of functionalized polymethacrylates (**1a–2a**) and polyacrylates (**3a–4a**) of a high molecular weight, small amounts of diisocyanates are sufficient to prepare crosslinked samples (**1b–4b**). For the preparation of crosslinked polysiloxanes, however,[9–12] much higher amounts of crosslinker are necessary, due to the lower molecular weight of the precursor polymers.

Some of the LC elastomers derived from main chain polymers are presented in Scheme II and Table 2. In this case the

Scheme II

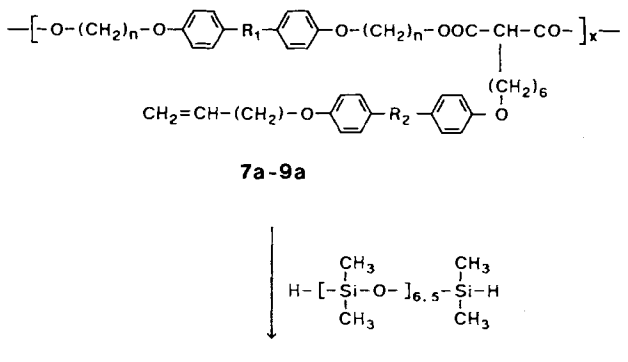

Table 2. Phase transitions of uncrosslinked (**a**) and crosslinked (**b**) LC main chain polymers [14, 19] (see Scheme II).

No.	R	Molecular weight (GPC)	Cross-linker (mol.-%)	Phase transitions[a]/K

crosslinking is performed by reaction of some of the olefinic double bonds of the polymer with the Si-H groups of an α, ω difunctionalized oligosiloxane.[14, 20] Thus crosslinked polymers with different smectic phases can be obtained.

In Scheme III and Table 3 some of the LC elastomers derived from "combined" polymers are presented. Again the

crosslinking is done by a hydrosililation reaction between the Si-H groups of the oligosiloxane and some of the double bonds at the end of the mesogenic side groups.[14, 19, 20] The "combined" LC polymers show a strong polymorphism (Tab. 3, see also[5b]) which means that different LC phases are often found for one polymer at different temperatures.

2.2. Properties of Achiral LC Elastomers

The basic properties of LC elastomers – such as: phase behavior, elasticity and orientability – are independent of their molecular structure (see Scheme I–III and Fig. 4).

The LC phase is retained for the crosslinked elastomers. X-Ray measurements performed with the uncrosslinked and the slightly crosslinked polymers (see Tab. 1–3) show the same LC phases.[14, 17–20] Only for higher crosslinking densities are changes of the X-ray pattern sometimes observed.[12] Thus the crosslinking reaction, which transforms a soluble polymer into a soft solid and prevents diffusion of the polymer chains, does not influence the LC order.

As long as the crosslinking density is low, the phase transition temperatures are not shifted significantly.[9, 13–17] Only a slight increase or decrease (±5 K) is observed (see Tab. 1–3 and Fig. 5) by DSC-measurements. A decrease of the phase transition temperature derives from the presence

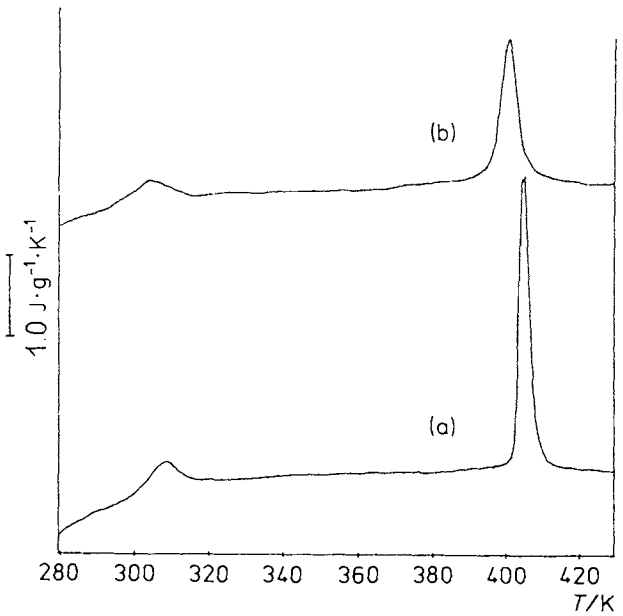

Fig. 5. DSC-measurements of the uncrosslinked main chain polymer **6a** (a) and the crosslinked elastomer **6b** (b) (Tab. 2), figure taken from ref. [14].

of the crosslinking molecules (diisocyanates or oligosiloxanes) at the netpoints, which are not mesogenic by themselves and disturb the LC order. An increase of the phase transition temperature may result from an increase of the molecular weight associated with the crosslinking reaction (an increase of the molecular weight increases the phase transition temperatures for uncrosslinked polymers).[21] Theory further predicts that the state of order during the crosslinking reaction (LC or isotropic phase) should influence the phase transition temperatures of the final network,[22] because the distribution of the netpoints should stabilize the state of order experienced during the crosslinking reaction.

All slightly crosslinked LC polymers show elastic properties (LC elastomers) both in the isotropic and in the LC phase. This is shown for one crosslinked side group polymer with a polymethacrylate chain by the mechanical-dynamical measurements shown in Figure 6[23] (the results of the crosslinked polysiloxanes are described elsewhere).[10, 12, 13, 24, 25] This behavior is also found for crosslinked main chain and "combined" polymers.[23, 26]

In the isotropic phase a "normal" rubber-like behavior is observed.[12, 13, 23–26] This is evident from the (rubber)-plateau in the real part of the compliance (J') at low frequencies (Fig. 6a). The plateau compliance is the same as that of slightly crosslinked elastomers that are not liquid crystalline. The decrease of J' at high frequencies, which is associated with a maximum in J'', is due to the dynamic glass process and the slippage of entanglements. The presence of LC phases at lower temperatures only shows up in a strong increase of the stress optical coefficient[10–13] at temperatures close to the transition into the nematic phase (pretransitional effects).

ADVANCED MATERIALS

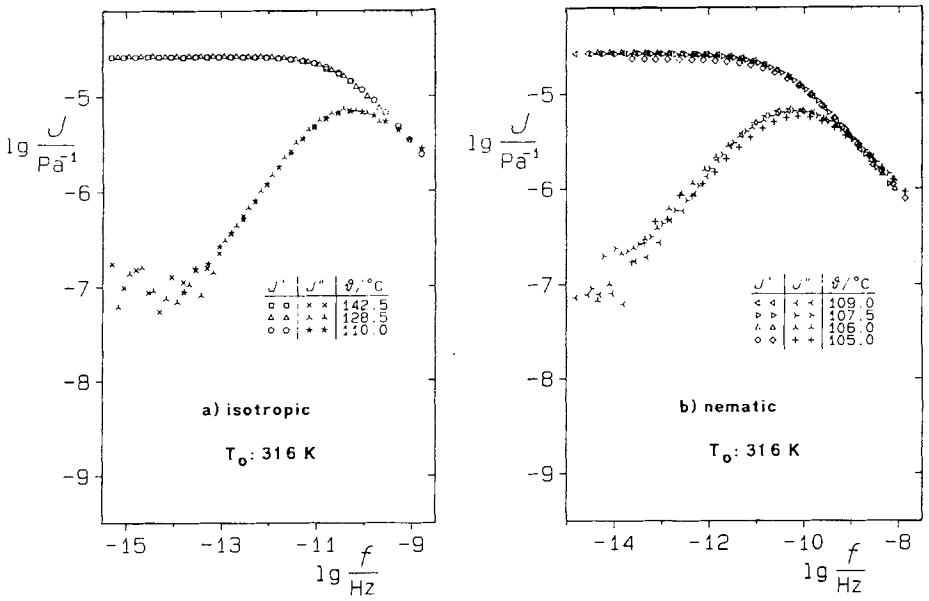

Fig. 6. Mastercurve obtained for the LC side group elastomer **2b** (Tab. 1). The real (J') and the imaginary (J'') part of the complex mechanical compliance is plotted. The measurements were performed in the isotropic (a) and in the unoriented nematic (b) phase (frequencies between 10^{-6} 10^{-2} Hz) and shifted to a reference temperature of 316 K. Measurement performed by *Hanus* and *Pechhold* [23].

In the nematic phase the plateau compliance is the same as in the isotropic phase (see Fig. 6b). This proves that the chain conformation is not significantly changed at the transition to the nematic phase.[27] This result is consistent with the results obtained by neutron scattering of uncrosslinked LC polymers of a similar structure,[28] which show that the radius of gyration is slightly anisotropic in the nematic phase, but the averaged value is the same as in the isotropic phase. At the transition into the smectic A phase (layer structure), the plateau compliance is reduced, but the material remains elastic.

Care has to be taken in interpreting the mechanical measurements in the LC phase, because different properties are found for macroscopically unoriented samples (this corresponds more to the isotropic phase) and for LC monodomains (anisotropic elastic properties). These monodomains show—in addition—changed dimensions in the stress-free state,[12, 25, 29] leading to a stress relaxation during formation. They can be produced—quite accidentally—by small strains during the measurement[10–14, 17–19, 24–26, 29] and sometimes they form spontaneously[12, 24] in highly crosslinked networks.

The mechanical orientability is the most prominent property of LC elastomers.[10–14, 17–19, 24–26, 29] If the network does not orient spontaneously in the LC phase (that means, if the ground state is macroscopically unoriented), then small strains (about 20%) are enough for the reversible formation of an LC monodomain (Fig. 8).[13, 25, 29] This orientation is achieved under equilibrium conditions far above the glass transition temperature. It is not necessary to freeze-in an orientation induced by flow, as in uncrosslinked LC polymers. *Schätzle* et al. were able to determine a threshold stress[25] for the reversible orientation of LC elastomers. Also a small shift of the phase transition temperatures of about 2 K can be induced by stretching[13, 25] and has been theoretically explained.[22, 30] The orientation induced by the same strain is orders of magnitude smaller if the elastomer is in the isotropic phase. This corresponds to the situation in non LC elastomers, for which strains up to 1000% are necessary to obtain a very well oriented sample. Such behavior is found for all types of LC elastomers (Fig. 4) independent of their molecular structure.[29] Differences that are expected e.g. between crosslinked side group and main chain polymers (Fig. 4), may be hidden behind differences in the crosslinking density and the network topology.

The measurement of the strain induced orientation is done with the help of birefringence measurements[10, 12, 25] (only isotropic phase), measurements of the IR-dichroism[11, 25] and X-ray measurements[17–19, 29] (isotropic and LC phase). In this way X-ray measurements, as presented in Figure 7 (polymer **3b** of Tab. 1) were obtained. This X-ray pattern can be used for an accurate assignment of the LC

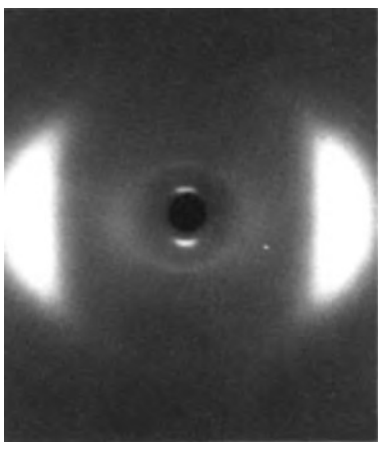

Fig. 7. Fiber pattern of elastomer **3b** (Tab. 1) in the smectic A phase (room temp.), strain $\Delta l/l_0 = 0.73$, fiber axis vertical, figure taken from ref. [17].

phases and, in addition, for a determination of the macroscopic orientation of the sample, as done by *Mitchell* et al.[18] for a similar elastomer (Fig. 8). The orientation, which is reached at an extension ratio of 1.3, corresponds to a monodomain of a nematic polymer. It can be frozen-in below the glass transition temperature.

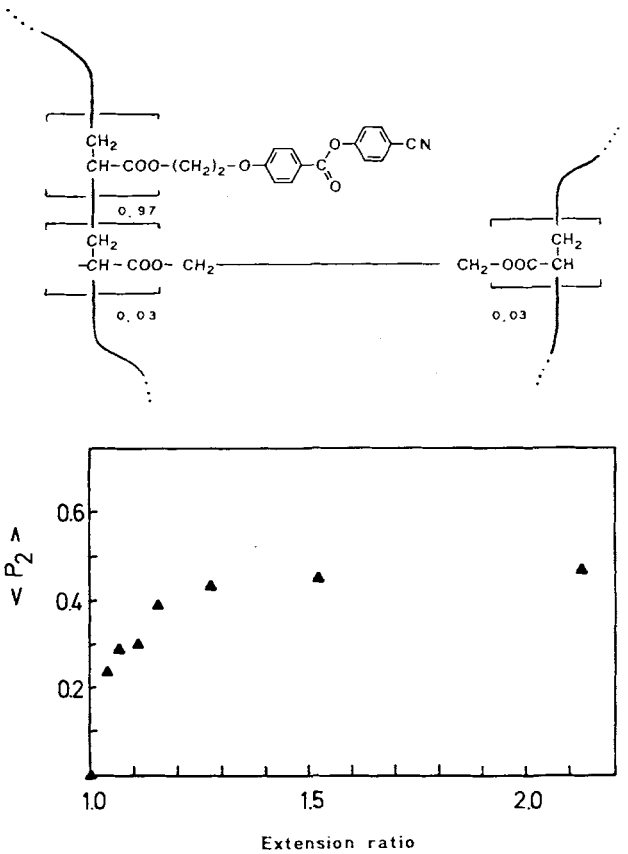

Fig. 8. A plot of the orientation parameter $\langle P_2 \rangle$ for the LC elastomer presented above; the ordinate corresponds to the extension applied. Figure taken from ref. [18] (*Mitchell* et al.).

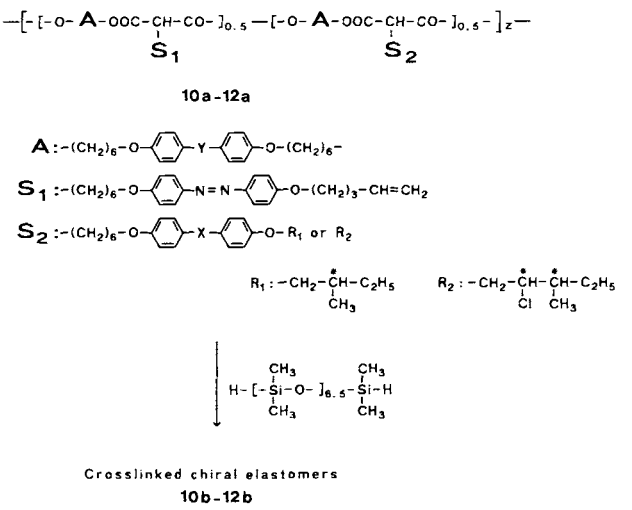

The mechanical orientability of the LC elastomers is presumably due to the anisotropic conformation, which the polymer chains adopt in the LC phase[28] (Fig. 3). Therefore the average distance between two crosslinks in a network does not only depend on the chain length between them, but also on the orientation relative to the long axis of the mesogenic groups. This leads to a coupling of the preferred orientation of polymer chains and mesogenic groups, which has been described theoretically by various authors.[22, 30]

The reversible mechanical orientability of LC elastomers is of considerable interest for the following reasons: For most applications LC phases must be well aligned. LC elastomers thus offer a simple way to do this under equilibrium conditions. The aligned samples can then be used e.g. for an accurate phase assignment by X-ray measurements (Fig. 7),[19, 26] for the determination of the orientation of polymer chains and mesogenic groups with respect to each other[10, 12, 17] or because of their optical properties. Their application as wave guides seems possible,[31] because the local orientation and thus the birefringence can be changed by local strains. In addition, the orientation of an unoriented LC sample into a monodomain transforms reversibly a highly turbid sample into a transparent one. Therefore applications as mechanical-optical switches may be considered.

The anisotropic dielectric properties should also be considered. The stretching of a sample leads to orientation and changes the effective dielectric constant. This can be detected dielectrically. In turn, the action of electric fields on the material can lead to shape variations of the sample,[15] because the elastomers (soft solids) try to orient the axis of their maximal dielectric constant parallel to the electric field.

2.3. Chiral LC Elastomers

Bearing in mind the mechanical orientability of LC elastomers, it seems interesting to look for elastomers which show very drastic changes of their properties during orientation. In this context LC elastomers which combine the properties already discussed with the properties of chiral phases (cholesteric or chiral smectic C* phases) are of considerable interest. These phases, prepared from chiral mesogens, are the chiral modifications of the nematic and the smectic C phase. They possess very special properties, which are: selective reflection of light (cholesteric phase)[1, 2, 32] and ferroelectric properties (chiral smectic C* phase)[33] (see Fig. 9). Besides low molar mass liquid crystals, polymers with the same phases[34, 35] have also been prepared. Since these properties are linked to the helical superstructure of the phases (Fig. 9a and c) it can be asked if it is possible to use a typical elastomer property – the orientability by stretching (mechanical field) – to untwist the helix (repeating distance: 0.2–2 μm). Such a possibility has been predicted theoretically.[30] In low molar mass liquid crystals[32, 33] the helical

Scheme IV

ADVANCED MATERIALS

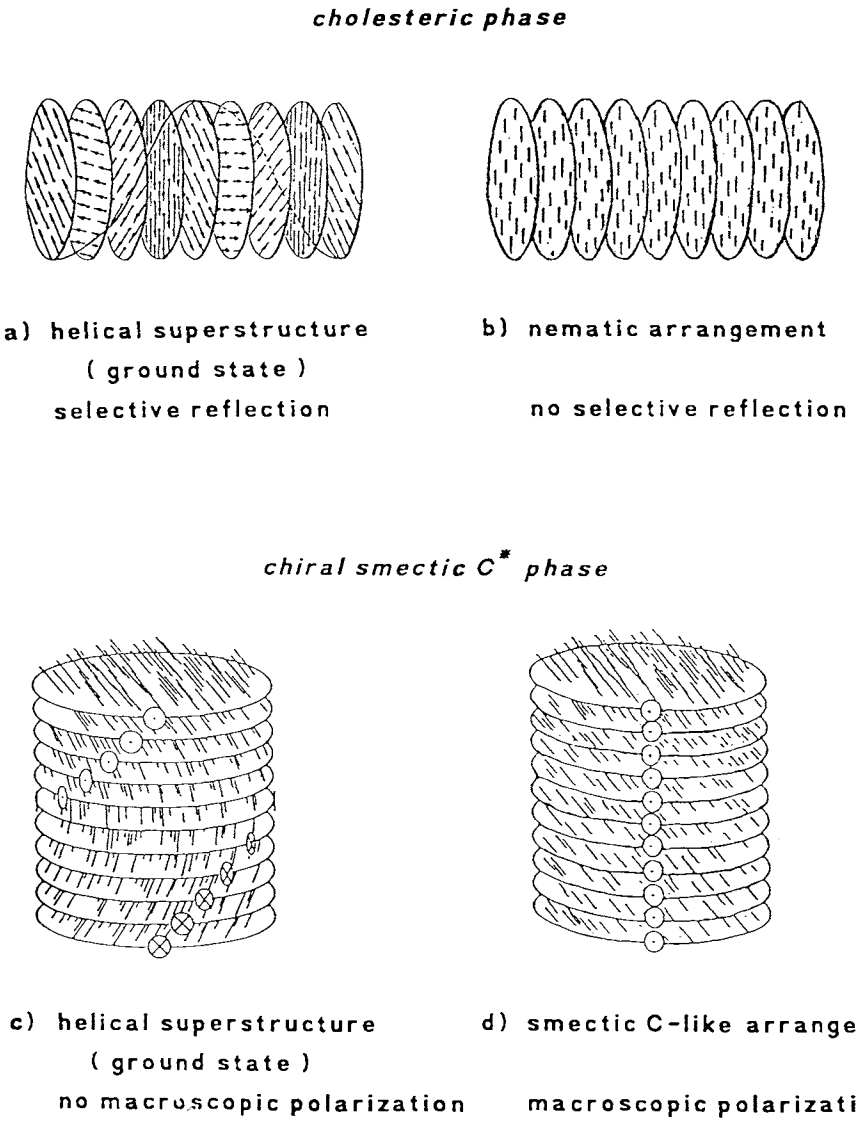

Fig. 9. Schematic representation of the cholesteric (a) and the chiral smectic C* (c) phase. Both phases have a helical superstructure in the ground state. The nematic arrangement (b) or the smectic C like arrangement (d) (untwisted states) can be induced by electric or magnetic fields or by stretching (LC elastomer).

structure can be untwisted by strong electric or magnetic fields, thus transforming the helical cholesteric phase (with selective reflection) into a nematic structure (without selective reflection, Fig. 9a and b) or the chiral smectic C* phase (without a macroscopic polarization) into a smectic C like structure (with a macroscopic polarization, Fig. 9c and d).

In order to investigate elastomers with these properties, a series of chiral crosslinkable polymers have been prepared (Tab. 4 and Scheme IV).[36, 37] For this purpose combined polymers were selected because they form broad smectic and nematic phases (see Tab. 3) if they are achiral, and cholesteric and chiral smectic C* phases[38] if they are chiral. The polymers thus prepared show cholesteric and chiral smectic C* phases in the uncrosslinked and crosslinked state (Tab. 4).

The phase assignment of these polymers was done by polarizing microscopy and by X-ray measurements,[37] proving that cholesteric and different smectic phases were present. The ferroelectric properties of the chiral smectic C* phase

can be determined by dielectric relaxation measurements.[39] The results obtained from polymer **12a** are presented in Figure 10.[40] In the chiral smectic C* phase, two very intensive dielectric loss processes are found, which are not present in the isotropic phase. Due to their high intensity and their temperature dependence, they cannot be local relaxation processes.[39] In analogy to low molar mass liquid crystals, these dielectric loss processes can be assigned as the soft mode and the Goldstone mode,[41] which are typical for chiral smectic C* phases (Fig. 9c). They correspond to fluctuations of the spontaneous electric polarization due to changes of the tilt angle (soft mode) or due to changes of the tilt direction at constant tilt angle (Goldstone mode, distortion of the helical structure).

The first X-ray measurements performed on the chiral elastomers prove that the helical superstructure in the cholesteric and chiral smectic C* phase can be untwisted by stretching.[37] This is presented in Figure 11 for the chiral smectic C* phase of elastomer **11b**. For small strains, a fiber pattern as presented in Figure 11a is obtained. They correspond to an oriented chiral smectic C* phase with a helical superstructure (Fig. 9c). For higher strains (about 400%) fiber pattern as presented in Figure 11b could be obtained. In this case it was necessary to cool the stretched sample down to the glass transition temperature in order to prevent a tearing of the sample during the measurement. These fiber patterns correspond to a smectic C like monodomain (Fig. 9d) without a helical superstructure. Therefore the sample should not have a macroscopic polarization for small strains (Fig. 9c and 11a) due to its helical superstructure, but it should have a macroscopic electric polarization (Fig. 9d and 11b) if it is highly strained.

Most of the work on chiral LC elastomers still remains to be done. For the future it is necessary to prepare e.g. elastomers with a still higher spontaneous polarization in the chiral smectic C* phase. In addition it should be possible to stretch the elastomers more highly (> 400%) and to obtain in this way a uniform orientation over the whole sample[37] (otherwise the polarizations arising from differently oriented domains will compensate each other). Despite these limitations the results of the X-ray measurements show that the chiral LC elastomers have the potential to act like a device that transforms a mechanical signal (the strain) into an optical signal (cholesteric phase, Fig. 9a and b) or an electrical signal (chiral smectic C* phase, Fig. 9c and d). In the last case (chiral smectic C* phase) the elastomer should behave like a piezo-element.

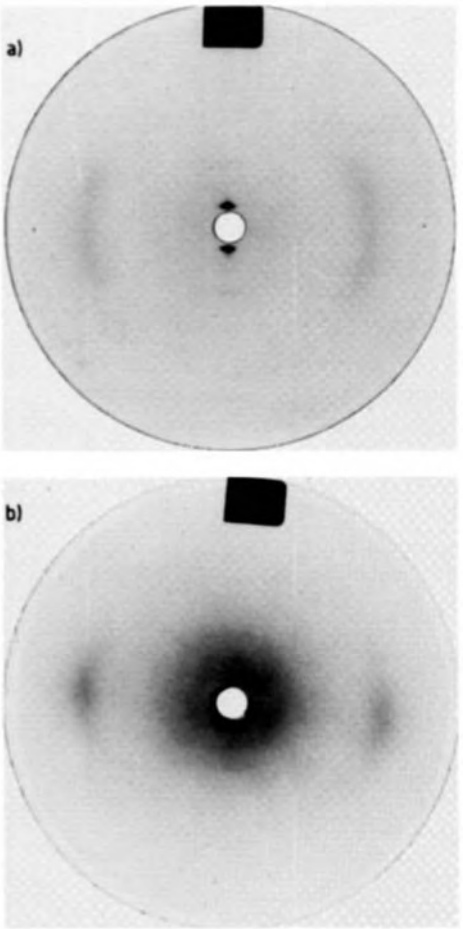

Fig. 11. X-Ray fiber pattern of the chiral elastomer **11b** (Tab. 4) in the chiral smectic C* phase [37], fiber axis vertical. a) a strain of 300% applied, temperature 363 K. b) a strain of more than 400% was applied at 360–370 K, the measurement was performed at room temperature. The wide angle reflections correspond to 4.4 Å and the small angle reflections correspond to 26–27 Å.

3. Summary and Outlook

Starting from a search for a detailed understanding of "classical" materials, such as liquid crystals, polymers and rubbers, material science today is directed to the investigation of more complex systems that combine different properties and functions with ordered structures. The interest in these more complex systems is twofold. On one hand new properties are expected, and on the other hand the study of the interaction of the different subsystems (e.g. polymer chains and mesogenic groups) is fascinating.

ADVANCED MATERIALS

LC elastomers belong to this group of materials. They combine a wide variety of properties such as: i) the mechanical orientability of rubbers, ii) the ordered structure and the mobility of LC phases and iii) the possibility as in polymers to freeze-in an induced orientation below T_g.

LC elastomers with different molecular structures can be prepared by crosslinking LC polymers, while retaining the LC phases. Their elasticity is comparable to "classical" networks. While the understanding of the interaction of the liquid crystalline and the rubber properties in LC elastomers is still at an early stage their mechanical orientability makes them interesting for academic research (phase assignment, structure investigation) and also for applications such as optical switches (turbid–clear) or as wave guides.

The combination of these properties with chiral phases (chiral LC elastomers) yields materials that transform mechanical strain into optical or electrical signals and elastomers with chiral smectic C* phases are likely to show piezo electric properties.

Superfine Oxide Powders—Flame Hydrolysis and Hydrothermal Synthesis

Nanocrystalline Ceramics
Powder Processing
Clean Room Technology
Sintering

By Gangolf W. Kriechbaum * and Peter Kleinschmit *

1. Introduction

The excitement surrounding the technical potential of ceramic materials has gained new support since the surprising physical properties of so-called nanocrystalline materials have been observed.[1] *Gleiter* and coworkers were able to show that a thin ceramic plate of TiO_2 with a nanocrystalline microstructure could be plastically deformed at a temperature as low as 180 °C. This behavior opens the way to new ceramic processing and forming techniques.

In the last decade a lot of research activities have been focused on the development of new synthetic methods for the production of sinter-active submicron ceramic powders. The state of the art of powder synthesis has been reviewed by several authors.[2–6]

This paper describes flame hydrolysis and hydrothermal synthesis, two techniques with the potential to yield superfine powders with a particle size in the nanometer range, and discusses problems involved with the synthesis and handling of superfine materials.

The step from conventional ceramics to high performance ceramics can be described as a change in size range. Conventional technical ceramics with grain sizes between 5 to more than 100 microns and flaw sizes in a similar range are made out of powders prepared by classical mixing-calcining-milling methods or out of refined minerals. High performance ceramics with grain sizes between 0.2 to less than 1 micron need chemically prepared powders in a submicron size range and processing techniques which prevent flaw sizes much bigger than the grain size. By far the most ceramic powders are still produced by conventional techniques but high performance ceramic applications are gaining in importance and therefore the share of chemically prepared powders increases.

Reducing the particle size and increasing the chemical and morphological homogeneity of the powders has led to some specific problems in synthesis and processing.

The need to work in clean rooms or in closed production lines in order to avoid contamination by dust and other particles which are omnipresent in normal unfiltered air is just one example of the required changes for submicron processing.

By improving powder quality and processing techniques and by the design of new microstructures, e.g. the development of toughening concepts like transformation toughening in ZrO_2, a tremendous improvement of strength, toughness and reliability has been accomplished in modern ceramic materials. The nanophase ceramics which go a further step in size reduction are a new challenge to both fields, powder synthesis and processing science.

2. Problems Involved in Processing Superfine Powders

Before synthesis of nanosized powders is discussed, a short description of possible problems involved with the synthesis and handling of fine powders will be given.

2.1. Processing Environment

An overview of the sizes of different airborne particulates is given in Figure 1. To obtain optimal strength and reliability data, maximum flaw sizes in ceramics should be in the range of the grain size. Taking into account that normal air contains between 10^7 to 10^8 particles/m^3 in the micron range, it becomes obvious, that a clean environment is one of the key requirements for submicron processing. This is necessary not only during synthesis but also during handling and shaping. For nanophase materials this becomes even more necessary but clean room techniques are very limited in a particle size range smaller than 0.1 micron.

2.2. Agglomerates and Aggregates

The tendency of fine powders to form uncontrolled agglomerates and aggregates has a strong influence on synthesis and processing. Interparticle cohesion increases strongly with decreasing particle size because of the greater significance of short range, weak forces like electrostatic forces and van der Waals forces, with the result that the strength of agglomerates increases with decreasing particle size. In powders with particle sizes below 50 nanometers strong agglom-

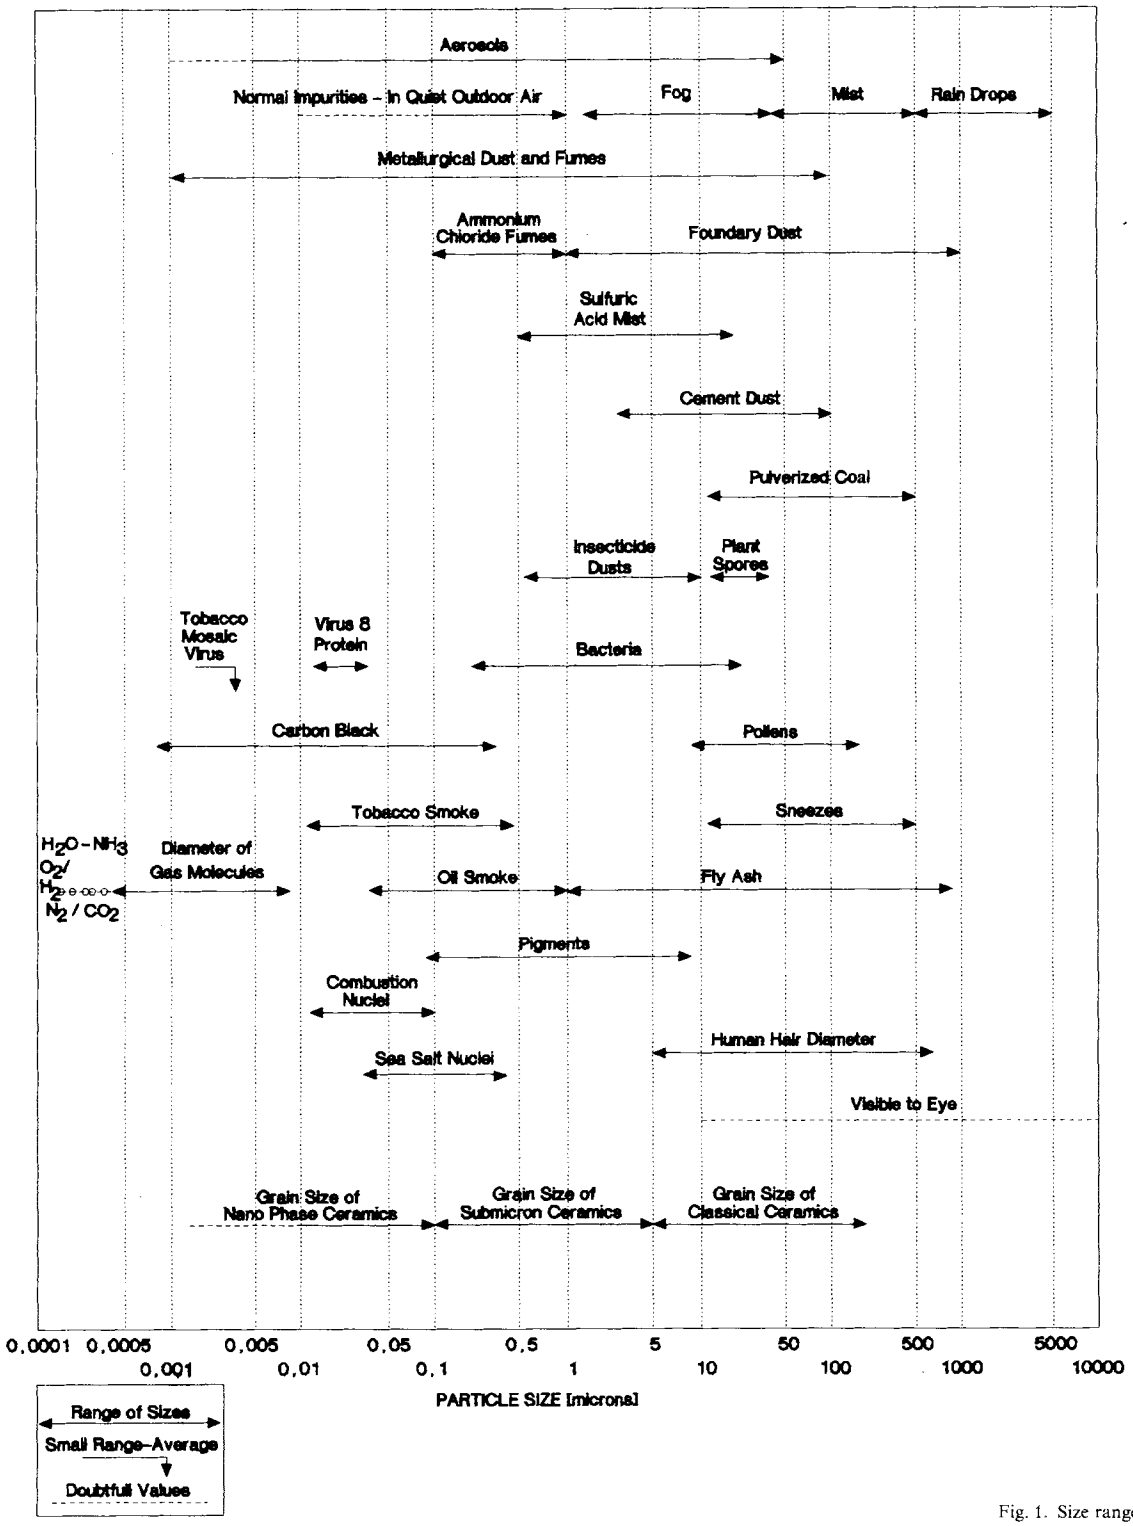

Fig. 1. Size ranges of airborne particulates.

erates can hardly be avoided because of the significance of the van der Waals attraction in this size region.[7] In addition, the increasing specific surface area resulting from the decreasing particle size leads to a greater tendency for vapor condensation on particle contacts. This causes bonds to form between particles and so further strengthens the existing agglomerates.[8] The negative effect of strong agglomerates on powder packing and morphological homogeneity of the green body is well described in the literature.[9-11] Inhomogeneities in the green body lead to structural flaws in the sintered product and increase the necessary sintering temperature because intra-agglomerate sintering occurs at lower

temperatures than inter-agglomerate sintering.[12, 13] In addition strength, toughness and reliability are decreased. Several concepts have been developed to improve particle agglomeration in submicron powders.

Recently, techniques for agglomeration control in wet-chemical powder synthesis have been reviewed by *Roosen* and *Hausner*.[14] Table 1 lists the techniques proposed for controlling agglomerate characteristics. To avoid agglomerates during synthesis or to destroy or eliminate agglomerates formed already are the two fundamental possibilities.

Destroying agglomerates after their formation by milling or sedimentation is limited to powders with agglomerate sizes bigger than 0.1 micron. For nanosized powders, ways to influence agglomerate characteristics during their formation have to be found. This is rather difficult to achieve because the main advantage of superfine particles, their very high sintering activity, becomes a major disadvantage during synthesis. Synthetic methods where high temperatures are involved, promote the formation of aggregates by forming solid bridges on particle contacts.

Therefore low temperature methods like gas-condensation techniques or small particle concentrations during high temperature treatment in a dispersed phase – gas phase or liquid phase – are necessary for the synthesis of weakly agglomerated nanosized powders.

2.3. Forming

The nanocrystalline TiO_2 plate mentioned earlier which showed ductile behavior[11] was shaped by in situ compaction of the powder by dry pressing with a pressure as high as 1.4 GPa.[15] No value of the achieved green density is given nor is it explained why a high pressure far beyond the usual pressure range, was applied. Poor packing of the synthesized powders may be one of the reasons. To obtain homogeneous, dense sintered structures from superfine powders, green bodies with a uniform pore size distribution are required. Since weak forces dominate the packing of dry ultrafine particles, dry forming techniques are not favored.

Wet forming processes like colloidal filtration[16] may be more successfull. Packing of fine powders in suspension can be improved substantially by the use of the appropriate pH range and by organic dispersants. *Sacks* has investigated the packing behavior of fine silica spheres and found that by proper control of the particle dispersion, sintering temperatures can be decreased by increasing the homogeneity of green compacts.[17]

Peter Kleinschmit was born in 1938 in Leipzig (GDR) and studied chemistry at the Universities of Hannover (FRG) and Vienna (Austria) gaining a Ph.D. for a study of "Chemistry in Molten Salts" in 1968. Since then he has occupied various positions with Degussa, starting as a Research Chemist and becoming a Board Assistant in 1970, a Plant Manager in 1973 and the Head of the Inorganic Research Department in 1975.

Gangolf Kriechbaum was born in Nürnberg (FRG) in 1953 and studied chemistry at both the University of Regensburg (FRG) gaining his Diploma in 1981, and the University of Frankfurt (FRG) where he gained a Ph.D. for his work on the "Reactivity of Metal-Metal Multiple Bonds" in the group of Prof. W. Herrmann in 1983. He then spent a year working with Prof. A. Cotton at Texas A & M University (USA) before joining Degussa as a Research Scientist in 1984.

ADVANCED MATERIALS

3. Synthesis of Superfine Powders

The nanophase TiO_2 ceramic described by *Gleiter* and coworkers was made out of a powder which had been synthesized by the so called gas-condensation method.[15] The principle of this synthetic technique is the evaporation of titanium metal in an oxygen free vacuum by resistance heating and the decomposition of the metal vapor on a liquid nitrogen cooled cold finger. Controlled oxidation of the deposited metal powder by introducing oxygen to the reactor finally produces titanium dioxide. The advantage of this method is that it works in a very clean, easily controlled environment.

On the other hand, gas-condensation is limited to very few chemical systems which are not necessarily in the focus of ceramic interest. Also, the turnover limits this technique to small scale operation and therefore other synthetic routes to nanosized powders have to be developed.

Because of their potential to yield superfine powders, flame hydrolysis and hydrothermal synthesis are synthetic routes which are promising for the preparation of suitable powders on an industrial scale.

3.1. Flame Hydrolysis

The reaction of volatizable compounds like for example $TiCl_4$ or $SiCl_4$ in an oxygen-hydrogen flame leads to highly dispersed oxides. This technique, called flame hydrolysis or the AEROSIL process, was originally developed by *Klöpfer*[18] and has been designed to make highly-dispersed silica. Meanwhile, flame hydrolysis has been used to produce a variety of different compounds, some of which are listed in Table 2.[19–21] A flow sheet of the process is shown in Figure 2. Silica, alumina and titania are produced on a commercial scale and have found numerous industrial applications, for example, as fillers and thickeners.[19]

Table 2. List of pyrogenic products [18].

Product	Raw Material	b.p. [°C]

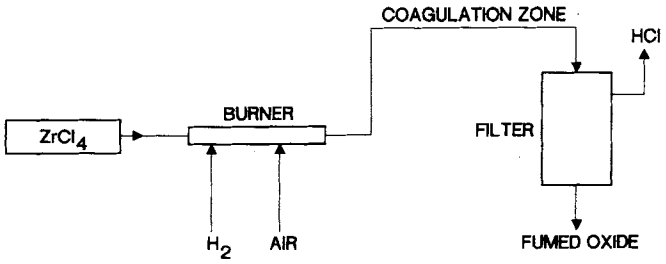

Fig. 2. General flow sheet for the preparation of ZrO_2 by flame hydrolysis [22].

The major advantages of flame hydrolysis are the high purity of the compounds, its chemical flexibility, and the possibility to synthesize mixed oxides which are homogeneous even on a molecular scale. In addition, powder properties like specific surface area and particle size can be easily controlled by varying the reaction conditions. The most important disadvantage for ceramic use is the very low bulk density of pyrogenic materials. Figure 3 shows transmission electron micrographs of some of the commercially available silica powders. Powders with particle sizes between 7 and 50 nanometers and specific surface areas between 50 and 380 M^2/g can be synthesized. For ceramic applications the chemical systems ZrO_2,ZrO_2–Al_2O_3, Al_2O_3–ZrO_2 and Al_2O_3–TiO_2 are of interest.

Promising results have been obtained on zirconia powders, synthesized by flame hydrolysis.[22] Powders with specific surface areas between 20 and 100 m^2/g and a particle size between 10 and 50 nm have been prepared. X-Ray diffraction (XRD) analysis showed that the pyrogenic ZrO_2 crystallizes in the tetragonal phase with only a small monoclinic part. The "as prepared" powder has a very low bulk density of about 150 g/l and therefore precompaction is necessary. The sintering experiments were performed on powders which were yttria doped and precompacted by spray drying. Densities of about 99% of theory were achieved at a sintering temperature of 1450 °C. The relatively high sintering temperature caused grain growth so that grain sizes of about 0.2 micrometers were obtained. The originally nanosized powder only preserves its size range when the applied sintering temperature is much lower.

The same authors have made silica stabilized aluminum titanate powders by cohydrolysis of $SiCl_4$, $AlCl_3$ and $TiCl_4$. The transmission electron micrograph of the powder shows spherical particles in a size range between 20 and 100 nanometers (Fig. 4).

Cold isostatically pressed compacts were densified at a temperature as low as 1300 °C to a density of more than 3.6 g/cm^3 and showed a grain size of much below 1 micron, which is rather small for aluminum titanate (Fig. 5). By flame hydrolysis with a specially designed burner nanosized zirconia powders have been coated with alumina.[23] The synthesized Al_2O_3–ZrO_2 particles have a size between 40 and 100 nm. Data on the sintering behavior of this material have not been published.

Pyrogenic aluminas differ fundamentally in their properties from other aluminas which are prepared by precipitation

ADVANCED MATERIALS

and/or solid state reactions. They have a primarily gamma structure with traces of delta and have a particle size of about 15 to 20 nm with a specific surface area of about 100 m^2/g.[19] Sintering of the "as prepared" powder is not very successful because of the phase transformation to α-alumina during the sintering process. A high sintering activity has been reported by *Kato* et al. when the chemical vapor deposition CVD derived Al_2O_3 powder was precalcinated at 1200 °C to 1350 °C. During the calcination process particle growth occurs and powders with particle sizes between 0.1 to 0.5 are obtained.[24] It has not been reported that nanosized alumina can be synthesized in its α-form by flame hydrolysis.

3.2. Hydrothermal Synthesis

Reactions in water above its boiling point and therefore under pressure, are called hydrothermal reactions. This very general definition illustrates that a variety of very different chemical processes are categorized under the heading hydrothermal reactions.

Historically the first hydrothermal experiments were performed by *Schafhäuptl*[38] who synthesized quartz crystals from amorphous silica although nature used hydrothermal reactions long before for the formation of numerous minerals. Although hydrothermal processing is a familiar technique very few examples of commercialization are known. Most important is the Bayer-process which includes a hydrothermal leaching step to form soluable sodium aluminates for separation from remaining solids. The synthetic and hardware aspects of hydrothermal synthesis have been reviewed by *Rabenau*.[26] This paper is limited to hydrothermal processes connected to superfine ceramic raw materials.

The different hydrothermal reaction types described in the literature are decomposition, oxidation, crystallization, precipitation, sintering, and leaching. For the synthesis of superfine ceramic oxides only hydrothermal precipitation and hydrothermal crystallization have to be considered. General flow sheets of both techniques are shown in Figure 6. While hydrothermal precipitation starts from clear metal salt solutions, hydrothermal crystallization uses hydroxide gels or sols. Hydrothermal synthesis yields oxide suspensions of crystalline metal oxides which in some cases can even be used for ceramic processes without a calcination step. A variety of different oxides have been synthesized by hydrothermal techniques (Table 3). For structural ceramics, zirconia, alumina, titania and mixed powders like Al_2O_3–ZrO_2, ZrO_2–Y_2O_3 and Al_2O_3–TiO_2 are the most relevant systems. As already mentioned, the major advantage of hydrothermal

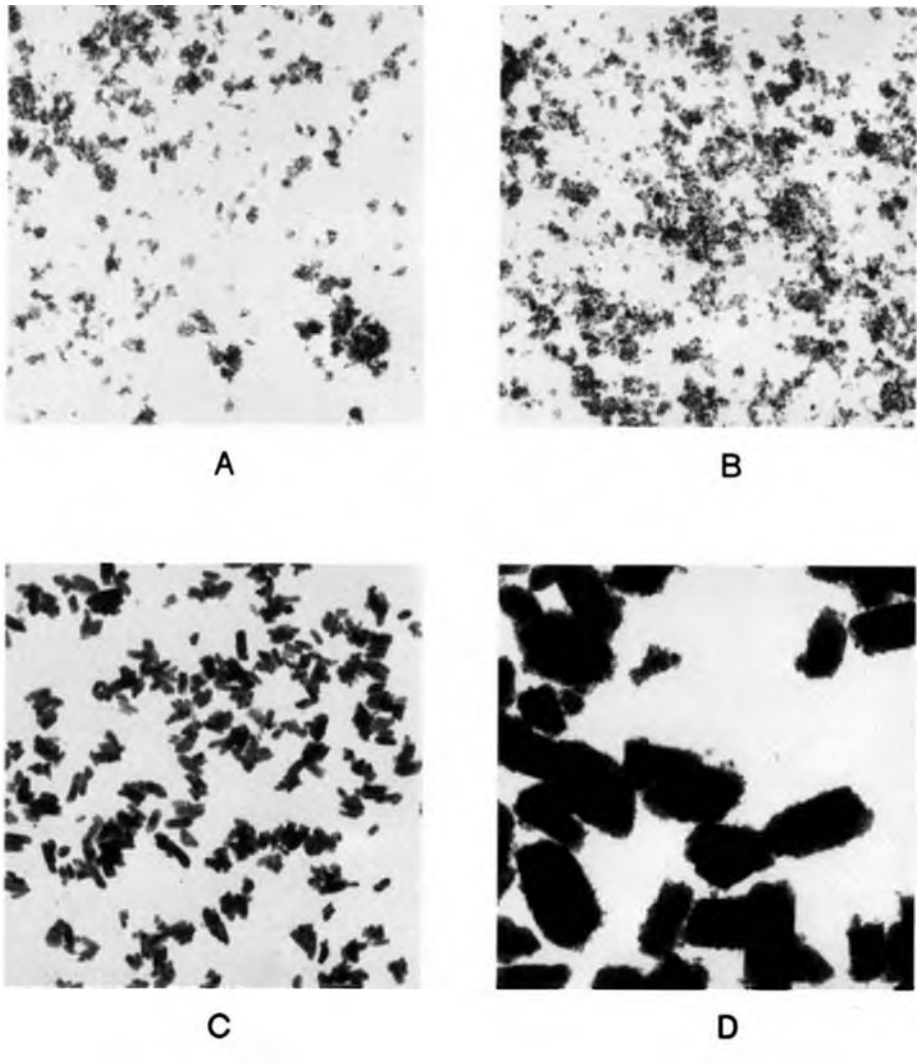

Fig. 8. Transmission electron micrographs of hydrothermally prepared Y_2O_3 doped ZrO_2 powders, synthesized at the same temperature but different NaOH-concentrations. (A: NaOH = 10^{-3} Mol, B: NaOH = 10^{-2} Mol, C: NaOH = 10^{-1} Mol, D: NaOH = 1 Mol) Mag. 1:100000.

processing is that high temperature calcination is not needed to form oxides.[27] Having no solid state calcination step the formation of hard agglomerates and aggregates can be more easily avoided which is not the case in sol-gel or coprecipitation methods where nanosized particles are formed which are also enlarged and aggregated when solid state crystallization to the oxide is performed.

One of the most promising candidates for hydrothermal synthesis is ZrO_2. The formation of highly dispersed ZrO_2 by hydrothermal precipitation from zirconium oxychloride or other zirconium salt solutions has been described by several authors.[27-31] Depending on the reaction conditions anhydrous monoclinic ZrO_2 with particle sizes between 3 and 10 nanometers and surface areas as high as 180 m^2/g can be obtained.

The very fine primary particles are agglomerated into regular shaped clusters in the narrow size range between 0.1 and 0.25 μm (Fig. 7).[32] For use in structural ceramics pure ZrO_2 has to be doped with Y_2O_3. To synthesize homogeneously doped zirconia the described precipitation method has to be modified because Y_2O_3 is not precipitated under acidic conditions.[33]

Using a thermally unstable compound like urea which decomposes at elevated temperatures and so changes the pH to higher values, is one of the possibilities to succeed in synthesizing Y_2O_3–ZrO_2 powders by hydrothermal precipitation.[34] Problems with material corrosion caused by the changing pH values during the reaction may limit this method to small scale production where teflon lined autoclaves can be easily used.

An alternative way to prepare superfine yttria-doped zirconia powders is the hydrothermal crystallization of hydrous zirconium and yttrium oxides.[33] The particle size of the synthesized powders can be varied according to the reaction conditions between 10 to about 500 nanometers.[32, 35] Figure 8 shows transmission electron micrographs of yttria-zirconia powders (3 mol-% Y_2O_3) synthesized at different pH values. With increasing $^{\ominus}OH$ concentration, particle size can be increased. Besides size, particle shape can also be controlled by the addition of mineralizers.[36]

ADVANCED MATERIALS

The published sintering results[32, 36] indicate that theoretical densities have almost been obtained with hydrothermal ZrO_2–Y_2O_3 powders. The dilatometer investigation shown in Figure 9, where the sintering behavior of a hydrothermal

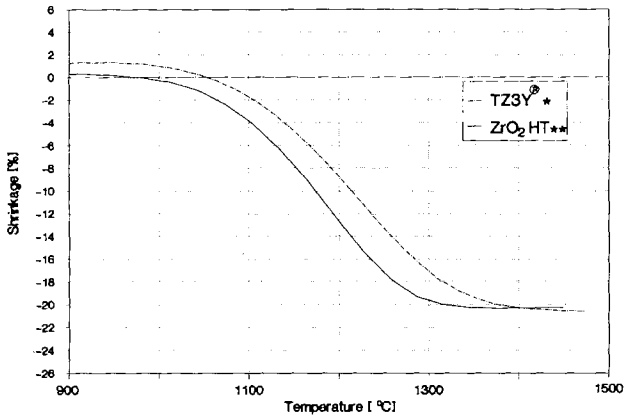

Fig. 9. Shrinkage vs. temperature of two Y_2O_3 doped ZrO_2 powders, one prepared by coprecipitation, (* Tosoh Co.) the other hydrothermally (** Degussa AG)

oxide powder is compared with a powder obtained by coprecipitation, clearly indicates that a decrease of sintering temperature can be achieved.[37] Necessary sintering temperatures are still too high to prevent grain growth during sintering and a grain size of 0.2 micrometer in the dense body is observed.

Hydrothermal crystallization can also be used for the synthesis of CaO,[38] MgO[39] and MgO–Y_2O_3[39] doped zirconia. The synthesis of Al_2O_3 and Al_2O_3–TiO_2 powders by hydrothermal crystallization has also been reported.[36] Published results show however that the powders obtained are not in the nanosized range.

4. Outlook

The synthesis of nanosized powders can be achieved by flame hydrolysis and hydrothermal synthesis. The poor packing of the fine powders is responsible for the fact that the advantages of these super fine materials with respect to sinterability and the possibility of yielding nanocrystalline materials have not been fully exploited. Research is needed to develop appropriate processing techniques for the compaction and the shaping of superfine powders.

Both discussed synthetic routes have already proved that upscaling is possible. If progress in the development of better handling and processing methods is achieved, flame hydrolysis and hydrothermal synthesis will become important techniques for the production of super fine oxidic ceramic raw materials which in turn will further improve the performance of ceramic materials.

ADVANCED MATERIALS

Liquid Crystals— New Compounds, New Applications

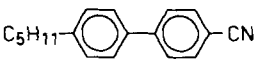
Thermotropic Phases
Disk-Like Nematics
Electrooptical Devices
Laser Optics

By Rudolf Eidenschink *

1. Introduction

Fluidity and long range molecular orientational order are the common characteristics of liquid crystal phases. Depending on temperature and pressure, rod-like molecules can form the well known nematic and various smectic phases which have an additional positional order.[1] Optically active molecules form special helical phases, the cholesteric phase formed being closely related to the nematic phase and its helical structure gives rise to temperature dependent selective reflection. Quite recently a new helical smectic phase, named the S_A^* phase, with an unusual structure has been found.[2]

Fluidity and order can be realized with disk-like molecules in a similar way.[3] In the so-called phasmids, for example, the rod-like core and the half-disk ends of the molecules generate mesophases structurally different from known phases.[4a] Polarization microscopy aided by differential scanning calorimetry and X-ray diffraction have been the main tools used for structural classification. Now, scanning tunnelling microscopy of liquid crystal layers on graphite is offering some exciting details of molecular arrangement.[4b, 4c] The patterns of molecular order of the above mentioned phases can be transferred to polymers with a huge applicational potential.



Until now the technical application of low molecular weight thermotropic liquid crystals has been almost restricted to electrooptical displays using nematic and smectic phases although nematic phases are of scientific interest as anisotropic solvents in NMR spectroscopy and foils with encapsulated cholesteric liquid crystals have found a small field of application in thermometry.[5]

In the case of polymers, fibers with high tensile liquid strength have reached a state of industrial production and lyotropic phases, colloid disperse systems being formed by lamellae or nonspherical micelles, are of fundamental importance for biological processes. In some novel compounds and mixtures the characteristics of thermotropic and lyotropic phases overlap. In the following article some main points of this fast developing field shall be touched upon, the emphasis being on nonpolymer thermotropic materials with a potential for new technical application.

cally important species (C = crystalline, S_A = smectic A, etc., N = nematic, I = isotropic, transition temperatures in °C.

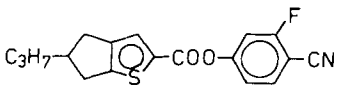
A nematic phase used for the twisted nematic cell[6] nowadays often contains 12 or more compounds in order to match the values of the parameters required: transition temperature from the nematic to the isotropic phase (T_{NI}), melting temperature, viscosity coefficients, elastic constants, optical and dielectric anisotropies and specific ohmic resistivity. A precondition for applicability is the long term stability of the compounds.

By now seemingly all simple molecular building elements permitting linear linking in order to obtain long shaped molecules have been applied.[7, 8, 9] An important task of research in this field is the fine tuning of special physical parameters of known classes of compounds. A good example is the systematic introduction of fluorine atoms.[8, 9, 10]

The newly introduced 1,3-bicyclo[1.1.1]pentylene moiety leads to a number of interesting compounds, exemplified by

ADVANCED MATERIALS

5. It was found, however, that the corresponding 1,4-bicyclo[2.2.2]octylene or 1,4-phenylene compounds generally have higher T_{NI} values.[12]



Replacing one 1,4-disubstituted six membered ring of a nematogenic molecule by a 1,3-disubstituted carbocyclic or heterocyclic five membered ring often yielded compounds with interesting physical properties. However, the decrease in the transition temperatures was prohibitive. To overcome this drawback, fused ring systems such as indanes[13] and s-hydrindacenes without a conventional ring system[14] have been synthesized. A particularly interesting example is the propanothiophen carboxylate **6**.[15]

New aspects of the field are opened up by some nematic transition metal complexes of Au, Ag, Pt, Pd and Ni[16], e.g. the platinum complex of 4'-pentylbiphenyl-4-carbonitrile **7**.

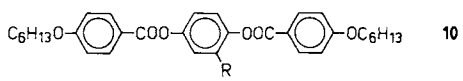
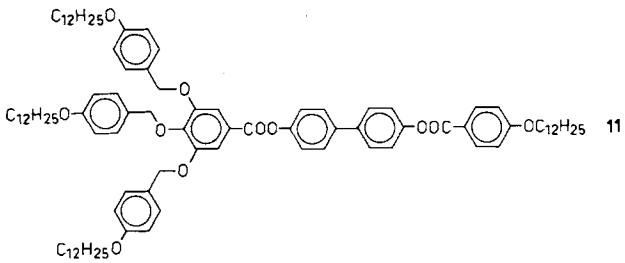
Some deviations from the usual building principle have become known. The fact that *trans,trans*-4'-alkylbicyclohexyl-4-carbonitriles like **8** are nematic has been explained in terms of association via the carbonitrile groups. It turns out, however, that bicyclohexyl compounds like **9** which do not undergo association because of steric deshielding are also nematic.[17]

8



9



C 25 S_B 30 N 66 I

If in esters of type **10**, R = H is substituted by n-C_nH_{2n+1}, T_{NI} decreases.[18] The fact that the nematic state can be observed even with very long alkyl chains (up to n = 16!) has been explained in terms of an energetically preferred conformation permitting this chain to run parallel to the rigid core.[9]

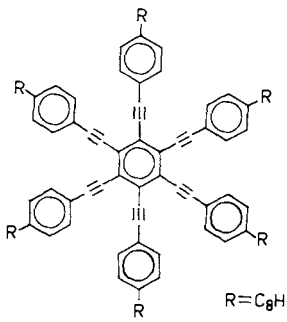
The free rotation around the longest molecular axis of the biphenyldiol-dibenzoate **11** is obviously restricted. This

10

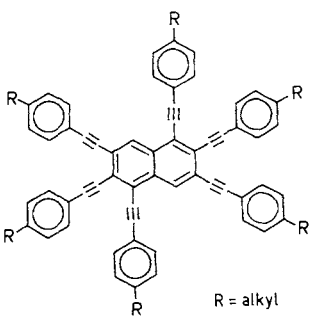
11

compound is the first example of a biaxial thermotropic nematic phase found among nonpolymer compounds.[19]

Today it is widely assumed that the occurrence of a thermotropic nematic phase is due to a combination of the at-



Rudolf Eidenschink worked as an engineer on selenium diodes and electroplating before moving to chemistry, completing a Doctoral Thesis in synthetic uses of anionic 1,3-cycloadditions at the University of Münster, FRG. After a postdoctoral fellowship at the University of Sussex, UK, he joined the company Merck in Darmstadt, FRG where he was responsible for the discovery and exploitation of a number of classes of liquid crystals, for example those known by the acronyms PCH, BCH, CCH, CBC, and CCN. In 1987 he left the group he had built up at Merck to found his own company, Nematel, which is situated in Mainz, FRG.

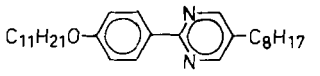


tracting dispersion forces and the hard core repulsion interactions, both of which are enhanced by the anisotropic shape. In the generalized van der Waals theory of *M. Cotter* and *W. M. Gelbart*[20] the first order phase transition from the isotropic to the nematic state at T_{NI} depends on the molecular package density and on a term for the attractive forces. The package density in a fluid can be assumed to depend on the ratio of molecular length over width.[9] Here—as with any molecular theory dealing with T_{NI}—the question of the conformation equilibrium is essential. In this context it was shown by ^{13}C-NMR of *trans*-1-alkoxy-4-alkoxy-carbonyl-cyclohexanes[21] that a distinct anomeric effect influences the concentration of the long shaped equatorial, equatorial-form in the conformational equilibrium. The hypothesis that the uncertainty of the local assignment of energy quanta passing between parallel molecules leads to an orientational effect was helpful in correlating chemical bonding parameters with T_{NI}.[22]

Hexaalkynylbenzenes like **12**[23] being the first disk-like nematic (N_D) hydrocarbons have no permanent dipole moment. The dielectric anisotropy of **12** due to electronic polarizibility made possible the realization of an electrooptical cell.[24]

Despite the long term instability of **12** this result gives impetus towards the development of displays with discotic phases proposed earlier.[25] In this context it is worth noting also that the 1,2,3,5,6,7-hexakis[phenylethynyl]naphthalenes **13**[26] form discotic phases with sequences comprised of

12

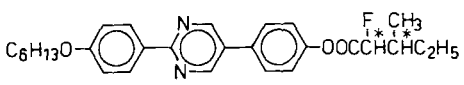


13

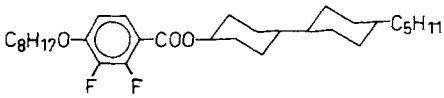
different columnar phases and the disk-like nematic phase in an order opposite to that usually observed.

3. Compounds Forming Smectic C Phases

The invention of the surface stabilized ferroelectric liquid crystal displays (SSFLC)[27] in 1980 initiated the search for stable compounds with broad temperature ranges of S_C phases. Compounds forming this phase with a tilt of the molecules in the smectic layers have at least two aromatic rings,[28] with a few exceptions (see, for example, compound **16**). A perpendicular dipole, off center, combined with a polarizable center are the general features of such molecules and the phenylpyrimidines **14**[29] which have this feature are often used as basic components of S_C phases.



14

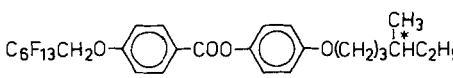


C 45 S_C 60 S_A 67 N 69 I

The environment of a molecule in an S_C phase can be described as monoclinic, with a 2-fold axis of symmetry and a mirror plane. To generate ferroelectricity, and to form a smectic S_C^* phase the mirror plane has to be removed. This is done by doping with an optically active compound, in most cases with an enantiotropic S_C^* phase. The spontaneous polarization P of thin layers (2 μm) can be expected to be high if high transverse dipole moments are connected as rigidly as possible to the chiral center and if intermolecular interactions impede the rotation around the long molecular axis. Compound **15**[30] synthesized from L(+)-isoleucine has a very high P of 400 nAs · cm^{-2}.

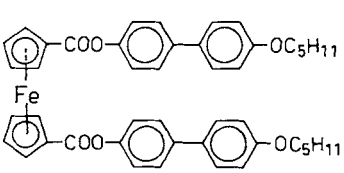
For low switching times in displays a small value of the coefficient of rotational viscosity[31] is advantageous. Here difluorobenzoates of the type **16**[32] are very useful.

15



16

C 90 S_C 98 N 170 I



It has been long known that substitution in the alkyl chains of a mesogenic compound by several fluorine atoms leads to an enhancement of smectic phases (mostly S_A) over the nematic phase. In the case of simple phenyl benzoates[33] S_C phases could be induced by special substitution patterns, as shown in **17**.

The ferrocene derivative **18** is another example of the integration of a transition metal complex into a mesogenic struc-

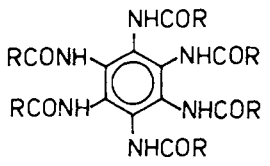
ADVANCED MATERIALS

ture. Despite the participation of four 1,4-phenylene units the transition temperature to the isotropic state is relatively low. This is explained by the presence of different geometric isomers.[34]

4. Compounds with Hydrogen Bonds



Compounds forming hydrogen bonds provide a variety of aspects not only for the well known aqueous lyotropics but more and more for thermotropic liquid crystals. *Trans*-4-alkylcyclohexane-carboxylic acids[35] and 1-(4-*trans*-4-alkylcyclohexyl-phenyl)-alkane-1,3-diones[36] being predominantly in their keto-enol form (**19**) have already been proposed for technical application in displays. Solutions of the high melting amide **20** in alkanes, chloroform or toluene are lyotropic nematic and can be oriented uniformly by a magnetic field.[37] This is probably due to the formation of intra and intermolecular hydrogen bonds.

The relatively low melting amides **21**[38] and **22**[39] have broad temperature ranges of thermotropic mesophases.

22

Although it was only 23 years after the synthesis of the liquid crystalline cholesteryl benzoate by *Reinitzer* in 1888 that the first 1-alkyl-o-glucosides with liquid crystal properties were synthesized,[40] the systematic search for liquid crystal derivatives of natural products in general and carbohydrates in particular is beginning[41,42,43] only now.

Interesting examples that exploit H-bonding are the columnar discotic phases formed by ionosite derivatives possibly having the supramolecular structure of **23** (R = alkyl).[44]

23

Also of interest are the 2-(*trans*-4-alkylcyclohexyl)-1,3-propandiols that form intermolecular hydrogen bonds in their S_A phases.[45] This molecular arrangement suggests the equivalent conductivity for $H^{\oplus}$ ions to be anisotropic. It was shown that diols are able to incorporate water that in certain concentrations enhances the thermodynamic stability of the S_A phase.[46] Generally speaking, with compounds forming intermolecular H-bonds, the characteristics of thermotropic and lyotropic liquid crystals begin to overlap.

5. Applications

5.1. New Electrooptical Devices

Today most of the liquid crystal displays are still twisted nematic cells. Recently major improvements have been made in the multiplexibility by using various techniques[6] which have a higher twist angle of the nematic layer (up to 270°) in common. The ratio of the elastic constants is regarded more and more as an important parameter for phases used in data screens. For pocket television screens the technique of an active matrix is favored, where one thin film transistor for every pixel switches a simple twisted nematic layer. The materials must be of very low viscosity and must have a high value for the product of dielectric constant and specific ohmic resistivity in order to limit the decrease of voltage at the pixels during the addressing cycle.[47] The above mentioned SSFL holds promise for a more economic realization.

A new and elegant technique to switch light using an electric field are the polymer dispersed liquid crystals (PDLC).[48,49] Droplets (2 to 5 μm in diameter) of a low molecular weight nematic phase are dispersed in an isotropic polymer (e.g. epoxy resin). Without an electric field the preferred direction of the nematic molecules is a statistical one

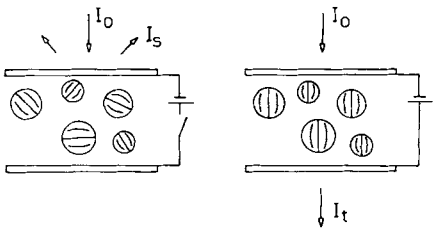

Fig. 1. Principle of PDLC films. I_0 = incident light, I_s = scattered light, I_t = transmitted light.

(Fig. 1). Incident light is scattered in all directions because of the mismatch of the refractive indices at the phase barriers. In an electric field the molecules have a preferred orientation because of their dielectric anisotropy. If the refractive index of the polymer is equal to the ordinary refractive index of the nematic phase the foil appears transparent. The PDLC is of interest for displays as well as solar control windows.

5.2. Laser Optics

The molecular order provided by the liquid crystal state makes possible some new applications of laser optics. Grids and other optical elements produced by a laser in a nematic phase can be used to switch another laser.[50] It has been claimed that switching times of fractions of nanoseconds can be achieved,[51] the molecular orientational movement in the laser field being the limiting factor.

To obtain materials with nonlinear optical properties, i.e. high values for the macroscopic hyperpolarizabilities ($X^{(1)}$) the integration of moieties with strong molecular hyperpolarizabilities (X) as side-chains of a liquid crystal polymer has been considered.[47] This might be exploited to build e.g. frequency doublers (high $X^{(2)}$) or to switch light by an electric field (high $X^{(3)}$, Pockels-effect). For high values of $X^{(2)}$ the moieties have to be ordered in an antiparallel way. To create a material with this feature, thin film techniques seem particularly suitable. Thin films being deposited as monomolecular layers of lyotropic lamellae onto a substrate[53] also have a good future in lithographics and antifriction layers. The molecular self organization in such layers is of fundamental significance in material science as well as in biology.[54]

5.3. Reaction Media

Influencing the kinetics of a chemical reaction by using anisotropic reaction media has in the past inspired many chemists. In recent times the possibilities have been substantiated. In the case of thermotropic liquid crystals[55] improvement of enantioselectivity in cholesteric phases and photochemical reactions are preferred topics. For technical application, lyotropic aqueous phases generally have a better perspective. A dramatic change of the rates of the acid-catalyzed hydrolysis of phosphinate esters in surfactant solutions has been observed going from a disk-like to a rod-like nematic phase.[58]

5.4. Engineering

The change of viscosity—a tensor quantity in mesomorphic phases—during phase transitions has some interesting aspects in engineering.[57, 58] The fast and reversible transitions accomplished by a change of temperature or pressure make possible a new method of construction of mechanical elements such as clutches, brakes, slide bearings and hydraulic devices.

6. Summary and Outlook

The growing interest in nonpolymer liquid crystal compounds in the past 20 years is attributed to the upswing in uses of liquid crystal displays. Synthetic chemistry and applied physics have promoted each other in a fruitful way. Besides some technologically important phases formed by rod-like molecules it has also become apparent that disk-like and so called phasmidic molecules exhibit fluidity and order. The building elements of molecular architecture are being extended to transition metal chemistry and hydrogen bonding, the latter with the potential to bridge the gap between thermotropic phases and the lyotropic liquid crystals which are of fundamental importance to biology. The technical exploitation of the special physical and physicochemical properties of the liquid crystal state can be regarded as being still in its initial state.

High Resolution Solid State NMR of Quadrupolar Nuclei

By Bernhard Blümich*

Nuclear magnetic resonance spectroscopy is a standard technique used for the structural analysis of liquid and dissolved samples. The information about the molecular structure is contained in narrow resonance lines at various isotropic chemical shift values, which can be assigned to different segments of a molecule. In solids, however, the chemical shift information is hidden under overlapping wide lineshapes. As a result of the reduced molecular mobility in the solid state, a number of orientation dependent spin interactions such as the quadrupolar and the dipolar couplings and the anisotropy of the chemical shielding (chemical shift) dominate the resonance. For spin 1/2 nuclei, for instance ^{13}C, ^{29}Si and ^{31}P, there is no quadrupolar interaction, but even under dipolar decoupling from the protons, the NMR spectrum typically shows many overlapping chemical shielding powder patterns, each of which can be a few kilohertz wide. The standard approach to high resolution solid state spectra for spin 1/2 nuclei then is magic angle spinning (MAS). The sample is packed into a gas-driven turbine which is spun at a rotation frequency of 3 to 10 kHz with the rotation axis inclined against the magnetic field by the magic angle of $\Phi_m = 54.7°$. In this case liquid-like high resolution spectra are obtained, which at slow spinning rates exhibit side bands at integer multiples of the rotation frequency away from the isotropic chemical shifts.[1]

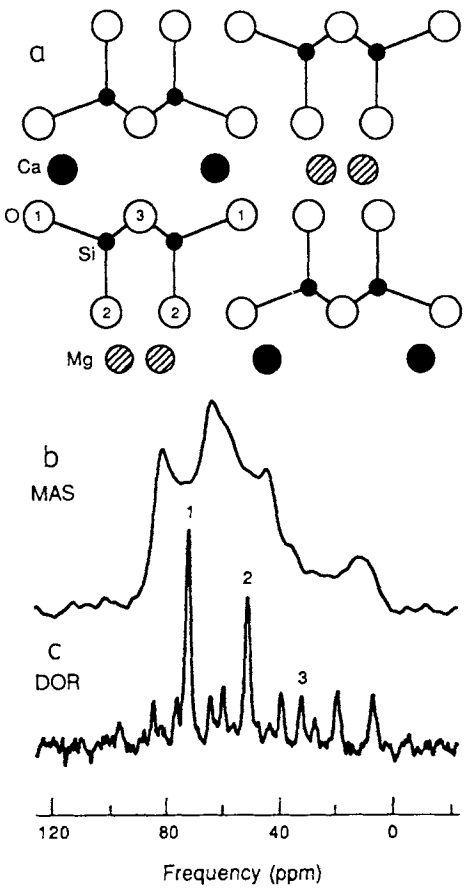
P.O. Box 3148, D-6500 Mainz (FRG)



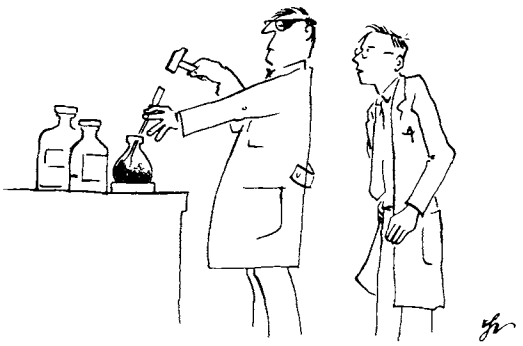


Fig. 1. a) Structure of diopside, $CaMgSi_2O_6$. Oxygen is represented by open circles with the three distinct sites labeled. b) MAS spectrum of ^{17}O in a sample of diopside. c) DOR spectrum with the outer rotor spinning at 680 Hz. (Adapted from ref. 4)

However, MAS is unable to fully remove the broadening of the central transition $(1/2 \leftrightarrow -1/2)$ of half-integer quadrupolar spins like ^{11}B, ^{17}O, ^{23}Na and ^{27}Al, because the linewidth is limited by second order quadrupolar broadening. Instead of just the second order Legendre polynomial, which determines the magic angle, the fourth order term also has to be eliminated.[2] This requires sample spinning around two axes, one at $\Phi_1 = 37.38°$ and the other at $\Phi_2 = 79.19°$. At first sight this seems impossible, but it can be done either in a 2D experiment with successive rotation around both axes involving flipping of the spinning axis (dynamic angle spinning: DAS) or by simultaneous rotation around both axes (double rotation: DOR).[3-5] Both experiments have recently been realized. A DAS probe is already available commercially with a flipping time of less than 40 ms.[6] However, the T_1 relaxation time must be longer than the flipping time for the experiment to work. The DOR experiment works with an ingeneously constructed rotor assembly, where a small rotor is embedded in a large rotor, each of the rotors spinning at one of the two angles Φ_1 and Φ_2.[3]

Figure 1 gives an example with the ^{17}O resonance of a powder of crystalline diopside.[4] The sample contains three distinct oxygen sites (a), which give rise to overlapping MAS powder patterns (b). With the DOR technique the wide line spectrum is broken down into narrow sideband resonances (c), where the isotropic centerband peaks can be assigned to the numbered oxygen sites. The linewidths are of the order of 100 Hz. This technique opens up a whole new area of NMR spectroscopy, where *high resolution spectra* can now be obtained for many nuclei of interest in ceramics, catalysis, geophysics and high temperature superconductivity.

Biomaterials Highlights III

Bone Replacements: Implant Materials and the Modes of Implant Fixation**

By Günther Heimke*

1. Introduction

During the last three decades the success rates of hard tissue replacements have increased considerably and have, thus, become a standard way of treatment. Based on early experiences, and taking advantage of the progress in material technology,[1, 2, 3] most of the directly material related reasons for reoperations could be either excluded completely or confined to extreme situations, like, for example, accidents in which the natural bone concerned would also have suffered severely. The causes for the remaining necessity for reintervention are essentially implant loosening or, in other words, failure of the implant fixing method.

This demonstrates that the kind of implant anchorage used is the key issue for any further improvement of the success rates of permanent orthopedic and dental implants. Many different ways of implant anchorage have been, and still are discussed, tested in-vitro and in animal experiments, and studied clinically. Some of them have successfully contributed to the improvements mentioned above and to the understanding of the remodeling reactions and the processes controlling them. A systematic survey of the modes of implant fixation[4] can facilitate the understanding of some of the different success rates and may even help to prevent some waste of effort and failure.

2. The Material Aspect of Implant Fixation

Like in all other fields, there are many viewpoints from which the materials used for a particular purpose can be surveyed and categorized. For implant materials a grouping according to the tissue reaction they stimulate in their environment can be regarded as adequate, as shown in Table 1.

The three terms characterizing the tissue reactions indicate some of possibilities of implant fixation in a bony environment. The list of influences on the sequence of reaction of the adjacent tissue, however, is not yet complete. Besides the essentially biochemical reactions mentioned in Table 1, there are nonmaterial-controlled influences on the remodeling of the bony tissue around implants. In addition to general aspects like age, health, and previous operations, the mechanical situation along the implant to bone interface plays an important role.[6, 7, 8] There is some similarity to fracture healing: a complete and stable union along a fracture site can be achieved only if the two surfaces can be brought together and maintained sufficiently motionlessness relative to each other during the healing period. The lack of rest along the interface will inevitably result in the formation of a soft tissue layer essentially consisting of bundles of collagen fibers mostly oriented parallel to the surfaces and containing only a few cells. Such creation of an artificial joint results in an additional mobility which, of course, is highly undesirable in this kind of treatment.

In fracture healing, the required motionlessness can be achieved by the application of a cast around the fractured bone, and if possible the two adjacent joints. Because of the remaining relative mobility of the two surfaces, the essential steps of fracture healing do not procede until a callus has been formed around the fracture site which provides the required additional stability. Another possibility is that the fragments are stabilized by pins (or so called nails) intro-

Table 1. Classification of implant materials according to the material influenced reactions in the surrounding bony tissue.

Class of material	Kind of influence	Tissue reaction	Typical materials in this class
biotolerant	ions and/or monomers go into solution, biochemical effects on differentiation and proliferation	distance osteogenesis[a]	stainless steels, polymethylmethacrylate (PMMA bone cement) Co based alloys, polyethylene
bioinert	no matter influencing the adjacent tissue goes into solution	contact osteogenesis[a]	Al_2O_3-ceramic, carbon, titanium
bioactive	bond formation by not yet completely understood processes	bonding osteogenesis[a]	Ca-phosphate based ceramics and Ca-phosphate containing glasses and glass-ceramics

a) These termes and definitions have been coined by Osborn [5].

duced into the medullary canal or by plates screwed onto the bone parts, if possible in a way in which the fracture site is under compression (pressure osteosynthesis).

Because the trauma caused by the insertion of an implant into a bony environment can be expected to be similar to that at a fracture site, the sequence of reactions along an implant to bone interface following this trauma cannot be expected to be more favorable than in fracture healing. However, there are additional handicaps for implants as nearly all their mechanical properties are different from those of bone. Thus, even after the most favorable healing processes, the differences of the mechanical compliances will result in a lasting discontinuity along all bone to implant interfaces.

Besides biochemical and mechanical compliance, two further material dependent aspects must be considered which influence the reliability of implant anchorage: the enzyme controlled immune response of the host tissue, and long term systemic effects. This latter point of view has been dealt with in the previous contribution (Biomaterials Highlights II[9]).

3. Mechanical Aspects of Implant Fixation

The forces acting along the bone to implant interfaces must be considered in two stages: first, for the healing period until a reliable equilibrium between the bone forming and the bone resorbing processes has been achieved around the implant and, second, for the rest of the lifetime of the implant which, hopefully, will be identical with the lifetime of the patient.

During the first stage, optimum conditions for fracture healing must be provided for all those interfaces along which a close bone to implant contact is vital for the correct functioning of the implant. The easiest way to realize this requirement is to keep the implant unloaded during this period. However, this is possible only in exceptional cases. The main problems of the second stage are the different mechanical compliances of the bony tissue, or tissues, and the implant. The possibilities and limitations for the design of implants resulting from these mechanical considerations have been dealt with in detail elsewhere[6, 7, 8] and have recently been summarized.[10]

The essential statement is: if all other influences are, or can be, excluded it is the stress and strain field created in the bony tissue around an implant that controls the interface remodeling. If, thus, the implant can be designed allowing for motionlessness along all those interfaces which are necessary for a stable anchorage, usually all load bearing interfaces, the conditions for fracture healing as well as for long term stability can be met.

4. The Modes of Implant Fixation

Table 2 summarizes the modes of implant fixation either realized, attempted, or aimed at in bone and joint surgery, and dental implantology.

Table 2. Modes of fixation for bone and joint replacements and dental implants.

Mode	Kind of interface	Kind of load transmission	Comments
Soft tissue encapsulation	identical with non-union of a fracture site	via soft tissue deformation	not reliable, but successful in exceptional cases for up to 20 yrs
Mechanical interlocking			
a) macroscopic porous coatings	partially soft, partially direct bony tissue contact	mixed, via direct bone contact partially only	not reliable, some severe difficulties in implant removal
b) microscopic surface porosity (flame sprayed powders)	direct bone contact	via direct bone contact	reliable and stable anchorage
c) controlled surface undulations	direct bone contact	via direct bone contact	reliable and stable anchorage
Isoelasticity	soft tissue encapsulation	via a soft tissue layer	not reliable
Bond formation via bioactivity	direct bone contact	via direct bone contact	fatigue of bioactive materials

4.1. The soft tissue mode

The reasons for soft tissue encapsulation are twofold: either the implant material is only partially biotolerant and the differentiation and proliferation of the bone forming cells is prevented or disturbed, or the shape of the implant does not provide sufficiently large surfaces along which relative movements can be prevented. The correlation between a soft tissue interlayer and implant failure has been clearly established for dental implants.[11] The stability of a soft tissue layer around total joint replacements anchored via the polymethylmethacrylate bone cement (PMMA) suffers severely from interactions with polyethylene wear particles resulting from the articulation between the polyethylene sockets and metal balls. The use of ceramic balls[2] can reduce the production of such wear debris considerably and, thus, extend the life expectancy of these implants.

4.2. Mechanical fixation modes

A mechanical interlocking between the bony tissue and the implant surfaces can be achieved in different ways with very different results:

4.2.1. Macroscopic porous coatings

Porous coatings mostly consisting of one or more layers of metal spheres sintered or otherwise attached to the surface of CoCrMo-alloys allow for the on- and ingrowth of load bearing bony structures as deeply as the stress and strain field reaches and, of course, only at interfaces along which a sufficient motionlessness can be provided during the healing

period. This mode of implant fixation has reached relatively wide application in the US. It has been stated recently that the success rates of such knee replacements are no better than with cemented devices.[12] Some initially very successful femoral components of hip prostheses had to be abandoned because of the severe destruction necessary for their removal.[13]

4.2.2. Coatings of sprayed powders

Coatings consisting of microscopic titanium powder particles flame or plasma sprayed onto the surfaces of the anchoring portions of several dental implants have achieved very high success rates in more than ten years of application. These implants are kept completely unloaded during the healing period by initially placing them underneath the gingiva and supplying them with a superstructure only after about three months. Figure 1 shows an example.

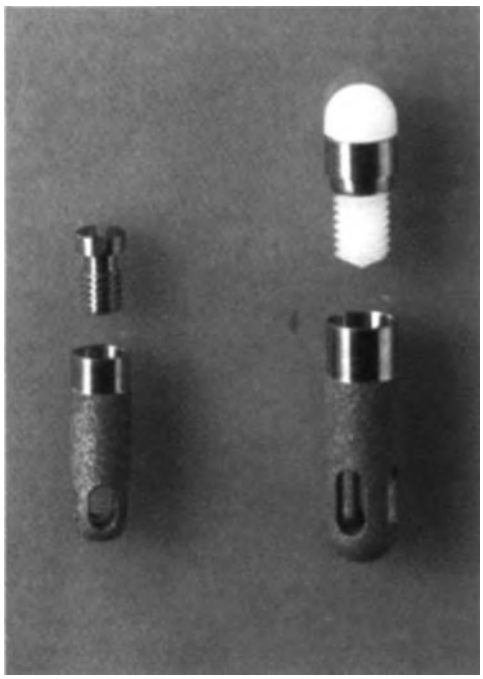

Fig. 1. Titanium dental implant (IMZ-implant) with Ti-powder particles flame sprayed onto the cylindrical surface. Note the openings for bony ingrowth and additional stabilization.

4.2.3. Controlled surface undulations

Controlled surface undulations can be regarded as a combination of shape elements of an implant which allow the control of the stress and strain field in the adjacent bone in order to minimize the effect of the differences in stiffness, and an optimization of the concept of porous coatings by providing the biomechanically favorable shape of the surface undulations (Fig. 2). This can result in an interlocking by which a close bone contact can be achieved[8] and maintained even along tangentially loaded interfaces.[8, 14]

Fig. 2. BMO- (biomechanically optimized-) Stepped Stem of the femoral component of the FRIALIT total hip replacement system made of the vanadium free TiAlFe alloy. Note the macroscopic steps and additional fine surface undulations providing for an interlocking along otherwise tangentially loaded interfaces.

4.2.4. The interfacial bonding mode

The anchorage of implants via an interfacial bond made possible by bioactive materials would very much facilitate implant design, the operation procedure, and, if it enhances bone formation, the post-operative treatment. Unfortunately, none of the bioactive materials have been found stable enough to withstand many years of shear loading. The same reactivity that allows for the bond formation obviously also accounts for the high mechanical fatigue. Presently, many attempts are underway to overcome these handicaps by coating the bioactive glasses, glass-ceramics, and ceramics onto mechanically strong substrate materials. Whether the aging and dissolution phenomena of such coatings can be overcome remains to be seen.

5. The Concept of Isoelasticity

The concept of the so-called isoelastic prosthesis is another attempt to avoid the problems resulting from the large differences of the mechanical performance of all metals and ceramics as compared to bony tissue. At a first glance, it might appear a reasonable approach to make the implant as

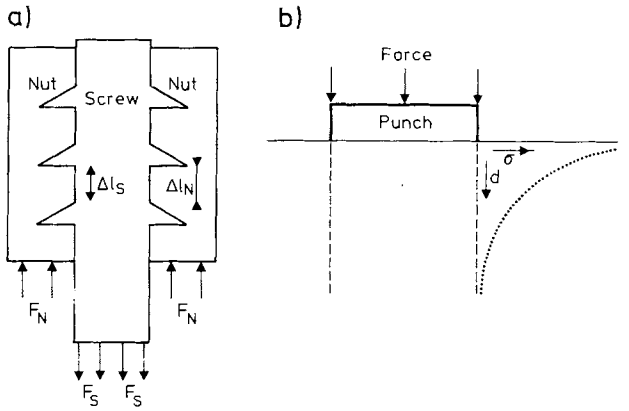

Fig. 3. a) The "nut and bolt" of identical materials results in a severe stress concentration on the first thread. Δl_S = elongation, Δl_N = compression. If the cross sections are equal $|\Delta l_S| = |-\Delta l_N|$, $\sum F_S = \sum F_N$. The cylinder underneath the circular punch (b) represents the situation of complete isoelasticity and of an ideal bonding to its environment within this half space. The dotted curve shows the stresses along the dashed interface between this cylinder and the environment and the extreme stress concentration towards the surface. It is this stress concentration that allows for all punching processes! σ stresses along d, d distance along dotted line.

stiff as the surrounding bone. As such an implant can be realized only with fiber reinforced plastics, this idea has found much attention in chemically oriented research groups. This concept, however, violates very basic and old rules of mechanical engineering. This has already been shown previously for two special cases[15, 16] and is explained on general terms in Figure 3.

6. Final Remark

The application of bone forming stimulants along implant to bone interfaces might be beneficial during part of the healing phase. As the stability of implant fixation essentially depends on the load pattern in the adjacent bony tissue and on the biochemical influences of the implant materials, hardly any contribution of such extracts can be expected for long term implant reliability.

The recent observation[17] of a particularly favorable adhesion of fibroblasts onto controlled surface undulations with dimensions in the one to two microns range can be regarded as a means to understand the bond formation on the Ti-powder coated surfaces. It appears that further results from this ongoing study will provide deeper insights into such surface mediated responses of cells and, thus, allow for further improvements of implant anchorage.

Conference Reports

Graphite Intercalation Compounds in Berlin

By Ralph Setton *

The fifth international symposium on graphite intercalation compounds sponsored by the Freie Universität Berlin, was held in Berlin (West), on May 22.–25., 1989. It was attended by 137 scientists from 17 countries, with West Germany, France, Japan and the United States contributing about 85% of the participants. Fourteen invited talks were presented, as well as 41 other papers and 73 posters. Following a well-established custom of these symposia, seventeen

[*] Dr. R. Setton

presentations were not directly related to graphite but involved other low-dimensional solids such as chalcogenides, conducting polymers, or layered hydroxides.

It has often been said that whoever wants to learn all about solid-state chemistry or physics need only study the graphite intercalation compounds (GICs), as shown by the following summary of the presentations.

The synthesis of graphite-like materials of composition BC_3, C_5N and BC_2N was described by *N. Bartlett*, Berkeley. In another plenary lecture, *J. Rouxel*, Nantes, discussed the design and synthesis of a large variety of low-dimensional compounds, whereas *T. J. Pinnavaia*, East Lansing, presented various synthetic layered pillared structures.

The thermodynamic requisites of intercalation were exposed by *A. Hérold*, Nancy, and *W. Metz*, Hamburg, discussed nucleation processes and threshold pressures. *P. Lagrange*, Nancy, described the intercalation of Cs–Sb and Cs–As alloys while co-intercalation from the vapor phase of potassium and rare earth elements was presented by *H. Suematsu*, Tokyo. A 1st-stage CoC_{14} was obtained electrochemically by *P. Touzain*, Grenoble, by reduction of a $CoCl_2$ GIC, whereas high pressure was used by *I. T. Belash*, Moscow, to synthesize 'super-rich' GICs of Li, Na, or K, all of them metastable at normal temperature and pressure.

Intercalate exchange was shown by *E. Stumpp*, Clausthal, and by *H. P. Boehm*, Munich, to be capable of yielding hitherto unknown metal halide GICs and *M. Inagaki*, Toyohashi, detailed the preparation of metal halide GICs from molten salts. New GICs of Nb or Ta fluorides, in which the valence state of the metal is not V but III or IV, were announced by *A. Hamwi*, Clermont, while *T. Nakajima*, Kyoto, described a series of GICs of various stages containing fluorides of Ti, V, Nb or Ta with excess fluorine, or the volatile oxyfluorides WO_2F_2 or WOF_4. GICs of molybdenum oxynitrate and of Ce, Hg, Pt or Au nitrates were described by *E. Stumpp*.

D. Guérard, Nancy, has completed the series of ternary GICs with alkali metals and hydrogen, some of them showing unexpected stability towards air and water. Similarly, the ternary alkaline earth-NH_3 GICs prepared by *E. Stumpp* complete the series started in 1955 by the late *W. Rüdorff*. In the ternary GICs prepared by *J. O. Besenhard*, Münster, *D. Billaud*, Nancy, or *K. Lüders*, Berlin, water or nitromethane is the third component solvating the intercalated anion. The ternary GIC studied by *F. Béguin*, Orléans, contains an organic molecule physisorbed at room temperature.

Somewhat similar to the ternary GICs, the bi-intercalation compound presented by *H. Suematsu* contains sequential layers of potassium and $MoCl_5$. Other structural determinations addressed phase transitions induced by pressure (*K. Syassen*, Stuttgart, *S. Matsuzaki*, Kumamoto, *O. E. Andersson*, Umeå, *I. T. Belash*) or by temperature (*F. Rousseaux*, Orléans, *P. Lagrange*, *P. Behrens*, Konstanz). Charge transfer between host lattice and guest was discussed by *S. Flandrois*, Bordeaux, *W. Metz*, *S. Ikehata*, Tokyo, *A. Métrot*, Reims, *R. Setton*, Orléans, and *H. Zabel*, Urbana. Closely related to these problems are the EXAFS and XANES measurements carried out by *W. Metz*, *A. Tressaud*, Bordeaux, and *G. Wortmann*, Berlin, while band structure calculations and experimental verifications of some of their features were given by *S. Rabii*, Philadelphia, *W. Berthold*, Dortmund, *K. Nakao*, Tsukuba, and *A. Charlier*, Metz. Problems of lattice dynamics were studied by *S. A. Solin* and by *S. D. Mahanti*, both from East Lansing, *H. C. Gupta*, New Delhi, *W. Lassmann*, Hannover, *J. E. Fischer*, Philadelphia, and new experimental methods for their study were presented by *Y. Yacoby*, Jerusalem.

Some physical methods of investigation, such as resistivity measurements or X-ray diffraction, are now so commonplace in solid-state studies that there is no point in detailing the cases in which they are used. It is interesting however to note that *W. Metz* showed that a new correction factor must be used to obtain good agreement between calculated and experimentally determined intensities of the X-ray spectra. Magnetic properties, both static and dynamic, also seem to be used so extensively (over 20 papers!) that individual presentation of the papers is impossible, in spite of the numerous interesting results thus obtained. More spectacular are the 'pictures' obtained by Scanning Tunneling Microscopy of the atoms on the external surfaces of GICs presented by *R. Wiesendanger*, Basel.

It is worth noting that increasing attention is paid to applications of GICs: as electrochemical sensors for charge in Pb batteries (*H. Krohn*, Duisburg), as catalysts for the synthesis of NH_3 (*K. Kalucki*, Szczecin), in rechargeable Li batteries (*M. Endo*, Nagano), in the separation of the isotopes of hydrogen (*T. Terai*, Tokyo), etc.

The Fifth International Symposium on Graphite Intercalation Compounds was a highly successful meeting in which the latest expertise in the field was made available and for which the organizers, Professors *K. Lüders* and *R. Schöllhorn*, are to be highly congratulated.

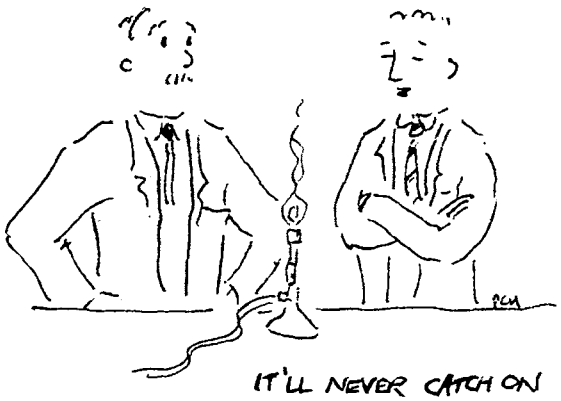
Solids: Dynamics and Kinetics in Siegen

By Hermann Schmalzried *

German physical chemists are organized in the "Deutsche Bunsengesellschaft". Their annual meetings on varying topics of current interest and importance are held each year at a different university, this year's, the 88th, being held from May 4.–6. in Siegen. The physical chemistry of solids links the two basic solid state sciences, chemistry and physics. The dramatic increase in effort and progress in the solid state sciences has been triggered by the growing need of materials in our technical civilization. As a response, this year's main topic of the "Bunsen-meeting" was formulated as "Solids: Dynamics and Kinetics".



Solid state kinetics deal with chemical processes in solids and particularly with their behavior within time. These processes occur under the influence of thermodynamic driving forces which act on the atomic particle ensembles of the solid. An example is the widely studied oxidation of metals in a tarnishing process.

Solid state dynamics deals with the restricted, and often correlated motions of localized atomic particles, an example of which is the vibration of an atom or a group of atoms in a crystal. Traditionally, kinetics is more the domain of the chemist, whereas dynamics has rather been investigated by the physicist.

The key problem in the physical chemistry of solids is the explanation of the parameters of phenomenological kinetic theory in terms of solid state dynamics. In line with this theme, the three plenary lectures of the Bunsen-meeting started with a contribution by *H. Stiller* (Jülich/Berlin, FRG), discussing in detail individual and collective local particle motions in crystalline solids. *J. W. Cahn* (Washington, USA), whose theme was the physical chemistry of stressed solids, pointed out the fundamental differences between solids and fluids when it comes to the formulation of driving forces for solid state reactions: Solids can store elastic energies stemming from nonhomogeneous stresses. *G. Petzow* (Stuttgart, FRG) illustrated how to produce new materials with desired (mechanical) properties which are based on kinetic processes, through structure design; his examples were essentially taken from the field of nonmetallic inorganic compounds.

In addition to these plenary lectures, five more invited speakers gave progress reports on various topics of solid state research: *S. Clough* (Nottingham, UK) dealt with "Gauge theory and molecular rotation in crystals",[1] *K. Funke*'s (Münster, FRG) topic was "Transport and relaxation in ionic crystals", and *J. Rouxel* (Nantes, France) discussed "Reactivity and phase transitions in the chemistry of low dimensional compounds". The current state of solid state electrochemistry was reviewed by *A. R. West* (Aberdeen, UK) in his report on "Solid electrolytes", and the final contribution of *H. Sixl* (Frankfurt, FRG) dealt with "Organic solids: possible applications in optics and electronics".[2]

More than twenty oral presentations in three sessions and forty poster contributions from different research groups and various research fields clearly illustrated the breadth of solid state research and the interdisciplinary character of solid state physical chemistry. Physicists, chemists, polymer scientists, ceramists, and metallurgists all demonstrated the impact that basic research can have in helping to solve practical problems in material science.

Physical chemistry is, to a large extent, an experimental science. It is therefore interesting to review the main experimental methods applied in current research, as reflected in this meeting. One notes that solid state electrochemistry in its broad sense, and its classical experiments, still plays an important role, particularly when it comes to interfaces. Structure and dynamics are largely explored using neutron techniques, because their advantage of energy discrimination overrides in importance the general availability of X-rays. Solid state NMR, Mössbauer-effect, PAC-experiments and related experimental methods that probe the charge or spin density of the atomic surroundings are indispensable if one studies motion and transport on an atomic and a macrosopic

ADVANCED MATERIALS

scale, although the more classical methods of sensing electromagnetic interactions between radiation and matter are being used continuously. In kinetic research it is found that in situ experiments, which for solids often mean high temperature experiments, are absolutely necessary. However, this makes the application of IR and visible light spectroscopy a most difficult task.

In a way it was interesting to note that electron microscopy is not used more by solid state physical chemists – at least in Germany. After all it is the (periodic) structure that distinguishes the solid from the fluid state and determines most of its properties including the kinetic and the dynamic ones, and high resolution electron microscopy offers spatial resolution on an atomic scale. Therefore it seems clear that electron microscopy will increasingly help us to understand the basis of solid state kinetics: the defect in the solid state. Additionally, modern chemical analysis results in a much better characterization of the solids under investigation than ever before. This is most important with regard to the fact that it is always the crystal defect, including chemical impurities, that (as is well known in semiconductor technology) govern many of the crystal properties.

In conclusion: The Bunsen-meeting has again illustrated the interdisciplinary character of physical chemistry and has fulfilled its role of promoting the exchange of ideas, this year in particular between the different groups which work in the broad field of solid state science.

Sol–Gel Processing in Bad Honnef

By Hans Reuter *

The 52nd seminar of the Dr. *Wilhelm Hereaus* and *Else Hereaus* Foundation entitled "Sol–Gel Processing for Glasses, Ceramics and Inorganic–Organic Polymers" was held from Monday, May 22nd, through Wednesday, May 24th, 1989 at the Physikzentrum in Bad Honnef, FRG.

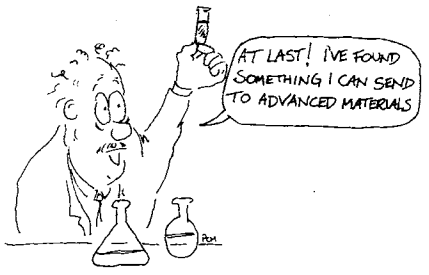
Basically the expression "Sol–Gel Process" means the formation of an amorphous solid, the gel, starting from a homogeneous liquid, a molecular dispersion or colloidal solution. The great amount of scientific and technological interest devoted to this process ranges from molecular chemistry to material science. One aim of the seminar was to bring together, in a small circle, scientists from these different fields to discuss in an interdisciplinary manner the numerous aspects of sol–gel-processing. Twenty invited speakers and about thirty further participants attended the meeting coming from both university laboratories and industry.

An instructive overview of the present industrial application of the sol–gel technique was given in the paper "Sol–Gel 1969–1989, Paths of Development and Products, Especially the Newer Ones" from *H. Dislich* (FRG), who also showed some remarkable examples of industrially fabricated, sol–gel derived products. Complementing this, *D. R. Uhlmann* (USA) illustrated in his lecture "General View of Sol–Gel Technologies" not only the present state of the art developments and the numerous unsolved problems but also the future possibilities of the technology.

One main problem is, that there is only little known about the chemistry which happens during the sol to gel transformation. This was analyzed in two papers. In the first one, "Monoorgano Tin Compounds as Model Substances for the Investigation of the Sol–Gel Process", *M. Jansen* (FRG) showed that with organometallic precursors it is possible to isolate crystalline oligomers, which can be studied by X-ray structure analysis in order to see directly how i.e. the solvent may influence the reaction path. In the second paper "Sol–Gel Chemistry of Transition Metal Oxides", *C. Sanchez* (France) demonstrated, using titanium alkoxides as an example, not only the role of solvent molecules but also that of other chemical additives like catalysts, stabilizing agents or drying control chemical additives.

The processes following gel formation, like drying and densification, were reviewed in the lectures of *G. W. Scherer* (USA) who talked about "Hypercritical Drying", "Aging and Syneresis" and "Sintering of Gels", while *D. J. Brinker* (USA) discussed the "Fundamentals of Thin Film Formation from Sol–Gel Solution" and the "Spinnability of Silica Sols: Structural and Rheological Criteria" dealing with the more practical aspects.

New experimental paths were pointed out by *C. Rüssel* (FRG) "Non-Oxide Ceramics by Sol–Gel Techniques" mak-



[*] Dr. H. Reuter
Institut für Anorganische Chemie
Universität Bonn, Gerhard-Domagk-Strasse 1
D-5300 Bonn 1 (FRG)

ing AlN by anodic dissolution of the metal in amines, by *U. Schubert* (FRG) "Sol–Gel Processing of Transition Metal Complexes" describing materials in which a transition metal complex moiety is bound by an inert spacer and an anchoring group to a silica gel matrix, and by *H. Schmidt* (FRG), who gave in his paper "Inorganic–Organic Polymers by Sol–Gel Techniques" first impressions about the manifold possibilities of organic modified silicates.

Many of the papers dealt with the possible applications of sol–gel derived materials. *J. Fricke* (FRG) "SiO_2-Aerogels—Structure, Properties, Applications" demonstrated that aerogels, due to their porosity, have very unusual but useful properties. Another example was presented in the paper "Oxide Gels, New Materials for Micro-Ionics" from *J. Livage* (France) who gave examples of systems which are good candidates for making "all-gel" derived micro-ionic devices.

On the whole, one can say that the goal of the meeting, of discussing the fundamental and applicationally oriented aspects of sol–gel processing with respect to material preparation, technology and structure/property relationships, was fulfilled, much to the credit of *H. Schmidt* from the Frauenhofer-Institut für Silicatforschung (Würzburg, FRG), who had composed this most interesting scientific program. This positive impression was not altered by the recognition that the great hopes for sol–gel technology have been somewhat overdone: today it is possible to make coatings by this method in considerable variety but until we succeed in making bulk materials on an industrial scale there will be much to do.

Materials Forum

Durable Thermometer for Molten Metals

Conventional thermometers used to measure the temperature of, for example, molten steel are usually destroyed very quickly by the environment and provide data for only 1–3 seconds.

A new thermometer, developed by Nippon Steel and the Asahi Glass Co. has a functioning lifetime of over 40 hours. This increased durability is achieved by encasing the thermometer in a tube made from the advanced ceramic zirconium boride which has a melting point of 3060 °C allowing continuous measurement of temperatures up to 1600 °C.

Continuous monitoring of the temperature enables the effects of defect inclusions to be located precisely, processing abnormalities to be prevented and energy to be saved.

Further information is available from the Nippon Steel Corporation, Königsallee 30, Düsseldorf 4, FRG.

Laser Microscope for Surfaces

Zygo has introduced the Maxim 3D three-dimensional noncontact laser microscope for the measurement of surface structure. Its optical design allows it to measure coated carbon surfaces as easily as polished aluminum substrates.

Combining the capabilities of an optical microscope with the measurement resolution of phase-measuring interferometry, the Maxim 3D can perform vertical, lateral, angular and positional measurements to 6 Å vertical resolution and less than 0.5-micrometer lateral resolution. Three-dimensional measurements allow accurate analysis of surface defects, which can be located at low magnification, then measured at higher magnification by rotating the turret. Details from Zygo Corporation, Laurel Brook Road, Middlefield, Connecticut 06450, USA.

Field Emission Scanning Electron Microscope

International Scientific Instruments of California, USA have introduced a new field emission scanning electron microscope called the DS-130F which offers high resolution and large-sample handling capability. It is a dual stage microscope which provides nanometer resolution in its top stage and maintains 2 nm resolution in the bottom stage even with a large sample (up to 6 inches diameter).

The DS-130F operates in the 10^{-8} torr range and even at an electron beam energy of 1 kV provides resolution in the top and bottom stages of 4 and 10 nm respectively. Further features are a new condenser lens system, a high brightness thermal field emission gun and the high stability of the emission current, which makes tip flashing unnecessary.

More details are available from International Scientific Instruments, 1457 McCarthy Boulevard, Milpitas, California 95035, USA.

New Generation of Turbomolecular Vacuum Pumps

TURBOVAC 150, 360 and 1000 V and H (see figure) from Leybold AG are universal turbomolecular pumps with continuous oil lubrication. The modular design of the pumps makes them suitable for various kind of applications including normal high vacuum research or demanding industrial tasks such as plasma etching. The pumps are highly reliable due to a well proven oil lubrication system. The bearings are continuously lubricated with filtered oil and any particles which beat the filter are flushed out by the oil.

The V-versions (vertical) are designed for upright installation only, while the H-version (horizontal) can be incorporated between the vertical and horizontal. With a modification kit the V-version can be converted at a later time for horizontal use.

Special Features: Inert gas seal system for the protection of the lubricant and bearings; Integral vent port to ensure "clean venting" of the pump; Simple oil level control and oil changing; Water or optional air-cooling; Inlet flanges in ISO-K, CF and ASA in different sizes available.

For more information contact Otmar Reuter, Leybold AG, Bonner Strasse 498, D-5000 Cologne 51, FRG. Tel. (0221)347-1556.

Intelligent Liquids

Liquids, whose viscosity can be dramatically altered in a fraction of a second by the application of an electric field have been developed by Bayer. Silicone oils mixed with aluminum silicate form the basis of the new materials whose aggregation state is regulated by the applied voltage which ranges up to 2000 V (with very low current).

Although Bayer have not yet developed market-ready applications for these "intelligent liquids", uses can be envisaged, for example, in shock absorbers in cars which can react immediately to every road contour. Other properties include thermal stability, an ignition point of over 250 °C and compatibility with elastomeric materials. Further details available from Bayer AG, Bayerwerk, D-5090 Leverkusen, FRG. Tel. (0214) 30-72215.

Superconductivity

The nature of the Fermi-liquid electronic states in the high-T_c uperconductor $Bi_2CaSr_2Cu_2O_8$ has, until recently, been a matter of controversy. Some workers have attributed the existence of these states to the 2p orbitals of the BiO plane and others to those of the CuO_2 plane.

If the Fermi-liquid states were supplied by the BiO plane, which is not present in other copper-oxide superconductors, then the mechanisms for superconductivity based on the Fermi-liquid states would lose there experimental basis.

Using scanning tunneling spectroscopy (STS), an extention of scanning tunneling microscopy (STM), combined with photoemission (PES) and inverse photoemission (IPES) spectroscopies, *Tanaka* et al., *Nature 339* (1989) 691, have shown, reassuringly, that the Fermi-liquid states reside not in the BiO planes but in the CuO_2 planes and this description of the states should provide an experimental basis on which models of high-T_c conductivity in the copper oxide materials can be built.

New Polyamide Curing Agent

Industrial Copolymers Limited (ICL), manufacturers of speciality resins, based in Preston, UK, has added a further product to its innovative range. The company announces the introduction of INCOREZ 147LV, a new polyamide curing agent for water dispersed epoxies which it claims, according to the Gardner scale, is the lowest color polyamide curing agent presently on the market.

INCOREZ 147LV is a major step forward in technology allowing formulators to achieve white coatings comparable in color with solvent based counterparts. INCOREZ 147LV also has a faster cure rate and is capable of being infinitely diluted with water, retains a high solids content of 75% and can be formulated into matt, semi-gloss and full gloss coatings.

A variety of coating markets is envisaged including solvent sensitive areas, abrasion resistant applications and primers for concrete. Additionally, the product can be used in cementitious screeds to improve chemical resistance and adhesion to damp substrates.

For more information contact *P. Mileham,* ICL, P.O. Box 7, London Road, Preston PR1 4AJ, Lancashire, UK. Tel. (0772) 59781.

K' 89

The 11th International Plastics and Rubber Trade Fair (Kunststoffe '89, K '89) runs from November 2.–9. 1989 in Düsseldorf, FRG. With over 220.000 visitors and 1700 exhibitors in 1986 the "K" is one of the biggest materials trade fairs and this year is expected to be even bigger. Approximately 50% of both the visitors and the exhibitors are from West Germany, the other half coming from more than 40 countries making it a truly international exhibition.

The fair is aimed at the innovative users of plastics and rubbers in for example automotive construction, electrical engineering, electronics and aerospace, exhibitors representing everything from raw materials producers to applications engineers.

Book Reviews

NLO, SiN, GaAs, CVD, Acronyms, and Abbreviations

Photorefractive Materials and Their Applications I: Fundamental Phenomena. By *P. Guenter* and *J.-P. Huignard.* Springer-Verlag, Berlin 1988. xvi, 295 pp., hard cover, DM 119.—ISBN 3-540-18332-9

The field of nonlinear optics has received quite a dramatic increase in interest lately from research groups both in industry and in academia. This development was initiated in the mid-seventies when it was recognized that reversible laser induced material changes, as observed in nonlinear optics, can actually be utilized to modify and process one light beam with another. Applications in optical signal processing, optical computing and realtime holography became feasible, and widespread technical use of the effects in image processing and fiber-optic switching can be envisaged in the not too distant future.

Photorefractive materials have played a key role in these developments and many important demonstrations of principles have been made with photorefractive crystals, e.g. in phase conjugation, pattern recognition and neural optical processing. The photorefractive effect is generally observed in doped inorganic single crystals, mainly $LiNbO_3$, $BaTiO_3$, $Bi_{12}SiO_{20}$, $KNbO_3$, InP or GaAs. Its main virtue is that relatively low light powers can induce large material changes, sources being for example helium–neon, diode or small argon lasers, at the expense, however, of relatively slow response times (milliseconds to hours). Being a rather complicated multistep process, the photorefractive effect was subject to a substantial body of material-centered research which is reviewed in this volume.

Generally the following sequential steps are involved: excitation of charge carriers from impurity centers upon light absorption, migration of these carriers to other impurities outside the illuminated area, and trapping there. The resulting space-charge field changes the refractive index via the electro-optic effect and hence modifies the optical properties of the material. Several theoretical models for this effect have been developed, with the band transport model of *N. V. Kukhtarev* being currently the most versatile and widely used.

The editors, both leading European researchers and pioneers in the field, have brought together a well balanced mixture of articles (four from the USA, two from the USSR and three from Europe) covering virtually all aspects of the above described process. After a very brief introduction, they summarize effects and materials mainly from an experimental point of view. A detailed treatment of the photorefractive effects in dielectric crystals by *G. Valley* and *J. Lam* follows, and all theoretical aspects of the band transport model are very clearly described by *N. V. Kukhtarev*. He also demonstrates the predictive power of his model. Spectroscopic investigations of photorefractive centers using optical techniques as well as ESR and Mössbauer spectroscopy are reviewed by *E. Kraetzig* and *O. F. Schirmer*. *R. A. Mullen* presents justification for the charge hopping model, which is the main theoretical model competing with the band transport model, and outlines boundaries between both descriptions as she summarizes the measurement of physical parameters of the material.

The following two articles describe two specific classes of photorefractive materials in more detail. *M. B. Klein* summarizes the properties of $BaTiO_3$, the material with the largest known photoinduced refractive index changes. The study of this material has been restricted to relatively few groups due to the difficulties in obtaining poled single crystals of good optical quality. A relatively recent development (since 1984) are photorefractive semiconductors which are reviewed by *A. M. Glass* and *J. Strait*. GaAs-Cr and InP-Fe are particularly interesting as they operate in the near infrared, close to the wavelengths of interest for fiber optic communications.

Finally, *S. I. Stepanov* and *M. P. Petrov* describe moving photoinduced gratings and their applications in coherent amplification and phase conjugation, leading naturally to the second volume of the series which is on applications of photorefractives. In reading the book, it becomes apparent that most of the research is actually prompted by the applications, and therefore the separation between materials and applications seems artificial in many places. The general level of understanding reached at the time of writing (late 1987) is such that the development of new improved photorefractive materials can be expected. New centers and host crystals should be predictable, and photorefractive organic polymeric composites seem also feasible in the view of the authors.

The reading of the book requires a fundamental knowledge of solid state physics, as well as some classical background in holography, image processing, phase conjugation or nonlinear optics. To this end the previous reading of selected chapters of the book "Laser-induced Dynamic Gratings" co-authored by *P. Guenter* (Springer Ser. Opt. Sci. Vol. 50) might be beneficial, especially to the inexperienced reader.

General conclusions: a very thorough overview from a materials point of view, quite complex in places, mainly for researchers entering or already active in nonlinear optics or related fields. The book is likely to become a standard reference for further research on photorefractive effects and materials.

Werner Blau
Department of Pure and Applied Physics
Trinity College, Dublin 2 (Ireland)

Electronic Structure and Optical Properties of Semiconductors. By *M. L. Cohen* and *J. R. Chelikowsky*. Springer-Verlag, Berlin 1988, xii, 264 pp., hard cover, DM 98,— ISBN 3-540-18818-5

In the preface to this book the authors state that they tried to strike a compromise between a reference text and an textbook. The authors have achieved their goal. It contains much compiled information on the optical properties of semiconductors, and whether one is interested in the technologically important semiconductors, such as Si, Ge and GaAs, or the obscure such as $ZnGeP_2$, the desired information is there. In the back of the book there are over fifty pages of references, so the active researcher can quickly find detailed information in a subject of interest.

The book should also be of considerable use to the newcomer to the area as it provides a very nice introduction to the theory of band structure calculations. The authors begin with the nearly-free electron and tight binding models to demonstrate the basic properties of electrons in a periodic potential and point out that these two methods represent the two extreme views of electrons in solids and therefore, the augmented plane wave and the orthogonal plane wave methods have been developed to more realistically describe the electronic structure of solids.

Although the authors give a completely adequate introduction to the theoretical methods, they spend most of the time describing the pseudopotential method and its variations. This is not surprising, considering that the authors have made contributions in this area for more than twenty years. They begin the chapter on pseudopotentials with the mathematical formalism, and go on to explain the empirical, self consistent and the ab initio variations not only providing details of the mathematical formalism, but also describing in detail the computational philosophy used in each pseudopotential variation.

The three chapters that follow are those that make this book quite special. In these chapters the authors explain how, once you have completed a band structure calculation, the results can be compared to experiments. When one experimentally measures the optical properties of a semiconductor, one does not measure the band structure but some property related to it. In these chapters the authors go through in detail the process of calculating response functions.

They then compare how the pseudopotential calculations and experimental determined values agree. This is the section of the book that truly sets it apart from other theoretical books on solid state physics. Numerous experimental methods and how they can be used to further understand the band structure of solids are described. These include not only optical methods, such as electroreflectance, but also surface analysis techniques, such as X-ray photoemission and ultraviolet photoemission spectroscopy.

The last section in the book, which consists of almost one hundred pages, is devoted to describing the optical properties of numerous semiconductors. This is an excellent reference section for anyone working in the field of semiconductor physics or optoelectronics. It begins with the elemental semiconductors Si, Ge and Sn and then goes on to describe the III-V and II-VI semiconductors. Not only are the optical properties of the zinc blende and diamond structure semiconductors described, but detailed information on the wurtzite semiconductors is also included.

This is a very fine book on the optical and electronic properties of semiconductors and should find a place on the bookshelf of everybody who is involved in the areas of semiconductor physics or optoelectronics.

Robert N. Bicknell-Tassius
Department of Physics, University of Würzburg
Am Hubland, D-8700 Würzburg (FRG)

Silicon-nitride in Electronics. By *V. J. Belyi* et al. Elsevier Science Publishers, Amsterdam 1988. viii, 340 pp., bound, US$ 100.— ISBN 0-444-42689-2

This book, originally written in Russian, describes the technology of silicon nitride film preparation on a silicon wafer. This subject is not new and therefore the authors intent is to present a collection of the properties and physical-chemical aspects, which govern the production.

In the first chapters, the reaction theories of all the gaseous production techniques are discussed. This is done in a style which is typical for a Russian theoretical book. However, one clearly recognizes that the formulas characterizing the process steps dramatically define the properties of the silicon nitride layer. In contrast to solid-state silicon nitride, which is widely resistant against chemical attack, a silicon nitride film, produced by vapor deposition techniques can be structurized by normal photolithographic techniques. The reader who is interested in a deep understanding of the fundamental parameters of the process would certainly read this chapter with interest. On the other side, the practical point of view is not forgotten. The process of the layer-deposition is described in detail.

In the following chapters, the basic principles of the deposition-process are emphasized more than the manufacturing techniques. Pictures of furnaces or other types of processing hardware, which are common to a book of this kind, are not given. However, a nearly complete literature list is provided.

The properties of the different types of films, produced using the different types of processes are discussed in detail. Curves and diagrams will help the reader, who is not so familiar with the formula-language. A more theoretically oriented user however, will be deeply impressed by the equations and the data, which can help him to calculate his process and compare the results to the electrical data given in this book. This collection of data explaining the influence of process parameters on the electrical properties is helpful to any producer of silicon nitride layers on silicon.

The data is presented in a format oriented for a semiconductor technologist. Band-diagrams and energy representa-

tions are given. These can be used by the circuit designer as input to his calculations on an integrated circuit. In the last chapter the applications for silicon nitride films are reviewed, including LOCOS process, EPROM devices, pH sensors, etc. This is done only briefly but a reader who needs more information can use the comprehensive literature list.

In summary, this book collects all the theoretical and practical aspects of the production of a silicon nitride film on a silicon-wafer. A user, who is working on this process and this material will certainly welcome this book as a process handbook or dictionary of the silicon nitride preparation process.

Hoechst AG P.O. Box 800320, D-6230 Frankfurt (FRG)

Textile Structural Composites. Edited by *T.-W. Chou* and *F. Ko*. Elsevier Science Publishers, Amsterdam 1988. xiii, 480 pp., bound, US$ 155.25. – ISBN 0-444-42992-1

Textile composites can be defined as the combination of a resin system with a textile fiber, yarn or fabric system. The various textile composite systems are described with reference to chopped fiber and filament yarn constructions, the different fabric and non-woven fabric structures, behavior, and related composites.

Basic principles of the mechanics of tensile deformation and theories describing the non-linear stress-strain relations of fabrics are covered, concentrating on the two basic structures, plain woven and plain knitted fabrics.

The characteristics of the braiding process, the wide composite applications, and mechanical performance along with the structure, formation, properties and analysis of 3-D fabrics are reviewed.

Dr. *S. M. Bishop* discusses the properties of carbon fiber fabric laminates. Woven fabrics combined with unidirectional tape structures are investigated and their advantages in terms of tensile, compressive, impact and fatigue properties are described. Prof. *T.-W. Chou* presents analytical and calculational models for determining the thermal and mechanical properties of woven fabric laminates. The fabrics studied are either made of one material or are hybrid fabrics. The properties determined, such as stiffness, strength and thermal expansion, are partly compared with experimental data. The paper by Prof. *I. M. Yang* and Prof. *T.-W. Chou* deals with the thermo-elastic analysis of triaxial woven fabrics and the laminates made therefrom. This theoretical study also covers non-orthogonal fabrics, which are compared with triaxial fabrics.

Dr. *S. R. Moghe* describes the development of a mathematical model for designing woven fabric laminates taking into account the different material properties and process parameters. The calculated values are presented.

Additional materials covered are flexible composites and coated fabrics.

The book on the whole gives a good and up-to-date account of the theoretical and practical aspects of textile intermediates and their behavior in composites.

K. Hillermeier
Enka AG P.O. Box 100149
D-5600 Wuppertal 1, FRG

PARAT. Index of Acronyms and Abbreviations in Electrical and Electronic Engineering. Compiled by *Büro Scientia*, Berlin. VCH Verlagsgesellschaft, Weinheim 1989. 538 pp., bound, DM 224. – ISBN 3-527-26842-1

The book lists about 45000 acronyms and abbreviations with their associated definitions. In an attempt to facilitate the use of the book the entries have been standardized by printing the acronyms and abbreviations in capital letters while the full texts of the comments appear in lower case. This is certainly helpful. Looking up terms is made easy by the large and clear print. The solid binding promises to stand well the heavy usage one expects for a reference book of this kind.

A German-speaking reader will look in vain for the explanation of BTX, DIN, EVU, or the like since only English terms are listed. This could be indicated in the title of the book by changing it to: "Index of English Acronyms...".

The book contains a wealth of valuable entries that are not restricted only to the area of electric and electronic engineering but that go far beyond. The terms reach from ACELSCO (associated civil engineers and land surveyors of santa clara county) on page 6 to YST (yukon standard time) on page 563. Of course, the reader will find most of the expressions he would look for in a book on electric and electronic terms e.g. CPU, TV, CRT, LCD, VHF, VLSI, WATS, ISDN, and many more. But one would also expect to see terms like MODEM or AI, and a materials scientist would be interested in MOS or HTSC (high-temperature superconductivity) all of which are not (yet) listed.

Many of the terms are related to computer technology or to military applications. Unavoidably many abbreviations have multiple meanings, for some of them, e.g. SP, MS, CC, or MC more than 50 different interpretations are listed. To show the broad scope of the book, here are some examples selected at random: referring to organizations/institutions/company names one finds entries like FCCN, CBO, ISO, IBM, PAA down to SAAD (san antonio air depot). Relating to projects/products there are ILLIAC, STAIRS or LLM (lunar landing mission or module). And among the more general concepts are listed DEPT, VAT, SQRT (square root), and PAYE (pay as you earn).

Keeping in mind that it is impossible to please everybody, the editors did a good job in selecting the material and in including many "exotic" terms that are rarely found elsewhere. Altogether this volume is a comprehensive and up-to-date reference tool for the individual scientist or engineer as

well as a valuable addition to any collection of reference books.

Hermann J. Graml
Siemens AG P.O. Box 830953
D-8000 München 83 (FRG)

Fiber Reinforcement for Composite Materials. Edited by *A. R. Bunsell*, Elsevier, New York 1988, ix, 538 pp., bound, US$ 171.– ISBN 0-444-42801-1

This book is the second volume of a publication series on composite materials edited by *R. B. Pipes* (Center of Composite Materials, University of Delaware). It deals with various types of synthetic fibers used as reinforcements in advanced composite materials. This volume is subdivided into various chapters giving a clear description of the manufacture, structures and applications of the different fibers, as well as a brief compilation of characterizing methods for single fibers. The chapters are authored by internationally well-known experts and arranged as follows: Chapter 1. *A. R. Bunsell:* Fiber development for composite materials. Chapter 2. *P. K. Gupta:* Glass fibers for composite materials. Chapter 3. *E. Fitzer, M. Heine:* Carbon fiber manufacture and surface treatment. Chapter 4. *A. Oberlin, M. Guigon:* The structure of carbon fibers. Chapter 5. *G. Calundann, M. Jaffe, R. S. Jones, H. Yoon:* High performance organic fibers for composite reinforcement. Chapter 6. *H. H. Yang:* Aramid fibers. Chapter 7. *P. Bouriot:* Polyester and polyamide fibers for elastomeric matrix composite materials. Chapter 8. *F. E. Wawner, Jr:* Boron and silicon carbide/carbon fibers. Chapter 9. *A. R. Bunsell, G. Simon, Y. Abe, M. Akiyama:* Ceramic fibers. Chapter 10. *R. Hagege, A. R. Bunsell:* Testing methods for single fibers.

The book gives a clear overview over the current "state of the art" and is very informative. However, the subdivision into CVD- and ceramic fibers is astonishing because the presented CVD-fibers are counted as ceramic fibers as well. The main interest of this volume is concerned with carbon, glass and organic fibers although fibers of interest in ceramic matrix composites have not been sufficiently covered. This is probably due to recent improvements of the known fibers and the development of new fibers. In summary this book is of great interest for scientists working with reinforcing components.

Materials for Optical Data Storage

By Michael Emmelius*, Georg Pawlowski *, and Hansjörg W. Vollmann*

Dedicated to Professor Wolfgang Hilger on the occasion of his 60th birthday

The outstanding feature of materials research in the eighties has been the convergence of basic research and practical application, leading to ever shorter cycles of innovation. This is especially true of materials which form the basis of key technologies. The mass storage units of the next generations of computers will be based on optical processes having a storage density which exceeds that of all hitherto known storage techniques that are practicable from the technical standpoint. In view of the fact that since 1982 read-only memories in the form of compact discs (CD-ROM) have become very successful in the field of audio electronics, research and development are now concentrated on materials for write-once (WORM) and erasable (EDRAW) storage systems. Suitable materials for optical data storage are substances in which data markings can be recorded and deleted respectively using semiconductor lasers. Materials development is centered on the synthesis of infrared-absorbing dyes for WORM memories and the production of rare earth/transition metal alloys for magneto-optical data recording. An introduction to CD-ROM technology will be followed by an overview of the state of development of the most important storage materials which are currently available commercially, and then the properties of these materials will be discussed with reference to selected examples.

1. Introduction

The storage of biological information represents one of the basic explanations for the existence of highly differentiated living organisms. The biological information medium DNA (*d*eoxyribo*n*ucleic *a*cid) is the substrate for numerous enzymes which, at the molecular level, store, read and erase genetic data. Combinations of the basic building blocks of DNA (uracil, adenine, cytosine and guanine) provide the code for protein amino-acids as well as addresses on the DNA for starting and stopping the DNA replication. Replication, which is equivalent to storage, commences at primer-formatted DNA segments. Because of corrective mechanisms, for appoximately every 10^{10} nucleotides combined, a maximum of one unit is incorrectly positioned. Erasure of genetic information occurs either during regulation of cell metabolism or as a result of chemical mutations of the base pairs. On considering the interrelationships of molecular biology from this rather formal point of view, parallels with the function of technical data stores are immediately evident. At the same time it is clear that what is involved here is a

fundamental principle,[1] which is implemented in nature and to which the physical structuring of information systems can be traced.[2]

Not only do biological and technical information carriers differ in numerous fundamental respects; they differ, above all, as regards the physical size and arrangement of their data units. The genetic information of a DNA molecule corresponds to an information density of 10^{21} bit cm^{-3} (three-dimensional storage), while technical memories of the highest information density hold approximately 10^{8} bit cm^{-2} (two-dimensional storage) (Fig. 1). In spite of the high rate at which miniaturization is progressing, as well as the use of new storage processes, it appears dubious whether the limit to storage at a molecular level can be overcome in the near future.[*] However, optical memories represent an important step in this direction, since they exceed the storage densities of hitherto well-established information media.

Research has been in progress on optical memories since the end of the sixties. However, it was not until 1982 that the breakthrough finally came with the audio compact disc; this was closely linked with the availability of new semiconductor lasers as light sources. In the field of consumer electronics, the conventional playback processes lost considerable ground, since it was not possible to achieve comparable levels of quality of reproduction using any other medium. Accordingly, it was an obvious step to utilize the potential of

Michael Emmelius was born in 1954 and studied chemistry and medicine at the University of Mainz, where he was awarded his doctorate for studies in the field of macromolecular chemistry under Professor H. Ringsdorf. In 1986 he joined the research department of the Information Technology Division at Hoechst AG and was entrusted with the development of photoresists. In 1988 he became assistant to the director of R&D in information technology. Since September 1989 he has been concerned with technical marketing. His scientific interest pivots around the physicochemical problems of materials research.

Georg Pawlowski was born in 1952 and studied chemistry at the University of Tübingen where he completed his doctoral work on conductive polymers under Professor M. Hanack. In 1981 he joined the research department of the Information Technology Division at Hoechst AG where his work was primarily concerned with "photoreactive polymers". In 1987 he became assistant to the director of R&D in information technology. He is at present leader of the photochemistry group in the central research department at Hoechst AG. His interest centers on the development of new radiation-sensitive materials.

Hansjörg W. Vollmann was born in 1933 and studied chemistry in Cologne, Bonn and Stuttgart. After gaining his doctorate for studies in preparative organic chemistry under Professor H. Brederek he worked for a short while as research chemist at Cassella AG. In 1964 he joined the central research department at Hoechst AG and worked in the area of intermediates and dyestuffs. In 1970 he was appointed in charge of the construction and direction of the central research department of the American Hoechst Corp. (now Hoechst Celanese Corp.) in Rhode Island, USA. Since 1978 he has been head of research and development in the Information Technology division at Hoechst AG. He is honorary professor for Industrial Chemistry at the University of Würzburg. His main scientific interest focuses on the products, processes and applications of photochemistry in information technology.

optical memories for the greatly expanding computer technology, since it is mainly the requirements of modern microelectronics which stimulate the search for faster and more powerful mass storage units. Circuits exhibiting very large scale integration permit access to 4MByte DRAM (*D*ynamic *R*andom *A*ccess *M*emory) from semiconductor memories and to the management of sophisticated software, which require permanent storage of increasing quantities of data. At the same time, there is a trend towards information storage in a more compact and robust, i.e. user-friendly, form. Accordingly, recent years have seen a broadly based advance in the development of appropriate materials, which has led to the initial marketing of optical data memories.

The present paper is concerned with the development of materials for optical data storage and gives special consideration to systems which can be applied on a technical scale and which are of commercial interest. An introduction to the most important concepts and processes will be followed by a discussion of the principles of Compact Disc and CD-ROM (*C*ompact *D*isc *R*ead *O*nly *M*emory) technology. The broad principles of optical readout and of the production of polymer storage discs with impressed information will be summarized in Section 3. Sections 4 and 5 give an overview of the most important materials and their properties for write-once (*W*rite *O*nce *R*ead *M*any, WORM) and erasable (*E*rasable *D*irect *R*ead *A*fter *W*rite, EDRAW) storage media. The main items covered are organic dyes for WORM systems and alloys of rare earth elements and transition metals for EDRAW systems.

There will be no discussion of metal coatings for WORM memories. More extensive references deal with compact disc and CD-ROM memories[1-5, 7] and with general aspects of optical memories,[5c] applications for optical data stores[8] and recording media for WORM and EDRAW memories.[6, 9-18]

2. Optical Memories

Audio and video CDs are optical memories which are based on a principle similar to that of gramophone records: information items are encoded in a structural pattern, from which the original information can be regained by means of a playback unit. In contrast to gramophone records, the readout takes place by a noncontact method using laser light. The information is impressed into a plastic plate and cannot be altered. CDs have meanwhile been used for other fields of application as well, outside the field of consumer electronics. The term CD-ROM has established widespread usage in connection with this type of information storage. This term signifies Compact Disk Read Only Memory (Data disk with k, in contrast to the audio/video disc with c). Write-once optical memories are designated as WORM systems. In contrast to the CD-ROM, it is possible for the user to record information. The principle of all WORM memories is based on an irreversible physical transformation of the recording medium, which is initiated by the irradiation of laser light. The following processes have been described:[5] formation of pits, bubbles, bumps, changes to the surface texture, phase change, switching of liquid-crystal phases, alloying of metal films and photochromic color change. In most cases, the reflectivity of the recording medium is altered by the marking process. This takes place locally at positions heated by the laser beam so that data spots are created, which are distinguished from the surrounding medium by their reflectivity. The physical marking process of EDRAW media is reversible, and thus enables the user to erase data which have been inscribed. EDRAW memories have been developed on the basis of magneto-optical materials, reversible phase transformations and photochromic dyes. In the first case, use is made of the magneto-optical effect: the rotation of the plane of polarization on reflection or transmission of laser light on or through magnetized material, in order to detect magnetic domains as data spots. The reversible phase change between crystalline and amorphous phases leads to an alteration of the reflectivity of the storage medium. The photochromic effect permits the marking of data on the basis of the differing absorption of a tautomeric dye molecule. Thus, in contrast to the two previously described storage methods, photochromic systems require the use of two laser sources. In addition, there exists a series of other reversible storage processes to which no technical significance is yet, however, ascribed.

The development of optical data storage is closely connected with the progress made in microelectronics. This applies both to the production of semiconductor lasers and also to the entire process technology which is necessary in order to produce structures in the μm range. The photoresists used for this purpose were primarily developed for the semiconductor industry, as were numerous vacuum coating processes for the preparation of metallic films. Accordingly, it was possible to use the know-how in vacuum technology for the construction of appropriate production plants for optical storage disks (Fig. 2).

Fig. 2. Vacuum coating machine for the production of magneto-optic disks. To reach the required clean room conditions the room is air conditioned with laminar flowing air, which is fed in through a filter in the roof and out through a floor grating.

The problems which are connected with particle contamination and its effect on production output are common to both the production of optical storage disks and the semiconductor industry. Both cases require processes with ex-

tremely stringent purity demands and acceptable particulate concentration tolerances.

3. Compact Disc Technology (CD-ROM)

Not only has CD-ROM technology laid the foundations, in terms of process technology, for optical information storage it has in addition stimulated the development of other storage systems (WORM, EDRAW) which are advanced and therefore in many ways significant for the future. The key to all optical processes resides in the availability of suitable radiation sources which, for mass production, must above all be small and cheap. With this background, it was the progress made in laser technology which, together with the development of semiconductor lasers, fulfilled all prerequisites for the successful marketing of optical storage systems. The experience gained from microelectronics made it possible to achieve miniaturization and the availability of a process technology for lasers which are suitable in terms of quality and price. A point of prime importance in the technology for the production of compact discs is the multiplication of the original information, in a manner similar to that used in the stamping of gramophone records. In the case of the CD, however, the size of the impressed structures—which is 0.5 to 2 μm—is several orders of magnitude smaller than those of a gramophone record. In order to produce corresponding dies and to use them in special injection molding processes, it was therefore necessary to find appropriate techniques which could be developed so as to include methods and materials known in the semiconductor industry. The outstanding quality of reproduction, which is highly important to the purchasers, and the decreasing cost have helped this new technology to achieve great market successes, especially in the audio sector.

This is not yet true of the CD-ROM data disk, which can store up to 650 Mbytes of information. A whole series of data banks are supplied in the form of CD-ROM disks, but in many cases there is no compatibility with the current operating systems and the standardization of interfaces and peripherals is proceeding only slowly. In spite of significant cost advantages (Fig. 3), certain technical problems such as,

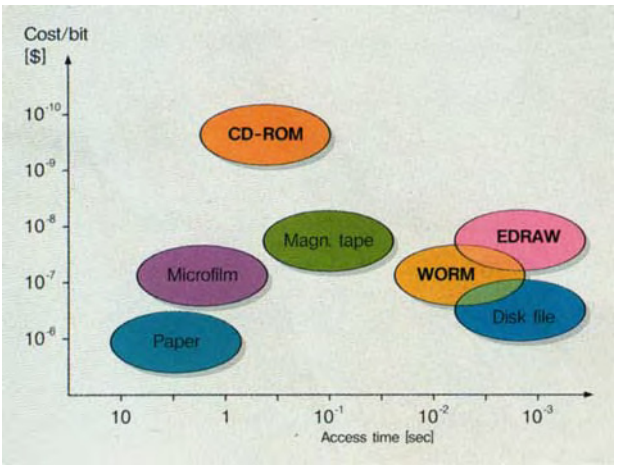

Fig. 3. Cost (US $) per bit and access times of classical and modern storage media [8e].

for example, the long access time of approximately 0.5 to 1 s, are still preventing widespread acceptance on the market.

Philips and Sony have initiated a joint project for the purpose of increasing the attractiveness of the data CD, and in 1987 specified the CD-I (Compact-Disk Interactive Media) in the so-called "Green Book" (forum for publication of standards). This amounts to a closed system which, using the multitasking operating system OS-9, is designed for microprocessors of the 68 family. As yet, there is no compatibility with MS-DOS. A further step in this direction is represented by the "Extended Architecture" which was first designed by Philips, Sony and Microsoft in August 1988 (CD-ROM XA). Using this system, it is also possible to use the data CD to store digital audio data and graphics in a similar manner as the CD-I is used but on a system-independent basis. While it is probable that new playback systems will be necessary for the CD-ROM XA, a different format can be operated with the CD players previously available: DVI (*D*igital *V*ideo *I*nteractive), which is based on a 100:1 data compression and decompression for digital video and should facilitate the PC-assisted processing of images. The beginnings of the technology of optical data storage go back as far as the late fifties; marketing in the form of the audio compact disc did not start until after 1982, as a result of the collaboration of Philips (basic research and disk development) and Sony (optics and playback unit). Following the immense market success of the new audio technology, several companies have become established as CD manufacturers, and joint efforts are meanwhile being made in the development of this technology by large companies: in 1985, Philips and DuPont founded PDO (*P*hilips *D*uPont *O*ptical), a joint venture company which is concerned with research and development of optical storage disks and which operates with Polygram (Hannover, FRG), the largest CD production site in the world.

The progress made in laser technology was tremendously important for the development of optical data storage. The first CD players were, in some cases, still operated using He-Ne or argon ion lasers. Since that time, all players have been equipped with semiconductor lasers, which can be produced inexpensively and in a more compact form. The widespread technical use of semiconductor lasers (emission wavelength ca. 780–840 nm) became possible only with their continuous operation at room temperature and long service lives.[19] To this end, it was necessary to reduce the threshold current of the lasers: the electrical power which is expended until the laser threshold is reached is lost in the form of heat and rapidly leads to the destruction of the optical system. The availability of appropriate semiconductor materials and the progress which has been made in the field of production engineering have created a situation in which semiconductor lasers can nowadays be supplied at very favorable prices (ca. US $ 3 each).

3.1. Digital Data Storage and Reproduction

Audio CDs and video CDs contain data in digitalized form which are read by means of a playback system (CD player consisting of disk drive and optical system) and are transmitted via analog-digital conversion to the output unit (loudspeaker and/or screen). The information carriers are

pits which are impressed into the surface of a plastic disk and are separated by the relief positions, the land (Fig. 4a). The pits, which are arranged in sequence and which have a depth of approximately 0.5 μm and a width of 0.8 μm, form tracks at a spacing of approximately 1.6 μm.[3,4] The disk consists of an injection-molded polycarbonate or polymethyl methacrylate substrate (diameter 12 cm) and is coated on the information-carrier side with a highly reflective aluminum film, which is protected against mechanical damage by a polymer layer.

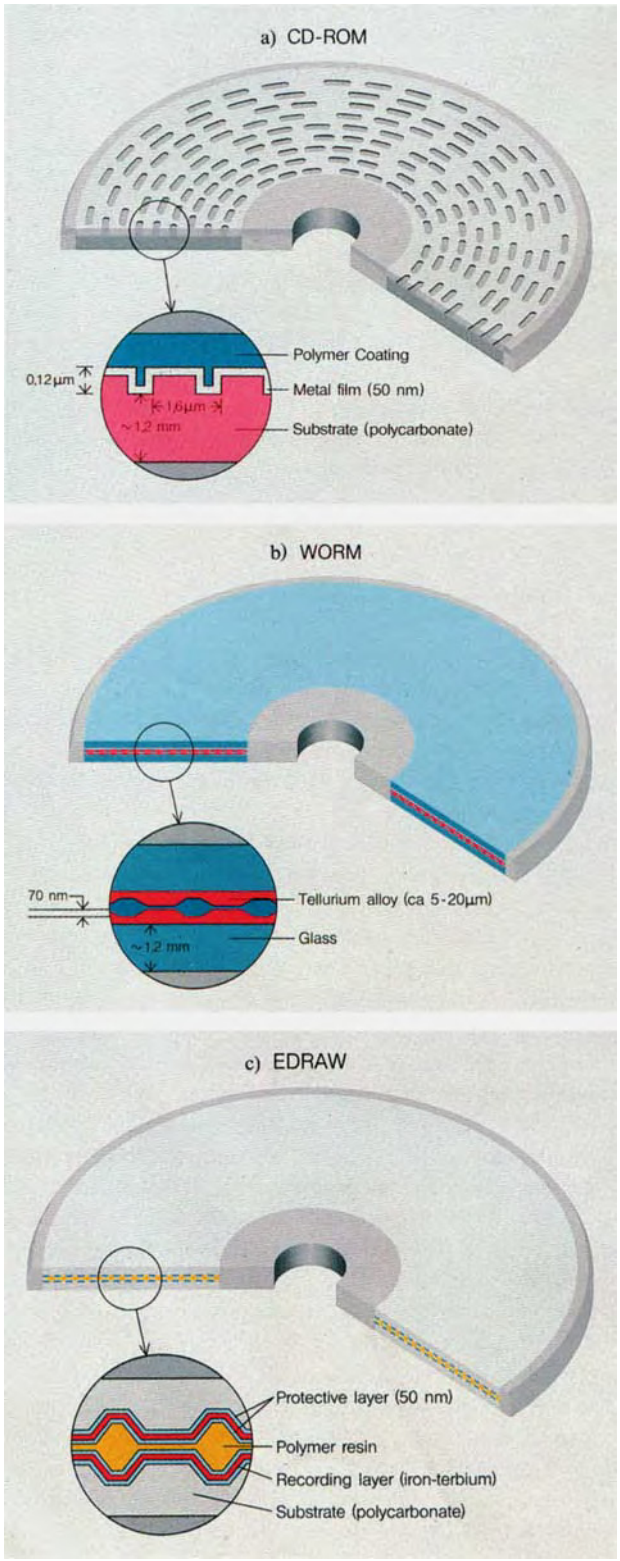

Fig. 4. Schematic representation of the construction of optical disks. a) CD-ROM disk. b) WORM disk as air-sandwich construction with a tellurium alloy as recording layer. c) EDRAW disk as three layer construction with a magneto-optic terbium-iron alloy as storage layer.

The playback unit includes an optical system which is located on a pivotable arm and is tracked to follow the pit track. The optical system focuses the light beam of the laser through the substrate onto the plane of the pits; the beam has a diameter of approximately 1 μm on the disk. The light reflected by the aluminum mirror is passed to a photodetector. When a pit is swept over, the signal intensity of the laser beam decreases significantly since the light is scattered by the pit structures. The optimal reflection conditions are on the land situated between the pits. In this way, it is possible to read binary data which are encoded in accordance with specified algorithms: reflection results in a high signal intensity and is recorded for example as 1; a signal intensity which is reduced by scattering represents 0.

The binary data form of the analog original sound recording is obtained by a frequency-dependent recording in audio channels: the signal level of each channel is given as a binary code word of 16 bits, to which error correction processing bits are also added. This gives rise to a bit stream encoding the sound recording. On playback of a CD disk, the decoding of the square-wave signal takes place in the electronic system of the recorder. Using electronic filters, the bit stream is broken down into the individual signals for sound (audio CD) and also for picture and color (video CD). In the case of a video CD, the picture is encoded by means of the spatial frequency of the pits along the track, while color and sound are encoded by modulation of the ratio of pit length to repetition rate. The signal fulfills additional functions which are essential for the recorder to operate properly. Disk rotation speed as well as focusing and tracking of the laser beam must be measured continuously and, where appropriate, automatically readjusted.[20] These servo functions avoid situations in which the laser beam, for example, "deviates" on the disk, jumps between pit tracks or "overlooks" pits. By means of special photodetectors, consisting of four subquadrants and each delivering a respective signal, several signals are generated electronically from the intensity/time progression of a laser beam, and these signals are available for servo functions. Another possibility consists in three beams being produced optically from a laser source, and then being used to scan the disk surface. These three additional signals are thus available for adjusting the optical system and the disk. Finally, it is necessary to constantly regulate the intensity of the laser light in order to maintain the optimal signal-to-noise ratio, and thus to obtain the same conditions for reading the information when the disk is played back at any position.

The compact disc system developed by Philips and Sony has meanwhile become a world standard, and has been licensed to many other companies. There are as yet no standardized formats for the WORM and EDRAW data disks. This applies both to the disk construction and to the write/read unit. One construction for the WORM data disk and one for the EDRAW data disk are shown in Figures 4b and 4c respectively. These represent some of the numerous systems which are currently at the development stage.

As far as the data disks are concerned, the main difference from the CD format is that the substrates are provided with one or more guide tracks which, using a laser beam, permit

orientation on the initially uninscribed disk. The impressing of the guide track, also referred to as a groove or track, creates elevated regions to receive the data markings. A series of possible formats are distinguished according to the mode of rotation of the disk and the form of the guide track:[3, 4] CLV (*C*onstant *L*inear *V*elocity), CAV (*C*onstant *A*ngular *V*elocity), spiral and concentric track arrangement. Where the speed of rotation of the disk is constant (CAV), the disk has linear speeds which are different inside and outside, and the data markings are larger outside than inside. Constant pit size requires constant linear velocity, and in this case the speed of rotation must be regulated as a function of the radius. For orientation purposes, marks are used within the guide track system, which divide the disk into sectors. If the marks are set at constant intervals beside a spiral track, this is referred to as the "sampled servo" format. In the continuous composite format tracking is achieved by direct evaluation of the signal reflected from the tracks. Due to the division of the CDs into sectors, the data file can be stored in a similar way to that applicable with the magnetic disk memories, not only on a serial basis but also in a dispersed configuration (sector offset with interleave factors). The format of a disk controls the maximum attainable storage density, so that the storage density is increased by appropriate changes to the formatting. For this purpose, it is, e.g., possible to write data directly by using track grooves. The second-order reflected beam then reproduces the information from only one side of the groove.[21]

The air-sandwich design (Philips) is shown in Figure 4b[22a] as an example of the design of a write-once data disk. The recording layer, a tellurium alloy, is coated onto the substrate which is provided with track grooves. Using appropriately dimensioned spacers at the center of the disk and at the edge of the disk, the size of the air gap is regulated when two disks are welded together. The composition of the gas in the gap can be chosen so that the air-sensitive layers are protected. However, it is still possible for the recording layer to be subjected to attack as a consequence of failures in the sealing of the disk construction; accordingly, in another design the air gap is filled with an inert polymer mixture.[22b] In addition to the direct coating of the substrate disk with a light-sensitive write layer, it is also possible to apply the information layer to a flexible fabric which is firmly clamped in a suitable disk construction (*S*ealed *D*isk *A*ssembly, SDA; Kodak).[22c] When data disks rotate (approximately 1800 rpm), in some cases relatively large forces act, and these have the effect of bending the flat substrate (radial run out); this can lead to difficulties in focusing and tracking the laser beam (cross talk). Thus, the suspension of a light-sensitive lightweight layer achieves the greatest possible mechanical decoupling between disk and layer.

The construction of magneto-optical storage systems[23, 24] (EDRAW, see Fig. 4c) is similar to that of WORM disks. A recording film made from rare earth elements and transition metals is located on a substrate provided with track grooves, between two protective layers consisting of amorphous silicon nitride or aluminum nitride. Encapsulation is necessary for the purpose of protecting the storage medium from oxidation. A polymer adhesive is applied to the outer protective layer in order to produce, by combination with a further substrate, a disk which can be inscribed on both sides. In addition to the protective function, amorphous nitride films also have the function of effecting the coupling-in and coupling-out of the laser light for optical writing, reading and erasure.

In the case of magneto-optical memories, two disk formats are currently under development: 3.5″ (approximately 130 MByte) and 5.25″ disks (approximately 300 MByte). The two formats will probably be used for different markets. 3.5″ disks and disk drives could be used for personal computers. The optical storage disk can fulfill two functions at the same time which previously would still have required separate components: the hard disk function as mass memory and the floppy disk function as exchangeable data file. The 5.25″ system will mainly be used for data archiving and data exchange at very high data rates.

In the case of the optical WORM and EDRAW systems, the operations of data encoding and decoding correspond to a large extent to the principles applied in magnet technology. Accordingly, in the field of computer operating systems it is necessary to make changes on introducing the optical storage technique only insofar as they relate to the matching of the interfaces to the optical disk drive. All data disk systems which are currently exhibited are to a large extent compatible with existing systems.

3.2. Production of Substrates

One of the prerequisites for the acceptance of new mass-produced products is high quality production, as well as high output in short periods of time at the lowest prices possible. Accordingly, the development of CD disk production was pursued, from the outset, with particular regard to these conditions, and has made a contribution to the success and commercial attractiveness of the CD technology.

There are essentially three processes for the multiple production of flat molded components: stamping, injection molding and injection stamping. The first represents a process which is widely used in the gramophone record industry, but which is not suitable for use in CD production since the requirements as regards dimensions and mold tolerances are more stringent by an order of magnitude (the submicron range). Injection molding and injection stamping can be used to achieve the desired structural interrelationships, injection stamping representing the most demanding technique. Both processes are used in the production of CD audio and video discs and in the production of substrates for WORM and EDRAW disks. The production is divided into the fabrication of the master and the preparation of substrates. Injection-molding dies are cast in a multistage process (mastering)[28, 30] which involves the latest technologies of microelectronics (Fig. 5). The mastering process begins with the cleaning and polishing of a glass disk which is required to construct the master. An adhering layer is applied by vapor deposition using an agent creating water-repellent properties, e.g. hexamethyldisilazane (HMDS), which coats the surface with a positive photoresist. The surface is exposed to a UV argon ion laser, which inscribes the pit structure in accordance with the digital information as played back from the master magnetic tape.[25] During subsequent development the exposed resist is dissolved away. At this stage it is

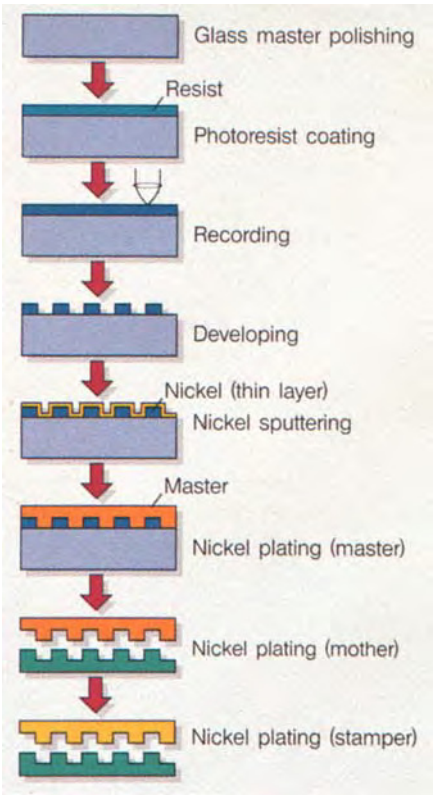

Fig. 5. Mastering process of the stamper for the injection molding optical disk. [30]

necessary to precisely control the development process since the geometry of the pits is influenced unfavorably by underdevelopment or over-development; this also applies, in the same way, to the imaging of the track guide grooves in WORM and EDRAW mastering.[29] The photoresist and the glass surface are then coated with a layer of metal (nickel in most cases) approximately 50–100 nm, either by vacuum vapor deposition or by sputtering. In this way, the master surface can be visually monitored before further processing and can be directly played back in a disk drive; an initial quality control is possible by comparing master and the master magnetic tape.

Further metallic layering to form the actual metal master is carried out using a currentless or electrolytic process.[26] After separating the master from the glass base, parent masters are produced by electroplating, and the individual injection-molding masters are formed from these parent masters by means of a second electroplating operation. By setting up such a "family of masters", it is possible to prepare new ones immediately without repeating the costly mastering process.[26] The mastering process specifies the quality of the finished disk, and accordingly numerous attempts have been made to improve critical process steps.[31]

Within narrow tolerances, the substrate materials for optical data storage systems must exhibit properties which are mainly determined by the nature of the data storage and reproduction. In most cases, the information is read through the disk, i.e. the laser beam must pass through the substrate material without loss of intensity and—in the particular case of magneto-optical systems—without change of polarization. This requires a substrate material of high optical homogeneity, purity and optical transmission and low birefringence. Bubbles, gel particles, inclusions, surface defects, and zones of turbidity due to impurities can give rise to scattering and absorption effects which cannot be compensated by the servo functions of the electronic and optical systems. Significant properties of the disk materials with regard to mechanics, optics, environment and productivity are represented in Figure 6 for polycarbonate (PC), polymethyl methacrylate (PMMA), polycarbonate–polystyrene blend (PC/PST) and

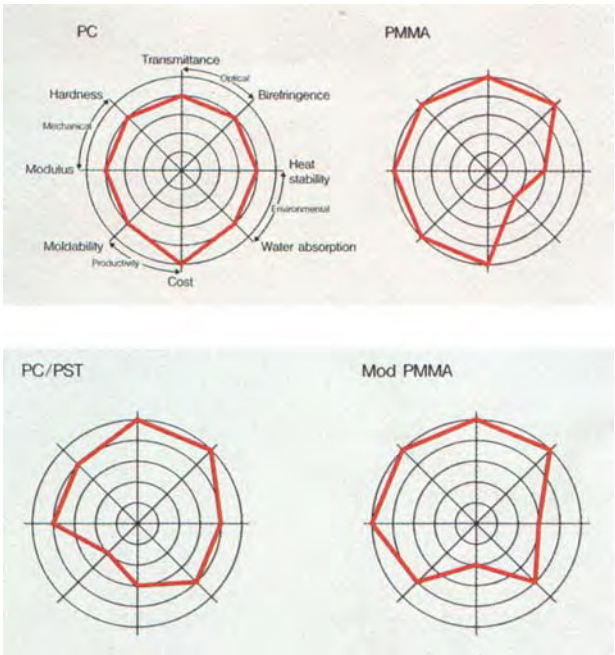

Fig. 6. Properties of polymeric substrate materials [32]. Parameters are represented regarding optical, mechanical and environmental properties and productivity of polycarbonate, polymethyl methacrylate, polycarbonate-polystyrene blend and modified polymethyl methacrylate. The performance of a polymer improves from the inner to the outer circle.

modified polymethyl methacrylate (Mod. PMMA).[32] A further criterion for the selection of a substrate material is its absorption of water, since swelling and thus distortion of the disks can arise as a result of water vapor. The sensitivity to moisture of certain recording media is very great, so that the water absorption of the substrate may be the limiting factor with respect to its use.[33] The severity of this problem may be reduced by the use of protective layers; however, it can represent a latent uncertainty regarding the long-term stability of data archives. It is possible to measure such effects quite well by accelerated storage tests; the manufacturers give their guarantees on the basis of these tests (required long-term stability: 10 years).

The birefringence of the flat polymer disks must be as small as possible; for example, it is specified at ± 50 nm for the Compact Disc. Birefringence occurs where a light wave in a medium propagates at differing velocity.[36, 37] Prerequisite for this is an anisotropic polarizability of the medium. In the case of a polycarbonate, this preferred direction of the polarizability is parallel to the polymer chain. Accordingly, the resultant birefringence is referred to as orientation birefringence. When forces act on a molded component of polycarbonate the birefringence alters in consequence of the movement of chain segments. In the course of the production

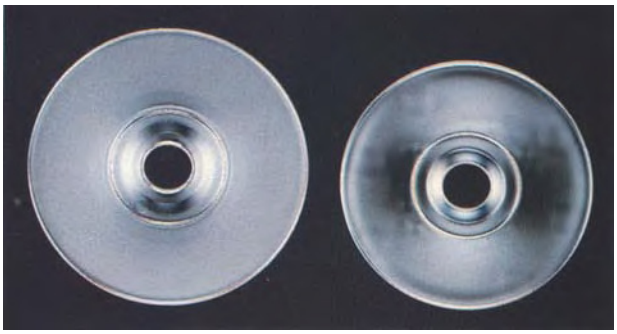

Fig. 7. Birefringence of injection molded polycarbonate substrates. The left disk fulfills the specification for an optical disk, the right disk is useless because of inhomogeneities.

process, for example by injection molding, it is possible for deformations to be frozen in as internal stresses. The resulting stress birefringence remains operative at room temperature; it may decrease or entirely disappear only at higher temperatures and on reaching the glass point.[34] The process of molding storage disks must accordingly be adapted to the specific birefringence properties of the polymer; in addition to this, it is necessary to include the effects of other production steps. The uniformity of the birefringence of disks can easily be monitored visually, for example, by placing substrates between two polarizing foils (Fig. 7). Reduction of the birefringence of substrate disks may be achieved by the use of polymer blends which consist of polymers having different anisotropic polarizabilities. Thus polycarbonate/polystyrene,[39] polyphenylene ether/polystyrene,[27] polymethyl methacrylate/polyvinylidene fluoride[38] and polymethyl methacrylate/polyvinyl chloride[39] blends can be prepared which are suitable for the production of disks. New types of polymers such as cyclic polyolefins, compounds with very low water absorption, are now being used for the production of substrates.

Instead of using injection molding or injection stamping, it is also possible to produce CD disks by a process developed by Philips (Fig. 8).[30, 40–43] In this "2P Process" (*photopolymerization*) a base plate is fixed at a defined spacing on a nickel stamper and the gap is filled with a photopolymerizable mixture. The mass is hardened by means of UV radiation and removed from the stamper together with the base plate as a completely structured disk. An advantageous feature of this process is the precise structural imaging, since the curable mixture can flow into every fine pit of the stamper. This process may be carried out using simple devices, and the quality of the raw liquid material is controlled at low costs. Moreover, the wear and tear of the stamper in this pressureless technique is considerably less than in other processes, whereby additional costs can be saved. The photopolymerizable mixture is composed, for example, of ethylene acrylates or ethylene methacrylates and photoinitiators.[35]

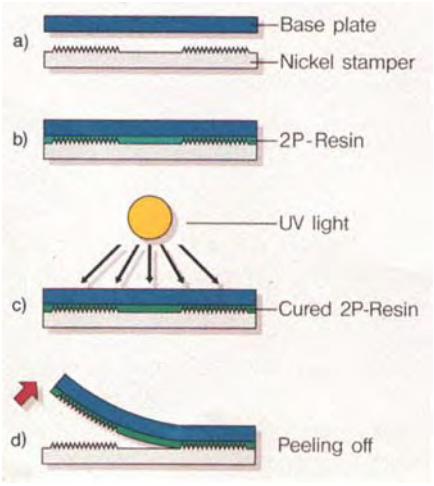

Fig. 8. 2P process for disc replication (2P = photopolymerization). [30] a) Production of plate and stamper. b) Filling with 2P polymer. c) Photopolymerisation. d) Separation of disk from stamper.

The problems associated with this process reside in long exposure times involved in the photopolymerization. The cycle times of injection molding machines are in the region of five seconds for the molding of a disk, but the UV curing of a mixture demands considerable optimization to achieve exposure times of similar brevity. Monomers and photoinitiators must virtually be 100% consumed in order to eliminate subsequent complications by diffusion into the storage medium. In the course of polymerization, a decrease in volume usually takes place as a result of the combination of the monomers, and the molded component shrinks accordingly. In the case of the 2P process a considerable proportion of the process-technology know-how is specifically based on keeping the volume shrinkage to a minimum.

4. Write-Once Storage Disks

The development work carried out on write-once optical storage disks has led to the first commercially available products which are marketed in combination with appropriate write/read systems. Write-once optical storage media are designated as WORM or DRAW (*D*irect *R*ead *A*fter *W*rite) systems; common to these is that they accept information from the user and can make this available again within short access times. WORM and DRAW systems differ from each other in that the latter can compare the stored with the specified information immediately after each inscription process, and thus correct readability is guaranteed.

A typical field of application for WORM memories is the archiving of data. Their objective is thus to replace the documentary or microfilm archiving which is customary nowadays in offices. With a diameter of 5.25 inches, commercially available storage disks offer a storage capacity of approximately 2×400 MBytes, which corresponds to the information content of approximately 150000 typed A4 pages. This mode of office filing, which is still unusual, will create new possibilities for information processing in view of the increase in direct electronic communication via telefax and electronic mail. Furthermore, write-once optical storage disks, just like CD-ROMs, may be used as data banks for reference works. In this case, the mixing of pictures, texts and data is possible. In addition, compact and fast-access "analog" image storage in the video field is also possible with these storage systems.[44]

While the advantages of write-once optical storage disks as compared with conventional filing (long access time, great

bulkiness, labor-intensive), microfilming (long access time, no freely selectable sorting facility, costly setting-up procedure) and storage by means of magnetic tapes (medium access time, inadequate data security, limited data service life) are clearly evident, they find in the magnetic disk systems, which are likewise under rapid development and which have exceptionally short access times, a genuine competition over which they have, to date, not yet been able to acquire precedence.

In order to compete against the magnetic storage technology, the following fundamental requirements must be placed on write-once optical storage disks: high storage capacity ($>10^8$ bit/cm^2), fast access times ($<10^{-2}$ s), low storage costs ($<10^{-7}$ DM/bit), high data service life (>10 years), high write sensitivity (<1 nJ/bit), reliable reproduction as a result of a high signal-to-noise ratio (>55 dB), low defect density ($<10^{-13}$ bit after correction) and easy handling of the entire system.

4.1. Principles of the Write/Read Mechanism

The selective, thermally induced and irreversible deformation, as well as the phase change of an active layer, the so-called recording layer, have become established as preferred methods for the inscription of write-once optical storage disks. In practice, radiation from semiconductor lasers having emission maxima between 780 and 840 nm is used. This absorption of energy results in a locally specific chemical-physical change of the active layer. As a result of this change, which is limited to a very small area and which is unambiguously defined, it is possible by means of a suitable reading mechanism to detect digital information and to convert it into a bit sequence.

The most widespread technique is based on an aperture-forming mechanism (ablative recording) (Fig. 9a). The active layer converts the closely concentrated irradiated laser light into thermal energy, which at approximately 1700 °C initiates complex physical processes.[45] This leads to the formation of a pit with the simultaneous localized alteration of the optical properties of the layer which are detected by means of the intensity variation of a weak laser beam. In order to convert the laser light into heat, the recording layer must consist of a material which absorbs radiation of the prescribed wavelength. Possible materials used are metals or amorphous dye films.

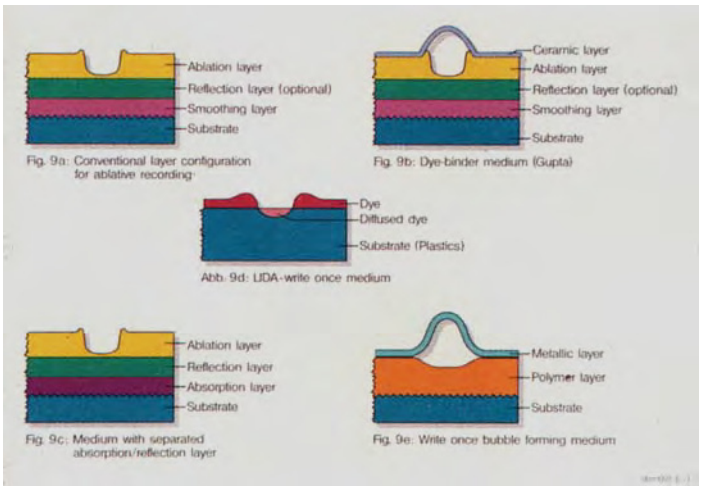

Fig. 9. Conventional layer configuration for ablative recording.

The basic structure of this type of write-once storage disks consists of a disk-shaped molded substrate unit, which is in most cases solid in structure and usually made of glass, aluminum, polymethyl methacrylate or polycarbonate. The recording layer is applied to this substrate unit and covered with a protective layer. Occasionally, an additional layer is introduced between substrate and recording medium; this improves the adhesion properties, reduces the microporosity of the substrate, and, where appropriate, prevents the diffusion of components of the active layer into the substrate. The microstructure of the substrate has a substantial influence on the background noise and thus on the quality of reproduction of a disk, which is characterized by the signal-to-noise ratio (SNR).

The active layer consists of a metallic or dye film, which has a thickness of approximately 50–200 Å and which, depending upon the material, is applied by sputtering, sublimation, or spin-coating from a solvent mixture, which is financially preferred but is only possible with soluble dye systems.[46] The long-term stability and optical constancy of pure dye films[47] is frequently limited as a result of agglomerate formation and the tendency to crystallize. These effects can be circumvented by using mixtures of the dyes with special polymers,[48] which not only considerably improve the stability of the recording layer but also the quality of the pit formation (dye-in-polymer (DIP) concept).[49] In addition to these, recording layers consisting of special polymer composites are also used.[50] *Gupta* modified the DIP configuration by applying a thin transparent ceramic layer to the recording layer[51] (Fig. 9b). In the course of the writing process, a pit is formed in the active layer and gas is evolved. The ceramic layer is likewise heated and bows as a result of the internal pressure generated in the pit. The bubble formed above the pit leads to a unification of the pit geometry and the still intact ceramic layer prevents thermally induced ejection of material. Both effects result in an outstanding signal-to-noise ratio of the medium (>65 dB).

Another variant consists in a separation of the functions of the recording layer into an absorption layer and a film forming pits (Fig. 9c).[52] This arrangement permits a fine optimization of the respective layer with regard to its specific task. A disadvantage of these multi-layer variants is that the additional layers lead to an increase in the layer defects and thus an increased bit error rate (BER) and rejection rate.

The LIDA concept (*L*aser *I*nduced *D*ye *A*mplification)[53] is based on the diffusion—brought about by laser light and thermally induced—of a dye into the substrate polymer (Fig. 9d). The resulting difference in the optical properties between pure dye film and molecularly dispersed dye is used for signal differentiation.[54]

Alternatively, it is possible to apply a temperature-sensitive layer beneath a metallic absorbing layer which is irreversibly expanded by the irradiation, for example by the evolution of a gas, and thus leads to bubble formation[55] (Fig. 9e). The altered light scattering of the reading beam is produced by the deformation of the film surface. A write-once storage disk using this arrangement has been exhibited by Thomson CSF under the designation of Gigadisk.

The formation of pits or bubbles has the effect of altering various optical properties of the recording layer, e.g. extinction, transmission, reflection or light scattering. In most cases, the readout of the information takes place by the write laser operating with relatively low radiative power, or occasionally by a read laser emitting at a different wavelength. In order to be able to inscribe and to read an optical storage disk on both sides, use is made of the altered reflection behavior of the active layer. The signal contrast can be considerably improved by the use of an additional thin, metallic reflective layer beneath the active layer. The mechanisms of pit and bubble formation in the active layer have been intensively investigated; the initial studies date back to *Mayden*[56] and *Kivits* et al.[57], who used thin tellurium films. According to *Kivits* et al.[58], the pit formation takes place in several stages. When the laser pulse strikes the metal foil, optical energy is converted into thermal energy; and within the narrowly defined irradiation region, temperatures are reached which are close to the boiling point of the metal. The duration of the absorption of energy during the laser pulse is so short that it is not possible for any thermal equilibria to become operative (superheating). The temperature profile occurring in the molten metal leads to surface tension gradients (Marangoni effect),[45,49b] as well as inhomogeneous pressure, bubble formation, and vaporization zones which lead to flow of the material and thereafter to a local broadening of the active layer with pit formation. As a result of the rapid cooling of the material after termination of the laser pulse this condition is frozen in, and the pit and edge geometry is determined. Comparable interrelationships may also be utilized regarding the pit formation in active layers based on organic materials.[15,45,49b] The dye molecules which undergo electron excitation upon irradiation convert the absorbed energy into vibrational, translational and rotational energy, resulting in thermal energy. On account of the low thermal conductivity of organic compounds, the heating is limited to a narrow local region. This heating leads to melting and vaporization or even decomposition of the molecule. The pit formation in organic materials is discussed controversially and is associated with thermally induced surface tension and melt viscosity phenomena,[59] the optical density of the recording layer[60] or the rheological properties of the active layer.[61]

In this case, it is necessary to find a compromise between film thickness and dye loading on the one hand and pit formation on the other, since the growth increases the absorption capacity, but in order to form pits, more material has to be discarded.

As compared with metal films, recording layers containing organic dyes which absorb IR radiation have numerous advantages, such as an increased resistance to atmospheric influences and lower toxicity.[13,15] In addition to this, especially in the DIP configuration, they combine high physicochemical stability, low thermal conductivity and relatively low melting or sublimation temperatures.

4.2. Dye Systems and Dye/Polymer Systems

The traditional task of dyes consisted in generating the coloration of requisites found in daily life. Consequently, the efforts put into their synthesis in the past were in particular directed towards providing dyes having absorption maxima in the visible range, i.e. between 420 and 700 nm, while dyes for absorption in the near infrared (NIR range) became of technical interest only with the advent of infrared photography. Accordingly, it is no surprise that virtually all dyes manufactured on a large industrial scale are of no interest for the purposes of optical data storage, since they exhibit no or only slight absorptions in the NIR range, while these absorptions are necessary when using diode lasers to achieve the pit formation temperatures in the write process and signal contrast levels in the readout process. However, considerable progress has been made in the meantime specifically in the synthesis of NIR-sensitive dyes.

If dyes are used as absorbers in write-once disks, then the following general requirements must be met: high absorption capacity for semiconductor laser radiation (780–840 nm), in order to require low write energies; a commensurate threshold value, which permits a distinction between the write and read process at the same wavelength; low thermal conductivity in order to achieve pits of sharply defined shape; good film formation; high stability in relation to light, heat and moisture; low toxicity; high thermal stability (for sublimates).

Depending upon their structure, dyes may be applied to a substrate by sublimation or spin-coating. Thus, without reference to the material concerned, it may be stated that according to the hitherto published results systems which have been applied by sublimation are superior to spin-coated dye solutions as regards stability towards atmospheric effects and the quality of pit formation, but are inferior in terms of signal-to-noise ratio. With frequent reading, the latter is caused by sublimation and leads, as a result of deposits, to a surface roughness which reduces the uniformity of the reflectivity of the layer.

4.3. Dyes for WORM Memories

The initial investigations on write-once disks based on dyes were carried out using non-directly-modulable gas lasers, for example argon ion lasers emitting at 488 nm, owing to the lack of NIR-sensitive dyes. Even at that time, the benefit of this technology became known and was protected under patent law. The dyes which were used included azo dyes,[62] ketocoumarins,[49b] quinones,[53b] fluorescein,[63] polyester yellow,[48,49a,60] or diethoxythioindigo.[64] Phthalocyanines,[65] naphthoquinones,[66] simple squarylium[67] and cyanine dyes[68] or triarylmethane dyes[69] proved to be suitable for recording information by means of helium–neon lasers (633 nm). The practical significance of these storage media is slight. Nevertheless, it should not be overlooked that it is possible to achieve a reduction of the pit geometry and thus, in principle, a higher storage density of the disk by light of shorter wavelength. The first paper which described the use of semiconductor lasers as write lasers was published in 1981 by *Jipson* and *Jones* (IBM).[47a] They used a hydroxysquarylium derivative (Fig. 10) as the recording layer, which was applied to the substrate by sublimation. This compound has good thermal and optical stability prop-

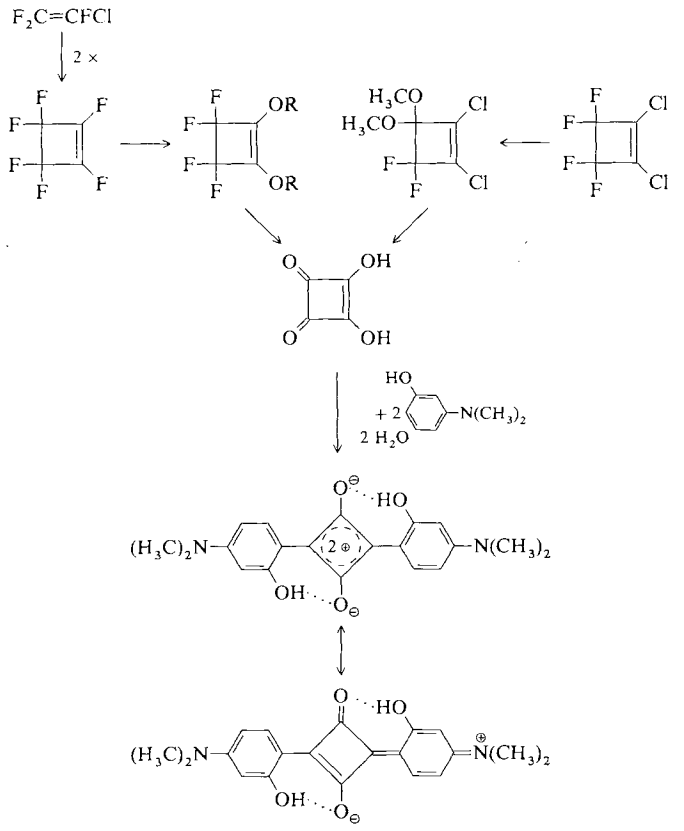

Fig. 10. Syntheses for squaric acid and a hydroxysquarylium derivative.

erties. The pit formation proceeded in a reproducible manner and is ascribed to pure sublimation processes.

However, such films are unsuitable for practical application since the sensitivity in the NIR range proved to be too low and the long-term stability proved to be inadequate in consequence of the tendency towards crystallization. In addition to this, the dye film did not demonstrate any threshold value for pit formation, as a result of which, following frequent read out, a loss of the data was observed. Similar results have been reported by *Kivits* et al.,[70] who used recording layers consisting of vanadylphthalocyanine. The number of NIR-sensitive dyes has greatly increased during recent years. In practical terms, four categories of dyes have, in particular, achieved significance: 1. methine dyes, 2. phthalocyanine derivatives, 3. specific condensed arenes, and 4. metal complexes. There are also many other examples of dyes which do not fall into this subclassification; some of these will be outlined after the discussion of the four classes of substances.

4.3.1. Methine Derivatives

The first compounds of this category to be investigated were heptamethine cyanines, with benzoxazole, benzothiazole, (benzoannelated) indole or quinoline moieties as terminal groups.[71] In addition to having high absorption coefficients, these compounds exhibit excellent reflection properties (up to 40% at 800 nm) and thus yield materials with good SNR values and high signal contrast. Indole derivatives are particularly preferred on account of their favorable solubility properties.[71a-d] Cyanine dye films are almost exclusively produced by application from solution. In order to coat the substrate with the dye, the latter must be soluble in solvents which do not attack the substrate material. Propanol, ethyl acetate and—less preferred—acetonitrile have proven to be suitable solvents. While the absorption maxima of the monomeric methine dyes in solution are relatively sharply localized, the half-width of the signals becomes broader in a polymer matrix with the formation of new maxima. This broadening of the signal is ascribed to dye aggregation.[54a, 72] The following properties distinguish the methine dyes as absorbers for write-once disks: they have a high molar extinction coefficient and require only small energies to form sharp and intense pits (approximately 0.5 nJ/pit), and a favorable signal-to-noise ratio results from the high reflectivity (> 30%). Methine dyes are photooxidized by singlet oxygen in the presence of light. The reaction is bimolecular and proceeds under unsensitized conditions relatively slowly on account of small quantum yields; however, it is accelerated by suitable sensitizers. The rate of decomposition increases with increasing methine chain length, and may be influenced by substituents in the heterocycle. The photodecomposition begins with 1,2-addition of $^1O_2$ to an exocyclic CC double bond.[73]

An increase in the stability may be achieved by the introduction of electron-withdrawing substituents, for example halogens or cyano groups, as a result of which a slight bathochromic shift of the absorption maximum takes place in consequence of a reduction of the LUMO (*L*owest *U*noccupied *M*olecular *O*rbital).[74] There are other possibilities for stabilization by introduction of a cyclic unit (Fig. 11) into the methine group.[75] It has been shown that particularly

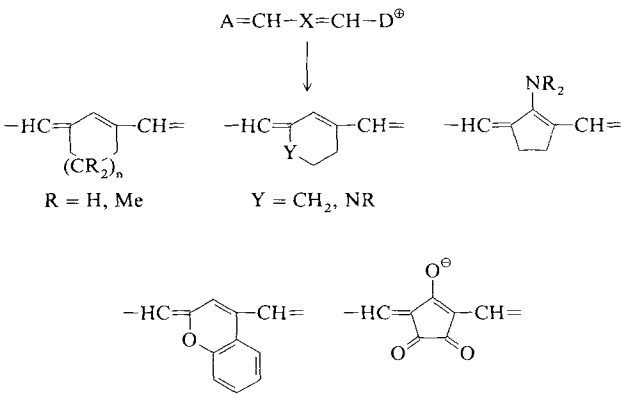

Fig. 11. Stabilization of methine dyes sensitive to oxidation by introduction of cyclic moieties. A = acceptor, D = donor.

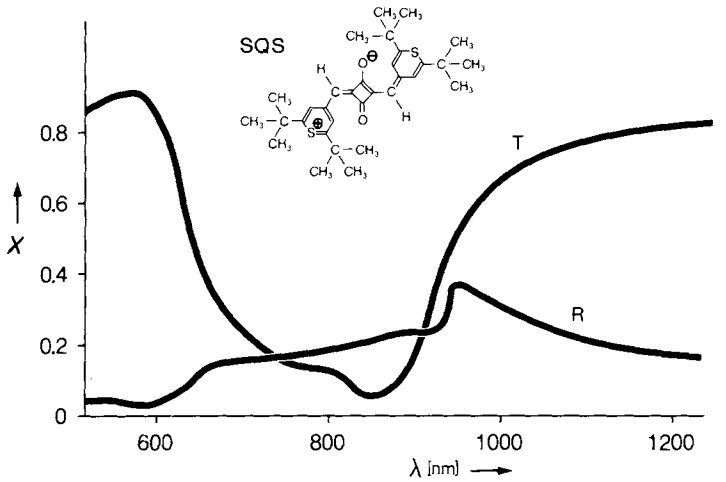
suitable compounds are those derivatives which contain squarylium[76] or croconium groups[77] like those shown in Figure 11 (bottom right) in the methine chain. These have been combined with the most widely varying terminal groups such as azulenium,[78] pyrylium,[79] benzo or naphthothiapyrylium,[80] naphtholactam[81] or oxoindolizine heterocycles.[82] Furthermore, storage media consisting of polymeric cyanine derivatives[83] or of tetra(dialkylaminophenyl)cyanines[84] have been proposed. The latter exhibit good solubility properties, but are inferior to the cyanines in their optical properties. However, they are more stable towards

singlet oxygen, and the addition of radical traps increases their stability.

The sensitivity to oxidation of the above indicated methine dyes may also be reduced by the addition of an oxygen trap.[85] Examples of suitable compounds are dithiolato complexes of platinum, cobalt and nickel[86] (see also Section 4.3.4) or aminium derivatives,[87] which can be obtained as salts. They are added to the mixture or directly attached to the dye.[88] Alternatively, salts with a cyanine dye as a cation and a radical trap as an anion can be used, e.g. a dithiolato derivative. These salts tend to be highly stable.[89]

A particularly intensively investigated group of methine dye derivatives comprises the squarylium dyes, which have been developed by Philips and Kodak.[84d, 84e] The compound SQS (Fig. 12) which forms an inner salt can be spin-



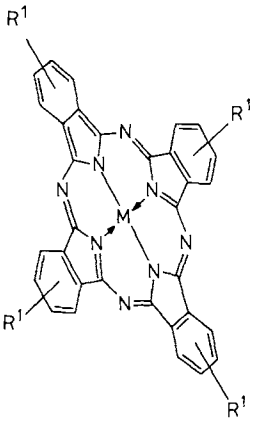


Fig. 12. Transmission (T) and reflection (R) spectra of a 90 nm thick film of the squarylium dye SQS suitable for a WORM medium. X = relative transmission or reflection [84d].

coated as a dye solution (approximately 50 g/L *n*-propanol), on account of the *tert*-butyl groups which increase the solubility. At 800 nm (Kr ion laser), an SQS film having a thickness of 90 nm reflects approximately 20%, and transmits approximately 10% (Fig. 12). Transmission and reflection are functions of the layer thickness; transmission decreases exponentially with layer thickness, while reflections are at a maximum at approximately 90 nm layer thickness in the case of SQS dye. The signal-to-noise ratio is a function of the irradiated energy.

A decisive factor regarding the suitability as archiving material is the aging behavior of the dye layer. When stored for relatively long periods at 90 °C, pure SQS films tend to crystallize, leading to a change in the optical properties (e.g. doubling of transmission after 20 days at 90 °C). This can, however, be controlled by the addition of small quantities of a polymer. At room temperature, the pure film also exhibits virtually no change. In the Z/AD test (temperature change between 25 and 65 °C with relative atmospheric humidity of 93%), the transmission of SQS varies by a factor of 2 after 40 days. SQS is rather stable towards light; this was tested at 40 °C and 65% atmospheric humidity using white light having an intensity of 1000 $W m^{-2}$; the SQS films showed varying stabilities, depending upon the environment. While water and oxygen alone generated only very slight changes in the optical properties of the recording layer, in the presence of both water and oxygen peroxides were formed and relatively large changes were observed. A reading test using a commercial NIR write/read laser revealed that after 10^8 reading processes no change in the optical properties was detected provided that a certain energy threshold value was not exceeded.[84d, 84e, 90]

4.3.2. *Phthalocyanine Derivatives*

Phthalocyanine (H_2Pc), a tetraaza[18]annulene or tetrabenzotetraazaporphyrin,[91] has proven to be a useful dye for write-once optical storage disks. In $Pc^{2\ominus}$, four isoindole units are cyclically connected to one another by nitrogen bridges. The two protons of the metal-free substance may be replaced by numerous metal atoms (MPc)[92] with valency three or higher. In this case axial residues situated perpendic-

ularly to the Pc plane can be introduced leading to a considerable improvement in the solubility of the virtually insoluble original substance[93] (Fig. 13). In the presence of peripheral substituents,[94, 95] the solubility in aqueous solutions or organic solvents is increased. Unsubstituted phthalocyanines (Pc) are easily synthesized in high yield and are compounds of high chemical stability. More important, phthalocyanines are attractive as optical recording media: they have high absorption coefficients $\varepsilon > 10^5$, they are thermally stable, they exhibit virtually no toxicity, they show an excellent stability towards atmospheric effects and they may be applied to the substrate by sublimation or, with appropriate substitution, by spin-coating. Their absorption properties are determined by the rigid, internal 18π electron system as a chromophore. They absorb especially well in the range of HeNe laser radiation (633 nm). In 1981, *Kivits* et al.[70] were the first to propose the use of phthalocyanines as absorbers in storage disks of the WORM type and to expand the range of spectral sensitivity of the particularly suitable vanadylphthalocyanine (VOPc), the absorption maximum

of which is at 730 nm, by thermal treatment;[96] this results in a broadening of the long-wavelength absorption band beyond 800 nm. Using this material, it became possible to produce a recording medium with a weak SNR with the use of a krypton laser (799 nm). A bathochromic shift and broadening of the longest-wavelength absorption maximum of phthalocyanines, e.g. in the case of MgPc, AlClPc, InClPc[97] or TiClPc,[98] may also be achieved by a THF or CH_2Cl_2 solvent or vapor treatment.

It is possible to achieve a bathochromic shift of the longest-wavelength absorption band by the use both of strongly electron-donating and -withdrawing substituents. Thus, in particular, hexadecafluoro derivatives of $Cu^{2\oplus}$, $Zn^{2\oplus}$, $Pb^{2\oplus}$ or $SnCl_2^{2\oplus}$ show high absorptions above 800 nm and are suitable for irradiation with semiconductor lasers.[99] Similar structural modifications, for example by the introduction of peripheral azo or thiol radicals, have been documented in numerous patent applications, predominantly by Japanese companies.[100]

Apart from these few exceptions, the influence of peripheral substituents on the absorption behavior proved to be minimal. However, if the conjugated system is enlarged by benzoannelation to give the naphthalocyanines (Nc) (Fig. 14), then a substantial bathochromic shift of the long-

wavelength absorption band may result. While the absorptions of the 1,2-naphthalic acid derivatives show, in this case, a slight bathochromic shift by 20 nm,[101] in the case of the 2,3-naphthalic acid derivatives shown in Figure 14 this effect is significantly more marked: displacements by more than 100 nm to 752 (PdNc) to 855 ($MnNc(OCOCH_3)$) have been observed.[102] However, by enlarging the π-system, the derivatives are less thermally stable and considerably difficult to synthesize.

The naphthalocyanines are even less soluble than the phthalocyanine compounds, and in most cases cannot be sublimed. In order to increase their range of application, soluble naphthalocyanine derivatives were therefore tested for their suitability as absorbers for write-once disks; this is possible, as with the MPc compounds, by peripheral or axial substitution. The solubility is increased by adding peripheral substituents, e.g. the bulky *tert*-butyl group.[103] Meanwhile, there have been reports of numerous naphthalocyanine derivatives which obtain their solubility by peripheral voluminous or long-chain alkyl radicals,[104] carboxylic acid esters of long-chain alcohols[105] or long-chain polyethers.[106]

The biaxial derivatives of silicon-naphthalocyanine ($SiNc^{2\oplus}$) (Fig. 15)[107] have been noted for their economical

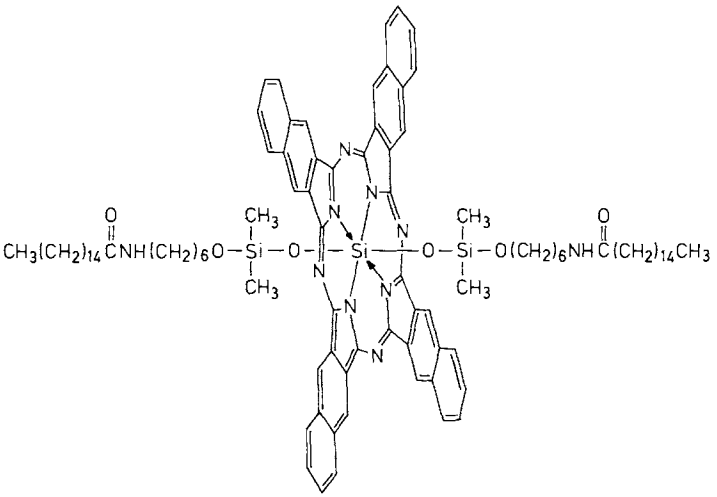

Fig. 15. Bisaxially substituted silicon-naphthalocyanine for WORM media.

synthetic properties as well as their outstanding optical properties. The axial substituents can be selected so that they guarantee adequate solubility as well as representing a type of polymeric matrix preventing the tendency towards crystallization or reagglomeration. Compounds of this type exhibit high absorptions in the range of 780–830 nm, a reflectivity exceeding 30% and a signal-to-noise ratio of > 50 dB.[107b] The use of a soluble, axially substituted aluminum-naphthalocyanine has been reported; in this case, at a write wavelength of 830 nm a sensitivity of 0.7 nJ/per pit, a reflectivity of 25%, a signal-to-noise ratio of 55 dB and a reduction of the signal-to-noise ratio after 1.5×10^6 reading cycles by less than 1 dB (1 mW readout energy at 830 nm) have been observed.[108] The derivatives must be extremely pure in order to reproduce signals without considerable output loss. The most recent patent applications claim naphthalocyanine derivatives for WORM memories, which are both axially and also peripherally substituted.[109] The synthesis of the naphthalocyanine system by peripheral substitution becomes very expensive since the corresponding 2,3-dicyanonaphthalene derivatives must be produced as intermediates. The expenditure and the raw material costs may be reduced by the use of phthalonaphthalocyanines.[110]

The naphthalocyanine derivatives represent an interesting alternative to methine dyes as absorbers of diode laser radi-

ation. Initial prototypes of WORM disks based on naphthalocyanines have already been put on the market.

4.3.3. Quinoid Polynuclear Aromatic Compounds

A further category of dyes to which reference is frequently made in the literature and which can be used as an absorber layer for WORM storage disks comprises the quinoid polynuclear aromatic compounds. The use of these compounds is based on a different concept: the dye molecules are rather small, generally of low solubility and, in contrast to the methine dyes, uncharged, so that they may be applied to the substrate by means of vapor deposition techniques (Figs. 16 and 17).

Although this method of coating is more complex and, in general, more costly, it also has its advantages. For example, where sublimation is carried out, any dissolution of a polymeric substrate is avoided, and the possibilities of providing the substrate with a polymeric intermediate layer to improve the total properties increase.

The most widely investigated group of dyes are amino derivatives of the 1,4-naphthoquinone type (Fig. 16), which have already been known for a long time in the dyeing industry as pigments with a broad color spectrum.[111] In terms of their reflectivity and sensitivity properties, they are less attractive than the known cyanine dye systems but offer higher chemical stability and give storage media with long service life of the data. The systematic examination of 1,4-naphthoquinone derivatives[112] absorbing in the NIR range was extended by *Matsuoka* et al. to anthraquinone, phenothiazinequinone and phenoselenazinequinone derivatives (Fig. 17)[113] and previously developed synthetic strategies by means of PPP molecular orbital computations.[114] In this case, it became evident that the long-wavelength absorption maximum was influenced both by a change in the donor- and in the acceptor-moieties, since the coloration of these compounds is generated by an intramolecular charge transfer. Derivatives of the type shown in Figure 16 contain the combination of a suitable donor and strong acceptors. In solution, they absorb at approximately 770 nm, with high molecular extinction coefficients, and respond to the radiation of commercial laser diodes. At a signal-to-noise ratio > 50 dB, an acceptable reflectivity of up to 25% was observed at 830 nm.[115] The substitution of the free amino group by alkyl or aryl radicals leads to a further bathochromic shift. In 1985, NEC announced a WORM storage disk based on the ethyl ether (Fig. 16, R = C_2H_5). Although these ethers exhibit optical properties which are on the whole acceptable, they have the disadvantage of high output losses on vacuum coating.

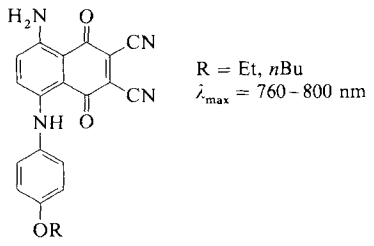

Fig. 16. 5,8-Diamino-1,4-naphthoquinones absorbing in the near infrared.

An improvement in the chemical and thermal stability (and thus in the sublimation properties) has been achieved by the phenothiazine or selenazinequinone derivatives (Fig. 17) and their isomers.[116] These compounds form homogeneous films with smooth surfaces.[117] Their absorption range is between 750 and 850 nm, and strongly electron-withdrawing substituents have a strong bathochromic effect.[118] Structurally related compounds used include specific indanthrene derivatives[119a,b] violanthrones,[119c] and amino-substituted phthaloylacridones.[120]

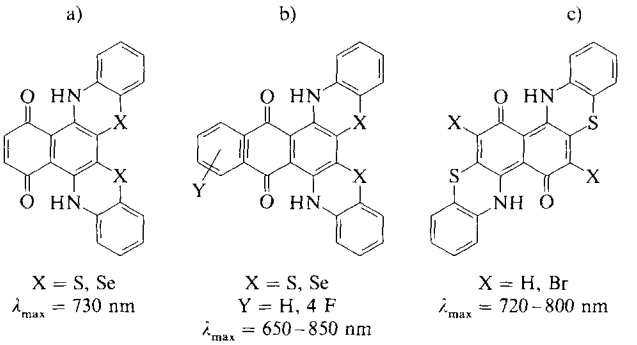

Fig. 17. Infrared absorbing phenothiazine and phenoselenazine derivatives with benzoquinone (a), naphthoquinone (b) and 1,4-diketo units (c).

4.3.4. Metal Complexes

While the phthalocyanine ligand ($Pc^{2\ominus}$) is itself a chromophore, there is a series of colorless, in most cases sulfur-containing ligands which absorb in the visible or near infrared range only as a result of 2:1 complexing by means of a metal ion. The long-wavelength absorption occurs due to the formation of a 10 π electron system in the complex. A typical example is represented by the dithiolatonickel complexes (Fig. 18), which can be isolated as salts or neutral complexes and exhibit absorption bands between 715 and 1300 nm in solution.[121] Other suitable metals are palladium, platinum or alternatively cobalt, copper, zinc and cadmium. In DIP

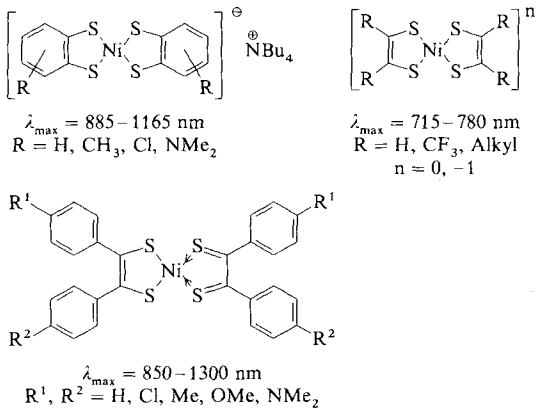

Fig. 18. Infrared absorbing dithiolatonickel complexes.

configurations, an additional bathochromic shift by 20–60 nm is observed, which limits the use of numerous compounds of this type in WORM storage disks.[122] The solubility of the easily accessible original substances[123] in organic solvents is moderate, but can be increased by appropriate substituents so that they can be spin-coated from solvents. However, the reflectivity values observed are distinctly inferior to those of cyanine dyes. For this reason, they probably will not be used alone as absorbers in WORM storage disks.

It has already been pointed out, in connection with the cyanines, that dithiolato complexes are very efficient oxygen traps and thus considerably increase the stability of cyanine absorber layers. In 1985, almost 60 patent applications were filed in which such combinations are claimed. At the present time, there is no precise concept concerning the protection mechanism. Closely related classes of compounds include α,α-diimino-*cis*-1,2-ethylenedithiolatonickel derivatives[124] or complexes in which aromatic *o*-diamines, *o*-aminothiols or *o*-selenols (λ_{max} = 780–900 nm),[125] indoanilines[126] or quinolinediones[127] are used as ligands.

4.3.5. Other Dyes

In addition to the most important classes of compounds which have been outlined in Sections 4.3.1–4.3.4, the patent literature also discloses a whole series of other NIR-absorbing compounds. These include specific aminoarylpentafulvenedicarbonitriles (λ_{max} = 680–785 nm),[128] ethynevinyl di- and triphenylcyclopropanes (λ_{max} = 530–820 nm),[129] and triquinocyclopropanes ($\lambda_{max} \approx$ 770 nm),[130] which can be applied by sublimation or, with appropriate substitution, by spin-coating, polypyrrole (1 nJ/pit at 830 nm)[131] and intermolecular charge transfer complexes with 5-nitro-2,3-dicyanonaphthoquinone as acceptor ($\lambda_{max} <$ 740 nm).[132]

5. Reversible Data Storage

The set of requirements imposed on erasable optical data stores is prescribed by the current specifications of the conventional magnet technology (Winchester disk drives), since the two technologies are designed for the same range of application. The storage densities of the EDRAW media which are in an initial marketing phase, currently amount to approximately 10^8 bit cm^{-2}, while hard disks on average achieve 10^6 bit cm^{-2}.[133–135] An increase in the bit density of magnetic hard disks to 10^7 bit cm^{-2} is under investigation by the use of special preparations of γ-Fe_2O_3 or new types of cobalt alloys.[141, 149] The direction of magnetization for a recording is not altered in the plane of the disk (longitudinal), but perpendicular to it so that magnetic domains <1 μm can be inscribed.[137]

In magnetic high-performance disk drives, the aerodynamic write/read head is guided at a height of approximately 0.1 μm,[136] and therefore it is possible for "head crash" to occur as a result of dust particles and vibrations. The disk-drive must therefore be mounted rigidly as well as protected from dust and other foreign particles. In contrast in the optical process, the corresponding components are situated at a non-critical spacing, which gives substantial insensitivity to particles, as well as no encapsulation of the disk and, in consequence thereof, an exchange facility and secure handling.

In optical data carriers, the density of the guide tracks (8000–9000 tracks cm^{-1}) is higher than with magnetic carriers (1000–1500 tracks cm^{-1}),[138] so that the storage capacity of optical systems is greater by a factor of 10 than that of the Winchester disks.[139, 140] On the other hand, data access via hard disks is considerably faster (8–20 ms) than with optical disks (30–50 ms) and the data rate, approximately 12 Mbyte s^{-1}, is two to three times greater than with optical recording processes. By increasing the speed of rotation to 4000 rpm and using a laser diode array, the data rates for optical media may be increased to 6 Mbyte s^{-1} or $>$10 Mbyte s^{-1}.[142, 143] It is expected that by about 1995 the access times may even be reduced to a value of 20 to 25 ms.[144] General requirements to be imposed on reversible storage media include bit error rates of approximately 10^{-12} (after correction), application cycles exceeding 10^7 and the "direct overwrite" of stored information. In a similar way to the write-once memories, a defined threshold value or a steep progression of the energy/sensitivity curve is required for the reversible types of marking of the EDRAW media. Other conditions include long-term stability of up to 10 years for the archiving of information and compatibility with existing hardware and software.

Several different materials may be used for reversible data storage, but only a few are at the stage of industrial application. It is required that the information can be easily read and erased, and this leads to a conflict which can be resolved only in circumstances in which a material at room temperature exhibits two conditions which can be selectively addressed and switched. However, many materials which are in principle appropriate are altered in their condition of marking when a laser beam is frequently used for readout.

The development of reversibly operating magneto-optical memories and phase transformation media has progressed to a stage at which marketing is imminent. The overview given below therefore concentrates on a description of these processes.

5.1. The Magneto-Optical Effect

The magneto-optical (M/O) effect can be used for the readout of data, since a rotation of the plane of polarization takes place as a result of the interaction of a polarized light beam with magnetic material (Fig. 19).[145] In this way, it is possible to read data markings in reflection (M/O Kerr effect) or in transmission (M/O Faraday effect). Writing and erasure by means of a laser beam is based on the temperature dependency of the magnetization (Fig. 19). A recording medium magnetized perpendicular to the disk is heated at definite positions, and the magnetization is flipped over into the opposite direction by a magnetic field. There are three categories of recording materials used: crystalline intermetallic compounds, amorphous rare earth/transition metal alloys (RETM), and ferrites.

The progression of the magnetization of alloys of rare earths and transition metals is shown as a function of the temperature in Figure 20.[10] The RETM alloys are included

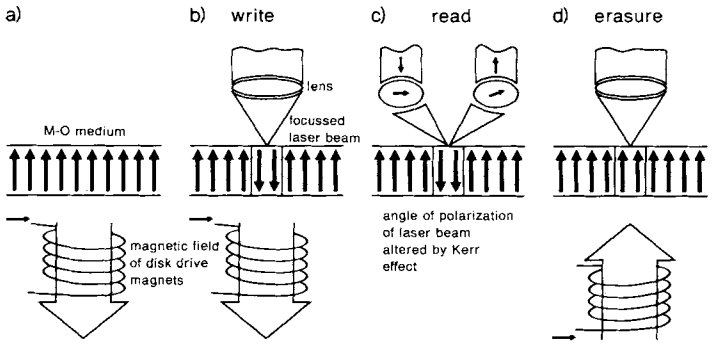

Fig. 19. Principle of magneto-optic (MO) data storage [145]: a) the perpendicular magnetization of the MO-medium is unaffected by magnetic field at room temperature; b) recording via heating by laser beam and turnover of the magnetization via a magnetic field; c) reading via Kerr effect; d) erasing via heating by laser beam and turnover of the magnetization according to original direction.

among the ferrimagnetic substances. The magnetic structure is characterized by the presence of various subunits, which are magnetically coupled and assume an antiparallel orientation. The temperature dependence of the magnetization of the subunits differs, so that the difference represents the spontaneous magnetization of the entire system. In this case, the orientation is perpendicular to the plane of the recording medium (perpendicular magnetic anisotropy). At low temperatures, the magnetic moment of the rare earth atoms is greater; at a higher temperature, the magnetic moment of the transition metal atoms predominates. Accordingly, as a result of the antiparallel configuration, the temperature progression of the total magnetization is characterized by two temperatures. The point of compensation is marked by the temperature (T_{comp}) at which the magnetizations are equal, and the net magnetization of the alloy becomes zero. In the event of an increase in temperature, the magnetic moments of both species of atoms disappear at the Curie point (T_{Curie}) and the alloy material becomes paramagnetic from this temperature upwards.

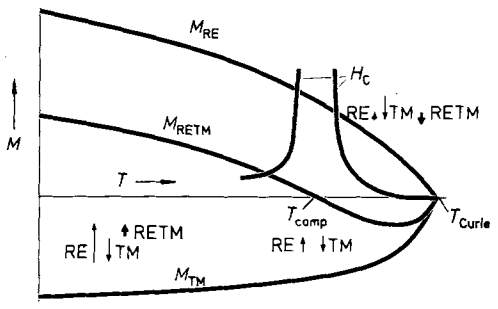

Fig. 20. Temperature dependence of magnetization M and coercitivity H_c of an alloy RETM of rare earth element (RE) and transition metal (TM) [10].

The preferred direction of the total magnetization is given by external magnetic fields. The stronger the external field and the lower the temperature, the more completely the external magnetic field forces the orientation of the elemental magnets in the field direction. On account of the high perpendicular anisotropy, the maximum attainable magnetization, i.e. the saturation magnetization, can be changed only in circumstances in which the external magnetic field reaches a threshold value, i.e. the coercive field strength (H_c). At the compensation temperature, the coercivity of a ferrimagnetic alloy is theoretically infinitely large, so that due to large magnetic coupling, the direction of the magnetization cannot be altered by external fields. Above T_{comp}, the coercive field strength falls again to small values and at the Curie point becomes zero.

Depending upon the writing temperature, a distinction is made between compensation point or Curie point writing. For compensation point writing, T_{comp} is set by the composition of the alloy to room temperature. The writing process takes place with simultaneous heating of the recording medium by a laser beam and application of an antiparallel external field by means of the disk drive magnet. As a result of heating, the coercive field strength diminishes and the direction of magnetization is flipped over in the heated area—the data bit—by application of an external field and read out by means of the Kerr effect. Curie point writing involves the heating of the metallic layer to achieve the elimination of the magnetic order at T_{Curie} and setting of the new preferred direction by an external magnetic field. The erasure process is distinguished from writing only by the direction of the field of the disk drive magnet.

In comparison with the magnet technology, the smaller data rates of the M/O technology are determined by an additional disk rotation, which is required for erasure, in order to create the orginal magnetic orientation on the disk. Thus, a total of two disk rotations must be executed for the writing of new data. Accordingly, M/O disk drives of the next generations will be provided with a direct overwrite device.[146, 147, 149] One possibility is the use of a magnetic head, the field of which switches the data spots heated by the laser in accordance with the bit stream (Magnetic Field Modulation Method). In this way, data rates exceeding 10 Mbyte s^{-1} have been achieved.[148] The distance between the head and the disk is 2–5 μm, so that conditions are not as critical as with the Winchester disk drives.

The layered structure of a storage medium is of prime importance for the optical properties. However, the RETM media adopt a certain special position, since they must be encapsulated with protective layers on account of their sensitivity to oxidation. The protective layers fulfill several functions: a barrier against oxygen, water vapor, substrate, and protective polymer lacquer, an antireflection layer for coupling in the laser light, and thermal insulation of the recording layer in order to keep the temperature of the substrate constant. In most cases, use is made of multilayer structures which, depending upon the construction and layer thicknesses, influence the maximum attainable signal intensity and sensitivity. Thus, reports have been given, for example, not only of simple systems consisting of an M/O layer, antireflection layer and metal mirror, but also of constructions consisting of a barrier film, two different M/O layers and an antireflection layer.[6, 23] In this way, the reflectivity of a RETM medium may be varied between approximately 4 and 30%. The materials used for barrier layers or dielectric layers are in most cases amorphous films of SiN, AlSiN, or BN.[153] Additionally, investigations have been carried out on TiO, TiON, TiN, AlSiON, SiO, AlN, SiON, ZnS and SiO_2.[151] For the setting of an optimal SNR, the materials

of barrier layers must exhibit amorphous structure, low birefringence, high transparency at the laser wavelength, low thermal conductivity, and must by easy to manufacture. The Kerr angle can be increased by appropriate selection of refractive index and layer thickness of the barrier film.[150, 152]

A prerequisite for the magneto-optical data storage is a perpendicular magnetic anisotropy of the recording medium. The causes of the anisotropy have, to date, not been fully clarified; it is generally assumed that three phenomena may occur: spin-orbit coupling, magnetic dipole interaction and magnetostriction.[156, 177, 222–225] However, it has been verified that a relationship exists between magnetic anisotropy and the process of preparation of the RETM layer. Amorphous RETM alloys can be produced by a multiplicity of vacuum coatings: thermal[154a] and electron-beam vapor deposition,[154b] ion-beam sputtering,[154c], RF sputtering,[154d] and DC magnetron sputtering[154e] have all been used with success. Certain properties of the materials can be influenced by the coating process to a far greater extent than by controlling the layer composition.[155] M/O films consisting of RETM alloys are produced by DC magnetron sputtering for the production of data stores.[157]

5.2. Magneto-Optical Materials

The interest in M/O materials for data recording dates back to work by *Williams* in 1956 in the Bell Laboratories; a hot needle was used to inscribe magnetic domains into a manganese/bismuth film which were read out by means of the Faraday effect.[158] Curie point writing using an electron beam was demonstrated in 1958 by *Mayer*,[159] and the Kerr effect was used for the first time for the detection of magnetic domains in 1960.[188] Compensation point writing was attempted in 1965 on $Gd_3Fe_5O_{12}$, a magnetic garnet.[160] Lasers were developed parallel to this work and gained increasing acceptance as a radiation source for writing, reading and erasure. These first M/O materials exhibit a series of properties which prevented large-scale technical use as storage media[161, 162] and led to the development of the RETM alloys, which are today the most important materials for M/O memories.

Chaudhari et al. were the first to show that gadolinium-cobalt and gadolinium-iron films exhibit spontaneous perpendicular magnetic anisotropy.[163] The variation of the compensation point between $-233\,^{\circ}C$ and $+230\,^{\circ}C$ was achieved by the selection of the $Gd_{1-x}Co_x$ composition. At the compensation point the coercivity showed a maximum, which was greatly dependent upon the method of production. In initial writing attempts at the compensation point, it was possible to inscribe data markings. In further investigations, it emerged that the stability of small magnetic domains is very low.

A fundamental disadvantage of GdCo resides in the difficulty of obtaining homogeneous layers with a constant compensation point. The compensation point decreasing from the center towards the edge is based on irregularities of oxygen traces in the layer.[169–173] In terms of magnetic properties, oxidizied gadolinium behaves differently from pure gadolinium; accordingly, the relative proportion of cobalt is increased, and as a result of this the compensation point drops. A difference of 2 atom-% in the cobalt content causes a change of T_{Curie} by approximately 50 K[188] (Fig. 21). It is possible to produce homogeneous GdCo films by applying a negative bias voltage to the substrate.[169, 174] It is assumed that the oxygen content of the film is reduced by increased argon ion bombardment.[169] In this case, an anisotropic distribution of Gd and Co is generated by selective resputtering of gadolinium atoms, and thereby the perpendicular magnetic anisotropy is built up as a function of the bias voltage.[175] A columnar structure is generated in the layer by the processes taking place during sputtering.[176] In other investigations, gadolinium was replaced by holmium[164] ($T_{comp} = 46\,^{\circ}C$) with the composition $Ho_{35}Co_{65}$. The coercive field strength of HoCo films is greater than the comparable GdCo layers, and it was possible to write stable data bits.

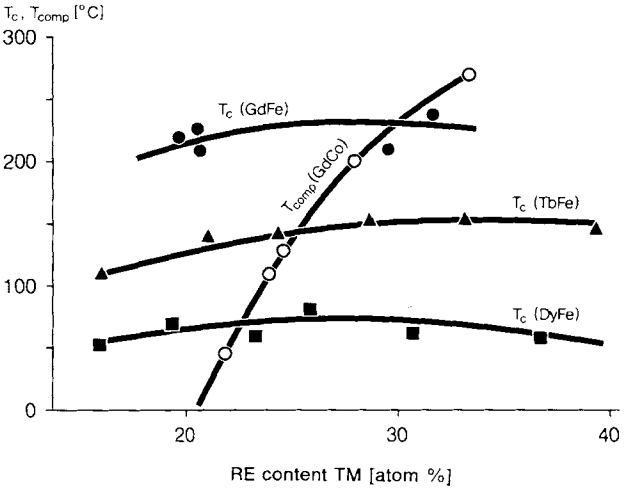

Fig. 21. Curie temperature T_C as a function of rare earth content of GdFe, TbFe, and DyFe alloys and compensation temperature T_{comp} of GdCo as a function of Gd content [188].

In Gd alloys, the replacement of cobalt by iron leads to the lowering of the Curie temperature (T_{Curie})[178–180] and Kerr angle.[181] The coercivity of GdFe alloys is, like that of GdCo, relatively small.[182] The properties of GdFe compounds can also be modified by alloying with other metals: yttrium increases H_c and reduces T_{Curie}; bismuth,[185] tin[186] and lead[187] increase the Faraday and Kerr effects; bismuth and tin cause the lowering of T_{Curie} and T_{comp}.[185, 186] If gadolinium is used in place of terbium in REFe alloys, materials of which the Curie temperatures are approximately 100 K below those of GdFe[188, 189] (Fig. 21) are formed. On going from gadolinium to terbium to dysprosium, the progressions of the T_{Curie} curves are displaced in almost constant intervals by 50–100 K in each case. The Curie temperatures of iron alloys are significantly less sensitive with respect to variation of the rare earth element content (Fig. 21).

In the case of the iron and cobalt alloys of gadolinium, compensation temperature writing is employed; in the case of terbium and dysprosium alloys, Curie point marking is mostly used. On comparing coercive force and spontaneous

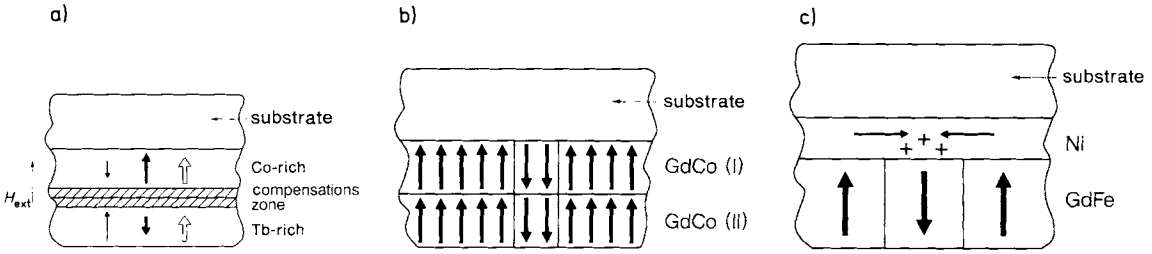

Fig. 22. Principle of MO layers for recording of small domains: a) double layer of TbCo alloy with Co enrichment in the upper and Tb enrichment in the lower film. The arrows indicate the preferred directions of the magnetic moments of the Tb (→) and Co atoms (⇒) as well as of the resulting magnetic netto moment of the layer (→); b) two GdCo layers (I and II) with compensation temperatures $T_{comp}(II) < T_{comp}(I) <$ room temperature; c) small magnetic domains in GdFe via exchange coupling with a nickel layer.

magnetization as a function of the temperature, similar marked differences are found as for the Curie points in the case of the iron alloys with the heavier rare earth metals (RE = Gd, Tb and Dy). GdFe alloys exhibit the already mentioned low coercive field strengths, which lead to instabilities on writing small bit domains. TbFe and DyFe are characterized by coercive field strengths of a few 100 000 A m^{-1} and steep temperature dependence of the magnetization; this is desired for the writing of small domains.

The methods by which the TbFe films are prepared determines to a great extent their properties. Uniaxial anisotropy K_u and saturation magnetization of TbFe films can be varied as a function of the substrate temperature;[190] in contrast, the perpendicular anisotropy of GdFe is almost independent of the substrate temperature. Using X-ray scattering, it was found that during the coating an oxidation of terbium to the suboxide takes place, which causes, at a relatively high temperature, the large drop in the saturation magnetization in terbium-rich films.

The magnetic and magneto-optical characteristic quantities of TbFe layers can, moreover, also be modified by the variation of the film thickness[191] and the pressure of the sputtering gas,[192] and can be optimized by selection of a suitable layer construction with respect to their dynamic write/read/erase properties.[193]

The mechanical conditions applicable to the substrate material can also have an effect on the magnetic anisotropy constant, and can generate orientation effects by anisotropic stresses (magnetostriction), for example in foils as carrier material for magneto-optical layers. Attempts at coating TbFe films onto Kapton foils by RF sputtering led to recording media with a high magnetic anisotropy, which could possibly be used as M/O tapes.[194]

The RETM alloys are particularly oxygen-sensitive and must be protected from the atmosphere for long-term storage. Within the individual alloy systems there are, however, significant differences. RECo films are far less subject to oxidation than REFe layers[165] and exhibit higher thermal stabilities.[167] The write sensitivity is very high in the region of the compensation composition on account of the sharp decline of H_c, so that it is possible to write using lasers of low energy; therefore the stability is greater upon frequent reading.[165]

Alloys of terbium and cobalt have been tested; unlike GdCo, these alloys are more stable and do not contain inhomogeneities of the layer when gadolinium is replaced by terbium. Using homogeneous TbCo films, it was not possible to achieve this;[195] by modulating the terbium/cobalt ratio within a film, it was possible to increase magnetic coercivity and resistance to oxidation.[196] Using bias RF sputtering, cobalt-rich films have been produced at a bias voltage of 100 V and terbium-rich ones without a bias (Fig. 22a). At a negative bias voltage, it is assumed that terbium is preferentially resputtered, so that a relative increase in the cobalt content results. The lattice positions which have become free in consequence of terbium resputtering are clearly occupied by the sputtering gas; this leads to a more porous microstructure and easier oxidizability than in the case of films sputtered without. In this way, films with up to 36 layers may be prepared; these have an average thickness between 80 and 100 Å. Between the layers, compensation zones are formed which result in a homogeneous layer only from a film thickness of approximately 40 Å. By appropriate selection of the layer composition of the terbium-rich layer, the compensation temperature has been set above room temperature so that in consequence of exchange coupling of the magnetic moments between the two layers, a high coercive field strength (ca. 320 000 A m^{-1} and above) is achieved. The Faraday rotation of TbCo media read out in reflection is mainly based on the cobalt sublattice and is less due to the influence of terbium,[197] in contrast to the TbFe alloys, in which both components contribute to the Faraday effect.[198] Effects of the exchange coupling of heterogeneously structured RETM films have also been investigated on GdFe/DyFe and GdFe/TbFe layers.[184]

In many cases the requirement for high write sensitivity is incompatible with the requirement for high domain stability, bit density and a high SNR both for T_{Curie} and T_{comp} writing. By decoupling the writing and reading processes onto two separate layers these weak points are avoided.[184] The write film should ideally exhibit high coercive field strength at a low Curie temperature in order to achieve high sensitivity and domain stability. The read layer must be coupled by means of exchange coupling to the spin moments of the write layer and also exhibit a high Curie temperature and coercive field strength for the transfer of written domains from the write onto the read layer. TbFe and DyFe layers were tested as write films in conjunction with deposition of a GdFe layer as read film.[184] In the case of TbFe/GdFe structures, coercive field strengths increased to a few 100 000 A m^{-1}, and an associated domain stability of up to approximately 1 μm were found. Accordingly, the properties of monofilms consisting of GdCo or GdFe were exceeded.

Another method for writing small magnetic domains consists in the use of two layers of GdCo with differing composition[165-167] (Fig. 22b). The compensation temperature T_{comp} of the upper layer (I) is set by the ratio of Gd to Co to be somewhat below room temperature, and T_{comp} of the lower layer (II) is below T_{comp} of the upper film. This means that at room temperature the saturation magnetization M_s and the demagnetizing field H_d of the upper layer are small (the field lines of an upwardly directed magnetic domain penetrate the surrounding layer in the reverse direction and therefore act in the sense of a demagnetizing field), while M_s and H_d are greater in the lower layer. In this way, domains of the upper film are stabilized. This also applies to the case in which the preferred direction of the anisotropic magnetization is not exactly vertical, but tilted.[168]

Small magnetic domains in the μm range can also be written with the aid of a layer of ferromagnetic material[183, 184] (Fig. 22c). It is assumed that by vapor deposition of a nickel film on the GdFe recording layer a written magnetic domain is stabilized by the formation of a locally closed domain in the longitudinally magnetized Ni film. The coercivity of the entire GdFe–Ni structure becomes greater and a higher magnetic field strength is required to switch the data bit.

Ternary and quaternary alloys of rare earths and transition metals open up a multiplicity of design possibilities for structure/property relations. The search for technically suitable M/O materials extends on a preferential basis to alloys of such transition elements as iron and cobalt with the heavy lanthanoids gadolinium, terbium, dysprosium, holmium, erbium, neodymium, praseodymium and samarium[10, 189] (Fig. 23a). In addition, films of the most widely varying

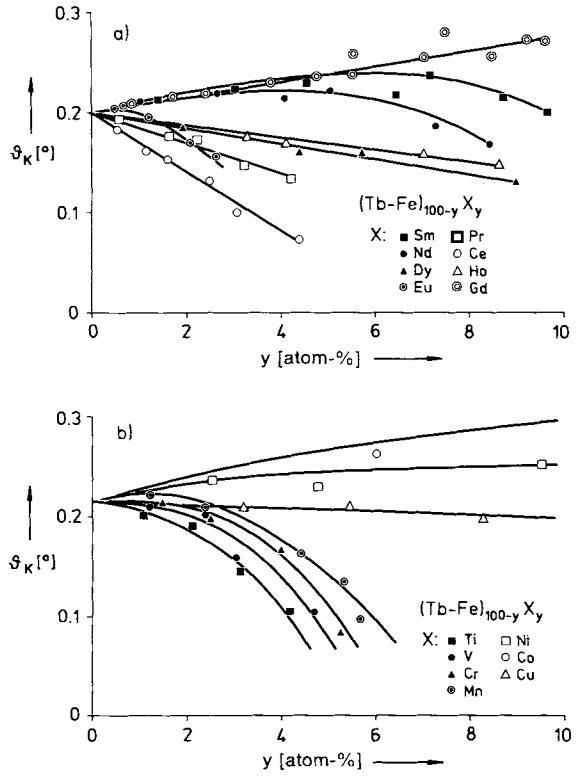

Fig. 23. Kerr rotation angle ϑ_K of $(FeTb)_{100-y}X_y$ alloys as a function of the composition. a) X = rare earth element. b) X = transition metal [189].

ternary and quaternary alloys have been described: with cerium, promethium and europium as rare earth elements,[189] and titanium, vanadium, chromium, manganese, nickel and copper as transition metals[199] (Fig. 23b), as well as various doping elements such as bismuth,[185] tin,[200] lead,[187] germanium,[201] molybdenum, gold,[202] silver, palladium, platinum[199] and uranium.[203a] In Figure 23 the Kerr angle ϑ_k of some ternary Tb-Fe alloys are shown as a function of the content of the third alloying component.

The number of the most promising alloys is, however, for marketable products, relatively small, and restricted to the GdTbFe, TbFeCo systems and their four component alloys with dysprosium and neodymium respectively. By using ternary GdTbFe alloys, it is possible to combine the properties of TbFe and GdFe:[206] the Kerr angle (ca. 0.30°) is about the same (TbFe 0.25°, GdFe 0.30°; at $\lambda = 800$ nm),[155] the Curie temperature (between 150–180 °C) is reduced as compared to GdFe (200–250 °C),[204] and the coercivity is increased.[203b]

Dynamic memories and reading experiments with GdTbFe films[205-207] demonstrate the usefulness of this ternary alloy system. In initial experiments, bit error probabilities of 10^{-3}–10^{-4} and 10^7 intact write cycles were obtained.[207] The magneto-optical rotation was optimized using different metal reflection layers (Au, Cu, Ag) and dielectric films (SiO_2).[208] By using a quaternary alloy of GdTbFe with dysprosium, it was possible to increase the signal from 0.7 (at 800 nm) to 1.7 (at 700 nm). By replacing gadolinium by dysprosium in ternary RETbFe alloys, the Kerr angle (Fig. 23a) and the Curie temperature are reduced.[208] The Kerr effect can be increased by a three-layer structure of Cu reflection layer, DyTbFe, and SiO_2 dielectric. The write process was executed with an 8 mW semiconductor laser. The optical transmission of the write/read/erase head showed approximately 44% power loss, so that it was possible to measure 4.5 mW write power and 2 mW read power on the disk. The prerequisites for the writing of magnetic domains < 1 μm were satisfied by a coercive field strength of ca. 80000 A m^{-1}, and the erasure of data bits could be performed by means of a 12000 A m^{-1} magnetic field.[208] The bit density of this system was quoted as being 1.5×10^7 bit cm^{-2}.

As shown for the binary REFe alloys, together with an increase in the order number of the lanthanoids it was possible to detect a lowering of the Curie temperature, even for ternary alloy systems (Fig. 24).[16] This applies in the same

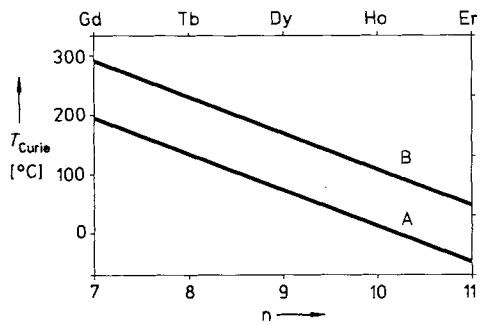

Fig. 24. Variation of Curie temperature T_{Curie} with substitution of rare earths for Tb in $(Tb_{1-x}Y_x)_{0.2}Fe_{0.8}$ (curve A) and in $(Tb_{1-x}Y_x)_{0.2}(Fe_{0.9}Co_{0.1})_{0.8}$ (curve B) where x is determined by the average number of 4f electrons in the alloy; $0 < x < 0.1$ [209].

way to iron and cobalt alloys; the Curie temperatures of the cobalt compounds are generally higher. The particular influence of the cobalt is also shown in comparison with the other transition elements. The curves in Figure 25 indicate the change in the Curie temperature of the amorphous Tb-Fe-

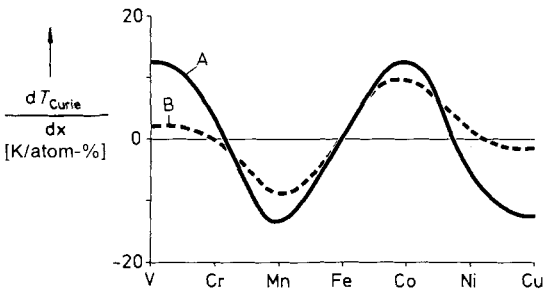

Fig. 25. Variation of Curie temperature T_{Curie} with substitution of small amounts of various transition metals (TM) in amorphous $Tb_{0.2}(Fe_{1-x}TM_x)_{0.8}$ (curve A) and in crystalline $Fe_{1-x}TM_x$ (curve B), respectively; $0 < x < 0.1$ [16].

transition metal alloys (A) and crystalline Fe-transition metal compounds (B) as a function of the transition metal (up to 10 atom-%) for several transition metals. Thus, with a fixed lanthanoid content, the Curie temperature can be set by the ratio of two transition elements.

The temperature dependencies of spatial arrangement, electron interaction, spin moment and exchange coupling give the interelations between magnetization, Curie temperature and Kerr effect.[209, 210] Figure 26 shows a plot of the

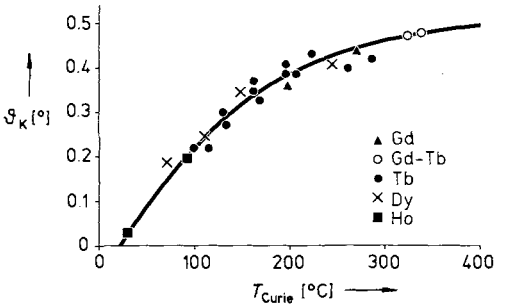

Fig. 26. Kerr rotation angle ϑ_k versus Curie temperature T_{Curie} for various rare earth substituted FeCo-alloy films. [209]

Kerr angles of several rare earth element-substituted FeCo alloys versus their Curie points. It is evident that for a magnetization which is higher at room temperature a larger Kerr angle results. In the case of alloying cobalt with TbFe and GdFe, the Kerr angles increase. The effect is particularly marked in the case of TbFe: in a $Tb_{16}Fe_{84}$ alloy, the Kerr angle increases from 0.18° to 0.37° for $Tb_{16}(Fe_{0.7}Co_{0.3})_{84}$; at the same time, the Curie temperature increases 4 K/atom-% Co.[211]

TbFeCo films are used in the majority of commercial storage disks,[212] accordingly, they have been extensively investigated. The properties of a M/O layer consisting of TbFeCo may be varied by the ratios of the components within very wide limits. $Tb_{28}Fe_{60}Co_{12}$ (RE-rich) and $Tb_{22}Fe_{68}Co_{10}$ (TM-rich) films were investigated for their use as storage media and were characterized with respect to their magneto-optical parameters.[213] Both layers exhibit a Curie temperature of 200 °C; however, there are differences in the saturation magnetization and coercive field strength. The storage layer with the larger iron content shows a higher saturation magnetization than the terbium-rich film. The marked magnetic domains become larger with increasing laser power and external field strength as a result of the dissipation of thermal energy and the consequent profile of the coercive field strength H_c in the layer. The domain size can be computed from the temperature progression in the film, assuming a gaussian distribution for the intensity of the laser beam, and to a first approximation is given by Equation (a) where

$$T(r)\ [°C] = 120 \exp(2r^2/0.6^2) + 80 \qquad (a)$$

r [μm] is the distance from the focal point to the laser source. This term is based on the assumption that at the focus the Curie temperature of 200 °C is reached and the laser beam has a radius of 0.6 μm.

With the aid of this equation and of the temperature dependence of H_c, the distribution of the coercive field strength $H_c(r)$ in the layer can be computed (Fig. 27). The domain

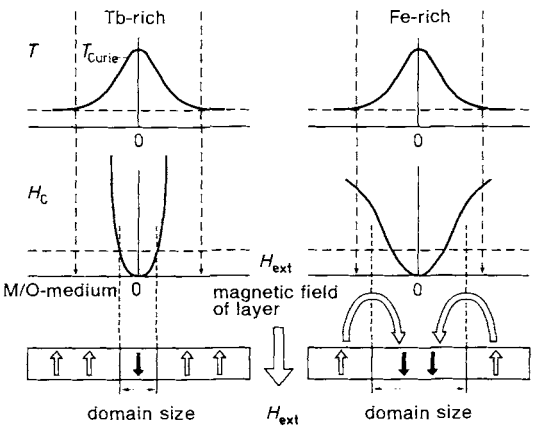

Fig. 27. Domain formation model for MO recording. [213] The profil of temperature T and coercivity H_c are represented for a Tb-rich ($Tb_{28}Fe_{60}Co_{12}$) and an Fe-rich ($Tb_{22}Fe_{68}Co_{10}$) film. The domain size in a Tb-rich film is smaller than in an Fe-rich film due to differences in saturation magnetization. The vertical dashed arrows in the upper part of the figure demonstrate the width of the laser beam. The horizontal dashed lines indicate the initial niveaus of T and H_c of the films.

radius r_s is then obtained from the balance of the magnetic fields in the layer [Equations (b) and (c)] as radius of the

$$H_c(r_s) = H_{ext} + H_d \qquad (b)$$

$$M_s = \chi \mu_0 H_d \qquad (c)$$

$$H_c(r_s) > H_{ext} + H_d \qquad (d)$$

circle in which (d) applies. χ is the magnetic susceptibility, μ_0 the magnetic induction constant and M_s the saturation magnetization. H_{ext} is the external magnetic field which is applied to switch the heated data spot and together with the magnetic field H_d generated by the recording layer must be greater

than the coercive field strength $H_c(r_s)$, in order to mark a pit (see Fig. 27).[213]

In consequence of the high saturation magnetization of the iron-rich layer, the demagnetizing magnetic field H_d of the $Tb_{22}Fe_{68}Co_{10}$ film is greater than that of the terbium-rich $Tb_{28}Fe_{60}Co_{12}$ film. In the case of an equal external magnetic field H_{ext}, the progression of $H_c(r_s)$ in the iron-rich layer is substantially broader due to the differing H_d fields, so that larger domains are written. This can be an advantage when the storage disk is rotated at high speeds and the temperature profile generated in the recording layer becomes narrower (high speed recording).

Media with a write characteristic comparable with that of the terbium-rich film are particularly suited for high recording densities. The demagnetizing field H_d generated by the magnetization of the magneto-optical film can, if the composition is suitable, become so large that the coercive field strength of the heated data spot is exceeded and writing can take place without an external magnetic field H_{ext}; this is true, for example, of $Tb_{22}Fe_{69}Co_9$ and $Tb_{26}Fe_{59}Co_{15}$. The form of the data spots is dependent upon the ratio of the individual magnetic fields on writing and erasure respectively and has an effect on the signal-to-noise ratio;[214-218] heat dissipation in the layer structure of the storage medium represents a significant boundary condition. The laser beam propagates heat, and therefore heat sinks in the form of insulating dielectric layers are introduced, which are located between the metallic reflection layer and the storage medium.[208] The dimensioning of such multi-layer structures consisting of an antireflection layer, a storage layer and a reflection layer as well as dielectric, requires considerable optimization. The radial temperature distribution in magneto-optical media has accordingly been the subject of numerous investigations, especially from the point of view of influencing the SNR.[216]

The modulation noise N_{mod} is the noise difference before and after writing, which can be measured on scanning the data markings and is a measure of the regularity of the magnetic domains. The smaller N_{mod} the greater is the optimally attainable SNR. As a result of an inhomogeneous temperature distribution (caused in consequence of fluctuation of the layer composition or within the laser beam) in a heated data spot, differences in the magnetization may arise between the center and the edge zone. Under particular conditions, these differences may become so large that instead of punctiform domains annular ones are written. These irregularly shaped data spots increase the modulation noise and reduce the SNR.

By way of analogy with the binary alloys, the SNR can be increased by specific layer structures. TbFeCo was used to produce layered films by means of sputtering, with which high SNRs were attainable.[217] The optimization of the signal-to-noise ratio, which is proportional to $\vartheta_k\sqrt{R}$ (R = reflectivity, ϑ_k = Kerr angle), was described for three-layer storage systems using TbFeCo and DyFeCo alloys.[218] The most suitable layer thicknesses for the dielectric film are those given at the largest possible Kerr angle and low reflectivity. Using $(Nd_{13}Dy_{87})_{30}(Fe_{84}Co_{16})_{70}$ films, data rates of 10 MByte s^{-1} for 5.25″ disks at 50 dB for the SNR value were achieved in dynamic write tests.[221] Moreover, investigations were carried out on quaternary RETM alloys of the TbXFeCO[219] and GdXFeCo type,[220] where X = Dy, Ho, and Er, in order to modify Curie temperature, coercive field strength, Kerr angle and magnetic anisotropy.

In contrast to the amorphous RETM alloys, ferrites are air-stable M/O materials which are capable of being used without costly protective layers. Recently, these oxides gained renewed importance after having lost significance for reasons associated with the difficult process technology and inadequate quality of reproduction.[239] Ferrites are mixed oxides consisting of trivalent iron and various metal cations which crystallize with spinel, garnet or hexagonal type structures.

In the field of data stores, hexagonal ferrites have been recognized as hard magnetic pigments for the magnetic technology.[226] As far as M/O storage is concerned, barium ferrites $BaFe_{12}O_{19}$ with a magnetoplumbite structure are of special interest. The barium ions can be replaced by strontium, lead or in some cases calcium ions, or alternatively by equimolar quantities of M^I (Na, K, Rb etc.) and M^{III} (La, Pr, Gd etc.). There are five magnetic sublattices with differing spin orientation of the $Fe^{3\oplus}$ ions. At a wavelength of 788 nm, $BaFe_{12}O_{19}$ shows a Kerr rotation of 0.22° which increases on partial replacement of the $Fe^{\oplus}$ by $Co^{2\oplus}$/$Ti^{4\oplus}$.[227] The coating of the substrate with a ferrite film can take place by epitaxy from the melt[228] or by reactive sputtering on glass disks at substrate temperatures above 550 °C.[229]

Ferrites having a spinel structure have the general composition MFe_2O_4 (M = $Co^{2\oplus}$, $Mn^{2\oplus}$, $Ni^{2\oplus}$, $Zn^{2\oplus}$ etc.). At 700 nm, chromium-substituted and rhodium-substituted cobalt spinels $CoM'_xFe_{2-x}O_4$(M′ = Cr, Rh) exhibit Kerr angles of approximately 0.3–0.5°. The Curie temperature of the cobalt spinel (x = 0) is 520 °C. The very high rate of heat loss, which arises in the course of the Curie point writing of thin layers of these materials, can be reduced by incorporation of a dielectric layer into a three-layer structure of the storage medium.[231] As a result of the incorporation of chromium or rhodium, the Curie temperature of the cobalt spinel is reduced: $M'_x = Rh_1$, $T_c = 62$ °C; $M'_x = Rh_{1.5}$, $T_{Curie} = -113$ °C; $M'_x = Cr_1$, $T_{Curie} = 107$ °C.[230] On account of the high saturation magnetization, domains are marked at T_{Curie} without an external magnetic field. In order to improve the magneto-optical properties, the combination of ferrites in mutually superimposed film layers was also tested, and, for example, using $NiFe_2O_4$ and $CoFe_2O_4$,[232] it is possible to produce aluminum-cobalt ferrites $CoAl_xFe_{2-x}O_4$ as film by sintering at 1250 °C; as the aluminum content rises, the Curie temperature falls from approximately 500 °C (x = 0.1) to 150 °C (x = 1.0).[233]

Ferrites having a garnet structure—$M_3Fe_5O_{12}$ (M = Y, Gd, Dy, Ga, Tb; $M_3 = M^IM^{II}M^{III}$)—are similar to the rare earth/transition metal alloys. In garnets of the type $Gd_{3-x}Bi_xFe_5O_{12}$, a displacement of the compensation temperature was measured as a function of x; $\Delta T_{comp} = 135$ K per atom-% Bi.[234] The sublattice of the $Gd^{3\oplus}$ ions couples antiparallel to the $Fe^{3\oplus}$ sublattice. At low temperatures, the moment of the rare earths is greatest, while at higher temperatures that of the iron ions is predominant. In the middle temperature range, a compensation temperature occurs.

In a similar way to the case of the RETM alloys, the magnetic anisotropy constant K_u is dependent on the condi-

tions of the film preparation, which can vary widely when the layers are prepared by liquid-phase epitaxy on the one hand and by sputtering on the other.[235] In spite of their outstanding physical and chemical stability, magneto-optical films consisting of ferrites are at present not yet suitable for industrial application in commercial products since the Curie temperatures are too high and light absorption and surface smoothness are too low. As a result of the crystalline structure, the signal noise is very high compared to that of the amorphous RETM materials. The possible coating methods for magneto-optical oxides require high temperatures ($>500\,^{\circ}C$), so that the use of polymeric substrates demands the development of special processes. $(GdBi)_3(FeAlGa)_5O_{12}$ could be sputtered by using a garnet target while maintaining a substrate temperature of 100 °C using an RF magnetron.[236] Composite films of RETM alloys and garnets have been produced, with the objective of combining sensitivity and storage density of amorphous compounds with the large Kerr angles of the crystalline ferrites. $(BiY)_3(FeGa)_5O_{12}$ layers have been covered with DyFe[237] and TbFe.[238] The Kerr angles of the composite layers were greater by a factor of 10 compared to the values of the amorphous compounds.

5.3. Materials for Reversible Phase Change

Reversible phase change of inorganic materials is the second alternative to the magnet technology which is currently under intensive investigation. Transitions between light-scattering crystalline and highly reflective amorphous phases permit the switching. The crystalline materials—alloys of elements of the fifth and sixth main group—change into an amorphous phase after pulsed laser irradiation from the melt with rapid cooling. The crystalline phase is formed again by extended heating beyond the glass point. The advantages of this storage technique are the simple optical system of the disk drive and high stability of the medium. Disadvantages are the incomplete recrystallization in the event of frequent overwriting, thus deforming the atomic lattice and destabilizing the inscribed information on repeated reading.[146, 240] This can be reduced by matching the laser energy to the number of cycles.[241]

The reversible properties of amorphous tellurium alloys were observed for the first time by *Ovshinsky*.[242] Using electron microscopy, it was found that amorphous and crystalline phases respectively are present which differ in their reflectivity.[243] The rates of crystallization from the amorphous condition were investigated on various materials and were ascribed to crystallization effects intensified by photons.[244] Other authors have not confirmed this finding.[246] In principle, the possibilities exist of writing either by the change from amorphous to crystalline or from crystalline to amorphous. *Von Gutfeld* et al. were the first to propose the phase change from crystalline to amorphous as a writing mode[245] which is also referred to as RM (*R*everse *M*ode) recording.

The advantage of this mode of data marking is that the crystallization rate limits the switching speed in the amorphous-crystalline mode. This is of importance with regard to computer application with the shortest possible write times; where erasure from amorphous to crystalline is concerned, longer switching times can be tolerated. Figure 28 represents the temperatures and pulse times for writing, reading and erasure in the case of RM recording. Before being used, the storage medium is heated by a floodlight (approximately

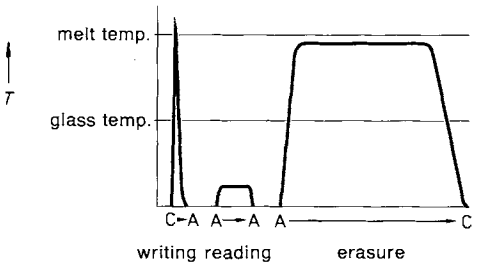

Fig. 28. Principle of reverse mode recording with amorphous (A) to crystalline (C) phase change materials [6]. The width of the signals corresponds to the pulse duration.

1–10 μs), in order to crystallize the film for the starting condition. Using short pulses—approximately 100 nsec and shorter—the marking of the amorphous domains takes place at high laser power. In this case, the material is melted briefly so that the crystalline arrangement is destroyed. After the pulse, the medium cools down at cooling rates of 10^9–$10^{11}\,K\,s^{-1}$, whereby the formation of a regular crystal lattice is prevented. The read beam has only a fraction of the energy of the write beam, in order to permit the appearance of changes even at very high numbers of cycles ($>10^6$). The energy of the erasure beam is selected so that the storage medium is heated beyond the glass point and recrystallization commences.

The particular objective of current developments is to increase the speed of switching (crystallization) and the stability at room temperature in order to guarantee data security. However, the improvement of the stability is also in most cases associated with longer crystallization times and results in longer pulse times for erasure. Within these conflicting requirements there resides a fundamental difficulty regarding the development of phase-change materials which can be used on a technical scale. The extension of the crystallization can, for example, follow from a phase separation taking place simultaneously during the crystallization since in this case diffusion-controlled transport processes limit the speed of crystallization.

Reference will be made herein to some current materials. High linear bit densities of 0.63 μm per bit were achieved with a PbTeSe alloy, which permitted, in a specific practical form, an increase in the density to 0.50 μm per bit.[247] In this way, it is possible to store approx. 1 GByte data capacities per side on a 5.25″ disk. Depending upon the tellurium content, indium-containing films of the $In_{50-x}Sb_{50}Te_x$ type may be switched very rapidly: with x = 1, 2, 5, 10 and 20, a pulse width of 50, 70, 90, 300 ns and 1 μs respectively was measured for the recrystallization from the amorphous phase.[248]

InSeTlCo alloys show a rapidly switchable phase change from amorphous to crystalline: the phase transformation takes place in 60 ns at a laser power of 14 mW[249] (Fig. 29). Based on a crystallization temperature of 320 °C and an acti-

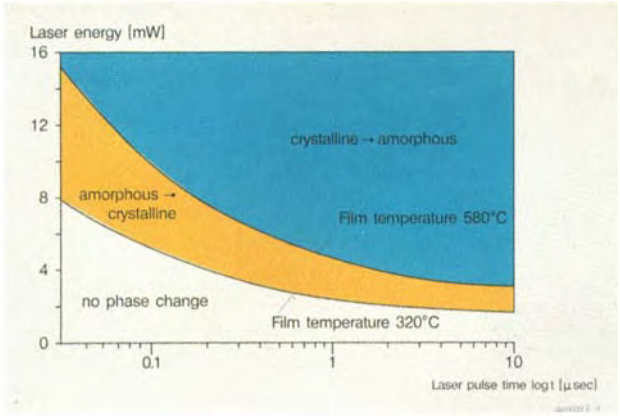

Fig. 29. Laser energy and pulse duration for the reversible phase transformation of an InSeTlCo alloy at two film temperatures [249].

vation energy of 3 eV, the result is approximately 100 years for the lifetime of amorphous domains. During recent times, progress has been reported regarding GeTeSn,[250] GeTeTi,[251] and InSePb[252] alloys.

6. Summary and Outlook

As a result of the success of CD technology, the development of write-once (WORM) and reversible (EDRAW) storage disks to the stage of marketing readiness has become a matter of prime importance in industry during recent years. The IR emission of the semiconductor lasers employed as light source makes the synthesis of novel IR-absorbing dyes necessary for WORM recording media. Specific compounds of the category of the polymethines, phthalo- and naphthalocyanines and dithiolatonickel complexes have already been used with success. In addition, metal alloys have been recognized to permit storage by means of a phase change. WORM memories are mainly used for data archiving; accordingly, a high degree of data security over long periods of time is required. Due to the sensitivity to oxidation of the inorganic WORM layers, there are some advantages of the dye media.

The most highly developed EDRAW memories are represented by the magneto-optical films consisting of rare earth/element/transition metal alloys. It is expected that they will be able to replace the currently dominant mass memories on the basis of magnet technology within broad fields. Their advantages are relatively high storage density, insensitivity to mechanical stress, and easy exchangeability and thus they follow the development trends of computer technology.

Developments of new optical disk drives will be a great incentive with regard to storage media. The use of optical reading systems based on laser arrays, of integrated optical systems together with polymeric optical waveguides, and of lasers with frequency doubling to generate smaller wavelengths will open up possibilities for further increasing the data rates and storage densities. In the near future, this will also initiate the production of novel recording layers. Alternatives to the memories discussed above could be represented by storage media which are based on photochromic dyes,[253] liquid-crystal polymers,[254] Langmuir–Blodgett films,[255] demixing effects in polymers,[256] crystallization effects in doped polymer matrices,[257] specific fluorescence dyes,[258] luminescence in doped aluminum oxide,[259] or storage processes utilizing the piezoelectric or pyroelectric effects,[260] scanning tunneling microscopy,[261] the birefringence relaxation of stretched dye–polymer films,[262] and the LIESST effect (*L*ight *I*nduced *E*xcited *S*pin *S*tate *T*rapping).[263] With other recording processes, the information densities of the industrially produced optical memories may even be exceeded: photochemical hole burning 10^{11} bit cm^{-2},[264] electron beam solid state memories 10^{12} bit cm^{-2}[265] and holographic memories 10^{14} bit cm^{-2}.[265] These recording media and processes have no practical significance yet; however, they form part of intensive research and development efforts as is evident from a research program of the Japanese MITI[266] and more recent publications in the field of photochemical hole burning.[267]

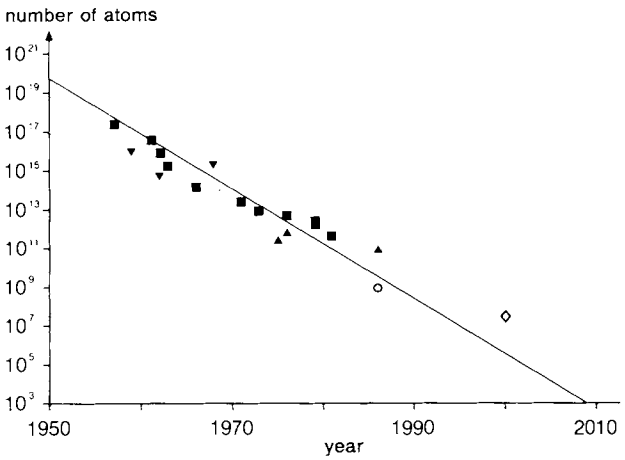

Fig. 30. Comparison for different storage technologies of number of atoms used to store a bit; the line represents the development of future technologies (after [2c]). ■ = Fixed disk, ▲ = magnetic bubble memory, ▼ = thin layer technique, ○ = optical memory, ◇ = molecular storage.

Projects which are concerned with the construction of molecular switches and molecular storage elements are framed in terms of molecular dimensions.[268] This work is concerned with the construction and the characterization of isolated simple models for investigating fundamental phenomena and the further development of model concepts concerning possible modes of operation of molecular memories.

In this connection, conceptual considerations take account of the significance of molecular order and supramolecular structures. Against this background, attempts have been made to utilize phenomena of self-organization in order to generate orientation and structure. Thus, there are parallels with the biological information system, which is characterized by the formation of highly ordered molecular systems. It appears that even future information systems can be developed using concepts which are based on principles realized in nature.

We express our thanks to Dr. B. Fischer, Dr. B. Löhr, and Dr. W. Wiedemann (Information Technology Division of Hoechst

AG, Wiesbaden) for helpful discussions, to Mrs. P. Sendelbeck, Mrs. S. Nink, Mrs. E. Himburg, Mrs. U. Jensen and Mrs. U. Kletschke for typing the article, and to Mrs. G. Wettlaufer and Mr. M. Utermark for the graphical material.

The Crystal Chemistry of High-Temperature Oxide Superconductors and Materials with Related Structures

By Hanskarl Müller-Buschbaum*

Dedicated to Professor Wolfgang Hilger on the occasion of his 60th birthday

Never before in human history has a chemical substance been the object of collaborative research by so many scientists of different disciplines as in the case of the first high-temperature (HT_c) oxide superconductor $La_{2-x}Sr_xCuO_4$. If the importance of a class of materials is measured by the number of papers published in a given period, the new superconductors hold the all-time record; moreover, this flood of publications also reflects the high expectations that are held worldwide for this class of substances. Every day seems to bring further surprises. From the two phases of HT_c oxide superconductors that were recognized at the outset there have developed within a period of scarcely two years a series of new materials which all show superconductivity at temperatures above the boiling point of liquid nitrogen; this property is undoubtedly closely related to the crystal chemistry of the individual phases and compounds. This article will report and discuss the resemblances and differences between the HT_c superconductors and materials with related structures.

1. Introduction

Twelve years ago when, in this journal,[1] I reported the crystal chemistry of oxometalates with planar coordination, despite taking a speculative view of these compounds I did not dare to guess that one of them, La_2CuO_4,[2, 3] with slight modifications, was to be the cause of a revolution.[4]

The original work on compounds of the general formula A_2MO_4, which form crystals of the same type as K_2NiF_4 (see structure in Fig. 1a), was concerned with the elongation of the MO_6 octahedra along the tetragonal c axis. An increase in the Cu–O or Ni–O interatomic distance is also observed in the compounds La_2CuO_4 (cf. Fig. 1b) and Nd_2NiO_4, whose structures are orthorhombically distorted variants of the K_2NiF_4 type.[5] In compounds of the formula A_2MO_4 where M is a Jahn–Teller-active ion such as Ni^{3+}, Mn^{3+}, or Cu^{2+}, the observed elongations of the MO_6 octahedra parallel to the c axis are 15% for $SrLaNiO_4$,[6] 21% for $SrNdMnO_4$,[7] and 29% for La_2CuO_4.[4, 8] When the Ni^{3+}, Mn^{3+}, or Cu^{2+} ions with octahedral coordination are replaced by Jahn–Teller-inactive ions such as Cr^{3+}, Al^{3+}, Co^{3+}, or Ni^{2+}, it is found that the MO_6 octahedra are also stretched along the [001] direction. The experimentally determined values of the octahedral stretching (M–O distances along the [001] direction relative to the M–O distances in the a/b plane) are 4% for $SrNdCrO_4$,[7] 11% for $SrNdAlO_4$,[9] $SrCeAlO_4$,[9] and $SrSmAlO_4$,[8] 5 to 11% for La_2CoO_4 and Sm_2CoO_4,[10] and 11% for Nd_2NiO_4.[5] These examples show that oxometalates with the K_2NiF_4

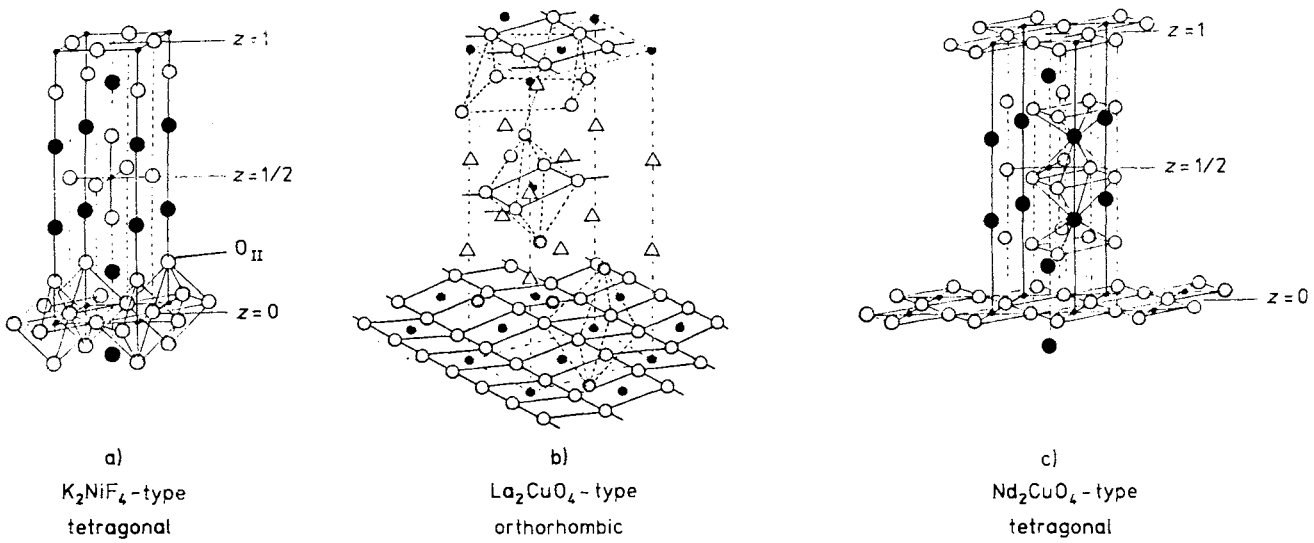

Fig. 1. Structure of compounds with the general formula A_2MO_4. z is a positional parameter. O_{II} denotes oxygen at lattice position II. a) K_2NiF_4-type structure. ● = K^+ (≙ A^{y+}), • = Ni^{2+} (≙ M^{x+}), ○ = F^- (≙ O^{2-}); $2y + x = 8$. The octahedra around the small ion M are shown. b) La_2CuO_4-type structure △ = La^{3+}, ● = Cu^{2+}, ○ = O^{2-}. The octahedra around Cu (small filled spheres) are shown by broken lines. c) Nd_2CuO_4-type structure with planar CuO_4 coordination. ● = Nd^{3+}, • = Cu^{2+}, ○ = O^{2-}.

structure or the orthorhombically distorted La_2CuO_4 structure exhibit an octahedral stretching which depends on the structural type. They also show that Jahn–Teller-active ions cause a significant increase in this elongation. This effect is largest for Cu^{2+}.

Naturally there was interest in discovering the cause of the structure-dependent octahedral stretching, especially since it seemed to bring the comparatively widely separated upper and lower apical oxygen atoms of the MO_6 octahedron (O_{II} in Fig. 1a) much too close to the bulky A atoms in A_2MO_4. The calculated lattice energy as a function of the z parameters of O_{II} and A (at the point $00z$ in each case) is shown in Figure 2 in the form of an energy surface diagram. There is

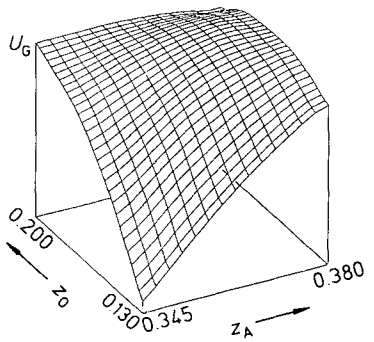

Fig. 2. Lattice energy U_G as a function of the parameters z_O (O_{II}, see Fig. 1a) and z_A in A_2MO_4 compounds (K_2NiF_4 type).

an optimum lattice energy at a position which is in good agreement with the experimentally determined z parameters of the O_{II} and A atoms. The octahedral stretching found in every case is therefore a consequence of the minimization of lattice energy. Before the discovery of the oxide superconductors, there was also interest in the electronic structures and magnetic properties of oxometalates of the K_2NiF_4 type,[11–23] and in structures of this type formed by substituting other atoms in place of A and at the same time altering the valence of the ion M.[24–30]

X-ray diffraction studies on microcrystalline samples initially suggested that all compounds with the general formula Ln_2CuO_4 (Ln = lanthanoid) crystallized with the K_2NiF_4-type structure.[31–34] However, a structure determination on single crystals gave the surprising result that the Cu^{2+} ions in Nd_2CuO_4 were coordinated not in an octahedral but in a planar fashion. This structure is shown in Figure 1c alongside the orthorhombic La_2CuO_4 structure (Fig. 1b) and the tetragonal K_2NiF_4 structure (Fig. 1a). This discovery stimulated further work which soon revealed that all the other lanthanoid elements capable of forming compounds of the general formula Ln_2CuO_4 (i.e., Sm, Eu, and Gd) give compounds with Cu^{2+} in a planar environment.[4] The same also applies to mixed crystals such as $NdGdCuO_4$, $NdSmCuO_4$,[36] and $LaNdCuO_4$.[37] Also relevant here is a study of the magnetic properties of the compounds Ln_2CuO_4 (Ln = Nd or Pr),[38] in which the remarkable assumption was made that the strongly reducing ion Pr^{3+} was present alongside Cu^{2+}. In summary, it should be emphasized that La_2CuO_4 is the only lanthanoid oxocuprate, Ln_2CuO_4, in which Cu^{2+} is coordinated in a (stretched) octahedral fashion.

2. The First HT_c Oxide Superconductor: $La_{2-x}Sr_xCuO_4$

The discovery of the first HT_c oxide superconductor[39] was followed by an unprecedented flood of publications on the physical properties of superconducting phases with the general formula $Ln_{2-x}M_xCuO_4$ in relation to their methods of synthesis, chemical constitution, and structure. The earliest papers[40–60] were concerned with replacing the lanthanoid ions by other metal ions M^{3+} with the same charge or by ions of alkaline-earth metals. The temperature region of the transition to the superconducting state was investigated as a function of the degree of substitution, the elements involved, the oxygen partial pressure, and the transition from orthorhombic symmetry (La_2CuO_4-type structure) to tetragonal symmetry (K_2NiF_4-type structure). At temperatures $T < 150$ K, $La_{1.85}Sr_{0.15}CuO_4$ undergoes a phase transition from tetragonal to orthorhombic.[61] When the La^{3+} ions in La_2CuO_4 are partly replaced by divalent ions to give $La_{2-x}M_xCuO_4$, where M = Ca^{2+}, Sr^{2+}, or Ba^{2+}, a compensating fraction of the Cu^{2+} ions become Cu^{3+} ions. For larger values of the doping coefficient x an O^{2-} deficit appears in the oxygen partial lattice. An early investigation of this behavior was reported in 1981,[58] but there are also more recent publications on the superconducting phases $Ln_{2-x}M_xCuO_{4-y}$, a few examples of which are listed in the references.[62–66] A recent publication[67] classifies the

Hanskarl Müller-Buschbaum was born in Thüringen in 1931. He studied chemistry and physics at the Universität Greifswald, where he received his doctorate in 1960 under H. Witzmann on UV-photoexcited borate luminophores. He then worked at Siemens in Munich on hard superconductors. In 1962, Müller-Buschbaum resumed his academic career under Wilhelm Klemm at the Universität Münster and, in 1965, he moved to the Universität Gießen, where he completed his "Habilitation" under Rudolf Hoppe on the generation of high temperatures with the low-pressure high-frequency plasma burner and its use in high-temperature solid-state reactions. In 1969, he accepted a "Lehrstuhl" in the Department of Inorganic Chemistry at the Universität Kiel. His work focuses on solid-state chemical reactions at high temperatures involving high-frequency plasma discharges and on the synthesis of entropy-supported metastable materials by CO_2 laser methods.

different phases so far observed in the La_2O_3–SrO–CuO system. Concurrent investigations have included calculations on the electronic structure,[68–74] a study on electron–electron correlation in $La_{2-x}Sr_xCuO_4$,[75] and several studies of the mechanism of superconductivity in the new copper oxide compounds.[76–80]

An annoying aspect of the early papers on $La_{2-x}M_xCuO_4$ (M = an alkaline-earth metal) was that several authors, in discussing the question whether the symmetry was orthorhombic or tetragonal, completely disregarded the fact that all the lanthanoid species except those with La^{3+} crystallize not with the La_2CuO_4-type structure but with the Nd_2CuO_4-type structure, which has planar-coordinated copper. Assuming that the superconduction took place in the planar Cu/O grid,[78, 79] it appeared very doubtful whether, in the preparation of microcrystalline samples by cosintering—a process almost reminiscent of alchemy—the Cu^{2+} ions had a stretched octahedral coordination. As was stated in Section 1, the existence of the upper and lower apical oxygen atoms O_{II} of the CuO_6 octahedra can only be proved unambiguously by neutron diffraction or single-crystal X-ray studies. The focus of interest in our investigations was therefore not so much the question of the orthorhombic distortion of the tetragonal K_2NiF_4 structure, but rather that of whether the Cu^{2+} or Cu^{3+} ions in the superconducting phase have a planar or a stretched octahedral coordination. Using improved techniques, several research groups[81–83] have succeeded in preparing single crystals of $La_{2-x}Sr_xCuO_4$ (x = 0.12 to 0.15) and unambiguously determining the position of the controversial oxygen atom (O_{II} in Fig. 1a). These investigations showed that the Cu^{2+} ion definitely occupies a markedly elongated octahedron and that the elongation along the [001] direction decreases with increasing introduction of Sr^{2+} ions at the La^{3+} positions.[83] Determining the symmetry is not so easy, since the question whether or not the higher tetragonal symmetry is present depends on detecting very small deviations of the atomic parameters from the tetragonal position 00z and slight differences in the temperature factor of the upper and lower apical oxygen atoms. However, recent work has succeeded in growing large single crystals of $La_{2-x}Sr_xCuO_4$ up to 10 mm long.[84]

The following question then arose: Why do oxocuprates of the Nd_2CuO_4 type not show superconducting properties? Could this be attributed to the paramagnetism of the ions in the series Pr^{3+} to Gd^{3+} or to the planar-coordinated copper (which would have been inconsistent with some of the proposed mechanisms), or was the Nd_2CuO_4-type structure much less favorable energetically than the orthorhombic La_2CuO_4 structure? To estimate the stabilities of the two crystal structures, the Coulomb contribution to the lattice energy (MAPLE value[85, 86]) was calculated for both the K_2NiF_4-type and the La_2CuO_4-type structures and also for a stepwise transition of the upper and lower apical oxygen atoms (O_{II} in Fig. 1a) from the 00z position ($z = 0.176$) to the position 0; ½; ¼ in the Nd_2CuO_4 structure. Figure 3 shows the MAPLE values for the oxygen atoms as a function of the O_{II} positional parameters. The result is surprising, since the two extreme situations in the stepwise shift of O_{II} from the K_2NiF_4-type to the Nd_2CuO_4-type have virtually identical Coulomb contributions to the lattice energy, and,

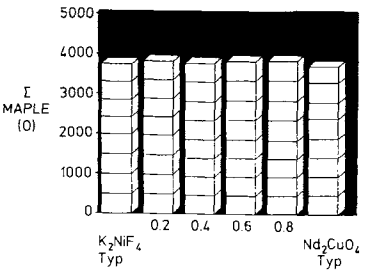

Fig. 3. Contributions of the Coulomb term (MAPLE) to the lattice energy for the K_2NiF_4- and Nd_2CuO_4-type structures, with stepwise transition from octahedral to planar coordination of the upper and lower apical oxygen ions. Ordinate: Sum of the MAPLE values for all oxygen atoms. Abscissa: Change in the positional parameter z for O_{II}.

furthermore, the shift of the O_{II} atoms gives no reduction in the Coulomb term at the hypothetical intermediate positions. Thus, energy considerations are not inconsistent with a planar Cu/O grid in the Nd_2CuO_4-type structure. The only possible conclusions were either that all lanthanoid ions that form Nd_2CuO_4-type structures (namely, Ce^{3+}, Pr^{3+}, Nd^{3+}, Sm^{3+}, and Gd^{3+}) suppress superconductivity owing to their magnetic properties or that superconductivity is not possible in oxocuprates with exclusively planar-coordinated copper.

In the field of oxide superconductors, however, new theories seem to become rapidly obsolete, for a paper then appeared[87] reporting superconductivity in cerium-doped oxocuprates $Ln_{2-x}Ce_xCuO_4$ (Ln = Pr^{3+}, Nd^{3+}, Sm^{3+}) which have the Nd_2CuO_4-type structure with planar-coordinated copper. This result provoked a number of theoretical considerations based on the idea that the addition of a fifth or sixth oxygen atom to planar CuO_4 grids leads to the formation of stretched tetragonal pyramids, or, as in La_2CuO_4, stretched octahedra. The other HT_c superconductors yet to be discussed also have these 4 + 1 or 4 + 2 oxygen polyhedra as a characteristic feature of their structures. Interestingly, the question whether pure La_2CuO_4 is also a superconductor has since received a positive answer. It had already been shown in 1973 that La_2CuO_4 is a metallic conductor.[88] Other authors found only semiconducting behavior,[89] but more recent publications reported superconductivity, both at particle boundaries[90] and in bulk.[91, 92] If La_2CuO_4 is partly fluorinated, thereby introducing a charge deficit in the anion partial lattice ($La_2CuO_{4-x}F_x$), a superconducting material with a T_c value of about 35 K is obtained.[93]

The crystal chemistry of the superconducting phases $La_{2-x}M_xCuO_4$ and $Nd_{2-x}Ce_xCuO_4$ fits into the pattern of previously known compounds. This relationship is shown in Figure 4. The K_2NiF_4-type structure in the center leads, by a small orthorhombic distortion, to the La_2CuO_4 structure. A doped La_2CuO_4 with the constitution $La_{1.8}Sr_{0.2}CuO_4$ was the first known HT_c superconductor. In Figure 4, two oxygen positions (O_I and O_{II}) in the K_2NiF_4-type structure have been marked. If, for example, O_{II} is moved from the 00z position ($z = 0.176$) to the position 0; ½; ¼, this gives, with no change in chemical constitution, the Nd_2CuO_4 structure with planar Cu/O grids. A derivative of this structure leads to the most recently discovered superconducting material, $Nd_{2-x}Ce_xCuO_4$, with $T_c = 35$ K. Here, for the first time in a superconducting material, the planar Cu/O polygons do not have O^{2-} neighbors to extend the network. In early research on oxide HT_c superconductors, great hopes were held out for

the compounds Sr_2CuO_3[94] and $SrCuO_2$.[95] If the trivalent lanthanum ion in La_2CuO_4 is formally replaced by Sr^{2+}, there is a deficit of two positive charges. Nature responds to this situation with a rearrangement from the K_2NiF_4-type structure to the Sr_2CuO_3 structure. If the oxygen atoms marked O_I in the K_2NiF_4-type structure in Figure 4 are removed, this gives Cu^{2+} a planar oxygen environment. The crystal structure has isolated chains of planar Cu/O polyhedra, joined at their corners; this is a characteristic feature of the Sr_2CuO_3-type structure. If an SrO group is formally removed from Sr_2CuO_3, the compound $SrCuO_2$ is obtained.[95] Figure 4 shows that, when Sr_2CuO_3 is transformed by an $a/2:c/2$ translation, the isolated $[CuO_3]_n^{4-}$ chains coalesce to form $[CuO_2]_n^{2-}$ double chains consisting of CuO_4 squares joined at their edges.

Also formally derived from the K_2NiF_4-type structure is a long-known fluorooxoferrate(III) with the formula Sr_2FeO_3F.[96] In this structure one of the original apical oxygen positions is occupied by randomly distributed O^{2-} and F^- ions. The evidence for this oxygen/fluorine distribution is based on plausible argument, since X-ray diffraction methods cannot distinguish between O^{2-} and F^-. An interesting feature of the structure is the FeO_5F octahedron, which is asymmetrically distorted. It is again stretched in the direction of the c axis in relation to the randomly occupied octahedral apical sites. If the O_{II} atoms in oxometalates of the K_2NiF_4 type are completely replaced by halogen ions, one obtains, for example, the halogenooxocuprate(II) compounds with the general formula $Sr_2CuO_2X_2$ ($X = Cl^-$,[97] Br^-[98]) or $Ca_2CuO_2X_2$ ($X = Cl^-$, Br^-[99]). In the search for new oxide superconductors, the partially halogenated materials will attract more interest[93] if preparative routes can be found which avoid the formation of the stable fluorite structures SrF_2 or BaF_2 when superconducting phases are reacted with fluorine or fluorides.

Although copper has up to now been an essential constituent of HT_c superconductors, as in $Ln_{2-x}M_xCuO_4$ and $Ln_{2-x}Ce_xCuO_4$, there has recently been renewed interest in

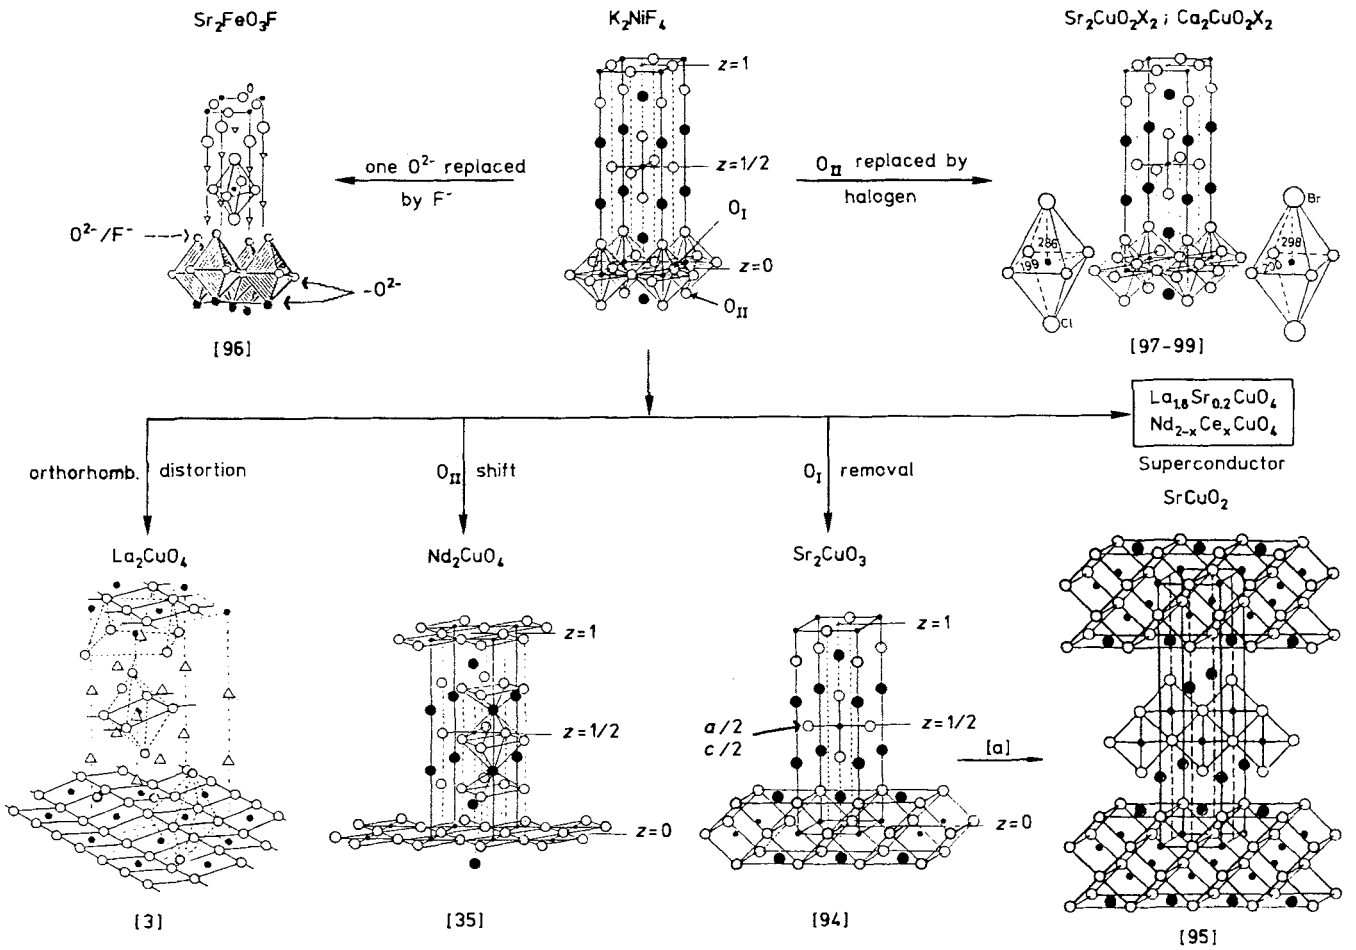

Fig. 4. Relationships between the K_2NiF_4-type structure and compounds with related structures. Step [a]: Remove SrO, shift by $a/2$ and $c/2$ (see text).

the formally similar oxonickelates.[5, 8, 100–103] One approach is to replace Cu^{2+} by Ni^{2+}.[104] A recent investigation using single crystals showed that in $Nd_2(Cu,Ni)O_4$[105] the orthorhombically distorted K_2NiF_4-type structure is formed in preference to the planar Nd_2CuO_4 type. Obviously Ni^{2+} stabilizes the octahedral mode of coordination, despite the fact that, as an element with a d^8 electronic configuration, it prefers planar coordination. A comparable situation is also found in $Nd_{1.5}Sr_{0.5}(Cu,Al)O_4$.[105] On the other hand, when Cu^{2+} is replaced by Al^{3+} it is easier to understand the formation of octahedral $(Cu,Al)O_6$ coordination, since a planar oxygen environment around Al^{3+} would be very surprising. Pt^{4+} also stabilizes the octahedral mode of coordination of Cu. Single crystals of

$La_{1.5}Sr_{0.5}(Cu_{0.75}Pt_{0.25})O_4$ have been prepared;[83] they have a structure practically identical to the K_2NiF_4 type (i.e., the orthorhombic distortion is extremely small). Our own experiments aimed at replacing as many La^{3+} ions as possible in $La_{2-x}Sr_xCuO_4$ by Sr^{2+} confirmed the finding by others[84] that the substitution fraction x can only be significantly increased by using a large excess of SrO. However, if Pt^{4+} is incorporated at the Cu^{2+} sites along with Cu^{2+}, the material reacts completely with whatever fraction of SrO is added to the mixture.[81] This supports results from other studies which showed that when La^{3+} in La_2CuO_4 is replaced by Sr^{2+} only a limited amount of conversion from Cu^{2+} to Cu^{3+} occurs.[58, 64, 65]

3. The Yttrium Superconductors

3.1. $YBa_2Cu_3O_{6+x}$

The real breakthrough in the discovery and development of superconducting oxide phases came with the very early identified $YBa_2Cu_3O_{6+x}$ system.[106, 107] Transition temperatures in the region of 90 to 93 K brought superconductivity for the first time within the range accessible with liquid nitrogen, which is cheaper than liquid helium by a factor of about 1000. The new material became known to many physicists and chemists as the "YBACU" superconductor, or the 1-2-3 superconductor[*] (1 Y, 2 Ba, 3 Cu), from its formula $YBa_2Cu_3O_{6+x}$. Thus, it was this compound that further stimulated the unprecedented increase in experiments and publications in this field. All these efforts were directed towards shifting the transition to still higher temperatures and to understanding the phenomenon of superconductivity in oxides. In this article it will only be possible to cite a limited selection from the wealth of publications. With regard to the early work on the Y 1-2-3 superconductor, it is sufficient to list only a few publications[108–119] which themselves contain references to many further papers. Naturally, a considerable amount of space in the bibliography is given to papers reporting experiments on substitution. In view of the fact that, starting from $La_{2-x}Sr_xCuO_4$, the successive replacement of La^{3+} by Y^{3+} and of Sr^{2+} by Ba^{2+} had led to $YBa_2Cu_3O_{6+x}$, it was hoped that further modification of the chemical constitution might result in higher T_c values. Many of these publications report on the replacement of Y^{3+} by other trivalent lanthanoid ions.[120–135] Some investigators have aimed to replace Ba^{2+} or Y^{3+} by ions of other alkaline-earth metals, and Cu^{2+} by other metals of the same subgroup.[136–145]

Quite a lot of research has been done on the dependence of the properties on synthesis and structure. It was quickly recognized that the occurrence of superconductivity, the sharpness of the transition from metallic conduction to superconductivity, and the relation to current density depend critically on the preparation conditions. Usually the starting materials ($BaCO_3$/$Ba(OH)_2 \cdot 8H_2O$, Y_2O_3, CuO) are first heated to a relatively high temperature (950–1000 °C); superconductivity is then achieved by processing the material in an oxygen-containing atmosphere. A number of papers[146–164] discuss important details such as the evolution of oxygen as the temperature is increased, the reorganization of the superconducting crystal lattice at moderate temperatures, and a phase transition which can occur depending on the chemical constitution and the temperature. Superconductivity in $YBa_2Cu_3O_{6+x}$ only begins to appear when $x > 0.5$. Some of the divalent copper must therefore be converted to the trivalent oxidation state. Since the ideal constitution $YBa_2Cu_3O_{7.0}$ cannot quite be reached with one Cu^{3+} ion and Cu^+ ions are also present, it has been suggested that charge neutrality is maintained by the presence of some oxygen in the -1 oxidation state. The publications cited here[165–171] refer to various studies of the oxidation state of copper. The superconducting phase $YBa_2Cu_3O_{6+x}$ ($0.5 < x < 0.93$) has an oxygen deficit, which depends on the thermal treatment in the presence of oxygen. It was therefore of interest to find out whether the O^{2-} vacancies in the oxygen partial lattice occur in an ordered or a disordered fashion. A related problem is the usual formation of twinned crystals, which cause difficulties in determining the structure by diffraction methods. For this reason $YBa_2Cu_3O_{6+x}$ crystals have also been studied by high-resolution transmission electron microscopy.[172–179]

The earlier studies using diffraction methods have been reviewed.[171, 180–184] Other publications[185, 186] review studies of crystal twinning. Neutron diffraction results that include temperature dependence have also been reported.[187–191] The key feature in all these diffraction experiments is the ordering of the vacancies, as well as its influence on the crystal structure and on T_c.[192–196] An investigation using Raman spectroscopy was recently reported;[197] by this method regions of the crystals unaffected by twinning could be clearly identified. Shortly afterwards, an untwinned single crystal of $YBa_2Cu_3O_{6.9}$ was isolated and studied by X-ray diffraction at different temperatures.[198] Also relevant here are two papers reporting measurements on the superconducting properties of single crystals,[199, 200] which contain references to other work on this topic.

Figure 5 shows a perspective drawing of the coordination polyhedra around the Cu, Y, and Ba ions. In Figures 5a and 5b the tetragonal pyramids of O^{2-} ions around Cu_{II} are indicated by hatching. The CuO_5 pyramids are joined at their base corners to form an infinite two-dimensional network of quasi-planar CuO_4 squares. The fifth oxygen (the apex of the pyramid) is considerably more removed in the [001] direction. These Cu^{2+} ions must therefore be regarded as having a 4 + 1 coordination. Figures 5a and 5b also indicate the square-planar coordination around Cu_I. One-dimensional infinite chains of Cu/O squares joined at their corners extend through the crystal in the direction of the *b* axis, as had also been found previously in Sr_2CuO_3.[94] Many of the papers on the replacement of Y^{3+}, Ba^{2+}, and especially Cu^{2+}/Cu^{3+}, which are cited here, were concerned with the question whether the superconducting properties were especially affected by replacing either the copper ions in the isolated chains or those with 4 + 1 coordination. Our calculations of the Coulomb contribution to the lattice energy using the MAPLE method[85, 86] show that, if we assume that Cu^{2+} is partially converted to Cu^{3+}, the Cu^{3+} ions should occur in the isolated chains.

[*] Owing to the growing number of superconducting systems, this nomenclature inevitably leads to errors unless a symbol denoting the particular system is included, in this case Y1-2-3.

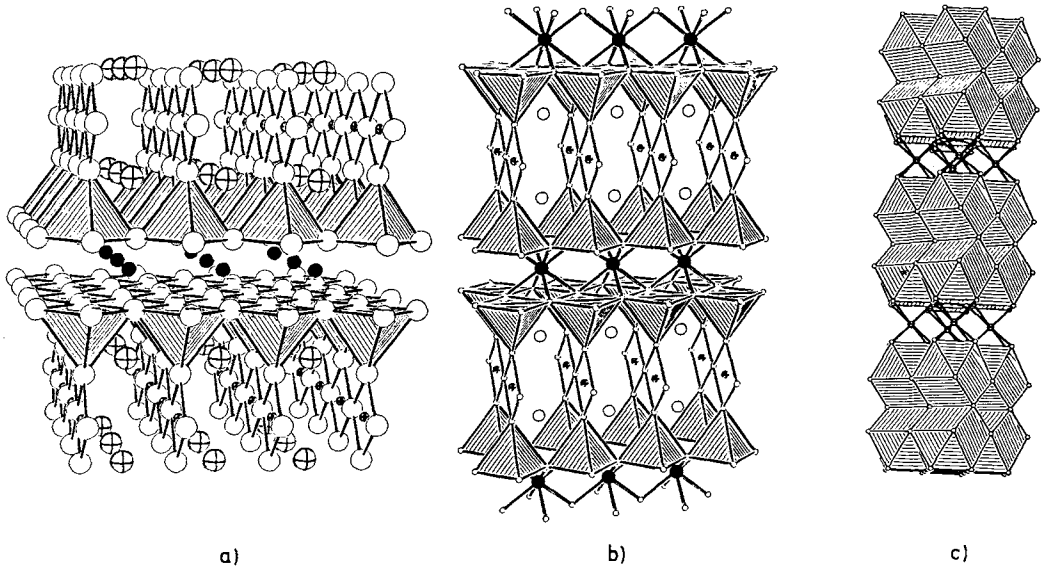

Fig. 5. Structure of $YBa_2Cu_3O_{6+x}$. a) Coordination of Cu^{2+}/Cu^{3+}. The tetragonal pyramids around Cu_{II} are hatched. ● = Y^{3+}, ⊕ = Ba^{2+}, ⊛ = Cu^{2+}, ○ = O^{2-}. b) Coordination of Cu^{2+}/Cu^{3+}, symbols as in a) with the $Y^{3+}-O^{2-}$ bonds also shown. ● = Y^{3+}, O = Ba^{2+}, ⊛ = Cu^{2+}, ○ = O^{2-}. The isolated CuO_4 chains (containing the Cu^{3+} ions) are indicated. c) Coordination of Ba^{2+} (see text). ⊖ = Y^{3+}, o = O^{2-}.

Figure 5b also reveals how the Y^{3+} ions are arranged between the layers of CuO_5 pyramids. Each Y^{3+} ion is surrounded by eight O^{2-} ions in the form of a slightly stretched cube. The coordination of the bulky Ba^{2+} ions is relatively complicated, with a geometry as shown in Figure 5c. The Ba^{2+} ion occupies a distorted rectangular antiprism with markedly different faces in the [001] direction.

From a crystallographic standpoint this HT_c superconductor is also related to other known compounds. Directly related compounds are $Sr_3Ti_2O_7$,[201] the compounds and solid phases with the general formula $La_{2-x}A_{1+x}Cu_2O_{6-x/2}$ (A = Ca or Sr),[202] and $Ln_{2-x}Sr_{1+x}Cu_2O_{6-x/2}$ (Ln = Sm–Gd).[203] Also belonging to this class are the barium oxoindates which were studied in the early 1980s; the system $BaO-In_2O_3$[204,205] gives rise to a series of compounds,[206,207] whose structures have only been determined very recently. Other compounds directly related to the $YBa_2Cu_3O_{6+x}$ superconductor are $Ba_3In_2O_6$,[206,207] $Ba_2SrIn_2O_6$,[208] and $BaSr_2In_2O_6$.[209] $Ca_3In_2O_6$[210] and $SrCa_2In_2O_6$,[211] although they have similar molecular formulas, are metastable compounds with their own unique crystal chemistry. The phases $La_{2-x}Sr_{1+x}Cu_2O_{6-x/2}$ and $Ba_3In_2O_6$, which are isotypes, can also be regarded as variants of the $Sr_3Ti_2O_7$-type structure.[201] These relationships are illustrated in Figure 6. The $Sr_3Ti_2O_7$ type (Fig. 6a) is an extension of the K_2NiF_4 structure shown in Figure 4. The

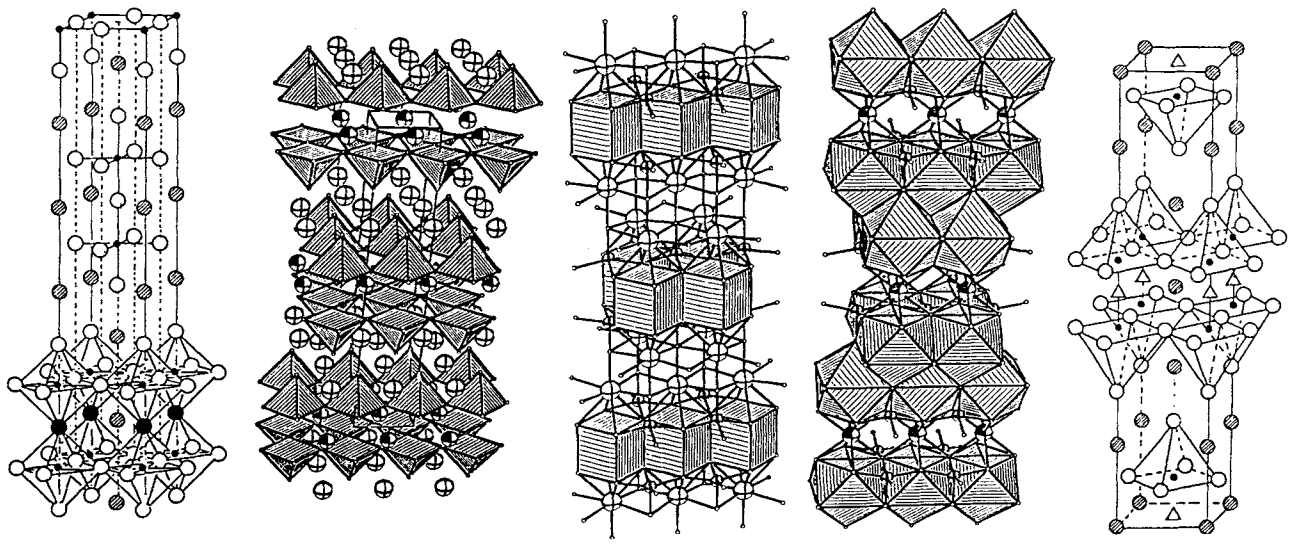

Fig. 6. Transition from the $Sr_3Ti_2O_7$-type structure (a) to $Ba_3In_2O_6$ (b)–(d) or $La_{2-x}A_{1+x}Cu_2O_{6-x/2}$ (e) (A = Ca, Sr; shown for A = Sr, x = 0) by removing the oxygen ions (O_{II}) marked by large filled circles. The InO_5 and CuO_5 pyramids are clearly shown in b) and e), respectively. In c), the stretched BaO_8 "cube" is shown and in d) the rectangular antiprism with a ninth O^{2-} neighbor. a) ◍ = Sr^{2+}, • = Ti^{4+}, ○ = O^{2-}; b) ⊕ = Ba^{2+}, InO_5 pyramids hatched, o = O^{2-}; c) ⊕ = Ba^{2+}, BaO_8 polyhedra hatched, ⊛ = In^{3+}; d) ⊕ = Ba^{2+}, ⊛ = In^{3+}, o = O^{2-}; e) ◍ = La^{3+}, △ = Sr^{2+}, ● = Cu^{2+}, ○ = O^{2-}.

essential difference between these two structures is that $Sr_3Ti_2O_7$ has a double layer of octahedra instead of a single two-dimensional layer as in K_2NiF_4. The spaces in the octahedral double layers shown in Figure 6a are occupied by alkaline-earth ions (hatched spheres); thus, in this region of the $Sr_3Ti_2O_7$ structure a perovskite layer is formed, with Sr^{2+} at the 12-coordinated sites and Ti^{4+} in the octahedral oxygen-coordinated sites. From this it is clear why these materials are referred to as perovskite-type superconductors. If the two Ti^{4+} ions of $Sr_3Ti_2O_7$ are replaced by two In^{3+} ions, the resulting positive charge deficit is corrected by loss of an O^{2-} ion, giving a crystal structure of the $Ba_3In_2O_6$ type (Fig. 6b–d). If, instead, two Sr^{2+} ions and the two Ti^{4+} ions are formally replaced by two La^{3+} ions and two Cu^{2+} ions, respectively, one obtains compounds such as $La_2SrCu_2O_6$ (Fig. 6e).[202,203] From Figure 6a it can be seen that the oxygen ions indicated by filled circles and lying between the layers of octahedra leave the crystal lattice, and the octahedra surrounding the Ti^{4+} ions in $Sr_3Ti_2O_7$ lose one of their shared apexes to form tetragonal pyramids around the In^{3+} ions of $Ba_3In_2O_6$ (Fig. 6b). When the marked oxygen ions are removed (cf. Fig. 6c), the 12-fold coordination around the alkaline-earth ion in $Sr_3Ti_2O_7$ is reduced to an 8-fold coordination, which can be described as a stretched cube. In the change from the $Sr_3Ti_2O_7$ structure to the $Ba_3In_2O_6$ structure, one part is left completely unaffected, namely, that part of the structure which also remained unaltered in the transition from the K_2NiF_4 type to the $Sr_3Ti_2O_7$ type. Consequently, the bulky alkaline-earth ions in this part of the structure, which lies between the layers of octahedra, have the 8 + 1 coordination characteristic of the K_2NiF_4 type.

From the relationships between $Sr_3Ti_2O_7$, $La_2SrCu_2O_6$, and $Ba_3In_2O_6$ it is possible to show how the latter two materials are structurally related to the superconductor $YBa_2Cu_3O_{6+x}$. Figure 7 illustrates the series of formal changes needed to transform the structure of, for example, the compound $Ba_3In_2O_6$ into that of the Y1-2-3 HT_c superconductor, $YBa_2Cu_3O_{6+x}$. In the $Ba_3In_2O_6$ and $La_2SrCu_2O_6$ structures the structural type is retained when Ba^{2+} is replaced by Sr^{2+}[209], although the process of filling the quasi-cubic holes in the lattice involves an interplay between the sizes of the ions and holes and the lattice energy. In the compounds $Ba_2SrIn_2O_6$ and $BaSr_2In_2O_6$, this means that the smaller Sr^{2+} ion prefers to occupy the quasi-cubic coordination sites between the layers of InO_5 pyramids. In $YBa_2Cu_3O_{6+x}$ similar layers of tetragonal CuO_5 pyramids are present, with Y^{3+} as the linking ion in the cubelike polyhedra. If, in $Ba_2SrIn_2O_6$, we formally replace all the In^{3+} ions by Cu^{2+} or Cu^{3+}, and all the Sr^{2+} ions by Y^{3+}, this already brings us very close to the structure of the Y1-2-3 superconductor. At the positions marked by arrows in Figure 7, a layer of CuO_5 pyramids undergoes shifts of $a/2$ and $b/2$, bringing the apexes

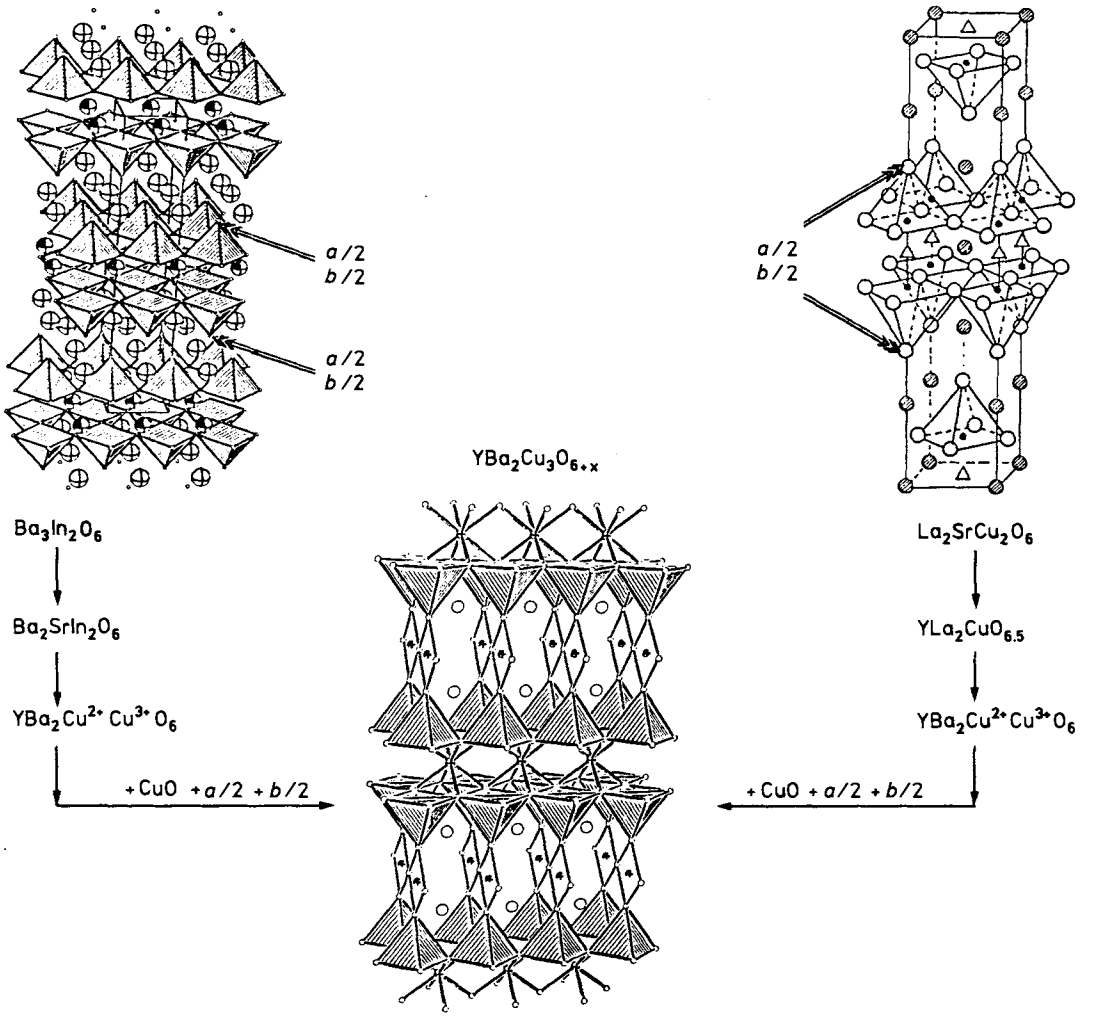

Fig. 7. Crystallographic relationships between $La_{2-x}A_{1+x}Cu_2O_{6-x/2}$ (A = Sr, x = 0), $Ba_3In_2O_6$, and the superconductor $YBa_2Cu_3O_{6+x}$.

of the pyramids into alignment. Incorporation of CuO leads to the square-planar polyhedra in $YBa_2Cu_3O_{6+x}$, which, by linking the apexes of the pyramids, give the isolated chains along the [001] direction as shown. Thus, $La_2SrCu_2O_6$ and $Ba_3In_2O_6$ (as well as $Ba_{3-x}Sr_xIn_2O_6$) have a close structural relationship to the HT_c superconductor $YBa_2Cu_3O_{6+x}$.

The Ba–Y–Cu–O system has been intensively studied;[212–215] spectroscopic methods have been used to investigate optical transitions,[216–220] and calorimetric measurements[221] have provided evidence of antiferromagnetism. Moreover, the electronic structure, bonding, and valence fluctuation in this system[222–226] and the mechanism of superconductivity in $YBa_2Cu_3O_{6+x}$ have also been studied.[227–229] Also of interest are further experiments on fluorination,[227,229] which at first seemed to offer great hopes of achieving considerably higher transition temperatures ($T_c > 150$ K).[230–232]

Our experiments along these lines showed that BaF_2 is preferentially formed, even when YOF or CuF_2 is used. Other authors have reported similar results.[233] It therefore seems very unlikely that the oxidation state in the anion partial lattice can be changed by incorporating fluorine.

3.2. $Y_2Ba_4Cu_7O_{14+x}$

In the course of measuring the effects of pressure and temperature on the quasi-binary system $YBa_2Cu_3O_{6+x}$-O_2,[234] a new phase with the chemical constitution $Y_2Ba_4Cu_7O_{14+x}$ was identified. The crystal structure of this new superconducting phase ($T_c \approx 40$ K) was determined by X-ray measurements on single crystals.[235] In Figures 8a and 8b this rather complex structure is shown as a ball-and-stick model and in the form of hatched polyhedra, respectively. There is an obvious resemblance to the structure of the $YBa_2Cu_3O_{6+x}$ superconductor. In this new phase, too, the Cu^{2+} and Cu^{3+} ions display a tetragonal-pyramidal coordination to O^{2-}. Copper is present at several different crystallographic positions. For Cu_{III} the CuO_5 pyramids are in parallel layers with their apexes facing each other. In contrast to $YBa_2Cu_3O_{6+x}$, however, the pyramid apexes in $Y_2Ba_4Cu_7O_{14+x}$ are laterally shifted relative to each other by a distance $b/2$. The main difference compared with the Y1-2-3 superconductor lies in the Cu/O double chains of Cu_{IV} (Fig. 8b), which consist of planar CuO_4 squares joined at their edges. These planar chains attached to the apexes of the Cu_{III} pyramids correspond exactly to the chains in $SrCuO_2$[95] (cf. Fig. 4), except that here the CuO_4 squares are slightly distorted. The layers of pyramids around Cu_{II} have their bases facing those of the Cu_{III} layer and are linked together by Y^{3+} ions, an arrangement which is similar to that in $YBa_2Cu_3O_{6+x}$. As revealed by Figure 8a, Cu_I can be regarded as being in a dumbbell configuration (i.e., with a linear coordination to oxygen). The O–Cu–O dumbbells link the pyramid apexes of the $Cu_{II}O_5$ polyhedra. The dumbbell-type coordination of Cu_I is only present so long as the sites O_{VIII} and O_{IX} are unoccupied. However, X-ray structural analysis indicates that these two sites have a 10% and 20% occupancy by oxygen, respectively. This can be interpreted to mean that in a micro-domain having 100% occupation at O_{VIII} and zero occupation at O_{IX}, Cu_I would have square-planar coordination. The resulting chains of planar

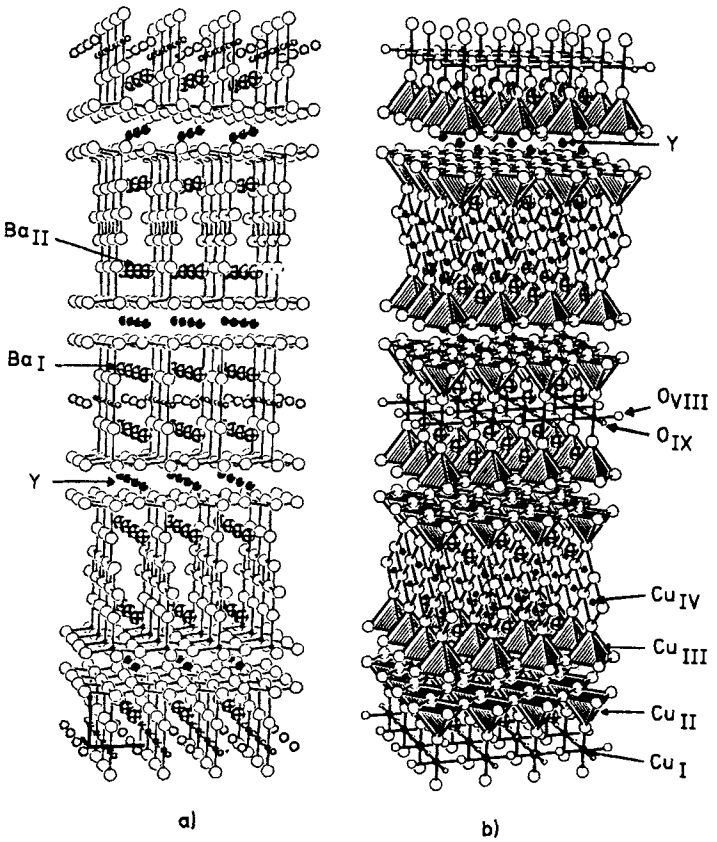

Fig. 8. Structure of $Y_2Ba_4Cu_7O_{14+x}$. a) Ball-and-stick model: ● = Y^{3+}, ⊕ = Ba^{2+}, • = Cu^{2+}, ○ = O^{2-}. b) The polyhedra around Cu_{II} and Cu_{III} are indicated by hatching. Cu_I is shown in an octahedral coordination (see text). Symbols as in a).

CuO_4 polygons run in a direction perpendicular to the Cu_{IV} double chains already described. If, instead, we consider the hypothetical case where only the O_{IX} sites are occupied, we again find that Cu_I has a square-planar coordination, giving corner-linked chains which run in the same direction as the Cu_{IV} double chains. If both the O_{VIII} and O_{IX} sites were fully occupied, Cu_I would have the octahedral coordination shown in Figure 9b. From this it can be concluded that, in the actual situation, dumbbells, planar polygons and octahedra are present in a statistical distribution with probabilities of 72%, 26%, and 2%, respectively.

Y^{3+} is surrounded by eight O^{2-} ions in the form of a cube. The O^{2-} ions forming the YO_8 polyhedra belong to the coordination spheres of Cu_{II} and Cu_{III}. This Y^{3+} environment corresponds to the coordination in $YBa_2Cu_3O_{6+x}$. The oxygen environment of the Ba^{2+} ions is more complex. Ba_I is surrounded by eight O^{2-} ions, if the O_{VIII} and O_{IX} sites are unoccupied, forming a rectangular antiprism with Ba^{2+} not quite in the center. If the O_{VIII} and O_{IX} positions are partly occupied, a distorted close-packed 12-fold coordination must be assumed. For example, Ba_{II} then lies in the region of the planar Cu/O double chain and the Cu_{III} pyramids. It has tenfold coordination, again with a rectangular antiprism and two extra O^{2-} ions. These extra neighbors belong to the coordination sphere of Cu_{IV}. Thus, the crystal structure of $Y_2Ba_4Cu_7O_{14+x}$ is made up of $YBa_2Cu_3O_{6+x}$ blocks with corner-linked planar CuO_4 chains and blocks with the constitution $YBa_2Cu_4O_8$,[235] which include edge-linked CuO_4 double chains.

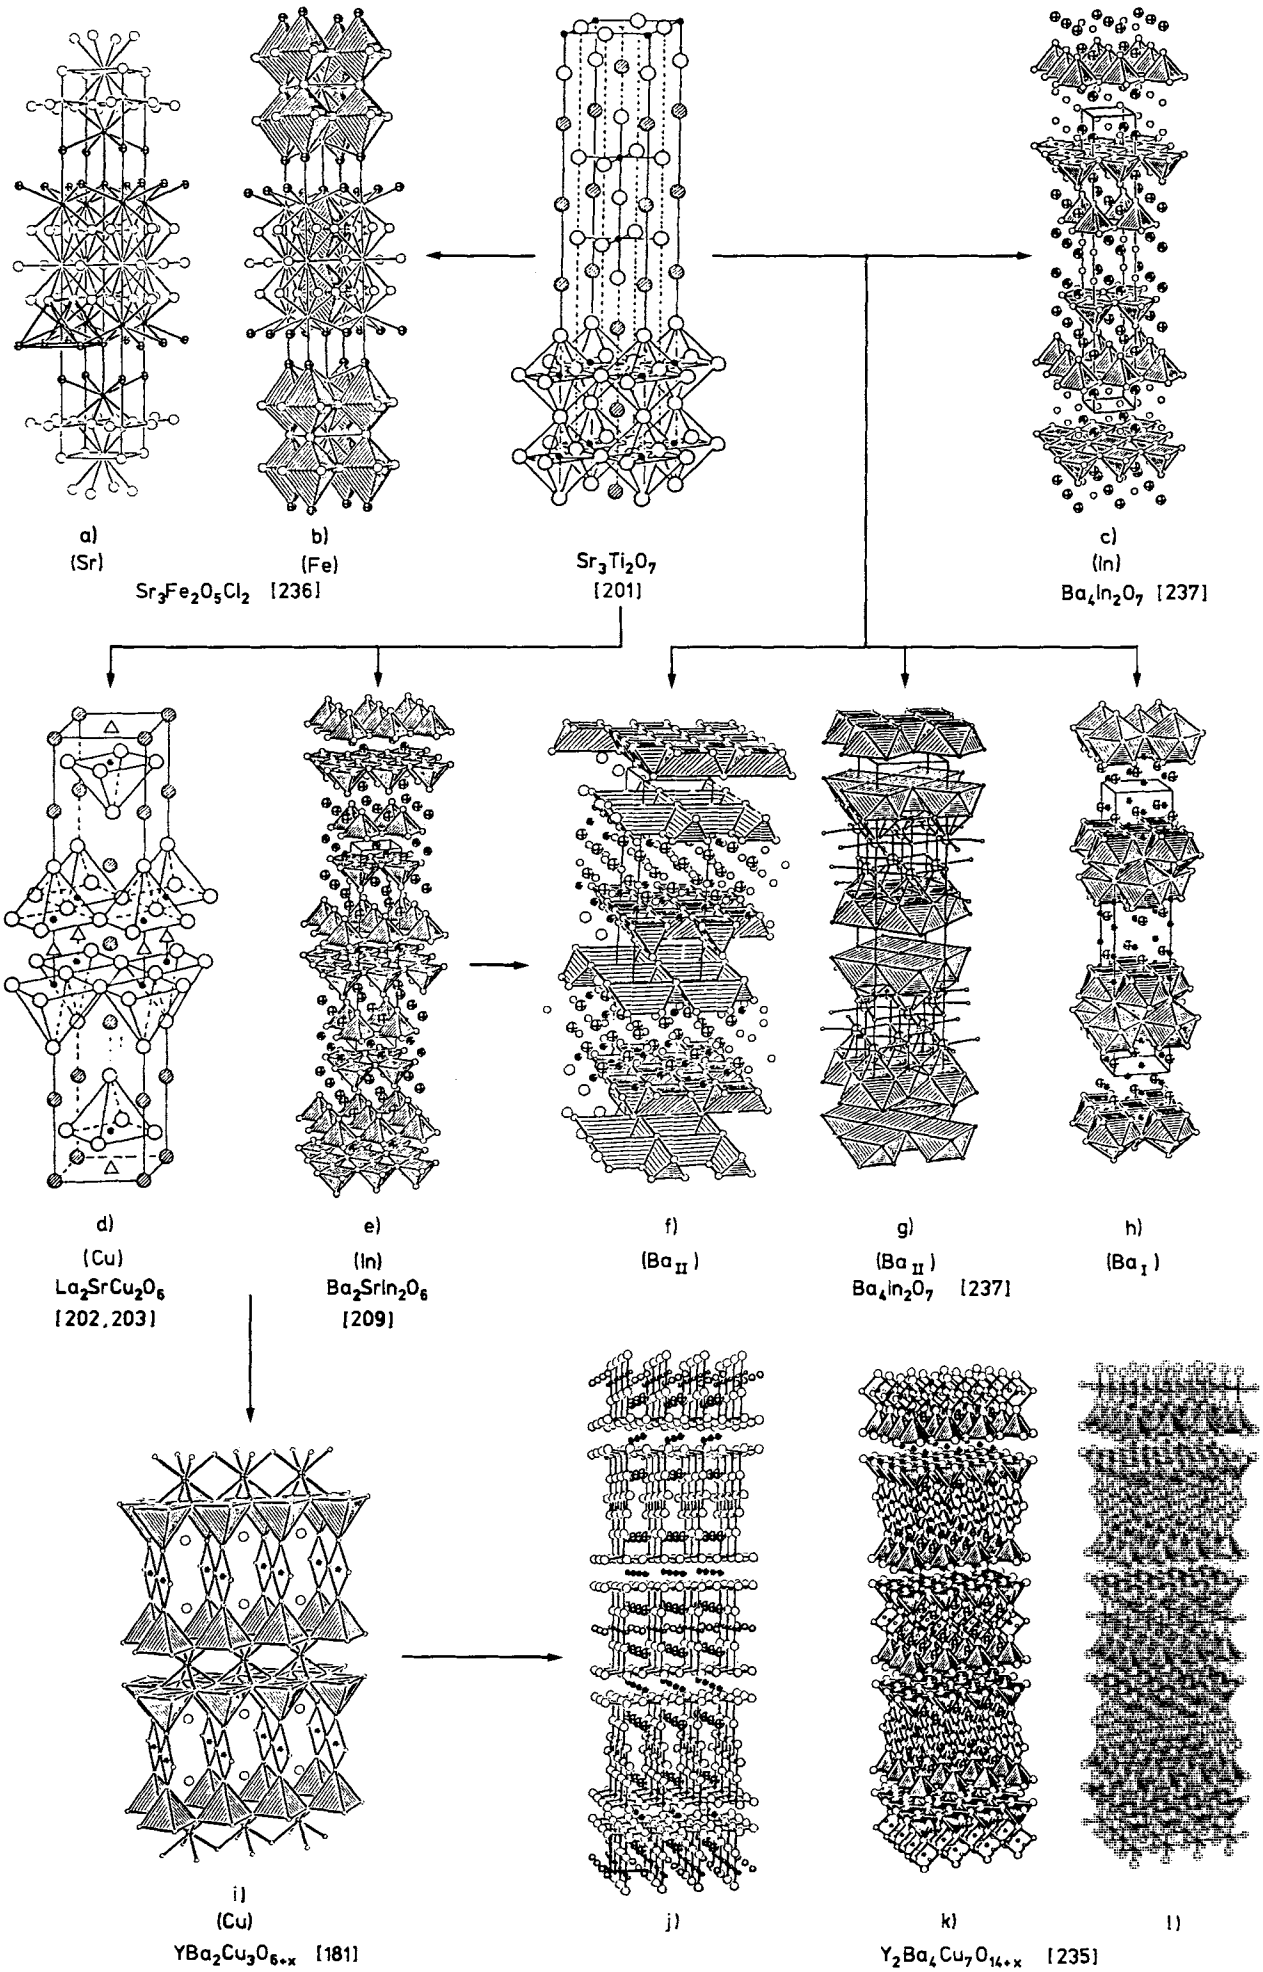

Fig. 9. Relationships between the $Sr_3Ti_2O_7$-type structure, the superconductors $YBa_2Cu_3O_{6+x}$ and $Y_2Ba_4Cu_7O_{14-x}$ and compounds with related crystal chemistry.

To conclude the discussion of the yttrium superconductors, it is appropriate to compare these with other related structures. Figure 9 shows some of these relationships, starting from the $Sr_3Ti_2O_7$-type structure.[201] Directly related to the latter is again a halogenooxoferrate, $Sr_3Fe_2O_5Cl_2$,[236] which contains Fe^{3+} in an octahedral coordination (Fig. 9a). Here there is a Cl^- ion at each of the apexes of the octahedra along the [001] direction which does not form a common linking point in the double layer of octahedra. Interestingly, the O^{2-} apexes forming the links in the double layer of octahedra are compressed, whereas the Cl^- corners of the CuO_5Cl octahedra (*trans* position) are stretched. From the $Sr_3Ti_2O_7$-type structure are derived the phases $La_{2-x}Sr_{1+x}Cu_2O_{6-x/2}$ ($x = 0$ in Fig. 9)[202,203] and the compound $Ba_2SrIn_2O_6$. As was already discussed in Section 3.1 (Fig. 7), $YBa_2Cu_3O_{6+x}$ (Fig. 9i) is directly related to the phase shown in Figure 9d and to the compound $Ba_2SrIn_2O_6$ (Fig. 9e).[209] Figures 9j-l show that the $Y_2Ba_4Cu_7O_{14+x}$ structures are also closely related to $YBa_2Cu_3O_{6+x}$ (Fig. 9i). Every second planar Cu/O chain is formally replaced by a double chain. Figure 9k, in contrast to Figure 8b, shows Cu_I in a planar O^{2-} coordination, which is conceivable for a micro-domain.

From the $Sr_3Ti_2O_7$ type one can also derive $Ba_4In_2O_7$.[237] Figure 9c shows the In/O environment for this compound. In this barium-rich oxoindate, In^{3+} again has five O^{2-} neighbors in the form of a tetragonal pyramid. The arrangements and linkages in the crystal structure correspond to the InO_5 coordination sphere of $Ba_3In_2O_6$. The extra BaO group spreads out the layers of pyramids, which are arranged with their bases facing each other. This increased spreading of the pyramid layers is one of the main differences between this structure and that of $Y_2Ba_4Cu_7O_{14+x}$ (compare Fig. 9c with Figs. 9k and 9l). The BaO polyhedra in $Ba_4In_2O_7$ are shown in Figures 9f–h. As in all these crystallographically related compounds, the BaO polyhedra are unaffected by changes in the crystal lattice. Thus, Ba_I has the 8 + 1 coordination which is characteristic of the K_2NiF_4- and $Sr_3Ti_2O_7$-type structures (cf. Figs. 5c and 6b–d). Ba_{II}, on the other hand, has a coordination sphere with one unoccupied oxygen site, which means that in the micro-domain Ba_{II} has a trigonal-prismatic coordination (Fig. 9f). The orientation of the elongated edge of the prism is alternately parallel to the *a* and *b* axes, which explains why the crystal does not cleave readily at this position. If the O_{II} sites mentioned above were fully occupied, Ba_{II} would have a rectangular antiprism of O^{2-} ions, with a considerably elongated rectangular face.[237]

4. The Bismuth Superconductors

Starting from $La_{2-x}Sr_xCuO_4$, the replacement of La^{3+} by Y^{3+} and of Sr^{2+} by Ba^{2+} led to the superconducting phase $YBa_2Cu_3O_{6+x}$. An urgent task, therefore, was to pursue such substitution reactions further in order to discover still more superconducting phases. The first high-T_c superconductor that contained neither yttrium nor a lanthanoid was found in the Bi-Sr-Cu-O system.[238] The fact that superconductivity had already been observed at about 20 K with the same mixture of components a year earlier[89] was almost overlooked. A number of subsequent studies[239–252] confirmed the original observation of at least two superconducting phases with transition temperatures between about 85 K and 108 K. Considerable efforts were put into elucidating the dependence of T_c on the preparation conditions,[253–259] the substitution,[260–262] and the crystal structure. Thus, electron and X-ray diffraction experiments were carried out on both microcrystalline material and single crystals, and, as in the case of $YBa_2Cu_3O_{6+x}$, high-resolution transmission electron microscopy was also used.[263–265] It was not long before a paper appeared reporting single-crystal X-ray diffraction results in combination with neutron diffraction,[266] and giving a complete description of the two superconducting phases, namely, $Bi_2(Sr_{1-x}Ca_x)_2CuO_{8-y}$ (I, Bi2-2-1) and $Bi_2(Sr_{1-x}Ca_x)_3Cu_2O_{10-y}$ (II, Bi2-3-2). Figure 10 shows a perspective view of the different coordination polyhedra surrounding Cu, Bi, and Sr/Ca in phase I. In Figure 10a the CuO_6 octahedra, stretched along the [001] direction, are indicated by hatching. The Cu^{2+} and Cu^{3+} ions have the same

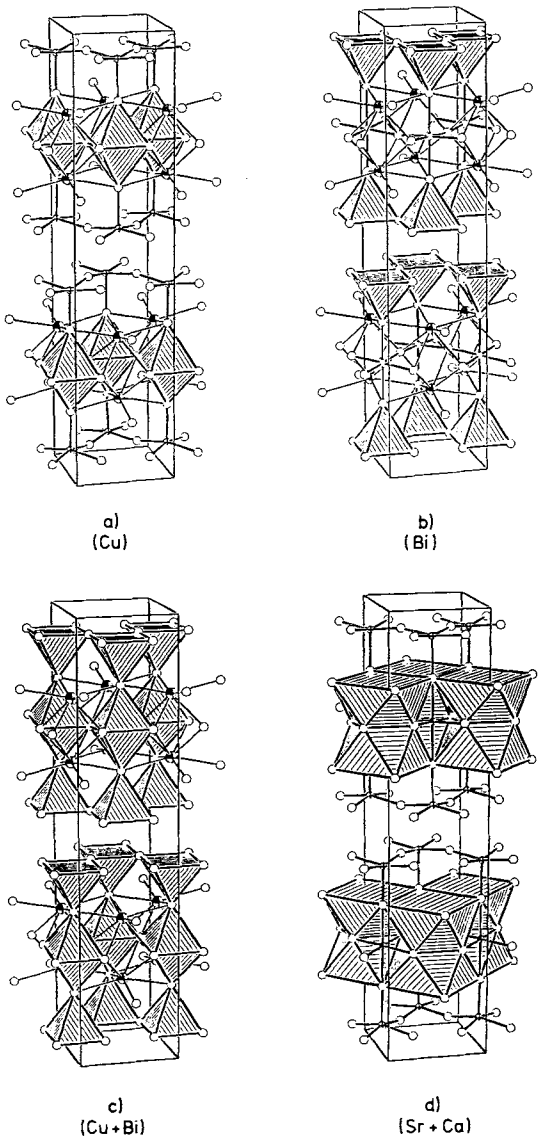

Fig. 10. Coordination polyhedra in the superconductor $Bi_2(Sr,Ca)_2CuO_{8-x}$ ("phase I"). a) Octahedral coordination around the copper ions indicated by hatching. b) Idealized BiO_5 polyhedra with ball-and-stick model of the Cu/O coordination. c) Linking between the CuO_6 octahedra and the idealized BiO_5 pyramids. d) The rectangular antiprism around the alkaline-earth ions.

coordination as in $La_{2-x}Sr_xCuO_4$. The bismuth ion occupies a tetragonal-pyramidal environment, which is shown in an idealized representation in Figure 10b. In preparing single crystals of phases I and II[266] it was found that, depending on the thermal treatment, crystals varying from black to brown were produced, although with no detectable effect on the structure; these also varied in their ability to oxidize HCl (liberation of Cl_2). The authors attribute this to defects in the $Bi_2O_{4-\delta}$ partial structure which were shown by neutron diffraction to be present. From this it appears that oxygen deficits can occur in the pyramid bases of the BiO_5 polyhedra. Figure 10c shows the typical corner linkage of the BiO_5-CuO_6-BiO_5 polyhedra along the [001] direction. The alkaline-earth ions (Sr^{2+} in the single crystal investigated here) are arranged within the Cu/Bi/O crystal packing (Fig. 10d), although not in the form of links between the layers of pyramids like the Y^{3+} ions in $YBa_2Cu_3O_{6+x}$. The coordination polyhedra of these alkaline-earth ions consist of highly distorted rectangular antiprisms (see Fig. 10d).

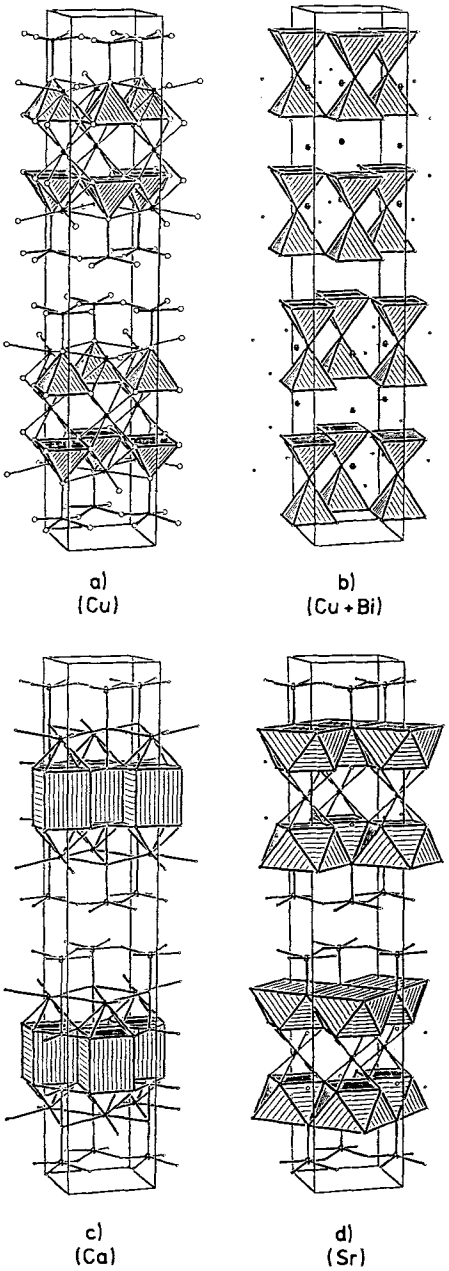

Fig. 11. Coordination polyhedra in the superconductor $Bi_2(Sr,Ca)_3Cu_2O_{10-x}$ ("phase II"). a) Tetragonal-pyramidal coordination of Cu^{2+}/Cu^{3+} by O^{2-}. The BiO_5 environment is shown in a ball-and-stick model. b) Linking of the CuO_5 and BiO_5 polyhedra. The BiO_5 pyramids are shown in an idealized representation. c) Coordination of Ca^{2+} by O^{2-}. d) Coordination of Sr^{2+} by O^{2-}.

The structure of the second superconducting phase, $Bi_2(Sr_{1-x}Ca_x)_3Cu_2O_{10-\delta}$, is derived from that of phase I. The coordination polyhedra are shown in Figure 11 in a perspective drawing. In Figure 11a the tetragonal pyramids of O^{2-} ions around Cu^{2+} and Cu^{3+} are indicated by hatching; Figure 11b shows in addition the tetragonal pyramids around Bi^{3+} and Bi^{5+}, which are linked to those of Figure 11a. In the Cu/O partial lattice one recognizes exactly the same structural units as in $YBa_2Cu_3O_{6+x}$, $La_{2-x}Sr_{1+x}Cu_2O_{6-x/2}$, and the indates $Ba_{3-x}Sr_xIn_2O_6$ (cf. Fig. 7), with the same spatial arrangement. These resemblances between phase II and the substances mentioned also apply to the Ca^{2+} ions intercalated between the layers of CuO_5 pyramids; as can be seen in Figure 11c, these have a stretched cubic coordination. The bulky Sr^{2+} ions occupy rectangular antiprisms in this case (see Fig. 11d), with the same distortion of the square faces along the [001] direction as was described earlier for the K_2NiF_4-type structure. In phase II, which contains less bismuth, Bi again undergoes valence changes depending on the oxygen treatment, resulting in varying degrees of oxygen deficiency in the Bi/O partial lattice. Details of compounds with orthorhombic symmetry, in which the Bi ions are bent out of the square face of the pyramid, can be found in the literature.[266]

5. The Thallium Superconductors

Research on the bismuth superconductors was followed by the discovery of further superconducting oxide phases based on thallium.[267, 268] Within a few months after this discovery, a succession of publications[191, 196, 269–284] reported several different types of thallium superconductors. The superconducting properties were evidently structure-dependent, and numerous studies on the crystal structures of these materials were therefore carried out; some examples are cited here.[285–292] Here again the elucidation of the crystal chemistry was helped by high-resolution transmission electron microscopy (cf. Refs. [293–295]). Two series of materials are now recognized, and a few examples will be described here.

5.1. Superconductors with One Thallium Atom per Unit

This group of materials has the general formula $TlBa_2Ca_{n-1}Cu_nO_{2n+3}$ with n = 2, 3, or 4 (cf. Refs. [283, 287–289, 292]). The three values of n give materials with the following constitutions, listed here with the commonly used abbreviations: (1) $TlBa_2CaCu_2O_{7+x}$ = 1-2-1-2 (specifically, Tl1-2-1-2), (2) $TlBa_2Ca_2Cu_3O_{9+x}$ = 1-2-2-3 (Tl1-2-2-3), and (3) $TlBa_2Ca_3Cu_4O_{10.5+x}$ = 1-2-3-4 (Tl1-2-3-4). In this article the Tl1-2-2-3 superconductor will be described. Figures 12a–c show the different coordination spheres around copper and thallium. The copper coordination is indicated in Figure 12a. Here we see the tetragonal-pyramidal environ-

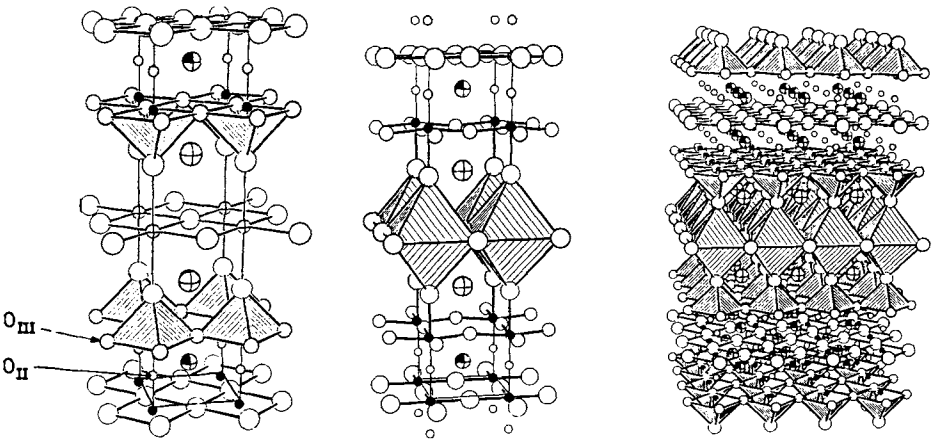

Fig. 12. Coordination polyhedra in the thallium superconductor $TlBa_2Ca_2Cu_3O_{9+x}$. a) Coordination around Cu^{2+}, with the tetragonal pyramids shown by hatching. Position O_{III} is shown in an idealized representation (i.e., fully occupied). O_{II} has a very low occupancy and is ignored here from a coordination standpoint. o = Tl^{3+}, ⊕ = Ba^{2+}, ⊕ = Ca^{2+}, ● = Cu^{2+}, ○ = O^{2-}. b) The octahedra around Tl^{3+} are indicated by hatching. Symbols as in a). c) Linking of the Cu/Tl-O^{2-} polyhedra. Symbols as in a).

ment (hatched) and, at the two ends of the unit cell, a square-planar CuO_4 coordination. The tetragonal CuO_5 pyramids are oriented with their distorted bases parallel to the *a/b* plane, linked at all their corners within this plane. The apexes of the pyramids are also stretched by about 11% in comparison with the interatomic distances of the base. These apexes are shared with the coordination spheres of the thallium ions and will be discussed again later. The planar CuO_4 squares are also oriented parallel to the *a/b* plane and are linked at their corners to form an infinite two-dimensional grid. This arrangement resembles the planar linking often found in oxocuprate(II) structures, for example in Nd_2CuO_4.[35] However, this description needs to be qualified, since there are some vacant oxygen sites in $TlBa_2Ca_2Cu_3O_{9+x}$.[287] In particular, the site marked O_{II} in Figure 12a has an unusually low occupancy. The position O_{III}, also marked, has an occupancy of about 80%. Consequently, Cu_{II}, whose coordination is shown in Figure 12a as tetragonal-pyramidal, can also have octahedral coordination in micro-domains, and the CuO_5 pyramids can also be oriented perpendicular to the plotted direction. Cu_I, at the position $x = 0$, $y = 0$, $z = 0$, also has pyramidal coordination in micro-domains of the crystal lattice owing to the partial occupancy of site O_{II}. However, since point position O_{II} only has an occupancy of about ⅓, the statistical probability of octahedral coordination around Cu_I is quite low.

As already mentioned, the thallium polyhedra are linked to the tetragonal pyramids of the CuO_5 environment. Figure 12b shows that the apex of each pyramid is also a corner of an octahedron of O^{2-} ions surrounding a Tl^{3+} ion. The TlO_6 octahedra are hardly distorted. It should be noted that the TlO_6 octahedra are joined by their edges in the *a/b* plane, and they do not have an oxygen deficit at any position.

The alkaline-earth ions are incorporated in an ordered pattern into the crystal structure. The Ca^{2+} ions are confined within the Cu–O partial lattice, with a cubic coordination to eight O^{2-} ions. The experimentally determined site occupancy factors[287] show that the Tl sites are partly vacant, and some of the Ca^{2+} sites are also occupied by Tl^{3+} ions. As shown in Figure 12c, the Ba^{2+} ions lie between the Tl and Cu polyhedra. Their coordination can be described as 8 + 3, since the partial vacancy of the O_{III} sites means that 12-fold coordination is not quite reached. Further work will improve our knowledge of these crystal structures. One of the older papers,[283] and also one recent paper,[292] report different occupancies, and even different positions, for the light ions.

5.2. Superconductors with Two Thallium Atoms per Unit

The second series of thallium oxide superconductors is described by the general formula $Tl_2Ba_2Ca_nCu_{n+1}O_{2n+6}$ with n = 0, 1, or 2. Up to now two forms with n = 0, having the constitution $Tl_2Ba_2CuO_6$, are known, and these are identified in the literature as o-2-2-0-1 (o-Tl2-2-0-1) and t-2-2-0-1 (t-Tl2-2-0-1) (o = orthorhombic, t = tetragonal). Figure 13a gives an overall picture of the structure, showing all the atoms in several unit cells. The coordination sphere of the copper ions is indicated by hatching. The stretching of the CuO_6 octahedra, amounting to about 39%, is clearly seen. The CuO_6 octahedra are joined at their corners to form a two-dimensional grid, which corresponds to the Cu/O coordination in $La_{2-x}Sr_xCuO_4$. In the orthorhombically distorted form[291] the apexes of the octahedra are slightly displaced. Figure 13b shows the oxygen environment of the Tl^{3+} ions, which is also octahedral. The Tl/O partial lattice consists of double layers of octahedra joined at their edges, with their bases tilted out of the common plane. The layers of CuO_6 octahedra are linked to the Tl/O double layers by common corners along the [001] direction. Adjacent CuO_6 and TlO_6 octahedron bases are inclined at 45° relative to each other. The linking pattern in this part of the crystal structure is therefore not of the perovskite type. The spaces in the $Tl_2CuO_6^{4-}$ lattice are occupied by Ba^{2+} ions; according to the experimentally determined distances, the Ba^{2+} ion has a coordination number C.N. = 9.

Inserting the value n = 1 into the general formula $Tl_2Ba_2Ca_nCu_{n+1}O_{2n+6}$ gives $Tl_2Ba_2CaCu_2O_{8+x}$ (Tl2-2-1-2),

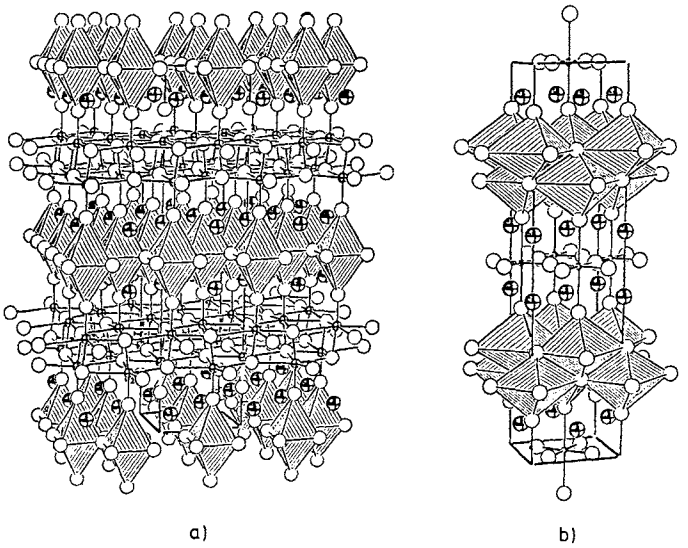

Fig. 13. Coordination polyhedra in Tl_2BaCuO_6. a) The octahedra around Cu^{2+} are shown by hatching. b) Double layers of compressed TlO_6 octahedra indicated by hatching. ⊕ = Ba^{2+} and ○ = O^{2-}.

which has the crystal structure shown in Figure 14. In Figure 14a the coordination around the copper ions in a unit cell is indicated. The Cu^{2+} and Cu^{3+} ions are again surrounded by O^{2-} in a tetragonal-pyramidal coordination, with the pyramid apexes oriented along the [001] direction showing an unusually large stretching of up to 40%. The arrangement of the pyramids corresponds to that in, for example, $YBa_2Cu_3O_{6+x}$. Figure 14b shows, over a larger region, the linking of the CuO_5 polyhedra to the double layer of TlO_6 octahedra formed by the joining of the latter at their edges. Certain regions of the crystal structure are identical to the structure of Tl_2BaCuO_6, as shown in Figure 13b. It should

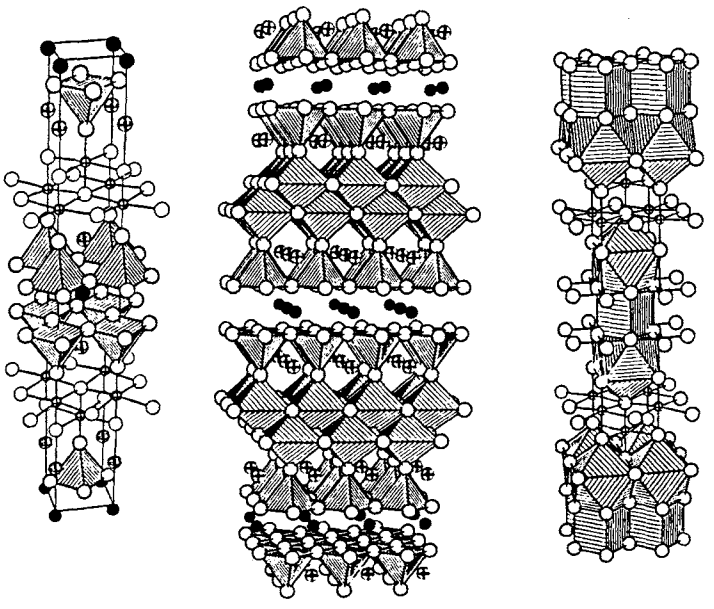

Fig. 14. Coordination polyhedra in $Tl_2Ba_2CaCu_2O_{8+x}$. a) The tetragonal pyramids around copper are shown hatched. ⊕ = Ba^{2+}, ⊛ = Tl^{3+}, ● = Ca^{2+}. b) Linking of the CuO_5 pyramids with the double layers of TlO_6 octahedra. Symbols as in a). c) Coordination around Ca^{2+} (cubic) and Ba^{2+} (a rectangular antiprism extended by neighboring ions).

be noted that in Figure 14 O_{III} is shown in an idealized representation. The experimentally observed split positional coordinates (16n) of $x = 0.104$, $y = 0$, $z = 0.782$ were idealized (4e) to $x = 0$, $y = 0$, $z = 0.782$ in order to show the crystal structure more clearly. Finally, Figure 14c shows the environment of the alkaline-earth ions.

The smaller Ca^{2+} ions have a cubic coordination, like Y^{3+} in $YBa_2Cu_3O_{6+x}$ or Sr^{2+} in $BaSr_2In_2O_6$ (cf. Figs. 5b and 6c). Ba^{2+} has a coordination number C.N. = 8 + 1, corresponding to a rectangular antiprism with one extra ion.

The third of these thallium-rich superconducting phases is well known and has the highest transition temperature of this series (T_c = 125 K); it has n = 2 and thus the formula $Tl_2Ba_2Ca_2Cu_3O_{10+x}$ (Tl2-2-2-3). Figures 15a–c show the coordination polyhedra around Cu, Tl, and Ca. In Figure 15a the tetragonal-pyramidal coordination of the copper ion is indicated by hatching. As in all the superconductors with CuO_5 polyhedra described up to now, the bases of the pyramids are oriented parallel to the *a*/*b* plane and are linked at all four base corners. The apexes of the pyramids are stretched to an unusual extent: 39% relative to the distances in the base of the pyramid. Figure 15a shows that there are further CuO polyhedra at $z = 0$ and $z = ½$, and, as in the oxocuprates (e.g., Nd_2CuO_4[35]), these are joined to form infinite two-dimensional grids. Within the crystal structure there are regions where copper ions are crowded together. Figure 15b shows the polyhedra around thallium. These compressed octahedra are joined together to form a double layer as in the other thallium superconductors. Along the [001] direction the CuO_5 pyramids and the TlO_6 octahedra are joined at their corners by shared oxygen ions, thus forming the spaces which contain the Ca^{2+} ions (small spheres with a quadrant) and the Ba^{2+} ions (larger spheres with a cross). The alkaline-earth ions are packed into the crystal lattice in an ordered pattern. Ba^{2+} has the 8 + 1 coordination which has already been described several times and is typical of the K^+ ions in the K_2NiF_4-type structure. Ca^{2+}, which is present only in the spaces of the Cu/O structure, again has a stretched cubic coordination, as shown, for example, in Figures 6b and 11c for $Ba_3In_2O_6$ and $Bi_2(Sr,Ca)_3Cu_2O_{10-x}$.

The structure of $Tl_2Ba_2Ca_2Cu_3O_{10+x}$ contains some detailed features which it is not possible to show in Figure 15. One such feature relates to the oxygen sites (16-fold lattice position marked by arrows in Figure 15b), which are in fact occupied by only four O^{2-} ions. The statistical distribution of four O^{2-} ions between 16 equivalent sites gives four possible positions for each one, located around the points marked in the figure. The actual positional coordinates, namely, $x = 0.100$, $y = 0$, $z = 0.775$, were idealized in Figures 15a–c by using the values $x = 0$, $y = 0$, $z = 0.775$. The experimentally observed split positions of the marked oxygen ions cause a distortion of the TlO_6 polyhedra, but without any bending out of the *a*/*b* plane.

We have just completed a determination of the structure[296] of the compound $Ba_8In_6O_{17}$, which is crystallographically related to the thallium-rich superconductor $Tl_2Ba_2Ca_2Cu_3O_{10+x}$. This structure is shown in Figures 16a and 16b alongside that of $Tl_2Ba_2Ca_2Cu_3O_{10+x}$ (Fig. 15a). The structure of $Ba_8In_6O_{17}$ is interesting because it belongs to the same family as the K_2NiF_4 and $Sr_3Ti_2O_7$ structures.

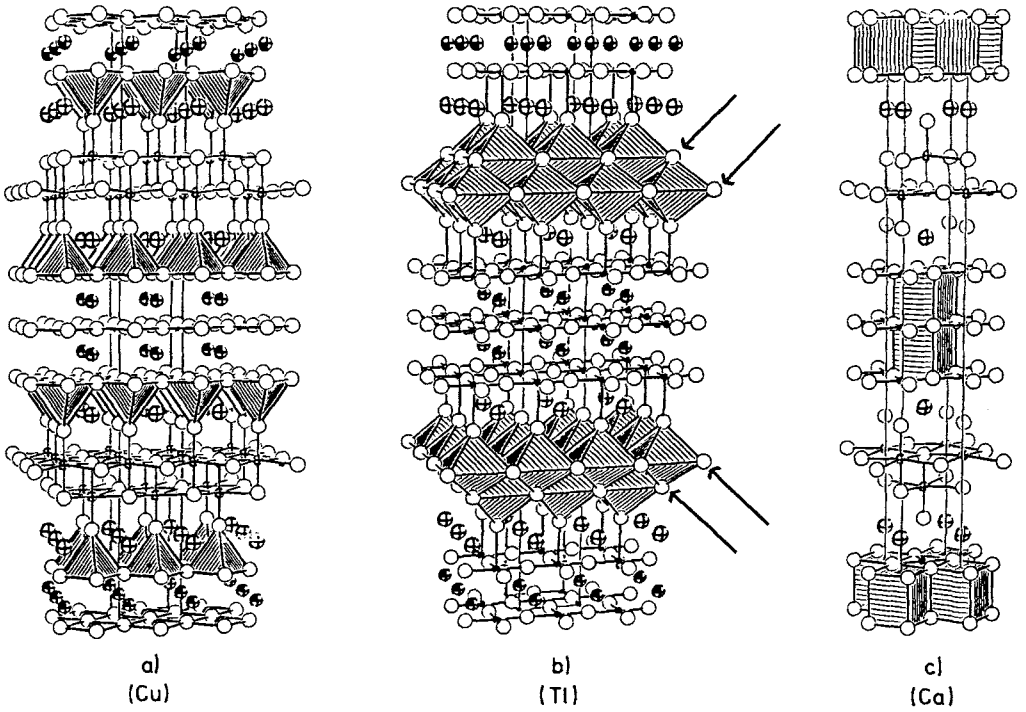

Fig. 15. Coordination polyhedra in $Tl_2Ba_2Ca_2Cu_3O_{10+x}$. a) CuO_5 pyramids around copper (hatched) and planar polygons at the beginning and middle of the unit cell. ⊕ = Ba^{2+}, ◐ = Ca^{2+}, partly substituted by Tl^{3+}, ○ = O^{2-}. b) Double layers of TlO_6 octahedra, shown hatched. The oxygen sites indicated by the arrows are only 25% occupied, and these positions are shown with idealized parameters (see text). Symbols as in a). c) Coordination polyhedra around Ca/Tl. Symbols as in a).

If the latter are extended by one layer of octahedra, the $Sr_4Ti_3O_{10}$-type structure is obtained.[201] This is shown for comparison in Figure 16c. If Ti^{4+} is replaced by In^{3+} and Sr^{2+} by Ba^{2+} in two formula units of $Sr_4Ti_3O_{10}$, one arrives at the constitutional formula $Ba_8In_6O_{17}$. In each of the octahedron base planes of the $Sr_4Ti_3O_{10}$ structure, marked by arrows in Figure 16c, there is half an O^{2-} ion missing per unit cell, so that in micro-domains of $Ba_8In_6O_{17}$ there are two InO_5 pyramids per octahedron layer per unit cell. An important property of these InO_5 pyramids is that their square faces are never oriented parallel to the *a*/*b* plane. The InO_5 pyramids occurring in the octahedron layer are not shown in Figure 16a; instead, the structure is shown with the idealized oxygen occupancy corresponding to the hypothetical formula "$Ba_8In_6O_{20}$". It is clearly evident that the middle octahedron in $Ba_8In_6O_{17}$ is stretched on both sides; this is a novel feature in indium chemistry. The outer octahedra, which adjoin the middle layer of octahedra, are both stretched and compressed, in a similar way to the FeO_5Cl octahedra in $Sr_3Fe_2O_5Cl_2$[236] (cf. Fig. 9b). The step from this to the thallium-rich superconductor $Tl_2Ba_2Ca_2Cu_3O_{10+x}$ (cf. Fig. 15a) shows that the entire Cu/O region, for example in the middle of the unit cell, can be constructed from triple layers of corner-linked octahedra (perovskite blocks), as in $Sr_4Ti_3O_{10}$ (Fig. 16c). If the upper and lower apical oxygen ions are removed from the middle layer of octahedra in the $Sr_4Ti_3O_{10}$-type structure, we obtain a planar MO_4-coordinated system bounded by two layers of pyramids. Thus, it is possible to derive the structure of the superconductor $Tl_2Ba_2Ca_2Cu_3O_{10+x}$ from the $Sr_4Ti_3O_{10}$ type, although here, in contrast to $YBa_2Cu_3O_{6+x}$, there is no chain of planar CuO_4 polyhedra between the apexes of the pyramids in the outer layer of octahedra, but instead a double layer of TlO_6 octahedra is inserted. In the formula $Tl_2[Ba_2Ca_2Cu_3O_{6+x}]O_3$, the partial structure inside the brackets is practically of the same type as $Sr_4Ti_3O_{10}$, with Cu^{2+} inserted into the layers of octahedra in place of Ti^{4+}.

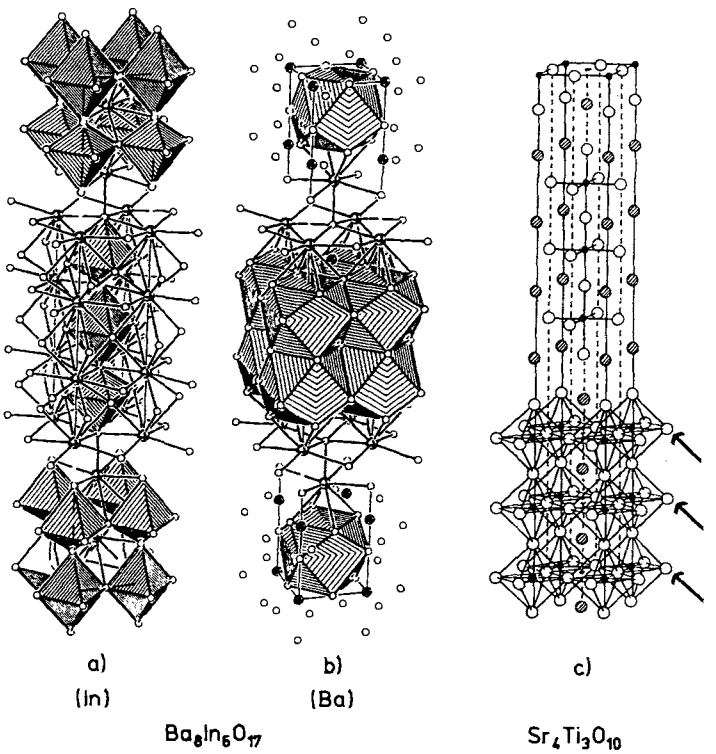

Fig. 16. Relationships between the $Sr_4Ti_3O_{10}$-type structure, $Ba_8In_6O_{17}$, and the superconductor $Tl_2Ba_2Ca_2Cu_3O_{10+x}$ (see Fig. 15a for CuO_5 pyramids around Cu in the superconductor). a) "InO_6" polyhedra in $Ba_8In_6O_{17}$. The octahedra shown here only occur in limited numbers (see text). b) Coordination of Ba^{2+} in $Ba_8In_6O_{17}$ assuming fully occupied oxygen sites. c) Incomplete unit cell of the $Sr_4Ti_3O_{10}$-type structure. The arrows indicate the O^{2-} layers in which $Ba_8In_6O_{17}$ has an oxygen deficiency. ◍ = Sr^{2+}, ● = Ti^{4+}, ○ = O^{2-}.

In the sequence from $Sr_4Ti_3O_{10}$ through $Sr_3Ti_2O_7$ to Sr_2TiO_4[201] (K_2NiF_4 type), the perovskite structure persists, though becoming a smaller proportion of the whole. These examples show that nature uses building blocks of the perovskite structure in many different superconducting phases.

6. The Lead Superconductor

The lead superconductors to be described here are not the classical perovskites such as $BaPb_{1-x}Bi_xO_3$[297] and their later derivatives (see, e.g., Ref. [298]), nor the materials obtained by partial substitution of the bismuth superconductors (see, e.g., Refs. [299, 300]), even though transition temperatures as high as 132 K have been reported[300] for the $(Bi_{1.9-x}Pb_xSb_{0.1})Sr_2Ca_2Cu_3O_y$ system with x = 0.3 and 0.4. The $Pb_2Sr_2ACu_3O_{8+x}$ system (A = Ln, Ca, Ln + Sr) and the phase $Pb_2Sr_{2.24}Nd_{0.76}Cu_3O_{8+x}$,[301] which will be described here, with a T_c of about 68 K, are interesting from a crystal chemical point of view. Figure 17 shows the structure of the latter system; in Figure 17a the tetragonal pyramids around the copper ions are indicated by hatching. This superconductor again fits into the general pattern in having CuO_5 polyhedra joined together in a two-dimensional grid. As in $YBa_2Cu_3O_{6+x}$ or $Tl_2Ba_2CaCu_2O_{8+x}$, the pyramids are aligned with their bases facing each other to form capped octahedra. The CuO_5 pyramids are all elongated up to 18%. The sites between the bases of the pyramids are occupied by strontium and neodymium ions in a random distribution. The coordination polyhedron is of the cubic type, which has already been described several times. Figure 17b shows PbO_5 polyhedra in addition to the CuO_5 pyramids. Although the CuO_5 and PbO_5 polyhedra share a common apex, the base planes of the two types of polyhedra are inclined at 45° to each other. The effect of this tilting is to alter the linking between the PbO_5 pyramids so that they are joined through all their edges to form a grid parallel to the *a*/*b* plane. An interesting feature of the lead superconductor structures is seen here, namely, the O–Cu–O dumbbells with monovalent copper which are aligned along the [001] direction in the middle of the structure. This twofold coordination, which is characteristic of Cu^+, forms a link along the direction of the *c* axis joining the bases of the PbO_5 pyramids.

Sr^{2+}, as the larger of the ions, occurs only in the gaps between the CuO_5 and PbO_5 pyramids. The polyhedron that is shown surrounding the large sphere marked with a quadrant is a rectangular antiprism extended by two neighboring ions.

7. Superconductor Byproducts

During the course of the innumerable experiments aimed at synthesizing superconductors almost every research group has come across new compounds, which have become known as "superconductor byproducts".

Since these byproducts represent reactions which compete with those leading to the superconductors, and therefore need to be eliminated from the solid-state reactions by a suitable choice of reaction conditions, it is very important to identify and understand them. A few examples, which also lead to some interesting conclusions about the crystal chemistry of HT_c superconductors will be described here. The compounds concerned are usually oxocuprates, but also occasionally oxoplatinates, which are formed by side reactions involving the platinum of the reaction vessel. Space will only allow these byproducts to be described briefly here.

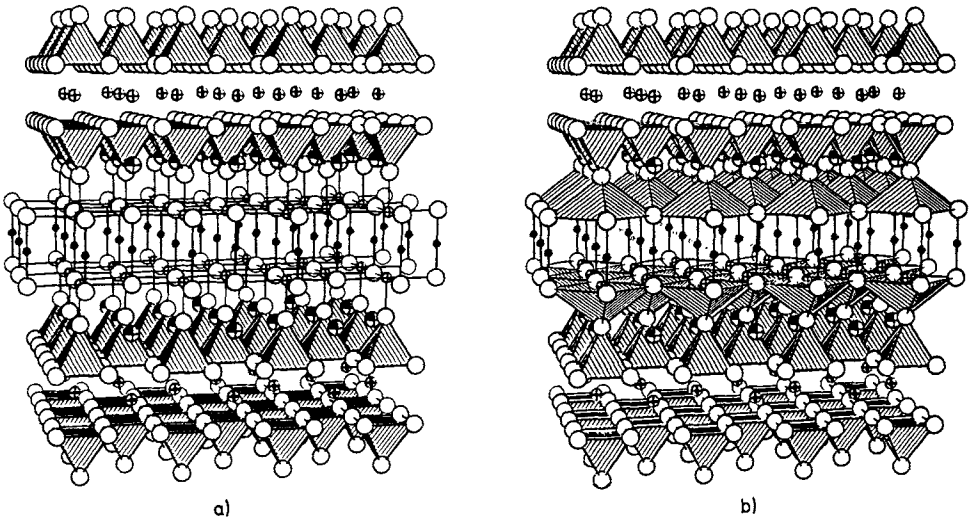

Fig. 17. Coordination polyhedra in $Pb_2Sr_{2.24}Nd_{0.76}Cu_3O_{8+x}$. a) Tetragonal pyramids around copper ions are shown hatched. ⊕ = Sr^{2+}, ⊕ = Sr^{2+}/Nd^{3+}; ● = Cu^+; ○ = O^{2-}. b) CuO_5 pyramids linked to PbO_5 pyramids, both shown hatched. The O–Cu^+–O dumbbells between the PbO pyramids are clearly shown. Symbols as in a).

7.1. Oxocuprates as Superconductor Byproducts

It should first be mentioned that, in the course of work on $YBa_2Cu_3O_{6+x}$, a well-known compound, $BaCuY_2O_5$,[302, 303] was rediscovered.[107, 304] The crystal structure of $BaCuY_2O_5$ was also refined by further measurements.[305] The $BaCuLn_2O_5$-type structure on which this is

based, with the characteristic isolated CuO_5 tetragonal pyramids, is formed by many of the lanthanoid elements.[304, 306, 307] It is interesting that Ni^{2+}, with octahedral coordination in the original $BaNiLn_2O_5$ structure, also crystallizes in the $BaCuLn_2O_5$-type structure with the smallest of the lanthanoid ions, Yb^{3+} and Lu^{3+}.[307–309] In contrast to the copper compounds, the Ni^{2+} ion in the NiO_5 tetragonal pyramid is surrounded by five equidistant O^{2-} ions.

7.1.1. $Sr_2CuO_2(CO_3)$

The compound $Sr_2CuO_2(CO_3)$ was a surprising discovery.[308] This dark gray substance is apparently an intermediate phase arising when $SrCO_3$ and CuO are allowed to react in the solid state to give the well-known compound Sr_2CuO_3.[94] The structure of Sr_2CuO_3, shown in Figure 4, is a variant of the K_2NiF_4 type.

It consists of isolated infinite one-dimensional chains made up of planar polyhedra linked at their corners. As Figure 18 shows, the Cu^{2+} ions in $Sr_2CuO_2(CO_3)$ also have

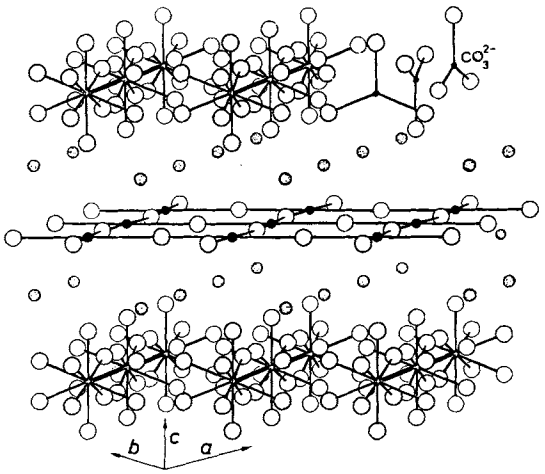

Fig. 18. Coordination polyhedra in $Sr_2CuO_2(CO_3)$ [306]. The planar grids of CuO squares and the orientations of the CO_3^{2-} groups are shown. ○ = Sr^{2+}, ● = Cu^{2+}, ○ = O^{2-}.

a square-planar coordination, in infinite two-dimensional layers of $[CuO_2]_n^{2-}$ units linked at the corners; these layers are combined with Sr^{2+} ions above and below to form $[Sr_2CuO_2]^{2+}$ blocks. These blocks in turn are joined by CO_3^{2-} groups. Figure 18 also shows that the carbonate groups exhibit an orientational disorder, with four equivalent orientations in the [110] planes.

7.1.2. $Sr_{14}Cu_{24}O_{38-\delta}$ and $La_6Ca_8Cu_{24}O_{39}$

These recently investigated crystal structures[310, 311] contain Cu^{2+} in a square-planar coordination. The overall structures can be regarded as made up of a tightly knit framework of $[Sr_2Cu_2O_3]^{2+}$ units enclosing a second partial structure of $[CuO_{2-\delta}]^{2-}$ units. Figure 19 shows that the outer framework contains $^2_\infty[Cu_2O_3\blacksquare]$ grids, where the solid square denotes defects. Inside this framework are arranged four isolated chains of edge-linked $CuO_{4-\delta}$ polyhedra, each shifted in phase relative to the others. The type of phase shift

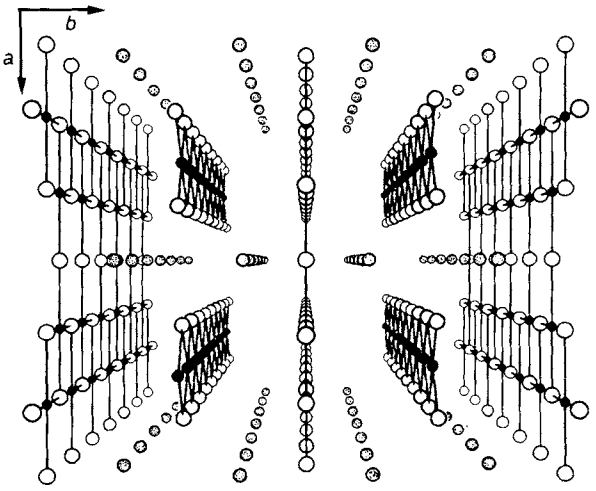

Fig. 19. Perspective view of the structure of $M_{14}Cu_{24}O_{38-\delta}$. ○ = M^{2+}, ● = Cu^{2+}, ○ = O^{2-}.

in each case determines the differences in structure between $Sr_{14}Cu_{24}O_{38-\delta}$ and $La_6Ca_8Cu_{24}O_{38}$. The recently published paper on these structures[312] is in good agreement with previous studies except for some significant differences in the stoichiometry. If an ideal situation with all the O^{2-} sites occupied is assumed, the formula $M_{14}Cu_{24}O_{41}$ is obtained. It has been shown[312] that the oxygen content in the crystal lattice is a function of the oxygen partial pressure during the synthesis of this substance. By varying the oxygen content, with otherwise identical preparative conditions, crystals with different oxygen occupancy have been prepared with formulas varying from $Sr_{14}Cu_{24}O_{38}$ to $Sr_{14}Cu_{24}O_{33}$.

7.1.3. $La_{8-x}Sr_xCu_8O_{20-x/2}$ and $La_4BaCu_5O_{13+x}$

Phases with the constitution $La_{8-x}Sr_xCu_8O_{20-x/2}$ with values of x varying from 1.28 to 1.92 have recently been described[313] and their metallic conduction properties have been investigated.[314] A typical region of the crystal structure is shown in Figure 20a. The octahedral coordination around Cu_I is indicated by hatching; it is interesting that the distances from Cu to the apical oxygens show a compression of about 5%. A second crystallographic copper site, Cu_{II}, has planar coordination to O^{2-}. In Figure 20a, the one-di-

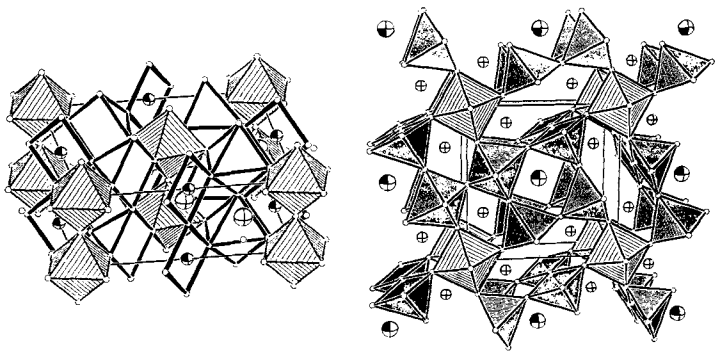

Fig. 20. a) Cu/O polyhedra in $La_{8-x}Sr_xCuO_{20-x/2}$. The octahedra around Cu^{2+} are shown hatched and the planar CuO_4 squares are indicated by thicker lines. The CuO_5 pyramids are shown in open form. ⊕ = Cu^{2+}. b) Cu/O polyhedra in $La_4BaCu_5O_{13+x}$. The CuO_6 octahedra are shown hatched and the CuO_5 pyramids are gray to black.

mensional chains of CuO_4 squares run through the crystal structure along the [001] direction in the middle of the unit-cell faces. The third site, Cu_{III}, has the tetragonal-pyramidal O^{2-} environment which is also often found in the superconductors. In Figure 20a, the CuO_5 polyhedra are shown by thicker lines. The authors[313] point out the resemblance to $La_4BaCu_5O_{13+x}$,[315,316] which also has CuO_5 polyhedra linked at their corners to CuO_6 octahedra to form a tunnel structure.

The structure of $La_4BaCu_5O_{13+x}$ is illustrated in Figure 20b. The most noticeable difference compared with $La_{8-x}Sr_xCu_8O_{20-x/2}$ is the absence of the Cu/O chains of planar corner-linked squares. Attempts to confirm the existence of an oxygen deficit in the lattice by more accurate determination of the occupancy factors, taking as an example a phase with the constitution $La_{6.4}Sr_{1.6}Cu_8O_{19.84}$, were unsuccessful. The oxygen deficiency is presumably shared equally between all the sites in the anion partial lattice. Further details are given in the original papers.[313,315]

7.1.4. $M_{10}Cu_{17}O_{29}$

In the course of preparing well-formed prismatic single crystals of the bismuth superconductor, an interesting new phase with the constitution $Bi_{0.31}Ca_{5.64}Sr_{4.05}Cu_{17}O_{29}$ was obtained.[317] It is essentially a bismuth-doped mixed crystal $M_{10}Cu_{17}O_{29}$, where M denotes alkaline-earth metals. The Cu/O coordination is shown in Figure 21. Planar-coordinated copper is present, for example in the form of isolated one-dimensional chains of edge-linked CuO_4 squares. Similar structural units have also been found in alkali-metal oxocuprates,[318-320] and in compounds with the constitution $M_{14}Cu_{24}O_{38-\delta}$ (M = alkaline-earth metal)[310-312] (cf. Fig. 19). The special feature of these chains compared with previously known oxocuprates is a torsional deformation within the square CuO_4 units, that is, a transition to tetrahedral coordination. The Cu/O regions at the beginning and middle of the unit cell are identical to the Cu/O partial lattice in $CaCu_2O_3$.[321] It is therefore useful from a crystallographic point of view to rewrite the formula $M_{10}Cu_{17}O_{29}$ as $M_{10}[(CuO_2)_7][(Cu_2O_3)_5]$. In the crystal structure the larger M ions occupy the spaces above the distorted oxygen squares shown in Figure 21.

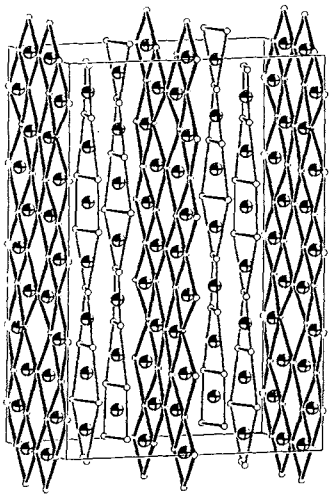

Fig. 21. The Cu/O coordination in $M_{10}Cu_{17}O_{29}$, as exemplified by $Bi_{0.31}Ca_{5.64}Sr_{4.05}Cu_{17}O_{29}$. ⊕ = Cu, ○ = O^{2-} (see text).

7.2. Oxocuprates and Oxoplatinates as Superconductor Byproducts

Superconducting phases prepared in corundum reaction vessels readily take up Al^{3+}, which usually has a deleterious effect on the superconductivity. This can be avoided by using crucibles of other materials such as platinum. However, platinum has only limited resistance to oxygen in alkaline media; it is therefore not surprising that various platinum-containing compounds or the oxoplatinates themselves have been found as by-products in research on superconductivity. One such substance, $La_{1.5}Sr_{0.5}(Cu_{0.75}Pt_{0.25})O_4$, has already been mentioned in Section 2;[83] it is not of interest here since it crystallizes with the well-known K_2NiF_4- type structure.

7.2.1. $Ba_2Y_2CuPtO_8$ and $Ba_2Er_2Cu_{1+x}Pt_{1-x}O_8$

Both these substances have the same crystal structure and they were studied almost at the same time.[322,323] To supplement the structural representations of $Ba_2Y_2CuPtO_8$ given in the literature,[322] the platinum and copper coordination is shown in Figure 22 from a different perspective. The octahedral coordination of Pt^{4+} to O^{2-} is indicated by hatching. This is a normal coordination sphere for Pt^{4+}. Cu^{2+} is again coordinated by O^{2-} in a tetragonal-pyramidal fashion, and we again find that the apex of the pyramid is stretched (by 6%). The Cu^{2+} ion lies practically in the base plane of this tetragonal pyramid. PtO_6 octahedra and CuO_5 pyramids are joined in a *cis* configuration at the corners of the octahedra, forming double chains along the direction of the *b* axis. The literature on this structure[322] draws attention to its relationship to $KPbCr_2F_9$.

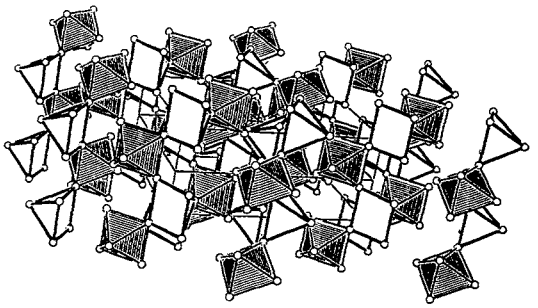

Fig. 22. Cu/O and Pt/O coordination in $Ba_2Y_2CuPtO_8$ and $Ba_2Er_2Cu_{1+x}Pt_{1-x}O_8$. The hatched octahedra are the polyhedra around Pt^{4+}, and the open tetragonal pyramids are the polyhedra around Cu^{2+}.

7.2.2. $Ba_3Ln_2PtCu_2O_{10}$ (Ln = Y, Ho)

Shiny metallic crystals, which appear dark green in transmitted light, were found to form from a reaction mixture consisting of Y_2O_3, $BaCO_3$, and CuO (0.5:2:3) in contact with the walls of a platinum crucible in air at about 600–700 °C.[324] X-ray diffraction studies gave a crystal structure with the coordination polyhedra shown in Figure 23. The structural features shown in Figures 23a–d, respectively, consist of capped trigonal prisms around Y^{3+}, a 12-fold

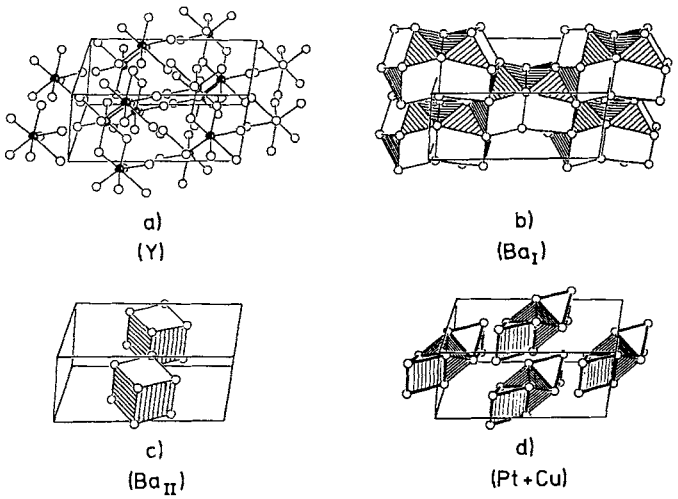

Fig. 23. Separate diagrams of the different polyhedra in $Ba_3Ln_2PtCu_2O_{10}$. a) Polyhedra around $Ln = Y^{3+}$. b) and c) Polyhedra around Ba^{2+}. d) Octahedra (finely hatched) around Pt^{4+} and tetragonal pyramids (partly hatched) around Cu^{2+}.

coordination around Ba_I, cubic coordination around Ba_{II}, and PtO_6 octahedra with CuO_5 pyramids. The corners of the unit cells in Figure 23c are also occupied by Ba_{II} in a cubic coordination, which is not shown here. The complete structure is obtained by superimposing all these partial structures. The main interest here is in the CuO_5 polyhedra, which are joined to the PtO_6 octahedra at their edges. This is a novel feature which sets the compound apart from other substances occurring in copper/platinum oxochemistry.

7.2.3. $Ba_8Pt_4Y_3O_{17.5}$

This section will conclude by describing a byproduct found in our own research. During the preparation of single crystals of the yttrium superconductor $YBa_2Cu_3O_{6+x}$ it was observed that at 1000 °C within 48 hours appreciable quantities of the platinum crucible material had coreacted.[325] The interesting structural feature of the new substance thus formed, $Ba_8Pt_4Y_3O_{17.5}$, is the discovery that Pt^{2+} and Pt^{4+} are present together. Here the divalent platinum ion in the oxoplatinate has the same role as the divalent copper ion in the mixed oxocuprate-oxoplatinates, but, in contrast to the chemistry of the oxocuprate, it forces the formation of isolated square-planar polyhedra around Pt^{2+}.[326] Figure 24 (cf. Ref. [327]) shows the characteristic coordination polyhedra around Y^{3+}, Pt^{4+}, and Pt^{2+}. The isolated PtO_4 squares rest on the centers of the faces of the cubic unit cells. The unit cells have $Pt^{4+}O_6$ octahedra at their corners, and the YO_6 octahedra are attached at the middle of each edge.

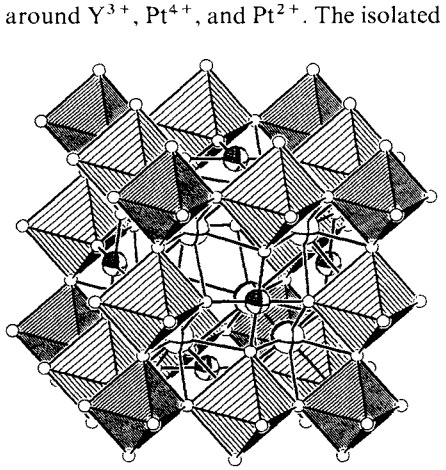

Fig. 24. Coordination polyhedra in $Ba_8Pt_4Y_3O_{17.5}$. Octahedra (hatched) around Y^{3+}, octahedra (gray) around Pt^{4+}; ⊕ = Ba^{2+}, ⊕ = Pt^{2+}, ○ = O^{2-}.

If the Pt^{2+} ions also had octahedral coordination and the centers of the unit cells were occupied by Ba^{2+} ions instead of being empty, $Ba_8Pt_4Y_3O_{17.5}$ would have been classified as a perovskite structure. Since Pt^{5+} is definitely not present in this structure, there must be a deficit in the oxygen partial lattice. A striking feature of the structure of $Ba_8Pt_4Y_3O_{17.5}$ is the fact that the center of the unit cell is unoccupied. This space is essentially due to the planarity of the Pt^{2+} coordination.

8. Concluding Remarks

The numerous studies carried out on oxide superconductors, with their widely differing chemical constitutions, show that all superconducting materials have certain common features, and superconductivity does not occur when these are absent. For example, all the materials have copper as part of their crystal structures, and, except for $Nd_{2-x}Ce_xCuO_4$, the coordination around Cu^{2+} or Cu^{3+} is always of a stretched tetragonal-pyramidal (C.N. = 4 + 1) or stretched octahedral (C.N. = 4 + 2) type. These are interesting observations for chemists involved in research on oxocuprates. From the standpoint of crystal chemistry the oxide superconductors and some of the byproducts described reveal Cu^{2+} in a new light. In the past I have promulgated the view that Cu^{2+} in oxocuprates has planar coordination, even when it forms part of the anionic partial lattice.[1] According to this view, the only circumstance in which Cu^{2+} could instead have octahedral coordination is as a cationic component of the oxometalates with severely stretched octahedra. Taking into account the superconductors and byproducts, this view now needs to be revised. The crystal structures described above show that copper is just as likely to be found in a tetragonal-pyramidal coordination to O^{2-}. In all the examples with pyramidal coordination the distance between Cu^{2+} and the apex of the pyramid is proportionately greater than the Cu–O distances in the square base. Since tetragonal pyramids can be regarded as capped octahedra, it seems as though Cu^{2+} is able to "remember" its role in an octahedron with tetragonal Jahn–Teller distortion. Apparently, the planar arrangement of oxygen around copper is not confined to Cu^{2+} with its d^9 configuration; instead, it seems that very small proportions of Cu^{3+} (d^8 configuration) in oxocuprates, whose presence was not previously recognized, quite generally induce the adoption of a planar oxygen environment. Research on the HT_c superconductors has also shown that Cu^{2+} is never present in isolation, but is accompanied by Cu^{3+} (and Cu^+), so that the properties of these materials are affected by mixed valences. This recognition has generated a reawakened interest in this long-familiar area of crystal chemistry.

The question of what changes would be seen in our world if the transition from metallic conduction to superconductivity could be shifted up to room temperature has already inspired much speculation. There is indeed still a long way to go in the direction of increased transition temperatures, and it may even require a breakthrough in a completely new direction, comparable with the step from the older metallic

superconductors to the new HT_c oxide superconductors. Extrapolating from the results of previous research, we may assume that with increasing transition temperatures the chemical substances used will become ever more complex and sensitive and it will be even more difficult to achieve the correct balance between the valence states of the metal ions and the oxygen deficit. New methods must therefore be found for carrying out syntheses with the necessary degree of control over the crystal lattice, if one is to have any chance at all of building into the lattice, according to a predetermined design, the structures which give superconductivity. But also the discovery of a high-T_c superconductor that does not contain copper would be a major step forward in the understanding of superconductivity in oxide systems.

Even if, in the 1990s, we are bound to reach an upper limit to T_c (as was the case for the metallic superconductors in the 1960s), no one who has been involved in this field of research would have wished to miss experiencing the enthusiasm that has driven it forward. It is to be hoped that other chemical substances to be discovered in the future will similarly stimulate collaboration between scientists on a worldwide scale.

Some of the studies carried out in my own laboratory and mentioned here were supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Bundesministerium für Forschung und Technologie. I and my collaborators express our thanks for this support. I am also grateful to some of my colleagues, Dr. Teske, graduate chemists Gutau, Lalla, Lang, Mader, and in particular to final-year student Hansen, for their help in preparing the figures which were produced using a modified ORTEP program[328, 326] at the University of Kiel computer center.

Light-Sensitive Molecular Building Blocks with Electron Transfer Activity: Synthesis and Properties of a Photochemically Switchable, Dicyanovinyl-Substituted Furan**

By *Jörg Daub,* Josef Salbeck, Thomas Knöchel, Christian Fischer, Horst Kunkely,* and *Knut M. Rapp*

Photochromic groups have the potential for serving as an "antenna" function; that is, they can be used to trigger photoinduced reactions in which the molecular structure, electronic structure, and physical characteristics of a substrate are reversibly altered. Such reactions are particularly easily demonstrated in the case of photochromic groups bound to polymers.[1–3] Multifunctional compounds with photochromic characteristics can thus behave as photochemically activated switches and sensors, the precise characteristics of which depend upon the nature of the functional groups. The magnitude of such an effect is governed by the extent to which the various groups interact.

We have previously demonstrated a significant influence of substituents upon the switchable photochromic system dihydroazulene **1** ⇄ vinylheptafulvene **2**, a system activated by visible light.[4] These studies have now been extended to include oligofunctional compounds in an attempt to examine the mutual influences exerted by a photochemically switchable substrate and various covalent or non-covalent functional groups[5a] or macromolecules.[5b, 6] Here we report results on the light-sensitive and electron-transfer-active reactant pair **1a** ⇄ **2a**. In these compounds the photochromic dihydroazulene unit is attached covalently to a dicyanovinyl substituent, which provides the electron-transfer capability. The connecting link is a 2,5-furandiyl residue. That the latter is capable of serving as an efficient transmitter of substituent effects is further demonstrated by the electron-transfer chemistry of **4**.

In contrast to **3**,[4a] room-temperature irradiation with visible light of a solution containing **1a** does not lead directly to observable photochromism. The only immediate change is the appearance of a weak absorption band in the electronic spectrum at 550 nm, suggesting that a small amount of **1a** has been converted to **2a**. However, if irradiation is conducted at −50 °C the originally orange solution changes to blue. The UV/VIS spectrum reveals a decrease in absorption at 440 nm and an intensification of the new band at 548 nm, which can be assigned unambiguously to the vinylheptafulvene **2a** (Fig. 1). These observations indicate that in the case of furan-substituted compounds of the type **1** ⇄ **2**, particularly if there are −M substituents in the furan ring, the reverse thermal reaction **2** → **1** is so rapid that room-temperature photochromism is prevented.

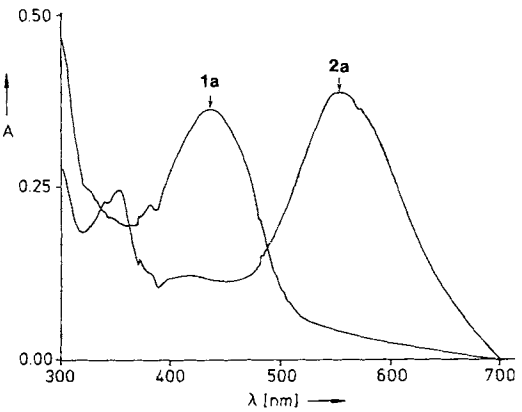

Fig. 1. Electronic spectrum of the photochromic system **1a** ⇄ **2a** at −50 °C in ethanol. Irradiation: ethanol film, mercury lamp (Osram HBO 100 W/2); Balzers filter K2 (420–480 nm); 30 s. Isosbestic points at 335, 362, and 468 nm. Ordinate: arbitrary units.

The reductive portion of the cyclic voltammogram for **1a** [in acetonitrile, tetrabutylammonium hexafluorophosphate as supporting electrolyte, vs. ferrocene (FOC)] reveals a signal ($E_{p,irr}$) at −1185 mV that clearly indicates irreversible formation of the radical anion $\mathbf{1a}^{\bullet\ominus}$. The model compound **4**, containing two dicyanovinyl groups, behaves differently; both cyclic voltammetry and UV/VIS spectroelectrochemistry suggest reversible conversion of **4** (yellow) into the radical anion $\mathbf{4}^{\bullet\ominus}$ (blue, $E_{1/2}$ = −890 mV vs. FOC) and the dianion $\mathbf{4}^{2\ominus}$ (orange, $E_{1/2}$ = −1240 mV vs. FOC) (Fig. 2). The locations of the most intensive absorption bands are: for the neutral compound **4**, 392 nm with a shoulder at 409 nm; for the radical anion $\mathbf{4}^{\bullet\ominus}$, 599 nm; and for the dianion $\mathbf{4}^{2\ominus}$, 493 nm with a shoulder at 467 nm. In the case of the benzoid analogue of **4** [i.e., a benzene ring bearing *p*-bis(dicyanovinyl) groups], both the radical anion and the dianion rapidly undergo further chemical reactions.[7, 8]

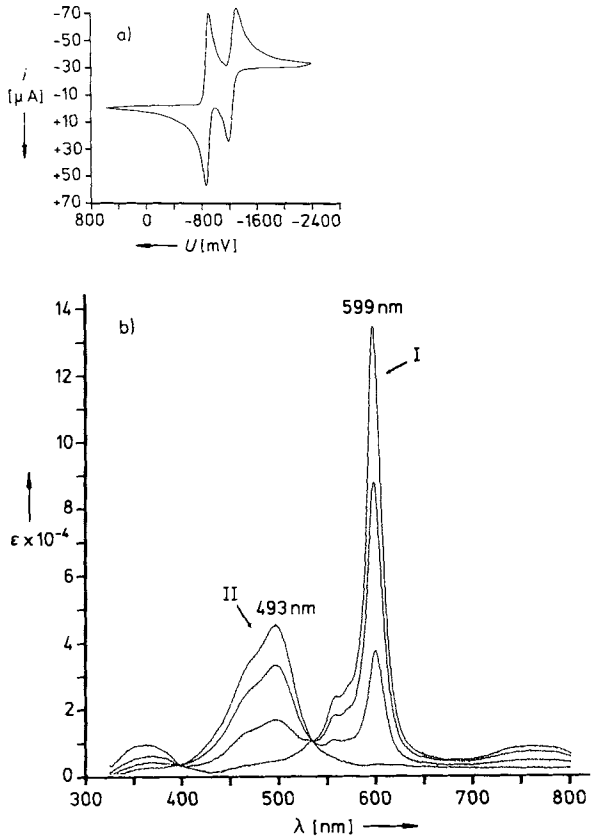
[**] This work was supported by the Volkswagen-Stiftung, the Bundesminister für Forschung und Technologie, and the Deutsche Forschungsgemeinschaft.



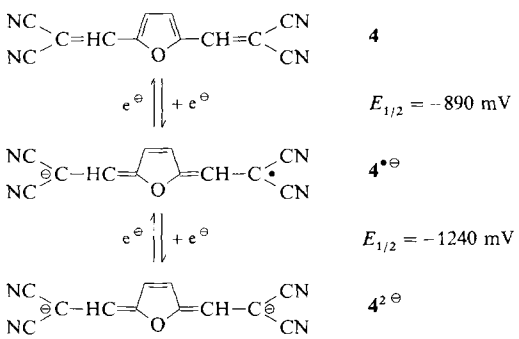


Fig. 2. (a) Cyclic voltammogram of the model compound **4** in acetonitrile ($c = 4 \times 10^{-3}$ M), 0.1 M tetrabutylammonium hexafluorophosphate as supporting electrolyte, potential data vs. ferrocene (FOC). (b) UV/VIS spectroelectrochemistry of **4** in acetonitrile ($c = 1 \times 10^{-3}$ M). Measurement conditions for curve I: -1000 mV vs. FOC (formation of $\mathbf{4}^{\bullet\ominus}$); for curve II: -1400 mV vs. FOC (formation of $\mathbf{4}^{2\ominus}$). Isosbestic points at 391 and 530 nm.

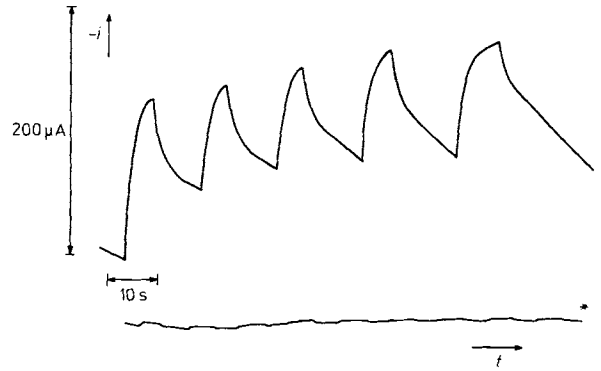
Photoelectrochemical experiments were carried out in a specially constructed cell[9] that permits irradiation of a solution of **1a** in acetonitrile with simultaneous detection of

current flow. Figure 3 shows the results in the form of a current/time curve for a sample subjected to a series of light pulses (5-sec duration) from a high-pressure xenon-mercury lamp (XBO). Current was measured as a function of the pulse train, maintaining a working potential of -1050 mV (vs. FOC). At this potential **1a** is inert, but **2a** is reduced to the radical anion $\mathbf{2a}^{\bullet\ominus}$, as is apparent from a comparison with the half-cell potential $E_{1/2}$ for $\mathbf{4}/\mathbf{4}^{\bullet\ominus}$. The intensity of the electrochemical signals diminishes with time, an indication that under these reaction conditions the radical anion $\mathbf{2a}^{\bullet\ominus}$



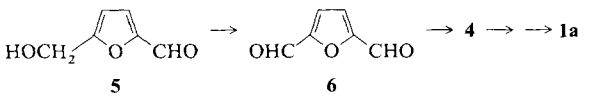


Fig. 3. Upper curve: photochemical switching effect upon irradiation of **1a** in acetonitrile ($c = 1 \times 10^{-3}$ M) at a potential of -1050 MV vs. FOC. Lower curve: no switching effect at a potential of -800 mV vs. FOC.

is subject to further transformations. Apparently the heptafulvene fragment in $\mathbf{2a}^{\bullet\ominus}$ lowers its chemical stability.

The observed results may be interpreted with respect to the electron-transfer characteristics of compounds **1a** and **2a** as follows: the bis(dicyanovinyl)furan derivative **2a** that arises from light-induced ring opening of **1a** is more readily reduced than **1a** itself. Therefore, establishment of an appropriate electrochemical potential permits detection of a cathode current.[10]

Compound **1a** was synthesized in part from substances of plant origin and in part from petrochemical reagents. The

electron-transfer portions of **1a** and **2a** were derived from D-fructose by way of the intermediate 5-(hydroxymethyl)furfural **5**.[11] Oxidation of **5** produced the dialdehyde **6** (barium manganate, 1,2-dichloroethane).[12] Knoevenagel condensation of **6** to **4** was carried out as a solid-state reaction (trituration of **6** in a mortar with malononitrile and neutral aluminum oxide, 70% yield).[13] [8+2] cycloaddition with 8-methoxyheptafulvene[15] and subsequent elimination of methanol (P_2O_5) produced the photochromic dihydroazulene **1a** in good yield.[4b, 16]

[10] Photochemical production of heptafulvene was demonstrated through cyclic voltammetry studies with a model compound based on **3**, one in which the $-OCH_3$ group was replaced by $-CN$. The signal obtained prior to irradiation had a peak potential of -1540 mV vs. FOC. This may be ascribed to formation of a short-lived radical anion of **3** ($-CN$ in place of $-OCH_3$). Irradiation led to a new signal with a peak potential of -1235 mV vs. FOC. This signal corresponds to irreversible formation of the radical anion derived from the heptafulvene that results from photochemical ring opening (C. Fischer, unpublished results). Technical difficulties have so far prevented similar experiments with **1/2**.

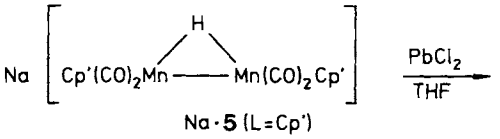
A mp = 207–208 °C has been reported for **4** prepared by a different method [14].

[{Cp'(CO)$_2$Mn}$_2$PbS*t*Bu]$^\ominus$; Completion of an Isoelectronic Series of Binuclear Complexes Containing Trigonal-Planar Coordinated Main Group Elements**

By *Frank Ettel, G. Huttner,** and *Laszlo Zsolnai*

Dedicated to Professor Margot Becke-Goehring on the occasion of her 75th birthday

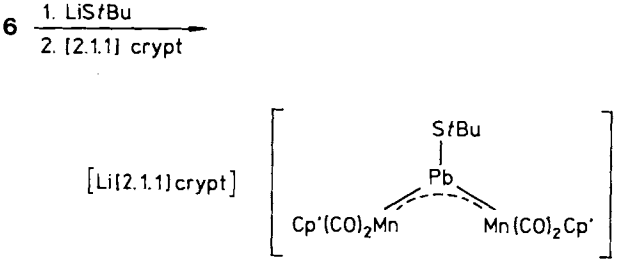
The relationship between dimetalla-allene systems and "inidene"-complexes[1] was recently demonstrated with the reaction sequence **1** → **2** → **3**[2, 3] for elements of the fifth main group as central atom.



Since the bonding pattern found in "inidene" complexes for elements of the fifth main group can also be realized with elements of the sixth main group, e.g. **4**,[4]

[{Cp(CO)$_2$Mn}$_2$SPh]$^\oplus$ **4**

we were encouraged to check for this bonding pattern also with elements of the fourth main group as bridge ligands by reaction of the corresponding heterocumulenes with Lewis bases.



The heterocumulenes [L(CO)$_2$Mn=X=Mn(CO)$_2$L] (L = Cp, Cp') were first described by *E. Weiss* et al. (X = Ge)[5, 6] and *W. A. Herrmann* et al. (X = Pb).[7] In the reaction of the hydrido complex **5**[8] with $PbCl_2$ or $GeCl_4$ we have now found a preparatively productive novel entry to these complexes, which serve as the necessary starting materials in this study.

The Pb-derivative **6** reacts spontaneously with alkali-metal thiolates to give anionic adducts (bathochromic shift of

[Cp'(CO)$_2$Mn=Pb=Mn(CO)$_2$Cp'] **6**

the ν_{CO} vibrations by ca. 30 cm^{-1}). By addition of cryptands to the reddish-brown solutions, the corresponding salts can be obtained in crystalline form.

For the derivative **7**, the expected trigonal-planar coordination of the lead atom could be confirmed by an X-ray structure analysis[9] (Fig. 1).

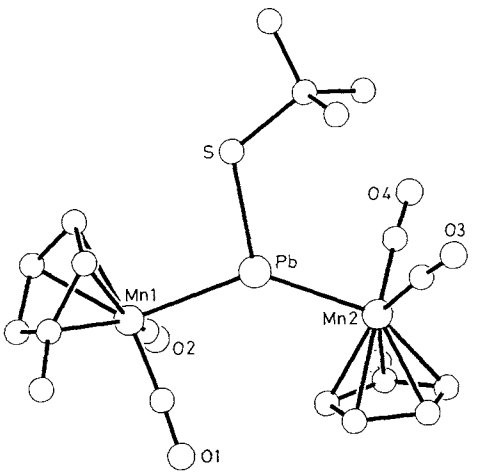


Fig. 1. Structure of **7** in the crystal.

[*] Prof. Dr. G. Huttner, Dipl.-Chem. F. Ettel, Dr. L. Zsolnai
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (FRG)

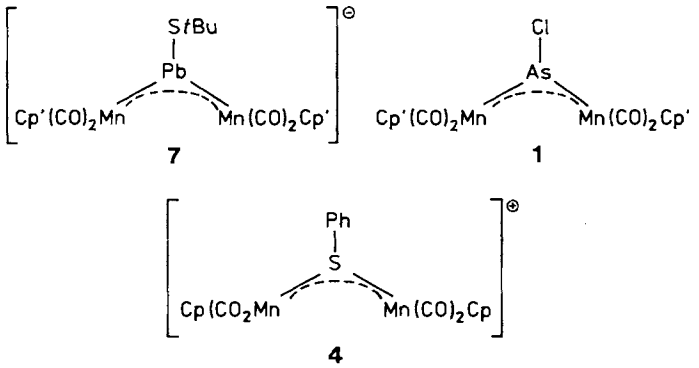
[**] This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft (SFB 247).

The maximum deviation from the best plane through the two Mn atoms, the S atom of the S*t*Bu substituent and the lead atom is 2.6 pm, and the Mn–Pb–Mn angle (135.5(1)°) is in good agreement with the corresponding angles in other compounds of the "inidene" type.[10]

The Pb–Mn bonds in **7** (257.4(3) pm) are somewhat longer than in the cumulene **6** with Cp instead of Cp′ (246.3(1) pm[7]). This change in bond length corresponds qualitatively to the changes which have been observed in the isoelectronic pair of arsenic compounds **1**/**2** and **3**/**2**.[2, 11]

The orientation of the S*t*Bu residue allows for a π-interaction between the S atom and the three-center 4π-electron system[10] of the Mn–Pb–Mn fragment: the *ipso*-C atom of the S*t*Bu substituent is located only 7 pm outside of the coordination plane of the lead atom. The observed orientation of the S*t*Bu substituent (Fig. 1) leads by necessity to a repulsive interaction with the $Cp'(CO)_2Mn$ fragment nearer to the *t*Bu group: the S–Pb–Mn2 angle is correspondingly large (123.98(1)° vs. S–Pb–Mn1 100.6(1)°). The π interaction between S and the Mn_2Pb unit is also manifested in a short Pb–S distance of 257.4(4) pm (cf. $[Cp'(CO)_2MnPb(SMes)_3]^{\ominus}$: Pb–S 260.3(6) pm[12]).

7 is the first "inidene" complex with a heavy element of the fourth main group as bridge atom (Fig. 2). The main group



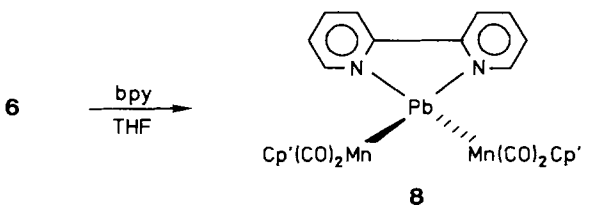


Fig. 2. Inidene complexes of elements of the fourth, fifth [10], and sixth [4] main groups.

atoms in such compounds are coordinatively unsaturated and can therefore add bases. In compounds with bridge elements from the fifth main group this unsaturated behavior is substantiated by many reactions.[10] The base adducts obtained are especially stable if the basic center is anchored via a chelate bridge on the main group element.[13]

Fully consistent with this, **6** forms neutral chelate complexes such as **8** upon reaction with neutral chelate ligands such as tmeda,[12] 1,10-phenanthroline(phen)[12] and 2,2′-bipyridine(bpy).

An X-ray structure analysis of **8** revealed (Fig. 3) that the lead atom has a distorted tetrahedral coordination geometry and that the Pb–Mn bonds (252.8(3) pm) are longer than in the starting compound **6**.

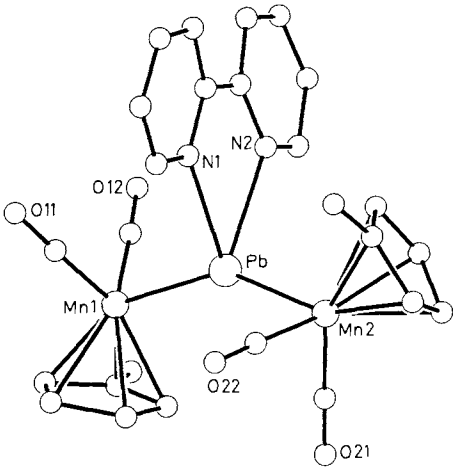

Fig. 3. Structure of **8** in the crystal.

The Mn–Pb–Mn angle with a value of 146.9(1)° lies in the range that is characteristic for isoelectronic chelate complexes of elements of the fifth main group.[13] The Pb–N bonds are comparatively long (255.9(9) pm);[14] however, Pb^{IV} centers are present in the reference compounds whereas **8**, like **6** and **7**, contains lead in the formal oxidation state 0. With respect to the coordination of the main group element, the silicon compound $[(hmpa)_2Si\{Fe(CO)_4\}_2]$[15] and the anionic base adduct complex of thallium $[Et_4N][\{Fe_2(CO)_8\}TlL]$ (L = tmeda, phen, bpy, ene)[16] are analogous to base adducts such as **8**.[16] The coordinatively unsaturated parent compounds of these analogues of **8** $[(L_nM)_2XR]^{n\ominus}$ (X = Si, n = 1; X = Tl, n = 2) and $[(L_nM)_2X]^{m\ominus}$ (X = Si, m = 0, X = Tl, n = 1) are so far unknown.

Experimental

All operations were carried out with freshly purified and distilled solvents under N_2. The silica gel (0.05–0.2 mm, J. T. Baker Chemicals) used for the chromatography was freed of oxygen in a vacuum for 3d and stored under N_2. IR spectra: Perkin Elmer 983G.

6: A solution of Na·**5** (L = Cp′; 1.0 g, 2.5 mmol) in 100 mL THF was treated with 2.0 g (10 mmol) of dry $PbCl_2$ and then stirred for 1 h at room temperature. The initially red solution turned dirty brown, and a grey precipitate formed. After passage through kieselgur on a frit and collection on silanated silica gel, column chromatography (silica gel, *l* = 25 cm, ∅ 2 cm) with pentane afforded a yellow zone ($[MnCp(CO)_3]$) and with toluene/pentane 1/2 a green zone ($[(\mu_3\text{-}Pb)\{Cp'(CO)_2Mn\}_3]$). Subsequent elution with diethyl ether afforded a dark-red zone, which after removal of the solvent furnished 370 mg (0.63 mmol) of **6**. Yield: 25% referred to **5**; characterization by comparison with authentic **6** (IR(THF): $\tilde{\nu}$ [cm^{-1}] = 1925 m, 1899 vs, 1860 vs, 1860 s [7].

[Li[2.1.1]crypt]-**7**: A solution of **6** (100 mg, 0.17 mmol) in THF (5 mL) was treated with 16.4 mg of Li*t*Bu in 5 mL of THF. The red color of the solution immediately deepened; the reaction is quantitative. Crystals of **7** were obtained as follows: after addition of 30 mg of [2.1.1]crypt the solution was concentrated to about 5 mL. Upon covering the red solution with a layer of 10 mL of Et_2O, Li[2.1.1]crypt **7** precipitated out within 5 d in the form of analytically pure, red needles. Yield: 38 mg (20% referred to **6**); m.p. 100 °C (decomp); correct C,H,S analysis. IR(THF): $\tilde{\nu}$ [cm^{-1}] = 1897 m, 1873 vs, 1837 s.

8: To a solution of **6** (100 mg, 0.17 mmol) in 5 mL of THF was added a solution of 26.5 mg (0.17 mmol) of bpy in 5 mL of THF. Immediately after the addition the IR spectrum showed the ν_{CO} bands of **8**. Deep-dark red, analytically pure crystals of **8** were obtained as follows: THF was removed from the solution at −20 °C until clouding was observed. The cloudy solution was then covered with a layer of 10 mL of Et_2O at 25 °C and diffusion allowed to take place for 5d. Yield: 38 mg (30% referred to 6); m.p. 130 °C (decomp); correct C,H,N analysis. IR(THF): $\tilde{\nu}$ [cm^{-1}] = 1925 w, 1899 s, 1887 vs, 1860 m, 1846 s.

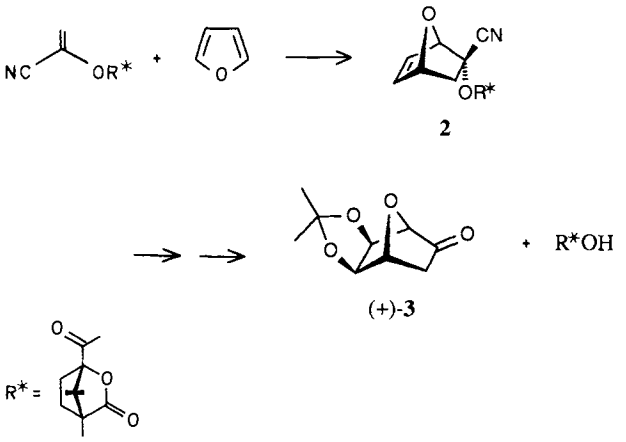
Total Synthesis of Allonojirimycin (5-Amino-5-deoxy-D-allopyranose)**

By *Yves Auberson* and *Pierre Vogel**

The substitution of the ring oxygen of furanoses and pyranoses by nitrogen[1,2] leads to a class of powerful and specific glycosidase inhibitors whose chemotherapeutic potential is now recognized.[3] Among the 5-amino-5-deoxyhexopyranoses the derivatives of D-glucose (gluconojirimycin),[1,4] D-mannose (mannojirimycin),[5] D-galactose (galactonojirimycin)[6,7] and L-altrose[3,8] have been described. Their 1-deoxy derivatives[3,8] as well as 5-amino-1,5-dideoxy-L-fucose[3,9] are also known. We present a short, total synthesis of the yet unknown allonojirimycin **1** (5-amino-5-deoxy-D-allopyranose) starting with the Diels–



1

Alder adduct **2** of furan and (–)-(1-cyanovinyl)-(1*S*)-camphanate.[10]

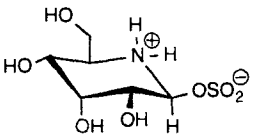
rue de la Barre 2, CH 1005 Lausanne (Switzerland)

[**] This work was supported by the Swiss National Science Foundation, the Fonds Herbette (Lausanne), and Hoffmann-La Roche & Cie, AG (Basel).

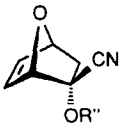
Double hydroxylation of **2** and protection of the glycol as an acetonide followed by saponification gives optically pure ketone (+)-**3** (60%) and (1S)-camphanic acid (recovery of the chiral auxiliary).[11] Ketone (+)-**3** is tranformed (three

steps, 72% overall) into bromolactone (–)-**4** as already described.[12] Treatment with allylic alcohol and CH_3SO_3H at 20 °C gives (–)-**5** (66%). Saponification of (–)-**5** (and other ester derivatives) with K_2CO_3, KOH or NH_3 leads to epimerization at C5 of the uronate. Selective hydrolysis of the allylic ester (–)-**5** into acid (–)-**6** (87%) is achieved by heating in $EtOH/H_2O$ 9:1 in the presence of 0.1 equiv. of $[Rh(PPh_3)_3Cl]$ and 0.2 equiv. of 1,4-diazabicyclo [2.2.2] octane (DABCO). The allyl ether → prop-1-enyl ether isomerization[13] is not observed under these conditions. Treatment of the potassium salt of (–)-**6** with NaN_3 (DMF, 60 °C, 8 h) affords azide (–)-**7** (90%) with retention of configuration.[14]



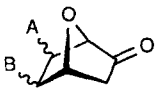
(–)-**4**

(–)-**5**:X=Br, R=R'= allyl
(–)-**6**:X=Br, R=H, R'= allyl
(–)-**7**:X=N_3, R=H, R'= allyl
(–)-**9**:X=N_3, R=Bn, R'= allyl

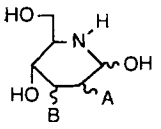


8:R'=*n*Pr
(–)-**10**:R'= allyl

Catalytical hydrogenation of (–)-**7** (H_2, Pt/C, EtOH) followed by reduction of the acid group with $BH_3 \cdot Me_2S$ (THF) furnishes **8** which affords the hydrochloride **1** · HCl (ca. 15%) on treatment with aqueous 1 N HCl. A better procedure was found by converting the cesium salt of (–)-**6** into the corresponding benzylic ester (–)-**9** (83%, based on (–)-**5**) by treatment first with CsN_3 and then with $PhCH_2Br$ in DMF. Reduction of (–)-**9** with $LiAlH_4$ in THF gives (–)-**10** (61%) which affords **1** · HCl on treatment with 1 N HCl. Its 360-MHz ^1H NMR spectrum is typical of allopyranose (^3J(H-C1,H-C2) = 9 Hz, ^3J(H-C4,H-C5) = 10.5 Hz) and not of talopyranose derivatives,[12] thus confirming the retention of configuration in reaction (–)-**6** + NaN_3 → (–)-**7** and the absence of epimerization at C5. Compound **1** · HCl is not stable in water and undergoes decomposition into pyridine derivatives at 20 °C. However, the bisulfite (–)-**11** (54%) obtained by treatment of (–)-**10** with SO_2/H_2O (50 °C, 3 d), then with SO_2/EtOH (0 °C), is a



stable, crystalline compound which could be fully characterized. Its 250-MHz ^{1}H NMR spectrum is similar to that of **1**·HCl and confirmed the pyranose structure (−)-**11** in D_2O.



(−)-**11**

13

14

Since the Diels–Alder adduct **12** [R″ = (1*R*)-camphanoyl] is also readily available, our synthesis can be applied to the preparation of 5-amino-5-deoxy-L-allopyranose. We have shown[15] that 7-oxabicyclo[2.2.1]hept-5-en-2-yl derivatives **2, 12** and their enones can be substituted at C5 and C6 with high regio- and stereoselectivity with various groups A and B giving systems **13**. Thus our synthetic approach should allow one, in principle, to obtain all kinds of 5-amino-5-deoxy-hexopyranose derivatives **14** readily.

Experimental Procedure

(−)-**5**: A mixture of (−)-**4** [12] (0.5 g, 1.54 mmol), allyl alcohol (10 mL) and CH_3SO_3H (90 μL) was kept at 20 °C for 18 h. After addition of saturated aqueous solution of $NaHCO_3$ (20 mL), the solvent was evaporated and the residue taken with CH_2Cl_2 and dried ($MgSO_4$). Filtration on silica gel (AcOEt/petroleum ether 1:2, R_f = 0.69) gave 426 mg (66%) colorless oil. $[\alpha]_D^{20} = -58$ (c = 1.55, CH_2Cl_2); IR (KBr): $\tilde{\nu}$ = 2980, 1740 cm^{-1}. [16]

(−)-**6**: A mixture of (−)-**5** (265 mg, 0.7 mmol), EtOH (18 mL), H_2O (2 mL), [$Rh(Ph_3P)_3Cl$] (70 mg, 0.07 mmol) and DABCO (18 mg, 0.14 mmol) was heated under reflux for 5 h. After addition of aq. 0.5 N KOH (20 mL) and solvent evaporation to ca. 20 mL, the mixture was washed twice with CH_2Cl_2 (20 mL). The aqueous phase was acidified with 1 N HCl (20 mL) and extracted four times with CH_2Cl_2 (25 mL). After drying ($MgSO_4$) and solvent evaporation 214 mg (87%) of a colorless oil was obtained. $[\alpha]_D^{20} = -74$ (c = 0.63, CH_2Cl_2); IR ($CDCl_3$): $\tilde{\nu}$ = 2980, 2940, 1720 cm^{-1}. [16]

(−)-**7**: The solution of the crude potassium salt of (−)-**6** (143 mg of acid, 0.42 mmol) was evaporated to dryness; the residue was dissolved in DMF (2.5 mL) and NaN_3 (61 mg, 0.92 mmol) was added. The solution was heated to 60 °C for 8 h. After dilution with 0.5 N NaOH (20 mL), the mixture was washed with CH_2Cl_2 (10 mL), then acidified with 1 N HCl (20 mL) and extracted three times with CH_2Cl_2 (10 mL). The extracts were combined, dried ($MgSO_4$) and the solvent evaporated, yielding 114 mg (90%) yellowish oil. IR ($CHCl_3$): $\tilde{\nu}$ = 2990, 2105, 1720 cm^{-1}. [16]

(−)-**9**: 378 mg of (−)-**6** (1 mmol) were neutralized by 182 mg of Cs_2CO_3 in 5 mL anhydrous DMF. After stirring at 20 °C for 15 min, CsN_3 (403 mg, 2.2 mmol) was added and the mixture heated to 60 °C for 8 h. After cooling to 20 °C, $PhCH_2Br$ (500 μL) was added. After stirring at 20 °C for 10 min, 1 N HCl (40 mL) was added and the mixture extracted three times with CH_2Cl_2 (20 mL). The organic phases were combined, washed with saturated aqueous solution of NaCl (20 mL) and dried ($MgSO_4$). After solvent evaporation, the residue was filtered on silica gel (AcOEt/petroleum ether 1:4, R_f = 0.5), yielding 419 mg (96%) yellowish oil. Purification by column chromatography on silica gel afforded an analytical sample of (−)-**9** (58%). $[\alpha]_D^{20} = -41$ (c = 0.96, CH_2Cl_2); IR ($CDCl_3$): $\tilde{\nu}$ = 2990, 2940, 2100, 1740 cm^{-1}; ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.39 (m; 5H), 5.75 (dddd, ^3J = 17, 10.5, 6, 5 Hz; 1H), 5.30, 5.22 (2 d, ^2J = 12 Hz), 5.18 (dm; 1H), 5.15 (dm; 1H), 5.11 (s; H-C1), 4.88 (dd, ^3J = 6.0, 1.0 Hz; H-C3), 4.63 (d, ^3J = 6 Hz; H-C2); 4.48 (dd, ^3J = 9.0, 1.0 Hz; H-C4), 4.06, 3.78 (2 ddt), 3.85 (d, ^3J = 9.0 Hz; H-C5), 1.48, 1.31 (2 s; 2 Me).[16]

(−)-**10**: A mixture of (−)-**9** (50 mg, 0.13 mmol), $LiAlH_4$ (14 mg) and anhydrous THF (2 mL) was stirred at 20 °C for 1 h. After addition of 1 N HCl (10 mL), the mixture was washed twice with CH_2Cl_2 (10 mL), then 2 N NaOH (10 mL) was added and the solution extracted twice with CH_2Cl_2 (10 mL). The extracts were combined, dried ($MgSO_4$) and the solvent evaporated to yield 21 mg (61%) colorless oil that solidifies slowly. $[\alpha]_D^{20} = -46.5$ (c = 0.72, CH_2Cl_2); IR (KBr): $\tilde{\nu}$ = 3380, 3300, 2990, 2940, 2860, 1378, 1080 cm^{-1}.

(+)-**10**, obtained from (±)-**3** as described above, is a colorless solid, m.p. = 83.5–84.5 °C.

1·HCl: A mixture of (−)-**10** (100 mg, 0.38 mmol) and 1 N HCl (2 mL) was kept at 20 °C for 18 h. Solvent evaporation gave an unstable, white solid. ^{1}H NMR (360 MHz, CD_3OD): δ = 4.59 (d, J = 9 Hz; H-C1), 4.14 (t, J = 2.5 Hz; H-C3), 3.96 (d, J = 3.5 Hz; H_2C6), 3.82 (dd, J = 10.5, 2.5 Hz; H-C4), 3.71 (dd, J = 9.0, 2.5 Hz; H-C2), 3.49 (dt, J = 10.5, 3.5 Hz; H-C5).

(−)-**11**: SO_2 was bubbled through a solution of (−)-**10** (100 mg, 0.38 mmol) in H_2O (2 mL) at 55 °C for 3 d. EtOH (2 mL) was added and the solution saturated with SO_2 at 0 °C. The precipitate was collected, yielding 54 mg (54%) colorless crystals. m.p. = 104–106 °C (dec.). $[\alpha]_D^{20} = -3.8$ (c = 1.55, H_2O); IR (KBr): $\tilde{\nu}$ = 3420, 3060–3020, 1570, 1425, 1210, 1065, 1045 cm^{-1}; ^{1}H NMR (250 MHz, D_2O): δ = 4.19 (d, J = 11 Hz; H-C1), 4.13 (dd, J = 2.5, 1.5 Hz; H-C3); 4.05 (dd, J = 11.0, 2.5 Hz; H-C2), 3.94, 3.84 (2 dd, ^2J = 13, ^3J = 2.5 Hz, H_2C6), 3.84 (dd, J = 11.0, 1.5 Hz, H-C4), 3.40 (dt, J = 11.0, 2.5 Hz, H-C5); ^{13}C NMR (90.55 MHz, CD_3OD/D_2O 1:4): δ = 71.8 (d, ^1J(C,H) = 151 Hz), 68.4 (d, ^1J(C,H) = 150 Hz), 68.3 (d, ^1J(C,H) = 150 Hz), 66.1 (d, ^1J(C,H) = 142 Hz; C1, C2, C3, C5), 58.5 (t, ^1J(C,H) = 146 Hz; C6), 57.5 (d, ^1J(C,H) = 164 Hz; C4). Satisfactory elemental analysis was found. Racemic (±)-**11**, m.p. = 143–145 °C (dec.).

Formation of 2,4,4-Trimethylthiete by Photodecarbonylation of 3,3,5-Trimethyl-2(3*H*)-thiophenone

By *Heiko Hinrichs* and *Paul Margaretha**

Irradiation of the carbonyl tautomers of hydroxythiophenes, for example, 2(5*H*)- and 3(2*H*)-thiophenones,[1,2] as well as their 1-oxides,[3] results in selective formation of new

[*] Prof. Dr. P. Margaretha, Dipl.-Chem. H. Hinrichs
Institut für Organische Chemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (FRG)

and interesting organosulfur compounds. Here we report that the previously uninvestigated 2(3*H*)-thiophenones react similarly. Thus, irradiation[4] of 3,3,5-trimethyl-2(3*H*)-thiophenone **1**[5] in MeOH, MeCN, or CH_2Cl_2 leads to a single (GC)[6] product, **2**, which was identified as a thiete on the basis of its spectroscopic data[7] and its quantitative transformation to 4-mercapto-4-methylpentan-2-one **3** upon addition of small amounts of water. A very small number of thietes have so far been prepared from 3-(*N*,*N*-dialkylamino)thietanes by Hofmann elimination.[8–10] The mercaptoketone **3**, isolated in 70% yield (based on **1**),[11] was identified on the basis of its ^{1}H NMR spectrum[12] and by comparison with an authentic sample.[13]

Noteworthy is the formation of only the *cyclic* product **2** upon decarbonylation of **4** (the known α,β-unsaturated thioketone **5** dimerizes to give a stable thiine,[14] which was not observed here). By contrast, preliminary findings indicate that 2(3*H*)-furanones[15] and 3-cyclopentenones[16] give exclusively *open-chain* products (α,β-unsaturated ketones and 1,3-dienes, respectively). This differing behavior of thiolactone **1** (or diradical **4**) was not predicted from CNDO calculations on model compounds.[17]

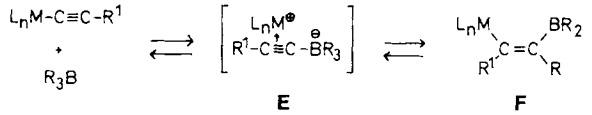
Triorganolead Cations Stabilized by Side-on Coordination to the C≡C Bond in Alkynylborates**

By *Bernd Wrackmeyer,** *Klaus Horchler*, and *Roland Boese*

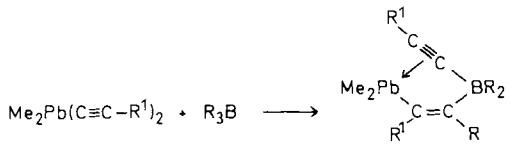


The many-faceted coordination chemistry of the C≡C bond (Scheme 1) is particularly well documented in the case of transition metals.[1] Apart from the η^1-bond in $L_nM-C\equiv C-R^1$,[2] main group elements mainly form dimers [e.g. $(R_2M-C\equiv C-Ph)_2$ with M = Be,[3a] Al,[3b] and Ga;[3c] there is also a gradual transition between structures of type **C** and **D**[3d]], oligomers (lithium alkynides,[4] Type **D**) or ionic acetylides (e.g. CaC_2[5]).

A [$\eta^2\{\sigma,\sigma\}$][1g,2] **B** [$\eta^2\{\pi,\pi\}$][1] **C** [$\eta^2\{\sigma,\pi\}$][1f,6] **D** [$\eta^1\{\sigma,\sigma\}$][1,3,4]

Scheme 1.

There are, however, few compounds in which the alkynide ligand bridges both a transition metal and a main group element as in **C** or **D**,[6] and such a bridging of two different main group elements was previously unknown. In many reactions of the alkynides $L_nM-C\equiv C-R^1$ with triorganoboranes, the M–alkynyl bond is cleaved (Scheme 2). Structure **E**, which is reminiscent of alkynylborates, has been suggested as an intermediate in the formation of **F**.[7] In **E**, which is similar to **C**, the cationic fragment is coordinated side-on to the C≡C bond.



Scheme 2. L_nM = Me_3Si, Me_3Sn, Me_3Pb, $(Et_3P)_2(MeC\equiv C)Pt$; R = alkyl; R^1 = H, alkyl, aryl, L_nM.

We have now been able to detect the intermediates **3** analogous to **E** in the reaction of bis(alkynyl)dimethyl-

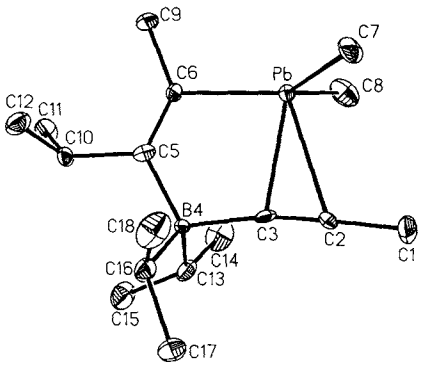
[a] 10–15% solutions in C_6D_6, Bruker AC 300, 26–28 °C, δ-values vs. Me_4Si (^{13}C) [$\delta(C_6D_6) = 128.0$], Et_2O-BF_3 (^{11}B) and Me_4Pb (^{207}Pb), in each case external; coupling constants $^nJ(^{207}Pb^{13}C)$ in Hz; (br) refers to broad ^{13}C NMR signals from carbons bonded to boron. [b] In [D_8]toluene at −20 °C [$\delta(C_6D_5CD_3) = 20.4$]. [c] Signal broad, since at room temperature the ring inversion is slow on the NMR timescale. [d] The methyl groups are diastereotopic. [e] $\delta(^{13}C(OMe)) = 51.7$ [3.3]. [f] After addition of pyridine (ratio **3b**/pyridine 1/1.5): $\delta(^{11}B) = -6.3$; $\delta(^{207}Pb) = 464.0$ (25 °C), 417 (0 °C), 384 (−20 °C), 363 (−40 °C), 353 (−60 °C).



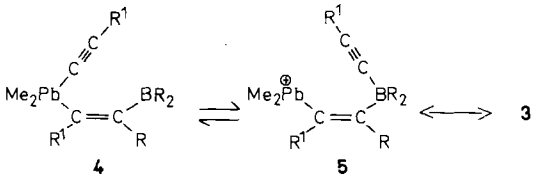


Fig. 1. Structure of **3b** in the crystal (hydrogen atoms not shown). Selected bond lengths [Å] and angles [°]: Pb-C2 2.648(6), Pb-C3 2.467(6), Pb-(mid point C2, C3) 2.487, Pb-C6 2.203(3), Pb-C7 2.222(7), Pb-C8 2.206(7), C1-C2 1.481(10), C2-C3 1.210(10), C3-B4 1.640(10), B4-C5 1.648(8), C5-C6 1.334(9); C6-Pb-C3 81.3(2), C6-Pb-C2 108.3(2), C6-Pb-C7 123.7(2), C6-Pb-C8 118.6(3), C7-Pb-C8 113.4(3), C1-C2-C3 177.3(7), C6-Pb-(mid point C2, C3) 96.5, C8-Pb-(mid point C2, C3) 99.1, C2-C3-B4 169.5(6), C3-B4-C5 111.2(5), B4-C5-C6 125.6(6), C5-C6-Pb 115.6(4), B4-C3-Pb-C6 6.8, C3-C2-Pb-C6 5.8, C3-B4-C5-C6 3.8, B4-C5-C6-Pb 2.7.

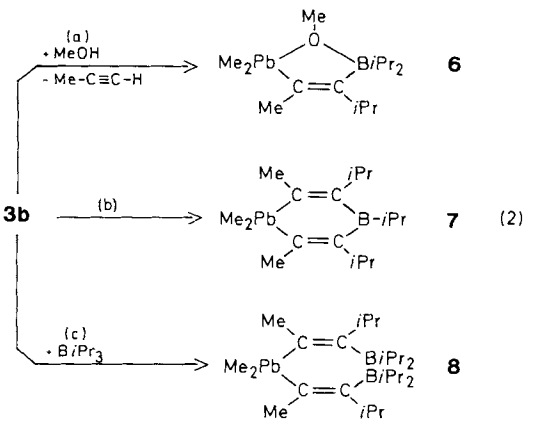
The first step of the reaction (formation of **4**, analogous to the transformation of **E** into **F**) is followed by a rapid intramolecular transfer of the alkynyl residue from the lead to the boron atom, giving the alkynylborate anion and the triorganolead cation, i.e. the mesomeric structure **5** (Scheme 3).



Scheme 3.

The cationic center in **5** is stabilized by the asymmetric side-on coordination of the lead atom to the C≡C bond; the lead atom thus achieves a distorted tetrahedral geometry, and the resulting ring is nearly planar. This confirms experimentally the mechanistic ideas presented earlier[7] for the 1,1-organoboration reaction and should thus be a suitable model for other borations,[10] as well as for many reactions of alkynyltriorganoborates with electrophiles.[11] The relative stability of the zwitterionic intermediate (Type **E**) as a function of the groups L_nM, R^1 and R provides an explanation for the reversibility of the 1,1-organoboration previously observed (where **F** reverts to **E** and to the starting materials).[7b]

The presence of **3** is demonstrated qualitatively by the ^{207}Pb NMR spectra of the reaction mixtures (δ_{Pb}^{207} = 630–750, shifted by $\Delta\delta$ 600–800 to lower field with respect to tetraorganoplumbanes[12]). The δ_B^{11} values are typical for tetracoordinated boron,[13] while the δ_C^{13} (C≡C) values are characteristic of the B–C≡C–R^1 group, the signal for the carbon atom bound to boron being extremely broad.[13] The agreement between the positions of the ^{13}C and ^{207}Pb signals of **3b** in solution and in the solid state[14] shows that the main features of the structure are retained in solution.

Compounds **3** decompose on warming above 40 °C (lead is deposited from **3a** even at 10–20 °C) and are very reactive; thus **3b** reacts with methanol to give **6**,[15a] undergoes intramolecular rearrangement to **7**,[15b] and yields **8** on treatment with further triisopropylborane[15c] [Eq. (2a)–(2c)]. The electrophilic nature of the lead atom is made clear by the interaction of **3b** with pyridine: the ^{207}Pb resonance of the complex is shifted by more than $\Delta\delta$ = 200 to lower frequencies.

(2)

The clean formation of **8** confirms that **3** is produced reversibly. With the exception of R^1 = *t*Bu and R = Et, it is

not possible to observe the formation of intermediates in reactions between BR_3 and bis(alkynyl)dimethylstannanes **1**, where Sn is used instead of Pb. In such reactions we only observe products corresponding, for example, to **7**[16b] and **8**.[16c]

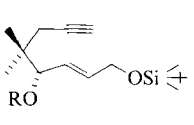
The Effect of Acetylene Substituents on a Pd^{II}-Catalyzed Cycloisomerization. Total Synthesis of (−)-Sterepolide and Assignment of Absolute Stereochemistry

By *Barry M. Trost,* Philip A. Hipskind, John Y. L. Chung, and Chuen Chan*

The curious biological and biochemical questions posed by sesquiterpenoid fungal metabolites enhance interest in their absolute stereochemistry and synthesis. The biosynthesis of cyclopentane-containing sesquiterpenes indicates that different classes arise by enantiomeric folding of farnesyl pyrophosphate by the various sesquiterpene synthetases.[1] Among the cyclopentane sesquiterpenes, the isolactaranes,[2] represented by isolactarorufin,[3] merulidial,[4] and sterepolide **1**,[5] constitute a relatively rare class compared to the more common and frequently co-occurring lactaranes. We therefore undertook an asymmetric synthesis of **1**[6] in order to develop a facile strategy to enantiomerically pure members of this family—a strategy which also might be modified to apply to related families such as marasmanes, illudanes, and sterpuranes—as well as to establish its absolute configuration.

In considering a strategy based upon an enyne cyclization as outlined in Scheme 1, we envision an intermediate **2** in

1 **2** **3** **4** **5**



Scheme 1. R = *p*-methoxybenzyl.

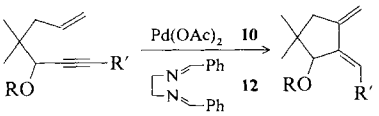
[**] We thank the National Institutes of Health, General Medical Sciences, for their generous support of our programs. We are specially grateful to Prof. *W. Ayer* for an authentic sample of (−)-sterepolide. Mass spectra were gratefully provided by the Mass Spectrometry Facility, University of California, San Francisco, supported by the NIH Division of Research Resources.

which C-1 becomes a stereogenic center. All the stereogenic centers of **1** are derived by propagation of the stereogenic center of diene **3** via a diastereoselective Diels–Alder reaction. The success of this sequence depends upon the ease of accessibility of enantiomerically pure diene **3**. The excellent enantioselective reductions of acetylenic ketones (cf. **5**)[7] made the enyne **4** the substrate of choice for a Pd^{II}-catalyzed cycloisomerization.

In our synthesis of racemic **1**,[6] we employed the related enyne substrate **6**, since our early work showed that substrates bearing alkyl substituents at the acetylenic terminus

6



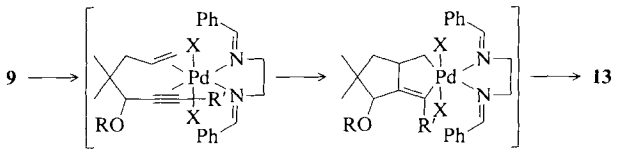
7: (*S*)
8: (*R*)

failed to react.[8] The awkwardness of a scalemic[9] synthesis via an enyne such as **6**, because of the difficulties in carrying out an asymmetric synthesis except through a resolution of the *O*-methylmandelate esters **7** and **8**, led us to reconsider the feasibility of expanding the scope of our Pd^{II}-catalyzed enyne cyclization to substrates containing disubstituted acetylenes.[10] The formation of 1,3-dienes, substrates for subsequent cycloaddition chemistry, provides further impetus for this study.

The substrate **9** offers a convenient template to explore the effect of the acetylene substituent on the efficacy of the cyclization. With palladium acetate **10** or bis(triarylphosphane)palladium acetate **11** as catalyst, poor reactions

$Pd(OAc)_2$ **10** $[Pd(Aryl_3P)_2(OAc)_2]$ **11**

occur with $R' = CH_3$, $SiMe_3$, Cl, SPh, CH_2SPh. When R′ is a strong electron-withdrawing group like acetyl, cyclization

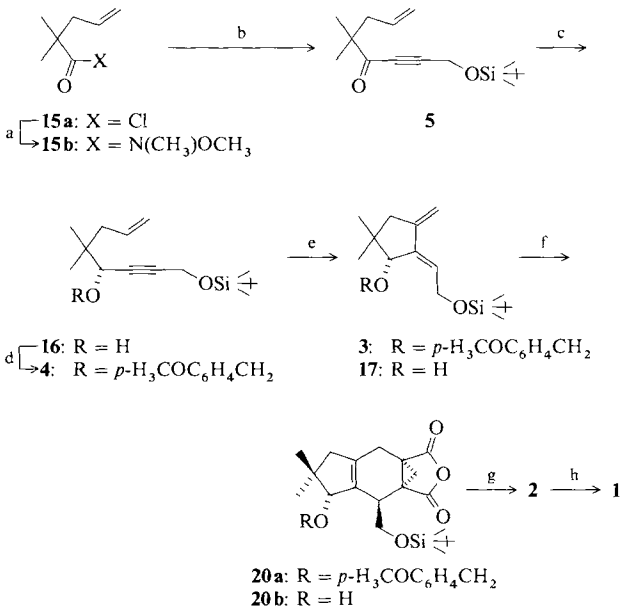


9 **13**

$R = p\text{-}H_3COC_6H_4CH_2$

a: $R' = COCH_3$, **b**: $R' = CH_2OCH_3$, **c**: $R' = CH_2CH_2OCH_3$, **d**: $R' = SiMe_3$, **e**: $R' = CH_3$, **f**: $R' = OC_2H_5$

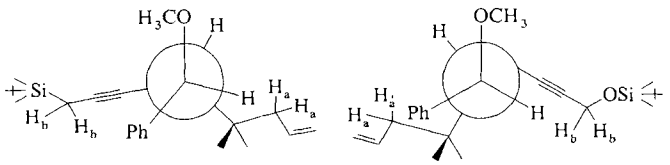
proceeds with **11** (aryl = phenyl or *o*-tolyl) but in only 20–40% yield.[11] Decreasing the electron-withdrawing capability of the substituent by switching to methoxymethyl or even more so by switching to methoxyethyl still affords low yields of **13**, and mixtures of isomeric products result. Furthermore, the rate of the reaction depends critically on the quality of complex **11**.



A dramatic change in the prospects of this cycloisomerization occurs by changing the ligands to *N*,*N*′-bis(benzylidene)ethylenediamine **12**.[12] For the acetyl substrate **9a**, the yield of **13a**[13] jumped to 67%. Most importantly, the other substrates, which either failed to react or led to mixtures of isomeric products, smoothly cyclize (substrate, % yield of cyclization product: **9b**, 77%; **9c**, 96%; **9d**, 89%; **9e**, 88%; **9f**, 32%).[13] In a typical reaction, a 0.2 M solution of substrate in benzene containing 5–15 mmol% each of **12** and palladium acetate **10** is heated at 60 °C. After complete reaction, the mixture is directly chromatographed to give **13**. A possible rationale for the remarkable role of ligand **12** on the efficacy of the cyclization compared to phosphane ligands invokes a mechanism (Scheme 2) in which this ligand can be thought to stabilize a Pd^{IV} species[14] much more effectively than the triarylphosphane ligands.[15]

14a **14b**

Scheme 2. R = *p*-methoxybenzyl; for R′ see above.



The successful cyclization of disubstituted acetylenic substrates led to a scalemic synthesis of the requisite diene **3** from the known acid chloride **15a** (Scheme 3).[16] Addition

Scheme 3. Synthesis of (−)-sterepolide **1**. a) $CH_3NHOCH_3 \cdot HCl$, pyridine, $CHCl_3$, 0 °C → RT, 96%. b) $LiC{\equiv}CCH_2OSiMe_2tBu$, THF, −78 °C, 98%. c) $LiAlH_4$/Darvon alcohol complex, ether, −100 °C, 100%, >98% *ee*. d) NaH, *p*-H_3C-$C_6H_4CH_2Br$, cat. Bu_4NI, THF, RT, 82%. e) 5% $Pd(OAc)_2$ **10**, 10% **12**, benzene, 70 °C, 81%. f) 1) 2-Bromomethylmaleic anhydride, benzene, 80 °C; 2) DBU, benzene, RT, 81%. g) Two steps (see [6]), 64%. h) Dichlorodicyano-*p*-benzoquinone, CH_2Cl_2, H_2O, then Pd/C, CH_2Cl_2, 85%.

of a 1.9 M solution of ketone **5** in ether to a 0.095 M solution of the $LiAlH_4$/Darvon alcohol complex at −100 °C at a rate of 10 mL h^{-1} gave a quantitative yield of the alcohol **16**. Assessment of the enantiomeric excess as >98% (NMR and VPC) and assignment of absolute configuration as *R* (NMR) rests upon analysis of the *O*-methylmandelate esters **18** and **19** of the two protected enantiomeric alcohols **4** (Scheme 4) which are shown in extended Newman projections (**18**, $\delta = 2.05$ (H_a), 4.23 (H_b); **19**, $\delta = 1.79$ (H_a), 4.34 (H_b)).[17] The assignment of the *R* configuration also derives from ample precedent in the Mosher reduction of acetylenic ketones.[7]

Gratifyingly, the **12**–$Pd(OAc)_2$ complex smoothly catalyzes the cycloisomerization of **4** to enantiomerically pure

18 19

Scheme 4. Esters **18** and **19**.

diene **3**.[13] Propagation of the stereochemical information of the carbinol center of **3** to the stereogenic centers of sterepolide **1** depends upon the diastereofacial selectivity of the Diels–Alder reaction, which we suspected would depend upon the choice of O substituent. Based upon the notion of a possible (but controversial) π-stacking interaction to direct the dienophile on the face of the diene distal to oxygen,[18] we chose the *p*-methoxybenzyl group. Indeed, cycloaddition with diene **3** followed by cyclopropyl ring closure produces a single diastereomeric tetracyclic anhydride **20a**. On the other hand, a similar sequence from diene **17** produces a 5:4:1 ratio of diastereomeric tetracyclic products. Completion of the synthesis following the protocol in the racemic series[6] produces (−)-**1**/m.p. 226–227 °C, $[\alpha]_x^{28}$ ($c = 0.56$, $CDCl_3$), x = Na D line, −112.7°; x = 557 nm, −113.2°; x = 546 nm, −130.4°; x = 435 nm, −234.3°; x = 405 nm, −275.4°).

Since the rotation of the natural product had not been recorded, we measured its rotation on a sample kindly supplied by *W. Ayer*. The excellent agreement of its rotation ($[\alpha]_D^{28}$ −111.4° ($c = 0.63$, $CDCl_3$)) with that of our synthetic sample, as well as a sharp mixed melting point (227–227.5 °C), confirm the identity of the two samples and establishes the absolute configuration depicted in Scheme 1. This assignment indicates that the isolactaranes derive from the same enantiomeric folding of the farnesyl pyrophosphate as has been established for the sterpuranes, illudanes, and marasmanes.

This facile route produces enantiomerically pure (−)-sterepolide **1** in 11 steps and 34% overall yield. In this strategy, a carbinol center, whose stereochemistry is ultimately destroyed in the final product, becomes a convenient stereochemical control element since its stereochemistry readily derives from asymmetric carbonyl reductions. Most importantly, the development of the *N,N'*-bis(benzylidene)ethylenediamine ligand **12** greatly extends the scope of this novel palladium-catalyzed cycloisomerization. The l-substituted dienes **13**, especially those bearing the l-ethoxy (**13f**) and l-trimethylsilyl (**13d**) substituents, are particularly valuable building blocks for further ring construction via cycloadditions.

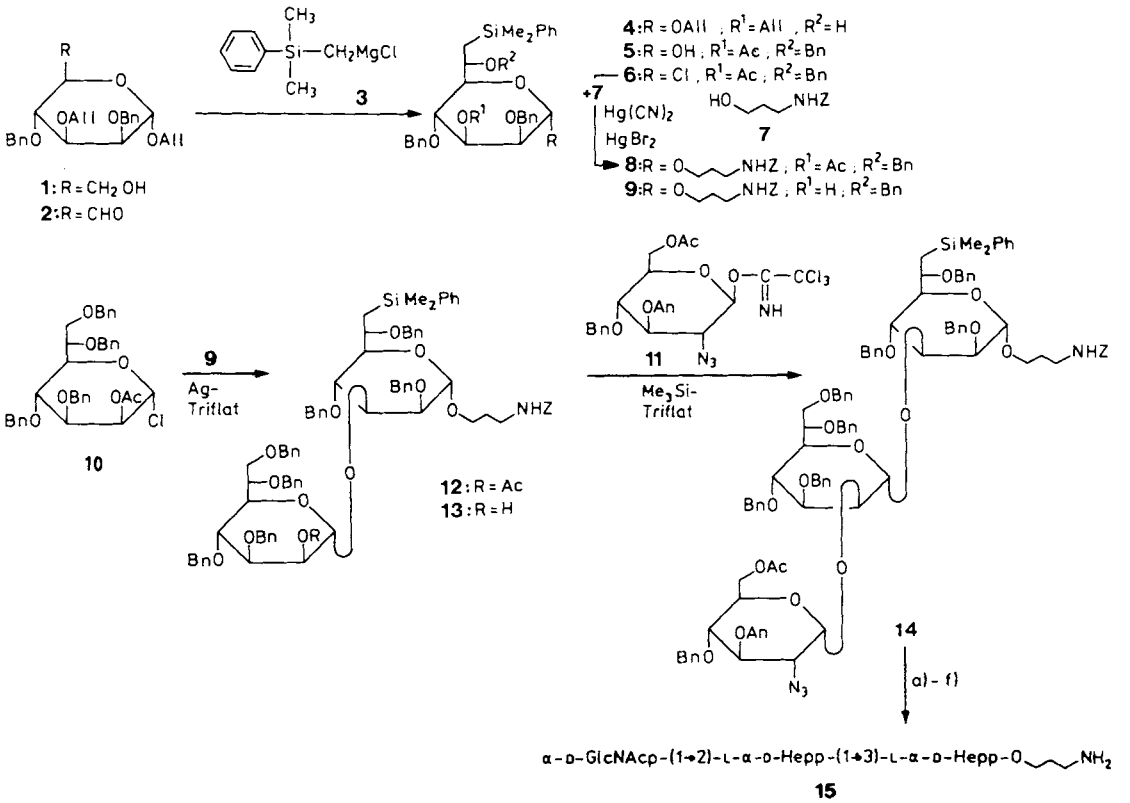
Application of the Dimethyl(phenyl)silyl Group as a Masked Form of the Hydroxy Group in the Synthesis of an L-*glycero*-α-D-*manno*-heptopyranoside-Containing Trisaccharide from the Dephosphorylated Inner Core Region of *Neisseria meningitidis***



By *G. J. P. H. Boons, M. Overhand, G. A. van der Marel,* and *J. H. van Boom**

Recently, the structures of the largest dephosphorylated oligosaccharides of the L2, L3 and L5 serotype lipopolysaccharides (LPS) of *Neisseria meningitidis* have been elucidated.[1] It was illustrated that the core region consisted of a structurally invariant outer core lacto-N-neotetraose unit and an inner core region showing microheterogeneity. Immunological studies indicated[2] that the determinants responsible for LPS serotype specificity and LPS cross-reactivity resided largely in the inner core of oligosaccharides and, further, that the presence of ethanolamine phosphate substituents in native LPS is not a major serological factor. In order to study the antigenicity of the inner core region and the specificity of antibodies raised against this antigenic region, we report the synthesis of an inner core dephosphorylated L5 trisaccharide containing a spacer suitable for conjugation with macromolecular carriers (Scheme 1).

An essential element in a synthetic route to **15** is the availability of suitably protected L-*glycero*-D-*manno*-heptopyranoside (L-D-Hepp) building blocks. Earlier studies indicated[3] that the diastereoselective hydroxymethylene extension of allyl α-D-*manno*-hexodialdo-1,5-pyranoside **2**

Scheme 1. a) Dioxane, CH_3OH, 4N NaOH (29:9:2, v/v), 3 h, 50 °C. b) Pyridine, $(CH_3CH_2)_3N$, H_2O (30:10:1, v/v), H_2S, 18 h, 20 °C. c) Ac_2O, pyridine (1:1, v/v), 3 h, 20 °C. d) AcOH, AcOOH, NaOAc, KBr, 2 h, 10–20 °C. e) CH_3OH, $NaOCH_3$. f) PdC, 18 h, 1 bar. Ag- and Me_3Si-triflate = silver and trimethylsilyl trifluoromethanesulfonate, respectively. All = allyl, Bn = benzyl, An = anisoyl, Z = benzyloxycarbonyl.

with the Grignard reagent **3** could be expected to give access to the key L-D-Hepp derivative **4** having at C-7 the dimethyl(phenyl)silyl group as a masked form of the hydroxy group. Thus Swern oxidation of **1**, prepared in an overall yield of 30% starting from allyl α-D-mannopyranoside,[4] and subsequent treatment of **2** with **3** afforded **4** in very good diastereomeric purity[3] (≥95%) and in 70% yield [$[\alpha]_D^{20} = +26.9$ ($c = 0.99$, $CHCl_3$)]. The latter was converted into **5** (overall yield of 42%) by the following well-established procedures: benzylation,[5] one-step deallylation,[6] acetylation and finally regioselective deacetylation.[7] Treatment of **5** with the Vilsmeier reagent[8] (chlorodimethylformamidinium chloride) furnished **6** which was coupled in situ with **7**, under Helferich conditions[9] in ether, to afford **8** [76% yield $[\alpha]_D^{20} = +32.4$ ($c = 1.05$, $CHCl_3$); 300 MHz ^1H NMR ($CDCl_3$, TMS): $\delta = 4.90$ (1-H, $J_{1,2} = 3.0$ Hz), 5.17 (3-H, $J_{2,3} = 2.0$ Hz, $J_{3,4} = 7.5$ Hz), 1.35 (7a-H and 7b-H)]. Zemplén deacetylation of **8** resulted in the quantitative isolation of **9**.

Ag-triflate[10] promoted glycosidation (in the absence of base) of acceptor **9** with donor **10**, obtained by a similar[11] silane-mediated hydroxymethylene process, furnished disaccharide **12** [72% yield, $[\alpha]_D^{20} = +19.8$ ($c = 1.0$, $CHCl_3$); 300 MHz ^1H NMR ($CDCl_3$, TMS): $\delta = 5.12$ (1-H, $J_{1,2} = 1.5$ Hz), 4.87 (1-H, $J_{1,2} = 2.0$ Hz), 1.36 (7a-H and 7b-H)].

Glycosyl imidate donor **11** was prepared in three steps (overall yield of 73%) by acetolysis[12] of 1,6-anhydro-2-azido-2-deoxy-3-*O*-anisoyl-4-*O*-benzyl-β-D-glucopyranose[13] followed by deacetylation[7] at C-1 and subsequent treatment[14] with trichloroacetonitrile in the presence of potassium carbonate.

Disaccharide **12** was converted to **13** by Zemplén deacetylation and coupled in the presence of trimethylsilyltriflate[15] and 4 Å molecular sieves (CH_2Cl_2) with the glycosyl donor **11**, to afford the fully-protected trisaccharide **14** [92% yield, $[\alpha]_D^{20} = +83.8$ ($c = 1.0$, $CHCl_3$); 300 MHz ^1H NMR ($CDCl_3$, TMS): $\delta = 5.27$ (1′-H, $J_{1,2} = 1.5$ Hz), 4.79, 4.71 (1″-H, $J_{1,2} = 3.0$), 1.36 (7a-H and 7b-H)].

For the deblocking of **14** the base labile groups are cleaved with NaOH. Subsequent reduction of the azido group with H_2S[16] is then followed by reacetylation of the amine and the two hydroxy functions with acetic anhydride. The Ph-Me_2Si moiety at C-7 is now unmasked[17] in the dark with KBr and AcOOH, and the two *O*-acetyl groups are subsequently removed under Zemplén conditions. Finally, the benzyloxycarbonyl and benzyl groups are cleaved hydrogenolytically in *tert*-butyl alcohol-water-acetic acid (5:1:1), and crude **15** thus obtained is purified on Sephadex LH-20. The overall yield of this six-step conversion from **14** to the deblocked and α-glycosidically linked trisaccharide **15** is 30% [$[\alpha]_D^{20} = +103.7$ ($c = 1.0$ H_2O); 300 MHz ^1H NMR (D_2O, referred to HDO, $\delta = 4.75$): $\delta = 5.34$ (1′-H, $J_{1,2} = 1.5$ Hz), 5.07 (1″-H, $J_{1,2} = 3.5$ Hz), 4.81 (1-H, $J_{1,2} = 1.5$ Hz)]. These values agree with the data of other L-D-Hepp containing oligosaccharides obtained via a different route[18] and with those of the natural product which, apart from the artificial spacer, contain this sequence.[1b]

The example demonstrates that the dimethyl(phenyl)silyl masking group is not only compatible with manipulations frequently applied in sugar chemistry to achieve selective protection of hydroxy groups, but also with reliable and highly stereoselective glycoside coupling procedures.

The Acetonitrile(pentafluorophenyl)xenon(II) Cation, $[MeCN–Xe–C_6F_5]^{\oplus}$: The First Structural Characterization of a Xenon–Carbon Bond**

By *Hermann Josef Frohn,* Stephanus Jakobs,* and *Gerald Henkel*

Since the synthesis of the first noble-gas compound in 1962,[1,2] xenon compounds containing Xe–F, Xe–O, and Xe–N bonds have been unambiguously characterized. The first Xe–C compound, $Xe(CF_3)_2$, reported by *Lagow* et al.[3] in 1979, has not been satisfactorily characterized by physical and spectroscopic data, nor is its identity supported by chemical reactions. In 1988 we isolated the Xe^{II} compound $[(C_6F_5Xe]^{\oplus}[C_6F_5BF_3]^{\ominus}$, characterized it in solution by ^{129}Xe and ^{19}F NMR spectroscopy, and verified the Xe–C bond by specific reactions.[4] Here we describe the synthesis, the molecular structure, the ^{129}Xe, ^{19}F, ^{13}C, and ^{11}B solution NMR spectra, and the reactivity of **1**, a further Xe–C compound. For the first time, we have succeeded in determining a Xe–C bond length and the distance between Xe^{II} and the nitrogen atom of a coordinated N base.

$[MeCN–Xe–C_6F_5]^{\oplus}[(C_6F_5)_2BF_2]^{\ominus}$ **1**

Low-temperature reaction of XeF_2 with $B(C_6F_5)_3$ in noncoordinating solvents affords $[C_6F_5Xe]^{\oplus}[(C_6F_5)_2BF_2]^{\ominus}$ as a sparingly soluble colorless solid, which readily dissolves in MeCN to form **1**. The Xe–C bond can be identified in MeCN solution by ^{129}Xe, ^{19}F, and ^{13}C NMR spectroscopy. The ^{129}Xe NMR spectrum contains a triplet at $\delta = -1956$ (standard, XeF_2; coupling with the *ortho* fluorine atoms of the aryl moiety, $^3J_{Xe,F} = 68.8$ Hz). Further couplings cannot be determined unambiguously from the ^{129}Xe NMR spectrum, since the signal halfwidth is 25.1 Hz. The $^3J_{F,Xe}$ coupling in the corresponding signal of the ^{19}F NMR spectrum is 68.6 Hz. One additional fluorine–xenon coupling, $^4J_{F,Xe} = 18.7$ Hz, was determined. A further indication for the Xe–C bond is the $^1J_{C,Xe}$ coupling of 119.0 Hz in the ^{13}C NMR spectrum. The chemical shifts of the $[C_6F_5Xe]^{\oplus}$ ion in MeCN also provide interesting information. In comparison with the isoelectronic C_6F_5I molecule, the *m*- and *p*-F signals in the ^{19}F NMR spectrum are shifted significantly downfield by Xe^{II} ($\Delta\delta_m = 5.4$, $\Delta\delta_p = 11.6$). The position of the *p*-F signal, which is extremely low-field for that of the C_6F_5 group, is comparable to the situation in C_6F_5Br(III and V) and C_6F_5I(III and V) compounds,[5–7] in which resonance interactions between the aryl moiety and the positive halogen atom through the *p*-F atom of the C_6F_5 group can be detected. With respect to the Xe^{II} system, this means that the aryl moiety reduces the charge density at Xe^{II} by back-bonding. The same argument explains the strikingly high-field position of the ^{129}Xe resonance compared with that of XeF_2. In this case, however, the solvation of the cation by MeCN can enhance the effect. In contrast to most known pentafluorophenyl element compounds, the C4 resonance is found at lower field than the C2,6 resonance in the ^{13}C NMR spectrum (see Table 1). Compound **1** and some pentafluorophenyl compounds of polyvalent halogens share this property.

Table 1. ^{129}Xe, ^{19}F, ^{13}C, and ^{11}B NMR data [a] for **1** in MeCN at −30 °C.

Nucleus	Chemical shifts [δ values] with assignment and coupling constants [Hz]
$[C_6F_5Xe]^{\oplus}$	
^{129}Xe	−1956 (t; 68.8 Hz; HWB 25.1 Hz) [$\delta(XeF_2) \equiv 0$]
^{19}F	−125.15 (*o*-F; dm; $^3J_{F,Xe} = 68.6$ Hz; rel. int. 2) [$\delta(CCl_3F) \equiv 0$]
	−142.00 (*p*-F; tt; $^3J_{F,F} = 20.6$ Hz; $^4J_{F,F} = 5.3$ Hz; rel. int. 1)
	−154.71 (*m*-F; dm; $^4J_{F,Xe} = 18.7$ Hz; rel. int. 2)
^{13}C	144.65 (C4; dtt; $^1J_{C,F} = 261.4$ Hz; $^2J_{C,F} = 14.0$ Hz; $^3J_{C,F} = 5.1$ Hz)
	143.20 (C2,6; ddm; $^1J_{C,F} = 259.6$ Hz; $^2J_{C,F} = 14.2$ Hz)
	137.62 (C3,5; dm; $^1J_{C,F} = 263.2$ Hz)
	82.77 (C1; dtm; $^1J_{C,Xe} = 119.0$ Hz; $^2J_{C,F} = 25.8$ Hz)
$[(C_6F_5)_2BF_2]^{\ominus}$	
^{19}F	−136.47 (*o*-F; m; rel. int. 4), −144.6 (BF_2; br. q; rel. int. 2), −160.53 (*p*-F; tt; $^3J_{F,F} = 19.8$ Hz; rel. int. 2), −165.34 (*m*-F; m; rel. int. 4)
^{13}C	146.94 (C2,6; dm; $^1J_{C,F} = 239.1$ Hz), 138.26 (C4; dtt; $^1J_{C,F} = 244.5$ Hz; $^2J_{C,F} = 14.2$ Hz; $^3J_{C,F} = 7.0$ Hz), 135.94 (C3,5; dm; $^2J_{C,F} = 246.0$ Hz), 120 (C1; s, HWB ca. 250 Hz)
^{11}B	5.54 (BF_2; t; $^1J_{B,F} = 57.6$ Hz) [$\delta(BF_4^{\ominus}) \equiv 0$]

[a] Measured on a Bruker WP 80 SY (^{13}C NMR spectrum with a Bruker WM 300). HWB = halfwidth.

The constitution of the $[(C_6F_5)_2BF_2]^{\ominus}$ ion was confirmed in solution by ^{19}F and ^{11}B NMR spectroscopy. In the ^{19}F NMR spectrum, the signal of the BF_2 group appears as a broadened quartet at $\delta = -144.6$; in the ^{11}B NMR spectrum, a broadened triplet with a $^1J_{B,F}$ coupling of 57.6 Hz is found at $\delta = 5.54$ (standard: $[BF_4]^{\ominus}$).

Single crystals, grown from MeCN solution, were investigated by X-ray crystallography[8] and showed that no signif-

Lotharstrasse 1, D-4100 Duisburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.

icant fluorine bridges were present between cation and anion (shortest intermolecular Xe–F distance 3.135(5) Å), such as are found, for example, in $[(FSO_2)_2NXe]^{\oplus}[Sb_3F_{16}]^{\ominus}$ [9] (2.457(8) Å). The $[C_6F_5Xe]^{\oplus}$ ion (Fig. 1) is coordinated by

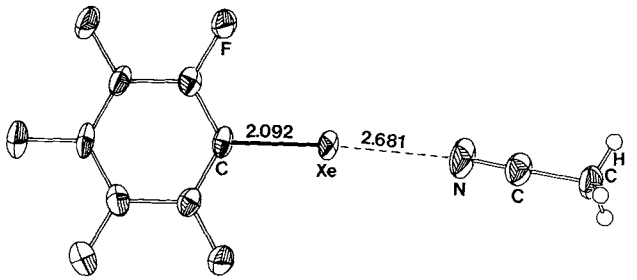

Fig. 1. Molecular structure of the $[MeCN–Xe–C_6F_5]^{\oplus}$ ion with thermal ellipsoids at 50% probability (150 K) and important Xe–ligand bond distances (standard error 0.008 Å). The C–Xe–N bond angle is 174.5(3)°.

the nitrogen atom of a MeCN molecule (C–Xe–N bond angle: 174.5(3)°). An additional MeCN molecule per formula unit is disordered and displays no contact to the cation. The Xe–C distance (2.092(8) Å) is comparable to the I–C distance in $C_6F_5I(O_2CC_6F_5)_2$ (2.072(4) Å).[10] Structural data for C_6F_5I, isoelectronic with $[C_6F_5Xe]^{\oplus}$, have not been reported. The coordination of $[C_6F_5Xe]^{\oplus}$ with MeCN (Xe–N distance 2.681(8) Å) lowers the effective charge density at Xe^{II} and is partly responsible for the extremely high-field position of the ^{129}Xe NMR signal. The measured Xe–N distance is significantly longer than those of the previously described Xe–N single bonds in $[(FSO_2)_2NXe]^{\oplus}$ [9] (2.02(1) Å) and $FXeN(SO_2F)_2$ [11] (2.200(3) Å). The coordination in **1** is presumably similar to that in the fluoro(nitrile)xenon(II) cations (in solution) described by *Schrobilgen* et al.[12]

Warming **1** above 14 °C results in slow decomposition. Perfluorobiphenyl and $(C_6F_5)_2BF$ were identified as the decomposition products. The thermal stability in MeCN solution is similar. Within 5 h at 0 °C, 30% of the Xe–C bonds have reacted; at 35 °C, 50% of the cations have reacted within 20 min. Pentafluorobenzene and oxidation products of this arene are found as additional decomposition products in solution.

Compound **1** is a typical electrophile, allowing C_6F_5 groups to be transferred to soft bases.[4] The formation of perfluorobiphenyl in the thermolysis may be regarded as an electrophilic pentafluorophenyl transfer to the nucleophilic aryl moiety in the anion. The anion can undergo exchange with Lewis acids such as BF_3 or AsF_5 [reaction (a)]. The previously unknown $(C_6F_5)_2BF$ is obtained as a coproduct and could be identified from its ^{19}F NMR spectrum [δ = −136.1 (*o*-F; m; rel. intensity 4), −156.4 (*p*-F, tt; 2), −164.0 (*m*-F; m; 4), −176.0 (BF; br. s; 1)].

$$\mathbf{1} + AsF_5 \xrightarrow[\leq -20\,^{\circ}C]{MeCN} [C_6F_5Xe]^{\oplus}[AsF_6]^{\ominus} + (C_6F_5)_2BF \qquad (a)$$

Experimental Procedure

All operations were performed under rigorously dried atmosphere (argon) in FEP apparatus.

1: A solution of $B(C_6F_5)_3$ (512 mg, 1 mmol) in CH_2Cl_2 at −40 °C was added dropwise to a solution of sublimed XeF_2 (339 mg, 2 mmol) in CH_2Cl_2 at −40 °C. After 10 min, a colorless solid precipitated. After 6 h, the precipitate was collected by filtration, washed at −78 °C with CH_2Cl_2, and dried under high vacuum at −40 °C. Yield: 627 mg (0.92 mmol, 92%) $[C_6F_5Xe]^{\oplus}[(C_6F_5)_2BF_2]^{\ominus}$. Single crystals were grown from saturated MeCN solution and washed with CH_2Cl_2. trophiles to the PP bond[1] and to proceed via structures of types **B**[2,3] and **E**[4] (Scheme 1). Addition of further electrophiles to these cyclophosphanes gives the cationic species **C**, **D**, and **F**[5,6] to **I**. Structures **C** and **D** are unlikely to be stable, since P–P bond cleavage would presumably take place. The synthesis of cation **F** has been described as being difficult.[6] A dication of type **G** has not yet been isolated.

Here we describe the unusual formation of a dication of type **G**. Reaction of 2,6-dimethoxyphenyl(trimethyl)stannane with chlorodifluorophosphane—in an attempt to synthesize 2,6-dimethoxyphenyl(difluoro)phosphane[8] by an alternative route—gave 1,1,2,3,3,4-hexakis(2,6-dimethoxyphenyl)-2,4-diphospha-1,3-diphosphoniacyclobutane difluorotrimethylstannate **1**, isolated as colorless crystals. Since MOPAC calculations predict that species of types **H** and **I** should be relatively unstable,[7] the dication in **1** presumably represents the final synthetically accessible member of the series **A** to **I**.

Scheme 1.

The dication in **1** is isoelectronic with 1,3-diphosphetanes, the hexasubstituted CPCP four-membered rings of which are also planar.[9] In the ^1H and ^{13}C NMR spectra[10] of **1**, the 2,6-dimethoxyphenyl substituents of the dication give rise to two sets of signals in a ratio of 1:2, corresponding to two aryl groups on the λ^3P atoms and four aryl groups on the λ^4P atoms. Thus, the λ^3P-bound substituents are *trans* to each other. The ^{31}P NMR spectrum of **1** consists of an A_2B_2 spin system,[11] like that observed by *Fluck* et al.[3] for a compound of type **B** with R = 2,4,6-tri(*tert*-butyl)phenyl. In the field desorption (FD) mass spectrum,[12] the dication in **1** could only be observed with ca. 1% intensity owing to rapid decomposition upon exposure to air. The structural parameters, important for understanding the λ^3P–λ^4P bonding, were determined by an X-ray diffraction study (Fig. 1).

Compound **1** crystallizes in the space group $P2_1/c$ with $Z = 2$.[13] The cation is crystallographically centrosymmetric and displays a planar four-membered ring, in which λ^3P and λ^4P atoms alternate and the substituents on the λ^3P atoms are *trans* to each other. The only slight anisotropy of the temperature factors (U_{ii} for P1, 0.034 to 0.038; for P2, 0.039 to 0.050) reveals that the ring is indeed planar and that apparent planarity is not caused by crystallographic disorder. All phosphorus atoms exhibit very short distances to three or four oxygen atoms (P1···O6 276 pm, P1···O12 278 pm, P1···O2 307 pm, P1···O8 305 pm, P2···O2′ 291 pm, P2···O18 279 pm, P2···O14 303 pm). Such short distances, which, in this case, are obviously also made possible by the positions of the *ortho* substituents on the phenyl ring, necessitate the assumption of attractive interactions between phosphorus and oxygen atoms (compare the sums of the van der Waals radii (328 pm[14])). This assumption is supported by the relatively rigid orientation of the nonbonding electron pairs on the oxygen atoms toward the phosphorus atoms (torsion angle C-O-C-C(-P) 166.8° to 178.9°; average 173.9°). The observed electrophilicity of the λ^3P atoms has also been described for other compounds.[15] The stability of the dication in **1** is also clearly due to the increase in the coordination number at the phosphorus atom. The P–P bond lengths (223.1 and 223.2 pm) and the P–C bond lengths (178.3–180.9 pm) lie in the usual ranges.

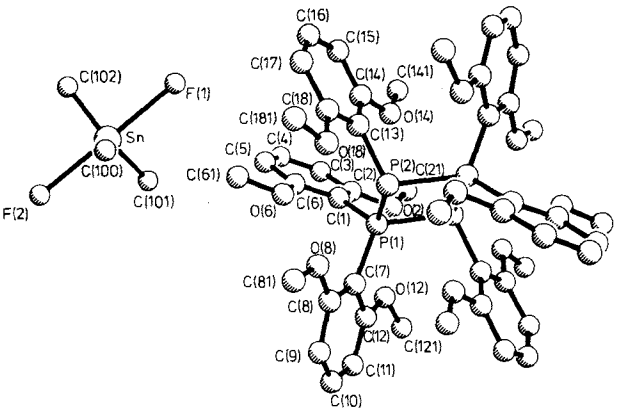

Fig. 1. Molecular structure of **1**.

The structure of an $[R_3SnF_2]^{\ominus}$ ion has not yet been described;[16] the anion in **1**, $[Me_3SnF_2]^{\ominus}$ (Fig. 2), displays an

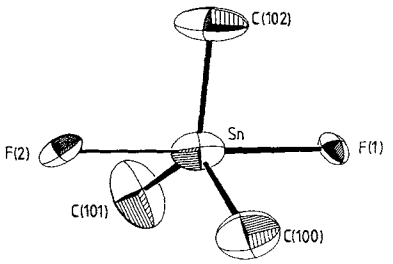

Fig. 2. Molecular structure of $[Me_3SnF_2]^{\ominus}$

only slightly distorted trigonal-bipyramidal geometry with axial fluorine atoms (maximum deviation from the ideal bonding angle, 1.8°). Owing to the negative charge, the Sn–F distances (259.6 and 260.7 pm) and the Sn–C distances (213.8–215.5 pm) are somewhat longer than those in the pentacoordinated tin compound fluorotris(trimethylsilylmethyl)stannane, $[(Me_3SiCH_2)_3SnF]$ (Sn-F 256.5 pm, Sn-C 210.1 pm),[17] which is present in the crystal as a fluorine-bridged polymer. Compared with the Sn-F bond (244.8 pm) in the tetracoordinated tin compound tri(cyclohexyl)fluorostannane,[18] the Sn-F bonds in **1** are lengthened by 15 and 16 pm owing to the increased coordination number and to the negative charge.

Experimental Procedure

1: Under inert atmosphere, 2,6-dimethoxyphenyl(trimethyl)stannane [19] (6.0 g, 0.02 mol) and iodine (ca. 5 mg) in 6 g of resorcinol dimethyl ether were placed in a thick-walled glass tube equipped with a Teflon stopcock, and PF_2Cl (4.5 g, 0.04 mol) was then condensed into the solution at $-196\,^{\circ}C/10^{-2}$ Torr. The reaction mixture was filtered after 50 days at 70 °C and the colorless crystals were washed with ca. 5 mL of CH_3CN and dried, affording 81 mg of **1** (m.p. 224–227 °C). Analysis: calculated (found), C 48.0 (47.5), H 5.4 (5.6). Com-

pound **1** spontaneously decomposes upon dissolution in $CDCl_3$ and is both air- and moisture-sensitive [21].

The First Macrocyclic Square-Planar Cobalt(III) Complex Relieves Ring Strain by Forming a Nonplanar Amide**

By *Terrence J. Collins** and *Erich S. Uffelman*

We are developing a series of oxidation-resistant macrocyclic tetraamide ligands to support highly oxidized and/or highly oxidizing middle and later transition-metal centers. Here we report that the tetradeprotonated form of the macrocycle, H_4-**1**, coordinates to cobalt to give a macrocyclic square-planar cobalt(III) complex.[1] This complex

H_4-**1**

contains one significantly nonplanar amide group. The source of the nonplanarity appears to be ring strain derived from a mismatch of the geometrical features of the macrocycle and the structural requirements of the square-planar metal center, a unique case of amide nonplanarity in inorganic chemistry.

Square-planar cobalt(III) complexes remain rare[1] and Li[Co(η^4-**1**)] is the first such macrocyclic complex. Although its ^{1}H NMR spectrum (Fig. 1) shows the paramagnetically shifted signals characteristic[1f, j, k] of square-planar cobalt(III), the solid-state structure is distorted from square-planar geometry. [Me_4N][Co(η^4-**1**)] crystallizes as two dis-

N4-C7-O4 (anion 1)	−22.31	−23.82	−0.60
N1-C1-O1 (anion 2)	18.64	16.87	4.84
N2-C3-O2 (anion 2)	4.26	4.18	6.34
N3-C5-O3 (anion 2)	8.70	11.97	0.22
N4-C7-O4 (anion 2)	−6.13	13.55	0.39

This result enrichens the class of ring-constrained nonplanar amido-*N* ligands.[5] Whereas, in other examples, an unstrained amide-containing chelate ring is forced into a strained configuration by the geometrical demands of additional ligands,[5e, f] this is the first example where the amido-*N* nonplanarity arises in the absence of ancillary ligand effects. The controlling ring-strain term appears to be similar to that of the medium-ring lactams of organic chemistry.[5a]

Although there is voluminous literature on macrocyclic polyamines and Schiff bases, only one example of a complex of a macrocyclic tetraamido ligand (a cyclic tetrapeptide) has been previously reported.[6a, b, 7] The copper(III) complex of that study proved susceptible to degradation via α-hydrogen (α to amido-*N*) abstraction.[6b] This problem has been solved in both acyclic[6c, 5e, 8] and macrocyclic systems by peralkylation or aromatization of the relevant ligand positions, steps that are proving to be significant in attaining oxidation-resistant ligands. The distortion at the metal from square planarity and the amide distortions observed in $[Co(\eta^4\text{-}\mathbf{1})]^{\ominus}$ highlight the subtlety encountered in designing ligand systems for highly oxidized metal centers. Macrocyclic tetraamide ligands have been used by us to afford structurally characterized manganese(V) oxo complexes.[9]

Experimental Procedure

$[Me_4N][Co(\eta^4\text{-}\mathbf{1})]$. H_4-**1** was dissolved in dry, deoxygenated THF, and a stoichiometric amount of *tert*-butyllithium was added to the frozen solution under nitrogen. $CoCl_2$ was added under nitrogen as soon as the THF finished thawing (−108 °C). As the suspension warmed to room temperature, a yellow-green precipitate (presumably a cobalt(II) complex) collected on the flask walls. After 30 min at room temperature, air was admitted and a bright red solution rapidly developed with concomitant disappearance of the yellow-green precipitate. Crude $Li[Co(\eta^4\text{-}\mathbf{1})]$ was obtained in 95% yield. The $[Me_4N]^{\oplus}$ salt was obtained by adding excess $[Me_4N][Cl]$ in water to an aqueous solution of the complex. The water was removed in vacuo, and a CH_2Cl_2/CH_3CN solution of the residue was treated with pentane to precipitate the LiCl and excess $[Me_4N][Cl]$. Bright red rectangular parallelepipeds, characterized by X-ray analysis, were obtained by diffusion of pentane into a $CH_2Cl_2/CHCl_3$ solution of $[Me_4N][Co(\eta^4\text{-}\mathbf{1})]$.

References [1g–i] concern innocent biuret ligands. References [1j, k] discuss aromatic and innocent aliphatic tetradentate diamide dialkoxide ligands.

[2] Crystal data: Single crystals of $[(CH_3)_4N][Co(\eta^4\text{-}\mathbf{1})]$. H_2O at 20 ± 1 °C, monoclinic, space group $P2_1/C-C_{2h}^5$ (No. 14) with $a = 17.221(3)$, $b = 19.075(6)$, $c = 21.797(6)$ Å, $\beta = 109.74(2)°$, $V = 6739(3)$ Å^3, $Z = 8$, $\varrho_{calcd} = 1.137$ g cm^{-3}; $\mu_a(Cu_{K\alpha}) = 5.2$ mm^{-1}). A total of 9248 independent absorption-corrected reflections having $2\theta(Cu_{K\alpha}) < 115.0°$ (the equivalent of 0.6 limiting $Cu_{K\alpha}$ spheres) were collected on a computer-controlled Nicolet autodiffractometer using θ-2θ scans and Ni-filtered $Cu_{K\alpha}$ radiation. The structure was solved by direct methods with the Nicolet SHELXTL software package as modified at Crystalytics Company. The structural parameters were refined to convergence (R_1(unweighted) = 0.054 for 4033 independent reflections having $2\theta_{CuK\alpha} < 115.0°$ and $I > 3\sigma(I)$) using counter-weighted cascade block-diagonal least-squares techniques and a structural model which incorporated anisotropic thermal parameters for 88 nonhydrogen atoms and isotropic thermal parameters for all hydrogen atoms. The 28 methyl groups were included in the refinement as idealized sp^3 rigid rotors. The remaining hydrogen atoms were fixed at idealized sp^3-hybridized positions with a C–H bond length of 0.96 Å. The calculated density is exclusive of disordered halocarbon solvent in the lattice. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (UK), on quoting the full journal citation.

[4] The twist angle τ and the pyramidalization terms χ_C and χ_N were obtained from the primary torsion angle data ω_1, ω_2, and ω_3 as follows: $\tau = (\omega_1 + \omega_2)/2$; $\chi_N = (\omega_2 - \omega_3 + \pi) \bmod 2\pi$; $\chi_C = (\omega_1 - \omega_3 + \pi) \bmod 2\pi$. Here we use the modified twist angle, $\bar{\tau}$: $\bar{\tau} = (\tau) \bmod \pi$ [5a]. $\bar{\tau}$ maximizes at $\pm 90°$ and can be interpreted as the angle between the idealized positions of the pπ orbitals on C and N. The pyramidalization terms maximize at $\pm 60°$.

[5] The other two classes are (1) cases where nonplanar amido-*N* ligands are thermodynamically favored over planar analogues accessible by isomerization at the metal center and (2) cases where steric effects can be identified as the principal cause of nonplanarity. a) T. The First Example of an *Ethylene*-Selective Soluble Ziegler Catalyst of the Zirconocene Class

By *Wolfgang A. Herrmann,* Jürgen Rohrmann,* Eberhardt Herdtweck, Walter Spaleck,* and *Andreas Winter*

Dedicated to Professor Wolfgang Hilger on the occasion of his 60th birthday

Combination of chiral, sterically rigid metallocene derivatives containing metals of the fourth subgroup with methylalumoxane (as cocatalyst) gives highly active, stereospecific catalysts for the polymerization of α-olefins.[1-4] The chiral complexes may be used as racemates. For instance, highly isotactic polypropylene with a narrow molecular-weight distribution can be prepared with the catalyst *rac*-[ethylene-1,2-(bis-4,5,6,7-tetrahydroindenyl)]zirconium dichloride **1**;[1] however, the average molecular weights of such polymers are too low for practical applications. Our goal was therefore to improve the catalyst properties by stepwise modification of the ligand system. In an initial approach, we have introduced silyl groups to vary the bridging of the two indenyl ligands.

Conversion of the bis(indenyl) systems **2a, b**, accessible from indenyllithium and the corresponding dichlorosilanes, to the dilithio compounds followed by reaction with zirconium tetrachloride (Scheme 1) yielded the new silyl-bridged complexes **3** and **4** as pure racemates. The similarly obtained *meso* forms could be *quantitatively* separated owing to their differing solubilities. Complete separation of the *meso* forms is necessary because the propylene polymerization otherwise leads to undesired atactic polymer.

The dimethylsilyl-bridged complex **3** exhibits particularly high activity in the polymerization of propylene in liquid monomer (bulk polymerization) with methylalumoxane as cocatalyst (Table 1) and affords polypropylene with an average molecular weight nearly twice as high as that obtained with **1**, the narrow molecular-weight distribution and high isotacticity being maintained. Surprisingly, metallocene **4** (with a longer bridge) is *completely inactive toward propylene*. To determine whether this drastic effect is due to the size of the olefin, we carried out polymerization experiments with ethylene for comparison and observed a fully unexpected *high activity of 4 toward ethylene*. This activity is lower than that of **3** by a factor of only 3 (Table 1). The lower ethylene activity of the two compounds in comparison with the propylene activity is due to the different polymerization procedures. The bis(indenyl) complex **4** is thus an *ethylene-selective catalyst*. Since the cause of this phenomenon presumably lies in the molecular structure of **4**, we characterized both metallocenes by X-ray structure analyses (Fig. 1).[6]

2a,b *rac*-**3**: X = $Si(CH_3)_2$

rac-**4**: X = $(CH_3)_2SiCH_2CH_2Si(CH_3)_2$

Scheme 1.

Table 1. Polymerization of propylene (bulk polymerization) and ethylene (suspension polymerization) at 65 °C.

Metallocene	Activity [(kg polymer) (mmol Zr)$^{-1}$ h^{-1}]	
	Propylene	Ethylene
3	110	19.3
4	0	6.5

As shown in Figure 1, top, the structure of the dimethylsilyl-bridged complex **3** (racemate) is similar to that of the ethylene-bridged derivative **1**, which has a C_2-symmetric ligand system.[5] This results in similar catalytic properties. The only salient difference is the larger angle between the two halves of the ligand system in **3** (62° compared with 55° in **1**) due to the one-atom bridge. The resulting increase in the accessibility of the $ZrCl_2$ group, the actual reaction center, is reflected in the high catalytic activity of **3**. By contrast, **4** displays an unsymmetrical arrangement of the ligand system. As shown in Figure 1, bottom, in which the $ZrCl_2$ unit is viewed from the same direction, the much longer Si–C–C–Si bridge is no longer found in the back of the molecule, but rather bulges to one side. As a result, the indenyl rings are twisted with respect to each other. The angle between the two halves of the ligand is 54°. The catalytic inactivity of metallocene **4** toward propylene is therefore due to shielding of the reaction center of the catalyst by the bulky bridge and by the indenyl ligand directed toward the $ZrCl_2$ function (Fig. 1, bottom, "upper" ligand). These structural features are less detrimental for the sterically less demanding ethylene molecule. For ethylene, therefore, the polymerization activity dramatically increases. These structural differences are also reflected in the colors of the complexes: **3** is orange, **4** yellow.

The findings presented here show that the selectivity of olefin polymerization catalysts of the zirconocene class can

be dramatically varied by structural and conformational changes.

Experimental Procedure

All operations were performed under argon atmosphere.

rac-**3**: A solution of **2a** [7] (5.60 g, 19.4 mmol) in 40 mL of THF was treated at room temperature with 15.5 mL (38.8 mmol) of *n*-butyllithium (2.5 M, *n*-hexane). After 2 h, the deep red solution was added dropwise over 4–6 h to a suspension of $ZrCl_4 \cdot 2$ THF (7.30 g, 19.4 mmol) in 60 mL of THF. The resulting reaction mixture was stirred for 2 h and the orange precipitate was collected by filtration and recrystallized from CH_2Cl_2, affording 1.20 g (14%) of *rac*-**3** as orange crystals, which slowly decompose above 200 °C. Correct elemental analyses and mass spectra ($m/z = 448$). ^{1}H NMR (400 MHz, $CDCl_3$, 28 °C): $\delta = 7.04$–7.60 (m, 8H, arom. H), 6.90 (dd, 2H, β-IndH), 6.08 (d, 2H, α-IndH), 1.12 (s, 6H, $SiCH_3$).

rac-**4**: A solution of **2b** (4.30 g, 12.5 mmol), prepared from indenyllithium and 1,2-bis(chlorodimethylsilyl)ethane, in 40 mL of THF was treated as described above with *n*-butyllithium (9.3 mL, 23.2 mmol) and $ZrCl_4 \cdot 2$ THF (4.40 g, 11.6 mmol). Cooling of the reaction solution to −35 °C led to the crystallization of *rac*-**4** (1.50 g, 25%) as yellow crystals, which melt at 246–249 °C. Correct elemental analyses and mass spectra ($m/z = 523$). ^{1}H NMR (270 MHz, $CDCl_3$, 28 °C): $\delta = 7.2$–7.9 (m, 8H, arom. H), 6.80 (dd, 2H, β-IndH), 5.58 (d, 2H, α-IndH), 0.99–1.29 (m, 4H, C_2H_4), 0.53 (s, 6H, $SiCH_3$), 0.23 (s, 6H, $SiCH_3$).

Propene polymerization: a) A dry 16-L steel reactor equipped with a thermostat was flushed with nitrogen and charged at 30 °C with 10 L of liquid propene. A solution (30 mL) of methylalumoxane in toluene (40 mmol Al; average molecular weight, cryoscopic, 900 g mol^{-1}) was then added. At the same time, *rac*-**3** (4.5 mg, 0.01 mmol) was dissolved in 20 mL of the same methylalumoxane solution in toluene (27 mmol Al) and allowed to stand for 15 min to "preactivate" it. The orange-red solution was then placed in the reactor, which was heated to 65 °C and kept at this temperature for 1 h. After the reactor had cooled to 20 °C and the pressure was released, the product was dried under vacuum. Yield: 1.10 kg polypropylene ($M_w = 44\,300$ g mol^{-1}; $M_w/M_n = 2.2$; II = 96.2%, ^{13}C NMR). b) In a similar experiment in which *rac*-**4** (62.1 mg, 0.12 mmol) was used, no polymer was isolated; the reactor contained only the propylene and the toluene used and decomposition products arising from the methylalumoxane.

Ethylene polymerization: a) The procedure was the same as that employed in propene polymerization. Instead of liquid propene, 10 L of a purified hydrocarbon fraction (100–120 °C) was used. After addition of methylalumoxane solution, ethylene (5 bar) was admitted. After termination of the polymerization, the product was collected by filtration and dried under vacuum. If 6.4 mg (0.014 mmol) of *rac*-**3** is used, 0.27 kg of polyethylene ($M_w = 201\,000$ g mol^{-1}; $M_w/M_n = 2.8$) is obtained. b) In a similar experiment in which *rac*-**4** (48.8 mg, 0.091 mmol) was used, 0.59 kg of polyethylene ($M_w = 480\,000$ g mol^{-1}, $M_w/M_n = 3.7$) was obtained.

Counterion Dependent Structural Diversity in Silver Polyselenides; Structures of the New Complex Anions $[Ag(Se_4)]_4^{4\ominus}$, $[Ag(Se_5)]_n^{n\ominus}$ and $[Ag_4(Se_4)_3]^{2\ominus}$ **

By *Mercouri G. Kanatzidis** and *Song-Ping Huang*

The chemistry of metal-polychalcogenide compounds particularly with heavier chalcogens, lately is attracting considerable interest.[1] The main reasons for this are the potential of using these compounds as precursors to solid state electronic materials[2, 3] and the fascinating and thus far unpredictable structural chemistry exhibited by the heavier polychalcogenides which often does not parallel that of the corresponding polysulfides.[1, 4] Recently, we have reported on a new homologous family of Group 11 polychalcogenides with the general formula $[M(Q_x)]_n^{n\ominus}$ (x = 4, M = Cu, Q = S[5] and M = Ag, Q = Se[6]) all of which have distinct one-dimensional structures. For example, $[Ag(Se_4)]_n^{n\ominus}$ crystallizes from a dimethylformamide (DMF) solution of $Ag^{\oplus}$ and $Se_x^{2\ominus}$ with $Ph_4P^{\oplus}$ as the cation. Since the lability of $Ag^{\oplus}/Se_x^{2\ominus}$ mixtures in strong polar solvents is high, with a variety of species participating in complex equilibria,[7] we thought that such a system might be particularly influenced to yield different final crystallization Ag/Se products by varying important crystallization factors such as the counterion. Indeed, we found a significant influence. We report here the syntheses and structures[8] of two new members of the $[M(Q_x)]_n^{n\ominus}$ family, $[Et_4N]_4[Ag(Se_4)]_4$ **1** and $\{[Me_4N][Ag(Se_5)]\}_n$ **2**, as well as of $[n\mathrm{Pr}_4N]_2[Ag_4(Se_4)_3]$ **3**. The latter compound does not belong to the $[M(Q_x)]_n^{n\ominus}$ family. To date none of these compounds find corresponding sulfur analogs.

The compounds **1** and **2** were obtained upon reaction of $AgNO_3$ and R_4NCl (R = Et, Me) with Na_2Se_5 in DMF according to Equation (a).

$$AgNO_3 + Na_2Se_5 + R_4NCl \rightarrow [(R_4N)Ag(Se_x)]_n + NaCl + NaNO_3 \quad \text{(a)}$$
$$x = 4,\ n = 4$$
$$x = 5,\ n = \infty$$

The structure of $[Ag(Se_4)]_4^{4\ominus}$ which is situated on a crystallographic inversion center, is shown in Figure 1 top. This is a discrete tetramer featuring two different kinds of $Ag^{\oplus}$ coordination. A planar rhombus of four silver atoms, symmetrically disposed around the inversion center, is "glued" together by four $Se_4^{2\ominus}$ ligands. Two of the silver atoms, Ag1 and Ag1′, are tetrahedrally coordinated while the other two, Ag2 and Ag2′, possess a trigonal planar coordination. The bridging $Se_4^{2\ominus}$ ligands are not equivalent and are divided into two sets. In one set, two $Se_4^{2\ominus}$ ligands are bridging three silver atoms, Ag1, Ag1′ and Ag2 with atoms Se1 and Se4 being μ_2 type. In the other set the two $Se_4^{2\ominus}$ ligands are bridging two silver atoms with only one terminal atom, Se8 being μ_2 type. The tetrahedral geometry around Ag1 is highly distorted with one very long "bond", Ag1-Se1 at 2.901(1) Å, a long Ag1-Se1′ bond at 2.708(1) Å and two normal bonds Ag1-Se8 and Ag1-Se4 at 2.641(1) and 2.644(1) Å respectively. The Ag1 atom is displaced from the center of the Se1 Se4 Se8 Se1′ tetrahedron towards the Se1 Se4 Se8 face. The angles around Ag1 deviate dramatically from the ideal tetrahedral angles (Fig. 1 top). The Ag1 atom lies 1.868(1) Å above the Se1′ Se4 Se8 plane. The geometry around Ag1 is best described as intermediate between trigonal planar and tetrahedral. The Ag···Ag distances in this cluster are as follows, Ag1-Ag1′ 2.917(1) Å, Ag1-Ag2 3.178(1) Å, Ag1-Ag2′ 3.482(1) Å. The $Se_4^{2\ominus}$ ligand chelating the Ag1 atom adopts a twist boat conformation while the corresponding ligand chelating the Ag2 atom is best described by an envelop conformation. The molecular structure of the anion in **1** is unique and bears no analog in metal polychalcogenide chemistry.

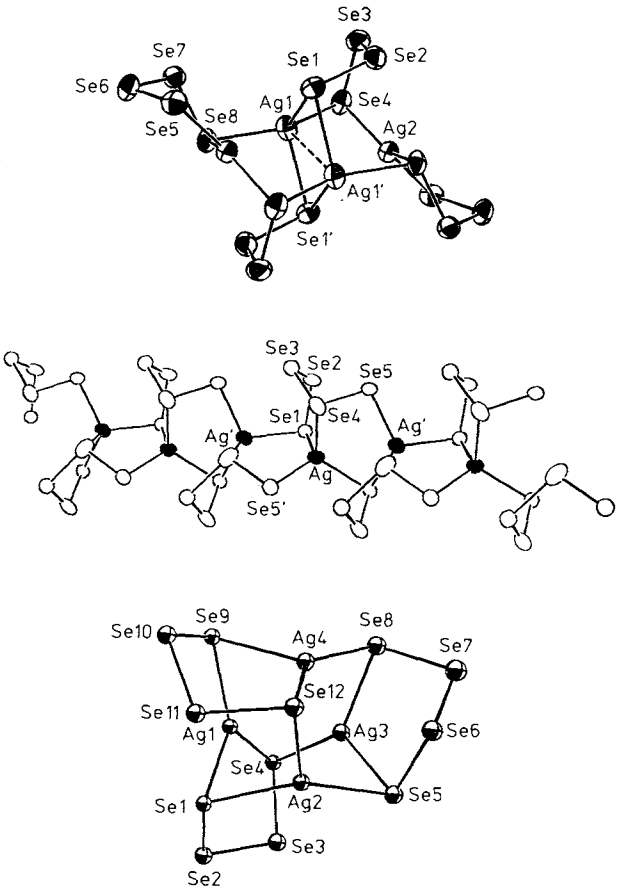

Fig. 1. Top: The structure of $[Ag(Se_4)]_4^{4\ominus}$ in the crystal. Distances [Å]: Ag2-Se4 2.583 (1), Ag2-Se5 2.596 (1), Ag2-Se8 2.616 (1), Se1-Se2 2.331 (2), Se2-Se3 2.341 (2), Se3-Se4 2.343 (2), Se5-Se6 2.340 (2), Se6-Se7 2.336 (2), Se7-Se8 2.350 (2). Angles [°]: Se1-Ag1-Se1 117.44 (4), Se1-Ag1-Se4 95.47 (4), Se1′-Ag1-Se4 100.43 (4), Se1-Ag1-Se8 94.76 (4), Se1′-Ag1-Se8 111.82 (4), Se8-Ag1-Se4 136.47 (4), Se5-Ag2-Se4 118.27 (4), Se4-Ag2-Se8 134.52 (4), Se5-Ag2-Se8 106.21 (4). Middle: The structure of $[Ag(Se_5)]_n^{n\ominus}$ in the crystal. Distances [Å]: Ag-Se1 2.633 (2), Ag′-Se1 2.670 (3), Ag-Se4 2.756 (2), Ag-Se5 2.648 (3), Se1-Se2 2.334 (3), Se2-Se3 2.329 (3), Se3-Se4 2.362 (4), Se4-Se5 2.324 (4). Angles [°]: Se1-Ag-Se1′ 115.40 (7), Se1-Ag-Se4 101.86 (8), Se1-Ag-Se5 122.34 (8), Se1-Ag-Se4′ 110.62 (8), Se1-Ag-Se5′ 109.49 (8), Se4-Ag-Se5 94.03 (7), Ag-Se1-Ag′ 91.11 (7). Bottom: The structure of $[Ag_4(Se_4)_3]^{2\ominus}$ in the crystal. Distances [Å] (standard deviation 0.001 Å): Ag1-Ag2 3.005, Ag1-Ag3 3.074, Ag2-Ag3 3.022, Ag2-Ag4 3.193, Ag3-Ag4 2.990, Ag4-Ag1 3.017, Ag1-Se1 2.621, Ag1-Se4 2.614, Ag1-Se9 2.554, Ag2-Se1 2.588, Ag2-Se5 2.552, Ag2-Se12 2.710, Ag3-Se4 2.545, Ag3-Se5 2.680, Ag3-Se8 2.589, Ag4-Se8 2.567, Ag4-Se9 2.634, Ag4-Se12 2.592, Se1-Se2 2.371, Se2-Se3 2.311, Se3-Se4 2.357, Se5-Se6 2.352, Se6-Se7 2.306, Se7-Se8 2.366, Se9-Se10 2.367, Se10-Se11 2.316, Se11-Se12 2.361. Angles [°] (standard deviation 0.02°): Se1-Ag1-Se4 104.52, Se1-Ag1-Se9 122.47, Se4-Ag1-Se9 132.97, Se1-Ag2-Se5 146.58, Se1-Ag2-Se12 101.15, Se5-Ag2-Se12 112.03, Se5-Ag3-Se4 119.72, Se5-Ag3-Se8 105.79, Se4-Ag3-Se8 134.14, Se8-Ag4-Se9 117.59, Se8-Ag4-Se12 136.83, Se9-Ag4-Se12 105.40. Average Ag-Se-Ag: 72 (2).

Contrary to the discrete molecular nature of **1**, the structure of **2** is composed of non-interacting $Me_4N^{\oplus}$ cations and one-dimensional, non-centrosymmetric $[Ag(Se_5)]_n^{n\ominus}$ macroanions (Fig. 1 middle). The structure of $[Ag(Se_5)]_n^{n\ominus}$ differs

[**] This work was supported by the Donors of the Petroleum Research Fund (administered by the American Chemical Society) and by the Center for Fundamental Materials Research at Michigan State University.

from the previously reported $[Ag(Se_4)]_n^{n\ominus}$[6] **4** in two ways. First, in **2** $Se_5^{2\ominus}$ instead of $Se_4^{2\ominus}$ ligands are present with distinct mode of ligation compared to those in **4**; second, the $Ag^{\oplus}$ atom in **2** assumes a tetrahedral geometry, compared to a trigonal planar one in **4**. The $Se_5^{2\ominus}$ ligands bridge three $Ag^{\oplus}$ atoms in an unprecedented fashion. In this bonding mode, the chelation of the $Se_5^{2\ominus}$ ligand occurs through the first and the fourth Se atoms forming a five-membered ring. The fifth terminal Se atom is then bonded to a neighboring $Ag^{\oplus}$ atom. The entire $[Ag(Se_5)]_n^{n\ominus}$ chain can be viewed as being made of fused five-membered $AgSe_4$ and Ag_2Se_3 rings. The structure of $[Ag(Se_5)]_n^{n\ominus}$ is also different from those recently reported for α- and β-$[Cu(S_4)]_n^{n\ominus}$[5] and represents a new structural motif for a one-dimensional material.

Interestingly when the counterion was changed to $nPr_4N^{\oplus}$, a different stoichiometry was adopted to yield **3** with the anion $[Ag_4(Se_4)_3]^{2\ominus}$. This complex anion features a tetrahedral array of $Ag^{\oplus}$ atoms held together by three $Se_4^{2\ominus}$ ligands forming a highly distorted Ag_4Se_6 central adamantane-like core in which all $Ag^{\oplus}$ ions assume a trigonal planar coordination (Fig. 1 bottom). The chelating mode of the $Se_4^{2\ominus}$ ligands is similar to that found in the isostructural series $[M_4(Q_4)_x(Q_5)_{3-x}]^{2\ominus}$ (M = Cu, Q = S,[9] Se;[10] M = Ag, Q = Se[10]). Contrary to the structural disorder encountered in the polyselenide ligands in $[Ag_4(Se_4)_x(Se_5)_{3-x}]^{2\ominus}$[10] (which crystallizes with $Ph_4P^{\oplus}$), **3** crystallizes with only $Se_4^{2\ominus}$ ligands and no disorder.

From the results reported here it is clear that a trend of the dependence of the $Ag^{\oplus}$ coordination sphere on the size of the counterion appears to emerge. Large cations such as $Ph_4P^{\oplus}$ and $nPr_4N^{\oplus}$ effect a lower $Ag^{\oplus}$ coordination number (i.e. trigonal planar in **3** and **4**) while small ones such as $Me_4N^{\oplus}$ favor a higher coordination number (i.e. tetrahedral in **1**). Apparently, intermediate size counterions such as $Et_4N^{\oplus}$ stabilize an intermediate average coordination number of 3.5 (both trigonal planar and tetrahedral). Such systematic correlation of counterion size/coordination number of coinage metals has been observed previously in the $R_4N^{\oplus}/M^{\oplus}$/halide systems,[11] M = $Cu^{\oplus}$, $Ag^{\oplus}$, and more recently recognized in other metal/ligand systems.[12]

At this stage, there is no apparent reason for these effects to be limited to the $Ag^{\oplus}/Se_x^{2\ominus}$ systems. We expect similar, although not necessarily analogous results with other congeners in this system (i.e. $Cu^{\oplus}$, $Au^{\oplus}$ and $S_x^{2\ominus}$, $Te_x^{2\ominus}$). Certainly the metal coordination numbers (CN) found in α- and β-$KCuS_4$[5] (CN = 4), $[Ph_4P]_2[NH_4][Cu_3(S_4)_3]$[13a] (CN = 3), $[Ph_4P]_2[Au_2S_8]$[9] (CN = 2), $[Ph_4P]_4[M_2S_{20}]$ (M = Cu,[13b] Ag[14a]) (CN = 3), $[Ph_4P]_2[Ag_2(S_6)_2]$[14b] (CN = 2), $[(Ph_3P)_2N][Ag(S_9)] \cdot S_8$[14c] (CN = 2) and $[Ph_4As][Au(S_9)]$[15] (CN = 2) are consistent with this contention.

Experimental Procedure

All manipulations were carried out in a glove-box under inert atmosphere. Na_2Se_5 was prepared dissolving the stoichiometric amount of the elements in liquid ammonia. Satisfactory elemental analyses were obtained from all compounds.

1 and **2**: The reaction of 0.30 mmol $AgNO_3$ with 2 equiv. of Na_2Se_5 in 50 mL DMF in the presence of 1 equiv. Et_4NCl and Me_4NCl respectively yields a dark brown solution which after filtration and dilution with ether affords red needles of **1** (96%) and **2** (93%) respectively.

3: The reaction of 0.60 mmol $AgNO_3$ with 1 equiv. of Na_2Se_5 in 50 mL DMF in the presence of 1 equiv. nPr_4NCl yields a dark brown solution which after filtration and dilution with ether affords red needles of **3** (75%).

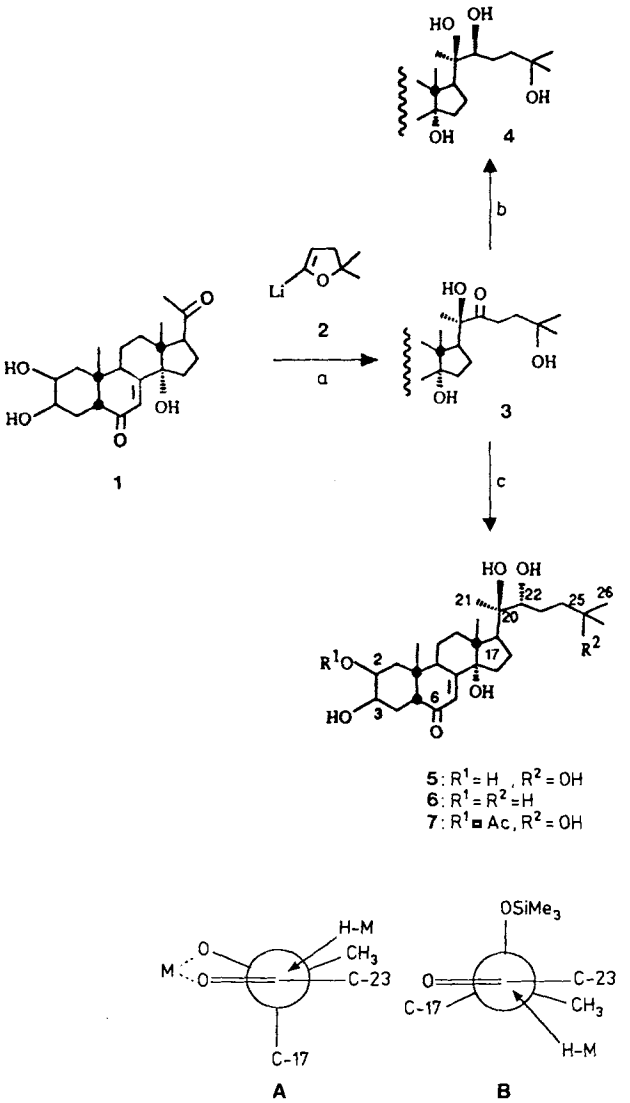
Side-chain Homologues of 20-Hydroxyecdysone: Synthesis, Configurational Assignment, and Biochemical Characterization**

By *Udo Hedtmann, Kurt Hobert, Ralf Klintz, Peter Welzel,* Jadwiga Frelek, Magdalena Strangmann-Diekmann, Antje Klöne,* and *Olaf Pongs**



The postembryonic development of insects and crustaceans is controlled by the steroid hormone 20-hydroxyecdysone **5**.[1] Like steroid hormones in vertebrates, 20-hydroxyecdysone probably regulates the expression of specific genes via an interaction of the steroid receptor complex with DNA and/or chromatin.[2] In contrast to vertebrate steroid hormone receptors,[3] the ecdysteroid receptor in invertebrates remains virtually uncharacterized.[4]

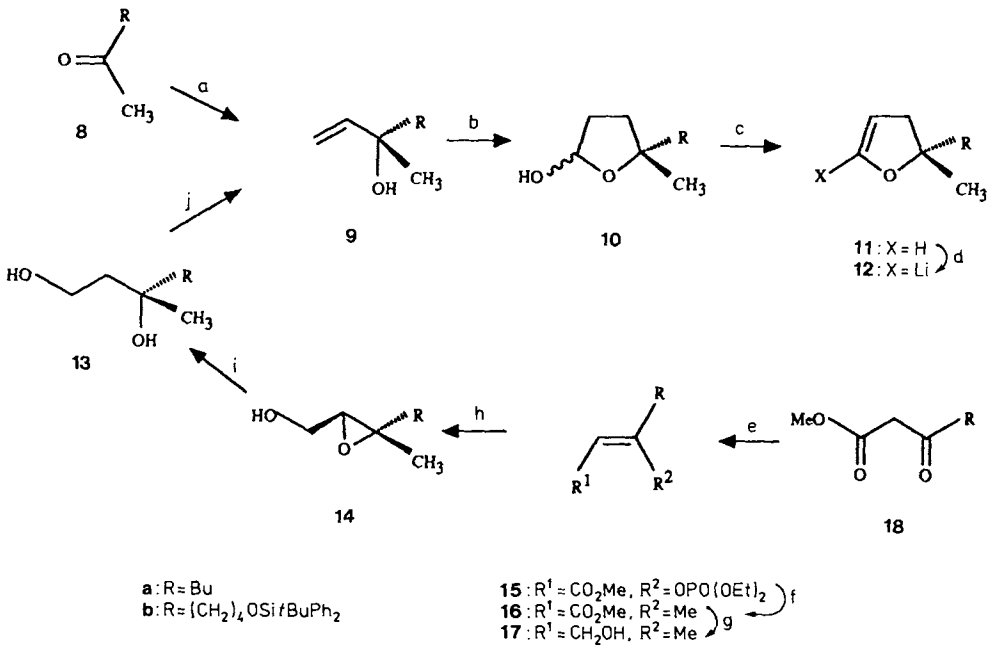
The low concentration of the receptor in target cells (e.g., cytoplasm and nuclei in the case of *Drosophila melanogaster* at various stages of development, or Kc cells), as well as the limited stability of the hormone–receptor complex in extracts from insect tissue, are probably responsible for the difficulties in the biochemical characterization of the ecdysteroid receptor.[4] If one were able to prepare a derivative of 20-hydroxyecdysone that a) contained a reactive functional group, b) was radioactively labeled, and c) proved biologically active, it would then be possible to a) use the reactive group to covalently bind the compound to the receptor, thereby permitting its identification[5] (affinity labeling[3b]) and b) attach it to a matrix in order to concentrate or even isolate the receptor through affinity chromatography.[6]

Unfortunately, essentially all the functional groups in **5** are required to ensure full biological activity,[7, 8] and cannot be used to attach a potential coupling group. In contrast, structural changes at the end of the side-chain appear not to cause a loss of activity (cf. ponasterone A **6**[8] and ref.[5a, c]).

We report here a flexible approach to the synthesis of ecdysteroids with substituents at C-26 (and C-27), together with the biological properties of the new compounds. One of these compounds meets the requirements of a ligand for affinity labeling and affinity chromatography experiments.

Poststerone **1** reacts with an excess of the lithium compound **2**, prepared from 2,2-dimethyl-2,3-dihydrofuran, to give an addition product the enol ether group of which can be cleaved with 0.1 N HCl producing **3** (Scheme 1). Reduction of **3** with $LiAlH(OtBu)_3$ leads to a 16:1 mixture of **4** and **5**.[9] This stereochemical result can be explained using the cyclic Cram model (cf. Scheme 1, **A**). By contrast, silylation of all the OH groups of **3** with trimethylsilyl triflate,[10] reduction of the keto groups at C-22 and C-6 with diisobutylaluminum hydride (DIBAH), oxidation of the allylic OH group at C-6 with MnO_2, and fluoride-induced removal of the silyl groups leads in an overall yield of 50% to a 39:1 mixture of **5** and **4**.[11] Thus, when the neighboring 20-OH group is silylated, the 22-CO group can be reduced with high Cram-selectivity (cf. Scheme 1, **B**). This approach to the synthesis of **5** from **3** is superior to the one we reported previously[9] in terms both of much higher diastereoselectivity and more reliable reproducibility.[12]

Scheme 1. a: 0.1 N HCl, THF/H_2O, 20 °C, 30 min.[9] b: $LiAlH(OtBu)_3$.[9] c: 1) 16 equiv. 2,6-dimethylpyridine, 8 equiv. trimethylsilyl triflate, THF, 20 °C, 1 h, 78%; 2) 7.5 equiv. DIBAH (1.2 M in toluene), THF, −78 → 0 °C, 4 h, extractive workup (water/diethyl ether) followed by careful drying; 3) 65 equiv. MnO_2, CH_2Cl_2, 20 °C, 16 h, 83% (for steps 2,3); 4) 6.5 equiv. Bu_4NF, THF, 1 h, 80%. Diastereomeric ratio determined by HPLC (5 μm RP-18, 25 cm × 0.4 cm, methanol/water = 3:4).



The 2,2,-disubstituted 2,3-dihydrofurans *rac*-**11a** and *rac*-**11b** required for preparing side-chain homologues of **5** were synthesized in three steps from ketones **8a** and **8b**, respectively,[13] guided by the procedure of *Botteghi*.[14] The dehydration step (**10** → **11**) is critical, and the reaction conditions listed in Scheme 2 must be followed meticulously. Enol ethers **11** react with *tert*-butyllithium to give the lithium compounds **12** (Scheme 2).

The 1:1 mixture of diastereomers **19a** and **20a** obtained from poststerone **1** and *rac*-**12a** (Scheme 3) could not be separated. On the other hand, the reduction products **21a** and **22a** from direct reduction of **19a** and **20a** with $LiAlH(OtBu)_3$ were separable by preparative HPLC, as were the derivatives **19b** and **20b** obtained from **19a** and **20a** by silylation. In order to establish the configurational relationships linking **21a** and **22a** with **19a** and **20a** the silyl groups

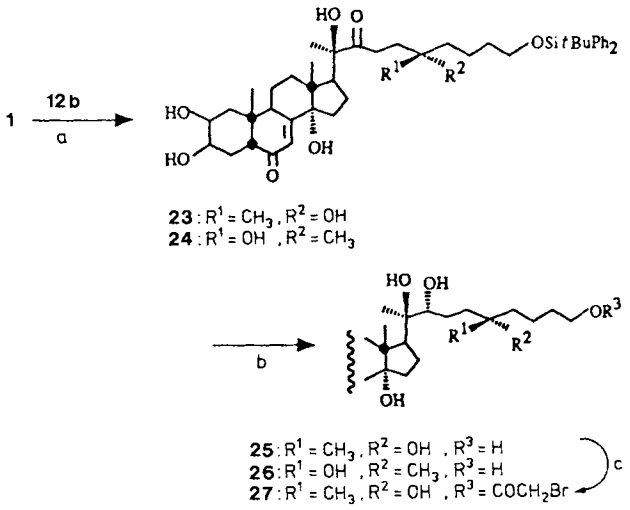
Red-Al®, THF, 0 °C, 6 h, 92% based on **17**, $[a]_D$ (*ee* > 86%) = +1.0 (*c* = 0.98, $CHCl_3$). j: Grieco elimination, [21] 77%, $[a]_D$ (*ee* > 86%) = +7.7 (*c* = 0.79, $CHCl_3$).

Scheme 3. a: cf. a in Scheme 1, [9] 85% of a 1:1 mixture of **19a** and **20a**. b: cf. c1) in Scheme 1, followed by preparative HPLC (5 μm Si 100, 2,2,4-trimethylpentane/dioxane/isopropanol = 200:0.20:0.25), 35% **19b**, 34% **20b**. c: **19a/20a** → **21a/22a**: cf. b in Scheme 1, [9] followed by preparative HPLC (5 μm RP-18, methanol/water = 1:1), 34% **21a**, 34% **22a**. d: **19b** → **21b** and **20b** → **22b**: cf. c1)–c3) in Scheme 1, 77% **21b**, 71% **22b**. e: **21b** → **21c** and **22b** → **22c** (and determination of the diastereomeric excess): cf. c4) in Scheme 1, 83% **21c**, 83% **22c**.

were removed from **19b** (**19b** → **19a**) and the resulting *pure* **19a** was reduced with $LiAlH(OtBu)_3$, leading to **21a**.



Reduction of **19b** and **20b** with DIBAH and subsequent re-oxidation of the 6-OH group with MnO_2 produced **21b** and **22b**, respectively, each contaminated with traces of the corresponding 22*S* isomer. Cleavage of the silyl ether groups followed by HPLC showed the diastereomeric excess in the DIBAH reduction step to be 94%.

The configurations at C-22 of **21a,c** and **22a,c** were established by the method of *Snatzke* et al. [CD analysis of the in situ complexes of optically active 1,2-diols with $Mo_2(OAc)_4$ [15]]. Details of this analysis will be reported elsewhere. The results are consistent with those of the ^{1}H-NMR studies, as summarized in Table 1. Thus, as in the case of **4** and **5**, for the pairs **21a/21c** and **22a/22c** the 21-CH_3 groups in the 22*S* isomers **a** are more deshielded. The configuration at C-25 in the compounds **19**–**22** has not yet been clarified, and is depicted arbitrarily in Scheme 3.

Table 1. ^{1}H-NMR signals for the 21-CH_3 groups of compounds **4**, **5**, **21a,c**, **22a,c**, **25**, and **26** (in [D_5]pyridine).

Config.	δ-Values (21-CH_3)			
22*S*	1.71 (**4**)	1.73 (**21a**)	1.73 (**22a**)	
22*R*	1.60 (**5**)	1.61 (**21c**)	1.61 (**22c**)	1.59 (**25**, **26**)

In analogy to the experiments described above, compounds **25** and **26** were prepared from **1** and *rac*-**12b** via the 22-ketones **23** and **24**, which could be separated by HPLC (Scheme 4).

Scheme 4. a: **1** + *rac*-**12b**: cf. a in Scheme 1, [9] followed by preparative HPLC (5 μm Si 100; 2,2,4-trimethylpentane/$CHCl_3$/ethanol = 15:5:1), 35% **23**, 32% **24**; **1** + **12b**: 50% **23** and **24** in the ratio > 93:7 (determined by HPLC). b: **23** → **25** and **24** → **26** cf. c in Scheme 1, 43% **25**, 40% **26**. c: 0.9 equiv. $BrCH_2COOH$, 1 equiv. dicyclohexylcarbodiimide, 0.1 equiv. 4-(dimethylamino)pyridine, THF, −20 °C, 3 h, 64%.

Table 2. Relative receptor-binding affinity (RBA) and relative puff induction (RPI) of ecdysone and the ecdysteroids **3**–**7**, **19a**, **20a**, **21c**, **22c**, and **25**–**27**.[a]

Compound	RBA	RPI
6	1000	1000
Ecdysone	0.3 ± 0.3	0.2 ± 0.2
3	5.3 ± 2	5 ± 3
4	inactive	inactive
5	14.0 ± 3	14 ± 4
7 [29]	1.0 ± 0.4	0.6 ± 0.4
19a	1.4 ± 0.4	0.8 ± 0.3
20a	1.4 ± 0.4	1 ± 0.3
21c	8.0 ± 0.4	8 ± 1
22c	11.3 ± 3	8 ± 2
25	5.3 ± 2	6 ± 1
26	8.0 ± 2	8 ± 2.5
27	15.0 ± 2	not tested

[a] RBA-values were determined by the method of *Ojasoo* et al.[25] The RBA-value for **6** was taken to be 1000. Binding constant at 4 °C for [$^3H_2$]-ponasterone A, [$^3H_2$]-**6**, with the ecdysteroid receptor preparations (ca. 200 fmol receptor/mg protein) from nuclei or cytoplasm: $(4.2 \pm 0.3) \times 10^{-9}$ M; for [$^3H_4$]-**5**: $(3.0 \pm 1.5) \times 10^{-7}$ M. The constants were established by the method of *Scatchard* [30] (average of three independent measurements). The ecdysteroid concentration producing half-maximum puff induction at 74 EF and 75B on salivary gland chromosomes of third instar *Drosophila* larvae was determined by the method of *Ashburner*.[28] The required concentration of **6** was taken to be 1000 and corresponding concentrations for the other ecdysteroids were based on this value, permitting computation of relative puff induction values (RPI). Reported values are averages taken over four measurements.

The *R*-configuration at C-22 follows from the reduction procedure employed and is supported by the chemical shift of the CH_3-21 protons (cf. Table 1). The configuration at C-25 was established by a stereochemically unambiguous synthesis. Thus, the dianion of methyl acetoacetate[16] was alkylated to give **18b** (cf. Scheme 2) from which trisubstituted alkene **16b** was stereoselectively prepared via the enol phosphate **15b** by the method of *Weiler* et al.[17] Reduction of the ester function with DIBAH led to allylic alcohol **17b**, the *E* configuration of which could be confirmed with an NOE experiment. **17b** was converted to the epoxy alcohol **14b** by Sharpless epoxidation (catalytic variant,[18] L-(+)-diethyl tartrate as auxiliary). Reduction with Red-Al[19] gave diol **13b**, a Mosher ester analysis of which revealed that the enantiomeric excess of the Sharpless epoxidation was at least 86%.[20] Grieco elimination[21] provided the desired optically active allylic alcohol (*S*)-**9b**, which was converted to (*S*)-**11b** by the method described above. The reaction of **1** with **12b**, prepared from (*S*)-**11b**, resulted almost exclusively in **23** (cf. Scheme 4).

As expected, the primary OH group in **25** could be esterified selectively with bromoacetic acid to give the bromoacetyl derivative **27**.[22] Biochemical properties of the various ecdysteroids are summarized in Table 2.

A salt extract of nuclei from *Drosophila* embryos (maximum age twelve hours)[23] and a lysate of cytoplasm from *Drosophila* pupae[24] were used to determine *in vitro* relative binding affinities (RBA)[25] to the ecdysteroid receptor. The RBA values were established by competition with either [23,23,24,24-$^3H_4$]-**5** or [24,25-]/[25,26-$^3H_2$]-**6** for binding to the ecdysteroid receptor proteins. Since there was essentially no difference between data obtained with the receptor preparations from nuclei and cytoplasm, only a single value is included in Table 2 for each ecdysteroid. The RBA values for ecdysone, **5**, and **6** are consistent with previously reported binding constants.[26, 27]

In addition, the extent of puff induction by the ecdysteroids on polytene chromosomes from the salivary glands of third instar *Drosophila* larvae was established.[28] This puff induction was determined quantitatively and, in analogy to RBA values, relative puff induction (RPI) values are reported corresponding to the ecdysteroid concentration required for half-maximal puff induction at loci 74EF and 75B on the third chromosome.

A comparison of the RBA and RPI values in Table 2 shows that there is no significant difference between the activity of the ecdysteroids to bind in vitro to the receptor and to induce in vivo puffs. We conclude, therefore, that the biological activity of the ecdysteroids is a consequence of their affinity to the receptor. Table 2 also confirms that the OH groups in ring A and in the side-chain are essential for complete biological activity. Ecdysone (lacking the OH group at C-20) and the 2-*O*-acetyl compound **7**[29] show only a fraction of the activity of **5**. The (22*S*)-isomer **4** is completely inactive, and the activity of the 22-ketone **3** is reduced to ca. 30%. It is also instructive to compare the values for **5** with those for **21c**, **22c**, **25**, and **26**. Elongation of the side-chain at C-26 apparently has little effect on the biological activity, and inversion of the configuration at C-25 does not result in a change in activity (cf. the values for **21c** and **22c**). This part of the steroid apparently does not interfere with the binding site of the receptor protein.[5a]

With respect to the problem posed in the introduction, it has now been shown that **27** (radioactively labeled in the bromoacetyl group) is a compound that is appropriate for affinity labeling of ecdysteroid receptors and for the preparation of an affinity matrix. Experiments along these lines are currently in progress.

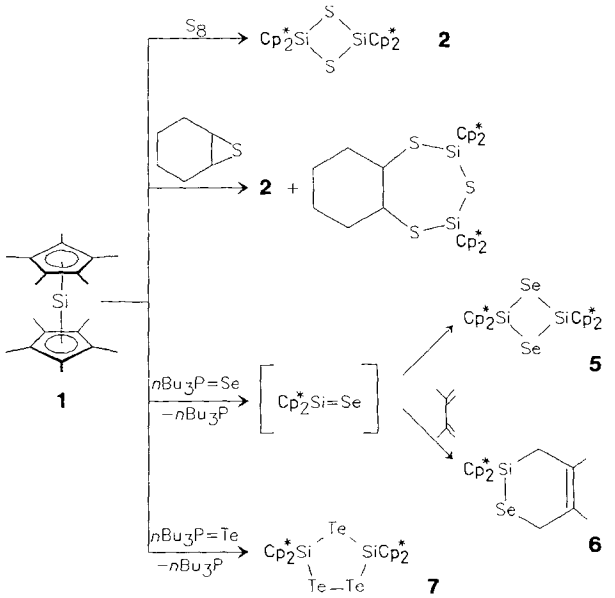
Reaction of Decamethylsilicocene with Sulfur, Selenium, and Tellurium: From a p_π–p_π System to New Heterocycles



By *Peter Jutzi,* Andreas Möhrke, Achim Müller,* and *Hartmut Bögge*

Decamethylsilicocene **1** is the first stable compound of divalent silicon.[1] According to our earlier investigations, this π complex reacts as a dialkylsilanediyl: for example, **1** undergoes insertion into element–hydrogen bonds[2] and [2+1] cycloadditions with double-bond systems of the type $X=C=Y$.[3] This behavior is due to the facile η^5–η^1 haptotropic rearrangement of the pentamethylcyclopentadienyl (Cp^*) ligands. An η^1-bonded Cp^* ligand at silicon has been shown to be very bulky.[4] For this reason, we decided to investigate whether simple combination of **1** with electron-sextet fragments X might offer an approach to kinetically stabilized p_π–p_π systems of the type $Cp^*_2Si=X$ [Eq. (a)]. In particular, we studied the reaction of **1** with sulfur, selenium, and tellurium sources (X = S, Se, Te).

$$R_2Si: + :\ddot{X} \rightarrow R_2Si=\ddot{X} \qquad \text{(a)}$$

Compound **1** reacts in benzene at room temperature with *cyclo*-S_8 in a nearly quantitative fashion to give 2,2,4,4-tetrakis(pentamethylcyclopentadienyl)-1,3,2,4-dithiadisiletane **2** (Scheme 1). The conceivable silathione intermediate, $Cp^*_2Si=S$, has not been detected so far; for example, trapping experiments with 2,3-dimethylbutadiene have been unsuccessful. If cyclohexene sulfide is used as the sulfur source, higher reaction temperatures are required. In addition to **2**, the novel bicyclic compound **3** was unexpectedly obtained. We were able to show that **3** is not formed from cyclohexene sulfide and **2**.

Reaction of **1** with tri-*n*-butylphosphane selenide[5] in benzene at room temperature led, again nearly quantitatively, to formation of diselenadisiletane **5**, which is analogous to **2**.[6] If the reaction is carried out in the presence of 2,3-dimethylbutadiene, the heterocycle **6** is obtained in good yield. Thus, it was possible to trap the intermediate silaselone **4** by [2+4] cycloaddition.[7] Apparently, however, **4** is not kinetically stable enough to be isolated under normal conditions.

Scheme 1. Reactions of **1** with sulfur, selenium, and tellurium.

The reaction of **1** with tri-*n*-butylphosphane telluride proceeds in an unexpected way.[5] At room temperature, or even at −30 °C, the dark red 1,2,4,3,5-tritelluradisilole **7** is formed. Intermediates have not yet been detected. Compound **7** is the first neutral silicon–tellurium heterocycle. The molecular structure of **7**, determined by X-ray analysis,[8] is shown in Figure 1 together with selected bond distances and angles. No X-ray structure data were previously available for molecular silicon–tellurium systems, though X-ray struc-

[+] X-ray structure analysis

tures have been determined for $K_6Si_2Te_6$,[9] $Na_6Si_2Te_6$,[10] and $K_4Si_4Te_{10}$.[11] Noteworthy in the structure of **7** are the large C–Si–C angles (approximately 118°), caused by the bulky Cp* ligands. The Te–Si–Te angles (approximately 104°) are correspondingly smaller than expected for tetrahedrally coordinated silicon. The Te–Te distance (2.681 Å) is comparatively[12] short; the dihedral angle Si1-Te1-Te2-Si2 is 51°. The Si–Te distances in **7** (2.529 Å) are slightly longer than the terminal Si–Te distances in the tellurosilicates above. For comparison, the Pauling method,[13] that is, the sum of the tetrahedron radii for covalent single bonds, gives a distance of 2.49 Å.

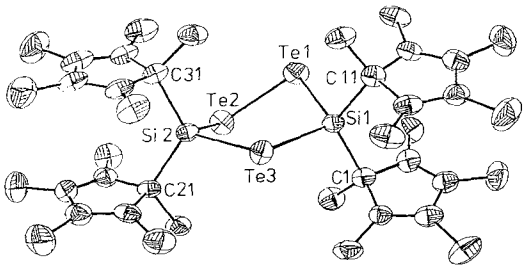

Fig. 1. Molecular structure of **7**. Important bond lengths [Å] and angles [°]: Si1–Te1 2.529(2), Si1-Te3 2.529(3), Te1-Te2 2.681(1); Te2-Te1-Si1 99.4(1), Te1-Te2-Si2 97.8(1), Si1-Te3-Si2 106.8(1), Te1-Si1-Te3 104.3(1), Te2-Si2-Te3 104.4(1).

The identity of the other new compounds (**2, 3, 5, 6**) was established by spectroscopic and analytical data. The functionality offered by the Cp* ligands[4] makes these compounds, as well as the heterocycle **7**, very interesting preparatively.

It remains to be determined whether the formation of **2, 3,** and **7** proceeds via double-bond systems of the type $Cp^*_2Si=X$. Detection of the silaselone **4**, however, should encourage reaction of other electron-sextet fragments with decamethylsilicocene **1** in order to synthesize compounds with (p–p)π bonds to silicon.

Experimental Procedure

2: A solution of **1** (1.2 g, 4.02 mmol) in 20 mL of benzene was treated with sulfur (640 mg) and the reaction mixture was stirred for 16 h at room temperature. The solvent was removed under vacuum and the residue was washed with carbon disulfide. Crystallization from toluene afforded 1.12 g (84%) of **2** (m.p. 330 °C). ^{1}H NMR (300.133 MHz, $CDCl_3$): $\delta = 1.45$, 1.69, 1.84 (each s, 12H:24H:24H; $C_5(CH_3)_5$). MS (CI isobutane): *m/z* 660 ($M^{\oplus}$, 31%), 525 ($M^{\oplus}-Cp^*$, 100).

2/3: **1** (1.66 g, 5.56 mmol) and cyclohexene sulfide (790 mg, 6.92 mmol) in 15 mL of toluene were heated at 105 °C for 2.5 h. After removal of the solvent by vacuum distillation, 20 mL of *n*-hexane was added to the colorless residue to form a suspension. Insoluble **2** (1.2 g, 65%) was separated. Concentration of the *n*-hexane phase gave **3** (400 mg, 19%) as colorless needles (m.p. 251 °C, dec.). ^{1}H NMR (300.133 MHz, $CDCl_3$): $\delta = 1.18$ (s, 6H; $C_5(CH_3)_5$), 1.28 (m, 4H; $-CH_2-CH_2-CH=$), 1.39, 1.66, 1.74, 1.76, 1.82, 1.90, 1.99, 2.03 (each s, 6H:12H:6H:6H:6H:6H:6H:6H; $C_5(CH_3)_5$), 2.31 (m, 4H; $-CH_2-CH_2-CH=$), 3.48 (m, 2H, $=CH-S-$). ^{29}Si NMR (59.595 MHz, $CDCl_3$): $\delta = 14.9$; MS (CI isobutane): 774 ($M^{\oplus}$). MS (EI, 70 eV): *m/z* 639 ($M^{\oplus}-Cp^*$, 39%), 505 [$M^{\oplus}$-($Cp^* + C_5(CH_3)_4CH_2$), 3], 309 [$(C_6H_{10}S_2Si\text{-}Cp^*)^{\oplus}$, 100].

5: **1** (500 mg, 1.7 mmol) was treated with tri-*n*-butylphosphane selenide (560 mg, 2.0 mmol) in 10 mL of benzene. The solution was stirred for 12 h at room temperature and the solvent then removed under vacuum. The residue was washed with *n*-pentane. Crystallization from toluene gave 560 mg (89%) of **4** as colorless needles (m.p. 335 °C). ^{1}H NMR (300.133 MHz; $CDCl_3$): $\delta = 1.55$, 1.68, 1.85 (each s, 12H:24H:24H; $C_5(CH_3)_5$). MS (70 eV): *m/z* 756/754 ($M^{\oplus}$, 1%), 621/619 ($M^{\oplus}-Cp^*$, 10), 487/485 [$M^{\oplus}-(Cp^* + C_5(CH_3)_4CH_2$), 41], 163 ($Cp^*Si^{\oplus}$, 100).

6: **1** (640 mg, 2.1 mmol) was dissolved in 5 mL of toluene and 5 mL of 2,3-dimethyl-1,3-butadiene. Tri-*n*-butylphosphane selenide (620 mg, 2.2 mmol) was added and the resulting solution was stirred for 18 h at room temperature. The solvent was removed under vacuum and the residue was recrystallized from a small amount of *n*-pentane, affording 586 mg (58%) of **4** (m.p. 121 °C). ^{1}H NMR (300.133 MHz, C_6D_6): $\delta = 1.13$ (s, 6H; $C_5(CH_3)_5$), 1.71 (s, 15H; $C_5(CH_3)_5/C=C-CH_3$), 1.85 (s, 9H; $C_5(CH_3)_5/C=C-CH_3$), 1.89 (s, 2H; Si–CH_2–), 1.97 (s, 6H; $C_5(CH_3)_5$), 2.84 (s, 2H; Se–CH_2–). ^{29}Si NMR (59.595 MHz, $CDCl_3$): $\delta = 25.2$. MS (70 eV): *m/z* 460 ($M^{\oplus}$, 5%), 325 ($M^{\oplus}-Cp^*$, 73), 243 [$M^{\oplus}-(Cp^* + C_6H_{10})$, 69], 135 ($Cp^{*\oplus}$, 100).

7: A solution of tri-*n*-butylphosphane telluride (1.32 g, 4.0 mmol) in 10 mL of toluene was added dropwise over 1 h to a solution of **1** (1.2 g, 4.0 mmol) in 15 mL of toluene at room temperature. The dark red solution was concentrated to dryness under vacuum and the residue was washed with a small amount of *n*-pentane. Crystallization from refluxing toluene afforded 1.49 g (76%) of **7** as dark red prisms (m.p. 227 °C, dec.). ^{1}H NMR (300.133 MHz, $CDCl_3$): $\delta = 1.25$, 1.72, 1.92 (each s, broad; 12H:24H:24H, $C_5(CH_3)_5$). ^{29}Si NMR (59.595 MHz, $CDCl_3$): $\delta = 13.0$. ^{125}Te NMR (94.714 MHz, $CDCl_3$): $\delta = -564$, -255. MS (70 eV): *m/z* 846 ($M^{\oplus}-Cp^*$, 4%), 711 ($M^{\oplus}-2Cp^*$, 4), 163 ($Cp^*Si^{\oplus}$, 100).

Water-Soluble Porphyrin Diglycosides with Photosensitizing Properties**

By *Gerd Fülling, Doris Schröder,* and *Burchard Franck**

Since the mid-1970s, photosensitizing porphyrins have been used in tumor therapy.[1] This photodynamic therapy (PDT) is based on the fact that suitable porphyrins become concentrated in tumor tissue and, upon subsequent irradiation with visible light in the presence of oxygen, specifically

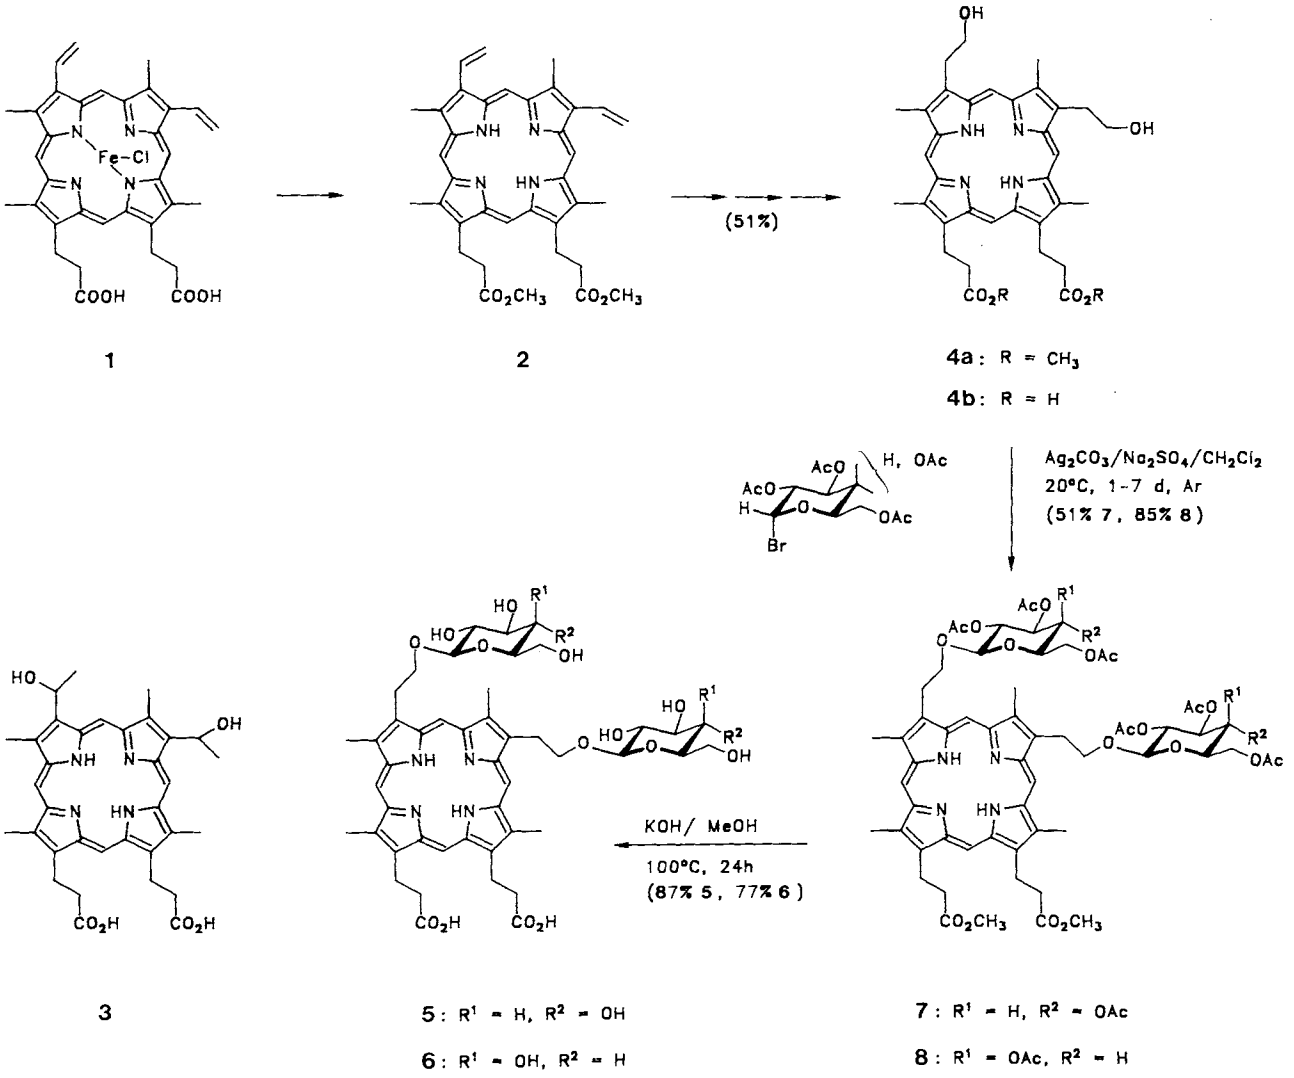
[**] Novel Porphyrinoids, Part 8. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 7: K.-H. Schumacher, B. Franck, *Angew. Chem. 101* (1989) 1292; *Angew. Chem. Int. Ed. Engl. 28* (1989) 1243.

destroy the tumor. A porphyrin mixture obtained from hemin **1**, the red pigment of blood, is most often used; it consists of hematoporphyrin **3** and related porphyrins and is called "hematoporphyrin derivative" (Hpd). Of topical interest is the use of Hpd to kill viruses in transfusion blood.[2]

The wider application of PDT requires photosensitizing porphyrins that are chemically pure, readily accessible, and structurally related to naturally occurring porphyrins. Furthermore, they should be rapidly excreted from the body after therapy. This property may be favored by improved water solubility of the porphyrins.

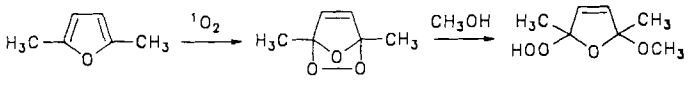


Here we report the first synthesis of porphyrin diglycosides that exhibit excellent water solubility and are efficient photosensitizers—namely, the diglucoside **5** and the digalactoside **6** of isohematoporphyrin **4b**.

In contrast to **3** and Hpd, compound **4b** is both chemically and sterically pure owing to its primary hydroxyl groups. Its dimethyl ester **4a** can be obtained from protoporphyrin dimethyl ester **2** in three steps (51% overall yield) as described by *Kenner* et al.[3] Diastereoselective *O*-glycosylation was accomplished in nonpolar solvents with a solid, surface-active silver catalyst and neighboring-group-active acetyl groups, affording stable β-diglycosides (Scheme 1).

The glycosylation with α-D-acetobromoglucose or α-D-acetobromogalactose, carried out at room temperature with TLC monitoring, was complete in 1–7 days depending on the quality of the freshly prepared silver carbonate.[5] Column chromatography with CH_2Cl_2:MeOH 50:1 on silica gel gave the octaacetylporphyrin diglucoside **7** (m.p. 118 °C) or digalactoside **8** (m.p. 100 °C) in 51 and 85% yield, respectively.[4] The β configuration at the glycosidic C atoms is unambiguously established by comparison of the ^{13}C NMR signals ($CDCl_3$) of C1 and C5 in the sugar moieties of **7** and **8** with those of the acetylated α- and β-methylglycosides of D-glucose and D-galactose.[6]

Conversion of the octaacetylporphyrin diglycosides **7** and **8** to the water-soluble, free diglycosides **5** and **6**, respectively, was accomplished by alkaline saponification. According to TLC monitoring, reaction was complete after refluxing with KOH/aqueous MeOH for 24 h (87 and 77% yield, respectively). These conditions show that the bis(D-glucosyl)isohematoporphyrin **5** and the bis(D-galactosyl)isohematoporphyrin **6** are extremely stable.



Diglucoside **5** exhibits a water solubility of 4%, which is unusually good for a porphyrin derivative: **5** is therefore a promising candidate for physiological investigations. The water solubility of digalactoside **6** is similarly high. The two isohematoporphyrin diglycosides **5** and **6** are both easily accessible from inexpensive hemin **1** in six steps (overall yields of 16 and 23%, respectively). Compounds **5**–**8** offer derivatives of a porphyrin natural product with a wide range of distribution coefficients and membrane interactions.

Scheme 1. Synthesis of isohematoporphyrin diglycosides **5** and **6** from isohematoporphyrin dimethyl ester **4a** [4].

With respect to medicinal applications of the isohematoporphyrin diglycosides **5–8**, it was important to know whether the polar sugar moiety would affect the photosensitizing activity. Of particular interest was the formation of singlet oxygen, which is thought to be involved in the antitumor activity of Hpd.[7]

The trapping reaction with 2,5-dimethylfuran **9**[8] under standard conditions proved suitable for comparative, quantitative determination of the amount of $^1O_2$ formed.[9]

9 **10** **11**

The results in Table 1 show that the new porphyrin diglycosides **5–8** are efficient photosensitizers. Each produces roughly a hundredfold amount of chemically reacted $^1O_2$ in 20 min. Thus, they are almost as efficient as the well-known photosensitizer Rose Bengal.

Table 1. Comparison of $^1O_2$ formation under standard conditions: 2,5-dimethylfuran **9** as trapping agent; quantitative determination (after methanolysis) of the amount of crystalline hydroperoxide **11** formed. Ca. 0.005 mmol of photosensitizer and 1.44 g (15 mmol) of **9** in 160 mL of benzene:MeOH (3:1); irradiation with a 150-W halogen lamp while O_2 is bubbled through the solution (20 min, 0 °C).

Sensitizer ([mg])	Yield of **11** based on **9** [%]
Isohematoporphyrin dimethyl ester **4a** (3.0)	18
Hematoporphyrin **3** (3.0)	30
Octaacetylporphyrin diglucoside **7** (4.8)	46
Octaacetylporphyrin digalactoside **8** (4.6)	19
Isohematoporphyrin diglucoside **5** (4.1)	22
Isohematoporphyrin digalactoside **6** (4.4)	28
Rose Bengal (5.4)	50
Control without sensitizer	–

Detailed investigations of the photophysical properties of the isohematoporphyrin diglucoside **5** and vinylogous porphyrinoids[10, 11] will soon be reported.[12]

Experimental Procedure

7: α-D-Acetobromoglucose (1.6 g, 3.9 mmol), sodium sulfate (3 g), and freshly prepared silver carbonate [5] (1.6 g) were added under argon to a solution of isohematoporphyrin dimethyl ester **4a** (172 mg, 0.27 mmol) in 250 mL of degassed, dry dichloromethane and the reaction mixture was stirred in the dark at room temperature for 24 h (TLC monitoring, chloroform:methanol 50:1, silica gel TCL plates F_{254}, Merck). The reaction mixture was then filtered through Celite and the filtrate was evaporated under vacuum. Column chromatography of the residue on 200 g of silica gel (Merck, particle size 0.063–0.2 mm) with chloroform gave 180 mg (51%) of red, microcrystalline octaacetylisohematoporphyrin diglucoside dimethyl ester **7**, m.p. 118 °C. EI-MS: *m/z* 1287 (100%, $M^{\oplus}$), 1200 (6, $M^{\oplus}-CH_2CH_2COOCH_3$), 927 (60, $M^{\oplus}-CH_2O$-glucose acetate). UV/VIS ($CHCl_3$): λ_{max} (log ε) = 400 (5.25), 499 (4.15), 533 (3.98), 568 (3.80), 595 (3.11), 622 nm (3.64). ^1H NMR (300 MHz, $CDCl_3$): $\delta = -3.84$ (s, 2H; NH), 9.99, 10.01, 10.08, 10.10 (4s, 1H each; *meso*-H). ^{13}C NMR (75.47 MHz, broadband-decoupled, $CDCl_3$): δ = 11.67, 11.75, 11.84 (pyrrole CH_3), 19.44, 19.52, 20.46, 20.51, 20.65 (acetyl-CH_3), 51.70 (ester CH_3), 61.99 (Glu-C6), 68.44 (Glu-C4), 71.06 (Glu-C2), 71.96 (Glu-C5), 72.87 (Glu-C3), 101.23 (Glu-C1), 96.41, 96.63, 96.75, 96.90 (*meso*-C).

8 was synthesized analogously.

5: A solution of **7** (51 mg, 0.04 mmol) and potassium hydroxide (80 mg) in 75 mL of methanol and 6 mL of distilled water was refluxed for 24 h. The reaction mixture was then allowed to cool to room temperature and neutralized by addition of acetic acid. Evaporation under vacuum afforded an oily residue, which was applied with a 10-mL syringe to a SEP-PAK C_{18} cartridge (Waters, Part. No. 51910), previously washed with methanol followed by water. The porphyrin diglucoside **5** was completely adsorbed on the cartridge and retained, so that inorganic components could be removed by washing with water and **5** could be subsequently eluted with methanol. Evaporation of the eluate gave 32 mg (87%) of red **5**, m.p. 180 °C. FD-MS: *m/z* 923 (100%, $M^{\oplus}$), UV/VIS (MeOH): λ_{max} (log ε) = 396 (5.00), 498 (3.77), 532 (3.62), 569 (3.46), 620 nm (3.26). ^1H NMR (300 MHz, [D_6]acetone, solution prepared by the SEP-PAK cartridge method, see above): $\delta = -4.0$ (s, 2H; NH), 9.92, 10.01, 10.07, 10.10 (4s; *meso*-H). ^{13}C NMR (75.47 MHz, broadband-decoupled, D_2O): δ = 9.2 (pyrrole CH_3), 61.0, 61.1 (Glu-C6), 69.7, 69.9 (Glu-C4), 73.5 (Glu-C2), 76.1, 76.2 (Glu-C3, Glu-C5), 95 (br., *meso*-C), 102.1, 102.8 (Glu-C1), 179 (COOH).

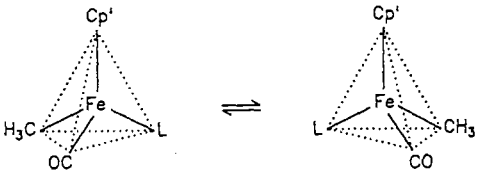
Thermal and Electrocatalytic Epimerization at Iron as the Chiral Center**

By *Henri Brunner,* Konrad Fisch, Peter G. Jones,* and *Josef Salbeck*



Optically active transition metal compounds in which the transition metal is the chiral center can be synthesized with the optically active aminophosphane ligands L and L'.[1]

(*S*)-(+)-$(C_6H_5)_2P$-N(CH_3)-CH(CH_3)C_6H_5 L
(*S*)-(−)-$(C_6H_5)_2P$-NH-CH(CH_3)C_6H_5 L'

[**] Optically active transition metal complexes. Part 96. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and BASF AG, Ludwigshafen. Part 95: P. Bladon, P. L. Pauson, H. Brunner, R. Eder, *J. Organomet. Chem. 355* (1988) 449.

Examples are the acetyl iron compounds (*RS*)- and (*SS*)-$[CpFe(CO)(L)COCH_3]$ (Cp = η-C_5H_5) and their analogues containing the ligand L′. In all cases, the epimerization at the iron atom occurs via dissociation of L and L′; because of the participation of chiral dihapto-acyl intermediates and the achiral rearrangement product $[CpFe(CO)_2CH_3]$, it is difficult to analyze this process.[2–4] Such complications do not occur in the epimerization of the methyl iron compounds **1**[5] and **2**.

$(-)_{436}$-($R_{Fe}S_C$)-**1a** $(+)_{436}$-($S_{Fe}S_C$)-**1b**
$(-)_{436}$-($R_{Fe}S_C$)-**2a** $(+)_{436}$-($S_{Fe}S_C$)-**2b**
1, Cp′ = Cyclopentadienyl (Cp); **2**, Cp′ = Indenyl (In)

The photochemical reaction of the prochiral compounds $[Cp'Fe(CO)_2CH_3]$, Cp′ = cyclopentadienyl or indenyl, with L proceeds via exchange of one of the two enantiotopic CO groups to give the compounds **1a,b**[5] and **2a,b**; the diastereomeric ratio is 50:50 in each case.[6] The isomers can be separated by preparative liquid chromatography and by fractional crystallization.[7] The absolute configurations of **1a** and **2a** have been determined by X-ray structural analysis;[8] these compounds take up remarkably similar conformations in the crystal (Fig. 1).

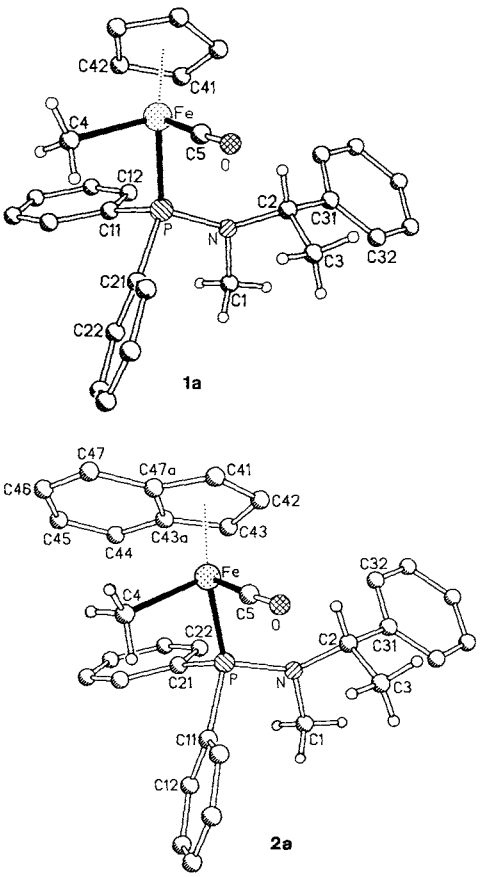

Fig. 1. Structures of $(-)_{436}$-($R_{Fe}S_C$)-**1a** and $(-)_{436}$-($R_{Fe}S_C$)-**2a** in the crystal.

The thermal epimerization of **1a** and **2a** in C_6D_6 is first order;[9] in both cases it was followed by baseline-separated ^1H NMR signals.[10] The rate of epimerization is not changed measurably when L is added, while in the presence of L′, a complete phosphane exchange occurs which is also first order. The epimerization of **2a** was shown to have a large positive entropy of activation (75 $J\,K^{-1}\,mol^{-1}$).[11]

These results suggest a dissociative epimerization mechanism whose rate-determining step is the cleavage of the Fe–L bond. The kinetic data for this process indicate that the intermediate or transition state is an achiral species.[12]

The indenyl complex **2a** ($t_{1/2}$ = 37 min, 50.0 °C) epimerizes 10–20 times faster than the cyclopentadienyl complex **1a** ($t_{1/2}$ = 70 min, 70.0 °C). We suggest that this relatively small acceleration is due to the increased steric interaction between the indenyl and aminophosphane ligands which favors phosphane dissociation. The absence of an "indenyl effect" (higher reactivity of the indenyl system compared to the analogous Cp system because of ring slippage[13, 14]) must be due to the absence of associative processes.

Significant differences were observed in the electrocatalytic configuration transformation of the iron complexes **1a** and **2a**, depending on the pentahapto-bonded π ligand. While the indenyl complex **2a** is epimerized completely within one minute at −35 °C in THF using sodium amalgam as the reducing agent,[15] the Cp compound **1a** surprisingly does not epimerize either at −35 °C or at +20 °C under the same conditions. In contrast to the Cp compound **1a**, the indenyl compound **2a** undergoes electron transfer to give a 19e-species which loses phosphane. The resulting 17e-radical anion changes its configuration before phosphane association and transfer of the electron back to the catalyst or substrate completes the catalytic cycle.

When the epimerization of **2a** is oxidatively induced with 50 mol-% $[Cp_2Fe][PF_6]$, it is incomplete at +20 °C in THF after 30 min; however, under the same conditions the epimerization of **1a** establishes thermodynamic equilibrium **1a**:**1b** = 62:38 after five minutes.

The cyclovoltammograms of **1a** and **2a** are in agreement with the behavior of the complexes with respect to the starting reagents used; while the reduction of **2a** shows an irreversible reduction wave at a peak potential of −2185 mV vs. SCE, no corresponding behavior is observed for **1a** up to the commencement of the reduction of the solvent at −2570 mV. The reduction of the indenyl compound **2a** is accompanied by a further rapid reaction. The voltammograms are however almost identical for the oxidation of **2a** (+240 mV) and **1a** (235 mV); in each case these are irreversible oxidation processes followed by other rapid reactions.[16] All observed oxidation and reduction potentials lie within the potential range of the starting reagents used for the electrocatalysis.

Thus, in the case of the oxidatively or reductively induced epimerization of **1a** and **2a**, we have detected for the first time a configuration transformation induced by electron transfer[17] which is accelerated enormously in comparison with the thermal reaction.

[6] The indenyl complex **2a,b** was prepared analogous to the Cp complex **1a,b**. [5] **2a,b** is chromatographed on Al_2O_3 in the absence of air; after removal of the starting materials, **2a,b** is eluted with pentane–diethyl ether (4:1) as a brown zone. Removal of the solvents yields **2a,b** as a powder.
[7] The diastereomers **1a** and **1b** were separated as previously described. [5] The separation of **2a** and **2b** was carried out as follows: 1 g of the 1:1 mixture was stirred rapidly in 10 mL pentane. The mother liquor was removed and the extraction of the residue repeated with 5 mL pentane. The residue remaining contains 300 mg of the diastereomer **2a** in optically pure form.

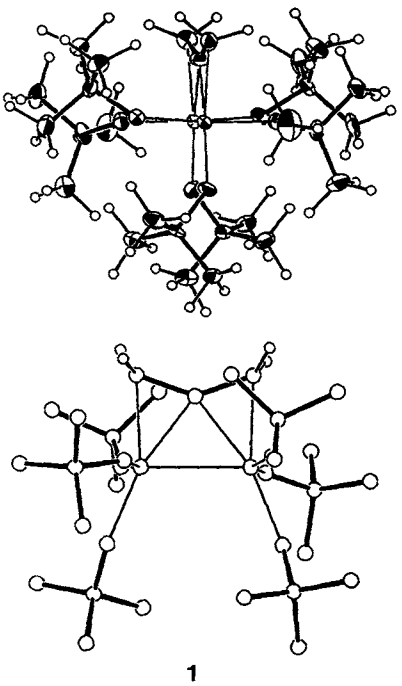
Versatile Modes of Allene Bonding in the Structures of $[W_2(OtBu)_6(C_3H_4)]$, $[W_2(OtBu)_6(C_3H_4)(CO)_2]$, and $[W_2(OtBu)_6(C_3H_4)_2]$

By *Roger H. Cayton, Stephanie T. Chacon, Malcolm H. Chisholm,* Mark J. Hampden-Smith, John C. Huffman, Kirsten Folting, Paul D. Ellis,* and *Beth A. Huggins*

The compounds $[M_2(OR)_6](M \equiv M)$ provide templates for developing organometallic chemistry.[1] In particular, the dinuclear center and the M≡M bond allow novel modes of coordination and reactivity. We report here three different modes of allene bonding in compounds **1–3**.

$[W_2(OtBu)_6(C_3H_4)]$ **1** $[W_2(OtBu)_6(C_3H_4)(CO)_2]$ **2** $[W_2(OtBu)_6(C_3H_4)_2]$ **3**



We recently reported the preparation of **1** from $[W_2(OtBu)_6]$ and allene in hydrocarbon solvents.[2] On the basis of NMR spectroscopic data, we proposed a μ-perpendicular allene coordination in which the C_3H_4 moiety had rehybridized to resemble that predicted[3] on theoretical grounds for the transition state for allene racemization.

Compound **1** reacts with CO (>2 equiv.) in hydrocarbon solvents to give complex **2**, which shows two CO stretching frequencies (1900 and 1830 cm^{-1}) in the IR spectrum and four *t*Bu groups in the ^1H and ^{13}C NMR spectra in the ratio 1:2:2:1. For the allene methylene groups one ^{13}C NMR signal and two ^1H NMR signals are observed.

Compound **1** and excess allene react in hydrocarbon solvents at <22 °C to give complex **3**, which, by NMR spectroscopy, has six different O*t*Bu groups, eight allenic protons, and six allenic carbon atoms. The allenic proton resonances form two separate ABCD spin systems.

We have been able to obtain crystals suitable for an X-ray analysis for **1–3** and find, contrary to our earlier prediction,[2] that the allene is aligned parallel to the W–W axis in **1**, whereas complexes **2** and **3** display other modes of bonding.[4]

Two views of compound **1** are shown in Figure 1. The structural parameters associated with the central W_2C_3 moiety indicate an extensive degree of $Wd_\pi - C_3p_\pi$ orbital mixing. Indeed, the C–C distance of 1.47(1) Å is essentially identical to a $C_{sp^2} - C_{sp^2}$ single-bond distance.[5]

1

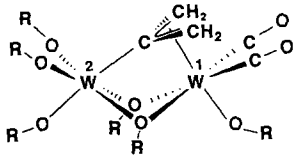


Fig. 1. Two drawings of complex **1** emphasizing the μ-parallel mode of allene-to-W_2 bonding. Pertinent distances [Å] (average) and angles [°]; W-W 2.583(1), C-C (allene) 1.47(1), W-CH_2 2.13(1), W-C 2.09(1), W-O 1.90(2); C-C-C 141(1).

The molecular structure of **2** is shown by a line drawing. The allene ligand, which may be viewed as part of a tungstaallyl(2−)moiety, is σ-bonded to one tungsten and

$\pi(\eta^3)$-bonded to the other.[6] The formal oxidation states of the two tungsten atoms are then +6 and +2 with the two CO ligands being bound to the d^4 W^1 center. The W–W distance is 3.0 Å, a nonbonding distance. The $W(CO)_2$ moiety in **2**, with its low values of $\tilde{\nu}$(CO) and small C–W–C angle (79°), is reminiscent of that in the Mo complex $[Mo(OtBu)_2(py)_2(CO)_2]$.[7]

2

3

The molecular structure of **3**, also shown by a line drawing, reveals a μ-tungstaallyl moiety similar to that found in the structure of **2** and, in addition, a terminal η^2-C_3H_4 ligand which formally may be viewed as replacing the *cis* carbonyl groups in **2**. However, the geometry about W1 is rather different in the two compounds. In **2** the coordination geometry approximates a distorted octahedral unit with the μ-C_3 ligand occupying one site, whereas in **3**, if the η^2-C_3H_4 ligand is considered to take up one position at the metal center, the local geometry corresponds to a square pyramid with the μ-C_3 ligand in the apical position. The W–O bond *trans* to the η^2-C_3H_4 ligand in the basal plane is very long (2.306(7) Å). The long C–C distance of the η^2-C_3H_4 moiety (1.44(1) Å), together with the long W–W distance (2.855(1) Å), indicates extensive Wd_π-to-Cπ^* back-bonding. The NMR data obtained for **3** in solution are entirely consistent with the observed molecular structure in the solid state and require that the η^2-C_3H_4 moiety and the other ligands are not fluxional.

Since the observed molecular structure of **1** is at variance with the previously proposed structure, we compared the bonding between a bent allene fragment and $[W_2(OtBu)_6]$ in the parallel and perpendicular modes. Moreover, we considered the possibility of a facile interconversion of μ-parallel and μ-perpendicular conformers. Such a process would allow the four allenic protons and three carbon atoms to "see" the two tungsten atoms as time-averaged and equivalent and thereby readily account for the observed satellite spectra arising from ^{183}W coupling (^{183}W, $I = ½$ 14.3% natural abundance).

Figure 2 shows the results from Fenske–Hall calculations[8] on the hypothetical molecule $[W_2(OH)_6(C_3H_4)]$ with the structural parameters taken from the structure of **1** (shown on the left side) and with the C_3 moiety rotated about the molecular C_2 axis of symmetry.

The μ-parallel moiety is found to be lower in energy. The extensive mixing of Wd_π–Wd_π and allene p_π orbitals is largely responsible for the lengthening of the C–C and W–W bonds. In particular, this is seen in the bonding of the $2a_1$ orbital, which favors the μ-parallel mode. The rotation of the C_3H_4 moiety about the pseudo-C_2 axis of symmetry is, however, a symmetry-allowed process with only filled–filled crossings being trivially avoided. An analysis of the HOMO and LUMO orbitals during rotation reveals that they do not exhibit an avoided crossing.

The possibility that the μ-allene in **1** was fluxional even in the solid state was investigated by recording the ^2H solid-state nonspinning NMR spectra[9] for $[W_2(OtBu)_6(C_3D_4)]$ ($[D_4]$**1**). The major spectral feature at 19° and −45 °C was a classic Pake doublet with a quadrupole coupling constant of 182.5 ± 0.5 kHz and an asymmetry parameter of 0.06 ± 0.2. The temperature independence and ease of saturation of this line shape are consistent with ^2H nuclei *not* undergoing significant molecular motion in the solid state on the ^2H NMR time scale (i.e., μs range). The observation of only one powder spectrum is consistent with the equivalent ^2H nuclei observed in the solid-state X-ray structure of $[D_4]$ **1**.

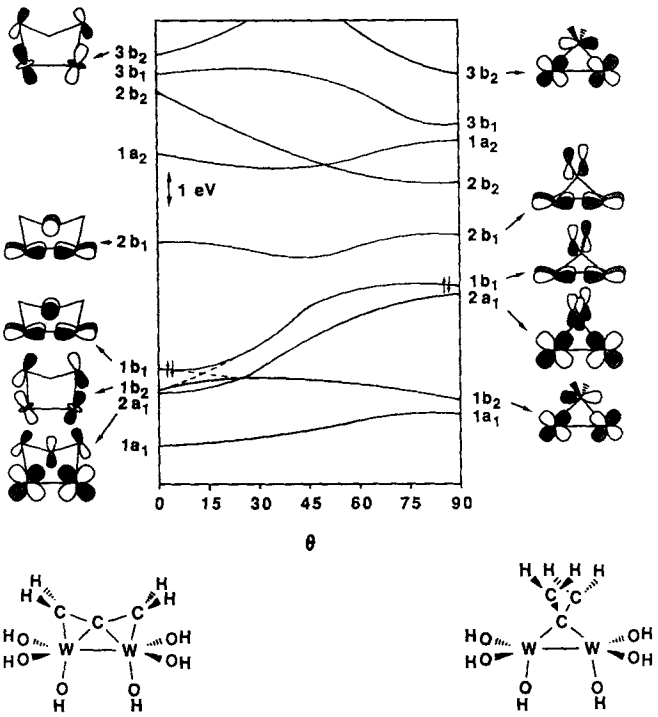

Fig. 2. A Walsh diagram depicting the variations in frontier orbital energies of $[W_2(OH)_6(C_3H_4)]$ obtained by rotating the allene moiety from a μ-parallel to a μ-perpendicular bonding mode. θ refers to the torsional angle between the C_3 plane and the W–W vector (in degrees). The arrows indicate the HOMO.

The bonding modes of allene in compounds **1**–**3** provide prime examples of the flexible modes of coordination available to unsaturated hydrocarbons in their ligation to $[M_2(OR)_6]$ compounds. In each compound the allene-to-tungsten bonding is different from that in the complex $[Cp_2Mo_2(CO)_4(C_3H_4)]$.[10] Whereas the μ-allene coordination in **2** and **3** has been seen before, that in **1**, involving the μ-parallel coordination, is unprecedented.[11] Evidently, μ-parallel–μ-perpendicular interconversions are not rapid in the solid state; whether they occur in solution remains a matter for further study.

4 6-Dimethylenetricyclo[3.3.0.0^{3,7}]octane-2-one and 2,4,6-Trimethylenetricyclo[3.3.0.0^{3,7}]octane**

By *Rolf Gleiter,* Christoph Sigwart,* and *Bernd Kissler*

The methylene substituted tricyclo[3.3.0.0^{3,7}]octane derivatives **1**–**4**[1] are not only appealing because of their molecular symmetry, they are also of interest with respect to the electronic interaction of the double bonds. Furthermore one must consider possible rearrangements due to the strained ring-skeleton. While the synthesis and properties of **1** and **2** have been reported recently,[2, 3] stellatriene **3**[1] and stellatetraene **4**[1] were unknown species at that time. Now the synthesis of **3** has been achieved along two paths, as shown in Scheme 1. Our first approach started with the aldehyde **6**,[4] which is available in four steps from the *endo* adduct of cyclopentadiene with maleic anhydride **5**. The second path which is shorter and more economic sets out with acetylallene **9** which may be prepared in two steps from acetylacetone **8**.[5] The key intermediate for both routes is the norbornene derivative **7** which yields the oxetane **10** in an intramolecular Paterno–Büchi reaction.[6] Treatment of **10** with lithium diisopropylamide (LDA) affords the regioselective cleavage of the oxetane ring to yield the alcohol **11**, which can be oxidized[7] to 4,6-dimethylenetricyclo-[3.3.0.0^{3,7}]octane-2-one **12**[8]. Stellatriene **3** is obtained from **12** by a Wittig reaction with "instant-ylide" at $-10\,^{\circ}C$.

Scheme 1. a) CH_3MgI/Et_2O; b) $CrO_3 \cdot 2py/CH_2Cl_2$; c) $C_5H_6/CH_2Cl_2/ZnCl_2$; d) $h\nu/C_6H_6$; e) LDA/THF; f) $[(C_6H_5)_3PCH_3]Br/NaNH_2$/THF, $-10\,^{\circ}C$.

The dienone **12** and the triene **3** contain—in a highly strained system—one and two 1,5-hexadiene units, respectively. Both systems react in a [3,3]sigmatropic rearrangement to the corresponding tricyclo[5.2.1.0^{4,10}]deca-1,6-diene derivatives **14**[8] and **13**[8], respectively ($\tau_{1/2}(50\,^{\circ}C) = 31$ min for **12**, $\tau_{1/2}(30\,^{\circ}C)$ ca. 30 min for **3**). Characteristic spectroscopic data of **3** and **12**–**14** are given in Table 1. **12** rearranges to **14** in a process following first order kinetics in [D_6]benzene with the activation parameters lg $A = 16.5$ and $E_a = 29.4$ kcal mol^{-1}. In contrast, **2** is not affected by this

13: ^{1}H NMR (C_6D_6, 300 MHz, 283 K): δ = 5.69 (1H, s, br), 5.06–5.04 (1H, m), 4.90 (1H, s, br), 4.77 (1H, s, br), 3.55 (1H, s, br), 3.22–3.08 (2H, m), 2.38–2.13 (5H, m)
14: ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 5.74–5.72 (1H, m), 5.09–5.07 (1H, m), 3.71 (1H, s, br), 3.12–2.68 (5H, m), 2.56–2.37 (2H, m); ^{13}C NMR ($CDCl_3$, 50.32 MHz): δ = 212.54 (s), 186.74 (s), 144.81 (s), 125.24 (d), 120.16 (d), 61.79 (d), 46.23 (d), 38.74 (t), 29.32 (6), 26.43 (t)

[a] Double intensity.

rearrangement even when heated to 100 °C for 15 min in a sealed tube.[9] To rationalize these findings we assume that the Cope rearrangement proceeds in two steps. In the rate determining step the central C–C single bond is broken first, forming the diradicals **15** and **16** in the case of **3** and **12**, respectively.[10] In the second step the products **13** and **14** are formed.

Species **17** would be the corresponding diradical intermediate in the case of **2**. A concerted process seems very unlike-

X=CH_2 **15**
X=O **16**

17

ly because the C=CH_2 moieties in **3** and **12** are pointing away from each other. Furthermore the rather high value for the preexponential factor supports also our view of a stepwise mechanism.

In line with these arguments are the results of force-field calculations (MMX[11]). These calculations predict an energy difference between **3** and **15** of only 1.20 kcal mol^{-1} while the energy difference between **2** and **17** is calculated to be 10.13 kcal mol^{-1}.[12] We ascribe this difference to two effects caused by the additional double bond in **3**: a) the increase in strain energy in **3** compared to **2** and b) an additional stabilization of **15** (one allyl-, one pentadienyl moiety) with respect to **17** (two allyl moieties).

The Structure of $BrF_6^{\ominus}$ and Related Compounds**

By *Ali Reza Mahjoub, Andrzej Hoser, Joachim Fuchs,* and *Konrad Seppelt**

Gaseous xenon hexafluoride has a flexible C_{3v} structure[1] and can be described on the basis of the electron-pair repulsion model; i.e., the non-bonding electron pair exercises a steric effect.[2] The only information previously available about the structure of the isoelectronic anions $IF_6^{\ominus}$ and $BrF_6^{\ominus}$ was that they were different, a conclusion drawn from powder diagrams and vibrational spectroscopic studies.[3–5] We have now succeeded in growing single crystals of $CsBrF_6$ from BrF_5 solutions at 80 °C. According to an X-ray structural analysis, the $BrF_6^{\ominus}$ ion exists as a nearly perfect octahedron in the space group $R\bar{3}$ (Fig. 1), and is therefore not consistent with the electron pair repulsion model. Consideration of crystallographic alternatives (e.g., disordered $R3$, $R3$, inversion-twinned $R3$) resulted in the same structure but with slightly less favorable characteristics. A comparison with the $BrF_4^{\ominus}$ ion, which is known to be square planar, demonstrated that the vibrational amplitudes of the fluorine atoms in $BrF_6^{\ominus}$ are not abnormal (Fig. 2).[6] The same structure of $BrF_6^{\ominus}$ is obtained from neutron diffraction of powdered $CsBrF_6$. Bond lengths and angles are virtually the same both at room temperature and at 5 K.

The observed octahedral symmetry cannot be simply a consequence of crystal lattice forces, because $BrF_6^{\ominus}$ dissolved in acetonitrile has been shown by vibrational spectroscopy also to be octahedral, although little can be said about the possibility of static or dynamic deviations.[7] In this sense $BrF_6^{\ominus}$ differs from such anions as $SeCl_6^{2\ominus}$, $TeCl_6^{2\ominus}$, and $SnCl_6^{4\ominus}$. The latter are apparently subject to dynamic distortions. Lattice forces distort these anions depending upon the type of lattice involved.[8] It is noteworthy that the ion $TeF_6^{2\ominus}$ has not been unequivocally observed thus far.

The reason for the structural differences between XeF_6 and $BrF_6^{\ominus}$ may lie in the fact that s electrons on bromine are strongly bound to the nucleus due to the incomplete shielding of the nucleus, caused by the first filled d shell. As a

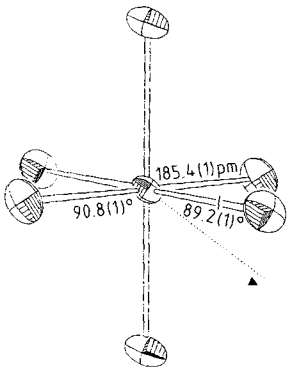

Fig. 1. Structure of the anion of $CsBrF_6$ in the crystalline state. The vibrational ellipsoids represent 50% probability. Dotted lines: three-fold crystallographic axes of rotation. $a = 522.7(1)$ pm, $\alpha = 96.501(2)°$, $R\bar{3}$ (No. 148), $Z = 1$. 2016 measured reflections between $2° \leq \Theta \leq 40°$, 580 independent reflections, 572 reflections with $I \geq 3\sigma(I)$, $R = 2.1\%$, $R_w = 2.8\%$. The crystals were obtained within a week from sealed PFA tubes containing excess BrF_5 and maintained at 80 °C. Such crystals are often twinned in the sense $x' = -x$, $y' = -y$, $z' = -z + (x + y) \cdot \cos\alpha$. A single crystal ($0.03 \times 0.04 \times 0.1$ mm) was embedded in paraffin oil at ca. −50 °C under nitrogen and measured at −160 °C with a CAD-4 diffractometer;[13] graphite monochromator, $Mo_{K\alpha}$ irradiation. Intensity measurements with speed varied as a function of I and maximum possible precision, $\omega\delta$ scan. Programs: SHELX, XTAL, SFLS;[14] least squares, full matrix.[15] Neutron diffraction: measured at the Institut Laue Langevin (Grenoble) on $CsBrF_6$ powder at 258 and 5 K. Bond lengths [pm] and angles [ ]: 298 K: Br-F 184.7(1), F-Br-F 91.3, 88.7, $R = 9.2\%$, $R_w = 13.1\%$. 5 K: Br-F 187.7(1), F-Br-F 90.7, 89.3, $R = 10.990$, $R_w = 17.4\%$.

result, the Br−F bond would be expected to show mainly p character. The substantial differences in bond length between $BrF_6^{\ominus}$ [185.4(1) pm] and the comparably octahedral cation $BrF_6^{\oplus}$ [ca. 169 pm[9]] would thus be explained by assuming that the nuclear charge in the anion is shielded by the centrosymmetric non-bonding electron pair. This difference also verifies the fact that the octahedral structure is not of steric origin, since the Xe−F bond length in XeF_6 (189.0 pm) is essentially identical to the Br−F bond length in $BrF_6^{\ominus}$.[10]

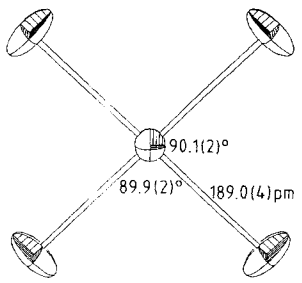

Fig. 2. Structure of the anion of $RbBrF_4$ in the crystalline state. The vibrational ellipsoids represent 50% probability. $a = 635.1(6)$, $c = 1148.9(10)$ pm, $I4/mcm$ (no. 140), $Z = 4$. 704 measured reflections between $2° \leq \Theta \leq 30°$, 204 independent reflections, 157 reflections with $I \geq 3\sigma(I)$, $R = 4.5\%$, $R_w = 4.4\%$, −60 °C. [15] $RbBrF_4$ was formed as a byproduct in the course of attempts to crystallize $RbBrF_6$.

Based on these considerations, $IF_6^{\ominus}$—like XeF_6—should not be octahedral. Unfortunately, crystallization experiments have in this case proven unsuccessful. In the system CsF/IF_5 the crystalline product obtained is CsI_3F_{16} (cf. [4]), and similarly in the system KF/IF_5 the only single crystals isolated had the composition $KI_3F_{16}^{\ominus}$. The anion $I_3F_{16}^{\ominus}$ has the same structure in both salts (Fig. 3), resembling a segment of the crystalline tetrameric XeF_6.[11] An analogy with $CsF \cdot 3XeOF_4$ is also appropriate.[12]

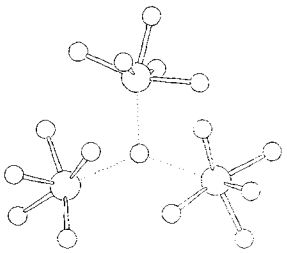

Fig. 3. Structure of the anions of CsI_3F_{16} and KI_3F_{16} in the crystalline state. CsI_3F_{16}: $a = 1379.0(11)$ pm, $P\bar{4}3n$ (no. 218), $Z = 8$. 4896 reflections, $2° \leq \Theta \leq 25°$, 521 independent reflections, 362 reflections with $I \geq 3\sigma(I)$, $R = 3.2\%$, $R_w = 2.8\%$, −60 °C. Bond lengths [pm] and angles [°]: I-F_{ax} 181(2), I-F_{eq} 185–190, $I\cdots F^{\ominus}$ 252.4(7), F_{ax}-I-F_{eq} 79–81, $F^{\ominus}\cdots$I-F_{ax} 146.8(8), $I\cdots F^{\ominus}\cdots I$ 118.7(4). [15] CsI_3F_{16} bears a crystallographic and structural resemblance to the salt $Cs[Xe_3O_3F_{13}]$. However, the latter crystallizes in the space group $Pa3$ (No. 203). [13] KI_3F_{16}: $a = 1353.5(5)$, $b = 1363.8(2)$, $c = 1342.1(4)$ pm, $\beta = 90.49°$ (3), $P2_1/c$ (no. 14), $Z = 8$. 7941 reflections between $2° \leq \Theta \leq 30°$, 7180 independent reflections, 6559 with $I \geq 3\sigma(I)$, $R = 6.0\%$, $R_w = 5.9\%$, −150 °C. Bond lengths [pm] and angles [°]: I-F_{ax} 182.5–185.2, I-F_{eq} 187.3–193.0, $I\cdots F^{\ominus}$ 247.7–251.4, F_{ax}-I-F_{eq} 77.8–82.0, $F^{\ominus}\cdots$I-F_{ax} 141.4–149.0, $I\cdots F^{\ominus}\cdots I$ 114.6–122.4 [15].

The anion $I_3F_{16}^{\ominus}$ is comprised of three square-pyramidal IF_5 molecules whose bond lengths and angles are essentially the same as those in gaseous IF_5. These three IF_5 molecules are joined by a bridging fluoride ion. The latter does not occupy the sixth coordination site on the iodine octahedron but is instead displaced somewhat to the side, an observation that provides additional indirect evidence for the steric effect of the non-bonding electron pair in IF_5.

Establishment of Configurations for the Two Diastereomeric *C*-Glucosylanthrones Aloin A and Aloin B

By *Hans W. Rauwald,* Karsten Lohse*, and *Jan W. Bats*

Aloin [10-(β-D-glucopyranosyl)-1,8-dihydroxy-3-hydroxymethyl-9(10*H*)-anthracenone] is the principal component and principal active ingredient in the world-wide used pharmaceutical agents *Aloe barbadensis and Aloe capensis*. It is known to be present in at least 68 aloe species.[1] Aloin was first isolated in 1851,[2] but the correct molecular formula was not established until 1945,[3] and only in 1952 was the compound shown to be a *C*-glucosylanthrone derivative.[4] The suggestion that aloin might exist in stereoisomeric forms[4] was confirmed by HPLC separation into the two diastereomers aloin B (**1**) and aloin A (**2**) in 1979.[5, 6] Partial synthesis[6] and ^{1}H NMR analysis[7] proved that the anthrone system is attached β with respect to the D-glucosyl residues in both aloins. It follows that **1** and **2** must differ

only with respect to the configuration at C10 itself. Recent exhaustive studies have demonstrated that a configurational assignment like that described in[6] and based on ^{1}H NMR data is not possible with the aloins because spectra of the two compounds show no significant differences in either chemical shifts or coupling constants.[7] It thus became necessary to establish the configurations by X-ray analysis.[7] Since aloin A and aloin B are readily separable in quantity by droplet countercurrent chromatography (DCCC),[8] large-scale crystallization experiments were feasible with both. The work had to be performed quickly, however, since the aloins are unstable in solution, where they are subject to interconversion via the tautomeric anthranol. Experiments with aloin A **2** resulted in needle-shaped crystals, but these were too slender to utilize for X-ray analysis. By contrast, aloin B **1** gave crystals that were quite adequate in size. In vivo experiments on the biosynthesis of the aloins have shown that **1** is actively synthesized by plants, whereas the isomer **2** arises in a secondary way through transformations of **1**.[9] Structural analysis on crystalline **1** provided unambiguous proof of the configurations at C10 for both diastereomers.

Figure 1 shows the molecular structure[10] of **1** in the crystalline state. Since the glucose is bound to the anthrone system as a β-D-glucosyl residue, the absolute configuration of **1** can be assigned as 10*R*, 1′*S*. The glucosyl residue has a chair conformation in which all substituents are equatorial

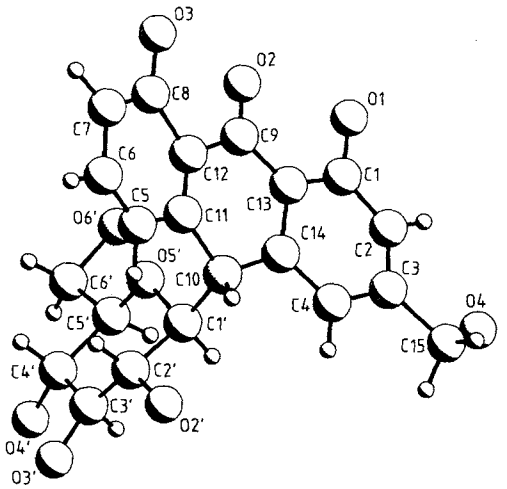

Fig. 1. Perspective drawing of the molecular structure of crystalline aloin B.

and all hydrogen atoms are axial. The A and C rings in the 1,8-dihydroxyanthrone system may be described as planar within the limits of experimental accuracy. Ring B, on the other hand, has a "sofa" or "envelope" conformation, in which C10 is raised out of the plane of the other five ring atoms by 0.29(2) Å. The glucopyranosyl residue at C10 is in axial, the hydrogen atom in equatorial position. The nonplanarity of ring B results in an angle of 16(2)° between rings A and C. This nonplanarity of the anthrone skeleton is a consequence of substitution at C10: unsubstituted 1,8-dihydroxyanthrone itself is planar.[11] The observed deviation from planarity in 1,1′,8,8′-tetrahydroxy-10,10′-bis-anthrone corresponds to that in aloin B **1**[12]. The torsion angles about the C10-C1′ bond [C14-C10-C1′-O5′: −79(2)°; C11-C10-

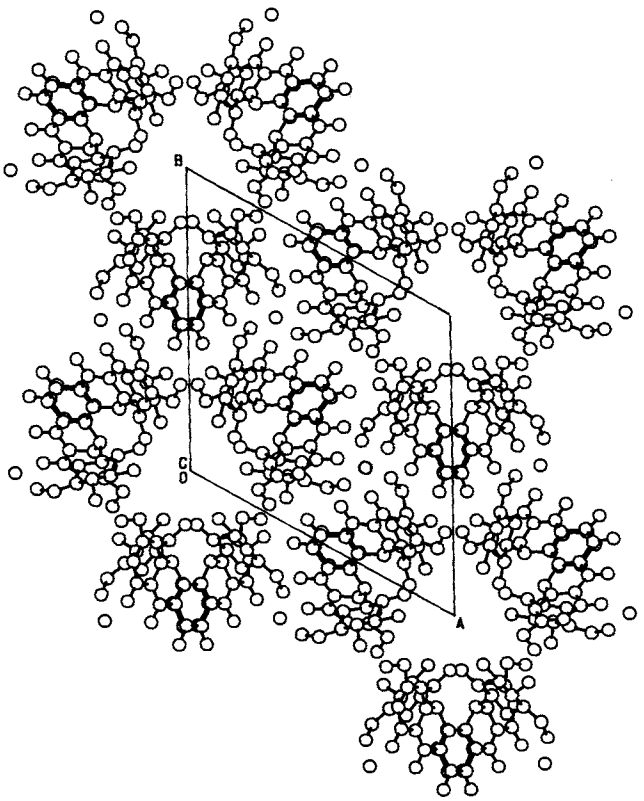

Fig. 2. Projection of the crystal structure of aloin B onto (001). The channels in the direction of the *c* axis contain disordered solvent.

C1'-O5': 48(2)°; H10-C10-C1'-O5':158°] reveal deviations from the staggered arrangement of about 15°, which may be a result of repulsion between H5 and H2'.

The crystal packing (Fig. 2) shows channels at least 4 Å in diameter along the *c* axis, where no atoms were found. The volume defined by such a channel is sufficient to permit incorporation of at least five positionally disordered water molecules. The resulting disorder within the channel is transmitted to some extent to adjacent atoms in the aloin B molecule (C15,C3',O2',O3', and O4').

Establishment of the configuration at C10 of aloin B as *R* simultaneously defines the configuration of aloin A (10*S*,1'*S*). Since the two substances may be regarded as parent structures for other naturally occuring diastereomeric 10-glucosylanthrones they should prove useful for making future comparisons within this class of compounds.

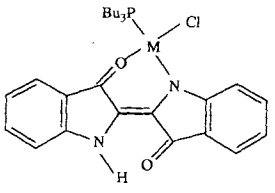
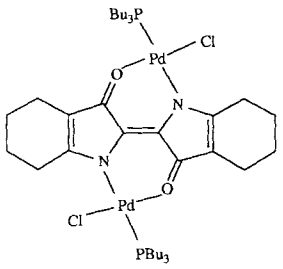
Indigo-Metal Complexes: Synthesis and Structure of Pd^{II} and Pt^{II} Compounds Containing the Anions of Indigo and Octahydroindigo as Mono- and Bis-Chelate Ligands**

By *Wolfgang Beck*, Christoph Schmidt, Rolf Wienold, Manfred Steimann,* and *Barbara Wagner*



Dedicated to Professor Wolfgang Lüttke on the occasion of his 70th birthday

It was *Adolf von Baeyer*, who, in Munich in 1883, firmly established the structure of indigo[1a] in what has been described as "probably the most difficult structure proof to that point accomplished".[1b] The existence of chelate complexes ML_2 **1** (M = $Ni^{2\oplus}$, $Co^{2\oplus}$, $Cu^{2\oplus}$, $Zn^{2\oplus}$; L = monoanion of indigo and certain derivatives) was demonstrated by *Kunz*[2] as well as by *Kuhn* and *Machemer*.[3] So far as we are aware, however, little attention has been paid to these complexes since 1930.[4]



The complexes **1** show little solubility in organic solvents. Despite numerous attempts we were unable to prepare crystals that were suitable for X-ray analysis. The synthesis of soluble, crystalline indigo complexes was finally accomplished by introduction of the ligand tri(*n*-butyl)phosphane. Green chelate complexes **2** and **3**, respectively, result from

1

2b : M = Pt

3

treatment of chlorine-bridged palladium(II) and platinum(II) compounds $[(nBu_3P)(Cl)M(\mu\text{-}Cl)]_2$ (M = Pd,Pt) with indigo or octahydroindigo in THF in the presence of sodium hydride or silver acetate.

Absorption bands in the UV/VIS spectrum of the complexes **2a** and **3** show bathochromic shifts relative to those of indigo itself.[5] According to X-ray structural analyses, the atoms palladium, imide nitrogen, and keto oxygen in **2a** (Fig. 1) and **3** (Fig. 2) lie in nearly planar six-membered rings (average deviation from planarity: 11 and 13 pm in **2a** and **3**, respectively). The monoanion of indigo functions as a monochelate ligand in **2a**, the dianion of octahydroindigo as a bischelate ligand in **3**. The four ligand atoms together with the central Pd deviate from planarity up to 6 pm (**2a**) and 30 pm (**3**), respectively. The two planar five-membered chelate rings are twisted out of the plane of the central C=C bond by 9.6° (**2a**) and 15° (**3**). Replacement of the bridging hydrogen atoms in indigo[6] by Pd produces virtually no change in the bond lengths in the five-membered rings or in the coordinated carbonyl groups (Table 1). The same is true of a structurally related Pd^{II} chelate complex of an a,β-ketoiminate.[7]

It is interesting to note that the bond of the free carbonyl group in **2a** [C2-O1 122.4(9) pm] is shorter than those of the coordinated carbonyl groups in **2a**, **3**, and indigo itself. This suggests that the inter- and intramolecular N–H···O bridging in free indigo[8a] has been disrupted. Crystals of **2a** con-

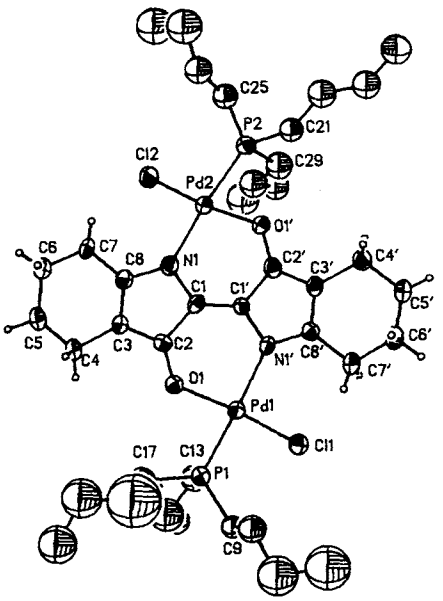

Fig. 2. Molecular structure of **3** at 21 °C in the crystal, 20% probability level. $P\bar{1}$, $a = 1274(1)$, $b = 1384(1)$, $c = 1489(1)$ pm, $\alpha = 63.85(7)$, $\beta = 77.42(7)$, $\gamma = 82.07(8)°$, $V = 2.297(4)$ nm^3, $Z = 2$, $\mu(Mo_{K\alpha}) = 0.99$ mm^{-1}, ω scan, $\Delta\omega = 1.4°$, $6 \le \omega \le 30°$ min^{-1}, $4 \le 2\Theta \le 50°$; 12359 reflections measured, of which were 7228 unique and 3696 observed [$I \ge 2\sigma(I)$], 338 parameters. Empirical absorption correction (Psi scan, using 11 reflections, 36 measurements each). $R = 0.077$, $R_w = 0.081$, $w = [\sigma^2(F_o) + 0.0007\,F_o^2]^{-1}$. Maximum of residual electron density 1.30×10^{-6} e pm^{-3}. Hydrogen atoms in calculated positions. The bond angles of the C atoms in one of the nBu$_3$P ligands (high U values) were fixed. Programs used: SHELX 86, SHELX 76 and SHELXTL-Plus. [10]

tain pairs of coplanar molecules that are rotated relative to each other by 180°, thereby eliminating the possibility of intermolecular N–H···O bridges. Apparently the twisting of the two five-membered rings about the central double bond in the indigo anion also interferes with conditions that are necessary for N–H···O bridging. The absence of such bridges is apparent from IR spectra (Table 2). Thus, the sharp ν_{NH} and ν_{CO} bands of the non-coordinated carbonyl groups in **1** and **2a** are shifted to higher wavenumbers relative to the corresponding bands of indigo.[8a]

[a] Non-coordinated C=O.

Additional complexes of indigo and related systems will be prepared in order to investigate their potential as energy transfer agents or catalysts.

Experimental Procedure

All work was conducted under nitrogen and in anhydrous solvents.

2a: A suspension of 24 mg (1 mmol) of NaH and 350 mg (1.33 mmol) of indigo (Fluka) in 10 mL of THF was heated for 15 min under reflux. After cooling the green suspension, 380 mg (0.5 mmol) of $[Cl_2PdP\textit{n}Bu_3]_2$ was added. The reaction solution was stirred for 3 h at room temperature and then filtered (glass frit, G4). Removal of the THF in vacuo left a dark residue that was dissolved in 5 mL of dichloromethane. This solution was filtered, and solvent was again removed in vacuo. **2a** was obtained as a dark, granular material; yield 300 mg (50%). Crystallization from dichloromethane/pentane. VIS spectroscopy ($CHCl_3$): $\lambda_{max} = 748$ nm, log $\varepsilon = 4.0$. ^{31}P NMR (109 MHz, CD_2Cl_2): $\delta = 23.47$. ^{1}H NMR (270 MHz, CD_2Cl_2): $\delta = 0.99$ (t,9H), 1.52–1.93 (m,18H), 6.9 (q,2H), 7.18 (d,1H), 7.37 (q,2H), 7.47 (d,1H), 7.58 (d,1H), 8.46 (d,1H), 9.07 (s,NH).

3: To a stirred suspension of 140 mg (0.5 mmol) of octahydroindigo[9] and 168 mg (1 mmol) of silver acetate in 10 mL of THF were added 500 mg (0.66 mmol) of $(Cl_2PdP\textit{n}Bu_3)_2$. The reaction mixture was stirred for 12 h at room temperature and filtered through a glass frit (G4). Solvent was removed in vacuo. The residue was taken up in 15 mL of ether and again filtered. Unreacted starting complex was precipitated by addition of 15 mL of pentane and cooling to −15 °C (3d). The cold solution was decanted and solvent was removed in vacuo. **3** was obtained as a dark green powder; yield 360 mg (75%). VIS spectroscopy ($CHCl_3$): $\lambda_{max} = 663$ nm, log $\varepsilon = 3.5$. ^{31}P NMR (109 MHz, CD_2Cl_2): $\delta = 21.6$. ^{1}H NMR (90 MHz, CD_2Cl_2): $\delta = 0.9$ (t, 18H), 1.4–1.8 (m,44H), 2.1 (t,4H); 3.0 (t,4H).

Stack-Type Redox Systems: Synthesis via Repeated Carbanion Alkylation and Electron Transfer Studies**

By *Jürgen Alexander, Marianne Ehrenfreund, Jürgen Fiedler, Walter Huber,* Hans-Joachim Räder,* and *Klaus Müllen**

Dedicated to Professor Wolfgang Lüttke on the occasion of his 70th birthday

Stack-type π-systems such as multiply layered phanes[1, 2] or radical cation salts[3] can be used as models for studying one-dimensional charge transport.[4] We recently reported the preparation of **3a** and **3b**, members of a new class of two-layer π-systems[5a] in which the disk-shaped subunits are bridged [14]-annulenes; in contrast to the phanes, the subunits are linked by bridging groups "within" the π-system, and the distance between the layers can readily be varied. We have now been able to synthesize *multiply layered* homologues of **3** with up to five single layers by means of a "one-pot" reaction in which the pyrene isomer **1**[5b, 6, 7] undergoes reductive alkylation. The multilayer redox systems are constructed from separate electroactive groups and can be subjected to successive electron transfer reactions.[5c–e]

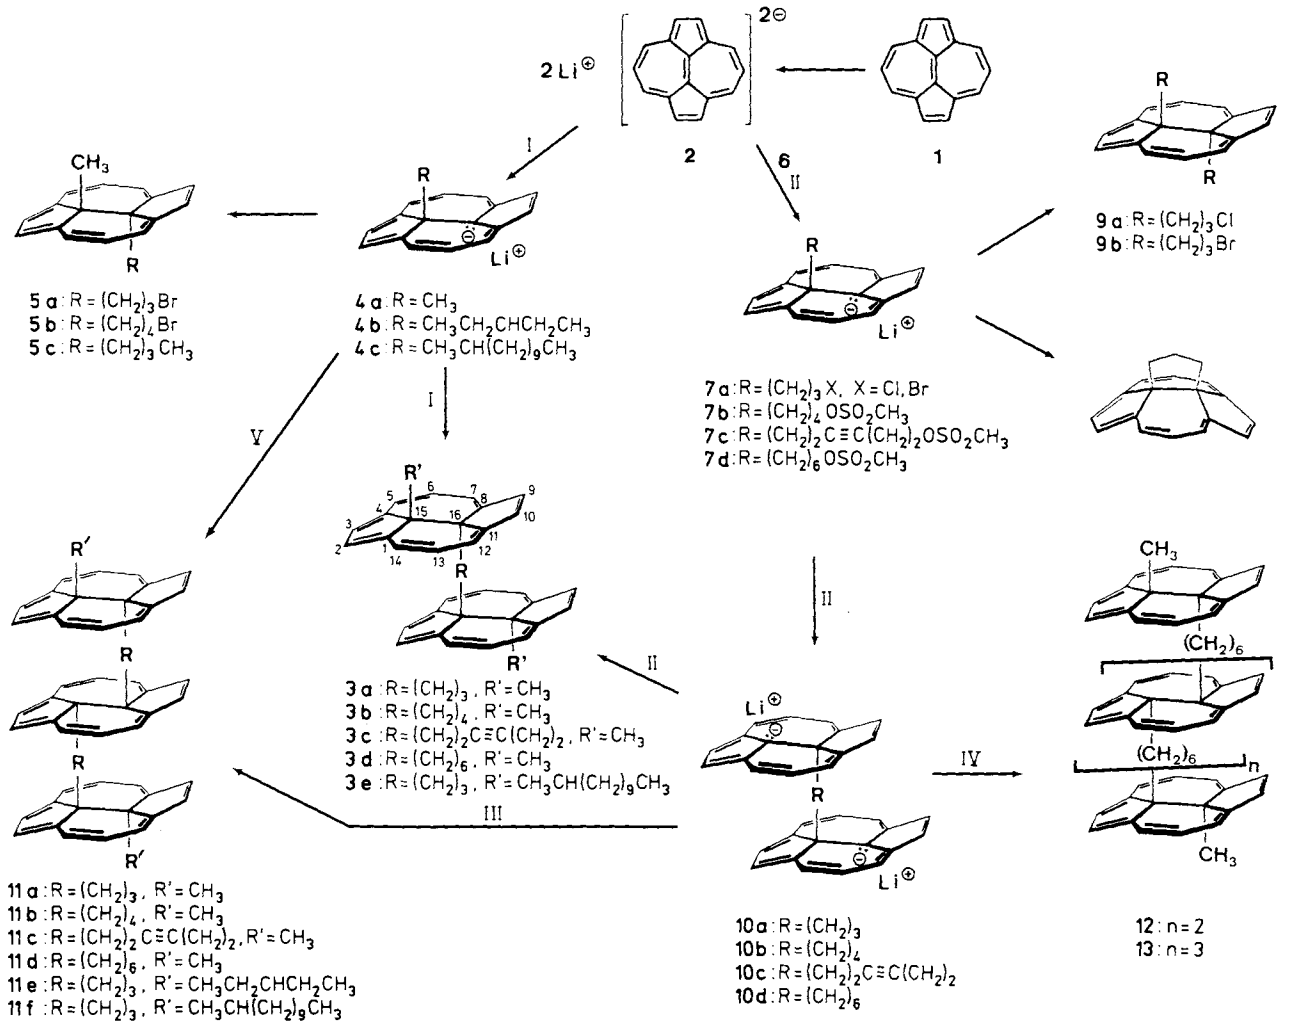
[**] Reductive transformations, Part 13. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 12: D. Bender, M. Przybylski, K. Müllen. *Makromol. Chem.*, in press.

The energies of interaction between the charged subunits and the nature of the charge distribution are important for the redox steps formed, and have been determined by cyclovoltammetry and ESR spectroscopy, respectively.

The synthesis of the two-layer compound **3** is made possible by the fact that **1** can be alkylated in a regioselective manner at the two central carbon atoms via the dilithium salt **2**.[5d, 6] It is thus, for example, possible to obtain the nucleophile **4a** and the electrophile **5a**; these can then undergo coupling to give **3a** in 95% yield[5a] (see Scheme 1, route I).[7]

Analogues with more than two layers should be available from a reaction in which the bifunctional nucleophile **2** ($=\mathbf{1}^{2\ominus}/2\,Li^{\oplus}$) is treated with bifunctional electrophiles such as **6**; the resulting monoalkylation products **7** are both electro- *and* nucleophilic and can in principle form stack-type compounds in a *poly*reaction. If, however, **2** is treated with 1,3-dichloropropane **6a**, the intermediate **7a** (X = Cl) reacts mainly via intramolecular cyclisation to give **8**. Stack-type molecules are not formed, and the expected diadduct **9a** is also only formed as a by-product, even if an excess of the alkylating agent is used (molar ratio **8**:**9a** = 5:3).[6] The bifunctional electrophile **9a** is, however, formed in 70% yield when 1-chloro/bromo-3-(trifluoromethylsulfonyloxy)-propane **6b** is used, since in this case **2** reacts only with the more reactive electrophilic group.



XRX'
6a: X = X' = Cl, R = $(CH_2)_3$
6b: X = Cl(Br), X' = OSO_2CF_3, R = $(CH_2)_3$
6c: X = X' = OSO_2CH_3, R = $(CH_2)_4$
6d: X = X' = OSO_2CH_3, R = $(CH_2)_2C{\equiv}C(CH_2)_2$
6e: X = X' = OSO_2CH_3, R = $(CH_2)_6$

The intramolecular cyclization of **7** to **8** can be prevented by variation of the alkylating agent; while the use of **6d** with a hex-3-ynediyl unit naturally prevents cyclization, the analogous hexanediyl (**6e**) and even the butanediyl (**6c**) agents also show no tendency to cyclization. When **6c** is allowed to react with 2.5 equivalents of **2**, followed by a trapping reaction with the monofunctional electrophile dimethyl sulfate, the double layer compounds **3b–d** are obtained in 32, 50 and 50% yield, respectively (after chromatography and recrystallization). The intermediates **7b–d** apparently react preferentially with **2** to form the dianions **10b–d**, which then undergo double methylation. Compounds **3** can thus be readily obtained via two routes (I,II).

It is significant that the "triple-decker" compounds **11c** and **11d**[8] are formed as by-products of the formation of the new systems **3c** and **3d** in yields of ca. 10%. This makes it certain that the dianions **10c** and **10d** can undergo further alkylation by **6d** or **6e** prior to the termination reaction with dimethyl sulfate (route III). The short-chain system **10b**, in contrast, is precipitated from the solution and thus cannot undergo further reactions.

We expect that the triply or multiply layered products will be formed in preference to the double layers **3** if a molar ratio of **2** to **6c–e** of 1:1 rather than 2.5:1 is used; in this case the nucleophilic positions of **10** will be alkylated by **6**, so that the alkylation sequence is continued. The reaction of **2** and **6e** (1:1, THF, 20 °C, 24 h) does indeed give a mixture of soluble oligomers in 70% yield (10% of **3d** are also formed); mass spectrometry indicates the mixture to contain the three, four- and five-layer systems **11d**, **12** and **13** which can be distinguished by ^1H NMR spectroscopy (routes III, IV).

It would be particularly attractive for studies of electron hopping processes between the annulene units in **3** and **11** to

Scheme 1.

be able to make the distances between the layers short: however, as we have seen, the formation of multilayer systems is hindered in the case of propanediyl bridges by the rapid cyclization of **7a** to give **8**, and in the case of butanediyl bridges by the low solubility of the intermediate **10b**.

These problems suggest an alternative procedure for stack formation: during the reaction of the bifunctional electrophile **9b** with **2** it might be possible to achieve repetitive attachment of layers without cyclization occurring. However, an electron transfer reaction between **2** and **9b** to give reoxidation of **2** is in fact the main reaction observed. Comparable reactions have been described for sterically hindered carbanion alkylation with *t*BuBr.[9] One possible solution is the use of the monoanion **4** (which is less redox-active than the dianion **2**) as the nucleophile, although in this case the number of π-systems which can be linked is limited to three. However, for the synthesis of compounds with short interlayer distances the solubility of the products must be increased by replacing the methyl group in the nucleophile **4** by a residue R with a longer chain (3-pentyl or 2-dodecyl). It is indeed possible to synthesize the soluble "triple-deckers" **11e** and **11f** with the shortest interlayer distance from **9b** and **4b** or **4c**[10] (see route V).

As expected from the diatropism of the annulene units, the ring protons in the multilayer compounds are deshielded, while the protons within the bridge are strongly shielded because they lie within the sphere of influence of several annulene layers. In **11e** the methylene protons in positions neighboring the central annulene unit absorb at $\delta = -7.17$ (see[8]).

In spite of the large interlayer distance, the protons of the methyl groups in the double-layer compound **3b** are surprisingly more strongly shielded than in the model system **5c** [$\delta(CH_3) = -4.84$ and -4.50, respectively]. The shielding also increases within the homologous series **3d, 11d, 12** and **13** [$\delta CH_3) = -4.72$ (**3d**), -4.74 (**11d**), -4.75 (**12**), -4.755 (**13**)]. The members of the series can thus clearly be distinguished.

The question as to whether such a stack constructed from separate electrophores is suitable for use as an electron storage system was first investigated by cyclovoltammetry (THF, nBu$_4$N as conducting salt, 0 °C, $v = 100$ mV s^{-1}) for **9c** ("monomer", R = CH$_3$CHCH$_2$CH$_3$), **3e** ("dimer") and **11f** ("trimer"). Compound **9c** is reduced reversibly to the radical anion at -2.16 V; **3e** shows two very close redox steps at ca. -2.18 V, which are due to uptake of one electron by each layer;[11] the half-wave potentials of these were determined by simulation to be -2.13 and -2.24 V. After correction for the entropy term[12] (two independent redox centers) the potential difference $E^1_{1/2} - E^2_{1/2} = 110$ mV gives an interaction energy of 1.78 kcal mol^{-1}. The cyclovoltammogram of **11f** also shows only two cathodic peak potentials with a shoulder in the anodic reoxidation peak. Computer simulation of the curve indicates a two-electron transfer at

-2.18 ($E^1_{1/2} - E^2_{1/2} < 20$ mV) and a one-electron transfer at $E^3_{1/2} = -2.30$ V. The corrected potential differences at 0 °C then give interaction energies of <0.24 ($1 \rightarrow 2$) and 1.80 kcal mol^{-1} ($2 \rightarrow 3$). The excess charges are apparently localized in the two outer redox centers in the dianion of **11f**. This "decoupling" corresponds to that in the "dimer" with a large interlayer distance.[11] Formation of the trianion requires the inner layer to become charged, and thus leads to an electrostatic interaction between the three neighboring subunits. However, the energy of 1.80 kcal mol^{-1}, which corresponds to two interlayer interactions in **11f**, is considerably smaller than would have been expected from the repulsion term in **3e**. The takeup of charge by higher oligomers should be describable in a manner completely analogous to that for **11f**.

The question occurs as to whether the unpaired electron in the radical anion which is the primary product of the reduction remains localized, or whether an intramolecular electron transfer which is fast with respect to the time-scale of ESR/ENDOR experiments leads to an effective delocalization over all the subunits. The rate of electron transfer depends on the distance between the electrophoric groups and the stability of the various ion pairs. In order to be able to study both contact ion pairs and solvent-separated ion pairs, the radical ions **11d–f** (with $K^{\oplus}$ as counterion) were prepared in several solvents (see Table 1). The size and multiplicity of the ESR hyperfine coupling constants were used as experimental criteria for distinguishing between spin localization and delocalization.[5a, c]

Table 1. ESR Coupling Constants [mT] for the radical monoanions **11d**$^{\bullet\ominus}$, **11e**$^{\bullet\ominus}$ and **11f**$^{\bullet\ominus}$ (in each case with $K^{\oplus}$ as counterion)[a, b].

[a] Solvent: 2-methyltetrahydrofuran, THF, DME, HMPT and mixtures of DME and THF or HMPT; temperature: −80 °C. [b] Coupling constants typical for a localized or delocalized form of the radical monoanion are denoted by * or ●, respectively. [c] The ESR spectra are not resolved, so that the multiplicity of the coupling constants could not be determined. [d] Broad ENDOR signal (ca. 0.03 mT); probably corresponds to several non-equivalent coupling constants.

Under all the experimental conditions used, the unpaired electron in the radical anion **11d**$^{\bullet\ominus}$ with the largest interlayer distance is localized within a single redox unit: the number of coupling constants observed indicates this to be the inner annulene layer. The radical anion **11f**$^{\bullet\ominus}$ in which the interlayer distance is shorter shows the same behavior in dimethoxyethane (DME). When however mixtures of DME and hexamethylphosphoric acid triamide (HMPA) are used, in which solvent-separated ion pairs are favored, the four coupling constants observed in the ENDOR spectrum are considerably smaller than those observed in DME. In addition, the largest coupling constant is much smaller than for a spin delocalization over two annulene layers as in **3a**$^{\bullet\ominus}$.[5a] Thus when the redox centers approach one another, and when the interaction between the anion and the counterion is weak, rapid electron transfer leads to an effective spin delocalization over all the annulene layers.

The situation in **11e**$^{\bullet\ominus}$ is even more complex, because under all the various experimental conditions spectra are obtained which point to the existence of both spin-localized *and* spin-delocalized forms.

Further reduction of the radical monoanions leads in all cases to triplet states. The mean distances between the unpaired electrons estimated from the zero-field parameters [D = 8.85 mT (**11e**$^{2\ominus}$/2 $K^{\oplus}$), 5.05 mT (**11d**$^{2\ominus}$/2 $K^{\oplus}$)] are ca. 650 and 820 pm respectively; they are thus in agreement with the cyclovoltammetric results indicating the localization of the excess charges on the outer π-units. Additional electron transfer processes then generate more highly charged radical anions, the coupling constants of which indicate a localization of the unpaired electron at single redox centers.

[10] The monoanionic intermediate **4** can be prepared from **2** and 1 equivalent of the alkylating agent, since the dianion **2** is much more reactive than **4**. However, the yield of **4** depends to a great extent on the nature of the electrophile. With comparatively reactive reagents such as primary alkyl halides and secondary alkyl tosylates the main products are the dialkyl adducts. **4b** was thus prepared using the less reactive 3-bromopentane.

The Chemistry of Macrocyclic Ligand Complexes. By *L. F. Lindoy*. Cambridge University Press, Cambridge 1989. viii, 269 pp., hard cover, £ 45.00. – ISBN 0-521-25261-X.

Bless them—macrocycles have been an excellent vehicle for the reunification of chemistry during these past three decades. Chemists, trained in research in the erstwhile parochial camps that also happened to rely upon macrocyclic compounds to achieve their rather limited ends, have begun to abandon their feudal practices and rediscover the power and satisfaction of the scientific method when it is applied to solving some of the "big problems" around in science today. *Len Lindoy*'s monograph captures much of the spirit and joy of this renaissance. Written through the eyes of someone who has largely seen macrocycles as ligands for transition metals, it devotes the best part of three chapters (3–5) to crown ethers, their lariat variants, and related synthetic receptors; it emphasizes their abilities to complex with organic cations, neutral organic molecules, inorganic anions, and metallo-organic guests, as well as with alkali metal and alkaline earth metal cations—including those intriguing situations where "alkalides" and "electrides" are generated; it features their applications in separation science (enantiomer differentiation by chiral hosts to cite but one example), in making simple devices and systems that are photochemically driven (e.g. membrane ion-transporters), and in promoting chemical reactions efficiently and selectively, i.e. behaving as phase-transfer catalysts and enzyme mimics. Room has also been found to extol the virtues of other wholly-synthetic molecular receptors (e.g. picket fence porphyrins and bisporphyrins, spherands, calixarenes, and cyclophanes) as well as one of nature's gifts—the cyclodextrins—both in their unadulterated forms and, after varying degrees of structural change, in search of enzyme-like catalytic activities, substrate specificities, and reaction selectivities. All this and more leads up to a discussion of the biomimetic chemistry of many (e.g. antibiotics, ionophores, vitamin B_{12}, chlorophyll, hemoglobin, myoglobin, and the cytochromes including P450) of nature's other macrocycles in the final chapter (9).

These topics are highlighted alongside an authoritative treatment (Chapters 1–3) of macrocycles—containing heteroatom-wise, nitrogen only, nitrogen and sulfur, nitrogen and phosphorus, and a very few, all-phosphorus and all-arsenic—intended for the complexation of cobalt, copper, and nickel for the most part. Their metal- and ligand-centered redox properties are discussed in Chapter 8 in the light of a detailed consideration in the preceding two chapters (6 and 7) of the thermodynamics and kinetics of complexation/decomplexation processes. The template effect is analyzed from both viewpoints. There are some gems of information that just have to make a lasting impression on any reader. What about this one as an example? Under acidic conditions, square-planar $[Ni(cyclam)]^{2\oplus}$ dissociates with a half-life of approximately 30 years! Sometimes these metals can be devils to get out of these macrocycles, but ways can be found at the end of Chapter 2 to demetallate. Stereochemical issues and mechanistic proposals keep surfacing, helping as they do to put some meaning into popular terms, such as chelate and macrocycle effects.

All in all, this monograph is the work of a scholar for scholars, be they practising "macrocyclists" or "those seeking an introduction to the field" to borrow a word and a phrase from the Preface. It represents one of the first courageous attempts by a single author to integrate the presentation of a multidisciplinary field. He is to be congratulated for taking up the challenge and then meeting it so successfully. The outcome is a trend-setter which is destined to become a classic in its time. It will suffer little from the literature "black-out" from 1986 onwards that unfortunately characterizes it—provided its readers get the "take-home" message, i.e. this is an area of chemistry that is on the move, so much so, that, sooner or later, it will be much bigger than macrocycles alone. As Professor *Lindoy* notes at the end of Chapter 7, "similar effects may occur for non-cyclic systems in which the donor atoms are constrained by attachment to a rigid backbone. That is, it has become increasingly apparent that many of the properties associated with simple macrocyclic systems also occur for metal ions bound in structurally rigid sites which are found, for example, in metalloenzymes." Has the time not come as well for "macrocyclists" to look beyond macrocycles?

Stereochemical Applications of Gas-Phase Electron Diffraction. Edited by *I. Hargittai* and *M. Hargittai*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. **Part A: The Electron Diffraction Technique.** xviii, 563 pp., hard cover, DM 210.00. – ISBN 3-527-26691-7/0-89573-337-4; **Part B: Structural Information for Selected Classes of Compounds.** xviii, 511 pp., hard cover, DM 210.00. – ISBN 3-527-26790-5/0-89573-292-0.

This title comprises two volumes which are quite different in content. The sub-title of Part A is "The Electron Diffraction Technique", that of Part B "Structural Information for Selected Classes of Compounds". The two books are remarkable in several respects. Most research groups presently active in the field have contributed to produce an exhaustive, up-to-date overview of the field in approximately 1100 pages. The kernel of the book is an accurate notion of molecular structure including both its static and dynamic aspects. Electron diffractionists have contributed significantly to this notion, in exemplary cooperation with specialists in related fields: rotational and vibrational spectroscopy, X-ray diffraction, ab initio and molecular mechanics calculations, to name but a few.

On the whole the editors have coordinated the various contributions well. A certain degree of redundancy can probably not be avoided in a book of this kind and, in fact, is probably necessary in order to display the multitude of approaches that has developed around *Mark*'s orginal experiment done about 60 years ago. The books are typeset and illustrated with high quality pictures. They deserve a readership far beyond the immediate (rather small) electron diffraction community and are recommended to anyone interested in molecular structure, both for the information and inspiration which they offer.

Part A. The Electron Diffraction Technique. In an introductory survey *I. Hargittai* describes the gas-phase electron diffraction (GED) technique of molecular structure determination for the benefit of those who need to use the structural information but are not familiar with the technique. He explains, among other things, the bewildering variety of structural parameters (e.g. r_g, r_a, r_z, r_c) used in the literature to take into account vibrational effects. The chapter sets the stage for a review by *Kuchitsu, Nakata* and *Yamamoto* on the joint use of GED and high resolution rotational spectroscopy – the respective results being affected differently by molecular vibrations – for accurate structure determination. In many cases the weaknesses of one technique are at least partially compensated for by the strengths of the other, and joining the two has led to a renaissance of both. From this success it is a small step to integrating other types of data into the interpretation of GED data. Two chapters describe the concerted use of GED and quantum chemical calculations (by *Schäfer, Ewbank, Siam, Chiu* and *Sellers*, and by *Geise* and *Pyckhout*). The limited information obtainable from low resolution rotational spectroscopy is shown to provide useful constraints for the interpretation of GED data, especially on mixtures of conformers (*Bohn*). In spite of differences in the state of aggregation, liquid crystal NMR results may often be combined with GED results (*Rankin*). Three of the chapters deal explicitly with dynamic aspects: vibrational information obtained from GED (*Spiridonov*), large amplitude motion (*Lowrey*) and the temperature dependence of GED structural parameters (*Fink* and *Kohl*). Another article discusses temperature dependent experiments in relation to conformational mixtures in the gas phase and associated thermodynamic quantities (*Hedberg*). *Bartell* reviews the status of electron scattering theory with respect to accuracy in structural analyses. Two chapters address small angle electron scattering and the information on electron distribution in very small molecules obtainable from such experiments (*Konaka* and *Shibata, Hirota*). The fact that both EXAFS and GED results are often represented as radial distribution curves provoked a discussion on common ground between the two (*Beagley*). Modern synchrotron sources have given a new impetus, not only to EXAFS studies, but also to gas phase X-ray diffraction investigations of electron distributions in small molecules (*Jijima, Nishikawa*, and *Mitsuhashi*). Experimental aspects of GED are summarized by *Tremmel* and *Hargittai*. The book has an author and a formula index which give ready access to the abundance of primary literature quoted in each chapter.

Part B. Structural Information for Selected Classes of Compounds. The second volume contains chapters on boron and silicon compounds (*Mastryukov*), nitrogen and phosphorus compounds (*Vilkov, Sadova*), oxygen and sulfur compounds (*Naumov*), fluorine derivatives (*Oberhammer*), saturated organic molecules (*Montgomery*), unsaturated organic molecules (*Traetteberg*), substituted benzene derivatives (*Domenicano*), organometallic compounds of main group elements (*Haaland*) and metal halides (*M. Hargittai*). It concludes with a discussion of the interaction of theoretical chemistry with GED (*Boggs*). An author and a formula index give access to molecular structure determinations of approximately 1500 compounds.

This volume is encyclopedic in character, especially the first six chapters. They are not easy to read, but the treasures of information encourage browsing. The choice of structural parameters reported in numerous tables is subjectively selective. The reader interested in detailed and complete information has to consult the primary literature. One would hope that sometime in the future the encyclopedic material of this and analogous previous books[*] will be available in a critically edited, computer readable data base, in order to make more room for discussion of the results.

The chapter on saturated organic molecules summarizes some of the assumptions necessary for analysis of large molecules with low symmetry, and thereby illustrates some limitations of GED. Another caveat is discussed with respect to organometallic compounds and metal halides which are often unstable and reactive; thus their identity cannot always be taken for granted. A further limitation of GED is that it measures averages of similar distances quite accurately but not their differences; from quantum chemical calculations, on the other hand, differences are much better determined than absolute distances. Similarly, ratios of force constants, but not their absolute values, may be computed by ab initio methods and combined with experimental frequencies to gain a better understanding of the vibrational aspects of molecular structure. The chapters mentioned here will help the non-specialist reader to gain a critical appreciation of GED structures.

The discussion of benzene derivatives is, in a way, the most interesting chapter. Not only does it critically discuss the reliability of the GED structures but it also addresses the problems of structural substituent effects and chemical bonding, by comparing all available and reliable information on the gas and crystalline phases.

Organic High Pressure Chemistry. Edited by *W. J. LeNoble*. Elsevier, Amsterdam 1988, xii, 489 pp., hard cover, HFl 320.00. – ISBN 0-444-43023-7

Following the appearance recently of numerous review articles on various aspects of organic reactions at high pressure, this monograph attempts to provide a comprehensive overview of the topic. As the editor indicates in his preface, this is not an easy task, since the number of high pressure laboratory systems, and consequently also the numbers of high pressure experiments published, have grown considerably in very recent times. As a result high pressure chemistry is developing from being a specialized field of work, accessible to only a few, into a widely used research method; pressure, as one of the variables in optimizing reaction conditions, thereby assumes an importance similar to that of temperature and solvent, for example.

[*] An extensive compilation complementary to this one has recently been published (Vilkov, Mastryukov and Sadova, *Determination of the Geometrical Structure of Free Molecules*, English translation, MIR Publishers, Moscow 1983).

In the book's 14 chapters the different subdivisions of the topic are described by 15 expert authors, who have themselves made important contributions to research in these fields. The latest developments in high pressure apparatus are not reported, however. Following an introduction written by the editor (Chapter 1, 18 pp.), which briefly outlines the main physical-chemical principles underlying the effects of pressure on reactions in compressed solutions, *O. Exner* in Chapter 2 (31 pp.) introduces empirical group increments for calculating molar volumes of many types of aliphatic, carbocyclic and heterocyclic compounds; these are as simple to use as the Benson increments for calculating enthalpies of formation. With the help of these molar volumes it is a simple matter to estimate the reaction volumes which are important for assessing pressure effects.

Chapters 3 (50 pp., *S. D. Haman*) and 4 (23 pp., *M. Sasaki* and *J. Osugi*) are concerned with pressure effects on chemical equilibria (e.g. for conformers, *cis–trans* double bond isomers, ionization reactions, etc.), and with kinetic isotope effects, especially the pressure dependence of the tunnel effect in hydrogen transfer reactions. Here the experimental results are compared with model calculations where these are available. In Chapter 5 (20 pp.) *T. Asano* discusses the effects of pressure on the hindered rotation in amides and on the *cis–trans* isomerization of compounds containing N=N, C=N and C=C bonds. The use of dynamic NMR spectroscopy at high pressures as a method for such studies is described. In Chapter 6 (61 pp.), which is devoted to pericyclic reactions, *G. Jenner* includes a detailed discussion of Diels-Alder reactions, whose pressure dependence has been studied very thoroughly. Also discussed here are other cycloaddition reactions ([2+2]-, [6+4]-, [8+2]- and 1,3-dipolar cycloadditions), en-reactions, and sigmatropic and electrocyclic rearrangements. Emphasis is placed here on the types of information which activation volumes and reaction volumes contain in relation to reaction mechanisms.

Chapters 7 (34 pp., *K. R. Brower*), 8 (16 pp., *E. Whalley* and *W. J. LeNoble*) and 9 (29 pp., *V. M. Zhulin*) deal with pressure effects on anionic, carbocationic and free radical reactions, respectively. Topics discussed in these chapters include acid-base equilibria, hydride transfer, nucleophilic substitutions, additions and eliminations, the problem of the classical versus the non-classical norbornyl cation, polymerization reactions, and the decomposition of azo and per-ester compounds. Here again mechanistic problems are in the foreground. In the following two chapters the main emphasis is on preparative organic chemistry. Chapter 10 (20 pp., *A. Rahm*) describes, amongst other reactions, the additions of organosilicon and organotin compounds to C=C and C=O bonds at high pressures, which are of particular interest for synthetic purposes. Under the title "Synthesis" in Chapter 11 (53 pp.), *J. Jurczak* provides an impressive review of reactions of importance in preparative chemistry which only proceed with good or very good yields at high pressures. This chapter is rounded off with examples of natural products syntheses in which the key steps require high pressures.

Chapter 12 (23 pp., *R. Schmidt* and *H.-D. Brauer*) and 13 (46 pp., *K. Heremans*) describe respectively the pressure dependence of photophysical and photochemical processes (such as intersystem crossing and the deactivation of excited states), and aspects of bioorganic chemistry, e.g. the effects of pressure on the structures of proteins and on enzyme activity. In the final contribution (Chapter 14, 12 pp.) *W. J. LeNoble* discusses the sorts of conclusions regarding mechanisms that can be drawn from pressure effects, taking a number of carbene and fragmentation reactions as examples.

Since this monograph has been written by a large number of authors representing very different chemical specialisms, which range from physical chemistry to preparative organic chemistry, it should appeal to readers with widely varying interests, and is a mine of information on published work which is scattered throughout the organic and physical chemistry journals, and is therefore difficult to keep track of. The literature citations extend up to 1986 inclusive. The coordination achieved by the editor is commendable. This has undoubtedly succeeded in avoiding over-frequent repetition of the same phenomena in different chapters. However, there are a few instances where it is pleasing to find the same experiment discussed from different points of view. There remains now the question as to what readership this book in the series "Studies in Organic Chemistry" is aimed at. Foremost undoubtedly is the research chemist who already has a basic knowledge of high pressure chemistry, and may need to carry out his or her own high pressure experiments.

It is difficult to understand why the price is so high. The authors' typescripts have been directly reproduced, and with modern text processing methods there can be no objection to this. However, one would expect the considerable reduction in production costs achieved by this means to keep down the purchase price. The fact that the price is much too high, unjustifiably so in my opinion, is unfortunately likely to prevent this monograph, which is full of useful information for non-specialists also, from reaching a wider readership.

Georg de Hevesy. 1885–1966. Festschrift. Edited by *G. Marx*. Akadémiai Kiadó, Budapest 1988. 165 pp., hard cover, DM 34.00. – ISBN 963-05-5230-2

This book contains the typewritten texts of the papers presented at a meeting held at the Eötvös University in Budapest on 26 September 1985 to commemorate the hundredth anniversary of the birth of *Georg von Hevesy*. First *György Marx* gives, by way of an introduction, an outline of *Hevesy*'s life and work. After studying in Budapest and at German universities he undertook a period of research with *Rutherford* in Manchester from 1911 to 1914. This familiarized him with radioactivity, and was also the start of a lifelong friendship with *Niels Bohr*. His teaching and research activities at Budapest University were interrupted by World War 1, and shortly after the end of the war they came to a stop due to the revolution. *Hevesy* emigrated to Denmark for the first time. From there he went in 1926 to Freiburg as Professor of Physical Chemistry. In 1934 he moved for the second time to Denmark. In 1943 he fled to Stockholm, and in 1945 became a Swedish citizen. His life ended in 1966 in Freiburg—perhaps finally reconciled? His relationship with Hungary is discussed at the end of this little book by *Gábor Palló*.

Hevesy's scientific work was extremely varied, as becomes clear from *Marx*'s article, and the quantity of it was also quite large, as is evident from the bibliography compiled by *Hilde Levi*, which lists 397 publications. In 1913, together with *Friedrich Paneth*, he invented radioactive labeling, and soon began to apply it to problems for which this was the only available method, such as self-diffusion in metals. The discovery of element 72, hafnium, using X-ray fluorescence spectroscopy, belongs to his first Copenhagen period. His time in Freiburg was dominated by geochemical topics such

as the dating of geological specimens using the radioactive decay of lead isotopes. Back once more in Copenhagen, he invented neutron activation analysis with *Hilde Levi*, then became increasingly involved in the applications of artificial radioactive isotopes in biology and medicine, initially using ^{32}P; from this work nuclear medicine developed. For his research on isotopes as tracers for investigating chemical reactions he received the Nobel Prize for Chemistry in 1943.

The lectures were linked under the general heading "Interdisciplinary Applications of Nuclear Methods". Only the first of these relates directly to *Hevesy;* in this *Gustaf Arrhenius* and *Hilde Levi* give a review of his geochemical and cosmochemical period from 1922 to 1935 (26 pp.). *Rudolf Mößbauer* describes the beginnings of the precision gamma-ray spectroscopy technique which is named after him (13 pp.), and following this *Vitalii Goldanskii* then discusses the method in greater detail, using examples of applications, mainly in the field of biomacromolecules (35 pp.). Next comes a contribution by *Ferenc Mezei* on the neutron spin-echo technique, again applied mainly to biomolecules; here an important field of research which originated at the place of the meeting was described (11 pp.). The book ends with a detailed review by *Kai Sieghahn* of the development and still continuing refinement of the ESCA (electron spectroscopy for chemical analysis) method (37 pp.).

This little book will be mainly useful to readers who are engaged in work in the fields dealt with in the individual papers. It should also be in every department library, as a way of keeping alive the memory of *Georg von Hevesy*, a gentleman scientist who had the resources to enable him to work for a considerable time without a salary, and thus to remain literally his own boss. There is something in the view which is occasionally put forward that the decline of science in this country began with the disappearance of the wealthy "Privatdozenten", for these people were truly independent.

Günter Herrmann [NB 990 IE]
Institut für Kernchemie
der Universität Mainz (FRG)

Carbocycle Construction in Terpene Synthesis. By *Tse-Lok Ho*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xiv, 768 pp., hard cover, DM 260.00. – ISBN 3-527-26582-1/0-89573-279-3

This book by *Ho* on ring-forming reactions in terpene synthesis is a long one. It has 760 pages, 1600 references and about 7000 structural formulas which are correctly drawn in nearly every case. What does the book offer the reader that is new? *Ho* places the ring-forming reaction as the central step in every synthesis, with the synthesis proceeding around it, before it and following it. This viewpoint strikes the reviewer as misleading, or at least biased. It can sometimes be appropriate, as in some of the more spectacular cationic cyclizations, e.g. in the synthesis of alnusenone (page 290), but it is an overstatement in many cases, especially for syntheses of which ring formation is a comparatively insignificant part, e.g. the formation of the second cyclopentane ring in the synthesis of pentalenolactone (page 92). This overemphasis on ring formation is reminiscent of total syntheses of natural products in which, say, 15 laborious stages are needed to prepare the precursor for the ingenious one-stage ring-closing reaction.

The book treats the subject defined above in 11 chapters: Robinson annelations, aldol condensations, Michael aldol condensations, Claisen and Dieckmann reactions, intramolecular alkylations, cationic cyclizations, Diels-Alder reactions, other thermal processes (i.e. [3 + 2]-, [4 + 3]-additions, etc., Wittig and Claisen rearrangements, electrocyclizations, etc.), free radical cyclizations, small ring syntheses (Simmons-Smith reaction, carbene chemistry, photochemical formation of cyclobutane, etc.), ring enlarging and ring contraction reactions, and a chapter on "transitory" ring formation reactions, i.e. those that subsequently serve other purposes, e.g. cyclopropane → gem-dimethyl.

The book also takes into account the most recent published work. Even the main text contains quite a number of 1987 references, while the 50 or so references contained in the appendix are mainly to papers published in 1988.

Unfortunately the information content of the reaction schemes is very scanty. Only for the centrally placed ring-forming reaction are some details of the reactants rather casually included, and even here without giving yields. More information here would have been very useful for quick reference, and rapid access to information is without doubt one of the main purposes of such a book.

The content of the book overlaps to a large extent with the chapters on mono-, sesqui- and triterpenes in the series "The Total Synthesis of Natural Products" by *ApSimon*. While it is true that *Ho* is seven to eight years more up-to-date, *ApSimon* is better in information content and clarity.

Finally, a few errors will be mentioned, more in order to show that the reviewer has read the book carefully than by way of serious criticism. On page 481 a CH_3 group is missing from the route to nootkatone, on page 335 *E*/*Z*-ocimenone was converted using isoprene, not ocimene, and the relevant reference is *Adams* (1975), not *Ayar* (1973, 1975). On page 215 the CH_3 and $ClCH_2$ groups are shown in the wrong positions in the ishwarone synthesis. But, as has already been said, these are unimportant details in a work such as this.

To summarize, the book constitutes a new attempt at presenting the formidable variety of terpene syntheses according to a different method of classification based on their ring-forming reactions. Since every such new approach offers the possibility that in thumbing through the book one can learn something new, or see something which is already familiar from a different viewpoint, it is a useful book for the synthetic chemist and, although rather expensive, is worth buying.

Georg Fráter [NB 966 IE]
Givaudan Forschungsgesellschaft AG
Dübendorf (Switzerland)

Analytical Artifacts: GC, MS, HPLC, TLC and PC. (Journal of Chromatography Library, Vol. 44). Edited by *B. S. Middleditch*. Elsevier, Amsterdam 1989. 1033 pp., hard cover, HFl 495.00. – ISBN 0-444-87158-6

Every honest analyst has at some time detected in his samples substances whose presence has at first seemed astonishing. In many cases it turns out, after further careful investigation, that these have found their way into the analytical samples in mysterious ways, through the operation of "Murphy's Law", during some purification or sample preparation step, or even during sampling. In publications mention of such occurrences is either shyly omitted, since no one willingly admits to having been stupid, or hidden away in incidental minor comments. After all, why not let others make the same mistakes?

It is surprising, therefore, that despite this there are so many wrong chromatographic interpretations to be found in

the literature; in this work they are systematically collected together in more than 1000 pages. In each case the pitfalls are described and listed under either the name of the wrongly identified substance or that which was responsible for introducing them. For example, under the keyword "Tenax", which is a polymer often used for concentrating trace organic impurities present in the atmosphere, are listed more than 40 compounds and compound classes that have allegedly been found in environmental samples, but which originated from the polymer itself. Perhaps it is already sufficiently well known that samples purified by gas chromatography or in reverse phase columns can be contaminated with siloxanes, but the fact that difficulties can arise with chromatographic tests for drugs, as used in the USA, if one has been eating poppy-seed bread rolls, not only illustrates the sensitivity of the chromatographic test method, but also emphasizes the need for care in interpreting analytical results.

Under the keyword "filter paper" are listed over 60 compounds, from simple hydrocarbons to steroids, which have been introduced during filtration. The book is enriched by many practical hints, ranging from sample injection procedures to the problems encountered in the determination of nitrosamines, and precautions against both false positive and false negative results in this case. There are also historical anecdotes concerning false analyses (e.g. the poisoning of *Napoleon* by arsenic, or the theory that the Philadelphia legionnaires were poisoned by tetracarbonylnickel, which arose because the samples were contaminated by nickel from a spatula), which enliven the book.

In addition to keywords of a general type, all the compounds identified as artefacts are listed alphabetically. In addition to the molecular formula, molecular mass, trivial and systematic names, and CAS and Merck index numbers, the compilation also includes mass spectra in many cases. Also provided are detailed descriptions (with literature references) of how and where the substance appeared as an artefact, and precautions that were taken to avoid errors. In addition to the usual index of compounds, the mass spectrometric data (base peak and 2nd and 3rd peaks) are also indexed in such a way that the corresponding substance can be quickly found.

Despite the relatively high price of HFl 495.00, this book should be regarded as essential reading for everyone seriously engaged in chromatographic trace analysis. The price is small when compared with the trouble, annoyance and expense caused by incorrect analyses.

Heinz Engelhardt [NB 983 IE]
Institut für Physikalische Chemie
der Universität Saarbrücken (FRG)

Name Reactions and Reagents in Organic Synthesis. By *B. P. Mundy* and *M. G. Ellerd*. Wiley, Chichester 1988. ix, 546 pp., hard cover, £ 27.05. – ISBN 0-471-83626-5

This is neither an ordinary book nor a systematic encyclopedia; rather it is a well-ordered card index that has been put between covers. The following layout is repeated 120–130 times on the left-hand pages: a first section consisting of the named reaction with an equation, a mechanism, and comments on its applicability; a second section containing reagents with their formulas, areas of application and methods of preparation, followed by about five literature references. On the right-hand page in each case are about five examples (in large print) of reactions taken from the papers cited.

The following are two examples: 1) Vilsmeier reactions for the regioselective formylation of an open-chain triene and for preparing selenoaldehydes are described. No yield is given for the first reaction (are the other isomers also formed?); the second reaction means nothing to me in the absence of any discussion of selenoaldehydes. The three other Vilsmeier reactions cited are of "normal" types, and can also be found in standard textbooks. 2) The most common application of *Mitsonubu*'s reagent is for OH-substitution in alcohols with a change of configuration. Here one also finds the esterification of carbon dioxide using pentanol. This is certainly surprising, but what purpose does this serve in organic synthesis? (see the book's title). The examples throughout are either very familiar or very exotic. There are so few surprises in the information given (see, for example, under the keywords formic acid and potassium hydride) that one shrugs one's shoulders and dismisses it as inconsequential. There is, moreover, no index of reaction types, and consequently it is not possible to search for particular ones.

The never-failing references to pages in *March*'s "Advanced Organic Chemistry" and *Fieser*'s "Reagents for Organic Synthesis" are evidence of painstaking student work. Basically the book is nothing more than this. None of the material has been treated in a novel way or freshly evaluated; instead it has merely been collected together and, on the whole, faithfully reproduced (an exception is the incorrectly shown bonding in the chair form of cyclohexane, e.g. on page 477). To misquote *Arno Schmidt*, the book remains a Zettel-Alptraum (card-index nightmare). Throughout the whole of the five hundred-odd large-format pages the same question keeps coming to mind: what is it meant to be?

Jürgen-Hinrich Fuhrhop [NB 986 IE]
Institut für Organische Chemie
der Freien Universität Berlin

Mechanistic Principles of Enzyme Activity. Edited by *J. F. Liebman* and *A. Greenberg*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. 404 pp., hard cover, DM 204.00. – ISBN 3-527-26907-X/0-89573-706-X

The field of enzyme chemistry has undergone a significant mutation over the last ten years thanks to advances in cognate biological technologies and in instrumentation. As a result, the focus of attention has broadened from the substrate and mechanisms of chemical catalysis to include detailed consideration of the properties of the protein relevant to catalysis. To reflect such a change in emphasis in the title of a multi-author book is extremely difficult and the familiar ring of many of the chapter titles also disguises the high scientific and intellectual content of many of the chapters.

We are dealing here with a book that not only presents the information currently available on several important topics but also shows how ideas have developed, identifies problems in current understanding, and indicates potential lines for future research. Further, where appropriate, there is a concise exposition of the theory relevant to the understanding of the problem, for example in the discussion of electron transfer in cytochromes (*Dixon*). Several other chapters deal with specific classes of enzymes including peptidases (zinc proteases, *Christianson* and *Lipscomb*; serine proteases, *Schowen*) and oxidases (hemoproteins, *Bruice*; flavin mixed function oxidases, *Bruice*; glutathione dependent aldehyde oxidation, *Creighton* and *Pourtomabbed*). Two others of general significance discuss stereoelectronic analysis (*Benner*)

and a modern view of intramolecularity, proximity, and strain (*Czarnik*). A further chapter, unusual for this type of work, covers the topic of porphyrin metallation reactions (*Lavallee*).

As always in books of this length (ca. 400 pp.) many areas of equal interest and importance are not covered. However I found several of the chapters so exciting and stimulating to read that I would consider this book an obligatory purchase for libraries and very meritorious of inclusion in the private collections of researchers active in any field of mechanistic enzyme chemistry.

Colin J. Suckling [NB 995 IE]

Sterol Biosynthesis Inhibitors. Pharmaceutical and Agrochemical Aspects. (Ellis Horwood Series in Biomedicine). Edited by *D. Berg* and *M. Plempel*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. 583 pp., hard cover, DM 220.00. – ISBN 3-527-26744-1/0-89573-671-3; ISSN 0930-3367

Inhibitors of sterol biosynthesis are nowadays indispensable for the treatment of fungal infections in human and veterinary medicine and for plant protection. Whereas 25 years ago they were still completely unknown, even in research laboratories, they now account for a considerable part of the sales of pharmaceutical and agrochemical manufacturers. An enormous amount of research on such products is carried out worldwide. The number of patents and publications has grown exponentially, and various classes of compounds with broad or selective activity have been discovered, some of which are yet to be introduced onto the market. There is a strong probability that the economic importance of sterol biosynthesis inhibitors will increase further and that they will find new applications. It is not surprising, therefore, that in addition to the monograph reviewed here two other books summarizing the current state of knowledge on these substances have been published during the last two years, viz: R. A. Fromtling (ed.): *Recent Trends in the Discovery, Development and Evaluation of Antifungal Agents*. J. R. Prous Science Publishers, Barcelona 1987, and V. St. Georgiev (ed.): *Antifungal Drugs (Ann. New York Acad. Sci. 544* (1988)). The latter two volumes concentrate on antifungal agents for human applications (all the important new antifungals are sterol biosynthesis inhibitors).

However, all three monographs contain contributions from the same authors on special aspects of particular agents, and these are even similar in content. How do the books differ, and what makes the present book especially valuable? It attempts for the first time to bring together the pharmaceutical and agrochemical aspects of sterol biosynthesis inhibitors, and also sets out to open a window on a possible new area of application. As is indicated below, the editors *D. Berg* and *M. Plempel* have essentially succeeded in these aims.

In Part 1 of the book the basic chemical and biochemical characteristics of the different classes of antifungal agents (e.g. azoles, morpholines, allylamines) are reviewed, covering work published up to 1987. This is followed by a chapter on the toxicology of azoles; it would have been better to include this in Part 3 with the article on the pharmacokinetics of this class of compounds, but it is nevertheless very useful. Toxicological aspects of azoles as a group, as they relate to the extent of investigations and the problems inherent in handling these compounds, are not usually discussed either at conferences or in scientific journals. The article here presents data from the Bayer toxicological laboratory on liver toxicity, embryo toxicity, and effects of steroidal hormones through inhibition of the cytochrome P-450 system. Other firms should follow this example!

Part 2 is devoted to the applications of sterol biosynthesis inhibitors in plant protection. The non-specialist reading this will be surprised at the similarity of the chemical structures, especially those of the new triazole fungicides, to those of the azole type human antifungal agents. Here one has a situation which is probably unique: substances of the same structural class which differ by only slight modifications are used in completely different market applications. Whether or not this situation can also lead to problems (e.g. through development of resistant strains) remains to be seen. By providing a wider circle of readers with a survey of the human and agricultural aspects of sterol biosynthesis inhibitors, this book may lead to a heightened awareness of such problems.

Part 3 deals with the chemotherapy of fungal infections in humans and animals, and indications for possible new treatments. Especially useful contributions are the article by *W. Ritter* on the pharmacokinetics of azoles, and the review of aromatase inhibitors by *D. F. Covey*. The latter article draws attention to a possible new application of azoles as an inhibitor of this cytochrome P-450 dependent enzyme, namely the inhibition of oestrogen-dependent tumors. The selective control of other processes that involve the synthesis of steroidal hormones and are regulated by highly specific cytochrome P-450 enzymes, by using specially tailored azoles, is still a utopian idea, but could soon become a reality.

This book is suitable both for newcomers to this rapidly developing field of research and application, and as a work of reference for the specialist. The way in which the book brings together information on these topics will contribute to useful discussion, and hence to the future development of the field.

Anton Stütz [NB 970 IE]
Sandoz Forschungsinstitut

Art in Organic Synthesis. 2nd Edition. By *N. Anand, J. S. Bindra* and *S. Ranganathan*. Wiley, Chichester 1988, xix, 427 pp., hard cover, £ 34.50. – ISBN 0-471-88738-2

"There is excitement, adventure, and challenge, and there can be great art, in organic synthesis." To illustrate this quotation from *Woodward*, by describing a selection of outstanding syntheses, was the declared objective of the authors in the first edition of "Art in Organic Synthesis", published in 1970. The rapid developments that have occurred since then in new synthetic targets, methods and reagents have necessitated a rewriting of this "state of the art" account.

The second edition which the same team of authors has now produced with a different publisher again presents, under about 100 subject headings, a colorful kaleidoscope of the power of organic synthetic methods. In the form of annotated flow charts, it summarizes important syntheses drawn from the whole spectrum of applications, providing a balanced mixture which contains about two-thirds on natural products and one-third on man-made compounds. An indication of the degree of topicality is given by the fact that the majority of the chapters of the first edition have been replaced by new ones; only a third or so are "classical"

teaching examples which have been retained almost unchanged. The examples range from simple structures such as adamantane, through many different steroids, alkaloids and antibiotics, spectacular polycyclic compounds such as [1.1.1]propellane, tetra-*tert*-butyltetrahedrane and dodecahedrane, through to gene synthesis. Although it is possible to quarrel with the authors' subjective selections in some cases, the wealth of topics included leaves only a very few others that one would have liked to see added. Each chapter begins with a brief introduction in which, after the occasional historical reference, the nub of the synthetic problem is described. This is followed by a concise diagrammatic representation of the synthetic route, amplified by footnotes and literature references. The main emphasis is on the strategic concept, and the list of reagents used is only occasionally supplemented by details of the reaction conditions. The book ends with detailed indexes of the structures synthesized, authors, reagents and reaction types (the latter are sometimes rather uncritically taken to excess, e.g. there are 50 references to the use of the commonplace reagent chromium trioxide, a number exceeded only by lithium aluminum hydride with 66 references).

The motives underlying such a compilation of "highlights" from organic synthesis are to be applauded. The authors have succeeded in compiling a selection of elegant applications of contemporary methods to both classical and currently topical problems, in such a way as to convey an appreciation of the changes that are developing in the type and complexity of the problems to be solved. However, although the examples chosen are very appropriate to the book's title, this makes it all the more regrettable that the presentation does not always meet a level of aesthetic excellence. The direct reproduction of the typescript which has been used to reduce the cost, evidently without editing by the publishers, has led to a large number of grammatical and typographical errors which detract from the enjoyment of reading the book (even the page headings, which are typeset, have not escaped this). One wishes that the authors and publishers had made better use of the 18 years that have passed since the first edition, so as to improve the content with more careful attention to details. Similarly the figures, and especially the structural formulas, are not free from defects (distorted geometries, missing or superfluous bonds, incomplete or incorrect representation of stereochemical relationships occurring at bond crossings or wedged projecting bonds). Occasionally one wishes that the perspectives used in the original papers had been followed more closely.

For some of the more important natural products and homologous series of polycyclic compounds, several known alternative synthetic routes are presented alongside each other, in the way adopted, for example, in the journal *Synform*. However, one cannot make a fair comparison of the different strategies and methods used in the various routes, as no yields are given. To suit this condensed method of presentation, an indication of the type of transformation (e.g. "Sharpless epoxidation") would in some cases be more informative, and more desirable from a didactic standpoint, than a mere listing of chemicals. The literature references extend in general up to 1985, and occasionally there are citations of 1986 papers; the older chapters have in general not been updated, and here the literature coverage only extends to 1969. Quite often one finds an early short communication cited rather than the more detailed article published later; often too there are no references to relevant or more recent review articles. Inadequate treatment of the literature also shows itself in inconsistencies in the form used for citations of the various journals (e.g. there are at least four versions of *Angew. Chem. Int. Ed. Engl.*).

One of the aims of the book is to serve as a textbook for advanced undergraduate and graduate students. However, in order to receive a recommendation without reservation it would need to be still further revised, e.g. in such a way as to take account of the merits of a rival "artist" from the same publishing house.[*] The question of what purpose the book can most appropriately serve is perhaps best answered by comparing it to a nice box of chocolates: an appropriate present for a friend, or for treating oneself to an occasional munch. However, this analogy is not fully satisfying, because even though the price is affordable one can get real truffles for less.

ADVANCED MATERIALS

How to Tailor Molecular Electronics or Why is Nature Taking the 'Soft' Approach?**

Editorial Essay

By Dietrich Haarer*

Dedicated to Professor Wolfgang Hilger on the occasion of his 60th birthday

1. Introduction

The more we are able to understand the efficiency of biological systems, the more our mind is tempted to design *Molecular Devices* whose efficiency is comparable to the efficiency which nature has achieved during its evolutionary path. Here are three examples:

a) The **capacity of the human brain** is of the order of 10^{15} bits. To mimic this memory-capacity with magnetic disks (typically 60 MByte; 50 Watt power consumption) one would need about two million disks, consuming about 0.1 Gigawatts of electric power. Our human brain does this job for as little as a couple of Watts. Granted, a magnetic store of the above size would be more reliable than our brain; however, its energy consumption differs from the biological systems by some 7 orders of magnitude.

b) Highest performance can be achieved with **semiconductor devices,** but assuming a price of \$10 for a 1 MBit chip, we would have to pay about 10 billion dollars to assemble a semiconductor memory of the capacity of the human brain.

c) The **sensitivity of the human eye** is comparable to that of a photomultiplier tube. On our retina we have in the order of 10^8 photon receptors of roughly the sensitivity of a photomultiplier tube. If we assume that a photomultiplier costs around \$100 (including power supply), we would have to pay about 10 billion dollars in order to build, by conventional means, an optical device with the same performance as the human eye.

The above examples may be fortuitous, and it is certainly accidental that our 'multiplier eye' turns out to cost as much as our 'megabit brain'. The examples show, however, that nature must have some design secrets which we cannot yet handle.

Even more astounding than its price/performance is the accuracy with which nature is able to process molecular information. Consider that the rate of mutation per base pair per replication of DNA is of the order of 10^{-10} (drosophila; see[1]). Even the accuracy of the translation of the genetic information into amino acids with 10^{-5} to 10^{-4} errors per amino acid position is very impressive.[2] These numbers beat, by any means, what can be technically achieved by present magnetic, optical or chemical schemes.

With nature being able to perform the above 'miracles' and with the limits of the silicon based technologies becoming more and more visible, it was an obvious step to consider a synthesis of electronic schemes and molecular schemes, long before the word *'molecular electronics'* was coined. Starting with the possibility of creating quite accurate molecular assemblies it was shown in the early 70's[3] that by using monolayer techniques, molecules could be assembled at well defined distances and that energy transfer and tunneling processes could be investigated experimentally[3] as well as theoretically.[4]

The capability of achieving 'design' on a molecular level led to concepts like the *molecular rectifier*[5] and *molecular shift registers*,[6] where molecular and semiconductor terminologies were fused to give a new dimension, namely *'Molecular Electronics'*.

Speakers at two recent meetings, a workshop in Bangor (UK)[7] and a meeting in Strasbourg (France)[8] presented two aspects of molecular design. In Bangor, aspects of 'Molecular Metals' (*F. Garnier*), 'Monolayers and Thin-Films' (*D. Bloor*) and 'Spectroscopy on a Molecular Scale' (*D. Haarer*) were the center of attention, whereas in Strasbourg it was the chemistry of synthesizing molecules which are selective as to the size, shape and ionic state of other molecules (*Lehn*,[9] *Stoddart*[10]) as well as biological aspects which deal with very large molecules like bacteriorhodopsin (*G. H. Khorana*) and molecular schemes which fall into the category of 'Topobiology' (*G.Edelman*) which provided the central theme. All of these are topics which reflect the wide range of interests in the field of molecular design.

Moreover, I would like to thank my colleagues *Büttner* and *Blumen* for valuable comments and my students at the University of Bayreuth for their contributions to this work.

ADVANCED MATERIALS

The question which I would like to discuss briefly in this article is the following: Why does nature use such large units like phycobilisomes, bacteriorhodopsin and the photoreactive center of *Rps viridis*[11,12] to perform electronic functions? (In the above mentioned examples, 'electronic functions' are functions which are triggered by photon absorption). Figure 1 shows the reaction center.[11] It is about 130 Å in length and has an elliptical cross section of 70 and 30 Å

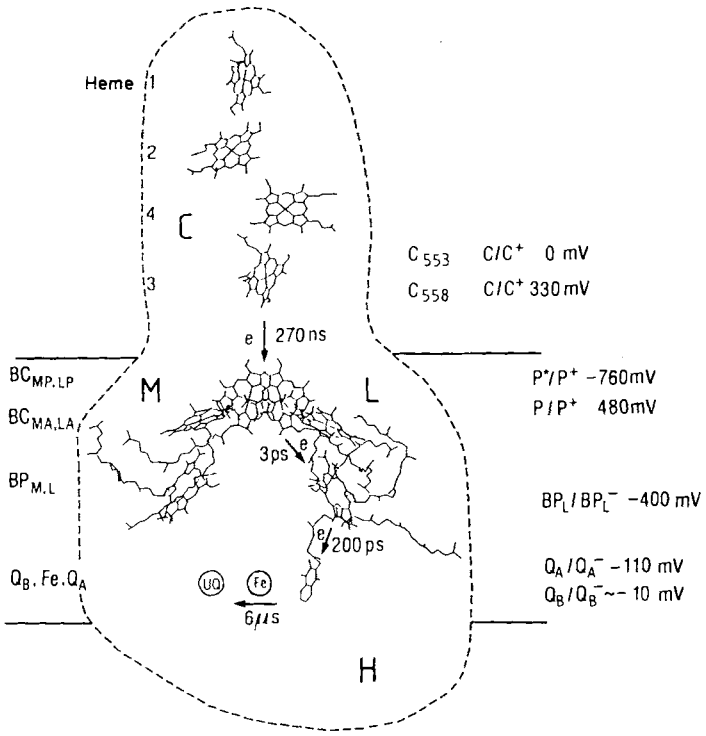

Fig. 1. Scheme of the structure of the reaction center of *Rps. viridis* showing the cofactor system, the outline of the protein subunits (C, M, L, H), the electron transfer half-times, and the redox potentials of defined intermediates [11].

respectively.[12] The total molecular weight is about 125 000, about 250 times larger than the dye molecule phthalocyanine, and about 1000 times as large as a small organic donor molecule like naphthalene.

Was nature wasteful with its valuable resources or does the large volume of 'biological machines' point towards a principle of *low densities of excited states* or *low charge carrier densities*, one of which may be the conditio sine qua non for the system to function? In typical configurations, as proposed for straightforward molecular electronics, one needs a high density of charge carriers where each charge carrier represents a bit of information and is, in general, confined to the space occupied by a small molecule. In other configurations one uses light to generate excited molecules at adjacent molecular sites (for instance donor-acceptor sites) in order to implement a clock which is able to shift molecular information along a molecular array. In other words, the charge density and the density of excited states tend to be of the order of one per small molecule. These situations are not easy to handle, as one knows from past experience with molecular crystals. Some of the following examples document what can happen if charges and excited states are brought into close proximity.

2. High Density of Excited States—Exciton Annihilation

Biological systems can be 'bleached' with low light levels and this seems to contradict the above statements about high densities. This contradiction, however, is not real, because nature has used certain construction principles:

- The dye-like molecules, absorbing in the visible spectral range, are present at a dilute concentration and surrounded by non-absorbing (and space filling) proteins.
- The systems are very complex, having subsystems with sub-picosecond electron transfer, nanosecond lifetimes, and microsecond to millisecond metastable states, which store chemical or electrical energy before allowing the systems to return to their ground state after the light has been switched off.

If one were to pack small molecules, similar to those which are often suggested for molecular electronics in close proximity to one another, and if one neglects long living interme-

Dietrich Haarer is Professor of Physics at the University of Bayreuth, FRG. A physicist by training, he received his Ph.D. in 1969 from the University of Stuttgart. With short interruptions he then worked until 1980 at the IBM research laboratory in San Jose, California, which he left as manager of the Organic Solids Department, to take up his current position. His research activities include laser spectroscopy and laser chemistry. He is an Editorial Advisor of Advanced Materials.

diates (which are undesirable in fast electronic systems because they would slow down molecular switches), one arrives at matrices resembling molecular crystals. Here we know that excited singlet states are delocalized (excitons, polarons) and annihilate i.e. transfer their valuable photon energy into heat if brought closer together than a typical distance of about 1000 Å.[13]

Having the above example in mind, nature has done two things to avoid annihilation: a) dye-like molecules with overlapping π-orbitals appear in dimers rather than in single crystal-like configurations and b) the dye molecules are surrounded by a large bulk of protein (solvent cage) which is transparent in the wavelength range of visible photons.

3. High Concentrations of Charge Carriers

3.1. The Electron-Hole Recombination Problem

Having made the point, that excited states do – in crystal-like media – not like to be packed closely, we have to discuss the same issue for charge carriers.

Light-induced charge carriers are always produced as electron-hole pairs, maintaining the total charge neutrality. Electron-hole pairs, however, have the tendency to annihilate unless they are created in a high electric field which is able to separate them. *Onsager* has calculated the probability of the geminate recombination of charge carriers performing a diffusionlike motion. Typical 'Onsager Radii', which define the distance at which the charge carriers thermalize, are of the order of 20 Å.[14, 15] Following the model of *Onsager*, the quantum yields for electron-hole separation approach unity as the field strength increases beyond 10^6 V/cm. For external fields this field strength is close to the dielectric breakdown. Molecular fields in biological systems may even be higher than the above quoted numbers for external technical fields.

3.2. The Space Charge Problem

One of the most severe problems if one wants to confine charge carriers to molecular-size boxes is the far reaching Coulomb force, which falls off slowly with $1/R$, where R is the distance between the charges. One problem, when dealing with molecular devices, will therefore be the difficulty of controlling charges using 'external fields', which are larger than the 'internal molecular fields' with which the charge carriers mutually interact. The simplest way of calculating the upper limit of how many charge carriers can be put into a molecular box, without exceeding the space charge conditions[16, 17] is the following: one calculates the capacitance C_m of a molecular capacitor of the size of a 'molecular device'. The condition to be fulfilled is that the molecular charge q_m must be smaller than $C_m \times U$, where U is the applied voltage. For simplicity I assume a plane parallel capacitor geometry with two disks of diameter R_D separated by a distance d (see also Fig. 2). This capacitor is filled with a dielectric medium of dielectric constant ε ranging between 10

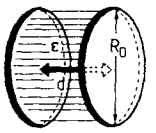

Fig. 2. Dimensions of a molecular capacitor – see text.

and 100. Now, the simple question to be answered will be the following: How many electrons can be packed into this device without running into space charge problems at a field of 10^6 V/cm (close to breakdown)? Doing this elementary calculation, one notes that the distance d does not enter into the figures, and one gets the result that it is only possible to pack 5×10^{-2} electrons into the box if ε is 10 and the diameter R_D is 10 Å.[18]

In spite of the crudeness of this estimate, I realize that it is quite difficult to control charges with external fields under conditions where the external field dominates (known from photoconduction experiments[15, 16, 19]). Since we cannot easily design a molecular deviced operating with 1/20 of an electronic charge, our recipe for avoiding space charge problems would be to take a capacitor diameter of 100 Å rather than 10 Å – and that's just what nature has done with biological devices, casting our mind back to the photoreactive center shown in Figure 1. A second comment should be made concerning the thickness d of the device. Since the thickness does not enter into the calculation (in our crude planar geometry model), it is always advantageous to deal with thin samples because here one can optimize the number of charges which can be controlled via external fields.

4. Conclusions

Admittedly, the above model assumptions are very crude, yet, they are based upon experiments with molecular crystals and polymer films and point to the fact that organic materials do not like high densities of excitated states. For instance, the molecular crystals, which were used for exciton annihilation experiments showed brown spots of carbonization after a few laser shots.[13] Organic materials also cannot accommodate many charges while still alowing us to control the charges individually. Certainly, one can make 'organic metals' like TTF-TCNQ and pack one electron and one hole into a charge transfer pair, but one is then dealing with metals, where the individual character of the charge carriers is lost in the Fermi-sea.

Taking into account all of the above 'hard restrictions' which must be satisfied in order to perform electronic processes on a molecular scale, we may not be so surprised that nature has chosen the 'soft' way in reaching its goals. It uses

ADVANCED MATERIALS

not so much the Coulombic approach with adjacent electrons and holes and not so much the excitonic approach with large single crystal-like structures and strongly coupling singlet excited states. More often, nature uses environments in which charges are screened, like *ionic* environments, *hydrogen bonded* environments and environments in which Van der Waals interactions dominate, and it also separates the active sites using bulky proteins. Fortunately, the fluid phase is an ideal medium for these interactions: geometries can be optimized, and defects which would be detrimental to a solid state device can heal in microseconds or milliseconds.

Not everybody will agree with this article, since it draws far reaching conclusions on the basis of simple model estimates. I hope, however, that the article is useful in the following sense: If some of the estimates turn out to be too skeptical, the article will stimulate experiments to prove that less severe conditions have to be fulfilled. Should the limitations be as severe as pointed out, we will have to proceed along the 'soft' path of molecular electronics. I believe that this can be done.

I will end the article with one example in a field of molecular electronics in which I have some knowledge and through this I would like to document that the soft approach can be realized. The example is photochemical hole burning.[20, 21] In these experiments, optical saturation is achieved by using a three level scheme (idealized here; in a true model more levels are involved). After exciting dye-like molecules to their first singlet state (two level picture), the photochemical change occurs mostly in states which are subsequently populated and have longer lifetimes (for instance triplet states). From these states the system then relaxes into a photochemical state (being labelled as the third state), whose lifetime can be infinitely long (at least at sufficiently low temperatures). In this scheme the photon information is *accumulated photochemically* in a third state, whose lifetime can be varied over wide ranges (microseconds to years). This kind of photochemistry even occurs at the lowest light levels. The system accumulates the photon information and, if enough photons have been accumulated a bit of digital information can be stored. This can occur at integrated energies of as little as one picojoule and it only works in systems in which the molecules which store molecular information are very dilute (10^{-3}–10^{-5} M)[21] So, from my present viewpoint, the future of molecular electronics is a bright one if we follow realistic design principles.

ADVANCED MATERIALS

Polymer Optical Fibers and Nonlinear Optical Device Principles**

Optoelectronics
Active LB Layers
Model Calculations
Fluorinated Polymers
Network Systems

By W. Groh, D. Lupo and H. Sixl*

Dedicated to Professor Wolfgang Hilger on the occasion of his 60th birthday

Basic principles of the present optoelectronic research activities at Hoechst AG are presented in this contribution. Within the diversified broad band spectrum of optoelectronic materials and applications our interest is focused on new types of polymer optical fibers and nonlinear optical device principles using organic Langmuir–Blodgett films and electrically poled polymers. The basic principles and the limits of the present research and development activities which have a high market potential are outlined.

1. Introduction

Polymeric materials have developed extraordinarily quickly in the last fifty years and now rank among the most important materials used in society and in industrial applications. New polymers with unusual optical and electrical properties are predicted to have a high market potential in the future. The combination of electrical and optical properties is especially attractive in modern electronics which develops more and more in the direction of optoelectronics with long term ambitions concerning all-optical devices. Optoelectronics plays a central role in computing and the handling of large amounts of data. Consequently material research using functionalized polymers with specially designed tailor-made properties becomes very important.

In the last few years, interest in polymer optical fibers (POF) has increased because of their low cost, easy handling and good flexibility even at large diameters.[1–5] These fibers are used for short-haul data transmission applications in computer links or in automobiles. However, the presently available fibers suffer from two major disadvantages, namely the relatively high loss of about 200 dB/km and the low maximum operating temperature of 80 to 90 °C, which is not sufficient for automotive applications. In distributed networks, even for short distance transmission, improvements in the optical loss are essential as will be shown in this contribution.

Nonlinear optical (NLO) effects have long ceased to be only a research curiosity or even research tool, and are being widely investigated and used in integrated optics and optoelectronic applications. For example, the electro-optic effect is used to build commercially available ultrafast electro-optic modulators, based on lithium niobate, which can modulate a continuous wave (CW) laser at multi-GHz frequencies. There are indications that for certain applications, organic materials will show significantly better performance than inorganic ones. The reasons for interest in organic materials and some of the problems to be solved before they can be used commercially are discussed in Section 3.

2. Polymer Optical Fibers

2.1. Model Calculations

The two important intrinsic loss factors in commercial polymethylmethacrylate (PMMA) optical fibers are C–H overtone absorption and Rayleigh scattering, which is mainly due to microscopic density fluctuations. Both factors lead to a theoretical lower loss limit of about 100 dB/km at 650 nm[1] with 90 dB/km due to overtone absorption as seen from Figure 1. Reduction of the loss is achieved by substituting the hydrogen atoms with heavier elements like deuterium which have lower energy absorption bands.

Deuteration, however, is a very expensive process and therefore other substituents have to be considered. Fluorination, for example, seems to be a good choice, but there is no information available in the literature about the positions and intensities of higher C–F vibrational overtones.

Light transmission measurements on perfluorinated compounds for a sample thickness of 10 cm show no C–F absorption in the visible spectral region as shown in Figure 2. Although this gives an upper limit for the C–F loss contribution the measurement is not sensitive enough to predict what loss a fiber consisting of this material would have, because

the length of the fiber is 10^4 to 10^5 times larger. Therefore theoretical calculations on the expected overtone band positions and intensities have been made.[4-6]

Overtone bands appear because molecular vibrations are not perfectly harmonic. This is expressed in a nonsymmetric potential curve and a non-zero anharmonicity constant x. From the Morse potential approximation (Fig. 3) we obtain the energy levels and the corresponding transitions. We can calculate the spectral position of any overtone band if we know the position of the fundamental vibration and the anharmonicity constant. From infrared spectroscopic data on hydrogenated, deuterated or halogenated compounds one can find ν_1 and also ν_2 for all interesting vibrations, from which the x-values can be calculated. If, for example, ν_1 and ν_2 were known for a certain molecular vibration, the positions of all higher overtones can be calculated.

Energy levels (Morse potential)

$$G(v) = \nu_0(v + \tfrac{1}{2}) - \nu_0 x(v + \tfrac{1}{2})^2$$

Transitions

$$\nu_v = G(v) - G(0) \rightarrow \boxed{\nu_v = \frac{\nu_1 v - \nu_1 x v(v+1)}{1 - 2x} \qquad v = 2,3,4,\ldots}$$

or if e.g. ν_1 and ν_2 are known $\Rightarrow x$

For experimentally accessible overtones, for example from C–H or C–D vibrations, one can evaluate the band strength from the spectrum if the number of contributing bonds,

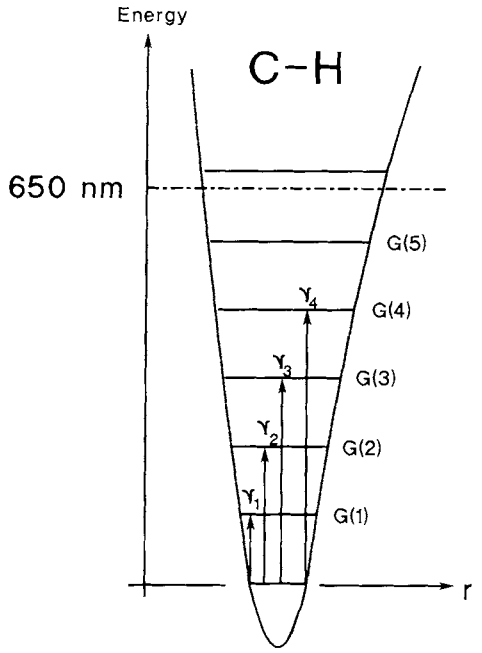

Fig. 3. Calculation of molecular vibrations with the Morse potential approximation.

molecular weight, density and sample thickness are known. Theoretical calculation of the interesting vibrations is also possible (with some approximations) due to the work of *Timm* and *Mecke*.[6, 7] We come out with a very simple equation for the band strength of an overtone normalized to the band strength of its fundamental. Any overtone band strength can be calculated if we know the anharmonicity constant x and the fundamental band strength $E(\nu_1)$, both of which can be extracted from an infrared spectrum of an appropriate compound.

This is illustrated in Figure 4, which shows selected parts of the infrared spectrum of a fluorinated model compound. Shown are the fundamental and overtone vibrational bands of the carbonyl group. From such spectra the exact band positions and intensities can be easily extracted. If, for example, the spectral positions of ν_1 and ν_2 are known, the anharmonicity constant and the positions of all other overtones can be calculated as shown above. We also obtain the band strength of the fundamental and can thus calculate all band strengths of the higher overtones which are not experimentally accessible.

The most important molecular vibrations in polymers are listed in Table 1. In a fluorine-containing methacrylate com-

Hans Sixl studied physics at the University of Stuttgart, FRG, gaining a Ph.D. in 1971 and habilitating in 1976. After this he spent some time at the Max Planck Institute for Solid State Research in Stuttgart and also in Grenoble working with Professor Dransfeld before returning to Stuttgart University to become Professor of Physics in 1981. Since 1986 he has been the Departmental Head of Applied Physics at Hoechst in Frankfurt, FRG.

ADVANCED MATERIALS

pound we have to consider the absorption due to the C–H bonds, the carbonyl group and the C–F bonds. Values for the spectral position of the fundamental, the band strengths and the anharmonicity constants are also given in Table 1. The C–H absorption is most pronounced because of its large anharmonicity constant.

Table 1. Important molecular vibrations in organic polymers.

bond	ν_1 [cm^{-1}]	$E(\nu_1)$ [cm mol^{-1}]	x	overtone quantum number in VIS
C–H	2950	6×10^5	1.9×10^{-2}	~ 5
C–D	2230	2.4×10^5	1.46×10^{-2}	~ 8
C=O	1846	9.6×10^6	6.5×10^{-3}	~ 9
C–F	1250	2.4×10^7	4×10^{-3}	~13
C–Cl	770	4.8×10^6	5.9×10^{-3}	~23

C–C and C–O vibrations cannot be treated using this simple model, because the dipole curves are much more complex and the approximation of a smooth dipole curve no longer holds. The spectral positions of the fundamental vibrations are known from the literature but there is little or no information about the corresponding overtone wavelengths and intensities. The intensity of the absorption of the C–C group, for example, depends strongly on the symmetry of the C–C bonds. There is experimental evidence that the fourth overtones of the C–C and C–O groups, expected in the 1200–1500 nm range, are already undetectable.[8, 9]

The results of the calculations are summarized in Figure 5. The symbols represent the calculated spectral overtone positions and the corresponding calculated band strengths. For the experimentally accessible low order C–H, C–D and C=O overtones we found very good agreement for the band positions. Experimental and theoretical band strengths coincide within a factor of 3 which is very good for such a simple model and sufficient for these considerations. The results for the experimentally inaccessibly high C–F and C=O, and also for C–Cl overtones are given. In the most important spectral region between 600 and 900 nm they are orders of magnitude lower in intensity than the C–H overtones and therefore should contribute negligibly to the losses in the fiber. The reasons are, firstly, the low anharmonicity constant of the C–F, C–Cl and C=O vibrations compared to C–H and, secondly, the low energy fundamentals which are in the far infrared. To get absorption in the visible spectral region, relatively high quantum states have to be excited which are therefore low in band strength. These are the two important factors dominating the absorption in the visible region.

The theoretical lower loss limit for fully halogenated polymers in the 600–900 nm region is therefore limited by Rayleigh scattering which is about 10 dB/km at 650 nm. From the theoretical point of view losses of a few dB/km should be attainable with optimized perfluorinated polymers.

Other expected advantages of fluorination are

- less scattering
- improved transparency at longer wavelengths where fast high power LEDs are available
- lower water uptake
- usually higher glass transition temperature.

The lower scattering losses of fluorinated polymers can be easily understood by considering the parameters responsible for scattering (Table 2). In the case of density fluctuations the loss is proportional to the eighth power of the refractive

Density fluctuations

$$D_D \sim \frac{1}{\lambda^4} n^8 \beta_T$$

Anisotropy fluctuations

$$D_A \sim \frac{1}{\lambda^4} n^4 N p \delta_0^2$$

Concentration fluctuations

where λ: wavelength. n: refractive index. β_T: isothermal compressibility. N: monomer concentration in the polymer. p: number of parallel monomers per structural unit. δ_0: monomer anisotropy.

index. It is known that fluorination reduces the refractive index and thus leads to less scattering. The same is true for anisotropy fluctuations which are pronounced in polymers with aromatic groups. In special cases like copolymers or polymer blends, additional inhomogeneities on the molecular scale have to be considered. They are very difficult to predict theoretically because of unknown interaction parameters and exact microscopic structures.

Unfortunately a complete fluorination seems to be impossible from a chemical point of view. Our investigations showed that completely halogenated monomers do not polymerize well. Two or three C–H or C–D groups have to remain in the molecule and therefore a realistic lower loss limit for existing fluoropolymers is in the 40–70 dB/km range.

2.2. Local Area Networks

In POF-Network-Systems the fiber loss is an important factor but the total flux budget also depends on the system configuration and the properties of the active and passive components.

In Figure 6a and b two basic network topographies, the tapped bus and the star bus are compared. Calculating the total path attenuation we consider the fiber attenuation, average connector losses of 1 dB, typical POF-coupler losses and also different LED-output powers for different data rates.

To simplify the calculations a circular arrangement of nodes has been assumed. In the tapped bus network the coupler losses are divided into the insertion loss, the tap loss and the coupling loss. Typical values for commercial taps are given in Table 2. The worst case of path loss can be calculated using the equation under Table 2, where α_c is the connector loss, α_f the fiber loss, and N the number of nodes.

In a passive star bus network the nodes are connected by polymer optical fibers via a star coupler (Fig. 6b). In this system we have a splitting loss due to the equal intensity

Table 2. Optical properties of the tapped bus network topography.

	Loss values of the tap	
loss	definition	value [dB]
Tap	$-10 \log (P_3/P_1)$	9
Insertion	$-10 \log (P_2/P_1)$	1
Coupling	$-10 \log (P_2/P_4)$	4

$\alpha_{TB} = \alpha_{coup} + 2 N \alpha_c + (N-2) \alpha_{in} + \alpha_{tap} + \alpha_f 2 \pi R$

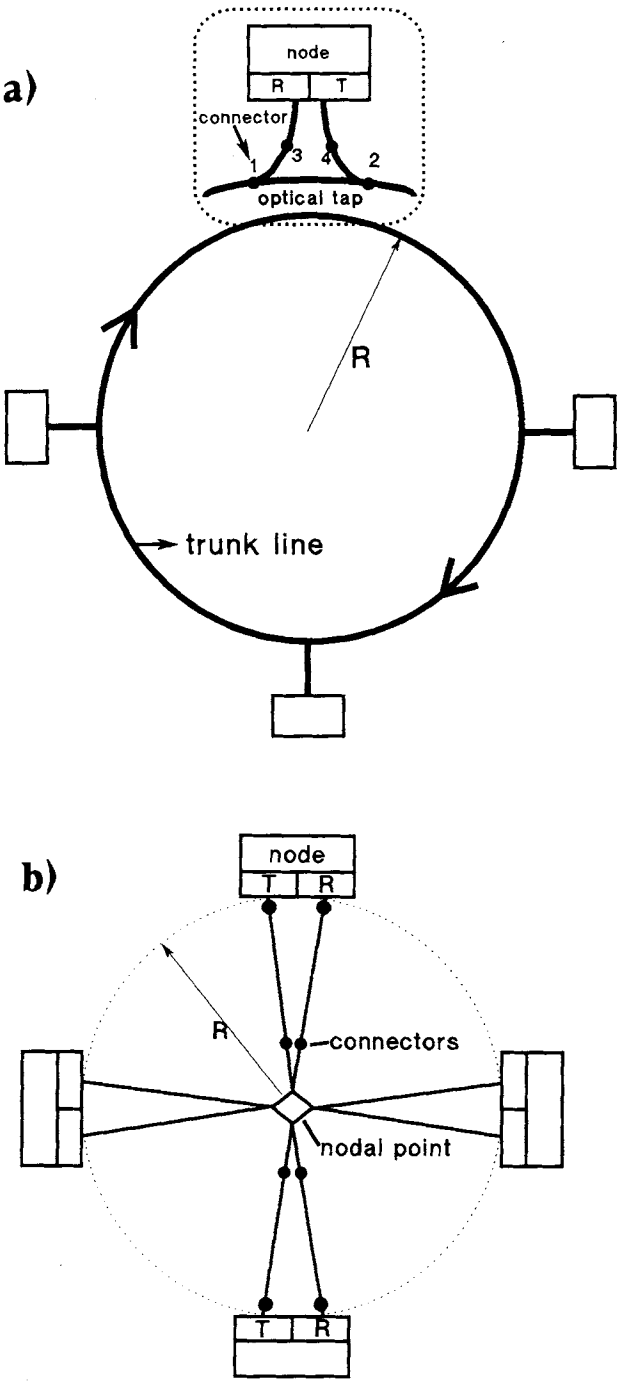

Fig. 6. Basic network topographies. a) Tapped bus network. b) Star bus network.

splitting to all nodes and an excess loss in the mixing region. The worst case of path attenuation can be calculated using the equation under Table 3. The system has four connectors, the excess loss depending on the number of nodes, the splitting loss which is 10 log N, and 2 R is the distance between an LED and a receiver. In a tapped bus the flux budget decreases linearly with the number of nodes, while for the star bus it decreases in proportion to the logarithm of the number of nodes.

ADVANCED MATERIALS

Table 3. Optical properties of the star bus network topography.

Loss values of the star		
nodes N	excess loss α_e [dB]	splitting loss α_{split} [dB]
2	1.5	3
4	2.5	6
6	3	7.8
8	3	9
10	3.5*	10

* extrapolated value

$\alpha_{SB} = 4\alpha_c + \alpha_e(N) + 10 \log N + \alpha_f \times 2R$

while for the star bus it decreases in proportion to the logarithm of the number of nodes.

Figure 7a shows the system budget for the tapped and star bus topography as a function of the number of nodes. The full lines correspond to a network radius of 2 meters, the dashed lines to 10 meters and the dashed-dotted lines to 50 meters radius. The horizontal lines at 16 dB and 28 dB indicate the flux ratio available for the network systems with 1.5 Mbaud and 40 Kbaud, respectively. The calculations were done for a PMMA fiber with 210 dB/km loss. Taking into account a system margin of 3 dB, only 3–5 subscribers can be connected via a star coupler in very local area networks like, for example, automobiles or robots. For short-haul, low data transmission, multinoded star-bus networks can be realized. Tapped bus systems only allow for low data transmission rates in networks of about 2 m size.

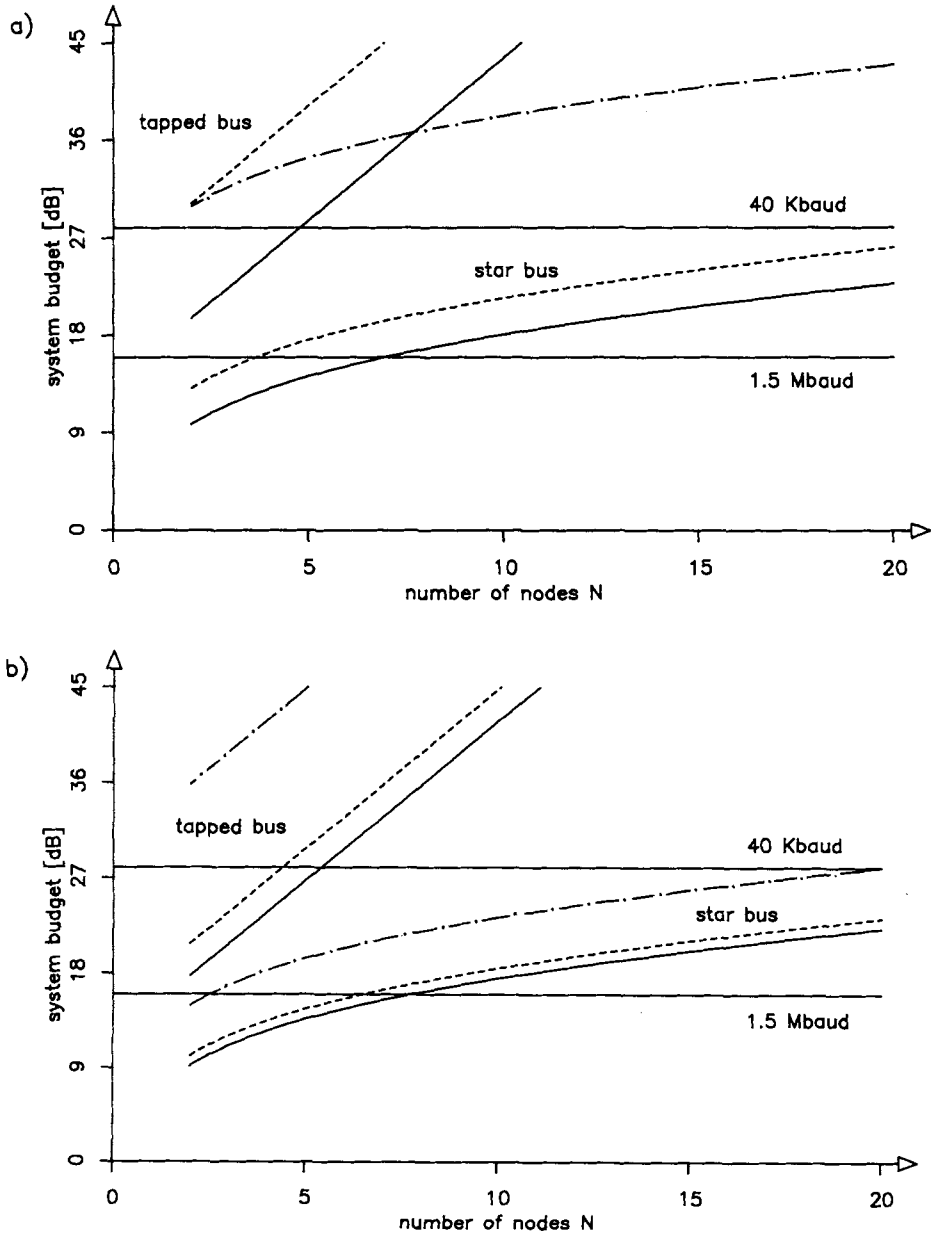

Fig. 7. System budget for tapped and star bus networks. a) Fiber loss: 210 dB/km. b) Fiber loss: 60 dB/km. The different network radii R = 2, 10, 50 meters are represented by full, dashed and dashed-dotted curves, respectively. The horizontal lines mark the assumed flux ratios of 28 and 16 dB for the indicated data transmission rates.

In very local area networks the system loss is mainly determined by the coupler losses and only to a much smaller degree by the fiber attenuation. For a radius of 2 meters, for example, the fiber loss contributes only 1 or 2 dB.

This can also be seen in Figure 7b, for which a fiber loss of only 60 dB/km was assumed. From the loss consideration explained above, 60 dB/km seems to be a realistic value for the loss of an optimized fluorinated polymer in the visible spectral region.

For very short distances the star bus system budgets do not differ significantly, due to the minor influence of the fiber attenuation compared to the coupler losses. For longer distances like 50 or 100 meters the improved fiber loss allows for multinoded star bus networks with a 40 Kbaud data rate, which is not possible with today's PMMA fibers. Even with a low loss fiber, high data rate applications can only be covered if not more than about 5 subscribers are connected. For tapped bus systems only very local area networks (2–10 m) with low data rates and not more than 5 subscribers are possible.

In conclusion a star bus system has the advantage of lower path attenuation, so a larger number of subscribers can be connected; it requires less receiver dynamic range, but the system has a larger overall fiber length. More complex systems can be made with a low loss fiber but the data rates have to be low and the system is still of limited size.

With the performances of the present active and passive components no complex high speed networks, working above 1 Mbaud, can be realized. To achieve a higher flux ratio improvements have to be made not only on passive components like fibers and couplers but also on transmitters and receivers.

3. Organic Materials for Nonlinear Optics

3.1. Basic Principles

The term "nonlinear optics" refers to effects which depend on quadratic or higher powers of the electric field strength. The interaction of an electric field $\vec{E}$ with a material can be described using a power series of the net polarization $\vec{P}$ of the material (Eq. 1).

$$\vec{P} = \vec{P}_0 + \chi^{(1)} \cdot \vec{E} + \chi^{(2)} : \vec{E}\vec{E} + \chi^{(3)} : \vec{E}\vec{E}\vec{E} + \ldots \quad (1)$$

$\chi^{(n)}$ is the nth order susceptibility which is a $(n+1)$th rank tensor. $\chi^{(1)}$ is responsible for the well known "linear" phenomenon of refraction. $\chi^{(2)}$, upon which we shall concentrate here, leads to quadratic effects such as optical second harmonic generation (SHG), parametric frequency mixing and the linear electro-optic effect. $\chi^{(3)}$ leads to such effects as intensity-dependent refractive indices and coherent anti-Stokes Raman spectroscopy (CARS).[10] Since the higher order susceptibilities are normally much smaller than $\chi^{(1)}$ nonlinear effects become noticeable only at high electric field strength, i.e. with lasers or with relatively high voltages over small distances.

In the mid-1970s it was discovered that certain types of organic molecules have much higher second-order nonlinearities and shorter switching times than the known inorganic materials such as potassium dihydrogen phosphate or lithium niobate.[11] The common characteristic of most such

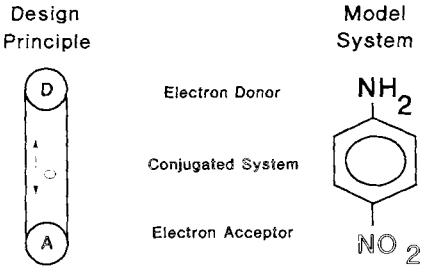

Fig. 8. Molecular design principle for high β species and the model system *p*-nitroaniline.

molecules is the presence of a conjugated π-electron system, providing easily polarized electrons, and donor and acceptor groups which provide the necessary asymmetry for second order effects. The design principles and a model system are shown in Figure 8. In organic systems one can thus speak of a *molecular* basis for the nonlinearity resulting from a polarization $\vec{p}$ of the charges in an individual molecule (Eq. 2).

$$\vec{p} = \vec{\mu}_0 + \alpha \cdot \vec{E} + \beta : \vec{E}\vec{E} + \gamma : \vec{E}\vec{E}\vec{E} + \ldots \quad (2)$$

where β and γ are the 2nd and 3rd order hyperpolarizabilities and μ_0 is the molecular dipole moment, although the absolute determination of these quantities presents considerable problems.[12]

A large value of β is not a sufficient condition for a high second order macroscopic susceptibility $\chi^{(2)}$, which is only non-zero for non-centrosymmetric systems. Furthermore the individual molecules should be aligned so that the individual nonlinearities add to each other as much as possible. β is related to $\chi^{(2)}$ through the relation (Eq. 3).

$$\chi^{(2)} = N\,\mathrm{F}\,\mathrm{D}\,\beta \quad (3)$$

where N is the density of nonlinear species, F stands for local-field correction factors and D stands for the effect of molecular orientation in converting from molecular coordinates and nonlinearity to macroscopic effects. Within the (sometimes questionable[13]) assumption that the molecular nonlinearity is dominated by the component β_{zzz} along the chromophore axis, a perfectly parallel orientation along the z-axis would for example lead to a maximum value of $\chi^{(2)}_{zzz}$. Of course such perfect orientations are practically nonexistent and can only be approximated.

Three main techniques are available to achieve a non-centrosymmetric orientation of the chromophores. One possi-

ADVANCED MATERIALS

bility is design of the molecule so that it crystallizes noncentrosymmetrically. High $\chi^{(2)}$ values and good quality single crystals have been achieved for several compounds,[14-16] and one can even buy organic frequency doubling crystals on the open market. However, the extension of organic crystal techniques to planar waveguided integrated optics devices is not straightforward and the crystal growth method does not seem to work for all chromophores.

Another technique is to put the chromophores into a polymer matrix, either physically (guest-host solutions) or chemically (side-chain polymers). The polymer is then heated to near the glass transition temperature and the (highly polar) chromophores are aligned by applying a high electric field ($\geq 10^5$ V/cm) across the polymer using either electrodes[17] or a corona discharge.[18] The polymer is subsequently cooled under continued application of the electric field to freeze in the orientation. This technique has the advantages of the flexibility of polymer processing techniques, chemical modification of polymer properties and the ability to make thin film waveguides of good optical quality. Limitations are the fairly low, Boltzmann-limited degree of order one can obtain in the poling field before dielectric breakdown and the tendency of the chromophores to relax after the electric field is removed, limiting the second order susceptibility one can attain in polymers for a given chromophore.

Susceptibilities well above that of the market leader for electro-optics, $LiNbO_3$, have been achieved with polymers which have been deposited in films, structured into waveguides and used to modulate light using the linear electro-optic (Pockels) effect. An example of such a device is shown schematically in Figure 9.[17,18] The active polymer with refractive index n_K, between cladding layers with n_M, forms a planar waveguide in which the optical electric field $\vec{E}(\omega)$ is confined through total internal reflection. An AC voltage is then applied perpendicular to the substrate and induces, through the Pockels effect, a modulation of the refractive index n in the active polymer (Eq. 4).

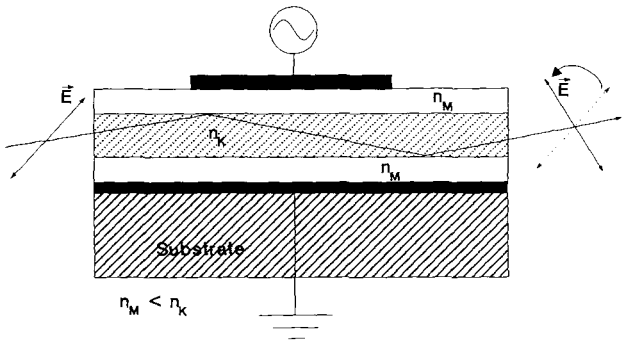

Fig. 9. Slab waveguide electro-optic modulator based on poled polymers.

The relationship between the Pockels coefficient Γ and $\chi^{(2)}$ is shown in Equation 5. The εs are the dielectric constants at the optical frequency ω and the much lower modulation frequency Ω. For light polarized diagonally to the substrate, i.e. coupled into TM (electric field perpendicular to the substrate) and TE (electric field parallel to the substrate) modes, the phase of the TM component relative to the TE mode is

$$(n^2)^{-1} = (n_0^2)^{-1} + \Gamma \vec{E} \tag{4}$$

$$\Gamma = \frac{2\chi^{(2)}}{\varepsilon(\omega)\,\varepsilon(\Omega)} \tag{5}$$

modulated. The resulting phase shift causes a rotation of the plane of polarized light; this polarization modulation can be converted to amplitude modulation by the addition of an analyzer after the device.

In order to take advantage of the fast switching times of organics and to design extremely high-speed modulators one must go to more sophisticated architectures which take the finite spatial extent of very short electrical impulses into account (so-called "traveling wave" electrode geometries). The NLO program at the Hoechst Celanese Corporation is

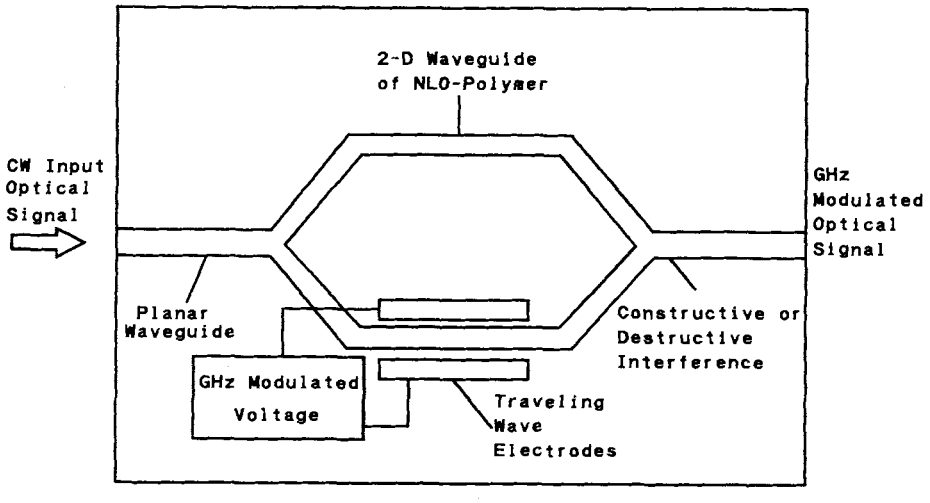

Fig. 10. Schematic representation of a polymeric Mach-Zehnder high frequency electro-optic modulator.

currently developing a multi-GHz traveling wave electro-optic modulator on the basis of a Mach-Zehnder interferometer[19] as shown in Figure 10. The microwave frequency electrical signal runs along a traveling wave electrode across one branch of the interferometer. Depending on the momentary voltage, one brings the two branches into or out of phase with each other, leading to constructive or destructive interference and thus direct intensity modulation of the light. Such devices are currently available based on $LiNbO_3$, but the ultimate attainable bandwidth is substantially less than that for organic materials.

3.2. NLO Active LB-Layers

Our investigations of nonlinear optical effects are focused on Langmuir–Blodgett (LB) films, which, due to their very high and often nearly ideal degree of order, yield the highest $\chi^{(2)}$ values measured to date,[20–22] but which are still at the stage of fundamental investigation. LB films with second order nonlinear optical properties are prepared using amphiphilic dyes, as shown in Figure 11, which contain a hydrophobic "tail", typically an alkyl chain, and a polar hydrophilic "head group", in NLO applications typically a donor-acceptor chromophore. A dilute solution of such species in a volatile solvent such as chloroform or methylene chloride is then spread onto a clean water surface in a film balance or "trough" (Fig. 12, top). After evaporation of the solvent (middle) the monolayer is compressed, leading to a highly oriented monolayer in which the head groups are next to the water surface and the tails are pointed away from it (bottom). This highly oriented monolayer can be transferred to a clean substrate a monolayer at a time, maintaining a high degree of order, by dipping the substrate through the interface into and out of the trough.

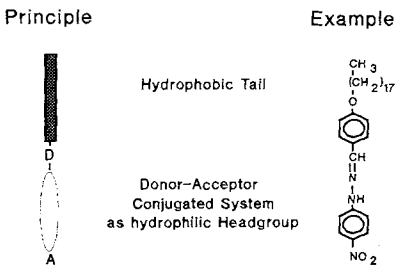

Fig. 11. Design of amphiphilic dyes for LB films with high second order optical nonlinearities.

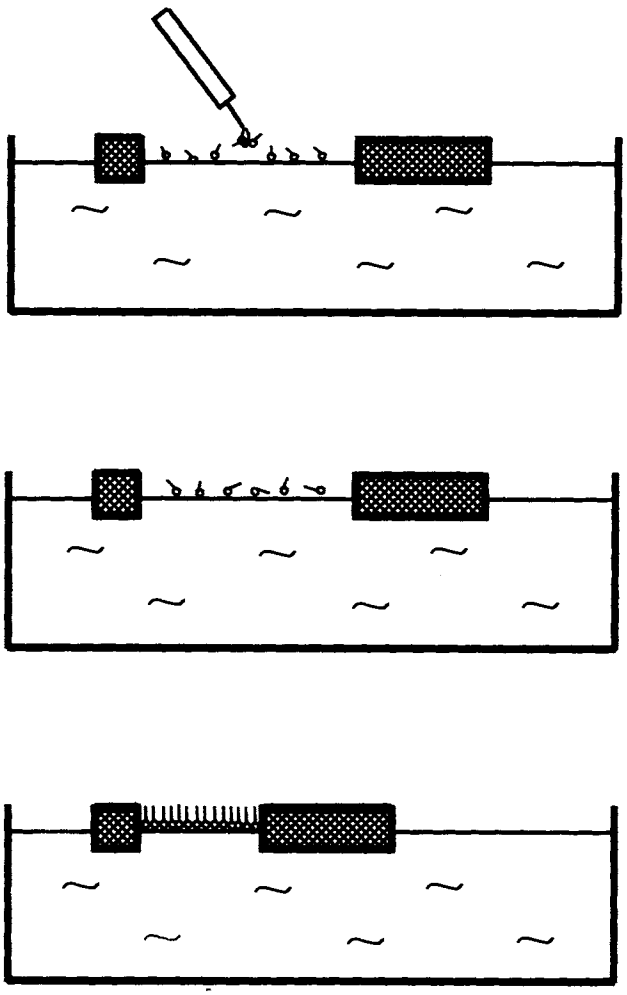

Fig. 12. Creation of oriented monolayers at the air-water interface.

By alternating an NLO active substance with a buffer layer (as shown in Fig. 13) or by alternating layers of molecules whose nonlinearities are in opposite directions with respect to the tails, using specially designed double well troughs, one can built up non-centrosymmetric multilayers with a high degree of order and thus very high susceptibilities. The exact control of film thickness (within the length of one molecule) and the possibility of film architecture on a molecular scale are two of the qualities which make Langmuir–Blodgett films promising for long-range applications in nonlinear integrated optics.

For fundamental studies of structure-property relationships and orientational phenomena, monolayers are practical model systems for study. The high susceptibilities of LB films lead to high signal to noise ratios even for a single

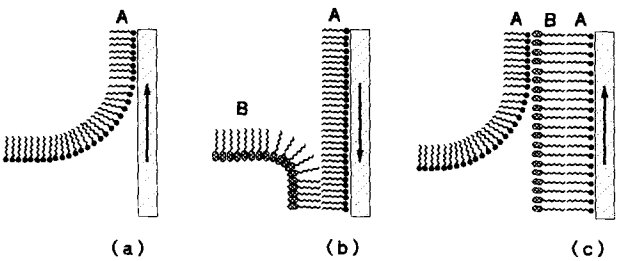

Fig. 13. Deposition of non-centrosymmetric Langmuir–Blodgett multilayers.

ADVANCED MATERIALS

monolayer. The experimental setup for studies of second harmonic generation in LB films is shown in Figure 14. The polarized beam from a pulsed Nd:YAG laser with a wavelength of 1064 nm is passed through the film deposited on a glass substrate, mounted on a rotation stage. Through the second order susceptibility of the film $\chi^{(2)}(-2\omega;\omega,\omega)$ a part of the laser light with circular frequency $\omega = 2\pi c/\lambda_0$ is converted to a harmonic wave at twice the frequency, i.e. with wavelength of 532 nm. The harmonic intensity, normalized by the intensity from a reference sample, is measured for different fundamental and harmonic polarizations as a function of incidence angle θ.

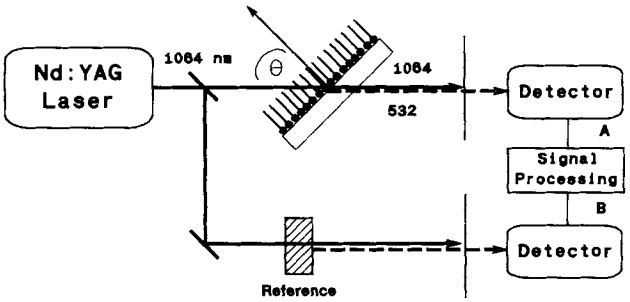

Fig. 14. Experimental apparatus for studying SHG in LB films.

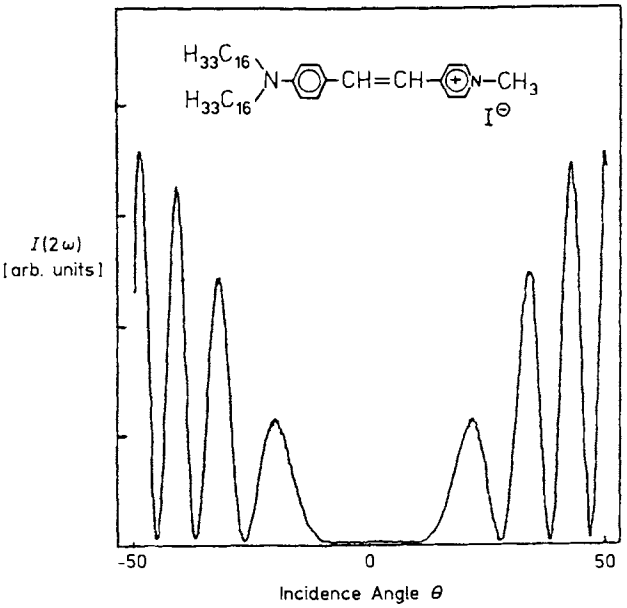
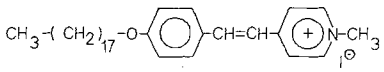
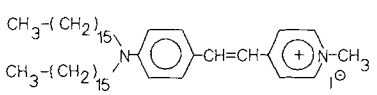
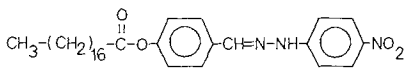
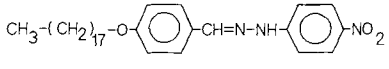
A typical curve for a monolayer of a highly nonlinear hemicyanine dye deposited on both sides of a glass substrate is shown in Figure 15. One sees a superposition of two angular dependences of the second harmonic intensity. The fast fringing pattern is indicative of samples in which the film is deposited on both sides of the substrate and is due to the dispersion in glass between ω and 2ω, which causes interference between the harmonic waves generated at the front and back surfaces of the substrate. A clean fringing pattern with near zero minima is a good indication of film homogeneity. The shape and height of the slowly varying envelope function depends on the orientation (position of intensity maxima) and the nonlinearity (the height of the curve) of the chromophores in the monolayers. The curve in Figure 15 is consistent with the common assumption that the chromophores are tilted from the substrate normal with a narrow distribution in the tilt angle φ and a statistical distribution in the azimuthal angle. Table 4 shows the nonlinearities and average tilt angles for several amphiphilic dyes which we have investigated.[20] $\chi^{(2)}$ is here a purely scalar quantity with all projection factors removed; the specific tensor components relevant to a particular experiment must be obtained through multiplication by the appropriate projection











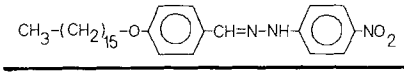


Fig. 15. Dependence of the second harmonic intensity on incidence angle for p-polarized fundamental and harmonic in a hemicyanine monolayer.

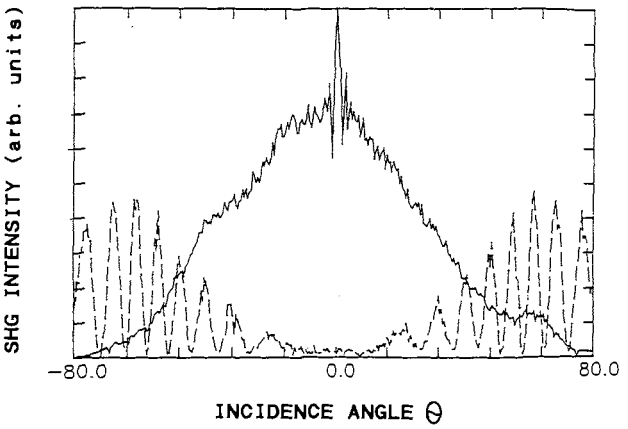
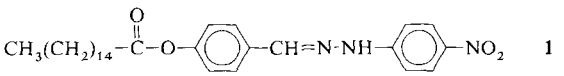
Table 4. Nonlinearities and average tilt angles for several amphiphilic dyes.

Structure	$X^{(2)}/10^{-6}$ esu	Ave. Tilt Angle/ °
	0.51	50
	6.25	50
	0.56	65
	1.80	60
	1.70	55

factors. For example, for a TM fundamental and a TM harmonic one would want $\chi^{(2)}_{zzz}$, which is in the simplest approximation given by $\chi^{(2)}_{zzz} \cong \chi^{(2)} \cos^3 \langle \varphi \rangle$.

Second harmonic generation can also be used as a probe of induced changes in orientation in LB films. Figure 16 shows two experimental SHG curves from measurements on the phenylhydrozone ester **1**, pure and diluted with acrylic acid *n*-octadecylamide.[23]





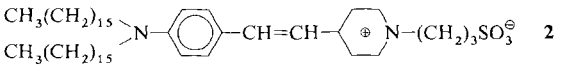


Fig. 16. SHG curves for monolayers of a phenylhydrazone ester, pure (solid line) and diluted with 40% acrylic acid *n*-octadecylamide (dashed line).

The curve for the pure dye is dramatically different from "normal" curves; the lack of fringes indicates poor sample homogeneity and the maximum intensity at normal incidence indicates that the chromophores are lying more or less flat. By diluting the dye with another amphiphilic species one can change the orientation drastically, improving the homogeneity and forcing the chromophores to "stand up".

In order to optimize deposited Langmuir-Blodgett films for nonlinear optics a better understanding of the nonlinear

1

2

optical properties of the monolayer films at the air-water interface is important. Second harmonic generation on reflection from the water surface can be used to monitor in situ the dependence of molecular orientation and nonlinearity on density, surface pressure, and relaxation and aggregation phenomena.[24] The experimental setup is shown schematically in Figure 17. The dependence of the reflected second harmonic intensity on the polarization of the fundamental and the harmonic is monitored as the film is compressed, expanded or held at constant pressure for a period of time. The second harmonic intensity for incidence angle θ is given by Equation 6.

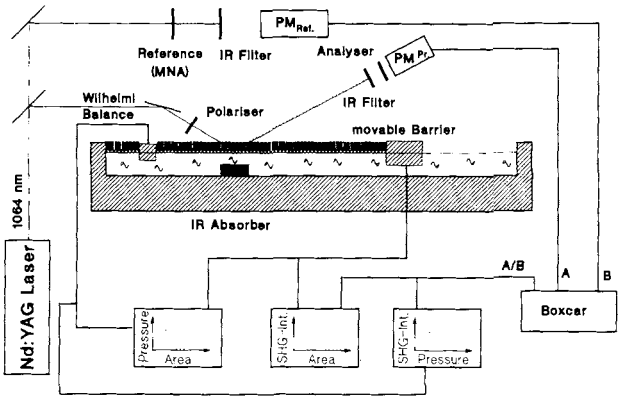

Fig. 17. Experimental apparatus for studies of SHG at the air-water interface.

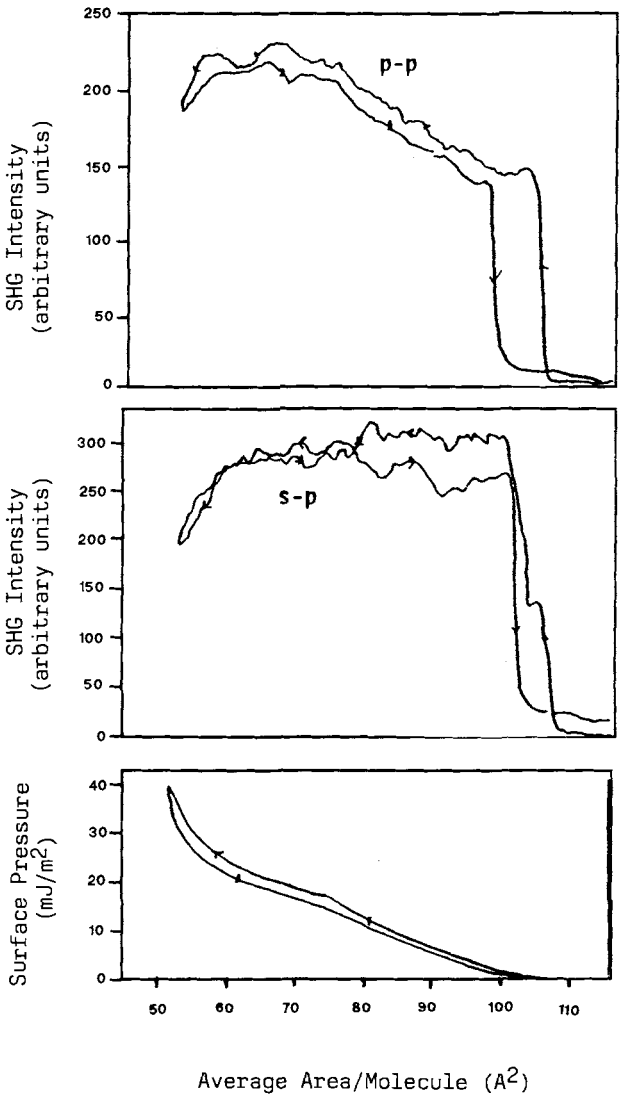

Fig. 18. Dependence of the second harmonic intensity from hemicyanine betaine **2** on water on surface area and the surface pressure-area isotherm. p–p: both fundamental and harmonic are p-polarized; s–p: fundamental is s-, harmonic p-polarized.

ADVANCED MATERIALS

$$I(2\omega) = \frac{32\, n^3\, \omega^3 \sec^2 \theta}{c^3} |\hat{e}(2\omega) \cdot \chi^{(2)} : \hat{e}(\omega)\hat{e}(\omega)|^2 I(\omega)^2 \quad (6)$$

where $I(\omega)$ is the intensity of the fundamental, the $\hat{e}$ are the polarization unit vectors for the fundamental and harmonic electric fields, c the speed of light and n the refractive index of the water substrate. The part between the modulus signs accounts for projection factors between fundamental, harmonic and the individual tensor components of $\chi^{(1)}$. Figure 18 shows the second harmonic intensity from the hemicyanine betaine **2** as a function of area per molecule. It is particularly interesting to note that the intensity does not increase significantly over the range of an almost twofold increase in density; in the absence of local field effects or orientational changes one would expect a fourfold increase in intensity over this range of surface areas.

4. Conclusion

A high susceptibility alone is of course not sufficient for applications of Langmuir–Blodgett films in nonlinear optics. Also necessary are high chemical and thermal stability, thick (a few hundred layers) films for planar waveguides with low loss coefficients and methods for forming structures in films without damaging their nonlinear optical properties. Progress has been made in each of these areas individually at Hoechst[25] and elsewhere.[26, 27] Combining all of these properties with high $\chi^{(2)}$ values is now the challenge.

Superconductivity at the Temperature of Dry Ice?

J. T. Chen et al. from Wayne State University and the Ford Motor Company recently repeatedly observed zero resistance at temperatures above 200 K in several multi-phase Y-Ba-Cu-O samples. They presented their results at the Third Annual Conference on Superconductivity and Applications held in Buffalo in late September. In the past, *Chen* and others have claimed to have seen evidence of superconductivity above 200 K, but up to now these phenomena turned out to be instable and generally vanished after a few thermal cycles. The key to the stabilization of the effect, *Chen* says, is a low-temperature oxygenation process carried out at temperatures between 50 and 150 °C in an O_2 atmosphere at 0.1 and 13 MPa for four to seven days. Samples were kept in an oxygen atmosphere during all measurements.

Chen et al. prepared samples of various compositions by conventional solid state reaction techniques, but only observed stable zero-resistance phenomena in samples having the nominal composition $Y_3Ba_6Cu_{11}O_y$. X-ray spectra of these samples showed $YBa_2Cu_3O_{7-x}$, Y_2BaCuO_5, and CuO as the predominant phases, but a small number of unidentified peaks were also seen. $YBa_2Cu_3O_{7-x}$ peaks showed preferential orientation with the *c*-axis perpendicular to the surface.

Chen's team determined resistance and current-voltage characteristics by cooling with liquid nitrogen or a mixture of dry ice and acetone. Zero resistance was found in several samples near 250 K. The zero-resistance phenomenon was observed over eleven days and for as many as 29 thermal cycles. Current-voltage characteristics show ohmic behavior at room temperature and an onset of nonlinearity in the range of 260 to 290 K. Magnetization measurements with a SQUID magnetometer did not reveal a complete Meissner effect, but *Chen* et al. observed small diamagnetic deviations and some hysteresis.

Although the findings of the team were well documented and measurements appear to have been done very carefully, there are still some questions that have to be resolved before one can be sure that the observed phenomenon is indeed superconductivity. The fact that zero-resistance was only seen in mixed-phase samples together with the extreme weak diamagnetic signal, could indicate some sort of grain boundary superconductivity, a suggestion *Chen* made in a paper scheduled for the November issue of *Modern Physics Letters B*. The oxygen environment of the samples, even during low temperature measurements, was clearly shown to be crucial, since the zero-resistance state vanished upon evacuating the oxygen atmosphere. It will be interesting to see whether these experiments can be reproduced by *Chen* and, even more importantly, by others.

ADVANCED MATERIALS

High-Performance Silicon Nitride Materials

Pressureless Sintering
Hot Isostatic Pressing
Sintering Aids
Powder Processing
Reinforced Ceramics
Silicon Slips

By Cornelia Boberski,* Rainer Hamminger, Marcell Peuckert, Fritz Aldinger, Reinhard Dillinger, Jürgen Heinrich and Jürgen Huber

Dedicated to Professor Wolfgang Hilger on the occasion of his 60th birthday

The past decade has seen greatly increased interest in ceramic materials with special combinations of properties. Their hardness, high resistance to abrasive and erosive wear, and their good corrosion resistance when used under extreme mechanical and thermal conditions have made ceramics increasingly attractive for applications in mechanical and apparatus engineering. Silicon nitride (Si_3N_4) in particular, is suitable for the development of a high-performance, high-temperature material for vehicle engine construction. Although the properties of Si_3N_4 materials have been consistently improved in the last few years, they are still not adequate to allow these materials to be used in series production parts, for example as valves in automotive engines. One of the main reasons for this is the wide scatter and low reproducibility of the property parameters, which means that component reliability does not yet meet market requirements. Hence, one aim of Si_3N_4 materials development is to reduce the structural flaws resulting from physical and chemical inhomogeneity. This objective can only be achieved through a fundamental understanding of all the processing steps, from powder production to the final processing of the components.

1. Introduction

Silicon nitride materials can be distinguished from one another by their composition and manufacturing technologies. Hot pressed (HPSN), pressureless sintered (SSN), reaction-bonded and post-sintered (SRBSN), hot isostatically pressed (HIPSN) and hot isostatically pressed post-densified reaction-bonded silicon nitride (HIPRBSN) all contain very small quantities of a second phase, which must be added as a sintering aid because of the high proportion of covalent bonding in Si_3N_4. In contrast, pure reaction-bonded silicon nitride (RBSN) is single-phased but still contains a residual porosity. This material is used successfully where chemical stability, rather than high strength, is of prime importance. If small amounts of sintering aids were added, the porous RBSN material then offers the possibility of post-densification and an increase in strength by means of hot isostatic pressing. On the other hand, dense silicon nitride materials are used wherever high strength is required, especially at high service temperatures.

However, the manufacture and utilization of ceramic materials can lead to difficulties. The thermal expansion, which is very low in comparison with that of metals, and the brittleness, i.e. the fact that it is impossible to reduce stresses by plastic deformation, require the especially careful design and handling of the manufactured parts. In brittle fracture, failure originates at defects that can arise during manufacture, processing, and also during application. The strength of the components is determined by the sizes and positions of the defects and by the fracture toughness and load. Consequently, strength is a probabilistic quantity that depends on the stressed volume. Failure always originates at a critical flaw in the specimen or component. These flaws in ceramics can be considered to be cracks, microcracks, pores, inclusions, grain boundaries or grain boundary phases and also structural inhomogeneities.

In developing high-performance Si_3N_4 materials it is necessary to avoid structural flaws $\geq 30\ \mu m$.[1] To achieve this goal, high-quality raw materials must be used and advanced processing applied where the optimization of each individual processing step is crucial. It must be assumed that the overall distribution of flaws in ceramic parts is the sum of different flaw distributions, each of which in turn represents a distribution with a specific physical content. Thus, the distribution of inherent flaws with small dimensions can adjoin or overlap processing, handling or randomly induced flaws, yielding the total observed technical distribution of structural flaws, and therefore the resulting technical range of strengths.[1] Consequently, to determine the probability of

failure of an engineering part, it does not suffice to test specimens of only one geometry and size (which is usually very small). Hence, efforts are now being made to test larger specimens and to replace the customary four-point bending test by the more suitable tensile test, because the stress distribution in the specimen is more uniform, and at the same time substantially larger volumes are involved.[2] To clearly show the possibilities for a further quality increase the following discussion will examine the especially promising Si_3N_4 materials SSN, RBSN and HIPRBSN more closely.

2. Pressureless-Sintered Silicon Nitride (SSN)

Because of the high proportion of covalent bonding in silicon nitride, and the associated low self-diffusion coefficient, and owing to its dissociation to silicon and nitrogen at relatively low temperatures, Si_3N_4 cannot be densified in the conventional way without the addition of sintering aids. Through the addition of certain sintering aids (see Section 2.3) a liquid-phase sintering process can be initiated, producing dense ceramic bodies.[3] Densification is strongly affected by the purity and fineness of the initial powders, processing methods, type and amount of sintering aids and sintering parameters.

The glass phase in the ceramic resulting from the liquid phase sintering process is responsible for the strength reduction at high temperatures (> 1000 °C), and therefore, the proportion of additives should be kept as small as possible.[4] In order to minimize the quantity of the liquid phase, high pressures and temperatures must be used during the sintering process. In gas-pressure sintering, the process is carried out under, for example, 100 bar of nitrogen, which counteracts any tendency of Si_3N_4 to decompose. Furthermore, sintering processes under applied pressure mechanically effect the densification of the residual porosity[5] and under optimal conditions lead to a compaction of the grains and hence high mechanical strength. However, the appearance of pronounced internal stresses due to this process must be regarded as critical.[6] The pressureless sintering process, on the other hand, has the major advantage that even large-volume and highly complex components can be produced in virtually their final form, meaning that no expensive finishing is required.

2.1. Powder Synthesis

The quality of the Si_3N_4 powder has a decisive influence on the properties and quality of the ceramic materials. The development of optimal powders requires the most comprehensive knowledge possible of the powder properties. Powders are characterized chiefly by their morphology, chemical composition and phase content. Table 1 shows the degree to which the properties of the powders affect their processing.[7] Sinterable Si_3N_4 powders of the type required for the production of high-performance ceramics must meet the following main requirements:

Table 1. Features of powder characterization.

Category	Characteristic	Dependent properties
Morphology	Grain size	Powder density
	Grain form	Free-flowing properties
	Agglomeration	Specific surface
	Grain size distribution	Homogeneity
Chemical composition	Main constituents	Surface properties
	Impurities	Dispersibility
Phase content	Degree of crystallization	Densification behavior
	α/β phase ratio	

- mean particle size in the submicron range (0.1 μm < d < 1 μm)
- narrow grain size distribution (but not equal-sized particles)
- equiaxial particle shape
- $\alpha/(\alpha + \beta)$-Si_3N_4 ratio > 95 vol.-%
- low oxygen content (< 1.5 wt.-%)
- low carbon content (< 0.2 wt.-%)
- low metallic impurities content (< 0.1 wt.-%)

There are four ways of obtaining Si_3N_4 powders: direct nitridation of silicon (A), carbothermal nitridation (B), thermal decomposition of silicon diimide (C) and gas-phase reaction (D). While the production routes A to C are already being exploited industrially, the gas-phase reaction has so far been carried out only on a laboratory scale. Very pure powders can be produced especially by the diimide process. Examples of typical grain size distributions of powders produced via routes A, C and D are shown in Figure 1.

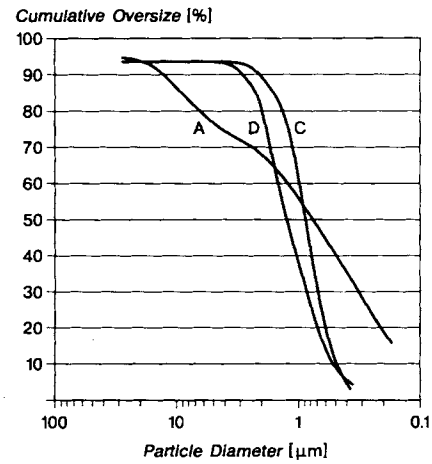

Fig. 1. Grain size distribution of silicon nitride powders produced by different methods: A: direct nitridation; C: diimide process; D: gas phase reaction.

The range between 0.1 and 1 μm for the average particle size is chosen in order to ensure a maximum green density[3] and low electrostatic forces.[7] The strength of the electrostatic attaction is determined by the synthesis process and the

post-treatment of the powders. However, the type of powder determines not only its agglomeration behavior but also its "deagglomeration" behavior in solution (dispersing behavior) which is important for molding by slip casting. Powder synthesized via route A can be very readily dispersed while it is considerably more difficult to disperse powders resulting from route C.

Figure 2 shows the mechanical strengths of sinter compacts composed of powders produced by different routes.

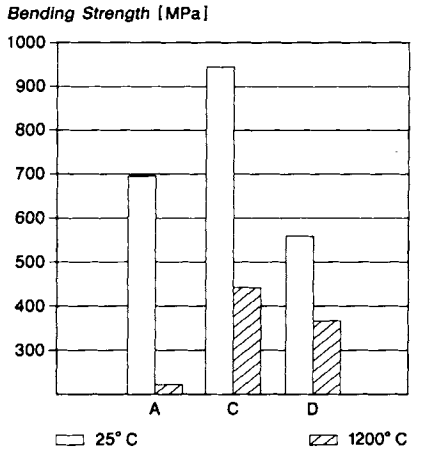

Fig. 2. Bending strength of ceramics composed of Si_3N_4-powders produced by different routes. A: direct nitridation; C: diimide process; D: gas phase reaction. α-Si_3N_4 powders were mixed with the sintering additives Y_2O_3, and Al_2O_3 in the ratio of Y_2O_3: Al_2O_3 of 2:1, and cold isostatically pressed and sintered in nitrogen at atmospheric pressure at 1800 °C. Strength was determined by the four-point bending test at 25 °C and 1200 °C.

Parts formed by cold isostatic pressing gave high strength at room temperature when powder C (diimide process) was used, which is characterized by high purity and very regular, equiaxial particles. In regard to the molding of parts from the powders, the powder type, the preparation methods and the molding processes must be very carefully adapted to one another.[8]

2.2. Powder Processing

During powder processing, the incorporation and homogeneous distribution of sintering aids, and the adjustment of a suitable grain size distribution of the mixed powders has to be achieved.

This is accomplished especially successfully by attritors or annular-gap ball mills. After the mixing and milling process, the preparation of agglomerates with a homogeneous particle distribution and appropriate shape follows. The drying and agglomeration of the mixture takes place in the spray dryer. After molding, either by cold isostatic pressing, slip casting or injection molding, any organic binder that may have been added must be removed. Finally, the high-temperature sintering process yields the densified ceramic component, which normally must be subjected to finishing work because of shrinkage imperfections and adhering firing skins. As an example of this production procedure, Figure 3 presents a typical processing sequence for the production of SSN components.

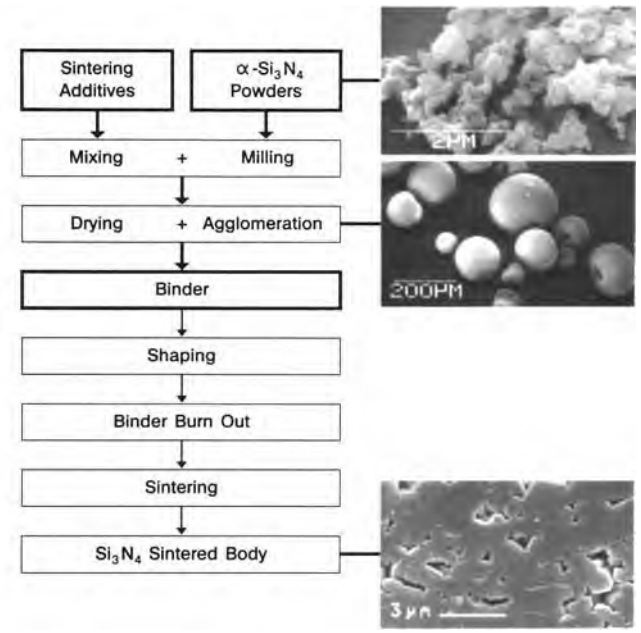

Fig. 3. Powder preparation and production of silicon nitride ceramics. (The introduction of raw materials is indicated by bold lines).

The experience of the last few years has shown that one of the major causes of failure of a ceramic component is the presence of foreign inclusions with diameters ≥ 30 µm. An analysis of these inclusions shows that even grains of dust can lead to the failure of ceramic components. Consequently, considerable efforts have been made to prepare the powder under cleanroom conditions in order to prevent contamination of the ceramic powder mixture with oversized dust particles. These facts are illustrated in Figure 4 with a typical structural flaw that is attributable to environmental contamination.

It must be pointed out in this connection that the results discussed in the following sections were obtained largely on materials that were produced under cleanroom (Class 3) conditions.

2.3. Reinforcement Concepts

The brittleness of ceramics is primarily caused by crack propagation. The objective of reinforcement concepts is, therefore, to increase the resistance of the microstructure to crack propagation.

ADVANCED MATERIALS

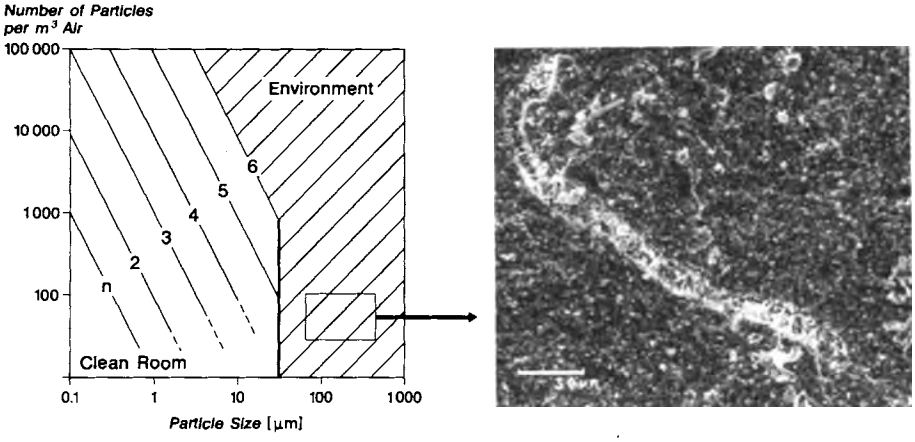

Fig. 4. Number and size of dust particles in different clean room classes. On the right, a fracture surface with a failure-initiating fault in a Si_3N_4 ceramic flaw can be seen. The flaw was caused by a dust particle of the kind found under normal environmental conditions.

The microstructure is determined essentially by the sintering aids which form a liquid phase during sintering. There are two possible types of sintering aids. First, oxides such as MgO, Y_2O_3 and Al_2O_3, which form amorphous or partially crystalline grain boundary phases because of their insolubility in Si_3N_4, and second, those which at suitable anion/cation ratios in Si_3N_4 lead to solid solutions (e.g. Be, Al).[9] In any case, the softening point, the viscosity and the amount of liquid phase are critical for densification and microstructural development. High viscosities always mean high aspect ratios of the precipitating β-Si_3N_4 grains.[4] This in turn acts to oppose good densification, meaning that these two mechanisms are frequently concurrent with each other. From the morphological point of view, good mechanical properties are best achieved by developing materials with high aspect ratios, with small mean grain sizes, low porosity and a minimal proportion of grain boundary phases. Below 1000 °C crack propagation under stress is influenced by different structural characteristics than at higher temperatures. Whereas at high temperatures strength is determined by the properties of grain boundary phases, at room temperature it is mainly the grain shape and size of Si_3N_4 that are decisive.[10]

In addition to specific structural development, two mechanisms essentially contribute to a reduction in crack propagation behavior at room temperature: first, crack deflection by mixed-in whiskers or fibers, or growth of in-situ whiskers or uniformly distributed micropores, and second, energy absorbtion by stress-induced phase conversion.[11] Most importantly, at high temperatures, the grain boundary slippage must be reduced by changing the chemical composition of the glassy phase and by the development of crystalline grain boundary phases.

Our own studies will therefore be presented below as typical examples of the reinforcement of SSN materials.

2.3.1. *In situ reinforcement by glass-forming additives*

Y_2O_3 and MgO have been the most often used sintering aids in the past. More recent work[12–14] has shown that the high-temperature properties in particular can be substantially improved by the use of oxides of the rare earth elements (RE*s*) as sintering aids. Therefore, Si_3N_4-powders have been mixed with various rare earth oxides and Al_2O_3 in a molar ratio of 2:1 (RE_2O_3: Al_2O_3 = 2:1).[15] The amounts used were chosen in such a way that in each trial the oxygen content contributed by the sintering additive was the same. In this way the influence of the rare earth oxides alone could be investigated. These powder mixtures were cold isostatically pressed and sintered under atmospheric pressure at 1800 °C.

In Figure 5 it can be seen that at room temperature as well as at high temperature the bending strength increases as the ionic radius of the rare earth oxides decreases.[16] Here the viscosity of the glass phases and the structural morphologies influenced by the rare earth oxides tend to counteract one another.[15] As a rule, densification can be improved by in-

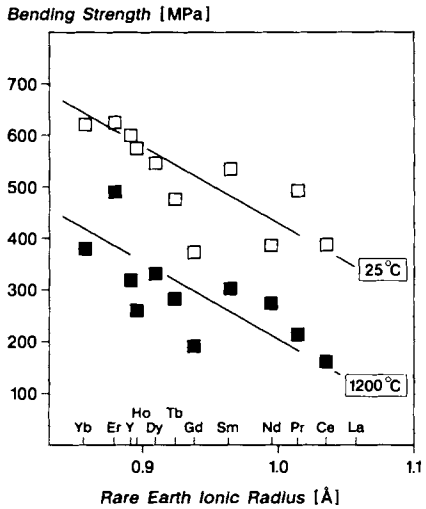

Fig. 5. In-situ reinforcement by the glass-forming intergranular phase. The Si_3N_4-powders were mixed with RE-oxides and Al_2O_3 as sintering aids (RE_2O_3:Al_2O_3 = 2:1). For specimen preparation compare the caption of Figure 2.

creasing the amount of additives with a lower melting point and lower viscosity[17] although exaggerated whisker growth can oppose densification. On the other hand, pronounced growth of elongated grains (Fig. 6) is very desirable in view of its reinforcement effect.

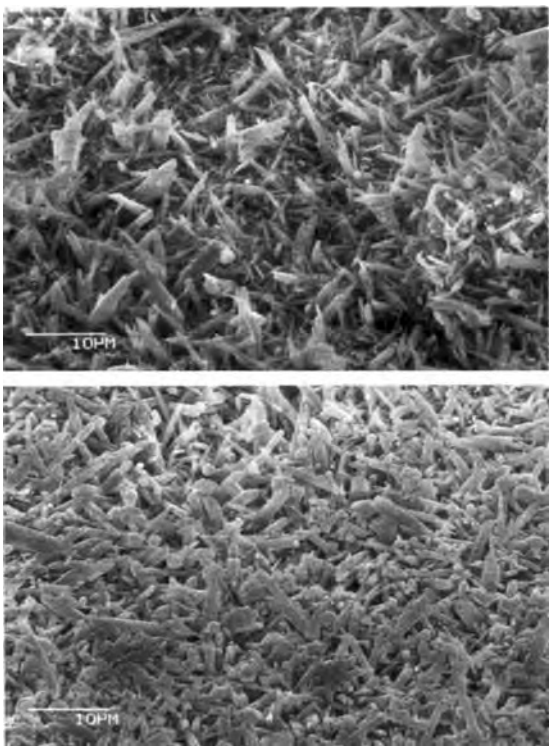

Fig. 6. Influence of the rare earths gadolinium (top) and dysprosium (bottom) on the growth of β-Si_3N_4 grains.

The higher the softening point of the glasses in the intergranular region, the more the grain boundary slippage will be prevented and the high-temperature strength improved. The exact composition of the glasses is not generally known. Probably, some nitrogen is dissolved in the glass phase. Studies of the Gd-Si-Al-O-N[18] and Nb-Si-Al-O-N[19] systems have shown that increasing substitution of nitrogen for oxygen in the glass network causes an increase in the glass transition temperature and a decrease of the thermal expansion coefficient. Possibly, the substitution of nitrogen is promoted by the incorporation of rare earth elements in the glass. Detailed studies with the help of advanced micro-analytical and surface analytical techniques,[20] are essential in verifying this interpretation.

2.3.2. *Crystallization of the amorphous grain boundary phases*

One further way of increasing the high-temperature strength is to crystallize the amorphous intergranular phase by tempering under nitrogen. Numerous investigations have been carried out on the Si_3N_4-SiO_2-Y_2O_3 system in order to study the crystallization of the glassy phase and its characterization,[21, 22] but rare earth oxides have also been investigated.[13, 14, 23] In further studies, the initial composition was again chosen in such a way that the ratio RE_2O_3:Al_2O_3 was exactly 2:1, i.e so that $RE_4Al_2O_9$ could crystallize. In practice, it was found that instead of $RE_4Al_2O_9$, mainly apatites $RE_5(SiO_4)_3N$, garnets $RE_3Al_5O_{12}$ and various silicate phases such as RE_2SiO_5 and $RE_2Si_2O_7$ crystallized at 1350 °C. When apatite was formed from any of the rare earth oxides the high-temperature strength was improved, while the crystallization of garnet and the silicate phases brought about only a slight improvement in strength.[16]

2.3.3. *Addition of dispersed crystalline phases*

The use of ZrO_2 as a sintering aid is known to improve the bending strength of Si_3N_4.[24] Apart from a minute glass phase fraction, ZrO_2 is present in the sintered structure as a crystalline intergranular phase. The strengthening mechanism of this Si_3N_4-ZrO_2 composite is based on a phase transformation mechanism, i.e. on the stress-induced change in the ZrO_2 from the tetragonal to the monoclinic modification, whereby the fracture energy can be absorbed.[25]

Since these mechanisms are effective only at temperatures below 1000 °C, trials were conducted with fully stabilized, cubic ZrO_2 and HfO_2. In these trials Al_2O_3 and Y_2O_3 were mixed with different proportions of HfO_2 and sintered at 1800 °C at atmospheric pressure. The proportion of Y_2O_3 was chosen to be so large that the cubic modification of HfO_2 is fully stabilized and, consequently, does not undergo a phase conversion on cooling.

Phase development during sintering is shown in Figure 7. The difference from a pure liquid-phase sintering process becomes very clear. The velocity of shrinkage is characterized by two maxima at about 1200 °C and 1400 °C (Fig. 7a). This shrinkage is accompanied by reaction of the sintering aids, formation of the glassy phase, and the phase transformation of Si_3N_4. The main shrinkage is associated with glass phase formation and α-β conversion of Si_3N_4.

Pure liquid-phase sintering is illustrated using the example of Y_2O_3/Al_2O_3 as the sintering aid (Fig. 7b). As soon as the additives react with one another, intergranular phases are formed which finally, at higher temperatures, are present only as a pure glassy phase. The α-β conversion of Si_3N_4 is associated with the formation of this glassy phase. After sintering, the original α-Si_3N_4-material has become β-Si_3N_4 with an oxinitride glass.

In contrast, the sintering aid HfO_2 remains crystalline but undergoes a phase conversion from the monoclinic to the cubic modification (Fig. 7c). It appears remarkable that this phase conversion is already concluded before the α-β phase conversion of Si_3N_4 takes place but seems to exert no influence on it. Thus, in addition to the β-Si_3N_4 grains and the glass phase with the constituents yttrium, aluminum, oxygen, silicon and nitrogen, the structure of the sinter compact

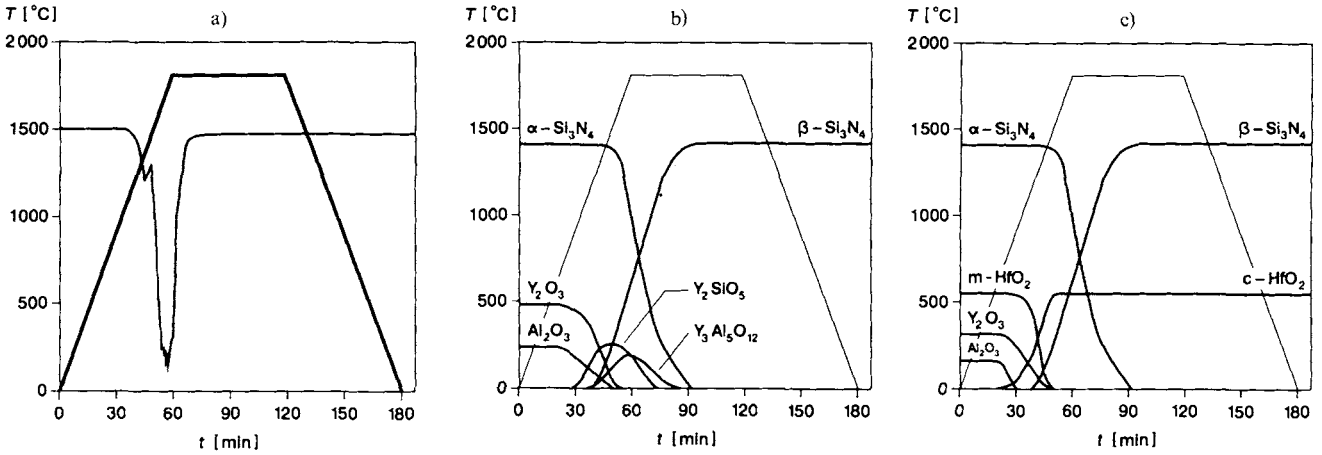

Fig. 7. Sintering behavior of Si_3N_4 with various sintering additives. The velocity of shrinkage is showin in (a) along with the sintering program (bold line): in 1 hour to 1800 °C, maintain for 1 hour; cool for 1 hour. 3. Reaction-Bonded and Hot Isostatically Pressed Reaction-Bonded Silicon Nitride

In contrast to the liquid-phase sintering process, in which the use of silicon nitride powders leads to a dense ceramic, in RBSN the ceramic is sintered making use of a gas-solid reaction between silicon and nitrogen. Ceramics which are produced in this way can be further densified by subsequent hot isostatic pressing.

3.1. Reaction-Bonded Silicon Nitride (RBSN)

Reaction-bonded silicon nitride is produced by the nitridation of moldings formed from silicon powder as shown in Equation 1.

$$3\,Si + 2\,N_2 \rightarrow Si_3N_4 \qquad (1)$$

The reaction in accordance with this equation can yield both the α- and the β-modifications. The accompanying volumetric expansion of approximately 22% leads in this reaction to a decrease in the overall porosity without any appreciable alteration in the outer dimensions of the specimen. The molding methods used include various pressing processes, slip casting, film casting and plastic processes such as extrusion and injection molding. After the molding aids are burned out, frequent presintering under an inert gas atmosphere follows. Following this step, the parts are strong enough to be worked (as graphite is worked) and in this way given their final shape. The moldings are then usually heat treated under nitrogen at atmospheric pressure and at temperatures between 1000 and 1450 °C. The attractiveness of this method lies in the minimal dimensional change which occurs during nitridation (< 0.1%), which means that no, or only minor machining of the final product is required. However, the components have a residual porosity of about 12%

to 30%, which has a strong influence on the mechanical properties.

The reaction between silicon and nitrogen is an exothermic process. The heat thus released can, because of an improperly programed temperature control, lead to excessive reaction rates and consequent local overheating. The result may be a melting of the silicon, which can bring the reaction to a standstill. No general rules governing the programing of temperature over time can be given for nitridation. However, the program depends on the furnace size, the amount of material being fired, the wall thickness of the parts, and the initial silicon grain size. The time required for complete nitridation can range from a few hours to several weeks, depending on the wall thickness. The maximum wall thickness that can be completely converted to silicon nitride is only approximately 30 mm, regardless of the length of the reaction time. For larger wall thicknesses the diffusion of nitrogen through silicon nitride becomes the rate-determining step, which causes the reaction rate to drop sharply.

In addition to the temperature control program, other nitridation conditions such as gas composition, gas pressure, temperature, time, and heating rate influence the course of the reaction and hence the structure and properties of this material.[4, 26] Whereas the molding process influences the packing density of the particles, the mean grain size and grain size distribution of the silicon powder, and the type and distribution of contaminants also affect the course of the reaction, and the structure and properties of RBSN.[27]

3.2. Hot Isostatically Pressed Reaction-Bonded Silicon Nitride (HIPRBSN)

Because of the relatively large shrinkage occurring during the densification of powder compacts, difficulties may appear during this process (contraction cracks, deformation), especially during the production of parts with complex shapes. For this reason RBSN with suitable sintering aids is also used as the starting material for hot isostatic pressing. In comparison with silicon nitride powder compacts the linear shrinkage here amounts only about 5–10%. The densification mechanisms are similar to those operating during the sintering of silicon nitride powder compacts. Pressure is applied to densify the material during the sintering process in order to accelerate the mechanisms responsible, such as particle rearrangement, diffusion, and plastic deformation. Pressure allows the amount of sintering aids to be reduced and improves especially the high-temperature strength. A reduction in the amount of sintering aids can also be achieved by crystallization of the amorphous grain boundary phase. Figure 9 shows a high-resolution micrograph of HIPRBSN, taken with a transmission electron microscope (TEM), showing a fully crystallized grain boundary phase: Y_2O_3 and Al_2O_3 were used as sintering aids.

The densification of RBSN by hot isostatic pressing permits the production of parts with narrow tolerances without,

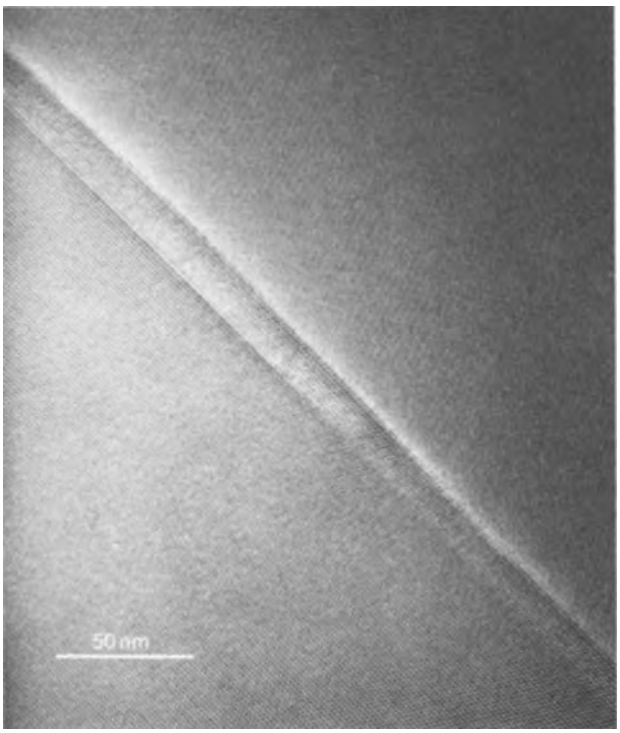

Fig. 9. TEM image of HIPRBSN with crystallized intergranular phase.

or with only minor machining being required. Furthermore, in comparison with conventional hot pressing, the uniform transmission of pressure results in isotropic material properties. Through the application of pressures up to more than 3000 bar, influence can be exerted on the densification behavior and grain growth and hence the optimization of material properties.[27] Below, the production of parts made of HIPRBSN is described in detail, with the slip casting of silicon powder in an aqueous system being used as the molding method, on which detailed reports have already been published.[28] In the first stage of slip development the silicon-water and silicon-sintering aid-water phase systems were investigated.

3.2.1. Hydrolysis in the silicon-water system

The addition of silicon powder to water should lead to intensive hydrolysis due to the normal electrode potential of the reaction shown in Equation 2.

$$Si + 2\,H_2O \rightarrow SiO_2 + 2\,H_2 \qquad (2)$$

The potential is strongly negative ($E = -0.875$ V), but silica is formed on the powder particle surface which produces a passivation layer which is insoluble in acids, thus preventing corrosion in acid media. Alkaline solution, however, can destroy the passivation layer according to Equation 3.

$$SiO_2 + 2\,OH^{\ominus} \rightarrow SiO_3^{2\ominus} + H_2O \qquad (3)$$

To characterize silicon hydrolysis, the amount of hydrogen formed was measured as a function of time at different pH values (Fig. 10).

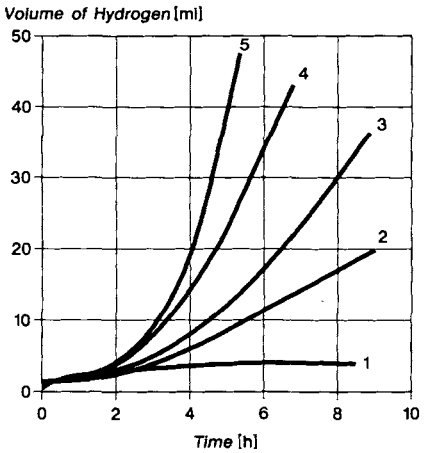

Fig. 10. Generation of hydrogen by the hydrolysis of silicon powder (50 wt.-%) in aqueous suspension plotted vs. time at different pH values: (1) pH = 2.4; (2) pH = 6.2; (3) pH = 10.0; (4) pH = 11.0; (5) pH = 12.0.

The higher the pH of the dispersion, the greater is the volume of hydrogen formed per unit time. Under strong alkaline conditions and at higher temperatures, the silicon is quantitatively decomposed, a reaction that is also used analytically for the determination of free silicon in SiSiC. In practice, it has been found that pH values above 9 are needed for the production of silicon slips.

3.2.2. *Viscosity of silicon slips*

Whereas at higher pH values hydrolysis of silicon powder can be observed, the usability of silicon slips under acid conditions is limited by a strong pH dependence of the slip viscosity. Towards the lower pH values the viscosity of the silicon powder dispersions increases sharply (Fig. 11).

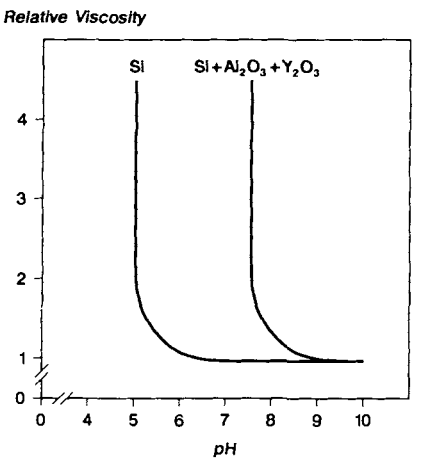

Fig. 11. Relative viscosity of an aqueous suspension with and without sintering aids as a function of pH (66.7 wt.-% solids; viscosity using Lehmann viscometer at pH 7).

Accordingly, below a certain pH-value the viscosity is too high to measure and therefore such dispersions are totally unsuitable for casting. The pH value at which the viscosity sharply rises depends on the powder concentration. At 75% powder content in the suspension it lies at pH 6, at 66% powder content at pH 4.5, while at 50% no such rise in viscosity can be observed down to a pH value of 2. To explain this phenomenon, reactions on the surface of the powder particles in the aqueous medium must be more closely examined (see 3.2.3.).

In summary, the pH range for preparing highly concentrated, chemically stable silicon slips of sufficiently low viscosity is limited to between 5 and 9.

3.2.3. *Surface reactions*

An analysis of silicon powders shows a silica content of about 1.5–2.0%. The silica forms a thin layer on the silicon particles and therefore the chemical behavior of the surface of silicon powder in water should be comparable with that of silica.

This behavior can be described as follows. Exposure to water leads to surface hydroxylation, enabling acid or base reactions to take place as shown in Equations 4 and 5.

$$\text{Si-OH} + \text{H}_3\text{O}^{\oplus} \rightarrow \text{Si-OH}_2^{\oplus} + \text{H}_2\text{O} \quad (4)$$

$$\text{Si-OH} + \text{OH}^{\ominus} \rightarrow \text{Si-O}^{\ominus} + \text{H}_2\text{O} \quad (5)$$

Silica is an acidic oxide, the reaction according to equation (5) can be expected to be dominant over a substantial range of pH values. That is the reason for the observation of a marked decrease of the pH when silicon powder is added to a basic solution. The reaction of the hydroxide ions with the silanol groups of the silicon surface reduces the $OH^{\ominus}$ concentration. The extent of this pH decrease depends on the specific surface of the dispersed particles and the degree of surface hydroxylation.

The following experimental finding can also be explained with equation (5). Over a wide range of pH values the zeta potential and hence the surface charge of the silicon particles is negative. For all powders examined, the particles were charged negatively at a pH greater than 2; this value represents the so-called "isoelectric point". At pH values higher than 2 the negative surface charge increases steadily, reaching its maximum at ca. -60 mV at a pH of around 7 (Fig. 12), and then remains constant up to higher pH values.

The zeta potential has an important influence on the state of particulate dispersion in suspensions.[30] Increasing surface potential generates an electrostatic barrier which prevents both contact between the individual particles and the formation of larger agglomerates of particles. The higher surface charge and the resulting electrostatic repulsion between the dispersed particles improves the properties of the dispersion, the viscosity is lowered and sedimentation decreases.

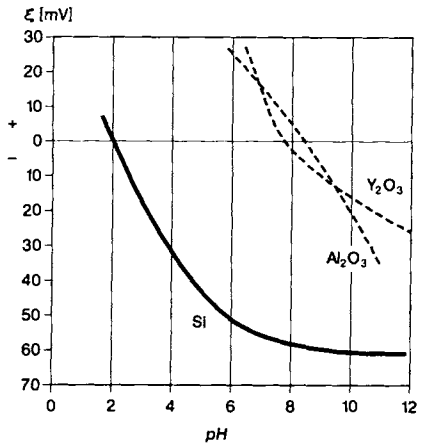

Fig. 12. Zeta potential (ζ) of silica, alumina and yttria powder particles in aqueous suspension as a function of pH.

3.2.4. *Addition of sintering aids*

The addition of the sintering aids Y_2O_3 and Al_2O_3 to an aqueous silicon suspension substantially influences the properties of the slip. Considering the importance of the surface charge to the sedimentation behavior, the viscosity, and the state of powder dispersion, the zeta potential of these powders was measured as a function of the pH value of the suspension (Fig. 12). For yttria the isoelectric point lies at a pH of ca. 8, the surface being charged positively at lower and negatively at higher pH values. Qualitatively the same result is observed for alumina powder dispersions with an isoelectric point at a pH of 8.5. Since the analogous point for silicon powder dispersions lies at a pH of 2, opposite signs of the surface charge of the components are observed in the pH range between 2 and 8.5 in aqueous suspensions of a mixture of these powders. This should lead to a higher viscosity of the slips because of the forces of electrostatic attraction. This assumption has been confirmed by experiment. For example, it is not possible to obtain a dispersion that contains all three powder types in an adequate concentration through mixing of the powders in distilled water (pH = 6.5). Because the silicon powder lowers the hydroxide ion concentration in alkaline dispersions, the initial pH must be chosen about three units higher than the desired final pH. The dependence of the relative viscosity of the sintering aid slip on pH has already been shown in Figure 11. The limit for the preparation of low-viscosity slips lies at pH 7.5.

3.2.5. *Material properties*

On the basis of the studies presented above, castable, low-viscosity and chemically stable slips can be prepared and cast. Depending on the silicon powder used, the densities of the slip cast and completely nitrided components lie between 2.40 and 2.65 g/cm^3. Subsequent densification is carried out in a high-pressure autoclave using nitrogen as the pressure transmission medium. For gas pressures at around 200 MPa the densification temperature lies at about 1800 °C. Holding times at the final temperature and the maximum pressure depend on the properties of the starting material. The linear shrinkage of the densified components is between 7 and 10%, depending on the initial density, much smaller than for other comparable sintering processes.

Figure 13 shows the distribution of four-point bending strengths in specimens cut from HIPRBSN sheets that had been produced by slip casting. The high Weibull modulus of $m = 23.42$ indicates that a structure with a very homogeneous distribution of flaws that could initiate failure can be achieved by the slip casting technique. Its strength exhibits a value of $\sigma_0 = 651$ MPa. It is possible to raise the strength of these materials through improvements in powder preparation that are especially designed for the purpose. A strength of 750 MPa with a Weibull modulus of 12 for isostatically pressed specimens could be achieved.

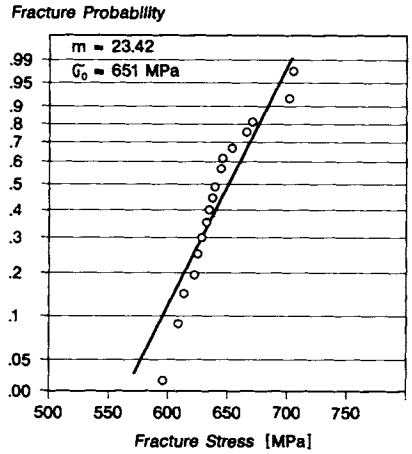

Fig. 13. Strength distribution of HIPRBSN slip cast moldings.

4. Conclusions

The results discussed in this report have revealed concepts that enable a fundamental improvement in the material properties of silicon nitride, such as the crystallization of the glass phase or the reduction in flaw frequency by using slip casting as the molding method. Additionally, these results demonstrate the different possibilities provided by the various processing methods for controlling material properties, component dimensions, shape, and production costs, etc. Although the process techniques for SSN and RBSN are fundamentally different, basic knowledge about the influence of the type and amount of sintering aids or the crystallization of the glassy phase can be applied to both types of material. Examples have been given here in order to show how basic knowledge can be expanded from findings in one subarea. These findings also clearly show that the powder preparation, the molding process or the sintering method

cannot be considered in isolation. In contrast, the individual steps of overall production must be adapted to one another. Thus the powder properties determine the suitability of the powder for a specific molding technique. That means that the developer of high-performance ceramics must be given the opportunity, as early as possible, to scale up his work in order to be able to incorporate the processing steps into the materials development with the help of parallel (and particularly nondestructive) testing methods.

Spatially Selective Conducting Patterns in Transparent Films Derived from Ladder Type Polymers**

By *Igal Belaish, Dan Davidov*, Heny Selig, Malcolm R. McLean*, and *Larry Dalton*

Conducting patterns can be created in the insulating pristine ladder type polymer films BBL and BBB (see Fig. 1) by spatially selective heating using laser annealing. The conducting regions consist of cross-linked, stable, ladder polymers. Subsequent fluorination leads to conducting patterns embedded in a completely *transparent* film. These features may lead to a variety of possible applications.

In the last decades there has been significant progress in the synthesis, processing, and characterization of rigid rod polymers.[1] A few examples of such polymers are shown in Figure 1. These polymers have exceptional properties such as high tensile strength and modulus.[2, 3] They are stable at

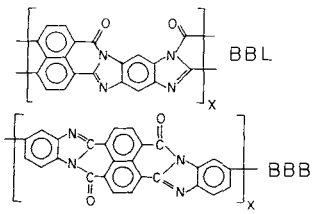

Fig. 1. Examples of ladder type polymers.

elevated temperatures (which may exceed 600 °C) and may be processed into fibers or highly packed films with excellent planar arrangements.[2] The conductivity of these rigid rod polymers can be controlled by thermal pyrolysis.[4]

Particularly, BBB polymer undergoes a phase transformation at a temperature T_p of 680 °C to a new ladder type polymer with high intrinsic conductivity.[4] Exposure of

pristine BBB (and BBL) to fluorine leads to a colorless, transparent material, while the heat treated polymers ($T_p > 700\,°C$) are hardly affected by fluorination.

The synthesis and processing of BBB and BBL has been described previously.[1] In this work we have used free standing films as well as films on glass substrates, both having thicknesses of about 20 μm. These films exhibit excellent planar arrangement of the polymer chains as shown by the large anisotropic resistivity $\varrho_\perp/\varrho_{||} \cong 1000$. Here $\varrho_\perp$ and $\varrho_{||}$ are the resistivities perpendicular and parallel to the film, respectively. Films of BBB are shiny brown and exhibit a room temperature in-plane conductivity σ_{RT} of 10^{-9} S/cm and an optical energy gap of approximately 1.8 eV.[5, 6]

Heat treatment of ladder type polymers changes the conductivity dramatically. Figure 2a shows the in-plane room temperature conductivity, σ_{RT}, for BBB subsequent to heat treatment at a temperature T_p ($200° \leq T_p \leq 1000\,°C$) for several minutes in a vacuum oven. As clearly seen, the room temperature conductivity changes by 10 orders of magnitude and reaches a value of 30 S/cm for $T_p = 950\,°C$. Even higher in-plane conductivities were achieved for polymers with better in-plane ordering. This change in conductivity is associated with a $\sim 30\%$ weight loss[7] and color changes. The highly conducting films are silvery-gray and stable in air.

A most dramatic change in conductivity (Fig. 2a) occurs for a pyrolysis temperature near $T_p \cong 680\,°C$. Indeed, a plot

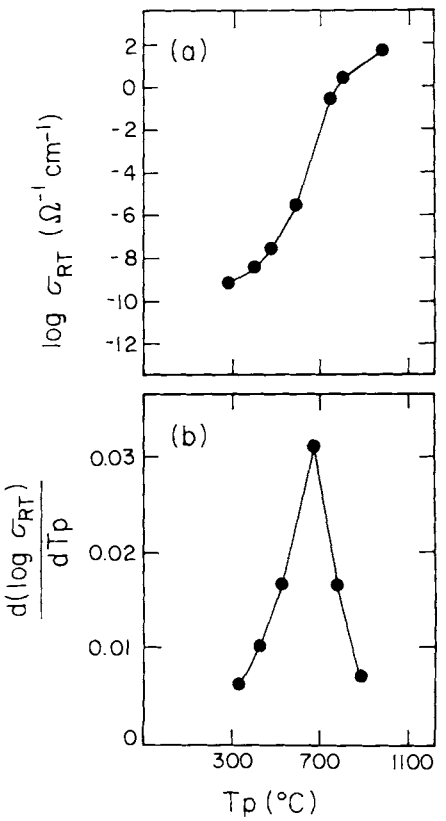

Fig. 2. a) The room temperature conductivity (but after annealing at T_p) vs. pyrolysis temperature T_p. b) A plot of $d(\log \sigma_{RT})/dT_p$. Note maximum at $T_p = 680\,°C$.

of $d(\log \sigma_{RT})/dT_p$ vs. T_p (Fig. 2b) shows the clear maximum at $T_p = 680\,°C$. We take this maximum as evidence for a transformation to a cross-linked network. Other evidence for such a phase transformation is provided by ESR studies[4] which indicate a clear maximum in the spin-density for $T_p \cong 680\,°C$. Photoluminescence measurements also suggest that the high temperature conducting, condensed aromatic structure is a different ladder polymer with a smaller band gap (1.4 eV).[8]

Pristine BBB and BBL were exposed to about 400 torr F_2 at room temperature. After exposure for several hours the brown shiny polymers became transparent and colorless. Optical absorption studies indicate that the energy gap is larger than 3.2 eV in the fluorinated material.[8] Infrared spectra of the product show strong absorptions in the C–F stretching region as well as absorptions in the 2900–3000 cm^{-1} range indicating the presence of C–H bonds. Weight uptake measurements (Table 1) using a Sartorius

Table 1. Weight uptake of pristine BBB and BBL.

material	initial weight (mg)	weight increase (mg)	F/BBL (BBB)
BBL	6.40	6.0	16.4 ± 0.5
	6.92	6.1	15.5 ± 0.5
	3.80	3.4	15.7 ± 0.5
BBB	12.26	13.5	23.6 ± 0.5
	12.40	12.7	22.0 ± 0.5
	7.49	7.0	20.1 ± 0.5

Magnetic Suspension Balance indicate that BBL and BBB take up about 16 and 22 fluorine atoms per monomer unit, respectively. This is exactly the number of aromatic carbon atoms per monomer unit (see Fig. 1) for BBL and BBB, respectively, suggesting formation of C–F bonds and partial or full conversion of the conjugated system to a saturated one. Exposure to air leads to a yellow transparent film after several days. The fluorinated materials are soluble in water, giving a yellow solution. Heat treated polymers ($T_p < 600\,°C$) also become transparent upon fluorination. However, *conducting polymers, heat treated at $T_p > 700\,°C$ are almost unaffected by exposure to fluorine* and retain their high conductivity and absorbance after exposure for several days. Exposure to higher fluorine pressure for longer periods converts the silvery-brown conducting polymers into a more bluish, rather than a transparent material. This shows that polymers heated above 700 °C exhibit different structures. In a few cases we found that fluorination of films which had been heat treated at around $T_p = 680\,°C$, may lead to transparent films with enhanced conductivities relative to pristine BBL and BBB.

The properties described above can be used to form spatially selective conductive patterns in a completely transparent film. This is achieved by shining laser light ($Ar^{\oplus}$, 2 watt/cm^2) through a metal mask or a slit onto the BBB insulating

ADVANCED MATERIALS

film on a glass substrate for several seconds. Figure 3a shows a series of embedded "conducting lines" of approximately 0.5 mm thickness in insulating BBB films treated in this way. The conductivity of these lines is approximately 50 S/cm. The conductivity of the shiny-brown polymer background remains unaffected by the laser heating. Using this masking technique, we can produce conducting lines approximately 10 μm in width (width is determined by the slit, laser focusing and exposure time). The pattern shown in Fig. 3a is stable in air and upon subsequent heating to 200 °C. We assume that laser annealing affects the polymer mainly through heating, so the "conducting lines" are composed of cross-linked polymers with the properties described above. Upon exposure to fluorine, the "conducting lines" remain unaffected, but the remaining pristine BBB becomes completely transparent and colorless. Figure 3b pictures this new structure consisting of "conducting lines" in a transparent material. This structure is stable in a humidity-free environment.

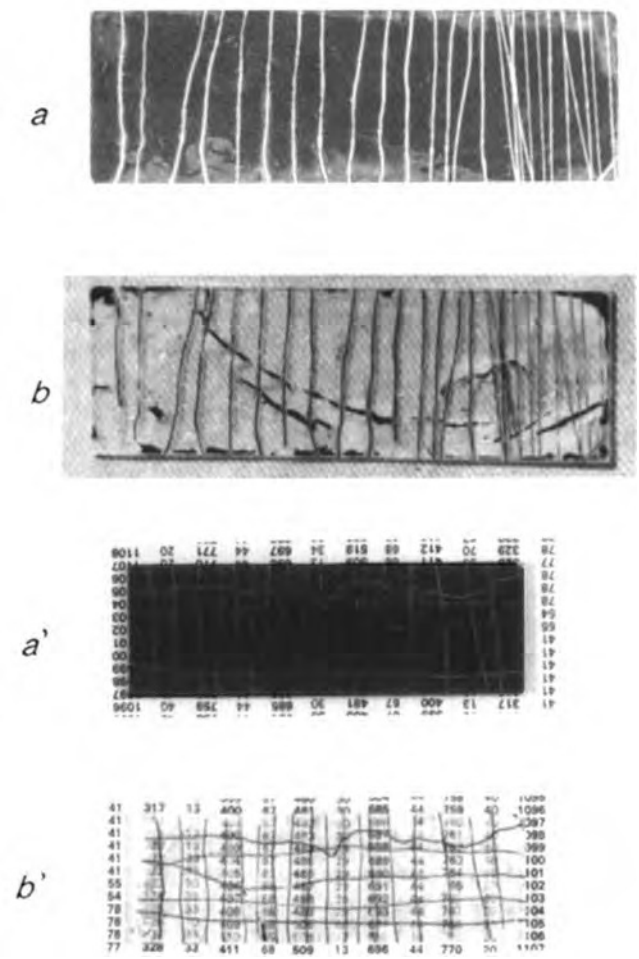

Fig. 3. a) "Conducting Lines" produced by the laser annealing technique in BBB polymer. The conducting lines are shiny-silver and reflect light and thus appear more bright in photo. a') Fine conducting lines produced by laser annealing of BBB. b) After fluorination: The "conducting lines" in a transparent film. b') Same as a', but after fluorination. (Numbers in background shown to emphasize degree of transparency).

We have now preliminary evidence that the heating and fluorination process affects other rigid-rod polymers as well. The transparent films so produced are optically anisotropic and less affected by humidity. The fluorination of polyacetylene was published recently[9] but in this case the fluorinated material is white rather than transparent.

The possibility to produce highly aligned transparent films with anisotropic optical properties and particularly the generation of spatially selective conductive patterns in insulating aligned transparent polymers opens new routes for applications in fields such as lithography, microelectronics, optics and molecular electronics. For instance, "writing" using selective laser heating and eliminating the rest of the film by fluorination and washing (using water or other solvents) might be important in both lithography and microelectronics. The fabrication of very fine grids composed of fine alternate stripes of conducting and transparent polymers with anisotropic optical properties is another interesting possibility. Optical disks should be considered as well. Generally speaking, the possibility to fabricate miniature conducting microstructures with novel electronic properties is now more realistic.

recently polyalkylanilines,[2] have had a large impact on the study of conductive polymers. Soluble polymers can be more fully characterized and more easily processed. Despite intensive study and synthetic effort, there are few tractable or soluble conjugated derivatives of polyacetylene.[3, 4] Substitution of polyacetylene via the polymerization of substituted acetylenes results in materials with low effective conjugation lengths, as evidenced by their high-energy visible absorption spectra and comparatively low iodine-doped conductivities.[5] This low conjugation length is presumably due to twisting around the single bonds in polyacetylene resulting from steric repulsions of the side groups[6, 7] (Fig. 1).

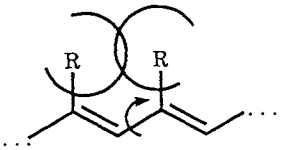

Fig. 1. Chain twisting in substituted polyacetylene.

Recently, *Klavetter* and *Grubbs* reported the synthesis of polyacetylene by the ring-opening metathesis polymerization[8] (ROMP) of cyclooctatetraene (COT).[9, 10] Here we report the ROMP of substituted cyclooctatetraenes: a route to a variety of highly conjugated, partially alkyl-substituted polyacetylenes. These polymers have a substituent on the average every eight carbons, rendering some of them partially soluble. Polymerization can be accomplished in a few minutes in a nitrogen drybox, resulting in free-standing films which are generally gold, shiny, and flexible.[11]

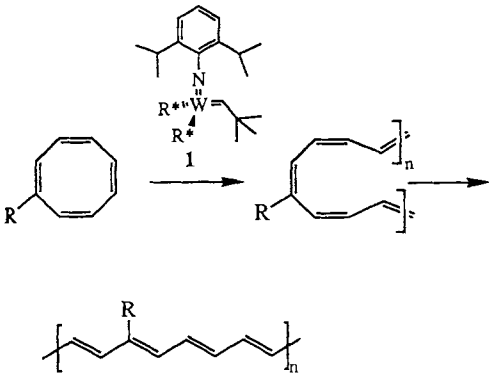

Fig. 2. Polymerization of Cycloocatatetraene Derivatives. R* = $(CF_3)_2(CH_3)CO$; R = Me, *n*Bu, octyl, octadecyl, Ph, *t*Bu, neopentyl.

These films can be iodine doped to a conductive state (Table 1). Moreover, in contrast to poly-cyclooctatetraene (polyacetylene) which shows large optical scattering losses due to its crystallinity, the alkylCOT polymers are amorphous and show low scattering losses.[12, 13]

[a] Based on the molecular formula $(C[H/R]I_y)_x$. [b] Spectra taken in tetrahydrofuran. Wavelength in nm. [c] Very small amount of material that leached out of the film.

Whereas poly-methylCOT, like polyacetylene, is somewhat brittle and completely insoluble, films of poly-RCOT with straight chain alkyl substituents of at least four carbons are flexible and partially soluble in solvents such as tetrahydrofuran (THF) and dichloromethane. When a film of poly-*n*-butyl-, poly-octyl- or poly-octadecylCOT was stirred with THF, a red/brown solution resulted that contained 1–2 mg/mL of polymer, and which turned blue upon standing overnight. Solutions stored under argon at −50 °C in the dark did not turn blue. We propose that the color change is due to an increased electron delocalization arising from the *cis* double bonds in the nascent polymer isomerizing to give a material with predominantly *trans* double bonds, although aggregation phenomena cannot be ruled out at this time.[14] Similar changes have been observed in the optical spectra of films of polyacetylene,[15] and the related poly-trimethylsilylCOT.[16] Also, red-shifts in the absorption spectra of short polyenes upon *cis-trans* isomerization have been observed by *Schrock* and coworkers.[17] If not diluted at least tenfold before isomerization, 1–2 mg/mL solutions of the *cis* polymer gelled or precipitated. The predominantly *cis* isomer of these polymers is soluble whereas the *trans* isomer is much less so. This observation is consistent with previous observations on oligomeric polyenes.

Nascent poly-neopentylCOT was completely soluble, but also precipitated upon isomerization to the *trans* form if not diluted. Blue suspensions that resulted from the isomerization of concentrated solutions, however, were recast into gold films that displayed iodine-doped conductivities two orders of magnitude higher than the original material. The aromatic side-chain derivative poly-phenylCOT was about as soluble as poly-*n*-butylCOT in the *cis* form, but was almost completely insoluble in the *trans* form. Poly-*t*-butylCOT was freely soluble but was yellow-orange in color, indicating a low effective conjugation length. Thus, modifications to the polymer backbone which increase its solubility seem to reduce its conjugation length.

Gel permeation chromatography on solutions of the "*cis*" polymers indicated that the solutions contained high molec-

ADVANCED MATERIALS

ular weight materials (Table 2) although molecular weight distributions were very broad in several cases. The retention times of the polymers generally increased after isomerization, suggesting an increase in hydrodynamic radius.

Table 2. Molecular weights.

polymer	M_n	M_w
Poly-*n*-ButylCOT	33200	153400
Poly-OctylCOT	35900	369000
Poly-*t*-ButylCOT	58300	71900
Poly-NeopentylCOT	23400	27100
Poly-PhenylCOT	30600	121100

The polymers were examined by ^{1}H NMR and Raman spectroscopy. The NMR spectra of all the polymers showed broad multiplets between 6 and 7 ppm and broad signals in the regions expected for the side groups, indicative of a polymeric, olefinic chain. Raman spectroscopy provided further evidence of a conjugated chain. Two peaks, assigned as the A_g C-C stretch (ν_1) and A_g C=C stretch (ν_2) in *trans*-polyacetylene were observed in all the spectra (Table 3), except for that of poly-phenylCOT, which displayed a complicated

Table 3. Raman stretching vibrations of polyacetylene derivatives (cm^{-1}).

polymer	ν_1	ν_2
Polyacetylene[18]	1090–1120	1470
Poly-MethylCOT	1126–1132	1516
Poly-*n*-ButylCOT	1132	1514
Poly-OctylCOT	1114–1128	1485
Poly-*t*-ButylCOT	1147	1539–1547
Poly-NeopentylCOT	1131	1509

spectrum dominated by phenyl stretches. No peaks were seen that corresponded to the *cis* form of polyacetylene, probably since no precautions were taken to prevent isomerisation caused by the 488 nm laser light. In unsubstituted polyacetylene the infrared C-H stretching vibrations at 740 cm^{-1} and 1015 cm^{-1} are diagnostic for *cis* and *trans* material, respectively. The infrared spectra of the substituted polyacetylenes are not as useful, since the vibrations of the side chains obscured those of the main chain.

Several attempts have been made to correlate the effective conjugation length of a polyene with its absorbance maximum. Based on the extrapolation of polyene absorption data obtained from a variety of workers[19, 20] to the band gap of polyacetylene,[21] the *trans* form of these polymers have an effective conjugation length of at least 25 double bonds. Lower energy absorption maxima are seen in the solid state. A thin film of poly-octylCOT has a broad absorption centered around 650 nm which is comparable to that observed for a thin film of native polyacetylene.[21]

In summary, ROMP of alkyl-substituted cyclooctatetraenes produces polyacetylene derivatives in which the substituents are placed at a sufficient distance apart to allow conjugation along the backbone of the polymer and still provide for solubility in the *cis* configuration. Work is underway using the RCOT/ROMP methodology to develop other polyacetylene derivatives which are more soluble, more conductive, and air-stable.

Experimental

Polymerization was effected by adding 50–150 equivalents of the liquid monomer to 1–2 mg of the tungsten alkylidene catalyst [22] dissolved in a minimum (200 μL) of pentane and 1–2 μL of THF. After the yellow solution began to turn orange/brown, it was transferred by pipette onto a glass plate and allowed to harden into a film over the course of an hour or so. Films were peeled from the plate and used for conductivity measurements. Doping was accomplished by exposing the films to iodine vapor for 3 to 6 hours in a previously evacuated chamber followed by pumping (<0.01 torr) for approximately one hour to remove excess iodine. Films exposed to iodine immediately became blue-black in color and remained flexible. Conductivities were measured using a four-point probe in a nitrogen drybox or a four-wire probe attached to a Schlenk line. [23] Similar conductivities were seen using both methods.

Monolayers and Langmuir–Blodgett Multilayers of Discotic Liquid Crystals?

By André Laschewsky*

1. Discotic Liquid Crystals

Discotic liquid crystals[1] were discovered in 1977. They are formed by disk-shaped molecules, i.e. typically by large planar aromatic, or by rather inflexible macrocyclic moieties, surrounded by a number of flexible so-called "wing groups". A selection of discotic liquid crystals (LCs) is shown in Figure 1.

Discotic LCs exhibit columnar mesophases which distinguish them from the well-known calamitic (rod-shaped) LCs. These columnar phases are characterized by stacks of the disk-shaped cores, packed in various ways.[1]

2. Monolayers and Langmuir–Blodgett Multilayers

Ordered monomolecular layers are formed by the self-organization of water-insoluble amphiphilic molecules at the gas-water interface.[3] The standard amphiphiles used for monolayers have a polar head group and one or two hydrophobic chains, e.g. fatty acids or phosphatidylcholines respectively. Under appropriate conditions, the monolayers of many amphiphiles can be transferred successively onto solid substrates, by dipping the substrate vertically or horizontally

through the monolayer.[3, 4] If the ordered monolayer structure is retained during the transfer process, these so-called Langmuir–Blodgett (LB) multilayers are characterized by molecularly defined thickness, defined anisotropic arrangement of the amphiphiles within the layers, and defined surface structure (Fig. 3). Therefore these ultrathin organic

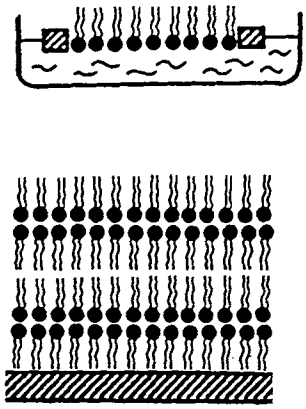

Fig. 3. Scheme of monolayers and Langmuir–Blodgett multilayers.

films are valuable systems for scientific studies, and many potential technical applications have been proposed.[4, 5]

The formation of monolayers is not restricted to standard amphiphiles. In principle any combination of the number of head groups and of hydrophobic chains is possible. Thus with hydrocarbon wing groups and polar cores, many discotic LCs meet the criteria of amphiphiles, even if they appear to be rather exotic. In fact, in the search for functionalized monolayers and multilayers, many rigid disk-shaped molecules have been investigated since the 1930s, in particular porphyrins and phthalocyanines.[3–5]

3. Theoretical Considerations on the Molecular Packing of Discotic LCs in Monolayers and Multilayers

The major interest in monolayers and LB-multilayers of discotic LCs derives from their "exotic" molecular shape. It is speculated as to whether this shape can modify the self-organization at the air–water interface to produce thin films of new structure. Perhaps, with a combination of liquid crystalline behavior and amphiphilic self-organization this can be achieved, as proposed in the concept of "amphotropic systems".[6] These ideas are illustrated in Figures 4 and 5.

When spread on the water surface, discotic LCs can orient in two extreme arrangements called "side on" and "edges on". With the wing groups acting as hydrophobic chains, four types of arrangements of the discotic LCs must be considered which are referred to as types A, B, C and D.

Through the deposition of the monolayers, four types of LB-multilayers of different structure can be produced, corresponding to the monolayer arrangements A–D.

Type A arrangement preserves the conformation of the discotic LCs in the bulk columnar phase, reduced to two-dimensions. Deposition of such monolayers, with the discotic cores of subsequent layers in register, would lead to columnar LC phases with molecularly defined heights of the columns[7] (Figs. 4a, 5a).

Type B arrangement (Figs. 4b, 5b) corresponds to classical amphiphilic behavior, as the disk-shaped core represents the polar part of the molecule. In this case, the conformation deviates considerably from the one in the bulk LC phase. The amphiphilic character is dominant. Deposition of type B monolayers produces the sandwich bilayer structure of classical LB multilayers, i.e. a structure similar to the smectic mesophases of rod-shaped LCs. Hence in bulk, unknown smectic phases of discotic LCs may be obtained via self-organization due to their amphiphilic character.

The "edge on" arrangements C and D imply that intermolecular interactions between the disk-shaped cores take place. In the special case of type C, strong interactions are required as some hydrophobic wing groups have unfavorably close contact with the water (Figs. 4c, 5c). That is, the discotic LC character of the molecules dominates the amphiphilic character. Such strong interactions may cause the

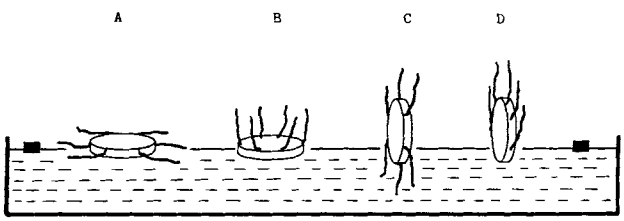

Fig. 4. Possible arrangements of discotic LCs at the gas–water interface: A = side on, chains random, B = side on, chains oriented, C = edge on, chains random, D = edge on, chains oriented.

discotic cores to form stacks, as seen for columnar mesophases (Fig. 2). If such "floating columns" are aligned in the monolayer, two-dimensional nematic columnar mesophases could be formed. If, however, such columns are deposited in register to LB-multilayers, thin columnar phases are produced where the columnar long axis is parallel to the surface of the support (Fig. 5c).

Type D arrangement (Figs. 4d, 5d) represents the compromise between self-organization due both to the amphiphilic and the discotic character. At the same time the interaction of the hydrophobic wing groups with water is small, whereas the interaction between the disk-shaped cores is fairly strong. As discussed for type C, type D arrangement would enable the formation of "floating columns" of the disks, with the possibility of two-dimensional nematic mesophases. Deposition of type D monolayers would create a novel hybrid structure of simultaneous columnar and smectic character (Fig. 5d).

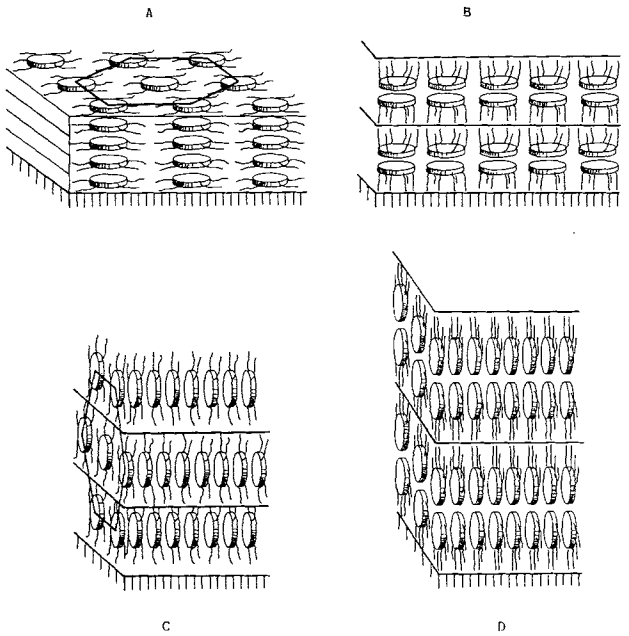

Fig. 5. Hypothetical structures of Langmuir-Blodgett multilayers obtained from discotic liquid crystals: A = side on, chains random, B = side on, chains oriented, C = edge on, chains random, D = edge on, chains oriented.

The monolayer and multilayer structures presented in Figs. 4 and 5 are only hypothetical, representing the "ideal cases". Intermediate or less ordered arrangements are possible, and three-dimensional aggregation may successfully compete with monolayer formation. Nevertheless, the possibility of designing such ordered structures of molecular dimensions is intriguing.

In addition to the unique structural combinations of liquid crystalline and amphiphilic structures, multilayers of many discotic LCs will be useful from the classical point of view as well. They could provide the particular properties expected from large non-liquid crystalline disk-shaped amphiphiles, e.g. improved thermal stability and conductivity or photoconductivity.[4, 5] In fact, the presence of the wing groups around the disk core in the discotic LCs will be an advantage in improving the solubility in the spreading solvents and probably decreasing the tendency to form microcrystallites at the gas–water interface.

4. Spreading Experiments with Discotic LCs

Up to now there have been only a few reports on spreading experiments with discotic LCs.[7–10, 17] Unfortunately, much of the experimental data available is ambiguous and therefore the conclusions drawn may be disputable. In general, surface pressure vs. area diagrams alone are not sufficient to determine the monolayer structure. Additional analysis, e.g. by ellipsometry, fluorescence microscopy, polarized UV/Vis/IR-spectroscopy, X-ray scattering or electron diffraction is required. Comparisons with the more plentiful investigations on non-liquid crystalline amphiphiles with disk-shaped moieties, e.g. porphyrins[11] and phthalocyanines, may prove to be helpful, but many of those results are also controversial.

Despite all shortcomings in monolayer experiments and their discussion, the present data suggest that extended hydrocarbon wing groups and strongly polar groups favor the "side on" arrangement of the disks, i.e. classical amphiphilic behavior, as observed for compound **6**.[10, 17] In contrast, weakly polar groups and rather short wing groups apparently favor "edge on" arrangements.[8] However, if the wing groups get too short, and the interaction of the disks too strong, three-dimensional crystallization may occur, as found for compound **2**.[12] In fact, the preferred arrangement of a discotic LC seems to depend on a subtle balance in the molecular architecture. The spreading behavior of the triphenylenes **2** and **3** may serve as such an example.[8] Thus, appropriate molecular design may allow us to control the type of self-organization in the monolayers.

5. LB-Multilayers of Discotic LCs

Reports on LB-multilayers of discotic LCs[8–9, 12] are even rarer than monolayer studies. As many of the monolayers are very stiff, deposition by the LB-technique can be difficult to achieve.[9] Successful transfer has been reported for triphenylenes **3** and **4**.[8] The presence of Bragg diffraction peaks in the X-ray data of the deposited LB-films (rarely observed in multilayers of disk-shaped amphiphiles) demonstrates an ordered layered structure, exemplifying the usefulness of discotic LCs for LB-multilayers. Their detailed structure is not yet clear, although the X-ray data of these triphenylene multilayers points to different types of arrangement of the discs such as type B for **4** and C for **3**.[8]

Interestingly, optical in-plane anisotropy has been observed in LB-multilayers of some phthalocyanines,[13, 14] supporting a two-dimensional nematoid arrangement of columnar stacks (implying types C or D). However, such in-plane anisotropies have recently been reported for the monolayers and multilayers of many amphiphiles,[5] and thus seem not to be unique for disk-shaped amphiphiles. The explanation of the in-plane anisotropy is still controversial.

6. Polymeric Discotic LCs

Because of the scarcity of data on low molecular weight discotic LCs, it is difficult to predict how polymeric discotic LCs will behave. The spreading behavior of classical polymeric amphiphiles is more complicated than that of their corresponding monomers,[3, 6] and this will also be true for the spreading behavior of monomeric and polymeric discotic LCs. If monolayer formation is still possible, a stabilization of the "edge on" arrangement of the disks may be expected. In particular, stack formation could be enhanced using a central polymer backbone.[15] However, with little data available,[12] it seems premature to discuss in depth the spreading of polymeric discotic LCs.

An alternative way to tailor "edge on" arranged monolayers may be the formation of charge-transfer complexes. The enhanced formation of molecular stacks and columnar mesophases by charge-transfer complexation has recently been shown in bulk discotic LCs,[16] and perhaps this method can be transferred to monolayers of discotic LCs.

7. Summary

The field of monolayer and multilayer films of discotic LCs is at its very beginning. The scope and limitations of this preparation method have not yet been explored, and little is known about the structures obtainable. However, the potential access to extraordinary, ordered thin films is fascinating, and will stimulate research in the future.

Surface Analysis I

Imaging Surfaces, Electric Charges and Magnetic Domains with the Atomic Force Microscope

By Jürgen P. Rabe*

The atomic force microscope (AFM) provides a means to record images of surfaces on the atomic length scale.[1, 2] It is closely related to both the scanning tunneling microscope (STM) and the stylus profilometer, combining atomic resolution with the ability to image insulating materials. In the AFM an ultrafine tip is mounted on a small lever and brought into close proximity of the sample (Fig. 1). For high resolution imaging, the force between tip and sample is measured sensitively by the deflection of the lever, using either electron tunneling or some optical detection scheme. As the tip is scanned across the sample, a contour map of constant force can be recorded. For true non-contact imaging at lower lateral resolution, a shift in the resonance frequency of the lever is detected, giving contours of constant force gradient. The key feature of the AFM is its ability to measure extremely small forces. In order to achieve this, the lever has to be as soft as possible. At the same time, it should have a high resonance frequency in order to minimize its sensitivity to vibrational noise from the environment. The solution to this is miniaturization. Indeed, with microfabricated levers and an optical detection system, a force sensitivity of the order of 10^{-9} N in water and 10^{-7} N in air has been achieved.[3] The number of forces contributing to the net force are manyfold, ranging from hard core repulsion at very small distances through van der Waals attraction and capillary forces to long range electrostatic and magnetic forces. In practice there exists a balance of several contributions.

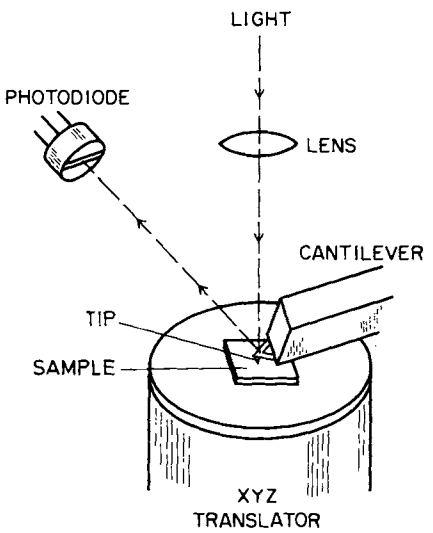

Fig. 1. The atomic force microscope (AFM) detects the vertical motion of the tip which is proportional to the force that the tip applies to the surface of the sample. The XYZ translator moves the sample in all three directions in space. In the particular detection scheme shown here the deflection of the laser beam, which is reflected from a cantilever, is measured sensitively by a two segment photodiode. The measurements can also be performed in fluid ambients like water [3].

Atomically resolved surface images have been obtained on both conducting and non-conducting materials like graphite,[2] boron nitride[4] or mica.[5] Also, the local step structure on some ionic crystal surfaces has been studied. For example, the (111) and (100) surfaces of chemically polished AgBr single crystals show some interesting differences.[6] While on the (111) surface, individual steps coinciding with both low index directions $\langle 0\bar{1}1 \rangle$ and $\langle 1\bar{2}1 \rangle$ were found, the (100) surface is dominated by crossing steps. These results may help to understand the different preferential J-aggregation of dyes occuring on these surfaces, a process which is of importance in photographic emulsion technology.

The ability of the AFM to image non-conductors enables it to be applied to organic materials, provided that the forces involved are small enough not to disrupt the sample. That this is indeed possible has been demonstrated for the surface of an amino acid crystal, DL-leucine,[7] and for a layer of polyalanine on glass.[5] Imaging an individual organic molecule, however, is even more demanding, since a single molecule can diffuse across the surface, particularly under the influence of the AFM tip. The adsorption energies must be particularly small if one wants to avoid a large distortion of the adsorbate on the surface. This, in turn, means that the forces applied by the AFM tip should be equally small. In this respect it is important to realize that surfaces in air are typically covered with an adsorbate layer of water and unknown contaminants causing a capillary force for small tip-

[*] Dr. J. P. Rabe
Max-Planck-Institut für Polymerforschung
Postfach 3148, D-6500 Mainz (FRG)

to-sample gaps which can exceed the externally applied forces. An elegant way to eliminate this force, besides operating in ultra high vacuum, appears to be operation under water or other fluid ambients.[3] Figure 2 shows ten AFM images of the clotting of the human blood protein, fibrinogen, adsorbed on mica before (A) and after introduction of the clotting enzyme thrombin into the aqueous ambient (B through J).[5] The role of the thrombin is to unmask some polymerization sites on the fibrinogen. The resulting fibrin monomers polymerize to form larger aggregates. Attempts to obtain high resolution images of single fibrinogen molecules suffered from a commonly encountered problem in both STM and AFM, namely that the adsorbates did not adhere well enough to the mica. However, as the fibrin monomers polymerized into the larger aggregates, they were more reproducibly imaged (Fig. 2B). The aggregates could still move, growing larger and connecting to each other (Figs. 2C through F) until a single chain spanned the whole field of view (Fig. 2G). Next, a second chain grew adjacent to the first (Fig. 2H), then a third (Fig. 2I) and finally nearly the whole field of view was covered with a fibrin net (Fig. 2J). While the resolution in these images is considerably lower than in the examples mentioned above, the results demonstrate the potential of the AFM to study processes occurring at the interphase between a solid and a liquid at molecular resolution and in real time. Also, higher resolution images may be achievable with microfabricated tips which are currently under development. A more fundamental limitation, namely the motion of the adsorbate on the surface may be circumvented by imaging in more viscous fluids or by lowering the temperature.

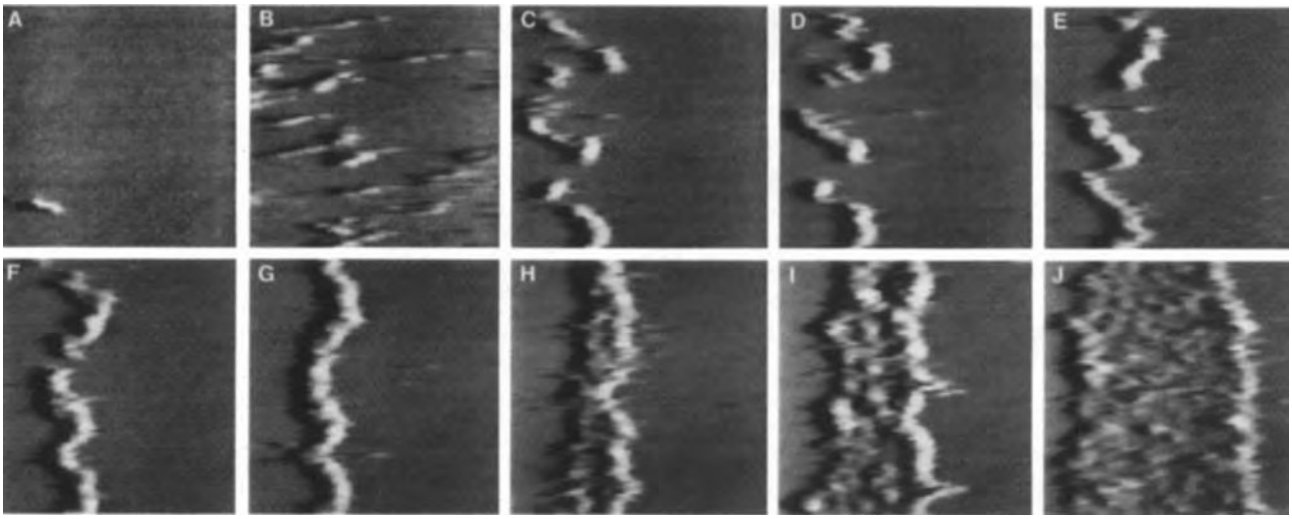

Fig. 2. Ten AFM images taken from a video tape that show clotting of the blood protein fibrinogen in real time. The images were selected from before introduction of the clotting enzyme thrombin (A), and at various times after its introduction between 9 min (B) through 33 min (J). Each image area is 450 nm × 450 nm [5].

The ability of the AFM to measure minute forces cannot only be used to image surface structure but also to elucidate other surface properties, for example, friction on an atomic scale.[8] Also intriguing is the imaging of electromagnetic forces at surfaces. Compared to the van der Waals force, electromagnetic forces are long range, i.e. they are dominating for large tip-to-sample separations. This makes imaging

Jürgen Rabe studied physics at RWTH Aachen, gaining his Diploma in 1981, and at the Technical University in Munich where he completed his doctoral work in 1984. He then spent two years as a Postdoctoral Fellow at the IBM Almaden Research Center in San Jose, California before taking up his present position on the Research Staff of the Max Planck Institute for Polymer Research in Mainz, FRG. His research interests include the chemical physics of ultrathin organic films, STM and related microscopies, and vibrational spectroscopy. From now on he will be writing regularly for Advanced Materials on aspects of surface analysis.

possible in a true non-contact mode. Recently it has been demonstrated that the AFM can be used to deposit and image localized charge on an insulator with a lateral resolution surpassing that of other currently available techniques.[9] A lever is oscillated near its resonance frequency at a tip-to-sample distance of the order of 100 nm. As the tip is scanned across the sample, variations in the tip-to-surface force gradient will alter the effective spring constant of the lever. The resulting change of its resonance frequency is detected as a change in the amplitude of the tip oscillation. If local charge is present on the surface, the tip will feel an additional force due to the coulomb attraction of the charge to its image charge in the tip. The measured force gradient contour will have a peak at the location of the charge. Moreover, by applying a voltage to an electrode behind the sample it is possible to determine the sign of the charge present. The amount of charge can be estimated by measuring the force as a function of distance. Initial experiments[9] have demonstrated the ability of the AFM to deposit and detect low charge levels on insulator surfaces with a lateral resolution of the order of 1 μm. The sensitivity was estimated to be about 100 electrons. The charge had been deposited by applying a voltage pulse to the tip. Interestingly, while charge on polymethylmethacrylate (PMMA) and sapphire samples was observed to decay over approximately 1 h in air, charge on mica and quartz appeared to dissipate so rapidly that it was impossible to obtain an image of a locally charged region.[9] An improved technique, employing a modulation of the bias of the back electrode on the sample[10] resulted in a further increase in resolution to 0.2 μm with an estimated sensitivity of 6 ± 3 electrons. With this, bipolar charging after contact charging has been observed in an area of about 10 μm diameter.[10] This is a surprising result, which could not be observed in previous tribocharging experiments with the lower lateral resolution. It may, however, help us to understand the spot-to-spot variations found in these earlier experiments. The above mentioned high resolution data may be complicated by the fact that they were obtained in air, with water possibly contributing to charge mobility at the surface. However, they demonstrate the ability of AFM to address very old but still unresolved problems on the underlying mechanisms in contact- or tribo-charging.

Magnetic forces can also be measured with a very similar setup, provided a magnetic tip of, for example, iron or nickel is used. Figure 3a shows an image of magnetic domains in a 2.5 μm thick NiFe film and Figure 3b shows the corresponding Kerr image, giving essentially the same structure.[11] Clearly, entire domains and domain walls are imaged with the AFM with submicron resolution. The inset in Figure 3 shows the direction of magnetization in each domain inferred from the images. The tip was scanned at a constant height of 150 nm above the surface, and it was concluded that the field of the tip did not move the walls significantly in this comparatively thick film. The image contrast at the wall is attributed to the sense of the rotation of the magnetization across the wall. However, a detailed interpretation of the complicated magnetic structure of domain walls in soft magnetic materials is still difficult. For a thinner film (30 nm), domain walls appeared to be narrower and more susceptible to stray magnetic fields. Therefore, the tip

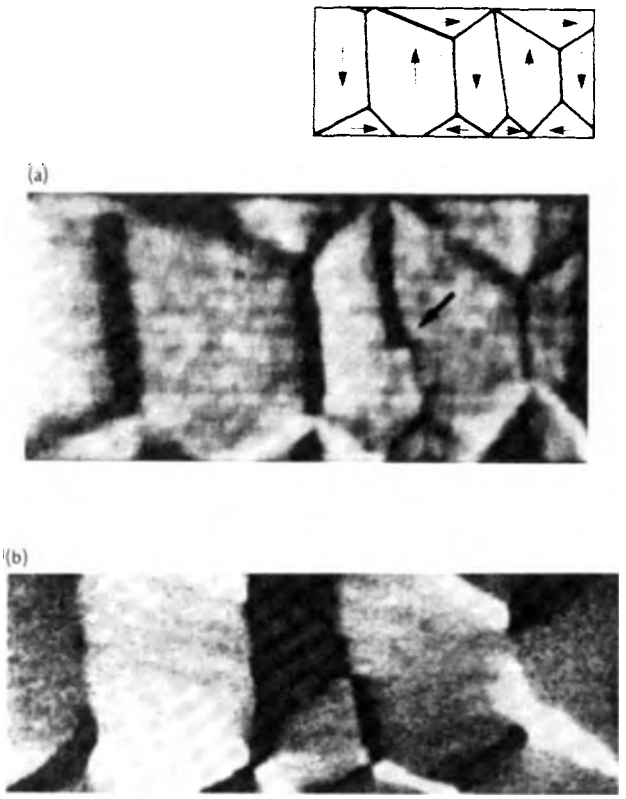

Fig. 3. (a) Magnetic force microscopy image and (b) Kerr image of domains in permalloy film. The imaged region is 50 μm × 30 μm; magnifications differ in horizontal and vertical directions. Arrow marks the location of a Bloch line [11].

could induce wall motion when brought sufficiently close to the surface.[11] While this may be disadvantageous in some cases, it is anticipated, that it will provide a means for studying magnetic properties such as wall motion coercivity on a microscopic scale. As far as resolution is concerned, a magnetic image of the domain pattern on a TbFeCo thin film on silicon has been obtained with a resolution of approximately 25 nm.[12] Clearly, a better understanding of the magnetic domain structure is of great fundamental and also technological interest as performance in magnetic recording devices depends on the detailed micromagnetic structure of the recording medium.

The results given above demonstrate the wide variety of forces which can be measured by the AFM on small lateral length scales. For high resolution surface imaging the advantage of AFM over STM is the ability of the former to image insulators. While this appears particularly promising for or-

ADVANCED MATERIALS

ganic systems, a further reduction of the forces applied during scanning is desirable.

Low Temperature Deposition of a CaF_2 Insulator Layer on GaAs*

Over recent years there has been widespread interest in the development of alternative insulators for silicon and GaAs, especially where these might be obtained in epitaxial layer form to permit the production of multilayer semiconductor-insulator structures.[1-3] Several workers have reported the growth of epitaxial CaF_2 on silicon[4-6] and GaAs.[7-9] The major problems in obtaining good quality films lie in the lattice mismatch between the layer and substrate (0.6% for Si; 3% for GaAs) and the thermal conductivity mismatch (α $CaF_2 = 1.9 \times 10^{-5}\ K^{-1}$; α Si $= 4 \times 10^{-6}\ K^{-1}$; α GaAs $= 6.9 \times 10^{-6}\ K^{-1}$). For GaAs applications the former has been overcome, partially at least, by the use of solid solutions of CaF_2–SrF_2, the composition $Ca_{0.44}Sr_{0.56}F_2$ being perfectly lattice-matched to GaAs at 25 °C.[10] The thermal expansion coefficient differences between GaAs, CaF_2, and SrF_2 produce strain at the film/substrate interface during cooling from the growth temperature. In the case of high elastic modulus material such as CaF_2 and CaF_2-rich alloys this leads to cracking, whilst the more plastic SrF_2 and SrF_2-rich alloys deform by dislocation generation, so that the layer becomes a poor substrate for subsequent semiconductor overgrowth. The best solution to this problem lies in a reduction of a growth temperature to minimize cooling strains. This demands a growth system which permits transport and low temperature decomposition of a suitable precursor, which must nevertheless remain sufficiently stable to withstand premature thermal decomposition.

Benac et al.[11] have recently reported polycrystalline growth by pyrolytic decomposition of bis(pentamethylcyclopentadienyl)calcium $(C_5Me_5)_2Ca$ in either SiF_4 or NF_3 at 150 °C. This low decomposition temperature may, however, lead to handling problems. At the observed growth rates of 10–100 μm/hr the product is polycrystalline CaF_2 with a grain size of 20–50 μm but X-ray photoelectron (XPS) studies show relatively high impurity levels (approximately 18% carbon and 7% oxygen) in these films.

Recent work at RSRE Malvern and Queen Mary College London has led to the development of a new approach to the deposition of CaF_2 on GaAs at low temperatures, which combines the advantages of the organometallic approach with those of photochemically-induced precursor decomposition. This permits the use of thermally stable precursors, thus reducing the risk of premature reaction outside the required deposition zone, and of gas phase reactions which generally result in poor epitaxy. Careful design of the photochemical reactor and the use of suitable projection masking in the incident photon beam can then be used to promote selected-area deposition.

The process is based on the photochemical decomposition of bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)calcium(II), $Ca(hfac)_2$, (Fig. 1) using xenon lamp radiation in the 180–300 nm waveband. The precursor compound was developed and synthesized at Queen Mary College, London.[12]

The material is obtained in the form of a pale yellow powder which sublimes at approximately 100 °C. It is impor-

tant to obtain the material in its anhydrous state as the hydrated or even partially hydrated compound does not appear to yield CaF_2 under the experimental conditions described here.[13] The material is thermally stable to approximately 300 °C, above which it can be pyrolytically decomposed to give CaF_2. In the photo-assisted decomposition process the precursor is transported from a bubbler held at 100 °C into a MOVPE reactor containing one or more substrates of GaAs heated to 100 °C (Fig. 2). The reactor pressure is approximately 10^{-1} Torr.

Radiation from a 450 watt xenon lamp is broad-band filtered (180–300 nm) and illuminates the substrate at normal incidence through an aperture in the furnace wall.

A deposited CaF_2 layer approximately 4000 Å thick is obtained at a deposition rate of around 30 Å min^{-1}. XPS analysis of the layer shows Ca and F peaks together with *small* carbon and oxygen (< 10%) peaks. X-Ray diffraction data indicate a polycrystalline CaF_2 layer with a high degree of preferred orientation. At this stage no attempt has been made to clean up the reactor or substrate prior to deposition and the polycrystallinity and impurity results are not unexpected. Work is now in progress to improve the layer structure. Further details of the photochemical process are awaiting publication.[14]

Conference Reports

Ceramics in Maastricht

By Richard J. Brook *

The combination of a new society and a new conference center brings a special atmosphere to any meeting. This proved true on the grand scale for the first meeting of the European Ceramic Society which was held in Maastricht, Netherlands, over the week 18.–23. June 1989.

The Society itself was founded in 1987 following negotiations between a number of the national ceramic societies in Europe. The coming into existence of the Society was in part prompted by discussions which took place between the American Ceramic Society and representatives of the several European societies at which the need for a coordinating group in Europe was clearly recognized. European colleagues will remember with gratitude the high professional standards which the American Ceramic Society followed in promoting these discussions and in sharing in the ensuing debates; the example of close professional collaboration at the international level afforded by these contacts is a notable and happy one.

The European Ceramic Society currently counts eleven countries among its membership: Belgium, France, Germany, Italy, the Netherlands, Norway, Portugal, Spain, Sweden, the United Kingdom and Yugoslavia. A major role for the new Society will be the organization of the set of conferences which are to continue the tradition established by the Science of Ceramics series. The first such meeting took the form of this conference organized by colleagues from the Netherlands Ceramic Society and the Netherlands Ceramic Federation at Maastricht.

The Maastricht Exhibition and Congress Center is a recently built facility opened in the Netherlands to cater for the holding of exhibitions, conferences, and business functions. The center consists of a group of auditoria, conference rooms, and exhibition halls coordinated into a building which also provides a range of shops, restaurants, cafeterias, hotels, and banks. The general impression is not unlike that given by the best quality of international airport except in that the participants have for the most part a less harassed appearance. The combination of a modern conference center and a neighboring town possessing a highly individual and charming character of the more established kind (open air cafés, tree-lined streets, a friendly and animated population – mostly on bicycles, buildings of high distinction) served to provide an atmosphere eminently suitable for concentrated scientific and technological discussion.

[*] Prof. R. J. Brook
Max Planck Institute for Metals Research, Powder Metallurgy Laboratory
Heisenbergstrasse 5, D-7000 Stuttgart 80 (FRG)

The meeting itself covered all aspects of the subject of ceramics. Focus was provided by a series of keynote lectures devoted to principal subject areas. These included treatments of basic science (*F. Thévenot*), of engineering ceramics (*F. Thümmler*), of traditional ceramics (*J. E. Enrique*), of electronic ceramics (*L. Cross*), of bioceramics (*G. Heimke*), of standardization (*G. C. Padgett*), and of high temperature superconductors (*S. Horiuchi*). A further plenary session was devoted to a lecture on the subject of microstructures (*R. J. Brook*) given to commemorate the striking contribution made to ceramics science and engineering by Prof. *A. L. Stuijts*. Professor *Stuijts* is everywhere acknowledged as having been a key figure in the development of magneto- and electroceramic materials; his special ability to operate at the interface between industrial applications and academic science served to make him a universally respected colleague, and it is fitting that his name should be associated with a plenary lecture that will form a regular feature at the conferences of the new Society.

The meeting spanned a full week and comprised a mix of technical presentations, of posters, of industrial visits and of exhibits of products from all sectors of the ceramics industry. Despite the length of the meeting, there were occasions when levels of concentration of an almost superhuman character were required on the part of participants (the digestion of 180 posters in parallel with a number of set sessions during a single day). Provision of the industrial visits as a caesura on the Wednesday afternoon gave just the degree of variety required to sustain energies.

In technical matters the meeting covered all aspects of ceramics but, as is common on such occasions, a degree of dominance on the part of the non-traditional ceramics sector could be recognized (the actual distribution of contributions was 180 from basic science, 115 from engineering ceramics, 64 from electrical ceramics, 42 from traditional ceramics, 18 from biological aspects, 27 from superconductors, and 3 from standardization). The integration of such themes within a common discipline will remain an important task for the new Society.

Dutch colleagues are to be congratulated for the imagination and effort which they devoted to the meeting. The assembly of 450 papers, of 80 exhibitors and of 1000 participants into a single professional community within Europe is no easy task; the fact that the meeting gave such a clear impression of a coherent group of participants is in no small part due to the vigor and enthusiasm with which the organizers set about their task. The role of the new Society as it seeks

to define its purpose will in the early stages be largely determined by such milestone events as this conference. The atmosphere of this first meeting was highly encouraging in this regard.

Responsibility for the Society now passes to the German Ceramic Society whose president, Prof. *Hans Hausner*, has succeeded Prof. *Rudi Metselaar* as president of the European Ceramic Society. On the basis of this first meeting one can look forward with confidence to the successor which will be held in Germany in two years time. Those who participated in Maastricht can have been left with little doubt that conferences of the European Ceramic Society will become a regular and respected element in the European materials scene.

Large Area Chromogenics in Gothenburg

By Tord Eriksson *

An international workshop on Large Area Chromogenics took place at Chalmers University of Technology in Gothenburg, Sweden, during a very full day, June 5th. It was organized by CoAT AB, The Center for Materials Science, and Chalmers Industri Teknik under the sponsorship of the Swedish Board for Technical Development. Eight invited researchers lectured on the state of the art of chromogenic materials. 50 invited representatives from industry listened and contributed to the ensuing discussions from, in particular, the applications point of view.

The workshop was opened by Professor *Olaf Meyer*, Head of the Eureka secretariat in Brussels, who gave a very much appreciated lecture entitled "Risk financing of hightech start-ups, especially in international cooperation".

The conference aimed at giving some answers to the following questions. What are the prospects and challenges for chromogenic materials? Where is the frontier in research? What are the applications, and when and how can they be commercially realized?

What is a chromogenic material? The question is certainly relevant since the concept was only recently introduced. The word comes from the greek χρωμα = color and γενεσιζ = creation. Chromogenic materials change their color – or more general optical properties such as transmission, reflection and absorption – due to an external influence such as applied voltage, incident light, temperature etc. These materials are classified as electrochromic, photochromic, thermochromic and some liquid crystal based materials.

Chromogenic materials could in the future be used to regulate the flow of light and/or solar energy through a window so that a suitable illumination and climatic comfort could be achieved. Other applications for these materials involve large area displays, rear view mirrors for cars, sun roofs etc.

[*] Dr. T. Eriksson
CoAT AB, Datavägen 21 B
S-43632 Askim (Sweden)

Professor *Granqvist* gave in his lecture a general insight into the prospects and challenges. A lot of applications sectors can be identified: architectural (energy efficiency, lighting), automotive (energy efficiency, anti-dazzling), aerospace (temperature control), information (displays of various kinds), military (camouflage/chamelionism). Technical problems still have to be solved before any commercialization is feasible. Large modulation of the optical properties is desired in many applications. The durability is sometimes an important requirement (in windows). The material has to be integrated in devices. A challenge of a more non-technical kind is that this technology is very interdisciplinary in nature. This means that, for instance, physicists and electrochemists have to cooperate to achieve an understanding of the coloration mechanism of electrochromic materials.

A lot of basic research has to be done in order to understand the mechanisms behind electrochromism. Dr. *Carl Lampert*, Lawrence Berkeley Laboratory, emphasized some research issues. The materials have to be characterized: optical properties, electrical properties, structure and chemistry, determination of coloration mechanism and overall stability. In addition a number of hitherto neglected materials should be studied. As to the complete devices the following aspects have to be considered: compatible ion storage electrodes, ion conductors for small positive ions such as $Li^{\oplus}$, $H^{\oplus}$, $K^{\oplus}$, polymeric electrolytes for lamination (an all solid state device is desirable), development of fabrication techniques, determination of device operating characteristics and stability testing of prototype devices.

Dr. *N. Lynam*, Donelly Corp., lectured on applications for electrochromic materials. Donelly is producing an electrochromic rear view mirror for cars. The design of such a device differs from that intended for a window in that it is not transparent but reflecting. The materials choice is also simpler since not all layers in the device have to be transparent.

ADVANCED MATERIALS

Dr. *Montgomery*, General Motors Res. Labs, reviewed the various existing liquid crystal systems and concentrated on those appearing to be most suited for large area switching devices. The polymer-dispersed and encapsulated liquid crystal films are either opaque (scattering) or transmitting, depending on the mismatch or match of the refractive indices of the liquid crystal particles and the host polymer. The operating temperatures are limited to the range $-20\,^{\circ}C$ to $+100\,^{\circ}C$. The response time makes them useful for most outdoor applications such as: solar control, automotive privacy, signs and eventually automotive displays. The on-state transmittance ($\sim 65\%$) restricts their use in areas where higher transmittances are required: windshields in cars and windows in buildings. For the future it seems important to reduce haze, increase durability, reduce operating voltage and improve solar attenuation characteristics so that this technology can find applications beyond its present technical limits.

Photochromism can be defined as a light-induced reversible photochemical process which results in a color change. The photochromic systems can be classified as either inorganic, organic, or those applying photophysical processes. Dr. *N. Chu*, American Optical Corp., suggested the following candidate materials: photochromic glasses, photochromic plastics activated by silver halides, and photochromic plastics activated by spirooxazines. The spirooxazines change from colorless to blue. They could find applications both in automotive windshields and sunroofs as well as for retrofit polyester films in glazings and window shades. However, the R&D program for the spirooxazines seems still to be in its infancy. The temperature sensitivity may be a problem, particularly in automotive applications. Also the light fatigue resistance limits the product lifetime and needs to be improved for window applications.

Dr. *T. Hjertberg* reported on research on conducting polymers. He identified the problems involved as: low stability, difficulties in processing due to bad mechanical properties and lower conductivity than desired. Dr. *O. Wennerström* reported on photochromic effects in organic materials.

A program that has caught a lot of interest is that reported by Professor *T. Lagervall*. His ferroelectric liquid crystal devices have an extremely short switching-time in addition to high contrast angles. This technology has already been commercialized by Canon for high definition information screens.

Professor *C.-G. Granqvist* reported on research carried out on a new electrochromic device based on Li_xWO_3 and VO_5. A new polymeric electrolyte with adhesive properties is applied as a lamination material in a five layer structure. He also reported on some very interesting results on thermochromic coatings made of VO_2. However, durability still has to be verified before marketing. The electrochromic device has reached the point of process development which has been triggered by the advent of the new solid polymeric electrolytes.

The workshop on Large Area Chromogenics was a very exciting and important meeting. Most intriguing is the fact that this area involves a large amount of high level basic research and will have a huge potential impact on daily life when this technology enters the market. It seems to be a supreme example of the synergetic effects achieved by combining academic research with industrial product development.

Storage and Transfer of Molecular Information in Strasbourg

By Jean-Paul Behr*

The European Parliament in Strasbourg housed the first congress "Espaces Européens des Sciences" from July 2–6, 1989. This symposium was organized by Fondation Alsace under the scientific direction of *J. M. Lehn* and *P. Chambon* and made possible the meeting of some thirty world renowned biologists, chemists and physicists to think over a common theme: "Storage and Transfer of Molecular Information". Although the time schedule was planned to imbricate disciplines and research fields, all lectures were centered on recognition processes at the molecular level, involving either the complex functions that workers in contemporary biology are trying to understand, or the highly elaborate molecules or molecular assemblies that chemists are able to make and handle, or approaches to the study of molecular signals and addressing that physicists are developing.

G. H. Khorana (MIT) opened the symposium by showing how light is transduced into chemical signals through rhodopsin molecules in highly organized systems as different as the eye's visual receptor cell and a photosensitive bacteria. The cascade of events in the former system was followed further down to the level of the nerve by *L. Stryer* (Stanford)

[*] Dr. J.-P. Behr
Institut Le Bel
Strasbourg (France)

whereas *M. Chabre* (Grenoble) proceeded to unravel the short term memory and signal amplification brought about by transducin; Other guanosine triphosphate (GTP)-binding proteins acting as intracellular messengers were reviewed by *Y. Kaziro* (Tokyo).

Soon it became clear that the crucial regions where things happen for biologists, chemists and physicists are liquid cristalline or solid-liquid interfaces. Electronic connection of the interior of redox enzymes to an electrode was cleverly done through a molecular charge relay by *A. Heller* (Austin) and his presentation was followed by other solid state aspects of information transfer (*H. C. Wolf*, Stuttgart; *H. McConnell*, Stanford). Oriented molecular films were reviewed by the pioneer of monolayer assemblies (*H. Kuhn*, Tschingel); chemical variations on bilayer membranes were introduced by *T. Kunitake* (Kyushu), and *H. Ringsdorf* (Mainz) reported in a humorous manner how these membranes could be made to perform complex molecular recognition functions. Supramolecular chemistry was brilliantly reviewed and illustrated with intertwined molecules by *F. Stoddart* (Sheffield).

Then a major question was raised. Are molecular computers feasible? This challenging call for new molecules was answered in the affirmative on a theoretical background (*J. Hopfield*, Caltech) but many technical difficulties appear at the interface between the molecular and macroscopic worlds (*D. Haarer*, Bayreuth—see the Editorial Essay in this issue) although the scanning tunneling microscope should allow us to address single molecules (*B. Michel*, IBM Rüschlikon). On the biomimetic side, *A. Eschenmoser* (ETH Zürich) and *C. Hélène* (Paris) have worked on chemical modifications of nucleic acids, whereas present and putative possibilities for tailored catalytic antibodies were presented by *R. A. Lerner* (La Jolla).

Immune response and morphogenesis are overwhelmingly complex physiological processes, yet after the lectures of *G. Edelman* (New-York) on topobiology, *R. Axel* (Columbia) on membrane receptors, and the more structural approach of *J. Strominger* (Harvard), even the journalists in the audience knew about cell to cell communication.

Where is the genetic information of living organisms stored, and how is it processed? Before the most eminent molecular geneticists took over, *M. Eigen* (Göttingen)

showed how the genetic code and self replicating molecules could originate, and *M. Lahav* (Rehovot) presented elegant interfacial crystallization experiments able to amplify chirality in a non-chiral environment. Then, *R. E. Dickerson* (UCLA), *S. C. Harrison* (Harvard), *A. Rich* (MIT) and *M. Ptashne* (Harvard) presented the various structural aspects of the regulation of gene expression at the transcriptional level, and *T. Steitz* (Yale) gave structural details of a tRNA synthetase. tRNA complexes are involved in translation of the genetic code.

The symposium ended with *S. Numa* (Kyoto) and *J. P. Changeux* (Paris) lecturing on a topic close to the first one: signal transfer in living systems, in this case, neurotransmitter receptors. On July 6, at 8 p.m., after some 35 hours of presentations and interdisciplinary discussions, the lecture theater was still full, a sign of the success of this meeting. This prompted *M. Neitzert*, President of Fondation Alsace (with the financial support of GMA, Matra, Rhône-Poulenc and Squibb) to plan the second meeting of this series for next year.

International Conference on Synthetic Metals (ICSM '90), 3–7 September 1990 in Tübingen, FRG

The conference will provide an interdisciplinary forum for the discussion of recent experimental and theoretical results in physics, chemistry, and the application of all synthetic metals (low-dimensional conductors). Sessions on the following topics are anticipated: Theory of organic conducting crystals, Synthesis and structure of new organic conducting crystals, Organic superconductors, Theory of organic conducting polymers, Synthesis and structure of organic conducting polymers, Properties of organic conducting polymers, Nonlinear optical properties, Pyropolymers and graphitic materials, Transition metal chalcogenides and oxides, Bronzes and other inorganic crystals, Other organic and inorganic conducting crystals, Ferromagnetic polymers and charge transfer salts, New low-dimensional materials, Application of synthetic metals.

Further information can be obtained from the German Chemical Society (GDCh) at the following address: GDCh, Dr. J. Wendenburg, Abt. Tagungen ICSM' 90, Varrentrappstr. 40, D-6000 Frankfurt 90, FRG, Telefax: 069/7917-475.

ADVANCED MATERIALS

Materials Science and Technology in Karlsruhe

By Bernd Eigenmann *

The scientific theme of the annual meeting of the German Society for Metals (Deutsche Gesellschaft für Metallkunde, DGM) held from May 16. to 18., 1989 in Karlsruhe (FRG) was "modern developments in materials science and materials technology". This title not only sketches out the course the DGM is intending to take in future, but also symbolizes the opening of the Society towards modern applications of metallic as well as non-metallic materials in materials science and technology. Since, in many cases, only compound materials of metallic and non-metallic components can meet the increasing specific requirements of modern structures, it appears necessary to include them into the field of activities. The subjects of many workshops of the DGM have already anticipated this trend. During this year's annual meeting, it was finally intended to symbolize the above described new developments in materials science and technology by changing the Society's name to German Society for Materials (Deutsche Gesellschaft für Materialkunde, DGM). This decision was supported by an overwhelming majority of the Society's members, and it terminated a process which lasted for more than a year in which the members of the Society tried to make up their minds about the consequences of the new requirements and tried to reconcile themselves with it.

At the opening ceremony, the president of the DGM, Prof. *G. Petzow* honored several members of the Society for their excellent research work. Prof. *Hans Warlimont* (Vacuumschmelze GmbH, Hanau) was awarded the Heyn Medal, the highest honor of the DGM, in recognition of his extraordinary contributions to the investigation of the basic principles of metallurgy and in the application of these principles to the development of metallic materials.

Dr. *Martin Bauser* (Wieland Werke AG, Ulm) and Prof. *Günther Sauer* (Hofmann KG, Wiesbaden) both received honorary memberships of the DGM for distinguished service to the Society, in particular for encouraging strong ties between industrial practice and scientific development.

The Tammann Medal was awarded to Prof. *Hans Paul Hougardy* (Max Planck Institute for Iron Research, Düsseldorf) recognizing his contribution to the quantitative understanding of structural transformations and their influence on stress in steel, and the Masing Memorial Prize went to Dr. *Werner Mader* (Max Planck Institute for Metals Research, Stuttgart) for his successful studies of the atomic structure of surfaces at oxide/metal boundaries.

[*] Dipl.-Ing. B. Eigenmann
Institut für Werkstoffkunde I, Universität Karlsruhe
P.O. Box 6980, D-7500 Karlsruhe (FRG)

In his annual report, the managing director of the DGM, Dr. *V. Schumacher*, pointed out that the spreading of the activities of the DGM to non-metallic materials would, however, not lead to an attempt to penetrate step by step into the field of research of other well-established scientific societies in Germany. The aim of the DGM was, according to Dr. *Schumacher*, rather to deepen interdisciplinary contacts and to promote common activities such as meetings, workshops, and conferences, and, of course, to establish and intensify personal contacts between DGM-members and other scientific organizations.

The annual meeting was terminated by a social evening, on the occasion of which not only a "Brigandebuffet" – whose roots in the history of Karlsruhe were explained by Prof. *E. Macherauch* – was offered, but also dancing, and finally Prof. F. *Thümmler* presented a humorous address to the ladies – especially the wives of scientists.

The annual meeting of the members was embedded in an impressive framework of scientific contributions. The conference was opened by a lecture traditionally dealing with a subject which is not related to materials science. Prof. *Wenzel* from the University of Karlsruhe, faculty of architecture, talked about the importance of new technologies for the renovation of old buildings. He explained different methods of reinforcing walls and entire buildings, using steel strings and cement and demonstrated how wooden structures can be reinforced either by wood or by steel. Special emphasis was laid on the refined techniques developed in Greece for the purpose of conserving ancient monuments.

During the conference, 10 plenary papers were presented dealing with the various aspects of modern developments in materials science and technology.

Prof. *Exner*, Max Planck Institute in Stuttgart, presented the advances in quantitative structure analysis. In his lecture, he discussed the stereometry, fractal geometry and mathematical morphology and pointed out the difficulties in describing complex dendritic structures of castings and pores in sintered materials.

Prof. *Cherdron*, Hoechst AG, Frankfurt, explained the chemical and structural differences between metals and organic polymers. The morphology and molecular structure of polymers was described and correlated with their properties. The theoretical aspects were well illustrated by a number of specific examples such as polymer liquid crystals, composites, and polymer alloys.

Generally, the properties of graphite are known. Up to now, however, they have only been exploited to a relatively

small extent. Prof. *Hüttinger*, University of Karlsruhe, showed that the high stiffness and toughness of this material up to high temperatures, due to the covalent bonding character in the graphite planes, offer potential applications, especially in the field of carbon fibers. On the other hand, it was shown that an economic production and use of these fibers as well as the minimization of their brittleness and their sensitivity to shear load parallel to the graphite planes still represents a challenge for both scientists and engineers.

Dr. *Meyer*, Thyssen Stahl AG, Duisburg, presented new developments in micro-alloyed steels. He showed that properties like the γ–α-transformation, texture formation, precipitation hardening, and yield strength can be varied over a wide range by small amounts of alloying elements, especially titanium. Good formability can be achieved as well as a high strength dual phase structure.

A survey of the most important methods of surface analysis was given by Dr. *Kirchheim*, Max Planck Institute, Stuttgart. He discussed the state of the art of AES, ESCA/XSP, SIMS, LEED, RHEED and the applications of these techniques to the study of catalyst surfaces, surface passivation, high temperature corrosion, and tribology. Moreover, he explained how inner surfaces can be analyzed, and how the effects of sintering additives in ceramics or the binding mechanisms of metal-polymer composites can be investigated.

Prof. *Holleck*, University of Karlsruhe, showed in an interesting way the relationship between the design and behavior of coatings. He explained the recent developments and trends in obtaining coatings by physical vapor deposition with improved properties, particularly emphasizing coatings with mixed phases, multilayer coatings and gradient coatings.

Prof. Dr. *Hougardy* gave an excellent survey of today's possibilities in calculating residual stresses and distortions resulting from the quenching and hardening processes of steels.

A review of the activities in developing superalloys was given by Dr. *Walser* from Sulzer AG, Winterthur. These efforts are mainly correlated with advances in aircraft and space technology where a permanent improvement of the performance of turbines and combustion chambers is needed. New materials can only be developed on the basis of an increasing knowledge of the influences of metal physics on the materials behavior. Besides the basic science, however, permanent improvements in production and application techniques of the materials are necessary.

Dr. *Riedel*, Fraunhofer Institute, Freiburg, reported on the modeling of deformation processes during the manufacturing and servicing of engine components. In this case, the term modeling has two meanings. On the one hand, the behavior of the component during manufacturing and service is described by means of numerical models, e.g. finite element calculations, and on the other hand, the derivation of macroscopic materials properties from microscopic models is attempted. For the time being, models for high temperature creep, which exceed the simple Newton creep model, are of particular interest. A model for ternary creep processes was presented, and examples for applications were given.

Finally, Prof. Dr. *Zum Gahr*, University of Karlsruhe, presented new results on the influence of the material used on friction and wear behavior, covering the field of metals, ceramics, and polymers. The wear mechanisms were illustrated, and the materials were classified with respect to their physical and chemical properties. Consequences on the wear behavior in the various tribological systems were explained, and optimized materials combinations were derived from this knowledge.

In addition to the plenary papers, 51 other papers and 145 posters were presented in 3 parallel sessions, covering the fields of plasticity, powder metallurgy, phase transformations, textures, recrystallization, fatigue, temperature resistance, surface layers, thermodynamics and constitution, engineering ceramics, computer aided modeling, fracture, high temperature fatigue, intermetallic phases, residual stresses, wear, interfaces, melting and crystallization, amorphous metals, superconductors, magnetism, composite materials, joining and cutting, and materials for nuclear technology.

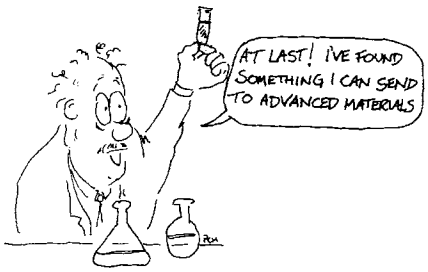
The scientific program was enriched by a number of interesting visits to places of cultural and technological importance in and around Karlsruhe and, finally, by a well organized hiking tour through the Pfälzer Wald on Saturday. The wonderful sunny day made it possible to visit four castles in the surroundings of Nothweiler dating from the 12th to the 16th centuries.

Summarizing, one can say that the annual meeting of the DGM gave a well balanced survey of the state of the art in materials science and technology and also valuable insights into future developments.

1990 E-MRS Strasbourg Conferences: (Symposia)

Spring Meeting (May 29.–June 7. 1990)

A High-T_c Superconductor Materials
B Metal Matrix Composites
C Magnetic Thin Films, Multilayers
D Surface Modification and Coatings
E Surface Processing and Laser Assisted Chemistry



Fall Meeting (Nov. 27.–30. 1990)

A Semiconductors in Optoelectronics
B Nonlinear Optical Materials
C Wide Band-Gap Semiconductors
D Characterization of Compound Semiconductors

Details from Prof. *P. Siffert*, B.P. 20, F-67037 Strasbourg Cedex (France), Tel. 8828 6543, Fax 8828 0990

Materials Forum

Companies and individuals wishing their news and views on advanced materials issues and products to be considered for coverage in this section should send press releases, correspondence and other details, in English, to: Materials Forum, ADVANCED MATERIALS, P.O. Box 101161, D-6940 Weinheim, Federal Republic of Germany.

Conducting PPS-Compounds

The lowest electrical resistance of partially crystalline "conducting" thermoplastics previously achieved has been in the range 10^2 to 10^3 Ohm cm. Newly developed poly(phenylene sulphide) based compounds from Bayer, marketed under the trade name Tedur, combine a further reduced resistivity (to 1 Ohm cm) with high performance up to approx 200 °C and are stable at voltages of 220 V.

Additives such as metal fibers, carbon black and graphite improve the electrical properties of the polymeric materials. They are stable against oxidation and chemical decomposition and can possess a wide range of mechanical properties.

Several of the Tedur materials have been developed for antistatic applications, for example, housings in photocopiers, encapsulants for microchips or in the handling of flammable solvents. Others, of the conducting type will be applied in heating systems including preheaters for air/fuel mixtures.

Euromat '89

The Federation of European Materials Societies (FEMS) holds its first European materials conference from 22.–24. November 1989 in Aachen, FRG. The organization of the event is in the hands of the German Materials Society (DGM) and it is intended that the conference should bring together materials scientists from all over Europe and elsewhere to participate in plenary and short lectures, poster exhibitions and workshops. Six topics have been selected to from the basis of major symposia. They are: powder metallurgy, high temperature materials, materials in electronics, interface science, microscopy, and biomaterials.

The program and further information are available from DGM e.V., Adenauerallee 21, D-6370 Oberursel, FRG. Tel. (0 61 71) 40 81. Fax (0 61 71) 5 25 54.

Liquid Crystalline Polymers

Extruded bands of Polystal (a liquid crystalline polymer produced by Bayer) have a lower density than glass fiber reinforced expoxide materials and exhibit high strength and a better modulus of elasticity. Due to these properties the new reinforced materials have revolutionized the production of, amongst other things, cross country skis.

The leading world producers of cross country skis, Fischer (Ried, Austria) incorporated Polystal into 40 000 pairs of skis for the 1988/89 season and have been delighted by the results. In cross country skiing it is particularly important to have good shock absorbtion and insulation against vibration as well as light weight and high strength.

Liquid crystalline polymers can be looked upon as self-reinforcing polymers. The macromolecules which make up these materials are aligned parallel to one another in the melt but on extrusion the materials also take on a macroscopic parallel ordering. These fiber-like materials exhibit good performance at temperatures from 120 °C to those more likely to be found in a snow covered landscape.

Further information is available from Bayer AG, D-5090 Leverkusen, FRG, Tel. (0214) 30-31162.

New Man

Norwegian Talc have recently strengthened their materials business management by employing *Jens Adolf Döhle*, a chemist with experience in laser technology. *Döhle* took over responsibility for customer service and applications information on advanced materials in January. The Norwegian Talc program for which he is responsible includes high-purity chemicals, thin film materials especially for high-T_c superconductor work as well as materials for sputtering and CVD. This is a fast growing market area for the company which until now has concentrated mainly on Germany, Austria, and a number of Eastern-Block countries.

Crystalline Isotactic Polypropylene

The arrangement of the polymer chains in crystalline synthetic polymers is generally anisotropic. In other words, the macromolecules which make up the polymers are aligned parallel to one another. This chain-axis parallelism has become almost an unchallenged principle of polymer crystallization as it seems consistent with the packing requirements of the rods, although the polymers studied so far are almost exclusively of the fibrous type. However, in a recent article in *'Nature'*, *Sergio Brückner* and *Stefano Valdo Meille* of the University of Udine, and the Polytechnic of Milan, Italy, respectively, have reported a study of polymers which do not readily form fibrous specimens. They have found that the structure of isotactic γ-polypropylene comprises layers which are two chains wide, similar to the α-

phase, but with the chain axes aligned in the adjacent bilayers at an angle of 80° to one another (see figure) resulting in

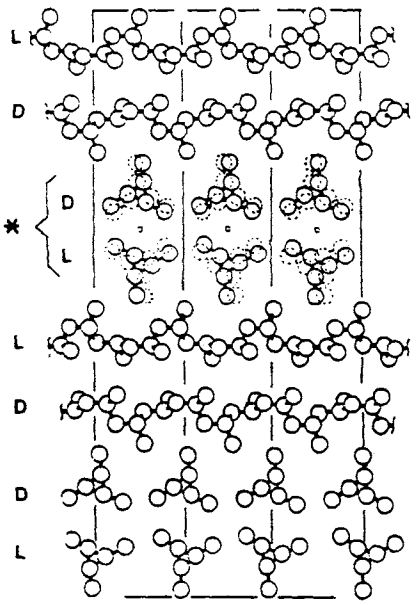


Fig. 1. Packing of γ-iPP. For the sake of clarity, coaxial anticlined helices are shown (dashed) only for some chains. The basic features of mutual chain arrangement and methyl-group interdigitation are shown. The labels D and L refer to the chirality of the helices belonging to the corresponding layer, and an asterisk identifies a bilayer of parallel chains.

favorable registration between helices. More about the unusual structure of γ-isotactic polypropylene where the non-parallel chains appear in a fully ordered array can be found in S. Brückner, S. V. Meille, *Nature 340* (1989) 455.

New Laser Glass

A new phosphate glass (APG-1) has been developed by Schott for use in high performance and high energy laser work. The glass is doped with neodymium and emits infrared light at a wavelength of 1053 nm. The new glass exhibits a high thermal shock stability and low thermal expansion ($\alpha = 7.6 \times 10^{-6}$/K) in the temperature range from 20 to 40 °C and is homogeneous.

Further details are available from Scott Glaswerke, Göttelmannstraße 17, P.O. Box 2480, D-6500 Mainz 1, FRG. Tel. (06131) 837328.

Quadrupole Mass Spectrometer

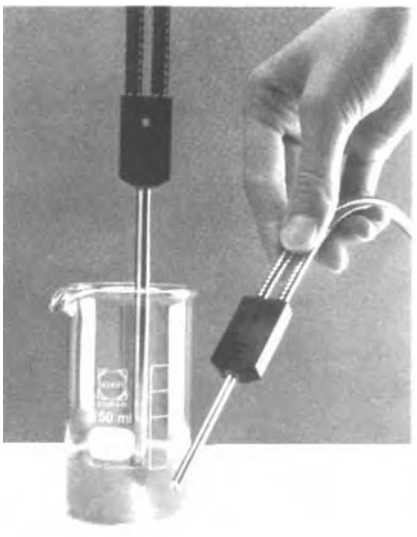
The QX 2000 Quadrupole Mass Spectrometer analyzes the composition of your process and residual gases – quickly and precisely. A single fingertip control lets you know immediately what gases are present in your vacuum chamber.

For ease of operation, the QX 2000 is menu driven via an integrated touch sensitive screen and uses a powerful computer (IBM AT compatible) with 640 kb RAM. Any important data can also be stored on a 3 1/2″ diskette drive floppy disk for recall and use at a later time.

The QX 2000 ensures early detection of problems which could otherwise jeopardize the operational integrity or safety of a process, such as: air leaks, changes in the water content of the process atmosphere, contamination due to oil or solvents, outgassing of materials under vacuum.

Typical applications include the areas of: IC and semiconductor fabrication, thin-film deposition techniques, laser industries, space simulation, materials research.

The QX 2000 offers more than conventional quadrupole mass spectrometers: simplicity of operation via the touch screen, high-resolution color monitor (640 × 350 Pixel, EGA standard), trend analysis for 12 user-selected masses, over a defined period of time. The display may be linear or logarithmic, covering up to 7 decades.



For further information please contact: Mr. M. Wasiletschko LEYBOLD, Bonner Strasse 498, D-5000 Köln 51, FRG, Phone: (0221) 347-1168 or in Great Britain: Mr. J. Holford, Phone: (01) 947 9744.

Materials Science in Bayreuth

The University of Bayreuth (FRG) in a northern area of Bavaria known as Oberfranken, has filled the first of three chairs in materials science which are to be the basis of the new Institute for Materials Science. Professor *Günther Ziegler*, previously at the German Research and Testing Establishment for Air and Space Travel (DLR) in Cologne takes up the challenge on November 1, 1989 and will be particularly responsible for the areas of ceramic composites. The other two planned chairs will be in polymer composites and metal surfaces and interfaces. The work in the institute will be applications oriented and will be based on the existing strengths of the university, solid state physics and polymer chemistry. Close cooperation with materials scientists at the University of Erlangen-Nürnberg some 85 km to the south is planned.

Fiber Optic Level Measurement

Schott have developed a level or depth measurement device for liquids based on fiber optic technology (see picture). The gauge is able to function in harsh conditions, for example, aggressive media, or in the region of explosions (highly shock

resistant), and can function at temperatures up to 200 °C. The recording and transfer of the measurement data is only affected by electromagnetic fields.

Further information is available from Schott Glaswerke, Göttelmannstraße 17, P.O. Box 2480, D-6500 Mainz 1, FRG, Tel. (06131) 837328.

Laser Power Monitor

OPhir Optics Jerusalem Ltd., have developed a new model, the PD-2A, to add to their range of power monitors. The newest addition to the range is based on a silicon photodiode where the spectral sensitivity with a resolution of 1 nm is recorded in the memory of the compact device. The desired wavelength is selected using a 4 way switch which also sets the corresponding calibration parameters from memory.

This calibration allows an accuracy of ±5% over the whole spectrum (350–1100 nm) to be achieved. For higher powers, to avoid saturation of the detector, a detachable filter is supplied extending the range of the device to 2 W.

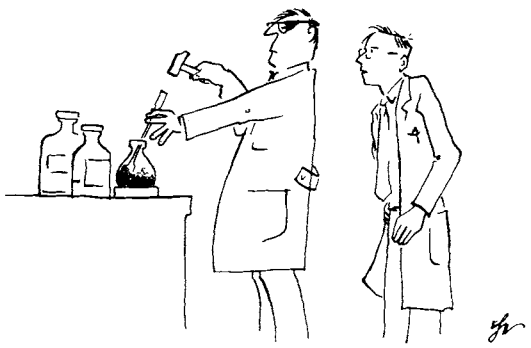
Further details are available from agents Optiglas GmbH, Boschstr. 12, D-8039 Puchheim, FRG, Tel. (089) 80 10 35.

Magnetic-Bearing Turbomolecular Pump

LEYBOLD will introduce in Europe an improved magnetic bearing turbomolecular pump concept designed to substantially improve pump life and virtually eliminate pump maintenance.

The bearing system consists of a combination of passive permanent magnetic bearings and only one active controlled bearing. The lubricant-free pump (the Turbovac 340 M, see figure) can be

mounted in any position desired. Its built-in power generator assures active bearing control even during electrical fluctuations or in case of complete power failure.



Highly resistant to shock and other currently known working conditions, this hydrocarbon-free pump will feature a maintenance-free, low vibration, and low noise level operation. Other features include: stable rotational speeds at high pressures, short start up and deceleration times and bearing purge gas protection. The solid state power control has built-in process control system for RS 232/24 V interfaces, drive control for backing pumps and pump set components and is sized for 1/2 19-inch rack mounting.

For further information, please contact Otmar Reuter, phone: West Germany (0221) 347-1556 or in Great Britain, John Holford, phone: 01-947 9744.

Materials Research in Germany – Annual Report

The annual report for 1988 on projects run under the aegis of the German BMFT, the government body concerned with research and technology, has recently appeared. The report, a healthy 1600+ pages, covers the progress made in projects concerning ceramics, powder metallurgy, polymers, composites, and tribology, projects which are running both in universities and in industry. The report has been produced by the BMFT in cooperation with the PLR, the Projektleitung Material- und Rohstofforschung and is available from the PLR, KFA Jülich, P.O. Box 1913, D-5170 Jülich, FRG. Tel. (02461) 61-0.

Book Reviews

Superconductors, Metals, Polymers, Electronics...

Introduction to the Modern Theory of Metals. By *Alan Cottrell*. The Institute of Metals, London 1988. 260 pp., hard cover, \$ 73.50, ISBN 0-904357-97-X

My first book review, written in Chicago in 1955, was on *Cottrell*'s "Theoretical Structural Metallurgy". At that time I was impressed by the non-physical argumentation which *Cottrell* used in that small book for the explanation of metallurgical phenomena, and it is a method I have often made use of during my career in physical metallurgy. Now, 35 years and many book reviews later, I have the opportunity to review the latest offering from *Cottrell*, another review of the basics of the metal state which attempts to incorporate the modern theories of today's metallurgists.

The book is intended to bring the post-war work of *Hume-Rothery* and *Raynor* up to date, work which *Cottrell* experienced at first hand during a stint as Professor in Birmingham from 1949 to 1955. Since that time he has worked at Harwell and at Cambridge, been a government science advisor, and Master of a college and Vice-Chancellor at the University of Cambridge. Here, during his retirement, he writes refreshingly on the electron theory of metals and alloys as if the intervening years had had no effect whatsoever. Truly a fascinating personality and performance!

The 10 chapters and 13 appendices (which make up more than one third of the book and contain the necessary mathematics) discuss the following points:

1. What is the definition of a metal? (Includes a discussion of the insulator-metal transition and electron delocalization).
2. Why are electrons 'free' (based on shielding and pseudopotentials)?
3. What is the effect of electron correlation?
4. What are the effects of band structure?
5. The cohesion in simple metals and the energies of lattice defects.
6. The d-shell transition metals and their magnetism.
7. The problems with Cu, Ag, and Au with respect to the Hume-Rothery rules for alloys.
8. The surface of metals.
9. Superconductors, including the high-T_c variety.

The physics of every example is explained well, the mathematical proofs being restricted to a minimum or confined to discussion in an appendix. The presentation makes the work highly readable, complete but concise. The metallurgist with some background in physics, or the physical chemist will gain much from reading the book. It is a masterpiece which provides an important education in the basic science that is applicable to many areas of materials science.

Peter Haasen
Institut für Metallphysik
Universität Göttingen
Hospitalstrasse 3/5, D-3400 Göttingen (FRG)

Studies of High Temperature Superconductors. Volume 1. Edited by *Anant Narlikar*. Nova Science Publishers, New York, 1989. xiv, 381 pp., bound, \$ 85.—ISBN 0-941743-44-3

The discovery of superconductivity in a La-Ba-Cu-O compound by *Bednorz* and *Müller* triggered a world wide race in the search for new superconducting materials with still higher transition temperatures. At the same time an enormous wave of publications was set in motion that continues today without any sign of diminishing. In order to ensure rapid publication, new journals mushroomed overnight everywhere, and it was extremely difficult to keep track of important developments.

Presently, three years after the beginning of high-T_c fever, the first books summarizing the current state of the art in the field are being published. The book in hand is the first volume of a series entitled *Studies of High Temperature Superconductors—Advances in Research and Applications*, edited by *Anant Narlikar* from the National Physical Laboratory in New Dehli, India. The underlying motivation for this series is the need for a convenient access to important advances in the field not only for scientists and engineers, but also for graduate students of physics, chemistry, materials science and related fields. Hence most of the chapters in each of the volumes have the character of a review article focusing on theoretical and experimental aspects of research in the field.

Volume one of this series contains 15 chapters, seven of which discuss theoretical approaches to high-T_c superconductivity. The remaining chapters summarize the processing of bulk and thin film materials, microstructural effects, elastic properties, and X-ray photon spectroscopy (XPS). *C. N. R. Rao* from the Indian Institute of Science gives an overview of the oxygen hole mechanism of superconductivity, including a review of available Auger and XPS data. *S. S. Jha* from the Tata Institute of Fundamental Research in Bombay reviews the generalized BCS pairing at the weak as well as the strong coupling limit, including a modified theory for layered crystals. A discussion of possible pairing mechanisms in high-T_c superconductors concludes this article.

J. P. Carbotte from McMaster University in Hamilton, Canada, and his colleague *F. Marsiglio* from the University of California at San Diego, USA, summarize boson exchange mechanisms and combined phonon-exciton mechanisms. A strong coupling approach to high-T_c superconductivity is considered by *J. Rammer* from the University of Bayreuth, FRG. Experimental studies allowing the assessment of the role of phonons in high-T_c superconductivity are included as well as a discussion of non-phonon and combined non-phonon and phonon mechanisms. *K. Machida* from Kyoto University considers electronically driven instabilities in a number of materials such as heavy Fermion superconductors, Cu-free cubic oxides, and the superconducting cuprates. *G. J. Hyland* from the University of Warwick, UK, looks at ground states of the parent compounds which are Mott-insulators and discusses the role of non-stoichiometry and altered valences in high-T_c superconductivity. Superconducting properties resulting from a short coherence length are discussed by *Y. Iye* from the University of Tokyo, Japan. He discusses fluctuations of diamagnetism and conductivity within the Ginzburg-Landau framework. Flux creep phenomena are discussed in the second part of the article.

Chemical aspects of the preparation of high-T_c superconductors are reviewed by *R. M. Iyer* and *J. V. Yakhmi* from Bhabba Atomic Research Center in Bombay, India. They discuss solid state and solution methods for the preparation of bulk superconductors. The oxygen stoichiometry of $YBa_2Cu_3O_{7-x}$ and processing for high critical current densities are reviewed as well as problems in synthesizing Bi and Tl superconductors. The following chapter by *A. V. Narlikar* et al. from National Physical Laboratory in New Delhi, India, is a comprehensive overview of substitution studies. Numerous tables and graphs summarize data and results of substitutions of the relevant lattice sites in $La_{2-x}Ba_xCuO_4$ and $YBa_2Cu_3O_{7-x}$ superconductors. A short section on substitutions in the Bi and Tl superconductors and an extensive bibliography with 144 entries concludes this review.

Sound velocity and measurements of the elastic constants are reviewed by *R. Srinivasan* from the Indian Institute of Technology. After a discussion of sound velocity data, he considers the possibility of structural change near 230 K; a number of measurements seem to point in that direction, e.g. sound velocity measurements, mechanical loss factors, specific heat, etc. Valence and conduction band XPS studies of high-T_c superconductors are summarized by *B. P. Padalia* and *P. K. Mehta* from the Indian Institute of Technology. The role of twins in $YBa_2Cu_3O_{7-x}$ is discussed at length by *C. J. Jou* and *J. Washburn* from the Lawrence Berkeley Laboratory, USA. Their proposed qualitative model for the formation of twins in $YBa_2Cu_3O_{7-x}$ is consistent with numerous experimental observations such as imperfect Meissner effect, remanent magnetization, etc.

Two chapters discuss thin film superconductors. *K. Wasa* and his colleagues from Matsushita Electric Industrial Co. Ltd. in Moriguchi, Japan, review basic thin film processing. After a short introduction listing the various deposition methods, the remainder of the article discusses deposition of a variety of high-T_c superconductors using RF-sputtering. *O. Meyer* from the Kernforschungszentrum in Karlsruhe, FRG, reviews the modification of thin films by ion beam irradiation and its effect on transport properties and electronic structure. The article closes with the discussion of application of ion beam modification techniques. Finally, the design, preparation, and characteristics of a superconducting three terminal device are discussed by *T. Kobay* and *U. Kabasawa* from Osaka University. Their "superconducting current switching transistor" shows a modest current modulation gain of 5 to 7. The authors close with a tentative interpretation of the current modulation mechanism on the basis of non-equilibrium superconductivity.

The volume certainly offers a wide range of topics and caters to a broad cross-section of scientists and engineers, just as the editor promised in the preface. Although the volume is somewhat heavily biased towards the theory side this will not be the case in future volumes as a glance into the list of planned articles reveals. The subject index in the back of the volume is a welcome supplement which enables the reader to cross-reference specific topics with other articles in the volume. On the negative side, some of the figures are of poor quality due either to the design of the responsible author or to the reproduction. It would improve this series if the editor would insist on higher quality supplied figures; a similar comment applies to the type styles, some of which are not suitable for camera-ready publications. Overall this first volume of the series is a good beginning and one can look forward to the forthcoming volumes.

Herbert Jaeger

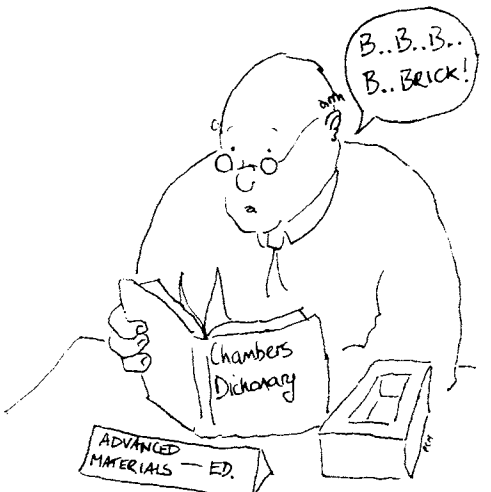
Heisenbergstrasse 5, 7000 Stuttgart 80 (FRG)

Chambers Science and Technology Dictionary. Edited by P. Walker, W & R Chambers/CUP, Cambridge 1989. xvi 1008 pp., hard cover, £ 30 – ISBN 1-85296-150-3

Professor *Peter Walker*, a former Professor of natural history at the University of Edinburgh, Scotland, and a distinguished collection of collaborators from fields as disparate as acoustics and zoology have combined to produce a reference work of the highest quality which covers many areas of materials science as well as, amongst 100 other areas, biology, geology, and printing.

With the rate of development of science and technology ever increasing, it is not only the educated layman who becomes baffled, but one professional may have trouble understanding terms used by another in a neighboring field.



define your terms,
you will permit me again to say
or we shall never understand one another
— Voltaire

This book, to quote from the Preface, "will help a physician to understand a term in molecular biology, the layman to comprehend a medical term and both to talk to their builder in an informed manner."

Extending this philosophy to physicists, chemists, metallurgists, ceramists and engineers, which the dictionary does, is certainly a worthwhile task and one that is supported wholeheartedly in the Editorial Office of ADVANCED MATERIALS.

Chambers' technical dictionaries have a history of almost 50 years. The Technical Dictionary (1940), was supplemented substantially in 1958 and further revisions were made in 1971 and 1974. It seems a particular truism that changes in science and technology in the intervening years appear to have been as great as in the whole of earlier history.

The book, it is claimed, is not intended to replace the expert's own specialist dictionaries but should supplement them, giving the user a source of information which is multidisciplinary in character. To quote from the Preface once again "understanding specialist terms is the first step in applying intelligent controls" and the quality and composition of this work will take the reader a long way towards that goal.

"UNDERSTANDING SPECIALIST TERMS IS THE FIRST STEP IN APPLYING INTELLIGENT CONTROLS"

The main body of the dictionary, some 983 pages, starts with *a* and ends with *zymo-*, and the words in between are, unsurprisingly, arranged in alphabetical order. Joking apart, the coverage of the dictionary is satisfactory, the descriptions concise but clear, in many cases making interesting reading.

The book also contains a Greek alphabet (always useful) and appendices which contain information ranging from ISO paper sizes, through chemical formulae and nomenclature, information on the chemical elements and the classification of the animal and plant kingdoms, to a table mapping geological time and another describing and listing SI units and conversion factors.

All in all, the dictionary is well thought out, produced in high quality and is a valuable reference work which can be recommended without reservation to laymen and specialists alike.

Students of all ages, in all fields of materials technology will find it a valuable companion.

Knowledge is of two kinds. We know a subject ourselves or we know where we can find information upon it
—Samuel Johnson

Chambers are to be congratulated.

Electronics Reliability and Measurement Technology—Non-Destructive Evaluation. Edited by *Joseph S. Heyman*, Noyes Publications, 1988, xii, 188 pp., bound, $ 39.–. ISBN 0-8155-1171-X

The title of the book is misleading. The reader expecting to find a description of the main nondestructive methods for reliability evaluations of electronics will be disappointed. The book consists of a collection of papers presented at a workshop held in June 1986 at NASA Langley Research Center and sponsored by NASA, the U.S. Air Force, the National Security Industrial Association, and the Aerospace Industry Association.

The first paper "Measurement Science and Manufacturing Science Research" gives an overview of the activities at some U.S. universities, sponsored by the Semiconductor Research Corporation.

The paper "Nondestructive SEM for Surface and Subsurface Wafer Imaging" describes the use of a scanning electron microscope as a tool for both failure analysis as well as device characterization. The main emphasis is on capacitive coupling voltage contrast and on nondestructive subsurface imaging of semiconductors.

The paper "Surface Inspection – Research and Development" gives a brief overview of the industrial approach to semiconductor and magnetic disc surface inspection methods and the paper "Sensors Developed for In-Process Thermal Sensing and Imaging" describes a silicon thermophile array for fabrication process control.

The paper "Wafer Level Reliability for High-Performance VLSI Design" deals with the problem that the lifetimes of devices using new technologies are far shorter than older ones and are coming close to system lifetime. In order to monitor reliability on the wafer level, the paper proposes to introduce test structures on the wafer which allow the evaluation of certain failure modes, such as electromigration of mobile ions within a short time.

Some further papers deal with

- microfocus X-ray imaging for solder quality and structure inspection

- measurement of opaque-film thickness by thermal waves
- intelligent laser soldering inspection and process control
- rupture testing of electrodeposited copper interconnections (is this a non-destructive evaluation?)
- heterodyne holographic interferometry and
- "whole wafer" scanning electron microscopy.

The last four papers apparently only consist of copies of view graphs used for presentation at the workshop. The main part of the book describes activities at some companies and universities in 1986 in the area of measurement technology and process control in semiconductor manufacturing. This may be of some interest to a few specialists in the field, but of more interest is a summary of findings and recommendations in the first part of the book. On six pages, the deficiencies of the U.S. semiconductor industry with regard to quality and reliability are listed. These few pages should be read thoroughly by all executives in the U.S. semiconductor industry, but they are of equal interest to quality managers in companies using microelectronics, and for semiconductor competitors in Japan and Europe.

Analysis of Polymers. An Introduction By *T. R. Crompton*, Pergamon Press, Oxford 1989, viii, 362 pp., bound, DM 165.– ISBN 0-08-033942-5.

The number of commercially available polymers has been increasing over the last decade and is still increasing rapidly, due not only to the synthesis of new polymers, including new statistical copolymers or block copolymers, but also to the increasing use of polymer blends or of polymers containing various kinds of additives. Scientists in industry and in universities as well as potential users of such polymers frequently have the need to know what kind of polymers they are confronted with and which kind of additives they may contain. This is a formidable task. Fortunately the number of possible analytical techniques has also increased and some of them are highly sophisticated. It is therefore often not easy to decide which of the techniques is the most promising and what kind of information they are able to provide.

This is where the book "Analysis of Polymers" comes in very handy. It has been designed both as an introduction and as a practical guide for students and analytical chemists in universities or industrial laboratories. To serve this purpose it contains detailed descriptions on the various approaches which can be persued in order to analyze the chemical structure of homo- and copolymers and also the composition of multicomponent systems.

The organization of the book is primarily not so much technique-oriented but rather problem-oriented, as illustrated by the following titles of selected chapters: determination of elements, determination of functional groups, fingerprinting of polymers, polymer microstructure, fractionation and molecular weight, additives in polymers and adventitious volatiles in polymers.

Experimental techniques in turn are introduced within these chapters and their applications are demonstrated for a variety of examples in each of the chapters. Among the many techniques for which the basic theory is treated and applications demonstrated are gas chromatography, IR- and UV-spectroscopy, NMR- and ESR-spectroscopy, polarography, X-ray fluorescence spectroscopy, Neutron activation analysis, electron probe microanalysis, thermogravimetric and differential scanning calorimetry, titration methods, to mention just some.

The book is very well written and the examples have been selected well. It contains, in addition to the features mentioned so far, a large number of illustrations, extensive tables concerned with the properties of selected polymers as well as more than 1000 references. The book gives an impressive up-to-date exposition of the state of the art of polymer analysis and it seems certain that it will serve as a highly useful reference work.

December 1989

4–5 **Advanced Materials by Sol-Gel Techniques, Eurogel '89**
Eur. Conf.
Colmar (France)
Contact: Fraunhofer-Inst. f. Silicatforsch., "Eurogel '89", Neunerplatz 2, D-8700 Würzburg, FRG

11–13 **CBE/MOMBE and Related Growth Techniques**
2nd Int. Conf.
Houston, TX (USA)
Contact: H.-D. Shih, Univ. of Houston, Sci. and Res. One, 4800 Calhoun Rd., Houston, TX 77004, USA, Tel. 713-749-3701, Fax 713-747-7724

11–16 **Physics of Semiconductor Devices**
5th Int. Workshop
New Delhi (India)
Contact: Dr. S. K. Sharma, IWPSD-89, Nat. Physical Lab., Dr. K. S. Krishnan Rd., New Delhi-110012, India, Tel. 586087

12–15 **Pacific Polymer**
Hawaii (USA)
Contact: J. C. Vogl, Pacific Polym. Federation, Polytechnic Univ., 333 Jay St., Brooklyn, NY 11201, USA

20–22 **Thin Films and Multilayers**
Mtg.
Warwick (UK)
Contact: Inst. of Physics, Magnetism Group, 47, Belgrave Sq., London SW1X 8QX, UK

31–2 **Corrosion-Erosion-Wear of Materials at Elevated Temperatures**
4th Int. Conf.
Berkeley, CA (USA)
Contact: A. V. Levy, Lawrence Berkeley Lab., MS 62-203, Univ. of Calif., Berkeley, CA 94720, USA, Tel. 415-486-5822

January 1990

10–14 **Superconductivity**
Int. Conf.
Bangalore (India)
Contact: Prof. S. V. Subramanyam, ICSC, Dept. of Physics, Indian Inst. of Sci., Bangalore 560012, India, Tel. 91-812-344411, Fax 91-812-341683

14–19 **Electro-Optics**
Conf.
Los Angeles, CA (USA)
Contact: SPIE, POB 10, Bellingham, Wa 98227-0010, USA, Tel. 206-676-3290, Fax 206-647-14445

15–18 ☛ **Advances in Composite Materials**
Int. Conf.
Bombay (India)
Contact: Prof. P. Ramakrishnan, Indian Inst. of Techn., Dept. of Metallurg. Eng., Poway, Bombay 400076, India

21–24 ☛ **Gallium Arsenide**
Symp.
Atlanta, GA (USA)
Contact: K. J. Sieger, Naval Res. Lab., Code 6852, Washington, DC 20375, USA

22–26 **Recrystallization in Metallic Materials**
Int. Conf.
Wollongong (Australia)
Contact: T. Chandra, Dept. of Metallurgy and Materials Eng., Univ. of Wollongong, Wollongong NSW 2500, Australia, Tel. 042-270008, Fax 042-270477

February 1990

4–7 **Ceramic Powder Processing**
3rd Int. Conf.
San Diego, CA (USA)
Contact: G. L. Messing, Pennsylvania State Univ., University Park, PA 16802, USA, Tel. 814-865-2262, Fax 814-865-2917

4–8 **18th Australian Polymer Symposium**
Bendigo, Vic. (Australia)
Contact: Dr. J. D. Wells, Bendigo College of Adv. Education, Bendigo, Victoria 2550, Australia

19–21 ☛ **Advanced Ceramics**
Conf.
Rosemont (Italy)
Contact: Soc. of Manufacturing Eng., One SMF Dr., POB 930, Dearborn, MI 48121, USA

19–22 **Advanced Metals & Ceramics**
1990 TMS Annu. Mtg.
Int. Conf.
Anaheim, CA (USA)
Contact: M. Karl, TMS, Meetings Dept., 420 Commonwealth Drive, Warrendale, PA 15086, USA, Tel. 412-776-9050, Fax 412-776-3770

21 **Block-Copolymers**
Mtg.
London (UK)
Contact: Dr. K. Petrak, Ciba-Geigy ADDR Unit, Wimblehurst Road, Horsham, West Sussex RM124AB, UK

21–23 **Armed Forces Communications and Electronics**
Long Beach, CA (USA)
Contact: Armed Forces Communications and Electronics Assoc., Headquarters, 4400 Fair Lakes Court, Fairfax, VA 22033, USA

21–23 **Composites '90**
2nd Int. Congr.
Wiesbaden (Fed. Rep. Germany) Contact: D. Schnabel, Demat Exposition Managing, POB 110611, D-6000 Frankfurt 11, FRG, Tel. 069-234331, Fax 069-253071

25–27 **Interphase Reactions and Interactions**
Freiburg (Fed. Rep. Germany.)
Contact: Prof. Dr. H.-J. Cantow, Hermann-Staudinger-Haus, Stefan-Meier-Str. 31, D-7800 Freiburg, FRG

25–2 **Advanced Devices and Systems**
Symp.
Santa Clara, CA (USA)
Contact: SPIE, P.O. Box 10, Bellingham, WA 98227-0010, USA

March 1990

4–9 **Microlithography**
Symp.
San Jose, CA (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng., Koblenzer Str. 34, D-5300 Bonn 2, FRG

12–16 **American Physical Society Meeting**
Anaheim, CA (USA)
Contact: W. W. Havens, J., Aps, 335 E., 45th St., New York, NY 10017, USA

12–16 **Optical Science and Engineering**
3rd Int. Congr.
The Hague (Netherlands)
Contact: Europtica Services I.C., 16, av. Bugeaud, F-75116 Paris, France

14–16 **Photovoltaic Solar Energy**
5th Int. Symp.
Staffelstein (Fed. Rep. Germany)
Contact: OTTI, D.-Martin-Luther-Str. 10, D-8400 Regensburg, FRG, Tel. 0941-58273/74/75, Fax 0941-54854

14–16 **Non-Metals in Metals**
Münster (Fed. Rep. Germany)
Contact: VDEh, Chemikerausschuß, POB 8209, D-4000 Düsseldorf 1, Tel. 0211-6707-441, Fax 0211-6707-310

17–21 **Advances in Semiconductors and Superconductors**
Symp.
San Diego, CA (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng., Koblenzer Str. 34, D-5300 Bonn 2, FRG

19–20 **Materials Characterization**
Symp.
Philadelphia, PA (USA)
Contact: A. T. Riga, Lubrizol Corp., 29400 Lakeland Blvd., Wickliffe, OH 44092, USA

19–22 **Polymeric Materials**
2nd Arab. Int. Conf.
Alexandria (Egypt)
Contact: Prof. S. Morsi, ACM, Inst. Grad. Studies and Res., 163 Horreya Ave., POB 832, Shatby, Alexandria, Egypt

20–22 **Materials Testing**
10th show
Birmingham (UK)

Contact: ASM Inst. Techn. Dept. Marketing Metals Park, OH 44073, USA

21–25 **Quantum Electronics**
17th Int. Conf.
Anaheim, CA (USA)
Contact: Optical Soc. of America Inc., 1816 Jefferson Pl., NW, Washington, DC 20036, USA

21–26 **Vacuum**
2nd Eur. Conf. + 11th Nat. Congr.
Trieste (Italy)
Contact: Dr. R. Molena, Consiglio Nazionale delle Ricerche, Istituto Tecnologia Materialii Metallici non Tradizionali, Via Bassini 15, I-20133 Milano, Italy

22–24 **Holography Applications**
Int. Conf.
Beijing (PR of China)
Contact: Prof. H. Da-hsiung, Beijing Inst. of Posts and Telecommunications, Beijing 100088, PR of China

22–26 **Optoelectronics**
Int. Symp.
Killarney (Ireland)
Contact: D. O'Connell, Trinity College, Dept. of Pure and Applied Physics, Dublin 2, Ireland

23–25 **Advances in Video Technology**
4th Symp.
Contact: ASTM, 1916 Race St., Philadelphia, PA 19103, USA

29–31 **Plastics-Metals-Ceramics**
11th Int. Conf.
Basel (Switzerland)
Contact: Dr. H. Hornfield, Consultex SA, CH-1261 Bogis-Bossey, Switzerland

June 1990

10–15 **Polycondensation and Related Reactions**
2nd Conf.
Gargano (Italy)
Contact: Prof. Er. E. Pilati, Dipart. di Chimica Appl. e Scienza dei Mat., Universita di Bologna, Viale Risorgimento 2, I-40136 Bologna, Italy

11–13 **Electroluminescence**
5th Workshop
Helsinki (Finland)
Contact: Prof. M. Leskelä, Dept. of Chem. Engineering, Helsinki Univ. of Technology, SF-02150 Espoo, Finland, Tel. 358-0-4512567, Fax 358-0-462373

11–14 **Precision Electromagnetic Measurements**
Conf.
Ottawa (Canada)
Contact: H. Lacoste, Nat. Res. Council of Can., Conf., Services, Ottawa, Ontario K1A ORA, Canada

11–15 **Metallurgical Coatings**
Int. Conf.
Beijing (PR of China)
Contact: Prof. Shi Changxu, No. 43 Baojia St., Xicheng District, Beijing, PR of China

13–15 **Atomic Layer Epitaxy**
1st Int. Symp.
Helsinki (Finland)
Contact: Prof. L. Niinistoe, Helsinki Univ. of Techn., Dept. of Chem. Eng., Kemistinitie 1, SF-02150 Espoo, Finland

18–21 **Metal-Organic Vapor Phase Epitaxy**
5th Int. Conf.
Aachen (Fed. Rep. Germany)
Contact: H. Henke, RWTH Aachen, Inst. f. Halbleitertechnik, Templergraben 55, D-5100 Aachen, FRG

18–22 **C-MRS International '90**
Beijing (PR of China)
Contact: Hengde Li, Dept. of Materials Sci. and Eng., Tsinghua Univ., Beijing 100084, China, Tel. 655646, Fax 861-256-2768

21–22 **Adhesion in Composites**
Symp.
Konstanz (Fed. Rep. Germany)
Contact: Dtsch. Gesellsch. f. Metallkd., Adenauerallee 21, D-6370 Oberursel, FRG

24–30 **Cimtec**
7th World Ceramics Congr.
Montecatini Terme (Italy)
Contact: World Ceramics Congress, POB 174, I-48018 Faenza, Italy, Tel. 546-664143, Fax 546-664138

25–27 **Surface Engineering**
Int. Conf.
Toronto (Canada)
Contact: Prof. S. A. Meguid, Univ. of Toronto, Dept. of Mechanical Eng., Toronto, Ontario M5S 1A4, Canada

July 1990

2–6 **Powder Metallurgy**
Int. Conf.
London (UK)
Contact: Inst. of Metals, Conf. Dept., Carlton Hse. Terrace, London SW1Y 5DB, UK

3–6 **Technology of Polymer Compounds and Energetic Materials**
21st Int. Annu. Conf.
Karlsruhe (Fed. Rep. Germany)
Contact: M. Wolff, Fraunhofer-Inst. f. Chem. Technologie, POB 1240, D-7507 Pfinztal 1, FRG

7–11 **Liquid Matter**
1st Conf.

Image Enhancement—Chemical, Digital, Visual

By Joachim Lohmann*

Digital image processing has become well known through the high quality of some spectacular satellite images. It has developed into a discipline in its own right within information science and now finds application, not only in space travel, but also in such diverse fields as, for example, robotics, medical imaging, and television technology. Image processing also occurs, however, in photographic films and biological visual systems. In these systems, too, recorded images are manipulated for better recognition. This poses the question as to whether similar principles of image processing are operative in these different image handling systems.

1. Introduction

The term "digital image processing" refers to the computer-aided modification of images and encompasses image enhancement (modification for better visual recognizability), image restoration (elimination of a systematic distortion), and image analysis (extraction of information) (Fig. 1). Several monographs on digital image processing are available.[1–5]

Generally the photographic film is known only as a means for image recording. But during chemical development the primary image—the latent image—is not only made visible but is improved in many respects. This forms the basis of modern color-negative films, which combine excellent reproduction of detail with high color saturation. The model for both digital image processing and, in many respects, for the photographic film is the visual system. It performs all the steps from image recording and image enhancement to image interpretation.

In this review the three systems—the chemical film, digital image processing, and the visual system—are compared solely from the standpoint of image enhancement. Naturally,

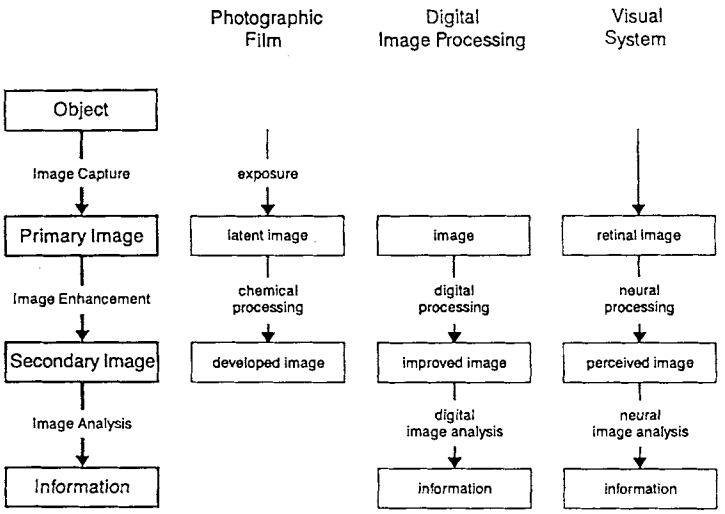

Fig. 1. Steps of image manipulation in the photographic film, in digital image processing and in the visual system.

very different physical and chemical mechanisms are operative in these systems, i.e. the image information is encoded in different languages; consequently, the comparison relates to the structure of these languages, to the algorithms of image processing. The discussion is restricted to the improvement

of three basic image properties, namely noise (Section 3), sharpness (Section 4) and color reproduction (Section 5).

2. Architecture of the Systems

In the following the essential elements of the three systems are briefly described.

2.1. Color Negative Film

Figure 2 shows the common three-layer structure of a color negative film. Each layer contains silver halide crystals which are sensitive to blue light or which are sensitized by appropriate dyes to green or red light. In addition, the layers contain dye-precursors, the couplers. Upon exposure to light, clusters of silver atoms Ag_n—the latent-image specks—are formed (Fig. 3). During the subsequent photographic development these silver clusters catalyze a redox reaction between the silver halide and the developer. The oxidized developer in turn reacts with the coupler to the image dye.

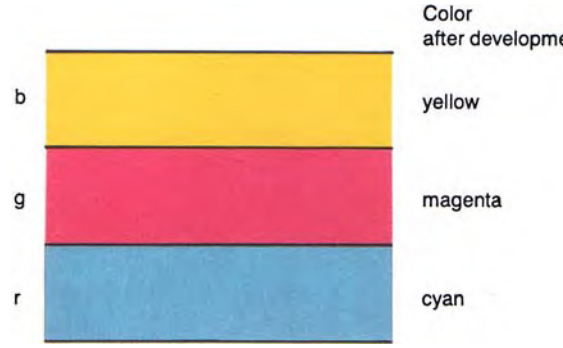

Fig. 2. General structure of a color negative film (△ silver halide crystals, ○ couplers); b blue-sensitive layer, g green-sensitive layer, and r red-sensitive layer; top: before development, bottom: after development.

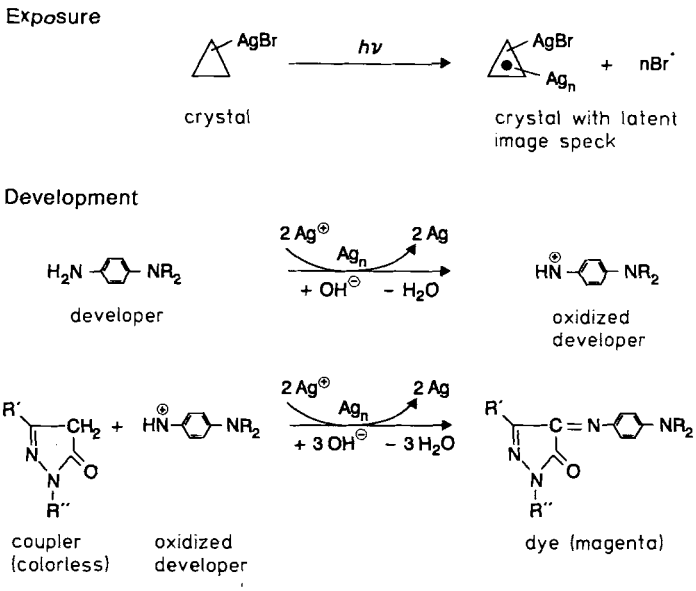

Fig. 3. Reactions during exposure and development of a color negative film (example: green-sensitive layer).

In modern color negative films there are some special couplers besides the standard couplers which fulfill image processing functions: colored couplers and development-inhibitor-releasing (DIR) couplers (Fig. 4).

The colored couplers are compounds which change their color on reaction with the oxidized developer[6]. In contrast, in the reaction of a DIR coupler with the oxidized developer, an inhibitor is released which can freely diffuse in the film in all directions[7]. Once adsorbed, the inhibitor contaminates the latent-image specks (Ag_n) and partially developed silver particles, thus decreasing their catalytic efficiency and retarding the development process.

The different reactions during chemical development of a color negative film are summarized in Figure 5.

Joachim Lohmann was born in 1939 in Hamburg. After a formal education (1959 to 1966) in Hamburg and Berlin he obtained his doctorate from the University of Hamburg in 1969 (supervisor H.-F. Grützmacher). He then spent a year carrying out postdoctoral research with Professor George Porter in London. Since 1971 he has been actively engaged in research at Agfa-Gevaert: at first, in Mortelsen (Belgium), where he was involved in research on silver-free photographic systems; since 1974 he has been working on photographic films and systems in Leverkusen, where he was appointed research director in 1981.

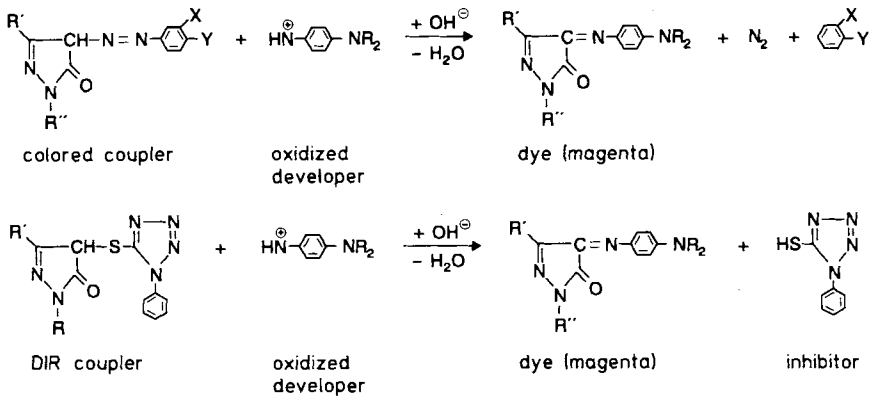

Fig. 4. Reactions of the oxidized developer with colored couplers and with DIR couplers in a color negative film.

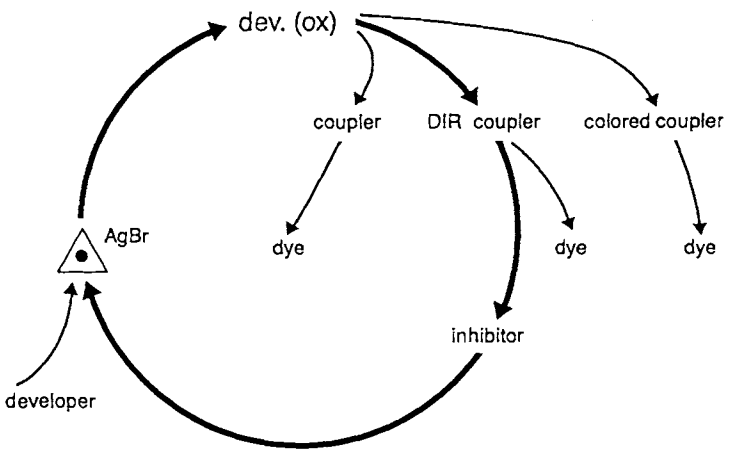

Fig. 5. Chemical processing of a color negative film.

2.2. Digital Image Processing

An analog image must first be digitized to render it accessible to digital processing (Fig. 6). A scanner reads the image by dividing the image area into discrete picture elements (pixels), and each element with the spatial coordinates x, y is assigned a quantized density value $f(x, y)$ (a pixel in a color image is assigned three quantized color densities). The smaller the pixels and the finer the density steps, the more precisely an image can be digitally described. The image function $f(x, y)$ corresponds to an array of numbers; processing results in a modified image function $g(x, y)$, the recording of which (e.g. by a laser on photographic paper) yields the improved image[8].

There are two modes in which the processing can be carried out (Fig. 7). In the spatial mode the numbers of the image function $f(x, y)$ are changed directly, either individually according to a given scheme (look-up tables) or as a function of the neighboring numbers. For processing in the frequency domain, the spatial function $f(x, y)$ is first transformed into a two-dimensional frequency function $F(u, v)$ using a Fourier transform, where u and v are the spatial frequency coordinates. The low frequencies contain information on luminance and coarse image structure, whereas the high frequencies contain information on reflectivity, edges, and granularity. Certain image properties can be enhanced or suppressed by amplification or reduction of the respective frequency range. A systematic distortion of the image produced by a moving camera or by an unfocussed objective lens (perturbation function **H**) can be eliminated by applying **H***, the inverse of the perturbation function.[3b] Thus, the frequency mode offers specific routes for image improvement, and in addition some mathematical operations are very much simplified. After processing the im-

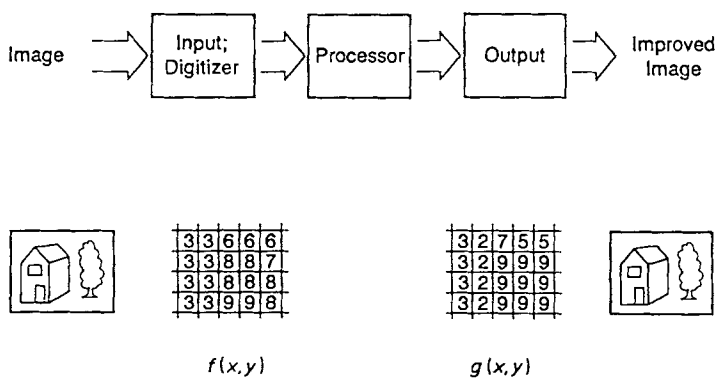

Fig. 6. Digital image processing.

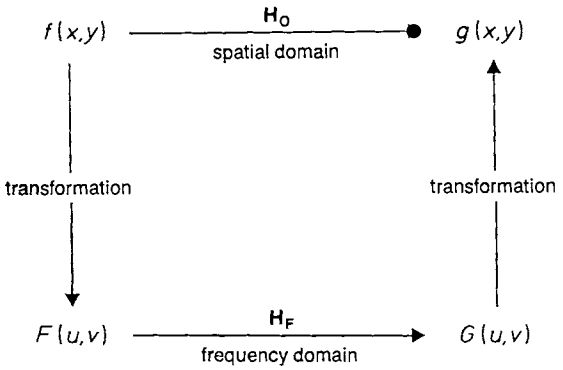

Fig. 7. Processing modes in digital image processing; x, y spatial coordinates; u, v spatial frequency coordinates; $f(x, y)$, $g(x, y)$ primary and improved image function in the spatial domain; $F(u, v)$, $G(u, v)$ primary and improved image function in the frequency domain; $\mathbf{H}_0$, $\mathbf{H}_F$ operators in the spatial and frequency domain.

proved frequency function $G(u, v)$ is transformed back into the modified spatial function $g(x, y)$.

Processing in the frequency domain is of great importance in digital image processing; frequency-dependent algorithms also seem to be operative in the visual system (see Section 4.3), but not in the photographic film. Processing in the frequency domain will therefore be dealt with only very briefly here.

2.3. Visual System

The human visual system consists of the eye (with its light-sensitive retina) and certain parts of the brain (Fig. 8). In the

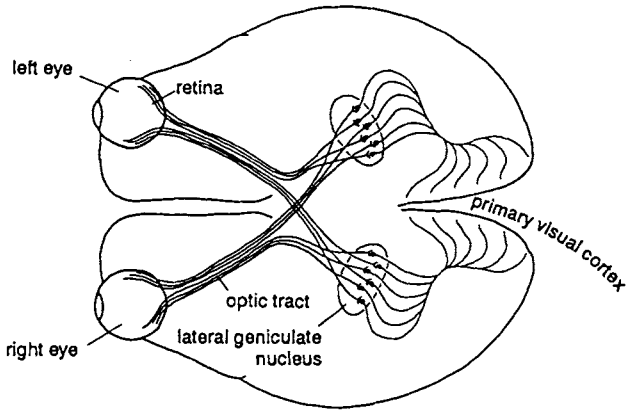

Fig. 8. Human visual system: view of the brain from below [9].

photoreceptor cells of the retina (Fig. 9) the incident light pulses are converted into electrical signals.[11, 12] The photoreceptor cells contain about 120 million rods which register only luminance, and about 6 million color-sensitive cones (three kinds of cone cells with different spectral sensitivities; absorption maxima at 440, 545 and 580 nm[6]). The signals flow via several intermediate cells which are connected crosswise to the ca. one million ganglion cells, and from there to the brain[13]. The complex network of cells in the retina indicates that image processing functions are carried out not only in the brain but also in the retina.

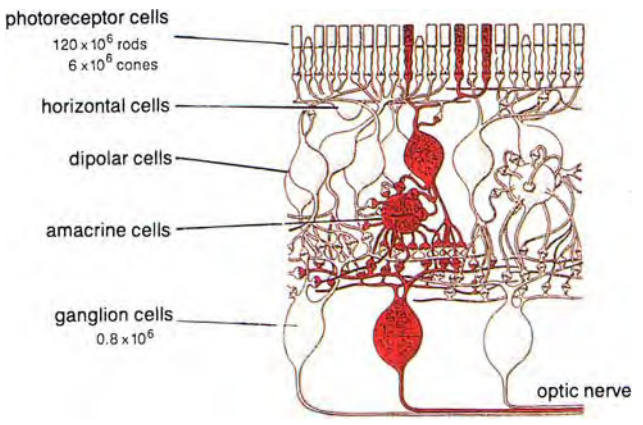

Fig. 9. Structure of the retina (taken from [10]).

3. Noise (Granularity)

Noise is the random variation of a signal and becomes more pronounced with increasing amplification.

3.1. Film

In photographic images the phenomenon of noise is known as granularity—the fluctuation of the optical density in a uniformly exposed image area on a microscopic scale. The relation between amplification and noise becomes evident by the fact that high-speed films are generally grainier and that push-processing (extension of development time to achieve higher speed) also increases granularity. The source for the granularity of a film lies in the random position and the response of the individual silver halide crystals. During development, the granularity of the silver image is translated into a granularity of the color image. This transformation, however, also provides the chance of improving the granularity.

In the presence of DIR couplers inhibitors are released during the development process which diffuse into the surrounding region and prevent the development of adjacent crystals; this leads to smaller dye clouds and results in less granularity (Fig. 10). Decisive in this method is that the sensitivity is not affected, for this is determined by the crystal size during exposure, which remains constant.

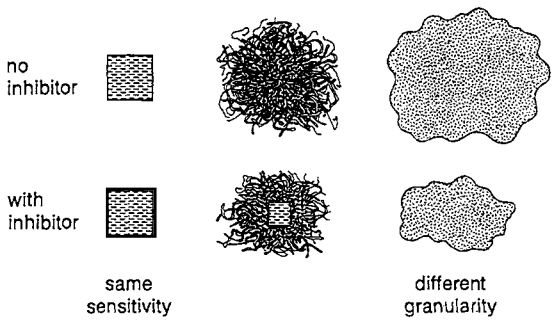

Fig. 10. Reduction of granularity in a color negative film by inhibitors which are released from DIR couplers.

This reduction of the granularity by DIR couplers is connected with the chemistry of chromogenic development. To exploit this effect for black-and-white films, the color "black" must be produced as a mixture of dyes. This is the concept of chromogenic black-and-white films.[14]

Furthermore, an incomplete transformation of the silver image into the dye image is achieved if the oxidized developer (see Fig. 5) is partially consumed by competitive non-chromogenic reactions. Potential competing reactions are the alkaline hydrolysis of the oxidized developer[15] (the more pronounced, the slower the coupling reaction), reactions with incorporated reducing compounds (e.g. dioctylhydroquinone), or reactions with incorporated couplers which produce colorless products.[16]

In all these cases the yield of dye based on the amount of silver halide is diminished. The reduced yield of dye must be

compensated for by an increase in silver halide coverage. An improvement of granularity thus has its price.

A completely different approach for decreasing the granularity is to design dyes with a certain diffusibility under the alkaline conditions of development.[17] Such a controlled diffusion smoothes out local differences in density and leads to a local density average. Figure 11 demonstrates by way of

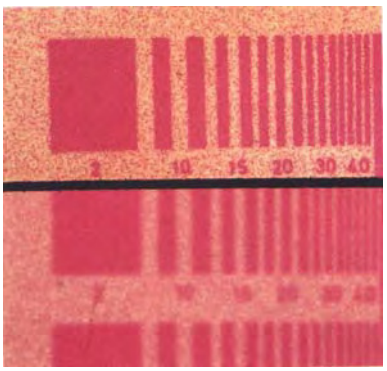

Fig. 11. Reduction of granularity in a color negative film by controlled diffusion of the image dyes.

example how the granularity is improved by this method, but at the same time it reveals the disadvantage of the method, namely the loss of definition with too much diffusion.

Similar to local averaging in one image, is averaging over several identical but independently taken images, which is achieved by exposure through a set of identical negatives. Owing to its random nature the granularity is reduced, but the image information is retained.

3.2. Digital Processing

In a digitized image, noise is the random fluctuation of the image function in a uniform field expressed as deviations of individual pixel values in an otherwise homogeneous field. Noise can be eliminated in a straightforward manner by substituting each number by the rounded-off local average (neighborhood averaging; spatial domain low pass filter). In the example shown in Figure 12, the local average is calculated as the algebraic mean of a particular number and its eight nearest neighbors.

Local digital averaging corresponds to averaging by diffusion in a film. In both cases the sharpness is affected. Therefore, rather complicated operators are applied in which adjacent pixels have lower weighting or in which the weighting of neighboring pixels is variable depending on the local gradient.[5] If the noise is characterized by a particularly high or

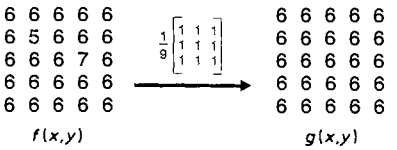

Fig. 12. Digital reduction of noise by local averaging.

low deviation of the signal from the local surround the noisy pixels can be improved selectively by defining thresholds. Only those pixel values are replaced by the local average value (i.e. the difference to the local surround is set equal to zero) whose differences from the local surround are higher or lower than preset thresholds (Fig. 13).[18] In this way, the

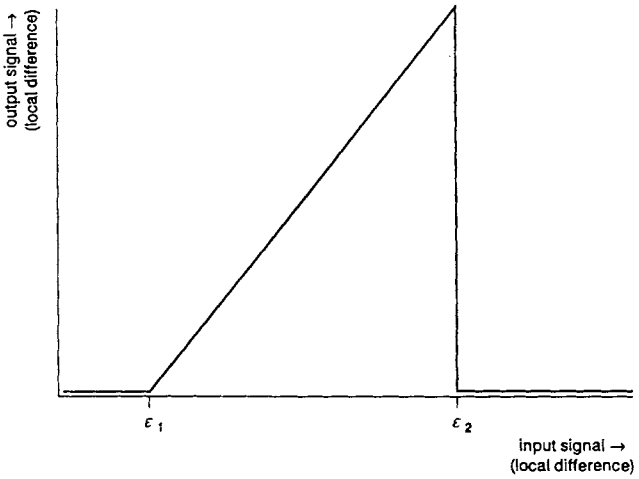

Fig. 13. Digital reduction of noise; restriction of local averaging to signals with low ($< \varepsilon_1$) or high ($> \varepsilon_2$) local differences from the surround.

white points in the lunar image of Figure 14 have been removed. In some cases it is advantageous to use the median of the surround pixels in place of the algebraic mean.[2]

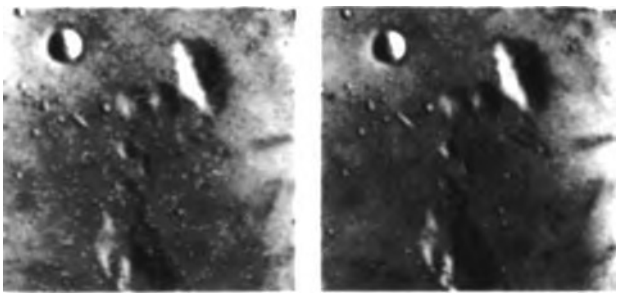

Fig. 14. Digital noise reduction by local averaging [2b].

Averaging over several independent images of the same object decreases granularity in digital images in the same way as in film images.

Another method having no parallel in film chemistry is carried out in the frequency domain. Noise is typically encoded in the high spatial frequencies. Filtering out the high frequencies preferentially suppresses noise (Fig. 15). However, this method also impairs the definition, but it is possible to minimize this by the use of special filters.[3c]

3.3. Visual System

We rarely experience noise in vision—only at near-darkness may we get an impression of flickering.[11, 19] Obviously, the visual system copes very effectively with noise.

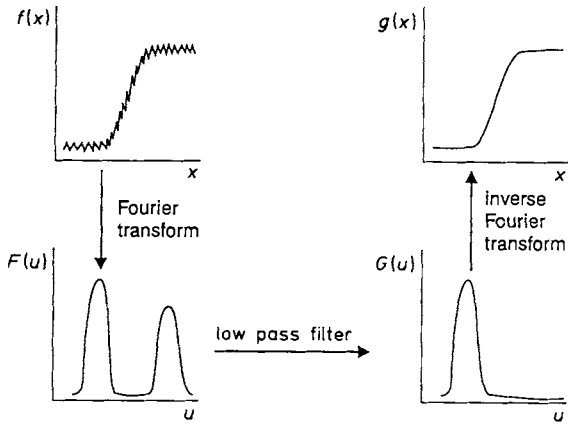

Fig. 15. Example of digital reduction of noise by application of a low-pass filter in the frequency domain (for explanation of symbols see Fig. 7).

Visual noise could have two sources: fluctuation of the input signal, which will be more pronounced at low light intensities (photon noise), or spatial-temporal deviations in the recording and transmission of the primary signals (system noise). The visual system masters intensity differences of $1:10^{10}$; the brain receives maximum differences of $1:10^{2}$.[20] This shows that the visual system can carefully control amplification, thus minimizing the noise problem.

Suppression of noise occurs in the visual system according to the same mechanism as applied in chemical and digital processing: by averaging both in spatial and in temporal mode.

- Spatial averaging: there are many more receptor cells than ganglion cells in the retina; each ganglion cell averages over approximately 100 receptor cells.
- Temporal averaging: the time resolution of the visual system is rather low; this forms the basis for cinematography. The eye cannot resolve individual images at frequencies of 20 images s^{-1} or higher[11, 21] but integrates the optical signals over a certain time span. The extent to which this improves granularity is immediately clear upon viewing an individual (still) image of a motion picture film. The temporal averaging is now no longer operative, and the coarse grain of the individual image becomes apparent.

An additional improvement of the signal-to-noise ratio is achieved in the visual system by transmitting only those signals to the brain which cross a certain (possibly adjustable) threshold.[22]

4. Sharpness

The sharpness of an image determines the quality of the reproduction of an edge (Fig. 16). The steeper the profile of a reproduced edge, the better the sharpness of the system. Improving sharpness means making an edge profile steeper or even overshooting the edges. Such an edge-effect improves the impression of sharpness.

4.1. Film

The sharpness of a color negative film can be chemically enhanced by two methods.

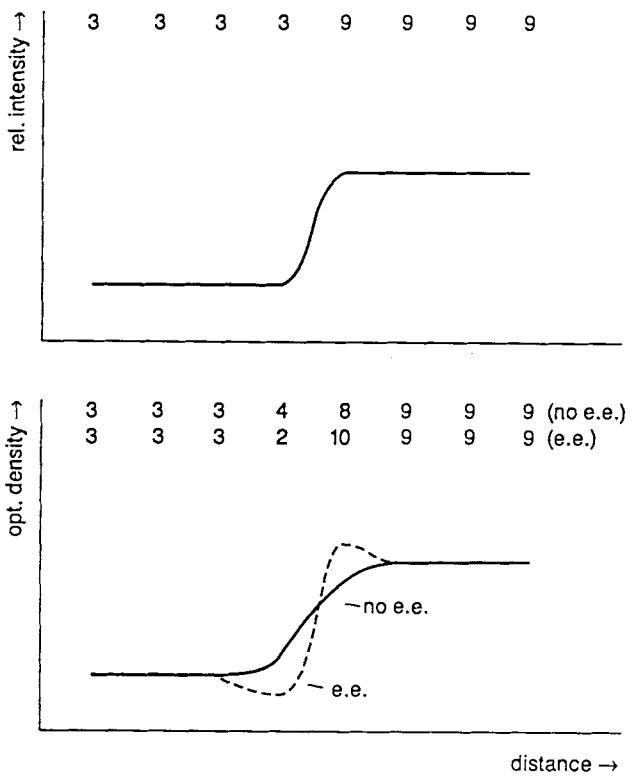

Fig. 16. Edge reproduction (in analog and digital notation). Top: original signal. Bottom: recorded signal with (e.e.) or without (no e.e.) edge effect.

The more important technique is that of "lateral inhibition" with inhibitors released from DIR couplers. Figure 17

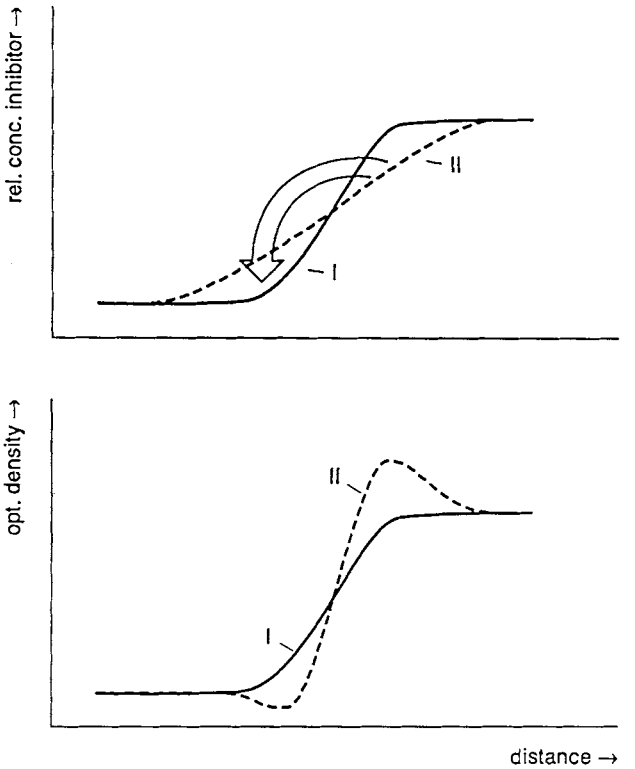

Fig. 17. Chemical generation of an edge effect in a film by lateral inhibition during the development process (schematic). Top: concentration of inhibitor without diffusion (—) and with diffusion (– – –). Bottom: corresponding optical densities.

shows the situation at an edge during development in the presence of a DIR couplers: image dye and inhibitor are formed on the high density side of the edge (see Section 2.1). Because of the concentration gradient the inhibitor diffuses in the direction indicated. That is, in the immediate vicinity of the edge the inhibitor concentration on the high density side decreases, while that on the low density side increases. The degree of development is affected accordingly. In this way an edge effect is generated. Chemical edge effects have been described quantitatively.[23]

The other method for improving sharpness is "unsharp masking", well known to darkroom specialists.[6] In this method a positive, unsharp image is printed in combination with the negative, sharp original image. Edge effects are thereby produced in the print. This principle can also be adapted for use in a film (Fig. 18). In this case a negative,

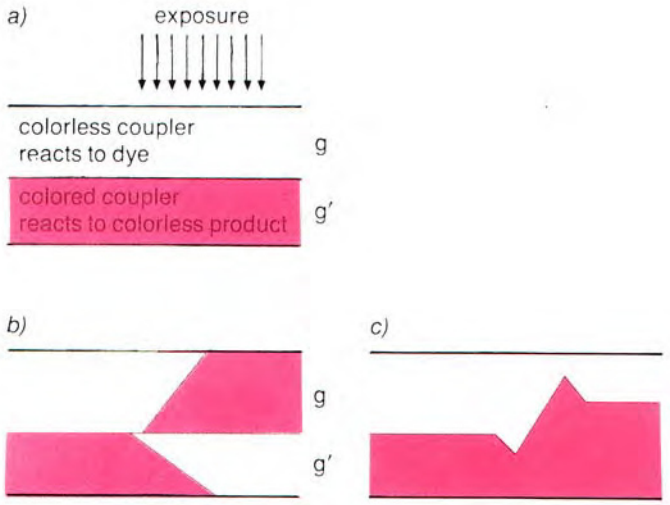

Fig. 18. Chemical generation of an edge effect by unsharp masking in the green-sensitive double layer of a color negative film (g, g': green-sensitive partial layers, K: coupler); a) before development, b) after development, c) summation of densities in the partial layers g and g'.

sharp partial image is generated in an upper layer and a positive unsharp, partial image in a lower layer. The total image from both partial images shows a clear edge effect.[24]

4.2. Digital Processing

There exist corresponding digital methods to both techniques for chemical enhancement of sharpness.

In digital "lateral inhibition" (center surround filter; high pass convolution mask[2]) each pixel value is modified, relative to its local surround. Figure 19 gives a simple example with the operator [− 1 3 − 1] to be applied to each number. The operator gives the instruction to take the threefold value of a particular number and to substract the values of both

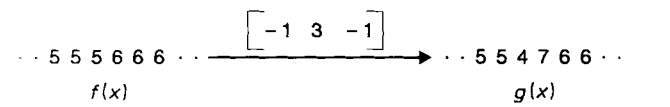

Fig. 19. Digital generation of an edge effect by lateral inhibition.

adjacent numbers. This operation transforms the left string $f(x)$ into the right string $g(x)$ exhibiting an edge effect. Thus, in digital lateral inhibition, each pixel is influenced in an inhibitory mode by its neighborhood—in analogy to chemical lateral inhibition.

Local differences are more or less emphasized depending on the form of the operator. For example, the operator [− 1 2 − 1] records differences only; this corresponds to a (negative) second derivative of the image function and leads to a contour image.

The calculation of local differences forms the basis of a whole class of methods for the enhancement of sharpness: gradient-technique,[3d] statistical differencing,[2c, 5] and use of second order derivative.[5] The combination of an original image function with its second order derivative results in an edge effect, as shown in the top portion of Figure 20.

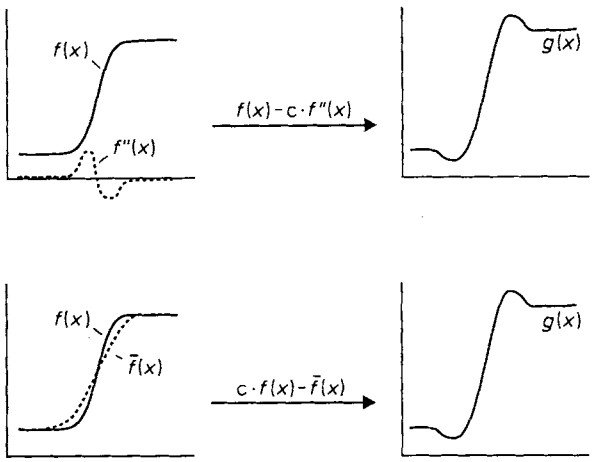

Fig. 20. Digital generation of an edge effect by combination of the original image function $f(x)$ — top: with its second order derivative $f''(x)$, bottom: with a function $\bar{f}(x)$ of reduced sharpness (unsharp masking).

Local lateral inhibition (or local differencing) amplifies signal differences and is therefore the counterpart of local averaging. Not only are edges enhanced, but also random signal differences, i.e. the noise. To overcome this dilemma, very sophisticated methods are applied or thresholds are introduced (see also Section 3.2). For example, the operator can be so modified that only local differences within preset threshold values ε_1 and ε_2 are amplified (Fig. 13), whereas local differences outside these thresholds are interpreted as noise and are suppressed.[5, 18]

In digital "unsharp masking" the original image function $f(x)$ is combined—in complete analogy to the corresponding chemical method—with a function of reduced sharpness $\bar{f}(x)$. Figure 20 (bottom) demonstrates that the resulting function exhibits an edge effect.[2, 4]

The digital methods for enhancing sharpness by processing in the frequency domain have no parallel in film chemistry. The information on edges is preferentially encoded in the high spatial frequencies; by amplification of this frequency range (high frequency emphasize filter) the edges can be emphasized.[2, 3, 5]

4.3. Visual System

An edge effect enhances recognition of details in the visual system, too. Figure 21 shows stepwise bands of different gray levels. This image gives the impression that the density in each band is increasing or decreasing near the edges. In fact, the density of the bands are completely uniform; the perceived edge effect is purely a visual phenomenon (Mach's bands[25]).

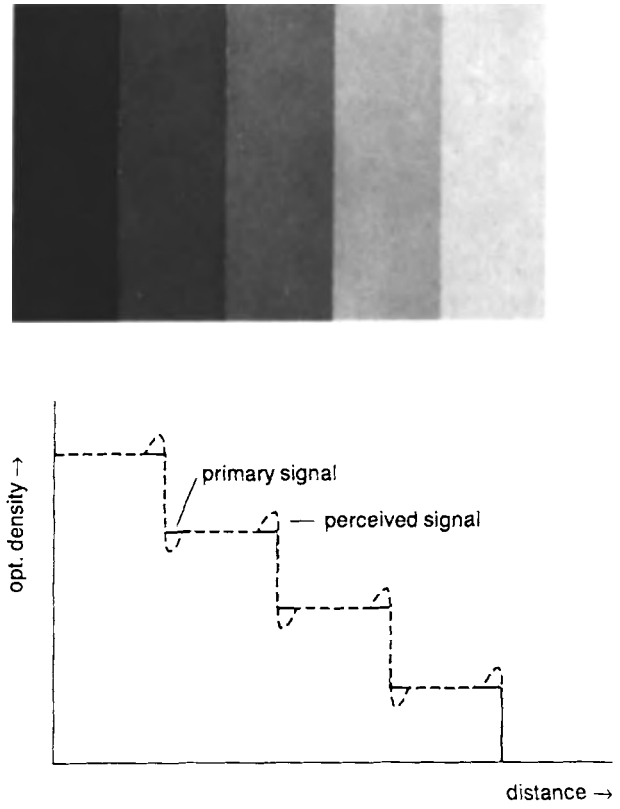

Fig. 21. Edge effect as visual phenomenon (Mach's bands).

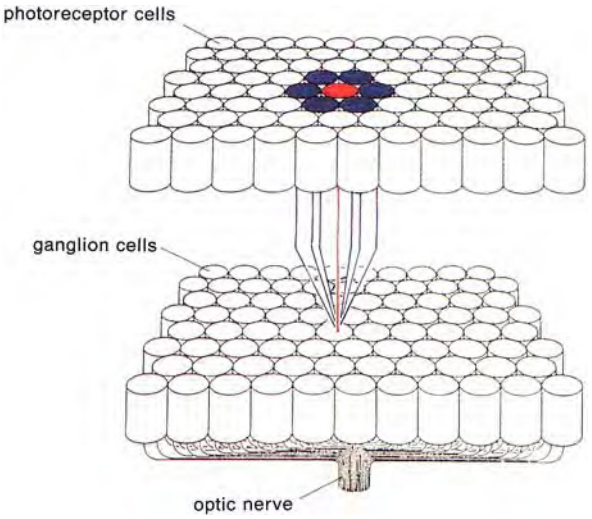

Fig. 22. Generation of edge effects in the visual system by lateral inhibition in the retina (from [26]).

The cause for the edge effects in the visual system is again lateral inhibition (Fig. 22). The receptor cells send activating signals (red) to the nearest ganglion cell but send inhibiting signals (blue) to more distant ganglion cells. Thus, each ganglion cell is subjected to a sum of activating and inhibiting signals. In complete analogy to chemical or digital lateral inhibition such a mechanism generates an edge effect.

The effect of lateral inhibition is also evident in the Hermann-effect: on viewing the black squares in Figure 23 ghost-spots are perceived at the intersections of the white bars between the black squares. At the intersections the lateral inhibition is relatively strong. Here, four inhibiting signals

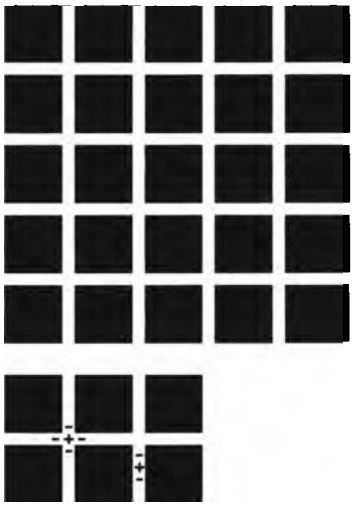

Fig. 23. Hermann effect; top: visual phenomenon; bottom: explanation.

from the surrounding region act on one activating signal, whereas in other white areas only two inhibiting signals act on one activating signal. The stronger lateral inhibition at the intersections gives the impression of lower brightness.[27]

Furthermore, the perception of sharpness in the visual system is spatial-frequency dependent: The visual resolution of a line pattern is better at medium spatial frequencies than at low or high spatial frequencies.[11, 25, 28]

5. Color Reproduction

Original colors are incorrectly recorded by any imaging system, e.g., by a film, because the dyes used have non-ideal absorptions (Fig. 24). When exposed, the color sensors of a film partially register wrong signals because of their non-ideal spectral response; for example, blue light is not only recorded in the blue-sensitive layer b, but to a certain extent also in the green-sensitive layer g. During printing the color information is falsified again, this time by the side-absorptions of the image dyes (the blue light of the printer is modulated not only by the yellow dye in b, but also to a minor extent by the magenta dye in g).

The situation can be described by a matrix of three equations (Fig. 25).[29] The equations contain six interference or

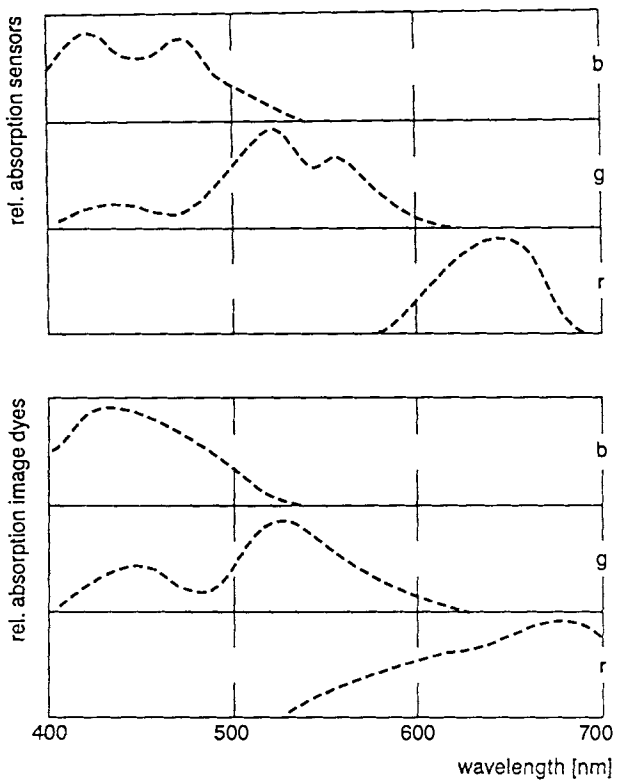

Fig. 24. Incorrect encoding of color signals in a color negative film by non-ideal absorption of the dyes used. Top: exposure. Bottom: read-out (printing).

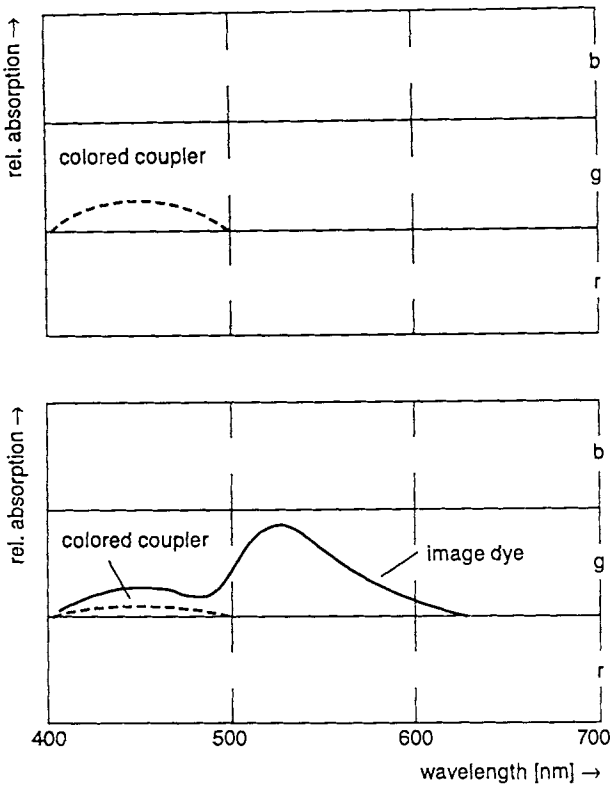

Fig. 26. Improvement of color reproduction in a color negative film by use of colored couplers; top: absorption of green-sensitive layer g before development; bottom: absorption of g after exposure and development.

correction terms which have different weighting. The mutual interference of the color signals affects color saturation and tone.

$$B' = +k_1B - k_2G - k_3R$$

$$G' = -k_4B + k_5G - k_6R$$

$$R' = -k_7B - k_8G + k_9R$$

Fig. 25. Calculation of the original color signals B', G' and R' from the degraded signals B, G and R; k_i are constants for a specific recording system.

5.1. Film

In the case of a film the color signals B,G, and R correspond to the optical densities (determined by the concentration of the respective dyes) as measured behind blue, green, and red filters.

The chemist has two methods available for improving (correcting) the color reproduction by interaction of the color signals with each other according to the matrix in Figure 25.[6, 29]

The first method involves the use of colored couplers (Fig. 26). For example, to correct for the yellow side-absorption of the magenta dye a yellow coupler is additionally incorporated into the green-sensitive layer; this coupler reacts with loss of its color. At a certain ratio of standard coupler and colored coupler the decrease in yellow density achieved by the reaction of the colored coupler compensates for the increase of the yellow density caused by the side-absorption of the magenta dye. The film exhibits a uniform yellow density before and after development which is filtered off in the printing process. Theoretically, all six interference terms can be corrected for by appropriate colored couplers. In practice only yellow colored couplers are used for the green-sensitive layer and red colored couplers for the red-sensitive layer. These colored couplers give color negative films an orange tint.

The other method "vertical inhibition", is based once again on the use of DIR couplers and the action of the inhibitors released during development. If, for example, a color negative film is exposed to a lot of green light and little blue light and red light, more magenta and less yellow dye and red dye are produced (Fig. 27). In the presence of a DIR coupler more inhibitor is released in layer g than in layers b and r. A vertical concentration gradient is built up, resulting in a diffusion of inhibitor from layer g into both adjacent layers, thus inhibiting development there. The situation can be arranged in such a way, that the development of the yellow dye in layer b is inhibited to such an extent that the undesired yellow side-absorption of the magenta dyeing is just compensated for. The diffusion of inhibitor out of the layer g simultaneously enhances the development in this layer. Both effects—the inhibition in the adjacent layers and the activation in the dominant layer—contribute to increased color saturation. The inhibitor of one layer acts on the other two layers (as shown in Fig. 27); incorporation of DIR couplers into all three layers generates a total of six inter-image effects, which correspond to the six correction terms in the matrix of Figure 25.

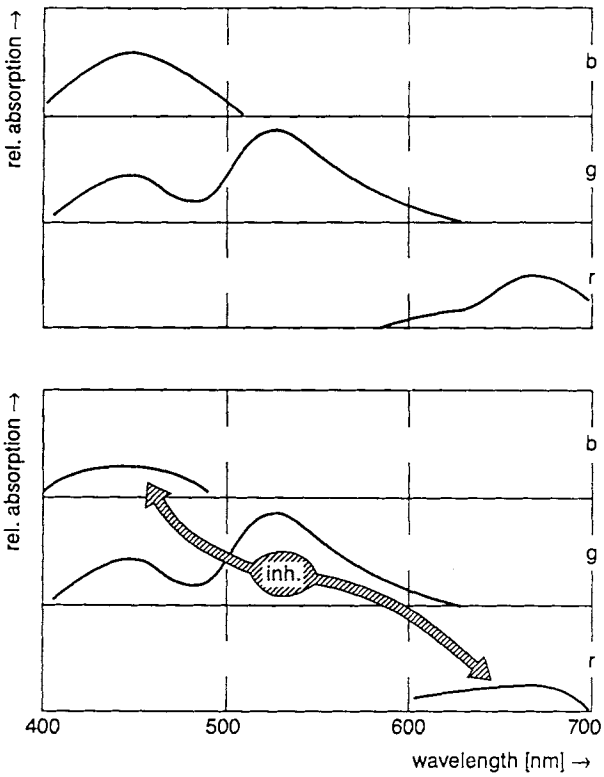

Fig. 27. Improvement of color reproduction in a color negative film by vertical inhibition. Top: absorption in the three partial layers of a developed film without vertical inhibition. Bottom: absorption in a film with vertical inhibition.

5.2. Digital Processing

In digital image processing the mutual interference of the color signals R, G and B can be eliminated by applying the matrix of Figure 25.[21a] The six correction terms are specific for a particular image system (for example for a particular type of film) which affords the input data for the digital image processing. After digital matrixing, the color failures of the original image are corrected with regard to tone and saturation.

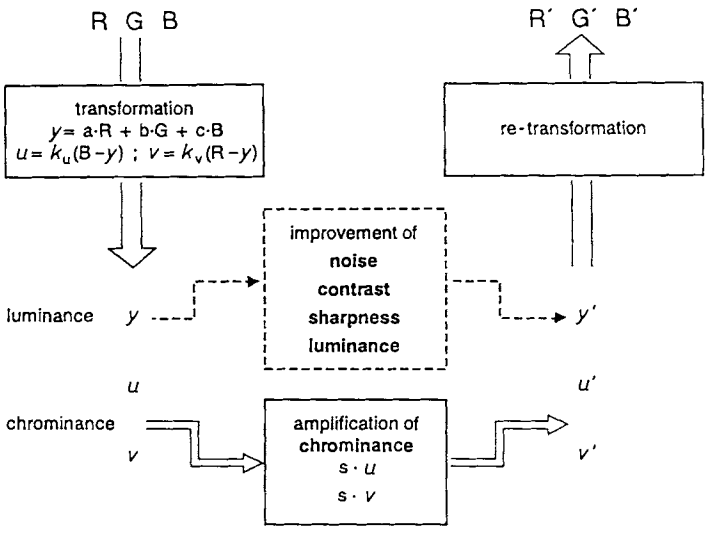

Fig. 28. Improvement of color saturation by digital amplification of chrominance and of image quality by modification of the luminance.

Another way to digitally influence color reproduction is by first transforming the input signals R, G and B into a luminance signal y and two chrominance signals u and v. The tranformations are given in Figure 28.[21c] The color saturation is increased if both chrominance signals are equally amplified. The luminance signal is used to improve noise, contrast, sharpness and brightness. The modified signals y', u' and v' are then converted into improved signals R′, G′ and B′. The increase in color saturation achieved by this method is shown in Figure 29.

Fig. 29. Top: conventional print of a slide. Bottom: print of same slide but with digital processing (digital image processing by CRT printer Agfa-Gevaert AG).

5.3. Visual System

Color results from a non-uniform excitation of the three kinds of color-sensitive receptor cells.

The visual system has the ability to perceive the colors of an object as constant regardless of the color of the illuminating light. This has been demonstrated by *Land*[30] in a decisive experiment shown in Figure 30: a color board is illuminated by three light sources (blue, green, red) and the reflectance striking the eye is measured. In the first case a certain reflectance R_1, G_1, B_1 strikes the eye from the blue field. In the second case the light sources are adjusted in such a way that exactly the same reflectance R_1, G_1, B_1 now comes from the formerly yellow-green field. We should expect that this field now appears blue. But this is not so; this field is seen as yellow-green in both cases, and similarly the other fields are perceived as unchanged with regard to their color. Obviously, the eye relates the color signals from any field to its surroundings. A triplet of relative signals determines the color perceived.

In the context of this comparison of processing algorithms it is also interesting that in the visual system the signals R, G

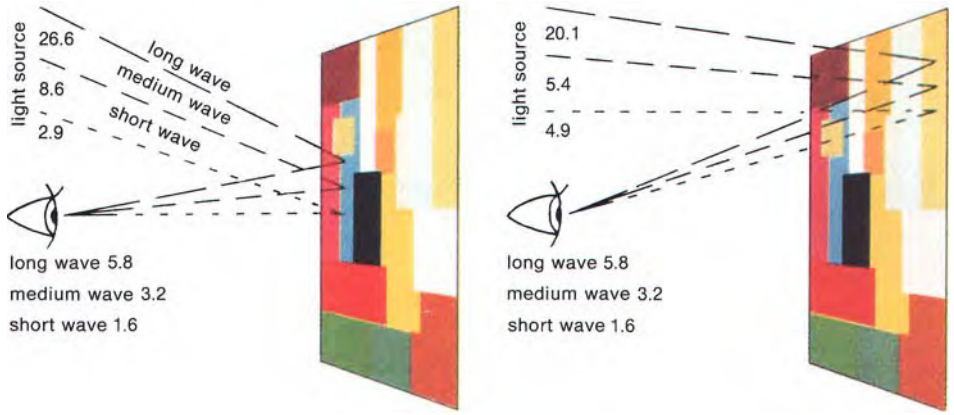

Fig. 30. Experiment for the demonstration of the eye's constancy of color perception. The values quoted are emission densities [$mWsr^{-1}m^{-2}$] (from [30]).

and B from the cone-shaped cells are combined locally in the retina in excitatory (+) and inhibitory (−) mode; the composite signals consist of two chrominance signals (R − G; B − R − G) and one luminance signal (R + G + B + rod signal). This model of opponent colors explains many phenomena of color perception[31, 32]; the model is similar to the mechanism of lateral inhibition (in the eye); whereby in both cases an activating center is surrounded by an inhibiting area.

6. Conclusion and Outlook

Table 1 summarizes and compares the methods for image enhancement discussed thus far. Although some methods are specific for certain systems, the analogies are evident.

Table 1. Comparison of image enhancing methods.

Image Property	FILM Chemical Processing	COMPUTER Digital Processing	VISUAL SYSTEM Neural Processing
Noise (Granularity)	• Averaging • Incomplete transform. Ag → Dye	• Averaging • Thresholding • Frequency filter	• Averaging • Thresholding
Sharpness	• Lateral inhibition • Unsharp masking	• Lateral inhibition • Unsharp masking • Frequency filter	• Lateral inhibition • Frequency filter
Color	• Matrixing – Colored couplers – Vertical inhibition	• Matrixing • Transformation RGB → Lum./Chrom. (Amplification Chrom.)	• Color Constancy • Transformation RGB → Lum./Chrom.

Noise is reduced by local or temporal averaging in all three image processing systems. Thresholds minimize the adverse effects of averaging on sharpness; they are applied in both digital and visual image processing.

Sharpness is improved in all three systems by edge effects caused by lateral inhibition. The method "unsharp masking" is used in chemical as well as in digital image processing. Frequency filters are common in digital processing and also in the visual system.

The correction of color reproduction in color negative films by matrixing (colored couplers or vertical inhibition) corresponds to matrixing in digital processing. In both cases, the R, G, and B color signals are corrected by mutual interaction. The transformation of the R, G and B signals into luminance and chrominance signals is used in both digital and visual processing.

Some striking analogies occur in the methods of image enhancement in these vastly different systems—the chemical film, the electronic computer, the biological visual system. The methods are written in codes specific to these systems; these are chemical reactions and diffusion in the film, electronic data processing in the computer, and neural mechanisms in the visual system.

The analogies described for image processing are relevant for the future of the photographic technology in two ways. Firstly, studying the similarities of digital and biological mechanisms for image enhancement may stimulate further improvement of the photographic film. Secondly, a competing technology becomes evident: A photographic image can be improved by chemical means incorporated into the film as well as by digital image processing in the finishing stage. Future films and their processing may perhaps be simplified because the computer takes over some processing functions. Whether chemical, parallel processing is superior to digital processing or whether the combination of both technologies will give the best results is still an open question.

I am very grateful to my colleague Dipl.-Ing. Eduard Wagensonner for his patience in explaining digital image processing to me.

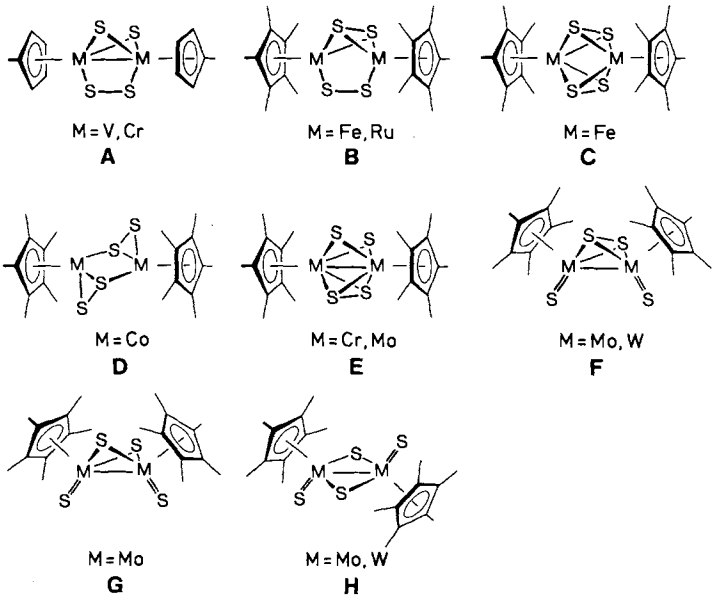
Synthesis, Structure and Reactivity of Sulfur-Rich Cyclopentadienyl-Transition Metal Complexes: Sulfur Chemistry from an Organometallic Point of View

By Joachim Wachter*

Metal-sulfur centers play an important role in the activity of metalloproteins in enzymatic catalysis and the activity of metal sulfides as heterogeneous catalysts. The systematic search for M–S model compounds led to the discovery of an interesting and novel structural chemistry, which stems from the numerous coordination possibilities of sulfur ligands. The intention of this review article is to present and outline new approaches to sulfur chemistry from the organometallic point of view. Reactive cyclopentadienyl-transition metal fragments incorporate elemental sulfur to give polynuclear sulfur-rich complexes, which can contain either mono-, di- or polysulfido ligands or several such ligands in combined form. The versatile structural chemistry of the complexes formed and their reactivity towards organic, inorganic and organometallic compounds are discussed, and examples of some simple and rational procedures for their synthesis starting from cyclopentadienylcarbonyl- and cyclopentadienylhydrido-complexes are outlined. Their reactivity is manifested in numerous metal- and ligand-centered reactions. Finally the, albeit far less extensive, complex chemistry of the other chalcogens (O, Se, Te) is also considered for comparison, thus providing a more detailed survey of particular aspects of this area of chemistry.

1. Introduction



The chemistry of soluble transition metal sulfides is virtually inexhaustible. Whether one is considering the stabilization of unusual bonding systems or molecular model compounds, the immense range of possibilities available to sulfur in metal complex ligands is impressive.

Metal–sulfur complexes are, for example, of special interest with regard to the modes of action and the structures of many enzymes. The as yet unsolved problem of the structure of the active center of nitrogenase—the enzyme system that converts atmospheric nitrogen into ammonia—is often cited as example to demonstrate just how difficult it is to obtain structural information of biological centers indirectly using even the best possible model complexes.[1]

Metal sulfides also play a role in the desulfurization of fossil fuels by hydrogenation (e.g. hydrodesulfurization, HDS).[2] Utilization of the worlds sulfur-containing resources in an economic and environmentally unobjectionable way demands that basic research be carried out on soluble model systems—the HDS process actually occurs on a heterogeneous metall sulfide surface.

It is obvious from the examples already quoted that simple model systems in the form of soluble transition metal sulfides are required in order to extend our existing knowledge of sulfur coordination chemistry. The effort being made in this direction is reflected in the number of reviews of complexes with mono-,[3] di-[4] and polysulfido ligands.[5] Parallel to these investigations a new research area has been opened up with the chemistry of polynuclear sulfur-rich transition metal complexes. The addition of elemental sulfur to reactive cyclopentadienylmetal fragments and subsequent fragmentation of the generally unisolable primary products leads predominantly to binuclear complexes. The advantages offered by this chemistry are the generally uncomplicated synthetic strategies, the good solubility of the products, and the readiness of the products to undergo further reactions. The use of cyclopentadienyl carbonyl complexes often enables the spectroscopic observation and isolation of intermediates that can provide valuable information about the degradation of the S_8 ring.

As already demonstrated in an earlier review of the structures of binuclear sulfur-rich cyclopentadienyl complexes,[6] the sulfur: metal ratio varies from 1:2 to 10:2. The structure

Scheme 1. Examples of possible structure types (A–H) for $[Cp_2^{(*)}M_2S_4]$ complexes.

[*] Dr. J. Wachter,
Institut für Anorganische Chemie der Universität
Universitätsstrasse 31,
D-8400 Regensburg (FRG)

of the relatively simple molecules $[Cp_2^{(*)}M_2S_4]$[*] has alone been formulated in eight different ways to date (Scheme 1). This immediately calls for a clarification and comparison of the background information concerning the formation, structure and reactivity of all these complexes in relation to the nature of the central metal and to the influence of the substituents in the $Cp^{(*)}$ ligand.

The number of analogous Se- and Te-complexes is still relatively small, but nevertheless the existing results allow a comparison to be made between the differing reactivities of the chalcogens and a given CpM fragment. Oxygen is an exception since there already exists an extensive V-complex and Re-complex chemistry.[7] Even so, a discussion of the structural peculiarities of its complexes in comparison to the complexes of its higher homologues would appear stimulating.

2. Syntheses and Structures

2.1. Cyclopentadienyl Sulfides and Selenides of the Electron-Deficient Transition Metals

Rings with an even number of members in which two $Cp_2^{(*)}M$ fragments are present but do not directly interact with each other, are characteristic of the complexes **1** of the group 4 metals. There are many diverse methods available for the synthesis of such complexes. Ti-complexes **1**, for example, are accessible by desulfurization of $Cp_2^{(*)}TiS_5$ with PR_3 (the number n of bridging chalcogen atoms in the product depends on the nucleophilicity of the phosphane[8]) or by the reaction of Cp'_2TiCl_2 with Li_2Se_2 (n = 2).[9] Reaction of carbonyl derivatives such as $Cp_2^{(*)}Ti(CO)_2$ with H_2S[10] or H_2Se[11] yields the kinetically labile complexes **1** (n = 1). These form symmetrical clusters at higher temperatures, e.g. $[Cp_4Ti_4Se_4]$. A less pungent and less toxic way to complexes of type **1** is via the reaction of Cp'_2Zr, prepared in situ, with elemental S or Se.[12] Two different sorts of chalcogen bridges can be found in $[Cp_4Hf_2(\mu\text{-}O)(\mu\text{-}Se_4)]$,[13] the only known binuclear hafnium compound. It is formed from Cp_2HfSe_5 by exposure to air.

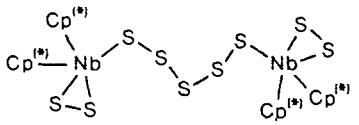
1, M = Ti, Zr
E = S, n = 1–3; E = Se, n = 1,2

The sulfur-rich vanadium complexes $[Cp_2^{(*)}V_2E_n]$ **2–4** (E = S, Se; n = 3–5) are structurally completely different from the binuclear complexes **1**. The diamagnetic compounds **2** can be prepared either by thermolysis of Cp'_2VE_5[14,15] or by dehalogenation of Cp_2VCl_2 with $Se(SiMe_3)_2$[16]. Since these reactions occur with the elimination of a $Cp^{(*)}$ ligand from each metal atom, the products strive to overcome their electron deficiency by utilizing three different chalcogen bridges as well as a metal–metal interaction (d_{V-V} 2.66–2.77 Å). An interesting and recurring phenomenon in complexes of the general composition $[Cp_2^{(*)}M_2S_n]$ ($n \geq 4$) is the stabilization of unusual electron configurations at the metal by M–E d_π–p_π interactions.[*] Such stabilizations may be the driving force for the unusual sulfur abstraction from **2a** ($Cp^{(*)} = Cp'$) by PBu_3 with formation of the 26e complexes **3**[18] and **4**.[17] Due to the very short V–S distances ($\bar{d}_{V-S}$ 2.23 Å) for *all* sulfur atoms, an alternative view of the general system of **3** and **4** with 34 valence electrons was suggested.[18]

E = S (a), Se (b)

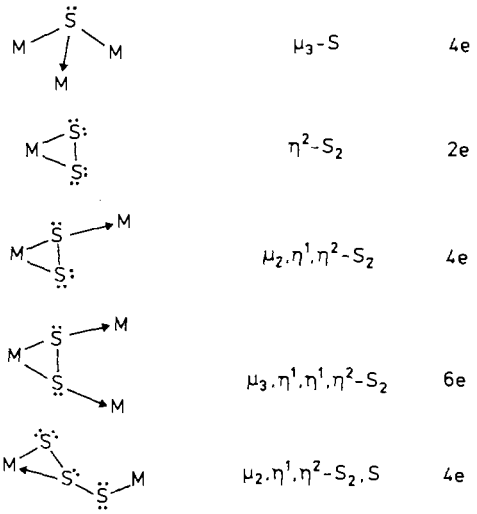
2a,b

3 **4**



[*] If not otherwise indicated the following abbreviations for the cyclopentadienyl ligands apply: Cp = C_5H_5, Cp' = MeC_5H_4, Cp* = C_5Me_5, $Cp^{(*)}$ = any other substituted cyclopentadienyl ring. These ligands are η^5-coordinated in all cases.

[*] With a neutral charge distribution the contribution of the chalcogen ligands to the electron count of **2** is 2(μ-E) + 2(μ,η^1-E_2) + 6 (μ,η^2-E_2) electrons, which together with the 2 × 10 electrons from the two $Cp^{(*)}V$ units adds up to 30 e [3, 4]. The alternative view with μ-$E^{2\ominus}$, μ,η^1-$E_2^{2\ominus}$, and μ,η^2-E_2^{2-} ligands (4 + 4 + 8) and two $V^{4\oplus}$ centers leads to a similar result.



Joachim Wachter was born in 1945 in Böhmen and spent his early years in Riedenburg (Bavaria). He studied chemistry up to Diploma level at the University of Munich and received his doctorate from the University of Regensburg under Prof. Dr. H. Brunner. 1978/79 he carried out postdoctoral research with Prof. J. G. Riess in Nizza. Since 1977 he has been "Akademischer Oberrat" at the University of Regensburg. His research interests lie in the field of organometallic–chalcogen complexes and metal–metal multiple bonds.

The examples of sulfur-rich CpNb dimers known to date apparently show more similarities to Ti-complexes than to V-complexes. Thus, in principle, $[Cp_4Nb_2S_2]$[19] belongs to the same structure type as **1**, despite its weak Nb–Nb interaction (d_{Nb-Nb} 3.23 Å). A mixture of most likely very similar polysulfido complexes is formed upon reaction of $(t\mathrm{BuC_5H_4})_2NbH_3$ with S_8. The structure of **5**, in which the

5

two $(t\mathrm{BuC_5H_4})_2Nb(\eta^2\text{-}S_2)$ units are connected by an S_5-chain, was determined by an X-ray crystallographic analysis.[20] The above-mentioned mixture of polysulfido complexes can, depending on the large number of S–S bonds, be converted in toluene at 100 °C into three trinuclear clusters of slightly less sulfur content, of which **6** and **7** have been fully characterized (Fig. 1). The niobium-sulfur skeleton of **6** shows not less than five different ligand types (Scheme 2).[20] The core of the molecule (Fig. 1a) is a much flattened Nb_3S tetrahedron, whose base is spanned by a triply bridging S_2 group. Two Nb–Nb bonds are each bridged by an η^1, η^2-S_2 ligand. In contrast, Nb1–Nb2 is bridged by an η^1, η^2-S_3 ligand. The coordination sphere of Nb3 is completed by a terminal η^2-S_2 ligand.

Scheme 2. Overview of representative sulfur ligand types found in **6**, their bonding, and the number of electrons which they—assumed as neutral—contribute to the bonding.

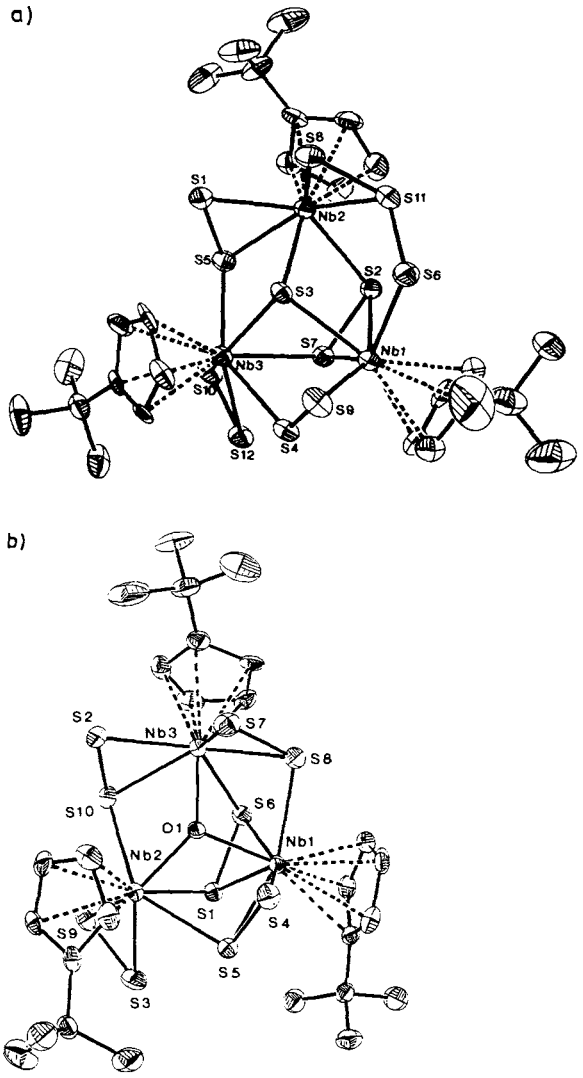


Fig. 1. a) Structure of $[(t\mathrm{BuC_5H_4})_3Nb_3S_{12}]$ **6** in the crystal. The S_2 ligand S4-S9 is bound η^2 to Nb1. b) Structure of $[(t\mathrm{BuC_5H_4})_3Nb_3S_{10}O]$ **7** in the crystal.

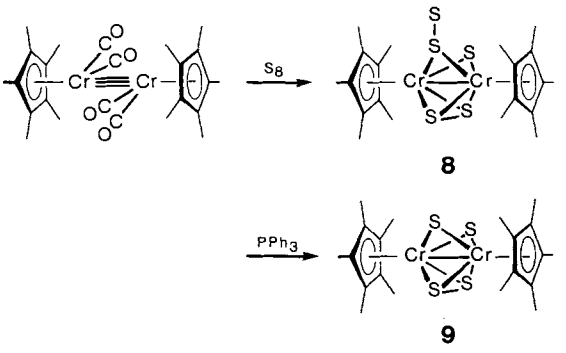
The structure of **7** (Fig. 1b), which can also be prepared directly from **6** by heating for a longer time in toluene solution, is closely related to that of **6**. At the apex of the central tetrahedron there is an oxygen atom, however, and instead of the S_3 ligand there is now only an η^1,η^2-S_2 ligand. This has no electronic consequences, but as a first principle of order a uniform orientation of the points of the edge-bridging S_2 ligands towards the top of the tetrahedron can be seen. This means that the compounds **6** and **7** differ in a remarkable way from the sulfur-bridged, but still halogen-containing clusters formed on reaction of $CpMHal_4$ (M = Nb, Ta) with $S(SiMe_3)_2$.[16]



The sulfurization of Cp-carbonyl-Nb derivatives has until now only been investigated sporadically, although this entry to sulfur-rich cyclopentadienyl complexes has proven very successful for the later transition metal elements. Thus, reaction of $[CpNb(CO)_3(thf)]$ with S_8 leads to the CO-free complex of the composition $[Cp_2Nb_2S_5]$. Its structure, however, is still unclear.[21] It therefore remains to be seen whether the complexes $[\{CpNb(CO)_2\}_2(\mu\text{-}S)_n]$ (n = 2,3) are formed as intermediates en route to complexes with less CO- but a higher sulfur-content upon reaction of H_2S or MeSH and $[CpNb(CO)_3(thf)]$.[21]

2.2. Binuclear Cyclopentadienyl Chalcogenides of the Chromium Triad

2.2.1. Complexes of the Type $[Cp_2^{(*)}Cr_2S_n]$ (n = 4,5)

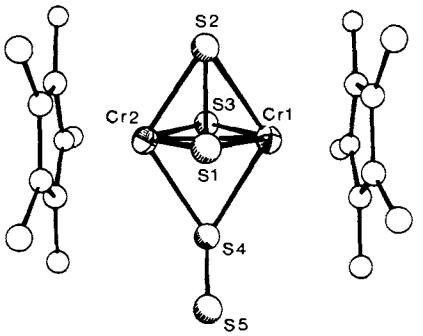
Due to the reactivity of their M–M triple bonds the complexes $[Cp'^{(*)}M(CO)_2]_2$ are generally the most suitable start-

ing materials for the synthesis of sulfur-rich binuclear complexes of the Cr triad. Thus for example, reaction of $[Cp^*Cr(CO)_2]_2$ and S_8 affords the complex **8**,[22] which in turn reacts with PPh_3 with elimination of sulfur to give **9**.[23] The complexes **8** and **9** are isoelectronic (each possessing 32

8

9

valence electrons) and therefore have similar structural frameworks resembling those of triple-decker compounds[22, 24] in which all bridging ligands lie in a plane perpendicular to the Cr–Cr vector and parallel to the Cp* rings. It is worth pointing out that **8** contains an η^1-S,S bridge, in which only one S atom is coordinated to both Cr atoms (Fig. 2). The bent character of this moiety (S5 is orien-



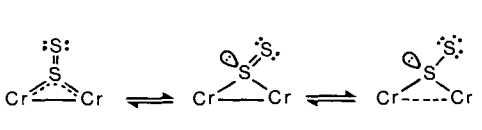


Fig. 2. Structure of **8** in the crystal.

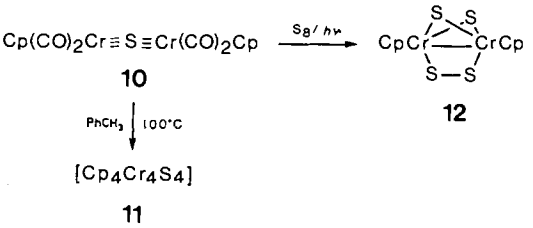
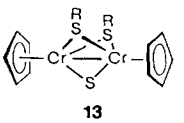
tated towards the η^2-S_2 ligand) suggests a 2e donor (Scheme 3, **J** and **K**) and therefore not the valence tautomer **I**, in which the η^1-S_2 ligand would effectively be a 4e donor. In contrast its SO homologue $[\{Cp(CO)_2Mn\}_2(\mu\text{-SO})]$ has the structure corresponding to **I**.[25] A participation of the reso-



I **J** **K**

Scheme 3. Possible valence tautomerism of the μ,η^1-S,S ligand of **8**.

nance structure **K** explains the relatively long S–S bond (2.101 Å) and the higher nucleophilicity of the terminal sulfur atom.[23, 24] The formation of the η^1-S_2 ligand is surprising, since it does not differ electronically from a μ-S ligand.

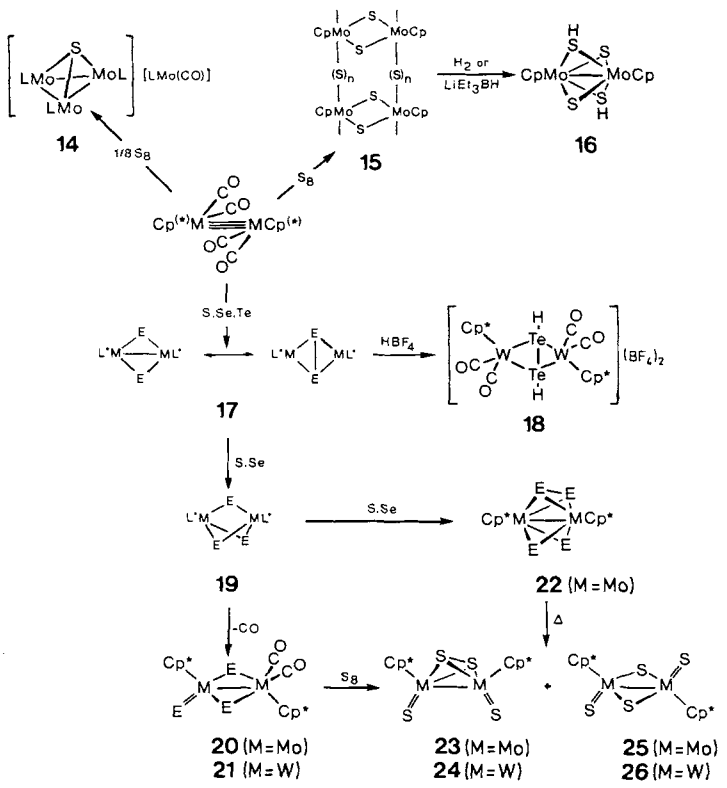


The reaction of $[CpCr(CO)_3]_2$ with S_8 is of a completely different character, since a relatively labile Cr–Cr single bond makes the insertion of sulfur possible. Other than in the case of dimers of the iron triad (see, for example, **36** and **41** in Section 2.4) with a Cr dimer maximally S_2 units are inserted into the M–M bond and only two CO ligands are substituted.[26] The main product **10** contains an almost linear CrSCr multiply bonded system.[27] Thermally, this readily undergoes cleavage of CO to give the 60e pseudocubane **11**. Photochemically, however, it can be transformed in the presence of sulfur into **12**.[28] From a structural point of view

10 **11** **12**

complex **12** has the same ligand set as the vanadium complex **3**. Formally, **12** (structure type **A** in Scheme 1) is related to **9** (structure type **E**) through a 90° rotation of the S_2 bridge (in contrast to the analogously built Mo sulfides (see Section 2.2.2) **9** and **12** are configurationally stable). Although the two complexes differ in their total electron count by four electrons, their magnetic behavior is very similar.

Also conceivable would be the existence of $[Cp_2Cr_2(\mu_1,\eta^2\text{-}S_2)(\mu\text{-S})]$, an even more sulfur-deficient compound than **9**. The isoelectronic dimethylthiolato complex **13** is al-



13

ready known. It shows antiferromagnetic behavior and serves as starting material for the synthesis of numerous S-bridged cluster compounds.[29]

2.2.2. *Cyclopentadienyl Sulfides and Selenides of Mo and W*

Since the M–M triple bond in $[Cp^{(*)}M(CO)_2]_2$ when M = Mo and W is generally more reactive than that when M = Cr,[30] the 'harvest' of sulfur-containing compounds is naturally richer. In contrast to the Cr system, even Se- und Te-containing compounds are occasionally isolated. As far as results up to now indicate, there are parallels between the reactivity of S and Se, while Te is distinctly less reactive. Particularly striking is the control of the course of reaction by the nature of the cyclopentadienyl ligand (Scheme 4), whereby steric effects may largely be decisive.

$[CpMo(CO)_2]_2$ reacts with substoichiometric amounts of sulfur to give **14**, whose cation contains an Mo_3S tetrahedron.[31] In contrast, with sulfur in excess the insoluble compound **15** is formed.[31–33] The formulation of **15** as a polymer would appear justified insofar as it can be converted under mild conditions with H_2[34] or $LiEt_3BH$ into the soluble hydrogensulfido-complex **16**.[35]

Scheme 4. Overview of the reactions of the chalcogens S,Se and Te with $[Cp^{(*)}M(CO_2)]_2$ (M = Mo, W; L = $Cp(CO)_2$, L* = $Cp^*(CO)_2$). **19**–**22**: **a**, E = S; **b**, E = Se. X-ray structurally characterized complexes shown in bold print.

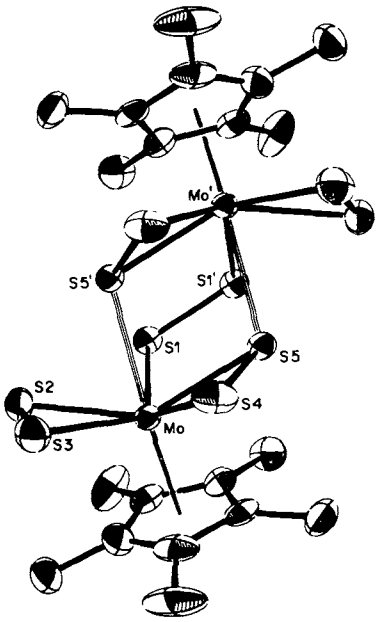
As demonstrated by the occurrence of the kinetically labile di- and tri-chalcogen products **17** and **19** in the reaction of $[Cp^*M(CO)_2]_2$ (M = Mo, W) with condensed sulfur or selenium vapor at low temperatures, there must be a stepwise addition of chalcogen fragments to the M≡M bonds.[36] In contrast, in order to introduce the much less reactive Te the reaction must be carried out at the temperature of boiling THF. The intermediate **17**, for which there are two conceivable isomeric forms, can in the case of the W–Te compound be captured as a stable complex salt **18** by double protonation. This contains the unusual Te_2H_2 ligand.[36]

The formation of the complexes **20** and **21** from **19** can be interpreted in terms of an intramolecular rearrangement of the E-ligand framework with partial CO elimination and formation of an M–M bond. **21a** is the first structurally characterized complex whose sulfur bridges are not symmetrical owing to the unusual polarization of the molecule.[37] Whereas the CO ligands of the Mo-intermediates **19** (M = Mo) and **20** are relatively easily substituted by sulfur or selenium (45 °C, toluene), the W-complex **21a** reacts only with S_8 under substantially more drastic conditions (115 °C) to give well defined complexes.[37, 38] **23**–**26** are the thermally most stable complexes of the whole synthetic sequence. In agreement with this, **22a** isomerizes in solution to give **23** and **25**.[37] Whereas the transformation **22a** → **23** can be described as an opening of both monosulfur bridges, the reaction **22a** → **25** requires the additional cleavage of the η^2-bridge.[39] Interestingly, the entire process is photochemically reversible, since irradiation of any one isomer gives the two other isomers.[40]

Although even more $[Cp_2^{(*)}Mo_2S_4]$ isomers are conceivable (cf. Scheme 1 and Ref. [41]), the reaction products derived from the reaction of $[CpMo(CO)_3H]$ with methylthiirane[42] or $[Cp^*Mo(CO)_3H]$ with S_8[33] belong, just like $[Cp'_2Mo_2S_4]$[33] to structural type **H** (Scheme 1), which is also realized in **25**.

A comparison of the structures of **22a**[37] and **25**[33] reveals a 'clamping' effect of the bridging ligands in **22a**: the formal Mo–Mo bond orders (2 for **22a**, 32 valence electrons (VE) and 3 for **25**, 30 VE) contradict the observed Mo–Mo distances of 2.599 and 2.905 Å, respectively. On the other hand, the Mo–S bridging bonds of **25** are on average ca. 0.06 Å shorter than in **22a**, which could point to a delocalization of the electrons of the bridging sulfur atoms in **25**. Such a delocalization is further supported by the distinctly lower nucleophilicity found for **25**[23] compared to that for **22a**.[23]

An interesting by-product of the reaction of $[Cp^*Mo(CO)_3H]$ with S_8 is **27**, which contains three different types of S_2 ligands (Fig. 3),[33] including the seemingly rare nonplanar η^1–S_2 bridge[4] (Mo-S1-S1'-Mo').



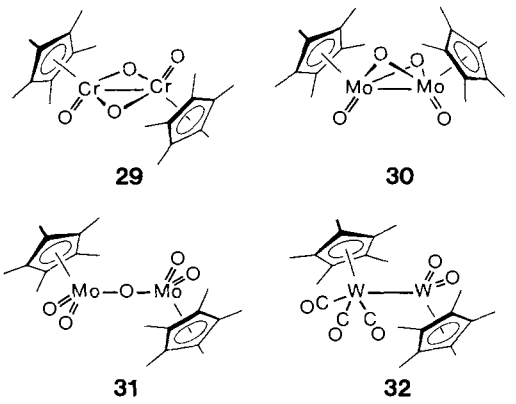


Fig. 3. Structure of $[Cp_2^*Mo_2S_{10}]$ **27** in the crystal [33].

2.2.3. *Cyclopentadienyl Oxo Complexes*

Even from the relatively few examples presented here (see Scheme 5) it can be seen that—with the exception of $[Cp_4Cr_4O_4]$[43] prepared by *E. O. Fischer* et al.—Cp-complexes of the Cr triad containing exclusively O-ligands have the same composition $[Cp_2^{(*)}M_2E_n]$ (n = 4,5) as their S-homologues. However, they differ considerably in many structural respects. One reason for this could be that the formal oxidation state of the metal center in the complexes with oxo ligands (Cr^V in **29**[45], Mo^{VI} in **31**,[45–47]) is frequently higher than in the complexes of the usual chalcogens. The only compound which can be directly derived from an already known sulfur complex, namely **25**, is $[Cp_2Mo_2(\mu\text{-}O)_2O_2]$ **28** with the structural type **H** (Scheme 1).[44]

Scheme 5. Examples for the structures of dinuclear Cp(*) oxo complexes of the chromium triad.

The absence of complexes with $O_2^{2\ominus}$ ligands is remarkable. Thus, e.g., the transfer of the peroxo ligand of $(t\text{BuNC})_2\text{Ni}(O_2)$ is only possible with the rupture of the O–O bond by the Mo≡Mo triple bond of $[Cp^*Mo(CO)_2]_2$.[48] The resulting complex **30** shows a folded Mo_2O_2 core like that of type **G** (Scheme 1). No structural equivalent in the $[Cp_2^{(*)}Mo_2S_4]$ system exists for the Cp^*MoO_2 moieties present in **31** and the nearly linear $O^{2\ominus}$ ligand that is linking them.[47]

There have been contradictory reports on the reaction of $[Cp^*W(CO)_2]_2$ with O_2: At first two products of the composition $[Cp_2^*W_2(CO)_2O_2]$ and $[Cp_2^*W_2O_4]$ were reported,[49] but then, in another experiment, the substitution of only one CO group could be established.[50] The X-ray structural analysis of **32** shows that, owing to the mixed oxidation states of its W atoms, this complex has a structure to some extent related to that of $[Cp_2^*W_2(CO)_2S_3]$ **21a**.[37]

Complexes which contain both oxo and thio ligands are accessible by reaction of the $[Cp_2^*Mo_2S_4]$ isomers **22a, 23** and **25** with atmospheric oxygen.[33, 51, 52] The progress of the reaction can be monitored quite well by ^{95}Mo-NMR spectroscopy, since the molybdenum centers suffer a shielding effect of $\Delta\delta = 400-600$ by introduction of oxygen.[53] The final products **33** are, according to X-ray structural

$$[Cp_2^*Mo_2S_4] \xrightarrow{O_2} [Cp_2^*Mo_2S_{4-n}O_n] + [Cp_2^*Mo_2S_4]\cdot SO_3$$

22a **33**, n = 1, 2 **34**

analyses, clearly of the structural types **G** and **H** (Scheme 1). The oxo ligands are always terminal, i.e. there are always two $S^{2\ominus}$ bridges present. Prerequisite for such a reaction with oxygen at the metal center (examples for an oxidation of the sulfur ligands have been well documented[54]) is obviously the presence of terminal sulfido or selenido ligands. Consistent with the course of the reaction of **22a** with O_2 is that the dioxo complex *syn*-$[Cp_2^*Mo_2(\mu\text{-Se})_2O_2]$ can be structurally characterized (type **G**), whereas this has not been possible for complexes with terminal Mo=Se moieties.[36, 38]

The sulfur released in the reaction of **22a, 23** and **25** with O_2 can be isolated in the form of an SO_3-adduct to the starting compound. It is assumed, however, that in such a reaction the complex with the most nucleophilic sulfur bridges, **22a**, is employed. Consistent with the comparatively large S–S distance (2.168(2) Å), **34** also chemically resembles

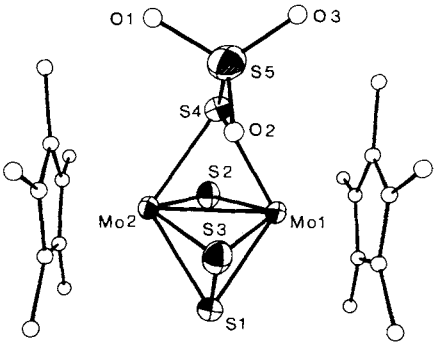

Fig. 4. Structure of **34** in the crystal.

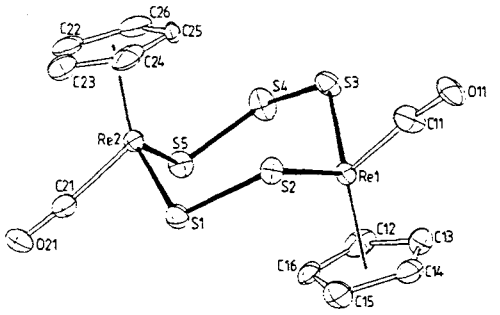
an SO_3-adduct of the $S^{2\ominus}$ bridge rather than a complex with an η^1-thiosulfato bridge.[52a, 55] Further information about the mechanism of the reaction can be found in Section 3.4.

2.3. Cyclopentadienyl Chalcogenides of Mn and Re

Generally applicable methods for the preparation of chalcogen-rich complexes of Mn and Re have not yet been developed. Thus, the reaction of S, Se and Te with $[Cp(CO)_2ML]$ (M = Mn, Re; L = thf, Et_2O) leads only to mono- and dichalcogen-bridged products of the $CpM(CO)_2$ fragment.[56] With regard to the subject of this review these complexes are somewhat of a 'dead end', since they do not react any further with chalcogens. The only structurally characterized complex with a higher sulfur content is $[\{CpRe(CO)\}_2S_5]$, **35**. This contains a puckered seven-membered ring (Fig. 5), in which an S_2 bridge and an S_3 bridge connect two CpRe(CO) moieties.[57] Thus, each Re center has only 16 valence electrons.



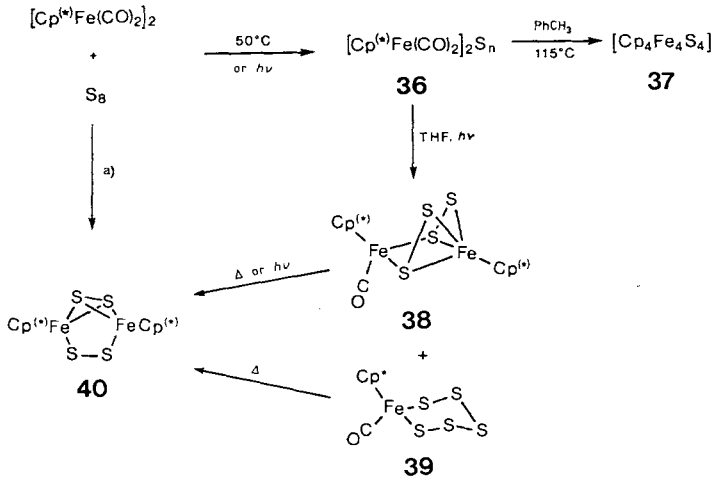


Fig. 5. Structure of **35** in the crystal [57].

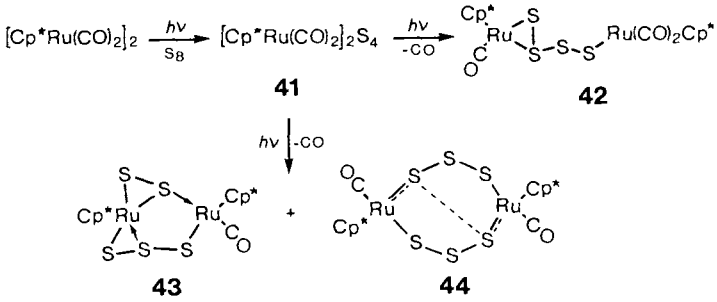
Two CO-free dinuclear complexes of the composition $[Cp_2^*Mn_2S_4]$ have been prepared from the reactions of Cp_2^*Mn and $Cp_2^*Mn_2(\mu\text{-CO})_3$ (*Mn≡Mn*), respectively, with S_8. The elucidation of the structures of these extremely air-sensitive compounds still proves to be quite a challenge.[6] $[Cp_2^*Re_2S_4]$ is reported to be obtained upon reaction of Cp^*ReOCl_2 with $(Me_3Si)_2S$, but this too requires better

structural characterization.[7c] The oxygen homologue $[Cp^*_2Re_2O_4]$ (structural type **H**, Scheme 1) is a typical example of how the chemistry exhibited by O- and S-complexes differs. It can be obtained by careful deoxygenation of Cp^*ReO_3 and represents a preparatively important and very reactive intermediate.[7c, 58]

2.4. Cyclopentadienyl Sulfides of Fe and Ru

Sulfur-rich cyclopentadienyliron complexes have so far only been prepared from $[Cp^{(*)}Fe(CO)_2]_2$ and elemental sulfur. Scheme 6 covers the differing types of influence exhibited by the substituents on the $Cp^{(*)}$ ring in the thermal reac-



Scheme 6. Overview of the reactions in the system $[Cp^{(*)}Fe(CO)_2]_2$/sulfur. a) Toluene, 115 °C, only starting from $[Cp^*Fe(CO)_2]_2$.

tion: when $Cp^{(*)}=Cp$ the 60 e heterocubane **37**[32, 59] is obtained, whereas when $Cp^{(*)}=Cp^*$ one obtains the complex **40**(Cp*)[60]. **40**(Cp) can, in contrast, only be prepared photochemically.[61] Both complexes **40** exhibit an interesting structural feature in that two η^1-S_2 and η^2-S_2 bridges are found perpendicular to each another.[60, 61] These diamagnetic molecules (34 valence electrons from $2Cp^{(*)} + \eta^1$-S_2 and η^2-S_2 bridges $+2Fe = 10 + 2 + 6 + 16$) have relatively large Fe–Fe distances (ca. 3.50 Å) and shortened Fe–S distances. The latter fact in particular proves that there is increased π-donation from the η^1-S_2 ligand coplanar to the Fe–Fe vector. The mixing of the sulfur p_x-orbitals perpendicular to the Fe_2S_2 plane with a set of metal d-orbitals of suitable symmetry may explain this effect.[62]

The products **36** derived from insertion of sulfur into the Fe–Fe bond are of intermediate character, of which the derivatives with $Cp^{(*)}=Cp$ can even be isolated. **36**(Cp, n = 3) can be converted into **37** in boiling toluene,[63] **36**(Cp, n = 5) reacts photochemically in THF solution to give **38**(Cp), which in solution exists in three isomeric forms, of which that given in Scheme 6 has been characterized by an X-ray structure analysis.[61a]

Recently, the permethylated intermediates **38**(Cp*) and **39** formed during the photolytic preparation of **40**(Cp*) could also be isolated.[64] In contrast to **40, 39** is paramagnetic (ESR signal at $g = 2.056(3)$).

Since $[Cp^*Ru(CO)_2]_2$ dissociates easily under photochemical conditions to give reactive 17 e fragments,[65] it seems likely that the mechanism for the uptake of S_8 is radical in nature.[66] The primarily formed compound is the tetrasulfido-bridged complex **41** (Scheme 7). This is either stabilized

Scheme 7. Overview of the reactions in the system $[Cp^*Ru(CO)_2]_2$/sulfur.

intramolecularly in the form of **42** with elimination of CO or reacts further to give the sulfur-rich compounds **43** and **44**.[67] In the course of the latter process an S_4 bridge is broken down and the sulfur fragments that are released are apparently so reactive that they recombine to form a second bridging ligand. In this sense the formation of **43** and **44** is favored by the addition of S_8. Under thermal conditions (toluene 115 °C) only **41** and **43** are formed. The structure of **43** can be described as a Ru_2S_3-ring with two sulfur atoms bridging two adjacent Ru–S bonds (Fig. 6), i.e. the sulfur

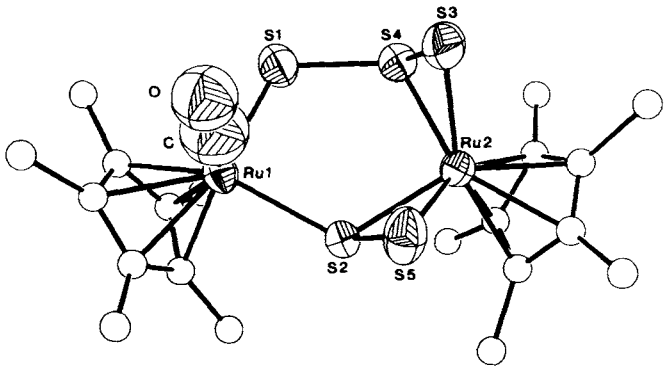


Fig. 6. Structure of **43** in the crystal.

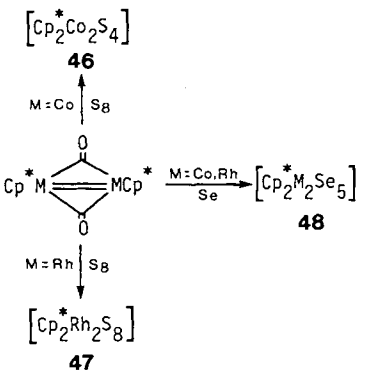
bridges are effectively pure σ-donors. The assumption of a folded eight-membered ring in **44**, in which two S_3-ligands bridge the Cp*(CO)Ru centers, is based on an analogy to the structurally characterized $[\{Cp'RuPPh_3\}_2S_6]$, which can be prepared from $[Cp'_2Ru_2(PPh_3)_4S_2]^{2\oplus}$ and $S_6^{2\ominus}$.[68] Compared to **43**, there are rather different bonding modes, e.g. a bicyclic Ru_2S_6 core as a consequence of relatively important transannular S–S interactions (d_{S-S} 2.77 Å). Concomittantly, the different Ru–S distances ($\Delta d = 0.11$ Å) prove that there is an additional π-donor stabilization of the Ru centers by one S-atom in each case.

With **36**(Cp, n = 4) and **5** as examples it could be shown that complexes with polysulfido ligands tend to undergo



thermal decomposition with the formation of clusters. In contrast to this the metal-sulfur rings in **43** and **44** are so stable that up to now no way has been found to convert them, e.g., into the Ru-analogue of **40**. In this connection it is hard to explain why just a slight modification of the substituents of the Cp ring has such a large effect on the reaction: $[(EtC_5Me_4)_2Ru_2(CO)_4]$ reacts with S_8 in boiling toluene to give $[(EtC_5Me_4)_2Ru_2S_4]$ **45** (structure type **B**) and other still not fully characterized CO-free products.[69]

It is known from the higher sulfur homologues, that Se can be inserted into the Fe–Fe bond of $[CpFe(CO)_2]_2$. The number of bridging members in the products $[\{CpFe(CO)_2\}_2(\mu\text{-}Se)_n]$ appears, however, to be limited to n = 1 and 2, respectively.[70] An excess of Se leads to the 60e heterocubane $[Cp_4Fe_4Se_4]$.[71]

2.5. Cyclopentadienyl Chalcogenides of Co and Rh

The substrates from the Co triad that were chosen for reactions with chalcogens were the M=M double bonded dimers $[Cp^*M(CO)]_2$ (M = Co, Rh). These react with sulfur and selenium but not Te under mild conditions, finally giving CO-free products which have different structures (**46**–**48**), depending on the chalcogen and the metal. **46** has the structure type **D** (Scheme 1), in which the two η^1,η^2-S_2 bridges each act as 4e donors. (Fig. 7a).[60] In contrast, the molecular structure of **47** contains two RhS_4 chelates, which are coupled with formation of a slightly puckered Rh_2S_3 five-membered ring (Fig. 7b).[72] This asymmetric method of coordination allows the donation of four electrons per ligand and is thus quite interesting, since up to now all bridging S_4 ligands have been found to act as 6e donors coordinated via their terminal atoms.[5] In contrast, two non-bridging S_4 chelating ligands are present in **51** (see Scheme 8), which is the precursor of **47**. The elimination of sulfur from **47** to give a complex analogous to **46** with a $Rh_2S_4^{2\oplus}$ core has not yet been successfully carried out—although a core of this type is found in $[(triphos)_2Rh_2S_4](BPh_4)_2$ **54**.[73]

The 36e complexes **48** (M = Rh, Co) may be regarded as triple-decker complexes of a special kind.[74] The middle deck is a planar pseudo-five-membered ring which is σ-bound through three coordination sites and consists of a $Se^{2\ominus}$ ligand and a $Se_4^{2\ominus}$ ligand (Fig. 7c). The relatively short intramolecular Se···Se distances of about 3.10 Å could be responsible for the stabilization of this bonding system. Weaker intermolecular Van-der-Waals interactions ($d_{Se\cdots Se}$ 3.50 Å) seem to be responsible for the anisotropic orienta-

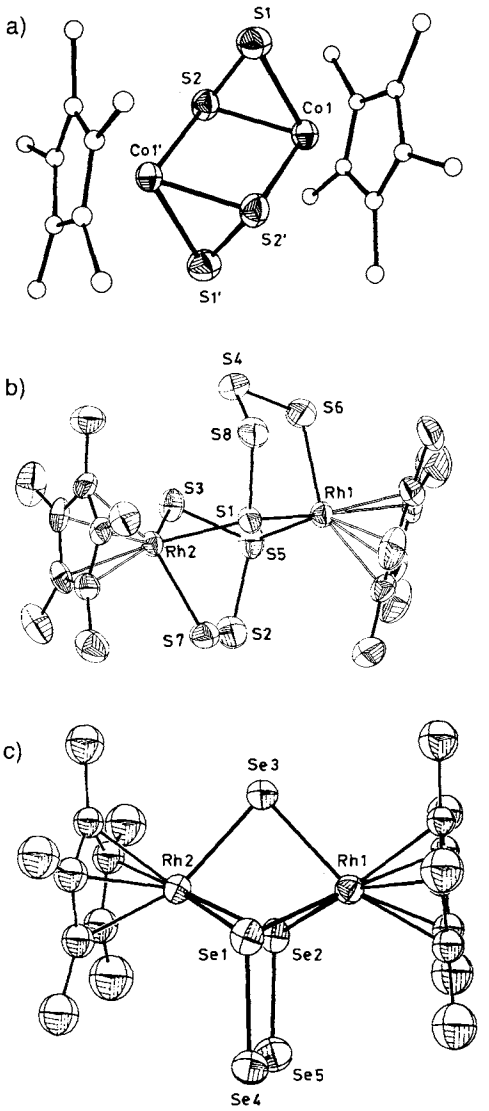


Fig. 7. Structures of a) **46**, b) **47** and c) **48** (M = Rh) in the crystal.

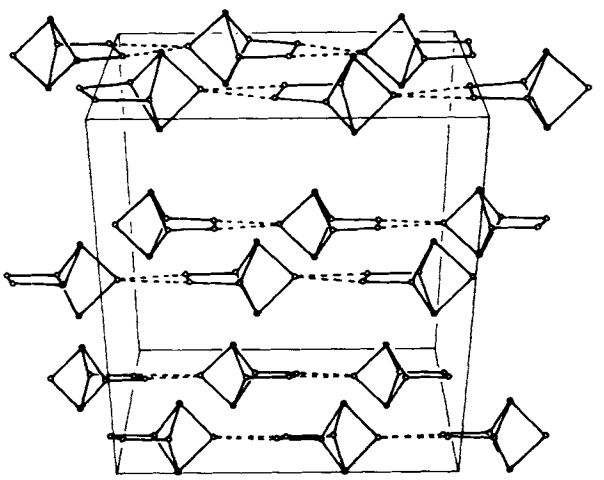

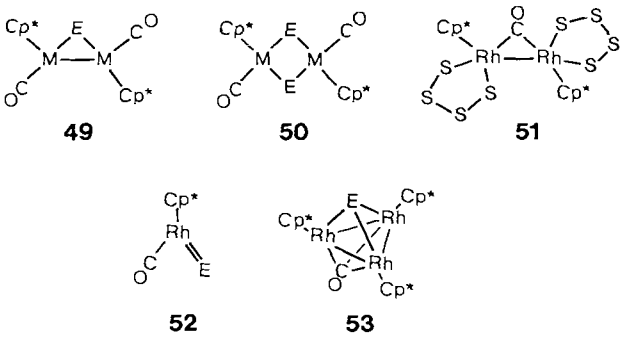

Fig. 8. Unit cell of **48** (M = Rh) (○ = Se atoms, ● = Rh atoms; the Cp* ligands have been omitted for clarity).

tion of the molecules in the crystal lattice. This is unusual for cyclopentadienyl complexes. All Se atoms lie in one plane, which, due to the parallel Cp* rings, gives it a compact layer structure (Fig. 8).

Investigations of the mechanism whereby the complexes **46**–**48** are formed must concentrate above all on evidence for and characterization of the mono- and dichalcogenide adducts at the M=M bond, **49** and **50** (Scheme 8), since the

49 **50** **51**

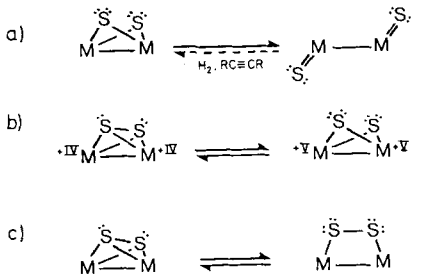
52 **53**

Scheme 8. Intermediates of the reactions of $[Cp^*M(CO)]_2$ (M = Co, Rh) with the chalcogens E (S, Se, Te).

incorporation and fragmentation of the chalcogen units occurs so quickly that they can hardly be followed, even by low-temperature IR spectroscopy.[74b] The stability of these complexes can certainly be traced to the influence of the central metal (some of the cobalt complexes are so labile that they can only be characterized by IR spectroscopy), but the reactivity of the chalcogen employed is also an important factor. The order of reactivity is $S_8 \approx Se_8 > Se_x > Te$. Due to oxidative addition of sulfur or selenium respectively (tellurium is not sufficiently reactive) at the metal centers of **49** and **50**, ME_4 chelating rings are ultimately formed. Only in the case of the Co/S system (**46**) does the degradation of the S_8 ring ultimately give an MS_2 unit. A further intermediate **51**[74b] with a symmetrically bridging CO ligand has been isolated in the Rh/S system. Solutions of **51** eliminate CO at room temperature with the formation of **47**.

Although it has not yet been directly proved, mononuclear complexes with metal-sulfur double bonds play a key role in the formation of sulfur-bridged binuclear complexes—this is at least true in the case of the $Cp^{(*)}(CO)_2M/S_8$ (M = Mn, Re) systems.[56] The complexes **52**, with noble gas configurations, also come into this category—indirect evidence for their existence has been obtained by studying the manner in which the complex **49** (M = Rh; E = S, Se) disproportionates to give the structurally characterized 48e clusters **53**.[64]

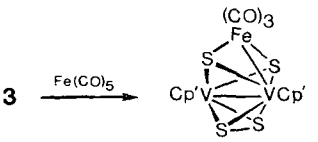
3. Reactions



3.1. Tranformations of Mono- and Disulfido Ligands

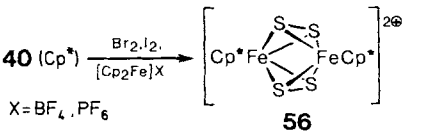
Due to their clear structures the complexes of the type $[Cp_2^{(*)}M_2S_4]$ are especially suitable for the study of ligand transformations. A special case, limited as yet to Mo and W complexes, is the opening of a pair of monosulfido bridges to two terminal M = S units (Scheme 9). The reverse reaction is not only photochemically possible, it is also induced by H_2 or unsaturated organic molecules, giving complexes such as **16**[33].

During the course of the isomerization **22a** → **25**[37] (Scheme 4) a reductive opening of the η^2-S_2 bridge with consequent flattening of the folded Mo_2S_2 four-membered ring was also observed. According to recent experimental findings this reaction could even proceed via a dissociative mechanism.[52b] The bridge opening occurs formally with a change in the metal oxidation state [b) in Scheme 9] represented by Equation (a):



$$2Mo^{IV} + S_2^{2\ominus} \rightarrow 2Mo(V) + 2S^{2\ominus} \qquad (a)$$

The reverse reaction, whose inorganic equivalent is the redox-condensation reaction of oxothiomolybdates and -tungstates $[MO_nS_{4-n}]^{2\ominus}$ (M = Mo, W; n = 0–2),[75] can be carried out photochemically.

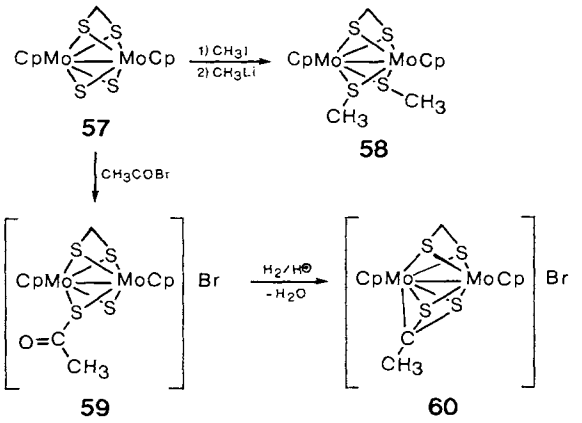


Scheme 9. Transformations of sulfur ligands in $[Cp_2^{(*)}M_2S_4]$ complexes. a) and b) M = Mo, W. c) M = V, Fe.

An elegant possibility of removing any electron deficiency arising at the metal centers, is the rearrangement of a μ,η^1-S_2 ligand to a μ,η^2-S_2 ligand [(c) in Scheme 9 from right to left]. This 90° rotation, which theoretically ought to be symmetry forbidden,[39] effectively gives the complex four more valence electrons. This explains, for example, why the 26e complex $[Cp'_2V_2S_4]$ **3** undergoes such a transformation to give the 48e trinuclear cluster **55** upon addition of an $Fe(CO)_3$ fragment at the monosulfido bridges.[76] In contrast to such chemically induced isomerizations[77] the electron-transfer induced η^1-$S_2 \rightarrow \eta^2$-S_2 isomerization of $[Cp^*_2Fe_2S_4]$

55

56



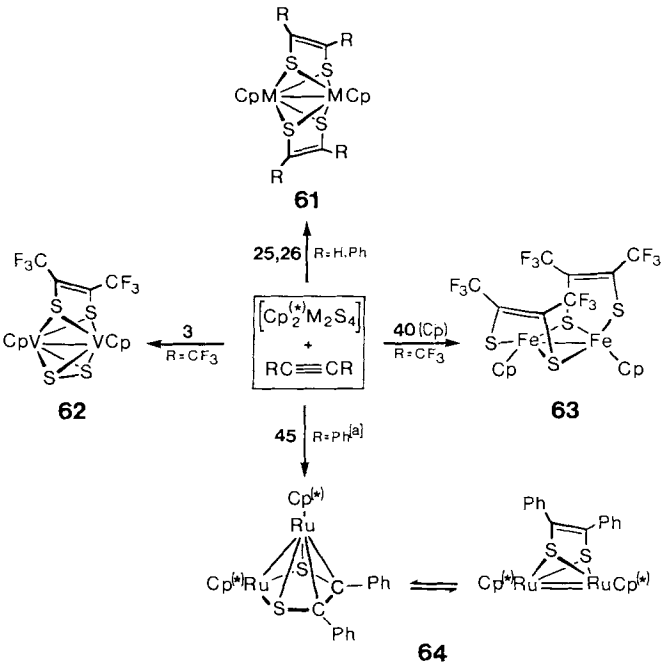
40(Cp*, structure type **B**) on oxidation is reversible—oxidation can be achieved with Br_2, I_2, $[Cp_2Fe]PF_6$ or even electrochemically, giving the dication **56** with an inert gas configuration. As in **40**(Cp*), the Fe–Fe distance in **56**, although

shortened by ca. 0.7 Å by the clamping effect of the two η^2-S_2 bridges, is non-bonding in nature.[78] Careful electrochemical investigations revealed the existence of an intermediate monocation, which quickly disproportionates to give **40**(Cp*) and **56**. Also remarkable is the stabilization of the S_2-bridges by the $Cp^{(*)}$-ligands, which, in principle, counteracts their possible elimination.[62]

3.2. Formation of S–C Bonds

3.2.1. The Alkylation of Sulfur Bridges

All sulfur ligands of the $Cp_2^{(*)}M_2S_4$ complexes presented in this paper have lone electron pairs and thus possess nucleophilic properties. Reaction with CH_3I leads predominantly to alkylation of the monosulfido bridges, whose nucleophilicity is only exceeded by the μ,η^1-S,S ligand in $[Cp^*_2Cr_2S_5]$ **8**.[23] Sulfur ligands whose lone pairs are withdrawn in order to stabilize the unsaturated metal centers via π-donation (e.g. in **2, 3, 40, 45**), are, in contrast, inert to alkylation by CH_3I. The monocationic complexes formed by such alkylation reactions are then susceptible to attack by nucleophiles, e.g. CH_3Li.[79] By such a reaction sequence, for example, the *cis*-dithiolato complex **58** is accessible from **57** (Scheme 10).[80]



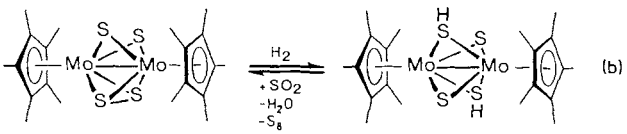
Scheme 10. Alkylation and acylation reactions at sulfur bridges using **57** as example.

In the complex **57**, which is accessible by reaction of the bis(hydrogensulfido) complex **16** with $CH_2Br_2/NaOCH_3$, two sulfur bridges are connected by a methylene bridge.[80] Owing to the two remaining cisoid $S^{2\ominus}$ bridges, **57** is without doubt a good model system for the molybdenum sulfide surfaces of commercial hydrotreating catalysts. Examples of alkylation reactions of **57** include, inter alia, the reductive cleavage of the C–Hal bonds of haloesters, acyl halides and vinyl bromides.[81] Of the complexes formed in this way the acetyl complex **59** is especially interesting, since it is able to activate H_2 with HHal elimination and then eliminate water in a complicated reaction sequence after addition of further acid. The complex salt **60** finally formed by this reaction contains a μ,η^2,η^3-dithioacetato ligand. Completely analogous to this C=O bond cleavage is the evolution of NH_3 from CH_3CN, whereby **60** is again formed.[82] Such reactions with expansion of the metal coordination sphere are very rare for the $[Cp_2^{(*)}M_2S_4]$-system. However, they show that, under certain circumstances, the central metal can act as a Lewis base.

3.2.2. Alkenedithiolato Complexes

It is impossible to arrange the reactions of complexes of the type $[Cp^*_2M_2S_4]$ with alkynes in a systematic scheme. This is again a consequence of the various reactivities of the sulfur ligands (Scheme 11).

Scheme 11. Overview of the formation of complexes with alkenedithiolato bridges from $[Cp_2^{(*)}M_2S_4]$ complexes ($Cp^{(*)}$ in **64** = η^5-C_5Me_4Et). [a] Reaction only in the presence of PBu_3.



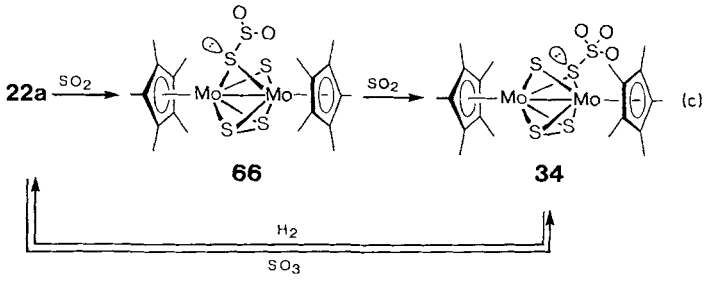
Only the Mo and W complexes **25** and **26**[33,83] react with unactivated alkynes. The bis(alkenedithiolato) complexes **61** thereby obtained can be reversibly hydrogenated under mild conditions to give bis(alkanedithiolato) complexes. The organic component of the dithiolato ligands is able to undergo exchange reactions with unsaturated hydrocarbons[41,83].

Complexes with π-donor sulfur ligands react only with electrophilic alkynes. Thus, $[Cp'_2V_2S_5]$, **2a**(Cp') reacts with hexafluorobutyne to give the mononuclear bischelate complex $[Cp'V\{SC(CF_3)=C(CF_3)S\}_2]$,[15] whereas $[Cp'_2V_2S_4]$ **3**, with 90° rotation of the η^1-S_2 ligand, affords **62** with a symmetrical alkenedithiolato bridge.[18] $[Cp_2Fe_2S_4]$ **40**(Cp) reacts with $CF_3C{\equiv}CCF_3$ with cleavage of both S_2 bridges to give the bisadduct **63**, in which the two μ,η^1,η^2-alkenedithiolato ligands are 4e donors. Of the two possible isomers only *cis*-**63** has been structurally characterized.[61b] The Ru-complex **45**, which is isostructural with **40**, (Section 2.4) reacts with PhC≡CPh only in the presence of the sulfur abstracting reagent PBu_3 to give the pentagonal-pyramidal *nido*-cluster **64**. ^{1}H-NMR spectroscopic findings in solution indicate that the equilibrium between the unusual μ,η^2,η^4-coordination and a symmetrically bridging η^2-coordination shown in Scheme 11 can be assumed for the cluster **64**.[69]

3.3. Formation of S–H Bonds

As long ago as 1949 it was shown that chemisorption of H_2 on MoS_2 occurs with the formation of SH ligands.[84] One such activation of H_2 on heterogeneous metal sulfide surfaces has been discussed as a possible step in the mechanism of the HDS catalysis.[85] In this context the complex $[Cp_2^{(*)}Mo_2S_2(SH)_2]$ (**16**; for synthesis see Scheme 4) is of special importance owing to the concomitant presence of sulfido- and mercapto-bridging ligands. For example **16** catalyzes the H/D exchange in a H_2D_2 mixture,[34] it hydrogenates N=N and C=N bonds under mild conditions[86] and adds thiols with elimination of H_2 to give thiolato complexes, and it reacts with C_2H_4 and C_2H_2, forming alkane- and alkenedithiolato complexes (e.g. **61**).[34]

An interesting reaction is the reduction of SO_2 with **65** to give H_2O and S_8 [Eq. (b)] which may proceed with formation of labile S–S bonds (see Section 3.4). The complex **22a** thus



(b)

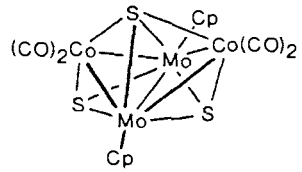
22a **65**

formed reacts with H_2 with cleavage of the disulfido bridge to give **65** again. The overall process can thus be formulated as a metal-catalyzed SO_2 reduction.[87] Attempts to hydrogenate the S_2 ligands in other $[Cp_2^{(*)}M_2S_4]$ complexes reveal that Mo is by a long way the most favorable center for such reactions. Thus, reactions of the Cr-complex **9**, which is isolobal with **22a**, and its more sulfur-rich precursor **8** with H_2 only proceed under high pressure and then with the formation of $[Cp_4^*Cr_4S_4]$. (Although the mechanism of this reaction is still not clear, it could be confirmed that the presence of H_2 is essential.)[23] In contrast, $[Cp_2^*Fe_2S_4]$ **40**(Cp*) is inert to H_2 up to 250 bar.[60]

3.4. Formation of S–S Bonds

As already indicated in Section 2.2.3 one of the products (**34**) formed upon reaction of **22a** with atmospheric oxygen contains a coordinated SO_3 ligand on the monosulfido bridge. The same product could be synthesized in much better yield by the direct reaction of SO_3·pyridine with **22a** [Eq. (c)].[88] This reaction can also be used to synthesize new

(c)

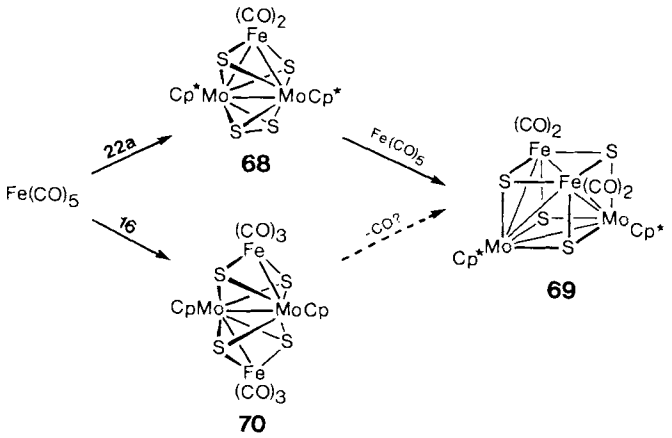


unusual ligands such as μ,η^1-S_3O_3 in **8**·SO_3[24] and μ,η^1-$SeSO_3$ in **49**·SO_3 (M=Rh, E=Se).[89]

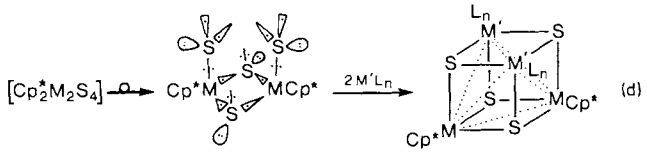
34 can also be prepared in a two-step reaction from **22a** and SO_2 [Eq. (c)]. Remarkably the initially formed SO_2-adduct **66** is oxidized to **34** by SO_2 and not by O_2—this has been proved using ^{18}O-labeling experiments.[90]. During the oxidation elemental sulfur is formed. Results so far would suggest that the oxidation proceeds with inversion at the S-atom, thus indicating the existence of further as yet unidentified intermediates. For the air "oxidation" of **22a** and similar complexes (above all **8**) the presence of sulfur, which is easily activated, is essential.[24] The oxidation of SO_2 to SO_3 by excess SO_2 can be assumed not only to occur on the complex but also in solution by a disproportionation reaction. In solution the SO_3 being a very strong electrophile is an excellent coordination reagent not only for sulfur but also for other chalcogen ligands as well.[24, 88]

Since **34** can be reduced to **22a** with H_2 [Eq. (c)] and since an excess of H_2 causes the formation of **65**, it has been suggested that the processes in Equations (b) and (c) can be summarized in a cycle,[87, 90] that is as an organometallic variant of the Claus process (oxidation of H_2S to S with atmospheric oxygen).

3.5. Synthesis of Tri- and Tetranuclear Clusters



A further outstanding property of a large number of the $[Cp_2^{(*)}M_2S_4]$ complexes is their ability to coordinate reactive or unsaturated metal fragments using the lone pairs of the sulfur ligands. Thus, the sulfur ligands enlarge their connectivity from μ_2 to μ_3 and exceptionally to μ_4. Whereas simple



67

adducts can only as a rule be characterized with difficulty, the 48e trinuclear clusters such as for example **55** (Section 3.1) or **68** are stable enough to be isolated and structurally characterized.[76, 91] Particularly characteristic of these 48e clusters is a trigonal-bipyramidal $M_2M'(\mu_3\text{-}S)_2$ framework, the M–M edge of which is spanned by a μ,η^2-S_2 ligand. This arrangement is of special interest as a building block for the construction of multimetallic chains. It is also capable of oxidatively adding a further metal fragment, striving for a cubane type structure with a $M_2M'_2S_4$ core.[91, 92]

A simple and efficient concept for the synthesis of homo- and heterometallic clusters containing an $M_2M'_2S_4$ core is that developed on the basis of $[Cp_2^*Cr_2S_5]$ **8** (which loses its labile S atom on reaction) and $[Cp_2^*Mo_2S_4]$ presented in Equation (d). Starting from any structural framework (**E**, **G** or **H**) the Cr and Mo dimers can, after transformation of all mono- and disulfido-ligands into four-electron donors,[93] function as potential 38e substrate ($2Cp^*M + 4\mu_3\text{-}S =$

$2 \times 11 + 4 \times 4$). These give 60e and 62e clusters with formation of M–S and M–M bonds on addition of two 11e or 12e $M'L_n$ fragments respectively.

Typical examples of directed syntheses of homo- and bimetallic clusters are listed in Table 1. $Cp^{(*)}M$ (M = Cr, Mo),[94] Fe(NO)[95] and Co(CO)[96] can serve as 11e fragments, i.e. also complex-fragments with easily substituted ligands, so that ligand substitutions in the clusters are possible without destroying the cluster skeleton. Thus, e.g., the CO ligands in $[Cp_2^*Cr_2Co_2(CO)_2S_4]$ can be successively substituted by $P(OMe)_3$ without fragmentation of the cluster framework.[97]

All the 60e $M_2M'_2S_4$ clusters possess a distorted cubic ('pseudocubane') structure with incorporated M_4 and S_4 tetrahedra—they have six M–M bonds for electronic reasons.[29, 97, 98] The attainment of the same cubic structure is also the motive behind the formation of the 56e, 58e, and 60e clusters, even if the presence of the vanadium atoms provokes magnetic anomalies. All Vanadium clusters are accessible from the 36e building block **3** (Table 1).

Addition of the 12e fragments $Mo(CO)_3$, $Fe(CO)_2$ or Cu-Cl to **22a** leads ultimately to stable 62e heterocubanes (Table 1) containing only five M–M bonds.[91, 100] Clusters with both oxo- *and* thio-ligands can be prepared in the same way. Thus, for example, the cluster $[Cp_2^*Mo_2Cr_2(CO)_6O_2S_2]$ can be isolated from the reaction of $[Cp_2^*Mo_2O_2S_2]$ with $[Cr(CO)_3(MeCN)_3]$.[52a]

The results obtained from the analogous reactions with **16** are less consistent. The reaction with $Ni(CO)_4$ is the only reaction which gives a product, namely $[Cp_2Mo_2Ni_2(CO)_2S_4]$, with the expected 62e pseudocubane type structure.[101] In contrast, $Co_2(CO)_8$ reacts with **16** not only with elimination of CO but also of H_2S, thus yielding **67**. Two edge-sharing Mo_2CoS tetrahedra spanned by a μ_4-S ligand are characteristic of this cluster.[101] The reaction of **16** with $Fe(CO)_5$[102] or $Fe_2(CO)_9$[101] also yields a completely different sort of product, the 66e cluster **70**. This has only 3 M–M bonds, all metal atoms lying in one plane. Whether **70** can be converted into a cluster of the type **69**, has evidently not been investigated.

It is not the SH ligands that are responsible for the differing behavior of **16**, but rather the $Cp^{(*)}$ ligands: the permethylated derivative **65** reacts with $Co_2(CO)_8$ to give $[Cp_2^*Mo_2Co_2(CO)_2S_4]$, which has a 'normal' 60e M_4S_4 core.[103]

4. Conclusion and Perspectives

This review should hopefully have illustrated the appeal of the extremely variable structural chemistry of sulfur ligands from the organometallic point of view with particular reference to the dimeric cyclopentadienyl-transition metal complexes. The reactivity potential of these complexes has also been outlined. The unpredictable coexistence of mono-, di- and polysulfur ligands as well as the abilities to undergo ligand transformations and to be effective π-donor ligands, guarantee future developments in the structural chemistry and reactivity of these complexes. Although it is relatively difficult to present rigid principles, it was possible to show by

$[Cp_2Mo_2S_2(SH)_2]$ **16**	$Ni(CO)_4$	THF; 25 °C	$[Cp_2Mo_2Ni_2(CO)_2S_4]$	62	[101]

[a] Number of valence electrons in the cluster.

means of thermal, photochemical or electrochemical investigations that some relationships exist within groups of certain complex types. Above all, it would appear that electrochemistry will play an important role in the future, for such investigations should not only make up for the general lack of redox-active inorganic metal–sulfur complexes[104] but also open up the possibility of investigating new reaction types.[78, 80, 83]

The search for mixed chalcogen–pnicogen ligands could be a particularly fruitful field in which to extend our present knowledge of complexes of Cp with O, Se and Te ligands. This is immediately apparent on comparing the structural relationships between, e.g., **48** and $[Cp_2^*Cr_2P_5]$[105] or $[Cp_2Mo_2As_5]$[106] despite their differing bonding systems. In this connection, the first success in this search may have been the formal substitution of one and of three P atoms of the *cyclo*-P_5 ligand of $[Cp_2^*Mo_2P_5]$ by sulfur atoms.[107]

Because of the nucleophilicity of their monosulfido ligands the sulfur-rich complexes of the vanadium and chromium triads exhibit model character for the study of heterogeneous metal sulfide surfaces in commercially important hydrodesulfurization catalyses.[108] However, with regard to the excellent HDS properties of RuS_2 and Rh_2S_3[109] the suitability of sulfur-rich Ru- and Rh-complexes described in this contribution would be well worth investigation.

Since the active centers of commercial HDS catalysts also consist of MoM'S phases (M' = Fe, Co, Ni)[110] the preparation of heteronuclear clusters with an M_4S_4 core [Eq. (d)] using the synthetic concepts developed for the complexes $[Cp_2^{(*)}M_2S_4]$ could be of some importance. Actually, novel sulfur-resistant CO hydrogenation and HDS catalysts can be prepared[111] from **67** and **70** by coating them on oxidic supports which are then calcinated in an H_2 atmosphere. It should also be pointed out that striving for a high Fe:M ratio (particularly when M = Mo) or replacing the Cp ligands by, e.g., dithiocarbamato ligands could lead to the creation of clusters of physiological importance.[112]

I should once again thank my own co-workers cited in the reference section for their engaged contribution. Since conventional spectroscopic data on the compounds mentioned do not lead to a definite structural conclusion because of the very simple ligand situation, X-ray structural analysis has been of considerable importance. I would therefore particularly like to thank Prof. Dr. M. L. Ziegler (Universität Heidelberg) and his co-workers for their continued support since the very early stages of this work, and Dr. U. Klement (Universität Regensburg). I am particularly indebted to Prof. Dr. H. Brunner for generous material support and for the goodwill this work required and to Frau Karin Kilgert for the preparation of the manuscript.

Fundamentals of Silicon Chemistry: Molecular States of Silicon-Containing Compounds**

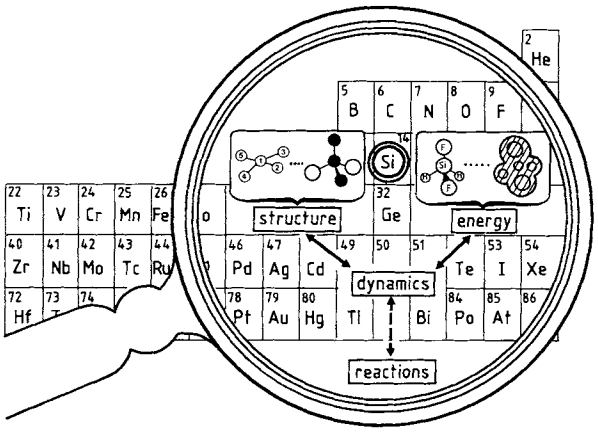
By Hans Bock*

Dedicated to Professor Wolfgang Hilger on the occasion of his 60th birthday

Silicon and its compounds have made possible the design of new materials, which, from computers to space travel, have helped to shape the technology of our 20th century. Conversely, the demands of new technology have stimulated the fast development of silicon chemistry as part of the "renaissance" of inorganic chemistry. This article uses selected examples of predominantly organosilicon compounds to discuss in simplified terms the measurement and assignment of suitable spectroscopic "molecular fingerprints" as well as the resulting benefit for the preparative chemist. The comparison of "equivalent" states of "chemically related" molecules is emphasized, based on perturbation arguments and supporting quantum-chemical models. Special attention is given to the relation between structure and energy, which allows us to understand and to predict the connectivity between and the spatial arrangement of silicon "building blocks", the energy-dependent electron distribution over the effective nuclear potentials of a molecular framework, and, especially, the partly considerable effects of "silicon substituents" on molecular properties. Future-directed extensions and applications include polysilane band structures, Rydberg states of chromophores containing silicon centers, redox reactions and ion-pair formation of silicon-substituted π systems, and molecular dynamic phenomena in solution or on thermal fragmentation in the gas phase. The main objective is a set of clear and practical rules for interpreting measurements and planning experiments.

Measure everything and make the unmeasurable measurable.
Galileo Galilei

One must have hypotheses and theories in order to organize one's knowledge; otherwise everything merely remains rubble.
Georg Christoph Lichtenberg



A sensible question can only be formulated with the help of a sensible theory.
Max Planck

1. What Can the Preparative Silicon Chemist Learn by Looking at Molecular Fingerprints?

In a time when at least one chemical publication appears in every one of the 525600 minutes of a 365-day year, the planning and evaluation of experiments as outlined by our scientific forefathers is a necessity.[8] In addition, the real building blocks of a chemist are no longer the over 10^7 molecules now known, but increasingly their numerous molecular and molecular-ion states[1-7] accessible via various routes of energy transfer (cf. Fig. 1a). These states are revealed by spectroscopic band or signal patterns, through which the respective compounds may be identified and characterized.[1, 3, 7] In addition to this analytical "ear-marking", such measurements afford as a rule valuable, but often unused information about the compound investigated, including the energies and the symmetries of its various states, as well as the energy-dependent electron distribution over its effective nuclear potentials. Let us, therefore, tentatively take a "molecular-state magnifying glass" (Scheme 1) and examine the relation between structure and energy for selected compounds of silicon, a nonmetal element. Let us also include equivalent states of chemically related molecules,[2] especially those containing the surrounding elements in the periodic table, in order to recognize additional useful relationships by correlating data from suitable measurements and/or quantum-chemical models. These correlations allow, for instance, the rationalization of the manifold of compounds and their diverse properties by a "red-line" subdivision into "parent systems" and their "substituent perturbations".[2, 4, 7] Thus, better use can be made of the extensive literature on valence-isoelectronic or structurally analogous compounds and of precalculable molecular properties[2, 5, 7] obtained by using quantum-chemical computer programs widely available for daily use. In addition, such a "static background" of structure–energy relationships will throw light on "dynamic phenomena", without which the largely

[**] 20th essay on molecular properties and models; shortened version of an introductory lecture at the US/Japan conference on "Advances in Silicon-Based Polymer Science", Makaha, Hawaii, 21 Nov. 1987. 19th Essay: [1]. See also earlier essays [2–6] as well as review [7].

Scheme 1. "Molecular-state magnifying glass" for the silicon chemist.

unknown microscopic pathways of chemical reactions, particularly those of medium-sized molecules,[6] cannot be described.

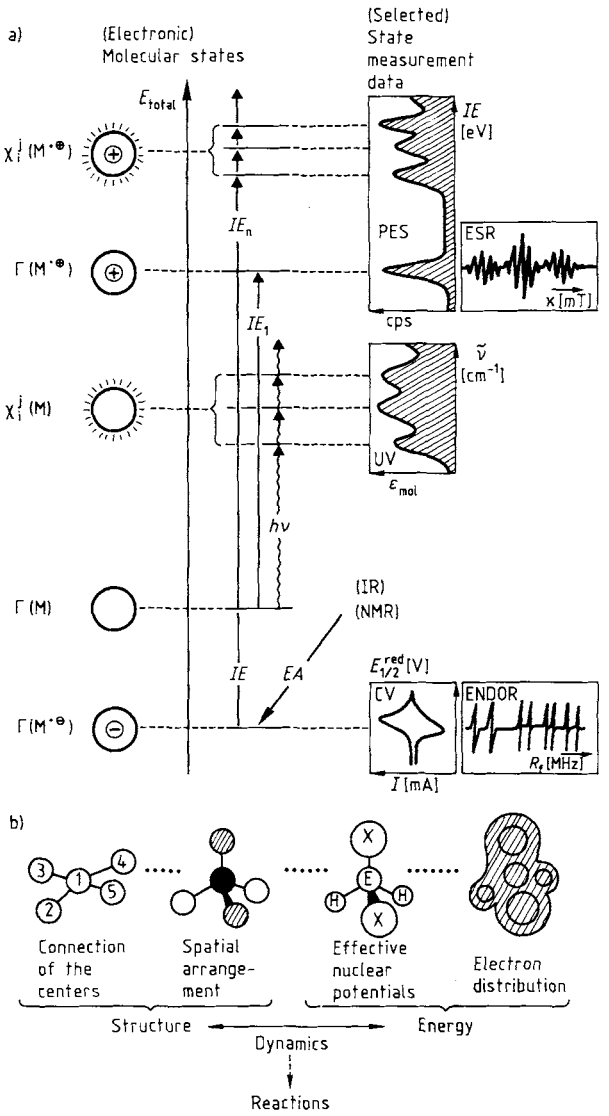
In general, molecules may be viewed[2] as self-dedicated computers, which, in "printing out" measurement data, provide complete (i.e., self-consistent and completely correlated) solutions of the Schrödinger equation. The question resulting from the rapid development of numerical quantum mechanics,[7a] as well as of vector computers, whether to measure or to calculate, is best answered with reference to how successful and stimulating the combination of the two proves to be. Among the numerous techniques of measurement now available, photoelectron (PE)[9] spectroscopy and electron spin resonance (ESR/ENDOR)[10] spectroscopy have proven themselves especially informative for preparatively oriented molecular-state investigations (Fig. 1a). "Vertically" recorded ionization energy patterns (i.e., those recorded with a time resolution on the order of 10^{-15} seconds) can be approximately correlated via Koopmans' theorem, $IE_n^v = -\varepsilon_j^{SCF}$, with the SCF eigenvalues[2] calculated for the neutral molecule M. PE spectrometers can thus be looked at as "eigenvalue meters". ESR/ENDOR signal patterns, on the other hand, are recorded "adiabatically" with a considerably smaller time resolution of about 10^{-7} seconds (i.e., long after the onset of molecular dynamics at about 10^{-13} seconds). These instruments can therefore be considered as "π-eigenfunction-squared meters", since the detected π-spin population ϱ_μ^π of radical and radical-ion centers can be correlated with the squared orbital coefficients, $\psi_\pi^2 \Rightarrow \sum_\mu c_{\pi\mu}^2$.[2] Obviously, the two methods complement each other owing to their different time resolutions and—coupled with quantum-chemical calculations—allow, for example, the determination of structural changes during one-electron oxidations, $M \rightarrow M^{\cdot\oplus} + e^{\ominus}$.

Starting from quantum-chemical precalculations and with extensive preparative efforts, the Frankfurt group[1-6] has carried out numerous investigations of compounds, especially those of the nonmetals B, C, N, P, S, and Si, by using the methods of measurement outlined in Figure 1a. For the element silicon, these investigations are summarized in the chronological pictogram of Scheme 2.

This article (cf. footnote to title) is based on the following results: the data obtained from measurements of the perturbation $\Delta\pi$ of π systems;[4] the PES ionization energies of various silicon compounds,[1] which allow the prediction of their oxidizability with $AlCl_3/H_2CCl_2$ to radical cations;[3] the thermal generation of unsaturated and reactive silicon compounds;[1] the development of ^{29}Si ENDOR spectroscopy[4] and its application to prove the existence of ion pairs in solution; experiments and hypersurface calculations[5] for the intramolecular elimination of H_2 from 1-silacyclohexa-2,5-diene. By way of introduction, both a PE-spectroscopically optimized gas-phase pyrolysis and an ESR-spectroscopically analyzed redox reaction in solution will illustrate the experimental procedure, the evaluation of molecular-state information, and the advantages of an approach combining preparation and measurement with supporting quantum-chemical calculations.

Generation of Phenyl Silaisocyanide in the Gas Phase: Starting from the literature report[11] that $H-N\equiv Si$ is produced on photolysis of H_3SiN_3 in a 4 K argon matrix, the

Hans Bock obtained his Ph.D. in 1958 from the Ludwigs Maximilians University in Munich, submitting a thesis on reactions of the rocket-fuel hydrazine, and his habilitation in 1964 based on investigations concerning relations between color and constitution of azo compounds. In the following three years as a visiting lecturer at the Federal Institute of Technology in Zurich, the three-volume book "The HMO Model and its Application" was compiled under the guidance of his mentor and friend Edgar Heilbronner and later translated into English, Japanese, and Chinese. In 1968 he received the Chemistry Award of the Academy of Science in Göttingen and the offer of an inorganic professorship at the Johann Wolfgang Goethe University of Frankfurt. Preparative nonmetal chemistry, in combination with physical measurements and quantum-chemical calculations has remained the trademark of his research group: Short-lived molecules, some of them found in interstellar space, are generated under nearly unimolecular conditions and identified by their PE-spectroscopic ionization fingerprints; radical ions and their ion pairs in aprotic solution are characterized by their ESR/ENDOR signal patterns and their respective molecular states; the accompanying structural changes are discussed based on calculated energy hypersurfaces. Professor Bock, a dedicated university teacher, has won numerous honors, among them the Frederic Stanley Kipping Award of the American Chemical Society and the Wilhelm Klemm Award of the German Chemical Society. Since 1977 he has been an External Scientific Member of the Max Planck Society, since 1981 an Adjunct Professor of The University of Michigan, Ann Arbor, and since 1984 a member of the Academy of Sciences and Literature at Mainz.



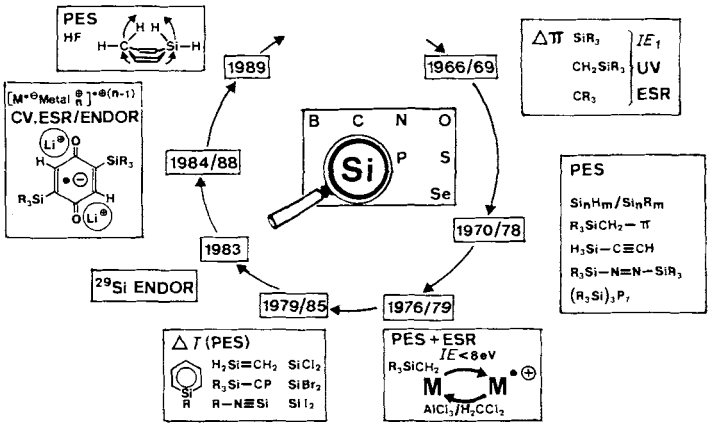


Fig. 1. Molecular states: (a) Schematic energy scale of electronic ground (Γ) and excited (χ_i^j) states of a neutral molecule M and its radical cation $M^{+\oplus}$ generated by ionization or oxidation or its radical anion $M^{-\ominus}$ resulting on electron attachment. As representative methods of measurement for many of the subsequently discussed silicon compounds, UV, PE, ESR, and ENDOR spectroscopy, as well as cyclovoltammetry (CV) have been selected. (b) Simplified scheme for the comparison of molecular states of chemically related compounds, emphasizing either the connection between centers, their spatial arrangement, their effective nuclear potentials, or the resulting electron distribution. Structural changes due to changes in energy involve molecular dynamics, which is of central importance for the still largely unknown reaction pathways of medium-sized molecules.

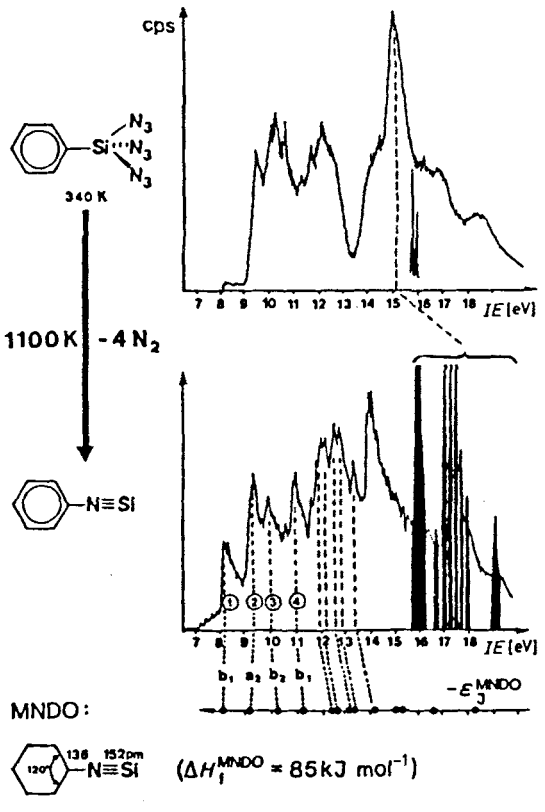
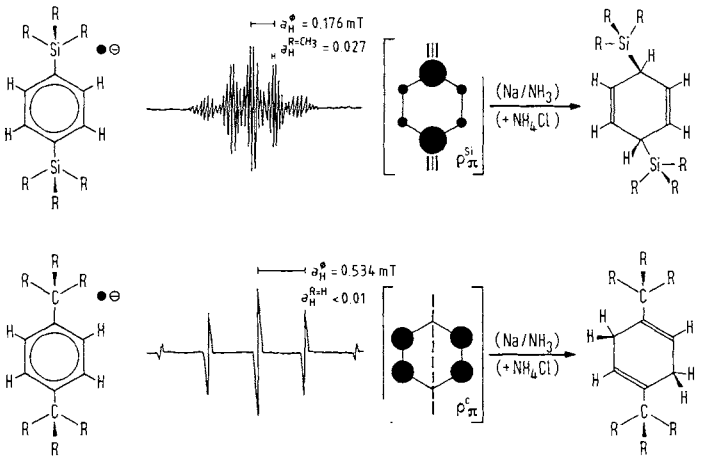
total energy, the structure, and the ionization pattern of the more stable phenyl derivative have been calculated (Scheme 3). Laboratory-scale azide exchange yields the starting material, triazido(phenyl)silane. Its controlled explosion in a flash pyrolysis apparatus under approximately unimolecular conditions ($p \approx 10^{-3}$ Pa, $c \approx 10^{-3}$ mM) can be carried out without danger.[12] Real-time PE-spectroscopic analysis of the band intensities revealed that the optimum reaction conditions required a temperature of 1100 K (i.e., red heat) for the complete elimination of four molecules of N_2 (Scheme 3: blackened ionization bands).



The identification of the first organosilicon compound with a triple bond to silicon and a silicon coordination number of 1 was accomplished by Koopmans' correlation of the

Scheme 2. The investigations on silicon compounds carried out by the Frankfurt group.



total of nine resolved low-energy ionization bands (Scheme 3) with calculated MNDO eigenvalues. The formation of the valence isomer H_5C_6-Si≡N, which is predicted to be 400 kJ mol^{-1} less stable, can be excluded, for example, by comparison of the radical-cation state sequence with that of the valence-isoelectronic carbon species $C_6H_5-N\equiv C$. Meanwhile, the PE-spectroscopic results have been confirmed by matrix isolation of H_5C_6-N≡Si.[7c, 11]

Birch Reduction of 1,4-Bis(trimethylsilyl)benzene: The ESR spectrum of the radical anion produced by treatment of a dimethoxyethane solution of this compound with potassium in a glass apparatus sealed under vacuum ($p \approx 10^{-1}$

Scheme 3. Generation of phenyl silaisocyanide by controlled explosion of triazido(phenyl)silane and its PE-spectroscopic identification. Triazido(phenyl)silane is prepared from trichloro(phenyl)silane by azide exchange with trimethylsilyl azide in the presence of $AlCl_3$ [12].

Pa)[13a] exhibits a quintet due to four equivalent phenyl protons. The signals, spaced 0.176 mT apart, are further split by the 18 equivalent methyl protons (R = CH_3; intensity ratio of outer line to inner line, 1:48 620). By contrast, the *p*-xylene radical anion, with a more strongly split quintet (R = H, a_H = 0.534 mT), shows no additional coupling with the six methyl protons; therefore, its substitution centers must be located in a nodal plane, in which the spin density ϱ_π is roughly zero and, concomitantly, the charge density negligible. In contrast, for the R_3Si-substituted radical anion, the spin density is small at the ring centers 2, 3, 5, and 6, as indicated by the smaller ring-proton couplings a_H, but large at the ring centers 1 and 4, as revealed by the resolved methyl proton splittings (Scheme 4, diagrams ϱ_π^{Si} and ϱ_π^{c}).

Scheme 4. Spin distribution in the valence-isoelectronic radical anions of 1,4-bis(trimethylsilyl)- and 1,4-dimethyl-substituted benzenes and the protonation products of their Birch reduction. R = H, CH_3; ∅ represents the phenyl protons.

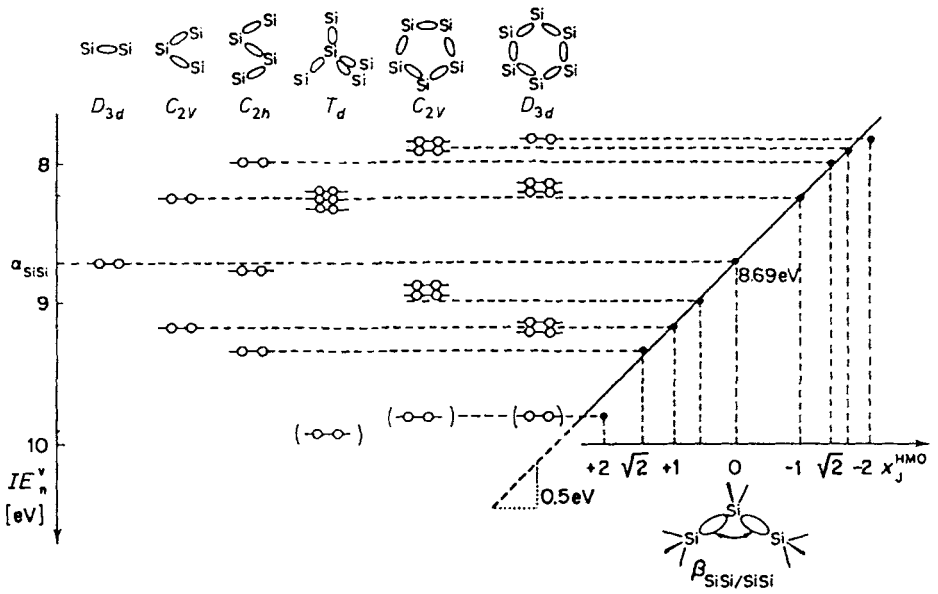
The interpretation of the differing ESR signal patterns leads to the expectation that Birch reductions using Na/NH_3 followed by protonation of the respective dianions with NH_4Cl should take place at different centers (i.e., those with the highest charge density). This is indeed observed[13b] (Scheme 4; R = CH_3): reduction of 1,4-bis(trimethylsilyl)-benzene and 1,4-di-*tert*-butylbenzene exclusively yields the corresponding cyclohexa-2,5-diene and cyclohexa-1,4-diene, respectively.

These examples, chosen from the extensive literature, give the following answer to the question posed in the title of this section: "more than he might have expected". The conditions for the preparation of $H_5C_6-N\equiv Si$ by gas-phase pyrolysis of triazido(phenyl)silane could not have been optimized without PE real-time analysis, and the reactive intermediate could not have been identified in the gas flow without comparing experimental and calculated ionization patterns.[12] The Birch reductions of R_3Si- and R_3C-substituted *p*-benzene derivatives in solution would presumably not have been studied and compared without the ESR-spectroscopic evidence of differing spin and charge distribution in their radical anions.[13] Both examples, therefore, encourage use of the molecular-state magnifying glass (Scheme 1) to look at other silicon compounds as well.[1, 13]

2. Molecular-State Comparison of Silicon-Containing Compounds

2.1. Experimental and Quantum-Chemical Starting Points

The properties of a molecule depend on its energy and vary particularly on uptake or removal of electrons.[2] A particular state of a molecule or a molecular ion is characterized by the energy difference to the preceding or the following state and by its electron distribution, that is, by its structure and dynamics (Fig. 1). Information about energy differences between molecular states of, for example, silicon compounds,[1-7] as well as about their structures and their properties, is accessible by numerous physical measurements[1, 3, 7, 9, 10] or by precise quantum-chemical calculations.[5, 7a]



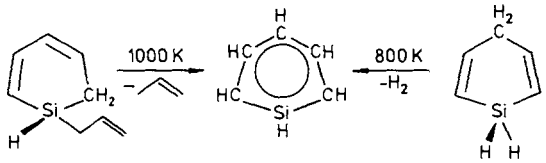
The multitude of states of a single molecule, especially on inclusion of its dynamics, and the numerous properties of each of these states are overwhelming and therefore inevitably outside the focus of interest of a synthetically oriented chemist, even if he analyzes and characterizes his compounds by physical measurements. What demands does he place on a suitable and useful molecular-state model? Above all, it should be as close to experiment, as flexible, and as general as possible, and it should allow him to use his extensive and detailed knowledge to define "chemically related" molecules and to compare their properties. These demands are largely fulfilled by a simplified molecular-state description (Fig. 1 b), which, depending on the specific requirements, emphasizes topological aspects, symmetry considerations, effective nuclear potentials, or electron distributions.[2] Quantum-chemical calculations,[5, 7a] performed with readily available computer programs or with the help of knowledgeable colleagues, are a valuable addition and allow these qualitative models to be extended further, especially with respect to structure–total energy relationships and pertinent total charge distributions. The following examples, taken predominantly from our investigations[1-6] (Scheme 2) and complemented by those from a recent comprehensive monograph on organosilicon compounds and their properties,[7] will illustrate procedures, advantages, and also some necessary caution.

2.2. The Connection of Silicon Building Blocks

Structural formulas of chemical compounds contain connecting lines, which correspond to the "handshaking" lemma of topology.[14] These lines should not be misinterpreted as representing two electrons each, since the historically developed shorthand notation for chemical formulas does not permit an exact description of the electron distribution, especially for multiple bonds or for higher coordination numbers. With this restriction, the application of topological connectivity concepts to the description of molecular states (Fig. 1 b) will be illustrated first for the PE-spectroscopic ionization patterns of polysilanes[1, 15] (Section 2.2.1) and then for the quantum-chemically predicted[16, 17] (1985/1987) and subsequently experimentally verified existence of three-dimensional polysilane polyhedra (Section 2.2.2).[18, 19]

2.2.1. SiSi Ionization Patterns of Polysilanes

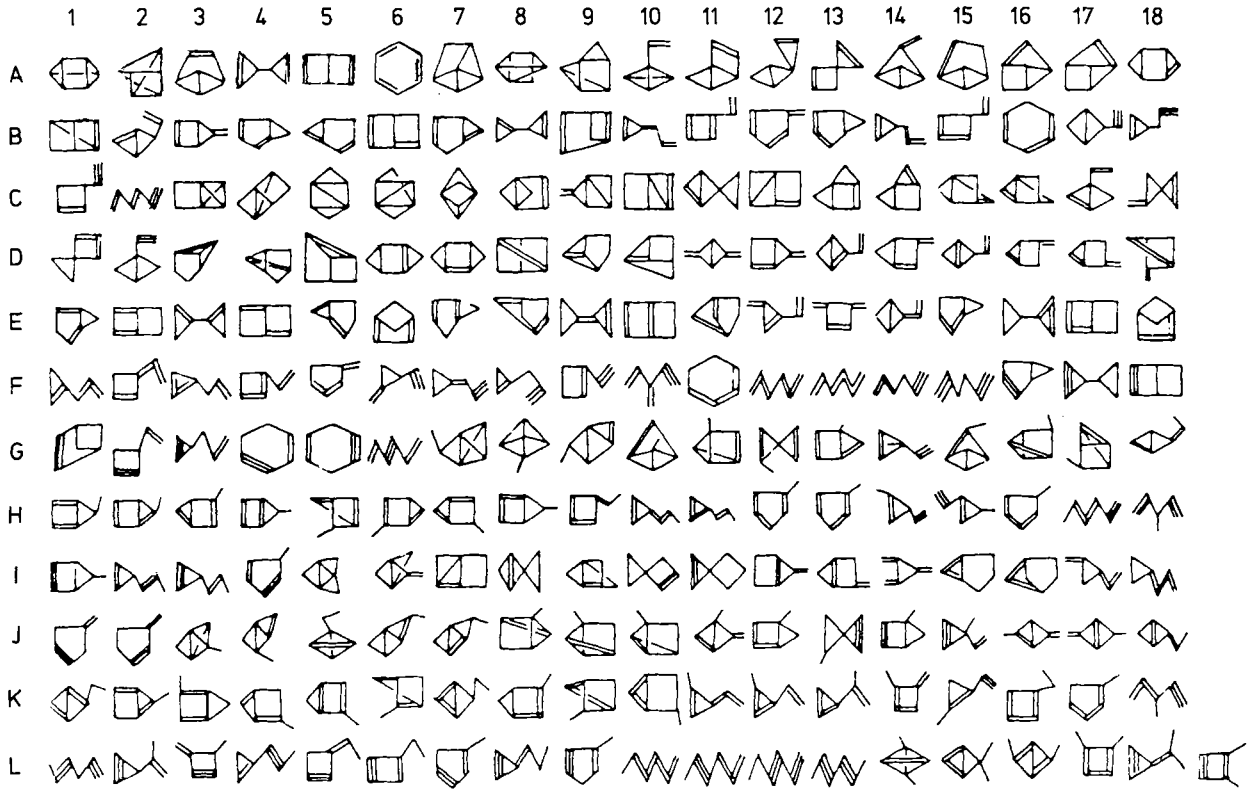
The photoelectron spectra[1, 15] of permethylated polysilanes exhibit characteristic band patterns in the low-energy region up to 10 eV, which have been assigned to radical-cation states with predominantly SiSi framework contribution.[1, 15] This suggests a correlation between the vertical ionization energy IE_n^v [eV] and the topological eigenvalue coefficients,[20] x_j^{HMO}, for the differing number of dissimilarly connected σ_{SiSi} building blocks (Scheme 5).



Scheme 5. SiSi ionization patterns of permethylated polysilanes and their correlation with topological eigenvalues.

The linear combination of bond orbitals (LCBO) model[15] clearly provides a fully occupied energy-level scheme, whose eigenvalues, $\varepsilon_j^{HMO} = \alpha_{SiSi} + x_j^{HMO}\beta_{SiSi/SiSi}$, on correlation with the vertical ionization energies IE_n^v [eV], yield a satisfactory linear regression. Its center is the Coulomb term $\alpha_{SiSi} = 8.69$ eV, and its gradient defines the interaction parameter $\beta_{SiSi/SiSi} \approx 0.5$ eV. For further elucidation, it should be noted that $\alpha_{SiSi} = 8.69$ eV is the first ionization energy of hexamethyldisilane and that the value $2\beta_{SiSi/SiSi} \approx 1.0$ eV corresponds to the difference between the two lowest ionization energies of octamethyltrisilane, $IE_{1,2}^v = 0.95$ eV. The applicability of a topological LCBO-MO model[1, 15] is further supported by the fact that the "alternating"[2, 20]—all the chains as well as the six-membered ring in Scheme 5—polysilanes show approximately equally spaced splitting patterns around α_{SiSi}[1] and that the highest SiSi ionization energies of the two rings, $IE_5^v = 9.80$ eV and $IE_6^v = 9.78$ eV,[1] agree, as expected from their identical eigenvalues, $\varepsilon_j^{HMO} = \alpha + 2\beta$. In addition, some of their lower-energy ionizations are predicted and found to be pairwise degenerate.[2, 20]

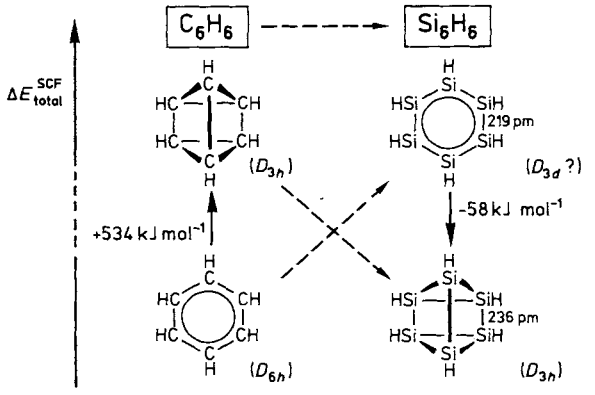
Altogether, the 21 IE_n^v values measured for polysilanes can be incorporated into the simple "isoconjugate" (i.e., consisting of equal subunits; cf. Fig. 3a) radical-cation-state model, which yields the experimental parameters α_{SiSi} and $\beta_{SiSi/SiSi}$. Comparison of the latter with the analogous π interaction in the $M^{\cdot\oplus}$ states of linear polyenes, $\beta_{C=C/C=C} \approx 1.2$ eV,[21] demonstrates that, despite the different values of the parameters, the positive charge in permethylated polysilane radical cations is largely delocalized over the SiSi skeleton[15] and thus explains the astoundingly small ionization energies measured.[1]



2.2.2. Structure and Total Energies of Polysilanes

Use of PE-spectroscopic ionization patterns (cf. Scheme 3) has also allowed the gas-phase thermolyses of 1-silacyclohexa-2,4-diene or 1-silacyclohexa-2,5-diene derivatives to silatoluene[22a] ($H \rightarrow CH_3$) or to silabenzene[22b] to be optimized for the first time (Scheme 6).[22]

Scheme 6. Preparation of silabenzene by gas-phase thermolysis of silacyclohexa-2,4-diene and silacyclohexa-2,5-diene.

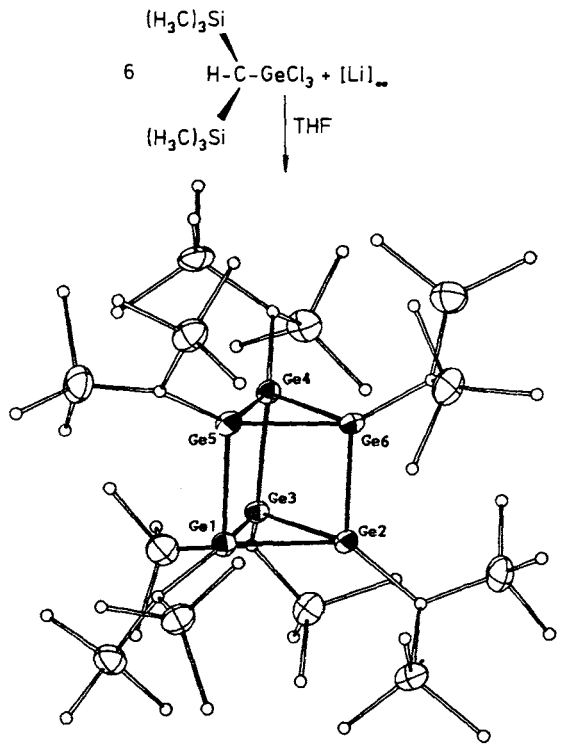


Assuming that sooner or later suitable starting materials for Si_6H_6 or its kinetically stabilized derivatives Si_6R_6 would be synthesized, spectacular structural proposals for these compounds have been put forward, based on quantum-chemical calculations,[16] partly including correlation energy (cf. Scheme 8). It should first be pointed out that molecules with n = 12 atoms possess $3n-6 = 30$ degrees of freedom. Therefore, the search for the respective total-energy minima has to be carried out in a 30-dimensional hyperspace. For the valence-isoelectronic system C_6H_6, when the coordination numbers were limited to ≤ 4 for carbon and 1 for hydrogen, an isomer computational program[23] "spat out" 217 topological possibilities (Scheme 7).

Scheme 7. Topological diagrams of the 217 C_6H_6 isomers with carbon coordination numbers ≤ 4.

In addition to the distillable D_{6h} hydrocarbon benzene (Scheme 7: A6), many of these molecular frameworks are known: the short-lived valence isomers prismane (A1), benzvalene (A3), and Dewar benzene (A5), as well as the more stable open-chain isomers such as 3-methylpenta-1,5-diyne (H18) and hexa-2,4-diyne (L13). On going from the "carbon world" to the neighboring "silicon world" with its reduced effective nuclear potential (see Section 2.4) and its larger covalent radius ($r_C = 77$ pm, $r_{Si} = 117$ pm)[24], calculations have predicted dramatic differences[16] (Scheme 8): In the case of Si_6H_6, the most stable valence isomer supposedly will not possess the famous Kekulé hexagon structure, but instead that of prismane, a highly explosive hydrocarbon.

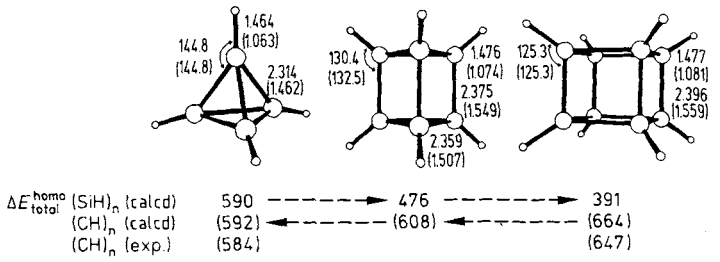
Hexasilaprismane is calculated to be 58 kJ mol^{-1} more stable than hexasilabenzene,[16] whose SiSi bond lengths of 219 pm are predicted to be closer to that of disilene $H_2Si{=}SiH_2$ (215 pm) than of disilane (236 pm), and which might exhibit a fluctuating D_{3d} boat conformation.[7a] The considerable SCF total-energy difference of 534 kJ mol^{-1} calculated between the C_6H_6 valence isomers[16,17] prismane and benzene cannot be exclusively explained either by a more pronounced "magic" 6π-electron delocalization in benzene or by the reduced ring strain in hexasilaprismane; the preferred coordination number 4 of the Si centers[7a,16] may be the most important contributing factor (Fig. 2). This effect is also reflected in the ionization differences ΔIE_n^v between the $^2T_2$ and $^2A_1$ radical-cation states of CH_4 (Scheme 16: 8.7 eV) and SiH_4 (Scheme 16: 5.6 eV).



Scheme 8. Total energies of the six-membered ring and prismane isomers of the ensembles C_6H_6 and Si_6H_6.

The quantum-chemical calculations, extended in the meantime to include derivatives of the higher element homologues Ge, Sn, and Pb,[17] have been recently[18] and surprisingly confirmed experimentally. Selection of the substituents -$CH(Si(CH_3)_3)_2$, which are sterically suitable and kinetically shielding, led to the isolation and structural characterization of a hexagermaprismane (Scheme 9).

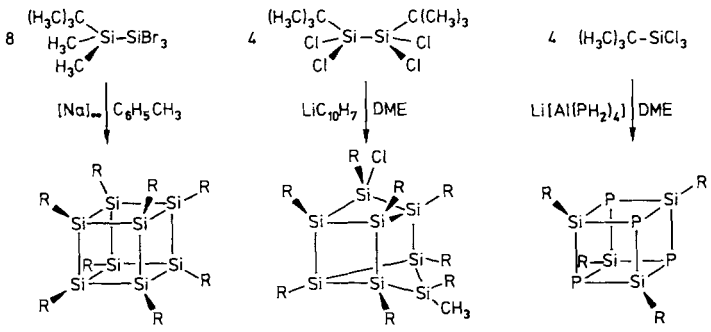
Within this context it should be pointed out that the strain energy in silicon polyhedra (e.g., $(SiH)_6$[17]) can be satisfactorily estimated quantum-chemically from the total-energy differences of "isodesmic" (constant composition) or—more precisely—"homodesmic" (unaltered subunits) reactions giving strain-free products.



$$\text{isodesmic} \atop \text{homodesmic} \; (SiH)_6 \begin{cases} +12\,SiH_4 \rightarrow 9\,H_3SiSiH_3 \\ +9\,H_3SiSiH_3 \rightarrow 6\,(H_3Si)_3SiH \end{cases}$$

Calculations with 6-31 G* basis sets[17] predict for the $(SiH)_{4,6,8}$ polyhedra—and in parentheses for the valence-

Scheme 9. Preparation of the first hexagermaprismane and its kinetic stabilization by steric shielding.



isoelectronic $(CH)_{4,6,8}$ polyhedra—the structures and strain energies ΔE_{total}^{homo} [kJ mol^{-1}] shown in Scheme 10.

Scheme 10. Ab initio SCF-calculated structures and strain energies of the valence-isoelectronic polyhedra $(SiH)_n$ and $(CH)_n$ with $n = 4$, 6, and 8. Values for $(CH)_n$ in parentheses. Bond angles in °, bond lengths in Å.

Comparison of these values with the experimental values[25] available for tetrahedrane and cubane support the reliability of the calculations. As the number of four-membered rings increases, the strain energy of Si_n polyhedra decreases, the value for octasilacubane being only 391 kJ mol^{-1}. This quantum-chemical prediction, suggesting to the preparative silicon chemist that octasilacubane and its derivatives should be preferred synthetic goals, has been repeatedly confirmed experimentally[19] (Scheme 11).

The quantum-chemically predicted[16, 17] (Schemes 8 and 10) and in the meantime—as the tip of an iceberg—synthesized[18, 19] (Schemes 9 and 11) novel polyhedra made up of group 14 elements should exhibit numerous interesting properties: thus, their calculated low first ionization energies suggest their oxidizability to the corresponding radical cations (cf. Section 2.5.4) and the PE spectra of polysilanes[1, 15] (Scheme 5) indicate an extensive delocalization of the positive charge. Additional predicted valence isomers[16] lead to the expectation of surprising dynamic phenomena,[26] and excitation into Rydberg states (cf. Section 3.2) should result in an interesting photochemistry[27] for suitable derivatives.

Scheme 11. Si_n ($n = 8$, 9) and Si_4P_4 polyhedral derivatives prepared in 1988/1989.

In terms of the stated goal of a simplified molecular-state description (Fig. 1), the SiSi ionization patterns (Scheme 5) illustrate different topological features of "isoconjugate" systems for the radical-cation states of polysilanes, just as the structure–energy relationships (Schemes 8 and 10) do for the ground states of polysilane polyhedra; that is, they reveal the dominant influence of connectivity between similar silicon building blocks. Both also demonstrate—in the rationalization of numerous measurement data and in suggestions for the synthesis of energetically favorable structures—the usefulness of such considerations for the silicon chemist.

2.3. The Silicon World: Coordination Numbers between 1 and 10

The "renaissance" of inorganic chemistry has also been inspired by the rapid development of the silicon sector. In the last ten years, countless "unsaturated" molecules with silicon centers of coordination numbers 1, 2, or 3 have been generated both in the gas phase[1, 28] and in matrices.[7c] Their isolation at room temperature could be achieved in most cases after introducing bulky substituents, that is, synthesis of kinetically stabilized derivatives[7c] (Fig. 2). Further progress has resulted from investigations of metal-rich silicide and Zintl phases,[29] which contain $Si_n^{m\ominus}$ polyanion-cluster lattice units such as $Si_4^{10\ominus}$ stars or $Si_4^{4\ominus}$ tetrahedra (Fig. 2). Unlike its neighboring element carbon, which prefers to form compounds with coordination numbers of 4 or less, the homologous silicon can rather easily accommodate five or six substituents.[7c] In the more recently reported bis(pentahapto) sandwich complexes[30] with cyclopentadienyl or dicarborane ligands,[30] the coordination sphere is enlarged to 10 (Fig. 2).

Future investigations will prove whether the existing "coordination number gap" between 6 and 10 can be filled and whether there is even a possibility of preparing novel silicon

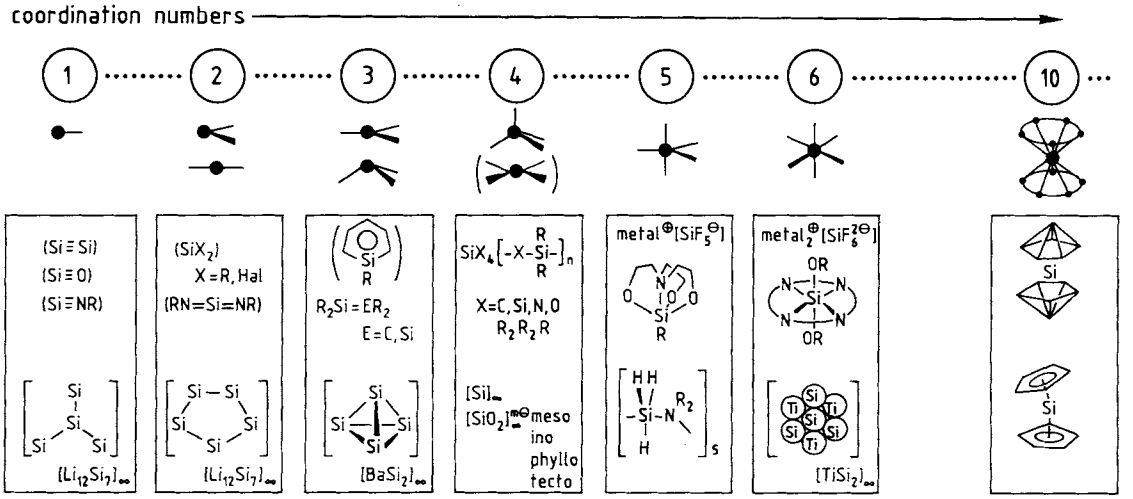


Fig. 2. Representative examples of a classification of silicon-containing molecules based on coordination numbers: silicon centers with coordination number 1 to 6 and 10 in covalent molecules and molecular ions and in solids (cf. text).

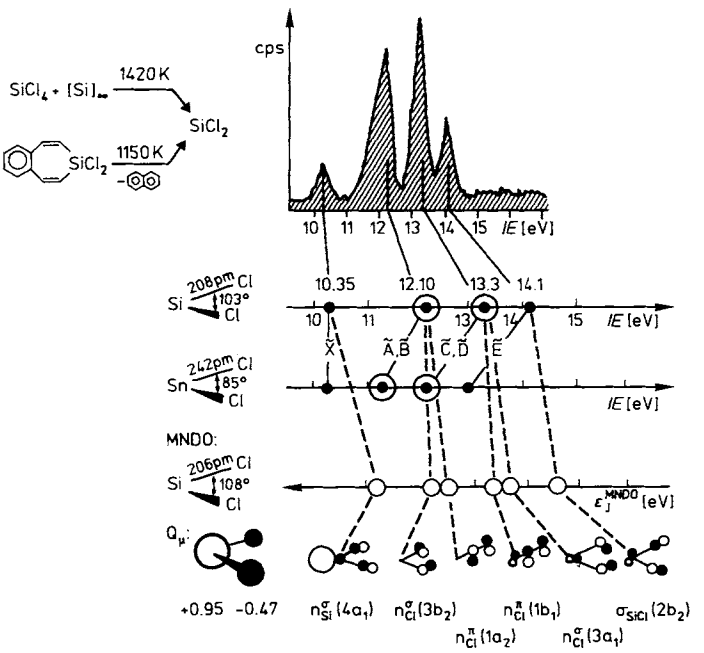
compounds with coordination numbers larger than 10—because it is perhaps difficult to imagine, reference is made to the uranium coordination number of 16 in $U(C_8H_8)_2$.[24] In the following discussion, which explicitly refers to recent literature surveys[7] concerning the current status of silicon chemistry and, in particular, the excellent summary of the quantum-chemical aspects contained therein,[7a] simplified molecular-state descriptions will be given for selected examples of compounds with coordination numbers 2, 5, and 10.

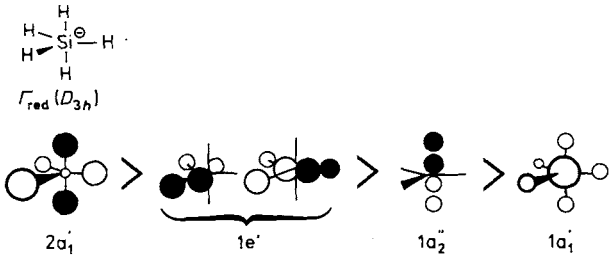


Dichlorosilanediyl (Dichlorosilylene), $SiCl_2$: This triatomic singlet molecule[7a] with a twofold-coordinated silicon center can be prepared via numerous routes.[4] It contains 18 valence electrons and, like the valence-isoelectronic compounds $SnCl_2$ and SO_2, is therefore bent according to the Walsh rules.[31] Its gas-phase structure (Scheme 12) has been determined by electron diffraction[32a] and its PE spectrum shows, as expected, six ionization bands in the He(I) region.[4, 32b]

The assignment of its radical-cation states can be accomplished by comparison with those of the valence-isoelectronic $SnCl_2$ or—via Koopmans' theorem—by use of MNDO-SCF calculations[32b] (Scheme 12), which, on complete geometry optimization, satisfactorily reproduce the structure and reveal that the $SiCl_2^{\bullet\oplus}$ radical ground state $\tilde{X}(^2A_1)$ originates from loss of one of the "nonbonding" electrons of the silicon electron pair in the molecular plane. The rather polar charge distribution Q_μ, calculated for the neutral molecule (Scheme 12), reflects the considerable differences in the effective Si and Cl nuclear potentials.

Silicon Pentahydride Anion, $SiH_5^\ominus$: This pentacoordinate silicon species was recently prepared in 32% yield by gas-phase reaction (a).[33a] According to extensive calculations,[7a, 33b] it possesses a D_{3h} trigonal-bipyramidal struc-

$$(H_5C_2)_3SiH_2^\ominus + SiH_4 \rightarrow SiH_5^\ominus + (H_5C_2)_3SiH \qquad (a)$$

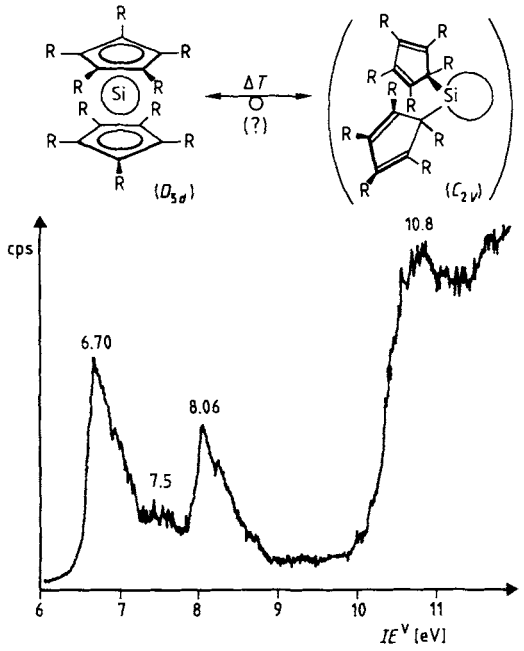


ture, in which the axial SiH distances are 10 pm longer than the equatorial distances. Only 9 kJ mol^{-1} higher on the energy hypersurface is a second minimum corresponding to a C_{4v} tetragonal pyramid. This result suggests fluxional behavior for $SiH_5^\ominus$ in the gas phase—as temperature-dependent NMR measurements have revealed for countless other pentacoordinate silicon compounds in solution.[7c]

Scheme 12. Gas-phase generation of $SiCl_2$ as well as PE-spectroscopic identification, molecular-state comparison with $SnCl_2$, and correlation with MNDO calculations.

Although noble-gas compounds such as XeF_2 have qualified the octet rule as a "closed shell-closed mind" intellectual exercise and multicenter bonding is not only generally accepted in electron-deficient compounds such as $H_2B(H)_2BH_2$,[34] a fictitious[35] "d-orbital participation" is

still erroneously invoked to explain certain properties of silicon compounds. Under the proviso that orbitals generally cannot be observables in experiments and that, at best, only the square of the wavefunction can be correlated with the electron density, the five occupied molecular orbitals of $SiH_5^{\ominus}$—without any 3d orbital contribution—are presented in Scheme 13.[7a]



Scheme 13. Qualitative molecular orbitals of $SiH_5^{\ominus}$ obtained with a 3s,p basis set without 3d functions.

Independent of the preceding arguments, higher p, d, and f "polarization functions" are often included in high-quality basis sets for quantum-chemical calculations at all centers of the respective molecules to increase the occupied "electron density volume" covered. The "Shakespearean" question, "to d or not to d?", however, can be answered by the preparative chemist with a straightforward "not to".

Decamethylsilicocene, $(\eta^5\text{-}C_5R_5)_2Si$, $R = CH_3$: Syntheses of valence-isoelectronic sandwich complexes of Pb, Sn, Ge, $Bi^{\oplus}$, and $As^{\oplus}$ have been reported since 1956. In the absence of steric constraints, their five-membered ring planes are tilted from the coplanar D_{5d} or D_{5h} ideal structure by angles of between 30° and 50°.[36] The bis(pentamethylcyclopentadienyl) silicon derivative, also containing a tenfold-coordinated silicon center[30] (Fig. 2), shows two different conformers in the unit cell with interplane angles of 0° (D_{5d}) and 25° (C_{2v}).[30a] Extensive calculations[7a, 36] indicate a rather flat potential trough, inside which the R_5C_5 rings, exhibiting very long CSi distances (232–254 pm), can move relative to the silicon center, crossing only low energy barriers. This "fluctional behavior" renders the interpretation of the PE spectrum[37] (Scheme 14) more difficult.

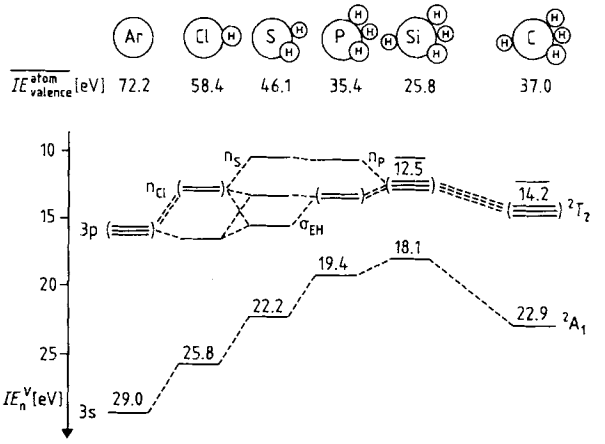
Thus, the electron-rich silanediyl-like Si center leads to a low first ionization potential of only 6.7 eV.[37] The total electron population at the Si center, calculated to comprise 13.5 of the 14 electrons, is in agreement with this finding and also explains the long SiC distances, which are indicative of only weak π interactions with the five-membered ring. Moreover, despite the use of a basis set[36] with d polarization functions, they were found to play no significant role in the π bonding[36] in the silicon sandwich (cf. Scheme 13).

In summary, the multifaceted silicon world between coordination numbers 1 and 10 (Fig. 2) can be rationalized by known bonding principles—as long as each topological connecting line is not misleadingly associated with two electrons: (singlet) silanediyls, SiX_2, with twofold-coordinated Si, contain a "silicon electron pair", in analogy to $SnCl_2$; the bonding in $SiH_5^{\ominus}$, like that in PF_5 and SF_6, is best described without fictitious d functions, and silicocene, $(\eta^5\text{-}C_5R_5)_2Si$, like numerous valence-isoelectronic sandwich π complexes,

Scheme 14. Low-energy region of the PE spectrum of decamethylsilicocene.

can be formulated with centers of coordination number 10. As helpful as numerically exact SCF calculations are for molecules with only a few centers, the recommendation to the preparative silicon chemist for his usually multiatomic compounds with numerous degrees of freedom is to look instead for chemically related substances and to compare their equivalent molecular states.[2] Above all, such a procedure is usually of advantage for complex dynamic phenomena, for example in "pseudorotating" molecules with central Si atoms displaying fivefold or higher coordination.[7e]

2.4. Silicon Centers and Their Small Effective Nuclear Charge

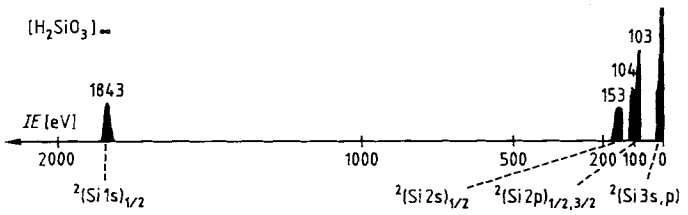


Let us return to the "normal" silicon coordination number of 4. The simplified molecular-state description (Fig. 1 b) ought to be expanded to include the effective nuclear charge Z_{eff}. Among the numerous literature suggestions, the concept of *Slater*,[38] in which the shielding contributions A_i of the nuclear charge Z are defined according to the quantum numbers n of the different electrons, has the following advantages: atoms or ionic radii can be rationalized in a lucid manner—for example, their contraction in the third period from Na (186 pm) through Si (117 pm) to Cl (99 pm) is a result of incomplete shielding ($A_i = 0.85$) of the respective increase ($\Delta Z = 1$) in nuclear charge (Table 1). Since the

Table 1. The dependence of effective nuclear charge, determined by the Slater method, on quantum numbers. A_i = shielding constant.

$Z_{eff} = Z - \sum_i A_i$

Electron orbitals	A_i for electrons in orbitals $n' > n$	$n' = n$	$n' = n-1$	$n' < n-1$
1s	0	0.30		
ns, np	0	0.35	0.85	1.00
nd, nf	0	0.35	1.00	1.00



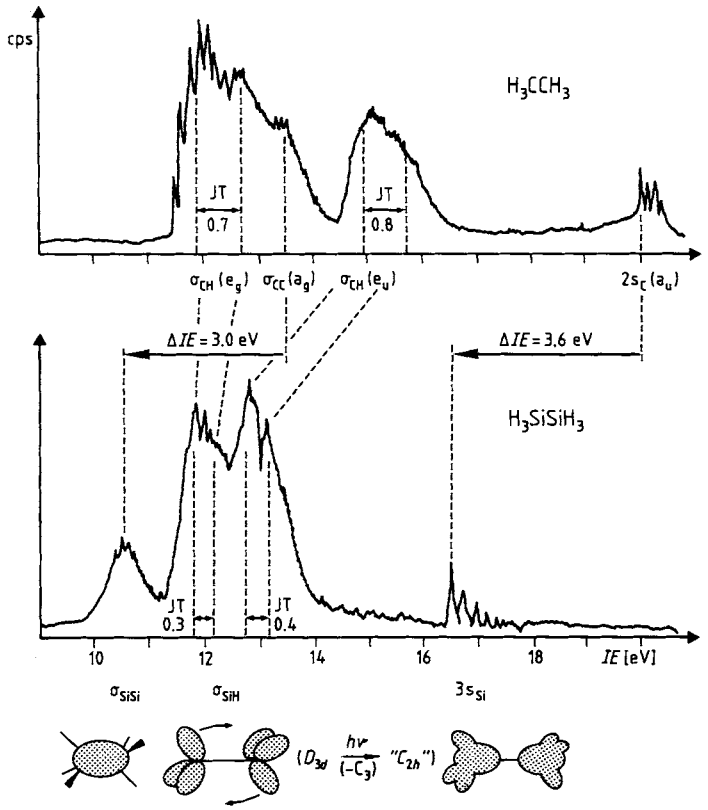
parameters A_i can be approximated from ionization energies,[38] they are "close to experiment" and contain electron correlation contributions. Furthermore, with small and justifiable additional assumptions, the Slater concept can also be used for molecules, even though their constituent atoms have lost their original identity. This approach, based on the numerous known vertical ionization energies into the different radical-cation states,[1,39,40] will be elaborated upon in the following selected examples: the X-PE spectrum of the inosilicate $[H_2SiO_3]_\infty$[39] (Scheme 15), the valence ionizations of the "united-atom" series from Ar to SiH_4[2] (Scheme 16), and a comparison of the radical-cation states of the valence-isoelectronic molecules H_3SiSiH_3 and H_3CCH_3[1] (Scheme 17). The "silicon-donor effect" derived from these examples and the resulting charge distribution will be qualitatively discussed by reference to the partly different structures of H_3C and H_3Si derivatives of the elements O, S, P, and N (Scheme 19).

Scheme 16. United-atom correlation of the valence ionization energies of Ar to SiH_4 and of CH_4.

2.4.1. PE-Spectroscopic Vertical Ionization Energies

X-PE Spectrum of $[H_2SiO_3]_\infty$: X-ray photoelectron spectroscopy (X-PES) conveys an impressive picture of "how electron shells are arranged about a certain effective nuclear potential" or—more precisely—what energies are required to generate a specific radical-cation state, a so-called electron-hole state. The X-PE spectrum of the polymeric inosilicate $[H_2SiO_3]_\infty$[39] (Scheme 15) reveals, for example, "how

Scheme 15. X-PE spectrum (ESCA ionization energies) of Si in the inosilicate $[H_2SiO_3]_\infty$.



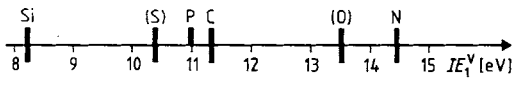
deep the 1s electrons are buried in the negative charge cloud" and shows that, owing to spin–orbit coupling, the Si(2p) doublet states, $^2(Si\,2p)_{1/2}$ and $^2(Si\,2p)_{3/2}$, are split, as expected, in the intensity ratio 2:4. It also shows that the Si(3s,p) valence-electron energy region, in which "all the chemistry takes place", is relatively narrow.

Valence Ionization Energies from Ar to SiH_4: If the end of the X-PES scale close to zero energy (Scheme 15) is expanded and, simultaneously, "nuclear protons" are pulled, one after another, from the noble gas argon as hydrogen atoms, then the united-atom molecular series HCl, H_2S, PH_3, SiH_4 results (Scheme 16). For characterization of the central nonmetal elements within the Slater concept, the mean atomic ionization energies $\overline{IE}^{atom}_{valence} = \sum IE_n/n$ for the respective n valence electrons may be considered.

The PE-spectroscopic comparison[2]—complemented by including CH_4[40]—shows both the region of the "3p valence band" and of the energetically higher 3s electron-hole states for Ar and the valence-isoelectronic species EH_n. In particular, the 3s ionization energies demonstrate the dominant influence of the effective nuclear charge. The "3s electron clouds", which are closer to the nucleus and approximately spherical, are increasingly more easily ionized[2] on decrease of the nuclear charges in steps of $\Delta Z = 1$ (compare also the mean atomic ionization energies $\overline{IE}^{atom}_{valence}$; Scheme 16), the difference between Ar and SiH_4 amounting to nearly 11 eV ($\triangleq$ 1060 kJ mol^{-1}). As expected, the ionizations of the 3p electrons, which are located farther from the nucleus, are more strongly influenced by the additional potentials of the hydrogens pulled from the united-atom argon and are therefore split into molecule-specific radical-cation states with dominant electron-pair (n_E) and bonding (σ_{EH}) contributions (Scheme 16). Nevertheless, the comparison of SiH_4 (principal quantum number $n_{Si} = 3$) and CH_4 ($n_C = 2$) demonstrates that, especially owing to the higher effective nuclear charge of carbon (Scheme 16: $\Delta\overline{IE}^{atom}_{valence} = 11.2$ eV), the two valence ionization energies increase by $\Delta IE(^2A_1) = 4.8$ eV and $\Delta IE(^2T_2) = 1.7$ eV.

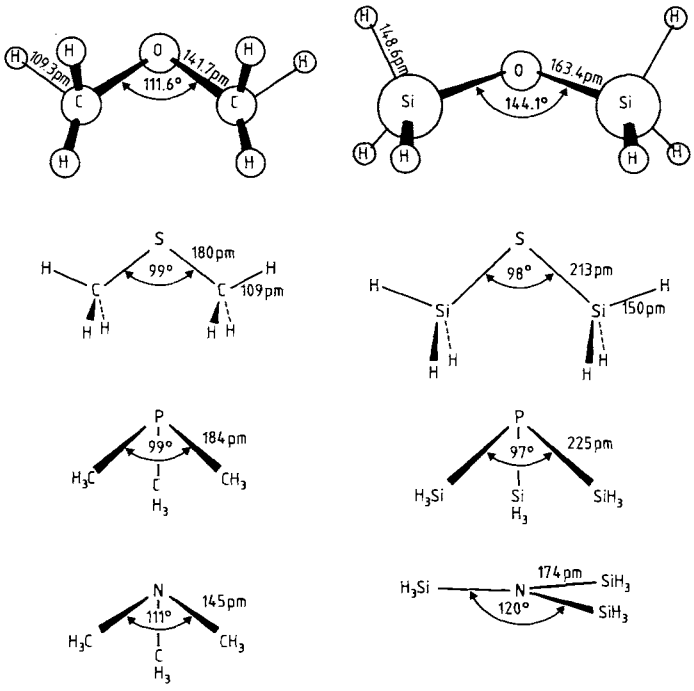
Radical-Cation-State Comparison of H_3SiSiH_3 and H_3CCH_3: The considerable difference between the effective nuclear charges of Si and C centers and the differing influence of this Si electron-donor effect on the individual molecular states are particularly evident in the valence-electron ionization patterns of the "smallest polymers" disilane[1] and ethane,[40] generated with He(I) photons (Scheme 17). The repeatedly investigated sequence of $H_3CCH_3^{\bullet\oplus}$ is assigned in the usual D_{3d} symmetry-group notation as $\tilde{X}(^2E_g) < \tilde{A}(^2A_g) < \tilde{B}(^2E_u) < \tilde{C}(^2A_u)$.[38] The twofold-degenerate $\sigma_{CH}(^2E)$ states show relatively large Jahn–Teller splittings of 0.7 and 0.8 eV, presumably due to the symmetry reduction $D_{3d} \rightarrow C_{2h}$, that is, removal of the threefold axis (C_3).

A comparison with the valence-isoelectronic disilane reveals surprisingly large differences: for example, the energy of the $H_3SiSiH_3^{\bullet\oplus}$ state with the largest $3s_{Si}$ component is lowered by $\Delta IE^v = 3.6$ eV (cf. Scheme 17). Also, the center of gravity of the four σ_{SiH} states (cf. Scheme 17: $\sigma_{CH}(e_g) + (e_u)$) decreases from 13.9 eV in $H_3CCH_3^{\bullet\oplus}$ to 12.5 eV in $H_3SiSiH_3^{\bullet\oplus}$ and, as a result of the longer bond ($d_{CC} = 153$ pm, $d_{SiSi} = 235$ pm), both the $\sigma_{SiH}(e_g/e_u)$ band splitting and the Jahn–Teller distortions are simultaneously diminished. The small effective nuclear charge of the silicon



Scheme 17. Comparison of the radical-cation states of ethane and disilane.

centers even causes a change in the $M^{\bullet\oplus}$-state sequence: relative to the ionization $\sigma_{CC}(a_g)$, the σ_{SiSi} ionization band moves out of the SiH region and is (shifted by $\Delta IE^v = 3.0$ eV) the $H_3SiSiH_3^{\bullet\oplus}$ ground state. In general, the low σ_{SiSi} ionization energies resulting from the smaller effective nuclear charge of Si centers give rise to significant differences in the properties of silanes and alkanes: examples include the applicability of the $\sigma_{SiSi/SiSi}$ interaction model (Scheme 5), the band structure of polysilanes (Scheme 32), and the oxidizability of polysilanes like $(Si(CH_3)_2)_6$ to their radical cations in solution (Scheme 27).



2.4.2. *Structures of H_3C and H_3Si Derivatives of the Elements O, S, P, and N*

The Slater concept of effective nuclear charges allows a comparative discussion of numerous molecular properties. The differing distribution of the same number of valence electrons over different skeletal potentials (Fig. 1 b) is exemplified by the gas-phase structures of the compounds $E(SiH_3)_n$ and $E(CH_3)_n$. The starting point of this discussion is supplied by the vertical ionization energies of nonmetal atoms (Scheme 18).

The single ionizations of O and S $(ns^2np^4) \rightarrow (ns^2np^3)^{\bullet\oplus}$ are placed in parentheses because they lead to energetically favorable cations with spherical symmetrical charge distributions and, therefore, the lower ionization energies deviate from a simplified Z_{eff} correlation. Nevertheless, a crude classification Si < C ~ P, S ≪ O, N is possible and suggests that especially the large difference in effective nuclear charge between Si and O and between Si and N will lead to considerably polar Si → O and Si → N bonds, that is, to high electron densities at the oxygen center of $H_3SiOSiH_3$ and at the N center of $N(SiH_3)_3$. From this point of view, the structures of the H_3C and H_3Si derivatives of the elements O, S, P, and N[41] (Scheme 19) can be comparatively discussed as follows: The differing gas-phase conformations of "doubly eclipsed" dimethyl ether and of "singly eclipsed" disiloxane and the widening of their internal angle (∢ COC = 111.6° to ∢ SiOSi = 144.1°) may be attributed to the considerable difference $Z_{eff}(Si) \ll Z_{eff}(O)$ and the high electron density consequently generated at the central oxygen. This, in turn, should lead to stronger "Coulombic repulsion" between the OSi bonds and, simultaneously, to improved hyperconjugative charge delocalization of the high n_O charge density into the four neighboring HSi bonds.[41a] Although such a line of reasoning touches on the limits of a simplified molecular-state description, it is supported by the comparable gas-phase structures of dimethylsulfide and disilathiane[41b] (Scheme 19). For these molecules, far smaller charge density differences on the two sulfur centers are expected ($Z_{eff}(Si) < Z_{eff}(C) \sim Z_{eff}(S)$). Also, the similar structures of $P(CH_3)_3$ and $P(SiH_3)_3$ and the dramatic differences between $N(CH_3)_3$ and $N(SiH_3)_3$ can be interpreted in an analogous manner: only the considerable difference $Z_{eff}(Si) \ll Z_{eff}(N)$ leads to such a large N electron density that a diminished repulsion between the NSi bonds and an improved π delocalization favors the observed planar NSi_3 molecular skeleton.[41]

Scheme 18. Vertical ionization energies of some nonmetal atoms (see text).

Scheme 19. Gas-phase structures of the methyl and silyl derivatives of O, S, P, and N.

As is often the case, the story is actually more complex.[42] Thus, disiloxane, despite its "vibrational distortion angle" of 144° determined by gas-phase electron diffraction (Scheme 19), exhibits IR excitations governed by D_{3d} selection rules;[42] that is, the molecule must possess a "quasi-linear" skeleton. The barrier to angle widening (∢ SiOSi from 144° to 180°) amounts to only 1.3 kJ mol^{-1}.[42] Therefore, qualitative structure–energy or structure–charge density discussions—like the preceding discussion based on Slater effective nuclear charges—although allowing chemically related compounds to be compared, can be put forward only with the proviso that the differing dynamic behavior of the individual molecules be neglected.

2.5. Silicon Substituent Effects on π Systems

Every chemist will presumably try—as indicated by the introductory quotations[8]—to disentangle the multitude of his compounds and to sort their molecular-state data (Fig. 1a) in the optimum way possible. There are countless different possibilities for selecting chemically related compounds within his area of research (Fig. 3). He may choose, for instance, topological features like coordination numbers (Fig. 2) or—especially for isoconjugate systems—the connection of the individual building blocks and their spatial arrangement (Section 2.2). For heteroconjugate systems, the different framework potentials (Section 2.4) and the respective number of valence electrons can be useful as the main criteria (Fig. 3).

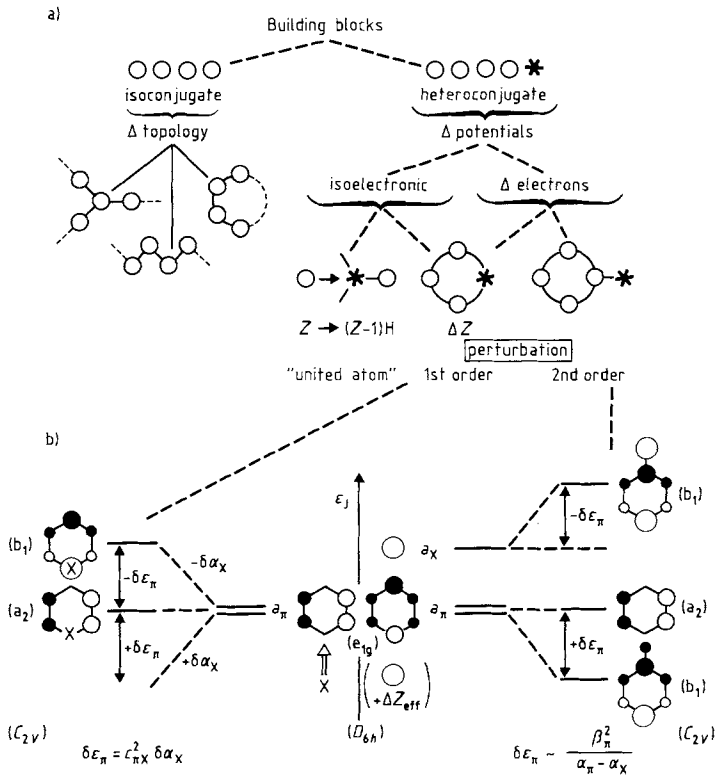


Fig. 3. Criteria for defining chemically related compounds. a) Subdivision into topologically determined isoconjugate and potential-determined heteroconjugate systems, which are appropriately further classified into valence isoelectronic systems and those with differing numbers of electrons as well as according to first-order perturbation by substitution within the molecular skeleton or according to second-order perturbation by additional substituents. b) First- and second-order perturbations are exemplified for benzene [20]: the lowering of the symmetry from D_{6h} to C_{2v} by monosubstitution lifts, among other things, the degeneracy of the $\pi(e_{1g})$ molecular orbitals. For first-order perturbation due to substitution (outside of a π nodal plane), electron donors lower the eigenvalue by $-\delta\varepsilon_\pi$ and electron acceptors raise it by $+\delta\varepsilon_\pi$. For second-order perturbation, the molecular orbitals of the same symmetry are "mixed" and will be lowered by $+\delta\varepsilon_\pi$ owing to additional bonding (O–O) interaction and raised by $-\delta\varepsilon_\pi$ owing to a corresponding antibonding (O–●) interaction. First-order perturbations like $\delta\alpha_x$ are proportional to the square of the coefficient ($c^2_{\pi\mu}$) of the perturbed center μ, while second-order perturbations increase with the square of the interaction parameter (β^2_π) as well as with the decreasing energy difference Δα between the starting levels.

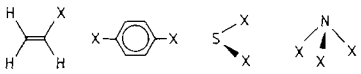

Every chemist will presumably try—as indicated by the introductory quotations[8]—to disentangle the multitude of his compounds and to sort their molecular-state data (Fig. 1a) in the optimum way possible. There are countless different possibilities for selecting chemically related compounds within his area of research (Fig. 3). He may choose, for instance, topological features like coordination numbers (Fig. 2) or—especially for isoconjugate systems—the connection of the individual building blocks and their spatial arrangement (Section 2.2). For heteroconjugate systems, the different framework potentials (Section 2.4) and the respective number of valence electrons can be useful as the main criteria (Fig. 3).

The widespread and useful subdivision of large molecules into parent systems and substituents and their comparison based on first- and second-order perturbation arguments[20] has proved to be tremendously valuable for organosilicon compounds as well. Therefore, the following examples are selected for additional illustration: the extreme σ-donor effects of β-trimethylsilyl groups[1,3] (Section 2.5.1), the "internal" and "external" first-order perturbations of the benzene π system[1,2,43] (Section 2.5.2), the second-order perturbation of the acetylene π system by H_3Si substituents[1,44] (Section 2.5.3), and the electron delocalization in organosilicon radical cations[3] (Section 2.5.4).

2.5.1. *Extreme Donor Effects of β-Trimethylsilyl Groups*

The donor effect of $(H_3C)_3SiCH_2$ substituents, discovered 20 years ago,[45] which, in particular, stabilizes the positive charge in radical cations (Section 2.5.3), is revealed by the low first ionization energies of π systems like ethene and benzene or of molecules with nonbonding electron pairs such as sulfides and amines[1,40,46] (Table 2).

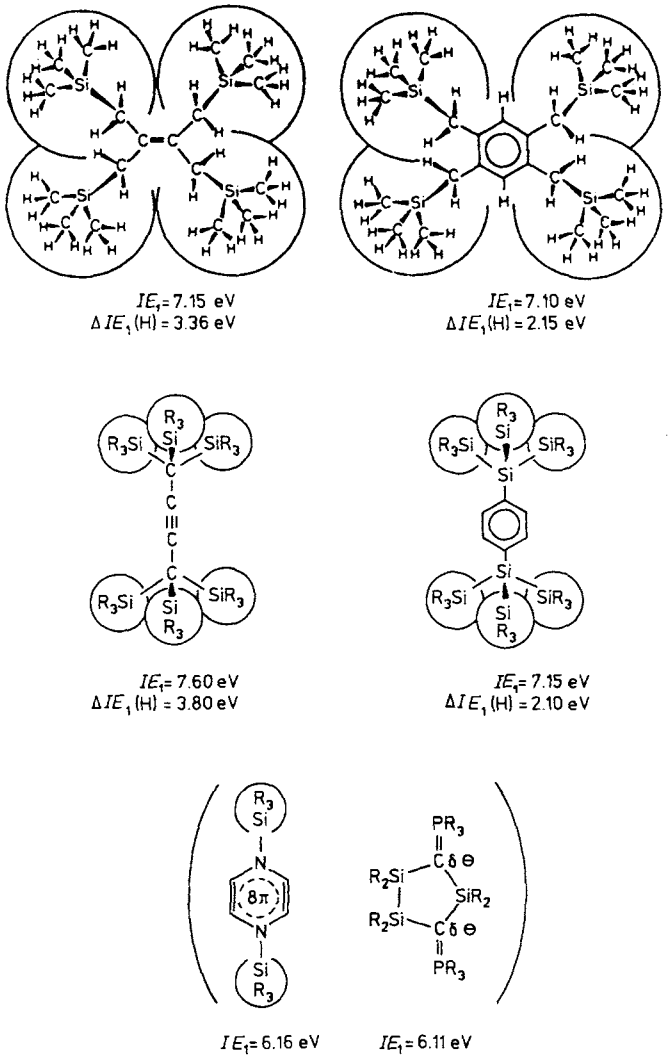

Table 2. Donor effect ΔIE^v_1(H) [eV] of substituents $CH_2Si(CH_3)_3$ on the π systems ethene and benzene as well as on the S and N systems containing lone pairs (see text). R = CH_3.

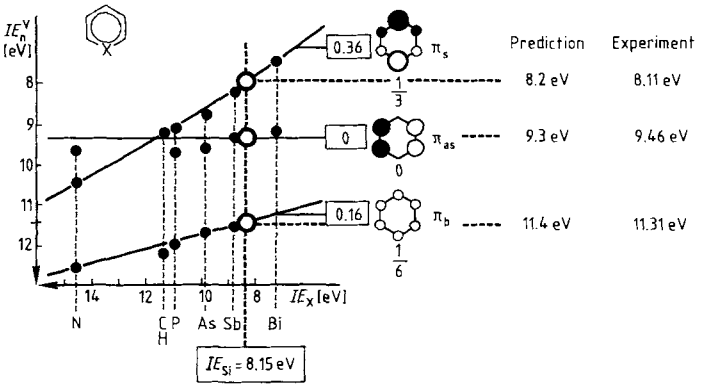
	X = H	SiH_3	R	SiR_3	CH_2SiR_3	ΔIE^v_1(H)
a	10.51	10.37	10.03	9.86	⇒9.10	1.41
b	9.25	(9.11)	8.44	8.7	⇒7.86	1.39
c	10.45	9.7	8.67	8.74	⇒8.04	2.41
d	10.85	9.7	8.44	8.60	⇒7.66	3.19

As demonstrated by the substituent effects $SiH_3 < CH_3 \sim Si(CH_3)_3 < CH_2Si(CH_3)_3$,[1,40] the vertical ionization energies are always lowered most by trimethylsilylmethyl groups.[1] The energy differences ΔIE^v_1(H) relative to the unsubstituted parent system depend, among other things, on the substituted center μ (ethene $c^2_{\pi,\mu} = 0.5 >$ benzene $c^2_{\pi,1/4} = 0.33$ and $Z_{eff}(N) > Z_{eff}(S)$) as well as on its steric shielding.

This is particularly obvious for the tetrasubstituted ethene and benzene derivatives (Scheme 20), whose bulky $(H_3C)_3Si$ groups are arranged alternately above and below the molecular plane: thus, in each case, the radical cations are almost tetrahedrally surrounded; their generation requires comparable ionization energies ($\sum_\mu c^2_{\pi\mu} = 1$[1]). Multiply R_3Si-substituted methyl and silyl groups also lead—al-



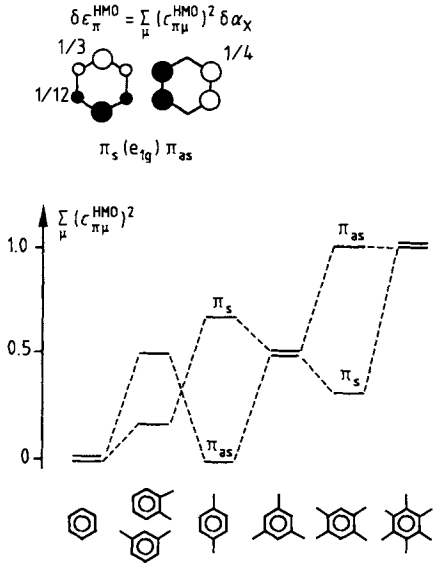
Scheme 20. Representative poly(trimethylsilyl)-substituted organosilicon compounds with unusually low vertical first ionization energies. R = CH_3.

though not additively[1, 43b]—to large ΔIE_1^v(H) values (Scheme 20). In contrast, the lowest first ionization energies of silicon compounds observed so far—only roughly 1 eV higher than that of the sodium atom—are not due to β-R_3Si substituents, but rather to molecule-specific factors, such as the eight π electrons in the 1,4-diazine system,[1] which formally contains eight π electrons, or to the interaction between the carbanionic centers in the five-membered ring bis-ylide[1] (Scheme 20, in parentheses). This assignment simultaneously sheds light on the origin of the "β-trimethylsilyl donor effect": the positive charge in the radical cation generated (Section 2.5.4) can be delocalized into the $(H_3C)_3Si$ groups predominantly by so-called π/σ_{CSi} or n_E/σ_{CSi} hyperconjugation and thus be stabilized (cf. Section 2.5.2).

2.5.2. Silicon First-Order Perturbation of the Benzene π System

Looking at organosilicon compounds with a "molecular-state-sensitive" eye (Scheme 1 and Fig. 1b) reveals numerous examples whose properties can be rationalized by first- and second-order perturbation arguments[2, 20] and thus be applied to chemically related molecules in equivalent states. The classical example is the 6π-electron system of benzene (Fig. 3b), for which substitution and the accompanying symmetry lowering lifts the degeneracy of the $\pi(e_{1g})$ states and, which, owing to its π-nodal planes (i.e., those of zero electron density), possesses unperturbed "standard states" for certain substitution patterns. In the following, "internal" first-order perturbations are illustrated by the prediction of the π-ionization energies of silabenzene[2] and "external" ones by the parameterization of the σ-donor effects of β-trimethylsilyl groups.[1, 43]

Prediction of the π-Ionization Energies of Silabenzene: A correlation (Scheme 21) between the PE-spectroscopically



Scheme 21. Correlation of the π-ionization energies of heterobenzenes C_5H_5X and the correct prediction for silabenzene [2]. For the experiments see [22].

determined vertical π-ionization energies of benzene and its monohetero derivatives $(HC)_5ER$ and the ionization energies ($^4S_{3/2} \rightarrow {}^3P_0$) of the perturbing atoms E has been reported.[47] The gradients of the resulting regression lines reflect the squared coefficients, $c_{\pi\mu}^2$, of the perturbed center μ (cf. Fig. 3b).

The silicon-atom ionization energy of 8.15 eV was inserted into the regression (Scheme 21) in 1977[2] and yielded correct approximate predictions of the π-ionization energies of silabenzene. These were experimentally measured only two years later, after a shortpath pyrolysis apparatus[48] had been developed to generate silabenzene, a molecule only stable under "unimolecular" conditions[49] (Scheme 6). Especially its band at 8.11 eV helped considerably in optimizing the reaction conditions by PE-spectroscopic real-time gas analysis.[48]

Parameterization of the Donor Effect of β-Trimethylsilyl Groups: According to the simple benzene π-perturbation model (Fig. 3b), the sums of squared HMO coefficients, $\sum_{\mu}(c_{\pi,\mu}^{HMO})^2$, obtained from the given values for π_s (1/3 and 1/12) and π_{as} (1/4), yield characteristic perturbation eigenvalue patterns for the different derivatives (Scheme 22). Their correlation with the PES ionization energies requires an additional inductive correction, $\Delta\sigma_{CH_2SiR_3}$, since the ionization energies IE_2^v for the monosubstituted and 1,4-disubstituted derivatives (9.00 and 8.75 eV, respectively) differ from the expected constant value of $IE_2^v(\pi_{as}) = 9.24$ eV. Both parameters, $\delta\alpha_{CH_2SiR_3}$ and $\Delta\sigma_{CH_2SiR_3}$ can be determined by a linear regression calculation[1] (Scheme 22, Table 3).

Scheme 22. First-order π perturbations for $(H_3C)_3SiH_2C$-substituted benzene (cf. text). The substituents are only shown schematically by lines.

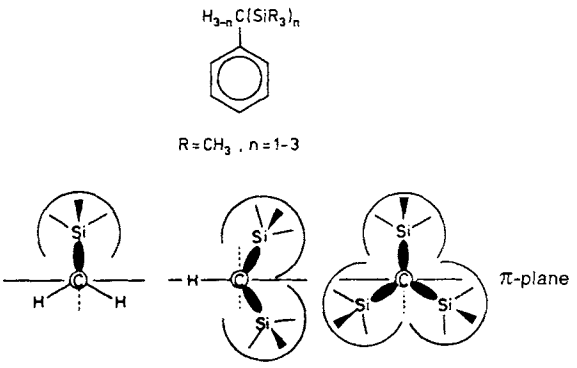
The linear relation (Table 3), which allows the prediction of π-ionization energies of $(H_3C)_3SiCH_2$-substituted benzenes to an accuracy of ±0.2 eV,[1, 43a] also demonstrates that, in addition to the "π/σ_{SiC} hyperconjugation", an inductive

Table 3. Values for Scheme 22. Benzene substituents: R = $CH_2Si(CH_3)_3$.

		Substitution pattern		
	C_6H_6	1	1,2	1,3
IE_1^v [eV]	9.24	8.35	8.05	8.05
IE_2^v [eV]	9.24	9.00	8.55	8.40
		Substitution pattern		
	1,4	1,3,5	1,2,4,5	complete
IE_1^v [eV]	7.75	7.85	7.10	7.40
IE_2^v [eV]	8.75	7.85	7.75	7.40

$IE_n^v = 9.24 - [\sum_\mu (c_{x\mu}^{HMO})^2 \delta\alpha_R + \sum_n \Delta\sigma_R] \Rightarrow \delta\alpha_R = 1.33$ eV; $\Delta\sigma_R = 0.24$ eV

component (Section 2.4: $Z_{eff}(Si) < Z_{eff}(C)$) also formally contributes to the extreme donor effect of β-trimethylsilyl groups (Section 2.5.1). Comparison with the analogously obtained parameters of the methyl groups, $\delta\alpha_{CH_3} = 0.86$ eV and $\sigma_{CH_3} = 0.09$ eV,[1, 43a] illustrates the considerable perturbation of the benzene π system caused by the $(H_3C)_3SiH_2C$ substituents, which, for instance, lower the first ionization energy of the 1,2,4,5-substituted derivative (7.1 eV, Table 3) below that of tetracyclic pyrene (7.4 eV) or of *p*-phenylenediamine (7.3 eV).



The steric overcrowding of poly(trimethylsilyl)-substituted benzenes can be demonstrated, for example, by correlation of the gas-phase ionization energies with the charge-transfer excitation energy of their tetracyanoethylene (TCNE) complexes in solution[43a] (Scheme 23).

The values in parentheses for the highly substituted derivatives deviate from the otherwise satisfactory linear relation because of the sterically enforced larger distances between the $(H_3C)_3SiH_2C$-surrounded donors and the acceptor molecule TCNE. The linear correlation (Scheme 23) allows, in addition, the determination of the first and second π-ionization energies of analogous benzene derivatives from the CT excitation energies of the respective donor–acceptor complexes formed in solution. These UV spectroscopic measurements are easy to perform, serving as a "test-tube photoelectron spectrometer".

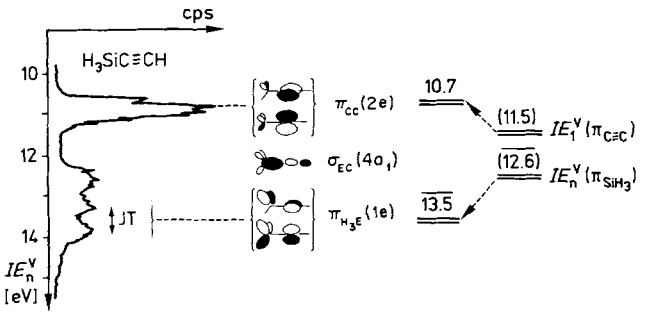
Scheme 23. "Test-tube PE spectrometer": Correlation of the charge-transfer excitation energies of TCNE complexes with π ionization energies of $(H_3C)_3SiH_2C$-substituted benzenes (see text). ● = $IE_1^v/\tilde{\nu}_1^{CT}$; ○ = $IE_2^v/\tilde{\nu}_2^{CT}$.

The donor effects of poly(trimethylsilyl)methyl substituents $(R_3Si)_nH_{3-n}C$ (R = CH_3) can also be parameterized as first-order perturbations.[1, 43b] Starting with the simplifying assumption of constant squared coefficients for the six-membered ring, the differing numbers of β-$(H_3C)_3Si$ groups are accounted for by angle-dependent contributions ($<\cos^2\omega>$) of the d_{CSi} and d_{CH} π-bonding components (Scheme 24, Table 4).

Scheme 24. Hyperconjugation model of the first-order π perturbations caused by $CH_{3-n}(SiR_3)_n$ groups on benzene (cf. text).

For the substituents $(R_3Si)_2HC$ and $(R_3Si)_3C$ in the preferred conformations (Scheme 24; $2<\cos^2 30°> = 1.5$ and $1<\cos^2 0°> + 2<\cos^2 60°> = 1.5$, respectively), identical first ionization energies are predicted and the experimental results agree satisfactorily: as expected, the two different substituents give rise to identical perturbations (Table 4: $IE_1^v = 8.10$ eV).

Table 4. Substituents and values for $H_5C_6-CX^1X^2X^3$ (Scheme 24; R = CH_3).



X^1	X^2	X^3	IE_1^v	IE_2^v
H	H	H	8.84	9.15
SiR_3	H	H	8.35	9.00
SiR_3	SiR_3	H	8.10	8.80
SiR_3	SiR_3	SiR_3	8.10	(< 8.9)

$IE_1 = 9.25 - \sum_{CX} d_{CX}^M \langle\cos^2\theta\rangle \Rightarrow d_{CSi} = 0.7$ eV, $d_{CH} = 0.3$ eV

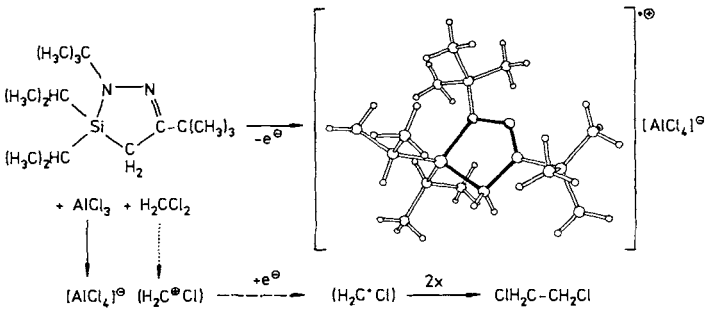
2.5.3. Second-Order Silicon Perturbation of the Acetylene π System

In second-order perturbations (Fig. 3b), orbitals of the same symmetry are assumed to interact and, within the MO model, split into an antibonding and a bonding linear combination; their mixing increases with the square of the interaction parameter, β_π^2, and with decreasing energy difference $\Delta\alpha$. For radical-cation states of a molecule, in which the corresponding stabilization and destabilization become particularly apparent, this implies a different delocalization of the positive charge remaining after ionization.

The simplest example of such a second-order perturbation for organosilicon compounds and also for π_{CC}/σ_{SiH_3} hyperconjugation[1, 44] is represented by silylacetylene, which yields explosive mixtures with air. The molecule $H_3Si-C\equiv CH$ can be formally subdivided into a cylindrical electron cloud around the CC bond and the C_{3v}-symmetric "three-blade H_3Si propeller" (Scheme 25). The interaction

Scheme 25. Silylacetylene: the clearest example of hyperconjugative second-order perturbations (cf. text).

between the two ^2E radical-cation states of identical symmetry can be determined by calibration with the ionization energies IE_1^v of $HC\equiv CH$ and the mean value $IE_n^v(SiH_3)$ of H_3SiSiH_3 (Scheme 17).[1, 44]

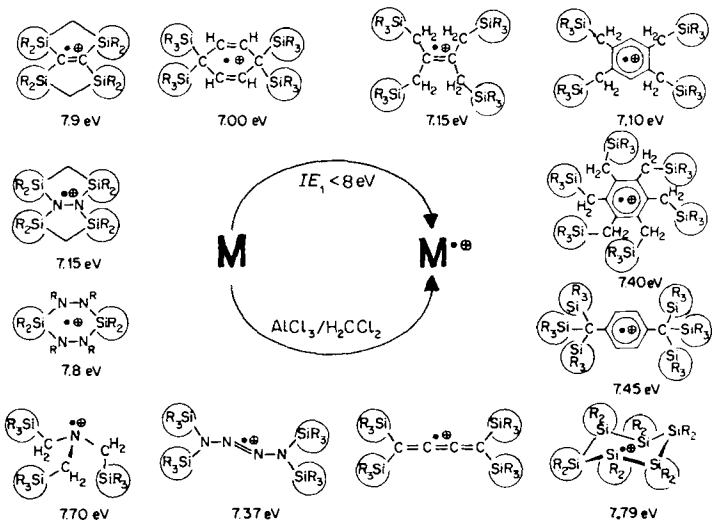


Inserting the respective ionization energies into the second-order interaction determinant (b) gives $\beta_{CC/SiH_3} = -1.2$ eV. Comparison with the analogous methylacetylene

$$\beta_\pi = \sqrt{(\alpha_{CC} - \varepsilon)(\alpha_{SiH_3} - \varepsilon)} = \sqrt{(IE_1^v(HC\equiv CH) - IE_1^v)(IE_n^v(SiH_3) - IE_1^v)} \quad (b)$$

interaction parameter $\beta_{CC/CH_3} = -2.1$ eV (cf. Scheme 17: $\alpha_{CH_3} = -14.2$ eV) shows that the π_{CC}/σ_{CH_3} hyperconjugation is even more effective—as expected from the shortening of the H_3C–C distance. By using the experimental parameters α_{CC}, α_{SiH_3}, and β_{CC/SiH_3}, the three π(e) ionization energies of doubly substituted disilylacetylene, $H_3SiC\equiv CSiH_3$, can also be correctly predicted.[44] Altogether, such hyperconjugative interaction models prove to be useful in the assignment and interpretation of numerous PES ionization patterns of silicon compounds: for example, the likewise C_{3v}-symmetric silicon halides H_3SiHal.[1]

2.5.4. One-Electron Oxidation of Organosilicon Compounds

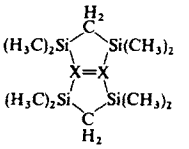


The small effective nuclear charge of silicon (Section 2.4) and, above all, the hyperconjugative charge delocalization by β-trimethylsilyl groups (Sections 2.5.1 and 2.5.2) lower the PE-spectroscopically determined first ionization energies of organosilicon compounds considerably relative to those of their carbon analogues[1] (cf. Table 2 and Schemes 20, 22, and 23). Thus, the experimentally proven stabilization of the positive charge in organosilicon radical cations generated by vertical photoionization within approximately 10^{-15} seconds, as well as the frequently observed parallel between ionization potentials in the gas phase and oxidation potentials in solvents of low polarity[1, 3, 50] leads to the expectation that a chemical and far slower ($< 10^{-10}$ s) adiabatic oxidation[1, 3] should also be possible and should allow the isolation of salts $[M^{\bullet\oplus}X^\ominus]$ with silicon-containing molecular cations $M^{\bullet\oplus}$. This is indeed the case (Scheme 26).[51]

Scheme 26. The assumed mechanism of selective one-electron oxidation by $AlCl_3/H_2CCCl_2$ (see text).

Discovered in 1976,[52] the selective one-electron oxidation of organosilicon compounds by $AlCl_3$ in water-free CH_2Cl_2 is most likely due to the chlorocarbenium ion, $H_2CCl^\oplus$, produced by $Cl^\ominus$ abstraction from the solvent H_2CCl_2, as substantiated by formation of the structurally characterized $AlCl_4^\ominus$ anion (Scheme 26). This carbenium ion, which presumably possesses an oxidation potential of +1.6 V as cyclovoltammetrically determined for the $AlCl_3/H_2CCl_2$ system,[50] could react to give the $H_2ClC^\bullet$ radical dimer, 1,2-dichloroethane,[51] which can be detected by gas chromatography (Scheme 26). The correlation of the (often irreversible) oxidation potentials of organosilicon molecules with their first ionization energies, $E^{ox}[V] = -4.58 + 0.78\ IE_1$ [eV],[50] allows an enormously useful prediction: all molecules[53] that exhibit a first ionization energy below 8 eV—as determined by either PE spectroscopy or UV spectroscopy of a suitable donor–acceptor complex (Scheme 23)—ought to be oxidized selectively to their radi-

cal cations by the oxygen-free $AlCl_3/H_2CCl_2$ system[1, 3, 53] (Scheme 27).

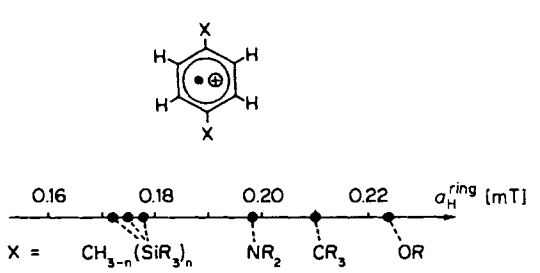


Scheme 27. Representative examples for organosilicon compounds with $IE_1 < 8$ eV and their $AlCl_3/CH_2Cl_2$ oxidation to radical cations. R = CH_3. Known IE_1^v values given.

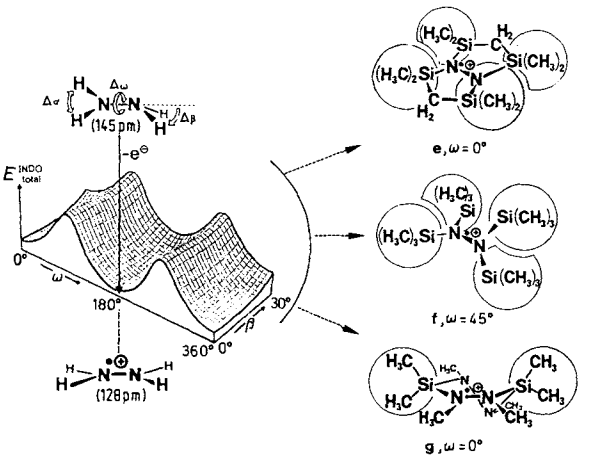
ESR/ENDOR spectroscopy,[10] best suited to identify and characterize paramagnetic species in solution, yields a wealth of information about the ground states (Fig. 1a) of organosilicon radical cations generated so elegantly in $AlCl_3/CH_2Cl_2$ solution (Scheme 27): the recorded signal patterns allow the spin distributions to be "read off", thereby establishing the structural changes due to "adiabatic" relaxation. Temperature-dependent measurements allow, moreover, the observation of molecular dynamics on the ESR/ENDOR time scale of approximately 10^{-7} seconds, which is longer by orders of magnitude than the 10^{-15} seconds needed for vertical photoionization or the 10^{-13} seconds before the onset of molecular vibrations. From the extensive ESR/ENDOR data[3] for the numerous one-electron oxidation products of organosilicon compounds, the following have been selected as representative.

Spin Distribution: Radical cations of benzene derivatives that are considerably perturbed by 1,4-disubstitution (Scheme 22, $\sum_{\mu} c_{\pi\mu}^2 = 2/3$) show the coupling constants a_H^{ring} given in Scheme 28 for the four equivalent benzene protons.

The substituents $CH_{3-n}(SiR_3)_n$ clearly give rise to a more effective π-spin delocalization than "prototype" donors such as OR or NR_2. This result is—despite dissimilarity of spin and charge—in agreement with the PE-spectroscopically observed hyperconjugative stabilization of the positive charge (Schemes 20, 22, and 24) in the vertically generated radical cations. From the coupling constants $a_{^{29}Si}$ and $a_H^{Si(CH_3)_2}$ of the $M^{\bullet\oplus}$ and $M^{\bullet\ominus}$ radical ions of tetrasilabicyclo[3.3.0]octane, which are presumed to each exhibit a planar framework (Scheme 29),[3, 52, 54] one can "read off", in addition, how



X=X	$C^{\bullet\oplus}=C$	$C^{\bullet\ominus}=C$	$N^{\bullet\oplus}=N$	
$a_{^{29}Si}$	2.271	0.685	0.500	[mT]
a_H	0.062	0.048	0.030	[mT]



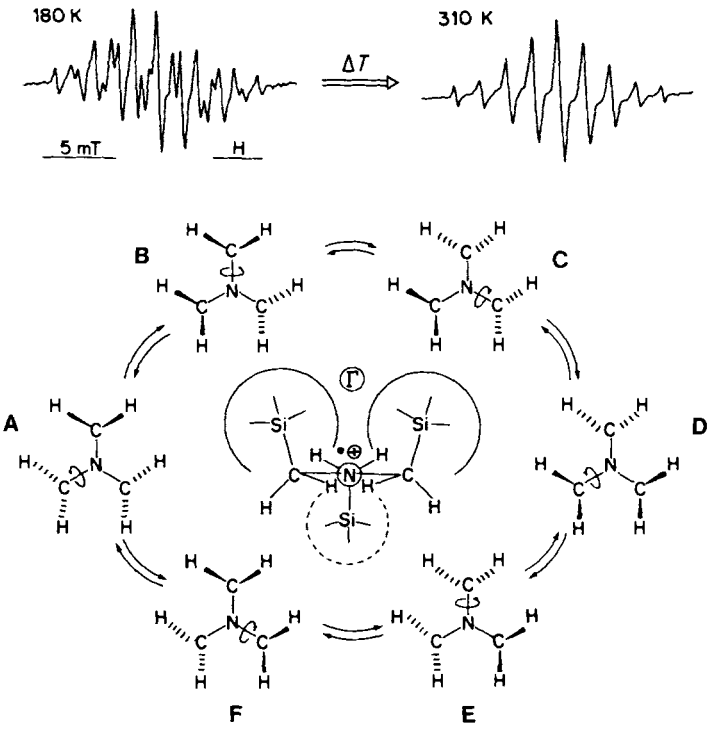
Scheme 29. Spin distribution in tetrasilabicyclo[3.3.0] radical cations (cf. text).

large the π-spin density in the $(H_3C)_2Si$ substituents of the $CC^{\bullet\oplus}$ radical cations actually is. In the two valence-isoelectronic $CC^{\bullet\ominus}$ and $NN^{\bullet\oplus}$ species, however, the unpaired electron is preferentially spread over the region of the central bond.

Structural Changes due to One-Electron Oxidation of Silylated Hydrazines: The changes in energy and electron distribution on vertical transition from the ground state of the neutral molecule to its radical-cation state ($\Gamma(M) \rightarrow \Gamma(M^{\bullet\oplus})$) (Fig. 1a) inevitably give rise, after the onset of molecular dynamics in the femtosecond region,[55] to "adiabatic changes in the "vertically frozen" molecular coordinates. When chemical oxidation in solution, $M + Ox^{\oplus} \rightarrow M^{\bullet\oplus} + Red$, is carried out instead of gas-phase photoionization, the structure of the oxidation product $M^{\bullet\oplus}$ can be determined from the ESR signal patterns[3, 53] and reproduced by quantum-chemical open-shell energy-hypersurface calculations.[1, 3, 5, 7a] For hydrazine and its $(H_3C)_nSi$ derivatives the following results are obtained (Scheme 30): The

Scheme 28. Spin distribution in substituted benzene radical cations (cf. text). R = CH_3.

Scheme 30. Energy hypersurface for the hydrazine radical cation and ESR-determined structures of organosilylhydrazine radical cations in solution (cf. text).



starting point is provided by INDO open-shell hypersurfaces for the six-atom parent radical cation $N_2H_4^{\bullet\oplus}$, the $3n - 6 = 12$ degrees of freedom of which are approximately covered by the three angular coordinates α(HNH), $\beta(NNH_2)$, and $\omega(H_2N-NH_2)$. According to the located energy minimum, the neutral C_2 molecule flattens on removal of an electron to a D_{2h} radical cation. For the three-electron two-center π bond formed, a shortening of the NN bond length from approximately 145 pm by $\Delta d_{NN} \approx$ 17 pm(!) to 128 pm has been calculated[56a] and, in the meantime, structurally confirmed.[56b]

From the simultaneously calculated angle-dependent ESR coupling constants,[56c] as well as by comparison with PES ionization energies, the following structural changes of the $(H_3C)_nSi$-substituted hydrazine derivatives result on one-electron oxidation[3] (Scheme 30): The bicyclic hydrazine is already almost planar in its neutral ground state—as confirmed by the enormous n_N/n_N splitting of $\Delta IE^v_{1,2} \approx$ 1.8 eV.[56c] In contrast, the dihedral angle of the open-chain derivative $M^{\bullet\oplus}$, which, according to the small difference in the ionization energies of only 0.2 eV, must possess two molecular halves almost perpendicular to each other, is diminished to the sterically enforced minimum value of $\omega \approx 45°$ in its radical cation, as proven by the a_N and a_H coupling constants.[56c] For the oxidized six-membered tetraazadisila ring **g**, the ESR signal pattern indicates a half-chair conformation with only one of $SiN^{\bullet\oplus}NSi$ molecular halves flattened. The intramolecular 'flipping" process is presumably slower than the ESR time scale of 10^{-7} seconds.[3] Altogether, the structural changes in the three chemically related silylhydrazine radical cations—despite compound-specific peculiarities—all occur in the same direction and, therefore, demonstrate the benefits of model energy-hypersurface calculations.[5, 7a]

Tris(trimethylsilyl)methylamine Radical Cation and Its "Cog Wheel" Dynamics: Many organosilicon radical cations with several β-trimethylsilyl groups (cf. Scheme 27) are sterically overcrowded and therefore rigid with respect to substituent rotations.[3] In contrast, the planar radical cation $[(H_3C)_3SiH_2C]_3N^{\bullet\oplus}$, which exhibits larger angles ($\sphericalangle$ CNC = 120°) between the individual ligands, shows a characteristic ESR line broadening on raising the temperature,[57] by which the 25 signals (1N + 3 × 2H) observed at 180 K are reduced to 9 (1N + 6H) at 310 K (Scheme 31).

This phenomenon is due to the rotation of each $(H_3C)_3SiH_2C$ substituent to the other side of the NC_3 molecular plane on the ESR time scale of 10^{-6} to 10^{-8} seconds. Because each side of the NC_3 plane offers room for only two of the bulky $(H_3C)_3Si$ groups, a "cog-wheel"-like coupled dynamic process (Scheme 31: **A** to **F**) results and the CH_2 protons become equivalent on the ESR time scale.[3, 57]

In summary, it has been established that all organosilicon compounds with first vertical ionization energies below 8 eV (Scheme 27) can be oxidized by $AlCl_3/H_2CCl_2$ (Scheme 26)[1, 13] to the corresponding radical cations.[1, 3] Their ESR/ENDOR signal patterns[3] show the influence of Si substitution on spin distributions (Schemes 28 and 29), characteristic changes in structure (Scheme 30), and molecular dynamics (Scheme 31) on the ESR time scale. The example of temperature-dependent ESR signal patterns reveals another molecular-state variable (Fig. 1), the storage of

Scheme 31. Temperature-dependent ESR spectra and the "cog wheel" molecular dynamics of the radical cation $N(CH_2SiR_3)_3^{\bullet\oplus}$, R = CH_3. In **A**–**F**, the R_3Si groups are omitted.

internal energy in the 3n − 6 degrees of freedom of n-atom three-dimensional molecules.

3. Silicon Chemistry: Molecular States as Retrospect or as Prospect?

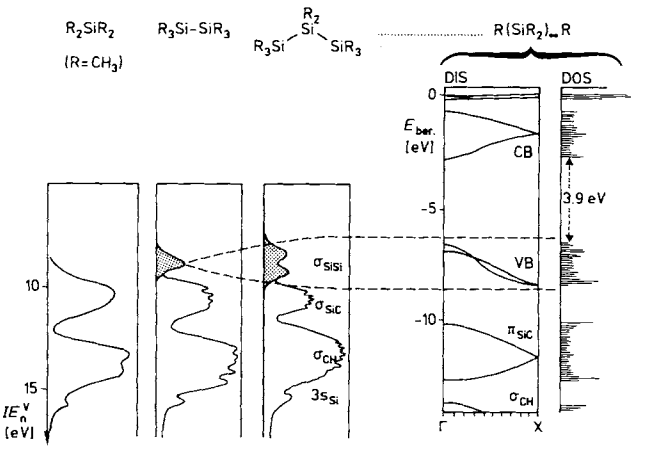
Faced with the "torrent" of silicon compounds[7] and the "sea" of their molecular states,[7] this article can illustrate at best only some aspects of selected examples. Nevertheless, it should always be kept in mind that each chemical species, formally describable by connecting its centers exhibiting specific potentials, through electrons, will—depending on its energy—possess different structures and exhibit different dynamics and hence differing properties. Such a general statement, however, is of little help to the preparative chemist, who would like to classify the multiplicity of compounds by chemical intuition. The procedure[2] suggested here, to compare equivalent states of chemically related molecules based on their measurement data, that is, to stay as close to experiment as possible and to support experiment by quantum-chemical models and calculations, is—although useful and well tested[1–7]—not the only one possible; force-field approximations and statistical methods offer alternative approaches. This also applies to the especially emphasized techniques of PES[1, 9] and ESR/ENDOR[3, 10] spectroscopy, even though they advantageously cover different time domains, the molecular ions investigated by them show particularly strong perturbations, and the energy differences or measured spin populations can be correlated—for example, via Koopman's theorem or the McConnell relation—with results from approximate calculations, even for

larger molecules. With these and further reservations, one last question referring to the introductory quotations will be asked: To what extent can our knowledge be organized (Section 3.1) and sensible questions be formulated (Section 3.2)?

3.1. Retrospect: Structure, Energy, Charge Distribution

To begin with, attention is drawn once more to the fact that the preparative silicon chemist daily looks at molecular fingerprints, that is, molecular-state patterns, in order to characterize his compounds by spectroscopic analysis. For highly reactive species, such as phenyl silaisocyanide (Scheme 3), dichlorosilanediyl (Scheme 12), silabenzene (Schemes 6 and 21), and 1,4-bis(trimethylsilyl)benzene radical anion (Scheme 4), none of which can be "put in a bottle", spectroscopic methods are frequently the only possibility for obtaining proof that these molecules exist.[1, 3, 7e]

Additional information hidden in the spectroscopic molecular-state patterns of silicon compounds can often be profitably evaluated—despite the complexity of these patterns—if equivalent states of chemically related compounds are compared. Frequently, striking aspects (Fig. 1) can be emphasized in the interpretation—such as the connection of molecular building blocks (Fig. 3, Schemes 5, 8, 10, 22, and 25, as well as Tables 2 and 3), the small effective nuclear charge of Si (Section 2.4 and Schemes 5, 21, and 27), the concomitantly changed charge distribution (Section 2.5 and Schemes 4, 5, 16, 17 and 19), and structure–energy relationships (Section 2.2.2 and Schemes 3, 19, and 30). All these aspects overlap—as is demonstrated, for example, in the discussion of the extreme donor effect of β-$(H_3C)_3Si$ groups[58] (Section 2.5.1, Schemes 22–24 and 27, as well as Tables 3 and 4)—and have to be complemented by considering the specific dynamics of the respective molecular states (Scheme 31). Quantum-chemical models (Schemes 5, 13, 16, and 17), on which first- and second-order perturbations can be based (Sections 2.5.2 and 2.5.3 and Schemes 4, 12, 17, 28, and 29) and numerically exact calculations of molecular properties (Schemes 3, 8, 10, 12, and 30) may serve as starting points and are a most valuable help in the evaluation of experiments.[1–7] Quantum-chemical predictions quoted in the text and confirmed experimentally include the existence of $H_5C_6-N\equiv Si$ (Scheme 3), as well as of Ge_6-prismane and Si_8-cubane (Section 2.2.2). Hypersurface calculations have also been used to make predictions concerning the structural changes and the ESR signal patterns of organosilylhydrazine radical cations (Scheme 30). Molecular-state correlations[1–7] proved to be reliable in all examples selected in this article; for example, the Birch protonation of benzene radical anions (Scheme 4), the estimation of the silabenzene π-ionization pattern (Scheme 21), the linear regression $IE^{v}_{1,2}/\tilde{\nu}^{CT}_{1,2}$ (Scheme 23), and the one-electron oxidizability of molecules with first ionization energies below 8 eV by the $AlCl_3/CH_2Cl_2$ redox system (Scheme 27).



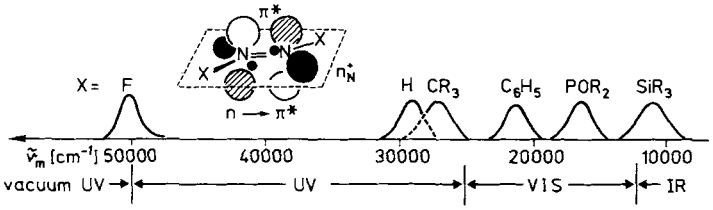
Altogether, these and further details of the molecular states of silicon-containing compounds[1–7] contribute to our essential knowledge of silicon chemistry. In particular, the molecular-state comparisons, for example with valence-isoelectronic carbon compounds,[1–7, 58] can be complemented by a variety of data obtained from other measurements and can be expanded to include numerous other compounds. This also helps in the determination of the differing substituent effects on individual molecular states (Fig. 1), which are useful for both the planning and the evaluation of experiments.[1–7, 58] The answer to the question concerning the benefits of molecular-state considerations for the preparative silicon chemist (Section 1) is, therefore, unequivocally a positive one. This statement can be further supported and extended by looking with the molecular-state magnifying glass (Scheme 1) at current and partially unsolved problems in silicon chemistry.

3.2. Prospect: Band Structures, Rydberg States, Contact Ion Pairs, Microscopic Reaction Pathways

The further development of silicon chemistry, which is in full swing, includes projects in which molecular-state measurements and their interpretation play an important role. Several of these projects will be outlined below.

Band Structures of Polysilanes: An understanding of band structures is of importance for developing novel photoconducting materials[7d, 59] with low ionization thresholds and narrow valence bands. As has already been discussed starting from a comparison of the radical-cation states of SiH_4/CH_4 (Scheme 16) and, especially, of H_3SiSiH_3/H_3CCH_3 (Scheme 17), the low effective nuclear charge of the silicon centers leads to low σ_{SiSi} ionization energies. This is particularly noteworthy in the case of permethylated polysilanes (Section 2.2.1), whose low-energy PE-spectroscopic band patterns were first interpreted 18 years ago[15] on the basis of a SiSi bond model (Scheme 5: $\alpha_{SiSi} \approx 8.7$ eV, $\beta_{SiSi/SiSi} \approx 0.5$ eV). Recently, the band structure[60] of the polymers $R(SiR_2)_\infty R$ of infinite chain length was calculated quantum-chemically (Scheme 32).[61]

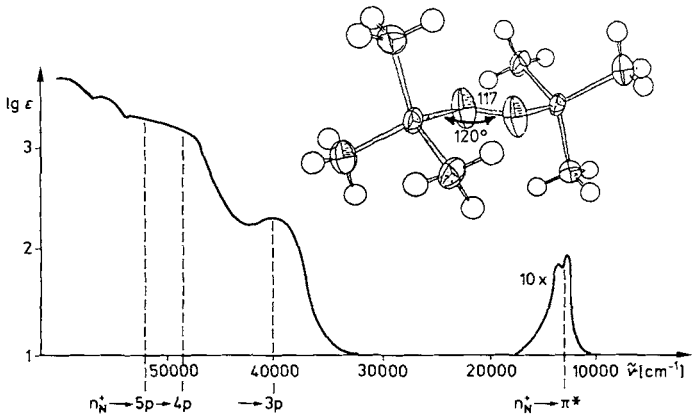
The ab initio calculations using Bloch functions[60] were calibrated[61] with the PE ionization energies of silanes.[1, 15] The wave vector $\boldsymbol{k}$ runs from $\Gamma(\boldsymbol{k} = 0)$ to $X(\boldsymbol{k} = \pi/a)$, where a is the lattice constant. The state "dispersion" (Scheme 32:



Scheme 32. Ionization patterns of permethylated silanes (cf. Scheme 5) and calculated band-structure dispersion (DIS) and state density (DOS) for polydimethylsilane $R(SiR_2)_\infty R$ [61].

DIS) shows a "$3p_{Si}$" valence band (VB) about 2 eV wide and an ionization threshold of 5.9 eV (cf. polyacetylene $H(HC=CH)_{\infty}H$:[59] threshold 2.2 eV, width 5–6 eV). Calculations revealed an unfilled $4s_{Si}$ conduction band (CB) some 3.9 eV above this valence band and, among others, π_{SiC}, σ_{CH}, and $3s_{Si}$ bands below it.[59, 61] The analogously scale-adjusted state-density diagram[61] (Scheme 32: DOS) agrees satisfactorily with the X-PES-determined values (cf. Schemes 15 and 16), which, conversely, confirm the calculated low ionization threshold and the narrow valence band width.[59] It should also be emphasized that the $M^{\bullet\oplus}$-state discussion of methylsilanes $R(SiR_2)_{1-5}R$[15] still serves today, 18 years later, as an interpretation tool and that the PES measurements[1, 15] are therefore of renewed use.

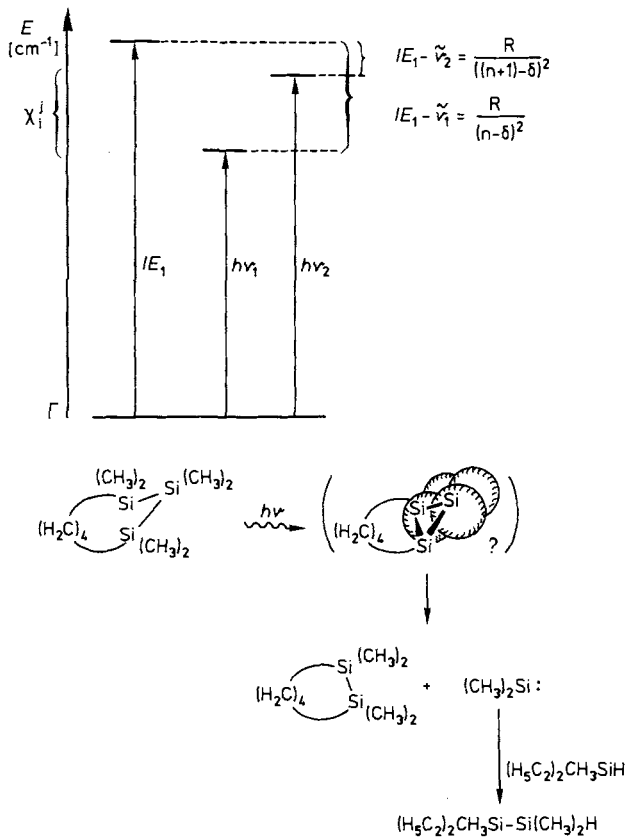
Rydberg States of the Blue Silicon Azo Compound $R_3Si-N=N-SiR_3$: One of the visible wonders of organosilicon chemistry is the unexpected blue color of bis(trimethylsilyl)diimine (-diazene).[62] Its $n_N^+ \rightarrow \pi^*$ excitation energy (cf. Scheme 33) is lowered relative to that of difluorodiimine by almost 40 000 $cm^{-1} \triangleq 5$ eV and even relative to that of the colorless valence-isoelectronic di-*tert*-butyl derivative by 14 500 $cm^{-1} \triangleq 1.8$ eV.[62]



The crystal structure of $R_3Si-N=N-SiR_3$[1, 2, 62] (Scheme 34) offers some clues to the origin of this enormous bathochromic shift of the $n_N^+ \rightarrow \pi^*$ transition[62] in the blue four-center chromophore $Si-N=N-Si$, which exceeds the one caused by two phenyl substituents in the 14-center π system of orange azobenzene (Scheme 33). It shows normal

Scheme 33. The $n \rightarrow \pi^*$ excitation energies of representative azo compounds.

angles ($\sphericalangle$ SiNN = 120°) but a dramatically shortened N=N bond distance of only 117 pm, that is, halfway between that in carbon azo compounds ($d_{N\equiv N} \approx 125$ pm) and that in elemental nitrogen ($d_{N\equiv N} = 111$ pm). This is one more example (cf. Scheme 19) of a structural distortion due to the differing effective nuclear charges of Si and N (Section 2.4.2) and reconfirms the high electron density ($IE_1 = 7.1$ eV[1, 62]) around the Si-substituted N centers.

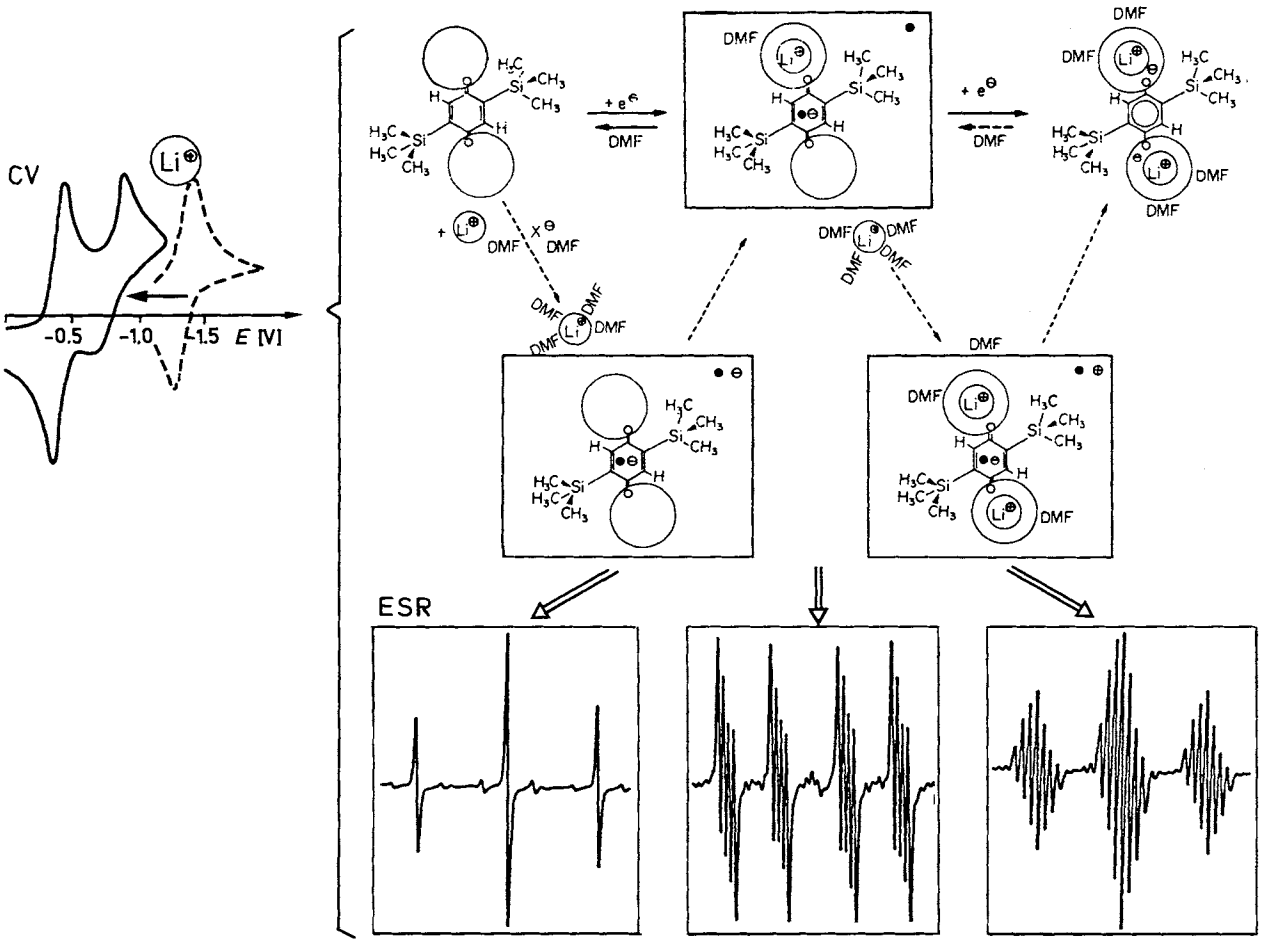


The assignment of the partially overlapping absorption bands in the UV and vacuum UV region of $R_3Si-N=N-SiR_3$ (Scheme 34) is of fundamental importance. According to an MO/CI estimate[1, 62] of the expected $n_N^- \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions for carbon azo compounds $R'-N=N-R'$,[63] the latter presumably requires an excitation energy of more than 70 000 cm^{-1}. Therefore, by starting from the lowest first ionization energy, $IE_1^v = 7.1$ eV, of the trimethylsilyl derivative $R_3Si-N=N-SiR_3$[1, 62] and taking reported[63] term values $R/(n-\delta)^2$ (Scheme 34), excitation energies into N-centered Rydberg states could be estimated (R = Rydberg constant). The excellent agreement

Scheme 34. Structure of $R_3Si-N=N-SiR_3$ and Rydberg assignment of its UV bands. R = CH_3.

between the experimentally recorded (Schemes 34 and 35: $\tilde{\nu}_2 = 40\,000\ cm^{-1}$, $\tilde{\nu}_3 = 49\,000\ cm^{-1}$, $\tilde{\nu}_4 = 52\,000\ cm^{-1}$) and the expected Rydberg ($n_N^+ \rightarrow np$) excitation energies of 40 000 cm^{-1}, 48 500 cm^{-1}, and 51 900 cm^{-1}, respectively, supports such an assignment (Scheme 34: $n_N^+ \rightarrow$ 3p, 4p, 5p; series limit $IE_1 = 7.1$ eV = 57 300 cm^{-1}[1, 62]).

For other organosilicon derivatives, analogous estimates predict silicon-centered Rydberg states. For example, subtraction of the first UV excitation energy of 1,2,3-trisilacycloheptane ($\tilde{\nu}_m = 46\,000\ cm^{-1}$) from the first ionization energy of octamethyltrisilane ($IE_1^v = 8.19$ eV $\triangleq$ 66 000

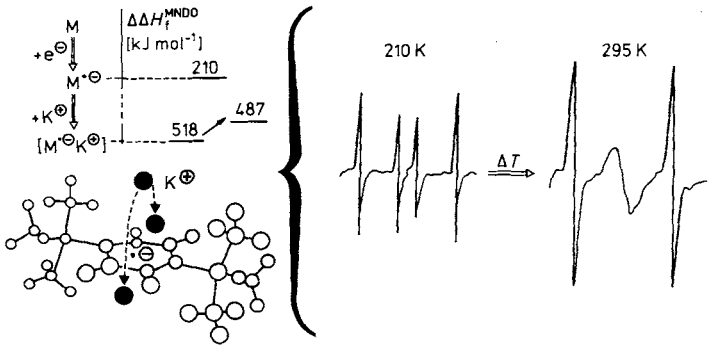


Scheme 35. Photochemical $(CH_3)_2Si$ elimination from trisilacycloheptane and suggestion of a "Rydberg excitation" transition state. R = Rydberg constant = 109 700 cm^{-1}; n = principal quantum number; δ = quantum defect. Term values $R/(n-\delta)^2$: d $\approx$ 12 000 cm^{-1}, p = 18 000 cm^{-1}, s $\approx$ 28 000 cm^{-1}.

cm^{-1} [1,15]; Scheme 5); gives a Rydberg term $R/(n-\delta)^2 \approx 20000\ cm^{-1}$. This term could correspond to a $\sigma_{SiSiSi} \rightarrow 4p_{Si}$ excitation and, in agreement with the measured UV intensity ($\varepsilon = 8000\ L\ mol^{-1}\ cm^{-1}$ [64]), would be allowed under local C_{2v} symmetry. Due to the enormous spatial extension of Rydberg states, which usually enclose large parts of a particular molecule,[63] such an assignment would explain the photochemical formation of a three-membered ring transition state and its relaxation by loss of dimethylsilanediyl, which can be captured by another disilane derivative[64] (Scheme 35).

Therefore, the loss of R_2Si from trisilanes upon irradiation with light of wavenumber $\tilde{\nu} = 39400\ cm^{-1}$, which is a key reaction for the preparation of the "dimer" $R_2Si{=}SiR_2$ (Fig. 2),[7b-d] presumably proceeds via a $4p_{Si}$ Rydberg excitation. The energetically relatively low-lying Rydberg states of organosilicon compounds could also be involved in many other photochemical reactions[7b] and, for example, contribute to the understanding of the still unsettled spin distribution in cyclosilane radical anions.[7d]

Contact Ion Pairs of Silylated p-Benzoquinones as Redox Intermediates: The microscopic pathway of the chemical reactions of medium-sized molecules, with their multifarious $3n-6$ degrees of freedom, is considered to be an almost unsolvable problem.[66] The preparative chemist can contribute partial information by specific synthesis, spectroscopic proof, and/or isolation of reactive intermediates.[69] In aprotic and largely nonpolar solvents, this often can be accomplished by additional "Coulombic interactions" between differently charged ions. Thus, by adding suitable salts $[Me^{\oplus}X^{\ominus}]$ to solutions of radical anions $M^{\bullet\ominus}$ (cf. Scheme 2), the formation of contact-ion-pair radicals $[M^{\bullet\ominus}Me^{\oplus}]^{\bullet}$ and triple-ion radical cations $[Me^{\oplus}M^{\bullet\ominus}Me^{\oplus}]^{\bullet\oplus}$ can be detected by ESR/ENDOR spectroscopy.[67] In some cases, these radical-anion salts can also be crystallized at low temperature and structurally characterized.[68]

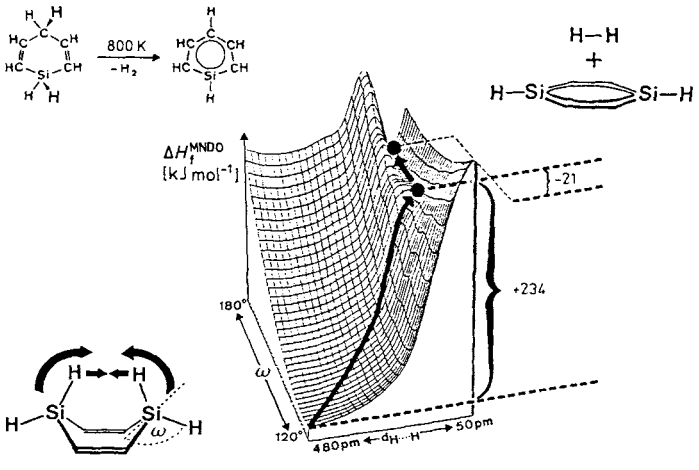


An especially illustrative example of an organosilicon compound is 2,5-bis(trimethylsilyl)-*p*-benzoquinone.[4,6,66] Its second, reversible half-wave potential (Scheme 36: CV- - -), on addition of the DMF-soluble $Li^{\oplus}[B(C_6H_5)_4)]^{\ominus}$ is lowered by 0.6 V and simultaneously becomes irreversible (Scheme 36: CV—). The presumed reduction pathway in the presence of excess lithium cation, which, owing to its small ionic radius ($r_{Li^{\oplus}} = 60$ pm), possesses a high effective ionic charge $1/r_{Li^{\oplus}}$, is supported by independent ESR/ENDOR measurements in THF.[4] A 1:2:1 triplet is observed for the solvated radical anion $M^{\bullet\ominus}$, owing to the two equivalent quinone hydrogens. The initially formed contact-ion-pair radical $[M^{\bullet\ominus}Li^{\oplus}]^{\bullet}$ shows a lowering of symmetry from C_{2v} to C_s owing to the "docking" of the $Li^{\oplus}$ ion and thus displays a doublet of doublets, the signals of which are each split into quartets by the ^7Li nuclear spin ($I = 3/2$). In the finally

Scheme 36. Electron transfer (CV) and ion-pair formation (ESR) on reduction of 2,5-bis(trimethylsilyl)-*p*-benzoquinone in aprotic solution, partly with added $Li^{\oplus}[B(C_6H_5)_4]^{\ominus}$ (cf. text).

resulting triplet radical cation $[Li^{\oplus}M^{\bullet\ominus}Li^{\oplus}]^{\bullet\oplus}$, the quinone hydrogens are again equivalent and the two docked $Li^{\oplus}$ ions cause an additional septet splitting. In this solvated contact triple ion, the final product, that is, the dilithium salt of 2,5-bis(trimethylsilyl)hydroquinone, is already preformed and, therefore, the second electron transfer takes place irreversibly at a dramatically lower reduction potential (Scheme 36; CV- - -).

The investigations concerning other contact ion pairs of 2,5-bis(trimethylsilyl)-*p*-benzosemiquinone with larger and, therefore, more loosely coordinated countercations,[4] such as $K^{\oplus}$ ($r_{K^{\oplus}} = 138$ pm), have been accompanied by approximate energy-hypersurface calculations[4] (cf. Scheme 37). They predict the geometry-optimized radical anion $M^{\bullet\ominus}$ to be more favorable relative to the neutral molecule M by $\Delta\Delta H_f^{MNDO} \approx 210$ kJ mol^{-1}, and the additional Coulomb stabilization in the contact ion pair, despite neglected solvation, should amount to 210 kJ mol^{-1}. Surprisingly, the energy-hypersurface calculations suggest that the $K^{\oplus}$ countercation should "fluctuate": to reach the saddlepoint 380 pm above the geometry-optimized quinone six-membered ring, an activation barrier of only approximately 30 kJ mol^{-1} would have to be surmounted[4] (Scheme 37).



Scheme 37. Dynamics of the contact-ion-pair radical $[K^{\oplus}O_2C_6H_2(SiR_3)_2^{\bullet\ominus}]^{\bullet}$: Energy hypersurface calculations ($\Delta\Delta H_f^{MNDO}$) and temperature-dependent ESR spectra (cf. text).

The predicted dynamics of the $K^{\oplus}$ contact ion pair can be confirmed by ESR spectroscopy (Scheme 37): At 210 K, the expected doublet of doublets is measured for the nonequivalent quinone hydrogens, whereas at 295 K a ^{1}H triplet indicates that, owing to $K^{\oplus}$ fluctuation, the quinone protons become equivalent on the ESR time scale of 10^{-7} seconds.

Altogether the CV and ESR/ENDOR data,[4] in combination with the quantum-chemical hypersurface calculations, thus provide, as exemplified by 2,5-bis(trimethylsilyl)-*p*-benzoquinone, some insight into the pathway of a consecutive two-electron reduction, although solvent effects are still neglected. The partially dynamic contact ion pairs discovered in the investigation could be of interest both bioinorganically because of their carrier properties and industrially as molecular switches.

Does Thermal H_2 Elimination from Silacyclohexadiene to Give Silabenzene Proceed Intramolecularly? Dynamic phenomena have already been covered in some detail as important molecular-state properties (Fig. 1) by selecting as examples the radical cation $(R_3SiCH_2)_3N^{\bullet\oplus}$ (Scheme 31) and the contact-ion-pair radical $[(R_3Si)_2C_6H_2O_2^{\bullet\ominus}K^{\oplus}]^{\bullet}$ (Scheme 37). Along the microscopic pathways of chemical reactions, they often play a decisive role[55] and thus their importance should not be underestimated. As concerns medium-sized molecules, however, their $3n-6$ degrees of freedom are rather restrictive and mostly lead to a nearly hopeless situation of multidimensional complexity.[5, 6, 66] Even the five-atom molecule methanimine, $H_2C=NH$, which is generated upon pyrolysis of methyl azide as a "chemically activated" species[12, 69] (i.e., with considerable energy stored in its $3\times5-6=9$ degrees of freedom) and, in the subsequent reaction channel, loses H_2 to give HCN, would have to be calculated quantum-chemically in a nine-dimensional hyperspace! For specific molecular conformations, some of the numerous degrees of freedom can often be more or less neglected by introducing additional assumptions.[5] Such an approach, although it crudely simplifies the rather complex reality, will be illustrated for the pyrolysis of 1-silacyclohexa-2,5-diene to silabenzene and H_2[22e] (Scheme 6) in a yellow-glowing flow tube at 800 K and under 10^{-4} Pa pressure—that is, under nearly unimolecular conditions.

In order to carry out an approximate energy-hypersurface calculation, the 36 degrees of freedom of the 14-atom molecule silacyclohexadiene must be drastically reduced.[5] One possibility is to introduce a mirror plane into the sila derivative by incorporating an additional silicon atom at the 4 position and to select as the dominant vibrational modes of its boat conformation the intramolecular bending characterized by both the angle ω between the CSiC triangle and the $(C=C)_2$ plane and the $d_{H\cdots H}$ distance representing additional "joints" at the two Si centers[70] (Scheme 38). Their variation ($\Delta\omega = 120° \rightarrow 180°$ and $\Delta d_{H\cdots H} = 480 \rightarrow 50$ pm) in about 10^3 separate and, in each case, geometry-optimized MNDO calculations,[71] produces a folded total-energy hypersurface, on which the "product valley" for 1,4-disilabenzene + H_2 is reached by crossing the saddlepoint indicated in Scheme 38.

Scheme 38. Model energy hypersurface for the intramolecular H_2 elimination from disilacyclohexadiene to give disilabenzene (cf. text).

Additional calculations of selected points for the actually investigated 1-silacyclohexa-2,5-diene,[70] which exhibits only C_s symmetry, yield as values closer to experiment an acti-

vation enthalpy of 175 kJ mol^{-1}, a saddlepoint structure with $\omega = 140°$ and $d_{H\cdots H} = 120$ pm and, for the considerably deeper product valley of the ensemble "C_5SiH_8" with the energetically more favorable products silabenzene and hydrogen, an enthalpy difference of -120 kJ mol^{-1}. Both the correspondence between the calculated activation barrier[70] and the PE-spectroscopically determined pyrolysis temperatures,[22c] as well as a comparison with the respective data for cyclohexa-1,4-diene and 1,4-dihydropyridine,[70] support the basic assumption for the hypersurface calculations that the thermal H_2 elimination from silacyclohexadiene to give silabenzene should proceed intramolecularly.[72]

The examples discussed above represent rather different topics, including polysilane band structure, possible Rydberg states in photochemical reactions of organosilicon compounds, evidence for and dynamics of Si-containing contact ion pairs, and an approximately calculated energy hypersurface of the supposedly intramolecular H_2 elimination from silacyclohexadiene. All of them illustrate that molecular-state considerations (Figs. 1 and 3) are also useful in the diverse world of silicon compounds (Fig. 2). At the same time, they demonstrate the increasing impact of both the constantly improved and the newly developed techniques of physical measurement and, above all, the effect of the avalanche of applications made possible by ever faster and numerically more precise quantum-chemical calculations, even for larger molecules. Both hardware and software are widely distributed nowadays and thus readily accessible. Of increasing importance, therefore, is an "intellectual tunneling" between the only seemingly different viewpoints of preparative and theoretical chemistry, which both meet in the reality of molecular states. It is to be hoped that the examples discussed here, selected[1-6] from the wide area of silicon chemistry,[7] may also contribute to bridging the fictitious gap between experiment and theory. It would be most rewarding could they convince the preparative silicon chemist of how profitable it is to take a look for himself at his fast developing and interesting area of research through the molecular-state magnifying glass (Scheme 1).

Thanks are due, above all, to my "theoretical" teachers and friends Edgar Heilbronner and Michael J. S. Dewar, who convinced a preparative inorganic chemist some 20 years ago of the usefulness of simple molecular orbital models and semiempirical calculations. The cited results of our research group have been obtained by committed and competent co-workers—those cited in the references are Bahman Solouki, Hartmut Alt†, Georg Brähler, Ralph Dammel, Walter Enßlin, Peter Hänel, Hans-Friedrich Herrmann, Bernhard Hierholzer, Wolfgang Kaim, Mitsuo Kira, Ulrike Lechner-Knoblauch, Jochen Meuret, Philip Mollère, Klaus Oswald, Pavel Rosmus, Hans Seidl, Andrej Semkow, and Klaus Wittel. Cooperation and discussions have stimulated close links to numerous colleagues, including T. J. Barton (Ames, Iowa), G. Becker (Stuttgart), D. Fenske (Karlsruhe), G. Fritz (Karlsruhe), R. Janoschek (Graz), H. Kurrek (Berlin), G. Maier (Gießen), J. Michl (Austin, Texas), H. Nöth (Munich), H. Sakurai (Sendai), P. von R. Schleyer (Erlangen), H. G. von Schnering (Stuttgart), M. Veith (Saarbrücken), R. West (Madison, Wisconsin), and, last but not least, N. Wiberg (Munich). For the most generous funding of our research, we would like to thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the State of Hessen, the Max Buchner, Adolf Messer, and Hermann Schlosser foundations, Hoechst AG, Degussa AG, and Dow Corning Corporation.

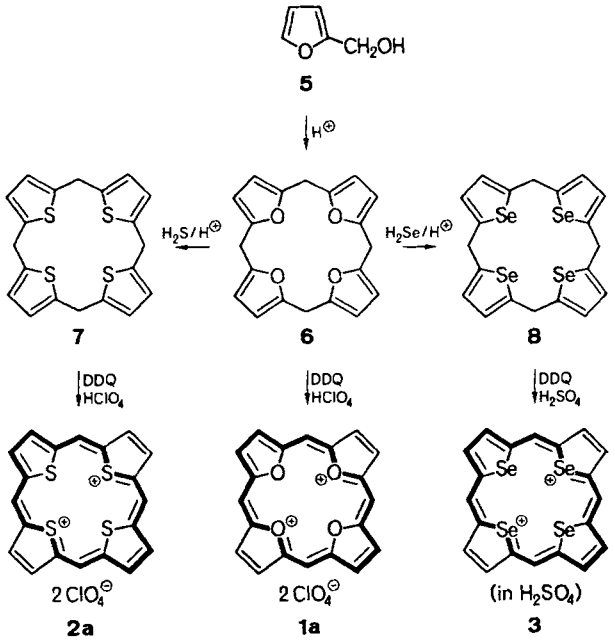
The Thiophene Analogue of Porphyrin: Tetrathiaporphyrin Dication



By *Emanuel Vogel,* Peter Röhrig, Martin Sicken, Bernd Knipp, Adalbert Herrmann, Michael Pohl, Hans Schmickler,* and *Johann Lex*

In spite of the long history of porphyrin chemistry,[1] tetraoxaporphyrin **1**, unlike porphyrin a dicationic species, was discovered only last year.[2] The synthesis of **1** (as perchlorate **1a**)—in the variant to be presented here—is surprising in its simplicity, for the compound can readily be prepared starting from furfuryl alcohol in merely a two-step sequence modeled after the biogenesis of porphyrin. **1** qualifies spectroscopically and in structural respects as an aromatic porphyrin, while its chemical behavior, as to be expected for a molecule with a carbenium ion/oxonium ion structure, is characterized by high reactivity towards nucleophiles.

1 X = O
2 X = S
3 X = Se
4 X = NCH_3

The current trend to broaden the basis of porphyrin chemistry by the development of novel porphyrinoid systems[3] and, not least, the discovery of **1**[2] has stimulated renewed interest in the tetrathiaporphyrin dication **2**,[4] which has hitherto escaped all efforts at its synthesis.[5] It seems certain that **2**, in contrast to **1**, does not have a planar ring skeleton, since the relatively large van-der-Waals radius of sulfur causes a marked steric hindrance in the S_4 core. According to force field calculations (MM2), **2** assumes a conformation in which all sulfur atoms protrude slightly out of the C_{20}-ring on the same side (C_{4v} symmetry).[6] Such a deviation from planarity should hardly affect the aromatic nature of **2** if one bears in mind the deformations porphyrins and bridged [4n+2]annulenes[8] are capable of tolerating without suffering serious loss of aromaticity. This conclusion derives added support from the presence of a pronounced diamagnetic ring current in the dicationic *N,N',N'',N'''*-tetramethyl-octakis(carbomethoxymethyl)porphyrin (derivative of **4**) described by *Franck* et al.,[9] in which the repulsion of the *N*-methyl groups leads to a strong puckering (or other deformation) of the molecule. Consequently, there is a good chance that the tetraselenaporphyrin dication **3**—despite an increase in the radius of the hetero atom by about 0.15 Å compared to sulfur—will likewise turn out to be an aromatic porphyrin.

We have now found that the crown ether tetraoxaporphyrinogen **6**[2b] not only enables the synthesis of the tetraoxaporphyrin dication **1** but also opens up an entry to the tetrathia- and tetraselenaporphyrin dications **2** and **3**, respectively. Interestingly, what was previously overlooked, tetraoxaporphyrinogen **6** is formed in small amounts in the much-investigated acid-catalyzed condensation of furfuryl alcohol **5**.[10] To prepare **6**, the most expedient way of carrying out the reaction involves treating a solution of **5** in dichloromethane with a solution of zinc chloride in 5% hydrochloric acid and vigorously stirring the mixture for 6 h. After conventional work-up of the reaction mixture, **6** is isolated by chromatography with toluene on silica gel; colorless needles from ethanol (m.p. 158–159 °C, yield 1%). Since **5** is a technical chemical and **6** is relatively easily separable, synthesizing the tetrafuranoid macrocycle on a preparative scale presents no difficulties, despite the preferred formation of linear condensation products. The conversion of **6** into the tetraoxaporphyrin dication **1** can be substantially improved compared to the original procedure,[2] namely by oxidizing **6** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in benzene solution (room temperature, 10 min), filtering off the resulting amorphous product, and treating this with conc. nitric acid. There results a red solution, from which, after addition of 70% perchloric acid and brief standing, pure **1a** separates in the form of violet needlelike crystals (yield 86%).

Tetrathiaporphyrinogen **7** can be regarded as the key compound for the synthesis of the tetrathiaporphyrin dication **2**.

[*] Prof. Dr. E. Vogel, P. Röhrig, M. Sicken, B. Knipp, A. Herrmann, M. Pohl, Dr. H. Schmickler, Dr. J. Lex
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (FRG)

In view of the failure of all previous efforts to construct thiaporphyrinogens by coupling suitable 2,2'-dithienylmethane derivatives,[5] it was hardly surprising that the inevitably attempted extension of the acid-catalyzed cyclic condensation of **5** to α-hydroxymethylthiophene likewise met without success. A way out of this dilemma was offered by a well-known proven reaction in furan chemistry: the transformation of furans into thiophenes with hydrogen sulfide in acidic medium.[11] It was found that **6** does indeed exchange the oxygen atoms remarkably smoothly with formation of **7** when H_2S and HCl are passed simultaneously into a solution of **6** in ethanol for 2 h at 0 °C and then 3 h at room temperature and the reaction mixture finally allowed to stand for 24 h; after filtration in toluene over silica gel and crystallization from the same solvent, **7** is obtained in the form of colorless cubic-shaped crystals (decomp. at 235 °C, yield 66%). Like **6**, **7** is stable towards atmospheric oxygen.

Tetrathiaporphyrinogen **7**, which shows spectra (see Table 2) analogous to those of **6** is found by an X-ray structure analysis[12] to be a centrosymmetric molecule in the crystal (Fig. 1). The four CH_2 groups lie in a plane, from

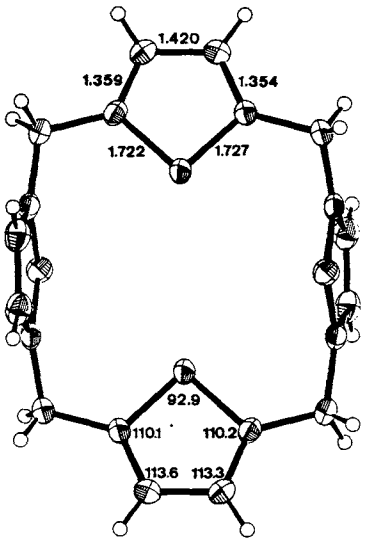


Fig. 1. Structure of **7** in the crystal. Selected bond lengths [Å] and angles [°]; standard deviations ca. 0.002 Å and 0.1°. The vibration ellipsoids are drawn at the 40% probability level.

which the thiophene rings are tilted in the way dictated by the symmetry center by 19.6 and 78.6°, respectively. In this conformation the shortest distance between sulfur atoms—given for neighboring thiophene rings—is 3.45 Å, which approximately corresponds to the spatial requirement of sulfur (twice the van-der-Waals radius: 3.70 Å).

The oxidation of **7** to the dication **2** (as perchlorate **2a**) is achieved by successive reaction of the thia crown ether with DDQ and perchloric acid,[13] whereby the following procedure is recommended: **7**, suspended in glacial acetic acid/nitromethane (5:1), is treated with DDQ in glacial acetic acid and the reaction mixture heated to 45 °C for 3 h. Upon evaporation of the homogeneous mixture to dryness there remains an amorphous residue; addition of 70% perchloric acid and subsequent stirring for 14 hours affords a deep-green solution with deposition of a black solid. When this solution is stored under a saturated water-vapor atmosphere for ca. 5 d, small violet (rodlike) crystals separate out, which according to the ^{1}H-NMR spectrum consist of pure **2a** (decomp. at 240 °C with deflagration, yield 25%). An analytically pure sample was obtained by dissolving the salt in 70% perchloric acid and repeating the crystallization procedure.

The tetrathia compound **2a** is taken up by common organic solvents, if at all, only with decomposition. With water, rapid nucleophilic attack resulting in a complex mixture of products takes place. Strong mineral acids, preferably sulfuric acid and perchloric acid (nitric acid leads to oxidative degradation) as well as liquid sulfur dioxide have proven to be the solvents of choice. Unlike **1a**, **2a** cannot be stored for extended periods of time; after several weeks, decomposition on the surface is noticed.

The ^{1}H-NMR spectrum of **2a** (Table 1), for which no temperature dependence could thus far be detected (room

Table 1. ^{1}H- NMR (300 MHz) and ^{13}C-NMR data (75.5 MHz) of **1a** and **2a** (68% $DClO_4$, CH_2Cl_2 int.) and of **3** (98% D_2SO_4, CH_2Cl_2 int.). Chemical shifts δ_H and δ_C and coupling constants J [Hz].

temperature down to −75 °C), corresponds to that of **1a**, for it shows only two signals (δ = 12.46 and 10.52) in the resonance region to be expected for a dicationic, aromatic **2**. Also with regard to the ^{13}C-NMR spectrum there is a close analogy to **1a**. Very distinct differences are observed, however, in the UV/VIS spectra of **2a** and **1a**. Whereas the spectrum of **1a** exhibits a sharp Soret band with high extinction and a series of Q bands, that of **2a**, while being of the same type, shows all bands to be strongly broadened and shifted to longer wavelengths (Fig. 2). Noteworthily, the spectrum of **2a** is strikingly similar to that of the derivative of **4** (as bromide) mentioned at the outset.[9a] This observation can

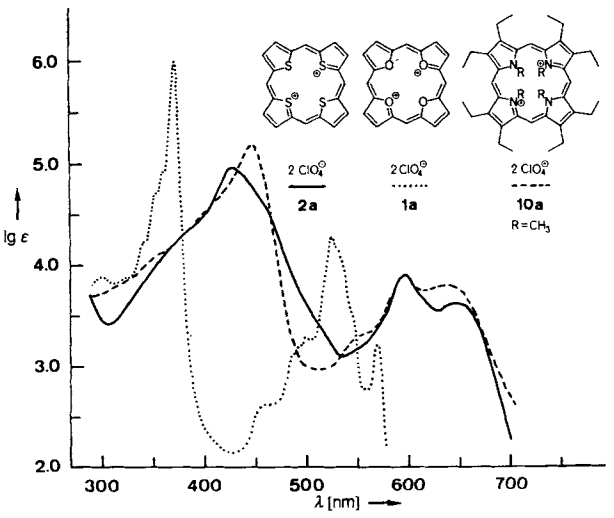

Fig. 2. UV/VIS spectra (96% H_2SO_4) of **1a**, **2a** and **10a**.

be regarded as the first experimental evidence that **2** deviates from planarity.

Concerning the IR spectrum of **2a** it should be noted that a certain relationship with that of **1a** exists regarding the band pattern; common to the spectra of both compounds is a relative paucity of bands.

The presumed non-planarity of **2** is confirmed by the X-ray structure analysis of the perchlorate **2a**[14] (Fig. 3). In **2**,

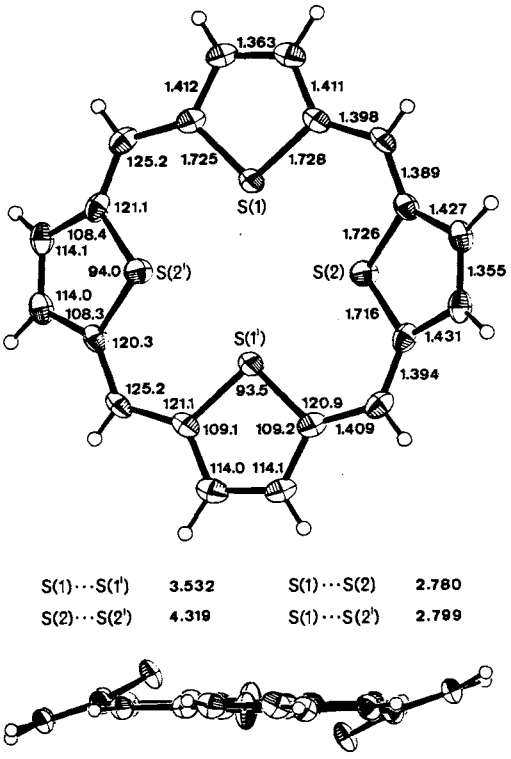

Fig. 3. Structure of **2a** in the crystal. Above: top view. Below: side view. Selected bond lengths and other distances [Å] together with bond angles [°]; standard deviations ca. 0.003 Å and 0.2°, respectively. The vibration ellipsoids are drawn at the 40% probability level.

which like **7** is centrosymmetric, the *meso*-methine carbon atoms lie in a plane, with respect to which the hetero five-membered rings are inclined by 3.7° and 22.8°, respectively. This deviation of the molecule from planarity is—in agreement with the conclusions drawn from the NMR findings—obviously too small to result in a significant loss of aromaticity, since the CC bonds in the hetero five-membered rings very markedly show the bond-length relation C_α-$C_\beta > C_\beta$-C_β[1b,c] typical for porphyrins (opposite to that in the parent heterocycles pyrrole, furan and thiophene). Consistent with the symmetry of the molecule the sulfur atoms also lie in a plane. The distance between neighboring sulfur atoms (2.78 and 2.80 Å, resp.) thereby falls about 1 Å short of double the van-der-Waals radius, so that it can be assumed that there are attractive interactions between these atoms.[15] Since the NMR spectra indicate only one sort of protons for the hetero five-membered rings, **2a** in solution—provided the nonplanar conformation in the solid state also applies in this case—must be a dynamic molecule in which the five-membered rings very rapidly exchange positions. The two perchlorate ions are, similarly to the situation in **1a**, arranged at normal distances above and below the dication.

The porphyrinogen **8** required for the synthesis of the tetraselenaporphyrin dication **3** was obtained from **6** and H_2Se under reaction conditions which essentially corresponded to those in the conversion of **6** into **7**;[16] microcrystalline powder from carbon disulfide (decomp. at 250 °C, yield 45%). **8** is air-stable and has spectra analogous to those of **6** and **7** (see Table 2). Reaction of **8** with DDQ in glacial

10a: ^{1}H-NMR (300 MHz, $CDCl_3$): δ = 9.94 (s, 5-H), 3.56 (m, 2a-H), 1.50 (t, 2b-H), −4.59 (s, N-CH_3); ^{13}C-NMR (75.5 MHz, $CDCl_3$): δ = 156.97, 141.51, 102.73, 34.54, 20.50, 16.56; MS (FAB): *m/z* 592 [(*M*- 2ClO_4)$^\oplus$, 100%]; UV/VIS (96% H_2SO_4): λ_{max} = 445 nm (ε = 157 000), 554 (2150) sh, 594 (8000), 637 (6550)

acetic acid and subsequent treatment of the residue remaining after removal of solvent with 98% sulfuric acid leads indeed to formation of the dication **3**—apparently still aromatic according to its NMR data (see Table 1)—but attempts to crystallize this as sulfate or other salt from the medium sulfuric acid have, as yet, met with no success. The use of perchloric acid is not helpful here, since **3** rapidly decomposes in its presence.

The previously noted close similarity of the UV/VIS spectra of **2a** and the octakis(carbomethoxymethyl) derivative of **4** invited attempts to determine the molecular geometry of an *N,N',N'',N'''*-tetramethylporphyrin dication by X-ray structure analysis. Compound **4**, regarded as especially desirable for the analysis (in combination with a suitable counterion), was ruled out because it was thus far not possible to gain access to the peripherally unsubstituted *N,N',N'',N'''*-tetramethylporphyrinogen. As alternative, therefore, the *N,N',N'',N'''*-tetramethyl-octaethylporphyrinogen **9** described by *Franck* and *Gosmann*[17] was subjected to oxidation employing the well proven reagent bromine in chloroform.[9] As confirmed by the NMR spectra and the elemental analysis of the product, this led to smooth formation of the expected *N,N',N'',N'''*-tetramethyl-octaethylporphyrin dication **10** as bromide.

Unfortunately, this could only be isolated in microcrystalline form, and thus, in view of the fact that the perchlo-

rates of **1** and **2** crystallize exceedingly well, it was converted into the perchlorate **10a** by addition of perchloric acid to a solution of the bromide in methanol/water (1:1); blue platelets from dichloromethane/hexane (1:4) (decomp. above 230 °C, yield 77% based on **9**).

In the ^{1}H-NMR spectrum (Table 2) of **10a** the resonance of 5-H (δ = 9.94) appears at noticeably higher field than in the spectra of **1a** and **2a** (Table 1); however, the strong shielding of the N-CH_3 protons (δ = −4.59) leaves no doubt that there is a pronounced diamagnetic ring current in the dication.[18]

The structure analysis of **10a**,[19] which presented no problems, revealed the dication **10** as a highly symmetric species characterized by a fourfold alternating axis (Fig. 4).

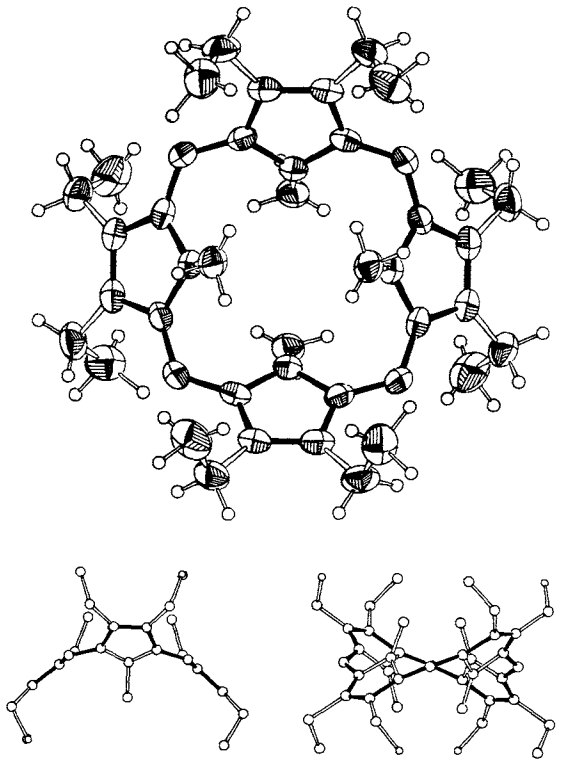

Fig. 4. Structure of **10a** in the crystal. The molecule has approximate D_{2d} symmetry (exactly S_4), as shown by the three chosen projections. Above: top view, looking in the direction of the crystallographic S_4 axis, vibration ellipsoids with 40% probability, selected bond lengths C_α–C_m: 1.411, C_α–C_β: 1.449, C_α–N: 1.391 (mean values), C_β–$C_{\beta'}$: 1.365 Å. Below: side views (without H atoms) from two directions differing by 45°: left, parallel to one of the two equivalent mirror planes; right, along one of the two equivalent C_2 axes.

As predicted, the conformation of **10** is largely determined by the steric hindrance of the *N*-methyl groups. The heterocyclic five-membered rings are each tilted by 39° with respect to the plane through the *meso*-methine carbon atoms, and torsion angles (C_β–C_α–C_m–$C_{\alpha'}$) of 29° occur at each of the eight C_α–C_m bonds of the ring skeleton. Moreover, the *N*-methyl groups are not coplanar with their respective five-membered rings but are bent at a significant angle (32°); this bending must be accompanied by a partial rehybridization of the nitrogen atoms from sp^2 to sp^3 (sum of the bond angles at nitrogen: 349.1°). Although the geometry of the ring skeleton in **10** should considerably impair p-orbital overlap, the pattern of the bond lengths in the dication, especially the CC bond-length relations in the heterocyclic five-membered rings (C_α-C_β > C_β-C_β), corresponds to the situation in porphyrins.[1b,c] Some interesting features of the arrangement of the perchlorate ions can only be alluded to at this juncture.[19]

The structurally closely related dicationic porphyrins **1**, **2** and **10** form a series in which the conformation of the ring skeleton varies from slightly puckered to strongly puckered. According to NMR and structural chemical criteria there is no significant decrease in aromaticity on going from **1** to **10**, impressively illustrating the ability of porphyrins of the present type to maintain an effective cyclic π-electron delocalization, even under unfavorable steric conditions.

[12] $C_{20}H_{16}S_4$, decomp. at 235 °C, crystals from toluene; monoclinic, space group $P2_1/c$, $Z = 2$; a = 9.743(2), b = 10.019(2), c = 9.336(2) Å, β = 109.80(2)°; ϱ_{calcd} = 1.490 g cm^{-3}; intensity measurements on a four-circle diffractometer, room temperature, λ_{Mo} = 0.71069 Å, Θ_{Mo} (max) = 27°; refinement (C,S anisotropic, H isotropic) taking into account 1879 reflections with $F_o > 4\sigma(F_o)$: R = 0.029, R_w = 0.038 [20].

[13] Tetrathiaporphyrinogen **7** shows a remarkably varying behavior towards oxidizing reagents: aside from being converted into the dication **2** (with

DDQ) it can also be converted into the corresponding tetraketone (ceric ammonium nitrate), into the monosulfone (peracids) as well as into a still unidentified red ionic species (electrochemically). By way of contrast, tetraoxaporphyrinogen **6** has thus far always afforded the dication **1** with all reagents which effect oxidation with retention of the ring skeleton. The electrochemical oxidation of **6** also gave **1** (private communication from Prof. *E. Steckhan*, Universität Bonn (FRG)).

[14] $C_{20}H_{12}Cl_2O_8S_4$, decomp. at 240 °C, crystals from $HClO_4$; triclinic, space group $P\bar{1}$, $Z = 1$; $a = 5.850(1)$, $b = 8.994(1)$, $c = 10.547(2)$ Å, $\alpha = 78.90(2)$, $\beta = 81.03(2)$, $\gamma = 82.19(2)°$; $\varrho_{calcd} = 1.800$ g cm^{-3}; measuring conditions as for **7**; refinement (C,Cl, O,S anisotropic, H isotropic) taking into account 1791 reflections with $F_o > 4\sigma(F_o)$; $R = 0.045$, $R_w = 0.053$ [20].

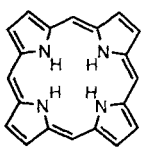
[15] In the case of **2a** there are no indications of bonding between sulfur atoms that lie opposite to each other in the porphyrin core—as has been assumed and is theoretically substantiated in the case of tetraphenyl-21,23-dithiaporphyrin on the basis of the extremely short S···S distances of 3.05 Å [4c, d].

[16] Concerning the acid-catalyzed conversion of furans into selenophenes see C. W. Bird, G. W. H. Cheeseman, A.-B. Hörnfeldt in A. R. Katritzky, C. W. Rees (Eds.): *Comprehensive Heterocyclic Chemistry, Vol. 4*, Pergamon Press, Oxford 1984, p. 968.

[17] M. Gosmann, *Dissertation*, Universität Münster 1986.

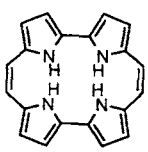
[18] *With regard to the δ values for 5-H and N-CH$_3$, the* ^{1}*H-NMR spectrum* of **10a** is, as expected, in good agreement with that of the octakis(carbomethoxymethyl) derivative of **4** (as bromide) [9a, c].

[19] $C_{40}H_{56}Cl_2N_4O_8$, decomp. at about 230 °C, crystals from dichloromethane/hexane (1:4); tetragonal, space group $P4/n$, $Z = 2$; $a = 14.866(3)$, $c = 9.441(2)$ Å; $\varrho_{calcd} = 1.260$ g cm^{-3}; measuring conditions as for **7**; refinement (C,Cl,N,O anisotropic, H isotropic), 1011 reflections with $F_o > 4\sigma(F_o)$; $R = 0.062$, $R = 0.065$. One of the two independent perchlorate ions is distorted [20].



[20] Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54209, the names of the authors, and the journal citation.

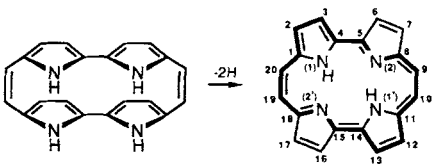
A Pyrrolophanediene-Porphycene Redox System



By *Emanuel Vogel,* Ilona Grigat, Matthias Köcher,* and *Johann Lex*

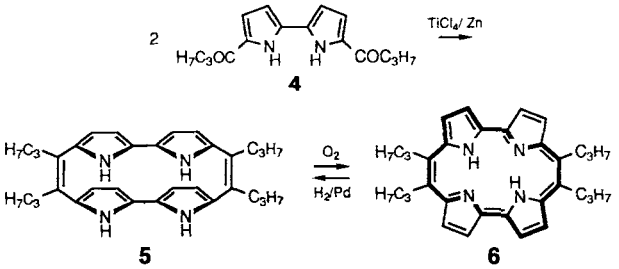
Isophlorin **1**, a still elusive dihydroporphyrin first referred to by *Woodward* some 30 years ago in connection with the synthesis of chlorophyll,[1] is a molecule equally interesting from the standpoint of porphyrin and annulene chemistry. It seems justified to regard **1** as a "cyclobutadiene homologue" since it constitutes an essentially planar [20]annulene associated with a degenerate, presumably very fast π-bond shift. As a consequence of its π-electron structure, **1** is expected to exhibit a pronounced tendency to undergo a two-electron oxidation with formation of resonance-stabilized diprotonated porphyrin, and hence to be a dihydroporphyrin of only fleeting existence.

The anticipated ready oxidizability of **1** would explain why *N,N'*-dihydroporphycene **2**, the analogue of **1** in the



1

2



porphycene series and the obvious intermediate in the synthesis of porphycene[2], has hitherto defied all attempts at its detection. Other than in the case of **1**, there is considerable steric hindrance of the NH-hydrogen atoms in **2**. For this reason **2** is in all probability not planar but has the pyrrolophanediene structure **2a**.[3,4] We have now found that *N,N'*-dihydroporphycenes are in certain cases isolable, are in fact pyrrolophanedienes, and, what was unforeseen, form redox systems with the corresponding porphycenes.

2a **3**

Examination of the stereochemistry of porphycene **3** reveals that peripheral alkyl groups, particularly in the 9, 10, 19, 20 as well as in the 3, 6, 13, 16 positions are capable of modulating the geometry of the tetrapyrrolic macrocycle relatively strongly through non-bonding interactions. A representative example of this is the 9,10,19,20-tetrapropylporphycene **6**, which is obtainable analogously to the synthesis of **3** by reductive coupling of the bipyrrole derivative **4** with titanium tetrachloride and zinc.[5] According to an X-ray structure analysis, **6**, like **3**, has a planar ring skeleton, but due to the repulsion of the propyl groups there is a convergence of the oppositely disposed nitrogen atoms, so that the N_4 core with the distances N(1)···N(2′) = 2.528(4) Å[6] and N(1)···N(2) = 2.898(4) Å now becomes decidedly rectangular in shape. This structural change not only influences the strength of the N-H···N hydrogen bonds and the tendency to undergo metal complex formation but, as revealed by the most recent studies, also leads to unexpected chemical reactions.

One such reaction is found in the catalytic hydrogenation of **6** with palladium/carbon in ethyl acetate. While the parent porphycene **3** under these hydrogenation conditions regioselectively affords the red-violet 2,3-dihydroporphycene, which can be regarded as a chlorin analogue,[7] **6** surprisingly gives a colorless dihydro compound (rectangular crystals from dichloromethane/hexane, decomp. at 180 °C, yield 25%, losses by re-oxidation to **6**). The finding that saturation of only one formal double bond dramatically reduces the conjugation immediately made one suspect that the product is the pyrrolophanediene *N,N'*-dihydro-9,10,19,20-tetrapropylporphycene **5**. The spectra (Table 1) and the X-ray structure analysis of the compound confirmed this.

4 **5** **6**

The ^{1}H-NMR spectrum of **5** shows only one ABX system for the pyrrole protons at δ = 6.94 (NH), 6.09 (2,7,12,17-H) and 6.02 (3,6,13,16-H) with coupling constants ($^4J_{2,NH}$ = 2.70 Hz, $^4J_{3,NH}$ = 2.47 Hz and $^3J_{2,3}$ = 3.48 Hz) typical for

[*] Prof. Dr. E. Vogel, I. Grigat, Dr. M. Köcher, Dr. J. Lex
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (FRG)

pyrrole rings, and a quartet (α-CH_2), a multiplet (β-CH_2) and a triplet (CH_3) for the propyl protons at $\delta = 2.44$, 1.51 and 0.95, respectively.[8] The loss of porphycene aromaticity is impressively reflected in these NMR data, as marked high-field shifts are observed, both for the vinylic pyrrole protons ($\Delta\delta = 3.3$) and (in the corresponding gradation) for the α-, β- and CH_3-propyl protons ($\Delta\delta = 1.9$, 0.9 and 0.5). The approximate invariance ($\Delta\delta = 0.1$) of the NH resonance signal appears understandable when one considers that opposing effects occur in **5**, namely a high-field shift due to disappearance of the strong N-H···N hydrogen bonds[9] and a downfield shift as a result of the collapse of the diamagnetic ring current in the macrocycle. Complementary to the simple ^{1}H-NMR spectrum, indicating a high molecular symmetry, eight signals are found in the ^{13}C-NMR spectrum of **5**.

Table 1. Selected physical data of **5** and **7**.

5: ^{1}H-NMR (300 MHz, $CDCl_3$): $\delta = 6.94$ (br.s, 4H; NH), 6.09 (m, 4H; 2,7,12,17-H), 6.02 (m, 4H; 3,6,13,16-H), 2.44 (q, 8H; α-CH_2), 1.51 (m, 8H; β-CH_2), 0.95 (t, 12H; CH_3); ^{13}C-NMR (75.5 MHz, $CDCl_3$): $\delta = 133.29$, 128.42, 125.61 (quaternary C atoms), 108.81 (C-2,7,12,17), 106.29 (C-3,6,13,16), 34.86 (α-CH_2), 22.44 (β-CH_2), 14.25 (CH_3); MS (EI, 70 eV): m/z 480 ($M^{\oplus}$, 100%), 451 (14%), 437 (22%), 240 ($M^{2\oplus}$, 5%); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3434, 3100, 2958, 2933, 2871, 1679, 1553, 1463, 1409, 1363, 1259, 1093, 1043, 772, 707, 586, 539; UV/VIS (cyclohexane): λ [nm] = 220 (ε = 23 700) sh, 278 (35 200), 320 (12 100) sh

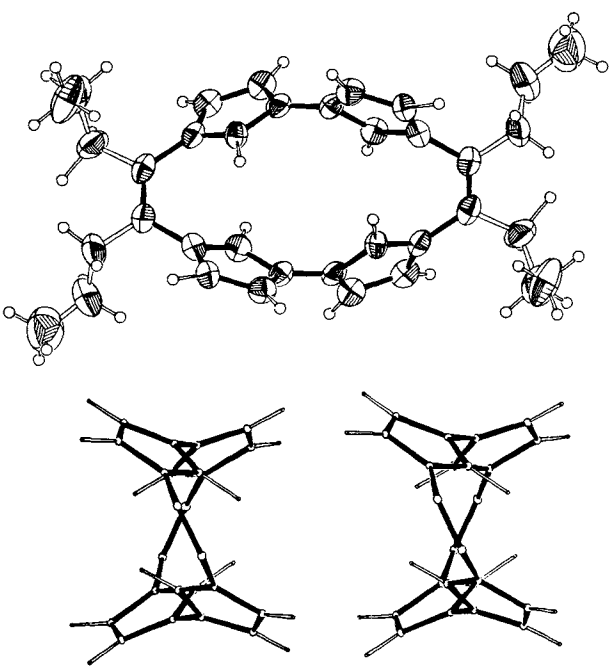
7: ^{1}H-NMR (300 MHz, $CDCl_3$): $\delta = 10.20$ (br.s, 1H; NH2), 8.80 (d, 1H; 13-H), 8.74 (dd, 1H; 16-H), 8.70 (dd, 1H; 17-H), 8.62 (d, 1H; 6-H), 8.50 (d, 1H; 12-H), 8.43 (d, 1H; 7-H), 6.77 (br.s, 1H; NH2'), 4.64 (m, 2H; 3-H), 4.33 (m, 2H; 2-H), 4.00 (q, 2H; α-CH_2), 3.96 (q, 2H; α-CH_2), 3.89 (q, 2H; α-CH_2), 3.36 (q, 2H; α-CH_2), 2.25 (m, 2H; β-CH_2), 2.22 (m, 2H; β-CH_2), 2.10 (m, 2H; β-CH_2), 1.95 (m, 2H; β-CH_2), 1.35 (t, 3H; CH_3), 1.34 (t, 3H; CH_3), 1.30 (t, 3H; CH_3), 1.28 (t, 3H; CH_3); ^{13}C-NMR (75.5 MHz, $CDCl_3$): $\delta = 166.67$, 157.77,147.17, 143.55, 135.28, 134.32, 133.40, 130.55, 129.70, 127.10, 123.83, 120.31 (quaternary C atoms), 126.09 (C-17), 126.04 (C-6), 122.81 (C-7), 121.39 (C-12), 120.41 (C-13), 119.11 (C-16), 38.16, 37.83, 37.68 (α-CH_2), 35.98 (C-2), 31.50 (C-3), 29.27, 28.85, 28.67, 25.34 (β-CH_2), 15.28, 15.19, 15.17, 15.11 (CH_3); MS (EI, 70 eV): m/z 480 ($M^{\oplus}$, 100%), 451 (28%), 437 (30%), 240 ($M^{2\oplus}$, 19%); IR (CsI): $\tilde{\nu}$ [cm^{-1}] = 3103, 2950, 2859, 1603, 1420, 1381, 1330, 1204, 1167, 1067, 1061, 760; UV/VIS (dichloromethane) [a]: λ [nm] = 353 (ε = 60 000) sh, 372 (82 000), 394 (54 000), 415 (79 000), 554 (13 500) sh, 597 (31 000), 630 (26 100)

[a] UV/VIS spectrum corrected calculationally for the presence of 2% of **6**.

In the UV/VIS spectrum of **5** no absorption appears above 400 nm. The IR spectrum is informative insofar as it contains a sharp band for the NH stretching vibration and thus corroborates the disappearance of the strong hydrogen bonds (no NH band could be reliably located in the spectrum of **3**).[10]

According to an X-ray structure analysis,[11] the dihydro compound **5**, in the crystalline state, clearly has the phanediene structure deduced from the spectra (Fig. 1). The geometry of the compound derives from the hypothetical planar structure primarily in such a way that, within each bipyrrole moiety, the pyrrole rings have rotated out of the plane in opposite sense. The dihedral angle between the pyrrole rings, arising from twisting and slight bending of the rings with respect to the central α–α'-bond due to strain, is 64.3°. The pyrrole rings as such show no deviation from planarity. Oppositely disposed pyrrole rings are to a crude approximation arranged antiparallel, as would be expected, since there are attractive dipole-dipole interactions with this orientation of the rings.[12] It is a manifestation of the distortion of the pyrrolophanediene skeleton that the ethene units, at which torsions of 7° occur, are not oriented parallel to each other but are at an angle of 47.8°.

Following the successful isolation and characterization of **5** (in the hydrogenation of **6**) it also proved possible to isolate the compound under rigorous exclusion of oxygen in the reductive coupling of **4** (always accompanied by small amounts of **6**) and thus to confirm the assumed intermediary formation of *N,N'*-dihydroporphycenes in the synthesis of porphycenes. The easy aromatization of **5** to **6** by atmospheric oxygen and other oxidizing agents in combination with the above mentioned hydrogenation makes **5**/**6** an extraordinary redox system.



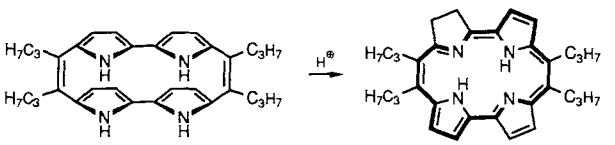


Fig. 1. Molecular structure of **5** in the crystal at −20 °C. Decisive for carrying out the analysis at the quoted temperature was that the D_2 symmetry of the molecule established at room temperature includes a dynamic disorder of the propyl groups (high temperature factors for the terminal carbon atoms). At −20 °C the propyl groups, which at the outset were crystallographically equivalent, adopt two different conformations, so that a lowering of the symmetry from D_2 to C_2 results for the overall molecule. The phane skeleton as such, on the other hand, retains D_2 symmetry at −20 °C. Top: view of the molecule in the direction of the C_2 axis, vibration ellipsoids (40% probability). Bottom: stereoview of the skeleton (without propyl groups), perpendicular to the C_2 axis along the bipyrrole units.

5 **7**

Concerning the course of the hydrogenation of **6** it is conceivable that, in parallel with the situation in the case of **3**, the 2,3-dihydro compound **7** is formed, and **5** therefore results from subsequent tautomerism of **7**. This alternative to direct *N,N'*-hydrogenation could, however, be ruled out, since, conversely, **5** tautomerizes to the 2,3-dihydro compound **7** upon treatment with a catalytic amount of conc. sulfuric acid in dichloromethane (yield 52%).[13] That **7** is stable under the conditions of the catalytic hydrogenation was confirmed by control experiments. The structure of **7** follows from the similarity of its spectra with those of 2,3-dihydroporphycene, and in particular from an X-ray structure analysis.[14]

The diminished oxidizability of *N,N'*-dihydro-9,10,19,20-tetrapropylporphycene **5** compared to that of the still unknown *N,N'*-dihydroporphycene parent compound **2**, which enabled its isolation, is apparently due to the fact that the rotation of the pyrrole rings into the planar or into a near-

planar conformation required for oxidation is hindered by non-bonding interactions between the propyl groups and the hydrogen atoms in the 2,7,12,17-positions. The favored hydrogenation of **6** with formation of **5** instead of the expected **7** is probably due to hitherto unexplained kinetic factors, since it is almost certain from the acid-catalyzed tautomerization of **5** to **7** that **7** is the thermodynamically more stable tautomer.

[8] In the ^{1}H-NMR spectrum, recorded between +70 °C and −80 °C, changes are observed below −30 °C which can be ascribed to an incipient hindrance to rotation of the alkyl groups.

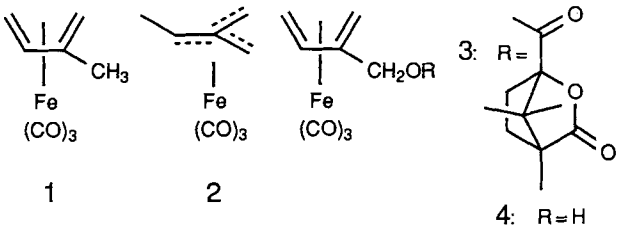
[9] Information on the deshielding of protons which participate in strong hydrogen bonds is given in a review by J. Emsley, *Chem. Soc. Rev. 9* (1980) 91.

[10] Concerning the influence of strong hydrogen bonds on the band position and band shape of the element-hydrogen vibrations involved, see: C. Sandorfy, *Top. Curr. Chem. 120* (1984) 41; A. Novak, *Struct. Bonding (Berlin) 18* (1974) 177; see also reference [9].

[11] **5**: $C_{32}H_{40}N_4$, decomp. at 180 °C, rectangular crystals from dichloromethane/hexane; measurement at room temperature: tetragonal, space group $P4/ncc$, $Z = 4$, $a = 16.458(4)$, $c = 10.699(3)$ Å; $\varrho_{calcd} = 1.103\ g\,cm^{-3}$; intensity measurements on a four-circle diffractometer [$\lambda_{Mo} = 0.71069$ Å, $\Theta_{Mo}(max) = 27°$]; refinement (C, N anisotropic, H isotropic) taking into account 565 reflections with $F_o > 4\sigma(F_o)$; $R = 0.095$, $R_w = 0.097$; the hydrogen atoms of the propyl groups were not taken into account in the refinement because of disorder. Measurement at −20 °C: orthorhombic, space group $Pccn$, $Z = 4$; $a = 16.099(2)$, $b = 16.716(2)$, $c = 10.619(1)$ Å; $\varrho_{calcd} = 1.117\ g\,cm^{-3}$; intensity measurements on a four-circle diffractometer [$\lambda_{Mo} = 0.71069$ Å, $\Theta_{Mo}(max) = 27°$]; refinement (C, N anisotropic, H isotropic) taking into account 998 reflections with $F_o > 4\sigma(F_o)$; $R = 0.059$, $R_w = 0.060$ [15].

[12] A. Gossauer: *Die Chemie der Pyrrole*, Springer, Berlin 1974, p. 71.

[13] The rearrangement of **5** into **7** under the given reaction conditions is practically irreversible. Owing to ready oxidation to the porphycene **6**, **7** usually contains 1–2% of the oxidation product even on careful work-up.



[14] **7**: $C_{32}H_{40}N_4$, m.p. 250–252 °C, rhombic crystals from dichloromethane/hexane; monoclinic, space group $P2_1/c$, $Z = 4$; $a = 17.507(3)$, $b = 9.938(2)$, $c = 15.742(3)$ Å, $\beta = 93.59(2)°$; $\varrho_{calcd} = 1.168\ g\,cm^{-3}$; intensity measurements on a four-circle diffractometer [room temperature, $\lambda_{Mo} = 0.71069$ Å, $\Theta_{Mo}(max) = 27°$]; refinement (C, N anisotropic, H isotropic) taking into account 1893 reflections with $F_o > 4\sigma(F_o)$; $R = 0.060$, $R_w = 0.062$. In analogy to the situation in the case of the porphycene 3/2,3-dihydroporphycene pair [7], the transition from **6** to **7** has no noticeable effect on the overall conformation of the ring skeleton (as before, planar). An accurate analysis of the bond lengths suggests that **7** is partially disordered in the crystal [15].

[15] Further details of the crystal structure investigations on **5** and **7** are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54208, the names of the authors, and the journal citation.

Optically Active Isoprene(tricarbonyl)iron(0) and Methyltrimethylenemethane(tricarbonyl)iron(0)**

By *Dag Kappes, Hans Gerlach,* Peter Zbinden, Max Dobler, Wilfried A. König, Ralph Krebber,* and *Gerhard Wenz*

About thirty acyclic chiral 1,3-diene(tricarbonyl)iron(0) complexes have so far been prepared in optically active form.[1] Only in the case of two compounds[2,3], however, has the absolute configuration of the tricarbonyliron(0) complex been determined by X-ray structure analysis of a derivative. We report here on the first synthesis of (+)-tricarbonyl(η^4-2-methyl-1,3-butadiene)iron(0) (+)-**1** and (−)-tricarbonyl(η^4-2-methylene-1,3-butanediyl)iron(0) (−)-**2** from the ester (+)-**3**.

1 2

The ester (+)-**3** was prepared by reaction of (±)-tricarbonyl(η^4-2-methylene-3-buten-1-ol)iron(0) (±)-**4**[4] with (−)-(1*S*,4*R*)-camphanoyl chloride[5] in pyridine and isolated as pure diastereomer (m.p. 127.7–129.3 °C) by twofold recrystallization from cyclohexane. An X-ray structure analysis of (+)-**3** showed[6] that it is the (1*S*,4*R*)-camphanoate of (+)-(2*S*,3*R*)-**4** (Fig. 1), i.e. the chirality sense in the tricarbonyliron moiety of the complex can be derived from the observed structure.

Reduction of (+)-**3** with BF_3 and Et_3SiH in dichloromethane at −78 °C leads to formation of (−)-**2** and (+)-**1** in the ratio 91:9. During this ionic hydrogenation[7] the carbocation generated from (+)-**3** with BF_3 is trapped mainly by hydride transfer to C4. The ^{1}H-NMR spectrum of (−)-**2** is identical to that reported by *Ehrlich* and *Emerson*[8] for (±)-**2**. The main product (−)-**2** isomerizes quantitatively to (+)-**1** within 5 min in 85% H_2SO_4 (cf. Ref. [8]) at 25 °C, probably by a protonation-deprotonation reaction.

König et al.[9] recently introduced new alkylated cyclodextrins as stationary phases in capillary chromatography, and they have been found to be excellently suitable for the analytical separation of enantiomers. Signals separated to the base line can be obtained for the enantiomers of **1** and **2** on a 50 m × 0.25 mm glass capillary column coated with octakis-

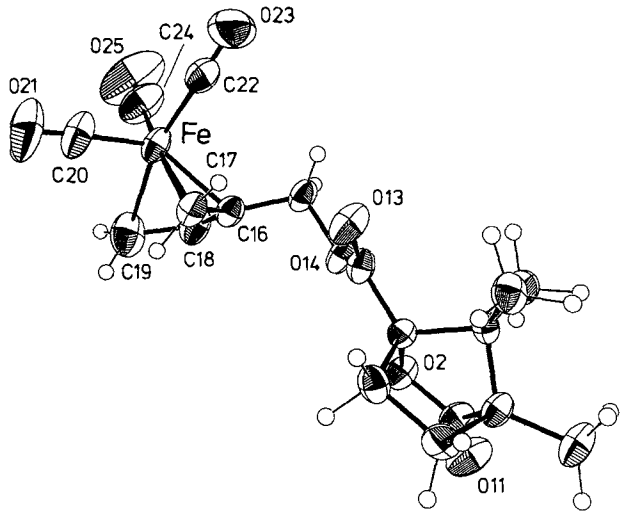

Fig. 1. Structure of **3** in the crystal (ORTEP, vibration ellipsoids with 50% probability); selected bond lengths [Å] and angles [°]: Fe-C16 2.040(4), Fe-C17 2.100(4), Fe-C18 2.058(5), Fe-C19 2.114(6), Fe-C20 1.778(4), Fe-C22 1.775(5), Fe-C24 1.811(5), C20-O21 1.137(5), C22-O23 1.144(7), C24-O25 1.126(6); Fe-C20-O21 177.8(7), Fe-C22-O23 179.1(6), Fe-C24-O25 177.7(6).

(2,3,6-tri-*O*-pentyl)-γ-cyclodextrin (Fig. 2).[10] The smooth separation of these unpolar enantiomers is indicative of an interaction with the inside of the cavity of the perpentylated γ-cyclodextrin (inclusion).

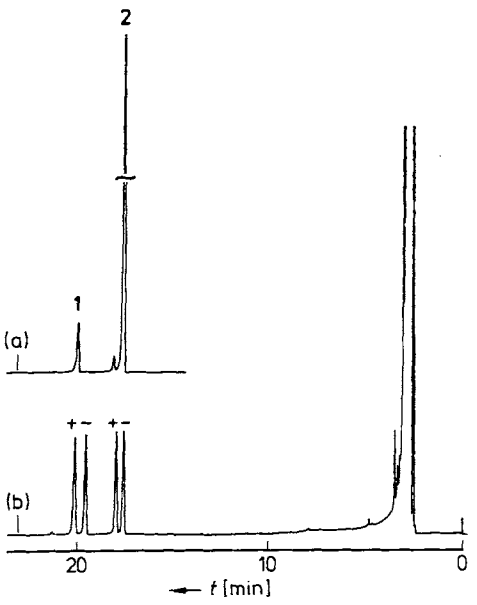

Fig. 2. a) Determination of the enantiomeric excess of the samples of (+)-**1** and (−)-**2**. b) For comparison chromatograms of (±)-**1** and (±)-**2** (50 m glass capillary column coated with perpentyl-γ-cyclodextrin, at 80 °C with hydrogen (1 bar) as carrier gas).

Using this method of separation the enantiomeric excess in the case of (−)-**2**, $[\alpha]_D = -68$, was found to be 96% *ee* and in the case of (+)-**1**, $[\alpha]_D = +63$, to be 88% *ee*. The ionic hydrogenation at −78 °C and the subsequent isomerization in H_2SO_4 apparently proceed almost without racemization. If both reactions are carried out at 25 °C, (−)-**2** is formed with 58% *ee* and—by subsequent isomerization—(+)-**1** with 54% *ee*, i.e. the carbocation intermediate of the ionic hydrogenation partially racemizes, presumably by rotation about the C2–C3 bond, before it is reduced by Et_3SiH. The maximum specific rotation of the pure enantiomers (+)-**1** and (−)-**2** can be calculated from the measured rotation values and the gas-chromatographically determined enantiomeric ratios to be $[\alpha]_D = +72$ ($CHCl_3$) and -71 ($CHCl_3$), respectively.

If it is assumed that the orientation of the organic ligands does not change during the ionic hydrogenation and acid-catalyzed isomerization, the (3*R*)-chirality sense for (−)-**2** and (2*S*,3*R*)-chirality sense for (+)-**1** can be derived from the known absolute configuration of the ester (+)-**3**, as given in the formula scheme.

It was of special interest to record the CD spectra of the complexes **1** and **2**.[11] The isoprene complex (+)-**1** shows two Cotton effects of opposite sign at 365 and 309 nm, while the complex (−)-**2** likewise shows two Cotton effects of opposite sign at 320 and 245 nm; these effects are presumably (cf. Ref. [3]) due to dissymmetrically perturbed iron d→d transitions. Both complexes show a strong negative Cotton effect at ca. 205 nm which can be ascribed to d → π* transitions.

Experimental

2: BF_3 gas was passed for ca. 5 min through a solution of (+)-**3** (1.007 g, 2.49 mmol) and Et_3SiH (730 mg, 6.3 mmol) in CH_2Cl_2 (30 mL) under N_2. After 2 hours' stirring at −78 °C the solution was treated with 20 mL of 2 N KOH and the resulting mixture, after warming, was extracted twice with 20 mL of CH_2Cl_2. The organic phases were washed with H_2O, filtered through a 5 cm-thick layer of silica gel, and evaporated down: 475 mg (91%) of (−)-**2** and (+)-**1** in the ratio 91:9 (GC). Chromatographic separation on silica gel with pentane afforded pure (−)-**2**, b.p. = 60 °C/10 torr; $[\alpha]_D = -68°$ ($c = 1.0$, $CHCl_3$).—UV (CH_3CN): $\varepsilon(\lambda[nm]) = 13000$ (240, shoulder).—CD (CH_3CN): $\Delta\varepsilon_{max}$ (λ[nm]) = −0.88 (320), +2.2 (245), −7 (206). −^{1}H-NMR (300 MHz, $CDCl_3$): $\delta = 1.33$ (d, $J = 6.8$ Hz, 3H), 1.61 (d, $J = 4.4$ Hz, 1H), 1.74 (s, 1H), 2.14 (d, $J = 2.3$ Hz, 1H), 2.53 (d, $J = 4.4$ Hz, 1H), 3.06 (qd, $J = 6.8$, 2.3 Hz, 1H).—^{13}C-NMR (75.5 MHz, $CDCl_3$): $\delta = 15.0$(q), 50.2(t), 52.3(t), 73.2(d), 103.9(s), 211.0(s), 211.5(s), 212.0(s).

1: The yellow solution of (−)-**2** (175 mg, 0.83 mmol) in 85% H_2SO_4 (2 mL), after 5 min at 25 °C, was diluted with 20 mL of H_2O and extracted twice with 30 mL of pentane. Residue from the organic phases: 95 mg (55%) (+)-**1** (after GC pure), b.p. = 60 °C/10 torr; $[\alpha]_D = +63°$ ($c = 0.9$, $CHCl_3$).—UV (CH_3CN): ε_{max} (λ[nm]) = 2100 (285).—CD (CH_3CN): $\Delta\varepsilon_{max}$ (λ[nm]) = −0.37 (365), +1.95(309), −8.0(202).—^{1}H-NMR and ^{13}C-NMR spectra ($CDCl_3$) identical to those given for (±)-**1** [12].

Copper(I)-Assisted Formation of an "Organic" Sandwich Structure: Structural Prerequisites for Luminescence of the Dinuclear Complexes [(μ-Bipyrimidine){Cu(PR$_3$)$_2$}$_2$]X$_2$**

By *Conny Vogler, Hans-Dieter Hausen, Wolfgang Kaim,* Stephan Kohlmann, Horst E. A. Kramer,* and *Jochen Rieker*

Weak inter- or intramolecular interactions, especially when combined and integrated into appropriate molecular "architecture", can lead to the formation of supramolecular structures with specific functionality.[1] Here we report a system that, owing to such interactions in the solid, shows strong luminescence from a metal-to-ligand charge-transfer (MLCT) excited state.

[(μ-bpym){Cu(PR$_3$)$_2$}$_2$](BF$_4$)$_2$ **1**

bpym =

Compounds **1**–**3**, which belong to the class of homodinuclear complexes containing the bridging ligand 2,2'-bipyrimidine (bpym),[2] can be synthesized by conventional procedures.[3] Compound **1a** exhibits a long-wavelength MLCT absorption band—$d^{10}(Cu) \rightarrow \pi_1^*$(bpym)—at λ_{max} = 438 nm (sh, lg ε ≈ 3.5) (see Fig. 1); π_1^*(bpym), the LUMO of **1a**, can also be populated electrochemically (E_{red} = −0.66 V vs. SCE in dichloromethane) and the resulting radical anion can be identified by absorption[4a] and ESR spectroscopy.[4b]

(BF$_4$)$_2$ **1a**

In the solid state, **1a**·CH_3OH·H_2O displays a surprisingly strong luminescence (Fig. 1), which is not as intense either in

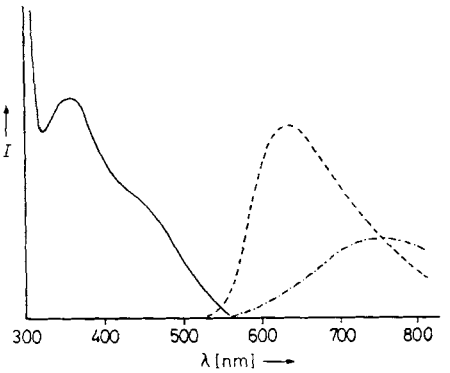

Fig. 1. **1a**: Absorption spectrum in $CHCl_3$ (—; λ_{max} = 357, 438 nm (sh)) as well as emission spectra in the solid state (– – –: λ_{max} = 630 nm) and ca. 10^{-4} M in $CHCl_3$ solution (–·–·–; λ_{max} = 758 nm), excitation with λ = 436 nm. Intensities not shown to scale.

solution (Fig. 1) or after anion exchange ($BF_4^{\ominus} \rightarrow PF_6^{\ominus}$, $ClO_4^{\ominus}$) or when most other monodentate phosphane ligands PR_3 (**1c, e–h, 2**) are used. Only complexes **1b**[5] and **1d**, in addition to the arsenic analogue of **1a**, show similar luminescence; of the complexes **3**, containing bidentate chelate ligands, only the complex with the 1,5-bis(diphenylphosphino)pentane ligand (n = 5) luminesces in the solid state.

Although luminescence has been observed for mononuclear complexes $[LCu(PPh_3)_2]^{\oplus}$ with L = 2,2-bipyridine or 1,10-phenanthroline derivatives, as well as similar ligands,[3] dinuclear bpym complexes with metal centers having d^6 configurations do not emit at all (Re^{I}[2b]) or only very weakly (Ru^{II},[2c] Mo^{0}[2a]).

The crystal structure analysis of **1a** (Fig. 2)[6] reveals the special prerequisites for solid-state luminescence. It is obvious that the intramolecular (562.2 pm)[7] and intermolecular (≥ 953.3 pm) metal–metal distances are appreciably greater than those in luminescing copper(I) halide clusters.[8] The space above and below the bpym bridging ligand of **1a** is just sufficient, however, to allow one (donor) phenyl ring of a triphenylphosphane ligand to interact in a π fashion with each side of the π-acceptor heterocycle. This results in a considerable distortion of the ligands from tetrahedral geometry around copper. The dihedral angles between the bpym plane and the Cu–P bonds are 98.0° for the two triphenylphosphane ligands involved in π coordination and 139.4° for the others. The angles between the best planes of the "organic" sandwich structure phenyl/bpym/phenyl are approximately 14°; the shortest atom–atom distance between the sandwich rings is only 315.0 pm for C1-C56. This value is significantly smaller than the sum of the van der Waals radii.

Phosphorus ligands with other aryl substituents are apparently no longer able to adopt the arrangement shown in Figure 2, which is required for π coordination of the bpym ligand, because of transannular repulsion between the

Important distances [pm] and angles [°]: Cu-Cu' 562.2(1), Cu-N1 208.7(2), Cu-N2' 211.9(2), Cu-P1 223.1(1), Cu-P2 229.5(1), N1-C1 134.0(3), C1-N2 134.2(3), C1-C1' 146.1(4), N2-C2 133.5(4), C2-C3 137.1(4), C3-C4 137.9(4), C4-N1 133.1(4), P-C 181.7(4)–183.1(3); N1-Cu-N2' 79.1(1) P1-Cu-P2 122.7(<1), N1-Cu-P1 125.5(1), N1-Cu-P2 99.8(1), N2'-Cu-P1 119.9(1), N2'-Cu-P2 99.7(1), Cu-P1-C11 109.7(1), Cu-P1-C21 118.8(1) Cu-P1-C31 115.2(1), Cu-P2-C41 117.0(1), Cu-P2-C51 104.7(1), Cu-P2-C61 118.1(1), C-P-C 102.5(1)–108.1(1).

phenyl rings (*para* substituents, **1e, f, g, h**) or owing to considerable change in the cone angle[9] (*ortho* substituents, **1c, 2**). Accordingly, no luminescence is observed for those systems. On the other hand, substituents in *meta* position, as in **1d**, or the use of a bis(diphenylphosphino)alkane chelate ligand having a sufficiently large "bite" angle (**3**, n = 5, P-Cu-P ≈ 120°) do not prevent a "π-sandwich" interaction; these complexes also luminesce, especially in the solid state.

In contrast to the situation in other Cu^I complex salts with $BF_4^\ominus$ as counterion,[10] this anion is not disordered in crystals of **1a**·CH_3OH·H_2O; rather long distances (300–305 pm) to the O atoms of the solvent molecules indicate only weak hydrogen bonds F···H-O. On replacement of $BF_4^\ominus$ by the still less basic anions $PF_6^\ominus$ or $ClO_4^\ominus$, system **1a** shows no or orders of magnitude smaller (< 1%) luminescence in the solid state.

Apparently, the flexibility possible in solution is sufficient to reduce appreciably the luminescence of **1a** (see Fig. 1). NMR and emission measurements at very low temperatures in solution should help to clarify this finding. The intense solid-state luminescence of **1a** could thus be due to the noncovalent interactions which, in combination, result in an effective decrease in molecular degrees of freedom. Thus, in contrast to the usually negative results obtained with dinuclear complexes,[2] the rate of internal conversion is dramatically decreased, radiationless deactivation is suppressed, and the intensity of luminescence therefore markedly increased.[11]

System **1a** is thus a further example[12] of the superb suitability of structurally flexible Cu^I as a "template" center for interactions between coordinated ligands.

Experimental Procedure

Dinuclear Cu^I complexes with bpym: 2,2'-Bipyrimidine (158 mg, 1 mmol) was suspended in 50 mL of methanol together with copper powder (95 mg, 1.5 mmol), $Cu(BF_4)_2$ (237 mg, 1 mmol), and PR_3 or $AsPh_3$ (4 mmol) or Ph_2P-$(CH_2)_n$-PPh_2 (2 mmol) and the mixture was refluxed for approximately 1 h. After filtration of the hot reaction mixture, the product was allowed to crystallize at −15 °C and then recrystallized from methanol. Yield 60–85%; correct elemental analyses. The hexafluorophosphates and perchlorates were prepared with $[Cu(CH_3CN)_4](PF_6)$ and $Cu(ClO_4)_2$, respectively, instead of $Cu(BF_4)_2$.

Ta_2Se: A Tantalum-Rich Selenide with a New Layer Structure

By *Bernd Harbrecht**

Preparative investigations on tantalum-rich systems containing, as additional components, a metal M of the iron group and sulfur or selenium have led to $M_2Ta_9S_6$ and $M_2Ta_{11}Se_8$, novel intermetallic compounds with remarkable structural[1] and electronic[2] properties. Chalcogenides with extended three-dimensional bonding networks[3] have been found to consist of strikingly open clusterlike structures, penetrated by channels surrounded by chalcogen atoms. The binary tantalum sulfides Ta_2S and Ta_6S, the latter of which forms monoclinic crystals,[4] have completely different struc-

Otto-Hahn-Strasse 6, D-4600 Dortmund 50 (FRG)

tures. Their metal frameworks consist of distorted, centered Ta_{13} icosahedra, which extend along a "fivefold axis of symmetry" to form chains, $^{1}_{\infty}[TaTa_{10/2}]$. New representatives of this class are the substitutional phases $M_xTa_{6-x}S$ (M = V, Cr; $x \leq 2.5$),[5] the triclinic modification of Ta_6S,[6] and $Ta_3S_{1.8}$.[7]

Similarly reduced tantalum selenides were previously unknown: TaSe, $Ta_{1.64}Se_2$, and Ta_2Se_3 are the most selenium-poor phases so far reported.[8] By reduction of $TaSe_2$ with tantalum in the melt, we were able to prepare Ta_2Se for the first time. Its simple structure reflects the unprecedented bonding in such metal-rich compounds.[3]

To synthesize Ta_2Se, a pellet (approximately 1 g) of Ta and $TaSe_2$, the latter formed from the elements (Ta:Se 2:1) in an evacuated and sealed quartz tube at 1170 K, was fused for a short period on both sides in an arc (35 V, approximately 60 A) on a water-cooled copper block under argon (0.11 Pa). Under these conditions, material loss caused by vaporization of selenium is less than 0.8%. The product, which has a metallic luster, decomposes slowly on exposure to air. In agreement with the single-crystal X-ray structure analysis,[9] examination of Guinier photographs of Ta- and Se-rich specimens reveals no evidence of a significant phase width.

Crystalline Ta_2Se represents a new structural type (Table 1), which is symmetry-related to the cubic, body-centered

Table 1. Structural parameters of Ta_2Se [9]: space group $P4/nmm$-D^7_{4h} (No. 129), $Z = 2$; $a = 337.5(1)$, $c = 983.2(1)$ pm; all atoms occupy the positions 2c (4mm symmetry): 1/4 1/4 z (center of inversion at the origin); B_{eq} in 10^4 pm^2, U_{ii} in pm^2, $U_{ij} = 0$.

Atom	z[a]	B_{aq}	U_{11}	U_{33}
Ta1	0.0776(2) [1/12]	0.36(2)	46(5)	44(8)
Ta2	0.7553(3) [3/4]	0.54(2)	63(6)	79(9)
Se1 [Ta3]	0.3665(6) [5/12]	0.70(6)	80(10)	110(20)

[a] For comparison, the positional parameters of bcc-Ta, transformed according to $P4/nmm$, are given in brackets [10].

modification of tantalum (bcc-Ta).[10] Viewed in terms of bcc-Ta, the structure of Ta_2Se can formally be regarded as an "ordered substitution phase" or as an "insertion phase". After every four Ta layers—the sequence corresponds to that along a in bcc-Ta—two Se layers are inserted (Fig. 1). The slightly oxidized metallic regions are formed by the Ta1 atoms, which, in each case, are surrounded by 13 Ta atoms (4×283.3, 4×289.7, 1×316.9, 4×337.5 pm) and one Se atom (284.1 pm). The peripheral layers adjacent to the Se atoms are formed from Ta2. They have four Se atoms (267.0 pm) and nine Ta atoms (4×289.7, 316.9, $4 \times$ 337.5 pm) as nearest neighbors. The Se atoms, which complete the coordination number to 14, lie in adjacent Se-Ta-Ta-Ta-Ta-Se networks. The Ta–Se separations (382.2 pm) are too large for Ta–Se bonds, which would lead to interpenetration of the layers. The structurally different functions of the Ta atoms are also revealed in the average distances Ta1-Ta (304.5 pm) and Ta2-Ta (313.6 pm); these differences are not as striking, however, as those in Ta_2S (289 and 314 pm).[4]

The greater distortions of the body-centered packing compared with those in the bcc-Ta fragments are revealed in specific displacements of the Se layers (cf. Table 1). The acentric coordination geometry about Se clearly indicates the disruption of the structure between the Se layers; there are strong bonds, such as that for atom Se3 in $Fe_2Ta_{11}Se_8$ ($< d$(Ta-Se)$> = 270.1$ pm[11]), to only five Ta atoms ($4 \times$ 267.0, 284.1 pm) of a tantalum fragment. The shortest distance between Se atoms of neighboring layers is 354.7 pm.

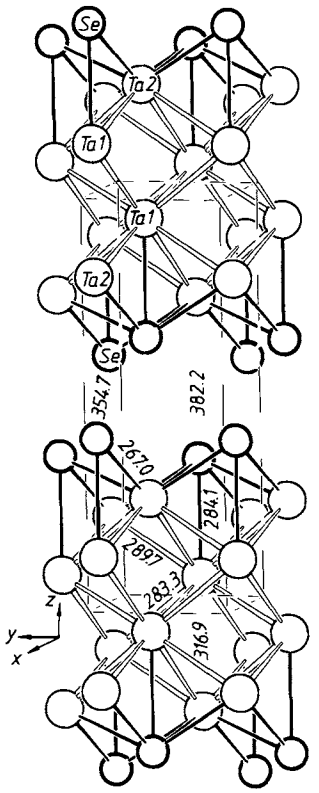

Fig. 1. SCHAKAL plot of the structure of Ta_2Se; atoms less than 315 pm apart are joined by lines.

Apparently, van der Waals interactions are responsible for holding together the Se–4Ta–Se networks.

According to these findings, Ta_2Se cannot be assigned structurally to the homomorphic ternary nitrides of the CrNbN type.[11] Their metal partial structure is isotypic to γ-CuTi,[12] likewise a bcc-related AB structure of the same symmetry. The N atoms occupy gaps within the distorted octahedra, which, in CrNbN, are formed by five Nb atoms and one Cr atom. In terms of the symmetry relationship to the bcc arrangement, the ideal $c:a$ ratio is 2 for γ-CuTi (γ-CuTi, 1.905; CaGaN, 2.117[13]), but 3 for Ta_2Se (actual value: 2.957).

Ta_2Se may be assigned to the class of quasi-two-dimensional materials and is the most metal-rich representative so far known. Its electronic properties should be of great interest (e.g., see Ref. [14]).

$K_4Al_2Nb_{11}O_{20}F$—The Missing Link in Cluster Condensation

By *Arndt Simon,* Jürgen Köhler, Robert Tischtau,* and *Gordon Miller*

Dedicated to Professor Reginald Gruehn on the occasion of his 60th birthday

Condensed metal clusters, that is, clusters linked by metal–metal bonds, are present in numerous compounds.[1] Particularly common are octahedral M_6 units joined to form one-, two-, and three-dimensional networks. These units are surrounded by nonmetal atoms above free edges or faces in such a way that M_6X_{12} and M_6X_8 clusters result.[2] The first steps of condensation have already been accomplished, namely, the synthesis and characterization of "oligomeric" clusters, though only those in which the octahedra are condensed through faces[3–5] or edges.[6–10] For nearly five years, we have attempted to realize the last remaining variant, condensation through the octahedral vertices. This "missing link"[11] has now been found in the compound $K_4Al_2Nb_{11}O_{20}F$.[12]

Figure 1 shows the discrete $Nb_{11}O^i_{20}O^a_8F^a_2$ clusters (for terminology see Ref. [2]) present in the structure of $K_4Al_2Nb_{11}O_{20}F$. These clusters contain two $Nb_6O^i_{12}$ units connected through the vertices of the Nb_6 octahedra.[13] All free octahedral vertices are coordinated by further O or F atoms (O^a, F^a). In the crystal, these clusters are linked to form $[Nb_{11}O^i_{12}O^{i-a}_{8/2}]O^{a-i}_{8/2}F^{a-a}_{2/2}$. The $Al^{3\oplus}$ ions occupy tetrahedral voids in the anion packing, and the $K^{\oplus}$ ions are surrounded cuboctahedrally by ten $O^{2\ominus}$ ions, one $F^{\ominus}$ ion, and one $K^{\oplus}$ ion (d_{K-K} = 330.5 pm). The $F^{\ominus}$ ion cannot be located unambiguously by X-ray analysis. The marked change in the c axis on introduction of $F^{\ominus}$ (cf. Ref. [12]), as well as summation of bond strengths, indicates that the $F^{\ominus}$ ion lies at the terminal, bridging X^{a-a} positions (Fig. 1). The electron count reveals that 24 electrons occupy M–M bonding states in the cluster. This experimental finding is in good agreement with extended Hückel MO calculations.[14]

Figure 2 shows the orbital correlations for the M–M bonding orbitals in the Nb_6O_{12} and $Nb_{11}O_{20}$ clusters. The condensation of two Nb_6O_{12} clusters raises the energy of an

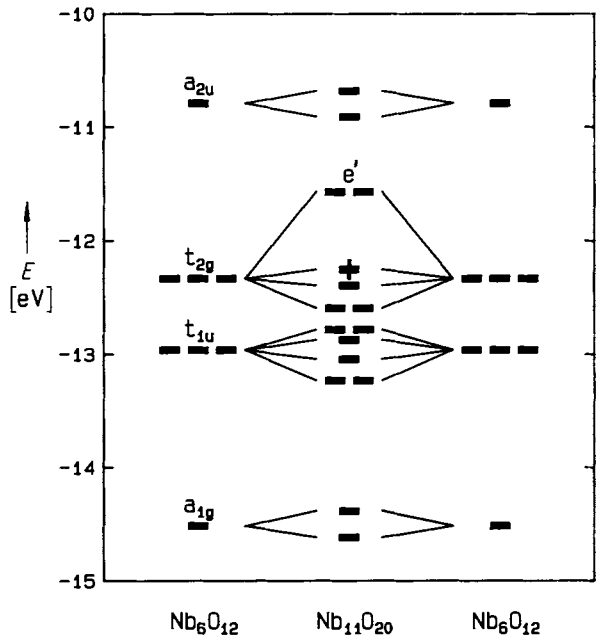

Fig. 2. Correlation of the MO diagram for the $Nb_{11}O_{20}$ cluster with the energy states of the isolated Nb_6O_{12} cluster.

e' orbital, arising from the bonding t_{2g} state of the octahedron, by nearly 0.9 eV. This is due, on the one hand, to an enhancement of the Nb–O^*_π interaction for the O atoms between the two octahedra and, on the other, to a weakening of the Nb–Nb bonding character of this orbital owing to the symmetry-determined node at the central Nb atom. Therefore, twelve low-lying M–M bonding orbitals are obtained; these can accept 24 electrons for maximum electronic stabilization.

In contrast to the large number of structures in which clusters of the M_6X_8 type, condensed through octahedral vertices, are present,[1,9] only a few examples involving the corresponding condensation of clusters of the M_6X_{12} type are known. Nonetheless, for the oxides, these examples rep-

Heisenbergstrasse 1, D-7000 Stuttgart 80 (FRG)

resent a nearly continuous series from discrete M_6X_{12} clusters toward increasing dimensionality of the cluster networks (Fig. 3).

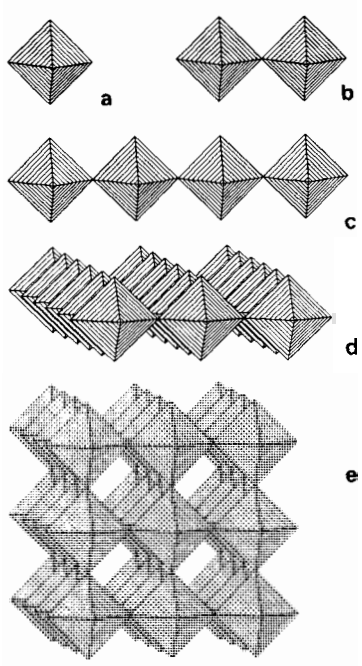

Fig. 3. Scheme for the condensation of M_6X_{12} clusters in various compounds. a) In all pictures the octahedron corresponds to the M_6 core in the M_6O_{12} cluster; b) octahedral pair in the $Nb_{11}O_{20}$ cluster; c) part of the octahedron chain in the structure of TiO (low-temperature modification); d) section of the octahedron layer in $Ba_2Nb_5O_9$; e) part of the NbO structure with octahedra linked through all vertices.

Many structures with discrete Nb_6O_{12} clusters are now known.[9, 15–21] The $Nb_{11}O_{20}$ cluster described here represents the first step in a condensation process leading, via the hypothetical oligomers of general composition $M_{5n+1}O_{8n+4}$ (n = number of octahedra), to the M_5O_8 chain, which is the only building unit in the structure of TiO (low-temperature modification).[1, 22] In the recently reported compounds $Sr_2Nb_5O_9$ and $Ba_2Nb_5O_9$, Nb_6O_{12} clusters are condensed through four octahedral vertices to form layers.[23, 24] The linking of all octahedral vertices according to $Nb_{6/2}O_{12/4}$ leads ultimately to the structure of NbO.[2] The existence of a "phasoid" in the Ba/Nb/O system with disordered fragments of the NbO structure in a perovskite matrix[24, 25] points to the possible existence of many other intermediates.

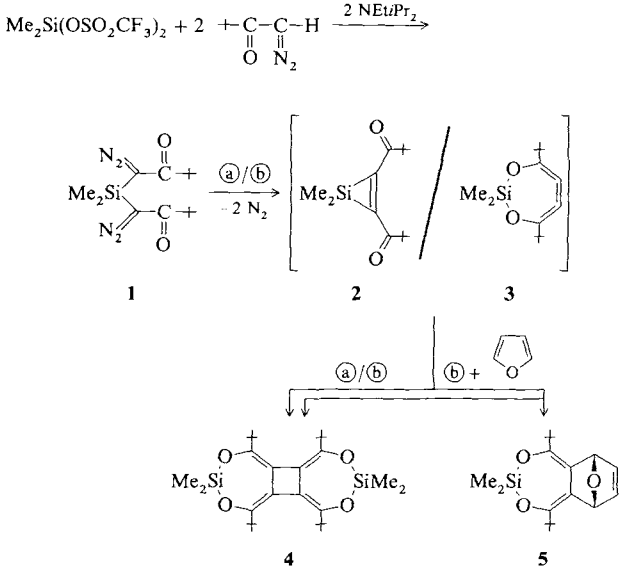
An Electron-Rich [4]Radialene**



By *Antonio Fronda* and *Gerhard Maas**

[4]Radialenes (tetraalkylidenecyclobutanes), the unusual topologies of which raise questions concerning structural and spectroscopic properties as well as bonding, are relatively uninvestigated species. Besides the parent compound[1] and a series of alkyl-[2, 3] and aryl-substituted[2, 4] [4]radialenes, only scattered examples containing other substituents are known.[5] If the alkyl-substituted systems are ignored, only a few examples of electron-rich derivatives have been reported.[5d, e] Here we describe the synthesis and structure of a new electron-rich [4]radialene

[*] Prof. Dr. G. Maas, Dipl.-Chem. A. Fronda
Fachbereich Chemie der Universität
Erwin-Schrödinger-Strasse, D-6750 Kaiserslautern (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

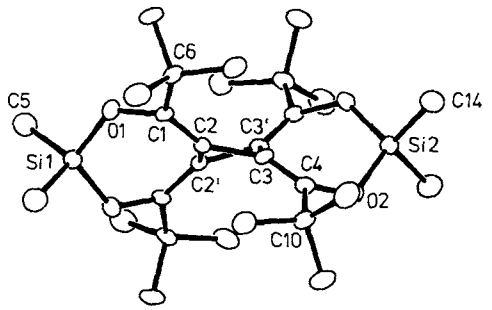
The starting material **1**, the first bis(1-diazo-2-oxoalkyl)silane, is accessible from dimethylsilyl bis(trifluoromethanesulfonate) and 1-diazo-3,3-dimethyl-2-butanone[6] (Scheme 1). The bis-diazo compound **1**, which is relatively unstable as a pure substance, affords the [4]radialene **4** in 38% yield upon decomposition catalyzed by copper(I) trifluoromethanesulfonate in cyclohexane.[7] When palladium(II) acetate in ether is used, the reaction is appreciably slower (yield 40%).

Scheme 1. ⓐ $Cu(O_3SCF_3) \cdot 0.5\,C_6H_6$ (3 mol%)/cyclohexane/2 h. ⓑ $Pd(OAc)_2$ (6 mol%)/ether/24 h.

Possible intermediates in the formation of **4** are the diacylsilirene **2** (formally the product of an intramolecular carbene dimerization) and 1,3-dioxa-2-sila-4,5,6-cycloheptatriene (**3**). Acylsilirenes have not yet been reported. Although the direct transformation **2** → **4**, consisting of dimerization followed by a fourfold 1,3-Si (C → O) shift, cannot be excluded,[8] the pathway involving ring expansion **2** → **3** seems more plausible. The latter rearrangement can be regarded as an intramolecular variant of the insertion of carbonyl groups into the Si–C bond of silirenes.[9] Finally, the direct formation of **3** from **1**, without the intermediacy of **2**, should also be considered.[10] The ability of the strained cyclocumulene **3** to undergo thermal or metal-catalyzed[2, 3] dimerization to **4** is self-evident.

When the palladium(II) acetate–catalyzed decomposition of **1** is carried out in the presence of furan (10 molar equivalents), the tricyclic compound **5** (18%) is obtained in addition to **4** (6%). Again, it cannot be concluded with certainty whether **5** is the product of a [2+4] cycloaddition to **2** (followed by Si (C → O) shift) or, instead, to **3**.[11]

With one exception,[12] [4]radialenes substituted on the four-membered ring are known to be folded.[5f, 13] The crystal structure analysis of **4**[14] reconfirms this observation (Fig. 1). The folding angle of 35.0° (tilting of the plane C2′-C3-C3′ with respect to the plane C2′-C2-C3) lies within the range of the highest values known so far (37.4° in a tetrakis(α-methoxycarbonylbenzylidene)cyclobutane isomer,[5f] 34.7° in octaphenyl[4]radialene[13]). This strong deformation is obviously the result of minimization of steric interactions between the spatially neighboring *t*Bu groups. The same cause presumably explains the twisting (albeit small, see caption to Fig. 1) around the exocyclic C=C bonds as



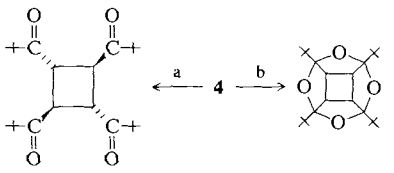


Fig. 1. Molecular structure of **4** (ORTEP). The molecule has crystallographic C_2 symmetry; the two Si atoms lie on the C_2 axis. Bond lengths [Å]: C2-C2′ 1.508(4), C2-C3 1.494(3), C2-C1 1.326(3), C3-C4 1.324(3), C1-O1 1.395(2), C4-O2 1.389(2), Si1-O1 1.638(2), Si2-O2 1.635(2); Bond angles [°]: C2′-C2-C3 87.3(1), C1-C2-C3 140.4(2), C1-C2-C2′ 126.8(2), C2-C3-C3′ 87.2(1), C2-C3-C4 140.6(2), C3′-C3-C4 127.0(2), C2-C1-C6 131.6(2), C3-C4-C10 130.9(2); Torsion angles [°]: C6-C1-C2-C3 − 6.9, O1-C1-C2-C2′ 18.6, C2-C3-C4-C10 − 5.1, C3′-C3-C4-O2 18.9, C2′-C2-C3-C3′ 24.5, C2-C3-C3′-C2′ − 24.7.

well as the pyramidalization of the cyclobutane carbon atoms (sum of angles at C2, 354.5°; at C3, 354.8°; deviation from the plane defined by the three bonding partners at C2, 0.180 Å; at C3, 0.175 Å). On the other hand, the *t*Bu-substituted C atoms nearly retain their planar coordination (sum of angles at C1, 359.4°; at C4, 359.3°).

Alkaline hydrolysis of **4** smoothly leads to tetra(1-oxoneopentyl)cyclobutane (**6**)[7] (Scheme 2); under the reaction conditions, the thermodynamically favored all-*trans* product is presumably favored. On the other hand, treatment of **4** with aqueous acid results in formation of the unusual pentacyclic polyketal **7**,[7] which displays an all-*cis* arrangement of

Scheme 2. a: MeOH, aq. NaOH (2.5 N) 1 h, 20 °C; 65% b: CH_2Cl_2/MeOH/HCl(6 N)(5/2/1), 4 h, reflux, 40%.

the substituents on the four-membered ring. The constitution of **7** is confirmed by the crystal structure analysis,[14] (Fig. 2) according to which **7** may be regarded as a tetra(oxa-

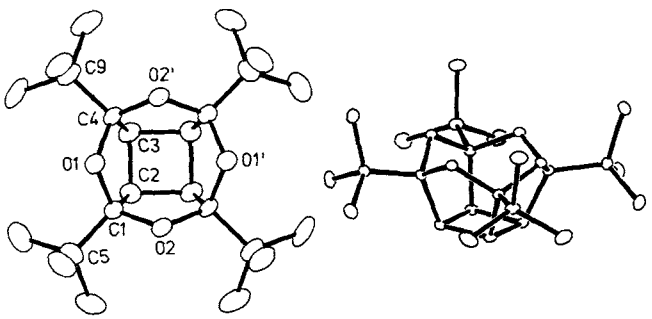

Fig. 2. Molecular structure of **7** (ORTEP). The molecule has crystallographic C_2 symmetry. Left: Viewed along the C_2 axis. Right: Viewed from the side. The average values for *d*(C–O) (1.472 Å), ∢ (C–O–C) (112.0°) and ∢ (O–C–O) (110.0°) in the crown-shaped tetraoxocane ring are significantly larger than those in isolated 1,3,5,7-tetraoxocane [17]. Further bond angles: C3-C4-C9 118.9(2), C2-C1-C5 118.9(2)°.

homo)cubane or as an oxygen analogue of [4]peristylane.[15] Furthermore, this result corroborates the constitutional assignment, based solely on the ^{1}H NMR and IR spectra, of a product obtained after ozonolysis of the *syn* dimer of tetramethylcyclobutadiene.[16]

Experimental Procedure

Dimethylsilyl bis(trifluoromethanesulfonate) (2.28 g, 6.4 mmol) was added dropwise at 0 °C to a solution of 1-diazo-3,3-dimethyl-2-butanone (1.61 g, 12.8 mmol) and ethyldiisopropylamine (2.23 mL, 12.8 mmol) in 40 mL of ether. After stirring for 5 h at room temperature, the reaction mixture was filtered and the solvent was replaced by 25 mL of cyclohexane. The resulting orange solution of **1** (IR(neat): $\tilde{\nu}$ (CN_2) = 2069 cm^{-1}) was then treated with copper(I) trifluoromethanesulfonate–benzene complex (90 mg, 0.3 mmol). After stirring for 12 h, the mixture was filtered, the solvent was removed at 20 °C/0.01 Torr, and the product was recrystallized from 4 mL of ether/methanol (1:1): 0.61 g (38%) of colorless **4** [7], m.p. 135 °C, was obtained.

Pd Clusters Containing As and PPh_3 Ligands: The Structures of $[Pd_9As_6(PPh_3)_8]$, $[Pd_2(As_2)(PPh_3)_4]$, and $[Pd_{20}As_{12}(PPh_3)_{12}]$**

By *Dieter Fenske,* Holm Fleischer*, and *Claudia Persau*

Dedicated to Professor Gerhard Fritz on the occasion of his 70th birthday

The reactions of $PhAs(SiMe_3)_2$ with $[MCl_2(PPh_3)_2]$ (M = Co, Ni) lead, even at room temperature, to cleavage of the As–C bond and formation of Me_3SiCl. The resulting cluster compounds **1**–**3** contain Co_4 tetrahedra (**1**) or cubic body-centered Ni_9 clusters (**2**,**3**).[1] We have now attempted to synthesize analogous Pd complexes.

$[Co_4(\mu_3\text{-}As)_3(\mu_3,\eta^3\text{-}As_3)(PPh_3)_4]$ **1**
$[Ni_9(\mu_4\text{-}As)_6(PPh_3)_5Cl_3]$ **2**
$[Ni_9(\mu_4\text{-}As)_6(PPh_3)_6Cl_2]$ **3**

We allowed the trinuclear cluster **4** to react with $As(SiMe_3)_3$ in THF[2] and observed, after a short period, the formation of a deep brown solution, from which, upon addition of a layer of heptane, black crystals of **5** formed. As a second reaction product, PPh_3S was identified.

$$\underset{\mathbf{4}}{[Pd_3(\mu_3\text{-}S)_2Cl_2(PPh_3)_4]} + As(SiMe_3)_3 \xrightarrow{THF} \underset{\mathbf{5}}{[Pd_9As_6(PPh_3)_8]} + PPh_3S$$

The IR spectrum of the diamagnetic cluster **5** corresponds, except for small shifts of some bands, to the spectra of other PPh_3-substituted clusters and therefore provides little information. The X-ray structure analysis of **5**[3] revealed a body-centered Pd_8 cube with a threefold axis of symmetry (Fig. 1).

The Pd atoms at the corners of the cube are coordinated by three μ_4-As atoms and the phosphorus atom of a PPh_3 ligand in a distorted tetrahedral fashion. The distances between corner Pd atoms are about 41 pm longer than the distances between the central Pd atom and corner Pd atoms. Thus, the bonding resembles that in the nickel cluster **2**,[1b] although the corresponding distances in **2** are about 30 pm shorter.

The distances between the μ_4-As atoms and the corner Pd atoms of the cube (247.5–248.7 pm) are only 22 pm shorter than those between them and the interstitial Pd atom. This

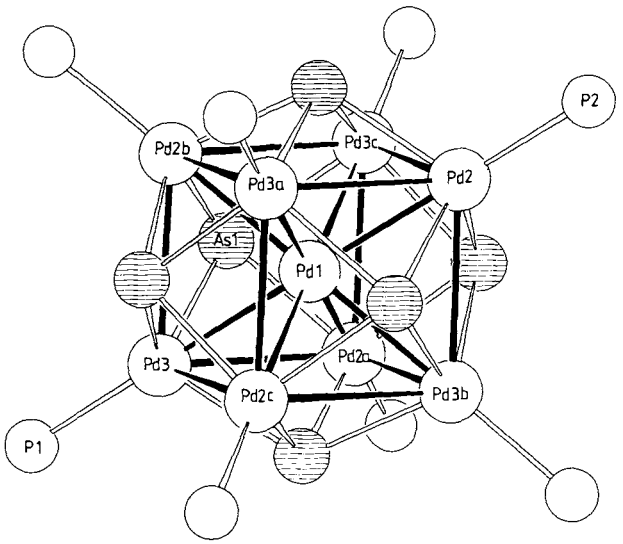

Fig. 1. Molecular structure of **5** (phenyl groups omitted). Important distances [pm] (±0.2 pm) and angles [°] (±0.05°): Pd1-Pd2 268.0, Pd1-Pd3 270.5, Pd2-Pd3a 310.9, Pd1-As1 270.4, Pd3-As1 248.7, Pd-P 230.5; Pd3a-Pd2-Pd3b 90.0, As1-Pd1-Pd2 125.26, As1-Pd1-Pd3 54.74 Pd2-Pd1-Pd3 180.0, Pd1-Pd2-P2 180.0.

central Pd atom has a coordination number of 14, since it is equally distant from the Pd and As atoms.

Cluster **5** contains 124 valence electrons (VE) and thus two electrons more than predicted by the 18-electron rule for body-centered cubes. The electron counting rules proposed by *Mingos* et al.[4] (VE = $12n_s + \Delta_i$) give 114 or 120 valence electrons for this type of cluster ($n_s = 8$; $\Delta_i = 18$ or 24, respectively); this result represents a substantial deviation from the actual number of valence electrons.

The following clusters can also be regarded as portions of cubic body-centered metal structures: $[Au_9(PPh_3)_8]^{\oplus}$,[5] $[Rh_{14}(CO)_{25}]^{4\ominus}$, and $[Rh_{14}(CO)_{26}]^{2\ominus}$.[6]

If, instead of **4**, the complex $[PdCl_2(PPh_3)_2]$ is allowed to react with $As(SiMe_3)_3$ in THF, dark yellow crystals of **6** can be isolated from the reaction solution after about two weeks.

$$[PdCl_2(PPh_3)_2] + As(SiMe_3)_3 \xrightarrow{THF} \underset{\mathbf{6}}{[Pd_2(As_2)(PPh_3)_4]} + \underset{\mathbf{7}}{[Pd_{20}As_{12}(PPh_3)_{12}]} + \mathbf{5}$$

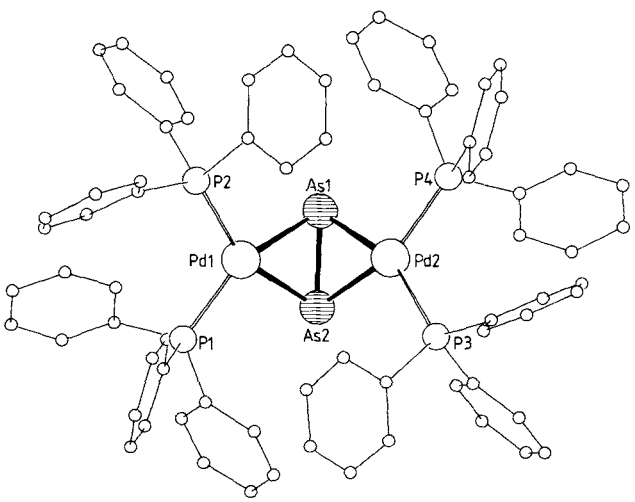

Fig. 2. Molecular structure of **6**. Important bond lengths [pm] (±0.1 pm) and angles [°] (±0.1°): Pd1-As1 252.2, Pd1-As2 245.5, Pd2-As1 245.8, Pd2-As2 251.5, As1-As2 227.4, Pd-P 232.8; As1-Pd1-As2 54.3, As1-Pd2-As2 54.4, Pd1-As1-Pd2 88.1, Pd1-As2-Pd2 88.3, P1-Pd1-P2 111.1, P3-Pd2-P4 110.9.

A crystal structure analysis[3] revealed that, in **6**, two $Pd(PPh_3)_2$ units are joined through a μ_2,η^2-As_2 bridge to form a "butterfly" structure. The As–As distance is similar to that in complexes such as $[Co_2As_2(CO)_6]$, $[Co_2(As_2)_2(CO)_5(PPh_3)]$, $[Cp_2M_2(CO)_4As_2]$ (M = Mo, W), and $[Cp^*_2Mn_2(CO)_4As_2]$.[7] Application of the usual counting rules gives 32 valence electrons for **6**. In agreement, a nonbonding Pd–Pd distance of 346 pm is found.

The formation of **6** is not surprising, since the reaction of $[(R_2PCH_2CH_2PR_2)NiCl_2]$ with $P(SiMe_3)_3$ also leads to a binuclear complex containing a bridging E_2 ligand.[8]

After separation of **6**, the filtrate was evaporated, the residue dissolved in toluene, and a layer of heptane added. A mixture of **5** and black crystals of a diamagnetic Pd_{20} cluster, **7**, crystallize within several days. The crystal structure analysis[3] shows that **7** consists of a Pd_8 cube (Pd11-Pd16, Pd18, Pd20), in which each edge is bridged by a μ_2-($PdPPh_3$) group (Fig. 3, top). Each of these bridges lies, within a deviation of 28–43 pm, within the best plane containing four Pd atoms

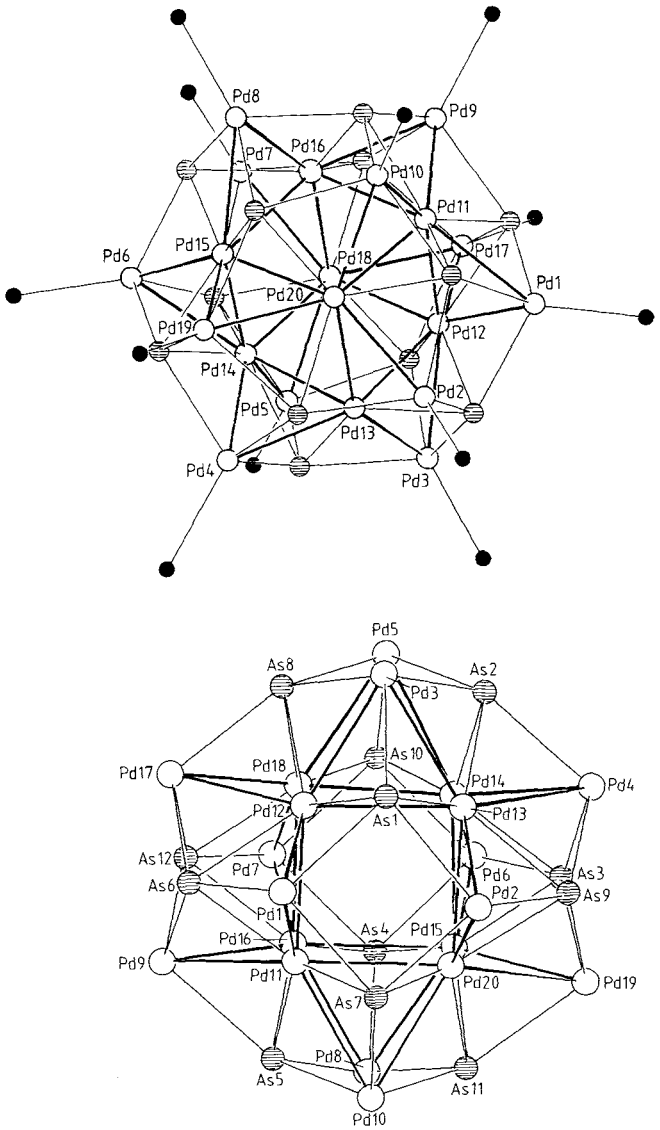

Fig. 3. Two views of the molecular structure of 7. Above: Phenyl groups omitted. Below: P atoms also omitted. ● = P atoms of the PPh_3 ligands, ◍ = As atoms. Important bond lengths [pm] (±0.2 pm) and angles (±0.2°): Pd-Pd (in the Pd_8 cube) 278.5–291.7, Pd-(μ_2-Pd) 274.1–279.8, Pd-P 229.6–230.7, As-Pd (in the Pd_8 cube) 240.0–247.2, As-(μ_2-Pd) 250.5–258.9; Pd-Pd-Pd (in the Pd_8 cube) 87.0–92.5, Pd-(μ_2-Pd)-Pd 60.3–61.3.

defining a side of the cube. Alternatively, the cluster framework of **7** can be described as a polyhedron formed by joining six Pd_6 rings and bridging the faces with μ_5-As atoms (Fig. 3, bottom).

The As–Pd distances are significantly shorter for the atoms of the Pd_8 cube than for the outer Pd atoms. These peripheral Pd atoms are each coordinated in a distorted tetrahedral fashion by three As ligands and one PPh_3 ligand.

The electron balance for clusters with $n > 13$ is often difficult to explain by using the usual models. If the As ligands are treated as three-electron donors and the PPh_3 ligands as two-electron donors, then **7** contains 260 valence electrons, that is, 28 electrons fewer than required by the 18-electron rule and 12 electrons more than expected according to the 16-electron rule. According to the concept proposed by *Mingos* ($n_s = 12$, $\Delta_i = 120$),[4] 264 valence electrons are obtained, that is, only four electrons more than the number calculated for **7**. Similarly large Pd clusters containing CO and PR_3 ligands have been synthesized and structurally characterized by *Mednikov* et al.: for example, $[Pd_{10}(CO)_{12}(PBu_3)_6]$, $[Pd_{23}(CO)_{22}(PEt_3)_{10}]$, and $[Pd_{38}(CO)_{28}(PEt_3)_{12}]$.[9]

Experimental Procedure

5: **4** (670 mg, 0.44 mmol) was suspended in 50 mL of THF and then treated with $As(SiMe_3)_3$ (0.26 mL, 0.88 mmol). Compound **4** dissolved rapidly with formation of a dark brown solution, which afforded 110 mg of a yellow microcrystalline precipitate of unknown composition after 7 d. Cluster **5** was obtained as black crystals by addition of a layer of heptane to the filtrate (yield 30% based on Pd).

6 and **7**: $[PdCl_2(PPh_3)_2]$ (2.12 g, 2.97 mmol) was suspended in 100 mL of THF and then treated with $As(SiMe_3)_3$ (2.97 g, 0.87 mL). Upon dissolution of the $[PdCl_2(PPh_3)_2]$ over 30–40 min, the solution turned dark brown. After about 1 h, the Pd complex had dissolved completely. The solution afforded small dark yellow crystals of **6** in small yield (15% based on Pd) when allowed to stand for 14 d. The solvent was removed from the still dark colored filtrate and the residue was washed with 50 mL of pentane and dissolved in 100 mL of toluene. After 2–3 weeks, a few large and uniform dark crystals of **7** had formed (yield 30%) together with crystals of **5** (yield 10%).

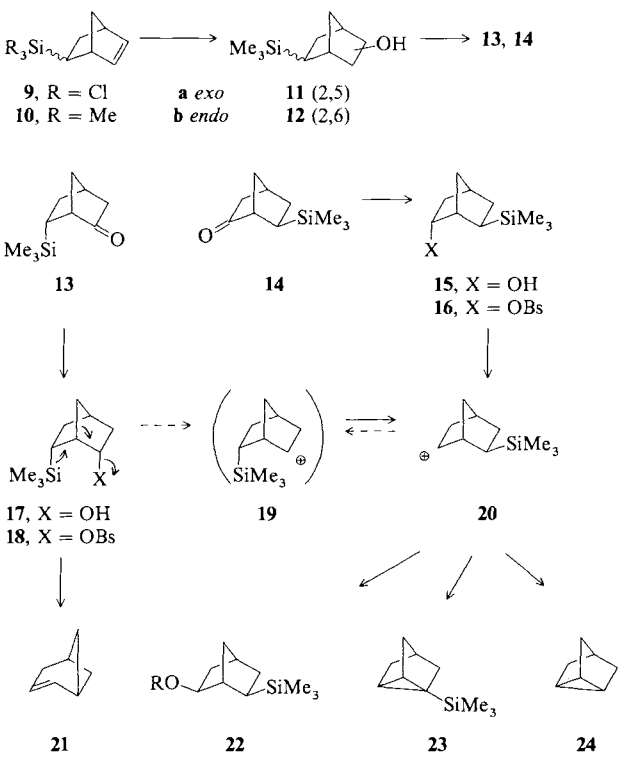
Si-Promoted Norbornyl–Norpinyl Rearrangements

By *Wolfgang Kirmse** and *Frank Söllenböhmer*

The ionization of *exo*-2-norbornyl derivatives (**1b**) occurs with participation of the C-1–C-6 bond (**1b** → **3**).[1] For *endo*-2-norbornyl derivatives (**1a**), a corresponding participation of the C-1–C-7 bond (**1a** → **4**) should likewise be possible. However, the ring strain thereby increases,[2] so that the k_c process **1** → **2** → **3** is often favored over the formation of the bridged ion **4** (Scheme 1). The large number of norpinyl–norbornyl rearrangements (**5** → **1**)[3] contrasts sharply, therefore, with the few examples of norbornyl–norpinyl rearrangements (**1** → **5**). Those few cases involve (1) the good leaving group nitrogen ($X = N_2^{\oplus}$) and (2) charge-destabilizing groups at C-3,[4] and/or charge-stabilizing groups at C-1.[5] Sulfonates, even in combination with (2), proved relatively ineffective as leaving groups; the best result so far is the formation of 5–9% of 2-norpinanone **8** from **6**.[6] We



Scheme 1.

have now found predominant norbornyl–norpinyl rearrangement for *endo*-2-norbornyl brosylates bearing an *endo*-6-$SiMe_3$ group.

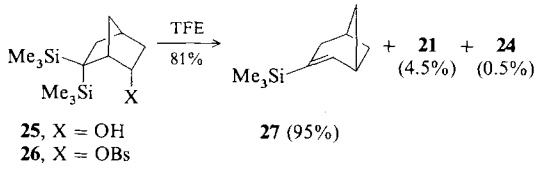
To synthesize the starting material, we separated the adducts **9a,b**, obtained by Diels–Alder addition of trichlorovinylsilane to cyclopentadiene, by Spaltrohr® distillation.[7] Methylation with methylmagnesium bromide,[8] hydroboration, separation of the regioisomers **11**/**12** by column chromatography, and oxidation with chromium trioxide/pyridine afforded the ketones **13**[9] and **14**.

Reduction of the ketones with $LiAlH_4$ gave predominantly (**13**, 95:5; **14**, 96:4) the *endo* alcohols **17** and **15**, respectively, which were purified by column chromatography and transformed into their brosylates **18** and **16**, respectively, by reaction with brosyl chloride/pyridine (Scheme 2).



Scheme 2.

On solvolysis of **18** in trifluoroethanol (TFE), we obtained mainly (86%) norpinene **21**.[10] The byproducts **22**–**24** were produced in a ratio similar to that found in solvolyses of **6** (Table 1). They are formed from the ions **19** and **20** (Wagner–Meerwein rearrangement) by substitution, deprotonation, and desilylation. We did not find a substitution product with *endo*-$SiMe_3$; apparently, the *exo* position of the trimethylsilyl group is strongly preferred for steric reasons.[11] The formation of norpinene from **18** can occur in a concerted fashion (see arrows in Scheme 2) or via intermediates of type **4**. In a concerted mechanism, **18** is expected to exhibit a faster rate of reaction than *endo*-2-norbornyl brosylate. In fact, however, **18** reacts 30 times slower (TFE, 25 °C).[12] Since the special effect of the *endo*-6-$SiMe_3$ groups is exerted in the product-determining step rather than in the rate-determining step, a cationic intermediate is probable.

Table 1. Solvolysis products of brosylates **16** and **18** (TFE, 2,6-dimethylpyridine, 75 °C, 16 h).

	Yield [%]	Product distribution [%] 21	22	23	24
16	70	–	13	37	50
18	83	86	1.5	6	6.5

Brosylation of 6,6-bis(trimethylsilyl)bicyclo[2.2.1]heptan-*endo*-2-ol (**25**), a compound described elsewhere,[13] to give **26** could only be accomplished in moderate yield (39%). Solvolysis of **26** in TFE gave 3-trimethylsilylnorpinene (**27**) as the main product (Scheme 3, Table 2). The byproducts **21** and **24** could have been formed by acidolysis of **27**. The norbornyl–norpinyl rearrangement is nearly complete for **26**. The behavior of brosylate **26** does not lie midway between that of **16** and **18**; instead, the effect of the *endo*-6-$SiMe_3$ group in **18** is further enhanced by the additional *exo*-6-$SiMe_3$ group. The branched reaction pathway discussed above (Scheme 1) explains this finding: although the *exo*-6-$SiMe_3$ group cannot promote formation of **4** or **4a** (cf. **16**), it does increase the stability (β-Si effect)[14] and promote the desilylation of this cationic intermediate.

Scheme 3.

27: $\delta = 0.05$ (s; Me_3Si), 1.32 (AA′ part of AA′XX′, $J = 8.1$, 7.8, 0.2 Hz; *endo*-6, 7-H), 2.11 (XX′ part of AA′XX′ split into a triplet, $J = 8.1$, 5.5, 0.7 Hz; *exo*-7-H), 2.41 (dd, $J = 2.9$, 2.0 Hz; 4-H), 2.47 (dq, $J = 6.2$, 5.5 Hz; 1-H), 2.64 (qt, $J = 5.5$, 2.9 Hz; 5-H), 6.61 (dtt, $J = 6.2$, 2.0, 0.7 Hz; 2-H)

With increasing number of silicon-controlled rearrangements[15] the examples of unusual reactions also increase. Recently, 1,3-aryl shifts were reported.[16] Our results show that the β-Si effect makes it possible for frameworks to rearrange in the direction of increasing strain.

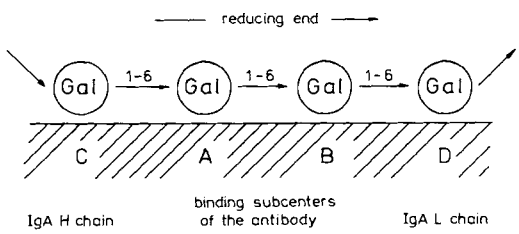
A "Spacer"-Modified Trisaccharide as Photolabile Ligand for Affinity Labeling of Antigalactan IgA X24**



By *Cornelis P. J. Glaudemans, Jochen Lehmann,** and *Markus Scheuring*

Many carbohydrate-binding proteins—for example, endoglycanases, lectins, transport proteins for oligosaccharides, and antibodies directed against polysaccharides and glycoconjugates—recognize and bind not only individual monosaccharides but also whole oligosaccharide sequences. Intensively investigated examples of such carbohydrate-binding proteins are the amylases from various sources. In 1970, *J. F. Robyt* and *D. French*[1] used kinetic studies to formulate a so-called subsite model—binding to five centers—for the binding region of α-amylase from porcine pancreas, an enzyme that binds maltose as the minimal structural unit of starch and specifically hydrolyzes the maltosyl bond.

The design of the first "spacer"-modified disaccharide, a maltotriose analogue, was based on this concept. This analogue, containing two D-glucose moieties linked through a six-membered acyclic segment, was synthesized and found to be a competitive inhibitor of the enzyme.[2] Spacer-modified oligosaccharides were designed for use as reactive probes of receptor proteins. The spacer, a flexible unit, replaces one or more rigid, bulky monosaccharide moieties. It can bear a reactive or activable group for chemical modification of the binding region. The affinity of the whole molecule should not be affected appreciably by this group. Affinity labeling is suitable for probing the binding region of enzymes whose structure, as in the case of the antibody used here, is known.

The applicability of this principle is confirmed here by the ability of the spacer-modified trisaccharide 8-azi-6,7,8,9,10-pentadeoxy-11-*O*-[β-D-galactopyranosyl-(1→6)-β-D-galactopyranosyl-]-D-*galacto*-undecaose (**1**) to bind to the monoclonal antigalactan IgA X24.[3,4] This immunoglobulin displays optimum affinity for a tetrameric segment of (1→6)-β-D-galactopyranan (Table 1), in which the four binding centers A, B, C, and D (see Scheme 1) exhibit decreasing

Schema 1. Schematic drawing of the mode of binding of a β-(1→6)-D-galactopyranan segment to the variable region of an appropriate antibody [4, 7].

binding affinity in that order for the monosaccharide moieties.[4] Photoaffinity labeling of IgA X24 was carried out previously with two β-D-galactosides of moderate affinity.[5, 6] In both cases, relatively unspecific labeling was observed; namely, both the L chain and the H chain were chemically modified. This result indicates either that binding occurred at various subcenters—that is, various ligand–receptor complexes were formed—or that the aglyconically bound, reactive groups were too flexible.

Compound **1** is designed so that, of the four subcenters,[4, 7] three, namely, A, C, and D, are occupied by galactosyl moieties and the fourth, B, is bridged by the spacer. The high affinity of compound **1** (1.1×10^5 M^{-1}), exceeding by far that of the structurally comparable disaccharide Gal_2[4] (Table 1), indicates an optimal, stable occupation of the four-

[b] The (1→6)-β-linked, reducing tetrasaccharide [16].

center binding region. Compound **1** can be prepared via a modified Koenigs–Knorr synthesis[8] by reaction of the undecaose derivative **2**, synthesized originally as a D-galactopyranose analogue,[9] with per-*O*-acetyl-*O*-β-D-galactopyranosyl-(1→6)-α-D-galactopyranosyl bromide (**3**)[10] followed by deprotection. Compound **3** was prepared according to a modified procedure[15] in improved yield (98% compared with 60%[10]). Treatment of **1** with β-galactosidase results in release of both galactose and the undecaose[9] of the reducing end. Both products were identified by thin layer chromatography with authentic samples.

Experimental Procedure

The affinity constants of **1** and IgA X24 were determined fluorometrically [5] (Table 1).

2,3,4,6-Tetra-*O*-acetyl-*O*-β-D-galactopyranosyl-(1→6)-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (**4**): 1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose (7 g, 27 mmol) [11] was dissolved in 15 mL of chloroform. Ag_2O (6.88 g, 29 mmol), anhydrous $CaSO_4$ (12.5 g), and 3-Å molecular sieves (3 g) were then added. The reaction vessel was placed for 1 h in an ultrasonicating bath. After addition of iodine (1.77 g, 14 mmol) to the stirred mixture, 2,3,4,6-tetra-*O*-acetyl-α-D-galactosyl bromide (12.2 g, 29 mmol) [12] in 10 mL of chloroform was added dropwise over one hour. The reaction mixture was stirred for an additional 22 h and insoluble matter was then removed by filtration. The filtrate was washed first with dilute, aqueous sodium thiosulfate, then with water, and subsequently dried (Na_2SO_4) and evaporated. Compound **4** was obtained as a colorless oil (11.3 g, 71%) and was pure by thin layer chromatography; $R_f = 0.27$, ethyl acetate/cyclohexane, 1:1. Compound **4** was used without further purification.

Per-*O*-acetyl-*O*-β-D-galactopyranosyl-(1→6)-α-D-galactopyranosyl bromide (**3**) [13]: **4** (10 g, 17 mmol) was dissolved in 50 mL of glacial acetic acid and water was added until a clouded solution was obtained. The reaction mixture was refluxed for 5 × 30 min, 5 mL of water being added after each interval of 30 min. The solution was concentrated under vacuum to half the original volume, the acetic acid was removed by repeated codistillation with water under vacuum, and the mixture was then evaporated to dryness. The residue was acetylated, as usual, in 40 mL of pyridine/acetic anhydride (2:1), followed by workup [14]. Purification was carried out by column chromatography on silica gel with ethyl acetate/cyclohexane, 1:1; $R_f = 0.16$. After evaporation of the corresponding fractions, **5** [13] was obtained as a colorless, solid foam (10.7 g, 94%; $[\alpha]_D^{20}$ −5° (chloroform)). Bromination of **5** was carried out by modification of a known procedure [10] at lower temperature (−5 °C) in the presence of acetic anhydride: **5** (0.2 g, 0.294 mmol) was dissolved in 15 mL of a 2:1 mixture of acetic anhydride and 30% HBr in acetic acid at 0 °C and the resulting mixture was cooled to −5 °C. After 48 h, the starting material had undergone complete reaction [10]. The workup was performed as usual and the crude product **3** was purified by column chromatography on silica gel (ethyl acetate/cyclohexane, 1:1; $R_f = 0.23$).

6,7,8,9,10-Pentadeoxy-11-*O*-per-*O*-acetyl-β-D-galactopyranosyl-(1→6)-β-D-galactopyranosyl-[-1,2:3,4-di-*O*-isopropylidene-8-azi-]-D-*galacto*-undeca-1,5-pyranose (**6**) [13]: **2** (0.3 g, 0.84 mmol) was coupled with **3** (680 mg, 9.2 mmol) in the presence of 7 g of silver silicate–alumina catalyst according to a Koenigs–Knorr synthesis modified by *H. Paulsen* et al. [8]. Compound **6** was obtained as a colorless foam (272 mg, 34%); $R_f = 0.32$, ethyl acetate/cyclohexane, 1:1.

1: **6** (270 mg, 0.27 mmol) was dissolved in 20 mL of chloroform and 2 mL of 99% trifluoroacetic acid and the reaction mixture was allowed to stand for 48 h. After concentration of the reaction solution under vacuum accompanied by repeated codistillation with methanol, the residue was dissolved in 20 mL of methanol and treated with 1 M sodium methoxide until the solution was alkaline. After complete conversion ($R_f = 0.22$, ethyl acetate/MeOH/H_2O, 4:2:1), the methanolic solution was evaporated and **1** was purified by HPLC (reversed phase); yield 100 mg (60%), $[\alpha]_D^{23}$ +65° (water).

$AsI_4^{\oplus}AlCl_4^{\ominus}$, a Salt of the Last Missing Tetrahaloarsonium Ion**

By *Inis Tornieporth-Oetting* and *Thomas Klapötke**

In their highest oxidation states, the nonmetals of the fourth row of the periodic table, As, Se, and Br, form rather unstable compounds.[1] Whereas PCl_5 and $SbCl_5$ are stable under normal conditions,[2] metastable $AsCl_5$ exists only at low temperature.[3] However, stable salts containing the binary cation $AsCl_4^{\oplus}$ have been described.[4-6] $AsBr_5$ and AsI_5 are unknown, though the synthesis of the $AsBr_4^{\oplus}$ ion in $AsBr_4^{\oplus}AsF_6^{\ominus}$ was recently accomplished.[6] $AsBr_4^{\oplus}AsF_6^{\ominus}$ is unstable, however, and decomposes irreversibly above $-78\,^{\circ}C$ to AsF_3 and Br_2. We have now attempted to prepare the last missing member in the series of tetrahaloarsenic(v) cations, $AsI_4^{\oplus}$.

From thermodynamic data we estimated that the formation of $AsI_4^{\oplus}AsF_6^{\ominus}$ from AsF_3 and I_2 is not possible ($\Delta H >$ 230 kJ mol^{-1}).[7] Furthermore, since decomposition to AsF_3 and I_2 is strongly favored, oxidation of AsI_3/I_2 with AsF_5 also seems unsuitable. On the other hand, a simple estimate (not a calculation!) based on a Born–Haber cycle (Scheme 1) showed that the reaction should be thermodynamically possible according to Equation (a) ($\Delta H = -7$ kJ mol^{-1}).

$$AsI_3(s) + ICl(s) + AlCl_3(s) \rightarrow \underset{\mathbf{1}}{AsI_4^{\oplus}AlCl_4^{\ominus}}(s) \qquad (a)$$

Scheme 1. Thermodynamic cycle for estimating the enthalpy of formation ΔH_f^0 of $AsI_4^{\oplus}AlCl_4^{\ominus}$ (1). All energies in kJ mol^{-1}. [a] $As^{\oplus}$–I bond energies, assumed to be 1.05 × As–I bond energies in AsI_3 [1] in analogy to $2\,AsF_3 + 2\,Cl_2 \rightarrow AsCl_4^{\oplus}AsF_6^{\ominus}$, $\Delta H = -104.5$ kJ mol^{-1}, i.e., $As^{\oplus}$–Cl bond energy = 324.0 kJ mol^{-1} and therefore 5% larger than As–Cl bond energies in $AsCl_3$. [b] $Cl^{\ominus}$ ion affinity [11]. [c] Lattice energy calculated from the molecular volume V_M [Å^3] by use of the following linear relation: 2325 $V_M^{-0.33}$ + 110 [12, 13]; $V_M(AsI_4^{\oplus})$ was set equal to $V_M(GeI_4)$ = 223 Å^3 [10], $V_M(AlCl_4^{\ominus})$ = 144 Å^3 [11]. [d] $\Delta H_f^0(AsI_4^{\oplus}AlCl_4^{\ominus}(s)) = -807.6$ kJ mol^{-1}. For reaction (a), the following values are thereby obtained: $\Delta H = -7.1$ kJ mol^{-1} ($\Delta H_f^0(AsI_3(s)) = -58.1$ [10], $\Delta H_f^0(ICl(s)) = -35.5$ [2], $\Delta H_f^0(AlCl_3(s)) = -706.8$ kJ mol^{-1} [10]).

Since decomposition of **1** to AsI_3, $AsCl_3$, $AlCl_3$, and I_2 is appreciably favored [Eq. (b), $\Delta H = -119$ kJ mol^{-1}],[8] reaction (a) was performed at lower temperature ($-95\,^{\circ}C$)

$$3\,\mathbf{1}\,(s) \rightarrow 2\,AsI_3(s) + AsCl_3(l) + 3\,I_2(s) + 3\,AlCl_3(s) \qquad (b)$$

and the reaction products were kept frozen in liquid nitrogen. Their characterization was accomplished by low-temperature Raman spectroscopy ($-110\,^{\circ}C$).[14]

After assignment of the respective frequencies to the $AlCl_4^{\ominus}$ ion and to two byproducts ($ICl_2^{\ominus}$,[15] $I_2Cl^{\oplus}$[16]), the four strong bands remaining can be assigned to the complex cation $AsI_4^{\oplus}$, which has T_d symmetry (Fig. 1). The Raman

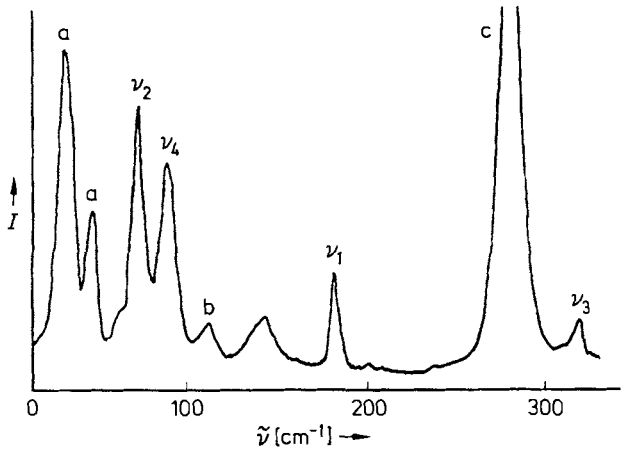

Fig. 1. Raman spectrum of **1** [14]. ν_1–ν_4: $AsI_4^{\oplus}$. Lattice vibrations: b, $AlCl_4^{\ominus}$; c, $ICl_2^{\ominus}$.

data for $AsI_4^{\oplus}$ are compared with those of the isoelectronic GeI_4 and the lighter homologues $AsBr_4^{\oplus}$ and $AsCl_4^{\oplus}$ in Table 1. As expected, the frequencies of $AsI_4^{\oplus}$ are all higher than those of GeI_4; the assignments are unambiguous owing to the relative intensities of the bands. Furthermore, the estimated values[17] for the ν_1 and ν_3 vibrational bands agree with the experimental values (Table 1). The spectrum displays neither AlI_3 bands nor the ν_1 band of I_2 (207 cm^{-1}[17]).

Table 1. Wavenumbers [cm^{-1}] and relative intensities (in parentheses) of the Raman-active fundamental vibrations ν_i of the tetrahedral $AsHal_4^{\oplus}$ ions (Hal = Cl, Br, I) and of GeI_4.

	$AsI_4^{\oplus}(AlCl_4^{\ominus})$ observed	$AsI_4^{\oplus}(AlCl_4^{\ominus})$ expected	GeI_4 [18]	$AsBr_4^{\oplus}$-($AsF_6^{\ominus}$) [6]	$AsCl_4^{\oplus}$-($AsF_6^{\ominus}$) [4]
ν_1	183 (40)	177	159 (80)	244 (100)	422 (100)
ν_2	72 (100)		60 (100)	88 (94)	156 (70)
ν_3	319 (20)	310	264 (20)	349 (28)	500 (50)
ν_4	87 (80)		80 (100)	115 (74)	187 (60)

[a] Calculated using $\tilde{\nu}(MI)/\tilde{\nu}(MCl) = 0.62$ for ν_3 and 0.42 for ν_1 [17].

At $-78\,^{\circ}C$, **1** decomposes spontaneously [Eq. (b), **danger of explosion**[19]] and both iodine and AsI_3 could be identified unequivocally by Raman spectroscopy; weak bands of $AlCl_3$ are observed in the IR spectrum of the decomposition product. In further experiments ($AsI_3/I_2/AlI_3$; AsI_3/IF/SbF_5; $AsI_3/0.5I_2/BF_3/0.5F_2$), we attempted to stabilize the $AsI_4^{\oplus}$ ion with other anions. $AlCl_4^{\ominus}$ proved to be the best suited counterion. The synthesis and characterization of the $AsI_4^{\oplus}$ ion in **1** confirms the existence of the last missing tetrahaloarsonium ion.

Experimental Procedure

1: ICl (0.1824 g, 1.123 mmol; Aldrich) was condensed into a thin-walled 5-mm-thick tube, distributed on the glass walls in the lower part of the tube (ca. 4 cm), and frozen in liquid nitrogen. After addition of a powdered mixture of AsI_3 (0.512 g, 1.124 mmol; Alfa) and $AlCl_3$ (0.300 g, 2.25 mmol; Aldrich) (two equivalents of $AlCl_3$ to prepare either the $AlCl_4^{\ominus}$ or the $Al_2Cl_7^{\ominus}$ salt), 0.5 mL of HCl(g) was condensed into the tube. The reaction mixture was warmed to

$-95\,^{\circ}C$, shaken for 30 min, and then allowed to warm slowly over 5-s periods at intervals of 5 min to $-78\,^{\circ}C$. The HCl was then removed under vacuum at $-95\,^{\circ}C$ and the remaining reaction mixture was kept frozen in liquid nitrogen until spectroscopic measurement.

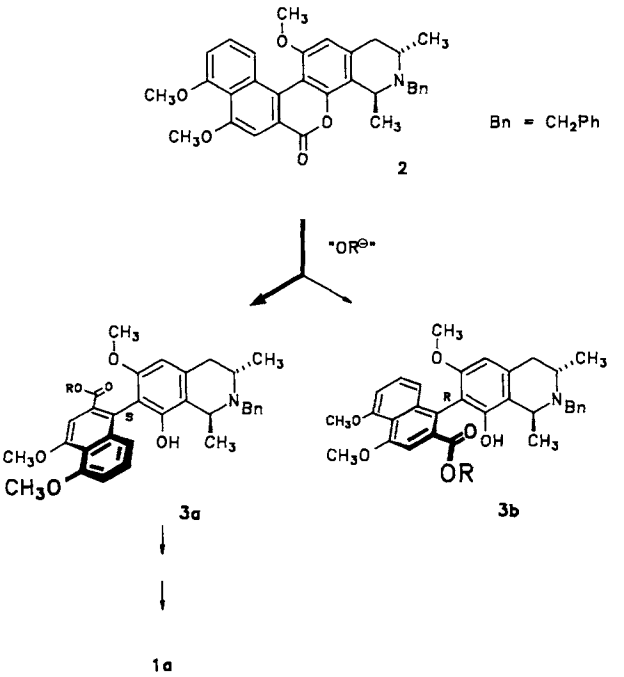
[19] **Warning:** In another experiment, we photolyzed a mixture of AsI_3, ICl, and $AlCl_3$ in the absence of solvent at low temperature (150-W high-pressure Hg lamp, cooled with N_2 (l), $\lambda = 254$ nm); the sample exploded upon warming, resulting in injury to a co-worker.

Atropdiastereoselective Ring Opening of Bridged, "Axial-Prostereogenic" Biaryls: Directed Synthesis of (+)-Ancistrocladisine**



By *Gerhard Bringmann** and *Helmut Reuscher*

The biaryl axis[1] is a central structural feature of a broad spectrum of natural products derived via different biosynthetic pathways and exhibiting a broad range of biological activities. We have recently introduced a novel concept for the directed synthesis of highly hindered biaryls; according to this approach, the two arenes are brought into favorable proximity by an ether- or esterlike auxiliary bridge and then coupled *intra*molecularly.[2] This method made possible the first synthetic entry to the structurally interesting class of naphthylisoquinoline alkaloids,[3, 4] for example, ancistrocladisine (**1a**).[4, 5]

Of particular stereochemical interest is the optically active synthetic intermediate **2**. Although this lactone already contains the biaryl axis, the latter is still largely planar owing to the CO bridge, so that the barrier to atropisomerization is dramatically lowered relative to that for the nonbridged biaryls **1** and **3**. In consequence, lactone **2** does *not yet* consist of atropisomers; instead, it is still "*axial-prostereogenic*".[4, 5] Reaction with external oxygen nucleophiles—for example, methanolic sodium hydroxide solution—results in opening of the lactone ring and formation of the atropisomeric esters **3a** and **3b** (Scheme 1). The desired atropdiastereomer **3a** can be transformed into ancistrocladisine (**1a**), and also isomer **3b** can be recycled, for example, by recyclization to the axial-prostereogenic lactone **2**.[4, 5]

1a

Scheme 1. Atropdiastereoselective ring opening of the axial-prostereogenic lactone **2** (for details see Table 1).

Still more interesting would be the stereoselective control of this ring-opening step, which has proceeded so far without significant asymmetric induction. Here we report on the *kinetically controlled atropdiastereoselective ring opening of the axial-prostereogenic lactone* **2** with oxygen nucleophiles for the directed synthesis of ancistrocladisine (**1a**).

The results of the ring-opening experiments are summarized in Table 1. In determining the atropisomeric ratios, not only the esters themselves but also, in particular, their reduction products, alcohols **3a',b'** (CH_2OH instead of CO_2R), were used, because, on the one hand, this approach simplifies the analysis and, on the other, these alcohols afford a preparatively more relevant picture of the efficiency of the procedure, since they are configurationally stable. Particularly noteworthy are the atropisomeric excesses achieved—under kinetic control—with even such small oxygen nucleophiles as methanol and, especially, isopropyl alcohol.

[**] Acetogenic Isoquinoline Alkaloids, Part 15. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank *L. Kinzinger* for technical assistance. Part 14: [5].

Table 1. Atropisomeric ratios obtained in the reaction **2** → **3a** + **3b**.

"RO$^{\ominus}$"/solvent [a]	Reaction time	Ratio [c] **3a**:**3b**
$CH_3ONa/MeOH$	15 s	15.3:1
$CH_3ONa/MeOH$	5 min	1.3:1
$CH_3OH/NaHCO_3$ [b]	60 min	3.3:1
i-C_3H_7OK/i-C_3H_7OH	10 s	20.9:1
	22 h	1:1.1
Li-(+)-mentholate/THF	10 min	23.2:1
Li-(−)-mentholate/THF	10 min	1:1.8

[a] The reactions were carried out with 0.06 mmol of lactone **2** and 2.5 equivalents of the oxygen nucleophile in 10 mL of solvent at room temperature. The reaction mixture was subsequently acidified with concentrated hydrochloric acid and evaporated under vacuum. Analysis was performed after conversion of esters **3a, b** to alcohols **3a',b'** by treatment with $LiAlH_4$ in tetrahydrofuran. [b] Ten equivalents of sodium hydrogen carbonate were used. [c] The atropisomeric ratio was determined by analytical HPLC (Lichrosorb Si60 (Knauer AG), $CH_2Cl_2/MeOH/NEt_3$ = 99.6/0.2/0.2; the more rapidly eluting alcohol has the configuration of ancistrocladisine (**1a**).

Relatively small in comparison to the internal asymmetric induction is the effect exerted by the absolute configuration of the *O*-nucleophile mentholate. Even in the best case, the atropisomeric excesses obtained are hardly higher than those obtained with, for example, isopropoxide. Thus, taking into consideration the availability and separability of the oxygen nucleophile as well as the stability of the respective esters **3a,b** to isomerization, the reaction with isopropoxide is overall preferred for stereoselective ring opening on a preparative scale (e.g., on a gram scale): isolated overall yield 83%; **3a**, R = i-C_3H_7, amorphous, $[\alpha]_D^{25} = -4.0$ ($c = 0.47$, $CHCl_3$); **3b**, R = i-C_3H_7: m.p. 145–147 °C, $[\alpha]_D^{25} = -84.7$ ($c = 0.38$, $CHCl_3$).

The ring-opening reaction described here—the key step in the atropisomer-selective synthesis of ancistrocladisine (**1a**)—allows the first directed transformation of an easily accessible prostereogenic biaryl axis into a stereogenic axis of defined configuration by stereoselective attack on a prostereogenic *center* linked to the axis, the lactone carbonyl group.[6] To the best of our knowledge, this principle makes possible the *first stereoselective synthesis of a biaryl natural product in which the biaryl axis is flanked on one of the rings by two identical ortho substituents* (two OCH_3 groups).[7]

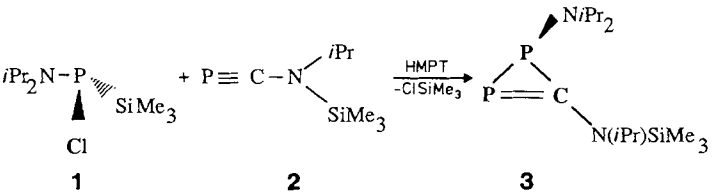
Synthesis and Structure of a 1*H*-Diphosphirene**

By *Edgar Niecke,* Rainer Streubel, Martin Nieger,* and *Dietmar Stalke*

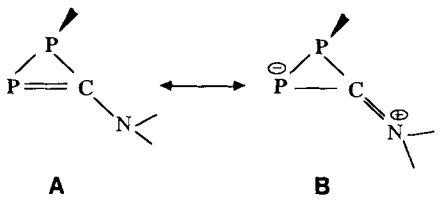


Dedicated to Professor Gerhard Fritz on the occasion of his 70th birthday

Phosphirenes, both in the 1*H*-form **I** as well as in the thermodynamically less favorable 2*H*-form **II**, have become well known in recent years through the works of *Mathey* et al.[1] and *Regitz* et al.[2] Replacement of a methylene group in **I** and **II** by a two-coordinate phosphorus atom leads to the previously unknown diphosphirenes **III** and **IV**, respectively (Scheme 1). As investigations on α-functional aminophosphanes have shown, halo(silyl)phosphanes such as **1** and compounds with polar double bonds react with formation of three-membered ring systems.[3] By extension of this synthetic principle to the P–C triple-bond system we have now gained access to **3**, the first 1*H*-diphosphirene **III**.[4]

Scheme 1. Phosphirenes and diphosphirenes; the lines symbolize bonds to arbitrary substituents.

The heterocycle **3**, accessible under mild conditions upon reaction of the functionalized aminophosphane **1**[5] with the phosphaalkyne **2**[6], is obtained as an extremely air-sensitive, deep-red liquid. By low-temperature crystallization from pentane, **3** can be obtained as a crystalline solid (m.p. −12 to −10 °C).



The composition and constitution of the compound are confirmed by elemental analysis, ^{31}P-, ^{1}H-, ^{13}C-NMR[8] and mass spectra[7] and by X-ray structure analysis. The occurrence of two pairs of signals in the ^{31}P-NMR spectrum is consistent with the presence of a diastereomeric pair (ratio 3:1). The position of the aminophosphane-phosphorus signal ($\delta = -118.7$ (−116.3)) corresponds to that of comparably substituted 1*H*-phosphirenes.[9] Unusual, on the other hand, is the high-field position of the σ^2-phosphorus signal

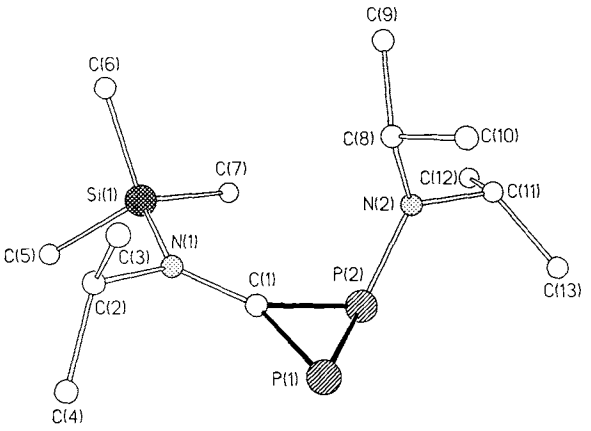
(14.9(4.6)) compared to the positions of the signals of other three-membered ring systems containing a phosphaalkene moiety.[2, 10] This would indicate substantial participation of resonance structure **B** as well as that of resonance structure **A** in the ground state of **3**. In any case, a comparison with the shielding of the ^{31}P nucleus in 2-amino-1,3-diphosphapropenes[11] suggests such an interpretation. Furthermore, the hindered rotation about the exocyclic C–N bond attributed to a participation of resonance structure **B** would also explain the occurrence of the diastereomeric pair recognizable in the NMR spectra.

A **B**

The presence of a four-electron 3-center (4e, 3c) PCN-p_π bond system is strongly supported by the result of the X-ray structure analysis (Fig. 1). The almost planar arrangement



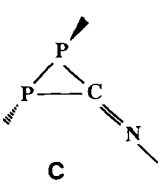


Fig. 1. Crystal structure of **3** with selected bond lengths [pm] and angles [°]: P(1)-C(1) 170.2(4), P(2)-C(1) 178.7(4), P(1)-P(2) 221.8(1), P(2)-N(2) 170.2(3), N(1)-C(1) 135.0(4); P(2)-P(1)-C(1) 52.3(1), P(1)-P(2)-C(1) 48.9(1), P(1)-P(2)-N(2) 111.5(1) [13].

of the P(1)–C(1)–N(1)–Si(1) atoms (dihedral angle: 178.6°) enables an effective π-donation of the amino nitrogen atom, which is manifested in the observed shortening of the C(1)–N(1) bond (135.0(4) pm) and stretching of the P(1)–C(1) bond (170.2(4) pm). Such a bonding situation is also found in the 2-amino-1,3-diphosphapropene $PhP=C(PPhSiMe_3)$-$N(o\text{-}ClC_6H_4)SiMe_3$, in which the P–C bond length (170.2 pm)[11] compares with that in **3**.

The weakening (stretching) of the P–C double bond brought about by the exocyclic π-donor is compensated by a comparable strengthening (shortening) of the P(2)–C(1) bond (178.7(4) pm). This correlation of the two P–C bond lengths and the shortening of the exocyclic C–N bond point to the structural transformation of the amino-1*H*-phosphirene into the thermodynamically more stable diphosphirane imine **C**.[12]

C

Experimental

3: 1.2 g (6.94 mmol) of **2** was cooled to 0 °C and slowly treated with stirring with 1.37 g (5.71 mmol) of **1**. The mixture was then treated with three drops of hexamethylphosphoric triamide and the cooling jacket removed. Stirring of the mixture was continued for ca. 1.5 h at room temperature and then all volatile components were removed in a high vacuum. The red, oily residue was taken up in a small amount of *n*-pentane and, after storage for 1 d at − 80 °C, orange crystals of **3** were obtained; these were isolated at low temperature (1.18 g, 67.9%). The melting point was found to be −12 to −10 °C.

First Isolation of Allenyl Azides**

By *Klaus Banert** and *Manfred Hagedorn*

Whereas numerous synthetic methods are known for vinyl azides,[1] all attempts so far to isolate allenyl azides have failed.[2-4] Recently, we showed that propargyl azides of type **1** isomerize to the allenyl azides **2** by migration of the azide group.[5] These species proved to be short-lived intermediates that cyclized rapidly to the triazafulvenes **3**, which could be trapped by nucleophiles such as methanol[6] to afford 1,2,3-triazoles of type **4**. The transformation of propargyl azides into allenyl azides does not only occur by shift of the azido group, but also through base catalysis (prototropic rearrangement).[7] Preparatively interesting yields of 1,2,3-triazoles, which are also formed in the subsequent reactions of azidobutatriene,[8] are thereby obtained.

Here we report on the first spectroscopic characterization and the first isolation of allenyl azides, thereby showing that these species are not merely reactive intermediates. Dilute solutions of the propargyl azides[9] **1a–e**[9a, 10, 7, 8, 12, 5] in $CDCl_3$ or [D_4]methanol at 40 °C give polymeric triazoles or monomeric **4**, respectively. ^1H and ^{13}C NMR spectroscopic monitoring of the reactions reveals signals of allenyl azides **2a** (≤3%), **2b** (≤1%), **2c** (≤3%), **2d** (≤7%), and **2e** (≤8%) (Table 1). In each case, the ratio **1/2** remains almost constant during the reaction; therefore, **2** is a short-lived (quasi-stationary) intermediate. The donor substituent R = Me obviously accelerates the ring closure to **3b**, thereby allowing only a small concentration of **2b** to build up. By contrast, the concentration of **2b**, which bears the weak acceptor substituent R = CH_2Cl, reaches a higher value. In concentrated solution, **1a** displays a particular tendency toward 1,3-dipolar cycloaddition;[13] dimers **5** and **6** are thereby formed in a ratio of approximately 1:3.[14] Starting from **1f**,[15] it is possible to detect allene **2f** (≤0.8%), which does not cyclize to **3f**, but rather rearranges rapidly to **7**. Thus, the intermediacy of **2f** in the known[15, 16] reaction **1f** → **7** is demonstrated for the first time.

The azides **2a–e** could be separated from the isomeric propargyl compounds by preparative gas chromatography (25–50 °C). All allenyl azides were characterized spectroscopically (Table 1). Particularly informative are the long-range couplings in the ^1H NMR spectra (^4J = 6.4 Hz; ^5J = 1.8–3.3 Hz), the signals of the central allene carbon atoms in the ^{13}C NMR spectra ($\delta \approx 200$), and the intense azide band in the IR spectra ($\tilde{\nu} \approx 2100\ cm^{-1}$). IR absorptions for the allene moiety, which are often weak, could not be found for **2a–d**.[17] The pure allenes **2c** and **2d**, colorless liquids, are stable for a short period at room temperature. On the other hand, **2a** had to be isolated in a GC trap cooled to −80 °C and then diluted with solvent as rapidly as possible. Thus, whereas pure **2a** proved to be very unstable, solutions of this substance can be used at room temperature for NMR spectroscopy.

In [D_4]methanol, **2a–d** afford the triazoles **4** quantitatively in a first-order reaction; the backward reaction to **1** was not observed. A plot of the rate constants versus the Taft σ^*

Table 1. Selected physical data for **2a–f**, **5**, and **6** [a].

2a: IR (CCl_4): $\tilde{\nu}$ = 2170, 2110, 1330, 1255, 900. ^1H NMR (CD_3OD): δ = 5.46 (d, J = 6.4, 2H), 6.01 (br. t, $J \approx 6$, 1H). ^{13}C NMR (CD_3OD): δ = 88.0 (td, J = 170, 6.5; C-3), 100.5 (dt, J = 194, 9; C-1), 204.8 (s; C-2). [**] Reactions of Unsaturated Azides, Part 9. This work was supported by the Deutsche Forschungsgemeinschaft. We thank *E. Reißaus* and *K. Vrobel* for careful assistance. Part 8: [8].

values[18] (Fig. 1) shows that acceptor substituents retard the ring closure to **3** and therefore the formation of **4**. In the absence of nucleophiles—for example, in chloroform solution—the allenyl azides polymerize. In the presence of tributyl(hexadecyl)phosphonium azide[19] in chloroform, **2d** is transformed into **2f**, which rapidly rearranges to **7** (maximum proportion of **2f**, 30%).

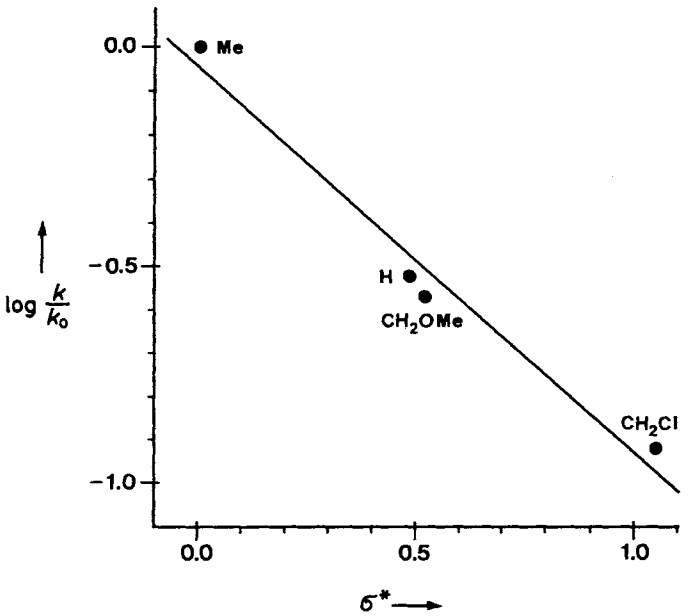

Fig. 1. Plot of $\log(k/k_0)$ versus Taft σ^* values for the reaction **2** → **4** in CD_3OD at 29 °C; $k(\mathbf{2a}) = 2.81 \times 10^{-5}\ s^{-1}$, $k_0 = k(\mathbf{2b}) = 9.34 \times 10^{-5}\ s^{-1}$, $k(\mathbf{2c}) = 2.53 \times 10^{-5}\ s^{-1}$, and $k(\mathbf{2d}) = 1.13 \times 10^{-5}\ s^{-1}$ give $\varrho^* = -0.87$.

Our results confirm that allenyl azides are better stabilized by acceptor substituents than by sterically demanding[2b] alkyl substituents which act as donors. The title compounds are of interest as potential precursors of the still unknown methylene azirines.[2b, c]

Indications of Cesium in a Higher Oxidation State**

By *Klaus Moock* and *Konrad Seppelt**

The idea that alkali metals could exist in a higher oxidation state than +1 is older than the first demonstration of noble gas compounds with oxidation states up to +8. Earlier reports on the preparation of KF_2, RbF_3 and CsF_3,[1, 2] however, proved to be completely false; the authors had presumably mistaken KHF_2 $RbClF_4$, and $CsClF_4$ for these compounds.[3, 4] *R. Hoppe* et al. estimated the enthalpy of formation of CsF_3 to be about $-85\ kJ\ mol^{-1}$.[5, 6] Because of the high lattice energy of CsF, the decomposition into CsF and F_2 should be extremely exothermic ($-445\ kJ\ mol^{-1}$). Although the lattice energy should remain nearly constant on fluorination of $Cs^{\oplus}SbF_6^{\ominus}$ to $CsF_2^{\oplus}SbF_6^{\ominus}$, all such attempts failed completely.[7] Cocondensation of KF, RbF, and CsF and fluorine in argon matrices affords compounds whose IR spectra can be interpreted in terms of the presence of $F_3^{\ominus}$,[8] in complete analogy to the well known trihalides. Thus, attempts to synthesize higher valence alkali-metal compounds with fluorine have so far failed.

During cyclovoltammetric investigations on $OTeF_5$-compounds[9] we observed an electrochemical activity in the system $Cs^{\oplus}OTeF_5^{\ominus}/CH_3CN$ in the extremely oxidative region at ca. +3 V (versus SCE). By painstakingly accurate tests we were able to show that this oxidation, which is still irreversible at −35 °C, is dependent upon the cesium concentration but cannot be attributed to the solvent, the electrolyte or the anion $OTeF_5^{\ominus}$. Thus, $K^{\oplus}OTeF_5^{\ominus}$, $Rb^{\oplus}OTeF_5^{\ominus}$, $HOTeF_5$ and $(n\text{Bu})_4N^{\oplus}OTeF_5^{\ominus}$ are inert in the oxidative region. The findings are always reproducible, providing a vacuum-tight electrochemical cell[10] and extremely pure acetonitrile or propionitrile are used.[11] To support the assumption that

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Dr. *U. Zenneck*, Universität Heidelberg, for recording the ESR spectra.

$Cs^{\oplus}$ is oxidized, we have also used cesium as $Cs^{\oplus}PF_6^{\ominus}$ and in the complexed forms as $[Cs^{\oplus}([18]crown-6)]PF_6^{\ominus}$ **1** and $[Cs^{\oplus}(crypt.2.2.2)]PF_6^{\ominus}$ **2**. The crown ethers/cryptands employed are obtainable in high purity, and they are "too small" for $Cs^{\oplus}$, so that a more stable complex is present after the oxidation through ion contraction. In fact, the oxidation takes place at a somewhat lower potential (+2.7 V in the case of the cryptate versus $\geq +3.0$ V in the case of $Cs^{\oplus}PF_6^{\ominus}$) (Table 1). The decrease of ca. 0.3 V through the cryptands

Table 1. Electrochemical data of $Cs^{\oplus}PF_6^{\ominus}$, $[Cs^{\oplus}([18]crown-6)]\ PF_6^{\ominus}$ **1**, and $[Cs^{\oplus}(crypt.2.2.2)]\ PF_6^{\ominus}$ **2**.

[a] $w = 1.3$ KHz, $\Delta E = 10$ mV. [b] All potentials are measured against $FeCp_2/FeCp_2^{\oplus}$ as internal standard referred to SCE. [c] Half-widths of the curves. [d] 0.1 mol L^{-1} in acetonitrile; supporting electrolyte $Et_4N^{\oplus}PF_6^{\ominus}$, three-electrode system (platinum).

corresponds to a change of energy of 29 kJ mol^{-1} and thus has the order of magnitude of a typical chelate effect. Once again it could be shown that the complex ligands, free or together with $K^{\oplus}$ or $Rb^{\oplus}$, are not oxidized. In the most favorable case of $[Cs^{\oplus}(crypt.2.2.2)]PF_6^{\ominus}$ **2** an oxidation could even be detected by alternating current polarography (Fig. 1).

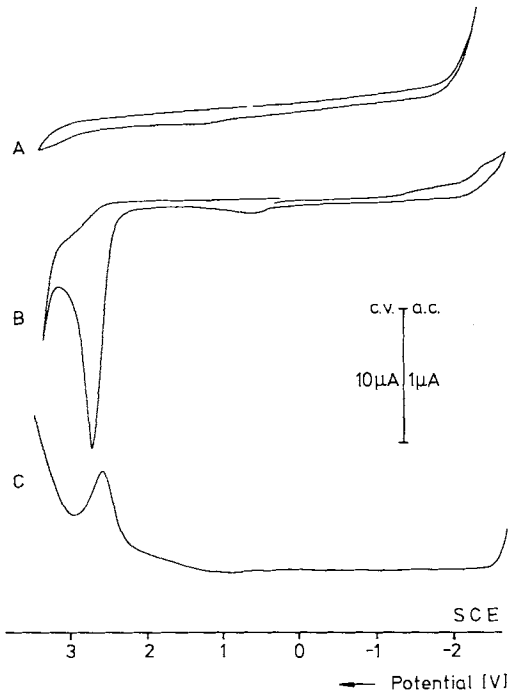

Fig. 1. Cyclovoltammogram (cv) of Kryptofix-2.2.2® (A) and $[Cs^{\oplus}(crypt.2.2.2)]PF_6^{\ominus}$ **2** (B), and alternating current polarogram (ac) of **2** (C).

H. Ahrens had already stated as long ago as 1956 that oxidations by chemical methods are possible if the relevant difference in ionization energy of the gas particle does not exceed 2400 kJ mol^{-1}.[12] In the case of $Cs^{\oplus}/Cs^{2\oplus}$ this is 2046 kJ mol^{-1}. From thermodynamic considerations and by analogy, however, it follows that not $Cs^{2\oplus}$ but at best $Cs^{3\oplus}$ should be stable. The gas reaction $2Cs^{2\oplus} \rightleftharpoons Cs^{3\oplus} + Cs^{\oplus}$ (856 kJ mol^{-1}) is exothermic and should not reverse, even upon solvation, because of the same total charge. Hence, we expect immediate further oxidation of $Cs^{2\oplus}$ to $Cs^{3\oplus}$. It would then also be understandable why ESR measurements were unsuccessful in simultaneous electrochemical oxidations. ($Cs^{2\oplus}$ with a nuclear spin 7/2 (100%) would be an excellent ESR probe—providing a minimum concentration of ca. 10^{-9} mol L^{-1} is achieved.) The isoelectronic system Xe/XeF_2, which is also irreversible, has a redox potential of 2.2 V in acid solution.[13] In this respect the higher values found for $Cs^{\oplus}/Cs^{2\oplus(3\oplus)}$ are fully consistent with expectation.[14]

A major argument against the conclusions drawn from the above findings is that an oxidation of the solvent, of the electrolyte, or of the cryptand takes place only with $Cs^{\oplus}$ catalysis. We do not refute that such oxidations proceed as secondary processes, but we cannot imagine a $Cs^{\oplus}$ catalysis without prior oxidation, because complex formation with the positive center (here $Cs^{\oplus}$) usually stabilizes the complex ligands against oxidation.

Although the isolation of a $Cs^{3\oplus}$ species has still to be reported, from the present results it would seem more feasible than was hitherto imagined. The use of cesium salts as oxidation transfer reagents in electrochemical processes is also conceivable.

Experimental

Electrochemical measurements: PAR 173 potentiostat, PAR 5208 lock-in-amplifier and PAR 175 programer, closed electrochemical cell [10]. Purification of acetonitrile as described in Ref. [11]; preparation of $OTeF_5$ salts according to Ref. [15].

$[Cs^{\oplus}(crypt\ 2.2.2)]PF_6^{\ominus}$: 0.57 g (2.05 mmol) of $CsPF_6$ and 0.77 g (2.05 mmol) of dried Kryptofix-2-2-2® (4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane) were each transferred in a glove box into separate limbs of a two-limbed flask fitted with magnetic stirrers. 5 mL of acetonitrile were distilled under vacuum into each limb. The two solutions were then united in the first limb of the flask and stirred for 30 min at room temperature. After decantation of the clear solution into the second limb of the flask the solvent was removed in a vacuum. There remained a white crystalline solid in almost quantitative yield. Correct elemantal analysis. IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 1296, 1259, 1234, 1170, 1102, 1074, 1065, 1051, 1018, 945, 926, 910, 873, 840 ($\nu_3PF_6^{\ominus}$), 774, 746, 557 ($\nu_4PF_6^{\ominus}$), 521, 507. [14] An accurate estimation of the redox potential $Cs^{\oplus}/Cs^{3\oplus}$ was not possible. True, the ionization potentials and the solvation energy of $Cs^{\oplus}$ are known, but $Cs^{3\oplus}$ is presumably not spherical-shaped but disk-shaped with a radius ratio of 1:2. The solvation energy of a charged particle depends approximately on r^{-1}. All desired redox potentials can be predicted when $60 \leq r_1$, $r_2 \leq 120$ pm.

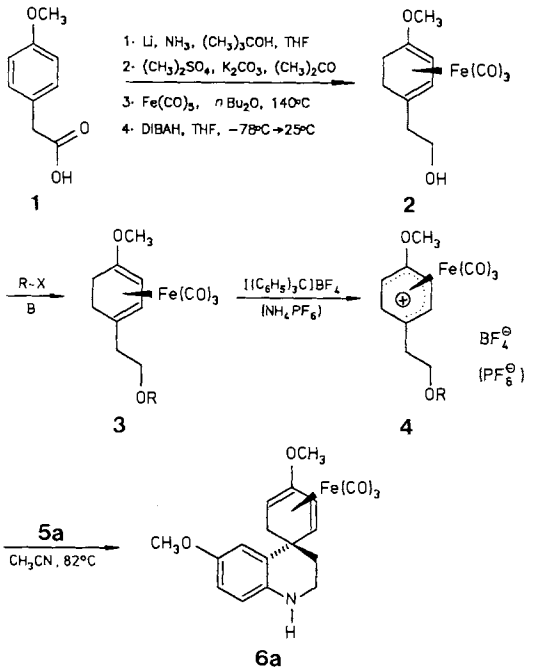
Iron-Mediated Diastereoselective Spiroannelation to the Spiro[1,2,3,4-tetrahydroquinoline-4,1′-cyclohexane] System and a Novel Rearrangement to 2,3-Dihydroindole Derivatives**

By *Hans-Joachim Knölker,** *Roland Boese*, and *Konrad Hartmann*

The use of iron-diene complexes in the synthesis of heterocycles recently opened up a versatile entry to carbazole derivatives.[1] We have now extended this concept to the synthesis of other nitrogen-heterocycles. Cyclization, instead of being carried out oxidatively, as hitherto, was now achieved via nucleophilic substitution. This permitted closure of the C–C bond and the C–N bond in a one-pot reaction and thus the stereoselective synthesis of spirocycles.



The discorhabdins[2] and prianosins[3] recently isolated from marine sources are distinguished by their high cytotoxic and antimicrobial activity. The discorhabdin D described only recently[4] also exhibits a strong antitumor activity in vivo. A common feature of these compounds is a spiro[1,2,3,4-tetrahydroquinoline-4,1′-cyclohexane] substructure. We report here on an iron-mediated diastereoselective entry to this ring system.

The addition of nucleophiles to tricarbonyl(η^5-1-alkyl-4-methoxycyclohexadienylium)iron cations enables the stereocontrolled synthesis of quaternary centers.[5] We have recently been able to show that iron-complexed cyclohexadienylium cations are very effective as mild electrophiles for the reaction with highly substituted electron-rich and thus oxidation-sensitive arylamines.[11] With the iron-complex salts **4** we have now succeeded for the first time in using this electrophilic substitution of aromatic systems for the diastereoselective generation of quaternary carbon atoms. Combination of this reaction with the subsequent in situ nucleophilic substitution of the leaving group in the side chain of **4** affords a new method for spiroannelation.

[**] Transition-metal Diene Complexes in Organic Synthesis, Part 3. This work was supported by the Volkswagen foundation and the Deutsche Forschungsgemeinschaft. We thank Dr. *V. Wray*, Gesellschaft für Biotechnologische Forschung, Braunschweig-Stöckheim für the ^{13}C and 2D-NMR spectra and Dr. *K.-H. Geiss*, BASF AG, Ludwigshafen, for a supply of pentacarbonyliron.—Part 2: [1b].

The iron-complex **2** is readily accessible in four steps from *p*-methoxyphenylacetic acid **1**.[6] Compound **2** is converted by *O*-functionalization (**3**) and hydride abstraction into the complex salts **4**. The spiroannelation with *p*-anisidine **5** leads diastereoselectively to the spiro[1,2,3,4-tetrahydroquinoline-4,1′-cyclohexane] derivative **6a** (Schema 1). Cyclization to

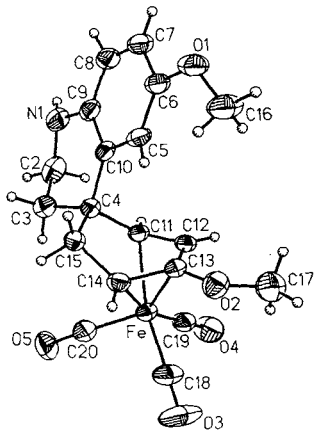
Scheme 1. DIBAH = diisobutylaluminum hydride, B = base.

6a still takes place even with the methoxy derivative **4a**. A systematic optimization of the spiroannelation could be achieved by varying the leaving group in the side-chain (Table 1). In some cases (**4a, c, d**), owing to the stability of the salt, the hexafluorophosphate had to be used. The route via the *p*-nitrobenzoate derivatives **3f** and **4f** proved to be the best over all three steps (**2** → **3** → **4** → **6a**).

Table 1. Variation of the leaving group R in the complex salt **4**, and results of the spirocyclization to **6a**.

R	**3**, Yield [%]	**4**, Yield [%]	**6a**, Yield [%]
CH_3	**3a**, 96 [6]	**4a**, 69 (PF_6^-) [6]	20
CH_3SO_2	**3b**, 94	**4b**, 77	53
4-$CH_3(C_6H_4)SO_2$	**3c**, 87	**4c**, 27 (PF_6^-)	54
CH_3CO	**3d**, 98 [6]	**4d**, 74 (PF_6^-) [6]	68
CF_3CO	**3e**, 80	**4e**, 80	53
4-$NO_2(C_6H_4)CO$	**3f**, 98	**4f**, 92	80

The structure of **6a** follows from spectroscopic data (^1H-, ^{13}C- and COSY-NMR spectra) and an X-ray structure analysis (Fig. 1).[7] The latter revealed that the aryl ring is *anti* to the $Fe(CO)_3$ group referred to the cyclohexadiene ring plane. This can be explained by the stereodirecting effect of the $Fe(CO)_3$ group (*anti* selectivity). With the amines **5b**–**5e** the same diastereoselectivity is observed in the spiroannelation as with **5a** (Scheme 2, Table 2). The stereochemistry was established by comparison of the ^1H- and ^{13}C-NMR spectra of **6b**–**6e** with those of **6a**. In addition, the synthesis of **6d** clearly demonstrates that the reaction with 3,4-disubstituted anilines is regiospecific.



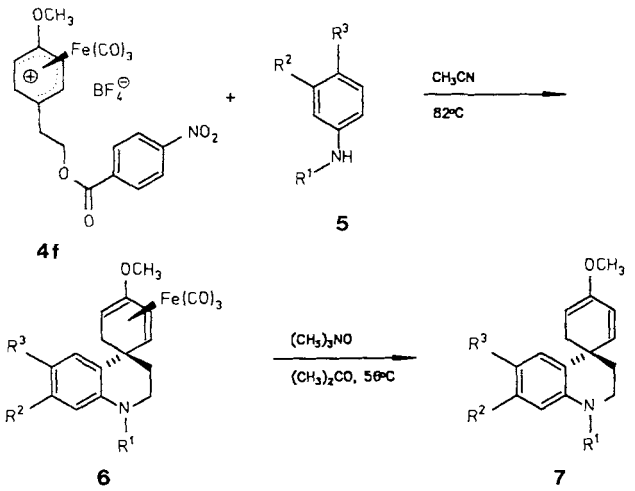


Fig. 1. Structure of **6a** in the crystal [7]. Selected bond lengths [Å]: Fe-C11 2.096(3), Fe-C12 2.054(4), Fe-C13 2.099(3), Fe-C14 2.116(4), C4-C11 1.529(5), C11-C12 1.432(6), C12-C13 1.412(6), C13-C14 1.437(6), C14-C15 1.516(6), C4-C15 1.561(6).

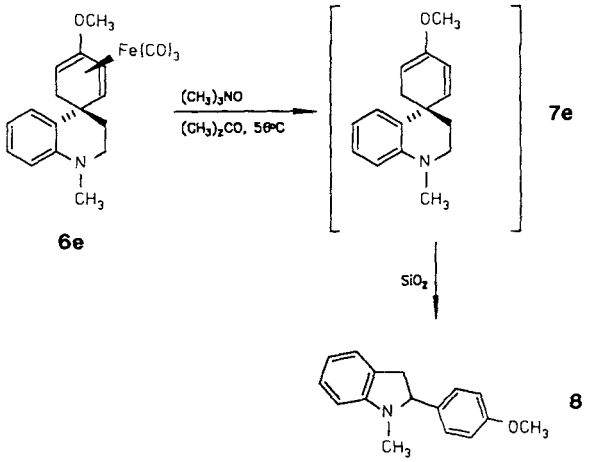
Scheme 2.



The complexes **6a–6d** can be demetalated with trimethylamine *N*-oxide[8] to give **7** (Scheme 2, Table 2). The yields of this reaction are strongly dependent on the reaction conditions (solvent, temperature, reaction time). Nevertheless, an optimization of the yields for each individual case was not carried out, since the metal complex **6** and its free ligand **7** each have the same R_f value. Thus all demetalations were performed under a standard set of conditions (10 equiv. Me_3NO, Me_2CO, 56 °C, 2–5 h).

Table 2. Yields of the spirocycles **6** and their demetalation to **7/8**.

5	R^1	R^2	R^3	**6**, Yield [%]	**7/8**, Yield [%]
5a	H	H	OCH_3	**6a**, 80	**7a**, 66
5b	H	H	H	**6b**, 55	**7b**, 47
5c	H	H	CH_3	**6c**, 58	**7c**, 48
5d	H	CH_3	CH_3	**6d**, 53	**7d**, 58
5e	CH_3	H	H	**6e**, 48	**8**, 68

Acid hydrolysis of the 2-methoxydiene moiety in **7a** to the corresponding enone affords a promising substrate for stereoselective Michael additions. Recomplexation of the free ligand **7a** (nonacarbonyldiiron, THF, 67 °C) leads exclusively to the *anti*-configurated complex **6a** again.

During the demetalation of **6a** a novel rearrangement occurs with ring contraction and aromatization to the dihydroindole derivative **8** (Scheme 3, Table 2). This reaction

Scheme 3.

proceeds via the free ligand **7e** which is oxidized to **8** during chromatography on silica gel. The structure of **8** was derived from spectroscopic data (^{1}H-, ^{13}C-, COLOC- and inverse ^{1}H-^{13}C-correlated NMR spectra). The driving force behind this rearrangement is undoubtedly aromatization of the cyclohexadiene ring. The influence of the substitution pattern of the arylamine component and the mechanism of this rearrangement are currently under investigation.

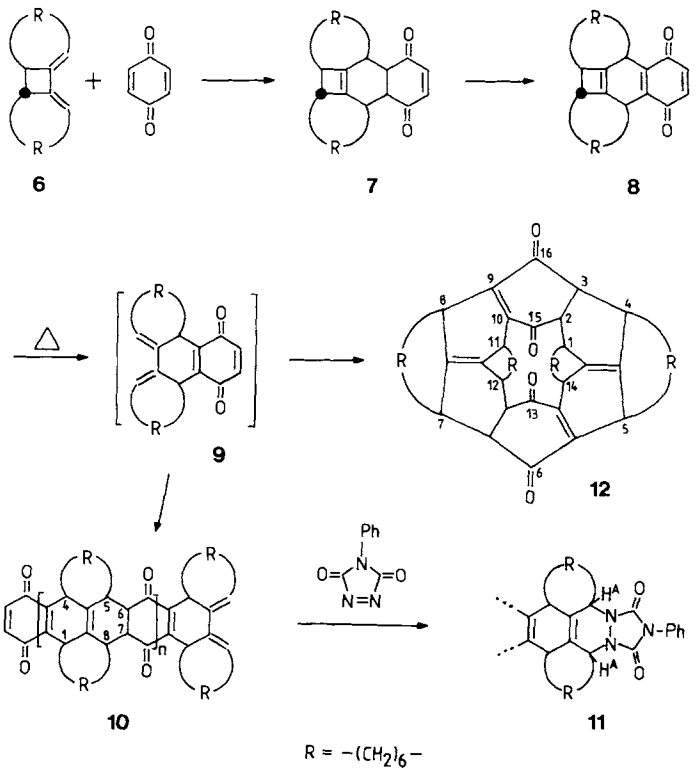
Double-Stranded Molecules: A [6]Beltene Derivative and the Corresponding Open-Chain Polymer**

By *Adelheid Godt, Volker Enkelmann,* and *Arnulf-Dieter Schlüter**



[n]Beltenes **1**, [n]collarenes **2** and [n]cyclacenes **3** have a double-stranded structure of linearly annelated, partly or completely unsaturated six-membered rings.[1] Owing to their cyclic, belt-like structure they are of interest, inter alia, for the study of orbital interactions and host/guest phenomena.[1, 2] A few representatives of this class of compounds recently became accessible, in particular, through the work of *Stoddart* et al.[3] Their open-chain, high molecular weight analogues, for example the ribbon-shaped polymers poly(butane-1,4:3,2-tetrayl) **4** and polyacene **5**, on the other hand, are still unknown, although they should attract great interest, especially from the materials science point of view.[4, 5] We report here on an efficient synthesis of the masked AB-type monomer **8**, which, depending upon the reaction conditions, can be used for the synthesis of the [6]beltene derivative **12** as well as for the synthesis of the corresponding ribbon-shaped polymer **10**. Both compounds are readily soluble, and the structure of **12** has been confirmed by a single-crystal structure analysis.

1 **2** **3** **4** **5**

We recently found that the repetitive Diels-Alder cyclization of bifunctional dienes and bifunctional dienophiles (AA and BB monomers, respectively) is a good method for the synthesis of structurally well-defined ribbon-shaped polymers.[6, 7] In order to gain access to polymers via a route free of stoichiometric problems we searched for an AB-type monomer. Our interest focussed on the compound **8**, which is readily accessible and should be reactive in the sense of the Diels-Alder cyclization.[8] Moreover, it contains flexible alkyl rings which are expected to lead to a significant increase in the solubility of the polymer.[9]

For the synthesis of **8**, the allene dimer **6**,[10] which is readily accessible on a 20 g-scale, was allowed to react with benzoquinone to give the cycloadduct **7** (Scheme 1). This was then oxidized to **8**.[11] When a highly concentrated solution of **8** is heated to 110 °C, an orbital symmetry allowed ring-opening of the cyclobutene ring[12] leads to formation of the required AB-type "monomer" **9**, which then polymerizes.[13] After work-up, an isolable low-molecular weight component and a polymer were obtained (ratio 1:3[14]; total mass balance 90%), the latter of which was assigned the structure **10**.[15] By fractional precipitation monomodally[16] distributed fractions could be obtained with osmometrically (toluene, room temperature) determined molecular weights $\bar{M}_n$ of 8500 (±300) to 116000 (±10000) g mol^{-1} (degree of polymerization $\bar{P}_n$ = 24–330).

6 **7** **8** **9** **10** **11** **12**

$R = -(CH_2)_6-$

Scheme 1.

The addition of the ring-opened monomer (and analogous terminal groups) to the quinoid terminal of the polymer in a growth step should lead to formation of *exo/endo* isomers, each of which can exhibit a different relative arrangement of the alkyl rings. It is therefore not surprising that the polymer **10** consists of a complex mixture of isomers. Its ^{13}C-NMR spectrum (Table 1) shows numerous closely grouped signals which still cannot be assigned individually. These groups lie in the expected shift regions.[17] Particularly informative are the ^{1}H-NMR spectra of low-molecular weight **10** ($n \approx 5$), which is easily accessible by fusion polymerization of **8**.[18] Not only are the typical signals for the polymer clearly recognizable but also the groups of signals for the two termini at $\delta = 5.9$ (diene H atoms) and $\delta = 6.7$ (quinone H atoms),

Table 1. ^{1}H- ($CDCl_3$, 300 MHz) and ^{13}C-NMR data ($CDCl_3$, 75 MHz) of **10** and **12**.

10: ^{1}H-NMR (all signals broad and unstructured): δ = 1.6 (24H), 2.6 (2H), 3.1 (2H), 3.7 (2H); ^{13}C-NMR (assignment via DEPT-sequence): δ = 26.3, 28.8 (CH_2), 32.9 (C-1(4)), 38.1 (CH_2), 43.5 (C-5(8)), 52.7 and 54.3 (C-6(7)), 131.8, 132.9 and 137.3 (C-4a(8a)), 147.1, 148.3, 149.5, 150.7, 151.0 and 151.7 (C-2(3)), 197.6 and 199.7 (C=O).

12: ^{1}H-NMR: δ = 1.15–2.15 (m, 24H), 2.64 (m, 4H; 1-,4-,7-,12-H), 2.86 (m, 4H; 5-,8-,11-,14-H), 3.05 (dd, J = 2.3, 4.2 Hz, 4H; 2-,3-,6a-,12a-H); ^{13}C-NMR: δ = 23.7–38.2 (6t), 37.4 (d; C-5,-8,-11,-14), 45.5 (d; C-1,-4,-7,-12), 53.2 (d; C-2,-3,-6a,-12a), 138.5 (s; C-4a,-7a,-11a,-14a), 154.8 (s; C-5a,-9,-10,-13a), 197.8 (s; C-6,-13,-15,-16).

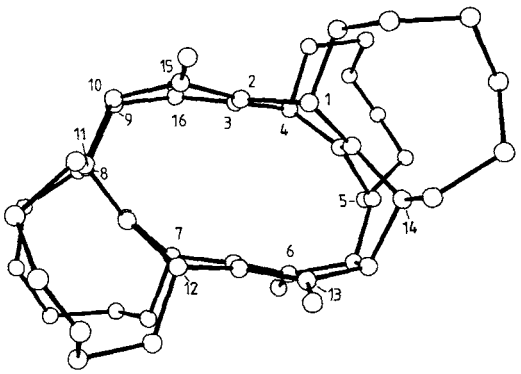
[**] This work was supported by the Bundesministerium für Forschung und Technologie (Project: "Planar Systems"). We thank Prof. Dr. *G. Wegner* for his interest in this work and for his continued support, *R. Dorn* for GPC and osmometric measurements, and *A. Wagner* for carrying out some of the experiments. *A.G.* thanks the Fonds der Chemischen Industrie for a Kekulé fellowship.

which, upon further heating of the material in solution disappear with a concomitant increase of the intensity of the polymer signals and of the molecular weight (GPC). Moreover, the dienoid terminal groups can be detected chemically by addition of *N*-phenyltriazoledione with formation of **11**.[19]

The low-molecular weight component, which was formed as by-product in the polymerization, was identified as the [6]beltene derivative **12**, the cyclic dimer of "**9**" (Table 1). This compound precipitated in stereochemically pure form (^{1}H- and ^{13}C-NMR spectra); the arrangement of the alkyl rings was established by a single-crystal structure analysis.[20] Figure 1 (ORTEP) shows a slightly flattened,[1a] double-stranded cyclic species, which according to the space-filling model (not shown) has only a small "unusable" cavity in the center. The smallest intramolecular distances between atoms that are not bound to each other are observed between the dihydroquinone rings (C3-C6a 3.70, C2-C12a, 3.47, C4-C5a 3.66, C1-C13a 3.60 Å); they lie in the range of the van-der-Waals distances.



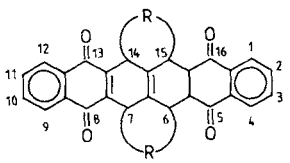


Fig. 1. Structure of **12** in the crystal.

By working in dilute solution it was possible to shift the polymer **10**:dimer **12** ratio from 3:1 to about 1:4 and thus to make the cyclic dimer conveniently accessible in g-amounts—for example, for investigations concerning the aromatizability (yield: 70%).[21]

The spatial shape of polymer **10** is determined by the double stranded structure with its many, presumably irregular kinks, such that a sort of "two-dimensional coil" could result. For investigation of the structure we synthesized the open-chain 2:1-adduct **13** as model compound.[11] This

13

compound (Fig. 2, ORTEP[20]) shows, apart from the benzene rings, a section of the chain of the polymer **10**. The intramolecular distances between the two limbs of the U-shaped adduct **13** lie in the range of the van-der-Waals distances (about 3.5 Å). Extrapolated to the case of polymer **10** this means that the double-stranded main chain is folded back on itself tightly at the corresponding kinks.

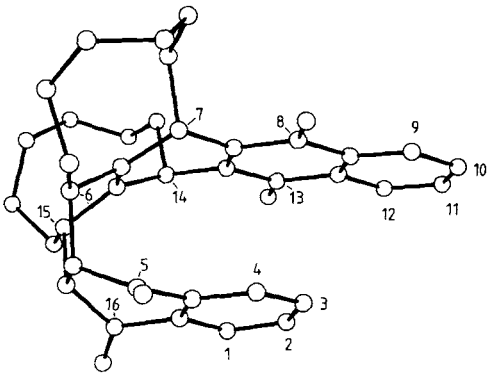

Fig. 2. Structure of **13** in the crystal. Selected distances [Å]: C13a-C16a 3.496(5), C7a-C4a 3.590(5), C7-C5 3.729(5), C14-C16 3.539(5).

Experimental

10: A solution of 3.6 g (10.3 mmol) of **8** in 3 mL of toluene was heated for 41 h at 110 °C, the mixture being diluted after 4 h with 5 mL of toluene. The resulting precipitate (**12**) was removed by filtration on a frit and the polymer recovered from the filtrate by addition of MeOH; yield of **10**: 2.5 g (69%).

12: A solution of **8** (1.62 g, 4.61 mmol) in toluene (300 mL) was heated under reflux for 3 h. After evaporating down the solution, yellowish crystals separated out; yield 1.13 g (70%). M.p. > 260 °C; EI-MS: *m/z* 700 ($M^{\oplus}$, 100%), 350 ($M/2^{\oplus}$, 22%).

[14] Owing to a superposition of signals in the ^{1}H-NMR spectrum of the crude mixture of **10** and **12**, only a rough estimation of the ratio can be given.

[15] Polymer **10** forms transparent, free-standing films which are relatively fragile. Viscosity measurements (toluene, room temperature) on a sample with $\bar{M}_n = 20000$ (vapor pressure osmosis) gave a Staudinger index of $\eta = 0.11$ dL g^{-1} (measurement range: 1.4–0.5 gd L^{-1}). Thermogravimetric measurements (heating rate 5 K min^{-1}; under N_2) show that the degradation proceeds in two steps. Between 280 and 410 °C ca. 25% and from 410–700 °C the remaining 75% of the sample underwent degradation.

[18] When the polymerization is carried out in the melt, the reaction mixture is so viscous, even at very low degrees of polymerization, that growth is brought to a standstill.

[19] The hydrogen atoms of **11** marked with an A appear as unstructured relatively broad signals at $\delta = 4.8$ or $\delta = 4.6$, presumably depending on their stereochemical arrangement.

[20] X-ray structure data of **12** and **13**: Enraf-Nonius CAD-4 diffractometer, room temperature, $Cu_{K\alpha}$ radiation, $\lambda = 1.5405$ Å, graphite monochromator. The structures were solved by direct methods (MULTAN). Empirical absorption correction, anisotropic temperature factors for O and C, refinement of the H atoms in the "riding mode" with fixed isotropic temperature factors. **12**: monoclinic, space group $P2_1/c$, $a = 13.0811(13)$, $b = 13.8608(34)$, $c = 11.1107(12)$ Å, $\beta = 114.602(8)$, $V = 1831.6$ Å^3, $Z = 2$, $\varrho_{calc} = 1.16$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 5.2$ cm^{-1}. 2088 reflections, 873 observed [$I \geq 2\sigma(I)$]. $R = 0.049$, $R_w = 0.053$. **13**: monoclinic, space group $P2_1/c$, $a = 11.1588(6)$, $b = 16.4549(8)$, $c = 17.170(3)$ Å, $\beta = 114.353(10)$, $V = 2872$ Å^3, $Z = 4$, $\varrho_{calc} = 1.29$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 6.12$ cm^{-1}. 4612 reflections, 3230 observed [$I \geq 2\sigma(I)$], $R = 0.053$, $R_w = 0.051$. Further details of crystal structure investigations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54210, the names of the authors, and the journal citation.

[21] In no case was the formation of [n]beltene derivatives with n ≠ 6 observed. GPC diagrams of representative mixtures show, apart from the polymer signal, only one further signal with longer retention time, which is unequivocally assigned to compound **12** by co-injection.

TlSPh and TlS*t*Bu, Thallium(I) Thiolates with Novel Cagelike Structural Units: $[Tl_5(SPh)_6]^{\ominus}[Tl_7(SPh)_6]^{\oplus}$ and $[Tl_8(StBu)_8]$**

By *Bernt Krebs** and *Andreas Brömmelhaus*

Dedicated to Professor Reginald Gruehn on the occasion of his 60th birthday

Very little has thus far been reported about molecular compounds of low-valent main group elements such as In^I, Tl^I, Sn^{II} and Pb^{II} with sulfur as ligand donor atom. This is especially true in the case of the thiolate complexes or mixed-ligand sulfide-thiolates of these elements, which, as oligomers and polymers, could have interesting structures and properties; further, they are of current interest as models for biologically important metal-coordination centers, e.g. in metallothioneins, and for studying the influence of the s^2 configuration of the metals and relativistic effects on reactivity, structure, bonding and possible metal–metal interactions. Although thallium(I) thiolates were first synthesized as long as 40 years ago,[1] their structural characterization has thus far not been possible. Novel electrochemical methods for their synthesis have been described recently.[2, 3] We have now been able to synthesize thallium(I) thiolates in crystalline form by direct reaction of Tl^I-salts with alkali-metal thiolates. As first compounds of this type, it was possible to characterize thallium(I) thiophenolate TlSPh **1** and thallium(I) *tert*-butyl sulfide TlS*t*Bu **2** by their vibrational spectra and by complete structural analyses. The yellow to orange-yellow compounds are sparingly soluble in all the usual solvents, are stable for a few days, but are sensitive to light.[4]

In the case of **1** the X-ray structure analysis[5] showed a remarkable polymeric structure. The highly symmetric crystal structure is made up of two novel cage-like structural units. They have the compositions $[Tl_5(SPh)_6]^{\ominus}$ **1a** and $[Tl_7(SPh)_6]^{\oplus}$ **1b** and are present in equal amounts in the structure; each unit **1a** is coupled with three units of **1b** and vice versa. **1a** has C_3 symmetry and can be described as a distorted octahedral array of sulfur atoms in which five of the eight faces of the octahedron are bridged by trigonal-pyramidally coordinated thallium atoms (Fig. 1, top). In a similar way **1b** (Fig. 1, bottom), which also has C_3 symmetry, consists of an almost regular octahedron of sulfur atoms in which now seven of the eight faces are bridged by trigonal-pyramidally coordinated thallium atoms. Three of these seven thallium atoms of **1b** (Tl6, 6a and 6b) are each addi-

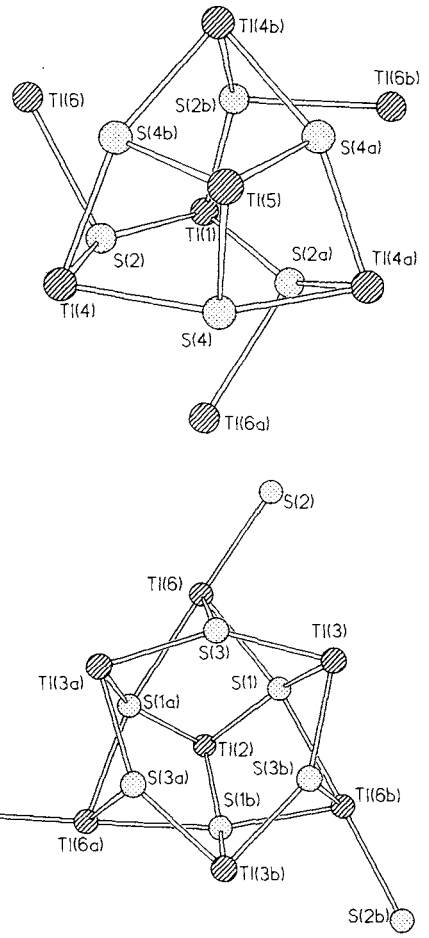

Fig. 1. Above: Structure of the Tl_5S_6 framework in the complex $[TlSPh]_n \equiv [\{Tl_5(SPh)_6\}\{Tl_7(SPh)_6\}]_n$ **1**. The phenyl groups of the SPh ligands have been omitted; Tl(6), Tl(6a), and Tl(6b) are part of neighboring $[Tl_7(SPh)_6]$ groups. Important bond lengths [Å] and angles [°]: Tl(1)-S(2) 2.936(11), Tl(4)-S(2) 2.876(12), Tl(4)-S(4) 2.989(12), Tl(4)-S(4b) 2.910(12), Tl(5)-S(4) 2.932(12); S(2)-Tl(1)-S(2a) 83.6(3), S(2)-Tl(4)-S(4) 91.8(3), S(2)-Tl(4)-S(4b) 79.9(3), S(4)-Tl(4)-S(4b) 77.0(4), S(4)-Tl(5)-S(4b) 77.6(3).—Below: Structure of the Tl_7S_6 framework in **1**. The phenyl groups of the SPh ligands are not shown. S(2), S(2a) and S(2b) are part of neighboring $[Tl_5(SPh)_6]$ groups. Important bond lengths [Å] and angles [°]: Tl(2)-S(1) 2.937(11), Tl(3)-S(1) 2.954(11), Tl(3)-S(3) 2.899(12), Tl(3)-S(3b) 2.891(12), Tl(6)-S(1) 3.163(11), Tl(6)-S(1a) 3.410(12), Tl(6)-S(2) 3.210(11), Tl(6)-S(3) 3.085(13); S(1)-Tl(2)-S(1a) 83.1(3), S(1)-Tl(3)-S(3) 76.3(3), S(1)-Tl(3)-S(3b) 81.7(3), S(3)-Tl(3)-S(3b) 91.0(4), S(1)-Tl(6)-S(1a) 72.5(3), S(1)-Tl(6)-S(2) 106.5(3), S(1)-Tl(6)-S(3) 70.8(3), S(2)-Tl(6)-S(1a) 175.9(3), S(2)-Tl(6)-S(3) 104.2(3), S(3)-Tl(6)-S(1a) 71.9(3).

tionally bound to a sulfur atom of three neighboring units of **1a** (S2, 2a and 2b), so that the Tl6 atoms are the only ones with a distorted pseudo-trigonal-bipyramidal coordination in the structure. The majority of sulfur atoms are surrounded by three thallium atoms and one phenyl C atom (S2,3,4), whereas S1 is bound square-pyramidally to four thallium atoms and one phenyl C atom.

TlS*t*Bu **2** consists of isolated octanuclear $[Tl_8(StBu)_8]$ molecules with the novel structure shown in Figure 2. The

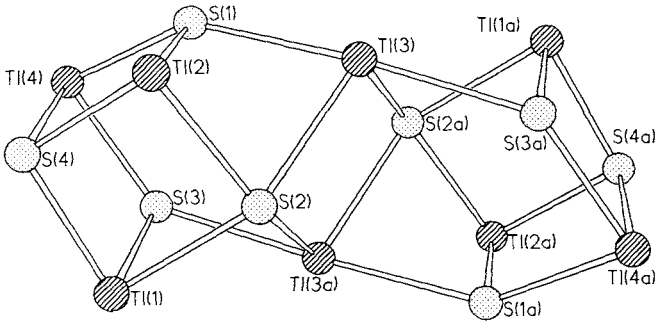

Fig. 2. Structure of the Tl_8S_8 framework in $[Tl_8(StBu)_8]$ **2**. The *tert*-butyl groups of the S*t*Bu ligands are not shown. Important bond lengths [Å] and angles [°]: Tl(1)-S(2) 3.004(5), Tl(1)-S(3) 2.818(7), Tl(1)-S(4) 2.832(8), Tl(2)-S(1) 2.846(7), Tl(2)-S(2) 2.980(8), Tl(2)-S(4) 2.849(7), Tl(3)-S(1) 3.264(6), Tl(3)-S(2) 3.093(6), Tl(3)-S(2a) 2.939(7), Tl(3)-S(3a) 3.193(6), Tl(4)-S(1) 2.830(6), Tl(4)-S(3) 2.863(7), Tl(4)-S(4) 3.030(7); S(2)-Tl(1)-S(3) 75.1(2), S(2)-Tl(1)-S(4) 88.3(2), S(3)-Tl(1)-S(4) 78.3(2), S(1)-Tl(2)-S(2) 83.2(2), S(1)-Tl(2)-S(4) 86.4(2), S(2)-Tl(2)-S(4) 88.4(2), S(1)-Tl(3)-S(2) 74.9(2), S(1)-Tl(3)-S(2a) 95.2(2), S(1)-Tl(3)-S(3a) 165.8(2), S(2)-Tl(3)-S(2a) 91.6(2), S(2)-Tl(3)-S(3a) 104.7(2), S(2a)-Tl(3)-S(3a) 70.6(2), S(1)-Tl(4)-S(3) 80.7(2), S(1)-Tl(4)-S(4) 83.3(2), S(3)-Tl(4)-S(4) 74.4(2).

centrosymmetric molecule consists of two cubane-like $[Tl_3(StBu)_4]$ subunits whose corners are alternately occupied by Tl and S, and in each of which one Tl corner is missing. Both halves of the molecule are coupled via two additional thallium atoms Tl3 and Tl3a with pseudo-trigonal-pyramidal coordination, resulting in formation of a central planar Tl_2S_2 four-membered ring. The thallium atoms of the cubane-like subunits are surrounded trigonal-pyramidally by three sulfur atoms, the sulfur atoms by three thallium atoms and one butyl-C-atom (S1, S3, S4) or tetragonal-pyramidally by four thallium atoms and one butyl-C-atom (S2).

Common features of the structures of **1** and **2** are, as expected, significantly longer Tl–S distances in the TlS_4 polyhedra (2.939–3.410 Å, mean value 3.170 Å) than in the trigonal-pyramidal TlS_3 polyhedra (2.818–3.030 Å, mean value 2.917 Å) and remarkably small S–Tl–S angles of 74.4–88.4° in the TlS_3 groups; the latter indicate repulsive Tl–Tl interactions within the cages and a large steric demand by the lone electron pairs on the Tl atoms. As indicated by the shortest intramolecular Tl–Tl distances of 4.235(3) Å (Tl4 $\cdots$ Tl5) in **1a**, 4.293(2) Å (Tl2 $\cdots$ Tl6) in **1b**, and 3.720(1) Å (Tl2 $\cdots$ Tl3) as well as 4.101(1) Å (Tl1 $\cdots$ Tl3a) in **2**, there are no structural arguments for bonding Tl–Tl interactions. However, there appear to be indications of specific intermolecular (weakly bonding) Tl–Tl interactions in TlS*t*Bu. Here, the stereochemically active lone electron pairs of Tl2 and Tl4 (Fig. 2) are closely neighboring in the channels of the crystal structure, whereby each $Tl_8(StBu)_8$ molecule is in close contact with four others via Tl2 $\cdots$ Tl2′ and Tl4 $\cdots$ Tl4′ distances of 3.864(3) and 3.749(2) Å, respectively.

The $[Tl_5(SPh)_6]^{\ominus}$, $[(Tl_7(SPh)_6]^{\oplus}$ and $[Tl_8(StBu)_8]$ cages have no counterparts in the chemistry of polynuclear metal-ligand systems. In the series of chemically related Tl^I–chalcogen complexes only di- and tetranuclear species have thus far been reported. Thus, thallium(I) methoxide TlOMe has a cubane-like $[Tl_4O_4]$ framework;[6] thallium(I) dithiocarbamates TlS_2CNR_2 contain dinuclear bipyramidal $[TlS_4Tl]$ cages with square-pyramidal coordination of the thallium, which are associated via weak Tl–S bonds in a variety of ways, depending upon the residue R, to give polymeric structures;[7] similarly, dinuclear TlO_2S_2Tl cages are present in the structures of thallium(I) D,L-cysteinate [Tl(D,L-CysH)][8] and thallium(I) tri-*tert*-butoxysilanethiolate [TlSSi(O*t*Bu)$_3$].[9]

Remarkable structural parallels exist between the hepta- and pentanuclear thallium(I) thiolate cages and some cage anions of the homoleptic thiolates of Cu^I and Ag^I, e.g. $[M_4(SR)_6]^{2\ominus}$, $[M_5(SR)_6]^{\ominus}$ and $[M_5(SR)_7]^{2\ominus}$,[10] in which, however, the metal atoms are surrounded linearly by two, or in a trigonal-planar coordination by three sulfur ligands, in contrast to the trigonal-pyramidal or pseudo-trigonal-bipyramidal coordination of the thallium.

Tetrakis(dimethylamino)ethylene Dication: Two CC Singly Bonded and Almost Perpendicularly Twisted $((H_3C)_2N)_2C^{\oplus}$ Carbenium Ions

By *Hans Bock,* Klaus Ruppert, Kurt Merzweiler, Dieter Fenske,** and *Helmut Goesmann*

Dedicated to Professor Edgar Heilbronner

The most simple hydrocarbon with a single π-bond, $H_2C=CH_2$, changes its structure on uptake of the $\pi \rightarrow \pi^*$ excitation energy by twisting of the two molecular halves.[1] Twofold adiabatic ionization requiring considerably higher energy, should produce a dication with a CC single bond between perpendicular $H_2C^{\oplus}$ subunits.[2] To substantiate this prediction, we allowed the fourfold $(H_3C)_2N$-donor-substituted and, therefore, more easily oxidized[3] tetrakis-(dimethylamino)ethylene to react with Cl_2 and Br_2[3,4] and determined the single crystal structures[5] of the resulting dichloride and dibromide salts (Fig. 1), which are stabilized by improved charge delocalization.[6]

Accordingly, the twofold oxidation of the electron-rich tetrakis(dimethylamino)ethylene **1** proceeds via tremendous structural changes (cf. Table 1 and Fig. 1). The two $((H_3C)_2N)_2C^{\oplus}$ molecular halves rotate relative to each other by up to 76° and the CC double bond lengthens to a CC single bond. Simultaneously, the CN single bonds are shortened by 16 pm (!) and the now planar $(H_3C)_2N^{\delta\oplus}$ groups are twisted to different extents out of the two CCN_2 planes. The energetically enforced two electron removal leads—according to geometry-optimized MNDO calculations, the results of which are supported by satisfactory agreement with the measured data—to the changes in charge distribution presented in Scheme 1.

Table 1. Calculated and experimentally determined characteristic structure parameters of tetrakis(dimethylamino)ethylene and its dication.

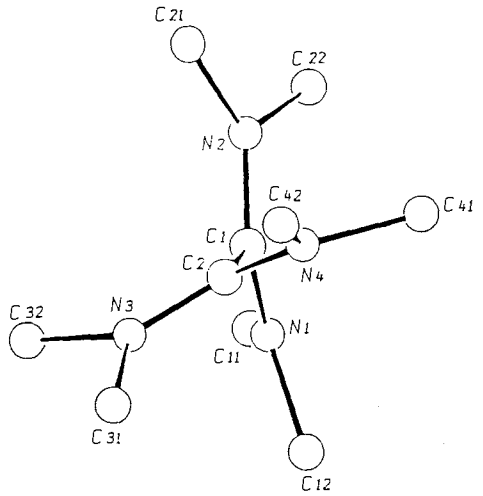
[**] Structures of Perturbed π Systems, Part 2, and Electron Transfer and Ion Pairing, Part 13. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Land Hessen.—Part 1: H. Bock, H.-F. Herrmann, D. Fenske, H. Goesmann, *Angew. Chem. 100* (1988) 1125; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1067; part 12: H. Bock, H.-F. Herrmann, *J. Am. Chem. Soc. 111* (1989) 7622.



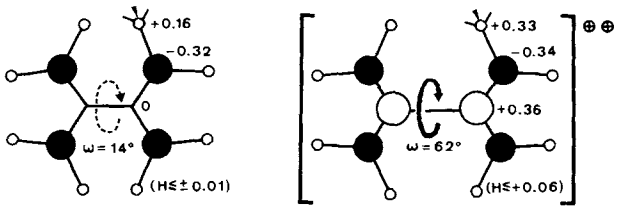


Fig. 1. Structure of the tetrakis(dimethylamino)ethylene dication in its dichloride and dibromide salts [5]. Most important distances [pm] and angles [°] for the dibromide (±1.5 pm, ±1°) and (in brackets) for the dichloride (±0.3 pm, ±0.2°), which contains a twofold crystallographic axis: C1-C2 151.2 (152.4), C1-N1 133.1 (132.0), C1-N2 131.9 (131.5), C2-N3 131.2 (131.5), C2-N4 129.7 (132.0); N1-C1-N2 125 (128.5), N3-C2-N4 127.2 (128.5), C11-N1-C12 113.8 (113.4), C21-N2-C22 115.7 (113.1), C31-N3-C32 115.1 (113.1), C41-N4-N42 112.3 (113.4); N1C1-C2N3 67.2 (75.8), C2C1-N1C11 23.0 (17.1), C2C1-N2C21 18.3 (18.5), C1C2-N3C31 24.4 (18.5), C1C2-N4C41 26.3 (17.1).

Owing to their higher effective nuclear charge, the pyramidally coordinated amino nitrogen centers in the neutral molecule are 'negativated' by the neighboring methyl groups, whereas the electron density at the trigonal planar coordinated carbon π centers remains balanced. In the dication on the other hand, 2/3 of the added positive charges are located at the threefold-coordinated carbon centers of the twisted CC single bond and 4/3 in the eight peripheral methyl groups. Thus, despite an almost constant negative charge on the amino nitrogens each $(H_3C)_2N$ substituent, as predicted by the MNDO valence electron densities (Scheme 1), carries a partial positive charge of about 1/3, i.e. the total charge distribution in the dication is also dominated by the high effective nuclear charge of the nitrogen centers. The Coulomb repulsion between the positive charges, delocalized in each of the $(R_2N)_2C^{\oplus}$ molecular halves, gives rise to both their twisting relative to each other as well as the charging of their "alkyl envelopes".

Scheme 1. MNDO charge distributions for tetrakis(dimethylamino)ethene and its dication.

The structures of the dications (Fig. 1, Table 1) are in accord with numerous other measured data.[3a] The ^{1}H-NMR spectrum,[3a] in contrast to that of the neutral molecule, shows two signals for the methyl group,[7] a result which confirms the fixation, also in solution, of the R_2N substituents due to drastically shortened R_2N–C bonds caused

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/1212-1684 $ 02.50/0

by the π charge delocalization. The vibrational spectrum[3a] exhibits two slightly split $\tilde{\nu}_{CN^{\oplus}}$ bands at 1667 and 1672 cm^{-1}, which corroborate a distorted $(N_2C–CN_2)^{2\oplus}$ skeleton lacking an inversion center. A comparison of the UV excitation energies at 36630 and 48800 cm^{-1} with that of the tetramethylformamidinium ion $((H_3C)_2N)_2CH^{\oplus}$ at 44640 cm^{-1} reveals the continued existence of π interaction between both molecular halves, and supports, also in solution, a twist angle of $0° < \omega(N_2C–CN_2) < 90°$, which reflects the counteracting effects of π conjugation and sterically inflicted rotational distortion.

An extensive literature search concerning analogous structural changes in other ethylene dications provided a hint of twisting ($\omega(S_2^{\oplus}C–C^{\oplus}S_2) \approx 60°$)[8a] in the tetrathiafulvalene dication, and for a dihedral angle $\omega(C_2^{\oplus}C–C^{\oplus}C_2) = 41°$ in that of tetra(*p*-methoxyphenyl)ethylene, which is bent at the C=C bond.[8b] In addition, it is pointed out that the two-electron oxidation of 1,2,4,5-tetrakis(dimethylamino)benzene generates a twisted π-conformation of the six-membered ring containing two $[Me_2NC–CNMe_2]^{\oplus}$ subunits, each of which show CC bond distances of 153 pm and dihedral angles of $\omega(NC–CN)^{\oplus} = 49°$.[8c]

Summarizing, the—according to molecular state arguments[9]—inevitable structural changes accompanying differences in energy, and especially differences in the number of valence electrons of a given molecule, thus predominantly lead, in the simplest alkene, $H_2C=CH_2$, and its derivatives, $X_2C=CX_2$, to an elongated CC bond, shortened CX bonds and a twisting of the two molecular halves relative to each other.

German version: *Angew. Chem. 102* (1989) 1715

[1] A summary of spectroscopic data and of quantum chemical results concerning the $\pi \rightarrow \pi^*$ excitation of ethylene ($\nu > 40000\ cm^{-1} = 5$ eV) into the singlet state $\tilde{A}(^1B_{1u})$ and its presumed D_{2d} structure exhibiting a dihedral angle $\omega = 90°$ between both molecular halves is given by M. B. Robin in: *Higher Excited States of Polyatomic Molecules, Vol. 2, 3,* Academic Press, New York 1975, 1985, pp: 2–22, 213–227, respectively; cf. also the references cited therein.

[2] K. Ruppert, *Diplomarbeit,* Universität Frankfurt 1989. Approximate geometry-optimized MNDO calculations predict for $[H_2C–CH_2]^{2\oplus}$ a total energy difference of $\Delta E \approx 27$ eV, a dihedral angle $\omega = 90°$ and a bond distance $d_{CC} = 146$ ppm. Ab initio SCF calculations (cf. e.g. K. Lammertsma, M. Barzaghi, G. A. Olah, J. A. Pople, A. J. Kos, P. von R. Schleyer, *J. Am. Chem. Soc. 105* (1983) 5252 or G. Frenking, W. Koch, H. Schwarz, *J. Comput. Chem. 7* (1986) 406) confirm the semiempirical result. The unknown structure of the 38-atom neutral molecule of the composition $((H_3C)_2N)_2C=C(N(CH_3)_2)_2$ is MNDO-optimized based on the assumption of pyramidal $(H_3C)_2N$ groups, and the resulting satisfactory correlation with measurement data can be illustrated by the calculated first vertical ionization energy of 7.0 eV (exp. 5.95 eV [3b]). For the dication, planar N_2C subunits with freely rotating R_2N groups are restrictively assumed and reasonable agreement with the slightly differing crystal structure data of the dibromide (2 H_2O, orthorhombic) [5] and the dichloride (2 H_2O, monoclinic C) [5] is achieved (cf. Table 1).

[3] Cf. a) redox investigations and preparation of salts: N. Wiberg, J. W. Buchler, *Chem. Ber. 96* (1963) 3223; summary: N. Wiberg, *Angew. Chem. 80* (1968) 809; *Angew. Chem. Int. Ed. Engl. 7* (1968) 766. b) PE spectrum: B. Cetinkaya, G. H. King, S. S. Krishnamurthy, M. F. Lappert, J. B. Pedley, *J. Chem. Soc. Chem. Commun. 1971,* 1370. c) Half-wave oxidation potential in aprotic ($c_{H^{\oplus}} < 1$ ppm) dimethylformamide solution (H. Bock, D. Jaculi, *Angew. Chem. 96* (1984) 298; *Angew. Chem. Int. Ed. Engl. 23* (1984) 305): the cyclovoltammogram exhibits an unstructured (two-electron) wave between $E_{pc} = -0.63$ V and $E_{pa} = -0.52$ V.

[4] Cf. [2]. Dichloride salt: 3 g (15 mmol) tetrakis(dimethylamino)ethylene were 'titrated' at −10 °C under Ar with an oxygen-free $Cl_2/HCCl_3$ solution until the orange color vanished. After solvent evaporation at room temperature in vacuo, the residue was dissolved in a minimum of CH_3OH and the salt precipitated by pouring the solution dropwise into 200 ml of cold diethyl ether; yield 4.0 g (97%), decomp. 243–247 °C, ^1H NMR (CD_3OD/TMS): $\delta = 3.41$ (s, 12H), 3.77 (s, 12H); IR cf. [3a]. The growth of a single crystal was achieved within six weeks in a two-limbed trap by slow difusion of *n*-hexane into the CH_3OH solution. Dibromide salt: After oxidation with 0.4 mL of Br_2 in 30 mL of carefully degassed $HCCl_3$ at 0 °C, 2.3 g (95%) of a hygroscopic powder precipitate from the orange-colored solution at room temperature. Decomposition at 280 °C; ^1H NMR identical to that of the dichloride; elemental analysis: C 33.06 (33.33), H 6.87 (6.67), N 15.29 (15.56). Growth of single crystal within about 24 h from 5 mL of a C_2H_5OH solution of 1 g of salt by superposing a layer of 3 mL of *n*-hexane (non-compliance of the concentrations quoted yields only powders).

[5] Crystal structure analysis: $[C_{10}H_{24}N_4]^{\oplus\oplus}Cl_2^{\ominus} \cdot 2\,H_2O$, space group *C*2/*c*, $Z = 4$, lattice constants (211 K): $a = 1524.3(8)$, $b = 763.7(4)$, $c = 1758.7(9)$ pm, $\beta = 125.25°(3)$, $V = 1672 \times 10^6$ pm^3, $\mu(Mo_{K\alpha}) = 3.38\ cm^{-1}$. Siemens AED-2 diffractometer, $3° < 2\Theta < 52°$, 1853 reflections, of which 1350 are independent with $I > 3\sigma(I)$. Direct methods, Cl, N, C and O positions anisotropically, detected H positions isotropically refined; $R = 0.039$, $R_w = 0.039$. The dication contains a twofold axis, crystallographically enforced. Angle sums around C1, C2, N1, N2, N3, N4 each 360°. Contact distances Cl–N 359–416 pm, O–N > 400 pm, Cl–O 323 pm. Additional structure parameters: $H_3C–N$ 147.5–148.3 pm. $[C_{10}H_{24}N_4]^{\oplus\oplus}Br_2^{\ominus} \cdot 2\,H_2O$: space group P_{cab}, $Z = 8$, lattice constants (218 K): $a = 928.3(9)$, $b = 2583.8(30)$, $c = 1474.0(15)$ pm, $V = 3535 \times 10^6$ pm^3. $\mu(Mo_{K\alpha}) = 44.81\ cm^{-1}$. Siemens AED-2 diffractometer, $3° < 2\Theta < 48°$, 6829 reflexes, of which 1718 are independent with $I > 2\sigma(I)$. Direct methods, Br, N, C and O positions anisotropically, detected H positions isotropically refined; $R = 0.085$, $R_w = 0.084$. Angle sums around C1, C2, N1, N2, N3, N4 each 360°. Most important contact distances Br–N 362–386 pm, O–N > 400 pm, Br–O 328–334 pm. Additional structural parameters: $H_3C–N$ 145.7–148.2 pm.—Details for both crystal structure determinations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54165, the names of the authors, and the literature citation.

[6] After submission of our manuscript, we were informed that the crystal structure of 1-$(PF_6^{\ominus})_2$ has been determined. In close agreement with our results for the dichloride and dibromide salts [4], a CC bond distance of 151 pm and a dihedral angle of 72° were found. C. Krieger, K. Elbl-Weiser, H. A. Staab, unpublished. We thank Professor *H. A. Staab,* Max-Planck Institut, Heidelberg, for communicating these unpublished data (cf. also [8c]).

[7] The signal pattern in the ESR spectrum of the radical cation $[((H_3C)_2N)_2C–C(N(CH_3)_2)]^{\cdot\oplus}$, generated by one-electron oxidation, also exhibits different ^1H couplings of 0.328 mT and 0.284 mT (K. Kuwata, D. H. Geske, *J. Am. Chem. Soc. 86* (1964) 2101; J. M. Fritsch, H. Weingarten, J. D. Wilson, *ibid. 92* (1970) 4038).

temperature-, and light-sensitive organic alkali-metal compounds. Their often complex crystal structures,[1b, 3] even after prolonged study, generate a rather "fairy-tale-like" impression, that is, one defying the usual bond rationalization based on formal charges. In our investigations[1a, 4] of dication and dianion salts of the simplest alkene, $H_2C=CH_2$, tetraphenylethylene was allowed to react in diethyl ether under argon (aprotic conditions, $c_H^{\oplus} < 1$ ppm) at room temperature with a sodium mirror obtained by vacuum distillation. After 24 hours of UV-controlled reaction in the dark-red diethyl ether solution, green crystals[5] can be isolated; they exhibit a metallic luster and possess a band structure[6] (Fig. 1).

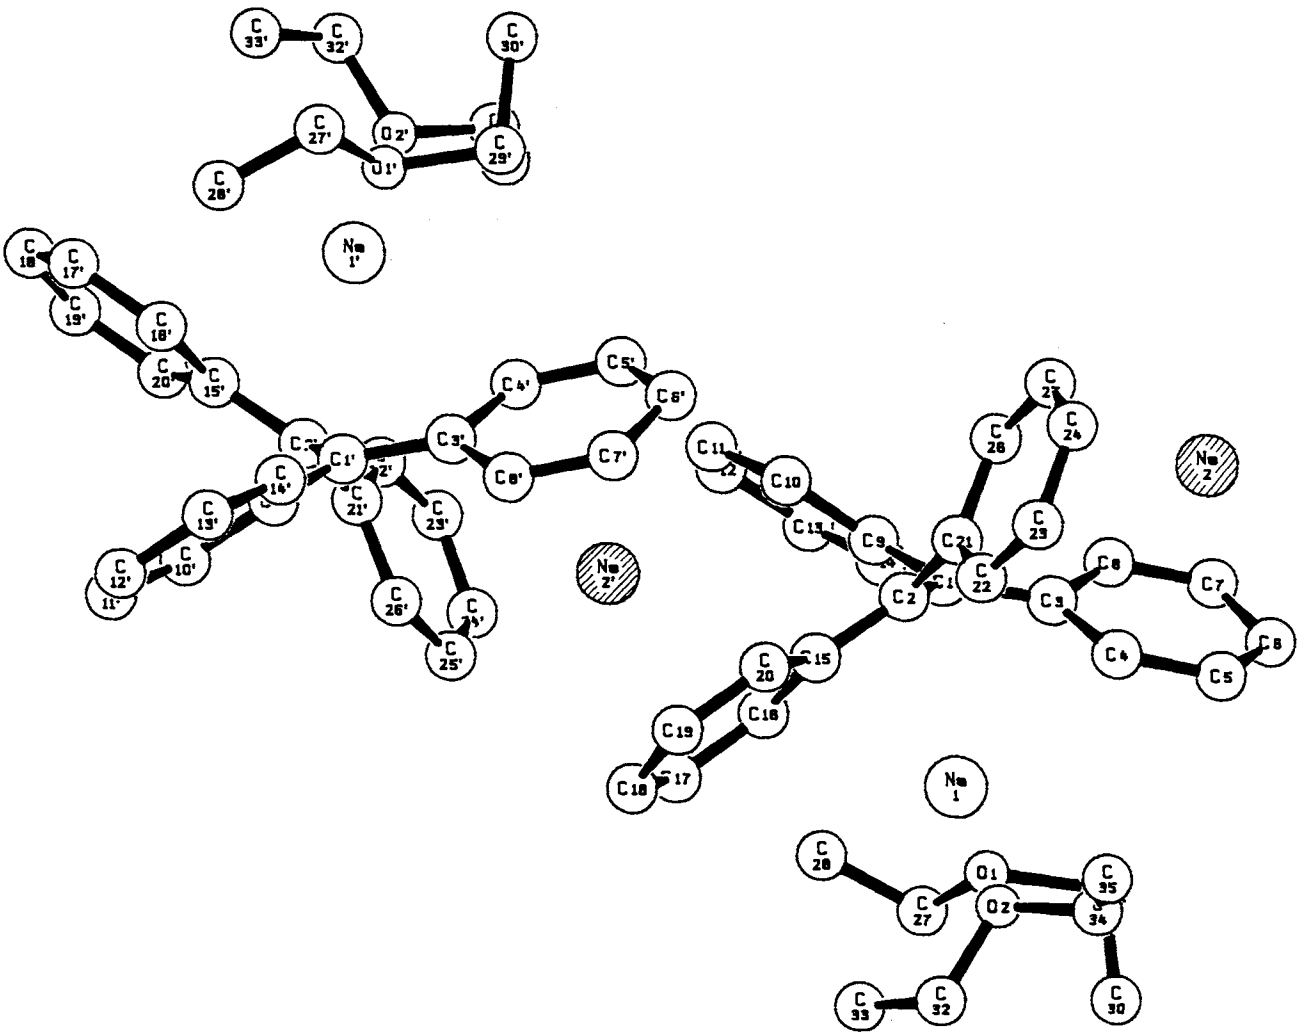

Fig. 1. Segment of the unit cell showing two ion pairs of tetraphenylethylenedisodium bis(diethyl ether), with the hatched sodium centers generating the band structure (cf. Figs. 2 and 3).

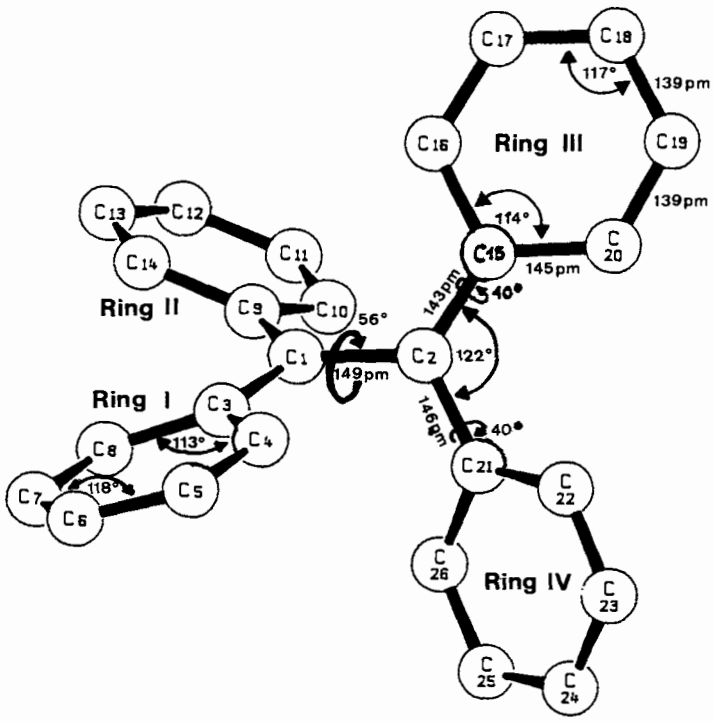
Advantageously, a discussion of the delicately balanced electron distribution along a tetraphenylethylenedisodium band starts with the organic chain links (Fig. 2). Upon two-electron reduction, the structure of tetraphenylethylene[7] is changed as follows: The two $(H_5C_6)_2C$ molecular halves twist through 56° relative to each other and the CC double bond is elongated by 13 pm (!) to a CC single bond. In contrast, the C–C_6H_5 distances are shortened by 3 to 6 pm and the twisting of the phenyl rings out of the C1–C3–C9 and C2–C15–C21 planes decreases to values between 10° and 40°. The simultaneous opening of the ethylene angles (e.g., C15–C2–C21 from 114° to 122°) provides further evidence that steric overcrowding is reduced in the dianion and, therefore, most of the structural changes are caused by electronic effects.[8] Partly geometry-optimized MNDO calculations[4] suggest that about 1/3 of the negative charge is localized at the carbon centers C1 and C2, whereas about 1/3 is delocalized in each of the four phenyl rings and causes substantial distortions of the still planar C_6 skeletons, especially in the predominantly Na-coordinating six-membered rings I and III. Thus, the *ipso* angle at C3 of the visibly stretched ring I is reduced to 113°[9] and, in the likewise elongated ring III, the CC bond distances differ by 6 pm (Fig. 2).

The sodium center, solvated by two diethyl ether ligands (Fig. 1: Na1), altogether is eightfold coordinated (Fig. 3, top). Its "zigzag" coordination sphere extends from the π bond C4–C3 in phenyl ring I via the negatively charged, trigonal-planar carbon centers C1 and C2 to the π bond C15–C16 of the phenyl substituent III. Comparable substructures containing metal (metal-ion) contacts to several different ligand parts are observed in numerous alkali-metal organometallic compounds.[3] Surprising, however, is the sandwichlike complexation of Na2, which is supposedly the first unsolvated sodium detected;[3] it connects two $[\{(H_5C_6)_2C\text{-}C(C_6H_5)_2\}^{2\ominus}Na^{\oplus}(OR_2)_2]^{\ominus}$ units and thus provides the link for the band structure (Fig. 1: Na2, hatched). This sodium center (Fig. 3) binds "hexahapto" to phenyl



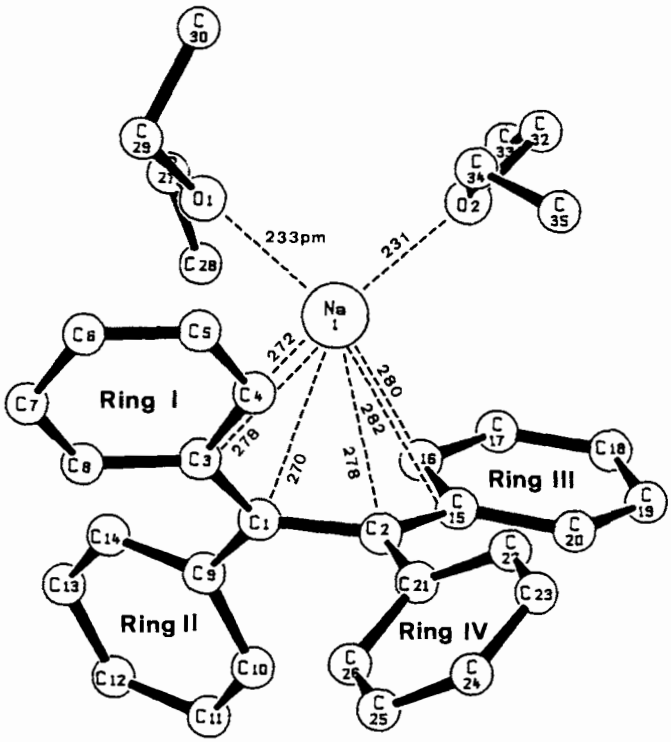


Fig. 2. Carbon skeleton of the tetraphenylethylene dianion.

ring III, which on its "backside" at the centers C15 and C16 already coordinates Na1, and "allyl-like" (C3′, C4′, and C5′) to phenyl ring I of the next tetraphenylethylene unit, which, conversely, on its backside at centers C3′ and C4′, complexes the respective Na1′. Additional contacts are formed to C26 of ring IV and, more distant, to C6′, C7′, and C8′ of ring III. Thus, altogether and depending on the "bond distance" limitation imposed, an Na2 coordination number between 10 and 14 results. In addition, it should be pointed out that the two phenyl rings I and III, each of which extend coordinative links on both sides to sodium centers, exhibit the smallest twist angles relative to the planes of the molecular halves (cf. Fig. 2: C2–C1–C3–C4 14° and C1–C2–C15–C16 10°) and also the longest CC bond distances between the respective Na-coordinated ring centers (Figs. 2 and 3).

For the rather unusual sandwichlike coordination of Na2, the following parallels have emerged from an extensive literature search: Lithium 7b*H*-indeno[1,2,3-*jk*]fluorenide contains a "dodecahapto" embedded Li center between each of its two coplanar, coaxial, and 386-pm-spaced phenyl ring pairs.[10a] In lithium 1,1,3,3-bis(2,2′-biphenylene)propenide diethyl ether, the Li-di(η^6-phenyl) sandwich between two different molecular units opens on one side by 56° owing to the additional R_2O solvation.[10b] In contrast, the Na center in $(H_5C_6)_3CNa \cdot TMEDA$, which also exhibits a band structure,[10c] prefers a rather short bond of only 264 pm to the carbanion center rather than a "polyhapto" coordination to the phenyl rings.

In tetraphenylethylenedisodium, which crystallizes from the diethyl ether solution after reduction with a sodium mirror, the two negative formal charges are largely delocalized,

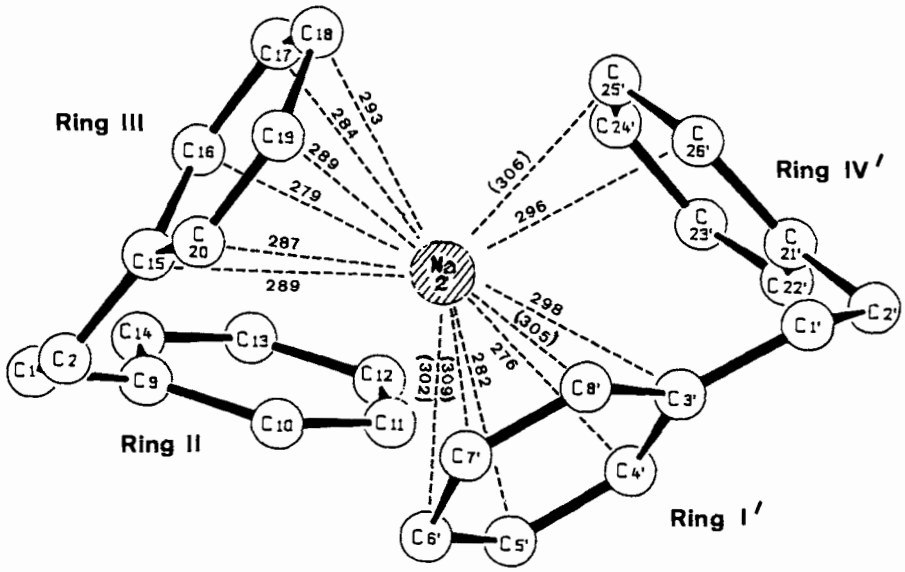

Fig. 3. Coordination spheres around the two different Na centers in tetraphenylethylenedisodium.

predominantly in the CC singly bonded and twisted diphenylcarbanion molecular halves and partly—owing to the sandwich complexation of Na2—also in the "one-dimensional" bands, which are separated from each other by the alternatingly "left-right" arranged countercations $^{\oplus}Na(OR_2)_2$. The unexpected formation of this solid-state structure may be tentatively rationalized by the following literature observations: tetraphenylethylene radical anion $M^{\bullet\ominus}$, generated by single electron transfer, is of comparable structure to the sterically overcrowded neutral molecule M[11a] and, therefore, in ether solution only forms "solvent separated", radical-ion pairs $(M^{\bullet\ominus}_{solv} \cdots Na^{\oplus}_{solv})$[11a] and thus preferentially disproportionates via $2\,M^{\bullet\ominus} \rightarrow M + M^{2\ominus}$ to its dianion.[11b] Owing to considerable structural changes, this can be stabilized as a contact ion pair $[M^{2\ominus}Na^{\oplus}_n]^{(2-n)\ominus}$ ($n \leq 2$), and presumably crystallizes under the reaction conditions chosen—like the dimer [fluorenone$^{\bullet\ominus}$Na$^{\oplus}$-(DME)$_2$]$_2$[11b]—in the band structure reported.

[2] Remark by *J. D. Dunitz*, ETH Zürich, on the occasion of a lecture at the Universität Frankfurt on January 9, 1989.

[3] Cf. reviews on the structures of organolithium compounds (W. N. Setzer, P. von R. Schleyer, *Adv. Organomet. Chem. 24* (1985) 353) as well as on organometallic derivatives of higher alkali metals (C. Schade, P. von R. Schleyer, *ibid. 27* (1987) 169), and references cited therein.

[4] K. Ruppert, *Diplomarbeit*, Universität Frankfurt 1989. Approximative geometry-optimized MNDO calculations neglecting the countercations predict for the fictive ethylene dianion the following (gas-phase) data. $\Delta E_{total} \approx 10$ eV, $\omega = 90°$, $d_{CC} \approx 140$ pm (for $Li_2C_2H_4$ cf. A. J. Kos, E. D. Jemmis, P. von R. Schleyer, R. Gleiter, U. Fischbach, J. A. Pople, *J. Am. Chem. Soc. 103* (1981) 4996). For the tetraphenylethylene dianion, the calculations started from the crystal structure data (exception: hexagonal C_6 rings) and on partial MNDO optimization (keeping $d_{CC} = 150$ pm and $\omega = 56°$ constant) the bond distances $d_{C\ phenyl} \approx 145$ pm and twist angles ω(phenyl) $\approx 35°$ result. The MNDO charge distribution is: C1 = C2 = −0.29, $C^{ortho}_{phenyl} = -0.13$, $C^{para}_{phenyl} = -0.21$. Calculations with cation simulating "sparkles" do not converge, cf. [8].

[5] Cf. [2]. Vacuum distillation of 70 mg (3 mmol) of Na in a Schlenk trap under Ar yields a sodium mirror, which reacts with 505 mg (1.5 mmol) tetraphenylethylene in 30 mL of water-free diethyl ether under Ar at room temperature within 24 h to a dark-red solution. ESR and UV/VIS spectra ($\nu_m \approx 21000$ cm^{-1}) do not provide evidence for the radical anion as an intermediate, which in its blue dimethoxyethane solution shows a characteristic absorption ($\tilde{\nu}_m = 15400$ cm^{-1}). The green, shiny metallic crystals precipitated are extremely air-sensitive and, therefore, have to be handled in a stream of N_2.

[6] Crystal structure analysis of $C_{26}H_{20}Na_2 \cdot 2\,O(C_2H_5)_2$: space group $P2_1/n$, $Z = 4$, lattice constants (210 K): $a = 997.8(5)$, $b = 1545.4(9)$, $c = 2025.1(10)$ pm, $\beta = 100.59°(4)$, $V = 3069.5 \times 10^6$ pm^3 · $\mu(Mo_{K\alpha}) = 0.63$ cm^{-1}, Siemens AED-2 diffractometer, $3° < 2\Theta < 52°$, 6199 reflections, of which 2932 are independent with $I > 2\sigma(I)$. Direct methods, Na, O, and C positions anisotropic, detected H positions isotropically refined; $R = 0.099$, $R_w = 0.102$. The unsatisfactory high R value is due to decomposition of the crystal in the X-ray beam; for the decomposition correction, an approximate linear relation has been assumed. Deviations in structural parameters (Figs. 1–3): ±1.5 pm and ±0.8°; angle sums of all six-membered rings 720 ± 0.5°. Further details of the crystal structure determination are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51466, the names of the authors and the literature citation.

[7] A. Hoekstra, A. Vos, *Acta Crystallogr. B31* (1975) 1722. Selected structural parameters: C1-C2 136 pm, C3-C1-C2-C15 8.4°, C15-C2-C21 114.4°, C-C_6H_5 150 pm, C1-C2-C_6H_5 43–57°, angle sum of all six-membered rings 720°. Cf. also the structure of the dianion of bifluorene, prepared by deprotonation (M. Walczack, G. D. Stucky, *J. Organomet. Chem. 97* (1975) 313), which possesses a CC bond distance elongated from 139 pm to 149 pm and a dihedral angle $\omega(C_2C\text{–}CC_2) = 48°$. In the largely interaction-free dianion of tetracyanoethylene (D. A. Dixon, J. S. Miller, *J. Am. Chem. Soc. 109* (1987) 3656) a central CC bond distance of 149 pm and a dihedral angle of 87° are observed. After submission of this publication, the crystal structure of tetrakis(trimethylsilyl)ethylenedilithium was published (A. Sekiguchi, T. Nakanishi, C. Kabuto, H. Sakurai, *J. Am. Chem. Soc. 111* (1989) 3748); the dihedral angle ($\omega = 34°$) is only slightly increased relative to that ($\omega = 34°$) of the sterically overcrowded parent molecule.

[8] Cf. M. A. Fox, D. Shultz, *J. Org. Chem. 53* (1988) 4386, and references cited therein. The MO calculations, according to which a planar dianion should be about 40 kJ mol^{-1} more stable than the one exhibiting orthogonal $(H_5C_6)_2C$ molecular halves, neglect the effect of the countercations (cf. also [2]); cf. also *J. Am. Chem. Soc. 111* (1989) 6311.

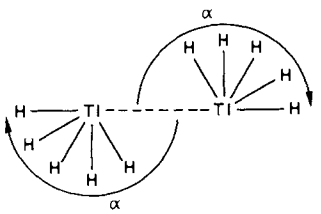
Tl^I–Tl^I Interactions in the Molecular State—an MO Analysis**

By *Christoph Janiak* and *Roald Hoffmann**

Are direct bonds possible between Tl^I or In^I atoms? The question is raised by the pentabenzylcyclopentadienylthallium dimer, $[(PhCH_2)_5C_5Tl]_2$ (**1a**)[1] and its isostructural indium analogue (**1b**),[2] both synthesized by *Schumann* and coworkers.[3]

1a, M = Tl
1b, M = In



Both centrosymmetric dimers feature a relatively covalent metal–cyclopentadienyl interaction, a metal–metal contact of 363 pm and a Cp'(centroid)–M–M angle of 131.8° (**1a**) or 136.5° (**1b**).[1, 2] Unambiguous Tl^I–Tl^I or In^I–In^I bonds are not yet known in molecular complexes, as they are, for example, for the related Ge^{II} or Sn^{II} in $[\{(Me_3Si)_2CH\}_2M]_2$.[4] To us a Tl···Tl contact only about 20 pm longer than in Tl metal,[5] occurring in the absence of bridging, is definitely suggestive of direct metal–metal bonding. A few bridged complexes with similar length Tl···Tl contacts are also

known.[6] However, the apparent consensus and a brief theoretical study[7] interpret these as resulting from the bridging coordination. A short Tl–Tl bond (284 pm), albeit between Tl^{II} centers, has recently been found in $Tl_{0.8}Sn_{0.6}Mo_7O_{11}$.[8]

An analysis of a model C_5H_5Tl dimer led us to focus on the significant role of the L–Tl–Tl angle (L = ligand). The gist of what we observe is retained as we simplify the C_5H_5 ligand to OCH_3,[6e] Te,[6f] and H. So in the sequel we focus on the simplest model, namely, HTlTlH (**2**), shown in

2

Scheme 1. Definition of the angle α in HTlTlH (**2**).

Scheme 1 with the important H–Tl–Tl angle α. Figure 1 shows a plot of the calculated overlap population as a function of α.[9]

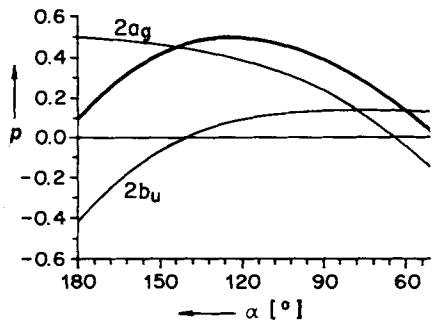

Fig. 1. Dependence of overlap population p on H–Tl–Tl angle α with Tl–Tl = 370 pm and Tl–H = 190 pm. Bold curve: total overlap populations. α = 180° corresponds to linear H_2Tl_2.

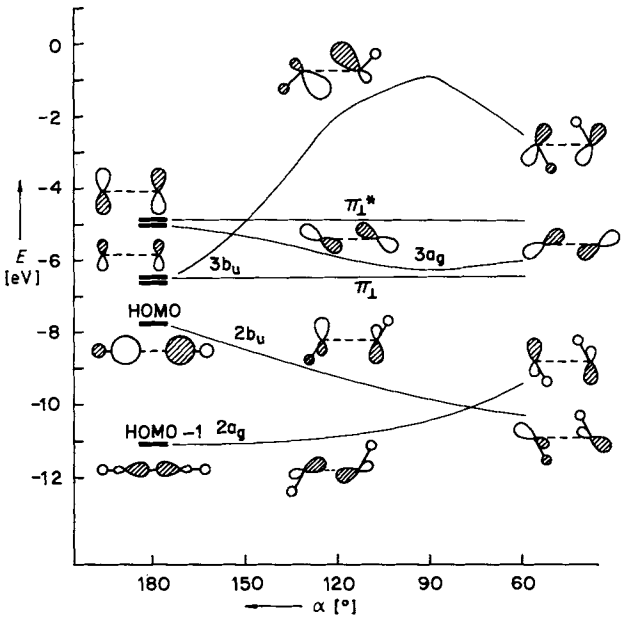
The surprising result is that the overlap population between the Tl atoms in **2** shows a dramatic increase, upon bending, to a substantial maximum at a H–Tl–Tl angle of around 120°, followed by an eventual decline towards the bridging geometry. For the more realistic Cp ligand, the Tl–Tl overlap populations at α = 180°, 131.6°, 120°, and 90° are 0.177, 0.347, 0.367, and 0.296, respectively (Tl–Tl = 370, Tl–Cp(centroid) = 249 pm).

Both the magnitude and the range of variation are extraordinary. The question raised in the beginning is answered with a definite yes: There is a Tl^I–Tl^I bond in these compounds, at least for a bent geometry.

How can there be a bond between two filled s^2 subshells, which is the way one might think of Tl^I or In^I? The answer is "it is a consequence of efficient mixing of formally vacant np orbitals, that is, hybridization". In the case at hand, a calculation on 120°-bent HTlTlH, using only a Tl 6s basis (i.e., no 6p orbitals) yields a Tl–Tl overlap population of − 0.026 (compare the + 0.490 from Fig. 1 for the case where both s and p orbitals on Tl are included). Changing an initial repulsion of closed subshells into an attraction, by inclusion of unfilled orbitals, is a general phenomenon. It can also be seen in d^{10}-d^{10} systems, such as Cu^I-Cu^I,[13] Pt^0-Pt^0,[14] and Au^I-Au^I,[15] whose bonding interactions are based on a d–s–p mixing. Relativistic effects may be important in the bonding of some of these systems as well as in the thallium dimer.[16]

For LTlTlL the relevant mixing is sp. In a sense this is no surprise—Tl is a main-group element. Perhaps it is worthwhile to draw an analogy with the "isoelectronic" $HCCH^{2\oplus}$. One would not doubt for a moment the necessity of sp hybridization or the presence of a C–C bond in this acetylene dication. But that just raises the further question: Why is LTlTlL bent? The acetylene analogy is not immediately helpful in this matter. There is also the remarkable sensitivity of the Tl–Tl bonding to the H–Tl–Tl angle displayed in Figure 1. We approach these questions by a decomposition of the total overlap population versus angle function (see Fig. 1) into its major components from the HOMO ($2b_u$) and the orbital below the HOMO ($2a_g$). From the slope of the curves, it is obvious that from 180° to 120° the $2b_u$ orbital dominates the changes in the overlap population, while from 120° to 60° the $2a_g$ orbital is the governing factor.

The origins of the bending can be traced with the help of a Walsh diagram for the relevant orbitals in **2** (Fig. 2). From



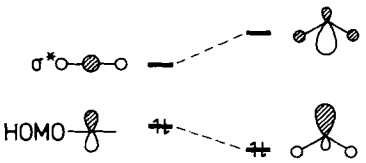


Fig. 2. Partial Walsh diagram for the bending in **2** with Tl–Tl = 370 pm and Tl–H = 190 pm. Symmetry labels are for point group C_{2h}; orbital drawings are schematic $\pi_\perp$, $\pi_\perp^*$: π sets perpendicular to the plane of the molecule.

the orbital sketches, it may be seen that the stabilization and change in character of $2b_u$ results from strong mixing with the empty $3b_u$ orbital—pushing both levels apart. The lowest energy for **2** is calculated around 105°.

What happens in the *trans* bending of HTlTlH is closely related to the critical orbital interactions in the pyramidalization of AH_3 systems (e.g., NH_3, $CH_3^\ominus$, PR_3) and the bending of AH_2 molecules (e.g., H_2O, H_2S).[17] The orbitals guiding these deformations are sketched for AH_2 in Scheme 2.

The controlling orbital (HOMO for both AH_3 and AH_2) is a lone pair centered on the A atom. This level decreases in

Scheme 2. The orbitals involved in bending of AH_2 molecules. Left: linear AH_2. Right: bent AH_2.

energy with bending, mixing in more s character and a hydrogen contribution from an empty A–H σ* orbital above, to give a stabilized filled orbital with A–H nonbonding character and an empty level which is destabilized and strongly A–H antibonding. The lone pair occupies a pure p orbital in the planar AH_3 or linear AH_2 geometry. The closer the higher σ* combination to the p orbital, the stronger is the tendency to bend. Essentially the same thing happens in HTlTlH. The only difference is that in the Tl case the upper orbital ($3b_u$) is of Tl p character, whereas in AH_3 and AH_2 it is the lower orbital. This can be traced to the long Tl–Tl separation. As soon as bending and therefore mixing begins, this distinction becomes unimportant. The $2b_u$ and $3b_u$ orbitals in **2** are close to each other in energy, which they are not in the isoelectronic $HCCH^{2\oplus}$.

While the $2b_u$ mixes very strongly with the $3b_u$ combination in the 180° to 120° range, thereby transforming its character from strongly antibonding to slightly bonding, the main Tl–Tl bonding orbital, $2a_g$, shows only very small interactions with orbitals of the same symmetry in this region. The $2a_g$ orbital thus retains its strongly bonding character (see Fig. 1). From 120° on, the mixing of $2a_g$ with other levels, however, gets much stronger as appropriate symmetry combinations come closer in energy. Hence, the $2a_g$ Tl–Tl overlap population drops rapidly to nonbonding as one approaches the bridging geometry. With the ligands in the bridging positions, both $2a_g$ and $2b_u$ can be considered as lone-pair combinations, with only a small overlap population between the thalliums. Another way of thinking about this mixing, governed by orbital level energies, is that it provides the opportunity for a stereochemically active lone pair.

To summarize: HTlTlH and CpTlTlCp want to bend at Tl as a result of a near resonance in the energy of the $2b_u$ (σ*) and $3b_u$ (π) orbitals. The factors favoring pyramidalization are similar to those for EL_2,EL_3 (and L_2EEL_2), except that the driving force is stronger in HTlTlH. There definitely is Tl^I–Tl^I bonding in these structures. The bonding in the formally s^2–s^2 closed subshell interaction is due to the mixing of formally empty p levels into the filled s combinations. We are now analyzing the full range of Tl^I–Tl^I interactions in molecular and extended structures.

Inter- and Intramolecular Photochemical C–H Activation in Matrices and in Solution with (η^6-Arene)(carbonyl)osmium Complexes**

By *Andrew McCamley, Robin N. Perutz,* Stefan Stahl,* and *Helmut Werner**

Dedicated to Professor Walter Strohmeier on the occasion of his 70th birthday

Matrix isolation has proved to be an effective means both for observing C–H activation of methane and for characterizing the coordinatively unsaturated complexes implicated in this process.[1, 2] However, the identification of the (methyl)hydride complexes resulting from insertion into methane [Eq. (a)] has rested so far on the observation of CO and

$$\left.\begin{matrix}[L_nMH_2] \xrightarrow[-H_2]{h\nu} \\ [L_nM(CO)] \xrightarrow[-CO]{h\nu}\end{matrix}\right\rangle \rightarrow [L_nM] \xrightarrow{CH_4} [L_nM(CH_3)H] \qquad \text{(a)}$$

MH stretching vibrations in the IR spectrum (e.g., in the formation of $[(\eta^5\text{-}C_5H_5)Ir(CO)(CH_3)H]$ from $[(\eta^5\text{-}C_5H_5)Ir(CO)_2]$).[1] Suitable precursors for such photochemi-

cal reactions include metal carbonyl, dihydride, and ethene complexes. In the latter case, elimination of ethene may compete with insertion into the C–H bonds of ethene, as has been demonstrated in the matrix photolysis of $[(\eta^5\text{-}C_5H_5)Ir(C_2H_4)_2]$.[3a] Recent experiments have shown a close link between the matrix and the solution reactivity.[1b, 3, 4]

We have now found that (1) the (η^6-arene)osmium complexes **1**–**4** undergo *inter-* or *intra*molecular C–H activation reactions on photolysis in low-temperature matrices and (2) some of these reactions may also be carried out in solution. As far as we are aware, **1** is the first (η^6-arene)dicarbonylosmium complex.[5] It was synthesized from **3**[6] by an unusual route via $[(Mes)Os(CO)H_3]^{\oplus}$ and $[(Mes)Os(CO)_2H]^{\oplus}$.[7] Complex **2** is obtained in good yield from $[(Mes)Os(CO)(CH_3)I]$[6] by reaction with Na/Hg in THF/EtOH; **4a** is obtained from $[(Mes)Os(CO)(CH_3)_2]$ by a route analogous to that already described for **4b**.[5b, 7]

$[(Mes)Os(CO)_2]$ **1** $[(Mes)Os(CO)(CH_3)H]$ **2** $[(Mes)Os(CO)H_2]$ **3**

$[(Mes)Os(CO)(C_2H_4)]$ **4a** $[(\eta^6\text{-}C_6H_6)Os(CO)(C_2H_4)]$ **4b**

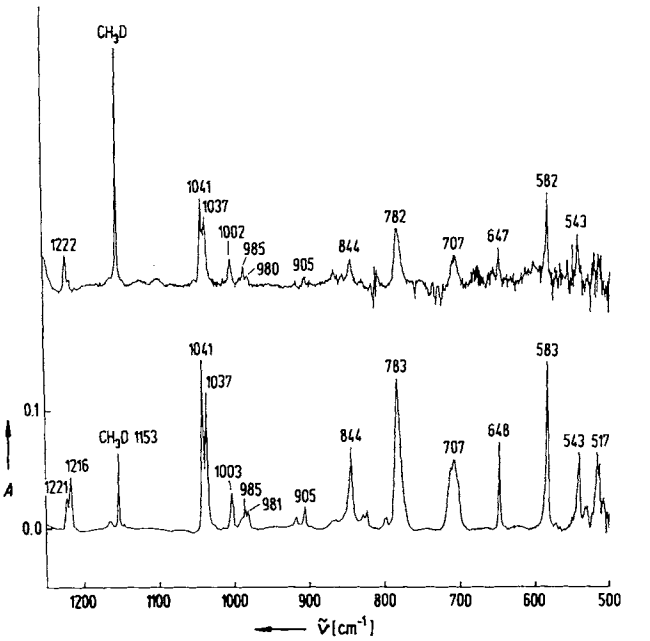
Mes = η^6-1,3,5-$Me_3C_6H_3$

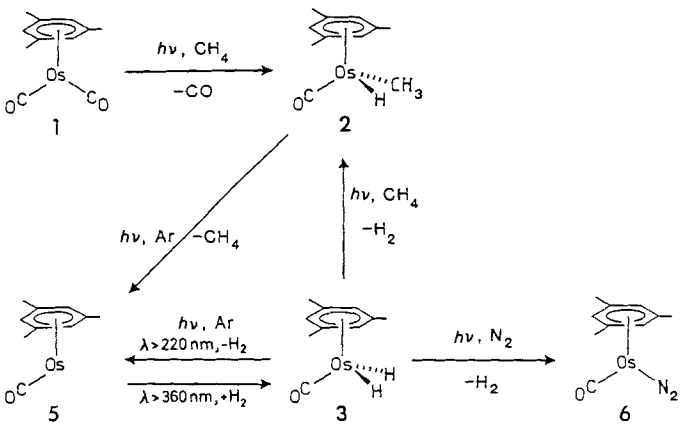
Complexes **1**–**4** may be sublimed into a matrix at 35–60 °C without decomposition. Complex **1** is photostable in argon matrices,[8] but proves reactive when isolated in solid methane. On photolysis ($\lambda > 290$ nm), the ν(CO) bands of **1** (1981, 1909 cm^{-1}) decrease and the band of free CO (2136 cm^{-1}) appears. A pair of new IR bands is detected close to 2085 cm^{-1} (w, br) together with a group of bands close to 1955 cm^{-1} and ca. nine further bands between 1200 and 450 cm^{-1}. All of the IR bands of **2** (sublimed into a methane matrix) are observed within 4 cm^{-1} of the corresponding modes of the photoproduct of **1**. The high-frequency modes of the photoproduct are assigned to ν(OsH) (ca. 2085 cm^{-1}) and ν(CO) (ca. 1955 cm^{-1}); they are split into several components because of multiple conformations and sites in the matrix. The exact *splitting pattern* is different in the photochemically generated product from that of **2** isolated directly. Nevertheless, this comparison provides secure evidence that irradiation of **1** results in CO loss and formation of **2** in solid methane.

Complex **3** shows ν(OsH) and ν(CO) modes at ca. 2081 and 1970 cm^{-1} when isolated in a methane matrix. On photolysis ($\lambda > 220$ nm), very little CO is released, but formation of **2** can be recognized both from its ν(CO) band and its low frequency modes. The yield of **2** is higher than on photolysis of **1**, but the ν(OsH) mode of **2** is obscured by the corresponding band of the precursor, **3**. The ν(CO) mode and the low-frequency modes are now observed within 1 cm^{-1} of those of **2** (Fig. 1), indicating that the expelled H_2 from **3** causes less perturbation than the expelled CO from **1**.

Further evidence for the reductive elimination of H_2 from **3** is obtained by photolysis in nitrogen matrices, which yields complex **6** (Scheme 1), isoelectronic with **1**. The NN and CO stretching modes of **6** are observed at 2108 and 1917 cm^{-1}. In $^{14}N_2/^{15}N_2$ (55:45) matrices, two NN stretching modes are observed for the $^{14}N_2$ and $^{15}N_2$ complexes (2108 and 2042 cm^{-1}, respectively).

The coordinatively unsaturated monocarbonyl **5** (Scheme 1) may be generated either by photolysis of **2** or **3** in argon matrices ($\lambda > 220$ nm). The formation of **5** from **3** may be partially reversed by long-wavelength irradiation ($\lambda > 365$ nm). As expected, its ν(CO) mode (1885 cm^{-1} when formed from **2**, 1889 cm^{-1} from **3**) lies at lower frequency than that of **6** (1917 cm^{-1}), which has an additional Os–N_2 bond. Photolysis of **2** in argon matrices also causes release of free methane, which can be identified by its characteristic bands at 2910 and 1305 cm^{-1}. However, photolysis of either **2** or **3** in argon matrices is complicated by the formation of other carbonyl products with higher frequency ν(CO) bands. A similar phenomenon has been observed for $[(\eta^5\text{-}C_5H_5)Ir(CO)H_2]$.[1c] The observations on **1**–**3**, **5**, and **6** (Scheme 1) show that the reaction proceeds via dissociation of CO or H_2 from **1** or **3** and oxidative addition of methane to the coordinatively unsaturated fragment **5**.





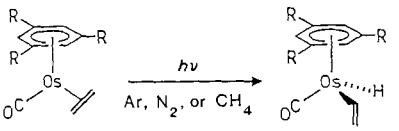


Fig. 1. Above: IR spectrum in the region $\tilde{\nu} < 1250$ cm^{-1} obtained following photolysis (620 min, $\lambda > 220$ nm) of **3** isolated in a methane matrix after computer subtraction of the residual bands of **3**. Below: **2**, deposited directly into a methane matrix. The band at 1153 cm^{-1} is due to CH_3D in natural abundance. The agreement between the two spectra demonstrates conclusively that **2** is formed by photolysis of **3**. A = absorbance.

Scheme 1. Photolysis of **1**–**3**.

Irradiation of **4a** in CH_4, N_2, and Ar matrices leads, not to **2**, **5**, or **6**, but to *intra*molecular C–H activation and formation of the hydrido(vinyl)osmium complex **7a** [Eq. (b)]. Complex **7a** has a ν(CO) mode shifted to high frequency

relative to **4a**, a ν(OsH) mode (ca. 2060 cm^{-1}), and three bands in the 1200–1600 cm^{-1} region characteristic of a vinyl group.[8] These bands occur within 9 cm^{-1} of those of $[(\eta^5\text{-}C_5H_5)Ir(C_2H_4)(C_2H_3)H]$ formed by the matrix photolysis of $[(\eta^5\text{-}C_5H_5)Ir(C_2H_4)_2]$.[3a] On photolysis of [(Mes)Os(CO)-(C_2D_4)], [D_4]**4a**, in argon matrices ($220 < \lambda < 360$ nm), no OsH vibration is detected at 2060 cm^{-1} and considerable shifts are observed in the bands below 1600 cm^{-1}. The absence of free C_2D_4 (722 cm^{-1}) demonstrates that ethene is not released in the reaction of [D_4]**4a**. Confirmation that insertion into the ethene C–H bonds has taken place, rather than into those of the mesitylene methyl groups, is obtained by repeating the experiments with **4b** and its C_2D_4-substituted analogue.

(b)

4a R=Me **7a** R=Me
4b R=H **7b** R=H

Irradiation of **4a** in solution ($\lambda > 290$ nm, [D_8]toluene, − 85 °C) also results in isomerization to **7a**.[9] As expected from recent investigations of related rhenium, iridium, and iron (vinyl)hydride complexes,[3a, 10–12] **7a** is stable in solution at room temperature. It isomerizes back to **4a** at 80 °C. The photolysis of **4a** in [D_8]toluene at − 80 °C under C_2D_4 (3 bar), or of [D_4] **4a** under C_2H_4 (3 bar), generates the corresponding isotopomer of **7a**. Since no C_2H_4/C_2D_4 exchange occurs, we conclude that the insertion into the ethene C–H bonds is either strictly intramolecular or occurs within the solvent cage. Preliminary results indicate that *inter*molecular C–H activation resulting in formation of [(Mes)Os(CO)(C_6H_4Me)H] occurs on photolysis of **1** or **3** in toluene *solution*.

Encapsulation of Polypyrrole Chains in Zeolite Channels**

By *Thomas Bein** and *Patricia Enzel*

Fundamental studies of the electronic structure and conduction mechanism of conducting polymers[1–3] would benefit substantially if the low-dimensional structures were available as decoupled, structurally well-defined entities. The design of molecularly isolated conducting or semiconducting[4–6] structures (with modified electronic properties) could potentially reduce the size of electronic circuitry to molecular dimensions.[7, 8]

We report the first successful synthesis of polypyrrole (Ppy) as potential "molecular wires" within the crystalline channel systems of zeolite Y and mordenite (M) molecular sieves (Fig. 1).[9] Zeolite Y is composed of sodalite cages

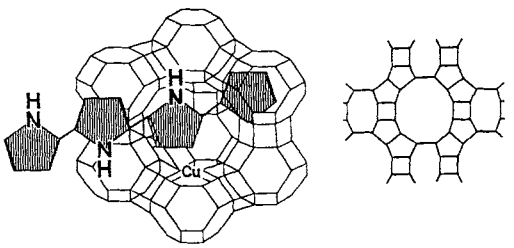

Fig. 1. Structures of zeolite Y with polypyrrole chain (left) and mordenite (right) viewed along the (001) axis.

(0.3-nm windows), interconnected by double six-rings of Si/Al, and of "supercages" with 0.8-nm windows, which together form a three-dimensional open framework with typical unit-cell composition $Na_{56}Al_{56}Si_{136}O_{384}$. Mordenite (M) features pseudo-one-dimensional twelve-ring channels, with

basic unit-cell composition $Na_8Al_8Si_{40}O_{96}$. The polypyrrole/zeolite hybrid materials differ fundamentally from previous systems in larger scale host structures,[10, 11] because the zeolite hosts can isolate *single* molecular chains in their molecule-size channel systems.[12]

When pyrrole (py) is allowed to diffuse into large-pore zeolites containing Fe^{III} or Cu^{II} ions,[13] the color of the resulting adducts—for example, $Cu_{15}Na_{26}Y(py)_{50}$ (**1**) or $Cu_{2.5}Na_3M(py)_{0.75}$ (**2**)—changes slowly from yellowish or greenish to different shades of turquoise green and black [Eq. (1)]; Na or Fe^{II} forms do not react. The polymerization reaction is one to two orders of magnitude slower in the zeolite hosts than in homogeneous solution, indicating diffusional limitations for the pyrrole in the channel system.

$$NaY + Cu(NO_3)_2/aq \xrightarrow{620\ K/10^{-5}\ torr} Cu^{II}NaY \xrightarrow[295\ K]{py\ vapor/} Ppy/Cu^{I}NaY \quad (1)$$

Intrazeolite polypyrrole shows IR bands quite similar to the typical set of bands characteristic for bulk polypyrrole;[14] however, certain shifts, which vary with host and preparation conditions, are observed. For instance, characteristic modes of **1** occur at 1573 (1540), 1460 (1450–1470), and 1312 (1280–1300) cm^{-1}, with the positions for bulk polypyrrole in parentheses (D in Fig. 2).[15] Although

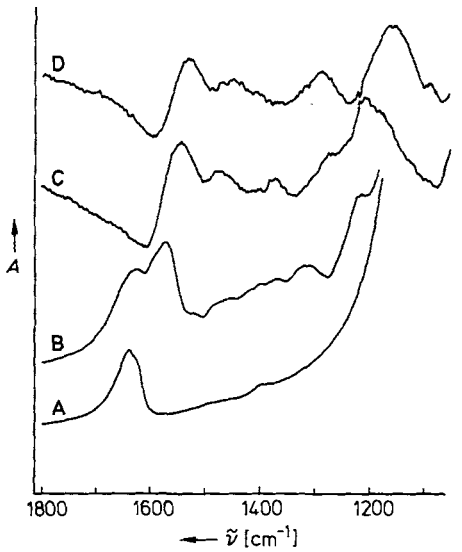

Fig. 2. FT-IR spectra (KBr pellets) of zeolite NaY (**A**), $Cu_{15}Na_{26}Y(py)_{50}$ **1** (**B**), polypyrrole extracted from **1** (**C**), and bulk polypyrrole (**D**). A = absorption.

proton generation is expected during polymerization, no clear hydroxyl features are resolved in the FT-IR spectra, probably due to strong electronic absorption features.[16] The resonance Raman spectrum of **1**[17] shows weak but resolved bands at 1598 and 1418 cm^{-1}, similar to those of Ppy film[18].

No deposition of polymer on the external surface of the zeolite crystals could be detected in electron micrographs. Since the polymerization depends upon a redox reaction with the *intrazeolite* Cu^{II} or Fe^{III} ions, most of the polymer must form inside the zeolite crystals. Consistent with the molecular-sieve properties of zeolites, treatment of the zeolite $Cu_8Na_{80}A$ (pore size 4.1 Å, smaller than pyrrole) with pyrrole did not produce detectable polymer (cf. **A** in Fig. 3).

The uptake of monomer into the zeolites is about two orders of magnitude higher than that expected from monolayer coverage of the surface of the zeolite crystals.[19] Based upon the optimal oxidant:pyrrole ratio of 2.4[14c] and the zeolite oxidant content, it follows that ca. six pyrrole molecules can be polymerized per unit cell in zeolite Y and ca. one in M. This corresponds to 13% of the pyrrole loading in Y and ca. 100% in M, fairly consistent with the amount of *polymer* recovered after dissolution of **1** in HF (4 pyrrole units per unit cell).[20] The excess monomer in the zeolites was below detection limits of the FT-IR measurements.

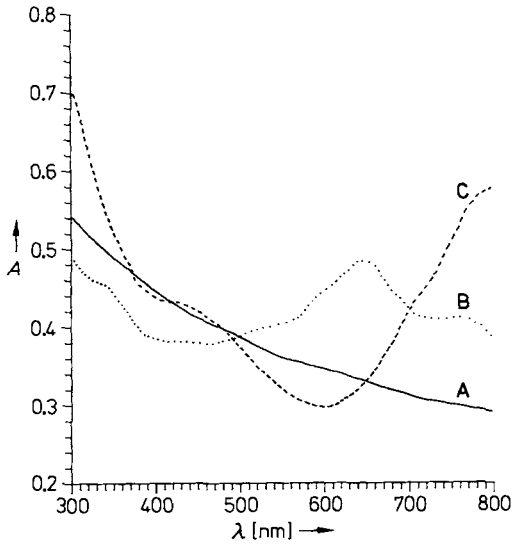

Fig. 3. UV/VIS spectra (glycerol dispersions) of $Cu_8Na_{80}A(py)_{0.3}$ (**3**) (**A**), $Cu_{2.5}Na_3M(py)_{0.75}$ (**2**) (**B**), and $Cu_{15}Na_{26}Y(py)_{50}$ (**1**) (**C**). A = absorption.

The UV/VIS spectrum of **1** shows features between 400 and 500 nm (ca. 2.7 eV) and below 650 nm (ca. 1.9 eV; **C** Fig. 3). Mordenite-based $Cu_{2.5}Na_3M(py)_{0.75}$ (**2**) also shows features at 650 and 330 nm (1.9 and 3.8 eV, **B** Fig. 3). Absorption maxima of electrochemically formed, highly doped polypyrrole at about 2.3 and 0.7 eV have been assigned to bipolaron states; the higher energy band shifted to lower values al lower oxidation levels.[21] The UV/VIS spectra probably reflect a higher oxidation level of polypyrrole in faujasite than in mordenite. ESR spectra of these samples confirm the low spin count expected for bipolaron formation,[22] and large line widths[23] (ca. 10 G) indicate strong dipolar interactions with the host. Preliminary conductivity measurements[24] of polypyrrole/zeolite samples show dramatic differences compared to bulk properties. Pressed zeolite samples deliberately coated with a thin film of polymer still show conductivities of about 10^{-6} S cm^{-1} versus 1–10 S cm^{-1} for bulk Ppy). In contrast, zeolites with *encapsulated* polymer chains do not show measurable conductivity (detection limit 10^{-9} S cm^{-1}). The agglomerated product resulting from dissolution of **1** in HF has spectroscopic properties very similar to bulk Ppy (cf. C in Fig. 2) and conductivity on the order of 0.0001 S cm^{-1}. These observations indicate that the *intrazeolite* heteroaromatic polymer chains are decoupled from each other and/or from the crystal surface, and that they probably have dramatically different transport properties. At this point is is not known if some chains in zeolite Y intersect in the spacious supercages (diameter 1.3 nm), while the one-dimensional channels of mordenite

force alignment along the (001) axis. NMR studies aimed at polymer chain-length determination are presently being carried out.

Continuing research on intrazeolite polypyrrole and other conducting polymers addresses issues such as the effect of different host pore sizes and topologies on the polymer chain length and transport properties of the resulting low-dimensional systems.

Monohapto versus Dihapto CO_2 Coordination in Bis(amine)Ni^0 Complexes: A CAS-SCF Study

By *Alain Dedieu** and *Florent Ingold*

$[NiL_2(CO_2)]$ complexes (L = phosphane, amine) are known to play a key role in many processes of organometallic chemistry.[1] For instance, they may be critical intermediates in various coupling reactions of CO_2 with alkenes, alkynes, aldehydes, imines, or even oxygen at Ni^0 centers.[1e–g, 2] They also display an interesting fluxional behavior: ^{31}P NMR spectra of a bisphosphane CO_2 complex of nickel, both in solution[3] and in liquid CO_2,[4] show a single resonance. This has been attributed to an η^1 coordination of CO_2 at the carbon atom (**A**) or to a fast dynamic process averaging the two η^2 coordination modes (e.g., **B**) either through the η^1-C coordination mode or through a fast rotation around the Ni–(η^2-CO_2) bond.[5] We report here the result of ab initio CAS-SCF calculations (CAS = complete active space), which indicate that another structure, characterized by an η^1 coordination mode at the oxygen atom (**C**) and by a strong diradical character, is close in energy to the η^2-CO_2 structure **B**, thereby providing a new perspective on the reactivity pattern of this class of complexes.

A **B** **C**

Preliminary SCF calculations were first carried out with the ASTERIX system of programs,[6] using a split valence-type basis set[7] and geometries assumed from related X-ray crystal structures or previous calculations on similar systems.[13] CAS-SCF calculations[18, 19] were then performed using the same geometries and basis set. Such multiconfiguration SCF-type calculations are necessary to include nondynamical correlation effects and to give a balanced description of the bond-forming and bond-breaking processes.[21] In particular, they provide an appropriate way (1) to take into account the manifold of low-lying electronic configurations, which is usually characteristic of nickel systems with a low coordination number,[22] and (2) to treat the diradical and closed-shell species with a similar degree of accuracy. They are also a convenient starting point for the study of dynamical correlation effects (currently under way). Including these effects (and also adding polarization functions) will probably improve the overall accuracy of the calculation but should not alter the main conclusions obtained at the present level of theory.[21]

The first salient result of the CAS-SCF calculations is the fact that the η^1-O structure **C** is found to be only 1.3 kcal mol^{-1} higher in energy than the η^2-CO_2 ground-state structure **B**.[23] A complete optimization of the two geometries might, of course, change this value somewhat, but not to a great extent. Both structures are therefore close to each other in energy, a result that was not expected on the basis of the preliminary SCF calculations.[24] The η^1-C structure **A** is computed to be much higher in energy (by

[*] Dr. A. Dedieu, F. Ingold
Laboratoire de Chimie Quantique, UPR 139 du CNRS
Université Louis Pasteur
4, rue Blaise Pascal, F-67000 Strasbourg (France)

46.8 kcal mol^{-1} at the CAS-SCF level[23]). In addition, a natural orbital analysis of the corresponding CAS-SCF wave functions points to a strong diradical character for the η^1-O structure **C**. The orbital occupations of the the bonding orbital between $d_{x^2-y^2}$ and $\pi^*_{CO_2}$ (the HOMO in the SCF ground-state wave function) and its antibonding counterpart (the LUMO) are 1.288 and 0.714, respectively.[25] Since these two orbitals are equally spread over the metal and the CO_2 ligand, the η^1-O structure **C** is probably best regarded as a 1,3 diradical centered on the nickel and carbon atoms. Most probably **C** has a singlet ground state, since the triplet state was computed to lie 4.1 kcal mol^{-1} above the singlet state.

These results suggest that the coupling reaction of CO_2 and C_2H_4, which has been observed experimentally at a Ni^0 center,[2b] might well involve a coordinated CO_2 attacked by the incoming olefin rather than an electrophilic attack on a coordinated C_2H_4 by the carbon dioxide. In both cases the attacked ligand has to slip in one way or another from an η^2 to an η^1 coordination mode.[26] But the η^1 geometry for the corresponding ethylene complex $[Ni(NH_3)_2(C_2H_4)]$ is found to be 29.0 kcal mol^{-1} above the η^2-C_2H_4 ground-state structure; hence, deformation of the η^2 geometry to the η^1 geometry is much less easy than deformation of the η^2-CO_2 structure **B** to the η^1-CO_2 structure **C**. This is reflected in the results obtained from CAS-SCF calculations performed for two geometries corresponding either to a 3-Å approach of C_2H_4 to the nickel atom of $[Ni(NH_3)_2(\eta^1\text{-}CO_2)]$ or to a 3-Å approach of CO_2 to the nickel atom of $[Ni(NH_3)_2(\eta^1\text{-}C_2H_4)]$.[27] The energy needed to reach the first geometry from the separated reactants, $[Ni(NH_3)_2(\eta^2\text{-}CO_2)]$ and C_2H_4, amounts to 14.9 kcal mol^{-1}, whereas the energy needed to reach the second geometry from the separated reactants, $[Ni(NH_3)_2(\eta^2\text{-}C_2H_4)]$ and CO_2, amounts to 36.1 kcal mol^{-1}. All these features are therefore consistent with C_2H_4 attack as the favored pathway. Work is now in progress to investigate in more detail these two reaction pathways and the influence of the ligand coordination pattern.

[13] Structural parameters: a) Dihapto complex **B**: The geometry of the CO_2 moiety was taken from the experimentally determined structure of $[Ni\{P(cyclo\text{-}C_6H_{11})_3\}_2(\eta^2\text{-}CO_2)]$ [14]; the Ni–N bond was set at 2.15 Å as in the previous SCF study of *Sakaki* et al. [15] and the N–Ni–N angle at 90° [16]. b) η^1-O structure **C**: The geometry of the $Ni(NH_3)_2$ unit was retained as in **B**, and the geometry of the Ni–CO_2 unit set as follows: Ni-O = 1.868 Å, C-O = 1.297 and 1.230 Å for the bound and nonbound C–O bonds, respectively; O–C–O angle = 130.3°. These values are taken from the X-ray crystal structure of the metallalactone complex $[Ni(dbu)_2(C_3O_2H_4)]$ (dbu = 1,8-diazabicyclo[5.4.0]undec-7-ene) [2a] and from an SCF optimization of the O–C–O angle. c) η^1-C structure **A**: The geometry of the $Ni(NH_3)_2$ unit was again retained as in **B**, and the geometry of the Ni–CO_2 unit was set according to the previous SCF calculation of *Sakaki* et al. [15]. For the NH_3 ligand the experimental geometry [17] was chosen.

[19] The active space of the CAS-SCF calculations was made of six active orbitals populated by eight electrons for the $[Ni(NH_3)_2(CO_2)]$ system. These active orbitals (d_{z^2}, $d_{x^2-y^2}$, 4s, π_{CO_2}, n π_{CO_2}, and $\pi^*_{CO_2}$) account for the main bonding interactions as well as for the sd hybridization features. For the $[Ni(NH_3)_2(CO_2)] + C_2H_4$ system, the $\pi_{C_2H_4}$ and $\pi^*_{C_2H_4}$ orbitals were added, giving rise to a set of eight active orbitals populated by ten electrons. The frozen core approximation [20] was used throughout the calculations in order to avoid error effects due to basis-set superposition.

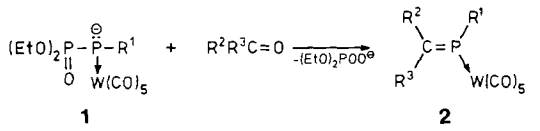
[22] See, for instance, a) M. R. A. Blomberg, U. B. Brandemark, P. E. M. Siegbahn, K. B. Mathisen, G. Karlström, *J. Phys. Chem. 89* (1985) 2171; b) P. O. Widmark, B. O. Roos, P. E. M. Siegbahn, *ibid. 89* (1985) 2180.

[23] The total CAS-SCF energies are: **B**, −1803.7096; **C**, −1803.7075; **A**, −1803.6351 Hartree (1 Hartree = 627.7 kcal mol^{-1}).

[24] The total SCF energies are: **B**, −1803.6196; **C**, −1803.5774; **A**, −1803.5190 Hartree.

[25] This corresponds to an important weight (35%) (in the CI expansion) of the configuration obtained through a double excitation from the HOMO to the LUMO with respect to the ground-state SCF configuration (whose weight in the CI expansion amounts to only 63%).

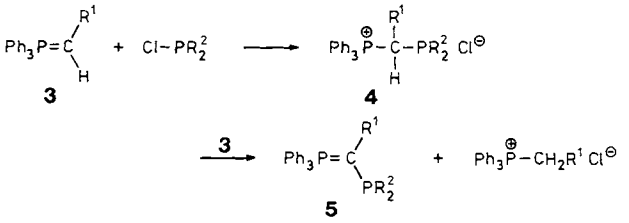
[26] The geometry of the metallactone ring corresponds either to an η^1-CO_2 or to an η^1-C_2H_4 unit. Moreover, the slippage of the ethylene ligand from the dihapto coordination mode to the monohapto coordination mode polarizes the C_2H_4 π orbital on the uncoordinated carbon atom, making it more prone to an electrophilic attack by CO_2.



[27] This corresponds to a C–C distance of about 2.5 Å. SCF calculations, which were also carried out for an approach of 2.5 Å (corresponding to a C–C distance of about 2 Å), yielded total energies which were already lower than the energies of the separated reactants.

Phosphaalkenes from Monochlorophosphanes and Alkylidenetriphenylphosphoranes

By *Gottfried Märkl** and *Walter Bauer*



The recently published synthesis by *F. Mathey* et al.[1] of complex-stabilized phosphaalkenes **2** by carbonyl olefination with the phosphorylphosphide complexes **1** leads us to describe a new general synthesis of phosphaalkenes **10** involving the reaction of alkylidenetriphenylphosphoranes **3** with chloro-(2,4,6-tri-*tert*-butylphenyl)phosphane **6**.

[*] Prof. Dr. G. Märkl, Dipl.-Chem. W. Bauer

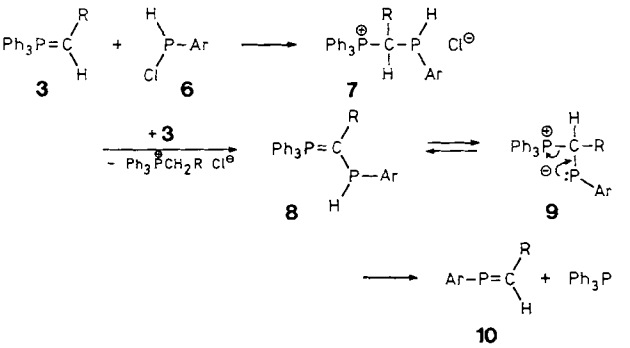
Universitätsstrasse 31, D-8400 Regensburg (FRG)

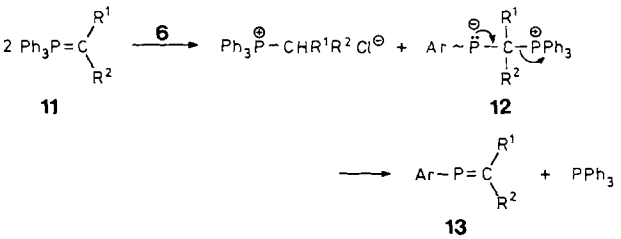


1 2

K. Issleib et al.[2] published several reports regarding the reaction of **3** with chlorophosphanes, a reaction that leads, depending upon the reaction conditions, either to the phosphonium salts **4** or—by transylidation with **3**[3]—to the phosphino-substituted alkylidenetriphenylphosphoranes **5**.

3 4 5

Treatment of chlorophosphane **6**[4] with two equivalents of a non-resonance stabilized monosubstituted methylenetriphenylphosphorane **3** (salt-containing ylide solution in THF, addition of **6** to **3**, benzene or THF as solvent, room temperature) initially causes rapid separation of one equivalent of phosphonium salt **7**. After 5 h it is possible to isolate phosphaalkenes **10** from the solution by column chromatography over heat-treated silica gel 60 with either petroleum ether (40–60 °C)/benzene (2:1) or petroleum ether alone. Benzene is suitable for subsequent elution of triphenylphosphane.



3 6 7 8 9 10

Ar = 2,4,6-tri-*tert*-butylphenyl; **a**: R = H, **b**: R = Me, **c**: R = Et, **d**: R = *n*-Pr, **e**: R = Ph

Phosphaalkenes **10** are formed by way of the phosphonium salts **7**, which undergo transylidation and are deprotonated with a second mole of ylide **3** to the phosphino-substituted alkylidenephosphoranes **8**. These are probably present in equilibrium with the betaines **9**, which ultimately fragment to **10** by elimination of triphenylphosphane (Table 1). A direct deprotonation of **7** to **9** cannot be ruled out (see below), but according to *K. Issleib* et al.[2] the relative pK_a values of **7** and protonated **3** make primary formation of the ylides **8** more probable.

Treatment of monochlorophosphane **6** with disubstituted methylenetriphenylphosphoranes **11** leads directly to the disubstituted phosphaalkenes **13** (Table 2). This means that intermediate phosphonium salts corresponding to **7**, which are incapable of forming ylides, must be deprotonated di-

rectly to **12** in order to permit fragmentation to phosphaalkenes **13** and triphenylphosphane.

Reactions of **6** with **11c** and **11d** proceed less satisfactorily, probably for steric reasons. Thus, in addition to formation of phosphalkenes **13c, d,** which cannot be isolated in pure form, ylide dehydrochlorination of **6** is also observed, leading to the diphosphene Ar–P=P–Ar isolated as orange-red crystals, m.p. = 170–180 °C, in yields up to 31 %.

Anion Coordination and Cl–H···Cl Bridges in the Low-melting Poly(Hydrogen Chloride) $Me_3N \cdot 5\,HCl$**

By *Dietrich Mootz** and *Jörg Hocken*

Adduct formation with hydrogen halides in large molar excess (beyond the composition of hydrogen dihalides) and the underlying structural principles have been studied in a systematic way only in the case of hydrogen *fluoride*.[1] We now wish to report the first characterization also of certain poly(hydrogen *chlorides*),[2] including a highly HCl-enriched phase of the system trimethylamine–HCl with the composition $Me_3N \cdot 5\,HCl$, melting congruently at -54 °C[3].

A crystal structure analysis of this phase[4] revealed an ionic compound with the formula $(Me_3NH)^{\oplus}[Cl(HCl)_4]^{\ominus}$, an interesting combination of anion coordination, hydrogen bonding, and ion-pair formation. The cation formed by protonation of the base Me_3N is accompanied by a complex anion (Fig. 1) in which a central $Cl^{\ominus}$ ion is coordinated by

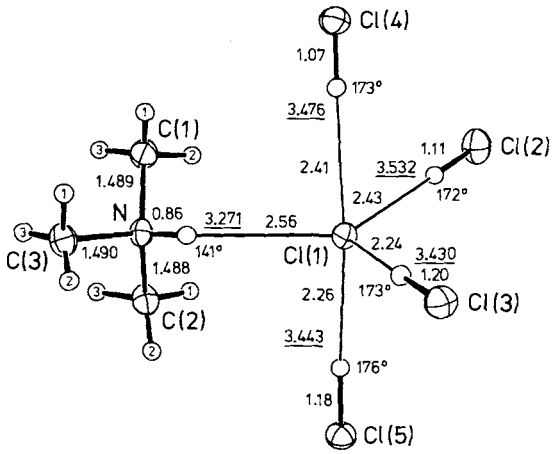

Fig. 1. The ion pair $(Me_3NH)^{\oplus}[Cl(HCl)_4]^{\ominus}$ as a structural element in the crystal structure of the phase $Me_3N-5\,HCl$, together with selected distances [Å] and angles [°]. Underlined values correspond to the overall distances Cl···Cl and N···Cl in the hydrogen bridges. Standard deviations are 0.001 Å for Cl···Cl, 0.002 Å for N···Cl, 0.004 Å for N–C, and 0.03–0.05 Å and 2–4° for distances and angles involving H atoms.

the remaining four HCl molecules of the formula unit via four hydrogen bonds of the relatively uncommon type Cl–H···Cl. In addition, the cation and complex anion are linked with each other by an N–H···Cl bridge. The overall coordination of the $Cl^{\ominus}$ ion thus constitutes a distorted trigonal bipyramid.

The significant deviation from linearity of the N–H···Cl bridge (with an angle at the H atom of only 141°) is explained by the fact that this bridge is but *one* component of a branched interaction N–H(···Cl)$_2$. The other component—leading to atom Cl(5) of an adjacent ion pair—is noticeably weaker, as indicated by the much larger N···Cl and H···Cl distances of 3.547 and 2.96 Å, respectively, and an even smaller angle at the H atom of 128°. The shortest Cl···Cl distance (apart from those involving hydrogen bonds) is one between $Cl^{\ominus}$ ions in adjacent ion pairs, determined to be 3.723 Å.

In contrast to the present case, complex anions in poly(hydrogen *fluorides*)[1] have never been found to possess more than four hydrogen bonds to a central halide ion. Provided the HF content is sufficiently high, these are characterized instead by extended or branched chains.

A Chiral Ag^I-Coordination Polymer with a Polydentate Chiral Ligand; Crystal Structure of the 1:1 Complex of CF_3SO_3Ag and *N*-[*N*-(5-Methylthenylidene)-L-methionyl]histamine**

By *Johan F. Modder, Gerard van Koten,* Kees Vrieze,* and *Anthony L. Spek*

Since chiral complexes play an essential role in many fields of chemistry,[1,2] the design and synthesis of chiral polydentate ligands, which on coordination to a metal center can selectively afford a complex in a single stereoisomeric form, is an important challenge. In research related to the modeling of the chromophore in copper proteins,[3] we recently embarked on a study of the coordination behavior of the chiral polydentate ligand *N*-[*N*-(5-methylthenylidene)-L-methionyl]histamine **1** towards the metal ions Ag^I and Cu^I. In **1** three different ligating groups are connected to the same stereogenic carbon center: a thioether group and an imidazole ring (both monodentate ligands) with S- and N-donor atoms, respectively, and a conjugated thiophenemethanimine unit as potential bidentate N,S-donor. CPK molecular model studies indicate that this ligand, when folded, might provide a cavity in which an N,N',S,S' donor array, related to the one present in Blue copper proteins,[4] is available for coordination to a single metal atom.

1

Reaction of **1** with AgO_3SCF_3 in a 1:1 molar ratio affords a product whose ^{1}H-NMR spectrum[5] is considerably different from that of the free ligand. Notable differences are the downfield shifts of the proton signals of the imine function ($\Delta\delta = 0.22$), of the methionine methyl group (0.18) and of the imidazole ring (H2 0.28, H5 0.21); furthermore, the histamine $C_\alpha H_2$-$C_\beta H_2$ signal pattern changes from an apparent A_2X_2 spin system for the free ligand to an apparent ABX_2 spin system for the complex.[6] These data indicate that there is coordination of the imine nitrogen, the methionine sulfur and at least one imidazole nitrogen atom together with spatial fixation of the histamine aliphatic chain.

An X-ray structure analysis[7] reveals that there are no discrete mononuclear units in the crystalline product, but, instead, a fascinating chiral polymer (Fig. 1) in which each ligand molecule is bound to three silver ions; this finding suggests that a folded geometry with coordination of one ligand to a single metal ion is energetically less favorable.[8] The unique rotation of this coordination polymer, which leads to a single stereoisomer with a Δ-helix,[9] seems to result from just a single stereogenic center—the C_α of L-methionine.

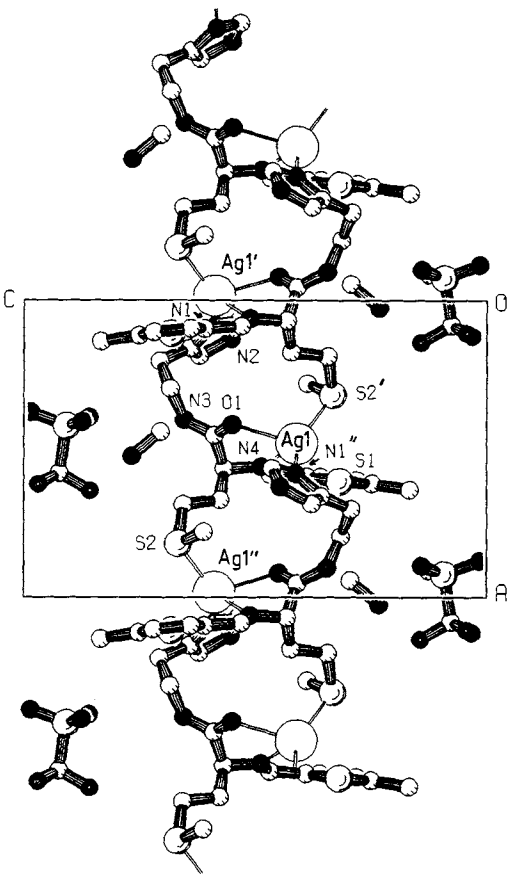

Fig. 1. Projection down the *b*-axis of part of the absolute structure of the polymeric 1:1-complex of AgO_3SCF_3 and *N*-[*N*-(5-methylthenylidene)-L-methionyl]histamine **1**. Symmetry operations by the screw axis are denoted by '(= $-1/2 + x$, $1/2 - y$, $1 - z$) and ''(= $1/2 + x$, $1/2 - y$, $1 - z$) respectively.

The compound also contains methanol, which acts as an acceptor for the amide hydrogen of the ligand and as a donor to an oxygen of an O_3SCF_3 anion. The nitrogen-bound imid-

azole-H is hydrogen bonded directly to another oxygen of $O_3SCF_3^{\ominus}$. The O_3SCF_3 anion does not, as intended, coordinate to silver.

Each Ag^I center (Fig. 2) lies almost exactly in the plane of the methionine S2′, imine N4 and imidazole N1″ atoms to which it is tightly bound. The amide O1 atom lies above this plane, but not directly over the Ag ion, owing to rigidity of the ligand. The relatively long distance of O1 from the metal atom (2.568(4) Å) implies a weak bond. The thiophene S1 atom is located on the other side of the plane; however, the Ag–S1 distance of 3.081(2) Å is too long to be considered a bond.[10] This long range interaction between the thiophene sulfur atom and the silver cation was expected on the basis of the X-ray structure data of some Ag^I complexes with ligands which only contain thiophenemethane-imine moieties.[3]

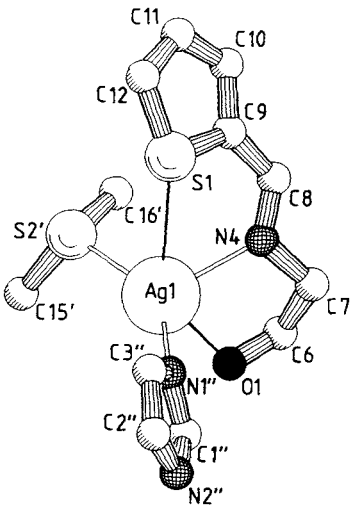

Fig. 2. Coordination geometry of the Ag-ion in the complex of AgO_3SCF_3 and **1**. Selected bond distances [Å] and angles [°]: Ag1-S2′, 2.509(2); Ag1-N1″ 2.219(4); Ag1-N4, 2.378(5); Ag1-O1, 2.568(4), Ag1-S1, 3.081(2); S2′-Ag1-N1″ 137.3(1), S2′-Ag1-N4, 106.7(1); N1″-Ag1-N4, 115.3(2); O1-Ag1-S2′, 110.6(1); O1-Ag1-N1″ 91.6(2); O1-Ag1-N4, 69.8(2).

The Ag^I-ion is best described as a trigonal-planar *N,N′,S*-coordinated, sp^2 hybridized ion, which binds the amide O1 atom and, to a lesser extent, the thiophene S1 atom via a dipole–cation interaction. Each Ag^I center in the sp^2 plane, when viewed along the axis perpendicular to it from S1 to O1, is *R* configurated.

The ^{1}H-NMR data of the complex are consistent with a structure of the complex in solution in which the Ag^I center is similarly coordinated as in the solid state; the degree of association is still unknown.

Some of the features of the metal coordination geometry found in this new complex may be relevant to a better understanding of the aspects that govern the structure and the physical and chemical properties of the Cu-N_2S_2 chromophore in Blue or Type I copper proteins.[4] Noteworthy in this respect are the M(I)–thioether-*S* bond, the M(I)–imidazole-*N* bond,[11,12] and perhaps also the long range M(I)–amide-*O* interaction.[12b]

From our results it is clear that **1** is not coordinated in a folded form to only one Ag^I center. On the contrary, the ligand is tailor-made to complex three silver ions, and, as a result of this coordination, a unique chiral polymer is formed. The occurrence of such a highly enantioselective polymerization, seemingly induced by a single stereogenic carbon center, is to our knowledge unprecedented. We are currently investigating the relevance of the ^{109}Ag-NMR shift found for this 1:1 complex of AgO_3SCF_3 and **1** (δ = 581).[13] Further studies include the synthesis and characterization of the corresponding Cu^I complex as well as modification of the ligand system (in order to create a pure N_2S_2 coordinated metal center) by replacing the thiophene by a sulfur donor with better coordinating properties.

Experimental

1: To protect the amino group, L-methionine (H-Met-OH) was converted quantitatively (295 K, commercial 2-*tert*-butyloxycarbonyloxyimino-2-phenylacetonitrile) into BOC-Met-OH. The latter was converted into its succinimide ester (273 K dicyclohexylcarbodiimide), thus activating the acid function, after which the histamine (Histam) unit was introduced via an amide bond. Subsequent removal of the amine protecting group with trifluoroacetic acid (TFA) yielded the salt H-Met-Histam · 2TFA. The free amine of this salt (generated *in situ*) was condensed with 5-methyl-2-thiophenecarbaldehyde in ethyl acetate at reflux over more than 3 equivalents of Na_2CO_3. Overall yield: 40%. Satisfactory elemental analyses were obtained[14].

[Ag **1**]$\infty(O_3SCF_3)\infty$: In a typical experiment, solutions of **1** (0.89 g, 2.5 mmol) in MeOH (25 ml) and of $Ag(I)O_3SCF_3$ (0.65 g, 2.5 mmol) in MeOH (25 ml) were mixed at room temperature, under exclusion of direct light. After stirring for 0.5 h, the solvent was evaporated and subsequently the solid, white residue was dried in vacuo. Satisfactory elemental analyses were obtained. Crystallization was achieved from a solvent mixture of MeOH, Et_2O and hexane cooled to 4 °C[7]; yield 0.92 g (60%).

[5] ^{1}H-NMR data (CD_3OD, 250 MHz, TMS ext., room temperature) of a 1:1 mixture of AgO_3SCF_3 and **1**: δ = 2.20 (m, Met: H_2C_β), 2.24 (s, Met: H_3C_ε), 2.50 (s, (5 Me)Th: H_3C), 2.57 (m, Met: H_2C_γ), 2.91 (t, Histam: H_2C_β), 3.53 (m, Histam: H_bC_α), 3.67 (m, Histam: H_aC_α), 4.18 (t, Met: HC_α), 6.89 (d, (5 Me)Th: H(4)), 7.09 (s, Histam: H(5)), 7.44 (d, (5 Me)Th: H(3)), 7.87 (s, Histam: H(2)), 8.51 (s, (5 Me)Th: H_{im}). COSY and NOESY experiments were carried out to aid assignment.

[6] Theoretically this spin system is ABXY in the free as well as the complexed ligand, due to the presence of the chiral C_α of methionine. However at the magnetic field used (5.87 T) the diastereotopicity of the CH_2 protons is not necessarily evident. The AB character of the histamine $C_\alpha H_2$ pattern was identified by irradiating the XY virtual triplet of the $C_\beta H_2$ at δ = 2.91.

[7] Crystal data of the 1:1 complex of AgO_3SCF_3 and **1**: $[C_{16}H_{22}N_4S_2Ag]^{\oplus}$ $[O_3SCF_3]^{\ominus} \cdot CH_4O$, orthorhombic, space group $P2_12_12_1$, with a = 11.339(1), b = 13.122(1) and c = 17.451(1) Å, V = 2596.5(3) Å^3, Z = 4, ϱ_{calc} = 1.636 g cm^{-3}, $F(000)$ = 1296, $\mu(Mo_{K\alpha})$ = 10.5 cm^{-1}; 3369 reflections with $1.2° < \Theta < 27.5°$ were collected for a block-shaped, ivory-colored crystal [0.42 × 0.42 × 0.48 mm] at 100 K on an Enraf-Nonius CAD4 F diffractometer with Zr filtered $Mo_{K\alpha}$-radiation (λ = 0.71073 Å). The structure was solved by standard Patterson and Fourier methods (SHELXS-86) and refined by full matrix least-squares (SHELX-76) to a final R value of 0.037 [R_w = 0.043, $w^{-1} = \sigma^2(F)$, S = 1.78, 371 parameters] for 2827 observed reflections with $I > 2.5\sigma(I)$. Hydrogen atoms were located from a difference map and their positions refined (except for those of the methyl groups that were introduced at calculated positions and refined with fixed geometry) with four common isotropic thermal parameters. A final difference map did not show any features outside the range −0.68 to 0.75 e Å^{-3}. Both enantiomorphic structures were refined; the one with the lowest R value corresponds to the absolute *S* configuration of the ligand used (Figure 1). Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, Lensfield Road, Cambridge CB2 1EW (England), on quoting the full literature citation.

[8] *Bosnich* et al. suggest also that their coordination complexes of Cu^I and Cu^{II} with a quadridentate ligand, containing all the binding sites of blue

copper proteins, may have polymeric structures as a result of ligand flexibility: J. Whelan, B. Bosnich, *Inorg. Chem. 25* (1986) 3671.

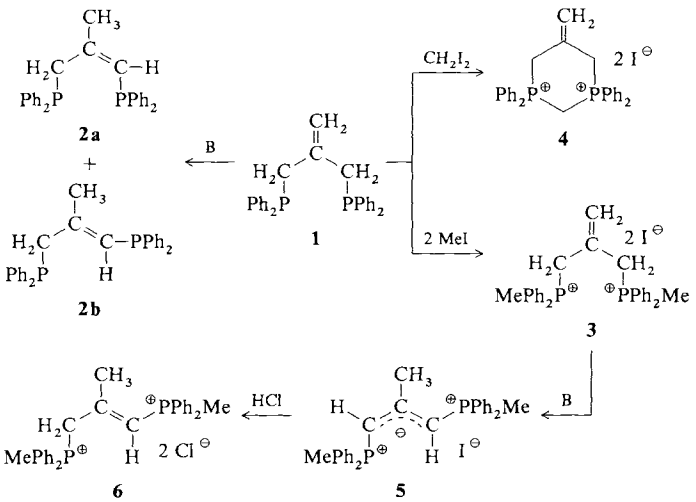
Generation, Stereochemistry, and Molecular Dynamics of a 1,3-Bis(phosphonio)propenide Cation**

By Hubert Schmidbaur, Christos Paschalidis, Oliver Steigelmann,* and *Gerhard Müller*

Allyl ions are the most simple resonance-stabilized π-systems in organic chemistry. Knowledge of their structure and molecular dynamics is of prime importance for an understanding of, e.g., allyl coordination to metals[1] and reaction pathways involving synthons with allyl-functionality.[2] Structural studies on classical metal propenide systems give ambiguous results regarding the stereochemistry of the free anions, since direct or indirect metal contacts cannot be excluded, either in the crystal or in the solution state[3]. The situation is not unlike the problem associated with the stereochemistry of "free" simple carbanions (or carbenium ions), where aggregation via the counterions $Li^\oplus$, $Na^\oplus$, $K^\oplus$, $MgX^\oplus$ etc. (or $X^\ominus$ in the case of carbenium ions) is a common feature.[4]

In previous studies we have been able to demonstrate that the configuration of carbanions can be determined by structural studies on phosphorus ylides, where the carbanionic charge is compensated intramolecularly by the phosphonium centers. Cyclopropanides and cyclobutanides[5] were shown to have distinctly pyramidal carbanionic centers, and even the simple methanides and 2-propanides are clearly species with nonplanar ylidic functions.[6] Moreover, it could be proven that bis(phosphonio)methanediides ("carbodiphosphoranes") are highly bent.[7] Following the preparation of a neutral phosphoniopropenide[8] we have now synthesized and structurally characterized the corresponding bis(phosphonio)propenide cation.



1,1,-Bis(diphenylphosphinomethyl)ethene, **1**,[9] was found to undergo facile base-catalyzed rearrangement, affording the two stereoisomers of 2-methyl-1,3-bis(diphenylphosphino)propene (**2a, b**; Scheme 1). This isomerization is not unexpected and has been observed previously in related systems.[10] In contrast, **1** reacts with excess iodomethane or diiodomethane to give **3**, containing a symmetrical open-chain dication, or **4**, containing a cyclic 1,3-diphosphonia dication, respectively.

[**] This work was generously supported by the Deutsche Forschungsgemeinschaft (Leibniz-Programm), by the Fonds der Chemischen Industrie, and by Hoechst AG, Knapsack (FRG)

Careful deprotonation of the dication in **3** using triethylethylidenephosphorane[11] as a transylidating agent[12] leads to the 2-methyl-1,3-bis[(methyl)diphenylphosphonio]-propenide monocation, which crystallizes as the iodide salt **5** in almost quantitative yield (87%). The only other product is tetraethylphosphonium iodide. Organolithium reagents, sodamide, or other strong bases can also be used for the conversion of **3** into **5**.

According to analytical, spectroscopic, and X-ray diffraction data, **5** is present as only one isomer with a stereochemistry as indicated in Scheme 1. Surprisingly, the reprotonation of **5** with ethereal HCl is equally stereoselective and yields only one dication isomer in the form of the salt **6** (the assignment in Scheme 1 is tentative). It should be noted that the dications of **3** and **6** are regioisomers when referring to (de)protonation.

Scheme 1. Reactions starting from the diphosphino compound **1**. B = base.

The NMR spectra of the salt **5** indicate the presence of two slightly nonequivalent diphenylmethylphosphonio groups in the anion at ambient temperature in $C_6D_5NO_2$ or CD_3CN as solvent. Similarly, the allyl carbon atoms C1 and C3 and their hydrogen atoms are only marginally nonequivalent, as expected for a configuration where the onium centers reside in *syn/anti* (*E/Z*) positions relative to the allylic system. ^{31}P- and ^{13}C-NMR chemical shifts are in the range typical for ylidic bonding, where onium character can be assigned to the phosphorus atoms (δ(P) = 7.9, 7.2), while carbanionic character appears to predominate at the neighboring carbon centers, whose resonances (δ(C1/C3) = 56.7/58.5) are clearly upfield from the olefinic region. By contrast, the resonance of the central carbon atom (C2) has its position in the aromatic region (δ(C2) = 167.6), in agreement also with the simple MO diagram for allylic anions[13] and with previous NMR data.[3]

The magnetic nonequivalence of P1/P2, C1/C3, and H1/H3 affords proof of rigidity of the anion configuration in solution at room temperature on the NMR time scale. The spectra are, however, temperature-dependent, and on heating a reversible collapse of pertinent signals can be detected. From the coalescence temperatures, a free activation energy for the rotational barrier of the allylic anion can be calculated. The result ($\Delta G^\ddagger = 20.5 \pm 1.0$ kcal/mol)[14] is in good agreement with data obtained previously for alkali-metal propenide solutions.[3] It should be noted that for small

cations like $Li^{\oplus}$ even greater geometrical changes are to be expected for the anions, which would lead to a complete change also of the molecular dynamics.[14b]

Figure 1 shows the result of a single crystal structure analysis of compound **5**.[15] As expected the allylic moiety is

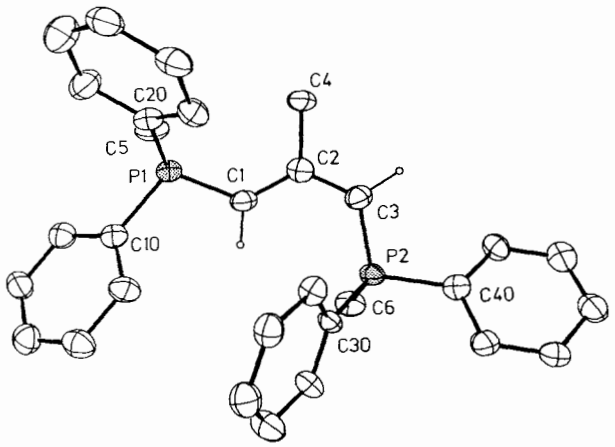

Fig. 1. Structure of the cation of **5** in the crystal (ORTEP, probability ellipsoids 50%; only the hydrogen atoms at C1/C3 are shown.) Selected bond distances [Å] and angles [°]: C1-C2 1.393(5), C2-C3 1.389(5), C2-C4 1.511(5); P1-C1 1.725(4), P2-C3 1.725(3); P1-C5 1.800(4), P2-C6 1.805(4); P1-C10 1.800(3) P1-C20 1.814(3), P2-C30 1.799(3), P2-C40 1.802(3). C1-C2-C3 124.8(3), C1-C2-C4 120.4(3), C3-C2-C4 114.8(3); P1-C1-C2 128.4(3), P2-C3-C2 125.9(3). Maximum deviation from the best plane through P1,P2,C1,C2,C3,C4 is 0.09 Å for C1. Iodide contacts are >3.8 Å.

planar, with the phosphorus substituents in *E*/*Z*-positions. The central carbon atom C2 is in a trigonal planar configuration with the methyl carbon at a normal aliphatic distance (C2–C4 = 1.511(5) Å) and two equidistant olefinic carbon atoms at C1–C2 = 1.393(5) and C2–C3 = 1.389(5) Å. Ylidic bonding is obvious from the distances P1–C1 = 1.725(4) and P2–C3 = 1.725(3) Å, when compard with the lengths of the other phosphorus-carbon bonds serving as "internal reference", and the lengths of the corresponding bonds of the precursor **1**.[9]

The iodide counteranion has no discrete cation contact in the crystal. In the absence of any prominent crystal packing effects, the propenide structure determined here can thus be taken as the unperturbed configuration of an (onium-stabilized) allylic anion. A comparison of the results with the numerous theoretical calculations on allyl systems that are now available will be dealt with in a future full paper.[16]

Experimental

The ^{1}H-, ^{13}C- and ^{31}P-NMR spectra were recorded at 270.05, 67.80 and 161.83 MHz. **2a, b**: A solution of 2.0 g (4.7 mmol) of **1** in 50 mL of tetrahydrofuran was treated with 10 g (0.91 mmol) of *t*BuOK and heated under reflux for 12 h. After removal of all volatile components by evaporation there remained a mixture of the two isomers as a colorless, viscous oil (1.9 g, 94%).—^{31}P{^{1}H}-NMR ($CDCl_3$): **2a**: $\delta = -13.5$, -30.7 (AB, $^4J(PP) = 5.7$ Hz); **2b**): $\delta = -17.1$, -27.2 (AB, $^4J(PP) = 2.8$ Hz).—^{13}C{^{1}H}-NMR ($CDCl_3$): **2a**: $\delta = 26.6$ (dd, $J(PC) = 10.27, 6.36$ Hz, CH_3), 36.0 (dd, $J(PC) = 24.94, 16.14$ Hz, CH_2), 151.7 (dd, $J(PC) = 25.9, 7.8$ Hz, =CP), 138.4 (A part of a AXX′ system, $N = 17.6$ Hz, $=CC_2$); **2b**: $\delta = 20.9$ (dd, $J(PC) = 24.9, 8.3$ Hz, CH_3), 42.2 (dd, $J(PC) = 16.1, 6.3$ Hz, CH_2), 150.1 (dd, $J(PC) = 26.4, 6.85$ Hz, =CP), 138.2 (A part of a AXX′ system, $N = 15.16$ Hz, CC_2). **3**: see Ref. [9]

4: A mixture of 2.0 g (4.7 mmol) of **1** and 0.38 mL (1.26 g, 4.7 mmol) of CH_2I_2 in 50 mL of CH_2Cl_2 was heated under reflux for 2 d. The precipitate was filtered off, washed, and dried in a vacuum (1.8 g, 56%), m.p. 215 °C (dec.). ^{31}P{^{1}H}-NMR ([D_6] DMSO): $\delta = 13.2$(s).—^{13}C{^{1}H}-NMR ([D_6] DMSO): $\delta = 13.27$ (t, $J(PC) = 40.0$ Hz, PCP), 26.89 (AA′ part of a AA′ XX′ system, $N = 50.36$ Hz, CCH_2P), 126.27 (t, $J(PC) = 10.3$ Hz, $=CH_2$), 127.98 (t, $J(PC) = 26.7$ Hz, $=CC_2$), one set of phenyl-C resonance signals.—^{1}H-NMR ([D_6] DMSO): $\delta = 4.8$ (A_2A_2' part of $A_2A_2'XX'$ system, $J(PH) = 14.65$ Hz, 4H, CCH_2P), 5.9 (t, $J(PH) = 15.26$ Hz, 2H, PCH_2P), 6.0 (br. s, 2H, $=CH_2$), 7.6–8.0 (m, 20H, Ph).

5: A suspension of 1.0 g (1.41 mmol) of the salt **3** in 100 mL of tetrahydrofuran was cooled to −40 °C and treated with a solution of 0.20 g (1.41 mmol) of $Et_3P=CHMe$ in 10 mL of the same solvent. The reaction mixture was allowed to warm to room temperature and stirred for 1 h. The precipitate was filtered off and recrystallized from toluene/acetonitrile (0.4 g Et_4PI). The filtrate was concentrated and the oily residue crystallized from benzene/hexane (**5**, 0.70 g, 87%, m.p. 174 °C).—^{31}P{^{1}H}-NMR (CD_3CN, 25 °C): $\delta = 7.89$, 7.18(s); ^{31}P{^{1}H}-NMR ($C_6D_5NO_2$, 25 °C): $\delta = 6.07$, 5.50; coalescence temperature (at 161.83 MHz): 369 K (96 °C).—^{13}C{^{1}H}-NMR (CD_3CN, −35 °C): $\delta = 10.93$ (d, $J(PC) = 63.1$ Hz, P*Me*), 13.13 (d, $J(PC) = 62.6$ Hz, P*Me*), 25.8 (dd, $J(PC) = 18.6, 8.3$ Hz, *Me*C), 56.7 (dd, $J(PC) = 118.6, 8.6$ Hz, PCH), 58.5 (dd, $J(PC) = 106.4, 17.8$ Hz, PCH), 167.6 (dd, $J(PC) = 6.86, 5.33$ Hz, *C*Me), two sets of phenyl-C resonance signals.—^{1}H-NMR ($C_6D_5NO_2$, 150 °C): $\delta = 1.98$ (s, MeC), 2.33 (d, $J(PH) = 12.9$ Hz, PMe), 3.51 (br. s, PCH), equivalent phenyl-H resonance signals.

LiCaN and Li_4SrN_2, Derivatives of the Fluorite and Lithium Nitride Structures**

By *Gerhard Cordier, Axel Gudat, Rüdiger Kniep,* and *Albrecht Rabenau**

Dedicated to Robert Juza on the occasion of his 85th birthday

Ternary nitrides[1] preferentially crystallize in the fluorite structure when the ionic radius ratio[2] $r(Li^{\oplus})/r(M^{n\oplus}) \geq 1$. The cations occupy the tetrahedral holes of the approximately cubic close-packed matrix of nitride ions either statistically ($LiMgN$[3]) or fully ordered ($LiZnN$,[3] Li_3AlN_2,[4] Li_3GaN_2,[4] Li_5GeN_3,[5] Li_5TiN_3,[5] Li_7VN_4,[6] and Li_7MnN_4[7]). The recently determined crystal structures of Li_3FeN_2, $Li_{15}Cr_2N_9$, and $Li_6(M)N_4$ (M = Cr, Mo, W)[8] are also consistent with this generalization. Within the alkaline earth series of compounds, the only member other than LiMgN ($r(Li^{\oplus})/r(Mg^{2\oplus}) = 1.0$) whose crystal structure has been reported is LiSrN.[9] LiSrN ($r(Li^{\oplus})/r(Sr^{2\oplus}) < 1$) crystallizes in the YCoC structure,[10] which is energetically more favorable than a hypothetical fluorite structure.[11] The homologous compound LiCaN[12] offers the possibility to investigate a crystal-chemical link between the LiMgN and LiSrN structures. Moreover, a Li-rich phase of the ternary Li-Sr-N system (Li_4SrN_2) has been prepared and its crystal structure determined. The structure bears a close relationship to the Li_3N structure.[13] Intermediate phases[14,15] were observed from the systems Li-Be-N and Li-Ba-N, but no suitable single crystals have so far been obtained.

LiCaN was prepared from the elements. In order to obtain single crystals suitable for structural analysis a tantalum crucible was charged with a mixture of lithium and calcium (molar ratio 6:1) and fused under argon at 250 °C. The temperature was subsequently increased, under 1 atm nitrogen, to 850 °C. LiCaN is obtained (along with Li_3N) as orange-colored single crystals with a plate-like habit. Single phase, polycrystalline samples of Li_4SrN_2 (dark metallic luster) were prepared by reaction of lithium nitride with strontium (molar ratio Li:Sr = 4:1) under nitrogen (1 atm). The melt was cooled from 700 °C to room temperature over a 12 hour period.

The crystal structure of LiCaN[16] (Fig. 1) is directly related to the fluorite structure. The calcium atoms occupy half the tetrahedral holes whereas the lithium atoms are displaced from the tetrahedral center positions of the approximately cubic close-packed nitrogen matrix, being only 0.135 Å from a tetrahedral face but 3.570(8) Å from the fourth nitrogen atom. Lithium atoms are thus coordinated to three nitrogen atoms (Li–N: 2.071(4)–2.108(8) Å), a situation similar to that found in the crystal structure of Li_3N[13] where Li atoms are coordinated in a planar arrangement within the Li_2N layers (Li–N: 2.130(1) Å). As a result of the special distribution of the cations (Fig. 1) infinite $^1_\infty[LiN_{3/3}]$ bands occur, which run in the [010] direction. These are one dimensional sections from the Li_2N layers in Li_3N[13] which, through nitrogen atoms shared with CaN_4 tetrahedra (Ca–N: 2.436(4)–2.472(2) Å; N–Ca–N: 98.6(1)–120.1(1)°), become interconnected into a three-dimensional structural

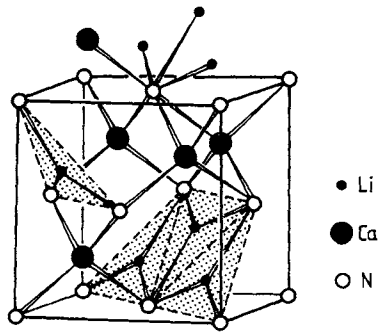

Fig. 1. Section from the crystal structure of LiCaN. Schematic representation: cubic face centered arrangement of nitrogen atoms; calcium in tetrahedral coordination; lithium displaced from the center of the tetrahedral hole to the tetrahedral face (LiN bands parallel to $[010]_{ortho}$); pentagonal bipyramidal coordination of the nitrogen atoms.

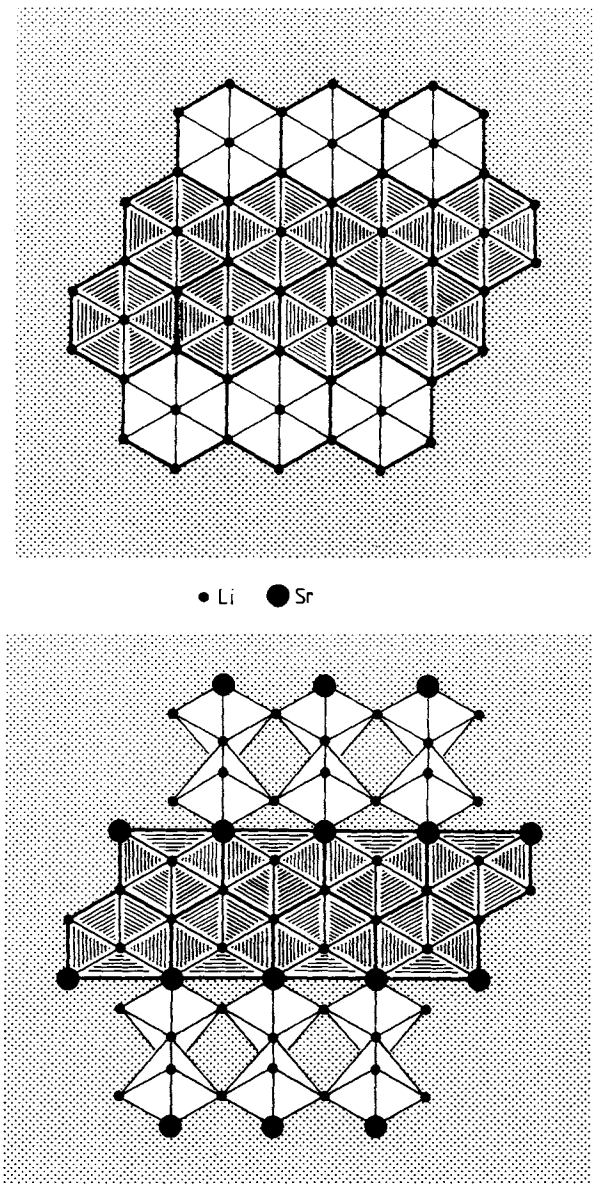

Fig. 2. Schematic representation of the coordination polyhedra (hexagonal and pentagonal bipyramids) around the nitrogen atoms in the structure of Li_3N (top, [001] projection) [13] and Li_4SrN_2 (bottom, [100] projection). In the second case, groups of layers are present in which the axes of pentagonal bipyramids lie either in the plane of the diagram (open polyhedra) or perpendicular to it (shaded polyhedra).

arrangement. The nitrogen atoms are coordinated in the form of a distorted pentagonal bipyramid, axially by two calcium atoms and equatorially by two calcium and three lithium atoms. The Ca_{ax}–N–Ca_{ax} angle is nearly linear at 177.5(3)°; the Ca_{ax}–N–$(Ca, Li)_{eq}$ angles lie between 81.5(2)° and 96.9(2)°. In the equatorial plane the angle subtended at nitrogen between two calcium atoms is 94.7(1)°; that between two lithium atoms is 62.0(2)°.

In the crystal structure of Li_4SrN_2[16] (bottom of Fig. 2) the N atoms are also coordinated within distorted pentagonal bipyramids, in this case involving $2 \times Li_{ax}$ and $2 \times Sr_{eq} + 3 \times Li_{eq}$. The angular relationships are comparable to those in the calcium compound (vide supra): Li_{ax}–N–Li_{ax} 174.4(3)°; Li_{ax}–N–$(Sr,Li)_{eq}$ 87.2(2)°–92.0(2)°; Sr_{eq}–N–Sr_{eq} 92.4(2)°; Li_{eq}–N–Li_{eq} 62.8(2)°. As implied in Figure 2 (bottom), the Li_4SrN_2 structure can be derived directly from the structure of Li_3N (Fig. 2, top)[13]. The three-dimensional framework of hexagonal bipyramids interconnected through equatorial edges and axial vertices in Li_3N ($NLi_{2/2}Li_{6/3}$) is cut into layers which in Li_4SrN_2 ($NLi_{2/2}Li_{3/3}Sr_{2/4}$) are in turn made up of pentagonal bipyramids. The layers run along [001]; each is turned 90° relative to the next, and they are connected to one another through shared strontium atoms. Strontium is therefore coordinated to four nitrogen atoms in a distorted tetrahedral geometry (Sr–N: 2.648(3) Å; N–Sr–N: 92.4(2)°–118.6(3)°). The Li–N bond lengths within the layers (Li_{ax}–N: 1.913(2) Å, Li_{eq}–N: 2.112(2)–2.149(2) Å) are just as graded as those in the structure of Li_3N[13] (Li_{ax}–N: 1.938 Å, Li_{eq}–N: 2.130(1). Impedance measurements show Li_4SrN_2 to be an ion conductor (activation energy 0.9(5) eV) but with a considerably lower ionic conductivity than Li_3N[17]. At 430 °C the ionic conductivity of Li_4SrN_2 is still an order of magnitude lower than that of pure Li_3N measured at room temperature.

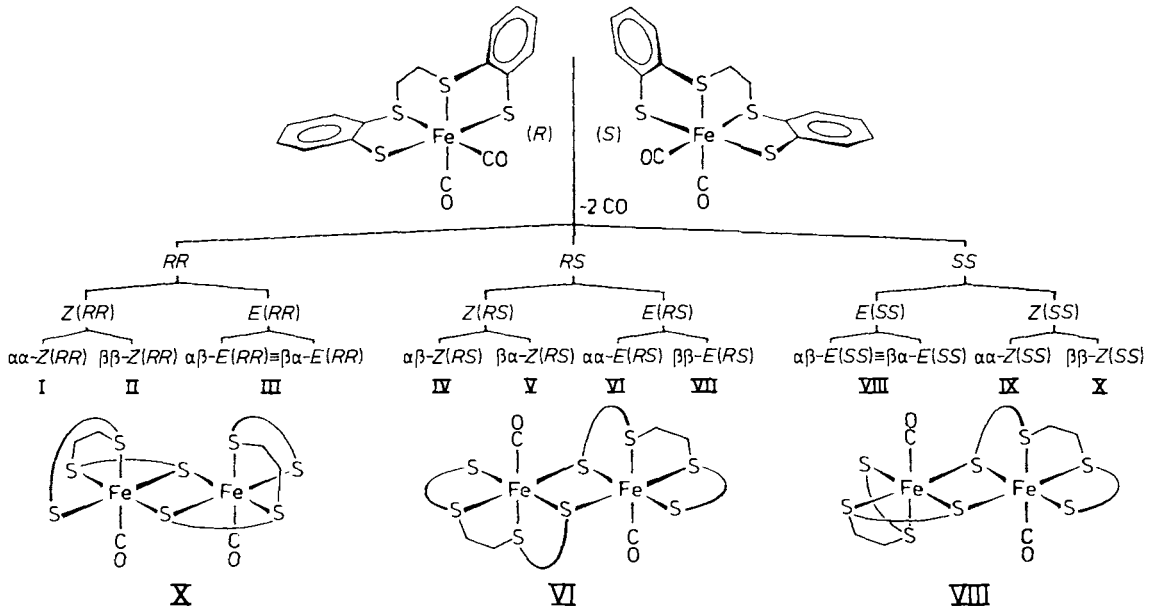
Chirality and Isomerism in Binuclear Iron Complexes with Sulfur Ligands: $[Fe(CO)(\mu\text{-}"S_4")]_2$, a Model Complex for Oxidoreductases**

By *Dieter Sellmann,* Robert Weiss,* and *Falk Knoch*

Numerous oxidoreductases, including nitrogenases and hydrogenases, have an active center consisting of iron atoms in a coordination sphere of sulfur atoms. However, much uncertainty remains about the precise structures of such multinuclear centers and the molecular processes associated with the corresponding catalytic reactions.[1a] Previously described model compounds of these centers are all only of the structural type; i.e., they do incorporate iron atoms and sulfido or thiolato ligands,[1b] are usually highly symmetric, but fail to react with such relevant substrates as CO, N_2, or H_2. What has generally not been considered with respect to model complexes is the fact that the metal centers in oxidoreductases are always chirotopic as a consequence of bonding to the protein shell.[2] This generalization applies even when the catalyzed reaction involves only achiral substrates or, as in the case of the iron centers in ferredoxins, when the iron centers are constituents of highly symmetrical subunits such as $[Fe_4S_4(SR)_4]$ clusters.[1a] Metallic centers in oxidoreductases must also provide free or potentially free coordination sites for the attachment of substrates.



In our search for model complexes of the active centers in nitrogenases and hydrogenases we have attempted to elaborate the iron complex **1** in such a way as to create multicentered chiral units with free or potentially free coordination sites at the Fe centers. Since **1** itself is chiral, it was of particular interest to ascertain what diastereomers would form in the course of a dimerization. We now report the isolation and structural characterization of the binuclear complex **2**,[3] which represents a new type of chiral complex. **2** contains two homochiral fragments with low-valent Fe centers that bind σ-π ligands, and it is formed upon dimerization of racemic precursor complexes according to equation (a).[4]

$$\underset{\mathbf{1}}{2\,[Fe(CO)_2("S_4")]} \xrightarrow[-2CO]{DMF/90\,^\circ C} \underset{\mathbf{2}}{[Fe(CO)(\mu\text{-}"S_4")]_2} \qquad (a)$$

Theoretically, the dimerization of $[Fe(CO)("S_4")]$ fragments might lead to ten diastereomers (Scheme 1, **I**–**X**). This assertion is based on the assumption of configurational stability at the Fe centers, however, since otherwise the number of diastereomers would be even larger (e.g., isomers with planar orientation of the sulfur ligands). Molecular models reveal that the conformation of the C_2H_4 bridge in **1** is fixed due to the rigid $C_6H_4S_2$ units (i.e., "inversion" of the bridge would lead to serious distortion of the angles at the Fe atom). Thus, dimerization can only lead to *RR*, *RS* and *SS* isomers.[5] In contrast to previously known binuclear complexes with chiral fragments,[6] each of these combinations in **2** is in principle the source of four isomers. Members of two of the resulting "pairs" are in fact identical, so the overall result

[**] $("S_4")^{2\ominus}$ = 2,2'-(ethylenedithio)dibenzenethiolate. Transition Metal Complexes with Sulfur Ligands, Part 51. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 50: D. Sellmann, O. Käppler, F. Knoch, M. Moll, *Z. Naturforsch.*, in press.

Scheme 1. Theoretically possible isomers of **2**, with schematic representations of the ββ-*Z*(*SS*), αα-*E*(*RS*), and βα-*E*(*SS*) isomers, ∩ = C_6H_4.

is ten structures that differ in the following ways:

a) The two CO ligands may point either in the same (*Z* isomers) or the opposite (*E* isomers) direction.

b) The bridging of the Fe centers takes place via two kinds of thiolato-S atoms which differ in only one respect: The *ortho* thioether-S atom at the respective benzene ring stands either *trans* to the remaining CO ligand (α-bridging) or *trans* to the second thiolato bridge (β-bridging).

Furthermore, in the case of the *RR* and *SS* isomers the *Z* form is only possible with αα- or ββ-, the *E* form only with βα- or αβ-linkage. The opposite is true for the *RS* isomers: the *Z* form is only possible with αβ- or βα-, and the *E* form only with αα- or ββ-bridging. The inversion-symmetric αα-*E*(*RS*) and ββ-*E*(*RS*) isomers **VI** and **VII** are *meso* forms of **2**.

Steric hindrance to dimerization is most likely to be associated with the various *Z* isomers. It was thus surprising to discover that the product **2** isolated upon reaction according to equation (a) could be shown by X-ray structural analysis[3] to consist of the enantiomeric pair αα-*Z*(*RR*)/αα-*Z*(*SS*). Figure 1 illustrates the structure of the αα-*Z*(*SS*) isomer of **2**.

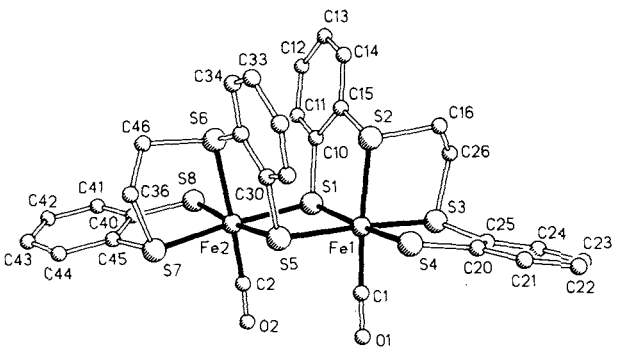

Fig. 1. Structure of αα-*Z*(*SS*)-**2** in the crystal (without H atoms). Important distances [*pm*] and angles [°]: Fe1-Fe2 342.0(1), Fe1-S1 230.2(3), Fe1-S2 230.5(3), Fe1-S3 225.8(3), Fe1-S4 229.8(3), Fe1-S5 232.7(3), Fe1-C1 174.4(11), Fe2-S1 233.0(3), Fe2-S5 229.4(3), Fe2-S6 231.3(3), Fe2-S7 225.1(3), Fe2-S8 230.5(3), Fe2-C2 174.5(10); Fe2-S1-Fe1 95.1(1), Fe2-S5-Fe1 95.4(1), S5-Fe1-S1 84.3(1), S5-Fe2-S1 84.4(1), C1-Fe1-S2 174.4(4), C2-Fe2-S6 177.1(4).

The diamagnetic complex **2** contains two homochiral [Fe(CO)("S_4")] fragments connected by thiolato ligands, and the resulting complex is also chiral. **2** possesses nearly C_2 symmetry, and the Fe^{II} centers, which have 18 e-configurations, are each coordinated pseudo-octahedrally to one CO ligand and five S atoms. Both the 18 e rule and the large Fe1-Fe2 separation argue against direct metal-metal interaction. The [Fe1-Fe2-S1-S5] four-membered ring is slightly folded, with a dihedral angle of 171°. The Fe–S distances are 225.1(3)–233.0(3) pm, and thus within the range regarded as typical for such complexes.

The differing steric requirements within the Fe coordination spheres in **2** is rather striking. One "half" of each molecule appears heavily overloaded due to the steric demands of the "S_4" ligands, while the other "half" is occupied only by the two CO ligands. In this respect, therefore, the structure of **2** is reminiscent of metalloproteins in which the folding of a peptide chain produces a distinctive spatial environment for the free coordination site. The two coordination sites on **2** that would result from release of CO should make it possible for bicentric and enantiofacial reactions to take place. That free coordination sites actually do result upon cleavage of CO from **2** is demonstrated by preliminary experiments leading to the isolation of $[Fe_2(CO)(NO)(\mu\text{-}"S_4")_2]PF_6$.

According to X-ray structural analysis, the homochiral [Fe(CO)("S_4")] fragments in **2** display exclusively α-bridging. This suggests that the regioselectivity observed during dimerization is due not to steric, but rather to electronic factors associated with the differing characteristics of the thiolate S atoms in the [Fe(CO)("S_4")] fragments. Attempts are currently being made to separate the racemic mixture.

Experimental Procedure

1270 mg (3.0 mmol) of **1** [7] *was dissolved in 50 mL of* dimethylformamide (DMF). The raspberry-colored solution was then filtered and warmed to 90 °C, causing it to turn reddish brown, and dark brown crystals of **2** began to separate. These were isolated after 48 h. Yield 70% (not optimized); IR (KBr): $\tilde{\nu}$ = 1965 cm^{-1} (CO); ^1H NMR ([D_7]DMF): $\delta \approx 6.8-8.4$ (m, 16H), 0.8–2.5 (m, 8H); correct elemental analysis.

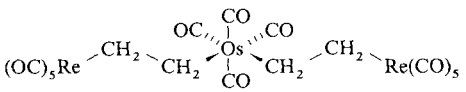
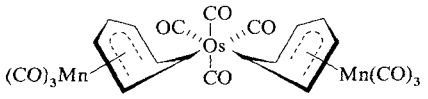
Directed Synthesis of Trinuclear Hydrocarbon-Bridged Complexes such as $[(OC)_5ReCH_2CH_2Os(CO)_4CH_2CH_2Re(CO)_5]$ **

By *Wolfgang Beck,* Burkhard Niemer,* and *Barbara Wagner*

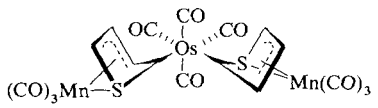


Dedicated to Professor Alfred Schmidpeter on the occasion of his 60th birthday

The nucleophilic addition of carbonylmetalates to coordinated, unsaturated hydrocarbons in cationic complexes is a method that lends itself to the directed synthesis of a variety of hydrocarbon-bridged complexes.[1] Previously we have utilized only monoanions for this purpose, for example $[Re(CO)_5]^{\ominus}$, leading to heterobimetallic complexes. We are now able to report that the dianion $[Os(CO)_4]^{2\ominus}$ [2, 3] permits the efficient synthesis of trinuclear hydrocarbon-bridged complexes (Scheme 1).



The complexes **1**–**4** were obtained in good yield by treatment of $[Os(CO)_4]^{2\ominus}$ with the cations **5**–**8** (in THF). The Re_2 compound **9** was identified as a byproduct of **1**. As in the case of the dialkyl(tetracarbonyl)osmium compounds *cis*-$[R_2Os(CO)_4]$,[3] the hydrocarbon bridges in **1**–**4** are *cis* to each other.



Scheme 1. HC = unsaturated hydrocarbon.

sive loss of CO. The ^{1}H-NMR spectrum of **1** shows the typical pattern for an AA'BB' system at $\delta = 2.00$. **1** is isolobal[8] with *n*-heptane, and can be regarded as a 1,7-dirhena-4-osma-*n*-heptane.

The $OsMn_2$ complex **2** displays the same dynamic behavior in solution as the bimetallic complex $[(OC)_3Mn(\mu\text{-}\eta^5\text{:}\eta^1\text{-}C_6H_6)Re(CO)_5]$.[10] Thus, the ^{1}H-NMR spectrum of **2** at 25 °C in [D$_8$]toluene shows only a broad signal at $\delta = 3.73$. Below -45 °C fluctuation is suppressed, so signals for the frozen cyclohexadienyl bridges appear. A benzene-bridged structure $[\{(OC)_3Mn^{\ominus}(\mu\text{-}\eta^4\text{:}\eta^2\text{-}C_6H_6)\}_2Os^{2\oplus}(CO)_4]$ with 18 valence electrons on each of the metal atoms seems plausible as a transition state for the fluctuation. Both the ^{1}H- and ^{13}C-NMR spectra of **3** contain double sets of signals, suggesting the formation of isomers. The molecular structure of crystalline **3** (Fig. 1) reveals *exo* placement of the

Maximum residual electron density 2.66, minimum residual electron density -1.55×10^{-6} e pm^{-3}. H-atoms placed in calculated positions.—Selected bond lengths [pm] and angles [°]: Os-C14 223(3), Os-C18 218(3), S1-C14 183(3), S1-C11 176(3), S2-C18 181(2), S2-C15 165(4), Mn1-S1 231(1), Mn2-S2 229(1); Os-C14-S1 119(1), Os-C14-C13 115(2), Os-C18-S2 120(1), Os-C18-C17 117(2), C18-Os-C14 87(1), C4-Os-C3 90(2).—Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG) by quoting the depository number CSD-54043, the names of the authors, and the journal citation.

$Os(CO)_4$ group on the two five-membered rings; the sulfur atoms are "*trans*" to each other. The two stereogenic carbon atoms bound to osmium have the same configuration. Bond lengths and angles in the $[Mn(CO)_3(thiophene)]$ unit are comparable to those in the adduct of cyanide with $[(CO)_3Mn(\eta^5\text{-thiophene})]^{\oplus}$, in which the C_4H_4S ring acts as an allylsulfide donor.[6] The Os–C σ-bonds of **3** have lengths (223(3) and 218(3) pm) similar to those in, for example, $[(OC)_4Os(CH_2C_6F_5)_2]$ (216(2) and 220(2) pm).[11] Addition of organic nucleophiles to metal-coordinated thiophene has been studied as a model reaction for the catalytic hydrodesulfurization of petroleum.[12]

Based on our experiences, $[Re(CO)_5]^{\ominus}$, $[Ru(CO)_2Cp]^{\ominus}$, and $[Os(CO)_4]^{2\ominus}$ are especially well-suited to the directed synthesis of hydrocarbon-bridged compounds. They are sufficiently nucleophilic for the purpose, and they also form stable metal-carbon σ-bonds. It is tempting to consider the preparation of higher polynuclear complexes through the use of highly reduced metal carbonyls[13] such as $[Re(CO)_4]^{3\ominus}$. Such polynuclear heterometallic complexes are of interest as potential precursors to heterogeneous catalysts.[14]

Experimental Procedure

All experiments were conducted under argon with carefully dried solvents.

4: To a beige suspension of 90 mg (0.26 mmol) of $Na_2Os(CO)_4$ in 5 mL of THF (−70 °C) were added 185 mg (0.52 mmol) of $[(C_7H_7)Mo(CO)_3][BF_4]$. The solvent was removed in vacuo at −25 °C from the red suspension after 1 h. The residue was then washed once with 10 mL of pentane, and **4** was extracted with 10 mL of CH_2Cl_2. Removal of solvent and drying (4 h) in high vacuum provided **4** as a red powder that gave dark red needles upon recrystallization from toluene (0 °C). Yield 190 mg (87%), decomposition above 110 °C.

The complexes **1** (colorless needles, yield 65%), **2**, and **3** (orange-yellow crystals, yield 40%) were prepared similarly, with slight modifications in the workup.

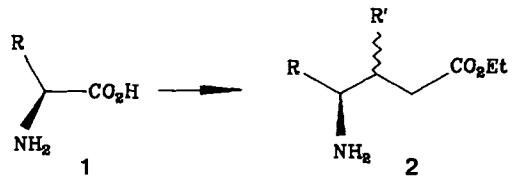
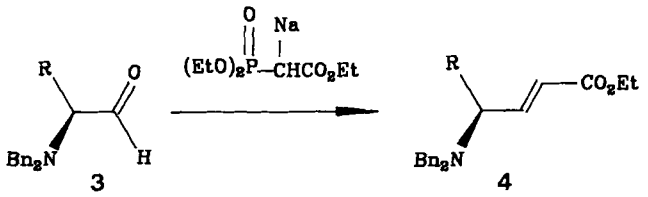
Stereoselective Synthesis of γ-Aminocarboxylates **



By *Manfred T. Reetz*,* and *Dirk Röhrig*

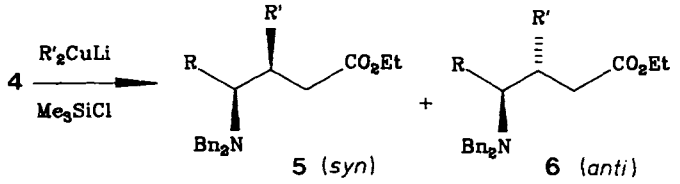
Owing to their well documented and potential biological and pharmacological activity the stereoselective synthesis of non-proteinogenic amino acids has assumed great importance.[1] We report here on a method whereby α-amino acids **1** can be converted into γ-amino acid esters of type **2** containing a new stereocenter. Accordingly, the stereoselective formation of the two possible diastereomers **2** can be controlled,



[*] Prof. Dr. M. T. Reetz, Dipl.-Chem. D. Röhrig
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 260) and the Fonds der Chemischen Industrie.

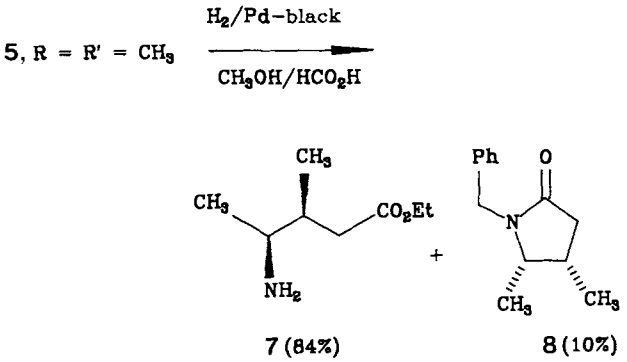
and no racemization occurs at the original stereocenter of the amino acid **1**.



Our interest was focussed on the concept that optically active α,β-unsaturated carboxylates **4** could undergo stereoselective Michael additions with suitable organocopper reagents, providing they are accessible in a prochirally pure form. This prerequisite could be fulfilled, since Wittig-Horner olefination of the *N*,*N*-dibenzyl-protected aldehydes **3**,[2] which are readily accessible from the amino acids **1**, led exclusively to the *E*-configurated products in good yields.

a: R = CH_3 (yield 73%), **b**: R = $PhCH_2$ (79%), **c**: Me_2CHCH_2 (82%)

Although the decisive cuprate addition with the Gilman reagents R'_2CuLi proved unsuccessful, the desired 1,4-addition could nevertheless be accomplished in good yields[4] and high diastereoselectivity with formation of the *syn*-configurated adducts **5** when the reaction was carried out in the



presence of trimethylchlorosilane[3] (Table 1). Not only the copper reagents but also the tin compound $(n\text{-}C_4H_9)_3SnLi$ could be added smoothly. Decisive for the high stereoselectivity are the nature and number of the protecting groups on the nitrogen: the mono-protected *tert*-butoxycarbonyl (Boc) analogue of **4b** reacts with cuprates with formation of 3:1 to 4:1 diastereomeric mixtures.[5]

In order to assign the relative configuration and check the enantiomeric purity, the protective groups of the pure diastereomers **5** were first removed with H_2/Pd black.[2] Thus, in the case of the adduct **5**, R = R′ = CH, the free amine could be isolated together with the mono-debenzylated and cyclized product **8**. NOE difference spectra provided proof of a *cis* arrangement of the substituents in the lactam **8** and thus conclusive evidence for a *syn*-configuration of the adducts **5**. The free amine was converted into the corresponding amide by reaction with (+)-3,3,3-trifluoro-2-methoxy-2-phenylpropionyl chloride according to the method of *Mosher* et al.[6] The ^1H-, ^{13}C- and ^{19}F-NMR spectra showed only a single set of signals—a clear indication that the synthesis and reactions of the α,β-unsaturated esters **4** are free of racemization.[7]

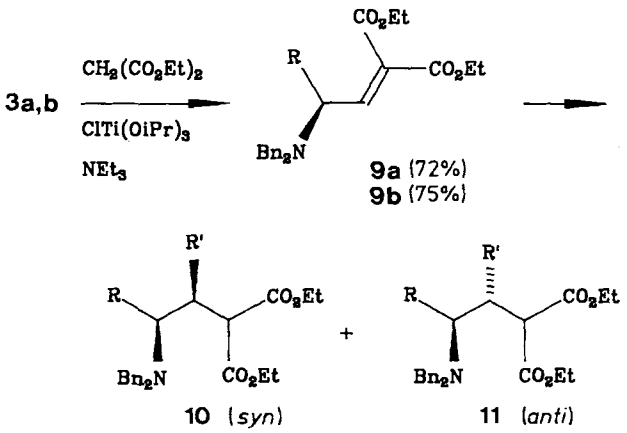


Table 1. Diastereoselective Michael additions to α,β-unsaturated carboxylates **4**.

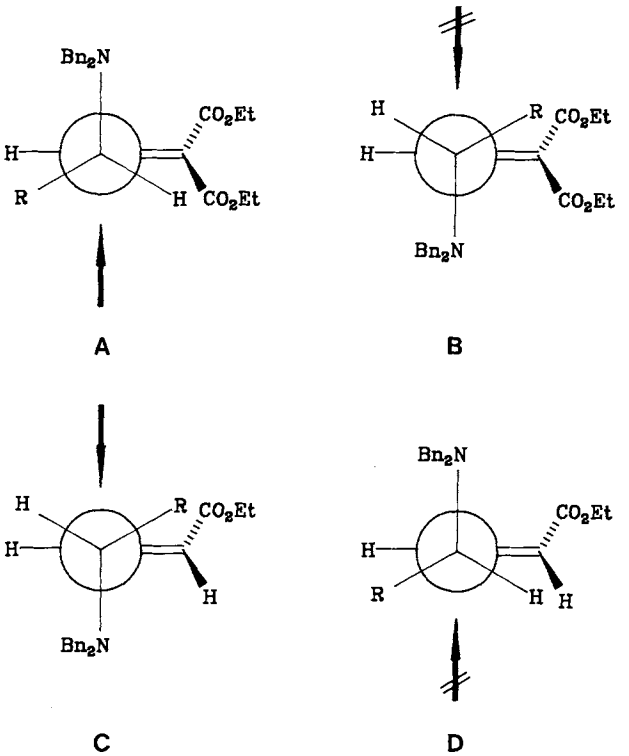
Ester	Reagent	T/t [°C]/[h]	Yield of **5** [%]	*syn*/*anti* ratio **5**:**6**
4a	$(CH_3)_2CuLi/Me_3SiCl$	−78/20	80	94:6
4a	$(n\text{-}C_4H_9)_2CuLi/Me_3SiCl$	−78/12	82	>95:<5
4a	$(C_6H_5)_2CuLi/Me_3SiCl$	−78/16	80	95:5
4b	$(CH_3)_2CuLi/Me_3SiCl$	−65/24	84	92:8
4b	$(n\text{-}C_4H_9)_2CuLi/Me_3SiCl$	−78/16	80	>95:<5
4b	$(CH_2{=}CH)_2CuLi/Me_3SiCl$	−78/18	46	94:6
4b	$(C_6H_5)_2CuLi/Me_3SiCl$	−78/16	78	95:5
4c	$(n\text{-}C_4H_9)_3SnLi$	−78/1	74	92:8
4c	$(CH_3)_2CuLi/Me_3SiCl$	−78/24	87	93:7
4c	$(n\text{-}C_4H_9)_2CuLi/Me_3SiCl$	−78/12	81	>95:<5
4c	$(CH_2{=}CH)_2CuLi/Me_3SiCl$	−78/24	41	94:6
4c	$(C_6H_5)_2CuLi/Me_3SiCl$	−78/16	80	>95:<5
4c	$(CH_3)_2CuLi/BF_3 \cdot OEt_2$	−78/12	71	>95:<5
4c	$(n\text{-}C_4H_9)_2CuLi/BF_3 \cdot OEt_2$	−78/12	70	93:7

In order to reverse the direction of the diastereoselectivity,[8] the diesters **9a**, **b** were prepared from the aldehydes **3a**, **b** by means of a titanium-mediated Knoevenagel condensation[9] and then allowed to react with organometallic reagents.

The reactions with R_2CuLi led indeed to unusually selective formation of the *anti*-adducts **11**[11] (Table 2). Since the diesters **9** are clearly better Michael acceptors than the monoesters **4**, the use of trimethylchlorosilane as additive was



unnecessary. Even Grignard reagents underwent 1,4-addition, albeit with somewhat less diastereoselectivity (Table 2).

Table 2. Diastereoselective Michael additions to the diesters **9**.

What is the origin of the diastereoselectivity in the above reactions? In the case of the diesters **9** a 1,3-allyl strain[12] possibly plays the decisive role. Accordingly, the conformation **A** would be preferred over **B**, since steric interaction between the residue R and the *cis*-oriented ester group would lead to an energetically unfavorable 1,3-allyl strain. The stereoselective formation of the *anti*-adducts is thus consistent with an *anti*-periplanar attack,[13] as indicated in conformation **A**. In the case of the monoester **4** the 1,3-allyl strain is of less importance (less interaction between R and H in conformation **C**), whereas the 1,2-allyl strain[14] in conformation **D** (interaction between R and H) gains importance

and even dominates. According to these concepts the *Z*-configurated analogues of the esters **4** should lead to the *anti*-adducts. The fact that only 40:60 diastereomeric mixtures were observed points to a possible *Z*/*E* isomerization during the cuprate addition.

No matter what the theoretical basis may be,[15] enantiomerically pure Michael acceptors of the type **4** and **9** with *N*,*N*-dibenzylamino moieties at the chirality center open up novel methods for the stereoselective synthesis of amino compounds with additional functional groups. Preliminary experiments show that the corresponding α,β-unsaturated ketones and sulfones are likewise readily accessible. Thus, the use of the "chiral pool" of the α-amino acids is extended.

[4] A solution of 5 mmol of the organocuprate in 20 mL of THF was treated at the given temperatures with 1.1 mmol of chlorotrimethylsilane, and then immediately thereafter with 1 mmol of the relevant α,β-unsaturated ester in 2 mL of THF. The mixture was stirred for the given length of time and finally poured very carefully into concentrated ammonium chloride solution. After 15 minutes' vigorous stirring the mixture was extracted with ether and the organic phase separated off and dried over $MgSO_4$. After removal of the solvent, oily products were obtained. These were purified by flash chromatography on silica gel (ethyl acetate/petroleum ether). Preliminary experiments with only 2.2 mmol of the cuprate gave the same results. For removal of the protecting group from **5a**, about 200 mg was treated with 50 mg of Pd-black in 10 mL of anhydrous methanol and with 2 mL of formic acid and hydrogenated under 1 atm of hydrogen. The course of the reaction was monitored by thin-layer chromatography. On completion of reaction the solution was decanted from the catalyst and filtered. The residue was washed with methanol and the combined filtrates evaporated down. The mixture of **7** and **8** was separated by column chromatography on silica gel. Preliminary experiments with the Pearlman catalyst $Pd(OH)_2$ (Cf. K. Yoshida, S. Nakajima, T. Wakamatsu, Y. Ban, M. Shibasaki, *Heterocycles 7* (1988) 1167) on the adducts **5**, **6** and **10**, **11** point to a uniform reaction.

[5] Since racemic phenylalanine was used as starting compound, it is not clear whether the Wittig olefination of the corresponding Boc-protected aldehyde proceeds without racemization. Boc-protected α-aminoaldehydes are clearly configurationally more stable than the *N*,*N*-dibenzyl analogues first prepared by us [2].

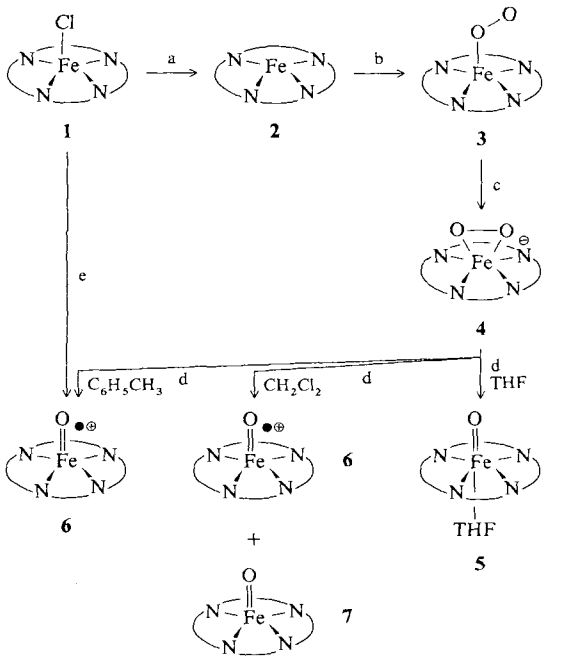
Oxoiron Porphyrin Species with High-Valent Iron: Formation by Solvent-Dependent Protonation of a Peroxoiron(III) Porphyrinate Derivative **

By *Dominique Mandon, Raymond Weiss,* Michaela Franke, Eckard Bill,* and *Alfred X. Trautwein**



The mechanism by which molecular oxygen is converted into an active oxygen ("oxenoid") intermediate by cytochrome P450 monooxygenases is still poorly understood in chemical terms.[1] A generally accepted working hypothesis, however, is that: a peroxoiron(III) species is formed by reduction of the dioxygen adduct of cytochrome P450 which yields, by protonation and heterolytic O–O bond cleavage, a π radical-cationic oxoiron(IV) porphyrinate species, similar to the well characterized compound I of Horse Radish Peroxidase (HRP I). This oxoiron(IV) porphyrinate π radical cation is presently the most attractive candidate for the active oxygen intermediate.[2–4] However, neither the formation of the peroxoiron(III) intermediate of cytochrome P450 nor its conversion into the oxoiron(IV) radical cation have thus far been observed. Consequently, the chemical properties of the known synthetic peroxoiron porphyrinate species, are of particular interest.[5–8] We have recently shown that the reaction of carbon dioxide with the peroxoiron(III) picket-fence porphyrinate **1** (Scheme 1) affords an oxoiron(IV) porphyrinate (cf. **5** in Scheme 2), presumably by homolytic O–O bond cleavage of an iron(III) peroxycarbonate intermediate.[9–11] *Khenkin* and *Shteinmann*[12] have suggested that the reaction of an acylating reagent with a peroxoiron(III) porphyrinate in toluene/acetonitrile leads to an acylperoxoiron(III) porphyrinate that decomposes by heterolytic O–O bond cleavage into an oxoiron(IV) porphyrinate π radical cation. We have now studied the protonation of the peroxoiron(III) porphyrinate **1** with tetrafluoroboric acid–diethyl ether adduct and report here the characterization of the species obtained by this highly solvent-dependent reaction.

1

Scheme 1. Structural formula and schematic drawing of the starting material **1**.

Reduction of the chloroiron(III) 5,10,15,20-tetrakis(*o*-pivalamidophenyl)porphyrinate **1** (Scheme 1) with zinc amalgam in dry degassed solvents at normal temperature leads to the iron(II) porphyrinate derivative **2**, which is four-coordinated (toluene, CH_2Cl_2) or six-coordinated (THF (Scheme 2). Treatment of **2** with O_2 at 220 K affords the five-coordinated dioxygen adduct **3** in toluene and CH_2Cl_2 and the corresponding six-coordinate species in THF and DMF.[13] The UV/VIS spectrum of **3** in toluene at 220 K presents

Scheme 2. a) Zinc amalgam, room temperature; b) oxygenation, 220 K; c) hydride reduction, 230 K; d) $HBF_4 \cdot Et_2O$, 190 K; e) *m*-chloroperoxybenzoic acid, toluene, 190 K. The steps a and b were carried out in toluene, in CH_2Cl_2, or in THF.

bands at λ_{max} = 422 and 536 nm. Generation of the peroxo-iron(III) anion **4** was carried out at 220–230 K, as previously described,[10] by reaction of **3** with sodiumdihydrido bis(2-methoxyethoxy)aluminate in the molar ratio 1:1. The reaction time is longer in toluene than in more polar solvents such as THF and DMF. However, on the basis of UV/VIS spectroscopic data, which are solvent-independent in the case of **4**, total conversion of **3** into **4** occurs at 220–230 K within one hour in toluene (λ_{max} = 438, 563, 604 nm).

Reaction of **4** in THF at 220 K with a THF solution of $HBF_4 \cdot Et_2O$ yields a bright red species **5**. The UV/VIS spectrum of **5** shows bands at 419 and 550 nm. Its ^{1}H-NMR spectrum (Bruker SY 200, [D_8] THF, 220 K, TMS) displays signals close to +7.2 (pyrrole H) and +12.9 (*o*-phenyl H) ppm. The zero-field Mössbauer spectrum obtained at 4.2 K with a sample of **5** enriched in ^{57}Fe consists of a quadrupole doublet with $\delta = 0.11 \pm 0.02$ mm s^{-1} (relative to α-Fe) and $\Delta E_q = 2.20 \pm 0.03$ mm s^{-1}. These spectral data indicate that **5** is identical with the oxoiron(IV) derivative which was obtained previously by reaction of **4** with carbon dioxide in THF at 220 K.[10] Compound **5** does not react with cyclohexene, and upon warming in THF solution to ambient temperature gives the ferric starting material **1** nearly quantitatively.

In contrast, reaction of **4** in toluene at 190 K with a suspension of $HBF_4 \cdot Et_2O$ in a small amount of CH_2Cl_2 affords a greenish transient species **6**. The identification of **6** as a π radical cationic oxoiron(IV) porphyrinate derivative[14] is based on the following observations: The UV/VIS spectrum of **6** (Fig. 1) recorded after decantation of the heterogeneous

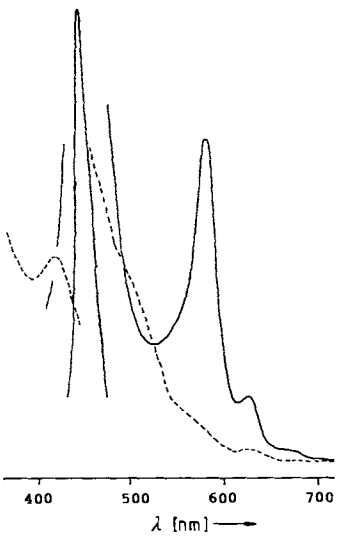

Fig. 1. Change in the UV/VIS. spectrum of **4** (—) upon addition of $HBF_4 \cdot Et_2O/CH_2Cl_2$ at 190 K in toluene (– – –) after 15 min. decantation).

medium, exhibits a weak and broad absorption in the Soret band region[15] (416 nm) and weak bands at 508 (shoulder) and 630 nm. The radical cation **6** is highly unstable; warming to 230 K causes bleaching of the sample. The Mössbauer spectrum of ^{57}Fe-enriched **6** obtained at 4.2 K, shows that approximately 75% of the sample[16] consisted of a species having an isomeric shift compatible with an iron(IV) species ($\delta = 0.09 \pm 0.02$ mm s^{-1}) but a much smaller quadrupole splitting ($\Delta E_q = 1.44 \pm 0.03$ mm s^{-1}) than the red oxo-iron(IV) porphyrinate derivative of type **5** which is obtained at 230 K in toluene upon reaction of **4** with carbon dioxide.

The zero-field Mössbauer spectrum of this species of type **5** obtained at 4.2 K consists of a quadrupole doublet characterized by an isomeric shift δ of 0.10 mm s^{-1} and a quadrupole splitting ΔE_q of 1.94 mm s^{-1}. A similar increase in the value of the quadrupole splitting has been observed at 4.2 K between the green π radical-cationic oxoiron(IV) tetramesitylporphyrinate (analogue of **6**) ($\delta = 0.06$, $\Delta E_q = 1.62$ mm s^{-1})[17, 18] and the corresponding neutral red oxoiron(IV) species (analogue of **5**) ($\delta = 0.04$, $\Delta E_q = 2.30$ mm s^{-1}).[19] Moreover, the external-field Mössbauer studies reveal that in **6** the π radical cation is only weakly coupled to the iron(IV) ($S = 1$) center. The Mössbauer spectra (Fig. 2) are superpo-

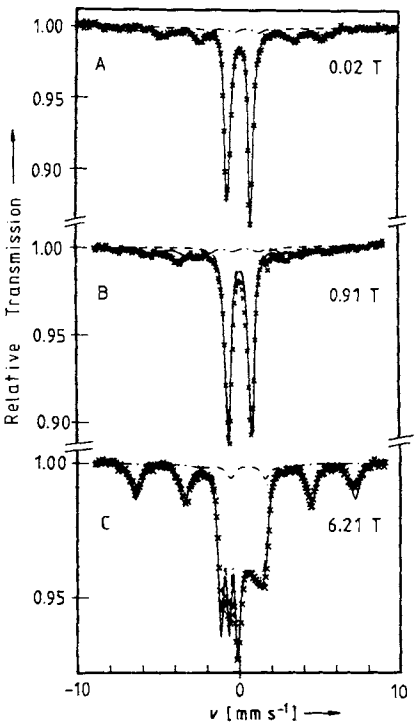

Fig. 2. Experimental Mössbauer spectra of **6** and a high-spin iron(III) species (75% and 25% of total absorption area) [16], recorded at 4.2 K with field applied perpendicular to the γ-beam; 0.02 T (A), 0.91 T (B), 6.21 T (C). The calculated powder spectra (broken lines: iron(III) species; unbroken lines: total spectrum of **6** and iron(III) species) represent spin-Hamiltonian simulations using the parameters listed in Table 1.

sitions of subspectra from **6** and a high-spin iron(III) contamination.[16] The calculated subspectra are spin-Hamiltonian simulations using the parameters listed in Table 1. The weak spin coupling of iron(IV) ($S = 1$) and the radical cationic porphyrinate moiety ($S' = 1/2$) is discerned in the weak-field spectra (Fig. 2A, 2B) from the slight magnetic splitting and the resultant asymmetry of the prominent line doublet. In particular, the magnetic-field dependence of this asymmetry cannot be simulated without spin coupling. Thus, **6** presents spectroscopic and magnetic properties which are very similar to those known for the well characterized HRP I.[21] We should mention, that strong spin coupling, as observed in oxoiron(IV) tetramesitylporphyrinate[18] yields completely different Mössbauer spectra in weak and in strong magnetic fields.

In order to further characterize this greenish species **6** we have studied its ^{1}H-NMR spectrum (Bruker SY200, [D_8]-toluene, 203 K). In contrast to the ^{1}H-NMR spectra of the π radical cationic oxoiron(IV) complexes of tetramesityl-

Table 1. Spin Hamiltonian [a] and Mössbauer parameters [b] of **6** and a high-spin iron(III) species used for the simulation [c] of powder spectra in the slow relaxation range (cf. Fig. 2).

Species	D [cm^{-1}]	E/D	ΔEq [$mm\,s^{-1}$]	η	$A_x = A_y = A_z$ [T]	δ [$mm\,s^{-1}$]	Γ [$mm\,s^{-1}$]	J [cm^{-1}]	S	S'
6	20	0	+1.44	0	−20	0.09	0.3	1	1	1/2
Iron(III) [d]	4.5	0	+0.30	0	−21	0.46	0.6	–	5/2	–

[a] The electronic Hamiltonian is given by $H_e = D[S_z^2 - 1/3\,S(S+1) + E/D\,(S_x^2 - S_y^2)] + S \cdot J \cdot S' + g\beta B \cdot (S+S')$. The electronic g-factor and the exchange coupling tensor are taken to be isotropic. D and E are zero-field splitting parameters, and B is the applied field. [b] The components of the hyperfine-coupling tensor A are part of the usual nuclear Hamiltonian used for simulating Mössbauer spectra. Quadrupole splitting ΔE_q, asymmetry parameter η, isomer shift δ and line width Γ correspond to 4.2 K; δ is given relative to α-Fe at room temperature. [c] For details see References [18, 20, 22]. [d] For the simulations of the iron(III) subspectra in Figure 2 we adopted axial symmetry, i.e. $E/D = 0$, $\eta = 0$ without further refinement.

porphyrin[17, 18, 21] and tetrakis(2,6-dichlorophenyl)porphyrin[22] the upfield shift of the β pyrrole protons and the downfield shift of the *m*-phenyl protons are less marked in the spectrum of **6**.[23] Indeed, this spectrum is characterized by two broad signals at $\delta = -6.5$ and $+13.0$ which we assign to the β-pyrrole and the *o*-phenyl proton resonances, respectively. Sharper signals at $\delta = +8.7$ and $+9.2$ are probably due to the *m*-, *m'*- and *p*-protons of the phenyl groups. Upon warming the sample, the signals of the π radical cation **6** already disappear at 230 K with formation of a weak residual spectrum typical for a high-spin iron(III) species.

Another route for the generation of **6** is the reaction in toluene at 190 K of the high-spin chloroiron(III) derivative **1** with two equivalents of *m*-chloroperoxybenzoic acid (*m*-CPBA). Both the stability, and spectroscopic features (UV/VIS, ^1H NMR, Mössbauer) are not significantly different from those displayed by **6**. Furthermore, in presence of catalytic amounts of **1**, cyclohexene is completely epoxidized in toluene at 220–230 K by *m*-CPBA.[24] Gas phase chromatography indicates that cyclohexene oxide is exclusively obtained without formation of hydroxylated or carbonylated derivatives.

In conclusion, the protonation at low-temperature of the peroxoiron(III) porphyrinate derivative **4** with $HBF_4 \cdot Et_2O$ yields in THF the red oxoiron(IV) porphyrinate species **5** and in toluene the greenish π radical cationic oxoiron(IV) porphyrinate **6**. This protonation reaction is highly solvent-dependent, only a mixture of **6** and **7** could be obtained in CH_2Cl_2. In DMF no oxoiron species with high-valent iron could be identified, only a mixture of iron(II) and iron(III) prophyrinates could be detected.[25]

[14] So far, it is not clear whether the oxo group present in **6** is located within the pickets or on the non-protected side of the porphyrin ring. We favor the former structure because **6**, although quite unstable, is still more stable than the radical cationic oxoiron(IV) species that one can generate at very low-temperature with non-protected porphyrins. Furthermore, the oxo group of **5** is located inside the molecular cavity of the picket-fence porphyrin (see Reference [10]).

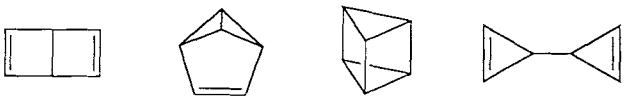
Bicycloprop-2-enyl (C_6H_6)**



By *Wilbur E. Billups** and *Michael M. Haley*

The valence bond isomers of benzene have been the object of intensive theoretical and synthetic studies. Dewar benzene (**1**) was synthesized in 1963 by *van Tamelen* and *Pappas*.[1]

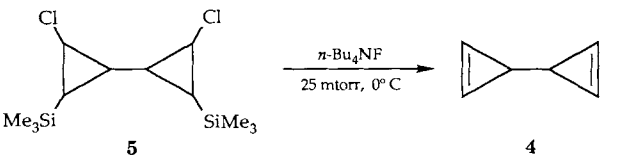
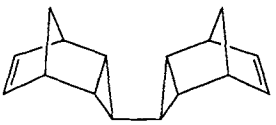
Benzvalene (**2**) was isolated in low yield from sensitized photolysis of benzene by *Wilzbach* et al. in 1967[2] and synthesized by *Katz* et al. in 1971.[3] Prismane (**3**) was prepared from **2** by *Katz* and *Acton* in 1973.[4] Although derivatives of bicycloprop-2-enyl **4** have been prepared,[5] the unsubstituted species, which has been calculated to be the $(CH)_6$ species of highest energy,[6] has eluded synthesis. We now wish to report the synthesis and characterization of this the remaining $(CH)_6$ isomer.



1 **2** **3** **4**

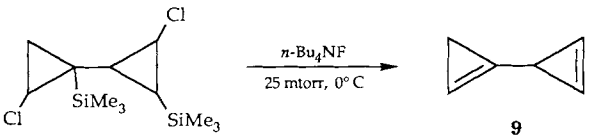
The starting material **5** was prepared from 1,4-bis(trimethylsilyl)buta-1,3-diene (**6**)[7] and chlorocarbene[8]. Treatment of **6** with an eightfold excess of chlorocarbene afforded the vinylcyclopropane **7** in 68% yield as a 60:40 mixture of *trans* and *cis* isomers.[9] Exposure of **7** to the same conditions resulted in the isolation of the bicyclopropyl **5** in 45% yield.[10]

6 **7** **5**



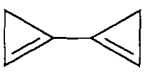
The slow introduction of **5** into a vacuum gas-solid reaction (VGSR) apparatus packed with tetra-*n*-butylammonium fluoride on glass helices[11] yielded bicycloprop-2-enyl **4** as the major product. The identity of **4** is based on its ^{1}H-NMR spectrum—a doublet at $\delta = 7.15$ (4H, $J = 1.3$ Hz) and a triplet at 1.45 (2H, $J = 1.3$ Hz). The NMR signals of **4** were persistent as a solution in CD_2Cl_2 was warmed from $-90\,^\circ C$ to $-10\,^\circ C$. Above $-10\,^\circ C$, however, these signals began to diminish. At room temperature **4** polymerizes into a solid yellow mass, in contrast to other bicycloprop-2-enyls which aromatize. Although the thermal rearrangement of bicycloprop-2-enyls to benzene derivatives is among the most exothermic unimolecular processes known ($\Delta H^\circ_{rxn} =$ 120 kcal/mol),[5] the polymerization of **4** is thought to proceed via an ene reaction characteristic of other simple cyclopropenes.[12]

5 **4**



When the walls of the liquid nitrogen trap used to collect **4** were coated with cyclopentadiene, the Diels-Alder adduct **8** could be isolated in 72% yield.[13]

Treatment of a solution of **4** in $CDCl_3$ with $AgBF_4$ at 0 °C resulted in nearly quantitative conversion into **1** along with a small amount of polymer.[14] The identity of **1** was confirmed by comparison with the ^{1}H-NMR spectrum of an authentic sample and by its isomerization to benzene.[2]



8

The fluoride-induced elimination of β-halosilanes in the gas phase has also been utilized in the synthesis of the isomeric bicyclopropenyl **9**.[15, 16]

9

Studies on the synthesis of the potentially useful synthon bicycloprop-1-enyl **10** will be reported shortly.

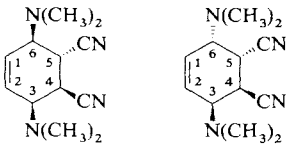
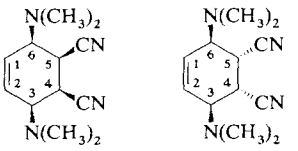
[4+2]-Cycloadditions with 1,4-Bis(*N*,*N*-dimethylamino)-1,3-dienes: Stereochemical Studies and Observation of Radical Ions**



By *Reiner Sustmann,** *Karin Lücking, Gebhard Kopp,* and *Michael Rese*

For a long time, and particularly following the presentation of the Woodward-Hoffmann rules, it was assumed that there is one universally valid mechanism for [4+2]-cycloadditions. Recent investigations, however, indicate that the mechanism is dependent on the pattern of substitution of the diene and the dienophile.[1] Thus, some cycloadditions proceed via diradicals,[1,2] while others are reported to proceed via polar intermediates.[3] Even an electron transfer with formation of radical ions has been proposed as primary step.[4] The observation of charge-transfer (CT) complexes and the analysis of their significance in Diels-Alder reactions have stimulated further discussion on the degree of charge transfer during these cycloadditions.[5-8] Herein we report on cycloadditions of the stereoisomeric dienes **1** and **2** and of the bicyclic diene **3** with dienophiles of different acceptor strength. A combination of stereochemical studies with electrochemical measurements and ESR investigations should provide information on the significance of electron transfer in the reactions.

1 **2** **3**



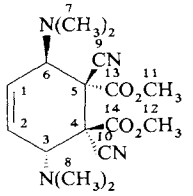
A solution of equimolar amounts ($c = 0.2$ M) of **1** and fumaric dinitrile in [D_6]benzene is dark violet (λ_{max} = 470 nm); this is attributed to a charge transfer (CT) complex. The solution of **2** with fumaric dinitrile absorbs at λ_{max} = 500 nm. In both cases a crude yield of 96% of the same cycloadduct **4** was determined ^{1}H-NMR spectroscopically after two weeks at 35 °C, i.e. the product obtained corresponded to what had been isolated earlier in 55% yield[9] upon reaction of **2** with fumaric dinitrile.

4 **5**

For **1**, this result can be explained in terms of a thermal isomerization of **1** to **2** prior to the cycloaddition and a rapid reaction of **2**, whereas for **2**, product formation can be rationalized in terms of concerted cycloaddition. This explanation is consistent with the observation that *Z*-1-substituted dienes react considerably slower than the *E* isomer.[10] It has been shown independently that **1** isomerizes quantitatively to **2** within 5 d at 35 °C. If the cycloaddition of **1** and fumaric dinitrile is carried out at 50 °C using the 16-fold higher concentration described in the literature,[9] the isomerization is suppressed and up to 96% of **5** is formed.[11] In each case it was demonstrated by mixing that 1.5% of the other isomer could have been detected by ^{1}H-NMR spectroscopy. The stereoselectivity of the reactions is accordingly ≥98.5%.

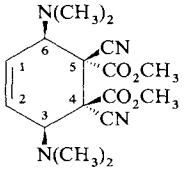
Maleic dinitrile reacts with **2** in benzene ($c = 0.2$ M for both components, $T = 35$ °C) within 23 d to give a mixture of **6a** and **6b** (96%, ratio 86:14, determined by ^{1}H-NMR spectroscopy). A CT complex is formed initially and absorbs at λ_{max} = 486 nm. The products could not be separated without decomposition and were characterized spectroscopically.[12] In the reaction of maleic dinitrile with **1** the same product was formed as in the reaction with **2**. Isomerization of **1** could not be suppressed upon reaction with the less reactive maleic dinitrile.

6a/6b



The reactions of the respective 1,2-dicyano-substituted dimethyl esters of fumaric acid and maleic acid with **1** and **2** were carried out (0.2 M solution of the components in methylene chloride) at −50 °C, since a higher temperature led to unidentifiable products. The reaction was complete within 5 min—the minimum time required for the recording of a ^{1}H-NMR spectrum after mixing the compounds—and a single adduct was always isolated (97%) with all four combinations of the reaction partners. At −95 °C formation of a bluish-green CT complex (λ_{max} = 540 nm) is briefly observed. The cycloadduct decomposes in solution at T ≥ −40 °C, but it can be isolated as a colorless microcrystalline solid by removal of the solvent at −50 °C. This cycloadduct is also unstable at higher temperatures, but it could be characterized spectroscopically.[13] In the mass spectrum the $M^{\oplus}$ peak appears at *m/z* 334 with a relative intensity of 1%. According to the spectroscopic data the cycloadduct must have either C_2 or C_s symmetry. In principle, six stereoisomers are possible, of which, however, two are already ruled out because of lack of symmetry. Of the remaining four, structure **7** is preferred since all the larger substituents can be arranged equatorially or pseudo-equatorially. In a concerted reaction, **7** would be formed upon reaction of the *E,Z*-diene **1** with the *E*-dienophile dimethyl 1,2-dicyanofumarate. The chemical shifts are consistent with those expected for such a substituted cyclohexene derivative.[14]

The *E,E*-diene **2** and the *E*-dienophile are configurationally stable for at least 3 h at −50 °C in methylene chloride even if the diene has been added to the dienophile or vice versa, as has been demonstrated ^{1}H-NMR spectroscopically. The *E,Z*-diene **1** and the *Z*-dienophile, however, isomerize when they are mixed at −50 °C in methylene chloride to give **2** and the *E*-dienophile, respectively. The rate of isomerization is a function of the concentration of the reaction partners. With 0.4 equivalents of the *Z*-dienophile the isomerization of **1** was complete after 5 min at −50 °C, whereas the dienophile was isomerized to only 60% under these conditions. Concomitant with the isomerization, the cycloadduct **7** was formed in amounts corresponding to that of the substoichiometric component. In the case of a concerted cy-

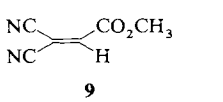


[*] Prof. Dr. R. Sustmann, Dr. K. Lücking, Dr. G. Kopp, Dipl.-Chem. M. Rese
Institut für Organische Chemie der Universität
Postfach 103764, D-4300 Essen 1 (FRG)

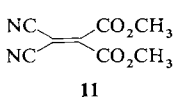
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

cloaddition after isomerization, the adduct **8** would have been expected instead of **7**. Because of the lower symmetry, the ^{1}H-NMR spectrum of **8** must, however, show more lines than that of **7**.

7

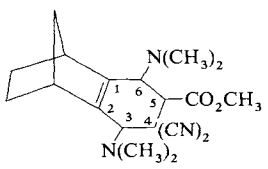


8

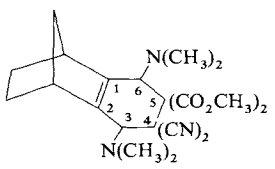


After mixing the *E,E*-diene **2** with the *E*-dienophile at $-95\,^\circ$C in CD_2Cl_2 a complex ^{1}H-NMR spectrum was obtained which showed hardly any signals left over from the starting materials and only very small signals for the product **7**. It was possibly the spectrum of conformers of a zwitterionic intermediate. On slow heating of this solution to $-50\,^\circ$C the signals of **7** became larger, while the other signals disappeared. **7** is thus clearly formed in a multistep reaction. After mixing the solutions of the components in CH_2Cl_2 at $-75\,^\circ$C, radical ions of both the diene as well as of the dienophile were observed ESR spectroscopically, as could be confirmed by the independent generation of $\mathbf{2}^{\bullet\oplus}$ (oxidation with $AgBF_4$) and of the dienophile (reduction in THF with Na/K alloy). Hyperfine coupling constants for the radical anion of dimethyl 1,2-dicyanofumarate were determined to be $a_H = 0.086$ mT (6H; OCH_3) and $a_N = 0.145$ mT (2N, CN). The large number of lines in the spectrum of $\mathbf{2}^{\bullet\oplus}$ precluded an accurate analysis.

The reaction of **3**—which had already been reacted with other dienophiles in earlier experiments[15]—with equimolar amounts of **9** at room temperature in the absence of solvent is strongly exothermic and yields only unidentifiable products. When the reaction was carried out in THF ($c = 0.17$ M, both components) a red solid could be isolated, which according to the ^{1}H- and ^{13}C-NMR spectra had the structure of the [4+2]-cycloadduct **10**.[16] The mass spectrum (chemical ionization CI) shows the expected $(M+H)^\oplus$ peak at 343 (54%). Attempts to purify this thermolabile adduct, which according to the ^{1}H-NMR spectrum is formed in 93% yield, met without success. Its coloration must be attributed to the presence of small amounts of an impurity. ESR spectroscopic examination of the solid revealed slight paramagnetism.



Equimolar amounts of **3** and **11** were allowed to react in THF at room temperature and in toluene at $-80\,^\circ$C. The ^{1}H- and ^{13}C-NMR spectra of the product, which was formed in 80% yield (^{1}H-NMR analysis with a standard), confirmed that a [4+2]-cycloaddition to give **12** had taken place.[16] The structure **12** is also supported by the CI-mass spectrum [m/z 401 ($M^\oplus+H$, 16%), 207 ($\mathbf{2}^\oplus+H$, 100%)]. Although **3** was allowed to react as a mixture of the *E,E*- and *E,Z*-isomers, only one diastereomer could be detected. Reaction of the isomeric mixture **3** with less reactive dienophiles leads to product mixtures.[17] The uniform product observed here points to a non-stereospecific, presumably multistep, reaction leading to the thermodynamically most stable product.



9

11

10

12

Radical ions are detectable in the ESR spectroscopic analysis of the reaction mixtures of **3** with **9** and **11**. Thus, the radical anion of **9** could be observed in THF between $-20\,^\circ$C and $+20\,^\circ$C. At $-20\,^\circ$C three sorts of radical ions are recognizable, of which two are assigned to conformers of $\mathbf{9}^{\bullet\ominus}$, because of their very similar splitting pattern. The third radical is $TCNE^{\bullet\ominus}$ (TCNE tetracyanoethylene). At $+20\,^\circ$C only one isomer of $\mathbf{9}^{\bullet\ominus}$ and $TCNE^{\bullet\ominus}$ are still recognizable [$\mathbf{9}^{\bullet\ominus}$: $a_H = 0.085$(3H), 0.343 mT(1H), $a_N = 0.135$(1N), 0.159 mT(1N)]. The presence of $TCNE^{\bullet\ominus}$ is surprising, but must result from a metathetical reaction of **9** with $\mathbf{9}^{\bullet\ominus}$. $TCNE^{\bullet\ominus}$ is the only radical ion that is detectable on mixing the solutions of **3** and **11**. The metathesis can only be of secondary importance, however, since the yields of cycloadducts are high.

The results show that the dienes **1**–**3** form radical ions with very reactive dienophiles. On the basis of polarographically determined redox potentials[18] the results can be interpreted quantitatively. Figure 1 shows the redox potentials

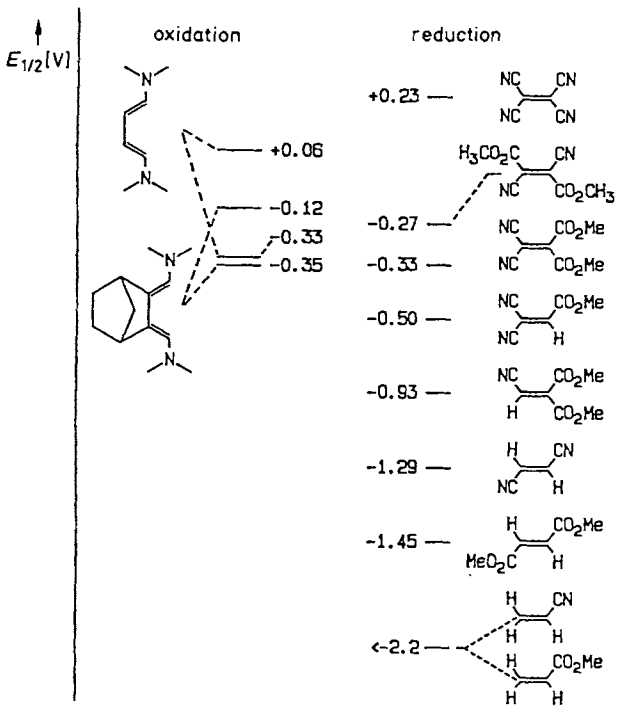


Fig. 1. Redox potentials $E_{1/2}$ vs. SCE for some dienes and dienophiles.

of the dienes and dienophiles, whereby two potentials are quoted for each of the dienes, one corresponding to the oxidation to the radical cation, and the other to the further oxidation to the dication. Owing to the measuring arrangement, reduction potentials ≤ -2.2 V could not be determined. *Hall* et al.[19] have investigated the reduction of the reactive dienophiles cyclovoltammetrically. With exception of TCNE and of the dimethyl esters of the 1,2-dicyanofumaric and 1,2-dicyanomaleic acids, the reductions were

irreversible. The sequences of the potentials determined polarographically by us and cyclovoltammetrically by *Hall* et al. are, with one exception, identical: we found a more negative reduction potential for dimethyl 2-cyanoethene-1,1-dicarboxylate than for methyl 3,3-dicyanoacrylate. Since the CN group is more strongly electron withdrawing than the CO_2Me group, the sequence found by us is in better agreement with that expected qualitatively.

From the experimental results, it emerges that electron transfer is observable when the reduction potential of the dienophiles is ≥ -0.50 V. Since no olefins with reduction potentials between -0.93 and -0.50 V are present, an exact limiting value cannot be quoted for the difference in redox potentials at which electron transfer is still visible. With the help of the Rehn-Weller equation,[20] not only can the free enthalpy of the reaction for the electron transfer be calculated but, assuming that the electron transfer has no additional activation barrier, also a maximum rate constant for this step.[21] According to Table 1, electron transfer is found

Table 1. ΔG and k_{max} for electron transfer from **3** to some dienophiles.

Dienophile	E_{red} [V] vs. SCE	ΔG_{SET} [a] [kcal mol^{-1}]	k_{max} [b] [M^{-1} s^{-1}]
$(NC)_2C=C(CN)_2$	+0.23	−13.37	1.0×10^{9}
$MeO_2C(NC)C=C(CN)CO_2Me$	−0.27	−1.84	1.0×10^{9}
$(NC)_2C=C(CO_2Me)_2$	−0.33	−0.46	1.0×10^{9}
$(NC)_2C=CHCO_2Me$	−0.50	+3.46	2.3×10^{8}
$NCHC=C(CO_2Me)_2$	−0.93	+13.37	2.1×10^{1}
NCHC=CHCN	−1.29	+21.68	2.0×10^{-5}
$MeO_2CHC=CHCO_2Me$	−1.45	+25.37	4.3×10^{-8}
$H_2C=CHCN$	<-2.2	$>+42.66$	$<1.3\times10^{-20}$
$H_2C=CHCO_2Me$	<-2.2	$>+42.66$	$<1.3\times10^{-20}$

[a] $\Delta G_{SET} = 23.06\,(E_{ox}\text{-}E_{Red}\text{-}C)$. [b] $1/k_{max} = 1/k_{diff} + 10^{-11}\exp(\Delta G_{SET}/RT)$.

when ΔG is negative or weakly positive. In these cases, the electron transfer should, according to the above premise, be diffusion controlled ($k_{max} \geq 10^9$ M^{-1} s^{-1}). The more positive ΔG is, the less likely is there an electron transfer. The cycloadditions of acrylonitrile and methyl acrylate with **3**[15] confirm that electron transfer-activation cannot participate in these reactions, since the rate constant for the electron transfer is prohibitively small.

The dramatic acceleration of reaction on occurrence of electron transfer could mean that it participates in product formation. However, it could also be that the diene/dienophile pairs are especially capable of forming zwitterions, either directly, starting from the neutral reaction partners, or from the radical ions. The stereochemical results, together with the results of the electron transfer studies lead to the following conclusions: If the electron transfer can be detected ESR spectroscopically, the product is formed in several steps. On the other hand, if no electron transfer can be observed spectroscopically, the cycloaddition is stereospecific. Since the large majority of diene/dienophile pairs, in [4+2]-cycloadditions have less pronounced donor/acceptor properties than the examples studied here, it may be assumed that electron transfer to form free radical ions is not the general mechanism for [4+2]-cycloadditions. Thus, the study of mechanistically limiting cases leads to an understanding of the behavior in "normal" cases.

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Dictionary of Organophosphorus Compounds. Edited by *R. S. Edmundson*. Chapman & Hall, London 1988. 1347 pp., hardcover, £ 305.00.—ISBN 0-412-25790-4

Although organophosphorus compounds are covered in several series, the publication of a "Dictionary of Organophosphorus Chemistry" is unparalleled. In view of the great importance of phosphorus and its compounds, such a publication is therefore potentially of great interest. How does the sole author deal with this vast topic? Are his efforts successful?

The first question posed by the potential user of such a handbook concerns the definition of an organophosphorus compound as used by the author to define the scope of the text. According to the dust jacket, over 20000 organophosphorus compounds are discussed (in almost 900 pages). What does the author consider to be an organophosphorus compound? A glance through the text reveals that the definition goes beyond systems containing P–C bonds; for example, there are numerous entries treating phosphorus compounds containing C–N–P, C–O–P, or C–S–P groupings, to name just a few. C is part of an organic moiety. This realization is most welcome from the viewpoint of the user. However, the user will find no metal complexes of organophosphorus(III) compounds, even those containing organic moieties directly bonded to phosphorus. Thus, it is not fully clear what the author considers to be an organophosphorus compound.

An especially important question in using this handbook is the ease of finding a particular compound. Compounds can be located in a number of ways: for example, by name, empirical formula, CAS Registry Number, or type of compound ("Type of Compound Index"). Although the nomenclature of organophosphorus compounds is more straightforward than that of other groups of compounds, it may be difficult to find some compounds through their names. In such cases, the empirical formula is always sufficient. The huge amount of information collected by the author is therefore readily accessible to the user.

A typical entry in the "Dictionary of Organophosphorus Compounds" usually refers to a parent compound (for example, a phosphonic acid) followed by data on its derivatives (for example, its salts, esters, and amides). The information usually includes the structural formula, the molecular mass, and selected physical constants. NMR and other spectroscopic data are not directly included, though numerous references to the literature are given. Useful are short general comments on the typical chemical behavior and toxicity of the compounds, always supported by leading references.

The book begins with a lengthy discussion of the nomenclature of organophosphorus compounds and includes, under the title "Sources of Further Information", a comprehensive list of textbooks and handbooks, as well as of review articles, covering all aspects of the chemistry of organophosphorus compounds (six pages). This list is well suited in providing access to the original literature, especially when a general orientation about a certain aspect of organophosphorus chemistry is desired.

A further question concerns the depth in which the original literature is treated. Chronologically, the literature is covered through 1986, though it is less clear how far back the primary literature is taken into consideration. To a large extent, the references appear to date from the last twenty-five years, a period during which the most important progress has been made, both qualitatively and quantitatively, in organophosphorus chemistry. It is noted that a small part of the entries (< 10%) were already included in the 5th edition of the "Dictionary of Organic Compounds" (1982) and that the style of the current "Dictionary of Organophosphorus Compounds" is strongly reminiscent of that work.

Immediately noticeable in glancing through the numerous references to the literature is that the bulk of them are references to journals. However, it is not clear according to what criteria—particularly, how thoroughly—these references were evaluated. A large amount of information on organophosphorus compounds is available in the patent literature. Although this handbook contains references to that source, how exhaustively it was evaluated is not clear.

A random check revealed that the references are by no means complete and that not all organophosphorus compounds reported during the last decades have been included. Thus, if a compound of interest is not found, a further literature search, for example through *Chemical Abstracts*, is warranted. The author does not appear to have addressed the question of how exhaustively the original literature has been examined. Checking concrete examples reveals a certain arbitrariness in the choice of literature references for particular compounds. The original literature is covered in more of a representative than an exhaustive fashion. For example, a typical preparation rather than the first synthesis is often cited.

I did not like the use of only one author's name followed, if necessary, by *et al.* in the literature citations. Although the highly desirable preparation of an author index would demand considerable work, it would increase the usefulness of this handbook. In the case of patents, not only the name of the inventor or discoverer but also that of the company should be given. The literature is not always correctly cited; in some cases, the information taken from the publications is inaccurate. Such shortcomings are not unexpected for a work of this scale and can be corrected in preparing the next edition. The dust jacket states that "Supplements" are planned.

It would be easy to criticize particular details in a work of this magnitude. Although I wish to avoid nitpicking, I cannot resist making one critical comment. Under No. P-00002 (p. 645), Parathion (= diethyl p-nitrophenyl thiophosphate) is discussed in some detail. However, the synthesis cited is that by American authors in 1948, whereas *Gerhard Schrader* (then at I.G. Farbenindustrie, Eberfeld), who first synthesized the compound in December 1944 and called it E 605, is not mentioned at all.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/1212-1716 $ 02.50/0

These reservations and criticisms should in no way detract from the value of this work. Organophosphorus chemists should be thankful to Dr. *Edmundson* for his overall successful undertaking, which will make their own work easier. Although the price of £ 305 will almost certainly prevent wide dissemination of this book, it should be purchased by every chemistry library.

der Technischen Universität Braunschweig (FRG)

The Technical Writer's Handbook. By *Matt Young*. University Science Books, Mill Valley, CA, 1989. xi, 232 pp., hardcover, $ 22.50.—ISBN 0-935702-60-1

Some style handbooks and usage dictionaries defeat their very purpose. They confront the well-intentioned writer with a jungle of dos, don'ts, and maybes and they beget rules having more to do with logic than with language. Like the much maligned schoolmarm who drilled students in a latinized English, they often discourage good writing by taking the fun out of writing. *The Technical Writer's Handbook* sidesteps these pitfalls. In the preface, *Matt Young* writes, "I ask for precision in writing, but I try to be flexible and have a healthy regard for usage." His highly readable book bears him out.

Despite its title, this book is primarily a usage dictionary, or, as Part II is titled, *An ABC of Technical Writing*. In Part I, only fourteen pages long, *Young* discusses three rules. To scientists who enjoy talking about their work but who, when forced to write, chew on their pencils or grow bleary-eyed staring at a computer display screen, he advises, "Write the way you talk; then polish." To scientists who find their sentences cluttered with commas, hyphens, and conjunctions, he suggests, "Write one thought per sentence." Following his own advice, he adds a corollary to the second rule: "Be explicit." To all scientists wanting to reach a wide audience, he recommends, "Write for the uninformed reader." These commonsense rules do not guarantee good scientific and technical writing, but they point the way. "Writing with Style and Clarity"—the subtitle of this book—requires pleasure in writing, a good feel for language, and, not least, the desire to be understood.

Part II, best read once through, contains an alphabetically organized discussion of word usage, grammar, and style. *False elegance*, for example, treats word choice and, in particular, elegant variation, the unjustified fear of repeating a word within a sentence or paragraph. "Comma-kazes"—those disposed to putting commas in the wrong places—will find help under *comma*. Other entries discuss such topics as parallel sentence structures (*principle of parallelism, list*), dangling participles and other wrongly placed modifiers (*dangling modifier, misplaced modifier*), problems with number (*singular or plural*), and the correct choice of verb tense (*tense*). The entries are short and to the point. *Young*'s conversational tone and effective use of humor spice the text. A *black hole*, for example, is defined as a noun that has collapsed under the weight of too many modifiers.

An ABC of Technical Writing is more than a mere usage dictionary, however. *Getting started, organization, manuscript preparation*, and *style manual*, not to mention *procrastination*, are just a few of the entries addressing the scientific paper itself. Under *private communication*, *Young* expresses the opinion that scientists with too many such connections should include complete mailing addresses as well. *Duplicate publications* condemns this practice and suggests, overoptimistically, that authors explicitly state that two papers are essentially the same. "Avoid implicit attacks on the writers rather than the manuscript" is one piece of advice in *refereeing*. The entry *Shakespeare* argues against using his work as a model for technical writing: "The language changes every day, and I look to modern writers for instruction on modern writing."

The Technical Writer's Handbook, like most language handbooks, contains much opinion and some questionable advice. For instance, *Young*'s efforts at spelling reform (he considers "analogue" obsolete) may or may not yield fruit. If *Noah Webster* had had his way, we would have "chimists" instead of chemists. Biologists might disagree with *Young*'s admonition against writing "wild-type bacterium" (see *type, -type*), which he thinks could refer to either a "modified wild bacterium" or a wild strain. "Wild type" is a well-defined term meaning the typical (nonmutant) form of an organism encountered in nature. Here *Young*'s training in physics makes him less of a pragmatist and more of a purist (see *permissivist, prescriptivist*). Moreover, his background also causes him to overlook some examples of relevance to, say, chemists. Under *vague words, vogue words*, for instance, he might have included the adjectives novel, elegant, and exquisite; so many compounds are novel, so many syntheses elegant, and so many processes exquisite these days that such words have become almost meaningless.

Unfortunately, the bibliography is inadequate. Comprehensive usage dictionaries, such as *Henry Fowler*'s *A Dictionary of Modern English Usage*, *Wilson Follet*'s *Modern American Usage*, or *A Dictionary of Contemporary American Usage* by *Bergen* and *Cornelia Evans*, are not mentioned. These sources contain more detailed discussions of many of the entries. The book contains few typographical errors, though *Young* should follow his own advice on spelling names correctly (see *names*) and change the name of the corecipient of the 1987 Nobel Prize in physics from Muller to Müller (or, arguably, Mueller) on page 151.

Correct use of language is just one element of style. It is common knowledge that the writing of some of the best stylists violates much conventional word usage, many of the rules of grammar, and all prescribed literary forms. The scientific writer would do well, however, to recall a word of advice from *The Elements of Style* by *William Strunk, Jr.*, and *E. B. White*: "No idiom is taboo, no accent forbidden; there is simply a better chance of doing well if the writer holds a steady course, enters the stream of English quietly, and does not thrash about." Like that classic, *The Technical Writer's Handbook* will help make writing that next paper or report a little easier and certainly more enjoyable. Indeed, pleasure in writing may be the most important element in writing with style and clarity. And remember: "If you have nothing more to say, just stop" (see *conclusions*).

David I. Loewus [NB 1030 IE]
Angewandte Chemie, Weinheim (FRG)

Immobilization of Cells. (Series: Biotechnology Monographs, Vol. 5). By *C. R. Phillips* and *Y. C. Poon*. Springer, Berlin 1988, viii, 167 pp., hardcover, DM 168.00.—ISBN 3-540-18637-9

The "Biotechnology Monographs", dealing in turn with various specific areas of biotechnology, have, within a very short period of time, developed into a series that is greatly valued by others besides biotechnologists.

Whereas most of the previous volumes have been concerned with special biotechnological processes such as the hydrolysis of cellulose, the anaerobic treatment of waste water, and the production of single cell protein, this latest volume is the second one (following that on coenzyme regeneration) to deal with a topic which is not specific to a particular process, namely the immobilization of cells for biological heterogeneous catalysis. In connection with this it is especially relevant to note that immobilized whole cells are now used in many biotechnological processes, and are in some cases an alternative to free cells. The reasons for this are not only the better control and higher cell densities that can be achieved, but also the lower costs, especially for large-scale processes.

The volume is divided into five chapters. Following an introductory chapter the basic techniques of immobilization are described. A broad distinction is made between mechanical containment of cells by pelletizing, encapsulation, or entrapment in polymers on the one hand, and covalent or ionic bonding to inert supports on the other.

By means of suitably chosen examples the third chapter deals with special, though frequently encountered, problems with immobilized cells, such as the inhibition of essential enzymes, or problems of solubility or mass transfer within the biocatalyst. Ways of overcoming these difficulties are suggested.

Chapter 4 focuses on the properties of immobilized biocatalysts, first considering each component of the system (the immobilized cells themselves, their active enzyme system, and the immobilization matrix), then looking at their interactions.

In the final chapter special emphasis is put on the engineering parameters. Variables already familiar from heterogeneous catalysis, such as the catalytic efficiency, the Sherwood number and the Thiele modulus are introduced, and their mathematical and technical relationships are described.

The book aims to provide an overview of the wide-ranging topic of cell immobilization. It gives an excellent account of the principles of the various immobilization methods, which is clear and detailed, citing numerous examples from the literature. It forms a very good introduction to the technology of cell immobilization, and is therefore also suitable as a textbook for advanced students of biology, chemistry, process engineering and biotechnology, although its use for this purpose will be limited to some extent by the relatively high price.

There is, regrettably, no adequately critical discussion of the different immobilization techniques. Also the scale of the processes described and the potential for scale-up are nowhere discussed in detail, and thus no clear distinction is made between laboratory processes and those that can be used on an industrial scale. One area with many applications in research and industry, the immobilization of mammalian cells, e.g. by means of the micro-carrier technique and related methods, is not mentioned at all. Despite these shortcomings, the book offers, both to beginners and to those experienced in the field, a good overview of cell immobilization, with a coverage which one could previously only obtain through a combination of several reviews and specialist articles.

ADVANCED MATERIALS

The Nature of Materials Science Publishing

Editorial Essay

By Peter Gregory *

The materials scientist, whether he thinks of himself as such, or whether he regards himself more as a metallurgist, chemist, physicist, ceramist or engineer must publish the results of his labors to complete the scientific process and to ensure career advancement or continued financial support. This is no different to scientists working in more clearly defined areas but a difference does arise when he consideres to which journal he should submit his manuscript.

As with other scientists, the worker in materials science would obviously wish that his "hot new results" are communicated to as large an audience of interested colleagues as possible. In the more classically defined areas of chemistry, biology, physics etc. there are a number of well established, high quality publications which cater for a specialist audience, as well as one or two highly popular journals which mix quality reports of new research results with articles of a more general nature. These more general articles are intended to bring new developments to the attention of the non-specialist but otherwise scientifically educated reader. These journals are namely *Nature* and *Science*.

This approach produces an excellent forum for the exchange of ideas and opinion across a wide range of disciplines. However, these highly respected journals, while catering well for the molecular biologists, earth scientists and astro- and particle physicists for example, cannot possibly blanket every area of science to an equal degree and therefore have weaknesses in their coverage of certain areas.

The nature of today's materials science is such that the interaction of experts from different fields is not only important but quite often essential and it is therefore unfortunate that those areas which are covered to a lesser extent by the leading journals of general science are just those with the greatest relevance to materials.

In the materials sector there are a large number of specialist journals serving restricted areas of the whole, and a few which purport, through their names, to be of a more general nature, but on closer inspection are found to lack true interdisciplinarity and to publish to a large extent only full papers.

Materials science, with its many facets and contributing technologies is ideally suited to the general forum approach to publishing where research results are combined with opinion, comment and information. The complexity of materials science, and the accompanying plethora of journals each dealing with their own specialist areas have made it increasingly difficult, alone on time grounds, to keep up with the literature in one field while maintaining an all important

overview of other areas. To provide that opportunity is exactly the intended function of *Advanced Materials*, the advent of which has been warmly welcomed, one reviewer[1] being moved to say:

"It is the (materials) journal one would most like to have delivered to a busy desk"

This is an opinion we are sure will be shared by an increasing number of ceramists, chemists, physicists, metallurgists and engineers as we move into what will undoubtedly be a fascinating and exciting future for materials science.

For our part, at *Advanced Materials*, we would like to thank both the readers and editorial team of *Angewandte Chemie* for their interest and support over the last eighteen months during which time the two journals were also published in a joint form. The complete separation of the two journals, which occurs in January, will give us the space and freedom to expand our coverage of all aspects of high-tech materials science while not giving *Angewandte Chemie* too strong a materials bias. We believe that we can provide the materials scientist with a readable, general forum for results and opinion which will help integrate all of our efforts and change the nature of materials science publishing.

Structural Characterization of Non-Oxide Chalcogenide Glasses using Solid State NMR **

Magic Angle Spinning
Internal Interactions
Selective Averaging
B/Si/P Based Glasses
Infrared Optics
Semiconductor Technology

By Hellmut Eckert *

Dedicated to Prof. W. Müller-Warmuth on the occasion of his 60th birthday

In spite of the long-standing importance of non-oxide chalcogenide glasses in infrared optics and semiconductor technology, concepts describing the structural principles governing glass formation in these systems are just emerging. Most recently, modern quantitative solid state NMR techniques have offered new unique insights into the structural organization of these systems. In this review, we discuss the basic principles of various experimental approaches and their application to boron- silicon,- and phosphorus chalcogenide glasses.

1. Introduction

Non-oxide chalcogenide glasses, which are based on the sulfides, selenides, and tellurides of the main group III–V elements, have recently gained much interest as materials for infrared-transparent optical fibers,[1] reversible conductivity switching devices,[2] semiconductors,[3] photoconductors, photoresists,[4] and solid electrolytes for battery applications.[5] Generally, glasses are often preferred over crystalline compounds because of their favorable mechanical and interfacing characteristics, and because their materials properties can be tailored for specific applications by continuously varying their composition or processing conditions. In the area of non-oxide chalcogenide glasses, however, substantial challenges have remained due to the air- and moisture sensitivity and the low glass transition temperatures of many systems.

Figure 1 shows the most common constituent elements of such glasses. During the last two decades, much work has been devoted to the phase diagrams, regions of glass-formation, and the thermodynamic and physicochemical properties of these systems.[6] It has been much more recently that, driven by the search for structural guidelines to optimize materials properties, the microstructure of these glasses has moved into the focus of attention. At the same time (and for similar reasons) chalcogenide glasses have become an increasingly attractive subject for theoreticians and solid-state physicists.[7–10]

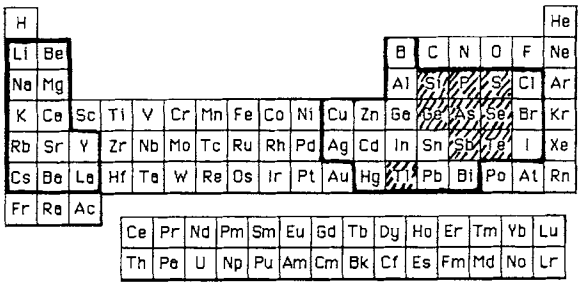

Fig. 1. Elements that participate in the formation of covalent non-oxidic glasses. Dashed lines indicates those elements that occur most commonly in such glasses.

According to most recent spectroscopic studies, the structure of chalcogenide glasses is characterized by several unique features not commonly found in other types of glasses. These features include: a) valence alternation pairs, b) new types of micro-environments not known in analogous crystalline compounds, and c) clusters or polymeric entities with a high degree of intermediate-range order. Figure 2 shows a few recent examples from the literature.

While these novel findings represent substantial progress, they mark only the beginning of a qualitative and quantitative understanding of chalcogenide glasses. The identification and quantification of specific structural features has often remained controversial, since most of the spectroscopic techniques used are not inherently quantitative and tend to emphasize ordered environments. Moreover, the proposals made for individual systems are conceptually somewhat divergent, which reflects a current inability to explain the

principles of non-oxide glass formation in more quantitative terms. There is a definite need for new experimental probes that can test the existing structural hypotheses in a more stringent manner than presently possible. Solid state NMR is an element-selective, inherently quantitative method ideally suited for this objective.[11] Since NMR is also spatially very selective, the spectroscopic information remains largely unaffected by the lack of periodicity in non-crystalline systems.

During 25 years of intense research, solid state NMR has proven very useful in developing structural concepts for oxide-based (silicate, borate, and phosphate) glasses.[12] In contrast, the unique power of this technique to provide structural information in chalcogenide systems is just emerging.

2. Information Content of Solid State NMR Spectra in Glasses

2.1. Fundamental Principles of the Technique

All nuclei containing an odd number of either protons or neutrons or both, possess angular momentum ("spin") and consequently, a magnetic moment. In the presence of an applied magnetic field B_0 (typical strength 1–14 T), these nuclei occupy quantized energy levels which are energetically non-degenerate and thus not equally populated. These population differences result in a macroscopic nuclear magnetization along the direction of B_0.

NMR spectroscopy measures the precise energy differences between such nuclear levels; this is done by stimulating transitions between them through the application of electromagnetic waves in the radio frequency region (1–600 MHz). At resonance, the condition

$$\omega = \gamma B_{\mathrm{loc}} \tag{1}$$

holds, where ω is the frequency of the electromagnetic radiation at which absorption occurs, γ is a nuclear constant, and B_{loc} is the strength of the magnetic field present at the nuclear sites. Usually, a short (1–10 μs length), intense (100–1000 W power) radiofrequency pulse is applied by the spectrometer that tips the magnetization into the plane perpendicular to the magnetic field direction ("90° pulse"). The precession of the magnetization in this plane then induces an ac voltage in a coil, which is amplified, detected, and stored in a computer. Fourier analysis of the acquired "free induction decay signal" then yields ω, the nuclear magnetic resonance frequency.

Signal averaging by repetitive pulsing is usually necessary. For truly quantitative information it is mandatory to allow for sufficient time between pulses to restore the magnetization along B_0 to its equilibrium value. The waiting time required depends on the relaxation time T_1 of the nuclei, which can range from a few ms to several hours in glasses.

2.2. Internal Interactions

The usefulness of NMR in addressing structural questions in matter stems from the fact that the magnitude of B_{loc} (and

Hellmut Eckert received his PhD in Physical Chemistry at the Westfälische Wilhelms Universität Münster, FRG, in 1982. After two postdoctoral years at Rutgers University, New Brunswick, New Jersey, he held a position as a staff Scientist at the Southern California Regional NMR Facility at the California Institute of Technology, from 1984–1987. Since July 1987, he has been an Assistant Professor of Chemistry at the University of California, Santa Barbara. Prof. Eckert's research is concerned with the synthesis of novel types of non-oxidic glasses and with the development of modern solid state NMR strategies for the structural analysis of disordered materials.

ADVANCED MATERIALS

hence the nuclear resonance frequency) is usually slightly different from B_0, due to various types of internal interactions: The *magnetic dipole-dipole interaction* describes the effect nearby magnetic moments from other atoms have on the local field of the nuclei under observation. The *chemical shift interaction* describes how the local field is modified by the electron clouds surrounding the nuclei, and finally, the *nuclear electric quadrupole coupling* describes the interaction of the asymmetric charge distribution in spin $> \frac{1}{2}$ nuclei with electrostatic field gradients generated by the chemical bonding environment. Each of these interactions is characterized by a few spectroscopic parameters, listed in Table 1.

Table 1. Interactions in solid state NMR, spectroscopic parameters and their selective measurement.

Interaction	Spectroscopic parameters	Selective measurement	Ref.
dipole-dipole	$M_{2hom.}$ (like nuclei)	$90°$–t_1–$180°$ echo decay	14
	$M_{2het.}$ (unlike nuclei)	$90_x°$–t_1–$90_y°$ echo decay	15
chemical shift	isotropic part, δ_{iso}	MAS-centerline position	13
	anisotropic part	MAS sideband intensities	17
quadrupole	coupling constant (e^2qQ/h)	MAS lineshape analysis, 2-D nutation NMR	16 16
	asym. parameter η	variable angle spinning	18

Mathematically, a tensorial description is used to appropriately reflect the fact that all of these interactions are anisotropic.[11] Consequently, the energy level perturbations (and hence the resonance conditions) depend on the orientation of the crystal (or molecule) with respect to the external magnetic field. Therefore, the spectrum observed in a powder or glass (the "NMR powder pattern") forms the envelope of all resonance conditions arising from all possible orientations.

If one of the three interactions discussed above is much larger than the other ones, the corresponding spectroscopic parameters are usually easily determined from such a powder pattern. However, frequently the various terms are of comparable magnitude, making the spectra difficult to analyze. The situation is complicated further in glasses, where the spectroscopic parameters would be more accurately represented in the form of distribution functions rather than unique values.

The NMR problem thus falls into two sub-tasks: a) accurate parametrization of the experimental spectra and b) correlating the spectroscopic parameters thus obtained with the desired structural information.

2.3. Selective Averaging Experiments

The first task is often approached by modifying the relative magnitudes of different interactions in a predictable fashion. Traditionally, this has been done by exploiting field dependence, isotopic dilution, or different isotopes of the same element. Alternatively, elegant selective averaging techniques that suppress certain interactions while leaving others unaffected are being increasingly utilized. Table 1 contains some of the approaches which are most generally applicable.[13–18] In the following, we will discuss briefly two of these techniques, which are of particular interest for the material covered in this review.

The first, most popular, selective averaging experiment uses mechanical sample rotation about an axis inclined by an angle β with respect to the external magnetic field direction.[13] This manipulation modulates the anisotropic part of the interaction by the term $(3\cos^2\beta - 1)$. At an angle of 54.7° the orientational dependence of the spectra is removed and a sharp, "liquid-like" resonance is observed at the isotropic chemical shift position. Solid state NMR spectra acquired with this technique are referred to as "MAS" (magic angle spinning) spectra. The isotropic chemical shift δ_{iso}, which is usually quoted in ppm with respect to a chosen reference standard (tetramethyl silane for ^{29}Si, 85% phosphoric acid for ^{31}P NMR), is the single most significant NMR observable for compound identification.

The second experiment involves the selective measurement of magnetic dipole-dipole couplings.[14, 15] The magnitude of the dipolar coupling is most commonly expressed in terms of the second moment M_2, the average squared local field present at the nuclei due to these interactions. This particular description in terms of a statistical quantity has the advantage that the details of the spin system (numbers and relative geometries of the interacting nuclei involved) need not be known for the analysis, and that homonuclear interactions (between like spins) and heteronuclear interactions (between unlike spins) can be separated.[19] The homonuclear part of M_2 can be measured selectively by spin-echo spectroscopy. Figure 3 illustrates the concept. In general, the free induction decay following a 90° radio frequency pulse on resonance can be refocused by a subsequent 180° pulse, resulting in a

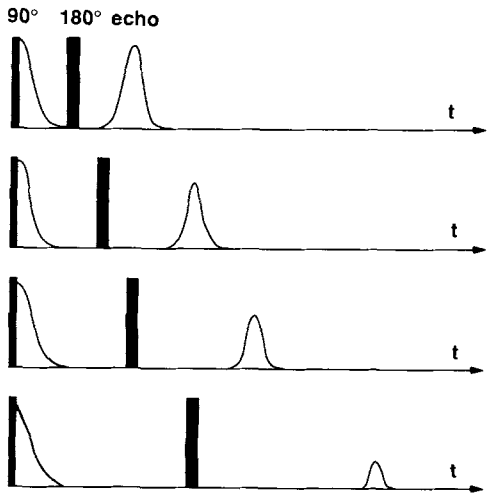

Fig. 3. NMR spin echo decay method for measuring homonuclear dipole-dipole couplings.

"spin echo" at a time $2t_1$ after the initial 90° pulse, where t_1 is the time delay between both pulses. Dipolar interactions among like nuclei, however, interfere with the refocusing process. Consequently the echo is diminished, depending on the length of the evolution time $2t_1$, i.e. the period over which the dipole coupling is operative.[14, 15] Very often, the echo height $I(2t_1)$ shows a Gaussian decay, whose steepness depends on the strength of the homonuclear interaction characterized by the second moment M_{2h}:

$$I(2t_1)/I(0) = \exp[-(2t_1)^2 M_{2h}/2] \quad (2)$$

Since most of the other solid state interactions are refocused by the above sequence, the measurement of the echo height under systematic incrementation of the evolution time $2t_1$ often affords a selective measurement of M_{2h} from the semi-logarithmic plot defined by Equation 2.

2.4. Correlation of NMR Parameters with Structural Information

Once the correct spectroscopic parameters have been extracted, the information needs to be related to concrete structural information. Important information is often already obtained from a detailed inspection of the compositional dependence of the spectra. Furthermore, the use of crystallographically well defined reference compounds is indispensible. These methodologically simple approaches are often combined with spectroscopic simulations based on computer-modeled trial structures. Of the various interactions summarized above, only the dipolar coupling is calculable from first principles. In contrast, the interpretation of chemical shifts and quadrupolar coupling constants requires the use of semi-empirical correlations. Furthermore, the specific information that can be obtained depends highly on the certain "personality" of the nucleus under study. Table 2 gives a summary of the basic properties of nuclei typically part of chalcogenide glasses. We will limit our discussion to ^{11}B, ^{29}Si, and ^{31}P, the prototype constituents of the glasses reviewed here.

^{11}B. ^{11}B NMR data in glasses show discrete sites B_3 and B_4, with triangular and tetrahedral coordination symmetries, respectively. These sites are separated by ca. 20 ppm in high-field ^{11}B MAS-NMR spectra,[20] and quantitative integration of the spectra yields N_4, the fraction of four-coordinate boron atoms:

$$N_4 = [B_4]/([B_4] + [B_3]) \quad (3)$$

A spectral separation can also be accomplished from traditional low-field NMR spectra on the basis of nuclear electric quadrupolar interactions.[12]

^{29}Si. ^{29}Si NMR data in glasses are usually interpreted in terms of various types of SiO_4 coordination polyhedra differing in the number of bridging Si–O–Si units. This is expressed by the $Q^{(n)}$ nomenclature, where n specifies the number of such bridges per silicon present. A large number of studies have been devoted to obtaining detailed quantitative information about the $Q^{(n)}$ speciation from MAS NMR data in crystalline silicates and silicate glasses.[21] Specifically, the NMR results on alkali-metal silicate glasses are in good agreement with the traditional network modification model, in which one mole of alkali-metal oxide generates two non-bridging oxygen atoms (see Figure 4).

Table 2. Nuclear properties of magnetic isotopes present in chalcogenide glasses.

nucleus	spin	natl. abund. [%]	resonance frequency at 7.05 T	comments on suitability for structural analysis in chalcogenide glasses
^{7}Li	3/2	92.58	116.59	sensitive, but limited range of δ
^{6}Li	1	7.42	44.15	limited range of δ, superior in resolution to ^{7}Li
^{11}B	3/2	80.42	96.25	sensitive, limited range of δ, MAS complicated by quadrupole effects
^{23}Na	3/2	100	79.35	sensitive, limited range of δ, MAS complicated by quadrupole effects
^{27}Al	5/2	100	78.17	sensitive, MAS complicated by quadrupole effects
^{29}Si	1/2	4.70	59.70	very long relaxation times (~ 1 h) wide range of δ small chemical shift anisotropies.
^{31}P	1/2	100	121.44	very sensitive, wide range of δ, large chemical shift anisotropies moderately long relaxation times
^{33}S	3/2	0.76	23.01	difficult to detect
^{73}Ge	9/2	7.76	10.47	large quadrupole moment,
^{75}As	3/2	100	51.38	poor resolution.
^{77}Se	1/2	7.58	57.20	difficult to detect, wide δ-range,
^{125}Te	1/2	7.00	94.79	extremely large chemical shift anisotropy, long relaxation times
^{205}Tl	1/2	70.50	173.12	very sensitive, wide δ range, extremely broad lines, difficult to detect with high-field instruments

ADVANCED MATERIALS

^{31}P. ^{31}P MAS-NMR has been used in a similar fashion to provide $Q^{(n)}$ speciation in a variety of phosphates and phosphate glasses.[22] In addition valuable information is available from the measurement of the internuclear ^{31}P–^{31}P interactions. Under rigid lattice conditions, M_{2h} (^{31}P) can be calculated from van Vleck theory:[19]

$$M_{2d} = 4/15\ (\mu_0/4\pi)^2\ I\ (I+1)\ \gamma^4\ \hbar^2\ N^{-1} \sum_{i \neq j} r_{ij}^{-6} \qquad (4)$$

where γ_I, I, N, and r_{ij} represent the ^{31}P gyromagnetic ratio, the spin quantum number (½), the number of nuclei involved, and the distances between them respectively. Equation 4 permits a direct calculation of an M_2 value from an assumed structure. The selective measurement of internuclear ^{31}P–^{31}P interactions affords a powerful tool for testing atomic distribution models in chalcogenide glasses.

3. Chalcogenide Glasses

3.1. Boron Based Glasses

Solid state NMR has been instrumental in the investigation of compound and glass formation in the systems B–S, B–Se, and B–S–Se.[23, 24] Specifically, NMR confirms that the structure of glassy B_2S_3 is based on the triangular $BS_{3/2}$ unit. In contrast, no such unit can be identified in corresponding B–Se glasses.[24] The composition "B_2Se_3" disproportionates into BSe_2 and an amorphous yellowish selenide B_xSe, which, according to the strong internuclear dipole couplings detected by NMR, must contain boron–boron bonds. This reflects the increasingly efficient competition of homoatomic (B–B and Se–Se) versus heteroatomic (B–Se) bond formation as the size of the chalcogen atom is increased.

Glassy B_2S_3 has a more uniform structure than glassy B_2O_3.[24] Nevertheless, the structural modification of B_2S_3 by Li_2S[25, 26] and Tl_2S[27] is an excellent analogy to the well-studied behavior of borate glasses.[12] Glasses in the systems $(Li_2S)_x(B_2S_3)_{1-x}$ and $(Tl_2S)_x(B_2S_3)_{1-x}$ are formed for $0 \leq x \leq 0.75$, with phase separation occurring at low x-values. In both cases, small amounts of Li_2S and Tl_2S cause a network transformation resulting in the production of four-coordinate boron atoms. Above a ratio $Li_2S(Tl_2S)/B_2S_3$ of 0.5, the number of four-coordinate boron atoms decreases again, because units containing non-bridging sulfur atoms are formed in this regime. This compositional dependence of N_4 is in good agreement with the respective oxygen-based systems.[12, 28]

3.2. Silicon Based Glasses

Besides offering promise for applications in infrared optics and semiconductor technology, silicon chalcogenide glasses are of fundamental interest in glass science. Vibrational spectroscopic data suggest that the structure of these glasses contains linear chain polymers composed of edge-sharing $SiSe_{4/2}$ units.[29] This finding is a striking exception from the general rule that glasses organize exclusively by corner-sharing of coordination polyhedra.

Figure 5 shows typical ^{29}Si MAS-NMR spectra in the system silicon–selenium.[30] Note that multiple sites are present, even in the stoichiometric glass of composition $SiSe_2$. The spectra show three distinct resonances which are assigned to Si atoms involved in zero, one and two edge-sharing tetrahedra, labeled $E^{(0)}$, $E^{(1)}$, and $E^{(2)}$ in Figure 5.[31] Increasing the selenium content in the glasses favors corner sharing. The evaluation of these units is made difficult by the extremely long T_1 values in these glasses.[30, 31] Absolute signal intensity calibrations with standards containing known amounts of silicon show that with 90° pulses and recycle delays of 2 h, 85–95% of the total Si atoms are detected in these systems.[30] This control experiment ensures that the speciation inferred from NMR is truly representative of the entire glass.

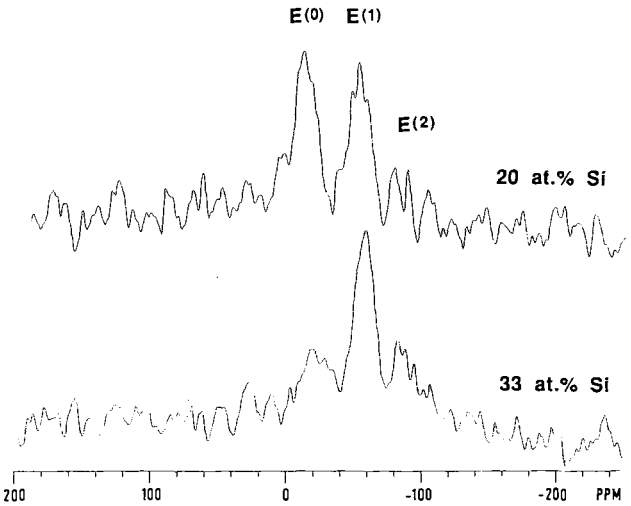

Fig. 5. ^{29}Si MAS-NMR spectra of glasses in the system Si–Se. The resonances are assigned to (from left to right in order of increasing field): corner-sharing $SiSe_{4/2}$ tetrahedra ($E^{(0)}$), $SiSe_{4/2}$ groups involved in one edge-sharing tetrahedron ($E^{(1)}$), and $SiSe_{4/2}$ groups involved in two edge-sharing tetrahedra ($E^{(2)}$), respectively. Note the compositional dependence. The poor signal-to-noise ratio arises from the extremely long spin-lattice relaxation times in these samples, requiring recycle delays of 2 h.

Lithium silicon sulfide glasses show promise for solid electrolyte applications.[32] The region of glass-formation of the system $(Li_2S)_x$-$(SiS_2)_{1-x}$ ranges from $x = 0$ to $x = 0.6$ (glasses formed in the compositional region $0 < x < 0.4$ may be phase separated). Given the unusual structural properties of the parent SiS_2 and $SiSe_2$ glasses, new types of microstructures might be expected in the glasses modified analogously by alkali metal sulfides. A detailed ^{29}Si MAS NMR study of the system Li_2S-SiS_2 was undertaken to test whether the $Q^{(n)}$

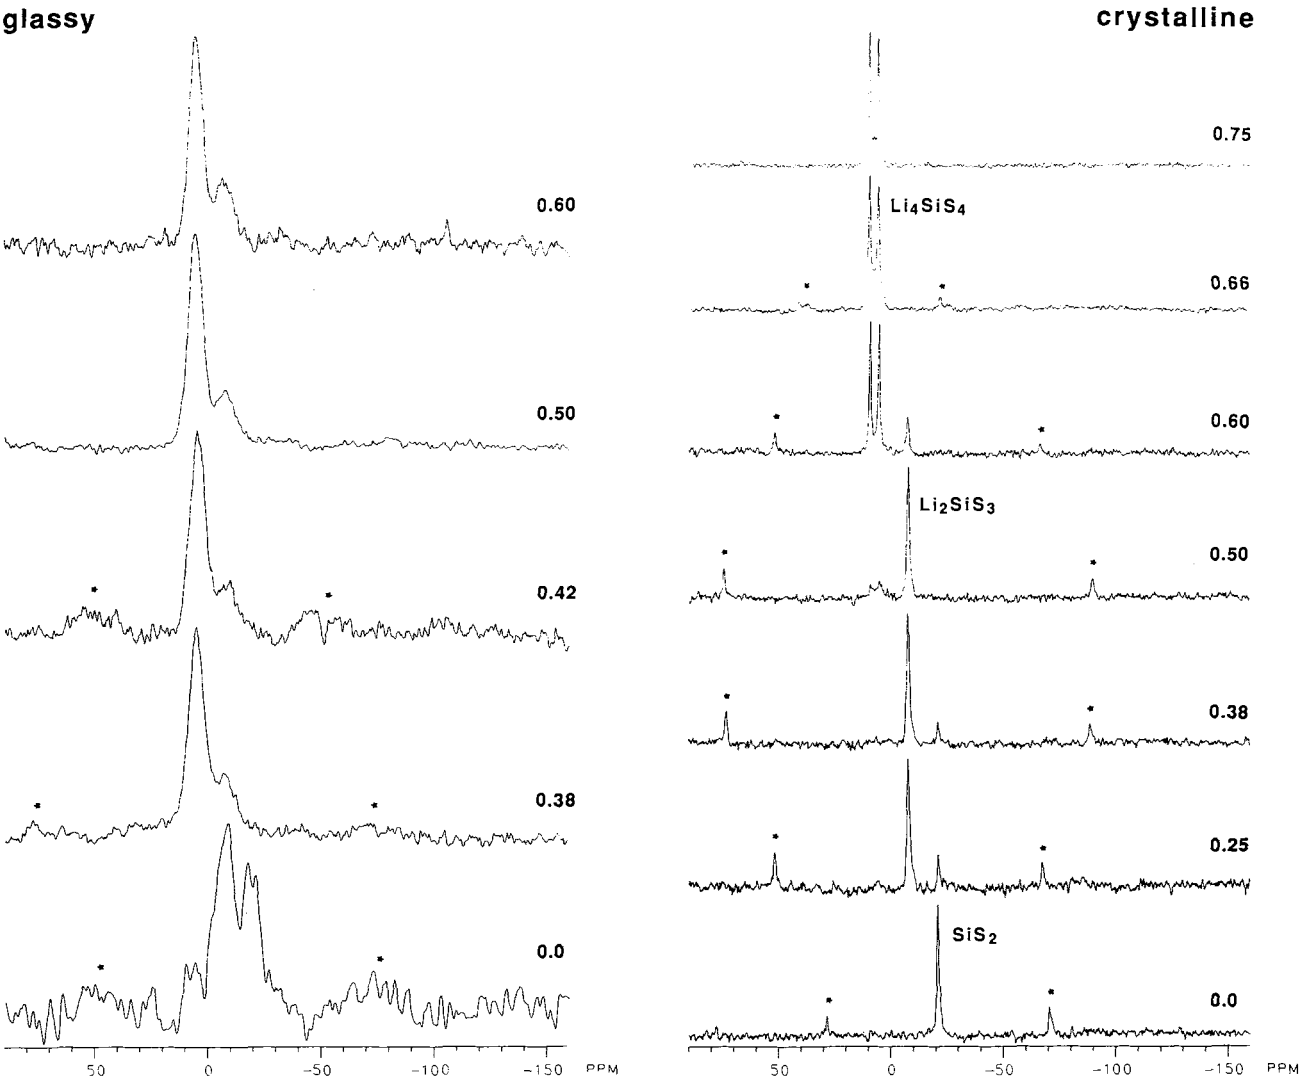

Fig. 6. 59.9 MHz ^{29}Si MAS-NMR spectra of glassy and crystalline samples in the system $(Li_2S)_x(SiS_2)_{1-x}$. For $x \geq 0.4$, the spectra show no obvious chemical shift evolution in the glasses, in contrast to the situation in the crystalline phases.

concept valid in the oxidic glasses (Figure 4) is also applicable to sulfide-based glasses.[33] The results are shown in Figure 6. Virtually no compositional evolution can be detected in the ternary glasses, whereas the corresponding crystallized specimens reveal marked changes. These findings were initially interpreted in terms of a constant number of non-bridging sulfur atoms regardless of Li_2S content. The two resonances were assigned to $Q^{(0)}$ species (major resonance around 4–8 ppm) and $Q^{(2)}$ species (minor peak around -6 to -10 ppm), based on previous assumptions in the literature[34] that the structures of Li_4SiS_4 and Li_2SiS_3 contain corner shared $Q^{(0)}$ and $Q^{(2)}$ environments (no single crystal X-ray work has been carried out). The original interpretation dismisses the traditional model of continous network modification and invokes a number of non-bridging sulfur atoms that is much larger than expected from the Li_2S content.

Subsequent work on a larger number of better characterized crystalline alkali thiosilicates[35] suggests that the chemical shift discrimination seen in the spectra of Figure 6a is most likely not due to the various $Q^{(n)}$ species but due to the number of edge sharing tetrahedra, $E^{(n)}$, in which the Si atom under consideration is involved.[36] According to this reinterpretation, the majority peak around 4–8 ppm arises from Si atoms involved exclusively in corner sharing with other tetrahedra ($E^{(0)}$), while the minority peak around -6 to -10 ppm is assigned to units engaging in edge-sharing with one other SiS_4 tetrahedron ($E^{(1)}$). Based on these assignments, the spectra reveal that Li_2S decreases the amount of edge-sharing dramatically, such that no $E^{(2)}$ units remain at 38 mole-% Li_2S or above. The work on the crystalline model compounds suggests further, that the chemical shift differences between Si atoms containing different numbers of non-bridging S atoms (i.e. the sulfide-analogs of the various $Q^{(n)}$

ADVANCED MATERIALS

species of Figure 4) are much smaller in sulfides than in oxides. Given the inherently broad MAS-NMR lines in the glasses, it is not possible to resolve individual peaks for these species. Therefore, there is no proof from NMR that the $Q^{(n)}$ concept is actually valid in sulfide glasses. If, however, the assumption is made as a working hypothesis, one arrives at the peak assignments summarized in Figure 7 in the form of

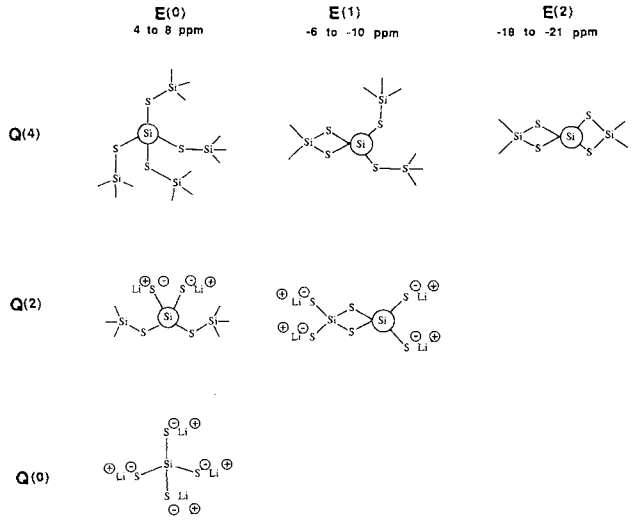

Fig. 7. Suggested peak assignments in the system Li_2S–SiS_2.

a matrix. Each microstructure can be represented by a $Q^{(n)}$ *and* an $E^{(n)}$ symbol. The NMR spectra then show that, at low Li_2S contents, the production of non-bridging sulfur atoms preferably occurs at the $E^{(1)}$ and $E^{(2)}$ sites. The constant ratio of $E^{(0)}$ to $E^{(1)}$ units at higher Li_2S contents suggests that some balance has been attained between the destruction of edge- and corner-sharing Si–S–Si units.

3.3. Phosphorus Based Glasses

Both the binary systems P–S and P–Se are well known to form stable glasses, with P concentrations ranging from 0–25 at.-% P in the former, and 0–52 as well as 62–80 at.-%.P in the latter system.[37–41] Phosphorus–Selenium glasses are of particular interest because of their infrared-transparency, their comparatively high stability in a moist atmosphere, and their resistance towards recrystallization. The microscopic structure of these glasses has been the subject of an interesting controversy. On the one hand, *Borisova* et al.[37] as well as *Blachnik* and coworkers[38] propose what basically amounts to a chemically ordered continuous random network model: at P contents below 40 at.-% the glasses contain $Se=PSe_{3/2}$, $PSe_{3/2}$ and Se–Se units only, whereas no P–P bonds exist. Above 40 at.-% P, these authors suggest an abrupt increase in the fraction of P–P bonds, hence rationalizing the steep increase of glass transition temperatures which is experimentally observed in this compositional region.

In sharp contrast, combined EXAFS and neutron diffraction studies point toward an entirely different glass structure based on P_4Se_n clusters ($5 \geq n \geq 3$, depending on the P/Se ratio) which are embedded in an Se-rich matrix.[42] Such an arrangement constitutes substantial intermediate range order, as has been recently suggested for other glass systems.

The two conflicting models differ largely with respect to the distribution of the P atoms in space. Figure 8 shows three

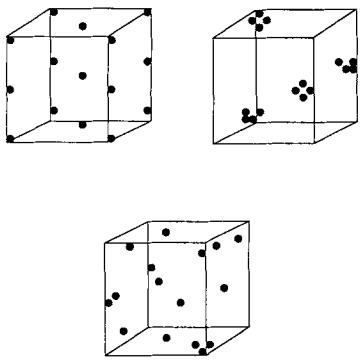

Fig. 8. Simple atomic distribution models for P atoms in P–Se glasses, corresponding to uniform, clustered, and random arrangements.

simplistic atomic distribution models for P–Se glasses, corresponding to a) a uniform, b) a clustered and c) a random distribution of P atoms. These arrangements are clearly distinguishable by the magnitude and the compositional dependence of the dipole-dipole couplings between the ^{31}P nuclear spins. Thus, using the spin-echo sequence discussed in Section 2, the second moments characterizing these internuclear

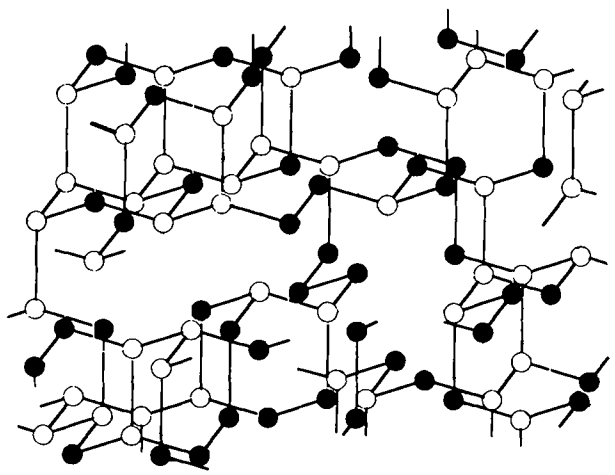

Fig. 9. Graphical illustration of the randomly occupied zinc blende structure used as a model for a P–Se glass containing 50 at.-% P. Open circles denote P atoms, filled circles Se atoms. The dotted lines represent non-bonding electron pairs pointing towards a vacancy in the structure.

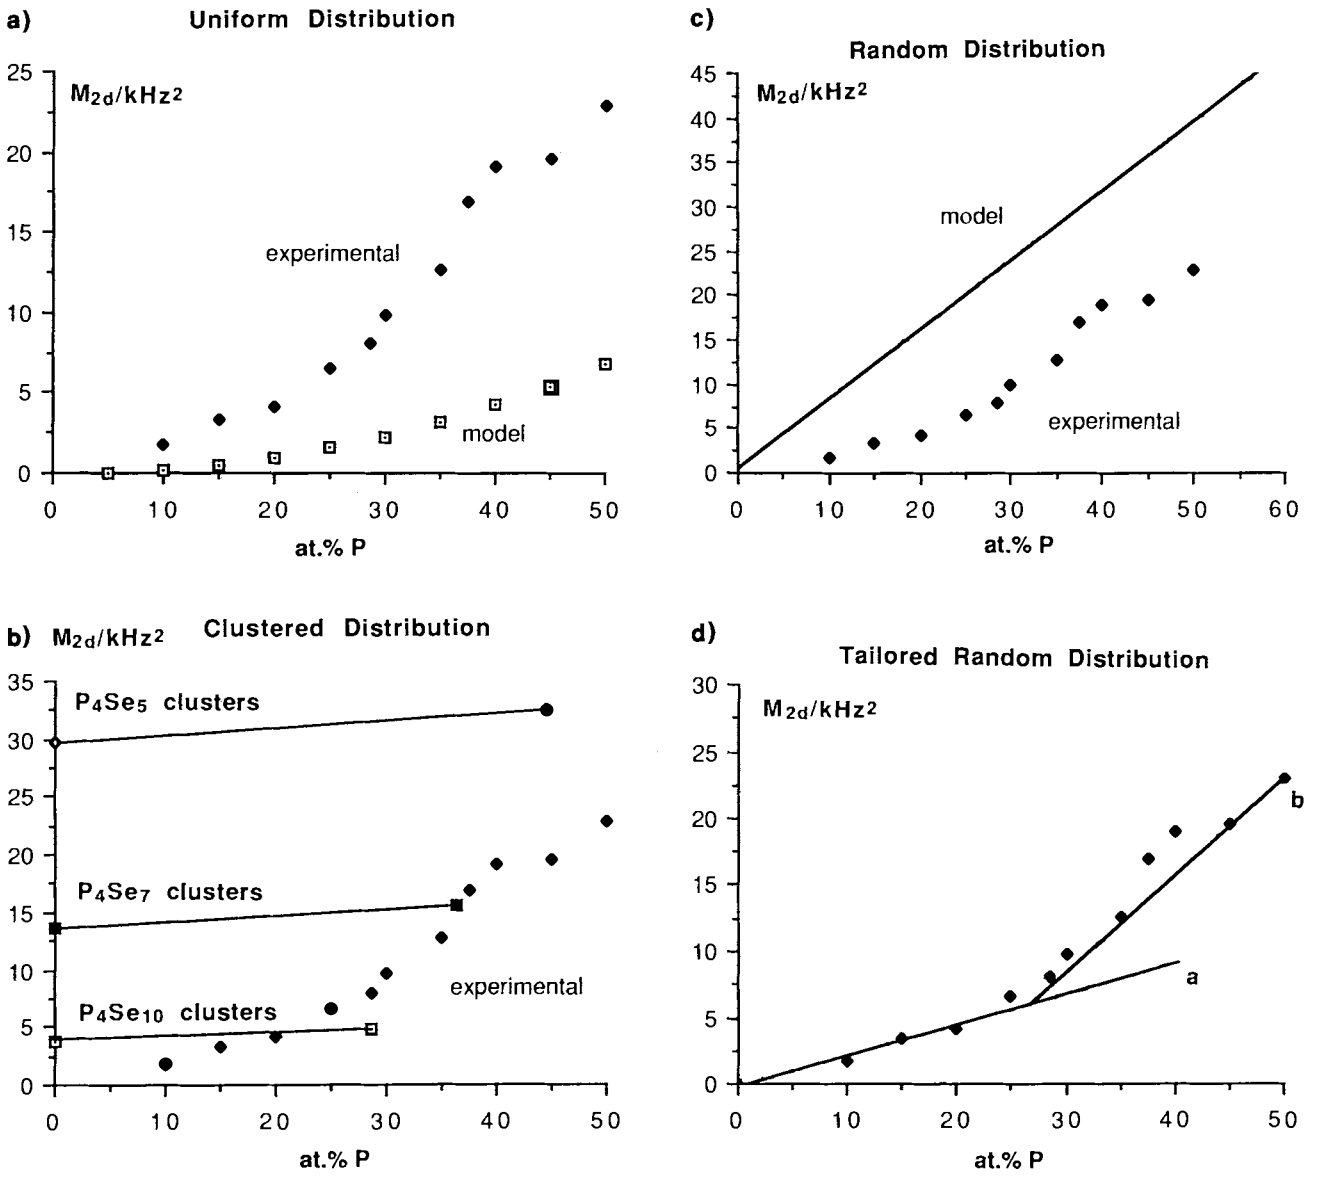

Fig. 10. Comparison of the compositional dependence of the ^{31}P dipolar second moment characterizing the strength of homonuclear ^{31}P–^{31}P dipolar interactions with calculations based on assumed atomic distribution models in P–Se glasses. See text for further discussion. The tailored random distribution assumes that no P–P bonds are present below 25 at.-% P (line a) and a probability of (X-25%) at all compositions with higher P contents X at.-% (line b).

interactions can be measured and compared with calculated values (using Equation 4) based on various assumed distribution models.

In order to simulate a random distribution, the P and Se atoms are positioned irregularly, according to their atomic percentages, over the sites of a cubic zinc blende structure. The chosen lattice constant (5.289 Å) constrains the nearest neighbor distance to 2.29 Å, corresponding to the average of typical P–P, P–Se, and Se–Se bond lengths. Furthermore, the random model incorporates the valency constraints of P and Se by distributing nonbonding electron pairs over additional lattice positions. Figure 9 shows an example of a random distribution generated in this way. This model reproduces the experimental densities of the glasses quite well (within 5–10%).

The comparison between calculated and experimental M_2 values is shown in Figure 10. Clearly, the experimental data are incompatible with either uniform, clustered or random distribution models. If however, the random model is adapted in terms of a reduced probability of P–P bonds, an excellent fit to the experimental data can be obtained. The comparison of Figure 10c with 10d indicates that, at any composition within the glass forming region, there is a distinct preference for P–Se over P–P bonds. Overall, the NMR results can be understood in terms of a random distribution of P and Se atoms over a glass structure, modeled as a defect

ADVANCED MATERIALS

zinc blende lattice, excluding P–P bonds below 25 at.-% P and admitting them in less than statistical proportions above 25 at.-%.[43,44]

While such dipolar measurements provide important insights concerning the statistics of P–P versus P–Se bonding in these glasses, they are unable to identify the distinct nearest neighbor environments present. Such information can be provided by MAS-NMR in conjunction with data obtained on crystalline reference compounds.[44–46] Figure 11 shows typical results in the P–Se system.[45] At P contents below 30 at.-%, two well-resolved peaks are observed which

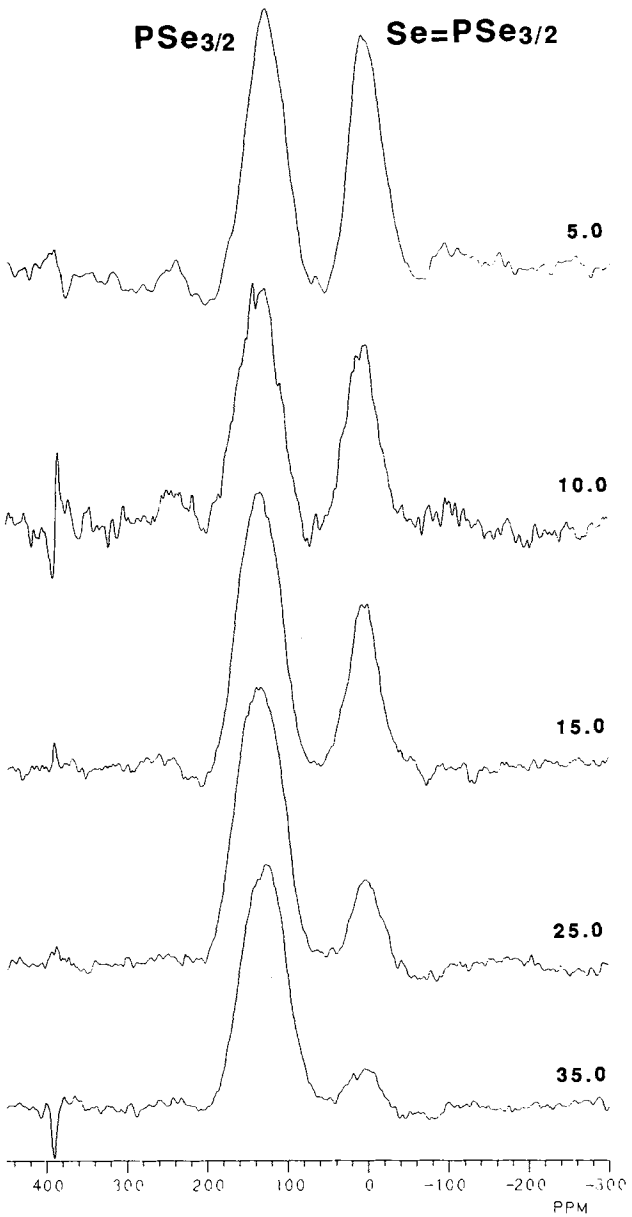

Fig. 11. 121.5 MHz ^{31}P MAS-NMR spectra of P–Se glasses. Numerals indicate at.-% phosphorus. The two resonances are assigned to three-coordinated ($PSe_{3/2}$ and $Se_{2/2}P–PSe_{2/2}$, downfield resonance, left) and four coordinated $Se=PSe_{3/2}$ species (upfield resonance, right), respectively.

are assigned to three-coordinated $PSe_{3/2}$ and tetrahedral $Se=PSe_{3/2}$ groups, respectively.

Quantitative integration of these spectra yields a phenomenological equilibrium constant K of 0.85 (at.-fraction)$^{-1}$ associated with the melt reaction $PSe_{3/2} + [Se_n]_{1/n} \rightarrow Se=PSe_{3/2}$. Figure 12 shows the experimental data for the fraction N_4 of

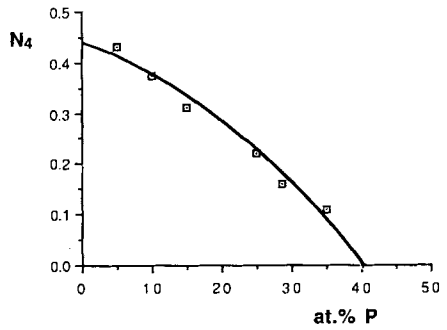

Fig. 12. Dependence of the fraction of four-coordinated $Se=PSe_{3/2}$ units, N_4, (open squares) on the atomic fraction of P atoms in P–Se glasses. The solid curve is calculated based on an equilibrium constant K = 0.85 (at.-fraction)$^{-1}$ of the reaction $PSe_{3/2} + Se \rightarrow Se=PSe_{3/2}$.

the four-coordinate P atoms as a function of composition and the corresponding theoretical fit. The near-unity value of K reflects the efficient competition of the three entities that take part in the above reaction, hence providing a thermodynamic rationale for the excessive tendency of glass-formation in this system.

It is interesting to compare these results with corresponding data obtained on the system P–S.[47] According to ^{31}P MAS and spin echo NMR data, the $S=PS_{3/2}$ grouping is the dominant structural unit within the entire glass forming region. This leads to crystallization of P_4S_9 and P_4S_{10} above 25 at.-% P. In fact, MAS-NMR studies of P–S glasses detect molecular P_4S_9 and P_4S_{10} entities well below the compositional glass-forming border. Likewise, NMR detects P_4Se_3 molecules in P–Se glasses with P contents well below the stoichiometry of this compound.[45] The presence of such molecular entities near and somewhat below the glass-forming border appears to be a general feature of glass formation in phosphorus chalcogenide systems.

4. Summary and Outlook

The experimental results covered in this review show that the degree to which the structural principles operative in non-oxide chalcogenide glasses differ from the bonding concepts used in the stoichiometrically analogous oxidic glasses depend greatly on the system under study. Specifically, in boron chalcogenide-based systems, there seems to be very close similarity between oxides and sulfides. In contrast, the edge-shared micro-environments identified in SiS_2, Si–Se,

and Li_2S–SiS_2 glasses are fundamentally new structures not known to exist in ordinary silica-based glasses. The latter statement also holds true for phosphorus chalcogenide glasses. Specifically in the P–Se glasses, there is a multitude of micro-environments, containing three- and four coordinate P atoms as well as various P–P bonded structures and, near the glassforming border, molecular cluster units.

The attractiveness of NMR spectroscopy for these systems lies in the opportunity of providing actual percentages with which these structural features occur, provided the experiments are done under quantitative conditions. Due to their element-selectivity, NMR methods have a decisive advantage over other competing structural probes for the compositionally more complex systems usually encountered in "real-life" practical applications. This advantage has already been exploited in our NMR studies of the co-former effect in Li_2S–B_2S_3–P_2S_5 and Li_2S–SiS_2–P_2S_5 glasses.[25,48] The studies reported here have laid the groundwork for such further investigations and the author hopes that this review will help to popularize the use of quantitative solid state NMR techniques in the structural elucidation of chalcogenide glasses.

ADVANCED MATERIALS

Polysilanes—A New Look at Some Old Materials

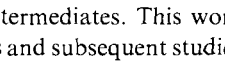
Radiation Sensitivity
Ceramic Precursors
Photoinitiators
Microlithography
Nonlinear Optics

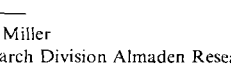
By Robert D. Miller *

In spite of the fact that the first polysilane derivatives were probably prepared in the mid 1920's, there was little scientific interest until recently. The synthesis of the first soluble homo and copolymers about 10 years ago has stimulated an explosive development of this class of materials. This brief review traces the historical development of the polysilanes and focuses on recent studies of polymer structure, electronic properties, photochemical reactions and mechanisms and finally on new applications.

1. Introduction

Substituted silane polymers, i.e. materials which contain only silicon atoms in the polymer backbone, represent a new class of radiation sensitive materials with very unusual electronic properties.[1, 2] The unique combination of physical, mechanical and electronic properties has recently stimulated a flurry of theoretical and experimental studies and has resulted in the discovery of potential applications. In this regard, the polysilanes have been investigated as (i) new thermal precursors to β-silicon carbide,[3, 4] (ii) a new class of photo and charge conducting materials,[5, 6] (iii) radiation sensitive materials for microlithography,[7–9] (iv) broad spectrum photoinitiators for free radical vinyl polymerizations[10] and recently (v) as materials with interesting nonlinear optical properties.[11, 12]





Historically these materials are quite old and the first aryl substituted materials were probably prepared in the 1920's by *Kipping*.[13] However, these early materials attracted little scientific attention, since they were highly crystalline, insoluble and intractable. In 1949, *Burkhard*[14] reported the preparation of the first alkyl derivative poly(dimethylsilane), (PDMS) by a similar synthetic route, i.e., the condensation of dichlorodimethylsilane with sodium metal. This material, like the earlier derivatives, also proved to be insoluble and intractable. The poor polymer properties of the early materials led workers to believe that these characteristics were generic to the class and as a result they attracted little interest until the middle 1970's when *Yajima* and coworkers[3] showed that PDMS could be converted to β-silicon carbide in a series of thermal steps which involved soluble and processable intermediates. This work rekindled the interest in polysilanes and subsequent studies produced the first soluble high molecular weight homo[15, 16] and copolymers.[17, 18] The preparation of the first soluble materials about 10 years ago initiated the modern era in the study of polysilane chemistry which continues today.

It is interesting that in spite of considerable efforts, the original Wurtz-type coupling shown below in Equation 1, with some experimental modifications, is still the most viable general procedure for the preparation of high molecular weight, linear polysilane derivatives. Usually the metal of choice for the condensation is sodium. Lithium tends to produce cyclic oligomers while potassium, particularly in polar solvents at elevated temperatures, often results in substantial degradation of the linear polymers to produce oligomers. In spite of the drawbacks of the Wurtz-type coupling procedure, i.e. low yields of high polymer and limited functional group tolerance, a large number of soluble, high molecular weight polysilanes have been prepared[1, 2] and a representative sample is shown in Table 1.

$$RR'SiCl_2 + 2\,Na \rightarrow \text{-}(RR'Si)_n\text{-} + 2\,NaCl \qquad (1)$$

When purified, most polysilanes are both thermally and oxidatively stable. Those with aromatic substituents attached to the backbone can often be melted and recast without significant decomposition. In general, the thermal stability of these materials is high and samples heated in nitrogen show little weight loss below 250 °C. The mechanical proper-

ties depend on the nature of the substituents and the polymer microstructure, and measured glass transition temperatures range from −75 °C to above 120 °C. In general, polymers with aromatic substituents tend to be more crystalline and higher melting.

Depending on the type of substituents and the reaction conditions employed, the Wurtz-type coupling procedure results in polymeric materials with a broad range of molecular weights varying from a few thousand to several million. The polymer molecular weights and dispersities can be controlled to some extent by judicious choice of the solvent and the polymerization conditions.[2, 7] The material properties can also be altered by the preparation of copolymers of structure $+R^1R^2Si)_n(SiR^3R^4+_m$, permitting further fine tuning of the mechanical and electronic characteristics. For this reason, a large number of structural and compositional copolymer variants have been described.[1, 2]

2. Spectral and Electronic Properties

It was the curious electronic properties of catenated silane oligomers which first attracted the attention of both theorists and experimentalists.[19] The spectral properties were consistent with significant delocalization of the sigma electrons in the sigma backbone. All soluble, high molecular weight polysilane derivatives absorb strongly in the UV and the absorption characteristics of a number of typical polysilane derivatives are shown in Table 2. Solution UV spectroscopic studies suggest that alkyl substituted polysilanes absorb in the region 300–325 nm, and the position of the absorption maximum depends on the steric bulk of the substituents.[20] Aryl substituents directly bonded to the backbone cause a red shift of 20–30 nm due to the electronic interaction of the substituent π orbitals with those of the silicon backbone. The absorption characteristics of linear substituted silane polymers also depend on the extent of catenation.[20] In this regard, both the position of the long wavelength absorption maxima and the molar absorptivities per silicon-silicon bond increase rapidly at first with increasing molecular weight, but approach limiting values beyond a degree of polymerization (chain length) of 40–50 as shown in Figure 1. The gross spectral characteristics of linear silicon catenates have been adequately rationalized computationally by simple linear

Robert D. Miller received his Ph.D. in organic chemistry from Cornell University in 1968 working with Professor A. T. Blomquist. After post-doctoral work at Union Carbide Research Institute on low temperature spectral characterization of reactive intermediates generated by flash vacuum pyrolytic techniques, he joined IBM Research in Yorktown Heights, New York as a member of a multidisciplinary "basic studies" group. In 1971, he moved to the San Jose Research Laboratory. His current research interests include: basic photochemical processes, radiation sensitive polymers, synthetic methods involving multifunctional synthons, spectroscopy and chemistry of reactive intermediates, the synthesis and characterization of highly strained and/or theoretically interesting molecules, and novel rearrangements promoted by structural strain. He is a member of the American Chemical Society and is presently on the editorial board for Chemical Reviews.

ADVANCED MATERIALS

combination of atomic orbitals (LCAO) or Sandorfy-type theoretical treatments.[19] However, the absorption spectra of the polysilanes also depend strongly on the backbone conformation,[21, 22] a fact which was not predicted from the simple molecular orbital treatments. More sophisticated semiempirical and ab initio studies are required to adequately describe the electronic ground state and the nature of the electronic transitions.[2] INDO/S calculations rationalize the conformational dependence of the absorption spectra in terms of long range 1,4-orbital interactions and predict furthermore that *trans* sequences should absorb at longer wavelengths than *gauche*. Moreover, these studies also suggest that the electronic excitation energy tends to localize in the *trans* segments even when they are quite short.[23, 24] A solution model for the dialkyl polysilanes, which has emerged from wavelength dependent fluorescence polarization studies, is one of a polymer chain composed of discrete chromophoric segments (presumably *trans* or nearly *trans* units of varying lengths). The individual spectral characteristics depend on the segment length and are partially electronically decoupled by conformational twists or kinks. These segments apparently communicate by rapid energy transfer.[24, 25] Such a model is also supported by the INDO/S calculations. Consistently, the experimental absorption and emission characteristics of polysilanes in solution may be adequately modeled[26] using rotational isomeric state theory (RIMS) assuming both a statistical distribution of chromophoric segments of varying lengths, and conformational defects which mediate the electronic interaction between the chromophores. As expected from such a model, the polysilanes are predicted to be thermochromic as is often the case, although the detailed conformational interpretation of the solution thermochromism[26, 27] is complicated by possible aggregation effects.

The fluorescence emission from most polysilane derivatives in solution is short-lived (75–200 ps)[24, 29] and the band width is much narrower than the corresponding absorption bands.[24, 26, 28] The short radiative lifetimes, narrow spectral band width, and lack of fine structure of the fluorescence is suggestive of a highly delocalized excited state. Comparison of the absorption and emission spectra of poly(di-*n*-hexylsilane) in solution suggests that emission is occurring from segments containing 20–36 silicon atoms, assuming that the oscillator strength is independent of the chromophore length.[24, 29] In contrast to the intense, narrow fluorescence reported for poly(di-*n*-alkylsilanes), a weak, broad, long-lived emission is often observed at longer wavelengths in rigid media. This has tenatively been attributed to phosphorescence.[25, 26, 28, 41] On the basis of band structure and width, *Zeigler* et al.[26, 41] have suggested that the triplet excitation is more localized and hence, may be responsible for the polymer photolability. While the apparent localized nature of the triplet excitation is more consistent with the observed photolability (vide infra), this connection has been unambiguously established only for poly(methyl-*n*-propylsilane).[28]

Many polysilane derivatives are strongly thermochromic in the solid state. This effect was first reported for poly(di-*n*-hexylsilane) (PDHS) (see Fig. 2)[22] and this material has been the object of many structural studies.[21, 30] In this case,

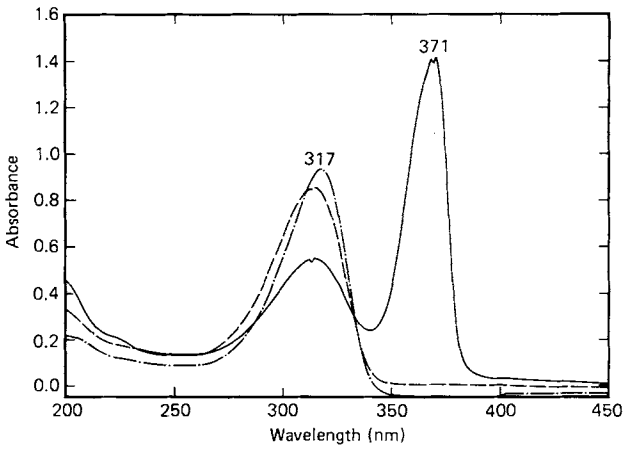

Fig. 2. UV absorption spectra of poly(di-*n*-hexylsilane): (●—●) solution in hexane; (—) thin film run immediately after baking at 100 °C, (—) thin film after standing at 20 °C for 3 h.

crystallization of the *n*-alkyl side chains enforces an all-*trans* planar backbone conformation which is responsible for the ~ 60 nm spectral red-shift. Above the transition temperature, which for PDHS is around 42 °C, the backbone conformationally disorders. It appears that for polysilane derivatives with sterically demanding substituents some type of intermolecular interaction in the solid state is necessary to enforce a stable planar all-*trans* conformation. This characteristic leads to a series of very subtle substituent effects which can dramatically effect the spectral properties. For example, poly(di-*n*-pentylsilane) (PDPS), in which side chain crystallization does not occur to a significant extent, adopts a 7/3 helical backbone conformation in the solid state at room temperature.[21] In this case, a deviation in the polymer backbone of only ~ 30° from *trans* planar results in a spectral blue-shift of almost 60 nm.

Recent studies suggest, however, that side chain crystallization does not always assure the formation of a stable, planar all-*trans* conformation for polysilanes with sterically demanding alkyl substituents. For example, poly(di-*n*-tetradecylsilane) (PDTDS) adopts a non-planar TGTG′ backbone conformation in spite of spectral evidence of side chain crystallization.[31] Apparently, the backbone retains sufficient flexibility for derivatives with long chain *n*-alkyl substituents, even in the presence of strong intermolecular interactions to allow alternative non-planar conformations. It is also interesting that PDTDS is still thermochromic, suggesting that the observation of a spectral red-shift need not necessarily be uniquely associated with the formation of planar all-*trans* backbone segments. We have also observed that the

introduction of sterically unsymmetrical substituents such as aryl groups, which can minimize intrachain steric interactions by rotation around the silicon-carbon substituent bond, can also produce dramatic spectral effects. For example, the poly(bis-alkylphenylsilanes) are among the most red-shifted of all polysilanes ($\lambda_{max} \sim 400$ nm) and the spectral data supports the presence of long *trans* sequences which persist even in solution.[32]

3. Radiation Sensitivity

Polysilane derivatives are sensitive to light and ionizing radiation both in solution and in the solid state. Irradiation causes a rapid bleaching of the long wavelength absorption, and the formation of lower molecular weight fragments.[20] This spectral bleaching, which is key to a number of applications (vide infra) is unusual and occurs because the absorption characteristics are a function of the polymer's molecular weight. The measured quantum yields for polymer scission in solution are high (0.25–1.0) although competitive crosslinking is often observed particularly when pendant unsaturated substituents are directly attached to the polymer backbone.[8, 20] The efficiency of both processes decreases markedly (50–100 fold) in the solid state. However, in every case that we have examined, photoscissioning predominates and this behavior can be considered to be characteristic of the linear polysilanes.

Exhaustive irradiation of soluble polysilanes at 254 nm in solution in the presence of trapping reagents such as trialkylsilanes or alcohols suggests that both silylenes and silyl radicals are intermediates (Equations 2a and 2b). Thermodynamic considerations and experimental studies[34] suggest that the silylene-forming reaction and the pathway to the silyl radicals are uncoupled and competing processes. In many respects, the photochemical decomposition of substituted silane high polymers resembles that previously reported for shorter chain oligosilanes.[33]

$$-\mathrm{SiRR'SiRR'SiRR'}- \xrightarrow{h\nu} \begin{cases} \ddot{\mathrm{S}}\mathrm{iRR'} + -\mathrm{SiRR'SiRR'}- & (2a) \\ -\mathrm{RR'Si}\cdot + \cdot\mathrm{SiRR'SiRR'}- & (2b) \end{cases}$$

However, recent mechanistic studies in solution suggest that the polymer photochemistry is more complex than first imagined. There is an unusual wavelength dependency and the quantum yield for the extrusion of silylenes decreases markedly with increasing irradiation wavelength, becoming very small above 300 nm.[34] On the other hand, the photodegradation proceeds at all wavelengths absorbed by the polymer as evidenced by the continuous spectral bleaching and decrease in molecular weight. Studies on isotopically labeled polymers show that silyl radicals produced by polymer chain scission disproportionate in addition to recombining. In addition, a new photochemical chain-cleavage reaction, i.e., 1,1-reductive elimination (see Equations 3a and 3b)[35] has been identified. The wavelength dependent photochemistry has been rationalized in terms of the proposed solution model for the polysilanes consisting of a statistical collection of chain segments of varying lengths with differing absorption characteristics which are only weakly electronically coupled due to conformational defects.[23, 24, 25, 26, 28]

$$-\mathrm{SiRR'SiRR'SiRR'}- \xrightarrow{h\nu} \begin{cases} -\mathrm{SiR_2R'} + \ddot{\mathrm{S}}\mathrm{iR'SiRR'}- & (3a) \\ -\mathrm{SiRR'_2} + \ddot{\mathrm{S}}\mathrm{iRSiRR'}- & (3b) \end{cases}$$

In summary, mechanistic studies in solution suggest that there are at least three photochemical pathways leading to polysilane molecular weight reduction: (i) substituted silylene extrusion and chain abridgement; (ii) silicon-silicon bond homolysis to produce chain-cleaved silyl radicals and (iii) 1,1-reductive elimination to produce chain silylenes. Current evidence indicates that these pathways are uncoupled and competing.

4. Potential Applications

4.1. Preceramic Precursors

The excellent thermal and mechanical properties, unusual electronic characteristics and photolability of the polysilanes have led to a number of potential applications, as enumerated in the introduction. The earliest uses for these materials were as preceramic precursors to β-silicon carbide. In the middle 1970's, *Yajima* and coworkers[3, 36] discovered that poly(dimethylsilane) (PDMS) could be converted, in the series of steps shown in Equation 4, to silicon carbide fibers of exceptional strength. Fibers of this type are now marketed under the trade-name of Nicalon. The intermediate carbosilanes are crucial intermediates, as they are soluble and can be either cast or spun. The initial thermolysis step can be bypassed by using soluble silane homo and copolymers and materials of this type can be employed either as impregnating reinforcing materials for porous ceramics such as silicon nitride or directly for the formation of β-silicon carbide.[4] Dimensional stability of fibers can be introduced either by surface oxidation, as in the *Yajima* process, or by the photocrosslinking of unsaturated polysilanes, prior to firing to 1200 °C.

$$(\mathrm{Me_2Si})_n \xrightarrow[\mathrm{Ar}]{450\,^\circ\mathrm{C}} \left(\mathrm{Si}(\mathrm{H})(\mathrm{Me})-\mathrm{CH_2}-\mathrm{Si}(\mathrm{H})(\mathrm{Me})-\mathrm{CH_2}\right)_n \xrightarrow[(2)\ \Delta,\ 1300\,^\circ\mathrm{C},\ \mathrm{N_2}]{(1)\ \Delta,\ 350\,^\circ\mathrm{C},\ \mathrm{Air}} \beta\text{-SiC} \qquad (4)$$

4.2. Photoinitiators for Vinyl Polymerizations

Recently *West* and *Wolff* have utilized the broad spectrum photolability of polysilane derivatives for the photoinitiation of a variety of vinyl polymerization reactions.[10] The polydispersities obtained for poly(ethyl acrylate) and poly-

ADVANCED MATERIALS

(styrene) produced in this manner were very similar to those observed in standard free radical initiated polymerizations suggesting that silyl radicals generated by chain scission may be responsible for initiation. Although the initiation efficiency is relatively low, this is partially compensated by the broad, active spectral range of the initiators and their very high extinction coefficients. In addition, vinyl polymerizations initiated by polysilane derivatives are curiously insensitive to the presence of oxygen. This sensitivity can be further decreased by the addition of certain antioxidants such as *tert*-amines and phosphines. The authors speculate that the in-situ generation of certain oxygen scavengers such as silenes, which are expected products from radical disproportionation, may be responsible for the reduced oxygen sensitivity.

4.3. Photo and Charge Conduction

The reduced spectral band gap of most polysilane derivatives relative to that of polymers with saturated carbon skeletons (~ 4 eV versus 8 eV) suggests that these material may comprise a new class of charge conducting and/or photoconducting media. In this regard, conducting films of a number of polysilane derivatives have been prepared either by doping with arsenic pentafluoride[18] or by casting from sulfuric acid solutions.[37] Similarly, the photo and charge conducting characteristics of a number of polysilane derivatives have been studied in some detail.[5,6] Drift mobilities of $\sim 10^{-4}$ cm^2/Vs have been measured both for the direct photogeneration of carriers[5] and for hole injection[6] from a variety of light absorbing substrates. For the polysilanes, charge conduction is by holes only. The measured charge drift mobilities are among the highest reported for amorphous polymers and are approximately four orders of magnitude greater than those described for poly(*N*-vinylcarbazole). Similarly, the measured activation energies (0.25–0.28 eV) which are associated with hole hopping, are also very low for an amorphous organic polymer. In photoconductivity studies on poly(methylphenylsilane), *Kepler* et al.[5] have estimated that the hole generation quantum efficiency approaches 1% at high electric fields and that the carrier lifetimes are in excess of several milliseconds.

The high discharge efficiencies, coupled with the large drift mobilities and nondispersive transport characteristics of the polysilanes are promising for potential Xerographic applications.

4.4. Microlithographs

The polysilanes have a number of unique material characteristics for certain lithographic applications, particularly those utilizing multilayer techniques. They are (i) thermally and oxidatively stable yet photochemically labile; (ii) strongly absorbing over a broad spectral range, yet bleachable; (iii) good film formers which are incompatible with most common organic carbon polymers; (iv) high in silicon content and hence, very resistant to etching under oxygen plasma conditions and (v) sensitive not only to light but also to various types of ionizing radiation (γ-ray, X-ray, e-beam, etc.). This combination of characteristics is ideally suited for a variety of multilayer lithographic processes. Accordingly they have been used as soluble, oxygen reactive ion etch (O_2-RIE) resistant barrier layers in trilevel schemes,[7] as new resists for ionizing radiation imaging,[21,38] as combined imaging and etch barrier layers in bilayer processes utilizing both wet[7–9,21,39] and dry development techniques[8,9,38–43] and as short wavelength contrast enhancing materials.[8,9,42,44] Space limitations prevent the detailed discussion of each application and the interested reader is referred to the reference list. The important concepts of bilayer imaging and contrast enhancement are discussed in more detail below.

Multilayer resist imaging schemes for the production of high resolution images offer certain advantages, particularly where troublesome chip topography causes difficulties for single layer schemes. In a bilayer process (see Fig. 3) the substrate with its topographic features is initially coated with a thick (1–5 μm) layer of a planarizing polymer which is usually not photosensitive. A thin imaging layer (0.15–0.5 μm) is then coated on top of the planarizing layer. Upon exposure, the top layer can be imaged and developed with high resolution because the imaging layer is very thin, flat and of uniform thickness. In principle, the initial develop-

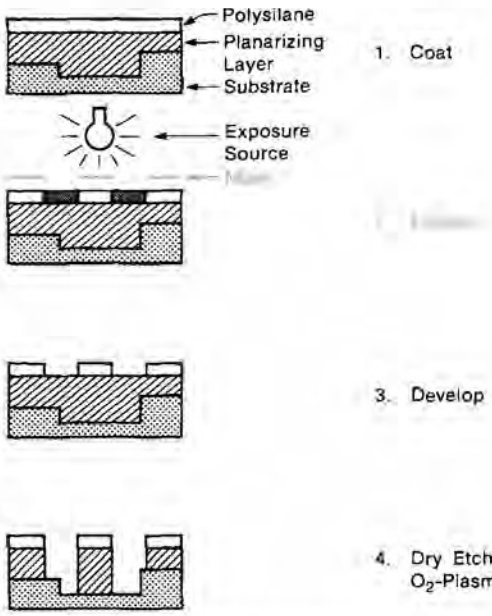

Fig. 3. Bilayer lithographic scheme utilizing a polysilane as the combination imaging and O_2-RIE resistant barrier layer. For ablative self-development in an all-dry process, the image is produced and developed directly during the exposure step.

ment could be either by a classical wet process or by dry, photoablative development. Transfer of these high resolution images through the planarizing polymer layer is usually accomplished by O_2-RIE plasma techniques, since highly anisotropic etching conditions can be employed to assure that the transfer of the initial photoimages maintains near-vertical side wall profiles. The successful utilization of such a scheme requires a photosensitive imaging layer which is also significantly more resistant to etching in the oxygen plasma than the planarizing polymer. The polysilanes are ideally suited for such procedures, since they are strongly absorbing in thin films and permit efficient light absorption, photosensitive over a broad spectral range, and resistant to O_2-RIE conditions due to the formation of a thin skin (50–100 Å) of etch-resistant SiO_x on the polymer surface. Accordingly, they have been utilized in a bilayer configuration for the production and transfer of high resolution images generated by exposure in either the near UV (350–400 nm)[8] or in the mid UV (300–340 nm) spectral regions.[7–9, 39] The use of shorter wavelength exposure sources (e.g., KrF excimer laser, 248 nm) in a 10X projection printing tool leads to significantly improved resolution and allows the delineation of sub 0.5 μm features in a bilayer configuration (see Fig. 4).[45]

The bilayer processes described above used classical wet development steps for the production of images in the irradiated polysilane layer. However, high resolution images can also be produced directly in a thin polysilane layer by photoablative imaging. In this process, the polysilane is exposed to a high intensity radiation source (e.g., an excimer laser) during which the polymer spontaneously degrades and volatilizes. Since the image thus produced is subsequently transferred by gas phase O_2-RIE techniques, the procedure constitutes an all-dry, solventless lithographic process requiring no wet development step. The production and transfer of submicron images in such an all-dry process utilizing certain polysilane derivatives for imaging and an UV excimer laser exposure source have been successfully demonstrated.[8, 9]

The generation of images by projection printing in cases where the photomask features are of comparable size to the exposure wavelength is complicated by diffraction distortion of the mask features at the photoresist surface. Contrast enhanced lithography[46] is a technique which employs a thin layer of an appropriate contrast enhancing layer coated on top of a conventional photoresist to improve the diffraction distorted mask image incident on the photoresist. Although a discussion of the concepts involved in the contrast enhancement of images is beyond the scope of this article, the reader is referred to the background information contained in the literature.[46] However, consideration of the process suggests that a workable contrast enhancing material should possess a number of characteristics: (i) it should be thermally and oxidatively stable; (ii) the material should be very strongly absorbing at the exposure wavelength and bleach rapidly upon irradiation and (iii) it should be incompatible with the underlying photoresist so that the material

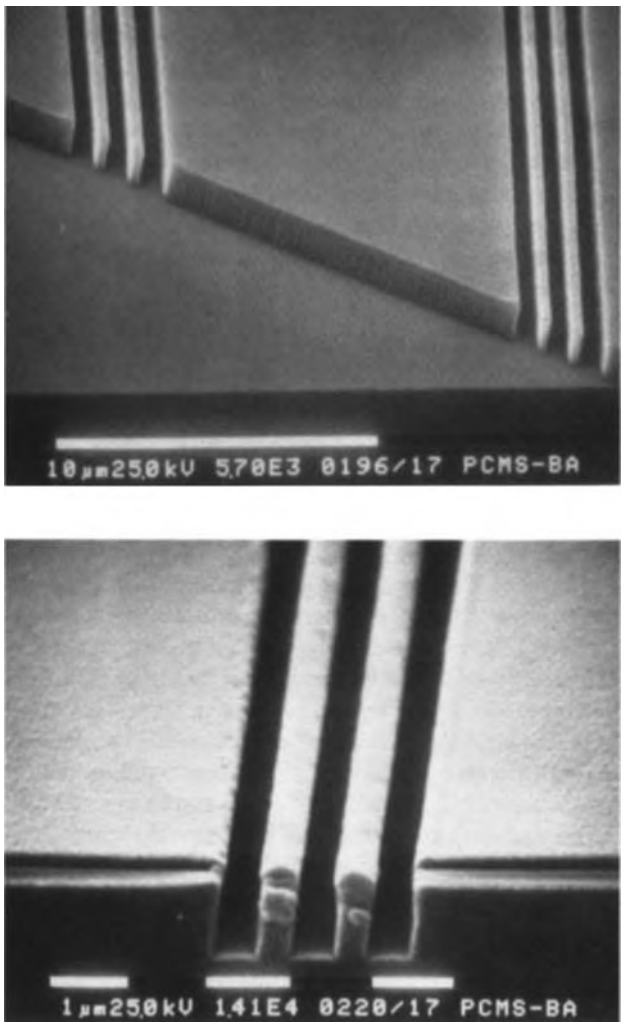

Fig. 4. Images produced in a polysilane bilayer configuration using a deep UV, KrF excimer laser exposure source (248 nm). Bilayer: 170 nm poly(cyclohexylmethylsilane) over 1.0 μm of hard baked AZ-type photoresist; 248 nm. 150 mJ/cm^2, developed 80/20 butyl acetate-isopropanol, O_2-RIE image transfer; (Top) 0.45 and 0.5 μm features, (Bottom) 0.4 μm features.

boundaries are clearly delineated. Initially it was also felt that the contrast enhancing layer should be removable prior to the development of the exposed photoresist, but recent studies indicate that this characteristic is not essential.

Certain of the polysilane derivatives not only satisfy the above criteria but also absorb and bleach at shorter wavelengths than commercial materials thus providing the possibility of realizing the enhanced resolution intrinsic to short wavelength exposure sources.[8, 9, 42, 44] A system composed of a conventional diazoquinone-novolac type photoresist overcoated with a thin layer of poly(cyclohexylmethylsilane) has been studied in detail and significant improvements in the image quality relative to the same photoresist without the contrast enhancing layer have been demonstrated.[8, 9, 44] Similar image enhancement for mid UV exposure using other polysilane derivatives[42] has been reported recently.

ADVANCED MATERIALS

4.5. Nonlinear Optical Properties

Finally, there is currently increased interest in the nonlinear optical properties of the materials due to their potential utility in optoelectronic or opto-optic devices for telecommunications and optical computing. In this regard, organic materials are of considerable interest because of their intrinsically large nonlinear susceptibilities, rapid response times and high threshold radiation damage values.[47] Furthermore, the utilization of third order effects eliminates the stringent requirements for an acentric molecular environment thus expanding the range of useful materials to polymeric systems.

Studies of the third order susceptibilities ($\chi^{(3)}$) of polymers to date have focused on highly polarizable materials containing conjugated π electron systems such as the polyacetylenes and diacetylenes, rigid rod aromatic polymers, ladder polymers, etc. While these materials have high intrinsic susceptibilities, many have other drawbacks such as limited processability, thermal and/or oxidative liability, nonideal spectral matching, etc.

The polysilanes represent a new class of potentially interesting nonlinear optical (NLO) materials. They are: (i) thermally and oxidatively stable, (ii) the σ-conjugated backbone is highly delocalized and absorbs very strongly in the UV region, (iii) electronic substituent effects can be transmitted over large distances and (iv) the polarizability is large, anisotropic and dependent on backbone conformation. In fact, many of the electronic properties of the polysilanes more closely resemble conjugated π systems than saturated σ bonded carbon-based polymers. In addition, the polysilanes are imagable to high resolution using standard lithographic techniques, an attribute potentially useful for guided wave applications.

Initial NLO measurements on polysilane derivatives have revealed some interesting properties. Relatively large $\chi^{(3)}$ values ranging from 10^{-11} to 10^{-12} esu[11,12,48,49] have been measured and the variation in these numbers with the film thickness suggests possible polymer orientational effects.[12] The resonant $\chi^{(3)}$ value measured for thin films of poly(di-*n*-hexylsilane) ($\sim 10^{-11}$ esu) is the largest reported for a polymeric system which is transparent in the visible and is comparable to values reported for rigid aromatic polymers such as poly(*p*-phenylenevinylene) and poly(*p*-phenylenebenzobisthiazole). Thermal effects on the third harmonic generation efficiency have been correlated with the known thermochromic characteristics of the polymers[12] and the picosecond time response[48] of the nonlinearity reported for poly(methylphenylsilane) is consistent with an electronic mechanism. In addition, biphotonic nonablative, nonlinear photochemical processes have been observed upon exposure to high intensity visible laser light. This photochemistry is anisotropic, and refractive index changes of greater than 2.5×10^{-2} (at 632.8 nm) have been induced due to selective polymer chain degradation in a direction parallel to the electric field of the laser light.[50] Birefringence changes of this magnitude are adequate for the fabrication of channel waveguides and birefringent grating structures.

Although the study of the NLO properties of polysilane derivatives is in its infancy, the unusual spectral properties, the substantial nonlinearities, the capacity for polymer orientation and the anisotropic photolability suggest that these materials are worthy of future investigation.

In summary, the polysilanes represent a new class of radiation sensitive polymers whose unusual electronic structure and properties, and thermochromic behavior are attracting considerable attention. Although most of the work to date has been science-oriented, the modern era of investigation is less than 10 years old. In spite of this, a number of potential applications for these interesting materials have been discovered and described.

^{15}N CPMAS NMR Study of the Structure of Polyaniline**

By *Bernd Wehrle, Hans-Heinrich Limbach,* John Mortensen,* and *Jürgen Heinze**

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

In the last few years the structure and properties of polyaniline (PANI) have attracted much interest.[1-12] Among the different techniques used in these studies, high resolution solid state ^{13}C NMR spectroscopy under the conditions of ^{1}H cross-polarization (CP), magic angle spinning (MAS), and proton decoupling[13-16] has been employed in order to elucidate the structure and the reactivity of this compound.[17-22] Using this method on chemically synthesized PANI, evidence for the emeraldine structure **I** (Fig. 1), which

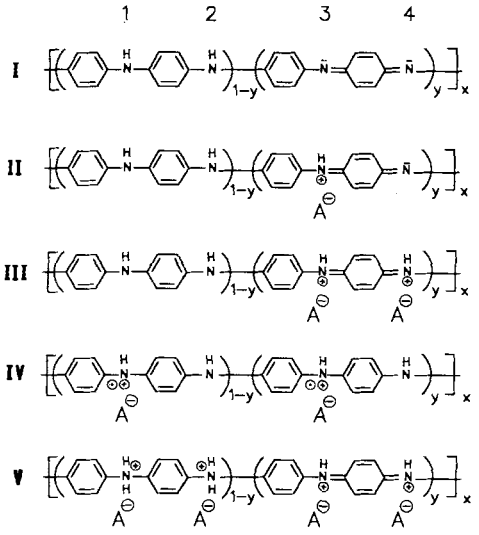

Fig. 1. Possible structures of polyaniline (PANI). Leucoemeraldine: **I**, y = 0; emeraldine: **I**, y = 0.5; pernigraniline: **I**, y = 1.

consists of alternating phenylenediamine and chinonimine units with y = 0.5 has been obtained. It is not known, however, whether PANI prepared by electropolymerization in media of different acidities[1, 7, 8, 20] is characterized by the same structure or whether structures with different y values as well as structures **II** to **V** (Fig. 1) also have to be considered.

Since solid, nitrogen containing heterocycles can conveniently be studied by ^{15}N CPMAS NMR spectroscopy of ^{15}N enriched materials[23-32] it is surprising that only one preliminary ^{15}N CPMAS paper on chemically synthesized PANI has been published.[32] Therefore, we report here the results of ^{15}N CPMAS NMR experiments[33] on various PANI-samples synthesized by electropolymerization[35] in $HClO_4$/water mixtures and subsequent discharge in acetonitrile.

Figure 2 shows ^{15}N CPMAS NMR spectra of three samples. The spectrum of sample 1 (Figure 2a) contains a sharp

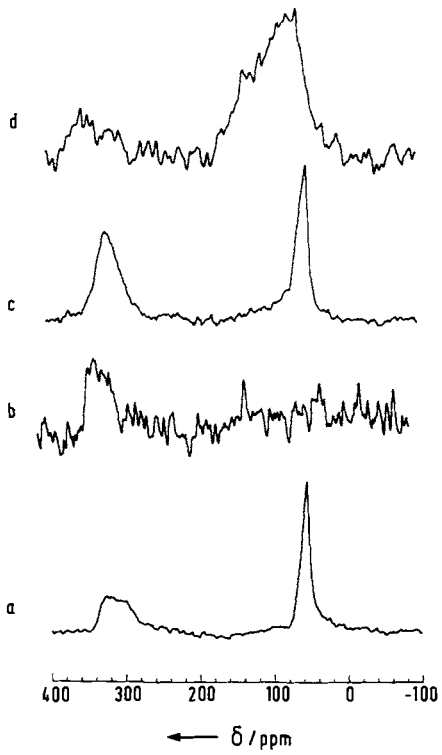

Fig. 2. ^{15}N CPMAS NMR spectra of electrochemically synthesized polyanilines (PANI): a) discharged sample 1; b) dephasing experiment performed on sample 1 with a delay of 100 μs; c) sample 2, as sample 1 but after thorough washing; d) sample 3, prepared in highly acidic conditions.

high field signal at ~ 60 ppm and a broad band at ~ 320 ppm. Figure 2b shows the result of a dipolar dephasing experiment[37] on the same sample in which only the magnetization of non-protonated nitrogen atoms survives. When sample 1 is carefully washed[35] we observe in

the ^{15}N spectra of the resulting sample 2 slight changes of the signal at low field as shown in Figure 2c.

The ^{15}N spectra of samples 1 and 2 are very similar to the spectrum shown in the literature[32] which was interpreted in terms of the emaraldine structure **I** with $y \approx 0.5$. The dipolar dephasing experiment in Figure 2b supports the assignment of the high field line to the protonated nitrogen atoms 1 and 2 in **I**. Their chemical shift is consistent with what is known about the chemical shifts of model compounds such as diphenylamine (65 ppm)[38] or the NH-nitrogen atoms of azophenine (Figure 3).[31] Note that unsubstituted aniline

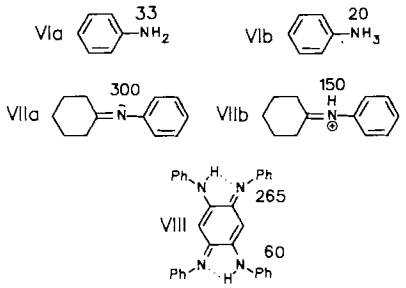

Fig. 3. ^{15}N chemical shifts of model compounds for PANI. **VI**: aniline, [38] **VII**: N-phenylcyclohexanonimine, [39] **VIII**: azophenine [31].

and anilinium appear at higher field, i.e. at 33 ppm and 20 ppm.[38] The dephasing experiment strongly indicates that the low field line has to be assigned to the non-protonated nitrogen 3 and 4 in **I** although they absorb at slightly lower field than the corresponding atoms in azophenine ($\sim$ 265 ppm).[31] Thus, our results support similar structures of PANI when synthesized chemically and electrochemically.

Dramatic changes of the spectra are, however, found when PANI is prepared electrochemically under strongly acid conditions (sample 3).[35] For such material, salt structures **III** and **IV** (Fig. 1) have been proposed.[20, 32] As shown in Figure 2d we observe for sample 3 two very broad lines at $\sim$ 100 and $\sim$ 350 ppm which represents a shift to lower field. The observation that the relative intensity of the high field line has increased, indicates a higher mole fraction of protonated ^{15}N atoms in sample 3.

These results are consistent with the presence of a superposition of all structures **I**, **II** and **III** in sample 3. Also, structure **V** cannot be completely excluded. We tentatively assign the low-field line in Figure 2d to the non-protonated nitrogen atoms 4 in **II**. By comparison with the protonation shift of compound **VII** in Figure 3 which is of the order of +150 ppm[39] we also tentatively assign the low field part of the high field line to atoms 3 and 4 in **III** as well as to atom 3 in **II**. The high field part stems then probably from the atoms 1 and 2 in **II** and **III**.

There are different phenomena which might contribute to the broadness of the high field line in Figure 2d. Firstly, one has to consider the effect of proton disorder arising from a superposition of **I, II,** and **III**. One also has to take a distribution of intermolecular interactions of the PANI subunits with the anions $A^{\ominus}$ into account. A look at structure **III** shows that the positive charge can only be localized as indicated if the $A^{\ominus}$ ions interact with particular nitrogen atoms. At longer distances between the nitrogen atoms and counter ions the differences of electronic charges and, subsequently, of nitrogen chemical shifts between the two subunits in **III** will disappear. Thus, a broad nitrogen-anion distribution function will lead to a broad distribution of chemical shifts in the region between 150 and 50 ppm, as observed in Figure 2d. Note that we can also not exclude the presence of semiquinone structures **IV**. Evidence for the existence of **IV** has been obtained by EPR[40] and magnetic susceptibility measurements.[41] Unfortunately, it is difficult to know where the ^{15}N signals of **IV** appear because they might be subject to paramagnetic or Knight shifts as well as to line broadening.

Finally, the linewidths in Figure 2d could also be influenced by electron and nuclear motions as well as spin dynamics. A fast migration of anions should lead to a breakdown of the nitrogen-anion distribution function, i.e. to line broadening and line narrowing of the lines in Figure 2d. Since the *p*-tolylsulfonate anions are bulky it is, however, not very probable that this phenomenon occurs within the NMR timescale. However, the situation could be different if smaller anions were employed.

We have shown that ^{15}N CPMAS NMR spectroscopy is a promising technique, useful for studying the structure of nitrogen containing heterocyclic polymers. Besides PANI we have also studied other materials such as polypyrrole (PPy) and related compounds. In contrast to PANI, we find for PPy only one inhomogeneously broadened ^{15}N signal at 120 ppm which is not significantly altered when the substance is oxidized. This means that even in neutral PPy, only protonated nitrogen atoms can be detected, as expected for a structure $(P^{y\oplus}X_y^{\ominus})_n$, $y \geq 0$. Further ^{15}N CPMAS results obtained for a completely different class of nitrogen containing polymers have been reported.[42]

[35] The PANI-samples were prepared with equipment described previously [36] as follows. Aniline-^{15}N was electropolymerized galvanostatically at a current density of 1 mA/cm^2 at a concentration of 0.1 mol l^{-1} using $HClO_4$/water mixtures as solvent. Samples 1 and 2 were prepared at a $HClO_4$ concentration of 1 mol l^{-1}, sample 3 at a concentration of 3 mol l^{-1}. The precipitates on the electrodes were washed with acetonitrile and dried in vacuo. Then the samples were discharged at a potential of -0.4 V vs. Ag/AgCl in acetonitrile containing 0.5 mol l^{-1} $LiClO_4$ as supporting electrolyte. Sample 2 was thoroughly washed with water and then with acetonitrile in contrast to sample 1 which was washed only superficially. Finally, all samples were dried in vacuo.

^{15}N CPMAS NMR Study of the Structure and Reactions of Phthalocyaninatopolysiloxane and its Precursors in the Solid State**

By *Bernd Wehrle, Hans-Heinrich Limbach*, Tilman Zipplies*, and *Michael Hanack**

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

The class of phthalocyaninatopolymetalloxanes $(PcMO)_n$ (Pc ≡ phthalocyanine, M ≡ Si, Ge, Fig. 1) has attracted considerable interest because of the high conductivity of these molecules after doping with iodine or other electron acceptors.[1–5] Since it has not yet been possible to perform crystal structure analyses on these compounds, information about the molecular structure of these materials has mainly been obtained[1–5] by solid state ^{13}C CPMAS NMR spectroscopy under the conditions of cross polarization (CP) and magic angle spinning (MAS).[6–9] Unfortunately, the ^{13}C CPMAS spectra of $(PcMO)_n$ contain a manifold of various aromatic carbon atoms sites which differ only slightly in their chemical shifts and which are difficult to assign.

In the past it has been shown that the structure and reactions of solid, nitrogen containing heterocycles can conveniently be studied using ^{15}N CPMAS NMR spectroscopy which requires, however, ^{15}N enriched samples.[10] We show here that this technique is also useful for studying the structure and the solid state reactivity of phthalocycaninatopolymetalloxanes.

The ^{15}N labeled compounds studied were prepared according to standard methods from 95% ^{15}N enriched phthalodinitrile via diimidoisoindoline.[11] This was reacted with $SiCl_4$ in quinoline to form dichlorophthalocyaninatosilicon $PcSiCl_2$ which was hydrolyzed in a mixture of pyridine and NaOH to form dihydroxyphthalocyaninatosilicon ^{15}N labeled $PcSo(OH)_2$, (**I**) whose structure is shown in Figure 1. **I** was then polymerized in a thermal balance under nitrogen at 450 °C to form ^{15}N labeled μ-oxo-phthalocyaninatosilicon $[PcSiO]_n$ (**II**); **II** was subsequently doped with iodine according to a literature method.[2] Thus, the ^{15}N labeled product $[(PcSiO)I_{1.1}]_n$ (**III**) was obtained. ^{15}N NMR experiments were carried out on all compounds **I**–**III** using instrumentation previously described.[11] For the low temperature experiments a self-built heat exchanger[12] was employed.

The room temperature ^{15}N CPMAS NMR spectra of the various phases of phthalocyaninatopolysiloxanes are shown

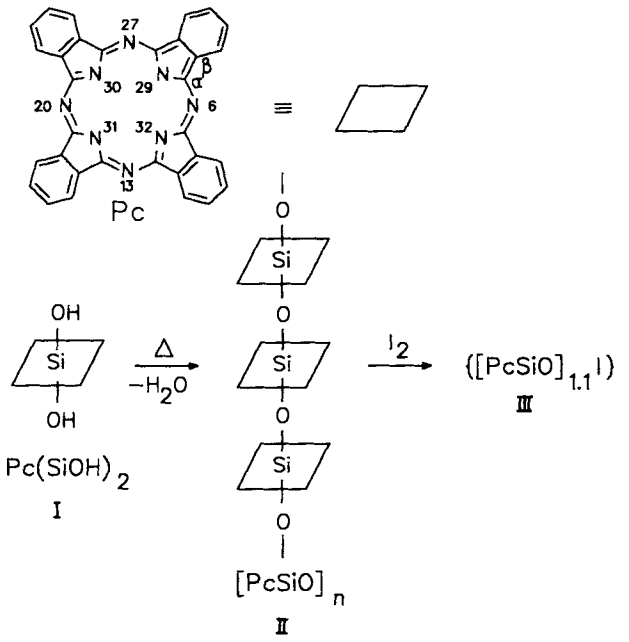

Fig. 1. Solid state polymerization of $PcSi(OH)_2$ to $(PcSiO)_n$ and subsequent oxidation to $[(PcSiO)I_{1.1}]_n$ with iodine; Pc ≡ phthalocyanine.

in Figure 2. For the monomeric precursor $PcSi(OH)_2$ three resonances are observed at 211, 199 and 170 ppm respectively. The assignment of the individual resonances are based on former ^{15}N CPMAS NMR studies of free base phthalocyanine.[11,12] The two low field lines stem from the outer nitrogen atoms N-6, N-13, N-20, and N-27. The inner core nitrogens give rise to the resonance at ~ 170 ppm. The inequivalence of the outer nitrogen atoms has been observed previously in the case of free base phthalocyanine.[11] The differences in the chemical shifts may either result (i) from a small deviation of the Pc macrocycle from a D_{4h} symmetry or (ii) from O–H···N hydrogen bonds between adjacent molecules as a consequence of intermolecular stacking.[13] In contrast to the monomeric form, the spectrum of the dehydrated polymeric form reveals only two resonances as shown in Figure 2b. The low field line which stems from the outer nitrogen atoms appears exactly in the middle of the monomer at 200 ppm, indicating a D_{4h} symmetry of the Pc macrocycle on the ^{15}N NMR timescale. This symmetry could be real or arise from rapid 90° jumps of the Pc macrocycle in **II**. The high field line has been shifted slightly upfield to 167 ppm as a result of small change of the electronic environment. The different signal intensities arise from different cross polarization dynamics and indicate the loss of the nearby OH protons in the polymer which facilitate cross polarization to the inner nitrogen atoms in $PcSi(OH)_2$, (**I**). Attempts to detect spin diffusion[14,15] between the outer and inner nitrogens in $[PcSiO]_n$, (**II**) were unsuccessful.

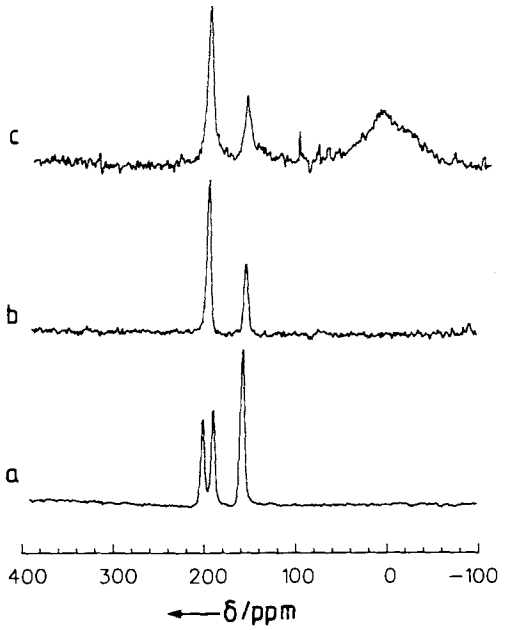

Fig. 2. ^{15}N CPMAS NMR spectra of 95% ^{15}N enriched phthalocyaninatosiloxanes at 9.12 MHz. (a) monomeric $PcSi(OH)_2$; (b) polymeric $(PcSiO)_n$; (c) partly oxidized polymeric $[(PcSiO)I_{1.1}]_n$. Experimental conditions: room temperature spectra, 5 mm o.d. rotors, spinning speed between 2.5 and 3.5 kHz, external reference $^{15}NH_4Cl$, 3 μs 90° pulses, 2.773 s repetition time, 7 kHz spectral width, 73 ms acquisition time; (a) 15 ms cross polarization time, 1480 scans; (b) and (c) 25 ms cross polarization time, 1390 scans.

In doping $[PcSiO]_n$ with iodine the spectra change dramatically as shown in Figure 2c. In addition to the familiar lines, a broad high field shifted resonance is observed. Careful line shape analysis shows that the signal consists of two lines, the stronger component appearing at 25 and the smaller component at 8 ppm; thus, in the doped compound the nitrogen signals are shifted between −160 and −180 ppm to high field. Note that not all material could be oxidized by doping with iodine; the observation of the presence of both shifted and unshifted signals in Figure 2c indicates the presence of coexisting clusters of conducting and isolating regions.

In order to obtain more information about **III** we have performed variable temperature measurements on this compound. The results are shown in Figure 3. Although the center of the broad high-field line seems to shift slightly to lower field as the temperature is raised, there is almost no temperature dependence on the line positions within the margin of error. This result is expected for Knight shifts resulting from interactions with conducting electrons; paramagnetic shifts arising from interactions with localized electrons should experience a much stronger temperature dependence.[16] Knight shifts are independent of the gyromagnetic ratio of the nucleus studied but proportional to the electron spin density at the latter;[16] the sign of spin densities is known to vary between adjacent atoms in π-electron systems. Thus, we can directly compare our results with the ^{13}C-Knight shifts reported previously for **III**.[6] These are + 280 ppm for the α-^{13}C atoms and −78 ppm for the β-^{13}C atoms. Thus, all carbon and nitrogen atoms adjacent to the α-^{13}C atom experience a positive Knight shift as expected. Whereas the small shift of the β-^{13}C atom signal is plausible, the much larger

ADVANCED MATERIALS

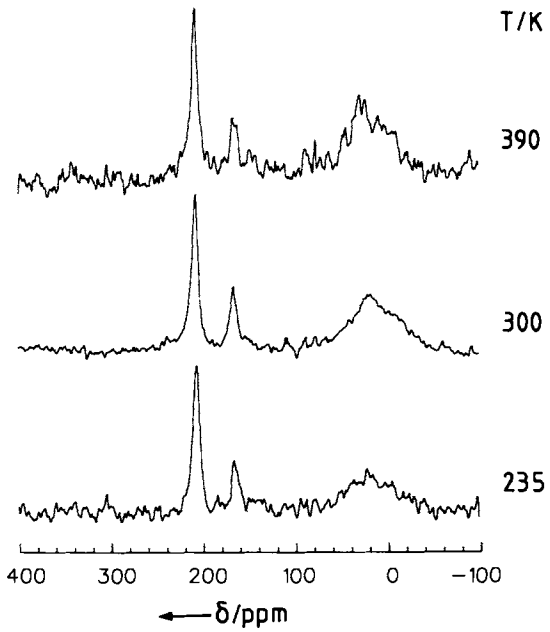

Fig. 3. ^{15}N CPMAS NMR spectra of partly oxidized $[(PcSiO)I_{1.1}]_n$ as a function of temperature. The spectra indicate slightly temperature dependent Knight-shifts of the oxidized material. Experimental conditions: 10 ms cross polarization time, 10 kHz spectral width, 52 ms acquisition time, otherwise same as Figure 2; (a) 2902 scans, (b) 15000 scans, (c) 7082 scans.

shift of the α-^{13}C spins as compared to the ^{15}N shifts needs further study.

In summary, it has been shown that structural changes of the solid state polymerization and the subsequent oxidation of ^{15}N labeled phthalocyaninatometalloxanes can be monitored by ^{15}N CPMAS NMR spectroscopy. In the oxidized state these materials are highly conductive, a fact confirmed by the observation of a ^{15}N Knight shift similar to the one observed by ^{13}C CPMAS spectroscopy. Conductive and non-conductive regions coexist and their relation can be estimated. Thus, ^{15}N CPMAS NMR spectroscopy provides interesting information on the structure and the reactions of this class of compounds.

A New Route to Highly Conducting Polyenes

By *Henning Hopf**, *Olaf Kretschmer*, and *Herbert Naarmann**

Dedicated to Professor Wolfgang Lüttke on the occasion of his 70th birthday

Since doped polyacetylene was shown to possess metallic conductivity in 1977 this class of organic polymers has been studied intensively.[1] The polyacetylenes used for these experiments may be prepared by various routes,[2] the polymerization of acetylene with Ziegler catalysts according to Shirakawa being a widely employed method.[3] Under certain conditions this approach provides mechanically stable polymer films which are of particular importance for the preparation of conducting material.

Regardless of the catalyst system used, it is an inherent disadvantage of this type of polymerization that ultimately a washing process will be required to remove the catalyst or its residues from the desired polymer preparation. In this communication we describe a method which avoids this pitfall and provides polyene films which form a solid layer on glass surfaces, ceramic plates, tubes etc.

Allene (propadiene) is condensed under high-vacuum into a 2l-round bottomed flask, and after several freeze-and-pump cycles to remove residual oxygen and volatile impurities the reaction vessel is sealed (internal pressure at room temperature ca. 1000 mb). After 20 h at 460 °C (high-temperature drying oven) the inner surface of the flask is covered completely by a deep-black, shiny-film which can be removed in patches and whose electric conductivity is 10^{-8} S/cm. When this film is doped by treating it for 30 min with a saturated solution of iodine in carbon tetrachloride[4] its appearance changes to a shiny gold. After solvent removal the conductivity has increased by a factor of 10^9.

Since allene is known to isomerize to propyne at elevated temperatures[5] we also investigated the polymerization of this hydrocarbon and several other alkynes under the above conditions. The results of these experiments are summarized in Table 1.

[*] Prof. H. Hopf, Cand.Chem. O. Kretschmer
Institut für Organische Chemie, Universität Braunschweig
Hagenring 30, D-3300 Braunschweig (FRG)
Dr. H. Naarmann
BASF Aktiengesellschaft, D-6700 Ludwigshafen (FRG)

Table 1. High-temperature polymerization of alkynes and diynes.

monomer	electric conductivity of polymer film [a] [S/cm]	
	undoped	doped with I_2
propyne	10^{-8}	10^{-1}
1-hexyne	10^{-9}	10^{-2}
butadiyne	10^{-8}	10
1,5-hexadiyne	10^{-6}	60

[a] Determined with the four-probe technique [4]

The reaction time of the polymerization experiments may be reduced considerably (8 h) by carrying out the above thermal processes in the presence of small amounts of various Lewis acids such as $FeCl_3$ or $MoCl_5$.

The undoped polymer films are insoluble in common solvents, possess up to 10% sp^3-hybridized carbon atoms as determined by ^{13}C NMR spectroscopy, and are more stable to air than a Shirakawa-polymer film. The oxygen-uptake of the latter amounts to 6% after 1 hour (in air, room temperature, humidity 50%) and reaches 14% after 24 hours under the same conditions. A polyene film prepared from propyne by our approach only absorbed 1.5 and 2.7% of oxygen after 1 and 24 hours respectively.

The simplicity of this new approach to conducting organic polymers makes it amenable to other highly unsaturated systems (other allenes, cumulenes, alkylacetylenes) and the results of presently performed experiments along these lines will be published in due course.

Research News/Inorganic Materials I

Glass-Ceramics in the Scheme of Inorganic Materials

By Graham Partridge*

1. Introduction

Glass and ceramic materials have been known for several thousands of years, the technology of preparation and diversity of composition and properties increasing, perhaps relatively slowly at first, but latterly much faster leading to the advanced materials which are becoming established in todays technology and which are expected to form the backbone of developments into the 21st century.

Originally it was considered that the various materials should be classed as insulating, and were distinct in composition and properties. However, these distinctions have become very blurred at the edges, for example, conducting ceramics such as silicon carbide and the superconducting materials such as yttrium–barium–copper oxide have appeared together with semiconducting glasses of the chalcogenide type. Indeed the blurring has gone even further with the advent of such materials as amorphous metals or metallic glasses. How should these be classified—as special glasses or special metals?

A further type of material which bridges the original gap between glasses and ceramics are glass-ceramics. These are much more recent in concept and possess many of the useful properties of the earlier materials. Essentially, they help to extend the overall range of materials and provide the technologist and materials designer with more opportunities to meet the increasing technological demands of today.

The present article, intended to form part of a series describing and discussing recent developments in these materials is aimed at introducing the materials and outlining their properties and general position in the overall scheme of inorganic materials. By way of introduction it is useful to consider what is meant by the various terms used for these materials.

2. Description of the Materials

2.1. Ceramics

The definition of ceramics provided by *Kingery*; "the art and science of making and using solid articles which have as their essential component, and are composed in large part of

inorganic, non-metallic materials"[1], covers not only porcelains and refractories, which are normally considered to be ceramics, but also glasses and glass-ceramics. More specifically, however, ceramics are polycrystalline materials, generally with some interstitial glassy phase present, the material being a product of high temperature solid and/or liquid phase reactions occurring between the initial inorganic crystal forms resulting in regrowth and restructuring of the crystal phases present.

Many of the earlier ceramics, such as porcelains and refractories, were essentially silicate-based materials, but many other types now exist which have been developed as the technological demands increase. These include pure oxide ceramics, for example alumina (Al_2O_3) and zirconia (ZrO_2) ceramics, nitrides such as silicon nitride (Si_3N_4) and boron nitride (BN), and carbides such as silicon carbide (SiC). All these are polycrystalline materials and can truly be considered as ceramics which are made by the sintering of powder precursors.

2.2. Glasses

There have been a number of attempts to provide a satisfactory definition of glass which would enable this type of material to be differentiated from the "all embracing" ceramic definition given above. These attempts have tried to take into account the fact that glasses are essentially supercooled, high viscosity liquids, possess an amorphous structure and can be obtained from a wide range of both inorganic and organic compositions.[2] Perhaps the most satisfactory definition is "glass is a non-crystalline solid"[3], since this includes all solid materials which are non-crystalline regardless of their composition and mode of formation. This latter definition comes closest to overcoming the great difficulty of attempting a broad classification of such widely diverse substances.

The majority of glasses which are known and made on a commercial scale consist of glass-forming systems based on silica (SiO_2) and boric oxide (B_2O_3). However, many other glass forming systems are known within the overall range of technical glasses based on oxides such as phosphorus pentoxide (P_2O_5) and alumina (Al_2O_3) and non-oxide glasses such as the chalcogenides (glasses based on sulphur, selenium or tellurium)[3b] and indeed elemental glasses, for example amorphous alloys. With these, as with all glass-forming systems, the range of compositions which will form glasses is influenced to some degree by the rates of cooling which may be employed from temperatures above the liquidus: fast rates extend the composition range. Limits are imposed, however, by what is achievable in practice, being influenced by the size of the article and constraints such as thermal stress build-up and resistance to thermal shock.

2.3. Glass-Ceramics

Glass-ceramics are essentially polycrystalline solids prepared by the controlled crystallization of what is now a wide range of glass compositions.[4, 5] These technologically important materials may perhaps be described as "wonder materials", and the first wonder may be that they exist at all. Glass is essentially a meta-stable material, with a disordered liquid-like structure, and would prefer to exist in a more ordered, crystallized condition. Nevertheless, for many glass compositions, particularly those which are produced commercially in large quantities, the emphasis over the years has been to prevent devitrification occurring. If the glass can be cooled successfully through the temperatures at which crystallization occurs, the high viscosity of the material prevents the structural reorganization which would develop crystals, and the product possesses an amorphous structure.

Devitrification, as it is normally understood in the glass industry, is an uncontrolled process which has a harmful effect since it can lead to sudden and unpredictable changes in viscosity which interfere with the working of glass making machinery. Additionally, localized high stresses can be generated arising from differential contraction between glass and crystal phases formed, resulting in a mechanically weak product.

It has been appreciated, for some time, however, that if crystallization could be controlled then useful materials

Graham Partridge graduated from the University of Sheffield in 1953 with a Batchelor of Science Degree in Chemistry and Physics. After National Service in the Royal Corps of Signals as a Radio Mechanic Instructor, during which he rose to the dizzy heights of Corporal, he joined the then English Electric Company in 1956 to work on glass and glass-ceramic materials. After the Company was merged with the General Electric Company in the late 1960s he was appointed head of the laboratory, now known as the Glass/Ceramics Group in 1972. Currently the Group forms part of the Engineering Research Centre (Stafford) of the joint UK/French Company GEC ALSTHOM. Graham has been responsible for the development of special glasses, glass-ceramics, ceramics and ceramic matrix composites, together with fabrication and processing technology to provide materials for use in many aspects of engineering and electronics. He has authored and co-authored more than 25 publications and is named as co-inventor on more than 25 patents on which a number of international patents have been based. From now on he will write regularly for Advanced Materials.

might be produced. Indeed, *Reaumur*,[6] in 1739 tried to produce a polycrystalline material by heating articles of a soda-lime-silica composition immersed in a mixture of sand and gypsum. However, crystallization occurred from the surface, resulting in weak and brittle articles. Although surface crystallization in certain glass compositions can now be controlled to provide high mechanical strength materials,[7] in the context of the discussion on bulk derived glass-ceramics this is an undesirable form of crystallization.

In the 1950's, research at Corning Glass Works in the USA led to the realization (it is claimed by serendipity) that, under suitable conditions and (at that time) in a restricted range of compositions, it was possible to produce a usable polycrystalline material by the controlled devitrification of a glass provided that sufficient nuclei were developed within the bulk of the glass on which crystals could subsequently grow.

The glass-ceramic process may thus be essentially divided into two parts. In the first, nuclei are developed in the glass body either by phase separation of the glass or by precipitation of a primary crystal phase during the first stages of a heat-treatment process as depicted in Figure 1. In order to

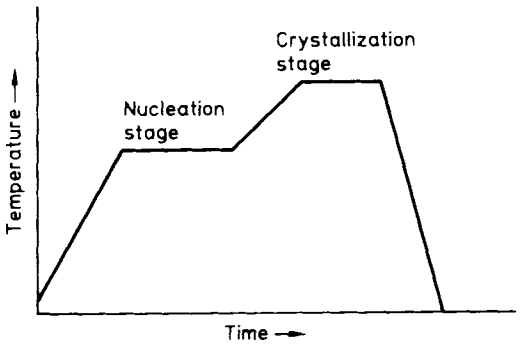

Fig. 1. Typical heat-treatment schedule for the production of glass-ceramics showing nucleation and crystallization holding stages.

develop the required quantity of nuclei it is usual to incorporate in the glass composition a nucleating agent. There have been many and varied such agents over the years of glass-ceramic development but the ones that are generally preferred in current developments are the oxides P_2O_5, TiO_2, and ZrO_2. Further heat-treatment to higher temperatures causes crystals to grow on the nuclei to form a closely interlocking crystal structure, with crystal sizes generally in the region of 1 μm, with a small proportion of interstitial residual glassy phase. In many cases, the crystallization processes can be very complex and the simple heat-treatment schedule depicted has to be modified to incorporate further holding stages in order to produce the desired materials and properties.

Alternatively, the glass may be reduced to powder and then processed in a similar manner to that discussed above for sintered ceramics. In this case the glass powder particles react together and because of the highly damaged state of the particles, surface crystallization may become dominant over bulk crystallization. Two possibilities exist in the use and development of sintered glass-ceramic materials. In the first, the compacted material is sintered to a vitreous body and is then subsequently heat-treated as in the case of the bulk materials above. Alternatively, nucleation and bulk crystallization occur during the same firing cycle as that used for the sintering step and this is to be preferred from an economic point of view.

The majority of glass-ceramic compositions are silicate based, although a number are known based on aluminate compositions. The many and varied compositions which can now be prepared as glass-ceramics the materials possess very different properties from those of the glasses from which they are derived. Mechanical properties are often improved and the linear thermal expansion characteristics of a glass-ceramic can be considerably different to those of its parent glass. Good electrical, particularly dielectric, properties are also produced as a result of the conversion of glass to glass-ceramic.

3. Properties

The general properties of the three types of inorganic materials discussed above are reviewed in this section. Detailed properties of materials relating to specific applications will be reviewed in future articles. Table 1 provides limited data for a number of inorganic materials.

3.1. Mechanical Properties

Although glass in its pristine state, for example newly drawn fiber, can possess very high mechanical strength with moduli of rupture above 7000 MPa, in practice, owing to surface damage, this is not realized and the practical moduli of rupture of glasses are in the range 50–120 MPa. Glass-ceramics are somewhat stronger and moduli of rupture up to 750 MPa have been realized. However, by far the strongest ceramic materials are derived from the sintered type of material with high strengths being obtained in oxide, carbide and nitride materials and particularly in materials such as yttria stabilized zirconia.

3.2. Electrical Properties

Owing to the presence of closed pores in sintered ceramics, their dielectric breakdown strengths are usually no higher than 20–25 $kV mm^{-1}$ whereas both glasses and glass-ceramics which do not contain closed pores can show dielectric breakdown strengths of 40–50 $kV mm^{-1}$. The dielectric properties of sintered ceramics and glass-ceramics cover sim-

ilar ranges, the properties being strongly dependent on the crystal phases (and interstitial glass phase) present in the material. In general, glasses show higher dielectric losses than crystalline materials at high frequencies although fused silica (SiO_2) is very good in this respect.

3.3. Thermal Properties

The linear thermal expansion characteristics of sintered ceramics and glasses cover similar ranges although it is difficult to obtain a satisfactory sintered material which possesses a very low expansion comparable to that of fused silica. At the high expansion end, linear thermal expansion coefficients greater than about $140 \times 10^7\,°C^{-1}$ can be obtained for sintered ceramics but the materials possessing such expansions are generally poor in terms of strength and resistance to attack by atmospheric moisture. Glass-ceramic materials, however, enable the overall expansion range to be extended and usable materials with linear thermal expansion coefficients ranging from negative to as high as $180 \times 10^{-7}\,°C^{-1}$ can readily be obtained. The thermal conductivities of glasses and glass-ceramics are low, comparable with those of zirconia ceramics. High thermal conductivities can only be obtained in selected sintered ceramics, for example, Al_2O_3, BeO, SiC.

In addition, in terms of increasing resistance to high temperatures, the order is glass, glass-ceramics, ceramics. Many glasses cannot withstand temperatures in excess of 500–600 °C for long periods although fused silica may be used to temperatures in the region of 1000 °C before devitrification becomes a problem. Glass-ceramics can operate for extended periods at temperatures of 700 °C to over 1200 °C. Sintered ceramics, however, can provide operational capability to temperatures of 2000 °C although protection by means of a neutral or reducing atmosphere may be necessary to achieve this.

4. Selection

The selection of an inorganic material depends, perhaps obviously it could be argued, on the properties specified for a particular application. Often the properties are interactive so that whilst it is relatively easy to optimize one or two properties required, the problem becomes increasingly more severe when three or more properties must be optimized. However, properties are not always the overriding criteria and attention frequently has to be paid to fabrication routes. A fabrication route necessary for the highest strength material may not be practical in a specific application and compromises have to be made. Thus selection of a material for a given application may be guided, perhaps on economic terms, and the materials expert then has to obtain the best properties possible with the designated material. Examples of selection will be given in future articles and reasons discussed.

Conference Reports

Powder Metallurgy (PM'89) in San Diego

By Rainhard Laag*

1. Introduction

At the PM'89 conference, held 10–14 June 1989 in San Diego, USA, the present state of metal powder injection molding (MIM) in the USA was presented in five sessions, each with 15 presentations where the leading researchers, producers and consumers of MIM parts demonstrated impressive progress in development and application. Currently, the most extended activities in institutional research and development are being made at Rensselaer Polytechnic Institute (RPI), Troy, NY. A considerable number of companies are also developing improved processing, but it is mostly of a proprietary nature.

Before discussing the individual presentations given at San Diego, the general state of the art will be briefly described. The development of new, high performance metal alloys requires rapid solidification process to control the microscale homogeneity of the chemical constituents. Investigations of powder production are, therefore, closely connected with the development of advanced forming and consolidation processes. Two examples of recent developments are Metal Powder Injection Molding (MIM) and sinter-hot isostatic pressing (Sinter-HIP). Both, as concepts, are attempts to conserve the physical properties of powders on a macroscopic scale. Between concept and finished part, however, the processing steps change the initial conditions of homogeneity and freedom from exogenous materials—both solids and gases.

Sinter-HIPing of powder compacts is a pressure assisted consolidation technique and is applicable to a wide size range of parts made from powders. It is beneficial to form a stable green body either by cold isostatic or by uniaxial pressing. Advanced metals like superalloy and intermetallic phase powders do not compact well. Therefore, the powder must be filled in glass or metal containers for consolidation. This encapsulating process increases the production costs (an additional step) especially since the containers are not reusable after HIPing. The advantage of Sinter-HIP consolidation is that relatively coarse powders can be used without any contamination being caused by binders or additives. This simplifies the conservation of the physical properties of the powders and helps to achieve an optimum in mechanical properties.

MIM is a hydrostatic-pressure forming and consolidation process used to produce small and complex shaped parts inexpensively in large quantities. A mixture of approximately 60 vol.-% fine metal powder and 40 vol.-% binder and lubricant can be formed much like a conventional plastic. The use of waxes like polyethylene or other thermoplastics provides the rheological basis allowing the mixture to flow into undercuts and corners in a way that the uniaxial pressing of lubricated metal powders cannot achieve. Dependent on the shape complexity, this process needs very fine powders to achieve homogeneous form filling. The forming process is a combination of thermoplastic pressure casting and conventional powder metallurgical technologies. Like all known processes, MIM has some advantages and disadvantages. The limitations are mainly in the compatibility of the powder/binder interface, the complete binder removal and the pressureless sinterability of the metal powders to near full density.

In order to combine the advantages of MIM with its achievable shape complexity with, for example, the high performance of superalloy and intermetallic phase materials, it is necessary to enhance the ability of MIM either to process coarser powder particles or to develop powder production techniques that allow the inexpensive preparation of fine prealloyed powders on an industrial scale. Because of MIM's potential to produce large quantities of parts, the use of fine powders produced by conventional techniques is currently much more expensive than the use of coarse powders. The savings are twofold, in powder costs and in economies of scale which often result in an exponential increase in cost effectiveness with the quantity of produced parts.

The main disadvantage of MIM is that the savings in processing are connected with an increase in impurity of the part because group III–IV metallic elements and refractory metals are highly reactive towards anionic elements like oxygen or nitrogen. A reduction of the powder particle size far below 100 μm increases the specific surface area of the powder so that the content of impurities can reach 1–2 wt.-%. At the higher temperatures necessary for consolidation, these impurities diffuse to grain boundaries and promote brittleness by forming strong oriented covalent bonds. The me-

[*] R. Laag
Max-Planck-Institut für Metallforschung
Institut für Werkstoffwissenschaft, Pulvermetallurgisches Laboratorium
Heisenbergstraße 5, D-7000 Stuttgart 80 (FRG)

chanical properties are very dependent on the amount of impurities. Another advantage of using coarse and spherical powder particles is their lower mechanical friction and their higher packing densities. This allows a higher powder loading in the binder. An additional increase in density can be achieved if special particle size distributions like bimodal or trimodal distributions are used. The higher the density of the green shape compared to the theoretical density, the smaller is the resulting shrinkage during sintering.

Today, the use of coarser particles is, however, limited. This has three main reasons:

- Super solidus sintering does not work as well with coarse particles because the surface area decreases with an increase in particle size.
- The internal friction of coarser particles is lower. After debinding, the parts are very sensitive to fragmentation before presintering. Typically the debinding process ends at much lower temperatures than necessary for presintering. This difference is especially noticeable for high temperature alloys.
- Solid state sintering of single phase high temperature alloys like intermetallic aluminides does not work because of the low diffusion rates in ordered lattice structures.

The overall advantage to the processing of fine powders is the superior form filling during molding which allows more complex shapes to be molded and gives a homogeneous distribution of binder and powder in the green body. Spherically shaped particles simplify the critical debinding process, enhance sinterability, and cause uniform dimensional shrinkage which reduces effort in tool design, quality control and finishing of the parts. The application of prealloyed powders achieves the additional advantage of a more homogeneous microstructure after sintering compared to the component or multicomponent powder mixtures.

Injection molding consists of four basic steps: powder-binder-formulation, injection molding, debinding and sintering. Although each step appears independent they are in some ways all related. Currently the interchange between the processing steps is not understood adequately. The procedure of producing parts is based on empirical results which are connected with long and expensive trial and error investigations. Up to now it is clear that the most sensitive factors are the powder properties, the constituents of the binder, the powder binder interfaces and the process variables of debinding and sintering. All these problems were addressed by the presentations in San Diego.

2. Powders

In the section on powders the need for the production of ultrafine powders below 20 μm in diameter was outlined. Three different atomization processes and one high energy milling process were shown. The microatomization of GTE Products Corporation, presented by *M. Pliwal* and *R. J. Holland*, produces spherical powders of tungsten, copper, aluminum and stainless steel by remelting sintered powder mixtures and forming prealloyed powders in a plasma jet. This relatively expensive procedure allows the production of prealloyed powders made from alloys with very high melting points. Another method, ultrasonic gas atomization, provides particles below 45 μm. The volume fraction of powders below 20 μm was small in comparison to the yield of other methods presented. The reason may be the low gas-mass stream that divides the melt stream into the required fine droplets. *K. P. Kao* (Defense Metallurgical Research Laboratory) presented fluid energy milling which he has used to process iron sponges to fine particles of spherical shape. These have a shorter debinding time and a better sinterability in comparison to iron carbonyl powder. With the exception of the ultrasonic gas atomization, all processes described in this session had the same disadvantage in being an additional production step in working with MIM and being expensive when larger quantities are produced.

3. Process Variables

The presentation by *D. Lee, K. F. Hens* and *L. A. Najmi* (RPI) was focused on the understanding of the conditions under which the injection molded parts could be produced. They have developed software packages which allow the examination of the form filling conditions with respect to the powder/binder mixture. The basic concept of the calculations is known from plastic injection molding. Additional difficulties arise due to the variation in molding temperature. If the binder shows a rapid change in viscosity, and segregation occurs inside the die, then density variations occur in the molded parts. The optimization of process parameters by extensive computer calculations demonstrates the need for

careful process control. The second presentation of this session (*D. A. Issitt*, European Advanced Materials Institute) illustrated the influence of powder characteristics, binder selection, rheology of the mixture, green strength, debinding, shrinkage and tolerance on the properties of the finished part. Here, the audience was told that only the carefully adjusted optimization of each individual process parameter will result in a product with the properties required for advanced technological applications. In the last presentation *T. Tonomura* (Multimaterial Japan Limited) illustrated factors that affect size tolerance and physical and mechanical properties. The high performance of injection molding was demonstrated even for cases where elemental powders were used.

4. Binders

This session dealt with the key problem of successful injection molding, the evaluation of binder systems and their compatibility to the surface chemistry of the powders. The presentation "Optimization of the Powder–Binder Mixture for Powder Injection Molding" given by *R. M. German* (RPI) was the highlight of the injection molding sessions. Based on his long term practical experience, he gave the audience an assessment of the powders and binders currently used in injection molding. A body of mathematics was described which is used to predict and optimize the design of injection molding powder/binder mixtures. Several factors were included in calculating the inherent packing density of a powder. It was shown how the packing characteristics are dependent on particle size, distribution and shape, agglomeration, surface active agents, internal powder porosity, mixture homogeneity, interparticle friction and the size of the mold. Modeling of the viscosity of the powder binder mixture, using several equations developed for concentrated suspension behavior was demonstrated. The method resulted in a predicted optimal mixture for injection molding for a given set of powder and binder attributes.

After the discussion of particle characteristics, the second presentation "Requirements of Binder for Powder Injection Molding" by *C. I. Chung* (RPI) tried to illuminate some of the secrets in binder development. As expected the specific requirements of a binder depend on the complexity, size and metallurgy of the desired part. The performance of the binder can be enhanced by mixing or blending the binder with other materials. The molecular length of all components of the binder must be smaller than the interstitial free path length between powders in order to obtain a microscopically uniform mixture.

5. Research

The purpose of this session included the evaluation of new materials applicable for injection molding in the future. Highly sensitive materials like titanium powder were shown to be moldable if the binder does not violate the surface chemistry of the powder. In the presentation given by *K. Ameyama* (Ritsumeikan University) on injection molding of fine titanium powder it was reported that binder consisting mainly of polybutylmethacrylate can be completely removed after molding and the titanium sintered to a density of about 94% theoretical density. Impact properties were measured and fracture was characterized in order to evaluate the processing (molding, sintering). Correlations between processing parameters and mechanical properties were established.

"Supersolidus Sintering of Coarse Powders and Its Application to Injection Molding", given by *P. F. Murley* (RPI) was an attempt to evaluate the applicability of injection molding for coarse powders. Here, obtaining a homogeneous distribution of binder, and debinding were the most critical steps of the process. Experiments with higher volume fractions of metal in the mixture showed that the disadvantages caused by a homogeneous binder distribution—pore formation during molding and incomplete debinding even after long cycle times—counteract the advantages expected from higher metal fractions. Microstructure development during super solidus sintering of bronze and nickel alloy powder was found to be highly sensitive to local temperature variations.

6. Applications

Three presentations covered the evaluation of profitable applications of MIM. Nickel–Steel parts for the automotive industry, office equipment, oil drilling and camera components were shown. Other profitable examples made from stainless steel are parts for computer equipment, dental instrumentation, orthodontic devices, chemical components, marine equipment, aerospace equipment and a Fender bass guitar. Parts made from some exotic materials like Kovar, Tungsten, Invar and Molybdenum were supplied to the electronics industry in the form of hermetically sealed packages—headers, eyelets, flanges, heatsinks and bases.

The problem of building inexpensive prototyes of mold forms for experiment and process optimization was sketched. A minimum production quantity of about 20,000 pieces per year was thought necessary to amortize tooling costs.

The PM'89 conference in San Diego covered the present state of the research, development and production of MIM. Much effort was made to develop processing and new applications for parts which should be very competitive with other powder metallurgical routes and castings. Standard processing known from plastic injection molding has been successfully transferred to the production of small parts made from carbonyl iron and nickel powders. The transition to more complex materials and the systematic evaluation of new compatible binder systems needs a lot more scientific work

ADVANCED MATERIALS

towards understanding the principles and dependency of the process. An ideal process would use inexpensively produced, gas atomized, fine and small sized powders of about 10 μm diameter with a compatible multicomponent binder system which provides a mild decomposition at relatively low debinding temperatures. Debinding, presintering and consolidation of injection molded parts in a Sinter-HIP furnace offers the possibility of a one step heat treatment which avoids handling of the debinded parts. Full density can be achieved by pressure assisted final stage HIP. In the USA, a multimillion dollar project, part of the Advanced Powder Processing program at Rensselaer Polytechnic Institute, is the beginning of a move from empirically based process development to a systematic development of the theoretical background.

The basic elegance and simplicity of the injection molding process must not lead to the assumption that fully dense parts of predictable final dimensions are produceable as easily as in plastic injection molding. Up to now the main problems arise after the actual molding, during debinding and sintering. Only complete control over all process parameters will result in high quality reproducable parts.

Macromolecular Physics in Lodz

By Hugh J. Byrne *

To the French Cistercians who founded the Abbey in Sulejow Lodz, Poland, the terms charge transport and activation energy had little meaning, and seldom were they to be seen meandering through the grounds digesting the importance of bipolarons and multiphoton resonances. However, for one week in September, the serenity of this decaying 12th century house of learning was disturbed as it played host to the 21st Euro-Physics Conference on Macromolecular Physics, held from 4–8 September.

The conference was focused on the topic of "Electrically and Optically Active Polymers", a field which has attracted the expertise of a diverse range of scientists including polymer and solid-state physicists as well as physical and synthetic chemists. Interest in these materials was generated by the discovery that it was possible to make thin films of polyacetylene, and was increased by the subsequent discovery that the conductivity of this material could be increased to metallic values by chemical doping. Since then, a great deal of activity has produced a large range of processible organic polymers whose properties have been studied. Of similar interest to the electrical properties of these materials are the optical and, in particular, the nonlinear optical properties. The highly delocalized π-electron backbone of these polymers should give rise to large nonlinear susceptibilities which may render these materials a possible alternative to inorganic materials in the developing fields of all-optical switching and signal processing. This conference was designed to review the progress and problems of understanding the nature and origins of these materials properties.

The key-note address was delivered by the conference chairman, *Prof. M. Kryszevski*, from the Polymer Institute of the Technical University of Lodz, who outlined the objectives of the conference. Particular importance was attributed to the necessity for a greater understanding of the dependence of the electrical and optical properties of these materials on their structure and morphology. In a field where the range of materials available is ever increasing and where the polymer morphology may vary from that of single crystal to that of solution, an understanding of this structure-properties relationship is as important as understanding the microscopic molecular properties. Indeed, the problems facing "homo polymerius" were effectively portrayed by *V. Enkelmann* from Mainz, FRG. In his presentation he described the number of possible inter and intra chain effects contributing to a bulk measurement of any polymer parameter. He stressed the need to control the macroscopic conductivity by means of molecular parameters. The approach taken was to move towards single crystal materials in which interchain hopping is controlled by the size of the molecular structure. In polythiophene and polyparaphenylene, substitution was employed to systematically control the interchain distance by steric effects. The temperature dependence of the conductivity was found to increase as the size of the substituent increased, indicating an increasing activation energy although the conductivity itself decreased. The transition from the dominance of interchain effects to that of intrachain effects was thus shown, and an empirical relationship between the activation energy and the interchain parameter was presented. A similarly strong correlation between the

[*] Prof. H. J. Byrne
Department of Pure and Applied Physics
Trinity College
Dublin 2 (Ireland)

structural and electronic properties of these systems was evident in the presentation of *P. Bernier* from Montpelier, France. NMR and ESR studies of the doping process of polyacetylene appear to confirm the stage-like nature of this process indicative of a step-wise restructuring of the material with increasing dopant concentration. They also reported that a new, dilute phase was identified. This correlation was highlighted by the work of *M. Stolka* et al. from Xerox in New York in which the charge transport in Si and Ge backbone polymers was studied over a wide range of temperatures, encompassing the glass transition temperature. At the glass transition temperature the activation energy of transport abruptly decreases to very low values, raising the comment from *H. Bässler* from Marburg, FRG, that transport in these materials is controlled by disorder.

The importance and nature of interchain transport mechanisms were outlined by *A. A. Zakhidov* of Tashkent, USSR and the stabilization of solitons, polarons, and bipolarons by interchain coupling effects between neighboring polyacetylene chains was proposed. This stabilization leads to the possibility of interchain optical transitions, influencing the nature of the photoinduced absorption spectrum.

In terms of electrical conductivity, the most promising material at the present time is the so-called Naarmann polyacetylene. The question as to why this particular form of polyacetylene (and indeed, only some samples within a batch) shows such high conductivities ($\sim 10^5\ S\,cm^{-1}$) was addressed by Dr. *T. Schimmel* of Bayreuth, FRG. The anisotropy of the conductivity was found to be ~ 50 but temperature independent, indicating a common limiting mechanism in both directions. This dependence was reported to fit best to the model of *Sheng* describing large, highly conducting regions separated by small gaps, with the rate of gap hopping being proportional to temperature. These barriers contribute to only 30–40% of any sample resistance and do not vary much between high and low conductivity samples. Transport is therefore deemed to be limited by the resistance of the high conductivity regions. As yet, however, the recipe for these highly conducting regions appears to be empirical.

The importance of new materials exhibiting new properties and of new processing techniques was also stressed in the key note address. The influence of the structural properties of poly(vinylidene fluoride) which has a strong piezoelectric activity, on the macroscopic polarization was discussed by *D. Geiss* from Taltow, GDR. It was demonstrated that even poorly crystalline polymers such as dye-doped poly(methylmethacrylate) can exhibit a significant piezoelectric activity upon poling. Polymer blends of poly(3-alkylthiophenes) were shown to exhibit improved mechanical properties by Dr. *V. Laakso* of Porvoo, Finland, whereas the soluble forms of polyacetylene described by *J. P. Pfleger* from Prague, Czechoslovakia, provided good optical quality materials for nonlinear optical measurements. In samples of poly(bisalkylthio-acetylene) a dramatic increase of conductivity was observed by *H. K. Roth* from Leipzig, GDR, upon laser treatment. This increase is associated with a color change from red to blue-black and a loss of solubility, and the process appears to be similar to polymer doping. The advantages of this technique over doping is the high spatial resolution available by using small laser focal diameters.

Investigation of the nonlinear optical properties of organic conjugated polymers is a field of research equally as active as that of their electrical properties, and already device applications have become realistic. Exploiting the large second order polarizability of poled organic polymers, guided wave structures may be made which act as phase and intensity modulators. A 2X2 electro-optic switch has been realized, as reported by *G. Mohlmann* from Akzo in the Netherlands. Waveguide losses are as low as, or lower than, $1\ dB\,cm^{-1}$, and further development should produce devices competitive with rival lithium niobate structures.

The second order nonlinearities utilized in these devices are not, however, intrinsic to the polymer backbone and exploitation of such an intrinsic nonlinearity for device applications appears to be further from realization. Highly conjugated polymers have been predicted to possess a large ultrafast nonlinearity which should be real in nature. Investigations of the nature of this nonlinearity using the technique of third harmonic generation were carried out by *F. Kajzar* of Saclay, France and also by *D. Neher* from Mainz. In the latter case, the materials studied were substituted polyphenyl acetylenes and poly(3-decylthiophenes) whereas in the former, they were poly(thienylthiophene) and poly(dithienyl benzene). In all cases a strong resonant enhancement of the process was observed. The influence of such multiphoton resonances on the degenerate four wave mixing signals at 1.064 μm in a range of polymers was discussed by *H. J. Byrne*, from Dublin, Ireland. In the case of poly(3-butyl thiophene) a strong three photon enhancement was observed, whereas in the much studied polyacetylenes poly 3 and 4 (BCMU) a two photon enhancement was observed. In poly(anthracene phenylenine) however, the nonlinearity is purely third order although a large imaginary contribution is measured. It appears therefore that in all cases, the nonlinearity is dominated by imaginary contributions, and it was suggested by *Byrne* that this represents an inherent limit to the material polarizability since all resonances in these materials are localized by virtue of the strong excitation-lattice coupling. The ultrafast nature of the nonlinearities in polyacetylene/poly methylmethacrylate copolymers was demonstrated by *Pfleger*, who also showed the detrimental effect of doping on the polymer nonlinearity. This observation highlights the divergence of the disciplines of electrically active and (nonlinear) optically active polymers.

As the intensity of research increases in this area, the number of realistic applications increases. As previously mentioned, electrooptic switching devices based on poled polymers are already approaching the standards set by their rival lithium niobate based devices. The strong mechanical properties of *Laakso*'s poly(3-alkyl thiophene) blends make them good materials for antistatic packaging. An impressive piece

ADVANCED MATERIALS

of precision work with a wide range of applications was presented by *J. Kikas* from Estonia. Spectral hole burning of dyes in polymer matrices produces holes with a spectral width as low as 10^{-2}–10^{-3} cm^{-1}. With this resolution, up to 10^3 holes may be burned per inhomogeneous band. The listed applications of such hole burning techniques included frequency selective optical memory, space and time domain holography, and the materials may be used as narrow band optical filters. Application of an external electric field gives rise to stark shifting of the holes, an effect which may be exploited as an optical modulator.

Within one week it is only possible to cover a small portion of the current developments in this expanding field. Presented above is merely a cross-section of the week, but a number of issues were, however, highlighted. Firstly, whereas the nature of the optical and nonlinear optical properties of conjugated polymers are still considered to be primarily determined by interchain effects, the material structure and morphology appears to be critical for the electrical properties. This structure-properties relationship was discussed at length, resulting in the recognition of the need for well defined structures, and systematic studies. In such a way, understanding and enhancement of electrical properties may be achieved through manipulation of material structure. On the other hand, in the case of the nonlinear optical properties of conjugated polymers, the suggestion of an intrinsic molecular limit to the magnitude of the response infers the need for further systematic studies on well defined molecular structures. The division between the two fields of research is highlighted by the fact that good electrical properties require material doping, a process which as a devastating effect on the nonlinear optical properties.

Despite the continuing complexity of both areas, progress towards an understanding of the dominant physical processes involved is being made. The resulting feeling of optimism was reflected in the atmosphere of a conference designed as an exchange between Eastern and Western Europe, held in a country in transition from one political idealogy to the other. Amidst this political, economic, and scientific complexity, the conference was a success.

Surface Modification Technology in Neuchâtel

By Peter K. Bachmann*

The "Third International Conference on Surface Modification Technologies" (SMT III) was held from 28 August–1 September in Neuchâtel, Switzerland. After Phoenix, Arizona and Chicago, Illinois, SMT III was the first of this series of conferences to take place outside the United States of America.

Neuchâtel, beautifully located at the foot of Mount Chaumont and at the shore of Lake Neuchâtel was chosen because it is also the home of the University of Neuchâtel and of CSEM, the Centre Suisse d'Electronique et de Microtechnique S.A., a private, non-profit R&D organization active in the fields of microelectronics, optoelectronics, sensors, micromechanics and material science. CSEM and TSM jointly organized and sponsored SMT III along with many other Swiss scientific societies, Swiss government agencies and the University of Neuchâtel, which provided the rooms and the infrastructure for the conference.

The objective of the "Surface Modification Technologies" conference series is to bring together physicists, chemists, metallurgists, manufacturing engineers, and other materials scientists from around the world to interact and utilize each other's capabilities in the cross pollination of ideas, and, indeed, 82 contributions from 20 different countries including Europe, Asia, Australia and North America are listed in the technical program. Quite interestingly for a conference held in Europe, the USA with 22 papers outnumbered Switzerland with 13 and West Germany with 10 contributions. Japan, on the other hand, had only two entries.

The sessions offered to an audience of approximately 160 participants included ● Diamond and Related Coatings, ● Characterization of Coatings, ● Physical Vapor Deposition, ● Chemical Vapor Deposition, ● Laser Alloying, ● Alternate Coating techniques, ● Laser Surface Treatment, ● Coatings for Space Applications, ● Ion Implantation, ● Electroplating, ● High Temperature Coatings, and were accompanied by an additional half-day poster session.

1. Wear and Corrosion Resistance

Similar to other coating oriented conferences, SMT III illustrated that many practical applications of modified surfaces are related to improved wear resistance or increased

[*] Dr. P. K. Bachmann
Philips Research Laboratories
P. O. Box 1980, D-5100 Aachen (FRG)

lifetime of bearings and cutting tools. Contributions to this field were scattered throughout the processing technology oriented sessions and made up approximately 30% of the conference papers. Examples of this topic include a presentation by *O. Knotek* (RWTH Aachen, FRG) on reactively sputtered ceramic coatings. The properties of Si_3N_4 ceramics were improved by adding a thin layer of Si–Al–O–N using reactive magnetron sputtering techniques. *W. Ensinger* (University of Heidelberg, FRG) presented a paper on the low temperature generation of ceramic coatings, for instance nitrides or carbides of boron, titanium, chromium aluminum or silicon using ion beam assisted deposition. Deposition temperatures well below 200 °C were made possible using this technique. *D. G. Bhat* (GTE Valenite, Troy, MI, USA), one of the conference co-organizers describing in his contribution how to improve the chemical wear resistance of Si_3N_4 cutting tools for the machining of steel by applying a computer-modeled titanium nitride layer that adheres excellently to the surface of the tool material.

An alternative to applying vapor deposited coatings to improve the performance of cutting tools was presented by *T. L. VanderWert*. (Innovex, Hopkins, MN, USA). By applying a pulsed magnetic field to relieve internal stresses the lifetime of any cutting tool material was shown to increase by 40% to 180%.

Another alternative to the deposition of carbide and nitride coatings that has gained attention in the Japanese industries was pointed out by *T. Arai* (Toyota, Aichi, Japan). In this approach, carbon or nitrogen containing materials are immersed into molten salt baths containing carbide or nitride forming elements. The coating is formed by chemical reaction on the substrate surface. The performance of this material is comparable to CVD or PVD coatings but the preparation process was found to be more efficient.

2. Superconductors

This topic was covered in three papers. The results of R.F. magnetron sputtering experiments (by *P. K. Srivastava*, CSEM, Neuchâtel), chemical vapor deposition (by *G. Wahl*, Asea Brown Boveri, Heidelberg) and spray pyrolysis of aqueous Y-Ba-Cu nitrates (by *S. P. S. Arya*, CSEM, Neuchâtel) were outlined. All of the methods are capable of producing the standard 1-2-3 material with transition temperatures around 90 K. The width of the transition region of films made by spray pyrolysis on alumina decreases upon applying a Y_2BaCuO_5 interfacial layer prior to the formation of the 1-2-3 coating.

3. Miscellaneous Coatings and Processes

The preparation of unusual material combinations was tackled by *J. W. Dini* (Lawrence Livermore Laboratory, Livermore, CA, USA) by utilizing combinations of processes. Thick (1 mm) copper coatings on glass which can subsequently be precision machined for optical purposes were obtained by first applying a PVD coating followed by the electroplating of the newly generated surface.

Part of a review by *P. K. Bachmann* (Philips Research Laboratories, Aachen) was devoted to a sucessfully industrialized CVD application, the preparation of high quality optical fibers for telecommunications applications by means of thermal and plasma induced chemical vapor deposition methods. Up to now the stringent requirements of ultraclean processing and the close matching of a desired refractive index profile are only met by CVD techniques. With respect to efficiency, dopability and refractive index profiling, plasma induced CVD has advantages over thermally initiated deposition processes. A number of papers in various sessions were related to the characterization of surfaces modified by laser treatment, plasma treatment, and ion bombardment. Special attention was on the characterization, modification, optimization and modeling of substrate-deposit interfaces to improve the adhesion of deposits.

4. Diamond and Related Coatings

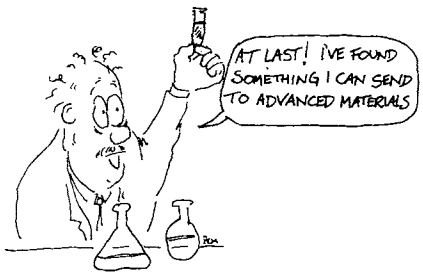
After more than 6 years of continuous research and development efforts in Japan and about 4 years after major US groups entered (or re-entered) the field, CVD grown diamond coatings are now considered a reality in Western Europe. This is illustrated by the first major diamond-related conference session held as part of SMT III as well as by the announcement of the first European conference solely devoted to diamond and related coatings, the "Diamond Films '90" planned for September 1990 in Montreux, Switzerland (for further information, please contact the author). Eight papers and one poster were associated with this emerging technology.

In his invited presentation on diamond as a heat sink material *M. Seal* (D. Drukker, Amsterdam, Holland) provided the link between the well established applications of

natural or high pressure synthesized diamond and the utilization of vapor deposited diamond thin and thick films. Diamond is known to be the material with the highest heat conductivity of any solid at room temperature and is applied as a heat sink for high power electronics. When designed and prepared properly, diamond films deposited from hydrocarbon/hydrogen mixtures at low pressure and substrate temperatures of approximately 1000 °C can be used for this purpose thus circumventing the size limitations of natural or high pressure synthesized diamond stones.

As a pleasant surprise to the organizers, *Boris V. Spitzyn* of the USSR Academy of Science in Moscow, USSR, was able to attend the conference. *Spitzyn* has been actively involved in diamond CVD since the early 1950's and was the first to ever apply for a patent on the vapor growth of diamond (on diamond substrates) in 1956. This patent, coauthored by *B. V. Derjaguin*, was finally granted in 1980. He outlined the history of diamond CVD which he rightfully terms diamond "crystallization" from the vapor phase and gave some insight into the basic mechanisms of diamond formation. The main trick is to etch the growing deposit with atomic hydrogen. Due to the higher etch rate, the thermodynamically more stable graphite is removed and pure diamond remains to form a film.

Various preparation methods, including thermal and plasma enhanced CVD techniques can be applied to form polycrystalline coatings on metals, semiconductors and insulators, e.g. Mo, Si and silica glass, as pointed out by *P. K. Bachmann* in the second part of his review on selected CVD applications. He also described applications other than heat sinks, such as cutting tool coatings, loudspeaker membranes, optical coatings and, using semiconducting doped diamond, high power/high speed electronics. Some of these applications are already commercially available, e.g. loudspeakers and certain tools, while additional efforts are still necessary to get the others to the market place. The main problems are currently adhesion for tool applications, scattering of the polycrystalline material for optical applications, and heteroepitaxy of single crystals for larger size electronics applications.



Homoepitaxial growth of diamond on various types of natural diamond is possible, however. In a contribution of *A. Badzian* (Materials Research Laboratory, Pennsylvania State University, PA, USA) the successful preparation of 160 μm thick vapor grown single crystal diamond layers was reported. The differences between the Raman spectra of the substrate and the deposit are neglegible, indicating the high quality of the deposited material. These findings were supported by the X-ray and infrared data of the epitaxial layer. This paper also covered some materials aspects of the C–N and the B–C–N system. The plasma CVD preparation of ternary phases that easily scratch diamond was claimed. Hardening of diamond by the implantation of nitrogen ions was also the topic of *S. Prawer* (Royal Inst. of Technology, Melbourne, Australia). The ion bombardment that improved the wear properties of diamond single crystals had to be applied at elevated temperatures. Another paper on post-growth treatment of diamond, given by *N. Chapliev* (Academy of Science, Moscow, USSR) described the effects of CO_2 laser pulses on CVD diamond surfaces. Pattern etching, the formation of well defined holes and surface smoothing were achieved using different atmospheres during the treatment. Two papers of the session were solely devoted to preparation techniques. *C. Benndorf* (University of Hamburg, FRG) presented a simple set up for microwave plasma CVD of diamond. His modification of this widely used method was to use a cylindrical, tunable resonator along with parts from a commercial microwave oven. Diamond deposition using a DC plasma torch was described by *P. K. Bachmann*. DC thermal plasmas are capable of diamond deposition rates of up to 500 μm/hour on small substrate areas. As pointed out in this presentation, a major drawback is the radially inhomogeneous composition of the coating. Only the central portion of the coating consists of high quality material. Other parts of the deposit are contaminated with graphitic phases. The method is suitable, however, for the preparation of bulk material on small areas. Diamonds also won the prize for "best poster" of the poster session. A presentation by *R. Haubner* (University of Vienna, Austria) outlined the influence of nitrogen added to the CVD gas phase. For nitrogen concentrations of more than 5% (in the gas phase) the crystallinity of the coatings deteriorates. At about 2%, large textured growth regions are observed. They exploited the "heated" filament thermal CVD method to grow diamond. All major preparation techniques currently applied worldwide for diamond CVD were, therefore, represented at SMT III.

SMT III was the first of its kind held outside the USA. The organizers will certainly benefit from this experience and further improve some organizational weak spots. The final program with a valid schedule of the papers should be available at least two weeks prior to the conference to allow attendees to plan their stay. The adjustment of the schedules of parallel sessions is a problem for any major conference and will certainly be improved at the next SMT. Despite these minor problems the conference was highly successful in providing a forum to freely exchange surface related ideas and collect results in various scientific fields. The proceedings of SMT III containing the peer reviewed full length papers will appear in book form (2 vols.) in November 1989 (available from TMS, 420 Commonwealth Drive, Warrendale, PA). The organization for SMT IV is already under way. The conference will be held 2–7 September, 1990 in Paris, France and the abstract deadline is December 1, 1989.

Erratum: In Figure 6 of the article Liquid Crystalline Elastomers by R. Zentel, *Adv. Mater. 1989*, 321; *Angew. Chem. Int. Ed. Engl. Adv. Mater. 28* (1989) 1407; *Angew. Chem. Adv. Mater. 101* (1989) 1437, the frequencies quoted in the legend should read "between 10^{-4} and 10^{2} Hz".

Materials Forum

Companies and individuals wishing their news and views on advanced materials issues and products to be considered for coverage in this section should send press releases, correspondence and other details, in English, to: Materials Forum, ADVANCED MATERIALS, P.O. Box 101161, D-6940 Weinheim, Federal Republic of Germany.

Seasons Greetings

The *Advanced Materials* production team would like to wish all our readers worldwide, a most merry Christmas and an enjoyable and happy New Year. Many of you will not know that *Advanced Materials* has, for the last year, also been published as part of the leading chemistry journal *Angewandte Chemie*. This will stop at the end of 1989, after which *Advanced Materials* will begin a totally independent existence, and its future, we are sure, will give us all cause to celebrate a successful New Year.

Japanese Materials

The Japanese Ministry for International Trade and Industry have just published the results of a survey on the commercialization of new materials. Of the 453 companies surveyed, 302 had been developing, producing or selling new materials with a total of 1822 new materials being recorded. These figures represent a three-fold increase in both companies and products over the period 1985–1988. The chemical industry had shown the best performance in penetrating the new materials market followed by the ceramics, non-ferrous metals, steel and textile industries.

The report, and further information can be obtained from Pera-Otis, Melton Mowbray, Leicestershire LE13 OPB, UK.

Low Pressure Plasma

The integration of the plasma treatment of materials or devices into the regular production line has, in the past, been hindered by the slowness of the treatment, which requires high vacuum and long plasma generation times. Using a combination of high performance pumps, and using microwaves to generate the plasma instead of the traditional megahertz frequency generators, the company Technics Plasma has developed a plasma treatment system which has an turnover time one-third that of previous ones. The system has already been successfully incorporated into the production of plastic housings for ignition coils by the company Beru, Ruprecht (Ludwigsburg, FRG). The housings have to be coated with epoxy resin but before this is done the surfaces are conditioned with plasma, ensuring strong bonding with the resin.

Further information on this first, fully automatic plasma treatment system is available from Technics Plasma GmbH, Dieselstrasse 22, D-8011 Kirchheim bei München, FRG. Tel. (089) 903 8021. Fax. (089) 903 9553.

Optical Storage Media

Six years since its introduction, the Audio Compact Disc (CD) has firmly established itself in entertainment electronics. Some 450 million of these silver discs were sold worldwide in 1988. Bayer AG played a decisive role in the development of suitable products for this application. Almost half the CDs sold around the world today are made from Makrolon CD 2000, a polycarbonate plastic from Bayer. Now that internationally valid standards for so-called "write once media" (WORM—write once read many) have been adopted, not only the WORM and CD ROM disc but also the CD video single have put life into the market for optical storage media for picture and data processing. Makrolon CD 2000 is also used successfully for these discs.

While the use of optical storage media was up to now limited to replacing old distribution techniques, such as records and print, the WORM disc is a new product which complements the newer techniques, such as micro-filming. With this system, the user is himself able to write data onto an optical storage disc and then read them out again as often as desired and without wear.

The Philips and Du Pont Optical (PDO) company has been selling WORM discs with a diameter of

The new WORM (write once read many) discs from Philips and Du Pont Optical (PDO) are made from Makrolon CD 2000, a polycarbonate from Bayer AG. They can be written on on both sides and are protected by a cassette. The formatted 5.25" disc offers the user 600 megabytes of free storage capacity. This corresponds to about 150,000 DIN sides of A4, written in binary code.

130 mm based on Makrolon CD 2000 since the end of 1988. Intensive efforts to improve the product quality, especially in the production area, enabled PDO to meet even the highest requirements for WORM discs, a raw bit error rate of 10^{-6}, with Makrolon. WORM discs can be written on on both sides and are protected by a cassette. The formatted disc offers the user approximately 600 megabytes of free storage capacity. This corresponds to approximately 150,000 sides of A4, written in binary code.

A new medium in entertainment electronics is the CD video single with a diameter of 120 mm, which boasts not only a digital audio section, but also a video part about 5 minutes long. Philips and Sony first introduced this disc on the US market at the start of 1988, launching it in Europe at the end of 1988.

The MO (magneto-optic) storage technique (erasable system) being tested at the moment makes particularly great demands on the birefringence which can only be met with difficulty by the polycarbonate grades available today. Bayer is developing new substrate materials based on thermoplastics and thermosetting plastics for this application. The products are undergoing market trials.

Further details are available from Abteilung Öffentlichkeitsarbeit, Bayer AG, D-5090 Leverkusen, Bayerwerk, FRG Tel. (0214) 30-81725

Materials Database

The first electronic materials database to be made available freely to the plastics industry was created by ICI. K'89 in Düsseldorf, 2–9 November, provided the launchpad for an updated version of the company's Engineering Plastics On Screen materials database EPOS 90.

The new version will not only be faster and more user friendly, but will also contain a more comprehensive coverage of available ICI polymers. As before, price data will be included, and EPOS 90 will be complemented by the latest version of the EPOS F fluoropolymer database.

The new system has been devised with a general, unified approach in mind which will be more compact, outline the technical advantages of using ICI materials, and will contain more detailed information for the design engineer.

Disks will be available in 5.25″ and 3.5″ formats and are designed to run on IBM PC's and compatible hardware.

Further information is available from Madeline Whitfield, ICI Advanced Materials, P.O. Box 6, Shire Park, Bessemer Road, Welwyn Garden City, Hertfordshire AL 7 1HD, UK. Tel. (0707) 323400. Fax. (0707) 335556.

Wiring Board Inspection System

Nippon Steel, and Eastern Co., Ltd., a leading manufacturer of printed wiring boards, have started production and sales of a jointly-developed automatic printed wiring board inspection system, the PT Series.

Printed wiring boards are having to accommodate an increasingly high density of components, and board manufacturers have been responding to these needs by providing multilayer boards and finer circuit lines.

With visual checks becoming unfeasible, there is a strong demand for systems which are capable of checking boards automatically. The PT Series was developed as the answer to these needs. Its principal features are:

1. A high-detection accuracy of 80 microns (the minimum width for inspection) and a maximum resolution of 5 microns.
2. A high-speed check can be performed at a rate of 3 m^2/min.
3. Two methods, feature extraction and comparison, can be used in parallel, so it can cover a wide range of applications, including checks of external and internal layers and phototools.
4. Full use of computers allows checking conditions to be set and imaging system settings to be determined automatically.

Nippon Steel accumulated its image processing and pattern recognition technology as a result of the surface inspection of steel sheets. Information processing technologies using computers have also been developed. In addition, the defect detection algorithm was applied to the system, which is based on the cross operator method developed by Professor *Gotaro Odawara* of the University of Tokyo's engineering faculty. The final link in the system was the advanced manufacturing capabilities and experience of Eastern.

Further information is available from Nippon Steel Corporation, Königsallee 30, D-4000 Düsseldorf, FRG. Tel. (0211) 320791. Fax (0211) 329368.

Intermetallic Alloys

Intermetallic alloys based on titanium, nickel and niobium aluminides are potentially interesting and important materials for future aircraft and aerospace applications. They can be used as monolithic or matrix materials for fiber reinforced compound materials.

For material development work in this field, Marko Materials, North Billerica, Massachusetts, USA, have developed a laboratory melt spinning unit for the production of rapidly solidified filaments, fibers and powder.

The Marko melt spinner permits the production of alloys of high purity, for example Fe-Nd-B magnet materials and high melting refractory alloys with melting temperatures up to 3000 °C (Tungsten, Columbium, Molybdenum). Another promising application is to produce high temperature superconductors based on Y-Ba-Cu.

The fully assembled, turnkey systems, many of which are already operating in research institutes in the USA and Japan, are now marketed in Europe by Industriekontor Rolf Hardt, Benrather Schlossufer 51, D-4000 Düsseldorf 13, FRG. Tel. (0211) 712828. Fax (0211) 71 31 86.

Book and Video Reviews

Nonlinear Optics, Lasers, Surface Analysis, NMR, etc. ...

Organic Materials for Non-linear Optics. Edited by *R. A. Hann* and *D. Bloor*, Royal Society of Chemistry, London 1989. xiv, 423 pp., bound, £ 45.00. – ISBN 0-85186-806-1

This book consists of the proceedings of the conference "Organic Materials for Non-linear Optics 1988" held at Oxford University in June 1988, and contains the manuscripts to the plenary lectures, short talks and posters presented at this meeting. The breadth of material covered here corresponds to the generality of the title and includes contributions over almost all current general themes in organic nonlinear optics research.

The first section of this volume deals primarily with theoretical calculations of molecular nonlinearities. The plenary contributions from *Hurst, Munn, Morley* and *Pugh* point out the significant progress made in calculating second order nonlinearities. Other contributions, e.g. from *Garito* et al., indicate that progress has been made in understanding the microscopic basis of third order effects, but that our understanding is still full of gaps and uncertainties, as is our understanding of the correlation between molecular structure and crystal packing, as pointed out in the section on crystals by *Gavezzotti*.

The short section on materials characterization contains a discussion by *Meredith* of the pros and cons of various methods of characterization of NLO materials, as well as an interesting discussion of an application of parametric effects in fast infrared detection by *Hierle* et al.

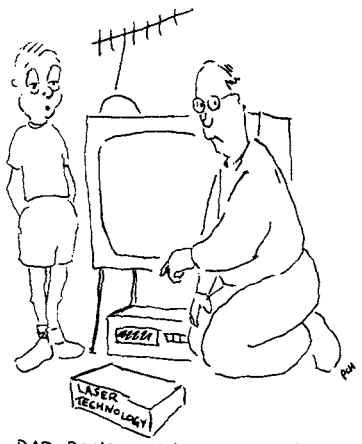
The next section of the book contains numerous contributions on small organic molecules, as crystals, in solution, or in films, where "small" is taken to include oligomers as well. Here, there is a balance of detailed characterizations of previously reported compounds (*Bailey* et al. and *Bosshard* et al.) and reports of novel structures for both second and third order effects (e.g. *Blanchard-Desce* et al., *Davis* et al., but not limited to these). This aspect is continued in the subsequent short section on organometallics, which have up to now received probably too little attention.

The section on polymeric materials covers several aspects and types of effects in nonlinear optical polymers, from an overview of materials and possible devices (e.g. *Ulrich* and *Möhlmann*) to ultrafast third-order processes (*Prasad*), with contributions as well on synthesis, liquid crystalline polymers and gels. The next section on materials deals with Langmuir-Blodgett films and monolayers at the air-water interface. Among the plenary lectures, *Peterson* summarizes the use of LB films as media for characterization and the requirements for an eventual use of such films in all-optical or electro-optic devices. *Shen*'s contribution summarizes the utility of nonlinear optical methods to study interfacial phenomena in situ. Further short contributions deal with such subjects as polymer amphiphilics, orientation and deposition methods.

An eventual application of organic materials in nonlinear optics depends to a large extent on the ability to construct working devices out of them and integrate them into other systems. The contribution from *Stegeman* reviews proof-of-principle all optical $\chi^{(3)}$ based devices, e.g. interferometers and directional couplers, but offers as well the sobering observation that we are several orders of magnitude away from substances which would lead to practical devices. The contribution from *Lytel* et al. shows on the other hand that we are much closer to commercial integrated optic devices on the basis of $\chi^{(2)}$ polymeric substances, demonstrating that high speed electro-optic modulation in waveguides has already been achieved.

There is quite a bit of information on numerous subjects in this volume. With the plenary lectures, one often has the feeling that one has seen a good deal of it before, but such talks are usually intended to be overviews. The newer information is concentrated in the short poster contributions, which were however too numerous to mention individually here, and it is in these contributions that one is more likely to find results that have not yet been published elsewhere. A critical discussion of both the merits and disadvantages of organic materials in view of advances in inorganic materials would have been welcome, but this was perhaps more the responsibility of the participants than of the editors.

"Organic Materials for Non-linear Optics" summarizes the state of the art in organics for NLO, with a European emphasis, and contains contributions from many of the leading researchers in many aspects of the field. Thus the book can be useful to the researcher trying to attain or maintain an overview of the wide field of organic materials for nonlinear optics. For more detailed information one can always refer to further work from the numerous authors represented in the book.



D. Lupo
Hoechst AG, Angewandte Physik
Postfach 800320, D-6230 Frankfurt 80 (FRG)

Lasertechnik. Grundlagen, Eigenschaften, Anwendung. VDI-Verlag, Düsseldorf 1989. DM 68. – ISBN 3-18-400879-0 (German language video cassette, 17 min.)

'Laser Technology' a la video show—Much too often we come home with a briefcase loaded with 'things to do' for the

weekend or for the evening and, in many cases, we return to work with the briefcase untouched because we were too tired in the evening and we needed some relaxation over the weekend. The video-quick-education may change this situation for the better or worse (who knows?).

After coming home from a long day, I had in my briefcase—among other things—the above video educational quicky (17 minutes) on 'Laser Technology'. The activation barrier of watching a video tape is low—in the case of this video tape, the message is presented at a level which is easy to understand and the pictures are fascinating. When my 16 year old son joined me at the TV and saw the pictures of a laser beam cutting through metal and welding steel he made the following remark: "Dad, I didn't know that your work was so interesting."

Now back to the content of the video cassette which was put together by the VDI (Verein Deutscher Ingenieure; German professional society of engineers) and which was sponsored by the BMFT (Germany Ministry of Research and Technology). The tape starts with a description of the main mechanisms of the laser, introducing words like 'stimulated emission' and 'inversion' without going into the intricacies of explaining why inversion can, in most cases, only be achieved by quite complex atomic schemes. Also the words 'coherence' and 'monochromaticity' are described on a rather qualitative level.

The video tape shows in greater detail and with very good graphical documentation technical applications like cutting, welding and surface hardening. For that purpose the main laser-tools are introduced briefly: The CO_2 laser, the solid state laser and the excimer laser. The subsequent applications are commented on from an engineering viewpoint and are very helpful for those who wonder why lasers are, in many cases, superior to conventional techniques for welding and hardening: it is the ease of handling the light beam via lightpipes and the ease of focusing power on a narrow spot or dissipating power in a thin layer. All the above features reduce the thermal stress which conventional methods often cause. So—all in all—the video cassette is, in my opinion, a success and its application will expand in the near future.

The only critical remark concerns the title. The title should be: 'Laser Technology in Materials Processing'. What has been left out are large areas of laser technology and laser applications. *Semiconductor lasers* which are in every laser printer which we use on a daily basis and lasers in data processing and communication technologies (glass fiber techniques) are completely omitted. This may reflect on some less developed areas of the German engineering menu or it may just be that the authors of the cassette forgot to implement the above area of 'information technology'. These are, however,—without doubt—part of the engineering sciences.

Since medical applications are also missing in the tape we come to the conclusion that it may be rather difficult to treat the full subject of 'laser technology' in one tape.

The only part of the tape which goes beyond materials technology is the part on holography; but that would have to be expanded because there are also optical memories and holographical optical schemes for storing and processing information, let alone the question of whether the complex subject of 'pattern recognition' by holographical schemes could be part of an educational tape.

In summary I think that the video tape is a success and – if it were not for the misleading title—I would rate it as excellent because I think that it will stimulate others to describe science and technology in a way which we can handle in the time between coming home and dinner. It may make our lives easier or the opposite—to answer this question I would have to consult my wife.

Inverse Gas Chromatography. Characterization of Polymers and Other Materials. Edited by *D. R. Lloyd, T. C. Ward,* and *H. P. Schreiber,* ACS Symposium Series 391, American Chemical Society, Washington, DC 1989. xi, 318 pp., bound, US $ 83.95. – ISBN 0-8412-1610-X

The book originates from a Symposium on Polymer Characterization held in Toronto, Canada in June 1988. As mentioned in the Preface, it contains 19 of 20 papers presented there, and three additional chapters were incorporated to broaden the scope of the book.

Inverse Gas Chromatography (IGC), first mentioned in 1966 as an analytical technique for studying bulk samples, has developed since then to become a viable and powerful method for the investigation of surface and bulk properties, especially of polymer materials. The name for this chromatographic technique was coined because the material under investigation is not introduced as a (temporary) component of the mobile phase, but it constitutes—at least in part—the

stationary phase. The aim of the experimenter is not the separation of a mixture of injected compounds but to inspect the retention behaviour of molecules introduced as probes in order to obtain information on the interactions between a probe molecule and the substrate under investigation.

The book reviewed here is the first to focus exclusively on IGC and therefore merits attention if for no other reason. Moreover, the editors have been successful in collecting contributions which cover a variety of applications which make obvious the wide spectrum of applications of the method.

The first, introductory chapter, written by two of the editors (*D. R. Lloyd, H. P. Schreiber*), gives a short overview of IGC and, in particular, of the contents of the volume. The remaining 21 chapters are divided into six sections. Chapters 2–4 are concerned with methodology and instrumentation. The next three sections focus on sorption and diffusion in polymers (4 chapters), polymer blend characterization (4 chapters), and surface and interface characterization (6 chapters). Analytical applications and special applications (2 chapters each) are covered by the last two sections.

The methodology and instrumentation section starts with a chapter by *A. E. Bolvari, T. C. Ward, P. A. Koning*, and *D. P. Sheehy* describing experimental techniques for IGC. Column techniques and their advantages and disadvantages are discussed: capillary columns (the substrate is coated on to the inner wall of the capillary), packed columns (packed with a solid support on to which the polymer has been coated) and fiber columns (the column is packed with the polymer fibers). In addition, some instrumental aspects are briefly considered, including the necessity for automation in IGC. Automation is also the subject of chapter 3 (by *J. E. Guillet, M. Romansky, G. J. Price*, and *R. van der Mark*). The authors give a review on fundamental aspects of measurements by IGC, such as the determination of transition temperatures, crystallinity, solubility, interaction parameters, surface areas, and adsorption isotherms. In chapter 4 (by *P. Hattam, Q. Du*, and *P. Munk*) results from a computer simulation study of the elution behavior of probes are compared with experiment. This study aims at improving the "quality" of the conclusions that can be drawn from IGC data.

In the next section, sorption and diffusion processes in polymers are covered. Chapter 5 by *G. J. Price* is concerned with an important application of IGC: the determination of solubility parameters δ. The author shows very interesting results; unfortunately, not a single equation is given which correlates variables measured by IGC to thermodynamic functions. Thus, it remains unclear from this chapter how the δ values have been calculated. The next chapter (by *B. Shiyao, S. Sourirajan, F. D. F. Talbot*, and *T. Matsuura*) is concerned with adsorption measurements on cellulosic materials and on polyethersulfone. Different gases and vapors of organic compounds were used as the probe molecules. Of particular interest are the results obtained with binary mixtures of gases and vapors. Thermodynamics of water sorption by two copolymers composed of vinylidene chloride and vinyl chloride or acrylonitrile are the subject of chapter 7 (by *P. G. Demertzis* and *M. G. Kontominas*). In addition to thermodynamic parameters of sorption (free energy, entropy, enthalpy, and activity coefficient), diffusion coefficients and activation energies for the diffusion of water vapor in the two copolymers were calculated from the chromatographic data. Solute diffusion in polymers is also the subject of the last chapter in this section. *D. Arnould* and *R. L. Lawrence* report on measurements carried out with different probes and polymethyl methacrylate as the substrate; the capillary column technique was used. The results are discussed with respect to the mechanism of diffusion and to the validity of different models of the diffusion process.

The next section starts with a chapter by *G. DiPaola-Baranyi* on studies of the thermodynamics of polymer blends by IGC. Three binary blends were studied at different compositions; thus interaction parameters were obtained as a function of the composition of the blends. It will be interesting to see the remarkable results confirmed by other techniques. That care has to be taken with experimental and data acquisition techniques in IGC when studying polymer blends is a conclusion drawn in chapter 10 by *M. J. El-Hibri, W. Cheng, P. Hattam*, and *P. Munk* from their theoretical and practical work. Phase diagrams for two polystyrene blends as based on IGC data are shown by *S. Klotz, H. Gräter*, and *H.-J. Cantow* in chapter 11. These authors report that a correct interpretation of the thermodynamics of mixtures of molten polymers can be obtained via IGC. *A. C. Su* and *J. R. Fried* (chapter 12) compared—on the basis of IGC data—the miscibility of the components of two binary blends and found the results to be in agreement with conclusions from studies on thermal and mechanical behavior.

The next four chapters deal with the surface and interface characterization of carbon fibers. *A. J. Vukov* and *D. G. Gray* (chapter 13) studied the dependence of surface characteristics on pretreatment at different temperatures, while *S. P. Wesson* and *R. E. Allred* (chapter 15) report on the surface energetics of plasma-treated fiber. In the contributions of *J. Schultz* and *L. Lavielle* (chapter 14) and *A. E. Bolvari* and *T. C. Ward* (chapter 16) adhesion between carbon fibers and different matrices is correlated with acid-base interactions. Altogether, these four chapters give an extensive overview on surface and adhesion properties of carbon fibers. Acid-base interactions are also shown to play an important role in adsorption of polymers on glass surfaces, as demonstrated by *E. Osmont* and *H. P. Schreiber* in chapter 17 for glass materials with differently treated surfaces. In the last chapter of this section, *E. Papirer, A. Vidal*, and *H. Balard* report on the use of IGC for the determination of surface energy characteristics of silica materials of different polarity, as obtained by heat treatment or by grafting reactions.

The next section (Analytical Applications) contains two chapters dealing with the characterization of polymers which can be used as stationary phases in gas chromatography. *R. J. Laub* and *O. S. Tyagi* made use of the correlation between retention and saturation vapor pressure of different solutes for characterizing the stationary phase. In chap-

ter 20, *J. H. Raymer, S. D. Cooper,* and *E. D. Pellizzari* compare the retention properties of four polyimide-based materials and a well-established polyphenylene oxide stationary phase by means of a deuterated tracer pulse technique.

The last two chapters are combined in a "Special Applications" section. *P. H. Neill* and *R. E. Winans* (chapter 21) report on the use of IGC to determine the alterations that coals and oxidized coals undergo when heated to 450 °C. Interpretation of the observed effects is made on the basis of results obtained by pyrolysis, plastometry, and microdilatometry. The final chapter of the volume (by *S. G. Gilbert*) deals with the determination of water sorption isotherms of starch materials.

A general drawback of multi-authored books also applies to this volume: although the contributions are well written, some information can be found in almost every chapter whereas other useful information may have been omitted. Unfortunately, the work which has been done by the editorial staff cannot be recognized by the reader of the book since he does not know anything about the original versions of the contributions. Nevertheless, contributions to a book should be "harmonized" to a certain extent. Thus, symbols should be used consistently throughout the volume. In this book, however, almost every author uses his own special symbols (e.g., five different symbols are used for the hold-up or dead time). Another example: Figure 3 of chapter 14 appears again in a much better version two chapters later; the latter version alone would have been sufficient. Finally, the last chapter is only of minor quality compared to the other chapters; in fact, it looks like a manuscript for an oral presentation, the figures are not explained in the text, and "the product tcKt" turns out to be a product of the factors "tc" and "Kt"!

Only a few errors have been observed (e.g., sub- and superscripts are missing with the symbols and units of Table 1 in chapter 13, and the heading of the last column of Table I in chapter 14 should read "γ_s^P" instead of "γ_s^D"). The subject index is of sufficient length (but, as an example, the entry "absorption" is missing). The reference lists of the individual chapters cover the literature until the beginning of 1988, thus providing the reader with information also on recent work.

In all, the book contains a wealth of highly interesting information, and it will be of value for specialists in the field as well as for the interested newcomer.

Franz Peter Schmitz
Lehrstuhl für Makromolekulare Chemie der RWTH
Worringerweg 1, D-5100 Aachen (FRG)

Transmission Electron Microscopy. By *L. Reimer.* Springer Series in Optical Sciences, Springer-Verlag, Second Edition, 1989, xiii, 547 pp., paperback, DM 128.—ISBN 3-540-50499-0

In 1906 *J. J. Thomson* was awarded the Nobel Prize for demonstrating that the electron was a particle. Thirty-one years later his son, *G. P. Thomson,* was awarded the Nobel Prize for demonstrating that the electron was a wave. In 1986 *Ernst Ruska* was awarded the Nobel Prize (long overdue) for utilizing both the particle and wave properties of electrons in designing the first electron microscope in 1931.

Electron microscopes are amongst the most widely used and the most important scientific instruments. They are essential equipment for biologists, chemists, geologists, materials scientists, physicists and others. There are many books on the subject, but this book by *Reimer* is, quite simply, the best. This second edition is a revision of his earlier book on Transmission Electron Microscopy (TEM), first published in 1984. In the last five years the field of TEM has expanded enormously and this revision very thoroughly updates and extends growth areas such as electron holography, lattice imaging with atomic resolution, electron energy-loss spectroscopy, etc.

The scope of the book covers both TEM and analytical electron microscopy. Even subjects like reflection electron microscopy from surfaces are discussed. Contents include the types of electron microscopes available, particle optics and electron lenses, wave optics, imaging, scanning transmission electron microscopy (STEM), electron-specimen interactions, contrast theory, high resolution electron microscopy (HREM) and analytical electron microscopy.

The main thrust of the book is to explain as clearly as possible the basic physical principles underlying transmission electron microscopy in all its various forms. In this Professor *Reimer* succeeds admirably. Although the book adopts a theoretical approach it is also full of useful practical advice. For example on p. 458 we are advised that 'Vacuum leaks can never be cured by heavy greasing but only by carefully polishing the sealing surfaces. Viton rings should be used in preference to rubber. All surfaces should be washed with methyl alcohol, which evaporates completely in air. Finger-marks should be avoided by wearing gloves'. This quotation also illustrates the easy-to-read crisp sentences that the author adopts.

The value of this book lies in its breadth, depth and accuracy. I have indicated its breadth above, but the book also digs deep into the fundamentals of the subject: for example there is a particularly clear exposition of the dynamical theory of electron diffraction, and of applications ranging from the critical voltage effect to the imaging of surface steps.

Concerning accuracy, there are many books on TEM which contain fundamental errors in understanding. This book, on the other hand, is reliable and accurate and reflects the scholarship one expects from Professor *Reimer*.

The book is for research students, post-doctoral scientists, lecturers and professors. It is good for teaching purposes and for reference. If you are an electron microscopist this book is the best: you should have it on your book shelves: I cannot recommend it too strongly.

C. J. Humphreys
Department of Materials Science and Engineering
The University of Liverpool
P.O. Box 147, Liverpool L69 3BX (UK)

Methods of Surface Analysis. Edited by *J. M. Walls*. Cambridge University Press, Cambridge 1989. x, 342 pages, bound, $ 80.– ISBN 0-521-30564-0

At present, surface analysis and related methods represent one of the fastest progressing technological fields. Therefore there is an increasing demand for appropriate books, introducing the newcomer to the principles of these methods and their range of applications.

The above mentioned book is a compendium of articles from experts who cover one method or one field of interest each. The book contains 9 chapters dealing with the 6 most common methods of surface analysis (AES, XPS, SSIMS, DSIMS, ISS, RBS) and 3 more general topics which aim at supplying the reader with the essential basic knowledge. This selection out of the large number of different surface analysis techniques is wise and concentrates on those methods with a broad range of applications. Three more methods are briefly dealt with: Sputtered Neutral Mass Spectrometry (SNMS), Laser Microprobe Analysis (LIMA) and Atom Probe Microanalysis.

The book is composed well, contains instructive drawings and images, but mainly deals with VG products, almost neglecting all other products, instrument manufactures and construction principles. There is, for example, in the chapter "State-of-the-art XPS" only a short remark about small spot ESCA and no reference to the SSL instrument and the new Uppsala machine, the XPS "jumbo" ESCA-300. Also the world's finest scanning SIMS instrument, built by Levi-Setti in Chicago, is not mentioned at all. The spatial resolution in Scanning Auger Microanalysis is about 350 Å with commercially available instruments (e.g. PHI-660) and not 2000 Å as stated in Chapter 1.

The more practically oriented analyst, who has to struggle with the tricky every-day samples, would like to find some more examples of typical applications in the many fields in which surface analytical instruments are used today. In addition, the sections on data processing and curve fitting are very brief and confined to a list of possible computer routines. More information would have been helpful.

If there are many authors, who contribute to a book, it is obviously always difficult to make it up in such a way, that everything fits together, that each writer uses the same formulas and expressions and that unnecessary repetition is avoided. The reviewer is of the opinion that these problems have been solved satisfactory.

Generally only few literature references are given, in some cases even too few, and they are often not mentioned in the text.

The book can be recommended without reservations for all VG instrument users and those being non-specialists, who are looking for an introduction into those surface analytical methods which are frequently used today, and who want to get information quickly on the appropriate technique to choose for a special applicational purpose.

Harald Hantsche
Bundesanstalt für Materialforschung u. -prüfung
Unter den Eichen 44–46, 1000 Berlin 45 (West)

Nuclear Magnetic Resonance, Vol. 18, Edited by *G. A. Webb*. Royal Society of Chemistry, Cambridge 1989. LVI, 511 pp., bound, $ 232.-, ISBN 0-85186-412-0.

The number of applications of nuclear magnetic resonance (NMR) spectroscopy is growing rapidly and NMR is increasingly used also in non-traditional areas of application like the investigation of solid and macromolecular materials. To a considerable degree its increasing popularity is a result of the continuing development of innovative methods and measurement procedures for instance in solid state and two-dimensional NMR. A comprehensive literature review about current NMR activities can be of value not only for the specialist but also for those interested in the applicational potential of the method.

The book reviews the NMR literature published between June 1987 (1986 in some cases) and May 1988. The 13 chapters cover different subjects, which are reviewed by specialists. The individual chapters are preceeded by a compilation of citations of 588 books and reviews. For this list, a subdivision into type of publication (books, regular review series, reviews in periodicals, etc.) has been chosen and not a classification according to subjects. Considering that there are references to reviews in each chapter on individual subjects the list seems redundant.

Chapter 1 (*C. J. Jameson*) covers the theory and physics of chemical shielding tensor values. Known as chemical shift in isotropic liquids, these values are essential for quantitative structural and dynamic solid state NMR. Chapter 2 (*M. J. Foster*) deals with the applications of nuclear shielding. Apart from ^{1}H and ^{13}C, chemical shift studies of nuclei such as ^{6}Li, ^{9}Be, $^{14,15}N$, ^{17}O, ^{19}F, etc. are reported. Spin-spin couplings are treated in Chapters 3 (theory: *J. Ostershede*) and 4 (applications: *J. C. Lindon* and *J. M. Williams*). Like the chemical shift values, the coupling constants give important information on molecular conformation. Different liquid state NMR techniques for their measurement as well as coupling between particular nuclei other than ^{1}H and ^{13}C

are reviewed. Chapter 5 (*H. Weingärtner*) is on nuclear spin relaxation in liquids and gases. Relaxation time studies which give information about molecular dynamics and molecular distance determination in biological macromolecules are included. Chapter 6 (*R. Dupree*) reviews solid state NMR. The chapter is subdivided into new techniques, theory, experimental, and several sections on different substances and areas of application like silicates, zeolites, ceramics, phase transitions, glasses, organic and inorganic solids, wood and coal. A number of tables efficiently guide the reader through the literature. Chapter 7 (*L. Y. Lian*) is entitled "Multiple Pulse NMR", a terminus technicus from solid state NMR, but deals with multi-dimensional NMR in liquids including the development of special excitation pulses. Chapter 8 (*D. B. Davies* and *H. G. Parkes*) surveys natural macromolecules, excluding biological studies, with many tables in the text. Chapter 9 (*F. Hatley*) reviews synthetic macromolecules, again largely in appealing tabular form. References to reviews are followed by sections on solution NMR studies of polymer structure by 1D and 2D NMR, polymer-polymer interaction in solution and gels, and on bulk polymers. The last section is subdivided into wideline ^{1}H NMR, high resolution NMR, NMR of deuterons and other nuclei, and applications to cellulose polymers. Relaxation and lineshape studies for the investigation of polymer dynamics are included as well as new magic angle spinning and cross-polarization techniques for the investigation of molecular order and polymer morphology. Chapter 10 (*C. Jones*) is dedicated to conformational analysis in liquid state NMR based on the measurement of indirect couplings, distance determination by cross-relaxation, and computer refinement. Chapter 11 (*P. G. Morris*) is concerned with NMR of living systems with subsections on NMR imaging and high resolution NMR. Chapter 12 (*K. G. Orrell*) treats NMR of paramagnetic species and Chapter 13 (*A. Khan*) NMR of liquid crystals and micellar solutions. The latter starts with a helpful introduction to the subject, which is missing in many of the other chapters. The smaller part of the material (4 pages) covers thermotropic liquid crystals, where solid state deuteron NMR is increasingly used for investigations of molecular order and mobility. The larger part (17 pages) deals with micellar solutions and lyotropic liquid crystals. Phase diagrams and phase structures in complex amphiphilic systems are investigated as well as multicomponent self-diffusion coefficients. Solid state NMR is applied more and more for studies of lipids and protein-lipid interactions.

The readability of the chapters is adequate and the chapters cover the subjects in sufficient depth to gain an understanding of the current state of research. The use of tables in some chapters (1, 6, 8, 9, 12) provides quick and easy access to the information and should be encouraged in future volumes. A list of symbols and an author index are helpful features. For materials science oriented NMR research, chapters 1, 6, 9 and 13 are most relevant. The book is in competition with review papers and computer literature searches on dedicated subjects. Considering also the price, the book is unlikely to be found in every science library.

SUBJECT INDEX

(a second page number to an entry indicates an erratum to the corresponding article)

(R) = Review Article (C) = Short Communication (B) = Book Review (L) = Correspondence (AM) = Advanced Materials

Ab initio calculations, Ab initio calculation of the structures and properties of molecules (B) 1404
- Aurophilicity as concerted effect: relativistic MO calculations on carbon-centered gold clusters (C) 1357
- Diisocyanogen or isocyanogen? (C) 761
- Electron densities, deformation densities, and chemical bonding (C) 597, 1074
- Monohapto versus dihapto CO_2 coordination in bis(amine)Ni^0 complexes: a CAS-SCF study (C) 1694
- Much less strained cubane analogues with Si, Ge, Sn, and Pb skeletons (C) 329
- On the stability of trioxo(η^5-cyclopentadienyl) compounds of manganese, technetium, and rhenium: an ab initio SCF study (C) 1228
- Organic dications: gas phase experiments and theory in concert (R) 1321
- Sodium pentaphosphacyclopentadienide (NaP_5) and the pentaphosphacyclopentadienide ion ($P_5^{\ominus}$): theoretical predictions of molecular structures, infrared and Raman spectra (C) 485
- The 7-norbornadienyl cation: an NMR/IGLO validation of its ab initio structure (C) 1042
- Tl^I-Tl^I interactions in the molecular state—an MO analysis (C) 1688
- Very short C—C single bonds and their origin. The central bond length in bitetrahedryl (C) 1226

Acepentalenes, Towards tribenzoacepentalene: tribenzotriquinacene, dihydrotribenzoacepentalenediide, and the tribenzoacepentalene radical anion (C) 595

Acetylacetonates, N-analogues of metal acetylacetonates: bis(1,2,6,7-tetracyano-3,5-diimino-3,5-dihydro-pyrrolizinido)metal(II), (metal = Fe, Ni, Cu, Zn); crystal structure of the copper derivative (C) 1049

Acetylene, Preparative acetylenic chemistry (B) 631

Additions, Addition of carboxamides to alkynyl trifluoromethyl sulfones (C) 1057

Advanced materials, editorial, Paving the way... (AM) 107

Affinity labeling, A "spacer"-modified trisaccharide as photolabile ligand for affinity labeling of antigalactan IgA X24 (C) 1669

Alkali-metal compounds, *N*-Cesiocarbazole · pmdta and *N*-potassiocarbazole · pmdta (PMDTA = *N,N,N',N'',N''*-pentamethyldiethylenetriamine). Cation size and multihapto bonding (C) 1224
- A new coordinating chiral lithium amide (C) 1044
- Are lithiosulfones configurationally stable? (C) 1025, 1282
- Asymmetric homoaldol reaction by enantioselective lithiation of a prochiral 2-butenyl carbamate (C) 69
- $[Et_4N]_6[Na_{14}Mo_{24}P_{17}O_{97}(OH)_{31}] \cdot xH_2O$: a hollow cluster filled with 12 $Na^{\oplus}$ ions and a H_3PO_4 molecule (C) 743
- $[H_2C(CH_2)_5NLi]_6$, the first cyclized lithium amide ladder: synthesis and structure of hexamethyleneimidolithium (C) 1241
- Hg_8 ("Mercubane") clusters in $Rb_{15}Hg_{16}$ (C) 1251
- Indications of cesium in a higher oxidation state (C) 1676
- K_4P_3, a compound containing the radical anion $P_3^{4\ominus}$ (C) 56
- LiSrN—a three dimensional structural arrangement of corner and edge sharing orthorhombic bipyramids, $NLi_{2/2}Sr_{4/4}$ (C) 201
- Model of a solvent-shared ion pair with N—H · · · C hydrogen bonds between amine and carbanion—crystal structure of [fluorenyllithium · 2 ethylenediamine]$_\infty$ (C) 72
- $Na_xMg_{5-x}Ga_9$, a new intermetallic phase as a link between Zintl phases and metals (C) 58
- Non-chelate-controlled addition of 1-bromo-1-lithio-1-alkenes to *O*-protected lactaldehydes (C) 896
- Organolithium methods (B) 632
- Pentabenzylcyclopentadienylpotassium · 3THF, an organopotassium compound with "piano stool" geometry (C) 735
- Stable open-chain 1,3-dilithium compounds by reaction of methylenecyclopropanes with lithium powder: 2,4-dilithio-1-butenes (C) 83
- Synthesis and structure of a phenylsodium solvate, bis[μ-phenyl(pentamethylenetriamine)-sodium] (C) 476
- The dienolate of (*R*)-2-*tert*-butyl-6-methyl-1,3-dioxin-4(2*H*)-one—a chiral acetoacetic ester d^4-reagent (C) 472
- The first PE-spectroscopic investigations of lithium, sodium, and potassium *tert*-butoxide (C) 895
- The structure of lithium compounds of sulfones, sulfoximides, sulfoxides, thioethers and 1,3-dithianes, nitriles, nitro compounds and hydrazones (R) 277
- The structures of 1,n-bis(9-lithio-9-fluorenyl)ethane · 8THF and -hexane · 8THF as models for solvent-separated ion pairs (C) 458
- X-ray structure analysis of α-lithiophenylacetonitrile · lithium diisopropylamide · 2 tetramethylethylenediamine —a "quasi-dianion complex" (C) 1392

Alkaline earth metal compounds, LiCaN and Li_4SrN_2, derivatives of the fluorite and lithium nitride structures (C) 1702

Alkaloids, Carbohydrates as chiral templates: stereoselective tandem Mannich-Michael reactions for the synthesis of piperidine alkaloids (C) 1067

Alkenes, Addition of free Me_2Ge: to alkenes and alkynes on glass surfaces in the presence of water (C) 1028
- $[\{Ph_3PCH_2C(CF_3)_2O\}NiH(PCy_3)]$: support for a nickel hydride mechanism in ethene oligomerization (C) 1011

Alkynes, A new class of DNA-cleaving molecules: pH-dependent DNA cleavage by propargylic and allenic sulfones (C) 1272
- Addition of carboxamides to alkynyl trifluoromethyl sulfones (C) 1057
- Addition of free Me_2Ge: to alkenes and alkynes on glass surfaces in the presence of water (C) 1028
- Hydrooligomerization of alkynes, a new catalytic reaction promoted by $[Co(py)_6]^{\oplus}$ in the presence of H_2 (C) 1009
- New intermediates in the cyclocotrimerization of thioxophosphorus(v) cations with alkynes (C) 448
- Triorganolead cations stabilized by side-on coordination to the C≡C bond in alkynylborates (C) 1500

Allenes, Versatile modes of allene bonding in the structures of $[W_2(OtBu)_6(C_3H_4)]$, $[W_2(OtBu)_6(C_3H_4)(CO)_2]$, and $[W_2(OtBu)_6(C_3H_4)_2]$ (C) 1523

Allenyl azides, First isolation of allenyl azides (C) 1675

Allonojirimycin, Total synthesis of allonojirimycin (5-amino-5-deoxy-D-allopyranose) (C) 1498

Alloys, Aluminum-rich metallic glasses (AM) 123
- Conference report (AM) 815
- Phase equilibria under stress (AM) 1128
- Production and application of rapidly quenched materials (AM) 947
- Ternary alloys—a comprehensive compendium of evaluated constitutional data and phase diagrams: volumes 1 and 2, ternary silver alloys (B) 524

Allyl anions, Generation, stereochemistry, and molecular dynamics of a 1,3-bis(phosphonio)propenide cation (C) 1700

Aloin, Establishment of configurations for the two diastereomeric C-glucosylanthrones aloin A und aloin B (C) 1528

Aluminum oxide, Structure of anodic coatings on aluminum (AM) 951

Amides, The first macrocyclic square-planar cobalt(III) complex relieves ring strain by forming a nonplanar amide (C) 1509

Amines, Anion coordination and Cl—H · · · Cl bridges in the low-melting poly(hydrogen chloride) $Me_3N \cdot 5HCl$ (C) 1697
- Formation of *N*-(deoxyguanosin-8-yl)-aniline in the in vitro reaction of *N*-acetoxyaniline with deoxyguanosine and DNA (C) 468
- Synthesis of *O*-acetyl-*N*-(4-biphenylyl)-hydroxylamine ("*N*-acetoxy-4-aminobiphenyl"), an ultimate metabolite of carcinogenic 4-aminobiphenyl, and its reaction with deoxyguanosine (C) 337
- The structure of hexaaminobenzene (C) 90

Amino acids, carbohydrates as chiral templates: stereoselective synthesis of β-amino acids (C) 1068
- Discovery of a D-stereospecific aminopeptidase and its use as a catalyst in organic synthesis (C) 450
- Stereoselective synthesis of γ-aminocarboxylates (C) 1706

Amorphous metals, Production and application of rapidly quenched materials (AM) 947

Analytical chemistry, Activation analysis with charged particles (B) 1072

Analytical methods, A guide to materials characterization and chemical analysis (B) 385
- Analysis of polymers. An introduction (B) 1595
- Analytical artifacts: GC, MS, HPLC, TLC and PC (B) 1537
- Imaging surfaces, electric charges and

magnetic domains with the atomic force microscope (AM) 1578
- Methods of surface analysis (B) 1764
- Problem-solving with microbeam analysis (B) 964
- Stereochemical applications of gas-phase electron diffraction. Parts A and B (B) 1534
- Using crystal birefringence to study molecular recognition (C) 330
Ancistrocladisine, Atropdiastereoselective ring opening of bridged, "axial-prostereogenic" biaryls: directed synthesis of (+)-ancistrocladisine (C) 1672
Annulenes, Di(1-pyridinio)- and di(1-bipyridindiio)dihydrodibenzotetraaza[14]annulenes (C) 1060
- Di(4-pyridinio)-, di(2-benzothiazolio)-, di(2[1,3-dithiolylio])- and diformyltetraaza[14]annulenes and tetraaza[14]annulenylene-homologous tetrathiafulvalenes (C) 1063
- From the bicyclo[3.3.0]octane framework to multiply bridged [12]annulenes and semibullvalenes (C) 1343
- Stack-type redox systems: synthesis via repeated carbanion alkylation and electron transfer studies (C) 1531
- The radical cation of *N,N'*-tetramethylene-*syn*-1,6:8,13-diimino[14]annulene. An experimental study of the N-N three-electron σ bond (C) 902
Anthrones, Establishment of configurations for the two diastereomeric *C*-glucosylanthrones aloin A und aloin B (C) 1528
Antibiotics, Biosynthetic studies on antibiotics (R) 146
- Intramolecular Diels–Alder reaction of vinylsulfonic acid esters (C) 202
- Pep5: structure elucidation of a large lantibiotic (C) 616
- Total synthesis of the antitumor antibiotic WF-3161 (C) 333
- Unsaturated 1,4-*cis*- and 1,4-*trans*-diaminotetradeoxycycloheptites—enantiomerically pure, polyfunctionalized tropa derivatives by enzymatic hydrolysis (C) 1253
Antibodies, Catalytic antibodies (R) 1283
Antigalactan, A "spacer"-modified trisaccharide as photolabile ligand for affinity labeling of antigalactan IgA X24 (C) 1669
Antimony compounds, $[Mes_2SbCu(PMe_3)_2]_2$: the first Cu^I antimonide (C) 1018
- Structural diversity in iodoantimonates; the anions $Sb_3I_{11}^{2\ominus}$, $Sb_5I_{18}^{3\ominus}$ and $Sb_6I_{22}^{4\ominus}$ (C) 344
Arene complexes, $(C_4Me_4NBH_3)_2Fe$—a metal complex isosteric with decamethylferrocene with characteristic metallocene disorder (C) 342
- Inter- and intramolecular photochemical C-H activation in matrices and in solution with (η^6-arene)(carbonyl)osmium complexes (C) 1690
- Synthesis and structure of a binuclear *syn*-coordinated μ-cycloheptatrienylhydrido complex with hindered C_7H_7 rotation (C) 345
Arenes, Activated aminocarbene complexes of the Fischer type: synthesis, structure, and annelation reactions (C) 1384
- Oxidative fluorination of arenes (C) 927
- Radical tri- and pentaanions of benzenedi- and benzenetriglyoxylate thioesters (C) 906
- The structure of hexaaminobenzene (C) 90
- The structure of the tetracation of hexaazaoctadecahydrocoronene, a simple substituted benzene (C) 92
Aromaticity, 3,3':4,4'-Bis(thieno[2,3-*b*]thiophene): a novel fused heteroarene (C) 1222
- Di(1-pyridinio)- and di(1-bipyridindiio)dihydrodibenzotetraaza[14]annulenes (C) 1060
- Di(4-pyridinio)-, di(2-benzothiazolio)-, di(2[1,3-dithiolylio])- and diformyltetraaza[14]annulenes and tetraaza[14]annulenylene-homologous tetrathiafulvalenes (C) 1063
- 1-Phenalenol: isolation and disproportionation (C) 1268
- $S_4(CN)_8$, a blue-black high-molecular sulfur-cyanogen compound with 6π- and 8π-electron structural elements (C) 609
- Towards tribenzoacepentalene: tribenzotriquinacene, dihydrotribenzoacepentalenediide, and the tribenzoacepentalene radical anion (C) 595
Arsenic compounds, $AsI_4^{\oplus}AlCl_4^{\ominus}$, a salt of the last missing tetrahaloarsonium ion (C) 1671
- Hexaarsabenzene as complex ligand (C) 212
- Insertion of $Cr(CO)_3$ into $As_7^{3\ominus}$ to form $[As_7Cr(CO)_3]^{3\ominus}$: an inorganic nortricyclane-to-norbornadiene conversion (C) 1032
- Octabromocyclohexaarsenate, $[As_6Br_8]^{2\ominus}$ (C) 185
- Pd clusters containing As and PPh_3 ligands: the structures of $[Pd_9As_6(PPh_3)_8]$, $[Pd_2(As_2)(PPh_3)_4]$, and $[Pd_{20}As_{12}(PPh_3)_{12}]$ (C) 1665
Aryl complexes, 2,4,6-Triisopropylphenylcopper, a new tetranuclear organocopper aggregate with unsymmetrically bridging σ-π bonded aryl ligands (C) 208
Arynes, Metal complexes of small cycloalkynes and arynes (A) 1296
Asymmetric syntheses, 3-Arylsulfonyloxazolidines as chiral templates: asymmetric synthesis of 2-substituted 2-hydroxycyclohexanecarbaldehydes from 2-hydroxymethylenecyclohexanone (C) 67
- Asymmetric homoaldol reaction by enantioselective lithiation of a prochiral 2-butenyl carbamate (C) 69
- Asymmetric oligomerization of propene and 1-butene with a zirconocene/alumoxane catalyst (C) 1216
- Chiral building blocks for the synthesis of triquinane sesquiterpenes: derivatives of 2-methylbicyclo[3.3.0]octan-3-ol from catalpol (C) 447
- Copper(I)-promoted Michael-addition reaction of organozincs of esters, nitriles, and α-amino acids (C) 351
- Flexible syntheses of optically active isocarbacyclins (C) 1282, 349
- Stereocontrolled total synthesis of (5*S*,6*R*)-, (5*S*,6*S*)-, (5*R*,6*R*)-, and (5*R*,6*S*)-, (7*E*,9*E*,11*Z*,14*Z*)-5,6-dihydroxy-7,9,11,14-icosatetraenoic acid (5,6-DiHETE) methyl esters (C) 587
- The enantiomers of the azole fungicide HWG-1608—asymmetric synthesis of a 2-hydroxyethyl azole fungicide (C) 462
Atomic force microscope, Imaging surfaces, electric charges and magnetic domains with the atomic force microscope (AM) 1578
Aurivillius phases, Aurivillius phases: a possible new class of metal oxide superconductors (C) 750
Aurophilicity, Aurophilicity as concerted effect: relativistic MO calculations on carbon-centered gold clusters (C) 1357
- Synthesis, structure, and bonding of the cation $[\{(C_6H_5)_3PAu\}_5C]^{\oplus}$ (C) 463
Azides, First isolation of allenyl azides (C) 1675
Bay boletus, Complexation of cesium 137 by the cap pigments of the bay boletus (*Xerocomus badius*) (C) 453
Beltenes, Double-stranded molecules: a [6]beltene derivative and the corresponding open-chain polymer (C) 1680
Benzene isomers, Bicycloprop-2-enyl (C_6H_6) (C) 1711
Benzodiquinoline, Benzo[1,2-*h*:4,3-*h'*]diquinoline ("1,14-diaza[5]helicene"): synthesis, structure, and properties (C) 86
Benzopyrenes, Selective 1:3 coupling of norbornene and iodobenzene: a facile synthesis of benzo[*e*]pyrenes with annelated cycloaliphatic moieties (C) 1037
Benzvalene, Photocycloadditions of benzvalene (C) 601
Benzylglyceraldehyde, 2-*O*-benzylglyceraldehyde: a synthetic building block available in both enantiomeric forms and configurationally stable owing to rapid oligomerization (C) 469
Best synthetic methods, Borane reagents (B) 354
- Organolithium methods (B) 632
Biaryls, Atropdiastereoselective ring opening of bridged, "axial-prostereogenic" biaryls: directed synthesis of (+)-ancistrocladisine (C) 1672
Bicyclobutanes, Shortened C-C bonds in coupled bicyclo[1.1.0]butanes (C) 473
Bicyclopropenyl, Bicycloprop-2-enyl (C_6H_6) (C) 1711
Binaphthalenes, Ethylenebis(sulfonyl)-bridged 1,1'-binaphthalene, an atropisomeric dienophile for highly diastereoselective Diels–Alder reactions (C) 766
Biochemistry, A new class of DNA-cleaving molecules: pH-dependent DNA cleavage by propargylic and allenic sulfones (C) 1272
- A structural basis of light energy and electron transfer in biology (Nobel lecture) (R) 848
- Catalytic antibodies (A) 1283
- Chaos und Ordnung: Die komplexe Struktur des Lebendigen (B) 1403
- Chemical modifications of biopolymers by quinones and quinone methides (R) 555
- The photosynthetic reaction center from the purple bacterium *Rhodopseudomonas viridis* (Nobel lecture) (R) 829
Bioinorganic chemistry, The bioinorganic chemistry of nickel (B) 632
Biomaterials, Advanced ceramics for biomedical applications (AM) 111
- Bone replacements: implant materials and the modes of implant fixation (AM) 1431
- Conference report (AM) 245
- Materials for biomedical applications—bone and joint replacements (AM) 518
- Materials for biomedical applications—high long-term success rates might pose new problems (AM) 956
Biomimetic syntheses, Biomimetic synthesis of an inverted porphyrinoid with peripheral N atoms (C) 1243
Biopolymers, Calorimetric studies of biopolymers and aggregates of phospholipids (R) 981
Biosynthesis, Biosynthetic studies on antibiotics (R) 146
Biotechnology, Immobilization of cells (B) 1717
Birefringence, Using crystal birefringence to study molecular recognition (C) 330
Bismuth compounds, A new oxygen sensor based on the thermoelectric power of solid solutions of Nb_2O_5 and Bi_2O_3 (C) 75

- $[\{Cp(CO)_2Mn\}_2(\mu\text{-}H)]^{\ominus}$: a new, versatile reagent (C) 446

Blood substitutes, blood substitutes, preparation, physiology and medical applications (B) 670

Boron compounds, A tetraborylphosphonium ion with a spiroheterocyclic structure (C) 217
- Advances in boron and the boranes (B) 1401
- Borane reagents (B) 354
- $LiBH_4(NaBH_4)/Me_3SiCl$, an unusually strong and versatile reducing agent (C) 218
- Methylboron oxide, $H_3C-B\equiv O$ (C) 88
- $[M(NMesBMes_2)_2]$(M = Cr, Ni): stable, distorted, two-coordinate d^4 and d^8 complexes (C) 316
- $NaBH_4$ reduction of ketones in the solid state (C) 320
- Phosphonioboratoacetylenes: C_2 stabilized by donor and acceptor molecules (C) 1219
- Stable methyleneboranes of high Lewis acidity (C) 781
- Tetraalkylidene-1,4-diboracyclohexanes from 3,4-dilithio-2,5-dimethyl-2,4-hexadiene; the first "hetero[6]radialene" with chair conformation (C) 477
- The solid-state structure of $Me_2B-O-BMe_2$ (C) 180
- The structure of a *C*-borylborirene with strong C-B hyperconjugation (C) 186
- Thermal cleavage and isomerization of 1,3-diboretanes to stable methyleneboranes (C) 784
- Triorganolead cations stabilized by side-on coordination to the $C\equiv C$ bond in alkynylborates (C) 1500

Bridging ligands, A phosphane—dithioformate adduct as a five-electron bridging ligand $[Mn_2(CO)_6\{S_2C(H)P(cyclo\text{-}C_6H_{11})_3\}_2]$ (C) 1014
- Complexes with an η^2-μ_2-SiO bridge. Structure of the bimetallic complex $[Fe(CO)_3\{\mu\text{-}Si(OMe)_2\text{-}OMe\}(\mu\text{-}dppm)PdCl]$(*Fe-Pd*) (C) 1361
- Directed synthesis of trinuclear hydrocarbon-bridged complexes such as $[(OC)_5ReCH_2CH_2Os(CO)_4CH_2CH_2\text{-}Re(CO)_5]$ (C) 1705
- $[Ir_2(\mu\text{-}CH_2)(CO)_4(Me_2PCH_2PMe_2)_2][CF_3SO_3]_2$, an unprecedented electrophilic methylene complex; $H^{\ominus}$ addition to prepare a bridging methyl complex (C) 1377
- Synthesis, structure and magnetic properties of a dinuclear manganese(II) complex with one μ-aqua and two μ-carboxylato bridges (C) 1365
- The first heterodinuclear complexes with bis(cyclopentadienyl)methane bridges (C) 1008

Bromoselenates, Bromoselenates(II,IV), a novel type of mixed valence compounds (C) 187

Butterfly clusters, A systhematic entry to butterfly-type $[M_4(CO)_{12}(\mu_4\text{-}XY)]$ clusters (C) 1059

Cage compounds, Cryptophane radical cations as components of three-dimensional charge-transfer salts (C) 1249
- Selective molecular recognition of trihydroxybenzenes (C) 79
- Structure and properties of the cryptophane-E/$CHCl_3$ complex, a stable van der Waals molecule (C) 1246
- The pagodane route to dodecahedranes: chemistry and structure of bissecododecahedranes (C) 298
- The pagodane route to dodecahedranes: polyfunctionalized homologous dodecahedranes and dodecahedrenes (C) 310
- The pagodane route to dodecahedranes: polyfunctionalized pentagonal dodecahedranes and dodecahedrenes (C) 305
- The pagodane route to dodecahedranes: 4,9,14,19-tetrasubstituted [1.1.1.1]pagodanes by intramolecular functionalization (C) 303
- The pagodane route to dodecahedranes: total synthesis and chemistry of 4,9,14,-19-tetrasubstituted [1.1.1.1]pagodanes (C) 300
- TlSPh and TlS*t*Bu, Thallium(I) thiolates with novel cagelike structural units: $[Tl_5(SPh)_6]^{\ominus}/[Tl_7(SPh)_6]^{\oplus}$ and $[Tl_8(StBu)_8]$ (C) 1682
- Trinacrene—a product of structure-directed synthesis (C) 1261

Calixarenes, Aggregation of metal ions with functionalized calixarenes: synthesis and structure of an octanuclear copper(I) chloride complex (C) 1376

Calorimetry, Calorimetric studies of biopolymers and aggregates of phospholipids (R) 981

Carbanions, Are lithiosulfones configurationally stable? (C) 1025, 1282
- Bis-stilbene systems: reduction to the tetraanions (C) 904
- Highly reduced porphyrins (C) 604
- Hydrogen bonds between an $NH_4^{\oplus}$ ion and a carbanion—crystal structure of ammonium 1,2,4-tricyanocyclopentadienide (C) 73
- Model of a solvent-shared ion pair with $N-H\cdots C$ hydrogen bonds between amine and carbanion—crystal structure of [fluorenyllithium · 2 ethylenediamine]$_\alpha$ (C) 72
- Stable open-chain 1,3-dilithium compounds by reaction of methylenecyclopropanes with lithium powder: 2,4-dilithio-1-butenes (C) 83
- Synthesis and structure of a phenylsodium solvate, bis[μ-phenyl(pentamethylenetriamine)-sodium] (C) 476
- Tetraphenylethylenedisodium: the band structure of the CC singly bonded, twisted $(C_6H_5)_2C^{\ominus}$ carbanions (C) 1685
- The structures of 1,n-bis(9-lithio-9-fluorenyl)ethane · 8THF and -hexane · 8THF as models for solvent-separated ion pairs (C) 458
- X-ray structure analysis of α-lithiophenylacetonitrile · lithium diisopropylamide · 2 tetramethylethylenediamine—a "quasi-dianion complex" (C) 1392

Carbazoles, *N*-Cesiocarbazole · pmdta and *N*-potassiocarbazole · pmdta (PMDTA = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine). Cation size and multihapto bonding (C) 1224

Carbazomycin A, Highly selective oxidations of $Fe(CO)_3$-cyclohexadiene complexes: synthesis of 4b,8a-dihydrocarbazol-3-ones and the first total synthesis of carbazomycin A (C) 223

Carbene complexes, Activated aminocarbene complexes of the Fischer type: synthesis, structure, and annelation reactions (C) 1384
- Heterogeneous, metathesis-active Schrock-type carbene complexes by reaction of carbyne tungsten(VI) complexes with silica gel (C) 62
- Metallocene carbene complexes and related compounds of titanium, zirconium, and hafnium (R) 397
- The mechanism of the Dötz reaction: chromacyclobutenes by alkyne-carbene coupling? (C) 908
- Vinylcarbene complexes of titanocene (C) 610

Carbenes, [Bis(diisopropylamino)phosphino]trimetylsilylcarbene: a stable nucleophilic carbene (C) 621

Carbenium ions, Tetrakis(dimethylamino)ethylene dication: two CC singly bonded and almost perpendicularly twisted $((CH_3)_2N)_2C^{\oplus}$ carbenium ions (C) 1684
- Unusual geometry of a sterically congested analogue of $(CH)_5^{\oplus}$ (C) 1232

Carbocycles, all-*cis*-1,4,7,10-cyclododecatetraene—X-ray structure analysis and photoelectron spectrum (C) 1379
- Bicycloprop-2-enyl (C_6H_6) (C) 1711
- 4,6-Dimethylenetricyclo[3.3.0.0^{3,7}]octane-2-one and 2,4,6-trimethylenetricyclo[3.3.0.0^{3,7}]octane (C) 1525
- Structure, deformation electron densities, photoelectron spectra, and reactivity of 3,4-dihydro-1*H*-cyclobuta[*a*]cyclopropa[*d*]benzene (C) 206

Carbohydrates, A "spacer"-modified trisaccharide as photolabile ligand for affinity labeling of antigalactan IgA X24 (C) 1669
- Application of the dimethyl(phenyl)silyl group as a masked form of the hydroxy group in the synthesis of an L-*glycero*-α-D-*manno*-heptopyranoside-containing trisaccharide from the dephosphorylated inner core region of *neisseria meningitidis* (C) 1504
- Carbohydrates as chiral templates: stereoselective synthesis of β-amino acids (C) 1068
- Carbohydrates as chiral templates: stereoselective tandem Mannich-Michael reactions for the synthesis of piperidine alkaloids (C) 1067
- Chiral cyclobutanones by [2 + 2]-cycloaddition of dichloroketene to carbohydrate enol ethers (C) 777
- Enantioselective aldol reaction of *tert*-butyl acetate using titanium-carbohydrate complexes (C) 495
- Enantioselective allylation of carbonyl compounds with titanium-carbohhydrate complexes (C) 494
- Enantioselective synthesis of D-*threo*-β-hydroxy-α-amino acids with titanium-carbohydrate complexes (C) 497
- Structure of chloro(cyclopentadienyl)-bis(1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranos-3-*O*-yl) titanate, a novel titanium-carbohydrate complex (C) 499
- Unsaturated 1,4-*cis*- and 1,4-*trans*-diaminotetradeoxycycloheptites—enantiomerically pure, polyfunctionalized tropa derivatives by enzymatic hydrolysis (C) 1253

Carbon-carbon bond lengths, Shortened C-C bonds in coupled bicyclo[1.1.0]butanes (C) 473
- Very short C—C single bonds and their origin. The central bond length in bitetrahedryl (C) 1226

Carbon-carbon linkage, Activated aminocarbene complexes of the Fischer type: synthesis, structure, and annelation reactions (C) 1384
- [Bis(diisopropylamino)phosphino]trimetylsilylcarbene: a stable nucleophilic carbene (C) 621
- Carbocycle construction in terpene synthesis (B) 1537
- Cyclizations via palladium-catalyzed allylic alkylations (R) 1173
- Enantioselective aldol reaction of *tert*-butyl acetate using titanium-carbohydrate complexes (C) 495
- Enantioselective allylation of carbonyl compounds with titanium-carbohhydrate complexes (C) 494
- Enantioselective synthesis of D-*threo*-β-

hydroxy-α-amino acids with titanium-carbohydrate complexes (C) 497
- Formation of a phosphaferracyclopentadiene ring by coupling of a phosphaalkyne with two fluoromethylidyne ligands (C) 321
- Hydrooligomerization of alkynes, a new catalytic reaction promoted by $[Co(py)_6]^{\oplus}$ in the presence of H_2 (C) 1009
- Intramolecular, stoichiometric (Li, Mg, Zn) and catalytic (Ni, Pd, Pt) metalloene reactions in organic synthesis (R) 38
- 2-Isocyanato-2-alkenoates—synthesis and reactions (C) 1053
- Monohapto versus dihapto CO_2 coordination in bis(amine)Ni^0 complexes: a CAS-SCF study (C) 1694
- Nickel(0)-catalyzed preparation of isomeric carboxamides—ligand-controlled β-H or β′-H elimination (C) 1035
- Non-chelate-controlled addition of 1-bromo-1-lithio-1-alkenes to *O*-protected lactaldehydes (C) 896
- On the formation of "free radicals" from alkylcobalt complexes (C) 325
- $[\{Ph_3PCH_2C(CF_3)_2O\}NiH(PCy_3)]$: support for a nickel hydride mechanism in ethene oligomerization (C) 1011
- Selective 1:3 coupling of norbornene and iodobenzene: a facile synthesis of benzo[*e*]pyrenes with annelated cycloaliphatic moieties (C) 1037
- The effect of acetylene substituents on a Pd^{II}-catalyzed cycloisomerization. Total synthesis of (−)-sterepolide and assignment of absolute stereochemistry (C) 1502
- The mechanism of the Dötz reaction: chromacyclobutenes by alkyne-carbene coupling? (C) 908
- Vinylcarbene complexes of titanocene (C) 610

Carbonylation, Chlorocarbon activation: catalytic carbonylation of dichloromethane and chlorobenzene (C) 1386

Carbyne complexes, Carbyne complexes (B) 354
- Alkyl and alkylidyne complexes of rhenium (C) 334
- Reactions of mono- and dinuclear metal-alkylidyne complexes with phosphaalkynes: C≡P and C≡Mo metathesis (C) 210

Carcinogenicity, Chemicals carcinogens. Activation mechanisms, structural and electronic factors, and reactivity (B) 932
- Combination effects in chemical carcinogenesis (B) 931
- Formation of *N*-(deoxyguanosin-8-yl)aniline in the in vitro reaction of *N*-acetoxyaniline with deoxyguanosine and DNA (C) 468
- Synthesis of *O*-acetyl-*N*-(4-biphenylyl)-hydroxylamine ("*N*-acetoxy-4-aminobiphenyl"), an ultimate metabolite of carcinogenic 4-aminobiphenyl, and its reaction with deoxyguanosine (C) 337

Catalysis, A *trans*-dimethyl derivative of octahedral Ti^{IV}: alkylation and arylation of Ti^{IV}-Schiff base complexes (C) 64
- A highly selective montmorillonite catalyst for hydrogenation of alkynes, alkenynes, and alkadienes (C) 465
- A joint structural characterization of colloidal platinum by EXAFS and high-resolution electron microscopy (C) 590
- A sensitive spectroscopic probe for monitoring changes in the coordination sphere of titanium: eight-membered dioxatitanacycles and their organometallic derivatives (C) 66
- Addition of free Me_2Ge: to alkenes and alkynes on glass surfaces in the presence of water (C) 1028
- Advanced catalysts: interfaces in the physical and biological sciences (AM) 1079
- Amide bond scission via bifunctional activation with bimetallic porphyrin systems with two different metal centers (C) 921
- Asymmetric oligomerization of propene and 1-butene with a zirconocene/alumoxane catalyst (C) 1216
- Catalysis on zeolites (B) 381
- Catalytic antibodies (A) 1283
- Chlorocarbon activation: catalytic carbonylation of dichloromethane and chlorobenzene (C) 1386
- Coupling of epoxides to Pt^{II}-complexes with carbon dioxide and the structure of a cyclic metallacarbonate (C) 767
- Cyclizations via palladium-catalyzed allylic alkylations (R) 1173
- Dimeric $[Cp_2Zr(CH_2O)]$, a novel (η^2-formaldehyde)metal complex from carbon monoxide (C) 630
- Double stereodifferentiation in the formation of isotactic polypropylene at chiral $(C_5H_4CHMePh)_2ZrCl_2$/methylalumoxane catalysts (C) 628
- Enantioselective reduction of α,β-unsaturated carboxylates with $NaBH_4$ and catalytic amounts of chiral cobalt semicorrin complexes (C) 60
- Heterogeneous, Metathesis-active Schrock-type carbene complexes by reaction of carbyne tungsten(VI) complexes with silica gel (C) 62
- Hydrooligomerization of alkynes, a new catalytic reaction promoted by $[Co(py)_6]^{\oplus}$ in the presence of H_2 (C) 1009
- Immobilization of cells (B) 1717
- Intramolecular, stoichiometric (Li, Mg, Zn) and catalytic (Ni, Pd, Pt) metalloene reactions in organic synthesis (R) 38
- Location of *para*-xylene in Yb-faujasite (zeolite Y) by neutron diffraction (C) 770
- Nickel(0)-catalyzed preparation of isomeric carboxamides—ligand-controlled β-H or β′-H elimination (C) 1035
- Phosphanorbornadienes as ligands in the transition metal-catalyzed synthesis of fine chemicals (C) 500
- $[\{Ph_3PCH_2C(CF_3)_2O\}NiH(PCy_3)]$: support for a nickel hydride mechanism in ethene oligomerization (C) 1011
- Probing changes in the structure and performance of a lithium nickel oxide catalyst by in situ X-ray diffraction during the high-temperature oxidative coupling of methane (AM) 808
- Pyrones as substrates for palladium-catalyzed [4+3] cycloadditions (C) 213
- Reaction mechanisms in heterogeneous catalysis; C-H activation as a case study (R) 135
- Revision and modification of the traditional mechanism of C-H/C-C activation by "naked" transition-metal ions (C) 607
- Selective 1:3 coupling of norbornene and iodobenzene: a facile synthesis of benzo[*e*]pyrenes with annelated cycloaliphatic moieties (C) 1037
- Selective hydrogenation of esters to alcohols with a catalyst prepared from Rh_2O_3, $Sn(n\text{-}C_4H_9)_4$, and SiO_2: evidence for site isolation (C) 347
- Selenium-catalyzed synthesis of *S*-alkyl thiocarbamates from amines, carbon monoxide, sulfur, and alkyl halides (C) 452
- Solid ion conductors in heterogeneous catalysis (R) 708
- The first example of an *ethylene*-selective soluble Ziegler catalyst of the zirconocene class (C) 1511

Catechol, *catena*-Poly[bis-μ-(*o*-oxyphenyleneoxy)silicon]: crystal structure of the orthosilicate of catechol (C) 623

Catenanes, A [2]catenane made to order (C) 1396

C_2 stabilization, Phosphonioboratoacetylenes: C_2 stabilized by donor and acceptor molecules (C) 1219

C-Cl activation, Chlorocarbon activation: catalytic carbonylation of dichloromethane and chlorobenzene (C) 1386

C-H activation, Reaction mechanisms in heterogeneous catalysis; C-H activation as a case study (R) 135
- Inter- and intramolecular photochemical C-H activation in matrices and in solution with (η^6-arene)(carbonyl)osmium complexes (C) 1690
- Multiple "remote functionalization" of different sites in flexible molecules by "anchored" bare Fe^I ions (C) 1277
- Revision and modification of the traditional mechanism of C-H/C-C activation by "naked" transition-metal ions (C) 607

Ceramics, Advanced ceramics for biomedical applications (AM) 111

- Residual enantiomerism and chromatographic resolution of a 1,1,2-triarylalkene (C) 199
- Visualization of chromatographic separations by NMR imaging (C) 1029
Chromium compounds, Direct observation of ground state splitting in the chromium(III) acetate trimer by inelastic neutron scattering (C) 930
- Insertion of $Cr(CO)_3$ into $As_7^{3\ominus}$ to form $[As_7Cr(CO)_3]^{3\ominus}$: an inorganic nortricyclane-to-norbornadiene conversion (C) 1032
Chromogenics, Conference report (AM) 1584
Clusters, Aurophilicity as concerted effect: relativistic MO calculations on carbon-centered gold clusters (C) 1357
- A novel type of anionic cluster containing a Pt_4Ag_2 core (C) 748
- A systhematic entry to butterfly-type $[M_4(CO)_{12}(\mu_4\text{-}XY)]$ clusters (C) 1059
- Agostic-type gold ligand and incipient μ_3-PPh_2 coordination in the $Au_2Pt_2P_6$ "hammock" skeleton of the cluster $[Au_2Pt_2(\mu\text{-}PPh_2)_2(PPh_3)_4][PF_6]_2$ (C) 923
- Alkoxide clusters of molybdenum and tungsten as templates for organometallic chemistry: comparison with carbonyl clusters of the later transition elements (R) 432
- Comments on the molecular structure and bonding in $[W_4Cl(O)(O\mathit{i}Pr)_9]$ and $[W_4(O)(O\mathit{i}Pr)_{10}]$. Analogies with tetranuclear carbonyl clusters (C) 1368
- Direct observation of ground state splitting in the chromium(III) acetate trimer by inelastic neutron scattering (C) 930
- $[Et_4N]_6[Na_{14}Mo_{24}P_{17}O_{97}(OH)_{31}] \cdot xH_2O$: a hollow cluster filled with 12 $Na^{\oplus}$ ions and a H_3PO_4 molecule (C) 743
- Formation of a phosphaferracyclopentadiene ring by coupling of a phosphaalkyne with two fluoromethylidyne ligands (C) 321
- Hg_8 ("Mercubane") clusters in $Rb_{15}Hg_{16}$ (C) 1251
- $K_4Al_2Nb_{11}O_{20}F$—the missing link in cluster condensation (C) 1662
- Nickel complexes containing sterically demanding thiolate ligands: $[Ni_8S(SC_4H_9)_9]^{\ominus}$, a mixed-valence nickel sulfide thiolate cluster, and $[Ni_4(SC_3H_7)_8]$, a homoleptic nickel thiolate (C) 61
- Novel nickel clusters with Se and Cp' as ligands: $[Ni_4Se_2(CO)BrCp'_3]$, $[Ni_6Se_4Cp'_5]$, $[Ni_{15}Se_{10}(CO)_3Cp'_8]$, and $[Ni_{15}Se_{10}(CO)Cl_2Cp'_8]$ (C) 1390
- $PbMo_5O_8$ and $Tl_{0.8}Sn_{0.6}Mo_7O_{11}$, novel clusters of molybdenum and thallium (C) 758
- Pd clusters containing As and PPh_3 ligands: the structures of $[Pd_9As_6(PPh_3)_8]$, $[Pd_2(As_2)(PPh_3)_4]$, and $[Pd_{20}As_{12}(PPh_3)_{12}]$ (C) 1665
- $Pt_{309}Phen_{36}O_{30\pm10}$, a four-shell platinum cluster (C) 778
- Stabilization of niobium(0) and tantalum(0) in mixed metal clusters containing silver atoms (C) 471
Coatings, Conference report (AM) 1755
Cobalt compounds, Amides nonplanar solely by C-N bond rotation (C) 912
- Bis[cyclooctane-1,5-diyl)di(pyrazol-1-yl)borato]cobalt: a polypyrazolylborate complex with two agostic hydrogen bonds (C) 205
- On the formation of "free radicals" from alkylcobalt complexes (C) 325
- The first macrocyclic square-planar cobalt(III) complex relieves ring strain by forming a nonplanar amide (C) 1509
Cocomplexation, The organization of two "soft" ($Cu^{2\oplus}$, $Ni^{2\oplus}$) metal centers in heterotrinuclear complexes of a macrocyclic ligand by cocomplexation with $Ba^{2\oplus}$ (C) 746
Colloids, A joint structural characterization of colloidal platinum by EXAFS and high-resolution electron microscopy (C) 590
- Foams and biliquid foams—aphrons (B) 384
- The complexation of gold colloids (C) 780
Complexes, Chain complexes with eleven metal atoms (C) 624
- Intermolecular complexes (B) 502
Complexes with chalcogen ligands, Novel nickel clusters with Se and Cp' as ligands: $[Ni_4Se_2(CO)BrCp'_3]$, $[Ni_6Se_4Cp'_5]$, $[Ni_{15}Se_{10}(CO)_3Cp'_8]$, and $[Ni_{15}Se_{10}(CO)Cl_2Cp'_8]$ (C) 1390
Complexes with hydrido ligands, $[\{Cp(CO)_2Mn\}_2(\mu\text{-}H)]^{\ominus}$: a new, versatile reagent (C) 446
- $[\{Ph_3PCH_2C(CF_3)_2O\}NiH(PCy_3)]$: support for a nickel hydride mechanism in ethene oligomerization (C) 1011
- Synthesis and structure of a binuclear *syn*-coordinated μ-cycloheptatrienyl hydrido complex with hindered C_7H_7 rotation (C) 345
Complexes with nitrogen ligands, *N*-Arylation and *N,N*-dibenzylation of coordinated N_2 with organic halides; differences in the reactivity of *trans*-$[Mo(N_2)_2(Me_8[16]aneS_4)]$ and its phosphane analogues (C) 1040
- A novel approach to ferroelectric liquid crystals: the first organotransition metal compound displaying this behavior (C) 1065
- Aminebis(ethene)nickel(0) complexes; structure of 1-azabicyclo[2.2.2]octanebis(ethene)nickel(0) (C) 772
- Copper(I)-assisted formation of an "organic" sandwich structure: structural prerequisites for luminescence in the dinuclear complexes $[(\mu\text{-bipyrimidine})\{Cu(PR_3)_2\}_2]X_2$ (C) 1659
- $[M(NMesBMes_2)_2](M=Cr, Ni)$: stable, distorted, two-coordinate d^4 and d^8 complexes (C) 316
- Nitrogenase model compounds: $[\mu\text{-}N_2H_2\{Fe("N_HS_4")\}_2]$, the prototype for the coordination of diazene to iron sulfur centers and its stabilization through strong N—H···S hydrogen bonds (C) 1271
- Platinum complexes of the anions $Se_2N_2^{2\ominus}$ and $Se_2N_2H^{\ominus}$; X-ray structure analysis of $[Pt(Se_2N_2H)(PMe_2Ph)_2]Cl$ (C) 1047
- Synthesis and analysis of polymetallaphosphazenes (C) 493
- Trigonal-bipyramidal lanthanoid complexes with interstitial oxygen atoms (C) 1033
- Two novel polyoxomolybdates containing the $(MoNO)^{3\oplus}$ unit: $[Mo_5Na(NO)O_{13}(OCH_3)_4]^{2\ominus}$ and $[Mo_6(NO)O_{18}]^{3\ominus}$ (C) 1363
Complexes with oxygen ligands, Indium 2,4,6-tris(trifluoromethyl)phenoxide—a dimer with the coordination number two at the indium atoms (C) 1383
- On the stability of trioxo(η^5-cyclopentadienyl) compounds of manganese, technetium, and rhenium: an ab initio SCF study (C) 1228
- Oxoiron porphyrin species with high-valent iron: formation by solvent-dependent protonation of a peroxoiron(III) porphyrinate derivative (C) 1709
- $[VO(O_2C\mathit{t}Bu)_3]$ and $[V_6O_6(\mu\text{-}O)_4(\mu\text{-}O_2CPh)_9]$: structural characterization of a mononuclear V^V and a (2+4)-nuclear $V^{IV}V^V_5$ carboxylato complex. Models for vanadate-dependent peroxidases (C) 1221
Complexes with phosphorus ligands, A phosphane—dithioformate adduct as a five-electron bridging ligand $[Mn_2(CO)_6\{S_2C(H)P(\mathit{cyclo}\text{-}C_6H_{11})_3\}_2]$ (C) 1014
- Aggregation of metal ions with functionalized calixarenes: synthesis and structure of an octanuclear copper(I) chloride complex (C) 1376
- Agostic-type gold ligand and incipient μ_3-PPh_2 coordination in the $Au_2Pt_2P_6$ "hammock" skeleton of the cluster $[Au_2Pt_2(\mu\text{-}PPh_2)_2(PPh_3)_4][PF_6]_2$ (C) 923

- New intermediates in the cyclocotrimerization of thioxophosphorus(v) cations with alkynes (C) 448
- Reductive dimerization of a phosphaalkyne with complexation to samarium (C) 445
- Tetraphosphacyclobutadiene as complex ligand (C) 1355

Complexes with sulfur ligands, A novel trimeric chiral copper(I) thiophenolate with intramolecular coordination (C) 341
- A phosphane—dithioformate adduct as a five-electron bridging ligand $[Mn_2(CO)_6\{S_2C(H)P(cyclo\text{-}C_6H_{11})_3\}_2]$ (C) 1014
- Chirality and isomerism in binuclear iron complexes with sulfur ligands: $[Fe(CO)(\mu\text{-}"S_4")]_2$, a model complex for oxidoreductases (C) 1703
- 17- to 19-Electron pentamethylcyclopentadienyl iron dithiocarbamate complexes. Formation of a Cp^*Fe^{IV} complex (C) 460
- $FeI_3SC(NMe_2)_2$, a neutral thiourea complex of iron(III) iodide (C) 776
- Nickel complexes containing sterically demanding thiolate ligands: $[Ni_8S(SC_4H_9)_9]^{\ominus}$, a mixed-valence nickel sulfide thiolate cluster, and $[Ni_4(SC_3H_7)_8]$, a homoleptic nickel thiolate (C) 61
- Self-reduction of $[Ph_4P][Nb(SCH_2CH_2CH_2S)_3]$ with formation of a Nb_2^{IV} complex (C) 98
- Synthesis and structure of $[(C_5H_5)_2TiS_4AsCH_3]$—a new reagent for the synthesis of sulfur-rich heterocycles (C) 1269
- Synthesis, structure and reactivity of sulfur-rich cyclopentadienyl-transition metal complexes: sulfur chemistry from an organometallic point of view (R) 1613

Composite materials, Conference report (AM) 817
- Fiber reinforcement for composite materials (B) 1443

- Inverse gas chromatography. Characterization of polymers and other materials (B) 1761
- Temperature dependent inversion of elution sequence in the resolution of α-amino acid enantiomers on chiral diamide selectors (C) 192

Gels, Crystals in Gels and Liesegang rings (B) 381

Generation of current, Chemical aspects of fusion technology (R) 1

Genes, Architecture of eukaryotic genes (B) 104
- Gene synthesis (R) 716

Germanium compounds, A base-stabilized Ge–S double bond (C) 1237
- A polyhedral oligogermane: 4,8-dibromoocta-*tert*-butyltetracyclo-[3.3.0.0^{2,7}.0^{3,6}]octagermane (C) 198
- A silicogermanate with a Si:Ge ratio ≥ 2—an MFI zeolite of novel composition (C) 81
- Addition of free Me_2Ge: to alkenes and alkynes on glass surfaces in the presence of water (C) 1028
- $[(Me_3Si)_2CHGe]_6$, the first hexagermaprismane (C) 55
- Synthesis and structure of digerma- and distannacyclobutenes (C) 603

Glass, Addition of free Me_2Ge: to alkenes and alkynes on glass surfaces in the presence of water (C) 1028

Glasses, Aluminum-rich metallic glasses (AM) 123
- Conference report (AM) 1132
- Glass-Ceramics in the scheme of inorganic materials (AM) 1746
- Structural characterization of non-oxide chalcogenide glasses by modern solid state NMR techniques (AM) 1723

Glycals, Enzymatic synthesis of selectively protected glycals (C) 220

Gold, The complexation of gold colloids (C) 780

Gold compounds, Agostic-type gold ligand and incipient μ_3-PPh_2 coordination in the $Au_2Pt_2P_6$ "hammock" skeleton of the cluster $[Au_2Pt_2(\mu\text{-}PPh_2)_2(PPh_3)_4][PF_6]_2$ (C) 923
- Aurophilicity as concerted effect: relativistic mo calculations on carbon-centered gold clusters (C) 1357
- Synthesis, structure, and bonding of the cation $[\{(C_6H_5)_3PAu\}_5C]^{\oplus}$ (C) 463

Graphite, Graphite fibers and filaments (B) 526

Halogen compounds, Alkylidene sulfur difluorides: $F_5S(F_3C)C{=}SF_2$ and $(F_3C)_2C{=}SF_2$. Synthesis, structure, and structure predictions (C) 769
- $AsI_4^{\oplus}AlCl_4^{\ominus}$, a salt of the last missing tetrahaloarsonium ion (C) 1671
- Bromoselenates (II,IV), a novel type of mixed valence compounds (C) 187
- $FeI_3SC(NMe_2)_2$, a neutral thiourea complex of iron(III) iodide (C) 776
- Structural diversity in iodoantimonates; the anions $Sb_3I_{11}^{2\ominus}$, $Sb_5I_{18}^{3\ominus}$ and $Sb_6I_{22}^{4\ominus}$ (C) 344

Helix, One-dimensional metal chains in a chiral environment—the crystal structure of helical bis(dicarbonylrhodium(I))- 3,3′-hexafluoroglutarylbis-(1*R*)-camphorate (C) 1019

HETE, A new synthesis of key intermediates for the preparation of 5,6-DiHETE and lipoxin A_4 (C) 755
- Stereocontrolled total synthesis of (5*S*,6*R*)- (5*S*,6*S*)- (5*R*,6*R*)-, and (5*R*,6*S*)- (7*E*,9*E*,11*Z*,14*Z*)-5,6-dihydroxy-7,9,11,14-icosatetraenoic acid (5,6-DiHETE) methyl esters (C) 587
- Total enantiospecific synthesis of (9*S*)- and (9*R*)-9-hydroxyeicosatetraenoic acid (9-HETE) methyl ester (C) 614

Heteroallyl anions, Synthesis, structure, and reactivity of a 1,3-diphospha-2-silaallyl anion (C) 751

Heteroarenes, 3,3′:4,4′-Bis(thieno[2,3-*b*]-thiophene): a novel fused heteroarene (C) 1222
- Azonia derivates of arenes: synthesis and properties of 10c-azoniafluoranthene (C) 588
- Benzo[1,2-*h*:4,3-*h*′]diquinoline ("1,14-diaza[5]helicene"): synthesis, structure, and properties (C) 86
- Di(1-pyridinio)- and di(1-bipyridindiio)dihydrodibenzotetraaza[14]annulenes (C) 1060
- Di(4-pyridinio)-, di(2-benzothiazolio)-, di(2[1,3-dithiolylio])- and diformyltetraaza[14]annulenes and tetraaza[14]annulenylene-homologous tetrathiafulvalenes (C) 1063
- Light-sensitive molecular building blocks with electron transfer activity: synthesis and properties of a photochemically switchable, dicyanovinyl-substituted furan (C) 1494
- New intermediates in the cyclocotrimerization of thioxophosphorus(v) cations with alkynes (C) 448
- Poly-[*N*,*N*-(1,4-divinylbenzene-β,β′-diyl)-4,4′-bipyridinium dibromide], a novel conducting viologen polymer (AM) 807
- Structures of quino[7,8-*h*]quinoline and quino[8,7-*h*]quinoline (C) 84
- Synthesis and crystal structure of a phospholyl anion (C) 1367

Heterocycles, A base-stabilized Ge–S double bond (C) 1237
- 3-Arylsulfonyloxazolidines as chiral templates: asymmetric synthesis of 2-substituted 2-hydroxycyclohexanecarbaldehydes from 2-hydroxymethylenecyclohexanone (C) 67
- 2-Chloro-2*H*-phosphirene/1-chloro-1*H*-phosphirene isomerization by [1,3]-chlorine shift (C) 225
- Azaoctabisvalenes (C) 1345
- Dimethyldioxasilirane (C) 898
- Formation of 2,4,4-trimethylthiete by photodecarbonylation of 3,3,5-trimethyl-2(3*H*)-thiophenone (C) 1499
- From 2,5-dihydropyrazines to 2*H*-1,4-diazepines and from benzodihydroarenes to benzocycloheptene derivatives, structural variants of the antidepressant protriptyline (C) 613
- Iron-mediated diastereoselective spiroannelation to the spiro[1,2,3,4-tetrahydroquinoline-4,1′-cyclohexane] system and a novel rearrangement to 2,3-dihydroindole derivatives (C) 1678
- Pentacoordinated elements of the 4th main group with four organic residues (C) 918
- Perspectives in photochromism: a novel system based on the 1,5-electrocyclization of heteroanalogous pentadienyl anions (R) 413
- Phosphanorbornadienes as ligands in the transition metal-catalyzed synthesis of fine chemicals (C) 500
- Reaction of decamethylsilicocene with sulfur, selenium, and tellurium: from a p_π-p_π system to new heterocycles (C) 1518
- $S_4(CN)_8$, a blue-black high-molecular sulfur-cyanogen compound with 6π- and 8π-electron structural elements (C) 609
- Surprising reactions of decamethylsilicocene with π-systems of the type $X{=}C{=}Y$ (C) 762
- Synthesis and structure of $[(C_5H_5)_2TiS_4AsCH_3]$—a new reagent for the synthesis of sulfur-rich heterocycles (C) 1269
- Synthesis and structure of digerma- and distannacyclobutenes (C) 603
- Synthesis and structure of $[\{(\eta^5\text{-}C_5Me_5)Ti(NH)\}_3N]$, a titanium imide nitride (C) 754
- Synthesis, characterization, and complexation of an unusual P_2Si_2 bicyclobutane with butterfly-structure: 2,2,4,4-tetramesityl-1,3-diphospha-2,4-disilabicyclo[1.1.0]butane (C) 1038
- Synthesis of the novel ring systems 1,2,3,4-oxazadisiletidine and 1,3,4,2,5-dioxazadisilolidine (C) 54
- Tellurobenzaldehyde by Staudinger-chalcogenation of the ylide benzylidenetriphenylphosphorane (C) 179
- Tetraalkylidene-1,4-diboracyclohexanes from 3,4-dilithio-2,5-dimethyl-2,4-hexadiene; the first "hetero[6]radialene" with chair conformation (C) 477
- 1,3,5-Trithia-2,4,6-triazapentalenyl—a stable sulfur-nitrogen radical (C) 920

Heterometallic compounds, A novel type of anionic cluster containing a Pt_4Ag_2 core (C) 748
- The first heterodinuclear complexes with bis(cyclopentadienyl)methane bridges (C) 1008

Heteropolyanions, $[Et_4N]_6$-$[Na_{14}Mo_{24}P_{17}O_{97}(OH)_{31}]\cdot x\,H_2O$: a hollow cluster filled with 12 $Na^{\oplus}$ ions and a H_3PO_4 molecule (C) 743
- $PbMo_5O_8$ and $Tl_{0.8}Sn_{0.6}Mo_7O_{11}$, novel clusters of molybdenum and thallium (C) 758

Hexaaminobenzene, The structure of hexaaminobenzene (C) 90

Hexaazaoctadecahydrocoronene, The structure of the tetracation of hexaazaoctadecahydrocoronene, a simple substituted benzene (C) 92

High pressure chemistry, Organic high pressure chemistry (B) 1535

Histamines, A chiral Ag^{I}-coordination polymer with a polydentate chiral ligand; crystal structure of the 1:1 complex of CF_3SO_3Ag and *N*-[*N*-(5-Methylthenylidene)-L-methionyl]histamine (C) 1698

History of chemistry, Georg de Hevesy. 1885–1966. Festschrift (B) 1536
- One pioneer or several pioneers? The discovery of noble-gas compounds (L) 636
- Superconductors: the breakthrough (B) 1139

- The Kevlar story—an advanced materials case study (AM) 649
- Zur Konformation des Cyclohexans. (Ostwalds Klassiker der exakten Wissenschaft, Band 274) (B) 105

Homobenzenes, Bridged *cis*-Tris-σ-homobenzenes: Heterodiademanes (C) 1351
- Stabilized *cis*-Tris-σ-homobenzenes: syntheses, [σ2+σ2+σ2] cycloreversions (C) 1348

Hormone antagonists, Drugs from emasculated hormones: the principle of syntopic antagonism (Nobel lecture) (R) 886

Host-guest chemistry, A polymolecular donor-acceptor stack made of paraquat and a 1,5-dihydroxynaphthalene-derived crown ether (C) 1394

- Additivities of electrostatic and hydrophobic interactions in host-guest complexes (C) 753
- Efficient Ion exchangers and receptors for organic and organometallic cations (C) 1263
- Encapsulation of polypyrrole chains in zeolite channels (C) 1692
- Spontaneous oxidation and in-situ polymerization of pyrrole in channels of the three-dimensional coordination polymer $[(Me_3Sn)_3Fe^{III}(CN)_6]_\infty$ (C) 1265

Houben-Weyl, Houben-Weyl. Methoden der Organischen Chemie. Band E20, Teil 1-3: Makromolekulare Stoffe (B) 634

Hydrogen bonds, A structure for the H-bonded complex of nylon-66 with perfluoroglutaric acid (C) 466
- Anion coordination and Cl−H···Cl bridges in the low-melting poly(hydrogen chloride) $Me_3N \cdot 5HCl$ (C) 1697
- Bis[cyclooctane-1,5-diyl)di(pyrazol-1-yl)borato]cobalt: a polypyrazolylborate complex with two agostic hydrogen bonds (C) 205
- hydrogen bonds between an $NH_4^\oplus$ ion and a carbanion—crystal structure of ammonium 1,2,4-tricyanocyclopentadienide (C) 73
- Model of a solvent-shared ion pair with N−H···C hydrogen bonds between amine and carbanion—crystal structure of [fluorenyllithium · 2 ethylenediamine]$_\infty$ (C) 72
- Nitrogenase model compounds: $[\mu\text{-}N_2H_2\{Fe(\text{“}N_HS_4\text{”})\}_2]$, the prototype for the coordination of diazene to iron sulfur centers and its stabilization through strong N−H···S hydrogen bonds (C) 1271

Hydrogenation, A highly selective montmorillonite catalyst for hydrogenation of alkynes, alkenynes, and alkadienes (C) 465
- Selective hydrogenation of esters to alcohols with a catalyst prepared from Rh_2O_3, $Sn(n\text{-}C_4H_9)_4$, and SiO_2: evidence for site isolation (C) 347

Hydrooligomerization, hydrooligomerization of alkynes, a new catalytic reaction promoted by $[Co(py)_6]^\oplus$ in the presence of H_2 (C) 1009

Hydroxyecdysone, Side-chain homologues of 20-hydroxyecdysone: synthesis, configurational assignment, and biochemical characterization (C) 1515

Hyperconjugation, The structure of a *C*-borylborirene with strong C-B hyperconjugation (C) 186

Image processing, Image enhancement—chemical, digital, visual (R) 1601

Implant devices, Advanced ceramics for biomedical applications (AM) 111
- Bone replacements: implant materials and the modes of implant fixation (AM) 1431
- Challenges in materials for health care applications (AM) 662

Indigo, Indigo-metal complexes: synthesis and structure of Pd^{II} and Pt^{II} compounds containing the anions of indigo and octahydroindigo as mono- and bischelate ligands (C) 1529

Indium compounds, Indium 2,4,6-tris(trifluoromethyl)phenoxide—a dimer with the coordination number two at the indium atoms (C) 1383

Industrial chemistry, Industrielle Organische Pigmente. Herstellung, Eigenschaften, Anwendung (B) 1073
- Materials for optical data storage (R) 1445
- Polymer optical fibers and nonlinear optical device principles (AM) 1548

Inorganic chemistry, Advanced inorganic chemistry (B) 1073

Intercalation, Conference report (AM) 1434
- Location of *para*-xylene in Yb-faujasite (zeolite Y) by neutron diffraction (C) 770

Interhalogene compounds, The structure of $BrF_6^\ominus$ and related compounds (C) 1526

Intermetallics, Conference report (AM) 243

Ion conductors, Solid ion conductors in heterogeneous catalysis (R) 708

Ion exchangers, Efficient ion exchangers and receptors for organic and organometallic cations (C) 1263

Ionophores, Lipophilic tartaric acid esters as enantioselective ionophores (R) 1147

Ions, Ions in solution: basic principles of chemical interactions (B) 103
- The structure of the tetracation of hexaazaoctadecahydrocoronene, a simple substituted benzene (C) 92

Iridium compounds, $[Ir_2(\mu\text{-}CH_2)(CO)_4(Me_2PCH_2PMe_2)_2][CF_3SO_3]_2$, an unprecedented electrophilic methylene complex; $H^\ominus$ addition to prepare a bridging methyl complex (C) 1377

Iron compounds, 17- to 19-electron pentamethylcyclopentadienyl iron dithiocarbamate complexes. Formation of a Cp^*Fe^{IV} complex (C) 460
- Chirality and isomerism in binuclear iron complexes with sulfur ligands: $[Fe(CO)(\mu\text{-}\text{“}S_4\text{”})]_2$, a model complex for oxidoreductases (C) 1703
- $(C_4Me_4NBH_3)_2Fe$—a metal complex isosteric with decamethylferrocene with characteristic metallocene disorder (C) 342
- Complexes with an $\eta^2\text{-}\mu_2$-SiO bridge. Structure of the bimetallic complex $[Fe(CO)_3\{\mu\text{-}Si(OMe)_2\text{-}OMe\}(\mu\text{-}dppm)PdCl]$(*Fe-Pd*) (C) 1361
- $FeI_3SC(NMe_2)_2$, a neutral thiourea complex of iron(III) iodide (C) 776
- Formation of a phosphaferracyclopentadiene ring by coupling of a phosphaalkyne with two fluoromethylidyne ligands (C) 321
- Highly selective oxidations of $Fe(CO)_3$-cyclohexadiene complexes: synthesis of 4b,8a-dihydrocarbazol-3-ones and the first total synthesis of carbazomycin A (C) 223
- Identification of $[(OC)_4Fe{=}Si(CH_3)_2 \cdot \{(H_3C)_2N\}_3PO]$ as intermediate in the formation of polysilanes from $(H_3C)_2SiCl_2$ and $[Na_2Fe(CO)_4]$ (C) 203
- Multiple “remote functionalization” of different sites in flexible molecules by “anchored” bare Fe^I ions (C) 1277
- Nitrogenase model compounds: $[\mu\text{-}N_2H_2\{Fe(\text{“}N_HS_4\text{”})\}_2]$, the prototype for the coordination of diazene to iron sulfur centers and its stabilization through strong N−H···S hydrogen bonds (C) 1271
- Optically active isoprene(tricarbonyl)-iron(0) and methyltrimethylenemethane(tricarbonyl)iron(0) (C) 1657
- Oxoiron porphyrin species with high-valent iron: formation by solvent-dependent protonation of a peroxoiron(III) porphyrinate derivative (C) 1709
- Pronounced anion dependence of valence detrapping temperature in mixed-valence 1′,1‴-disubstituted biferrocenium salts (C) 1388
- Thermal and electrocatalytic epimerization at iron as the chiral center (C) 1521
- Two ferrole isomers in equilibrium: experimental confirmation of an old hypothesis (C) 318

Isocarbacyclins, Flexible syntheses of optically active isocarbacyclins (C) 1282, 349

Isocyanatoalkenoates, 2-Isocyanato-2-alkenoates—synthesis and reactions (C) 1053

Isocyanogen, Diisocyanogen or isocyanogen? (C) 761

Isomerization, The effect of acetylene substituents on a Pd^{II}-catalyzed cycloisomerization. Total synthesis of (−)-sterepolide and assignment of absolute stereochemistry (C) 1502
- Thermal and electrocatalytic epimerization at iron as the chiral center (C) 1521
- Two ferrole isomers in equilibrium: experimental confirmation of an old hypothesis (C) 318

Kinetics, Additivities of electrostatic and hydrophobic interactions in host-guest complexes (C) 753
- Kinetics of electrochemical metal dissolution (B) 935

Knot compounds, A synthetic molecular trefoil knot (C) 189

Lanthanoid compounds, Complexation of a novel organoytterbium(II) ligand with dimethylplatinum(II) : crystal structure of the resulting heterobimetallic complex (C) 1370
- $HoAl_3Cl_{12}$ in crystalline form (C) 1364
- Magneto-optical recording and data storage materials (AM) 235
- Reductive dimerization of a phosphaalkyne with complexation to samarium (C) 445
- Trigonal-bipyramidal lanthanoid complexes with interstitial oxygen atoms (C) 1033

Lasers, Lasertechnik (B) 1760

Lead compounds, $[\{Cp'(CO)_2Mn\}_2PbS\textit{t}Bu]^\ominus$; completion of an isoelectronic series of binuclear complexes containing trigonal-planar coordinated main group elements (C) 1496
- Triorganolead cations stabilized by side-on coordination to the C≡C bond in alkynylborates (C) 1500

Ligand transfers, Triple-decker complexes as intermediates in ring-ligand transfers (C) 737

Lipoxin A_4, A new synthesis of key intermediates for the preparation of 5,6-DiHETE and lipoxin A_4 (C) 755

Liquid crystals, A novel approach to ferroelectric liquid crystals: the first organotransition metal compound displaying this behavior (C) 1065
- Conference report (AM) 959, 961
- Dichroic dyes and liquid crystalline side chain polymers (AM) 940
- Induction of liquid crystalline phases: formation of discotic systems by doping amorphous polymers with electron acceptors (C) 914
- Liquid crystalline elastomers (AM) 1407
- Liquid crystals—new compounds, new applications (AM) 1424, 1757
- Materials processing—a key factor (AM) 644
- Monolayers and Langmuir-Blodgett multilayers of discotic liquid crystals? (AM) 1574
- Side chain liquid crystal polymers (B) 1140
- Siloxane copolymers with laterally and terminally attached mesogenic side chains (AM) 1120

- Thermotropic liquid crystals, fundamentals (B) 383
Liquid films, Thin liquid films (B) 527
Luminescence, Copper(I)-assisted formation of an "organic" sandwich structure: structural prerequisites for luminescence in the dinuclear complexes [(μ-bipyrimidine){Cu(PR$_3$)$_2$}$_2$]X$_2$ (C) 1659

Macrocycles, A [2]catenane made to order (C) 1396
- A polymolecular donor-acceptor stack made of paraquat and a 1,5-dihydroxynaphthalene-derived crown ether (C) 1394
- Polymer benzo[15]crown-5 complexes as sensor materials for solvent vapors—aromatic halogenated hydrocarbons and polar solvents (AM) 813
- Stereoregular oligomerization by repetitive Diels–Alder reactions (C) 1258
- The chemistry of macrocyclic ligand complexes (B) 1534
- The first macrocyclic square-planar cobalt(III) complex relieves ring strain by forming a nonplanar amide (C) 1509
- The organization of two "soft" ($Cu^{2\oplus}$, $Ni^{2\oplus}$) metal centers in heterotrinuclear complexes of a macrocyclic ligand by cocomplexation with $Ba^{2\oplus}$ (C) 746

Macromolecular chemistry, Houben-Weyl. Methoden der Organischen Chemie. Band E20, Teil 1-3: Makromolekulare Stoffe (B) 634
Macromolecular physics, Conference report (AM) 1753
Magnesium compounds, $Na_xMg_{5-x}Ga_9$, a new intermetallic phase as a link between zintl phases and metals (C) 58
Magnetic materials, Conference report (AM) 1134, 958, 961
Magneto-optics, Conference report (AM) 1134
- Magneto-optical recording and data storage materials (AM) 235

Manganese compounds, A phosphane–dithioformate adduct as a five-electron bridging ligand [Mn$_2$(CO)$_6${S$_2$C(H)P(*cyclo*-C$_6$H$_{11}$)$_3$}$_2$] (C) 1014
- [{Cp(CO)$_2$Mn}$_2$(μ-H)]$^{\ominus}$: a new, versatile reagent (C) 446
- [{Cp′(CO)$_2$Mn}$_2$PbS*t*Bu]$^{\ominus}$; completion of an isoelectronic series of binuclear complexes containing trigonal-planar coordinated main group elements (C) 1496
- Synthesis, structure and magnetic properties of a dinuclear manganese(II) complex with one μ-aqua and two μ-carboxylato bridges (C) 1365
- The active sites in manganese-containing metalloproteins and inorganic model complexes (A) 1153
- The first heterodinuclear complexes with bis(cyclopentadienyl)methane bridges (C) 1008

Mass spectrometry, Dithia dications from cyclic and acyclic precursors by gas-phase oxidation ("charge stripping") of 3e/2c-radical cations (C) 1275
- Inorganic mass spectrometry (B) 101
- Laser desorption/ionization mass spectrometry of proteins of mass 100000 to 250000 Dalton (C) 760
- Multiple "remote functionalization" of different sites in flexible molecules by "anchored" bare Fe^{I} ions (C) 1277
- Organic dications: gas phase experiments and theory in concert (A) 1321

Materials science, Advanced materials R&D—planning for the future (AM) 229
- Conference report (AM) 1587, 246
- European materials societies (AM) 357
- Improving effectiveness in materials research (AM) 667
- Materials for optical data storage (R) 1445
- Materials for the next millenium (AM) 1088
- Materials research—current issues and future directions (AM) 638
- Materials science and engineering in Britain (AM) 1077
- The European ceramic society (ECerS) (AM) 1406
- The European materials research society (E-MRS) (AM) 938
- The nature of materials science publishing (AM) 1721

Matrix isolation, Ethynol: photochemical generation in an argon matrix, IR spectrum, and photoisomerization to ketene (C) 181
- Dimethyldioxasilirane (C) 898

Mercury compounds, Hg_8 ("Mercubane") clusters in $Rb_{15}Hg_{16}$ (C) 1251
- Pentamethylcyclopentadienylmercury chloride: an organomercury compound with novel battlement-like structure (C) 611

Metal chains, Chain complexes with eleven metal atoms (C) 624
- One-dimensional metal chains in a chiral environment—the crystal structure of helical bis(dicarbonylrhodium(I))-3,3′-hexafluoroglutarylbis-(1*R*)-camphorate (C) 1019

Metallacycles, Dimeric [Cp$_2$Zr(CH$_2$O)], a novel (η^2-formaldehyde)metal complex from carbon monoxide (C) 630
- Single-source III/V precursors: a new approach to gallium arsenide and related semiconductors (R) 1208

Metalloproteins, The active sites in manganese-containing metalloproteins and inorganic model complexes (R) 1153
Metal-metal bonds, Tl^{I}-Tl^{I} interactions in the molecular state—an MO analysis (C) 1688
Metal-metal multiple bonds, Alkoxide clusters of molybdenum and tungsten as templates for organometallic chemistry: comparison with carbonyl clusters of the later transition elements (R) 432
- [{Cp(CO)$_2$Mn}$_2$(μ-H)]$^{\ominus}$: a new, versatile reagent (C) 446

Metal oxides, The crystal chemistry of high-temperature oxide superconductors and materials with related structures (R) 1472
Metals, Introduction to the modern theory of metals (B) 1592
Metathesis, Heterogeneous, metathesis-active Schrock-type carbene complexes by reaction of carbyne tungsten(VI) complexes with silica gel (C) 62
- Reactions of mono- and dinuclear metal-alkylidyne complexes with phosphaalkynes: C≡P and C≡Mo metathesis (C) 210

Michael additions, Copper(I)-promoted Michael-addition reaction of organozincs of esters, nitriles, and α-amino acids (C) 351
Mixed-valence compounds, bromoselenates(II,IV), a novel type of mixed valence compounds (C) 187
- Nickel complexes containing sterically demanding thiolate ligands: [Ni$_8$S(SC$_4$H$_9$)$_9$]$^{\ominus}$, a mixed-valence nickel sulfide thiolate cluster, and [Ni$_4$(SC$_3$H$_7$)$_8$], a homoleptic nickel thiolate (C) 61
- Pronounced anion dependence of valence detrapping temperature in mixed-valence 1′,1‴-disubstituted biferrocenium salts (C) 1388

Molecular beam epitaxy, Metal organic chemical vapor deposition (MOCVD) perspectives and prospects (AM) 1110
- Tailoring semiconductor crystals to atomic dimensions (AM) 1098

Molecular design, Structure-directed synthesis of new organic materials (AM) 1103
Molecular electronics, Conference report (AM) 520
- How to tailor molecular electronics or why is nature taking the 'soft' approach? (AM) 1544

Molecular recognition, Conference report (AM) 1585
- Selective molecular recognition of trihydroxybenzenes (C) 79
- Using crystal birefringence to study molecular recognition (C) 330

Molybdenum compounds, Alkoxide clusters of molybdenum and tungsten as templates for organometallic chemistry: comparison with carbonyl clusters of the later transition elements (R) 432
- *N*-Arylation and *N,N*-dibenzylation of coordinated N$_2$ with organic halides; differences in the reactivity of *trans*-[Mo(N$_2$)$_2$(Me$_8$[16]aneS$_4$)] and its phosphane analogues (C) 1040
- Hexaarsabenzene as complex ligand (C) 212
- Two novel polyoxomolybdates containing the $(MoNO)^{3\oplus}$ unit: [Mo$_5$Na(NO)-O$_{13}$(OCH$_3$)$_4$]$^{2\ominus}$ and [Mo$_6$(NO)O$_{18}$]$^{3\ominus}$ (C) 1363

Montmorillonites, A highly selective montmorillonite catalyst for hydrogenation of alkynes, alkenynes, and alkadienes (C) 465
Multiple bonds, A base-stabilized Ge–S double bond (C) 1237
- Alkylidene sulfur difluorides: F$_5$S(F$_3$C)C=SF$_2$ and (F$_3$C)$_2$C=SF$_2$. Synthesis, structure, and structure predictions (C) 769
- Bis(trifluoromethyl)sulfene (CF$_3$)$_2$C=SO$_2$, isolated as adduct (C) 221
- *t*Bu$_2$P-P=PBr*t*Bu$_2$ · LiBr and formation of *t*Bu$_2$P-P (C) 315
- [{Cp′(CO)$_2$Mn}$_2$PbS*t*Bu]$^{\ominus}$; completion of an isoelectronic series of binuclear complexes containing trigonal-planar coordinated main group elements (C) 1496
- Formation and reactivity of silicon-sulfur and silicon-selenium double bonds. The first X-ray structure of a silanethione (C) 1016
- Metal-ligand multiple bonds (B) 790
- Methylboron oxide, H$_3$C–B≡O (C) 88
- Stable methyleneboranes of high Lewis acidity (C) 781
- Synthesis, structure, and reactivity of diphosphenes having a *cis*-configuration (C) 215
- The structure of a *C*-borylborirene with strong C-B hyperconjugation (C) 186
- Thermal cleavage and isomerization of 1,3-diboretanes to stable methyleneboranes (C) 784
- Versatile modes of allene bonding in the structures of [W$_2$(O*t*Bu)$_6$(C$_3$H$_4$)], [W$_2$(O*t*Bu)$_6$(C$_3$H$_4$)(CO)$_2$], and [W$_2$(O*t*Bu)$_6$(C$_3$H$_4$)$_2$] (C) 1523

Name reactions, name reactions and reagents in organic synthesis (B) 1538
Natural products, A new synthesis of key intermediates for the preparation of 5,6-DiHETE and lipoxin A$_4$ (C) 755

- Biosynthetic studies on antibiotics (R) 146
- Chemical modifications of biopolymers by quinones and quinone methides (R) 555
- Chiral building blocks for the synthesis of triquinane sesquiterpenes: derivatives of 2-methylbicyclo[3.3.0]octan-3-ol from catalpol (C) 447
- Enzymatic synthesis of selectively protected glycals (C) 220
- Establishment of configurations for the two diastereomeric *C*-glucosylanthrones aloin A und aloin B (C) 1528
- Flexible syntheses of optically active isocarbacyclins (C) 1282, 349
- Highly selective oxidations of $Fe(CO)_3$-cyclohexadiene complexes: synthesis of 4b,8a-dihydrocarbazol-3-ones and the first total synthesis of carbazomycin A (C) 223
- Intramolecular, stoichiometric (Li, Mg, Zn) and catalytic (Ni, Pd, Pt) metalloene reactions in organic synthesis (R) 38
- Isolation, synthesis, and absolute configuration of filbertone—the principal flavor component of the hazelnut (C) 1022
- On the structure of eumelanins: identification of constitutional patterns by solid-state NMR spectroscopy (C) 741
- Stereo- and regiospecific 6-*endo*-*trig*-cyclization of aryl radicals, an entry to novel progesterone-antagonists of the androstane series (C) 773
- Stereocontrolled total synthesis of (5*S*,6*R*)-, (5*S*,6*S*)-, (5*R*,6*R*)-, and (5*R*,6*S*)-, (7*E*,9*E*,11*Z*,14*Z*)-5,6-dihydroxy-7,9,11,14-icosatetraenoic acid (5,6-DiHETE) methyl esters (C) 587
- The effect of acetylene substituents on a Pd^{II}-catalyzed cycloisomerization. Total synthesis of (−)-sterepolide and assignment of absolute stereochemistry (C) 1502
- Total enantiospecific synthesis of (9*S*)- and (9*R*)-9-hydroxyeicosatetraenoic acid (9-HETE) methyl ester (C) 614
- Total synthesis of the antitumor antibiotic WF-3161 (C) 333

Neisseria meningitidis, Application of the dimethyl(phenyl)silyl group as a masked form of the hydroxy group in the synthesis of an L-*glycero*-α-D-*manno*-heptopyranoside-containing trisaccharide from the dephosphorylated inner core region of *neisseria meningitidis* (C) 1504

Neutron diffraction, Double-bond geometry of norbornene: neutron diffraction measurement of a derivative at 15 K (C) 1239

Nickel compounds, Aminebis(ethene)-nickel(0) complexes; structure of 1-azabicyclo[2.2.2]octanebis(ethene)nickel(0) (C) 772
- Monohapto versus dihapto CO_2 coordination in bis(amine)Ni^0 complexes: a CAS-SCF study (C) 1694
- Nickel(0)-catalyzed preparation of isomeric carboxamides—ligand-controlled β-H or β′-H elimination (C) 1035
- Nickel complexes containing sterically demanding thiolate ligands: $[Ni_8S(SC_4H_9)_9]^{\ominus}$, a mixed-valence nickel sulfide thiolate cluster, and $[Ni_4(SC_3H_7)_8]$, a homoleptic nickel thiolate (C) 61
- Novel nickel clusters with Se and Cp′ as ligands: $[Ni_4Se_2(CO)BrCp'_3]$, $[Ni_6Se_4Cp'_5]$, $[Ni_{15}Se_{10}(CO)_3Cp'_8]$, and $[Ni_{15}Se_{10}(CO)Cl_2Cp'_8]$ (C) 1390
- $[\{Ph_3PCH_2C(CF_3)_2O\}NiH(PCy_3)]$: support for a nickel hydride mechanism in ethene oligomerization (C) 1011
- The bioinorganic chemistry of nickel (B) 632

Niobium compounds, A new oxygen sensor based on the thermoelectric power of solid solutions of Nb_2O_5 and Bi_2O_3 (C) 75
- $K_4Al_2Nb_{11}O_{20}F$—the missing link in cluster condensation (C) 1662
- Self-reduction of $[Ph_4P][Nb(SCH_2CH_2CH_2S)_3]$ with formation of a Nb_2^{IV} complex (C) 98
- Stabilization of niobium(0) and tantalum(0) in mixed metal clusters containing silver atoms (C) 471

Nirile imines, A distillable *C*- and *N*-silylated nirile imine (C) 1250

Nitrides, LiCaN and Li_4SrN_2, derivatives of the fluorite and lithium nitride structures (C) 1702
- Synthesis and structure of $[\{(\eta^5\text{-}C_5Me_5)Ti(NH)\}_3N]$, a titanium imide nitride (C) 754

Nitrogen compounds, A distillable *C*- and *N*-silylated nirile imine (C) 1250
- *N*-Arylation and *N*,*N*-dibenzylation of coordinated N_2 with organic halides; differences in the reactivity of *trans*-$[Mo(N_2)_2(Me_8[16]aneS_4)]$ and its phosphane analogues (C) 1040
- Azonia derivates of arenes: synthesis and properties of 10c-azoniafluoranthene (C) 588
- 2,3-Dihydro-1*H*-1,2,4-triazol-1-yls, a novel group of stable radicals (C) 491
- N-analogues of metal acetylacetonates: bis(1,2,6,7-tetracyano-3,5-diimino-3,5-dihydro-pyrrolizinido)metal(II), (metal = Fe, Ni, Cu, Zn); crystal structure of the copper derivative (C) 1049
- Nitrile oxides, nitrones and nitronates in organic synthesis. Novel strategies in synthesis (B) 227
- The first tricyclic diaziridines—a simple synthetic route (C) 1381
- 1,3,5-Trithia-2,4,6-triazapentalenyl—a stable sulfur-nitrogen radical (C) 920

NMR imaging, Biomedical magnetic resonance imaging. Principles, methodology and applications (B) 791

NMR spectroscopy, A sensitive spectroscopic probe for monitoring changes in the coordination sphere of titanium: eight-membered dioxatitanacycles and their organometallic derivatives (C) 66
- A synthetic molecular trefoil knot (C) 189
- Are lithiosulfones configurationally stable? (C) 1025, 1282
- Biomedical magnetic resonance imaging. Principles, methodology and applications (B) 791
- Biosynthetic studies on antibiotics (R) 146
- Complete identification of C-C connectivities by two-dimensional INADEQUATE NMR spectroscopy with composite pulses (C) 738
- High resolution solid state NMR of quadrupolar nuclei (AM) 1429
- Investigation of the tautomerism of ^{15}N-labeled hydroporphyrins by dynamic NMR spectroscopy (C) 76
- ^{15}N CPMAS NMR study of the structure and reactions of phthalocyaninato-polysiloxane and its precursors in the solid state (AM) 1743
- ^{15}N CPMAS NMR study of the structure of polyaniline (AM) 1741
- Nuclear magnetic resonance (B) 1764
- On the structure of eumelanins: identification of constitutional patterns by solid-state NMR spectroscopy (C) 741
- Pentacoordinated elements of the 4th main group with four organic residues (C) 918
- Synthesis of the novel ring systems 1,2,3,4-oxazadisiletidine and 1,3,4,2,5-dioxazadisilolidine (C) 54
- Structural characterization of non-oxide chalcogenide glasses by modern solid state NMR techniques (AM) 1723
- The 7-norbornadienyl cation: an NMR/IGLO validation of its ab initio structure (C) 1042
- Two-dimensional NMR methods for establishing molecular connectivity. A chemist's guide to experiment selection, performance and interpretation (B) 1071
- Visualization of chromatographic separations by NMR imaging (C) 1029

Nobel lecture, A structural basis of light energy and electron transfer in biology (Nobel lecture) (R) 848
- Drugs from emasculated hormones: the principle of syntopic antagonism (Nobel lecture) (R) 886
- Selective inhibitors of dihydrofolate reductase (Nobel lecture) (R) 879
- The photosynthetic reaction center from the purple bacterium *Rhodopseudomonas viridis* (Nobel lecture) (R) 829
- The purine path to chemotherapy (Nobel lecture) (R) 870

Noble-gas compounds, One pioneer or several pioneers? The discovery of noble-gas compounds (L) 636
- The acetonitrile(pentafluorophenyl)xenon(II) cation, $[MeCN-Xe-C_6F_5]^{\oplus}$: the first structural characterization of a xenon-carbon bond (C) 1506

Nonlinear optics, Polymer optical fibers and nonlinear optical device principles (AM) 1548

Nonplanar amides, Amides nonplanar solely by C-N bond rotation (C) 912

Norbornadienyl cation, The 7-norbornadienyl cation: an NMR/IGLO validation of its ab initio structure (C) 1042

Norbornanes, Si-promoted norbornyl-norpinyl rearrangements (C) 1667

Norbornenes, Double-bond geometry of norbornene: neutron diffraction measurement of a derivative at 15 K (C) 1239

Norpinanes, Si-promoted norbornyl-norpinyl rearrangements (C) 1667

Nuclear chemistry, Chemical aspects of fusion technology (R) 1
- Georg de Hevesy. 1885–1966. Festschrift (B) 1536

Nucleic acids, Sequence dependence of template-directed syntheses of hexadeoxynucleotide derivatives with 3′–5′ pyrophosphate linkage (C) 1235

Oligomerizations, Asymmetric oligomerization of propene and 1-butene with a zirconocene/alumoxane catalyst (C) 1216
- Hydrooligomerization of alkynes, a new catalytic reaction promoted by $[Co(py)_6]^{\oplus}$ in the presence of H_2 (C) 1009
- $[\{Ph_3PCH_2C(CF_3)_2O\}NiH(PCy_3)]$: support for a nickel hydride mechanism in ethene oligomerization (C) 1011
- Stereoregular oligomerization by repetitive Diels–Alder reactions (C) 1258

Optics, Conference report (AM) 1584
- Electronic structure and optical properties of semiconductors (B) 1441
- Organic materials for non-linear optics (B) 1760
- Photorefractive materials and their applications I: fundamental phenomena (B) 1440

- Substituted silane polymers—a new look at some old materials (AM) 1733

Organic chemistry, Organic high pressure chemistry (B) 1535

Organic conductors, A new route to highly conducting polyenes (AM) 1745
- Binary alloys of 2,5-disubstituted DCNQI radical anion salts of copper and their electrical conductivity (C) 1245
- Functionalized conducting polymers—towards intelligent materials (AM) 513
- One-dimensional conductors (Springer series in solid state science 72) (B) 526
- Poly-[*N*,*N*-(1,4-divinylbenzene-β,β'-diyl)-4,4'-bipyridinium dibromide], a novel conducting viologen polymer (AM) 807
- Radical anion salts of naphthalenetetracarboxylic acid derivatives—a novel class of electrically conducting compounds (C) 483
- Spatially selective conducting patterns in transparent films derived from ladder type polymers (AM) 1569
- Superconductivity at 7.5 K and ambient pressure in polycrystalline pressed samples of β_p-(BEDT-TTF)$_2$I$_3$ (AM) 953

Organic synthesis, A synthetic molecular trefoil knot (C) 189
- Art in organic synthesis (B) 1539
- Nitrile oxides, nitrones and nitronates in organic synthesis. Novel strategies in synthesis (B) 227
- Organoselenium chemistry I. Functional group transformations (B) 227
- The dienolate of (*R*)-2-*tert*-butyl-6-methyl-1,3-dioxin-4(2*H*)-one—a chiral acetoacetic ester d^4-reagent (C) 472

Organometallic chemistry, An overview (B) 100
- Principles of organometallic chemistry (B) 934

Osmium compounds, Directed synthesis of trinuclear hydrocarbon-bridged complexes such as [(OC)$_5$ReCH$_2$CH$_2$-Os(CO)$_4$CH$_2$CH$_2$Re(CO)$_5$] (C) 1705
- Inter- and intramolecular photochemical C-H activation in matrices and in solution with (η^6-arene)(carbonyl)osmium complexes (C) 1690

Oxalic acid orthoamides, Photochemical formation of a stable oxalic acid orthoamide with a propellane structure (C) 338

Oxazolidines, 3-Arylsulfonyloxazolidines as chiral templates: asymmetric synthesis of 2-substituted 2-hydroxycyclohexanecarbaldehydes from 2-hydroxymethylenecyclohexanone (C) 67

Oxazolidinones, (4*RS*,5*R*)- and (4*RS*,5*S*)-4-Methoxy-5-methyloxazolidin-2-one derivatives of threonine—interesting chiral amidoalkylating reagents (C) 1399

Oxidations, Highly selective oxidations of Fe(CO)$_3$-cyclohexadiene complexes: synthesis of 4b,8a-dihydrocarbazol-3-ones and the first total synthesis of carbazomycin A (C) 223
- Spontaneous oxidation and in-situ polymerization of pyrrole in channels of the three-dimensional coordination polymer [(Me$_3$Sn)$_3$Fe^{III}(CN)$_6$]$_\infty$ (C) 1265

Oxygen compounds, Trigonal-bipyramidal lanthanoid complexes with interstitial oxygen atoms (C) 1033

Oxygen sensors, A new oxygen sensor based on the thermoelectric power of solid solutions of Nb_2O_5 and Bi_2O_3 (C) 75

Pagodane route, The pagodane route to dodecahedranes: chemistry and structure of bissecododecahedranes (C) 298
- The pagodane route to dodecahedranes: polyfunctionalized homologous dodecahedranes and dodecahedrenes (C) 310
- The pagodane route to dodecahedranes: polyfunctionalized pentagonal dodecahedranes and dodecahedrenes (C) 305
- The pagodane route to dodecahedranes: 4,9,14,19-tetrasubstituted [1.1.1.1]pagodanes by intramolecular functionalization (C) 303
- The pagodane route to dodecahedranes: total synthesis and chemistry of 4,9,14,19-tetrasubstituted [1.1.1.1]pagodanes (C) 300

Palladium compounds, A novel approach to ferroelectric liquid crystals: the first organotransition metal compound displaying this behavior (C) 1065
- Complexes with an η^2-μ_2-SiO bridge. Structure of the bimetallic complex [Fe(CO)$_3${μ-Si(OMe)$_2$-OMe}(μ-dppm)PdCl] (*Fe-Pd*) (C) 1361
- Indigo-metal complexes: synthesis and structure of Pd^{II} and Pt^{II} compounds containing the anions of indigo and octahydroindigo as mono- and bis-chelate ligands (C) 1529
- Pd clusters containing As and PPh$_3$ ligands: the structures of [Pd$_9$As$_6$(PPh$_3$)$_8$], [Pd$_2$(As$_2$)(PPh$_3$)$_4$], and [Pd$_{20}$As$_{12}$(PPh$_3$)$_{12}$] (C) 1665

Parat, PARAT. Index of acronyms and abbreviations in electrical and electronic engineering (B) 1442

Peptides, 2'-Aminomethylbiphenyl-2-carboxylic acid as component of a cyclopeptide; crystal structure and conformation in solution (C) 486
- Correlation of the dynamic behavior of *n*-alkyl ligands of the stationary phase with the retention times of paracelsin peptides in reserved phase HPLC (C) 327
- Pep5: structure elucidation of a large lantibiotic (C) 616
- Synthesis of (*S*,*S*)-diisotyrosine and its incorporation in an ansa tripeptide (C) 929

Pharmaceuticals, Arzneimittel—Fortschritte 1972 bis 1985 (B) 102
- Controlled release of drugs: polymers and aggregate systems (B) 1137
- Drugs from emasculated hormones: the principle of syntopic antagonism (Nobel lecture) (R) 886
- Selective inhibitors of dihydrofolate reductase (Nobel lecture) (R) 879
- Synthesis and pharmacological properties of a novel cardioactive steroid (C) 1359
- The purine path to chemotherapy (Nobel lecture) (R) 870

Phenalenol, 1-Phenalenol: isolation and disproportionation (C) 1268

Phosphaalkenes, A new route to phosphaalkenes (C) 740
- Phosphaalkenes from monochlorophosphanes and alkylidenetriphenyl Phosphoranes (C) 1695

Phosphaalkynes, A stable amino-substituted phosphaalkyne (C) 53
- Formation of a phosphaferracyclopentadiene ring by coupling of a phosphaalkyne with two fluoromethylidyne ligands (C) 321
- Reactions of mono- and dinuclear metal-alkylidyne complexes with phosphaalkynes: C≡P and C≡Mo metathesis (C) 210
- Reductive dimerization of a phosphaalkyne with complexation to samarium (C) 445
- Tetra-*tert*-butyltetraphosphacubane: the first thermal cyclooligomerization of a phosphaalkyne (C) 1013

Phosphazenes, Synthesis and analysis of polymetallaphosphazenes (C) 493

Phospholipids, Calorimetric studies of biopolymers and aggregates of phospholipids (R) 981
- Chain-substituted lipids as substrates for phospholipase A$_2$ (C) 1218

Phosphorus compounds, A tetraborylphosphonium ion with a spiroheterocyclic structure (C) 217
- [Bis(diisopropylamino)phosphino]trimetylsilylcarbene: a stable nucleophilic carbene (C) 621
- tBu$_2$P-P=PBrtBu$_2$ · LiBr and formation of tBu$_2$P-P (C) 315
- (tBuSiP)$_4$—the first silaphosphacubane (C) 339, 502
- 2-Chloro-2*H*-phosphirene/1-chloro-1*H*-phosphirene isomerization by [1,3]-chlorine shift (C) 225
- Dictionary of organophosphorus compounds (B) 1716
- Generation and ionization pattern of the iso(valence)electronic compounds ClP(=O)$_2$ and ClP(=S)$_2$ (C) 1373
- Generation, stereochemistry, and molecular dynamics of a 1,3-bis(phosphonio)propenide cation (C) 1700
- K$_4$P$_3$, a compound containing the radical anion $P_3^{4\ominus}$ (C) 56
- [P$_4$Aryl$_6$][Me$_3$SnF$_2$]$_2$ (Aryl = 2,6-(MeO)$_2$C$_6$H$_3$): an unusual ion pair consisting of a planar 2,4-diphospha-1,3-diphosphoniacyclobutane dication and the difluorotrimethylstannate anion (C) 1507
- Phosphaalkenes from monochlorophosphanes and alkylidenetriphenyl Phosphoranes (C) 1695
- Phosphanorbornadienes as ligands in the transition metal-catalyzed synthesis of fine chemicals (C) 500
- Phosphonioboratoacetylenes: C$_2$ stabilized by donor and acceptor molecules (C) 1219
- Polycyclic polyphosphorus hydrocarbons (C) 900
- Synthesis and crystal structure of a phospholyl anion (C) 1367
- Synthesis and structure of a 1*H*-Diphosphirene (C) 1673
- Synthesis, characterization, and complexation of an unusual P$_2$Si$_2$ bicyclobutane with butterfly-structure: 2,2,4,4-tetramesityl-1,3-diphospha-2,4-disilabicyclo[1.1.0]butane (C) 1038
- Synthesis, structure, and reactivity of a 1,3-diphospha-2-silaallyl anion (C) 751
- Synthesis, structure, and reactivity of diphosphenes having a *cis*-configuration (C) 215
- Water elimination from phosphorus-oxygen compounds: the formation of 2-phosphapropene by thermolysis of dimethylphosphane oxide (C) 911

Phosphorus homocycles, P$_6$(C$_5$Me$_5$)$_2$, a tricyclic polyphosphane (C) 600
- P$_{14}$*i*Pr$_4$—the first hexacyclic organophosphane (C) 1231
- Sodium pentaphosphacyclopentadienide (NaP$_5$) and the pentaphosphacyclopentadienide ion ($P_5^\ominus$): theoretical predictions of molecular structures, infrared and Raman spectra (C) 485
- Tetra-*tert*-butyltetraphosphacubane:

the first thermal cyclooligomerization of a phosphaalkyne (C) 1013
- Tetraphosphacyclobutadiene as complex ligand (C) 1355
Photochemistry, Efficient photoinduced intramolecular energy transfer in an oblique bis-porphyrin system (C) 593
- Ethynol: photochemical generation in an argon matrix, IR spectrum, and photoisomerization to ketene (C) 181
- Formation of 2,4,4-trimethylthiete by photodecarbonylation of 3,3,5-trimethyl-2(3*H*)-thiophenone (C) 1499
- Inter- and intramolecular photochemical C-H activation in matrices and in solution with (η^6-arene)(carbonyl)osmium complexes (C) 1690
- Light-sensitive molecular building blocks with electron transfer activity: synthesis and properties of a photochemically switchable, dicyanovinyl-substituted furan (C) 1494
- Photocycloadditions of benzvalene (C) 601
- Photochemical formation of a stable oxalic acid orthoamide with a propellane structure (C) 338
- Regiochemistry of the intramolecular [2+2]-photocycloaddition of cyclohexenone to vinyl ethers (C) 925
- The beginnings of organic photochemistry (R) 1193
Photochromism, Perspectives in photochromism: a novel system based on the 1,5-electrocyclization of heteroanalogous pentadienyl anions (R) 413
Photoelectron spectroscopy, all-*cis*-1,4,7,10-cyclododecatetraene—X-ray structure analysis and photoelectron spectrum (C) 1379
- Diisocyanogen or isocyanogen? (C) 761
- Fundamentals of silicon chemistry: molecular states of silicon-containing compounds (R) 1627
- Generation and ionization pattern of the iso(valence)electronic compounds $ClP(=O)_2$ and $ClP(=S)_2$ (C) 1373
- Methylboron oxide, $H_3C-B\equiv O$ (C) 88
- Structure, deformation electron densities, photoelectron spectra, and reactivity of 3,4-dihydro-1*H*-cyclobuta[*a*]cyclopropa[*d*]benzene (C) 206
- The first PE-spectroscopic investigations of lithium, sodium, and potassium *tert*-butoxide (C) 895
Photography, Image enhancement—chemical, digital, visual (R) 1601
Photosensitizers, Water-soluble porphyrin diglycosides with photosensitizing properties (C) 1519
Photosynthesis, A structural basis of light energy and electron transfer in biology (Nobel lecture) (R) 848
- Synthesis, structure and magnetic properties of a dinuclear manganese(II) complex with one μ-aqua and two μ-carboxylato bridges (C) 1365
- The photosynthetic reaction center from the purple bacterium *Rhodopseudomonas viridis* (Nobel lecture) (R) 829
Phthalocyaninatopolysiloxane, ^{15}NCPMAS NMR study of the structure and reactions of phthalocyaninatopolysiloxane and its precursors in the solid state (AM) 1743
Physical chemistry, Angular momentum: understanding spatial aspects in chemistry and physics (B) 932
Pigments, Industrielle Organische Pigmente. Herstellung, Eigenschaften, Anwendung (B) 1073
Platinum, A joint structural characterization of colloidal platinum by EXAFS and high-resolution electron microscopy (C) 590
Platinum compounds, A novel type of anionic cluster containing a Pt_4Ag_2 core (C) 748
- Agostic-type gold ligand and incipient μ_3-PPh_2 coordination in the $Au_2Pt_2P_6$ "hammock" skeleton of the cluster $[Au_2Pt_2(\mu\text{-}PPh_2)_2(PPh_3)_4][PF_6]_2$ (C) 923
- Complexation of a novel organoytterbium(II) ligand with dimethylplatinum(II): crystal structure of the resulting heterobimetallic complex (C) 1370
- Coupling of epoxides to Pt^{II}-complexes with carbon dioxide and the structure of a cyclic metallacarbonate (C) 767
- Indigo-metal complexes: synthesis and structure of Pd^{II} and Pt^{II} compounds containing the anions of indigo and octahydroindigo as mono- and bis-chelate ligands (C) 1529
- Platinum complexes of the anions $Se_2N_2^{2\ominus}$ and $Se_2N_2H^{\ominus}$; X-ray structure analysis of $[Pt(Se_2N_2H)(PMe_2Ph)_2]Cl$ (C) 1047
- $Pt_{309}Phen^{*}_{36}O_{30\pm10}$, a four-shell platinum cluster (C) 778
Polyacetylenes, Highly conjugated, substituted polyacetylenes via the ring-opening metathesis polymerization of substituted cyclooctatetraenes (AM) 1571
Polyaniline, ^{15}N CPMAS NMR study of the structure of polyaniline (AM) 1741
Polycycles, A polyhedral oligogermane: 4,8-dibromo-octa-*tert*-butyltetracyclo[3.3.0.0^{2,7}.0^{3,6}]octagermane (C) 198
- Diels-Alder adducts on the *b* side of naphthalene: rapid cycloreversion of *o*-quinodimethanes (C) 1353
- 4,6-Dimethylenetricyclo[3.3.0.0^{3,7}]octane-2-one and 2,4,6-trimethylenetricyclo[3.3.0.0^{3,7}]octane (C) 1525
- From tetraspiranes to bispropellanes (C) 94
- From the bicyclo[3.3.0]octane framework to multiply bridged [12]annulenes and semibullvalenes (C) 1343
- $[(Me_3Si)_2CHGe]_6$, the first hexagermaprismane (C) 55
- Polycyclic polyphosphorus hydrocarbons (C) 900
- Synthesis of a rigid electron-donor/acceptor compound—evidence for intramolecular charge separation (C) 619
- Tri-*tert*-butyl(trimethylsilyl)tricyclo-[1.1.0.0^{2,4}]butane—a second tetrahedrane derivative (C) 1050
Polymerization, Encapsulation of polypyrrole chains in zeolite channels (C) 1692
- Highly conjugated, substituted polyacetylenes via the ring-opening metathesis polymerization of substituted cyclooctatetraenes (AM) 1571
Polymers, A new route to highly conducting polyenes (AM) 1745
- A polymeric technetium compound of the composition $[Tc_2O_3(C_5Me_5)]_n$ (C) 1055

- Probing changes in the structure and performance of a lithium nickel oxide catalyst by in situ X-ray diffraction during the high-temperature oxidative coupling of methane (AM) 808
- Reaction mechanisms in heterogeneous catalysis; C-H activation as a case study (R) 135
- Regiochemistry of the intramolecular [2+2]-photocycloaddition of cyclohexenone to vinyl ethers (C) 925
- Revision and modification of the traditional mechanism of C-H/C-C activation by "naked" transition-metal ions (C) 607
- The stereoselectivity of intermolecular free radical reactions (R) 969
- The mechanism of the Dötz reaction: chromacyclobutenes by alkyne-carbene coupling? (C) 908
- Water elimination from phosphorusoxygen compounds: the formation of 2-phosphapropene by thermolysis of dimethylphosphane oxide (C) 911

Reagents, A new coordinating chiral lithium amide (C) 1044
- A new synthesis of key intermediates for the preparation of 5,6-DiHETE and lipoxin A_4 (C) 755
- 2-*O*-benzylglyceraldehyde: a synthetic building block available in both enantiomeric forms and configurationally stable owing to rapid oligomerization (C) 469
- Chiral building blocks for the synthesis of triquinane sesquiterpenes: derivatives of 2-methylbicyclo[3.3.0]octan-3-ol from catalpol (C) 447
- $[H_2C(CH_2)_5NLi]_6$, the first cyclized lithium amide ladder: synthesis and structure of hexamethyleneimidolithium (C) 1241
- (4*RS*,5*R*)- and (4*RS*,5*S*)-4-Methoxy-5-methyloxazolidin-2-one derivatives of threonine—interesting chiral amidoalkylating reagents (C) 1399
- Name reactions and reagents in organic synthesis (B) 1538
- Synthesis and structure of $[(C_5H_5)_2TiS_4AsCH_3]$—a new reagent for the synthesis of sulfur-rich heterocycles (C) 1269
- The dienolate of (*R*)-2-*tert*-butyl-6-methyl-1,3-dioxin-4(2*H*)-one—a chiral acetoacetic ester d^4-reagent (C) 472

Rearrangements, From 2,5-dihydropyrazines to 2*H*-1,4-diazepines and from benzodihydroarenes to benzocyclohep-

tene derivatives, structural variants of the antidepressant protriptyline (C) 613
- From tetraspiranes to bispropellanes (C) 94
- Insertion of $Cr(CO)_3$ into $As_7^{3\ominus}$ to form $[As_7Cr(CO)_3]^{3\ominus}$: an inorganic nortricyclane-to-norbornadiene conversion (C) 1032
- Iron-mediated diastereoselectivespiroannelation to the spiro[1,2,3,4tetrahydroquinoline-4,1'-cyclohexane] system and a novel rearrangement to 2,3-dihydroindole derivatives (C) 1678
- Si-promoted norbornyl-norpinyl rearrangements (C) 1667

Redox systems, A pyrrolophanediene-porphycene redox system (C) 1655
- Stack-type redox systems: synthesis via repeated carbanion alkylation and electron transfer studies (C) 1531

Reductions, Enantioselective reduction of α,β-unsaturated carboxylates with $NaBH_4$ and catalytic amounts of chiral cobalt semicorrin complexes (C) 60
- Highly reduced porphyrins (C) 604
- $LiBH_4(NaBH_4)/Me_3SiCl$, an unusually strong and versatile reducing agent (C) 218
- Metal-induced reduction of sulfur dioxide to sulfur monoxide and sulfur (C) 1342
- $NaBH_4$ reduction of ketones in the solid state (C) 320
- Self-reduction of $[Ph_4P][Nb(SCH_2CH_2CH_2S)_3]$ with formation of a Nb_2^{IV} complex (C) 98

Rhenium compounds, Alkyl and alkylidyne complexes of rhenium (C) 334
- Directed synthesis of trinuclear hydrocarbon-bridged complexes such as $[(OC)_5ReCH_2CH_2Os(CO)_4CH_2CH_2Re(CO)_5]$ (C) 1705

Rhodium compounds, Amide bond scission via bifunctional activation with bimetallic porphyrin systems with two different metal centers (C) 921
- One-dimensional metal chains in a chiral environment—the crystal structure of helical bis(dicarbonylrhodium(I))-3,3'-hexafluoroglutarylbis-(1*R*)-camphorate (C) 1019
- Selective hydrogenation of esters to alcohols with a catalyst prepared from Rh_2O_3, $Sn(n\text{-}C_4H_9)_4$, and SiO_2: evidence for site isolation (C) 347

Rotation, Angular momentum: understanding spatial aspects in chemistry and physics (B) 932

Ruthenium compounds, The novel complex $[LRu^{IV}(\mu\text{-}O)_3Ru^{IV}L][PF_6]_2 \cdot H_2O$—a molecular section of the structures of $BaRu^{IV}O_3$(high-pressure phase) and $Ba_{5/6}Sr_{1/6}Ru^{IV}O_3$ (C) 763

Sandwich complexes, $(C_4Me_4NBH_3)_2Fe$—a metal complex isosteric with decamethylferrocene with characteristic metallocene disorder (C) 342
- Hexaarsabenzene as complex ligand (C) 212
- Pronounced anion dependence of valence detrapping temperature in mixed-valence 1',1'''-disubstituted biferrocenium salts (C) 1388
- Reaction of decamethylsilicocene with sulfur, selenium, and tellurium: from a p_π-p_π system to new heterocycles (C) 1518
- Tetraphosphacyclobutadiene as complex ligand (C) 1355
- The 30-electron rule for triple-decker complexes—vanadium, niobium and tantalum complexes as illustrative examples (C) 319
- Triple-decker complexes as intermediates in ring-ligand transfers (C) 737

Scanning Tunneling Microscopy, Imaging organic molecules with the scanning tunneling microscope (AM) 1127
- Surface chemistry with the scanning tunneling microscope (AM) 117

Selenium compounds, bromoselenates(II,IV), a novel type of mixed valence compounds (C) 187
- Counterion dependent structural diversity in silver polyselenides; structures of the new complex anions $[Ag(Se_4)]_4^{4\ominus}$, $[Ag(Se_5)]_n^{n\ominus}$ and $[Ag_4(Se_4)_3]^{2\ominus}$ (C) 1513
- Organoselenium chemistry I. Functional group transformations (B) 227
- Platinum complexes of the anions $Se_2N_2^{2\ominus}$ and $Se_2N_2H^{\ominus}$; X-ray structure analysis of $[Pt(Se_2N_2H)(PMe_2Ph)_2]Cl$ (C) 1047
- Selenium-catalyzed synthesis of *S*-alkyl thiocarbamates from amines, carbon monoxide, sulfur, and alkyl halides (C) 452
- Ta_2Se: a tantalum-rich selenide with a new layer structure (C) 1660
- The thiophene analogue of porphyrin: tetrathiaporphyrin dication (C) 1651

Semibullvalenes, From the bicyclo[3.3.0]-octane framework to multiply bridged [12]annulenes and semibullvalenes (C) 1343

Semiconductors, Electronic structure and optical properties of semiconductors (B) 1441
- Low temperature deposition of a CaF_2 insulator layer on GaAs (AM) 1581
- Materials issues in electronic systems (AM) 640
- Metal organic chemical vapor deposition (MOCVD) perspectives and prospects (AM) 1110
- Optical nonlinearities and instabilities in semiconductors (B) 672
- Semiconductor electrodes (B) 386
- Silicon-nitride in electronics (B) 1441
- Single-source III/V precursors: a new approach to gallium arsenide and related semiconductors (A) 1208
- Structural characterization of non-oxide chalcogenide glasses by modern solid state NMR techniques (AM) 1723
- Tailoring semiconductor crystals to atomic dimensions (AM) 1098

Semi-empirical calculations, Generation and ionization pattern of the iso(valence)electronic compounds $ClP(=O)_2$ and $ClP(=S)_2$ (C) 1373
- Mechanism of the hetero-Diels–Alder reaction of oxadienes and alkenes: calculation of the acrolein/ethene system (C) 1371
- Tetrakis(dimethylamino)ethylene dication: two CC singly bonded and almost perpendicularly twisted $((CH_3)_2N)_2C^{\oplus}$ carbenium ions (C) 1684
- Tetraphenylethylenedisodium: the band structure of the CC singly bonded, twisted $(C_6H_5)_2C^{\ominus}$ carbanions (C) 1685

Sensors, A new oxygen sensor based on the thermoelectric power of solid solutions of Nb_2O_5 and Bi_2O_3 (C) 75
- Advanced zeolite materials science (AM) 359
- Functionalized conducting polymers—towards intelligent materials (AM) 513
- Polymer benzo[15]crown-5 complexes as sensor materials for solvent vapors—aromatic halogenated hydrocarbons and polar solvents (AM) 813
- Structure-directed synthesis of new organic materials (AM) 1103

Separations, Synthesis and separations using functional polymers (B) 383

Sesquiterpenes, Chiral building blocks for the synthesis of triquinane sesquiterpenes: derivatives of 2-methylbicyclo[3.3.0]octan-3-ol from catalpol (C) 447

Silanediyls, Disilene *versus* silanediyl ("silylene") additions to CN and NCO bonds (C) 95, 228

Silicon compounds, A compound containing hexacoordinated silicon—a model for nucleophilic attack on anionic, pentacoordinated silicon species? (C) 489
- A silicogermanate with a Si:Ge ratio ≥ 2—an MFI zeolite of novel composition (C) 81
- An electron-rich [4]radialene (C) 1663
- $(t\text{BuSiP})_4$—the first silaphosphacubane (C) 339, 502
- *catena*-Poly[bis-μ-(*o*-oxyphenyleneoxy)-silicon]: crystal structure of the orthosilicate of catechol (C) 623
- Dimethyldioxasilirane (C) 898
- Disilene *versus* silanediyl ("silylene") additions to CN and NCO bonds (C) 95, 228
- Formation and reactivity of silicon-sulfur and silicon-selenium double bonds. The first X-ray structure of a silanethione (C) 1016
- Fundamentals of silicon chemistry: molecular states of silicon-containing compounds (R) 1627
- 1,2,9,10,17,18-Hexasila[2.2.2](1,3,5)cyclophane, a cage-like phane containing three Si-Si units (C) 757
- High-performance silicon nitride materials (AM) 1560
- Identification of $[(OC)_4Fe{=}Si(CH_3)_2 \cdot \{(H_3C)_2N\}_3PO]$ as intermediate in the formation of polysilanes from $(H_3C)_2SiCl_2$ and $[Na_2Fe(CO)_4]$ (C) 203
- ^{15}N CPMAS NMR study of the structure and reactions of phthalocyaninato-polysiloxane and its precursors in the solid state (AM) 1743
- Siloxane copolymers with laterally and terminally attached mesogenic side chains (AM) 1120
- Substituted silane polymers—a new look at some old materials (AM) 1733
- Surprising reactions of decamethylsilicocene with π-systems of the type $X{=}C{=}Y$ (C) 762
- Synthesis, characterization, and complexation of an unusual P_2Si_2 bicyclobutane with butterfly-structure: 2,2,4,4-tetramesityl-1,3-diphospha-2,4-disilabicyclo[1.1.0]butane (C) 1038
- Synthesis of the novel ring systems 1,2,3,4-oxazadisiletidine and 1,3,4,2,5-dioxazadisilolidine (C) 54

Silver compounds, A chiral Ag^I-coordination polymer with a polydentate chiral ligand; crystal structure of the 1:1 complex of CF_3SO_3Ag and *N*-[*N*-(5-Methylthenylidene)-L-methionyl]histamine (C) 1698
- A novel type of anionic cluster containing a Pt_4Ag_2 core (C) 748
- Amide bond scission via bifunctional activation with bimetallic porphyrin systems with two different metal centers (C) 921
- Counterion dependent structural diversity in silver polyselenides; structures of the new complex anions $[Ag(Se_4)]_4^{4\ominus}$, $[Ag(Se_5)]_n^{n\ominus}$ and $[Ag_4(Se_4)_3]^{2\ominus}$ (C) 1513
- Stabilization of niobium(0) and tantalum(0) in mixed metal clusters containing silver atoms (C) 471

Sol-gel processing, Conference report (AM) 1437

Solid solutions, A new oxygen sensor based on the thermoelectric power of solid solutions of Nb_2O_5 and Bi_2O_3 (C) 75
– Symmetry reduction in solid solutions: a new method for materials design (AM) 377
Solid state chemistry, Conference report (AM) 1436
– Electrons in solids: an introductory survey (B) 671
– High resolution solid state NMR of quadrupolar nuclei (AM) 1429
– $K_4Al_2Nb_{11}O_{20}F$—the missing link in cluster condensation (C) 1662
– LiCaN and Li_4SrN_2, derivatives of the fluorite and lithium nitride structures (C) 1702
– $NaBH_4$ reduction of ketones in the solid state (C) 320
– Solids and surfaces: a chemist's view of bonding in extended structures (B) 1070
– Ta_2Se: a tantalum-rich selenide with a new layer structure (C) 1660
– The crystal chemistry of high-temperature oxide superconductors and materials with related structures (R) 1472
– The influence of packing effects on the solid-state fluorescence of diketopyrrolopyrroles (C) 478
Solid state physics, Gauge theory—a new outlook on solid state dynamics (AM) 1124
Solutions, ions in solution: basic principles of chemical interactions (B) 103
Solvent effects, Solvents and solvent effects in organic chemistry (B) 104
Spectroscopy, spectroscopy of surfaces (B) 963
– Theory and methods of calculation of molecular spectra (B) 1281
Spiro compounds, A tetraborylphosphonium ion with a spiroheterocyclic structure (C) 217
– From tetraspiranes to bispropellanes (C) 94
– Iron-mediated diastereoselective spiroannelation to the spiro[1,2,3,4tetrahydroquinoline-4,1′-cyclohexane] system and a novel rearrangement to 2,3-dihydroindole derivatives (C) 1678
Stereochemistry, Retention of configuration in the non-Darwinian evolution of cytochrome c (C) 71
– Stereochemical applications of gas-phase electron diffraction. Part A and B (B) 1534
Stereoselectivity, The stereoselectivity of intermolecular free radical reactions (R) 969
Sterepolide, The effect of acetylene substituents on a Pd^{II}-catalyzed cycloisomerization. Total synthesis of (−)-sterepolide and assignment of absolute stereochemistry (C) 1502
Steroids, Side-chain homologues of 20-hydroxyecdysone: synthesis, configurational assignment, and biochemical characterization (C) 1515
– Stereo- and regiospecific 6-*endo*-*trig*-cyclization of aryl radicals, an entry to novel progesterone-antagonists of the androstane series (C) 773
– Synthesis and pharmacological properties of a novel cardioactive steroid (C) 1359
Sterols, Sterol biosynthesis inhibitors. Pharmaceutical and agrochemical aspects (B) 1539
Stiff-chain polymers, 2-Pentyltricyclo-[1.1.1.$0^{1,3}$]pentane and its homopolymer, a soluble poly([1.1.1]propellane) (C) 456
– Stiff-chain polymers—structure, phase behavior, and properties (R) 253
Stilbenes, Bis-stilbene systems: reduction to the tetraanions (C) 904
Strained rings, Azaoctabisvalenes (C) 1345
– Bridged *cis*-Tris-σ-homobenzenes: Heterodiademanes (C) 1351
– 4,6-Dimethylenetricyclo[3.3.0.$0^{3,7}$]octane-2-one and 2,4,6-trimethylenetricyclo[3.3.0.$0^{3,7}$]octane (C) 1525
– Shortened C-C bonds in coupled bicyclo[1.1.0]butanes (C) 473
– Stabilized *cis*-Tris-σ-homobenzenes: syntheses, [$\sigma2+\sigma2+\sigma2$] cycloreversions (C) 1348
– Structure, deformation electron densities, photoelectron spectra, and reactivity of 3,4-dihydro-1*H*-cyclobuta[*a*]cyclopropa[*d*]benzene (C) 206
– Synthesis and structure of a 1*H*-Diphosphirene (C) 1673
– Synthesis, characterization, and complexation of an unusual P_2Si_2 bicyclobutane with butterfly-structure: 2,2,4,4-tetramesityl-1,3-diphospha-2,4-disilabicyclo[1.1.0]butane (C) 1038
– Tri-*tert*-butyl(trimethylsilyl)tricyclo-[1.1.0.$0^{2,4}$]butane—a second tetrahedrane derivative (C) 1050
– Unusual geometry of a sterically congested analogue of $(CH)_5^{\oplus}$ (C) 1232
– Very short C—C single bonds and their origin. The central bond length in bitetrahedryl (C) 1226
Strontium compounds, LiSrN—a three dimensional structural arrangement of corner and edge sharing orthorhombic bipyramids, $NLi_{2/2}Sr_{4/4}$ (C) 201
Structure elucidation, Anion coordination and Cl−H···Cl bridges in the low-melting poly(hydrogen chloride) $Me_3N \cdot 5HCl$ (C) 1697
– *N*-Cesiocarbazole · pmdta and *N*-potassiocarbazole · pmdta (PMDTA = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine). Cation size and multihapto bonding (C) 1224
– Complete identification of C-C connectivities by two-dimensional INADEQUATE NMR spectroscopy with composite pulses (C) 738
– all-*cis*-1,4,7,10-cyclododecatetraene—X-ray structure analysis and photoelectron spectrum (C) 1379
– Do any AB_n molecules have anomalous shapes? ν_3 of TiF_4 and TiF_3 and their relevance to the shape of TiF_2 (C) 313
– Double-bond geometry of norbornene: neutron diffraction measurement of a derivative at 15 K (C) 1239
– $K_4Al_2Nb_{11}O_{20}F$—the missing link in cluster condensation (C) 1662
– LiCaN and Li_4SrN_2, derivatives of the fluorite and lithium nitride structures (C) 1702
– Organic dications: gas phase experiments and theory in concert (A) 1321
– $[P_4Aryl_6][Me_3SnF_2]_2$ (Aryl = 2,6-$(MeO)_2C_6H_3$): an unusual ion pair consisting of a planar 2,4-diphospha-1,3-diphosphoniacyclobutane dication and the difluorotrimethylstannate anion (C) 1507
– Structure of anodic coatings on aluminum (AM) 951
– Ta_2Se: a tantalum-rich selenide with a new layer structure (C) 1660
– The acetonitrile(pentafluorophenyl)xenon(II) cation, $[MeCN-Xe-C_6F_5]^{\oplus}$: the first structural characterization of a xenon-carbon bond (C) 1506
– Two-dimensional NMR methods for establishing molecular connectivity. A chemist's guide to experiment selection, performance and interpretation (B) 1071
– X-ray structure analysis of α-lithiophenylacetonitrile · lithium diisopropylamide · 2 tetramethylethylenediamine—a "quasi-dianion complex" (C) 1392
Studies in organic chemistry, Preparative acetylenic chemistry (B) 631
Studies in physical and theoretical chemistry, kinetics of electrochemical metal dissolution (B) 935
– Computational chemistry. An emphasis on practical calculations (B) 1071

Sulfenes, Bis(trifluoromethyl)sulfene $(CF_3)_2C=SO_2$, isolated as adduct (C) 221
Sulfur compounds, Alkylidene sulfur difluorides: $F_5S(F_3C)C=SF_2$ and $(F_3C)_2C=SF_2$. Synthesis, structure, and structure predictions (C) 769
– 3,3′:4,4′-Bis(thieno[2,3-*b*]thiophene): a novel fused heteroarene (C) 1222
– Bis(trifluoromethyl)sulfene $(CF_3)_2C=SO_2$, isolated as adduct (C) 221
– Dithia dications from cyclic and acyclic precursors by gas-phase oxidation ("charge stripping") of 3e/2c-radical cations (C) 1275
– Formation and reactivity of silicon-sulfur and silicon-selenium double bonds. The first X-ray structure of a silanethione (C) 1016
– Formation of 2,4,4-trimethylthiete by photodecarbonylation of 3,3,5-trimethyl-2(3*H*)-thiophenone (C) 1499
– Metal-induced reduction of sulfur dioxide to sulfur monoxide and sulfur (C) 1342
– Modeling organic surfaces with self-assembled monolayers (AM) 506
– $S_4(CN)_8$, a blue-black high-molecular sulfur-cyanogen compound with 6π- and 8π-electron structural elements (C) 609
– Sulfur-cyanide pentafluoride SF_5NC (C) 1255
– Sulfur-pentafluoride isocyanide, SF_5NC (C) 1256
– Synthesis, structure and reactivity of sulfur-rich cyclopentadienyl-transition metal complexes: sulfur chemistry from an organometallic point of view (R) 1613
– The chemistry of sulphones and sulphoxides (B) 1070
– The thiophene analogue of porphyrin: tetrathiaporphyrin dication (C) 1651
– Thiosulfinic acids: a new class of chiral organosulfur compounds (C) 97
– TlSPh and TlS*t*Bu, Thallium(I) thiolates with novel cagelike structural units: $[Tl_5(SPh)_6]^{\ominus}/[Tl_7(SPh)_6]^{\oplus}$ and $[Tl_8(StBu)_8]$ (C) 1682
– 1,3,5-Trithia-2,4,6-triazapentalenyl—a stable sulfur-nitrogen radical (C) 920
Superconductors, aurivillius phases: a possible new class of metal oxide superconductors (C) 750
– Ferroelectricity and superconductivity (AM) 379
– Conference report (AM) 124
– Generation of complex metal oxides by aerosol processes: superconducting ceramic particles and films (AM) 794
– High resolution electron microscopy of the high-T_c superconductor $Bi_{2+x}Sr_2Ca_{1-x}Cu_2O_{8+\delta}$ (AM) 810
– Materials issues in electronic systems (AM) 640
– Studies of high temperature superconductors (B) 1592
– Superconductivity at 7.5 K and ambient pressure in polycrystalline pressed samples of β_p-$(BEDT\text{-}TTF)_2I_3$ (AM) 953

- Superconductors: the breakthrough (B) 1139
- The crystal chemistry of high-temperature oxide superconductors and materials with related structures (R) 1472

Surfaces, Addition of free Me_2Ge: to alkenes and alkynes on glass surfaces in the presence of water (C) 1028
- Conference report (AM) 1755, 523
- Imaging organic molecules with the scanning tunneling microscope (AM) 1127
- Imaging surfaces, electric charges and magnetic domains with the atomic force microscope (AM) 1578
- Metal organic chemical vapor deposition (MOCVD) perspectives and prospects (AM) 1110
- Methods of surface analysis (B) 1764
- Modeling organic surfaces with self-assembled monolayers (AM) 506
- Solids and surfaces: a chemist's view of bonding in extended structures (B) 1070
- Spectroscopy of surfaces (B) 963
- Structure of anodic coatings on aluminum (AM) 951
- Surface chemistry with the scanning tunneling microscope (AM) 117
- Tailoring semiconductor crystals to atomic dimensions (AM) 1098

Symmetry reduction, symmetry reduction in solid solutions: a new method for materials design (AM) 377

Synchrotron radiation, Introduction to synchrotron radiation (B) 791

Synthetic methods, Application of the dimethyl(phenyl)silyl group as a masked form of the hydroxy group in the synthesis of an L-*glycero*-α-D-*manno*-heptopyranoside-containing trisaccharide from the dephosphorylated inner core region of *neisseria meningitidis* (C) 1504
- Cyclizations via palladium-catalyzed allylic alkylations (R) 1173
- Gene synthesis (R) 716
- General aspects and optimization of enantioselective biocatalysis in organic solvents: the use of lipases (R) 695
- Intramolecular, stoichiometric (Li, Mg, Zn) and catalytic (Ni, Pd, Pt) metalloene reactions in organic synthesis (R) 38
- Side-chain homologues of 20-hydroxyecdysone: synthesis, configurational assignment, and biochemical characterization (C) 1515
- The stereoselectivity of intermolecular free radical reactions (R) 969

Tantalum compounds, Stabilization of niobium(0) and tantalum(0) in mixed metal clusters containing silver atoms (C) 471
- Ta_2Se: a tantalum-rich selenide with a new layer structure (C) 1660

Tartaric acid esters, Lipophilic tartaric acid esters as enantioselective ionophores (R) 1147

Tautomerization, Ethynol: photochemical generation in an argon matrix, IR spectrum, and photoisomerization to ketene (C) 181
- Investigation of the tautomerism of ^{15}N-labeled hydroporphyrins by dynamic NMR spectroscopy (C) 76

Technetium compounds, A polymeric technetium compound of the composition $[Tc_2O_3(C_5Me_5)]_n$ (C) 1055

Tellurobenzaldehyde, tellurobenzaldehyde by Staudinger-chalcogenation of the ylide benzylidenetriphenylphosphorane (C) 179

Template syntheses, A chemical approach to protein design—template-assembled synthetic proteins (TASP) (R) 535
- A synthetic molecular trefoil knot (C) 189
- 3-Arylsulfonyloxazolidines as chiral templates: asymmetric synthesis of 2-substituted 2-hydroxycyclohexanecarbaldehydes from 2-hydroxymethylenecyclohexanone (C) 67
- Carbohydrates as chiral templates: stereoselective synthesis of β-amino acids (C) 1068
- Carbohydrates as chiral templates: stereoselective tandem Mannich-Michael reactions for the synthesis of piperidine alkaloids (C) 1067
- Sequence dependence of template-directed syntheses of hexadeoxynucleotide derivatives with 3′—5′ pyrophosphate linkage (C) 1235

Terpenes, Carbocycle construction in terpene synthesis (B) 1537

Tetrahedranes, Tri-*tert*-butyl(trimethylsilyl)tricyclo[1.1.0.$0^{2,4}$]butane—a second tetrahedrane derivative (C) 1050

Textiles, Polymer modified textile materials (B) 384

Thallium compounds, Tl^I-Tl^I interactions in the molecular state—an MO analysis (C) 1688
- TlSPh and TlS*t*Bu, Thallium(I) thiolates with novel cagelike structural units: $[Tl_5(SPh)_6]^{\ominus}[Tl_7(SPh)_6]^{\oplus}$ and $[Tl_8(StBu)_8]$ (C) 1682

The chemistry of functional groups, The chemistry of sulphones and sulphoxides (B) 1070

Theoretical chemistry, theoretical chemistry en route to a theory of chemistry (R) 268
- Covalent versus dative bonds to main group metals, a useful distinction (R) 992
- Fundamentals of silicon chemistry: molecular states of silicon-containing compounds (R) 1627
- Introduction to the modern theory of metals (B) 1592
- Structure and dynamics of chiral molecules (R) 571
- The active site of glutathione reductase: an example of near transition-state structures (C) 1023
- Theory and methods of calculation of molecular spectra (B) 1281

Thermolysis, Water elimination from phosphorus-oxygen compounds: the formation of 2-phosphapropene by thermolysis of dimethylphosphane oxide (C) 911

Thin films, A novel monolithic thin-film electroluminescent device with extrinsic memory (AM) 241
- Generation of complex metal oxides by aerosol processes: superconducting ceramic particles and films (AM) 794
- Low temperature deposition of a CaF_2 insulator layer on GaAs (AM) 1581
- Monolayers and Langmuir-Blodgett multilayers of discotic liquid crystals? (AM) 1574

Thiocarbamates, Selenium-catalyzed synthesis of *S*-alkyl thiocarbamates from amines, carbon monoxide, sulfur, and alkyl halides (C) 452

Thioesters, Radical tri- and pentaanions of benzenedi- and benzenetriglyoxylate thioesters (C) 906

Thiosulfinic acids, a new class of chiral organosulfur compounds (C) 97

Tin compounds, $[P_4Aryl_6][Me_3SnF_2]_2$ (Aryl = 2,6-$(MeO)_2C_6H_3$): an unusual ion pair consisting of a planar 2,4-diphospha-1,3-diphosphoniacyclobutane dication and the difluorotrimethylstannate anion (C) 1507
- Synthesis and structure of digerma- and distannacyclobutenes (C) 603

Titanium compounds, A *trans*-dimethyl derivative of octahedral Ti^{IV}: alkylation and arylation of Ti^{IV}-Schiff base complexes (C) 64
- A sensitive spectroscopic probe for monitoring changes in the coordination sphere of titanium: eight-membered dioxatitanacycles and their organometallic derivatives (C) 66
- Do any AB_n molecules have anomalous shapes? ν_3 of TiF_4 and TiF_3 and their relevance to the shape of TiF_2 (C) 313
- Enantioselective aldol reaction of *tert*-butyl acetate using titanium-carbohydrate complexes (C) 495
- Enantioselective allylation of carbonyl compounds with titanium-carbohydrate complexes (C) 494
- Enantioselective synthesis of D-*threo*-β-hydroxy-α-amino acids with titanium-carbohydrate complexes (C) 497
- Metallocene carbene complexes and related compounds of titanium, zirconium, and hafnium (R) 397
- Structure of chloro(cyclopentadienyl)-bis(1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranos-3-*O*-yl) titanate, a novel titanium-carbohydrate complex (C) 499
- Synthesis and structure of $[(C_5H_5)_2TiS_4AsCH_3]$—a new reagent for the synthesis of sulfur-rich heterocycles (C) 1269
- Synthesis and structure of $[\{(\eta^5\text{-}C_5Me_5)Ti(NH)\}_3N]$, a titanium imide nitride (C) 754
- Vinylcarbene complexes of titanocene (C) 610

Trace analysis, Activation analysis with charged particles (B) 1072

Transition state, Mechanism of the hetero-Diels–Alder reaction of oxadienes and alkenes: calculation of the acrolein/ethene system (C) 1371
- The active site of glutathione reductase: an example of near transition-state structures (C) 1023

Triazoles, 2,3-Dihydro-1*H*-1,2,4-triazol-1-yls, a novel group of stable radicals (C) 491
- First isolation of allenyl azides (C) 1675

Trinacrene, trinacrene—a product of structure-directed synthesis (C) 1261

Tropa derivatives, Unsaturated 1,4-*cis*- and 1,4-*trans*-diaminotetradeoxycycloheptites—enantiomerically pure, polyfunctionalized tropa derivatives by enzymatic hydrolysis (C) 1253

Tungsten compounds, Alkoxide clusters of molybdenum and tungsten as templates for organometallic chemistry: comparison with carbonyl clusters of the later transition elements (R) 432
- Comments on the molecular structure and bonding in $[W_4Cl(O)(OiPr)_9]$ and $[W_4(O)(OiPr)_{10}]$. Analogies with tetranuclear carbonyl clusters (C) 1368
- Versatile modes of allene bonding in the structures of $[W_2(OtBu)_6(C_3H_4)]$, $[W_2(OtBu)_6(C_3H_4)(CO)_2]$, and $[W_2(OtBu)_6(C_3H_4)_2]$ (C) 1523

Valenes, Azaoctabisvalenes (C) 1345

Vanadium compounds, $[VO(O_2CtBu)_3]$ and $[V_6O_6(\mu\text{-}O)_4(\mu\text{-}O_2CPh)_9]$: structural characterization of a mononuclear V^V and a (2+4)-nuclear $V^{IV}V^V_5$ carboxylato complex. Models for vanadate-dependent peroxidases (C) 1221

Van der Waals molecules, Structure and properties of the cryptophane-E/$CHCl_3$ complex, a stable van der Waals molecule (C) 1246

Vapor Deposition, Conference report (AM) 1755
Vinylsulfonic acid esters, Intramolecular Diels–Alder reaction of vinylsulfonic acid esters (C) 202
Viologens, Poly-[*N*,*N*-(1,4-divinylbenzene-β,β'-diyl)-4,4'-bipyridinium dibromide], a novel conducting viologen polymer (AM) 807

Wade's rules, The 30-electron rule for triple-decker complexes—vanadium, niobium and tantalum complexes as illustrative examples (C) 319

Xenon compounds, The acetonitrile-(pentafluorophenyl)xenon(II) cation, $[MeCN-Xe-C_6F_5]^{\oplus}$: the first structural characterization of a xenon-carbon bond (C) 1506

Ylides, Tellurobenzaldehyde by Staudinger-chalcogenation of the ylide benzylidenetriphenylphosphorane (C) 179

Zeolites, A silicogermanate with a Si:Ge ratio ≥ 2—an MFI zeolite of novel composition (C) 81
- Advanced zeolite materials science (AM) 359
- Catalysis on zeolites (B) 381
- Encapsulation of polypyrrole chains in zeolite channels (C) 1692
- Location of *para*-xylene in Yb-faujasite (zeolite Y) by neutron diffraction (C) 770
- Zeolite molecular sieves (B) 964

Ziegler catalysts, The first example of an *ethylene*-selective soluble Ziegler catalyst of the zirconocene class (C) 1511
Zinc compounds, Copper(I)-promoted Michael-addition reaction of organozincs of esters, nitriles, and α-amino acids (C) 351
Zintl phases, $Na_xMg_{5-x}Ga_9$, a new intermetallic phase as a link between zintl phases and metals (C) 58
Zirconium compounds, Asymmetric oligomerization of propene and 1-butene with a zirconocene/alumoxane catalyst (C) 1216
- Dimeric $[Cp_2Zr(CH_2O)]$, a novel (η^2-formaldehyde)metal complex from carbon monoxide (C) 630
- Double stereodifferentiation in the formation of isotactic polypropylene at chiral $(C_5H_4CHMePh)_2ZrCl_2$/methylalumoxane catalysts (C) 628
- Metallocene carbene complexes and related compounds of titanium, zirconium, and hafnium (R) 397
- The first example of an *ethylene*-selective soluble Ziegler catalyst of the zirconocene class (C) 1511
