation, $[\{(C_6H_5)_3PAu\}_5C]^{\oplus}$, in which the central C atom is surrounded by five gold atoms.

The starting material for this new cation is bis(dimethoxyboryl)methane **1**,[9] which reacted in the expected way[7,8] with triphenylphosphanegold(I) chloride in the presence of cesium fluoride in hexamethylphosphoric triamide. Whereas the stoichiometry in earlier examples was more or less straightforward,[7] it is largely ambiguous here owing to the formation of several side products. Therefore, Equation (a) does not completely balance.

$$\underset{\mathbf{1}}{CH_2[B(OCH_3)_2]_2} \xrightarrow[\text{HMPA, 24 h, 20 °C}]{[(C_6H_5)_3PAuCl]/CsF} \underset{\mathbf{2}}{[\{(C_6H_5)_3PAu\}_5C]^{\oplus}BF_4^{\ominus}} \quad (a)$$

[+] X-ray structure analysis

The yield of **2** (84%!), however, is very satisfactory. The dication $[\{(C_6H_5)_3PAu\}_6C]^{2\oplus}$ is also present in small amounts in the reaction mixture. Only for very long reaction times does it eventually become the main product.

Compound **2** precipitates as yellow, rhombic crystals (with three molecules of dichloromethane per formula unit) from CH_2Cl_2/benzene or CH_2Cl_2/diethyl ether. The compound is readily soluble in halogenated hydrocarbons, slightly soluble in benzene, and insoluble in both diethyl ether and petroleum ether. The substance turns brown above 202 °C and melts at 243–245 °C. Between − 45 and + 45 °C, the solutions of **2** in CD_2Cl_2 show only one sharp $^{31}P\{^1H\}$ NMR signal, the chemical shift of which ($\delta = 32.1$) is distinct from that of the $[(LAu)_6C]^{2\oplus}$ ion (L = Ph_3P: $\delta = 27.7$). The ^1H NMR spectrum of **2** only shows a multiplet at $\delta = 7.0$–7.6, but the $^{13}C\{^1H\}$ NMR spectrum is so well resolved that particularly the resonances of C_{ipso} ($\delta = 132.4$, $^1J = 50.4$ Hz) and C_{ortho} ($\delta = 134.4$, $N = 14.7$) reveal a higher-order splitting, which indicates a $^4J(PP')$ long-range coupling. Similar observations were made earlier for $[(LAu)_6C]^{2\oplus}$, where an AXX'_4X'' spin system was found. As in the previous cases (above), the NMR signal of the central C atom of **2** could not be localized. The anion $BF_4^{\ominus}$ is identified by its known resonances. All NMR spectra indicate diamagnetism in the samples.

The X-ray structure analysis[10] confirmed that the composition corresponds to the cations $[\{(C_6H_5)_3PAu\}_5C]^{\oplus}$ and the anions $BF_4^{\ominus}$; in addition, it showed the presence of three CH_2Cl_2 solvate molecules per formula unit for the rhombic crystals (space group $R\bar{3}$) grown from CH_2Cl_2/diethyl ether. The cation has crystallographic C_3 symmetry. The five gold atoms occupy the corners of a slightly distorted, carbon-centered trigonal bipyramid (Fig. 1). This framework is characterized by close axial–equatorial contacts ($Au_{ax}\cdots Au_{eq}$) of 2.987(1) and 2.903(1) Å and longer $Au_{eq}\cdots Au_{eq}$ distances of 3.600(1) Å. The distances Au-C1 (2.079(5), 2.080(5), and 2.093(5) Å) hardly differ. Each gold atom is bonded to a $(C_6H_5)_3P$ ligand. The angles C1-Au-P are 173.0(3)° for Au_{eq} and 180° for Au_{ax} for the given symmetry.

A simple MO diagram can also be used to describe the bonding in the cation of **2** (Fig. 2). Assuming the idealized point group D_{3h}, the five C1-directed gold orbitals (sp hybrid orbitals) and the C1 atomic orbitals give rise to four bonding MOs according to symmetry criteria; these bonding MOs can be exactly filled by the eight valence electrons available, thereby giving a diamagnetic ground state. The LUMO is a nonbonding orbital; its relatively small separation in energy from the HOMO presumably causes the light absorption in the visible region. The scheme in Figure 2 ignores the energy contributions expected for Au···Au interactions, which are probably responsible for the stability of the species $[(LAu)_5C]^{\oplus}$ and for the spontaneous addition of a fifth $LAu^{\oplus}$ fragment to the tetraauriomethane unit $(LAu)_4C$ ("aurophilicity").[11] The importance of relativistic effects has already been discussed elsewhere.[12] For systems whose binding can be described according to Figure 2, a reduction in energy is expected when the symmetry is lowered from D_{3h} to C_{3v}. It remains an open question whether the slight distortion found in the cation of **2** can be interpreted in these terms or whether simple ligand–ligand repulsion or packing effects determine the symmetry lowering.

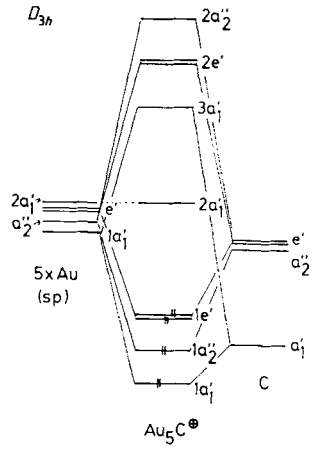

Fig. 2. MO diagram for describing the bonding in the cation $[\{(C_6H_5)_3PAu\}_5C]^{\oplus}$. Assuming the idealized point group D_{3h}, the orbitals of the central C atom and the five σ orbitals (sp hybrid orbitals) of the Au atoms are ordered according to symmetry.

Ab initio calculations, assuming a trigonal-bipyramidal structure, have predicted a "global" stability for $Li_5C^{\oplus}$; in fact, this species has been observed by mass spectrometry.[13] For $H_5C^{\oplus}$, on the other hand, the calculations indicate that a low-symmetry structure is favored (point group C_s). It should be noted that the cations $[(LAu)_5C]^{\oplus}$, $Li_5C^{\oplus}$, and $H_5C^{\oplus}$ do not belong to the class of compounds with "hypervalent" atoms,[14] but rather to the electron-deficient systems, since the Au–C bonds of **2** have a bond order of $4/5 = 0.8$ according to the MO scheme. Therefore, the Au···Au interactions should indeed strongly determine the stability of such species.

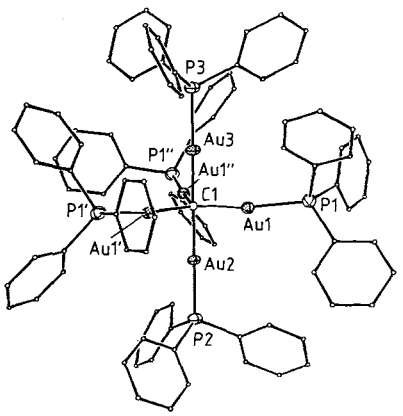

Fig. 1. Molecular structure of the cation of **2** with numbered atoms. Selected distances [Å] and angles [°]: Au1-Au2 2.987(1), Au1-Au3 2.903(1), Au1-Au1' 3.600(1), C1-Au1 2.079(5), C1-Au2 2.080(5), C1-Au3 2.093(5), Au1-P1 2.290(2), Au2-P2 2.264(3), Au3-P3 2.261(3); Au1-C1-Au2 91.8(3), Au1-C1-Au3 88.2(3), Au1-C1-Au1' 119.9(1); P1-Au1-C1 173.0(3).

Experimental Procedure

A solution of **1** (0.3 g, 1.88 mmol) in 10 mL of HMPA was slowly added dropwise to a stirred suspension of CsF (7.4 g, 48.7 mmol) in a solution of $[Ph_3PAuCl]$ (1.87 g, 3.78 mmol) in 40 mL of HMPA at room temperature. After stirring for 24 h at 20 °C, the reaction mixture was filtered and the filter cake was washed with 5 mL of CH_2Cl_2. The combined filtrates were then diluted with 20 mL of benzene. Addition of pentane resulted in formation of a yellow precipitate which was reprecipitated twice from CH_2Cl_2/benzene and three times from CH_2Cl_2/diethyl ether. Yield 1.52 g (84% based on $[Ph_3AuCl]$), m.p. 243–245 °C; correct elemental analysis.

A Highly Selective Montmorillonite Catalyst for Hydrogenation of Alkynes, Alkenynes, and Alkadienes**

By *Boyapati Manoranjan Choudary,** *Gangavaram Vasantha Madhava Sharma,* and *Patibandla Bharathi*

Transition-metal complexes immobilized on a montmorillonite support, a class of smectite clay, are known to induce enhanced selectivity towards terminal alkynes and alkenes in hydrogenation reactions.[1, 2] Recently, we reported the synthesis and characterization of a montmorillonite-supported bipyridinepalladium(II) acetate complex[3] which was found to hydrogenate alkynes and alkenes more effectively than analogous polymer-anchored bipyridinepalladium(II) complexes.[4]

We report here that the montmorillonite-supported complex (see Experimental Procedure) catalyzes the *cis*-selective hydrogenation of the C–C triple bond in alkynes and alkenynes and the regioselective hydrogenation of alkadienes to alkenes.

Hydrogenation of triple bonds, irrespective of their position, always precedes that of double bonds. The high *cis*-selectivity in the hydrogenation of triple bonds in variously substituted alkynes and in conjugated and unconjugated alkenynes (Table 1) demonstrates the versatility of this catalytic system.

By contrast, the effectiveness of the widely used Lindlar catalyst and *Osborn*'s cationic rhodium complex catalyst strongly depends on the compound being hydrogenated. Lindlar catalyst and the recently reported Pd/W system rarely exceed 92% *cis*-selectivity in the semihydrogenation of triple bonds in simple alkynes.[5] A striking failure of the Lindlar catalyst is observed in the semihydrogenation of ethyl phenylpropiolate, which primarily gave totally hydrogenated product.[6] Similarly, a rhodium cationic complex afforded poor selectivity in the semihydrogenation of 1,4-butynediol, although the *cis*-selectivity exhibited by the complex is as high as 99% in most cases.[6] Further, the recovery of the complex from the reaction medium is difficult.

The most impressive and unusual finding in the present study is the totally regioselective 1,2 addition in the hydrogenation of 1,4-substituted, 1,3-butadienes by the catalytic system described here. The selectivity includes the hydrogenation of the less hindered double bond in unsymmetrical dienes and of the *trans* in preference to the *cis* double bond in symmetrical dienes. Selective 1,2 additions in the hydrogenation of butadienes can be ascribed to η^2 coordination of the diene at the palladium center. This selective η^2 coordination may be due to the restricted space available in montmorillonite for η^4 coordination.

The bipyridinepalladium complex is a near-inactive homogeneous catalyst, and the polymer-bound complex[4] is known for its poor *cis* selectivity and regioselectivity in the hydrogenation of diphenylacetylene and sorbic acid, respectively. The selectivity of the montmorillonite-supported catalyst may be due to the preferred orientation of the substrate,

Regional Research Laboratory
Hyderabad 500007 (India)

governed by the least possible repulsion with the oxygens of the silicate layers of the support, and to the spatial requirements of the substrate–Pd^{II} adduct.

The stereoselectivity displayed by the montmorillonite–Pd^{II} catalyst offers a useful tool for organic synthesis, especially of biologically active compounds such as carbohydrates, leukotrienes, prostaglandins, and pheromones.

Experimental Procedure

All operations were carried out under inert atmosphere unless specified otherwise.

Preparation of the catalyst: H-montmorillonite, prepared from natural montmorillonite K 10 (Fluka, surface area 232 $m^2 g^{-1}$; surface acidity, 0.85 mmol NH_3 adsorbed per gram of support; mesh size < 200) by treatment with saturated sodium chloride solution followed by 0.1 N HCl, was allowed to react with excess $SOCl_2$ in dry benzene under reflux for 24 h to give chloromontmorillonite. The chloromontmorillonite (5 g) was suspended in dry THF and cooled to $-80\,^{\circ}C$ and excess *n*-butyllithium (6.25 mL, 10 mmol, 1.6 M in hexane) was added to the stirred suspension. The solution was stirred at $0\,^{\circ}C$ for 4 h and then allowed to warm to room temperature. After the solution was stirred for 1 h at room temperature, bipyridine (3 g, 19 mmol) was added as a solid and the solution was brought to reflux for 4 h. The reaction mixture turned purple during refluxing. It was allowed to cool to room temperature and air was bubbled through the solution until the entire solution had become yellow. The resulting montmorillonite bipyridine was thoroughly washed with THF, ethyl acetate, and benzene and was subjected to Soxhlet extraction for 24 h with THF to remove any adhering bipyridine. Reaction with $Pd(OAc)_2$ (0.11 g, 0.5 mmol) in benzene under stirring for 6 h gave the catalyst, which was thoroughly washed with benzene and THF (nitrogen content, 0.4 mmol g^{-1}; Pd, 0.2 mmol g^{-1}; surface area, 10.7 $m^2 g^{-1}$; surface acidity, 0.445 mmol NH_3 adsorbed per gram of catalyst; mesh size < 200).

Hydrogenation: The hydrogenation reactions were conducted under very mild conditions, at room temperature and atmospheric pressure in 100-mL flasks. The catalyst (0.048 mmol) was pretreated in THF (6 mL) with hydrogen in a classical hydrogenation apparatus; then the substrate (4.8 mmol) was introduced and hydrogenation was continued until the theoretical volume of hydrogen had been absorbed. The catalyst was removed by simple filtration and the reaction mixture was purified by column chromatography. All the products were characterized by spectral data.

A Structure for the H-Bonded Complex of Nylon-66 with Perfluoroglutaric Acid

By *Michal Harel, Meir Lahav,* Leslie Leiserowitz,* Jan van Mil*, and *E. Wasserman**

Crystalline complexes of biopolymers with small molecules are being reported with increasing frequency.[1] Yet reports of such combinations with man-made polymers have been rare.[2] Among the few examples are the adducts of nylon-66, nylon-6, and Kevlar with perfluoroglutaric, -adipic, and -succinic acid.[3] These complexes are also unusual in that hydrogen bonds involving the acid functionalities cause hydrocarbon and fluorocarbon components to mix on the molecular level despite the phase separation often found with such combinations. However, only speculations have been available as to their structures. Here we summarize a multifaceted approach which has yielded an unusual arrangement for one such complex, the crystalline phase of nylon-66 with perfluoroglutaric acid **1**. The techniques employed were X-ray powder diffraction, crystal density measurements, molecular packing considerations, and solid-state ^{13}C NMR spectroscopy.

$HO_2C(CF_2)_3CO_2H$ **1**

A crystalline complex was obtained by stirring a chloroform solution of **1** (0.1 M) with solid nylon-66 at room temperature. Elemental analysis indicated the presence of two molecules of **1** per C_{12} repeat unit of nylon-66. Decomposition of the complex by stirring in water and titrating the dissolved acid yielded the same polyamide/acid ratio.

The solid-state NMR spectrum of the complex had a sharp singlet at $\delta \approx 178$ for the polyamide carbonyl and a broad multiplet at $\delta \approx 162$ for the acid carbonyl. This broadening suggested either disorder or nonequivalent acid units.[4] The latter alternative is consistent with the stoichiometry of two diacids per C_{12} repeat. Only one molecule of **1** per nylon C_{12} is required for saturation of the hydrogen-bonding capabilities of an amide group.

The analysis of the crystal structure was based on the peaks in an X-ray powder scan using $Co_{K\alpha}$ radiation. A triclinic cell was selected and refined by *Visser*'s automated method.[5] The fit between observed and calculated $d(hkl)$ spacings is given in Table 1. The cell constants are: $a = 8.54$, $b = 17.75$, $c = 4.73$ Å, $\alpha = 92.2$, $\beta = 98.7$, $\gamma = 93.7\,^{\circ}$, $V = 707.4$ Å^3; $\rho_{calcd} = 1.67\ g\,cm^{-3}$ for $Z = 2$ with molecular formula (nylon, **1**) $C_6H_{11}NO$, $C_5H_2O_4F_6$, $\rho_{obs.} = 1.59\ g\,cm^{-3}$.

The packing of the nylon chains is essentially determined from the cell constants. The *a,b* layer of the nylon is depicted in Figure 1a. The 17.7-Å axis closely matches the axial length of 17.2 Å in uncomplexed nylon-66,[6] an all-*trans* extended structure. The conformation of nylon in the adduct approximates that of the neat polymer. The length of the chain is increased from 17.2 to 17.7 Å by holding the C–C bond length at 1.54 Å and increasing the C–C–C angle to 114.5°. The nylon molecules are thus parallel to the *b* axis and stacked along *c* forming *b,c* layers. With these extended polymer chains the orientation of the diacid is effectively con-

strained to parallel that of the polyamide. Indeed, the *a* axis of 8.5 Å is compatible with adjacent nylon layers interleaved by *b,c* layers of **1** (Fig. 1a). The ratio of nylon amide to acid carboxyl groups is 1:2. We have assumed that the molecules are arranged so that the maximum number of O–H and N–H proton donors and oxygen proton acceptors participate in hydrogen bonds. The conformation and orientation of the molecules of **1** were adjusted so that the greatest stabilization by two- or three-center hydrogen bonds was realized (Fig. 1).

The pseudo space group symmetry of the *a,b* layer structure of the nylon component is monoclinic $P112/m$; i.e., the layer contains a twofold axis perpendicular to the *a,b* plane and a mirror plane within the layer. The pseudo twofold symmetry of the *a,b* nylon layer suggests that the two "crystallographically independent" molecules of **1** are centered on the pseudo twofold axes at $x,y \approx (1/2, 0)$ and $(1/2, 1/2)$. The diacid[7] centered on (1/2, 0) **A** (Fig. 1), can span the nylon amides separated by 7.6 Å, since the intramolecular distance between the carboxyl groups is ca 7.2 Å for a coplanar extended carbon skeleton. The two carboxyls of **A** each adopt an antiplanar conformation to form O–H · · · O(amide) bonds and bridge the nylon chains separated by the 8.5-Å *a* axis. This antiplanar O=C–O–H conformation, albeit rare in carboxylic acids,[9] has been found in a derivative of proline[10] and in 1,4-cubanedicarboxylic acid.[11] To form the O–H · · · O(amide) bonds, the plane of each carboxyl becomes perpendicular to that of the glutaric carbon chain. The molecule **A** forms hydrogen bonds along the *b* axis with the carboxyl groups of the two straddling **B** molecules centered on the pseudo twofold axes at $x,y \approx (1/2, 1/2)$ and $(1/2, -1/2)$. The carboxyls of **B** adopt the more frequently observed synplanar O=C–O–H conformations to form the O–H · · · O(acid) hydrogen bonds. The ensembles of acid molecules **A** and **B** may be related either by pseudo translation or by a pseudo glide plane along *b*. The latter would appear to be preferred, as shown in Figure 1b, to allow the carboxyl groups to form linear O–H · · · O bonds and coplanar O–H · · · O=C groups. The different environments of acids **A** and **B** are consistent with the broad ^{13}C NMR signal at $\delta = 162$.

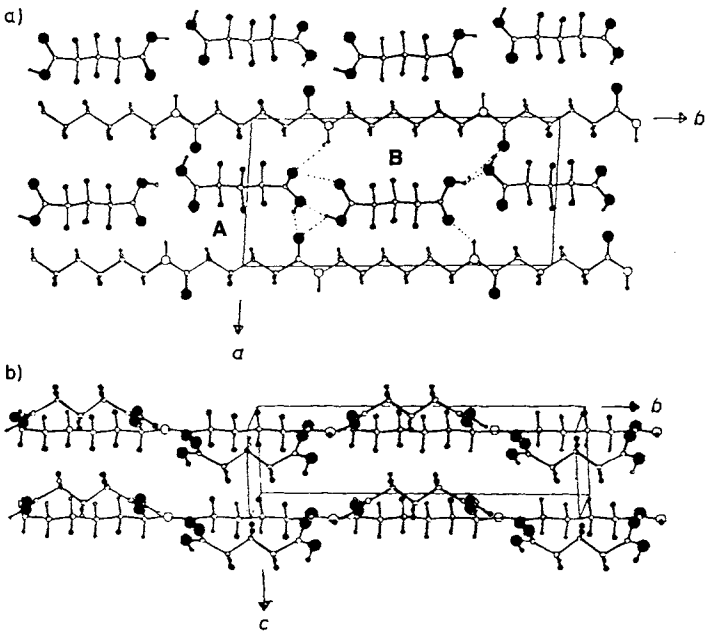

Fig. 1. Packing arrangement of nylon-66/1 viewed along the *c* axis (a) and the *a* axis (b). ● = H,F; ○ = C; ● = O; ○ = N.

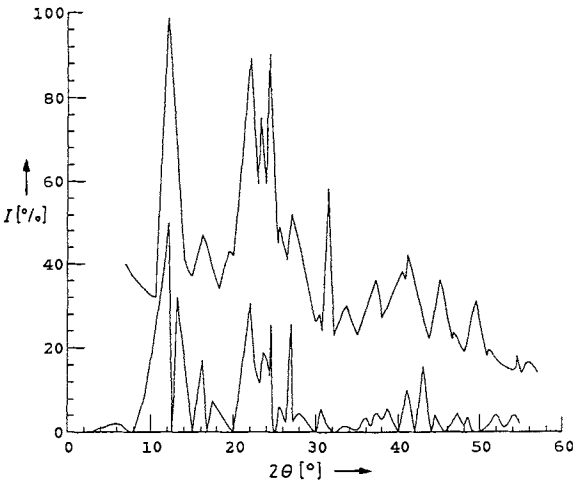

Fig. 2. Experimental (upper curve) and calculated (lower curve) X-ray diffraction powder intensity patterns as a function of Bragg angle 2θ (for $Co_{K\alpha}$ radiation) of nylon-66/1.

The X-ray powder pattern, calculated from the above coordinates, is in good agreement with experiment below $2\theta \approx 25°$ (Fig. 2), indicating the validity of the large-scale features of the model. The deviations at higher Bragg angles (as well as the lower observed density $\rho_{exp.}$ above) may arise from local disorder and "amorphous" regions.[12]

The network of hydrogen bonds can explain why the formation of an adduct between the diacid and nylon-66 is sensitive to the length of the diacid. Shorter and longer acids will not match the spacing between the hydrogen-bond-forming amides of the polymer; neither perfluorosuccinic nor perfluoroadipic acid forms an adduct with nylon-66.[3, 13] The conformation and orientation of **1** also leads to efficient packing of the fluorocarbon chains along the 4.7-Å *c* axis. An analogous array would be more open with the nonfluorinated glutaric acid, which does not form an adduct with nylon-66.[3, 14]

The reasonable F · · · F contacts between molecules of **1** separated by the 4.7-Å axis is achieved by stacking CF_2 arrays. A similar arrangement is found in the high-pressure form of polytetrafluoroethylene, whose chains, with a planar carbon backbone, are stacked along a 5-Å axis.[15] In the nylon/**1** complex the hydrocarbon and fluorocarbon groups can each pack efficiently along the 4.7-Å axis because the planes of their carbon backbones are almost perpendicular. The proximity of the fluorines of the diacid to hydrogens of the nylon is noteworthy, suggesting some compatibility of these often disparate components. The attraction of negative fluorine to slightly positive hydrogens may be a contributing factor.

[12] Rotations of the planes of carbon atoms and *syn–anti* interconversion of a carboxyl may contribute to the deviations. These have appeared in molecular dynamic simulations by Dr. *J. J. Wendoloski*, personal communication.
[13] This is in contrast to the formation of stable complexes between nylon-6 and perfluorosuccinic, -adipic, and -glutaric acids.
[14] Other structural variations might occur if, in order to effect better packing of chains along the 4.7-Å *c* axis, the nylon adopts a helical conformation, as in γ-nylon. Then, the alternate amide groups are interlinked by N-H · · · O (amide) bonds along the *c* axis. Furthermore, the interleaving carboxyl groups, adjacent to such amide groups, could still form O-H · · · O (amide) bonds, although distorted as in the crystal structure of urea.

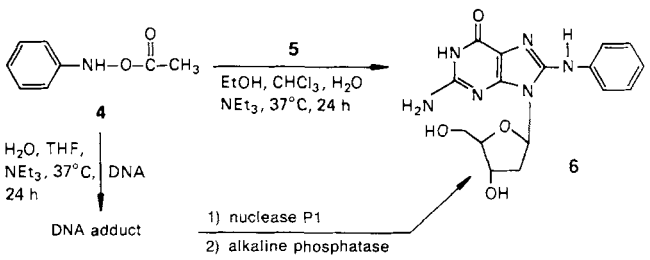
Formation of *N*-(Deoxyguanosin-8-yl)aniline in the in vitro Reaction of *N*-Acetoxyaniline with Deoxyguanosine and DNA**

By *Michael Famulok* and *Gernot Boche**



The acute toxicity of aniline **1** is due to the formation of methemoglobin; the metabolite phenylhydroxylamine **2** appears to play the crucial role in this process.[1, 2] In the Ames test,[3a] **1** and **2** exhibit mutagenicity in the *S. typhimurium* TA 98 strain only in the presence of norharmane (H-pyrido-[4,3-*b*]indole = β-carboline) and rat liver homogenate.[3b, c] In animal experiments, no tumor induction in $B6C3F_1$ mice was observed even after feeding them high doses of aniline hydrochloride (6000 and 12000 ppm) for long periods (103 weeks). By contrast, half of that amount of aniline hydrochloride (3000 and 6000 ppm, respectively, 103 weeks) caused Fischer 344 rats to develop sarcomas in the spleen.[4] Of interest, therefore, is the observation that ^{14}C-labeled aniline binds to DNA in the kidneys, colon, and spleen of rats, whereas practically no DNA binding could be detected in mice.[5] Both recent[6a] and earlier investigations[6b] have further shown that *N*-acetoxyarylamines are key metabolites in the carcinogenesis of aromatic amines. They are formed by *O*-acetylation of arylhydroxylamines or by *N,O*-transacetylation of the corresponding hydroxamic acids[6] (Scheme 1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

Scheme 2.

We recently showed that *O*-acetyl-*N*-(4-biphenylyl)hydroxylamine (*N*-acetoxy-4-aminobiphenyl)[8a] and *O*-acetyl-*N*-(2-naphthyl)hydroxylamine("*N*-acetoxy-2-naphthylamine")[8b] react with deoxyguanosine **5** to give adducts that have been isolated by other authors[9] from the DNA of the bladder epithelium of dogs after they were treated with 4-biphenylamine and 2-naphthylamine, respectively. Here we report that a corresponding metabolite of **1**, compound **4**, which can form in vivo from **2** and **3**,[6] reacts with **5** to give an adduct, *N*-(deoxyguanosin-8-yl)aniline **6**. Further, we were able to show that **6** is also formed in the in vitro reaction of **4** with DNA (Scheme 2).

Adduct **6** is a new compound; previous attempts using "activated aniline derivatives" to prepare an adduct of aniline **1** and **5** by in vitro electrophilic substitution failed.[10] Only adducts of **5** with aromatic amines known to be strong carcinogens have been known so far.[8, 11]

To show that **4** also reacts with DNA, the DNA was cleaved hydrolytically after reaction and the DNA hydrolysate was analyzed by HPLC. Figure 1a shows the HPLC profile of the adduct **6**; Figure 1b shows that of the hydrolysate after reaction of **4** with DNA under the same conditions. A concentration determination[13] revealed that 0.26% of the deoxyguanosine molecules present in the DNA had undergone amination by **4** to form the deoxyguanosine C8 adduct of the DNA.

In conclusion, **4**, a potential metabolite and ultimate carcinogen of aniline **1** covalently binds in vitro to deoxyguanosine **5** and DNA to form the deoxyguanosine C8 adduct **6**.

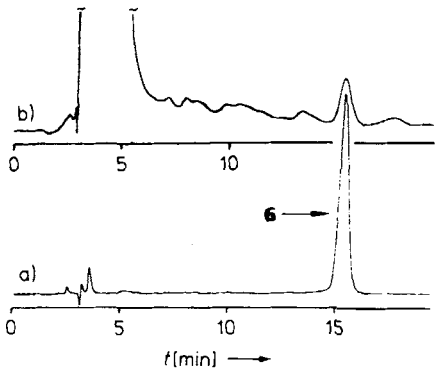

Fig. 1. a) HPLC profile of **6**. b) HPLC profile of the DNA hydrolysate after reaction of **4** with DNA. HPLC conditions: Nucleosil RP 18, 7 μm, 230- × 6-mm column, UV absorption at 260 nm, 35% CH_3OH, flow rate 0.7 mL min^{-1}, retention time of **6**, 15.4 min [12].

Experimental Procedure

Preparation of **4**: Compound **4** was first prepared in solution by *A. M. Lobo* et al. [14]; we have now isolated and completely characterized **4**. AcCN (2.07 g, 30.0 mmol) in 20 mL of Et_2O was added to a solution of **2** (3.27 g, 30.0 mmol) and NEt_3 (3.54 g, 35.0 mmol) in 50 mL of Et_2O (−40 °C, 20 min). The solution was stirred for 3 h at −15 °C, dried with $MgSO_4$ at 0 °C, and filtered. The oil

remaining after removal of the solvent in vacuo was dissolved in 10 mL of CH_2Cl_2, and 120 mL of petroleum ether (40–60 °C) was than added. The solution was concentrated to 70 mL and cooled for 3 h at −30 °C. The crystals that formed were collected and dried at −20 °C. Yield: 2.95 g (65%); m.p. 27–29 °C (not corrected); correct C,H,N elemental analysis (the sample was weighed and maintained at −78 °C until combustion). NMR (400 MHz, $CDCl_3$, 230 K): $\delta(^1H)$ = 2.24 (s, 3H), 7.07 (d, 2H), 7.11 (t, 1H), 7.35 (t, 2H), 8.86 (s, 1H, NH); $\delta(^{13}C)$ = 19.22, 116.36, 123.89, 129.00, 146.08, 170.78; IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3253, 1758, 1603, 1494, 1378, 1220, 723.

Reaction of **4** with **5** to give **6**: Compounds **4** (605 mg, 4.00 mmol) and **5** (1.07 g, 4.00 mmol) and NEt_3 (455 mg, 4.50 mmol) were stirred in a 7:3:4 mixture (70 mL) of EtOH, $CHCl_3$, and H_2O under N_2 for 24 h at 37 °C. After removal of the solvent, the residue was dissolved in 400 mL of H_2O and the resulting solution was extracted with 150 mL of Et_2O (6 ×) and 100 mL of *n*BuOH (5 ×). After removal of the *n*BuOH, the residue was dissolved in 10 mL of 50% CH_3OH and **6** was purified by HPLC (30% CH_3OH, 230 × 20 mm), LiChrosorb, RP 18, 7 μm, 1400 psi = 98 bar). Yield: 6%. NMR (400 MHz, [D_6]DMSO): $\delta(^1H)$ = 2.02 (m, 1H), 3.76 (m, 2H), 3.93 (m, 1H), 4.43 (m, 1H), 5.36 (s, 1H, OH), 5.98 (s, 1H, OH), 6.33 (q, 1H), 6.45 (s, 2H, NH_2), 6.90 (t, 1H), 7.25 (t, 2H), 7.73 (d, 2H), 8.63 (s, 1H, NH), 10.83 (s, 1H, NH), a sugar H is overlapped by DMSO signals; $\delta(^{13}C)$ (^1J(C, H)[Hz]) = 38.39 (t, 131.28), 61.20 (t, 141.33), 71.14 (d, 150.52), 82.72 (d, 163.03), 87.08 (d, 146.00), 112.14 (s), 117.21 (d, 162.10), 120.44 (d, 160.00), 128.39 (d, 158.10), 140.77 (s), 143.11 (s), 149.39 (s), 153.01 (s), 156.03 (s); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3343, 3206, 1681, 1600, 1562, 1498, 1355, 1099, 751; UV (CH_3OH): λ_{max}[nm] = 283.0, 204.0; FD-MS: *m/z* 358 ($M^{\oplus}$, 26.1%), 359 ($M^{\oplus}$ + H, 100), 381 ($M^{\oplus}$ + Na, 33.5).

Reaction of **4** with DNA to give **6**: A solution of calf thymus DNA (30 mg), **4** (30 mg, 0.2 mmol), and NEt_3 (17 mg, 0.17 mmol) in 20 mL of H_2O/THF (1/1) was kept for 20 h at 37 °C. After removal of the THF, extraction with 25 mL of Et_2O (3 ×), and addition of 10 mL of H_2O, the H_2O phase was treated with 2 mL of a 3 M NaOAc solution and 50 mL of EtOH. The DNA was precipitated at −20 °C, centrifuged at 10000 rpm for 10 min, and washed twice with 70% EtOH. After addition of 30 mL of H_2O, 1 mL of the solution contained 0.95 mg of DNA (UV determination of concentration). Following the literature procedure [15], 0.95 mg of DNA was hydrolyzed with nuclease P1 and alkaline phosphatase and the enzymes were then precipitated by addition of 800 μL of 3 M NaOAc solution and 20 mL of EtOH at −20 °C and removed by centrifugation. The solvent was removed from the supernatant and the residue was dissolved in 1 mL of 35% CH_3OH and analyzed by HPLC.

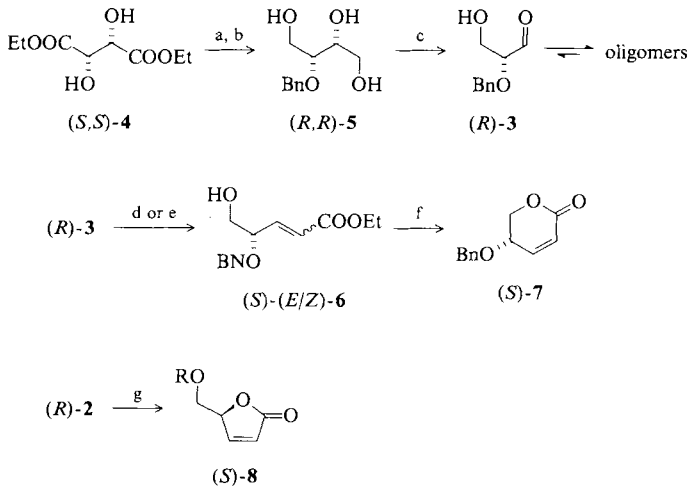
2-*O*-Benzylglyceraldehyde: A Synthetic Building Block Available in Both Enantiomeric Forms and Configurationally Stable Owing to Rapid Oligomerization**

By *Volker Jäger** and *Volkmar Wehner*

Optically active C_3 building blocks of type **1** are of great importance in organic synthesis.[1] Thus far, the key part is taken by 2,3-*O*-isopropylideneglyceraldehyde **2**, whose two enantiomers are readily accessible[1, 2] and which finds highly diverse uses due to the free aldehyde and the protected diol function. However, **2** is not stable as a monomer and undergoes racemization on storage.[3]

1 **2** **3**



In principle, glyceraldehyde derivatives with one free and one protected hydroxyl group could offer new applications, since O^2/O^3 are more strongly differentiated and regio- and stereoselectivities may be altered by action of the free hydroxyl group in the first or subsequent steps. We report here a new, simple synthesis of both enantiomers of such a compound, namely, **3**, as well as some transformations that confirm this and which, in addition, prove **3** to be configurationally stable at room temperature.

(*R*)-2-*O*-Benzylglyceraldehyde, (*R*)-**3**, was prepared earlier from D-mannitol (four steps, ca. 5% overall yield) or D-glucose (six steps, ca. 50%) and used directly without further analysis.[4] Both enantiomers, (*R*)-**3** and (*S*)-**3**, are now readily obtained, as shown in Scheme 1, from the corresponding tartrates **4** via the known 2-*O*-benzylthreitols **5**[5] (three steps, ca. 70% overall yield). The freshly prepared aldehyde **3**, obtained as a colorless oil upon distillation, initially has a fruitlike odor; upon standing, it turns sirupy, then becomes a waxy, odorless solid. This behavior is reminiscent of the oligomerization and polymerization known for similar hydroxyaldehydes.[6] Indeed, neat **3** evolves into a mixture of at least ten oligo-/stereoisomers. The ^{13}C NMR spectrum of a sample recorded after 17 h showed a small peak at δ = 202.4 (*C*HO), but at least 32 signals in the region δ = 60–100 where three are expected for the monomeric aldehyde **3**.

What about the configurational stability (C-2) of **3**, the crucial factor determining its preparative utility? The rapid oligomerization [to (hemi)acetals] gave fair promise that the racemization observed for *monomeric* relatives such as **2** might be obviated. The optical rotation of freshly distilled (*R*)-**3** in ethanol was found to be + 21.7 (c = 1.23), which decreased rapidly (+ 16.1 after 6 h), but later increased slowly and finally remained constant at + 30.3 (± 0.8) after 19 d!

Drauz* (Degussa AG, Hanau) for donation of chemicals, and *H. Sattler* for experimental assistance.

Scheme 1. Preparation and Horner/Wittig products of **3**. The formulas give starting materials and products with respect to (*R*)-**3**; all reactions were carried out in both series of enantiomers. The structures of **6** and **7** were confirmed by spectroscopic data (IR, ^1H, ^{13}C NMR) and correct elemental analyses. a, b) According to *Seebach* et al. [5]: PhCHO, TosOH · H_2O (cat.), C_6H_6, reflux; m.p. 45 °C; then $LiAlH_4$, $AlCl_3$, CH_2Cl_2, − 40 °C to reflux temperature; overall yield ca. 75% **5**. c) $NaIO_4$, H_2O, 20 °C; 90–96% **3**; b.p. ca. 140 °C/0.005 torr (short-path distillation); 5–50-mmol scale. d) $(EtO)_2P(O)CH_2COOEt$, NaH, THF, 0 °C; addition of **3** at − 78 °C, then allowed to warm to room temperature; 76–78% **6** (colorless oil) with $E:Z = > 97:3$, enantiomer ratio > 97:3 according to NMR analysis with 5.8% (+)-Eu(hfc)$_3$ and comparison with (*S*):(*R*) mixtures (86:14 and 33:67); boiling range 150–180 °C (bath temperature, kugelrohr)/0.08 torr; (*S*)-(*E*)-**6**: $[\alpha]_D^{22}$ + 73.8 (*c* = 0.90, $CHCl_3$), (*R*)-(*E*)-**6**: $[\alpha]_D^{22}$ − 74.4 (*c* = 0.90, $CHCl_3$). e) $Ph_3P=CH-COOEt$, MeOH, 0 °C, 94% (*S*)-**6** or (*R*)-**6** with $Z:E = 76:24$ (according to ^1H, ^{13}C NMR) and a small amount of **7** (3–5%), which increases at the expense of (*Z*)-**6** on standing. f) TosOH · H_2O (0.1 equiv.), toluene, 20 °C; MPLC (LiChroprep Si-60, petroleum ether/ethyl acetate 2:1, detection of 254 nm); colorless crystals, m.p. 71–71.5 °C, 53–55% yield; (*S*)-**7**: $[\alpha]_D^{21}$ + 121.6 (*c* = 0.852, $CHCl_3$); (*R*)-**7**: $[\alpha]_D^{21}$ − 120.9 (*c* = 0.852, $CHCl_3$); enantiomeric ratio > 96:4 according to NMR analysis with 8.5 mol% (+)-Eu(hfc)$_3$ and comparison with a 71:29 mixture [9]. g) see [2b].

Similar behavior ("mutarotation") is known for (*R*)- and (*S*)-glyceraldehyde.[6]

Next: Is it possible to preserve this presumed configurational stability (with respect to C-2) of the oligomeric mixture formed from **3** in subsequent reactions, in particular with respect to C–C bond formation? In order to answer this, we converted **3** into the pentenoic esters **6**: analogous Horner and Wittig reactions with **2** had earlier led to popular C_5 building blocks with *E* and *Z* selectivity, respectively.[2b, 7] Starting from (*R*)-**3** and using potassium carbonate as base,[8a] the Horner phosphonate procedure afforded, after 45 h at room temperature, 49% of the "pure" (^1H NMR) *E*-ester **6**. However, on addition of the optically active shift reagent (+)-Eu(hfc)$_3$, this turned out to be a 73:27 mixture of the (*S*)/(*R*) enantiomers. When the sodium phosphonate was prepared prior to use, the reaction occurred appreciably faster;[8b] **6** was formed with an *E*/*Z* ratio of > 97:3 in high enantiomeric purity (see Scheme 1).

The *Z*-selective Wittig reaction with ethoxycarbonylmethylenetriphenylphosphorane in absolute, acid-free methanol (according to the "Kishi footnote"[7]) gave a 94% yield of pentenoic esters **6** as a 24:76 mixture of *E*/*Z* isomers starting from either (*R*)- or (*S*)-**3**. The *Z* compounds readily undergo acid-catalyzed lactonization to give the penten-5-olides **7**, which, according to NMR analysis, are also enantiomerically "pure" (i.e., enantiomeric ratio > 96:4; see Scheme 1).[9] Fully analogous results were obtained for samples of (*R*)- and (*S*)-**3** that had been stored for eight weeks at room temperature and had turned into waxlike solids.

The cyclization of (*Z*)-**6** to the six-membered lactone **7** demonstrates that the use of benzylglyceraldehyde **3** offers new possibilities that are complementary to those given by the acetonides **2**. The analogous sequence, starting from (*S*)-**2**, had earlier led to the five-membered lactone (*S*)-**8**[2b] (see Scheme 1); recently, this route was employed as part of an efficient synthesis of 3′-azidothymidine (AZT or ZDV).[10]

We expect the benzylglyceraldehydes **3** and the new building blocks **6** and **7** derived therefrom to find manifold uses in organic synthesis.

Stabilization of Niobium(0) and Tantalum(0) in Mixed Metal Clusters containing Silver Atoms**

By *Fausto Calderazzo,** *Guido Pampaloni, Ullrich Englert,* and *Joachim Strähle*

Clusters with supporting bridge ligands are rare among Group 5 metals, the only crystallographically established example being $[Cp_3Nb_3(CO)_7]$[1] ($Cp = \eta^5$-C_5H_5). On the other hand, halo-, oxo-, and sulfido-bridged clusters of vanadium, niobium and tantalum in oxidation states higher than I are well documented in the literature.[2] Vanadium(0) compounds are readily accessible,[3] whereas niobium(0) and tantalum(0) complexes mostly have to be prepared by metal vaporization.[4] Among the mixed metal clusters $[\{(PPh_3)Au\}_3V(CO)_5]$ has been prepared and structurally characterized,[5] while a positive oxidation state for niobium has been found[6] in $[\{(PPh_3)Au\}_2Nb(C_5H_4R)_2]^{\oplus}$.

We now wish to report the first structurally characterized carbonyl clusters containing niobium and tantalum in the formal zero oxidation state.

The reactions of **1** (dmpe = 1,2-bis(dimethylphosphino)ethane) with silver salts of poorly coordinating anions, namely $AgNO_2$ and $AgBF_4$, in THF at room temperature afford compounds of analytical composition **2** [Eq. (a)].

$$3\ NEt_4[M(CO)_4(dmpe)] + 3\ AgNO_2 \longrightarrow \underset{\mathbf{1}}{} \quad \underset{\mathbf{2}}{[AgM(CO)_4(dmpe)]_3} + 3\ NEt_4NO_2 \quad (a)$$

a, M = Nb; **b**, M = Ta

The solid state structures of **2** were established by single crystal X-ray diffraction methods.[7] Both compounds are isotypic, as shown by Gandolfi photographs of the single crystals used for subsequent intensity measurements.

The complexes **2** are structurally related to the osmium[12] and iron-platinum[13] raft-like clusters. The ten non-hydrogen atoms in the asymmetric unit are arranged around the intersection of a crystallographic threefold axis with three twofold axes, i.e. the point symmetry of the resulting molecule is D_3, the three silver atoms and the three Group 5 metal atoms lying in the plane containing the twofold axes (Fig. 1).

The arrangement of the metal atoms in almost equilateral triangles corresponds to that of a (111) plane in a close-packed metal structure, the intermetallic angles being all close to 60°. The almost identical Ag–Ag distances of 2.842 Å in **2a** and **2b** are shorter than in silver metal (2.883 Å).[14] In the intermetallic cubic Laves phase $NaAg_2$, which contains a network of corner-connected Ag_4 tetrahedra, the Ag–Ag distances are 2.810 Å.[15] Moreover, a Ag–Ag distance of 2.994(6) Å has been found[16] in the heterometallic cluster $[Pt_2Ag_2Cl_4(C_6F_5)_4]^{2\ominus}$. The distances between Ag and Nb or Ta in **2a** and **2b** are also very similar (2.888 Å) and might be compared with the sum of the metallic radii (2.91 Å[14]).

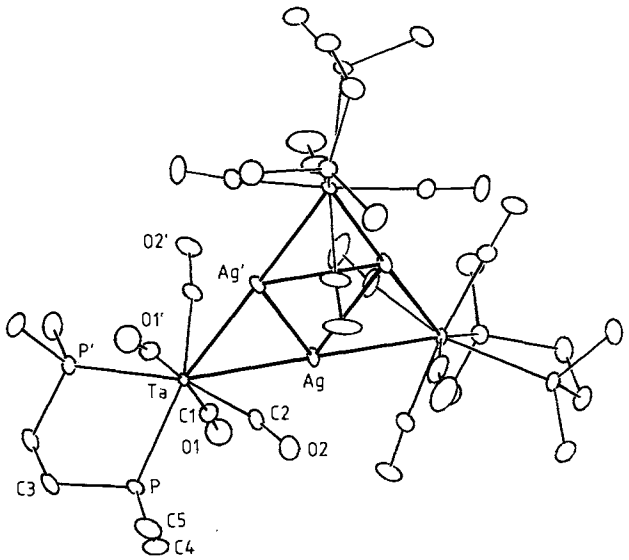

Fig. 1. ORTEP view of **2b** (thermal ellipsoids are drawn at the 10% probability level). Selected interatomic distances [Å] and angles [°]: **2a**; Ag-Nb 2.8879(2), Ag-Ag' 2.8424(5), Nb-C1 2.079(4), Nb-C2 2.103(4), Ag-C1 2.768(4), Ag-C2 2.593(4), Ag-Nb-Ag' 58.96(1), Nb-C1-O1 175.6(3), Nb-C2-O2 169.4(3); **2b**: Ag-Ta 2.8884(2), Ag-Ag' 2.8418(8), Ta-C1 2.049(4), Ta-C2 2.082(5), Ag-C1 2.784(4), Ag-C2 2.614(5), Ag-Ta-Ag' 58.93(2), Ta-C1-O1 177.6(4), Ta-C2-O2 172.1(4).

The coordination polyhedron for the Group 5 metal atom in **2**, for which 84 cluster electrons have been calculated, may be regarded as a distorted square antiprism. Bonding in raft-like clusters has been discussed by *Mingos* and *Evans*[17] and it has been shown that the known examples, containing both axial and equatorial ligands[12] or equatorial ligands only[13] on the metal atom occupying the central position on the edge of the equilateral triangle, contain 90 or 86 electrons, respectively.

The reactivity of these clusters is now under investigation.

Experimental

Only the preparation of **2b** is described in detail, since **2a** can be obtained analogously.

A solution **1b** [18] (0.471 g, 0.82 mmol) in THF (300 ml) was treated at room temperature with $AgNO_2$ [19] (0.257 g, 1.67 mmol) under an argon atmosphere. The reaction mixture was warmed at 45 °C for 30 minutes, cooled to room temperature and filtered. The solvent was partially removed in vacuo at 0 °C until some red-orange solid began to separate. When the volume of the solvent was reduced to ca. 30 ml, the solid was filtered and dried in vacuo at room temperature (0.164 g). The filtered solution was cooled to −30 °C affording a second crop (0.02 g) of **2b** (40% total yield with respect to tantalum) as red-orange crystals [20]. $\chi_M^{corr} = +1.1 \times 10^{-8}$ m^3 mol^{-1} at 20 °C; diamagnetic correction $= -1.1 \times 10^{-8}$ m^3 mol^{-1}.—Compound **2b** was also obtained upon reaction of **1b** with $AgBF_4$ in THF at −60 °C (identification via IR spectrum and element analysis.

The Dienolate of (*R*)-2-*tert*-Butyl-6-methyl-1,3-dioxin-4(2*H*)-one—a Chiral Acetoacetic Ester d^4-Reagent**

By *Dieter Seebach,** *Ulf Misslitz*, and *Peter Uhlmann*

We recently reported[1] an efficient conversion of (*R*)-3-hydroxybutanoic acid into the title compound **1**, which has emerged as a valuable building block for the synthesis of enantiomerically pure compounds (EPC syntheses):[2] cuprates, Cu(I)-doped Grignard reagents, thiolates and catalytically activated hydrogen add to C-6 of the heterocycle exclusively with relative topicity *ul*.[3]

In view of the fact that there are hardly any *chiral* synthetic equivalents[4a] of the acetoacetic ester dianion,[4b] it appeared promising to study the reactivity of the dienolate derivatives **2** generated from the dioxinone **1** and Li, Na, or K hexamethyldisilazide, as well as of the corresponding silyldienol ethers [**2**, M = $SiMe_3$, Si(*t*Bu)Me_2].

The Li dienolate reacts with acetaldehyde at the C-5 ring position to give essentially one[5] diastereoisomer **3a** (20:1). In contrast, products **4a–h** of hydroxybenzylation at the exocyclic C-1 position are formed highly regioselectively with aromatic aldehydes and ketones (modest stereoselectivity, $\leq 3:1$), substituents on the benzene ring influencing the yield more than the diastereodifferentiation.

Scheme 1. a) $MN(SiMe_3)_2$ (M = Li, Na, K), THF, −75 °C, 1 h. b) With M = Li; Alkyl-CHO, −105 °C, 1 h. c) With M = Li; R^1R^2CO, −105 °C (R^1 = Aryl, R^2 = H) or −75 °C (R^1 = Aryl, R^2 + H), 1 h. d) Me_3SiCl or Me_2(*t*Bu)SiCl, −75 to 0 °C, 16 h. e) Aryl-CH=CH-CHO, Lewis acid, CH_2Cl_2, −75 °C, (R^1 = Aryl), 6 h. f) With M = Li, Na or K, R^1-CH=CH-CHO, −105 °C, 1 h.

To our surprise, α,β-unsaturated aldehydes such as crotonaldehyde and cinnamaldehyde combine with the same Li dienolate in a Michael addition of the exocyclic nucleophilic center (a^3/d^4-coupling), with very high regio-[5] and stereoselectivity (ca. 20:1, products **6**). The 1,2-adducts **5**, on the other hand, were obtained from the reaction of the silylenol ethers **2**-$SiMe_3$ or -Si(*t*Bu)Me_2 with α,β-unsaturat-

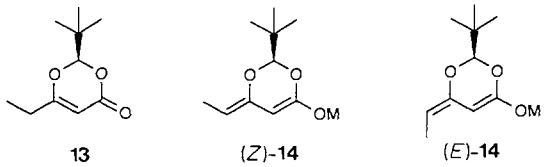
[c] Major diastereoisomer: m.p. 143–144 °C, $[\alpha]_D = -144$ ($c = 1.0$, EtOH). [d] $[\alpha]_D = -65.0$ ($c = 1.5$, CH_2Cl_2). [e] $[\alpha]_D = -132$ ($c = 2.4$, CH_2Cl_2).

ed β-arylaldehydes such as cinnamaldehyde in the presence of Lewis acids (see Scheme 1 and Table 1).



The configurations of the following products were determined by chemical correlations: **3a, 4a** and **5a**, as well as **10**, the (*Z*)-silyldienol ether derivative of **6a** (see Scheme 2). Thus, the acetaldehyde adduct **3a** was hydrogenated (→ **7**) and the product rearranged to the achiral (optically inactive) dioxanecarboxylic acid **8** with C_s-symmetry, under acid catalysis conditions (the substitution pattern of the six-membered rings in **7** and **8** being confirmed by NOE measurements). A diastereomerically pure sample of the major

product **4a** was converted into the known (*S*)-3-hydroxy-3-phenylpropanoic acid[6] (**9**, > 95% *ee*) by ozonolysis of the dioxinone double bond. Similarly, treatment with ozone, reduction of the resulting aldehyde group and lactonization under acidic conditions converted the products **5a** and **10** into optically active samples of the known butyrolactones **11**[7] and **12**,[8] respectively.

Not having carried out any mechanistic investigations as yet, we refrain from speculating about possible reasons for the observed selectivities and leave more or less obvious explanations to the imagination of the reader.[9] We hope to gain some valuable relevant information in this connection from ongoing studies of the reactions of *E*/*Z*-dienol derivatives **14** (M = Li, Na, K, SiR_3) generated from the ethyl-substituted[1] heterocycle **13**.

13 (*Z*)-**14** (*E*)-**14**

Finally, it should be pointed out that structures of type **4** and **5**, and their conversion into 3,5-dihydroxycarboxylic acids are of interest with regard to the syntheses of compactin and its analogues.[10]

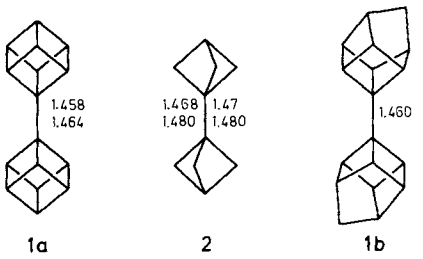
Shortened C–C Bonds in Coupled Bicyclo[1.1.0]butanes**



By *Otto Ermer,* Peter Bell, Jörg Schäfer* and *Günter Szeimies*

Bonds involved in widened bond angles are shortened. We have recently exemplified this for the case of 1,4-cubanedi-

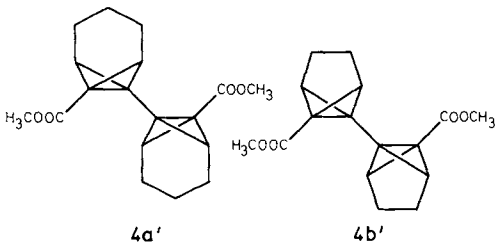
[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.



carboxylic acid, whose $C(sp^3)$–$C(sp^2)$ single bonds are shortened by ca. 0.04 Å, since they participate in three exocyclic CCC angles widened by 16.0° (average) beyond the tetrahedral value. This led us to the prediction that the central CC single bonds in the coupled cubane and bicyclo[1.1.1]pentane systems **1a** and **2**, respectively, should be shortened by about 0.08 Å to 1.46 Å, since they participate in six similarly widened CCC angles.[1] This prediction has now been confirmed experimentally several times, also for the similarly coupled homocubane **1b**; the respective bond lengths [Å] determined by X-ray analysis for parent systems and derivatives are reproduced in the formula diagrams.[2]

The central CC bond of the 1,1'-coupled bicyclo[1.1.0]butane **3** may be expected to be shortened still further, since the exocyclic angles at the tertiary carbon atoms of bicyclo[1.1.0]butane exceed the tetrahedral value, on average, by 20.2°,[3] and are thus larger than in cubane or bicyclo[1.1.1]pentane. The introduction of short bridges as in **4**, with $n \leq 2$, should lead to further shortenings; according to model considerations, **4a** ($n = 3$) is, in the present context, comparable with **3**.

Thus, in the series from **4a** (**3**) through **4b** and **4c** we are faced with further growing widenings of the angles at the central CC bond until, in the ultimate member bitetrahedryl **4d** ($n = 0$), values near arc $\cos(-\sqrt{2/3}) - 109.5 = 35.3°$ are reached. The latter extreme case of bitetrahedryl **4d** with a presumably ultrashort central CC bond is obviously hypothetical and hardly realizable; with due reference to tetra-*tert*-butyltetrahedrane,[4] the hexa-*tert*-butyl derivative **4d'** could be feasible and stable. As a rough estimate for the maximally conceivable bond shortening by angle widening, the length of the central CC single bond (1.384(2) Å) in diacetylene **5**[5] may eventually be used. Viewing acetylene as "bicyclo[0.0.0]ethane," formal angle widenings of $180 - 109.5 = 70.5°$[6] and a bond shortening of $1.54 - 1.38 = 0.16$ Å are obtained. Herein we describe the structure analyses of the two esters **4a'** and **4b'**,[7] which we have carried out in an attempt to "approach" the extreme bitetrahedryl **4d**. As expected, particularly short central CC bonds are observed in both cases.

Important findings of the crystal structure analyses[8] are summarized in Figure 1. Both coupled bicyclo[1.1.0]butane derivatives **4a'** and **4b'** are centrosymmetric in the crystal. Ignoring the ester groups, C_{2h} symmetry is closely approximated. Nonetheless, however, the conformation about the central CC bond is by no means ideally staggered, since, as a result of the relatively unsymmetric angle distortions at C(1) and C(1') not even approximate local C_3 symmetry is present about this bond: as the torsion angles and Newman projections of Figure 1 show, a plane may be drawn through C(1) and C(1') such that the four bonded C atoms lie on one side of this plane! The length of the central CC bond in **4a'** is 1.445(3) Å (librationally corrected 1.448 Å) and the adjacent bond angles are on average widened by 18.7° out to 128.2°. As expected, the central CC bond in **4b'** is shortened still somewhat further to 1.440(2) Å (libr. corrected 1.443 Å) in view of the adjacent angles being widened on average by 21.4° out to 130.9° (Fig. 1). To our knowledge this is the shortest non-cyclic (unbent) CC single bond between saturated, tetravalent C atoms observed so far.[9]

The CC bonds between the bicyclobutane skeletons and the ester groups in **4a'** and **4b'** are more severely shortened (by ca. 0.07 Å; Fig. 1) than would be expected on the grounds of the angle widenings alone. Presumably conjugation effects between the carbonyl group and the cyclopropane rings are responsible for this. Conversely, the CC bonds common to the annelated three-membered rings are remarkably long (1.547(3) Å in **4a'**, 1.532(2) Å in **4b'**; 1.497(3) Å in bicyclo[1.1.0]butane[3]). Consideration of comparable bicyclo[1.1.0]butane derivatives[10] shows that the conjugation between carbonyl group and three-membered ring may again be responsible.

The longest known single bonds between saturated, tetravalent C atoms are stretched by ca. 0.10 Å with respect to the normal value (1.54 Å).[11] In **4a'** and **4b'** the other extreme is reached, with the central bond shortened by just this amount, so that a variation of altogether ca. 0.20 Å is now recorded experimentally for such bonds. The length of the central CC bond in **4b'** (1.440(2) Å) may be regarded as an upper limit of that in bitetrahedryl **4d**. A narrower experimental delimitation would be possible by studying the cou-

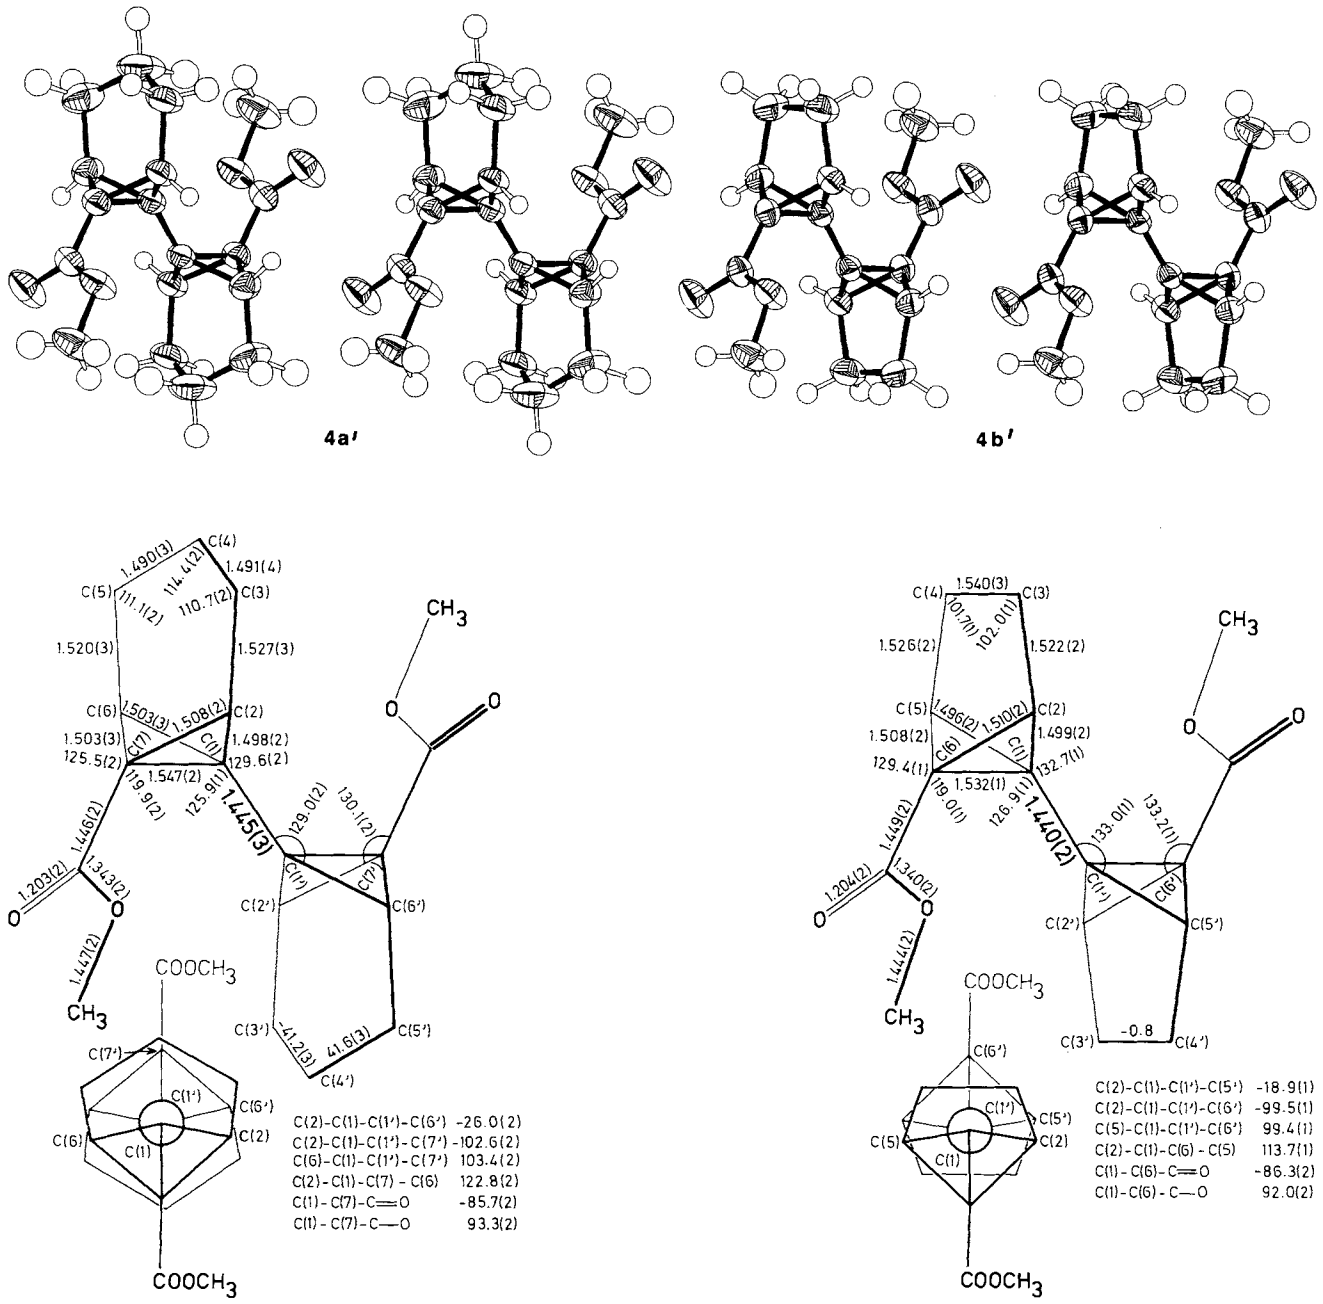


Fig. 1. Structures of **4a'** (left) and **4b'** (right) in the crystal. Top: stereoviews with vibrational ellipsoids at the 50% probability level; temperature factors of the H atoms trebled. Bottom: bond lengths [Å], selected bond and torsion angles [°], Newman projections along C(1)–C(1'), and atomic numbering.

pled homotetrahedrane **4c**, whose six internal CCC angles should be widened on average by about 28° to 138° (estimate based on structural data for tricyclo[2.1.0.0^{2,5}]pentane[10] itself). These angle openings approach those in **4d** already to within ca. 7°. (The system **4c** is unknown, but appears to have a fair chance of being turned into reality, so that the most extreme shortening of a CC bond thus seems experimentally attainable). In tetra-*tert*-butyltetrahedrane the CC bonds between the tetrahedrane skeleton and the *tert*-butyl groups are shortened on average by 0.05 Å to 1.49 Å.[12] Based on the successful extrapolation of the lengths of the central CC bonds in bicubyl **1a** and 1,1'-bi(bicyclo-[1.1.1]pentyl) **2** from 1,4-cubanedicarboxylic acid, a shortening of 0.10 Å would be expected for the central CC bond of bitetrahedryl **4d**. This estimate is not very reliable, however, since the corresponding three independent CC bond lengths in crystalline tetra-*tert*-butyltetrahedrane display substantial scatter and are not particularly precise (1.480–1.503 Å, $\sigma \approx 0.005$ Å[12]). In the light of the findings for **4a'** and **4b'** the estimated shortening indeed appears too low, presumably owing to some weak non-bonding H···H repulsions in tetra-*tert*-butyltetrahedrane which counteract the CC bond contractions.

[2] a) Coupled Cubanes: R. Gilardi, M. Maggini, P. E. Eaton, *J. Am. Chem. Soc. 110* (1988) 7232. The authors discuss a central CC shortening of even 0.114 Å for **1a** and criticize our pre-estimate of 0.08 Å [1]. In doing so, they refer to a CC reference length of 1.572 Å based on bond lengths between quaternary C atoms in hydrocarbons, for example 1,1'-biadamantyl. This length, however, may not be regarded as a standard value for an unstrained CC single bond, yet is to be viewed as stretched due to nonbonding H ··· H repulsions. The $C(sp^3)$–$C(sp^2)$ shortening of 0.04 Å observed in 1,4-cubanedicarboxylic acid arises exclusively from angle widening without involvement of nonbonding interactions. Consequently, our predicted shortening of 0.08 Å in **1a** and **2** [1] could meaningfully only refer to the usual standard length of an unstrained CC single bond of 1.54 Å. The shortenings measured in the meantime for **1a** and **2** (and **1b**) thus agree very satisfactorily with our prognosis. b) Coupled bicyclo[1.1.1]pentanes: U. Bunz, K. Polborn, H.-U. Wagner, G. [9] The *generally* shortest distances between single bonded, tetravalent C atoms probably occur in two tricyclo[2.1.0.0^{2,5}]pentan-3-one derivatives. For the distance between the two C atoms common to the three-membered rings, *Irngartinger* et al. have measured values of 1.417(1) [10a] and 1.416(2) Å [10b]. It should be noted, however, that these three-membered ring bonds, in contrast to the exocyclic central CC bond in the coupled systems discussed here, are severely bent and thus the bond length definition becomes problematic.

Synthesis and Structure of a Phenylsodium Solvate, Bis[μ-phenyl(pentamethyldiethylenetriamine)-sodium] **

By *Uwe Schümann, Ulrich Behrens,* and *Erwin Weiss* *

Phenylsodium was known for quite some time before it could be prepared in a relatively pure form by reaction (a).

$$LiPh + NaO\mathit{t}Bu \rightarrow NaPh + LiO\mathit{t}Bu \quad (a)$$

As in the case of phenyllithium, single crystals were not obtainable; hence the structure of these important alkali-metal compounds have thus far remained unsolved. Phenyllithium has, however, already been investigated X-ray crystallographically in three different solvated forms and, depending upon the solvent, was found to be present as tetramer (**1**), dimer (**2**) or monomer (**3**).

$[PhLi(OEt_2)]_4$[3] **1** $[PhLi(tmeda)]_2$[4] **2** $[PhLi(pmdta)]$[5a, 6] **3**

tmeda = tetramethylethylenediamine
pmdta = pentamethyldiethylenetriamine

The complexes **1**–**3** are thus excellent models for demonstrating the influence of a solvent on the structure of organolithium compounds. The degree of association of the complexes decreases with increasing hapticity of the ligands. The tridentate ligand pmdta was found to be the most suitable ligand for the stabilization of the monomeric form, also in the case of alkyllithium compounds.[6] We therefore decided to employ it in our attempted synthesis of a phenylsodium solvate.

Reaction of NaPh with pmdta in hexane led indeed to a 1:1 adduct (**4**), from which crystals suitable enough for an X-ray structure analysis could be obtained. The structure is shown in Figure 1.[7]

$[PhNa(pmdta)]_2$ **4**

Contrary to what has been found in the case of LiPh, the solvate of NaPh with the tridentate ligand pmdta is not monomeric but dimeric, thus reflecting the larger ionic radius of $Na^{\oplus}$, i.e. $Li^{\oplus}$ favors the coordination number 4 in many of its solvates, whereas a higher coordination number is possible in the case of $Na^{\oplus}$.

The $Na^{\oplus}$ ions in **4** are coordinated in an extremely distorted trigonal-pyramidal geometry; the N–Na–N angles are only about 67.6°. The central N atom (N2) of the three N atoms is much more weakly bonded than the two terminal N atoms, since its lone pair cannot be optimally oriented towards the $Na^{\oplus}$ ion.

Comparative considerations[8] show that N–metal–N angles of 80–87° occur in organolithium compounds, and of 67–77° in organosodium compounds. According to *Stucky* et al.,[9] in agreement with this the N–M–N angle in tmeda complexes should be 85° for M = Li and 56° for M = K. As in other phenyl-metal compounds the phenyl rings in **4** are planar, but the C–C–C angles deviate from 120°; for the C atom (C1) directly adjacent to the metal atom the angle is only 111.7°.

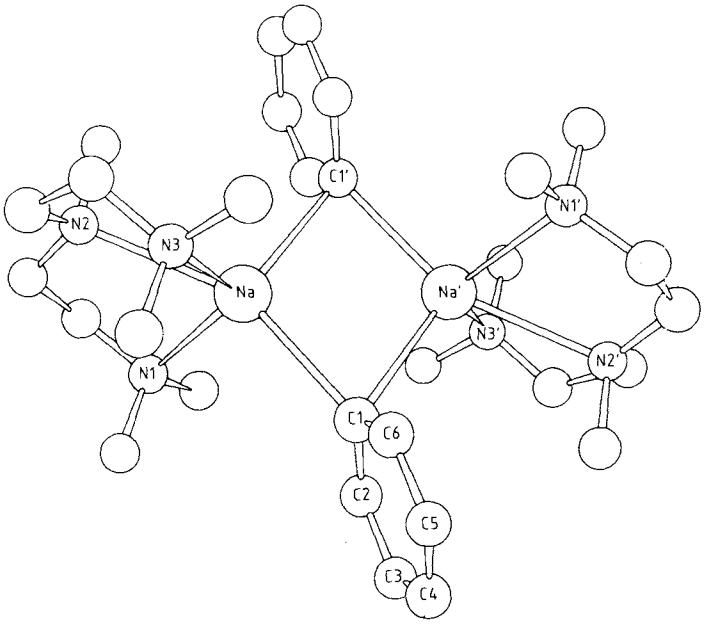

Fig. 1. Structure of **4** in the crystal. ORTEP plot of the centrosymmetric molecule. Important bond lengths [pm] and angles [°]: Na-C1 265.8(4), Na-C1' 268.2(6), Na-N1 264.6(3), Na-N2 271.2(3), Na-N3 260.9(3), Na-Na' 323.7(3), C-C (phenyl) 138.6 (mean value, min. 134.4, max. 141.0); N-C 145.3 (mean value, min. 142.9, max. 148.7); Na-C1-Na' 74.6, C1-Na-C1' 105.4, N1-Na-N2 67.6, N2-Na-N3 67.7, N1-Na-N3 119.1(1), C1-Na-N1 102.5(1), C1-Na-N3 99.7(1), C2-C1-C6 111.7(3), C1-C2-C3 124.3(4), C2-C3-C4 120.8(4), C3-C4-C5 119.3(5), C4-C5-C6 119.0(4), C5-C6-C1 124.9(4).

Experimental

All operations were carried out under an inert gas and with carefully dried solvents. For the synthesis of phenylsodium according to equation (a) [2], it is advisable to recrystallize the NaO*t*Bu before use; sublimation leads to considerable losses and less pure products. A suspension of 0.25 g (2.5 mmol) of NaPh (containing ca. 0.6 weight-% Li, corresponding to 7.3 mol-% LiPh) in 30 mL of hexane was brought into solution by addition of 1.2 mL (5.8 mmol) of anhydrous pmdta. Upon completion of the addition, a part of the phenylsodium already in solution re-precipitated as a white powder. The supernatant, intensely red solution was pipetted off and yielded, after cooling to $-30\,^{\circ}C$, 1.17 g (17%) of **4** in the form of coarsely crystalline light-brown, pyrophoric platelets (correct analysis for Na, C, H, N). Single crystals suitable for an X-ray structure analysis were obtained from the mother liquor.

Tetraalkylidene-1,4-diboracyclohexanes from 3,4-Dilithio-2,5-dimethyl-2,4-hexadiene; the First "Hetero[6]radialene" with Chair Conformation**

By *Adalbert Maercker**, *Walter Brieden*, *Thomas Schmidt*, and *Heinz Dieter Lutz*

We recently reported the synthesis and structure of the first "dimetalla[6]radialene" **2a**.[1] In the crystalline state it has a twist conformation. Besides **2a**, only one further "hetero[6]radialene" has so far been reported in the literature, the corresponding sulfur compound **2b**, which was obtained—likewise with twist conformation—in a multistep synthesis.[2] In the meantime we have been able to prepare **2b** quite easily, and analogously to **2a**, from 3,4-dilithio-2,5-dimethyl-2,4-hexadiene **1**,[3] whereby it is advantageous to convert the sulfur dichloride into diimidazolyl sulfide prior to the reaction.[4]

1 **2**

a: X = Me_2Sn **c**: X = *t*BuB
b: X = S **d**: X = Ph_2NB

Since boraheterocycles are currently the subject of intensive studies—both theoretically and preparatively[5]—we have also tried to synthesize 1,4-dibora[6]radialenes by our method, particularly as these compounds can be expected to exhibit interesting properties with regard to their stereochemistry, NMR spectroscopy, and reactivity towards dienophiles.

Reaction of **1**[6, 7] with *tert*-butyldichloroborane in diethyl ether at $-50\,^{\circ}C$ leads to formation of a colorless, crystalline substance that is surprisingly stable towards air and hydrolysis, and which, according to the spectroscopic data,[8] is 1,4-di(*tert*-butyl)-2,3,5,6-tetra-2-propylidene-1,4-diboracyclohexane **2c** (yield 34%, not optimized, remainder presumably polymers). However, before any comments could be made about the conformation, an X-ray structure analysis[9] had to be carried out. It was established that **2c** is in fact the first "hetero[6]radialene" with chair conformation (Fig. 1).

Remarkable features of the structure of **2c** are, on the one hand, the large dihedral angles in the two butadiene units (with 74° and 73° they are only 10° smaller than in the analogous ditin compound **2a**, which has a twist conformation) and, on the other, that the central bonds of the butadiene units, which exhibit practically no double bond character, are, with lengths of 1.511(4) and 1.517(4) Å, identical with the corresponding distances in **2a**, i.e. there is no detectable influence of the heteroatoms on these bonds.

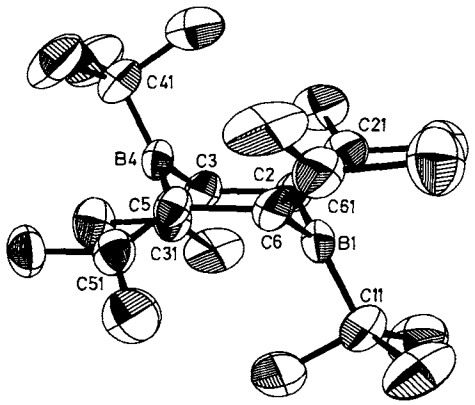
[**] Polylithium Organic Compounds, Part 10. This work was supported by the Stiftung Volkswagenwerk and the Fonds der Chemischen Industrie.—Part 9: A. Maercker, K.-D. Klein, *Angew. Chem. 101* (1989) 63; *Angew. Chem. Int. Ed. Engl. 28* (1989) 83.



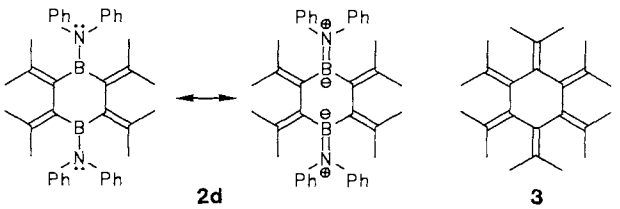


Fig. 1. Molecular structure of **2c** (thermal ellipsoids at the 50% probability level). Important bond lengths [Å] and angles [°]: B1-C2 1.566(4), C2-C3 1.511(4), C3-B4 1.572(5), B4-C5 1.568(4), C5-C6 1.517(4), C6-B1 1.567(4), B1-C11 1.590(5), B4-C41 1.586(5), C2-C21 1.338(4), C3-C31 1.344(4), C5-C51 1.343(4), C6-C61 1.341(4); C2-B1-C6 113.0(3), C2-B1-C11 122.5(3), C6-B1-C11 122.6(3), B1-C2-C3 110.2(2), B1-C2-C21 125.8(3), C3-C2-C21 123.2(3), C2-C3-B4 110.0(2), C2-C3-C31 123.0(3), B4-C3-C31 126.2(3), C3-B4-C5 112.8(3), C3-B4-C41 122.6(3), C5-B4-C41 122.6(3), B4-C5-C6 109.5(2), B4-C5-C51 126.6(3), C6-C5-C51 123.3(3), B1-C6-C5 110.3(2), B1-C6-C61 126.2(3), C5-C6-C61 122.7(3); dihedral angles C21-C2-C3-C31 74.0(2), C61-C6-C5-C51 73.4(2).

In contrast to the disulfur compound **2b**[2]—but in analogy to **2a**[1]—**2c** does not react with 4-phenyl-1,2,4-triazole-3,5-dione in a [4 + 2]-cycloaddition. Probably the coplanar attitude of the isopropylidene groups is additionally thwarted by the *tert*-butyl groups on the boron atoms.

A further 1,4-dibora[6]radialene, **2d**, could be prepared analogously in 38% yield by reaction of **1** with dichloro(*N,N*-diphenylamino)borane. **2d** is likewise a colorless, crystalline air-stable compound, whose structure was confirmed NMR spectroscopically and mass spectroscopically.[11]

Whether **2d**, like **2c**, has a chair conformation is not known. The relationship of **2d** with the isocyclic [6]radialene **3**, which is strikingly evident in the mesomeric resonance structure with B=N double bonds, leads us to presume, however, that **2d**, in analogy to **3**,[12] has a chair conformation. The importance of the ionic resonance structure in describing the bonding of **2d** manifests itself in the ^{11}B NMR spectrum: as expected[13] the resonance of **2d** ($\delta \approx 43$) absorbs at very much higher field than that of **2c** ($\delta \approx 77$).

Even knowing that **2c**, other than **2a, b**, assumes a chair conformation, it was not possible to discover any indications of this difference in the ^{1}H or ^{13}C NMR spectra. Furthermore, the spectra of the crude products also did not show any evidence of the presence of di-2-propylideneboracyclopropanes, which are conceivable as intermediates of the reaction of **1** with dihaloboranes.

Experimental

2c: A solution of *tert*-butyldichloroborane (7.0 g, 0.05 mol) [14] in diethyl ether (100 mL) was added dropwise within 2 h to a stirred 1.0 M solution of **1** (50 mL, 0.05 mol) [6, 7] in diethyl ether (diluted with 150 mL of diethyl ether) at −50 °C. After warming to room temperature and aqueous work-up the reaction mixture was evaporated down in a rotary evaporator and treated with a small amount of methanol. **2c** crystallized (3.0 g, 34%) [8]; m.p. 241–243 °C (from ethanol), correct elemental analysis (C, H, B).

2d: A 1.0 M solution of **1** (50 mL, 0.05 mol) [6, 7] in diethyl ether (diluted with 150 mL of diethyl ether) was added dropwise within 2 h to a stirred solution of dichloro(*N,N*-diphenylamino)borane [15] (12.5 g, 0.05 mol) in diethyl ether (200 mL) at −60 °C; work-up as in the case of **2c**. **2d** was obtained (5.4 g, 38%) [11]; m.p. 265–266 °C (from dichloromethane), correct elemental analysis (C, H, B).

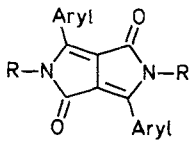
The Influence of Packing Effects on the Solid-State Fluorescence of Diketopyrrolopyrroles**



By *Heinz Langhals,* Thomas Potrawa, Heinrich Nöth*, and *Gerald Linti*

Very little is known about the influence of the crystal structure of a compound on its fluorescence quantum yield.[1]

This interrelationship will be examined more closely with the diketopyrrolopyrroles **1** as examples. Diketopyrrolopyrroles are important organic pigments.[2] It has recently been found that if they bear suitable substituents they can be used as light-fast fluorescent dyes, even in homogeneous solution,[4] and that they exhibit characteristically large Stokes shifts and high fluorescence quantum yields; consequently they are of interest for dye-lasers or fluorescence-solar collectors.[5]

1

2

It has been observed that some of the dyes, e.g. **1**, R = CH_3, aryl = 3,5-tBu$_2$C$_6$H$_3$, **1**, R = C_2H_5, aryl = 2-$CH_3C_6H_4$, or **1**, R = H, aryl = 2-$CH_3C_6H_4$ exhibit an intense solid-state fluorescence, whereas others, e.g. **1**, R = H, aryl = C_6H_5, fluoresce only weakly as solids. This difference disappears in solution. The dye **2** is an important link between these types, since it has two modifications: the thermodynamically stable yellow form **2a** shows an intense solid-state fluorescence, while the orange colored form **2b** fluoresces only weakly. To investigate the influence of packing effects on the solid-state fluorescence the crystal structures of each modification were determined by X-ray diffraction analysis (Fig. 1).[6, 7]

Both modifications crystallize monoclinically. Their crystallographically determined densities differ very little. In both crystal lattices the chromophores are similarly stacked, but differently ordered with respect to each other. No dimeric pairs are found, neither in **2a** nor in **2b**. Charge transfer (CT) interactions are not likely to be the reason for the low fluorescence quantum yields of **2b**, since in each case electron-rich molecular moieties are relatively far removed from electron-deficient moieties of the neighboring molecules (see Fig. 2; the shortest intermolecular distance between C=O and O–CH_3 is 4.38 Å for **2a** and 3.95 Å for **2b**).

Intramolecular CT interactions are also ruled out, since the electron-rich methoxy groups in both modifications are far apart from the carbonyl groups (4.16 Å in **2a** and 4.36 Å in **2b**) and the distances differ only negligibly. Furthermore, no significant dependence of the fluorescence quantum yield on the solvent polarity is observed in solution; the fluorescence quantum yield in chloroform and acetonitrile differ only very little.

A marked difference between the two modifications is, however, the distance between the chromophore planes in the crystal lattice. In the weakly fluorescing form **2b** the chromophores lie essentially under one another (Fig. 2 bottom) and are 3.81 Å apart. The concomitant strong interaction of the chromophores leads to a bathochromic shift of the orange colored absorption compared to the solution (cf. also J aggregates[8]). In the yellow modification **2a**, on the other hand, the chromophores are tightly compressed against each other. A chromophore-chromophore interaction can occur only with the next but one layer, and this is already at a distance of 6.18 Å; the interactions are therefore negligible.

We believe that the small distance of the chromophores in **2b** leads not only to a long-wavelength absorption, but also to a strong interaction of the electron system and lattice vibrations, since a periodic change of the chromophore distance gives rise to a periodic change in the UV/VIS absorption or fluorescence spectrum. The electronic excitation can flow into lattice vibrations via the coupling (cf. also Ref. [9]), and internal conversion (IC) is therefore required. The fluorescence deactivation is, however, of no importance in the case of the pigment **2a** because of the greater distance of the chromophores. The interactions are already weak and are hardly influenced by lattice vibrations—the chromophores are isolated in the crystal lattice just as they are in a dilute solution. This explains the strong solid-state fluorescence of the pigment.

Because of the special properties of the dye **2**, new optical memories could be developed in which the information is

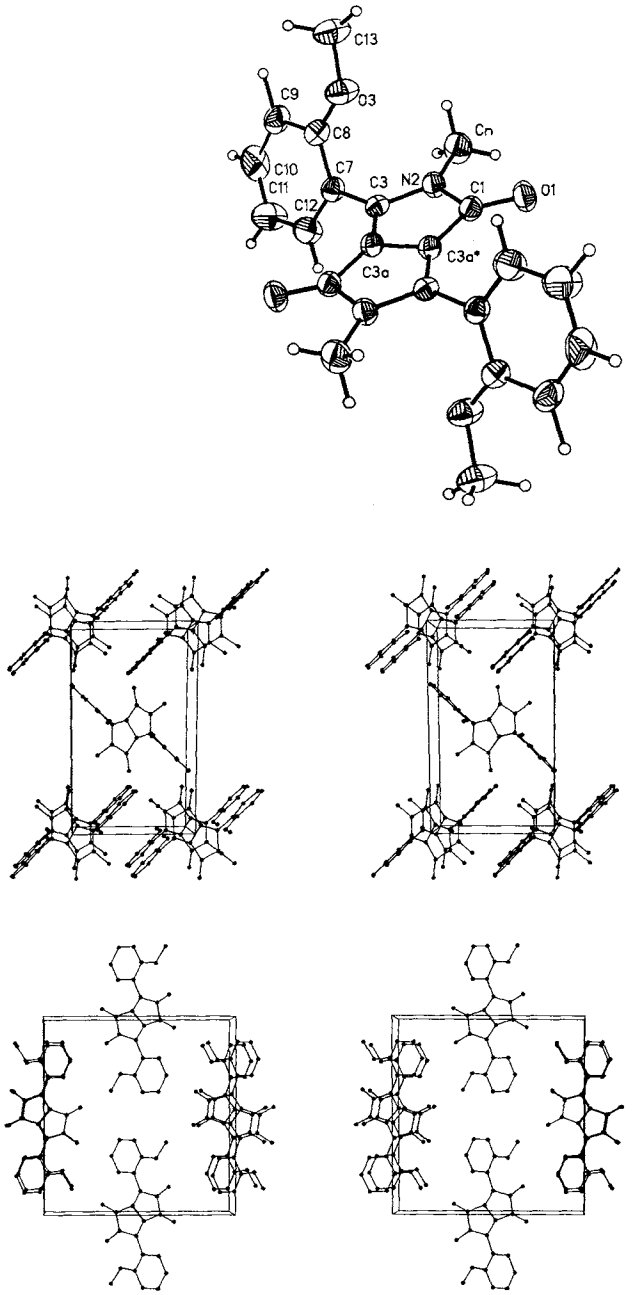

Fig. 1. Structure of **2** (top) and crystal lattices (stereoviews) of the two modifications **2a** (center) and **2b** (bottom).

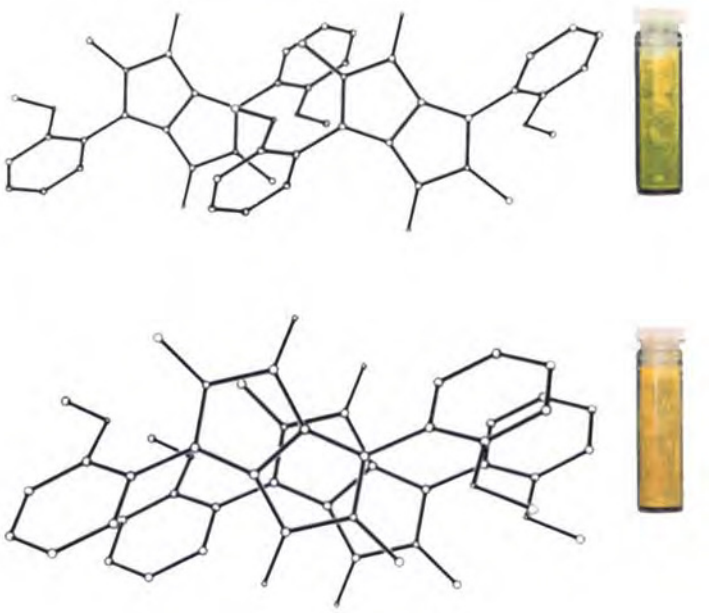

Fig. 2. Arrangement of the chromophores of **2a** (top) and **2b** (bottom) in the crystal lattice (view perpendicular to the chromophore plane). Alongside the structure diagrams, samples of the substances are shown as powders fixed on glass.

recorded by conversion of **2b** into **2a**. The read-out of the information is accomplished via the fluorescence and thus offers the advantage of simple, robust optics. Because of the great tendency of the dye to crystallize from homogeneous solution in the modification **2b**, an optical memory can also be erased. For this purpose, for example, **2b** is mixed in the ratio 1:5 with extra-pure anthracene. Conversion into the strongly fluorescing **2a** is induced by heating with a laser beam to just under 200 °C. For erasing this information the mixture is heated to just over the melting point of anthracene which then dissolves the pigment. Upon rapid cooling, anthracene crystallizes again, in admixture with **2b**.

For the synthesis of **2**, 2-methoxybenzonitrile is condensed with diisopropyl succinate, under usual reaction conditions,[3, 10] to give the corresponding diketopyrrolopyrrole, and then alkylated with methyl tosylate.[3, 11] Upon recrystallization the thermodynamically unstable modification **2b** is obtained, which is irreversibly converted at 195 °C into the stable yellow modification **2b**. The conversion enthalpy is -1.5 kcal mol^{-1}. Crystals of the yellow modification **2a** (in admixture with **2b**) can also be obtained by innoculation of a supersaturated dye solution.

Experimental

3,6-Bis(2-methoxyphenyl)-2,5-dihydropyrrolo[3,4-*c*]pyrrole-1,4-dione: A mixture of 2-methoxybenzonitrile (12.51 g, 93.95 mmol), KO*t*Bu (10.75 g) and isopropyl succinate (9.57 g, 46.8 mmol) was allowed to react as described in Refs. [3, 10] and then subjected to work-up. Yield: 400 mg (2.4%) of dark-red glimmering crystals, M.p. 336–337 °C (decomp., from toluene).—R_f (silica gel, toluene/acetone = 4:1) = 0.20. IR (KBr): $\tilde{\nu}$ = 3398 cm^{-1} (m), 3305 (m), 1641 (s), 1591 (s), 1563 (s), 1490 (m), 1256 (s), 1185 (m), 1119 (s), 832 (m), 750 (s), 651 (m), 575 (m). UV (DMF): λ_{max} (lg ε) = 525 nm (4.496), 489 (4.397), 460 (sh). Fluorescence (DMF): λ_{max} = 533 nm, 575. MS (70 eV) *m/z* = 348 (100%), 333 (3), 317 (4), 255 (6), 225 (4), 174 (10, $M^{2\oplus}$), 135 (9), 92 (33), 91 (39).

3,6-Bis(2-methoxyphenyl)-2,5-dimethyl-2,5-dihydropyrrolo[3,4-*c*]-pyrrole-1,4-dione (**2a**, **2b**): A mixture of the precursor (400 mg, 1.14 mmol) and *p*-toluenesulfonic acid methyl ester (2.08 g, 11.2 mmol) was allowed to react with a solution of K_2CO_3 (1.2 g) in DMF (5 mL) as described in Refs. [2, 11] and then subjected to work-up. Yield: 360 mg (84%) of orange crystals (**2b**). Transformation point 195 °C, m.p. 281–282 °C (from ethanol/chloroform 3:1).—R_f (*tert*-butyl methyl ether) = 0.44. IR (KBr): $\tilde{\nu}$ = 2940 cm^{-1} (w), 2835 (w), 1680 (s), 1616 (m), 1595 (m), 1488 (m), 1465 (m), 1437 (m), 1424 (w), 1252 (s), 1223 (w), 1033 (m), 756 (m), 744 (m), 636 (w). UV ($CHCl_3$): λ_{max} (lg ε) = 454 nm (4.206). Fluoroescence ($CHCl_3$): λ_{max} = 514 nm. Fluorescence quantum yield: $\Phi(CHCl_3)$ = 0.68, $\Phi(CH_3CN)$ = 0.59. ^{1}H-NMR ($CDCl_3$): δ = 3.00 (s, 6H), 3.83 (s, 6H), 6.84–7.12 (m, 4H), 7.28–7.60 (m, 4H). ^{13}C-NMR ($CDCl_3$): δ = 28.35 (q), 55.52 (q), 109.43 (s), 111.34 (d), 117.49 (s), 121.07 (d), 131.94 (d), 132.48 (d), 146.60 (s), 157.05 (s), 162.14 (s). MS (70 eV) *m/z* = 376 (100%, $M^{\oplus}$), 361 (4), 345 (6), 318 (5), 283 (10), 214 (9), 200 (8), 186 (9), 148 (52), 135 (21), 133 (34), 105 (18), 91 (12), 77 (7).—**2a**: UV (solid): absorption edge at 518 nm (point of inflection). Fluorescence (solid): λ_{max} = 525 nm.—**2b**: UV (solid): adsorption edge at 532 nm (point of inflection). Fluorescence (solid): λ_{max} = 555 nm (weak).

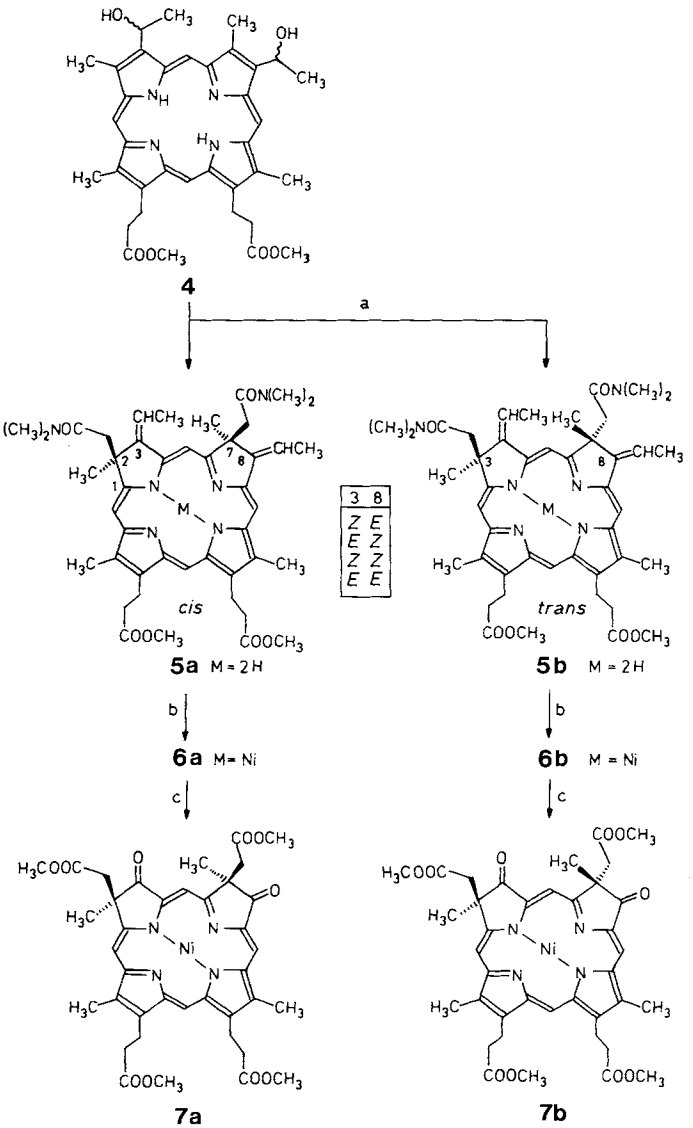
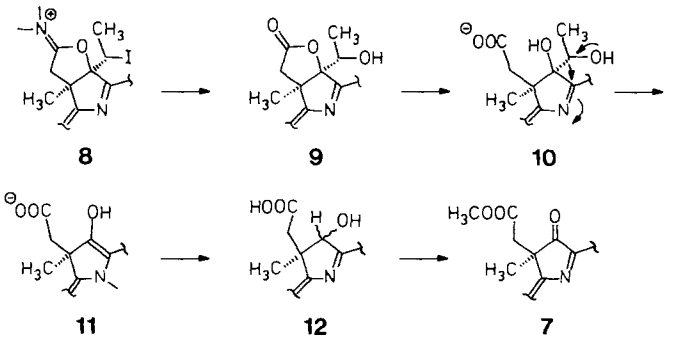
isobacteriochlorin framework **3**. Partially hydrogenated derivatives of the metal-free macrocycles **1a, b** have been recognized as biosynthetic precursors for vitamin B_{12};[1,4] the iron-containing derivatives play a central role as cofactors in nitrile- and sulfite-reducing enzymes of bacteria and plants. Metal-free dioxoisobacteriochlorins could possibly also gain medical importance as photosentizers in photodynamic tumor therapy.

1a R = H, M = 2H
1b R = CH_3, M = 2H
1c R = H, M = Fe



2



3

The biological and chemical importance of these natural products, which occur only in trace amounts, and the difficulty of isolating them, even on a very small scale, prompted the search for selective synthetic routes. Besides numerous syntheses of model compounds,[5] so far only one circuitous total synthesis of **1a**[6] and one unselective partial synthesis of **2**[5h] have been described. We now report a simple route for synthesizing the isobacteriochlorin skeleton by double amide acetal Claisen rearrangement from the inexpensive hematoporphyrin dimethyl ester **4**. Via this route, the geminally dialkylated structural elements in rings A and B are obtained at the same time. Cleavage of the incorporated amide groups and of the new exocyclic double bonds then leads directly to isobacteriochlorins **7** with the substitution pattern of **2** (Scheme 1).

The ester **4**[7] is available in any desired amount from slaughter-house wastes as direct transformation product of the red blood pigment heme and is thus an ideal economical and ecological starting material for the synthesis of compounds with complex porphinoid structures. The isobacteriochlorin chromophore with dialkylated 2 and 7 positions is formed upon double amide acetal Claisen rearrangement[8] at the hydroxyalkyl substituents of **4**. Since **4** is present as a binary diastereomeric mixture, the two stereoisomeric isobacteriochlorins of type **5a** and **5b** are formed with *cis*- and *trans* arrangement, respectively, of the newly introduced acetamide side chains. The *cis*/*trans* diastereomers can easily be separated chromatographically. In each of these *cis* and *trans* diastereoisomers there are four double-bond isomers, which originate from the newly formed exocyclic double bonds at the 3 and 8 positions. Owing to the stereoselective course of the Claisen rearrangement, the (*Z*,*Z*) isomers predominate.[8d] A clean chromatographic separation of the double-bond isomers is extremely difficult; fortunately it is not even necessary, because of the 3,8-oxo substitution in the target structures. The cleavage of the amide groups and of the double bonds, which is necessary for the further synthesis, could not be achieved under conventional hydrolysis and oxidation conditions even with the robust nickel complexes **6**, because of the lability of the chromophoric system. It can, however, be accomplished surprisingly easily, if both reactions are coupled with each other (Scheme 2). Iodolactonization leads via the immonium ester **8** to hydrolysis of the amide groups and oxidation of the double bonds.[9] The initially incorporated iodine is probably substituted by OH under the reaction conditions via neighboring group participation of the lactone oxygen. The resulting structures **9** containing a five-membered lactone ring, hydroxy substituents and the familiar isobacteriochlorin chromophore could be deduced unequivocally from the IR, mass and electron spectra. A more detailed characterization of the hydroxylactones **9** was not attempted because of the complex stereochemistry.

Scheme 1. Reaction conditions: a) $CH_3C(OCH_3)_2N(CH_3)_2$, *o*-xylene, 4-Å molecular sieve, argon, 160 °C, 2 h; flash chromatography, silica gel, CH_2Cl_2 + methyl acetate + MeOH (10 + 5 + 0.5), yield of **5** 50%. b) 2 equiv. Ni^{II} acetylacetonate, $CHCl_3$, reflux, chromatography Alox N III, CH_2Cl_2 + methyl acetate + MeOH (10 + 5 + 0.5), yield each 90%. c) 3 equiv. I_2, THF + H_2O (1 + 1), argon 25 °C, 6 h; flash chromatography, silica gel, CH_2Cl_2 + methyl acetate + MeOH (10 + 5 + 0.5); 2. 5 M KOH, MeOH, 60 °C, 24 h; 5 M HCl, 60 °C, 30 min; 3. CH_2N_2, Et_2O/MeOH, 25 °C, 2 h; flash chromatography, silica gel, CH_2Cl_2 + methyl acetate (10 + 1); yield after crystallization 47%.—All the compounds were prepared as enantiomeric mixtures. All new compounds, insofar as crystalline, are characterized by elemental analysis, UV/VIS, ^{1}H-NMR and mass spectra.

Scheme 2. Cleavage of the amide groups and the exocyclic double bonds of **6**, for access to **7**.

The alkaline hydrolysis of the lactones **9** is accompanied by retroaldol-type fragmentation, in the course of which the originally exocyclic double bonds at positions 3 and 8 are removed quite easily. Retroaldol-like processes of this type are well documented in porphyrin chemistry and have already been exploited synthetically.[10] Tautomerization, spontaneous subsequent oxidation of **12** to give the stable dioxoisobacteriochlorin-type structure, and esterification to **7** (Table 1) complete the synthesis.

Table 1. Selected spectroscopic data of **7a** and **7b**.

7a: UV/VIS ($CHCl_3$): λ_{max} (ε) = 386 (39 670), 437 (43 940), 585 (12 850), 619 nm (40 692); ^1H NMR ($CDCl_3$, 360 MHz): δ = 1.65, 1.71 (2s, each 3H, CH_3 an C-2 and C-7), 3.56 (s, 2H, 2- or 7-CH_2), 3.61 (d, ^2J = 3 Hz, 2H, 2- or 7-CH_2), 8.12, 8.17, 9.00, 9.07 (4s, je 1H, CH); MS (270 °C): *m/z* (rel. int. [%]) 770 (100, $M^{\oplus}$), 697 (45, $M^{\oplus} - CH_2CO_2CH_3$)
7b: UV/VIS ($CHCl_3$): λ_{max} (ε) = 385 (38 900), 436 (43 800), 586 (13 660), 617 nm (39 600); ^1H NMR ($CDCl_3$, 360 MHz): δ = 1.53, 1.57 (2s, each 3H, CH_3 an C-2 and C-7), 3.70 (AB system, J_{AB} = 17 Hz, 2- or 7-CH_2), 3.76 (AB system, J_{AB} = 17.5 Hz, 2- or 7-CH_2), 8.04, 8.12, 8.98, 9.03 (4s, each 1H, CH); MS (230 °C): *m/z* (rel. int. [%]) 770 (100, $M^{\oplus}$), 697 (68, $M^{\oplus} - CH_2CO_2CH_3$)

Assignment of the configurations of the pure crystalline diastereomers **7a** and **7b** is based on a crystal structure analysis[11] of **7a** (Fig. 1), in which the naturally occurring *cis*-configuration was found. The ligand system of the planar tetracoordinated nickel atom is, as expected, not planar in itself but deformed in a saddle-shaped fashion (ruffling). The carbon atoms of the methine bridges lie pairwise above and below the ring plane formed by the metal atom and its coordinated nitrogen atoms. The reasons for the deformation of the ligand system of metal-porphyrins have been investigated and discussed in detail.[12] A comparison with these findings shows that the dioxoisobacteriochlorin **7a** with its trigonal 3,8-carbon atoms deviates less from planarity than would be expected for tetrahydroporphyrins with tetrahedrally coordinated 3,8 centers.[13] In order to clarify whether the saddle-shaped structure is responsible for the biological function of heme d_1 **2** we are currently attempting the synthesis of this natural product according to the concept presented here.

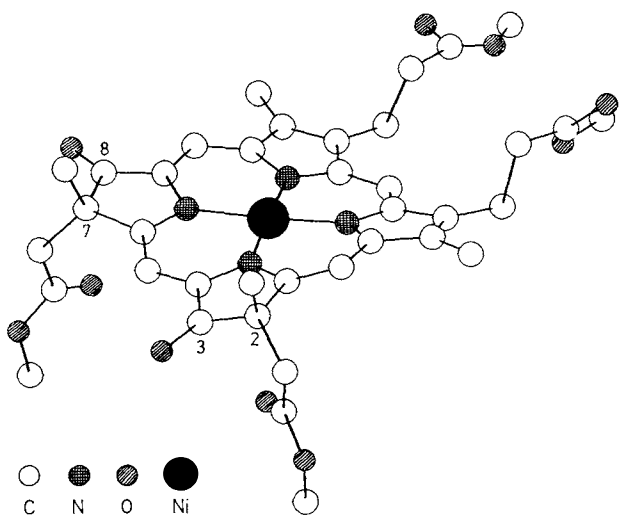


Fig. 1. Crystal structure of **7a**. Sideview showing the saddle-shaped deformation (ruffling) of the ligand system.

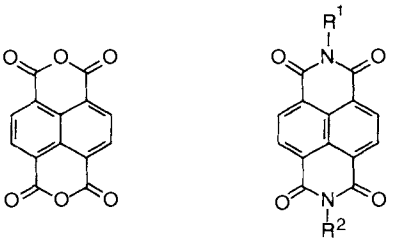
[13] A parameter d_m has been defined [Ref. 12b] for the extent of deformation of a ligand by ruffling. In the porphinoid and corrinoid nickel complexes known so far the values for d_m lie between 0.738 for highly deformed nickelhexahydroporphyrins and 0.181 for almost planar nickeltetradehydrocorrins. The nickel isobacteriochlorin **7a** exhibits a slight deformation with a d_m parameter of 0.32.

Radical Anion Salts of Naphthalenetetracarboxylic Acid Derivatives—a Novel Class of Electrically Conducting Compounds**

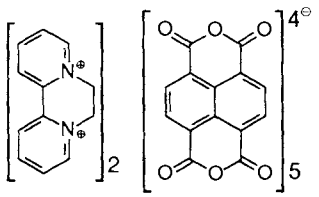
By *Gerhard Heywang,* Liborius Born, Hans-Georg Fitzky, Tillmann Hassel, Jürgen Hocker, Hans-Klaus Müller, Bernd Pittel* and *Sigmar Roth*



Dedicated to Professor Hans Rudolph on the occasion of his 60th birthday

In numerous studies[1, 2] of the charge-transfer complex of tetracyanoquinodimethane (TCNQ) and tetrathiafulvalene (TTF), general structural principles have been elaborated for electrically conducting molecular crystals. Since access to the charge-transfer complexes known so far is, in all cases relatively difficult, further, more readily variable radical anion salts are of special interest. We report herein on some new electrically conducting compounds based on naphthalenetetracarboxylic acid derivatives.

Nelson[3] detected a radical cation $\mathbf{1}^{\odot\ominus}$ ESR spectroscopically upon electroreduction of the naphthalenetetracarboxylic acid dianhydride **1** (NTDA). According to our calculations the electron affinity (EA) of **1** is comparable to that of TCNQ both according to the PPP method as well as the MNDO method: PPP: $EA_{TCNQ} = 4.30$, $EA_1 = 4.03$ eV; MNDO: vertical: $EA_{TCNQ} = 2.80$, $EA_1 = 2.87$ eV. Since the LCAO coefficients of the LUMO at the anhydride oxygen atoms of **1** are equal to zero, naphthalenetetracarboxylic acid diimides **2** should exhibit a comparable acceptor behavior.



The electrochemical reduction of **1** in the presence of tetramethylammonium methyl sulfate leads to bluish-black needles with a metallic luster and the composition $[N(CH_3)_4]^{\oplus} \cdot \mathbf{1}^{\odot\ominus}$ (= **3a**) ($\sigma = 1.2 \times 10^{-4}$ S cm^{-1}). A number of other complex salts can be prepared analogously from **1** (Table 1).

Upon electrolysis in the presence of dication-methyl sulfates their anion is also incorporated into the complex salts (see **3e** and **3g**). Replacement of a $\mathbf{1}^{\odot\ominus}$ unit by a methyl sulfate ion gives rise to an increase in the conductivity by two powers of ten (cf. **3d**/**3e** and **3f**/**3g**). The complex salts **3h** and **3i** show an unusual stoichiometry and the best conductivities. The X-ray structure analysis[4] of **3h** (Fig. 1) supports the proposed stack-like structure and shows a lengthening of the CO double bond from approx. 1.185 to 1.200–1.212 Å for all NTDA units. From the stoichiometry of **3h** it follows that four electrons are shared by five molecules of **1**. The separation of the NTDA planes in **1**

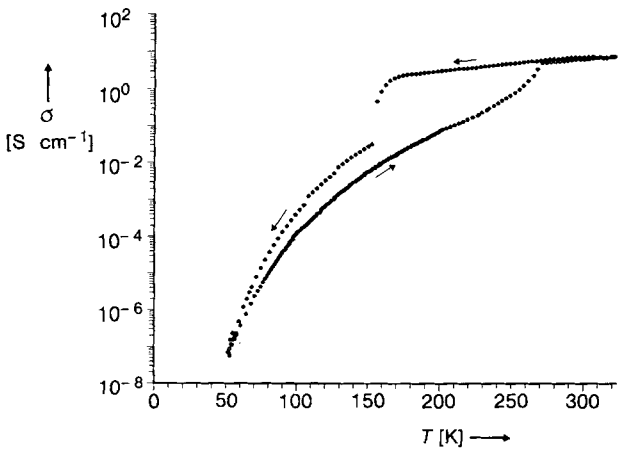
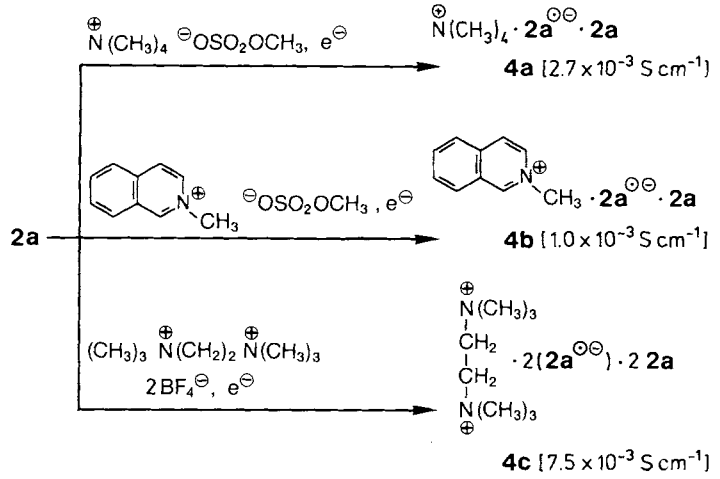
(3.21–3.36 Å) is comparable with the separation of the molecular planes in TCNQ complexes[5].

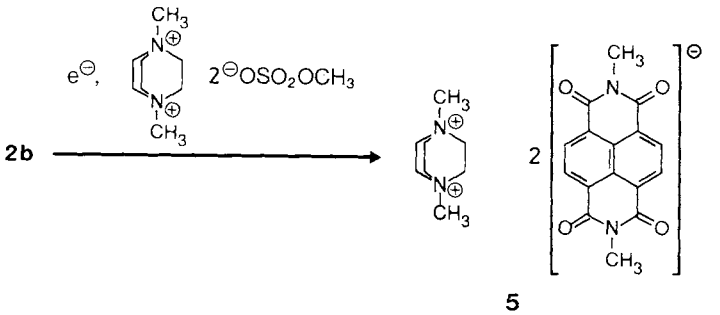
Table 1. Radical anion salts of NTDA **1**.

Cpd	Composition [a]	Supporting electrolyte XY or XY_2	Conductivity σ [S cm^{-1}] pellet [b] (crystal [c])
3a	$X^{\oplus}\,1^{\odot\ominus}$	$[N(CH_3)_4](OSO_2OCH_3)$	1.2×10^{-4}
3b	$X^{\odot}\,1^{\odot\ominus}$		5.7×10^{-4}
3c	$X^{\oplus}\,1^{\odot\ominus}$		4.0×10^{-3}
3d	$X^{2\oplus}\,2(1^{\odot\ominus})$	$A(BF_4)_2$[d]	3.0×10^{-5} (5.0×10^{-3})
3e	$X^{2\oplus}\,1^{\odot\ominus}\,Y^{\ominus}$	$A(OSO_2OCH_3)_2$[d]	4.0×10^{-3}
3f	$X^{2\oplus}\,2(1^{\odot\ominus})$		3.7×10^{-5}
3g	$X^{2\oplus}\,1^{\odot\ominus}\,Y^{\ominus}$		4.2×10^{-3} (5.0×10^{-1})
3h	$2X^{2\oplus}\,(5\,1)^{4\ominus}$		5.0×10^{-2} (7.5–10)
3i	$2X^{2\oplus}\,(5\,1)^{4\ominus}$		3.0×10^{-2}

[a] From elemental analyses which agree with the calculated values (± 0.3%). [b] Conductivity measurement under a pressure of 17.64 kN cm^{-2} by four-point contact. [c] Crystal needles of at least 1 mm in length were brought into contact with four annealed 20-μm gold wires via conducting silver and measured. [d] A = $(CH_3)_3NCH_2CH_2N(CH_3)_3$.







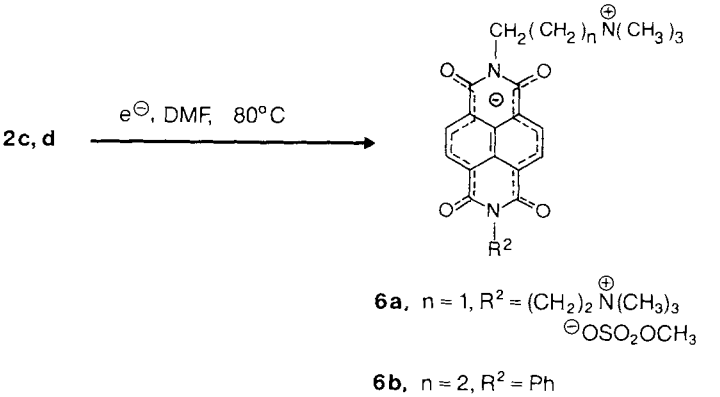


Fig. 2. Temperature dependence of the electrical conductivity σ of the complex **3h**, measured on a crystal needle of about 2 mm in length.

The electrical conductivity of **3h** (Fig. 2) is practically temperature-independent over a wide range. On cooling below 150 K, a phase transition, as is to be expected in the case of one-dimensional organic conductors,[6] is observed. The result is a rapid decrease in conductivity.

Electrochemical reduction of **2a** leads, independently of the supporting electrolyte employed, to the complex salts **4**, in which equal numbers of $\mathbf{2a}^{\odot\ominus}$ ions and **2a** molecules are present in each case.

6a, n = 1, $R^2 = (CH_2)_2\overset{\oplus}{N}(CH_3)_3\ \ominus OSO_2OCH_3$

6b, n = 2, R^2 = Ph

In contrast, the electrocrystallization of **2b** affords complex salts in which no neutral diimide molecules are present, e.g., **5** ($\sigma = 4.6\times10^{-6}$ S cm^{-1}). Despite their sparing solubility the naphthalenetetracarboxylic acid diimides **2c** and **2d** can be reduced to the complex salts **6a** and **6b**, respectively, in the absence of a supporting electrolyte.

The conductivities of the salts **6**, which because of the bulky trimethylammonium substituents do not necessarily

exhibit the planarity required for organic conductors, are surprisingly high (**6a**: $7 \times 10^{-3}\,S\,cm^{-1}$; **6b**: $3.5 \times 10^{-4}\,S\,cm^{-1}$).

Experimental

3h: A solution of **1** (268 mg, 1 mmol) and 5,6-dihydro-4a,6a-phenanthrolindionium bis(tetrafluoroborate) (1.77 g, 5 mmol) in 100 mL of dimethylformamide (DMF) was electrolyzed at 20 °C and a current of 1.5 mA for 21.5 h in a 100-mL electrolytic cell fitted with two 16 cm^2 platinum electrodes (separation 1 cm). A cell potential of 1.8 V was established. 249 mg of the radical anion salt were deposited at the cathode (73%, current yield 48.5%) in the form of bluish-black needles with a metallic luster, which decomposed without melting at 360 °C; satisfactory C, H, N analyses. IR spectrum: very broad bonds with low intensity, $\tilde{\nu}_{CO}$ = 1678, 1720 cm^{-1}; ESR spectrum: g = 2.0036, 0.6 spins/complex (reference standard "strong pitch" from Bruker).

Sodium Pentaphosphacyclopentadienide (NaP_5) and the Pentaphosphacyclopentadienide Ion ($P_5^{\ominus}$): Theoretical Predictions of Molecular Structures, Infrared and Raman Spectra**

By *Tracy P. Hamilton* and *Henry F. Schaefer III**

A recent review[1] and a communication[2] to this journal have reported the synthesis and some properties of NaP_5 and $P_5^{\ominus}$. Sodium pentaphosphacyclopentadienide solutions are golden orange, extremely sensitive to oxidation, and stable for 7–10 days in concentrations of 10^{-2} M at room temperature. From the shape of the ultraviolet (electronic) spectrum *Baudler* and co-workers[2] concluded that $P_5^{\ominus}$ is aromatic, as might be suggested from the presence of six π-electrons. $P_5^{\ominus}$ has also been observed[3] (along with $P_n^{\ominus}$, n = 1–4, 6–9) in the negative ion mass spectrum of red phosphorus at 325 °C.

Baudler et al.[2] report features of the infrared and Raman spectra in their 1988 communication. Specifically they assign an intense IR band at 815 cm^{-1} and a medium-intense polarized Raman band at 463 cm^{-1} to the vibrational modes E_1' and A_1' of the planar, five-atom ring of D_{5h} symmetry. The IR fundamental assigned at 815 cm^{-1} appeared very suspicious to us, since even diatomic P_2 (with a formal triple bond) has a lower P–P stretching freqency, ω_e = 781 cm^{-1}.[4] $P_2^{\oplus}$ and $P_2^{\ominus}$, which both have higher formal bond orders (2 1/2) than expected for $P_5^{\ominus}$ with D_{5h} symmetry, have harmonic vibrational frequencies[3, 4] $\omega_e(P_2^{\oplus})$ = 672 cm^{-1} and $\omega_e(P_2^{\ominus}) = 640 \pm 50$ cm^{-1}. Thus a P–P stretching vibrational frequency as high as 815 cm^{-1} for $P_5^{\ominus}$ would appear counterintuitive to us.

We now report the use of ab initio molecular quantum mechanics in a study of the $P_5^{\ominus}$ and NaP_5 systems. Three basis sets of contracted gaussian functions were used in conjuction with the self-consistent-field (SCF) method. The smallest basis set was the 3-21G* set of *Pople* et al.,[5] the double zeta plus polarization (DZ + P) basis used here was that of *Huzinaga*[6] and *Dunning* and *Hay*.[7] The orbital exponent for the set of six d-like functions on each phosphorus atom was α = 0.5. The largest basis set appended diffuse s and p functions on P in order to better describe the anionic character of the $P_5^{\ominus}$ negative ion. In this DZ + P + diffuse basis set, the orbital exponents of the added primitive gaussian functions were[8] $\alpha_s(P) = 0.0348$ and $\alpha_p(P) = 0.0348$. For the $P_5^{\ominus}$ anion, the numbers of contracted gaussian functions were thus 95 (3-21G*), 120 (DZ + P) and 140 (DZ + P + diffuse).

The predicted SCF molecular structures for NaP_5 and $P_5^{\ominus}$ are shown in Figure 1. All geometrical parameters were optimized and each structure was proven to be a minimum. The P–P distances in the P_5 ring are 2.081 Å ($P_5^{\ominus}$, 3-21G*) and 2.093 Å (NaP_5, 3-21G*), i.e. the interaction of the $Na^{\oplus}$ ion with the $P_5^{\ominus}$ ring increases the ring bond distances by 0.013 Å, a result that should be reasonably independent of the basis set. In the isolated $P_5^{\ominus}$ anion, the bond distance changes very little as the basis set is increased in size from 3-21G* to DZ + P [r(P–P) increases by 0.012 Å] to DZ + P + diffuse (a further increase of 0.002 Å). Based on past experience,[9] one would expect the final predicted P–P distance in $P_5^{\ominus}$ (DZ + P + diffuse SCF; 2.095 Å) to be reliable to within ± 0.02 Å.

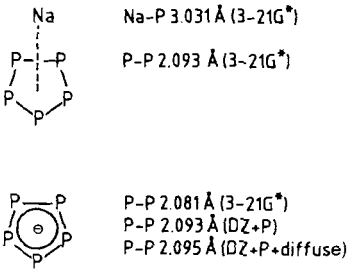

Fig. 1. Ab initio theoretical predictions of the molecular structures of $P_5^{\ominus}$ and NaP_5. All structures have been demonstrated to be true equilibrium geometries via harmonic vibrational analyses (see text).

Does our prediction of r_e(P–P) = 2.095 ± 0.02 Å for $P_5^{\ominus}$ make a statement about the aromaticity of this molecular ion? The two experimentally known P–P single bond distances in the gas phase are 2.219 Å (diphosphane P_2H_4[10]) and 2.223 Å (tetraphosphorus P_4[11]). Since the P–P bonds

[**] Contribution CCQC No. 44. This work was supported by the US Air Force Office of Scientific Research under Grant AFOSR-88-0167. We thank Dr. *Brian Yates* for suggesting this problem.

in $P_5^{\ominus}$ are 0.12 Å shorter than these two classic P–P single bonds, we conclude that *on the basis of its molecular structure* (there may be other valid criteria[12]) conjugative effects are important for $P_5^{\ominus}$.

The predicted harmonic vibrational frequencies and infrared intensities for the isolated $P_5^{\ominus}$ anion are seen in Table 1.

Table 1. Predicted SCF total energies [hartree] and harmonic vibrational frequencies [cm^{-1}] for the $P_5^{\ominus}$ ion. Only the E_1' fundamental is allowed in the infrared, and the very weak E_1' IR intensities are given in km mol^{-1} in parentheses.

Basis set	3-21G*	DZ + P	DZ + P + diffuse
Total energy	−1695.55363	−1703.68491	−1703.70000
Fundamentals			
P–P stretch E_1'	575 (0.01)	568 (0.02)	564 (0.07)
P–P stretch E_2'	548	535	532
P–P stretch A_1'	523	514	509
In-plane ring deform. E_2'	349	341	336
Out-of-plane puckering E_2''	234	229	224

It is clear that these results are not concordant with *Baudler*'s assignment of an intense IR band at 815 cm^{-1} to the D_{5h} structure of $P_5^{\ominus}$. First, the predicted E_1' harmonic vibrational frequency is much lower, 564 cm^{-1} (DZ + P + diffuse SCF). Further corrections[13] for electron correlation and anharmonicity will only serve to lower the 564 cm^{-1} prediction. Second, the E_1' fundamental of $P_5^{\ominus}$ assigned by *Baudler* et al. is predicted here to have a very low IR intensity, namely 0.07 km mol^{-1}.

Could the attachment of $Na^{\oplus}$ to $P_5^{\ominus}$ radically change the predicted IR spectrum of $P_5^{\ominus}$? With the 3-21G* basis set, the SCF harmonic vibrational frequencies are 560 (E_1), 533 (E_2), 510 (A_1), 351 (E_2), 244 (E_2), 212 (A_1), and 122 cm^{-1} (E_1). Thus, the attachment of $Na^{\oplus}$ in a C_{5v} symmetrical arrangement (as suggested by *Baudler*) does shift the E_1' vibrational frequency, but downward and by only 15 cm^{-1} (from 575 to 560 cm^{-1}). Moreover, the IR intensity is increased, but only to 0.5 km mol^{-1}, still very weak. Thus, the feature observed by *Baudler* et al. at 815 cm^{-1} cannot be one of the fundamental vibrational frequencies of a NaP_5 molecule with C_{5v} symmetry.

The present theoretical study *is* in harmony with *Baudler*'s assignment of a medium-intense polarized Raman band at 463 cm^{-1} to the A_1' P–P stretching fundamental. The ab initio[14] 3-21G* A_1' Raman intensity is 63 $Å^4$ amu^{-1}, which value may be characterized as "medium-intense" by comparison with known Raman intensities[15] (cf. e.g. 302 $Å^4$ amu^{-1} for the strongest Raman band (A_{1g}) in ethane and 6 $Å^4$ amu^{-1} for the analogous weaker Raman band (A_g) in ethylene). Our DZ + P + diffuse SCF prediction places the harmonic vibrational frequency at 509 cm^{-1}, or 9.9% above experiment. This is just the sort of error one would expect[9] from the neglect of correlation effects and anharmonicity in the theoretical treatment. Thus, theory and experiment concur for the observed Raman band but conflict for the assigned intense IR band at 815 cm^{-1}.

Can we suggest a possible interpretation of the strong IR band observed by *Baudler* et al.[2]? Conceivably. The $P_3^{\ominus}$ ion, which is valence isoelectronic with N_2O, probably has a $D_{\infty h}$ structure with short P–P bonds (1.920 Å) and an asymmetric P–P stretch ω_3 = 886 cm^{-1} at the DZ + P SCF level of theory. This harmonic vibrational frequency lies 8.7% above that observed by *Baudler* et al. and has a very large IR intensity, 338 km mol^{-1}. Thus, the theoretical asymmetric P–P stretch for $P_3^{\ominus}$ fits the Baudler $P_5^{\ominus}$ assignment very closely. However, *Baudler* et al. present no evidence that the NaP_5 studied experimentally may have been contaminated by NaP_3.

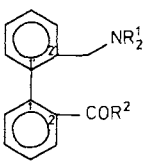
2′-Aminomethylbiphenyl-2-carboxylic Acid as Component of a Cyclopeptide; Crystal Structure and Conformation in Solution**

By *Volker Brandmeier, Martin Feigel** and *Matthias Bremer*

One of the main objectives in peptide chemistry is to achieve a preferred conformation in a peptide unit by the incorporation of pseudo-amino acids.[1–3] Since relatively rigid natural peptides contain aromatic groups as spacers,[4] it is reasonable to assume that inflexibility may be realizable in the same way in syntheses with pseudo-amino acids. Even the fixation of antiparallel peptide chains to a β-pleated sheet seems possible with arenes, whereby the bridge molecules serve as substitute for the β-turn.[1d] We report here on the incorporation of 2′-aminomethylphenyl-2-carboxylic acid **1** in a cyclopeptide.



Formation of a cyclic array from two units of **1** and two L-amino acids affords, e.g., the compound **3**. If **1** is considered as substitute for the two central amino acids of a β-turn,

[*] Dr. M. Feigel, Dipl.-Chem. V. Brandmeier, Dipl.-Chem. M. Bremer

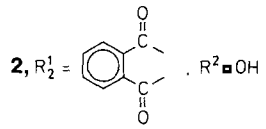
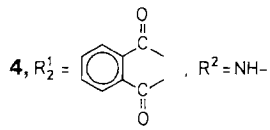
[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Hoechst AG for carrying out the analyses.

then **3** is an analogue of a cyclohexapeptide. Cyclohexapeptides often have a structure determined by two β-turns which remains unchanged in the solid state and in solution.[5] Is a similar structure preferred with **1** in the ring?



Three diastereomers which differ in the atropisomerism of the biphenyl moieties are expected for the cyclic compound **3**. The two isomers with biphenyl units of the same configuration (*R,R* or *S,S*) have C_2 symmetry, whereas the isomer with *R,S*-configurated biphenyl units is C_1 symmetric.



1, $R^1 = H, R^2 = OH$

3

2, $R^1_2 =$, $R^2 = OH$

4, $R^1_2 =$, $R^2 = NH\text{-}CH(iPr)\text{-}COOMe$

The pseudo-amino acid **1** is accessible as *N*-phthalimide-protected derivative **2** in 60% yield in two steps from diphenic anhydride.[6] Coupling of methyl valinate to **4**, cleavage of the protecting group with hydrazine, and cyclodimerization (azide method according to *Medzihradszky*, see Ref. [7]) affords **3** in moderate yield (22%) as a mixture of three isomers **3A**, **3B** and **3C**, which can be separated chromatographically (15% **3A**, 5% **3B**, 2% **3C**). The ^{1}H-NMR spectra show that **3A** and **3C** are isomers with C_2 symmetry (single set of signals), whereas **3B** has C_1 symmetry. When **3A** is dissolved in $CDCl_3$ and the solution is kept at 55 °C for 24 h a 1:1:1 mixture of the three isomers **3A**–**3C** is obtained. A mixture of all three isomers is also formed from **3A**, **3B** or **3C** in dimethyl sulfoxide (DMSO) after briefly heating to 80 °C. When the chromatographically separated isomers are crystallized from acetonitrile, **3A** is obtained in crystalline form from fraction 1 (= **3A**). **3C** (C_2 symmetry) crystallizes in both cases from fractions 2 (= **3B**) or 3 (= **3C**). **3B** could so far not be obtained in crystalline form.

This relatively rapid, reversible interconversion of the isomers (solvent, temperature, half-life (ca): $CDCl_3$, 55 °C, 10 h; DMSO, 80 °C, a few minutes) rules out any difference in the chirality of the amino acid valine in **3A**, **3B** and **3C**, for a much slower epimerization would be expected without base catalysis. The isomerization is thus apparently an atropisomerization of the biphenyl units. **3B** with C_1 symmetry contains *R*- and *S*-configurated biphenyl units, whereas **3A** and **3C** (each with C_2 symmetry) contain *R,R*- or *S,S*-configurated biphenyl units.

The X-ray structure analysis shows that **3A** has almost C_2 symmetry in the solid state (Fig. 1, because of the incorporation of one acetonitrile molecule per molecule of **3A** in the crystal, the isopropyl groups have different orientation, so that the actual symmetry is only C_1). Both valine units have identical configuration. The chirality analysis by hydrolysis and chiral gas chromatography showed the presence of L-valine; thus, the biphenyl moieties in **3A** have *S,S*-configuration, and in **3C**, correspondingly, *R,R*-configuration.

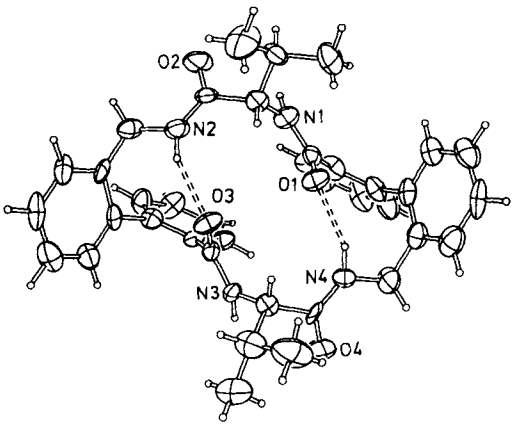


Fig. 1. Structure of **3A** in the crystal [13] (ORTEP).

All amide bonds of **3A** are *trans*-oriented in the solid state. The phenyl rings in the biphenyl units are twisted by torsion angles of 109 and 108° respectively. A striking feature is that each of the carbonyl groups on the biphenyl units is twisted about 40° from the ring plane of the arene in the direction of the amide proton of the same biphenyl unit. The C atoms of these carbonyl groups are located 10° outside of the ring planes. The two peptide torsion angles φ(−124.7, −118.9) and ψ(96.6, 98.6) at the valine units lie in the energetically flat region of the Ramachandran diagram (between the geometries of idealized β-pleated sheet and γ-loop).[14] Bond lengths and torsion angles of the isopropyl side chains are within the range of statistical variance of an analysis of the side chain conformations of valine units in crystal structures.[8] The bond angles in the lower valine unit in Figure 1 deviate up to 4° from the statistical mean, which is not unusual in strained systems.[8]

The O–N distances between CO (biphenyl) and CH_2NH are 2.87 (N4–O1) and 2.83 Å (N2–O3), respectively, and thus lie in a range typical for hydrogen bonded O and N atoms.[9] The reversal of the peptide chain is achieved by the pseudo-amino acid **1**, but the observed pattern cannot be compared very well with known peptide loop patterns. Under no circumstances is a pseudo β-turn present, since the NH and CO groups of the two valine units would then form hydrogen bonds between the chains. Rather, one can speak of a δ-turn; this, however, has thus far only been found with central *cis* amide bonds.[10, 3a]

Is the solid-state conformation **3A** also retained in solution? The ^{1}H NMR spectrum of **3A** shows only one set of signals, i.e. C_2 symmetry is observed, at least on a time average. The values determined from coupling constants (in $CDCl_3$) for the NH–CH dihedral angles are in good agreement with the angles in the solid state (Table 1). ^{1}H NMR data also confirm the presence of the two H bonds: both the temperature gradients ($\Delta\delta/\Delta T \times 10^3$ [K^{-1}] in DMSO: 3.2 (CH_2NH), 7.2 (*i*PrCHNH)) as well as the solvent dependence of the chemical shifts of the amide protons ($\delta_{DMSO} - \delta_{CDCl_3}$: 0.0 ($CH_2NH$), 1.6 (*i*PrCHNH) show that the amide protons, which form H bonds in the solid state, are shielded against the solvent in solution, not however the amide protons which are free in the solid state.

The spatial environment of the protons in the solid state is also retained in solution ($CDCl_3$): all cross signals in

[a] Two values per dihedral angle because of C_1 symmetry of the solid state conformation (see text and Fig. 1).

2D NOE NMR spectra (NOESY or ROESY[11]) correspond to short H–H distances in the solid state (Table 2). The converse, namely that each short H–H distance in the solid state gives a cross signal in the NMR spectrum in solution, also holds true.

Table 2. NOE effects in the ^1H NMR spectra of **3A** in $CDCl_3$ and corresponding proton–proton distances in the solid state. Cross signals between aryl protons are not taken into consideration.

[a] Two values per proton pair because of the C_1 symmetry of the solid state conformation.

Thus, all NMR data suggest that the conformation determined by the X-ray structure analysis is retained in $CDCl_3$; in the polar solvent DMSO, however, the structure of **3A** is less rigid. DMSO solvates the polar amide bonds better, so that intramolecular interactions are no longer effective. This manifests itself in the faster transformation of the atropisomers in DMSO and in the coupling constants (Table 1), which are rather mean values of the coupling constants of several conformations.

With **3A** it has thus been possible for the first time to determine the influence of a biphenyl-containing pseudo-amino acid (**1**) on the conformation of a cyclopeptide (**3**), both in the solid state as well as in solution. The conformation of the atropisomer **3A** is identical in the crystal and in $CDCl_3$; in DMSO, deviations are possible. **1**, as part of the cyclopeptide, effects a reversal of the peptide chain and thereby generates a new type of peptide loop. Derivatives with other amino acids will show whether the cross-linking of the antiparallel peptide chains by hydrogen bridges also exists in longer chains.

Experimental

N-(2′-Phthalimidomethylbiphenyl-2-carbonyl)valine methyl ester **4**: A solution of **2** [6] (3.27 g, 9.2 mmol) and H-Val-OMe·HCl (1.53 g, 9.2 mmol) in CH_2Cl_2 (50 mL) was treated at −10 °C, first with 5.5 mL (50 mmol) of *N*-methylmorpholine (NMM) and then dropwise with 6.2 mL of a 50% solution of propylphosphonic acid anhydride (39 mmol). After removal of the solvent by evaporation the residue was taken up in ethyl acetate, washed with saturated $NaHCO_3$ solution, saturated NaCl solution and 5% $NaHSO_4$ solution, and dried over $MgSO_4$. The oily **4** obtained after removal of the ethyl acetate by evaporation was used in the next step of the synthesis without further purification (yield: 3.3 g, 77%).—^1H NMR (400 MHz, $CDCl_3$, 23 °C, 2 sets of signals because of biphenyl atropisomerism): δ = 7.90–7.25 (m, 12H; H_{aryl}), 7.66 (d, 1H; NH), 7.58 (d, 1H; NH), 4.93 (2 AB, 4H; CH_2), 4.50 (dd, 1H; *i*PrCH), 3.83 (dd, 1H; *i*PrCH), 3.70 (s, 3H; OMe), 3.37 (s, 3H; OMe), 2.02 (m, 1H; Me_2CH), 1.86 (m, 1H; Me_2CH), 0.78 (2d, 6H; 2 CH_3), 0.51 (d, 3H; CH_3), 0.37 (d, 3H; CH_3).—EI-MS: *m/z* (%) 470 (62, $M^{\oplus}$), 411 (21), 339 (61), 310 (100), 160 (99).

3: A solution of **4** (3.17 g, 6.7 mmol) in methanol (30 mL) was treated with 4.0 mL (80 mmol) of $N_2H_4 \cdot H_2O$ and the mixture stirred for 15 h at room temperature. The precipitated phthalhydrazide was filtered off and the filtrate evaporated down and dried. The residue (**1**, but R^2 = Val-hydrazide) was taken up in THF (50 mL) and the solution cooled to −20 °C. After addition of conc. HCl (5.6 mL) and a solution of 500 mg (7.2 mmol) of $NaNO_2$ in 5 mL of water the resulting suspension was stirred for 90 min. After dilution with 25 mL of THF (cooled to −10 °C) and addition of 11.0 mL (100 mmol) of NMM the mixture was warmed within ca. 12 h to 0 °C and allowed to stand at room temperature for 2 d. The solvent was then removed by evaporation and the residue was taken up in 300 mL of ethyl acetate and washed with $NaHCO_3$, NaCl, and $NaHSO_4$ solutions. The crude product obtained after drying and removal of the solvent was purified by column chromatography (silica gel 60, $CHCl_3$/THF = 5/1). Three fractions were collected (yields: fraction 1 (= **3A**): 330 mg, 15%; fraction 2 (= **3B**): 8 mg, 5%; fraction 3 (= **3C**): 29 mg, 2%). The three fractions were first characterized by ^1H NMR and DCI-MS and then recrystallized from acetonitrile. Crystalline fractions of **3A** and **3C**, after hydrolysis and derivatization as perfluoropropionylvaline isopropyl esters, were investigated by gas chromatography on a Chirasil-Val capillary column for their enantiomeric purity. The results were, in the case of **3A** 93.8% L-Val and 6.2% D-Val and in the case of **3C** 93.6% L-Val and 6.4 D-Val.—Selected data for **3A**: m.p. 207–220 °C. Satisfactory C, H, N analysis.—^1H NMR (400 MHz, $CDCl_3$, 23 °C): δ = 8.33 (b, 2H; CH_2NH), 7.53–6.93 (m, 16H; aryl), 6.12 (d, 2H; $CHNH$), 4.25 (AB, 4H; CH_2), 4.08 (t, 2H,; *i*PrCH), 2.03 (m, 2H; Me_2CH), 0.82 (d, 6H; CH_3), 0.72 (d, 6H; CH_3). $^{13}C\{^1H\}$ NMR (100.5 MHz, $CDCl_3$): δ = 170.2 (CH−C=O), 167.7 (Aryl-C=O), 141.4, 140.4, 134.1, 134.0, 130.9, 130.7, 130.4, 128.2, 128.1, 127.6, 127.5, 127.3 (C_{aryl}), 58.5 (*i*PrCH), 43.4 (Aryl-CH_2), 29.5 (Me_2CH), 19.3 (CH_3), 17.8 (CH_3). DCI-MS (NH_3, negative): *m/z* (%) 616 (100, $M^{\ominus}$), 426 (2), 408 (2), 241 (10), 162 (6).

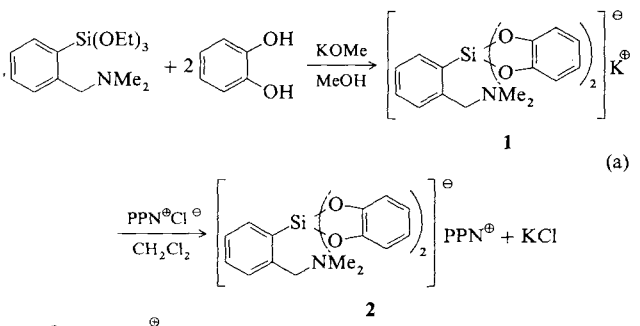
A Compound Containing Hexacoordinated Silicon —a Model for Nucleophilic Attack on Anionic, Pentacoordinated Silicon Species?

By *Francis Carré, Geneviève Cerveau, Claude Chuit, Robert J. P. Corriu,** and *Catherine Réyé*.

Species containing hexacoordinated silicon have been proposed as intermediates (or transition states) in the course of chemical reactions at silicon.[1, 6] Such species are uncharged when they are formed by nucleophilic solvents such as hexamethylphosphoric triamide (HMPA) dimethylformamide (DMF) or dimethyl sulfoxide; this is the case in the racemization,[1] hydrolysis or alcoholysis of chlorosilanes.[3] Anionic complexes result in the activation of SiH[4], SiO[4, 7, 8], SiN[9] and SiC[10, 11] bonds by fluoride anions; this provides a very useful catalytic procedure for organic syntheses. Recently, the role of such hypervalent silicon species (both penta- and hexacoordinated) has been most clearly demonstrated in the case of group transfer polymerization.[6] In all cases the mechanisms proposed[2] involve nucleophilic attack on an anionic or neutral pentacoordinated silicon species (Scheme 1).



Scheme 1. Cat = $F^{\ominus}$, $RCO_2^{\ominus}$, HMPA, DMSO.

We have already reported on nucleophilic reactions at the anionic, pentacoordinated silicon center of catechol silicates[12] and shown the enhanced reactivity of pentavalent species (neutral[13] or anionic[14]) compared to that of the corresponding four-coordinate neutral species.

The concept developed by *Dunitz* et al.[15] that molecular interactions in the solid state provide an indication of preferred pathways in chemical reactions motivated our interest in attempting to synthesize an anionic pentacoordinated silicon complex which might become hexacoordinated through a dative Si ← N bond. Such a compound would provide a model for nucleophilic attack on an anionic, pentacoordinated silicon atom.

Herein, we wish to report on the structure of the (PPN)-silicate **2** (PPN = bis(triphenylphosphoranylidene)ammonium)[16] prepared according to equation (a).

(a)

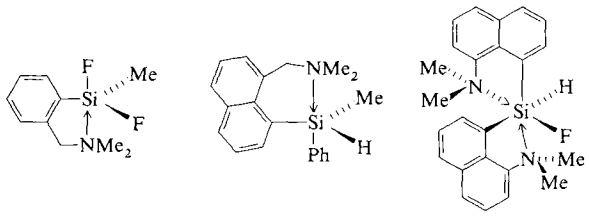
Selected bond lengths [Å] and bond angles [°] = Si-O1 1.779(7), Si-O2 1.785(7), Si-O3 1.785(6), Si-O4 1.776(7), Si-C91 1.917(9), Si-N 2.157(7); O1-Si-O3 175.2(3), O2-Si-N 172.6(3), O4-Si-C91 167.3(4), C91-Si-N 80.2(3), O1-Si-O2 89.6(3), O3-Si-O4 87.4(3).

carbon bond C91-Si, 1.917(9) Å, is exceptionally long (1.87 to 1.88 Å in Ph_4Si[18]). The four silicon–oxygen bond lengths are equal within the limits of experimental error (average 1.781(6) Å); noteworthy is that this value is significantly longer than that reported for the corresponding bonds in the anion of **3a** (average 1.747 Å[19]) and also longer than the values reported by *Holmes* et al.[20] for three related anions with pentacoordinated silicon (average of 1.744 Å). In contrast, the lengths of the six Si–O bonds in the anion of

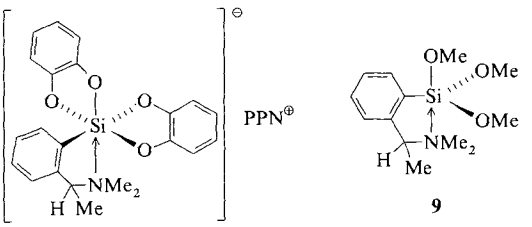


3a, M = Me_4N
3b, M = Na

4

4[21], a species with hexacoordinated silicon, are very similar to those in **2** (between 1.765 Å and 1.813(3) Å, average value 1.784 Å). We are therefore of the opinion that **2** more closely resembles a hexacoordinated species with formal doubly negatively charged silicon than a pentacoordinated species. This view is consistent with the short Si ← N distance: the length of the dative Si ← N bond (2.15 Å) is comparable to that observed in silatranes (5-aza-2,8,9-trioxa-1-silabicyclo[3.3.3]undecanes)[22] (2.0 to 2.4 Å), and shorter

than those in neutral compounds with pentacoordinated (e.g. **5**, **6**)[5, 23] and hexacoordinated silicon (e.g. **7**).[24]



5 Si–N 2.35 Å

6 2.66 Å

7 2.68, 2.64 Å

In solution, the ^{29}Si chemical shift of **2** ($\delta = -121.2$) is similar to that of the hexacoordinated silicates of catechol,[25] while a shift of $\delta(^{29}Si) = -87.4$ is observed for the sodium salt **3b**.[12b] The ^1H NMR spectrum of **2** clearly shows the resonance of the NMe_2 groups as a sharp singlet even at low temperature (−100 °C). The lack of diastereotopism of the Me groups (NMe_2) can be explained either in terms of an intramolecular non-dissociative isomerization process such as a Bailar twist[26] or in terms of a rapid equilibrium between open and closed forms allowing rotation and inversion at the nitrogen center.

To clarify this point we synthesized the silicate **8**[27] in which, because of the chirality of the benzylic carbon, the NMe_2 group is rendered diastereotopic when the nitrogen atom is coordinated at silicon even when isomerization processes take place at the silicon. (The insertion of a chiral benzyl group had already allowed us to distinguish clearly between pseudorotation and ring opening-closing processes in the case of pentacoordinated silicon compounds.[28])

8

9

The ^1H NMR spectra of **8** recorded at several temperatures showed only one coalescence due to the chirality of the benzylic carbon (Fig. 2). This observation and that with the complex **2** (sharp singlet for the NMe_2 group) can be regarded as signs for an intramolecular non-dissociative isomerization process around silicon.

Moreover this ^1H NMR study (Fig. 2) allowed the evaluation of the free energy of activation of the Si ← N bond breaking: $\Delta G^* = 10.25$ kcal mol^{-1} ($T = -58$ °C). In the case of the trimethoxy compound **9**, ΔG^* was found to be 7.6 kcal mol ($T = -110$ °C).[29] This activation energy difference between the anionic compound and the neutral compound clearly indicates the high tendency of the anionic compound to undergo nucleophilic attack and confirms the increase in reactivity towards strong nucleophiles observed with anionic pentacoordinated silicon compounds, compared to that of the corresponding tetravalent neutral species.[13]

Thus, the hexacoordinate structure of **2** with almost regular octahedral angles and a short Si ← N bond (2.15 Å) provides strong support for the possibility of nucleophilic attack on an anionic pentacoordinated silicon species through a hexacoordinate intermediate, as postulated several years ago.[2] Furthermore, it is worth noting that the regular isomerization process around the silicon atom observed for **2** and **8** needs a very low activation energy since it persists even at very low temperatures.

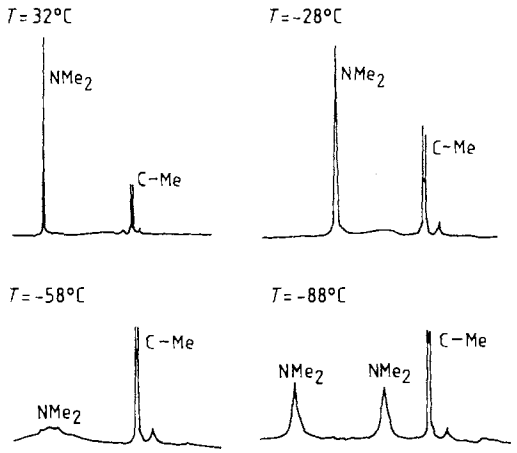


Fig. 2. ^1H NMR spectra of **8** at different temperatures, solvent CD_2Cl_2.

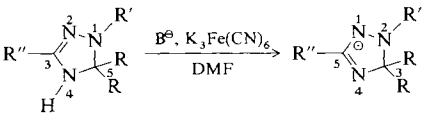
2,3-Dihydro-1*H*-1,2,4-triazol-1-yls, a Novel Group of Stable Radicals**



By *Franz A. Neugebauer,* Hans Fischer,* and *Claus Krieger*

After addition of tetracyanoethylene, $FeCl_3$ or BF_3-ether, solutions of leucoverdazyl **1** show a strong ESR signal. The partially resolved ESR spectrum was assigned to the leucoverdazyl radical cation $\mathbf{1}^{\odot\oplus}$.[1]

This surprising detection of a leucoverdazyl radical cation prompted us to check the observations. By chromatographic separation of the reaction mixtures, e.g. of the solution of **1** in formic acid, we were able to isolate a stable monomeric radical. The ESR spectrum of this radical (Fig. 1) is virtually the same as the ESR spectrum of the solution of **1** in 1,4-dioxane + BF_3-ether, regarding its spectral range and hyperfine structure. The constitution of the radical was deduced from chemical reactions and confirmed by X-ray structure analysis (Fig. 2). Accordingly the radical is 2,3-dihydro-2,3,3,5-tetraphenyl-1*H*-1,2,4-triazol-1-yl **3a**.[2] Hydrogenation of **3a** (0.5 mol H_2, $Pd/BaSO_4$) led to the leuco compound **2a**,[2] methylation of which afforded only the 1-methyl derivative **4a**,[2] obviously for steric reasons.—Evidence for the radical cation $\mathbf{1}^{\odot\oplus}$ was not found.

The 4,5-dihydro-1*H*-1,2,4-triazoles **2** were found to be suitable educts for the generation of radicals of type **3**. Compound **2a** (m.p. 192–193 °C, yield 72%) was prepared from **1** by thermal ring contraction. Reaction of *N*-phenylacetamidrazone with dichlorodiphenylmethane and BaO in dimethylformamide afforded **2b** (m.p. 179–180 °C, yield 41%). **2c** was obtained by reaction of *N*-phenyl-benzohydrazonyl chloride with 9-aminofluorene (m.p. 231–232 °C, yield 31%). All the compounds have been satisfactorily characterized.[2]

2 **3**

	R	R	R′	R″
a	Ph	Ph	Ph	Ph
b	Ph	Ph	Ph	Me
c	2,2′-biphenyldiyl			Ph
d	Me	Me	Me	Ph

The stable radicals **3a–c**[2] can be obtained from **2a–c** by dehydrogenation, e.g., with PbO_2, Ag_2O or $K_3Fe(CN)_6$. **3a** crystallizes from ethyl acetate in the form of black prisms (m.p. 162–163 °C, yield 90%). The ESR spectrum of **3a** is reproduced in Figure 1. **3b** crystallizes from cyclohexane/petrol ether (b.p. 40 °C) as dark-brown crystals (m.p. 77–78 °C, yield 51%), while **3c** separates from cyclohexane in the form of black crystals (m.p. 170–171 °C, yield 77%). The stability of the radicals decreases considerably when the phenyl substituents in positions 2 and 3 are replaced by methyl groups. It was not possible to isolate the radical **3d** obtained from **2d**.[3] All ENDOR/TRIPLE data are collected in Table 1.

Table 1. Isotropic HFS coupling constants [mT] of **3a–d** in toluene; ENDOR/TRIPLE at 230 K [a].

	3a	**3b**	**3c**	**3d**
$a(N^1)$	0.644	0.654	0.647	+0.642
$a(N^2)$	0.758	0.755	0.726	+1.049
$a(N^4)$	0.395	0.379	0.380	+0.398
a(H)(2-CH_3)				+0.953
a(H)(3,3-CH_3)				−0.051
a(H)(2,4,6-H von 2-Ph)	−0.196	−0.202	−0.200	
a(H)(3,5-H von 2-Ph)	+0.069	+0.068	+0.067	
a(H)(5-CH_3)		−0.090		
a(H)[b]	≈ +0.0017	0.020	+0.040	
a(H)[b]			+0.019	

[a] The tentative assignments of the $a(N^1)$ and $a(N^2)$ couplings have to be confirmed by ^{15}N-labeling; ENDOR data conversion 1 mT = 28.042 MHz. [b] The assignment of this proton coupling, apparently from the substituents R, is still open.

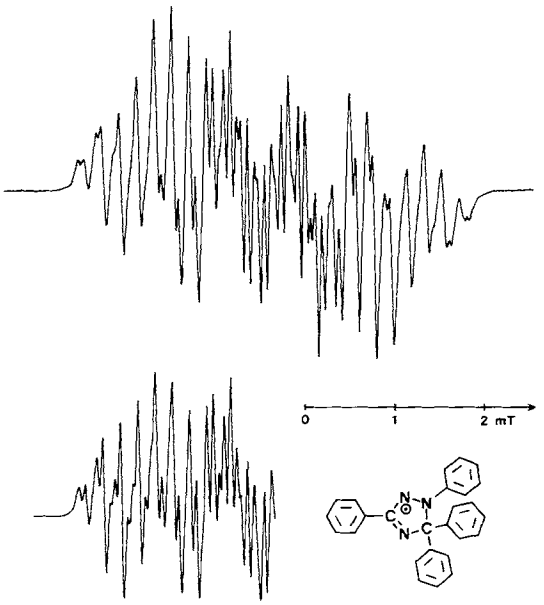

Fig. 1. ESR spectrum of **3a** in toluene (297 K); the lower half-spectrum is a simulation using the data $a(N^1) = 0.645$, $a(N^2) = 0.760$, $a(N^4) = 0.395$, a(H) (2,4,6-H of 2-Ph) = 0.195, a(H) (3,5-H of 2-Ph) = 0.070 mT.

The X-ray structure analysis of **3a**[4] reveals an almost planar 2,3-dihydro-1*H*-1,2,4-triazol-1-yl ring (Fig. 2), with the conjugated phenyl substituents in positions 2 and 5 almost coplanar. The N(1)–C(5) and N(1)–N(2) distances, which indicate considerable double-bond character (≈ 50%), correspond to the bond lengths of comparable hydrazyl partial structures; 1,3,5-triphenylverdazyl: C–N = 138, N–N = 135 pm,[5] 2,2-diphenyl-1-picrylhydrazyl: N–N = 133 pm.[6] The N–C_{Ph} bonds of these radicals are ≈ 142 pm long. The somewhat shorter N(2)–C(A1) distance (139.6 pm) in **3a** is a good indication that the unpaired electron is slightly more delocalized into the coplanar oriented *N*-phenyl ring. Consistent with this, relatively large couplings are found for the protons of the *N*-phenyl substituents by ESR. The C(5)–N(4) distance (130.5 pm) in **3a** almost corresponds to a C=N double bond (≈ 125 pm); the adjacent N(4)–C(3) bond is a perfect single bond (C–N ≈ 147 pm). The C(3)–N(2) distance is exceptionally large (150.6 pm). Most probably, this is a result of the steric repulsion of the three closely adjacent phenyl substituents on C(3) and N(2). According to the structure data of **3a** and the ESR-ENDOR results, the radicals **3a–d** have a π-SOMO which is mainly localized on N(1), N(2) and N(4). **3a–c** are

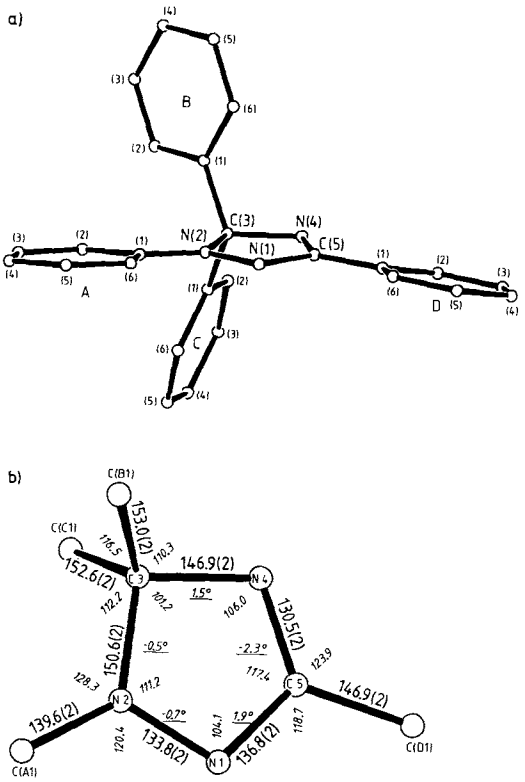

Fig. 2. Structure of **3a** in the crystal. a) Perspective drawing; b) bond lengths [pm], bond angles [°], and torsion angles [°] of the central 2,3-dihydro-1*H*-1,2,4-triazol-1-yl ring.

stable derivatives of the parent radical 2,3-dihydro-1*H*-1,2,4-triazol-1-yl, which has been observed by ENDOR (100 K) after ^{60}Co-γ-irradiation of 1,2,4-triazole single crystals:[7] $a[H^2(NH)] \approx -0.85$, $a(H^{3,3}) \approx +5.6$, $a(H^5) \approx -0.1$ mT; no a(N) data. The β-coupling of the protons in position 3 is one of the largest known proton couplings [H°: a(H) ≈ 50.6 mT]. This special case is a result of the binding of the methylene group to the two terminal atoms of a 5 π electron system (Whiffen rule[8]). Our synthesis of **3a–d** now provides the possibility of determining the comparative α- and β-^{13}C couplings in this system. This is currently being investigated.

Synthesis and Analysis of Polymetallaphosphazenes**

By *Herbert W. Roesky** and *Michaela Lücke*

In the past few years increasing interest has been directed to an area of research that is not just confined to the traditional limits of inorganic chemistry. Thus, interactions between elements of the main- and sub-groups of the periodic table lead to novel catalysts and new precursors for ceramic and electronic materials.[1] *Allcock* et al. have recently reported the synthesis of polyphosphazenes containing metal complex fragments in the side chain, which they are now investigating with regard to their suitability as such catalytic systems etc.[2] We have now succeeded in incorporating transition metals directly into the polymer chain and thus in obtaining the first polymetallaphosphazenes.

In these novel polymers a phosphorus atom is replaced by a transition metal in each monomer unit; they are obtained via a ring-opening reaction[3] upon heating **1**[4] or **2**[5] in xylene.

1, M = Mo
2, M = W

3, M = Mo
4, M = W

The properties of **3** and **4** are noteworthy: they are virtually inert towards hydrolysis, even in boiling water, and they do not decompose below about 300 °C. Elemental analyses show that no eliminations occur as side reactions. The molecular weights of the fractions soluble in THF have been determined by HPLC[6] and viscometry[7] using polystyrene calibration standards.[8] Based on HPLC-measurements of the THF soluble fractions we have obtained molecular weights of 11 800 and 34 500 for **3** and 11 800, 34 500, and 68 000 for **4** (Table 1). The limiting viscosities obtained for the soluble fractions of **3** and **4** from the viscosity measurements were compared with those of the polystyrene calibration standards (Fig. 1).[9] The results yielded mean molecular weights of 24 000 for **3** and 37 000 for **4**.

Table 1. Molecular weights of the THF-soluble fractions of **3** and **4** and their percentage amounts.

Polymer	Mol.wt. [a]	Fraction of polymer with this mol.wt. [%]
3	11 800	41
	34 500	57
4	11 800	31
	34 500	40
	68 000	28

[a] The molecular weights determined by HPLC could be confirmed by GPC measurements.

Since **3** and **4** exhibit polyelectrolyte character, tetraethylammonium tetrafluoroborate had to be added as supporting electrolyte to ensure a normal run of these viscosity measurements.[10] We shall report elsewhere on the possible applications of these polymetallaphosphazenes.

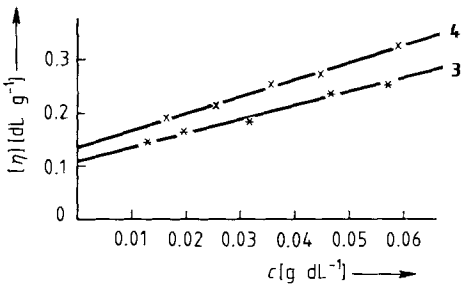

Fig. 1. Limiting viscosities of the polymer mixtures for the determination of the average molecular weights $\bar{M}$ of **3** and **4** (**3**: $[\eta]$ $(c \rightarrow 0) = 0.11$; $\bar{M} = 24000$; **4**: $[\eta]$ $(c \rightarrow 0) = 0.14$, $\bar{M} = 37000$).

Experimental:

3: A solution of **1** (0.2 g, 0.32 mmol) in dry xylene (50 mL) was stirred at room temperature under an atmosphere of N_2 for 1 h and then gradually warmed to 40 °C. After 1.5–2 h the temperature was raised to 80 °C. The reaction was complete after 12–16 h. After removal of the solvent (oil-pump vacuum, 10^{-3} torr) there remained a bright yellow, fine powder which was up to 55% soluble in xylene. This fraction was also soluble in THF, and inert to boiling water.—IR: $\tilde{\nu}$ = 1590 w, 1485 w, 1440 m, 1410 w, 1260 vs, 1220 w, 1170 m, 1100 s, 1040 s, 960 m, 940 m, 900 m, 860 m, 800 vs, 740 w, 730 m, 690 m, 580 w, 540 s, 510 m cm^{-1}.

4: A solution of **2** (0.2 g, 0.28 mmol) in dry xylene (50 mL) was stirred at room temperature under an atmosphere of N_2 for 1 h. The mixture was then heated for 1 h at 60 °C and a further 20 h at 110 °C. After removal of the solvent (oil-pump vacuum) there remained a light-brown solid which was up to 50% soluble in xylene. This fraction was also soluble in THF, and was inert towards boiling water.—IR: $\tilde{\nu}$ = 1590 w, 1480 w, 1435 vs, 1400 w, 1260 vs, 1175 w, 1150 w, 1120 s, 1060 m, 1035 m, 1020 m, 995 w, 970 m, 923 m, 800 s, 770 w, 750 m, 730 vs, 690 sh, 610 w, 550 s, 500 s cm^{-1}.

Enantioselective Allylation of Carbonyl Compounds with Titanium-Carbohydrate Complexes**

By *Martin Riediker** and *Rudolf O. Duthaler*

Among the stereoselective reactions reported so far the allylation of carbonyl compounds is unique in that several stereogenic centers can be generated in one step and the products exhibit versatile functionality.[1] High enantioselectivity and double stereocontrol are achieved with allylmetal compounds containing chiral ligands, especially good results being obtained with allylboron compounds,[2] allylstannanes[3] and allylsilanes.[4] Largely due to the pioneering work of *Seebach* et al.[5a] and *Reetz*,[5b] allyltitanium compounds and other organotitanates have been established as inexpensive, easily accessible and ecologically unobjectionable reagents. The chiral titanium complexes investigated so far, which have mainly been developed for asymmetric alkylation, were, however, not suited for the enantioselective transfer of allyl groups.[6, 7] The high diastereocontrol which can be achieved with such allyltitanium reagents[5, 8] would, nevertheless, lead one to expect that good enantioselectivity should also be realizable under suitable conditions. One of the first successes in this context was the high induction which was achieved in the transfer of chiral allyl groups to aldehydes.[9]

By reaction of cyclopentadienyltitanium(IV) trichloride **1**[10] with commercially available 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose ("diacetone-glucose")/triethylamine we obtained the stable dialkoxy(chloro)cyclopentadienyl titanate **2**, which, in the absence of moisture, can be stored either as stock solution in ether (0.05–0.1 M) or toluene (0.1–0.2 M) or as crystalline solid after precipitation with hexane

Scheme 1. a) 1,2:5,6-Di-*O*-isopropylidene-α-D-glucofuranose/Et_3N/Et_2O, room temperature (RT); b) Et_2O, 0 °C; c) 1. −78 °C, 2. H_2O/THF, −30 °C to RT.

(Scheme 1). Highly stereoselective reagents can be prepared from this novel complex by exchange of the remaining chloro ligand for transferable groups.[11]

Thus, reaction of **2** with allylmagnesium chloride affords the allyltitanium complex **3**, which is brought to reaction in situ at −74 °C with aldehydes; addition at the *re*-side leads, with numerous substrates, to homoallyl alcohols **4** in good yields and with high enantiomeric purity (Scheme 1, Table 1). The temperature dependence of this reaction is astonishingly small; thus, reaction with benzaldehyde at 0 °C furnishes the product **4a** with 80% *ee*. By controlled hydrolysis the filterable titanate **5** can be precipitated and by treatment with HCl (g) reconverted into $CpTiCl_3$ **1**.[16] In the process the chiral auxiliary diisopropylideneglucose can either be recovered or, after hydrolysis with 0.1 N HCl, be separated by aqueous extraction.

Table 1. Enantioselective allylation of aldehydes with the reagent **3** (cf. Scheme 1).

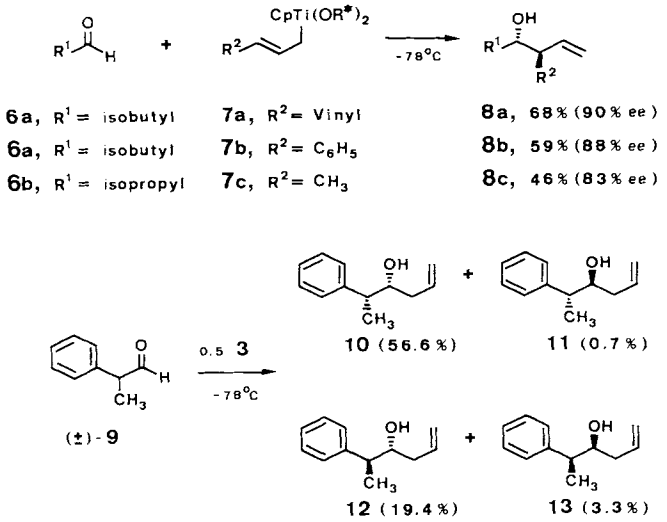
Cyclohexyl [g]	**4n**	78	*R*	92	[3]	+ 8.2	(0.6)
tert-Butyl	**4o**	58	*R*	88	[2a]	+10.3	(10.5)

[a] The yields are, in general, not optimized. [b] Determination of the enantiomeric excess by capillary GC (Chirasil-L-Val* [12]) after derivatization with isopropyl isocyanate (**4a, b, d, h, i, k–m, o**) or (*R*)-(+)-3,3,3-trifluoro-2-methoxy-2-phenylpropionyl chloride [13] (**4g, j, n**) or by HPLC on a "Baker-bond Chiral Ionic DNBPG Column" (**4c, f**) or on cellulose triacetate [14] (**4e**). [c] The signs of the rotations in benzene correspond to the configurational assignments in the cited works. [d] Concentration in benzene. [e] New compound; the configuration was assigned on the basis of analogies. [f] In Et_2O. [g] In EtOH.

As exemplified in Scheme 2 with the reactions of **6a, b**, titanates such as **7a–c** with substituted allyl groups are also highly enantioselective allylating reagents. These compounds are prepared from the corresponding lithium or Grignard reagents. As in the case of achiral allyltitanates[5, 8] the diastereomeric purity of the products **8b, c** is near the limit of detection (≥ 99%).[12]



Reaction of racemic hydratopaldehyde **9** with 0.5 equivalents of allyl titanate **3** leads to formation of the stereoisomeric homoallyl alcohols **10–13** (80% based on **3**) in the ratio 70.8:0.9:24.2:4.1, whereby **10/11** are the products from (*R*)-**9** and **12/13** those from (*S*)-**9** (Scheme 2). The moderate differentiation of enantiomers (2.5:1) as well as the higher diastereoselectivity in the case of the more reactive enantiomer (*R*)-**9** (97% *de*, matched case) would indicate a certain Cram selectivity of the reagent **3**, which, however, is outweighed by the enantiofacial differentiation (71% *de* in the case of (*S*)-**9**, mismatched case).

The titanium reagent **3** exhibits the usual chemoselectivity:[5] at −74 °C it does not react with ketones. At 0 °C, however, aryl ketones are transferred smoothly into tertiary homoallyl alcohols, but the asymmetric induction is, as expected, small (ca. 50% *ee*; 80% *ee*, however, in the case of acetophenone). In contrast to the allyl compounds, analogous alkyl- and aryltitanates do not react with aldehydes, even at elevated temperatures.

[**] Enantioselective Syntheses with Titanium-Carbohydrate Complexes, Part 1.

Scheme 2.

With the chiral reagents **3** and **7a–c** the enantioselective allylation of aldehydes has been achieved for the first time with organotitanium compounds. Boron reagents[12] exhibit a similar stereoselectivity, but the advantage of titanium chemistry[5] must not be overlooked, e.g. simple preparation, chemoselectivity, inexpensive auxiliaries, as well as the possibility of recovering diisopropylideneglucose and $CpTiCl_3$ **1**. Still a drawback of this method is, however, that the high price of L-glucose impedes an equally good access to the other enantiomers of the homoallyl alcohols **4**. Concerted efforts are therefore currently directed at solving this problem with other ligands.

Experimental

Stock solution of **2** in ether: A solution/suspension of **1** (11.0 g, 50 mmol, freshly sublimed[10]) in Et_2O (400 mL, distilled over Na/benzophenone) was treated with 26.0 g (0.1 mol) of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (R*OH, crystallized from cyclohexane) under argon in the absence of moisture. After 2 min at room temperature (RT) a solution of 15.2 mL (110 mmol) of Et_3N in 125 mL of Et_2O was added dropwise to the stirred mixture within 1 h. The resulting suspension was stirred for ca. 15 h; the $Et_3N \cdot HCl$ was then filtered off under argon and washed three times with ca. 50 mL of Et_2O (14.2 g of $Et_3N \cdot HCl$ vacuum dried). The content of **2** in the yellow filtrate (0.09 M) was calculated from the volume of the solution assuming a quantitative conversion.

(*R*)-1-Phenyl-3-buten-1-ol (**4a**): 7.2 mL of a 1.25 M solution of allylmagnesium chloride in THF (Aldrich, 9 mmol) was added dropwise within 10 min at 0 °C under argon to 110 mL of a ca. 0.09 M solution of **2** in Et_2O (9.9 mmol). After stirring for 1 h at 0 °C the orange suspension was cooled to −74 °C and treated within 5 min with 0.8 mL (8 mmol) of benzaldehyde. The mixture was stirred for 2 h at −74 °C, warmed to ca. −30 °C and hydrolyzed by addition of 16 mL of a ca. 5 M solution of H_2O in THF (1 h, RT). Filtration, washing with Et_2O and drying (high vacuum) yielded 4.2 g of **5** (yellowish solid). The filtrate was evaporated and the solid residue stirred with 100 mL of hexane. Subsequent filtration furnished 4.4 g of R*OH. Chromatography (80 g silica gel, hexane: AcOEt 3:1) finally afforded 1.01 g (85%) of **4a** (90% *ee*, determined as described in [12]).

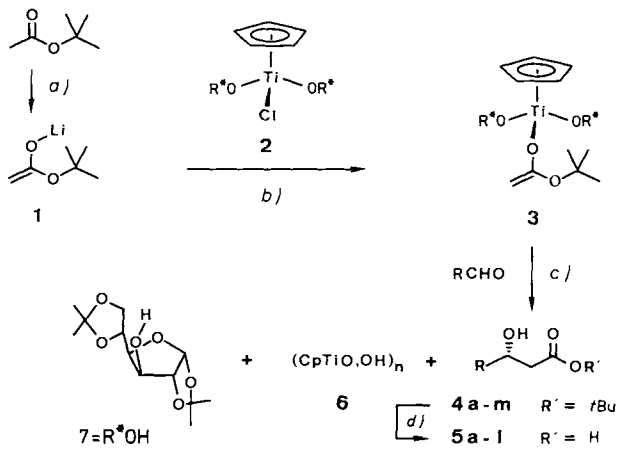
Enantioselective Aldol Reaction of *tert*-Butyl Acetate using Titanium-Carbohydrate Complexes**



By *Rudolf O. Duthaler,* Peter Herold, Willy Lottenbach, Konrad Oertle,* and *Martin Riediker*

The Aldol reaction is one of the most important methods for the stereoselective construction of complex acyclic molecules.[1] Covalently bound chiral auxiliaries readily induce high stereoselectivity in the case of propionate enolates, whereas in the case of acetate enolates this could hitherto only be achieved via a circuitous route involving auxiliary substituents.[2] More recently, methods have been developed which enable the stereoselective addition of α-unsubstituted enolates.[3] A particularly efficient approach makes use of metal complexes with chiral ligands.[4] It should, however, be mentioned, that many β-hydroxy esters (such as **4**) are accessible by enantioselective reduction of the corresponding β-oxo esters as well.[5]

The successful asymmetric allylation of carbonyl compounds with novel cyclopentadienyltitanium-carbohydrate complexes[6] motivated us to apply this principle also to the acetate-Aldol reaction.[7] We have found that, in this way, a variety of β-hydroxycarboxylic acids are accessible in 90–95% optical purity (Scheme 1, Table 1).

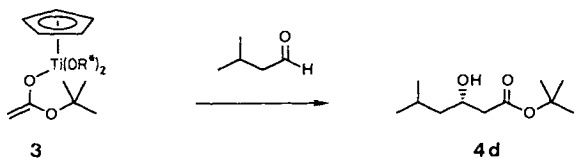
[**] Enantioselective Syntheses with Titanium-Carbohydrate Complexes, Part 2.—Part 1: [6].



Scheme 1. a) Li-diisopropylamide, Li-cyclohexyl(isopropyl)amide or Li-dicyclohexylamide/Et_2O/−74 °C; b) 1 h −30 °C or 24 h −74 °C; c) 2 h −74 °C, H_2O; d) CF_3CO_2H/100 mbar/1–5 h (RT) or 2 N NaOH/16 h RT. (Residue R, see Table 1 below.)

Transmetalation of the relatively stable lithium enolate **1** of *tert*-butyl acetate with chloro(cyclopentadienyl)-bis(1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranos-3-*O*-yl) titanate **2** as stock solution in toluene (0.09–0.2 M) or Et_2O (0.05–0.09 M[6] furnishes the titanium enolate **3**, which is brought to reaction in situ with aldehydes to give the hydroxy esters **4a–m**. In analogy to the allylation[6] the enolate preferably adds to the *re*-side of the aldehydes. With the exception of **4m**, the *tert*-butyl esters **4** can be converted into the acids **5a–l** either by cleavage with acid or by basic hydrolysis; in the case of crystalline compounds, crystallization from cyclohexane generally affords optically pure samples.

The titanium oxide complex **6** formed during hydrolytic work-up can be filtered off and reconverted into $CpTiCl_3$, the starting material for the complex **2**, by treatment with HCl.[6] The chiral auxiliary is either separated unchanged or, after acetal hydrolysis in 0.1 N HCl, extracted with water.

On optimization of the reaction conditions it was found that transmetalation of the lithium enolate **1** at −74 °C proceeds very slowly (24 h) and can be accelerated significantly by warming to ca. −30 °C (≈ 1 h). Since the lithium amide bases apparently do not react with the titanate **2**, it is even possible to add the *tert*-butyl acetate and the titanium reagent simultaneously to the base. The titanium enolate **3** tolerates elevated temperatures and, astonishingly, the enantioselectivity of the Aldol reaction is almost temperature independent, as shown in Scheme 2 for isovaleraldehyde; the reaction can even be carried out at room temperature without significant loss of optical induction.

Scheme 2.

T [°C]	**4d**, Yield [%]	**4d**, *ee* [%]
−74	81	94
−30	68	92
−15	72	95
0	68	95
+27	60	96

The chirally modified titanium reagent **3** is thus a novel acetate enolate, which adds with striking enantiofacial differentiation to the *re*-side of many aldehydes. The optical purity of the β-hydroxy acids **5** formed thereby is as high as in the best known methods.[3, 4] However, the reaction can be carried out at higher temperatures, and the tedious synthesis of a chiral auxiliary, the reaction steps for introduction and removal of the auxiliary reagent as well as the synthesis of special derivatives (cf. Ref. [4c]) are circumvented. Moreover, not only can the non-toxic titanium complex be recovered in a simple way via **6**, but, in most cases, also the inexpensive commercially available auxiliary **7** by crystallization. Since (L)-glucose is relatively expensive, work aimed at making the enantiomers of **4** and **5** accessible by the same principle is in progress.

Table 1. β-Hydroxy esters **4** and β-hydroxy acids **5** by enantioselective Aldol reaction of the titanium enolate **3** (cf. Scheme 1).

[a] Determined by capillary GC (Chirasil L-Val*) of the *O*-(*N*-isopropylamino)carbonyl-*N*-isopropyl-substituted amide of the acid **5** [8]. [b] The configuration was assigned on the basis of a comparison of published rotation values (**5b, c** [5a]; **5a, e, g, l** [9]; **5i** [10]) or by analogy (rotation, sequence of elution upon capillary GC [8b]) (**5d, f, h, j, k, m**). [c] Simultaneous addition of *tert*-butyl acetate and **2** to the Li-dicyclohexylamide. [d] ≥ 99% *ee* after crystallization from cyclohexane. [e] Owing to solubility problems the Aldol reaction was carried out at −40 °C. [f] Determined by ^1H NMR spectroscopy of the (*R*)-(+)-3,3,3-trifluoro-2-metboxy-2-phenylpropionic acid esters [11] of **4c, i, j, l, m**. [g] The racemate crystallizes as conglomerate of the enantiomers (m.p. IR, cf. [12]). [h] In CH_3OH. [i] Unstable compound.

Experimental

A solution of dicyclohexylamine (14.5 g, 80 mmol) in absolute ether (150 mL) was treated at −25 °C with 43.7 mL (70 mmol) of 1.6 M butyllithium in hexane. After 30 min at −25 °C, the mixture was cooled to −74 °C and a solution of 6.96 g (60 mmol) of *tert*-butyl acetate in 40 mL of absolute ether was added dropwise within 35 min. After stirring for 30 min at −74 °C 842 mL (80 mmol) of a 0.095 M solution of **2** in toluene, precooled to −74 °C, was transferred within 40 min to this mixture via a cannula. After 1 h at −74 °C the mixture was warmed in 25 min to −30 °C, stirred at this temperature for 30 min and finally recooled to −74 °C. A solution of the aldehyde (60 mmol) in absolute ether (30 mL) was then added dropwise within 40 min and the mixture stirred for 2 h at −74 °C. After hydrolysis with 130 mL of a 5 M solution of H_2O in THF and stirring for 1 h at room temperature (RT), the titanium compounds were recovered by filtration (Celite®). The filtrate was washed with 100 mL of saturated NaCl solution, the aqueous phase extracted twice with ether. For hydrolysis of **7**, the residue of the dried ($MgSO_4$) organic phase was stirred with 1 L of 0.1 N HCl at RT. The β-hydroxy ester **4** was isolated by extraction with ether and purified by column chromatography (silica gel).

Enantioselective Synthesis of D-*threo*-β-Hydroxy-α-amino Acids with Titanium-Carbohydrate Complexes**

By *Guido Bold,* Rudolf O. Duthaler,* and *Martin Riediker*

Stimulated by the successful isolation of structurally interesting, uncommon α-amino acids having remarkable biological properties[1] great progress has been made in recent years in the enantioselective synthesis of such compounds.[2] Diastereoselective reactions of chiral glycine derivatives have proven particular successful, whereby, aside from the alkylation of enolates,[3] the Aldol reaction plays an especially significant role, since this leads to the important class of β-hydroxy-α-amino acids.[4] However, the removal and separation of the chiral auxiliaries are usually tedious and, in some cases, limit the scope of application of these methods. In this respect the use of chiral metal complexes is more advantageous, particularly in catalytic processes such as the gold(I)-catalyzed addition of ethyl isocyanate to aldehydes, which affords β-hydroxy-α-amino acids with high stereoselectivity.[5]

We therefore decided to apply our novel titanium-carbohydrate complexes,[6] which have proven to be especially useful in enantioselective allylation[7a] and acetate-Aldol reactions,[7b] to reactions of substituted enolates. The lithium enolate **2** of ethyl (2-(2,2,5,5-tetramethyl-1-aza-2,5-disilacyclopent-1-yl)acetate **1**[8] can be transmetalated in a slow reaction with chloro(cyclopentadienyl)bis(1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranos-3-yl) titanate **3**.[7] Subsequent Aldol reaction of the titanium enolate **4** yields D-*threo*-β-hydroxy-α-amino acid esters **5** with astonishingly high stereoselectivity (Scheme 1, Table 1). As previously in the allylation[7a] and acetate-Aldol reaction,[7b] the addition occurs preferentially from the *re*-side of the aldehydes. In comparison with the unselective reactions of the lithium enolates of *N*-bis-silylated glycine esters,[16] the high *syn*-selectivity of this reaction is remarkable as well. Although the free amino acid esters **5** can be isolated, it is advisable to protect the amino function, e.g. as *tert*-butyl carbamates **6** or as formamides **7**.

Scheme 1. a) Li-diisopropylamide or Li-cyclohexylisopropylamide/THF, −78 °C; b) THF/Et_2O, 17 h, −78 °C; c) inverse addition, −78 °C to room temperature (RT), hydrolysis; d) Boc_2O/$NaHCO_3$/dioxane/H_2O, 2.5 h RT; e) HCO_2Et, 5.5 h reflux.

The titanate **8** that precipitates upon hydrolysis can be separated by filtration and converted into $CpTiCl_3$, the starting material for the reagent **3**.[7] By extraction with solvents the chiral auxiliary **9** can also be separated from the polar, water-soluble products **5**.

[a] Determination by capillary GC (Chirasil-L-Val)[R] [9], 90–180 °C, 2 °C min^{-1}, after derivatization with trifluoroacetic anhydride. The stereoisomeric mixture of the unselective reaction of the Li-enolate **2** served as reference. [b] Comparison with D-threonine (see [a]). [c] Hydrolysis to the free amino acid: $[\alpha]_D = -19.4°$ ($c = 1$, 5 N HCl) [10, 11] (^{1}H NMR). [d] 24 h RT for the Aldol reaction. [e] Assignment based on analogy [9b] (see [a]). [f] Conversion into methyl 2-*tert*-butoxycarbonylamino-3-(*tert*-butyldimethylsiloxy)-4-pentenoate or *tert*-butyl *N*-(2,2-dimethyl-4-vinyl-1,3-dioxan-5'-yl)carbamate, comparison with the literature data [12]. [g] Derivatization with Ac_2O/pyridine, otherwise as [a]. [h] Hydrolysis to phenylserine: $[\alpha]_D = +52°$ ($c = 0.8$, 6 N HCl) [13, 4b] (^{1}H NMR). [i] According to ^{1}H NMR. [j] Derivatization with *N,O*-bis(trimethylsilyl)acetamide, otherwise as [a]. [k] Aldehyde prepared by ozonolysis (O_3/CH_2Cl_2, −78 °C, Me_2S, 0 °C-RT, 19 h) of di-*tert*-butyl fumarate [14] (b.p. 50 °C/28 mbar). Ozonolysis in CH_3OH: CH_2Cl_2 3:1 [15] gives another product, presumably a (semi)acetal.

The titanium complex **4** is thus a novel, chirally modified glycine enolate which reacts with high stereoselectivity with a variety of aldehydes to give D-*threo*-β-hydroxy-α-amino acids. Noticeably lower selectivity has so far only been observed with methyl glyoxylate (→ **7g**).[17] A better result, however, is obtained with *tert*-butyl glyoxylate (→ **7h**). Advantages compared to other methods[4, 5] are the easily accessible, commercially available chiral auxiliary, the recoverability of the reagents, the flexibility in the choice of the *N*-protecting group in the product, and the ease of liberation of the amino acid merely by ester hydrolysis.

10, z = CO_2CH_2Ph **11** (49%)

Scheme 2. a) 1. −78 °C to RT, 2. Work-up, 3. 5 N HCl, 2 h 100 °C.

The reaction of **4** with the modified glutamic acid semialdehyde **10**[18] outlined in Scheme 2 shows that sensitive substrates are compatible with the reaction conditions. The product 2,6-diamino-3-hydroxy-heptane diacid **11** is a constituent of microbial cell walls.[19] According to the ^{13}C NMR spectrum, **11** is stereochemically pure; the (2*R*,3*S*)-configuration was assigned in analogy to the other examples and is thus not strictly proven.

Experimental

A solution of cyclohexylisopropylamine (2.26 mL, 13.5 mmol) in dry THF (60 mL) was treated at −20 °C with 7.6 mL (12.2 mmol) of a 1.6 M solution of butyllithium in hexane (argon). After 20 min the mixture was cooled to −78 °C and treated dropwise with a solution of ethyl(2,2,5,5-tetramethyl-1-aza-2,5-disilacyclopent-1-yl)acetate (3.0 g, 12.24 mmol) **1** [8] in 60 mL of THF. After 1 h, 142 mL (13.5 mmol) of a 0.095 M solution of **3** in ether [7] was added to the mixture, which, after stirring for 17 h at −78 °C, was transferred via a steel cannula under argon pressure into a solution of the aldehyde (13.5 mmol) in 15 mL of THF cooled to −78 °C. After 17 h at −78 °C the reaction mixture was allowed to warm slowly to room temperature (ca. 3 h), stirred for ca. 2 h (longer if necessary, cf. the reaction with pivaldehyde (→ **6c**)), and hydrolyzed with 1.5 mL of water. After ca. 2 h, **8** was collected by filtration. There are then several variants for the isolation of the product from the filtrate: a) After addition of a 10% NaCl solution the bis(silyl) derivative of the product can be extracted with ether together with **9**. A part of **9** can be separated by crystallization from cyclohexane (150 mL). For the *N*-desilylation, the residue from the mother liquor is stirred for 2 h in a mixture of 4.5 mL AcOH, 24 mL of H_2O and 120 mL of THF. After careful evaporation in a high vacuum the residue is either directly chromatographed (silica gel, CH_2Cl_2:EtOh 9:1, +1% of 25% NH_3) (→ **5**) or first derivatized: 5.3 g (24.5 mmol) of di-*tert*-butyl dicarbonate, $NaHCO_3$ (6.7 g) in dioxane:H_2O 1:1 (80 mL), 2 h RT (→ **6**) or ethyl formate, 5.5 h heating under reflux (→ **7**).

b) After the separation of **8**, the filtrate is treated with 24 mL H_2O and 4.5 mL AcOH and stirred for 2 h at RT. After evaporation to a third of the volume, **9** is extracted three times with 150 mL of ether. After washing three times with 100 mL 0.05 N HCl, the aqueous phase is adjusted to pH 4 and evaporated down under high vacuum. The subsequent steps are then as described under (a).

Structure of Chloro(cyclopentadienyl)bis(1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranos-3-O-yl) Titanate, a Novel Titanium-Carbohydrate Complex**

By *Martin Riediker, Andreas Hafner,* Umberto Piantini, Grety Rihs,* and *Antonio Togni**

In the preceding communications[1] we have shown that complex **1** is of special importance as a precursor for enantioselective allyl and ester enolate additions to aldehydes. This novel Ti^{IV}-complex with monodentate "sugar ligands" is the first representative of a new class of compounds[2] and can be isolated as a yellowish powder, which is very sensitive to hydrolysis.[3] To throw some light on the mechanism of chirality transfer its structure has been determined, both in the solid state (X-ray analysis) and in solution (NMR spectroscopy).

$TiCp(OR^*)_2Cl$ **1**

$Cp = \eta^5\text{-}C_6H_5$; OR* = 1,2:5,6-Di-*O*-isopropylidene-α-D-glucofuranoso-3-*O*-yl

Figure 1 shows the crystal structure of **1**. Table 1 contains selected bond lengths, bond angles, and torsion angles.

The complex **1** is monomeric. The coordination geometry is best described as a three-legged piano stool arrangement. Additional Ti–O interactions can be ruled out, because the shortest non-bonding Ti–O distance (Ti1–038) is 414 pm. The Ti–O bond lengths of 180.9(8) and 178.6(8) pm are about 5 pm shorter than in **2** (185.5(2) pm)[7] and 10 pm shorter than in **3** (190.3(2) pm),[8] but ca. 5 pm longer than in **4** (175.0(2) pm).[7] The Ti–O–C bond angles (145.8(8)° und 153.1(9)°) reflect the double bond character of the Ti–O bond. Values of 133.2(2)°, 145.5° and 166.2(2)°, respectively, were measured for **2**,[7] **3**,[8] and **4**.[7]

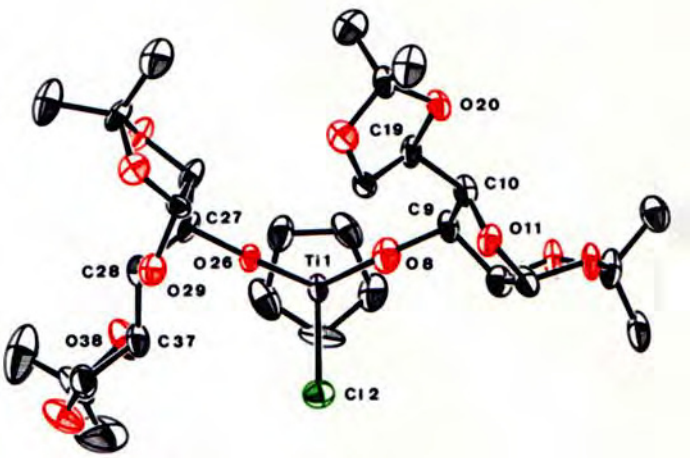

Fig. 1. ORTEP drawing of **1**. Projection along the Cp_{center}-Ti axis (vibration ellipsoids at the 20% probability level).

Table 1. Selected bond lengths, dihedral angles, and torsion angles of **1**.

$[CpTiCl_2O\text{-}CMe_2\text{-}CMe_2\text{-}OCl_2TiCp]$ **4**

The torsion angles of the freely rotating single bonds in the two carbohydrate ligands (cf. Table 1) differ considerably. The orientation of the ligands relative to the Cp ring is therefore completely different. The dioxolane ring (with C-5 and C-6 of the glucose) of one carbohydrate ligand is facing towards the Cp ring whereas in the other ligand it is situated opposite to the Cp ring. Due to this conformation the $Ti(OR^*)_2$ fragment forms a chiral cavity at the titanium atom. The Cp ligand borders the upper side of the cavity, while the chloro ligand borders the opposite side.

Different sets of signals are observed for the two carbohydrate ligands of complex **1**, both in the ^1H NMR and in the ^{13}C NMR spectrum (Table 2). The assignment of the ^1H resonances of the two ligands was possible with the aid of H, H–COSY and homonuclear difference NOE experiments. Measurements at variable temperatures (−100 to +100 °C)

[**] Enantioselective Syntheses with Titanium-Carbohydrate Complexes, Part 4. - Part 3: [1c]

gave no indication of an inversion at the metal center or of a rapid ligand exchange. Furthermore, no further conformational isomers could be detected, even at $-100\,^{\circ}C$, so that it can be assumed that a relatively rigid conformation exists in solution. Since the H, H coupling constants of the ligands are practically identical to those of the free 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, greater deformations of the glucose skeleton due to complexation can be ruled out. However, no data on the H–C4′–C5′–H torsion angle is available, because $J_{4'\text{-}H,5'\text{-}H}$ coupling constants could not be determined. Since no NOEs are observed between protons that do not belong to the same carbohydrate unit, these two ligands must be spatially separated. A strong NOE with the Cp ligand is, however, exhibited by the 3-H and 3′-H protons. Due to the fact that the NOEs are practically identical, these two protons must lie approximately the same distance from the Cp ring. 7-CH_3^{syn} exhibits a weak NOE with the Cp ligand; this indicates that this methyl group is also located near to the Cp ring. Additional NOEs with the Cp ligand were not observed. These observations strongly suggest a similar conformation of the complex **1** in solution and in the solid state.

The chloro ligand can be replaced in a metathesis reaction, either by an η^1-allyl or an ester enolate ligand. These ligands can then be transferred with high enantioselectivity to aldehydes.[1] The reagent **5** used for the allylation could be isolated and characterized by ^{13}C-NMR (Table 2). From a comparison of the ^{13}C-T_1 relaxation times with those of **1** it could be concluded that the complex **5** is monomeric.

$[TiCp(OR^*)_2(CH_2-CH=CH_2)]$ **5**

The two 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranosyl ligands again show two different sets of signals, even at room temperature. There is no indication of a rapid ligand exchange or an inversion at the metal center taking place. The chiral cavity found in the complex **1** is apparently retained also in the complex **5**. The product enantioselectivities obtained for the reactions of **5** can be reasonably attributed to a coordination of the aldehyde in such a chiral cavity.

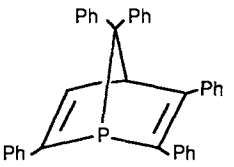
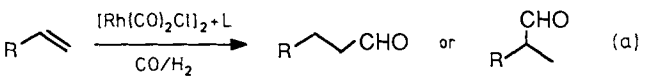
Phosphanorbornadienes as Ligands in the Transition Metal-Catalyzed Synthesis of Fine Chemicals**



By *Denis Neibecker** and *Régis Réau*

Since *Wilkinson* et al.[1] demonstrated that rhodium-phosphane complexes are by far the best catalysts for the hydroformylation of α-olefins, many works have been devoted to improving the activity and selectivity of these catalytic systems by varying the phosphane.[2] In spite of the large number of phosphanes tested, the hydroformylation of olefins, especially functionalized ones, has not yet been accomplished with enough selectivity to become a valuable synthetic tool. As a consequence, new phosphanes are potentially of interest for the development of more efficient catalytic systems.

The phosphanorbornadienes **1** and **2**, first described by *Mathey* et al. in 1981, are now readily available compounds,[3] which, according to their Tolman's parameters,[4] are hindered and poor σ-donor ligands.[5]



1

2

Since it is well established that phosphanes exhibiting such stereoelectronic properties enhance both the activity and selectivity of the rhodium catalyst in the hydroformylation of olefins,[6] we decided to investigate catalysts generated in situ from phosphanorbornadiene and $[Rh(CO)_2Cl]_2$ as catalyst precursors, a conventional method in hydroformylation chemistry[2] [Eq. (a); dppb = 1,4-bis(diphenylphosphino)butane].

(a)

3, R = *n*Bu **4**, R = Ph **5**, R = COOEt

L = PPh_3, dppb, **1**, **2**

At first, we compared the activities of the phosphanorbornadienes in the hydroformylation of 1-hexene under conventional conditions[2] with those of triphenylphosphane, the phosphane ligand used on an industrial scale[7] (Table 1).

The (phosphanorbornadiene)rhodium complexes exhibit the same stereoselectivity as the triphenylphosphane rhodium complex—predominantly *n*-heptanal, **3**, is formed—but

Table 1. Hydroformylation of 1-hexene. [a]

Phosphane	Conversion [%]	Yield of Aldehydes [%]	3 [%]	TOF [b] [h^{-1}]
PPh_3	6	100	71	39
1	27	100	68	204
2	62	100	68	402

[a] [Substrate]/[Rh] = 220, [phosphane]/[Rh] = 5, 80 °C, CO/H_2 (1/1) 20 bar, 20 min. [b] TOF turnover frequency defined as mol of substrate hydroformylated per mol of catalyst per hour.

they are much more active. No side reactions such as hydrogenation or isomerization of the substrate are observed. These findings led us to examine the hydroformylation of functionalized olefins, namely styrene and ethyl acrylate.

Preliminary runs performed with styrene at 40 °C revealed that only the rhodium complex of **2** provided an efficient catalytic system. It then was used under milder conditions for comparison with triphenylphosphane, which is reported to be the most efficient ligand for rhodium-catalyzed styrene hydroformylation[8] (Table 2).

Table 2. Hydroformylation of styrene [a].

Phosphane	Conversion [%]	Yield of Aldehydes [%]	4 [%]	TOF [b] [h^{-1}]
PPh_3	10	100	95	3.6
2	46	100	91	17

[a] [Substrate]/[Rh] = 220, [phosphane]/[Rh] = 5, 25 °C, CO/H_2 (1/1) 20 bar, 360 min. [b] See footnote in Table 1.

The results quoted in Table 2 show that phosphanorbornadiene **2** is a more efficient ligand than triphenylphosphane for the hydroformylation of styrene. This result is promising not only for the selective production of hydratropaldehyde **4** (a starting material for cosmetics, polymers and pharmaceuticals[9]) but also for the synthesis of 2-arylpropionaldehydes and therefore of the corresponding acids which are now commonly used as antiinflammatory drugs.[10]

Finally, the hydroformylation of ethyl acrylate was studied. It is reported that this reaction requires drastic conditions (typically 150 °C, 100 bar) and that only (diphosphane)rhodium complexes are catalytically active.[11] In spite of these results, the activity of the (phosphanorbornadiene)rhodium systems in the hydroformylation of ethyl acrylate at 25 °C was investigated. The (dppb)Rh system, which is the most active and selective catalyst system described so far[12] for this reaction, served for comparison.

The results (Table 3) show that the hydroformylation of ethyl acrylate does indeed proceed under mild conditions. Furthermore, it is shown for the first time that this reaction can be catalyzed effectively by (monophosphane)rhodium systems. Ethyl 2-formylpropionate **5** selectivity reaches 100%, and the phosphanorbornadienes **1** and **2** induce a better activity than the best diphosphane described so far.

Table 3. Hydroformylation of ethyl acrylate [a].

Phosphane	Conversion [%]	Yield of Aldehydes [%]	5 [%]	TOF [b] [h^{-1}]
dppb	56	100	100	11
2	71	100	100	14
1	70	100	100	15

[a] [Substrate]/[Rh] = 220, [phosphane]/[Rh] = 5, 25 °C, CO/H_2 (1/1) 20 bar, 720 min. [b] See footnote in Table 1.

In conclusion, this work demonstrates that phosphanorbornadienes are valuable ligands for rhodium catalysts for the hydroformylation of olefins. These original phosphanes lead to highly selective and active catalytic systems under very mild conditions. Considering the diversity of the investigated substrates, these new catalytic systems may be used for a large variety of olefins, especially functionalized ones.

Experimental

The hydroformylation reactions were performed in a home-made 100-mL Teflon-coated stainless steel autoclave, equipped with a magnetic stirrer, a safety valve, a ball valve for the introduction of liquids, a manometer and an argon/gas inlet-outlet valve. In a typical run, 0.02 mmol of $[Rh(CO)_2Cl]_2$ and 0.2 mmol of ligand were placed in the autoclave. The atmosphere was replaced by argon and a toluene solution (8 mL) containing the substrate (9 mmol) and NEt_3 (0.4 mmol) was introduced through the ball valve. This valve was closed and the autoclave was pressurized with CO (10 bar) and H_2 (10 bar) and thermostated at the required temperature in about 5 min. After the reaction time quoted in the Tables, the autoclave was cooled to −40 °C and vented in ca. 1 h in a well-ventilated hood. The reaction products were collected under argon into a Schlenk tube with toluene and analyzed by gas chromatography. Conversion of the substrates and stereoselectivity with respect to the aldehydes **3**, **4** and **5** were determined relative to internal standards.

Intermolecular Complexes. (Series: Studies in Physical and Theoretical Chemistry, Vol. 52). By *P. Hobza* and *R. Zahradnik*. Elsevier, Amsterdam 1988. 308 pp., hard cover, HFl 245.00.—ISBN 0-444-98943-9

Experimental and theoretical studies of intermolecular complexes are becoming an ever more important part of physical chemistry, and many review articles on the topic have been published in the last few years. The authors of this volume have taken on the task of providing a more comprehensive overview of recent developments in the area of intermolecular interactions.

In a short introductory chapter the scope of the book is defined, the basic features of intermolecular interactions are summarized, and reference is made to earlier reviews of the topic. This is followed by a discussion of theoretical approaches to the problem, and the numerical methods that are now routinely used for calculations on intermolecular interactions. The methods covered range from those based on configuration interaction (CI) and perturbation theory, through self-consistent field (SCF) methods, to the completely empirical methods. Detailed derivations are not given. A knowledge of the necessary formalism for the various methods is generally assumed. On the other hand, the capabilities, and also the limitations, of the various methods are illustrated using examples taken from the literature. The third chapter consists of a very brief summary of experimental techniques.

The next chapter contains a detailed and systematic survey of quantum chemical calculations and experimental results concerning the structures and spectroscopic properties of isolated dimers (ranging from inert gas dimers through various hydrogen-bonded complexes to G–C base pairs. The final chapter is an interesting account of biochemical aspects, in which van der Waals complexes play an important role.

With such a wide range of topics it is understandable that they are often merely broached without a deeper analysis, and that the selection of systems for discussion and of methods of calculation is considerably influenced by the authors' own field of work on ab initio calculation methods. However, this in no way diminishes the worth of the book—on the contrary it is clearly and comprehensibly written, and with more than 1200 references it offers a comprehensive and unbiased coverage of the literature, although regrettably only up to 1984.

The book can be thoroughly recommended to all chemists as a source book for preparing lectures, and as an introduction to the field. For specialists working in the area of intermolecular interactions, especially hydrogen bonding, this book is essential reading; it is also an extremely useful work of reference by virtue of the large amount of tabulated data and literature references which it contains.

ADVANCED MATERIALS

Polymers as Advanced Materials

Editorial Essay

By Claus D. Eisenbach* and Dietrich Haarer*

The bottleneck in the development of new technologies is often defined by the limitations of the available materials. Obvious examples for such limitations in materials parameters are a) that charge carrier mobilities can control the maximum frequency in semiconductors or b) that the read/write speeds and signal-to-noise ratios of possible optical stores depend on the sensitivity of the storage media. Progress in these and other fields has been mostly due to interdisciplinary efforts: The improved production of epitaxially grown semiconductor layers has contributed as much to the development of semiconductors as has the art of producing thin, sputtered films to the development of optical storage media, and polymer science is crucial to the success of many device applications. In the semiconductor industry, for instance, polymers play a crucial role as photoresists, dielectric layers, and packaging materials, or in the field of optical data stores, polymeric materials can be used as substrates as well as in the form of thin films as data carriers. In high performance polymers the combination of low weight, moderate thermal stability and high tensile strength, has further improved fiber reinforced materials, and has lead to major breakthroughs in aerospace technology.

Polymer science is a young discipline which has lately made large steps towards innovative materials and processes. This is a consequence of the almost unlimited scope for the molecular design of macromolecules, and of blending polymers with low or high molecular weight components. Polymer processing and molding, not to speak of composites, will also make major contributions to the further development of advanced materials. The field of "materials science" has increased in importance relative to physics and chemistry. This trend is documented by the increase in the representation of the "materials science" research faculty staff in the US program of the Interdisciplinary Laboratories (IDLs)/Materials Laboratories (MRLs) from 19% in 1970 to 35% in 1985.[1]

Polymers are ideal examples of structural and functional materials because of their versatility in practically all areas of modern life and technology. Some of their outstanding properties are high elasticity, stiffness, toughness, strength, good thermal resistance, and high chemical stability. Typical examples of their uses are high impact thermoplasts, thermoplastic elastomers, ultrahigh modulus fibers and temperature resistant polymers. An extension of the potential of engineering plastics beyond the organic multiphase polymer systems is given by the combination of polymers with non-polymeric and/or non-organic materials resulting in high performance composites. Progress in this area is favored by the growing research activity in interface phenomena and thin coatings and films. Finally, the electronic properties of polymers or macromolecular systems open up fascinating prospects for storing, processing and transmitting of data, as has been outlined by recent developments in the area of polymeric light waveguides, non-linear optics or conducting polymers.

It is a primary objective of basic materials science to develop a detailed knowledge of the structure-property relationships in macromolecular systems in order to understand how the molecular architecture of the individual polymer chain influences the morphology and superstructure of the polymeric materials. This goal can only be achieved by an interdisciplinary research and development effort, combining the natural sciences and engineering. As a result of the funding situation in West Germany, these considerations have resulted in an effort by researchers from different fields and from both academic and industrial laboratories to cooperate more closely, to participate in joint research programs and even in the establishment of new institutes supported through governmental and industrial research funds. This is reflected by the natural science activities of central research institutions and of universities such as those in Darmstadt and Kaiserslautern. Polymer materials science is especially strong in Freiburg, Mainz and Bayreuth, emphasized by the recent founding of the Max Planck Institute for Polymer Research (Mainz) and the Institute for Materials Science (Bayreuth).

The situation in Bayreuth, where both authors are working illustrates the general concept of the concerted efforts in materials science. Macromolecular topics have been highly emphasized in both the Chemistry and Physics departments leading to a great deal of interdepartmental research: Our program ranges from the synthesis of new macromolecular and micellar systems, through their extensive characterization to specific investigations, e.g. electronic processes in synthetic and biological macromolecular systems. The newly established Institute of Materials Science was conceived as a place of interaction between basic and applied research and is well situated within this environment to interact with the high temperature-geo scientists in the university as well as the local ceramics and electronics industries.

In order to promote this interdisciplinary approach to materials science a symposium was held in Bayreuth from 10.–12. April at which topics of current interest from the areas of polymeric, structural and functional materials were

presented and discussed, complemented by contributions from the related fields of inorganic/organic polymers and ceramics. It is planned to integrate the inorganic non-metallic materials into the future symposium programs, corresponding to our wishes for the development of materials science in Bayreuth. A key issue and primary concern of this meeting was to discuss the different facets of fundamental and applied research and thus provide a platform for the dialogue between people working in academia and in industrial research institutions. The symposium focused on strategies and steps towards polymers with new and unusual properties, and experimental results and theoretical concepts of the structure-property relationship of organic polymeric materials. Furthermore, connections, similarities and analogies between polymeric materials, and ceramics or inorganic materials in general became visible. Also in this respect, first signs have become apparent at a recent materials science conference organized by the West German Ministry of Science and Technology (BMFT).[2] Among the subjects which were highlighted at this meeting, polymers have made remarkable progress in high-tech applications such as information technology, where tailor-made photoconductive media dominate the field of electro-photography and are finding application in modern techniques of offset-printing. The impact which non-linar optical polymeric materials will make on the advancement of integrated optics was assessed and without doubt the use of polymers as light fibers is a feasible and interesting application. Research into conductive polymeric materials has recently made progress in terms of an increased understanding of the basic processes, but applications for example, in the field of rechargeable batteries are still at an early stage and can therefore not be fully assessed. Liquid crystalline polymers will probably make significant progress in the near future, although it is not yet clear whether it will be the mechanical aspects, (flow viscosity during processing etc.) or the optical aspects of this new class of polymers which will carry the main impact. The mechanical properties of new polymeric materials like copolymers and polymer blends will, without doubt, be a field of active research, where new synthetic materials will be of eminent importance. A question to be answered is, whether or not reinforced polymeric materials can only be made through macroscopic reinforcement with carbon- or glass-fibers, or whether they can also be made by "molecular reinforcement", i.e. by synthesizing molecularly ordered macromolecules with rod-like elements which form structures with a higher degree of order.

Several of the long-term goals of materials research were compiled at a recent IUPAC-meeting in Japan.[3] One of these goals is the development of "molecular devices", for which the basic questions are still unanswered, namely how to manipulate data at a molecular level, but towards which steps have been taken in laser techniques like hole burning or electric techniques like tunnelling microscopy, where ultra-high frequency resolution or spatial resolution can be achieved. However, we have long to wait before the elegant schemes of dynamic biological systems can be incorporated into technical systems as the difficult task of tailoring macromolecules to mimic self-organization phenomena, and molecular reinforcement of macromolecular systems in synthetic polymeric materials has first to be mastered. Molecular schemes like those in nature also require systems which are far from thermodynamic equilibrium. Here we have to explore the largely unknown field of molecular assembly which is certainly different from most present synthetic procedures. If these and many other materials related problems are to be effectively solved it is clear that an interdisciplinary approach is needed, and we are sure that it is this approach which will lead us to new frontiers to the benefit of all.

Dr. Claus D. Eisenbach is Professor of Macromolecular Chemistry at the University of Bayreuth. He studied chemistry at the University of Mainz, where he obtained his Ph.D. in 1974. After two postdoctoral years at the University of Massachusetts in Amherst, USA, he started a university career in Freiburg. In 1984 he became a professor of Macromolecular Chemistry at the University of Karlsruhe, and in 1986 he moved to Bayreuth. His research activities cover polymer synthesis and photoreactions in polymers.

Dr. Dietrich Haarer is Professor of Physics at the University of Bayreuth. A physicist by training, he received his Ph.D. in 1969 from the University of Stuttgart. With short interruptions he then worked until 1980 at the IBM research laboratory in San Jose, California, which he left as manager of the Organic Solids Department taking up his current position. His research activities include laser spectroscopy and laser chemistry. He is an Editorial Advisor for Advanced Materials.

ADVANCED MATERIALS

Modeling Organic Surfaces with Self-Assembled Monolayers**

Interfacial Structure
Wettability
Long-Chain Thiols
on Gold

By Colin D. Bain* and George M. Whitesides*

The interfacial properties of organic materials are of critical importance in many applications, especially the control of wettability, adhesion, tribology, and corrosion. The relationships between the microscopic structure of an organic surface and its macroscopic physical properties are, however, only poorly understood. This short review presents a model system that has the ease of preparation and the structural definition required to provide a firm understanding of interfacial phenomena. Long-chain thiols, $HS(CH_2)_nX$, adsorb from solution onto gold and form densely packed, oriented monolayers. By varying the terminal functional group, X, of the thiol, organic surfaces can be created having a wide range of structures and properties. More complex systems can be constructed by coadsorbing two or more thiols with different terminal functional groups or with different chain lengths onto a common gold substrate. By these techniques, controlled degrees of disorder can be introduced into model surfaces. We have used these systems to explore the relationships between the microscopic structure of the monolayers on a molecular and supramolecular scale and their macroscopic properties. Wettability is a macroscopic interfacial property that has proven of particular interest.

1. Introduction

Much of modern materials science has been devoted to the discovery, development and production of materials with desired combinations of bulk mechanical, electrical or optical properties. In an increasing number of materials systems, however, performance is determined not only by the properties of the bulk but also by the characteristics of interfaces either within the material or between the material and the outside world. Examples abound: the strength and toughness of a carbon fiber composite is strongly influenced by the bond between the fiber and the polymer matrix; cracks may propagate rapidly along grain boundaries; the biological response to implanted materials is critically determined by the properties of their surfaces; surface states can pin the Fermi level in semiconductors; water and oil repellency are determined by the outermost few angströms of a material; optical losses occur through reflection, scattering and non-linear processes at interfaces. As trends towards miniaturization continue, the ratio of surface to volume increases and the importance of understanding and controlling interfacial properties grows commensurately.

The goal of relating the microscopic (atomic, molecular and supramolecular) structure of a surface to its macroscopic physical, chemical or biological properties (wettability, corrosion resistance, adhesive strength, biocompatibility) is not trivial, and may prove as great a challenge as the development of new materials. Attaining this goal is made more difficult by the complexity and inaccessibility of many interfaces of practical importance. Consequently, the ability to create model surfaces in which the structure is controlled on an atomic scale plays a vital role. Epitaxial growth techniques, such as molecular beam epitaxy (MBE) and vacuum pyrolysis epitaxy (VPE), have provided a way forward in the study of semiconductors and ceramics, but such techniques cannot easily be applied to the synthesis of model organic surfaces. Recently it has become clear that organic monolayer films offer the level of structural control required for detailed studies of organic surfaces. Of all the types of monolayer film studied since *Benjamin Franklin* first poured oil onto Clapham Pond, two systems appear particularly promising: monolayers prepared by adsorption of alkanethiols on gold,[1] silver, copper or platinum, and those generated by reaction of alkyltrichlorosilanes with silicon or glass.[2] In this review we will concentrate on monolayers of alkylsulfur compounds on gold, with the emphasis on our own research. First, we will discuss the difference between these self-assembled monolayers and films produced by the Langmuir–Blodgett (LB) technique. We will then summarize the structural properties of monolayers generated by adsorption of thiols on gold. The bulk of the review is devoted to explaining, with examples, how the structure of the monolayer–air or monolayer–liquid interface can be varied in a controlled manner, and to discussing the types of information that can be derived from studies of model organic surfaces.

2. Langmuir–Blodgett and Self-Assembled Monolayers

The traditional means of forming an organic monolayer film is to spread an insoluble compound on an aqueous subphase, compress the film mechanically with a barrier until the molecules are densely packed and oriented approximately normal to the surface, and then to transfer this monolayer, if desired, to a solid substrate by "dipping" (Fig. 1 top). Much elegant work has been performed using these LB monolayers,[3] and the LB technique is particularly useful when multilayers are desired. LB monolayers, however, suffer several drawbacks as model systems for studying interfacial properties. First, they are only metastable and tend to relax into more stable structural forms. Surface properties of LB films are most easily studied after the film has been transferred to a solid substrate, a procedure that may be complicated by changes in the structure of the monolayer during the transfer process. Second, they are not normally chemically bonded to the substrate and hence are not robust. LB monolayers can often be removed from a substrate simply by rinsing with either aqueous or non-aqueous solvents. Third, one is restricted to compounds that form LB films on water and that can be transferred intact to a substrate. It is, in particular, difficult to generate surfaces exposing polar functional groups at the monolayer–air interface by this technique. It is also difficult to form highly crystalline monolayers since they tend to be brittle and crack easily upon compression or during transfer.

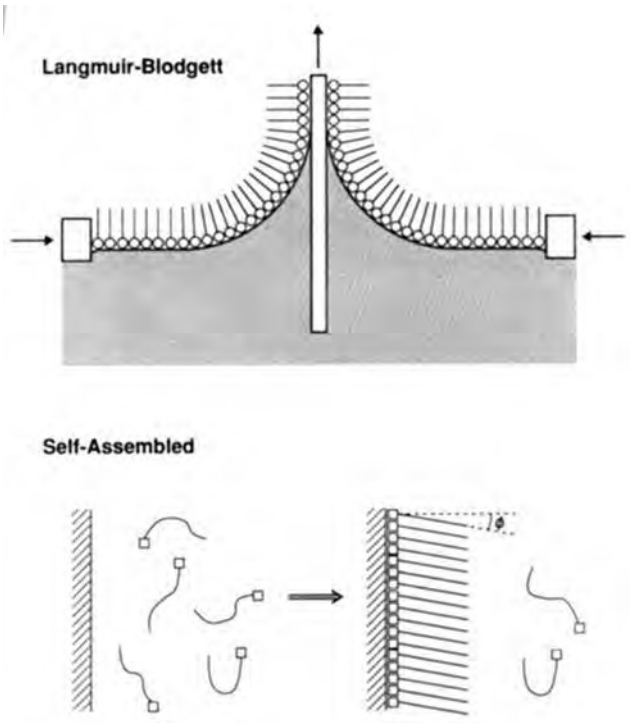

Fig. 1. Top: A Langmuir–Blodgett monolayer can be transferred from the surface of water to a hydrophilic solid by raising the substrate through the water–air interface while maintaining a constant surface pressure with movable barriers. Bottom: Self-assembled monolayers form spontaneously upon immersion of the substrate in a dilute solution of the adsorbate. Monolayer formation is driven by a strong, specific interaction between the head group (squares) and the surface of the substrate. One such system comprises thiols, RSH, adsorbed onto films of noble metals, such as gold, silver and copper. The cant (Φ) of the hydrocarbon chains varies with the choice of substrate.

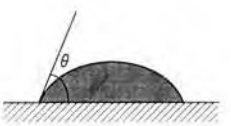
Self-assembled monolayers rely on a strong specific interaction between an adsorbate and a substrate to drive the spontaneous formation of a monolayer film (Fig. 1 bottom).[4] To prepare a self-assembled monolayer, the substrate is simply immersed in a dilute (ca. 1 mM) solution of the adsorbate at room temperature for an interval varying from a few minutes to several days, depending on the system. The principal substrate in our studies has been a gold film (1000–2000 Å thick) evaporated onto a polished silicon wafer, and we have used long-chain organosulfur compounds, typically thiols, $HS(CH_2)_nX$, as adsorbates. The densely packed, oriented films that result are thermodynamically stable and mechanically robust. Monolayers of thiols on gold can be removed from the solutions from which they have been adsorbed and immersed in aqueous or non-aqueous solvents, in acid or in base, without apparent adverse effects. The range of organic species that can be incorporated into these monolayers is large: few ligands compete effectively with a thiol in coordinating to the gold, and the thiol group is sufficiently unreactive to be compatible with most other functional groups. A variety of chemical reactions can also be performed on the monolayers in order to interrogate the structure or to modify the surface. Self-assembled monolayers of thiols adsorbed on gold are thus well suited for our studies.

We,[5] and others,[2, 6] have also used alkyltrichlorosilanes as precursors to monolayers of alkylsiloxanes on glass or silicon. These monolayers exhibit greater thermal, chemical (except in the presence of aqueous base) and mechanical stability than thiols adsorbed on gold: they can even be heated in boiling water or scrubbed vigorously without degradation. The high reactivity of the $SiCl_3$ group limits the chemistry of surfaces that can be created directly by adsorption of alkyltrichlorosilanes on silicon. The thermal and chemical stability of the monolayers does, however, allow extensive synthetic modification of pre-formed films. *Ulman* et al.[6] using a modification of a technique proposed by *Sagiv* et al.[7] have recently demonstrated the feasibility of monolayer-by-monolayer synthesis of high-quality multilayer films with alkyltrichlorosilanes. These multilayers have great potential for controlling the bulk optical and electrical properties of thin films, but are beyond the scope of this review.

3. Structure of Monolayers of Thiols on Gold

Our investigations have centered on the adsorption onto gold of linear thiols, $HS(CH_2)_nX$, where $n \geq 10$ and X is any one of a wide range of functional groups that are compatible with thiols and that do not disrupt the packing of the hydrocarbon chains. We and others have characterized the result-



ing films by a range of techniques including ellipsometry, transmission electron microscopy (TEM), contact angle determination, reflection adsorption infrared spectroscopy (RAIRS), X-ray photoelectron spectroscopy (XPS) and electrochemistry.[8–13] The picture that emerges is of a pin-hole-free, monolayer film comprising a densely packed array of *trans*-extended hydrocarbon chains, strongly anchored to the gold surface through the sulfur atom, and tilted approximately 30° from the normal to the surface. The nature of the bonding between sulfur and gold has not yet been established incontrovertibly, but available evidence points to both alkanethiols and dialkyl disulfides generating gold thiolates (Au—SR) upon adsorption. (For clarity we will use terms such as "monolayer of alkanethiol" in this review to indicate the molecular precursor, even though the actual species on the surface is probably a thiolate). The tail group, X, is the predominant chemical functionality exposed at the surface. The essential structure of the monolayer appears to be preserved for a number of tail groups exhibiting a range of intermolecular interactions.[11] Except for short chains ($n < 10$), the structure of the monolayer and the properties of the monolayer–liquid or monolayer–air interface appear to be largely independent of the length of the hydrocarbon chain.[9]

This last observation is significant. If we are to use monolayers of thiols on gold as models for other surfaces, or to study interfacial phenomena in general, it is important that the gold substrate and the sulfur–gold interface do not affect the measured properties at the monolayer–ambient interface. The gold does have an indirect effect on the properties of the monolayer through its influence on the cant of the hydrocarbon chains and hence on the orientation of the tail group at the surface of the monolayer. (If the organic monolayer is very thin, the polarizability of the gold substrate will also influence the wetting of the surface.) Small changes in the orientation of functional groups at the surface can lead to measurable changes in interfacial properties. For example, the chain tilt of monolayers of thiols adsorbed on silver is approximately zero, compared with ca. 30° on gold; the contact angle of water on a monolayer terminated by hydroxy groups on silver (X = OH) is 20°,[6] whereas on gold angles of < 15° are observed. This residual influence of the substrate is not necessarily a disadvantage: the fact that we can even ask questions about the influence of the orientation of a functional group on the macroscopic properties of an interface is a testimony to the power of the technique of self-assembly.

4. Effect of the Chemical Structure of an Interface on Wettability

Wettability is a representative macroscopic physical property of surfaces that we have studied extensively. An understanding of the microscopic basis of wettability is important for two reasons: first, many technologies rely on controlling wettability; and second, the wettability of a flat surface is determined by interfacial free energies and hence reflects intermolecular interactions at the solid–liquid and solid–vapor interfaces.[14] In fact, wettability appears to be an extremely sensitive analytical tool for elucidating the structure of surfaces. Wettability is quantified by the measurement of the contact angle, θ, between the tangent to a drop of liquid where it meets the surface and the surface itself. Different liquids probe different molecular forces. Water senses primarily polar functional groups in the substrate, whereas a hydrocarbon, such as hexadecane, interacts purely by dispersive forces. Different values of the contact angle may be observed for drop edges that have advanced or receded across the surface prior to measurement. Although this hysteresis in the contact angle undoubtedly carries a wealth of structural information about the surface, no microscopic theory yet exists that explains the origin of hysteresis.

Table 1. Advancing contact angles θ_a of water and hexadecane on monolayers of representative thiols on gold

Thiol	$\theta_a(H_2O)$ [°]	$\theta_a(C_{16}H_{34})$ [°]
$HS(CH_2)_2(CF_2)_5CF_3$	118	71
$HS(CH_2)_{17}CH_3$	112	47
$HS(CH_2)_{17}CH=CH_2$	107	39
$HS(CH_2)_{19}Br$ [a]	97	< 5
$HS(CH_2)_{11}OCOCF_3$ [d]	96	62
$HS(CH_2)_{19}F$ [a]	95	< 5
$HS(CH_2)_{19}Cl$ [a]	83	< 5
$HS(CH_2)_{16}OCH_3$	75	41
$HS(CH_2)_{10}CO_2CH_3$	67	28
$HS(CH_2)_{11}CN$ [b]	63	< 5
$HS(CH_2)_{10}CONH_2$ [c]	13	< 5
$HS(CH_2)_{15}CO_2H$	< 10	< 5
$HS(CH_2)_{11}OH$	< 10	< 5

From [1], except [a] *B. Burbaum*, unpublished results, [b] *P. Laibinis*, unpublished result, [c] *L. Janes*, unpublished result. [d] By reaction of a monolayer formed from $HS(CH_2)_{11}OH$ with trifluoroacetic anhydride.

A large range of functional groups can be expressed at the surface of a monolayer of a thiol on gold. Thiols with highly polar tail groups, such as carboxylic acids, form monolayers that are wetted by water and by all non-reactive organic liquids. Fluorinated thiols form monolayers that are more water- and oil-repellent than Teflon. The hydrophobicity and oleophobicity of the surface can be varied almost independently between these two extremes (Table 1). In general, the lower the surface tension, γ_{lv}, of the probe liquid, the smaller the contact angle. By judicious choice of tail group, this relationship can be reversed. For example, a monolayer of $HS(CH_2)CO_2CH_3$ is wetted by acetonitrile (γ_{lv} = 29.3 mN m^{-1}; $\theta \approx 0°$) but not by hexadecane (γ_{lv} = 27.2 mN m^{-1}; $\theta = 28°$). We have, however, not yet succeeded in mimicking the unusual properties of the surface of

water itself, which is wetted by water (since any pure liquid wets itself) but not by hexadecane.

One of the key questions that we have sought to answer is how wettability is influenced by the depth of a species beneath the solid–liquid interface. The strength of the interaction between two bodies separated by a third medium can be calculated from bulk optical properties by Lifshitz theory. Given the short range of the intermolecular interactions that determine the wetting of organic surfaces, such continuum theories can at best provide only an approximate answer. Using monolayers we can tackle this problem from a molecular perspective.[4] Figure 2 plots the contact angles of

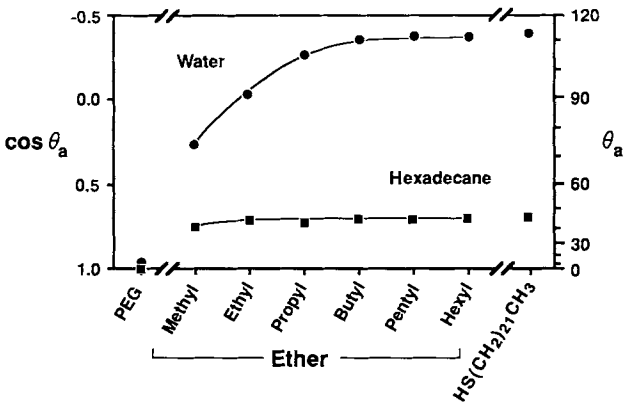


Fig. 2. ω-Mercaptoethers, $HS(CH_2)_{16}O(CH_2)_nCH_3$, adsorb from ethanol onto gold and form monolayers in which the depth of the polar ether group beneath the outer surface of the monolayer increases with increasing n. The advancing contact angles θ_a of water and hexadecane are shown as a function of the length of the terminal alkyl chain. Also shown are the contact angles on polyethylene glycol (PEG) and on a monolayer of docosanethiol on gold, models of surfaces in which ether groups are, respectively, fully exposed to the contacting liquid, and completely buried.

water and hexadecane on monolayers of ether-terminated alkanethiols, $HS(CH_2)_{16}O(CH_2)_nCH_3$, n = 0–5. In this study[15] the polar ether group was buried progressively deeper beneath the monolayer–liquid interface by increasing the length of the terminal alkyl chain. The contact angles of hexadecane confirm that the dispersion interaction between the ether group and hexadecane is very short range, dropping to essentially zero when a 2 Å thickness of hydrocarbon material intervenes. Water was able to sense the polar ether group at greater depths beneath the monolayer–water interface: a butyl group was required to screen the ether oxygen fully from the supernatant drop. Similar results have been obtained using amides in place of ethers.[16] Thus we see that one only needs to control the structure of the outermost few angströms of a smooth solid in order to determine its wetting properties. Furthermore, as an analytical technique, wettability approaches the best UHV spectroscopies in terms of surface sensitivity.

5. Construction of Complex Interfaces

5.1. Multiple Functional Groups

The ability to synthesize surfaces containing a unique functional group helps us to understand the contributions of individual chemical species to interfacial properties. Real surfaces, however, are complex both chemically and structurally. There is no a priori reason to assume that the different chemical components in an interface behave independently and hence that the properties of a multi-component surface can be inferred with confidence from the properties of surfaces composed of structured arrays of the pure components. The first step in extending our model to approximate real surfaces more closely is to introduce more than one functional group into the monolayer. To a certain extent this end can be achieved by performing reactions on the monolayer after formation. More generally, we can generate polyfunctional surfaces by coadsorbing two or more thiols on gold.

In interpreting coadsorption experiments, two questions immediately present themselves. First, does the composition of the monolayer reflect the relative concentrations of the two components in solution? Second, do the different components in the monolayer phase segregate into macroscopic domains? The answer to both questions appears to be no. The composition of the monolayer is strongly influenced by interactions between the adsorbates and the solvent and among the tail groups within the monolayer. Changing the nature of the solvent, from ethanol to isooctane for example,[11] can dramatically alter the composition of a monolayer even when the concentrations in solution remain unchanged. If the adsorption components have different chain lengths, cohesive interactions between crystalline hydrocarbon chains favor incorporation of the longer chain into the monolayer. Far from merely being an inconvenience, the relationships between the composition of the monolayer and the concentrations of the adsorbates provide a handle on the molecular interactions present in the monolayer, and offer valuable insights into other processes of self-assembly, such as membrane and micelle formation.

The question of the distribution of components within the monolayer is more difficult to resolve. Although numerous pieces of evidence militate against the formation of macroscopic islands ($\geq$ 1000 Å across), the components are almost certainly not randomly dispersed, but form small clusters, as they do in solution (if by doing so the free energy is lowered). A better knowledge of the pair distribution function in these "mixed monolayers" would improve our understanding of real surfaces which, too, reconstruct to minimize their free energy.

A simple example of a mixed monolayer which displays the essential features of a coadsorption experiment is $HS(CH_2)_{11}OH/HS(CH_2)_{10}CH_3$ adsorbed from ethanol onto gold.[17] Figure 3A displays the relationship between the mole fraction χ^{OH} of $HS(CH_2)_{11}OH$ in the adsorption solu-

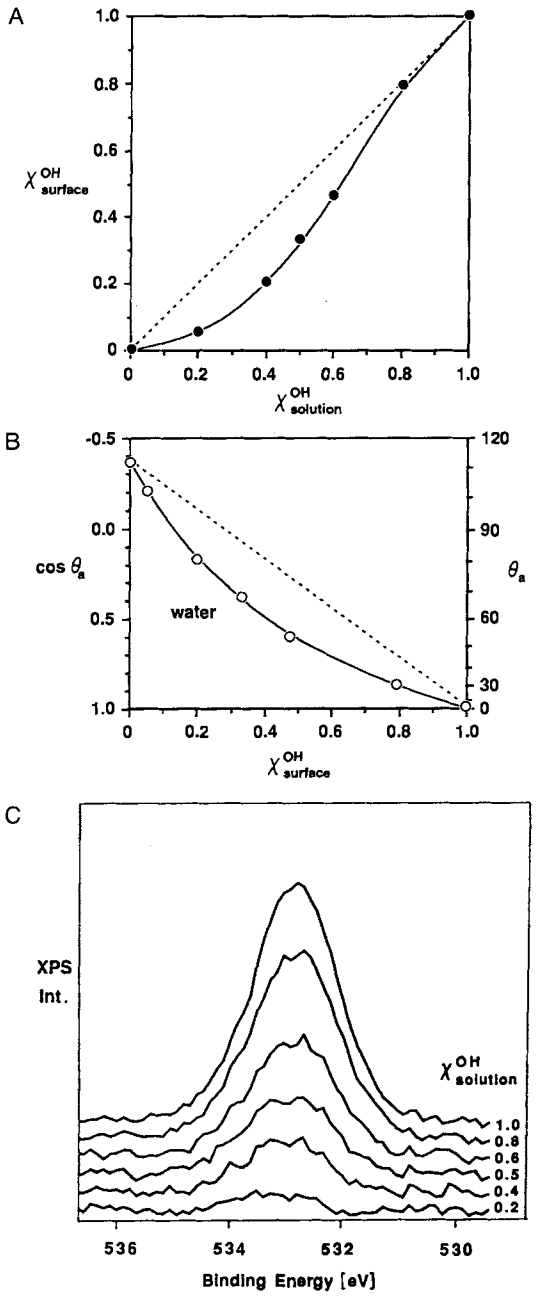

Fig. 3. Monolayers exposing both methyl and hydroxy groups at the surface of the monolayer may be formed by adsorption from solutions containing mixtures of $HS(CH_2)_{11}OH$ and $HS(CH_2)_{10}CH_3$. A) Plots of the mole fraction of the hydroxy-terminated chain in the monolayer as a function of the mole fraction in solution. For clarity, the calculation of the mole fraction in solution included only the thiol species; B) plot of the advancing contact angle of water as a function of the composition of the monolayer; C) the oxygen (1s) region of the XPS spectra of the monolayers (XPS intensity in arbitrary units). The areas under these peaks were used to calculate the compositions of the monolayers.

tion and in the monolayer. The compositions of the monolayers were determined from the intensity of the O(1s) peak obtained by XPS (Fig. 3C). From solutions in ethanol there is a preference for adsorption of the methyl-terminated thiol. Adsorption of $HS(CH_2)_{11}OH$ is particularly disfavored at low concentrations, possibly due to incomplete hydrogen-bonding of the terminal hydroxy groups in the nonpolar environment provided by the surrounding methyl groups at the surface of the monolayer. The advancing contact angle of water is shown in Figure 3B as a function of the mole fraction, χ^{OH}, of the hydroxy-terminated component in the monolayer. If the wettability of a mixed monolayer were simply a linear combination of the wetting properties of the constituent components, we would expect a linear relationship between $\cos\theta_a$ and χ^{OH}. The actual graph is concave: the hydroxy groups at the surface of the monolayer are more hydrophilic at low χ^{OH}, when they are in a nonpolar environment, than at high χ^{OH}, when they are surrounded by other OH groups to which they can hydrogen bond. This result is consistent with the observed bias against adsorption of hydroxy groups at low χ^{OH}.

Although mixed monolayers such as these may seem simple, the correlations between wettability and structure derived from such systems have proved invaluable in improving our understanding of a complex organic surface—chromic-acid-oxidized polyethylene—which contains a mixture of polar and nonpolar functionality.[18] Comparison of the polymer with mixed monolayers supported the hypothesis that the polyethylene surface was composed of domains comprising largely polar or largely nonpolar groups, rather than containing a homogeneous distribution throughout the functionalized interphase.

The principles established for simple systems composed of two thiols are readily generalizable to cases in which both thiols are terminated by complex functional groups or in which there are more than two components in the monolayer.

5.2. Control over Surface Disorder

Many real surfaces differ from the model monolayers discussed so far in another important respect: they are disordered. The chains and tail groups in the densely packed, oriented monolayers presented above do not have the degrees of freedom available in an amorphous polymer or a fluid biological surface. As a consequence, the monolayer cannot reconstruct in response to changes in its environment, and we cannot easily use these monolayers to study dynamic processes at interfaces. We can introduce free volume, with the conformational freedom that entails, into the outer part of the monolayer by coadsorbing two thiols with different chain lengths.[1,19,20] We expect the resulting mixed monolayers to have two distinct phases: the inner part, adjacent to the gold surface, remains densely packed (and hence insulates the monolayer–liquid or monolayer–air interface from the influence of the substrate), but the outer part of the monolayer contains fewer hydrocarbon chains per unit area and is free to become disordered (Fig. 4). By placing functional groups at the ends of the shorter chains, in the transition region between the ordered and disordered phases of the monolayer,[20] we can also introduce a degree

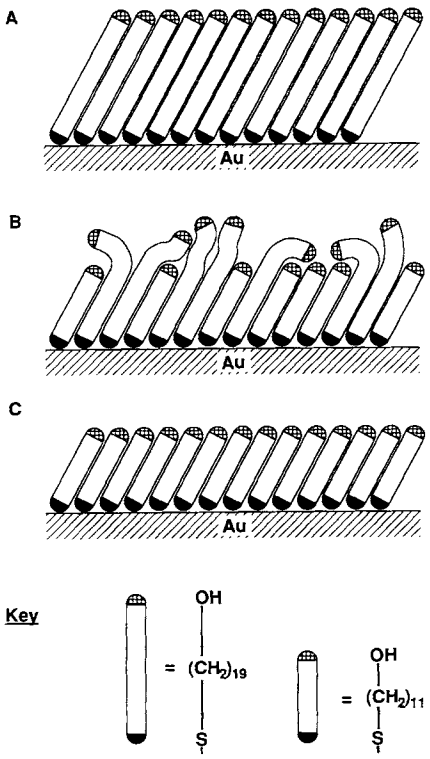

Fig. 4. Schematic illustration of monolayers of hydroxy-terminated thiols on gold. A) Pure monolayer of $HS(CH_2)_{19}OH$; B) monolayer containing equal amounts of $HS(CH_2)_{19}OH$ and $HS(CH_2)_{11}OH$. The inner part of the monolayer is densely packed, the outer part loosely packed and disordered; C) pure monolayer of $HS(CH_2)_{11}OH$.

of three-dimensionality beyond that achievable simply by varying the position of a functional group in a polymethylene chain.

The consequences of introducing disorder into the outer part of the monolayer can be seen clearly in monolayers composed of mixtures of $HS(CH_2)_{11}OH$ and $HS(CH_2)_{19}OH$ (Fig. 5).[19] Pure monolayers of either species expose only polar hydroxy groups at the monolayer–liquid interface and hence yield very low contact angles with water ($\theta < 15°$). In a mixed monolayer, however, the last eight carbons of the longer chains can form a disordered, liquid-like layer on top of the densely-packed lower phase of the monolayer. Since this disordered region exposes nonpolar polymethylene chains to the water drop, we expect to see a sharp increase in the contact angle (Fig. 5). The observation of just such a maximum confirms our model and rules out the formation of large, single-component domains within the monolayer: each of these domains would expose only hydroxy groups at the surface and hence the mixed monolayers would be wetted by water, independent of composition. Comparison of the contact angles in Figure 5 with those shown in Figure 3 suggests that even the most disordered mixed monolayer still exposes an approximately 2:1 ratio of polar hydroxy to nonpolar methylene groups to a water drop. This ratio is not

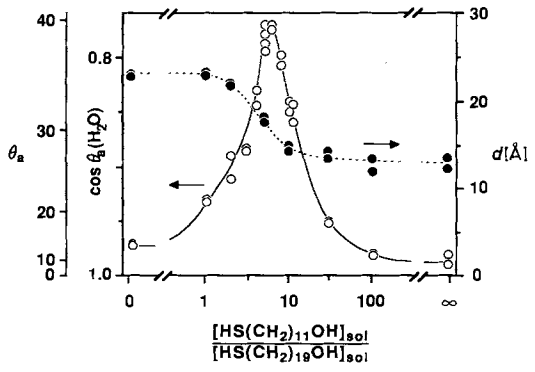

Fig. 5. Ellipsometric thickness d and advancing contact angles θ_a of water for mixed monolayers of $HS(CH_2)_{19}OH$ and $HS(CH_2)_{11}OH$. The abscissa represents the ratio of concentrations of $HS(CH_2)_{19}OH$ to $HS(CH_2)_{11}OH$ in solution. The maximum in contact angle correlates approximately with the monolayer shown schematically in Figure 4B.

C) Advancing contact angles of water, hexadecane and bicyclohexyl.

unreasonable. We would expect the monolayer to reconstruct to maximize hydrogen-bonding and to minimize the number of hydrophobic contacts.

If the two thiols are terminated by methyl groups instead of hydroxy groups, then the resulting mixed monolayers allow us to probe the effect of local structure on dispersive interactions and on the hydrophobic effect. Figure 6 shows the ellipsometric thickness d, XPS intensities and contact angles θ_a for monolayers adsorbed from mixtures of $HS(CH_2)_{11}CH_3$ and $HS(CH_2)_{21}CH_3$ in isooctane. (The first two techniques serve to establish the composition of the monolayer.) Pure monolayers of either component expose a densely packed array of methyl groups at the surface of the monolayer, and are both hydrophobic and oleophobic. The surface of a monolayer containing an approximately equal mixture of the two components resembles a liquid, linear hydrocarbon. The advancing contact angle of water θ_a is insensitive to the detailed structure of the hydrocarbon surface. On the other hand, hydrocarbon liquids, such as bicyclohexyl and hexadecane, show large changes in contact angle in response to variations in the structure of the surface. A corollary of these observations is that variations in the strength of the hydrophobic effect arise largely from hydrocarbon–hydrocarbon interactions rather than hydrocarbon–water interactions. There is also some evidence[11] that decane can penetrate into holes left in a monolayer of $HS(CH_2)_{21}CH_3$ by the presence of molecules of $HS(CH_2)_{11}CH_3$—a primitive type of molecular recognition.

6. Concluding Remarks

We can only arrive at a detailed understanding of the complex physical and chemical properties of surfaces through the study of well-defined model systems. Phenomena such as wetting, adhesion, and friction are all functions (albeit complicated ones) of the microscopic chemical structure of a surface. Self-assembled monolayer films of thiols on gold are model systems in which the microscopic structural attributes of an organic surface can be varied independently and the influence on interfacial properties determined. We believe that they, and other related systems, will provide the bridge between the physical-organic chemistry of solutions and the materials science of organic solids. The research presented here is only a first step towards developing an understanding of organic surfaces. We still have to learn more about measuring and controlling the lateral distribution of functional groups. Many interesting features of wetting—especially the influence of roughness and chemical heterogeneity, and the origin of hysteresis—are still not understood. We have barely touched upon interfacial properties other than wetting, such as adhesion, friction and electrochemistry. Much remains to be learned about the physical-organic chemistry of condensed interphases.

Self-assembled monolayers are more than mere model systems for the surfaces of materials. They provide a starting point for practical technologies to solve interfacial problems. Two examples are the use of monolayers of alkylsiloxanes to promote adhesion or, with the opposite intent, to prevent catalyst particles from sticking to the walls of reactors. The intermolecular interactions controlling the structure of self-assembled monolayers are also acting in other spontaneously assembling systems. In studying them we will learn more about membranes, micelles and microemulsions.

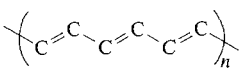
Functionalized Conducting Polymers—Towards Intelligent Materials

Molecular Electronics
Wires, Sensors, Transducers
Polymer Modified Electrodes

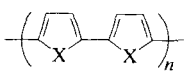
By Francis Garnier*

Organic conjugated polymers and oligomers constitute a three-dimensional network of molecular wires, in which all monomeric units can be functionalized with various prosthetic groups. By varying the nature of these groups, specific interactions with external physical or chemical phenomena can be developed in these materials, leading to molecular devices such as sensors, transducers, memories and logic operators. Chemists have already mastered the realization of many of these functional elements, which mimic those existing in organized beings. The further assembly of these elements in multifunctionalized organic conducting polymers and oligomers will represent the next step towards intelligent materials.



1. Introduction

Inter (between, within), *legere* (to read, to bring together, to choose). The study of all the functions that underlie *intelligence* has long been one of the major goals of science. The analysis of the elements that define organized beings has up to now been the privileged sphere of biology, which has aimed at the understanding, down to the molecular level, of the fundamental processes associated with the faculties of sensing and controlling the environment. On the physical sciences side, electronics is one of the methods developed by men for imitating some of these basic functions in macroscopic devices such as sensors, memories and logic circuits. In these research areas chemistry has mainly had a supporting role, whether conceptual, for explaining the chemical processes involved, or experimental, in the synthesis of model molecules mimicking such biological functions, and also in making the materials needed for electronic devices.

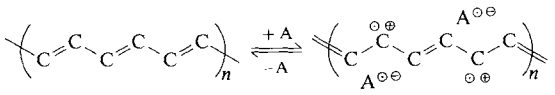


Chemistry has, however, recently developed methods for the a priori control of molecular properties,[1] and a fascinating challenge has now emerged: is it now conceivable to progress beyond the macroscopic approach used in conventional electronics, and also to bypass the inherent complexity of biological systems, in order to build new materials able to perform at a molecular level the basic functions, i.e. recognition, control of chemical processes, memory and logic, which define intelligent structures? Ideas that were regarded a few years ago as long term speculation,[2] are now approaching reality, based on the fact that chemists have learned how to build molecular wires and incorporate into them various types of functions. These new materials are functionalized organic conducting polymers and oligomers, and this article reports on the advances in research which will lead to such molecular devices being constructed in the near future.

2. Molecular Wires

The concept of molecular wires stems from about ten years ago, when it was shown that the individual macromolecular chains of organic conjugated polymers possess a high intrinsic electrical conductivity.[3] These organic conducting polymers have since aroused much interest, and a deep knowledge has been gathered on their physical and chemical properties. The macromolecular chains of these polymers show a regular alternation of single and double bonds, in the manner of the prototype polyacetylene.[4] Other classes of conducting polymers were later synthesized, including polypyrrole,[5] polythiophene,[6] and polyaniline.[7]

Polyacetylene



Polypyrrole (X = NH)
Polythiophene (X = S)

The conjugation of the π-electron system creates a molecular orbital which extends throughout the polymer chain. Using the concept of the one-electron model as a first approximation, these low dimensional materials can be described by a fully occupied valence band and an empty conduction band, formed by the conjugated π and π* systems, respectively. In this state these polymers show semiconducting properties associated with a band gap of about 2 eV. The injection of holes or electrons into these chains, by p-type or n-type doping respectively, leads to electrical conduction, due to the creation of soliton or polaron states in the gap. This doping is performed by the inclusion of electron acceptors, such as halogens, or electron donors, such as alkaline metals, which intercalate between the conjugated polymer chains and lead to their oxidation or reduction, respectively. It must be pointed out that this term of doping is employed

2 rue Dunant, F-94320 Thiais (France)

here in a chemical sense and not in the commonly accepted one in solid state physics. The conductivity values depend on the amount of electrons or holes created in the polymer chains, which is determined by the concentration of dopant in the polymer. Very high concentrations of dopants A can be achieved: up to one dopant species for every two or three units of monomer M contained in the polymer, corresponding to $[A]/[M] \approx 0.3-0.5$. The conductivity can reach values as high as that of metals such as Pt or Fe, $\sigma = 2 \times 10^5\ S\ cm^{-1}$, as was recently demonstrated by *Naarmann* et al. in the case of polyacetylene;[8] however, a real metallic state has not yet been obtained as shown by the behavior as a function of temperature.

This doping reaction, which is reversible and can be electrochemically driven, confers on these polymers interesting electroactive properties. It has been shown that even for polymer layers up to hundreds of microns thick the whole polymer is entirely electroactive, implying that the polymer chains stretch throughout these layers. Some defects evidently exist in these chains, such as interruption of conjugation and branching, but interchain hopping of charges allows all the chains to be electroactive. The doping process thus involves every two or three monomer units along all polymer chains, and it can be considered as operating at the molecular level of these conducting polymers (Scheme 1).

Scheme 1. Reversible doping of polyacetylene with an electron acceptor A.

Films of organic conducting polymers behave as organic electrodes, which can be charged and discharged with large amounts of dopants, and this characteristic has been the starting point for numerous studies on "organic batteries",[3] mainly based on polypyrrole and polyaniline and already commercialized, and also on some electrochromic devices.[9] In these applications, the electroactive polymer chains are considered as playing only the passive role of a conducting network for hosting incoming dopant anions, and their potential has thus been largely underestimated. As a matter of fact, these macromolecular conjugated chains, formed by the theoretically infinite coupling of monomer units, possess an intrinsic electrical conduction, and thus represent true molecular wires, i.e. wires consisting of just a one molecule sequence. Furthermore, the fact that every second or third monomer unit along all these wires is involved in the doping–undoping process means that all these monomer units can in theory be individually electrically addressed in the whole polymer layer. This interaction at a molecular level thus opens up the field of molecular devices.

3. Molecular Sensors and Transducers

These molecular wires form unique routes for the reversible transfer of electronic information between an electrode, onto which these polymer chains are grafted, and various prosthetic groups R, which can be covalently bonded as side groups all along the conducting chains (Fig. 1). Depending on the nature of R, these structures can act as molecular sensors or molecular transducers.

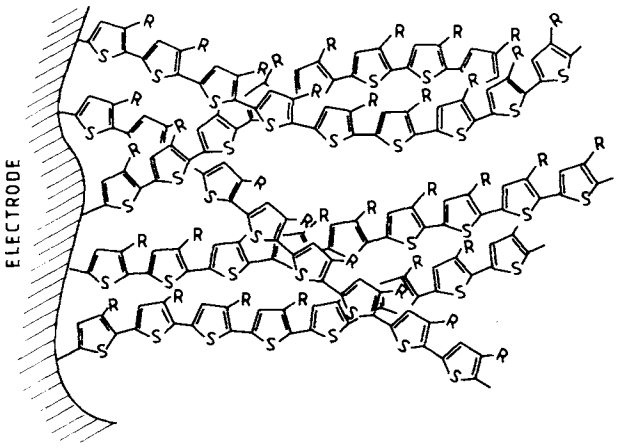

Fig. 1 Three-dimensional distribution of prosthetic groups R along ideally conjugated polythiophene chains grafted onto an electrode.

Owing to the richness of chemical synthesis, a large variety of functions can theoretically be incorporated into these conducting polymers by the initial synthesis of a functionalized monomer. This second generation of organic conducting polymers, obtained by their functionalization, has recently excited much interest in view of its great potential, and many experiments have been proposed. This functionalization is experimentally difficult since the steric and electronic properties of most of the interesting substituents on monomers are not easily compatible with the synthesis of a conducting polymer. Thus the electrical conduction in these macromolecular chains requires the stereoregular alternation of single and double bonds, and any structural defect, such as an sp^3 carbon atom or a chain end, is known to result in the interruption of conjugation and hence of conduction. The polymerization reaction is difficult to control, and it has been observed that the more sterically demanding a substituted monomer is, the higher is the concentration of defects in its corresponding polymer. Thus, most of the examples which will be described in the following suffer from a very low electrical conductivity ($\sigma \approx 10^{-4}\ S\ cm^{-1}$). Recently, however, by carefully analyzing the steric and electronic factors which, for a given substituent on a monomer, control the conducting and electroactive properties of the corresponding polymer, we have developed the concept of a "functionalization environment" which allows these problems to be overcome.[10]

Provided that these criteria are fulfilled, substituents can now be envisaged that will give specific interactions with almost any kind of external physical or chemical phenomenon. Examples of *physical quantities* that can be sensed

by the use of appropriate R groups are photon fluxes, electric fields and magnetic fields.

The principle of photon sensing has already been demonstrated by the bonding of the well known photoactive metal complex $Ru(bpy)_3^{2\oplus}$ to the monomeric units of polypyrrole.[11] This functionalized polymer has indeed shown a photoresponse, although its intrinsic electronic conduction has not yet been mastered due to the large steric constraints of the metal complex ($\sigma \approx 10^{-4}$ S cm^{-1}). The principle of sensitivity to a magnetic field B has also been proposed recently,[12] using a nitroxide radical grafted on polydiacetylene; the results are, however, a subject of controversy. Even if not yet experimentally demonstrated, the sensitivity to an electric field E is within reach, by substituting a highly polarizable group as already envisioned.[2] The application of an electric field will induce a large dipole moment on the side chain of the conducting system and create electron sinks or electron reservoirs which will lead to a modification of the charge transport properties of the main conducting chain.

Selective chemical interactions with the environment can also be developed in these electroactive polymers by appropriate functionalization. The most significant features which govern fundamental processes in biological systems involve recognition, whether of ions, as in transmembranous transfers, or of optically active species. Both of these recognition phenomena have already been imitated at the molecular level by appropriate functionalization of conducting polymers. Thus, ionic selectivity has been demonstrated in the case of a new class of polymers, the poly(dibenzo crown ethers), which contain crown ethers of variable size.[13] Owing to the well known specific complexation of cations by crown ethers, a highly selective uptake of various cations in solution has been observed with these polymers. A second example relates to the covalent binding of a polyether substituent onto the monomeric units of polypyrrole, which also induce selective complexation of cations such as $Li^{\oplus}$.[14] These last two ion selective materials, however, still suffer from a low electronic conductivity of the polymer backbone, due to the fact that the polymerization reaction is not yet well controlled. On the other hand, by applying the concept of functionalization environment, we were recently able to synthesize polythiophene derivatives substituted with polyether groups, showing both a high electrical conductivity ($\sigma = 10$ S cm^{-1}) and ionic selectivity.[10] The interest in controlling these two properties at the same time arises from the possibility of new materials having both an electronic and an ionic conductivity, which mimic membrane processes and thus open up a large potential in the realization of ion selective electrochemically controlled membranes.

Perhaps the most challenging recognition property concerns enantioselectivity, i.e. the ability to discriminate between optically active substrates. We have recently succeeded in achieving this ultimate type of recognition, by the controlled functionalization of polythiophenes. Thiophene monomers bearing large chiral groups such as R* = (2 *S*)-(+)-$(CH_2)_3OCH(Et)C_6H_5$ were first synthesized, and then electropolymerized as thin films on an electrode. The characterization of the resulting polymer has confirmed that it is chiral (specific rotation = + 3000°), and still conducting ($\sigma = 12$ S cm^{-1}) and electroactive, despite having such bulky substituents. When used as an organic electrode in an electrolytic medium with $ClO_4^{\ominus}$ anions, a reversible, electrochemically driven doping–undoping process is observed. If an optically active anion such as (1 *S*)-(+)-10- or (1 *R*)-(−)-10-camphorsulfonate is used instead of $ClO_4^{\ominus}$, this chiral organic electrode shows a different response depending on the camphorsulfonate enantiomer used (Fig. 2). A ratio of about two has been observed for the oxidation rates at comparable doping levels of the chiral doping matrix, thus defining its selectivity towards these enantiomers.[15] We have also confirmed that when the enantiomer R* = (2 *R*)-(−)-$(CH_2)_3OCH(Et)C_6H_5$ is used as side group on the polythiophene chain, a reverse selectivity is observed for the camphorsulfonate enantiomers.

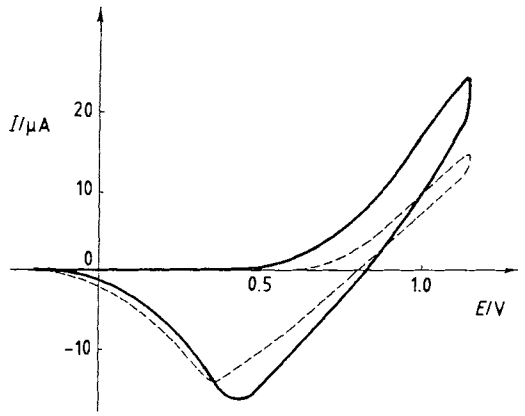

Fig. 2. Cyclic voltammogram of chiral polythiophene using optically active chiral anion as doping agent: (——), (– – –): (+)- and (−)-10-camphorsulfonate, respectively. E vs. saturated calomel electrode.

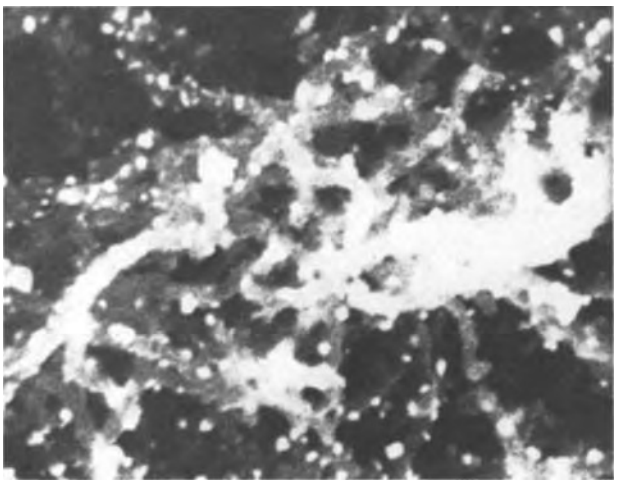
This effect has been interpreted on the basis of the chiral environment created by the bulky R* groups around the polythiophene conducting chains. During the doping process, the anions have to percolate through this chiral environment in order to reach the thiophene rings and produce the electronic doping interaction. These results are the first unambiguous evidence that electroactive functionalized polymers are capable of molecular recognition of enantiomers during the electrochemical doping process. This configurational selectivity imposed by the chiral environment appears to mimic the structural control in enzymes caused by the protein subunits surrounding their active site.

4. Molecular Catalysts

The functionalized polymer–enzyme analogy can be carried further, since functionalized conducting polymers are not only able to act as molecular sensors and transducers, but also allow the control of chemical reactions by the incorporation of redox centers or of metallic submicroaggregates able to induce electrocatalytic processes. Thus, many types

of redox centers such as metalloporphyrins,[16] ferrocene,[17] metal complexes of bipyridines,[18] and nickel cyclames[19] have already been either covalently bonded or electrostatically included in polypyrrole. Various submicroaggregates of metals such as Pt, Pd, Cu, Ni, Ag have also been incorporated in polythiophenes by an electrochemical deposition method which allows precise control of the size and spatial distribution of these aggregates (Fig. 3).[20] Pt and Cu for instance have been shown by Extended X-Ray Absorption Fine Structure (EXAFS) to exist as coordinated atoms or as small clusters along the individual conducting chains.[21] When the size of the metal particles is increased, aggregates can be visualized by scanning electron microscopy (SEM), appearing then as deposits (size ca. 20 nm) on polymer fibers (diameter ca. 10 nm), in which the disposition of the individual polymer chains is not yet well understood.



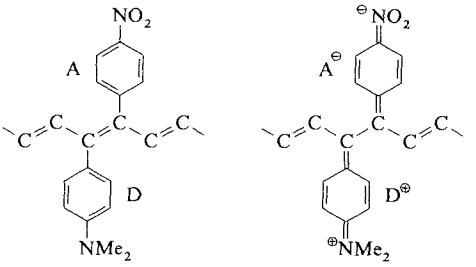


Fig. 3. Scanning electron micrograph of silver aggregates deposited along the conducting fibers of polymethylthiophene. Enlargement: 30 000 ×.

These redox and metal centers can be electrochemically addressed through the conducting chains of the polymer, allowing the controlled triggering of fundamental chemical processes such as the reduction of $H^{\oplus}$,[20] CO_2[19] or O_2,[20] or the oxidation of H_2O[22] or ROH.[23] High catalytic activity has been demonstrated,[20] resulting from the molecular distribution of these catalytic centers in three-dimensional materials of hundreds of microns in thickness. Furthermore, the regioselectivity observed, e.g. in the catalytic hydrogenation of unsaturated compounds with substituted polypyrroles,[24] indicates that the reactions proceed under a stereochemical control exerted by the environment of the catalytic centers in the conducting polymers. This result is very promising in relation to the possibility of using conducting polymers with chiral substituents such as those described in the previous section, for inducing asymmetry during these catalytic reactions through a template effect, although such an effect has still to be experimentally demonstrated.

These few examples show how far chemists have already gone in the realization of molecular materials capable to perform physical and chemical recognition, to transfer molecular signals, and to induce electrocatalytic reactions. Of course, the phenomena of molecular recognition, signal transfer and catalytic control are also known for individual molecules and supramolecules in homogeneous phases.[1] The important step achieved with functionalized conducting polymers is the assembly of these functional elements in a three-dimensional architecture based on a network of molecular wires able to carry electronic information to and from these elements. There is still a long way to go before these elaborate structures can be addressed at a molecular level.

5. Molecular Electronics

The introduction of memory effects and logic functions in these materials is the field of molecular electronics. In molecular wires switching, gating and amplification functions result from the ability to modulate their charge transfer properties, and memory effects are directly related to bistability phenomena. For example, donor (D)–acceptor(A) systems in which a charge separation can be photochemically induced can be covalently bonded as side groups along the conducting chains; by altering the amount of charge transfer between D and A the extent of conjugation, and thus the charge transport properties of the chains, can be modified. Such a type of "push-pull" mechanism[2] is depicted in Scheme 2.

Scheme 2. Left: conjugated conducting chain of polyacetylene; right: interruption of conjugation and conduction due to charge transfer D → A.

If we use a D–A system in which the extent of charge transfer is controlled by an external variable such as light intensity, the charge transport properties of the conducting polymer chains can be modulated ("molecular modulation" of a signal). If a very large variation of this charge transfer is imposed, electron sinks will be created along the conducting chains which will hinder any conduction, thus leading to molecular switches. Considerable knowledge of such D–A systems is already available, e.g. in dye chemistry. As a consequence of the very short time scale associated with light excitation phenomena, which typically lies in the order of 10^{-15} s for reaching Franck–Condon states, ultra-fast modulation and switching can be expected with these new molecular structures.

Memory effects will be obtained if bistable structures showing some hysteresis can be produced. Bistability is al-

ready a well studied phenomenon, and molecular systems exhibiting this effect have been proposed, based, for example, on an antiferroelectric to ferroelectric transition induced by the application of an external field,[25] on a ferrimagnetic to ferromagnetic transition in heterobimetallic complexes,[26] or on the more familiar modification of optical properties that occurs in photochromic molecules following a light pulse.

Unlike inorganic semiconductors, where the semiconducting properties are associated with a macroscopic solid state, whether crystalline or amorphous, in organic molecules the properties are intrinsic to the molecules. The new concept of molecular semiconductors opens up a new field, both theoretically and with regard to applications.[27] The semiconducting properties of undoped conjugated polymers such as polyacetylene and polythiophene have been used in various devices, such as Schottky junctions,[29] homo- and heterojunctions,[29] organic–inorganic junctions,[30] and field-effect transistors.[31] Although the results are promising, it has been acknowledged in all these investigations that the devices suffer from the very poor semiconducting properties of these conjugated polymers. As already observed for most organic semiconductors, these materials have large concentrations of structural defects and impurities, which create efficient traps and recombination centers. Thus the carrier mobility which is one of the most important characteristics for a semiconductor, is very low, rarely exceeding $10^{-5}\,cm^2\,V^{-1}\,s^{-1}$, a value which has to be compared with about $1\,cm^2\,V^{-1}\,s^{-1}$ for a classical amorphous inorganic semiconductor such as Si, and more than $10^2\,cm^2\,V^{-1}\,s^{-1}$ for monocrystalline Si. A large improvement in the semiconducting properties of these organic materials thus appeared essential in order to consider them for electronics applications. An important achievement has been the use of conjugated oligomers instead of the corresponding polymers. Oligomers can be synthesized as chemical compounds with a well defined structure and a much lower concentration of defects and impurities than the corresponding polymers. By controlling the conjugation length, it is possible to prepare oligomers showing almost the same band-gap energy as the parent polymers, and their solubility and low molecular weight allow them to be easily processed by vacuum or by Langmuir–Blodgett techniques. The most important advantage is their structural homogeneity, which leads to carrier mobility values as high as $2\times10^{-2}\,cm^2\,V^{-1}\,s^{-1}$ in the case of thiophene oligomers.[32] This spectacular increase in mobility underlines the major role played by structural defects for limiting the charge transport properties in polymer chains. Thus, conjugated oligomers, which can be functionalized in the same way with prosthetic groups R, appear to be promising in meeting the requirements for applications in electronics.

A last important aspect which deserves attention concerns the tunability of the electronic properties of these organic semiconductors compared to inorganic semiconductors. Indeed, the characteristics of electronic devices, junctions and transistors, are mainly determined by the intrinsic electronic properties of their n- and p-type semiconducting components. The common inorganic semiconductors, such as Si, GaAs and InP, have discrete band energy values, which impose limits on the characteristics of the corresponding devices. On the other hand, in organic materials which are capable of either large or subtle chemical modifications, these band energy values can be controlled over a wide range, and can thus be tuned in order to achieve almost any desired characteristic. Functionalized organic conjugated polymers and oligomers will thus be able to perform memory and logic functions. Compared to conventional inorganic materials, the easy tuning of their electronic properties offers a promise as great as the first proposals, some decades ago, for using polymers instead of metals.

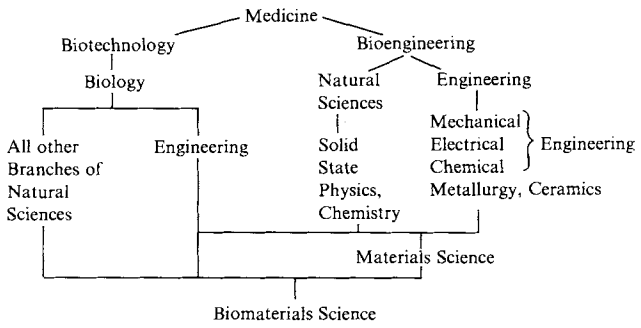
Biomaterials Highlights

Materials for Biomedical Applications—Bone and Joint Replacements

By Günther Heimke*

This contribution is the first of a sequence of reports on the recent developments in the field of the so-called "biomaterials", which, of course, are not at all "bio" or living materials but, rather, replace those living materials which have ceased to serve their purpose.

The science of biomaterials can be regarded as another prototype of the many interdisciplinary fields of research which have emerged during the last decades. It gained general recognition about the mid nineteen seventies as evidenced by the foundation of societies for biomaterials or similar organizations in most of the industrialized nations of the world. In 1980 the European Society for Biomaterials organized the 1st World Congress on Biomaterials in Vienna, Austria, while the 3rd World Biomaterials Congress in Kyoto, Japan, in April 1988 attracted more than 1000 participants. The 4th Congress of this type will again be organized by the European Society and is scheduled for 1992 in Berlin. Besides these world congresses, individual biomaterials societies organize meetings in their own particular areas. The next US conference will be held in Orlando, Florida towards the end of April 1989, and the 8th European Conference on Biomaterials will be in Heidelberg, Germany, from the 7th to the 9th of September 1989, immediately followed by a more specialized symposium entitled "Ceramics in Medicine".



The field of biomaterials is, of course, one branch of the large area of contact between medicine and the natural sciences and engineering disciplines. Actually, there are two such contact areas; biotechnology and bioengineering. The term biotechnology is now mostly used to describe all activities related to the application of modern biology, in particular the possibility of genetic manipulation of micro organisms, to medicine, chemistry, and all other fields of natural science and engineering. The term bioengineering comprises all other contact areas of the natural sciences and engineering to medicine. Scheme 1 is an attempt to express these correlations and to define the position of biomaterials within such a framework.

In most reports on biomaterials in the different fields of medicine, much more emphasis is placed on the different kinds of tissue reactions the materials stimulate or avoid, than to the materials themselves. The reason is obvious: Most of the presently used implant materials have already acquired bulk properties which satisfy the requirements of their particular applications, and therefore, interest is focussed on the reaction along the interface between the biological tissue and the material. At an early stage of biomaterials development the first approximation was that both

From now on, Professor Günther Heimke (Clemson University, S.C., USA) will be providing a quarterly report on various aspects of biomaterials research and development which will be published as the Biomaterials Highlights column of Advanced Materials. Günther Heimke was educated as a physicist with emphasis on solid state physics at the University of Heidelberg and at the Martin-Luther-Universität, Halle, where he gained an M.Sc. and a D.Sc. After several years of university teaching and research into magnetic materials, in particular ceramic magnets, he moved to the industrial sector continuing work on magnets in both West Germany and in the USA before joining Friedrichsfeld GmbH, taking responsibility for the research and development of oxide ceramics. It was here that he became involved with biomaterials, introducing the use of alumina ceramic materials in medical devices, such as joint replacements and dental implants. After his retirement he recieved an invitation to be a guest professor at the Department of Bioengineering, School of Engineering, Clemson University, where he is now a research professor. He has authored and co-authored more than 150 publications and two books, and holds more than 40 German patents on which many international patents are based.

Scheme 1. The position of the science of biomaterials within the branches of biotechnology and bioengineering.

sides of this interface were required to remain in their original state for as long as possible. But it was soon realized that this was a severe oversimplification if looked at from both sides of the interface.

The tissue adjacent to the implant has, because of this implantation, been separated from those portions which have just been replaced by the implant, and has therefore been deprived of about half of its nutrition pathway. In addition, most of the remaining blood vessels meeting this interface have been blocked by blood clots. Cells have been damaged, and their remnants together with other disrupted materials like collagen stimulate defence processes mainly aimed at their removal.

On the materials side, the electrolytic environment can cause many reactions, starting with the removal of the layers originally absorbed in air or during sterilization, and continuing via, for example, the formation of metal organic complexes, to cell mediated processes. These reactions vary from tissue to tissue and also from material to material.

The knowledge about these interfacial processes has not yet been summarized and generalized in a manner which allows sufficiently reliable predictions about the degree of compatibility of a new candidate implant material to be made. This statement already points to one difficulty; there is no general biocompatibility. The kind of tissue reaction to an implant depends not only on the type of surrounding tissue (e.g. muscle, bone, blood, skin) but also on many more parameters, like the degree of vascularization, stresses and strains, or relative motion.

The dense, highly pure alumina ceramic can be used to demonstrate this problem: This oxide ceramic is now widely regarded as the prototype of a bioinert material as nearly nothing goes into solution, and densely adsorbed body molecules even "camouflage" such an implant against the body's immune system. Thus, if implanted in connective tissue (muscle, bone) all reactions have been shown to be essentially controlled by the stress and strain field created in the surrounding tissue and the relative motions resulting from them. As this stress and strain field can be controlled by the shape of the implant, a reliable osseo-integration of such implants can be achieved in bony tissue, as has been documented by the clinical success rates of dental implants and acetabular components of total hip replacements in long term follow-up studies.[1-4] This same material cannot be used in the cardiovascular system because of its blood clotting potential.[5] The reasons for this behavior have not yet been fully understood. Some attempts to correlate the initial process of clot formation to surface properties like the work function or the band gap and width have not yet led to conclusive results.[6]

Because of this lack of a sufficiently general set of rules for the selection or tailoring of implant materials, it will be the task of this series to present the most recent knowledge and developments in a sequence of contributions, each devoted to the most recent achievements in one particular field of implantology. Observations made at the combined meeting of the American Orthopedic Research Society and the American Academy of Orthopedic Surgeons (AAOS) in Las Vegas in February 1989 are the motivation behind these reports in the field of bone and joint replacements. In comparing the topics of the papers presented during these meetings with those presented on similar occasions in the early and even in the mid eighties, some shift can be seen as expressed in Table 1.

Table 1. The shift of emphasis in research on bone and joint replacement materials during the last decade.

Time period	Basic materials related research	Clinical studies
Late seventies and early eighties	Description of the results of interface reactions to potential new implant materials	Relatively short term follow-up studies with essentially phenomenologic description of results
Late eighties	Nearly no new materials; studies on causes for different kinds of interface reactions, e.g. from immunological points of view	Eight to more than ten years follow-up studies with attempts to statistically analyse results.

In basic materials related research it appears that the ceramics explored essentially during the seventies (see the recent survey in this journal[7]) have been the last large, unique group of solids introduced into the field of implant materials. Now, some hopes for further improvements rest with different kinds of material combinations like fiber reinforced plastics, e.g. for bone plates in order to avoid the stress shielding which is assumed to compromise the results of metal plates.

One means for implant fixation, porous coatings consisting of beads sintered or otherwise attached to the surfaces of the anchoring portions of joint replacements, have become widely used, particularly in the USA since the late seventies. Now, longer term clinical follow-up studies increasingly reveal that the success rates are not much better or more predictable than with implants anchored via the polymethylmethacrylate bone cement. This has even resulted in recommendations to abandon such coatings completely and return to the cementing technique.[8]

In order to overcome these problems much interest is presently focused on bioactive coatings (hydroxyapatite [HA] ceramics, Ca-phosphate containing glasses or glass-ceramics). Nearly all experts in this field agreed at last years biomaterials meeting in Kyoto, Japan, that dissolution of at least the HA coatings occurs within about four to six years in the body environment, and that only their combination with undulating surfaces will provide the reliable mechanical interlocking with the surrounding bony tissue necessary to yield some improvements.

The multivariant statistical evaluations of the more recent follow-up studies gave further details on the influence of different implant shapes and sizes as well as operational procedures. There was even the recommendation to abandon the use of conically shaped acetabular components (*D. A. Fisher*, Indianapolis, IN, USA and *T. H. Mallory*, Columbus, OH, USA, paper no. 9 of the AAOS Meeting). A marked detrimental influence of medication by making interface remodeling necessary for osseo-integration was demonstrated for indomethacin and ibuprofen and, to a lesser degree, aspirin (*T. M. Trancik* and *M. Mills*, Trans. 35th Meeting ORS, Las Vegas, 1989, p. 338).

Besides the overview already given in Table 1, it appears that the now nearly 30 years (since *Charnley*'s introduction of the PMMA bone cement) of large scale clinical experience with implants in orthopedic surgery allow for a much more detailed understanding of implant related responses and many of the side effects. Their feedback in the application of implants, however, will become more and more difficult to judge because of the relatively high success rates already achieved.

Conference Reports

Molecular Electronics—Science and Technology

By Ari Aviram*

The conference on molecular electronics took place during the week of February 19. to 24. 1989 on the island of Hawaii in Kona, under the sponsorship of the Engineering Foundation. Seventy scientists took part in the program that consisted of 34 invited talks, 16 contributed talks and 10 posters.

Molecular Electronics is the study of molecular properties that may lead to signal processing. Though the name of the field implies technological applications, the state of the art is at a stage that requires considerable basic science groundwork to foster a solid foundation for building future technology. In essence this is an exciting aspect of the field, since it provides an opportunity to break new ground in our understanding of the molecular universe and to develop new techniques for interaction with single molecules or small groups of molecules.

Recent advances in nanolithography and scanning tunneling microscopy have given a boost to the field of molecular electronics. As such, the conference program was organized around these developments as well as several other themes that represent the multidisciplinary facets of this young science. The organizers prepared the program to probe the following questions: What are the limits of current solid state technology? What is the status of nanolithography? What are the current approaches to molecular signal processing and the theoretical basis for those approaches? What are the current methods that will permit interaction between the macrocosm and the molecular world?

The trend for miniaturization and compaction in current solid state technology for microchip fabrication may stall

when the dimensions of individual conventional devices reach a few hundred Angstroms. This was the assessment presented by Dr. *Robert Keyes* of IBM. These dimensions are still large when molecules are considered since molecules are on a scale of tens of Angstroms. Therefore, it is expected that molecular electronics will only become more desirable when lithography dimensions of about one hundred Angstroms are reached. Nanolithography, the art and technology responsible for fabrication of the fine patterns which are the essence of the microchip, has already reached dimensions in laboratory demonstrations that permit interaction with molecules. This was reported by four leading scientists in the field; Professor *Pease* of Stanford, Professor *Smith* of MIT, Professor *Wilkinson* of Glasgow University and Dr. *Chang* of IBM.

The advances reported, offer exciting possibilities for the fabrication of molecular electronic components. Fabrication of microstructures with linewidths in the 10 nm to 100 nm region is now well established. Not only simple structures for quantum transport studies have been fabricated, but complex circuits and chips for silicon field effect transistors (FET's) and GaAs high electron mobility transistors (HEMTs) with gate lengths down to 70 nm have also been successfully fabricated and perform well. While the electron beam method remains the key lithography approach, focused ion beam and X-ray proximity printing techniques are now available with resolution down to 30 nm. Very thin resist material based on Langmuir–Blodgett films suitable for nanolithography have been developed with defect density almost as low as conventional resists now used in the integrated circuit manufacturing. The use of the scanning tunneling microscope (STM) as a nanofarbrication tool with the capability of directly manipulating molecules and selectively pinning and unpinning molecules with feature sizes as small as 0.4 nm was also shown. These represent the smallest man-made structures ever reported, and the STM may well prove to be a key technique for the fabrication of the sub-10 nm structures needed for molecular electronics in the future. However, it was pointed out by Dr. *Chang* and by Professor *Smith* that although it is possible to produce today the patterns needed for molecular electronics, mass-producing them is something else altogether. The electron beam method currently employed is too slow for commercial applications at the one hundred Angstrom level and a significant amount of development work has to be invested in order to produce a satisfactory commercial nanolithography technology for molecular electronics.

Following these insights on nanolithography, the program focused on current techniques that enable interaction with molecules. Attention centered on applications of STM. Among the participants was Nobel Laureate Dr. *Heinrich Rohrer* of IBM, co-inventor of the STM. Dr. *Rohrer* discussed a new technique of molecular electrochemistry with the STM. This technique permits electrochemical alteration of single molecules or groups of molecules that are addressed with the STM tip. The whole spectrum of current achievements with the STM was presented in a lecture presented by Professor *Calvin Quate* of Stanford University. He showed the ability of this instrument to disclose detailed aspects of molecular activity, such as the sequence of molecular interactions that leads to blood clotting.

The core of the program consisted of presentations regarding various approaches to molecular electronics. Three basic approaches emerged as the dominant representatives of current thinking. One is molecular photonics, also termed "Optical Computing". This approach was outlined by a number of speakers who discussed theoretical aspects as well as the preparation and properties of new materials. Professor *Robert Munn* from UMIST, Manchester, described new computational techniques to calculate linear and nonlinear optical and dielectric properties of molecular crystals, and Professor *David Bloor* from Queen Mary College, described optical studies of the third-order optical non-linearities of polydiacetylenes, and progress towards nonlinear optical devices using these materials.

Another approach was that of Professor *John Barker* from Glasgow, who presented arguments that the best architecture of a molecular computer would require departure from current von Neumann architecture and development of cellular automata. He presented molecular structures that form the proper logic for this architecture.

The third approach outlined was the new theory for molecular electronics that describes molecular switches and a blueprint for future molecular electronic devices. This concept was presented by Dr. *Ari Aviram* of IBM. The theory describes cross-structured molecules that can be employed in a planar technology to fabricate memory cells, logic gates and other components that are needed to form complete molecular integrated circuits.

The conference devoted a large portion of the program to theoretical papers that give justification to the field. Theories were presented for intramolecular electron transfer and the formalism for computing such events. The two presentations by Professor *Mark Ratner* from Northwestern and Professor *Noel Hush* from University of Sydney were important in this respect. Also, the formalism of computing the efficiency of molecular switches was presented in a paper by Dr. *Christian Joachim* of CNRS, France.

Contributions of special interest included electrochemical enzyme control, by Professor *Masuo Aizawa* of Tokyo Institute of Technology, and a synthetic approach to molecular switches outlined by Professor *Jean-Pierre Launay* of Pierre et Marie Curie University in Paris. Also significant was the talk by Professor *Gareth Roberts* of Oxford University who described novel applications of organic thin films to a variety of devices including night vision telescopes.

The conference Molecular Electronics – Science and Technology was a very exciting and important meeting. It produced the recognition that molecular electronics is not just a gleam in the margins of theoretical papers but rather a new and important field of science that is nourished by many supporting sciences and technologies.

Ceramics in Bologna

By Suk-Joong L. Kang*

The 7th International Symposium on Ceramics (7th SIMCER) was held from December 14–17, 1988 in Bologna, Italy. The meeting was organized by the Centro Ceramico in Bologna as part of the 900th anniversary celebrations of Bologna University, and about 730 participants from nearly 30 countries throughout the world attended. Two sessions were organized to run in parallel, one for advanced ceramics, and the other for more traditional ceramics. Approximately 100 papers and posters were presented in the advanced ceramics sessions and about 50 in the traditional ceramics sessions.

The advanced ceramics meeting consisted of six sessions: 1) Superconductivity, 2) Composites, 3) Ceramics on Duty, 4) Processing of High Tech Ceramics, 5) Electronic Ceramics and 6) Structural Ceramics, each being opened by one or two plenary lectures and lasting for half a day.

In the first lecture, *D. R. Clarke* (U.S.A.) presented "Ceramic Superconductors; Relationships between Processing, Microstructure and Properties", emphasizing state-of-the-art research in oxide superconductors and future tasks. The lecture was followed by several contributed papers and a general discussion on the future prospects for these materials. Compared to their bright future in micro-electronics, their application in power transmission systems was thought to be much more difficult.

The afternoon session began with two lectures: "Principles of Design with Ceramic Matrix Composites" (*A. G. Evans*, U.S.A.) and "Whisker Reinforced Ceramics; Toughening Behavior and Properties" (*P. Becker*, U.S.A.). The first described the design principles of composite materials based on fracture mechanics and experimental observations at interfaces and the second gave an overview of recent experimental results.

On the second day, in the session entitled "Ceramics on Duty", microstructure development and the dependence of mechanical properties upon the sintering and environmental conditions were discussed for various materials, ranging from structural ceramics, such as SiC and Si_3N_4, to electronic ceramics, such as $SrTiO_3$. In the afternoon session, "Processing of High Tech Ceramics", *G. Onoda* (U.S.A.) discussed "Basic Phenomena in Ceramic Forming Processes", pointing out the volume expansion of powder mixtures caused by shearing and the problems this brings in powder processing.

On the morning of the 16th, in the "Electronic Ceramics" session *R. E. Newnham* (U.S.A.) lectured on "Electro-Ceramics; the Age of Integration and Miniaturization", and emphasized an important trend in electroceramics research, that of integration and miniaturization of sensors and actuators, after which about ten papers on various materials were presented. The lecture on "Structural Ceramics" given by *F. Thümmler* (FRG), summerizing the range of ceramic materials and components used as structural parts and presenting future trends in the field, was followed in the afternoon by eight other papers.

The last day was separated in the program and devoted to a special meeting "Zirconia 88". *D. Broussand* (France) gave a talk on the "Effect of Powder Characteristics on Forming and Microstructure Development of ZrO_2-Y_2O_3 Ceramics", presenting test results on four kinds of commercial powders. Among the subsequent contributed papers, the paper on "Numerical Methods for the Calculation of Stress Intensity Factors" (*W. Müller*, FRG) provided a relaxed and pleasant time for the audience by demonstrating the toughening effect of ZrO_2 particles by using a movie film, which in fact could be used effectively for demonstration purposes in university courses.

In addition to invited lectures and the presentation of papers, poster presentations were also made in the afternoons of the 14th and 16th, and, although approximately one third of the posters were missing, those that were presented were informative and of high quality.

The success of this small conference, which can boast the participation of numerous representative people, may well be due to the good opportunity given for the discussion of the problems and advances in high-tech ceramics lead by leading scientists in the relevant fields. Despite the small number of papers presented the conference covered an almost unlimited number of topics in advanced ceramics. The materials dealt with were also so multivarious that many of them were mentioned only once or twice during the whole meeting. This was advantageous for the people who wanted to get a general view of the current topics and latest results, but disadvantageous to those who were more interested in specific areas. On the whole, it was an informative and agreeable meeting and the organizers should be congratulated.

Heisenbergstraße 5, D-7000 Stuttgart 80 (FRG)

Atomic Steps on Surfaces

By Martin Henzler *

A special workshop on atomic steps at surfaces and interfaces (organized by *M. Henzler, W. Ranke* and *M. Scheffler*) was held at the Ringberg Castle in Rottach-Egern, FRG, from January 15–18, 1989. Due to the hospitality of the Max-Planck-Gesellschaft the participants from Germany (West and East), other European countries and the USA had an ideal meeting place for extensive discussions on an exciting topic.

In surface science in the past, surfaces have been frequently dealt with as if they were free of defects. This simplification was mainly due to the lack of reliable measurements of the defects and a lack of theory concerning deviations from periodicity. However, over the last twenty years, a few groups have developed defect analysis via profile analysis of diffraction spots. Other techniques, especially microscopy have contributed a lot, so that now the atomic step is the best investigated defect at surfaces. It was therefore worthwhile to put together all available information on steps with respect to verification, theory and properties into one workshop.

It was very helpful to have all the powerful structure elucidation methods reviewed, such as the various microscopies (transmission electron microscopy by *H. Bethge* and *H. Höche*, both Halle, GDR; low energy electron microscopy by *E. G. Bauer*, Clausthal, FRG; scanning tunnel microscopy by *R. M. Feenstra*, Yorktown Heights, USA, and *R. J. Behm*, München, FRG) which reveal many details and beautiful images. The diffraction techniques (low energy electron diffraction by *M. G. Lagally*, Madison, USA, and *W. Moritz*, München, FRG; helium atom scattering by *J. P. Toennies*, Göttingen, FRG; X-ray scattering by *E. Vlieg*, Amsterdam, Netherlands) are complementary due to their ability to supply quantitative information.

If the existence of steps, their shape, density, and distribution on a surface is known, it is of interest, which kind of properties may be influenced or even determined by those steps. Some theoretical reviews on total energy calculations for semiconductors (*J. Chadi*, Palo Alto, USA) and for metals (*P. M. Marcus*, Yorktown Heights, USA) showed atom arrangements at steps to be quite different from ideal lattice sites. There are now a wide variety of well established and quantitatively measured properties due to the presence of steps. Some properties are inherently coupled with steps, like crystal growth, which was discussed experimentally (*E. Bauser*, Stuttgart, FRG, and *H. Höche*, Halle, GDR) and theoretically with quite different methods and aspects (*E. V. Albano*, Mainz, FRG, and *G. Stoyanov*, Sofia, Bulgaria). Of course, many studies on adsorption, desorption and reaction clearly show the quite different effects of steps (*K. Wandelt*, Bonn, FRG; *C. Benndorf*, Hamburg, FRG, and *G. A. Somorjai*, Berkeley, USA). Over twenty posters exhibited many details of important new developments.

All these results demonstrated, that atomic steps are not just unknown or disliked disturbances of an otherwise well-defined experiment. Including steps in all considerations brings the investigated surface closer to reality and to reproducibility. It is clear that the experiments on the best, defect free surfaces are better described and discussed when defects like steps are included. This extension is needed, since many properties are strongly influenced, e.g. for adsorption, the edge sites have a different binding energy and different vibrational modes. Due to this knowledge, many high index faces are under investigation, since they provide two or more very different surface sites. Although these faces are not yet known in as much detail as the low index phases, both microscopy and diffraction provide an increasing amount of detail. Finally a new field of properties becomes available by the inclusion of step properties. Any variation of the shape of a surface during the experiment requires the formation or variation of steps. There was an interesting discussion on the probability of crossing a step during surface diffusion. The roughening of a step during growth, due to heating is a more and more tractable phenomenon. The behavior of adsorbates at steps may change drastically and a study of this may lead to a detailed description of catalysis. Some adsorbates may even initiate a rearrangement of step atoms so that the surface forms new facets. Therefore the stability of surfaces is now to be studied taking into account processes at steps.

Of course, steps are not the only present and only important defects on surfaces. They are, however, the best investigated, and are therefore the model for all other defects. The workshop provided not just the state of the art information, but helped to combine the available information to form new ideas.

Book Reviews

Ternary Alloys

Ternary Alloys—A Comprehensive Compendium of Evaluated Constitutional Data and Phase Diagrams: Volumes 1 and 2, Ternary Silver Alloys. Edited by *G. Petzow* and *G. Effenberg*. Principal reviewer: *H. L. Lukas*. VCH Verlagsgesellschaft, Weinheim, Fed. Rep. Germany/VCH Publishers, New York, N.Y., U.S.A. 1988, Vol. 1, 612 pp. Vol. 2, 624 pp. £ 250 per volume (special arrangements for series subscribers). ISBN 3-527-26941-X and 3-527-26942-8

Metallurgists, like any other kind of scientist, have numerous useful tools of their trade, and a few indispensable ones. Prominent among the indispensable ones are phase diagrams. They are equally necessary to researchers who seek to develop new alloys or improve existing ones, and to producers who seek to optimize the properties of standard alloys by modifications to manufacture or heat-treatment. Modern metallurgy would simply not exist without them.

The first really accurate phase diagram (Cu–Sn) was determined by *Heycock* and *Neville*, two Cambridge chemists, and published in 1904. Only 32 years later, a notable German pioneer, *Max Hansen*, published *Der Aufbau der Zweistofflegierungen:* this reported on the phase constitution of 828 metallic systems and included 456 critically evaluated phase diagrams. After the war, three separate revisions and supplements of this work appeared and other critical compilations of binary phase diagrams were published subsequently. The key word is 'critical': somebody has to make judgements between conflicting data and interpretations. To organize and institutionalize, on a worldwide basis, the heavy task of assembling information, evaluating and reviewing it, an Alloy Phase Diagram International Commission (APDIC) was set up some years ago and a journal, *Bulletin of Alloy Phase Diagrams*, instituted.

One might suppose that the availability of so many binary phase diagrams would satisfy the needs of most metallurgists, but in fact alloys become ever more complex, and many contain at least three major constituents. Ternary diagrams have, therefore, become increasingly important in recent years, and many have been evaluated for, and published in, the *Bulletin*. In its last issue an editorial tells the reader that up to now, 635 binary systems have already been evaluated and published in the journal, its Indian sister journal, or in books, and over 400 more are in progress. In December 1988, the *Bulletin* informed the reader, 606 ternary systems had also been evaluated and published, and 408 had been evaluated but not yet published. As a proportion of possible ternary systems (bearing in mind that more than half of the elements are metals) this is still only modest, but it must be borne in mind that the effort involved in determining a ternary system is much greater than for a binary. (The great English metallurgist *R. S. Bradley*, for instance, spent over a decade of single-minded labor around the middle of the century on the determination of the Al-Fe-Ni diagram alone).

The ca. 2000 binary and ternary phase diagrams now reasonably well established (many others have only been cursorily surveyed) are a truly tiny fraction of the possible total. Figure 1 (note the logarithmic ordinate scale) was published recently by one of the editors, *G. Petzow*, of the volumes under review. Allowing for 100 elements (including a few transuranics) the number of possible 50-element systems exceeds by a large margin the age of the universe in seconds.

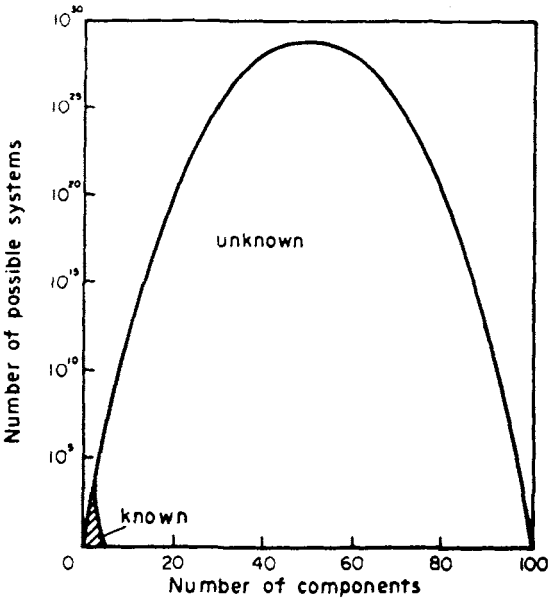

Fig. 1. Numbers of known and unknown heterogeneous systems.

Fortunately, 50ary phase diagrams run into such formidable problems of determination, evaluation and depiction that we can comfortably forget about them; even quaternary and quinary systems, which are occasionally published, are hard to determine and harder to understand when published. What really matters to practitioners is the availability of numerous reliable and conveniently available ternary systems. The new series on which the German evaluators and the publishers have now courageously embarked clearly will fulfil this need.

The two volumes under review incorporate critically evaluated data for 446 ternary systems containing silver, critically updated to January 1988 and based on over 1900 publications of experimental work, taken from the huge database maintained at the Max-Planck-Institut für Metallforschung in Stuttgart, with German Government support. Though

the calculation of phase diagrams from thermochemical data has made great strides recently, this approach is apparently not yet being used for these volumes, because of the very high standards of accuracy which are being adopted and because of the difficulty in securing adequately precise 'optimization' for the three constituent binaries of each ternary system, which is a prerequisite for ternary calculations. For many though not all of the 446 systems, ternary diagrams are included; evaluated binary diagrams are also included where these are not readily available in one of the standard volumes of binaries already published.

Each system is the responsibility of an individual evaluator, 20 of whom contributed to these two volumes and although half of these 20 are German, many nationalities are represented. Each evaluation was then critically reviewed by one of a small band of reviewers. This has become universal practice in all assessments of ternary diagrams under the broad aegis of APDIC as the present volumes are. The reviewers and the original evaluators, if need be, met to resolve their differences at one of the numerous editorial conferences held at a specially provided rural idyll.

The task of producing volumes like these is truly daunting, quite apart from the successive levels of evaluation and reviewing to which all the work is subject. Finding the original publications (many in exceedingly obscure periodicals); assessing their reliability; turning the diagrams into standard format; finding and assembling crystallographic information about the phases (structure types and lattice parameters are cited); creating isothermal and 'vertical' sections; in particular, drawing up the involved 'reaction schemes' for the more complex ternary systems which have become de rigueur for serious depictions of ternary diagrams, to render them more intelligible; computer-based creation of final drawings and checking of the final printed form... all this has called for a very large team of participants both in Stuttgart and elsewhere, and at the publishers a very long term commitment to a colossal task, as well as generous Government funding without which the (admittedly) high price of the volumes would have gone right through the roof.

The stated objective of the series is to have so much information not just cited but presented in the volumes that most users will never need to got to the original literature. In this reviewer's opinion, that objective has been achieved.

The next set of volumes, three in number, on ternaries containing aluminum, is at an advanced state of preparation and is due to be published this year. It should be noted that as the series progresses, the task will become gradually less onerous. This can be appreciated by noting that the two "Ag" volumes incorporate 28 Ag-Al-X systems, and none of these 28 need be repeated in the "Al" volumes. This 'reduction effect' will become more pronounced as successive volumes are published.

There have been other compilations of ternary phase diagrams in book form. First one should point out a publication entitled *Phase Diagrams for Ceramists,* published by the American Ceramic Society originally in 1964 and repeatedly updated since. This contains information on many binary, ternary, quaternary and even a few quinary systems of ceramics. The ceramists are entirely separate from the APDIC organization. (There are no compilations of phase diagrams of polymers, and indeed very few such diagrams exist. The concept of phase equilibria is only making slow headway in the polymer world, though both theorists and experimentalists are now working extensively on the concept of miscibility and separation of phases in 'polymer blends').

India has played a large part in the international metallurgical effort, and many evaluations have originated there; *Raghavan* in Delhi has published three volumes on Fe ternaries (the latest has just appeared) with one more to come. Even so, the four Indian volumes only scratch the surface of the enormous range of Fe ternaries! In America, a Cu-O-X volume is expected to appear soon (again, clearly, a small subset of Cu ternaries) while in Britain, as a result of work initiated years ago by that prince of evaluators, the late *Geoffrey Raynor,* a volume of Au ternaries is expected to be published soon by the Institute of Metals. The editor of this is *Alan Prince,* who is now the doyen of British evaluators and has played a substantial part in the two Ag volumes under review here. When the Stuttgart team gets to Au, which should not be long in view of its position in the alphabet, arrangements will undoubtedly be made to make full use of the British work, to avoid needless duplication, but presumably the information in the British volume will all be included in the VCH series, which is intended to be as comprehensive as is humanly possible.

It is entirely appropriate that the massive international effort which has created this first fruit, the silver volumes, should be centered in Stuttgart. Many of the early phase diagrams were determined by the German pioneer, *Gustav Tammann.* Germany has long had an indigenous tradition of high-class metallography, including a training program for metallographers which has no equal; metallography (and the ability to judge critically the results of metallographic investigations) is an essential constituent of phase diagram determination and evaluation. *Max Hansen,* the father of phase diagram evaluation, worked at the Stuttgart Institute, and as the editors of the silver volume indicate in their preface, they are seeking to create a sort of '*ternary Hansen*'. In this ambitious task, to judge from its first fruit, they have triumphantly succeeded, and the publishers also deserve every credit for their courage and long-term commitment in bringing this venture to the public.

Organic Conductors, Fibers, Thin Films...

One-Dimensional Conductors. (Springer Series in Solid State Science 72.) By *S. Kagoshima, H. Nagasawa* and *T. Sambongi*. Springer-Verlag Berlin 1988. xii, 235 pp., hard cover, DM 99.—ISBN 3-540-18154-7

This volume is a very good introduction to the physics and electronic properties of one-dimensional conductors. After a brief introduction describing the features of one-dimensional conductors the basic theoretical aspects of a one-dimensional electron system are explained. Thus the important concepts of the one-dimensional conduction band, the Peierls instability and transition, the electron-phonon coupling and Kohn anomaly, the nesting of the Fermi surface, charge density waves, fluctuations in one dimension, and the role of the Coulomb interaction are described and discussed. In addition, a comparison of the conditions in two and three dimensions is made. This chapter serves as an excellent introduction to the field for graduate and undergraduate students of physics and chemistry, as well as for researchers in other fields of solid state physics.

In Chapters III to VII the chemical and physical properties of typical one-dimensional conductors are reviewed. The review starts with TTF-TCNQ and related materials, giving a reasonably complete survey of their properties, starting with crystal growth, followed by the electrical and magnetic properties and the behavior of the charge density wave. This part is important because it was in crystals of TTF-TCNQ that more or less all the typical one-dimensional phenomena were first experimentally observed. In addition, this chapter contains descriptions of the properties of some other TTF salts, as well as of the Bechgaard salts $(TMTSF)_2X$. For the latter in particular the superconducting properties of the $(TMTSF)_2PF_6$ and $(TMTSF)_2AsF_6$ salts under pressure are explained. The superconductivity at ambient pressure in $(TMTSF)_2ClO_4$ is mentioned only briefly, and the properties of the many important BEDT-TTF radical salts discovered since 1982 are discussed only on one page, giving some cause for criticism. The original text was written in 1981 in Japan and printed there in 1982. The review on the various materials is therefore more or less complete up to 1980. In the preface the authors mention that in rewriting the volume for the Springer Series in Solid State Science they revised the contents and updated each chapter in the light of recent developments in this field. The updating of all the chapters is, however, by far too short and incomplete, so that in all cases the newest ideas and developments in the field are more or less lacking. In this sense the contents of the volume unfortunately do not represent the "state of the art".

In Chapters IV and V the properties of the inorganic materials MX_3 ($NbSe_3$, TaS_3, $TaSe_3$ etc.) and of the Krogmann salts KCP are described, with an emphasis on the important concept of charge density waves. The optical and magnetic properties, as well as some structural aspects of one-dimensional systems, are also discussed with an account of some experimental results. In the next very short chapter the properties of the linear chain polymers $(CH)_x$ and $(SN)_x$ are presented. Here again the latest experimental results and theoretical ideas on polyacetylene are missing, but the reader is certainly introduced to the problems, and especially to the concept of solitons in polymers. In the last chapter the synthesis, structure, conductivity and superconductivity of the linear chain mercury compounds are discussed.

Despite some criticism, mainly regarding the scant coverage of experimental results since 1980, the volume certainly achieves its aim of providing an introduction to the field of one-dimensional conductors, and it was high time that such a survey was written.

Graphite Fibers and Filaments. Springer Series in Materials Science, Vol. 5. By *M. S. Dresselhaus, G. Dresselhaus, K. Sugihara, I. L. Spain* and *H. A. Goldberg*. Springer, Berlin/Heidelberg 1988. x, 382 pp., hard cover, DM 122.00.—ISBN 3-540-18938-6

News of the publication of "Graphite Fibers and Filaments" might lead one to ask whether it is really necessary or desirable to add yet another volume to the already existing monographs and review articles on carbon fibers. However, after looking more closely through the contents of this book one can answer yes to the question. One important reason is the topicality of this progress report, as the whole field is certainly still undergoing rapid development; an additional reason of even more crucial importance is that the book concentrates on the physical properties of the fibers.

The idea of writing this book arose at a specialist conference, and the names of the team of authors, from MIT, Colorado State University and Hoechst Celanese, were a guarantee that the material would be competently covered. In doing so the authors have not hesitated to include their original contributions to fill gaps in the literature that became apparent.

Following a brief description of the existing types of fibers, their manufacture is treated in the second chapter. The synthesis of the types of carbon fibers derived from rayon, polyacrylonitrile and mesophase pitch as precursors is briefly covered. More space is given to the preparation and the mechanism of growth of carbon filaments produced by

thermal decomposition of hydrocarbons in the presence of metallic catalysts, the so-called CCVD (catalytic chemical vapor-deposited) filaments.

In the chapter "Structure" a basis is laid down for all the discussions that follow concerning the properties of the fibers. Starting from the crystal structure of graphite and the structural defects that are observed, the different types of filaments with partially graphitic structure are described, as well as highly disordered fibers. The picture thus developed is supported by results from X-ray diffraction, small angle scattering and electron microscopy.

The chapter "Lattice Properties" begins with a description of the lattice dynamics of single crystal graphite and the related elastic constants, and goes on to develop models for the fibers, taking into account the effects of defects. Techniques for structural characterization are described, in particular Raman spectroscopy which provides a sensitive method for non-destructive analysis of the spatial distribution of lattice disorder in carbon fibers.

After the preparatory treatment of fundamentals, the central theme of the book is reached, namely the thermal, mechanical, electronic, magnetic and high-temperature properties of carbon fibers (138 pp.). The anomalous temperature dependence of the in-plane lattice constants and the corresponding temperature dependence of the thermal expansion coefficient are taken as a basis for understanding the experimental behavior of fibers from different sources. The mechanical properties are of crucial importance for technological applications. Although the theoretical tensile strength and elastic modulus of an ideal graphite lattice are not fully realized in practice, the strength-to-mass ratios of fibers and fiber-resin composites are superior to those of metals. The degree of orientation, nature of defects, stacking arrangement of the fibrils, and uniformity of stress within the fiber influence the models and are shown to determine the experimental properties of the technical fibers.

The high degree of ordering in CCVD fibers ensures that, in every chapter of the book, this type is given preferential treatment compared with the fibers based on pitch and polyacrylonitrile which are currently used in engineering applications. The authors expect the production costs of vapor-grown fibers to fall to comparable levels in the future, with market penetration into all areas of application where the short fiber length is adequate.

Special chapters are devoted to intercalation and ion implantation. The intercalation reaction starts at the free ends of the fibers and is facilitated by a high degree of structural order, so here again vapor-grown fibers dominate the discussion. The applications of fibers and composites receive only a condensed treatment in the last chapter (35 pp.).

Of the 500 literature references listed, a large proportion are for the years 1984 to 1987. The detailed subject index (22 pp.) greatly facilitates using the book as a work of reference. However, it would have been desirable to include a summary of the numerical properties of fibers and filaments made by different processes and after-treatments in the form of an appendix table. This well produced book can be recommended without reservation, and has the potential to become a standard work on the physical properties of carbon fibers, especially if the authors are also prepared to take on the job of updating the treatment in the future.

Ferdinand von Sturm
Biberbach (FRG)

Thin Liquid Films. Edited by *I. B. Ivanov*. Marcel Dekker Inc, New York 1988. 1160 pp., bound, US $ 295.— ISBN 0-8247-7763-8

The editor has undertaken the tremendous task of bringing together 23 leading experts in the field of liquid films, to contribute to this volume which is intended to cover comprehensively and systematically the major aspects of this rapidly developing field.

Thin liquid films are very important in many technological and biological areas such as oil recovery, coating, the etching or protection of microelectronic elements and cell communication in biology, but these subjects are not covered by this book. Instead it considers basic principles and processes, and there is definitely a need for a well-founded collection and critical evaluation of the status of research in this fundamental area.

The book is organized into 15 chapters with the first six arranged in a logical way whereas the others are important but could partly be presented in a different order. At the beginning there are two chapters on thermodynamics followed by one on the statistical mechanics of inhomogeneous films. Then van der Waals interactions, electrostatic interactions and steric interactions are analyzed and described in consecutive chapters. Very important for the theoretical understanding are the problems of drainage and hydrodynamic stability and this is presumably the reason why these specialized areas are presented following the fundamental theory.

Then a separate chapter is devoted to quasielastic light scattering from liquid films, because this technique shows great promise in the study of dynamic properties. The coalescence of dispersions is then considered theoretically for various practical situations and the results are compared extensively with experimental data. The same holds for the chapter on equilibrium properties of free films and the stability of foams and emulsions. The section on interfacial rheological properties of surfactant films then presents experimental data and briefly relates them with theoretical models.

The next chapter then considers ordering processes and forces in liquid crystalline films, comparing theory and experiment. A long chapter on black lipid membranes then mostly concentrates on electrochemical and photochemical studies displaying relevant theories and drawing many conclusions about biological processes (bioenergetics and physiology). In the final chapter the electrical breakdown of bilayer lipid membranes is analyzed theoretically. This process

has been of high theoretical interest for years but is also of biological relevance for processes like cell fusion.

The editor has managed to smoothly connect these chapters avoiding much duplication of information from the different contributors. The contributions are very thoroughly written and edited, and the illustrations are well conceived. The book contains numerous important references which are complete up to about 1984 but are fewer in number for the following years, depending on the subject and on the insight of the corresponding authors into recent literature.

The book is highly recommended for those scientists looking for a detailed, in depth treatment and understanding of the principal mechanisms since theoretical questions are discussed exhaustively. It contains extended and critical reviews of specialized topics and is thus very valuable. However, I do not think that the book will find a broad readership, despite the fact that the field is expanding: It contains more than 1100 pages and is too demanding for the student or non-expert. Thus, I am afraid it will not contribute as much as intended to a cross-disciplinary discussion.

In criticizing the large volume of the book it is very daring to list subjects which I had wished to be included. However, since in my view progress in the field has to a large extend been due to the availability of new characterization techniques there should have been one contribution on these new methods. Examples of these techniques are evanescent wave techniques applied in optical and Raman spectroscopy or in X-ray and neutron scattering, and nonlinear optical techniques and IR spectroscopy which are useful in the study of the structure of liquid films. Various classical techniques like optical microscopy have gained new importance through developments of affordable image analysis systems. There are also several groups involved in computer simulations of the behavior of surfactants at interfaces and these studies, started in the last decade, will gain considerable value in the near future. These things are unfortunately not mentioned in the book. Despite these deficiencies, this is a very important work for those wanting to specialize in some aspects and for those that need an in depth coverage of thin films but I am skeptical, despite personal wishes, that it will find a broad readership.

der Universität Mainz (FRG)

Inorganic and Organometallic Polymers (ACS Symposium Series 360). Edited by *M. Zeldin, K. J. Wynne* and *H. R. Allcock*. American Chemical Society, Washington 1988. xii, 512 pp., bound, US $ 119.95.—ISBN 0-8412-1442-5

This book reviews the field of inorganic-organic polymers—polysilanes, polysilazanes, polysiloxanes, polyphosphazene, boron-containing polymers and other related polymers—both from a fundamental point of view and with regard to their uses in advanced materials (if such a distinction is still necessary). Such a book was needed since this field is in rapid development. The origin of the book was a symposium held on this topic in Denver in April 1987, which accounts for the very large number of authors involved. A serious effort seems to have been made to avoid the inconsistancies and overlapping inherent in this type of publication. The scientific content is of high quality throughout the book, the presentation is well harmonized, and the indexes (authors, affiliation, subject) are useful guidelines for finding the topics of interest. Only a few typographical errors have been noticed. The drawings are of good quality and accompanied by explicit captions. The book is divided into seven sections, with special emphasis on the chemistry of polysilanes.

A brief preface and an introduction are given before the various fields are reviewed. The part devoted to polysilanes and polycarbosilanes constitutes one fourth of the book. It is justified by the high level of activity on this topic. The historical parts of most chapters overlap each other and, more than once, the chemical pathways shown and the types of synthesis described are repeated. Apart from these minor points, this section is well documented and presented and very informative. It should be read by anyone who intends to begin work in this area. It is also very useful for the specialist who wants to find fairly recent references in this burgeoning field. *F. S. Kipping* is usefully cited as the grandfather of this organosilicon chemistry. This was necessary since many other pioneers in other disciplines have been forgotten. All aspects of the polysilane field are treated: synthesis, characterization, spectroscopic data (absorption and fluorescence) structures, computational information, new synthetic routes, kinetic experiments and mechanisms.

The second section is related to polysilazanes and also suffers from the overlapping of certain chapters. However, as previously, the quality of each section more than compensates for this minor inconvenience. This part is of appropriate length (40 pages) for as are all the other sections of this book.

The chapter treating polysiloxanes is more conventional, since this field is well documented and most readers are familiar with the chemistry of the siloxane group, the various derivatives which can be formed, and the expected properties of the materials. The amphipathic nature of the polysiloxane derivatives is usefully recalled and related to some specific properties: biocompability, resistance to atomic oxygen, adhesiveness, etc. The chapter devoted to molecular metals is not altogether consistent with the previous sections, and relevant pioneering work is not mentioned. The brief section concerned with chemical routes which avoid the use of elemental silicon for making alkyl silicates would have been better inserted into another chapter.

The section on polyphosphazene is written by leading experts in the field, as are most of the other sections. All the latest developments in this now firmly established field are covered.

The use of sol-gel processes for making materials is usefully treated, with special emphasis on SiO_2 and TiO_2 based

materials. The first of these chapters (*C. J. Brinter* et al.) is a good and simple introduction to the field. The possibility of making new devices (field effect transistors with sensor properties) is briefly, perhaps too briefly, mentioned in the next chapter. The use of TiO_2 films as photoanodes for the decomposition of water is treated in another section (*S. Sakka* et al.). It is regrettable that their potential usefulness is not compared with that of single crystal devices.

The section on boron-containing polymers is more speculative, but an interest in them as precursors to boron-nitrogen oligomers is mentioned (*S. Y. Shaw*) and the postulated mechanisms involved in the fabrication of preceramics are described (*K. J. Panorek* et al.).

Finally, a few miscellaneous metal and metalloid containing polymers are treated in the final section: metallo-tetraphenylporphyrins, poly(trisbipyridine) metal complexes, oligomeric organotin compounds, etc.

In conclusion, this book will very probably serve both as a reference book for readers familiar with this area, and as an introduction for engineers wishing to acquire a basic knowledge in this important field.

Paris (France)

Solid/Liquid Dispersions. Edited by *Th. F. Tadros*. Academic Press, London 1987. xii, 331 pp., bound, £ 25.—ISBN 0-12-682178-X

This book deals with the preparation, stabilization and flocculation of dispersions, and also describes their rheological properties. The material is divided into 13 chapters written by experts in the field as follows:

Chapter 1: Introduction (*T. F. Tadros*). This introductory chapter gives a short overview of the technological importance of dispersions. The reader is referred to the appropriate later chapters for further details, and a few of the results from these chapters are summarized in advance.

Chapter 2: The preparation of solid/liquid dispersions (*D. J. Walbridge*). This chapter is concerned with the preparation and stabilization of dispersions. Methods for preparing both polymeric latexes and inorganic colloids, by means of precipitation reactions or by comminution of large particles, are discussed. The basic principles of dispersing agents for aqueous and non-aqueous systems are described.

Chapter 3: The structure of the liquid/solid interface and the electrical double layer (*J. Lyklema*). This chapter deals mainly with the electrical double layer at interfaces between solid bodies and liquid media.

Chapter 4: The stability of solid/liquid dispersions (*B. H.-Bijsterbosch*). This chapter is concerned with the DVLO theory, repulsive and attractive interactions between two particles, and the kinetic aspects of coagulation.

Chapter 5: Adsorption of surface-active agents at the solid/liquid interface (*E. Aveyard*). In this chapter the adsorption of surface-active agents at interfaces between solids and liquids is discussed. In particular the importance of the role played by the surface electrical charge on the particles is considered in more detail.

Chapter 6: Adsorption of polymers at the solid/liquid interface (*T. Cosgrove*). This chapter is concerned with the adsorption of polymers at the interfaces between solids and liquids. The discussion here deals mainly with the conformations of the polymers and the thickness of the adsorbed layer.

Chapter 7: The stability of solid/liquid dispersions in the presence of polymers (*B. Vincent*). In this chapter the author emphasizes the effects of adsorption on the aggregation of the dispersed particles and on the stability of dispersions.

Chapter 8: Flocculation by polymers and polyelectrolytes (*J. Gregory*). This chapter is devoted to the flocculation of dispersions by polymers and polyelectrolytes, including also a brief discussion of the thermodynamics and kinetics of flocculation.

Chapter 9: The properties of concentrated dispersions (*R. H. Ottewill*). In this chapter the author briefly describes how, on the basis of small angle neutron scattering studies, information can be obtained about the structures of concentrated dispersions; the relationship between the structure and the shear modulus of the system is also discussed.

Chapter 10: Rheology of colloidal dispersions (*J. W. Goodwin*). This chapter deals with the fundamentals of the rheological behavior of concentrated dispersions. A short overview of the various rheological phenomena is given. In addition the various measurement techniques used for characterizing the rheological behavior of concentrated dispersions are discussed in more detail.

Chapter 11: The sedimentation of suspensions and methods for preventing the formation of dilatant sediments (*T. F. Tadros*). This chapter deals with the sedimentation of dispersions and the formation or avoidance of sediments.

Chapter 12: The use of spectroscopic pK_a probes for determining electrostatic boundary potentials (*T. W. Healy, B. Lovelock* and *F. Grieser*). The specialized title of this chapter sets it aside from the pattern of the preceding chapters. The authors here describe how spectroscopic probes can be used to determine electrostatic boundary potentials.

Chapter 13: Summary of the properties of suspensions (*T. F. Tadros*). In this final chapter the editor summarizes the topics covered in the preceding chapters, drawing together the various macroscopic properties of dispersions.

In almost all the chapters the treatment is virtually limited to presenting the theoretical basis for the processes and phenomena described. These basic principles are often only supported by schematic diagrams. Only in comparatively rare cases is the opportunity taken to illustrate the theory by giving actual experimental results. The book is especially suitable for anyone wishing to begin work in the area of dispersions. The chapters are written clearly and simply; they do not break any new ground, i.e. almost everything

contained here can also be found in other textbooks of colloid chemistry or electrochemistry. Nevertheless, it is useful to have these fundamentals, which are essential to the theoretical understanding of dispersions, collected together in a compact form, and the book fulfills this requirement to a large extent. There is a small disadvantage arising from the fact that the individual chapters have been written by different authors; this means that one often finds repetitions of material which is not strictly necessary for the understanding of the discussion.

A Chemical Approach to Protein Design— Template-Assembled Synthetic Proteins (TASP)

By Manfred Mutter* and Stéphane Vuilleumier

In memoriam Emil Thomas Kaiser

Advances in methodology in both chemistry and molecular biology allow us to take a fresh look at protein science. Chemical synthesis of peptides and site-directed mutagenesis are now standard research tools, paving the way for the construction of new proteins with tailor-made structural and functional properties. The decisive hurdle on the way lies not in the synthesis of the molecules proper but rather in a better understanding of the complex folding pathways of polypeptide chains into spatially well-defined structures. Can the chemist use his synthetic tools to *bypass* the notorious "folding problem?" In this article, we present a new approach developed in our laboratory, which opens a chemical route to artificial proteins with predetermined three-dimensional structures, allowing a first step towards the synthesis of new proteins with functional properties.

Synthetic analogs of globular proteins are unknown. The capability of adopting a dense globular configuration stabilized by self-interactions and of transforming reversibly to the random coil are characteristics peculiar to the chain molecules of globular proteins alone.
P. J. Flory[1]

1. Introduction

Over the last few years, vigorous research efforts and advances in peptide and protein synthesis, modification, and analysis have led us to believe that a thorough understanding of the "big questions" of protein chemistry[2, 3] lies within reach. Dealing with the flood of data they are now in a position to produce easily and quickly, chemists and molecular biologists have attempted to pinpoint the molecular determinants of protein folding, structure, and function. Their ultimate ambition is the creation of new proteins ("protein design") with tailor-made structural and functional properties.[4] How distant is this fascinating goal? The purpose of the present article is to give an answer to this question, by reviewing the advances in the field of protein design that have occurred since our last review article.[4] We shall first consider the aspects of protein structure relevant to the design of new proteins and show that the modification of natural proteins by recombinant DNA methods ("protein engineering") and the construction of new polypeptide chains designed to fold in specific ways ("protein de novo design") are complementary and convergent methods that yield valuable insights into the prospects and limitations of protein design. In the second part of this article, we shall

[*] Prof. Dr. M. Mutter[+], Dipl.-Natw. S. Vuilleumier

concentrate on a new general approach we have developed for the construction of artificial proteins that relies on the potential of synthetic chemistry, emphasizing the role the chemist may play in the interdisciplinary adventure of protein design.

1.1. Proteins and Chemists

The advent of gene technology[5] has made possible the identification, gene cloning and sequencing, expression, and isolation of virtually any protein. As a result, proteins will play an increasingly important role in tomorrow's pharmaceuticals.[6] Therefore, chemists have shown increasing interest in understanding proteins in molecular and atomic detail.

Protein chemistry has been a challenge for chemists ever since *Emil Fischer* attempted the synthesis of polypeptides[7] into "... the longest possible chain, in order to compare the obtained products with natural proteins ".[8] We now know that natural evolution has been most restrictive in the selection of sequences. For example, in a polypeptide chain of 100 amino acids, the 20 proteinogenic amino acids allow 20^{100} different proteins (a number greater than the estimate of atoms in the universe) to be constructed. Humans, in comparison, possess a mere 10^4-10^5 different genes suited to code for proteins. Sequences, however, are hardly the whole story: natural proteins are unique in the world of polymers in that they adopt a dense, well-defined, globular conformation,[1] an additional and essential feature probably unanticipated by *Fischer*. The same structural type is adopted by many different sequences,[9] but short identical sequences may adopt different conformations in different proteins.[10] Most human-designed polypeptide chains do not fold and present themselves as flexible coils in solution, indicating strict requirements for globularity. This is where the protein designer meets the "famous" folding problem.[11, 12]

1.2. The Protein Knows How to Fold[13]

So have we really learned how the protein does it, as *Edsall* proposed twenty years ago? The classical work of *Anfinsen* and co-workers[14] on ribonuclease A has shown that, for at least some proteins, the amino acid sequence contains the full information needed to determine the correct conformation of the protein and that the protein can be denatured and renatured without loss of enzymatic activity. In other words, the free energy of folding determines the reversible transition between the unfolded and the folded state. However, it is still unclear if thermodynamic stability, as implied above, is the sole determinant of protein conformation. The question whether the global minimum of the conformational energy surface of a polypeptide chain, rather than a local one, is reached upon folding is still an open one. Sampling of all possible chain conformations would take an impossibly long time,[15] implying that kinetics also plays a role in folding. However, this is only valid for the unrealistic case where there are no restrictions by long-range interactions in the conformational space of the chain. Neither kinetic limitations nor metastability need to be assumed to account for the native structure of proteins if the volume of the chain excluded upon folding and the fact that the possible conformations are not all of equal energy are taken into consideration.[16]

1.3. Ball and Chain

The complexity of protein folding has always been a source of encouragement for hypotheses and speculation. It is perhaps sensible, therefore, to summarize what is known about the basics of protein structure.

Natural proteins are linear chains of amino acids linked by amide (peptide) bonds. The amino acid residues along the chain form a sequence, the *primary structure*. The polypeptide chain is intrinsically flexible owing to rotational freedom around the N–C_α and C_α-CO bonds of each amino acid unit, defined by the backbone dihedral angles ϕ and ψ, respectively.[2, 3] Limitations on the range of these rotation angles, and hence on the conformational space of the chain, arise from unfavorable interactions.[17] Even so, the number of possible conformers for a chain of the length of a typical protein is astronomical, since an unfolded ("random coil") polypeptide chain has virtually complete conformational freedom.[18] The native state of a protein is a tightly packed,[19] highly ordered structure. Thus, conformational entropy is a significant term in the energy balance between folded and unfolded states,[16] although the estimation of its magnitude is still very difficult. The important constraints of tight packing give rise to regular structural motifs, called *secondary-structure* elements.[2, 3, 9, 16] The α-helix,[20] β-sheet,[21] and β-turns[22] are well-known examples and some of the aspects relevant to protein design will be discussed in more detail in Section 3.2. These secondary-structure elements are assembled in compact arrangements that constitute the three-dimensional structure of the protein, the *tertiary structure*.

It has been proposed that the folding process follows the logic of protein structural hierarchy. Hydrogen-bonded secondary structures have been thought to act as seeds[23] for folding, since they may form early on and direct rapid and efficient folding. However, experimental study of pathways and structural characterization of folding intermediates,[11, 12, 23] while proving difficult owing to the high cooperativity of the folding transition, point to "nativelike" intermediates. A presently popular model is that the refolding chain rapidly collapses to a compact state where secondary structure is present ("the molten globule"), to then rearrange into the final structure.[24] Significantly, it is still discussed whether or not there is only one folding pathway for a given polypeptide chain.[25]

Finally, it should be emphasized here that the situation in vivo does not have to be that of the test-tube. For example, enzymes have been found which can catalyze disulfide bond rearrangement and peptidyl-prolyl *cis–trans* isomerization,[26] as well as prevent formation of improperly folded structures and assist in refolding.[27]

1.4. The Complex Interplay of Different Energy Contributions Determines Protein Stability

What are, then, the intrinsic factors in the polypeptide chain that stabilize it in a defined three-dimensional confor-

mation? The unfavorable conformational entropy term[16] (see Section 1.3) is compensated for by many different factors in folded proteins (Fig. 1, Table 1).

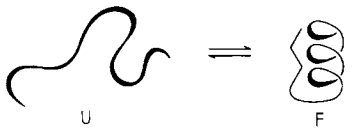

Fig. 1. The energy equation for the folding of a short polypeptide chain into a folding unit. ΔG, the Gibbs free energy of folding, is the sum of enthalpy terms (ΔH) and solvation entropy (ΔS_{solv}) and chain entropy (ΔS_{chain}) terms. The small absolute value of this ΔG originates in the small difference between the energies of the folded (F) and unfolded (U) states (see Table 1). Therefore, an accurate prediction of protein stability is difficult.

$$\Delta G_{F-U} = \Delta H - T\Delta S_{solv} - T\Delta S_{chain}$$

Table 1. An estimation of the various energy contributions which determine protein stability (from [2]).

Energy contributions	ΔG_{F-U} [kcal mol^{-1}]
Conformation entropy	+330 to +1000
Unfavorable interactions in F	+200
Hydrophobic interactions	−264
Van der Waals interactions	−227
Required hydrogen bonds, other	− 49 to −719
Observed ΔG_{F-U}	− 5 to −10

Interactions of the chain with the solvent surroundings cause nonpolar side chains to cluster together in the protein interior, while hydrophilic, charged groups tend to be at the protein surface. This *"hydrophobic interaction"* effect was first predicted and discussed by *Kauzmann*[28] before any protein structure had been solved by X-ray analysis. It has since been intensively studied in terms of the tendency of amino acid derivatives to partition between a polar and an apolar phase[29] and in terms of the contributions of different atom types to solvation free energy of the protein.[30]

The two main secondary-structure types, the α-helix and the β-sheet, are maintained by an extensive *H-bond* network.[2, 3, 9] Most groups capable of hydrogen bonding in proteins appear to be hydrogen-bonded.[31] It is still unclear in what way H-bonds inside a protein are more stable than those between solvent and protein. Whereas the energetic contribution of an isolated H-bond to the overall stability of a protein is probably very small, the cooperative formation of H-bonds most certainly has an important role in protein folding and stability.

The relative importance of *electrostatic forces* depends very much on the estimation of the value of the dielectric constant ε. It is unclear just where and when polarity at the protein surface will be similar to that of water ($\varepsilon \approx 81$) and which ε value best describes the situation inside a given protein (see Ref. [32] for a commentary). *Ion-pair interactions* stabilize tertiary rather than secondary structure and are mostly found at the protein's surface.[33] Dipole interactions[34, 35] have been intensively studied in the case of α-helices. The helix dipole is parallel to the helix axis and points to the N-terminus of the helix, yielding a net partial positive charge at the N-terminus and a net partial negative charge at the C-terminus; this fact has been put forward to explain the occurrence of *antiparallel*, rather than parallel, helical bundles in proteins.

Other forces, such as covalent forces, attractive dispersion forces, and van der Waals repulsion forces,[2, 3] contribute to the energies of both the folded and unfolded state. They may be regarded as less important in influencing the folding in a particular three-dimensional structure, although they have to be taken into account in computations.

The disulfide bond between two cysteines acts as a special structure-stabilizing device. It behaves, in effect, as a *cross-link* which "holds" the structure together. Cross-links constrain the unfolded state to a much smaller collection of conformers, reducing its conformational entropy and making the native state[36, 37] more favorable energetically.

By focusing on the "static" elements of protein structure, we may have created the impression that proteins are rigid, motionless macromolecules. This, naturally, is not true, since flexibility plays an important role at all levels of protein structure and function.[38] A protein may be described as consisting of a collection of substates.[39] There is a whole branch of protein science which is concerned with protein dynamics.[40]

There is one main lesson to be learned from studies on the stability of proteins. The overall energy difference between unfolded and folded states of a protein is *small*[2, 3, 18, 28, 41] (on the order of 5–10 kcal mol^{-1}) in comparison to the total stabilizing and destabilizing energy contributions involved, making protein stability difficult to estimate or calculate.

2. From Structural Prediction to Structure Design

Computations of peptide and protein structure[42] are hampered by numerous pitfalls. Energy minimization of macromolecular systems requires extensive computer time because of the many variables involved. The energy functions in use are still dependent on each researcher's estimation of the relative importance of the different energy terms. This can make comparisons of modeled structures difficult. Moreover, the problem of taking solvent and entropy factors into account in the calculations has, in spite of significant advances,[43] still not been definitely resolved.

Because it is not yet possible to predict the structure from the sequence,[44] we must still rely on more or less elaborate guesswork. This remains an important yet unsatisfactory aspect of protein science. Computers, which have become indispensable to interpret the sequence data produced by gene technology,[45] are now a standard tool in the laboratory. Commercial software packages offering numerous prediction algorithms and "sequence crunching" facilities[46] are available. These semiempirical methods of structure prediction have a long history. The most widely used prediction code is still probably that of *Chou* and *Fasman*,[47] which assigns to each amino acid a probability to be part of an α-helix, β-turn, or β-sheet, based on the statistical analysis of the occurrence of each amino acid in each type of secondary structure of protein X-ray structures known at high-resolution. Other methods include the method of *Garnier* et al.,[48] based on information theory, the statistical mechanical approach of *Tanaka* and *Scheraga*,[49] and methods based on stereochemical considerations. These can range from simple, visual aids such as the helical wheel[50] (Fig. 2) and net[51] representations to the sophisticated set of rules of *Lim*.[52]

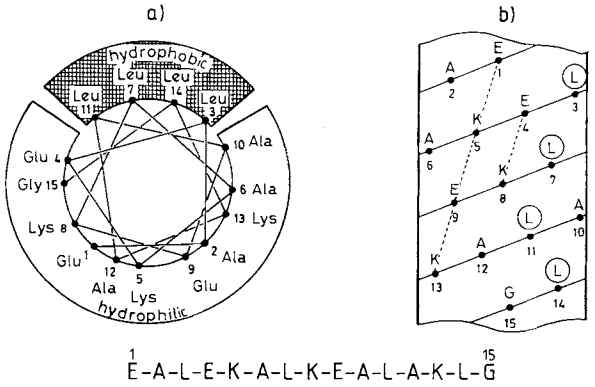

Fig. 2. The helical wheel [50] (a) and net [51] (b) representations, emphasizing amphiphilicity and favorable electrostatic interactions, respectively [35], in the sequence Glu-Ala-Leu-Glu-Lys-Ala-Leu-Lys-Glu-Ala-Leu-Ala-Lys-Leu-Gly [53].

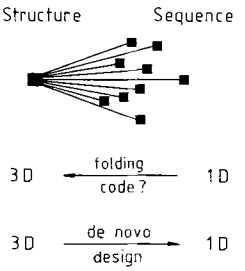

Fig. 4. We are still unable to predict if and how a given polypeptide sequence will fold into a (unique) three-dimensional conformation. In protein de novo design, an opposite approach is taken by trying to find a new sequence (primary structure) which is compatible with an initially chosen three-dimensional structure and folds into this structure under adequate conditions. The rationale for this approach lies in the knowledge, gained from solved X-ray structures, that different polypeptide sequences can have the same structural fold (the "degenerate folding code").

Recently, various combinatorial, pattern-matching approaches have been introduced[54] based on modern computing languages and technology. These bring some improvement at the price of introducing more variables derived from solved X-ray structures. These structural prediction schemes, despite all refinements, have not fared better than 60% in a three-state (α, β, random coil) model.[55] This is because they all rely on sequence (i.e., on local interactions) and cannot take into account the *long-range interactions* that significantly determine the final conformation of a polypeptide chain[44] in the absence of a solved X-ray structure from a related sequence (for detailed recent discussions of structure prediction, see Refs. [54–56]).

In summary, we have to admit that in spite of decades of research on protein folding[11,12] and structure,[2,3,9] our knowledge is not adequate to predict if a given polypeptide sequence will fold and, if so, what its structure will be. We have gained important insights into the rules that determine protein topology (Fig. 3), particularly by X-ray crystallography, and it can be anticipated that the systematic search of data bases will uncover yet more "hidden" motifs of protein structure; however, we still know very little about any rules of folding.[57] Here lies the main obstacle to be overcome on the way to protein design. The fact that an arbitrarily conceived polypeptide sequence will probably have little tendency to fold in a three-dimensional conformation strongly supports this view. This unsatisfactory state of affairs has led to the idea (Fig. 4) of finding all sequences compatible with a given structure (a *"prefolded backbone"*[57]). First expressed in this form by *Drexler*,[58] it has since been given a computational treatment.[59] This development is only one example illustrating the increasing "symbiosis" between biological and computer science. Until now, protein design has very much been the domain of molecular modeling[64] and knowledge-based protein design,[65] and has had the tendency to confine itself to the colorful world of computer screens. Of course, experimental work with the designed molecules will always be necessary to assess the adequacy of our ideas and representations about protein structure and folding.

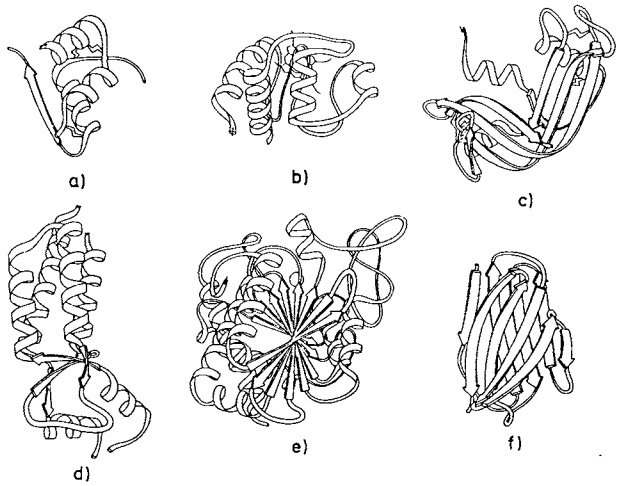

Fig. 3. Examples of protein packing arrangements, as drawn by *J. S. Richardson* [9] based on the solved X-ray structures. a) Insulin (small, disulfide-rich); b) cytochrome C (small, metal-rich); c) ribonuclease A (antiparallel β structure); d) tobacco mosaic virus protein (antiparallel up-and-down α-helix bundle); e) carboxypeptidase (parallel α/β structure); f) immunoglobulin V_L domain (antiparallel β greek key β-barrel structure). The drawings are not on the same scale.

3. Protein Design: A Scientific Challenge with Important Implications

One might ask what sense it makes to redesign what already exists in nature. Has it not always been the ultimate goal of the synthetic chemist to devise and synthesize new molecules with well-defined and interesting properties? Most of all, would the construction of new proteins unknown by nature not show convincingly that we really do understand in some way the complex interplay of primary, secondary, and tertiary structure of natural proteins? From this point of view, the construction of artificial proteins plays a role in protein chemistry similar to that of total synthesis in natural products chemistry.

Apart from the scientifically satisfying goal of being capable of synthesizing new and interesting macromolecules, there is a real need in research and industry for tailor-made molecules that accomplish tasks similar to those of naturally occurring proteins or enzymes, but under different conditions and with different specificities.

Will we succeed in becoming chemical *architects*? In the absence of clear rules which would allow the construction of a building from the ground up (de novo design), it seems

more promising to first transform existing ones (natural proteins) step by step. This is the approach of "protein engineering", which is discussed in Section 3.1 in view of its potential for the construction of new proteins.

3.1. Protein Engineering: Manipulating a Natural Tertiary Structure

Among the tools of genetic engineering,[62] the new technique of site-directed mutagenesis[63] has had an enormous impact in the few years since its introduction (see Ref. [64]). This approach allows one to alter the amino acid sequence of a protein by introducing an appropriately mismatched synthetic oligonucleotide into the protein gene (Fig. 5a). The "non-invasiveness" and selectivity of the technique has decisively expanded the classical approach of chemical modification of proteins.[65] Although unusual for the "traditional" chemist, it constitutes a relatively "safe" approach to protein design, because the starting point is an amino acid sequence

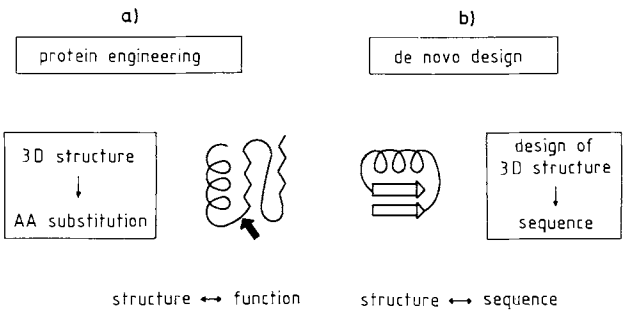

Fig. 5. Protein engineering and de novo design are two convergent approaches for the construction of new proteins. In protein engineering (a), point mutations are made by site-directed mutagenesis in the sequence of a natural protein, allowing for detailed studies on the relationship between sequence, structure, and function (AA = amino acid). In de novo design (b), the target three-dimensional conformation is designed from first principles. Here, the major hurdle is to find a sequence that will fold in the predetermined three-dimensional conformation.

which is *known to fold* in a tertiary structure. On the other hand, only limited modifications may be undertaken if one is to preserve the structural or functional integrity of the system under study. This is a direct consequence of the subtle equilibrium between the folded and unfolded form of a protein (see Section 1.4).

It would be presumptuous to review here the achievements and possibilities of "protein engineering", especially since there is already an excellent introductory monograph on the subject.[66] However, we would like to mention briefly some of the recent achievements which illustrate the potential of the technique in guiding us towards a better understanding of important features of protein stability and folding, a preliminary condition of efficient protein design.

The work dealing with the stabilization of enzymatic catalysts is of direct industrial relevance: T4 lysozyme has been temperature-stabilized by the introduction of a disulfide bond;[37,67] the stability of the protease subtilisin has been improved with respect to oxidation, heat, and alkali,[68] and its substrate specificity has been modified by alteration of steric, hydrophobic, and electrostatic complementarity at the binding site.[68]

Site-directed mutagenesis studies on enzymology classics such as trypsin[69] and carboxypeptidase[70] have caused reassessment and refinement of our description of the catalytic mechanisms involved. For Tyr-tRNA synthetase, site-directed mutagenesis has led to a description of the mechanism of catalysis[71] at a level of detail which could not have been reached before the introduction of this technique.

Site-directed mutagenesis has also afforded new insights into protein structure and folding. Owing to the wealth of data recently published on this subject, we can only mention a few representative examples. It was shown that secondary-structure elements play an important role in the folding and structural stability of dihydrofolate reductase.[72] A lysine-to-leucine mutation in an amphipathic helix sequence of bovine growth hormone slows the folding process and causes increased precipitation in refolding experiments, pointing to the stabilization of an associated folding intermediate by the aggregation of amphiphilic helices.[73]

A proline-to-alanine mutation in thioredoxin suppresses the slowest phase of folding, demonstrating the essential role of the proline residue in the process.[74] Another study of proline isomerization with staphylococcal nuclease suggests that this phenomenon could be relevant to both the folded and unfolded states.[75] In this same model system, the changes observed upon mutation in the enthalpy and entropy of reversible denaturation have been explained by changes in the solvation and/or the conformation of the denatured state.[76]

Systematic changes in the sequence of the N-terminal domain of the phage λ repressor reveal the nonuniformity of structural information: while some positions along the sequence are critical, with changes capable of tipping the balance between folding and unfolding, others are relatively unimportant in a structural sense and a wide range of substitutions and modifications at these positions are possible.[77] Intensive studies with the T4-lysozyme system have led to significant insights into protein stability.[78] This protein has been found to be surprisingly tolerant of mutations made at its surface, while mutations that make it more temperature-sensitive occur in regions of rather low mobility and low solvent accessibility in the folded protein. Numerous replacements of a proline located at the C-terminus of a T4-lysozyme helix extend this helix without increasing protein stability.[79] This implies either that the intrahelical H-bonds are not more stable than protein–solvent H-bonds or that the resultant helix does not interact with the rest of the protein as well as it does in the wild-type enzyme.

Further experiments with T4 lysozyme[80] have permitted the experimental study of side-chain hydrophobicity in protein systems, making a comparison of the results with the various hydrophobicity scales for amino acid derivatives possible.[29] Another study of hydrophobic interactions has been initiated for the packing of amphiphilic α-helices and β-sheets with ribonuclease as a model.[81] Also, first experimental insights on the contribution of the helix dipole[35] to protein stability have been gained.[82] Finally, site-directed mutagenesis is leading us to a quantitative understanding of hydrogen bonding.[83] Selected aspects of this rapidly growing field have recently been reviewed.[84]

The important results just mentioned make it clear that protein de novo design will strongly benefit from a deeper

understanding of tertiary-structure formation emerging from this technique. Site-directed mutagenesis allows the study of exquisitely specific and systematic modifications in protein-size systems. However, the very complexity of the effects of the introduced change is often difficult to understand, analyze, and quantitate.

This suggests that synthetic peptide chemistry can be an approach of choice in helping us to understand the relevant forces in protein structure, by permitting us to study them in model systems of lower complexity. In this sense, protein engineering and de novo design by chemical methods represent *convergent* approaches for the construction of novel proteins (cf. Fig. 5).

3.2. Protein de novo Design: The Construction of a Predetermined Three-Dimensional Conformation from Elementary Building Blocks

The complexity of protein folding makes it difficult to synthesize a new sequence that will adopt the designed conformation (Fig. 5b). Is there any way to bypass the problem? The patterns and regularities, presented above, that are to be found in protein structure lend credit to this somewhat optimistic view. Examples include:

1. the *limited diversity* of structural topologies[9, 85] observed in natural proteins (Fig. 3);
2. the *degeneracy* of the folding code (many different sequences being able to adopt a given structure, Fig. 4);
3. improved knowledge of the relation between sequence and secondary structure (model studies with synthetic peptides, see below) and of the factors influencing protein folding and stability (site-directed mutagenesis, see Section 3.1).

The working strategy in protein de novo design is based on the current ideas of folding and structure already described. The tertiary structure of a protein is considered in terms of the assembly of secondary-structure[9, 85, 86] elements joined by turns,[22] bulges, loops,[87] or less ordered chain segments (Fig. 6).

Sequence blocks are designed that have a high propensity to adopt defined conformations based on experimentally or semiempirically determined conformational parameters of the amino acid residues; they are then assembled into small "globular tertiary structures", so-called *folding units*. Of course, both gene-technological and chemical approaches to de novo design of proteins are possible. However, attempts to design new proteins *directly* by the use of DNA recombinant methods have not to our knowledge been described in the literature. As mentioned above, the complexity of the protein-size systems that can be studied by gene-technological methods can often make clear-cut answers difficult to obtain.

In de novo design with chemical methods, the topic we will concentrate on for the remainder of this article, only small proteins seem to lie within reach due to practical limitations in synthesis and purification (see below). The folding of such short polypeptides into compact, globular structures is particularly unfavorable[4, 89] due to the following factors:

1. the high flexibility of linear polypeptides (small excluded volume effects);

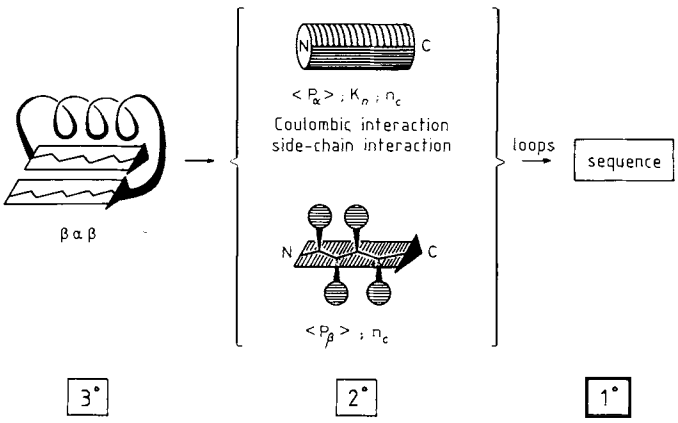

Fig. 6. The analysis of tertiary structure (3°) is based on current ideas on protein folding and topology, shown here for the case of a βαβ folding unit. The tertiary structure is considered in terms of assembly of secondary-structure (2°) elements joined by short peptide segments (turns, loops). Application of prediction parameters such as Chou–Fasman [47] propensities for an amino acid to be in an α-helix ($\langle P_\alpha \rangle$) or β-sheet ($\langle P_\beta \rangle$, the Zimm–Bragg [88] coefficient for helix elongation (K_n), or the experimentally determined critical chain lengths for α-helix or β-sheet formation (n_c), as well as consideration of favorable Coulombic and side-chain interactions [35], leads to the design of sequences (primary structure, 1°) with potential for adopting amphiphilic structures compatible with the chosen structural fold.

2. the small volume-to-surface ratio, which limits the number of possible hydrophobic interactions (S_{solv} in Fig. 1, the major driving force for folding);
3. the lack of the long-range interactions found in natural proteins, which contribute to the stabilization of secondary structures.

These detrimental factors can be compensated for by amphiphilic secondary-structure blocks,[4, 90] which can provide a contribution to intramolecular folding by interacting to form an energetically favorable structure with a proteinlike hydrophobic core and a hydrophilic surface (Fig. 7).

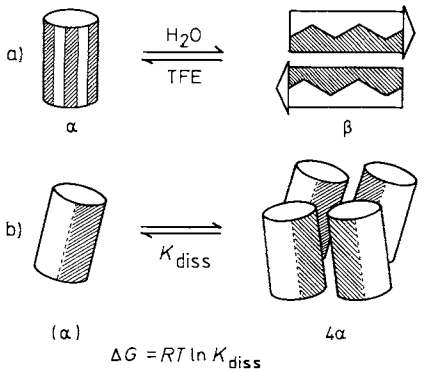

Fig. 7. The amphiphilicity of secondary-structure building blocks is the driving force for self-assembly. a) Amphiphilic sequences of the type $(A-B)_n$, where A and B denote hydrophobic (e.g., Leu, Val) and hydrophilic (e.g., Glu, Lys) amino acids, respectively, have a high tendency to associate in aqueous medium, possibly in a β-conformation-forming bilayer with hydrophobic core and hydrophilic surface [91]. 2,2,2-Trifluoroethanol (TFE) can shift the conformational equilibrium towards α-helix formation. b) Amphiphilic helices have a strong tendency to self-assemble into more or less defined multimeric complexes. For example, primary sequences of the type $(A\text{-}A\text{-}B\text{-}B)_n$ seem to have a tendency for preferentially forming four-helix-bundle (4α) structures. In one instance, the free energy of tetramerization (ΔG) has been estimated to be 20 kcal mol^{-1} for helices of medium size [92].

3.2.1. *Designing the Secondary-Structure Blocks*

Systematic experimental studies with synthetic model peptides have proved to be very useful in the design of peptide blocks, providing a sound experimental alternative to the prediction and energy calculation algorithms. This is of particular relevance for protein design, the ultimate goal of structure prediction and design being the experimental confirmation of its adequacy.

The first systematic studies on defined peptide models were initiated more than 20 years ago with homooligopeptides. These yielded valuable experimental insights into the fundamental phenomenon of secondary-structure formation, in particular the critical chain length for α-helix and β-sheet formation as a function of amino acid residue and experimental conditions.[93, 94] These studies were expanded by the use of "host–guest" cooligopeptides.[95] This idea originates from macrocyclic organic chemistry[96] and was successfully applied to polypeptides for the derivation of the Zimm–Bragg σ,s parameters[91] describing the α-helix-to-random-coil transition.[97] By measuring the influence of a given residue (guest) on the conformational properties of the homopolymer host peptide, the helical potential of the guest residue could be indirectly determined. Detailed studies of secondary structure succeeded through the synthesis of well-defined synthetic host–guest peptides; eventually, the importance of neighboring-residue effects on the stability of β-sheet and α-helix structures could be assessed for the first time.[94, 98–101] The tentative, experimental conformational propensities that could be defined for many amino acids showed that the conformational preferences derived from a statistical analysis of protein X-ray structures do not necessarily apply to small peptides, as has also been noted by other workers.[102] A valuable "spin-off" of these results was the study of the impact of conformation-dependent physicochemical features of peptides on peptide synthesis.[98, 99, 103]

Homooligopeptides and cooligopeptides, of course, are a far cry from the peptide sequences encountered in natural proteins, but ideally lend themselves to the design of secondary-structure blocks with predetermined properties such as block length and hydrophobicity. With regard to protein design, amphiphilic structures are of particular importance.

The synthesis of cooligopeptides consisting of alternating hydrophilic and hydrophobic amino acids with chain lengths between 6 and 10 residues allowed the assessment of the *β-structure-forming* potential[100] of such amphiphilic structures (Table 2). Solubility problems, which usually make a conformational analysis difficult, could be avoided by the use of polyethylene glycol as a solubilizing C-terminal protecting group.[104] In this manner, β-structure-forming oligopeptides, whose insolubility is notorious,[105] could also be studied in aqueous solution. As can be seen from Table 2, the critical chain length for β-structure formation (6–11 residues) is in the range observed for β-structure blocks in proteins.[106] The surprisingly high propensity of this type of amphiphilic peptide for β-structure formation in aqueous solution (comparable to the behavior of hydrophobic homooligopeptides[107]) is best explained by the formation of a peptide bilayer-sheet[91] (Fig. 7), in which the hydrophilic residues are oriented towards the aqueous phase. Sequence-specific effects, as well as sufficient overall hydrophobicity

Table 2. Experimentally determined critical number of dipeptide units n_c necessary for β-structure formation in amphiphilic oligopeptides of different sequences (PEG = polyethylene glycol as C-terminal protecting group).

Peptide	Solvent	n_c	Chain length
$(Ile\text{-}Gln)_n$-Ile-Gly-PEG	H_2O	2	6
$(Ile\text{-}Thr)_n$-Gly-OH	CF_3CH_2OH	3	7
$(Thr\text{-}Val)_n$-Gly-OH	H_2O	4	9
$(Ser\text{-}Leu)_n$-Gly-PEG	H_2O	4	9
$(Ser\text{-}Ala)_n$-Ser-PEG	H_2O	>4	> 9
$(Val\text{-}Lys)_n$-Gly-PEG	H_2O, pH 10	>5	>11

(in order to increase the solvation entropy S_{solv}) also seem to influence the stability of this type of structure.[108]

The critical chain length for *α-helix* formation[110] was found to be in the range of 10–15 residues in helix-supporting media like 2,2,2-trifluoroethanol, depending on the helix-forming potential of the individual residues. A dramatic reduction of the critical chain length can be achieved by the incorporation of α-aminoisobutyric acid (Aib), which has a strong helix-inducing effect.[113] The large number of helical Aib-containing peptides described[110–112] allow some guidelines for the design of helical building blocks to be formulated. The helix stability increases with increasing number of Aib residues; i.e., the critical chain length is reduced. Incorporation of Aib should allow the formation of an amphiphilic α-helix when the sequence is displayed in the helical-wheel representation (cf. Fig. 2). As shown in Figure 8, an amphiphilic Aib-containing peptide of 18 residues

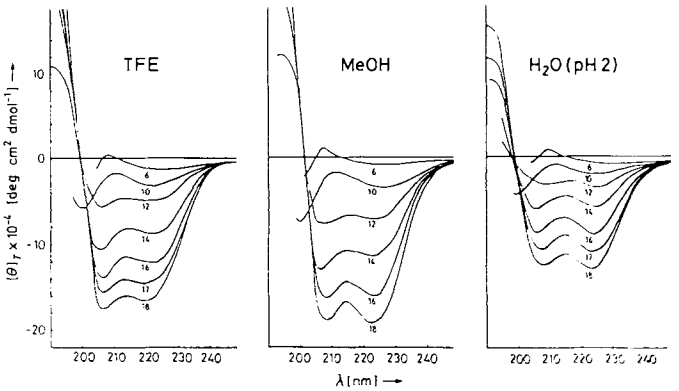

Fig. 8. Chain-length dependence of α-helix formation for the sequence Pro-Glu-[Ala-Aib-Glu-Aib]$_{1-4}$ [109], as found by circular dichroism (CD), in trifluoroethanol, methanol, and water (pH 2) at a concentration of 1 mg mL^{-1}. It is possible to estimate the helical content of the peptide from the total ellipticities $[\theta]_T$ shown on the ordinate axis. Introduction of the non-proteinogenic amino acid α-aminobutyric acid (Aib) favors helix formation [109–112]. The numbers under the curves give the number of amino acid esters per peptide. For example, the sequence with 12 amino acid residues is: Pro-Glu-(Ala-Aib-Glu-Aib)$_2$-Ala-Aib.

displays a well-developed helix in a number of solvents and particularly in water;[109–112] replacement of Aib by Ala in such peptides leads to a significant reduction in the helical content of the peptide.[112] Recently, a number of elegant strategies for the synthesis of α-methyl derivatives of amino acids have been described,[114] so that it is to be expected that these will become valuable building blocks for the conformational stabilization of helical sequences.[115]

3.2.2. *What Can Peptides Teach Us about Proteins and vice versa?*

In view of the notable advances in the conformational analysis of natural peptides made possible by modern spectroscopic techniques of NMR,[116] CD,[117] and IR,[118] the experimental study and optimization of secondary-structure formation is no longer a fundamental problem. Indeed, conformational aspects of peptides have become the focus of much interest in their relation to biological function. In turn, this has led to some general insights into the role and occurrence of secondary structure in natural proteins. Detailed studies on the conditions for secondary-structure formation in "natural" sequences[35, 119] have already caused an unanticipated expansion of the Zimm–Bragg theory of helix formation,[120] since the experimentally observed helical content in these short peptides is significantly higher than predicted by theory. This supports models of protein folding where secondary structures form early on during folding.[23, 24] Very recently, synthetic peptide models have been used to study protein folding pathways.[121]

Synthetic peptide models may also be used to try to mimic certain properties of macromolecular systems (e.g., protein surfaces). In such instances, the flexibility of a peptide can be deliberately reduced by the introduction of some kind of restriction (chemical or physicochemical) in its conformational space. Along with the pioneering studies of *E. T. Kaiser* with amphiphilic helical peptide hormones and toxins,[90] representative examples have included experiments with peptides for calmodulin binding,[122] zinc-binding peptides with zinc-finger conformation,[123] protein ion-channel models,[124] receptor mimics,[125] DNA-binding peptides,[126] and antigenic peptides with conformational features of protein-immunogen epitopes.[127]

Model peptides will continue to be useful in the future for the design of polypeptides of defined tertiary structure, and perhaps, ultimately, for the prediction of structure from sequence. They may also prove helpful in correlating physicochemical properties with sequence and sequence with conformation. The main hurdle in de novo design does not reside in the formation of secondary structure itself, but rather in the assembly of secondary structures to a tertiary structure. The experimental gap between secondary and tertiary structure will be a most important aspect of research in the field of peptide and protein structure.

3.2.3. *From Secondary to Tertiary Structure: The Long Journey of "de novo" Designed Proteins from the Computer Screen to the Test-tube.*

Significantly, experimental feedback at this higher structural level has been sparse until now, if one considers the few attempts in this direction that have been described in the literature. Examples include a 34-residue ββα peptide designed to bind nucleic acids,[128] a four-stranded antiparallel β-pleated sheet that binds DDT,[129, 130] a synthetic model of tropomyosin designed to form a two-stranded α-helical structure (coiled coils),[131] a study of repeating peptides designed to adopt a cross β-conformation,[132] two folding units with βαβ packing arrangement of 38- and 35-residue length,[133] and the chemical synthesis of a 66-residue protein with antiparallel β-structure ("betabellin").[134, 135] In what seems to be the most successful achievement to date, a four-helix bundle was assembled step by step. First, it could be shown that amphiphilic helical sequences associated predominantly to a tetramer in aqueous solution.[136] The chemical synthesis of the corresponding dimer[92] (a 35-mer consisting of two helices linked by a turn) resulted in increased stability of the four-helix bundle formed by self-association. Finally, the physicochemical and conformational properties of the designed proteins were used to design and synthesize by recombinant DNA techniques a single-chain four-helix-bundle protein.[137, 138] Preliminary results indicate that the postulated four-helix bundle is indeed formed. However, it must be noted that in the absence of X-ray structure or detailed NMR studies for any of the "artificial proteins" described, it has not yet been possible to bring unequivocal proof for the designed structures.

In our view, the paucity of published research in this area reflects the unfavorable solution properties of designed peptides. This gives rise to a twofold problem: the insolubility of fully protected, growing peptide chains causes difficulties during synthesis, and the deprotected, unfolded peptide product tends to aggregate and so to be insoluble as well. The propensity for intermolecular aggregation—as a competing process to intramolecular folding—seems to be a central, intrinsic problem in the design of artificial proteins. This is actually something to be expected if one considers the energetic contributions to protein stability (Fig. 1, Table 1) and their consequences for de novo design.

1. In order to fold in a globular structure, a polypeptide chain must be hydrophobic enough so that the *entropy of solvation*, S_{solv}, gained upon folding more than compensates for the loss of chain entropy, S_{chain} (Table 1).
2. In order to *reduce the chain entropy*, S_{chain}, of the unfolded state (i.e., to "destabilize" it), as well as to "seed" folding, the secondary-structure blocks must be partially folded even in the absence of long-range interactions. Strictly amphipathic α-helices and β-sheets may be used to achieve this. On the other hand, the pronounced amphiphilicity in the unfolded block makes these molecules sensitive to *intermolecular aggregation*.

Clearly, an adequate balance between hydrophobicity and hydrophilicity of the target molecule is very difficult to achieve. Of course, this "two-step" strategy of first designing secondary-structure blocks and then connecting them by loops and turns to obtain folding units may very well turn out to be too gross an approximation of folding pathways. A better understanding of the importance of loops and turns for structure and folding[92, 137, 138] could bring some improvements. In any case, the "perfect" design ("overdesign"[135]) of three-dimensional conformations is presently neither sufficient nor adequate to compensate for our still imperfect knowledge of folding mechanisms. Here lie "big open spaces" for research in protein design.

These difficulties do not exclude the occasional "single hit", as the examples cited above can testify. But one main question for future, *rational* protein design will be: Can we, following a *general* strategy, design proteins of defined three-dimensional conformation in a first step and introduce functional properties into these structures in a second step?

In this regard, it is our conviction that synthetic chemistry has novel and important contributions to make to some of the most basic problems of de novo design. Before we engage in a discussion of protein design with "chemical tools", we first take a critical look at the craft of the peptide chemist, the chemical synthesis of peptides and proteins.

4. Chemical Peptide and Protein Synthesis: Art or Handicraft?

The chemical synthesis of peptides reflects an effort which spans over a century. To attempt an exhaustive overview would be an affront to the contributors who would inevitably be passed over in the process. Rather, we will try to discuss the achievements, problems, and prospects in the field relevant to protein design and refer the interested reader to leading monographs[139-141] and recent symposia reports[142] for more comprehensive background information.

Peptide synthesis appears to have become routine. First, peptide synthesis can be performed with the help of fully automated "synthesizers" which deliver primary sequences of up to 50 amino acids in a short time and on a variable scale. Second, DNA recombinant techniques allow, in principle, the synthesis of any amino acid sequence; even large-scale production has been made possible in a few instances.[6] In view of this situation, one is tempted to conclude that peptide and protein synthesis no longer are subjects for scientific investigation. In fact, there is no doubt that the progress and achievements in peptide synthesis, mainly stimulated by *Merrifield*'s method of solid-phase synthesis[143] and, more recently, by DNA recombinant methods applied to peptide synthesis,[5,6,123,130,137,138,144,145] have overshadowed some unsolved and longstanding problems in peptide and protein chemistry. In spite of the success of these synthetic methods, there is no unique, generally applicable procedure for building up a peptide or a protein. As shown in Table 3, every method has its characteristic scope and limitations. The ultimate use of the synthetic product must determine the synthetic strategy.

It is indisputable that the advent of solid-phase peptide synthesis[143] has helped chemical synthesis to become an important tool in the study of this class of biopolymers.[147] However, owing to the great expectations held for future achievements in peptide and protein chemistry, it is perhaps appropriate to pause and reconsider its possibilities and its limitations in order to evaluate the kind of answers we can expect in the future. In 1971, *E. Wünsch*[160] summarized the achievements of peptide chemistry at the time. Classical peptide chemistry in solution had already reached its golden age. The methods for amino acid protection, activation, and coupling and for peptide purification and analysis constituted an impressive body of knowledge. By contrast, some fundamental limitations of solid-phase peptide synthesis, which was in its eighth year of existence, were becoming evident, which *Wünsch* described as the "inborn errors" ("Geburtsfehler") of the solid-phase method:

1. the absolute necessity of quantitative coupling in each step due to the impossibility of purification of intermediates;
2. the large excess of *N*-protected amino acid derivatives necessary to ensure quantitative coupling;
3. the hazardous effect of side reactions that can occur during amino acid activation, coupling, and deprotection stages due to the impossibility of intermediate purification;
4. the critical analytical controls for quantitative coupling (which also are chemical reactions) are submitted to the same limitations as the coupling reaction itself;

Table 3. Comparison of the different methods in use today for peptide and protein synthesis (AA = amino acid).

Method	Main features	Advantages	Shortcomings	References[a]
Synthesis in solution [b]	< 100 AA residues	purification of intermediates; high purity	know-how; time-intensive; solubility problems	[139*, 146]
Solid-phase synthesis [b]	< 50 AA residues (although > 100 often attempted)	simple, fast screening, automatic	purification problems; analytical controls	[147*, 148*, 92, 129, 133, 149, 150]
Condensation of fragments obtained by solid-phase synthesis [b]	< 100 AA residues	use of purified fragments	low solubility and yield; racemization	[151]
Polyethylene glycol-supported synthesis [b]	< 30 AA residues	solubilization; homogeneous reaction conditions	difficult automation; isolation of peptide	[104*, 133]
Semisynthesis [b]	protein fragments, proteins	minimal protection	optimization; no routine	[152*, 153]
Enzymatic synthesis [b]	AA's → proteins	selectivity, no racemization aqueous media, solubility	optimization; no routine	[154*, 155]
Recombinant techniques [c]	DNA protein-size	"nature pure" "endless supply"	gene expression, product isolation, gene product renaturation	[5*, 6*, 144*, 123, 130, 137, 138, 145, 156]

[c] Genetic methods, limited to natural sequences.

5. the solubility problems of protected amino acid derivatives; swelling problems of the peptide resin due to aggregation effects during chain elongation and the related problems of hindered reactant diffusion;
6. the often harsh deprotection conditions after completion of synthesis.

Have we made progress in resolving these problems? There have been a number of important methodological improvements. For example, we now have a better knowledge of side-chain protection chemistry and possess better methods for anchoring peptides on polymeric supports.[148] The side reactions that occur during coupling and deprotection of the different protecting groups are now better known.[161] An important renewal occurred with the introduction of an alternative synthetic strategy to the acid-labile Boc/Bzl standard combination for main/side-chain protection, namely, the milder base-labile Fmoc/*t*Bu combination[162] for which new polymer supports have been developed.[163] But the decisive impulse for the enormous expansion of automated peptide synthesis has probably been due to advances in purification procedures, notably reverse-phase HPLC. Unfortunately, it is perhaps just the unanticipated usefulness of synthetic peptides in modern biology[164] (and hence the increased popularity of the solid-phase method despite the major shortcomings listed above) that has made more research in the methodology somewhat unattractive.

Indeed, it should not be forgotten that there are some pending problems in chemical peptide synthesis, such as the impact of conformational effects on solvation properties and coupling kinetics. Systematic studies in our laboratory on secondary structure formation in solution and on polymer-bound peptides showed that conformational transitions during chain elongation (e.g., from random-coil to β-sheet conformation) may result in a dramatic reduction in the rate of the coupling step.[98, 99] Since we still know little about secondary-structure formation of fully protected peptides, we can make only limited predictions on the influence of these conformational effects on the course of synthesis.[98, 99, 103] Each peptide displays some characteristic properties and is therefore a unique, complex entity. This is the reason why there can be no general standard procedure for peptide synthesis.

What are the perspectives for chemical peptide and protein synthesis? Can it establish itself as a valuable complement, or even alternative, to DNA recombinant techniques? Clearly, the incorporation of nonproteinogenic amino acids and unnatural building blocks remains the privilege of the chemist and represents an increasingly valuable asset in modern drug design, as well as in investigations on peptide and protein conformation, structure–activitiy relationships, or macromolecular recognition.

Perhaps the most fascinating prospect of chemical synthesis of peptides and proteins is offered by de novo design of proteins, a research area still very much in its infancy. The efficient and reliable synthesis of even small protein domains (folding units of 50–100 residues) will require in most cases the combination of different synthetic strategies. Methods involving the condensation of fully protected fragments either in solution or on the insoluble support (see Table 3 for references) are now finding increasing popularity. In the long term, the combined use of the chemical and biochemical techniques presented in Table 3 will be essential for a full exploitation of the potential of synthesis for the construction of new proteins (Fig. 9).

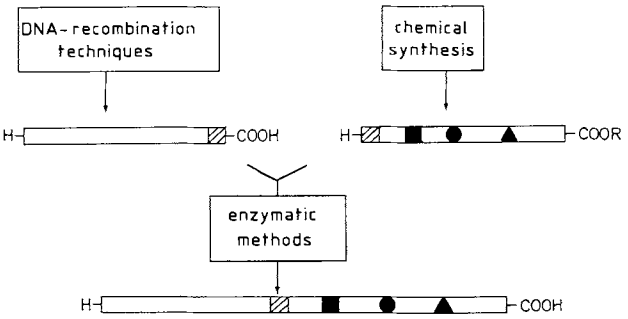

Fig. 9. A hypothetical scheme illustrating the potential of the combination of different methods for the synthesis of proteins. A polypeptide fragment produced by DNA recombination techniques (left) is coupled enzymatically (minimal side-chain protection) to a chemically synthesized fragment (right) containing non-proteinogenic amino acids, mimetics, or spectroscopic probes (solid symbols).

In this respect, synthesis itself does not seem to constitute the most difficult problem along the way. Indeed, one might even consider the fundamental synthetic problems to be essentially solved, since the tools of gene technology make it in principle possible to build up any amino acid sequence, and the chemical methods of peptide and protein synthesis, invaluable for their unlimited potential for structural modification, are more restricted by the necessary time and know-how expense than by the methodology itself.

5. The Use of Chemical Tools in Protein Design

The major question for protein de novo design lies in the search for polypeptide sequences that fold in a certain three-dimensional conformation, rather than in the chemical establishment of the sequence. However, the chances for solving this "folding problem" in the near future are low. The results of protein engineering have shown just how complex a relation there is between the primary sequence and tertiary structure in natural proteins. Indeed, it seems almost hopeless to try to get a grasp of the patterns of evolutionary selection and optimization in order to derive some general rules for the construction of new proteins.

In this context, the question as to whether linear polypeptide chains have the most suitable structural features to form globular structures seems justified. Although this can only be a mere speculation, it might be that Mother Nature had no other choice. Once the ribosomal synthesis "plant" yielding linear polypeptides from genetic information in linear form had been developed, she had to "learn", in an evolutionary process of optimization, how to fold sequences into biologically useful conformations. Along these lines, a newly formulated hypothesis[137] proposes that protein sequences have evolved not only to fold into unique three-dimensional conformations, but also to exclude alternative conformations. Could this be a very exclusive and unusual property of natural proteins? The fact that the number of proteins occur-

ring in nature only represents a vanishingly small percentage of all the possible polypeptide sequences is in support of this idea.

Can the chemist circumvent the long and difficult pathway of evolution by making use of the synthetic tools at his disposal?[89] Is it possible to construct peptidic architectures with a higher propensity for folding into a globular conformation than linear polypeptides? The construction of peptide chains with an *unnatural connectivity* (for example, branched structures, Fig. 10) could represent an example of this. Surprisingly, peptide chemists involved in protein design have made little use of what may be their most powerful tool.

Fig. 10. Strategies for protein de novo design. The construction of tertiary structures from secondary-structure elements can occur by two different approaches, as shown here for a four-helix-bundle protein. In order to reach the designed tetrameric structure (middle, see Fig. 7b), which arises through self-association of the amphiphilic helix blocks, the helices may be linked by loops to yield a polypeptide chain (left, see [138]) with the linear connectivity found in natural proteins. In contrast, the same packing arrangement may be reached by grafting the individual helix blocks onto a carrier molecule (template). These template-assembled synthetic proteins (TASP) have an unnatural, branched connectivity of the peptide chains, and thus are accessible only by synthetic chemistry.

A number of research groups have been involved in the construction of artificial proteinlike structures. We proposed that peptide blocks be assembled on a multifunctional carrier molecule, for example in the construction of enzyme models.[4, 165] A similar concept was applied by *Heidemann* et al.[166] for the study of triple-helix formation in collagen models. The use of multifunctional linkers in the construction of a β-barrel-forming protein ("betabellin") by solid-phase synthesis[134, 135, 167] and, very recently, of a disulfide bridge cross-link for the design of parallel two-stranded coiled coils in tropomyosin models[168] have also been reported.

5.1. Template-Assembled Synthetic Proteins (TASP)

We have recently taken these ideas further into a general, novel strategy for the construction of proteinlike tertiary structures, in an attempt to merge the possibilities of synthetic organic chemistry with the features of protein structure.[169] Amphiphilic secondary-structure-forming peptide blocks are fixed on a tailor-made template molecule, which directs the peptide chains into proteinlike packing arrangements. Accordingly, we termed the resulting macromolecules template-assembled synthetic proteins (TASP, Fig. 11).

Thus, rather than being linked by loops to a linear polypeptide chain, secondary-structure-forming peptide blocks are assembled by covalent attachment to a carrier molecule, resulting in a branched structure (Fig. 10). This difference in connectivity of the chain has important consequences with respect to the adoption of a globular conformation: while the linear assembly of β-sheet and α-helical peptide blocks necessitates a specific folding process to achieve formation of the postulated folding unit, the branched molecule can more directly adopt a compact structure. The multifunctional carrier molecule plays a determining role in this respect by (1) favoring intramolecular interactions between the covalently fixed peptide blocks and (2) predetermining the packing topology of the TASP molecule (Fig. 12) by the number, type, and spatial arrangement of its functional groups (peptide block "anchoring points"). Hence, the carrier is not merely a structure-stabilizing cross-link but can be considered as a *template* for the onset of the three-dimensional conformation of the designed molecule.

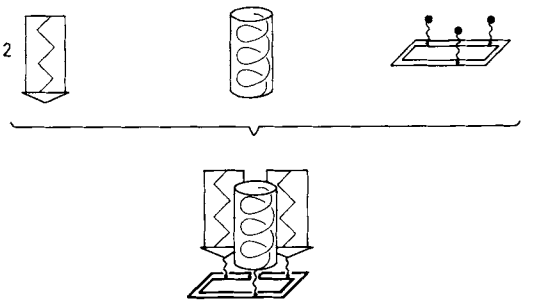

Fig. 11. Template-assembled synthetic proteins (TASP) as a new concept for the construction of artificial proteins. Amphiphilic secondary-structure-forming peptide blocks (α-helices, β-sheets) are grafted onto an adequate carrier molecule (template). In this example, two β-sheet blocks and an α-helix block are assembled on a trifunctional template molecule to a βαβ-like folding unit.

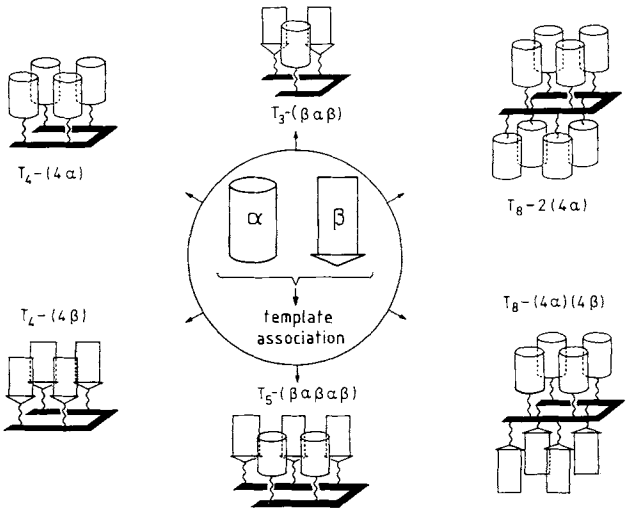

Fig. 12. Schematic representation of different possible packing arrangements (topologies) in TASP molecules (T_n, T = template molecule, n = number of attachment sites on T; α, β, amphiphilic peptide blocks with tendency for helix (α) and β-sheet (β) secondary-structure formation). The number, nature, and spatial orientation of the attachment sites in the carrier molecule predetermine the topological features of the TASP molecule and thus act as a *template* for the folding of the molecule in the predetermined structure.

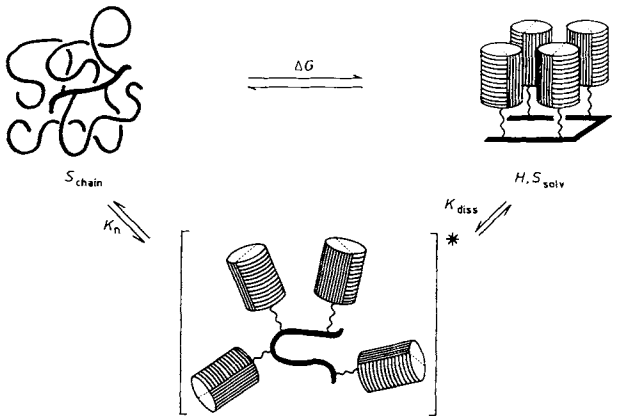
5.2. TASP Molecules: The Chemist's Escape from the Folding Problem?

The conceptual simplicity of this strategy enables us to discuss some fundamental aspects of the energetics (with respect to folding) of TASP molecules. The template molecule induces intramolecular interactions between covalently bound peptide chains, so that the unfolded molecule has a

high coil density (to be compared, perhaps, to the "collapsed state" of a linear polypeptide chain). The amphiphilicity of the secondary structure that forms under adequate (renaturing) conditions leads to the self-association of these template-bound peptides to a compact structure ("intramolecular collapse") as hydrophobic interactions are optimized. Hence, the formation of secondary structures (nucleation step) becomes the rate-limiting step for folding (Fig. 13).



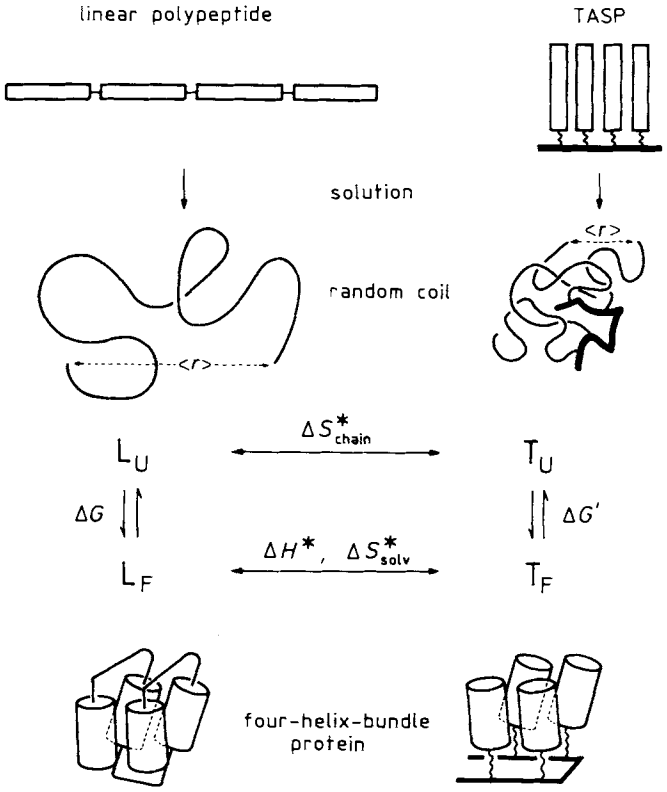


Fig. 13. Hypothetical folding pathway of TASP molecules, shown for the four-helix-bundle arrangement. The unordered, branched "compact" molecule is thought to reach a globular-like state through a rate-limiting nucleation step in which secondary structure is formed and the chain entropy, S_{chain}, decreases in comparison to the unfolded state. This process can be described by the Zimm–Bragg equation $K_n = \sigma s^n$ (σ and s denote the helix nucleation and growth parameters, respectively, for every amino acid; n, chain length [88]). In the intramolecular association of amphiphilic peptide blocks, increase in the solvation entropy, S_{solv}, (release of associated water molecules in the formation of a hydrophobic core), determines the greater part of the driving force for folding. The free energy of tetramerization may be described by $K_{diss} = [\alpha]^4/[4\alpha]$. In the hypothetical intermediate, indicated by an asterisk, intramolecular interactions are forced by the covalent bonds between peptide blocks and template, so that the propensity of intermolecular aggregation typical of amphiphilic peptide chains is significantly reduced.

Owing to this simple mechanism of "folding", the assembly of secondary-structure blocks in TASP molecules should not encounter the substantial energy barriers postulated for the folding pathway of linear peptide chains (Fig. 14).

From an experimental point of view, the phenomenon of self-association is very important. The short-range interactions induced by the template between amphiphilic peptides make intermolecular aggregation less likely than intramolecular contacts. This means that the susceptibility towards aggregation should be reduced in TASP molecules in comparison to linear polypeptides.

The branched structure of TASP molecules causes high volume density and therefore significant "excluded volume effects" in the random-coil state of the molecule. Consequently, the chain entropy (S_{chain}) of the "unfolded" state is decreased, resulting in a potentially larger value of ΔG_{F-U} (cf. Fig. 1).[89] A qualitative comparison (Fig. 14) of linear (L) and branched (T) polypeptides further illustrates this point. The destabilization of the unfolded state in branched molecules (supplying, ΔS^*_{chain}, Fig. 14) represents a source of increased thermodynamic stability (ΔG^*_{L-T}) for the folded TASP molecule (T_F) compared to the corresponding linear polypeptide (L_F) (provided the packing, and hence the enthalpies, H, and solvation entropies, S_{solv}, of the folded

$$\Delta G^*_{L-T} = \Delta G' - \Delta G \approx \Delta S^*_{chain}$$

Fig. 14. Schematic representation of thermodynamic aspects of the folding of linear (L) and branched (T) polypeptides. While the unordered (U) conformation of both molecules under poorly solvating conditions (near the so-called theta point) is exclusively determined by short-range interactions, extensive "excluded volume effects" [1] arise as a consequence of long-range interactions, when the chain enjoys good solvation. This can be expressed in terms of an increase of the end-to-end vector $\langle r \rangle$. Due to the higher coil density in the branched molecule, the number of accessible conformations is smaller than in the linear molecule, causing a decrease in the chain entropy, S_{chain}. This, in turn, leads to a destabilization of the unfolded state T_U of the branched molecule. Under the assumption that the intramolecular interactions in the folded state (F) are similar in both linear and branched molecules (i.e., $\Delta H^*, \Delta S^* \approx 0$), the branched molecule will be stabilized relative to the linear by a difference in free energy $\Delta G^*_{L-T} = \Delta S^*_{chain}$, as can be taken from the figure. TASP molecules should therefore be more stable thermodynamically than linear polypeptides of equivalent packing arrangement (here, a four-helix-bundle structure). This aspect of the energetics is of great importance with respect to subsequent modification of the structure in order, for example, to introduce functionality into the molecular structure.

molecules L_F and T_F are of comparable magnitude). Therefore, we predict that TASP molecules will be more stable thermodynamically than their linear counterparts. The energetic aspects of TASP molecules are of importance when considering the final goals of protein design, namely, the incorporation of functional properties in predetermined three-dimensional structures (Section 6).

5.3. The Design and Construction of TASP Molecules

The most noteworthy feature of the present approach is its application to the design of proteins having different packing arrangements (topologies) (cf. Fig. 12). The computer-assisted design of TASP molecules proceeds in four steps:

1. design of amphiphilic peptide blocks according to the rules of secondary-structure formation (Fig. 15a);

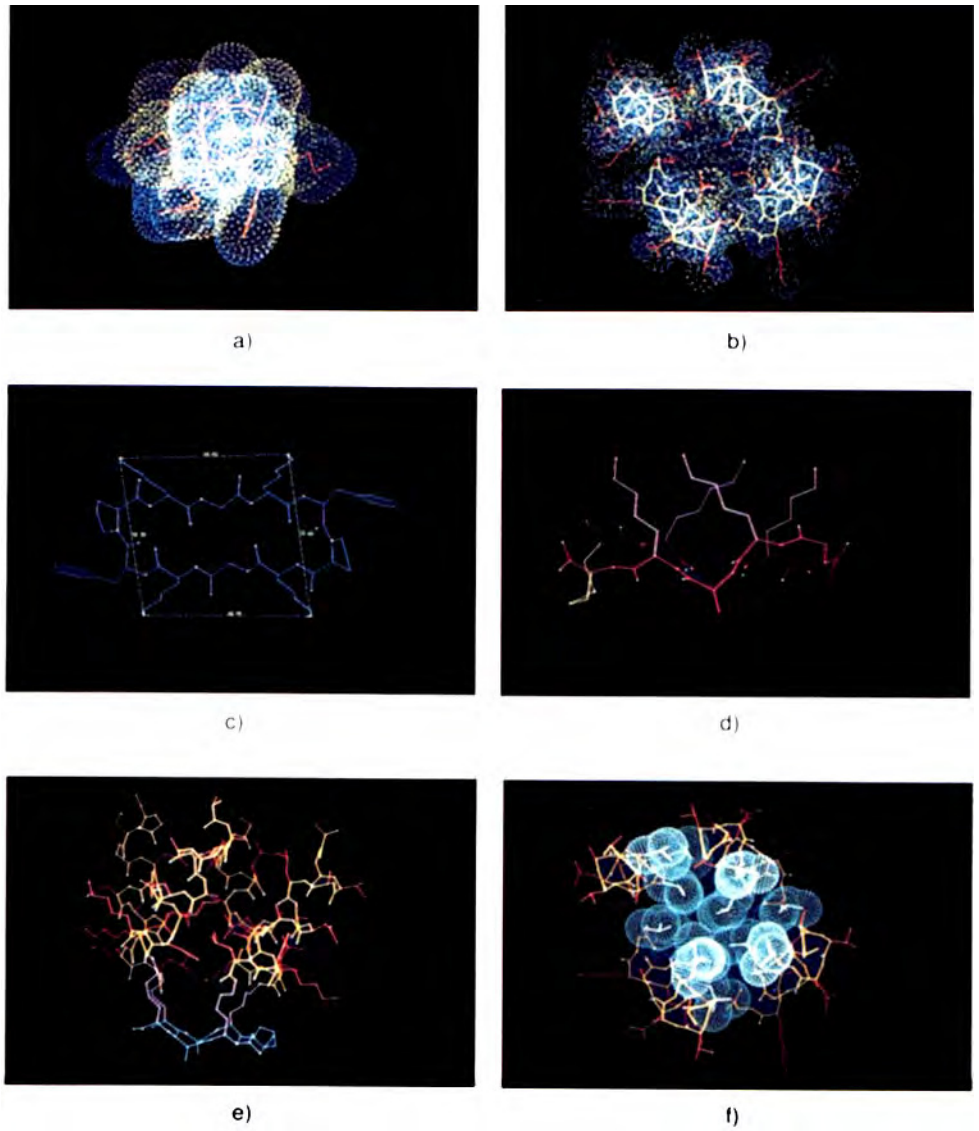

Fig. 15. TASP design by computer-assisted molecular modeling (using the "Roche interactive molecular graphic system" (RIMG) [170], taking a "four-helix-bundle" TASP as an example (T_4-(4α) in Fig. 12). a) The design of secondary-structure blocks. Computer-generated standard helix (seen from the end of the helix cylinder) for the sequence Glu-Ala-Leu-Glu-Lys-Ala-Leu-Lys-Glu-Ala-Leu-Ala-Lys-Leu (cf. Fig. 2). The dotted van der Waals surfaces of hydrophobic (yellow) and hydrophilic (blue) residue side chains highlight the amphiphilic nature of the sequence. b) "Self-association" of the helices into a four-helix-bundle arrangement, with the hydrophobic side chains (Leu) on the inside and the hydrophilic groups (Lys, Glu) on the outside surface. (c) Design of an adequate template: the cyclic decapeptide of sequence *cyclo*(-Pro-Lys-Ala-Lys-(D)Phe-)$_2$ (an analogue of gramicidine S [171]). The relative distance between ε-amino groups of the lysine side chains is about 10–11 Å (dotted square, yellow) in this energetically favored conformation (two antiparallel β-strands (Lys-Ala-Lys) joined by two type-II β-turns (D-Phe-Pro)). The tetrafunctional molecule is therefore ideally suited to act as a template in directing the formation of a four-helix-bundle structure (see Fig. 15e, f). d) Side view of the cyclic template molecule *cyclo*(-Cys-Lys-Ala-Lys-Pro-Gly-Lys-Ala-Lys-Cys-). Ring closure occurs through a disulfide bond (yellow) between the cysteines (peptide backbone red, lysine side chains magenta). e) Side view of a template-assembled four-helix-bundle protein [172]. The C-terminal carboxyls of the four helices (Fig. 15b) are linked to the four ε-amino groups of the template lysines by amide bond formation (the template is an open-chain variant of the one shown in Fig. 15d). While the template backbone is held in place, the lysine side chains (magenta) and the covalently bound helices (yellow and red) are left to undergo conformational relaxation, free rotation around all their bonds being allowed. This results in a strain-free, energetically favorable conformation. f) The same molecule as in Fig. 15e, seen in an end-on view, from the N-terminal end of the four-helix cylinder. The formation of a hydrophobic core in the inside of the four-helix bundle is emphasized by the van der Waals surfaces of the leucine side chains. The helix axes in this favorable conformation are tilted towards each other in a manner reminiscent of four-helix bundles in natural proteins (helix backbone in yellow, hydrophilic side chains in red).

2. self-association of the peptide blocks to multimer systems having predefined packing arrangements so that favorable interactions arise ("conformational relaxation") (Fig. 15b);
3. design of an adequate template and attachment of the peptide block assembly to the template functional groups (Fig. 15c and 15d);
4. conformational energy minimization of the template-assembled protein to obtain a modeled (hypothetical conformation of the TASP molecule (Fig. 15e and 15f).

In principle, any multifunctional molecule (e.g., cyclic peptides, peptides with conformational constraints, saccharides, and polycyclic, aliphatic, or aromatic systems) with adequate spatial arrangement of the attachment sites may serve as a template molecule (Fig. 16).

In our exploratory studies, we used oligopeptides as templates because the well-established orthogonal[173] main- and side-chain protection techniques of peptide chemistry provide the necessary flexibility for the synthesis of TASP molecules (Figs. 17, 18).

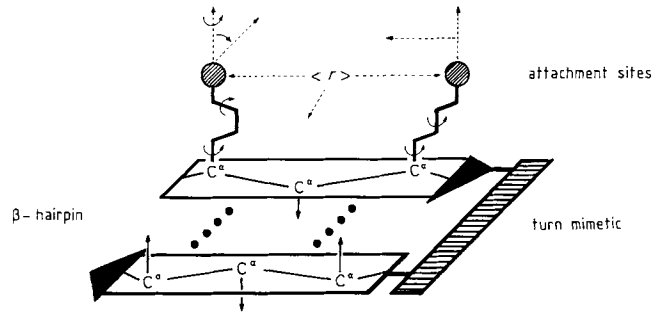

Fig. 16. Schematic representation of a template molecule for TASP design. On the right, incorporation of a turn mimetic [158] (here, a rigid bifunctional molecule matching the spatial requirements of a type-II β-turn) can stabilize the β-hairpin conformation required by design (see Fig. 15d). Rotational freedom around their C–C methylene bonds allow the lysine side chains to meet the requirements in average distances, $\langle r \rangle$, between the attachment sites (here the ε-amino groups of the lysines) suitable for the construction of TASP molecules with proteinlike packing arrangements.

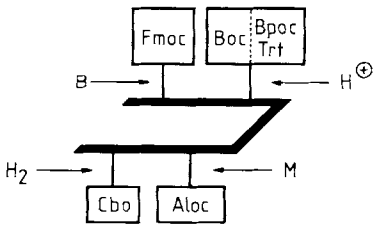

Fig. 17. The selective removal of one protecting group in the presence of many others (orthogonal protection[173]) is a prerequisite in order to fully exploit the potential of the TASP strategy. The protecting groups shown here as examples are Fmoc (9-fluorenylmethyloxycarbonyl), cleaved by base (B); Boc (*tert*-butyloxycarbonyl), Bpoc (biphenyl-*iso*-propyloxycarbonyl), and Trt (trityl), which are differentially sensitive to acids ($H^{\oplus}$); Cbo (benzyloxycarbonyl), cleaved by hydrogenation (H_2); and Aloc (allyloxycarbonyl), which can be cleaved by Pd^0 metal complexes (M). See also Figs. 18 and 19 for experimental examples.

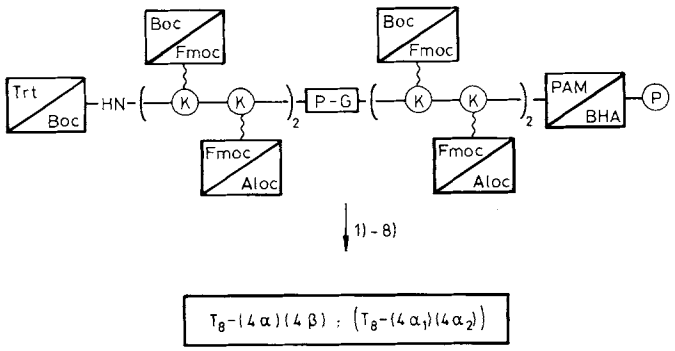

Fig. 18. Synthetic strategy for the synthesis of two-"domain" TASPs [174] of types T_8-(4α)(4β) and T_8-(4α_1)(4α_2) (Fig. 12). The template was assembled on a phenylacetamidomethyl (PAM) resin (P, cross-linked polystyrene) by stepwise addition of N^{α}-Trt (trityl) amino acids with N^{ε}-Fmoc (9-fluorenylmethyloxycarbonyl) and N^{ε}-Boc (*tert*-butyloxycarbonyl) side-chain protection of the lysine (K) ε-amino groups. In an alternative synthesis, the protecting-group combination N^{α}-Boc/N^{ε}-Fmoc/N^{ε}-Aloc (allyloxycarbonyl) was used on a benzhydrylamine (BHA) resin. Thus, as indicated, selective cleavage of the orthogonally protected ε-amino groups of the template lysines allows for the establishment of the two different "domains", 4α and 4β (see Fig. 24a) or 4α_1 and 4α_2. Steps: 1) Trt-(Boc) cleavage; 2) *N*-acylation; 3) Boc (Fmoc) cleavage; 4) 15(13) coupling cycles α(α_1); 5) Fmoc (Aloc) cleavage; 6) 9(15) coupling cycles β (α_2); 7) *N*-acyclation; 8) removal of protecting groups and cleavage from resin.

The model template shown in Fig. 15c is a cyclic decapeptide with two antiparallel β-sheet segments (Lys-Ala-Lys) linked by two β-turns, based on the gramicidin S structure.[171] Computer-assisted molecular modeling shows that the four ε-amino groups of the lysine side chains are properly spaced, in a low-energy conformation, for the construction of a four-helix-bundle tertiary structure (Fig. 15).

The construction of TASP molecules is achieved by the standard strategies of peptide synthesis (solution[139] and polymer-supported synthesis methods;[104, 148] an example is shown in Fig. 18). The applicability of the template approach is not restricted by synthetic considerations. Orthogonal protection techniques (Fig. 17), in combination with segment condensation strategies (Fig. 19), allow the chemical synthesis of a variety of TASP topologies. It is possible to link peptide blocks of different sequences and opposite orientation. For example, experimental evidence on the influence of the dipole as a function of the parallel or antiparallel arrangement of the chains[34] could be gained.

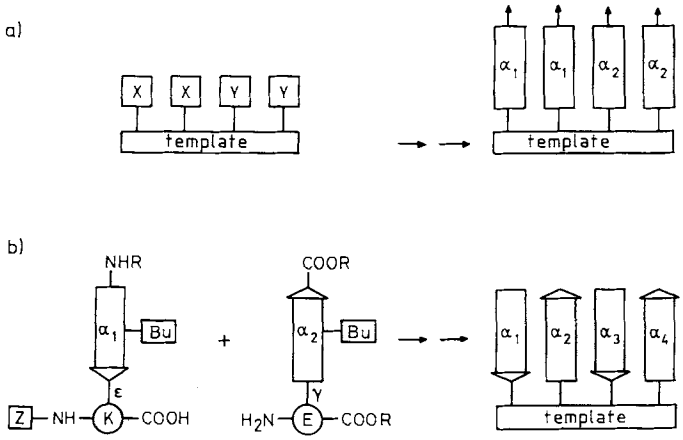

Fig. 19. Synthetic strategies in TASP design: the selective deprotection of protecting groups (see Figs. 17 and 18) allows for the synthesis of TASP molecules with secondary-structure blocks of different sequences. a) The *parallel* assembly of four-helices with two different sequences α_1 and α_2 after independent removal of the protecting groups X and Y, respectively. The synthesis can occur stepwise from the C-terminus or by fragment condensation. b) The block condensation of fully protected peptide sequences in solution allows the synthesis of TASPs with *antiparallel* arrangement of secondary-structure blocks (K, lysine; E, glutamic acid; Z-, Bu-, benzyloxycarbonyl and *tert*-butyl-based protecting groups, respectively).

Stepwise polymer-supported synthesis is the best strategy for rapid evaluation of the overall properties of a designed molecule, whereas segment condensation techniques in solution guarantee higher flexibility and of course better structural reliability (Fig. 19). Is is important to note that the establishment of the postulated tertiary structure only occurs after removal of all side-chain protecting groups at the end of the synthesis. Thus, the synthesis of TASP molecules does not suffer from any specific limitations in comparison to that of linear peptides.[98, 99, 103]

5.4. Properties of TASP Molecules

So far, we have described examples of TASP molecules with βαβ-,[175] 4α-,[172, 176] and 4α/4β-like topologies[174] (Fig. 12) following the methods described above (Fig. 20).

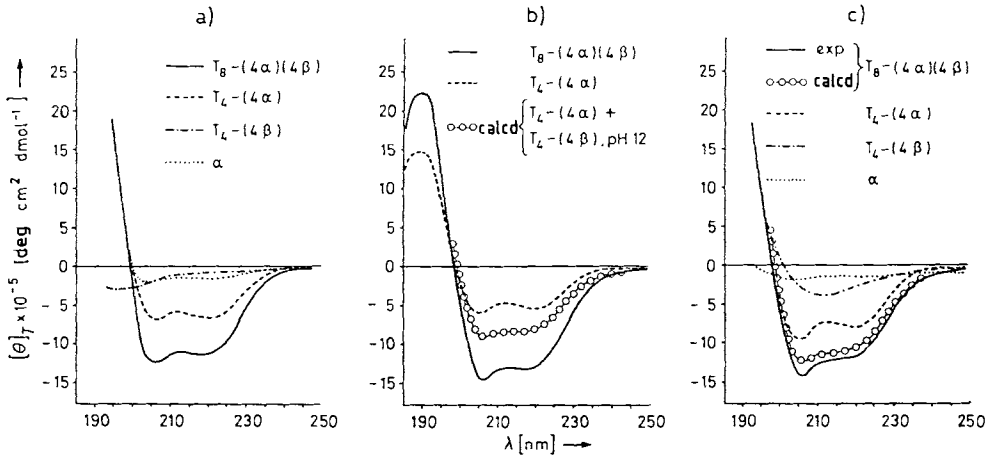

Fig. 20. CD spectra of T_8-(4α)(4β), a representative two-"domain" TASP in buffer at pH 5 (a), pH 7 (b), and pH 12 (c) at a concentration of 0.1 mM (taken from [174]). The sequences are: T_8: Ac-[Lys(α)-Lys(β)]$_2$-Pro-Gly-[Lys(β)-Lys(α)]$_2$-εCA-GlyOH (εCA = ε-amino caproic acid spacer). α: Ac-Glu-Ala-Leu-Glu-Lys-Ala-Leu-Lys-Glu-Ala-Leu-Ala-Leu-Ala-Lys-Leu-Gly-; β: Ac-[Val-Lys]$_4$-Gly-. The ellipticities of the two-"domain" TASP T_8-(4α)(4β) correspond to the experimentally determined values for the individual single "domains" T_4-(4α) and T_4-(4β) at pH 12; at pH 7, a considerable template-enhanced stabilization of the secondary structures is observed. Note that the single peptide block (α) does not show significant helix formation, pointing, again, to the structure-inducing effect of the template (see text).

These experimental studies already point to some characteristic properties of these molecules (Fig. 20), even if a more complete picture of their structural and dynamic properties can only be gained by further work, in particular detailed NMR studies.

1. TASP molecules show good solubility and occur as a rule as monomeric species in aqueous solution. With respect to the postulated structure and its hypothetical "folding mechanism", this finding is of great importance. Indeed, as already mentioned, the highly amphiphilic nature of the secondary-structure blocks explains their strong tendency for aggregation. This can be observed in linear amphiphilic polypeptides of similar size and amino acid composition (such as α-helix and β-sheet oligopeptide blocks joined by loops), where undirected interactions between the blocks often hinder the desired intramolecular folding. In contrast, the covalent grafting of these blocks to the template molecule leads to a forced spatial proximity of the amphiphilic peptide blocks, favoring intramolecular interactions. The intrinsic propensity for aggregation of such blocks can lead in the case of TASP molecules to the desired, compact monomeric species,[175] in which polar side chains point towards the solvent and impart good solubility to the TASP molecule.
2. Spectroscopic measurements (mostly CD and IR) show that the tendency for adopting secondary structure is higher in oligopeptides when they are template-associated. This "template-induced effect" is most striking when secondary-structure formation is observed at a chain length lower than the experimentally determined critical chain length of the same block on its own (Fig. 20).

These results can all be interpreted in terms of the model discussed above. The stabilization of amphiphilic secondary structures in TASP molecules is the consequence of interactions between neighboring peptide blocks on the template. In contrast to the situation met in "isolated" oligopeptides, the critical chain length for secondary structure formation in TASP molecules is comparable to the length of secondary-structure elements observed in natural globular proteins.[106] This stabilization of the blocks arises from the increase in solvation entropy due to release of associated water molecules to the solvent as a hydrophobic "core" is formed between them (through the "hydrophobic interaction"[28]), a process favored by the fixation of the peptide blocks on the template.

Current studies on the denaturation of TASP molecules confirm the above model. They suggest that TASP molecules could show higher stability than their linear polypeptide counterparts with a natural fold (see Section 5.1 and Fig. 14).

The main challenge now is to obtain information on the structural features of TASP molecules in the greatest possible detail. Efforts towards this goal are under way in our laboratory. We are presently synthesizing TASP molecules using different methods of conventional peptide synthesis in solution (Fig. 19) in an attempt to obtain crystallizable products.

6. Prospects and Challenges in Protein Design by Chemical Methods

As we learn an increasing amount about the redesign of secondary structural regions in molecules where tertiary structure is all important, we are moving closer to the time when it will be possible to put together what we have learned about building molecules in regions outside the active site with the work which we have done on the active sites so that we can consider the construction of whole enzymatic systems with new structural features and catalytic functions.

E. T. Kaiser[179]

TASP molecules are a new class of macromolecules, exhibiting structural features of both synthetic polymers (branched chains, graft polymers) and globular proteins (peptide building blocks, hydrophobic core, hydrophilic sur-

face). TASP design is a domain of synthetic organic chemistry. The possibilities for structural variation are limited only by the chemist's intuition (Fig. 21).

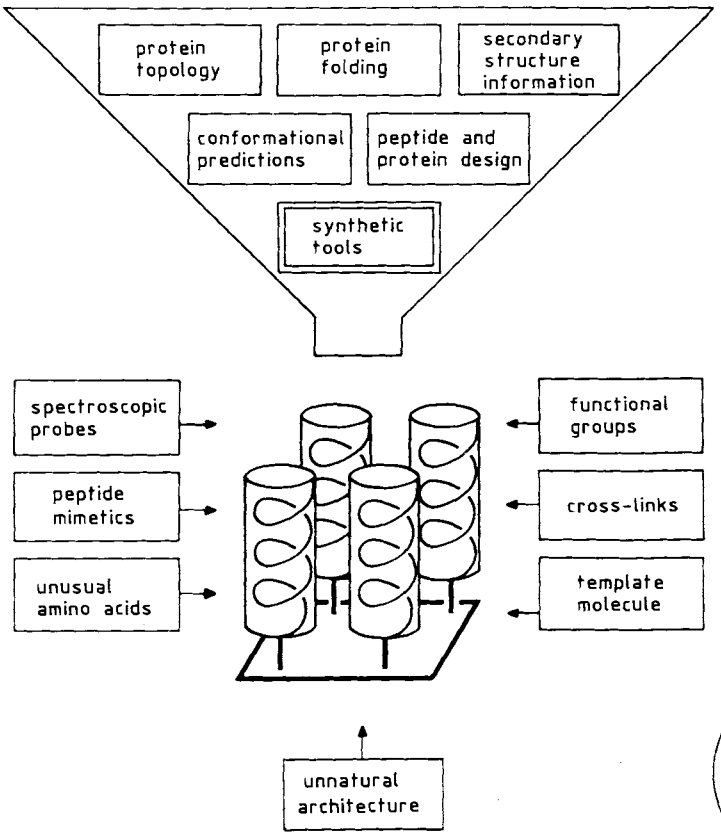

Fig. 21. Nature's rules and chemist's tools [89]: the unification of our knowledge about structure and function of natural proteins with the synthetic tools of the chemist possibly opens new perspectives for the resolution of the folding problem in the construction of new proteins. TASP molecules represent a new generation of macromolecules that exhibit features of both natural proteins (globular structure) and synthetic polymers (unnatural architecture).

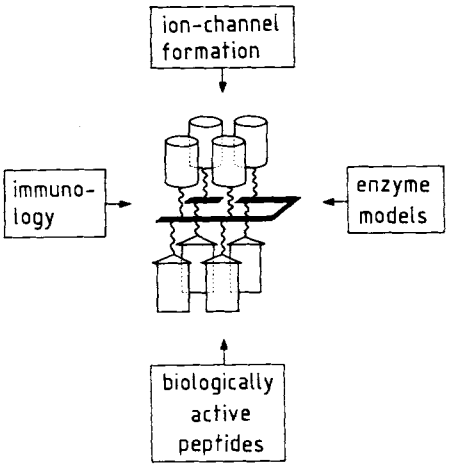

Fig. 22. Application of TASP. From the design of a tertiary structure to function: Once access to molecules with predetermined three-dimensional conformation has been gained, the incorporation of functional properties is the next step in protein design. (see also Figs. 23 and 24). *Sasaki* and *Kaiser* recently reported a molecule that was designed according to these principles and exhibited catalytic activity [176].

On the basis of the results presented in Section 5, we cannot resist proposing that the present approach may represent a generally applicable strategy for the construction of artificial proteins of a variety of structural types, thereby offering a surprising possible solution to the central problem in today's protein de novo design: the troublesome folding process of a linear polypeptide chain into a globular structure can be bypassed by the construction of molecules with an "inbuilt" driving force for folding ("template effect"). Once in a position to design molecules with a predetermined three-dimensional conformation, we will have made the critical step towards the incorporation of function in proteinlike macromolecules (Fig. 22). In this respect, it is encouraging to note that the energetics of such systems (see above, Fig. 14) indicate that TASP molecules may be more tolerant to structure modification than the corresponding linear polypeptides.

Happily enough, interdisciplinary approaches using the methods of both chemistry and molecular biology to study the fascinating questions of modern molecular biology have recently met with success. It seems worthwhile to consider attempts towards tailor-made protein models such as catalytic antibodies,[176, 177] "hybrid enzymes",[178] and enzymes with altered active sites[179] from the perspective of TASP design.

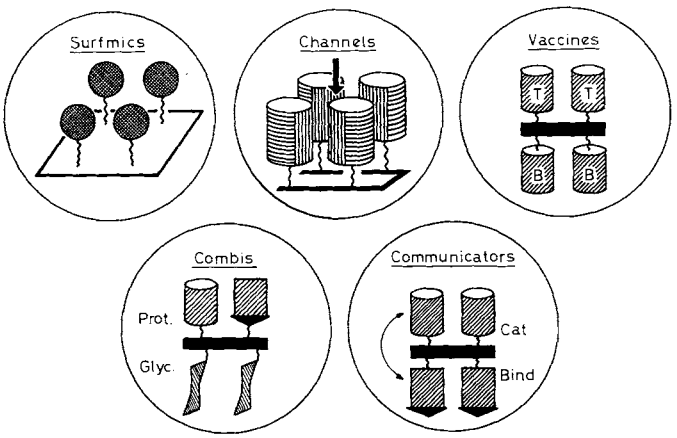

Fig. 23. Perspectives of protein design using the TASP approach. The "reconstruction" of receptor, catalytic, or antigenic sites from a natural protein or enzyme to a tailor-made TASP molecule is of great interest. "Surfmics" would be surface mimetics in which side chains of functionally relevant surface residues are assembled on a template matching the spatial requirements of the active site of the protein. "Communicators" could be molecules such as two-"domain" TASPs (for example, with both a catalytic and a binding site) and "vaccines" would be molecules containing both B and T cell epitopes. "Channels" of well-defined size could emerge from putting various numbers of amphiphilic, membrane-spanning helices (with formation of a hydrophilic core and a hydrophobic surface [184]) on a specially designed template. A "glycoprotein-like" molecule might be obtained by combining peptidic and glycosidic elements on a template ("combis") following the principles of TASP synthesis described in the text. Exploratory studies on the design and synthesis of such "functional" TASP molecules are in progress in our laboratory.

The schematically drawn TASP molecules shown in Figure 23 point to such possibilities. The design and synthesis of such systems will be a platform for interdisciplinary research in the near future. Perhaps the computer-created molecules shown in Figure 24 will not remain on the screen much longer.

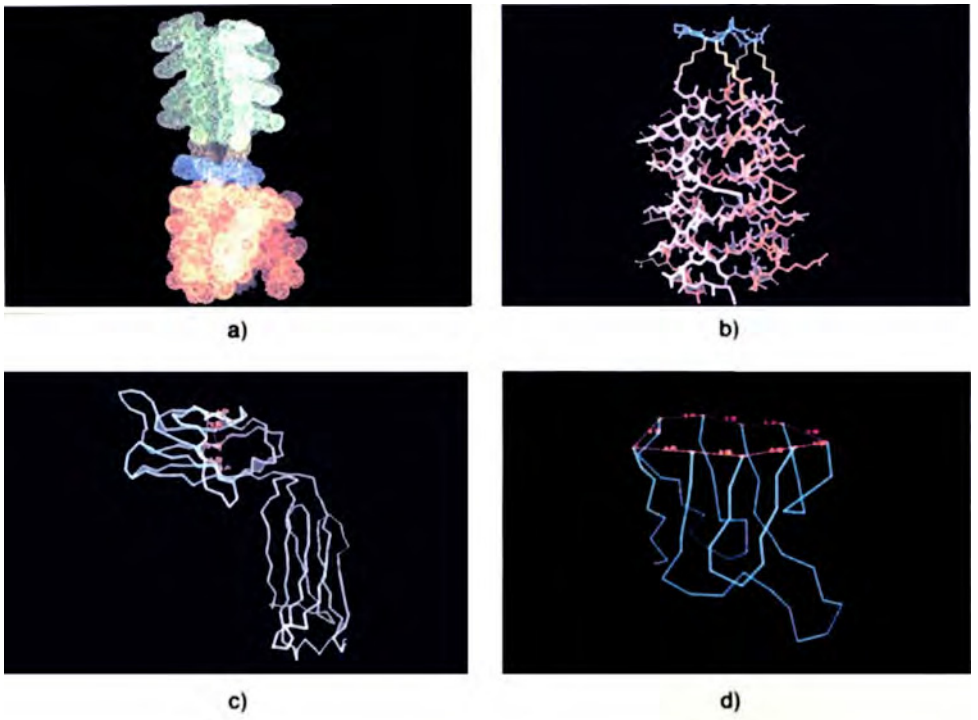

Fig. 24. Possible applications of the TASP approach for the design of functional artificial proteins. To date, most of these examples exist only on the computer screens they were designed on. Fortunately, we were able to take some pictures before the structures disappeared. We are now actively trying to find them again in the test-tube. a) Side view of a template-assembled "two-domain" protein model [174] (T_8-(4α)(4β) in Fig. 12) (template in blue, lysine side chains in yellow, four-helix-bundle structure in red, 4β structure in green). The independent functionalization of the two folding units opens a variety of possibilities (see Figs. 22 and 23). b) Template-assembled model of the ROP protein [180], a biologically relevant TASP molecule. The four-helix bundle protein ROP, which consists of a helix-turn-helix dimer was modeled so as to allow a covalent fixation of the four helices (white, red, magenta, ocher) on a tetrafunctional template (blue, lysine side chains in yellow). After conformational relaxation of the template, the TASP ROP model showed a strain-free three-dimensional conformation with a packing arrangement similar to that of the natural structure [181]. c) TASP molecules with binding properties: The variable domain of the phosphocholine-binding immunoglobulin McPC 603 Fab fragment [182] (left) was cut (red line) from the rest of the protein and grafted onto a tailor-made template (right). The synthetic accessibility of protein subdomains following this ideas [183] could extend the template concept still further.

The authors gratefully acknowledge the financial support of the Swiss National Science Foundation, the Hoffmann-La Roche Research Foundation, and the CIBA Foundation. S. V. thanks the "Stiftung der schweizerischen chemischen Industrie" for a doctoral grant. M. M. would like to express his thanks to all cited co-workers past and present, as well as to Priv.-Doz. Dr. K. Müller and Dr. K. Gubernator, Hoffmann-La Roche, Basel, for their essential collaboration in the molecular modeling work. We thank R. Bielmann for drawing the figures.

Chemical Modifications of Biopolymers by Quinones and Quinone Methides

By Martin G. Peter*

Many quinones and their precursors, which are transformed oxidatively into quinones and/or quinone methides, are important natural products. As secondary metabolites, they frequently possess antibiotic and cytotoxic activities, in addition to acting sometimes as pathogens. Several plants and animals, especially insects, use quinonoid substances for defense, often with spectacular results. On the macromolecular level, quinone methides have a key role in the plant kingdom in lignin biosynthesis; the biosynthesis of melanoproteins exemplifies the reactions of *o*-quinones in the animal kingdom. In insects, cross-linking of structural proteins through quinones and quinone methides results in the construction of the sclerotized exoskeleton. For mankind, the reactivity of quinones in biological systems has far-reaching consequences of pharmaceutical, toxicological, and technical relevance. The examples in this review show that a common principle underlies these reactions, namely, the chemical modification of biopolymers. As demonstrated particularly well in a more detailed discussion of the chemical principles of insect cuticle sclerotization, several major and important new results have emerged from the development and applications of modern methods of sample separation and from solid-state NMR spectroscopy.

1. Introduction

Quinones, quinone methides, and often their phenolic precursors are widely distributed in nature. A large number of phenolic and quinonoid compounds occur as secondary metabolites,[1] and numerous examples are given in reviews on natural products of plants,[2, 3] marine organisms,[4] fungi,[5] and insects.[6] This review covers the irreversible reactions of quinonoids in biochemical environments. Thus, quinonoids that participate in reversible primary metabolic processes, such as electron transport, are not described here. The term "quinonoids" is meant to include *o*- and *p*-quinones in addition to any reactive intermediates that can form upon oxidation of a diphenol.

Quinonoids often show pronounced biological activities, such as antibiotic, cytotoxic, or allergenic actions, and they may serve the organism producing them as a weapon for defense. The biological activity of many quinonoids consists ultimately in chemical modification and denaturation of biopolymers, thereby damaging the exposed organism. When we look, however, at the organism that produces phenols together with the appropriate oxidative enzymes, interaction of quinones or quinone methides with macromolecules is usually beneficial, as exemplified by the biosynthesis of melanoproteins in animals, lignopolysaccharides in plants, and sclerotins in insects. One example of a useful technical application of protein–quinone interactions is the tanning of animal hides in the production of leather.

However, undesired and even deleterious results of protein–quinone interactions are exemplified by the toxicity of certain xenobiotic phenolic substances, which can eventually cause allergies, liver damage, or cancer. Aberrant metabolism of phenolic compounds may also have pathological consequences. Another unfavorable effect of quinonoid substances is the decrease in the nutritional value of vegetable and fruit foodstuffs in the presence of plant phenols or tannins.

An understanding of the chemical principles of quinone reactions in biological systems is of great importance, not only for finding new technical applications or developing methods for interfering to our benefit with undesired and deleterious effects of quinones, but also for gaining insight into fundamental processes of life.

Our views on the reactions of quinonoids in biological systems are mostly derived from the results of studies in preparative or mechanistic organic chemistry. A large variety of diphenols and oxidants as well as quinones and nucleophiles have been employed in organic synthesis for the construction of quinone derivatives, and the great preparative value of the various reactions is amply documented in several excellent reviews.[7–10]

In contrast, studies on the reactions of quinonoid compounds in biological systems have rarely led to an unambiguous structural characterization of the reaction products. One of the reasons is immediately obvious to the preparative organic chemist: the primary reaction products are unstable themselves. They readily undergo secondary reactions which are difficult, if not impossible, to control in an aqueous environment. Some ideas on the pathways of secondary reactions can be derived from the structures of new, unexpected products that again have been discovered during synthetic or mechanistic studies, and several examples will be discussed in this review. Besides this more classical approach, many significant discoveries have emerged from the availability of advanced methods of product separation and modern spectroscopic techniques including ESR as well as high-field and solid-state NMR spectroscopy.

An evaluation of our present knowledge on the reactions of quinones and quinone methides in biological systems will be useful for a critical assessment of the molecular aspects of

their biochemical behavior and may also help to clarify some of the remaining ambiguities. The first part of this review provides a general description of the reactions of quinones, including a few selected examples of obvious biological relevance. A brief review on polyphenol–biopolymer complexes is then followed by a critical evaluation of the structural and biological aspects of chemical modification of proteins, polysaccharides, and nucleic acids. Radical reactions are not treated separately. They will be mentioned when there is evidence for the participation of radical intermediates in biopolymer modifications. Finally, the mechanisms of insect cuticle sclerotization will be discussed as a particularly puzzling example of the fascinating roles of quinone–biopolymer interactions in nature.

2. General Principles

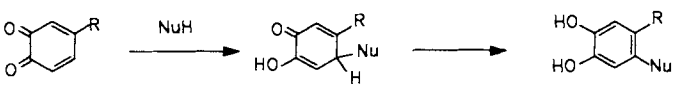
2.1. Biological Oxidation of Phenols

The enzyme-catalyzed oxidations that lead to quinones and quinone methides from 4-alkyl 1,2-diphenols and 4-alkyl monophenols are summarized in Scheme 1.[11,12] 2-Alkyl 1,4-diphenols react analogously.

Scheme 1. For Ⓐ, Ⓑ, Ⓒ see text.

The enzymes involved in the primary oxidation step are of three principal types. Tyrosinase (monophenol monooxygenase; EC 1.14.18.1) hydroxylates a monophenol in the *o*-position. This enzyme also has diphenoloxidase activity, transforming an *o*-diphenol into an *o*-quinone by two-electron transfer. Semiquinone radical anions are detectable by ESR spectroscopy in aqueous solution when the oxidation is performed in the presence of diamagnetic metal ions.[13,14] These radicals are generated by comproportionation of an *o*-quinone and excess *o*-diphenol.[13,15] Both *o*- and *p*-diphenols are also oxidized by diphenoloxidases of the laccase type, which catalyze one-electron transfers. Tautomerization of the alkylquinones leads to the corresponding quinone methides (Scheme 1, pathway Ⓐ).

Peroxidase/H_2O_2-catalyzed oxidation of monophenols yields phenoxyl radicals in a one-electron transfer. When the side chain of a 4-alkyl monophenol is unsaturated and in conjugation with the phenoxyl radical, a *p*-quinone methide radical is one of the possible resonance structures. When the side chain is saturated, radical abstraction is required for quinone methide formation (Scheme 1; pathway Ⓑ). Peroxidase/H_2O_2 oxidation of diphenols leads to semiquinone radicals, and the corresponding radical anions of *o*-diphenols have been observed by ESR spectroscopy, again as complexes with divalent metal ions.[13,16] Semiquinone radicals can also form through one-electron reductions of quinones by several flavoenzymes, such as NADPH-cytochrome P-450 reductase. Reduction of oxygen by semiquinone radicals yields superoxide anion radicals.[17] A quinone-mediated shuttle of electrons from superoxide to hydrogen peroxide then results in the formation of hydroxyl radicals.[18] A description of the mechanisms of protein modification by the highly cytotoxic and mutagenic oxygen radicals[19] is beyond the scope of this review.



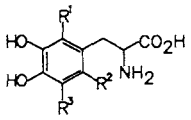
Finally, quinone methides may form through oxidative introduction of a leaving group into the side chain and subsequent elimination of HL (Scheme 1; pathway Ⓒ). This reaction sequence is important, for example, in the metabolism of certain monophenolic xenobiotics. It starts usually with a hydroxylation mediated by cytochrome P-450.

Quinones can form under physiological conditions also in nonenzymatic reactions. Autooxidation of a phenolic compound leads to a phenoxyl or to a semiquinone radical that can add molecular oxygen. The quinol hydroperoxide then decays to the corresponding quinone.[20,21]

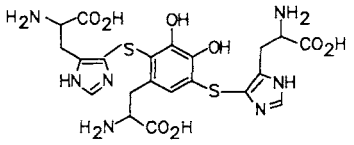
Quinones and quinone methides are electrophilic species that will react with a variety of nucleophiles by vinylogous addition. Phenoxyl and semiquinone radicals, besides being intermediates in quinone methide formation, are likely to react further by phenolic coupling. Both nucleophilic addition and oxidative phenolic coupling are also fundamental processes in the polymerization of phenolic compounds.

2.2. Nucleophilic Addition

The vinylogous, Michael-type addition of a nucleophile to the α,β-unsaturated carbonyl system of a quinone is a well-known reaction (Scheme 2).



Scheme 2. R = H, alkyl.

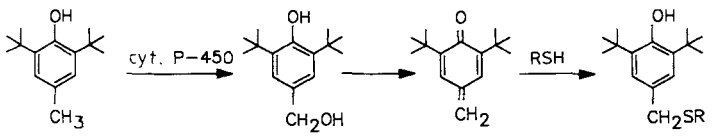


The primary addition product is a substituted *o*-diphenol which, in the presence of an oxidant (e.g., excess quinone) will yield a substituted *o*-quinone. Depending on the reaction conditions and the type of nucleophile, further reactions may follow; if R = H, for example, a second Michael addition followed by an oxidation may lead to a bis-substituted quinone. According to the terminology that has been created by *Wanzlick*,[7] such reaction sequences are classified as A-D-A-D, where A and D mean addition and dehydrogenation, respectively. The overall pathway applies to *p*-quinones and to quinone methides in analogous ways.

The addition of nucleophiles to quinones and quinone methides occurs in biological systems usually as a spontaneous, nonenzymatic reaction. The nucleophiles, available from functional groups of polypeptides, polysaccharides, and nucleic acids, are thiols, thioethers, primary and secondary amines, and hydroxyl groups. The biological relevance of Scheme 2 is illustrated in the following with a few examples of reactions which have led to structurally defined products.

Oxidation of Dopa by means of tyrosinase in the presence of cysteine yields a mixture of the 1,4- and 1,6-thiol-addition products **1–4**,[22] which are important intermediates in phaeomelanin biosynthesis (see Section 3). The main component (74%) is the 1,6-addition product 5-cysteinyl-Dopa **1**. However, *Kalyanamaran* et al.[23] observed by ESR spectroscopy only the 1,4-addition product of cysteine to 4-methyl-*o*-benzoquinone, generated by periodate oxidation of 4-methylcatechol at pH 3.0 in the presence of $Zn^{2\oplus}$ ions. Vinylogous thiol addition to 2-methyl-1,4-naphthoquinone (menadione) leads to semiquinone radical anions even in the absence of spin-stabilizing metal ions.[24]

1–4

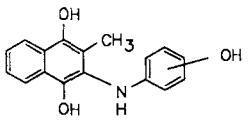


5

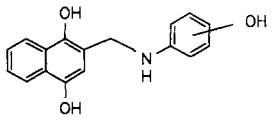
1: $R^1 = R^2 = H$, $R^3 = SCH_2CH(NH_3^{\oplus})COO^{\ominus}$
2: $R^1 = R^3 = H$, $R^2 = SCH_2CH(NH_3^{\oplus})COO^{\ominus}$
3: $R^1 = SCH_2CH(NH_3^{\oplus})COO^{\ominus}$, $R^2 = R^3 = H$
4: $R^1 = R^3 = SCH_2CH(NH_3^{\oplus})COO^{\ominus}$, $R^2 = H$

Biogenetically related to bis(cysteinyl)-Dopa **4** is the naturally occurring adenochromine **5**, which presumably is a precursor of adenochromes, the iron-binding pigments of *Octopus vulgaris*. Degradation of adenochrome revealed one of the components to be the unusual amino acid 5-mercaptohistidine linked to a Dopa moiety.[25]

Thiols may also add to quinone methides, as has been demonstrated conclusively through isolation of the adduct **6**, formed by addition of cysteine to the quinone methide generated from 2,6-di-*tert*-butyl-4-methylphenol (Scheme 3; cf. Scheme 1, pathway Ⓒ).[26]



6

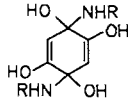


Scheme 3.

Primary and secondary amines yield, in general, addition products according to Scheme 2 (for reviews, see Refs. [7, 9, 10]). Owing to the basicity of the amino nitrogen, the reaction is strongly pH dependent. Reaction of aniline ($pK_a = 4.6$) with *o*-benzoquinone in glacial acetic acid to form the bis-addition product was first observed in 1913.[27] The same product is also obtained in aqueous buffer at physiological pH when catechol is oxidized in situ by means of tyrosinase in the presence of aniline.[28, 29] Semiquinone radical anions are generated in the presence of $Zn^{2\oplus}$ during addition of aniline to 4-methyl-*o*-benzoquinone.[23]

The addition of an aromatic amine to an *o*-quinone methide in tautomeric equilibrium with the corresponding *p*-quinone is exemplified in Scheme 4 (cf. Scheme 1, pathway Ⓐ). The reaction of 3- or 4-hydroxyaminophenol with menadione in methanol/acetic acid leads to the classical Michael-type addition product **7** and to the *o*-quinone methide adduct **8**.[30]

7

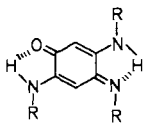


8

Scheme 4.

Under aprotic conditions, aliphatic amines ($pK_a = 9-11$) will also lead to A-D-A-D products in appreciable yields. A classical example is the preparation of 4,5-bis(dimethylamino)-1,2-benzoquinone in dry acetone.[31] Some related 1,4-addition products from the tyrosinase-catalyzed oxidation of 4-methylcatechol in the presence of β-alanine methyl ester have been isolated, along with Schiff bases, in rather low yields and characterized by spectroscopic methods.[32]

The *o*-quinone formed in the oxidation of dopamine can cyclize to 2,3-dihydroindole-5,6-diol. Determination of the relative rates of intramolecular and intermolecular additions of amines and thiols to electrochemically generated dopamine-quinone in aqueous buffer at pH 7.4[33] has revealed that the SH group of cysteine reacts ca. two times faster than that of glutathione and ca. 200 times faster than aniline, the addition of which is ca. ten times faster than the intramolecular cyclization of dopamine. This again is faster than the addition of α-amino groups of amino acids by a factor of about two. The preference for intramolecular cyclization as compared to intermolecular addition has also been demonstrated by conducting the oxidation of Dopa in the presence of *p*-benzoquinone.[34]



A fundamentally different reaction of amines is the nucleophilic 1,2 addition to a quinonoid carbonyl group. A recent example is the formation of the tetrols **9** from several biogenic amines and 2,5-dihydroxy-*p*-benzoquinone in ethanolic solution.[35] Under the same conditions, histamine adds with the primary amino rather than with the imidazole nitrogen. With *p*-benzoquinone, the usual 2,5-disubstituted products are generated through the A-D-A-D sequence.

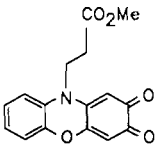
9

R = $PhCH_2CH_2$, $p-HO-C_6H_4CH_2CH_2$, 4-imidazolyl-CH_2CH_2

The 1,2-carbonyl addition is usually followed by dehydration to the corresponding Schiff base. Thus, the A-D-A-D condensation product from aniline and *o*-benzoquinone has long been known.[27–29] The corresponding products **10** have been obtained from *o*-quinones and aliphatic amines in methanol[36] or glacial acetic acid,[32] although the reaction mixtures are extremely complex and the yields are sometimes exceedingly low.

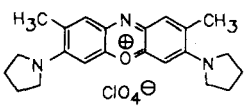
10

R = Me, Et, *n*Bu [36], $CH_2CH_2COOCH_3$ [32]



Another way of generating Schiff bases starts with vinylogous 1,4 addition to, for example, an *o*-quinone, followed by reoxidation and tautomerization to the 2-hydroxy-*p*-quinone imine. Schiff base formation with aliphatic amines, particularly α-amino acids, may be followed by Strecker degradation, that is, rearrangement and ultimately deamination.

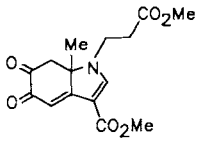
2.3. Formation of Heterocyclic Compounds



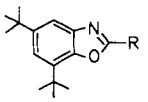
A considerable variety of heterocyclic compounds are known to arise from secondary transformations of the initial quinone and quinone methide addition products. The pertinent literature from the fields of biology and biochemistry documents that, with the exception of the intermediates in melanin biosynthesis (see Section 3), little attention has usually been paid to the idea that biopolymer modification may eventually also occur in such secondary reactions. Since we cannot a priori exclude the possibility that secondary reactions are biologically important, it is appropriate to present a few examples of the formation of heterocyclic derivatives from quinonoid compounds in reactions of possible biological relevance (for a review, see Ref. [37]).

Reaction of *p*-benzoquinone with *o*-aminophenol in glacial acetic acid yields 2-aminophenoxazin-3-one, in addition to higher-condensed heterocyclic ring systems.[38] 2-Aminophenoxazin-3-one is also generated upon oxidation of *o*-aminophenol mediated by oxyhemoglobin in human erythrocytes.[39] The phenoxazine ring system occurs in nature as a structural element in the actinomycin antibiotics and in certain insect pigments, the ommochromes. Their biomimetic preparation has been studied along with the enzymatic reactions involved in their biosynthesis (for reviews, see Refs. [7, 40, 41]). 2-Aminothiophenols yield the corresponding phenothiazinones in an analogous reaction.[42, 43]

Phenoxazinones may also form during the reaction of an *o*-quinone with an aliphatic amine. Compound **11** was isolated in low yield after oxidation of catechol in the presence of β-alanine methyl ester in glacial acetic acid.[32] An intermediate in this reaction is obviously the corresponding *N*-alkyl-*o*-aminophenol, which adds in an A-D-A-D sequence to a second molecule of *o*-benzoquinone. Similarly, the phenoxazine salt **12** is prepared from various α-amino acids and 5-methyl-4-pyrrolidino-1,2-benzoquinone in aqueous methanol.[44] In this case, the nitrogen atom is most likely derived from the α-amino acid, which loses its side chain in a Strecker-type degradation sequence.

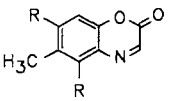


11

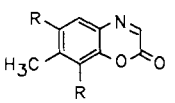


12

The rather unusual indole derivative **13** is formed in small amounts during oxidation of 4-methylcatechol in the presence of β-alanine methyl ester in acetic acid.[45] Apparently, Nenitzescu-type addition of the enamine that forms by a dehydrogenation of β-alanine methyl ester and nitrogen addition of another amino ester to the *o*-quinone in the usual 1,4 fashion is followed by cyclization and deamination.

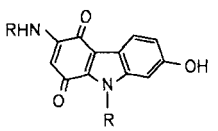


13



14

More highly substituted *o*-quinones, such as 3,5-di-*tert*-butyl-*o*-benzoquinone, react with primary amines of the type $R\text{-}CH_2\text{-}NH_2$ to yield stable addition/condensation products, such as the benzoxazole **14**.[46] In this case, Schiff base formation is followed by rearrangement and intramolecular oxidative cyclization. Likewise, the reaction of 3,5-di-*tert*-butyl-*o*-benzoquinone with α-amino acid esters leads to the corresponding benzoxazinones.[47] Addition-condensation of glycine ethyl ester with 4-methyl-*o*-quinone yields a product that has been described as either **15** or **16**.[48]



15

16

R = $NHCH_2COOEt$

Dimerization of 2-alkylamino-*p*-benzoquinones leads to the carbazole derivatives **17**, which have been found after reactions of primary alkylamines[49] or glycine ethyl ester[48] with *p*-benzoquinone.

17

R = alkyl, CH_2COOEt

3. On the Structures of Polyphenol–Biopolymer Complexes

Polyphenolic biopolymers are in general highly complex materials and our knowledge of their structures is rather fragmentary. A tremendous amount of work involving model reactions, degradation, and biosynthetic studies has led to recognition of partial structures from which overall constitutions have been derived. Though it is not the intention of this article to review the chemistry of polyphenolic polymers, it may be useful to recall first some basic facts before considering the interactions of these polymers with other biopolymers. An overview on the principal classes of polyphenolic polymers is given in Table 1.

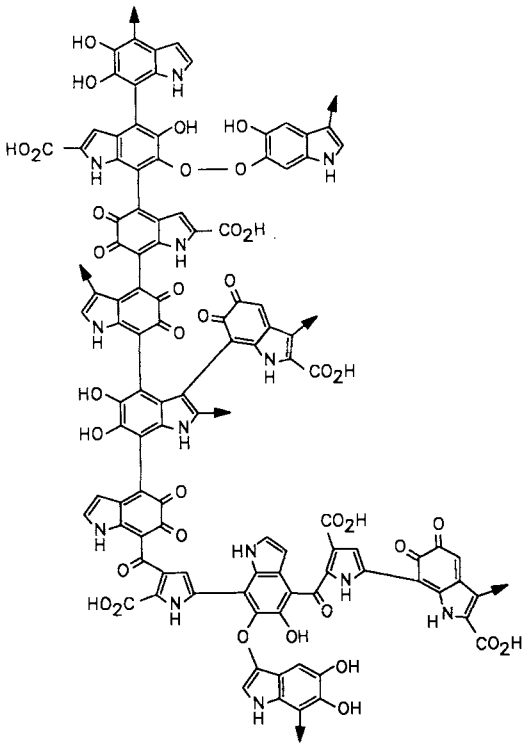


Table 1. Classes of polyphenolic biopolymers

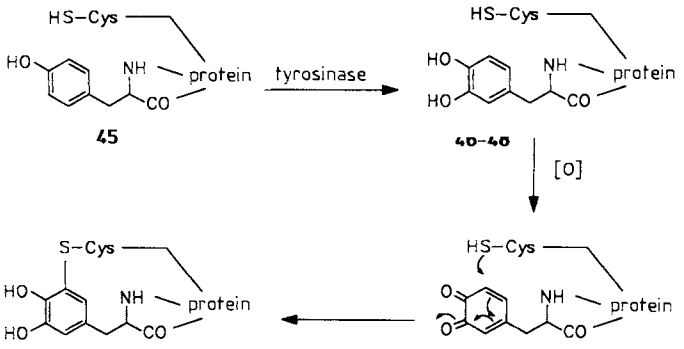
Polymer	Phenolic monomer	Ref.
eumelanin	Dopa, dopamine, or noradrenaline	[50, 51]
phaeomelanin	Dopa and cysteine	[50, 52]
allomelanins	catechols containing no nitrogen	[50]
lignin	methoxy(propyl)phenols	[53, 54]
fungal lignin	styrylpyrones	[55]
brown algae tannins	phloroglucinol	[56, 57, 58]
condensed tannins	flavanols	[59, 60]
hydrolyzable tannins	gallic acid and glucose	[61]
humic acids	various	[62]

The binding interactions between polyphenolic polymerization products of quinonoids and other biopolymers—i.e., proteins, polysaccharides, and nucleic acids—are caused in principle by the following processes:

1. Covalent trapping of reactive intermediates, such as quinones, quinone methides, or radicals, during any stage of the polymerization process. In this case, the complex of the polyphenol and biopolymer is formed either by continuation of the polyphenolic polymerization or by addition of a functional group of the biopolymer to a reactive center of a polyphenol.
2. Noncovalent association between the biopolymer and the polyphenol. In this case, stabilization is achieved predominantly by a multiplicity of hydrogen bonds, in addition to electrostatic and hydrophobic interactions.
3. Cross-linking of biopolymers by a combination of covalent and noncovalent forces.

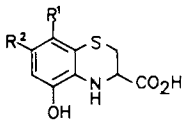
Tyrosinase-catalyzed oxidation of tyrosine or Dopa leads to a highly inhomogeneous black polymer, eumelanin (see Refs. [50, 51] for reviews and definition of various melanins and Ref. [63] for discussions of the mechanisms of melanin formation). An intermediate in the polymerization process is 2,3-dihydro-5,6-dihydroxyindole-2-carboxylic acid which arises from Dopa-quinone by an intramolecular 1,4 addition of the α-amino group. A generally accepted scheme for the structure of Dopa-melanin is depicted in Scheme 5.[50, 51] The polymer contains C–N, C–C, and C–O bonds which are formed through addition of the corresponding nucleophiles to intermediate *o*-quinonoid species or by oxidative phenolic coupling reactions. The structure is further complicated by the presence of pyrrolecarboxylic acid units that arise from degradation of indolic entities. ESR spectra of both synthetic and natural eumelanins reveal the presence of *o*-semiquinone radicals in these polymers.[64, 65] Quinone methides are not considered as significant intermediates in eumelanin biosynthesis.



Scheme 5.

Low-molecular-weight tyrosine-containing peptides also polymerize upon oxidation with tyrosinase.[66] Depending on the position of the amino acid in the peptide sequence, different types of intermediates are distinguishable by UV spectroscopy: *N*-terminal tyrosine yields a Dopa-quinone residue, whereas tyrosine in the peptide chain or at the *C*-terminus leads to *N*-acyl Dopa-quinone units. In contrast to the eumelanins, which form by oxidative polymerization of free tyrosine, the polymers of peptidic tyrosine are soluble in water.

Natural eumelanin is always associated tightly with protein. When Dopa is oxidized by means of tyrosinase in the presence of various proteins, cysteinyl-Dopa residues are isolated after acid hydrolysis of the reaction product.[67] Recently, *Ito* et al. showed that peptide-bound 5-cysteinyl-Dopa residues are formed when proteins are subjected to oxidation with tyrosinase.[68] The mechanism of the reaction is understood as an enzyme-catalyzed hydroxylation of tyrosine residues followed by further oxidation of the resulting Dopa residues and nucleophilic addition of peptidic cysteinyl SH groups (Scheme 6).

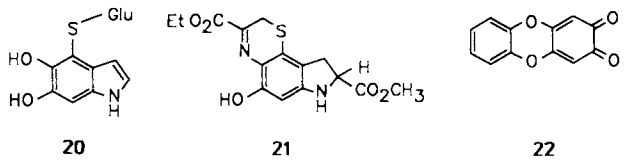


These results demonstrate conclusively that melanoprotein biosynthesis involves Michael-type 1,6 additions of cysteinyl SH groups to Dopa-quinone, generated by hydroxylation of either free or peptidic tyrosine and subsequent oxidation of the resulting Dopa residues.

Scheme 6.

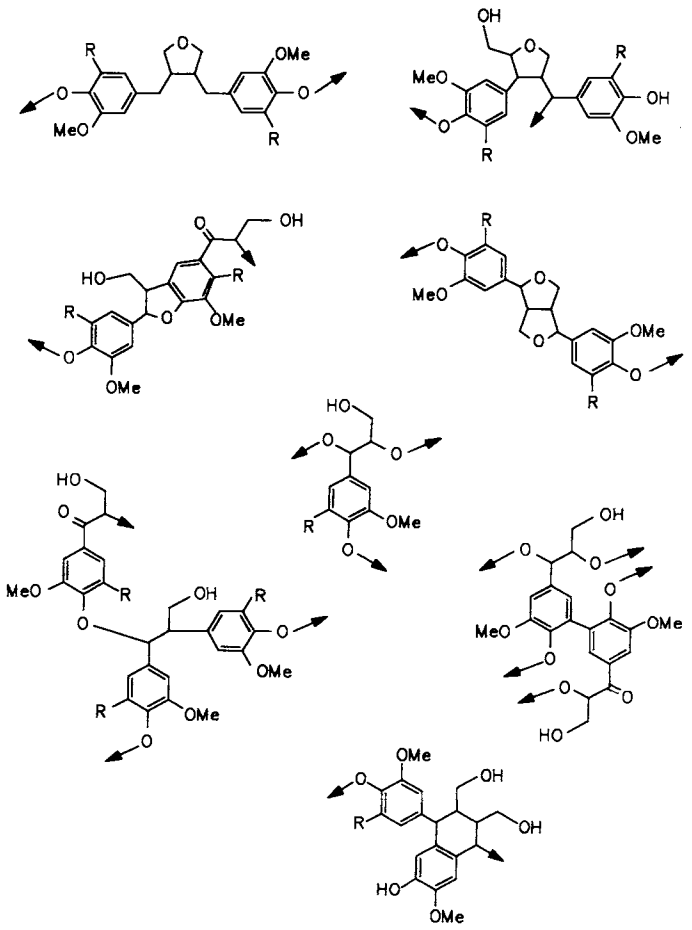
It is assumed that the structure of dopamine melanin is similar to that of Dopa melanin. However, application of CP/MAS ^{13}C NMR spectroscopy has recently revealed that the polymer of dopamine contains high amounts of aliphatic carbon atoms.[69] Therefore, in contrast to the formation of Dopa melanin, the polymerization must occur largely via dihydroindole and dopamine units.

Oxidation of Dopa in the presence of cysteine leads to the brown phaeomelanins. The principal intermediates are the cysteinyl-Dopa derivatives **1**–**4** and the benzothiazines **18** and **19**, which are formed through intramolecular cyclization via the corresponding *o*-quinone imine.[52] Apparently, Schiff base formation and reduction by excess diphenol is favored over intramolecular 1,4 Michael addition of nitrogen in this case. Recent investigations by means of ^{13}C NMR spectroscopy indicate that the polymerization of 5-cysteinyl-Dopa occurs also with partial degradation of the side chains of the Dopa and the cysteinyl moieties.[70]



18, 19

18: $R^1 = H$, $R^2 = CH_2CH(NH_3^{\oplus})COO^{\ominus}$
19: $R^1 = CH_2CH(NH_3^{\oplus})COO^{\ominus}$, $R^2 = H$

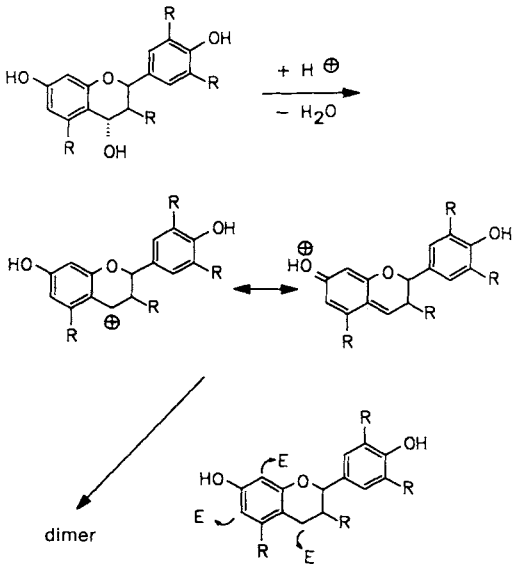


The distinction between eumelanins and phaeomelanins seems to be rather arbitrary. Though 5-cysteinyl-Dopa is a poor substrate of tyrosinase, its enzymatic oxidation is accelerated by Dopa. Thus, Dopa and 5-cysteinyl-Dopa will copolymerize under oxidative conditions, and the relative amounts of the two diphenols in the polymers are reflected by the sulfur contents.[71] Such mixed eumelanins/phaeomelanins can be characterized by ESR spectroscopy.[72]

Tyrosinase-catalyzed oxidation of 5,6-dihydroxyindole leads in the presence of glutathione to adduct **20**.[73] The tetrahydrothiazinoindole **21** was isolated from a reaction of dopachrome methyl ester with cysteine ethyl ester or glutathione.[74] The structures of these compounds are most interesting with respect to melanoprotein biosynthesis. They suggest that covalent linkages can form by SH addition not only to Dopa-quinone but also to reactive indolic intermediates.

Enzymatic oxidation of catechols that do not contain nucleophilic nitrogen leads to dark polymers, the allomelanins or catecholmelanins. Chemical investigations on their structure (reviewed in Ref. [50]) have only revealed that C–C and C–O bonds are formed. The latter may arise both by Michael-type addition of H_2O to an *o*-quinone and by addition of phenolic hydroxyl groups of unoxidized substrate. It is not always clear whether nucleophilic additions or radical reactions are involved. One of the reaction products in the enzymatic oxidation of catechol is the dibenzodioxinquinone **22**.[75] More recently, **22** was synthesized on a preparative scale from catechol.[76] The dibenzodioxin ring system is found in nature in the ecklonoquinones.[76]

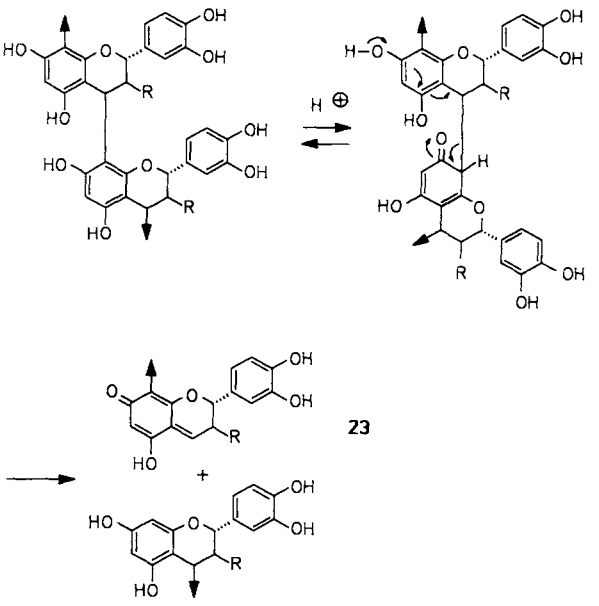
Nitrogen has been found in various allomelanins (see Ref. [50] for a review). It is reasonable to assume that the nitrogen is introduced into these polymers in the form of amino acid residues, since the biosynthesis starts from nitrogen-free catechol precursors. The presence of nitrogen is not necessarily indicative of an intact amino acid–polyphenol linkage, since Strecker degradation may have occurred (cf. formula **12**).



Scheme 7. R = H, OMe.

Freudenberg's classical work[53] revealed that lignins are formed by polymerization of *p*-hydroxy-*m*-methoxyphenylpropyl units. The initial one-electron oxidation is performed by a peroxidase, and intermediates are free radicals and *p*-quinone methides (cf. Scheme 1, pathway Ⓑ). Some principal structural elements of the polymer are depicted in Scheme 7.[54] Lignins do not contain detectable amounts of nitrogen.

The tannins of brown algae contain C–O and C–C linkages between adjacent phloroglucinol units.[57, 58] Their biosynthesis most likely follows oxidative coupling pathways between phenoxyl and aryl radicals. Covalent binding with amino acid residues of proteins could result from similar processes involving tyrosine. Indeed, nitrogen has been found in varying amounts in high-molecular-weight algal tannins.[56] Sulfur can be present in the form of sulfate.[58] Oligomeric phloroglucinols occur also in several fern species,[77] but their structure differs principally from that of the algal polymers by a linkage of the aromatic units via methylene bridges.



The vegetable tannins are grouped into two classes, the hydrolyzable and the condensed tannins. The hydrolyzable tannins are composed of glucose and oligomers of gallic acid which are combined by oxidative phenolic coupling.[61] The condensed tannins are generated from 3- and 4-hydroxyflavanols. The elegant studies of *Roux* and *Ferreira*[59] on the biomimetic synthesis of condensed tannins suggest that intermediates are either carbocations or quinone methides. Polymerization occurs via nucleophilic carbon addition (Scheme 8).

Scheme 8. R = H, OH.

binding is observed at pH values in the range 3–5. This has been taken as evidence for ionic interactions between positively charged lysine and arginine residues with acidic groups of the tannins.[79] Strong binding occurs also with synthetic polymers that do not contain basic functionalities, such as polyamides, polyvinylpyrrolidones, or urea–formaldehyde resins. In this case the polyphenol–polyamide complex must be stabilized by hydrogen bonds between phenolic hydroxyl and amide carbonyl groups. The degree of polymerization in condensed tannins must be ≥ 6 in order to effect denaturation of protein.[80] Quantitative analyses of noncovalent protein–polyphenol interactions have been published recently.[81]

Chaotropic reagents have varying effects on the stability of tannin–protein complexes. Thus, 8 M urea effectively strips hydrolyzable, but not condensed tannins, from collagen. Apparently, there are also covalent linkages in the aggregates of proteins and condensed tannins. For example, quinone methide **23**, formed from polymeric proanthocyanidin at pH 4.1 according to the hypothetical mechanism in Scheme 9, could react with nucleophilic functional groups of the protein.[82] Evidence for the formation of a quinone methide from 4,7-flavandiol in acidic solution has been obtained by UV spectroscopy in the presence of thiophenol.[83] Alternatively, the corresponding carbenium ion may be the reactive intermediate. Trapping of such intermediates by nitrogen or oxygen nucleophiles has so far not been reported.

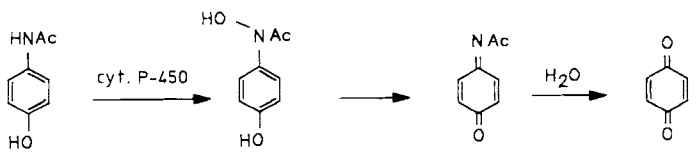
Scheme 9. R = H, OH.

Owing to the technical applications in the tanning of leather and the undesired effects on vegetable foodstuffs, there is considerable interest in tannin–protein interactions. A comprehensive, though somewhat outdated, review on this subject is available in the classical book by *Gustavson*.[78] According to traditional views, both groups of tannins interact with collagen by noncovalent forces. A maximum of

Probably the most complex natural polymers are the humic acids, and an admirable compilation of their chemistry and biochemistry has been published.[62] It is well established that they arise inter alia from polyphenolic polymers and contain heteroelements of proteinaceous origin. They are sometimes considered as the end products of the decomposition of various biomaterials in the soil.

4. Reactions of Functional Groups of Biopolymers with Quinones and Quinone Methides

In Section 3, we have considered biologically important macromolecular polyphenol–biopolymer complexes with respect to the structural principles governing the association of the two components. We shall now discuss correlations of observed biological activities of quinonoids with structural modifications of the various cellular components.

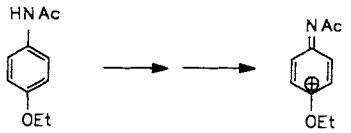


4.1. Reactions of Thiols and Sulfides

In the aqueous intracellular environment, the strongest nucleophiles are the cysteinyl SH groups. UV-spectroscopic evidence for the reaction between cysteine and various quinones was reported first by *Mason* and *Peterson*,[84] who studied models for melanoprotein biosynthesis, and later by *Pierpoint*[85] in an investigation of the enzymatic oxidation of chlorogenic and caffeic acids in the presence of amino acids. Actually, the first proof for the structure of the addition products of cysteine to an *o*-quinone was presented by *Ito* and *Prota*,[22] who isolated the cysteinyl-Dopa isomers **1**–**4**.

Besides the reactions occurring in melanoprotein biosynthesis, addition of the thiol group of cysteine-containing peptides is amply documented by isolation of glutathionyl-SH adducts from in vitro and in vivo transformations of several phenols and quinonoids.

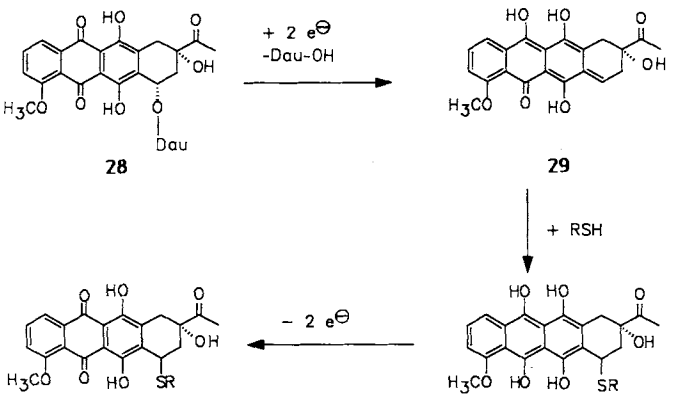
Estradiol is converted by tyrosinase into a mixture of 2,3,17- and 3,4,17-estratriol; in the presence of $Zn^{2\oplus}$, semiquinone radicals are observed.[13] The catechol estrogens produce semiquinone radicals also upon autooxidation in alkaline solution or under the action of peroxidase/H_2O_2. The 3,4-catechol is presumably more cytotoxic than the 2,3-catechol.[13] Addition of glutathionyl SH to the *o*-quinone that results from oxidation of 17-ethynyl-3,4,17-estratriol has been discussed in the context of 17-ethynyl-2,17-estradiol binding to rat liver microsomes.[86]



The analgetic drug 4-hydroxyacetanilide (paracetamol) **24** may cause liver necrosis when administered to mammals in high doses. The cytotoxic effects result from metabolic conversion of **24** to *N*-acetyl-*p*-benzoquinone imine **25** and hydrolysis of **25** to *p*-benzoquinone (Scheme 10). Oxidation of **24** is catalyzed by a cytochrome P-450-dependent monooxygenase[87] or by prostaglandin H synthetase.[88] Formation of 3-(glutathion-*S*-yl)-4-hydroxyacetanilide has been observed in vitro.[87, 88] After the cells are depleted of glutathione, liver damage results most likely from covalent binding of **25** to proteins. Besides SH addition, **25** undergoes extensive polymerization under physiological conditions.

24 **25**

Scheme 10.

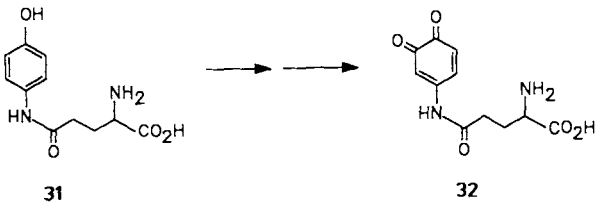


Replacement of the hydroxyl group of **24** by an ethoxy group leads to another analgetic, phenacetin **26**. In contrast to **24**, phenacetin is weakly carcinogenic. This difference has been ascribed to the oxidative formation of the nitrenium ion **27** rather than a *p*-quinone imine from **26**[89] (Scheme 11).

26 **27**

Scheme 11.

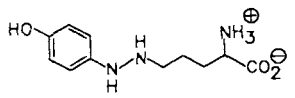
The antitumor activity of daunomycin **28** and related anthraquinone antibiotics has been associated with intercalation into DNA, cross-linking of double strands, and induction of single-strand breaking, either by interactions with oxygen radicals or by nucleophilic addition (for a review, see Ref. [90]). Biopolymer modification in the latter reaction is suggested by the isolation of the products **30** from model reactions in which the quinone methide **29** was generated by elimination of the sugar moiety from the enzymatically reduced anthraquinone (Scheme 12).[91]



28 **29** **30**

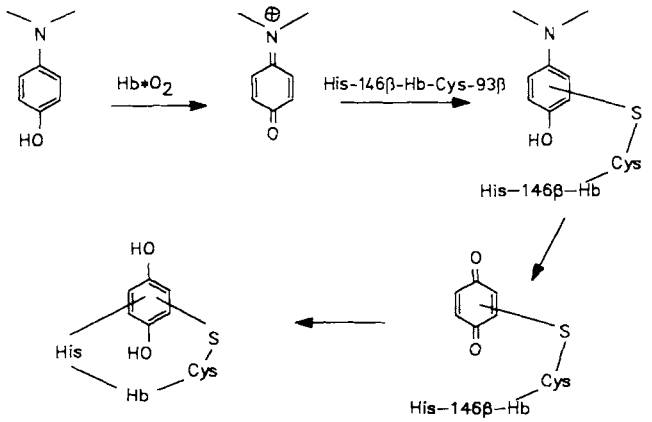
Scheme 12. Dau = 1-β-3-amino-2,3,6-trideoxy-L-lyxohexosyl; R = $CH_2CH(NHCOCH_3)COOH$, β-D-glucosyl.

Some cysteinyl-Dopa compounds and cysteaminyl phenols show selective cytotoxic activity and inhibit growth of certain tumors.[92] It is thought that this biological activity rests on the quinonoid oxidation product (e.g., of **1**) which again may act as a scavenger for SH groups of enzymes involved in DNA biosynthesis.



The glutaminyl derivative **31** is a natural product from the mushroom *Agraricus bisporus*.[93] Enzymatic oxidation of **31** leads to the corresponding benzoquinone **32** (Scheme 13), which is a powerful inhibitor of sulfhydryl-dependent respiratory enzymes[93] and shows antineoplastic activity in murine melanoma cells.[94]

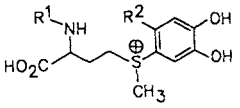
31 32



Scheme 13.

The unusual phenylhydrazine **33** occurs together with 4-diazocyclohexadienone in the related fungus *A. xanthoderma*, extracts of which possess strong antibiotic and cytotoxic activity.[95]

33

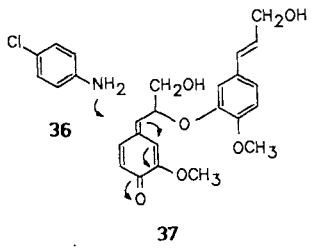


Oxidation of 4-(dimethylamino)phenol by oxyhemoglobin leads to loss of a cysteine and a histidine residue.[96] It has been postulated that cysteine-93β of hemoglobin adds to the *p*-quinone iminium ion, and autooxidation of the adduct is followed by hydrolysis and addition of histidine-146β to the substituted *p*-quinone (Scheme 14). Though the structure of the adduct has not been proven in detail, supporting evidence for this pathway was provided by tryptic digestion of the final product and subsequent amino acid analysis.

Scheme 14.

Aberrant metabolism of brain catecholamines may lead to severe neurological disorders. It has been suggested that the abnormal oxidation of certain neurotransmitters results in covalent modification of proteins in catecholaminergic neurons.[33] Supporting evidence was obtained by isolation of 6-(2-aminoethyl)-2,3,5-trihydroxyphenyl-glutathione from an in vitro oxidation of the highly neurotoxic 6-hydroxydopamine in the presence of glutathione as well as from an in vivo system.[97]

Vinylogous sulfide addition of peptidic methionine residues to *o*-benzoquinone at varying pH values was suggested as a tool for investigations on the structure and conformation of proteins.[98] Indirect evidence for the 1,4 addition of *N*-acetylmethionine to *o*-benzoquinone[99] or Dopa-quinone[100] was obtained from UV-spectroscopic investigations, which suggested the structures **34** and **35**, respectively. At physiological pH, however, failure to detect a sulfide–quinone addition product was reported.[23]



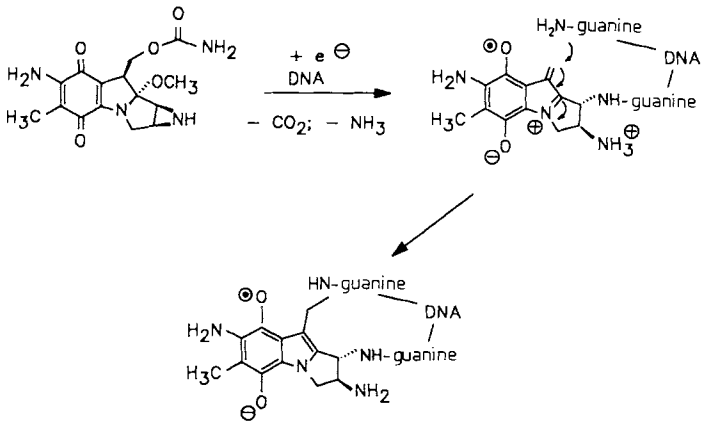
34,35

34: R^1 = Ac, R^2 = H
35: R^1 = H, R^2 = $CH_2CH(NH_3^{\oplus})COOH^{\ominus}$

Likewise, reaction of the rare amino acid selenomethionine (see Ref. [101] for a review) with *o*-benzoquinone in 1 N HCl has been studied.[102] The structure of the product was proposed to be analogous to **34**.

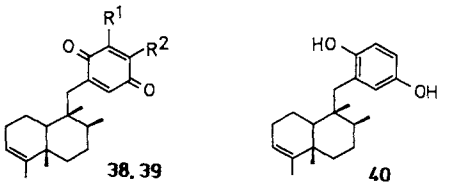
4.2. Reactions of Amino Groups

Incorporation of an aromatic amine into a synthetic lignin has been observed upon peroxidase/H_2O_2-catalyzed copolymerization of **36** with coniferyl alcohol at pH 7.5[103] (Scheme 15). Addition of **36** to the quinone methide **37** was evident from ^1H and ^{13}C NMR spectra of the product mixture.



36 **37**

Scheme 15.



Heteroaromatic amines are very abundant in nucleic acids, and additions of base residues to quinones or quinone methides are conceivable. However, the corresponding addition products have apparently not been isolated. Though not related directly to the reactivity of a quinone according to Scheme 2, it is interesting to note that the antitumor agent mitomycin C cross-links DNA via addition of guanine residues, as depicted in Scheme 16.[104] The reaction proceeds probably via an iminium ion rather than the formerly postulated quinone methide.

Another group of biologically active quinonoid natural products should be mentioned here, though their mode of action has not yet been elucidated. The sesquiterpenoid monoaminoquinones **38** and **39** were isolated from the sponge *Dysidea avara*.[105] Most likely, they arise as artifacts

Scheme 16.

from the parent *p*-diphenol avarol **40** during the extraction procedure. Avarol **40** and the aminoquinones **38** and **39** show pronounced inhibition of sea-urchin egg development. Related compounds from the sponge *Smenospongia sp.* possess cytotoxic and antimicrobial activity.[106]

38, 39 **40**

38: $R^1 = H$; $R^2 = NHCH_3$
39: $R^1 = NHCH_3$, $R^2 = H$

Aliphatic amines ($pK_a = 9-11$) occur in biological systems in great variety. Primary amines include the catecholamines, the ε-amino groups of either free or peptidic lysine, and the α-amino groups of amino acids and *N*-terminal residues in polypeptides. Proline and hydroxyproline are secondary amines, and the imidazole nitrogen of histidine ($pK_a = 6.05$) occupies an intermediate position between aromatic and aliphatic amines.

Though leading usually to intractable complex mixtures, reactions of amino acids and proteins with enzymatically generated quinones have been studied in great detail by spectroscopic methods, such as UV[84, 85] and, more recently, ESR spectroscopy.[23] Isolation of a structurally defined reaction product was not attempted in these investigations. Thus, *Mason* and *Peterson*[84] described the absence of a reaction of 3-substituted indole and 4-substituted imidazole as well as of the serine hydroxyl group and amido, ureido, and guanidino nitrogen, with a variety of *o*-quinones generated from the parent diphenols with *o*-diphenol oxidase in aqueous buffer. The UV spectra indicated, however, some reactions with primary and secondary aliphatic amines and thiols. Similar results were obtained by *Pierpoint*,[85] who interpreted UV spectra of mixtures of phenoloxidase, amino acids, and chlorogenic or caffeic acid as an indication for the addition of primary α-amino groups and the ε-amino group of lysine to the *o*-quinones.

Absence of the reaction of a primary amine with the *o*-quinone of *N*-acetyldopamine at physiological pH has been reported from ESR studies conducted under conditions of spin stabilization with $Zn^{2\oplus}$.[14] *Kalyanamaran* et al.,[23] using a similar experimental protocol, have drawn the following conclusions: α-amino groups of amino acids form 1,4-addition products at pH ≥ 8; with lysine and histidine, addition occurs with the α-amino rather than with the ε-amino and imidazole nitrogen, respectively; the secondary amino group of hydroxyproline adds even at physiological pH; the *N*-terminal amino groups of peptides also react at lower pH values, owing to the decreasing basicity seen with increasing numbers of amino acids. The addition of proline nitrogen to 4-methyl-*o*-benzoquinone was first suggested by *Jackson* and *Kendal*[107] some 40 years ago in a study on the violet pigment formed upon exposure of crude extracts of potatoes or mushrooms to air. However, according to *Weaver* et al.,[93] this color is caused by the presence of γ-glutaminyl-3,4-benzoquinone **32**.

Poison ivy (*Toxicodendron radicans*, Anacardiaceae) contains urushiol, which consists of a mixture of the 3-hexadec(en)yl and 3-pentadec(en)yl catechols **41**. The urushiols act as potent allergens, causing severe skin irritation upon repeated contact with the plant. It is thought that the toxicity of the diphenolic compounds results from their oxidation to *o*-quinones, in addition to the presence of the lipophilic side chains. Their mechanism of action has been described as an oxidative addition to serum protein through mercapto or terminal amino groups according to Scheme 2. This results in chemically modified polypeptides which are allergenic. This view has been supported indirectly by isolation of corresponding derivatives in model experiments[108] as well as in studies on the binding of the oxidation products (presumably *o*-quinones) of various alkyl-substituted diphenols to proteins.[109] When γ-globulin was washed through a column cotaining quinone-coated Celite, binding of the protein was most extensive when the quinone was derived from 3-pentadecylcatechol, whereas 4-methyl-, 5-methyl-, or 6-methyl-3-pentadecyl-*o*-benzoquinone resulted in diminished binding of protein. The presence of more than one methyl group, such as in 4,5-dimethyl- or 4,5,6-trimethyl-3-pentadecyl-*o*-benzoquinone abolished protein binding nearly completely.[109]

More recently, cross-reactivity of urushiol analogues in urushiol-sensitized Guinea pigs has been demonstrated with compounds **42** and **43**.[110] Blocking of the amino group in **42** or **43** in the form of the methanesulfonamide resulted in loss of cross-reactivity in sensitized animals. Resorcinol derivatives did not cross-react with urushiol. It should be noted that the *p*-quinone primin **44** also shows pronounced allergenic activity (for a review, see Ref. [3]).

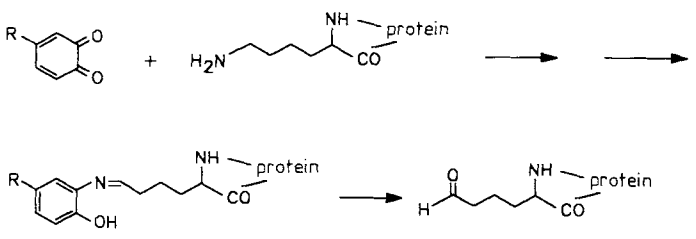
41: $R^1 = R^2 = OH$,
$R^3 = n\text{-}C_{15}H_{31}$, $n\text{-}C_{15}H_{29}$, $n\text{-}C_{16}H_{33}$, $n\text{-}C_{16}H_{31}$
42: $R^1 = OH$, $R^2 = NH_2$, $R^3 = C_nH_{2n+1}$ (n = 13, 15, 17)
43: $R^1 = NH_2$, $R^2 = OH$, $R^3 = C_nH_{2n+1}$ (n = 13, 15, 17)



Plant materials often undergo extensive browning when wounded tissue is exposed to air. This browning reaction leads to a decrease in the nutritional value of vegetable food-

stuffs, and it is understood as an oxidative modification of lysine residues in proteins by plant phenolics. A novel approach towards the identification of quinonoid–lysine addition products is offered by high-resolution mass spectroscopy of degradation products of hydrogenated plant proteins.[111, 112] The results obtained upon analysis of the extremely complex product mixtures provided some, though not fully convincing, evidence for the presence of an addition product between lysine and caffeic acid.

A similar reaction between chlorogenic acid and the ε-amino group of lysine has been suggested in order to explain the partial inactivation of a potato virus upon exposure to chlorogenic acid and phenol oxidase.[113, 114] Cross-linking of protein subunits was observed, and digestion with trypsin (which cleaves peptide bonds adjacent to lysine residues) was less extensive with the cross-linked than with monomeric diphenol–protein reaction product. It was suggested that the mechanism of cross-linking involves a D-1,4-A-D-1,6-A sequence, resulting in a 3,5-diamino-4-alkyldiphenol. Alternatively, coupling of two catechol units via an aryl ether linkage was considered.[113] The stoichiometry of binding of chlorogenoquinone was dependent on the pH of the reaction mixture: at pH 7.0, there was a 1:1 ratio between chlorogenic acid and protein subunit, whereas a ratio of 2:1 was observed at pH 7.8.

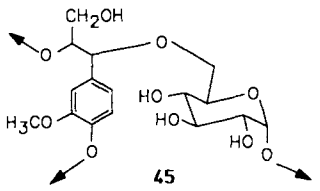
A highly interesting example of the occurrence of 3,4-dihydroxyphenylalanine residues in a protein has been found in the periostracum[115] and in the phenol glands[116] of the mussel *Mytilus edulis*. The byssus of the same molluscs also contains a catechol oxidase,[117] and it is believed that the enzyme oxidizes peptidic Dopa units to the corresponding *o*-quinones, which then add ε-amino groups of lysine residues. Though cross-linking via cysteinyl SH groups is also a possibility (cf. Scheme 6), the protein contains no cysteine and only traces of methionine.[116] Thus, a unique type of natural glue is formed that enables the mussel to adhere tightly to the surface of a support. It is noteworthy in this context that the natural product primin **44** and some homologues possess molluscicidal activity.[118]

Sequential addition of two ε-amino groups of lysine residues to quinones must not necessarily represent the only pathway of protein cross-linking in biological systems that do not contain sulfur nucleophiles. When the addition reaction is followed by rearrangement and hydrolysis of the azomethine (Scheme 17), an aldehyde is generated in a Strecker-type reaction. The aldehyde is itself reactive as both an electrophilic amino-group acceptor and a component in aldol condensations. Further rearrangements and reactions can follow. They represent one of the principally possible structural modifications in collagen and related proteins (for a review, see Ref. [119].

Scheme 17.

α-Aminoadipic acid could be isolated after catechol/peroxidase/H_2O_2-mediated protein modification, followed by performic acid oxidation and hydrolysis.[120] Protein cross-linking by various catechols and peroxidase/H_2O_2 was also described[121, 122] but structures of the cross-links have not yet been determined. Treatment of proteins with peroxidase/H_2O_2 in the absence of catechols leads to oxidative coupling of tyrosine residues.[123]

Mechanism-based inactivation of tyrosinase during oxidation of catechol has long been known (for a review, see Ref. [124]). An earlier report, describing covalent attachment of radiolabeled catechol, presumably through nucleophilic groups of the enzyme,[125] is obviously not confirmed by the results of *Lerch*,[124, 126] who showed that, though a histidine residue at the active site was destroyed during catalysis, only insignificant amounts of substrate were bound covalently to the protein.



Addition products of amines to an intermediate *o*-quinone methide, which was derived from pyridoxol under rather harsh conditions, have been investigated in order to provide models for the neurotoxic action of certain vitamin B_6 derivatives.[127] Though possible in principle, an addition of amino acids or proteins to quinone methides in a biochemical environment has so far not been confirmed experimentally.

4.3. Reactions of Hydroxyl Groups

The most abundant oxygen nucleophile in biological systems is, of course, water. Other candidates for nucleophilic addition include carbohydrates and the hydroxyl groups of serine, threonine, and hydroxyproline residues. Furthermore, the phenolic hydroxyl groups of the substrates themselves can act as nucleophiles, and many examples for this type of C–O bond formation are found in the field of natural products chemistry. Reactions of alcohols with *p*-quinones are of considerable value in preparative organic chemistry.[10] The addition of carboxylates should be considered in this context also.

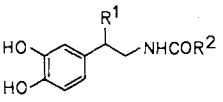
With respect to protein modification, no example of the addition of hydroxyl functions of serine, threonine, or hydroxyproline to a quinone has been reported so far. However, *p*-quinone has been used to immobilize enzymes on hydroxyalkyl methacrylate polymers[128] and on polysaccharides.[129] The nature of the reactions involved has not been determined in detail. Since the polymers are first activated by *p*-benzoquinones, formation of C–O bonds through nucleophilic addition is conceivable. After reoxidation, the protein is attached presumably via mercapto or amino group addition. Thus, the sequence is A(hydroxyl group to benzoquinone)-D-A(protein to quinone-modified polymer).

The addition of hydroxyl groups of polypeptides to intermediates in lignin biosynthesis has not yet been observed. However, lignin does contain C–O bonds from carbohydrates, as was first suggested by *Freudenberg*.[53] The structures of the linkages have been indirectly identified after digestion with cellulase followed by methylation analysis of a lignin–carbohydrate complex from *Pinus densiflora* wood.[130] A representative example is given in formula **45**. Other types of C–O bonds, namely, ether linkages to ferulic

45

acid and ester linkages to *p*-coumaric acid, exist in wheat straw.[131]

5. The Mechanisms of Insect Cuticle Sclerotization



In the foregoing sections, we have seen that reactions of quinonoids with biopolymers result in a variety of types of covalent and noncovalent bonding, in addition to secondary modifications such as deamination or reactions with oxygen radicals. We shall now turn to a fascinating process in nature, namely, the hardening and darkening of the exoskeleton of insects. This subject has been studied quite vigorously in recent years and we shall ask ourselves to what extent the results of chemical investigations of other biological systems may also be valid for this process.

Arthropods in general require a stiff exoskeleton for maintaining such essential life functions as muscle attachment, body structure, and protection against chemical or mechanical threats from the environment. In insects, the process of hardening of the cuticle is termed "sclerotization", and it is often accompanied by darkening of the cuticle. The most prominent examples can be seen in the more or less dark brown cuticles of many insect pupae. In the larval stage, stiffening of the mandibles is necessary to provide the functionally intact organs for food intake. From a more practical viewpoint, the study of sclerotization might suggest new approaches in insect control, since inhibition of this process would be lethal to insects. One of the prerequisites for the development of new insecticides is, of course, some idea about their possible mode of action.

The molecular mechanisms of insect cuticle sclerotization have long attracted the attention of many researchers. However, the numerous attempts to elucidate the chemistry of this process have met with rather limited success. In fact, several hypotheses still exist concerning the nature of the interactions of polyphenols with structural proteins and chitin, and at least some experimental evidence has been obtained for nearly all of them.[132] It is generally assumed that structural proteins are covalently modified and cross-linked by *o*-quinones and *p*-quinone methides that are generated by enzymatic oxidation of *N*-acyl-3,4-dihydroxyphenethylamines. According to other hypotheses, sclerotization is effected by noncovalent polyphenol–protein interactions and by a decrease of water in the cuticle. Several reviews have appeared in the last few years,[132–135] and only the most conclusive results shall be included here together with some important historical observations.

The earliest investigation on the mechanism of sclerotization goes back to *Pryor*, who, in 1940, described the hardening of cockroach egg cases[136] and of insect cuticle[137] as a result of covalent cross-linking of proteins by *o*-quinones. He also suggested the name "sclerotin" for the brown protein–quinone complex. Reactions of peptidic amino groups was assumed after the observation that pretreatment of the proteins with formaldehyde prevented sclerotin formation. Very important is also *Pryor*'s assumption that the stiffness of the cuticle may increase owing to quinone polymerization in the "meshes of the protein network".[136]

The principal sclerotization substrate was identified in the classical work of *Karlson*'s group some 25 years ago; they isolated *N*-acetyldopamine **46** from larvae of the blowfly *Calliphora erythrocephala*[138] and, subsequently, from other insect species.[139] Another principal sclerotization agent is *N*-β-alanyldopamine **47**,[140] which, in contrast to **46**, contains a free primary amino group.

46–48

46: $R^1 = H$, $R^2 = CH_3$
47: $R^1 = H$, $R^2 = CH_2CH_2NH_2$
48: $R^1 = OH$, $R^2 = CH_3$

The fundamental role of the dopamine derivatives in sclerotization is now well established. Inhibition of Dopa decarboxylase by α-methyl-Dopa or carbidopa (deamino-α-hydrazino-α-methyl-Dopa) interferes with the biosynthesis of the sclerotization agents.[141, 142] Pupae of the fly *Lucilia cuprina* that were treated with such compounds during immature stages display a light color and die from dehydration.

The idea that enzymatic oxidation of the diphenols yields *o*-quinones, which cannot cyclize to indole derivatives and therefore react according to Scheme 2, has been presented many times in the literature. According to these hypotheses, cross-linking occurs between ε-amino groups of lysine residues through either a D-1,4-A-D-1,6-A or a D-1,4-A-D condensation sequence, followed by Schiff base formation. Since mercapto groups are present in cuticle proteins, if at all, only to a small extent,[143] participation of ε-lysine amino groups is likely.

Inhibition of the phenoloxidase in mosquitoes with 2,6-di-*tert*-butyl-4-(α,α-dimethylbenzyl)phenol prevents sclerotization of the pupal cuticle and the pupae die rapidly after the molt.[144] The cross-linking of tyrosine-rich proteins, which can be achieved with tyrosinase in the presence of **46** or **47**,[145b] is inhibited by the resorcinol analogue *N*-acetyl-2-hydroxytyramine by an as yet unknown mechanism.[146]

The isolation of a bis-lysine adduct from hardened insect material has been reported only once.[147] The original data have not been published so far, and therefore this most important result is not accessible to evaluation. Other indications for reactions of amino groups during sclerotization are derived indirectly from differences in the amounts of lysine in hydrolysates of sclerotized and soft cuticles.[133, 143, 148] The participation of histidine residues in protein modification has been demonstrated by application of CP/MAS NMR spectroscopy to cuticles of insect pupae that had been fed [1,3-$^{15}N_2$]histidine and [*phenyl*-^{13}C]dopamine.[149] The results revealed clearly the presence of ^{15}N–^{13}C linkages, but it is not possible to decide whether attachment of a dopamine metabolite to protein results in cross-linking. Participation

of histidine in sclerotization is also evident from comparative amino acid analysis.[150]

Several lines of evidence indicate that, besides cross-linking of insect cuticle proteins via basic amino acid residues and *o*-quinones, other mechanisms are involved in sclerotization. Racemic *N*-acetylnoradrenaline **48** was isolated from reaction mixtures containing **46** and powdered insect cuticle. Likewise, oxidation of 4-methylcatechol with cuticle from flies leads to 3,4-dihydroxybenzyl alcohol and to 3,4-dihydroxybenzaldehyde.[151] These results indicate a side-chain hydroxylation mechanism which is not consistent with an enzyme-controlled reaction.[152, 153] Since dopamine-β-hydroxylase is known to produce (*R*)-noradrenaline from dopamine, the occurrence of racemic **48** must be explained by a rearrangement of the *o*-quinone of *N*-acetyldopamine to the corresponding *p*-quinone methide and nonstereoselective addition of water to this electrophilic species. In analogy to the biosynthesis of lignin, the formation of racemic **48** is most likely a side reaction in the polymerization of **46** in insect cuticle (cf. Scheme 1, pathways Ⓑ and Ⓒ). The enzyme that catalyzes quinone methide formation has not yet been isolated. It is interesting to note that tyrosinase catalyzes the oxidative decarboxylation of 3,4-dihydroxymandelate to protocatechuic aldehyde, presumably via the *p*-quinone methide.[154] An impressive number of side-chain-oxidized derivatives and benzodioxin dimers of **46** and **47** have been isolated from cuticles of various insects (for reviews, see Refs. [132, 133]), but their functional role in sclerotization has not been elucidated in molecular terms.

The tan color of most sclerotized insect cuticles indicates extensive polymerization of the phenolic precursors. Dark cuticles contain eumelanin in varying amounts[40, 148, 155] besides polyphenolic polymers that arise from the oxidation of the sclerotization substrates via reactive *o*-quinones and *p*-quinone methides. The presence of melanin in sclerotized cuticle has also been demonstrated by ESR spectroscopy.[14, 64] Copolymerization of peptidic tyrosine residues with sclerotization substrates has been observed in a few instances.[156, 157] Investigation of insoluble materials by CP/MAS ^{13}C NMR spectroscopy provides a nondestructive method for the observation of polyphenolic polymers, and its application has revealed the presence of 1,2-diphenoxy carbon atoms in sclerotized insect cuticle.[158]

Melanization and sclerotization of insect cuticles are separate processes, as was first recognized by *Karlson* et al. in 1962,[159] who also discovered the presence of the nonproteinogenic amino acid β-alanine in sclerotized cuticle of the blowfly *Calliphora erythrocephala*.[160] It appears now that this amino acid is present in all sclerotized cuticles and that it plays an essential role in the regulation of the balance between melanin and sclerotin formation.[155] Mutants of the fruit fly *Drosophila melanogaster* that are unable to biosynthesize β-alanine or to transport the amino acid into the cuticle incorporate Dopa or dopamine into black eumelanin.[161] The stiffness of the cuticle is decreased in these cases.[162] Likewise, ethyl hydrazinoacetate, an inhibitor of β-alanine biosynthesis or transport, causes a black coloration of the pupae of *Manduca sexta*, which normally are brown.[163] Probably, β-alanine is necessary for acylation of dopamine, thus preventing intramolecular oxidative cyclization and facilitating protein cross-linking by intermolecular nucleophilic addition. Since *N*-β-alanyldopamine **47** is, in fact, a component of the sclerotization process, this hypothesis appears quite attractive. However, the question whether cross-linking occurs on the monomeric or on the polymeric level remains unanswered. According to another theory, binding of β-alanine to chitin is required for the correct packing of the macromolecular network in the cuticle.[162] The β-alanine-mediated browning of chitin[162] results most likely from Maillard-type reactions.[119, 164]

Chitin is not a necessary component for sclerotin formation, since *o*-quinones and protein are sufficient to harden and darken the egg cases of cockroaches which are devoid of chitin.[136] However, when chitin deposition is blocked by diflubenzuron, the cuticles may blacken[165] and sclerotization can be affected (for a review, see Ref. [166]). Noncovalent binding of *N*-acetyldopamine-derived polymer to chitin has been reported.[167]

Chitin appears to be tightly associated with protein, but the types of bonds are unknown. Again, covalent polysaccharide–protein linkages are in principle possible, either through acyl linkages between amino or hydroxyl groups or through glycosidic coupling of polypeptides with the reducing sugar unit. Attempts to isolate conjugates of amino sugar and amino acids have so far not been successful. Therefore, the question concerning the molecular architecture of chitin–protein–polyphenol complexes remains unanswered. If glycosidic bonds are formed between the reducing terminus of chitin and ε-amino groups of lysine, rearrangement and subsequent hydrolysis could eventually lead to allysine residues (cf. Scheme 17). This mechanism is analogous to that of the glucose-mediated covalent cross-linking of collagen.[168]

According to other theories, the importance of covalent interaction is generally overemphasized and sclerotization results from the reduction of the water content in the cuticle and from noncovalent binding of proteins to polymers of the *N*-acylcatecholamines.[152, 169] Those polymers do not contain appreciable amounts of indole units, since intramolecular cyclization of the quinones of *N*-acylcatecholamines is very slow. Therefore, despite their origin from dopamine derivatives, they are to be classified as allomelanins (see Section 3). In view of the possibility of quinone methide formation, one expects the properties of these polymers to be similar to those of condensed tannins and lignin. Their interaction with proteins would thus lead to noncovalent interactions as well as random covalent binding.

6. Summary and Prospect

Reactions of quinones and quinone methides have many important and often spectacular results in nature. In this article, we have considered defensive systems, toxic effects, and diminishing of the value of vegetable foodstuffs. We have also seen examples of the construction of macromolecular, highly complex polymers as essential prerequisites for the sustaining of life in various organisms. On the molecular level, the common principle is always a chemical modification of biopolymers, either covalent or noncovalent. Quite often, reactions of sulfur nucleophiles with quinones and quinone methides prevail. When sulfur is absent, modifications occur via nitrogen nucleophiles in proteins and via

oxygen nucleophiles in polysaccharides. Finally, biopolymer modifications can be induced indirectly, for example, through deamination or quinone-mediated electron-transfer processes which result in the formation of oxygen radicals.

Some of the past theories of covalent quinone–protein binding, which were derived from model systems, have to be revised. It appears that the role of ε-amino groups of lysine residues is less important for covalent binding than has been assumed previously. Certainly, there are decreases in the number of lysine residues after the reaction of a protein with quinones. However, lysine may also suffer oxidative deamination. Blocking of lysine with aldehydes also decreases binding of quinones. This does not prove covalent binding, since noncovalent interactions will also be impaired when the aldehyde reaction leads to deamination or to loss of positive charges. It appears that the imidazole nitrogens of histidine residues are much more important in nucleophilic addition than the ε-amino groups of lysine.

The most significant and spectacular advances in the direct observation of insoluble biopolymers have been achieved by applications of solid-state NMR spectroscopy.[69, 149, 158] However, not all speculations are resolved now and nature presents many variations, including noncovalent binding and C–C bond formation by oxidative coupling. A thorough experimental investigation is mandatory in any case if questions concerning molecular structure are raised.

Several issues may be raised at this point for future discussions: The study of protein–quinone interactions, such as those involved in natural defense mechanisms and sclerotization processes, provides a basis for seeking new pharmaceutical applications (cf. daunomycin) or avoiding toxic effects (cf. paracetamol). The knowledge of the biosynthesis and structural principles of macromolecular networks may help in the design of new compounds for medical use, such as those interfering with melanogenesis in melanoma cells, or for agricultural applications, such as those impairing the construction of a sclerotized exoskeleton in insect pests. Finally, new materials can be envisaged that share such properties as hardness with lignocellulose, or stiffness and low density with the exoskeleton of insects, or strength with the byssal threads of the common fouling mussel. The construction of new materials from chemically modified proteins has been suggested recently[170] and, with advancing techniques in protein design and engineering, the time may have arrived to look more closely into this matter. Thus, an understanding of the principles of the reactions of quinones in biological systems is important from a practical viewpoint. However, our desire to analyze the unknown in order to discover causal relationships and to unravel nature's molecular construction plans is motivated above all by sheer curiosity.

Much of the work cited from this laboratory was performed by a number of skilled students whose names appear in the references. I am indebted to them for their encouraging engagement and endurance. Quite a few of the ideas discussed in this article were born in stimulating discussions with many colleagues, and I am grateful especially to Prof. P. Karlson (Marburg), Prof. W. Steglich (Bonn), and Dr. G. F. Weirich (Beltsville). Several projects were only successful through the cooperativity of colleagues in zoology: Prof. A. Egelhaaf (Cologne), the late Prof. H. Emmerich (Darmstadt), Prof. K. Scheller (Würzburg), and Prof. R. Keller (Bonn). Most of the experimental work mentioned was funded generously by the Deutsche Forschungsgemeinschaft to whom I am particularly indebted for a Heisenberg Award. Further support from the Fonds der Chemischen Industrie is gratefully acknowledged.

Structure and Dynamics of Chiral Molecules**

By Martin Quack*

Could there be chiral methane? What is the characteristic structural feature (in a physicochemical sense) of a molecule? This question dates back to *Louis Pasteur*, the discoverer of molecular chirality, and since the work of *van't Hoff* and *Le Bel* is generally considered by chemists as solved. In the present article it is pointed out that there exist fundamentally conflicting theoretical views of the physical origin of molecular chirality. These views predict consequences that could, in principle, be distinguished experimentally, but at present there is no conclusive experimental evidence available. Possible experiments are suggested that test different hypotheses. The importance of the magnitude of the parity-violating energy difference ΔE_{PV} in molecules due to the weak nuclear force for both the structure and spectra of chiral molecules and for the kinetics of racemization is discussed. The chemical relaxation rate coefficient of chiral molecules with some appreciable energy of excitation is derived for several limiting cases of a simple statistical mechanical model, which takes ΔE_{PV} into account.

"Si les principes immédiats de la vie immédiate sont dissymétriques, c'est que, à leur élaboration, présidents des forces cosmiques dissymétriques; c'est là, suivant moi, un des liens entre la vie à la surface de la terre et le cosmos, c'est-à-dire l'ensemble des forces répandues dans l'univers".[***]
L. Pasteur[19]

1. Introduction

Since Pasteur's first separation of crystals of racemic organic compounds (such as the sodium ammonium salt of tartaric acid) into left- and right-handed, optically active compounds 140 years ago,[1] two major questions related to this observation of chirality have been addressed repeatedly:

1. What is the origin of chirality in *molecular physics* and thus the "nature" or intrinsic structural feature of a chiral molecule or chiral substance?
2. What is the origin of chirality in (molecular) *biology* (i.e. the *chiral bias* favoring some enantiomers over others)?

These two questions are quite distinct, although related to each other. The second question concerns one of the more obvious, major unsolved problems in biochemical research.[2-17] We shall concentrate here on the first question, which is considered by many to be solved. This is not so, as we shall demonstrate. It may be that proper consideration of the first question will help to solve the second.

Even today the "structure" of chiral molecules is discussed by most chemists in terms of *macroscopic molecular models* in three dimensional space in the framework of conventional stereochemistry.[1c, 3, 18-23] It was recognized by *Friedrich Hund*[24] that in the framework of quantum mechanics certain problems arise with classical stereochemistry due to the possibility of tunneling, which connects left- and right-handed structures. *Hund* provided an immediate apparent solution to these problems by considering the time scales for interconversion between enantiomers (see Section 2.2). *Primas*[25] pointed out, however, that this solution does not explain, why one cannot buy in a drug store the substance corresponding to the coherent superposition of left- and right-handed states of chiral molecules such as alanine. Of course the reason for this may be trivial, the superposition states may be unstable and thus difficult to store in bottles (one cannot buy free radicals such as CH_3 in bottles in a drug store, but there is good evidence for their existence). However, a *possible* solution of "Primas' paradox" is the nonexistence of these achiral states of chiral molecules, which leads to the more recent discussions of chirality.[26-32] These invoke either essential interactions with the radiation field, or else with other external agents in order to explain the physics of chiral molecules.

Finally, after the discovery of the chiral symmetry violating weak nuclear interaction[33-41] it would appear natural to assume that this force has also fundamental implications for the physics of chiral molecules.[10, 11, 17, 42-54] In contrast to the other three fundamental forces of physics (strong nuclear forces, electromagnetic interaction, and gravitation) this "weak interaction" is intrinsically chiral. It is responsible for the β-decay of the neutron. It has been shown to lead to a nonconservation of the quantum number "parity" in nuclear decay processes[34] and in atomic spectroscopy.[40] In chemistry it has a most striking, as yet hypothetical, consequence: Under appropriate conditions it leads to a parity-violating energy difference E_{PV}[10, 11] between two enantiomers **R** and **L**, in thermodynamic terms, i.e. to a thermodynamic reaction energy $\Delta_R U_0^0$ different from zero

The main, first part will be published separately. The first Hund/Klemm lecture forms the basis of a review by H. Bock and R. Dammel in *Angew. Chem.* 99 (1987) 518; *Angew. Chem. Int. Ed.* 26 (1987) 504.

[***] If the foundations of life are dissymmetric, then because of dissymmetric cosmic forces operating at their origin; this, I think, is one of the links between the life on this earth and the cosmos, that is the totality of forces in the universe.

for the racemization (a) (leaving the sign undetermined; see also appendix); $|\Delta_R U_0^0| \equiv |\Delta E_{PV}|$.

$$\mathbf{L} \rightleftharpoons \mathbf{R} \qquad \text{(a)}$$

All of the above mentioned discussions of molecular chirality result in differing views about the actual "structure" (in a general, physicochemical sense) of chiral molecules and substances. These differences should not be dismissed entirely as problems in the realm of bad terminology or philosophy. Rather, we shall demonstrate that the different views correspond to different theories of chirality with conflicting predictions concerning the outcome of certain experiments. To decide unequivoqually which theories must be dismissed, one must perform an experiment which discriminates between them. To date, there is essentially no experimental evidence available on some central questions and this aspect has been largely overlooked in the theoretical discussions of the problem. The present paper is intended to fill this gap. Some possible experiments[50] will be discussed.

2. A Critical Discussion of Different Points of View Concerning Molecular Chirality

In this section we shall summarize some of the general aspects and predictions of the various theories of chirality. Predictions for specific experiments will be given in Section 3.

2.1. Macroscopic Molecular Models and Classical Mechanics: "The Classical Hypothesis"

The original description of chiral molecules was given in terms of molecular models that are the microscopic analogue of macroscopic models satisfying the laws of classical mechanics of our everyday world.[1, 18-21] It is in essence also the starting point of the organic stereochemists models. In modern language one would take the approximate Born-Oppenheimer potentials as true effective potential functions for the essentially classical motion of the heavy nuclei. These potentials may then either be symmetrical with respect to space inversion or there may be a slight asymmetry if there is a parity-violating term. In the former case the occurrence of left- and right-handed enantiomers arises from the initial conditions of a given experiment. It would arise quite naturally and is *not* difficult to understand. Because of the experimentally established energetic equivalence (to within rather large experimental error!) this was the historically prevalent point of view.[18-21] *Pasteur* seems to have seriously considered also an intrinsic asymmetry. In this latter case enantiomerism would be rather similar to all other kinds of isomerism with a small $\Delta_R U_0^0$.

With the advent of quantum mechanics, governing also molecular vibrations and rotations, one might consider the classical point of view as irrelevant and superseded.[24] However, one might also take an extreme outsider's point of view along the following lines: The motion corresponding to the interconversion of enantiomers in complex organic molecules is of very low frequency. It may be that for such motions quantum mechanics becomes invalid, and classical mechanics (or something similar) is *intrinsically* valid (i.e. not just as an approximation to quantum mechanics). There is no computational test of sufficient accuracy in the quantum chemistry of enantiomers, which could disprove such a hypothesis. More interestingly, we are not aware *of any direct experimental test*. Such tests might search for either tunneling in the *symmetric* case (absent in classical mechanics) or look for direct violations of the quantum mechanical superposition principle, which is irrelevant for Newtonian mechanics both in the symmetric and asymmetric cases.

Before discussing specific experiments, it should be pointed out, that the "classical hypothesis" seems rather inconsistent and theoretically remote. There is no good reason for treating electrons and nuclei on a totally different footing, which is implied by taking the Born-Oppenheimer potentials as more than an approximate trick. In reality there is no good reason to assume that there are such potentials and one should consistently treat *both* electrons and nuclei by the same mechanics (quantum or classical). There *is* sufficient evidence for excluding a classical mechanical treatment for the electronic motions in enantiomers. One would thus be tempted to discard the classical hypothesis on theoretical grounds. In the absence of direct experimental tests, some might wish to resist this temptation.

2.2. The Quantum Mechanical Point of View with a Space Reflection Invariant Hamiltonian: "*Hund*'s Hypothesis"

Hund[24] recognized that in quantum mechanics there will be a small splitting $\Delta E_{\pm}$ due to tunneling between eigenstates of positive and negative overall parity, if the total hamiltonian $\boldsymbol{H}$ is invariant under space reflection for the potentially enantiomeric molecular system. The eigenfunctions of $\boldsymbol{H}$ would thus be achiral. Their superposition results in left- and right-handed enantiomers, which are *time dependent molecular states*. *Hund* estimated the time dependence for typical compounds and concluded that on ordinary time scales the tunneling contribution to interconversion would be negligible: The enantiomers are predicted to be kinetically stable.

In order to avoid certain confusions that sometimes arise, we should stress that there is no reason whatsoever to request that a molecule or chemical compound should correspond to an eigenstate of $\boldsymbol{H}$. Many molecules are known to exist as kinetically stable entities, often even as scattering resonances in the continuum far above the ground state of $\boldsymbol{H}$. A simple example is formaldehyde H_2CO, which is unstable with respect to decomposition into $H_2 + CO$, according to current thermodynamic data ($\Delta_R H_0^0 = -1.7 \pm 6$ kJ mol^{-1}, a more pronounced example is $N_2H_4 = N_2 + 2\,H_2$, $\Delta_R H_0^0 = -109$ kJ mol^{-1}). These molecules are kinetically stable. In this context it may be useful to provide some orders of magnitude. The racemization of aspartic acid is among the fastest for amino acids and is believed to occur unimolecularly under certain conditions.[56, 60] At 310 K the rate constant is $k_{rac} \simeq 2.7 \times 10^{-11}$ s, corresponding to a chemical relaxation time of about 1200 years. Most of the reaction occurs by thermal excitation over a barrier of about 125 kJ mol^{-1}.

Hund's hypothesis is perfectly consistent with all available experimental evidence. One may raise, however, some theoretical objections. The first, and certainly most serious one, concerns the influence of parity-violating perturbations due to the weak nuclear force. As this was only discovered in 1956,[33-35] *Hund* could not know about it. In 1927 it seemed apparently too remote to even hypothesize about this possibility. Today we must take it into account.[6, 10, 11, 42-55] However, this does not automatically invalidate *Hund*'s hypothesis for the fundamental structure and dynamics of enantiomers, whose properties depend critically on certain parameters, the splitting $\Delta E_{\pm}$ due to tunneling and the parity-violating splitting ΔE_{PV} (see appendix). Only when the inequality (1) holds will *Hund*'s hypothesis be valid. Current theory would seem to exclude the inequality (1) for a number of typical cases.[10, 11] However, from an experimental point of view the question is open.[50]

$$\Delta E_{\pm} \gg E_{PV} \tag{1}$$

The second objection was raised by *Pfeifer*.[26] He points out that *Hund*'s treatment neglects some interactions with the radiation field. If these are included, *Pfeifer* finds that the achiral eigenstates are removed and that the chiral states correspond to stable states of the system due to a superselection rule. Experimentally, this point also remains open.[50]

The third and perhaps least serious objection comes from a discussion of collisional effects by *Harris* and *Stodolsky*.[30] To the extent that at very low gas densities the idealization of a collision free molecule is adequate, this work complements *Hund*'s work but does not reject his hypothesis (for a discussion of crystallization see Ref. [57]).

2.3. Influence of the Radiation Field: *Pfeifer*'s "Superselection Rule Hypothesis"

Pfeifer pointed out two weaknesses of *Hund*'s treatment.[26, 58, 59] Firstly, *Hund* does not explicitly account for the *apparent* absence of "isomers of well defined parity".[50] These would thus seem to be unstable or nonexistent, in contrast to the established high stability of enantiomers. This objection may or may not be taken seriously. Certainly the repeated statement[58, 27] that "according to experiment space reflection invariant pure states for enantiomeric molecules do not exist" is incorrect, as to the best of our knowledge no experimental evidence has ever been presented for the *absence* of states of well defined parity (there is no evidence for their *existence* either, but that is a different matter, see Section 3.1). Thus, *Hund*'s treatment would seem to be somewhat incomplete but not necessarily incorrect. However, the first observation led *Pfeifer* to note that secondly, *Hund* omits to treat the interactions with the radiation field, which cannot be entirely removed. When *Pfeifer* includes these, he finds[58] within the framework of algebraic quantum mechanics (see also Ref. [27]) a superselection rule, which, indeed, excludes on theoretical grounds the existence of states of well defined parity under certain conditions for enantiomeric systems. Thus, even without parity violating terms in the hamiltonian, the stable ground state of enantiomeric systems corresponds to left- and right-handed isomers and not to the symmetric state of positive parity.

Pfeifer's superselection rule certainly constitutes a most striking theoretical finding. He also gives some numerical estimates for molecules.[26, 58] However, there is no direct experimental test of the superselection rule hypothesis as yet.[26, 50] On the theoretical side, some aspects of *Pfeifer*'s treatment have been revised or extended.[27] One might also raise at least two general theoretical objections to *Pfeifer*'s treatment:

1. *Maxwell*'s equations and quantum field theory have equations of motion that are space reflection invariant, as is the molecular hamiltonian in the approximation used by *Pfeifer*. Thus from general symmetry considerations his result would seem undesirable, if not impossible.

2. It is not clear whether the infinite boundary conditions for the field used by *Pfeifer*, excluding gravitation, can correspond to any real physical situation or are meaningful idealizations. The two objections are related and we realize, of course, that the symmetry breaking is the *essence* of *Pfeifer*'s theory. As the theoretical situation is not entirely clear, we would summarize that *experimentally* the question is definitely open.

2.4. The Stabilization of Enantiomers by Collision: "The Collision Hypothesis"

It has been suggested that interactions with some external medium, in particular also collisions in a gas, tend to stabilize enantiomers (**L** and **R**) and destabilize parity isomers (+ and −)[30, 31, 32] (see also Ref. [59]). In discussing a Bloch type relaxation equation for the density matrix $\boldsymbol{P}$ of a two level problem in the $|\mathbf{L}>$ and $|\mathbf{R}>$ basis, *Harris* and *Stodolsky* derive the equation (2) for the relaxation to equilibrium for the population difference Δp of **L** and **R** (if $p^e_{\mathbf{L}} \simeq p^e_{\mathbf{R}}$ for the equilibrium population p^e).

$$\Delta p(t) = \boldsymbol{P}_{\mathbf{LL}} - \boldsymbol{P}_{\mathbf{RR}} = \Delta p(0) \exp[-(\bar{\delta}^2/\bar{\lambda})\, t] \tag{2}$$

Here, one has $\bar{\lambda}^{-1} \approx T_2$, the phase relaxation rate constant that can be assumed to be proportional to the collision frequency in a gas, and $\Delta E_{\pm} = 2\,\bar{\delta}$, the tunneling splitting for the parity states, which can be related to the rate of racemization in the absence of collisions (Section 4). Equation (2) is assumed to hold in the case of strong damping, i.e. $(\bar{\lambda}/\bar{\delta}) \gg 1$. One has the seemingly paradoxical result that the *population relaxation rate* $T_1^{-1} \simeq \bar{\delta}^2/\bar{\lambda}$ and thus the racemization rate constant k_{rac} are inversely proportional to the collision rate. But, normally, in the low pressure range of unimolecular reactions (of which racemizations are special cases) one has $k \propto$ collision rate, i.e. just the opposite behavior. This results from the mechanism of an ordinary unimolecular reaction, which involves a collisional activation process to energized states with fast reaction.[60, 70] The model of *Harris* and *Stodolsky* applies to the "low temperature limit" two state model of racemization only.

It is this starting point which one may criticize: In real polyatomic molecules, the two state model would apply only at exceedingly low temperatures $T \ll 1$ K, where all molecules are in the rotational and vibrational ground state. This will be difficult to achieve. A second criticism of the model comes from its neglect of the radiation field. One can

estimate that under dilute beam conditions thermal radiative transitions between ground and vibrationally excited states may be at least as important if not more so than transitions by collisions.[50] Thirdly, as noted also by *Harris* and *Stodolsky*, there are cases of low collision rate and sufficiently fast inversion rate, where *Hund*'s model would be applicable. One might then ask for the "structure" of the isolated molecule.

Whether or not the *Harris* and *Stodolsky* model is relevant to the stabilization or existence of long-lived enantiomers in dilute gases for real molecules at ordinary temperatures could be decided only by the direct experimental determination of the molecular relaxation parameters. To our knowledge, there exists no experimental evidence either supporting or denying this hypothesis. Thus, the theory merits an experimental test, possibilities for which will be discussed in Section 3.

2.5. Weak Nuclear Interaction and Parity Violation in Molecules

The first new aspect (after quantum mechanics and *Hund*) in terms of the *physics* of molecular chirality was certainly the discovery of the parity-violating weak nuclear force.[33-35] Parity violation in physics in general and for chiral molecules in particular clearly was not foreseen by theoretical reasoning alone. Parity violation leads to a slight energy difference for the **L** and **R** isomers. Recent estimates on the basis of fairly detailed quantum chemical calculations place the parity-violating energy difference of enantiomers ΔE_{PV} in the range of 10^{-14} J mol^{-1} or about 10^{-4} to 10^{-5} Hz in frequency units.[10, 11] If this is accepted, the structure of enantiomers would be dominated by this energy difference. Tunneling from **L** to **R** would be quite negligible for typical molecules at low temperatures and the probability density for true molecular eigenstates associated mostly with one enantiomer (say **L**) would be negligible for that part of the configuration space associated with the other enantiomer (**R**). Optical isomers would then resemble ordinary isomers **A** and **B**, such as *cis-trans* isomers, separated by an energy difference ΔE_{AB} at the zero-point level. For these the eigenstates of the molecular hamiltonian are sufficiently well localized at low energies that they may be associated with one isomer only.

From the theoretical side this situation appears to be fairly well understood. However, there exists no experimental test yet. Clearly, a direct experimental measurement of the parity-violating energy difference would be in order.[50] If the experimentally measured ΔE_{PV} were to be much smaller than the theoretical prediction, it might be that there are many optically active molecules, for which parity violation would be dynamically unimportant.

From a fundamental point of view the structural hypothesis of enantiomers based upon parity violation is the most interesting one, as it is based on symmetry arguments[61] closely related to general conservation laws[71] following the thoughts of *A. E. Noether*. Understanding the structure of enantiomers in terms of the parity-violating energy difference by a quantitative measurement might have consequences beyond physical stereochemistry in the realm of the physics of fundamental symmetries.[50, 62]

2.6. Symmetry Breaking *de facto* or *de lege*

At this point it may be useful to distinguish the symmetry breaking through initial conditions in the ordinary classical (Section 2.1) or quantum (Section 2.2) theory from the symmetry breaking by *violation* of the fundamental symmetry law of parity conservation (Section 2.5).

If the initial conditions of a physical system can be chosen in different, but symmetrically equivalent ways, the symmetry of the *phenomena* or the actual state of motion will not necessarily reflect the underlying symmetry. A classical mass point moving in a symmetrical double well potential will be localized on one side, if it lies below the barrier of the double well. The direction of motion of the planets around the sun is well defined and does not reflect the symmetry of the law of motion or of space. The same is true for the **L** and **R** enantiomers in the classical situation or *Hund*'s hypothesis. And a cigarette without filter will be lit at *one end*, even if it is symmetrical.

The symmetry of the underlying law or structure is broken *de facto* by the chosen initial conditions. But the underlying symmetrical law allows also the opposite, *symmetrically equivalent* solution. In the quantum case (Section 2.2) one has then the interesting possibility of a symmetrical state of motion by the superposition principle, but such a symmetrical state is no more likely than the asymmetrical state. In classical mechanics this symmetrical state does not exist, as the superposition principle is lacking.

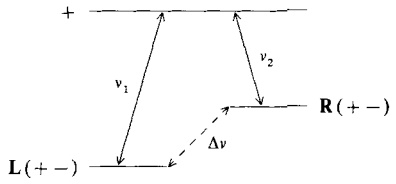
If, however, the symmetry is already broken in the underlying law of motion (asymmetrical double well for the classical mass point, parity violation for **L** and **R**, cigarette with a filter), then the two states of motion are not symmetrically equivalent, and we speak of symmetry breaking *de lege*. If the symmetry breaking *de lege* is small, then in quantum mechanics a very nearly symmetrical state can be generated by linear superposition, which will evolve slowly in time with respect to its symmetry properties (time-dependent symmetry violation).

These two situations of symmetry breaking *de facto* and *de lege* are obviously quite different and should be distinguished by appropriate terminology, as proposed. There is a third class of symmetry breaking, which is commonly named "*spontaneous*".[63] It arises with an intrinsically symmetrical dynamical structure and *Pfeifer*'s hypothesis is an example of this. One might add that one view of parity violation introduces this as a spontaneous symmetry breaking in a cosmological context. Thus, the parity-violating molecular hamiltonian of our present world arises as a particular solution out of a fundamentally symmetrical situation at the origin of our universe. It may be that the **L** isomer of a given molecule is more stable than the **R** isomer in our world; this view implies that another world may exist in which the reverse would be true. This view of parity violation is nevertheless consistent with the statement that the left-right symmetry-breaking in our world is *de lege*, as the laws of motion are now defined in the present context.

2.7. "Totaliter aliter"

Before discussing experiments discriminating between current hypotheses of the structure of chiral molecules, one should consider the possibility that the experimental result will contradict *all* current hypotheses and is thus "totally different" (totaliter aliter[64]). Such a discussion must necessarily be speculative, as otherwise we could have listed yet another, specific alternative. Effects that have not been considered so far and that may influence the structure of chiral molecules are time reversal symmetry violation and gravitation. Both are very small at the molecular level, but one is talking about small effects anyway. At the other end of the spectrum one has configuration interaction of the molecular low energy states with excited electronic states and dissociative states that are achiral. This might influence the $\Delta E_{\pm}$ in an unpredicted way, as it is usually calculated as a tunneling splitting in the electronic ground state. At still higher energies there are states, where the particle concept (electrons and nuclei) of molecular structure is no longer useful. The effects of configuration interaction with such high energy field states (including increasing numbers of positrons, antiprotons etc.) are small, but not easy to predict and may perhaps lead to surprising consequences for the very small energy effects that we consider in chiral molecules. Finally, there might be effects from an as yet unknown force.

Even this list is not complete. Together with the five specific alternatives mentioned before it should convince the reader, that no definite statement on the structure of chiral molecules will be possible without direct experimental tests, even if *some* of the theoretical alternatives may seem remote or might even be excluded as inconsistent with currently established facts by a sufficiently careful analysis.



3. Experimental Tests

We shall discuss possible experimental tests of the hypotheses, labeled **1–5** following the order of Section 2. In each case we shall discuss the *principle* of the experiment, not the details of its realization, which are complex and often not obvious, and its capabilities to distinguish between the various hypotheses.

3.1. The Principles of the Experimental Testing of Various Hypotheses Concerning Molecular Chirality

1. The first class of experiments concerns the spectroscopy of separate enantiomers. Proposals and actual experiments of high accuracy have been communicated in the radiofrequency and infrared ranges. If the weak nuclear force has sufficient influence, the absorption frequencies for the individual **R** and **L** isomers will be slightly different. Measurements with CO_2 lasers have been attempted on CHFClBr by *Kompanets* et al.[43] but gave a null result. Experiments on camphor by *Arimondo* et al.[52] gave the same absorption frequencies for D and L to an accuracy $\Delta\nu/\nu$ of 10^{-8}, probably still far away from an expected effect, although no accurate calculations have been carried out. Calculations for NMR chemical shifts predict differences of about 1 mHz, which may be measurable but have not yet been proven experimentally.[47–49] If successful, these experiments are, in principle, able to discriminate the inversion symmetrical hypotheses **1–4** from the asymmetrical **5**. They do not give, however, a direct measure of the parity-violating energy difference of enantiomers ΔE_{PV}. We note that in atomic spectroscopy the search for effects from the weak nuclear force has been successful,[39–41] and for diatomic molecules there are some null results available in searches for both parity and time-reversal symmetry-violation.[51, 53, 54]

2. The second class of experiments concerns spectroscopic transitions *between* the **R** and **L** isomers. When ΔE_{PV} is much larger than the splitting due to tunneling, one-photon transitions (at mHz frequencies) are strictly forbidden. However, a two-photon transition with an intermediate state of well defined parity will be allowed according to the following scheme:

Scheme 1. Two-photon transfer between the enantiomers **R** and **L**.

Possible transitions in this case may involve an excited electronic state that is achiral and has rovibronic levels of well defined parity. The corresponding transitions would occur in the visible or UV part of the spectrum.

Stabilizing two lasers at the transition frequencies ν_1 and ν_2 of the **L** and **R** isomers one could measure the beating between them, which may occur on the time scale of hours. This experiment is technically very difficult as it requires long time stabilization of the frequency to within $\Delta\nu/\nu \approx 10^{-19}$, quite apart from other difficulties. A slightly more favorable situation would occur for special molecules, having a small tunneling splitting ($\Delta E_{\pm} \ll \Delta E_{PV}$) in the vibrational ground state and a large one ($\Delta E_{\pm} \geq \Delta E_{PV}$) in a vibrationally excited state of the electronic ground state. Scheme 1 would then allow a measurement in the IR with a gain of a factor of about ten concerning the required accuracy. In even more special cases, it may be possible to measure the highly forbidden transition $\mathbf{L} \leftrightarrow \mathbf{R}$ at the frequency $\Delta\nu$ directly. This will happen, when tunneling is just sufficient to mix the **L** and **R** wave functions slightly, still preserving the dominant asymmetry. The $\mathbf{L} \leftrightarrow \mathbf{R}$ transition will then be slightly allowed as it acquires a weak inversion transition character. Of course, such optical isomers are necessarily rather short-lived, and are not the most typical cases. The second class of experiments allows us to measure ΔE_{PV} and thus to decide to what extent inversion symmetry is violated *de lege* or not (i.e. preferring hypothesis **5** to the others).

3. A third class of experiments is somewhat speculative at present. It would be based on the kinetic selection of **L** and **R** isomers due to the asymmetric kinetics in the case of an appreciable ΔE_{PV}:

$$\mathbf{L} \underset{k_{LR}}{\overset{k_{RL}}{\rightleftharpoons}} \mathbf{R} \qquad \text{(b)}$$

$$\frac{k_{RL}}{k_{LR}} = 1 \pm \bar{A} \qquad (3)$$

with $\bar{A}$ of the order of 10^{-18}. This is not directly measurable, but in relation with nonequilibrium kinetic schemes in evolutionary times, mechanisms have been discussed that would lead to a measurable selection of **L** or **R**.[7-9, 12] *If* a mechanism of this kind could be found for a quantitatively well understood laboratory reaction, the measured selection rate for **L** or **R** could be interpreted in terms of $\bar{A}$ and finally ΔE_{PV}. Such an experiment would be an outstanding achievement in chemical kinetics, but at present there are no ideas as to how it could be realized. It might also be possible to unravel the mechanism of the natural selection of optical isomers in prebiotic times from fossil documents and thereby obtain the relevant parameters. Again this is at present a remote possibility. If ever such evaluations became possible they would discriminate hypothesis **5** against the others and, perhaps, provide a result for ΔE_{PV} in certain molecules.

4. Another experiment has been proposed, which is based on the generation of states of well defined parity and the observation of the time dependence of parity.[50] The principle of the experiment is based on three steps: a) Preparation of molecular states of well defined parity (for instance (+) from optically active molecules (**R** or **L**) of ill defined parity in the electronic ground state. b) Free evolution of the isolated molecule with initially well defined parity (+). Under this condition the probability for negative parity will increase quadratically with time; for short times Equation (4) holds.[50] For long times one has an oscillation with period τ [Eq. (5)].

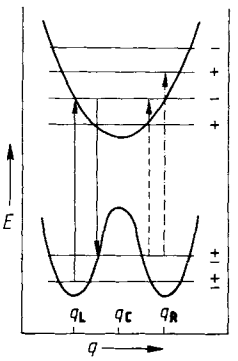
$$p_- = (\pi \Delta E_{PV} t/h)^2 \tag{4}$$

$$\tau_\pm = h/\Delta E_{PV} \tag{5}$$

c) Spectroscopic observation of the population of states of the "forbidden" parity (for example p_-) as a function of time. According to Equations (4) or (5) one can evaluate ΔE_{PV} and again distinguish hypothesis **5** from the others. This experiment allows us, however, also to decide between hypothesis **2** and **1** or **3**. In the preparation step [Eq. (6)] of the experiment one generates a linear superposition state λ_+ [Eq. (6)],

$$\chi_+ = (\lambda + \varrho)/\sqrt{2} \tag{6}$$

where λ and ϱ are the eigenfunctions of the **L** and **R** isomers (cf. Appendix). According to the quantum mechanical superposition principle this is always possible whether or not there is a sizeable ΔE_{PV} (hypotheses **2** and **5**). According to the classical hypothesis **1** or the superselection rule hypothesis **3**[26] the preparation step will generate only **R** or **L** or mixtures of **R** and **L**. These can be distinguished experimentally from the χ_+ state by the dipole absorption spectrum. χ_+ has only strong electric dipole absorptions to states of negative parity whereas **L** and **R** and mixtures have strong electric dipole absorption to both positive and negative rovibronic states. Thus, in an appropriate electronic transition, for example,[50] hypotheses **1** and **3** would predict a spectrum with about twice as many lines than predicted by hypotheses **2** and **5**. The experiment provides a direct test of the superposition principle for enantiomers. It would not allow one to differentiate between hypotheses **1** and **3**, which both require violation of the quantum mechanical superposition principle. Hypothesis **1** is in a sense a very general hypothesis and **3** might be thought to be a special, precise formulation. In that sense a distinction between **1** and **3** would become meaningful only if precise alternatives were formulated. This class of experiments would be a test for all possible hypotheses except **4** and is thus very powerful. We have also discussed in detail[50] that the experiment should be practical, even if difficult and expensive in its setup. Although the experiment is subject to numerous obvious complications, the evidence presented in Ref. [50] and further investigations[65] all suggest that the experiment can be realized with a guarantee of a definite outcome, whichever this may be. Complications could arise if ΔE_{PV} is either very small or much larger than currently predicted. If ΔE_{PV} is very small, from the absence of parity evolution one could then only derive an upper *limit* on ΔE_{PV}. If ΔE_{PV} is very large, the oscillation of parity might be so fast that it would *simulate* an **L**–**R** mixture, leading to the incorrect conclusion that hypotheses **1** or **3** are appropriate. By increasing time resolution, it should be easy to avoid such an error. Also, a very large ΔE_{PV} would be easily measured by a class 2 experiment and if established, proper precautions could be taken. We might also mention that the technique of *Kukolich* et al.[68] could be useful in the realization of our experiment (see also the related discussion below). Another realization involving excited electronic states is sketched in Figure 1.[50]



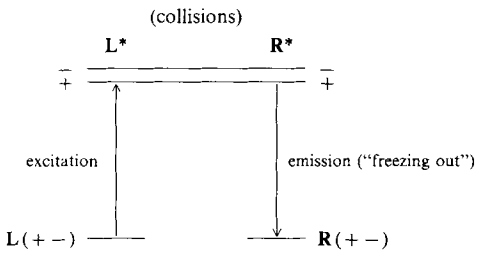


Fig. 1. Scheme for the generation of states of well defined parity (if possible) in a molecule that is chiral in the electronic ground state. The ground state potential has a high barrier for racemization, the excited state a low barrier or none as shown. q = inversion coordinate. In a first optical transition (↑) one generates a state of well defined parity (−) in the excited state, and in the second (↓) in the ground state. The dashed lines indicate the spectroscopic observation of the outcome of the experiment (after Ref. [50]).

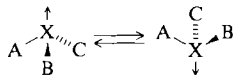


5. The final class of experiments would test the collisional hypothesis **4** perhaps by observation of the time dependence of optical activity.[30] A nontrivial time dependence will only be observed for rather quickly interconverting enantiomers, according to current estimates of ΔE_{PV}. A possible realization of the experiment would follow Scheme 2.

In a molecular beam of stable **L** and **R** isomers a pump laser would be used to excite the **L** isomer, for example, to an electronic or vibrational state in which the splitting due to tunneling is sufficient to allow interconversion at an observable rate, ideally complete inversion to **R** within a time of free flight in the beam. This transformation could be followed as a function of the length of flight along the beam by measuring the optical activity by Raman scattering[66] perhaps with CARS or Fourier transform techniques[67] in or-

Scheme 2. Experiment for testing the collision hypothesis **4** via the time dependence of the optical activity.

der to increase sensitivity (a serious problem in measuring optical activity). One might also increase sensitivity by freezing out the transformed molecules with a dump laser and collecting the stable "product" **R** for some time until sufficient material for the experimental sensitivity is available. In the free evolution stage of the experiment p_+ and p_- would remain constant and $p_{\mathbf{R}}$ and $p_{\mathbf{L}}$ would oscillate as suggested by *Harris* and *Stodolsky*. According to their prediction, this oscillation should *be slowed down* if we allow for collisions with some background gas in the molecular beam chamber. One needs just to investigate the $\mathbf{L} \rightarrow \mathbf{R}$ interconversion as a function of gas pressure, using Equation (2) for the evaluation of the relevant parameters. If the effect predicted by *Harris* and *Stodolsky* is observed, their hypothesis **4** would be confirmed for the molecular system in question, and one might, by systematic investigations, obtain an understanding of the circumstances in which the collisional stabilization of enantiomers is relevant (see also Section 4). A complication will arise in all these experiments, because a real molecule is not a two level system and even if the initial state is a coherent superposition of just two states, collisions will tend to transfer excitation to other states. It may also be useful to study the $\mathbf{L} \rightarrow \mathbf{R}$ oscillations by observations of quantities other than optical activity. A promising technique could be based upon the experiment of *Kukolich* et al.,[68] who studied collision cross sections of parity states (−) and of superposition states (+ −) in ammonia. They used the measurement of polarization in a microwave cavity (their case 2 experiment), which may be more sensitive than the measurement of optical activity. Indeed this experiment could be carried out in a very imaginative way in selected high *J, K* states of *near* symmetric tops with almost oriented molecules:

(c)

As indicated by the dipole moment arrows in Equation (c), the $\mathbf{L} \rightarrow \mathbf{R}$ interconversion in an oriented molecular beam will change the macroscopic electric dipole moment orientation and this could be detected. The dynamic situation can again become very complex with collisions.[69]

We have shown in this section that meaningful *real* experiments (as opposed to thought experiments) could test the different hypotheses on the structure of enantiomers. The hypotheses provide significantly different predictions for the various experiments. An appropriate combination of the different experiments discussed here would allow us to exclude all but one of the hypotheses, but we do not know which one would remain intact, even though intuition may suggest one. As discussed in Section 2.7, perhaps none of the hypotheses would survive the test, but this appears unlikely. At present, to the best of our knowledge, there is no definite experimental evidence available whatsoever. It should be obvious that the outcome of the experiments will depend in general also upon molecular parameters. Different hypotheses may therefore be correct for different molecules. It is then in order to discuss the scope of these hypotheses to make predictions concerning the influence of molecular parameters.

3.2. The Influence of Molecular Parameters

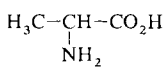
Molecular properties can influence considerably the nature of chirality in a given molecule. The most obvious case in question arises for *Hund*'s hypothesis and the parity-violation hypothesis. The inequality (1) determines which one applies. We have fairly standard techniques to estimate $\Delta E_{\pm}$, although it may sometimes be difficult to calculate the reaction path and barrier height for racemization by accurate ab initio techniques. The calculation of ΔE_{PV} by ab initio methods has just started.[10, 11] It is not clear yet (to the author) to what extent one can be certain that all the important effects have been included in the calculations. In this sense, too, an experimental test would be important. If current theoretical results are accepted, one would be able to calculate the relevant parameters in inequality (1) for simple molecules. More investigations of ΔE_{PV} are needed.

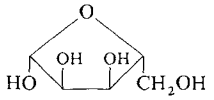
The classical hypothesis (**1**) is, at present, purely qualitative. *Pfeifer* has tried to make some estimates, for which molecular parameters his superselection rule should be applicable.[26, 58] The problem deserves more quantitative theoretical investigations.[27] The interested experimentalist would like to know from the theoretician, for which molecules and at what energies the symmetry breaking phase transition occurs, if it happens at all. Probably the isolated two-level approximation has to be abandoned for realistic estimates.

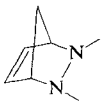
Harris and *Stodolsky*[30] have provided a collision theory formulation for their hypothesis. So far, no one has actually calculated quantitative cross sections for specific examples. Before planning experiments, such calculations would be helpful. The most serious problems will arise from the multistate nature of real molecules. That is, a large multichannel scattering calculation will be required, even if many channels are closed.

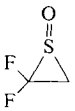
For the purpose of estimating collisional effects on the various doublet states of enantiomers, one may consider the results on ammonia inversion sublevels.[68] Here it is found that in the basis of parity states effective cross sections for T_1 and T_2 processes are somewhat larger than gas kinetic values and of about the same order of magnitude in inert gas collision partners, T_1 being shorter than T_2 with dipolar collision partners. This can be understood by a mechanism of dipolar relaxation connecting the parity sublevels but not the **R**–**L** sublevels. One can show that for a *degenerate* two-level problem, T_1 for the parity basis χ corresponds to T_2 for the ϱ–λ basis (see Appendix). Extrapolating from these results one would thus assume fast, approximately gas kinetic phase relaxation for the density matrix in the (ϱ, λ) basis and fast

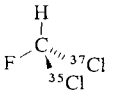
Table 1. Some chiral molecules of particular theoretical or experimental interest.

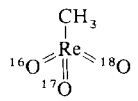


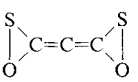


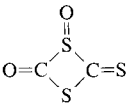


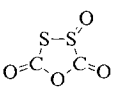


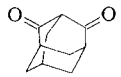


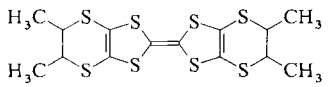












Molecule	Name	Remarks and references
		volatile, gas phase spectroscopy [43] possible: IR-laser chemistry
	camphor	(volatile) gas phase spectroscopy [52]
	alanine	theory: $\Delta E_{PV}^{max} \approx 10^{-13}$ J mol^{-1} (L more stable [10, 11])

population relaxation in the χ_+, χ_- basis. On the other hand, by the same argument as for other isomerizations with high barriers, one would assume slow population relaxation T_1 in the (ϱ, λ) basis. This would easily explain why the "isomers of well defined parity" are not normally found in nature (*Primas*' paradox): They are collisionally unstable and equilibrate at about the gas kinetic collision rate. The arguments given above for collisions hold also for thermal background radiation, which will probably, via vibrationally excited states, quickly interconvert the + and − isomers but not **L** and **R**.[50] Quantitative experimental results on these cross sections are lacking, however, and would be obtained by a combination of experiments of type (4) and (5). Thus, some of the experiments discussed in Section 3.1 would provide information on molecular stationary state, collisional and radiative kinetic properties.

For carrying out spectroscopic experiments on the foundations of molecular chirality, it may be useful to choose from a list of suitable molecules. Criteria are: 1. Simplicity (few atoms); 2. volatile compounds; 3. heavy nuclei (for a large ΔE_{PV}); 4. a limited number of nuclei with spin (perhaps a "spinless" molecule, except for the NMR experiments) in order to remove close degeneracies in the spectra; 5. for some investigations molecules with modest energy barriers for racemization. Table 1 summarizes some molecules that may be considered, including a few for which ΔE_{PV} has been calculated. In a search, it transpired that "spinless" enantiomeric compounds are not known, and some are proposed to stimulate the imagination of the synthetic chemist.

4. The Kinetics of Racemization

Molecular structures are in general time dependent and thus an understanding of the dynamics of chiral molecules and of the kinetics of racemization is required in relation to their structural properties. Racemization reactions are a special class of isomerization reactions, which can be dealt within the framework of unimolecular rate theory.[70] Under ordinary "high temperature" conditions they can be discussed approximately in terms of a quasiclassical barrier crossing in the theory of reversible unimolecular reactions[72] or, even more simply by the kinetic scheme in Eqs. (b) and (3) with a very small $\bar{A}$. The rate constants will follow the Arrhenius law (7).

$$k_{RL} \simeq k_{LR} \simeq A \exp(-E_A/RT) \tag{7}$$

Another limit is the symmetrical two level tunneling model of racemization which does not lead to kinetic equations but to oscillatory motion.[24] The period of oscillation ($\Delta E_{PV} \simeq 0$) is given by Equation (8).

$$\tau = h/\Delta E_{\pm} \tag{8}$$

These descriptions are textbook material in the realm of kinetics[60] or of spectroscopy ("ammonia inversion").[73] The treatment of *Harris* and *Stodolsky*[30] extends the "low temperature" two-level tunneling model to cases involving parity violation and collisions. We shall not discuss these simplified models further but rather refer to the extensive literature on this subject.

Closer inspection of the dynamics of racemization shows, however, that it has certain very special features because of the *approximate* nonrigid molecular symmetry of space inversion and energy equivalence of **L** and **R** isomers.[71, 74–76] These special kinetic properties have not been discussed before for real chiral molecules at finite energies, where, in general, a very large number of quantum states renders statistical approximations useful.[77] We shall consider the strongly quantized case at energies below the classical energy barrier. Here, the reaction is dominated by quantum tunneling and quasiclassical barrier crossing is not a useful concept. In this case, the molecular spectrum shows close degeneracies associated with the interplay of ΔE_{PV} and $\Delta E_{\pm}$ and the average spacing of molecular states $\delta = \varrho^{-1}$ (ϱ = density of rovibronic or nurovibronic states subject to symmetry constraints[76]). This situation leads to very peculiar kinetic properties, depending on these three parameters. Similar behavior is expected for other isomerizations with a very small energy difference between reactant and product states, but in the case of chiral molecules it is essential for symmetry reasons and it thus reveals some of the fundamental properties of chiral molecules. We shall discuss some simple limiting cases of the kinetics of racemization in turn. We start by disregarding collisional and radiative transitions and give a phenomenological discussion of their effects at the end.

The experimental situation that one should have in mind in the following discussion of racemization of an ensemble of isolated molecules is a cold molecular beam in high vacuum, for instance a supersonic jet, excited to some energy $E \pm \Delta E$, for instance with a laser, such that $\Delta E \gg \delta$ but $\Delta E \ll E < E_0$ (classical threshold for racemization). We shall thus calculate the statistical, microcanonical racemization rate under these conditions. Thermal rate constants can be derived from this.

If an ordinary microcanonical equilibrium were obtained in these racemizations, it would be governed by the densities of states ϱ of the **R** and **L** enantiomers. In order to get an estimate for this we may use a semiclassical approximation for the harmonic density of states [Eqs. (9) and (10)][70] and neglect to a first approximation the differences between the frequencies $\nu_i^{\mathbf{L}}$ and $\nu_i^{\mathbf{R}}$ of the isomers (but not ΔE_{PV}).

$$\varrho_{\mathbf{L}} = \frac{(E + aE_Z^{\mathbf{L}})^{s-1}}{\prod_i h\nu_i^{\mathbf{L}}} \tag{9}$$

$$\varrho_{\mathbf{R}} = \frac{(E + aE_Z^{\mathbf{R}} + \Delta E_{PV})^{s-1}}{\prod_i h\nu_i^{\mathbf{R}}} \tag{10}$$

Hence, with s vibrational degrees of freedom, and with vibrational zero point energies $E_Z^{\mathbf{L}} \simeq E_Z^{\mathbf{R}}$ and vibration frequencies $\nu_i^{\mathbf{L}} \simeq \nu_i^{\mathbf{R}}$ one gets, setting $E' = E + aE_Z$ (with an energy dependent "constant" $0 \leq a \leq 1$) the Equations (11) and (12).

$$K_{micro} = \frac{k_{\mathbf{RL}}^{micro}}{k_{\mathbf{LR}}^{micro}} \simeq \left(\frac{E' + \Delta E_{PV}}{E'}\right)^{s-1} \tag{11}$$

$$\ln(K_{micro}) = (s-1)\ln\left(1 + \frac{\Delta E_{PV}}{E'}\right) \simeq (s-1)\frac{\Delta E_{PV}}{E'} \tag{12}$$

Thus, with $\Delta E_{PV} \ll E'$, K_{micro} will deviate very little from 1 (say, typically, by 10^{-18}). The actual situation is more complicated.

4.1. "Fast Tunneling" with Negligible Parity Violation and Small Densities of States

The time evolution for the isolated chiral molecule is governed by the differential equation (13) for the time evolution operator $\boldsymbol{U}$,[78] which solves the time-dependent Schrödinger equation for Ψ and the Liouville-von Neumann equation for P according to equations (14)–(16).

$$i\hbar\frac{\partial \boldsymbol{U}}{\partial t} = \boldsymbol{H}\,\boldsymbol{U} \tag{13}$$

$$\boldsymbol{U}(t) = \exp(-i\,\boldsymbol{H}t/\hbar) \tag{14}$$

$$\Psi(t) = \boldsymbol{U}(t)\,\Psi(0) \tag{15}$$

$$\boldsymbol{P}(t) = \boldsymbol{U}(t)\,\boldsymbol{P}(0)\,\boldsymbol{U}^{+}(t) \tag{16}$$

$\Psi(t)$ is the wave function of a molecule and $\boldsymbol{P}(t)$ the density operator of an ensemble, respectively. In order to consider racemization or the time dependence of optical activity, we could write these equations as matrix equations in the basis of molecular states of well defined handedness (ϱ_i and λ_i). These are not generally eigenstates of $\boldsymbol{H}$ and thus the matrix representation of $\boldsymbol{H}$ will contain off-diagonal contributions. One can calculate these off-diagonal contributions by means of the Born Oppenheimer approximation in terms of a tunneling through the potential barrier, but this is by no means a necessary or exact description of the problem and is given here only for visualization. If the rovibronic density ϱ of molecular states is low [inequality (17)],

$$\delta = \varrho^{-1} \gg \Delta E_{\pm},\ \Delta E_{PV} \tag{17}$$

the total hamiltonian matrix is approximately block diagonal, with two dimensional blocks of the form (18),

$$\boldsymbol{H}^{(2)} = \begin{pmatrix} \langle E_k\rangle - \Delta E_{PV}^{(k)}/2 & \Delta E_{\pm}^{(k)}/2 \\ \Delta E_{\pm}^{(k)}/2 & \langle E_k\rangle + \Delta E_{PV}^{k}/2 \end{pmatrix} \tag{18}$$

$\langle E_k\rangle$ is the average diagonal energy of the k th two-dimensional block. We shall make use of circular frequencies instead of energy parameters [Eqs. (12) and (20)].

$$D_k = 2\pi\Delta E_{\pm}^{(k)}/h \tag{19}$$

$$\Delta_k = 2\pi\Delta E_{PV}^{(k)}/h \tag{20}$$

Suppose we have an equal initial population in N quantum states of the pure **L** isomer [Eq. (21)].

$$p_{\mathbf{L}}(0) = \sum_{j=1}^{N} P_{jj(\mathbf{L})}(0) = 1 \tag{21}$$

The time evolution of the population of the **R** isomer is given by (22) (cf. Ref. [77] and Appendix).

$$p_{\mathbf{R}}(t) = N^{-1}\sum_{i=1}^{N}\frac{D_i^2}{D_i^2 + \Delta_i^2}\left[\sin\left(\frac{t}{2}\sqrt{D_i^2 + \Delta_i^2}\right)\right]^2 \tag{22}$$

We consider now the special case $D_k \gg \Delta_k \approx 0$. In practice this applies always at high energies, with large tunneling frequencies (say $10^6\ s^{-1}$ or more); one then obtains (23).

$$p_{\mathbf{R}}(t) \simeq N^{-1}\sum_{i=1}^{N}\left[\sin\left(\frac{tD_i}{2}\right)\right]^2 \tag{23}$$

The D_i at energy $E \pm \Delta E$ will vary widely. For states that are highly excited in the coordinate associated with the tunneling motion, D_i will be large, for other states it will be small. This situation is well known for the case of ammonia, where excitation of the NH stretching modes increases the inversion splitting only slightly.[73] Even if the coupling of vibrational modes is large, at high energies, the most reasonable assumption would be that the D_i are randomly distributed according to some distribution function $G(D)$ with the average $\langle D_i^2(E)\rangle$ increasing with molecular energy E. If N is very large, we can replace the sum in Eq. (23) by an integral, neglecting terms of the order 1/N [Eq. (24)].

$$p_{\mathbf{R}}(t) = \int_{-\infty}^{+\infty} dD\,G(D)[\sin tD/2]^2 \Big/ \int_{-\infty}^{+\infty} dD\,G(D) \tag{24}$$

In this description, the detailed rovibrational molecular dynamics is contained in the spectral distribution function $G(D)$. Little is known as to what this may be. We shall

consider two possible assumptions: (25) and the Lorentz function (27). From (25) we get (26), while (27) gives (28).

$$G(D) = \begin{cases} \text{constant}, & -D_{max} < D < D_{max} \\ 0 & \text{otherwise} \end{cases} \quad (25)$$

$$p_R(t) = \frac{1}{2}\left[1 - \frac{\sin(D_{max}t)}{D_{max}t}\right] \quad (26)$$

$$G(D) = D_L/[\pi(D^2 + D_L^2)] \quad (27)$$

$$p_R(t) = \tfrac{1}{2}[1 - \exp(-D_L t)] \quad (28)$$

Both approaches give an approximate relaxation to the expected microcanonical equilibrium $(t \to \infty)\ p_L \approx p_R \approx 1/2$ (for $\Delta E_{PV} \to 0$). Only in the second case is this relaxation truly exponential with a chemical relaxation time $\tau_R = 1/D_L$. Real distribution functions for D will probably be characterized by some maximum value D_{max} such as in Equation (26), corresponding to the one-dimensional model with a tunneling splitting D_{max} calculated with *all* the energy in the racemization mode. One can develop detailed models for $G(D)$. The main result here is that in real, excited molecules under the conditions discussed *one will observe relaxation to zero optical activity even without collisions*. This is in contrast with the two-level prediction of oscillatory optical activity. Before discussing other limiting cases we should give typical experimental conditions, in which the present case will apply. For a molecule SOFCl after IR multiphoton excitation or a molecule such as ($\overline{CF_2NClCH_2}$) after overtone laser excitation of CH modes one will expect such a behavior. The density of states is still quite small and the tunneling splitting can always be made sufficiently large ($D \gg \Delta$) by adequate excitation. Racemization in the beam can then be sufficiently fast (ns to ms time range) that both collisions and spontaneous and thermally induced radiative transitions are negligible: we are talking about conditions that may prevail in real experiments. In principle, one can also excite selectively one pair of tunneling levels and observe oscillatory dependence, but this is less important in practice.

4.2. Large Parity-Violating Energy Difference ΔE_{PV} and "Slow Tunneling", with a Small Density of States

Current calculations suggest that, at low energies, ΔE_{PV} will exceed $\Delta E_{\pm}$ in chiral molecules. As long as Equation (17) is satisfied, we still obtain the block diagonal structure of $\boldsymbol{H}$ as given by Equation (18). By the arguments given in Section 4.1 one obtains from Equation (22) with normalized distribution functions $F(\Delta)$ and $G(D)$ Equation (29).

$$p_R(t) = \int_{-\infty}^{+\infty} d\Delta F(\Delta) \int_{-\infty}^{+\infty} dD G(D) \frac{D^2}{D^2 + \Delta^2}\left[\sin\left(\frac{t}{2}\sqrt{D^2 + \Delta^2}\right)\right]^2 \quad (29)$$

ΔE_{PV} is essentially an electronic property depending upon the electronic wave function at the positions of the nuclei.[6, 10, 11, 45, 49] Although this certainly depends on the rovibrational state, it makes sense to take it as being constant, particularly for rigid molecules without large amplitude motions (except for racemization). The distribution function $F(\Delta)$ is thus approximately a Dirac delta distribution $\delta(\Delta - \Delta_c)$. On the other hand, D will vary in a wide range from D_a to D_b, as discussed before. In order to obtain a simple result we assume that (30) applies.

$$G(D) = \frac{\sqrt{D^2 + \Delta_c^2}}{N_0 D} \text{ for } D_a < D < D_b \quad (30)$$

with N_0 as normalization constant, so that $\int_{-\infty}^{+\infty} G(D)\,dD = 1$.

$$N_0 = \sqrt{D_b^2 + \Delta_c^2} - \sqrt{D_a^2 + \Delta_c^2} - \Delta \ln\left\{\frac{D_a(\Delta + \sqrt{D_b^2 + \Delta_c^2})}{D_b(\Delta + \sqrt{D_a^2 + \Delta_c^2})}\right\} \quad (31)$$

For $\Delta_c \ll D$ one obtains a constant distribution and results equivalent to Equation (26). For $\Delta_c \gg D$, $G(D)$ is proportional to $1/D$ (assuming positive D_a and D_b). One obtains Equation (32).

$$p_R(t) = \frac{1}{2N_0}\left\{(\sqrt{\Delta_c^2 + D_b^2} - \sqrt{\Delta_c^2 + D_a^2}) - \frac{1}{t}[\sin(t\sqrt{\Delta_c^2 + D_b^2} - \sin(t\sqrt{\Delta_c^2 + D_a^2})]\right\} \quad (32)$$

As $t \to \infty$ this relaxes, with some oscillations, to a stationary value [Eq. (33)].

$$p_R(\infty) = \frac{1}{2N_0}\{\sqrt{D_b^2 + \Delta_c^2} - \sqrt{D_a^2 + \Delta_c^2}\} \quad (33)$$

These expressions are valid for all ratios of Δ_c, D_a, and D_b. When we assume $\Delta_c \gg D_a, D_b$, we find the somewhat simpler result (34).

$$p_R(\infty) = \left\{1 + \frac{4\Delta_c^2}{D_b^2 - D_a^2}\ln\left(\frac{D_b}{D_a}\right)\right\}^{-1} \quad (34)$$

Only in Equation (34) have we made use of $\Delta_c \gg D_a, D_b$, thus that $p_R(\infty)$ remains small. *Again p_R does not oscillate as* $t \to \infty$ (neglecting terms of the order 1/N). Under these conditions an initial optical activity due to the condition $p_L(0) = 1$ will relax to a somewhat smaller than initial but still large value. In contrast to the result of Section 4.1, one cannot be sure that this result will be applicable in practice, neglecting collisional and radiative effects. This will only be true, if for some molecule the ΔE_{PV} is quite large. In this case we could learn about ΔE_{PV} from the kinetics of racemization. Fundamentally similar results are also obtained for the physically less likely case that ΔE_{PV} varies strongly with the rovibrational quantum state. Assuming for instance $F(\Delta)$ and $G(D)$ to be constant in the interval $-\Delta_m \le \Delta \le +\Delta_m$ and $-D_m \le D \le +D_m$ and zero outside, one finds a relaxed $(t \to \infty)$ population ($\Delta_m \gg D_m$) [Eq. (35)].

$$p_R(\infty) = \left(\frac{\pi D_m}{8\Delta_m}\right) + \frac{1}{4}\left[1 - \left(\frac{D_m^2 + \Delta_m^2}{D_m \Delta_m}\right)\arctan\left(\frac{D_m}{\Delta_m}\right)\right] \quad (35)$$

Separate forward and backward fluxes cannot be defined in any of these cases. Probability "appears" through tunnel-

ing across the boundary. Nevertheless, if one defines forward and backward rate coefficients in a kinetic relaxation scheme [Eq. (b) in Section 3.1], which is approximately possible, the rate coefficients depend upon the initial state and do not satisfy the detailed balance relationship Equations (3) or (11). This is an unusual situation in kinetics, which has, however, been encountered before.[77]

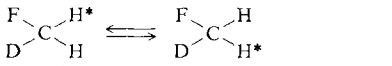
4.3. Very Large Densities of States: Pauli Equation for Racemization

For polyatomic molecules with more than 10 to 20 heavy atoms one can estimate with approximations such as Eq. (9) or by more accurate calculations[76] that the density of rovibronic states even at modest energies (≈ 50 kJ mol^{-1}) quickly becomes sufficiently large that (36) holds true.

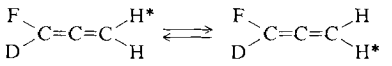
$$\delta = \varrho^{-1} \ll \Delta E_{\pm}, (\Delta E_{\mathrm{PV}}) \tag{36}$$

The hamiltonian matrix can no longer be brought into the block diagonal structure as in Equation (18) and, in general, any level of the **R** isomer will be coupled to many levels of the **L** isomer and vice versa. A finite matrix expansion of Equations (13)–(16) would then require matrices of the order of at least many times $\Delta E_{\pm}\,\varrho$ or $\Delta E_{\mathrm{PV}}\,\varrho$, which will be large numbers. Making use of statistical assumptions that have been discussed in detail elsewhere[77, 79] one can derive a Pauli equation for the specific rate coefficients $k_{\mathbf{RL}}^{\mathrm{micro}}(E)$ and $k_{\mathbf{LR}}^{\mathrm{micro}}(E)$ as a function of excitation energy E [Eqs. (37) and (38)].

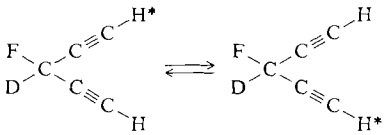
$$k_{\mathbf{RL}}^{\mathrm{micro}}(E) = 2\pi \langle D_{\mathbf{RL}}^2 \rangle \varrho_{\mathbf{R}}^{\omega} \tag{37}$$



$$k_{\mathbf{LR}}^{\mathrm{micro}}(E) = 2\pi \langle D_{\mathbf{LR}}^2 \rangle \varrho_{\mathbf{L}}^{\omega} \tag{38}$$



$\langle D_{\mathbf{LR}}^2 \rangle$ is the mean square "tunneling" coupling between all quantum states of **R** and **L** isomers at energy **E** in an interval ΔE which is large enough to render the average meaningful ($D_{\mathbf{RL}}$ *cannot* be calculated directly by a two-level tunneling model). The $\varrho^{\omega} = h\varrho/2\pi$ are the densities of states in circular frequency units. In contrast to the results of Section 4.2, Equations (37) and (38) satisfy the detailed balance relationship in Equations (11) and (12). The optical activity will relax to zero (practically) with a relaxation time $\tau_{\mathbf{R}} = 1/(k_{\mathbf{RL}} + k_{\mathbf{LR}})$. Again, it will not oscillate. The density of states ϱ that has to be considered in the inequality (36) is not the full density of states but rather only the density of those states that are effectively coupled (by matrix elements of the order $\sqrt{\langle D_{\mathbf{LR}}^2 \rangle}$). The transition between the situations in Sections 4.1 and 4.2 ("cases C" of Ref. [77]) and the Pauli equation ("case B" of Ref. [77]) will happen at values $\varrho^{-1} \simeq \Delta E_{\pm}$. From studying this transition experimentally one would thus learn about the coupling dynamics between the **R** and **L** isomers in real polyatomic molecules, beyond the two-level approximation. The experiment would simply use the rapid increase of both ϱ and $\Delta E_{\pm}$ with excitation energy. The infrared laser chemistry of racemization has recently been discussed in this context.[77b]



4.4. Dynamic Chirality and the Possible Existence of Chiral Methane

The common description of chiral molecules is based upon a Born-Oppenheimer potential with a double well and a barrier (such as in Fig. 1), which separates the two enantiomers. Racemization may occur in this description either by quantum tunneling through the barrier or by a quasiclassical barrier crossing above the barrier. We have stressed before that this description is unnecessary. This may appear obvious, because an observed *phenomenon* such as chirality, cannot depend on some arbitrary approximation that we use for its description. Atomic chirality is known to occur where this description would be meaningless.[41] It may be useful to complement these general observations with specific *molecular* examples of *dynamical chirality* beyond Born-Oppenheimer potentials.

Work by *Mecke*[80] and more recently by *Child* and *Lawton*[81] and others[82] suggests that high overtone excitation of high frequency modes in molecules with equivalent X–H modes may lead to long-lived localized vibrational excitations ("local modes"), in the following examples marked by asterisks.

(d)

(e)

(f)

Molecules with such localized vibrational excitations are chiral. The coupling including racemization is entirely vibrational (rotational) and unrelated to any electronic potential barriers. Although the lifetimes for localized states have probably been overestimated in early work,[81, 83] current evidence suggests that whereas the racemization (d) may occur on the subpicosecond time scale, the racemization (e) should be slower and in the case of acetylenic CH (or also alcoholic OH) stretching modes may exceed many picoseconds.[84] Such dynamic chirality could be studied by time resolved vibrational spectroscopy.[85] No direct experimental evidence has yet been presented, but one can be fairly certain from indirect evidence that the phenomenon exists.

Another kind of dynamic chirality has recently been proposed on the basis of localized *electronic* carbonyl excitation in an adamantanedione.[86] The chirality and its lifetime has not yet been established experimentally. Optical activity in vibrationally twisted allene has been discussed as well.[88] One should realize that also *rotation* may induce a dynamic asymmetry or chirality, for example by centrifugal distortion (for magnetic effects see Ref. [89]).

A particularly interesting case of dynamic chirality is methane, by tradition the prototype of an achiral, highly symmetric, tetrahedral molecule.[20] We shall discuss the consequences of parity violation and methane inversion from the present point of view. Figure 2 gives a rotational

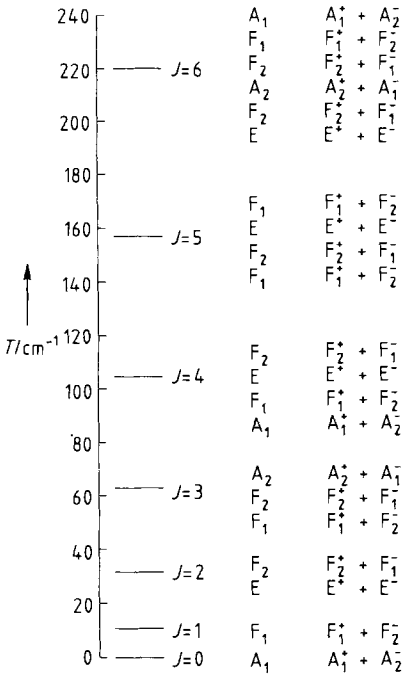


Fig. 2. Rotational energy level scheme for methane with symmetry assignments as explained in the text (after Ref. [100]). T = term value = $E/(hc)$ (for nomenclature cf. also Ref. [75]).

energy level scheme for methane. The zero order spherical top levels shown at the left-hand side are split by centrifugal distortion into sublevels, classified in the point group species (A_1, A_2, E, F_1, F_2) as shown in the middle. These strongly J-dependent splittings are large, of the order of 0.1 cm^{-1} here, and can be much larger. Each of these levels is further split by a very small amount into a sublevel of positive and negative parity (+, −) as indicated by the molecular symmetry group species notation on the right-hand side.[74, 75] (In Ref. [99] a different nomenclature has been used. According to the authors involved, the current nomenclature from Ref. [75] should be preferred.) It turns out that for CH_4 only the $A_2^{\pm}$ (combining with nuclear spin $I = 2$), the $F_1^{\pm}$ (combining with nuclear spin $I = 1$) and the $E^{\pm}$ (combining with nuclear spin $I = 0$) exist, because of the Pauli principle. Thus the $A_{1,2}$ and $F_{1,2}$ levels in T_D have all well defined parity (either + or −) and there is no inversion splitting for these. However, the $E^{\pm}$ pair does occur. Whereas in an asymmetrically substituted molecule with a high barrier the $\pm$ splitting due to tunneling must be very small for symmetry reasons, in a symmetrical molecule such as methane there are further contributions to this splitting, which are still very small but which are potentially much larger than the tunneling splitting. According to all current quantum chemical evidence the inversion splitting must be very small in methane.[97] There have also been experimental investigations on this question.[98, 99]

Nevertheless, for special dynamical reasons, or by using the influence of external fields as in atoms,[40, 41] the splitting may be made very small for some E^+, E^- level pair, so that $\Delta E_{\pm} \ll \Delta E_{PV}$. In this case ΔE_{PV} will generate new levels ϱ and λ (see Appendix), which have no well defined parity and are chiral: The probability density distribution $|\Psi_{\lambda,\varrho}(x,y,z)|^2$ for the four protons around the carbon nucleus will be asymmetric. This effect can be tested by a spectroscopic experiment (in principle also by diffraction methods, but accuracy will be too low there). It leads in any case to a fundamental revision of the stereochemical concepts introduced by *van't Hoff* and *Le Bel* some 100 years ago.[20]

4.5. Effects of Collisional and Radiative Processes

A complete treatment of collisional and radiative processes in a complex multilevel problem is beyond the scope of this article. However, we shall provide a phenomenological discussion of the effects expected in relation to the kinetic schemes in Sections 4.1. to 4.3. These complement the two-level treatment of collisions given by *Harris* and *Stodolsky*.[44]

Collisional and radiative effects can be introduced in general in a *reduced* density matrix equation of motion by adding non-Hamiltonian terms (cf. Eq. (16)). They can also be simulated approximately by phenomenologically adding contributions from a continuous spectrum to the molecular hamiltonian (Eqs. (13) and (18)), for instance in the form of complex energies $E_k - i\Gamma_k/2$ with a width Γ_k. The effect on kinetic schemes as described in Sections 4.1 to 4.3 is known. The width has the effect of changing the density of states from a Dirac δ-distribution to a more continuous function.[77] Then, by connecting the blocks of the effective hamiltonian instead of the relaxation [Eqs. (26), (28) or (32)] one has a transition to the Pauli equation rate coefficients (37) and (38). This changes somewhat the relaxation rate, but always leads to *complete racemization* at $t \to \infty$. In this sense collisions and spontaneous and thermal radiative processes *promote* racemization. This is somewhat in contrast to the result of *Harris* and *Stodolsky*,[44] not because their theoretical result would be subject to doubt, but because here we consider a complex multilevel problem at finite energy, whereas their result refers to the $T \to 0$, $E \to 0$ limit of a pure two-level problem. Of course, the present qualitative predictions can be tested by experiments similar to those we have proposed in Section 3. There is no evidence available on chiral molecules. However, in a dynamically very similar case of IR-multiphoton excitation, collisions were, indeed, found to enhance the corresponding equilibration process by the mechanism discussed above, which has also been established experimentally.[87]

5. Conclusions

We have demonstrated that different current hypotheses about the physical-chemical structure of chiral molecules lead to experimentally distinguishable consequences. Possible experiments using spectroscopic probes of molecular quantum state structure or probing the kinetics of racemization have been proposed. Although difficult and expensive (on the chemical, not particle physics scale) they would seem worthwhile in order to experimentally settle the questions posed.

It has been known to chemists and biologists for 140 years that chiral molecules carry a message for living beings: Chirality determines the fragrance of fruits, it can make all the

difference between bitter and sweet and it may distinguish healthy drug from deadly poison.[101] Chiral molecules recognize each other not just as key and lock but as hand and glove. It is also believed by many that chiral compounds in nature are messengers of the evolution of living beings.

It seems to be much less well known that molecular chirality may carry an as yet hidden message on the subtle physical forces governing molecular structure and dynamics and, perhaps, following the motto by *Pasteur*, on the structure of our universe.

I am most grateful to A. Ross and R. Marquardt, who kindly read and criticized the manuscript. Various aspects of the problem have been discussed with A. Amann, L. D. Barron, J. Dunitz, P. Pfeifer, V. Prelog, H. Primas, J. Robert, and P. von R. Schleyer. This work is financially supported by the Schweizerischer Nationalfonds and the Schweizerischer Schulrat.

Appendix: Some equations for the matrix representations of the two level problem with near degeneracies.

The hamiltonian matrix has the form (A 1). The eigenvalues for a hermitian operator $\boldsymbol{H}$ (A 2) follow from (A 3).

$$\boldsymbol{H} = \begin{pmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{pmatrix} \tag{A 1}$$

$$H_{12}H_{21} = H_{12}H_{12}^{*} = |H_{12}|^2 \tag{A 2}$$

$$E_{1,2} = \frac{H_{11} + H_{22}}{2} \pm \frac{1}{2}[(H_{11} - H_{22})^2 + 4|H_{12}|^2]^{\frac{1}{2}} \tag{A 3}$$

If we work in the basis $\chi_{\pm}$ of states of well defined parity and take ΔE_{PV} as perturbation one may identify (with real H_{12} and positive $\Delta E_{\pm}$) the expressions (A 4) and (A 5).

$$\Delta E_{PV} = 2H_{12} \tag{A 4}$$

$$H_{11} = -\Delta E_{\pm}/2 = -H_{22} \tag{A 5}$$

If we work in the basis of "left" and "right" handed states λ and ϱ, one has (positive ΔE_{PV}) the equations (A 6) and (A 7).

$$H'_{11} = -\Delta E_{PV}/2 = -H'_{22} \tag{A 6}$$

$$\Delta E_{\pm} = 2H'_{12} \tag{A 7}$$

The eigenvalues with respect to the average energy $(E_1 + E_2)/2 = \langle E \rangle \equiv 0$ are obviously the same ($\Delta E_{\pm}$ and ΔE_{PV} are defined real, positive) [(A 8)]. It is immaterial, whether ΔE_{PV} (Ref. [50]) or the tunneling $\Delta E_{\pm}$ (Section 4) is introduced as "perturbation".

$$E_{1,2} = \langle E \rangle \pm \frac{1}{2}(\Delta E_{\pm}^2 + \Delta E_{PV}^2)^{\frac{1}{2}} \tag{A 8}$$

Eigenvectors for the example of basis χ are given by (A 9) where x and y are defined via S [Eq. (A 10)] according to (A 11) and (A 12).

$$\boldsymbol{C} = \begin{pmatrix} x & y \\ -y & x \end{pmatrix} \tag{A 9}$$

$$S = (\Delta E_{\pm}^2 + \Delta E_{PV}^2)^{\frac{1}{2}} \tag{A 10}$$

$$x^2 = \frac{S + \Delta E_{\pm}}{2S} \tag{A 11}$$

$$y^2 = \frac{S - \Delta E_{\pm}}{2S} \tag{A 12}$$

The signs of the roots $\sqrt{x^2}$ and $\sqrt{y^2}$ can be taken in various combinations respecting $\boldsymbol{C}^{T}\boldsymbol{C} = \boldsymbol{I}$ (S is defined positive). One has by convention $E_1 < E_2$ and $H_{11} < H_{22}$. Some sign combinations in Ref. [50] were inconsistent with the correct figure ($E_{\lambda} < E_{\varrho}$). Figure 3 represents the situation ($x = y = 1/\sqrt{2}$ [Eq. (A 13)–(A 16)].

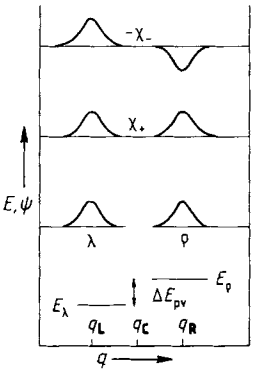

Fig. 3. Scheme for wave functions in a nearly degenerate situation ($\Delta E_{\pm} \approx 0$) in a chiral molecule (see text).

$$\lambda = \frac{1}{\sqrt{2}}(\chi_+ - \chi_-) \tag{A 13}$$

$$\varrho = \frac{1}{\sqrt{2}}(\chi_+ + \chi_-) \tag{A 14}$$

$$\chi_+ = \frac{1}{\sqrt{2}}(\lambda + \varrho) \tag{A 15}$$

$$-\chi_- = \frac{1}{\sqrt{2}}(\lambda + \varrho) \tag{A 16}$$

According to the superposition principle (if valid) these can always be generated by one of the methods of Section 3. The time evolution results from Equation (A 17) giving Equation (22) for $P_{RR} = p_R$, for example.

$$\boldsymbol{U} = \boldsymbol{C}\begin{pmatrix} \exp(-iE_1 t/\hbar) & 0 \\ 0 & \exp(-iE_2 t/\hbar) \end{pmatrix}\boldsymbol{C}^{T} \tag{A 17}$$

The density matrix with the elements $P_{ij} = \langle c_i c_j^* \rangle$ ($\langle\ \rangle$ = average over an appropriate ensemble) has the form (A 18) in the λ-ϱ basis and the form (A 19) in the $\chi_\pm$ basis.

$$\begin{pmatrix} P_{RR} & P_{RL} \\ P_{LR} & P_{LL} \end{pmatrix} = \boldsymbol{P}^{\lambda,\varrho} \tag{A 18}$$

$$\begin{pmatrix} P_{++} & P_{+-} \\ P_{-+} & P_{--} \end{pmatrix} = \boldsymbol{P}^{\chi_\pm} \tag{A 19}$$

For the degenerate system (or nearly degenerate system) at any temperature with $kT \gg S$ (A 10) Equation (A 20) holds.

$$\boldsymbol{P}^{\lambda,\varrho} = \boldsymbol{P}^{\chi_\pm} = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix} \tag{A 20}$$

$\boldsymbol{P}$ is invariant under the basis transformation (as any other constant diagonal matrix), also in the many level case, if $\boldsymbol{H}$ is block diagonal as in Equation (18). A racemic mixture of **R** and **L** is identical to a mixture of + and − in terms of any observable ensemble property. A common model for $\boldsymbol{P}$, simplified for the degenerate case, considered as a reduced density matrix of the molecule interacting by collisions or otherwise with a thermal bath gives the expressions (A 21) and (A 22), from which the relationships (A 24) and (A 25) can be derived for the relaxation times given here by τ_1 and τ_2 with the basis transformation (A 23).

$$(P_{11} - P_{22}) = (P_{11}^0 - P_{22}^0)\exp(-t/\tau_1) \tag{A 21}$$

$$P_{12} = P_{12}^0 \exp(-t/\tau_2) \tag{A 22}$$

$$\boldsymbol{P}^{\chi_\pm} = \boldsymbol{C}\boldsymbol{P}^{\varrho,\lambda}\boldsymbol{C}^{\mathrm{T}} \tag{A 23}$$

$$\tau_1^{\chi_\pm} = \tau_2^{\varrho,\lambda} \tag{A 24}$$

$$\tau_2^{\chi_\pm} = \tau_1^{\varrho,\lambda} \tag{A 25}$$

Here we have made use of the reality of $\boldsymbol{P}$ in the case of a degenerate model, because $E_{1,2}$ can be set to zero without loss of generality. To within this approximation the assignment of "phase" or "population" relaxation times τ_1 and τ_2 is arbitrary in the two level problem (cf. Section 3).

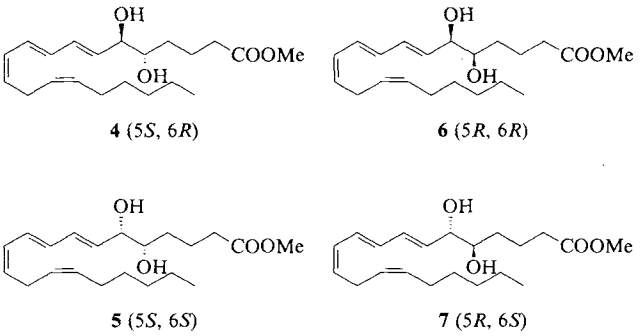
Stereocontrolled Total Synthesis of (5*S*,6*R*)-, (5*S*,6*S*)-, (5*R*,6*R*)-, and (5*R*,6*S*)-(7*E*,9*E*,11*Z*,14*Z*)-5,6-Dihydroxy-7,9,11,14-icosatetraenoic Acid (5,6-DiHETE) Methyl Esters**

By *K. C. Nicolaou,** *J. Y. Ramphal, J. M. Palazon,* and *R. A. Spanevello*



(5*S*,6*R*)-(7*E*,9*E*,11*Z*,14*Z*)-5,6-Ddihydroxy-7,9,11,14-icosatetraenoic acid (5,6-DiHETE) **1** is a naturally occurring and biologically active metabolite of arachidonic acid derived from leukotriene A_4 (LTA_4) by regio- and stereoselective hydrolysis (Scheme 1).[1]

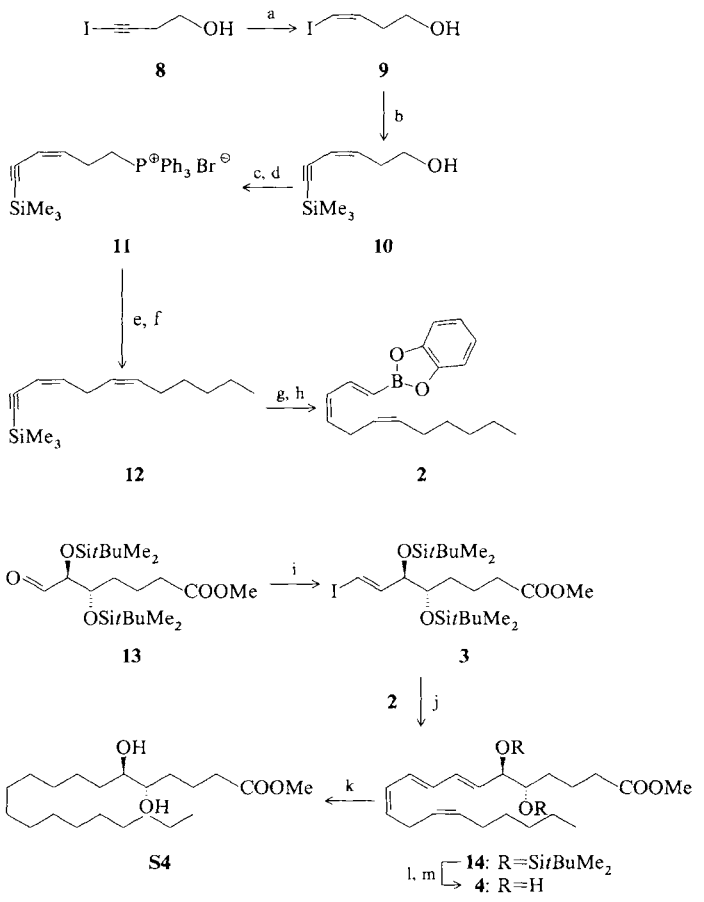
Scheme 1. Biogenetic generation and retrosynthetic analysis of (5*S*,6*R*)-DiHETE **1**. LT_4 = leukotriene A_4.

Nonenzymatic hydrolysis of LTA_4 leads to the isomeric (5*R*,6*R*)-DiHETE. In order to render these compounds readily available for biological studies and to compare their actions with those of lipoxin A_4,[2] we embarked on a program directed towards the synthesis of all four 5,6-isomeric DiHETE methyl esters (**4**–**7**, Scheme 2) as well as their fully saturated derivatives **S4**–**S7**.

The general and flexible strategy for the construction of the targeted DiHETE derivatives was based on the retrosynthetic analysis shown in Scheme 1. Thus, disconnection of

Scheme 2. Structures of synthesized DiHETE methyl esters **4**–**7**.

the bond between C-8 and C-9 accompanied by suitable functional group manipulation led to intermediates **2** and **3** as potential precursors. The Pd^0–TlOH–catalyzed coupling reaction of vinyl borane derivatives with vinyl halides developed by *Kishi* et al.[3,4] was envisioned as the key synthetic step to produce the skeleton of **1** from fragments **2** and **3** (Scheme 1).



Scheme 3 details the synthesis of (5*S*,6*R*)-DiHETE methyl ester **4**. Thus, selective reduction of the alkynyl iodide **8** gave the vinyl iodide **9** in 54% yield. Coupling of **9** with trimethylsilylacetylene assisted with $Pd(PPh_3)_4$ and CuI as catalysts afforded enyne **10** in 90% yield.[5] Sequential treatment of **10** with Ph_3P/CBr_4 and then with PPh_3 gave phosphonium salt **11** (92%) via the corresponding bromide (91%). Generation of the ylide from **11** with $KN(SiMe_3)_2$ followed by addition of hexanal resulted in the formation of the dienyne **12** as the major product accompanied by its *trans* isomer at the newly formed double bond (82% total yield, *cis*:*trans* ca. 4:1). Chromatographic separation of **12** from its isomer, followed by desilylation (79%) and regioselective hydroboration[6] with benzodioxaborole gave the requisite vinyl boronate **2** (55%). Compound **2** was then coupled with the vinyl iodide **3** (synthesized from the previously known aldehyde **13**[5] by a $CrCl_2$-mediated[7] reaction with iodoform, 70% yield) under the Kishi conditions [$Pd(PPh_3)_4$–TlOH],[3] affording the DiHETE skeleton **14** (55%). Finally, fluoride-induced desilylation of **14**, followed by diazomethane treatment (to methylate varying amounts of carboxylic acid formed) gave (5*S*,6*R*)-DiHETE methyl ester **4** in 85% overall yield.[8] Exhaustive hydrogenation of **4** smoothly led to the saturated compound **S4** (80%).

The total synthesis of the remaining DiHETE methyl esters **5**–**7** (Scheme 2) and their saturated counterparts **S5**–**S7** proceeded along similar lines from vinyl boronate **2** and the appropriate stereoisomers of vinyl iodide **3**, readily available from the corresponding aldehydes[5] as mentioned above. The described chemistry simplifies the construction of these linear icosanoids[9] and makes them readily available for further studies.

Experimental Procedure

Coupling of 2 with 3 to give 14: To a 250-mL round-bottom flask equipped with a magnetic stirrer was added **2** (103 mg, 0.37 mmol) in 5 mL of THF followed by hexane (30 mL). The solution was degassed by bubbling argon for 15 min before adding a degassed solution of 10% aqueous TlOH (2.52 mL, 1.14 mmol) with vigorous stirring over a period of 3 min at room temperature (RT). A THF solution (1 mL) of **3** (143 mg, 0.26 mmol) was then added followed by immediate addition of $Pd(PPh_3)_4$ (75 mg, 0.065 mmol) in 3 mL of THF. The reaction mixture was stirred for 0.5 h (TLC monitoring) at 25 °C and then transferred to a separatory funnel, diluted with ether (150 mL), and washed with saturated

sodium chloride solution (15 mL). The organic phase was dried ($MgSO_4$) and filtered through a celite pad, concentrated, and subjected to flash column chromatography (silica, 3% ether in petroleum ether), furnishing **14** as a colorless oil (82 mg, 55%). **14**: $R_f = 0.31$ (silica, 3% ether in petroleum ether); $[\alpha]_D^{20}$ +2.93° ($c = 0.48$, $CHCl_3$). MS: calculated for $C_{33}H_{62}O_4Si_2$, 578.418; found, 579.426 ($M+1$). IR (neat): $\tilde{\nu}_{max}$ = 3010, 2940, 2860, 1755, 1470, 1440, 1358, 1267, 1170, 1112, 1000, 840, 780 cm^{-1}. UV (CH_3OH): λ_{max} = 205, 262 (sh), 274, 285 (sh) nm. ^1H NMR ($CDCl_3$, 500 MHz): $\delta = 6.45$ (t, $J = 12.59$ Hz, 1H, olefinic), 6.16 (m, 2H, olefinic), 6.01 (t, $J = 10.88$ Hz, 1H, olefinic), 5.61 (dd, $J = 15.38$, 7.49 Hz, 1H, olefinic), 5.39 (m, 3H, olefinic), 3.98 (t, $J = 4.32$ Hz, 1H, CH-OSi), 3.67 (s, 3H, $COOCH_3$), 3.56 (q, $J = 3.05$ Hz, 1H, CHOSi), 2.92 (t, $J = 7.30$ Hz, 2H, bis-allylic), 2.25 (t, $J = 7.52$ Hz, 2H, CH_2COOCH_3), 2.05 (q, $J = 6.92$ Hz, 2H, allylic), 1.55 (m, 2H, CH_2), 1.28 (m, 8H, CH_2), 0.88 (m, 21H, 2 × *Si*t*Bu*, CH_3), 0.04 (s, 12H, $SiMe_2$).

Desilylation of ***14*** *to give* ***4*****:** Compound **14** (76 mg, 0.13 mmol) was azeotropically dried with benzene and dissolved in dry THF (3.0 mL). The magnetically stirred solution was treated with tetra-*n*-butylammonium fluoride (*1 M* solution in THF, 300 µL, 0.300 mmol) at 25 °C. Stirring was continued for 3 h at RT while the reaction was monitored by TLC. The solution was then diluted with ether (100 mL) and washed with pH 6 phosphate buffer (1 mL). The organic layer was separated and washed with saturated sodium chloride solution (2 mL), dried ($MgSO_4$), and concentrated. Ether (25 mL) was added followed by cooling to 0 °C and diazomethane treatment to give, after concentration, the crude methyl ester, which was subjected to flash column chromatography (silica, ether), furnishing pure **4** as a colorless oil (38.6 mg, 85%). **4**: $R_f = 0.52$ (silica, ether); $[\alpha]_D^{20}$ +0.91° ($c = 0.44$, $CHCl_3$). MS: calculated for $C_{21}H_{34}O_4$, 350.246; found, 333.243 ($M-OH$). IR (neat): $\tilde{\nu}_{max}$ = 3385, 3000, 2910, 2825, 1728, 1425, 1240, 1156, 1072, 988, 905, 722 cm^{-1}. UV (CH_3OH): λ_{max} = 320, 283 (sh), 274, 261 (sh) 205 nm. ^1H NMR ($CDCl_3$, 500 MHz): $\delta = 6.52$ (dd, $J = 14.47$, 11.01 Hz, 1H, olefinic), 6.35 (dd, $J = 15.22$, 10.55 Hz, 1H, olefinic), 6.19 (dd, $J = 14.46$ Hz, 10.41 Hz, 1H, olefinic), 6.03 (t, $J = 10.90$ Hz, 1H, olefinic), 5.72 (dd, $J = 15.05$, 7.05 Hz, 1H, olefinic), 5.42 (m, 2H, olefinic), 5.39 (m, 1H, olefinic), 4.11 (m, 1H, $CH-OH$), 3.68 (m, 1H, $CH-OH$), 3.64 (s, 3H, $COOCH_3$), 2.91 (t, $J = 7.12$ Hz, 2H, bis-allylic), 2.33 (t, $J = 6.70$ Hz, 2H, CH_2COOCH_3), 2.15 (s, 2H, O*H*), 2.03 (q, $J = 7.02$ Hz, 2H, allylic), 1.23 (m, 10H, CH_2), 0.86 (t, $J = 6.47$ Hz, 3H, CH_3).

Hydrogenation of ***4*** *to give* ***S4*****:** To a 25-mL round-bottom flask equipped with a magnetic stirrer and filled with argon was placed a solution of **4** (40 mg, 0.069 mmol) in distilled methanol (2 mL) and 10% Pd/C (8 mg, 20% by weight). The argon was replaced with hydrogen and the reaction mixture was vigorously stirred under hydrogen for 18 h while monitored by TLC. The hydrogen was removed and the catalyst was filtered off through a celite pad. The solution was concentrated and subjected to flash column chromatography (silica, 10% petroleum ether in ether), furnishing saturated **4** as a white waxy solid (19.8 mg, 80%). 4: $R_f = 0.47$ (silica, ether); $[\alpha]_D^{20}$ + 0.55° ($c = 0.55$, $CHCl_3$). MS calculated for $C_{21}H_{42}O_4$, 358.131; found, 376.343 ($M + NH_4$): IR ($CHCl_3$): $\tilde{\nu}_{max}$ = 3420, 3020, 2930, 2858, 1730, 1467, 1440, 1218, 755, 670 cm^{-1}. ^1H NMR ($CDCl_3$, 500 MHz): $\delta = 3.65$ (s, 3H, $COOCH_3$), 3.57 (m, 2H, *CH*-OH), 2.35 (t, $J = 7.36$ Hz, 2H, CH_2COOCH_3), 1.84 (s, 1H, OH), 1.58 (s, 1H, OH), 1.47–1.42 (m, 5H, CH_2), 1.23 (s. 25H, CH_2), 0.86 (t, $J = 6.77$ Hz, 3H, CH_3).

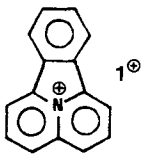
[8] Small amounts of the δ-lactone corresponding to **4** were also formed in this reaction. Conversion of this lactone to **4** was easily accomplished by exposure to Et_3N in methanol.

[9] All new compounds exhibited satisfactory spectroscopic and analytical and/or exact mass data. Yields refer to chromatographically and spectroscopically homogeneous materials.

Azonia Derivatives of Arenes: Synthesis and Properties of 10c-Azoniafluoranthene **



By *Marc Fourmigué,* Kamal Boubekeur, Patrick Batail,* and *Klaus Bechgaard*

Radical cation salts of arenes such as naphthalene and fluoranthene exhibit an extremely narrow solid-state EPR line (10–20 mG, compared to 1.35 G for DPPH[11]). This is believed to be due to the strongly one-dimensional nature of the conducting electrons and related to the metallic behavior arising from a strict 2:1 stoichiometry of the mixed-valent $(aryl)_2X$ salts.[2, 3] Promising applications of these compounds as magnetic field probes are restricted, however, because of their lack of stability.[4]

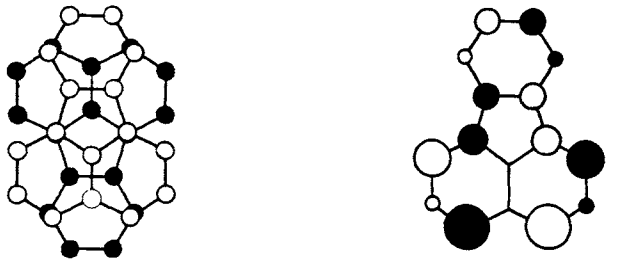
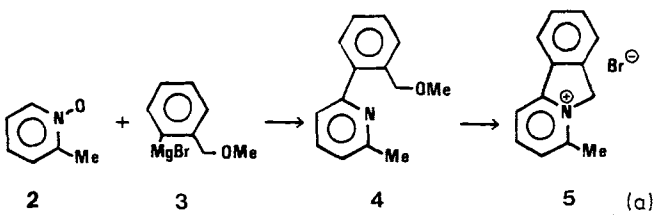
Heteroatom substitution at appropriate positions in the carbon framework of the arene molecule is expected to enhance the stability of the corresponding radical species. We therefore investigated the closed-shell cation $\mathbf{1}^{\oplus}$, which is isoelectronic with fluoranthene. We report here the synthesis and characterization of $\mathbf{1}^{\oplus}$ and demonstrate that its reduction affords the neutral radical $\mathbf{1}^{\odot}$, which is isoelectronic with the fluoranthene radical anion and was characterized by EPR and cyclic voltammetry experiments.

The cation $\mathbf{1}^{\oplus}$ is especially attractive for the following reasons (Fig. 1): (1) the crisscross mode of overlap of 2:1 fluoranthenium salts, which actually minimizes the intradimer van der Waals interactions, should be preserved in $\mathbf{1}^{\odot}$ in the solid state and in $(\mathbf{1})_2X$ salts;[5, 6] (2) there is essentially no odd-electron density in the SOMO of $\mathbf{1}^{\odot}$ at the nitrogen atom. Therefore, the hyperfine interaction with the nitrogen atom ($S = 1$) is minimal and consequently no EPR line broadening should occur in the solid because of the replacement of C by N.





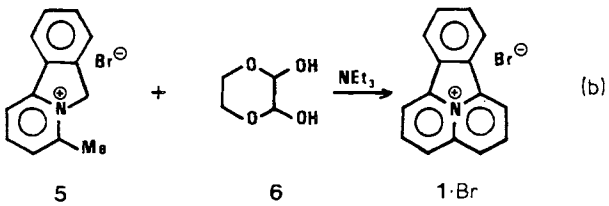


Fig. 1. Left: The overlap between adjacent molecules in the fluoranthenium salts [5]. Right: The electronic density in the fluoranthene LUMO. Radii are proportional to the coefficients of the LUMO [16].

The cation $\mathbf{1}^{\oplus}$ was synthesized as follows: The salt **5**, with two potentially nucleophilic sites available for a Westphal condensation with an α-dioxo compound, was selected as starting material for the synthesis of $\mathbf{1}^{\oplus}$.[6] Compound **5** was obtained in two steps [Eq. (a)],[7] starting with the known addition of alkyl or aryl Grignard reagents to pyridine *N*-oxide.[8]

2 **3** **4** **5** (a)

The use of the *ortho*-substituted bromobenzene **3** gives the pyridine **4**, isolated in 40% yield after a dehydration step with acetic anhydride. Hydrolysis of **4** in concentrated HBr, concomitant with the intramolecular quaternization, leads directly to the salt **5**. Reaction of **5** with the anhydrous glyoxal equivalent **6**[9] in the presence of an equimolar amount of triethylamine allows the double condensation and simultaneous elimination to give the fully aromatized bromide salt $\mathbf{1}^{\oplus}$ [Eq. (b)].

5 **6** **1**·Br (b)

Cyclic voltammetry experiments performed in acetonitrile (NBu_4PF_6, 0.1 M) demonstrate that $\mathbf{1}^{\oplus}$ is reduced at $E_{1/2} = -0.9$ V versus SCE. Sweep-rate dependance of the voltammogram indicates a quasi-reversible behavior.[10] This is in contrast to most of the pyridinium-like cations (e.g., *N*-methylpyridinium, -quinolinium, -acridinium, -quinolizinium, and acridizinium) in which reduction to the neutral radical is irreversible unless the cation carries an electron-attracting substituent at the position of highest electron density in the LUMO.[11]

The neutral radical generated by reduction of $\mathbf{1}^{\oplus}$ in acetonitrile solution on Na/Hg amalgam is persistent for several hours when kept under oxygen-free conditions. The EPR solution spectrum gives five equally spaced, rather broad lines with an apparent hyperfine splitting (a_H) of 5.17 G. This spectrum is similar to that of the isoelectronic fluoranthene radical anion ($a_{H3} = 5.24$, $a_{H1} = 3.93$, $a_{H8} = 1.2$ G[12]) when line broadening occurs. Attempts to isolate the neutral radical $\mathbf{1}^{\odot}$ in the solid state have been so far unsuccessful.

In order to characterize this new heterocyclic structure more completely, we also carried out an X-ray crystal structure investigation of $\mathbf{1} \cdot PF_6$. The cation is essentially planar. The single salient structural difference with fluoranthene is a significant contraction of the bond lengths around the nitrogen atom (Fig. 2).

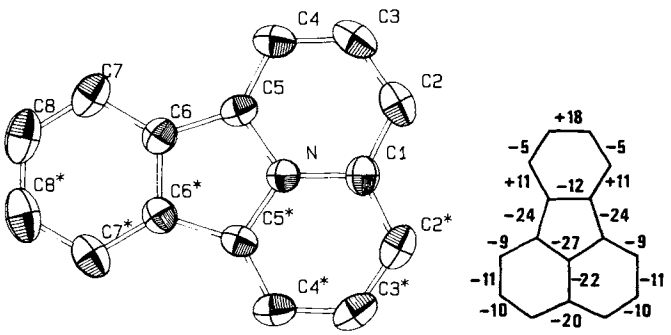

Fig. 2. Molecular structure of $\mathbf{1} \cdot PF_6$ [13]. Ellipsoids are scaled to enclose 50% of the electronic density. Significant bond distances [Å] and angles [°]: N-C1 1.378(5), N-C5 1.384(4), C1-C2 1.402(4), C2-C3 1.358(5), C3-C4 1.400(5), C4-C5 1.358(5), C5-C6 1.452(4), C6-C6* 1.402(5), C6-C7 1.395(5), C7-C8 1.381(5), C8-C8* 1.396(6); C1-N-C5 123.7(2), C5-N-C5* 112.6(3), N-C1-C2 115.8(2), C2-C1-C2* 128.3(4), C1-C2-C3 121.0(3), C2-C3-C4 121.7(3), C3-C4-C5 118.4(3), C4-C5-N 119.4(3), N-C5-C6 105.6(3), C4-C5-C6 135.0(3), C5-C6-C6* 108.1(3), C5-C6-C7 130.8(3), C6*-C6-C7 121.1(3), C6-C7-C8 117.4(3), C7-C8-C8* 121.5(3). Experimental Procedure

4: A THF solution of 2-methylpyridine N-oxide (75.3 g, 0.69 mol) [15] was added dropwise to a THF solution of **3**, prepared from the corresponding *ortho*-substituted bromobenzene (138.7 g, 0.69 mol, Mg (16.8 g, 0.69 mol), and EtBr (18.8 g, 0.17 mol) in dry THF. The mixture was stirred ca. 12 h. Hydrolysis yielded a pasty white precipitate. The THF solution was decanted and the precipitate washed with $CHCl_3$. The combined solutions were washed with 0.1 N NaOH followed by 0.1 N HCl and then evaporated. The neutral clear oil was boiled with 500 mL of acetic anhydride for 3 h. After evaporation of the anhydride, the dark residue was treated with 200 mL of 0.1 N NaOH and extracted with toluene three times. The combined solution was extracted with 2 N HCl and the acidic solution cooled and basified with concentrated NaOH. The supernatant oil was extracted with ether and the solution was dried with $MgSO_4$ and evaporated. Vacuum distillation yielded a slightly fluorescent oil (60 g; 41%), b.p. 114–116 °C (0.5 torr). ^{1}H NMR ($CDCl_3$, 60 MHz, TMS): δ = 2.55 (s, 3H, Me-C), 3.3 (3H, s, OMe), 4.55 (2H, s, CH_2), 7.0–7.7 (7H, m, aryl H). Correct C,H,N elemental analysis.

5: A solution of **4** (60 g, 0.28 mol) in 48% HBr (500 mL) and AcOH (500 mL) was refluxed for 4 h. Evaporation and recrystallization from EtOH yielded **5** as its bromide (47.4 g, 64%), m.p. 245–248 °C. ^{1}H NMR (CF_3CO_2H, 60 MHz, TMS): δ = 3.0 (3H, s, Me), 5.75 (2H, s, CH_2), 7.7–8.6 (7H, m, aryl H). UV/VIS (EtOH): λ [nm] = 252 (lg ε = 4.08), 318 (4.02). Correct C,H,N analysis.

1$^{\oplus}$: A solution of **5** (13 g, 0.05 mol), **6** (7 g, 0.05 mol), and Et_3N (7 mL, 0.05 mol) in EtOH was refluxed for 1 h, then cooled, evaporated, and precipitated by addition of Et_2O. The dark crystalline product was recrystallized twice from EtOH/AcOEt (1:1) and then from dimethyl sulfoxide (DMSO) (yield of **1** · Br: 4.7 g, 33%). Addition of 70% HPF_6 to an ethanolic solution of **1** · Br resulted in the precipitation of a $PF_6^{\ominus}$ salt, which was recrystallized from acetonitrile as transparent needles. ^{1}H NMR ([D$_6$]DMSO, 90 MHz, TMS): δ = 9.5 (2H, d), 8.7–9.2 (6H, m), 8.15 (2H, pseudo q). ^{13}C NMR ([D$_6$]DMSO, 22.6 MHz, TMS): δ = 139.17, 137.73, 136.43, 131.75, 129.80, 126.35, 123.04, 120.83. UV/VIS (EtOH): λ [nm] = 220 (lg ε = 4.58), 240 (4.15), 252 (4.16), 272 (4.4), 295 (3.96), 306 (sh, 3.89), 343 (sh, 3.77), 358 (3.92), 377 (3.86). Correct C,H,N analysis.

A Joint Structural Characterization of Colloidal Platinum by EXAFS and High-Resolution Electron Microscopy

By *Daniel G. Duff, Peter P. Edwards*, John Evans, J. Trevor Gauntlett, David A. Jefferson, Brian F. G. Johnson, Angus I. Kirkland,* and *David J. Smith*

The structures and morphologies adopted by small metal particles continue to attract widespread interest. Of particular importance in this regard are the structures of particles of metals such as Pd, Pt, Ru, and Cu, which find extensive application in commercial catalysis.

To date, the most successful techniques for probing the structure of such species have been bright- and dark-field transmission electron microscopy (TEM)[1, 2] to yield information about the morphology and surfaces in projection, coupled with electron diffraction data from larger particles to yield unit-cell dimensions and orientation, and high resolution electron microscopy (HREM) to yield precise information on the atomic arrangement and the nature of defect structures such as twin planes and stacking faults.[3–5] However, when faced with the task of characterizing particles from a colloidal solution, special problems arise. Although the homogeneity of the sol may be reliably ascertained by examining more than one specimen grid and a number of grid squares within each, there still remains the possibility that what is imaged in the electron microscope may not be the same as the species present in solution. Electron microscopy necessitates desiccation of the sample followed by electron irradiation: indeed, *Thomas, Millward,* and *Harriman*[6] have noted beam-induced reduction of iridium dioxide colloids, and preliminary results of our own suggest that for very small particles this may happen too quickly to be observed in some systems.

Hence we require an *ensemble* technique capable of operating on solutions to confirm the structural information provided by electron microscopy. Visible spectrophotometry provides only limited and qualitative information concerning particle size and degree of aggregation. However, EXAFS provides exactly the required information on the particle structure with limited perturbation of the system and, although not ideal where long-range order is concerned, is especially useful in the regime of small particle size (30-Å diameter and below). It is thus ideally complementary to an electron-microscopic study.

In this communication we therefore report a joint structural characterization of a platinum sol by EXAFS and HREM. Our results confirm that the HREM images obtained represent an accurate reflection of the structure of the particles present in solution in this case.

The synthesis is an adaptation of one previously described.[7, 8] A greater residual molar ratio of polymer to

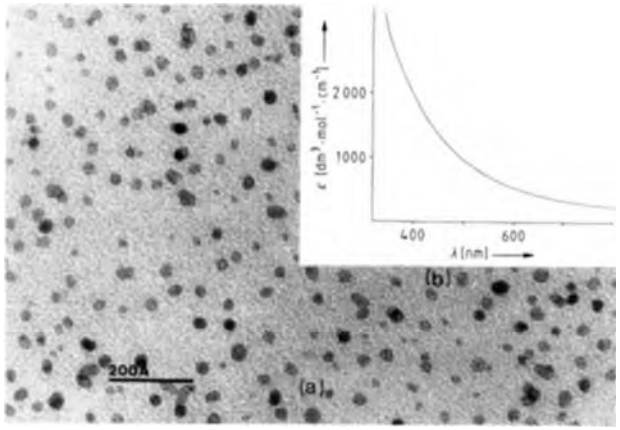

Fig. 1 a) A typical low-resolution transmission electron micrograph of particles from the platinum sol. b) The optical extinction of the sol in the visible region of the spectrum.

metal (54.05 versus 40.95) was used in a more concentrated preparation, and a concentration of metal of 10^{-2} M was employed. TEM of the dark brown sol (Fig. 1 a) reveals small particles with minimal aggregation on the grid. The optical spectrum (Fig. 1 b) shows the featureless absorbance decreasing to long wavelengths typical for platinum sols. As previously noted[9] for platinum colloids prepared by different routes, a double-log plot of absorbance against wavelength is linear over the wavelength range 400–600 nm. The gradient (−3.3) corresponds well with the values reported by *Furlong* et al.[9] for well-dispersed sols of small particles, aggregated sols displaying flatter spectral curves and consequently straight lines of shallower gradient in the double-log plot. These results confirm the genuinely well-dispersed nature of the sol as revealed by TEM. Syntheses performed at the concentrations used by *Hirai* et al.[7, 8] and those using a tenth of the metal and polymer concentrations employed here (10^{-3} M Pt and 0.3 g polyvinylpyrrolidone (PVP)) both showed a high frequency of aggregated particles.

A size-distribution histogram measured from 100 particles from the low-resolution micrographs is presented in Figure 2. The mean (equivalent circle) diameter of the measured particles is 26 Å with a standard deviation of 11 Å, yielding a coefficient of variation of 43%. The volume-weighted mean particle diameter is 31 Å.

High-resolution electron microscopy showed the majority of particles present to have structures based on apparently perfect fcc packing with the particles exhibiting roughly hexagonal outlines in projection when viewed down a ⟨110⟩ direction, suggesting an approximate cubeoctahedral morphology. Some images were also recorded of particles in

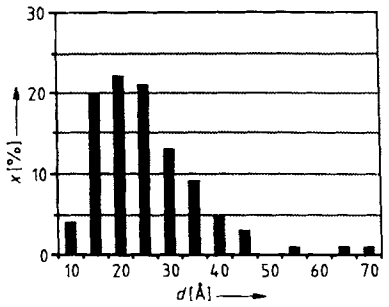

Fig. 2. A histogram of particle diameters measured from low-resolution electron micrographs. x = percentage of particles, d = equivalent circle diameter.

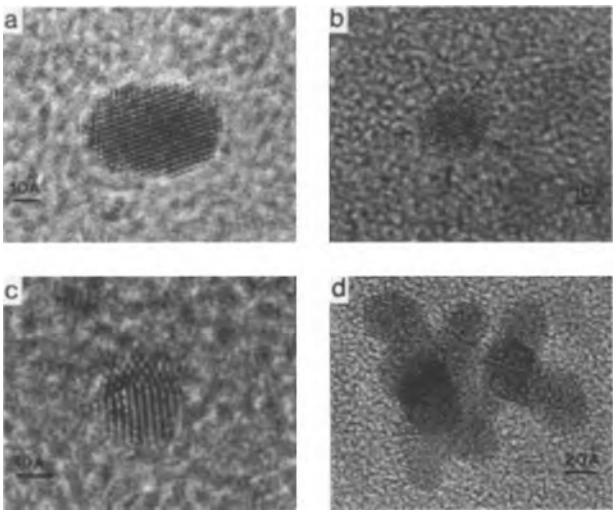

Fig. 3 a) A high-resolution image of an apparently perfect fcc Pt particle in a <110> orientation. b) An image of an apparently perfect decahedral particle viewed down the fivefold symmetry axis. c) A similar particle but tilted further from this axis. d) A <100>-oriented agglomerate of apparently perfect fcc particles as observed in the more dilute sols referred to in the text.

⟨100⟩ orientations. A typical image of a small particle is shown in Figure 3 a, clearly indicating the apparently perfect fcc lattice; while the particle possesses flat {111} surfaces, the {100} surfaces appear noticeably roughened. This second feature is similar to that observed by *Schmid* et al.[11] for small Pt particles prepared by electron-beam decomposition of the cluster $[Pt_{55}(AstBu_3)_{12}Cl_{20}]$.[12] However, the adatom growth processes on {100} faces observed by *Schmid* et al. were not observed here, even during real-time recording of the images via a video tape recorder (VTR) system. Furthermore, the well-defined surfaces present on these particles are in contrast to the more rounded surfaces observed for small Pt particles supported on carbon black.[13]

Although the majority of particles conformed to the above description, a significant percentage showed alternative structures. A very small number of decahedral multiply twinned particles were observed (Fig. 3 b, c) and, in addition to these, some particles apparently displayed single microtwins on {111} planes. Recent image simulation studies[14] have indicated that such decahedral particles tilted from the fivefold symmetry axis may give rise to images apparently containing single microtwins, and therefore these particles could also contribute to the multiply twinned fraction. Nonetheless, the vast majority of particles showed no obvious radial twinning. Complications could also arise from the specific concentrations employed: in particular, when sols prepared at different metal and polymer concentrations were examined, aggregates of particles were frequently observed on the specimen grid (Fig. 3d), although it is significant that the individual particles making up this aggregate are clearly perfect fcc crystals. Full details of these related sols will be published elsewhere.[15]

The acquired EXAFS data lends strong support to the assignment of the colloidal particles in solution as fcc platinum crystallites. Comparison of experimental EXAFS data for colloidal platinum and the bulk metal are shown in Figure 4 a. The similarity in the two structures is obvious from their k^3-weighted EXAFS spectra (Fig. 4 a). The close correlation of their Fourier transforms is also noteworthy (Fig. 4 b), the radius ratios in the radial distribution function being excellent evidence for fcc packing. However, there is a small difference in the frequency of the two spectra, notice

Table 1. Experimental EXAFS data for colloidal and bulk platinum.

	Pt metal	Pt colloid
E0	12.1(5)	12.7(8)
R1	2.748(1)	2.737(2)
A1	0.0104(1)	0.0115(2)
R	25.3	38.1

able at > 11 Å^{-1}. Fourier filtration around the first shells allows the major component of this difference to be identified. Refinement of E0, R1, and A1 (see *Experimental Procedure*) converges to minima listed in Table 1.

The source of the frequency difference between the spectra is the difference in the interatomic distance to the first coordination shell. This distance, in colloidal platinum, is 0.011(2) Å less than in the bulk metal, indicating relaxation of fcc packing in the colloid structure. The Debye–Waller factor for the first coordination shell in the colloid spectrum is given for an amended first-shell occupancy of 11.2. The following approximations were made in assuming this. From the particle size distribution an average spherical particle volume of 16470 Å^3 was calculated. Since the particle has close-packed structure, the actual volume occupied by metal atoms is 74% of this value or 12190 Å^3, which corresponds to 1110 atoms. Approximately 250 of these are on the surface with 9 or less nearest neighbors. These surface atoms were assumed to have 8.5 nearest neighbors each, giving an average coordination number throughout the particle of 11.2.

If the coordination number is allowed to refine freely with the other three parameters, a minimum is reached when N = 9.9(7). The interatomic distance and E0 are unaffected while A1 falls to 0.0108(5). A coordination number of ten is more reasonable for a nonspherical particle with a greater proportion of atoms at the surface, such as in the colloid. However, similar refinement of the same parameters for the bulk metal reaches an almost identical minimum (N1 = 9.7(5); A1 = 0.0092(3)), thus illustrating how refinement of two highly correlated parameters can lead to false minima. Therefore, calculated values of the first-shell occupancy were employed at all times.

Relaxation of the surface structure on certain faces of the colloidal particle, where the lower coordination number introduces distortions away from close packing, results in a higher Debye–Waller factor for the first coordination shell. A small fraction of non-fcc particles would also be expected to have a similar effect, and disorder due to larger-amplitude vibrations than in the bulk will also occur.

Lattice contractions in small platinum particles have previously been reported.[16–18] Our results show a lattice contraction of 0.4%, well within the limits of theoretical calculations[19] for this particle size. However, the electron diffraction results of *Solliard* and *Flueli*,[18] when extrapolated to a volume-weighted mean particle diameter of 31 Å, yielded a contraction of 0.6% (still concurring with the calculations). This difference possibly arises from surface adsorption on the sol particles by species such as oxygen, thereby changing the nature of the surface stresses (*Solliard* and *Flueli* worked on vacuum-evaporated particles and, presumably, cleaner surfaces than those present in this system). EXAFS has previously been used to measure relaxations in platinum clusters of 12-Å diameter in which a contraction of 4.3% was found,[17] but this contraction was very sensitive to gas adsorption, almost vanishing when the particles were exposed to hydrogen.

We have thus demonstrated the usefulness of a combined EXAFS/electron-microscopic investigation as a tool in the elucidation of small-particle structures. EXAFS is suited to the determination of accurate lattice parameters such as the observed contraction of the particles in solution. HREM, however, yields data on short-range defect and minority structures inaccessible to EXAFS. In particular, the potential of EXAFS for probing the nature of extremely small solution species cannot be overemphasized in view of the proposed importance of such species in the nucleation and growth processes operative in colloidal solution.

Experimental Procedure

The synthesis was performed in a 100-mL round-bottomed Pyrex flask, rigorously cleaned as follows. A cleaning mixture containing hydrofluoric acid, nitric acid, and a surfactant (Lipsol) was prepared following a method previously described in the literature [20]. The flask was filled with this mixture and left for 10 min. The cleaning fluid was decanted off and the flask rinsed ten times with hot tap water, five times with laboratory-supply distilled water, and three times with water distilled in a glass apparatus. Polytetrafluoroethylene (PTFE) stirring beads were cleaned of metal by soaking in aqua regia for several hours, followed by extensive rinsing as above. The flask was then arranged as for the reaction with the stirring bead added and glass-distilled water was boiled under reflux for 30 min therein and decanted.

A solution of H_2PtCl_4 (248 mg; Johnson Matthey Chemicals plc, 39.34% Pt) in glass-distilled water (25 mL) was added to a solution of PVP (3 g; Polysciences Inc., weight-average molecular weight 10000) in analytical reagent grade methanol (25 mL) with stirring (PTFE-coated magnetic stirring bead). The stirring bead was then removed and the mixture heated to boiling under a nitrogen atmosphere. After 70 min boiling under reflux, the sol was allowed to cool. A small volume (< 1 mL) was removed for electron microscopy. An aliquot (5 mL) of ca. 0.2 M sodium hydroxide solution was then added and the sol concentrated down to ca. 5 mL while purging with nitrogen. There was no change in color during the last two processes and redilution revealed no change in optical spectrum. This sample was then retained for EXAFS.

Optical spectroscopy of the sol was performed using a PYE-Unicam SP-8800 spectrophotometer. Spectra were recorded in the range 400–800 nm with the

samples contained in quartz cells of 1-mm path length. Although the sols were prepared under nitrogen, exposure to air caused no noticeable change in the optical appearance of the sol, and no effort was made to protect the samples for EXAFS and HREM from air.

Specimens for electron microscopy were prepared by allowing a drop of the sol to contact briefly an amorphous carbon film supported on a copper grid. Initial TEM examination was carried out using a standard JEOL JEM-200CX fitted with a standard side-entry double-tilt goniometer and operated at 200 kV, subsequent high-resolution studies employing either our modified JEOL JEM-200CX [21] (C_s = 0.52 mm, C_c = 1.05 mm at 200 kV) or a JEOL JEM-4000EX (C_s = 1.0 mm, C_c = 1.7 mm at 400 kV) for structural characterization at interpretable point resolutions of 1.95 Å and 1.7 Å, respectively. For these studies suitably oriented particles were located on the grid on a trial-and-error basis. Care was taken to ensure the correct alignment of the illumination system [22], and residual objective-lens astigmatism was corrected by observations of the granularity of the amorphous carbon film. All high-resolution micrographs were recorded at electron-optical magnifications in the range 300000 to 700000.

EXAFS spectra were obtained from the highly concentrated (ca. 0.1 M) sol in transmittance mode on Beam Line 9 of the Synchrotron Radiation Source at the SERC Daresbury Laboratory, and the spectrum of platinum metal powder (Johnson Matthey Chemicals) also obtained for comparison. Background subtraction was achieved using smooth polynomial curves for both pre- and post-edge in the program PAXAS [23]. Window limits for Fourier filtration of the spectra around the first shell were 1.98 to 3.42 Å and 1.97 to 3.47 Å for the metal and the colloid, respectively, in the non-phase-shifted spectra. Fourier filtration has two functions; it ensures that any contributions from more distant shells are removed and produces a spectrum with 200 evenly distributed points in k space.

All calculations employed the spherical wave theory of *Lee* and *Pendry* [24], utilizing algorithms suitable for polycrystalline or amorphous samples [25]. Twenty-five phase shifts were used in calculating the backscattering terms. The excited atom wave function was calculated for an atom in which the outer electrons are fully relaxed in the presence of a 2p core hole. A constant imaginary potential of -7 eV was used to model inelastic processes. This low value is an adequate model for the short core hole lifetimes of metals.

Analysis involved least-squares minimization of the fit index

$$S_i(k^3(X_i^T - X_i^E))^2$$

where X_i^T and X_i^E are the theoretical and experimental EXAFS, respectively. However, this is dependent on the absolute amplitude of the spectrum. A discrepancy index, R, is therefore reported as a measure of the precision of the fit.

$$R = \frac{\int |(X^T(k) - X^E(k))| k^3 \, dk \times 100}{\int |X^E(k)| k^3 \, dk}$$

The parameters refined were: the interatomic distance from the absorber to the nearest-neighbor backscattering shell, R1; the Debye–Waller factor for the first shell of nearest neighbors, A1, described by $A1 = 2\,s^2$; the energy of the emitted photoelectron at $k = 0$, E0.

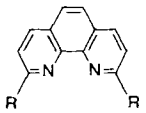
Efficient Photoinduced Intramolecular Energy Transfer in an Oblique Bis-Porphyrin System

By *Sylvie Chardon-Noblat, Jean-Pierre Sauvage,** and *Paul Mathis*

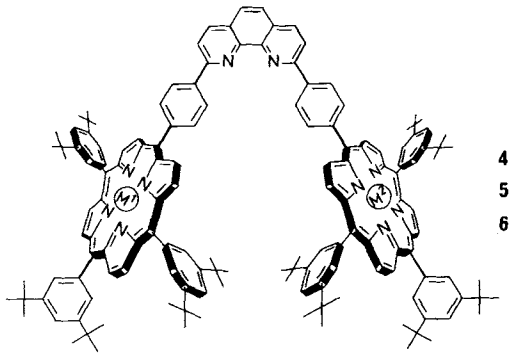
Multifunctional molecular systems able to perform intramolecular electron or energy transport are of particular relevance both for handling and carrying signals at the molecular level[1] and for understanding the function of the chromophores involved in natural photosynthetic systems.[2] In order to mimic the initial charge-separation step of photosynthesis, numerous bipartite compounds consisting of a porphyrin linked to an electron acceptor[3] have been synthesized and studied, a promising extension being provided by tripartite systems consisting of an electron donor, a porphyrin, and an electron acceptor.[4] Energy transfer and migration is also of great importance in natural photosynthesis.

Intramolecular singlet energy transfer has been observed in covalently linked but highly flexible bis-porphyrin systems.[5] We have recently described a rigid oblique bis-porphyrin[6] built on a 1,10-phenanthroline spacer insuring geometrical features close to those found in the reaction center of photosynthetic bacteria.[7] We now report a method for rapid synthesis of the bis-porphyrin system **5** as well as its intramolecular energy-transfer properties.



Compound **1** was obtained as previously described[6] from 4-lithiotoluene and 1,10-phenanthroline in 65% yield. Treatment of **1** with *N*-bromosuccinimide (3 equivalents) in refluxing benzene under light irradiation ($\lambda > 320$ nm; 30 min) gave **2**. After filtration, washing (H_2O), and solvent evaporation, the crude product was directly treated with NaOH in refluxing propionic acid. Workup and chromatographic purification (silica; CH_2Cl_2/AcOEt) afforded **3** as a yellow, glassy solid in 20% yield from **1**.

Compound **3** was allowed to react with pyrrole and 3,5-di-*tert*-butylbenzaldehyde (1:16:15) in refluxing propionic acid for 16 h. After workup, repeated chromatographic separation on silica (hexane/toluene), and recrystallization in benzene/ethanol, a 2.6% yield of **4** was obtained as a purple solid. Compound **7** was isolated from the same reaction mixture in 16% yield.



Compound **4** was treated with 1.1 equivalents of zinc acetate in CH_3OH/CH_2Cl_2 (1:3) under reflux for 1.5 h. After chromatography (alumina; CH_2Cl_2/hexane), the three com-

[a] Cyclic voltammetry measurements on 2.5×10^{-4} M solutions (**4**–**6**) or 5×10^{-4} M solutions (**7**, **8**) in degassed CH_2Cl_2 on Pt wire; successive redox potentials of reversible couples in *V* vs. SCE with 0.1 M $nBu_4N^{\oplus}BF_4^{\ominus}$ in CH_3CN junction; 0.1 M $nBu_4N^{\oplus}BF_4^{\ominus}$ as supporting electrolyte; scan rate, 80 mV s^{-1}.

The absorption spectra of **4**, **5**, and **6** in CH_2Cl_2 display a single, relatively sharp Soret band (at $\lambda = 421.5$ nm with $\varepsilon = 1.1 \times 10^6$ cm^{-1} mol^{-1} L for **5**). The spectra correspond rather precisely to those of **7** or **7** + **8** (data not shown). This indicates that the two chromophores are not or only very weakly coupled, in contrast to *Tabushi*'s gable porphyrin.[8] Interesting observations related to the influence of the geometry of the system on the inter-chromophore interaction have recently been reported for flat, twisted, and gable bis-porphyrins.[9, 10] Some dipole–dipole interaction seems to exist in the gable system, contrary to the presently described molecules. This different behavior may originate in larger edge-to-edge (ca. 9 Å) and center-to-center (ca. 13 Å) separation of the two porphyrin units in **5** compared with gable bis-porphyrins.[8, 9]

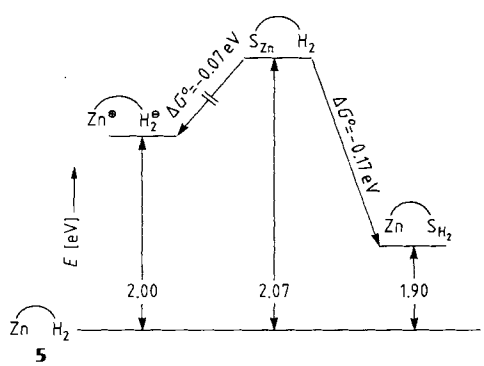

Table 2. Emission data of the porphyrin compounds **4**–**8** [a].

Compound	λ_{max} (emission, relative intensity in parentheses) [nm]		
4	–	654 (120)	720 (30)
5	–	654 (180)	718 (30)
6	603 (40)	653 (30)	–
7	–	654 (100)	718 (30)
8	600 (70)	651 (60)	–

[a] Emission spectra at room temperature in degassed CH_2Cl_2; 2×10^{-6} M porphyrin in each case; excitation wavelength, 550 nm.

In contrast to its absorption spectrum, the emission spectrum of the mixed dimer **5** is dramatically different from the superposition of the spectra of its constitutive parts (Table 2). Interestingly, the singlet state of the zinc-containing porphyrin in **5** is completely quenched (600 nm) whereas the emission spectrum corresponding to the non-metalated part (singlet state) is strongly enhanced: at 654 nm, the emission intensity of **5** is 1.8 times that of **7**. This shows that efficient energy transfer has occurred between the zinc porphyrin part (singlet energy donor) and the non-metalated subunit (singlet energy acceptor). It is the singlet state of this latter porphyrinic subunit that is generated regardless of which porphyrinic part is photoexcited in the initial photonic process. As a reference, the emission spectrum of a mixture of **7** and **8** is roughly the superposition of the emission spectra of the two components.

The efficient photoinduced intramolecular energy transfer observed in **5** is in agreement with the energy level of the singlet excited state of each component of the bis-porphyrin (Scheme 1). The ΔG° values and the energy levels were calculated using the electrochemical data (Table 1) and the emission spectra (Table 2). Clearly, the driving force for the electron-transfer reaction (0.07 eV) is much smaller than that for the intramolecular energy migration (0.17 eV).

5

Scheme 1. Energy transfer in electronically excited **5**. Zn = Zn-containing porphyrinic part; H_2 = non-metalated porphyrinic part; S = excited singlet state.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0505-0594 $ 02.50/0

Excitation of **5**, **7**, and **8** (10^{-4} M in degassed CH_2Cl_2 at room temperature) by a 20-ps laser pulse at 530 nm was used for transient absorption measurements at 820 nm (triplet state absorption; see Ref. [11]) with an apparatus already described.[12] Simultaneously, time-resolved emission measurements were performed. In **5**, emission at 600 nm is completely quenched whereas emission at 660 nm is enhanced as compared to **7** under the same conditions. The formation rate of the triplet state localized on the non-metalated subunit (10^8 s^{-1} at room temperature in degassed CH_2Cl_2) is similar to the decay rate of the singlet state (non-metalated ring). Furthermore, the emission quantum yield at 660 nm and the quantum yield of triplet state generation (absorption at 820 nm) for **5** are roughly twice those for **7**, corroborating the data of Table 2 obtained by classical emission spectroscopy. No evidence was obtained for light-induced electron transfer. These observations are in full agreement with the postulated reaction of efficient intramolecular singlet energy transfer from the zinc porphyrin part to the non-metalated ring.

The present oblique bis-porphyrin may be related to the hypothetical mechanism of the photosynthetic bacterial reaction center. Energy migration from the special pair to the isolated bacteriochlorophyll followed by electron transfer or initial electron transfer from the special pair may be operative.[2]

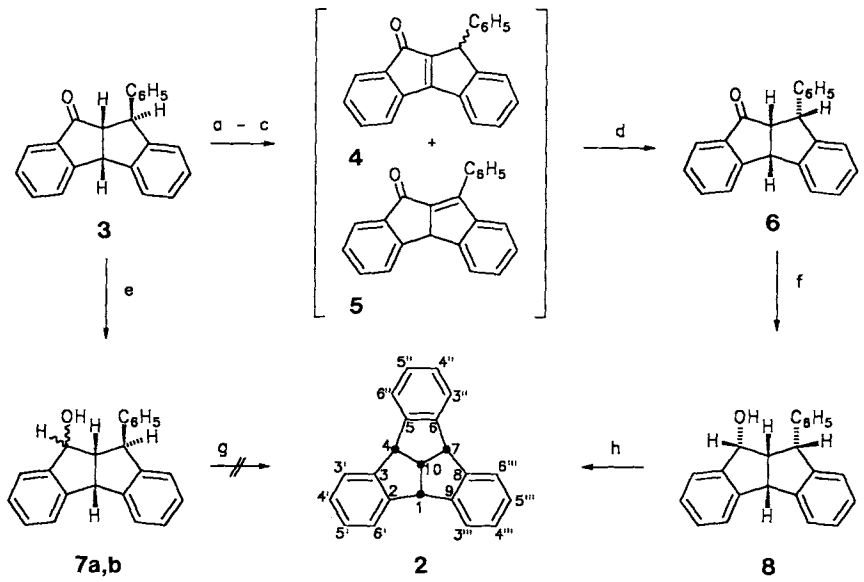
Towards Tribenzoacepentalene: Tribenzotriquinacene, Dihydrotribenzoacepentalenediide, and the Tribenzoacepentalene Radical Anion**

By *Dietmar Kuck,** *Andreas Schuster, Björk Ohlhorst, Volker Sinnwell,* and *Armin de Meijere**

Dedicated to Professor Kurt Heyns on the occasion of his 80th birthday

Benzoannelation can increase the stability of cyclically conjugated, nonaromatic hydrocarbons that, owing to unfavorable electron configuration and/or unfavorable HOMO energies, are unstable and therefore highly reactive. To explore this possibility for acepentalene **1**, only the dianion of which, $\mathbf{1}^{2\ominus}$, is so far known,[1] we synthesized tribenzotriquinacene (tetrahydrotribenzoacepentalene) **2** and investigated its deprotonation-dehydrogenation both in solution and in the gas phase.



1 $\quad$ $\mathbf{1}^{2\ominus}/2K^{\oplus}$ $\quad$ **2**

Tribenzotriquinacenes with substituents on the central C atom are accessible by double cyclodehydration of the correspondingly substituted 2-benzhydryl-1,3-indandiols.[2] The unsubstituted hydrocarbon **2**, however, could be obtained only in low yields via this route. Starting from cinnamic acid, *Baker* et al.[3] synthesized the diquinane ketone **3** in three steps; bromination/dehydrobromination then gave the enone **4** in moderate yield. In our attempts to synthesize **2** and higher benzoannelated centropolyquinanes,[4] the ketone **3** and the alcohols **7a, b**[3] derived therefrom were identified as 8-*exo*-phenyl stereoisomers on the basis of their mass spectra;[5] thus, the cyclodehydration **7** → **2** attempted by *Baker* et al.[3] was doomed to failure for steric reasons. The enone **4**, together with the isomer **5**,[8] is accessible on a preparative scale (overall yield 25%, Scheme 1) by an alternative route involving phenylsulfenylation of **3**, oxidation, and thermal elimination of the phenylsulfinyl derivative.[6, 7] Subsequently, **4** and **5** can be rehydrogenated with palladium on charcoal in dioxane to afford the isomeric diquinane ketone **6** with high selectivity. After reduction to the alcohol **8**, bearing an *endo*-phenyl group, the cyclodehydration to the tricyclic compound **2** occurs readily, as expected. Compound **2** crystallizes from hot xylene as sparingly soluble, colorless, long, hard needles having an unusually high melting point (390 °C). The identity of **2** was established on the basis of its analytical[9] and spectroscopic data.[10]

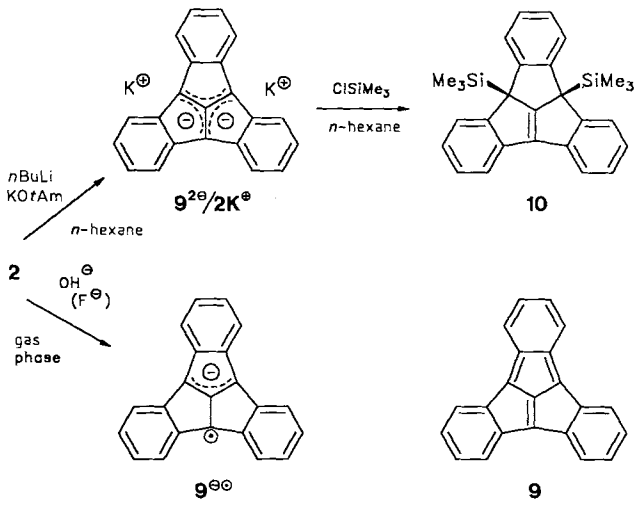
Scheme 1. a) $LiNiPr_2$/THF, −40 °C → 0 °C, $(PhS)_2$/THF, room temperature (RT), 1 h (76%); b) *m*-chloroperoxybenzoic acid/CH_2Cl_2, −30 °C → RT, then 10 h (91%); c) Δ/toluene, 110 °C, 4 d (36%); d) H_2/Pd,C/dioxane, RT (71% [9]); e) $LiAlH_4/Et_2O$ [3] or $Al(OiPr)_3$/*i*PrOH/toluene [3]; f) $LiAlH_4/Et_2O$, 3 h, 36 °C (95%); g) $CuSO_4$/xylene [3]; h) H_3PO_4/xylene, 135 °C, 4 h (58%). The numbering in **2** is unsystematic; the numbers 1–10 refer to the triquinacene.



Upon treatment of a suspension of **2** in *n*-hexane with *n*-butyllithium and potassium *tert*-amyl alkoxide (molar ratio 1:4.7:2.5), the mixture turns carmine red within 30 min. After 24 h at room temperature and an additional 24 h at reflux temperature, the reaction mixture was filtered under argon. The red-brown solid was washed four times with *n*-hexane and once with diethyl ether and then dried at 40 °C/0.1 torr. In addition to dipotassium dihydrotribenzoacepentalenediide ($\mathbf{9}^{2\ominus}/2K^{\oplus}$),[11] the pyrophoric solid contained lithium and potassium as the hydrides and *tert*-amyl alkoxides, as well as, possibly, butyllithium. Despite the impurities, $\mathbf{9}^{2\ominus}$ could be unambiguously characterized by NMR spectroscopy in [D_{10}]dimethoxyethane (Table 1). Particularly surprising is the position of the signal of the central C atom (C-10) at extremely high field ($\delta = 173.17$); its assignment is confirmed by the unchanged half-width ($\nu_{1/2} = 5.5$ Hz) in the broadband- and "gated"-decoupled ^{13}C NMR spectrum. This ^{13}C chemical shift and those of the peripheral acepentalene C atoms (C-2,3,5,6,8,9) indicate that, for $\mathbf{9}^{2\ominus}$, another resonance structure besides that with Y-like delocalization[12] of the negative charges, shown here, contributes even less to the resonance hybrid than for $\mathbf{1}^{2\ominus}$.

Table 1. Characteristic NMR data for dipotassium dihydrotribenzoacepentalenediide $\mathbf{9}^{2\ominus}/2K^{\oplus}$ and its trapping product **10**. For numbering, see Scheme 1. The cross peaks of magnetically equivalent atoms are not listed separately.

$\mathbf{9}^{2\ominus}$: ^1H NMR (400 MHz, [D_{10}]DME, 293 K): $\delta = 6.69$ (AA'BB, $^3J = 5.57$ Hz, 6H, 4',5',4'',5'',4''',5'''-H), 7.74 (AA'BB', $^3J = 5.57$ Hz, 6H, 3',6',3'',6'',3''',6'''-H), ^{13}C NMR (100.62 MHz, [D_{10}]DME, 273 K, "gated"): $\delta = 99.86$ (s, $\nu_{1/2} = 9$ Hz, C-1,4,7), 113.95 (d, C-4',5',4'',5'',4''',5''', $^1J_{CH} = 146$ Hz), 119.59 (d, C-3',6',3'',6'',3''',6''', $^1J_{CH} = 146$ Hz), 137.77 (s, C-2,3,5,6,8,9), 173.17 (s, $\nu_{1/2} = 5.5$ Hz, C-10). In the H,C-COLOC spectrum[13] (SF(2) = 100.62 MHz, SF(1) = 400.14 MHz), the following cross peaks were found: C-1/3',6'-H, C-2/3',5',6'-H, C-3'/4',5'-H, C-4'/3',6'-H

10: ^1H NMR (400 MHz, [D_8]THF, 297 K): $\delta = 0.22$ (s, 18H, $Si(CH_3)_3$), 7.10 (AA'BB', $^3J = 5.8$ Hz, 2H, 4'',5''-H), 7.14 (dt, $^3J = 7.6$, $^4J = 1.1$ Hz, 2H, 3',6''-H); 7.27 (dt, $^3J = 7.6$, $^4J = 1.1$ Hz, 2H, 5',4'''-H); 7.42 (AA'BB', $^3J = 5.8$ Hz, 2H, 3'',6''-H), 7.69 (dd, $^3J = 7.4$ Hz, 2H, 6',3'''-H), 7.72 (dd, $^3J = 7.6$ Hz, 2H, 4',5'''-H). Assignment of the protons was made from the H,H COSY spectrum: ^{13}C NMR (100.62 MHz, [D_8]THF, 297 K): $\delta = 0.49$ (−, $Si(CH_3)_3$), 61.60 (0, C-4,7), 121.60 (−, C-3',6'''), 124.50 (−, C-4',5'''), 125.88 (−, C-6',3'''), 125.91 (−, C-3'',6''), 128.86 (−, C-4'',5''), 127.10 (−, C-5',4'''), 143.66 (0, C-2,9), 148.76 (0, C-5,6), 156.46 (0, C-1), 159.4 (0, C-3,8), 182.32 (0, C-10). The assignment was made from the DEPT spectrum with 135° pulse (+ = positive signal for CH_2; − = negative signal for CH, CH_3; 0 = no signal for quart. C) and a C-H correlation.—In the H,C-COLOC spectrum[13] (SF2 = 100.62 MHz, SF1 = 400.14 MHz), the following cross peaks were found: C-1/6'-H, C-2/3',5',6'-H, C-3/3',4',6'-H, C-4/CH_3,3',6''-H, C-5/5'',6''-H

The chemical proof for the constitution of $\mathbf{9}^{2\ominus}$ was accomplished, as for $\mathbf{1}^{2\ominus}$,[1] by trapping with chlorotrimethylsilane in *n*-hexane. The bis(trimethylsilyl)dihydrotribenzoacepentalene **10** (colorless crystals, m.p. 191 °C (dec.); for spectroscopic data, see Table 1), isolated in 97% yield (based on **2**), was much easier to purify than the corresponding parent compound; in addition, $\mathbf{9}^{2\ominus}/2K^{\oplus}$ is markedly more stable than $\mathbf{1}^{2\ominus}/2K^{\oplus}$. The special stabilization of $\mathbf{9}^{2\ominus}$ is also supported by the fact that it is formed from 10-methyltribenzotriquinacene[2] with formal expulsion of methane under the same conditions as it is formed from **2**.

In the gas phase, compound **2** also undergoes ready deprotonation to give the monoanion $[2-H]^{\ominus}$ under the conditions of negative chemical ionization (NCI).[14,15] Moreover, at low pressure of the reactant gas (i.e., for a higher average excitation of the $[2-H]^{\ominus}$ ions), predominant formation of $[2-2H]^{\ominus\odot}$ and $[2-4H]^{\ominus\odot}$ ions ($\triangleq \mathbf{9}^{\ominus\odot}$) is observed, indicating elimination or abstraction of up to three hydrogen atoms (see Fig. 1). Correspondingly, the NCI spectrum of 10-methyltribenzotriquinacene[2] is governed by the $[M-2H-CH_4]^{\ominus\odot}$ peak at low reactant gas pressures. Apparently, therefore, the (unsolvated!) radical anion $\mathbf{9}^{\ominus\odot}$ of

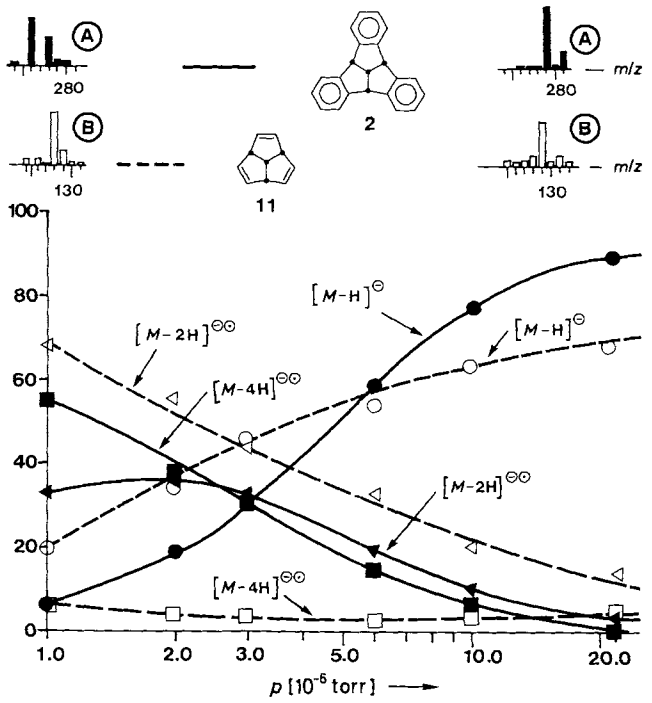


Fig. 1. Relative ion abundances in the NCI (N_2O/CH_4) mass spectra [15] of triquinacene **11** (– – –) and tribenzotriquinacene **2** (——) as a function of the (nominal) pressure of the reactant gas. (The values are ^{13}C-corrected and normalized with respect to $\Sigma[C_{22}H_x]^{\ominus}$ and $\Sigma[C_{10}H_y]^{\ominus}$, respectively.) (A) and (B): the [M – nH] region of the NCI-MS of **2** (M = 280) and **11** (M = 130), respectively.

tribenzoacepentalene **9** is very stable—in marked contrast to **1**. Under identical conditions, triquinacene **11** is deprotonated to the monoanion $[\mathbf{11}-H]^{\ominus}$, but, at lower pressure of the reactant gas, only $[\mathbf{11}-2H]^{\ominus\ominus}$ along with a small amount of $[\mathbf{11}-4H]^{\ominus\ominus}$ ($\triangleq \mathbf{1}^{\ominus\ominus}$, see Fig. 1) is formed. Accordingly, the neutral tribenzoacepentalene **9** must also be appreciably more stable than the parent system **1** and might even be detectable in pure form.

Electron Densities, Deformation Densities, and Chemical Bonding**

By *W. H. Eugen Schwarz,* Klaus Ruedenberg, Lothar Mensching, Lance L. Miller, Petros Valtazanos,* and *Wolfgang von Niessen*

The frequently postulated relationship between electron density and chemical bonding has so far been investigated in two different, although fundamentally related, ways. According to the older method,[1,2] one uses the difference density $\Delta\varrho = \varrho_{molecule} - \Sigma\varrho_{atoms}$, where $\varrho_{molecule}$ is the electron density of the molecule and ϱ_{atom} the spherically averaged density of an unperturbed, correctly positioned atom. A chemical bond should be characterized by a positive $\Delta\varrho$ between the atoms. According to the more recent method,[3,4] instead of $\Delta\varrho$ one uses the second derivative of the molecular density $\nabla^2\varrho_{molecule}$. Large negative values of $\nabla^2\varrho_{molecule}$ between two atoms, especially in comparison with the spherically averaged atomic densities, are regarded as an indication of chemical bonding.

The ground states of most atoms with open valence shells, however, are degenerate (e.g., ^2P states for $C(1s^22s^22p^2)$ and $F(1s^22s^22p^5)$); that is, their electron density is anisotropic. The electron density of the free atoms can be oriented (e.g., F in the ^2P_z state, see Fig. 1c) without any increase in energy. Thus, molecules and crystals can be envisioned as consisting of suitably *positioned and oriented* atoms (whereby, owing to the Heisenberg uncertainty principle, even the positioning of noninteracting atoms requires the zero-point vibrational energy). The positions of the atomic cores along with their

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the U.S. Department of Energy (Office of Basic Energy Sciences, Contract No. 7405-Eng-82), NATO, and the Fonds der Chemischen Industrie. We thank Prof. Dr. *C. Krüger* for the experimental triazine data and Priv.-Doz. Dr. *B. Engelen* for helpful comments.

vibrational "smears", as well as the orientation and occupation of the open valence shells, is determined by the interactions between the atoms in the molecule or crystal. "Positional parameters" and "directional parameters" therefore provide information on these interactions. Particularly the directional parameters appear to be sensitive to the intermolecular interactions (see the discussion regarding Fig. 4b).

The interatomic interactions are often further revealed in a comparatively small deformation of the atomic electron densities. A shift of charge toward the center of the bond indicates normal covalent bonding. Constructive quantum-mechanical interference[5] of partially occupied, *strongly* overlapping, oriented AOs, as described well by the MO model, leads to an increase in density in the region of overlap and, at the same time, to a reduction in the functional describing the kinetic energy of the electrons ("electron sharing"). However, covalent bonds are also possible between partially occupied, *weakly* overlapping AOs if, owing to electron correlation, as described well in the VB model, the Coulombic repulsion between the electrons is reduced. This "correlation covalence" (e.g., in dichromium compounds[6]) is revealed to only a small extent in the charge density.

In the density analyses mentioned at the beginning, details are easily lost.[7, 8] Thus, the difference density $\Delta\varrho$ for F_2, derived from spherically averaged F-atom densities (electron configuration $1s^2 2s^2 2p_x^{5/3} 2p_y^{5/3} 2p_z^{5/3}$) shows an extreme density deficit along the bond axis and in the region of the lone pairs in σ orbitals (Fig. 1a). $\nabla^2 \varrho_{\text{molecule}}$ also fails to indicate the presence of a normal covalent bond.[8] Oriented, nonspherical F atoms ($1s^2 2s^2 2p_x^2 2p_y^2 2p_z^1$) can also be used as references, however (Fig. 1c); in this case the F–F σ bond arises quite naturally from the singly occupied F $2p_z$ AOs. The corresponding "chemical" deformation density in Figure 1b gives the characteristic charge shift for lone pairs in σ orbitals (A) as well as the small bond charge (B) characteristic of a weakly covalent σ bond.

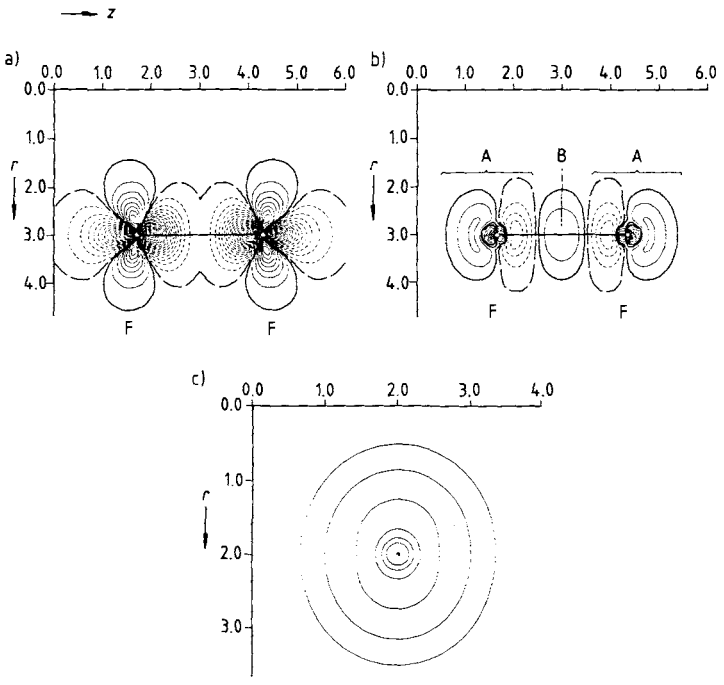

Fig. 1. Ab initio SCF electron difference densities of F_2. r in atomic units (1 a.u. = 0.529 Å). $\Delta\varrho$ values of the contour lines: —— $n \times 0.27$ eÅ^{-3} ($n = 1,2,3\ldots$), – – – – $n \times 0.27$ eÅ^{-3}, —— 0.07 Å^{-3}, – – – – 0.07 eÅ^{-3}. a) "Usual" difference densities derived from spherically averaged F-atom densities. b) "Chemical" deformation densities derived from oriented ground-state F atoms ($F\ 1s^2 2s^2 2p_x^2 2p_y^2 2p_z^1$). A = lone pair; B = bond charge. c) Total density of the oriented ground-state F atom (different scale!; $\Delta\varrho$ values of the contour lines: 0.67, 2, 6.7, 20, 67, 200 eÅ^{-3}).

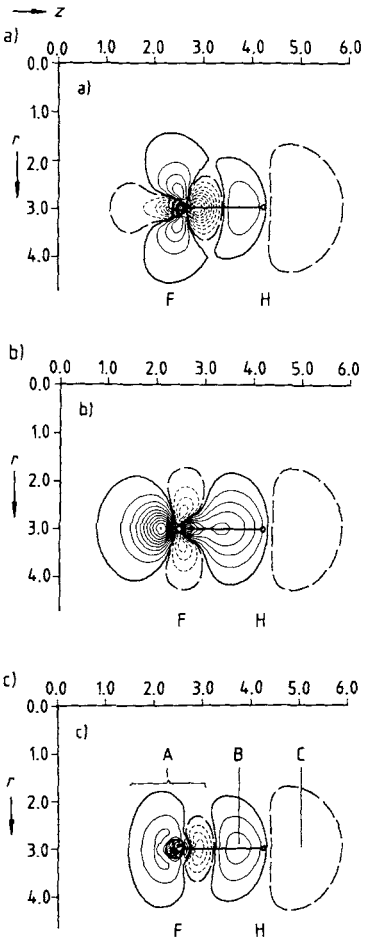

Fig. 2. Ab initio SCF electron difference densities of HF; cf. caption to Fig. 1. a) "Usual" difference densities derived from spherically averaged F-atom densities. b) "Naive" difference densities derived from maximally oriented F atom. c) "Chemical" deformation densities derived from empirically determined orientation of the F atom ($1s^2 2s^2 2p_x^{1.79} 2p_y^{1.79} 2p_z^{1.42}$). C = charge deficit of H ($H^{\delta\oplus}$).

Figure 2 shows difference densities of HF. Figure 2a was derived from spherically averaged F-atom densities and Figure 2b from completely oriented densities. Both difference densities are extremely large and hardly comparable to those in other molecules. Apparently, it is not wise to derive $\Delta\varrho$ from arbitrarily determined (spherically averaged or completely oriented) atom densities.

We have therefore developed a procedure to establish unambiguously both positions and orientations of the ground-state densities in molecules by means of an extremal principle, starting either from the calculated molecular electron density distribution[9] or from experimental X-ray diffraction data.[10] In the latter case, the coordinates and vibrational parameters of the atomic cores are fitted preferentially to the scattering data for large angles and the parameters for occupation and orientation of the valence shells to the data for small angles.

Analysis of the theoretical SCF densities of HF yields the occupation $2p_x^{1.79} 2p_y^{1.79} 2p_z^{1.42}$ for F, which represents a com-

promise between an oriented F atom in a nonpolar covalent bond and a spherical F anion in a purely ionic bond. The difference density in Figure 2c, derived for a uniquely defined, optimally oriented F atom, describes the true deformation of the atomic ground states of the HF molecule. This "chemical" deformation density displays three salient features: the charge shift characteristic of lone pairs in σ orbitals; the bond charge typical of a normally strong σ bond; and the decrease in charge density "behind" the hydrogen typical of acidic hydrogen (C).

Difference densities of singlet methylene are shown in Figure 3. For optimal fitting of the open 2p shell of the ground-state C atom to the molecular situation, which results in a 2p occupation $p_x^{0.94}p_y^{0.06}p_z^{1.00}$, the "chemical" deformation densities shown in Figures 3c and 3d are obtained. They show the charge shift typical of lone pairs in σ orbitals, the bond charge typical of a normal covalent σ bond, and the increase in density at the nuclear center typical of a neutrally bonded H atom. Figures 3a and 3b were derived for a spherically averaged C-atom density ($C\ 1s^2 2s^2 2p_x^{2/3} 2p_y^{2/3} 2p_z^{2/3}$). Again, all finer details of the molecular electron density are concealed by what is "in reality" the quadrupolar oriented electron density of the ground-state C atom in methylene.

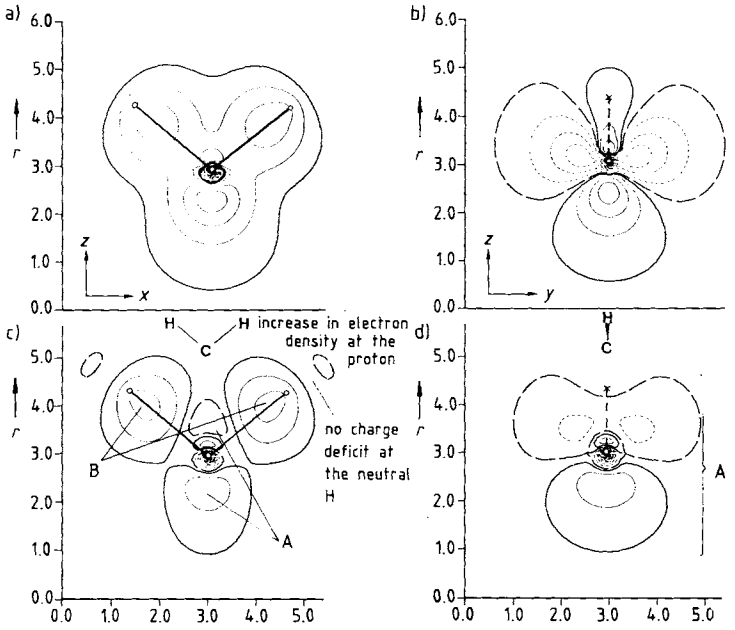

Fig. 3. Ab initio SCF electron difference densities of singlet methylene; cf. caption to Fig. 1. a) and b) "Usual" difference densities derived from spherically averaged C-atom densities ($C\ 1s^2 2s^2 2p_x^{2/3} 2p_y^{2/3} 2p_z^{2/3}$). c) and d) "Chemical" deformation densities derived from empirically optimized orientation of the ground-state C atom ($C\ 1s^2 2s^2 2p_x^{0.94} 2p_y^{0.06} 2p_z^{1.00}$).

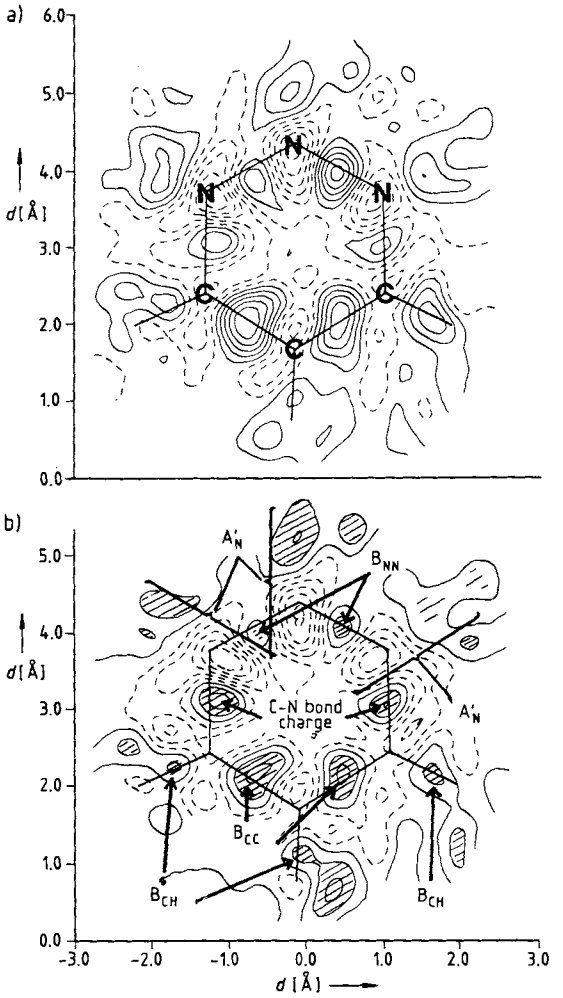

Fig. 4. Experimental static electron difference densities of 1,2,3-triazine [11]. $\Delta\varrho$ values of contour lines: —— $n \times 0.1\ e\text{Å}^{-3}$, ------ $-n \times 0.1\ e\text{Å}^{-3}$. a) "Usual" difference densities derived from spherically averaged C- and N-atom densities. b) "Chemical" deformation densities derived from oriented, optimally occupied p AOs. The curley brackets marked with A'_N indicate the dipolar charge shift corresponding to the lone pair on N. B_{CH}, B_{CC}, and B_{NN} denote the bond charges between the respective atoms.

Figure 4 shows the "experimental" difference density of 1,2,3-triazine in the standard form.[11] It is difficult to interpret in detail the pronounced qualitative asymmetry. Fitting of the p AO occupation to the molecular electron density affords $p_t^{1.08}p_r^{0.68}p_\pi^{0.24}$ for the C atoms and $p_t^{1.04}p_r^{1.42}p_\pi^{0.54}$ for the N atoms; the tangential and radial AOs, p_t and p_r, are strongly twisted, however (see Ref. [10]). The orbital occupations of the middle and terminal atoms of the E_3 units (E = C, N) do not differ significantly from each other. The high Np_r occupation is an indication of the lone pairs and also points to mixing of energetically higher-lying doublet states of the p^3 ground-state configuration of the N atom. The polarity of the molecule is reflected in the different Cp_π and Np_π occupations, whereas the p_t AOs forming the σ bonds in the ring are nearly identically occupied. The corresponding "chemical" deformation density in Figure 4b reflects the nearly ideal symmetry of the molecular framework in the crystal. The bond charges decrease on going from C-C to C-N to N-N. The strong interactions between the molecules in the crystal are manifested in the different twistings of the p AOs from the symmetry-adapted positions,[10] but influence the "chemical" deformation densities to only a small extent.

Electron densities allow the characterization of covalent bonds of "normal MO type" as well as of intermolecular interactions. The prerequisite for the reasonable construction and discussion of difference densities, however, is not to derive these arbitrarily from spherically averaged atomic ground-state densities. Combined refinement starting from the experimental or theoretical electron density data of a molecule allows the determination of not only the positional parameters of the atoms but also their respective directional parameters and quadrupole moments. Qualitative atomic

parameters as well as qualitative deformation density maps that are readily interpretable in chemical terms can then be obtained.

$P_6(C_5Me_5)_2$, a Tricyclic Polyphosphane

By *Peter Jutzi,* Rainer Kroos, Achim Müller,* and *Michael Penk*

Our detailed knowledge on cyclic polyphosphanes is due primarily to the extensive investigations of *M. Baudler* and her co-workers.[1] The structural diversity of this class of compounds is fascinating and is only exceeded by that of cyclic hydrocarbons. We describe here a preparatively simple route to a tricyclohexaphosphane with a previously unknown type of structure.

Upon heating tris(pentamethylcyclopentadienyl)cyclotriphosphane **1**[2] for several hours in refluxing benzene, 2,3,4,6-tetrakis(pentamethylcyclopentadienyl)bicyclo[3.1.0]-hexaphosphane **2** is formed in nearly quantitative yield [Eq. (a)]. Compound **2** crystallizes from *n*-hexane as yellow needles (mp. 98 °C (dec.), sealed tube), which are only slightly sensitive to air. The structure of **2** was determined by analysis of the two-dimensional ^{31}P–^{31}P shift-correlated NMR spectrum (COSY type) and from an X-ray structure analysis.[3] The structure is similar to that of P_6tBu_4,[4] the only compound so far known with this structure.

$$2\,(PC_5Me_5)_3 \xrightarrow[-(C_5Me_5)_2]{\Delta} P_6(C_5Me_5)_4 \xrightarrow[-(C_5Me_5)_2]{\Delta} P_6(C_5Me_5)_2 \quad (a)$$

1 **2** **3**

Thermolysis of **2** in refluxing xylene leads to the formation of 3,4-bis(pentamethylcyclopentadienyl)tricyclo[3.1.0.0^{2,6}]-hexaphosphane **3** in 46% yield [Eq. (a)]. Compound **3** is obtained from *n*-hexane as bright yellow rhombic crystals (m.p. 183 °C (dec.), sealed tube), which are only slightly sensitive to air.[5] Like **2**, compound **3** ist very soluble in aromatic hydrocarbons and in THF but less soluble in *n*-hexane. The structure was again elucidated by NMR spectroscopy and by X-ray structure analysis.

The 121-MHz ^{31}P NMR spectrum of **3** exhibits three groups of mirror-symmetric signals at $\delta = 105$, 70, and -237 (intensities 1:1:1). The high-field signal is a triplet, that at $\delta = 70$ corresponds to an AA'BB' system, and that at $\delta = 105$ is a complex multiplet.[6] The extreme high-field shift of one signal group and the high symmetry of the spectrum indicate that **3** has a tricyclo[3.1.0.0^{2,6}]hexaphosphane-type structure. The connectivity of the phosphorus atoms is revealed by analysis of the two-dimensional $^{31}P-^{31}P$ shift-correlated NMR spectrum (COSY type). Owing to the asymmetric environment of the two organosubstituted phosphorus atoms in **3**, both the sp^2 carbon atoms of the prochiral pentamethylcyclopentadienyl rings and their respective methyl groups are expected to be magnetically nonequivalent and diastereotopic. The ^{13}C NMR spectrum displays the four signals corresponding to the sp^2 carbon atoms. The mass spectrum of **3** shows, in addition to the molecular-ion ($M^{\oplus}$) peak, the peaks of the fragments $M^{\oplus} - C_5Me_5$ and $C_5Me_5^{\oplus}$.

The X-ray structure analysis[7] of **3** corroborates the structure determined from the spectroscopic data (Fig. 1). The P_2

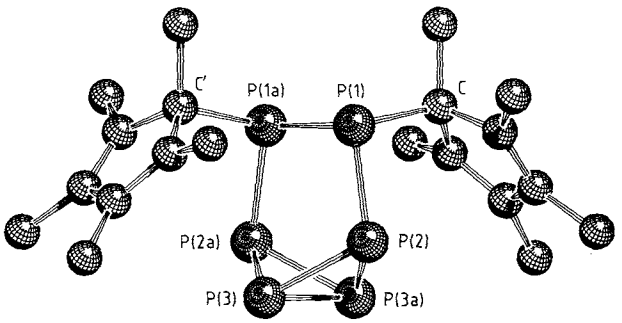

Fig. 1. The molecular structure of **3** [8]. Important bond lengths [Å], bond angles [°], and torsional angles [°]: P(1)–P(1a) 2.160 (2), P(1)–P(2) 2.184 (1), P(2)–P(3) 2.195 (1), P(2)–P(3a) 2.191(1), P(3)–P(3a) 2.192 (2); P(3)–P(3a)–P(2a) 59.9 (1), P(3)–P(2a)–P(3a) 60.0 (1), P(2a)–P(3)–P(3a) 60.1 (1), P(1)–P(2)–P(3) 107.3 (1), P(1)–P(2)–P(3a) 103.8(1), P(1a)–P(1)–P(2) 103.6 (1), P(2a)–P(3)–P(2) 94.2 (1), P(2)–P(1)–C 101.6 (1), P(1a)–P(1)–C 104.4 (1); P(2)–P(1)–P(1a)–P(2a) 10.7, C–P(1)–P(1a)–C' 158.6.

bridge results in an *endo–endo* substitution that is novel for phosphorus compounds with the bicyclo[1.1.0]tetraphosphane ("butterfly") structural element. This is markedly reflected in the ^{31}P NMR signals of the peripheral phosphorus atoms ($\delta = 105$), which are shifted strongly downfield compared with those of other phosphorus butterfly compounds.[2, 9]

The phosphorus–phosphorus bonds in **3** (average 2.187 Å) are significantly shorter than in **2** (average 2.225 Å) or P_4 (2.21 Å). Surprisingly, the bond between the two organosubstituted phosphorus atoms (2.160 Å) is quite short. The folding angle between the phosphorus triangles is 115.5° and is therefore 10° larger than in other structurally characterized phosphorus butterfly compounds.[9a, b, 10] The transannular phosphorus–phosphorus distance (P(2)-P(2a)) is 3.212 Å. Compound **3** can be viewed as a phospho-

[+] X-ray structure analysis

rus analogue of 3,4-dihydrobenzvalene or as a P_4 tetrahedron open at one edge and bridged by a P_2R_2 unit. The considerable stability of 3 toward air may be ascribed to the good steric shielding of the phosphorus framework by the pentamethylcyclopentadienyl ligands.

The syntheses of **2** and **3** from **1** are further examples of the preparative utility of the labile phosphorus–carbon bond in pentamethylcyclopentadienyl-substituted phosphorus compounds.[9c, 11] Clearly, the new cyclophosphanes **2** and **3** with their functionalized P_6R_x frameworks have promising synthetic potential.[11d]

Experimental Procedure

2: A solution of **1** (3.40 g, 6.82 mmol) in 35 mL of benzene was refluxed for 20 h. The solvent was then removed under vacuum from the clear, orange reaction solution until the viscous residue (ca. 3.5 g) began to form bubbles. Shortly after addition of 7 mL of *n*-hexane, the deep orange oil solidified to a yellow crystalline mass. After removal of the supernatant liquid, **2** was recrystallized from *n*-hexane. Yield: 2.05 g (66%) **2** · *n*-C_6H_{14}; correct elemental analysis. ^{1}H NMR (300 MHz, C_6D_6): δ = 0.9–2.2 (complex multiplet; C_5Me_5, *n*-C_6H_{14}). ^{13}C NMR (75 MHz, C_6D_6): δ = 11.0–23.0 (Me), 57.4–59.7 (P-C), 134.8, 135.5, 136.0, 136.4, 139.7, 141.0, 141.6, 141.7 (sp^2-C). ^{31}P NMR (121 MHz, C_6D_6): δ = 78 (2P), 60 (1P), –121 (2P), –129 (1P). MS (*m/z*; rel. int.): $P_6(C_5Me_5)_3^{\oplus}$ (591; 18), $P_6(C_5Me_5)_2^{\oplus}$ (456; 2), $P_3(C_5Me_5)_2^{\oplus}$ (363; 4), $P_6(C_5Me_5)^{\oplus}$ (321; 34), $C_5Me_5^{\oplus}$ (135; 100).

3: **2** · *n*-C_6H_{14} (5.50 g, 6.77 mmol) was refluxed in 70 mL of xylene for 45 min. After removal of the solvent, the orange residue was treated with 20 mL of *n*-hexane. The precipitated pale yellow powder (ca. 2.5 g) was filtered off and recrystallized several times from *n*-hexane. Yield: 1.42 g (46%) **3**; correct elemental analysis. ^{1}H NMR (300 MHz, C_6D_6): δ = 1.3–2.1, ^{13}C NMR (75 MHz, C_6D_6): δ = 10.9–21.7 (Me), 57.4 (P-C), 136.8, 137.7, 139.5, 140.2 (sp^2-C). ^{31}P NMR (121 MHz, C_6D_6): δ = 105, 70, –237 (intensities 1:1:1). MS (*m/z*; rel. int.): $M^{\oplus}$ (456; 9), $P_6(C_5Me_5)^{\oplus}$ (321; 44), $C_5Me_5^{\oplus}$ (135; 100).

Photocycloadditions of Benzvalene**

By *Manfred Christl** and *Max Braun*

In 1975, *Katz* and *Turro* et al.[1] reported that the sensitized photolysis of benzvalene **1** can lead to two rearrangements. Transformation to benzene occurs with sensitizers with a triplet energy $E_T > 65$ kcal mol^{-1}, whereas automerization (1,3-C migration) is induced by those with $E_T <$ 63 kcal mol^{-1}. Although the sensitizers used were mainly ketones, which are typical substrates for the Paterno–Büchi reaction,[2] the authors mentioned no products with oxetane structure. In view of the high reactivity of benzvalene toward a wide variety of electrophiles,[3] we wanted to know whether, besides the isomerizations noted above, photochemical cycloadditions of **1** take place.

Irradiation[4] of **1**[5] in the presence of acetone and benzophenone (E_T = 78 and 69 kcal mol^{-1}, respectively[2a]) resulted in the formation of benzene. However, with biacetyl (E_T = 56 kcal mol^{-1}[2a]), benzil (54 kcal mol^{-1}[2a]), methyl phenylglyoxylate (61.9 kcal mol^{-1},[6a] irradiation at –30 °C), 1,4-benzoquinone (50 kcal mol^{-1}[2a]), and chloranil (56.4 kcal mol^{-1},[6b] irradiation at –30 °C), the oxetanes **2** (19%), **4** (22%), **5** (38%), **6** (25%), and **7** (51%), respectively, were obtained.[7] In the experiment with biacetyl, we observed, in addition to **2**, the oxadihydrosemibullvalene **3** (**2**:**3** ≈ 30:1), which is also accessible, together with a small amount of its diastereomer, in 48% yield by treatment of **2** with $AgBF_4$ in $CDCl_3$ at 20 °C.[7] The experiment with chloranil afforded pure **7** only at –30 °C; at 20 °C, besides **7**, the rearrangement product **8**[7] (**7**:**8** = 4:1) was formed. For selected physical data for **2**–**8**, see Table 1.

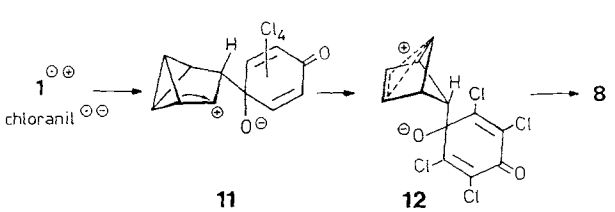
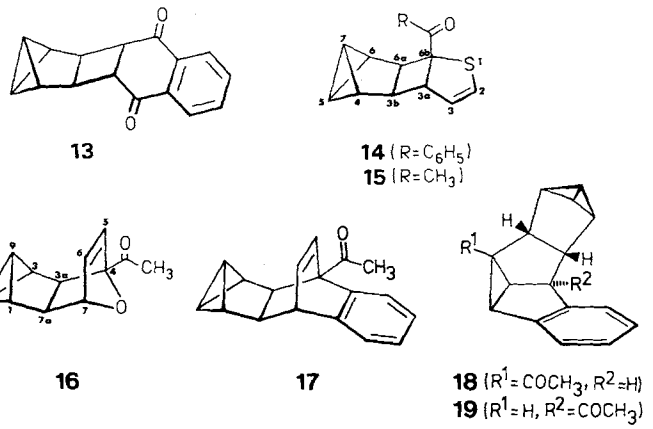
[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.



The formation of **3** confirms the multistep mechanism of the Paterno–Büchi reaction.[2] Compound **1** and biacetyl in its triplet state presumably give the diradical **9**, which can then either cyclize to **2** or undergo a cyclopropylmethyl–homoallyl rearrangement,[3a] to afford **10**, provided that, of the two C–C bonds in question in **9**, the bond *cis* to the biacetyl moiety breaks. Diradical **10** would then collapse to **3**. In agreement with this mechanism, [1,6-D_2]benzvalene yields the dideuterated products [3,4-D_2]-**2** and [2,8-D_2]-**3**.



9 **10**

The finding that the labels in **2** are limited to positions 3 and 4[8] rules out the automerization of **1** by the excited sensitizer biacetyl. We arrived at the same conclusion by recovering unused [D_2]-**1** and allowing it to react with 2,4,6-trimethylbenzonitrile oxide. In the resulting dihydroisoxazole,[9] we found the deuterium atoms also restricted to the bicyclobutane bridgehead positions.[8] Interestingly, *Katz* and *Turro* et al.[1] included biacetyl in their table of sensitizers but did not enter a quantum yield for the automerization of **1**. The latter was given as ca. 0.2 for benzil as sensitizer. We have now confirmed that excited benzil effects the automerization of **1**. Adduct [D_2]-**4** was obtained from [1,6-D_2]-**1** with the ratio of the labels in positions 1 (6), 2 (5), and 3 (4) being 1:3:45.[8] Analysis of the 2,4,6-trimethylbenzonitrile oxide adduct revealed that the labels in unused [D_2]-**1** were more evenly distributed, namely in a ratio of 1:2:4 in the positions corresponding to those in **4**.[8] Irradiation of 1,4-benzoquinone and 2-benzoylthiophene (see below) in the presence of [1,6-D_2]-**1** did not lead to a 1,3-C migration in [1,6-D_2]-**1**. Whether benzvalene **1** undergoes automerization in the presence of ketones in the triplet state (E_T < 63 kcal mol^{-1}), therefore, is a question of relative reaction rates. With biacetyl, 1,4-benzoquinone, and 2-benzoylthiophene, the cycloaddition occurs appreciably faster than the energy transfer required for automerization of **1**; the two rates are similar in the case of benzil.

The structure of the product **8** indicates that it is not formed via a diradical analogous to **9**. A radical ion pair is known to be formed upon irradiation of chloranil in the presence of a donor;[10a] for **1** as donor, this was shown by CIDNP signals of **1** and benzene.[10b] Thus, **8** is presumably formed via the radical ion pair, which collapses to zwitterion

11. A Wagner–Meerwein rearrangement in the cationic moiety of **11** involving migration of the bicyclobutane bridgehead carbon atom *trans* to the anionic moiety[3] would then have to occur to give **12**, which would subsequently yield **8**.

In contrast to the reaction with 1,4-benzoquinone, irradiation[4] of **1**[5] with 1,4-naphthoquinone (E_T = 57 kcal mol^{-1}[6c]) at −30 °C gave the cyclobutane **13**[7] (17%). Motivated by the work of *Cantrell*,[11] we also employed 2-benzoylthiophene (62.6 kcal mol^{-1}[11]) at room temperature as well as 2-acetylthiophene (64.5 kcal mol^{-1}[11]) and 2-acetylfuran (64.9 kcal mol^{-1}[11]) at −30 °C and obtained the [2 + 2] cycloadducts **14** (21%), and **15** (27%) as well as the [4 + 2] cycloadduct **16** (19%) together with its diastereomer (6%).[7] At −30 °C, excited 1-acetylnaphthalene (56.4 kcal mol^{-1}[6a]) and **1**[5] gave initially the [4 + 2] cycloadduct **17** (25%). Upon further irradiation, however, **17** was converted at a similar rate into **18** (41%) and **19** (9%)[7] (di-π-methane rearrangement). Selected physical data for **13**–**19** are given in Table 1.

We obtained no cycloadduct from **1** and cyclopent-2-en-1-one (E_T = 74 kcal mol^{-1}[2a]). In conclusion, **1**, too, can undergo photochemical cycloadditions, provided that the reaction partner has a triplet energy E_T < 65 kcal mol^{-1}.

Synthesis and Structure of Digerma- and Distannacyclobutenes **

By *Adolf Krebs*,* *Andrea Jacobsen-Bauer*, *Erhard Haupt*, *Michael Veith*,* and *Volker Huch*

The first germirenes (germacyclopropenes) were synthesized by reaction of 3,3,6,6-tetramethyl-1-thiacyclohept-4-yne **1** with suitable precursors of dialkylgermylenes (dialkylgermanediyls);[1] **1** combines high reactivity of the C–C triple bond with steric shielding of the resulting addition product, thereby often making possible the synthesis of systems otherwise accessible only with difficulty.[2] Since, until recently, no addition reactions of stannylenes to C–C triple bonds had been described,[3] we allowed **1** to react with the stabilized diaminogermylene **2**[4] as well as the diaminostannylene **3**[4] and obtained, in addition to the digermacyclobutene **4**, the first distannacyclobutene **5**. Compounds **4** and **5** are both dispiro compounds.

Addition of **1** to the red solution of **3** in various solvents (benzene, THF, *n*-hexane, diethyl ether) resulted in immediate precipitation of a yellow solid, whose ^1H and ^{13}C NMR spectroscopic data in concentrated solution indicate the formation of the 1:2 adduct **5**. In dilute solution, however, only the ^1H NMR signals of the starting materials were observed; in the ^{13}C NMR spectrum of **5**, the signal for the sp-hybridized C atom of **1** was absent. Proof for the presence of an Sn–Sn bond was provided by the ^{119}Sn NMR spectrum, which showed a signal at $\delta = +155$ (rel. to $Sn(CH_3)_4$; $J(^{119}Sn, ^{117}Sn) = 3723$ Hz). Compound **4** was synthesized in a similar way from **1** and **2**.

1 **2** El = Ge **4** El = Ge
3 El = Sn **5** El = Sn

The results of the X-ray structure analyses of **4** and **5** are given in Figure 1. They confirm the structure derived for **5** in solution. In both cases, there is a central four-membered ring containing two sp^2-hybridized carbon atoms and two four-fold coordinated germanium or tin atoms, respectively. Whereas in **5** the nearly planar peripheral diazasilastanna four-membered rings are perpendicular to the completely planar central distannacyclobutene (**5** has a C_2 axis in the crystal, the thiacycloheptene unit being disordered; only one of the two variants is shown in Fig. 1), the diazasilagerma four-membered rings in **4**, which are also planar, are twisted

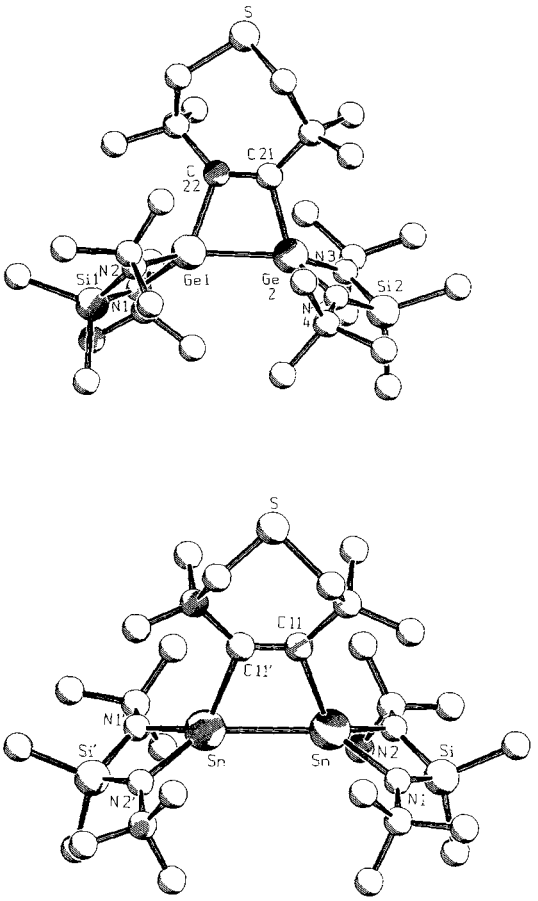
[**] Cyclic Diazastannylenes, Part 29. Part 28: M. Veith, V. Huch, R. Lisowsky, P. Hobein, *Z. Anorg. Allg. Chem.*, in press.



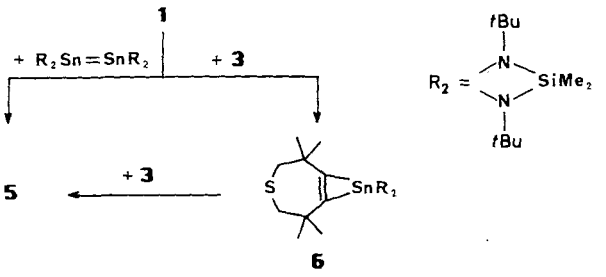


Fig. 1. Molecular structures of **4** (top) and **5** (bottom). Important bond lengths [Å] and angles [°] [5] in the dimetallacyclobutenes: **4**: Ge1-Ge2 2.459 (1), Ge1-C22 2.030 (7), Ge2-C21 2.028 (6), C21-C22 = 1.34 (1); C22-Ge1-Ge2 73.3 (1), Ge2-C21-C22 105.0 (1). **5**: Sn-Sn' 2.803 (1), Sn-C11 2.27 (1), C11-C11' 1.31 (2); C11-Sn-Sn' 70.7 (2), Sn-C11-C11' 109.3 (3) [5].

away from orthogonal positions with respect to the slightly puckered digermacyclobutene. This twisting is due to the sterically demanding *tert*-butyl groups on the nitrogen atoms of the two peripheral rings. Compound **5** is not twisted because the Sn–Sn distance is 0.344 Å longer, thereby reducing this steric interaction.

Whereas the bond lengths and angles of the central ring of **4** are in the expected range, the C=C bond in **5** is quite short (1.31 Å versus the expected value of 1.34 Å) and the Sn–C bonds are very long (2.27 Å versus the expected value of 2.17 Å). [6] For comparison, in the stannirene synthesized by *Sita* et al., [3] the bond lengths are d(C=C) = 1.34 Å and d(Sn-C) = 2.14 Å. The Sn–C bond is thus very weak, which would also explain the dissociation to the starting compounds observed in solution.

Compound **5** could have formed either via the stannirene **6** and subsequent insertion of **3** or by a [2 + 2] cycloaddition

of **1** and a dimer of **3** having an Sn–Sn double bond; since such dimers of **3** are not known [7] whereas a stannirene has already been isolated, [3] we believe that the pathway via **6** is more likely. Both pathways to the 1,2-digermacyclobutene are possible in the case of the dialkylgermylenes. [8] Phosphadistannacyclobutenes, however, are probably formed by [2 + 2] cycloaddition. [9]

Experimental Procedure

4, 5: Compound **1** (0.78 g, 4.68 mmol) was added dropwise under argon to **2** (1.28 g, 4.68 mmol) or **3** (1.5 g, 4.68 mmol) in 5 mL of dry benzene at + 10 °C over 5 min, resulting in the formation of yellow crystals. After purification (**4**, recrystallization from benzene; **5**, sublimation at 40–50 °C/10^{-3} torr), 1.43 g of **4** (86%) or 1.05 g of **5** (56%) was obtained.

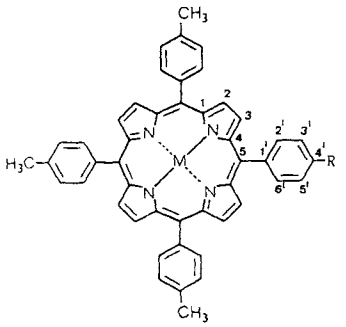
Highly Reduced Porphyrins**



By *Robert Cosmo, Christian Kautz, Klaus Meerholz, Jürgen Heinze,** und *Klaus Müllen**

Can an organic π system be used to store charge by successive addition of electrons and is the storage capacity increased on going to higher analogues containing several redox centers? We have examined this question for the first time for porphyrins [1] and have found that the zinc complex **1** of *meso*-tetratolylporphyrin **2** can reversibly accept six electrons. The NMR spectra of the intermediate di- and tetra-

anions demonstrate their annulene-like bonding. We "doubled" the zinc porphyrin complex **1** to form the stilbene-bridged diporphyrinyl system **3** and examined its redox properties in analogy to those of **1**. Complex **3** forms a dodecaanion!

Reduction of **1**[2,3] in [D_8]THF at $-78\,^{\circ}C$ with active lithium or potassium results in several color changes; however, the characterization of a diamagnetic primary product (green-red) or a secondary product (black) by high-resolution NMR spectroscopy was only possible when the reaction was followed spectroscopically and the concentration of the intermediate radical anions was minimized. The number and the charge-induced shifts of the ^1H and ^{13}C NMR signals of the diamagnetic species (Table 1), as well as trapping experiments with dimethyl sulfate[4] and mass-spectrometric characterization of the adducts, show that a dianion and a tetraanion with intact porphyrin frameworks are formed.

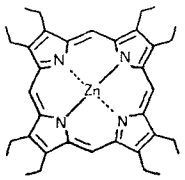

Table 1. ^1H and ^{13}C NMR chemical shifts ([D_8]THF]) of the porphyrins **1** and **4** and of the corresponding amines.

[a] Signal assignment by selective decoupling.

The salient features of the ^1H NMR spectra are the resonances of the β protons of the pyrrole units at high field ($\delta_H = -0.9$) in the dianion and at low field ($\delta_H = 6.70$)–despite charge-induced shielding–in the tetraanion. If the bonding in the neutral compound **1** is related to that in a diatropic diaza[18]annulene,[5,6] it follows necessarily that the corresponding dianion (tetraanion) has a paratropic (diatropic) 20 π (22 π) perimeter. We were able to carry out corresponding redox experiments involving dianion and tetraanion formation with an [18]annulene.[7] The paratropism of a doubly charged porphyrin perimeter is especially revealed in the resonance of the *meso* proton ($\delta_H = -3.9$) in the dianion (lithium salt) of the octaethyl zinc porphyrin **4**.[8]

4

The ^{13}C NMR spectrum of $\mathbf{1}^{4\ominus}$/4 $Li^{\oplus}$ provides information on the charge distribution. Whereas all carbon centers of the porphyrin ring experience an appreciable shielding upon tetraanion formation (see Table 1), the centers of the phenyl rings are deshielded. This finding indicates that, owing to twisting, the phenyl groups are not significantly involved in the charge delocalization.[9]

The cyclovoltammetric measurement of the reduction of **1** in absolutely dry dimethylamine[10] with tetrabutylammonium bromide as conducting electrolyte at temperatures below $-20\,^{\circ}C$ (Fig. 1 and Table 2) confirms that a stable tetraanion is formed. Furthermore, it shows that **1** can be reversibly reduced all the way to the hexaanion. The reduction of **1** to the dianion occurs in one-electron steps having separated potentials of $E^0(\mathbf{1}/\mathbf{1}^{\ominus}) = -1.44$ and $E^0(\mathbf{1}/\mathbf{1}^{2\ominus}) = -1.98$ V, whereas both the tetraanion and the hexaanion are formed in formal "two-electron" reactions at $E^0(\mathbf{1}^{2\ominus}/\mathbf{1}^{4\ominus}) = -2.78$ and $E^0(\mathbf{1}^{4\ominus}/\mathbf{1}^{6\ominus}) = -3.20$ V. Simulations revealed that the normal-potential separation between the $\mathbf{1}^{2\ominus}/\mathbf{1}^{3\ominus}$ ($\mathbf{1}^{4\ominus}/\mathbf{1}^{5\ominus}$) and the $\mathbf{1}^{3\ominus}/\mathbf{1}^{4\ominus}$ ($\mathbf{1}^{5\ominus}/\mathbf{1}^{6\ominus}$) redox pair is only 40 (50) mV.

Independent of the NMR data, cyclovoltammetric measurements on the Zn-free porphyrin system **2** showed that only the charge state of the porphyrin framework and not that of the $Zn^{2\oplus}$ ion is changed upon reduction of **1**. Here, too, six redox steps are observed (Table 2). However, the

Table 2. Redox potentials E^0 [V] of the compounds **1**–**4** [a].

	1	**2**	**3**	**4**

$R^{8\ominus}/R^{10\ominus}$	–	–	– 3.02 (70) [b]	–
$R^{10\ominus}/R^{12\ominus}$	–	–	– 3.27 [c]	–

[a] All potentials were determined by cyclic voltammetry with 10^{-3} M solutions of R in Me_2NH/0.1 M NBu_4Br with respect to the Ag/AgCl electrode (calibration with $Cp_2Co^{\oplus}/Cp_2Co$); $T = -65\,^{\circ}C$. [b] "Two-electron" redox steps (one-electron potential separation [mV] in parentheses). [c] $T = -85\,^{\circ}C$.

anions of **2** are appreciably less stable than those of **1**, so that, even for moderately fast scan rates, secondary reactions can occur, despite the low temperatures employed.

Previous cyclovoltammetric investigations on the formation of highly charged porphyrins had always shown[11,12] that protonated secondary products are formed beyond the trianion stage.[12] This is also true for the octaethyl zinc porphyrin **4**, which we were able, for the first time, to reduce reversibly to the tetraanion. The extreme potential values of – 3.08 and – 3.25 V, respectively, for the $\mathbf{4}^{2\ominus}/\mathbf{4}^{3\ominus}$ and $\mathbf{4}^{3\ominus}/\mathbf{4}^{4\ominus}$ redox pairs confirm, at the same time, that these stages are only accessible with difficulty by chemical reduction.

The connection of two porphyrin moieties through a stilbene group enticed us because stilbene is also a good electron acceptor ($E^0 = -2.26$ vs. Ag/AgCl) and because twisting around the formal single bond would allow a "decoupling" of the two moieties as well as a minimization of the Coulombic repulsion in the anions. The synthesis of the diporphyrinyl system 4,4'-bis[5-(10,15,20-tris(*p*-tolyl)porphyrinyl)]stilbene (as its zinc complex **3**) starts from the monobromo compound **5**,[2] which was metalated with butyllithium (9.2 equiv., 0 °C, diethyl ether, 2 h) and then formylated by reaction with dimethylformamide (6.8 equiv., 0 °C, 30 min) and hydrolysis with 2.5 M HCl to give the aldehyde **6**[13] (24% yield after chromatography on silica and recrystallization from $CHCl_3/CH_3OH$ 1/1). Compound **6** was converted into the zinc complex **7** (98% after recrystallization from $CHCl_3/CH_3OH$) by reaction with zinc acetate dihydrate[3] and then subjected to McMurry coupling[14] ($TiCl_4$/Zn, THF, 0 °C). Chromatography on silica and recrystallization ($CHCl_3/CH_3OH$) afforded the wine-red diporphyrinyl derivative **3** in 32% yield; **3** was sufficiently soluble in chloroform (1 mg in 0.14 mL $CHCl_3$).[15]

3: M=Zn

The cyclovoltammetric experiment in dimethylamine now shows (see Fig. 1 and Table 2) that **3** is reduced to the tetraanion in two formal "two-electron" redox steps. Two potentially separated, reversible one-electron transfers are observed for the next redox reactions; the first already occurs at – 2.32 V owing to the enlarged conjugation of the entire system—the stilbene bridge has to be coplanar with the two porphyrin frameworks in this charge state. The shift of the next electron transfer by 350 mV [$E^0(\mathbf{3}^{5\ominus}/\mathbf{3}^{6\ominus}) = -2.67$ V] is explained by the fact that the accumulation of charge to form the second trianionic electrophore is energetically disfavored by the Coulombic interaction through the coplanar stilbene bridge. After this critical charge state is attained, the sixfold charged dimer reversibly accepts another six (!) electrons to form the dodecaanion: however, the last stage already lies in the region of current rise due to electrolyte reduction. Since the electron transfers again occur in formal "two-electron" redox steps, the further accumulation of charge must take place locally in the two porphyrin units, without larger Coulombic effects acting through the stilbene bridge.

Thus, a tetraaryl porphyrin is a highly efficient electron acceptor. A doubling of the storage capacity per molecule can be achieved by suitable linking of the two porphyrin units. Current work is aimed at the development of analogous charge storage systems containing more than two porphyrin redox centers.

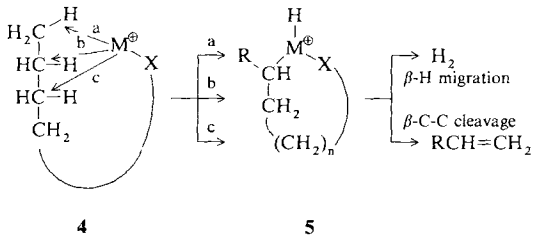
Revision and Modification of the Traditional Mechanism of C–H/C–C Activation by "Naked" Transition-Metal Ions**

By *Sigurd Karraß, Karsten Eller, Christian Schulze,* and *Helmut Schwarz**



Many reactions of "naked" (i.e., ligand- and counterion-free) transition-metal ions $M^{\oplus}$ with substituted alkanes **1** in the gas phase can be satisfactorily explained in terms of a mechanism formulated for the first time by *Allison* and *Ridge*[1] (Scheme 1). Oxidative addition of the C–X bond to $M^{\oplus}$ (**1** → **2**) is followed by a β-hydrogen transfer; the resulting olefin complex **3** undergoes competitive loss of HX (reductive elimination) and $RCH{=}CH_2$.

1 **2** **3**

Scheme 1. X = OH, halogen, NH_2

For longer-chain CN-substituted *n*-alkanes (cf. **4**, X = CN), we recently found a new type of reaction.[2] In this case, the dominant process is due to an interaction of remote C–H bonds with the transition-metal ion $M^{\oplus}$ "anchored" to the functional group ("remote functionalization"[3]). Depending on $M^{\oplus}$ (e.g., $Fe^{\oplus}$, $Co^{\oplus}$, $Ni^{\oplus}$), *different* segments of the alkyl chain are activated in an oxidative addition (Scheme 2).

4 **5**

Scheme 2.

We report here on experiments that reveal a significant variant in the mechanism of the metal-ion-induced activation of C–H and C–C bonds and, further, provide insight into several fundamental aspects of elementary reactions of organometallic chemistry.

Electron-impact ionization (100 eV) of a mixture of $Fe(CO)_5$ and $C_3H_7NH_2$ (1:5) in a mass spectrometer affords a complex of composition $C_3H_9NFe^{\oplus}$, which, in a tandem mass spectrometry (MSMS) experiment,[4] gives the products shown in Equation (a). The identity of the neutral molecules, based on the mass differences (Δ*m*), is firmly established for energetic reasons.[5] Their origin can be determined by investigation of the $Fe^{\oplus}$ complexes of the deuterated propylamines **6a–d** (Table 1).

	Δm	Neutral molecule	[%]

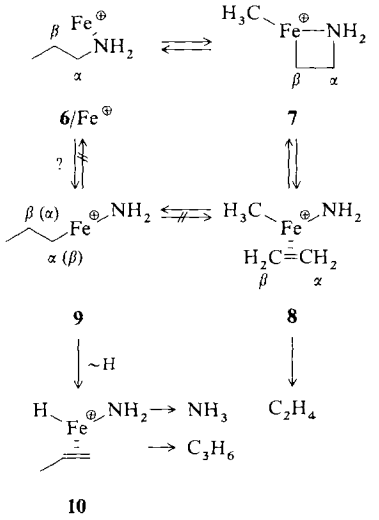
[a] The product distribution is normalized with respect to the corresponding neutral compound ($\Sigma_{isotopomer}$ = 100%).



It was found that molecular hydrogen originates exclusively from the β and γ positions of the alkyl chain (1,2-elimination); hydrogen shifts do not occur. Scheme 2 (X = NH_2; pathway a) provides a satisfactory description of the reaction mechanism. Oxidative addition of an N–H bond, followed by β-H transfer and reductive elimination of H_2 to give an $Fe^{\oplus}$-complexed imine, plays *no* role.[6]

The elimination of ethylene from the complex $C_3H_7NH_2/Fe^{\oplus}$ is not explainable in terms of Scheme 1, since only propene should be formed from propylamine. The reaction mechanism shown in Scheme 2 is also wrong, since ethylene originates specifically from the α- and β-methylene groups of the amine (Table 1). The α- and β-methylene groups are also involved in the formation of NH_3 and C_3H_6—in fact, to the same extent (± 2%). According to Scheme 1, NH_3 should contain a hydrogen atom only from the β position of the alkyl chain, and this hydrogen atom should be absent in the propene formed (R = CH_3). The data in Table 1 show that, before the elimination of ammonia or propene, the α- and β-methylene groups are equilibrated. Hydrogen shifts (e.g., via dyotropic rearrangement[7]) are ruled out here (no loss of a hydrogen atom from the α-CH_2 group). Instead a (formal) interchange of the two *intact* methylene groups takes place, possibly via the olefin complex **8** (Scheme 3). Complex **8**

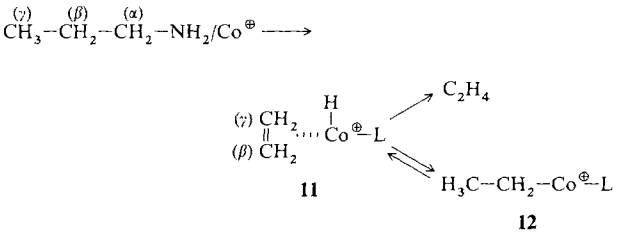
could be formed by a combination of oxidative addition and cycloreversion (**6**/$Fe^{\oplus}$ → **7** → **8**) and fulfills two functions: (1) as immediate precursor for the elimination of $C^{\alpha}C^{\beta}H_4$; (2) as intermediate for the equilibration of the C(α)/C(β) methylene groups. Although the details of the equilibration are not known and thermodynamic data for the system $C_3H_7NH_2/Fe^{\oplus}$ are not yet available, it is not unreasonable to assume that a rotation around the $Fe^{\oplus}$-(C_2H_4) bond requires less energy than, for example, an alkene elimination.[8] Insertion of the olefin into the metal–carbon bond—a gas-phase analogue of the Ziegler–Natta reaction[9]—affords **9**, which can be formally regarded as the product of the direct insertion of $Fe^{\oplus}$ into the C–N bond of **6**/$Fe^{\oplus}$. Compound **9** undergoes fast, irreversible β-H transfer to give the propene complex **10**, which eliminates C_3H_6 and NH_3.

Scheme 3.

Whether **6**/$Fe^{\oplus}$–**9** are interconverted reversibly or whether these isomerizations are irreversible reactions is not known with certainty for all pairs, but can be determined for partial steps. At the very least, we consider the β-methyl transfer **9** → **8** unlikely as a necessary condition for the equilibration of C(α)/C(β) in an intermediate **9** generated directly from **6**, since this reaction could not be found in any system so far investigated by us.[2f, 10] We also rule out the reaction **9** → **6**/$Fe^{\oplus}$, since the β-H shift **9** → **10** should occur appreciably faster than the conceivable competing reactions. The direct reaction **6**/$Fe^{\oplus}$ → **9**, which, in view of the divergent thermodynamic data,[1b, 11] cannot be excluded on this basis, must be markedly slower than the rearrangement **6**/$Fe^{\oplus}$ ⇄ **7** ⇄ **8**. Sufficient precedence is known for the reversibility of the step **7** ⇄ **8** as well as for the reductive opening of metallacycles.[12, 13]

Other alternatives (e.g., an $Fe^{\oplus}$-induced isomerization $nC_3H_7NH_2 \rightarrow iC_3H_7NH_2$) were eliminated in favor of the reaction mechanism shown in Scheme 3. Both the distribution of label (Table 1) and the finding that exclusively H_2 (95%) and CH_4 (5%) are formed from independently generated $iC_3H_7NH_2/Fe^{\oplus}$ definitively rule out this variant.



The gas-phase chemistry of the $C_3H_7NH_2/Co^{\oplus}$ complex ($Co^{\oplus}$ is generated by fast atom bombardment (FAB) of $CoCl_2$ with xenon (8 keV)[2f]) differs from that of the $C_3H_7NH_2/Fe^{\oplus}$ complex. In the MSMS experiment, the products shown in Equation (b) are formed unimolecularly; their origin was elucidated by investigations using the labeled amines.

	Δm	Neutral molecule	[%]	
$nC_3H_7NH_2/Co^{\oplus}$	2	H_2	12	(b)
	28	C_2H_4	81	
6/$Co^{\oplus}$	60	CoH	7	

Molecular hydrogen originates, as in the case of $nC_3H_7NH_2/Fe^{\oplus}$, exclusively from the β and γ positions (1,2-elimination); H scrambling was not observed.

Neutral CoH is formed by $Co^{\oplus}$-induced hydride abstraction[6, 11] from the α-methylene group of the amine (loss of CoD from **6b**/$Co^{\oplus}$ and of CoH from the $Co^{\oplus}$ complexes of the other isotopomers of **6**). The specificity of the reaction presumably is related to the facile formation of an iminium ion $CH_3CH_2CH{=}NH_2^{\oplus}$.

In contrast to $Fe^{\oplus}$, $Co^{\oplus}$ generates the olefin from the C(β)/C(γ) positions of the propylamine (loss of C_2H_4) instead of $C_2H_2D_2$ for **6b**/$Co^{\oplus}$). The investigation of the $Co^{\oplus}$ complexes of **6c** and **6d** reveals, however, that an incomplete hydrogen exchange within the β/γ positions must precede the ethylene elimination. Thus, $C_2H_2D_2$ and C_2H_3D are formed in a ratio of 2.8:1 from **6c** and $C_2H_2D_2$ and C_2HD_3 in a ratio of 2.7:1 from **6d**/$Co^{\oplus}$. For a complete exchange of an A_3B_2 system (A,B = H,D), the isotopomers $C_2A_2B_2$ and C_2A_3B, respectively, should be eliminated from **6c**/$Co^{\oplus}$ and **6d**/$Co^{\oplus}$ in the ratio 1.5:1. Presumably, the direct olefin elimination competes with the preceding exchange reaction of type **11** ⇄ **12** (Scheme 4).

Scheme 4. L = CH_2NH_2.

Collisional activation results in the formation of ca. 20% ethylene from the C(α)/C(β) positions of propylamine. The probable intermediate is a $Co^{\oplus}$ complex analogous to **8** (Scheme 3).

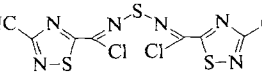
$S_4(CN)_8$, a Blue-Black High-Molecular Sulfur–Cyanogen Compound with 6π- and 8π-Electron Structural Elements**

By *Jörg Sundermeyer, Herbert W. Roesky,** and *Mathias Noltemeyer*

Paracyanogen films $(CN)_x$ are semiconductors at room temperature[1] and exhibit photoconductivity in the visible region.[2] Their structure has not yet been elucidated. To the best of our knowledge, in fact, no high-molecular compounds containing four or more cyanogen units covalently linked through heteroatoms have been structurally confirmed. The blue-black $S_4(CN)_8$, described here, is the first such compound having the general formula $S_x(CN)_y$.[3]



As we have already reported, reaction of cyanogen with elemental sulfur and copper as catalyst in dimethylformamide (DMF) gives 1,2,4-thiadiazole-3,5-dicarbonitrile **1**.[4]

$$2(CN)_2 + 1/8\ S_8 \xrightarrow[\text{[Cu]}]{\text{DMF}} S(CN)_4 \equiv \mathbf{1}$$

In the presence of catalytically active chloride ions, **1** reacts regioselectively with sulfur dichloride at the cyano function adjacent to sulfur to yield the reactive bis(imidoyl chloride) **2**.[5] Treatment of **2** with thiourea and pyridine results in

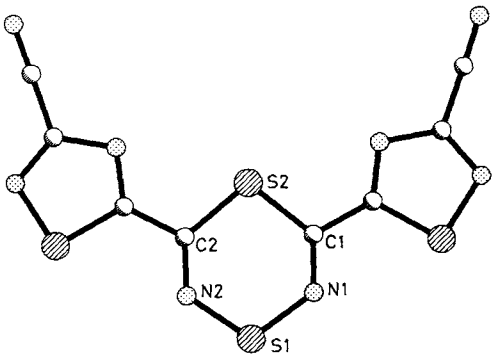
$$2\ \mathbf{1} + SCl_2 \xrightarrow[\text{[Cl}^{\ominus}\text{]}]{\text{THF}} S_3(CN)_8Cl_2 \equiv \mathbf{2}$$

spontaneous formation of a violet-blue reaction solution, from which blue-black crystalline needles of composition $S_4(CN)_8$ **3** (yield 55%) can be isolated.

$$\mathbf{2} \xrightarrow[(H_2N)_2CS]{\text{MeCN}} \xrightarrow[\text{pyridine}]{\text{MeCN}} S_4(CN)_8 \quad \mathbf{3}$$

The ^{13}C NMR spectrum of **3** shows four signals, indicating a structure with pairwise equivalent carbon atoms. No C≡N vibrational band is present in the IR spectrum. Raman-spectroscopic investigations failed owing to the strong fluorescence of **3**. The UV/VIS spectrum in MeCN shows four absorption maxima at λ = 543, 351, 286, and 218 nm.

Long black needles were obtained from toluene/pentane. Figure 1 shows the result of the single-crystal X-ray structure analysis of these crystals.[6]



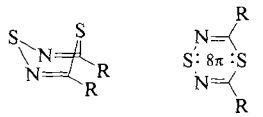


Fig. 1. Molecular structure of **3**. Selected bond lengths [pm] and angles [°]: S1-N1 165(8), N1-C1 126(4), C1-S2 178(9), S2-C2 179(1), C2-N2 128(1), N2-S1 165(2); N1-S1-N2 109.5(4), C1-S2-C2 99.5(5), S1-N1-C1 125.7(7), N1-C1-S2 129.7(7); torsional angle: N2-S1-N1-C1 6.9(0), S2-C2-N2-S1 0.1(1); Coplanarity of the symmetrical halves of the molecule: ± 1 pm.

In **3**, four cyanogen units are covalently linked through four sulfur atoms without cleavage of the respective C–C bonds, thereby forming a tricyclic system consisting of a central six-membered 1,4,2,6-dithiadiazine ring symmetrically substituted in the 3,5 positions with two 1,2,4-thiadiazole-3-carbonitrile ring systems. The three heterocycles are conjugated.

Recently, *C. W. Rees* et al.[7] characterized a phenyl-substituted 1,4,2,6-dithiadiazine of type **I**, which was formed in small yield upon reaction of diphenylacetylene with S_4N_4. The ring system **I** is not planar but rather adopts a boat conformation. Therefore, the orange compound **I**, R = Ph, is aromatic and not antiaromatic.

I

II

By contrast, the ring system of type **II** present in **3** deviates only slightly from planarity (max. deviation 6 (8) pm), and **3** is characterized by a blue-black color both in solution and in the crystal. In both compounds, the π bonds are localized. These three characteristics were also observed for six-membered CNS ring systems with 8π antiaromatic electron structure, first reported several years ago.[8]

We ascribe the structural differences between the two compounds to the different electronic properties of the substituents R. The thiadiazolyl moiety in **3** has a higher electron affinity than the phenyl moiety in *Rees'* compound. The electronic influence of the ligands on the planarity and electronic structure of unsaturated CNS heterocycles has also been observed for variously substituted 1,5-dithia-2,4,6,8-tetrazocines.[9]

Compound **3** opens up new perspectives in the search for high-molecular crystalline oligomers constructed mainly from condensed cyanogen molecules.

Experimental Procedure

5,5'-(1,4,2,6-Dithiadiazine-3,5-diyl)bis(1,2,4-thiadiazole-3-carbonitrile) **3**: **2** (7.50 g, 20 mmol) [5] and powdered thiourea (1.52 g, 20 mmol) were stirred in 150 mL of MeCN for 1 h at 40 °C. The suspension of greenish-yellow, microcrystalline solid thereby formed was filtered at 0 °C and the solid was washed with 50 mL of ether and then resuspended in 100 mL of MeCN. Pyridine (3.20 g, 40 mmol), diluted with 20 mL of MeCN, was added dropwise over 1 h at room temperature to this suspension; the resulting mixture immediately turned blue-black. After ca. 2 h, when almost all yellow solid had gone into solution, the volatiles were removed at 40 °C/0.01 mbar and the blue-black residue was extracted with 3 × 20 mL of toluene. Slow diffusion of pentane vapor into the concentrated toluene extracts resulted in the formation of long, blue-black needles, which lost toluene from the crystal lattice at 125 °C/0.01 mbar. Blue-black crystals (3.70 g, 55%; m.p. 169–170 °C) were thereby obtained. IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 1576, 1520, 1475, 1390, 1304, 1292, 988, 978, 857, 842, 812, 788, 710, 678, 665, 625, 555, 505, 432, 410. FI-MS: *m/z* 336 ($M^{\oplus}$, 100%). EI-MS: *m/z* 336 ($M^{\oplus}$, 55%), 252 ($M^{\oplus}-S(CN)_2$, 4), 200 ($M^{\oplus}-S(CN)_4$, 85%), 154 ($M^{\oplus}-S(CN)_4-SN$, 100%). ^{13}C NMR ($CDCl_3$): δ = 183.4, 147.1, 143.6, 111.2. UV-VIS (CH_3CN): λ_{max} [nm] = 218 (ε = 37200), 286 (20000), 351 (3680), 543 (3320).

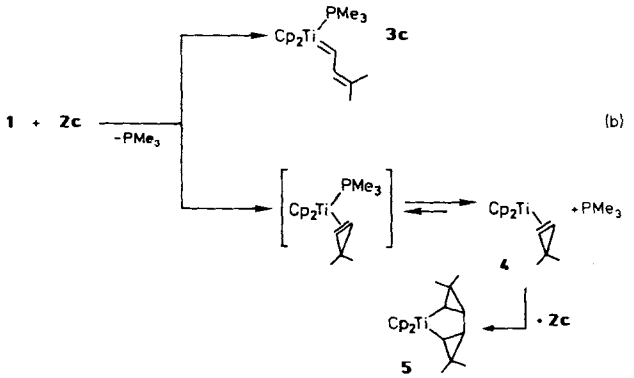
Vinylcarbene Complexes of Titanocene

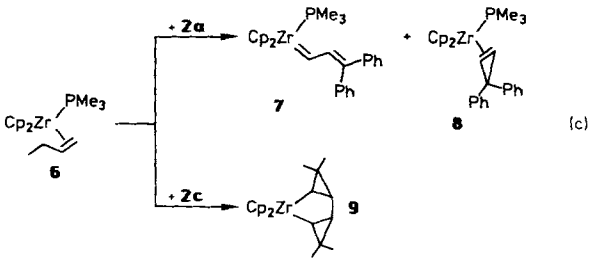
By *Paul Binger,* Patrik Müller, Reinhard Benn,* and *Richard Mynott*

Titanocenecarbenes, usually obtained in situ from bis(cyclopentadienyl)titanacyclobutanes or the Tebbe reagent, are highly interesting, newly developed reagents in organic synthesis,[1] e.g., for the olefination of carbonyl compounds,[1] enolate formation,[2] olefin metathesis[3] and ring-opening polymerization.[4] Despite this broad spectrum of applications, surprisingly few titanocenecarbene complexes have thus far been isolated and characterized. Those described include alkylidene complexes detectable only in solution,[5, 6] some 1-allenylidene complexes[7] and a 2,2-dimethylbut-3-enylidene complex,[8] all stabilized by trialkylphosphane ligands.

We have now succeeded in preparing representatives of the previously unknown titanocene(vinylcarbene) complexes in a most simple way. Reaction of the readily accessible cyclopropenes[9] **2a** and **2b** with titanocenebis(trimethylphosphane) **1**[10] affords the titanocene(vinylcarbene) complexes **3a** and **3b** as microcrystalline, red powders in yields of 81% and 72%, respectively [Eq. (a)].



(a)



a, R=R'=Ph; **b**, R=Me, R'=Ph; **c**, R=R'=Me

The multifunctional behavior of the cyclopropenes towards transition metal compounds, long known in the case of Ni^0- and Pd^0-catalyzed cycloadditions,[11] is evident again in the reaction of 3,3-dimethylcyclopropene **2c** with **1** [Eq. (b)] or in the reaction of **2a** with (1-butene)(trimethylphosphane)zirconocene **6**[12] [Eq. (c)]. **1** reacts differently with **2c** depending on the molar ratio and the reaction conditions. With **2c** in excess (**1**:**2c** = 1:4; dropwise addition of an etheral solution of **1** to **2c** at 0 °C), the complex **5** is obtained. Equimolar amounts of **1** and **2c**, on the other hand, afford a mixture of the titanium complexes **3c** and **4** at 0 °C in a ratio of ca. 2:1. An NMR study showed that the complexes **3c** and **4** are formed in a ratio of ca. 2:1 at −30 °C; above 0 °C **4** reacts with further **2c** to give **5**.

[*] Prof. Dr. P. Binger, Dipl.-Chem. P. Müller, Priv.-Doz. Dr. R. Benn, Dr. R. Mynott
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a.d. Ruhr (FRG)

Reaction of **2a** and **6**[12] at 20 °C leads to the formation of equal amounts of the (diphenylvinyl)carbene complex **7** and the (η^2-diphenylcyclopropene) complex **8**, while the 3,3-dimethylcyclopropene **2c** reacts with **6** exclusively with oxidative coupling to give **9**. The complexes **7** and **8** do not equilibrate, nor can they be interconverted into each other by heating. These findings suggest that the vinylcarbene complexes **3a–3c** and **7** are formed by direct opening of the three-membered ring and not via an η^2-cyclopropene complex as intermediate.

The structures of the vinylcarbene complexes **3a–3c** and **7** can be unequivocally confirmed by NMR spectroscopy. The characteristic downfield shift to $\delta = 12.54–12.93$[13] is observed for the carbene proton 1-H [for numbering see Eq. (a)]. The downfield shift of the olefin proton 2-H ($\delta = 7.44–8.32$) is also significant. The presence of two Cp signals in the spectra of **3**[13] indicates that trimethylphosphane is bound perpendicular to the plane of the Ti=C double bond. Overall, the data indicate a tetrahedral structure for the complexes **3a–3c** and **7**. The ^{13}C NMR spectra are consistent with these structures, the chemical shift of the carbene C atoms ($\delta = 284–286$) being especially indicative.[6]

The synthesis of the titanium compounds **3a–3c** as outlined here opens up a novel entry to carbene complexes of titanium. At the same time, this finding demonstrates that, under certain conditions, transition metal compounds are able to convert cyclopropenes into vinylcarbenes. Hitherto, such a reaction has only been postulated, on the basis of reaction products formed catalytically from cyclopropenes.[11,14] With one exception,[15] attempts to synthesize vinylcarbene-transition metal complexes have led only to (vinylketene)metal complexes,[11] metallacyclohexadienes or (η^4-cyclopentadiene)metal complexes.[16]

Experimental

3a: A solution of **1** (3.18 g, 9.63 mmol) in pentane (200 mL) was treated dropwise at 0 °C with **2a** (1.85 g, 9.63 mmol). The cooling bath was removed and the solution stirred for 3 h at room temperature. The precipitated red, microcrystalline powder was then filtered. Yield 3.5 g (81%) of **3a** after washing twice with 10 mL of pentane and drying at 10^{-3} torr; decomp. at ca. 50 °C. 0.4 g (72%) of **3b** (decomp. at ca. 50 °C) was obtained analogously from **1** (0.48 g, 1.45 mmol) and **2b** (0.2 g, 1.5 mmol).

Pentamethylcyclopentadienylmercury Chloride: An Organomercury Compound with Novel Battlement-like Structure

By Jörg Lorberth, Theo F. Berlitz, and Werner Massa*

Dedicated to Professor Michael Fredrick Lappert on the occasion of his 50th birthday

The chemistry of the pentamethylcyclopentadienyl-complexes of main group metals is full of surprises:[1] for example, Cp* (Cp* = C_5Me_5) as η^1-bound ligand in the tin compounds [$Cp^*_2SnX_2$] is eliminated by an unknown mechanism

and forms, via C–C coupling, $C_{20}H_{30}$, decamethyldicyclopentadiene (dimeric Cp*),[2] the gas-phase and solid-state structures of which have already been reported.[3, 4] On attempting to synthesize $SbCp^*_3$ and $SbCp^*_5$ by reaction of $SbCl_3$ and $SbCl_5$, respectively, with KCp* we obtained $[\eta^1$-Cp*Sb$]_4$ and decamethyldicyclopentadiene.[5, 6] In another Cp*-main group metal compound, $[Cp^*_2BiCl]$, the ligand is η^5-bound: above $-30\,^\circ C$ it is eliminated with formation of $C_{20}H_{30}$[6, 7] and $[Cp^*BiCl_2]$.[8]

We have now investigated the reaction of potassium pentamethylcyclopentadienide with $HgCl_2$ at room temperature in ether; the title compound **1** was obtained in 74% yield.

$$HgCl_2 + KCp^* \longrightarrow 1/n\,[Cl\text{–}Hg\text{–}Cp^*]_n + KCl$$
$$\mathbf{1}$$

Decomposition, presumably of $HgCp^*_2$, which is formed in small amounts, still leads to elemental mercury and $C_{20}H_{30}$. Probably the reductive elimination of the hydrocarbon is a general reaction with such compounds and is difficult to suppress.

The crystal structure of $[Cp^*\text{–}Hg\text{–}Cl]_\infty$ **1** was determined by X-ray crystallography.[9] The basic units of this novel structural type consist of almost linear [Cl–Hg–Cp*] groups (Cl–Hg–C angles: 174 and 177°). These units are joined together via weak Hg···Cl contacts (310–324 pm) to give a double-chain structure (see Figs. 1 and 2).

Other than in the case of $[HgCl_2(PMe_3)]$, whose Cl–Hg–P dumbbells are all perpendicular to a planar ladder-like chain,[10] in **1** the covalent Hg–Cl bonds participate in the construction of the double chain: pairs of parallely oriented piece sections of a ladder. Because of the bulkiness of the Cp* terminals the dumbbells in such pairs—linked by symmetry centers—are oriented antiparallel. The incorporation of these dumbbell pairs as sidepiece sections is only possible with strong folding of the double chain; the folding angle at the "crosspieces" with short Hg–Cl bonds (Hg2–Cl2) is 129°, at those with long Hg1···Cl1 contacts 88°, thus resulting in a battlement-like structure of the double chain.

The pentamethylcyclopentadienyl rings do not deviate significantly from planarity (at Hg1 maximaly 1.3(15), at Hg2 maximally 3.5(11) pm). They are bent from the Hg–C bond axis at angles of about 113 and 108°, respectively, and form an organic protective covering round the "$[Hg_2Cl_2]_\infty$ battlement-like structure" (Fig. 3).

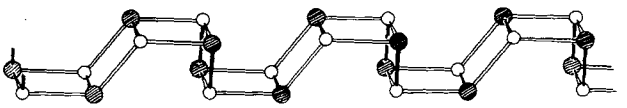

Fig. 1. Double chain or battlement-like structure of **1**. Hatched: Hg; white: Cl; C not shown. For details see text.

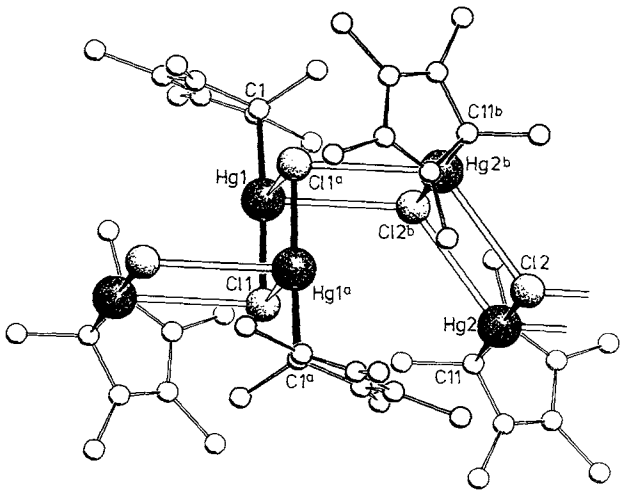

Fig. 2. Section of the polymer structure of **1** view approx. along the *c* axis. Chain orientation along the *a* axis (SCHAKAL drawing) [15]. Important bond lengths [pm] and angles [°]: Hg1-Cl1 236.1(5), Hg1-C1 208(2), Hg1-Cl1^a 309.8(5), Hg1-Cl2^b 323.8(7), Hg2-Cl2 235.0(6), Hg2-C11 210(2), Hg2^b-Cl1^a 323.2(6), Hg2-Cl2^b 317.7(6); Cl1–Hg1–C1 173.9(5), Cl1-Hg1-Cl1^a 87.2(2), Hg1-Cl1-Hg1^a 92.8(2), Cl1^a-Hg1-Cl2^b 75.2(2), Hg1-Cl1^a-Hg2^b 91.3(2), Cl1^a-Hg2^b-Cl2^b 86.1(2), Hg1-Cl2^b-Hg2^b 107.1(2), Cl2-Hg2-C11 176.8(7), Cl2-Hg2-Cl2^b 85.4(2), Hg2-Cl2-Hg2^b 94.6(2), Cl1-Hg1-Cl2^b 86.2(2), Hg1^a-Cl1^a-Hg2^b 90.4(2), Cl1^a-Hg2^b-Cl2 126.8(2), Hg1-Cl2^b-Hg2 128.2(2).

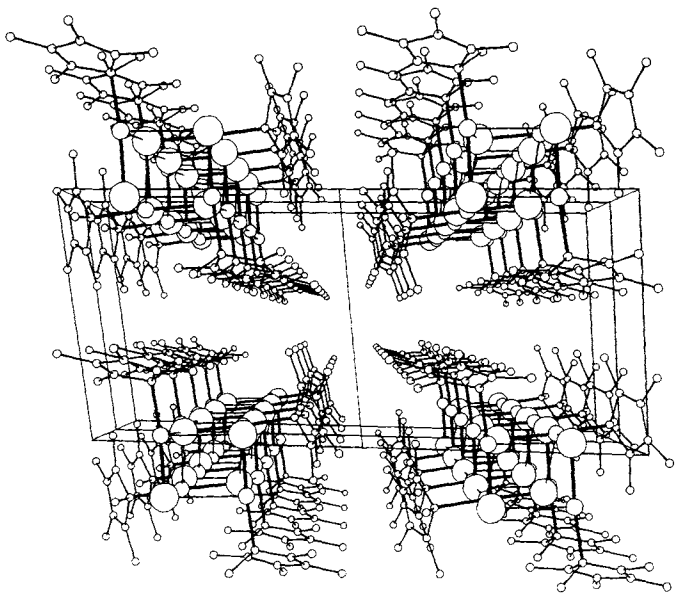

Fig. 3. Perspective ORTEP drawing [16] of the chain structure and packing of the double chains of **1** (projection along the *a* axis).

Double chain structures are also found, aside from in the already mentioned $[HgCl_2(PMe_3)]$, in, e.g., $[pyr\text{–}Cu\text{–}I]_\infty$ (pyr = C_5H_5N),[11] $[CH_3CN\text{–}Cu\text{–}Br]_\infty$[12] and $[F\text{–}Sn\text{–}NCS]_\infty$;[13] however, they are built of tetrahedral building blocks and exhibit simple zig-zag folding. $[Cp\text{–}Sn\text{–}Cl]_\infty$, with a formula type most comparable with the title compound, has a weakly folded ladder-like double chain structure in which all Cp–Sn–Cl dumbbells form "crosspieces".[14]

Experimental

1: A mixture of 3.83 g (14.1 mmol) of $HgCl_2$ and 2.46 g (14.1 mmol) of KCp* in 100 mL of absolute diethyl ether was heated under reflux for 12 h. The ether solution was filtered from the grey, fine-grained precipitate and concentrated by evaporation. On cooling the concentrated solution to $-37\,^\circ C$, yellow needle-like crystals separated out (m.p. 43 °C (decomp. at ca. 78 °C); yield 3.88 g (74%)).—^{1}H NMR ($CDCl_3$), 300 MHz, int. TMS): $\delta \approx 0.98$ (s, $^3J(^{199}Hg\text{–}C\text{–}C\text{–}^1H)$ 62.55 Hz), 1.59(s), 1.75(s).—^{13}C NMR ($CDCl_3$, 300 MHz, int. TMS): δ = 10.8, 12.42, 19.19 (all s, CH_3), 59.60, 132.98, 141.55 (all s, ring atoms).—EI-MS (70 eV), main fragments *m/z* rel. to base peak. 370 (3.95%, $M^\oplus$); 270(13.13%, $C_{20}H_{30}$); 200 (1.84%, Hg); 135 (100%, C_5Me_5); 105 (20.54%, C_5Me_3).

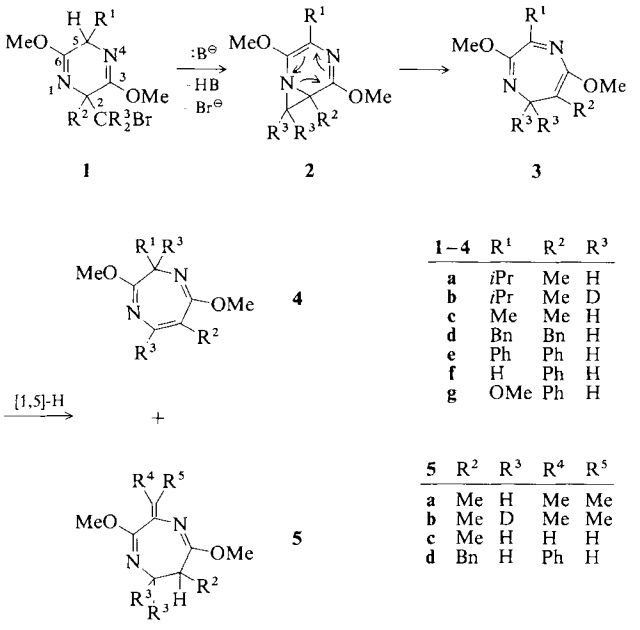
From 2,5-Dihydropyrazines to 2*H*-1,4-Diazepines and from Benzodihydroarenes to Benzocycloheptene Derivatives, Structural Variants of the Antidepressant Protriptyline



By *Ulrich Schöllkopf** and *Joachim Mittendorf*

Dedicated to Sir Derek Barton on the occasion of his 70th birthday

In our studies of the asymmetric synthesis of non-proteinogenic amino acids according to the bislactim method[1] we have observed that bislactim ethers **1** with a nucleofugal leaving group on C-1′ undergo a novel ring expansion of the six-membered ring to a seven-membered ring in the presence of bases such as potassium hydroxide or potassium *tert*-butoxide in dimethyl sulfoxide (DMSO) or dimethylformamide (DMF) at room temperature, whereby diazepines **4** are formed (Scheme 1). If R^1 is a CHR_2 group, relatively large amounts of dihydrodiazepines **5** are also formed, the ratio **4**:**5** depending upon the reaction conditions (Table 1).

As has been shown by a mechanistic study with deuterium-labeled compounds (e.g. **1b**),[3] the ring expansion begins with the deprotonation of **1** at C-5 and formation of the heteronorcaradiene **2**. This rearranges electrocyclically to 5*H*-1,4-diazepine **3**. So far we have only been able to isolate **3g**; the 1,4-diazepines **3a–f** undergo further rapid reaction involving a [1,5]-sigmatropic shift to give **4**. When $R^1 = CHR_2$ a deprotonation-reprotonation reaction is possible at the stage of **3** in the presence of a base, leading to the dihydrodiazepines **5**.

As already mentioned, when R^1 = OMe (**1g**) the "cycloheptatriene intermediate" **3g** is isolable, since the additional imino ether group strongly stabilizes the ground state. With

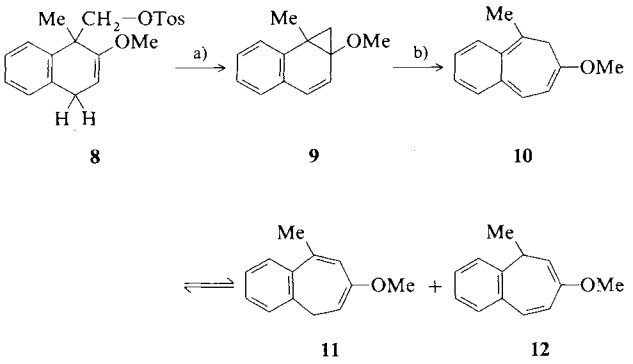
5	R^2	R^3	R^4	R^5
a	Me	H	Me	Me
b	Me	D	Me	Me
c	Me	H	H	H
d	Bn	H	Ph	H

Table 1. Reaction conditions of the ring expansion of **1** and yields of **4** and **5** [8].

1	Base/Solvent	T [°C]	t [h]	Yield [%] **4**	**5**
a	KO*t*Bu/DMSO	50	1	–	75
a	$DMSO^{\ominus}\ Li^{\oplus}$/DMSO	25	10	8	62
a	KOH/DMSO	25	24	73	6
a	KOH/DMSO	50	5	93	< 0.5
a	KOH/DMF	25	24	62	1
c	KOH/DMSO	25	96	14	44
c	KO*t*Bu/DMSO	50	1	–	71
d	KOH/DMSO	25	24	–	73
e	KOH/DMSO:DMF (1:1)	0	4	87	–
f	KOH/DMSO	25	2	59	–
g	KO*t*Bu/DMSO	25	0.2	7[a]	–

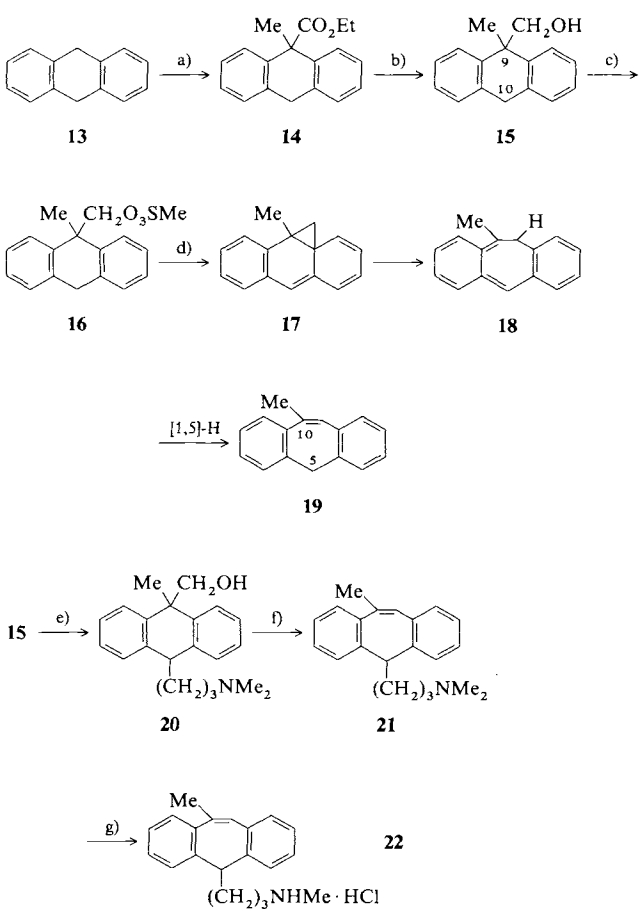
[a] Initially **3g** is obtained, which upon heating for 1 h at 90 °C completely rearranges to **4g**.

3g the (irreversible) transannular 1,5-hydrogen shift to give **4g** can be kinetically monitored. The rate constants are $k = (4.385 \pm 0.033) \times 10^{-4}\ s^{-1}$ at 70 °C and $(1.023 \pm 0.011) \times 10^{-4}\ s^{-1}$ at 55 °C.[4] In contrast, the rate constants for the isomerization **6** → **7**, the prototype of the transannular [1,5]-hydrogen shift are $k = 4.8 \times 10^{-8}\ s^{-1}$ at 98 °C, $6.6 \times 10^{-7}\ s^{-1}$ at 121 °C and $3.2 \times 10^{-6}\ s^{-1}$ at 140 °C.[5] Hence, the isomerization **3g** → **4g** at 70 °C is ca. 10^5 times faster than the reaction **6** → **7**. If one sets a lower limit of 96 kJmol^{-1} of the activation barrier of the [1,5]-hydrogen shifts **3** → **4**, in which **3** is not isolable, then it can be estimated that this rearrangement is at least 10^7 times faster than the rearrangement **6** → **7**.[7]



6 **7**

As expected, the ring expansion is not limited to the 2,5-dihydropyrazines, but can also be extended to analogous all-carbon compounds. Thus, reaction of the 1,4-dihydronaphthalene **8**[9] with potassium *tert*-butoxide affords the norcaradiene derivative **9**, which, on heating, is converted



[*] Prof. Dr. U. Schöllkopf, Dipl.-Chem. J. Mittendorf
Institut für Organische Chemie der Universität
Tammannstrasse 2, D-3400 Göttingen (FRG)

via the "cycloheptatriene intermediate" **10** into a mixture of the benzocycloheptenes **11** and **12** (Scheme 2).

Scheme 2. Reaction conditions: a) KO*t*Bu, DMSO, 25 °C; 93%. b) 250 °C in *n*-icosane; 85% [8].

In an analogous way 9,10-dihydroanthracene **13** furnishes 10-methyl-5*H*-dibenzo[*a*,*d*]cycloheptene **19** via the intermediates **14** to **18** (Scheme 3). After introduction of a 3-dimethylaminopropyl group at position 10 of **15**, the compound **22** is formed analogously via the intermediates **20** and **21** (Scheme 3). Compound **22** warrants attention as 10-methyl analogue of the antidepressant protriptyline®. Since the substituent in position 10 of **22** is variable within wide limits, the ring expansion method described here opens up a simple and productive entry to structural variants of protriptyline.

Scheme 3. Reaction conditions: a) 1. *n*BuLi, THF, −78 °C; 2. Dropwise addition to $ClCO_2Et$ (fourfold excess) in THF, −78 °C; 3. KO*t*Bu, THF, 0 °C; 4. MeI, 0 °C; 85%. b) $LiAlH_4$, ther; 96%. c) $MeSO_2Cl$, NEt_3; 93%. d) KO*t*Bu, DMSO, 25 °C; 94%. e) 1. 2 equiv. *n*BuLi, THF, 0 °C; 2. $ClCH_2CH_2CH_2NMe_2$, 0 °C; 81%. f) 1. $MeSO_2Cl$, NEt_3; 2. KO*t*Bu, DMSO, 25 °C; 79%. g) 1. $ClCO_2Ph$, CH_2Cl_2, 25 °C; 2. NaOH, 50% aqueous ethanol, reflux; 3. HCl; 67% [8].

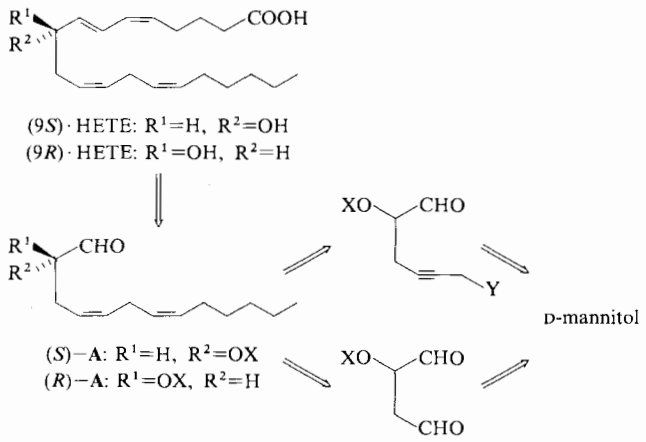
[4] The mole fraction of **3** was determined ^1H NMR spectroscopically as a function of time.
[5] A. P. ter Borg, H. Kloosterziel, N. van Meurs, *Recl. Trav. Chim. Pays-Jas 84* (1965) 717.
[6] *H. Kessler*, Angew. Chem. 82 (1970) 237; *Angew. Chem. Int. Ed. Engl. 9* (1970) 219.
[7] This easier [1,5]-hydrogen shift is said to be due to a change in the orbital energies and orbital coefficients (see also C. B. Argo, J. T. Sharp, *J. Chem. Soc. Perkin Trans. 1 1984*, 1581; N. Hoshi, H. Hagiwara, H. Uda, *Chem. Lett. 1979*, 1291, 1295, N. Hoshi, H. Uda, *J. Chem. Soc. Chem. Commun. 1981*, 1163). In the transition state of the rearrangement **3** → **4** the imino ether group has a relatively strong electron-withdrawing effect on both ends of the azapentadiene system. The energy of the HOMO of the azapentadienyl radical should be lowered thereby and the transition state should be stabilized compared to that in the cycloheptatriene system **6** (I. Fleming: *Frontier Orbitals and Organic Reactions*, Wiley, Chichester 1978, p. 27).
[8] Correct C,H analyses and ^1H and ^{13}C NMR and mass spectra were obtained for all the described compounds.

Total Enantiospecific Synthesis of (9*S*)- and (9*R*)-9-Hydroxyeicosatetraenoic Acid (9-HETE) Methyl Ester



By *Michèle Saniere, Yves Le Merrer, Brigitte Barbe, Thierry Koscielniak, Jacques Dumas, Dominique Micas-Languin*, and *Jean-Claude Depezay**

It has recently been demonstrated that leukotrienes (LTC_4, LTD_4 and LTE_4) are formed in the central nervous system.[1] Furthermore, 9-hydroxyeicosatetraenoic acid (9-HETE) was isolated from incubations of sliced rat brain tissue,[2] thus pointing to a direct lipoxygenase activity in the brain. The formation of 9-HETE had previously never been observed in mammalian tissues.

Two syntheses of (±)9-HETE and (9*S*)-HETE have already been published.[3] In the interest of fully evaluating the biological properties of 9-HETE it was desirable to obtain adequate supplies of both enantiomers. We report here on the synthesis of the enantiomeric 9-HETE methyl esters from

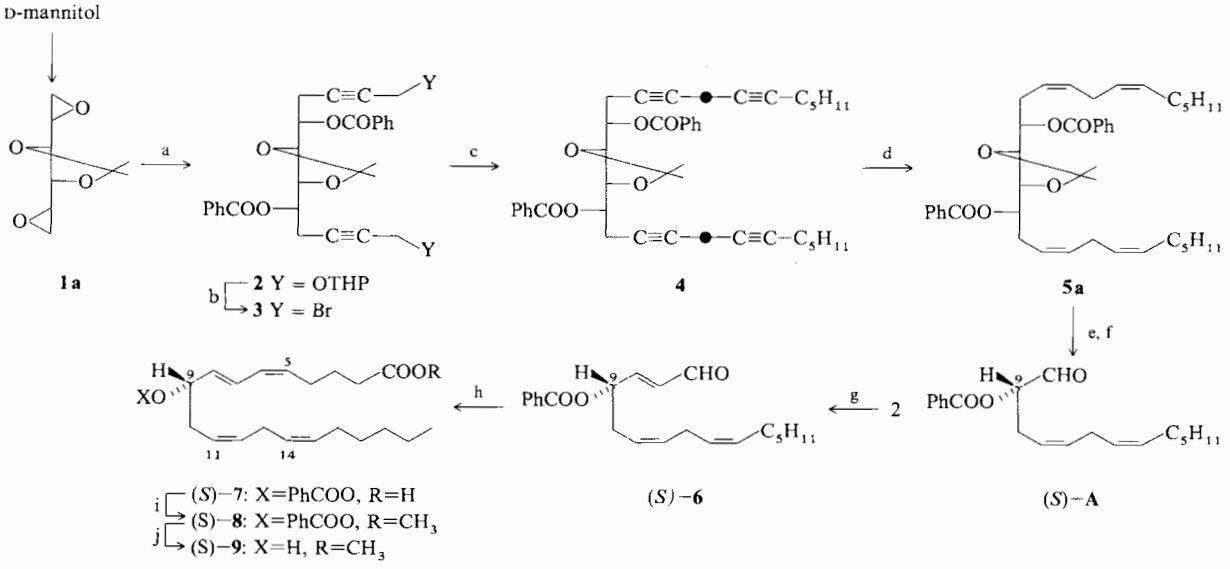
D-mannitol. The chiral protected α-hydroxyaldehydes (*R*)-**A** and (*S*)-**A** are the key intermediates for these syntheses. To obtain enantiomerically pure α-hydroxyaldehyde **A** with *R*- or *S*-configuration from D-mannitol we used two different methods, one providing selective access to the *R*-configurated aldehyde, the other to the *S*-configurated aldehyde (Scheme 1). Each method can be used for selective access to *R*- or to *S*- configurated aldehydes.

Scheme 1. Retrosynthetic analysis. X = protecting group (see Scheme 2).

Scheme 2 outlines the synthesis of (9*S*)-HETE from the enantiomerically pure diepoxide **1a**,[4] nucleophilic ring-opening of which by 2-lithio-2-propynyl tetrahydropyranyl ether, followed by benzoylation *in situ* afforded **2**. Direct conversion into the dibromide **3**,[5] and coupling with cuprate of 1-heptyne[3] in excess led to the tetrayne **4** (50% overall yield based on **1a**). Direct nucleophilic opening of diepoxide **1a** by various organometallics of decadiyne led to the tetrayne **4** in poor yield (ca. 15%). Selective hydrogenation of **4** to the tetraene **5a**, followed by removal of the ketal and oxidative cleavage of the resulting 3,4-diol gave the protected chiral α-hydroxyaldehyde (*S*)-**A** $[\alpha]_D^{20} = -11°$ (c = 1.2, CH_2Cl_2).

Reaction of (*S*)-**A** with formylmethylene(triphenyl)phosphorane afforded the unsaturated aldehyde (*S*)-**6** in 70% yield, $[\alpha]_D^{20} = +67°$ (c = 1.3, CH_2Cl_2), whose selective *cis* olefination with the ylide derived from the 4-carboxybutyl (triphenyl)phosphonium bromide furnished (*S*)-**7**[6] in 75% yield, $[\alpha]_D^{20} = +51°$ (c = 1.6, CH_2Cl_2). Esterification with diazomethane to give (*S*)-**8** followed by treatment with K_2CO_3 in methanol finally gave the HETE methyl ester (*S*)-**9**. ^{1}H NMR spectroscopic data for **A, 6, 7** and **9** are listed in Table 1.

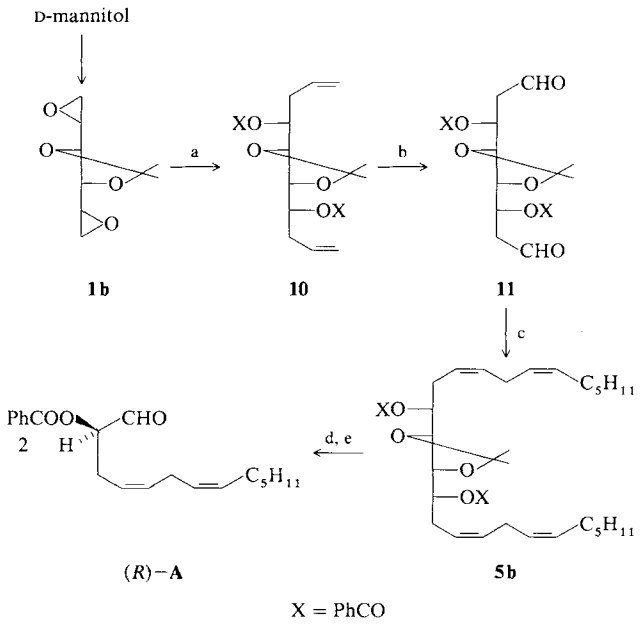
Table 1. ^{1}H NMR data for compounds **A, 6, 7** and **9** (250 MHz, $CDCl_3$). Numbering sequence of carbons as for **9**.



A: δ = 9.64 (s, 1H, CHO); 8.1, 7.50 (m, 5H, Ph); 5.6–5.2 (m, 5H, H-9,11,12,14,15); 2.81 (t, 2H, H-13, J = 7 Hz); 2.72 (t, 2H, H-9, J = 7 Hz); 2.01 (q, 2H, H-16, J = 7 Hz); 1.27 (m, 6H, H-17,18,19,); 0.86 (t, 3H, H-20, J = 7 Hz).

6: δ = 9.55 (d, 1H, CHO, J = 7.5 Hz); 7.90, 7.30 (m, 5H, Ph); 6.85 (dd, 1H, H-8, J = 4.5, 16 Hz); 6.30 (ddd, 1H, H-7, J = 1.5, 7.5, 16 Hz); 5.80 (m, 1H, H-9); 5.54–5.28 (m, 4H, H-11,12,14,15); 2.85 (m, 2H, H-13); 2.60 (m, 2H, H-10); 2.00 (m, 2H, H-16); 1.30 (m, 6H, H-17,18,19); 0.86 (t, 3H, H-20, J = 7 Hz).

7: δ = 8.1 7.5 (m, 5H, Ph); 6.58 (dd, 1H, H-7, J = 11, 16 Hz); 6.01 (t, 1H, H-6, J = 11 Hz); 5.66 (dd, 1H, H-8, J = 7.5, 16 Hz); 5.60–5.20 (m, 6H, H-5,9,11,12,14,15); 1.90–2.79 (m, 10H, H-2,4,10,13,16); 1.70 (m, 2H, H-3); 1.23 (m, 6H, H-17,18,19); 0.86 (t, J = 7 Hz, 3H, H-20).



9: δ = 6.48 (ddd, 1H, H-7, J = 1.5, 11, 15.5 Hz); 6.0 (t, 1H, H-6, J = 11 Hz); 5.7 (dd, 1H, H-8, J = 6, 15.5 Hz); 5.4 (m, 5H, H-5,11,12,14,15); 4.2 (m, 1H, H-9); 3.68 (s, 3H, OCH_3); 2.8 (m, 2H, H-13); 1.9–2.5 (m, 8H, H-2,4,10,16); 1.70 (m, 2H, H-3); 1.25 (m, 6H, H-17,18,19); 0.9 (t, J = 7 Hz, 3H, H-20).

We also obtained the (9*R*)-HETE methyl ester from D-mannitol (Scheme 3): nucleophilic opening of the enantiomerically pure D-mannitol derivative **1b**[4] with lithium cyanodivinylcuprate,[7] followed by benzoylation *in situ* afforded **10** (90%), ozonolysis of which led to the crude di-

Scheme 2. [9] a) −5 °C, LiC≡C−CH_2OTHP (4 equiv.), THF/$(Me_2N)_3PO$ (HMPA) 10/1, reflux 20 h, then 0 °C, PhCOCl (5 equiv.), 80%; b) $Ph_2PC_2H_4PPh_2$-$2Br_2$ (4 equiv.), CH_2Cl_2, 1.5 h, 25 °C, 70%; c) C_5H_{11}−C≡CH (4 equiv.), CuBr · Me_2S (2 equiv.), THF, 30 min, −10 °C; then −78 °C, BuLi (2 equiv.), −78 °C → −40 °C, 20 min; then **3**, −78 °C → 0 °C; then HMPA, 0 °C − room temperature (RT), ca. 12 h, 90%; d) H_2, 5% Pd/$BaSO_4$, 1% quinoline, ethyl acetate, 60%; e) F_3C−COOH/H_2O 9/1, −5 °C, 30 min, 100%; f) $Pb(OAc)_4$ (1.2 equiv.), CH_2Cl_2, −10 °C, 1 h, 75%; g) $Ph_3P^{\oplus}$−CH_2−CHO $Br^{\ominus}$ (1.1 equiv.), NEt_3 (1.4 equiv.), C_6H_6, 25 °C, 24 h, 70%; h) $Ph_3P^{\oplus}$−$(CH_2)_4$−COOH $Br^{\ominus}$ (2.8 equiv.), $(CH_3)_3Si$−NLi−$Si(CH_3)_3$ (5.3 equiv.), THF/HMPA 4/1, 0 °C; then −78 °C, **6**, 75%; i) CH_2N_2, Et_2O; j) K_2CO_3, MeOH.

aldehyde **11**. This unstable dialdehyde (highly prone to elimination of benzoic acid) was not purfied but condensed immediately with the ylide derived from the (Z)-non-3-en-1-yl(triphenyl)phosphonium bromide[8] (overall yield based on **10** was 50%). Hydrolysis of the ketal function and oxidative cleavage of the resulting 3,4-diol afforded the protected α-hydroxyaldehyde (*R*)-**A**, $[\alpha]_D^{20} = +11°$ (c = 1.14, CH_2Cl_2).

Scheme 3. [9]. a) $(CH_2=CH)_2CuCNLi_2$ (3 equiv.), THF, −78 °C; −78 °C → RT, 2 h; then −40 °C, PhCOCl (6 equiv.), −40 °C → RT, 40 min, 90%; b) O_3, CH_2Cl_2, −78 °C, then Ph_3P (2 equiv.), −78 °C → RT, 24 h; c) (Z)-$Ph_3P^{\oplus}(CH_2)_2CH=CH-C_5H_{11}$ $Br^{\ominus}$ (4 equiv.), THF, BuLi (3.9 equiv.), −78 °C, 1 h, then **11**, −78 °C → RT, 2 h, yield (b + c) 50%; d) $F_3C-COOH/H_2O$ 9/1, −5 °C, 30 min, 100%; e) $Pb(OAc)_4$ (1.2 equiv.), CH_2Cl_2, −10 °C, 30 min, 76%.

Using the previously described reactions, the aldehyde (*R*)-**A** was transformed into the (9*R*)-HETE methyl ester. Analysis of the (9*S*)- and (9*R*)-HETE methyl esters using a chiral phase HPLC column revealed in each case the presence of a single enantiomer.

The method reported here can be used for the synthesis of various HETEs, metabolites of arachidonic acid.

Pep5: Structure Elucidation of a Large Lantibiotic**

By *Roland Kellner, Günther Jung,* Michaela Josten, Cortina Kaletta, Karl-Dieter Entian,* and *Hans-Georg Sahl*

Dedicated to Professor Hans Zähner on the occasion of his 60th birthday

The thioether amino acids lanthionine (Lan) and 3-methyllanthionine (MeLan, cf. Fig. 1) have been identified in several biologically active polypeptides produced by Gram-positive bacteria. For these peptide antibiotics, we have proposed the collective name *lantibiotics*.[1] So far, the structures of eight lantibiotics have been elucidated. The most important lantibiotic is nisin,[2] produced by several *Streptococcus lactis* strains, which has found application as a food preservative;[3] others are subtilin,[4] cinnamycin and duramycin,[5] ancovenin,[6] epidermin,[7] Ro09-0198,[8], and gallidermin.[9] In addition to Lan and MeLan, most lantibiotics contain 2,3-unsaturated amino acids. The occurrence of the unusual amino acids causes considerable difficulties in determining the structure, as they are not detected unless specific modifications to sequenceable residues are made.

Recent isolation of the epidermin[7] structural gene from *Staphylococcus epidermidis* showed that lantibiotics are encoded by distinct genes.[1] This finding confirmed the hypothesis[10] that these peptide antibiotics originate from ribosomally synthesized precursor peptides as postulated, e.g., for epidermin.[7a] Recently, the structural genes were sequenced for subtilin,[11] nisin,[12,13] and gallidermin.[14]

All precursor sequences (prelantibiotics) consist of a leader sequence followed by a prosequence from which the lantibiotic is formed by modification.

Here, we report the structure elucidation of the large and strongly basic lantibiotic Pep5.[15] Pep5 is a membrane-modifying polypeptide. In lipid membranes it forms voltage-dependent ion channels by aggregation, and the conductance states depend on the number of monomers involved in the aggregate.[15c] The chemical sequencing enabled us to propose a prolantibiotic (cf. Fig. 4), to synthesize an appropriate DNA probe for isolating the Pep5 structural gene, and to determine the prelantibiotic including its leader sequence.[16]

Table 1. Some characteristic data of Pep5.

Amino acid composition: L-Ala (4), L-Arg (2), L-Asn (1), L-Gln (2), L-Gly (3), L-Ile (1), L-Leu (2), L-Lys (6), L-Phe (1), L-Pro (1), L-Val (2), *meso*-Lan (2), (2*S*,3*S*,6*R*)-3-MeLan (1), Dhb (2); N^{α}-2-oxobutyryl.

HPLC: Gradient: 12% B to 40% B in 15 min. Eluent A: 0.1% Tfa in water. Eluent B: 0.1% Tfa; 80% acetonitrile; 20% water.

Conditions: Nucleosil $5C_{18}$, 4.6 × 250 mm; flowrate 1 mL min^{-1}; UV detection 214 nm; retention time: 23 min.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 323 and Sa 292/4-2) and the Fonds der Chemischen Industrie. We thank *G. J. Nicholson* for expert technical assistance. A doctorate stipend (*C. S.*) was given by Dechema, and *K.-D. E.* is the recipient of a Heisenberg grant from the Deutsche Forschungsgemeinschaft.

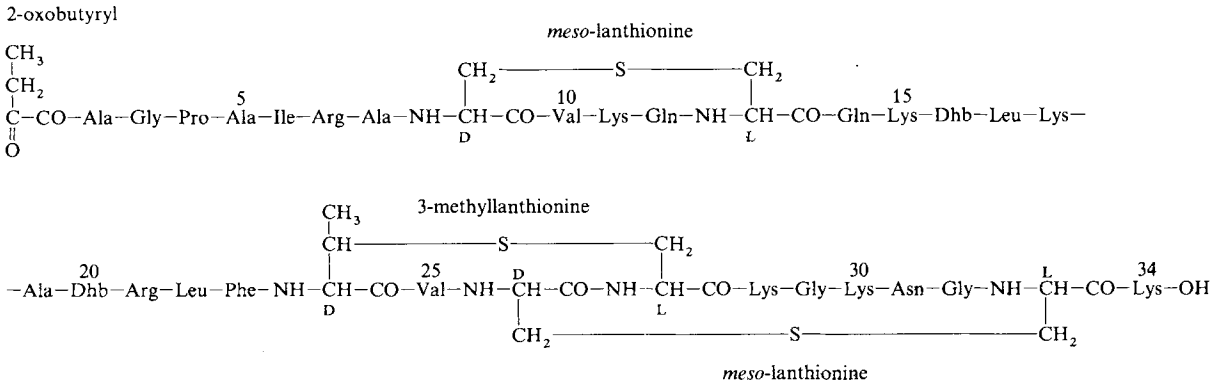

Fig. 1. Structure of the tricyclic lantibiotic Pep5. All amino acids have L-configuration with the exception of the *N*-terminal half of *meso*-lanthionine and (2*S*,3*S*,6*R*)-3-methyllanthionine. Dhb = dehydrobutyrine = 2-aminobut-2-enoic acid.

The polypeptide antibiotic Pep5 (Fig. 1) was isolated from culture supernatants of *Staphylococcus epidermidis* 5.[15] The acidic hydrolyzate of Pep5 contained twenty-five protein amino acids, two lanthionines and one 3-methyllanthionine (cf. Table 1). The configurational analysis by gas chromatography of trifluoroacetyl-amino acid *n*-propylesters on chiral stationary phases[17] revealed *meso*-lanthionine (Lan) and (2*S*,3*S*,6*R*)-3-methyllanthionine (MeLan); unsaturated amino acids were detected after chemical derivatization. The native antibiotic was *N*-terminally blocked, and therefore chemical and enzymic degradation failed. Having a content of eight cationic amino acids and an isoelectric point pI > 10.5, Pep5 is very hydrophilic and strongly basic and its chromatography therefore causes many problems. Moreover, a high number of enzymic cleavage sites and, particularly, the presence of two dehydrobutyrines (Dhb) caused further complications when elucidating the structure.

The key for sequencing the complex lantibiotic was the enzymic cleavage with chymotrypsin and endoproteinase Arg-C (Fig. 2). Other proteases, for example trypsin, gave a complex mixture of many fragments. The most important results were obtained by Edman degradation (Fig. 3),[18] even though the information was limited by the particular properties of the unusual components. Lanthionine and 3-

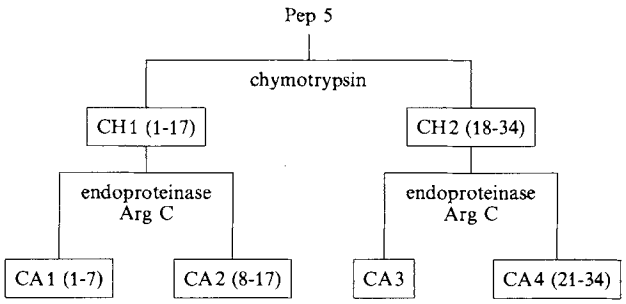

Fig. 2. Survey of enzymic cleavage used in sequencing the heterodet tricyclic 34-peptide antibiotic Pep5.

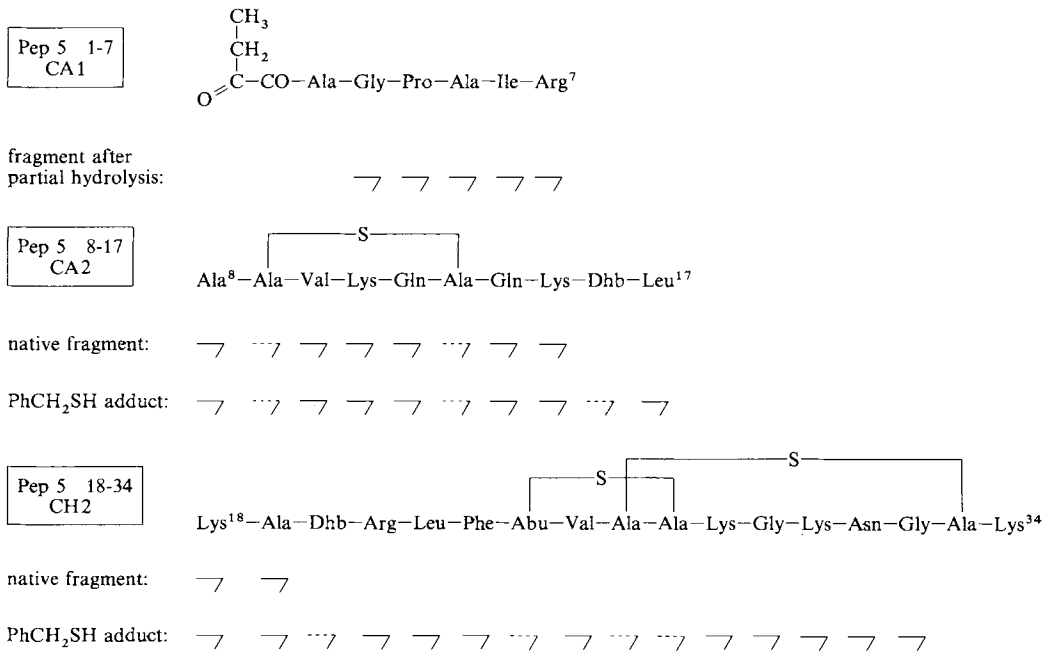

Fig. 3. Sequence information obtained by Edman degradation [18] of isolated fragments of Pep5 (cf. Fig. 2) and benzylthioalcohol adduct [19] (---), no PTH derivative was detected). Abu = α-aminobutyric acid.

methyllanthionine were not detectable during automated pulsed liquid-phase sequencing, because of the sulfide bridges and the peculiar chromatographic properties of their bis-PTH-derivatives. Fortunately, the Edman degradation proceeded further after the gap due to the Lan or MeLan residue. By contrast, the α,β-unsaturated amino acids blocked the Edman degradation by deamination with formation of an *N*-terminal 2-oxobutyryl residue, as found for position 14 in epidermin[7] and gallidermin.[9] The main products of chymotryptic cleavage of Pep5 were the two fragments, CH1 and CH2. The *N*-terminal part of Pep5, CH1, was further cleaved by endoproteinase Arg-C to give the fragments CA1 and CA2. Fragment CA1 was found to be *N*-terminally blocked as the native polypeptide, and the Edman degradation of CA2 stopped after eight residues. After adding benzylthioalcohol to the double bond,[19] the sequence 8–17 was obtained whereby positions 9 and 13 belonged to a Lan-residue and position 16 to an unsaturated amino acid.

In the same way the degradation of the C-terminal part of Pep5, CH2, stopped already after two amino acids, and again derivatization with benzylthioalcohol revealed the prolonged amino acid sequence 18–32. Hence, an additional unsaturated amino acid must have been located at position 20. The backbone positions for one Lan and one MeLan-residue were shown to be positions 24, 26, 27 and 33. After adding benzylthioalcohol, the acidic total hydrolyzates of Pep5 and its fragments were analyzed by GC-MS and *S*-benzyl-3-methylcysteine was detected as the addition product of Dhb. Lan and MeLan were detected again by GC-MS, but no further unusual residue was observed. The C-terminal residues of the fragments were obtained after cleavage with carboxypeptidase *A*/*B*.

26 to 33 for Lan. The fragment Leu^{22}-Phe^{23}-Abu^{24} was detected in the positive FAB mass spectrum of CA4 and, furthermore, different characteristic fragments resulted from the neighboring sulfur atoms containing sequence Ala^{26}(S)-Ala^{27}(S). The bridging positions were established in accordance to Pro-Pep5 with Thr/Cys as the precursor for MeLan and Ser/Cys for Lan (Fig. 4). The partial acid hydrolysis of Pep5 showed the turn segment Gly^3-Pro^4-Ala^5 to be preferably cleavable, and sequencing the isolated hydrolytic fragments established the amino acid sequence 3–15. From the amino acid composition, one Ala residue appeared to be missing and so must have been located at position 2.

Using ^{13}C NMR, Pep5 was found to contain a 2-oxobutyryl-residue probably located at the *N*-terminus. Therefore the tentative sequence of fragment CA1 consisting of 2-oxobutyryl-Ala^2-Gly-Pro-Ala-Ile-Arg^7 (Fig. 1), was synthesized and compared with the enzymatic fragment CA1 by HPLC and FAB-MS. This comparison showed the two fragments to be identical.

To sum up, Pep5 was shown to contain a 34-residue backbone (Fig. 1) and this was confirmed by FAB-MS and ^{13}C NMR. The 2-oxobutyryl residue at the *N*-terminus originating from threonine of the prelantibiotic is counted as position one. With the sequence of Pep5 obtained, the elucidation of the corresponding linear prepeptide sequence could be revealed by genetic methods.[1] This prepeptide sequence confirmed the chemically derived amino acid sequence and especially the positions of the unusual amino acids. The sequence of Pep5 shows no homology to any of the eight lantibiotics known so far. Thus, the versatility of the enzymes catalyzing the transformation of prelantibiotics to the various lantibiotics is remarkable, and one may expect a great potential for achieving useful biotransformations of

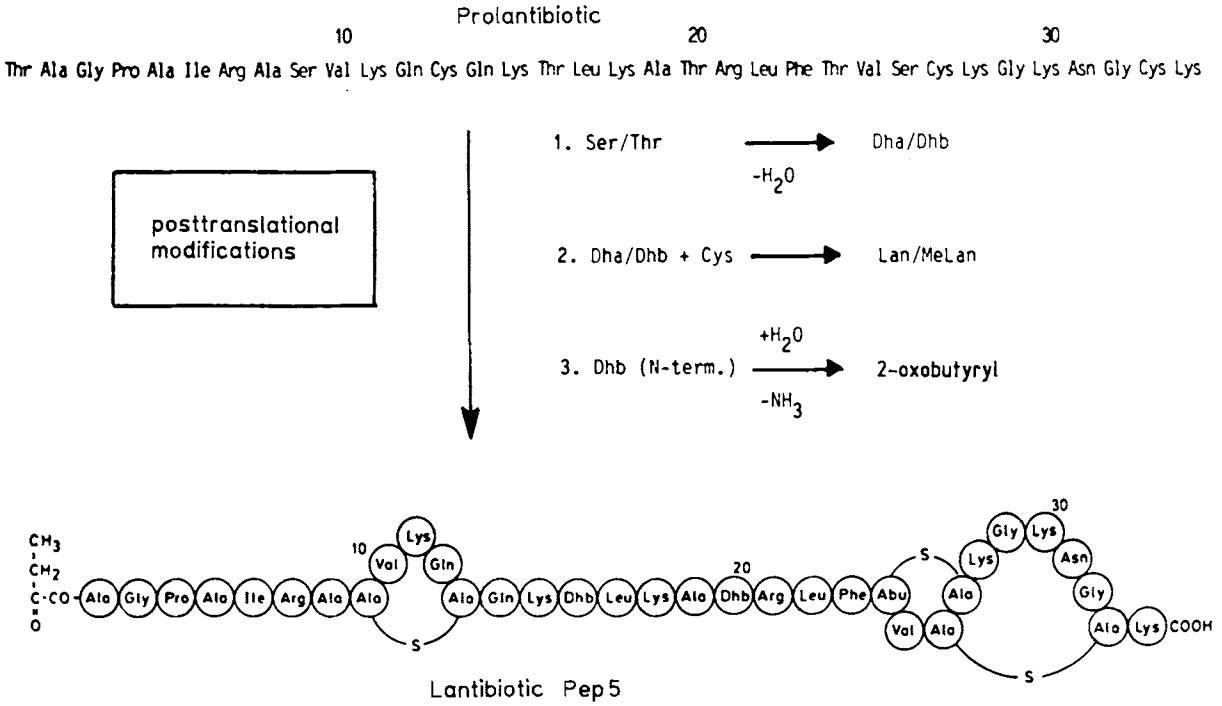

Fig. 4. Biosynthesis of lantibiotic Pep5. The ribosomally synthesized propeptide of Pep5 is posttranslationally modified by water elimination from L-serine and L-threonine residues and stereospecific addition of thiol groups of L-cysteines to the resulting possibly intermediate double bonds of dehydroalanine (Dha) and dehydrobutyrine (Dhb), thus forming *meso*-lanthionine and (2*S*,3*S*,6*R*)-3-methyllanthionine. Thereby the α-carbon atoms of the originally hydroxylated amino acids become D-configurated. The *N*-terminal dehydrobutyrine is unstable and after deamination a 2-oxobutyryl residue is formed.

Assignment of the thioether bridges in the C-terminal fragment CA4 was achieved by FAB-MS (*m*/*z* 1349 [M + $H^{\oplus}$]) and involved positions 24 to 27 for MeLan and suitably designed precursor peptides. However, none of the enzymes acting in lantibiotic biosynthesis has been isolated so far.

Synthesis of a Rigid Electron-Donor/Acceptor Compound–Evidence for Intramolecular Charge Separation**

By *Hans Heitele,** *Peter Finckh,* and *Maria Elisabeth Michel-Beyerle*

Particularly suitable for investigating the factors which determine the rate of electron transfer reactions[1–12] are compounds in which an electron donor and an electron acceptor are rigidly bound together.[3–6] The mutual diffusion of the reaction partners and possible changes of conformation during the reaction are thereby excluded. Our investigations on electron transfer processes[10–12] have now led to the compound **5**, in which a (electronically excited) naphthylene residue acts as electron donor and a dicyanoethylidene residue as electron acceptor. Compound **8** served as reference standard for fluorescence measurements.

Essentially all the steps of the synthesis of **5** and **8** can be taken from Ref. [3]. (Scheme 1). Upon fusion, acenaphthalene reacts with polychlorocyclopentadienes at 110 °C in a Diels-Alder reaction to give the *endo* products **1** and **6** in 70–75% yield. By reduction with a large excess of sodium in boiling ethanol/THF and rearomatization by heating with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) in benzene all the chlorine atoms can be replaced by hydrogen atoms (**2**, **7**; 63 and 32% yield respectively). The double bond is hydrogenated at normal pressure in ethyl acetate on 10% Pd/C (**3** and **8**). The ketal **3** is then cleaved in a mixture of THF and 40% H_2SO_4 (1:1) to give the ketone **4** (yield 78%), which upon Knoevenagel condensation with malonodinitrile in a Dean and Stark condenser (for removal of H_2O) affords the desired product **5** (yield 79%). All compounds form colorless crystals.

Scheme 1. Synthesis of the donor/acceptor compound **5** and the reference compound **8**.

The structures of the products are confirmed by ^{1}H NMR and mass spectra (Table 1). The large upfield shift ($\delta = 0.6$–0.9) of two of the four protons of the ethylene bridge in **3**, **4**, **5** and **8** in the *endo* isomers can be explained, in particular, by a ring current effect on the H atoms lying directly above the naphthalene system. The larger extinction coefficient in **5** at ca. 290 nm compared to that in **8** indicates a direct charge transfer absorption[3] in **5** below 300 nm.

A comparison of the fluorescence spectra[13] (not corrected) of the compounds **5** and **8** in methanol and *n*-hexane affords the first evidence for their electron transfer properties (Fig. 1). The shapes of the spectra of **5** and **8** in methanol are almost identical, the relative quantum yield ϕ in the case of **5** is, however, only 1% of the yield for **8**. The strong quenching is probably attributable to an intramolecular electron transfer from the excited naphthylene residue to the dicyanoethylidene residue, which competes with the fluorescence of the naphthylene residue. Intermolecular quenching processes can be ruled out because of the low concentration of the sample. From the ratio of the quantum yields $\phi_5/\phi_8 \leq 0.01$ and the fluorescence lifetime $\tau_8 \approx 40$ ns, a lower limit of ca. 2.5×10^9 s^{-1} can be given for the electron transfer rate in **5**.[14] The free enthalpy of this reaction in

[a] The ^{1}H NMR spectra were recorded at 60 MHz in $CDCl_3$ and the mass spectra at 70 eV.

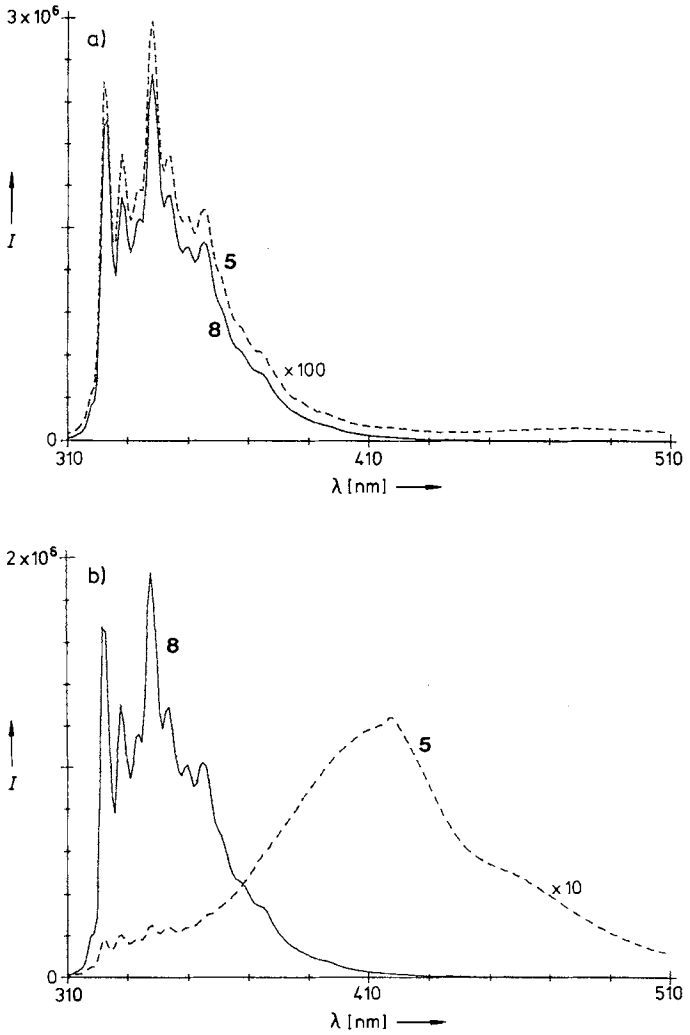

Fig. 1. Fluorescence spectra of the compounds **5** and **8** in methanol (a) and *n*-hexane (b). Spectra of **5**; 100 × and 10 ×, respectively.

methanol is estimated to be ca. −0.9 eV.[15] The emission spectrum of **5** in hexane shows, besides a small donor fluorescence with similar quantum yields as in methanol, a broad fluorescence band with a maximum at ca. 415 nm. The fluorescence excitation spectra in *n*-hexane (not shown) do not change upon variation of the wavelength of the observed fluorescence light between 330 and 470 nm and agree with the excitation spectrum of **8**, i.e. the initial state of the red-shifted emission is populated via the excitation of the napthylene residue. The strong quenching of the donor fluorescence shows that the intramolecular electron transfer in **5** is also thermodynamically possible in apolar solvents. The emission at 415 nm is presumably due to a recombination fluorescence (transition from the charge transfer state into the ground state of the molecule).[3] In polar solvents this emission is shifted into the infrared and its intensity decreases dramatically.[3] This explains the absence of a red shifted fluorescence band of **5** in methanol. A confirmation of this preliminary interpretation, however, requires further time resolved measurements.

The advantages of compound **5** are its simple synthesis, its completely rigid structure, the fact that electron transfer is possible in arbitrary solvents, and the long fluorescence lifetime of the unquenched donor, which makes changes in the rate—by decreasing the temperature—of three orders of magnitude measureable.

[13] Sample concentration 10^{-5} M, excitation wavelength 295 nm. The spectra are independent of the excitation wavelength between 290 and 320 nm. All samples were prepared shortly before the measurement and carefully freed of oxygen.
[14] Electron transfer rate $k = 1/\tau_8$ ($\phi_8/\phi_5 - 1$). Fluorescing impurities (e.g. residues of **4**) of ≤1% in **5** cannot, as yet, be excluded. The actual transfer rate could therefore be significantly greater than 2.5×10^9 s^{-1}.
[15] The free enthalpy of the electron transfer ΔG^0 is given by $\Delta G^0 = E_{ox} - E_{red} - e^2/\varepsilon d - \Delta E_{00}$, with the oxidation potential of the donor (acenaphthene) $E_{ox} \approx 1.35$ V [16], the reduction potential of the acceptor $E_{red} \approx -1.70$ V [3], the excitation energy of the acceptor $\Delta E_{00} = 3.85$ eV (from the absorption spectrum), and the coulomb energy of the ion pair with the ionic distance $d = 6$ Å and the dielectric constant of the solvent (methanol) $\varepsilon = 32$. This gives $\Delta G^0 \approx -0.9$ eV in methanol.

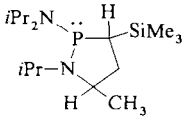
[Bis(diisopropylamino)phosphino]trimethylsilylcarbene: A Stable Nucleophilic Carbene**

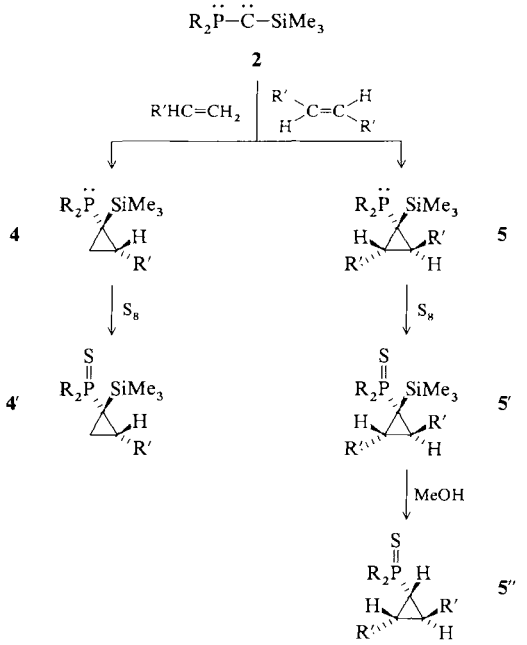
By *Alain Igau, Antoine Baceiredo, Georges Trinquier,* and *Guy Bertrand**



Recently, we were able to show that the thermolysis of [bis(diisopropylamino)phosphino](trimethylsilyl)diazomethane **1a**[1] leads, after loss of nitrogen, to a stable compound **2** ("1,1-Bis(diisopropylamino)-2-trimethylsilyl-1-phosphaacetylene")[2]. The NMR data and reactivity of **2** towards trimethylsilyl chloride, dimethyl sulfoxide and trimethylsilyl azide are characteristic for a phosphorus–carbon multiple bond (Scheme 1).

Scheme 1.

It is well-known[3] that α,α'-biscarbenes, generated from the corresponding bisdiazo derivatives **1b**, are stable compounds; however, from their reactivity they must be regarded as alkynes rather than as stable biscarbenes.



The only argument for the carbene character of **2** was based on the formation of the azaphospholidine **3** (carbene insertion into a carbon-hydrogen bond of an isopropyl substituent) upon thermolysis of **2** at 300 °C.[2] The experimental conditions used and the regioselectivity of the ring closure are consistent with this argument.

3

We now wish to report definitive evidence for the carbene character of **2**, based on cyclopropanation reactions, oxirane formation, and [1 + 1] addition to isocyanides.

Compound **2** does not react with alkyl-substituted alkenes or conjugated dienes,[4] but readily adds to electron-poor olefins such as methyl acrylate and dimethyl fumarate with formation of the cyclopropane derivatives **4** and **5**.[5] Reaction with sulfur affords the compounds **4'** and **5'** in 95 and 87% yield, respectively. In both cases only one diastereoisomer is obtained. The NMR spectroscopic data (see Table 1) of **4, 4', 5, 5'** and **5''** (obtained by methanolysis of **5'**), suggest a *syn* attack of the carbene **2**,[6] with retention of the stereochemistry about the double bond (Scheme 2). Compound **2** does not react with dimethyl maleate: the difference in reactivity between *cis* and *trans*-olefins towards carbenes has already been noted by *Moss* et al. with the methoxy(phenyl)carbene.[7] Note that products **4** and **5** are also obtained when the diazo derivative **1a** is irradiated, at 300 nm, in the presence of a stoichiometric amount of the corresponding alkene.

Scheme 2.

Electrophilic carbenes are known to react with carbonyl groups through the oxygen lone pair to give carbonyl ylides ($R_2C=\overset{\oplus}{O}-\overset{\ominus}{C}X_2$).[8] These 1,3 dipolar species are usually characterized by [3 + 2] cycloaddition or can even be isolated;[9] a small amount of the corresponding oxiranes is sometimes obtained.[8a, 10] Compound **2** does not react with dimethyl ketone but readily adds to benzaldehyde and cinnamaldehyde, affording oxiranes **6** and **7**. After treatment with elemental sulfur, **6'** and **7'** were isolated in 80 and 82% yield, respectively, as only one diastereoisomer. These results strongly suggest a concerted mechanism (route a): a zwitterionic intermediate such as **8** would have probably induced an oxygen attack at the phosphorus atom with subsequent formation of a phosphorylalkene (route b). Indeed, when a very electron-poor carbonyl group, such as ethyl cyanoformate, is used, a mixture of *Z*- and *E*-phosphorylalkenes **9** (Table 1) is obtained, and no trace of the corresponding oxiranes is detected (Scheme 3).[11]

Scheme 3.

Lastly, carbene **2** reacts with *tert*-butyl isocyanide to give the corresponding ketene imine **10**, which was isolated, after sulfuration, as **10′** in 90% yield. The reaction of **2** to give **10** can be considered as a carbene–carbene coupling reaction.

These findings, as a whole, clearly establish that **2** is a nucleophilic carbene. Due to the phosphorus lone pair conjugation, the p_π LUMO is expected to lie significantly high in energy, preventing any electrophilic character. According to simple extended Hückel calculations, **2** should be located between dimethoxycarbene and dimethylamino(methoxy)-carbene on the "Moss carbene selectivity scale":[12] in the model $H_2P\ddot{C}H$ the p_π LUMO is calculated at −9.2 eV while it lies at −9.6 and −8.9 eV in $(MeO)_2\ddot{C}$ and $MeO\ddot{C}NMe_2$, respectively. On the other hand, the $n_\sigma > p_\pi$ separation is calculated at 2.7 eV for $H_2P\ddot{C}H$, 2.5 eV for $(MeO)_2\ddot{C}$, and 3.1 eV for $MeO\ddot{C}NMe_2$.

The stereospecificity of the cyclopropane formation as well as the coupling reaction with *tert*-butyl isocyanide suggest that **2** has a singlet ground state, although ab initio calculations[13] revealed a singlet-triplet energy separation of only 3 kcal mol^{-1} in favor of the singlet state.

catena-Poly[bis-μ-(*o*-oxyphenyleneoxy)silicon]: Crystal Structure of the Orthosilicate of Catechol **

By *Wolfgang Hönle, Urszula Dettlaff-Weglikowska, Leonard Walz*, and *Hans Georg von Schnering**

The surprising conclusion drawn from the studies of *Meyer* and *Nagorsen*[1] on the structure of the title compound **1**, according to which a square-planar SiO_4 coordination is present, has led to recurrent discussion. With good reason, *Dunitz*[2] has pointed out that the argument used by *Meyer* and *Nagorsen* is not free of flaws and he suspects that the crystals investigated were not those of compound **1** but of the product of hydrolysis, namely catechol **2**. Neither the subsequent reply by *Nagorsen* and *Meyer*[3] nor theoretical studies[4] have as yet solved this problem. The true nature of this compound can not be elucidated from the structures of similar compounds, since the uncertainity relating to compound **1** always remains.

$[Si(o\text{-}O-C_6H_4-O)_2]_n$ **1** $o\text{-}HO-C_6H_4-OH$ **2**

The orthosilicate **1** is formed from $SiCl_4$ and catechol in solvents[5, 6] or from catechol and Si/Cu under H_2 in an autoclave.[7] Depending on the work-up, a transparent, amber colored resin,[5] or colorless glass[7] or colorless powder[6] is obtained. Apparently only *Meyer* and *Nargorsen* have succeeded in obtaining single crystals of **1**, but precisely these crystals, however, could have been catechol. Thus, the problem to be solved is clearly well-defined: 1) crystals of **1** must be prepared, and the structure must be determined; 2) it must be established whether these crystals are identical or not with those prepared by *Meyer* and *Nargorsen*.

The starting material for growing the crystals was prepared as previously described.[6, 8] The product thus obtained by us is a colorless X-ray amorphous powder. Single crystals of **1** are formed without complications and always reproducibly by sublimation in sealed, carefully baked-out ampules (length 15 cm, outer diameter 1.3 cm) under high vacuum ($p < 10^{-4}$ Pa) over the temperature range from 540 K to 523 K within four weeks. The sublimation can also be carried out at lower temperatures (540 K to 493 K). At $T < 423$ K, however, glassy, X-ray amorphous material separates out. The crystals are colorless, transparent, in part strongly intergrown robust rods, which upon subjection to the slightest mechanical stress separate into fibers like asbestos and become opaque. The structure determination was carried out on a 3-mm long fragment using only a selected glass-clear region for the intensity measurement.[9] Under such unfavorable conditions the structure determination (see below) is obviously not as accurate as usual.

According to differential thermal analysis in sealed quartz ampoules the crude product and selected crystals behave differently during the *first stage of heating*: the amorphous crude product shows a broad *exothermic* effect at 450 K (≈180 °C) and melts at 538 K (not sharply). The crystals melt without this effect at 543 K (sharply). During the *second* (and subsequent) *heating*, both samples exhibit the exothermic transformation before reaching the melting point. X-ray photographs at different temperatures show that the molten sample always forms X-ray amorphous phases during cooling, which then crystallize on heating to 450 K (exothermic effect). The crystalline phase is always identical with that obtained on sublimation. There are no indications of the formation of a second (e.g. monomeric) modification. The thermogravimetric analysis in a high vacuum ($p < 10^{-4}$ Pa) reveals the onset of sublimation already at 295 K and strong increase of this process at 430 K. As already described[6] the mass spectrum shows only the molecular peak (m/z 244) and the peaks of the fragments.

The crystal structure (Fig. 1) consists of one-dimensional infinite polymers $^1_\infty[Si(O-C_6H_4-O-)_{4/2}]$ with *tetrahedral*

[**] Our thanks are due to Herrn Ing. grad *C. Mensing* for carrying out the mass spectrometric measurements, Frau *S. Lacher* for performing the sublimation experiments, and Herrn Ing. grad *J. Curda* (all Max-Planck-Institut für Festkörperforschung, Stuttgart) for kindly recording the temperature-dependent powder diffraction measurements.

SiO_4 coordination. The bidentate *o*-phenylenedioxy groups are bound as bridge ligands and in all cases to two Si atoms. 1,3,6,8-Tetraoxa-2,7-disilacyclodeca-4,9-dienes (*trans,trans*-conformation) are coupled in a 2,7-spiro fashion along the polymer strands. The dihedral angle at the spiro atom is 90.2°. The strands are arranged in a hexagonal rodlike packing (a_{hex} = 938 pm, $\gamma = 118.15° \approx 120°$) and are held together only by van der Waals forces, which is consistent with the asbestos-like mechanical behavior of the crystals. The bond lengths $\bar{d}$(Si–O) = 160.5 pm are at the lower limits of the values previously determined in analogous compounds.[10] The bond angles O–Si–O vary over a broad range between 104.7 and 116.0°, whereby the smaller angles are endocyclic. The Si–O–C bond angles are relatively constant (131.4–135.6°), with the mean value 134° corresponding well to typical values observed for silicates.[10] An interesting feature is the position of the Si atoms relative to the ring planes of the ligands, which are characterized by the dihedral angle δ between the planes of the phenylene rings and the planes E_i(Si–O_i–C_j): $\delta(E_1) = 68.5°$, $\delta(E_2) = 35.5°$, $\delta(E_3) = 39.4°$, $\delta(E_4) = 87.2°$. Thus, the donor functions of the O atoms do not lie in the ring plane ($\delta = 0°$), as is usual in chelates. The inclination of the planes E_2 and E_3 to the ring plane is comparable with that in, e.g., "tris(catecholamide)iron" (an iron complex with three *N,N'*-dimethyl-2,3-dihydroxyterephthalamide units that, are bound via the methyl groups to two benzene rings),[12] while the planes E_1 and E_4 are almost oriented perpendicular to the ring plane.

Concerning the identity of the previously investigated crystals[1, 3] some questions still remain open, which actually can be answered only by the aforementioned authors. In our experiments, small amounts of the hydrolysis product catechol **2** were formed initially (m.p. 381 K), and since crystals of **1** rapidly become dull upon hydrolysis in air, there would be the tendency in this case to seek out accumulated crystals of **2** as the more interesting. Nevertheless, the lattice constants quoted by *Meyer* and *Nagorsen* deviate beyond the error limits of the correspondingly transformed values for catechol,[11] so that the question now is whether a further modification of **1** exists, e.g. with monomeric units. The cell volume would be suitable (165.53 $cm^3\,mol^{-1}$ according to Ref. [1], cf. 160.79 $cm^3\,mol^{-1}$ for compound **1**). However, with the observed values d(Si–O) = 162 pm, d(O–C) = 140 pm, one obtains an angle at the Si atom of 106° and for the angle at the O atom a value of 102°. The monomer would thus show considerable strain at the oxygen atom, which is removed by formation of the polymer. Such strain does not occur if the SiO_2 fragment is part of a six-membered ring, as in bis(1,8-naphthylenedioxy)silane,[13] or if aliphatic C atoms participate in the SiO_2–C_2 five-membered ring.[14] A further strong argument arises from the structure of the product of the first reaction step $(O_2C_6H_4)SiCl_2$, which crystallizes as dimer,[15] and can be regarded as a section of the polymeric structure of **1**.

Chain Complexes with Eleven Metal Atoms**

By *Simon J. Davies, Judith A. K. Howard, Rupert J. Musgrove*, and *F. Gordon A. Stone**

The preparation of polynuclear metal complexes by rational procedures, rather than by serendipitous methods, represents a major challenge. For species with bonds between tungsten and platinum we have employed compounds of the Type **1** containing three metal atoms as precursors.[1] Chain-type complexes containing up to seven metal atoms may be obtained readily, and in a sequential manner, using the reagents $[Pt(cod)_2]$ or $[W(\equiv CR)(CO)_2Cp]$ as appropriate (Scheme 1). By using $[Ni(cod)_2]$ or $[Mo(\equiv CR)(CO)_2Cp]$[1, 2] the method has been successfully extended to incorporate Ni or Mo atoms in the chains. The various polynuclear metal compounds generally exist in solution as mixtures of diastereoisomers.[3] Attempts to extend the length of the chains via procedures which involve the intermediacy of heptanuclear metal clusters such as **3** with terminal C=M groups (M = Mo or W) have proved unsuccessful. This is because the stereochemistry of the previously available intermediates favored the formation of metallacycles ('star-clus-

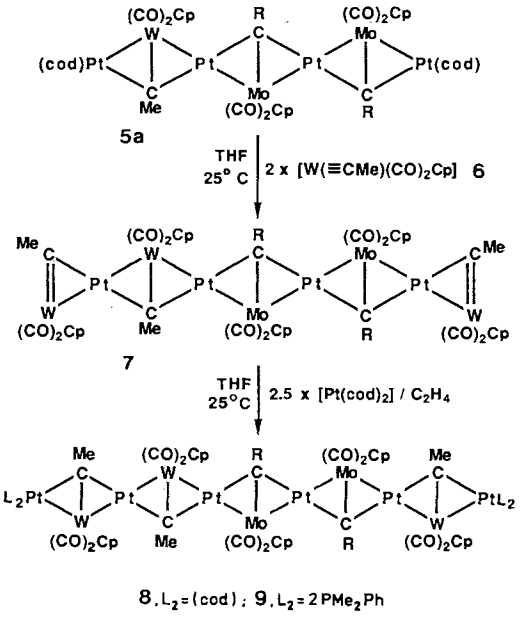
[**] This work was supported by the U.S. Air Force of Scientific Research (Grant 86-0125).



Scheme 1. Stepwise synthesis of polynuclear tungsten-platinum complexes. Numbers in circles refer to metal atoms in chains.
W≡CR = [W(≡CR)(CO)$_2$Cp]; R = alkyl; Cp = η^5-C_5H_5
Pt(cod) = [Pt(cod)$_2$]/C_2H_4; cod = 1,5-cyclooctadiene.

ters', Fig. 1a).[4] This problem has now been overcome by identifying heptanuclear metal compounds of type **5** having terminal Pt(cod) groups, which do not have chain conformations favoring metallacycle formation.

$[Mo_2WPt_3(\mu\text{-CMe})(\mu_3\text{-}CC_6H_4Me\text{-}4)_2(CO)_6(cod)Cp_3]$ **4a**

Treatment of th hexanuclear cluster **4a**[1b] with 1.5 equivalents of [Pt(cod)$_2$] in THF (tetrahydrofuran) afforded brown crystals of the heptanuclear species **5a**. It formed as a single isomer,[5] which then served (Scheme 2) as a starting compound for the synthesis of the nona- and undecanuclear compounds **7** and **8**, respectively. Only one isomer of each compound is formed, as revealed by the observation of signals corresponding to only one species in their NMR spectra.[5] It was not possible to grow crystals of **8** for an X-ray diffraction study. To overcome this difficulty treatment of **8** with PMe_2Ph in excess replaced the cod groups to yield quantitatively **9**, a product which did give suitable crystals.

Scheme 2. Stepwise synthesis of polynuclear metal clusters. R = C_6H_4Me-4.

The structure of **9** resulting from the X-ray analysis is shown in Figure 1b.[6] The molecule consists of five μ_3-$CMPt_2$ (M = Mo or W) groups linked together through four of the Pt atoms sharing vertices. Of the six Pt atoms present, all but Pt(1) and Pt(6) are approximately tetrahedrally coordinated by alkylidynemetal fragments. However, Pt(1) and Pt(6)

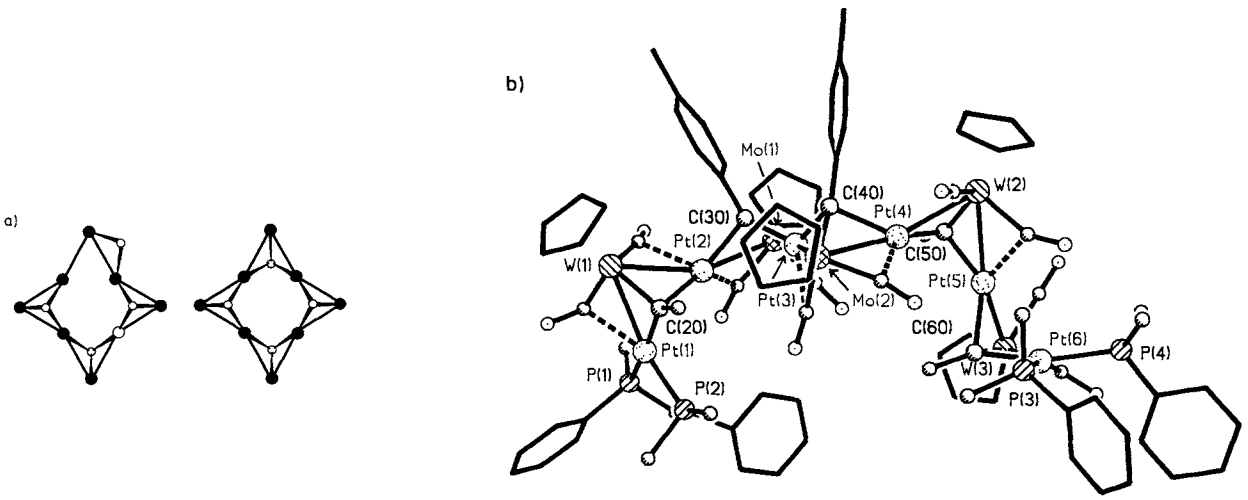


Fig. 1. a) The core structures of the 'asymmetric' and 'symmetric' isomers of the 'star-clusters' $[M_4M'_4(\mu\text{-CR})_4(CO)_8Cp_4]$ (M = Mo or W, M' = Ni or Pt) showing the metal atoms and the ligated carbon atoms of the alkylidyne groups. In solution, the asymmetric species, with one edge-bridging alkylidyne ligand, isomerize into the symmetrical isomers with four triply-bridging alkylidyne groups. These are sited alternately above and below the eight-metal atom rings. Experimental procedures may be adapted so as to produce metallacycles with different metal atom sequences, e.g. Mo · Pt · W · Ni · W · Pt · Mo · Ni or W · Pt · Mo · Ni · W · Pt · Mo · Ni. b) Structure of compound **9** in the crystal. Selected bond lengths [Å] (mean distances): Pt–W 2.751, Pt–Mo 2.745, Pt · · · Pt 3.040, μ_3-C–W 2.04, μ_3-C–Mo 1.98, P–Pt 2.30.

have essentially square planar coordination geometries, being ligated by one alkylidynetungsten fragment and two PMe_2Ph groups. All the CO ligands, except C(7)O(7) and C(9)O(9), semibridge W–Pt bonds.

Experimental

5a: A cold (0 °C) ethylene-saturated solution of $[Pt(cod)_2]$ (0.05 g, 0.12 mmol) in THF (20 mL) was treated with a solution of **4a** (0.15 g, 0.09 mmol) in the same solvent (25 mL). After 4 hours' stirring, the solvent was removed in vacuo and the residue was dissolved in CH_2Cl_2/light petroleum (15 mL, 4/1) and chromatographed on alumina. Elution with the same solvent mixture gave a brown eluate from which microcrystals of **5a** (0.11 g, 62%) were recovered after removal of solvent.

7: A solution of **5a** (0.15 g, 0.08 mmol) in THF (15 mL) was added to a solution of **6** (0.10 g, 0.30 mmol) in THF (10 mL). The mixture was stirred under C_2H_4 pressure (2 atm) for 3 h. The solvent was removed in vacuo, and the residue was dissolved in CH_2Cl_2 (10 mL) and chromatographed on alumina. Elution with the same solvent removed initially unreacted **6** followed by a brown fraction containing **7**. Removal of solvent in vacuo and crystallization from CH_2Cl_2/light petroleum gave **7** (0.17 g, 92%).

8, 9: A solution of **7** (0.15 g, 0.06 mmol) in THF (20 mL) was slowly added to a C_2H_4-saturated solution of $[Pt(cod)_2]$ (0.06 g, 0.17 mmol) in THF (20 mL, 0 °C). After warming to room temperature in vacuo and stirring for 3 h the residue was dissolved in CH_2Cl_2 (10 mL) and chromatographed. Elution with the same solvent removed a brown fraction, removal of solvent from which gave **8** (0.15 g, 80%), crystallized from CH_2Cl_2/light petroleum. Treatment of **8** (0.15 g, 0.05 mmol) in CH_2Cl_2 (15 mL) with PMe_2Ph (0.04 g, 0.30 mmol) for 30 min gave **9** (0.15 g, 90%).

[2] S. J. Davies, F. G. A. Stone, *J. Chem. Soc. Dalton Trans. 1989*, 785.

[3] The two C≡W bonds in the enantiomeric trimetal compounds **1** are at right angles to each other. Addition of a Pt(cod) fragment to one of these bonds occurs in such a manner as to produce the product **2** in two diastereomeric forms [1]. With increasing chain length, for each species the number of possible diastereoisomers increases. For the heptanuclear metal compounds there is a maximum of ten isomers, based on the different ways in which the metal triangles comprising the chain can be linked. However, not all the possible isomers (detected by NMR studies) are formed, presumably for steric reasons. Separation of the isomers by chromatography is generally possible, although re-equilibration occurs in solution [1, 2].

Chromatographic Separation of the Excess Enantiomer under Achiral Conditions**

By *Rudolf Matusch** and *Carsten Coors*

Enantioselective syntheses result in the formation of a non-racemic mixture of products in which one enantiomer predominates.[1] Whenever a pure enantiomer cannot be isolated in pure form by crystallization, some resolution method has to be employed. The search for an efficient method can be very time consuming, success being uncertain. But the advantage offered by the non-racemic mixture compared to the racemate still remains methodologically unexploited. We report here on the chromatographic separation of the excess enantiomer under achiral conditions.

Instead of trying to remove the undesired enantiomer, as in the resolution method we saw a general route in the separation of the excess enantiomer from the residual racemate.[2, 3] If the solvent chosen for a polar non-racemic mixture is so unpolar that self-asociation is possible in solution, homochiral and heterochiral associates can be formed.[4] These associates are diastereomeric and can thus be differentiated by achiral methods. Hence, in principle a chromatographic separation on an achiral stationary phase with an achiral mobile phase is possible.

In order to prevent decomposition of the associates on the stationary phase and/or to promote their formation, the phase must possess adequate donor properties and be spatially adaptable. We therefore chose, in contrast to other authors,[3] aminopropylsilica gel (LiChrosorb®-amine) as the stationary phase. The amino group is a good donor and can form hydrogen bonds. Furthermore, the propyl chain is long and flexible enough to enable the associates to bind (tentacle effect) without disadvantageously influencing the existing interactions.

As Figure 1a shows, the chromatography of 1,1′-bi-2-naphthol **1** with only 33% *ee* leads to a distinct separation into two signals with a difference in the retention times of 2.9 min. The synchronously recorded optical rotation increases sharply at first and after reaching a maximum decreases in accord with the UV curve. At the minimum of the UV curve, however, it drops steeply to zero. That is, the excess enantiomer is first eluted and then the non-rotating racemate and not vice versa. Accordingly, from a mechanistic point of view a temporary chiral imposition as a cause of the separation can be ruled out.

On loading a mixture with 86% *ee* (Fig. 1b) the difference in the retention times between excess enantiomer and racemate increases to 10.7 min. The separation factor α[5] is thus improved on increasing the enantiomeric excess.

The corresponding polarimeter curve is essentially of the same form as in Figure 1a, but the sharp drop on passage of the racemate is less clearly recognizable since the sensitivity limit of the flow polarimeter is reached. The detailed analysis of the eluate by analytical HPLC on a chiral stationary phase (ionic Pirkle phase[6]) shows that only the pure enantiomer is present down to the minimum of the UV curve, the racemate being first observed in the fraction following.

Since the formation of the diastereomeric associates is concentration dependent, the separation factor α is further enhanced upon increasing the loaded amount of material

[**] Based on a lecture at the Jahrestagung der Deutschen Pharmazeutischen Gesellschaft, September 9, 1988, in Erlangen.

($\alpha = 1.24$ for 2.5 μg; $\alpha = 1.28$ for 10 μg; $\alpha = 1.39$ for 35 μg and $\alpha = 1.46$ for 100 μg throughput of a mixture with 86% *ee*). Thus α depends both on the enantiomeric composition and the amount of material loaded.

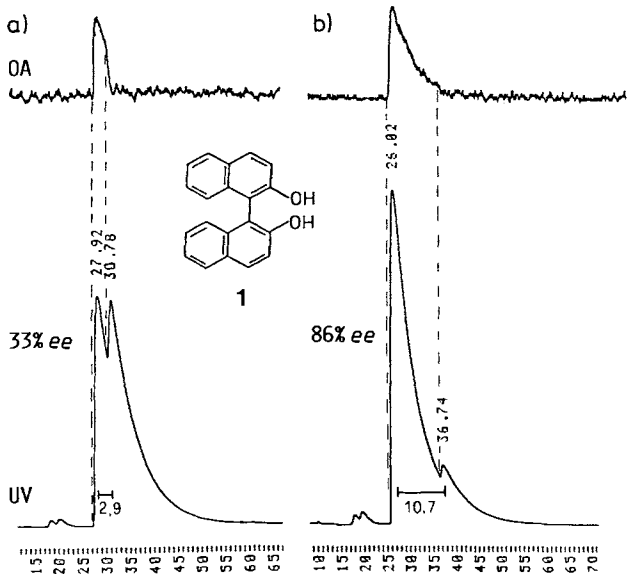

Fig. 1. Chromatography of 100 μg of 1,1'-bi-2-naphthol **1** with a) 33% *ee* and b) 86% *ee*. Bottom: UV detection, $\lambda = 228$ nm; top optical activity (OA, angle of rotation). Column: 250 × 4 mm ID, LiChrosorb®-amine, 5 μm; flowrate: 1 mL min^{-1}, hexane:2-propanol 6:4. Abscissa: t [min].

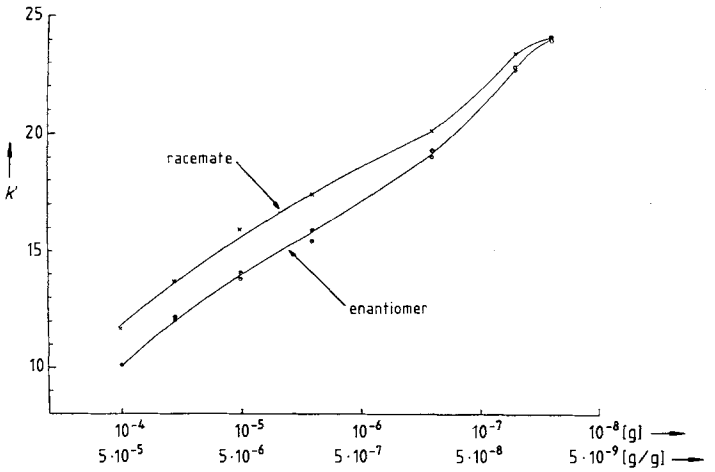
For further clarification, the retention times in the range of 100 μg to 0.025 μg were determined for the pure enantiomers and the racemate (Fig. 2). As expected the pure



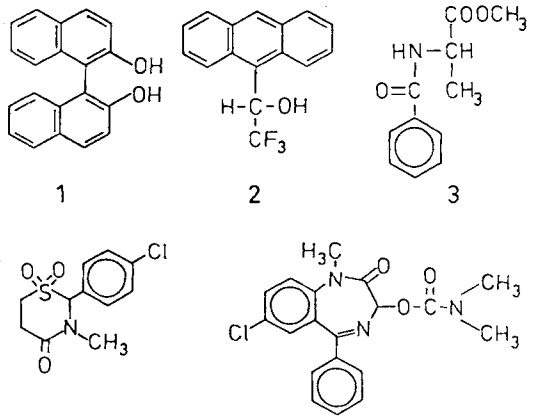


Fig. 2. Retention (given as capacity factor k' [5]) of (+/−)-, (+)-, and (−)-1,1'-bi-2-naphthol **1** versus amount of sample and amount of sample/amount of sorptive medium (semilog). Conditions as in Figure 1.

enantiomers behave similarly, whereas the racemate shows increased retention in each case. Only at loaded amounts which are four orders of magnitude less than in the case of "normal", i.e. non-complexing compounds, is the retention time noticeably constant.[7] The curve of the pure enantiomers also intercepts that of the racemate at this point. The explanation for this behavior is simple: below this concentration the medium gets diluted to such an extent that association is negligible and practically only monomers are still present. Their behavior on achiral phases is, however, logically the same.

In order to determine the scope of application of the method we arbitrarily chose, besides **1**, another four compounds: the chiral shift reagent 1-anthryl-2,2,2-trifluoroethanol **2**, *N*-benzoylalanine methyl ester **3**, and two drugs, the tranquilizer chloromezanone **4** and the benzodiazepine camazepam **5**.

Hexane/2-propanol mixtures were suitable for the separation of the excess enantiomer on Lichrosorb®-amine phases for all compounds except **2**, where hexane/dichloromethane was used. In all cases the excess enantiomer was eluted prior to the racemate. In no case did we observe splitting of the UV signal upon variation of the stationary phase (e.g. silica gel, Diol, RP18). Thus, the importance of the aminopropylsilica gel phase clearly manifests itself, and the postulated mechanism of separation is highly plausible.

In summary, it may be said that, in the separation of the excess enantiomer, a material property is effective whose practical application has hitherto been underestimated: the different interaction of homochiral and heterochiral associates with the stationary phase. Its exploitation, complementary to the progress made chemically by enantioselective synthesis, thus provides a chromatographic method for the isolation of the pure enantiomer, hitherto lacking, which ensures success even when the enantioselectivity is not quantitative.

Double Stereodifferentiation in the Formation of Isotactic Polypropylene at Chiral $(C_5H_4CHMePh)_2ZrCl_2$/Methylalumoxane Catalysts**

By *Gerhard Erker,** *Rainer Nolte, Yi-Hung Tsay,* and *Carl Krüger*

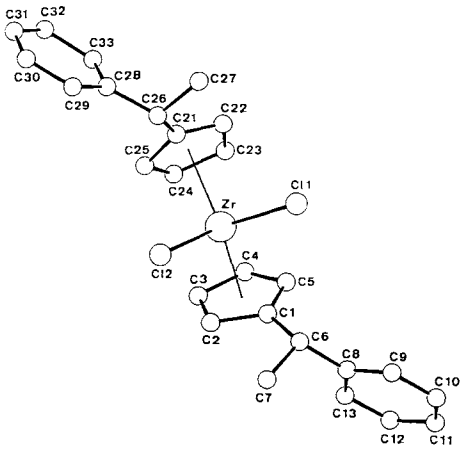
The formation of two types of isotactic polypropylene at soluble $(RC_5H_4)_2MX_2$/alkylalumoxane catalysts (M = Ti, Zr, Hf) is well known. Isotactic block polymers (type 2, Scheme 1) can be prepared using achiral transition metal components (e.g. Cp_2TiPh_2);[1] the diastereoselectivity of the reaction is here effected by chirality centers at the end of the growing chain (chain end control). Isotactic polypropylene of type **1** (Scheme 1) is obtained using catalysts prepared from the chiral, Cp-bridged ansa-titanocene and -zirconocene complexes developed by *Brintzinger* et al.[2] In this case the chiral transition-metal center is controlling the stereoselectivity (enantiomorphic site control). Any "errors" occurring during polymer formation are corrected immediately and not propagated as in the case of type 2 polymer formation.

Scheme 1. Isotactic polypropylene type 1 (enantiomorphic site control) and type 2 (chain end control).

In fact, it is to be expected that these two different kinds of diastereoselective control of the C–C coupling of propene units are not independent, but mutally strengthen or weaken each other using a chiral catalyst. We have now been able to demonstrate experimentally for the first time the influence of double stereodifferentiation[3] in the formation of isotactic polypropylene using a *rac*-$(C_5H_4CHMePh)_2ZrCl_2$/$(AlMeO)_n$ catalyst.

We have prepared the known compound bis[(1-phenylethyl)cyclopentadienyl]zirconium dichloride **1**[4] via a novel synthetic variation: reaction of 6-methyl-6-phenylfulvene with isobutyllithium in ether afforded (1-phenylethyl)-cyclopentadienyllithium (60%), which, on treatment with zirconium tetrachloride in a 2:1 molar ratio in THF, furnished **1** as a diastereomeric mixture (73%). Repeated fractional crystallization gave *rac*-**1** containing < 1% *meso* diastereomer.[5a]

Complex *rac*-**1** was characterized by an X-ray structure analysis (Fig. 1).[5b] A remarkable feature is the chiral, approximately C_2 symmetric metallocene conformation in the crystal. The chiral substituents at the cyclopentadienyl units are oriented synclinally. The observed arrangement of the cyclopentadienyl units (methyl groups at C6 and C26 inwards, phenyl groups outwards) may be the sterically most favorable orientation. Presumably this conformation (**A**) is favored over that of the $R^*C_5H_4$–M rotational isomer (**B**), even in solution.



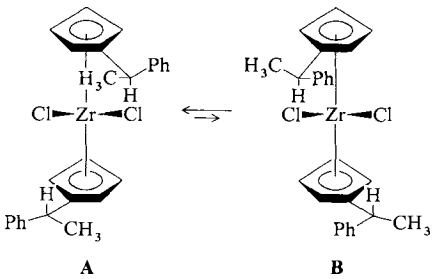


Fig. 1. Structure of *rac*-**1** in the crystal. Selected bond lengths [Å] and angles [°] Zr–Cl1 2.462 (2), Zr–Cl2 2.456 (2); Cl1-Zr-Cl2 96.6 (1), C1-C6-C7 113 (1), C1-C6-C8 111.8 (9), C7-C6-C8 111 (1).

We have used the *rac*-**1**/methylalumoxane system as a catalyst for the polymerization of propene. In a typical experiment with *rac*-**1**/$(AlMeO)_n$ (ratio Al/Zr = 3400) in toluene at − 79 °C we obtained isotactic polypropylene (catalyst activity: 143 g polymer/gZr · h). The configuration of the polymer ($\bar{M}_n$ = 10 000) was determined from the crude reaction product, without further work-up, by ^{13}C NMR spectroscopy.[1,6]

Under the conditions chosen for the ^{13}C NMR analysis (1,2,4-trichlorobenzene, 50 MHz, 92 °C) the signals of the methyl groups are satisfactorily resolved on the pentad level (Fig. 2, top). The polymer was quantitatively analyzed by applying the usual statistical treatment. The polymer obtained consists of ca. 35% of isotactic polypropylene of type 1 (enantiomorphic site control, $\alpha = 0.94$; average length of the sequences containing only m-diads $\langle m\rangle_{n,\alpha} = 16$) and ca. 65% of type 2 (chain end control, $\sigma = 0.85$, $\langle m\rangle_{n,\sigma} = 6.7$). The observed (calculated) relative intensities of the methyl ^{13}C NMR signals are: mmmm 0.60 (0.60), mmmr 0.16 (0.15), rmmr 0.02 (0.01), mmrr 0.06 (0.05), mmrm + rmrr 0.12 (0.13), mrmr 0.03 (0.02), rrrr 0.00 (0.00), rrrm 0.00 (0.00), mrrm 0.01 (0.01) (Fig. 2, top). The stereoselectivity of the propene C–C coupling at the *rac*-**1**/$(AlMeO)_n$

catalyst changes only slightly with increasing temperature (-55 °C: 32% type 1, $\alpha = 0.95$, 68% type 2, $\sigma = 0.79$; -33 °C: 24% type 1, $\alpha = 0.96$, 76% type 2, $\sigma = 0.74$).

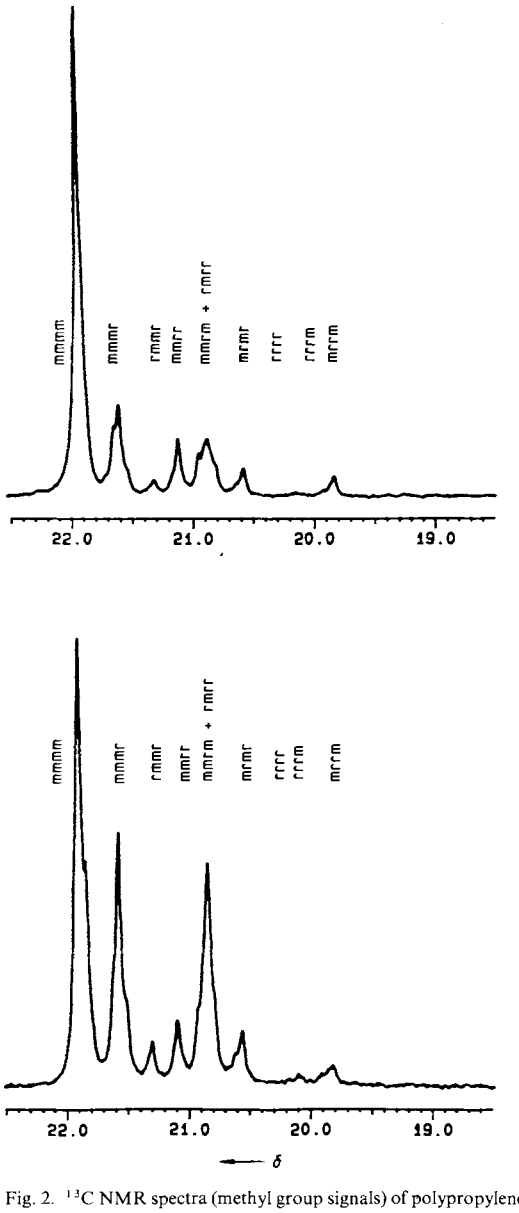

Fig. 2. ^{13}C NMR spectra (methyl group signals) of polypropylene, obtained at $(C_5H_4CHMePh)_2ZrCl_2$/methylalumoxane catalysts at -79 °C. Top: *rac*-**1**/*meso*-**1** > 99/1; bottom: 45/55.

According to the solubility behavior only a single type of polymer is obtained. Apparently a block polymer containing isotactic polypropylene of types 1 and 2 is formed at the *rac*-**1**/$(AlMeO)_n$ catalyst. Double stereodifferentiation (by the chiral metal center *and* the chiral chain end) leads thereby to an increase in $\langle m \rangle_{n,\alpha}$ (matched pair) and a decrease in $\langle m \rangle_{n,\sigma}$ (mismatched pair), assuming general isotactic stereocontrol by the chain end. According to this interpretation removal of the chirality information of the transition metal center under otherwise essentially unchanged steric conditions should result in the formation of a purely isotactic type-2 polymer. There is experimental evidence for this. The C–C coupling of propene at a soluble catalyst derived from methylalumoxane and a 55/45 mixture of *meso*-**1** and *rac*-**1** affords isotactic block polymers of type 2 at low temperatures (-50 °C; Al/Zr = 830; 132 g polypropylene/gZr · h, $\bar{M}_\eta = 28\,000$, $\sigma = 0.79$; -79 °C: Al/Zr = 860; 10 g polypropylene/gZr · h $\bar{M}_\eta = 35\,000$, $\sigma = 0.81$, $\langle m \rangle_{n,\sigma} \approx 5.3$; observed (calculated) relative intensities of the methyl-^{13}C NMR signals: mmmm 0.43 (0.43), mmmr 0.21 (0.20), rmmr 0.03 (0.02), mmrr 0.05 (0.05), mmrm + rmrr 0.22 (0.21), mrmr 0.04 (0.05), rrrr 0.00 (0.00), rrrm 0.01 (0.01), mrrm 0.02 (0.02); Fig. 2, bottom).[9]

In the development of asymmetric syntheses of low molecular weight organic compounds by olefin C–C coupling reactions at optically active homogeneous Ziegler catalysts,[10] stereochemically unproductive control by the chiral chain end must be excluded. In the case of conformationally flexible bent metallocene systems this can possibly be achieved by the use of bulky, chiral tertiary alkyl substituents attached to the cyclopentadienyl units, which, in contrast to the secondary alkyl substituents used in the case of **1**, favor a *trans* orientation in the lateral sectors of the bent metallocene unit.

Dimeric $[Cp_2Zr(CH_2O)]$, a Novel (η^2-Formaldehyde)metal Complex from Carbon Monoxide **

By *Gerhard Erker,* Ursula Hoffmann, Roland Zwettler, Peter Betz,* and *Carl Krüger*

In the temperature range of interest for metal-catalyzed reactions in the condensed phase the formation of formaldehyde from H_2 and CO is endothermic,[1] whereas the formation of η^2-formaldehyde ligands in the coordination sphere of a metal is usually exothermic. Nevertheless, only a few examples of $(\eta^2\text{-}CH_2O)ML_n$ complexes are so far known in which the formaldehyde unit was synthesized by means of a carbonylation reaction.[2] We present here the very productive synthesis of a reactive (η^2-formaldehyde)zirconocene complex and describe some fundamental reactions of the metallaoxirane moiety.

According to *Floriani* et al.[3] carbon monoxide is hydrozirconated at room temperature and ambient pressure to give the dinuclear complex **1**. The stable substitution product **2** can be prepared by reaction of **1** with 2 molar equivalents of phenyllithium.[4] Not unexpectedly, the reaction with methyllithium proceeds somewhat differently. Presumably, in this case the methyl-bridged compound **3** is formed as an intermediate, which readily decomposes into its mononuclear organometallic components under the reaction conditions. We have isolated dimethylzirconocene **4** (quantitative yield) and dimeric (η^2-formaldehyde)zirconocene **5** (67%) as stable reaction products.

1 2 3 4 5

According to the results of an X-ray structure analysis,[5] in the complex **5** two (η^2-formaldehyde)zirconocene units are coupled to each other via their oxygen atoms, using the available lateral coordination sites at the bent metallocene. The Zr–O bonds in the three-membered ring are somewhat shorter than those connecting the monomeric $(\eta^2\text{-}CH_2O)ZrCp_2$ units. The C–O bonds are long; the Zr–C distance in the three-membered ring is typical for a ZrC_{sp^3} single bond. The $(\overline{CH_2\text{-}O})Zr$ units in **5** have metallaoxirane character.[6a, 7a]

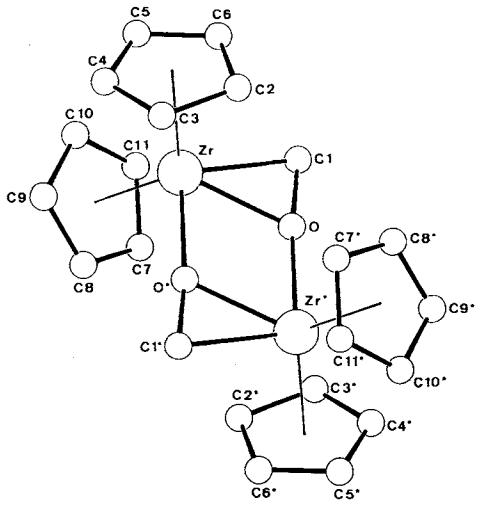

Fig. 1. Molecular structure of **5** in the crystal. Selected bond lengths [Å] and angles [°]: Zr-O 2.103 (2), Zr-C1 2.243 (3), C1-O 1.395 (4), Zr*-O 2.200 (2); O-C1-Zr 65.9 (2), C1-O-Zr 76.8 (2), C1-Zr-O 37.3 (1), Zr*-O-Zr 109.5 (1), Zr*-O-C1 173.5 (2), O*-Zr-O 70.5 (1).

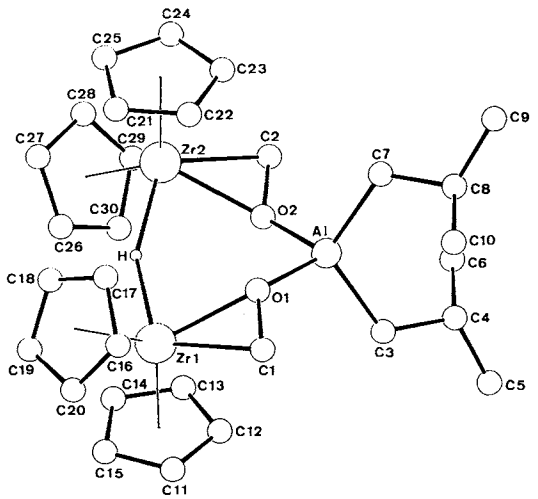
Thermolysis (170 °C, 3 h) of the dimer **5** affords the known cyclotrimeric compound $[(\overline{CH_2\text{-}O})ZrCp_2]_3$.[8a] Complex **5** adds to many carbonylmetal complexes with opening of the reactive Zr–C bond of a metallaoxirane unit. At room temperature, **5** reacts with $CpCo(CO)_2$ selectively to give the adduct **6**.[7b, 8b] It also reacts with alkyl- and hydrido-aluminum complexes; upon reaction with diisobutylaluminum hydride at room temperature it forms the metallacyclic adduct **7**[7c] (Fig. 2). An X-ray structure analysis revealed that



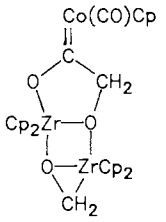


Fig. 2. Molecular structure of **7** in the crystal. Selected bond lengths [Å] and angles [°]: Zr1-O1, 2.153 (3), Zr1-C1 2.248 (5) C1-O1 1.430 (6), Zr2-O2 2.156 (3), Zr2-C2 2.230 (5), C2-O2 1.430 (6), Al-O1 1.815 (3), Al-O2 1.811 (3); Zr1-O1-Al 138.6 (2), Zr2-O2-Al 137.9 (2).

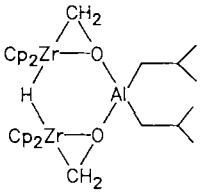

the (η^2-formaldehyde)zirconocene units in **7** also have pronounced metallaoxirane character.[9]

BOOK REVIEWS

Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for qualified book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Bundesrepublik Deutschland. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Preparative Acetylenic Chemistry (Series: Studies in Organic Chemistry, Vol. 34). 2nd Edition. By *L. Brandsma*. Elsevier, Amsterdam 1988. x, 322 pp., hard cover, HFl 220.00.—ISBN 0-444-42960-3

This book is a completely reviewed and updated version of the original 1971 publication, and has been enlarged by more than 100 pages. It is aimed at advanced students and preparative organic chemists.

As in other books by the same author (L. Brandsma, H. D. Verkruijsse: *Synthesis of Acetylenes, Allenes and Cumulenes*, Elsevier, Amsterdam 1981; L. Brandsma, H. D. Verkruijsse: *Preparative Polar Organometallic Chemistry*, Springer, Berlin 1987), all the preparative methods contained here have been carefully tested. The reader benefits from the author's many years of experience in acetylenic chemistry. The recommended reaction conditions take into account the reactivities of the starting compounds and intermediates. In practice a lack of knowledge of reactivities often leads to reactants being unnecessarily stirred under reflux for hours, despite the fact that the reaction is in fact completed within a few minutes. Much time and money can be saved when accurate information on reaction durations and reproducible laboratory recipes are available.

The topics covered in the book's twelve chapters are as follows. Chapter 1 gives practical advice of a general nature, and describes a number of extremely useful tricks from the author's wealth of experience. The rest of the chapters are: 2. Metallation of Acetylenes; 3. Functionalization of Metallated Acetylenes with Alkyl Halides, α-Haloethers, Epoxides and Alkyl Orthoformates; 4. Ethynylation and Alkynylation of Carbonyl Compounds; 5. Carboxylation, Alkylation and Related Reactions; 6. Silylation, Stannylation and Phosphorylation; 7. Sulfenylations and Related Reactions; 8. Halogenation and Cyanation; 9. Introduction of the Triple Bond by Elimination and Addition-elimination Reactions; 10. Couplings of Acetylenes Assisted by Copper and Palladium Compounds; 11. Base-promoted Interconversions of Acetylenes; 12. Miscellaneous Preparations of Acetylenic Derivatives. More than 500 acetylene derivatives, which can

be classified into 20 different groups on the basis of their functionality, are described in these chapters.

The concise factual style and the orderly arrangement of the material are pleasing features. Regrettably the pages do not have a headline identifying the chapter, and as a result cross-referencing often involves the reader in thumbing through the pages for a long time to find the required passage. The layout is attractive and the text contains hardly any printing errors. Although there are only 241 literature references this does not imply that the coverage is superficial; the smallness of the total is entirely a result of the author's rigorous criteria for choosing references.

To summarize, it can be said that this book, which is structured in the style of *Organic Syntheses*, gives an excellent and detailed overview of important synthetic building blocks containing C≡C bonds that are simple and obtainable in good yields. When the synthetic methods are read in conjunction with the "Introductions" which precede over half of them and the appended "Notes" on each one, the work is seen to be more than a mere "cook-book". It will certainly contribute to acetylenes assuming an even more important role in future in the planning of synthetic routes. The book will undoubtedly have a place in the standard reference collection of every chemistry library.

Organolithium Methods. (Series: Best Synthetic Methods.) By *B. J. Wakefield*. Academic Press, New York 1988. xvii, 189 pp., hard cover, $ 29.50.—ISBN 0-12-730940-3

The present reviewer has already remarked in this journal[*] that he regards the series title "Best Synthetic Methods" as a misleading description. Nevertheless, the volume on "Organolithium Methods" by *Wakefield* is very successful as an introduction to the topic with a strong emphasis on practical aspects. The author confines his treatment to organolithium compounds which are *not* stabilized by mesomeric effects (with the exceptions of allyl and benzyl derivatives of lithium). There are occasional passing references, perhaps unintentional, to the chemistry of compounds such as lithium enolates, but to cover these fully would have made the book too long.

The logical construction of the book together with its detailed contents list and the subject index allow one to quickly find the relevant chapter for each topic of interest (although the index is rather scanty). The introductory chapter is likely to be of particular value for newcomers to the field, such as students about to undertake their first work using organolithium compounds; it deals very briefly with constitution, reactivity and solvent effects, and, most importantly, gives much practical advice on matters such as the drying of solvents, use of inert atmosphere, handling of organolithium compounds, and quantitative analysis, illustrated in some cases by drawings of suitable apparatus.

The next chapter is devoted to the preparation of organolithium compounds, with a systematic and very instructive presentation of the principles, which are then translated into practical terms by giving laboratory recipes, most of which have been tested, and clear tables. The following chapters deal with the addition reactions of organolithium compounds to systems with multiple bonds, with the main emphasis, naturally, on carbonyl compounds as electrophiles. Next follow substitution reactions with the formation of C-C or C-heteroatom bonds, and related types of reactions. The following chapter describes some methods whereby organolithium compounds can be used to prepare organoboron, organosilicon and organophosphorus compounds, and—though only in outline—other organometallic species. Lastly, possibilities for using elimination reactions to form arynes, carbenes and ylides are briefly mentioned.

Every chapter includes detailed laboratory recipes and numerous examples in the form of tables. The relevant literature citations have been compiled with great thoroughness up to 1986; even a few references to work published in 1987 are included, making the coverage pleasingly up-to-date.

As each chapter includes a brief but succinct introduction summarizing the main features of current knowledge about mechanisms (or sometimes the lack of it), one can obtain from the book not only numerous practical hints and stimulating ideas, but also some basic science. Unfortunately, though, there is no reference to the principle of polar reversal of reactivity (umpolung), which has been and still is especially important for organolithium compounds.

The book is very attractively produced, and there are comparatively few printing errors (e.g., the formula scheme on page 37 has gone somewhat wrong). It is to be hoped that this book by *Wakefield* will achieve a wide circulation. It should at least be available in all libraries. However, although it would be especially useful to students, they will probably find it too expensive.

The Bioinorganic Chemistry of Nickel. Edited by *J. R. Lancaster, Jr.* VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xviii, 337 pp., hard cover, DM 175.00.—ISBN 3-527-26692-5/0-89573-338-2

Nickel was first discovered to play a physiological role in a biological system in 1965, and it was first found in a metalloenzyme a decade later. It is, in retrospect, surprising that the discovery of the importance of nickel in biology was made so late, but the fortunate result of this delay is that for nickel, unlike copper and iron, the tools of modern inorganic spectroscopy were used right from the beginning of the investigations of the biochemical properties of each newly discovered metal-containing biological system. The accounts of the elucidation of the properties of nickel-containing biological systems therefore read like a series of ongoing scientific detective stories. This is a well-written and well-organized volume that will be useful to a large number of readers. In addition, it is fortunate when a book such as this one describing a new field of research is written early enough that introductory material describing the methodology used, and the accounts of the background and current status of the field, all fit into one reasonably sized volume.

The volume consists of 14 chapters, each written by different experts in the field. The first four chapters provide the reader with an excellent introduction to the inorganic chemistry and spectroscopy of nickel. They are each written at an appropriate level that will enable the non-specialist to understand and to appreciate the significance of the spectroscopic results presented in the later chapters describing specific nickel-containing biological systems. These chapters are "The Coordination Chemistry of Nickel: An Introductory Survey" (*C. L. Coyle* and *E. I. Steifel*), "Nickel(III) Chemis-

[*] *Angew. Chem. Int. Ed. Engl.* 27 (1988) 1567

try and Properties of the Peptide Complexes of Ni(II) and Ni(III)" (*D. W. Margerum* and *S. L. Anliker*), "The EPR Spectra of Odd-Electron Nickel Ions in Biological Systems: Theory for d^7 and d^9 Ions" (*J. C. Salerno*), and "Electronic and Molecular Structure of Biological Nickel as Studied by X-ray Absorption Spectroscopy" (*M. K. Eidsness, R. J. Sullivan,* and *R. A. Scott*). The next two chapters provide an excellent overview of the role of nickel in biology: "Nickel in Biology: Nickel as an Essential Trace Element" (*D. Ankel-Fuchs* and *R. K. Thauer*) and "Biological Transport of Nickel" (*H. L. Drake*). The remaining eight chapters comprise more than half of the volume and describe in detail the results of the investigations of each of the types of nickel-containing metalloenzymes that have been found. They are "Urease—a Ni(II) Metalloenzyme" (*R. K. Andrews, R. L. Blakeley,* and *B. Zerner*), "Nickel in Hydrogenases from Sulfate-Reducing, Photosynthetic, and Hydrogen-Oxidizing Bacteria" (*R. Cammack, V. M. Fernandez,* and *K. Schneider*), "(Ni, Fe)Hydrogenases from Sulfate-Reducing Bacteria: Nickel Catalytic and Regulatory Roles" (*J. J. G. Moura, M. Teixeira, I. Moura* and *J. LeGall*), "Hydrogenases of *Methanobacterium thermoautotrophicum* strain ΔH" (*N. R. Bastian, D. A. Wink, L. P. Wackett, D. J. Livingston, L. M. Jordan, J. Fox, W. H. Orme-Johnston,* and *C. T. Walsh*), "Methyl-*S*-Coenzyme-M-Reductase: A Nickel-Dependent Enzyme Catalyzing the Terminal Redox Step in Methane Biogenesis" (*L. P. Wackett, J. F. Honek, T. P. Begley, S. L. Shames, E. C. Niederhoffer, R. P. Hausinger, W. H. Orme-Johnston,* and *C. T. Walsh*), "Structure and Properties of Coenzyme F_{430}" (*A. Pfaltz*), "Carbon Monoxide Dehydrogenase of Acetogens" (*G. Diekert*), and "Nickel in CO Dehydrogenase" (*S. W. Ragsdale, H. G. Wood, T. A. Morton, L. G. Ljungdahl,* and *D. V. DerVartanian*).

This book is a welcome addition to the literature of bioinorganic chemistry. It should be purchased by chemistry libraries and added to the personal libraries of bioinorganic chemists interested in nickel. It will also provide useful supplementary material for courses in bioinorganic chemistry. New workers in the field of nickel biochemistry will probably use this volume as a starting point in the future. (One warning: my copy has several pages where the print is very light. It might be a good idea to check your copy before you write your name in it.)

Math/Chem/Comp 1987. Edited by *R. C. Lacher*. Elsevier, Amsterdam 1988. 378 pp., $ 144.75.—ISBN 0-444-42930-1

This book, with its rather repulsive title, contains the proceedings of a conference on the interfaces between mathematics, chemistry and computer science which was held in Dubrovnik in June 1987. The conference is organized jointly by Florida State University and the Rugjer-Bošković Institute, Zagreb; according to the book's preface the meeting aims to encourage both interdisciplinary studies and those within a single discipline. The book contains 24 articles, which can be roughly grouped into the following topic areas: 1) Supercomputers and Chemistry, 2) Knot Theory, 3) Graph Theory and 4) Polymers. The main emphasis is not, as one might suppose from the abbreviation "Comp", on numerical quantum chemistry, but on topological methods of characterizing widely differing chemical structures.

The first two articles (by *D. Edelson* and *D. Edelson* et al., respectively) on supercomputers (vector computers) set out to review the current situation and likely future developments in the numerical treatment of scientific problems, a theme which has already been given a good deal of space in other publications during the past year. The second article reports specifically on the project at Florida State University to develop an expert system for chemistry.

The second section is more interesting. It includes an introduction to knot theory by *J. Simon* which is well worth reading; this is a special field of topology which has recently proved very useful for characterizing non-rigid cyclic polymers. Some advances have also occurred in the mathematics of knot theory; for example it has become possible to distinguish between the two chiral forms of the trefoil knot by means of the topological invariants (Jones polynomials) associated with them. However, for the reader interested in chemical aspects and applications it is regrettable that there are no contributions here on topics such as knotted strands of cyclic DNA molecules, the imaging of which has recently become possible through new experimental techniques.

A considerable proportion of the book is concerned with applications of graph theory in chemistry. The objective of graph theory is to translate structural characteristics of molecules into (mathematically defined) properties of graphs, and then to correlate these with physical-chemical properties, as described in the article by *N. Trinajstić*. The method is especially suitable for planar structures such as conjugated chains, which are dealt with in the article by *M. Randić* and *N. Trinajstić*. It emerges from the book that work is also in progress on a "three-dimensional graph theory" (*M. Randić*), for characterizing large molecules, i.e. synthetic and natural polymers. A reference to a 1985 paper indicates that graph theory can even contribute to cancer research, although this strikes the present reviewer as rather over-optimistic. Two articles by *R. Randell* deal with so-called conformation spaces, the object of which is to arrive at a description of flexible structures in chemistry. A typical problem posed here is: what is the minimum number of atoms in a cyclic structure for knotting to become possible?

The last of the main themes of the book and of the conference, polymers, brings into play the well known current catchphrases of this field: knot theory again, random walks, including those in restricted geometries (polymers in porous media), "lattice animals", scaling and critical exponents, Ising models. An exception to this is the review article by *L. Mandelkern* and *A. J. Peacock*, dealing from a purely phenomenological standpoint with the relationship between structure and mechanical properties of crystalline polymers. An analytical topological invariant for describing coiled polymer systems, the winding number, is introduced by *M. G. Brereton*. This quantity, defined as a path integral, does not distinguish as effectively between topologically different situations as do the polynomials of knot theory, but for dynamic processes its change or conservation provides an important indication of the type of reaction mechanism. Methods of analyzing polymers and branched polymers using the concepts of random walks or lattice animals have already been in common use for several years. Relationships to the description of disordered systems by fractals can be shown, and the renormalization theory which receives special mention in the article by *D. S. Gaunt* can also be used. Taken as a whole the section on polymers is the most interesting part of the book, as many physically relevant concepts are discussed here, and the articles give an insight into a large area of current research.

The value of having an index is not confined to textbooks; its presence would also be appreciated in this conference report. The price of the book is scarcely affordable for the private purchaser, and the same remains true for our libraries with their meagre budgets.

Werner Gans [NB 948 IE]

Houben-Weyl. Methoden der Organischen Chemie. Band E 20, Teil 1–3: Makromolekulare Stoffe. Edited by *H. Barte* and *J. Falbe*. Thieme, Stuttgart 1987. Part 1: lxxviii, pp. 1–688, bound, ISBN 3-13-219004-7; Part 2: xxx, pp. 689–1794, bound, ISBN 3-13-219004-7; Part 3: xxi, pp. 1795–2958, bound, ISBN 3-13-219004-7; price for Parts 1–3: DM 3400.00 (subscription and pre-ordered price: DM 3060.00).

There can hardly be a single chemistry library in the German-speaking world where "Houben-Weyl" is not to be found. It is a standard work of reference with which one is already familiar as a student, and which one reaches for whenever it becomes necessary to master a new topic.

It is certainly remarkable that a quarter of a century ago, under the series title "Methods of Organic Chemistry", the topic of "Macromolecular Substances" was already also included, in two volumes. The last twenty years have brought far-reaching changes in the polymer field, creating a pressing need for a revised version of this standard work. The breadth of the areas to be covered makes it impossible for the revision to be undertaken by only a small team of authors, let alone by one. There is no doubt that the editors have succeeded in engaging the services of many eminent experts to rewrite the different sections. There is a high degree of consistency in the style of treatment, and in view of the number of authors (86!) one may conclude from this that there has been a considerable amount of editing. Rules of nomenclature have been followed to a sensible extent, which contributes a good deal to easy readability.

The Part 1 volume is devoted entirely to preparative methods. A general introduction provides an easy entry into the field for the chemist who is less familiar with polymers. About 140 pages deal with the various methods for initiating the polymerization of monomers with multiple CC bonds. There is still much activity in this area, as shown by the fact that in some articles over 50% of the citations refer to work in the last ten years. Throughout the work as a whole the high proportion of recent citations provides a good overview of the main features of current research.

The largest amount of space is given to the description of free radical initiation. In describing the initiation of polymerization by CC cleavage, by azo initiators, peroxides, diacylperoxides and percarbonates, new results are included, and particular attention is given to systems with technological relevance. In addition to the conventional initiators, others such as the metal (O) compound/alkyl halide systems and electrochemical initiation are described. The term "living polymerization", which is wrongly applied in the literature to certain free radical polymerizations, is here rejected as being inaccurate, but to be consistent the section entitled "Living free radicals" should have been called "Long-lived free radicals". Polymerization initiation using energetic and high-intensity radiations is nowadays especially important in the manufacture of semiconductor chips and printed circuit boards, and it is pleasing to find that this "laser polymer chemistry" is described in detail.

Cationic polymerization and living polymerization have long seemed to be contradictory. This has changed. In the account of the current position in anionic polymerization, the main emphasis is on new results concerning ways of influencing the microstructure of polydienes, functionalization, and influencing copolymerization parameters. In the discussion of initiators for Ziegler-Natta coordination polymerization the current state of knowledge is summarized, with particular attention to the technologically important supported catalysts, to "linear low density" polyethylene, and to influences on the microstructure of polydienes. Group transfer polymerization is now just five years old, and the progress made on this topic is shown by a wealth of new results.

The theory of copolymerization is discussed from the standpoint of its practical applicability by the preparative chemist.

Over 200 pages are devoted to polymerization methods; particular emphasis is laid on technical polymerization procedures, as in bulk polymerization, and in solution, emulsion, suspension, precipitation and gas phase polymerization methods. Emulsion polymerization (approx. 100 pp.) is treated theoretically, and the colloidal properties of the products, such as the stability of the emulsions, coagulation and film formation, are reviewed. In the section on suspension polymerization the technologically important Pickering dispersing agents are discussed, as is also the synthesis of macroporous supports. Fluid bed processes for the polymerization of formaldehyde or ethylene are found under the heading "Gas phase polymerization". The equipment required for plasma polymerization and the capabilities of the method are also described. Solid phase polymerization and polymerization in thin films allow ordered systems to be produced. In addition to the classical case of diacetylene polymerization, polymerization in perovskites, inclusion compounds and ultrathin films are described.

The synthesis of carbon-heteroatom polymers is treated in the chapters that deal with the polymerization of monomers with CO or CN multiple bonds and with ring-opening polymerizations. The number of heterocyclic compounds that have been used in ring-opening polymerizations has grown enormously in the last 25 years; a short section is devoted to the free radical polymerization of heterocycles, but the main emphasis in this chapter is on the cationic and anionic ring-opening polymerization of heterocycles. The mechanistic aspects of the polymerization of oxacycles and lactones are clearly set out. Access to the literature on the copolymerization behavior of cyclic ethers is facilitated by the inclusion of more than 50 references.

In the chapter on "Polyadditions" the main emphasis is on polyurethane chemistry. The problems of synthesizing oligourethanes of uniform molecular structure are discussed in detail. The notion which *Otto Bayer* introduced of tailored synthesis in polyurethane chemistry is discussed, taking as an example the synthesis of segmented polyurethane elastomers. Other topics treated are the silane/olefin addition and the applications of the Diels-Alder reaction. Notwithstanding the enormous importance of the diisocyanate/diol reaction, the potential underlying the principle of polyaddition is still far from being exhausted.

The chapter on "Polycondensations" begins with a very comprehensive survey of the known structure-building reactions, but unfortunately no critical evaluation of yields and side-reactions is included. The prepolymer technique, which is especially suitable for synthesizing crosslinked polymers, is described in detail in accordance with its practical importance. Considerable space is also given to the description of

ordered structures in polycondensates in the form of segmented or block copolymers. The section on structure-property relationships is especially valuable for the preparative chemist. However, the generalizations that are made, e.g. concerning T_g and T_m, should only be regarded as approximate rules with many exceptions. The problems and the advantages and disadvantages of polycondensation in melts, in solutions and on surfaces are thoroughly discussed.

In considering reactions on macromolecules as a method of synthesis, the importance of the effects of neighboring groups on the structure of the polymer thus formed is usually underestimated. This chapter provides a good overview of this topic. Graft polymerization reactions offer a wide range of possibilities for modifying polymers, and are used in many different forms in industrial processes. In this article the choice of a suitable initiator for a given graft polymerization system is clearly explained.

The final chapter of the Part 1 volume describes modifications obtained by combining polymers. As well as interpenetrating networks, polymer blends offer ways of combining properties to achieve a desired result. The principles of producing modified polymers with high impact strength and thermoplastic elastomers are described.

In the Part 2 and Part 3 volumes the emphasis is on the different chemical classes of macromolecular substances. Over 100 pages are devoted to the polymerization of olefins, and the various methods are critically evaluated. Many laboratory recipes for both homo- and copolymerization are given. The densely packed information ranges from phase diagrams to safety aspects. Questions such as which comonomers should be used to stabilize an emulsion or to improve the adhesion strength of a film are answered, as well as those relating to ways of obtaining higher stereospecificity in the polymerization of propene. Under diene polymerization (over 100 pp.) the main emphasis is on microstructure, but in addition reaction regulators, and modifications through copolymerization and incorporating stabilizers are discussed. Metathesis reactions can nowadays be carried out as a form of living polymerization. However, many questions concerning the stereochemistry still remain unanswered. Here the current state of knowledge in this area is carefully set out. The section on "Styrene polymerization" concentrates on modifications, e.g. by copolymerization, grafting or ionic block copolymerization. It is remarkable that over 90% of the citations refer to the period since the publication of the previous edition. In addition fluoroolefins, chloroolefins, vinyl ethers, vinyl esters, unsaturated aldehydes and acrylic compounds as monomers are carefully and expertly discussed. Polymerization reactions of acetylenic monomers are not confined to acetylene itself—details of the polymerization of more than 40 acetylene derivatives are included. Diines too undergo polyaddition reactions to give many different polymers. Aliphatic and aromatic polyethers and aliphatic polyacetals are polymers that exhibit a very wide range of properties profiles. For these the importance of including alongside the polymerization processes the properties of the resulting polymers has been recognized, and representative data on technical products are also listed.

Polyesters in all their many variants are described in 50 pages. In addition to the familiar aryl-aliphatic polyesters there are detailed descriptions of unsaturated polyester resins, alkyd resins and polycarbonates. Sulfur-containing aliphatic and aromatic polymers are treated in the following chapter. These too include products of basically different types: on the one hand alternating copolymers of olefins and sulfur dioxide formed by free radical polymerization, which degrade easily as indicated by their low ceiling temperatures, and on the other hand high performance materials such as polyphenylenesulfide and polyphenylenesulfone.

In the area of polymers with main-chain nitrogen atoms the longest chapters are those on polyamides, polyurethanes and polyureas. The chapter on "Polyamides" deals with various polyheterocycles including polyimides, polyamidimides and polyether-imides, some of which also appear in Part 3 under the heading "Special polymers". Considerable advances have been made in the last 25 years in the field of ionomeric polyurethanes, and accordingly the preparative aspects of introducing ionic groups are discussed. In these 150 pages on polyurethanes an impressive account is given of the many possible variations of the molecular architecture. Other chapters in this volume are devoted to polymers with P, B, Si and metals as heteroatoms.

In the Part 3 volume phenolic and amino resins are described. In order to tailor the properties profile of formaldehyde resins to suit the many different applications a detailed knowledge of the basic reaction steps is essential. The short synopsis of areas of application given here is very useful. Epoxide resins are now more than 40 years old. In addition to their best known area of application in high performance composites, the wide range of variations that are possible in the underlying chemistry of starting materials and curing agents, as described here, opens up many different areas of use, e.g. in paints and other surface treatments.

The long third chapter of Part 3 (200 pp.) recognizes the enormous practical importance of the production of chemically modified polymers. The treatment is divided into synthetic polymers and polysaccharides. Under synthetic polymers a number of reactions have had to be omitted because of the need to be selective; those sacrificed include hydrolysis of esters and amides, imidization reactions and cyclization reactions in general. However, this still leaves a very wide range of topics. The conversion of polysaccharides is one of the oldest processes of polymer chemistry. Under the heading "Renewable raw materials" this has again become an important topic today. After a general discussion of structure-property relationships as influenced by the complex pattern of substitution, individual groups of cellulose ethers and cellulose esters are discussed. Special sections are devoted to starch and guarane derivatives.

In the next chapter we return to polymers produced by synthetic reactions. This chapter, on "Special polymers", is very varied in content. The topics covered are polymers formed by condensed heterocyclic rings, products from polymerization of ketene, polymers from carbon dioxide, liquid crystal polymers, chiral polymers and inorganic polymer chains. The section on "Condensed heterocyclic rings" is a good survey of the high temperature polymers known at present. That on "Liquid crystal polymers" suffers a little from the fact that aromatic polyesters and amides are treated elsewhere. The section on "Chiral polymers" consists of only one table. Under the heading "Inorganic polymers", polyphosphazenes, polyorganosilanes, silicones and polymers synthesized from metal phthalocyanines are described.

A considerable amount of space is given to characterization methods. Although the determination of chemical constitution by decomposition has nowadays become less important compared with spectroscopic methods, the analysis of end groups remains a problem, and this chapter offers some help in that respect. In the section on "Physical methods of polymer characterization", difficulties that may be encountered are briefly summarized and references are given for more detailed reading.

The final chapter of the work is concerned with toxicology and with environmental aspects of polymers. This is followed by a bibliography (approx. 100 pp.) listing further literature, mainly reviews, under the individual chapter headings. It is doubtful whether a reader who only makes occasional use of the work will find this additional material; perhaps it should have been put after the introduction or at the ends of the chapters.

As so often happens, there are problems with the subject index. One is used to looking for polystyrene (Polystyrol) under "Poly...". After realizing that one must look under "Styrol", further difficulties arise with "Polyethersulfon", as here one has to search under "Sulfon"; however, "Polyetherketon" does not appear under either "Etherketon" or "Keton".

The work contains hardly any printing errors, and the typography and presentation are attractive. There are a few errors which are likely to cause a smile: "Schmutzkolloide" on p. 188; in the contents list and in the index the Smith-Ebert theory appears instead of the emulsion theory, and on p. LIV under "General articles on large molecules" the "Encyclopedia of Polymer Science and Technology" is also cited.

The few shortcomings are small when weighed against the scientific value of the work. As an up-to-date work of reference for all scientists involved in polymer chemistry it is indispensable, and it will soon find its place in the libraries of polymer science departments and institutes. However, for those universities where macromolecular chemistry is not strongly represented the price may prove to be a serious obstacle.

CORRESPONDENCE

One Pioneer or Several Pioneers? The Discovery of Noble-Gas Compounds

P. Laszlo and *G. J. Schrobilgen* have submitted the following **Addendum** to their article on noble-gas compounds (*Angew. Chem. 100* (1988) 495; *Angew. Chem. Int. Ed. Engl. 27* (1988) 479).

A letter from *Henry Selig* of August 29, 1988,[*] differs in the sequence of events, in respect to a key finding, from *John Malm*'s recollections, which we had no reason to doubt and have followed in our account. In Dr. *Selig*'s words: "... most members of the Argonne fluorine research group had gone to the Estes Park, Colorado, fluorine symposium leaving *Claassen, Malm* and myself behind. The actual experiment was planned by the three of us and carried out during that week. On the day of the very first experiment, Friday, August 2, 1962 *John Malm* was at home ill and *Claassen* and I conducted the experiment by heating Xe + F_2 in a nickel can at 400 °C. After pumping off the volatile materials and not finding any xenon we were still sceptical. We phoned *Malm* at home to apprise him of the results. The following week we identified the material in the weighing can as XeF_4, presenting our colleagues returning from Estes Park with a fait accompli."

We gratefully acknowledge Dr. *Selig*'s version of the first synthesis of XeF_4 at Argonne, an interesting variant with respect to the story we had reported. Our account, let us remind the readers, has as its main focus the prehistory of the discovery of noble-gas compounds.

ADVANCED MATERIALS

Materials Research—Current Issues and Future Directions

Editorial Essay

By John W. Collette* and Joel S. Miller*

"I am making the first announcement of a brand new chemical textile fiber. This textile fiber is the first man-made organic textile fiber prepared wholly from materials from the mineral kingdom...; Though wholly fabricated from such common materials as coal, water, and air, Nylon can be fashioned into filaments as strong as steel, as fine as a spider's web, yet more elastic than any of the common natural fibers."[1] This announcement by Du Pont's Vice-President, Dr. *Charles Stine*, on October 27, 1938, caught the public attention and can, perhaps more than any other single event, be viewed as the beginning of the *Age of Polymers*. Few if any futurists would have predicted how the subsequent avalanche of synthetic polymers would change the way man thinks about and uses materials. As part of the 50th anniversary celebrations of Nylon the "Advanced Materials Conference on Current Issues and Future Directions in Materials Research" was held in Wilmington, Delaware, USA, on October 23.–24., 1988. It provided an opportunity to focus on the theme of shaping the future in the evolving new world of materials and material systems.

Historically, the commercialization of Nylon culminated several decades of technological advances in Europe and the United States which had seen the growth of a polymer industry based largely on the chemical modification of cellulose. Major research efforts were also under way seeking a substitute for natural rubber. Then within one decade, a completely new series of synthetic materials—Neoprene rubber, styrene/butadiene rubber, polystyrene, polyvinylchloride, polyvinylbutyral, polymethylmethacrylate, Nylon and Teflon were developed which provided properties previously unattainable. Fifty years after its introduction, the worldwide market for nylon polyamides has grown to an annual size of 12 billion pounds. Sales are still expanding at a rate significantly faster than the gross national product. This, however, represents only a fraction of the global business in synthetic polymers.

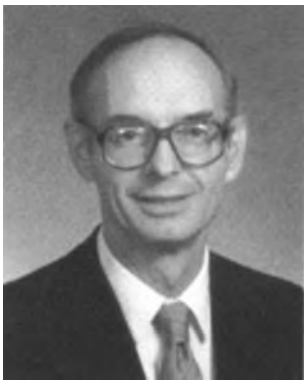
There have been many technological developments during this period. New scientific advances in synthesis, in physical techniques, and in computational capabilities are increasing our ability to make, characterize, and understand the properties of specifically structured materials. The coalescence of macromolecular, metallurgical, and ceramic technologies around a common need to provide specific structural properties has catalyzed interdisciplinary work and synergized the translation of advances in one field to others. The increasing overlap of science with technology has seen scientific advances moving rapidly into technological development and advances in technology catalyzing scientific investigations into new materials.

Dr. *Ardent Bement*, Vice President for Technology at TRW Inc., in a keynote introduction to the conference, noted that never before have materials engineers been able to offer so many options to the design engineers in assisting them to reconcile conflicting ideals of efficiency, economy, functionality, durability, and aesthetics.[2] *Bement* provided a historical perspective of synthetic polymers in the evolution of materials science. He looked forward to even more exciting developments as microelectronic technology is combined with materials to provide a new generation of smart materials systems.

Prof. *Merton Flemings*, in his presentation entitled "National Perspectives on Materials Science and Engineering," observed that materials technologies are a key element in improved productivity and overall economic growth.[3] All leading nations and industries have targeted materials, and especially advanced polymers, as a theme for research emphasis. *Flemings* succinctly reviewed the preliminary findings from a forthcoming National Research Council Study on "Opportunities and Needs in Materials Science and Engineering" which he co-chaired. This study has identified important opportunities for improved materials in the aerospace, electronics, health care, automotive, chemical, and energy industries. Noteworthy conclusions include an urgent need for increased efforts on the synthesis and processing of materials and on education. Furthermore, improved interdisciplinary interaction between chemists involved in synthesis, physicists and physical chemists involved in structure and property determination, and engineers who process the material and fabricate the product are critical to future progress.

These themes were reiterated in the major technical talks (on which the following articles in this issue are based): Dr. *Michael Salkind* described the revolution taking place in aerospace materials to meet the challenges of lower weight with higher operating temperatures. The future will see increasing effort on so-called smart systems which can respond dynamically to external stresses (exemplified by the flying replica of the extinct reptile *Quetzalcoatl Northropi*). Dr. *David McCall* outlined the materials challenges in electronics applications as the drive towards miniaturization exacer-

[*] Dr. J. W. Collette, Dr. J. S. Miller
E. I. du Pont de Nemours & Co., Inc.
Central Research & Development, Experimental Station, Building 328
Wilmington, DE 19898 (USA)



bates the complex interactions between the metals, ceramics, and polymers used in these systems. Prof. *David Williams* emphasized the embryonic character of materials technology in healthcare applications. Current materials used to replace bones or other body parts generally have only a single, simple function, usually a mechanical one. Truly functional replacements which combine mechanical properties with biological characteristics will require major advances in understanding how natural materials function and in the design of smart materials. Prof. *Walter Michaeli* used liquid crystal polymers to exemplify the importance of processing on materials properties. He also showed the value of computer modeling to guide part design based on knowledge of the behavior of the polymer during processing.

The importance of interdisciplinary work and of a systems approach to materials application was vividly apparent in the history of the development of Kevlar aramid fiber by Drs. *David Tanner, James Fitzgerald,* and *Brian Phillips.* With a highly engineered material such as Kevlar, market emphasis shifts from simply selling the product, to providing a system which meets a functional need. A complex composite, for example, may involve both organic and inorganic fiber reinforcement in a matrix of two or more different resins, all chosen to provide specific properties. The materials scientist has to be concerned not only that each individual material has the optimum properties needed but has also to understand the complex interactions between them in the final system.

The interdisciplinary nature inherent in materials research, the globalization of scientific effort and the intense international competition in advanced materials are combining to bring about many changes: partnerships between different companies to share technology, increased industrial/academic collaboration, and an effort by the government to facilitate technology transfer from government laboratories. This has affected the way research and development is carried out and placed new demands on the current science and engineering educational system. The particular issues of education and of collaboration between industry, academia, and government were addressed by the panel of industrial, academic, and government representatives. For a critical summary of this discussion see Prof. *Gerhard Wegner*'s contribution in this issue. The panel highlighted many of the changes already taking place. These include: 1) increased industrial support of academic research; 2) more collaborative programs between industry and individual university scientists; 3) visiting scientist programs to bring academic researchers to industry; 4) government policies aimed at encouraging effective liaisons between the different sectors; and 5) an increase in interdisciplinary training and research in academia. Some major gaps are the virtual absence of industrial scientists taking sabbaticals at universities and the limited number of Americans who study in Japan. A major issue discussed was how to increase interdisciplinary programs at universities without sacrificing the quality of the scientific training.

The materials field has never been so vibrant and full of expanding opportunities as it is today. Materials science is truly a dynamic global science of growing critical importance to mankind. The conceptual focus of materials research is changing from using available materials, to designing systems and materials in the context of a functional application. A major challenge for the future is to assure a climate which is conducive to effective R & D. We must optimize the fruitful partnership between industry, universities, and government. Educational programs at universities must be strengthened, and must recognize that advances will require experts who can communicate and cooperate in interdisciplinary programs. These goals must be met if we are to remain competitive in an increasingly technological world.

John W. Collette was chairman of the Organizing Committee for the Advanced Materials Conference held for the 50th anniversary of Nylon. A native of Calgary, Canada, he received his Ph.D. from the University of California (Berkeley) in 1958. He then joined Du Pont and has held a variety of managerial positions in polymer research and development. In 1987 he assumed his present position as Assistant to the Vice President of the Central R & D department. He holds 28 patents and has authored 22 publications in the fields of synthetic elastomers, high performance coatings, and polymerization catalysis.

Joel S. Miller received his Ph.D. from UCLA (1971). After a postdoctoral fellowship at Stanford University he joined the Xerox Webster Research Center in 1972 and in 1978 the Occidental Research Corporation. In 1983 he joined the Central R & D Department at Du Pont where he is currently a Research Supervisor for solid state science. His research interests focus on the solid state properties of molecular compounds and charge transfer complexes as well as the surface modification of solids. In addition to holding patents he has edited five monographs and published over 160 papers.

ADVANCED MATERIALS

Materials Issues in Electronic Systems

Chip Encapsulation
Semiconductors
Superconductors
Dielectrics
Multilayer Boards

By David W. McCall *

1. Introduction

The materials of electronic systems as illustrated in Figure 1 can be summarized in terms of relatively few basic elements and compounds. Integrated circuit (IC) chips are made of single crystal doped silicon with aluminum metallization and silicon dioxide or silicon nitride dielectrics. A glass (P-glass) or silicon nitride is used for passivation. For protection the chips are encapsulated in a plastic or ceramic package. Electrical connections are made via gold or aluminum wires from chip bonding pads, to leadframes constructed of copper or an alloy of iron and nickel. The leadframes are attached by solder to printed circuit boards that are composed of epoxy–glass (or sometimes polyimide) substrates which support copper interconnection patterns. In some cases alumina substrates are employed with refractory metals. Connections to other boards are made through connectors composed of molded plastic (poly(diallyl phthalate), poly(phenylene sulfide), etc.) with beryllium/copper contact fingers, and cables with copper conductors insulated with extruded plastic.

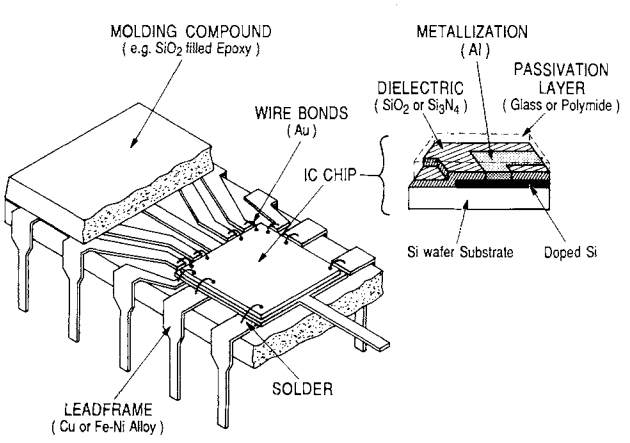

Fig. 1. Materials usage in integrated circuit chips.

This summary, while substantially accurate for the great majority of circuits, fails to reveal the enormous amount of materials engineering work that makes the manufacture and use of electronic systems possible. Each material has been carefully tailored for specific purposes, and issues of material compatibility are of critical importance. Process sequences, involving hundreds of steps, must be chosen such that conditions later in the sequence do not undermine structures formed earlier. The dimensions of all features of electronic circuits, from IC's to printed wiring boards have been decreasing logarithmically since the 1960's (Figure 2). As the

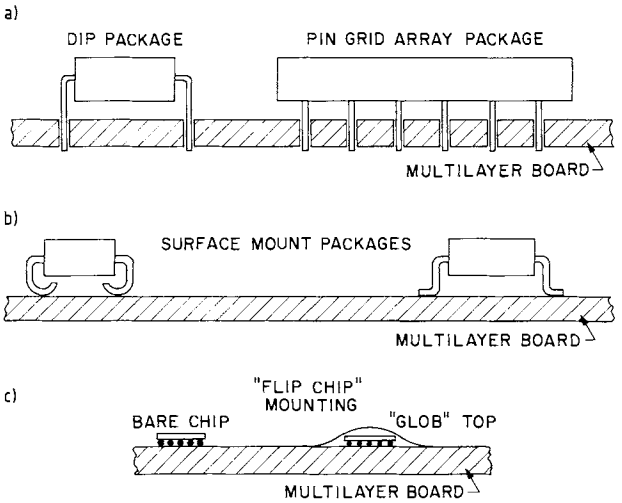

Fig. 2. Evolution of IC chip feature and interconnection dimensions for printed wiring boards (PWB), hybrids, and multichip modules (MCM).

circuit dimensions are reduced to two or three orders of magnitude above the sizes of the atoms themselves, compatibility of materials and processes becomes more important.

The foregoing capsule description includes only the materials that remain in the final product. In fact, many other materials are necessary to the processes that give rise to the structures, e.g. photoresists and electron beam resists, that define the lateral patterns on ever finer scales (a few thousand Ångstroms). Organometallic precursors are also employed to deposit metal films. Process control is increasingly critical, e.g., gate oxides of the order of 100 Å are necessary in advanced devices. Ion implantation places precisely known concentrations at controlled depths and molecular beam epitaxy lays down coherent layers atom-by-atom.

The packaging materials of the chip have different but extremely challenging demands. The package must provide

[*] Dr. D. W. McCall
AT & T Bell Laboratories
Murray Hill, NJ 07974 (USA)

timing information to all parts of all chips with manageable skew. Data must be delivered to and from chips with delays that are consistent with chip circuit switching times, and an increasing number of access points are required as chips evolve. Electrical power and ground must be supplied over leads of small impedance, which means extremely short paths. The heat generated by the chip circuitry must be transmitted to the environment effectively to prevent the chip temperature from rising disastrously. In material terms, the electrical signal paths require high conductivity metals such as copper, aluminum, gold, etc., and low dielectric constant insulation, e.g., polyimides and fluorinated polymers. The speed of light is a practical limiting factor in advanced circuits. For power delivery, high conductivity metals are again necessary, but high capacitance (i.e., low impedance) physically close to the chip requires high dielectric constant capacitor materials, usually ceramic. Thermal conductivity favors metal and other ceramic paths, as polymers are thermal insulators.

The thermal coefficient of expansion (TCE) is a critical factor in package design as mechanical stresses are created when temperature changes occur in manufacture, temperature cycle testing and use. Silicon has a low TCE compared with common metals and organic polymers. The problem, however, becomes more serious as the chip size decreases. Thinner sections of the molded body are more susceptible to thermal-mechanically induced failure by cracking. The TCE of polymeric materials can be controlled by addition of low TCE fillers, as is conventional for molding compounds and printed wiring board resins. Many packaging and interconnection materials are composites designed to improve the TCE match. The use of Kevlar fibers as reinforcement for polymer matrices is promising for TCE control. Also, there is a certain class of polyimides which has, by molecular design, been shown to exhibit very low TCE.

2. Materials Opportunities

Opportunities for material innovation continue to grow. After many years of promise GaAs is now finding real applications in advanced computers. Beryllium oxide, aluminum nitride and silicon carbide offer high thermal conductivity, and among the inorganic insulators, silica and cordierite have relatively low dielectric constants but suffer from poor thermal conductivity. Polymers offer low dielectric constants with opportunities for further substantial reduction in fluorinated materials. In all of these considerations material compatibility, adhesion, ionic impurities and many other factors are critical.

The physical properties of typically used organic, inorganic, and metallic materials are listed in Table 1. To give a more specific description of the use of organic materials in electronic systems, three areas will be discussed: chip packaging materials, printed circuit substrates, and interlayer dielectrics in hybrid circuits and other advanced structures.

2.1. Integrated Chip Packaging

Chip packaging is an area that requires careful attention to matters of material compatibility and process feasibility.

Table 1. Interconnection and Packaging Materials [a].

	T [°C]	ϱ [g cm^{-3}]	ε'	ε''	σ [Ω cm]	TCE [ppm K^{-1}]	K [W cm^{-1} K^{-1}]	Uses
Organics								
Epoxy (70% SiO_2)	170	1.8	3.8	0.03	4×10^{16}	20	0.002	Packaging

[a] T: Melting, glass transition, softening or processing temperature, as appropriate; ϱ: Density; ε': Dielectric constant, permittivity; ε'': Dielectric loss, tan $\delta \equiv \varepsilon''/\varepsilon'$ = dissipation factor; σ: Resistivity; TCE: Thermal coefficient of expansion; K: Thermal conductivity.

As noted in Figure 2, the following steps are involved. The silicon chip is die bonded to a leadframe (usually copper or a nickel–iron alloy) employing either solder or a polymeric adhesive (gold alloy or silver-filled epoxy). The leadframe is then wire-bonded (gold or aluminum wire) to the bonding pads on the active side of the chip. The circuit may or may not be encapsulated with a conformal coating (silicone rubber or gel) and the assembly is transfer molded, usually silica-filled epoxy, leaving only the external leadframe visible. The component parts (silicon, copper, silica-filled epoxy, other) exhibit a considerable range of TCE's and considerable stresses develop as the package is cooled from the relatively high molding temperature. This stress may be reduced by increasing the concentration of silica filler (thus reducing the TCE) and addition of elastomeric materials to the epoxy. Good adhesion between the epoxy and the chip and leadframe surfaces is important as this reduces the effects of stress. For a large memory, the filler must be very pure, i.e., low in α-particle emitters, e.g., Th or U. The epoxy must be of low viscosity when it fills the mold cavity or it will distort the metal parts, particularly the gold or aluminum wires. The epoxy molding material preform should have minimal sensitivity to moisture and other extraneous factors which affect processing. At this time all of the foregoing processing and property factors have been accomodated by well-engineered epoxy molding compounds. Displacement of epoxies by other materials is unlikely in the foreseeable future.

An alternative to the transfer molding process is the use of chip carriers made of alumina or pre-molded plastic, usually epoxy or poly(phenylene sulfide). These options are easier to implement than direct epoxy encapsulation when the number of chip leads becomes large. Price, package area and lead impedance are high for chip carriers, and molded packages will probably continue to dominate where their use can be accomplished with reasonable yields. For finely spaced package leads (e.g., 0.635 mm) and large numbers of leads (> 100) the choice is not obvious. As lead counts approach 200, wire bonding and leadframe design become much more difficult and tape automated bonding (TAB) another packaging approach involving copper fanout patterns plated on a polyimide film, will grow in importance.

2.2. Chip or Package Attachment

The two major types of chip packaging, molded epoxy or hermetic ceramic, can exist in a variety of forms. Dual in line packages (DIP) and pin grid array packages have pins that are inserted through the printed circuit board and soldered into place, Figure 3a. A more recent development, called surface mount assembly (SMA) employs the same basic package types but the package leads are soldered to pads on the surface of the circuit board, Figure 3b. Components can be mounted on both sides with SMA and the absence of holes through the board leaves more room for circuit traces and interlayer vias. A still more efficient method is to directly attach the unpackaged chip to the circuit board by "flip chip" solder attachment, Figure 3c. This uses even less area of the printed circuit board and allows for more densely packed circuitry.

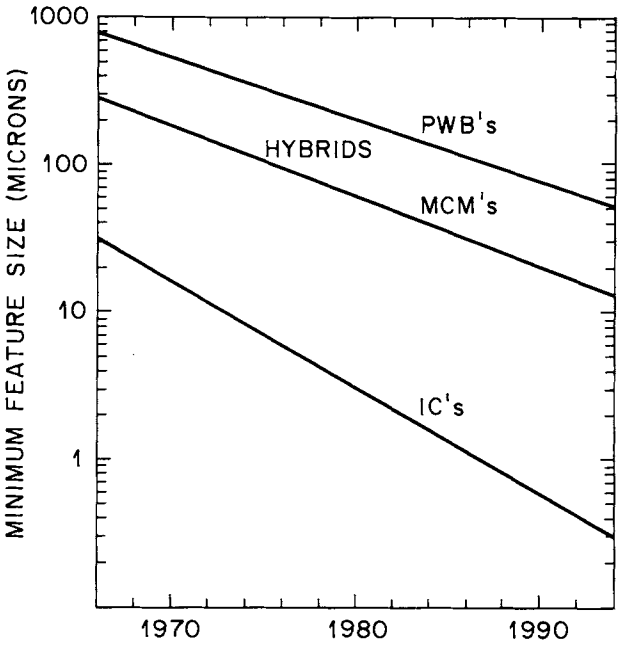

Fig. 3. Mounting options a) pins inserted in printed circuit boards; b) surface mount; c) "flip chip" mount.

2.3. Printed Circuit Boards

Packaged chips are interconnected by attachment to multilayer printed wiring boards (MLB's). These MLB structures are composed of copper circuit patterns on insulating substrates. Typically two to perhaps a dozen circuit layers are employed but advanced circuits may contain more than forty layers. The substrate dielectric is usually an epoxy polymer (based on the diglycidyl ether of bisphenol A) reinforced with glass fiber fabric. Multilayer structures are formed by printing copper circuits on partially cured (B-staged) epoxy and piling up the carefully registered sheets for final cure under pressure. Connections between layers (vias) are formed by drilling holes through the cured MLB and plating copper on the walls of the holes. Surface mount boards which have "buried" and "blind" vias are manufactured by similar but more complex processes.

As MLB circuits evolve to meet more difficult operating conditions and performance demands, the epoxy–glass–copper MLB materials will be challenged. Copper has no near-term competitors at this time. New epoxy compositions (highly functionalized novolacs) are being introduced for the most advanced circuits and their use will grow over the next few years. For circuits required to perform at high temperatures, polyimide and BT-resins (bis-maleimide/triazine) offer capabilities in the 300 °C region. When a low dielectric constant is needed, organic fibers (e.g., polyaramide) will be

ADVANCED MATERIALS

substituted for glass fiber reinforcement. Lower dielectric constant resins including hydrocarbons (e.g., bicyclobutadiene) and tetrafluoroethylene may also come into use. There will be many opportunities for special purpose compositions, but the epoxies are unlikely to be displaced in most conventional MLB applications.

2.4. Interlayer Dielectric

Organic dielectric layers are now being used in hybrid circuits which consist of metal patterns on alumina substrates. These patterns have dimensions between the range encountered in MLB's and those found on chips. Triazine formulations and polyimides are used in these applications. In recent years a great deal of activity has been devoted to the use of very fine interconnection circuits built up on silicon wafer substrates. Polyimides are generally the material of choice for this technology and many variations are being developed. Polyimides have been developed with very low and controllable TCE's. Dielectric constant, water absorption and other properties have been improved. Photopatternable materials are available but not widely used at this time. In some designs polyimides are being used as interlayer dielectrics on silicon chips. This is a very active area with polyimide formulation clearly dominant.

3. New Materials

The need for high conductivity interconnects has stimulated interest in the new oxide superconductors. This is an area that is developing rapidly and should be followed closely. Even if the formidable processing problems and current density limitations can be overcome, there will remain the question of high frequency performance. Present oxide superconductors are not very good at high frequencies and maximum current densities are rather low. If circuits are to be cooled to liquid nitrogen temperature, copper and aluminum will offer a substantial (a factor of eight) conductivity improvement. It should be kept in mind that the speed of signal transmission cannot be better than the speed of light which will be governed by the square root of the dielectric constant. Even so, superconductors continue to receive attention as candidates for interconnection structures and should be followed as a long-term option.

Finally, we mention diamond. Promising advances are being made with regard to the preparation of synthetic diamond films. If suitable films can be prepared in a manner compatible with other elements in electronic systems, diamond offers extremely attractive properties. The hardness, TCE and especially thermal conductivity are uniquely favorable. This is an active and promising line of research.

4. Conclusion

Electronic systems have evolved to the point at which opportunities for introducing new materials are highly favorable. As physical limits on circuit speed and power are approached, the advantages of special materials will increase.

Materials Processing—a Key Factor

Injection and Extrusion Molding
Process Optimization
Computer Aided Design
Liquid Crystal Polymers

By Walter Michaeli *

1. Introduction

New polymers, computer-integrated manufacturing and quality requirements ask for a daily new, and never ending attempt to answer the question of how to optimize processing. The answer is very complex and requires fundamental knowledge of how, for a given polymer, the structure of a product correlates to its processing conditions since this influences crucially its final properties and performance.

Processing conditions are often dependent on the specific design of the processing equipment, the quality of the control systems, handling and pretreatment, for example, drying and compounding, and on environmental conditions. Moreover, the change of one parameter during processing can affect final product properties. Therefore, it is necessary to study the individual influences on a given material. However, before optimizing material processing it is first essential to optimize the plastics part design. It is the objective of many R & D departments in industry and academia to define rules, models, and software packages according to which a part is to be designed and processed. This has to be combined with the innovative potential of those who create new polymers.

In view of the increasingly more complex requirements put on part properties, computer-aided processes for part and tool design have become generally established in planning departments, and the necessary software packages are steadily improving. This will help to avoid a poor design and will lead to better processing and improved quality. Let me give some examples: As advanced composites with infinite fibers are formed during processing, the possibility of affecting product properties at this stage is increased. Voids and air entrapments have a tremendous influence on the mechanical properties of such a composite. This can be shown impressively by applying an interlaminar shear load, since the voids are mainly formed between the fiber and the matrix[1] and have a negative influence on the bonding. The strong influence of the void content on the interlaminar shear strength during dynamic loading is demonstrated in Figure 1.

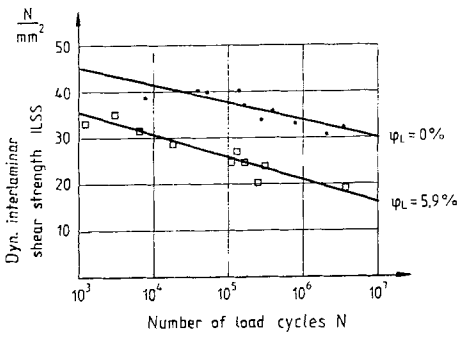

Fig. 1. The influence of void content φ_L on the mechanical properties of an FRP laminate, a composite material.

Another very important factor in part design and processing is the fiber orientation. Deviations from the given fiber orientation, e.g. of only 5°, may lead to a drop in strength of about 40 % for a fiber content of 60 vol-% (Figure 2).[2] This

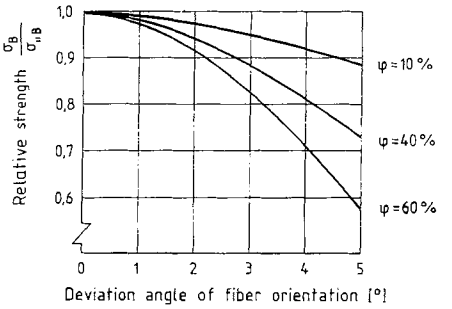

Fig. 2. The influence of fiber orientation on the mechanical properties of composite parts. φ = Filament volume ratio.

gives an idea of the importance of the reproducible laydown of fibers during material processing. There are many other key factors in material processing. To discuss them all is impossible but it is my intention to cover the most essential parameters used to set up process models, which give the key to separate and estimate the effect of single processing conditions on future products.

Manufacturing philosophy is that the final properties of a plastic part made from a well defined polymer should be independent of the production process used, in as much that it is the inner structure/morphology, crystallinity, fiber dispersion and distribution, orientation, and internal stress pattern, which determine the properties. However, if we analyze the processing of thermoplastic materials, we find that the structure formed is a function of thermal and mechanical

ADVANCED MATERIALS

influences. The absolute values of structural characteristics, like orientation or crystallinity, vary for different processes or products but can always be derived from the specific process conditions. Therefore, we have to analyze a process in terms of single steps for which the processing parameters are defined, and for which the internal properties (structure) and final properties are then determined.[3] This is depicted in Figure 3.

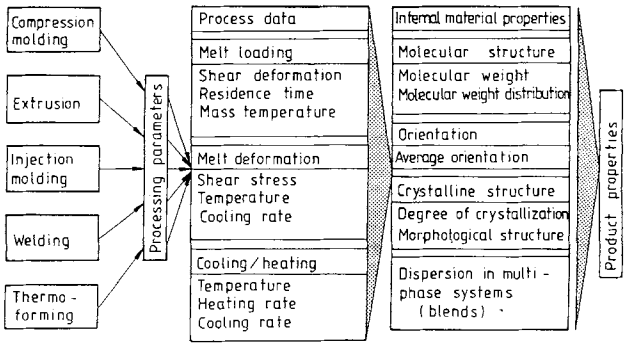

Fig. 3. Production process to part properties.

Process data are independent of molding- and processing equipment and are derived or calculated from the processing conditions and the specific geometrical boundary conditions of the equipment.

The material is more loaded (e.g. sheared, heated) during compression molding than during extrusion and therefore we expect alterations on the molecular level. A comparison of extrusion and injection molding gives a similar set of process data, but the pressure level and the shearing forces in injection molding are significantly higher than in extrusion.[3] The structural parameters (like orientation or boundary layers) are less distinct in extrusion. Similar cooling gradients exist, but due to the melt flow during the packing phase, high deformation rates at fairly low melt temperatures influence the internal structure. The morphology and internal stress patterns can be correlated for both processes to the cooling, pressure, and deformation conditions. A detailed analysis of these factors allows us to better understand materials processing.

2.1. Component (Part) Properties

To illustrate how properties, e.g. mechanical properties, are influenced by the internal morphology consider the following examples.[3] Figure 4 gives the thermal coefficient of expansion as a function of the degree of stretching λ (which correlates to orientation)[4] for different materials. Figure 5 shows for polypropylene (PP) how the Young's modulus E_0 and the tensile stress σ_s are influenced by crystallinity,[5] which is a function of the cooling and material deformation conditions during processing.

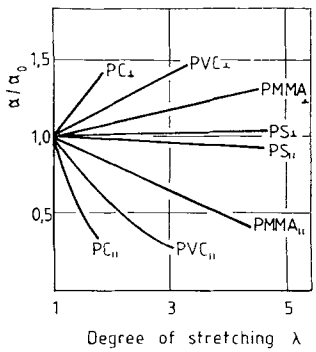

Fig. 4. Thermal expansion coefficient as a function of the degree of stretching.

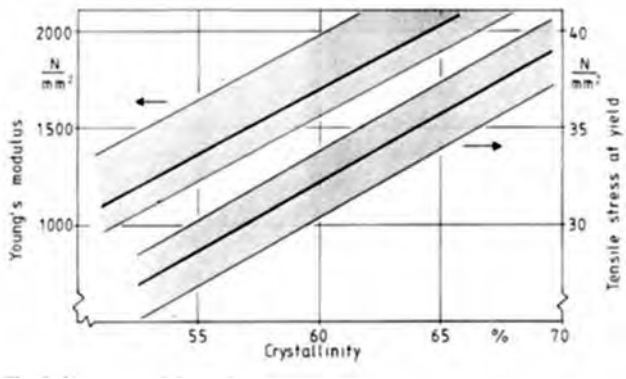

Fig. 5. Young's modulus and tensile stress (for polypropylene) as a function of crystallinity.

2.2. Influence of Melt Loading on Part Properties

The state of a thermoplastic material[3] while being processed and molded into a plastic part is defined by:

- melt loading (degradation)
- melt deformation (orientation) and
- cooling conditions

A certain molecular weight is necessary to achieve product properties like impact and corrosion resistance or dimensional stability under mechanical loading. Molecular weight and flow properties can be correlated, and also give a good correlation to degradation when the melt is loaded.[3] Figure 6[3] describes the effect of melt loading on the melt vis-

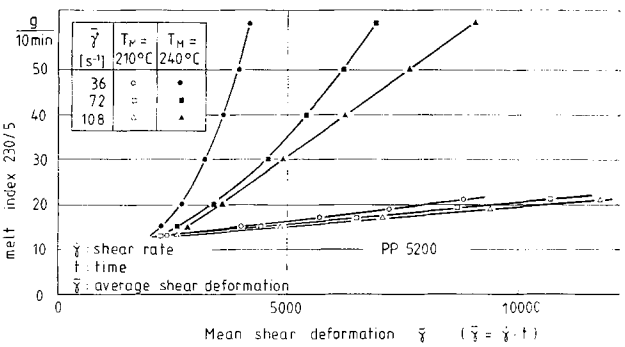

Fig. 6. Melt loading of polypropylene (PP).

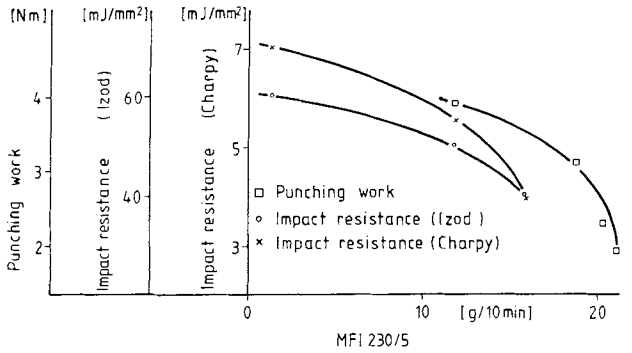

Fig. 7. Change in impact strength according to melt flow index (MFI).

cosity (melt index) as a function of mass temperature and shear deformation during extrusion. The significance of the mass temperature can clearly be seen. These experiments were made in extrusion but injection molding shows the same tendencies. Tensile tests often do not reveal the significance of the degradation, but impact resistance tests show how significantly chain scission influences performance (Fig. 7).[13]

3. Modeling of Part Design and Processing

If we wish to follow a straight line from the initial idea to the final product we have to structure our approach. The world-wide tendency to use software packages to guide us from the idea to the product is perhaps the strongest driving force bringing structure and unity to our approach. All steps from the idea to the final product have to be defined and have to be under control. This may sound simple to some or like utopia to others, but it is an essential objective.

The first step is to define the requirements the part has to fulfill (Fig. 8), and to select the right material.[6] Several software houses, and a large number of raw material manufacturers offer data banks for polymer materials, some even enabling the potential user to store his own proprietary knowledge and call it up as required.

The next step is the first layout of the geometry of the part. CAD-Macros defining and generating specific design elements of parts like snap-fit joints, gears, screw joints, rib reinforcements etc. are a most valuable tool and help to avoid poor designs. All design rules for the part will be automatically generated and observed. Fairly simple programs applying the basic rules of mechanics help to predimension a part. Here non-linear viscoelastic stress-strain relationships can be taken into consideration. The use of Finite Elements Methods (FEM) is commonplace in cases where the critical molding situation cannot be analyzed closely enough using empirical methods, or where complex or critical loads are involved. During mechanical analysis and structure optimization using FEM computer programs, the generally inhomogeneous, anisotropic and non-linear material behavior of plastics can be numerically approximated.

The next step is to check a design against accepted design rules (Figure 8). A software package for injection molded parts has been developed at our institute which examines the part geometry for material accumulations, draft angles and undercuts, checks the demoldability of a part and even defines the parting lines of a mold.[6]

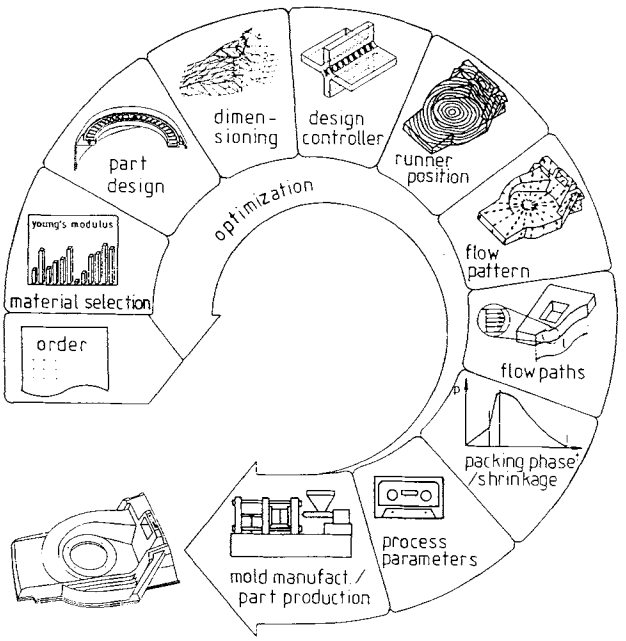

Fig. 8. Part and mold development.

At first sight, these rules and computer programs may appear to be trivial and obvious to the experienced designer. However, the automatic control of the geometry provides an additional check and helps to reduce costs by avoiding problems during materials processing. Such systems still have to be developed for advanced composites, where they will be especially important. The logical consequence of using a computer-guided approach in part design is also to use the computer to simulate processing and detect possible problems before going to the factory floor. The processing conditions can also be optimized in order to get the most out of the material with optimum economy.

Our institute has developed such a program system, called CADFORM-CADMOULD,[6] which incorporates programs

- for calculating the temporal melt front advance, which gives information about weld-lines, air entrapments, and the pressure distribution during the mold filling phase (Figure 9)
- for calculating the shear rates, shear stresses and melt temperatures along freely selected flow paths
- for analysis of the holding pressure phase and estimation of the shrinkage

- for determining the most favorable machine operating point and its dependence on operating parameters; say, to find better processing conditions
- for predicting the orientation pattern

This information is important to help design the mold and to minimize processing problems. In injection molding and extrusion, such programs for the rheological, thermal, and mechanical mold design are frequently and successfully used. Models for reactive materials processing are under development.

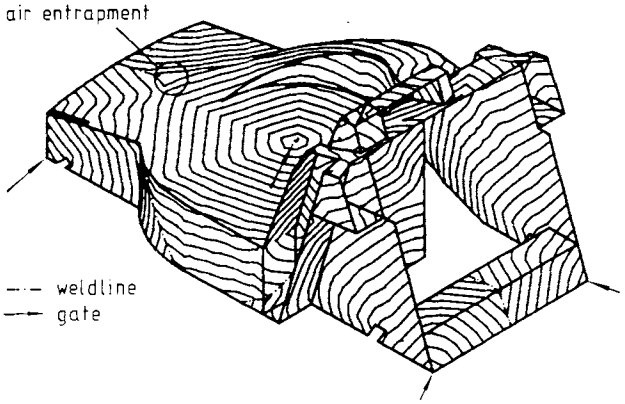

Fig. 9. Filling pattern of a complex part.

Modeling also provides the data to run the equipment, and it is no longer regarded as magic in advanced injection molding, to generate the best machine settings using a computer simulation, and to transfer these data directly to the control cabinet of the machine via the central and machine computers.[7, 8] It is very important to realize that next to reproducibility, proper transfer of information is a key factor in material processing, as is the choice of the most suitable equipment. If one knows, for example, the pressure drop in a cavity of an injection mold, one can predict the necessary clamping force and select the right machine. Such machine selection algorithms which are oriented towards optimum materials processing are to some extent already in existence.[9]

3.1. Processing and Properties of Short-Fiber Reinforced Polymers

If we want to make a part out of a short-fiber reinforced thermoplastic material we want to predict its mechanical properties and see how process variations will affect quality. Many independent investigations have found a symmetrical set-up of layers with different main fiber orientations in injection molded parts. The center layer is about 15% of the cross-section, the sheared layers about two-times 37.5% and the boundary layers about two-times 5%. This distribution

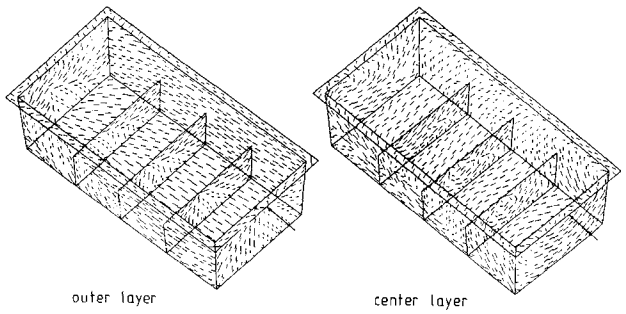

Fig. 10. Computed orientation of fibers.

varies little with injection rate, mass and mold wall temperature, or packing pressure for common wall thicknesses of the molding,[10] and holds true for almost all injection molded parts.

However, we have to keep in mind that there is always a distribution in fiber length and orientation angle, relative to the main orientation direction if we want to predict mechanical part performance. With the models described we can predict the fiber orientation according to the flow pattern during the filling of the cavity. The main orientation directions of the fibers are shown in Figure 10 for the center (core) and outer layers. We see the orientation in flow direction next to the wall and the perpendicular fiber arrangement in the central area.

The designer of a molding, and finally the customer, are in general interested in the overall mechanical properties of a part, and not only in the fiber orientation. Of special interest here, is the anisotropic elastic material behavior at each point of the molding. If this is known one can calculate the overall mechanical properties.[10]

3.2. Processing of Liquid Crystal Polymers

Modeling is a key factor in the processing of liquid crystal polymers (LCP). These new, self-reinforcing materials are very sensitive to their processing conditions. They show mechanical properties similar to steel and ceramics in the main orientation directions, but show little strength or stiffness transverse to the molecular chains. The orientation model shown in Figure 10 can also be found in these polymers (Fig. 11).[11] An attempt to predict their mechanical properties in the same way as for the short-fiber reinforced materials mentioned previously is presently being examined in our Institute.

There is still one problematic area in processing LCP's. The problem relates to those points where two flow fronts come into contact and form a weld-line. Figure 12 shows how two melt fronts will align parallel to each other.[12] This configuration results in poor mechanical performance, but it is possible to overcome this weakness to some extent by controlling the flow, through mold design and filling condi-

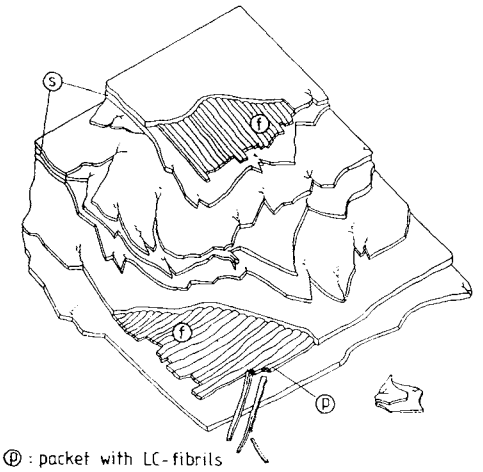

Fig. 11. Model of the "plywood-like structure" of liquid crystal polymers in moldings.

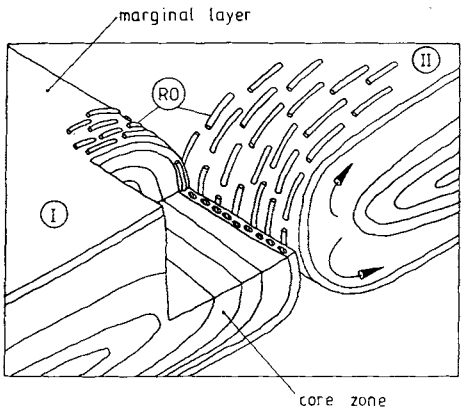

Fig. 12. Welding line in liquid crystal polymer molding. RO: Orientations in the marginal layers. I, II: Partial streams of the melt.

tions. Due to the anisotropic material properties, the analysis of the mold filling in conjunction with the calculation of the orientation pattern, is essential in order to exploit the high mechanical potential of this highly interesting group of polymers.

3.3. Processing of Composites

Advanced composites with endless fibers are relatively new materials with which many engineers and designers have little experience. Comprehensive rules, models, and design methods for composite parts have not been available to designers who are used to working with conventional materials. Today, however, composite parts are gaining importance in general mechanical engineering, especially in the design of rapidly moving parts which have to have a low weight. Designers now must deal with an added set of rules[13]:

- Anisotropic material properties. A part is stiff and strong in the fiber direction but weaker and more compliant in the perpendicular direction.
- Material properties are influenced by processing conditions. For example, the fiber content is influenced by the tension in the filament, the pressure in the parts, and by resin flow.
- Different material failure modes, e.g., if the interlaminar shear strength is exceeded, delamination occurs.

Therefore systematic sets of rules have emerged to aid the designer in laying out a composite part. The special rules that apply to fiber reinforced composites are now being incorporated into a computer aided design (CAD) and engineering (CAE) software program called CADFIBER. With this program, one can make predictions on part properties within reasonable time frames, reducing expensive and time consuming trial and error experiments to a minimum. When completely developed and implemented, CADFIBER will be able to design a part and simulate on minicomputers the processing of that part. The software program is composed of four main modules: materials data bank, construction and dimensioning, process simulation, and quality assurance.

4. Self-Optimization in Materials Processing

In materials processing, be it in product design, equipment design or in process adjustment and control, we are always striving for perfection. Optimization strategies which structure and direct our approach to our final goal are very helpful and of increasing importance. We are experimenting with the so called "evolution strategy" according to *Rechenberg*,[14] which is well suited for optimizing flow channels. We are also applying this strategy to optimize the parameters of electric controllers on-line during processing, and for adjusting injection molding machines. The initial results are very encouraging and will lead to new dimensions in answering questions concerning the optimization of materials processing.

In this paper the necessity to be assisted by the computer has been stressed. Although computerization is an essential factor in materials processing, we are aware that man, who analyzes and acts, is still *the* key factor. I have described an engineering point of view of materials processing. A chemist or a physicist might have another approach and may interpret things differently. That is good, since it is always best to look at things with different eyes. Let us put our expertise, knowledge and will together and face the challenge of future materials processing.

The Kevlar Story—an Advanced Materials Case Study

Process Development
High Performance Fibers
High Impact Composites
Rigid-Rod Polymers

By David Tanner, James A. Fitzgerald, and Brian R. Phillips*

1. Introduction

The Kevlar story is an excellent example of the innovation process where a laboratory discovery is placed into commercial production. It started in the early 1960's with an identified need. In 1965, this led to an important scientific discovery. At this time the research and development phase was entered and in 1972 a 1 000 000 lb per year market development plant was built. By 1982 full commercialization was reached with a 45 000 000 lb/yr. plant. During this period several tough hurdles were encountered. To overcome these obstacles a multi-disciplinary approach was almost always required.

2. The Need for a Heat Resistant Stiff Fiber

The invention of Nylon and subsequent textile fibers provided powerful vision and direction for the research effort aimed at 'super' fibers. In the early 1960's Du Pont was driven by two goals, a fiber with the heat-resistance of asbestos and the stiffness of glass. A fiber of this type could be visualized to fill many market needs. Experimental work indicated that the route to such a material lay with stiff chain aromatic polyamides. These materials, however, had evaded the scientist by virtue of their extreme insolubility and intractability.

3. The Discovery of a Rigid Rod Spinnable Polymer

In 1965 *Stephanie Kwolek*, a research scientist at the Du Pont Experimental Station in Wilmington, made a major discovery. She found that *p*-aminobenzoic acid could be polymerized and solubilized under special conditions to yield a rigid-rod spinnable polymer. Initially, when these polymer solutions were first made, it was not believed that they would spin into fibers since the solution was opaque and could not be clarified by heating or filtration. This implied that there was inert matter dispersed in the spin dope which would plug the spinneret holes. However, the fibers spun well. We now know that this capacity was due to the formation of polymer

[*] Dr. D. Tanner, Dr. J. A. Fitzgerald, Dr. B. R. Phillips
Fibers Department, E. I. Du Pont de Nemours & Co., Inc.
Wilmington, DE 19898 (USA)

liquid crystals. The stress–strain curve of the first aramid fiber tested was startling, and the test was re-run several times for confirmation. A true step change in properties was achieved vs. existing synthetic textile fibers.[1]

The behavior of rigid-rod molecules in solution is quite different from flexible molecules (Fig. 1). Flexible polymers like Nylon, in dilute solution, have a low level of entanglement. However, at higher concentrations the random coils become highly entangled. Spinning and drawing lead to only partially extended chains due to the high level of entanglements. Hence, properties such as tenacity and modulus reach only a small fraction of the theoretical values.

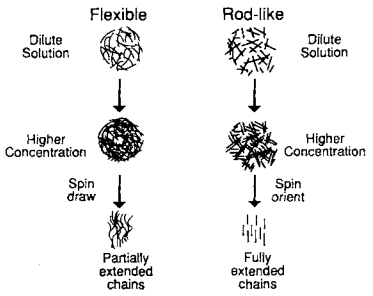

Fig. 1. Schematic illustration of the solution behavior of rigid and flexible polymers.

On the other hand, due to their rod-like conformation, more rigid polymers like the *p*-aramids, in going from dilute to higher concentration do not form random coils. At a critical concentration they can no longer populate the solution randomly. At this point, in order to pack more molecules into the solvent, they are forced to align parallel to each other in randomly oriented liquid crystalline domains.[2, 3] Under shear, as in a spinneret capillary, the liquid crystalline domains orient in the direction of the deformation. This leads to fully extended chains in fibers and the observed high strength and modulus.

4. Research and Development

Following *Kwolek*'s discovery, the first obstacle was encountered, i.e., the *p*-aminobenzoic acid raw material was too costly to justify scale-up. At this point a major research and development program was launched. The aim was to develop a deeper understanding of the formation of liquid crystalline solutions and to identify a lower cost rigid-rod polymer system. This effort led to a variety of rigid polymers with potential for formation of liquid crystalline spinning solutions and strong, stiff fibers.[4–6] The best candidate was the polymer from *p*-phenylenediamine and terephthalic acid (PPD-T). This polymer eventually became the basis for Kevlar. It had the lowest cost ingredients, the highest symmetry, and theoretically the highest stiffness. However, to produce the best properties the spinning solvent had to be 100% sulfuric acid, and the resulting spinning solutions were very viscous. Low spinning speeds were needed for good properties and therefore the process was uneconomical.

Thus, the second obstacle was encountered; the process was not practical. This became starkly apparent when the researchers first described the invention to the manufacturing and engineering groups who would have to design, build and operate the plant. They didn't want it! The sulfuric acid solvent was unconventional and highly corrosive, process yields and throughput were very low, and investment very high. These are the realities that research people do not pay much attention to when they are at the frontiers of discovery.

A major breakthrough came when another Du Pont research scientist, *Herbert Blades*, made two crucial discoveries.[7, 8] First, he found that PPD-T and sulfuric acid form a crystalline complex at a polymer concentration of 20% (vs. 10–12% by previous workers). He unexpectedly formed this complex by going against conventional wisdom and heating the polymer solution containing the 100% sulfuric acid. This complex melts around 70 °C and is composed of PPD-T:sulfuric acid in the ratio 1:10. This enabled spinning at much higher polymer concentrations than had been previously possible.

The second advance was in spinning where he used an air gap between the spinneret face and the quench bath (Fig. 2). When the PPD-T/sulfuric acid complex was melted and spun through the air gap into cold water, very high spinning speeds could be obtained through attenuation of the molten

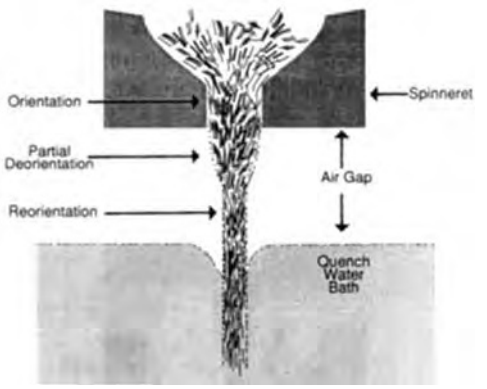

Fig. 2. Schematic of air gap spinning high concentration PPD-T solutions in sulfuric acid.

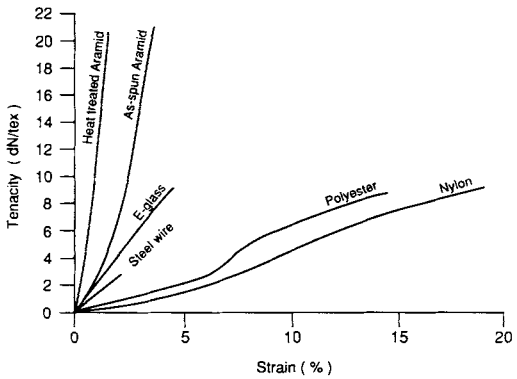
spinning solution in the air gap. Although partial deorientation occurs as the polymer solution emerges from the spinneret, the very high extensional shear in the air gap results in extraordinary orientation and tensile properties of the final as-spun fiber (Fig. 3). The air gap spinning technology gave birth to an improved product version which is today's Kevlar and ultimately led to Du Pont's heat strengthened high modulus Kevlar 49 product.



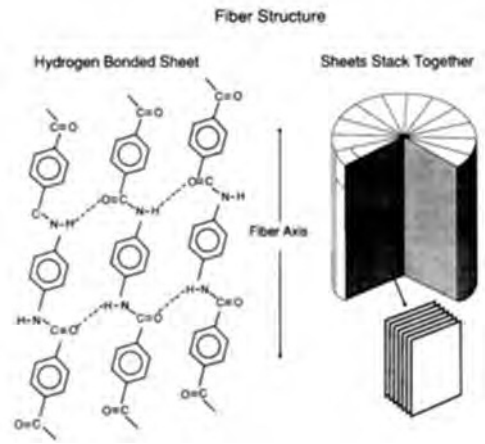


Fig. 3. Stress strain curves of reinforcing fibers.

The reason for these truly outstanding mechanical properties most likely lies in the microstructure of the fiber. Kevlar is a hydrogen bonded highly crystalline material.[9] Sheets of cells extend across the radius of the fiber resulting in almost perfect radial as well as longitudinal order. This level of three-dimensional order had never been observed in a fiber before. Kevlar has a molecular orientation parallel to the fiber axis, and a well defined radial crystalline orientation (Fig. 4).

5. Scale-Up to a Market Development Plant

The air-gap spinning discovery was an invention worthy of scale-up. The product was certainly unique, the process scalable and the economics satisfactory. The next step in the innovation process and the next obstacle was to scale-up to a market development plant. Translation of a laboratory discovery to a practical, scalable, commercializable process is one of the hardest tasks faced by any technology-driven industry. In the case of Kevlar, a task force of dozens of scientists and engineers of many disciplines was assembled. Some of the Wilmington researchers moved to the plant site in Richmond, VA, USA. The task was to develop the manufacturing basic data and tackle scale-up. In less than two years from *Blades'* laboratory discoveries, Kevlar was being shipped from a 1 000 000 lb per year market development plant. This timetable, considering the complexity of the process, was unprecedented in the Du Pont Fibers Department. Five years later the commercial product was being produced in a 15 million pound per year plant.

During the scale-up stage several difficult hurdles were encountered, some quite unusual and unexpected. A complex laboratory process had to be translated into a workable plant operation. The ingredients were corrosive, there were environmental concerns such as waste disposal, and the polymerization solvent had an unexpectedly high level of toxicity. Two of these hurdles are described below.

An unusual environmental problem arose involving waste disposal. The spinning solution is based on a complex containing five moles of sulfuric acid per PPD-T amide bond (or four pounds of sulfuric acid per pound of polymer). Disposal of the spent acid after spinning was a problem. The best option turned out to be conversion of the sulfuric acid into calcium sulfate (gypsum). For every pound of fiber seven pounds of gypsum is generated. This year the Kevlar plant is generating a lot of gypsum—quite a storage problem! As a matter of interest, the produced gypsum is attractive to both wallboard and cement manufacturers, and eventually the gypsum will be recycled.

The second hurdle deals with toxic materials. In the Kevlar process, two solvents are used. The spinning solvent is sulfuric acid, discussed above, and the polymerization solvent was hexamethylphosphoramide (HMPA). The Kevlar business was in the scale-up stage on a fast track heading toward full commercialization. Suddenly it came to a self-imposed barrier—the toxicity of the HMPA polymerization solvent. Du Pont pays much attention to the toxicity and handling of hazardous materials. Use of HMPA on a large scale was new, but the material was well known for many years and there were no highly unusual toxic effects reported. To be completely sure about HMPA toxicity, a lifetime exposure study with rats was initiated by Du Pont to determine any possible carcinogenicity potential.[10] This study was one of the first of its kind, and carried out purely as a precautionary measure. The results of that study showed that HMPA was an experimental animal carcinogen. Immediate steps were taken in the handling of HMPA to be certain that there was no hazard to the workers, the community, or the customers.

It is, however, preferable not to use a potentially hazardous material if a safer alternative can be found. Therefore, a crash technical program was mounted to find an HMPA replacement. The task was to find an acceptable polymerization solvent of low toxicity; one that would give polymer yielding fiber properties identical to those already introduced to the trade, as well as fitting into the process and the expensive equipment layout designed for polymerization in

HMPA. The chemistry turned out to be relatively straightforward.[11] The combination of *N*-methylpyrrolidone (NMP) and calcium chloride was selected as the solvent of choice. The engineering and product development were, however, formidable challenges.

Polymerization in NMP/$CaCl_2$ proceeded smoothly and a high inherent viscosity polymer was obtained with no difficulty. The polymer, however, could not be spun to the equivalent tenacity of the same inherent viscosity polymer prepared in HMPA. The problem turned out to be molecular weight distribution. The data showed that at equal inherent viscosity, the average molecular weight of polymer made in the NMP/$CaCl_2$ system was lower than in the HMPA system. Using a gel permeation chromatography technique, this difference was traced to the presence of a large low molecular weight fraction in the NMP/$CaCl_2$ system (Fig. 5). Further analysis showed that this resulted from precipitation of oligomers from the polymerization mixture. These were not

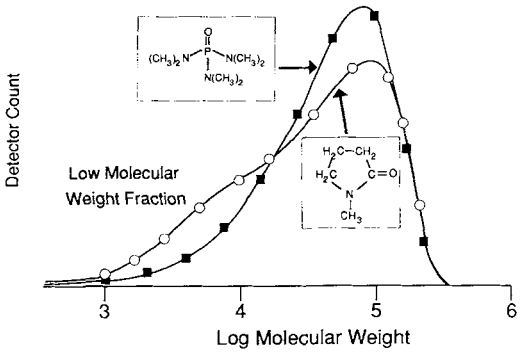

Fig. 5. Molecular weight distribution curve for PPD-T prepared in HMPA and in NMP/$CaCl_2$ by gel permeation chromatography (GPC).

present in the HMPA system because of it's superior solvating power. The problem was solved through the design of a reactor system to eliminate early nucleation and precipitation of low molecular weight polymer. This is another example where solving a problem required multidisciplinary chemical and engineering skills. Extensive internal and trade testing demonstrated that the Kevlar fibers made in the two polymerization systems were indistinguishable.

The program to find an alternative solvent took an estimated 40 man-years of technical effort. Throughout the scale-up phase there was an underlying confidence in the multidisciplinary team. There was no hurdle that could not be jumped, although at times it took considerable energy and support to do so.

6. Full Commercialization of Kevlar

Thus far, the need, the discovery phase, the obstacles in moving the R & D along, and the process development hurdles in scale-up to a market development plant have been described. Perhaps an even greater challenge was to demonstrate the market potential of Kevlar. This was necessary to justify the final step in the innovation process, a full scale commercial plant requiring a huge US $ 400,000,000 investment. Hence, throughout the development there was intensive parallel effort to find practical applications for this new fiber. For Kevlar to be a commercial success a sufficient value in use had to be found versus incumbent fibers like Nylon, steel, fiberglass and carbon to warrant a pricing structure that made economic sense.

7. Systems Approach to Applications for Kevlar

Early in the development, it was recognized that Kevlar was a unique fiber that would not automatically fit into existing applications. This became apparent from initial evaluation in tires, ballistics, composites, ropes, cables, etc. Each application had to be looked at as a "system" requiring a systems approach. Early partnerships with customers were vital to success. This part of the program can be as scientifically challenging and exciting as the *p*-aramid discovery itself.

As a framework for thinking about the total system a simple tetrahedral model can be visualized (Fig. 6). At the base, each corner represents a different knowledge center in the development. At the left corner is the chemical structure, e.g., the polymer composition. At the right corner is the physical structure, e.g., the degree of orientation or crystallinity. The back corner represents the fiber properties, e.g., tensile or surface characteristics. Ongoing iteration between these three base corners, which can be referred to as molecular and process engineering, is important. However, this model adds a third dimension at the apex of the tetrahedron. It involves the creative integration of the base technologies to give an advanced, composite structure. The selection of design criteria for parts, devices, and objects, i.e., "systems" engineering, has been vital to Kevlar product development. It requires the combined talents of professionals in many disciplines. A final advanced structure usually involves much interaction between each corner of the tetrahedron and

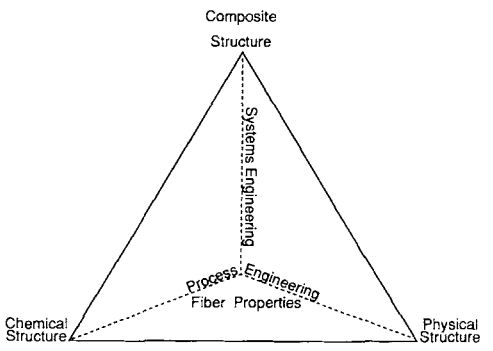

Fig. 6. Tetrahedral model of a systems approach to applications development.

sometimes multiple products organized into an integrated total system.

To illustrate the systems approach, two examples have been selected: Kevlar in ropes and cables and in composites. The main driving force for Kevlar in ropes and cables is the high strength per unit weight, inherent low elongation and low creep. In air, the specific strength is seven times, and in sea water more than twenty times that of steel. This means one can use smaller, lighter more easily handled lines. In long lengths where the self-weight of steel becomes critical, Kevlar can offer a greater payload.

The application to be described is that of a riser-tensioner line. The systems technology involved a specially engineered rope design to reduce internal stresses in order to increase wear life. Riser-tensioner lines are used on floating offshore oil drilling platforms, where their purpose is to keep the rise pipe or outer drill casing at a constant elevation and under uniform tension while the vessel surges with the waves. These are normally 44 mm diameter steel wire ropes which experience considerable cycling over pulleys as the platform moves. Laboratory studies had shown that small diameter Kevlar ropes could far surpass steel in cycling performance over pulleys. However, scale-up of the best small constructions to 44 mm diameter surprisingly gave rope lifetimes that were only 5–10% that of steel wire rope. Analysis showed that internal forces in the twisted rope rise rapidly with increasing diameter.[12, 13] These internal loads stem from radial squeezing forces which increase rapidly with increasing twist levels, bringing pressure against the pulleys and leading to high frictional heating, high internal abrasion, and shear fatigue failure of yarn as the rope elements move.

Cooperation with steel cable manufacturers lead to several design changes (i.e., Fig. 7) which improved the lifetime of

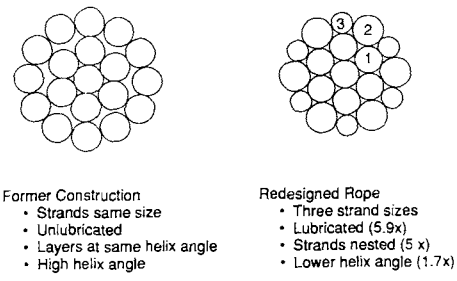

Fig. 7. Rope constructions.

Kevlar ropes over 50-fold. On the left is the former construction, and on the right the redesigned rope. One change was to increase the number of strand sizes from one to three. The purpose was to minimize cross-overs of inner and outer strand layers by nesting the outer strands in the inner layer. This compacted the structure and spread the lateral loads uniformly over a greater area giving a five-fold improvement in lifetime. A second change was to lubricate the strands by jacketing each strand with a braid impregnated with fluorocarbons. This reduced friction, heat buildup, abrasion and internal shear stresses resulting in a six-fold improvement. The third approach was to optimize the twist helix angle to minimize radial squeezing forces without seriously affecting other rope properties. This gave an additional two-fold improvement. The result was a rope having more than three times the life of steel in severe laboratory tests and more than five times in service. More than a dozen oil rigs have utilized Kevlar riser-tensioner lines, including those from major drilling contractors such as Santa Fe International, Western Oceanic, Zapata and Sedco.

A future application of Kevlar rope under development is that of deep water mooring lines for the same type of oil platforms that use riser-tensioner lines. Here the light weight of Kevlar gives less sag than heavy steel chain or steel wire rope. This allows operation at water depths several times that of steel. A one million pound break strength Kevlar rope has been deployed by Conoco in the Gulf of Mexico and by Petrobras off the coast of Brazil.

The next systems example involves the use of Kevlar in aircraft composites. The materials base is Kevlar, carbon fiber, and epoxy resin. The driving force is high tensile strength and modulus per unit of weight and toughness. The systems technology involves hybrids of Kevlar and carbon fibers reinforcing an epoxy resin to gain the best balance of mechanical properties and damage tolerance, i.e., the ability to tolerate abuse and to survive a catastrophic impact. Carbon fiber confers high stiffness and compressive strength but because of its rigid coplanar ring structure it is unyielding and fails by brittle fracture. Hence, it is unable to survive a catastrophic impact.

Kevlar has structural features that lead to good damage tolerance because of a ductile compressive failure mode. This can occur by a compressive buckling of PPD-T chains. At a compressive strain of about 0.5%, we believe that a buckling of *p*-aramid molecules occurs by molecular rotation of the amide C–N bonds to accomodate configurational changes. Figure 8 shows the shift that we believe is occurring from the *trans* configuration shown on the left to the *cis* shown on the right. This can result in a yielding to the imposed stress without bond cleavage. The result is an accordion-like collapse on impact. This continues to be a useful model for explaining the compressive properties of Kevlar composites.[14]

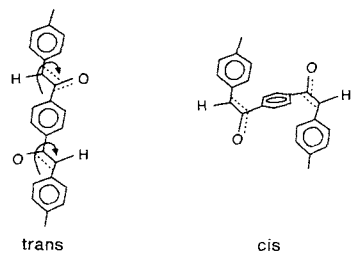

Fig. 8. PPD-T chain buckling under compression.

The response of Kevlar to compressive strain resembles that of aluminum. This metal-like ductility of Kevlar reinforced composites is illustrated by the flexural stress-strain behavior for epoxy matrix composites containing carbon, glass, Kevlar, and aluminum (Fig. 9). This is because in

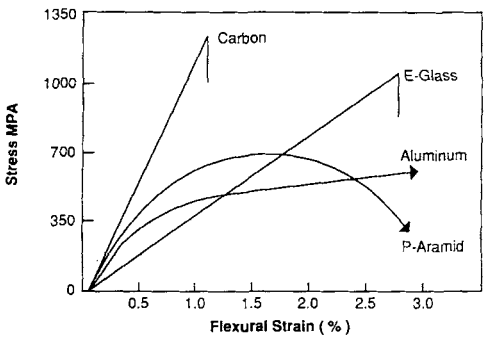

Fig. 9. Flexural stress strain curves of unidirectional epoxy matrix composites.

bending, one side of the composite is in compression and the accordion-like "yielding" contributes to the metal-like behavior. Crashworthy composite systems have been explored using a crushed tube test to compare materials. This test involves the crushing of filament wound tubes with a drop-weight impact tester. There is a marked difference between the failure modes of Kevlar aramid and carbon fiber-wound tubes. The tube reinforced with Kevlar fails by a progressive buckling mode, similar to that observed for an aluminum tube. The structure is damaged but still intact and able to sustain a load. The carbon fiber-wound tube shatters. However, it does reach and sustain a higher load just prior to failure, and absorbs more total energy in the crushing process than does the tube wound with Kevlar.

Hybrid technology that combines Kevlar and carbon fiber as a wound structure offers a better balance of properties. High energy absorption, within 7% of that of the all-carbon tubes, and good structural integrity after crushing, approaching that of the aramid-wound tube, is achieved. Hybrid composites of Kevlar and carbon fibers are used in commercial aircraft such as the Boeing 767, 757, and 737, as well as in helicopters and commuter aircraft. Other applications under development include filament wound structures, for example, those used in Trident missile cases and in pressure vessels. The Kevlar provides external damage protection, particularly during transport.

8. Summary

Limited space permits description of only two examples of Kevlar applications research. There are numerous others. In the early product development there were some indications that Kevlar would go mainly into tire reinforcement. This has turned out not to be true. In the mid-seventies Kevlar was participating in only ten market segments and less than fifty specific applications, but today, it is in more than twenty market segments, serving more than two hundred applications, and continued growth is anticipated. Kevlar is produced in a 45 million pound plant in Richmond, VA, USA. In 1988, a second plant was started up in Northern Ireland and plans for a third plant in Japan were announced. The Kevlar innovation story exemplifies the kind of obstacles, interdisciplinary skills and systems approach involved in bringing a laboratory discovery to commercial reality. The story is still unfolding and applications currently not envisioned will undoubtedly become important in the future.

Materials Processing

By Michael Salkind*

As we approach the second century of aerospace, increased emphasis is being placed on endurance, reliability, ease of manufacture, and lower cost, in addition to weight saving. This change in emphasis will have a major effect on not only the selection of materials, but on how materials are integrated into the total system design process. Subsonic aircraft will continue to play a major role in our future with emphasis on increased durability and lower cost. Non-metals that do not corrode are attractive; however, the issues of reliable fracture resistance to ensure safety and durability as well as ease of manufacture and inspection will be key. Higher performance engines and hypersonic aircraft will require higher temperature materials (including a substantial amount of non-metals) along with reliable toughness and ease of manufacture. In space, weight will continue to be a major driving force along with the need for long term vacuum and radiation stability. Ease of assembly and multifunctional use (e.g. electrically or thermally conducting structure) will be additional needs for spacecraft materials. We have reached a point in the evolution of structural materials where we are moving away from processing naturally occurring materials toward synthesizing designed microstructures to perform specific functions. The mathematical modeling of microstructure–property relationships and new chemical and biotechnical synthesis techniques appear to be critical technologies for the future. In addition, the future materials developer will need a broader understanding of the total structural life cycle so that the impact of utilization, maintenance, and training requirements in the design of new materials can be considered.

1. Introduction

For more than 40 years, mankind has not had a major war nor used a nuclear weapon in anger. The USA and USSR are experiencing a decided recent warming in relations and western economic hegemony seems to be yielding to the Pacific miracle. We are seeing more and more transnational companies which challenge some of our assumptions about national economic competitiveness and indeed the definition of a company or a nation. In 1964, General *Schriever* said "The traditional geographical barriers are really meaningless in today's world ... (which) emphasizes ... the inseparability of political, military, economic, and psychological factors."[1] We are coming to grips with the facts that our environment is delicate and that our natural resources are finite. Against this background, we can conclude that the 21st century, the second century for aerospace, will surely bring great change.

The first century of aerospace was clearly dominated by performance considerations. In the future we will still be pushing back the weight and temperature barriers but within the context of limited mineral, financial, and human resources. We will need to provide improved performance for more capable military vehicles, more economical transport vehicles, and new hypersonic vehicles and spacecraft. However, these new capabilities must be more affordable, more reliable, easier to maintain, and less demanding of our environment, including our mineral and energy resources. An historical summary of tactical aircraft costs showing the inexorable climb in unit cost, Figure 1, led *Norman Augustine* to postulate that:

> "In the year 2054, the entire defense budget will purchase just one tactical aircraft. This aircraft will have to be shared by the Air Force and Navy three and a half days each per week, except for leap year, when it will be made available to the Marines for the extra day."
>
> *Augustine's First Law*[2]

Augustine's "first law" may be amusing hyperbole, but the underlying data are real and, taken together with the global economic realities, indicate that cost must be a far more significant consideration in future aerospace systems.

Maintenance costs of tactical aircraft also indicate the inexorable upward trend.[2] *Augustine* concluded:

> "Aircraft flight in the 21st century will always be in a westerly direction, preferably supersonic, to provide the additional hours needed each day to maintain all the broken parts ..."
>
> *Augustine's Second Law*[2]

[**] The author would like to thank his colleagues at AFOSR, *J. Dimmock, G. Haritos, A. Rosenstein, L. Schioler*, and *D. Ulrich*, for their assistance in preparing and reviewing the manuscript.

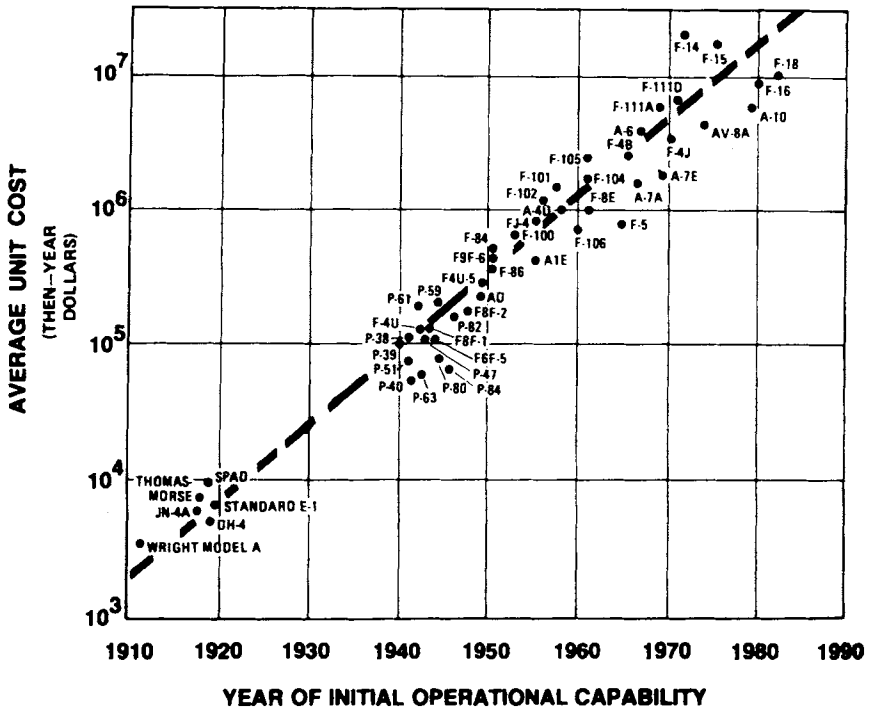

Fig. 1. The unit cost of tactical aircraft has increased consistently by a factor of four every ten years since the beginning of the aviation age. After *Augustine* [2].

Human resource support requirements are rising logarithmically while the capabilities are not. Thus we must conclude that in the 21st century, we will need to produce aerospace systems with more performance, but which, at the same time, are more affordable and supportable.

2. A New Age

"What Age is next?" asks an Alcoa advertisement.[3] *Forney* points out that we have, in rapid succession, entered the Atomic Age, the Space Age, the Information Age, and now the Age of Composites.[4] General *Schriever* called the advent of composites a new age in materials, comparable to the advent of the Iron Age.[1] *Inomori* has said we are entering Shin Sekki Jiddai (the New Stone Age).[5] The Alcoa advertisement goes on to say that we are entering the Engineered Materials Age. Clearly, composites, advanced ceramics, and metal alloys are all subsets of engineered materials or what *Drucker* describes as "... design of the microstructure to give any combination of macroscopic properties."[6] A recent study by the U.S. Congressional Office of Technology Assessment entitled "Advanced Materials By Design" captures this perspective.[7]

We are therefore experiencing a rapid change in materials technology simultaneously with rapid changes in the performance and economic demands on new materials. It is imperative that we see our role as *designers* of materials within the broader context of a systems design. The contrast between design with composites and design with metals is presented in Figure 2. Although the figure relates to fiber composites,

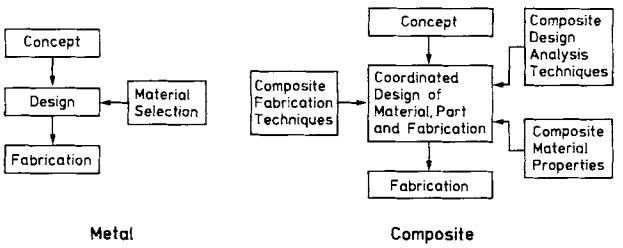

Fig. 2. The advent of materials with engineered microstructures, such as composites, is changing the way materials design is integrated into the total systems design. After *Salkind* [8].

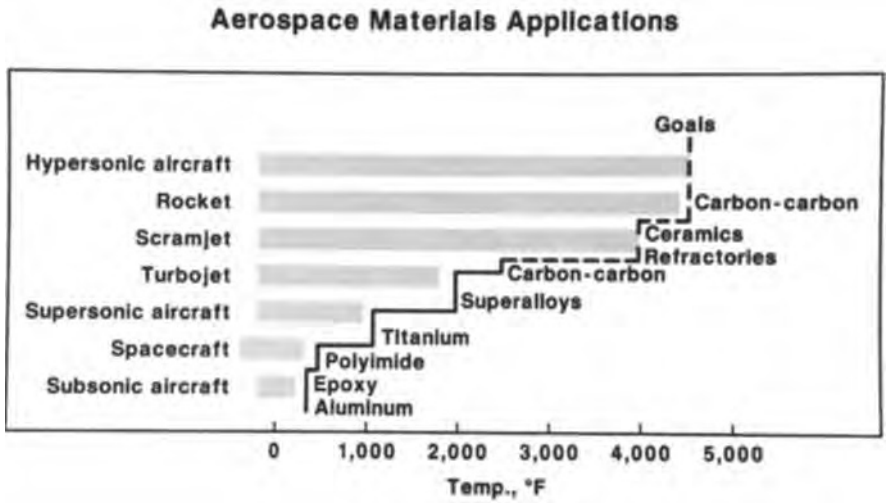
it is a microcosm of the newer approach of designing the microstructure (whether metal, ceramic and/or polymer) for the requirement, compared with the former approach of separate materials development. The materials designer must be part of a design team that considers not only the function, but also the manufacture and life-cycle support of the system. This changing perspective implies changes in how we define ourselves, our organizational roles, our educational goals, and the context of future materials research. Materials research and development is no longer just the purview of the Materials Department.

3. Aerospace Needs

Types of aerospace systems and their range of operating temperatures, together with the capabilities of structural materials are summarized in Figure 3.[9] Materials are the limit-

ADVANCED MATERIALS



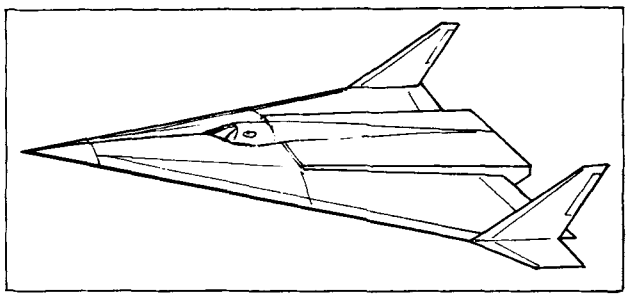


Fig. 3. Summary of Aerospace Materials Requirements and Materials Capabilities. After [9]. $x\,°F = \frac{5}{9}(x-32)\,°C$.

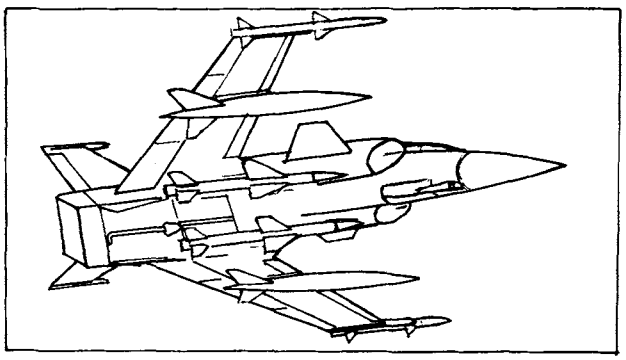
ing technology at the higher temperatures. Over the entire range of temperatures, both materials performance and cost are critical to the mission or commercial success of the system.



The National Aero-Space Plane (NASP) embodies both significant weight and temperature challenges. Such a hypersonic (Mach 5+) aircraft would take off and land on conventional runways and have both military and commercial applicability. A technology demonstrator, designated the X-30,[10] is planned to be flown in the 1990's to explore the complex aerodynamic, propulsion, structures and materials challenges for the next generation of operational aircraft. *Hadcock*[11] has projected the probable airframe materials and design criteria for such aircraft, as shown in Figure 4. The likely propulsion system, a supersonic ramjet or SCRAMJET, is basically an integral part of the airframe. Multi-phase materials with engineered microstructures will be dominant in such aircraft.

The Advanced Tactical Fighter (ATF) will be the Air Force's major tactical weapons system in the early 21st century.[12] It will combine high maneuverability with supersonic cruise, and employ low-observable technologies. In addition to superior performance, it must have double the maintenance interval of current fighters, be more readily supportable, and meet stringent cost requirements. *Hadcock* has summarized the probable material usage and design drivers for future fighters, Figure 5.[11] As with the NASP,

	Airframe Materials	Airframe Design Criteria
Wing/Fins	Oxidation-Stable Carbon/Carbon	Fail Safe
Fuselage	Superplastic Formed/Diffusion Bonded Refractory Alloys	Damage Tolerant

[a] $x\,°F = \frac{5}{9}(x-32)\,°C$.

the requirements are primarily multi-phase materials requiring engineered microstructures. The requirement for low-observable technology, including radar and infrared signatures, strongly drives the choice of the structural configuration as well as the material selection, particularly for stealth technology aircraft such as the B-2.[13] The materials for such aircraft must be designed to meet not only structural but also electromagnetic requirements. Such multiple purpose designs require the materials engineer (and ultimately the materials researcher) to define his or her role within the broader systems design concept as described earlier.

The joint Department of Defense/NASA/Industry Integrated High Performance Turbine Engine Technology (IHPTET) program[14] has the goal of doubling the performance (thrust-to-weight-ratio) of turbine engines by the beginning of the next century. The materials challenge, Table 1, involves major usage of non-metallic materials which have traditionally been avoided because of their low toughness.[14]

Although first cost, and total cost of ownership, are becoming far more important for military aircraft, such considerations have always been dominant for commercial aircraft. There currently exists an economic dilemma in terms of new materials usage in commercial planes.[15] Whereas the soaring fuel prices of the 1970's accelerated the need for fuel efficient technologies, including composites and aluminum–lithium alloys for weight reduction, the oil glut of the 1980's slowed down the introduction of new aircraft and consequently new technologies. According to *Swihart* the price premium that the market would bear for a 10% fuel saving dropped from 16% in the 1970's to 2.5% in 1985.[15] The cost of ownership has replaced the fuel cost as the largest part of the commercial transport direct operating cost.[16] The next generation of transport aircraft will likely consist of derivatives of current models. As a result, the opportunities for introduction of new materials will be very much dependent upon economic considerations. For composites, which could be as much as 65% of the structural weight of new transports,[16] the cost of fabrication is a major factor. The emphasis on cost further reinforces the theme that the materials design must be more fully integrated into the systems design.

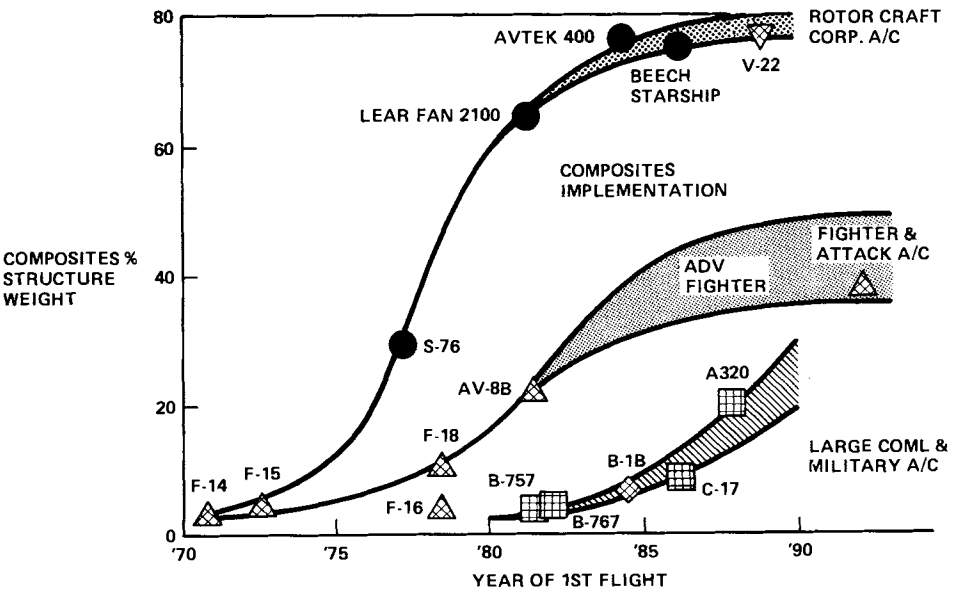

Fig. 6. Increased Usage of Composites in Aircraft. After *Hadcock* [11].

The introduction of new materials, such as composites, has been more rapid in helicopters and light aircraft than in tactical or transport aircraft, Figure 6.[11] Prototype all-composite helicopters have been built[17-19] and have demonstrated the potential for significant (30%) cost reduction. The cost reduction accrues primarily from an order of magnitude reduction in the number of parts and the attendant assembly labor reduction, which more than overshadows the higher materials costs.

There is significant future potential for both military and civilian usage of space. Whether or not the current world situation slows the development of space weapons, there will be a need for both military and civilian communication, surveillance, and navigational satellites. In addition, there is the potential for exploiting the space environment for materials (including biological materials) processing. The NASA Space Station represents a major thrust in space in the 21st Century. Because of the high launch costs, weight remains a more dominant factor in spacecraft than aircraft; however, long term durability continues to be an increasingly important consideration. The combined effects of vacuum, radiation, and thermal cycling are particularly challenging, especially for non-metals. The use of metal matrix composites for microwave packaging is typical of the emerging need to integrate the materials design with the total system requirement.[20] In this case the material functions simultaneously as a structure and a heat rejection mechanism, and meets stringent electromagnetic and thermal stability requirements. So-called "smart materials", that have embedded sensors and can change characteristics as required, are the obvious extension of the integration of materials design with systems design.

4. Research Opportunities

In examining research opportunities it is clear that we must posture ourselves to design microstructures to meet a broadened range of requirements. The relationship between microstructure and properties is the traditional domain of the materials scientist. The classic work of *Hall*[21] and *Petch*[22] in the 1950's, relating grain size in steel to mechanical properties, established the significance of quantitative microstructure–property relationships. There is a need to establish these relationships in a more precise quantitative form than has been done in the past. Traditional continuum mechanics, based on the assumption of homogeneous continua, cannot handle multi-phase materials nor discontinuities such as damage. Although micromechanics has been developed to handle some simple aspects of fiber composites, a new level of materials mechanics is needed to provide the mathematical basis to truly design a general microstructure.[23] Such an approach requires extensive collaboration between materials and mechanics researchers. There is also a need for a more precise and universal mathematical description of microstructure as the common language of this collaboration. Some metallurgical approaches[24,25] coupled with the use of fractals[26-28] appear promising. Fractal dimension can be a powerful mathematical description of microstructure. We need a standardized language to describe the shape and size distribution of each phase (including interfaces) and its spatial arrangement. Such a scheme must be able to characterize such complex structural materials as soils (solid particles plus liquid and gas phases), chemically bonded ceramics (including concrete and cement), and deliberately porous materials.

5. Tough Materials

It is clear that in developing a new quantitative mechanics of microstructures, the property we call toughness is probably least understood. Our emergence from the Stone Age, more than five thousand years ago, was prompted by the lack of toughness of ceramics. Because metals exhibit extensive plastic deformation, we have come to equate ductility with toughness and have assumed, erroneously, that uses of materials exhibiting little or no plastic deformation are limited by their brittleness or low toughness. In recent years, experience with multi-phase materials, especially fiber composites, has taught us that there are microstructural alternatives to plastic deformation which can handle stress concentrations and exhibit significant toughness.

Toughness tests normally involve notched or pre-cracked specimens and measure resistance to damage propagation. For inhomogeneous anisotropic materials, it is not always clear how such measured properties relate to actual performance in structures. The following discussion treats such measured resistance to damage propagation as an indicator of toughness. Ceramic and carbon fiber reinforced glass-ceramics have exhibited macroscopic toughness values over 20 MPa $m^{1/2}$ which is comparable to metal alloys.[29-30] *Cook* and *Gordon* described how the fiber matrix interface can open to blunt a crack, which is analogous to plastic deformation blunting the crack tip in metals.[31] The role of the fiber interface in imparting toughness has been the subject of extensive discussion. Fiber surface treatment has been shown to dramatically change the toughness of fiber reinforced polymers,[35] hydrated cement,[36] and ceramic/ceramic composites.[37-39] The research challenge of understanding the microstructure–toughness relationship is also dependent upon the complex state of stress determined by the other microstructural characteristics, such as the relative properties of the phases and their shape, size, and spatial arrangement.[37,40-44] The exact mechanism of toughening will be dependent upon the interaction of the relative and absolute properties of the phases and the interface. In addition to the composite approach to providing toughness to otherwise brittle materials, there have also been extensive efforts to control[48,49] and characterize microstructural defects and to provide phase transformation toughening.[50]

The groundwork for the required mathematical mechanics treatment of microstructure–property relationships has begun. *Kunin* has extended the description of elastic media to include microstructure.[51] Major efforts have been made to account for damage,[52, 53] and inelastic behavior.[54] A concerted effort is needed by materials and mechanics researchers to develop a more precise mathematical basis for the design of microstructure.

6. Biological Models for Designed Microstructures

In a fascinating new book, *Gordon* points out that living organisms provide manifold examples of structural materials, engineered within a total system design including cost (defined as metabolic cost).[55] Bone is a marvelous example of an engineered microstructure. It is a fiber composite containing stiff hydroxyapatite fibers in a collagen matrix. The fibers are oriented to resist the principal loads and, because living bone is constantly dissolving and regenerating its structure, can reorient the microstructure to respond to changes in loading (e.g. a fracture). In addition, bone microstructure simultaneously performs non-structural functions such as conveying blood via built-in tubular cells. Bone is not as structurally efficient as wood (another living engineered fiber composite), because it is optimized to function along with tendons and muscles in a total structural system.

In a remarkable example of man imitating nature, *MacCready* et al. built a flying replica of the extinct reptile *Quetzalcoatl Northropi* (QN).[56] In the course of doing so, he studied the detailed design of engineered materials in birds within the context of complex system design (Fig. 7). A key design factor in the QN replica was an on-board control system (brain analog) to maintain structural and dynamic flight stability under changing loading conditions. The structural materials design could not carry the flight loads in the absence of the control system, which was inadvertently demonstrated when the QN was accidently launched with its control system off. Analogously, the human body cannot stand straight with its control system (brain) off. So-called smart materials, containing sensors and actuators to change structural characteristics, are future materials research opportunities which could mimic the integrated systems of biological materials.

Fig. 7. A man-made *Quetzalcoatl Northropi* incorporating nature's design concepts. The materials design was fully integrated with structural and control design. Photo courtesy of Aerovironment Corp [56].

7. Processing Opportunities

Perhaps one of the most challenging materials research opportunities is processing. Not only will we be challenged to economically produce geometrically precise microstructures, but we will also likely shift away from energy intensive thermal processing toward more low temperature chemical and even biological processing. This will require an additional shift in our perspective and a blurring of the traditional roles of materials supplier, processer, and user.

Sol–Gel processing of ceramics is an example of a new lower temperature chemical technique.[57, 58] It consists of polymerizing a porous ceramic gel from solution and subsequently drying and densifying it. The technique allows processing below 500 °C compared with traditional melt processing at three times that temperature. Recent research has focussed on chemical additives to control the kinetics and therefore the pore size, distribution, and residual stresses.[59] Perhaps more important than low temperature processing, is the opportunity to produce composites by sol–gel processing.[58] By dispersing two or more phases in the sol, precisely controlled multiphase microstructures can be produced at fine scale. The term nanostructure or nanocomposite has been used to describe such structures with nanometer scale phased dimensions. Because the size of each phase is only a few atomic layers, such materials tend to have properties significantly different from bulk properties.[60] This has significant potential for both structural and electronic applications.

Another approach is reaction processing, in which the components react chemically in the solid state with a gas or liquid phase to provide densification.[61] An extreme example of this is self-propagating high temperature synthesis involving a combustion reaction.[62] The LANXIDE process involves forming solid oxide structures by the controlled reaction of a molten metal with an oxidizing vapor. By conducting the reaction in the presence of a solid second phase, composites can be fabricated.[63]

A very intriguing materials research opportunity lies in mimicking the way living organisms process ceramic composite structures such as bone and shell. *Calvert* and *Broad* have used such bio-mimetic processing to produce metal oxide materials.[64] Coupled with our new insights into the

structure of DNA and the ability to bioengineer designer organisms, it seems a natural extension to design organisms to produce precisely defined microstructures.

There are also significant research opportunities in the area of processing metal alloys and metal matrix composites.[65, 66] Castings are attractive because of the low cost and their potential for production of net-shape or near net-shape parts. Processes such as directional solidification to control or eliminate grain boundaries and hot isostatic pressing to eliminate defects have moved castings from the low to the high performance arena. Whisker reinforced cast aluminum exhibits properties approaching polymer matrix composites with the inherent low cost and handling familiarity of metals.[67, 68] The key technological issue is processing to provide a controlled whisker dispersion. Intermetallics have significant potential for higher temperature application, but with significant processing challenges.[69, 70]

The technology of polymers has been traditionally process oriented. The engineering of polymer chains probably represents the most extensive use of engineered microstructures.[71–73] Some of the newer oriented polymer fibers compete with some of the best inorganic fiber reinforcements. An exciting outgrowth of this area is the possibility of simultaneously polymerizing rigid rod fiber polymers in a matrix of a more flexible polymer thus creating a molecular composite.[73] Thermoplastic polymers are attractive because of their lower processing cost and cycle time compared with thermosets.[74, 75] Research challenges include synthesizing new higher performance (including higher temperature) thermoplastics with improved environmental resistance along with improved processability in composites. Polymer blending offers the potential for providing ease of processing with improved performance.[76, 77]

8. Conclusion

There are exciting challenges facing the materials research community. Although the technical needs are well known, and many important new approaches are well defined, it is important for the materials scientist to see himself or herself in a broadly expanded context. The design of materials as a part of the overall systems design will become the norm. As a result, such factors as cost, durability, supportability, and specialized functions will take on added importance in materials science, engineering research and education. Important research opportunities include joint materials–mechanics efforts to provide precise mathematical microstructural design tools, and new chemical and biochemical processing techniques to synthesize the designed microstructures. In particular, the advent of bioengineering offers the possibility of genetically engineering new biological species to produce precisely designed microstructures.

Challenges in Materials for Health Care Applications

Implanted Devices
Tissue Replacements
Biocompatible Polymers

By David F. Williams*

Important issues face the use of advanced materials in medical applications. It is now possible to replace or augment many tissues and parts of the body by implanted devices, but there are still severe limitations to functions they are able to perform and problems associated with their compatibility with the tissues. Biomaterials of the future need to simulate more closely the tissues they are replacing and both the current position and future outlook are reviewed in this light.

1. Introduction

In the fifty years that have now passed since the invention of Nylon by *Wallace Carothers*, we have witnessed many changes in materials science and in the contribution of materials science to the welfare of mankind. This paper will discuss and review the current status of, and future challenges for, the uses of materials in one specific aspect of this contribution, that of implantation within the tissues of the human body.

There are many reasons why it is necessary or desirable to place some of today's advanced materials within the body,[1] but it is not the purpose of this paper to review them in detail. Some of the major reasons, and the current technical advances that have been made, are now well-known (Table 1). The twin diseases of rheumatoid and osteoarthritis are unfortunately very common, but the surgical technique of joint replacement, developed to overcome the pain and disability caused by these diseases is widely practiced, and has become a familiar landmark of late twentieth century surgery. Cataracts in the eye are now effectively treated in some half

Table 1. Some current applications of implanted devices.

Clinical area	Implant	Tissue replaced or augmented
Orthopedic surgery	Total joint replacement	Bone, cartilage
	Fracture fixation	Bone
	Ligament repair	Ligament
Cardiovascular surgery	Mechanical heart valve	Valve leaflet
	Bioprosthetic heart valve	Valve leaflet
	Vascular prosthesis	Blood vessel
	Pacemaker	Nerve
Ophthalmology	Intraocular lens	Lens
	Keratoprosthesis	Cornea
Ear, nose and throat	Ossicular replacement	Bone
	Cochlear stimulation	Cochlea/nerve
Maxillofacial	Dental implant	Teeth
	Fracture fixation	Bone
	Mandibular reconstruction	Bone
Plastic surgery	Breast reconstruction	Soft tissue

a million patients a year by the removal of the offending clouded lens and its replacement with a polymeric intraocular lens. Dental caries and, to a lesser extent, periodontal disease, affect most people at some stage, and the various procedures of restorative dentistry used to replace or treat these tissues utilize a great variety and volume of synthetic materials. Fewer people suffer from disease of the cardiovascular and peripheral vascular system, but the problems, when they arise, are of far greater consequence and significance. One method of treatment of such disease is the surgical replacement of the affected tissue.

Within this range of uses, the precise requirements of function will also be varied. It must be noted that, at the present time, the functions performed by the materials and devices of implant reconstructive surgery are quite simple in relation to the functions of the tissues they replace. Ideally, a replacement should possess all of the functional characteristics of the tissues, but this is rarely possible. In most cases it is a simple mechanical or physical function that is obtained, very frequently the implant merely acting as a space filler. It is very exceptional for more complex functions, especially involving biological activity, to be sought or achieved. The challenge for materials in these applications is to provide more sophisticated function, including biological and pharmacological function, while maintaining the appropriate mechanical or physical performance.

2. The Functional Replacement of Tissues

If it is intended to replace diseased, damaged or otherwise lost tissue by a functionally analogous structure, it is sensible to consider the nature and characteristics of these natural tissues. At the molecular level there are many different components involved. Water is the most abundant compound; this is not a trivial comment, since virtually all synthetic materials are unhydrated. Dissolved in this water are a variety of acids and bases as well as a vast array of both soluble and structural proteins, carbohydrates, lipids and nucleic acids. Complex as these organic molecules may be, the development of materials to simulate or mimic them is not the real problem. Figure 1 demonstrates the close similarity between the repeating molecular units in a synthetic polyamide, and two common, although non-human organic molecules, silk and wool. Many other examples can be found of the essential

Nylon $\cdots\cdots C(=O)-NH-(CH_2)_n-C(=O)-NH-(CH_2)_y-C(=O)\cdots\cdots$

Silk $\cdots\cdots C(=O)-NH-CH_2-C(=O)-NH-CH_2-C(=O)\cdots\cdots$

Wool $\cdots\cdots C(=O)-NH-\underset{R}{CH}-C(=O)-NH-\underset{R}{CH}-C(=O)\cdots\cdots$

Fig. 1. A comparison of the molecular structures of a synthetic polymer (Nylon) and two natural polymers (silk, wool). After *Richardson*.

equivalence of the repeat units in natural biopolymers and synthetic polymers.

The real problem lies with the fact that these molecules constitute just the basic level in the structural hierarchy of tissues and that the higher levels are far more difficult to rebuild. The tissue itself, apart from the water, contains both cellular and extracellular structures. Cells are not only varied in their structure and function, but are also extremely complex entities whose activity is as much dependent upon the ability to receive information, for example for highly specific receptors on their membranes, as on the ability to react to this information. Perhaps the simplest cell is the erythrocyte, or red blood cell, since this consists of a thin membrane which contains a solution of hemoglobin. It has been possible to prepare structures which simulate this cell and possess some of the functions of hemoglobin transport, but the development of more complex artificial cells using conventional materials is rather difficult to contemplate.

Cells possess varying degrees of mobility. Some, notably those of the musculo-skeletal system, are essentially fixed within an extracellular matrix. This matrix often consists largely of structural proteins such as collagen and elastin and is in some cases reinforced by deposits of minerals, specifically hydroxyapatite in the case of bone, dentine and enamel. In this type of system it is as much the spatial distribution of the various components and their interfacial relationships that control the performance of the tissue, as it is the molecular nature of the components themselves.

The structure of bone provides an excellent example of this, which is, of course, very relevant to implantable devices.[3] The structural protein of bone is collagen, which has a well recognized molecular and fibrillar structure. The collagen is itself arranged with a microstructure, described in terms of a Haversian system, in which there are cylindrical, concentric layers of collagen (Fig. 2). There are lengthwise

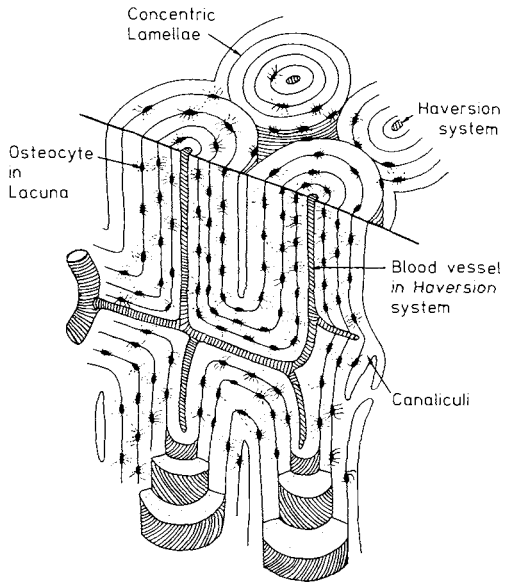

Fig. 2. The structure of bone.

canals containing blood vessels, small spaces containing the blood cells and a myriad of ultrafine canals, the canaliculi. The collagen contains a multitude of nanometer-sized crystallites of calcium hydroxyapatite.

At a macroscopic level, the bone may be arranged in a reasonably dense way (cortical bone) which comprises most of the major structural part of long bones such as the femur and tibia, or it may be arranged in a more open, porous form, known as cancellous bone, which is found in the ribs, the pelvis and elsewhere.

The mechanical and physical properties of a bone (as a structure) depend on all of the molecular, microstructural and macroscopic arrangements discussed above, making it a multicomponent composite structure, with considerable anisotropy. The functional characteristics of bone are complicated even more by its viable, dynamic nature. It does contain cells, which are in a state of constant turnover, and it does require a blood supply. Resistance to fatigue crack propagation is dependent on the vital ability of bone to blunt cracks. The relationship between the mineral phase and the collagen is controlled by mechanical stress via a number of mechanisms including piezoelectric and streaming potential effects. These and many other phenomena demonstrate the acute relationship between mechanical properties and biological characteristics which control functional performance.

Since bone, with this structure complexity, is one of the most straightforward of tissues to replace from a functional point of view, it is easy to appreciate the enormous difficulty of replacing some of the other tissues of the body. Two examples will serve to emphasize this point.

Skeletal muscle consists at the molecular level of proteins such as myosin and actin. They form long myofibrils combined to form muscle fiber which are arranged in bundles to form the muscular structure (Fig. 3). The molecular and fibrillar arrangement allows very high extensibility without excessive interatomic forces, a characteristic which is difficult to achieve in all but a few synthetic elastomers. The ability to elongate and contract, however, is not a simple passive function, but involves active movement of calcium ions, under the influence of electrical impulses, which initiates myosin and actin interactions and the sliding of myofibrils. The challenges to the functional replacement of muscle lie both within the extraordinary elastic performance and the ability to incorporate transducers in order to translate electrical impulses into elastic deformation.

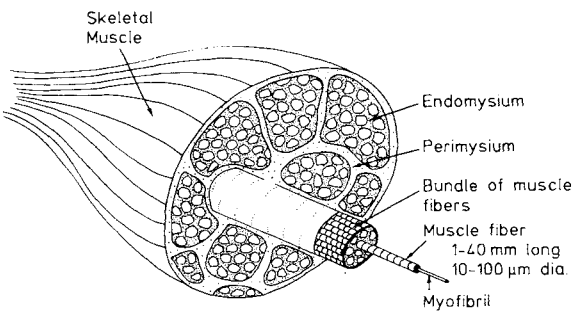

Fig. 3. The structure of skeletal muscle.

The vascular system, both in relation to the cardiac and peripheral circulation, appears to have a simple function, that of providing a series of conduits along which blood can flow, and gently assisting that flow. In reality, the mechanisms involved in producing the optimal hemodynamic conditions so that the organs and tissues receive their blood most efficiently are very complex. Considering the arterial system, an artery consists of a cylindrical connective tissue layer, a smooth-muscle layer within this, a cylindrical elastin membrane and finally, on the inner aspect, a layer of endothelial cells (Fig. 4). The functions of importance are two-

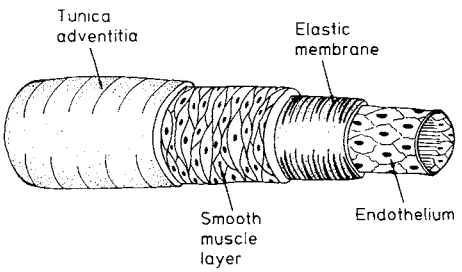

Fig. 4. The structure of an arterial wall.

fold, relating to the mechanical performance of the wall and also the interaction between the endothelial cells (or underlying connective tissue if damaged) and the blood. The mechanical performance is vital. Since it is necessary for blood to flow with laminar characteristics under pulsatile conditions, both the elasticity, compliance and geometry are important. Of equal, if not greater, importance is the need for this contact with flowing blood to take place without adverse effects on the blood. Blood is a medium that contains several defense mechanisms that can only operate under certain conditions, for example, blood has the ability to clot if the vessel is damaged. The clotting mechanism is very complex, but represents a sensitive balance between a variety of biochemical events. This balance can be easily upset and it is therefore a major functional requirement of these tissues that they do not themselves adversely interfere with these mechanisms.

3. The Characteristics of Current Biomaterials

At the present time, a wide selection of materials is used in implant surgery (Table 2) but in the majority of cases, because only a simple, single function is sought, these materials bear little resemblance to the tissues they replace. Examples include metals and alloys, such as an amalgam of mercury, silver and tin which replaces tooth structure,[4] and cobalt-based alloys, 316 stainless steel, titanium or Ti-Al-V alloys which replace or augment bone.[5] Clearly, these metallic materials have no molecular or structural similarities with

Table 2. Major currently used biomaterials.

Class	Material	Use
Metal	Amalgam	Restoration of teeth
	Titanium/Ti–Al–V	Bone replacement/repair Dental implant Maxillofacial implants Encapsulation of electronic devices
	Stainless steel	Bone replacement/repair
	Co-Cr alloy	Bone replacement/repair
Ceramic	Alumina	Bone, joint and tooth replacement
	Hydroxyapatite	Coating on bone/tooth replacement Bone augmentation
Polymer	Polyurethanes	Arteries and other blood contact devices
	Polymethylmethacrylate	Dental restorations Ophthalmology Fixation of bone/joint prostheses
	Polytetrafluoroethylene	Arteries, soft tissue
	Polyethylene	Joint replacement
	Polyesters	Arteries, sutures

the tissues. There are also some ceramics. High purity alumina and transformation-toughened alumina possess some attractive properties of wear resistance and inertness,[6] but otherwise are quite unlike natural tissues.

Polymer-based materials are widely used[7] and possess a greater claim for similarity with tissues than most materials. However, they still fall short, for although they are based, as indicated earlier, on an organic backbone, it is extremely difficult to organize their microstructure in an appropriately biological way. Current polymers in use include polyethylene and polypropylene, acrylics, polyamides, polyesters (both aromatic and aliphatic) polyurethanes and silicone polymers. Most of these are single phase structures, either thermoplastics, cross-linked polymers or elastomers, with little evidence of any structural hierarchy. In some cases multiphase structures with domains and segments are available and of course certain composites, both fiber and particulate, are emerging. Even here, however, there are still major structural differences from the anisotropic heterogeneous natural products.

4. Some Concepts in the Development of Biologically Analogous Materials

A few concepts and ideas that have emerged during the last few years are beginning to show real promise in the search for biologically analogous materials.[8] It should be said that the ultimate solution is the use of natural tissue itself. In many ways this is the most obvious and indeed oldest solution, for transplanted tissues have been used in selected cases for many years. Ranging from skin and bone grafts at one end of the range to heart transplants at the other, these materials and procedures are very variable in their success and applicability. The most successful procedures are those where simple tissues are transplanted from one part of a patient to another, but the occasions where a patient has an adequate supply of the required tissue, and when the loss from the donor site is repairable, are few and far between. The most difficult are those, such as major organ transplants, where donor and recipient are different, and although great strides have been made with immunosuppressive drugs to improve their acceptability, transplants of this type are always likely to have major problems facing their use.

Most of the technical as opposed to ethical and logistic problems associated with transplanted tissue relate to sterility and antigenicity issues. Foreign tissue generally elicits a response from the immune system and of course all tissue products transferred from one human to another have to be carefully screened for viruses such as those involved with hepatitis and AIDS. One potential solution to the dilemma of using natural tissues, but being concerned about sterility and antigenicity issues, is to take such tissues and treat them, rendering them non-viable but sterile and non-antigenic. The construction of prosthetic heart valves has employed this concept, with the use of bovine pericardium (the muscular tissue of the heart-wall of cows) or porcine valve tissue, in the fashioning of the leaflets of mitral and aortic valves, after fixation in glutaraldehyde.[9] While giving better biological performance than the alternative mechanical valves, these do suffer problems of long term calcification and degradation. It is not clear whether any treated soft tissue obtained in this way will ever be sufficiently stable for long term use in the body. Some success has been achieved with the use of bone harvested from donors and treated in some appropriate way, for example freeze-drying.

Tissue which is either transplanted in a viable state, or treated and rendered non-viable, usually retains its heterogeneity. An alternative approach to using these structurally complex tissues is to separate individual components from the tissue and use these for their specific properties. These components may be obtained by separation techniques using donor tissue or synthesized directly. Two examples are described here. First, there is considerable interest in the use of collagen preparations, especially for injection as soluble materials for cosmetic surgery.[10] Secondly, the mineral phase of bone, hydroxyapatite, may be used for bone reconstruction or bone bonding applications either in its own right as an alternative to bone graft or as a coating on a tough substrate. In the latter case there is strong evidence that synthetic apatite allows new tissue-derived hydroxyapatite to be deposited epitaxially on its surface, hence producing material–tissue bonding.[11]

As a ceramic, hydroxyapatite cannot offer all of the properties of bone itself and suffers from inferior mechanical properties. Some attempts have been made to produce composite materials that are structurally analogous to bone in the hope of finding equivalent properties. One example actually employs hydroxyapatite as the dispersed phase in a ma-

trix of polyethylene.[12] Others, including some carbon fiber reinforced thermoplastics, are less biological in composition, but possibly better mechanically. In situations where it is desirable to apply a biomaterial which can be shaped to a prepared bone cavity or to augment a deficient bone structure, for example the ridge of the mandible in patients without teeth, the same hydroxyapatite can be incorporated into some natural polymerizable substance. Of increasing interest here is the use of a fibrin glue as a matrix for the preparation of a composite with hydroxyapatite.

The assumption that natural tissue is the best replacement material, together with the problems of supply logistics, ethics, technique and acceptability, have resulted in several attempts to encourage regeneration of the patient's own tissues. Several years ago, for example, an "artificial" artery was prepared by the implantation of a mandril into tissues and utilizing the fibrous capsule that formed around it, although this was not particularly successful.[13] More recently, porous surfaces and totally porous materials have been employed, which, by manipulation of the pore characteristics can allow tissue ingrowth.[14] This may be used to secure anchorage of an implant to tissue via a porous surface or, when using a degradable porous material, complete tissue regeneration. Since it is usually only connective tissue that is able to regenerate in this way there are significant limitations to this approach and it cannot be used for highly specialized tissue.

The concept of using the biomaterial as a vehicle or matrix to support the growth of natural tissue has been taken in a different direction through the use of biomaterial-supported cells grown in culture. It is possible for certain cells, isolated from tissue and maintained under strictly controlled conditions in the laboratory, to carry out their usual function. If cells are taken from the tissue of a patient and grown in culture to an effective condition and concentration, they may be reimplanted, with an appropriate support, where they can provide an effective 'natural' replacement. This is being used, for example, for an artificial skin, in which epithelial cells from a patient with a major burns injury can be incorporated into a suitable degradable matrix and used in place of a skin graft. Also, endothelial cells may be cultured onto the surface of a vascular prosthesis, which will present a more natural surface to the flowing blood.[15]

A combination of cells and synthetic polymer has also been employed, at least experimentally, for an entirely different reason. The application mentioned above can only work if the cells are derived from the same patient in whom they are to be used because of the problem of the immune response to foreign proteins. If the cells of interest are not readily available in that patient, problems arise. Such a situation is seen in diabetic patients, for example. They do not have the cells that produce insulin, the Islets of Langerhans, and it is not possible to transplant such cells from a donor as they would be recognized as foreign and attacked by the immune defence system. However, it is possible to encapsulate donor cells in a polymeric membrane. If the structural characteristics of this membrane are selected carefully, it can allow the transport of glucose and insulin between the cells and the surrounding tissue, but prevent the passage of the much larger protein molecules of the immune system, inhibiting their immunological rejection.[16] This concept is leading to the development of so-called hybrid artificial organs such as, in this case, the pancreas.

A final approach to be mentioned here involves the surface modification of engineering materials to provide more biologically acceptable interfaces, especially those which attempt to mimic natural interfaces. Most examples are of blood-contacting surfaces.

Blood is a highly complex and sophisticated tissue which in the healthy patient flows through the cardiovascular and peripheral vascular systems without any interaction with the vessel walls. This lack of interaction represents a delicate balance between several events and many factors play a role. One of the more important factors is the relationship between the circulating platelets and the vessel wall.[17] Platelets do not normally interact with the endothelium, largely because the cells release a variety of substances, especially prostacyclin, which inhibit such interactions. If the vessel is damaged, or if a foreign material is placed within the vessel, then the platelets recognize a non-endothelial surface, adhere to it, and initiate a sequence leading to the formation of a clot. While this is a desirable reaction in the case of vessel injury, it is undesirable in the case of a biomaterial implanted within the vascular system for reconstructive purposes. There are many different approaches to controlling these blood interactions, but in one case a synthetic analogue of prostacyclin has been attached to the material surface. Such a surface imitates the natural endothelial surface and prevents platelet deposition.[18]

5. General Conclusions

This brief review has highlighted the major problems of implanting synthetic materials for advanced applications in the human body. If we are to succeed in using materials with greater reliability and more sophisticated performance, we need to face the challenges of developing advanced materials to meet the combined requirements of functional performance and biocompatibility. The more this approach leads to a merging of the concepts of synthetic materials and of natural materials, the better the prospects.

Panel Discussion

Improving Effectiveness in Materials Research

By Gerhard Wegner*

High temperature materials, electronic materials, composites and superconductors are featured as regularly in the business press as in scientific journals. Materials science receives heavy management attention as well as public and political interest worldwide. The Materials Research Society (MRS), founded only a few years ago in the US, is rapidly growing into one of the largest professional societies, with offshoots on other continents. Despite the obvious successes of materials science as a field of industrial relevance and academic concern, the people involved do not seem to be very satisfied. One of the key issues is finding the proper balance between industrial or market driven research and development and the necessity to conduct in depth research of a basic nature to find and understand new materials. This issue is intimately related to the role of industry in defining and supporting research areas in academic institutions. Conversely, the transfer of basic knowledge, new insights and novel methods from the ivory tower of the university to the harsh and competitive ground of the industrial world does not seem to work well and finds many obstacles.

This, in a nutshell, was the content of a panel discussion organized and directed by Du Pont's *Rudolf Pariser*, Director for Advanced Materials Science in the Central Research and Development Center at Wilmington, Delaware, USA. The panel discussion was part of an Advanced Materials Conference celebrating the 50th anniversary of Nylon and the invention of Teflon, both products being cornerstones of the commercialization of polymeric materials.

[*] Prof. G. Wegner
Max-Planck-Institut für Polymerforschung
Jakob-Welder-Weg 11, D-6500 Mainz (FRG)

A Climate of Worldwide Competition and Collaboration

"The climate in Du Pont research is characterized by increasing worldwide competition and collaboration, the globalization of business and the need to respond quickly and specifically to market needs, energy and raw materials resources and environmental issues...", Dr. *Pariser* told the audience of more than 150 invited scientists from US and foreign universities, research institutes and agencies involved in materials science studies.

Du Pont's approach to research and development reflects the change of attitude towards materials science worldwide. As little as ten years ago, the laboratories were organized to emphasize specific polymeric materials, such as elastomers or textile fibers with relatively little interaction between them. Today, research has expanded beyond polymers and includes ceramics and metals as well. The emphasis is on materials systems and systems functionality. New fields are under development based on polymer composites and structural ceramics, inorganic fibers and molecular composites. Thus, an advanced materials laboratory has been created where many materials disciplines are combined into one organization with broad functional research themes. The trend is toward multidisciplinarity among the research staff as well. In addition, Du Pont has a rapidly increasing involvement with US universities. The more than US $ 25 million which were spent by Du Pont in 1988 alone to support university research programs was a substantial part of the total US $ 630 million by which US industry supported R & D at American universities.

Support of academic programs cannot be seen independently from the hiring policy. "We at Du Pont," Dr. *Pariser* said, "have always tried to hire the very best students. We are also emphasizing the ability to collaborate and interact with others, to communicate, and to show a high degree of initiative and self-management." As a policy, Du Pont tries to hire the best students from the classical disciplines, frequently from the top rated universities, despite the fact that these graduates need substantial reeducation and another two or more years further training to adapt to the R & D subjects of industry. Secondly, graduates are hired with specific expertise which is urgently required, for the exploration of polymer composites, thin film techniques or ceramic processing. The contribution of these graduates can be of immediate value but there exists the problem that they may be too specialized and lack the flexibility needed to respond to future challenges.

The rapid development of materials science and its impact on chemical industry obviously requires changes of emphasis in the education of scientists and engineers alike. An interdisciplinary education is absolutely necessary, otherwise the students and graduates will not learn to adapt to the unexpected developments which, for good reasons, are the basis for the further success of industry.

Graduate Education in Materials

What should an active and successful Department of Materials Science look like? How should it be organized? What about the balance between "core" subjects and specialized training programs?

These questions were raised by Dr. *Anthony Evans,* Chairman of the Department of Materials at the University of California, Santa Barbara. As a general philosophy he suggested a multidisciplinary curriculum with three fields of specialization. These, for example, could be:

- Structural materials
  (advanced composites, light weight alloys, tough ceramics)
- Electronic materials
  (compound semiconductors, optoelectronic devices, quantum wells)
- Macromolecular materials
  (high-strength fibers, interfaces, conducting polymers)

Furthermore, training and research projects should be favored, which have the integrated concept of devising a model, testing the properties and establishing the role of processing in the quality control of the materials and devices. This requires substantial investment in capital equipment and continuous support to maintain sophisticated equipment. Among others, the following facilities should be made available for training and research: machinery to process ceramics, metals, and polymer fibers and to prepare surface structures (molecular beam epitaxy); all methods for structure investigation, notably electron microscopy (SEM, TEM etc.) and, last but not least, sufficient computing hardware. Dr. *Evans* also emphasized the role of unconventional industry–university relationships which help to motivate the research students and faculty. Among other suggestions he mentioned "research condominiums," a term which describes a joint university–industry research program in which space, facilities, students and faculty are shared for a certain time to solve a specific but interdisciplinary problem which is of interest to one or more industrial partners. The active participation of researchers from industry in such "research condominiums" is the necessary ingredient which differentiates this from conventional industry supported programs.

The Impact of Government Policies

"The problem of revitalization of civilian R & D effort in the US is compounded by the heavy emphasis on military programs in our federal R & D budget. We spend almost twice as much on the military programs as on civilian efforts, with relatively little payoff in economic terms. This puts us at a significant disadvantage compared to our trading partners." This was one of a number of rather blunt statements by Dr. *John H. Moore,* Deputy Director of the National Science Foundation, describing current trends in the US-federal policy towards science and technology. He greatly deplored the fact that when only civilian R & D is considered, the US rate of investment, at 1.9% of the gross national product (GNP), is only about two-thirds the level of Japan and below that of West Germany and France. On the other hand, Dr. *Moore* reported, there was a major shift of the administration away from supporting applied research and development programs and toward basic research. As a result, basic research now gets about 40% of the non-defensive federal R & D dollar today as opposed to about 23% in 1977. Although the administration and its institutions recognize the importance of basic research as fundamental for further economic development, they also emphasize increased interaction between industry and academia. "We need explicit mechanisms," Dr. *Moore* said, "to make sure that results of our (academic) laboratories flow smoothly into industry." One such mechanism is the establishment of Engineering Research Centers (ERC's). Center topics include combustion processes, biotechnology, process engineering, robotics in microelectronics processing, composite materials and intelligent systems engineering. NSF presently supports 18 ERC's and plans to increase that number.

A Change of Culture is Needed

"University researchers will have to lose any lingering disdain for concern about marketability and profit of their discoveries. They will have to learn that directed research does

not automatically represent a threat to free academic inquiry" said Dr. *Alan Schriesheim,* Director of Argonne National Laboratory and Professor of Chemistry at the University of Chicago, to a somewhat startled audience. He reported on his attempts to increase the sensitivity of the research staff of the Argonne National Laboratory to the commercial potential of their work. One feature was to make patents and R & D awards a legitimate factor in promotion applications along with the traditional scientific publication list. Another feature was the creation of a Technology Transfer Center which became pro-active rather than re-active to commercial opportunity.

The Need of Goal Oriented Basic Research

Effective communication in the materials area is a challenge which requires the interdisciplinary approach illustrated in this issue of Advanced Materials. The Materials Research Society (MRS) has also taken on the challenge by sponsoring multidisciplinary meetings, *Kathleen C. Taylor,* past president of the MRS, told the audience. In addition, the MRS attempts to fill the gap between basic research and application by emphasizing goal oriented basic research. Improved effectiveness in research is reached by fast communication of recent results; however, it is not recommended to abandon peer review which would lead to a rapid decline in the quality of the published reports.

Dr. *Kathleen Taylor* is head of the Physical Chemistry Department at the General Motors Research Laboratory and is thus an expert at considering the needs in materials in the automobile industry. Summarizing the current trends and needs in that industry, she pointed to the increasing importance of plastics and composite materials. Plastics now comprise more than 200 lb of the weight of each vehicle, and when all polymer-based materials are considered including elastomers, paints, adhesives and sealants, this number is 400 lb. Reduction of the production costs in the manufacturing process and the decrease in number of individual parts by integral design is the advantage offered by polymers over conventional materials. The major deficiencies of ceramics as substitutes for metals are still the low reliability caused by brittle failure and the high cost of fabrication.

Another issue is the development of long life batteries, a prerequisite if the electric vehicle is to become a common feature. Fuel cell technology will require that efficient low cost membranes and electrocatalysts become available. Last but not least, it becomes more and more important to predict performance based upon a knowledge of chemical-physical characteristics and operating parameters—a wide open field for theoretical work.

Specialists or Generalists—the Role of Education

Coming back to the initial remarks of Dr. *Pariser* on the role of education and the impact of industry–university relationships in materials science, Harvard's Professor *George M. Whitesides* commented on the function of the universities. The key problem is that it takes a very long time to learn how to educate a good expert in a decent time and that professors are faced with the problem of teaching the right subject. Although being a chaired professor himself, he did not hesitate to remark that professors in general are not amenable to new ideas. He suggested therefore that industry should give preference to assistant professors who are eager to open up their own field of expertise. Professor *Whitesides* emphasized furthermore that if one wants to establish a meaningful interaction between industry and university the motivation must be clear. Finally, technology transfer will never work unless accompanied by the transfer of personnel. He thus called for an increased exchange of personnel over shorter or longer periods between university laboratories and industrial sites.

What is the Message?

Did the panel discussion convey a message to the audience, to the public, to the scientific community? This foreign observer, invited as a guest to participate in the celebration of the 50th anniversary of Nylon and Teflon, was left with mixed feelings. Du Pont deserves applause for the attempt to focus on the intellectual background of commercial enterprises in chemical industry and on the role of basic and academic research for past and present developments of product lines in materials. Many of the statements made by panelists from industry will be taken as encouragement by those who fight for better recognition of materials science as an academic subject in universities and academic circles. On the other hand, no solutions were given—and probably can never properly be given—how to bridge the gap between the needs of industry for more specific research on actual products and processing, and the aspiration of academia to work on very general aspects and laws controlling materials structure and dynamics.

Not too surprising to the foreign guest, the panel discussion was almost entirely centered on the US despite the initial remarks of Dr. *Pariser* on the global issues. Non-US developments were only mentioned in the context of how US industry and the US educational system could maintain leadership in technology and business or regain ground lost in the recent years to Japan or to Europe. The competition by Japan was seen as the major issue by many of the panelists although there are similar problems in this country when it comes to the central point of how materials science and materials science centers can be properly supported, and oriented toward goals worth the money invested.

Overall the panel discussion gave a snapshot of the current state of mind of US materials scientists in industry, universities and academic research centers, and that is certainly helpful for further orientation.

ADVANCED MATERIALS

Book Reviews

From Blood Substitutes to Semiconductors and beyond

Blood Substitutes. Preparation, Physiology and Medical Applications. Edited by *K. C. Lowe*, VCH Verlagsgesellschaft, Weinheim, 1988. 187 pp., bound, DM 168.—ISBN 3-527-26556-2.

The development of a blood substitute and, more generally, an effective injectable oxygen carrier, has become a pressing but considerable challenge. Extensive progress has been achieved in recent years. It is the objective of the multiauthor book edited by *K. C. Lowe* to provide a review of the state of the art in the field. It deals with both simple plasma substitutes for volume restoration and oxygen-delivering fluids, whether the latter are based on hemoglobin or on fluorocarbons as the gas carrier.

In an easy-to-read first chapter, *E. S. Parry* sets the search for O_2-carrying blood substitutes in a historical perspective. The chapter is mainly (ca. 85%) devoted to a detailed up-to-date account of the vicissitudes of the hemoglobin approach since the turn of the century, and of the progress achieved in recent years, but without attempting to minimize the numerous questions and concerns which remain to be answered before human trials can be safely envisaged. The more recent fluorocarbon and synthetic chelate approaches unfortunately receive a much shorter and scantier treatment, with literature coverage up to 1982 only; this leaves out the most recent developments, but the reader will fortunately find these in subsequent chapters.

Chapter 2 by *K. Messmer* is devoted to plasma substitutes for rapid volume restoration after hemorrhage. The author discusses and compares the role, advantages, limitations and adverse effects of isotonic electrolyte solutions, plasma substitutes based on natural colloids prepared from human plasma or placenta, and artificial colloids including dextran, gelatin and hydroxyethyl starch. While plasma substitutes have been used on a routine basis for several decades now, it is shown that there is still room for improvement and that they constitute an active field of research with, for example, the successful development of hapten inhibition of dextran-induced anaphylactic reactions, and exploration of the concept of small volume resuscitation by hypertonic/hyperosmotic solutions.

In Chapter 3 *G. W. Odling-Smee* and *B. G. Wilson* discuss hemoglobin as a blood substitute, and show how successive modifications—pyridoxylation then polymerization—can improve its oxygen-delivering capacity and intravascular persistence, which are both strongly reduced when hemoglobin is extracted from its natural environment. The authors give a brief summary of contradictory reports on the effectiveness and safety of such preparations, and end by stressing the outstanding problems, namely cardiovascular effects and effectiveness in the presence of red cells, which in the authors' opinion need to be addressed before they would recommend them for use in humans.

There follows a too-short chapter by *T. M. S. Chang* which concentrates on microencapsulation of hemoglobin as a way of preserving its oxygen-unloading characteristics, and (again) on cross-linked hemoglobins. A section on toxicity and safety expresses the author's concern about the immunogenicity of the modified crosslinked hemoglobins.

Polymerized pyridoxylated hemoglobins consist, indeed, of complex mixtures of chemically modified materials, difficult to reproduce, and each one of these more or less randomly occurring modifications can be the source of immunogenic problems. The chemist will remain unsatisfied, as none of the three chapters devoted to the modified hemoglobin approach to blood substitutes broaches the central and difficult question of the chemistry involved in these reactions. This is all the more regrettable as the lack of insight into what is really happening to the hemoglobin molecule, as well as the diversity, poor definition and poor reproducibility of the resulting preparations are probable reasons for many contradictory reports.

Turning to the fluorocarbon approach, *J. G. Riess* and *M. Le Blanc* give an authoritative and thoroughly documented account of the state of the art, including the criteria of selection, preparation procedures and properties of fluorocarbons and surfactants, formulation, preparation, characteristics and control of the emulsions. A stringent analysis of the shortcomings of the Fluosol-DA-type first generation of preparations enables them to delineate what research should be done with the aim of improving on this early emulsion. Emphasis is then laid on the advances that have already been achieved with respect to Fluosol-DA. Among these, the discovery of fluorocarbons with much shorter organ dwell time, and the preparation of five times more concentrated and room temperature stable fluid emulsions, are certainly the most remarkable breakthroughs. This strongly consolidates the potential of the fluorocarbon approach to blood substitutes, including use in case of hemorrhagic shock, where the early emulsions had only limited efficacy. Further improvement is shown to depend in large part on the synthesis and

selection of new biocompatible surfactants, more specifically designed for emulsifying fluorocarbons.

A solid chapter by *N. S. Faithfull* discusses the potential of fluorocarbon emulsions in medicine and research. The author's reminder that it is the carrier's oxygen delivering capacity rather than its oxygen dissolving capacity which is important, is welcome. He then emphasizes that the potential of fluorocarbon emulsions goes considerably beyond that of a substitute for blood. Microcirculatory support of the myocardium and central nervous system, use in radiology or for radiosensitization of hypoxic tumors, for organ preservation or during cardiopulmonary bypass, or percutaneous transluminal coronary angioplasty, treatment of respiratory failure, and stimulation of killer macrophages are among the most promising avenues that are being explored. The reader may regret that some of these applications are not discussed in greater depth.

K. C. Lowe left for himself the difficult task of summarizing the biological assessment of fluorocarbon emulsions, which is treated in a meticulous, detailed manner. Particular consideration is given to the uptake of emulsion components into lymphoid tissues and the reticuloendothelial system, and to the consequences these may have on immune defence in the recipients. Unfortunately the greater part of the available data still concern the early fluorocarbon-poor and Pluronic F-68 containing emulsions, Fluosol-DA and Fluosol-43. It will nevertheless be of great use by providing the reader with extensive information and numerous protocols which should prove helpful for evaluating the newer emulsions. The need for improved biocompatibility with respect to Fluosol-DA is indeed high-lighted.

Chapter 8, by *G. M. Vercellotti* and *D. E. Hammerschmidt*, reviews the clinical studies that have so far involved fluorocarbon emulsions. Again these studies concern *solely Fluosol-DA*; the data analyzed highlight the side effects and limitations of this particular preparation. These are by no means representative and cannot be extrapolated to other fluorocarbon emulsions. The authors then discuss the possible mechanisms for the adverse reactions noted with Fluosol-DA, and show that they can be assigned primarily to complement activation by Pluronic F-68, the main surfactant used in this preparation. As a result they call for the development of emulsions with a lower ability to activate plasma complement.

On the whole, *Lowe*'s book, in spite of some omissions (the chemistry of modified hemoglobin, for example) and repetitions (the compositions of Fluosol-DA is given no less than three times), inevitable in such a multi-author enterprise, reaches its objective. It is timely and useful—useful as it summarizes a considerable amount of recent information in a relatively small, compact volume—timely in view of the increasing demand for substitutes for blood, triggered by increased difficulties of transfusion, and also because the decisive breakthroughs that have recently been achieved, especially in the fluorocarbon approach, should lead to new preparations now becoming available for research.

There are few typographical errors in the text; the same is unfortunately not true of the chemical formulas and equations, which sadly appears to be a common fault in medically-oriented books.

Pierre Vierling
Department of Chemistry
University of Nice-Sophia Antipolis (France)

Electrons in Solids: An Introductory Survey. By *R. H. Bube*. Academic Press Inc., San Diego 1988. xiv, 315 pp., bound, $ 39.50.—ISBN 0-12-138552-3

The book is intended as an introductory survey for students with a background in materials science or other engineering disciplines. This is explicitly stated by the author in the preface to the first edition. The second edition has been updated in some chapters by including recent developments, and an additional chapter on "sample problems" has been included in the appendix.

The presentation is clear and supported by very good illustrations. Since the reader is not expected to have a knowledge of electrodynamics, quantum mechanics or basic solid state physics, the author has to cover a lot of ground before he can present the facts on various properties of solid state materials. In the first chapters he therefore has to give a short description of the above mentioned basic physics. After having discussed the general properties of waves in Chapters 1 and 2, he continues by describing lattice waves and light waves in Chapters 3 and 4. The usual examples of quantum mechanics are described in Chapter 5, and in the next two chapters the simplest models of solids are presented, namely the free electron model and the tight binding description. In the second half of the book we find the main topic, with chapters on optical, electrical and magnetic properties, and an additional chapter on junctions between different materials.

The treatment contains a good mixture of phenomenological descriptions, formal presentations of basic formulas, and comparison with experimental results. Nevertheless, I have the feeling that a student reading Chapter 4, for example, where on 14 pages the Maxwell equations are presented, may have difficulties in really understanding these basic equations. A good list of further references including textbooks on this subject should at least have been provided. The same problem for the reader might also arise with the topics in the other six introductory chapters.

The second half of the book discusses a quite extensive list of properties of the solid state, and again the clarity of the presentation is to be admired. The chapter on optical properties presents an overview of the various absorption processes. Unfortunately, there is no discussion on new developments, e.g. on various aspects of laser physics. The next chapter on electrical properties discusses the basic relaxation

mechanism in semiconductors, and a few pages are devoted to effects in superconductors. A topic of special interest for students in engineering science is presented in the chapter on junctions between various materials. The new and interesting properties of quantum wells and superlattices are only briefly touched on, and there is no discussion of the quantum Hall effect, for example. A final chapter on magnetic materials presents some basic facts on diamagnetism and ferromagnetism, and also includes a discussion of new magnetic materials. Looking through these chapters the question again arises whether a student in the engineering disciplines will really obtain a basic understanding of the various phenomena. I therefore suggest that further references to textbooks and original literature should be included at the end of each chapter.

The appendix includes useful formulas, as well as the above mentioned discussion of problems, which I think are very helpful for students. The list of problems at the end of the book is also attractive.

The book can be recommended for undergraduates with an engineering background, as a suitable introductory text on solid state physics. However, in teaching such a course one should give the students further material for background reading in the various topics.

der Universität Bayreuth (FRG)

Optical Nonlinearities and Instabilities in Semiconductors. Edited by *H. Haug*. Academic Press, San Diego 1988. xi, 440 pp., bound, $ 65.—ISBN 0-12-332915-9

The investigation of optical nonlinearities in semiconductor materials and devices has recently become a field of rapidly increasing interest, mainly due to possible applications in optical data processing. Most important for these applications are the so called "resonance enhanced" nonlinear optical processes, which occur when the photon energy of the optical field is close to an electronic resonance of the semiconductor material, e.g. the fundamental band edge. According to the editor's statement in the introduction, the present book attempts to bring together all the investigations of the resonance enhanced nonlinear optical properties of semiconductors and their manifestation in optical instabilities. In the reviewer's opinion, this attempt has been highly successful.

The book contains 16 independent review articles on different, partly related topics, written by different authors, together with an introduction by the editor which contains some historical comments and a brief summary of the definitions and concepts employed to describe the nonlinear effects. The list of authors includes many leading scientists representing some of the most active laboratories in the field.

Most of the articles are devoted to optical nonlinearities due to electronic processes in semiconductors, including free carrier effects such as band filling, band gap shrinkage and inter-band absorption, as well as excitonic nonlinearities; however, thermally induced optical nonlinearities are also discussed (e.g. the contribution by *Wherret, Walker* and *Tooley*). Special attention is also paid to nonlinear phenomena in electronic systems with reduced dimensionality, as in semiconductor quantum well structures, and to optical nonlinearities in semiconductor devices, in particular semiconductor lasers.

The combination of theoretical and experimental work is one of the special features of this book. Fortunately, experiment and theory are not treated separately; instead, a close connection is maintained throughout the book, by means of jointly written reports, and careful arrangement of the respective papers.

The theoretical contributions cover fundamental topics such as the microscopic theory of optical band edge nonlinearities (*Haug*), the theory of dense nonequilibrium exciton systems (*Schäfer*), the nonlinear optical properties of semiconductor quantum wells (*Chemla, Miller* and *Schmitt-Rink*), including electric field effects as well as more device orientated problems such as the theoretical description of optical instabilities in semiconductors (*Koch*).

The experimental data collected in the present book cover bulk phenomena in different II–VI compounds, including semiconductor doped glasses (*Klingshirn, Peyghambarian* and *Gibbs*), exciton and biexciton processes in III–V (*Ulbrich*) and II–VI semiconductors (*Levy, Hönerlage* and *Grun*), optical phase conjugation (*Claude, Chase, Hulin* and *Mysyrowicz*), electronic transport (*Mahler, Kuhn, Forschel* and *Hillmer*), and some of the most recent results on optical nonlinearities in quantum well structures (*Chemla* et al.; *Miller* et al.; *Peyghambarian* et al.).

Device applications are described in several reports; in particular, self-electro-optic effect devices (SEED) based on electric field induced nonlinearities in quantum wells (*Miller* et al.), as well as bulk semiconductors (*Jäger* and *Forsmann*) are discussed. Finally, semiconductor lasers—which are essentially nonlinear optical devices—are considered in detail, including optical bistability in laser amplifiers (*Adams, Westlake* and *O'Mahony*), semiconductor lasers (*Harder* and *Yariv*), and higher order instabilities in semiconductor lasers, including chaotic emission (*Shore* and *Rozzi*).

The book provides a comprehensive overview of the basic physics and device applications of resonance enhanced nonlinear optical phenomena in semiconductors at a high scientific level. It is mainly addressed to research students and active research workers in this area, and for them this book will be indispensable.

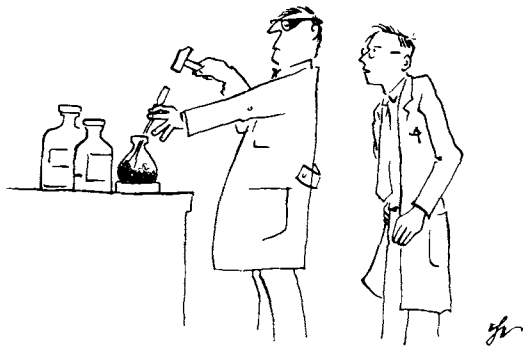
Rubberlike Elasticity—A Molecular Primer. By *J. E. Mark* and *B. Erman*. Wiley, Chichester 1988. viii, 196 pp., bound, £ 23.70.—ISBN 0-471-61499-8

This book is written by two former coworkers of the late *P. J. Flory*, and both of them are very active and highly esteemed scientists in the field of polymer networks. One of them (*J. E. Mark*) has developed new synthetic concepts for 20 years to obtain cross-linked materials with new and unconventional properties, the other (*B. Erman*) has specialized in problems concerning the theoretical description of rubber-like elasticity. However this book is not designed for experts in the area. Its approach is more that of an introductory course for chemists or engineers who wish to be confronted with the fundamental aspects of rubber-like elasticity and its molecular origin.

The first part of the book can be understood if the reader is familiar with some basic concepts of physical chemistry. Here, some rubber-like materials are presented and typical problems concerning network structure and routes of preparation are discussed. The basic theoretical concepts are presented without claiming completeness. Most of the logical steps are accompanied by references which simplify a reworking for readers with deeper interests. At the end of the first part, the dependence of the elastic force on deformation, temperature and structure is presented by means of typical examples of the authors' work. By reading through these chapters one becomes familiar with strain experiments and their physical meaning.



The purpose of part B of the book is completely different. Here, the authors wish to confront modern topics of network research, both new synthetic concepts and new methods for the characterization of network properties. This is very hard to realize, especially in a compressed and popular form, and consequently some of the chapters presented are fragmentary, (e.g. the treatment of neutron scattering experiments on networks) and a couple of modern developments are missing completely. However, the presentation of the authors' recent work in this area, for instance the treatise of bimodal networks and filled elastomers is convincing. Hence it should be regarded as a very personal point of view of the future of cross-linked materials.

However, in my opinion a good opportunity to give more detailed information to a readership with deeper interests has been missed. The later chapters are unbalanced in proportion, and their title "additional topics" may be misunderstood as an unstructured enumeration of sometimes very impressive, but sometimes not worked out, concepts. The textbook character of the first part should not be transfered to the second part. The very personal view-point of "modern topics" must be underlined, and with this understanding one can even enjoy some of the exceptionally elegant ideas which are presented. It is up to the readers with broader interests to complete their information with other publications.

In my opinion the book is not the missing textbook on polymer networks but it is a brief and stimulating introduction to this area of polymer materials. It can be recommended to all scientists who wish to learn something about networks without the necessity of a detailed discourse on special problems in research.

The Search for Highly Colored Organic Compounds

By Jürgen Fabian* and Rudolf Zahradník*

Until now the study of organic compounds in which the π-electron system is excited by absorbed light has been mainly concentrated on the ultraviolet and visible regions of the electromagnetic spectrum. Various new applications, such as the use of conjugated organic compounds as dye lasers or as materials for storing information with the help of diode lasers, led to the synthesis of new compounds which absorb light in the near infrared (NIR). It is possible to use structure–color relationships to predict the properties of such new compounds when they belong to dyestuff classes which have already been studied in detail; in this case the approach involves decreasing the energy difference between the ground state and the first excited state. A less conventional starting point is provided by molecular structures in which from the outset there is only a very small energy difference between the lowest-energy electronic states; such diradicaloid molecules occupy a special position among the various types of organic compounds. It is possible by means of suitable structural modification to stabilize such molecules in a singlet form which absorbs light at very long wavelengths (i.e. at small wave numbers).

1. Introduction

During its history of more than a century color chemistry has produced thousands of colored molecules; today these are used in many fields other than as textile colorings. Over the last twenty years research has been concentrated mainly on dyes with specific and optimized properties ("tailormade dyes"). Theoretical methods have been used increasingly in pursuing this goal: complex syntheses are attempted only when the required spectral properties are to be expected on the basis of either empirical experience or theoretical considerations.[1] While the need for compounds which absorb at long wavelengths ("deeply colored" compounds) initially involved blue and green textile dyes, much more attention has been paid recently to non-textile dyes which absorb at wavelengths even longer (more "bathochromic") than those typical for known substances. These compounds have an absorption band at the boundary of the visible region (ca. 750 nm) and in the neighboring area of the near infrared (above 750 nm). If the wavelengths usually used by organic chemists and color chemists[2] are converted into the physically more appropriate wave numbers (these are proportional to the energy), then the spectral region of interest lies at wave numbers below ca. $\tilde{\nu} \approx 1.33\ \mu m^{-1}$ (see Fig. 1). Such compounds can serve as receptors for infrared light or as NIR dye lasers.[3] The former are used in the manufacture of optical storage disks which react to light emitted in the near infrared at ca. 800 nm either by cryptoion lasers[4a] or by the particularly economical semiconductor (GaAs or GaAlAs) lasers.[4b, 4c] The application of organic NIR dyes in the following areas is also being studied: in liquid crystal displays,[1a, 5a] in the photosemiconductor layer of laser printers,[5b] as absorbers in laser filters[1a] or in plasts in plant

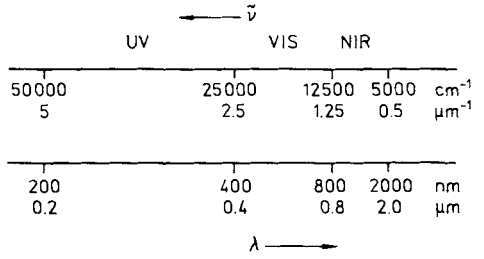

Fig. 1. The ultraviolet (UV), visible (VIS) and near infrared (NIR) spectral regions in wave number ($\tilde{\nu}$) and wavelength (λ) units.

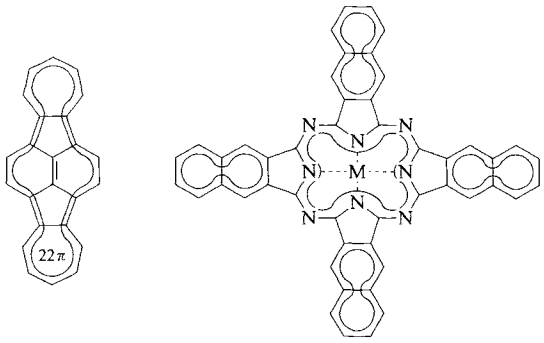
chemistry,[5c] as photochemotherapeutic agents[6] and as fluorescence dyes in HPLC laser fluorimetry.[7] The number of compounds available for such applications is at present very limited.

Known dyes have shown themselves to be suitable starting points in the search for compounds which absorb at extremely long wavelengths; they can be dealt with on the basis of either empirical experience or theoretical knowledge.[1] However, as we shall show in this article, it is also possible to begin from a completely different conceptual starting point: in this approach we shall consider diradicaloid compounds and vary their molecular structure in order to obtain compounds which absorb at long wavelengths.

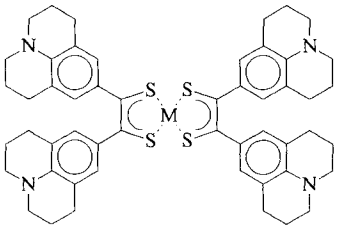
Some examples will show that the conventional approach can also lead to the same compounds with absorption bands at long wavelengths. We should therefore commence by stating that the change in the reference point and in the point of view is intended less as a new type of classification of the deeply colored compounds than as a method for stimulating chemical intuition in the search for deeply colored systems.

2. On the Long-Wavelength Absorption of Some Conjugated Organic Compounds

In the course of studies on linear and cyclic conjugated hydrocarbons it has been observed that the absorption wavelength cannot be increased beyond a certain limit simply by increasing the size of the π-electron system: thus, the absorption maximum in carotenoid polyenes is shifted only up to ca. 600 nm.[8] The color of a film of pure *trans*-polyacetylene **1**, which is a unidimensional solid, varies between copper-red and blue;[9a] while the absorption coefficient increases rapidly below ca. 900 nm, even here the absorption maximum lies at only ca. 650 nm.[9b] In the case of the aromatic [18]annulenes **2** the long-wavelength absorption shoulder just reaches into the near infrared:[10] however, no absorption band at longer wavelengths is observed when the ring size is increased.[11]



1 **2**

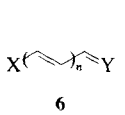


1: $\lambda \approx 650$ nm/$\tilde{\nu} \approx 1.53$ μm^{-1}, as a film [9b]
2: 768 nm/1.30 μm^{-1} (lg $\varepsilon = 2.15$), in chloroform [10].

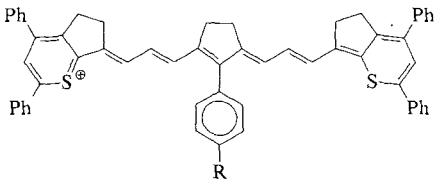
The failure of the absorption wavelength to increase further in long-chain polyenes and large-ring annulenes is considered to be due to a localization (fixation) of the conjugated bonding system in bonds with preponderantly single or double bond character. This bond fixation is interpreted as an electron-vibration interaction of the molecule (Jahn-Teller distortion) or as an electron-photon interaction of the solid (Peierls distortion).[12a] Theoretical studies have shown that the properties of long-chain polyenes are determined by electron correlation effects.[12b, 12c] In the case of ring systems the bond fixation corresponds to the loss of the delocalization of the conjugated bonding system present in benzene ([6]annulene) and still present to a large extent in [18]annulene. In addition, various configurations are possible for larger rings, non-planar arrangements often being preferred.[11b] However, even when the molecule is forced into a nearly planar configuration by a transannular bond or by substituents,[13, 14] NMR spectroscopy has shown that the higher annulenes become increasingly polyenic. This has again been demonstrated recently in a comparison between a structurally partially fixed [38]annulene[14] and smaller rings in the same series. The loss of the benzenoid ("aromatic") character with increasing ring size is in agreement with theoretical considerations.[12b, 15]

However, cyclic hydrocarbons with a fixed geometry which favors electron delocalization do indeed exhibit absorption bands which lie in the infrared region (e.g. **3**[16]): in this connection we should mention the tetraazaporphyrins, which are related to [18]annulene,[5b, 17a] thus in compound **4** a central metal atom is incorporated into a rigid structure. Long-wave absorptions are also observed for other metal chelates. Dithiolenes such as **5** absorb in the visible or near infrared,[17b-d] and in suitable solvents even up to 1400 nm.[17c] In these planar complexes the transition metal forms part of the π-system; the absorption band of longest wavelength is due to a $\pi \rightarrow \pi^*$ transition.[18]

3 **4**



5

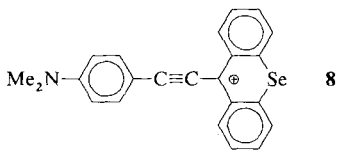


3: $\lambda = 900-1500$ nm/$\tilde{\nu} = 1.11-0.71$ μm^{-1} [16];
4: M = AlOH: 1204 nm/0.83 μm^{-1}, in acetyl chloride/$AlBr_3$ [17a];
5: M = Ni: 1298 nm/0.77 μm^{-1} (lg $\varepsilon = 4.68$), in dichloroethane [17c].

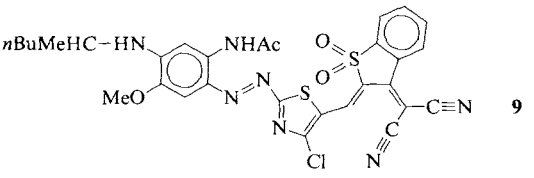
The polymethines **6** provide a general entry to extremely deeply-colored systems; polymethines differ from the polyenes **1** in that one of the terminal carbon atoms carries a donor group and the other an acceptor group. In this case we are dealing with meropolymethine dyes, merocyanines **6a** or, when the end groups are equivalent, with cyanine dyes (**6b**)

or oxonol dyes (**6c**).[8] The parent compounds for these three series are the streptopolymethines **6** and **7**.

6

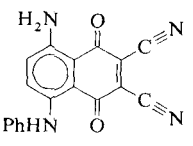


7

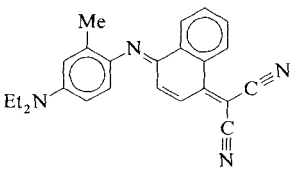


6a: X = NR_2; Y = O; **6b**: X = Y = $NR_2^{1/2\oplus}$; **6c**: X = Y = $O^{1/2\ominus}$;
7a: R = H: λ = 1500 nm/$\tilde{\nu}$ = 0.66 μm^{-1}, in dichlorobenzene [20b];
7b: R = $NHMe_2^{\oplus}$: 1500 nm/0.66 μm^{-1} (lg ε = 4.75) in dichloromethane [20c].

A large number of relatively stable NIR dyes has been made available by incorporating suitable cyclic end groups and by using methylene groups to stiffen the polymethine chains;[20] in the case of the polymethines **7** the absorption band lies at 1500 nm.[20b, c] While at present no upper limit for the absorption wavelength of the polymethine dyes is apparent, a limiting wavelength is expected for the unidimensional solid; this will depend on the end groups present.[21]



NIR dyes can also be found in other types of compounds which, though formally related to the polymethine dyes, traditionally form separate classes of dyes. These include the xanthenylium, thioxanthenylium and selenoxanthenylium dyes (e.g. **8**),[22] azo dyes (e.g. **9**),[23] naphtho- and anthraquinones (e.g. **10**),[5c, 24] indophenols and analogues (e.g. **11**)[25a] and other merocyanine-like dyes.[25b, c]



8

9

10

11

8: λ = 802 nm/$\tilde{\nu}$ = 1.25 μm^{-1} (lg ε = 4.93), in chloroform [22];
9: 778 nm/1.29 μm^{-1} (4.92), in dichloromethane [23];
10: 760 nm/1.32 μm^{-1}, in cyclohexane [24a];
11: 761 nm/1.31 μm^{-1} (4.49), in chloroform [25a].

The preparation of these and other dyes[26] was made easier by the application of quantum-chemical models and computation methods, in which a known chromophore structure was modified either in totality or as a linked donor-acceptor system. The theoretical estimation of the color-determining $\pi \rightarrow \pi^*$ transitions involved the use of a topological approach on the basis of the Hückel MO method, and also in some cases graph theory;[27] however, the main tool was the Pariser-Parr-Pople [PPP] method.[1a, 8b]

Since the color-determining electron transition in polymethines is very well described as a transition between the highest occupied MO (HOMO) and the lowest unoccupied MO (LUMO), qualitative approaches for decreasing the spectral excitation energy often involve diminishing the energy difference between the frontier orbitals (Fig. 2, left-hand

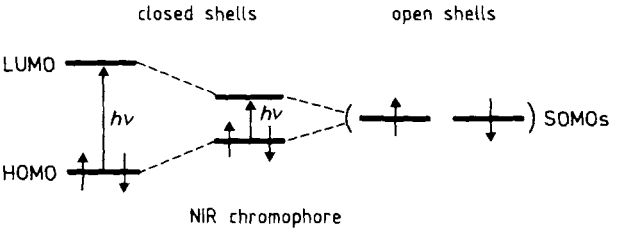


Fig. 2. HOMO-LUMO energy separation and spectral excitation energy of singlet configurations. SOMO = singly occupied molecular orbital.

side); even the simplest perturbation theory considerations can be very useful for this purpose.[8a] As the HOMO-LUMO energy difference decreases, so also does the spectral excitation energy; thus the absorption band will be shifted to longer wavelengths. Such arguments are generally used for structures which are of a more or less classical type.

One can however envisage that a small HOMO-LUMO difference can also be due to other factors. There are a number of structures with degenerate or nearly degenerate MOs which are occupied by only two electrons: these are diradical or diradicaloid compounds. When the MOs are degenerate the spectral excitation energy in fact appears to be zero when the electron interaction is not taken into account. The diradicals of interest here are acyclic or cyclic π,π-diradicals (π,π-diyls). The highly symmetrical compounds trimethylenemethane (C_{3v} symmetry) and cyclobutadiene (D_{2h} symmetry) are examples of hydrocarbon diradicals (compare Fig. 3); their degenerate MOs are non-bonding (NBMOs). *Zhixing* and *Sigun*[28] have shown how the occurrence of degenerate

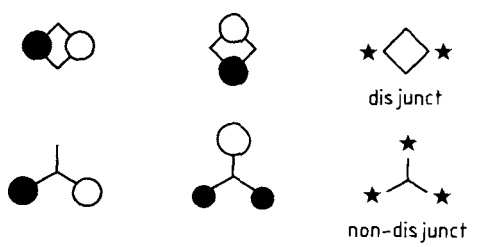

Fig. 3. The characteristics of the degenerate non-bonding π-MOs of two diradicals; the MOs can be either fully localized on different atoms (cyclobutadiene as a disjunct alternant diradical) or can have atoms in common (trimethylenemethane as a non-disjunct alternant diradical). A classification is possible using the "starring" procedure (see text).

NBMOs can be recognized from the topological matrix of the hydrocarbons.

A more detailed analysis of the degenerate MOs has shown that the linear combinations of the delocalized wave functions can either be localized on different atoms of the π-system (as for example in the case of cyclobutadiene, Fig. 3) or can have contributions common to like atoms (e.g. trimethylenemethane). According to the nomenclature used by *Borden* and *Davidson*, molecules of the first type are known as disjunct, alternant diradicals.[29a, b] These include alternant hydrocarbons in which the numbers of starred and unstarred atoms in the π-system are equal.[29c] This classification is of interest when the question posed is whether the diradical exists as a singlet or a triplet molecule.

The probability of obtaining a singlet configuration will always increase when the orbital degeneracy is removed. If the energy difference between the HOMO and the LUMO is small, we can expect an absorption at relatively long wavelengths.[30]

3. Chromophores Derived from Diradicaloid Compounds

3.1. Some General Remarks Concerning the Electronic Structure of Diradicals

The picture shown in Figure 2 of an electronic state in which two degenerate π-MOs are each occupied by one electron requires refinement. As was shown in detail by *Salem* and *Rowland*[31a, b] and by *Michl*,[31c] the diradicals defined in the two-electron-two-orbital model can take up one of six different electron configurations (compare Fig. 4): these correspond to a triplet state (T_1) and three singlet states (S_0, S_1, S_2).

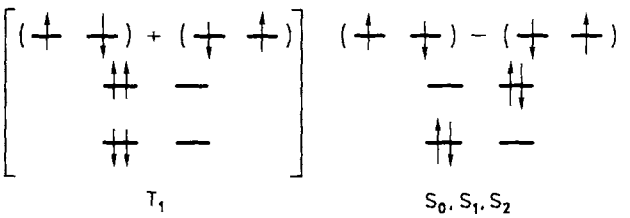

Fig. 4. The four electronic states of a diradical which result from different occupancy of two degenerate MOs by two electrons, taking the electron spin into account.

If the interactions between the electrons are taken into account, the energies of these configurations are in general no longer equal. *Bonačić-Koutecký*, *Koutecký* and *Michl* have dealt in detail with the relative energies of diradicals in the two-electron-two-orbital model in connection with the interpretation of the photophysical and photochemical properties of unsaturated organic molecules.[31d] In the case of the "homosymmetric" ("perfect") diradicals the degeneracy between S_0 and T_1 states is retained only for the so-called "pair" biradicals: these include the square cyclobutadiene shown in Figure 3. Of more interest for our discussions in this article are those diradicals in which the degeneracy between S_0 and S_1 is not lifted. According to *Bonačić-Koutecký* et al.[31d] these are always the "axial diradicals", which include trimethylenemethane (see Fig. 3). Although the energy difference between the singlet state S_0 and the triplet state T_1 is not an optimum criterium for a diradical, an S_0-T_1 splitting of the order of *RT* (ca. 10 kJ/mol) can be regarded as a characteristic feature of diradicals.[31e] The two-electron-two-orbital model also implies that an excitation from the lowest energy singlet state lies at lower energy than that of a triplet-triplet excitation, since the model includes only one single triplet state.[31e]

A configuration interaction is included in quantum-chemical calculations for diradicals. In the simplest calculations based on the two-electron-two-orbital method this interaction is limited to three singlet configurations (3 × 3 CI). In semiempirical calculations using the MNDO method the SCF wave functions are obtained in an approximation in which the valence electron system forms an open shell (half-electron method).[32] For limitation to a 2 × 2 CI a closed shell is assumed, and the configuration of the ground state is mixed with that of the doubly excited state. In principle the approach known as the two-configuration SCF method (TCSCF) is better: it has also been used in a semiempirical all-valence-electron approximation.[33] In MNDOC calculations electron correlations are treated in terms of perturbation theory.[34]

Reliable predictions regarding the energy spectrum of diradical structures only become possible when complex ab initio calculations are carried out. In the case of π,π-diyls these include all configurations of the π-space; MRD-CI and MCSCF-CI calculations include a suitable selection of configurations.[29a, 31d] However, because of the extreme complexity of the calculations the term schemes of larger conjugated organic molecules have not so far become available using these methods. Detailed calculations carried out for small molecules have shown that Hund's rule, which was derived for atoms and which requires that the triplet state of the diradicals should be of lower energy than the singlet state, should not strictly apply.[29a, 35, 36] The disjunct, alternant diradicals already mentioned are potential candidates for molecules with a singlet ground state. The relative stability with respect to the triplet state is said to be due to dynamic spin polarization.[36]

The degree to which the degeneracy of the MOs is lifted, and the energy difference between the HOMO and the LUMO increased, parallels the stabilization of the singlet state with respect to the triplet state. The "perfect" diradical undergoes a transition via a "non-perfect" diradicaloid[31d] to a normal molecule. The lifting of the degeneracy can have different origins; for instance, heteroatoms or groups containing heteroatoms may have replaced the CH or CH_2 groups of the diradical hydrocarbons. The reason may however also lie in a dynamic instability of the hydrocarbon which leads to a molecule of lower symmetry:[37] this phenomenon is known as the Jahn-Teller effect. Depending on the type of substitution, one or another Jahn-Teller distorted structure may occur in the derivatives of these diradicals.[38]

The diradical character of a diradicaloid structure can be judged on the basis of various criteria.[39] The occupation numbers of the natural orbitals, which are obtained from the density matrix, have proved particularly suitable.[39c] A fur-

ther criterion relates to the relative energies of the singlet and triplet states of lowest energy: according to *Wirz*[31e] a compound is a diradicaloid when the energy of the singlet-triplet splitting (S_0/T_1) lies between ca. 10 and 100 kJ/mol (800–8000 cm^{-1}); thus the energy difference can be greater than the thermal energy at room temperature.

According to the two-electron-two-orbital model we expect a term scheme for the diradicaloid singlet state which, apart from the triplet state, contains at least one excited singlet state which lies lower in energy than the ground state (Fig. 5). The $S_0 \rightarrow S_1$ excitation is then responsible for the long-wavelength light absorption.

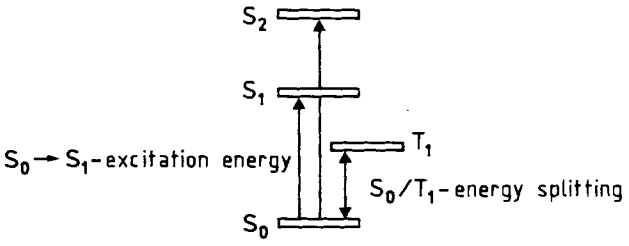

Fig. 5. Relative energies for the states of a diradical using the two-electron-two-orbital model for a diradicaloid with singlet ground state.

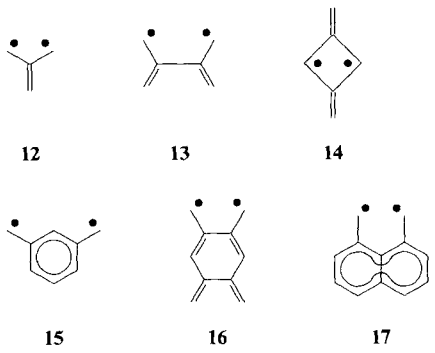
When the spectral excitation energy is described by a transition from the HOMO (a) to the LUMO (b), the singlet-singlet excitation energy ΔE_{ab} is, to a close approximation, given by Equation (1):

$$\Delta E_{ab} = \varepsilon_b - \varepsilon_a - J_{ab} + 2K_{ab} \quad (1)$$



According to Equation (1) ΔE_{ab} is equal to the energy difference between the HOMO and the LUMO (ε_a, ε_b) minus the molecular Coulomb repulsion integral J_{ab} plus double the exchange integral K_{ab}. If the frontier orbitals formed from the degenerate MO describe spaces occupied by the electrons which are almost separate, K_{ab} will be relatively small; small K_{ab} values lead to a long-wavelength light absorption.[40] However, this same electron distribution character is also connected with a low transition probability for the electronic excitation, since then the transition dipole D_{ab} is relatively small. Since the oscillator strength f, which is proportional to the integral of the area under the absorption band, is given by Equation (2):

$$f = 1.085 \times 10^{-5}\, \Delta E_{ab}\, D_{ab}^2 \quad (2)$$

D_{ab} must be sufficiently large to compensate for the decrease in the oscillator strength which necessarily results from a small value of ΔE_{ab}.

3.2. Diradicaloid Non-Kekulé Structures

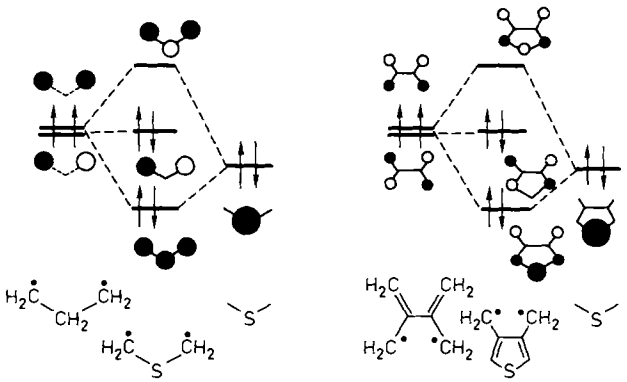
One group of diradicaloid compounds has "non-Kekulé" structures, i.e. the compounds cannot be described by conventional (Kekulé) structural formulas without the use of a long formal bond. They are derivatives of the hydrocarbons **12**–**17**, the diradical character of which is made clear by the following valence bond formulas.

These diradicals have been investigated in detail in the last few years,[29a] and they are now more readily available.[41] The compounds **12**–**17**[42–47] and some of their simple derivatives have shown themselves to be triplet diradicals.

Theoretical predictions according to which the singlet states of **13** and **16** should be of lower energy than the triplet states[35] have not so far been confirmed experimentally.[43,46]

According to PPP calculations carried out by *Gisin* and *Wirz*[48a] the triplet-triplet absorptions for a number of π,π-diradicals lie in the visible spectral range. Experimental details are available for **14**,[44] **15**[45] and the methylene-bridged **17**.[47] The discussion above suggests that singlet-singlet excitations should lie at lower energies than triplet-triplet absorptions. The absorption band of the singlet-singlet absorption was calculated to lie at 1000 nm for **17**[31e] and well above 1000 nm for **14**.[48b]

In order to stabilize the singlet state of a non-Kekulé hydrocarbon in comparison with the triplet state it is necessary to carry out a suitable structural modification of the hydrocarbon diradical. As shown in Figure 6 for the trimethylene **18a** (X = CH_2),[49] the replacement of the central CH_2 group by an atom X (with a doubly occupied p orbital) leads to a splitting of the NBMOs. Since only the symmetrical combination of the p_π-orbitals of the terminal carbon atoms[50] overlaps with the p_π-orbital of the heteroatom, the degeneracy is lifted and the lowest energy electronic transition is described by a one-electron transition from the symmetrical HOMO to the antisymmetrical LUMO. In Figure 6



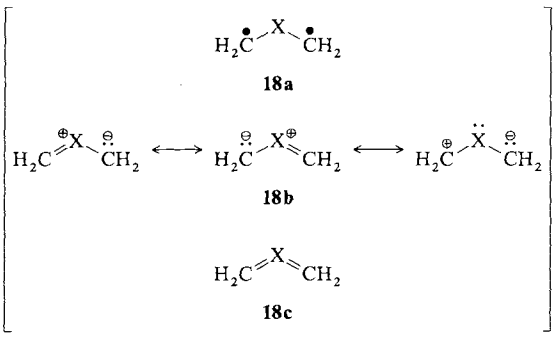


Fig. 6. Lifting of the degeneracy of the NBMOs of trimethylene (**18a**, X = CH_2) [50] when CH_2 is replaced by S (left) and on cyclization of trimethyleneethane **13** by means of S (right) via overlap of the symmetrical MOs of the diradicals with the p_π-orbital of the heteroatom.

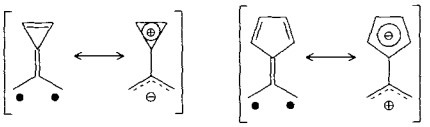
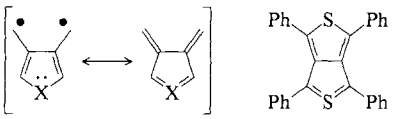
this splitting is shown for the substitution of CH_2 by σ-bivalent sulfur to give **18a**, X = S.



According to perturbation theory considerations in the MO picture, the HOMO-LUMO difference will, however, only be small when the heteroatom X is more electronegative than carbon and/or when the p_π-orbitals of carbon and the heteroatom overlap only slightly. When this prerequisite is not fulfilled, as for example in the case considered where X is sulfur, the π-system is more strongly delocalized and the degree of diradicaloid character is either slight or negligible. In this case the electronic structure is better represented by valence bond formulations such as **18b** in which X is a donor atom. One of the mesomeric structures of **18b** indicates the presence of 1,3-dipolar properties, which are often used in the interpretation of cycloaddition reactions of trimethylene and its derivatives.[51] In formula **18c** the heteroatom is bonded to the carbon atoms via an extension of its electron octet.[52]

18a **18b** **18c**

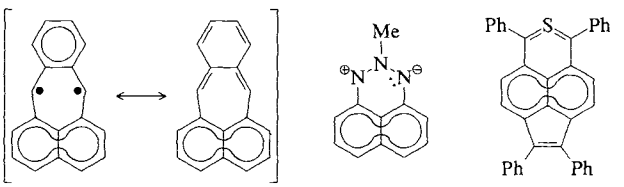


Before we discuss some derivatives of the biradical hydrocarbons **12–19**, it should be noted that here, just as for **18a–c**, the representation of the compound by a single valence bond structure is not possible. However, for the sake of simplicity and in spite of their deficiencies we have below used valence bond formulas of the type found in the literature.

Problems of this type exist not only for compounds containing heteroatoms but for the hydrocarbons themselves: a betaine structure is also indicated in the case of the non-Kekulé hydrocarbons **19** and **20**, which belong to the group of the non-alternant hydrocarbons. In contrast to **12–18, 19** and **20** do not have degenerate MOs but are still to be classified as diradicaloid hydrocarbons.[39c, 53]

19 **20**

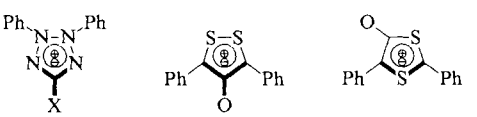
The heterocycles 3,4-dimethylenefuran and 3,4-dimethylenethiophene (**21**, X = O, S) can be considered to be derivatives of trimethyleneethane **13**. These heterocycles have been synthesized;[54] their purple-red color is due to a singlet-singlet transition. The intensity of the color absorption band in **21** (X = S) is relatively high. The introduction of a heteroatom into **13** leads to the lifting of the degeneracy of the NBMOs (see Fig. 6), and the triplet hydrocarbon is converted into a heterocycle with singlet character. It has been shown by ab initio calculations[56] that the S_0/T_1 splitting increases with increasing donor ability of the heteroatom.



21 **22**

21: X = O: λ = 560 nm/$\tilde{\nu}$ = 1.79 μm^{-1} (lg ε > 3);
21: X = S: 572 nm/1.75 μm^{-1} (>4), in toluene [54];
22: 550 nm/1.82 μm^{-1} (4.01), in cyclohexane [55].

The synthetically available thieno[3,4-*c*]thiophene, which has been described according to formula **22** as a heterocycle with "tetravalent sulfur", is related to **21** (X = S) and also absorbs at relatively long wavelengths.[55] **22** differs in color from the isomeric thienothiophenes, which are classical thiophene derivatives with σ-bivalent sulfur.

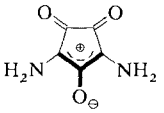


Derivatives of **17** include the blue pleiadene **23** and the (also blue) heterocycles **24** and **25**, which exhibit only relatively weak long-wavelength absorptions.

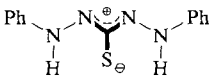
23 **24** **25**

23: $\lambda \approx$ 690 nm/$\tilde{\nu} \approx$ 1.45 μm^{-1}, in 3-methylpentane [57];
24: 607 nm/1.65 μm^{-1} (lg ε = 2.98), film [58];
25: 665 nm/1.50 μm^{-1} (3.37), in dichloromethane [59].

At this point we should also mention mesoionic compounds[60] which absorb at relatively long wavelengths when they contain sulfur as the heteroatom. Again their absorption bands lie at wavelengths considerably greater than those for isomeric non-mesoionic heterocycles; examples are compounds **26–28**. In the formulas shown below the diradical substructure, which is derived either from **12** (an example of a mesoion of the first kind) or from **18** (an example of a mesoion of the second kind), is denoted by bolder bonds.



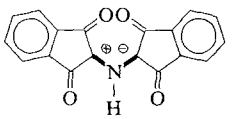
26 **27** **28**



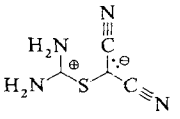
26: X = O: λ = 350 nm/$\tilde{\nu}$ = 2.86 μm^{-1} (lg ε = 3.68), in chloroform [61];
26: X = S: 468 nm/2.14 μm^{-1} (3.07), in chloroform [61];
26: X = $C(CH_2)_2$: 468 nm/2.14 μm^{-1} (2.97), in acetonitrile [62];
27: 575 nm/1.74 μm^{-1} (4.23), in benzene [63];
28: 553 nm/1.81 μm^{-1} (4.11), in dioxane [64].

Exactly as has been shown for **23**,[57] doubly excited configurations are also of importance in the description of mesoionic compounds, as for example in the case of the 1,2-dithiolylium-4-olates (e.g. **27**), which also absorb at relatively long wavelengths.[65, 66]

The diradicaloid oxyallyl substructure is also present in croconic acid derivatives such as **29**; however, it is so distorted that the singlet-singlet excitation energy is relatively large, and the compound is only yellow in color.[67] A substitution product of the diazathioxyallyl, however, absorbs at much longer wavelengths. The dithizone **30**, which has a chain structure with respect to **26** (X = S), dissolves in organic solvents to give a green solution.[68, 69]



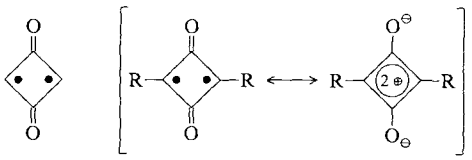
29



30

29: λ = 440 nm/$\tilde{\nu}$ = 2.27 μm^{-1} (lg ε = 4.11), in dichloromethane [67a];
30: 617 nm/1.62 μm^{-1} (4.44), in hexane [68].

31, which is derived from the diradicaloid **18**, has been described[70] as a stable dipolar azomethine ylide; its structure has been determined by X-ray crystallography. As in the case of capto-datively stabilized thiocarbonyl ylides such as **32**, the spectral excitation energy is relatively high,[71] and deeply-colored compounds of this type are so far unknown.

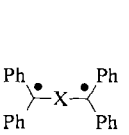


31

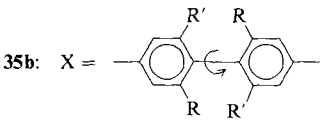
32

31: λ = 485 nm/$\tilde{\nu}$ = 2.06 μm^{-1} (lg ε = 4.20), in chloroform [70].

Finally, we should mention compounds in which several carbon atoms of a non-Kekulé hydrocarbon have been replaced by heteroatoms; although such a substitution removes the degeneracy in diradicals such as **15** and **17**, some derivatives do in fact exist as triplet molecules.[35c, 72] The dicarbonyl compound **33** formed by substitution of the exocyclic CH_2 group in **14** by oxygen is, according to *Gleiter* and *Hoffmann*, a singlet molecule ($\lambda_{calc.}$ = 610 nm).[73] **33**, which is so far unknown, forms a building block for the squaraines of general structure **34**; these absorb at long wavelengths and are of interest because of their possible application as materials for electrophotographic reproduction, in solar cells and in optical storage disks.[4a, 74] These compounds are generally described as betaine-type cyclobutenediylium diolates; however, according to the results of ab initio calculations for **34a** (NR_2 = NH_2) they do not in fact have such an electronic structure.[75]



33



34a: R = NR_2
34b: R = NHC_6H_5
34c: R = *p*-$C_6H_4NH_2$

The diradical character of the parent hydrocarbon **14** is apparently destroyed by substitution; the color variation from **34a** (NR_2 = piperidine, yellow) via **34b** (red) to **34c** (blue)[8b, 76] apparently reflects the increasing π-delocalization rather than a stepwise perturbation of a diradicaloid electronic structure.

Compounds in which two radical fragments are only weakly coupled are closely related to diradicaloid non-Kekulé structures. While the bridging of two diphenylmethyl radicals via *p*-diphenylene to give the orange-red Thiel hydrocarbon **35a** results in a quinoid structure,[77] bridging via a twisted π-electron system should result in retention of the diradicaloid structure; examples are Tschitschibabin's hydrocarbon and its derivatives[77, 78] and Müller's hydrocarbon.[78e]

35a: X =

35b: X =

35a, R = R′ = H: λ = 574 nm/$\tilde{\nu}$ = 1.74 μm^{-1} (lg ε = 5.02), in benzene [77];
35b, R = H, R′ = Me: 600 nm/1.67 μm^{-1}, 690 nm/1.4 μm^{-1}, in benzene [78a].

35b, R = R′ = H, which has been obtained in the form of green crystals with a metallic sheen or as a violet powder[77] exists at room temperature to the extent of 98% in a singlet state.[78b] The methyl-substituted compound **35b**, like various chlorine-substituted products[78c, d] is certainly twisted about the central C–C bond.[79] The spectra of the unsubstituted hydrocarbon and the derivatives mentioned above exhibit an intense absorption at λ > 600 nm; only in the case of **35b** has the UV/VIS spectrum also been measured above 600 nm, and it has been found to have an additional weak absorption at almost 700 nm.[78a, 80]

Tschitschibabin's hydrocarbon and compounds of this type form a transition to another class of diradicaloid compounds which can be classified in terms of an intra- or intermolecular charge transfer model.

3.3. Diradicaloid Structures with Charge Transfer

A diradicaloid electronic system will form when an unsaturated compound is twisted about the double bond.[29a, 31b, 82] In the extreme case the two molecular frag-

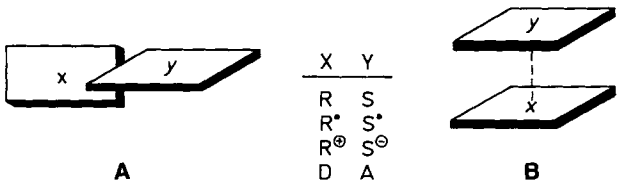


Fig. 7. Schematic representation of the geometry of a twisted molecule **A** and a sandwich complex **B** with partial structures X and Y. The fragments or single molecules X, Y represent radicals ($R^•$, $S^•$), ions ($R^⊕$, $S^⊖$) or donor and acceptor systems (D, A) of organic compounds with conjugated bonds.

ments will, as shown in Figure 7 by **A**, be approximately orthogonal.

The formation of a singlet ground state in diradicaloid structures of this type can be explained on the basis of the molecule-in-a-molecule model.[82] The no-bond (NB) ground state defined by the radical fragments is superimposed by a conformation which describes charge transfer (CT) in opposite directions; the mixing of the two configurations describes bonding between the two fragments (if these do in fact interact). If charge transfer plays a much more important role for the excited state than for the ground state, the transition from ground to excited state caused by light absorption will be accompanied by charge transfer; in such a case we are dealing with a charge transfer (CT) transition. However, the present case is that of a symmetrical molecule, so that the opposing charge transfer processes do not here lead to an effective charge shift: instead we have a charge redistribution (charge resonance, CR). In order to avoid any misunderstanding it is thus desirable in such cases to refer to a CR rather than a CT transition; this transition can lead to a long-wave CR band in the absorption spectrum.

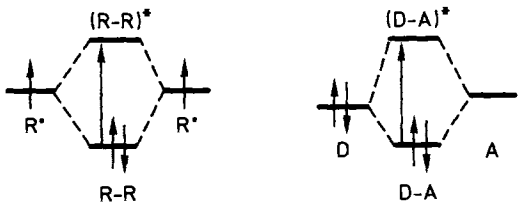

Fig. 8. Orbital splitting via overlap of the SOMOs of two radicals in a dimer structure (left) and of the HOMOs of a donor molecule with the LUMO of an acceptor molecule in a donor-acceptor complex with electronic excitation of CR or CT type respectively (right).

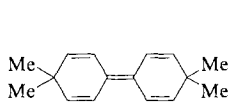
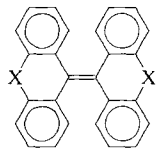
In Figure 8 the CR and CT absorptions are indicated in an MO picture for diradicaloid electron systems; the interacting MOs are of equal or approximately equal energy. For radical fragments R they are singly occupied (SOMOs), while the MO of a donor fragment (the HOMO) formally supplies two electrons to the bond and the lowest unoccupied MO of the acceptor fragment (the LUMO) none.

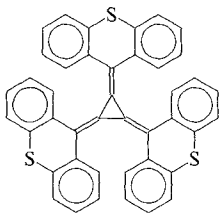


Our knowledge of compounds which are twisted about the double bond is limited. A torsion of this type must be forced by steric constraints, as for example in the case of the bridgehead olefin **36**.

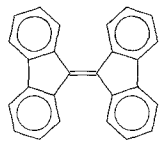


36

While the expected large effect on the electronic excitation is clearly present, it will hardly be possible to obtain highly colored compounds routinely on such a basis.[83]



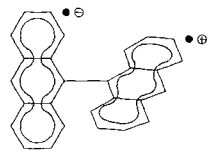
In sterically strained cross-conjugated compounds such as the dendralene hydrocarbon **37**,[84] dianthrone **38a**[85a, b] or dixanthylene **38b**,[85c, d] torsion about the double bond is replaced by folding. The green thermochromic form of the dianthrone **38a** is however due to a structure in which there is torsion about the double bond:[86] according to quantum-chemical calculations the torsional angle θ is ca. 57°.[33a, 87] The thermochromic form of the dixanthylene **38b** is probably also twisted.[88a, b] The recently synthesized highly colored [3]radialenes[88c, d] (e.g. **39**) are also definitely non-planar molecules.



37

38a: X = CO
38b: X = O

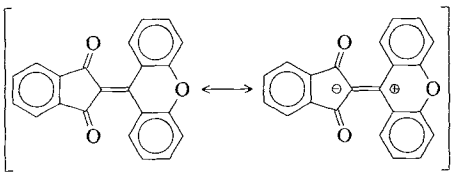
39



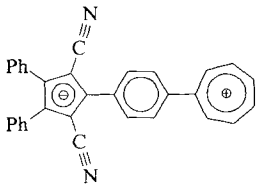
40

38a: λ = 675 nm/$\tilde{\nu}$ = 1.48 μm^{-1} (lg ε = 4.19), in dimethyl phthalate at 349 K [86b];
39: 600 nm/1.67 μm^{-1} (4.48), in dichloromethane [88c];
40: 460 nm/2.17 μm^{-1} (4.34), in benzene [89a].

Only in the case of 9,9'-bifluorenylidene **40** has the torsion of the molecule about the double bond been demonstrated by X-ray crystallography.[89a, b] Here the dihedral angle is relatively small (θ = 39°); the hydrocarbon is red. According to quantum-chemical calculations carried out using a semi-empirical two-configuration SCF method[33a, b] the twisted form of the difluorenylidene represents a global minimum while that of the dianthrone corresponds only to a local minimum on the potential energy hypersurface.



The situation can be expected to be similar for compounds with two dissimilar molecular "halves"; in this connection the TICT (Twisted Intramolecular Charge Transfer) molecules, which are at present the subject of intensive investigation,[90] should be considered; these include the twisted betainic 9,9'-dianthryl **41**.[90b, 91]



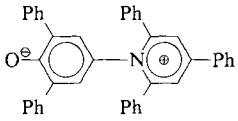
41

However, **41** and similar molecules are in fact relaxed molecules in an excited state; this can be recognized by the existence of an anomalous fluorescence or a rapid radiationless deactivation.[90b] The light absorption of interest here can be detected only by rapid spectroscopic methods; such studies[91a] have confirmed the twisted structure **41**, since characteristic absorptions of the fragment molecules could be detected. However, no information has yet been provided on the expected light absorption by **41** at extremely long wavelengths.

A betaine structure appears preferable when a diradicaloid structure is allowed to form from an unsymmetrical compound via torsion about a double bond. Although a few sterically hindered compounds of this type are known, little information is available on their molecular structure and spectral absorption. An example is compound **42** which was described by *Schönberg* et al. as being almost black in the solid state, deep blue when melted and violet in solution; in this compound the dihedral angle θ is 42.7°.[92] *Sandström* et al. showed that non-symmetrical sterically hindered double bond systems ("push-pull ethylenes") can also undergo a folding of the molecule rather than a torsion.[93]

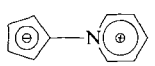
42

43



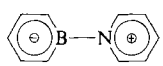
43: $\lambda = 934\,\text{nm}/\tilde{\nu} = 1.01\ \mu\text{m}^{-1}$, in bromobenzene; 672 nm/1.59 μm^{-1} ($\lg \varepsilon = 4.23$), in dimethyl sulfoxide [94].

Another type of compound with a basically similar structure, whose absorption in non-polar solvents lies well into the NIR, is derived from **43**.[94] The betaine character of **43** can be recognized from the hypsochromic shift of the color band which occurs when the non-polar solvent is replaced by a polar solvent (negative solvatochromic effect).

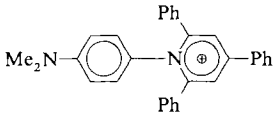


An interesting type of compound, whose long-wavelength spectral transition is characterized by a CT band, is provided by the extremely strongly solvatochromic pyridinium phenoxides (e.g. **44a**); these have been studied by *Reichardt* et al.[95] X-ray crystallography has shown that **44a** is also non-planar ($\theta = 65°$).

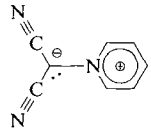
However, pyridinium betaines or colored pyridinium salts such as **44** (which are typical of many other conjugated organic compounds with similar structures) will only exhibit an absorption at long wavelengths when certain preconditions are fulfilled.



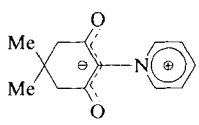
On the one hand, one half of the molecule (or a residue in the molecule) must be a strong electron donor (low ionization energy for the molecule derived from it), while the second half (or another residue) must be a strong electron acceptor (high electron affinity of the corresponding molecule). In this case the HOMO of the donor and the LUMO of the acceptor are almost degenerate, the CT excitation energy is small (long-wavelength CT band), and the compounds have structures of a diradicaloid type. The CT excitation energy will increase parallel to the extent that the donor and acceptor abilities diminish (left-hand side of Fig. 9a).



44a



44b



44c

44d

44e

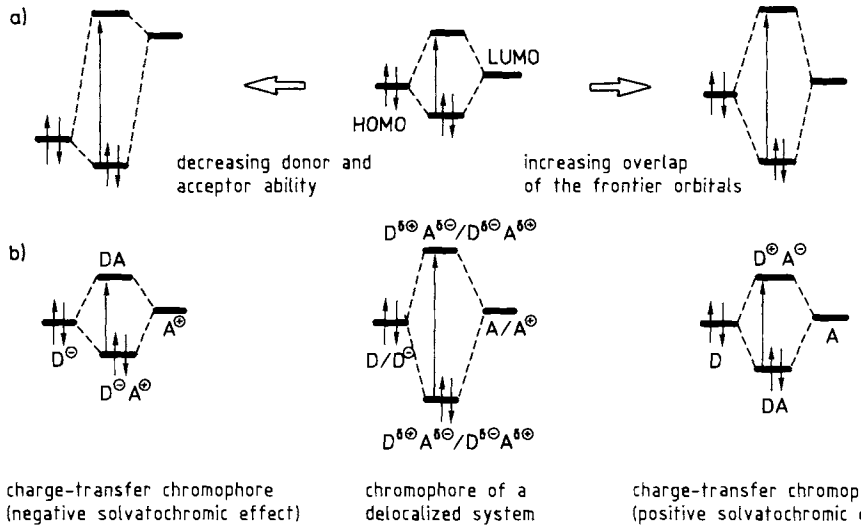
44f

44a: $\lambda = 795\,\text{nm}/\tilde{\nu} = 1.26\ \mu\text{m}^{-1}$ ($\lg \varepsilon \approx 4.1$), in dioxane [95];
44b: 495 nm/2.02 μm^{-1} (4.28), in acetonitrile [96];
44c: 472 nm/2.12 μm^{-1} (3.45), in tetrahydrofuran [97];
44d: 468 nm/2.14 μm^{-1} (3.76), in dichloromethane [98];
44e: 393 nm/2.54 μm^{-1} (4.33), in acetonitrile [99];
44f: 358 nm/2.79 μm^{-1} (3.24), in 85% ethanol [100].

However, the absorption wavelength also depends on the overlap between the donor and acceptor fragments. Even when an absorption at a very long wavelength is expected from the nature of the fragments, it can fail to occur because there is a good overlap of the fragment MOs. A poor overlap is often caused by torsion within a donor-acceptor molecule X-Y (X = D, Y = A), as indicated by **A** in Figure 7. We can thus understand that the color band in a number of pyridinium compounds of type **44** occurs at long wavelengths, while in other compounds it occurs at relatively short wavelengths.

It must also be remembered in the interpretation of light absorption that the character of the chromophore changes with increasing overlap of the donor and acceptor fragments. Two extreme cases are shown on the left- and right-hand sides in Figure 9b: a molecule which is electrically neutral is on the left-hand side a betaine in the ground state, and is characterized by the formula $D^{\ominus}\,A^{\oplus}$. The electronic excitation, which is accompanied by an electron shift, then leads to DA. The decrease in the dipole moment caused by the excitation is generally accompanied by a negative solvatochromic effect. In the second case, on the right-hand side of the figure, the ground state is represented by DA, and $D^{\oplus}A^{\ominus}$ characterizes the excited state.[101] The excitation causes an increase in the dipole moment, and a positive solvatochromic effect will result. However, whether in fact such a charge transfer occurs and leads to a long-wave absorption depends entirely on the conditions discussed above.

If as the result of a good overlap between the fragments a considerable charge shift occurs even in the ground state, then the latter is not satisfactorily characterized either by $D^{\ominus}A^{\oplus}$ or by DA. Instead we must write $D^{\delta\oplus}A^{\delta\ominus}$ or $D^{\delta\ominus}A^{\delta\oplus}$



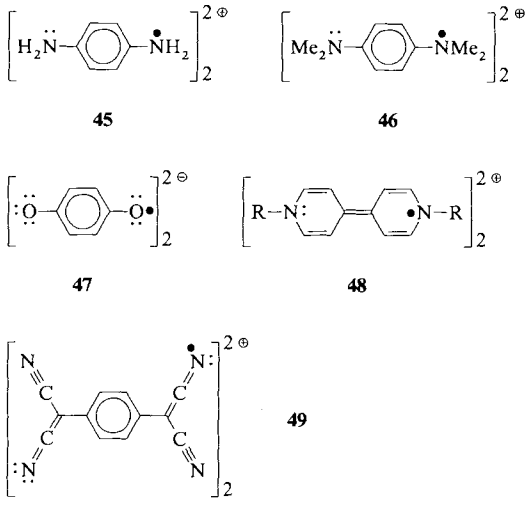


Fig. 9. a) Increase of the excitation energy (hypsochromic shift of the color band) as the result of an increasing HOMO-LUMO interaction and b) different characteristics of the change in charge distribution on excitation (vertical transitions).

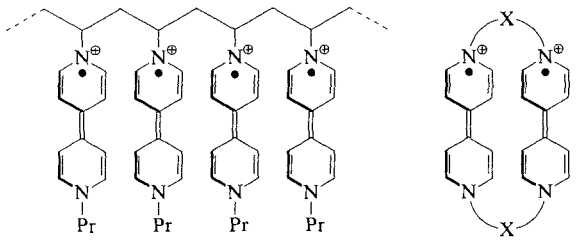
and in this case the same type of electron distribution is also present in the excited state. This is shown in the center of Figure 9b. Since the electron excitation is no longer accompanied by a charge shift between the fragments but by a redistribution of the charge within the molecule as a whole, we are no longer dealing with a CT chromophore; the chromophore of a new delocalized π-system has been formed.[102]

The above discussion can also be applied to compounds which are not joined by a σ-bond (or several σ-bonds) as in case **A** in Figure 7, but in which intermolecular interactions lead to the formation of an aggregate (case **B**). Such an aggregate of organic π-systems, which can be a dimer (X = Y) or a donor-acceptor complex (X ≠ Y) exists preferentially in a stacked arrangement. In the Figure this arrangement in space is only indicated in principle. The overlap in sandwich complexes is naturally only small, and an absorption at relatively long wavelengths is thus observed.

A large number of π-radicals exhibit a long-wavelength absorption at higher radical concentrations or at lower temperatures which is not observed for the monomer. The tendency to dimerization is particularly pronounced in the case of radical anions of Wurster and Weitz types. The dimers (also called "pimers"[103]), which in contrast to the monomers exist in a singlet state, absorb at longer wavelengths than the radicals themselves:[106] examples are the dimers **45** to **49**.

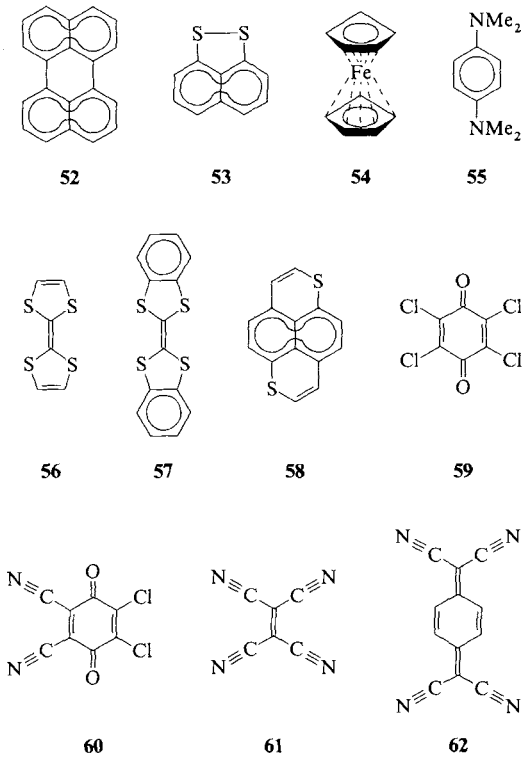


Since dimeric radicals can be described in terms of a symmetrical combination of CT-configurations, we are again dealing with an electronic excitation of the CR type.[107] The formation of dimeric structures can also be detected in the absorption spectra of polymers,[108] for example in **50**. The sandwich structure of the dimers is indicated by the spectra of compounds in which radicals are terminally bridged, e.g. **51**.[109] For the reasons stated above, the position of the dimer absorption should, for any one monomer, depend on the degree of overlap present: the absorption wavelength for compounds of type **51** does indeed increase with increasing distance between the radical fragments.[109]

45: λ = 605 nm/$\tilde{\nu}$ = 1.65 μm^{-1}, in ethanol [104a];
46: 780 nm/1.28 μm^{-1}, in ethanol [104a];
47: 585 nm/1.71 μm^{-1}, in ethanol [104a];
48: 870 nm/1.15 μm^{-1}, in water [103];
49: 1282 nm/0.78 μm^{-1}, in the crystal [105c].

The same long-wavelength band which is observed in solution for crystalline halides and perchlorates of radical cations[104b-d, 110] and for alkali metal salts of radical anions[105] is also observed (with small variations in the absorption wavelength) in their absorption and reflection spectra. The singlet-triplet energy splitting of the dimer band in salts of Wurster's blue is only ca. 250 cm^{-1}.[110] Crystallographic studies have shown that these radicals also dimerize in a stacked form.[111] The formation of the dimeric structures is accompanied by a decrease in the paramagnetic susceptibility.

When dissimilar partners are involved in aggregation (X ≠ Y) as in **B** (Fig. 7), charge-transfer complexes are formed; these have been studied in detail.[112] In the two-



50 51

50: λ = 860 nm/$\tilde{\nu}$ = 1.19 μm^{-1}, in water [108b];
51, X = *o*-phenylene: 840 nm/1.19 μm^{-1}, in methanol [109];
51, X = *m*-phenylene: 920 nm/1.09 μm^{-1}, in methanol [109].

electron-two-orbital picture of the diradicaloid structure, both electrons are provided by the donor molecule. When the prerequisites referred to for compound **A** (X ≠ Y) are met, intermolecular CT bands are observed in the NIR. Examples are provided by the following complexes: the fused hydrocarbon perylene **52** and tetracyanoethylene (TCNE) **61** (**52/61:** λ = 870, 900 nm in dichloromethane[113]), the heterocycle naphthalene disulfide **53** and tetracyanoquinodimethane (TCNQ) **62** (**53/62:** λ = 925 nm in dichloromethane[114]) and the organometallic compound ferrocene and TCNE **61** (**54/61:** λ = 900 and 1075 nm in cyclohexane[115]). These absorption bands are of low intensity (lg $\varepsilon \approx 2$). As has been shown for **52/61** and many other cases, the same CT band can be detected in the spectrum of the solid. The band at the longest wavelength undergoes a bathochromic shift with respect to that in solution of almost 1000 cm^{-1}.[113]

A linking together of the donor-acceptor molecule via σ-bonds makes it possible to predetermine the spatial positions of the partial structures and to study steric influences on the spectral absorption. The overlap of the frontier orbitals is often increased by the bridging, so that the color band is shifted to shorter wavelengths. When for steric reasons overlap is either poor or impossible, an absorption at relatively long wavelengths is observed. *Murata*[116] has demonstrated this for triptycenes in which donor-substituted benzenes were linked to TCNQ. In a theoretical study, *Vogler*[117] has predicted the conditions under which an electron transition from the donor to the acceptor fragment will occur in a CT compound of the cyclophane type, thus leading to a diradical-ion ground state.

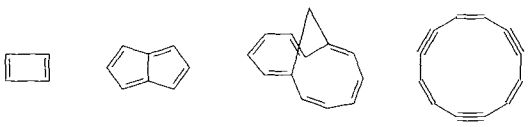
Radical ions can also be detected when CT complexes are studied in polar rather than non-polar solvents,[118] for example the system **55/59** in acetonitrile.[118a] In the case of **55/62** the equilibrium constant and the thermodynamic parameters have been determined for the equilibrium between the neutral compounds and the radical ions in acetonitrile. The tendency for electron transitions to occur is even larger in the crystalline state.[119] If the donor and (or) acceptor molecules form separate stacks in the crystal, then (as already stated) the long-wavelength absorption of a dimer structure (a CR band) is observed.[104b-d] The antiferromagnetic interaction of the radicals can also be inferred from the magnetic susceptibility value.[104c, 120] As for the CR bands of the dimeric radicals in solution, an absorption at ca. 1.0 μm (10000 cm^{-1}) is observed in saltlike CT complexes such as the crystalline complex **55/59**.[104c]

52 53 54 55

56 57 58 59

60 61 62

CT complexes are also known which absorb at considerably longer wavelengths; their absorption bands can lie even above 3 μm (at ca. 3000 cm^{-1}).[121-123] In such cases the electronic excitation spectrum overlaps the vibrational spectrum.[124] This unusual absorption behavior was observed by *Iida*[121] and later studied in detail by *Torrance* et al.[122] These extremely long-wavelength absorptions occur when the CT complex shows conducting properties. An important prerequisite is the formation of separate stacks for the complex partners in the crystal and a partial electron transfer between the molecules within the stacks; such complexes are thus also referred to as mixed valence CT complexes.[122b]

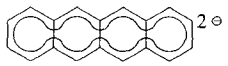


The absorption bands of these complexes are due to factors different from those responsible for the CT and CR bands of diradicaloid systems. They have their origin in the occurrence of free charge carriers[125] and have been interpreted in terms of band models.[122a] *Torrance* et al.[122c] and *Saito* et al.[123] have shown clearly from the reflection spectra of CT complexes (in KBr) that variation of the complex partner can cause a transition from the neutral complex (ionicity ca. zero) via the mixed-valence complex (ionicity ca. 0.5) to the complex of the radical salt (ionicity ca. 1); this transition is accompanied by characteristic changes in the spectra. While the neutral complex **57/62** shows a typical CT band, the organic conductors **56/62** and **57/60,** which are mixed-valence complexes, absorb at ca. 3.3 μm (3000 cm^{-1}).[122c] The complex **56/60,** however, is a radical salt, and the typical dimer band of the radicals caused by a CR transition is observed. A theoretical interpretation of the spectra of the various complexes has been given by *J. Tanaka* et al.[123c] A recent report has appeared on the IR spectra of mixed-valence complexes derived from Weitz-type donors, which also exhibit electrical conductivity and a spectral behavior analogous to, e.g., **58/62**.[123d]

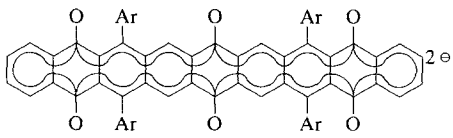
3.4. Diradicaloid Cyclopolymethine-Type Structures

Electronic structures with a diradicaloid character can also be derived from cyclic conjugated systems. It can readily be seen from Frost's circle, a mnemonic method for deriving the MO energies of monocyclic hydrocarbons,[126] that occupancy of the MOs of such hydrocarbons by a total of $4n$ π-electrons leads to the presence of degenerate MOs which contain a total of two electrons; these MOs can be bonding, non-bonding or antibonding. Such molecules form anti-Hückel systems, for which *Breslow*[127a] and *Dewar*[127b] have coined the term antiaromatic. In the past few years a great deal of information has become available on such compounds.[128]

These molecules are distorted because of a second-order Jahn-Teller effect; annulenes with $4n$ π-electrons thus exist in a singlet ground state. When bond alternance is introduced via the choice of the resonance integrals $\beta_{C=C}$ and β_{C-C} in the Hückel approximation, a HOMO-LUMO energy difference of $2(\beta_{C=C} - \beta_{C-C})$ is obtained, independent of the ring size;[129] the $\pi \rightarrow \pi^*$ transition of lowest energy is forbidden. Even when the electronic interactions are taken into account there is no clear dependence of the absorption wavelength on ring size; according to PPP calculations the color of such compounds should vary between red and blue. This agrees with experimental results: thus [16]annulene is described as being purple.[11a] However, according to X-ray crystallography [16]annulene is non-planar, and D NMR studies show that in solution there is an equilibrium between conformers.[11b]



Cyclobutadiene **63** occupies a special position within the series of $4n$ π-annulenes. Studies on a peralkylated cyclobutadiene have indicated the (adiabatic) S_0/T_1 energy splitting to be only 50 kJ/mole,[130] so that this compound can also be described as a diradicaloid; however, an extremely large bond alternance, which has been confirmed experimentally for several derivatives,[131, 132] leads to an absorption at relatively short wavelengths.[130] According to ab initio calculations the absorption band observed for **63**[130b] corresponds to the $S_0 \rightarrow S_1$ transition of lowest energy.[130c]

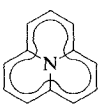


63 **64** **65** **66**

63: $\lambda \approx 300$ nm/$\tilde{\nu} \approx 3.33$ μm^{-1}, in a matrix [130b];
64: 594 nm/1.68 μm^{-1} ($\lg \varepsilon = 1.87$), in hexane [133];
65: 425 nm/2.35 μm^{-1} (2.38), in cyclohexane [134];
66: ca. 480 nm/$\approx$ 2.08 μm^{-1} ($\approx$ 2.2), in isooctane [135].

Planarity can be induced in cyclic compounds by the introduction of a transannular bond or a bridge (e.g. CH_2) or by "stiffening" the ring by replacement of a double bond by a triple bond (e.g. in **64–66**): however, π-bond equalization cannot be forced.[133, 136] The latter is realized better in acene dianions (e.g. **67**)[137] and their heteroanalogues[138] as far as the perimeter bonds are concerned; these ions are red, blue or green in solution, depending on the degree of annelation.[139] A clear relationship exists between the energy difference and the paramagnetic ring current determined from the NMR chemical shifts.[137]

67



68

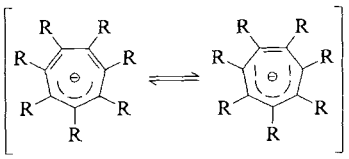
67: $\lambda = 673$ nm/$\tilde{\nu} = 1.49$ μm^{-1} ($\lg \varepsilon = 4.76$), in 1,2-dimethoxyethane [139b];
68: Ar = *p*-$(CH_3)_3C-C_6H_4$: 1900 nm/0.53 μm^{-1} (4.88) [140].

Dianions should be stabilized by acceptor substituents and dications by donor substituents; the long-wavelength light absorption of these ions does not necessarily have to be related to the presence of a diradicaloid "antiaromatic" chromophore. The electron configuration of prime importance in a description of the excited state of lowest energy is one which can in principle be derived from the two lowest unoccupied MOs of the corresponding neutral compound in the case of the anion and from the two highest occupied MOs in the case of the cation. From this point of view we are dealing with "unnatural" electronic transitions of the $\pi^* \rightarrow \pi^*$ or $\pi \rightarrow \pi$ type, in contrast to the "natural" $\pi \rightarrow \pi^*$ transitions. The differences in the energies of these MOs suggest that the former will lead to a light absorption at longer wavelengths than will the latter; such a picture had already proved extremely useful in the interpretation of the extremely long-wavelength absorption of many organic radicals.[26, 140] It also allows us to understand the extremely long wavelength (1–2 μm) of the absorption of the dianion of the triquinone **68**, which *Miller* et al. had observed in the study of the absorption spectra of polyacenequinone radicals.[140]

A simple derivative of the "antiaromatic" [12]annulene is [3.3.3]cyclazine **69**. This compound is probably characterized by a fairly complete equalization of the CC bond lengths; the color band of **69** lies in the near infrared.[141] Stepwise replacement of CH in the perimeter by nitrogen shifts the band from the infrared into the visible and finally into the UV region.[141a, 142]

69

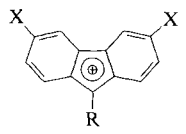
$\lambda = 1290$ nm/$\tilde{\nu} = 0.78$ μm^{-1}, in hexane [141a].



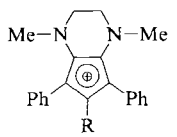
In contrast to the situation for rings with an even number of atoms, a long-wave absorption is expected for ionic rings

with $4n$ π-electrons even when a Jahn-Teller distortion leads to the formation of polyenic or carbopolymethine substructures. An exception is formed by the cyclopropenide, which ab initio calculations[143] indicate to be non-planar (see formula **70**).

70

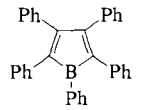


71

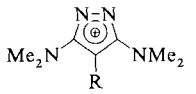


72

72: R = H: $\lambda \approx 750$ nm/$\tilde{\nu} \approx 1.33$ μm^{-1}, in tetrahydrofuran [153a];
72: R = Ph: 563 nm/1.78 μm^{-1}, in propylamine [153b].



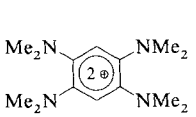
An absorption in the near infrared has been calculated[144] to occur for a planar structure of the Jahn-Teller distorted cyclopentadienyl cation **71**.[145] Pentaphenyl-**71**, which in solution has singlet and triplet molecules in equilibrium, is blue.[146] The products of benzo-condensation **73**[147,148] and amino-substitution **74**[149] are also long-wavelength absorbers (deeply colored); they have been characterized by their UV-VIS spectra and in some cases isolated.



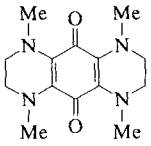
73

74

75

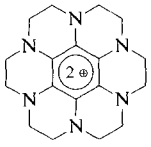


76



73: X = R = H: $\lambda = 670$ nm/$\tilde{\nu} = 1.49$ μm^{-1} (lg $\varepsilon \approx 3.1$), in conc. sulfuric acid [147];
73: X = NMe_2, R = Ph: 955 nm/1.05 μm^{-1} (≈ 4.3), in acetic acid [148];
74: R = NMe_2: 624 nm/1.60 μm^{-1} (2.71), in dichloromethane [149a];
74: R = OEt: 735 nm/1.36 μm^{-1}, in acetic anhydride [149a];
75: 567 nm/1.76 μm^{-1}, in toluene [151];
76: 583 nm/1.72 μm^{-1} (3.71), in acetonitrile [152].

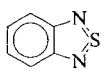
Apart from the cyclopentadienylium salts, heterocycles such as **75** and **76**, the parent molecules of which are π-isoelectronic with **71**, are worthy of mention. The synthesis of these carbocyclic and heterocyclic cation salts and other diradicaloid structures was stimulated by studies on ferromagnetic organic compounds.[150]



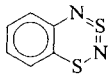
The stabilization of the cycloheptatrienyl anion **72**, which has been suggested to exist in a blue solution,[153] should be favored by acceptor substituents.[154] X-ray crystallography[155] showed that the recently prepared deep violet tetraiodide of the dication **77** is, as expected for a substituted antiaromatic dication, distorted; it contains two separate trimethinecyanine substructures.[156] In this connection we should also mention highly colored stellaquinones[157] such as the recently prepared **78**.[158]

77

78

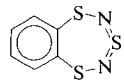


79



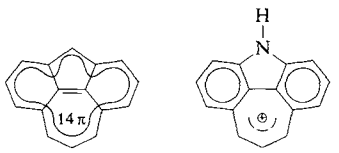
77: $\lambda = 573$ nm/$\tilde{\nu} = 1.74$ μm^{-1} (lg $\varepsilon = 3.38$), in acetonitrile [155];
78: 627 nm/1.59 μm^{-1} (2.28), in dichloromethane [158];
79: 523 nm/1.91 μm^{-1} (4.16), in acetonitrile [159b].

If the benzene dication bears six substituents, as in **79**, symmetry considerations indicate that it will again have a doubly degenerate MO containing two electrons. **79** has been shown by ESR spectroscopy to be a triplet molecule;[159a] however, the singlet molecule has been predicted to be 0.9 kcal/mol lower in energy in acetonitrile solution than the triplet molecule.[159b]



Heterocyclic compounds with $4n$ π-electrons can also exhibit a longer-wavelength absorption than the $(4n + 2)$ π-systems if their π-electron systems are planar: for example the heterocycle **81**, which is iso-π-electronic with a 12 π-hydrocarbon, absorbs at noticeably longer wavelengths than do **80** and **82** which have 10 and 14 π-electrons respectively.[160]

80

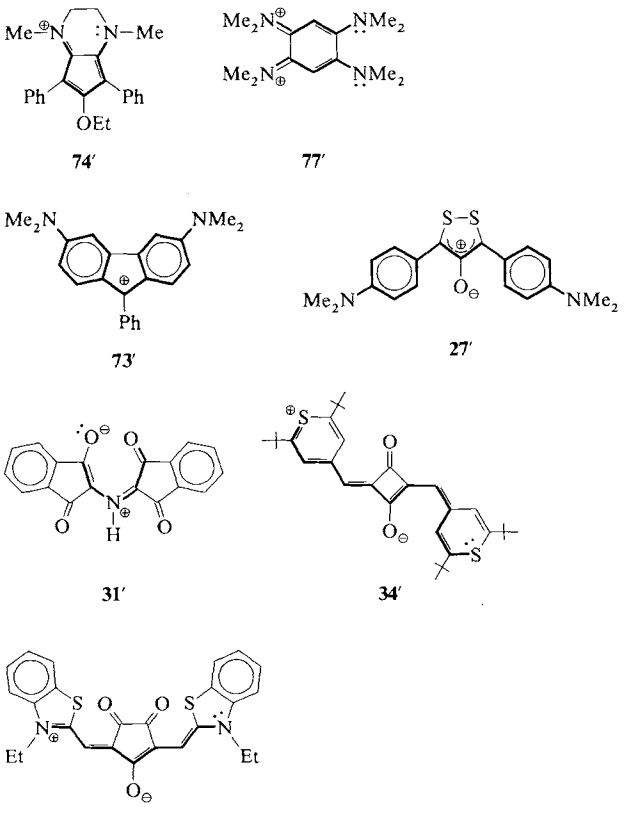


81

82

80: $\lambda = 304$ nm/$\tilde{\nu} = 3.29$ μm^{-1} (lg $\varepsilon = 4.15$), in cyclohexane;
81: 617 nm/1.62 μm^{-1} [160];
82: 384 nm/2.60 μm^{-1} [160].

In the above discussion we have dealt only with hydrocarbons in which the diradicaloid character is linked with the presence of $4n$ π-electrons in the perimeter ring; we shall now deal with the question as to whether under certain structural conditions a perimeter with $(4n + 2)$ π-electrons can also exhibit diradicaloid character. Examples of such behavior can perhaps be found for non-alternant hydrocarbons, which are often characterized by an absorption at relatively long wavelengths.[161] *Heilbronner* et al.[162] carried out a theoretical study on the cyclohepta[*def*]fluorene **83** and came to the conclusion that this (still unknown) hydrocarbon, which has 14 π-electrons in the outer ring and a central double bond, should exist as a triplet diradical.[163]



83 **84**

84: $\lambda \approx 690$ nm/$\tilde{\nu} \approx 1.45$ μm^{-1} ($\lg \varepsilon = 3.3$), in 60% $HClO_4$ [164].

Wirz et al. have suggested[164] that replacement of one of the methine groups in **83** by a heteroatom-containing group, as in **84**, will lead to a singlet molecule which will absorb at relatively long wavelengths; the heterocycle **84** is blue.

4. Classical *versus* Diradicaloid Chromophores

The compounds discussed above were investigated more or less from the point of view of diradicaloid structures; in this sense we can speak of colored substances with diradicaloid chromophores. However, this by no means excludes another reference for the color-determining π-electron system. This conclusion becomes particularly clear when the polymethine concept[8, 102] is used for the derivation of color-structure relationships. Many of the compounds listed above can indeed be considered as strongly structurally modified polymethine dyes, the absorption wavelengths of which can be qualitatively estimated with the help of empirical color rules. To make this clear we have again represented a number of the dyes dealt with above in terms of valence bond formulations which contain a polymethine substructure; the latter is emphasized by the use of bold bonding dashes.

Thus **74**, in the form of **74′**, can be derived from a streptopolymethinecyanine which has undergone cyclization via an additional bond.[156, 165] The long-wavelength absorption of the dye **77**, written as **77′**, consists of two weakly coupled trimethinecyanine units. Like **73′** and **27′** the compounds **73** and **27** are derivatives of a diphenylmethane and a vinylogous diphenylmethane dye respectively, while **31** in the form of **31′** is a protonated oxonol dye. Compounds with structures **34** and **29** have also been referred to above: in the case of the squarylium dye **34′** ($\lambda = 799$ nm[4a]) and the croconylium dye **29′** ($\lambda = 830$ nm[67b]) their relationship with polymethine dyes is made clear by the introduction of terminal heterocyclic groups; the carbonyl groups form bridges and the oxide residues substituents in *meso*-positions in heterocyclic polymethine dyes.[8b]

Whether or not these or other alternative formulations and chromophore reference structures have any justification can be decided on the basis of an objective analysis of the wave functions. It is possible using the configuration analysis method (CA) introduced by *Baba, Suzuki* and *Takemura*[166a] to relate the ground and excited states of the dyes to those structures which contain the same number of π-electrons and either a corresponding molecular skeleton or a composite molecule. The relationships between the ground states and the lowest-energy singly excited states of the chromophoric system or of a chromophoric system containing the subchromophore of the composite molecule can be evaluated on the basis of a number of suitable indices.[166] For example, it can be demonstrated by CA for **73** that in spite of the NIR absorption of this compound its relationship to the π-electron states of the diphenylmethane dyes is much closer than that to a structure constructed from a (Jahn-Teller distorted) diradicaloid cyclopentadienylium and two butadiene fragments. In Figure 10 the more or less completely hatched areas indicate graphically that the wave functions of the ground and first ππ* excited states of **74** are only very

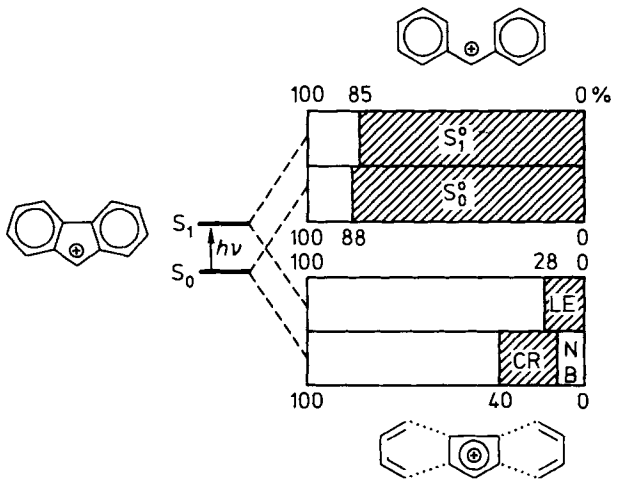


Fig. 10. Characterization of the ground and lowest excited states of the fluorenyl cation with respect to the ground and lowest excited state of the diphenylmethyl cation (top) and a composite molecule (bottom) consisting of a Jahn-Teller distorted cyclopentadienyl cation and two butadiene fragments. The degree of completeness of the representation in % is evaluated by projection of the wave function (configuration analysis). The contributions of the configurations in the composite molecule consist in the main of the no-bond (NB) ground state, the configuration of the lowest-energy local excitation (LE) in the five-membered ring and the configuration of the lowest-energy charge resonance (CR) from the butadiene fragments to the five-membered ring.

poorly described by the wave function of the fragmented molecule, while a comparison with the diphenylmethane dye resulting from the removal of only one bond gives a much better picture.[167] Because of the close relationships of the wave functions in the latter case, which are due to a good correlation of the MOs, *Dewar* et al. were able to successfully explain with MOs the spectral effects of the diphenylmethane dyes upon cyclization.[168] Configuration analyses have shown that relationships between chromophoric systems cannot reliably be described by the similarity of their spectral excitation energies but rather by correlation of the wave functions of those states which are responsible for the light absorption.[169]

Whether an NIR chromophore is regarded as the result of a diradicaloid structure or rather as a perturbed classical chromophore, the problem remains basically the same. If the spectral excitation energy falls to ca. 0.85 μm (1.2 μm^{-1}), the energy difference between S_0 and T_1 automatically becomes so small that we must refer to the compound as a diradicaloid: all the problems which occur in the description of such an electronic state will then be present.

5. Conclusion

At the beginning of the century it seemed likely on the basis of the studies then carried out on radical salts that the color band of dyes could be shifted from the visible into the near infrared, so that "higher-order colors" would occur;[170] today, in contrast, reliable information exists on NIR absorptions of many organic compounds resulting from an excitation of their electronic systems. In the case of light absorption by molecules from a singlet ground state these extend to almost 2 μm (0.5 μm^{-1}). Many dyes have been isolated which are suitable for information recording using commercial diode lasers at ca. 0.8 μm (1.25 μm^{-1}). A number of deeply colored compounds were obtained as "by-products" in the course of searches for organic conductors and ferromagnetics.

Although the specific modification of known chromophores has already made possible an approach to many chromophores which absorb at long wavelengths in the visible and NIR, the diradicaloid approach may provide pointers for the existence of further NIR chromophores which differ more radically from the conventional chromophores. However, the diradicaloid nature of compounds which absorb at very long wavelengths also indicates the difficulties which exist in the theoretical treatment of these chromophores. A limitation of the configuration interaction to singly excited configurations, which in the case of chromophores active in the UV/VIS region is justified by experience, becomes questionable for NIR chromophores. Proven semiempirical methods for the description of the $\pi \rightarrow \pi^*$ transitions of conjugated organic systems, such as the PPP method, are not suited to numerical predictions unless careful reparametrization is carried out when multiply-excited configurations are to be taken into account or when a complete CI is required.[171] A treatment of the vibronic interaction of NIR chromophores of the dimensions of organic dyes is also still outstanding.

We thank Prof. Dr. S. Hünig (Würzburg) and Prof. Dr. H. Bock (Frankfurt/Main) for their critical reading of the manuscript and for many useful comments.

[18] In this report we have not discussed metal complexes with organic ligands, since the metal is responsible for their long-wavelength absorption; these are complexes whose spectral absorption is due to $d \rightarrow d^*$ transitions of transition metals [19a]. We have also not dealt with complexes which contain two metal atoms in different oxidation states and which exhibit relatively intense absorptions up to ca. 1600 nm (0.6 μm^{-1}) (mixed valence complexes) [19b]. These include the Ru^{II}/Ru^{III}-pyrazine complexes [19d] known as *Creutz-Taube* compounds and the ferrocene-type Fe^{II}/Fe^{III} complexes.

[50] For the sake of clarity we shall neglect overlap with the central CH_2 group in the diradical trimethylene **18a** ($X = CH_2$) in our treatment using the π-approximation.
[51] Thiocarbonyl ylides such as thioformylium methylide (**18b**, X = S) are, like other ylides (1,3-dipoles), building blocks in cycloaddition reactions. See: A. Hosomi, S. Hayashi, K. Hoashi, S. Kohra, Y. Tominaga, *J. Chem. Soc. Chem. Commun. 1987*, 1442; R. Huisgen, C. Fulka, I. Kalwinsch, L. Xingya, G. Mloston, J. R. Moran, A. Pröbstl, *Bull. Soc. Chim. Belg. 93* (1984) 511; S. Araki, Y. Butsugan, *Chem. Letters 1985*, 1639. The blue-black conducting polymer polyisothionaphthene (band gap ca. 1 eV [9c]) contains thiocarbonyl ylide substructures, and dimers and clusters of the heteroanalogous azomethine ylides are of interest because their electronic structures are similar to that of the ferromagnetic CuO. See: K. Yamaguchi, Y. Takahara, T. Fueno, K. Nakasuji, I. Murata, *J. Appl. Phys. 27* (1988) L766.
[52] A formulation such as **18c** is often used when X is sulfur or an atom of another element of a higher group in the periodic table. Although in this case ab initio calculations indicate a higher contribution of d-type polarization functions at sulfur than in sulfur atoms in conventional sulfides, such a formula does not describe the actual situation satisfactorily. A larger contribution of polarization functions for heteroatoms in ylides is surprisingly also found when only second-row elements are present in the molecule. See: S. D. Kahn, W. J. Hehre, J. A. Pople, *J. Am. Chem. Soc. 109* (1987) 1871. For earlier discussions on hypervalency in valence bond formulas of betaine-type compounds see G. Berthier, B. Levy, L. Paoloni, *Theor. Chim. Acta 16* (1970) 316.

[66] Estimates of spectral absorption of diradicaloid π-systems made using the PPP method, which normally does not take higher excited configurations into account, are not reliable. While the calculated wavelengths of the absorption bands for compounds such as **21** (X = S) with parameters used earlier for sulfur in sulfur heterocycles (J. Fabian, A. Mehlhorn, R. Zahradník, *J. Phys. Chem. 72* (1968) 3975) with a variable β_{CC} method for CC (J. Fabian, G. Tröger, *Teor. Eksp. Khim. 7* (1971) 170) and MNDO/2 × 2-CI geometries (J. Fabian, P. Birner, *Wiss. Z. Techn. Univ. Dresden 37* (1988) 119) lie relatively close to the experimental data, (**21**: λ_{calc} = 519 nm, λ_{exp} = 572 nm [54a]), the absorption wavelengths calculated for betaine-type olate and thiolate structures are much too high (see for example calculations for dithizone [68]).

[69] Only recently has it been shown by X-ray crystallography and spectral studies in solution that dithizone has the structure represented by **30**. It was previously assumed that in solution dithizone is a mixture of the tautomers *C*-mercaptoformazan and *N,N'*-diphenylthiocarbazone (see [68] and references cited therein) or a mixture of the latter compound and its deprotonated form: M. R. Mahmoud, A. A. Abd El Gaber, A. M. El Roudi, E. M. Soliman, *Spectrochim. Acta 43A* (1987) 1281.
[70] R. Grigg, J. F. Malone, T. Mongkolaussavaratana, S. Thianpatanagul, *J. Chem. Soc., Chem. Commun. 1986*, 421. Tautomeric structures were previously suggested for **31**, the protonated from of "Ruhemann's purple". It is however unclear why, in contrast to the normal situation, the protonation of the anionic dyes at nitrogen leads to a hypsochromic shift of the color band.

[79] X-ray crystallographic studies on Tschitschibabin's hydrocarbon showed unexpectedly that in the crystal the hydrocarbon has an almost planar biphenylylene bridge. In contrast to Thiel's hydrocarbon a quinoid bonding system is not formed.

[80] As was shown in [78 d] for the perchlorinated Tschitschibabin hydrocarbon, the intense absorption corresponds in wavelength to that of the perchlorinated diphenylmethyl radical. Just as for **35a**, the triplet structure of this derivative was demonstrated by its spectrum.

[81] Twisted ethene (dimethylene) and its heteroanalogues are transition structures in an *E/Z* isomerization. According to *Bonačić-Koutecký* et al. [31 d] an orthogonal arrangement of two planar CH_2 fragments gives a homosymmetric diradical, while at smaller dihedral angles a homosymmetric diradicaloid is present. Rotation about a double bond is of importance in the phenomenon of vision.

[101] A cursory examination indicates that the diradicaloid TICT state mentioned above corresponds to an excitation state of type $D^{\oplus}A^{\ominus}$. However, this state does not result from vertical excitation of the molecule, but only after a "horizontal" relaxation process.

[102] The change in the nature of the bond in the delocalized dye chromophore was already described by *Th. Förster* in the language of resonance theory: *Z. Phys. Chem. B 47* (1940) 245; *ibid. B 48* (1941) 12. However, it was *Dähne's* contribution to have recognized the characteristic electronic structure of the polymethines and the importance of the polymethine state for the dyes. It is a characteristic of the polymethines that the π-charges which alternate along the chain undergo redistribution on excitation: see S. Dähne, *Z. Chem. 5* (1965) 441; S. Dähne, D. Leupold, *Ber. Bunsenges. Phys. Chem. 70* (1966) 618; S. Dähne, F. Moldenhauer in R. W. Taft (Ed.): *Progress in Physical Organic Chemistry, Vol. 15*, Wiley, New York 1985, p. 1 ff., and references cited therein.

[103] The term "pimer" (or π-mer), which is due to *Kosower* (E. M. Kosower, J. L. Cotter, *J. Am. Chem. Soc. 86* (1964) 5524; E. M. Kosower, J. Hajdu, *ibid. 93* (1971) 2534) has the advantage of being clearly distinct from the dimerization with concomitant formation of a σ-bond which is typical for many radicals.

[106] The pimerization leads to a change in color. The color of monomeric **48**, caused by an absorption at ca. 600 nm, changes to violet on dimerization because of the hypsochromic shift of this band [103]. The term "viologen" for the oxidized form of the radical (and "violenes" for polymethine radicals in general cf. S. Hünig, *Pure Appl. Chem. 15* (1967) 109) results from the incorrect assumption that the violet color of **48** is due to the radical. See Ref. [109].

[107] The term "CT band" is widely used in the literature because of the theoretical interpretation of this absorption of the dimerized radical in terms of a molecule which is described as a symmetrical combination of two (opposing) CT configurations (K. H. Hausser, J. N. Murrell, *J. Chem. Phys. 27* (1957) 500); for the theory see also K. Kimura, T. Yamazaki, S. Katsumata, *J. Phys. Chem. 75* (1971) 1768 and [123 d].

[124] An example was recently reported: A. Aumüller, P. Erk, S. Hünig, H. Meixner, J.-U. von Schütz, H.-P. Werner, *Liebigs Ann. Chem. 1987*, 977.

[125] The spectral behavior of the mixed-valence complexes is reminiscent of dimers which exist as free radicals. They absorb at wavelengths considerably longer than do the radicals of the monomers; cf. B. Badger, B. Brocklehurst, *Trans. Faraday Soc. 65* (1969) 2588; A. Kira, S. Arai, M. Imamura, *J. Chem. Phys. 54* (1971) 4890. The color-determining transitions of these dimers are of doublet-doublet character [26]. Thus we are not dealing here with singlet-singlet transitions as in the CR bands of dimers as they are formed on dimerization.

[126] The regular polygon of the monocyclic ring of interest is placed in a circle of radius 2β in such a way that an apex is pointing downwards. The points where the polygon touches the circle give the energy of the Hückel-MOs. For example, when a three-, four- or five-membered ring is populated by four π-electrons then two of these electrons must occupy two MOs of equal energy. For a detailed treatment see: W. [132] The CC bond lengths of cyclobutadienes were found to be ca. 1.34 and 1.60 Å [131], while the bond lengths in polyenes and cyclopolyenes are ca. 1.45 and 1.35 Å respectively. The extreme distortion of **63** is an expression of a destabilization of the square arrangement. The destabilization of the $4n$ π-annulenes decreases rapidly with increasing ring size. According to ab initio calculations **63** is the only annulene with a π-destabilization; see R. C. Haddon, *Pure Appl. Chem. 58* (1986) 129. Higher $4n$ π- and $(4n + 2)$ π-annulenes then differ only in their paramagnetic ring current.

General Aspects and Optimization of Enantioselective Biocatalysis in Organic Solvents: The Use of Lipases

New Synthetic Methods (76)

By Ching-Shih Chen* and Charles J. Sih*

Enantioselective biocatalysis in nonaqueous media is becoming increasingly important in preparative synthetic chemistry. This article discusses (1) the general catalytic properties of enzymes in nonaqueous environments, (2) the basic principles that govern lipase-catalyzed enantioselective esterification and transesterification reactions in organic media for the preparation of optically active acids and alcohols, (3) the determination of kinetic and thermodynamic parameters, and (4) the quantitative analysis of published data.

1. Introduction

Enzymatic reactions are generally conducted in aqueous media because of the general notion that an aqueous environment is optimal for maintaining the catalytically active conformations of the enzyme protein for binding and catalysis. In an aqueous medium, the folding of a soluble enzyme protein is driven by the tendency of hydrophobic amino acid residues to be excluded from water, so that they are buried in the interior of the molecule, whereas the charged and hydrophilic residues are on the surface in contact with the aqueous solvent. When water is replaced with an apolar solvent, the interior hydrophobic residues tend to disperse, resulting in a reorganization of the enzyme tertiary structure. This conjecture implies that the conformation of the enzyme protein is drastically altered and, in the extreme case, the enzyme pocket may be viewed as "turned inside out"[1] in organic media. Consequently, the catalytic behavior of the enzyme is expected to be less optimal than in water. This perception has perhaps impeded the investigation of the stereoselective properties of enzymes in nonaqueous media in the past. In more recent years, however, it has become increasingly apparent that many biocatalytic reactions in nonaqueous media can proceed with high degrees of enantioselectivity.

It has been known for some time that a variety of enzymes are catalytically active in apolar media (Table 1), and some of these enzymes have been used for the transformation of water-insoluble substrates[2] (such as the transesterification of fats) and for peptide synthesis[26] via reversal of the hydrolytic process. However, the enantioselective properties of the lipases[2-20] (triglycerol acylhydrolases EC 3.1.1.3), in particular, have attracted the attention of synthetic organic chemists because of their synthetic utility. Lipases are uniquely stable in nonpolar organic solvents and have the remarkable ability of assuming a variety of conformations to accomodate substrates of varying sizes and stereochemical complexities. Moreover, compounds that are unstable in water (anhydrides, halogenated compounds, etc.) could be used as substrates in nonaqueous media. But more importantly, lipase-catalyzed esterification reactions in organic solvents are often more enantioselective than the corresponding hydrolytic reactions in water. For these reasons, nonaqueous biocatalytic technology is becoming increasingly important as a method for the preparation of homochiral (optically active) compounds. This article is intended to bring this methodology to the attention of synthetic chemists by discussing the basic principles and the more recent studies, but limiting the treatment to the enantioselective properties of lipases in nonaqueous media. The recent development of enzyme catalysis in reverse micelles[31] and supercritical fluids[32] is not covered, and the enzymology and kinetics of lipases have been discussed elsewhere.[33]

Table 1. Representative enzyme catalysis in organic media.

Biocatalyst	Solvent	Catalyzed reaction	Ref.
Lipases (crude powder)	apolar solvents	ester synthesis/ interchange, peptide synthesis, macrocyclic lactone formation	[2-20] [21, 22] [23-25]
Proteases (thermolysin, subtilisin, *chymotrypsin*)	ethyl acetate, amyl alcohol, etc.	peptide synthesis	[26]
Immobilized carboxyesterase	methyl propionate	enantioselective acylation of racemic alcohols	[2, 9]
Immobilized alcohol dehydrogenase	isopropyl alcohol	asymmetric reduction of ketonic substrates	[27]
Immobilized polyphenol oxidase	*chloroform*	oxidative conversion of phenols to *o*-quinones	[28]
Immobilized mandelonitrile lyase	ethyl acetate	synthesis of optically active *R*-cyanohydrins	[29]
Cholesterol oxidase	heptane, CCl_4, butyl acetate	oxidation of 3β-hydroxy-steroids	[30]

2. Enzyme Catalysis in Organic Solvents – General Considerations

Three types of solvent systems are used in biocatalytic conversions: water-miscible organic cosolvent systems, anhydrous organic solvents (< 1% water), and biphasic systems consisting of water and a water-immiscible organic solvent. The potential advantages of conducting biocatalytic reactions in these solvent media have been summarized by many workers:[34-38] (1) efficient catalysis may be achieved with substrates poorly soluble in water; (2) reactions catalyzed by hydrolytic enzymes may be shifted towards the synthetic direction; (3) undesirable side reactions in organic media as well as substrate and product inhibition may be

reduced; (4) recovery of product and biocatalyst from systems may be easier; (5) enzymes may be more stable in anhydrous organic media.

Water-miscible organic cosolvents such as acetone, methanol, ethanol, dimethylformamide (DMF), and dimethyl sulfoxide (DMSO) are often added to the aqueous reaction media to increase the solubility of substrates that are poorly soluble in water.[38] Moreover, they have been frequently used in peptide synthesis to shift the ionic equilibrium. By lowering the dielectric constant of the medium, the organic cosolvent diminishes the hydration of ionic groups, thereby reducing the acidity of the carboxyl group and the basicity of the α-amino group.[39] However, while lower concentrations of these polar solvents may not have serious adverse effects (concentrations of DMSO as high as 20% have been used in lipase-catalyzed enantioselective hydrolyses of ester[40]), higher solvent concentrations do progressively lead to protein denaturation and the attendant loss of stereochemical specificity. The use of suitable quantities of polar cosolvents may enhance the reaction rate and, in some cases, may also improve the stereoselectivity of biocatalytic systems.[41-43] However, this article will concentrate only on biocatalysis in anhydrous organic solvents or in biphasic solvent systems consisting of water and a water-immiscible organic solvent. Of special interest is the lipase-catalyzed esterification and transesterification reactions in organic solvents, because the observed enantioselectivity of condensation reactions in organic media is often higher than that of the corresponding hydrolytic reactions in water.[10, 18]

It is now well known that lipases can accept a broad range of artificial substrates of varying sizes in both aqueous and apolar media, which suggests that the protein backbone of lipases is flexible and can adopt a variety of conformations to accommodate substrate molecules. Thus, lipases must possess low energetic barriers for conformational transitions, a behavior reminiscent of "induced-fit"[44] enzymes. These features make it rather difficult for one to predict the stereochemical interaction of the enzyme with substrates. That is, in some cases the enantioselectivity of hydrolysis of esters in water is higher than the corresponding esterification reaction or vice versa. However, when hydrolytic reactions in aqueous media proceed with poor enantioselectivity, the corresponding esterification mode in organic solvent should be examined. In contrast, for "non-induced fit" enzymes, which possess more rigid conformations (high energetic barriers for the disruption of noncovalent forces), one envisages that they need not undergo major conformational changes to assume the catalytically active conformation in nonaqueous environments. Thus, this class of enzymes is expected to lose only a modicum of catalytic activity and enantioselectivity when water is replaced with apolar media, because the catalytic cavity is retained in nonaqueous media. However, these enzymes tend to have a more rigid substrate specificity and enhancement of enantioselectivity in apolar media is not expected.

The thermodynamic changes during formation of an enzyme–substrate (EnzSu) complex in water and in organic media have been considered by *Kieboom*.[45] In aqueous solutions, the polar groups in the catalytic site of the enzyme and the substrate molecules form hydrogen bonds with water. In the process of enzyme–substrate complexation, some

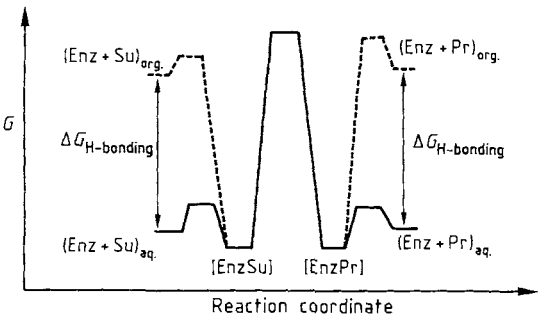

Fig. 1. Comparison of free energy profiles in aqueous solutions and organic solvents for an enzyme reaction in which substrate and product form hydrogen bonds with solvent water. Enz = enzyme, Su = substrate, Pr = product, H-bond = hydrogen bond.

of the hydrogen bonds are disrupted and the energy required for this disruption also contributes to the free energy change of complex formation (ΔG_{aq}) (Fig. 1). On the other hand, in a non-hydrogen-bonding solvent, the EnzSu-forming process does not involve the disruption of hydrogen bonds and the free energy of EnzSu complex formation[45] ($\Delta G_{org.}$) is given by Equation (1),

$$\Delta G_{org.} = \Delta G_{aq} - (n_{Enz} + n_{Su})\,\Delta G_{H\text{-bonding}} \quad (1)$$

where n_{Enz} and n_{Su} denote the number of hydrogen bonds disrupted between water and, respectively, the enzyme active site and the substrate. Thus, the relationship of the apparent association constants of the EnzSu complex in water ($K_{a\,(aq.)}$) and organic solvent ($K_{a\,(org.)}$) can be expressed by Equation (2).

$$K_{a\,(aq.)} = \exp[-(n_{Su} + n_{Enz})\,\Delta G_{H\text{-bonding}}\,RT] \cdot K_{a\,(org.)} \quad (2)$$

$$K_a = [EnzSu]/[Enz][Su]$$

It is noteworthy that although the energy of hydrogen bonding is relatively weak (4.5 kcal mol^{-1}), a transition from an aqueous to an apolar environment may result in an extremely large apparent association constant for either enzyme–substrate or enzyme–product complex for highly polar substrate molecules (e.g., polyhydroxy compounds or their phosphate derivatives) (Table 2). As a consequence, severe substrate and/or product inhibition will occur.

Table 2. Effect of hydrogen bonding energy on enzyme–substrate complexation in apolar solvents. Calculated for non-hydrogen-bonding solvents such as isooctane and hexane.

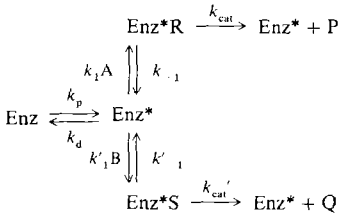
the lipase of *Geotrichum candidum* have been investigated by X-ray analysis, which, at 6-Å[46] and 2.8-Å[47] resolution, revealed the presence of nine α-helices and four β-strands. The helical content was calculated to be about 20%. The molecule is ellipsoidal with dimensions of $50 \times 50 \times 70$ Å. Near the molecular center, there exists a large cleft, which is assumed to be the active site of the enzyme.

Very few studies have been made on the structure and function of lipases. For pancreatic lipase, serine and histidine residues and a carboxylate group were found to be essential for activity,[48] but in the case of *G. candidum*, there seems to be no involvement of a reactive serine residue. On the other hand, the lipase of *Humicola lanuginosa* requires histidine and tyrosine residues and a carboxylate group for activity.[49]

Lipases are characterized by a common catalytic feature – the involvement of a lipid–water interface in their catalytic process.[33] This unique feature of interfacial catalysis provides the lipases with an inherent affinity for hydrophobic environments and distinguishes them from other hydrolytic enzymes.



The general principles of interfacial enzyme catalysis were put forward by *Verger* et al.[50] and may be envisaged by Scheme 1, where Enz is enzyme in solution, Enz* is enzyme "penetrated" in the interface. Su represents lipid substrate molecules at the interface, and Pr represents reaction products.

Scheme 1.

Inherent in this model is the presence of two successive equilibria. The first step describes the reversible binding of the enzyme to the interface, which is designated as the penetration step and is assumed to confer on the biocatalyst a new conformation, Enz*. The second step is the reversible binding of the "penetrated" enzyme, Enz*, with the substrate, Su, to form Enz*Su, which undergoes catalysis to regenerate Enz* with liberation of products, Pr.

Using this concept, the action of lipolysis of two insoluble competing enantiomers,[51] A and B, may be envisioned as shown in Scheme 2.

Scheme 2.

This model makes the assumption that the catalytic step is irreversible, as is the case during initial stages of the reaction. It differs from the conventional enzyme model[52] for two competing substrates only by the presence of the additional Enz ⇄ Enz* interconversion step and is similar to the "C induced-fit" model described by *Fersht*.[53] Since the surface-active properties of the enantiomers are identical, the ratio k_d/k_p is a constant and independent of the relative concentration of the enantiomers in the interface. As a consequence, the penetration step does not participate in the discrimination process[44] and the enantioselectivity of *irreversible* lipase-catalyzed reactions in water-immiscible organic solvents or in anhydrous organic media also obeys the classical homocompetitive equation [Eq. (3)]. k_{cat}/K_m is the apparent second-order rate constant for the reaction of the enzyme and the substrate at infinitely low substrate concentrations to give product(s). k_{cat} and K_m denote catalytic and Michaelis constants, respectively, and E is the enantiomeric ratio.[52]

$$\frac{\ln([A]/[A_0])}{\ln([B]/[B_0])} = E = \frac{(k_{cat}/K_m)_A}{(k_{cat}/K_m)_B} \quad (3)$$

This relationship has indeed been independently confirmed by steady-state kinetics derivation. Moreover, kinetic data of phospholipase[50] and lipase[51] appear to obey this model reasonably well.

4. Stereochemical Specificity of Lipase Catalysis in Solvents

In organic solvents, lipases catalyze the transfer of acyl groups from suitable donors to a wide array of acceptors other than water. Depending on the type of acyl donors and acceptors, lipase-catalyzed reactions include esterification, transesterification, amidation, peptide synthesis, and macrocyclic lactone formation. Of these, enantioselective ester synthesis/interchange is of interest because it provides synthetic chemists with a facile method for the preparation of optically active acids and alcohols. Mechanistically, enzymatic ester synthesis/interchange has some features in common with the corresponding hydrolytic reaction, but the underlying principles governing the stereochemical specificity are somewhat different and thus warrant consideration.

4.1. Resolution of Racemic Acids via Enantioselective Ester Synthesis

The kinetics of lipase-catalyzed acyl transfer in organic media may be represented by a ping-pong reaction mechanism,[54] as depicted in Scheme 3. This synthetic mechanism is analogous to that of a hydrolytic reaction when $R^2 = H$. However, ester synthesis/interchange is further complicated by the reversibility of enzyme catalysis with the participation of an acyl acceptor (R^2OH), whose concentration and species may alter the thermodynamic and/or kinetic functions of the catalytic system.[10] Nevertheless, this synthetic mode of catalysis in organic media may often yield a higher degree of enantioselectivity than the corresponding hydrolytic reaction in water. The rationale may be envisaged as follows:

$$\text{Enz} \underset{-RCO_2R^1k_2}{\overset{+RCO_2R^1k_1}{\rightleftharpoons}} \text{Enz} \cdot RCO_2R^1 \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \text{RCO-Enz} \cdot R^1OH$$

$$\underset{+R^1OHk_6}{\overset{-R^1OHk_5}{\rightleftharpoons}} \text{RCO-Enz} \underset{-R^2OHk_8}{\overset{+R^2OHk_7}{\rightleftharpoons}} \text{RCO-Enz} \cdot R^2OH$$

$$\underset{k_{10}}{\overset{k_9}{\rightleftharpoons}} \text{ENZ} \cdot RCO_2R^2 \underset{+RCO_2R^2k_{12}}{\overset{-RCO_2R^2k_{11}}{\rightleftharpoons}} \text{Enz}$$

$$\text{Enz} \underset{-R'CO_2R^1k_2'}{\overset{+R'CO_2R^1k_1'}{\rightleftharpoons}} \text{Enz} \cdot R'CO_2R^1 \underset{k_4'}{\overset{k_3'}{\rightleftharpoons}} \text{R'CO-Enz} \cdot R^1OH$$

$$\underset{+R^1OHk_6'}{\overset{-R^1OHk_5'}{\rightleftharpoons}} \text{R'CO-Enz} \underset{-R^2OHk_8'}{\overset{+R^2OHk_7'}{\rightleftharpoons}} \text{R'CO-Enz} \cdot R^2OH$$

$$\underset{k_{10}'}{\overset{k_9'}{\rightleftharpoons}} \text{Enz} \cdot R'CO_2R^2 \underset{+R'CO_2R^2k_{12}'}{\overset{-R'CO_2R^2k_{11}'}{\rightleftharpoons}} \text{Enz}$$

Scheme 3.

During the initial stages of the reaction, the complex catalytic sequence shown in Scheme 1 may be reduced to a minimal reaction mechanism consisting of the presence of two bond-breaking and two bond-forming steps (Scheme 4),

$$\underset{\mathbf{A}}{\text{Enz} + RCO_2R^1} \xrightarrow{-R^1OHk_a} \text{RCO-Enz} \xrightarrow{+R^2OHk_b} \text{Enz} + \underset{\mathbf{P}}{RCO_2R^2}$$

$$\underset{\mathbf{B}}{\text{Enz} + R'CO_2R^1} \xrightarrow{-R^1OHk_a'} \text{R'CO-Enz} \xrightarrow{+R^2OHk_b'} \text{Enz} + \underset{\mathbf{Q}}{R'CO_2R^2}$$

Scheme 4.

where k_a, k_b, k_a', and k_b' are net rate constants.[55] Kinetically, k_a and k_a' are equivalent to k_{cat}/K_m for A and B, respectively; k_b and k_b' represent the gross binding and catalytic performance of each diastereomeric acyl-enzyme complex toward the achiral nucleophile (R^2OH). The implication of these net rate constants can be further illustrated by the free energy diagram in Figure 2, where k_a and k_b are given by Equations 4 and 5, respectively. T_1 and T_2 refer to transition states.

$$k_a = \exp(-\Delta G_{T1}/RT) \tag{4}$$

$$k_b = \exp(-\Delta G_{T2}/RT) \tag{5}$$

If the reaction rate of substrate A is v_A and that of the competing substrate B is v_B, then application of the net rate constant method of *Cleland*[55] yields Equations (6) and (7), respectively.

$$[\text{Enz}]_0/v_A = 1/k_a[A] + (1/k_b + k_a'[B]/k_a k_b'[A]) \cdot 1/[\text{ROH}] \tag{6}$$

$$[\text{Enz}]_0/v_B = 1/k_a'[B] + (1/k_b' + k_A[A]/k_a' k_b[B]) \cdot 1/[\text{ROH}] \tag{7}$$

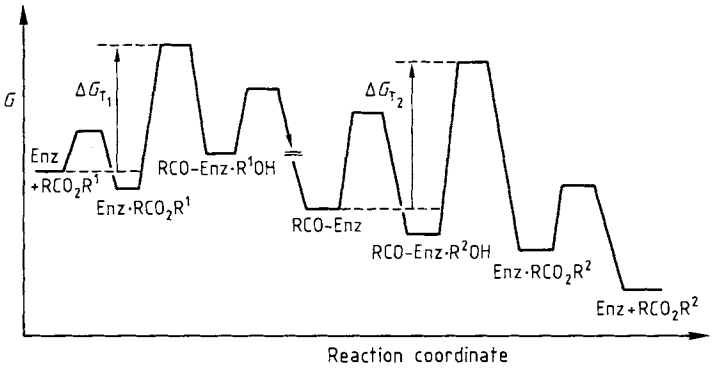


Fig. 2. Reaction-coordinate diagram illustrating a lipase-catalyzed esterification reaction.

These equations clearly indicate that the discrimination between two competing substrates depends on the entire reaction sequence.

For hydrolytic reactions, there will be a partial loss of specificity due to the high concentration of water solvent (55.5 M). As a consequence, the second terms in Equations (6) and (7), contributed mainly by the steps following the first irreversible step, can be neglected. Thus, Equations (8) and (9) are obtained.

$$[\text{Enz}]_0/v_A = 1/k_a[A] \tag{8}$$

$$[\text{Enz}]_0/v_B = 1/k_a'[B] \tag{9}$$

Combining Equations (8) and (9) affords the familiar Equation (10),[52] which indicates that in hydrolytic reac-

$$v_A/v_B = (k_a/k_a') \cdot ([A]/[B]) \tag{10}$$

tions, the enantioselectivity is solely contributed by the catalytic sequence leading to and including the first irreversible step. This difference explains why, in some instances, the enantiomeric purity can often be enhanced by conducting biocatalytic ester synthesis/interchange in organic solvents in lieu of the corresponding hydrolytic reaction in water.[10, 18, 57]

One should keep in mind that in enzyme-catalyzed condensation reactions, the gradual accumulation of products (R^1OH and RCO_2R^2) during the reaction will give rise to reverse catalysis. Thus, the equilibrium constant (K) plays a pivotal role not only in the expression of enzymatic enantioselectivity, but also in the maximal obtainable chemical conversion [$c = 1/(1 + K)$]. To envisage the progressive changes of the stereochemical behavior of enzymes, the reaction scheme is further simplified to Equations (11) and (12),

$$\text{Enz} + \text{A} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{Enz} + \text{P} \tag{11}$$

$$\text{Enz} + \text{B} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \text{Enz} + \text{Q} \tag{12}$$

where k_1, k_2, k_3, and k_4 are the rate constants for the forward and backward reactions. In an achiral environment, the equilibrium constants for the pair of enantiomers should be equal [Eq. (13)].

$$K = k_2/k_1 = k_4/k_3 \tag{13}$$

This relationship reveals that the sense of preferred chirality for the forward and reverse reactions is retained; i.e., if $k_2 > k_4$, then $k_1 > k_3$.

For reversible biocatalytic systems, assuming that the acyl acceptor is kept at saturating levels, a new expression, which incorporates the thermodynamic parameter K, is required for the calculation of the enantiomeric ratio, E [Eq. (14)], where $E = k_1/k_3$.

$$\frac{\ln[1-(1+K)(1-[A]/[A]_0)]}{\ln[1-(1+K)(1-[B]/[B]_0)]} = E \tag{14}$$

When k_2 and $k_4 = 0$, Equation (14) is reduced to the homocompetitive Equation (3) for the irreversible case.[52] Alternatively, Equation (14) may be transformed into Equations (15) and (16) to relate the extent of conversion (c) and the enantiomeric excess of substrate (ee_S) and product (ee_P).

$$\frac{\ln[1-(1+K)(c+ee_S\{1-c\})]}{\ln[1-(1+K)(c-ee_S\{1-c\})]} = E \tag{15}$$

$$\frac{\ln[1-(1+K)c(1+ee_P)]}{\ln[1-(1+K)c(1-ee_P)]} = E \tag{16}$$

These equations show that the enantioselectivity of enzyme-catalyzed synthesis depends on the complex interaction of both kinetic (E) and thermodynamic (K) functions. The computer-generated graphs[10] of Equations (15) and (16) (Fig. 3) show that the optical yield of both fractions is

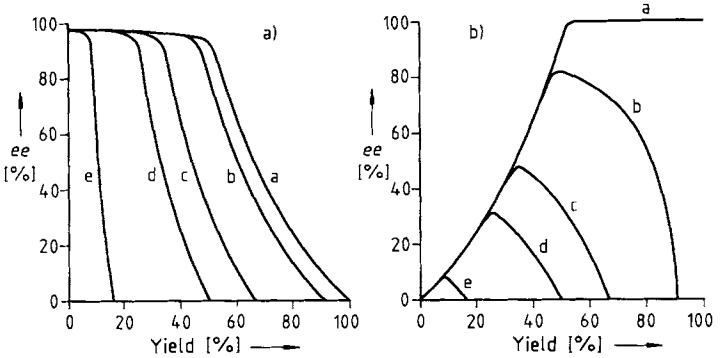

Fig. 3. Expression of the percentage enantiomeric excess of product (A) and remaining substrate fractions (B) as a function of the percentage conversion for $E = 100$ and $K = 0$ (a), 0.1 (b), 0.5 (c), 1.0 (d), and 5.0 (e) [10]. These curves were computer generated from Equations (13) and (14). [Reprinted with permission from *J. Am. Chem. Soc., 109* (1987) 2812. Copyright 1987 American Chemical Society.]

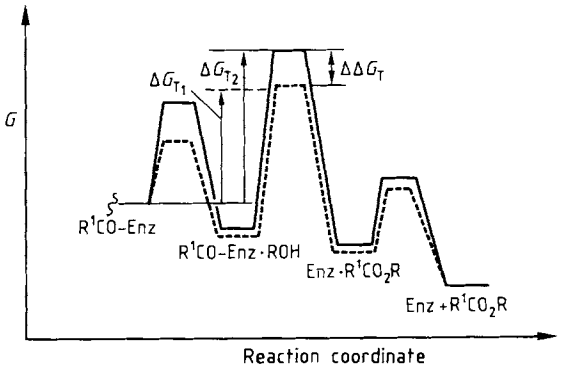
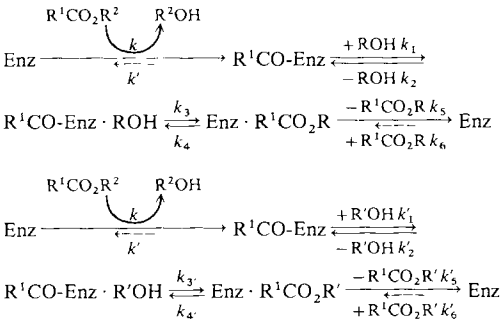
inversely related to the magnitude of K. In addition, high optical purity of the remaining substrate ($ee_S \geq 99\%$) cannot be attained by extending the conversion much beyond 50% even with a very small K value. These graphic representations allow one to predict precisely when to stop the kinetic resolution to maximize chemical and optical yields after the values of E and K have been defined.

4.2. Resolution of Racemic Alcohols via Enantioselective Ester Synthesis

In Scheme 5, ROH (A) and R'OH (B) represent two competing enantiomers. The nucleophilic group of each enantiomer may interact differently with the acyl-enzyme (R^1CO-Enz) to give different transition states (Fig. 4), and the size of this activation energy difference ($\Delta\Delta G_T$) will dictate the enantioselectivity of biocatalysis. Of the factors that influence the stereochemical properties of the biocatalytic system, the acyl donor is of special importance, and its role can be summarized as follows: (1) Because the kinetic differentiation between two enantiomers is independent of the transfer of the acyl group to the enzyme, the type of acyl donor, either acid or ester, does not affect discrimination or the E value. (2) Since the acyl group of the acyl-enzyme exerts steric and/or stereoelectronic effects on the deacylation process, it is possible, in principle, to achieve high enantioselective esterification by the selection of a suitable acyl donor. (3) Since the reaction is reversible, the concentration and the type of acyl donor may alter the equilibrium constant, which in turn influences the biocatalytic stereochemical behavior.





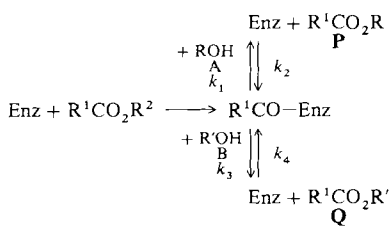


Fig. 4. Reaction-coordinate diagram illustrating an enzymatic resolution of a racemic alcohol via enantiospecific esterification. ----, enantiomer 1; ——, enantiomer 2.

Scheme 5.

To facilitate the kinetic treatment, the mechanism outlined in Scheme 5 may be simplified to Scheme 6.

Scheme 6.

The rate of disappearance of two enantiomers A and B can be described by Equations (17) and (18).

$$v_A = k_1[A][RCO\text{-}Enz] - k_2[P][Enz] \quad (17)$$

$$v_B = k_3[B][RCO\text{-}Enz] - k_4[Q][Enz] \quad (18)$$

These equations show that the relative concentration of acyl-enzyme and free enzyme affects both reaction rates. At saturating levels of acyl donor, the ratio of the acyl-enzyme to free enzyme remains constant. The combination of Equations (17) and (18) and the integration of the resulting equation lead to the same format as Equations (15) and (16). However, at low concentrations of the acyl donor, the amounts of acyl-enzyme and free enzyme vary as the reaction proceeds.[56] As a result, the stereochemical behavior of the system becomes more complicated and cannot be predicted by Equations (15) and (16). Practically speaking, it would be desirable to keep all the free enzyme in the acylated form so that the reverse reaction is negligible.

5. Experimental Considerations

5.1. Selection of Organic Solvent

The type of organic solvent will have profound effects on the reaction kinetics and stability of the biocatalyst. In general, the catalytic efficiency of enzymes diminishes as the polarity of the solvent increases.[57] Hydrophilic solvents may denature enzymes by penetrating into the hydrophobic core of proteins, thus disrupting their delicate functional structures,[58] or by stripping off the essential water from the enzyme.[59] Recently, some general empirical rules have been formulated for the optimization of biocatalytic activity in different organic solvents. The parameter P, the partition coefficient of the solvent between octanol and water,[60] was introduced as a quantitative measure of solvent polarity[61, 62] (Table 4). Generally, the catalytic activity is low in polar solvents having a log $P < 2$, is moderate in solvents having a log P between 2 and 4, and is high in apolar solvents having a log $P > 4$. However, the instability of biocatalysts in polar solvents can often be partially overcome by immobilizing the enzymes on hydrophilic supports.[61] (A detailed account of this "medium-engineering" of biocatalytic systems is given in Ref. [61].)

Another consideration is the solubility of substrate and product in the media.[63] Enzymes are catalysts and only serve to accelerate the attainment of chemical equilibrium. Therefore, the physical properties of the apolar environments may affect the position of equilibrium and thus the chemical yield of the enzyme reaction. It is conceivable that for lipase catalysis, owing to the unique interfacial catalytic property, one would choose a solvent system in which the substrate can form micelles or emulsions whereas the product is fully dispersed in solution. As a rule, apolar solvents such as hexane, isooctane, toluene, and cyclohexane are commonly used for lipase-mediated reactions. Also, halogenated hydrocarbons,[64] such as trichlorotrifluoroethane, and *tert*-butyl and diisopropyl ethers[65] have been successfully employed. However, when the substrates are highly hydrophilic, polar solvents such as DMF, pyridine, and butanol may be used at the expense of enzyme stability or immobilized enzymes may be employed.[61]

Table 4. The log P values of some commonly used solvents [a].

Solvent	log P	Comments
dodecane	6.6	Apolar solvents, suitable for reactions in which dry enzyme powders are used
octane	4.5	
heptane	4.0	
hexane	3.5	
cyclohexane	3.2	
toluene	2.5	
benzene	2.0	Moderately to highly polar solvents; may reduce enzyme's catalytic efficiency; enzyme immobilization is recommended for optimal activity.
chloroform	2.0	
butyl acetate	1.7	
diethyl ether	0.85	
butanol	0.80	
pyridine	0.71	
ethyl acetate	0.68	
tetrahydrofuran	0.49	
acetone	−0.23	
ethanol	−0.24

methanol	−0.76	
diemethylformamide	−1.0	
dioxane	−1.1	
dimethyl sulfoxide	−1.3	

[a] See [61] for a complete list of log P values of solvents. P is the partition coefficient in a standard octanol–water two-phase system.

5.2. Water Content of Organic Media

Esterification and transesterification reactions may be carried out in either monophasic, nearly anhydrous organic media (water content < 1 %) or in aqueous-organic biphasic systems. In the latter, the enzyme resides in the aqueous phase, surrounded by an organic phase. Since enzymes are insoluble in hydrophobic organic solvents, they form suspensions. Hence, unless the reaction mixture is stirred or shaken, the enzyme settles. Although published experimental procedures give no clear indication as to the optimal amount of exogenous water to be added to the organic solvent, there is a consensus that some water is absolutely needed for the catalytic function of the enzyme.[66] This is because water is involved in various types of noncovalent bonding interactions for the maintenance of catalytically active conformations of enzymes. For some esterification reactions, the immiscible organic solvent is saturated with water, because the rate of reaction appears to increase as the water content increases.[23] On the other hand, anhydrous organic media (no addition of exogenous water) are preferred for lactonization[25] (intramolecular esterification). In this case, the reaction rate is relatively slow and higher temperature (e.g., 65 °C) is used.

5.3. Choice of Acyl Donors and Acyl Acceptors

Another consideration is the choice of substrates; i.e., either chiral racemic acids or the corresponding chiral racemic esters could be used as substrates. Mechanistically, these two types of reactions proceed via different transition states for all steps leading to and including the formation of the acyl-enzyme intermediate (Scheme 1). Hence, despite the apparent similarity, the E and K values for esterification and ester interchange may be different. Also, the physical state of the substrate has a pronounced effect on the enzymatic rate. For

instance, in an organic medium, the ester substrate is fully dispersed and is less susceptible to enzymatic lipolysis due to a lack of lipid–water interface. On the other hand, the acid substrate forms micelles or emulsions, which are readily attacked by the lipase. However, if the acid is insoluble in the organic medium, the reaction rate is markedly reduced due to the sluggish enzymatic action on a solid substrate, but the physical separation of the substrate from the product is often much easier for the acid substrate than for the ester substrate.

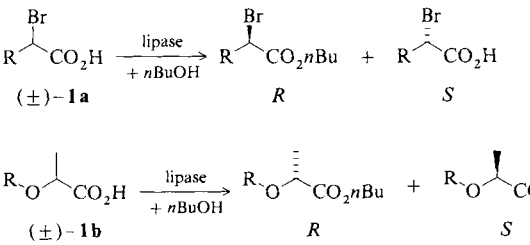
To achieve high enantioselective esterification, it is imperative to minimize the extent of the reverse reaction. Several strategies may be used to circumvent the thermodynamic restraint imposed by equilibrium. These include: the use of enolesters[19] (R^1OH = aldehyde or acetone) or anhydride[18] as acyl donors so that no alcohol or water molecules are formed; the selection of a suitable acyl acceptor (R^2OH = secondary alcohol) to prevent the backward reaction;[10] the removal of R^1OH to shift the equilibrium position (e.g., by adding molecular sieve to remove water in esterification reactions); and the addition of a large excess of acyl acceptor to the medium to reduce the relative concentration of the competing nucleophile, R^1OH[10] (Scheme 3).

5.4. Determination of E and K Values

The enantioselectivity of biocatalytic reactions is normally expressed as the E value,[52] a biochemical constant that is independent of substrate concentration and the extent of conversion. Lipase-catalyzed esterification or transesterification reactions in aqueous-organic biphasic or anhydrous organic media also obey the conventional homocompetitive equation provided that the reaction is irreversible (saturating amounts of achiral acyl donor and acceptors are present). At the initial stages of the reaction, little product has accumulated. Normally, reversibility of the reaction becomes a significant problem only at conversions around 40% or greater (Fig. 3). Consequently, if the enantiomeric excess of the substrate (ee_S) and the product (ee_P) is determined at low conversions (< 20%), one can calculate the extent of conversion (c) using Equation (19).

$$c = \frac{ee_S}{ee_S + ee_P} \tag{19}$$

The E value can then be readily calculated using either Equation (20) or (21).[52]



$$E = \frac{\ln[(1-c)(1-ee_S)]}{\ln[(1-c)(1+ee_S)]} \tag{20}$$

$$E = \frac{\ln[1-c(1+ee_P)]}{\ln[1-c(1-ee_P)]} \tag{21}$$

Moreover, by inserting the values of E, c, ee_S, and ee_P determined at a conversion greater than 40% into Equations (15) and (16), the value of K can also be determined.

The need for a quantitative treatment of biocatalytic resolution data in organic media may be best illustrated by an analysis of some published results (Tables 5 and 6). In the lipase-catalyzed enantioselective esterification of (±)-2-bromohexanoic acid **1a** and (±)-2-*p*-chlorophenoxy)propionic acid **1b**,[17] 1-butanol was used as the acyl acceptor. It is noteworthy that even though the reaction was conducted in hexane with only a very small amount of exogenous water (0.1%), the reactions are clearly reversible. Using Equations (20) and (21), the E values were calculated from the data of Table 5. As can be seen, the E value decreased from 300 (30% conversion) to 3 (67% conversion) for **1a** and from 17 (45% conversion) to 4 (65% conversion) for **1b**. If the reactions were irreversible, the E values should remain constant throughout the reaction. A similar observation was noted during the enantioselective esterification of (±)-menthol **1** using dodecanoic acid as the acyl donor.[6] Again, the E value decreased from a value of 92 (45% conversion) to 17 (57% conversion). Therefore, when the reactions are reversible, Equations (15) and (16) should be used instead of Equations (20) and (21) for the calculation of the E value to take into account the contribution of the equilibrium constant, K.

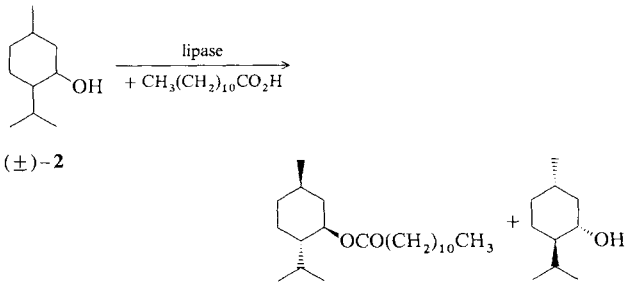


Table 5. Reversible enantioselective esterification of chiral racemic acids **1** catalyzed by *C. cylindracea* lipase with 1-butanol as acyl acceptor in hexane (containing 0.1% H_2O) [7]. *ee* = enantiomeric excess, E = enantioselectivity.

Substrate R	t [h]	Conversion [%]	*ee* [%] Product (*R* ester)	*ee* [%] Substrate (*S* acid)	E [a]
1a n-C_4H_9	19	30	99	–	300
	48	67	–	62	3
1b p-ClC_6H_4	40	45	79	–	17
	168	65	–	65	4

[a] Calculated using either Equation (20) or (21).

Table 6. Reversible enantioselective esterification of chiral racemic alcohol **2** catalyzed by *C. cylindracea* lipase with dodecanoic acid as acyl donor in hexane or heptane [6][a].

T [°C]	t [h]	Conversion [%]	*ee* [%] Product (ester)	*ee* [%] Substrate (alcohol)	E
45	8	45	95	–	92
40	88	57	69	88	17

[a] Ref. [6] does not indicate which solvent was used.

5.5. Determination of the Kinetic Parameters V_{max} and K_m
