Frequently, it is of interest to know which of the kinetic parameters, the Michaelis constant, K_m, or the catalytic constant, V_{max}, is altered when a substituent is introduced onto the substrate molecule. As mentioned earlier, lipase-catalyzed reactions occur at the oil–water or micelle–water interface.[33] Since the lipase is reversibly adsorbed at the interface, the experimentally determined "apparent K_m" may represent the dissociation constant of the interfacial enzyme–substrate complex, termed interfacial K_m^*. Also, the "apparent V_{max}" measured at saturating amounts of lipid substrate is also an apparent quantity, namely, the real V_{max} multiplied by the factor $Su/(K_m^* + Su)$. This factor tells us what fraction of the enzyme molecules are in the Enz*Su form.

To overcome the complexity of this interfacial surface problem, *Hirohara* et al.[67] selected experimental conditions under which all enzyme molecules are adsorbed to the interface by increasing the area of interface with vigorous stirring (1000 rpm) and increasing the amount of substrate under these conditions. They assumed that the concentration of the enzyme in solution is that at the interface. Lineweaver–Burk plots with substrate concentration expressed in mole L^{-1} instead of $m^2\ L^{-1}$ gave straight lines to allow the calculation of K_m and V_{max}. In any event, accurate noncompetitive measurement of K_m and V_{max} is a difficult problem, especially the K_m for the more slowly reacting enantiomer.

In theory, the kinetic parameters, K_m and V_{max}, for both enantiomers, A and B, can also be calculated directly from competitive measurements using Equations (22) and (23),[68]

$$t(V_{max}/K_m)_A + ([A] - [A]_0)[1/(K_m)_A] + ([A]^{1/E} - [A]_0^{1/E}) \cdot x \cdot E \cdot [1/(K_m)_B] = \ln [A]_0/[A] \quad (22)$$

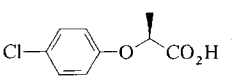
$$t(V_{max}/K_m)_B + ([B] - [B]_0)[1/(K_m)_B] + ([B]^E - [B]_0^E)(y/E) \cdot [1/(K_m)_A] = \ln [B]_0/[B] \quad (23)$$

where $[A]_0$ and $[B]_0$ denote initial concentrations, E is the enantiomeric ratio, $x = ([B]_0/[A]_0^{1/E})$, $y = ([A]_0/[B]_0^E)$, t = time, and $(K_m)_A$, $(K_m)_B$, $(V_{max})_A$, and $(V_{max})_B$ are the Michaelis constants and maximal velocities for A and B, respectively. By inserting the E value and at least three sets of experimental data $[(t_1, [A]_1), (t_2, [A]_2), (t_3, [A]_3)$ and $(t_1, [B]_1), (t_2, [B]_2), (t_3, [B]_3)]$ into Equations (22) and (23), respectively, the values of V_{max}/K_m, K_m, and V_{max} for each enantiomer A and B may be readily calculated.

6. Asymmetric Catalysis in Organic Solvents

Because lipase-catalyzed reactions are generally conducted in the hydrolytic mode in water,[69] it is not too surprising to find that there are relatively few published examples of enantioselective and enantiotopically selective esterification reactions in nonaqueous media. Nevertheless, the data presented in Tables 7–11 should provide chemists with a glimpse of the usefulness of this unconventional methodology. Although Equations (15) and (16) should be employed for the calculation of the E values, the equilibrium constants for these systems were unfortunately not determined. Therefore, the E values listed in Tables 7, 9, and 11 were calculated using Equations (20) and (21), and they represent apparent minimal values rather than intrinsic E values.

6.1. Optically Active Carboxylic Acids and Esters



Most of the biocatalytic kinetic resolutions of chiral racemic acids were conducted in the hydrolytic mode in water,[69] because the hydrolytic rate in water is generally faster than the corresponding rate of esterification in organic media. That is, if the hydrolytic rate in water is slow, the corresponding rate of esterification in organic media in most cases is expected to proceed at an even slower rate. Hence, more enzyme is required for esterification in nonaqueous media.

The catalytic activity of enzymes is strongly influenced by both electronic and steric effects. For example, acids that possess electron-donating or bulky substituents (e.g., isopropyl or larger) adjacent to the carboxyl function are attacked slowly or not at all by lipases and the rate-determining segment of the reaction is the formation of the acyl-enzyme complex. In these cases, transesterification may be used as a means of improving the catalytic rate; the chiral racemic acid is first converted nonenzymatically into an activated ester (e.g., chloroethyl ester), which is more susceptible to nucleophilic attack by the biocatalyst. Using the lipase of *Candida cylindracea*, *Klibanov* et al.[7] observed good catalytic activity and enantioselectivity with substrates that possess an electron-withdrawing group adjacent to the carboxyl function, such as **1a** and **1b**, whereas low catalytic activity was noted with other substrates devoid of an electron-withdrawing substituent.

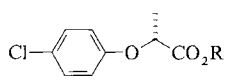


Table 7 compares the enantioselectivity of esterification versus hydrolysis of 2-(*p*-chlorophenoxy)propionates. In both sets of experiments, the observed enantioselectivity (E value) of esterification in organic media is four- to fivefold higher than the corresponding hydrolytic reaction in water. Similarly, the data in Table 8 show that the enantiomeric excess (*ee*) of the product, (*S*)-3-methylglutarate monomethyl ester, is higher when the product is prepared by enzymatic acylation by the corresponding anhydride in organic solvent[18a] than by enzymatic hydrolysis of the diester in water.

As far as the influence of the acyl acceptor on enantioselectivity is concerned, no prediction may be made with any degree of confidence at this stage. Although one might surmise that the enantioselectivity may perhaps be improved by the use of a chiral alcohol, in many cases the observed enantioselectivity using achiral alcohols as acyl acceptors is superior to that of chiral alcohols.[77] However, the matching of appropriate racemic acids with racemic alcohols in a double kinetic resolution experiment is an exciting area that warrants systematic exploration in the future.

The existence of reverse hydrolysis during the lipase-mediated enantioselective formation of 2-(*p*-chlorophenoxy)-propionic esters[10] **1c, d** is illustrated in Figure 5a. The *Candida* lipase preferentially attacked the (*R*) enantiomer in the

presence of an excess amount of 1-butanol as the acyl acceptor. The E value for this system was moderate ($E = 12$) and the K value was found to be 0.15. As shown in Figure 5a, the characteristic feature of such a reversible system is that the optical purity of the remaining substrate (ee_S) decreases as the conversion is extended beyond 50%. This is in marked contrast to the irreversible case where ee_S increases as the conversion is extended. Figure 5b illustrates the advantage of using cyclohexanol as the acyl acceptor, because esters of secondary alcohols are more resistant to enzymatic hydrolysis than those of primary alcohols. The K value for this system is reduced to 0.02.

6.2. Optically Active Alcohols

With the exception of certain sterically hindered alcohols, lipases catalyze the asymmetric acylation of a wide range

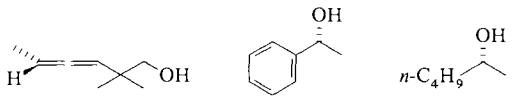
Fig. 5. of cyclic and acyclic substrates with moderate to high enantioselectivity (Tables 9 and 10). To achieve highly enantioselective acylation, the selection of a suitable biocatalyst and the optimization of reaction conditions are important.



The acyl donor can have a marked effect on the stereochemical behavior of the enzyme system. This is illustrated by the examples of enantioselective acylation of racemic 1-phenethanol (±)-**9** mediated by *Candida cylindracea* lipase[70] (Table 11).

While the physical states of the acyl donor, either as an ester in a fully dispersed form or as an acid in a micelle form, had no effect on the enantioselectivity, different catalytic rates were observed. For example, the rate of the reaction using tributyrin (tributyrylglycerin) as the acyl donor was only about one-fifth of that of butyric acid. On the other hand, increasing the chain length of the acyl group from C_4 to C_{12} led to higher values of enantiomeric ratio E, but no significant difference in enantioselectivity was noted for acyl donors with chain lengths between C_{12} and C_{16}. Similar observations were reported for the *Mucor miehei* lipase, which was used for the resolution of (±)-2-octanol via enantioselective acylation.[16] In this case, the E value increased to > 50 with chain lengths of alkanoic acid up to C_8; it declined beyond C_8 but only to rise again to > 50 for the C_{16} acid. Therefore, it is noteworthy that the optimal chain

length of the acyl donor required for maximal enantioselection varies with the enzyme and the substrate.

The presence of competing enzymes in the crude lipase preparations should also be considered. In general, lipases from microbial sources are produced extracellularly and are virtually homogeneous in terms of lipolytic activity.[33] In contrast, crude mammalian and plant lipase preparations contain several other interfering enzymes, including proteases and esterases, which may possess opposite or poor stereo-

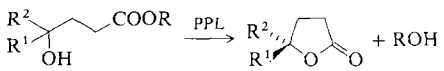
selectivity as compared with the lipase. As a consequence, low optical yields or unreproducible results are often encountered in using these crude lipases, depending on the state of the enzyme preparations. Therefore, to enhance the optical yield, a number of measures can be taken. These include:

treatment of the crude enzyme preparation with chemical reagents[71] (e.g., serine protease inhibitors) to inactivate interfering enzymes; treatment of the crude enzyme preparation by physical means (e.g., partial protein purification; lyophilization) to remove or selectively inactivate competing enzymes; and selection of a suitable acyl donor which serves as a poorer substrate for interfering enzymes and/or as a more efficient substrate for the target enzyme. These strategies of optical purity enhancement are illustrated by a number of recent examples where crude porcine pancreatic lipase (PPL) was used.

PPL exhibited a moderate enantioselectivity in the esterification of (±)-sulcatol (±)-**14**.[13] When the commercial Sigma crude PPL preparation was dehydrated to constant weight under vacuum, a threefold increase in the E value was noted. Although a general increase in the chain length of the acyl moiety had little effect on the enzyme specificity, the use of an activated ester, trifluoroethyl dodecanoate resulted in a fourfold increase in the E value. A combination of enzyme dehydration and ester selection gave rise to a nearly tenfold increase in E value.



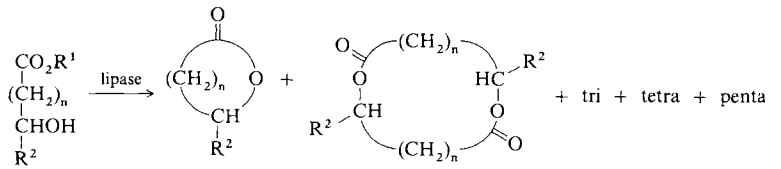
(±)-**14**

Some of the asymmetric esterification reactions in organic solvents were actually mediated by the competing enzymes in the crude lipase preparation. A recent study by *Ramos Tombo* et al.[72] has shown that an esterase fraction from crude PPL catalyzed highly enantioselective acylation of 2-substituted 1,3-propanediol, whereas pure PPL was virtually inactive. In addition, several hydrolytic enzymes, including cholesterol esterase and chymotrypsin, are present in crude PPL preparations. For example, the claim[22] that crude porcine pancreatic lipase (PPL) catalyzes the formation of peptide bonds may well be due to the contaminating chymotrypsin present in the preparation. Therefore, partial purification of enzyme preparations may result in more enantioselective biocatalysts. Finally, it is interesting to note the existence of pancreatic colipase whose main function appears to be to restore the activity of the bile-salt-inhibited lipase. However, it is unclear as to whether colipase can alter the V_{max} and K_m of the pancreatic lipase.[80]

6.3. Macrocyclic Lactones

Lipases have been used for the preparative syntheses of macrocyclic lactones via the lactonization of hydroxy acids and esters in organic solvents.[23, 24] However, more recent studies[73] show that the product profile varies with the length of the hydroxy acid and the lipase and is considerably more complex than those reported previously.[23, 24] For example, when 10-hydroxydecanoic acid was exposed to a variety of lipases in anhydrous isooctane, no decanolide was detected; instead, a complex mixture of di-, tri-, tetra-, and pentalactones was formed in different ratios depending on the lipase used. A similar product profile was obtained using methyl 10-hydroxydecanoate as substrate. On the other hand, hexadecanolide was found to be the dominant product after exposure of 16-hydroxyhexadecanoic acid to the lipases, except the lipase of *Mucor miehei* which formed hexadecanodiolide predominantly. Chiral (ω-1)-hydroxy acids (C_8 and C_{13}) were also lactonized by the lipases to yield a mixture mainly of di- and trilactones, but no monolactones were detected (Table 12). The enantioselectivity of the intramolecular esterification was examined using a series of acyclic diastereomeric dimers, prepared from (*R*)- and (*S*)-7-hydroxyoctanoic acids.[74] The relative rates of diolide formation were found to follow the order $R,R > R,S > S,S$, and no cyclization was noted with the (*S*,*R*) diastereomer. These results indicate that the stereochemistry of the hydroxyl at both chiral centers appears to influence the lactonization reaction.[73]

Porcine pancreatic lipase (PPL) in anhydrous organic solvents such as dry ether catalyzed the lactonization of a number of esters of γ-hydroxy acids **25** in nearly quantitative yields.[75] This highly enantioselective process was used for the synthesis of (*S*)-(−)-γ-methylbutyrolactone **26** ($R^1 = CH_3$; $R^2 = H$; $E = > 100$), (*R*)-(+)-methylbutyrolactone **26** ($R^1 = H$, $R^2 = CH_3$), and optically active γ-phenylbutyrolactone (the presence of the (*R*) or (*S*) form was not established).



25 **26**

It was found that α-substituted γ-hydroxy esters were very poor substrates for the enzyme. The initial rates of lactonization of α-bromo-γ-hydroxybutyrate and of α-methyl-γ-hydroxybutyrate were, respectively, 200 and 50 times lower than that of γ-hydroxybutyrate. It is interesting to note that the PPL-catalyzed hydrolyses of γ-, δ-, and ε-chiral racemic lactones in water[76] proceeded with only modest enantioselectivity; E values ranged from 3 to 20.

Lipases also catalyzed the formation of macrocyclic lactones via the condensation of diacids and diols in anhydrous nonpolar organic solvents such as isooctane.[25] The major products of this reaction were mono- and dilactones accompanied by linear oligomeric esters and a small quantity of trilactones in some systems. The yield of the lactone products varied not only with different substrates, but also with reaction conditions. Optimal temperature for lactonization was between 55 and 75 °C; at lower temperatures (≤ 45 °C), oligomeric esters were the dominant products. Lipases accommodated acyclic diacids **27** (m = 2–12) and diols **28** (n = 5–16) of various sizes. However, the optimum yield of lactones was achieved when the size of the ring is in the range of 24–28.

Cyclic diacids and diols as well as acyclic diacids and diols bearing heteroatoms[77] also served as lactonization substrates for the lipases. However, the enantioselectivity of this unique biocatalytic reaction has yet to be systematically studied.

7. Epilogue

Enantioselective biocatalysis in organic media is a rapidly developing field but it is still at an early stage, because there is still much to learn about enzyme protein conformations in water and in organic media. Nevertheless, the usefulness of this nonaqueous methodology is clearly indicated by a number of published reports. Thus far, only the enantioselective properties of lipase-catalyzed esterification and transesterification reactions have been exploited to a large extent. By choosing a biocatalyst and an acceptor or donor in a suitable organic solvent, the biocatalytic reaction may often be more enantioselective than the corresponding hydrolytic reaction in water. As such, it provides the synthetic chemist with an additional methodology for the preparation of optically active compounds.

It is important to recognize the potential broad range of biocatalysts that may be used for biocatalytic resolution in organic media. We are therefore in the midst of an exciting stage in the development of this field. We hope this article will stimulate interest and greater activity in this relatively new area.

Solid Ion Conductors in Heterogeneous Catalysis

By Hans-Günther Lintz* and Costas Georgios Vayenas*

The electrochemical measurement of oxygen activity using ion-conducting solid electrolytes (λ-sensors) has become widely known, at least since the application of three-way catalysts in the postcombustion of exhaust gases from spark-ignition engines. However, the use of solid ion conductors is not limited to control devices. There are various other potential applications and numerous problems which can be studied: the formation of oxides in the course of catalytic reactions on metal surfaces, the improvement of selectivity and yield of catalytic reactions, such as the epoxidation of ethylene on silver catalysts and, finally, the cogeneration of electrical energy during oxidation reactions, such as the partial oxidation of methanol to formaldehyde.

1. Introduction

Solid ion conductors have found numerous applications in research and in technology. Electrochemical measurements in the domain of thermodynamics (free enthalpies, partial pressures, activities) and of kinetics (oxygen diffusion on metals, formation of coating layers) are widely known.[1, 2] Ion conducting solids are used in fuel cells, batteries, sensors and as chemotronic components.[3] Examples of special applications are: in research, the measurement of inertial forces,[4] and in industry the measurement of pH in aqueous systems at high temperatures and pressures.[5] So far only oxygen ion conductors have been used in the field of heterogeneous catalysis. Among the rare earth oxides ZrO_2, ThO_2 and CeO_2 (see Table 1 in Ref. [3]), zirconium dioxide is the most frequently used. It is usually doped with Y_2O_3 instead of CaO in order to maintain high conductivity in the low temperature range.

The electrochemical measurement of oxygen activity using oxygen ion conductors has become widely known since the introduction of catalytic converters for the post-treatment of automobile exhausts. Hydrocarbons, carbon monoxide and nitrogen oxides are simultaneously eliminated on three-way catalysts when the exhaust gas composition is within certain specified limits. The oxygen content in the exhaust is measured by the so-called λ-sensor and the air-to-fuel ratio of the engine feed is controlled accordingly. The oxygen content in the exhaust gas is determined electrochemically by measuring the potential difference between the electrodes of the solid electrolyte cell.

exhaust | electrode || solid electrolyte || electrode | air
(measuring side) (reference side)

However, the application of solid ion conductors in heterogeneous catalysis is not restricted to regulation and control. *Wagner*[6] had originally proposed the use of solid electrolyte potentiometry (SEP) for the measurement of oxygen activity simultaneously with the reaction rate during oxidation reactions. In this case an open system is investigated in (measuring side) constitutes simultaneously the catalytically active surface. The measurement of the oxygen activity thus leads to a quantity which is characteristic of the catalyst surface under reaction conditions. *Vayenas* and *Saltsburg*[7] were the first to perform such measurements during the investigation of SO_2 oxidation on platinum. In addition there had been early attempts to influence the reaction kinetics by electrochemical transport of oxygen from or to the catalyst surface using the same device and applying an external potential.[8] Finally, the possibility has been investigated[9] of using the potential difference generated by an electrochemical reaction between the electrodes in order to simultaneously generate electrical power and useful chemical products.

In the following we first describe the principles of the electrochemical measurements and the methods of preparation of the galvanic cell and of the electrodes. We then discuss some examples of the three different applications of solid ion conductors in the field of heterogeneous catalysis.

2. Principles of Measurement and Electrode Preparation

The potentiometric determination of pH is the most well known electrochemical method for measuring an activity. When the normal hydrogen electrode is used, the potential determining reaction takes place at the three-phase boundary line between the gas, the metal and the electrolyte. The pH of a solution relative to the known hydrogen ion activity in a second solution is determined by measuring the potential difference between the two electrodes of a galvanic cell when the same hydrogen partial pressure is imposed on both electrodes.

When an oxygen partial pressure is measured electrochemically using a solid electrolyte cell, again the potential determining reaction (1)

$$O_2 + 4\,e^- \rightleftarrows 2\,O^{2-} \qquad (1)$$

takes place at the three-phase boundary line gas–electrode–electrolyte. In contrast to the pH measurement, the oxygen ion activity is now the same at both electrodes but the oxygen partial pressure is different. The potentiometric measurement thus indicates the value of the oxygen partial pressure $p^{M}_{O_2}$ at the working electrode relative to the known value $p^{R}_{O_2}$

at the reference side (e.g., air), according to the Nernst equation.

$$E = \frac{RT}{4F} \ln \frac{p^{M}_{O_2}}{p^{R}_{O_2}} \qquad (2)$$

The experimental setup is depicted schematically in Figure 1.

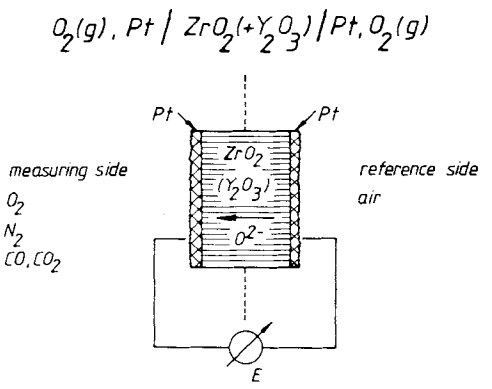

Fig. 1. The electrochemical cell: schematic diagram of the measuring arrangement.

The validity of the Nernst equation is based on the following assumptions:

- there is only one potential determining reaction, namely reaction (1);
- the conductivity of the solid electrolyte is exclusively due to oxygen ions;
- the elementary steps of reaction (1) at both electrodes are in equilibrium.

The first requirement is always fulfilled in mixtures of oxygen and inert gases. Also it has been proven that in the case of the electrolyte normally used, i.e. Y_2O_3-doped zirconium dioxide, the numbers of electrons and cations transferred are negligibly small.[10-12]

The third assumption is in principle fulfilled only under open-circuit conditions, but can be closely approximated in practice. Considering as an example the case of platinum electrodes one can distinguish the following elementary steps:

- dissociative chemisorption of oxygen
- concentration equilibrium within the chemisorbed layer
- electrochemical reaction at the gas–metal–electrolyte three-phase boundary line

Figure 2 shows a schematic diagram of a porous electrode. The above assumptions require the absence of concentration gradients both in the gas phase and in the chemisorbed layer. Moreover, there must be no concentration polarization within the electrolyte.

In the measurement proposed by *Wagner*[6] the electrode on the working side is simultaneously the catalyst. If, for example, carbon monoxide and oxygen are present in the gas phase, the reaction (3)

$$CO + 1/2\ O_2 \rightarrow CO_2 \qquad (3)$$

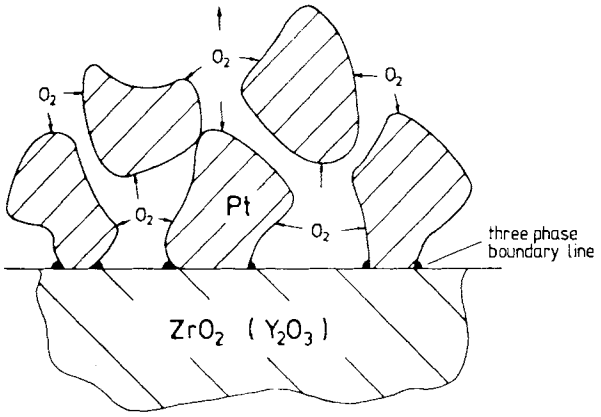

Fig. 2. Schematic diagram of the porous platinum electrode.

will take place at the electrode surface. Consequently, not only oxygen and carbon monoxide, but also carbon dioxide are in contact with the working electrode. This is shown schematically in Figure 3. The oxygen activity at the electrode will, in general, no longer be in equilibrium with the oxygen activity (partial pressure) in the gas phase. One now potentiometrically measures a quantity which is characteristic of the catalyst surface under reaction conditions. The value $p^{V}_{O_2}$ of the oxygen partial pressure, calculated from the measured potential difference by means of the Nernst equation, is now, in general, smaller than the partial pressure value in the gas phase $p^{M}_{O_2}$. The value of $p^{V}_{O_2}$ corresponds to a virtual oxygen pressure which would be in equilibrium with the oxygen activity at the electrode catalyst surface in the absence of reaction.

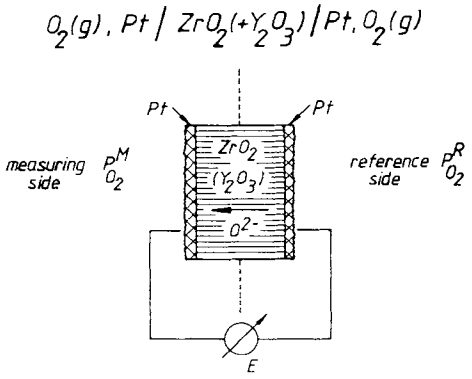

Fig. 3. The electrochemical cell (open system): schematic diagram of the setup for potentiometric measurements in a reacting system.

Naturally, the formal application of Equation (2) in the case of a reaction system is meaningful only if the potential determining reaction is still unambiguously described by Equation (1) despite the presence of additional species.

The oxygen activity value obtained potentiometrically is not an equilibrium value but is determined primarily by the oxygen coverage of the electrode under stationary conditions. This stationary value of the activity may be altered by oxygen ion transport to or from the catalyst surface by the application of an external voltage. The aim of this approach is to change the rate or selectivity of the catalytic reaction. One may consider as an example the partial oxidation of

methanol on Ag where the goal is to promote the formation of formaldehyde [Eq. (4a)]

$$CH_3OH + 1/2\,O_2 \rightarrow CH_2O + H_2O \qquad (4a)$$

which competes with the complete oxidation [Eq. (4b)]

$$CH_3OH + 3/2\,O_2 \rightarrow CO_2 + 2\,H_2O \qquad (4b)$$

A typical experimental setup is shown in Figure 4 where the oxygen ion current between the catalyst and the counter electrode is controlled galvanostatically. A third (reference) electrode can also be used as shown in Figure 4 to monitor the catalyst potential.

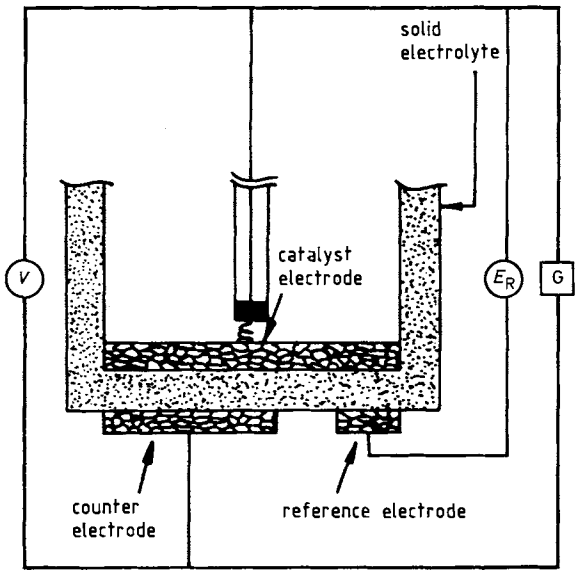

Fig. 4. Three-electrode system for controlling the oxygen ion current. V: applied potential: E_R: catalyst potential with respect to reference electrode; G: galvanostat.

A conceptually similar device can be used to study the possibility of simultaneously producing chemicals and electrical energy in a fuel cell. In this mode of operation no gas phase oxygen is fed to the anode and oxygen is supplied entirely by O^{2-} transport through the solid electrolyte. In the case of the partial oxidation of methanol to formaldehyde [Eq. (4a)] the anodic reaction is [(Eq. (5)]:

$$CH_3OH + O^{2-} \rightarrow CH_2O + H_2O + 2\,e^- \qquad (5)$$

The corresponding oxygen reduction to O^{2-} at the cathode is again described by Equation (1).

Oxygen activity measurements are useful only when they can be performed within the temperature range of interest for catalytic processes. The lower temperature limit for potentiometric measurements is determined by the fact that at low temperatures (e.g. $< 300\,^{\circ}C$) the Nernst equation is no longer satisfied due to polarization phenomena.

In order to avoid concentration polarization in the electrolyte it is important for the solid electrolyte to have the highest possible conductivity. Consequently, Y_3O_3-doped zirconium dioxide is generally used instead of CaO-doped zirconium dioxide. Furthermore, the three-phase boundary line must be extended as far as possible to avoid activation polarization effects, which have been observed during potentiometric measurements in the case of Pt/O_2 electrodes in the low-temperature range.[13] The length of the three-phase boundary line is determined by the mode of electrode preparation. The quality of electrodes can be assessed by measuring the exchange current density.

Porous electrodes can be prepared by vacuum evaporation,[14] electron beam evaporation,[15] or sputtering.[8] However, metal pastes or paints are used in most studies. The pastes are applied to form a thin layer on the solid electrolyte and are then subjected to an appropriate temperature treatment, usually in air. The organic material is evaporated or oxidized during the thermal treatment. Such pastes are commercially available and have been used in the preparation of platinum,[7,16-20] silver,[16,21] gold,[16,22] and nickel[23] electrodes. Because the pastes frequently contain fluxing agents, the possibility of catalyst contamination has to be checked[20] in the study of heterogeneous kinetics. A modified preparation technique uses powdered metal oxides suspended in an organic matrix. The porous oxide layer is reduced after drying.[24]

If one aims to determine the oxygen activity at the surface of an oxide catalyst, there are two main possibilities for preparing the solid electrolyte cell. If the oxide conductivity is sufficiently high then the potential determining reaction (1) can proceed at the three-phase boundary line gas–oxide–electrolyte. In other cases the oxide is directly deposited on a porous metal electrode[25,26] and the electrochemical reaction takes place at the three-phase boundary line oxide–metal–electrode. However, in this case the oxide layer must be impervious, since any reaction of the gas phase at the metal electrode would falsify both the kinetic and the potentiometric measurements.

3. Applications of Solid Ion Conductors in Heterogeneous Catalysis

3.1. Potentiometric Measurement of the Oxygen Activity on Catalyst Surfaces under Operating Conditions

During these measurements the temperature T and the reactant concentrations c_i are control variables and are kept constant. The measured quantities are the reaction rate $r\,(T, c_i)$ and the potential difference E between the catalyst and the reference electrode. It is convenient in the presentation of results to use the corresponding oxygen activity a_0 rather than the virtual oxygen partial pressure $p^{v}_{O_2}$ derived by using the Nernst equation (2), particularly when oxidants other than oxygen are involved [Eq. (6)].

$$a_0^2 \equiv p^{v}_{O_2} \qquad (6)$$

After the initial study of SO_2 oxidation on platinum mentioned in Section 1,[7] the potentiometric method has been used in a series of investigations involving the oxidation of ethylene on silver[21] and platinum,[27] the oxidation of propene on silver,[28] the sorption of oxygen on platinum,[29] the oxidation of platinum[30] and the interaction of carbon monoxide and oxygen on platinum.[19,31,32]

In the latter case the question has also been addressed as to whether the reaction (1)

$$O_2 + 4\,e^- \rightleftarrows 2\,O^{2-} \qquad (1)$$

is the only potential determining electrode reaction. If the competing reaction (7)

$$CO + 2\,O^{2-} \rightleftarrows CO_2 + 4\,e^- \qquad (7)$$

takes place simultaneously then a mixed potential will be measured.[32] This question has been discussed in detail.[33, 34, 38]

The benefits and limitations of the potentiometric method (SEP) had already become apparent after the first investigation:[7]

- The assumption of equilibrium between gaseous oxygen and chemisorbed oxygen, frequently used to interpret kinetic results, is generally not valid. The oxygen activity measured at the catalyst surface can be orders of magnitude lower than the gas phase oxygen activity.
- The domains of gas phase composition in which a distinct rate law is obeyed correspond to definite ranges of surface oxygen activity as a function of gas composition. The technique is not restricted to high vacuum conditions and allows the study of catalysis under pressure and temperature conditions relevant to industrial practice.

On the other hand, the measured oxygen activity is a thermodynamic property which does not permit any direct calculation of the oxygen concentration at the surface, i.e., of the oxygen surface coverage. This would be possible only with the additional knowledge of the oxygen adsorption isotherm. Therefore, such thermodynamic observations alone do not, in general, lead to more certain conclusions regarding the surface elementary reactions than does the experimentally determined dependence of reaction rate on gas composition.

An example of the above mentioned relationship between kinetically distinguishable domains and ranges of surface oxygen activity is shown in Figure 5 for the case of carbon monoxide oxidation by nitrogen monoxide on platinum.[35] As shown in this figure (Fig. 5b) high values of surface oxygen activity are measured in the range where the reaction rate is first order in carbon monoxide. When the reaction order with respect to carbon monoxide changes from first order to negative order there is an abrupt concomitant decrease in oxygen activity to extremely low values. However, the values corresponding to equilibrium with the gas phase are never attained. The observation that the rate is apparently inhibited by nitrogen monoxide (Fig. 5a) at high NO gas concentrations ($X_{NO} = 0.08$) can be easily explained by the fact that an increasing amount of undissociated NO is adsorbed on the surface. This explanation is not inconsistent with the experimentally measured surface oxygen activity values.[35, 63]

The potentiometric measurements give essential information under conditions where the phase composition of the catalyst may change during the course of the reaction and where this phase change is kinetically controlled. In these cases the experimental value of the surface oxygen activity

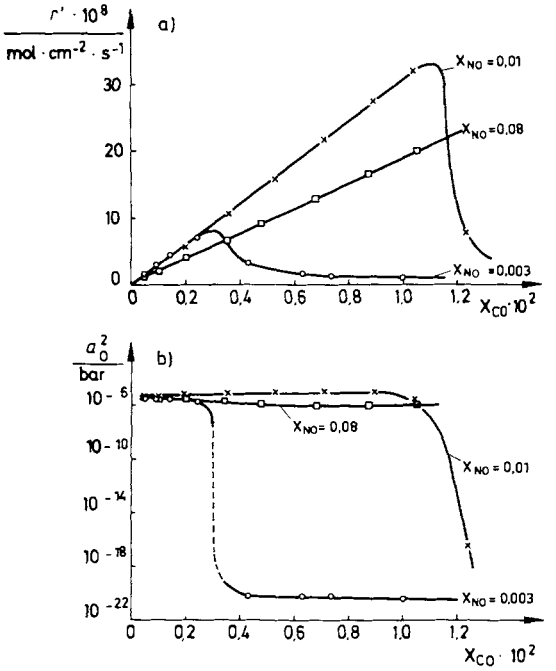

Fig. 5. Oxidation of carbon monoxide by nitrogen monoxide on platinum. a) Specific reaction rate r' and b) oxygen activity a_O^2 for different NO mole fractions at constant $T = 773$ K; $p = 1$ bar.

indicates the phase which is thermodynamically stable, and the variation in reaction rate shows the extent to which a phase change has indeed taken place. This has been demonstrated, for example, in the case of platinum oxide formation during carbon monoxide oxidation on platinum.[36]

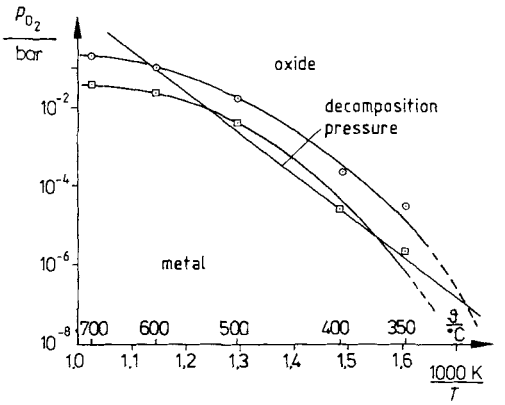

Fig. 6. Oxidation of carbon monoxide by oxygen on platinum. Temperature dependence of the oxygen activity at the platinum surface under reaction conditions; $X_{CO} = 3 \times 10^{-3}$; O: $X_{O_2} = 0.2$; □: $X_{O_2} = 0.04$ (after Ref. [36]).

Figure 6 shows the temperature dependence of the dissociation pressure of surface platinum oxide[30] and of the potentiometrically determined surface oxygen activity values under constant reactant partial pressures at 1 bar total pressure. It can be seen that over a certain temperature range the oxygen activity at the catalyst surface is greater than the dissociation pressure. Within this domain platinum oxide is the thermodynamically stable phase. At high temperatures the dissociation pressure is higher than the surface oxygen activity and, consequently, the metal is stable. In the low temperature range the surface is covered by chemisorbed CO and therefore the oxygen activity is again too low to permit

oxide formation. The thermodynamically allowed oxide formation in the intermediate temperature range has been observed under operational conditions and has been confirmed by photoelectron spectroscopy.[36]

The phase transformation of solids is considered to be one of the causes of non-linear phenomena in heterogeneous catalysis and of the occurrence of reaction rate oscillations.[37] The usefulness of the potentiometric method is not restricted to oxygen activity measurements under stable steady state conditions. It can also be used to monitor variations in oxygen activity. An example is given in Figure 7, again for the case of CO oxidation on Pt.[38] This figure shows the variation with time of both the effluent CO_2 mole fraction in the system (as a measure of the reaction rate r', Fig. 7a, c) and the potential difference E (Fig. 7b, d). Both temporal variations show clearly the same pattern. The differences in the two sets of data shown, which were obtained under identical conditions, arise from different catalyst pretreatment. The Pt catalyst is either preoxidized (Fig. 7a, b) or prereduced (Fig. 7c, d).

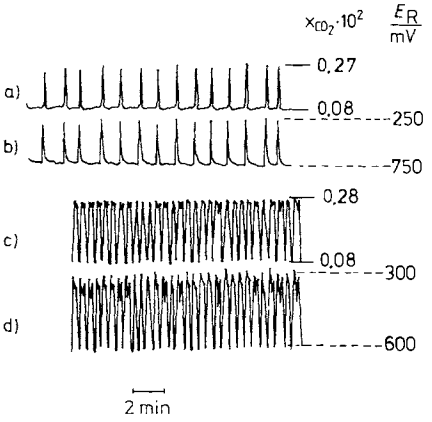

Fig. 7. Oxidation of carbon monoxide by oxygen on platinum. Oscillations of reaction rate and oxygen activity at the catalyst surface during the reaction at 610 K. a)–d), see text. Reactor inlet gas mixture composition: $X_{O_2} = 4.26 \times 10^{-2}$; $X_{CO} = 3.85 \times 10^{-3}$; balance N_2. Reaction rate: $1.3 < r' \times 10^9 < 4.5$ mol cm^{-2} s^{-1}.

Such measurements have been performed during the study of ethylene oxidation on platinum,[27] carbon monoxide oxidation on platinum[19, 32, 38] and hydrogen oxidation on nickel.[39] The results unequivocally confirm the hypothesis that periodic oxidation and reduction of the solid is the main cause of rate oscillations.

Kinetically induced transitions in the phase composition of solid catalysts are particularly important in technical applications when, as in the case of the partial oxidation of hydrocarbons, the selectivity of the reaction is altered substantially.[40] In such cases the surface oxygen activity must be maintained and controlled between specific limits to promote the desired reaction, even when the gas phase composition changes during the course of the reaction. The relationship between selectivity and oxygen activity can be studied in principle by the potentiometric method if one succeeds in working with oxide or oxide-covered electrodes. Increased efforts have been undertaken recently in this direction.[25, 41, 42]

3.2. Modification of the Course of Catalytic Reactions by Electrochemical Transport of Oxygen from or to the Catalyst Surface

Oxygen can be transferred from or to the catalytically active electrode by application of an external voltage to a stabilized zirconium dioxide cell. In the following we refer to this procedure as electrochemical oxygen transport. The surface oxygen activity can be altered by electrochemical oxygen transport even at constant gaseous composition. The aim of the procedure is to influence the course of the catalytic reaction by the additional source or sink of oxygen.

The catalytic reaction rate can now be measured as a function of temperature, gas composition and galvanostatically controlled current i: $r = r(T, c_i, i)$. The change in reaction rate [Eq. (8)] can be compared with the rate of electro-

$$\Delta r = r(i) - r(i = 0) \tag{8}$$

chemical oxygen transport $i/2F$. One can define an enhancement factor Λ[59] from:

$$\Lambda = \frac{\Delta r}{|i/2F|} \tag{9}$$

The case $|\Lambda| > 1$ is called non-Faradaic behavior,[59] sincethe variation in catalytic rate is larger than the rate of oxygen transport. The effect has been confirmed unambiguously.[59–62]

In the following we first summarize the results of previous studies.

The decomposition of nitrogen monoxide on platinum is inhibited by chemisorbed oxygen. *Amirnazmi* et al.[43] give the following kinetic expression (10) for the decomposition rate:

$$r = \frac{k\,[NO]}{1 + K[O_2]} \tag{10}$$

When the surface oxygen is eliminated electrochemically then the reaction rate increases.[8] A rather unexpected increase in the rate of NO decomposition was observed when the applied external voltage exceeded a certain critical value.[22] This effect was attributed to zirconium dioxide reduction at the cathode and formation of metallic zirconium. The observed critical potential value of 2.2 V is in good agreement with the thermodynamically computed decomposition voltage of ZrO_2, i.e., 2.28 V at 900 °C. It has been reported[44] that practically the same decomposition voltage value applies to the solid electrolyte used, i.e. 10 mol-% Y_2O_3 in ZrO_2.

The effect of the decrease in oxygen activity caused by cathodic currents has been studied for the case of carbon monoxide methanation on Pt, Fe, Ni and Co.[17] It was found that the rate of methanation could be increased by a factor of up to five. Cathodic currents promote the rate of CO disproportionation but the effect may again be related to partial reduction of the electrolyte.[17]

The rate of metal-catalyzed oxidations is usually increased by electrochemical oxygen transport to the catalyst. In a first attempt to influence the selectivity of a partial oxidation reaction, the oxidative dehydrogenation of ethylbenzene to styrene on platinum was investigated in a solid electrolyte

cell operating as a fuel cell with ethylbenzene as the fuel.[45] It was found that the rate of CO_2 production increases linearly with the current density, while the rate of styrene production is enhanced to a lesser extent. Consequently, the selectivity of the partial oxidation is not influenced positively on increasing the current in this reaction system.

Hayakawa et al.[14] have studied the oxidation of propene on gold, which was found to be inactive under open-circuit conditions. Electrochemical oxygen transport to the gold catalyst led to the formation of acrolein and other partial and complete oxidation products. The rate of acrolein production was found to increase in proportion to the rate of electrochemical oxygen transport. Only preliminary results have been reported so far regarding attempts to influence the oxidative coupling of methane to C_2-hydrocarbons by electrochemical oxygen transport.[24, 26, 46]

The effect of electrochemical oxygen transport on the epoxidation of ethene and propene on silver catalysts has been investigated in more detail.[47, 48] It was found that the selectivity and yield of ethene oxide can be strongly influenced by electrochemical oxygen transport to the catalytically active surface. It was also observed that the increase in oxidation rate can be more than two orders of magnitude higher than the rate of electrochemical oxygen transport to the catalyst. This shows that the state of the catalyst changes considerably. The catalyst modification was found to be reversible. The catalytic rate relaxation time constants during galvanostatic transients are of the order of several minutes. This marked effect was originally explained by assuming that electrochemical oxygen transport to or from the catalyst changes the surface concentration of a catalytically active silver-oxygen species.

The results obtained during ethene and propene epoxidation on silver illustrated for the first time the possibility of a non-Faradaic electrochemical modification of catalytic activity (NEMCA). It has recently been found[59–62] that the effect is not limited to epoxidation reactions on Ag. The various reactions which have been found so far to exhibit the NEMCA effect, i.e., non-Faradaic behavior, are listed in Table 1. For most of the reactions studied[59–62] it has been

Table 1. List of reactions showing non-Faradaic behavior (taken from [59]).

Reactants	Products	Catalyst	ϑ/°C	Λ	Ref.
$CH_2{=}CH_2$, O_2	ethene oxide, CO_2	Ag	320–420	300	[47]
propene, O_2	propene oxide, CO_2	Ag	320–420	300	[48]
$CH_2{=}CH_2$, O_2	CO_2	Pt	260–420	15000	[59]
CO, O_2	CO_2	Pt	300–550	500	[59]
CH_3OH	H_2CO, CO, H_2	Ag	550–700	−10	[59]
CH_3OH, O_2	CO_2, H_2CO	Pt	400–500	12000	[59]

found that over wide ranges of temperature, gas composition and applied current, catalytic rates depend exponentially on the catalyst potential [Eq. (11)]:

$$\ln\frac{k(i)}{k(i=0)} = \frac{aF}{RT}(E_R - E_R^*) \qquad (11)$$

where E_R is the catalyst potential with respect to the reference electrode and a and E_R^* are catalyst- and reaction-specific constants.[60–62]

The electrochemically induced modification of catalytic activity and the formation of certain phases could be of interest as a method of controlling the catalytic behavior of solids. As an example one can consider the case of carbon monoxide oxidation on platinum. As already discussed in Section 3.1, one can explain the observed reaction rate oscillations by assuming that the surface is subject to periodic oxidation and reduction. It is now possible to resort to electrochemical oxygen transport in order to exceed the necessary oxygen activity values for triggering the rate oscillations.

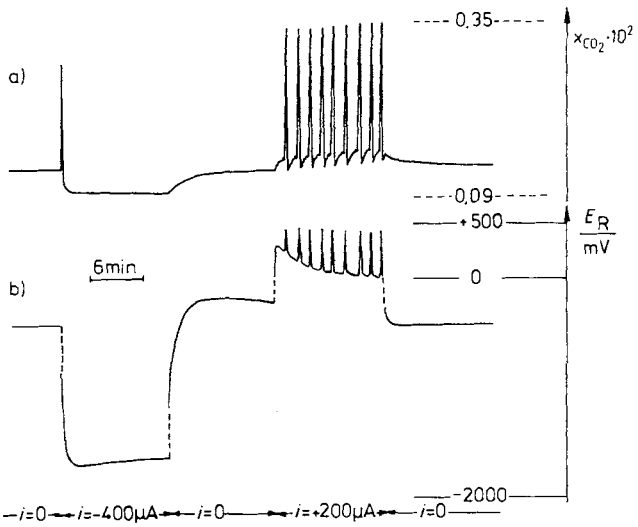

Fig. 8. Oxidation of carbon monoxide by oxygen on platinum. Modification of reaction rate by electrochemical oxygen transport, $T = 570$ K. Reactor inlet gas mixture composition: $X_{O_2} = 0.16$; $X_{CO} = 4.7\times10^{-3}$; balance N_2.

Figure 8 shows some results that have been obtained in this way. The mole fraction of the reaction product CO_2 is shown in the upper part (a) and the resulting potential of the catalyst with respect to the reference (air, Pt) electrode in the lower part (b) of the figure. At the beginning, without electrochemical oxygen transfer, the resulting oxygen activity is low and the value of the equivalent virtual oxygen pressure, 1.7×10^{-14} bar, is considerably lower than the decomposition pressure of PtO_2 at the reaction temperature, i.e., 4.8×10^{-8} bar.[30] Consequently oxygen removal from the catalyst created by a cathodic current ($i = -400$ μA) leads only to a decrease in reaction rate. If, however, an anodic current is applied ($i = +200$ μA) sufficient oxygen is supplied to the surface to exceed the corresponding oxygen activity value for oxide formation and reaction rate oscillations are induced. The final measurement under open-circuit conditions shows that the behavior of the system is reversible, as the initial values of reaction rate and potential are obtained again. The interactions between oscillations and electrochemical oxygen transfer are discussed in detail elsewhere.[49]

3.3. Cogeneration of Chemicals and Electrical Energy in Catalytic Processes

The application of oxygen ion conductors in fuel cells has been studied in detail. Results obtained with hydrogen and carbon monoxide as fuels have been reviewed recently.[50]

In addition, it has recently been proposed to combine the concepts of a fuel cell and of a chemical reactor. This aims at the cogeneration of chemicals and electrical power. The concept was first demonstrated in 1980 when electrical energy was produced during the anodic oxidation of ammonia to nitric oxide at the platinum electrode of a fuel cell.[9, 51] Subsequent studies have shown that several other exothermic reactions of technological interest can be carried out in solid electrolyte fuel cells with appropriate electrocatalytic anodes. The reactions which have been investigated so far are the oxidation of methanol to formaldehyde,[52] the synthesis of HCN in the Andrussow process,[53] the oxidative dehydrogenation of ethylbenzene to styrene[45, 54] and of 1-butene to butadiene[55] as well as the oxidation of H_2S to SO_2.[56] The results and possibilities have recently been discussed in detail.[57]

We therefore limit ourselves to the example of methanol partial oxidation to formaldehyde on a silver anode.[57] The cell is operated between 800 K and 900 K. The oxygen necessary for the oxidation reaction is supplied to the anode by spontaneous O^{2-} transport through the solid electrolyte. Oxygen anions O^{2-} are produced at the cathode, which is exposed to air. Typical results, presented in Figure 9, show

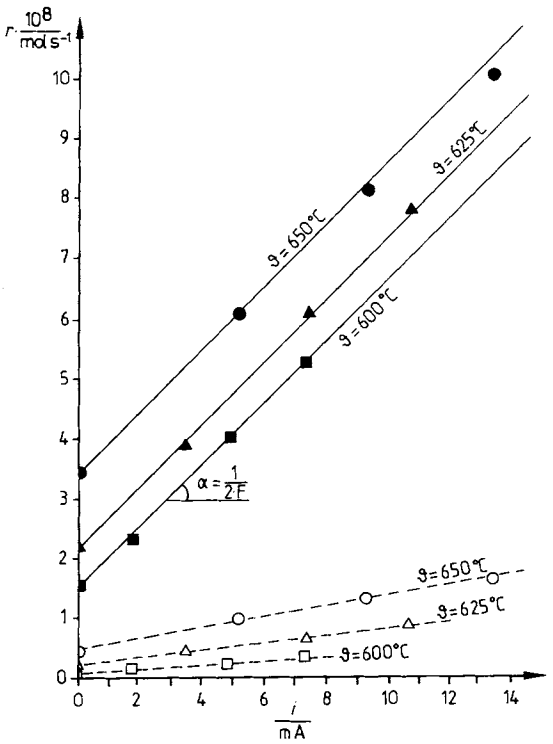

Fig. 9. Partial oxidation of methanol by oxygen on silver with simultaneous generation of electrical current. Reactor inlet gas mixture composition: $X_{CH_3OH} = 5.1 \times 10^{-2}$; balance N_2. ●, ■, ▲ = H_2CO; ○, □, △ = CO, CO_2. (Current is controlled by the resistance of the external circuit.)

that up to 95% of the methanol is oxidized to formaldehyde in the lower temperature range. The results prove that good product selectivity, which is essential even if one aims at cogeneration, can be attained under conditions where the production of electrical energy is possible. The rate measured without oxygen transfer ($i = 0$) is due to the catalytic dehydrogenation of methanol to formaldehyde and CO and to other secondary catalytic reactions.[57]

Conventional state-of-the-art solid electrolyte fuel cells exhibit power densities of the order of 400 mW cm^{-2} for thousands of hours.[58] In the above cited investigation the power density was of the order of a few mW cm^{-2}. No information is yet available on the long term cell performance. Clearly, the state of development is still in its infancy.

Outlook

There are various applications of solid oxygen ion conductors in the domain of heterogeneous catalysis. Different investigations reviewed in this article have different motivations. They range from the search for fundamental information regarding elementary catalytic steps to the, currently distant, industrial scale applications.

Presently, the applications of the different electrochemical methods are focused on the study and interpretation of elementary reaction kinetics and on explaining the efficiency of catalytically active solids. The potentiometric method (SEP) is particularly useful in this context. Future investigations will be concerned with extending the measurements to lower temperatures and also to oxide catalysts. In the latter case, particularly, SEP should give indications as to why and how product selectivity and the existence of certain solid phases can be controlled and maintained by various promotors and additives in many commercial catalysts of special composition.

The galvanostatic investigations have revealed the effect of non-Faradaic electrochemical modification of catalytic activity (NEMCA)[59–62] where both the rate and selectivity of catalytic reactions can be altered dramatically. However, potential industrial applications cannot yet be evaluated.

Investigations on the cogeneration of electrical energy and chemicals are still in a preliminary stage. Future applications will depend crucially on the commercialization of hydrogen fueled solid electrolyte fuel cells. If the latter become commercially available they could be used for chemical cogeneration purposes after minor modifications.

The present article resulted from the collaboration of our two Institutes in Karlsruhe and Patras which is sponsored by the Volkswagen foundation. We are very grateful for this support. Helpful discussions with Professor Lothar Riekert are gratefully acknowledged.

Gene Synthesis

By Joachim W. Engels* and Eugen Uhlmann*

Dedicated to Professor Hansgeorg Gareis on the occasion of his 60th birthday

New Synthetic Methods (77)

Oligonucleotide synthesis, until a few years ago the rather exotic preserve of a few experts, has become an integral part of the arsenal of molecular-biological techniques. The last decade, in particular, has seen unbelievably rapid development in this area. DNA synthesis has been automated and can now produce genes greater than 1000 base pairs in length. Tailor-made synthetic genes also permit the synthesis of altered or even novel proteins (de novo protein design) by gene-technological methods. Together with modern methods of gene isolation, sequencing, and expression, gene synthesis has played a major part in the enormous advances achieved in gene technology.

1. Introduction

The basic structure and chemical nature of DNA have been known since *Watson* and *Crick*'s fundamental paper of 1953.[1] Starting from nucleotide chains built up of sugar, phosphate, and heterocycles (Fig. 1), the primary structure of the double helix can be deduced as two single strands running antiparallel to each other. Because of complementarity between the individual heterocycles and the hydrogen bonds that are therefore possible between them, an ordered structure results. To describe such complex molecules in a short but comprehensible manner, the following nomenclature has been adopted. The heterocycles in the DNA, called nucleobases, are given the abbreviations A (adenine), C (cytosine, G (guanine), and T (thymine), while the fundamental sugar, 2′-deoxyribose, is indicated with d and has the numbering 1′ to 5′. Figure 1 shows a section of a dodecamer whose X-ray structure[2] forms the basis of our current understanding of B-DNA, one of the three-dimensional forms of DNA. In chemical DNA synthesis, the two complementary strands are constructed separately; i.e., only single-stranded DNA (oligonucleotides) can be synthesized. These are then hybridized (formation of hydrogen bonds) and linked to larger DNA units by enzymatic coupling in order to construct genes or their regulatory units. Although there are several definitions of a gene, our working definition[3] here is that genes are the DNA sequences responsible for the production of polypeptides. With DNA recombination techniques, it is now possible to construct any given DNA, whether synthetic or natural, to reproduce it, and to convert it into polypeptides using whole cell systems.

Starting with the chemical basis of oligonucleotide synthesis and its automation, we will describe actual chemoenzymatic gene synthesis[4–7] and its applications, which open the door to completely new peptides and proteins. The fundamentals for applying the methods outlined here have already been described in detail in this journal.[7,8]

2. Synthesis and Application of Oligonucleotides

2.1. Strategies in Oligonucleotide Synthesis

Oligonucleotides are polymers built up by the polycondensation of nucleoside phosphates. In this process, synthesis is possible in two directions, by 3′–5′ and 5′–3′ phosphate coupling. Because of the higher reactivity of the primary hydroxyl group, the 3′–5′ direction is the one used almost exclusively in synthesis, while nature uses the reverse direction, based on 5′-triphosphates.

Synthesis of a long oligomer or of a polymer can be carried out either by stepwise addition of single monomers or by coupling of oligomeric building blocks. Since DNA consists of only four different nucleotides, 16 dimeric oligonucleotide blocks[9–11] or 64 (4^3) trimeric ones can be prepared,[12,13] and these can be used as building blocks in the synthesis of any desired DNA sequence. Both concepts have been realized. In choosing between them, two factors must be considered: the difficulty of synthesizing the oligonucleotide blocks and the yields obtainable by monomer addition. The diagram in Figure 2 correlates the coupling yield with the length of the DNA and convincingly shows that for a yield of 99% per addition – which, astonishingly, can be achieved for all four nucleotides – pieces long enough to be used in gene synthesis can be synthesized in acceptable yields. In practical solid-phase synthesis, the stepwise addition of monomeric building blocks has become standard.

2.2. Methods for Oligonucleotide Synthesis

Methods for synthesizing defined oligonucleotides are differentiated primarily by the way in which the phosphate ester bond is formed. Thus, according to the nature of the phosphorus component, one distinguishes the so-called triester (Fig. 3a), phosphite (Fig. 3b, X = Cl), phosphoramidite (Fig. 3b, X = N*i*Pr$_2$), and H-phosphonate (Fig. 3c) methods. The corresponding protected nucleoside derivative functions as the starting compound. Although an enormous number of protecting groups are known[14] and have also been tested in oligonucleotide synthesis,[15–18] only a few are routinely used, owing to automation (and commercialization) of DNA synthesis. These are primarily those introduced by *Khorana* et al.:[19] acyl groups on the exocyclic amino functions of adenine, guanine, and cytosine and a

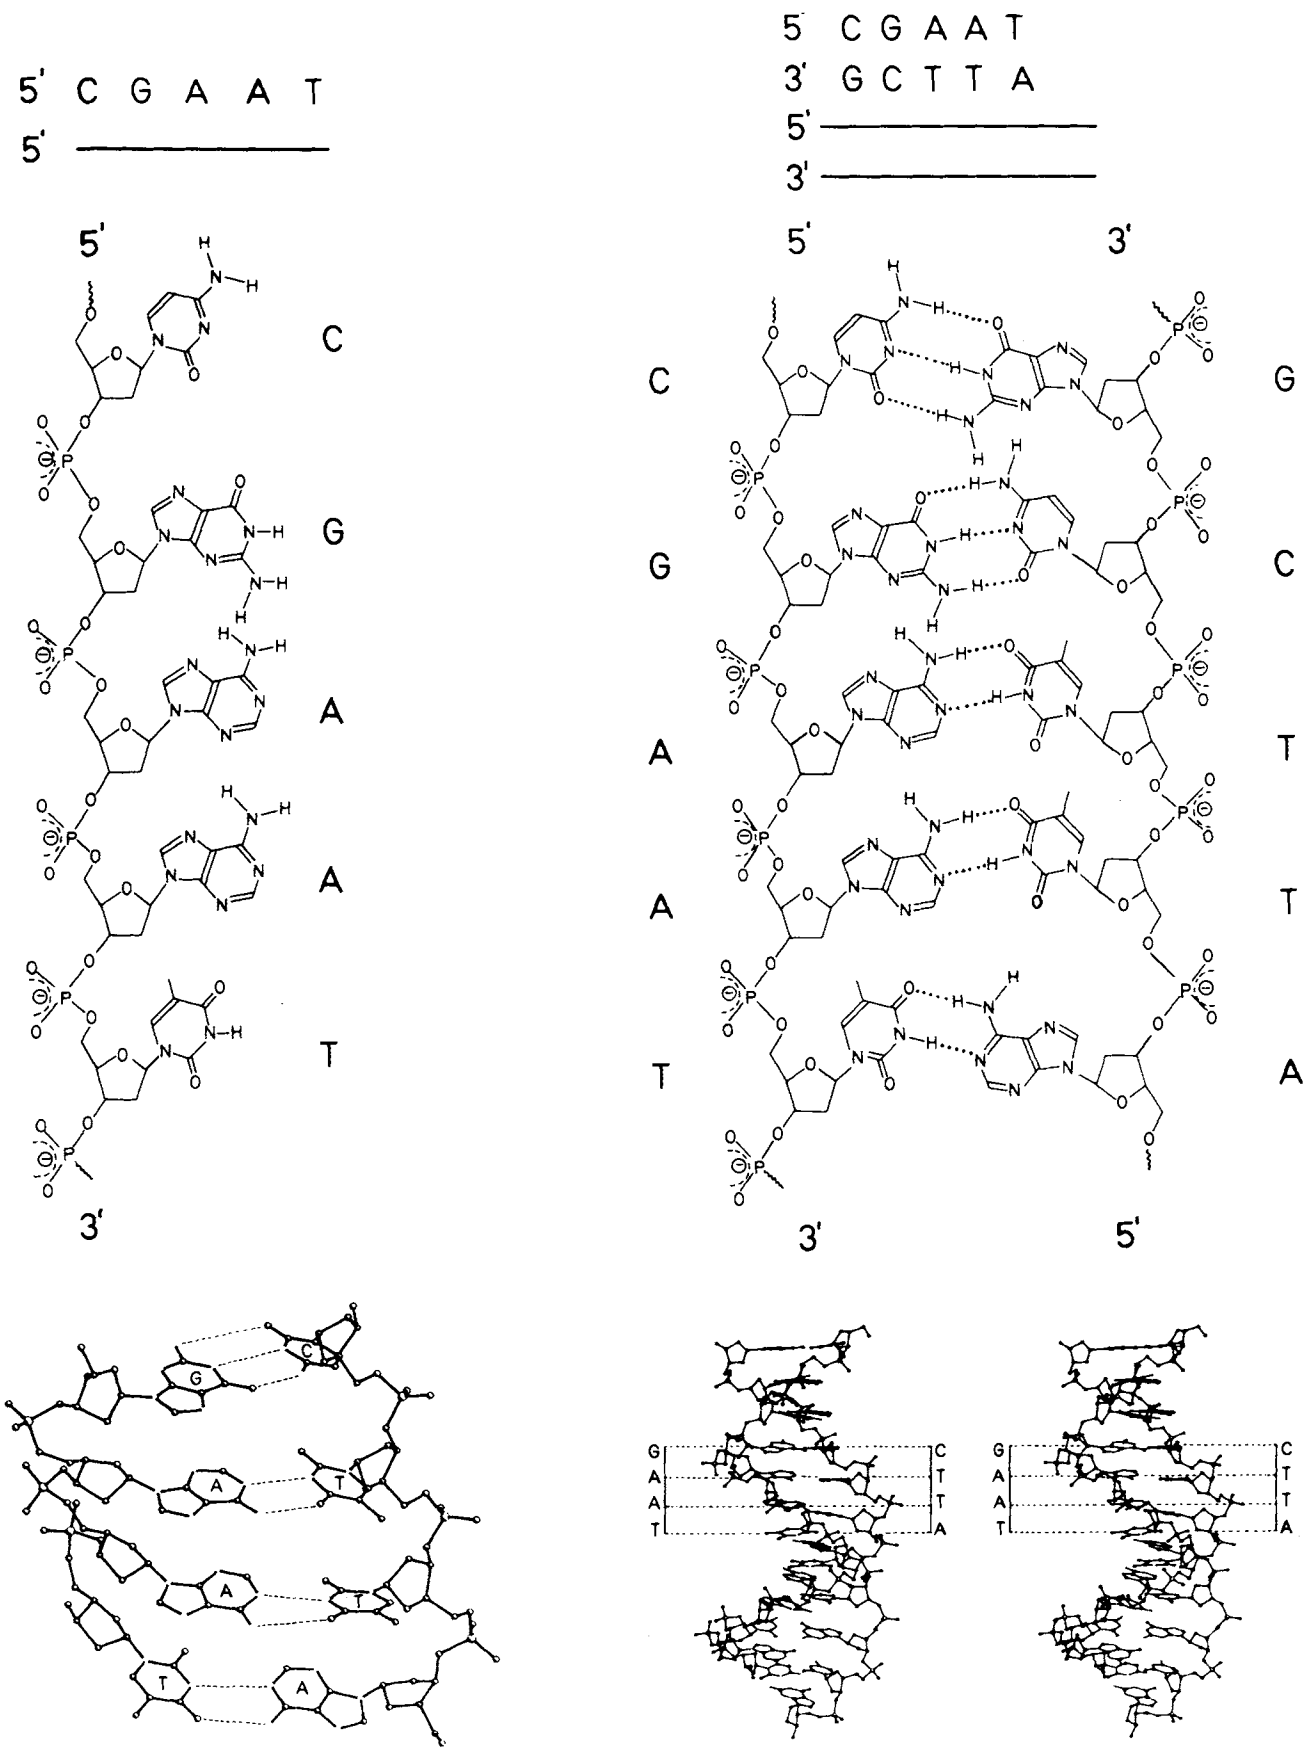

Fig. 1. Single-stranded and double-stranded B-DNA (dodecamer) CGCGAATTCGCG. Top left: 5'-CGAAT single strand. Top right: Idealized Watson–Crick base pairing. Bottom left: Section GAAT, retaining the base pairing. Bottom right: Stereopair of dodecamer.

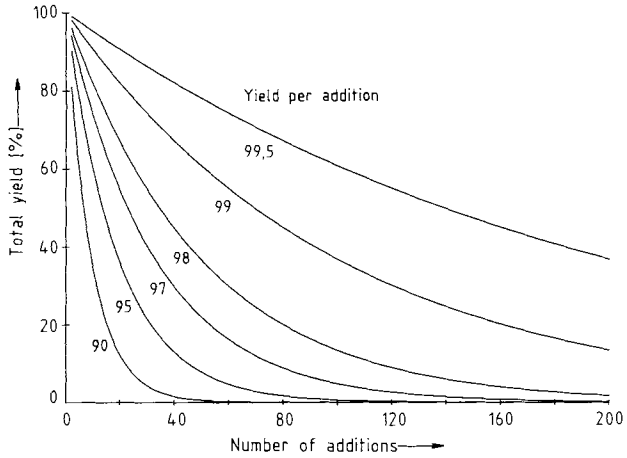

Fig. 2. Correlation of total yield per addition with the number of reaction cycles (i.e., the length of the DNA).

dimethoxytrityl group on the 5'-hydroxyl group of the deoxyribose. Today, they can be introduced easily and in good yield by the "transient protection" method of *Ti* et al.[20] Intermediate protection of the sugar OH groups as their trimethylsilyl ethers allows the amino groups to be specifically protected by acylation reagents. More labile acyl[21] and amidine[22, 23] protecting groups are finding increasing use;

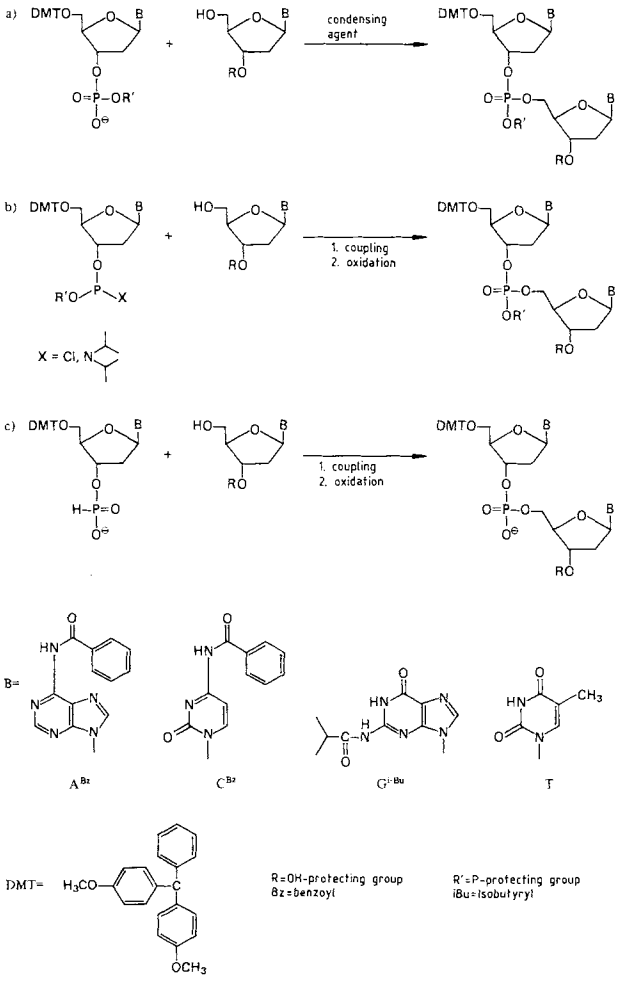

Fig. 3. Methods of oligonucleotide synthesis: a) triester, b) amidite, and c) H-phosphonate.

they are of particular advantage in the synthesis of modified DNA with more labile functionality. A comprehensive list of all the protecting groups used in oligonucleotide synthesis up to 1986 can be found in *Sonveaux*.[18] Especially when synthetic methods using very reactive phosphorus derivatives are employed, it is important to consider undesired derivatization of the amide functions of guanine and thymine.[24–26] Here, too, several protecting groups have been used to convert the amide into the iminoether.[27–30] For the phosphoramidite method, we have been able to show that optimization of the synthesis is preferable to excessive use of protecting groups.[31]

The corresponding protected nucleosides are then phosphorylated with suitable reagents. These can be either mono- or bifunctional. For synthesis on a solid support by the Merrifield strategy, however, it has proved advantageous to synthesize stable monomeric nucleotide building blocks which can be stored ready to be used as needed in synthesis. A multitude of different functions have been used as protecting groups on phosphorus.[18] Here, too, as with the nucleobases, automation has brought about simplification. A point worth mentioning is the chemical mechanism by which the phosphorus protecting group is removed. Reactions at phosphate phosphorus have been shown by *Westheimer* et al.[32] to proceed by addition-elimination mechanisms, with the possibility of pseudorotations. To avoid potential problems, such as undesired hydrolysis, protecting groups are preferred in which attack of the reagent takes place directly at the protecting groups without affecting the phosphate center.[33] Alkyl groups such as methyl and benzyl have been used here, as have β-cyanoethyl, arylsulfonylethyl, arylethyl, and haloethyl groups, all of which can be removed by β-elimination. Isomerization of the phosphate bond is largely prevented and strand breaks avoided by this strategy.

2.2.1. *Triester Method*

This synthetic method (Fig. 3a) was introduced by *Todd* et al.[34] and is based on suitable activation of a protected nucleoside phosphate diester with acid derivatives of the arylsulfonic acid azolide type. The activated phosphate diester then reacts with the unprotected 5'-OH of the nucleoside, giving the corresponding dinucleoside phosphate triester. A large number of such reagents have been used[35–38] as their phosphoric and sulfonic acid derivatives. Of the azolides, tetrazole and 3-nitrotriazole have proved particularly useful. The low initial reactivity of P^V compounds can thus be increased to a sufficient level. Decisive advantages of this method include the good stability of the starting diesters and their potential recovery (e.g., as barium salts).[39] A disadvantage lies in the side reactions brought about by the condensing agent (e.g., sulfonation at the 5'-OH position).

2.2.2. *Phosphoramidite Method*

Here, a suitably protected nucleoside phosphoramidite (Fig. 3b) is converted into a phosphite triester by reaction with a 5'-OH nucleoside in the presence of tetrazole. Subsequent oxidation leads to the corresponding triester (see Fig. 3a). The higher reactivity of P^{III} compounds has always made them attractive starting materials,[40] but for routine oligonucleotide synthesis their poor handleability and

availability and especially the difficulty of storing the monomeric building blocks have hampered their use. With the introduction by *Caruthers* et al.[41,42] of phosphoramidites, which can be activated by acid, the breakthrough was made. Although the initial choice fell on the dimethylamino group as the amidite component and on the methoxy protecting group,[43] today, after further optimization of reaction conditions, the diisopropylamino compound,[44] in combination with a β-cyanoethyl protecting group,[45] is regarded as the best compromise. The most important advantage of this method is the activation by the mild reagent tetrazole, which is practically free of side reactions.

2.2.3. H-Phosphonate Method

Todd et al.[46] were quick to recognize and use the synthetic potential of H-phosphonates. Here, a protected nucleoside H-phosphonate (Fig. 3c) is converted into a dinucleoside phosphonate diester by reaction with a 5'-OH nucleoside in the presence of a condensing agent, usually an acid chloride.[47,48] Subsequent oxidation leads to the corresponding triester. No intermediate protecting group is required on the phosphorus, and the oxidation of the H-phosphonate is carried out only at the end of the synthesis, not after each addition, as in the amidite method. On the other hand, side reactions (acylations) of the condensing agent (e.g., pivaloyl chloride) do occur, as in the triester method. Moreover, the yields in the H-phosphonate method do not match those of the phosphoramidite method, despite optimization (e.g., use of adamantoyl chloride as the condensing agent).[49]

2.3. Oligonucleotide Syntheses on Solid Supports

Because oligonucleotide synthesis is a repetitive technique, synthesis on a solid support has come to be preferred to synthesis in solution or polycondensation.[50] Since the introduction of solid-phase synthesis by *Merrifield*[51] and *Letsinger*,[52,53] the following fundamental requirements have been worked out: (1) The polymeric matrix must be insoluble and as inert as possible in the solvent used. (2) Functional groups on the polymeric support must allow covalent binding of the product to be synthesized. (3) The structure of the polymer must not interfere with the chemical reaction too much (e.g., by hindering diffusion of the reacting molecules).

A large number of materials have been tested, from polystyrene[54] to polyacrylamide,[55] cellulose,[56] polytetrafluoroethylene,[57] and silica gel.[9,58,59] The most widely used today are silica gel and specially defined glass beads, so-called controlled pore glass (CPG) material.[44,60,61] The solid support is connected to the initial nucleoside through a spacer (most simply an alkylamine; Fig. 4). Since synthesis proceeds in the 3'–5' direction, the initial nucleoside is linked to the spacer through its 3'-hydroxyl function and a dicarboxylic acid (e.g., succinic acid).[59] At present, supports carrying the four nucleosides A, G, C, and T or a universal anchor[62] are in use.

Of the requirements listed above, the first two are easy to satisfy. However, the requirement that the solid support have as little effect as possible on the growing chain is not so

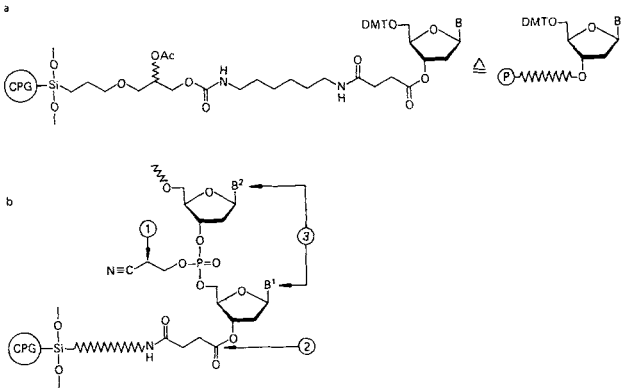

Fig. 4. a) Attachment of the starting nucleoside to the solid support. b) Cleavage (1) of the protecting group on phosphorus, (2) of the oligonucleotide from the support, and (3) of the base protecting groups.

easily met. A very good compromise has been found in the CPG materials now being successfully used. It is interesting to note that when 500-Å CPG material is used, the coupling yield of each addition decreases when a length of 80 bases is exceeded. Changing to 1000-Å material, however, permits synthesis of chain lengths of up to 200 bases.[63] The support material appears to be a decisive limiting factor of the method.

The strategy for carrying out simultaneous syntheses is also worth mentioning here. For solid-phase synthesis, automatic synthesizers have been in use since 1980. With these, one or several (three or four) oligonucleotides can be synthesized simultaneously. However, since in principle only four different reactants (A,G,C,T) are possible in the synthesis of natural DNA, the filter-disc method[64–66] (20 to 100 oligonucleotides) has proved itself as an alternative. The handicaps of this method are slightly reduced yields and difficulties in automation.

Automation was the decisive step in making oligonucleotide synthesis broadly applicable. Thus, the synthetic protocols that had been worked out were put together into the reaction cycle shown schematically in Figure 5. The important steps in such a cycle are:

1. deprotection of the 5'-OH position by treatment with acid;
2. activation of the nucleotide component with tetrazole;
3. addition of the nucleotide;
4. capping of unreacted 5'-OH groups;
5. oxidation (in the case of P^{III} compounds).

Several washes were placed between these crucial chemical steps to rinse away excess reagents and equilibrate the reactions concerned. While steps (1)–(3) are routine for all methods, the necessity of step (4), the capping of unreacted 5'-OH groups, is disputed. Although the individual additions are practically quantitative, this step has proved invaluable in avoiding failure sequences. After completion of the synthesis on the solid support, the oligonucleotides are freed from their protecting groups while still in the automatic synthesizer (step (6), Fig. 5). As a result, cleavage conditions are also simplified. In the phosphoramidite method – which we favor – this reaction is carried out with concentrated aqueous ammonia. The nucleotide mixture obtained is then purified by efficient methods like preparative gel electrophoresis or high-performance liquid chromatography (HPLC).[67]

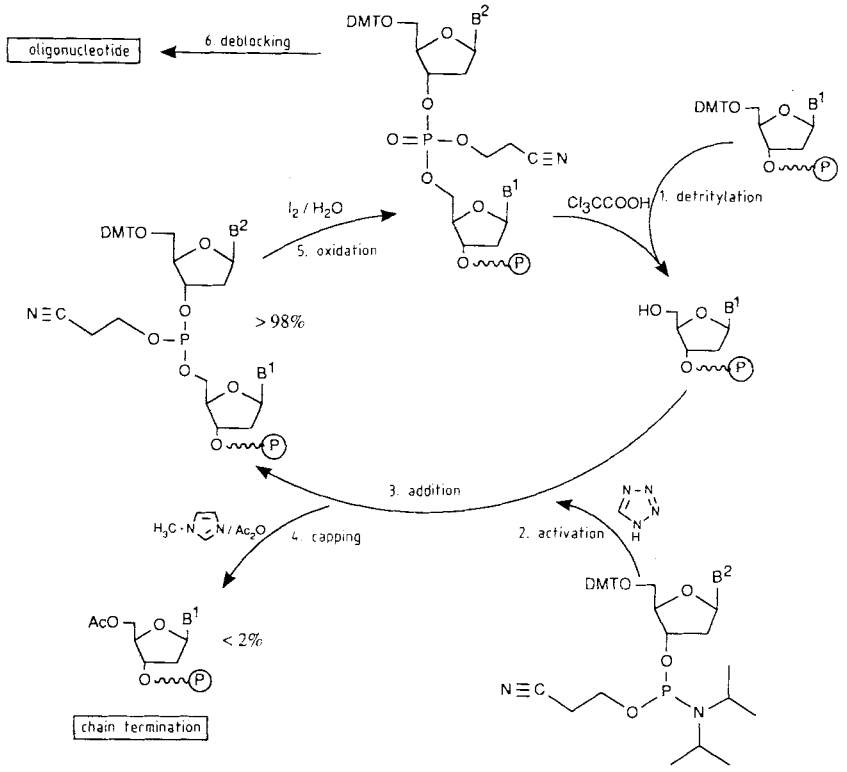

Fig. 5. Synthetic cycle for the phosphoramidite method.

2.4. Application of Synthetic Oligonucleotides

On the basis of the complementarity principle formulated by *Watson* and *Crick*, oligodeoxynucleotides can hybridize with both DNA and RNA. Experiments have shown that the duplex with exact base-pair complementarity is the highest melting. By gradual annealing, therefore, extremely specific analyses can be performed. This principle appears to give especially promising results in genome analysis (i.e., the diagnosis of gene defects).[68] This aspect will not be dealt with further here; rather, the application of the synthesized oligonucleotide building blocks to gene synthesis will be discussed in detail.

3. Construction of Synthetic Genes

3.1. Historical Development of Gene Synthesis

Before methods for the design and synthesis of genes are discussed in detail, the enormous developments in DNA synthesis during the last two decades will be illustrated with a few instructive examples (Table 1). In the sixties and early seventies, crucial pioneering work was carried out by *Khorana* et al., who synthesized the genes for yeast alanine-specific transfer RNA (tRNA)[69] and *E. coli* tyrosine-suppressor tRNA.[70–82] The fundamental methods and strategies developed there are still being used for the synthesis of numerous genes.

Table 1. Historical developments in gene synthesis.

Gene for	Length of the gene [bp]	Number of oligo-nucleotides	Method for oligonucleotide synthesis [a]	Length of synthesized oligonucleotide	Length of overlap	Year of appearance	Ref.
Alanine-specific tRNA from yeast	77	15	diester	5–20	4–7	1970	[69]
Angiotensin II	33	7	diester	6–11	5–6	1975	[83]
Tyrosine-suppressor tRNA from *E. coli*	126	26	diester	6–13	4–7	1976	[70–82]
Somatostatin	56	8	triester	11–16	5–8	1977	[84]
Insulin							
B chain	104	18	blocks of triester	10–12	4–6	1978	[85]
A chain	77	12	blocks of triesters	10–15	5–8		
Interferon-α	514	67	triester/sp	14–21	7–10	1981	[87]
Epidermal growth factor	170	10	amidite/sp	11–59	7–24	1983	[97]
Interferon-γ	453	66	chloridite/sp	9–14	5–8	1984	[116]
Interferon-γ	452	34	amidite/sp	18–33	6 [b]	1984	[115]
Growth hormone	584	78	triester/sp	7–26	4–10	1984	[89]
Interleukin-2 receptor protein	753	38	amidite/sp/A	27–51	6–12 [b]	1986	[90]
Bovine rhodopsin	1057	72	amidite/sp/A	15–40	4–5 [b]	1986	[168]
Bovine prochymosin [d]	1108	28	amidite/sp/A	59–102	4 [b]		
	1126	26		72–102	7–8 [b]	1987	[92]
HMG CoA reductase	1400	19	amidite/sp/A	86–147	[c]	1988	[93]
t-Plasminogen activator	1610	101	amidite/sp/A	17–37	4–20	1988	[91]

[a] sp = solid phase; A = automated DNA synthesis. [b] Preformed duplex DNA. [c] Not by ligation of the oligonucleotides. [d] Two syntheses performed.

Despite *Khorana*'s sensational work and exceptional successes, the time was not yet ripe for application of synthetic genes, since many of the important molecular-biological tools and techniques (e.g., restriction enzymes, DNA sequencing) were not discovered or developed until later. The real breakthrough did not occur until a decade later, with the synthesis and expression of structural genes (i.e., genes that code for valuable peptides or proteins). "Expression" of a gene is understood as its transcription into a messenger RNA (mRNA) and subsequent translation of the mRNA into the corresponding polypeptide. Although by 1975, *Köster* et al.[83] had reported the first successful synthesis of a structural gene, that coding for the octapeptide angiotensin II, the breakthrough in synthetic genes took a few more years, since this gene could not be successfully expressed at that time. The route to expression of synthetic genes had thus been foreshadowed, but the expression of the first synthetic gene in bacteria, achieved by *Itakura* et al. in 1977,[84] was without doubt one of the highlights of genetic engineering. The tetradecapeptide obtained, somatostatin, was, in addition, the first peptide hormone to be detected in *E. coli* produced by recombinant DNA methods. In another remarkable paper the following year, the same research group reported the successful synthesis of the insulin A and B chains,[85] which were later expressed in *E. coli*.[86]

A further milestone in the history of gene synthesis was the total synthesis of the gene for leukocyte interferon (IFN-α) in 1981.[87] The length of the gene, 514 base pairs (bp), coding for 166 amino acids, was impressive, as was the fact that for the first time the synthetic gene was derived not from the peptide sequence but from the published nucleotide sequence (cDNA).[88] Previously, genes had been produced manually and in solution, a process which would have been impracticable for a gene of this size. Only since the introduction of solid-phase techniques has the synthesis of larger genes of the length of the interferon gene, for example, become a reality. With the introduction of the technique of sequential cloning, the construction of larger genes became possible. Sequential cloning means division of a gene into fragments which are cloned separately and, only after verification of the partial sequences, combined to form the total gene. For example, the syntheses of a gene for human growth hormone (192 amino acids), put together in two fragments from 78 oligonucleotides, was accomplished in 1984.[89] The gene syntheses published after 1984 have been largely carried out using DNA synthesizers.

The first example of a synthetic gene for a receptor protein was presented in 1986.[90] It consisted of 753 base pairs and was synthesized from only 38 synthetic oligonucleotides via three subclones. The longest synthetic gene to date contains 1610 base pairs and codes for human t-plasminogen activator (h-tPA).[91] This gene required the synthesis of 101 oligonucleotides with an average length of 32 nucleotide units. With a cycle time of 12.5 min per nucleotide addition, one can thus calculate a total synthesis time of about 30 days for the entire tPA gene. The main task was linking together the 101 oligonucleotides to make the complete gene.[91]

Indirectly, Table 1 reflects the extremely rapid progress in oligonucleotide synthesis in recent years, as seen in the growing chain length of the oligonucleotides used. If one ignores the tPA gene for the moment, the trend is clearly towards the use of longer oligonucleotides,[92,93] simplifying construction of the gene and also admitting the development of new strategies for gene synthesis. It is not difficult to predict that in the future great but easily justifiable efforts will go into making even longer synthetic genes.

To date, over 150 genes have been synthesized, coding for hormones,[83-85,89,94-113] interferons and lymphokines,[90,127-130] growth factors,[131-140] enzymes,[92,93,141-152] neuropeptides,[153-157] calcium-binding proteins,[158,159] gastrointestinal peptides,[106,160] proteinase inhibitors,[161-167] and other products.[69,82,91,168-188]

3.2. Routes to Double-Stranded DNA

3.2.1. Fundamental Enzymatic Reactions: The DNA Ligase and DNA Polymerase Reactions

Genetic information is stored in the form of the nucleotide triplet in the coding strand of DNA and indirectly in the noncoding strand. The double helix structure of DNA (Fig. 1) serves to stabilize the DNA and is also a requirement for its replication. The natural ability of single-stranded oligo- or polynucleotides to bind to one another in a defined manner through base pairing can be exploited for the construction of double-stranded DNA from suitable chemically synthesized oligonucleotides.

In principle, two types of enzymatic reactions can be applied in the construction of double-stranded DNA, those catalyzed by DNA ligase and DNA polymerase. The enzyme T4-DNA ligase catalyzes the formation of phosphodiester bonds between neighboring 5'-phosphate and 3'-hydroxyl ends in a DNA duplex in the presence of ATP (Fig. 6). Sin-

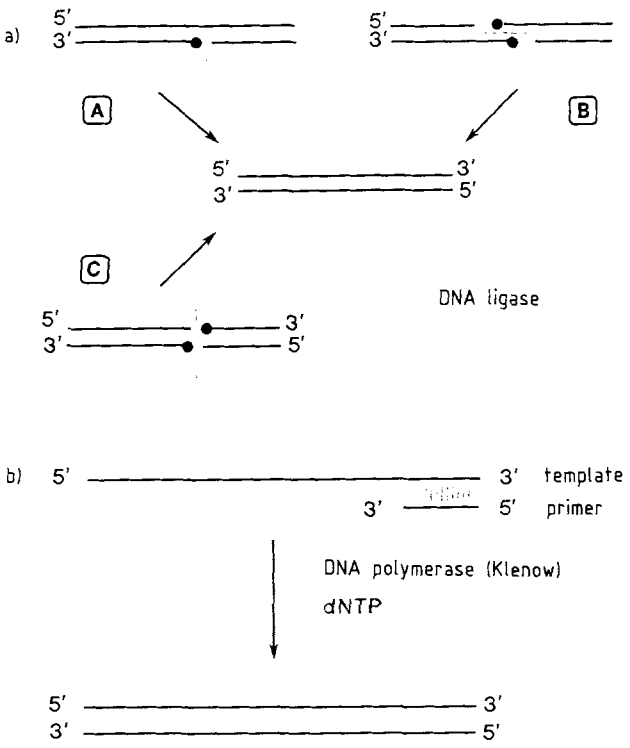

Fig. 6. Fundamental enzymatic reactions in the construction of double-stranded DNA from oligonucleotides: a) DNA ligase reaction; b) DNA polymerase reaction.

gle-stranded oligonucleotides, by contrast, are not substrates of DNA ligases. In reaction-type A, the oligonucleotides to be coupled are held together by an intact region on the complementary oligonucleotide. In contrast, in reaction-type B the overlapping ends of the two strands are joined. Like the DNA fragments that arise from cutting with restriction enzymes, the ends can be ligated in a 5′-overhanging or a 3′-overhanging manner. Reaction-type C, in which "blunt ends" are ligated, is rarely used in gene synthesis, since the lack of base pairing leads to low selectivity in this reaction. In addition, these blunt-end ligations are much less efficient than so-called sticky-end ligations. If the oligonucleotides to be joined have not already been synthesized as 5′-phosphates,[189, 190] phosphorylation of the 5′-hydroxyl nucleotides with polynucleotide kinase and ATP is necessary. In this enzymatic step, the oligonucleotides can be radioactively labeled using [γ-^{32}P]ATP, a process which can be useful in the ligation of subnanomolar quantities. The enzyme DNA polymerase I (Klenow fragment), which lacks the 5′–3′ exonuclease activity of the complete enzyme, can, in the presence of the deoxynucleoside 5′-triphosphates, synthesize a complementary copy of a single-stranded polynucleotide, starting at the 3′-hydroxyl end of a short, hybridized oligonucleotide primer (Fig. 6b). In principle, this "fill-in" reaction can be performed by any of the DNA polymerases from other organisms that have been used for DNA sequencing according to the *Sanger* procedure.[202]

3.2.2. *Strategies for Gene Synthesis*

Retrosynthetically, the gene to be synthesized can be dissected into single-stranded oligonucleotides along any of the paths A–E in Figure 7. The number of required oligonucleotides will depend on their length.

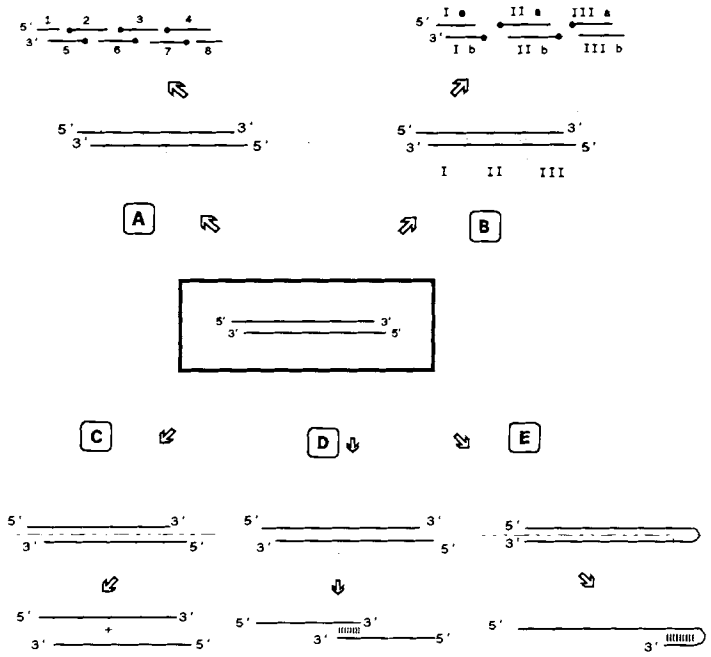

Fig. 7. Strategies for gene synthesis: A) ligation procedure according to *Khorana*; B) sequential ligation of preformed DNA duplexes; C) direct hybridization and cloning of longer oligonucleotides; D) fill-in method for overlapping oligonucleotides; E) fill-in method for autoprimer oligonucleotides.

Path A: Ligation of Overlapping Oligonucleotides by the Khorana Procedure

The classical procedure of *Khorana*[69, 191] is outlined in path A. It is based on ligation-type A of Figure 6a, whereby the gaps to be closed are situated alternately in the upper and lower strands. This strategy requires the synthesis of a set of overlapping oligonucleotides (here, for example, eight of them) and their ligation to form a complete gene or gene fragment. Only the internal oligonucleotides (2–7) must be present as their 5′-phosphates. Because of base complementarity, heating a solution of all the oligonucleotides and cooling it slowly results in correct annealing and formation of a hybrid molecule that is not yet covalently bonded. In the presence of ATP, DNA ligase then generates the desired phosphodiester bonds. In this way, for example, 20 oligonucleotides could be coupled in a single ligase reaction to give a 280-bp structural gene.[131] In our hands, however, six to ten oligonucleotides proved optimal with regard to yield and size of the gene. The general rule is that the yield of the completely ligated product falls as the number of oligonucleotides to be coupled in a reaction increases.[176] Using longer oligonucleotides of 40 to 60 bases leads to an increase in the efficiency of the enzymatic ligation reactions.[192]

Ligation according to path A is exemplified by the synthesis of a gene for tyrosine-suppressor tRNA from *E. coli*, reported by *Khorana* et al. in twelve consecutive publications in 1976.[70–81] The 126-bp gene was first divided into four fragments, and these were then further divided into a total of 26 oligonucleotides. This was done in such a way that at least four to six base pairs could overlap between the individual oligonucleotides. Another aspect was the economy of the synthesis, for example the repeated use of synthetic blocks. The total synthesis of the gene thus required the chemical synthesis of 26 oligonucleotides by the phosphodiester method, which at that time was the most labor-intensive part of the synthesis. These oligonucleotides were then ligated in groups into four fragments, which were subsequently coupled to give the complete gene. Coupling of the fragments proved to be quicker and more efficient than the previous ligation of single-stranded oligonucleotides, a fact that was taken into account in later developments (cf. strategy B). Today, *Khorana*'s ligation procedure is still the most popular strategy, especially for oligonucleotide chain lengths between 15 and 50 units. Since the filter-disc method[64–66] works mainly in this length region and can also be used to synthesize a large number of oligonucleotides simultaneously, ligation strategy A is the method of choice in this case. These days, longer genes are divided into several subclones (subfragments)[115] and are not constructed in a ligation cascade without intermediate cloning, as was the case for the leukocyte interferon gene.[87] Among others, the 1610-bp gene for tPA[91] was constructed from 101 oligonucleotides by this strategy, via three subclones.

Path B: Sequential Ligation of Preformed DNA Duplexes

Just as DNA can be cut with restriction enzymes, genes can also be retrosynthetically divided into smaller DNA fragments. This approach presumes a certain chain length for the synthesized oligonucleotides, however, in order that stable DNA duplexes are formed. Strategy B has the advan-

tage over strategy A that the oligonucleotides are hybridized pairwise into small DNA double strands, which can then be ligated, either sequentially or in one pot, to form the complete gene in good yield. In this way undesired hybridizations are prevented (for example, Ia with IIb in Fig. 7). DNA double strands can also be easily purified on agarose gels (2–4%). The overlapping ends can be planned to overlap either 3′ or 5′, as desired. Usually overlaps of four to eight bases are chosen, but overlaps of up to twelve base pairs have been used with success.[90] Although longer overlaps lead to more stable hybrids, with large overlaps one is potentially struggling against problems of secondary structure (cf. Section 4.1) and incorrect intermolecular interactions, so that a compromise must be sought between the opposing effects.

Path C: Direct Hybridization and Cloning of Longer Oligonucleotides

Division of a gene into a coding and a noncoding strand is the simplest possible route to the total synthesis of a gene, but was not practicable in the past because chemical synthesis could not produce oligonucleotides of sufficient length. Today, however, the synthesis of oligonucleotides up to 200 units in length is possible. This means that genes or gene fragments coding for up to 65 amino acids are accessible by the synthesis of only two oligonucleotides and their hybridization. Recently, the synthesis and cloning of a calcitonin gene by this procedure was reported for the first time.[109] This strategy has the following advantages: the manual work to be performed is greatly reduced, since no enzymatic ligation is required; the chemical synthesis is performed by a synthesizer; purification of only two oligonucleotides is needed. On application of sequential cloning (subcloning) of gene fragments, this strategy also becomes an attractive method for the synthesis of larger genes. In principle it is a logical further development of the preformation of DNA duplexes (strategy B). Depending on the chain length of the oligonucleotides used and on the choice of retrosynthetic cleavages, there is a smooth transition from strategy A through B to C. In this light, subcloning is nothing more than moving the sequential ligation of preformed duplexes into a plasmid, though with the great advantages that the sequence of the synthetic fragments can be verified at an intermediate stage and that an inexhaustible source of the particular gene fragment is obtained. A combination of strategies B and C is found in the synthesis of the ca. 1100-bp-long gene for bovine prochymosin.[92]

Path D: Fill-in Method of Overlapping Oligonucloeotides

The so-called fill-in procedure, making use of DNA polymerase, was farsightedly suggested by *Khorana*[191] in 1968, but was not realized until 1982 by *Rossi* et al.[193] It relies on the synthesis of two long oligonucleotides with perfect base-pairing sequences at their 3′ ends. After correct hybridization of these oligonucleotides, the DNA polymerase (Klenow) reaction shown schematically in Figure 6b can be applied, with the 3′ end of each strand acting as a primer for template-dependent synthesis of a copy of the other strand. In this manner some 40% of the chemical synthesis work can be spared. Nonetheless, this strategy has not really become established and only a few examples are known.[161, 162, 178, 194–196] The size of the gene fragments used has been about 60 to 100 base pairs. In our own work on the synthesis of a gene fragment for interferon-γ[3] we encountered the following problems: (1) Difficulties sometimes arise in "filling-in" the last nucleotide at the 5′ end. It is therefore advisable to synthesize two or three extra nucleotides, which can later be cleaved off with an appropriate restriction enzyme. Restriction enzymes that, on cutting, leave overhanging ends, are advantageous, since these ends are easier to ligate than blunt ones. (2) Product quality was seldom as good as the DNA obtained from ligase reactions. We therefore think that the main problem in this strategy is the formation of unwanted secondary structures, especially when, for reasons of economy, very long oligonucleotides are used.

Path E: Fill-in Method using Autoprimer Oligonucleotides

One immediate consequence of these disadvantages was the introduction of a new method, which also uses the intrinsically economic DNA polymerase reaction.[197, 198] This strategy is based on the use of long oligonucleotides carrying a short, repeated sequence at the 3′ end. The resulting hairpin structure is unusually stable[198–201] and serves as a primer in the DNA polymerase-catalyzed formation of the complementary strand. This type of oligonucleotide is accordingly designated an "autoprimer". Following the fill-in reaction with the deoxynucleotide triphosphates, easily ligated, overhanging ends are generated by cleavage with appropriate restriction enzymes, which simultaneously dissolve the hairpin structure. Use of autoprimer oligonucleotides (strategy E) has numerous advantages over overlapping oligonucleotides (strategy D): (1) No special hybridization is necessary, since the autoprimer oligonucleotides are obtained in their entropically favored hairpin configuration. (2) The strand-separation activity of the DNA polymerase is circumvented, since the primer is covalently bound to the template. (3) One has the option of synthesizing either the coding or the noncoding strand, and constructing the complementary strand with the aid of the problem-free, enzymatic polymerase reaction. In this way the chemical synthesis of long purine-rich sequences, which often affords problems, can be avoided.

Thus, a 117-bp gene for calcitonin-Gly(33) could be produced[197] from a single 140-base oligonucleotide. With the aid of subcloning techniques, however, genes of any size can be synthesized. For example, from only three autoprimer oligonucleotides it was possible, by enzymatic processing, to synthesize a 310-bp fragment.[198] Just as in *Sanger*'s DNA-sequencing procedure,[202] which is also based on the DNA-polymerase reaction, four to eight reactions can be carried out simultaneously without difficulty.

3.2.3. Selection Criteria: Gene Size, Oligonucleotide Length, Mutation Frequency

In planning the synthesis of a gene, the following questions must first be considered. How long is the gene? Can it be synthesized as one block, or must it be divided into gene fragments? What chemical methods are available for synthesis of the oligonucleotides, and what oligonucleotide lengths can be achieved?

In principle, one attempts to synthesize a gene in one cloning step from the longest possible oligonucleotides, since there is then a minimum number of oligonucleotides to purify and of ligation points to couple. Set against this, however, is the mutation frequency, which rises with the chain length of the oligonucleotides and becomes a limiting factor as the gene grows longer. Recently reported mutation frequencies lie between 0.05% and 0.32% per oligonucleotide.[92, 173, 198, 203, 204] Taking an average value of 0.15%, in every 1000 nucleotides about one or two errors are to be expected. The chance, then, of finding a correct clone in direct cloning of a 500-bp gene is at best 50%. In practice, therefore, one has to sequence at least two clones in order to identify a correct one. All kinds of mutations are found: transitions, transversions, insertions, and deletions. The most frequent, however, appears to be the mutation of a GC base pair into an AT base pair.[139, 204] A possible explanation for this is a chemical modification of the carboxamide function (O^6) of deoxyguanosine during oligonucleotide synthesis. On treatment with ammonia, the base 2,6-diaminopurine may be formed at the corresponding position and can base-pair with both cytosine and thymine.

The longest subcloned gene fragment to date, with 710 base pairs, codes for the serine protease domain of tPA.[91] Following the cloning of this fragment, three clones were sequenced, of which one was correct and the other two showed a total of three mutations. At the present time it is advisable to subdivide large genes into fragments of about 250 to 300 base pairs, so that the labor saved in the gene construction is not overcompensated for by subsequent DNA sequencing. Table 2 compares the mutation frequencies per oligonucleotide pair given in recent articles. While for short oligonucleotides (33-bp average)[173] only every twelfth clone shows an error, for longer oligonucleotides (85 to 132 bp) this is the case for about every fourth clone.[92, 203] A significantly lower error frequency is observed when autoprimer oligonucleotides are used in a fill-in reaction. This is reasonable, since only one strand of the DNA is chemically synthesized, while the opposite strand is formed by a virtually error-free enzymatic reaction. All in all, the mutation frequency very clearly reflects the purity of the oligonucleotides used, so optimal retrosynthetic analysis of a gene may only be possible after some experience has been gained. Selection criteria other than those named are also of practical significance and will be discussed later. Subdivision of a gene into various small subclones, for example, can be worthwhile despite the greater initial effort involved, if many variants of the gene are to be synthesized subsequently.

Table 2. Mutation frequency in cloning synthetic oligonucleotides.

Number of oligonucleotide pairs	Strategy used in gene synthesis (cf. Fig. 7)	Mutation frequency per oligonucleotide pair x/y [b]	[%]	Ref.
33	A	1/12	8	[173]
105	E	2/18	11	[198]
85	B, C [a]	34/139	24	[92]
132	C	10/36	28	[203]
80	C	8/20	40	[204]
100	B	6/9	67	[139]

[a] Combination of various strategies, including the "shot-gun" method.
[b] x = number of incorrect clones; y = total number of clones sequenced.

3.3. Rapid Methods of Gene Synthesis

In this section, several special variations on the principal methods outlined above will be described. These allow rapid synthesis of genes, but no longer conform to the ideal of the original *Khorana* papers, namely, the characterization of the intermediate products. These rapid methods were made possible by the enormous progress made both in nucleotide synthesis and DNA sequencing and in the utilization of more efficient selection procedures in the cloning step.

3.3.1. The "Shotgun" Method

In this procedure, the gene is put together from a number of overlapping oligonucleotides without intermediate control or purification, by immediately ligating it into an appropriate M13 vector and cloning it in *E. coli* (Fig. 8a). *Grundström* et al.[205] have reported the synthesis of a number of SV40 DNA segments which were constructed from a set of 15 oligonucleotides. Since the synthetic DNA fragment contains the overhanging sequences for incorporation into a suitable vector, only completely ligated products possessing the correct ends are finally integrated into the vector. Incompletely ligated products do not lead to recircularization of the vector and therefore remain mute. It was found that about half of the clones analyzed contained the desired sequence.[205] Starting with five sets of oligonucleotides, containing eleven, three times seven, and two oligonucleotides, *Brodin* et al.[158] produced a gene for a bovine Ca-binding protein. Since then, numerous other gene syntheses of this type have been published.

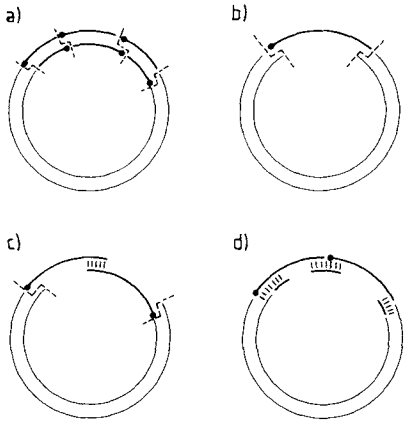

Fig. 8. Rapid procedures for gene synthesis: a) shotgun procedure; b) single-stranded cloning of an oligonucleotide; c) single-stranded cloning of 3'-overlapping oligonucleotides; d) single-stranded cloning using an auxiliary oligonucleotide.

"In vivtro" cloning[206] is a further development of the shotgun method, where the enzymatic machinery of the cell is utilized to phosphorylate and to ligate the synthetic oligonucleotides. Since the procedure combines the characteristics of in vitro and in vivo reactions, the term "in vivtro" appears justified. Basically, one proceeds as in the shotgun technique, but hybridizes the oligonucleotides directly with a

suitable open vector and further transforms them in competent cells without in vitro phosphorylation and ligation.

3.3.2. *Single-Strand Cloning by Repair of DNA Gaps*

In principle, the genetic information in a gene is defined by one DNA strand, while the second strand serves to maintain the double-helical structure, thus allowing replication and proofreading. Almost half the chemical synthesis work can therefore be spared if single-stranded DNA is ligated into vectors suitable for this task. On subsequent transformation of bacteria with these incomplete vectors, the repair machinery of the host cells completes the vector ("in vivo" gap repair). This procedure was realized[207] in the synthesis of a gene fragment coding for amino acids 198–231 of bacteriorhodopsin. Here, an oligonucleotide was ligated, patchlike, into a vector having a 3'-overhanging, single-stranded DNA sequence on one side and a 5'-overhanging sequence on the other, complementary to the 5' and 3' ends, respectively, of the oligonucleotide (see Fig. 8b). Up to now this method has only been applied to relatively short oligonucleotides and the efficiency observed has been low.[208] By using an "in vitro fill-in" reaction (or a tricky sequential ligation procedure) and a large excess of oligonucleotide, the desired clones were obtained in significantly increased yields.[209] Finding pairs of restriction enzymes that always open the vector with 5' and 3' overhangs is not a limiting factor if one uses two single-stranded oligonucleotides hybridized through their complementary 3' ends (Fig. 8c). In this case a vector possessing 5'-overhanging ends on both sides can also be used for ligation.[207] To raise the ligation yield, auxiliary oligonucleotides can also be employed, in order to lengthen the double-stranded region at the ligation points. Thus, the cloning of a 290-bp gene was recently reported;[185] it was made from two long oligonucleotides (144 and 139 bases) which were coupled together through three smaller oligonucleotides (11–16 bases) and ligated into a vector (Fig. 8d). As far as the efficiency of this variant is concerned, it was reported that of 48 clones analyzed, seven contained the desired gene, and of three completely sequenced clones only one possessed the correct sequence.

Although the ideas behind Figures 8c and 8d could theoretically be expanded as far as desired by using a still larger number of oligonucleotides, there are practical limits, since yields fall with an increasing number of oligonucleotides. Under certain circumstances, single-stranded ligation of oligonucleotides bearing a ribonucleotide at their 3' end, catalyzed by T4 RNA ligase, could be of benefit here.[210–212]

The M13-insertion technique is a special form of in vitro mutagenesis.[213] The principle of oligonucleotide-directed site-specific M13 mutagenesis (cf. Section 4.2) is based on designing an oligonucleotide that is complementary to a single-stranded M13 template, but has a single base mismatch which generates the desired mutation (see Fig. 11). After annealing the oligonucleotide onto the template, the second strand is formed with the aid of DNA polymerase. Finally, the vector is circularized with DNA ligase. In order to insert a long DNA sequence into a defined site in the vector (gene synthesis)[214] this must replace the mismatch. After replication of the partially mismatched vector, appropriate methods are used to select the clones with the desired insert from the wild-type clones which are generated at the same time. An interesting further application of single-stranded cloning to gene synthesis is based on oligonucleotide-directed repair of a DNA double-stranded break.[215]

3.3.3. *Solid-Phase Gene Synthesis*

In Section 2.2, it was stated that in a ligase reaction the yield of fully ligated products decreases as the number of oligonucleotides to be coupled increases. From this, it seems that sequential coupling of small gene fragments is an advantage and that an excess of the fragment to be ligated may greatly increase the yield. Just as an oligonucleotide may be synthesized on a solid support, entire genes may be built up by repetitive ligation of gene fragments. The advantages of solid-phase gene synthesis were first described by *Hostomský* et al.,[164] using the example of a bovine colostrum trypsin inhibitor gene. In the initial step, a starter oligonucleotide was anchored covalently by its 3' end to Sephacryl S-500, using cyanogen bromide activation. In the subsequent stepwise addition, DNA duplexes, prepared from three to four oligonucleotides by hybridization, were annealed to complementary oligonucleotides through relatively long overhanging ends of 15 nucleotides. At this stage the growing chain is therefore held together merely by the hydrogen bonds of the bases. In the last elongation step, the entire gene is covalently linked together with DNA ligase. The linearized cloning vector is best added while the gene is still on the support and before the whole construct is cleaved from it and circularized. This procedure has the advantage that only complete DNA chains with the appropriate ends can be integrated into the vector. The time-consuming derivatization of the solid support with the anchor oligonucleotide is a disadvantage, as are the unprotected, long overhangs on the oligonucleotides, which can potentially interact with themselves and thereby lead to inefficient or even incorrect ligation.

Problems of this nature can easily be avoided, however, by fixing partially double-stranded anchor oligonucleotides onto the support via appropriately modified unpaired nucleotides.[216] In addition, the autoprimer oligonucleotides described in the previous section are of great benefit in the chain extension, if one generates overhanging ends on only one side by restriction enzyme digestion after the fill-in reaction and retains the loop structure on the other. By using an excess of these fragments, they can be ligated very efficiently onto the growing chain.[198] The hairpin structure, which prevents multiple addition, can be removed by scission with a suitable restriction enzyme, allowing a further chain extension.

3.4. Construction Planning for Synthetic Genes

The quality of the planning for a synthetic gene is crucial both in the success of the gene synthesis and in successful expression of the gene. Systematic planning, drawing on computer programs, is therefore to be recommended, following the flow diagram shown in Figure 9, for example. The bigger the gene to be synthesized, the more detailed and polished the synthetic planning will have to be. Plans for expression will be discussed in Section 3.4.2. Obviously,

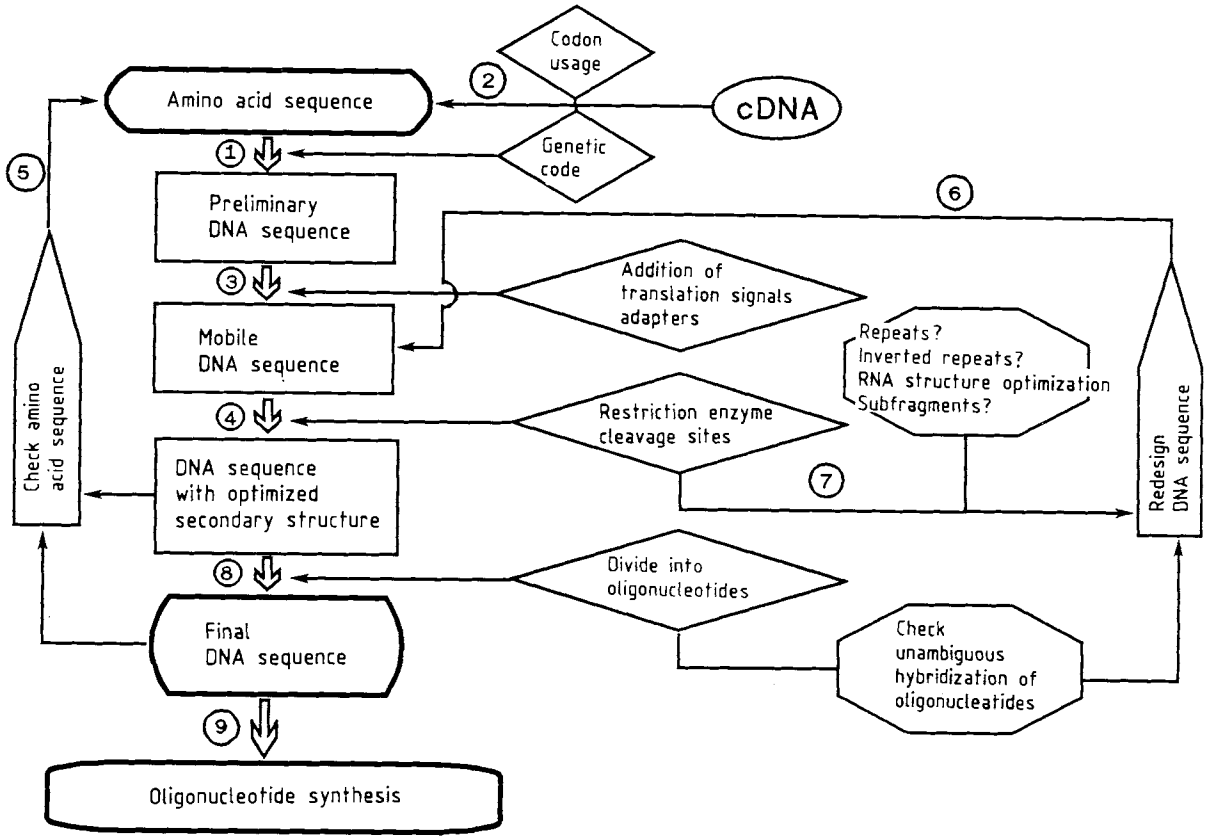

Fig. 9. Planning and design of a synthetic gene.

however, these considerations must play a part in the final design of a gene.

3.4.1. Design of a Synthetic Gene

Genetic Code and Host Specificity of the DNA

Total synthesis of a gene is especially useful when the amino acid sequence of a protein has been determined but the DNA sequence of the corresponding gene is not yet known. If one knows the genetic code (Table 3), the amino acid sequence can be translated into a DNA sequence (step 1, Fig. 9). The genetic code is degenerate, however; this means that for most amino acids several nucleotide triplets can be chosen. Because synonymous codons are not used with the same frequency in natural DNA and also because the nonstatistical use of these codons is related to the level of gene expression, there seems to be a set of "optimal" codons for synthetic genes. According to the species of host organism, one follows the codon usage of genes that are highly expressed in *E. coli*,[217-219] for example, or in other hosts.[220,221] The value of this codon usage should not be overrated, though, at least in the case of *E. coli*, because so far no conclusive experimental data on this problem are available. Nonetheless, preferred codon usage has been taken into consideration for most synthetic genes.

Table 3. Codon usage in strongly and weakly expressed genes in *E. coli* (from *Grosjean* and *Fiers* [217]). Codon pairs that are read by only one tRNA are framed. Amber, ochre, and opal correspond to stop codons.

	U			C			A			G			
		strong	weak		strong	weak		strong	weak		strong	weak	
U	Phe	39	151	Ser	93	36	Tyr	34	96	Cys	13	34	U
		113	102		87	49		98	65		23	39	C
	Leu	12	71		6	37	ochre			opal			A
		16	64		12	62	amber			Trp	25	66	G
C	Leu	26	73	Pro	21	29	His	19	95	Arg	223	99	U
		33	69		2	46		75	59		101	133	C
		→ 3	22		26	45	Gln	38	90		→ 3	27	A
		345	294		162	101		169	166		→ 1	42	G
A	Ile	67	156	Thr	103	46	Asn	13	101	Ser	10	56	U
		262	118		137	119		159	98		49	61	C
		→ 2	27		15	32	Lys	259	163	Arg	→ 3	28	A
	Met	140	130		28	76		106	44		→ 1	17	G
G	Val	192	108	Ala	173	87	Asp	116	183	Gly	226	124	U
		41	66		48	178		204	106		174	140	C
		119	48		119	107	Glu	333	210		→ 4	42	A
		83	123		129	149		106	98		→ 14	66	G

Chemical gene synthesis is also useful, though, when the amino acid sequence has been derived by back-translation of the cDNA sequence. Apart from the adjustment to optimal codons (step 2), this also has the advantage of the speed with which tailor-made genes are accessible. Since proteins are often synthesized as precursors in nature, the cDNA is frequently missing the corresponding translation signals. A start codon (ATG) for methionine, plus one or two translation stop codons and additional adaptor sequences for the integration of the synthetic gene into a plasmid, can easily be added to a coding sequence for synthetic genes and leads to a mobile DNA sequence (step 3). Reconstruction of isolated cDNA often requires considerable effort in order to arrive at a mobile DNA sequence.

Restriction Enzyme Cleavage Sites

The introduceability of unique restriction enzyme scission sites into a synthetic gene (step 4) is one of the greatest ad-

vantages of synthetic genes over natural, isolated genes. Such restriction sites, which generally are evenly distributed over the gene sequence, are not only helpful in subcloning during the construction of a gene, but also permit easy variation (mutagenesis) of the original DNA sequence (cf. Section 4.2). Restriction sites that lead to the formation of cohesive ends on cleavage are preferred (Table 4). Such sites are

Table 4. Recognition sequences for some selected restriction enzymes.

Recognition sequence [a]	Restriction enzyme
5'-G↓AATTC- 3'-CTTAA↑GA	EcoR I
5'-CTGCA↓G- 3'-G↑ACGTC-	Pst I

made use of in the cloning of genes or in the subcloning of gene fragments. They are also present in commercially available plasmids, for example the pUC plasmids[222] or the M13mp plasmids,[223] which contain polylinkers (multiple cloning sites).

However, if the restriction sites required are not available in the commercial plasmids, temporary restriction sites can be used. One possibility is to increase the length of the gene or gene fragment by a few nucleotides, in order to incorporate a clonable (temporary) recognition sequence. After integration of the gene into a suitable plasmid and replication, the desired gene sequence can be isolated by cutting with the originally planned restriction enzymes.

Another possibility for the generation of temporary restriction sites is to build a short string of nucleotides into the DNA sequence to give a clonable restriction enzyme recognition sequence. The additional nucleotides can be removed later by successive cleavage with the relevant restriction enzyme, and single-strand-specific nuclease S1.[195]

The planning of unique restriction sites is relatively complex and can only be performed with appropriate computer programs.[224, 225] At present about 600 different restriction enzymes are known.[226–228]

Secondary Structure Considerations

After optimization of a DNA sequence with respect to codon usage and restriction sites, the secondary structure of the corresponding mRNA must be examined (step 7). Direct repetitions of nucleotide sequences ("repeats") can interfere with the construction of the gene, while inverted repeats can lead additionally to undesired secondary structures in the mRNA, making efficient expression of the gene impossible. Hairpin structures, which inhibit the initiation of translation, can drastically diminish expression.[229, 230] In dividing a gene up into oligonucleotides (step 8), each of the oligonucleotides must be checked for adverse intra- and intermolecular interactions. A large number of programs are available for calculating desired and undesired secondary structures and interactions.[224, 231–233] The necessity of reasonably comprehensive calculations depends very much on the strategy used for gene construction (Fig. 7). If a relatively large number of short oligonucleotides are used in a single hybridization step, clearly many more undesired interactions are to be expected than in the hybridization and subsequent cloning of long oligonucleotides.[203]

In designing a synthetic gene all the points discussed so far must be taken into consideration. If one does this stepwise, as shown in Figure 9, repeated alterations of the DNA sequence can be necessary (step 6: redesign), for example, after steps 4, 7, and 8. Since errors can creep in here, it is a good idea to check the amino acid sequence from time to time by back-translation of the DNA sequence (step 5). The actual experiment begins with the chemical synthesis of the oligonucleotides (step 9).

3.4.2. Strategies for Expression of Synthetic Genes

There are three fundamental procedures for the expression of synthetic or natural genes: (1) direct expression, (2) expression as a fusion protein, (3) transport expression (Fig. 10).

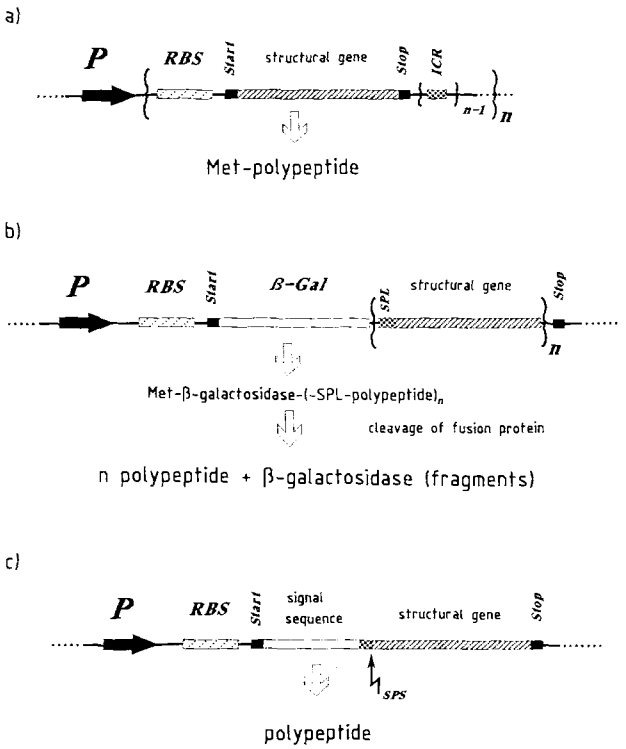

Fig. 10. Strategies for expression of synthetic genes: a) direct expression; b) expression as a fusion protein; c) transport expression. ICR = intercistronic region, P = promoter, RBS = ribosome binding site, SPL = cleavage linker, SPS = signal peptidase.

Direct Expression

Direct expression of a gene under the control of a constitutive or inducible[115] regulatory unit is the simplest mode of

expression in prokaryotes, provided the product being formed is stable and nontoxic to the host organism (Fig. 10a, $n = 1$). Since the structural gene must be preceded by a translation start codon, coding for methionine, a methionyl protein is formed. In most cases the additional methionine does not interfere with the activity of the protein, but it can be removed by cleavage with cyanogen bromide or with specific aminopeptidases.[140] In order to increase the expression yield, direct expression can also be carried out on a polycistronic tandem gene system. This variation, in which n copies of the same structural gene (Fig. 10a, $n = 2, 3 \ldots$), one behind the other, are separated by intercistronic regions (ICR), makes use of the gene-dosage effect. In a similar manner to polycistronic bacterial lactose or tryptophan operons, the common transcription unit consists of a promoter and a ribosome binding site (RBS) and forms a single mRNA. This methodology has been applied successfully in the expression of leukocyte interferon;[234] the amount of interferon expressed was directly proportional to the number of interferon genes in the plasmid ($n = 1$ to 4).

Expression as a Fusion Protein

The direct expression of polypeptides 50–80 amino acids in length often fails because these relatively small proteins are rapidly proteolytically degraded in the host organism. Thus, the tetradecapeptide somatostatin could only be successfully expressed by stabilization as a fusion protein with β-galactosidase (Fig. 10b). The somatostatin was isolated by cyanogen bromide cleavage from the fusion protein, which consisted of about 1000 amino-terminal amino acids of the β-galactosidase, followed by methionine and the tetradecapeptide somatostatin moiety. If the desired protein contains an internal methionine, alternative cleavage sequences must be planned at the gene level: e.g., Asp-Pro (acid-labile),[235] Asn-Gly (hydroxylamine),[236] Arg-Arg (trypsin, carboxypeptidase B),[237] or Ile-Glu-Gly-Arg (blood coagulation factor X_a).[238] Often just a small fused moiety yields sufficient stabilization; examples include portions of Trp E,[99] interferon-γ,[100] or growth hormone[144] or short homooligopeptide tails.[239] One variant is the inclusion of several genes, which are not, however, separated by intercistronic regions as described above, but are linked instead by cleavage sequences. In the case of proinsulin, which because of its short half-life in *E. coli* ($t_{1/2} = 2$ min) cannot be directly expressed in good yields, stable fusion proteins could be synthesized by coupling three or four genes to each other (Fig. 10b, $n = 3$ or 4) through a cleavage linker (SPL) coding for Arg-Arg-Asn-Ser-Met.[240] By cleavage of the fusion protein with cyanogen bromide and subsequent treatment with trypsin/carboxypeptidase B, proinsulin was obtained. This multigene-copy procedure has been described for substance P,[153] growth hormone releasing factor,[102] and Met-enkephalin,[154] among others, and has the clear advantage over β-galactosidase fusions that the host cells have to produce less ballast, which can interfere in the cleavage and workup of the fusion protein.

Transport Expression

A serious disadvantage of expression as a fusion protein is that the proteins are generally obtained in a biologically inactive form. Occasionally the folding of the proteins into biologically active structures can be difficult. With transport expression (Fig. 10c) a procedure is now available which largely allows one to avoid the problems discussed above (additional methionine, protein folding, disulfide bridge formation, protease lability). Its advantage is based on the fact that the growing polypeptide chain is channeled out through the cytoplasmic membrane with the aid of a signal sequence and hence out of the reducing cytoplasmic environment. According to the hypothesis of *Blobel* and *Dobberstein*,[241] the signal sequence is cleaved off by a signal peptidase (SPS) as the polypeptide passes through the membrane. For example, epidermal growth factor (EGF),[101] hirudine,[242] and growth hormone[243] have all been transported into the periplasm of *E. coli* using the signal sequence of alkaline phosphatase. We have previously reported a synthetic DNA fragment for the signal peptide of alkaline phosphatase, which allows proinsulin secretion.[244] For transport expression purposes, however, *E. coli* is not necessarily the host organism of choice. Better product yields are often obtained in other organisms like staphylococci,[245] *B. subtilis*,[246] or yeast, because the product is then secreted into the medium. *Saccharomyces cerevisiae* is of special interest in connection with the α-factor signal sequence,[247, 248] with which the synthetic genes for atrial natriuretic peptide[98] and for connective tissue activating peptide were successfully expressed, for example. However, one problem in transport expression into the medium, which should not be underestimated, is that of host-cell extracellular proteases, if these are able to degrade the expressed product. In yeast, glycosylatable proteins may also be converted into glycoproteins whose glycosyl moiety is not identical with that of the natural product.

4. Applications and Advantages of Synthetic Genes

4.1. Tailor-made Genes

Especially for small proteins of up to about 200 amino acids whose primary structures have been clarified by peptide sequencing, chemical enzymatic synthesis offers an alternative to the isolation of the natural gene. Synthetic genes for proteins of this size can now be synthesized and cloned in a few weeks or months. In contrast to natural genes, which, after isolation, have to be reconstructed to allow expression (in bacteria, for example), synthetic genes can be planned right from the start so that they can be expressed immediately after cloning. As demonstrated in the previous section, host specificity can be taken into consideration here by using preferred codons. In addition, unique restriction-enzyme recognition sites can be built into synthetic genes at reasonable intervals (about every 50 to 100 bp), greatly simplifying subsequent alteration of the genes and gene products. Finally, gene synthesis can also include regulatory DNA sequences which achieve transcription and translation of the structural gene. Specific alteration of structural genes or of regulatory DNA sequences is a valuable method in the study of structure–activity and structure–function relationships.

4.2. Specific Alteration and Optimization of Protein Properties

Although today DNA from any given source can be specifically altered using so-called oligonucleotide-directed site-specific M13 mutagenesis (cf. Section 3.3.2),[249] synthetic DNA is predestined for such use. While the various methods for implementation of M13 mutagenesis[213,249-255] always yield the wild-type gene along with the desired mutant, modular or cassette mutagenesis, when correctly performed, leads exclusively to the specifically altered gene (Fig. 11). After correct planning of a synthetic gene, suitably positioned restriction sites permit rapid alteration of the protein product: a DNA segment flanked by two unique restriction sites is replaced by a corresponding fragment containing the mutation (modular mutagenesis[255]). Thus, particular genes[96,141,159,169] have been specifically planned with regard to subsequent alterations. In the case of growth hormone releasing hormone (GHRH), we replaced the codon for methionine 27 with a codon for leucine, in order to allow the GHRH derivative to be liberated from a fusion protein with β-galactosidase by cyanogen bromide cleavage.[96] Using so-called cassette mutagenesis, the DNA fragment to be changed is replaced by a cassette of oligonucleotides that have not been synthesized in an unambiguous manner.[256,257] This generates numerous mutants in one cloning step. Particular forms of cassette mutagenesis permit the cloning of single-stranded oligonucleotides.[208,209,258]

Alterations in enzymes can, for example, make them resistant to oxidation,[259] shift their pH dependence,[260] or even achieve a reversal of an allosteric inhibition into an activation.[261] Pharmacologically interesting proteins like γ-interferon[262] or interleukin-2[263,264] have been successfully subjected to structure–activity studies. In the most favorable case, mutations led to an increase in biological activity, as in two particular muteins of interleukin-1[265] and interleukin-2.[266]

Genes can also be altered in such a way that selective post-translational modification of the expressed precursor protein is possible. Thus, in nature many smaller proteins (<50 amino acids) occur as their C-terminal carboxylic amides, which in prokaryotes are not directly accessible by expression. Recently, we were able to show[96,267] that, by planning at the DNA level, a precursor of GHRH can be synthesized which contains an additional glycine at the C-terminus. This serves as a signal for an amino-acid-amidating enzyme[268] to convert the precursor protein into the desired GHRH carboxamide.

One particular variation of gene synthesis, also called the "hybrid" or "mispairing" procedure, permits simultaneous

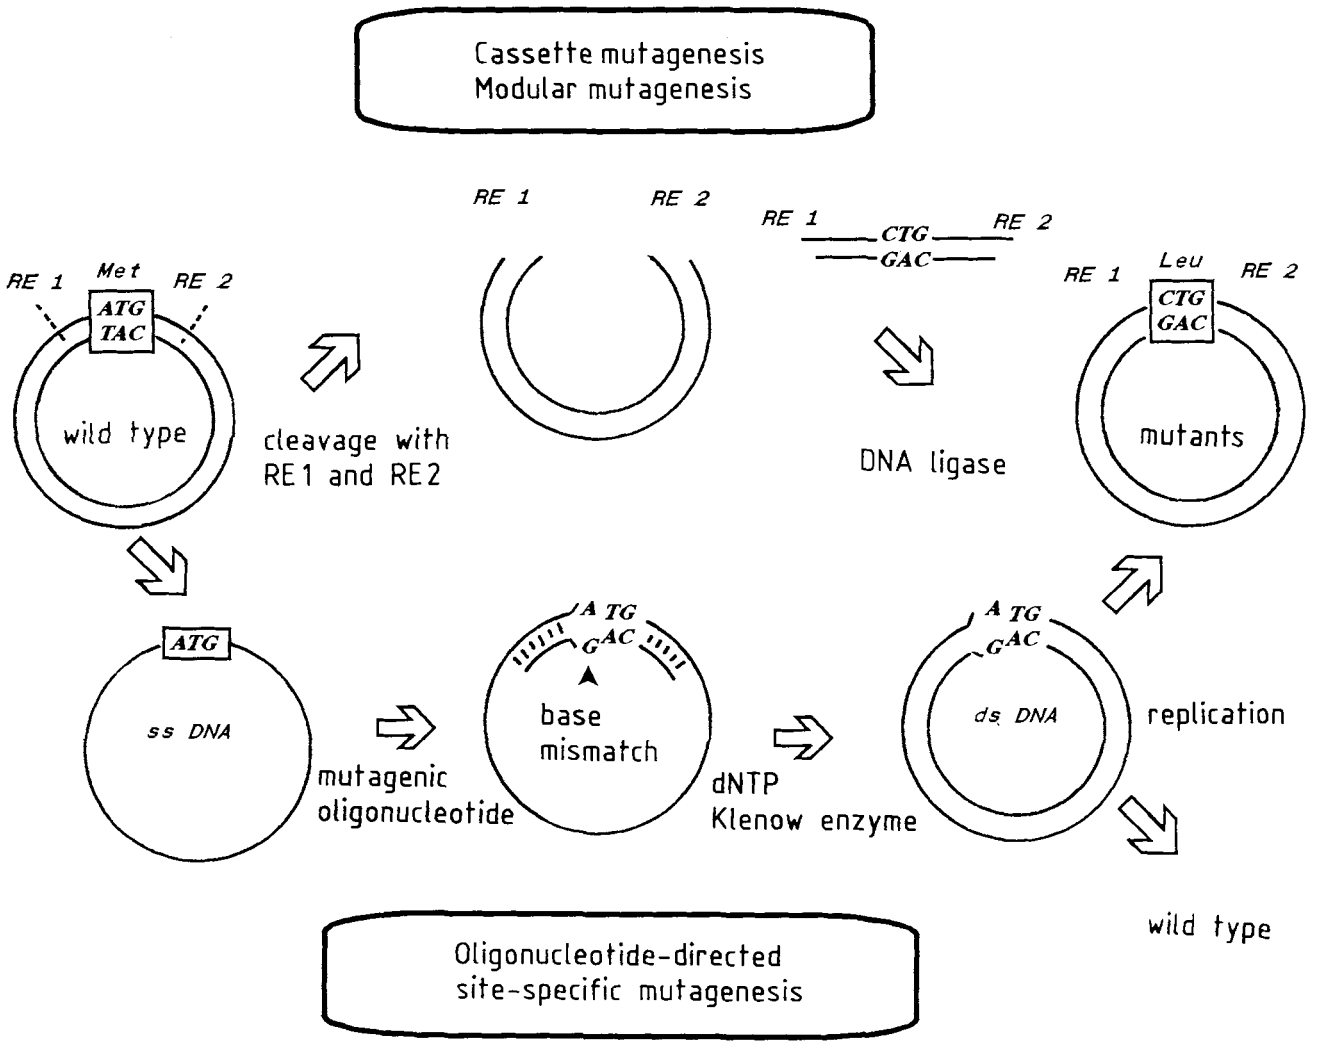

Fig. 11. Alternative methods for specific alteration of a gene.

production of closely related genes. A partially base-mismatched gene is synthesized whose two strands code for different proteins.[95] Thus, a gene was synthesized where one strand coded for human epidermal growth factor (hEGF), while the other coded indirectly for mouse EGF.[132]

4.3. Control of Gene Expression by Synthetic DNA

A further tremendous advantage of synthetic genes is that, in addition to the structural gene, the transcription or translation control regions that direct the expression of the synthetic gene can also be included in the synthesis planning. Using the building-block system, individual control elements can be put together in a modular way to form a complete regulatory unit. In the expression of interferon-γ, for example, we used a synthetic regulatory unit[3] consisting of an idealized promoter, an operator, and a ribosome binding site. One should not, however, gain the impression that a combination of individually very efficient modules always leads to optimal gene expression; in practice, the reverse can also occur. Rather, the great value of the building block system is that a very great number of different module combinations can be synthesized quickly and efficiently in order to find the optimal combination for gene expression.

Transcription can be controlled by synthetic promoters, operators, and terminators. By using synthetic ribosome binding sites and by planning a favorable mRNA secondary structure, translation can also be positively influenced. A promoter is a special DNA sequence which interacts with the RNA polymerase to allow synthesis of the mRNA. The efficiency of this control region, which is generally found in the nontranslated 5′ region, is crucial for the amount of mRNA formed. Numerous promoters have already been synthesized.[3, 196, 269–274]

Promoters may be always switched on (constitutive) or of an inducible type. Those that can be regulated also contain, in addition to the RNA polymerase interaction region described above, a so-called operator. Probably the best-investigated system is the lac operon,[275] which is subject to negative regulation; the start of transcription is inhibited by binding of the lac-repressor protein to the lac-operator sequence. By adding isopropyl-β-D-thiogalactopyranoside (IPTG), which forces the repressor into a form which cannot bind the operator, the lac promoter can be induced. Interestingly, idealized synthetic lac operators have been synthesized[276, 277] which bind to the lac repressor up to eight times more strongly than the natural operator. By coupling of a constitutive promoter to a lac-operator sequence, an inducible system can be synthesized.[278]

Particularly when strong promoters are used to initiate transcription, an efficient transcription terminator is an advantage. Thus, the expression yield for interferon-α was increased by a factor of two[279] and that for EGF by one of five to ten[280] when strong terminators were added downstream of the structural gene. Sensibly, synthetic terminators were cosynthesized with the corresponding gene.[158]

The efficiency of translation of the mRNA is controlled by the ribosome binding site (RBS) and the mRNA structure. The RBS in prokaryotes is most usually the sequence AAGGA, also called the Shine–Dalgarno (SD) sequence.[281] It is responsible for initiation of protein biosynthesis, by binding to the 3′ end of the 16S RNA. The SD sequence is generally four to nine nucleotides long and is found some three to twelve nucleotides upstream of the translation start codon. Genes from eukaryotic sources have no RBS that is recognized by prokaryotic ribosomes. Synthetic RBSs have therefore been used for some time for the expression of eukaryotic genes in bacteria.[3, 279, 280, 282–284] Apparently, the RBS should be easily accessible to the 16S RNA. One assumes that the RBS also includes that portion of the structural gene coding for the amino-terminal region of the protein, and it therefore seems reasonable to track down adverse secondary structures with suitable computer programs.[231–233] In the expression of interferon-α, fluctuations of a factor of fifty were observed when nucleotides in particular positions close to the translation initiation region were exchanged. These results could be explained on the basis of mRNA secondary-structure calculations.[230] From our own studies on the expression of interferon-γ we have learned, however, that predictions of the level of expression using mRNA structural calculations alone are barely possible. Expression must, after all, be experimentally optimized.

5. Future Prospects

Recombination techniques, especially those based on synthetic genes and oligonucleotides, have led to a wealth of biologically active proteins. It has become clearer, however, that our understanding of the structure and function of more complex polypeptides is very limited. In searching for an answer to the question "Which protein sequence gives which properties?", polypeptide synthesis from synthetic genes ideally complements chemical peptide synthesis.[285, 286] Because of the general validity of the genetic code, it is possible to synthesize a corresponding DNA for any polypeptide, or, more generally, for any defined sequence of linked amino acids, and to express it by recombination in a suitable vector for the host organism concerned. The synthesis of new and unknown polypeptides,[143, 180] so-called de novo protein design,[287–291] should be especially stressed here, since it now allows us to build novel proteins and to test the underlying hypotheses concerning their construction and properties (Fig. 12). In the scheme shown in Figure 12, the relation-

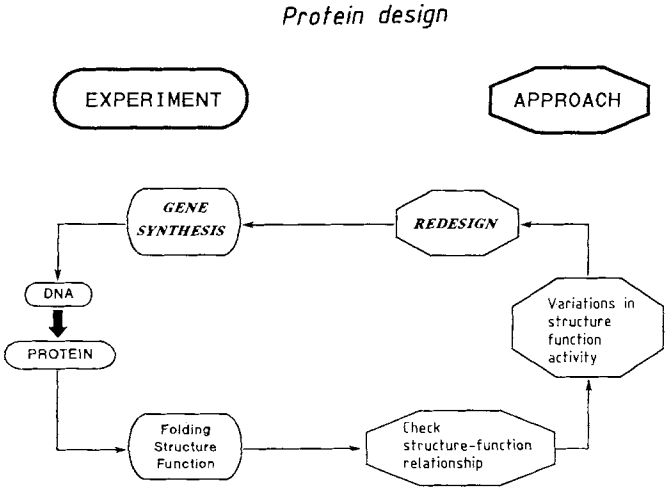

Fig. 12. De novo protein design using synthetic genes.

ship between protein sequence, structure and function, and the underlying DNA sequence is portrayed as a cyclic type of process.

As yet the prediction of protein tertiary structure is a largely unsolved problem.[292] The synthesis of certain secondary structures like α-helices and β-pleated sheets is of special interest.[293] These structures are more predictable[294] and form supersecondary structures or so-called motifs. An experiment of this sort, with a helix bundle composed of four α-helices, is currently being addressed by both peptide chemistry and recombinant techniques. A gene coding for the product has been synthesized, and the artificial product can indeed be produced by expression in *E. coli*.[295] For future research in this field it is encouraging to note that this work constitutes an experimental starting point for one of the greatest challenges in molecular biology, the determination of the relationship between peptide sequence, polypeptide structure, and function.

We are grateful to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Bundesministerium für Forschung und Technologie, and Hoechst AG for their financial support. Special thanks are due to E. Groeneveld for preparation of the text and to H. Zimmermann for the diagrams.

Pentabenzylcyclopentadienylpotassium · 3 THF, an Organopotassium Compound with "Piano Stool" Geometry

By *Jörg Lorberth,* Sung-Hee Shin, Sigrid Wocadlo,* and *Werner Massa*

The anions of pentamethylcyclopentadiene[1] and pentabenzylcyclopentadiene are good ligands for stabilizing complexes of both transition metals and main-group metals in low oxidation states. Recent examples include Sb^{I} compounds[2] for pentamethylcyclopentadienide and Ge^{II}, Sn^{II}, Pb^{II},[3] and Tl^{I} compounds for pentabenzylcyclopentadienide.[4,5]

We have now obtained the potassium salt **1** of the "bulky" pentabenzylcyclopentadiene, $C_5H(CH_2C_6H_5)_5$, in a smooth reaction as described by Equation (a).

$$K + C_5H(CH_2C_6H_5)_5 \xrightarrow{THF} \underset{\mathbf{1}}{K[C_5(CH_2C_6H_5)_5] \cdot 3\,THF} + \tfrac{1}{2}H_2 \qquad (a)$$

In contrast to organolithium and -sodium compounds, only a few crystal structures of the corresponding potassium compounds have been reported;[6] for example, the molecular and crystal structures of KCD_3[7] and $K[C_5H_4(SiMe_3)]$[8] were described only recently. We have obtained single crystals of **1** and have subjected these to X-ray structure analysis.[9] The potassium ion is bonded in an η^5 fashion to a planar cyclopentadienyl ring, the "ring slippage" being only 17.4 pm. The three oxygen atoms of the THF molecules complete the coordination polyhedron around the central atom to give a coordination number of 8 (Fig. 1).

Three of the benzyl substituents and the three THF molecules are oriented in an eclipsed fashion with respect to one another, so that the geometry around the potassium ion may also be described as a trigonal prism, two faces of which are capped by benzyl substituents; in KCH_3, the $CH_3^{\ominus}$ ions are coordinated by the $K^{\oplus}$ ions in a trigonal-prismatic fashion and the $K^{\oplus}$ ions, in turn, are surrounded pseudooctahedrally by $CH_3^{\ominus}$ ions.[10]

One THF molecule is bent away for steric reasons, thus clearly demonstrating the large spatial demands of the benzyl groups. In the dimer $[Tl^{I}\{C_5(CH_2C_6H_5)_5\}]_2$, three benzyl substituents of each Cp ring are oriented towards the heavy atom[3] and largely shield the two thallium ions. The first X-ray structure analysis of a transition-metal

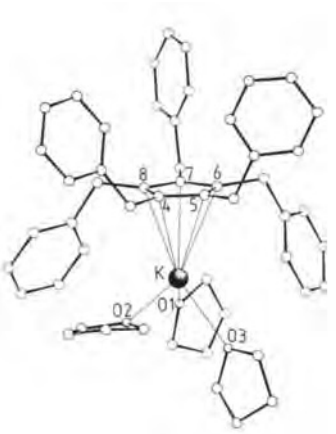

Fig. 1. SCHAKAL drawing [15] of the structure of **1** in the crystal. Important distances [pm] and angles [°]: K-O1 269.0(4), K-O2 273.7(4), K-O3 277.9(5) (average 273.5), K-C4 296.8(5), K-C5 305.1(5), K-C6 309.5(5), K-C7 307.0(5), K-C8 298.9(5) (average 303.5), K-Cp ring center 278.8(3), "ring slippage" = distance between the perpendicular projection of the metal on the ring plane and the ring center 17.4, C4-C5 143.3(7), C5-C6 140.5(7), C6-C7 139.6(7), C7-C8 141.0(7), C4-C8 139.7(7) (average 140.8); O1-K-O2 118.2(1), O1-K-O3 92.3(1), O2-K-O3 75.4(1).

complex containing a pentabenzylcyclopentadienyl ligand, $[\{C_5(CH_2C_6H_5)_5\}Co(CO)_2]$, shows that four of the five benzyl groups are oriented away from cobalt.[10]

The K–Cp(ring center) distance is 278.8(3) pm, the average K–C distance 303.5 pm. For comparison, the K–C distance in KCH_3 (center of gravity of the CH_3 group) is 322[11] and the average value of the K–C distances in $K[C_5H_4(SiMe_3)]$ is 300 pm.[8] The average K–O distance is 273.5 pm; the distance to the O1–O2–O3 plane, which forms an angle of 19.4° with the nearly planar cyclopentadienyl ring (maximal deviation of the C atoms from the "best plane" 4.9 pm), is 133(1) pm. For comparison, the average K–O distance in $K[C_5(NO_2)_2Cl_3]$, in which the potassium ion is surrounded by an irregular octahedron of oxygen atoms,[12] is ca. 258–294 pm and in $K[C_5(CO_2Me)_5] \cdot MeOH$ ca. 264–288 pm.[13]

The C–C bond lengths in the Cp ring vary only from 139.6(7) to 143.3(7) pm, averaging 140.8 pm, and are therefore similar to those in cyclopentadiene, C_5H_6 (141 pm).[14]

Experimental Procedure

Potassium (2.27 g, 58.09 mmol), the surface of which was cleaned with 1-butanol prior to use, was dissolved in 100 mL of liquid NH_3 in a 250-mL Schlenk flask. NH_3 was evaporated and the powdery residue was dried under high vacuum and then suspended in 80 mL of dry THF. Pentabenzylcyclopentadiene (30 g, 58.09 mmol), dissolved in 50 mL of dry THF, was added dropwise to this suspension at room temperature. After the potassium metal had gone into solution, the reaction solution was kept at ca. −37 °C; colorless, transparent crystals with a melting range of 35–45 °C (uncorrected) were obtained: the yield was 31.33 g (ca. 70%).

[9] **1** crystallizes in the space group $P2_1/n$; $Z = 4$; $a = 1198.2(7)$, $b = 1530.6(2)$, $c = 2458.7(13)$ pm, $\beta = 102.07(3)°$. 3875 observed reflections with $F_o > 3\sigma(F_o)$ were measured on a four-circle diffractometer (CAD4, Enraf-Nonius) with $Cu_{K\alpha}$ radiation at 193 K; no absorption correction ($\mu = 12\ cm^{-1}$). The structure was solved by direct methods. All heavy atoms were refined with anisotropic temperature factors; the H atoms were included at calculated positions with groupwise common isotropic temperature factors (509 parameters). The use of weighting factors $w = 1/\sigma^2(F_o)$ and inclusion of an extinction correction [F_c(corr.) $= F_c(1 - \varepsilon F_c^2/\sin\theta)$ with $\varepsilon = 1.8 \times 10^{-7}$] resulted in residual indices of $R = 0.070$ and $R_w = 0.055$ [16]. Gas-Chromatographic Enantiomer Separation of Unfunctionalized Cycloalkanes on Permethylated β-Cyclodextrin**

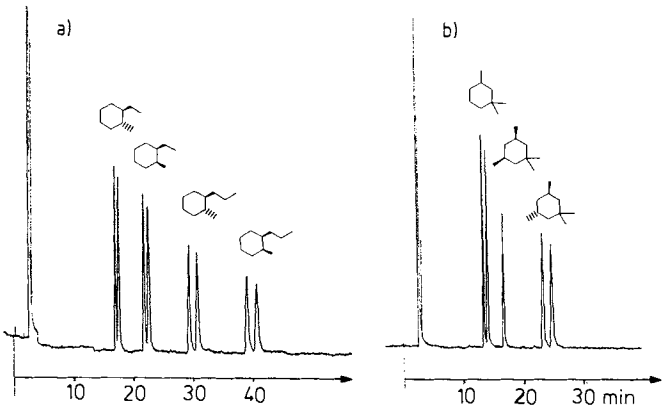
By *Volker Schurig,* Hans-Peter Nowotny,* and *Dieter Schmalzing*

The enantiomer separation of simple, unfunctionalized, saturated hydrocarbons is a challenge,[1] since no procedure based on the formation of diastereomers or on chemical, diastereomeric interaction with chiral auxiliaries (NMR, GC)[2] can be used. Even the determination of optical purity is often difficult owing to unknown maximum specific rotations. In 1981, we began experiments on the gas-chromatographic separation of the enantiomers of tetraalkylmethanes, $R^1R^2R^3R^4C$ (R = alkyl), on glass capillary columns coated with permethylated β-cyclodextrins in polysiloxane solution.[3] Although these experiments have been unsuccessful so far, it has recently been shown that peralkylated cyclodextrins are suitable for the enantiomer separation of unfunctionalized olefins.[4, 5] Packed columns coated with α-cyclodextrin in formamide were also successfully used, despite their poor efficiency, to separate the enantiomers of *trans*-pinane (semiquantitatively) and *cis*-pinane[6] as well as the diastereomers of *cis*/*trans*-dimethylcycloalkanes. In the latter case, the chiral isomers were not resolved into enantiomers.[7]

The quantitative separation of a series of alkylcyclohexanes by gas chromatography has now been achieved on permethylated β-cyclodextrin in OV-1701 on glass capillaries between 23 and 60 °C (cf. Fig. 1 and Table 1).



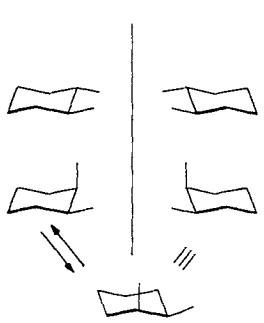


Fig. 1. a) Separation of the enantiomers of *trans*- and *cis*-1-ethyl-2-methylcyclohexane and *trans*- and *cis*-1-methyl-2-propylcyclohexane on a glass capillary column (25-m × 0.25-mm inner diameter) coated with 10% heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin in OV-1701 (0.08 m). Oven temperature 50 °C; carrier gas pressure 0.7 bar helium. b) Separation of the enantiomers and diastereomers of 1,1,3-trimethylcyclohexane and *cis*- and *trans*-1,1,3,5-tetramethylcyclohexane; conditions same as in a) except for the oven temperature (45 °C).

Table 1. Gas-chromatographic data for enantiomer separation on permethyl-β-cyclodextrin in OV-1701.

Compound	T [°C]	p [bar]	Separation factor α	Resolution R_s
trans-1,2-dimethylcyclohexane	23	1.0	1.06	0.85
trans-1,3-dimethylcyclohexane	23	1.0	1.07	1.28
cis-1-ethyl-2-methylcyclohexane	60	0.7	1.04	1.40
trans-1-ethyl-2-methylcyclohexane	60	0.7	1.03	1.00
cis-1-methyl-2-propylcyclohexane	60	1.0	1.03	1.60
trans-1-methyl-2-propylcyclohexane	60	1.0	1.04	1.69
1,1,3-trimethylcyclohexane	60	0.7	1.05	1.47
trans-1,1,3,5-tetramethylcyclohexane	60	0.7	1.05	2.00
cis-pinane	40	1.0	1.10	2.28
trans-pinane	40	1.0	1.03	0.89

Since the enantiomers of both *cis*-1-ethyl-2-methylcyclohexane and *cis*-1-methyl-2-propylcyclohexane are separated, the cyclodextrin phase should, in principle, discriminate between the enantiomers of the homologous *cis*-1,2-dimethylcyclohexane, the chair conformation of which is chiral. Rapid inversion of the chair conformation, however, leads (without change in configuration at the chiral centers) to formation of the enantiomeric conformer.[8] The appearance of only one peak is therefore interpreted as an interesting example of an extremely rapid enantiomerization ("peak coalescence of the first kind"[9]).

Hitherto, the investigation of the separation of enantiomers on cyclodextrin phases has not allowed a clear distinction to be made between the contributions from the nonpolar interactions in the interior of the cavity (inclusion) and

the polar interactions with the alkoxy groups on the outside of the torus. Our results on unfunctionalized, saturated hydrocarbons, for which polar interactions can be excluded, indicate that inclusion represents the decisive contribution, whereby the methoxy groups shield the cavity only slightly and, moreover, increase the flexibility of the cyclodextrin ring ("induced fit").[10] Heptakis(2,6-di-*O*-methyl-3-*O*-trifluoroacetyl)-β-cyclodextrin does not separate the enantiomers of the cycloalkanes discussed here.

The direct separation of the enantiomers of unfunctionalized cycloalkanes described here allows a simple investigation of enantioselective synthesis (e.g., asymmetric hydrogenation of aromatic or olefinic compounds) or of enzymatic or chemical transformations (kinetic resolution of enantiomers). The method is also suitable for extrapolation and quantification of chiroptic data.

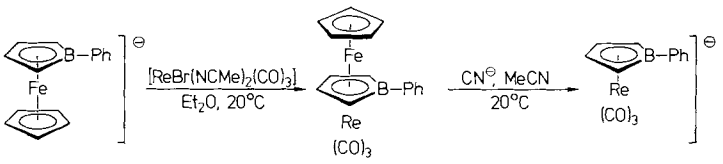
Triple-Decker Complexes as Intermediates in Ring-Ligand Transfers**



By *Gerhard E. Herberich,** *Barry J. Dunne*, and *Bernd Heßner*

The principle and the preparative value of ring-ligand transfer[2] was first shown by *Maitlis* et al. for (cyclobutadiene)metal complexes.[3] They found, for example, that $[(\eta^4\text{-}C_4Ph_4)PdBr_2]_2$ reacts with $Fe(CO)_5$ to give $[(\eta^4\text{-}C_4Ph_4)Fe(CO)_3]$, Pd metal, CO, and $FeBr_2$.[3b] They suggested a mechanism in which the transferred ligand is never free but, instead, changes its metallic center via intermediates of type **1** with a monofacially bridging ligand.[3b] This hypothesis is supported by the identification of compounds with monofacially bridging ligands.[4] However, the Maitlis mechanism has not yet been proved and several mechanistic alternatives are conceivable. We show here that, for 1*H*-borole complexes, ring-ligand transfer can also occur via triple-decker intermediates **2** with bifacially bridging ring ligands.

1 **2**

The sodium borataferrocene Na-**3**[5] reacts with $[ReBr(NCMe)_2(CO)_3]$[6] as electrophile in ether to give the stable, wine-red triple-decker complex **4**. The triple-decker structure of **4** is confirmed by the typical small coupling constant $N = {}^3J_{23} + {}^4J_{24}$ of 4.1 Hz for the bridging borole ligands.[7] Nucleophilic degradation with KCN transforms **4** into the rhenate **5**,[8] which can be isolated as $NMe_4^{\oplus}$ salt **6** ($N = 5.9$ Hz) or, after protonation, as hydride **7** ($N = 6.2$ Hz). The overall result of the electrophilic stacking reaction and nucleophilic degradation is the transfer of the 1*H*-borole ligand from iron to rhenium.

3 **4** **5**

$[(\eta^5\text{-}C_4H_4BPh)ReH(CO)_3]$ **7**

The neutral cobalt complex **8**[7] undergoes a similar electrophilic stacking reaction with **9a**[9] in acetone to afford the reddish-brown triple-decker salt **10a**, which is isolable in pure form and undergoes degradation with NaI in acetone[8] to give the known (borole)ruthenium complex **11a**.[10] The labile triple-decker salt **10b** was observed in the analogous reaction with the iridium complex **9b**[11] in an NMR tube; in this case, however, the degradation product **11b** appears in the reaction mixture before the cobalt complex **8** is completely consumed. Again, the preparative degradation is carried out with NaI.

$$[CpCo(\eta^5\text{-}C_4H_4BPh)] + [LM(OCMe_2)_3](BF_4)_2 \rightarrow$$
8
9a; LM = $Ru(\eta^6\text{-}C_6Me_6)$
9b; LM = $Ir(\eta^5\text{-}C_5Me_5)$

$$[(\mu\text{-}\eta^5\text{-}C_4H_4BPh)(CoCp)(ML)](BF_4)_2 \xrightarrow{NaI} [LM(\eta^5\text{-}C_4H_4BPh)]$$
10a, b **11a, b**

The transfer of the borole ligands affords the first borole complexes of rhenium (**4**–**7**) and iridium (**10b, 11b**) and, at the same time, the first triple-decker complexes of these metals. The direct observation of triple-decker intermediates was made possible by the way in which the reaction was performed.

Even when no intermediates are observed in ring-ligand transfers, it is possible, in principle, to distinguish between the different mechanisms. According to the Maitlis mechanism, the transferred ligand is coordinated to the *same* side in the starting material and the product. By contrast, the transferred ligand is bound to *different* sides in the starting material and product when the reaction proceeds via triple-decker intermediates. If the reaction involves a free ligand, on the other hand, the stereochemical information is lost. Chiral complexes should allow one to distinguish between these cases.

[**] Triple-Decker Complexes, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 6: [1].

Experimental Procedure

4: $[Re(NCMe)_2(CO)_3]$ (825 mg, 1.91 mmol) was added to Na · **3** (625 mg, 2.22 mmol) in 50 mL of Et_2O and the reaction mixture was stirred for ca. 12 h. Filtration, concentration, and crystallization from Et_2O/hexane at −30 °C afforded 701 mg (69%) of **4** as wine-red crystals, m.p. 146 °C, dec. at 289 °C [12]. MS: *m/z* 532 (90%, $M^{\oplus}$), 448 (100, $M^{\oplus}$ − 3 CO). IR (hexane): $\tilde{\nu}$(CO) = 2032, 1945, 1935 cm^{-1}. ^1H NMR (80 MHz, CD_2Cl_2, int. TMS): δ = 7.70 (m, $2H_o$), 7.38 (m, $2H_m + H_p$), 4.27 (s, CpH), 4.94 (m, borole H−3,4), 3.32 (m, borole H−2,5, N = 4.1 Hz). ^{11}B NMR (32.08 MHz, CD_2Cl_2, ext. $BF_3 \cdot OEt_2$): δ = 11.2.

Degradation of **4** to give **6** and **7**: Compound **4** (264 mg, 0.497 mmol) in 40 mL of acetonitrile and KCN (0.35 g, 5.4 mmol) were stirred in the dark for 3 d at room temperature. The solvent was removed, the residue was dissolved in water, and the resulting solution was filtered. **6**: Addition of NMe_4Br (102 mg, 0.66 mmol) to the aqueous filtrate resulted in precipitation of a colorless crude product. Recrystallization from CH_2Cl_2/OEt_2 afforded 164 mg (68%) of **6** as thin, colorless plates m.p. 141–142 °C, dec. at 265 °C [12]. IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1970, 1867, 1855 sh cm^{-1}. ^1H NMR (80 MHz, CD_2Cl_2, int. TMS): δ = 7.45 (m, $2H_o$), 7.08 (m, $2H_m + H_p$), 5.01 (m, borole H−3,4), 3.56 (m, borole H−2,5, N = 5.9 Hz), 2.82 (s, NMe_4). ^{11}B NMR (32.08 MHz, CD_2Cl_2, ext. $BF_3 \cdot OEt_2$): δ = 16.3.

7: The aqueous filtrate obtained from the degradation of **4** was layered with pentane, acidified with 85% phosphoric acid (0.40 mL, 5.9 mmol), and extracted with pentane. Concentration of the pale yellow extract solution, drying with Na_2SO_4, and crystallization at −30 °C afforded 128 mg (63%) of **7** as orange-yellow needles, m.p. 77 °C, dec. at 243 °C [12]. IR (hexane): $\tilde{\nu}$(CO) = 2054, 1987, 1982 cm^{-1}. ^1H NMR (80 MHz, [D$_6$]acetone, int. TMS): δ = 7.57 (m, $2H_o$), 7.15 (m, $2H_m + H_p$), 4.61 (m, borole H−3,4), 3.39 (m, borole H−2,5, N = 6.2 Hz), −7.59 (s, ReH). ^{11}B NMR (32.08 MHz, CD_2Cl_2, ext. $BF_3 \cdot OEt_2$): δ = 6.3.

10a: $AgBF_4$ (195 mg, 1.00 mmol) in 15 mL of acetone was added to $[(\eta^6\text{-}C_6Me_6)RuCl_2]_2$ [9b] in 10 mL of acetone, the precipitated AgCl was filtered off after 30 min, **8** (132 mg, 0.50 mmol) [7] was added to the filtrate, and the resulting solution was kept at room temperature for 16 h. Concentration to 10 mL and addition of 50 mL of OEt_2 afforded 198 mg (57%) of reddish-brown needles of **10a**, m.p. 190 °C (dec.) [12]. ^1H NMR (80 MHz, [D$_6$]acetone, int. TMS): δ = 7.90 (m, $2H_o$), 7.50 (m, $2H_m + H_p$), 6.05 (s, Cp), 6.42 (m, borole H−3,4), 5.17 (m, borole H−2,5), 2.20 (s, C_6Me_6). ^{11}B NMR (32.08 MHz, [D$_6$]acetone, ext. $BF_3 \cdot OEt_2$): δ = 13.0, −0.8.

11a: Compound **10a** (443 mg, 632 µmol) and NaI (0.75 g, 5.0 mmol) were stirred in 20 mL of acetone for 2 h at room temperature. Removal of the acetone, extraction of the residue into OEt_2, filtration through Al_2O_3, and crystallization from CH_2Cl_2 afforded 84 mg (33%) of **11a**.

10b, 11b: $[(\eta^5\text{-}C_5Me_5)IrCl_2]_2$ [11b] in 20 mL of acetone, $AgBF_4$ (390 mg, 2.00 mmol) in 30 mL of acetone, and **8** (264 mg, 1.00 mmol) were treated as described for **10a, 11a**. NaI (1.5 g, 10 mmol) was then added and the resulting solution was stirred for an additional 20 h at room temperature. Workup as described for **11a** gave 156 mg (33%) of **11b** as colorless plates m.p. 158–160 °C [12]. **10b**: ^1H NMR (80 MHz, [D$_6$]acetone, int. TMS): δ = 7.9 (m, $2H_o$), 7.5 (m, $2H_m + H_p$), 6.17 (s, Cp), 6.46 (m, borole H−3,4), 5.35 (m, borole H−2,5, N = 3.2 Hz), 1.88 (s, C_5Me_5). ^{11}B NMR (32.08 MHz, [D$_6$]acetone, ext. $BF_3 \cdot OEt_2$): δ = 13, −0.5. **11b**: ^1H NMR (80 MHz, [D$_6$]acetone, int. TMS): δ = 7.42 (m, $2H_o$), 7.16 (m, $2H_m + H_p$), 4.77 (m, borole H−3,4), 3.89 (m, borole H−2,5, N = 5.0 MHz), 1.88 (s, C_5Me_5). ^{11}B NMR (32.08 MHz, [D$_6$]acetone, ext. $BF_3 \cdot OEt_2$): δ = 11.9.

Complete Identification of C–C Connectivities by Two-Dimensional INADEQUATE NMR Spectroscopy with Composite Pulses

By *Jörg Lambert, Hans Jochen Kuhn, and Joachim Buddrus* *

Two-dimensional INADEQUATE NMR spectra (*I*ncredible *N*atural *A*bundance *D*ouble *Qua*ntum *T*ransfer *E*xperiment)[1, 2] allow a direct and unambiguous elucidation of C–C connectivities and have become an important tool for determining constitutions of organic molecules.[3] The wide use of this technique, however, has been opposed not only by its low sensitivity but also by the fact that satellite signals belonging to large double-quantum frequencies are often of very weak intensity ("off-resonance" effects). We report here a modified 2D INADEQUATE experiment that avoids these intensity drawbacks.

Off-resonance effects are due to a high-frequency field strength B_1 that, compared with the width of the ^{13}C frequency range f, is too small ($\gamma B_1/2\pi < f$, cf. Ref. [4]); they

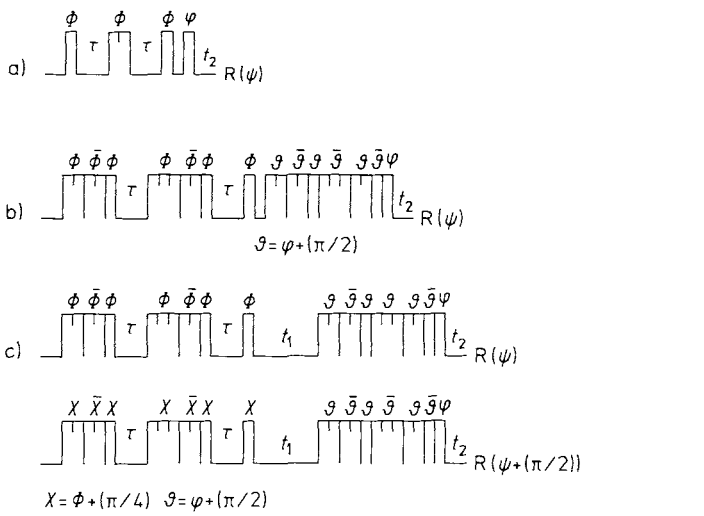

Fig. 1. INADEQUATE pulse sequences. Rectangles with zero, one, and two "cuts" symbolize 90°, 180°, and 270° pulses, respectively. Φ, φ, ϑ, χ, and ψ give the phases of the transmitter and receiver R; bars over the phase symbols (e.g., $\bar{\Phi}$) indicate inverted phases. The phases have fixed relationships to one another. $\tau = 1/(4J(c, c))$; t_2 = acquisition time. a) One-dimensional experiment, simple pulses; for phase relationship see [3]. b) One-dimensional experiment, composite pulses. c) Two-dimensional experiment, composite pulses. The FIDs of the two pulse sequences are added.

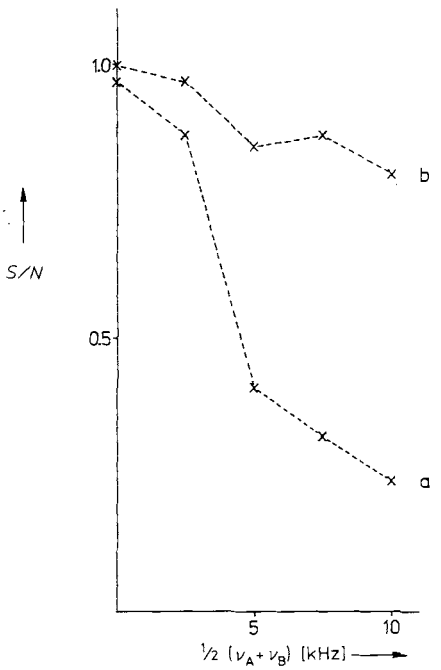
are especially noticeable in an INADEQUATE experiment, since, in this case, pulses are applied to two ^{13}C nuclei.[5, 6] To eliminate the off-resonance effects, composite pulses have been suggested and were used in a *one-dimensional* version of the INADEQUATE experiment.[5, 7] These sequences also compensate for inhomogeneities in the B_1 field, which especially appear when concentrated solutions of ionic compounds are employed.[8]

Two-dimensional INADEQUATE NMR spectra, which are of incomparably greater value in determining constitutions, may be obtained with quadrature detection in the f_1 dimension either by the method of *Bax* et al.[1] or by that of *Mareci* and *Freeman*.[2] The former approach involves inserting a 45_z° pulse into the delay time t_1; the latter uses a read pulse $\alpha \neq 90^\circ$ (e.g., 135°). The second method is ca. 20% more sensitive, but its application with composite pulses is difficult owing to the required 135° pulse.[9] We therefore chose the first method for establishing a pulse sequence made up of composite pulses—although the likewise off-resonance-sensitive 45_z° pulse was replaced with a 45° phase shift of the first three pulses in the experiment (Fig. 1).



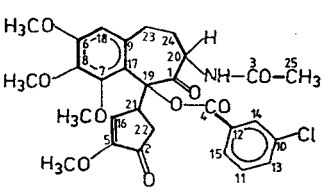


Fig. 2. Signal/noise ratio (S/N) of the satellite signals generated by the 2D INADEQUATE experiment performed on 2-butanol as a function of the offset parameter $(\nu_A + \nu_B)/2$ [12]. Length of the 90° pulse, 25 μs (10-mm probe head). Curve a obtained by the pulse sequence described in [1] with simple pulses, curve b by the pulse sequence shown in Figure 1c with composite pulses.

Figure 2 compares the experimental offset dependence of the signal intensities of the model compound 2-butanol over a range of 10 000 Hz for the 2D INADEQUATE experiment with and without composite pulses. The intensity increases by a factor of up to three when the sequence with composite pulses is used.

The sequence with composite pulses allowed elucidation of the structure of the product obtained upon oxidation of **1** with *m*-chloroperbenzoic acid followed by workup under basic conditions (Fig. 3). This product could not be identified unambiguously either by standard NMR techniques[10] or by X-ray structure analysis (unsuitable crystals).

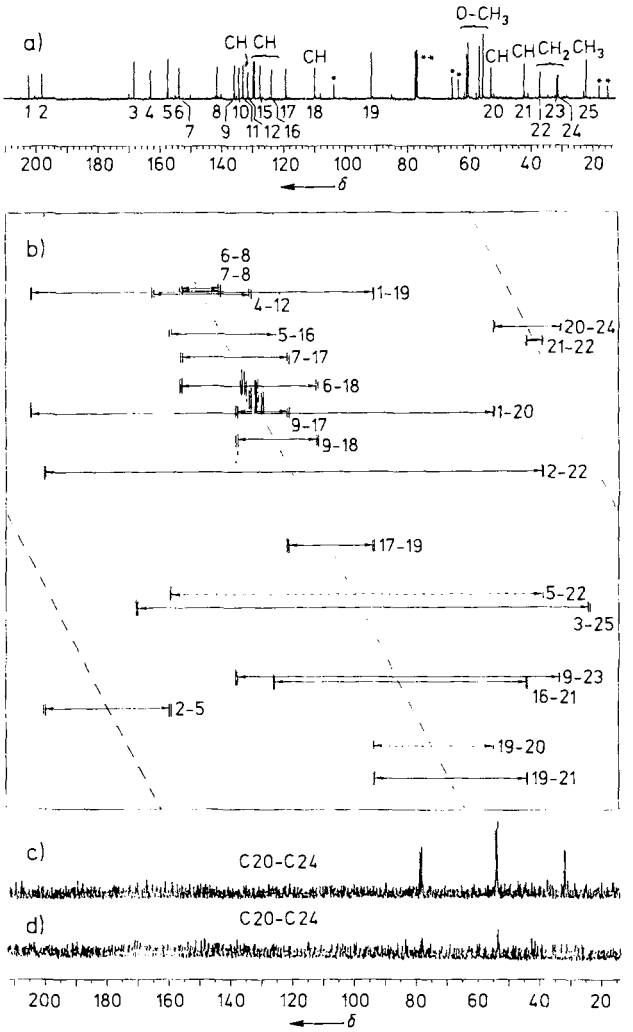

Fig. 3. 100-MHz ^{13}C NMR spectra of **2** (1.4 g) and [Cr(acac)$_3$] (15 mg) in 3.5 mL of $CDCl_3$. a) Proton-decoupled spectrum with signal assignment according to the numbering in the above formula. Signals not assigned to CH_n are due to quaternary C atoms. * = signals due to impurities; ** = signals of $CDCl_3$. b) 2D INADEQUATE NMR spectrum [13]: for pulse sequence see Figure 1c: t_1 noise of the $CDCl_3$ signal removed for clarity. c) Spectral trace of the connectivity C20–C24 from b). d) Spectral trace of the same connectivity recorded with the simple pulse sequence described in [2].

The 2D INADEQUATE NMR spectrum with composite pulses (Fig. 3b) directly shows the presence of a carbon framework corresponding to that of **2**.[11] By contrast, the 2D INADEQUATE NMR spectrum recorded with simple pulses does not reveal some C–C connectivities. The spectral traces in Figures 3c and 3d show just how large these differences can be.

Composite pulses overcome the problem of unequal signal intensities in 2D INADEQUATE NMR spectra in a striking way, even for broad frequency regions. Moreover, they result in a significant increase in sensitivity for this unsensitive technique.

[8] W. E. Hull, Heidelberg, personal communication.
[9] If the suggestion of *W. E. Hull* (*Methods Stereochem. Anal. 9* (1987) 198) is taken and the last 90° pulse of the read-pulse cluster in Figure 1b is replaced by a 135° pulse, one obtains a sequence compensating for the off-resonance effects, but all satellite signals with negative frequencies appear reflected on the line $f_1 = 0$. This reflection obscures the spectrum, thus obviating much of the advantage of the two-dimensional version.
[10] J. Buddrus, A. Defoin, C. Krüger, Y.-H. Tsay, H. J. Kuhn, unpublished.
[11] The configuration could not be determined, not even from the large NOE effect (H NMR spectrum) between the methoxy group on C-5 and the methyl group on C-3.
[12] The offset parameter is equal here to half of the double-quantum frequency.
[13] $\tau = 1/(4J)$, ($J = 45$ Hz). $f_2 = 19920$ Hz (8K data points), $f_1 = 19920$ Hz (64 data points). 64 rows with 1536 accumulations each were recorded. Repeat interval 4 s (total time 4.5 days). The FID in f_2 was multiplied by an exponential function, that in f_1 by a Gauss function after zero filling to 128. The connectivity 23–24 cannot be identified, since a strongly coupled AB spin system is present; connectivities obtained from long-range couplings are shown by broken lines; the signals of the chlorophenyl moiety were assigned in part by comparison with literature values.

A New Route to Phosphaalkenes**

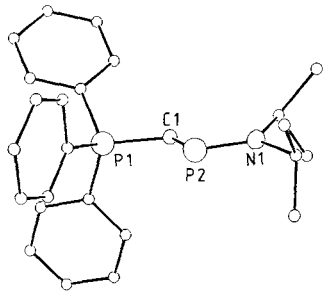
By *Hansjörg Grützmacher** and *Hans Pritzkow*

2-Phosphonio-substituted 1-phospha-1-alkenes[1, 2] are interesting because, formally, a phosphonium and a phosphenium ion compete in them for the electron density on the bridging carbon atom (Scheme 1).[3] We report here a new synthesis of these compounds.

Scheme 1.

The phosphonio-substituted phosphaalkenes **2a–c** are obtainable in yields of > 90% by reaction of the readily accessible phosphinomethylenetriphenylphosphoranes **1a, 1b**[4] with two equivalents of $BF_3 \cdot OEt_2$ or $AlCl_3$ in CH_2Cl_2. The ^{31}P NMR signals of the low-coordinated phosphorus atoms in **2a** and **2b**, $\delta = 303.5$ and 302.5, respectively, are characteristic of both phosphenium ions and phosphaalkenes.[5] As in the 1-(2-phosphaethenyl)-1-phosphoniaindans described by *Karsch* et al.,[11] the ^{13}C NMR signals of the bridging carbon atoms are shifted markedly to high field (**2a**, $\delta = 88.40$; **2b**, $\delta = 104.29$) – which is untypical of phosphaalkenes.

An X-ray structure investigation of **2a**[6] (Fig. 1) revealed that the length of the P1–C1 bond (1.79 Å) lies in the range



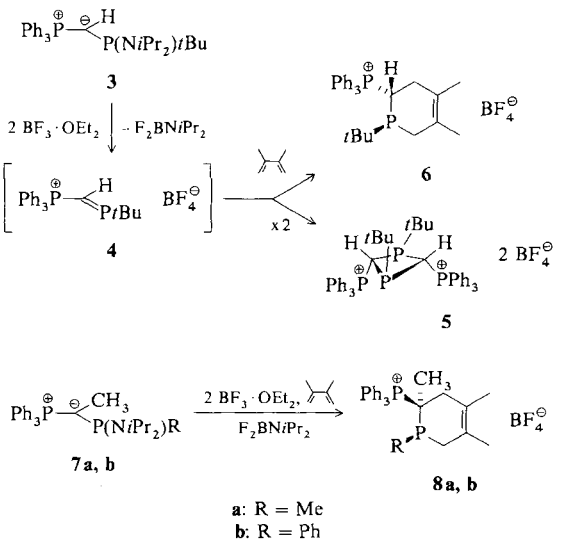


Fig. 1. Molecular structure of **2a**. Important bond lengths [Å] and angles [°]: P1-C1 1.788(14), C1-P2 1.684(14), P2-N1 1.617(13); P1-C1-P2 115.5(8), C1-P2-N1 105.3(7).

observed for P^v–$C(sp^2)$ single bonds, whereas the P2–C1 bond (1.68 Å) is much shorter and typical of phosphaalkenes.[7] The slight increase in length compared with the bonds in *P*-aryl-substituted phosphaalkenes[8] is presumably due to the conjugation of the lone pair on N1 with the P=C bond. The relatively short P2–N1 bond (1.61 Å) further supports this conjecture. In addition to the bands of the phenyl groups, the UV/VIS spectra (in CH_3CN) of **2a** and **2b** show bands for the C=P π–π^* transition at $\lambda = 307$ nm ($\varepsilon = 0.61 \times 10^3$ L mol^{-1} cm^{-1}) and 316 nm (2.4×10^3 L mol^{-1} cm^{-1}), respectively. The phosphaalkenes with coplanar amino substituents on phosphorus that *Gudat* and *Niecke* synthesized and investigated by UV/VIS spectroscopy are excited in the same wavelength region (e.g., $(Me_3Si)_2C{=}P{-}NiPr_2$, 307 nm; $(Me_3Si)_2C{=}P{-}NMe_2$, 317 nm).[9]

An attempt to synthesize the *P*-alkyl-substituted derivative **4** was unsuccessful – instead, the head-to-tail dimer **5** was obtained and characterized by NMR spectroscopy and X-ray structure analysis.[10] 1,3-Diphosphetanes are well

Scheme 2.

known as dimerization products of phosphaalkenes.[11] The intermediacy of **4** was confirmed by trapping experiments with 2,3-dimethylbutadiene; the product **6**, formed by [2 + 4] cycloaddition to the P=C bond, was obtained in nearly quantitative yield.[12] Similarly, the reaction of **7a, b** with $BF_3 \cdot OEt_2$ in the presence of 2,3-dimethylbutadiene in excess leads to the heterocycles **8a** and **8b**. However, the reaction of **7b** is not uniform. Loss of F_2BPh, instead of F_2BNiPr_2, results in the formation of **2b** as a side product. Compounds **6, 8a**, and **8b**[13] are formed as racemates with no observed formation of diastereomers. This finding supports a concerted [2 + 4] cycloaddition. Compounds **2a** and **2b** do not react with 2,3-dimethylbutadiene under the conditions described here. Moreover, products of a [1 + 4] cycloaddition were not observed.[14]

The bonding parameters obtained from a structure investigation and the data derived from the UV/VIS spectra of **2a** and **2b**, as well as the reactivity of compounds **4, 7a**, and **7b**, are similar to those of previously reported phosphaalkenes. The syntheses described here offer attractive variants for the synthesis of phosphaalkenes, since the phosphinomethylenetriphenylphosphoranes required as starting materials are readily accessible and widely variable.

On the Structure of Eumelanins: Identification of Constitutional Patterns by Solid-State NMR Spectroscopy**

By *Martin G. Peter** and *Hans Förster*

Melanins are complex polyphenolic polymers. They are usually formed in nature by enzyme-catalyzed oxidative polymerization of *o*-diphenols (for reviews, see Refs. [1–3]). The deep black eumelanins, derived from Dopa **1** or dopamine **3**, are distinguished from the yellow to brown phaeomelanins obtained from Dopa in the presence of cysteine. Characteristic of eumelanins are the indole units, which are formed from catecholamines by intramolecular addition of the amino groups to the oxidatively generated *o*-quinones (Fig. 1). During polymerization of these indoles, C–C and C–O bonds are formed by nucleophilic additions and by oxidative radical phenol couplings. Allomelanins are polyarenes obtained from nitrogen-free catechols.

In contrast to Dopa-melanin, dopamine-melanin is basic in character and is capable of being benzoylated to a greater extent than Dopa-melanin.[1] According to *Swan*,[2] Dopamelanin has the following statistical composition (Fig. 1): ca. 10% **1** and **2**, ca. 10% **7** and **9**, ca. 65% **11** and **12**, and ca. 15% pyrrolecarboxylic acids. Dopamine-melanin contains ca. 35% **3** and **4**, ca. 55% **11, 12, 8,** and **10**, and ca. 10% pyrrolecarboxylic acid units. The latter are not shown in Figure 1 (cf. Refs. [1, 2, 5]). The relative amounts of noncyclic units in Dopa- and dopamine-melanin correspond roughly to the ratio of the rate constants k_c of the cyclization (Dopa, $k_c = 72$ s^{-1};[6] dopamine, $k_c = 25.6$ s^{-1}[7]). The rates of rearrangement of dopachrome **9** and dopaminochrome **10** to 5,6-dihydroxyindole **11** have not yet

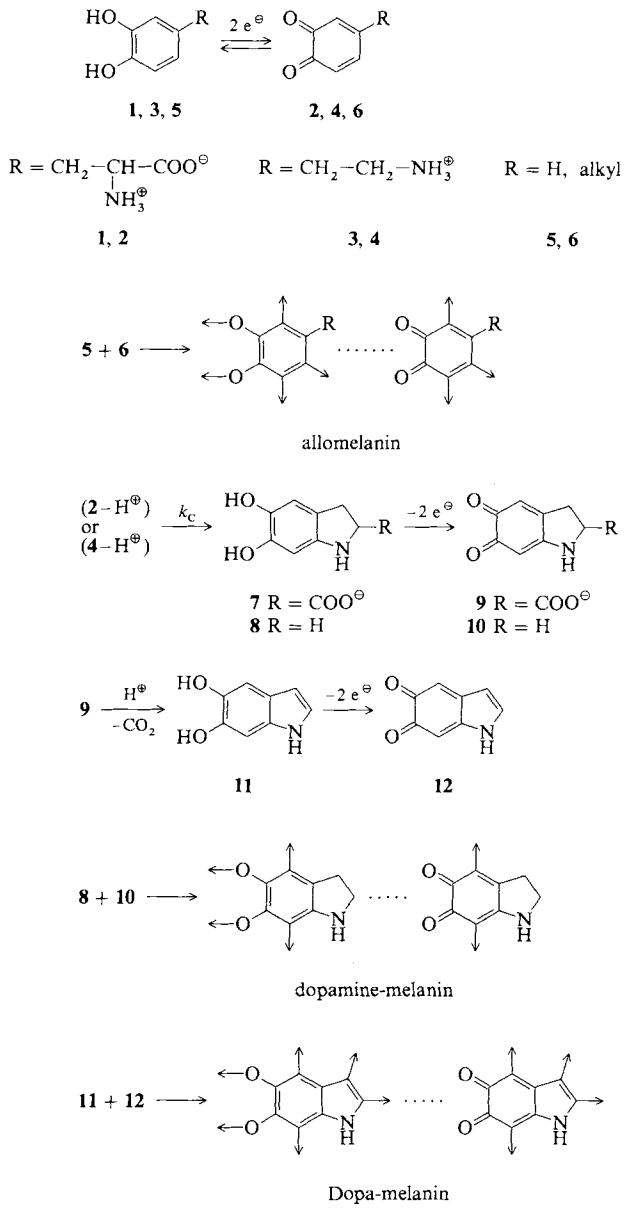

Fig. 1. Schematic drawing of the formation of melanins from catechols.

been determined to the best of our knowledge. In basic to neutral media, however, the decarboxylation of the dihydroindole should proceed faster than the deprotonation. The dopamine-melanin generated at pH 7 should therefore consist to a larger extent of dopamine and dihydroindole units than of indole units.

These conclusions are confirmed by solid-state ^{13}C NMR spectra. We prepared Dopa- and dopamine-melanin by oxidation of Dopa and dopamine, respectively, with excess $K_3[Fe(CN)_6]$ in water. The elemental analysis (double determination) gave the following results for Dopa-melanin: $49.02 \pm 0.03\%$ C, $3.71 \pm 0.01\%$ H, and $8.29 \pm 0.03\%$ N ($C_9H_{8.15}N_{1.30}$). For dopamine-melanin, the values were $50.83 \pm 0.11\%$ C, $4.20 \pm 0.03\%$ H, and $9.52 \pm 0.01\%$ N ($C_8H_{7.92}N_{1.28}$).

The CP/MAS ^{13}C NMR spectrum of Dopa-melanin is shown in Figure 2b. The signal assignment given in Table 1 was made by comparison with the solid-state ^{13}C NMR spectrum of Dopa (Fig. 2a).

In the aliphatic region, the side-chain C atoms of the Dopa units and C2 of the dihydroindole units can also be identified upon improvement of the resolution by Gauss modification.

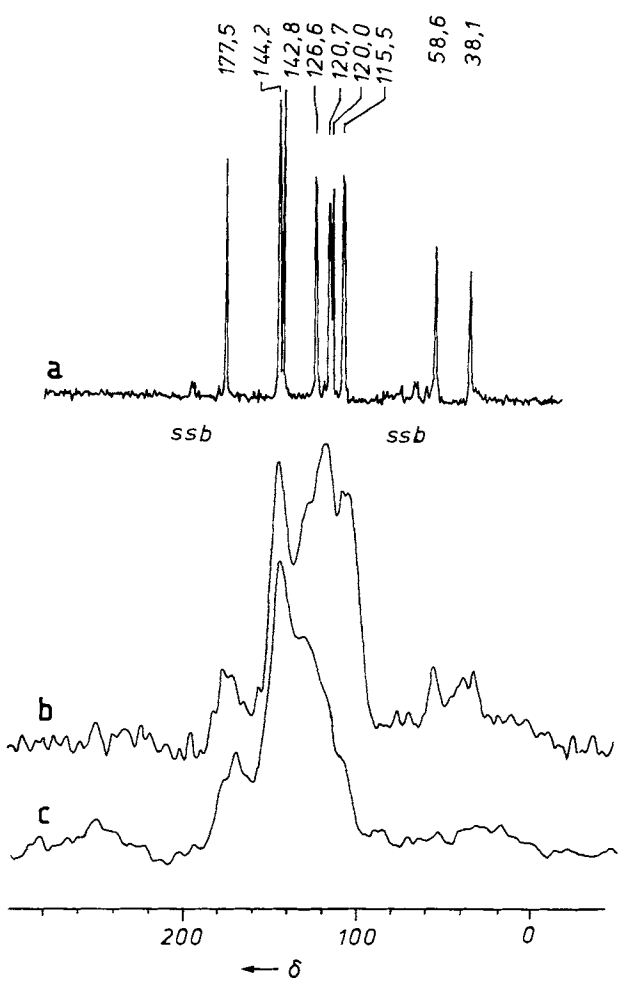

Fig. 2. CP/MAS ^{13}C NMR spectra of a) Dopa, b) Dopa-melanin, and c) Dopa-melanin recorded with an NQS sequence using 60-μs delay times; $^1H-^{13}C$ cross-polarization with sample rotation around the magic angle; spin frequency 5.19 kHz; decoupling field strength 20 G; contact time 500 μs; 1606 accumulations at 297 K; rotation side bands (SSB) were largely suppressed.

Table 1. Assignment of the signal groups in the CP/MAS ^{13}C NMR spectrum of Dopa-melanin (Fig. 2b).

δ	Assignment
175	Carboxyl and quinoid carbonyl C atoms
144	Diphenolic phenoxy C atoms
127–116	Arene *C*-H and *C*-C; C2, C3a, C4, and C6a of indole units
107–104	C3 of indole and pyrrole units
54, 36, and 31	Side-chain C atoms of noncyclized Dopa and C2 of dihyroindole units

If the resonances of non-quaternary C atoms are suppressed with an NQS sequence, the signals in the aliphatic region as well as those of the respective indole and pyrrole C atoms at $\delta = 107-104$ disappear (Fig. 2c). In the region of the arene C atoms, a decrease in intensity is observed owing to the suppression of the resonances of the unsubstituted phenyl and indole C atoms. Thus, the partial structures contained in the constitutional scheme of Dopa-melanin are unambiguously confirmed by the solid-state ^{13}C NMR spectrum.

The CP/MAS ^{13}C NMR spectrum of dopamine-melanin, shown in Figure 3b, differs markedly from that of Dopa-melanin (cf. Fig. 2b). Owing to the absence of carboxyl groups in the starting material, the carbonyl resonances ($\delta \approx 170$) are weaker than in Dopa-melanin. The C-3 signals of the unsubstituted indole and pyrrole units can hardly be

identified for dopamine-melanin. The intense aliphatic signals correlate unambiguously with the side-chain C atoms of dopamine (Fig. 3a); the signal of dihydroindole C2, expected at $\delta \approx 46$, is not resolved. Suppression of non-quaternary C atoms affords a spectrum very similar to that of the NQS spectrum of dopa-melanin (Fig. 3c).

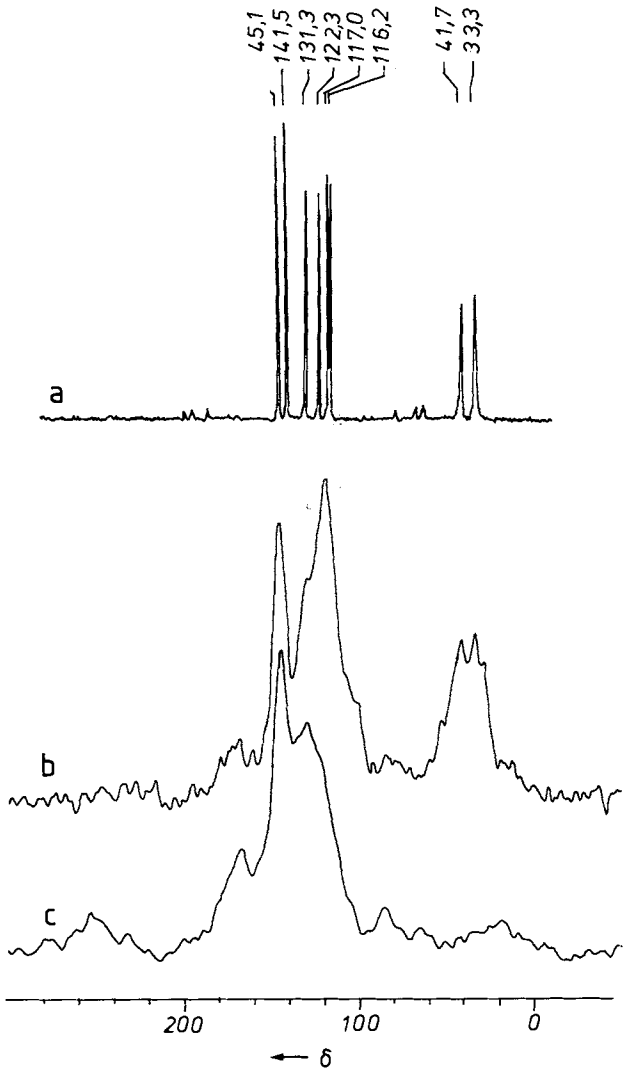

Fig. 3. CP/MAS ^{13}C NMR spectra of a) dopamine (hydrochloride), b) dopamine-melanin, and c) dopamine-melanin recorded with an NQS sequence using 60-μs delay times. For measuring parameters, see Figure 2.

Comparison of the relative intensities of individual groups of signals in the spectra of the monomeric precursor and the polymer reveal that dopamine-melanin contains a much larger proportion of unmodified side chains compared with Dopa-melanin. Accordingly, dopamine-melanin is formed to a correspondingly greater extent by polymerization of the open-chain precursors **3** and **4** (Fig. 1) and contains substructures of the allomelanin type (cf. the polymerization of **5** and **6** in Fig. 1). In addition, constitutional patterns resulting from copolymerization of **3** and **4** with **8, 10, 11,** and **12** are present to a lesser extent. In Dopa-melanin, on the other hand, the polymerization of **11** with **12** predominates.

The solid-state ^{13}C NMR spectra also allow an estimate of the oxidation state of the polymer. Comparison of the intensities of the carbonyl and the diphenolic phenoxy C signals reveals a high proportion of catechol units; this indicates that the polymerization occurs by oxidative phenol couplings.

Duff et al.[8] recently described CP/MAS ^{13}C and ^{15}N NMR spectra of autooxidatively generated Dopa-melanin as well as of melanoma- and sepia-melanin, isolated from biological material. The signal assignments largely agree with those in Figure 2b discussed here. However, the indole, pyrrole, and dihydroindole units in the spectrum published in Ref. [8] are not unambiguously identifiable owing to the comparatively low resolution. In the CP/MAS ^{15}N NMR spectrum, on the other hand, signals for aliphatic amino groups are present.

The CP/MAS ^{13}C NMR spectrum of melanin generated enzymatically from tyrosine with tyrosinase (monophenol monooxygenase, EC 1.14.18.1) agrees qualitatively with Figure 2b, although the carboxyl/carbonyl signals in tyrosine-melanin are more intense. The signals of the phenoxy C atoms at $\delta \approx 145$ are less intense than those of the other arene C atoms. However, indole C3 atoms and pyrrole C atoms can be unambiguously identified. The CP/MAS ^{13}C NMR spectrum of a phaeomelanin, prepared by oxidation of a mixture of Dopa and cysteine with $K_3[Fe(CN)_6]$, is characterized above all by the prominent carboxyl signal and the signals of the aliphatic amino-acid C atoms.

The results show that solid-state NMR spectroscopy is very suitable for nondestructive investigation of complex biopolymers. The analysis of the constitutional pattern not only leads to new insights into structural relationships, but also is essential for the assignment of unknown polyphenolic natural products to specific melanin classes.

Experimental Procedure

Preparation of Dopa-melanin: A solution of L-Dopa (1.0 g, 5.07 mmol) and $K_3[Fe(CN)_6]$ (8 g, 23.4 mmol) in 1 L of H_2O was adjusted to pH 8 with ca. 2 N KOH and then stirred vigorously in an open Erlenmeyer flask at 22 °C. After 7 h, the reaction mixture was acidified with 10 mL of conc. HCl. The black melanin that settled out was centrifuged off and washed thoroughly with 10 × 50 mL of H_2O. It was then suspended in H_2O and lyophilized. Yield: 897 mg Dopa-melanin. Dopamine-melanin was synthesized similarly.

$[Et_4N]_6[Na_{14}Mo_{24}P_{17}O_{97}(OH)_{31}] \cdot xH_2O$: A Hollow Cluster Filled with 12 $Na^{\oplus}$ Ions and a H_3PO_4 Molecule

By *Robert C. Haushalter** and *Frank W. Lai*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Compared to the solid-state layer and tunnel structures composed of either all octahedral or all tetrahedral building blocks, relatively little attention has been given to solids built up from octahedral-tetrahedral frameworks.[1] During our

[*] Dr. R. C. Haushalter, F. W. Lai

recent investigations of the factors affecting framework formation and stability in the mixed octahedral-tetrahedral system M-Mo-P-O (M = metal cation) in the solid-state compounds built up from MoO_6 octahedra and PO_4 tetrahedra, we and others discovered a large number of new tunnel or layer structures. These compounds include $Cs_2Mo_4P_6O_{26}$,[2] $Cs_4Mo_8P_{12}O_{52}$,[2] $AgMo_5P_8O_{33}$,[3] $CsMoP_2O_7$,[4] $Cs_4Mo_{10}P_{18}O_{66}$,[5] $Cs_4Mo_6P_{10}O_{38}$,[6] and $Mo_3P_5SiO_{19}$[7] as well as metal–metal-bonded $[Mo_4O_4]^{6\oplus}$ cubes in $Cs_3Mo_5P_6O_{25}$[8] and $Cs_3Mo_4P_3O_{16}$,[9] all of which contain Mo in an oxidation state less than + 6. Since these reduced molybdenum phosphates formed so readily in the solid state, we were interested to see if similar species could exist in solution.

The chemistry of molybdenum in phosphoric acid solution is dominated by the familiar heteropolymolybdates, Keggin-type anions, and other species with Mo in an oxidation state

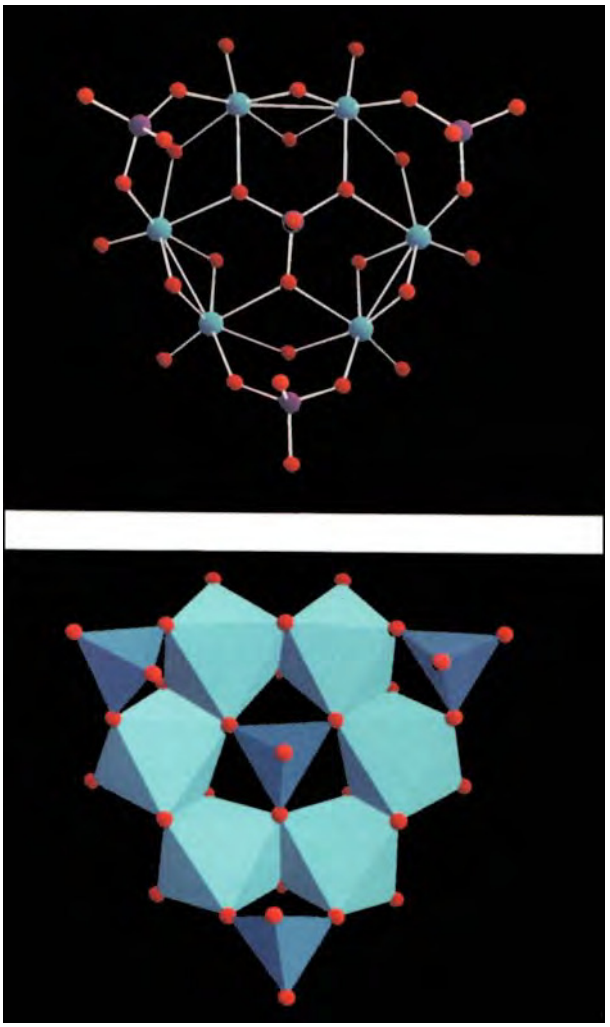

Fig. 1. Chem-X representation [16] of the $[Mo_6P_4O_{24}(OH)_7]^{5\ominus}$ ion perpendicular to the plane defined by the six Mo atoms. Top: Ball-and-stick model. O, red; P, violet; Mo, light blue. Bottom: Polyhedral representation, emphasizing the edge-sharing octahedra. MoO_6 octahedra, light blue; PO_4 tetrahedra, dark blue; O, red.

near + 6,[10] but at least one low-valent molybdenum phosphate with a Mo–Mo bond[11] is known. We have found that if the oxidation state of Mo is maintained at + 5 or below, several novel reduced molybdenum phosphates can be isolated from phosphoric acid solution. The synthesis and structure of one such phosphate, **1**,[12] a hollow cluster enclosing twelve $Na^{\oplus}$ ions and a phosphoric acid molecule, is described here.

$[Et_4N]_6[Na_{14}Mo_{24}P_{17}O_{97}(OH)_{31}] \cdot xH_2O$ **1**

Hydrothermal treatment of a mixture of Na_2MoO_4, Mo, Et_4NOH, H_3PO_4, and H_2O in a mole ratio of 2:1:2:6:100 (200 °C, 3 d) gives, in addition to some unreacted Mo metal, a >90% yield (based on sodium molybdate) of dark red crystals of **1**. Compound **1** was identified by a single-crystal

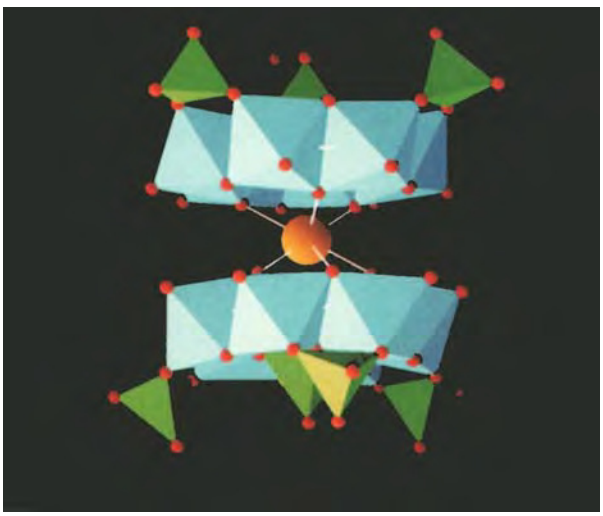

Fig. 2. Structure of the $Na^{\oplus}$-bridged dimer of $[Mo_6P_4O_{24}(OH)_7]^{5\ominus}$. MoO_6 octahedra, light blue; PO_4 tetrahedra, green; $Na^{\oplus}$, yellow.

X-ray diffraction study combined with subsequent comparison of the powder X-ray diffraction pattern of the bulk sample with the simulated pattern generated from the coordinates of the single-crystal data. Without the presence of the Mo metal, the familiar heteropolymolybdates are the major Mo-containing species obtained.

The solid-state structure of **1** is interesting because of the unique $[Na_{12}Mo_{24}P_{17}O_{97}(OH)_{31}]^{8\ominus}$ clusters present as well as an unusual motif of intersecting, $Et_4N^{\oplus}$-filled tunnels. The basic structural building block in **1** is the novel anion **2**,

$[Mo_6P_4O_{24}(OH)_7]^{5\ominus}$ **2**

which is shown in Figure 1 and consists of six MoO_6 octahedra, each containing an Mo=O group and sharing two edges with neighboring octahedra (Fig. 1). This $[\mu^2\text{-O–Mo=O}]_2$ unit is commonly found with $Mo^{5\oplus}$ coordinated to oxo ligands.[13] Mo–Mo single bonds (2.59 Å) alternate with nonbonding Mo···Mo contacts (3.55 Å). The unique central phosphate group has one terminal OH and provides three μ^3 oxygens that bridge the bonding Mo···Mo contacts, while the remaining three PO_4 groups each have two terminal OH groups and span the nonbonding Mo–Mo contacts.

In **1**, and other molybdenum phosphates,[6] the anion **2** is bonded to another identical anion via an octahedrally coordinated $Na^{\oplus}$ ion to give a dimer of Mo_6 subunits (Fig. 2) with the $Na^{\oplus}$ ion enclosed by an octahedron of oxygen atoms and shielded from the external environment by the twelve intermeshing Mo=O groups. Note that all of the PO_4 groups lie on one side of the plane defined by the six Mo atoms (Fig. 2).

The three-dimensional structure[14] of **1** is built up in the cubic space group $Pn\bar{3}$ from the dimers as follows: four different dimers are bound to each other through one end into a complicated hydrogen-bonded pattern and are centered about the Wyckoff *a* site (site symmetry 23) at 1/4, 1/4, 1/4. This yields a large, hollow $[Mo_{24}P_{16}O_{96}(OH)_{28}]$ aggregate

(Fig. 3), which also displays overall 23 symmetry (i.e., the four $[Mo_6P_4O_{24}(OH)_7]$ clusters lie at the vertices of a tetrahedron with the Mo_6 plane perpendicular to the threefold axis of the tetrahedron.). This mode of aggregation leaves a large void, which is filled with a H_3PO_4 group, whose P atom is on the special position at 1/4, 1/4, 1/4, and twelve $Na^{\oplus}$ ions that are coordinated to oxygens on the interior surface of the $[Mo_6P_4O_{24}(OH)_7]_4$ cluster (Fig. 3). The unique central

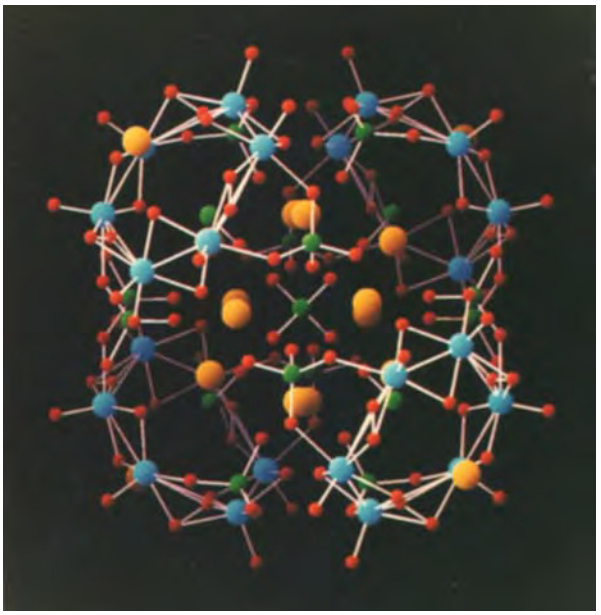

Fig. 3. Ball-and-stick representation of the $[Na_{12}MO_{24}P_{17}O_{97}(OH)_{31}]^{8\ominus}$ cluster in **1**. Mo, light blue; P, green; O, red; Na, yellow.

H_3PO_4 molecule is hydrogen bonded to the other phosphates that are part of the dimer[12] and is enclosed in a distorted icosahedron of $Na^{\oplus}$ ions with each O atom of the phosphate bonded to three $Na^{\oplus}$ ions (Fig. 3). The other ends of the four dimers forming this large unit take part in the formation of four different $[Mo_{24}P_{17}O_{97}(OH)_{31}]$ clusters.

An alternative description of the anionic framework in this compound is that of $[Na_{12}Mo_{24}P_{17}O_{97}(OH)_{31}]^{8\ominus}$ clusters connected into a tetrahedral array by $Na^{\oplus}$ ions. The voids left by packing the anions together form an unusual array of one-dimensional tunnels, which are filled with $Et_4N^{\oplus}$ ions and run parallel to the six $\langle 100 \rangle$ directions in the unit cell as shown in Figure 4. If one considers the cubic unit cell to be divided into octants, then the P atoms of the central H_3PO_4 molecules of the $[Mo_{24}P_{17}O_{97}(OH)_{31}]$ clusters are at 1/4, 1/4, 1/4 and 3/4, 3/4, 3/4, while the one-dimensional tunnels intersect at the centers of the other six octants. There are also six water molecules per Mo_{24} unit. These water molecules, which were difficult to model satisfactorily, sit on threefold rotation and threefold inversion axes (two on the Wyckoff *c* site and four on the *e* site).

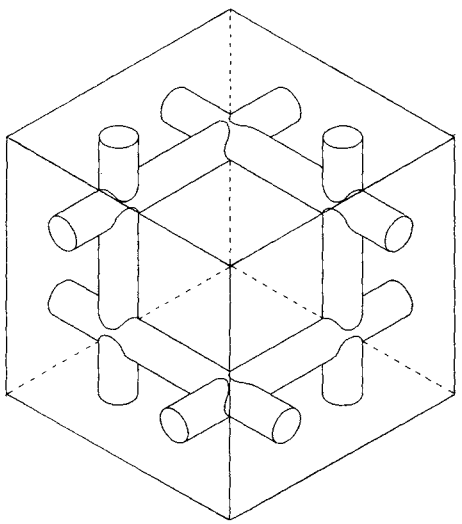

Fig. 4. A schematic view of the $Et_4N^{\oplus}$-filled tunnels in **1**.

These results show that it is possible to prepare molybdenum phosphates in acidic aqueous solution that differ greatly from the well-known heteropolymolybdates. The assembly of such a complex structure as **1** in very high yield from simple starting materials is somewhat surprising. As will be discussed elsewhere,[6] one possible rationalization for the gross structure of this and other molybdenum phosphates prepared by us may be in terms of hydrophilic-hydrophobic interactions, since the MoO_6 groups appear to be relatively less polar than the phosphate portion of the structure. For example, in **1**, the sixteen PO_4 groups are oriented toward the $Na^{\oplus}$ ions and the unique H_3PO_4 molecule in the interior of the aggregate, while the twenty-four Mo=O groups are all on the exterior facing the relatively nonpolar tetraalkylammonium ions. In other words, the tunnels containing the relatively nonpolar $Et_4N^{\oplus}$ ions are "lined" with Mo=O groups as shown in the projection of the unit cell contents in Figure 5. The overall structure is reminiscent of a small amount of a polar species and a detergent in a nonpolar liquid. This material may be an interesting candidate for a description in terms of periodic minimal surfaces.[15]

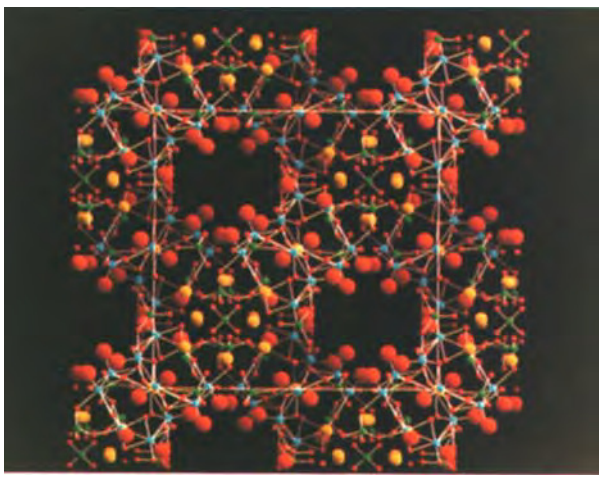

Fig. 5. The unit cell of **1** with the Mo=O oxygen atoms (red) represented with exaggerated size to emphasize their segregation onto the "lining" of the tunnels where the $Et_4N^{\oplus}$ ions reside (not shown). Mo, light blue; P, green; Na, yellow.

[12] This formulation for this material assumes, based on the observed geometry and the P–O bond lengths, that all of the terminal OH groups on the PO_4 groups, including the unique central PO_4, are protonated. Bond strength–bond length calculations, based on the observed Mo–O bond lengths and the geometry about the Mo atoms, clearly show the Mo to be in the + 5 oxidation state. If one assumes that all Mo atoms are $Mo^{5\oplus}$ and the solvate water molecules are not protonated, then the central phosphate is required to be H_3PO_4, consistent with the observed hydrogen-bonding pattern.

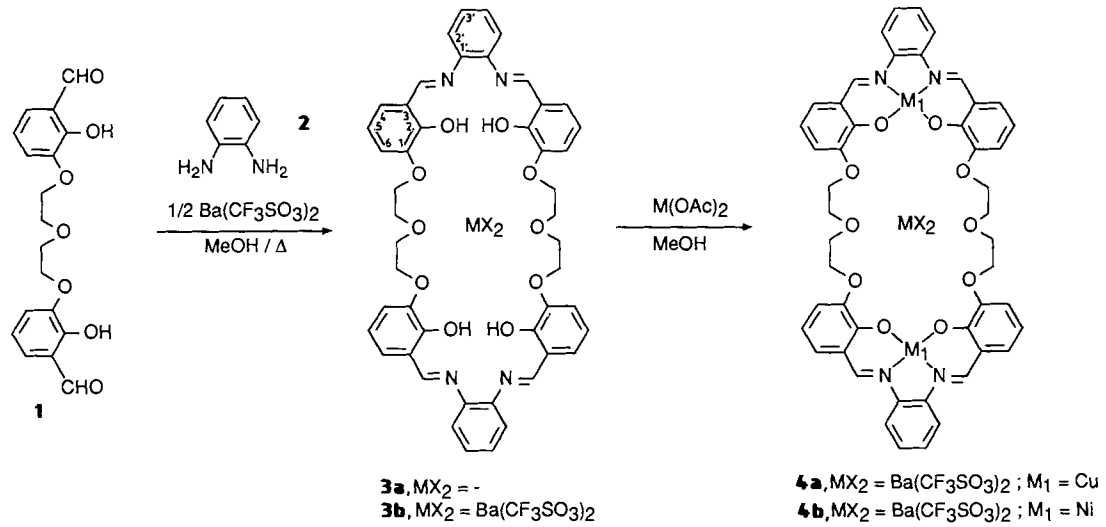
The Organization of Two "Soft" ($Cu^{2\oplus}$, $Ni^{2\oplus}$) Metal Centers in Heterotrinuclear Complexes of a Macrocyclic Ligand by Cocomplexation with $Ba^{2\oplus}$ **

By *Frank C. J. M. van Veggel, Martinus Bos, Sybolt Harkema, Willem Verboom*, and *David N. Reinhoudt* *



Almost all the reported model compounds for the active site in dicopper metalloproteins like hemocyanin, tyrosinase, and dopamine β-hydroxylase[1] contain dinucleating ligands in which a hydroxide, a phenolate, or an alkoxide group acts as a bridge between the two copper sites. As part of our work on the complexation of neutral molecules by macrocyclic receptor molecules,[2] we have recently reported the complexation of urea and its derivatives by macrocycles in which "soft" cations are immobilized as electrophilic centers.[3] In addition, we have shown that hard cations, like alkali and alkaline-earth cations, can be cocomplexed in such metallomacrocycles to give heterodinuclear complexes.[4, 5]

We describe here the synthesis of a barium complex containing a novel type of macrocyclic ligand and its subsequent reaction with copper or nickel acetate to yield heterotrinuclear complexes in which the arrangement of the two soft metal centers is completely different from that in known dicopper complexes.

The synthesis of the complexes **3b** and **4**, containing the macrocyclic ligand **3a**, is outlined in Scheme 1. Complex **3b** was prepared by simultaneous slow addition of a solution of *o*-phenylenediamine (**2**) and a solution of the dialdehyde **1**[6] to a refluxing solution of $Ba(CF_3SO_3)_2$ in MeOH and obtained as a red crystalline material in 63% yield.[7] The FAB mass spectrum of **3b** shows the parent peak at *m/z* 1123, which corresponds to $[M-CF_3SO_3]^{\oplus}$.

Ruby red crystals of **3b** were obtained by slow diffusion of petroleum ether into a solution of **3b** in MeOH. The structure of one of the two independent molecules in the asymmetric unit is shown in Figure 1.

The macrocycle is folded around the barium, thereby allowing coordination by all ten oxygen atoms of the macrocycle ($Ba^{2\oplus}\cdots O$ 2.69–3.14 Å). The eleventh position around the barium ion is occupied by an oxygen of a triflate ion ($Ba^{2\oplus}\cdots O$ 2.82 Å). The two conjugated *N,N'-o*-phenylenebis(salicylidenaminato) (salophen) units are not planar, the angles between the two opposite aromatic rings being 17.3 and 29.5°. The mean planes through the four heteroatoms of the salophen units are approximately parallel, with an angle of 12.6°.

Scheme 1.

The conversion of the barium complex **3b** into the trinuclear complexes **4** was carried out by reaction with 2 equivalents of copper or nickel acetate.[8, 9] The parent peaks in the FAB mass spectra of **4a** (*m/z* 1245) and

P.O. Box 217, NL-7500 AE Enschede (The Netherlands)

[**] We thank Akzo International Research BV for financial support and Prof. *N. Nibbering* and *R. R. Fokkens*, Amsterdam, for recording the FAB mass spectra.

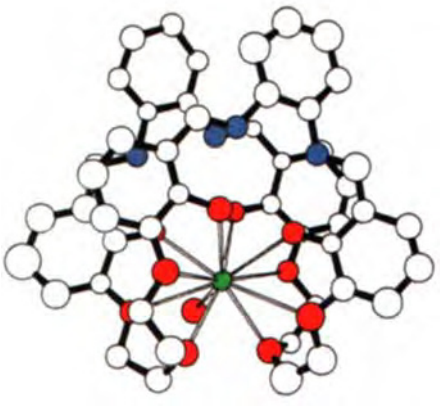

Fig. 1. Crystal structure of **3b**. The asymmetric unit contains two independent molecules, of which one is shown. The noncoordinating triflate ion and hydrogen atoms are omitted for clarity. Green = Ba, red = O, blue = N. Crystal data [16]: triclinic, $a = 21.950(2)$, $b = 16.993(2)$, $c = 14.502(2)$ Å, $\alpha = 84.15(5)$, $\beta = 79.04(5)$, $\gamma = 88.79(5)°$, $V = 5283(8)$ Å^3, space group $P\bar{1}$, $Z = 4$, $\varrho_{calcd} = 1.60$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 9.18$ cm^{-1}. Final R factor for 4388 significant [$I > 5\,\sigma(I)$, $\theta = 3-25°$] reflections is 0.060.

4b (m/z 1234) correspond to $[M-CF_3SO_3]^{\oplus}$ and $[M-CF_3SO_3+H]^{\oplus}$, respectively.

Suitable crystals for an X-ray analysis of the dicopper/barium complex **4a** were obtained by slow diffusion of Et_2O into a solution of **4a** in a mixture of MeOH and CH_3CN (1:1). The structure of the folded macrocycle is shown in Figure 2. It is similar to that of **3b**.

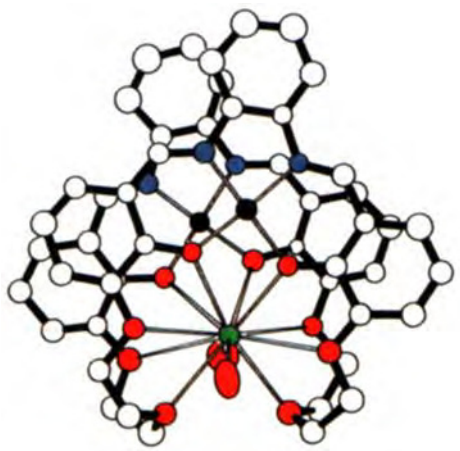

Fig. 2. Crystal structure of **4a** · 2 H_2O. Only the coordinating oxygen atom of the triflate anion (ellipse) is drawn for clarity. The noncoordinating triflate ion, water molecule, and hydrogen atoms are omitted for clarity. Green = Ba, black = Cu, red = O, blue = N. Crystal data [16]: orthorhombic, $a = 28.589(9)$, $b = 27.786(4)$, $c = 13.383(3)$ Å, $V = 10631(6)$ Å^3, space group $Pbca$, $Z = 8$, $\varrho_{calcd} = 1.74$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 16.9$ cm^{-1}. Final R factor for 2589 significant [$I > 3\,\sigma(I)$, $\theta = 3-22.5°$] reflections is 0.078.

The two copper ions in **4a** are complexed in an almost square-planar fashion in the "soft" salophen cavities and the barium ion is complexed in the large polyether cavity. The two conjugated salophen parts of the macrocycle are not completely planar, the angles between the opposite aromatic rings being 8.2 and 8.7°. The mean planes through the coordinating atoms of the copper ions are approximately parallel, with an angle of 5.8°. A view perpendicular to one salophen unit shows that the other unit is not exactly under it but displaced by about 1.4 Å. The barium ion is coordinated by all ten oxygens of the macrocycle ($Ba^{2\oplus}\cdots O$ 2.76–3.63 Å), one water molecule ($Ba^{2\oplus}\cdots O$ 3.01 Å), and one triflate ion ($Ba^{2\oplus}\cdots O$ 2.89 Å). The metal–metal distances in the cation cluster **4a** are: $Ba^{2\oplus}\cdots Cu^{2\oplus}$ 3.70 and 3.85; $Cu^{2\oplus}\cdots Cu^{2\oplus}$ 3.50 Å. The angle $Cu^{2\oplus}$-$Ba^{2\oplus}$-$Cu^{2\oplus}$ is 55.1°.

Dark red single crystals of the dinickel/barium complex **4b** were similarly obtained by slow diffusion of Et_2O into a solution of **4b** in a mixture of CH_3CN and dimethyl sulfoxide (DMSO). The structure of **4b** resembles that of **4a**. The two nickel ions are complexed in the "soft" salophen cavities in an almost square-planar fashion. The mean planes through the coordinating atoms of the nickel ions are approximately parallel to each other, with an angle of 7.4°. A view perpendicular to one salophen unit shows that the other unit is not exactly under it but displaced by about 0.95 Å. The barium ion is complexed in the "hard" cavity by all crown ether oxygens ($Ba^{2\oplus}\cdots O$ 2.72–3.09 Å) and one water molecule ($Ba^{2\oplus}\cdots O$ 2.87 Å). The metal–metal distances in the cation cluster **4b** are: $Ba^{2\oplus}\cdots Ni^{2\oplus}$ 3.66 and 3.73; $Ni^{2\oplus}\cdots Ni^{2\oplus}$ 3.42 Å. The angle $Ni^{2\oplus}$-$Ba^{2\oplus}$-$Ni^{2\oplus}$ is 55.1°.

The electrochemical properties of the trinuclear complexes **4a** and **4b** were investigated by polarography and cyclic voltammetry at a mercury drop electrode in DMSO with 0.1 M $Et_4N^{\oplus}ClO_4^{\ominus}$ as supporting electrolyte.[10]

The polarogram of the dicopper/barium complex **4a** shows two waves between −0.2 and −1.4 V [$E_{1/2} = -1.065$ and −1.110 V (slope 52 and 50 mV, respectively)].[11] The ratio of the limiting currents is 1, which indicates two one-electron reductions.[12] Cyclic voltammograms of **4a** were recorded at scan rates of 0.5 to 6 V s^{-1}. At these scan rates the two-step process is reflected as a shoulder on a peak in the reductive as well as in the oxidative sweep. This two-electron reduction/oxidation is *chemically* reversible, because, when five scans at scan rates of 0.5 and 6 V s^{-1} were applied, five identical cyclic voltammograms were recorded. This reduction can be regarded as taking place by a simple EE mechanism, that is, two one-electron transfers via a (formally) M_1^{II}/M_1^{I} oxidation state to a (formally) M_1^{I}/M_1^{I} oxidation state.

The polarogram of **4b** shows two waves between −0.2 and −1.4 V [$E_{1/2} = -1.036$ and −1.137 V (slope 50 and 46 mV, respectively)].[11] The ratio of the limiting currents is about 1. The cyclic voltammograms of **4b** at scan rates

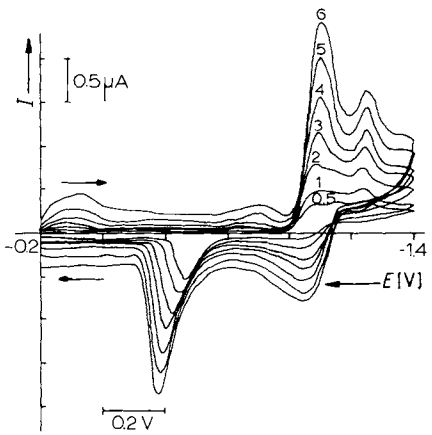

Fig. 3. Cyclic voltammograms of **4b** in DMSO, with 0.1 M $Et_4N^{\oplus}ClO_4^{\ominus}$ as supporting electrolyte, at scan rates of 0.5 to 6 V s^{-1} (shown on the curves); vs. Ag/AgCl.

of 0.5 to 6 V s^{-1} between −0.2 and −1.4 V are shown in Figure 3.

Cyclic voltammetry showed that the reduction/oxidation of **4b** is also *chemically* reversible, because, when 30 scans were applied at scan rates of 2 and 6 V s^{-1} between −0.2 and −1.4 V, 30 identical voltammograms were recorded. However, this reduction/oxidation cannot be regarded as two simple one-electron transfers[13] but is complicated by reversible intra- and intermolecular C–C coupling of two (reduced) C=N bonds. This reductive C–C coupling of two C=N bonds in Ni(salophen) units has also been observed in the solid state by *Floriani* et al. upon reduction of Ni(salophen) with one equivalent of lithium and sodium metal.[14] They showed that the C–C coupling product could be oxidized to give the original Ni(salophen), which demonstrates the reversibility of this reductive C–C coupling. The reduced Ni(salophen) can be regarded as a complex of Ni^{II} with a radical anion ligand, as was demonstrated by *Gosden* et al.[15] by ESR measurements of reduced Ni(salophen) at 77 K.

Currently we are studying the interaction of the trinuclear complexes **4** with small anions and neutral molecules.

[9] The barium-free dicopper and dinickel complexes could be made by reaction of **3a** with two equivalents of copper and nickel acetate, respectively, but these complexes are insoluble in all normal organic solvents.

[10] Measurements were performed in 0.1 M $Et_4N^{\oplus}ClO_4^{\ominus}$ solution in DMSO at 20 °C. The apparatus was operated in a three-electrode mode with a mercury drop as cathode, a platinum wire as auxiliary electrode, and an Ag/AgCl electrode as reference. The reference electrode (Ag/AgCl) was filled with 1 M Et_4NCl in MeOH and brought into contact via a salt bridge, filled with 0.1 M $Et_4N^{\oplus}ClO_4^{\ominus}$ in DMSO, with the sample solution. See [4,5] for a more detailed description of the apparatus and procedures.

[11] Determination of the half-wave potentials ($E_{1/2}$) was done manually. The slopes were estimated with $E_{3/4}-E_{1/4}$. The peak at about −0.3 V, which occurs at higher scan rates, is due to capacitance effects. This peak is also found in the blank.

[12] The one-electron reduction of the Cu(salophen) unit is well known; see, e.g., D. F. Rohrbach, W. R. Heineman, E. Deutsch, *Inorg. Chem. 18* (1979) 2536.

[13] The one-electron reduction of the Ni(salophen) unit is well known; see, e.g. [15].

A Novel Type of Anionic Cluster Containing a Pt_4Ag_2 Core**

By *Rafael Usón, Juan Forniés, Milagros Tomás,* and *José M. Casas*

The electron-rich metal centers in mono- and binuclear platinum(II) complexes containing perhalophenyl ligands are able to donate electron density to suitable Lewis acids, such as $Ag^{\oplus}$ and $(AgL)^{\oplus}$, to afford unusual polynuclear complexes containing Pt→Ag bonds.[1–6] Specifically, the anionic binuclear complexes **1** react with $AgClO_4$ without elimination of AgX to give the trinuclear complexes **2**.

$(NBu_4)_2[Pt_2(\mu\text{-}X)_2(C_6F_5)_4]$ **1**

$(NBu_4)[Pt_2Ag(\mu\text{-}X)_2(C_6F_5)_4OEt_2]$ **2**

a, X = Cl; **b**, X = Br; **c**, $X = C_6F_5$

The structures of **2a** and **2c** have been established by single-crystal X-ray studies. In both cases[4, 5] the bent binuclear $[Pt_2(\mu\text{-}X)_2(C_6F_5)_4]$ fragment acts as a bidentate chelating ligand with both platinum donor atoms bonded to the silver atom through otherwise unsupported Pt→Ag bonds. The diethyl ether molecule is coordinated to the silver atom (Fig. 1).

However, the analogous binuclear pentachlorophenyl derivatives **3**[7] behave differently. Upon reaction with $AgClO_4$ (under similar conditions as those used in the syn-

[**] This work was supported by the Spanish Comisión Asesora de Investigación Científica y Técnica (CAICYT) (project PB85-0128).

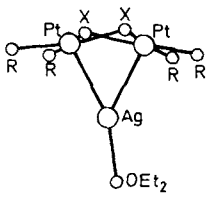

Fig. 1. Schematic drawing of the structure of **2**. R = C_6H_5.

thesis of **2**), they afford complexes **4**[8] with the same stoichiometry as **2** but lacking the OEt_2 molecule.

$(NBu_4)_2[Pt_2(\mu\text{-}X)_2(C_6Cl_5)_4]$ **3**

$\{(NBu_4)[Pt_2Ag(\mu\text{-}X)_2(C_6Cl_5)_4]\}_2$ **4**

a, X = Cl; **b**, X = Br

This difference, along with previous observations revealing dramatic structural differences between pentafluoro-[1] and pentachlorophenyl[2] platinum(II) derivatives of *identical* stoichiometry, **5** and **6**, respectively, made it worthwhile

$\{(NBu_4)[PtAgCl_2(C_6X_5)_2]\}_n$

5, X = F, n = 2; **6**, X = Cl, n = ∞

to solve[9] the structure of complex **4a**, which happens to be unprecedented and very different from that of **2** (see Fig. 1).

Complex **4a** consists of a hexanuclear anion $[Pt_4Ag_2(\mu\text{-}Cl)_4(C_6Cl_5)_8]^{2\ominus}$ and two $NBu_4^{\oplus}$ cations. The cluster (Fig. 2)

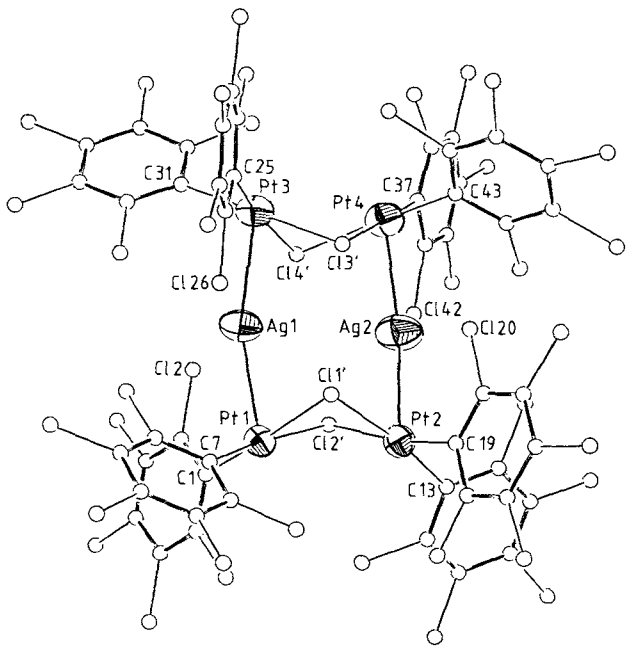

Fig. 2. Molecular structure of the anion $[Pt_4Ag_2Cl_4(C_6Cl_5)_8]^{2\ominus}$ **4a**. Selected bond lengths [Å] and bond angles [°]. Ag1-Pt1 2.766(4), Ag1-Pt3 2.755(4), Ag2-Pt2 2.781(4), Ag2-Pt4 2.748(4), Pt1-C1 2.003(23), Pt1-C7 2.069(24), Pt1-Cl1′ 2.429(12), Pt1-Cl2′ 2.429(4), Pt2-C13 2.009(26), Pt2-C19 1.965(23), Pt2-Cl1′ 2.390(11), Pt2-Cl2′ 2.424(11), Pt3-C25 1.973(25), Pt3-C31 2.085(26), Pt3-Cl3′ 2.403(11), Pt3-Cl4′ 2.440(12), Pt4-C37 2.017(30), Pt4-C43 1.976(32), Pt4-Cl3′ 2.407(12), Pt4-Cl4′ 2.424(12); Pt1-Ag1-Pt3 163.2(8), Pt2-Ag2-Pt4 163.3(2), Pt1-Cl′-Pt2 85.5(4), Pt1-Cl2′-Pt2 84.8(3), Pt3-Cl3′-Pt4 85.5(4), Pt3-Cl4′-Pt4 84.3(4).

comprises two $[Pt_2(\mu\text{-}Cl)_2(C_6Cl_5)_4]$ units doubly bridging two Ag atoms. The best least-square plane through the six metal atoms almost contains Ag1 (0.007 Å), but the other metal atoms lie distinctly above (Pt2 0.344; Pt3 0.268 Å) or below (Pt1 0.283; Ag2 0.263; Pt4 0.224 Å) this plane.[10] The Pt–Ag bond distances are given in the caption to Figure 1. The long Ag–Ag distance (3.87 Å) excludes any bonding interaction. The environment around each platinum atom is a distorted square pyramid, but the Ag–Pt bond is not perpendicular to the basal plane (formed by the platinum atom, two chlorine atoms, and two carbon atoms). The deviations are in the range 18.83–26.25°.[10] The dihedral angles, formed by the planes Pt1-Cl1′-Cl2′ and Pt2-Cl1′-Cl2′ and by the planes Pt3-Cl3′-Cl4′ and Pt4-Cl3′-Cl4 are 129.25 and 127.70°.[10] The long distance between Pt1 and Pt2 (3.272(3) Å) and between Pt3 and Pt4 (3.265(3) Å) excludes any significant Pt–Pt bond.

The environment of the silver atom is not linear; the Pt–Ag–Pt angles are 163.2(3) and 163.3(3)°. Furthermore, short contacts with *o*-Cl atoms of the C_6Cl_5 groups are observed, as in other perhalophenyl platinum–silver complexes. In fact, Ag1 shows contacts to Cl2 (2.783(14) Å) and Cl26 (2.788(13) Å) and Ag2 shows contacts to Cl20 (2.821(13)) and Cl42 (2.867(14) Å). These contacts of each Ag atom with two *o*-Cl atoms are shorter than any previously observed ones in pentachlorophenyl platinum–silver complexes.[2, 11] We think they imply donation of electron density (*o*-Cl → Ag), thereby enhancing the stability of the cluster. Moreover, the bridging chloride ligands are also close to the silver atoms, although some of these contacts are here longer and more irregular: Ag1-Cl1′ 3.033(11); Ag1-Cl3′ 3.145(12), Ag1-Cl4′ 3.159(11); Ag2-Cl1′ 3.285(11), Ag2-Cl2′ 2.826(12), Ag2-Cl3′ 3.024(13) Å. If these bridging chloride ligands are also donating electron density to the silver atoms, this situation would be another unprecedented feature in this very unusual structure.

Aurivillius Phases: A Possible New Class of Metal Oxide Superconductors**

By *Kyeong Ae Yee, Thomas A. Albright, Dongwoon Jung,* and *Myung-Hwan Whangbo**

A number of $AB_{n-1}M_nO_{3n+1}$ phases contain layered M_nO_{3n+1} perovskite structures, where M is typically an early transition metal (e.g., Ti, Nb, Ta, Cr, W, Fe), B is an electropositive atom (e.g., Na, K, Ca, Sr, Ba, Gd, La, Y, Pr, Sn, Pb, Bi), and n is the number of MO_2 layers within the perovskite slab.[1-3] The prototype perovskite slabs for n = 1, 2, and 4 are shown in **1**, **2**, and **3**, respectively. Most Aurivillius phases, for which A represents Bi_2O_2 layers separating the perovskite slabs and $n \leq 5$, are ferroelectric materials. In a similar class of $AB_{n-1}M_nO_{3n+1}$ compounds with A = Li, Na, K, Rb, Cs, Tl, Sr, Ba, or NR_4 (R = alkyl), perovskite slabs with n as large as 7 have been reported.[4] The crystal structures of Aurivillius phases are strikingly similar to those of the new high-temperature Bi–Ca–Sr–Cu–O and Tl–Ca–Ba–Cu–O superconductors,[5] as has been pointed out by *von Schnering* et al.[5b] However, the electron count at the metal is d^0 in known Aurivillius phases, while it is close to d^9 in the copper–oxide superconductors. On the basis of tight-binding band structure calculations[6-8] on **1–3**, we shall show that layered perovskite structures of the Aurivillius type with metal electron counting close to d^3 have electronic structures strikingly similar to those of the Cu–O superconductors and thus might form a new class of superconductors.

● M, ⊘ B, ○ oxygen

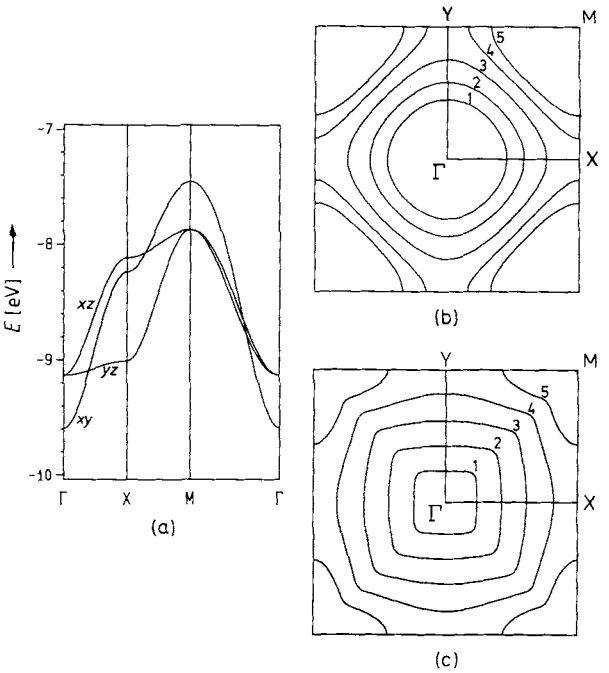

Fig. 1. a) Dispersion relations of the t_{2g}-block bands calculated for a TiO_4 layer in **1**, where $\Gamma = (0,0)$, $X = (a^*/2,0)$, and $M = (a^*/2, b^*/2)$. Fermi surfaces of the xy band in (b) and the xz band in (c), calculated for a d^x (x = 1–5) electron count, where the numbers 1–5 refer to the d-electron count d^1–d^5, respectively.

Figure 1a shows the dispersion relations of the t_{2g}-block bonds calculated for a TiO_4 layer (**1**, M = Ti). The dispersion characteristics and density-of-states profile of the xy band are very similar to the x^2-y^2 bands of the CuO_2 layers in Cu–O superconductors.[9,10] Here, xy is antibonding to oxygen p orbitals in a π fashion, whereas, in the Cu–O layers x^2-y^2 is antibonding to oxygen in a σ sense. The Fermi surfaces calculated for d^x (x = 1–5) are shown in Figure 1b and 1c for the xy and xz bands, respectively. The yz band has Fermi surfaces identical with those of the xz band but centered at the M point. Since all the Fermi surfaces are closed, the three bands are two-dimensional metallic. In particular, the Fermi surfaces for a d^3 count are very close in shape to those found for the nearly half-filled x^2-y^2 bands of the copper–oxide superconductors.[9,10] Thus, layered perovskite structures of the Aurivillius type with electron counting close to d^3 might give rise to a new class of superconductors. Valence or charge fluctuations, presumed to be essential for the Cu–O superconductors,[9b,11] would be present in such perovskite slabs. Hole states (at M or O), introduced via chemical doping or having the s bands associated with B (for $n \geq 2$), cut across the Fermi surface. The linear electron-hole

electron-pair model[12] will operate in a way analogous to that suggested for the Cu–O superconductors: concerted in-plane M–O breathing motions can be established via local Jahn–Teller instabilities. Our band calculations on **1** with two Bi_2O_2 layers sandwiching it show no significant contribution of the Bi_2O_2 layers to the t_{2g}-block bands. Our calculations on **2** and **3** without the embedded atoms, B, show that the essential features of the t_{2g}-block bands remain unaltered. Small coupling exists between the xz and yz bands via the out-of-plane oxygen atoms that bridge the MO_2 layers, while the xy bands are not coupled via the out-of-plane oxygen atoms. The x^2-y^2 bands of the Cu–O superconductors behave identically.[9, 10]

So far, all synthetic work on the $AB_{n-1}M_nO_{3n+1}$ phases has been directed towards d^0 systems. The wide tolerance for atomic substitution of A, B, and M suggests that higher d-electron variants are possible. The t_{2g}-block bands of **2** and **3** are strongly perturbed by embedded Bi atoms (although this may well be an artifact of parameterization); thus, more electropositive atoms are suggested for B. With n = 4 as a working example, species **4**–**7** are possible.

$(Bi_2O_2)Pb_3W_4O_{13}$ (d^3 electron count at each W) **4**

$(Bi_2O_2)LaPb_2W_4O_{13}$ ($d^{2.75}$) **5**

$La_4W_4O_{13}$ ($d^{2.5}$) **6**

$YLa_3W_4O_{13}$ ($d^{2.5}$) **7**

Another viable series of candidates for superconductivity, phases with an electron count close to d^1 at M, should not be discounted. If the out-of-plane M–O distances become shorter than the in-plane ones, as expected for higher electron counts,[13] the xz and yz bands will be raised and the xy band can become nearly half-filled, even with d^1 metals. For the n = 4 model, **8** and **9** are possibilities, which lead to d^1 for

$(Bi_2O_2)Ba_{1+x}La_{2-x}Nb_4O_{13}$ (x = 0) **8**

$Sr_{2+x}La_{2-x}Nb_4O_{13}$ (x = 0) **9**

x = 0. The latter composition is particularly interesting in view of the recent report of high-temperature superconductivity in Sr–La–Nb–O films.[14] Substitution of the out-of-plane oxygens with stronger π-donor nitrogen atoms may also serve to push the xz and yz bands above the xy band. For n values other than 4, a large number of stoichiometries can also be proposed. We are well aware of fluorite or pyrochlore structural alternatives and also of the electronic instabilities such as charge and spin density waves that may frustrate superconductivity. We have not pinpointed a global mechanism for superconductivity nor calculated a T_c for any of these materials. Nevertheless, the persistent electronic analogy between these layered structures and the Cu–O superconductors strongly merits experimental investigation.

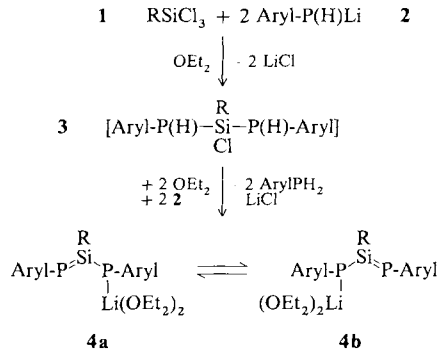
Synthesis, Structure, and Reactivity of a 1,3-Diphospha-2-silaallyl Anion**

By *Edgar Niecke,* Elke Klein,* and *Martin Nieger*

The formal replacement of the two terminal positions in allyl anion **A**[1] by phosphorus centers of coordination number 2 leads to the 1,3-diphosphaallyl system **B**,[2] which is becoming increasingly important as a complex ligand.[3] We report here the synthesis of the 1,3-diphospha-2-silaallyl anion **C**, which is analogous to **B** and is the first example of a stable, delocalized 3p(π) bonding system.



A **B** **C**

The surprisingly simple preparation of **C** was achieved in a one-pot reaction by treatment of *tert*-butyltrichlorosilane **1** with four equivalents of lithiophosphane **2** in diethyl ether.[4] The lithium salt of the allyl anion is obtained as the diether adduct **4** in the form of deep red, extremely moisture-sensitive, thermally stable crystals (m.p. 150–152 °C). These are

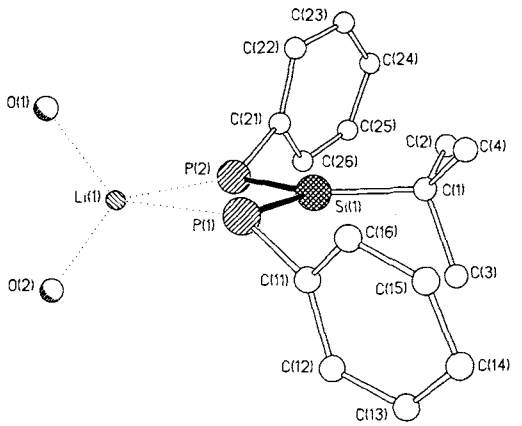
stable for several weeks under inert atmosphere at room temperature. The constitution of **4** was established by elemental analysis, NMR spectroscopy,[5] and X-ray structure analysis.[6]

R = *t*Bu; Aryl = 2,4,6-*t*Bu$_3$C$_6$H$_2$

The ^{31}P NMR spectrum of **4** (25 °C, C_6D_6) displays four equally spaced lines in the high-field region ($\delta = -45.1$), thus showing an interaction with the lithium nucleus ($J_{PLi} = 46.5$ Hz).[5] This finding can be interpreted in terms of a rapid exchange process, **4a** $\rightleftharpoons$ **4b**.

The X-ray structure analysis[6] (Fig. 1) corroborates the spectroscopic results. In the solid state, **4** is present as an



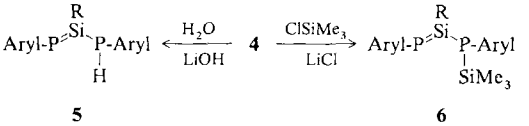


Fig. 1. Molecular structure of **4** (peripheral groups omitted). Important bond lengths [pm] and angles [°]: Si1-P1 211.4(3), Si1-P2 211.3(3), Si1-C1 191.5(7) Li1-P1 263.9(14), Li1-P2 267.0(13), Li1-O1 193.9(13), Li1-O2 193.8(12); P1-Si1-P2 104.9(1), Si1-P1-Li1 88.8(3), P1-Li1-P2 78.3(3), Si1-P2-Li1 88.0(3), O1-Li1-O2 110.1(6). The atoms P1-Si1-P2-Li1 lie in a plane ($\sigma = 0.20$ pm).

η^2-lithio-1,3-diphospha-2-silaallyl system ("frozen transition state" of **4a** $\rightleftharpoons$ **4b**); the position of the lithium with respect to the P1–Si1–P2 plane of **4** is indicative of a σ complex. Owing to the coordination of the lithium to two phosphorus centers, the Li–P bonds (264–267 pm) are, as expected, longer than those in the lithiophosphanes investigated so far.[7] The bonding in the anion fragment with the observed planar arrangement of the framework C11-P1-Si1 [-C1]-P2-C21, as well as the very short P–Si distances (211 pm; sum of the covalent radii for a single bond, 224 pm[8]), is in agreement with a description of **4** as a four-electron, three-center 3 p(π) bonding system. The relatively small P1–Si1–P2 angle (105°) may be ascribed to the chelating effect of the lithium atom. Both aryl ligands are orthogonal to the p(π) system owing primarily to steric effects ("steric bulk" of the *tert*-butyl groups). The coordination vacancies at lithium are filled by two solvent molecules (Et_2O), which create a distorted tetrahedral geometry for the "cation".

In the presence of traces of moisture, **4** is immediately converted into the phosphino derivative **5**. Reaction of **4** with trimethylchlorosilane affords the silylphosphino compound **6**. Both **5** and **6** contain a P–Si double bond, as revealed by the ^{31}P NMR spectra (**5**, $\delta = 142$, -125 ($J_{PP} = 6$ Hz); **6**, $\delta = 83.3$, -110.1 ($J_{PP} = 63$ Hz)). Such compounds are well known through the work of *Bickelhaupt* et al.[9]

Experimental Procedure

4: 2,4,6-*t*Bu$_3$-C$_6$H$_2$PH$_2$ (4.18 g, 15 mmol) [10] in 20 mL of anhydrous ether was treated at room temperature with an equimolar amount of *n*-butyllithium (15% in *n*-hexane). The reaction mixture was then stirred for 1 h. The solution of the lithiophosphane **2** obtained in this way was added slowly dropwise to **1** (0.72 g, 3.75 mmol) in 15 mL of anhydrous ether at -65 °C. The resulting gold-yellow solution turned deep red on warming to 25 °C. The ^{31}P NMR spectrum of the reaction mixture shows, in addition to the signals of **4**, only those of the primary phosphane [9] ($\delta = -132$ (t, $J_{PH} = 207$ Hz)). After evaporation of the solvent, the residue was dissolved in dry *n*-hexane, the LiCl was filtered off, and the filtrate was concentrated in vacuo. Deep red crystals of **4** were obtained from an ether/hexane mixture (1:3): yield 2.25 g (77%).

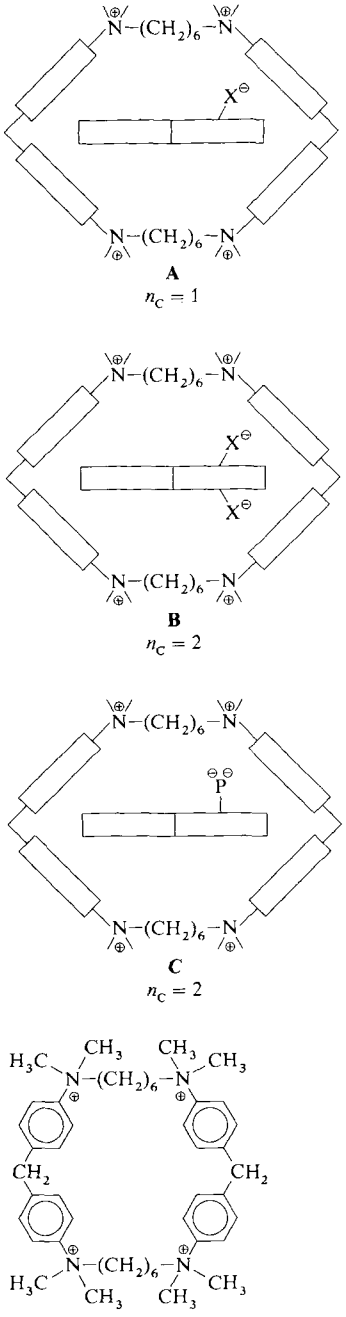
Additivities of Electrostatic and Hydrophobic Interactions in Host–Guest Complexes**



By *Hans-Jörg Schneider** and *Isolde Theis*

Noncovalent interactions play a major role in biological systems as well as in synthetic host–guest complexes. The importance of quantification of electrostatic contributions[1] has been recognized, for example, in the study of enzyme–substrate binding mechanisms by site-directed mutagenesis[2] and of polyamine binding to nucleic acids.[3] Synthetic analogues of receptor–substrate complexes[4] offer the advantage of planned variations of the nature and the geometries of interacting groups within relatively well defined conformations. We demonstrate here that the analysis of salt bridges in a large number of very different synthetic receptor models in water gives a surprisingly uniform value of 5 ± 1 kJ mol^{-1} per ion pair as long as electrostatic interactions dominate.

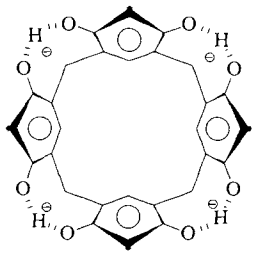
Many substrates and coenzymes are bound by electrostatic as well as by hydrophobic forces. The complexes **A**–**C** (Scheme 1), formed between azoniacyclophanes **1** and naphthalene derivatives bearing negative charges,[5,6] are examples in which the predominant lipophilic or hydrophobic binding contributions can be quantified by the dependence of the association constants on solvent hydrophobicity.[7] Since many electroneutral naphthalene derivatives show quite similar complexation free energies of $\Delta G = 19 \pm 1$ kJ mol^{-1} (Table 1, row a), one can subtract these values from the higher ΔG values observed for corresponding compounds of similar shape bearing anionic substituents X in order to obtain typical Coulomb interaction increments. Measurements with four naphthalene derivatives with anionic substituents at C-2 indeed show a rather uniform increase of $\Delta G \approx 3$ kJ mol^{-1} (Table 1, row b). With anionic substituents at C-1 (row c) a similar value is observed, particularly if the substituent is attached to an intervening CH_2 or O group which allows a better contact of $X^{\ominus}$ to the $^{\oplus}N$ counterion of the macrocycle; otherwise, the predominating pseudoequatorial inclusion of the naphthalene unit,[8] necessary for an optimal hydrophobic interaction, would be distorted. Similar reasons may explain the small ΔG increase observed for substrates with $X^{\ominus}$ at C-1 and C-8 (Table 1, row d; cf. **B** in Scheme 1); only if the position of the charges allows the simultaneous contact of both charged substituents with the host counterion is a concomitant ΔG increase observed; this is remarkably the case when both charges reside in *one* phosphate unit (**C** in Scheme 1).

The complex **D** (Scheme 2) formed from a macrocyclic tetraphenolate **2** with four delocalized negative charges and a host compound, represents a case in which Coulomb interactions dominate almost entirely. This is shown, for instance, by the decrease in the complexation free energy ΔG for the substrates Y from 25 kJ mol^{-1} for Y = $^{\oplus}NMe_4$ to 4 kJ mol^{-1} for Y = $HOCMe_3$.[9] If one considers the interactions in all of these complexes[9] to be additive, the resulting Coulomb interaction between singly charged ions ($n_c = 1$) is $\Delta G = 21/4 = 5.2$ kJ mol^{-1}.

Association constants in water for complexes held together *exclusively* by electrostatic forces have been reported. Those determined by *Williams* et al.[10] for complexes of type

Scheme 1.

E (Scheme 2) all fall into the same range within the limits of error, yielding 5 ± 1 kJ mol^{-1} per salt bridge ($n_c = 1$) for 25 different salts. The same values are obtained for the complexes of type **F** and **G** (Scheme 2) described by *Lehn* et al.[4a,11] if those systems are disregarded in which the counterions for geometric reasons cannot contact each other closely and if the interactions between one ion and several counterions at similar distances are counted separately.



Thus, the complexation free energies of more than 35 complexes can be described by a simple Coulomb correlation (Fig. 1). The underlying cation–anion combinations comprise groups of quite different sizes, polarizabilities, and charge densities: $^{\oplus}NH_2R_2$, $^{\oplus}NR_4$ (R = alkyl), aromatic positively charged nitrogen heterocycles, $CO_2^{\ominus}$, $HPO_4^{\ominus}$, $PO_4^{2\ominus}$, and charge-delocalized phenolates. As a first approximation it is obviously sufficient to consider only the electrostatic interactions between nearest neighbors.

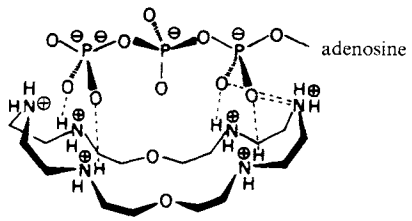
2



D
$n_C = 4$

E
$n_C = 2$

F
$n_C = 2 \times 3$

G
$n_C = 2 \times 3 + 2 \times 3$

Scheme 2.

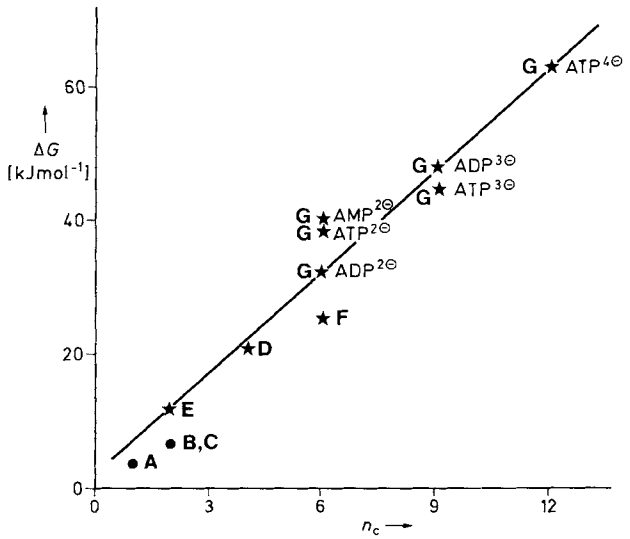


Fig. 1. Complexation free energies ΔG in water plotted versus the number of ion pairs (n_c). Correlation coefficient $r = 0.967$; reliability measure $\Psi = 8\%$; weight = 1.0 for **D** (5 values)[8], **E** (25 values)[10], **F**[11], **G**[11]; weight = 0.0 for **A**–**C**.

Apparently, the differences in complexation free energies between the charged systems **A** to **C** (Table 1, rows b–d) and their electroneutral counterparts (row a) are uniformly smaller ($\Delta G \approx 3$ kJ mol^{-1}) than the general Coulomb increment (ca. 5 kJ mol^{-1}). The reason for this can be seen in the decrease in the hydrophobic van der Waals interactions – which dominate in all these complexes[6, 7] – upon introduction of the charged groups in the naphthalene guest molecules, so that the Coulomb attraction gained is partially compensated.

Synthesis and Structure of $[\{(\eta^5\text{-}C_5Me_5)Ti(NH)\}_3N]$, a Titanium Imide Nitride **

By *Herbert W. Roesky,** *Yüniu Bai,* and *Mathias Noltemeyer*

In our investigations of metal–nitrogen heterocycles, we recently succeeded in synthesizing $[Cp^*TaN(Cl)]_3$, which can be regarded as a trimer of a metal nitride, by reaction of Cp^*TaCl_4 ($Cp^* = C_5Me_5$) with $N(SnMe_3)_3$.[1] Whereas metal nitrides are known to have a wide variety of structures,[2] transition-metal complexes with NH ligands (imides) have been little investigated. Imides might occur as intermediates in the formation of TiN from $TiCl_4$ and ammonia.[3] We now report an imide nitride of titanium, prepared by reaction of Cp^*TiMe_3 **1**[4] with excess ammonia at room temperature. Loss of methane leads to the formation of $[\{Cp^*Ti(NH)\}_3N]$ **2** in good yield.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the VW-Stiftung, and the Fonds der Chemischen Industrie.

Evidence for the composition and structure of **2** is already provided by the ^{1}H NMR spectrum and the mass spectrum. Equivalent pentamethylcyclopentadienyl ($\delta = 2.01$) and NH ($\delta = 13.4$) groups are found. The molecular ion (m/z 608) is observed with 100% relative intensity in the mass spectrum. In the field-ionization mass spectrum, only the signal of $[M + 1]^{\oplus}$ (m/z 609) appears. The IR spectrum shows two of the three (2 A', 1 A'') absorptions (3357 and 3345 cm^{-1}) expected for C_s symmetry. We assign these to the N–H valence vibrations.

Single crystals suitable for an X-ray structure analysis (Fig. 1)[5] were obtained by recrystallization from *n*-hexane.

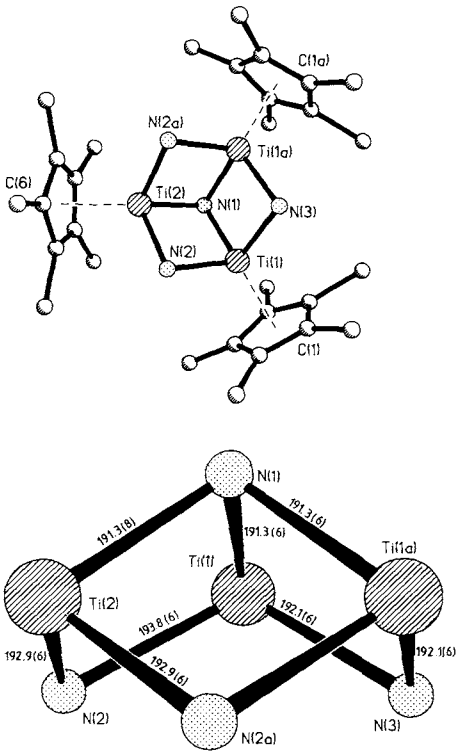

Fig. 1. Molecular structure of **2**. Top: View from above. Below: Side view of the Ti_3N_4 core. Selected bond lengths [pm] and angles [°]: Ti(1)-Ti(2) 280.3(3); Ti(2)-Ti(1)-N(1) 42.9(2), N(1)-Ti(1)-N(2) 85.9(3), N(1)-Ti(1)-N(3) 85.8(3). Further bond lengths are given in the lower part of the figure.

The six-membered $(TiNH)_3$ ring with tetrahedrally coordinated titanium atoms exists in chair conformation. The three titanium atoms are bridged by a further nitrogen atom, N(1). The molecule exhibits C_s symmetry (mirror plane through Ti(2), N(1), N(3)). The Ti–N bond lengths (average 192.4 pm) lie between those in $[CpTiCl_2NPPh_2]$ (177.5 (13) pm)[6] and $[CpTiCl_2NPPh_2NS(O)Me_2]$ (176.4(2) pm)[7] on the one hand and those in $[\{PhC(NSiMe_3)_2\}_2TiCl_2]$ (206.6 and 210.1 pm)[8] on the other.

Oxygen-containing titanium compounds with similar structures have been described by *Garcia Blanco* et al.[9] and *Bottomley* et al.[10] Methyl-substituted organometallic compounds are well known,[11] so that their reaction with ammonia should afford further imides and nitrides.

Experimental Procedure

Excess ammonia was admitted over 3 h to a solution of **1** (1.14 g, 5 mmol) in 30 mL of *n*-hexane at room temperature. The initially yellow solution turned red and a yellow solid formed. The reaction was over when no more solid precipitated. Excess ammonia and the solvent were then removed in vacuo and the residue was washed with a small amount of *n*-hexane. Yield: 0.67 g (67%) of **2**. The compound slowly decomposes above 200 °C. Only a doublet is present in the ^{15}N NMR spectrum ($CDCl_3$, ext. $MeNO_2$): $\delta = 90.7$ ($^1J_{NH} = 63.5$ Hz).

A New Synthesis of Key Intermediates for the Preparation of 5,6-DiHETE and Lipoxin A_4

By *Agnès Gigou, Jean-Paul Lellouche, Jean-Pierre Beaucourt,* Loïc Toupet,* and *René Grée**

Polyhydroxylated metabolites of the arachidonic acid cascade are attractive target molecules not only because of their

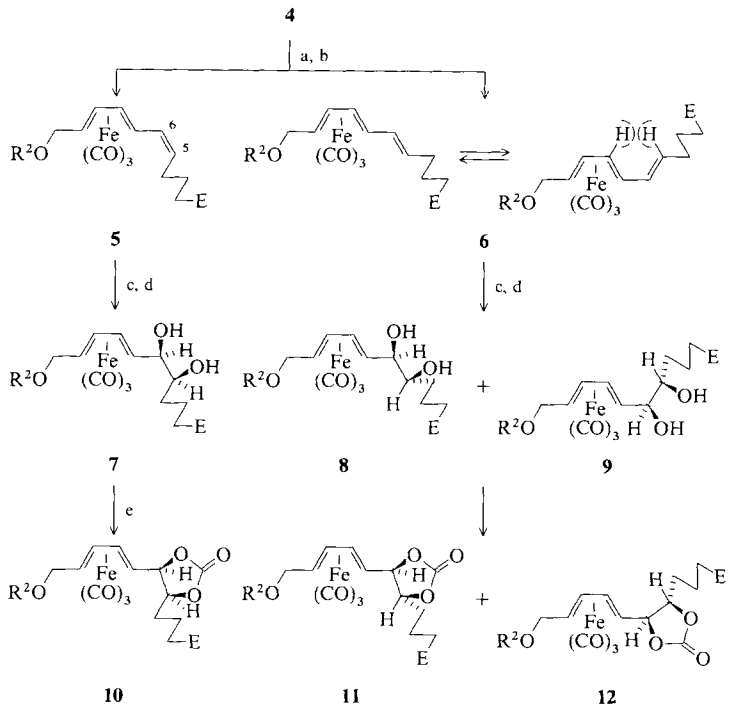
interesting stereochemistry but also because of their potent biological properties. 5,6-DiHETE **1**[1] and lipoxin A_4 **2**[2] (Scheme 1) are representative examples of a group of metabolites characterized by a glycol structure vicinal to a polyenic system. The carbonates **3a** and **3b**, which are key intermediates for the total synthesis of **1** and **2** have already been prepared by multistep sequences starting from 2-deoxy-D-ribose (for the *erythro* isomer) and from xylose (for the *threo* isomer).[3]

1 **2** **3a–d** **4**



Scheme 1. **3a, b**, $R^1 = C_2H_5$; **3c, d**, $R^1 = CH_3$; **4**, $R^2 = SiPh_2tBu$. The *erythro* isomers **3a,c** have the (5*S*,6*R*) configuration, the *threo*-isomers **3b,d** the (5*S*,6*S*) configuration.

Here we describe a new, stereoselective synthesis of racemic **3c** and **3d** starting from the butadiene–tricarbonyl–iron complex **4**.[4] The key step of this novel approach is the diastereoselective osmylation of double bonds vicinal to the organometallic complex fragment.[5]

The Wittig reaction of **4** with 5-(triphenylphosphoranediyl)pentenoic acid, followed by in situ esterification, gives a 4:1 mixture of the complexed trienes **5** and **6** (Scheme 2), which are easily separated by chromatography.[6] Their osmylation occurs readily and without decomplexation to give, in almost quantitative yield, only one complexed diol **7** starting from **5** and two diastereoisomeric diols **8** and **9** starting from **6** (HPLC and 300-MHz ^{1}H NMR controls). Compound **7** is converted into the carbonate **10** (63% overall yield from **5**; see Table 1 for spectral data); in the same way, the diols **8** and **9** give a 9:1 mixture of the two complexed *threo* carbonates **11** and **12** (77–81% overall yield from **6**), which can be separated by chromatography.

The configurations of the carbonates **10–12** have been unambiguously established by X-ray crystallography.[7] Interestingly, in each case, the addition of OsO_4 to the free double bond occurs *anti* to the $Fe(CO)_3$ moiety; for the *E* alkene, it is possible to consider an equilibrium between the *s-trans* conformer (leading to **8**) and the *s-cis* conformer (giving the minor derivative **9**). This result is in good agreement with the addition of diazo compounds to structurally related trienes.[8]

Correlation of these derivatives with carbonates **3c** and **3d** is done by a three-step sequence: decomplexation ($Ce^{4\oplus}$, MeOH, −15 °C, 80–95%), desilylation ($nBu_4N^{\oplus}F^{\ominus}$, 3 H_2O, THF, 0 °C, *erythro* 80%, *threo* 77%), and oxidation (pyridinium dichromate, CH_2Cl_2, 20 °C, *erythro* 80%, *threo* ≥95%) leads to racemic **3c** starting from **10**, while its isomer **3d** is exclusively obtained starting from **11**.[10]

5 **6** **7** **8** **9** **10** **11** **12**

Scheme 2. E = CO_2Me; $R^2 = SiPh_2tBu$. 0.5 mmol **4** was employed. a) $Br^{\ominus}Ph_3P^{\oplus}(CH_2)_4CO_2H$ (0.92 mmol, 1.83 equiv.), $(Me_3Si)_2NLi$ (1.83 mmol, 1.83 equiv.), THF (4.5 mL), HMPA (0.6 mL), 1.5 h −20 °C → 0 °C; **4** (0.5 mmol), THF (2.5 mL), 1.5 h −78 °C, then 1.5 h −20 °C. b) Me_2SO_4 (4.2 mmol, 8.4 equiv.), 18 h, −10 °C (80–90% from **4**). c) **5** or **6** (0.4 mmol), OsO_4 (0.6 mmol, 1.5 equiv.), Py (8 mL), 2 h 20 °C. d) $Na_2S_2O_5$ (10.5 mmol), H_2O (20 mL), 16 h, 20 °C (95% from **5** or **6**). e) **7** (0.43 mmol), Im_2CO (0.47 mmol, 1.09 equiv.), benzene (13 mL), 2 h 40 °C, then Im_2CO (0.47 mmol, 1.09 equv.), 1 h 64 °C (66%). f) **8** + **9** (0.21 mmol), Im_2CO (1.05 mmol, 5.0 equiv.), benzene (11 mL), 1 h 20 °C (81–85%).

Table 1. Spectral data of **10**.

IR (KBr pellet): $\tilde{\nu}$ = 2045 (s), 1985 (s), 1950 (s), 1790 (s), 1735 (m) cm^{-1}. MS(EI): *m/z* 504.1 (8.6%), 448.0 (5.7%), 28.0 (100.0%). ^{1}H NMR (300 MHz, C_6D_6): δ = 0.32 (dd, 1H, *J* = 8.5, 7.3 Hz), 1.07–1.21 (m, 1H), 1.16 (s, 9H), 1.22–1.30 (m, 2H), 1.32–1.70 (m, 2H), 1.94 (t, 2H, *J* = 6.8 Hz), 3.34 (s, 3H), 3.50 (dd, 1H, *J* = 6.2, 12.3 Hz), 3.64 (dd, 1H, *J* = 7.6, 8.1 Hz), 3.72 (dd, 1H, *J* = 5.2, 12.4 Hz), 3.75 (dt, 1H, *J* = 7.2, 6.6 Hz), 4.46 (dd, 1H, *J* = 5.1, 7.7 Hz), 4.57 (dd, 1H, *J* = 5.1, 8.8 Hz), 7.20–7.30 (m, 6H), 7.70–7.80 (m, 4H).

These results confirm the potential of the butadiene–tricarbonyl–iron complexes in synthesis and some aspects of this approach are noteworthy:

1. Although this preliminary study has been done only in racemic form, extension to asymmetric synthesis appears possible since **4** has recently been resolved.[9]
2. It should be possible to take advantage of the presence of the $Fe(CO)_3$ moiety to differentiate between the two hydroxyl groups in **7** and **8**[12] and then to obtain new modified analogues of fatty acid metabolites.
3. This methodology could be extended to other derivatives such as 11,12- or 14,15-DiHETE. This is currently under investigation in our laboratories.

Experimental Procedure

7: To a solution of the alkene **5** (240.0 mg, 0.41 mmol) in anhydrous pyridine (5 mL) was added dropwise 3 mL (1.45 equiv.) of a 0.2 M osmium tetroxide solution in pyridine under nitrogen at 20 °C. The mixture was stirred for 2 h at 20 °C. The osmate ester, added with an excess of an aqueous solution of $Na_2S_2O_5$ (10.5 mmol, 18.0 equiv.), was decomposed by stirring the mixture for 16 h. The dark red solution was transferred to a separatory funnel containing

25 mL of 3% hydrochloric acid and extracted with two 25-mL portions of ethyl acetate. The combined organic phases were washed with a saturated ammonium chloride solution (2 × 10 mL), dried over anhydrous $MgSO_4$, and concentrated under reduced pressure. The resulting yellow oil was then filtered in methanol on a KC 18 reverse-phase cartridge (SEP PAK) to yield 96% of the diol **7**, which was used in the next step without further purification.

10: To a solution of the *erythro* diol **7** (266.9 mg, 0.43 mmol) in anhydrous benzene (1 mL) was added dropwise a suspension of *N,N'*-carbonyldiimidazole (76 mg, 0.47 mmol; 1.09 equiv.) in anhydrous benzene (10 mL). The mixture was stirred for 1 h at 45 °C, then a second portion of *N,N'*-carbonyldiimidazole (76 mg, 0.43 mmole; 1.09 equiv.) was added at 64 °C. Stirring was continued for 1.5 h at this temperature and the mixture was then transferred to a separatory funnel containing water (25 mL) and extracted with ethyl acetate (3 × 25 mL). The combined organic layers were washed with water (3 × 25 mL), dried over anhydrous $MgSO_4$, and concentrated under reduced pressure. The resulting cake was purified by flash chromatography on silica gel (eluant: cyclohexane:ethyl acetate 80:20), yielding 209 mg (75%) of pure yellow crystalline carbonate **10**.

11/12: The carbonation of the mixture of *threo* diols **8** and **9** was simpler, since it occurred within 1.5 h at 20 °C following one addition of *N,N'*-carbonyldiimidazole (170 mg, 5.0 equiv.). Extraction and chromatographic separation of the two yellow crystalline *threo* carbonates **11** and **12** were performed as described above for **10** (**11** + **12**: 115.9 mg, 85% overall yield, **11**:**12** = 90:10).

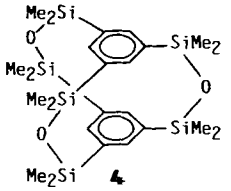
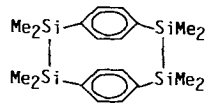
[12] Preliminary results indicate, for instance, that selective monotosylation of **7** and **8** is possible in position 5.

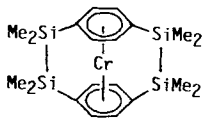


1,2,9,10,17,18-Hexasila[2.2.2](1,3,5)cyclophane, a Cage-like Phane Containing Three Si–Si Units**

By *Akira Sekiguchi, Tetsuo Yatabe, Chizuko Kabuto,* and *Hideki Sakurai**

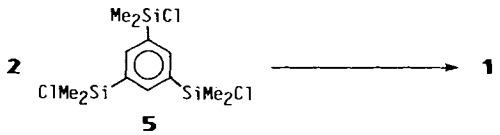


In connection with our studies on cyclophanes containing Si–Si units,[1] we herein report the physical and chemical properties and X-ray structure analysis of the cyclophane **1**, which contains three Si_2Me_4 units. In 1986 we reported the preparation of 1,1,2,2,9,9,10,10-octamethyl-1,2,9,10-tetrasila[2.2]paracyclophane **2** by reaction of a Grignard reagent derived from bis(*p*-bromophenyl)tetramethyldisilane with 1,2-dichlorotetramethyldisilane.[1b] The unique properties of **2** resulting from the through-bond interaction of σ – π mixing between Si–Si bonds and aromatic π-systems are demonstrated.[1c]



1

4



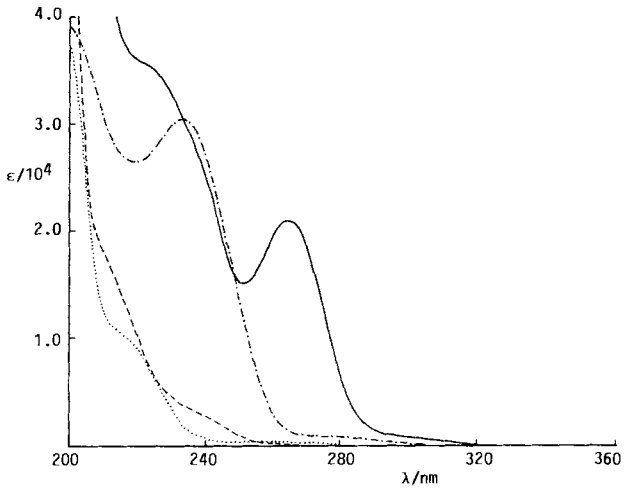
2

3

Shortly after our report,[1b] *Elschenbroich* et al. described the synthesis of (octamethyltetrasila-η^{12}-[2.2]paracyclophane)chromium **3** in 3.5% yield by a coupling reaction of bis[η^6-1,4-di(chlorodimethylsilyl)benzene]chromium with naphthalenelithium.[2] A template effect was indicated. This prompted us to attempt a direct coupling of 1,4-di(chlorodimethylsilyl)benzene under various conditions. The compound **2** was indeed obtained in 2.2% yield upon reaction with sodium in the presence of [18]crown-6. Furthermore, we have extended this reaction to a one-step synthesis of **1** via a reductive coupling reaction of 1,3,5-tris(chlorodimethylsilyl)benzene. The properties of **1** are of special interest because of the extremely rigid structure and the strong σ – π conjugation to be expected in such a system.

Reductive coupling of 1,3,5-tris(chlorodimethylsilyl)benzene **5** with sodium in toluene in the presence of [18]crown-6 afforded the cyclophane **1**.[3] This provides the most direct route to **1**, but the yields are minimal (0.22%). The presence of [18]crown-6 is essential, for without the crown ether only polymeric substances were obtained, and no **1**.

5



The cyclophane **1** is stable and remains unchanged upon heating to 300 °C. **1** is, however, readily oxidized at the

[*] Prof. Dr. H. Sakurai, Dr. A. Sekigurchi, Dipl.-Chem. T. Yatabe, Dr. C. Kabuto

Sendai, 980 (Japan)

[**] Chemistry of Organosilicon Compounds, Part 258.–Part 257: K. Sakamoto, K. Obata, H. Hirata, M. Nakajima, H. Sakurai, *J. Am. Chem. Soc.*, in press

Si–Si units by trimethylamine oxide in refluxing benzene, giving the cyclophane **4** containing Si–O–Si bonds.[4]

In the ^{1}H NMR spectrum, the aromatic protons of **1** appear at $\delta = 6.69$ and are shifted appreciably upfield compared to those of **2** ($\delta = 6.79$); this points to shortening of the inter-ring distance. The UV spectrum of **1** shows an absorption maximum at 264 nm ($\varepsilon = 20\,900$), whereas **4** exhibits no marked absorption band (see Fig. 1). The UV spectra of the related compounds, 1,3,5-tris(pentamethyldisiloxanyl)benzene **6** and 1,3,5-tris(pentamethyldisiloxanyl)-benzene **7** are also shown in Figure 1. The large bathochromic shift in the spectrum of **1** relative to that that in the spectrum of **6** ($\lambda = 233$ nm, $\varepsilon = 30\,500$) is the result of a strong interaction of the Si–Si σ bonds with the π-systems in the ground state.[5] Such an orbital interaction causes considerable destablization of the HOMO level.

1,3,5-$(Me_3Si-SiMe_2)_3C_6H_3$ **6** 1,3,5-$(Me_3Si-O-SiMe_2)_3C_6H_3$ **7**

Fig. 1. Electronic absorption spectra of **1** (–), **4** (-------), **6** (–·–·–·–), and **7** (·····) in hexane.

The crystal structure of **1** is shown in Figure 2.[6] The molecule has no crystallographic symmetry; the three Si–Si bonds have different lengths, and, on average are slightly longer (2.378 Å) than a normal Si–Si bond (2.34 Å), while those in **2** (2.376 Å) are almost the same as each other. The aromatic carbon atoms (C1, C3, C5, C7, C9, C11) attached to the silicon atoms lie only slightly outside (0.003–0.029 Å) the mean planes of the aromatic rings. However, the Si–C(ring) bonds deviate considerably from the planes of the benzene rings (av. 14.1°), similarly as in the case of **2** (15.0°).

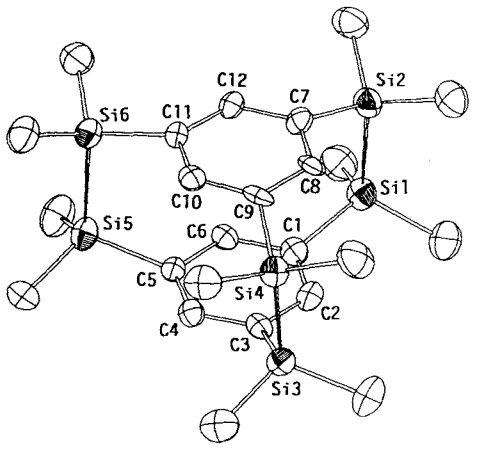

Fig. 2. ORTEP drawing of **1**: All hydrogen atoms omitted for clarity. Selected bond lengths and [Å] angles [°]: Si(1)–Si(2) 2.378(6), Si(3)–Si(4) 2.373(6), Si(5)–Si(6) 2.384(5); Selected bond C(1)–Si(1)–Si(2) 102.6(4), C(3)–Si(3)–Si(4) 104.3(4), C(5)–Si(5)–Si(6) 104.7(4), C(7)–Si(2)–Si(1) 105.7(4), C(9)–Si(4)–Si(3) 105.4(4), C(11)–Si(6)–Si(5) 104.1(4); Interplanar angles (°): C(2)–C(1)–C(6)/Si(1)–C(1) 11.0, C(2)–C(3)–C(4)/Si(3)–C(3) 13.5, C(4)–C(5)–C(6)/Si(5)–C(5) 12.6, C(8)–C(7)–C12)/Si(2)–C(7) 14.8, C(8)–C(9)–C(10)/Si(4) C(9) 16.6, C(10)–C(11)–C(12)/Si(6)–C(11) 16.2.

The two aromatic rings are arranged in the eclipsed position. The average distance between the two aromatic rings is 3.32 Å, much greater than that in [2.2.2](1,3,5)cyclophane (2.79 Å),[7] but somewhat shorter than that in **2** (3.40 Å).

Experimental

A suspension of molten sodium (0.71 g, 30.9 mmol) in boiling toluene was treated dropwise in the presence of [18]crown-6 (1.31 g, 4.96 mmol) with a toluene solution of 1,3,5-tris(chlorodimethylsilyl)benzene (1.74 g, 4.89 mmol). Chromatography on silica gel with hexane and subsequent separation by GLC furnished 2.7 mg (0.22%) of pure **1** as a white solid.

$PbMo_5O_8$ and $Tl_{0.8}Sn_{0.6}Mo_7O_{11}$, Novel Clusters of Molybdenum and Thallium

By *R. Dronskowski* and *A. Simon**

The structures of numerous reduced oxomolybdate phases can be described with the concept of condensed metal clusters.[1] The structure of $NaMo_4O_6$[2] contains *infinite* chains of *trans*-edge-sharing Mo_6 octahedra; but examples of *oligomeric* chain-like building blocks are also known: according to single crystal investigations, $In_3Mo_{11}O_{17}$ and

[*] Prof. Dr. A. Simon, Dipl.-Chem. R. Dronskowski
Max-Planck-Institut für Festkörperforschung
Heisenbergstr. 1, D-7000 Stuttgart 80 (FRG)

$In_{11}Mo_{40}O_{62}$ contain chain fragments of n = 5, or n = 4 and 5 *trans*-edge-sharing Mo_6 octahedra, respectively.[3,4] The limiting case of the isolated Mo_6 octahedron is realized in the structure of $BaMo_6O_{10}$.[5] X-ray powder investigations on $LaMo_5O_8$ indicate the existence of chain fragments consisting of n = 2 condensed metal octahedra.[6]

With $PbMo_5O_8$ **1** a further compound isotypic with $LaMo_5O_8$ was obtained, which with a slightly different electron balance, contains clusters of n = 2 condensed octahedra.[7,8] $Tl_{0.8}Sn_{0.6}Mo_7O_{11}$ **2** is structurally closely related with **1** and contains the hitherto missing cluster of the series consisting of n = 3 condensed octahedra.[7,9]

Figure 1 shows [010] projections of the metal-atom substructures for both compounds, from which the layered stacking of octahedral twins (and octahedral triplets) is clearly recognizable.

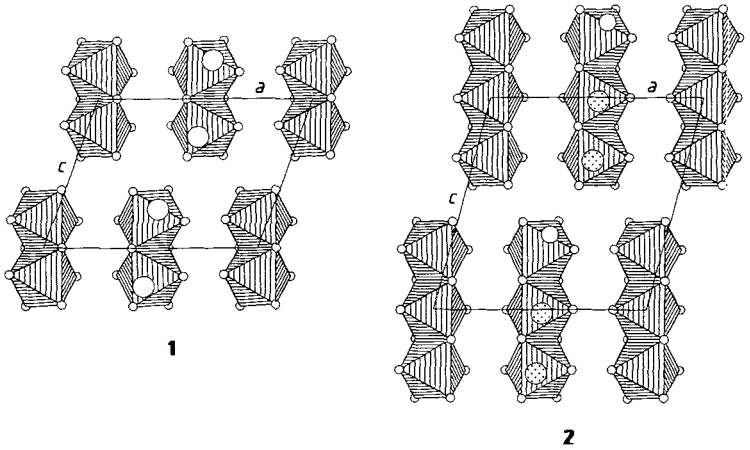

Fig. 1. Polyhedral projection [19] of the condensed Mo_6 octahedra in **1** and **2** along [010]; Mo atoms as small circles. (Cluster centers in $0\frac{1}{2}0$ and $\frac{1}{2}00$; Pb,Tl, Sn in $y \approx \frac{1}{2}$.) In **1** Pb atoms as large circles; in **2** Tl atoms as large dotted circles, Sn atoms as medium sized open circles (only one of the two possible positions of the Sn-Tl-Tl sequence is shown, cf. Ref. [9]).

The Mo_6 octahedra are surrounded at all free edges (in the manner of the M_6X_{12} cluster) by O atoms. In the crystal, O atoms occupy further positions at the apices of octahedra of neighboring clusters (Fig. 2).

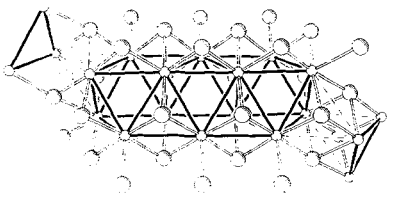

Fig. 2. Perspective diagram [16] of the molybdenum cluster in **2**; Mo atoms as small circles, O atoms as large circles. The shortest inter-cluster bonds are shown as unbroken thin lines, the longer as broken lines. (To give a better view of the inter-cluster bonds one O atom on the right has been omitted.)

All the compounds thus far reported in which fragments of the Mo_4O_6 chain (n = 1 to 5 condensed Mo_6 octahedra) have been identified as building blocks show an identical coupling of the clusters which can be described by the general formula $Mo_{4n+2}O_{6n+2}O_{4/2}$.

The Mo-O distances in **1** range from 195 to 215 pm (average 206 pm); in **2** they lie between 191 and 218 pm (average 206 pm). They do not differ significantly from those in $In_{11}Mo_{40}O_{62}$ (average 207 pm).

The Mo-Mo distances in the cluster of **1** lie between 261 and 284 pm (average 275 pm). The shortest distances between neighboring cluster units (278, 303(2×) and 308 pm(2×)) are surprisingly short. In the octahedral triplet of **2** the Mo-Mo distances are 270 to 286 pm (average 278 pm). The shortest inter-cluster distances here are 299, 304(2×) and 312 pm(2×). A comparison with the average Mo-Mo distances in $In_{11}Mo_{40}O_{62}$ (intra-cluster: 279 pm; inter-cluster: ≥ 320 pm) shows that the intra-cluster distances are scarcely affected by the degree of condensation, whereas the inter-cluster distances with shorter chain lengths (and increasing charge on the counterion) markedly decrease.

This finding is qualitatively easy to explain: the optimal valence electron concentration per Mo atom for Mo-Mo bonds in such oligomeric clusters has been estimated by way of appropriate fragmentation.[10] Accordingly, the values (in each case ± 0.2) 2.9 (n = 2), 3.1 (n = 3) and 3.2 (n = 4) are expected. Excess electrons must be accomodated in bonds between the clusters. The short inter-cluster distances quoted (see Fig. 2) correspond, according to *Pauling*,[11] to a bond order of 1.3 for the cluster in **1** and of 0.9 for the cluster in **2**. As expected, for $LaMo_5O_8$[6] this value (1.6) is higher than for $PbMo_5O_8$ **1**.

For a quantitative electron balance the valence of the cations (Pb, Tl, Sn) must be analyzed: according to bond length-bond strength calculations[12,13] the Pb atoms in **1** are present as isolated $Pb^{2\oplus}$; the next nearest Pb atoms are at a (nonbonding) distance of 372 pm.

Interestingly, in **2** one finds pairs of Tl atoms which are shifted towards each other from the centroid of their respective coordination polyhedron (cube). This leads to a distance d(Tl-Tl) = 284.0(3) pm, which corresponds to a single bond.[14] The analysis of the Tl-O distances gives $Tl^{2\oplus}$ for these two Tl atoms. Hence, (by stabilization with oligomeric transition metal clusters[3]) the formation of a Tl-Tl bond is achieved. M-M bonded Tl_2 units have, to our knowledge, never been described structurally. The Tl-Sn distance in **2** (374 pm) is non-bonding; the Sn atoms, as expected according to the Sn-O distances, are present as $Sn^{2\oplus}$.

With inclusion of the valence of the Pb (and Tl/Sn) atoms and the number of the electrons in inter-cluster bonds (see above), the Mo valence electron concentrations for intra-cluster bonds in **1** are calculated to be 2.94 and in **2** to be 3.12, in very good agreement with the above predictions for the optimal values.

[7] Stoichiometric amounts of powdered Mo (LAB, Merck), MoO_2 (Ventron) and elemental Pb (p.a. Merck) (or Tl/Sn (LAB/p.a. Merck)) were well mixed and pelletized. The synthesis was carried out in evacuated quartz glass ampules heated to 1200-1300 °C for 7 d. Black, metallic shiny crystals were formed in almost quantitative yields.
[8] $PbMo_5O_8$ crystallizes in smooth platelets with hexagonal (!) habit; the unit cell, however, has monoclinic symmetry, as can be shown by electron diffraction analyses of powdered material [18]. Precession layer photographs confirm that the monoclinic cell tripletizes about the b axis (60°). The monoclinic b axis and the face normal of the platelet coincide thereby. By pulverizing the triplets, fragments were obtained with ca. 0.04 mm-edges, each of which showed only reflections of an individual monoclinic crystal. The investigation showed: space group $P2_1/a$ (No. 14),

$a = 999.3(2)$, $b = 924.7(1)$, $c = 753.6(2)$ pm, $\beta = 109.39(2)°$, $Z = 4$, Enraf-Nonius CAD4 four-circle diffractometer, $Mo_{K\alpha}$; 2099 reflections, 1235 with $|F_0| \geq 3\sigma|F_0|$; solution of structure by direct methods [15], refinement by least squares method [16]; $R_{aniso} = 0.057$, $R_w = 0.047$ [9b].

[9] a) The irregular shapes of the crystals of $Tl_{0.8}Sn_{0.6}Mo_7O_{11}$ resemble the star-shaped crystals of $In_{11}Mo_{40}O_{62}$. The investigation of an undistorted crystal obtained as described in Ref. [8] gave: space group $P2_1/a$ (No. 14), $a = 997.2(1)$, $b = 936.2(1)$, $c = 1036.2(1)$ pm, $\beta = 104.14(1)°$, $Z = 4$; Syntex $P\bar{1}$ four-circle diffractometer, $Mo_{K\alpha}$; 1822 reflections, 1438 with $|F_0| \geq 3\sigma|F_0|$; solution of structure by direct methods [15], refinement by least squares method [16], $R_{aniso} = 0.051$, $R_w = 0.046$. In the refined structure the Sn–Tl–Tl unit shows a positional disorder about the inversion center. X-ray crystallographically, each unit gives the composition $Sn_{0.6}Tl_{0.4}Tl_{0.4}$. This composition corresponds within the limits of experimental error to that determined analytically. In Figure 1, only one of the two possible orientations is shown. Refinements in the acentric space groups Pc or $P2_1$ assuming an inversion twin (Program SFLS [17]) led only to R values of about 0.19; b) Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53673, the names of the authors, and the journal citation.

Laser Desorption/Ionization Mass Spectrometry of Proteins of Mass 100 000 to 250 000 Dalton**

By *Michael Karas,* Ute Bahr, Arndt Ingendoh,* and *Franz Hillenkamp*

In the last few years several new ionization techniques have been developed for the mass spectrometric analysis of thermally labile biomolecules. With these so-called "soft" ionization methods the accessible mass range has been continuously extended. While fast atom bombardment (FAB) or liquid secondary ion mass spectrometry (SIMS) find their main applications in the mass range below 5000 Dalton, plasma desorption mass spectrometry (PD-MS) made it possible for the first to ionize proteins of up to 35 000 Dalton;[1] however, it is routinely used below 15 000 Dalton only.[2,3]

Recently, it was reported that ultraviolet-laser desorption/ionization (UVLDI) mass spectrometry, up to now mainly used for analysis of small molecules up to 1000 Dalton, is able to desorb and ionize proteins in the 100 000 Dalton range.[4–6] This technique requires embedding the proteins in a matrix which resonantly absorbs the incident laser light.

We report here new results with the matrix-assisted UV-laser desorption showing that this method promises to become a fast, sensitive and precise method for detemining the molecular weights of proteins in the mass range up to at least 250 000 Dalton.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Bundesministerium für Forschung und Technologie. Technical support by Finnigan MAT, Bremen, is thankfully acknowledged.

The mass spectrometer used is a time-of-flight instrument with 3 keV acceleration energy. For desorption and ionization of the sample a frequency-quadrupled Nd-YAG l at 266 nm wavelength and a pulse width of 10 ns is used pical laser parameters are focus diameters between 10–50 μm and irradiances of $1-5 \times 10^7$ W/cm^2. For detection the ions are post-accelerated to 20 keV. The ion signals for each laser pulse were recorded and stored with a transient recorder (LeCroy 9400) at a time resolution of 40 or 80 ns/chanal. Each spectrum covers the whole mass range. The spectra shown are sum spectra of 30–50 single laser shots.

The proteins β-D-galactosidase (*e. coli*; Sigma G 8511) and catalase (bovine liver; Serva 26902) were used as obtained, glucose isomerase was provided by Prof. *Witzel*, Münster. 10^{-6} M solutions of proteins in highly purified water were mixed with nicotinic acid as matrix in a molar ratio of 1:50 000. 1 μL of this solution (corresponding to 500 fmol of protein) was dripped onto a silver target and dried. Total time for sample preparation and measurement is typically 10 minutes.

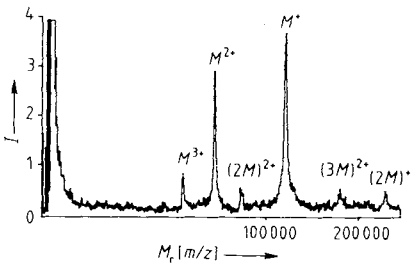

Fig. 1. LDI mass spectrum of β-D-galactosidase. Measured molecular weight: 117 130. Sum of 30 single spectra. I = relative intensity in arbitrary units.

Figure 1 shows the LDI mass spectrum of β-D-galactosidase. The molecular weight as determined by the peak centroids is 117 130. The base peak represents the singly charged molecular ion. The multiply charged molecular ions like $M^{2\oplus}$ and $M^{3\oplus}$, as well as cluster ions like $(2M)^{\oplus}$, $(3M)^{2\oplus}$ and $(2M)^{3\oplus}$ are typical for LDI spectra of high molecular weight proteins. Their appearance and relative intensity distribution depend on the laser irradiance used for desorption. Generally, the singly charged molecular ion forms the base peak of the protein ions.

Although the ion peaks in these spectra are rather wide, corresponding to a mass resolution of about $m/\Delta m = 50$, the peak centroids can be determined with a much better precision. For several proteins independent mass calibration of successive spectra, based on one or more matrix ions in the low mass range and the integer mass relation of multiply charged and oligomer ions of the protein yielded a standard deviation of 0.1 % or less. In cases in which the exact absolute mass of the proteins used for the analysis was known to that accuracy with certainty, the known and measured masses agreed within this uncertainty. In a few other cases deviations up to 1 % occurred, which however, could also derive from an inaccurate mass determination from the supplier.

Figure 2 shows the spectrum of glucose isomerase, summed over 30 single shot spectra. Again, the singly charged molecular ion with a measured mass of 172 400 shows up in surprisingly high intensity. The velocity of these ions at the conversion dynode is only 0.48×10^4 m/s^{-1}. The detection efficiency should therefore be very low.[7] Again multiply charged molecular ions $M^{n\oplus}$ (n = 2 – 4) are found

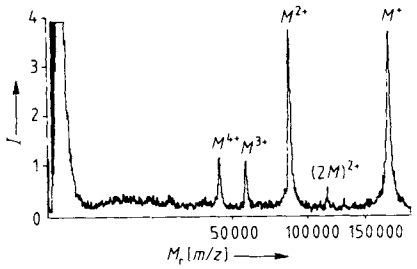

Fig. 2. LDI mass spectrum of glucose isomerase. Measured molecular weight: 172420. Sum of 30 single spectra.

as well as a cluster ion $(2M)^{3\oplus}$ with lower intensity. All signals can be used to improve mass determination precision. The fact that glucose isomerase, which consists of four noncovalently bound subunits, is desorbed at least predominantly, if not only as the intact protein is a further proof for the extreme softness of the matrix-UVLDI technique.

The total sample amount deposited on the target was 500 fmol, spread over an area of several mm^2. At least several thousand single spectra can be obtained from such a preparation. An estimate of the sample consumption per single spectrum gives ca. 10^{-17} mol[6] leaving much room for a further reduction of sample amount necessary.

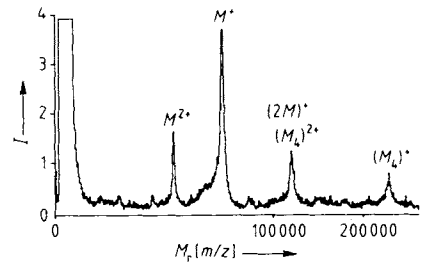

Fig. 3. LDI mass spectrum of catalase. Measured molecular weight: 236230. Sum of 50 single spectra.

Figure 3 shows the spectrum of catalase with a measured molecular weight of 236230, summed over 50 single laser shots. Again, the molecular ion, $(M_4)^{\oplus}$, consisting of 4 equal subunits with a molecular weight of 59060 each, is clearly detected, as well as the doubly charged species $(M_4)^{2\oplus}$. Because of the absence of a triply charged molecular ion it can be concluded that the peak at m/z 59060 originates from the singly charged subunit $(M_1)^{\oplus}$ and not the quadruply charged molecular ion $(M_4)^{4\oplus}$. Correspondingly the signal at m/z 29500 represents the doubly charged subunit $(M_1)^{2\oplus}$. Whether or not the protein mostly decayed into its subunits upon preparation (and evaporation of the solvent) already, or the decomposition was predominantly induced by or during the desorption process still needs further investigation.

As in all desorption techniques sample preparation plays the key role in LDI of high mass molecules. Highly purified samples and the use of ultrapure water for protein and matrix solutions is a prerequisite for a successful mass analysis, indicating that the salt contamination commonly present can disturb the homogeneity of the protein-matrix-association necessary for high mass ion desorption. Under such conditions, all spectra show a very good signal-to-noise ratio. The mass spectra shown are typical for matrix-UVLDI: so far no fragmentation of covalent bonds has been observed. The intense signals in the mass range below ca. 1000 Dalton are caused exclusively by the matrix. Whether a successive fragmentation, which would most suitably be done by a second laser, enables sequencing of peptides and proteins comparably to Collision-Induced-Dissociation has yet to be investigated.

Diisocyanogen or Isocyanogen?**

By Lorenz S. Cederbaum, Francesco Tarantelli, Hans-Georg Weikert, Markus Scheller,* and *Horst Köppel*

While the stable cyanogen molecule (NCCN) has long been known, the synthesis of its isomers diisocyanogen (CN-NC) and isocyanogen (CNCN) has posed considerable difficulties. Only recently has the experimental formation of CN-NC been reported for the first time.[1] The precursor norbornadienone azine was flash-pyrolyzed and the ^{13}C and ^{14}N NMR spectra of the pyrolysis products were consistent with the presence of CNNC.[1] More recently the He(I) photoelectron (PE) spectrum of CNNC was reported.[2] This clean spectrum was interpreted on the basis of experimental considerations augmented by the results of Hartree-Fock-Slater calculations. The calculations indicated the presence of strong correlation effects and made it quite clear that more sophisticated theoretical methods are necessary to correctly understand the experimental findings.[2]

The PE spectrum of cyanogen has been successfully calculated in the past using Green's functions theory.[3] We have now computed the PE spectrum of CNNC using both Green's functions and configuration interaction (CI) methods. The CI result is shown in Figure 1c. It is seen that the calculated spectrum does not compare with the experimental spectrum, which is schematically depicted in Figure 1a. In particular, the energy difference between the two σ-ionization potentials is much smaller than the experimental one. This difference is very constant with respect to the various calculations performed. In addition, the calculated π_u-ionization potential is, over and beyond the uncertainties of the theory, too large compared to the experimental value. We should mention that correlation effects are indeed substantial and an interpretation of the calculated spectrum via orbital energies is rather meaningless.

The geometry of CNNC used for the calculation of the PE spectrum was optimized at the CI level and was found, due to the presence of correlation effects, to be somewhat different from the SCF geometry reported in the literature[4]

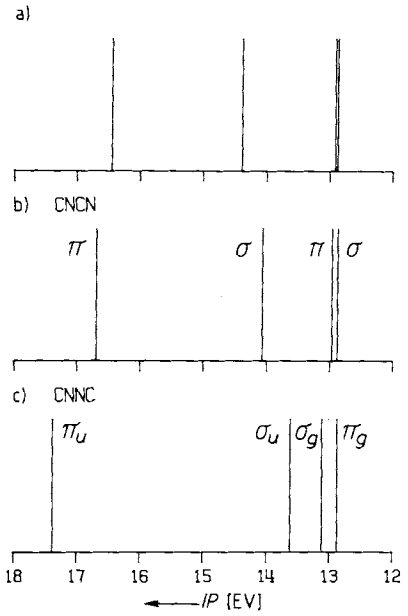
[**] We thank *C. A. deLange* for making the PE spectrum available prior to publication and for many interesting discussions.



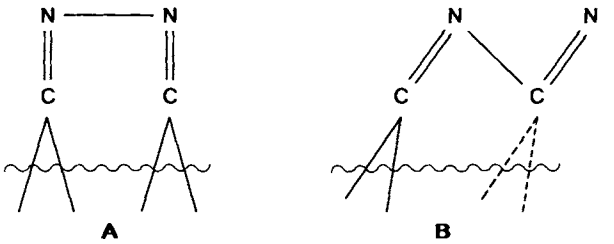


Fig. 1. a) The experimental [2] (schematic drawing) and b), c) calculated PE spectra.

(R_{CN} = 1.181 Å, R_{NN} = 1.291 Å). This difference in geometry is, however, by far too small to lead to substantial changes of the ionization potentials. In particular, the $\sigma_g - \sigma_u$ separation remains unchanged. To remedy the situation we searched for a linear but non-symmetric CNNC (a non-linear CNNC would exhibit six ionization potentials instead of the four found in the PE spectrum). Although we have invested considerably in this search and the potential energy surface has been found to be very flat along the asymmetric distortion, no additional minima could be detected and we conclude that CNNC is indeed symmetric. Moreover, we must conclude that the molecule whose PE spectrum has been measured is *not* diisocyanogen.

Since the molecule that has been synthesized contains two C atoms and two N atoms, we must assume that either a different isomer has been obtained, or that CNNC has isomerized to the more stable CNCN before the PE spectrum was recorded. The spectrum, however, does not exhibit signs of an additional isomer and, therefore, we tend to assume that it is not CNNC which has been synthesized. **B** is *one* possible explanation for the formation of CNCN from norbornadienone azine, whereas **A** would correspond to the formation of CNNC as suggested in Ref. [1].

Since the NMR measurements are carried out in the condensed phase we cannot rule out the formation of ordered CN-chains.

The ionization potentials of CNCN have been calculated before[5] and agree well with the experimental values.[2] To be consistent with the calculation on CNNC, we have repeated the calculation of the PE spectrum of CNCN using the same procedures and basis sets as for the newly computed CI geometry (CNC'N': R_{CN} = 1.180 Å, $R_{NC'}$ = 1.320 Å, $R_{C'N'}$ = 1.157 Å). The technical details of the Green's function and CI calculations of both CNCN and CNNC will be given elsewhere.[6] The resulting PE spectrum of CNCN is shown in Figure 1 b. It compares very convincingly with the experimental spectrum (Fig. 1 a). It is now obvious that the measurements in Ref. [2] were performed on CNCN.[7]

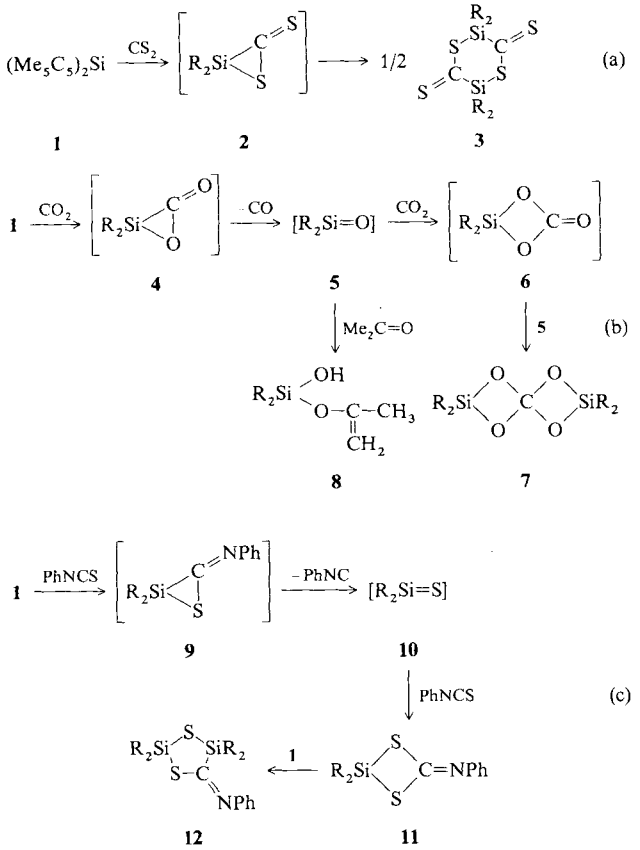
Surprising Reactions of Decamethylsilicocene with π-Systems of the Type X=C=Y

By *Peter Jutzi** and *Andreas Möhrke*



We recently reported the synthesis of decamethylsilicocene **1**.[1] This metallocene-like π-complex is so far the only divalent silicon compound that is stable under normal conditions. In the framework of our investigations of the chemistry of **1** we have, inter alia,[2] carried out reactions with simple organic compounds of the type X=C=Y. In the following we describe some, in part, surprising observations we made in the reaction of **1** with carbon disulfide, carbon dioxide, and phenyl isothiocyanate.

Already at room temperature **1** reacts with carbon disulfide in benzene solution to give the cyclic thioester **3** in almost quantitative yield. This suggests that the reaction involves an initial [2+1]-cycloaddition leading to the unstable thiasilirane **2**, which immediately dimerizes to give **3** [Eq. (a)].

The reaction of **1** with carbon dioxide proceeds quite differently: passage of CO_2 into a solution of **1** in toluene at room temperature surprisingly leads to almost quantitative formation of the spiro compound **7**. The reaction probably proceeds as follows: the initial [2+1]-cycloaddition product **4** formed analogously to Equation (a) loses carbon monoxide to give the silanone **5**, which reacts with carbon dioxide in a [2+2]-cycloaddition to give the cyclic silanediyl carboxylate **6**; this then reacts with further silanone **5** to give the final product **7** [Eq. (b)]. The carbon monoxide formed in this reaction sequence was detected in the form of a carbonyl complex.[3] If the reaction according to Equation (b) is carried out in the presence of acetone the hydroxysilylenol ether

Postfach 8640, D-4800 Bielefeld (FRG)

8 is formed quantitatively in an ene reaction via the postulated intermediate silanone **5**.

Scheme 1. R = C_5Me_5.

1 reacts somewhat differently with phenyl isothiocyanate: In toluene at about 60 °C, the dithiasiletane **11** is formed in high yields. In accord with the reaction postulated in Equation (c) an initial [2+2]-cycloaddition leads to the silirane **9** analogous to **2** and **4**; the three-membered ring system **9** then reacts with further phenyl isothiocyanate to give **11**. In contrast to **6**, the heterocycle **11** is stable under the reaction conditions. The phenyl isocyanide required as byproduct can be detected NMR spectroscopically.[5] So far it has not been possible to trap the postulated intermediate silathione **10**.

Reaction of **1** and **11** in toluene at about 100 °C leads via insertion of **1** between one of the two sulfur–carbon bonds of **11** to formation of the dithiodisilolane **12**. If the reaction of **1** with phenyl isocyanate is carried out from the beginning at higher temperature **12** is formed directly, irrespective of the molar ratio of the reactants.

The composition and constitution of **3, 7, 8, 11** and **12** are confirmed by NMR and MS spectra and by elemental analyses. In contrast to **1**, the pentamethylcyclopentadienyl ligand in these compounds is in each case bound monohapto to the silicon atom. The slight change in hapticity is presumably the reason for **1**, which is extremely electron-rich in the ground state due to π-bonding, being able to react as an electron deficient dialkylsilanediyl.[6] To our knowledge the heterocycles forming the basis of the compounds **3, 7, 11** and **12** were hitherto unknown. The pentamethylcyclopentadienyl ligand lends an additional functionality to this system.

As shown by the reactions (a)–(c) the reaction of decamethylsilicocene **1** with substrates of the type X=C=Y provides access to novel silacycles. Moreover, the possibility of generating pπ–pπ double-bonded systems $R_2Si{=}X$ from reactive three-membered ring precursors of the type $R_2\overline{Si-X-C}=Y$ deserves special mention.

Experimental

3: A solution of **1** (0.60 g, 2.0 mmol) in benzene (10 mL) was treated with 1.26 mL (20.0 mmol) of carbon disulfide and the mixture allowed to stand for 20 h at room temperature. Upon subsequent addition of *n*-pentane a fine, colorless precipitate separated out which, after filtration and crystallization from toluene, precipitated in the form of colorless cubes. Yield: 85%; m.p. 237 °C; ^{29}Si NMR ($CDCl_3$): $\delta = +21.6$; MS (70 eV): *m/z* 748 ($M^{\oplus}$, 12%).

7: Carbon dioxide was passed through a solution of **1** (1.46 g, 4.9 mmol) in toluene (25 mL) at room temperature for 3 h. Thereafter, the solution was stirred for a further 16 h in a CO_2 atmosphere. The solvent was removed under vacuum and the residue washed with *n*-pentane and crystallized from toluene. Yield 83%; m.p. 175 °C (decomp.); ^{29}Si NMR($CDCl_3$): $\delta = +10.3$; MS (70 eV): *m/z* 672 ($M^{\oplus}$, 29%).

8: CO_2 was passed through a solution of **1** (1.59 g, 5.36 mmol) in acetone (70 mL) at room temperature for 1 h and the solution stirred for a further 18 h in a CO_2 atmosphere. After removal of the solvent the residue was purified by sublimation (0.01 bar, 90 °C). Yield 92%; m.p. 42 °C; ^{29}Si NMR ($CDCl_3$): $\delta = -24.0$; MS (70 eV): *m/z* 372 ($M^{\oplus}$, 21%).

11/12: A solution of **1** (1.50 g, 5.03 mmol) in toluene was treated with 1.5 mL (12.5 mmol) of phenyl isothiocyanate and the mixture stored at 65 °C for 5 h (**11**) and 100 °C for 20 h (**12**) respectively. After removal of volatile components by distillation there remained an orange-red residue, which was recrystallized from *n*-pentane (**11**) and toluene (**12**), respectively. **11**: pale yellow rhombs, yield 55%; m.p. 118 °C (decomp); ^{29}Si NMR ($CDCl_3$): $\delta = +12.0$, MS (70 eV): *m/z* 465 ($M^{\oplus}$, 4%). **12**: bright yellow powder, yield 67%; m.p. 264 °C; ^{29}Si NMR ($CDCl_3$): $\delta = +21.4, -0.4$; MS (70 eV): 763 ($M^{\oplus}$, 60%).

$[O_3Ru^{IV}(\mu\text{-}O)_3Ru^{IV}O_3]$ units with a very short Ru···Ru distance (2.473 Å).[1, 2] These units are then coupled edge-to-edge via oxo bridges in the crystalline state. The magnetic properties of these oxides (weak antiferromagnetism?) are not yet fully understood. This motivated our interest to synthesize a binuclear complex with two face-sharing, octahedrally coordinated L'_3Ru^{IV}-units and three μ_2-oxo bridges and to study its magnetic properties. Such complexes were hitherto unknown.

Oxidation of the blue, mixed-valence complex **1**, described here for the first time, with $S_2O_8^{2\ominus}$ at pH = 7 furnishes the Ru_2^{III}-complex **2**; subsequent atmospheric oxidation of this species in alkaline solution (pH > 10) leads to **3**, a tri(μ-oxo)diruthenium(IV) complex. **1**, **2** and **3** were isolated in crystalline form as hexafluorophosphate salts; the structures of **1a** and **3a** were determined X-ray crystallographically.[3]

L = *N*,*N*′,*N*″-trimethyl-1,4,7-triazacyclononane, $C_9H_{21}N_3$

Figure 1 shows the structure of the cation **1**; that of the cation **3** in crystals of **3a** is very similar. In both cases we

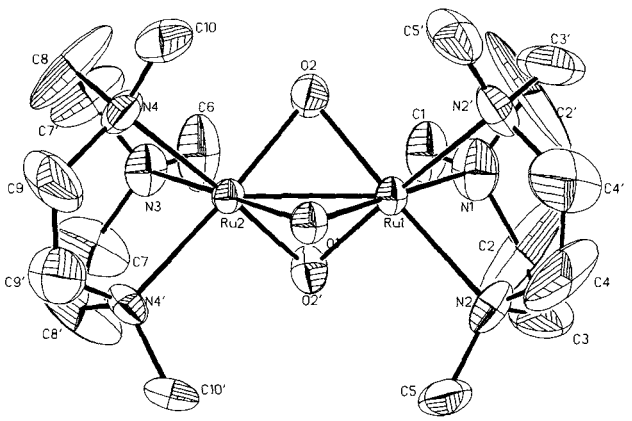

Fig. 1. Structure of the cation **1** of **1a**. The structures of the cation **3** of **3a** is similar and is not shown here. Important bond lengths [Å] and angles [°] in **1**: Ru1–Ru2 2.401 (2), Ru1–O1 1.96(1), Ru1–O2 1.967(7), Ru1–N1 2.22(2), Ru1–N2 2.20(1), Ru2–O1 1.943(9), Ru2–O2 1.950(7), Ru2–N3 2.17(1), Ru2–N4 2.18(1); Ru1–O1–Ru2 76.0(3), Ru1–O2–Ru2 75.5(3), N–Ru–N (mean) 82.4(5), O–Ru–O (mean) 86.7(5), N–Ru–O (mean) 95.6(5).—Important bond lengths [Å] and angles [°] in **3**: Ru1–Ru2 2.363(2), Ru1–O1 1.937(9), Ru1–O2 1.918(7), Ru1–N1 2.15(1), Ru1–N2 2.136(9), Ru2–O1 1.899(9), Ru2–O2 1.919(7), Ru2–N3 2.14(1), Ru2–N4 2.14(1), Ru1–O1–Ru2 76.1(3), Ru1–O2–Ru2 76.0(3), N–Ru–N (mean) 82.2(4), O–Ru–O (mean) 86.5, N–Ru–O (mean) 95.7.

have a binuclear complex consisting of two face-sharing octahedra (three hydroxo- and three-oxo bridges, respectively); the $[N_3RuO_3RuN_3]$ frameworks each have idealized D_{3h} symmetry.

2 has an analogous structure with three (μ-OH)-bridges.[4] A comparison of the Ru···Ru distances in **1** and **3** with those in the cation **4** of **4a**[5] shows that direct Ru–Ru bonds are present in **1** and **3** whereas *no* such bond exists in the

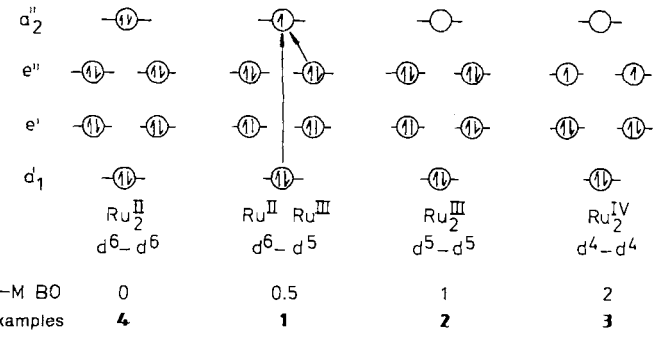

Fig. 2. MO scheme of the metal–metal bond in face-sharing complexes of the type $[L'RuX_3RuL']^{n\oplus}$ (X = OH, O). The two allowed electronic transitions for **1** are indicated by arrows.

diamagnetic $[Ru^{II}(\mu\text{-}OH)_3Ru^{II}]^{\oplus}$ complexes (such as **4**) (Ru···Ru ≈ 2.98 Å).[5, 6]

$[(\eta^6\text{-}C_6H_6)Ru^{II}(\mu\text{-}OH)_3Ru^{II}(\eta^6\text{-}C_6H_6)]Cl \cdot 3H_2O$ **4a**

Figure 2 shows the MO scheme for face-sharing octahedra with D_{3h} symmetry.[7] One bonding σ orbital (a'_1) and two degenerate, bonding π orbitals (e′) and the corresponding antibonding orbitals (a''_2, e″) can be constructed from the t_{2g} atomic orbitals of the Ru centers. In Ru_2^{II} complexes these orbitals are occupied, and the resulting Ru···Ru bond order (BO) is therefore zero; in **1** the formal BO is 0.5, then in **2** 1.0, and in **3** it is 2.0. The Ru–Ru distance in **1** and **3** decreases with increasing oxidation state of the Ru centers.

The magnetic behavior of these complexes is consistent with the MO scheme (Fig. 2): the Ru_2^{II} species such as **4a** are diamagnetic (d^6 low-spin configuration at each Ru^{II} center); **1a** has a temperature-independent magnetic moment between 9 K and 293 K (μ = 1.73 μ_B), corresponding to one unpaired electron per binuclear unit. **2a** is diamagnetic, and **3a** has a temperature-dependent magnetic moment. At 293 K it corresponds to almost two unpaired electrons per binuclear unit (μ_{eff}(9 K) = 1.77 μ_B; μ_{eff} (293 K) = 2.26 μ_B per binuclear unit).[10]

The electron spectra of **1**, **2** and **3** are shown in Figure 3. The spectrum of **1** is typical for mixed-valence complexes of

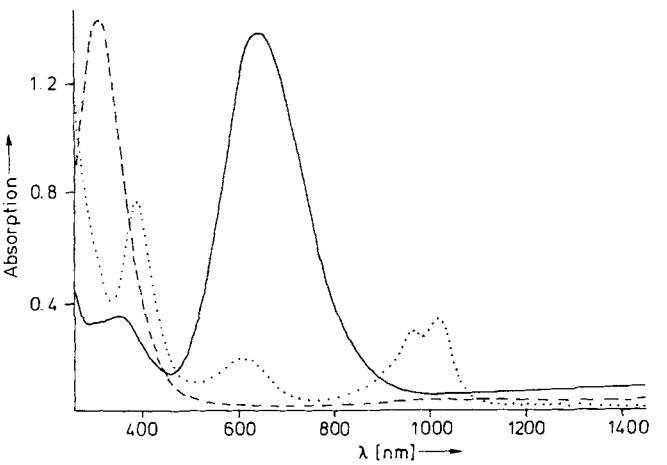

Fig. 3. Electron spectra of **1** (—), **2** (-----) and **3** (·····) in CH_3CN at 20 °C. ([**1**] = 3.8×10^{-4} M; [**2**] = 1.95×10^{-4} M; [**3**] 3.7×10^{-4} M; 1-cm cell). Absorption maxima in the NIR region (> 1400 nm) are not shown.

the type $[Ru(\mu\text{-}X)_3Ru]^{2\oplus}$ (X = Cl,Br).[8] **1** is the first tri(μ-hydroxo)diruthenium complex of this type. The intense band at 648 nm is, as usual, assigned to the $\sigma \rightarrow \sigma^*$ transition ($a_1' \rightarrow a_2''$; Fig. 2) and the weaker band in the NIR region at 1470 nm to the $e'' \rightarrow a_2''$ transition. The unpaired electron in **1** is completely delocalized; both Ru ions are equivalent. The degree of oxidation is 2.5 on the time scale for electronic transitions and vibrations, since the observed half-width of the band at 648 nm of $\approx 4400\ cm^{-1}$ is smaller than it is when calculated according to the Hush relationship ($[\Delta\tilde{\nu}_{1/2} = 2310\ \tilde{\nu}_{max}]^{1/2}$) for complexes of class II according to *Robin* and *Day* ($5970\ cm^{-1}$); and it is independent of the solvent.

The cyclovoltammogram (CV) of **1a** in CH_3CN (Pt electrode; 0.1 M nBu_4NPF_6) shows a reversible one electron transition at −0.11 V versus the normal hydrogen electrode (NHE);[9] the same transition was observed when **2a** was used as starting material [Eq. (1)].

$$\underset{\mathbf{2}}{[LRu(\mu\text{-}OH)_3RuL]^{3\oplus}} + e^{\ominus} \rightleftharpoons \underset{\mathbf{1}}{[LRu(\mu\text{-}OH)_3RuL]^{2\oplus}} \quad (1)$$

Under the same conditions, the CV of **3a** in CH_3CN shows two reversible one-electron transitions at $E^1_{1/2} = +1.12$ V and $E^2_{1/2} = -0.46$ V versus NHE, which correspond to an oxidation of **3** to the mixed valence $Ru^{IV}Ru^{V}$ complex **5** and a reduction to the mixed valence $Ru^{III}Ru^{IV}$ complex **6** [Eqs. (2, 3)]. The assignment of oxidation steps to individual metal centers is only to be understood formally here; delocalized valences are not to be ruled out.

$$\underset{\mathbf{5}}{[LRu^{IV}(\mu\text{-}O)_3Ru^{V}L]^{3\oplus}} + e^{\ominus} \rightleftharpoons \underset{\mathbf{3}}{[LRu^{IV}(\mu\text{-}O)_3Ru^{IV}L]^{2\oplus}} \quad (2)$$

$$\mathbf{3} + e^{\ominus} \rightleftharpoons \underset{\mathbf{6}}{[LRu^{III}(\mu\text{-}O)_3Ru^{IV}L]^{\oplus}} \quad (3)$$

Coulometric measurements on **3a** in CH_3NO_2 at +1.05 V versus ferrocenium/ferrocene revealed that 0.99 ± 0.1 electrons are removed per cation **3**. The color of the solution changes thereby from dark green to bright green; a subsequently measured CV agreed with that of **3a**. A similar electrochemical behavior was recently described by *Anson* et al.[12a] and *Meyer* et al. for two μ-oxo-bridged diruthenium complexes in solution. $Ru^{IV}Ru^{V}$ complexes exhibit catalytic activity in the oxidation of H_2O and alcohols.[12b] This aspect is currently being investigated for the case of **3**.

3 is the first tri(μ-oxo)diruthenium(IV) complex with an extremely short Ru–Ru bond of 2.363(2) Å. Its magnetic properties closely resemble those of the ternary oxides $BaRuO_3$ (H4 high-pressure phase) and $Ba_{5/6}Sr_{1/6}RuO_3$.[10] The $[Ru(O_3)Ru]$ unit in **3** is thus to be regarded as a section from the structure of these oxides.

Experimental

1a: To a suspension of 0.25 g (0.25 mmol) $[L_2Ru^{III}_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2] \cdot [PF_6]_2$ [11] in 15 mL H_2O was added 25 g of Zn amalgam (Zn content 2–3%) and the mixture adjusted to pH 2 with a small amount of 0.05 M H_2SO_4. After 2 hours' heating at 50 °C in the absence of air the clear yellow solution was separated from the Zn amalgam and treated with NaOH (pH = 12) and 0.30 g of $NaPF_6$. Upon gently heating in the presence of air the color of the solution turned deep blue and crystallization of blue **1a** was observed. Stirring of the solution was continued for a further hour at 20 °C in the absence of air and, after cooling to 0 °C, the blue crystals were filtered off and recrystallized from alkaline, aqueous solution. Yield 0.08 g (35%). UV/VIS (CH_3CN): λ_{max} (ε, L $mol^{-1}\ cm^{-1}$ per binuclear complex) = 1470(240), 648 (3.3×10^3), 354(925).

2a: A solution of **1a** (0.10 g, 0.11 mmol) in warm H_2O (15 mL) was treated with a solution of $Na_2S_2O_8$ (0.04 g, 0.16 mmol) in H_2O (3 mL). The color of the solution changed from blue to yellow. After briefly heating to 90 °C the solution was treated with 0.25 g of $NaPF_6$ and cooled to 0 °C for 12 h. Yellow-green crystals of **2a** separated out. Yield 0.11 g (95%). UV/VIS (CH_3CN): λ_{max} (ε, L $mol^{-1}\ cm^{-1}$ per binuclear complex) = 1634(323), 1450(sh), 1150(200), 314(7.4×10^3).

3a: A solution of **2a** (0.10 g, 1.1 mmol) in H_2O (10 mL) was treated with 0.02 g of NaOH and the stirred mixture heated at 80 °C for 10 min in the presence of air. The yellow solution turned dark green. The warm solution was then treated with 0.05 g of $NaPF_6$ dissolved in 1 mL of H_2O. After 12 h at 0 °C green crystals of **3a** could be filtered off. Yield 0.05 g (60%). UV/VIS (CH_3CN): λ_{max}(ε, L $mol^{-1}\ cm^{-1}$ per binuclear complex) = 1010(897), 964(754), 612(461), 391 (1.94×10^3).

All the complexes gave correct elemental analyses.

[9] Experimentally, the redox potentials were measured against the internal standard ferrocenium/ferrocene, for which a redox potential in CH_3CN of 0.40 V versus NHE was assumed: H. M. Koep, H. Wendt, H. Strehlow, *Z. Elektrochem. 64* (1960) 483.

[10] The magnetic moment per Ru^{IV} center in $Ba_{5/6}Sr_{1/6}RuO_3$ [1c] varies from 0.69 μ_B (77 K) to 2.10 μ_B (971 K); in the case of **3a** somewhat higher values were measured: 1.25 μ_B/Ru (93 K) and 1.60 μ_B/Ru (293 K). It is conceivable that the unpaired electrons of one binuclear complex in the oxide are coupled weakly antiferromagnetically with those of a second and a third complex and thus the effective magnetic moments in the oxide are somewhat lower than in **3a**. The similarity of the magnetic properties in the oxide and in **3a** is, however, remarkable; it is determined, above all, by the binuclear $[Ru^{IV}(\mu\text{-}O)_3Ru^{IV}]$ unit.

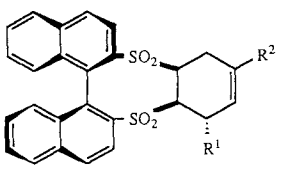
Ethylenebis(sulfonyl)-bridged 1,1′-Binaphthalene, an Atropisomeric Dienophile for Highly Diastereoselective Diels-Alder Reactions

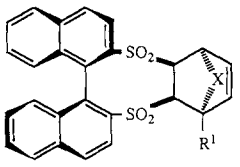
By *Sergio Cossu, Giovanna Delogu, Ottorino De Lucchi,* Davide Fabbri,* and *Giulia Licini*

The recent development of (*Z*)- and (*E*)-1,2-bis(phenylsulfonyl)ethylenes as reactive equivalents of ethylene[1] and acetylene[2] in cycloaddition reactions[3] has led to a noticeable improvement in the synthesis of otherwise difficulty accessible molecules[1,2] and to the preparation of new ones.[4] We now wish to report on the cycloaddition behavior of the title compound **1**,[5] a chiral variant of the above mentioned dienophiles, which, owing to its peculiar structure, exhibits enhanced reactivity.[6] Dienophile **1** reacts with virtually complete diastereoselection (a single adduct as determined by 200-MHz ^{1}H NMR spectra) with a number of non-symmetric dienes and represents the first specifically designed equivalent of acetylene in asymmetric Diels-Alder reactions. Furthermore, **1** is the first example of an atropisomeric sulfur dienophile and of an asymmetric dienophile possessing a rigid C_2 symmetry intrinsic in the shape of the molecule and not arising from chiral carbon or sulfur atoms.[7]



1

For the synthesis of **1**, racemic[8] or optically active[9] disodium [1,1′-binaphthalene]-2,2′-dithiolate was allowed to react with (*Z*)-1,2-dichloroethylene to give the disulfide **1**, S instead of SO_2 (m.p. 210 °C),[2] which was oxidized to the disulfone **1** (m.p. 320 °C). Optically active [1,1′-binaphthalene]-2,2′-dithioethers, which are accessible by kinetically controlled enantioselective oxidations with modified Sharpless reagents,[10] can also be transformed into **1**.



Addition at room temperature of 1-methoxy-3-(trimethylsilyloxy)-1,3-butadiene directly into an NMR tube containing a deuterochloroform solution of dienophile **1** leads to disappearence of the signals of the starting reagents and formation of a new set of signals which is attributable to a single diastereoisomer. Upon addition of ether, crystalline **2a** precipitated in almost quantitative yield. The orientation of the substituents relative to the binaphthyl group was determined on the basis of NMR data, NOE experiments and correlation of the spectral data with those of **2d** (see below) whose stereochemistry has been ascertained by X-ray analysis. Surprisingly, the methoxy group is *trans* to the two sulfonyl groups, thereby suggesting an *exo* transition state.[11]

The rigid conformational array of the dienophile **1**, which has two of the four oxygens in the plane containing the double bond and the other two parallel to each other but pointing in opposite directions (see structural formula of **1**). This geometry is probably decisive for the diastereoselectivity of the cycloaddition.

In order to determine the effect of the position of the substituents in the diene, reactions with various 1- and 2-substituted dienes have been carried out.[12] In reactions with 1-substituted dienes (both open chain and cyclic), exclusively one diastereoisomer was formed (cf. **2b–d**), even with (*E*)-1,3-piperylene in which the stereochemical bias is controlled only by a methyl group.[13] Of the 2-substituted dienes examined, only 2-trimethylsilyloxy-1,3-butadiene produced a single stereoisomer (**2e**), while isoprene gave a ca. 8:2 mixture of adducts (cf. **2f** as predominating isomer). The position of the substituents in these adducts was established, as before, on the basis of ^{1}H NMR spectral data. Cyclic dienes gave *endo* products, as was deduced from the ^{1}H-NMR coupling constants (cf. **2g, h**). The adduct **2h** was reduced with sodium amalgam in buffered methanol (NaH_2PO_4) to give the corresponding bicyclic diene, thus confirming the applicability of **1** as acetylene equivalent in cycloaddition reactions.

2a: R^1 = OMe, R^2 = $OSiMe_3$ (m.p. 185–186 °C)
2b: R^1 = OMe, R^2 = H (m.p. 250 °C)
2c: R^1 = $OSiMe_3$, R^2 = H (m.p. 266–268 °C)
2d: R^1 = Me, R^2 = H (m.p. 311–313 °C)
2e: R^1 = H, R^2 = $OSiMe_3$ (m.p. 230 °C)
2f: R^1 = H, R^2 = Me

2g: R^1 = OMe, X = O (m.p. 180 °C)
2h: R^1 = OMe, X = $-(CH_2)_2-$ (m.p. 307 °C)

The dienophile described herein is only one example of the several chiral synthons which may be accessible from [1,1′-binaphthalene]-2,2′-dithiol and whose diastereoselectivity is effected by atropisomerism.

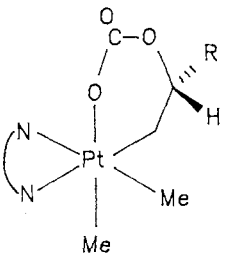
[12] All reactions for checking the diastereoselectivity were carried out directly in the NMR tube in deuterochloroform mixtures and for the preparative runs in dichloromethane. All reactions were complete within 24–48 h at room temperature, except for isoprene whose reaction was run in refluxing chloroform. Isolated yields are in all cases > 90%. All the new compounds have been fully characterized. The simplicity of the reaction is remarkable as in many instances simple mixing of the reagents at room temperature leads to precipitation of a single crystalline adduct.
[13] An X-ray structure determination confirms the stereochemical assignment. The diffractometric analysis was performed by Dr. *G. Valle* (Centro Studi Biopolimeri del C.N.R., via Marzolo 1, I-35131 Padova, Italy).

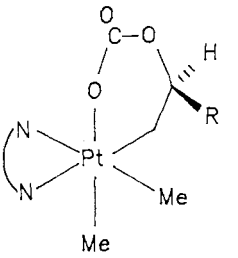
Coupling of Epoxides to Pt^{II}-Complexes with Carbon Dioxide and the Structure of a Cyclic Metallacarbonate**

By *Khin-Than Aye, George Ferguson,* Alan J. Lough* and *Richard J. Puddephatt**

The use of both epoxides and carbon dioxide as reagents in organic synthesis has been increasing rapidly, and transition metal catalysts are often necessary.[1–6] One important example is the coupling of epoxides with CO_2 to give cyclic carbonates;[3–6] and for electron rich catalysts such as $[M(PR_3)_4]$, M = Ni or Pd, the general mechanism of Scheme 1 has been proposed.[5]



The formation of oxametallacyclobutanes, **B**, by oxidative addition of epoxides has been observed only with activated epoxides such as tetracyanoethylene oxide[7] or in a cryogenic matrix.[8] This is especially unfortunate since oxametallacyclobutanes are also thought to be key intermediates in the oxidation of alkenes to epoxides by cytochrome P-450, and the catalytic step in which the epoxide is formed by reductive elimination is obviously related to the reverse of the first step in Scheme 1 (**A** → **B**).[9] We are therefore prompted to report the oxidative addition of some



Scheme 1.

simple epoxides to the complexes $[PtMe_2(\widehat{NN})]$ (**1a**: $\widehat{NN}$ = 2,2′-bipyridine; **1b**: $\widehat{NN}$ = 1,10-phenanthroline), in which the unstable complexes **B** are trapped by reaction with carbon dioxide to give the stable metallacarbonate complexes **C**. Similar metallacarbonates have recently been reported to be formed upon reaction of carbon dioxide with $[Ir(CH_2CMe_2O)(\eta\text{-}C_5Me_5)(PMe_3)]$ and with $[RhClH(CH_2COMe)(PMe_3)_3]$.[10]

Reaction of **1a** or **1b**, which are highly reactive towards oxidative addition,[11,12] with ethylene oxide under inert atmosphere gave a mixture of products, but under one atmosphere of CO_2 the products **2a** and **2b** were formed cleanly. The reactions are complete within 1–2 days at 0 °C, and even ambient CO_2 pressure is sufficient to give **2a** and **2b** as major products.

Cpd	$\widehat{NN}$	R
2a,	bpy	H
2b,	phen	H
3a,	bpy	Ph
3b,	phen	Ph
4a,	bpy	CH_2OPh
4b,	phen	CH_2OPh

Cpd	$\widehat{NN}$	R
3a′,	bpy	Ph
3b′,	phen	Ph
4a′,	bpy	CH_2OPh
4b′,	phen	CH_2OPh

Figure 1 shows the crystal structure of **2b**.[13] The six-membered platinum-containing heterocycle adopts a boat conformation and there is a marked bowing of the 1,10-phenanthroline ring.

The analogous compounds **3a,b** and **4a,b** are formed upon reaction of styrene oxide and 2-(phenoxymethyl)oxirane, respectively, with **1a, b**, and each was shown by NMR to exist as a mixture of isomeric forms (for example, **3a/3a′**) which could not be separated. The NMR data, especially the ^{13}C NMR data, showed clearly that the substituent R was in the β-position to the platinium in all cases studied. Thus, the α-carbon atom could easily be identified by the large value of

1a	$PhOCH_2CHCH_2O$	9.2×10^{-5}	48 ± 2	−160 ± 15

[a] k_2, at 25 °C, is measured for disappearance of **1a** but, when measured in the presence of CO_2, also applies to formation of **3a/a′** or **4a/a′** (see text).

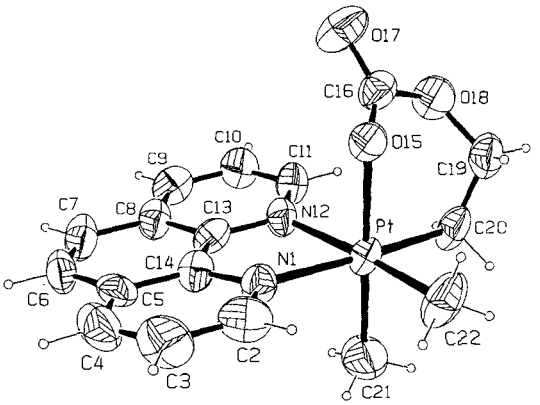

Fig. 1. Crystal structure of **2b**. Important bond lengths [Å] and angles [°]: Pt–O15 21.144(9); O15–C16 1.235(16); C16–O17 1.236(16); C16–O18 1.388(15); O18–C19 1.428(17); C19–C20 1.480(22); C20–Pt 2.034(14); O15–Pt–C20 89.3(5).

$^1J_{PtC}$ = 663–707 Hz and was shown to be a CH_2 group in every case by APT measurements (Table 1).

The kinetics of the reaction could be followed by monitoring the decay of the band due to **1** at 475 nm in the UV/VIS spectrum. Using a large excess of epoxide, the reactions followed first order kinetics and the first order rate constants were linearly dependent on the concentration of epoxide but were independent of the concentration of CO_2. Thus, overall second order kinetics, first order in both platinum(II) and epoxide reagent, were established. This indicates that the rate determining step involves oxidative addition of the epoxide (formation of **B** in Scheme 1) and that the subsequent CO_2 insertion is fast. The activation parameters given in Table 2 are typical of those expected for an S_N2 oxidative addition mechanism, and suggest that a dipolar intermediate $[Me_2(\widehat{NN})Pt^{\oplus}-CH_2CHRO^{\ominus}]$ is formed by nucleophilic attack by platinum(II) on the least substituted carbon atom of the epoxide steric effects are then responsible for the observed selectivity on formation of complexes **3** and **4**. This finding gives strong support for the mechanism of catalysis in Scheme 1,[5, 10] and also suggests that the formation of epoxides in transition metal catalysis[9] may involve dipolar intermediates.

[13] Crystallstructure data of **2b**: $C_{17}H_{18}N_2O_3Pt\cdot0.5C_5H_{12}$, M_r = 1059.02, monoclinic, space group $C2/c$ (No. 15), a = 28.793(7) Å, b = 11.823(3) Å, c = 12.473(2) Å, β = 93.30(2)°, V = 4239.0 Å^3, Z = 8, ρ_{calcd} = 1.66 g cm^{-3}, $F(000)$ = 2056, $Mo_{K\alpha}$ radiation (λ = 0.71073 Å), $\mu(Mo_{K\alpha})$ = 67.1 cm^{-1}. Intensity data were measured at 23 °C using an Enraf-Nonius CAD4 diffractometer; Lorentz, polarization, and absorption corrections were applied to the data. The structure was solved by the heavy atom method. A loosely held *n*-pentane molecule of solvation with 0.5 occupancy was also found. Full matrix least-squares refinement, with hydrogens allowed for as riding atoms, gave R_1 = 0.045 and R_2 = 0.063 for 2451 reflections with $I \geq 3\sigma(I)$. A final difference map was devoid of chemically significant features. – The atomic coordinates for this work are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (UK). Alkylidene Sulfur Difluorides: $F_5S(F_3C)C=SF_2$ and $(F_3C)_2C=SF_2$. Synthesis, Structure, and Structure Predictions**

By *Reinhard Damerius, Konrad Seppelt,** and *Joseph S. Thrasher*

In the isomerization reaction between $F_5S-HC=CF_2$ **1** and $F_4S=CH-CF_3$ in the presence of highly active CsF,[1] we have obtained a compound of formula **3** in very small yield. A detailed investigation of this reaction has led to a smooth synthesis of this compound, the first alkylidene sulfur difluoride.

$$F_5S-HC=CF_2 \xrightarrow[CsF]{SF_4} [(F_5S)(F_3C)HC-SF_3] \xrightarrow[-HF]{} F_5S(F_3C)C=SF_2$$
1 **2** **3**

The alkylidene sulfur difluoride **3** is a colorless, stable liquid at room temperature and can be characterized by the usual physical methods. The ^{19}F NMR spectrum is particularly revealing; the F_5S, F_3C, and $\rangle C=SF_2$ resonances are clearly separated from one another and fully coupled (see *Experimental Procedure*). Moreover, compound **3** is present as two isomers in a ratio of ca. 8:1. Accordingly, the plane formed by the substituents on carbon bisects the SF_2 angle (see Fig. 1).

3a **3b** **6**

Fig. 1. Structural model of alkylidene sulfur difluoride **3** (isomers **3a** and **3b**) as well as of **6**.

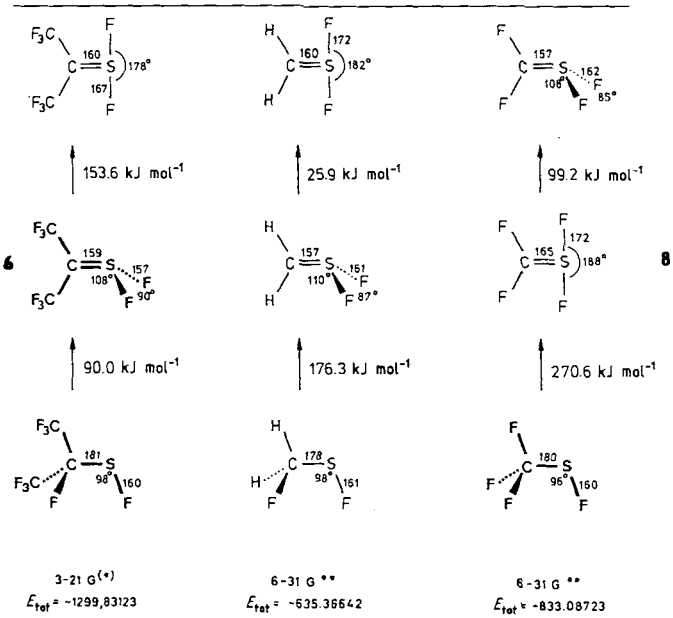
Interconversion of the isomers is not observed up to 100 °C: thus, the torsional barrier for the C=S double bond (or the inversion barrier of the $\rangle C=SF_2$ group) can be estimated to be at least 100 kJ mol^{-1}.

The corresponding reaction of $F_3C-HC=CF_2$ affords $(F_3C)_2C=SF_2$ **6** in poor yields; owing to its characteristic rearrangement to $(F_3C)_2FC-SF$ **7**, compound **6** cannot be synthesized in pure form. The ^{19}F NMR spectra of **6** show nonequivalence of the F_3C groups. This is expected from the structural principles derived for **3** (see Fig. 1). It has not been possible so far to extend this simple synthesis reaction to other olefins.

The observed structural rigidity of compounds **3** and **6**, which is a characteristic feature of double bonds, contrasts sharply with the free rotation around the C–S bond in the sulfur ylides **4**.[2] Of all phosphorus ylides reported, only one example is known in which rotation around the P–C bond is hindered below -10 °C and this is presumably due to steric factors.[3] For the recently discovered compound $OFC-HC=SF_2=O$, C=S torsion is frozen out below -30 °C.[4]

The reactivity of the alkylidene sulfur difluorides **3** and **6** also differs from that of the sulfur ylides **4**, which are mainly employed as carbene sources. By contrast, **3** and **6** are transformed into the sulfenyl fluorides **5** and **7**, respectively, upon irradiation or slow heating.

$$\underset{\mathbf{4}}{R_2\overset{\ominus}{C}-\overset{\oplus}{S}R'_2} \longrightarrow R_2C: + SR'_2$$



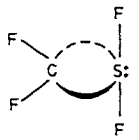
$$\underset{\mathbf{3}}{F_5S(F_3C)C=SF_2} \xrightarrow[\Delta,\,100\,^\circ C]{h\nu,\,20\,^\circ C} \underset{\mathbf{5}}{F_5S(F_3C)FC-SF}$$

$$\underset{\mathbf{6}}{(F_3C)_2C=SF_2} \xrightarrow{\Delta\,40\,^\circ C} \underset{\mathbf{7}}{(F_3C)_2FC-SF}$$

Only a few sulfenyl fluorides have been reported so far;[5–7] these are moderately stable derivatives of the very unstable SF_2.[8] The 1,2-fluorine shift is reminiscent of the transformation of FS–SF to $S=SF_2$.[9] From a thermodynamic point of view, a reversal of the stability in favor of the single bond is plausible. In this rearrangement, the CF bond is formed at the expense of a weaker SF bond.

If the structural isomers **3** and **6** are simplified to $H_2C=SF_2$ and those of **5** and **7** to H_2FC-SF, one obtains molecular structures whose sizes and relative energies are accessible to ab initio methods of calculation [(3–21G(*))-6–31G**]. The ground state is H_2FC-SF in the *gauche* conformation; the other rotamers are higher in energy by 5–30 kJ mol^{-1}. $H_2C=SF_2$, corresponding to the structures shown in Figure 1, is higher in energy by 176.3 kJ mol^{-1}. It has a short C=S bond length of 157 pm (see Table 1; cf. 155 pm in $H_2C=SF_4$[10]).

Table 1. Ab initio results for alkylidene sulfur difluorides $R_2C=SF_2$ compared with those for fluoroalkyl sulfenyl difluorides R_2FC-SF. Bond lengths in pm, E_{tot} in Hartree; known compounds drawn with thick lines.



The energies of the isomer pair **6/7** could only be calculated with the 3–21 G(*) basis set; the energy difference in this case is 90.0 kJ mol^{-1}. The energy value obtained upon rota-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie as well as by a generous allotment of computer time by the Alabama Supercomputer Network.

tion of the $=SF_2$ group by 90° relative to the $=C(CF_3)_2$ group is 91 kJ mol^{-1} higher; this provides a qualitative idea of the amount of C–S double bonding, which was calculated to be approximately 122 kJ mol^{-1} for alkylidene sulfur tetrafluorides.[1]

The calculation could also be performed for the isomer pair $F_2C=SF_2/F_3C-SF$ using once again the larger basis set. Surprisingly, a new structure **8** was predicted to be more stable. This molecule is fully planar and the SF_2 group is nearly linear. The C–S π bond lies outside of the molecular plane to the extent of 98%. This atomic arrangement corresponds to a minimum since all eigenvalues of the second-derivative matrix are positive. This molecule, which cannot be easily described according to conventional models, presents a challenge for the experimentalist. A possible model is of-

8

fered by **8**. It has thus been shown once again that SF_5 substitution stabilizes unusual bonding patterns.

Experimental Procedure

3: **1** (3.8 g, 20 mmol), SF_4 (2.16 g, 20 mmol), and CsF (9 g, 59 mmol) were stirred in a stainless-steel autoclave at 70 °C for 3 d. The product was isolated in a −78 °C trap by fractional condensation under dynamic vacuum. Colorless liquid (b.p. 64 °C, extrapolated from the vapor pressure curve), overall yield of the isomeric mixture 84%, isomer ratio 8:1 (according to ^{19}F NMR). Raman (liq.): strong bands at $\tilde{\nu}$ = 989.0 (s,p), 734.5 (s,p), 717.0 (vs,p), 678.0 (vs,p), 466.5 (s,p), 453.5 (vs,p), 406.0 (s,p), 324.0 (s,dp), 314.0 (s,dp), 288.0 (vs,p), 231.0 (s,dp) cm^{-1}. IR (gas): strong bands at $\tilde{\nu}$ = 1274 (vs), 1228 (vs), 1180 (vs), 901 (vs), 887 (vs), 854 (vs), 834 (s) cm^{-1}. ^{19}F NMR (84.25 MHz, CCl_3F), $AB_4C_2D_3$ type (values for the minor isomer in parentheses): δ_A = 73.2 (77.1), δ_B = 80.0 (86.5), δ_C = −3.6 (−7.5), δ_D = −54.6 (−55.2), J_{AB} = 147.3 (144.0), J_{AC} = 2.0 (1.5), J_{AD} = 1.4 (1.1), J_{BC} = 20.5 (23.0), J_{BD} = 10.1 (11.1), J_{CD} = 18.8 (17.2) Hz. MS: m/z 278 ($M^{\oplus}$, 45% based on $SF_5^{\oplus}$ = 100%) as well as numerous lighter fragments.

5: Irradiation of **3** in a pyrex glass apparatus for 1 h at 20 °C with a high-pressure Hg lamp gave pure **5**. Colorless liquid (b.p. 55 °C, extrapolated from the vapor pressure curve), quantitative yield. Raman (liq.): strong bands at $\tilde{\nu}$ = 1147.5 (s,p), 733.0 (s,p), 702.5 (vs,p), 682.0 (vs,p), 402.0 (vs,p), 278.0 (s,p), 244.0 (s,p) cm^{-1}. IR (gas): strong bands at $\tilde{\nu}$ = 1256 (s), 1240 (s), 1232 (vs), 1216 (vs), 1033 (s), 1028 (s), 905 (vs), 888 (vs), 834 (s), 795 (s) cm^{-1}. ^{19}F NMR (84.25 MHz, CCl_3F), AB_4C_3DE type: δ_A = 66.4, δ_B = 55.0, δ_C = −73.8, δ_D = −125.0 (CF), δ_E = −329.5 (SF), J_{AB} = 146.3, J_{BC} = 22.5, J_{BD} = 5.4, J_{BE} = 3.6, J_{CD} = 26.0, J_{CE} = 3.6, J_{DE} = 11.0 Hz. MS: m/z 278 ($M^{\oplus}$, 5% based on $S_2^{\oplus}$ = 100%) as well as numerous lighter fragments.

6: $F_3C-HC=CF_2$ (2.64 g, 20 mmol) [11], SF_4 (2.16 g, 20 mmol), and CsF (9 g, 59 mmol) were agitated in an autoclave at 20 °C for 5 d. Thermally unstable **6**, together with **7**, was formed. Yield 2%. ^{19}F NMR (84.25 MHz, CCl_3F), $A_2B_3C_3$ type: δ_A = −5.5, δ_B = −55.9, δ_C = −56.4, J_{AB} = 16.2, J_{AC} = 18.6, J_{BC} = 6.3 Hz. Warming to 40 °C resulted in complete rearrangement to **7** (for physical data see [5]).

Ab initio calculations: GAUSSIAN 86 program, geometry optimization with 3-21 G(*) (*: d orbitals on sulfur) and, if possible, energy optimization of this geometry with 6-31 G** basis set (**: d orbitals on S, C, F, p orbitals on H).

Location of *para*-Xylene in Yb-Faujasite (Zeolite Y) by Neutron Diffraction**

By *Mirjam Czjzek, Thomas Vogt,* and *Hartmut Fuess**

Synthetic Y-zeolite is employed as catalyst in the petrochemical industry, e.g. in isomerizations and alkylation.[1] The activity and selectivity of the Y-zeolites (mineral name faujasite) increases when the alkali metal ions are replaced by ions of the rare-earth metals.[2, 3]

In the isomerization of xylenes, disproportionation occurs as competing reaction. Both reactions proceed via a carbocation, and toluene and trimethylbenzenes as well as the isomeric xylenes are as products.[4, 5] On using an H-Y-zeolite as catalyst, mainly the products of disproportionation are obtained, whereas when Y-zeolites with rare-earth cations are employed the amount of isomerization products increases with increasing content of rare-earth cations.

To gain an insight into the catalytic process at the molecular level, a knowledge of the structural arrangement of the chemisorbed molecules in the zeolite is required. A knowledge of the structure and the thermodynamic, kinetic and spectroscopic data are prerequisite for a discussion of theoretical models.[6] Since single crystals of catalytically synthetic zeolites are seldom available for a structure analysis, the analysis of powder data has to be resorted to. For this purpose the Rietveld method for the profile analyses[7] of highly resolved neutron powder pattern has proven advantageous. The first results obtained for the location of chemisorbed molecules in zeolites have only recently been reported.[8, 9] We have now investigated the isomerization of *para*-xylene in Yb-zeolite Y (Yb-Y) and report here on the location of the xylene molecules in the zeolite framework.

The sample of Yb-Y was prepared from synthetic Y-zeolite (Union Carbide) by cation exchange with a 0.04 molar aqueous $Yb(NO_3)_3$ solution. The sample was dehydrated by slowly heating to 400 °C in a stream of oxygen and thereafter under vacuum for 12 h. Chemisorption of 0.25 ml of deuterated *p*-xylene in 3.22 g of Yb-Y was achieved within 2.5 h at room temperature in a vacuum. The sample was characterized by the composition $Yb_{13}Na_{17}Al_{56}Si_{136}O_{384}$ 9.4 C_8H_{10}. Neutron powder spectra were recorded on the D1A diffractometer[10] at the Institut Laue-Langevin (Grenoble).[11] The positions of the cations in the zeolite loaded with *p*-xylene differ only slightly from those in the pure Yb-Y.[12] Figure 1 shows the neutron powder pattern.

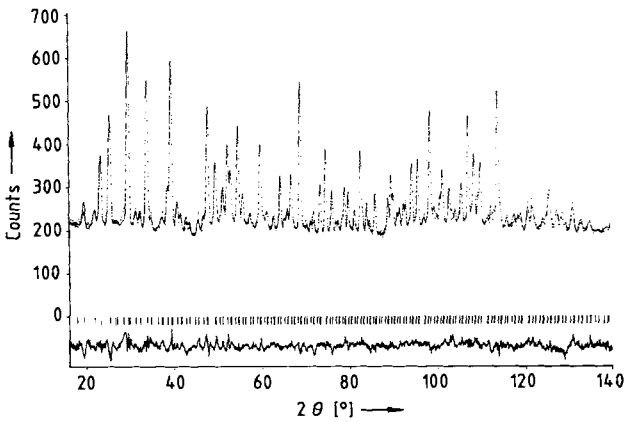

Fig. 1. Neutron diffraction pattern of Yb-faujasite with *p*-xylene. Dots: experiment. Upper curve: calculated diagram. Line series: positions of reflections. Lower curve: difference between observed and calculated intensities.

The $Yb^{3\oplus}$ ions are located at the position SI′ in the sodalite cage. Ce[14] and La[15] have already been found in this position too. The 17 $Na^{\oplus}$ ions are located in the six-membered ring windows between sodalite- and supercage. A comparison of the lattice constants of Na-Y (2485.36(3) pm[8]), Yb-Y (2458.50(6) pm[12]) and Yb-Y · 9.4 C_8D_{10} (2454.92(6) pm) reveals that the lattice contracts. $Yb^{3\oplus}$ is surrounded octahedrally by three oxygen atoms of the lattice at a distance of 239.2 pm and three water molecules at a distance of 236.3(14) pm. This interaction of the Yb ion with the framework gives rise to a lengthening of the Si–O(3) bond in the framework from 166.6(4) pm in Na-Y to 168.0(7) pm in Yb-Y. This bond is further lengthened to 171.31(8) pm by chemisorption of C_8D_{10}. The Si–O(4) bond, whose oxygen is not bound to the cations, on the other hand, is shortened from 164.8(4) pm in Na-Y through 157.5(7) pm to 156.6(8) pm in Yb-Y-C_8H_{10}. The position of the *p*-xylene molecules was determined by difference Fourier syntheses and refined with incorporation of structural boundary conditions (chemical constraints) for the geometry of the adsorbed molecule according to *Waser*.[16] For each supercage there are two crystallographically different positions, each of which is present four times (Fig. 2). The molecules are arranged perpendicular to the threefold axis. With eight super cages per cell, complete occupation leads to 32 molecules per position in the unit cell. Such a complete occupation of this type, however, is not possible for steric reasons. In position A there are on average 2 molecules, in position B 7.4. This corresponds to an average occupancy of 1.175 molecules of *p*-xylene per supercage, distributed over the eight crystallographic positions. If more than one molecule resides at an equivalent position in the cage then the molecular planes form an angle of 59.4°. The shortest C–C distance between the methyl groups of two molecules is 360(10) pm. The ring planes in the two positions A and B are rotated through 30° with respect to each other. The deuterium atom D(3) of the methyl group in position A is at a distance of 273(6) pm from O(1) and 273(6) pm from O(4). The deuterium atom D(6) of the methyl group in the *p*-xylene of position B is at a short distance of 270(6) pm from O(1)′ and in the *para* position thereto at a large distance of 301(6) pm from O(1)′. These distances are indicative of an interaction of the methyl group of the *p*-xylene with the skeletal framework.

The centroid of the aromatic ring in position A is at a distance of 255(5) pm from $Na^{\oplus}$ whereas in position B the distance is much shorter (241(5) pm). Similar short distances have been observed by *Fitch* et al.[8] in Na-Y · C_6D_6. They found a distance of 270(1) pm at lower occupancy and of 264(1) pm at higher occupancy. They interpret their results in terms of a cluster formation of neighboring arene molecules; a homogeneous distribution of the molecules on the supercage does not occur. This is also demonstrated by small angle measurements,[7] which show that, with occupancies of more than one molecule per supercage, the cluster formation will be given preference over the homogeneous distribution. Also ^2H NMR investigations by *Zibrowius* et al.[18] on chemisorbed benzene in Y-zeolites afford evidence of strong intermolecular interactions of the chemisorbed molecules and of a possible interaction of the π-electrons of the benzene rings with the Na ions.

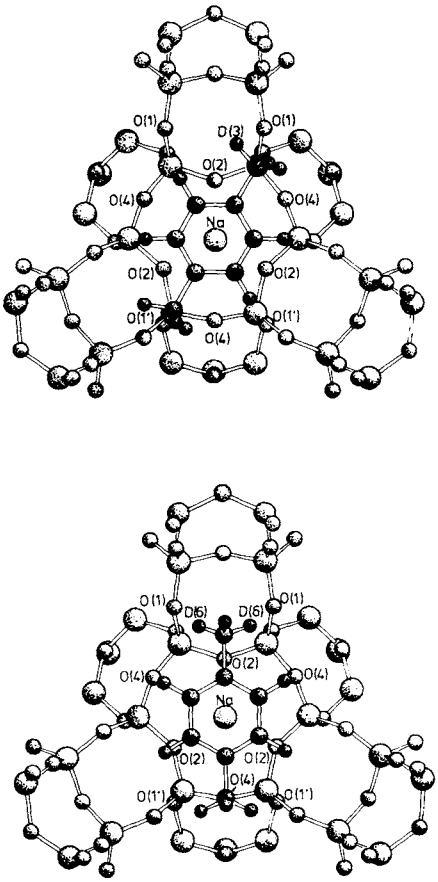

Fig. 2. Position of the *p*-xylene molecule in the supercage of Yb-faujasite. By rotating the molecule through 60° and 120° one obtains further symmetry-equivalent positions. The molecule appears (statistically distributed) in all three positions. Above: position A. Below: position B.

[11] The samples were transferred under He into cylinder-shaped vanadium containers (16 mm diameter) sealed with an indium wire. The spectrum was measured at 5K with a wavelength of 190.51 pm in the 2θ range of 6–156° in steps of 0.05°. Rietveld refinements [13] in the space group $Fd\bar{3}m$ led to the following figures of merit: $R(wp) = \sqrt{\sigma[w(y_{obs} - y_{calc})^2]/\sigma[wy_{obs}]^2} = 0.115$ with $R(\exp) = \sqrt{[N - P + c]/\sigma[wy_{obs}]^2} = 0.068$ and $R(I) = (\sigma[\mathrm{Mod}(I_{obs} - I_{calc})/\sigma y_{obs}) = 0.073$. The positions of the carbon atoms of the *p*-xylene were taken from difference Fourier maps. Deuterium positions were first calculated and subsequently refined with chemical constraints [16]. The range up to 16° in 2θ was excluded from the refinement since the first four Bragg reflections show an asymmetry due to the finite detector opening that cannot be fitted with the fundamental Gauss profile.

Amine-Bis(ethene)nickel(0) Complexes; Structure of 1-Azabicyclo[2.2.2]octanebis(ethene)nickel(0)**

By *Wilfried Kaschube, Klaus R. Pörschke,** *Werner Bonrath, Carl Krüger,* and *Günther Wilke*

Behrens and *Hieber* et al. reported that in liquid NH_3 or in pyridine above −25 °C $Ni(CO)_4$ forms readily disproportionating substitution complexes $[(NH_3)Ni(CO)_3]$ and $[(NH_3)_2Ni(CO)_2]$ (isolated as mixture)[3a] or $[(C_5H_5N)Ni(CO)_3]$ (IR detection).[3b] According to the HSAB concept of *Pearson*,[4] in the former compounds the "soft" Lewis acid nickel(0) is coordinated by a "hard" base. Our investigations show a decrease in acceptor strength of nickel(0) for the σ-donors $R^{\ominus}$ [5] and $H^{\ominus}$ [6] in the series

$$Ni(cdt) < Ni(C_2H_4)_2 < Ni(CO)_3$$

(cdt = *trans,trans,trans*-1,5,9-cyclododecatriene). Thus the amine–nickel(0) bond of the alkene-stabilized complexes should be even more labile than that of the carbonyl derivatives. It was therefore surprising that isolable, crystalline complexes of the type $[(amine)Ni(C_2H_4)_2]$ could be obtained,[7] whose syntheses and properties we describe herein.

Equimolar amounts of tris(ethene)nickel(0)[8] and 1-azabicyclo[2.2.2]octane in pentane afford a clear yellow reaction solution below 0 °C, from which small yellow cuboids of the title compound **1** separate in 70% yield on cooling to −78 °C. The crystals of **1** slowly decompose above 0 °C. Upon reaction of solid **1** with cyclooctatetraene ethene is liberated quantitatively and can thus be determined; in THF solution, **1** reacts smoothly with cyclooctadiene (cod) at −30 °C with displacement of all ligands to give $Ni(cod)_2$.

Analogously to the preparation of **1**, the complex **2** (long yellow needles, 56%) is obtained with the secondary amine Et_2NH, whereas no reaction is observed with NEt_3. Passage of ammonia into a solution of $Ni(C_2H_4)_3$ in pentane at −78 °C leads to immediate separation of **3** as a yellow precipitate (decomp. −50 °C). With pyridine a red solution was obtained, from which **4** crystallized as yellow cubes (86%), while with the diamine 1,4-diazabicyclo[2.2.2]octane the binuclear complex **5** (fine yellow cubes, 21%, decomp. at 20 °C) was isolated. Tetramethylethylenediamine (tmeda) possibly reacts with $Ni(C_2H_4)_3$ to form a binuclear complex analogous to **5**, which however could not be isolated.[9] The reactions according to Equations (a) and (b) are obviously equilibrium reactions.

$$Ni(C_2H_4)_3 \xrightarrow[-C_2H_4]{+\text{ amine}} \begin{cases} [(C_7H_{13}N)Ni(C_2H_4)_2] & \mathbf{1} \\ [(Et_2NH)Ni(C_2H_4)_2] & \mathbf{2} \\ [(H_3N)Ni(C_2H_4)_2] & \mathbf{3} \\ [(C_5H_5N)Ni(C_2H_4)_2] & \mathbf{4} \end{cases} \quad (a)$$

$$2\ Ni(C_2H_4)_3 \xrightarrow[-2\ C_2H_4]{+\text{ diamine}} [(\mu\text{-}C_6H_{12}N_2)\{Ni(C_2H_4)_2\}_2] \quad \mathbf{5} \quad (b)$$

amine = 1-azabicyclo[2.2.2]octane, diethylamine, ammonia;
diamine = 1,4-diazabicyclo[2.2.2]octane

The compounds **1**–**5** are very soluble in cold ether and THF. The 200-MHz ^1H NMR ([D_8]toluene) and 75.5-MHz ^{13}C NMR spectra ([D_8]THF) of **1** showed signals for the ethene ligands at $\delta(H) = 2.95$ and $\delta(C) = 55.7$, no broadening or splitting of which is observable down to −80 °C (^1H) and −100 °C (^{13}C), respectively; the ethene ligands obviously rotate about the bond axes to the nickel atom with a relatively low energy barrier. The shielding of the ethene protons and C atoms is less than in the corresponding phosphane complexes, in which the ethene rotation can, in addition, be frozen-in (cf. $(Me_3P)Ni(C_2H_4)_2$ in [D_8]THF, −80 °C: $\delta(H) = 2.44, 2.31$; $\delta(C) = 49.4, 48.7$; $\Delta G^{\neq} = 43.4$ kJ mol^{-1}).[5b]

The crystal structure analysis (173 K) of **1**[10] (Fig. 1) showed a trigonal planar coordination of the nickel, with an

[+] Single crystal X-ray analysis.

[**] Amine–Nickel Complexes, Part 5 and On the Lewis Acidity of Nickel(0), Part 11 – Parts 4 and 10: [1] and [2], respectively.

ethene ligand and the amine nitrogen atom each occupying a coordination site. Ni, N, C3, C4 and C5 lie in a mirror plane determined by the space-group. The two equivalent ethene ligands are attached coplanar to the nickel with NiC distances which, within the limits of experimental error, are equal. The angle subtended at the nickel to the mid-points of the ethene ligands in **1** is 126.2°; the corresponding angle at the N atom is 116.9°. The other structurally investigated ligand-Ni(C_2H_4)$_2$ complexes[2, 5a, 11] have lower symmetries than **1**. The Ni–N distance in **1** (2.068(3) Å) lies between the values found for (tmeda)nickel(0) complexes with trigonal-planar (1.97–2.02 Å; with strong π-acceptors)[12] and tetrahedral coordination geometry of the nickel (2.14–2.17 Å).[1, 13] As in the free amine,[14] the C–N–C angles in the 1-azabicyclo[2.2.2]octane ligands are 107.4° (mean value).

1 reacts with CO in THF at 0 °C to give the carbonyl complex **6**, which can be isolated at −78 °C in the form of yellow cubic shaped crystals (37%, recrystallizable from pentane); if the reaction is carried out below 0 °C more byproducts are formed. The IR spectrum of **6** shows C≡O valence vibrations ($\tilde{\nu}$ = 2030 (A_1) and 1970 cm^{-1}(E)) as are characteristic for L–Ni(CO)$_3$ complexes.[15] We could not isolate a pyridine derivative formed by reaction of **4** with CO either (cf. Ref. [3b]).

$$\underset{\mathbf{1}}{(C_7H_{13}N)Ni(C_2H_4)_2} + 3\,CO \xrightarrow[THF]{0\,^\circ C} \underset{\mathbf{6}}{(C_7H_{13}N)Ni(CO)_3} + 2\,C_2H_4$$

Formation of an adduct of Ni(cdt) with amines was not observed. The decrease in acceptor strength of nickel(0) as outlined at the beginning (in extension of Ref. [6b], Eq. (1) and Ref. [5c], Eq. (2)) we now have the following sequence of reduced σ-donor strength of the ligands:

$$R^{\ominus} > R_3Al-H^{\ominus} \geq R_3P^{\oplus}-CH_2^{\ominus} > Me_2S(O)^{\oplus}-CH_2^{\ominus} \approx R_3N$$

Experimental

1: A reaction solution of 10 mmol of Ni(C_2H_4)$_3$ [8] and 1.11 g (10 mmol) of 1-azabicyclo[2.2.2]octane in 20 mL of pentane was freed of excess ethene at −30 °C by stirring under vacuum (oil pump); sparingly soluble impurities were then removed by filtration. On cooling the filtrate below −50 °C yellow cuboid crystals separated out; these were, after withdrawing the mother liquor with a capillary pipette, washed twice with cold pentane, and dried in a high vacuum at −60 °C. Yield 1.55 g (70%); correct elemental analysis. 400-MHz ^{1}H NMR ([D$_8$]toluene, −80 °C): δ = 2.95 (8H, C_2H_4), 2.77 (6H, NCH_2), 1.28 (1H, CH), 1.00 (6H, CH_2); 75.5-MHz ^{13}C NMR ([D$_8$]THF, −80 °C): δ = 55.7 (4C, C_2H_4), 53.6 (3C, NCH_2), 27.35 (3C, CH_2), 21.2 (1C, CH).

2: Procedure as for **1**, but with 731 mg (10.0 mmol) of Et_2NH. At −78 °C long needles, yield 1.05 g (56%). 200-MHz ^{1}H NMR ([D$_8$]THF, −80 °C): δ = 4.74 (m, 1H, ^3J(HH) = 11.4 and 3.4 Hz, NH), 2.82 (m, 2H, ^2J(HH) = −10.9 Hz, $^3J(HH)_{CH_3}$ = 7.1 Hz, NC*H*H), 2.65 (m, 2H, $^3J(HH)_{CH_3}$ = 7.3 Hz, NCH*H*), 2.30 (8H, C_2H_4), 1.11 (t, 6H, CH_3); 75.5-MHz ^{13}C NMR ([D$_8$]THF, −80 °C): δ = 51.45 (4C, C_2H_4), 49.8 (2C, NCH_2), 15.7 (2C, CH_3).

3: Procedure as for **1**, but with 250 mL (ca. 10 mmol) of gaseous NH_3 at −78 °C. A bright yellow precipitate immediately separated out; this was recovered by filtration, washed twice with cold pentane and dried at −78 °C in a high vacuum. Yield 990 mg (75%); decomp. −50 °C, an elemental analysis could not be carried out. 200-MHz ^{1}H NMR ([D$_8$]THF, −80 °C): δ = 2.74 (3H, NH_3), 2.25 (8H, C_2H_4).

4: Procedure as for **1**, but with 791 mg (10.0 mmol) of pyridine. Fine yellow crystals separated out from the bright-red filtrate at −78 °C. Yield 1.66 g (86%). 200-MHz ^{1}H NMR ([D$_8$]THF, −80 °C): δ = 8.79 (2H, NCH), 7.80 (1H, CH), 7.41 (2H, CH, C_5H_5N), 2.51 (8H, C_2H_4); 75.5-MHz ^{13}C NMR ([D$_8$]THF, −80 °C): δ = 152.7 (2C, NCH), 136.2 (1C, CH), 125.5 (2C, CH, C_5H_5N), 55.4 (4C, C_2H_4).

5: Procedure as for **1**, but with 560 mg (5.0 mmol) of 1,4-diazabicyclo-[2.2.2]octane in 20 mL of ether. At −50 °C fine yellow crystals, yield 360 mg (21%). 400-MHz ^{1}H NMR ([D$_8$]THF, −80 °C): δ = 3.17 (12H, NCH_2), 2.41 (16H, C_2H_4); 75.5-MHz ^{13}C NMR ([D$_8$]toluene, −105 °C): δ = 55.8 (8C, C_2H_4), 52.6 (6C, NCH_2).

6: 330 mL (13.5 mmol) of CO were taken up at 0 °C in a stirred solution of **1** (2.21 g, 10.0 mmol) in ether (60 mL). The dark-brown precipitate that separated out was removed by filtration and the filtrate evaporated to dryness under vacuum (oil pump) at −30 °C. the yellow crude product (756 mg, 37%) was recrystallized from pentane. Yellow cubic crystals; yield 395 mg (20%); correct elemental analysis. IR (THF solution): $\tilde{\nu}$[cm^{-1}] = 2030 (A_1), 1970 (E, C≡O).

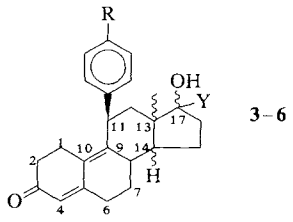
Stereo- and Regiospecific 6-*endo-trig*-Cyclization of Aryl Radicals, an Entry to Novel Progesterone-Antagonists of the Androstane Series

By *Eckhard Ottow,* Günter Neef,* and *Rudolf Wiechert*

An elegant, preparatively simple route[1] to 11 β-substituted steroids **2** of the estrane series, namely the regio- and stereospecific S_N2'-opening of the α,β-unsaturated epoxides **1** has been known since the end of the seventies.

[*] Dr. E. Ottow, Dr. G. Neef, Prof. Dr. R. Wiechert
Schering AG, Institut für Arzneimittelchemie
Müllerstrasse 170–178, D-1000 Berlin 65



(a)

1 **2**

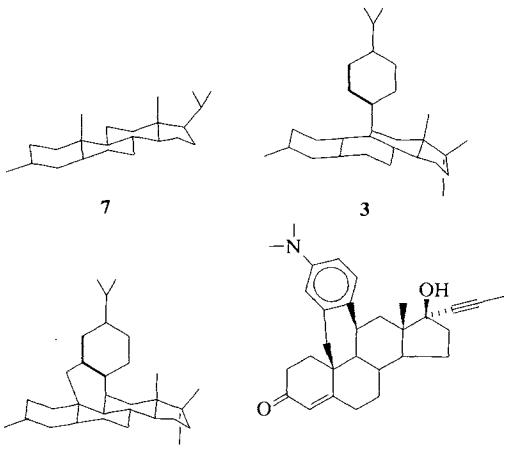
a, Z = OCH_2CH_2O, X = C≡N, Y = $OSiMe_3$
b, Z = $OCH_2C(CH_3)_2CH_2O$, X = OH, Y = H
R = alkyl, aryl; M = Li, MgCl, MgBr

At the beginning of the eighties this key reaction enabled the synthesis of the first competitive progesterone antagonists.[2] The exploration of the pharmacological profile and potential of these antihormones on the one hand, and the search for new antigestagens on the other, have since then been the subject of intensive studies.[3]

The competitive antiprogesterones **3–6** (Table 1)[4] that have so far been reported contain, aside from the antigestagen pharmacophore – the 11 β-aryl-substituent – also a 4,9-diene-3-oxo system.

3–6

Table 1. Characterization of the antiprogesterones **3–6**.

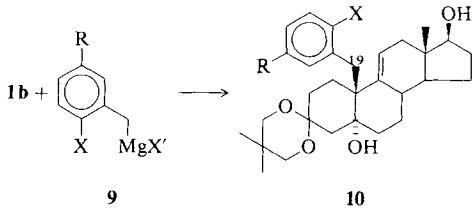


Cp.	Designation	Configuration at C-13	C-14	Position of 17-OH	R	Y
3	RU 38 486	β	α	β	$N(CH_3)_2$	$C\equiv C-CH_3$
4	ZK 112 993	β	α	β	$COCH_3$	$C\equiv C-CH_3$
5	ZK 98 299	α	α	α	$N(CH_3)_2$	$CH_2CH_2CH_2OH$
6	ZK 131 589	β	β	α	$N(CH_3)_2$	$CH_2CH_2CH_2OH$

This clearly demonstrates in which way the synthetic entry according to (a) on the one hand and the established sterically demanding 11 β-substituent on the other restrict conceivable variations at the carbon atoms 9 and 10 of these steroids. The approximate coplanarity of the 9,11 bond with the plane of the phenyl ring, as is revealed by X-ray structure analyses of the antigestagens **3–6**,[5] makes it plausible why even attempts to incorporate the least sterically demanding of all residues, a hydrogen atom, in the 10 β-position have failed.[6]

The coplanarity leads to a strong steric hindrance between the *ortho* proton of the 11-aryl moiety, which is turned towards the carbon atom 10, and a potential 10 β-substituent. This hindrance and a comparison of the structure with that of the natural gestagen, progesterone **7**, make a methylene bridging, as in the enone **8**, appear extremely attractive as synthetic goal (Scheme 1).

The establishment of this structural element was accomplished surprisingly easy by radical initiated cyclization of 19-(2-haloaryl)-9(11)-androstene derivatives **10**. These are accessible in good yields by 1,2-opening of the epoxide **1b** with (2-haloaryl)methylmagnesium halides **9**[7] (Table 2).



Of the conceivable methods[8] for the generation of the necessary intermediary phenyl radicals **11** (see Scheme 2) two

Antigestagens of the androstane series

7 **3** **8**

in particular were used: the reaction with lithium and that with tributylstannane. On treating the aryl halides **10a–g** (the starting material **10g** (X = Br) was obtained by bromination of the dehalogenation product **13f** with *N*-bromosuccinimide in dichloromethane in the presence of triethylamine) with lithium in a mixture of tetrahydrofuran and liquid ammonia at − 65 °C the cyclization proceeds in good to very good yields independently of the nature of the halogen[9] (Table 3). The ratio of cyclization product **14** to noncyclized dehalogenation product **13** (Scheme 2) is thereby influenced by the halide ion as already described by *Bunnett* et al.[10]

The more reactive bromobenzenes **10e** and **10g** can also be cyclized with tributylstannane in toluene with the same success[11] (Table 3).

Particularly noteworthy is the regioselectivity of this ring closure. The perfect 6-*endo-trig*-regiospecificity[12] is in complete contrast to the reaction course in more simple systems.[13] As various studies have shown, especially the excellent preparative and mechanistic investigations of *Beckwith* et al.,[15] analogous alkenylphenyl radicals cyclize preferen-

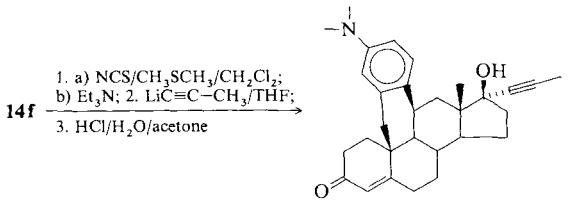
10g	Li	9 : 1	85



tially or exclusively in a 5-*exo-trig* fashion. Thus, for example, predominantly the five-membered ring compound **16** is formed from the phenyl radical **15**.

A neophyl rearrangement[16] in analogy to **15** → **A** → **B** → **C** → **17**, evidently[16] explaining larger amounts of six-membered ring products in certain cases, is unlikely in the case of **11** for energetic reasons. Semiquantitative estimations[18] of the relative energies of the transition states of direct 5-*exo-trig*- and 6-*endo-trig*-cyclizations that have to be taken into consideration in analogy to the force field calculations carried out by *Beckwith* et al.[19] are in good agreement with the experimental results.

In the simplest cases, conversion of the intermediates **14** into the finally desired active substances merely requires attachment of a side chain to carbon atom 17 and the removal of the protective groups. As example, in the case of **14f** the introduction of a 17α-propynyl group to give **8** is demonstrated [Eq. (c); NCS = *N*-chlorosuccimimide].

The described regiospecific 6-*endo-trig*- cyclization of the 19-(2-haloaryl)-9(11)-androstene derivative **10** is thus a general route to the synthesis of antigestagens of the androstane series. Structural modifications of the A/B part of these

(c)

steroid antihormones, as are known from potent synthetic gestagens,[20] are thus accessible for the first time or at least in simpler ways. Moreover, the double fixation of the 11 β-substituents opens up the possibility of specifically characterizing the gestagen/antigestagen binding site of the progesterone receptor with respect to the spatial environment of the arene.

Experimental

13a–f/14a–f [21]: 80 mL of anhydrous ammonia was condensed at −78 °C in the absence of moisture into a round flask. After addition of 2 mmol of lithium and appearance of the characteristic blue color the mixture was treated with a solution of 5 mmol of the aryl halide **10** in 160 mL of tetrahydrofuran. The resulting mixture was then stirred for 20 min (DC control) and the excess lithium removed by dropwise addition of ethanol (decoloration). The major part of the ammonia was then removed by evaporation, the reaction mixture poured into water, and the aqueous phase extracted several times with ethyl acetate. The combined organic phases were washed with sodium chloride solution, dried over sodium sulfate and evaporated to dryness under vacuum. The residue was either chromatographed on aluminum oxide (neutral, grade III) with ethyl acetate/hexane or taken up in a suitable solvent and the mother liquor remaining after crystallization of **13** chromatographed as described above (see Table 3).

$FeI_3SC(NMe_2)_2$, a Neutral Thiourea Complex of Iron(III) Iodide**

By *Siegfried Pohl,** *Ulrich Bierbach,* and *Wolfgang Saak*

According to the textbooks, iron(III) iodide compounds are either unstable or nonexistent.[1] Recently, the synthesis of FeI_3 from $FeI_2(CO)_4$ and iodine was reported.[2] In solution the compound decomposes to FeI_2 and iodine, but in the solid state it can be stored for several months. So far, however, a characterization of the solid has not been possible, since it could only be isolated in small amounts.

By reaction of iron(II) iodide, iodine and tetramethylthiourea in dichloromethane we have now been able to prepare triiodo(1,1,3,3-tetramethylthiourea-*S*)iron(III) **1** in almost quantitative yield according to Equation (a).[3] The

$$FeI_2 + \tfrac{1}{2} I_2 + SC(NMe_2)_2 \rightarrow \underset{\mathbf{1}}{FeI_3SC(NMe_2)_2} \qquad (a)$$

compound was characterized by IR and UV/VIS spectra, elemental analysis, and an X-ray structure analysis.[4]

The iron(III) center in **1** is coordinated tetrahedrally by three iodine atoms and one sulfur atom (Fig. 1). The Fe–I distances compare with the values that have also been found in tetraiodoferrate(III) ions.[5,6] The Fe–S distance

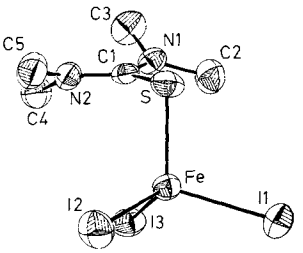

Fig. 1. Structure of **1** in the crystal (ORTEP, vibration ellipsoids at the 50% probability level). Important bond lengths [Å] and angles [°]: [pm] Fe–I1 255.3(1), Fe–I2 253.0(1), Fe–I3 253.7(1), Fe–S 231.1(2), C1–S 174.6(7), C1–N1 133.8(9), C1–N2 133.2(9); I1–Fe–I2 111.6(1), I1–Fe–I3 110.3(1), I2–Fe–I3 108.6(1), S–Fe–I1 106.2(1), S–Fe–I2 110.7(1), S–Fe–I3 109.3(1), C1–S–Fe 101.4(2). The planes through N1–C2–C3 and N2–C4–C5 are rotated through 27.4° and −24.9°, respectively, with respect to the plane through S–C1–N1–N2.

found in tetraiodoferrate(III) ions.[5,6] The Fe–S distance (231.1 pm) is only slightly greater than the Fe–S bond lengths in $Et_4N[Fe^{III}(SPh)_4]$ (mean value 229.6 pm).[7]

The synthesis of **1** parallels that of tetraiodoferrate(III) [Eq. (b)].[8,9]

$$FeI_2 + \tfrac{1}{2} I_2 + I^{\ominus} \xrightarrow{CH_2Cl_2} FeI_4^{\ominus} \qquad (b)$$

Like $FeI_4^{\ominus}$ (e.g., as Et_4NFeI_4), **1** is thermodynamically stable towards self-decomposition under normal conditions. Even with additional ligands, **1** and $FeI_4^{\ominus}$ react analogously—in each case iron is reduced [Eqs. (c) and (d), resp.].[8]

$$2\ \underset{\mathbf{1}}{FeI_3SC(NMe_2)_2} + 2\ SC(NMe_2)_2 \xrightarrow{CH_2Cl_2} \underset{\mathbf{2}}{Fe_2I_4[SC(NMe_2)_2]_3} + I_2 \cdot SC(NMe_2)_2 \qquad (c)$$

$$2\ FeI_4^{\ominus} + 3\ I^{\ominus} \xrightarrow{CH_2Cl_2} 2\ FeI_4^{2\ominus} + I_3^{\ominus} \qquad (d)$$

This reduction of iron with excess ligand is probably the reason for iron(III) iodide compounds being regarded as unstable.

In contrast to $FeI_4^{\ominus}$,[6] however, **1** reacts with iodine—with oxidation of tetramethylthiourea [Eq. (e)]. (The compounds **2** and **3** were also characterized by X-ray structure analysis.[10])

$$2\ \underset{\mathbf{1}}{FeI_3SC(NMe_2)_2} + I_2 \xrightarrow{CH_2Cl_2} \underset{\mathbf{3}}{[(Me_2N)_2CS-SC(NMe_2)_2]^{2\oplus}(FeI_4^{\ominus})_2} \qquad (e)$$

A reaction comparable with (e) with an oxidizing agent which, unlike iodide, does not coordinate in reduced form to iron, is possibly the most favorable route to FeI_3.

[9] For the synthesis of $FeI_4^{\ominus}$ from $FeCl_4^{\ominus}$ see J. L. Ryan, *Inorg. Chem. 8* (1969) 2058. The observed rapid decomposition of $FeI_4^{\ominus}$ at normal temperature motivated attempted syntheses at low temperatures. According to our results, however, this decomposition is not due to a thermodynamic instability towards self-decomposition, but exclusively to the behavior of $FeI_4^{\ominus}$ towards excess ligand (see text).

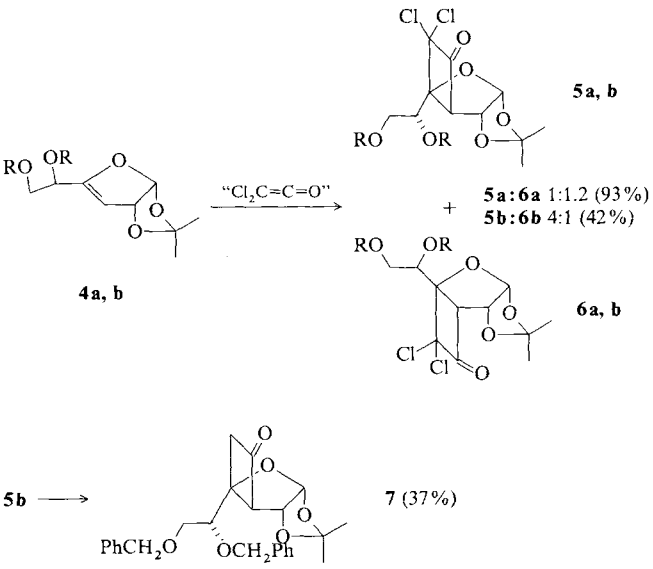
Chiral Cyclobutanones by [2+2]-Cycloaddition of Dichloroketene to Carbohydrate Enol Ethers**

By *Hartmut Redlich,* Jan B. Lenfers,* and *Jürgen Kopf*



Reaction of dichloroketene[1] (generated in situ) with carbohydrate derivatives containing an enol ether unit (**1a,b, 4a,b,** and **8a,b**)[2] furnishes the [2+2]-cycloaddition products (**2a,b, 5a,b, 6a,b** and **9a,b**),[3] in some cases in excellent yields. Reduction of these compounds with zinc/glacial acetic acid leads to dehalogenated chiral cyclobutanones (**3a,b, 7** and **10a,b**).[4] Optically active cyclobutanones, which are preparatively valuable building blocks, can be obtained very easily in this way. Thus, e.g., with compound **10a** a Baeyer-Villiger oxidation can be carried out to give the corresponding lactone.

1a, b — **2a** (89%), **2b** (95%) — **3a** (55%), **3b** (58%)

a: R^1 = OAc, R^2 = H; **b**: R^1 = H, R^2 = OAc

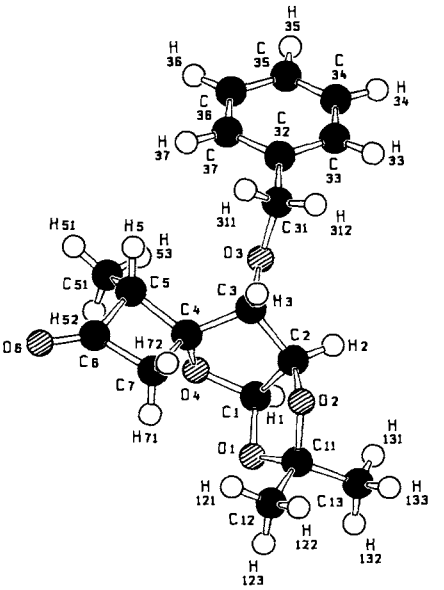
In the case of **1a,b** and **8a,b,** the stereochemical course of the addition of dichloroketene to the carbohydrate enol ether is uniform; as a result of the regiochemistry established by the enol ether, in each case only one of the possible diastereomers is formed. Should the reaction of the two glycals **1a,b** to give the "α-oriented" products **2a,b** seem plausible, then an interpretation of the findings for the reactions of **4a,b, 8a,b** and **11** is more difficult. Extensive data for comparison from carbohydrate chemistry demonstrate that sp^3- and sp^2-hybridized carbon atoms at positions 3 and 4 of derivatives of 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose are almost always attacked from above the sugar ring plane (the β side), irrespective of the reagent used. In contrast, in the case of **4a** (R,R = isopropylidene) attack from the α-side is slightly favored (**5a:6a** 1:1.2). If the protecting

4a, b — **5a, b** — **5a:6a** 1:1.2 (93%) + **5b:6b** 4:1 (42%) — **6a, b**

5b → **7** (37%)

a: R, R = $>CMe_2$; **b**: CH_2Ph

groups on C5 and C6 are replaced by $PhCH_2O$ groups (**4b**), then the expected product **5b** is formed in excess (**5b:6b** 4:1). The (*E*)/(*Z*) isomers **8a,b** are attacked exclusively from the α-side. The structures of the resulting compounds **9a,b** and of the dehalogenated secondary products **10a,b** could not be elucidated NMR spectroscopically. Upon irradiation at the frequency of H3 of compound **10a**, NOE experiments reveal an interaction with both H5 as well as H72 (for numbering cf. Fig. 1). Hence, only the (*Z*)-geometry is verified in



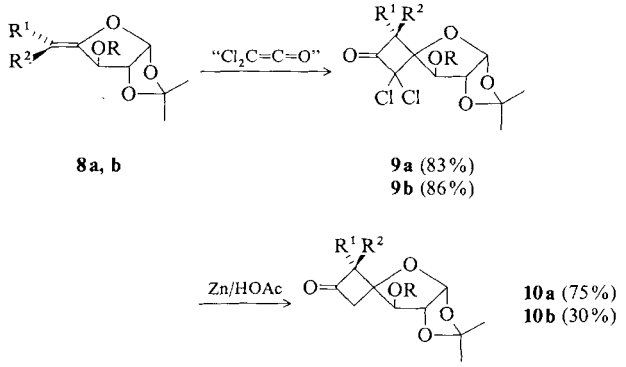


Fig. 1. Crystal structure of **10a**.

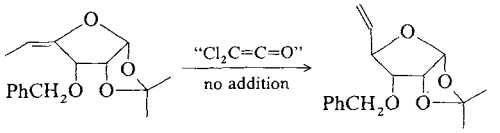
[+] X-ray structure analysis

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the starting olefin **8a**. An X-ray structure analysis of **10a**[6] (cf. SCHAKAL diagram[7] in Fig. 1) was necessary, however, before conclusions could be drawn about the unusual stereochemical course of the reaction, according to which the dichloroketene adds to the double bond from the α-side. This would seem to be possible only when the dichloroketene generated "in situ" is fixed in the sphere of the carbohydrate derivative **8a** such that the orientation of the addition is not controlled by normal steric effects. In particular the two halogen atoms of the dichloroketene must penetrate far into



8a, b → **9a** (83%), **9b** (86%)

→ **10a** (75%), **10b** (30%)

a: R^1 = Me, R^2 = H, **b**: R^1 = H, R^2 = Me
R = CH_2Ph

the concave region of the sugar molecule during the addition – an orientation which normally cannot be expected.

11 → **12** (50%)

The compound **11** 3-epimeric to the olefin **8b** does not add dichloroketene. Instead, the double bond migrates, and predominantly the olefin **12** is formed. It is thus clear that merely a slight shielding of the α-side by the 3-*O*-benzyl group in **11** changes the course of the reaction.

Experimental

Reaction with dichloroketene: A well-stirred suspension of the respective sugar (1 mmol) and zinc powder activated with copper [1] (330 mg, 5 mmol) in absolute diethyl ether (10 mL) was treated dropwise under nitrogen with a solution of trichloroacetyl chloride (0.36 g, 2 mmol) in absolute diethyl ether (5 mL) such that the reaction temperature did not exceed 30 °C (2 h). After a further two hours at room temperature the mixture was treated with 15 mL of pentane and the reaction solution decanted off from precipitated zinc salts. The residue was washed once with 10 mL of pentane/diethyl ether (1:1), and the organic phase was washed with 10 mL of saturated $NaHCO_3$, dried over $MgSO_4$ and filtered. The combined organic phases were evaporated down and the concentrate co-distilled several times with toluene under vacuum. The resulting syrup can, as a rule, be characterized NMR spectroscopically without resort to further purification.

Reduction with zinc: A solution of the dichlorocyclobutanone derivative (1 mmol) in glacial acetic acid (5 mL) was stirred at 50 °C and treated portionwise with a total of 10 mmol of zinc powder. On completion of reaction (up to 7 h) the mixture was cooled to room temperature, filtered, and the filtrate concentrated by evaporation under vacuum. In order to remove the last traces of glacial acetic acid the concentrate was co-distilled several times with toluene. The residue was taken up in diethyl ether, washed with water, and the organic phase dried over Na_2SO_4, filtered, and evaporated down under vacuum. The product was finally purified by column chromatography.

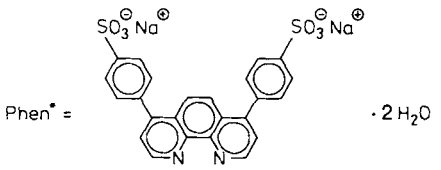
$Pt_{309}Phen^*_{36}O_{30\pm10}$, a Four-Shell Platinum Cluster **

By *Günter Schmid*,* *Bernd Morun*, and *Jan-Olle Malm*



In medium to large transition-metal clusters, the arrangement of the metal atoms increasingly resembles that of the metal itself as the size of the clusters increases. Therefore, most clusters may be described as cutouts of metal lattices, the outer atoms being protected by suitable ligands in order to prevent intermolecular interactions and coagulation processes like those observed for naked clusters.[1] The systematic construction of higher-nuclear clusters according to the principle of cubic (ccp) or hexagonal (hcp) close packing results in the attainment of "magic numbers" when a complete outer form is reached, namely, a cubeoctahedron (for ccp) or an anticubeoctahedron (for hcp). This process can

[**] Large Transition-Metal Clusters, Part 7. This work was supported by the Commission of the European Community, Brüssel, the Fonds der Chemischen Industrie, and the Swedish National Science Research Council. We would like to thank Prof. Dr. *F. Bandermann* and *D. Jacobi*, Institut für Technische Chemie der Universität Essen for ultracentrifuge determinations of the molecular weights. Part 6: G. Schmid, N. Klein, L. Korste, U. Kreibig, D. Schönauer, *Polyhedron 7* (1988) 605.

best be understood in terms of the shell model, according to which the first shell consists of 12 atoms, the second shell 42 atoms, and, in general, the n-th shell $(10n^2 + 2)$ atoms. So far, ligand-stabilized clusters containing 13 (one shell),[2] 55 (two shells),[3,4] and roughly 561 atoms (five shells)[5,6] have been prepared.

We have now succeeded in synthesizing a four-shell platinum cluster. It is impossible, of course, to give the exact number of metal atoms in such large clusters. However, electron microscopy clearly and reliably reveals the number of [110] and [100] atomic planes (shells) and allows a justifiable estimate of the ideal number of atoms. The exact determination of the ligands is not straightforward either. The number of oxygen atoms in the present case is especially difficult to determine.

The platinum cluster is synthesized by stirring an acetic acid solution of platinum(II) acetate and Phen* · H_2O (molar ratio 7–8:1) under hydrogen until gas absorption has ceased (2.5–3 h). The brown-black reaction solution is then exposed to an oxygen atmosphere to oxidize the free surface atoms. Workup yields a water-soluble, air-stable cluster of idealized composition $Pt_{309}Phen^*_{36}O_{30\pm10}$ in ca. 30% yield. This composition is derived from (1) multiple elemental analyses of all elements present, (2) molecular-weight determinations using an ultracentrifuge,[7] and (3) transmission-electron-microscopy investigations. The above formula corresponds to a molecular weight of 81.368 g mol^{-1}. Repeated molecular-weight determinations on aqueous solutions of the cluster give an average value of 79.500 with an error range of ca. ± 10% owing to the method used.

To perform the electron-microscopy investigations, the platinum cluster was dissolved in an acetone–water mixture. A carbon-coated copper grid was dipped into the solution and then transferred to the JEM 4000 EX transmission electron microscope, operating at 400 kV. The ca. 0.16-nm resolution of the microscope is sufficient for atomic resolution of the [110] and [100] directions in platinum. High-resolution electron microscopy and image simulation have repeatedly demonstrated the ability to distinguish between various types of structures and particle forms of metal fragments.[8,9] The platinum clusters investigated here have nearly exclusively cubeoctahedral structure with cubic close-packed atoms. Figure 1 shows a typical sample of the Pt_{309} cluster. Such large-area images are important for establishing the uniformity of the samples. The largest number of clusters by far have a diameter of 1.7–1.8 nm, as calculated for a four-shell platinum cluster.

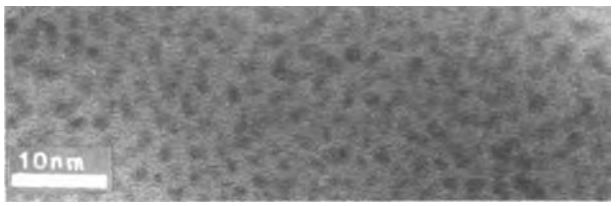

Fig. 1. Typical micrograph of a Pt_{309} cluster on amorphous carbon. The cluster particles that have not undergone any aggregation processes have diameters of 1.7–1.8 nm (very good agreement with the size of a four-shell Pt cluster).

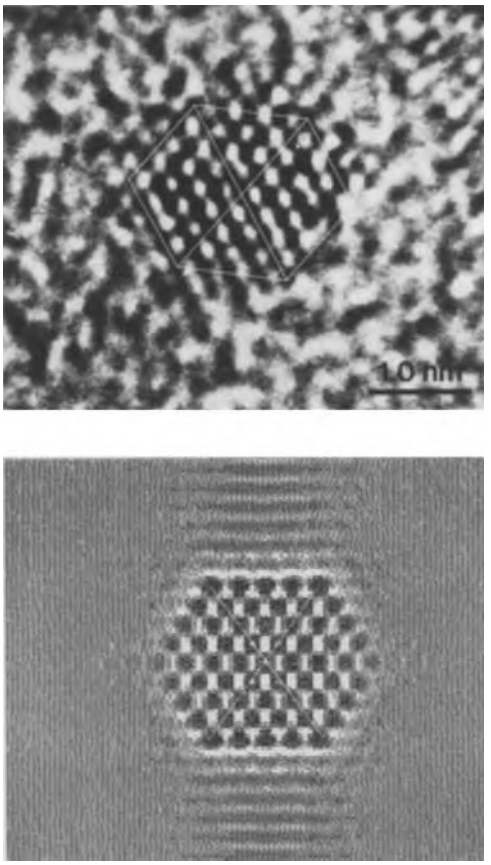

Fig. 2. Top: High-resolution transmission-electron micrograph of a four-shell Pt cluster in the [110] direction. Because of the contrast of the amorphous carbon support, it is difficult to distinguish completely the surface atoms. Nonetheless, the cubeoctahedral shape is clearly revealed. The diameter (111 separations) is 1.8 nm (calcd 1.81 nm). Bottom: Computer-simulated image of an M_{309} cluster in the [110] direction.

The structure of a single cluster is shown in Figure 2. Readily apparent is the ccp arrangement of the 309 Pt atoms in the [110] direction. For comparison, Figure 2 also shows a computer simulation of a four-shell cluster viewed from the same direction.

X-ray powder diffraction diagrams of several samples show very broad reflections, the maxima of which agree with the values obtained for metallic platinum. Reflections were observed for $d_{111} = 2.26$ Å ($Pt_{met.}$: 2.265), $d_{220} = 1.38$ Å ($Pt_{met.}$: 1.387), and $d_{113} = 1.18$ Å ($Pt_{met.}$: 1.1826). From the half-width of the [111] reflections[10] the particle sizes were calculated to be 17.5 ± 1 Å. Owing to the large half-widths and the relatively low reflection intensities, this value is subject to a relatively large error, but it lies in the correct range.

The presence of 33 Phen* ligands in the four-shell cluster is readily explained by the model and leads to an optimal "envelope" of the Pt_{309} core of the cluster. More difficult to understand is the oxygen content determined by elemental analysis. Crystalline Phen* · H_2O contains three molecules of water per molecule, one on each of the SO_3Na groups and one between the N atoms. The latter should be absent in the complexed state, whereas the former should still be bound to the sulfone groups in the cluster, as deduced from a comparison of the IR spectra of hydrated and nonhydrated SO_3Na groups.[11] Thus, 288 oxygen atoms should be present in the 36 Phen* ligands. The value of 6.22 ± 0.24% O determined by elemental analysis leaves 30 ± 10 atoms to occupy the platinum atoms at the surface. The error of ±0.24% results from five oxygen determinations on different samples. For a

constant number of Phen* ligands, the small variation in the analytical value has a marked effect on the surface oxygen atoms. It is not yet possible to determine whether these are bound as O_2 units or as $O^{2\ominus}$. We suspect the presence of O_2 groups.

Experimental Procedure

Platinum(II) acetate (380 mg, 1.2 mmol) was placed under N_2 atomosphere in a 100-mL flask, which was connected through a stopcock with a 100-mL gas burette, and then dissolved in 40 mL of conc. acetic acid with stirring. Phen* · H_2O (95 mg, 0.16 mmol) was dissolved in 1 mL of H_2O and treated with 20 mL of conc. acetic acid. The resulting solution was then added to the solution of the platinum salt. The apparatus was subsequently flushed with H_2. After 15–20 min, the solution began to absorb gas, the uptake ending after 2.5–3 h [H_2 consumption 38–39 mL (ca. 1.7 mmol)]. During hydrogen uptake, the solution turned brown-black. The hydrogen was flushed out with nitrogen and the apparatus was then filled with oxygen. Upon stirring, the solution absorbed O_2, the uptake ending after consumption of 17–18 mL (ca. 0.8 mmol). A black solid was separated using a laboratory centrifuge and then treated several times with conc. acetic acid followed each time by centrifugation, until the solution was colorless. The product was treated with ethanol in the same way. After drying under vacuum, the solid was treated with completely desalted water. The remaining undissolved solid was washed several times with water. Removal of water from the combined centrifuge fractions under vacuum yielded 60–70 mg of a black product, which was stored under N_2 (prolonged exposure of the product to air results in changes which are reflected in an increasing oxygen content). Elemental analysis (average value of five determinations performed on different samples): found, C 12.62 ± 1.0, H 0.81 ± 0.07, N 1.13 ± 0.12, Na 1.95 ± 0.20, O 6.22 ± 0.24, Pt 74.5 ± 0.5, S 2.49 ± 0.26%; calcd for $C_{864}H_{648}N_{72}Na_{72}O_{318}Pt_{309}S_{72}$, C 12.75, H 0.80, N 1.24, Na 2.03, O 6.25, Pt 74.09, S 2.84.

The Complexation of Gold Colloids**

By *Günter Schmid** and *Andreas Lehnert*

The formation of metallic states is still one of the largely unexplained phenomena of chemistry and physics. However, the development of cluster chemistry in recent years has led to considerable advances in our understanding, insofar as we can now use a long series of increasingly larger clusters to follow, in atomic steps, the formation of very small cutouts of metal lattices.[1] Clusters with specific ("magic") numbers of metal atoms appear to be characterized by particular stability; they are frequently formed if metal atoms are allowed to aggregate with minimal disturbance, M_{13},[2] M_{55},[3,4] M_{309},[5] and M_{561}[6,7] clusters are striking examples. Although metallic properties have not been observed for any of these clusters, behavior untypical of low-molecular clusters has been found.[8] The concept of a meta-metal has been developed to account for these properties.[8]

The transition from a cluster to a colloid can be assumed to occur in a continuous fashion, although examples of intermediate species are lacking. There is a huge gap between the largest ligand-stabilized cluster of ca. 2.5-nm diameter[6,7] and a small colloid of 10–20-nm diameter. Nonetheless, the same chemical principles should hold for colloids as for clusters. Two important differences should be noted, however. Colloids display a size distribution, which, in some cases, can be down to ±10%, and they are generally polycrystalline. Still, colloids can serve as models for very large clusters, as shown by the results presented here.

Colloids have already been stabilized by protecting colloids, which prevent the coagulation of the colloids in solution. Examples include gelatins, albumin and other peptides,[9] and macromolecules like polyethyleneimine, polyvinylimidazole,[10] and polyvinyl alcohol.[11] To the best of our knowledge, however, colloids have never been treated in terms of clusters and stabilized by the low-molecular-weight ligands known from complex chemistry.

We employed an aqueous solution of gold colloids prepared according to the sodium citrate method,[12] since their size distribution should be relatively narrow (ca. 20 nm ± 10%). We treated this solution with the water-soluble phosphane $(C_6H_5)_2PC_6H_4SO_3Na$, which has proved useful in the chemistry of large clusters.[13] Since it was difficult to specify the molar ratio exactly, we used a large excess of the ligand (Au: ligand ca. 1:1). The ligand-stabilized colloids are accessible in a largely pure form as follows: After addition of phosphane, the solution, which is still red, is concentrated under water-pump vacuum at room temperature until most of the colloid has separated out as a black precipitate and the solution is practically colorless. The precipitate, collected by centrifugation, dissolves instantly in water, the solution turning dark red. A second purification is accomplished by precipitating the stabilized colloid with ethanol from the aqueous solution, centrifuging off the precipitate, and drying it under vacuum. From 50 mg of gold, 60 mg of phosphane-stabilized colloid is obtained as golden leaves, which redissolve in water to give almost any desired concentration. These golden leaves contain on the average 90% gold and 5% carbon, which corresponds to an Au:ligand ratio of approximately 20:1. The adsorption of other species (e.g., $Cl^{\ominus}$ ions) on the colloids surface in amounts below the limits of analytical detection cannot be ruled out. An overall negative surface charge of the colloids is revealed by electrophoresis experiments, which show a migration of the colloids toward the anode. The particle sizes of the gold colloids remain practically unchanged upon coordination of phosphane molecules, as shown by comparison of the UV/VIS spectra. Both the original colloid solution and an aqueous solution prepared from isolated, phosphane-stabilized colloid show an absorption maximum at $\lambda = 520$ nm.

Molecular-weight determinations with an analytical ultracentrifuge[14] gave a value of $(38 \pm 8) \times 10^6$ g mol^{-1}, which, in turn, allowed calculation of the volume of the gold colloids, not including the ligand shell. From the volume, a diameter of 18 ± 1 nm was determined.[15]

The average particle diameter can also be determined from X-ray diffraction experiments. X-ray powder diffraction diagrams of the isolated colloid show all reflections of metallic gold, which proves that the gold atoms in this case are arranged primarily in a cubic face-centered lattice, as in the bulk metal. The presence of significant amounts of icosahedral or polytetrahedral[16] structures, which were postulated earlier, can therefore be ruled out. The average particle size of the metal nuclei (17 nm) was determined from the half-width of the intense [111] reflection by use of the Scherrer formula.[17]

Evaluation of the electron-microscopic image (Fig. 1) of a sample of the phosphane-stabilized colloid gave nearly a

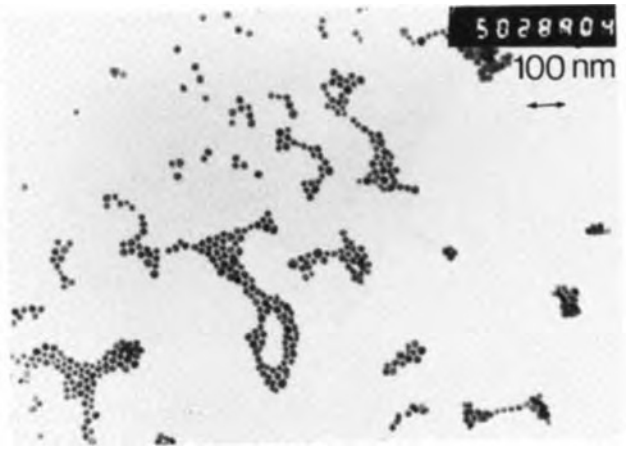

Fig. 1. Electron-microscopic images of phosphane-stabilized gold colloids obtained from aqueous solution (100 kV). Distribution maximum, 18.6 ± 0.1 nm.

Gauss distribution with a maximum at 18.6 ± 0.1 nm and a standard deviation of 2.8 nm.[18]

In summary, gold colloids can be regarded as extremely large clusters and isolated as their solid "phosphane complexes". These complexes are readily soluble in water, so that colloid solutions of any desired concentration can be prepared and stored. Further, colloids prepared in this way can also be investigated in the solid state. Of particular interest are conductivity measurements, especially in comparison with measurements performed on clusters with identical or similar ligands. Preliminary attempts to stabilize Cu, Ag, Pd, and Pt colloids in a similar way are in progress.

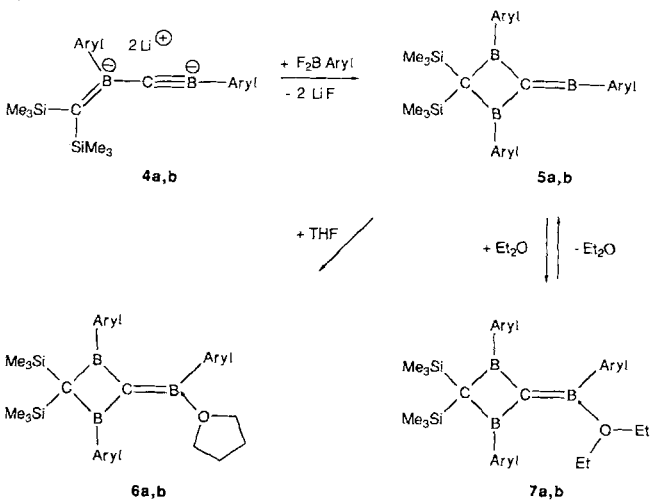
Stable Methyleneboranes of High Lewis Acidity**



By *Ralf Hunold, Monika Pilz, Jürgen Allwohn, Matthias Stadler, Werner Massa, Paul von Ragué Schleyer*, and *Armin Berndt**

Methyleneboranes **1** with empty p-orbitals on boron should be strong Lewis acids.[1] The previously described stable methyleneboranes of type **2**[2] and **3**[3] are at best only weak[4, 5] Lewis acids since their empty p-orbital on the boron is filled up intramolecularly by neighboring electron pairs.

1 **2** **3**

The existence of methyleneboranes of high Lewis acidity could hitherto only be demonstrated by trapping reactions.[4, 6] We now present the 2-boranediyl-1,3-diboretanes **5a,b** as stable methyleneboranes which form adducts with weak Lewis bases such as THF and diethyl ether. Moreover, they add 4-*tert*-butylpyridine. **5a,b** are formed by reaction of the dilithium compounds **4a**[7] and **4b** with mesityl and duryldifluoroborane, respectively, in pentane at room temperature.

a: Aryl = 2,4,6-$Me_3C_6H_2$; **b**: Aryl = 2,3,5,6-Me_4C_6H

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

With THF, **5a,b** form the stable tetrahydrofuran adducts **6a,b**. The diethyl ether adducts **7a,b** which are obtained upon crystallization of **5a,b** from diethyl ether, are in strongly temperature-dependent equilibrium with **5a,b** and diethyl ether in solution ($CDCl_3$, CD_2Cl_2). At room temperature, the ^{13}C NMR spectra of **7a,b** are almost identical to those of **5a,b** and diethyl ether; at $-80\,^{\circ}C$ on the other hand they resemble those of the THF adducts **6a,b**. That is, the electron deficiency of the dicoordinated boron atom in **5** is not satisfied intramolecularly to the extent found in **2** and **3**. Hence of all the isolable methyleneboranes, **5a** and **5b** are so far the closest to the prototype **1** with a formally empty p-orbital on the dicoordinated boron atom.

An insight into the electronic structure of the B-C double bond in **5** is provided by the crystal structure[8] of **5b** (Fig. 1a) and its comparison with that of **7b** (Fig. 1b) as well as by the ^{11}B and ^{13}C NMR shifts (Table 1).

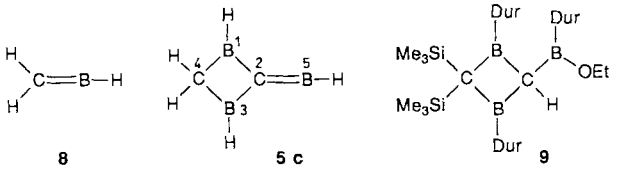
6a: m.p. 128 °C (decomp.), yield: NMR-spectroscopically quantitative; ^1H-NMR: $\delta = 0.00$ (s, 18H, $Si(CH_3)_3$), 1.74 (m, 4H, CH_2 of THF), 2.02 (s, 6H, CH_3), 2.12 (s, 9H, CH_3), 2.23 (s, 12H, CH_3), 3.58 (m, 4H, OCH_2 of THF), 6.48 (s, 2H, *m*-H), 6.50 (s, 4H, *m*-H); ^{13}C-NMR (–60 °C): $\delta = 5.8$ (6C, $Si(CH_3)_3$), 21.2, 22.6 (each 2C, CH_3), 21.3 (1C, *p*-CH_3), 25.3 (4C, *o*-CH_3), 26.3 (2C, CH_2 of THF), 50.7 (1C, Si_2C), 79.4 (br., 2C, OCH_2 of THF), 127.4 (2C, *m*-C), 127.7 (4C, *m*-C), 134.7 (2C, *p*-C), 136.4 (1C, *i*-C), 137.6 (1C, *p*-C), 138.8 (4C, *o*-C), 139.9 (2C, *o*-C), 140.4 (br., 1C, CB_3), 144.8 (2C, *i*-C); ^{11}B-NMR: 56 ($\nu_{1/2} = 2200$ Hz)



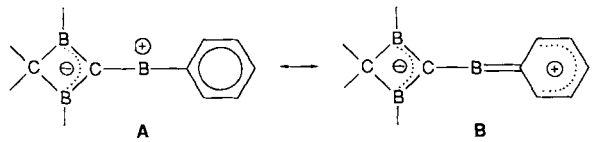
6b: m.p. 116 °C, yield: NMR-spectroscopically quantitative; ^1H-NMR: $\delta = 0.01$ (s, 18H, $Si(CH_3)_3$), 1.85 (m, 4H, CH_2 of THF), 1.87, 1.96 (each s, each 6H, CH_3), 2.04, 2.12 (each s, each 12H, CH_3), 4.13 (m, 4H, OCH_2 of THF), 6.68 (s, 2H, *p*-H), 6.72 (s, 1H, *p*-H); ^{13}C-NMR (–40 °C) $\delta = 5.3$ (6C, $Si(CH_3)_3$), 19.5 19.8 (each 2C, CH_3), 20.1, 21.9 (each 4C, CH_3), 24.9 (br., 2C, CH_2 of THF), 51.4 (1C, Si_2C), 78.3 (br., 2C, OCH_2 of THF), 128.4 (2C, *p*-C), 130.6 (1C, *p*-C), 131.7 (4C, *o*-C), 132.5 (2C, *o*-C), 134.1 (4C, *m*-C), 134.7 (2C, *m*-C), 137.7 (br., 1C, CB_3), 138.5 (br., 1C, *i*-C), 147.0 (br., 2C, *i*-C); ^{11}B-NMR (toluene): $\delta = 58$ ($\nu_{1/2} = 2380$ Hz)

7a: loses Et_2O at 40 °C, yield 70%; ^1H-NMR: $\delta = 0.24$ (s, 18H, $Si(CH_3)_3$), 1.23 (t, 6H, CH_3 of Et_2O), 2.23 (s, 6H, CH_3), 2.28 (s, 3H, *p*-CH_3), 2.29 (s, 6H, CH_3), 2.51 (s, 12H, *o*-CH_3), 3.56 (q, 4H, CH_2 of Et_2O), 6.78 (s, 2H, *m*-H), 6.79 (s, 4H, *m*-H); ^{13}C-NMR (CD_2Cl_2, –80 °C): $\delta = 4.6$ (6C, $Si(CH_3)_3$), 13.3 (br., 2C, CH_3 of Et_2O), 20.6, 22.3 (each 2C, CH_3), 20.8 (1C, *p*-CH_3), 24.4 (4C, *o*-CH_3), 50.0 (1C, Si_2C), 74.0 (br., 2C, CH_2 of Et_2O), 126.6 (6C, *m*-C), 133.5 (1C, *i*-C), 134.1 (2C, *p*-C), 136.6 (br., 1C, CB_3), 137.0 (1C, *p*-C), 138.1 (4C, *o*-C), 139.5 (2C, *o*-C), 143.4 (2C, *i*-C)

7b: loses Et_2O at 40 °C, yield 70%; ^1H-NMR: $\delta = 0.17$ (s, 18H, $Si(CH_3)_3$), 1.25 (t, 6H, CH_3 of Et_2O), 1.96, 1.98 (each s, each 6H, CH_3), 2.19, 2.37 (each s, each 12H, CH_3), 3.60 (q, 4H, CH_2 of Et_2O), 6.90 (s, 2H, *p*-H), 7.03 (s, 1H, *p*-H); ^{13}C-NMR (–55 °C): $\delta = 4.8$ (br., q, 6C, $Si(CH_3)_3$), 13.2 (q, 2C, CH_3 of Et_2O), 19.3, 19.93 (each q, each 2C, CH_3), 19,85, 21.9 (each q, each 4C, CH_3), 50.9 (br. s, 1C, Si_2C), 74.6 (br., t, 2C, CH_2 of Et_2O), 128.6 (d, 2C, *p*-C), 130.5 (d, 1C, *p*-C), 132.0 (s, 4C, *o*-C), 132.6 (s, 2C, *o*-C), 134.3 (s, 4C, *m*-C), 135.2 (s, 2C, *m*-C), 136.9 (br. s, 1C, CB_3), 137.3 (br. s, 1C, *i*-C), 147.3 (br. s, 2C, *i*-C)

9 (from **5b** and EtOH): m.p. 149 °C, yield: NMR-spectroscopically quantitative; ^1H-NMR: $\delta = 0.04$, 0.36 (each s, each 9H, $Si(CH_3)_3$), 0.96 (t, $^3J = 7.0$ Hz, 3H, OCH_2CH_3), 1.53, 2.04 (each s each 6H, CH_3), 2.13, 2.18 (each s, each 12H, CH_3), 2.71 (s, 1H, B_3CH), 3.51 (q, $^3J = 7.0$ Hz, 2H, OCH_2CH_3), 6.79 (s, 1H, *p*-H), 6.91 (s, 2H, *p*-H); ^{13}C-NMR: $\delta = 4.5$, 5.9 (each q, each 3C, $Si(CH_3)_3$), 16.3 (q, 1C, $BOCH_2CH_3$), 17.9, 19.3 (each q, each 2C, CH_3), 19.7, 22.0 (2q, each 4C, CH_3), 62.1 (t, 1C, $BOCH_2CH_3$), 69.4 (s, 1C, Si_2C), 71.3 (d, $^1J_{C,H} = 100.4$ Hz, 1C, B_3C), 130.2 (d, 1C, *p*-C), 130.5 (d, 2C, *p*-C), 132.8, 133.2 (each s, each 4C, *o*- and *p*-C), 132.6, 133.4 (each s, each 2C, *o*- and *p*-C), 143.6 (br. s, 1C, *i*-C), 144.2 (br. s, 2C, *i*-C); ^{11}B-NMR: $\delta = 51$ (1B, CBO, $\nu_{1/2} = 1700$ Hz), 77 (2B, BC_2, $\nu_{1/2} = 2213$ Hz)

The B-C double bond in **5b** (137 pm[9]) is shorter than in amino(methylene)boranes **3** (139[3c]–142[3b] pm) and of similar length to that calculated for the unsubstituted methyleneborane **8** (138 pm, 6-31 G*).[10] The B-C distances calculated (6-31 G*) for the unsubstituted boranediyl-1,3-diboretane **5c** agree excellently with those in **5b** (Table 2).



8 **5c** **9**

Dur = 2,3,5,6-Me_4C_6H

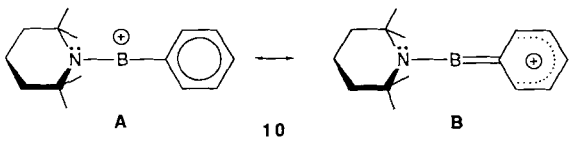


Table 2. Experimental (**5b**, cf. Fig. 1a) and calculated (6-31 G*) (**5c**) C–B distances [pm] in boranediyl-1,3-diboretanes.

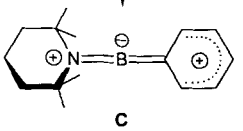
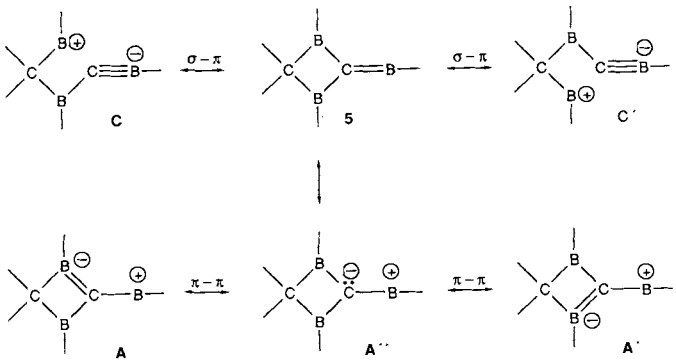
	5b (exp.)	**5c** (calcd)
C2–B5	137.4(8)	137.3
C2–B1	155.7(8)	155.9
C2–B3	156.6(8)	155.9
C4–B1	160.3(8)	159.9
C4–B3	159.8(8)	159.9



From the similarity in the lengths of the B-C double bonds in **5b,c** and **8** it may not be concluded however that the boron atoms of the four-membered ring have no significant influence on the electronic structure of the B-C double bond. In **5a,b** these boron atoms are shielded by $\Delta\delta \approx 15$ compared to the corresponding ones in **9** (cf. Table 1), i.e. they carry negative π-charge corresponding to the resonance formula **5a,b A**. In the case of **5c** a Mulliken population analysis gives π-charges of −0.173 each on the ring boron atoms B1 and B3, −0.159 on C2 and +0.504 on the exocyclic boron atom B5.[11]

A **5 a,b** **B**



A **10** **B**

C

The positive charge on B5 leads to delocalization of the π electrons of the aryl ring on B5 corresponding to the resonance formula **5a,b B**; this manifests itself in deshielding of the *ortho* and *para* C atoms of $\Delta\delta = 6-9$ compared to the corresponding atoms in aryl rings on B1 and B3. In the amido(phenyl)boron cation **10**[13] the corresponding delocalization (**B**) leads to deshielding of the *ortho* and *para* C atoms of $\Delta\delta = 9-14$.

The boron p-orbital in the plane of the aryl ring is, in the case of **10**, filled up by delocalization of the electron pair on the nitrogen, resulting in a normal allene geometry with *orthogonal* π systems and substituent planes. In contrast **5b** has a *planar*[14] heteroallene framework (anti-van't-Hoff geometry[15]). In **5** the electron deficiency on B5 in the plane of the aryl ring is stabilized by hyperconjugation[16] with the C2–B σ bonds of the four-membered ring corresponding to the resonance formulas **5C,C'**.

C **5** **C'**

A **A''** **A'**

Mulliken population analysis of **5c** indicates a π charge of −0.194 in the p-orbital on B5 in the B_2CB plane. A comparison of the resonance formulas **5C,C'** (σ-π delocalization) and **5A,A'** (π–π delocalization) shows that the two effects compensate themselves regarding bond strengthening and weakening if they are comparatively strong. In addition, the formal charges arising from opposing delocalizations, are then removed.

The significantly longer C2–B1 and C2–B3 bonds in **5b** (155.7, 156.6 pm) compared to those in **7b** (152.2, 150.7 pm) inspite of similar π–π delocalization in **5** and **7**,[17] indicate C–B hyperconjugation corresponding to **5C,C'**.

[8] X-ray structure analysis of **5b**: $C_{38}H_{57}B_3Si_2$, space group *Pbca*, $Z = 8$, $a = 930.3(2)$, $b = 3925.0(3)$, $c = 2038.4(4)$. 3278 unique reflections with $F_0 > 3\sigma$ measured on a four-circle diffractometer (CAD4, Enraf Nonius) with $Cu_{K\alpha}$ radiation at −90 °C; no absorption correction ($\mu = 9.5\ cm^{-1}$),

methyl groups refined as rigid groups using isotropic temperature factors groupwise for the H atoms. Anisotropic temperature factors were used for all other atoms. 460 parameters, $R = 0.0704$, $wR = 0.0558$ (weighting $w = 1/\sigma^2(F_o)$). **7b**: $C_{42}H_{67}B_3Si_2O$, space group $P2_1/c$, $Z = 4$, $a = 2226.8(11)$, $b = 913.7(2)$, $c = 2040.4(8)$ pm, $\beta = 92.59(3)°$. 4131 unique reflections with $F_o > 3\sigma$ measured corresponding to **5b**, no absorption correction ($\mu = 9.1\ cm^{-1}$), methyl groups refined as rigid groups using isotropic temperature factors groupwise for the H atoms. Anisotropic temperature factors used for all other atoms. Refinement in a block diagonal matrix method with threefold blocking. 519 parameters, $R = 0.0699$, $wR = 0.0644$ (weighting $w = 1/\sigma^2(F_o)$). – The moderate reliability factors for **5b** and **7b** may be due to numerous strongly vibrating methyl groups. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energy, Physik, Mathematik, GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-53790, the names of the authors, and the journal citation.

[9] The length of the B-C double bond in **7b** (143 pm) is comparable with that in $(mesityl)_2B^{\ominus}=CH_2$ (144 pm; M. M. Olmstead, P. P. Power, K. J. Weese, *J. Am. Chem. Soc. 109* (1987) 2541) which also has a tricoordinated boron atom.

[10] P. von R. Schleyer, D. Kost, *J. Am. Chem. Soc. 110* (1988) 2105, and references cited therein.

[11] π-Charges of −0.18 and −0.22 on the C atom and of +0.18 and +0.22 on the B atom respectively have been calculated for **8** [12, 2c]; that is, the different electronegativities of boron (2.0) and carbon (2.5) alone lead to far less polarity of the π-bond part of the B-C double bond. 3-21 G calculations show that **5c** is a stronger Lewis acid than **8**: the bonding energy of H_2O to **5c** is about 3 kcal mol^{-1} greater than that of H_2O to **8**, and the B–O distance in the H_2O-adduct of **5c** (158.7 pm) is distinctly shorter than in the H_2O adduct of **8** (162.6 pm).

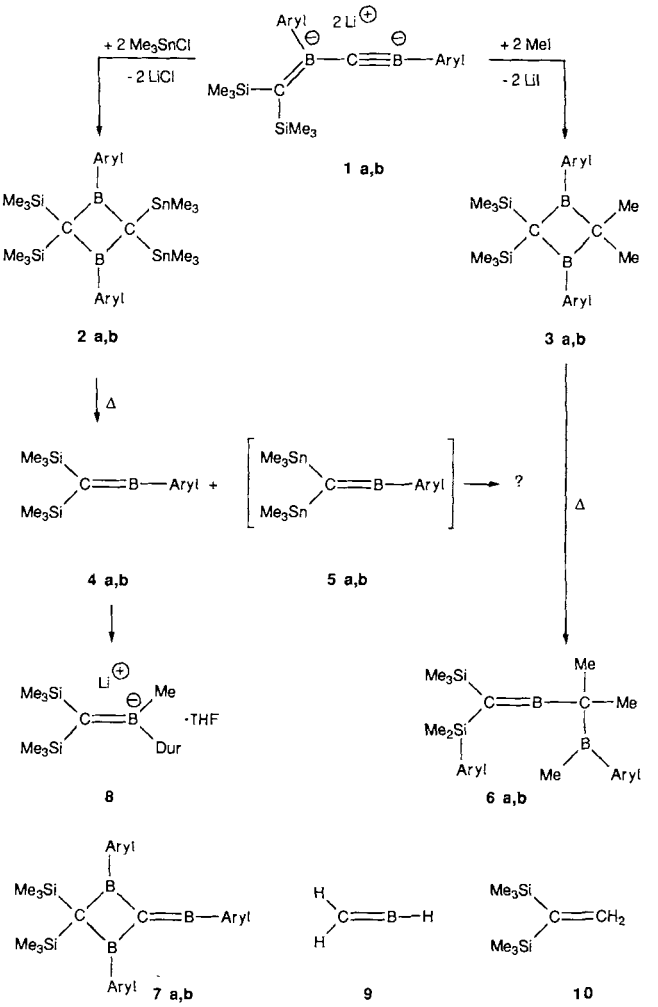
[12] B. T. Luke, J. A. Pople, M.-B. Krogh-Jespersen, Y. Apeloig, M. Karni, J. Chandrasekhar, P. von R. Schleyer, *J. Am. Chem. Soc. 108* (1986) 270.

[13] H. Nöth, R. Staudigl, H. U. Wagner, *Inorg. Chem. 21* (1982) 706.

[14] In the crystal of **5b** the duryl group on the dicoordinated boron atom B5 lies almost in the B1, C2, B3 plane (interplanar angle 12.7(4)°); the 1,3-diboretane rings are folded at the B···B axis through 23.2(6)° (**5b**) and 21.8(5)° (**7b**), respectively.

[15] K. Krogh-Jespersen, D. Cremer, D. Poppinger, J. A. Pople, P. von R. Schleyer, J. Chandrasekhar, *J. Am. Chem. Soc. 101* (1979) 4843.

[16] *Nöth* et al. [13] have already drawn attention to the importance of C-C and C-H hyperconjugation in diphenylboron cation and in amido(organo)boron cations. C-B hyperconjugation is considerably more effective owing to the lower electronegativity of boron, particularly of boron with negative π charge: cf. A. Höfner, B. Ziegler, W. Massa, A. Berndt, *Angew. Chem. 101* (1989) 188; *Angew. Chem. Int. Ed. Engl. 28* (1989) 186 and references cited therein.



[17] Similar π–π delocalization in **5** and **7** follows from the similarity of the ^{11}B shifts of B1 and B3 in **5b** (61) and **6b** (58) and the almost identical ^{13}C NMR data of **6b** and **7b**, which justify assumption of a similar electronic structure for **7b** as for **6b**. In the case of **7b**, $\delta(^{11}B)$ is not experimentally accessible. Attempts to determine the crystal structure of **6b** have so far been unsuccessful.

Thermal Cleavage and Isomerization of 1,3-Diboretanes to Stable Methyleneboranes**

By *Monika Pilz, Matthias Stadler, Ralf Hunold, Jürgen Allwohn, Werner Massa,* and *Armin Berndt**

The dilithium compounds **1a, b**[1] react with two equivalents of trimethyltin chloride and with methyl iodide to give the 1,3-diboretanes **2a, b** and **3a, b** respectively. Upon melting (148 and 177 °C, respectively) **2a, b** furnish the readily volatile methyleneboranes **4a, b**, which can be separated by condensation (yield ca. 35%) from mixtures of predominantly higher boiling products of still unknown structure. We presume that the diboretanes **2a, b** are converted via a cycloreversion[2] into **4a, b** and **5a, b** and that the latter react further to secondary products. Upon melting (157 and 152 °C, resp.) the 1,3-diboretanes **3a, b** are cleanly transformed into the methyleneboranes **6a, b**; the four-membered ring is opened at a bond to the silyl-substituted C atom, a methyl group migrates from silicon to boron, and an aryl group migrates from the other boron atom to the silicon atom.

In contrast to **7a, b**,[11] **4a, b** add neither diethyl ether nor THF, but, like **7a, b**, form deep-red adducts with 4-*tert*-butylpyridine.[3] Reaction of **4b** with methyllithium leads to formation of the duryl(methyl)methyleneborate **8**.

a: Aryl = 2,4,6-$Me_3C_6H_2$ (= Mes); **b**: Aryl = 2,3,5,6-Me_4C_6H (= Dur)

The structures of **2–4, 6** and **8** are consistent with the ^1H-, ^{13}C- and ^{11}B-NMR spectra (Table 1); the structure of **6b** is confirmed by an X-ray structure analysis[4] (Fig. 1).

The C1–B1–C2 angle is 177°, the sum of the bond angles at C1 360°; that is, B1 is practically linear coordinated, and C1 trigonal-planar coordinated. The boron-carbon double bond in **6b** (136 pm) is slightly shorter than that found in the boranediyl-1,3-diboretane **7b** (137 pm),[11] and that calculated for the unsubstituted methyleneborane **9** (138 pm, 6-31 G*).[5]

Table 1. Some physical data of the compounds **2**–**4** and **6** and **8**. Spectra in $CDCl_3$, **8** in [D_8]THF.

2a: pale yellow crystals, m.p. 148 °C (decomp.), yield 93%; ^{1}H-NMR: $\delta = 0.04, 0.06$ (each s, each 18 H, $Si(CH_3)_3$ and $Sn(CH_3)_3$), 2.26 (s, 6 H, *p*-CH_3), 2.46 (s, 12 H, *o*-CH_3), 6.76 (s, 4 H, *m*-H); ^{13}C-NMR: $\delta = -0.4$ (6 C, $Sn(CH_3)_3$), 6.7 (6 C, $Si(CH_3)_3$), 21.2 (2 C, *p*-CH_3), 25.6 (4 C, *o*-CH_3), 46.6, 49.0 (each br., each 1 C, CB_2), 129.0 (4 C, *m*-C), 138.3 (2 C, *p*-C), 138.9 (4 C, *o*-C), 142.2 (br., 2 C, *i*-C); ^{11}B-NMR: $\delta = 82$ ($\nu_{1/2} = 1400$ Hz)

2b: colorless crystals, m.p. 177 °C (decomp.), yield 98%; ^{1}H-NMR: $\delta = 0.00$, 0.55 (each s, each 18 H, $Si(CH_3)_3$ and $Sn(CH_3)_3$), 2.18, 2.37 (each s, each 12 H, *o*- and *m*-CH_3), 6.92 (s, 2 H, *p*-H); ^{13}C-NMR: $\delta = -0.5$ (q, 6 C, $Sn(CH_3)_3$), 6.3 (q, 6 C, $Si(CH_3)_3$), 20.0, 23.3 (each q, each 4 C, *o*- and *m*-CH_3), 47.5, 49.9 (each br. s, each 1 C, CB_2), 131.7 (d, 2 C, *p*-C), 133.6, 134.4 (each s, each 4 C, *o*- and *m*-C), 145.5 (br. s, 2 C, *i*-C); ^{11}B-NMR: $\delta = 81$ ($\nu_{1/2} = 1445$ Hz)

3a: bright-yellow crystals, m.p. 157 °C (decomp.), yield 89%; ^{1}H-NMR: $\delta = 0.19$ (s, 18 H, $Si(CH_3)_3$), 1.33 (s, 6 H, $C(CH_3)_2$), 2.28 (s, 6 H, *p*-CH_3), 2.37 (s, 12 H, *o*-CH_3), 6.80 (s, 4 H, *m*-H); ^{13}C-NMR: $\delta = 6.5$ (6 C, $Si(CH_3)_3$), 21.0 (2 C, *p*-CH_3), 24.5 (4 C, *o*-CH_3), 25.9 (2 C, $C(CH_3)_2$), 53.4, 64.1 (each br., each 1 C, CB_2), 128.0 (4 C, *m*-C), 137.9 (2 C, *p*-C), 138.7 (br., 2 C, *i*-C), 139.7 (4 C, *o*-C); ^{11}B-NMR: $\delta = 76$ ($\nu_{1/2} = 1000$ Hz)

3b: colorless crystals, m.p. 152 °C (decomp.), yield: NMR-spectroscopically quantitative; ^{1}H-NMR: $\delta = 0.31$ (s, 18 H, $Si(CH_3)_3$), 1.47 (s, 6 H, $C(CH_3)_2$), 2.33, 2.38 (each s, each 12 H, *o*- and *m*-CH_3), 7.09 (s, 2 H, *p*-H); ^{13}C-NMR: $\delta = 6.6$ (q, 6 C, $Si(CH_3)_3$), 19.8, 21.9 (each q, each 4 C, *o*- and *m*-CH_3), 25.8 (q, 2 C, $C(CH_3)_2$), 52.1, 64.4 (each br. s, each 1 C, CB_2), 131.7 (d, 2 C, *p*-C), 133.3, 135.0 (each s, each 4 C, *o*- and *m*-C), 142.7 (br. s, 2 C, *i*-C); ^{11}B-NMR: $\delta = 77$ ($\nu_{1/2} = 1360$ Hz)

4a: bright-yellow liquid, b.p. 60 °C/5×10^{-3} torr, yield 35%; ^{1}H-NMR: $\delta = 0.40$ (s, 18 H, $Si(CH_3)_3$), 2.61 (s, 3 H, *p*-CH_3), 2.83 (s, 6 H, *o*-CH_3), 7.11 (s, 2 H, *m*-H); ^{13}C-NMR: $\delta = 4.0$ (q, 6 C, $Si(CH_3)_3$), 21.8 (q, 1 C, *p*-CH_3), 23.3 (q, 2 C, *o*-CH_3), 61.5 (br. s, 1 C, Si_2CB), 123.7 (br. s, 1 C, *i*-C), 127.6 (d, 2 C, *m*-C), 144.3 (s, 1 C, *p*-C), 148.8 (s, 2 C, *o*-C); ^{11}B-NMR: $\delta = 63$ ($\nu_{1/2} = 1020$ Hz); IR (film): $\tilde{\nu}$ (C=^{11}B, C=^{10}B) = 1639, 1681 cm^{-1}

4b: bright-yellow liquid, b.p. 76 °C/5×10^{-4} torr, yield 42%; ^{1}H-NMR: $\delta = 0.33$ (s, 18 H, $Si(CH_3)_3$), 2.35, 2.75 (each s, each 6 H, *o*- and *m*-CH_3), 7.26 (s, 1 H, *p*-H); ^{13}C-NMR: $\delta = 4.0$ (q, 6 C, $Si(CH_3)_3$), 19.6, 20.8 (each q, each 2 C, *o*- and *m*-CH_3), 60.9 (br. s, 1 C, Si_2CB), 127.5 (br. s, 1 C, *i*-C), 133.7, 144.2 (each s, each 2 C, *o*- and *m*-C), 137.0 (d, 1 C, *p*-C); ^{11}B-NMR: $\delta = 63$ ($\nu_{1/2} = 1274$ Hz); IR (film): $\tilde{\nu}$ (C=^{11}B, C=^{10}B) = 1638, 1680 cm^{-1}

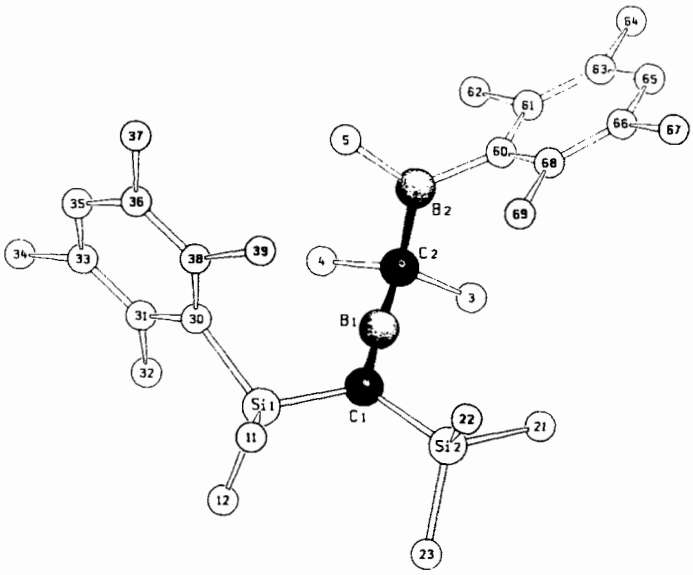
6a: pale yellow oil, yield: NMR-spectroscopically ca. 95%; ^{1}H-NMR: $\delta = 0.23$ (s, 9 H, $Si(CH_3)_3$), 0.69 (s, 6 H, $Si(CH_3)_2$), 1.17 (s, 3 H, B-CH_3), 1.22 (s, 6 H, $C(CH_3)_2$), 2.39, 2.41 (each s, each 3 H, *p*-CH_3), 2.27, 2.72 (each s, each 6 H, *o*-CH_3), 6.92, 6.93 (each s, each 2 H, *m*-H); ^{13}C-NMR: $\delta = 4.1$ (q, 3 C, $Si(CH_3)_3$), 8.6 (q, 2 C, $Si(CH_3)_2$), 14.4 (br. q, 1 C, B-CH_3), 20.9 (q, 1 C, *p*-CH_3), 21.0 (q, 3 C, 2 CH_3 and *p*-CH_3), 22.5, 25.1 (each q, each 2 C, CH_3), 29.1 (br. s, 1 C, $C(CH_3)_2$), 55.4 (br. s, 1 C, Si_2CB), 127.3, 129.3 (each d, each 2 C, *m*-C), 134.3 (s, 2 C, *o*-C), 135.4 (s, 1 C, *i*-C of Si-Mes), 136.5, 138.2 (each s, each 1 C, *p*-C), 143.8 (br. s, 1 C, *i*-C of B-Mes), 144.1 (s, 2 C, *o*-C); ^{11}B-NMR (toluene, 90 °C): $\delta = 87, 69$ ($\nu_{1/2} = 500$ and 550 Hz)

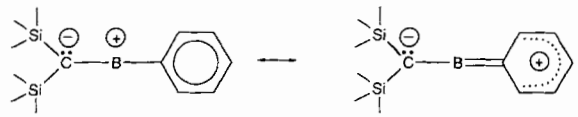
6b: colorless crystals, m.p. 69 °C, yield: NMR-spectroscopically quantitative; ^{1}H-NMR: $\delta = 0.15$ (s, 9 H, $Si(CH_3)_3$), 0.58 (s, 6 H, $Si(CH_3)_2$), 0.99 (s, 3 H, B-CH_3), 1.05 (s, 6 H, $C(CH_3)_2$), 2.02, 2.21, 2.23, 2.49 (each s, each 6 H, *o*- and *m*-CH_3), 6.89, 6.98 (each s, each 1 H, *p*-H); ^{13}C-NMR: $\delta = 4.2$ (q, 3 C, $Si(CH_3)_3$), 9.1 (q, 2 C, $Si(CH_3)_2$), 14.2 (br. q, 1 C, B-CH_3), 19.1, 20.1, 20.6, 21.5 (each q, each 2 C, *o*- and *m*-CH_3), 21.1 (q, 2 C, $C(CH_3)_2$), 28.9 (br. s, 1 C, $C(CH_3)_2$), 55.4 (br. s, 1 C, Si_2CB), 130.3, 132.6 (each d, each 1 C, *p*-C), 129.9, 133.4, 136.7, 140.1 (each s, each 2 C, *o*- and *m*-C), 140.2 (s, 1 C, *i*-C of Si-Dur), 147.2 (br. s, 1 C, *i*-C of B-Dur); ^{11}B-NMR (toluene, 90 °C): $\delta = 86, 69$ ($\nu_{1/2} = 600$ and 700 Hz)

8: ^{1}H-NMR: $\delta = -0.52, 0.00$ (each s, each 9 H, $Si(CH_3)_3$), 0.31 (s, 3 H, B-CH_3), 1.74 (t, 4 H, CH_2 of THF), 2.00, 2.14 (each s, each 6 H, *o*- and *m*-CH_3), 3.59 (t, 4 H, OCH_2 of THF), 6.32 (s, 1 H, *p*-H); ^{13}C-NMR (−40 °C): $\delta = 6.5$, 7.6 (each q, each 3 C, $Si(CH_3)_3$), 13.7 (br. q, 1 C, B-CH_3), 20.1, 20.8 (each q, each 2 C, *o*- and *m*-CH_3), 26.3 (t, 2 C, CH_2 of THF), 65.3 (br. s, 1 C, Si_2CB), 68.3 (t, 2 C, OCH_2 of THF), 126.3 (d, 1 C, *p*-C), 130.3, 132.8 (each s, each 2 C, *o*- and *m*-C), 163.3 (br. s, 1 C, *i*-C); ^{11}B-NMR: $\delta = 49$ ($\nu_{1/2} = 510$ Hz)

The similarity of **4a, b** and **6a, b**[6] is immediately apparent in the chemical shifts of the atoms of the B–C double bonds (see also Table 1):

	4a	**4b**	**6a**	**6b**
$\delta(^{13}C)$	61.5	60.9	55.4	55.4
$\delta(^{11}B)$	63	63	69	69





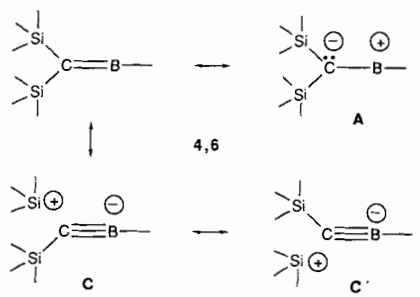


Fig. 1. Schakal drawing of the molecular structure of **6b** in the crystal. Important bond lengths [pm] and angles [°]: C1–B1 136.3(9), C2–B1 156(1), C2–B2 158.7(8), Si1–C1 182.8(6), Si2–C1 187.6(6), Si1–C30 189.6(6), B2–C60 157.7(9), B2–C5 155(1); C1–B1–C2 176.6(7), B1–C2–B2 106.8(5), Si1–C1–Si2 122.0(3), Si1–C1–B1 120.1(5), Si2–C1–B1 117.9(5), C2–B2–C60 121.6(6); B1–C2–B2–C60 110.2(7), C31–C30–Si1–C1 106.3(5), C61–C60–B2–C2 84.6(7), B1–C1–Si1–C30 −22.5(5).

The C atoms of the B–C double bonds are, for tricoordinated C-atoms, very strongly shielded (by $\Delta\delta = 93-98$) compared to the C atom bound to two trimethylsilyl groups in **10** ($\delta(^{13}C) = 153.5$).[7] From their chemical shifts, π charges of ca. −0.5 can be estimated for these C-atoms using the modified Spieseke-Schneider relationship.[8] The corresponding positive π charge (resonance formula **A**), on boron leads in **4a, b** to significant delocalization of the π-electrons of the aryl rings (resonance formula **B**). This is shown by the similar deshielding of their *ortho*- and *para*-C atoms as in **7a, b**.[1]

4 a,b

The polarity of the B–C π bond, which is due to different electronegativity of boron (2.0) and carbon (2.5), is considerably smaller: For **9**, π charges of ca. −0.2 at the C atom and ca. +0.2 at the B atom were calculated.[9, 10] The substantially stronger polarity of the B–C π bond in **4** and **6** can easily be explained by the silyl substituents. They can stabilize negative charge in the α-position[11] and empty orbitals in the β-position (β-Si-effect)[12] – usually of carbenium

ions, here on a partly positive boron atom – by C–Si hyperconjugation (resonance formulas **C, C'**).[13]

We consider the C–Si hyperconjugation to be the main reason for the B–C double bond in **6b** being very short in spite of weaker π-bonding (resonance formula A).[15] The electronic stabilization of the B–C double bond by the silyl groups might also contribute to the easy formation of **4** and **6**. In addition, the steric requirements of the silyl substituents contribute decisively to the kinetic stability of these methyleneboranes.

Clark, A. J. Kos, G. W. Spitznagel, C. Rohde, D. Arad, K. N. Houk, N. G. Rondan, *ibid. 106* (1984) 6467.
[12] For the stabilization of vinyl cations isoelectronic with methyleneboranes by β-silyl substituents see: S. G. Wierschke, J. Chandrasekhar, W. L. Jorgensen, *J. Am. Chem. Soc. 107* (1985) 1496.
[13] The geometric requirements for C–Si hyperconjugation [14] are optimal in bis(silyl)methyleneboranes such as **4** and **6** since an empty p-orbital on the boron lies in the plane of the C–Si σ-bonds. Furthermore, greater overlap is facilitated by the short B=C distance. The σ-π interaction is energetically favored by the positivization of the boron atom, i.e. the increase in its electronegativity (lowering of the LUMOs).

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Coordination Compounds en gros and en détail

Comprehensive Coordination Chemistry. The Synthesis, Reactions, Properties and Applications of Coordination Compounds. (In 7 volumes). Edited by *G. Wilkinson, R. Gillard* and *J. A. McCleverty*. Pergamon Press, Oxford 1987. Approx. 7000 pp. in total, hard cover, $ 2450.00.– ISBN 0-08-026232-5

Volume 1: Theory and Background

A total of 18 authors have here set themselves the task of compiling the introductory volume of this new work of reference. Its 17 chapters aim to provide the intending user of "Comprehensive Coordination Chemistry" with a summary of those general aspects of chemistry that are relevant to coordination compounds. The volume concludes with a subject index and a formula index.

The chapters that have been chosen for inclusion in this introductory volume can be divided into several subject groups. Chapters 1.1 and 1.2 are historical reviews of the development of coordination chemistry. The period up to 1930 is dealt with by *G. B. Kauffman*, who is well known for his reviews and essays on this subject, while the period from 1930 on is covered by an outstanding coordination chemist, *J. C. Bailar, Jr.*, who has himself made important contributions to the development of the field. These two introductory chapters undoubtedly provide useful background knowledge on this segment of inorganic chemistry, though Chapter 1.2 can highlight only the most important trends and insights. The custom of starting a major collected work with the historical development of the field of study, describing not only

its chronology but also the scientists involved and their individual contributions, is one that is worth preserving. Other chapters too in this volume are very impressive. *D. L. Kepert*'s treatment of coordination numbers and geometries (Chapter 2), in which complexes with coordination numbers from 5 to 12 are discussed on the basis of the VSEPR principle, is detailed, sound and well illustrated with figures, its only omission being the absence of alternative descriptions of coordination polyhedra and their polytopic rearrangements (e.g. those based on quantum mechanics). Chapter 3 is a lesson by *T. B. Sloan* on the nomenclature of coordination compounds; the necessity for this and the content of the article are beyond question. In Chapter 4 *I. G. Dance* provides a very useful classification of metal cluster compounds and clathrates in list form (with clear structural formulas which are a welcome aid to the reader). As is always the case with undertakings of this sort, the question arises here (as also in other chapters) of how up-to-date the information can be made. Published work up to 1983 is taken into account, but quite a lot has happened in the field of clusters in the intervening years. A few of the sections in this chapter, such as those on bonding (where only clusters of the cubane type are covered), or on synthetic methods (one and a half pages of text), are too rudimentary. In Chapter 5, on isomerism in coordination complexes, the ground covered by *J. M. Harrowfield* and *S. B. Wild* is essentially the same as is usually treated in inorganic chemistry textbooks or elementary lecture courses on complex chemistry, apart from unnecessarily introducing the newly coined words "allogonism" and "allogone" in connection with geometrical isomers, failing to mention the "bond-stretch" isomerism whose existence was recently established, and the inclusion of some material which overlaps with that in Chapter 2. Ligand field theory and its modifications, and the "angular overlap" model, which are treated in Chapter 6 (*B. N. Figgis*), are undoubtedly an important part of the theoretical background of coordination chemistry, but after looking through this chapter one is left with doubts about its usefulness. These topics are treated in several excellent and considerably more detailed monographs and textbooks (not least those by the same author). Many of the points are merely touched on briefly (e.g. "Excited States and Photochemistry" is given only one and a half lines of text with four literature references), and the omission of other electronic structural theories of coordination compounds from this chapter, the only one devoted to bonding theory, gives a somewhat unbalanced picture of the quantum chemistry of inorganic complexes.

A further five chapters deal with the general theme "Reaction Mechanisms". Chapters 7.1 on substitutions (*M. L. Tobe*), 7.2 on electron transfer reactions (*T. J. Meyer* and *H. Taube*), and 7.3 on photochemical processes (*C. Kutal* and *A. W. Adamson*), are all written by authors whose names are inseparable from the respective chapter titles. They are impressive, especially that which has the doyen of this subject, *Taube*, as one of its authors. The treatment of photochemical processes includes more than 200 literature references; newcomers to the research topic will note this with considerable satisfaction, as there is scarcely one useful monograph on this topic, and even less in the way of textbooks. Chapter 4, in which *D. St. C. Black* fills the greater part of the 44 pages with formula schemes, mainly describing the reactions of metal-bonded chelate ligands, is followed by a short chapter by *H. E. LeMay, Jr.* on solid state reactions of coordination compounds, which reveals how little knowledge exists about this area. Next follow three very brief reviews of electrochemical aspects of coordination chemistry. Although it is true that brevity can often be the soul of wit, it seems odd that the first of these three chapters (with its very general sounding title "Electrochemistry and Coordination Chemistry") by *C. J. Pickett* contains only material which could easily have been integrated into the two following chapters (by *D. H. Vaughan* and *C. J. Pickett* respectively). These latter two are likewise not very informative, and could have been combined together. Following Chapter 9 by *D. H. Vaughan*, from which one learns something about solvent effects on the rates of reactions, redox potentials and equilibrium constants of coordination compounds, the final chapter by *H. M. N. H. Irving* reviews the important applications of coordination compounds in analytical chemistry. This article again is mainly useful for its collection of relevant literature references, which gives the non-specialist easy access to appropriate background reading.

The overall impression from this first volume of "Comprehensive Coordination Chemistry" is one of rather wide variations in the quality, quantity, usefulness and importance of the individual chapters. Excellent surveys appear alongside other chapters that could with equal benefit be replaced by lists of relevant review articles. It would perhaps be not such an outrageous idea if multi-volume works of this sort were to have, instead of a whole volume devoted to "Theory and Background", just one chapter covering as many as possible of the most up-to-date relevant reviews and monographs, even though the saving of one volume would probably not lead to a significant reduction in the price of the whole set.

Volume 2: Ligands

In multi-volume works it is a truism that a systematic and well-organized treatment of the subject makes the collection attractive, and reduces the gaps left for other authors and publishers to fill; in practice, however, a successful recipe is not found in every case. Comparing the present work with "Comprehensive Organometallic Chemistry"[*] it emerges that significant progress has been made in this respect. Volume 2 (together with Vol. 6) gives probably one of the most obvious indications of this.

In the past the attitudes of metal complex chemists and organometallic chemists have been strongly metal-orientated. In contrast, there is now a trend towards thinking more in terms of ligands. Which ligand should one choose in order to make a complex more stable or more labile? Which ligand offers the best possibilities as an analytical probe? How can molecules in the coordination sphere be switched around? This volume directly or indirectly answers many of these and similar questions. For this reason the collection will become an important standard work, not only for organometallic chemists but also for organic chemists, biochemists and biologists. There are, of course, too many instances of overlapping in content between this and the other volumes, and this must ultimately have an effect on the total price of the work. However, the volume on "Ligands" is so useful that such a consideration will not prevent it being bought.

The ligands are grouped according to the obvious classification based on donor atoms. Thus there are eight chapters on nitrogen-containing ligands, one on ligands containing elements of Main Group 5, with the greatest emphasis on phosphorus, nine on oxygen-containing ligands, six on sulfur-containing ligands, and one each on ligands in which the

[*] Cf. *Angew. Chem. 95* (1983) 819; *Angew. Chem. Int. Ed. Engl. 22* (1983) 797.

donor atom is selenium, tellurium, a halogen or hydrogen. A further eight chapters deal with ligands having two or more different donor atoms. Especially noteworthy is the extensive treatment of macrocycles with nitrogen and oxygen donor centers (sulfur analogs of these are listed only briefly under thioethers). Next a separate chapter is devoted to ligands of natural origin (covered only very briefly, however, omitting alkaloids for example). Further chapters treat cyanides and fulminates, then ligands containing silicon, germanium, tin and lead, and lastly mercury as a ligand; however, the analogous copper ligands and the gold ligands which have been particularly thoroughly studied are unaccountably omitted.

In more than a thousand pages many well-known experts have here applied their best efforts to bringing order to this many-faceted subject. The result stands up to scrutiny; it is a mine of information for all chemists, from the student to the committed researcher or the industrial chemist. An "exhaustive" treatment is, of course, something aimed for but never fully attained. Some readers will find that "their" ligands are not covered or are not given due attention. Those that may be missed include the nitrido ligand, the intentionally (but unjustifiably) omitted dinitrogen, thiazyl fluoride and thioformaldehyde ligands, and the trialkylamines, especially with regard to their interaction with alkali metal ions. Many of the chapters contain useful directions concerning nomenclature. Regrettably, though, hardly any of the chapters give an indication of the date up to which the literature has been scanned.

Unfortunately the editors have missed an important opportunity by failing to impose uniformity in the manner whereby the properties and bonding capabilities of the ligands are presented and discussed; this would have made comparisons easier, an important matter from the reader's standpoint. The only chapter sub-sections in which this has been done are 13.2 to 13.4 (N-donor ligands), 15.2 (on the ligands O_2, $O_2^{\ominus}$ and $O_2^{2\ominus}$), 16.1 to 16.3 (S-donor ligands) and 19 (hydrogen and hydrides); the discussion on the bonding of ligands containing phosphorus and its homologs is especially worth mentioning. In many of the articles the authors have been content to include sub-sections with titles such as "Properties", "Structure", "Spectroscopic Data" or "Types of Coordination". However, to describe the ligands the authors use many different concepts or terms: the coordination number, "soft" or "hard", a good or poor donor or acceptor, the position in the spectroscopic series; information on isoelectronic ligands is occasionally given. The energies of the HOMOs or LUMOs are missing, as are their relative sizes.

At the end of the volume there is a subject index (37 pages) and a formula index (75 pages). Unfortunately the latter is only arranged according to the metal atoms, with the result that a ligand can be located from its empirical formula only with difficulty.

Frank H. Köhler

Volume 3: Main Group and Early Transition Elements

Volume 3, with 25 chapters consisting of 1400 pages, describes the coordination chemistry of the Main Group elements and the "early transition elements". The article on the coordination chemistry of phosphorus could not be completed in time, and will appear later in the journal *Polyhedron* (note also "Technetium" in Volume 4). All the chapters (except that on molybdenum) have a similar construction, being arranged according to the various ligands for a given central atom. This results in a consistency within the volume which is by no means always found in multi-author reference works of this type. Organometallic/metalloid compounds have deliberately been excluded, with very few exceptions, a fact which is not immediately apparent from the title of the reference work, but is explained in the preface. Readers are there referred to the sister series "Comprehensive Organometallic Chemistry" for this class of compounds.

The first 300 pages are devoted to the coordination chemistry of the Main Group elements. The contribution by *D. E. Fenton* on the coordination behavior of the alkali and alkaline earth metals (70 pp., with 598 references extending up to 1985) has turned out very successfully, with the main emphasis, as expected, on the complexation of these metals with polydentate and macrocyclic ligands (crown ethers, cryptates, porphyrins etc.). The resulting structures are shown very clearly, either schematically or as pictorial molecular diagrams. This feature proves especially useful in the final section of the chapter (10 pp.), which deals with naturally occurring ionophores as ligands. The currently topical question of what factors influence the selectivity and the stability of the complexes is discussed in detail.

The chapter on the coordination chemistry of boron by *J. Emri* and *B. Györi* (20 pp., 172 references extending up to 1984) treats the complexes, classified according to ligands, in text linked to tables, each with a separate bibliography; thus the reader has no difficulty in quickly finding the required reference. This useful arrangement is also found in the other chapters.

The following chapters by *M. J. Taylor* on the coordination chemistry of aluminum and gallium (37 pp., 690 references up to 1985) and by *D. G. Tuck* dealing with indium and thallium (22 pp., 438 references up to 1983) are packed with much information; however, as might be guessed from the small numbers of pages, the form of presentation is less user-friendly in this case. Complicated structures are merely described rather than drawn, and the reader is hurried from one heading to the next.

The chapter by *P. G. Harrison* on the coordination chemistry of silicon, germanium, tin and lead (40 pp., 663 references up to 1985) reviews a considerable amount of well-established knowledge, but also includes a more topical section on "Multiple Bonding Involving Silicon, Germanium and Tin". Thus the chapter does not completely exclude the occurrence of carbon itself as a "ligand". Several pages are also devoted to the cyclopentadiene ligand and to the related carbaboranes. The presentation as a whole lacks clarity, and cannot be said to be satisfactory. Moreover, many aspects of the chemistry of these elements cannot be regarded as "coordination chemistry" without straining the definition.

The chapter by *C. A. McAuliffe* on the coordination chemistry of arsenic, antimony and bismuth consists of 56 pages, and reviews 272 publications (extending up to 1985) in a clear comprehensible style. The three elements are treated separately. Although this procedure facilitates searching for specific compounds, comparisons within the triad of elements, which can often be very useful, are thereby made more difficult; in a "parallel" method of treatment such comparisons emerge naturally. However, the easy style makes refreshing reading, and valuable glimpses of matters of current controversy are included.

The appropriately brief chapters on the coordination chemistry of sulfur, selenium, tellurium and polonium (*F. J. Berry*, 8 pp., 85 references up to 1983), and of the halogens and inert gases (*A. J. Edwards*, 10 pp., 102 references up to

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0606-0788 $ 02.50/0

1984), are followed by chapters on the "Early Transition Metals" (i.e. titanium to chromium, the lanthanides and the actinides). A separate chapter is devoted to the iso- and heteropolyanions (*M. T. Pope*, 25 pp., 140 references up to 1985). The coordination chemistry of molybdenum is covered in six chapters, written respectively by *A. G. Sykes, G. L. Leigh, R. L. Richards, C. D. Garner, J. M. Charnock* and *E. I. Stiefel*. These molybdenum chapters have been placed at the end for reasons of timing, and are preceded by the chapters on titanium (*C. A. McAuliffe* and *D. S. Baratt*), zirconium and hafnium (*R. C. Fay*), vanadium (*L. F. Vilas Boas* and *J. Costa Pessoa*), niobium and tantalum (*L. G. Hubert-Pfalzgraf, M. Postel* and *J. G. Riess*), chromium (*L. F. Larkworthy, K. B. Nolan* and *P. O'Brien*), tungsten (*Z. Dori*), the lanthanides (*F. A. Hart*) and the actinides (*K. W. Bagnall*). All the chapters are competently written, and they will be useful to a wide readership. In contrast the preceding 300 pages on the coordination chemistry of the Main Group elements are out of place in this volume.

Hubert Schmidbaur
Anorganisch-chemisches Institut
der Technischen Universität München, Garching (FRG)

Volume 4: Middle Transition Elements

Having already introduced the semantically questionable terms "early" and "late" to classify the transition elements, this bad practice is now continued in Volume 4 of the work with the so-called "middle transition elements". These comprise the elements of the manganese, iron and cobalt groups of the Periodic Table. The coordination chemistry of these elements—with the exception of the article on technetium, which was not ready in time and will appear later in the journal *Polyhedron*—is described in 1400 pages, the contributions being of a consistently high quality. The chapter on manganese (by *B. Chiswell, E. D. McKenzie* and *L. F. Lindoy*) is quite extensive, well organized and reasonably comprehensive; the only area dealt with too briefly is that of manganese compounds with coordination numbers of five to seven. Another pleasing contribution to this volume is the carefully prepared account of the inorganic chemistry of rhenium, which is skilfully organized according to ligands and structural units. However, the treatment in this chapter of the higher valency hydrides especially seems unsatisfactory with regard to completeness and presentation; the applications of this class of compounds in the chemistry of "CH activation" ought to have been included (e.g. the work of *Felkin*). The chapter on rhenium (*K. A. Conner* and *R. A. Walton*) is a valuable mine of information for all whose work involves this element, or who would like to make a start in rhenium chemistry. The two chapters on iron also are clearly structured, under the heading of Fe(II) complexes and lower oxidation states (*P. N. Hawker* and *M. V. Twigg*) and that of Fe(III) compounds and higher oxidation states (*S. M. Nelson*). However, these chapters lack detailed descriptions of biologically relevant systems with an adequate coverage of the literature, and also references to modern developments in organo-iron chemistry. For the contribution on osmium the editors have found in *W. P. Griffith* an especially competent and expert author. This chapter, clearly set out according to ligands, with sub-divisions for the different oxidation states of osmium, is a really excellent resource for researchers engaged in osmium chemistry. The expert selection and presentation of the structural chemistry details here deserves a special mention. The author also gives a correct and historically aware account of the development of the osmium tetraoxide catalyzed olefin oxidation process (*cis*-hydroxylation, p. 590 ff.). The elements cobalt (*D. A. Buckingham* and *C. R. Clark*) and rhodium (*V. H. Jardine* and *P. S. Sheridan*) receive the most extensive and detailed treatment (altogether 460 pages and 2500 references). The Wilkinson complexes of the $ClRh(PR_3)_3$ type are deservedly given the most detailed treatment including tables. In the chapter on iridium (*N. Serpone* and *M. A. Jamieson*), with its sometimes badly proportioned pictorial formulas (e.g. on pages 1102, 1105, 1112, 1115 and 1151), a pleasing feature is the account of the catalytic activity of this element (see the tables on page 1159); although short, it includes a very useful compilation of key references.

Wolfgang A. Herrmann
Anorganisch-chemisches Institut
der Technischen Universität München, Garching (FRG)

Volume 5: Late Transition Elements

This volume contains chapters on the coordination chemistry of the nickel, copper and zinc triads of the Periodic Table. It begins with an excellent survey of the coordination chemistry of nickel by *L. Sacconi, F. Mani* and *A. Bencini*. In this, the longest of the chapters with about 350 pages, more than 3200 publications are competently reviewed. In a few instances literature published up to 1985 is included, but in general the coverage extends up to 1984. The material is arranged primarily according to increasing nickel oxidation states, then further divided according to ligands. An especially commendable and useful feature is the clear way in which the different ligand systems are presented, as also are the many tabulations of physical-chemical data and the enumeration of related ligand systems. It is only by these means that an adequate coverage of the large variety of ligands can be given. In this and the following chapters important molecular structures are reproduced directly from the original papers, in contrast to the practices usually followed in tertiary publications of this sort. In addition stereochemical diagrams are used in important cases to make intermolecular interactions clearer to the reader. This form of representation is a welcome aid, as it helps one to understand three-dimensional molecular relationships.

D. M. Roundhill, in his chapter on the coordination chemistry of platinum, with 182 pages of text and about 2000 literature references, adopts a quite different arrangement of the material. Here the system is based on the ligands, ordered according to the position of the donor atom in the Periodic Table—a method of classification which does not always make for clarity of presentation.

In the account of the coordination chemistry of copper by *B. J. Hathaway*, which is quite a lengthy one with 250 pages, the spatial relationships of the many cluster compounds included are in some cases not shown very effectively. The coordination chemistry of silver (*R. J. Lancashire*) is treated in a less comprehensive fashion, with only 500 literature references.

R. J. Puddephatt's contribution on the coordination chemistry of gold illustrates that much advantage can be gained by having articles on related topics written by the same author, even though the aims may be different. Although some overlapping is almost inevitable in works of this scale, such an arrangement would have considerably reduced the duplication between articles in this series and others in the sister series "Comprehensive Organometallic Chemistry".

The article on zinc and cadmium (122 pp., 1470 references) by *R. H. Prince* includes detailed sections devoted to

industrial applications and to biological aspects of these elements, which are very useful. Although these important facets are also touched on in the chapter on copper, they are absent or less clearly stated in the rest of the chapters. The account by *K. Brodersen* and *H. U. Hummel* of the coordination chemistry of mercury (124 pp., 600 references) follows very conventional lines in the choice of material, indicating an outlook which has now almost disappeared from the German literature. Even the introduction strikes one as awkward and constrained.

To conclude these comments, the articles on the coordination chemistry of palladium by *C. F. J. Barnard* and *M. J. H. Russell,* and by *A. T. Hutton* and *C. P. Morley,* both much too brief, with altogether only 660 literature references (only a few of which are more recent than 1980), give a rather inadequate account of the current state of knowledge in this field. Applications, such as those to catalysis, are not discussed at all. These chapters are definite weaknesses of the volume, and the reader would be well advised to refer also to the complementary volume of "Comprehensive Organometallic Chemistry" (see footnote on p. 787) for additional information.

Carl Krüger
Max-Planck-Institut für Kohlenforschung
Mülheim a. d. Ruhr (FRG)

Volume 6: Applications

In the 16 chapters of this volume, experts from universities and industry describe the applications and importance of coordination chemistry in a wide variety of currently topical fields. It is no surprise to find that the publications cited show a bias towards those in the English language. On the other hand it is regrettable in a work published in 1987 that, whereas the important and lengthy chapter by *M. N. Hughes* cites papers as recent as 1986, in others, such as those on "Dyes and Pigments" (Chapter 58) and on "Applications in Photography" (Chapter 59), the most recent citations are to 1983 papers (and even these are only patents or patent applications). As a result the usefulness of these parts of Volume 6 as reports on the "current" situation in applied research is considerably reduced. This turns out to be the case for all the areas that are undergoing rapid development, e.g. in "Electrochemical Applications" (Chapter 57), and in "Compounds with Novel Electrical Properties" (Chapter 60), although it is true that there are as yet few actual applications in the form of fully developed systems.

Chapter 61 consists of five sections: "Stoichiometric Reactions of Coordinated Ligands", "Catalytic Activation of Small Molecules" (which in particular describes hydrogenations, hydroformylations and carbonylations, classified according to the metals involved), "Metal Complexes in Oxidation Reactions", "Lewis Acid Catalysis in Reactions of Coordinated Ligands", and "Decomposition of Water into its Elements".

The treatment of biological and medical aspects in Chapter 62.1 (the longest) is detailed and pleasingly up-to-date, as are those on the applications of coordination compounds in chemotherapy (Chapter 62.2) and in radiopharmacology (Chapter 65).

Geochemical aspects and prebiotic systems are discussed in Chapter 64. The articles on "Metal Extraction" (hydrometallurgy) (Chapter 63) and on "Nuclear Fuel Cycles" (Chapter 65) describe well-established technological applications. Finally Chapter 66 summarizes miscellaneous applications, ranging from hydrogen storage to uses in agricultural chemistry and in reducing toxic smoke emission from burning of PVC.

Despite the fact that the literature coverage is not always ideal, this is on the whole a well-written and very clearly presented volume, and reading through it or merely browsing will reveal plenty of new ideas, and perhaps surprises, whether the reader's interests lie in basic research or in applications. This useful volume should find a place in every library, as an aid both to those starting in a new field and to others wishing to round off their knowledge.

Anorganisch-chemisches Institut
der Technischen Universität München, Garching (FRG)

Volume 7: Indexes

The formula and subject indexes for Volumes 1 to 6 are collected together in this volume. It also includes a list of review articles relevant to this subject area.

[NB 920 IE]

Metal-Ligand Multiple Bonds. By *W. A. Nugent* and *J. M. Mayer.* Wiley, Chichester/New York 1988. xi, 334 pp., hardcover, £ 35.15/$ 55.00. – ISBN 0-471-85440-9

This superb book by *W. A. Nugent* and *J. A. Mayer* on metal–ligand multiple bonds provides a thorough review on the chemistry of transition-metal complexes with M–O, M–N, and M–C multiple bonds. This is the first time that these related types of complexes have been treated together comprehensively and compared with one another.

The seven chapters describe the electronic and geometric structures, the synthesis and spectroscopic properties, and the reactivity and catalytic activity of these complexes. The first chapter introduces the different types of complexes: oxo complexes, nitrido, imido, and hydrazido complexes, and different compounds with M–C multiple bonds, including Fischer- and Schrock-type carbene complexes as well as carbyne complexes. Unfortunately, complexes in which the metal exhibits multiple bonds to main-group elements other than O, N, and C are not discussed, although these complexes are equally interesting and a focus of current attention. Inclusion of these complexes would have allowed more extensive comparisons. Presumably, however, this would also have led to an unwieldy text. In the second chapter, the bonding and electronic structure of these complexes are discussed. The following two chapters provide a detailed description of the currently available routes to compounds with metal–ligand multiple bonds and a summary of their vibrational and NMR spectra. The O, N, and C NMR resonances are discussed extensively. Chapter five offers a comprehensive review of the crystal structures and, in particular, the M–O, M–N, and M–C bond lengths. Chapters six and seven thoroughly treat the reactivity of metal–ligand multiple bonds and their role in catalysis.

This book is a gold mine for all chemists interested in the area of metal–ligand multiple bonds or requiring specific information on such complexes. Especially valuable is the exhaustive literature survey, including publications appearing in 1987, which may be rapidly scanned and helps the reader in finding answers to specific questions. The book is excellent as a basic text for advanced study in courses and seminars. Despite the cutbacks in library budgets, which have placed severe limitations on the purchase of new mono-

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0606-0790 $ 02.50/0

graphs, this book is an essential acquisition for every chemistry library. Only in this way will it be readily available to students. The numerous, clearly drawn figures, tables, and formulas are didactically well placed in the text, which has been carefully proofread and is practically free of errors. An exception, however, is found in Table 4.7, where the columns for ν_s and ν_{as} of the M=N=M bridge vibrations are interchanged. Moreover, it would have been better to refer to antisymmetric vibrations instead of asymmetric vibrations.

All in all, this book is a must for every chemistry library and for every scientist interested in this area, as well as for advanced students. I recommend it without reservation.

Joachim Strähle [NB 978 IE]
Institut für Anorganische Chemie
der Universität Tübingen (FRG)

Biomedical Magnetic Resonance Imaging. Principles, Methodology and Applications. Edited by *F. W. Wehrli, D. Shaw,* and *J. B. Kneeland.* VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xviii, 601 pp., hardcover, DM 195.00.—ISBN 3-527-26701-8/0-89573-349-8

This book of 600 pages describes the physical basis, clinical applications, and recent developments (up to 1986) in the field of NMR imaging and *in vivo* NMR spectroscopy. It consists of 13 chapters written by a total of 18 physicists and medical scientists with relevant experience.

The method-oriented part of the book gives an account of the fundamentals of NMR spectroscopy and of the techniques used to produce spatially resolved NMR signals. These chapters are particularly successful, since they are not merely a repetition of conventional introductions to NMR spectroscopy, but constantly keep in mind the special conditions of *in vivo* experiments. Some of the topics treated are the spatial resolution, image contrast, relaxation phenomena, the use of paramagnetic agents for enhancing contrast, (rapid) imaging techniques and gradient switching, techniques for suppressing water signals, effects of the chemical shift, detection of flow processes, problems caused by motion, and the use of surface coils. Other sections are concerned with special topics such as NMR imaging using nuclei other than hydrogen (fluorine, phosphorus, sodium), problems of spatial localization in *in vivo* NMR spectroscopy, and spectroscopic imaging. One chapter is devoted to safety aspects.

Since this area of research, especially *in vivo* NMR spectroscopy, is developing very rapidly, some of the evaluations and predictions given here are already out of date as a consequence of the date of completion of the manuscript. For example, the limitation of spectroscopic applications to studies of energy metabolism by ^{31}P NMR measurements is no longer valid. Major advances in image-controlled localized ^{1}H NMR spectroscopy, with scientific and medical applications in studies of the metabolism of amino acids and neurotransmitters in the human brain, were reported only during last year.

Clinical applications discussed are those relating to the central nervous system, the cardiovascular system, the abdominal and pelvic regions, and the skeletal muscular system. Unfortunately, some of the examples are based on old image material. Not enough space is given to the important brain and spine studies, and for cardiac applications the greatly increased capabilities offered by ECG-synchronized ciné NMR imaging studies are not mentioned. Nevertheless, the clinical chapters provide non-medical readers with valuable insights into the importance of the techniques in medicine; for those who are only interested in using the methods for clinical applications, other more extensive collections of imaging data are available.

Taken as a whole the book commendably follows the main stream of developments and applications. This is undoubtedly due to the editors' and authors' close connections with industry and clinical practice. In this continually changing area of research *realistic* developments in *in vivo* NMR are always characterized by their human applicability. This feature seems to be a prerequisite for a successful adaptation of "classical" NMR techniques to the field. The individual articles are detailed for an introduction, but not long-winded, and they are competently written. The book is very clearly structured, and the method-oriented sections especially are very well prepared from a learning point of view. An extensive bibliography at the end of each chapter provides easy access to the original literature. In contrast to some other "rapidly produced" works on NMR imaging, this book is a valuable addition to the literature. It is suitable for chemists, physicists, biologists and medical scientists who wish to begin work in this field, or would like to gain a deeper understanding of it, or who simply need a work of reference to direct them to further reading in their daily work.

Jens Frahm [NB 942 IE]
Max-Planck-Institut für Biophysikalische Chemie
Göttingen (FRG)

Introduction to Synchrotron Radiation. By *G. Margaritondo.* Oxford University Press, Oxford 1988, xi, 280 pp., hard cover, £ 32.00.—ISBN 0-19-504524-6

Amongst the growing number of publications on synchrotron radiation this book by *G. Margaritondo* occupies a special position: here the wealth of applications of synchrotron radiation in chemistry, physics, biology, medicine and engineering is treated as a consistent whole by a single author. The numerous cross-references link together topics that appear widely disparate: to give an example, the concept of phase space runs like a scarlet thread through subjects ranging from the production of synchrotron radiation in electron storage rings, and the design of synchrotron radiation guides, mirrors and monochromators, to the interaction of the radiation with the samples being studied.

One third of the book is concerned with the description of sources of synchrotron radiation and with instruments for using such radiation. Optical components and detectors are discussed, as well as wigglers and undulators that are incorporated into the latest storage rings for the production of synchrotron radiation tailored for specific applications. Also not neglected, of course, is the outlook for third generation storage rings, of which the chief representative is the European ESRF synchrotron radiation facility in Grenoble. The information given about working conditions in the vicinity of synchrotron radiation sources is also very useful.

The following third of the book deals with the applications of synchrotron radiation in optical spectroscopy, X-ray absorption spectroscopy and photoemission spectroscopy, also including spin-polarized photoemission. The importance of these techniques in surface studies is discussed in detail.

Of the various elastic X-ray scattering techniques, one which has profited at a relatively early stage from the laser-like collimation of synchrotron radiation is low angle X-ray scattering. This is also the case in X-ray topography. By taking advantage of anomalous dispersion one can introduce some features of spectroscopy into X-ray structural analysis. Techniques for determining the phase of the scattered X-rad-

iation are described in detail in view of the growing importance of this method. Lastly the importance of the polarization of synchrotron radiation for measuring magnetic X-ray scattering is discussed.

X-ray lithography is associated with some important industrial applications, and the investigation of coronary arteries (angiography) by differential absorption measurements on iodine offers definite prospects for becoming a routine application of synchrotron radiation in medical diagnosis. Other promising possibilities for synchrotron radiation include X-ray microscopy, time-resolved fluorescence measurements, X-ray stationary waves and inelastic X-ray scattering. However, mention should also have been made here of Mössbauer scattering.

The book is not a substitute for further reading of more comprehensive handbooks on synchrotron radiation, but is intended rather as an elementary introduction. The author has achieved this aim to the full by means of clear descriptions avoiding complicated formulas, illustrated by attractive diagrams. The book is highly recommended, especially for readers from all fields of science, engineering and medicine who are beginners in the use of synchrotron radiation.

Heinrich Stuhrmann [NB 964 IE]
GKSS Forschungszentrum
Geesthacht GmbH, Geesthacht (FRG)

Electron Nuclear Double Resonance Spectroscopy of Radicals in Solution. By *H. Kurreck, B. Kirste* and *W. Lubitz*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xii, 374 pp., hardcover, DM 148.00.—ISBN 3-527-26791-3/0-89573-324-2

This monograph on applications of ENDOR (Electron Nuclear Double Resonance) spectroscopy to studies of free radicals in solution, in both organic chemistry and biology, has been written by acknowledged experts in this field, and fills a gap in the existing range of books.

ESR spectrometers have been commercially available for about 25 years, and provide the organic chemist with a routine method for studying free radicals in solution. ENDOR spectroscopy was developed more than 30 years ago as a technique for simplifying complex ESR spectra; however, it was then a laborious procedure, and was only used in special cases. A few years ago ENDOR instruments were introduced commercially, making this method also accessible to the organic chemist who uses routine equipment. It is therefore likely that it will be used increasingly in the future, especially in studying radicals with very large numbers of coupling nuclei, where the interpretation of the ESR spectra would otherwise be impossible, or at best ambiguous.

The book is aimed at two groups of readers. Firstly it takes into account the needs of the reader who wishes to learn about the ways in which the ENDOR technique can be used in organic and biological chemistry. Secondly it offers the specialist a review of results obtained up to now. The arrangement of the contents reflects these two aims.

The introduction explains the basic fundamentals for the non-specialist in a concise and easily understandable form. This is followed by two more detailed chapters dealing with the principles and theory of the method; the first of these is aimed mainly at the organic chemist, while the second—written in collaboration with a physicist (Dr. *Plato* of the Free University of Berlin)—is addressed mainly to the spectroscopist. The fourth chapter, which is devoted to the basic principles of ENDOR spectroscopy applied to hetero nuclei, completes the general part of the book.

The fifth chapter deals systematically with ENDOR spectroscopic observations on various types of free radicals in solution, grouped according to the identity of the central atom. This is a clearly presented and critical summary of the results, with many literature references to enable the interested reader to delve further. The last third of the book consists of four chapters describing some special applications of ENDOR spectroscopy: studies of intramolecular dynamic processes, free radicals in liquid crystals, organic multi-spin systems, and biological systems.

The book will undoubtedly become an indispensable item in every library that aims to give a complete picture of the applications of spectroscopic methods in organic chemistry. It is not intended as an alternative to other monographs on the ESR spectroscopy of free radicals in solution, but as an extension of these. The appearance of a new complete work on ESR spectroscopy would therefore be very welcome—for example a revised and updated edition of the standard work published in 1970 by *Scheffler* and *Stegmann*. At present the reader needing more complete data on the ESR spectroscopy of free radicals in solution must rely on the comprehensive tabulated work provided in Landolt-Börnstein.

Generation of Complex Metal Oxides by Aerosol Processes: Superconducting Ceramic Particles and Films

Aerosol Decomposition
Superconducting Films
Oxygen Diffusion
Ferroelectric Ceramics
Ferrimagnetic Ceramics
Powder Generation

By Toivo T. Kodas*

Complex metal oxides, including ferroelectric, ferrimagnetic and superconducting ceramics, have a variety of technologically useful properties that can be exploited for a number of applications. Fabrication of complex metal oxide ceramics with specific properties requires high-purity powders with controlled chemical compositions, size distributions, and morphologies. Powders with these characteristics can be produced by aerosol processes in which fine particles are generated in gaseous flow systems. The particles can also be deposited from the gas phase onto surfaces to form films. This paper will discuss the use of aerosol processes for the generation of complex metal oxide powders. A review of aerosol processes will be presented first, followed by a discussion of the methods used for the generation of superconducting ceramic powders. Examples include the production of $YBa_2Cu_3O_7$, $La_{1.85}Sr_{0.15}CuO_4$, and Tl-Ca-Ba-Cu-O powders and films. Emphasis will be placed on defining the conditions required for the generation of chemically homogeneous particles with controlled morphologies.

1. Introduction

The fabrication of complex metal oxides with specific electrical, magnetic, optical and superconductor properties begins with molecular precursors which must be transformed into the product film or part. A versatile class of methods for accomplishing this transformation is aerosol processes. The term aerosol process is used here to describe systems in which particles are formed in the gas phase as the result of chemical or physical processes and systems in which particles or droplets are deposited from the gas phase onto surfaces to form films. For this discussion, the terms particle and droplet will include clusters, collections of a small number of atoms or molecules in which an appreciable fraction of the atoms or molecules are at the surface.[1, 2] Table 1 lists the major types of aerosol processes that have been used for the generation of metal oxide particles and films. Systems such as laser-heated reactors[3] which have been used primarily for non-oxide ceramics are not included.

The processes in Table 1 can be grouped into gas to particle conversion, intraparticle reaction, and hybrid processes. In gas to particle conversion processes (Fig. 1) a supersaturated vapor of a condensable gaseous species is formed either as the result of chemical reactions which create new molecules[4, 5] or physical processes such as cooling which reduce the vapor pressure of the condensable species.[6] At a sufficiently high supersaturation, new particle formation occurs by homogeneous nucleation. Nucleation is followed by particle growth, and for sufficiently high particle concentrations, by coagulation and agglomeration. Gas to particle conversion processes can be coupled with particle deposition from the gas phase to provide methods for film fabrication.[7] Particle deposition from the gas phase onto surfaces can take place by mechanisms including impaction, thermophoresis, and diffusion.[8–10]

In intraparticle reaction processes, often called spray pyrolysis, evaporative decomposition, spray roasting or aero-

ADVANCED MATERIALS

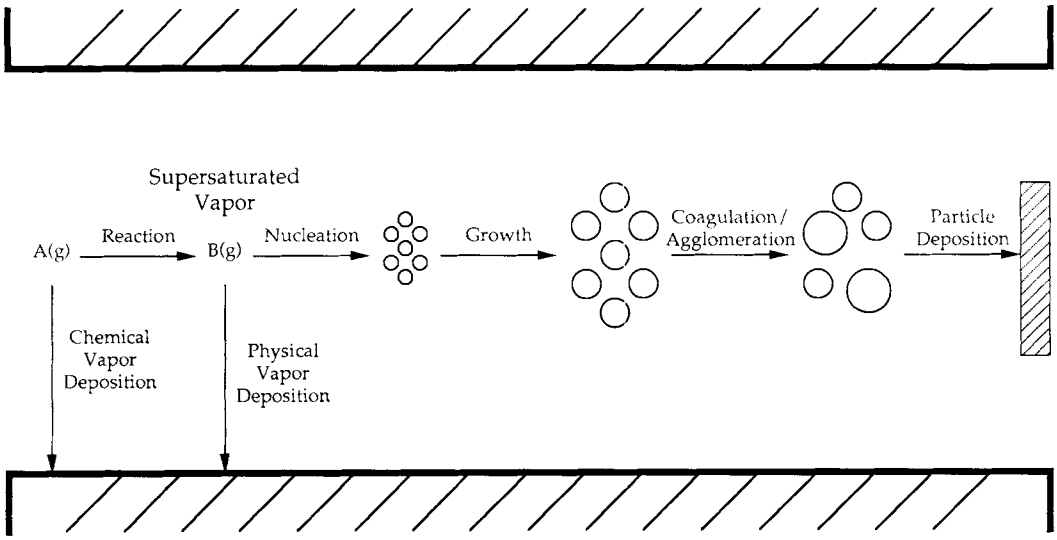

Fig. 1. Particle generation by gas to particle conversion.

sol decomposition, particles containing precursors are formed mechanically using a droplet or particle generator (Fig. 2a). The precursors in each particle are then reacted with a gaseous species or are pyrolyzed in the particulate phase to form the product. A modification of the aerosol decomposition process, spray pyrolysis (the same name as for the powder generation process), or the pyrosol process, can be used for film generation. The liquid droplets are deposited onto a heated substrate where the precursors decompose, and further heating results in the formation of the product film. One variation of this process is to first form solid particles in the gas phase, deposit them onto a substrate, and sinter them to form the solid ceramic film.[11] Another variation (Fig. 2b) is to use volatile reactants which evaporate into the gas phase and deposit materials by chemical vapor deposition. Although gas to particle conversion processes and intraparticle reaction processes provide convenient groups for classifying aerosol processes, some methods incorporate elements of both processes. For example, in the hybrid process cited in Table 1, droplets of an organometallic species can be formed by nucleation and condensational growth and then be converted to a ceramic species by intraparticle chemical reaction.

Aerosol methods have been used to produce a wide variety of metal oxide ceramics as shown in Table 2. These studies have shown that aerosol processes allow the generation of particles with a unique combination of properties that in many cases cannot be obtained by other processes. Typical properties include:

- high purity
- single-crystal or polycrystalline
- multicomponent materials
- coated/multilayer or chemically homogeneous
- porous or non-porous
- size from clusters to 5 μm
- unagglomerated, soft or hard agglomerates

An example of a process which can produce complex metal oxide powders with these characteristics, aerosol decomposition, will be discussed later.

The advantages of aerosol deposition for film fabrication include:

- high purity
- multicomponent materials
- high deposition rates

One of the best examples of a process which exploits these advantages for film formation is optical fiber production in which high-purity SiO_2 is deposited at high rates onto the inside surface of a tube which is eventually filled in and drawn into an optical waveguide.[12]

Aerosol processes for the generation of metal oxide ceramics have been used primarily for simple metal oxides and to a lesser extent for complex metal oxides containing two metallic or semiconducting species (Table 2). A smaller number of studies have examined the generation of powders containing three or more of these species. However, rapidly advancing technologies in areas such as superconductivity, electronics, solar cells, optics, and high-tech ceramics for structural applications are requiring increasingly complex materials which often contain three or more metallic or semiconducting species in addition to oxygen, nitrogen and other nonmetallic species. Examples of such materials are given in Table 3. Both powders and films with controlled chemical compositions and microstructures are required.

This paper will discuss the use of aerosol processing for the fabrication of complex metal oxide ceramic powders and films. Emphasis will be placed on the aerosol decomposition process for powder and film generation (see Tables 1 and 2) since it is the only aerosol technique that has demonstrated the ability to produce complex metal oxides. The present status of research in this area will be discussed first. Superconducting ceramic powder generation by intraparticle reac-

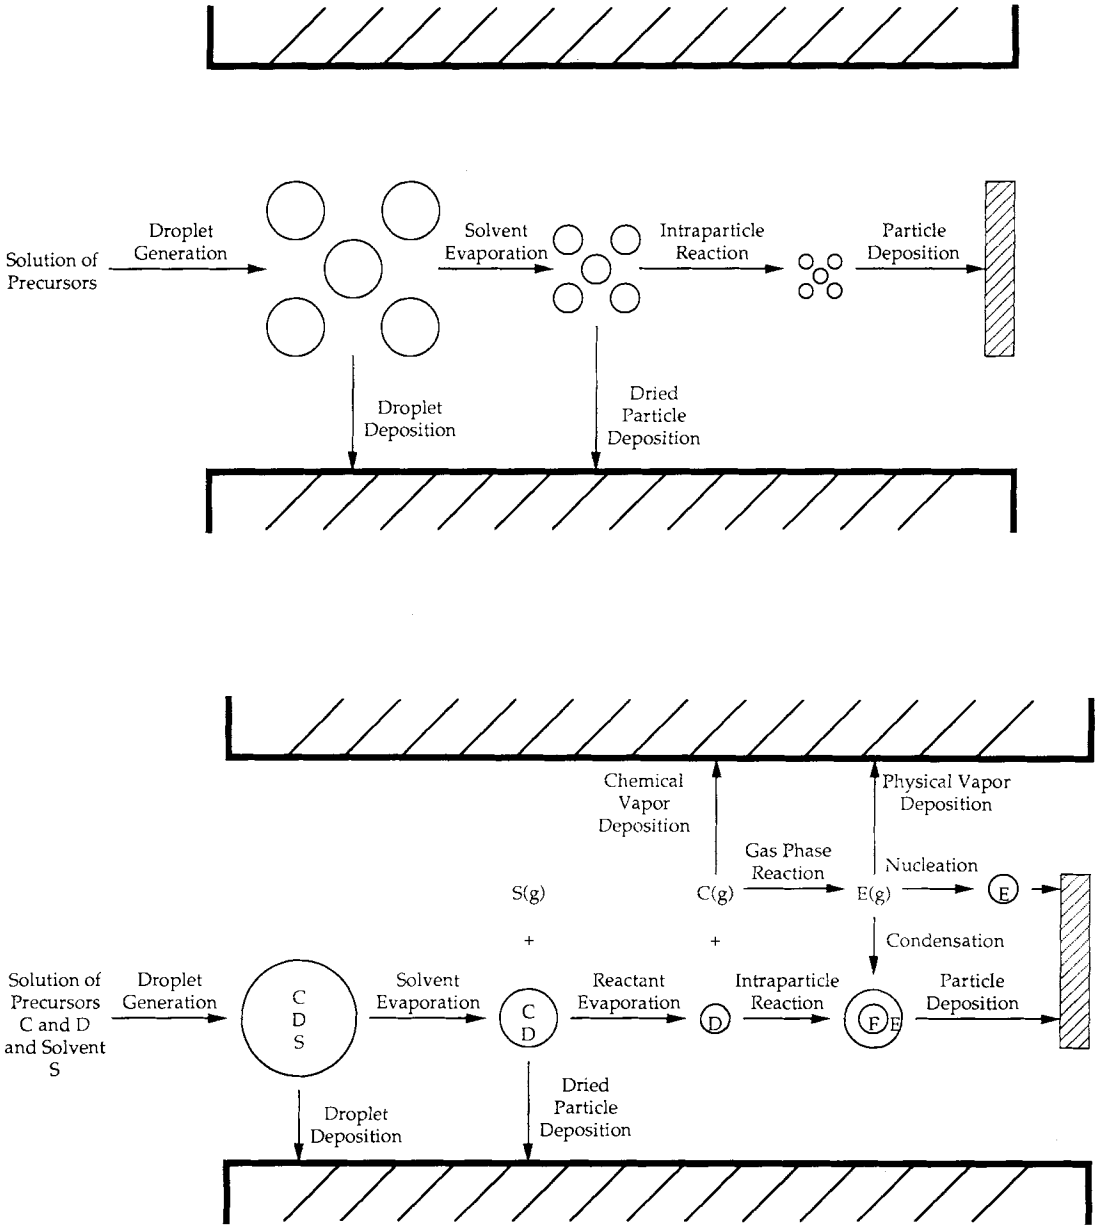

Fig. 2. Particle generation by aerosol decomposition. a) Pure intraparticle reaction and b) combined intraparticle reaction and gas to particle conversion.

tion and a combination of gas to particle conversion and intraparticle reaction will be discussed along with deposition of the particles onto surfaces to form films. New results will be presented with a review of previous work. Emphasis will be placed on describing the physical and chemical processes which control the chemical composition and morphology of complex metal oxide particles and films produced by aerosol decomposition. A goal of the paper is to identify the problems which must be solved in order to increase the range and number of applications of aerosol processes for the generation of powders and films.

2. Present Status of Research on Aerosol Processing of Complex Metal Oxides

2.1. Theory

Gas to particle conversion and intraparticle reaction methods for powder generation can involve a variety of physicochemical processes (see Figs. 1, 2a and b). These processes include:

- gas-phase chemical reactions
- single-particle chemical processes such as surface and intraparticle chemical reactions

- single-particle physical processes such as nucleation, evaporation and condensation
- multi-particle physical processes such as coagulation and agglomeration
- mass transport including diffusion and deposition of gases and particles
- heat and momentum transport leading to nonuniform velocity and temperature fields
- effects associated with plasmas, photons, electric fields, supercritical fluids, and other complicating features

The processes which occur depend on the mode of aerosol reactor operation. One of the simplest cases, aerosol decomposition, can involve only intraparticle chemical reactions for particles in nonuniform temperature and velocity fields (Fig. 2a). Gas to particle conversion processes can, however, involve many of the processes mentioned above (Fig. 1). Similarly, aerosol decomposition processes with one or more volatile species (Fig. 2b) can involve many of these processes. Because of this variety of processes that can occur, a complete understanding of aerosol methods for film and particle generation will only be obtained by an interdisciplinary approach.

A large number of studies have theoretically examined the behavior of aerosol processes for film and particle generation. However, few have studied the behavior of multicomponent systems. Fortunately, many of the results from single-component systems can be used to understand qualitatively the behavior of the more complicated multicomponent systems. Models for single-component systems incorporating gas phase reaction, particle formation and growth, nonuniform velocity profiles and diffusion of gaseous reactants and products in flow systems have been developed.[13–23] The added complexities of coagulation and transport of particles have also been added to these models.[24–25] The aerosol dynamics in well-mixed systems (continuously stirred tank reactor) with exponential residence time distributions have been examined,[26,27] and the roles of particle nucleation, growth and coagulation in determining particle characteristics have been studied in detail.[28–35,99] These and other studies have provided a basis for the understanding of the aerosol dynamics in a variety of systems for powder and film generation.

2.2. Experimental Results

The only aerosol method that has demonstrated the ability to produce chemically homogeneous complex metal oxides, including superconducting ceramics,[11,36–41] is aerosol decomposition. The powder generation process begins by pass-

ing a solution of precursors through an aerosol generator to form fine droplets.[42] The droplets are then passed through a furnace where chemical reactions convert the precursors to the product powder which is then collected on a filter.

This process has several advantages over gas to particle conversion processes for the generation of multicomponent materials. Particles with a uniform chemical composition can be produced in many cases since the precursors are present in the correct stoichiometry in each droplet produced by the aerosol generator. Volatile precursors are not required; thus, a wide variety of reactants can be used while avoiding the need for carbon-containing precursors. Gas to particle conversion or nucleation processes have not been successful in producing multicomponent materials due primarily to difficulties in controlling the nucleation process when several species are involved (see section 3.2.2). In contrast, aerosol decomposition processes can produce multicomponent materials. The generation of multicomponent ceramic powders can be carried out on an industrial scale using only a few unit operations; the ability to scale up these systems for production of ton-quantities of conventional ceramic oxide powders has already been demonstrated.[43, 44]

The morphology of particles produced by aerosol decomposition strongly influences the properties of ceramics produced by sintering the particles. The primary difficulty with the intraparticle reaction route for powder generation has been that in most cases porous polycrystalline particles have been formed.[43–48] This morphology can lead to difficulties in sintering to near-theoretical density, a crucial problem for superconducting ceramics where porosity can lead to degraded superconductor and mechanical properties.

The morphology of the particles depends on a variety of physicochemical processes including reactant crystallization in the particle during solvent evaporation, chemical reaction in the particles, and transport of gaseous reactants and products into and out of the particles. Few studies have examined how solvent evaporation influences the final particle morphology. Conditions leading to solid particles during evaporation are believed to be a nuclei-free system, high solute solubility, low drying rates and low relative humidities.[49] The rate of intraparticle reaction of water vapor with metal alkoxide droplets has been measured optically, but little information about particle morphology was reported.[50]

A variety of precursors have been used for the generation of ceramic powders by aerosol decomposition. They include chlorides, oxalates, lactates, citrates, nitrates, acetates, alkoxides, sulfates and acetylacetonates (Table 2). However, only a few studies have examined the role of the precursors in determining the morphology of particles produced by spray pyrolysis. The difference between using nitrate, chloride and acetate salts of Mg as precursors for MgO generation has been examined.[46, 51] The acetate gave dispersed particles while the nitrate and chloride gave large aggregates. A similar study was carried out for ZnO, NiO, $NiMn_2O_4$, $ZnFe_2O_3$, and Fe_2O_3 generation from the nitrate and acetate salts. The acetates gave powders ranging from hard aggregates to fine unagglomerated particles while the nitrates gave hard agglomerates under all conditions.[52] However, unagglomerated $YBa_2Cu_3O_7$ particles have been obtained by aerosol decomposition using the nitrates.[36–41] Little information is available for other precursors.

The processing of powders produced by aerosol decomposition has been investigated only in a few studies. Examples include processing of Al_2O_3 to form 96% dense ceramic[45, 53] and $MgAl_2O_4$ to form 93% dense material.[54] The processing of most other powders produced by aerosol techniques (see Table 2) has not been investigated. Further work is required to characterize the powders and to study the fabrication of ceramics using these powders.

Films of many materials have been deposited by spray pyrolysis (see reviews[55, 56] and Table 2). The gas phase processes occurring during film generation are similar to those occurring during powder generation by spray pyrolysis (Figs. 2a and b). As for powder generation, few studies have used modern aerosol techniques to determine how the properties of the films can be improved by controlling the droplet size distribution, reactor design and operating conditions. Instead, the large majority of these studies have concentrated on characterizing the electrical, optical, and magnetic properties of simple metal oxide films.

Deposition of particles from the gas phase onto surfaces followed by sintering has been used for many years for the fabrication of optical waveguides.[12] However, this process has only recently been exploited for the generation of films of materials other than SiO_2. An example is the formation of thick films of superconducting ceramics by the deposition of superconducting ceramic particles formed by aerosol decomposition[11] (see section 3.5). Advantages of the process include in situ formation of films while minimizing exposure to contaminants, adaptability to different chemical systems, and the integration of materials synthesis and processing steps. A modification of this process has been used to produce Bi-Sr-Ca-Cu-O films.[57] Amorphous particles generated by a non-aerosol process were entrained in a carrier gas to form an aerosol and then deposited from the gas phase onto heated surfaces to form crystalline films. Films have also been generated by simultaneous deposition of particles and vapor from the gas phase. Deposition rates were orders of magnitude higher than those achieved by conventional chemical vapor deposition processes.[7]

3. Generation of Superconducting Ceramics by Aerosol Decomposition

Typical superconducting ceramics contain three or more metallic species and oxygen. Examples include Bi-Pb-Sr-Ca-Cu-O, Tl-Pb-Ca-Ba-Cu-O and Y-Ba-Cu-O. The motivation behind using aerosol processes for superconducting powder generation is the need for high-purity multi-component powder composed of unagglomerated particles with a uni-

form chemical composition and controlled size distribution,[58-60] characteristics which can only be obtained by aerosol decomposition. No other aerosol methods have demonstrated the ability to produce complex metal oxide powders with these characteristics. A further motivation for studies of these materials is that, because of the large number and variety of species involved, they are excellent model systems for studies of the generation of other ceramic powders by aerosol processes (Table 3).

3.1. Experimental

Powders were generated by the following method. Metal-containing species were dissolved in a solvent and passed through an aerosol droplet generator to form micron-sized solution droplets. Aqueous solutions of the nitrate salts of the metals are used to minimize carbon contamination from either the solvent or precursors. The droplets were then passed through a furnace where chemical reaction took place to convert the reactants to the product powder. Average residence times were typically 1 to 25 seconds with temperatures of 800–1200 °C. The powders were collected on silver-membrane filters to minimize contamination. Powders based on the $YBa_2Cu_3O_7$, $La_{2-x}Sr_xCuO_4$, Bi-Sr-Ca-Cu-O, and Tl-Ca-Ba-Cu-O systems have been generated by this technique.[11, 36-41]

3.2. Mechanism of Particle Formation

The process of forming ceramic particles by aerosol decomposition can be viewed in the simplest case as the drying of droplets followed by solid and liquid phase chemical reactions in a microreactor (the particle) suspended in a gas to form the product. However, the actual behavior of the system is in many cases more complicated. The microreactor can exhibit two types of behavior which are determined by the nature of the species transported into the gas phase. If only nonmetallic species (O_2, CO, CO_2, NO, NO_2) are transported across the particle/gas interface, only intraparticle and surface reactions occur, and the product stoichiometry can be precisely controlled during mixing of the precursor solution (Fig. 2a). As will be shown, samples of $YBa_2Cu_3O_7$ and $La_{1.85}Sr_{0.15}CuO_4$ formed from the metal nitrates exhibit this type of behavior. If metal-containing species are exchanged across the interface, gas phase, surface and intraparticle chemical reactions can occur. In this case, control of the stoichiometry and phase purity becomes far more difficult than for the case of a purely intraparticle reaction. An example of a system exhibiting this type of behavior is the formation of Tl-Ca-Ba-Cu-O from the metal nitrates where volatile Tl-containing species are transported across the particle/gas interface.

3.2.1. Intraparticle Reaction: $YBa_2Cu_3O_7$ and $La_{1.85}Sr_{0.15}CuO_4$

In the purely intraparticle reaction mode where only gaseous species are transported across the particle/gas interface (Fig. 2a) the solvent evaporates from the droplets formed by the aerosol generator followed by nucleation of the metal salts in the particle to form one or more solid phases. This is followed at higher temperatures by decomposition of the metal salts in the particles to form reaction intermediates. As the reaction proceeds, these intermediates diffuse together and react to form the final product. Since no metal-containing species leave the particles, the spread of the particle size distribution is limited by the spread of the size distribution of the droplets formed by the aerosol generator. Thus, nearly monodispersed particles can be produced by using ultrasonic droplet generators.[38, 40, 41]

The intraparticle reaction mode occurs during formation of $YBa_2Cu_3O_7$ by decomposition of metal nitrates. The melting points of the oxides of Cu, Y, and Ba (1326–2410 °C) are far above the typical reactor operating temperature (900–1000 °C); thus, evaporation of the oxides does not occur. Similarly, no evidence of evaporation of any of the nitrate species or reaction intermediates was found by examination of the powders by transmission electron microscopy (TEM) electron diffraction, X-ray diffraction, and wet chemical analysis of the composition of the powders. Since the Y, Ba, and Cu are confined to the particles, it is possible to form $YBa_2Cu_3O_7$ particles (Fig. 3) with the following characteristics:[36, 37]

- Completely reacted (thermogravimetric analysis (TGA))
- Single phase (X-ray diffraction (XRD))
- Superconducting with $T_c > 90$ K (magnetic susceptibility)

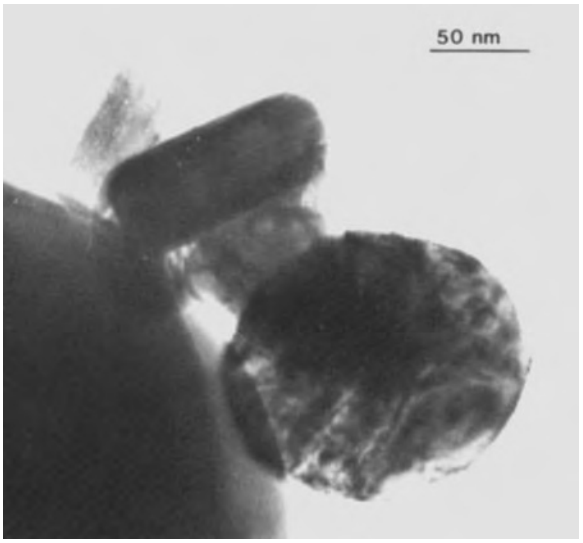

Fig. 3. Single-crystal $YBa_2Cu_3O_7$ particles generated by aerosol decomposition at 1000 °C.

- Single-crystal particles (electron diffraction)
- Uniform composition from particle to particle (energy dispersive spectroscopy (EDS))
- Solid particles (TEM and Brunauer, Emmett, Teller (BET) surface area measurements)
- Fully oxygenated (iodometric titration)
- 1:2:3 ratio of Y:Ba:Cu (wet chemical analysis)
- Equiaxed and spherical shapes

Similar results were obtained for the $La_{1.85}Sr_{0.15}CuO_4$ system. The X-ray diffraction pattern for the powder generated by aerosol decomposition of the nitrates at 1100 °C is shown in Figure 4. TGA showed that the material was fully reacted. Sintered and annealed material had a T_c at approximately 35 K.

Although $YBa_2Cu_3O_7$ and $La_{1.85}Sr_{0.15}CuO_4$ particles with a uniform chemical composition can be formed, cases exist where intraparticle reaction leads to chemically nonuniform particles. One example is the formation of $YFeO_3$ and Fe_2O_3 instead of yttrium-iron garnet ($Y_3Fe_5O_{12}$) during intraparticle reaction of the sulfates of yttrium and iron at 1000 °C. The preferential formation of the $YFeO_3$ and Fe_2O_3 was attributed to fast nucleation of the $YFeO_3$ phase.[61] Another example of the formation of multiphase materials by aerosol decomposition is the generation of Bi-Sr-Ca-Cu-O powders by reaction of the nitrates. Experiments under conditions which produced single phase $YBa_2Cu_3O_7$ and $La_{1.85}Sr_{0.15}CuO_4$ produced only multiphase Bi-Sr-Ca-Cu-O particles. In this case, both thermodynamic and kinetic limitations may have been responsible for the multiphase material.

3.2.2. Combined Intraparticle Reaction and Gas to Particle Conversion: Tl-Ca-Ba-Cu-O

Spray pyrolysis systems for powder generation can also be operated under conditions where both intraparticle reaction and gas-to-particle conversion occur (Fig. 2b). Gas to particle conversion can occur if one or more of the precursors (C and D), reaction intermediates, or reaction products (E and F) are transported across the particle/gas interface. The precursors or reaction intermediates in the gas phase (C) can react to form products which may be the same as or different from the products of intraparticle reaction (E). Any of the gaseous species, either after being formed by chemical reaction in the gas phase or during cooling while exiting the reactor, may condense on the walls of the system, condense on the particles from which they evaporated, or nucleate homogeneously to form new particles. These types of behavior have been observed during the operation of single and multicomponent systems. Zinc acetate evaporation, gas phase chemical reaction and nucleation to form ZnO has been observed during ZnO particle formation,[47, 62] and Na_2O loss has been observed during generation of powders containing Na, Mg and Al by spray pyrolysis.[53]

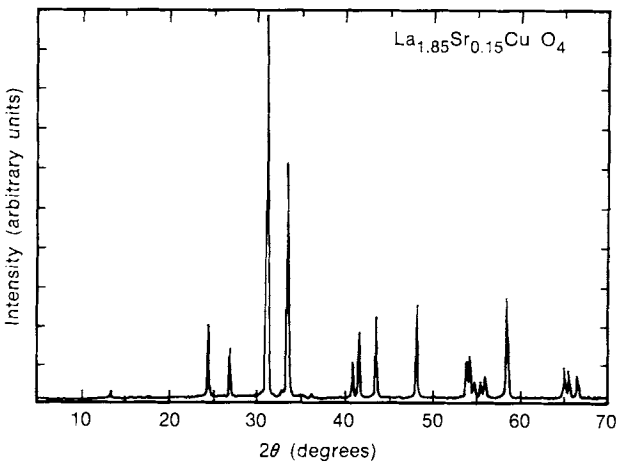

Fig. 4. X-Ray diffraction pattern for $La_{1.85}Sr_{0.15}CuO_4$ generated by aerosol decomposition at 1100 °C showing single-phase material.

The physicochemical processes shown in Figure 2b influence the properties of the product powders and hence the properties of ceramics produced from the powders. Total condensation onto the existing particles (particles of F coated with E) restores the initial stoichiometry, but only in a volume average sense; the particles are no longer chemically homogeneous and consist of a multicomponent core covered by a single-component layer of the condensed material. Homogeneous nucleation to form new particles (E) without condensation on the walls again conserves the composition of the powders averaged over the total particle volume. However, the powder consists of fine particles of one material (E) mixed with larger particles of E and F which are now depleted in the volatile species (E). Condensation on the walls results in a change in the volume average composition of the powder. Since the fraction of the volatile species remaining in the particles is difficult to control, this situation is usually the least desirable of the possibilities. Fortunately, wall losses can be eliminated by appropriate design and operation of the reactor. Studies of gas to particle conversion in tubular flow reactors suggest that rapid cooling rates which lead to high saturation ratios will result in new particle formation.[13–21] Slow cooling rates allow condensation on the particles and walls since the saturation ratio can be kept below the critical value for particle formation. The relative amounts of condensation on the walls and particles are controlled mainly by the surface area of the preexisting particles and the reactor radius. Larger aerosol surface areas and larger reactors favor condensation onto existing particles.

Experiments at a variety of temperatures and reactor residence times showed that aerosol decomposition of the Tl, Ca, Ba, and Cu nitrates resulted in particle generation by a combination of intraparticle reaction and evaporation/condensation. X-ray diffraction of collected powders showed only peaks corresponding to Tl_2O_3 (Fig. 5). TEM, EDS and electron diffraction analysis of the powders, however, showed that the Ca, Ba and Cu were present mainly in an

ADVANCED MATERIALS

amorphous form with the Tl present in a crystalline oxide form on the surfaces of the particles (Fig. 6). Wet chemical analysis of collected powders showed that all the species were present in the appropriate ratios, except for Tl whose concentration was reduced by up to 50%. The observed Tl loss from the particles was consistent with the observation of a coating on the walls of the system. The coated particles (depleted of Tl by 50%) could be sintered to produce Tl-Ca-Ba-Cu-O ceramics showing zero resistance at 110 K (onset at 125 K) (Fig. 7).

These results can be explained by the high volatility of the Tl-containing species. Under typical conditions, Tl nitrates, Tl_2O_3 and Tl_2O evaporate into the gas phase resulting in loss of Tl from the particles. Because of the high vapor pressure of the Tl_2O (roughly 500 Torr at 1000 °C),[63] the Tl exists mainly in the gas phase until cooling while exiting the reactor where the Tl-containing species condense and coat the existing particles. The particles are not superconducting as produced since the Tl was not in contact with the Ba, Ca and Cu at the temperature required for formation of any of the superconducting phases. However, EDS analysis suggested that the Ca, Ba and Cu in each particle were well-mixed. Since the mobilities of Tl species are high at typical processing temperatures, Tl-coated Bi-Sr-Ca-O particles may provide a beneficial route for formation of this particular class of superconducting ceramics.

In the case where two or more species enter the gas phase, a multicomponent nucleation/condensation problem can occur. This may take place for superconductors containing Tl and Pb[64] in which two components have significant vapor pressures under typical operating conditions (approximately 1 Torr for PbO and 500 Torr for Tl_2O at 1000 °C)[63] or for systems in which two or more precursors have significant vapor pressures under the operating conditions. This type of system has not been studied extensively, but useful information can be obtained from studies of the behavior of single-component aerosol flow reactors relying on gas-to-particle conversion.[13-35] This work and that by other investigators has shown that the aerosol dynamics depend strongly on the rate of formation, surface energy, and vapor pressure of the condensing species. These parameters are usually different

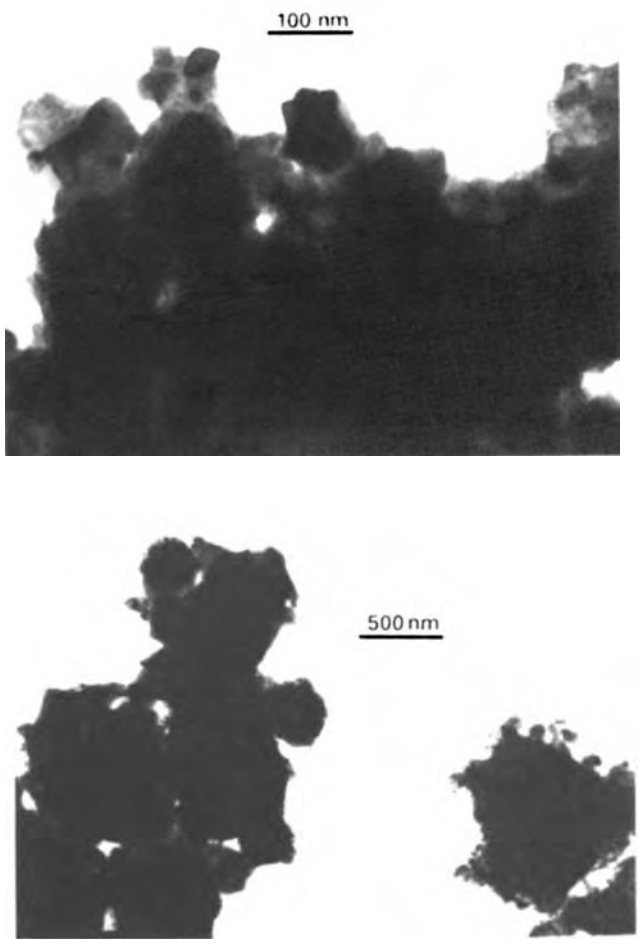

Fig. 6. Powder generated by aerosol decomposition of Tl, Ca, Ba, and Cu in 2:2:2:3 ratio. Energy dispersive spectroscopy showed the presence of Tl-containing crystallites on the surface of the particles.

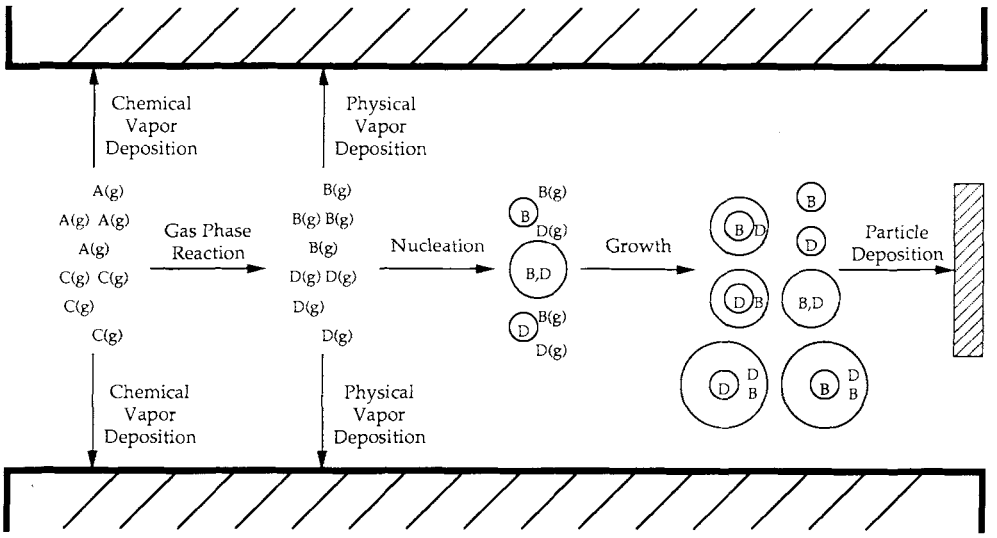

Fig. 8. Physicochemical processes occurring during a two component reaction/nucleation/condensation process.

for each species resulting in unequal nucleation rates and unequal condensation rates on existing particles and walls. Thus, simultaneous condensation to form chemically homogeneous particles is difficult to achieve. Instead, nucleation of separate particles of each species can occur.

Figure 8 shows some of the processes that can occur for two reactant species in the gas phase in the absence of existing particles. The situation in the presence of existing particles, as would be the case for aerosol decomposition, is even more complicated. Particles of one product (B), the other product (D) and a mixture of both products (B and D) may be formed by homogeneous nucleation. These species may grow by addition of B and D from the vapor phase. Many particle compositions and morphologies are possible: uniform mixtures of B and D, pure B, pure D, B coated with D, D coated with B, and other combinations.

The result of the processes outlined above is particles with a broad size distribution, a nonuniform distribution of chemical species with respect to particle size, and a nonuniform chemical composition within each particle. The spread of the size distribution and the distribution of the various chemical species with respect to particle size strongly influence the properties of superconducting ceramics obtained by processing the powders. Broad particle size distributions can lead to difficulties in obtaining high density material. Nonuniform chemical composition within a particle and from particle to particle leads to inhomogeneous material resulting in degraded superconductor properties. Thus, research is required to determine if the nucleation process can be controlled to provide particles with predetermined compositions: for example, a uniform mixture of B and D or particles of one species coated with the other species.

3.2.3. Implications For Other Systems

Although the previous sections discussed superconducting ceramic powder generation by intraparticle chemical reaction and a combination of intraparticle chemical reaction and gas to particle conversion, the results have implications for other systems where particles containing superconducting ceramics or their precursors are formed or suspended in a gas at high temperatures. Examples (Table 1) of such processes include plasma spraying, flame spraying and spray pyrolysis systems for film generation and plasma reactors, flame reactors, and electrohydrodynamic atomization[65] for powder production.

Because of the small particle dimensions involved, transport processes for individual particles in the gas phase can occur extremely rapidly. In general, transport of a reactant, intermediate or product to or from the interior of an aerosol particle consists of three steps, gas phase transport, interfacial processes including adsorption and chemical reaction and transport in the particle.[8-10] The time needed for the gas phase concentration profile around an aerosol particle to achieve a steady state for typical conditions is in the order of microseconds or less for a 1 μm particle. The time to reach interfacial equilibrium is a function of the operating conditions, but can be rapid compared to the characteristic time for solid state diffusion.[8] Thus, the time required for a volatile species to evaporate from a particle or for a species such as oxygen to diffuse into a particle can be controlled by the rate of diffusion in the solid or liquid particle. Further generalizations are difficult, however, because diffusion coefficients in liquids and solids vary tremendously with changes in temperature and composition.

An estimate of the time required for complete evaporation of a species from a particle can be made for the Tl-containing ceramics. If gase phase transport and interfacial processes are rapid, the time depends on the diffusion coefficient of the Tl-containing species in the particle. A diffusion coefficient of 10^{-8} cm^2/sec will allow complete evaporation in roughly 1 second for a 1 μm particle. Thus, if the particle's residence time at the elevated temperatures is greater than 1 second, complete evaporation can occur. In the case of plasma spray or flame spray processes, the heating of Tl-containing particles may result in the loss of Tl from the particles and subsequent segregation of Tl from the other species. A similar situation may occur during spray pyrolysis for film generation. As a droplet is transported to the substrate it is heated, and Tl-containing species may evaporate into the gas phase. Since deposition rates for particles and gaseous species can differ greatly,[22] this mechanism can lead to the incorrect stoichiometry in the deposited films.

3.3. Control of Particle Morphology and Phase Purity

Although most previous studies of particle formation from the nitrates have produced porous particles,[45–48] single-crystal $YBa_2Cu_3O_7$ particles (Fig. 3) can be formed from the nitrates by aerosol decomposition at temperatures near 1000 °C.[39] Single-crystal particle formation is favored by operating at reactor temperatures near the melting point of the material being formed. Thus, operation at lower temperatures can result in porous polycrystalline particles.[39] Other conditions that favor single-crystal particle formation include long residence times and small particle diameters which allow diffusion and reaction in each particle to form solid particles.

Particle formation proceeds as follows. Water droplets containing the nitrate salts of the metals enter the heated reactor where the water evaporates to form porous particles. As the temperature increases, the metal salts decompose to yield porous particles composed of the metal oxides. As the particles are heated further, the metal oxides react and nucleate to form a crystallite of the superconducting phase at a temperature near its metling point. Because of the high temperature relative to the melting point and the short diffusion distances involved, diffusion of the species in the particle to the crystallite results in a collapse of the porous particle to form a solid particle and complete mixing of the various species to form the product. Alternatively, the particle may start as a polycrystalline entity and the preferential growth of one crystallite at the expense of the other crystallites may lead to single-crystal particles.

Materials generation by chemical reaction in a microreactor (each particle) has one major advantage over bulk solid state chemical reaction. In bulk solid state reaction processes, liquid phases that form can percolate through the material resulting in macroscopic segregation. Further heating results only in further aggregation. In contrast, any liquid phases formed during reaction in a particle suspended in a gas are confined to the particle. Since the liquid phase cannot leave the micron-sized particle, macroscopic aggregation of species cannot occur. Thus, the thermodynamically favored product can eventually be formed even when prior melting of the reactants, intermediates or products has occurred.

3.4. Oxygen Diffusion in Single-Crystal $YBa_2Cu_3O_7$ Aerosol Particles

Intraparticle mass transport processes play a critical role in determining the properties of superconducting ceramics. As discussed earlier for the Tl-Ca-Ba-Cu-O system, these processes determine whether or not chemically homogeneous material is obtained. These transport processes can also control the oxygen content of superconducting ceramics. $YBa_2Cu_3O_{7-x}$ formed at temperatures of 900–1000 °C is not a superconductor and must be annealed in oxygen at temperatures of the order of 500 °C to allow the oxygen to diffuse into the material and convert it to the superconductor.[66] Previous methods for the measurement of oxygen diffusion coefficients in $YBa_2Cu_3O_{7-x}$ have examined sintered and annealed material.[67–70] In general, diffusion in sintered ceramics can proceed by several mechanisms including bulk, surface and grain boundary diffusion. Thus, the apparent diffusion coefficient depends in a complicated way on the concentration and distribution of impurities, the structure of grain boundaries and the density of the sintered ceramic part. The relative importance of these different diffusion mechanisms could be sorted out if bulk diffusion coefficients were available.

Bulk diffusion coefficients for oxygen in $YBa_2Cu_3O_{7-x}$ can be obtained by measuring the time required to oxygenate equiaxed single-crystal aerosol particles of known size suspended in oxygen. A temperature-averaged diffusion coefficient was obtained from experiments in which the size of the particles, their oxygen content after being cooled to roughly 100 °C, and the temperature/time history of the particles were measured.[71] Titration measurements[72] gave an oxygen content of $7.04 \pm .03$ for the $YBa_2Cu_3O_{7-x}$ powder indicating that the particles were fully oxygenated. XRD and TGA also showed that the powder was fully oxygenated. Oxygenation of the powder is limited by the time needed for oxygen to diffuse into the largest particles. This time is of the order of r_p^2/D where r_p is the radius of the largest particles and D is the diffusion coefficient of oxygen in $YBa_2Cu_3O_{7-x}$ averaged over the temperature range where diffusion took place.[73] The largest particle radius observed was roughly 1 μm. The time the particles spent cooling from 1000 °C to 100 °C was less than 10 seconds. Thus, the temperature averaged diffusion coefficient was roughly 10^{-9} cm^2/sec. The primary advantage of this method is the ability to measure diffusion coefficients for

single crystals in the absence of grain boundary effects and impurities. Further work is necessary to obtain diffusion coefficients as a function of temperature.

3.5. Thick Film Formation by Aerosol Deposition

Aerosol deposition has been used extensively for the generation of optical waveguides.[112] The formation of thick films of other materials has been investigated only in a few cases. This section will discuss recent results for the formation of thick $YBa_2Cu_3O_7$ films by aerosol deposition.

The fabrication of superconductor/metal wires and tapes with high critical current densities is complicated by difficulties in eliminating impurities such as carbon and obtaining the correct oxygen content in the superconductor. These problems can be minimized by producing high-purity $YBa_2Cu_3O_7$ particles in a gaseous flow system as described earlier, depositing the particles directly from the gas phase onto surfaces by thermophoresis, and then sintering and annealing the deposited particulate films in an oxygen flow to form thick superconducting coatings.[111] Copper tubes with uniform, adherent coatings on their inside surfaces were produced. The coatings showed sharp superconducting transitions above 91 K and critical current densities (J_c) of roughly 100 A cm^{-2}. Advantages of the process include the ease of obtaining the correct oxygen content in the superconductor (since oxygen can be passed through the center of the tube) and the ability to fabricate wires and tapes with arbitrary shapes. A similar process has been used to produce thick Bi-Sr-Ca-Cu-O films with J_c of 8000 A cm^{-2}.[74] Further work is necessary to improve the J_c values and to investigate the formation of thick films on other types of substrates.

4. Summary and Conclusions

The most successful aerosol process for generation of complex metal oxides is aerosol decomposition without transport of metal-containing species across the particle/gas interface. This process has demonstrated the ability to produce $YBa_2Cu_3O_7$ and $La_{1.85}Sr_{0.15}CuO_4$ particles with the following properties:

- Single-crystal
- Fully oxygenated
- Single phase
- Superconducting as produced with $T_c > 90$ K
- Equiaxed and spherical shape
- Uniform chemical composition

An advantage of carrying out materials synthesis in a micron-sized reactor (an aerosol particle) is that segregation is minimized since any liquid phases formed cannot leave the particle. This can be contrasted with bulk processes where macroscopic segregation of species can occur when liquid phases are formed.

Aerosol decomposition can also be carried out under conditions for which metal-containing species can be transported across the particle/gas interface. This can result in the formation of new particles, vapor wall losses, and condensation on existing particles. An example of this mode of reactor operation for superconducting ceramics is generation of Tl-containing powders. In this case, Tl-Ca-Ba-Cu-O particles with a nonuniform chemical composition and a nonuniform distribution of Tl with respect to particle size are obtained. In addition, the particles are not superconducting as produced. However, the particles which consist of a core containing Ca, Ba, and Cu coated with Tl oxides can be processed to produce bulk superconducting ceramics. Thus, the Tl-coated particles provide a useful starting point for the fabrication of bulk ceramics.

Superconducting ceramic aerosol particles can also be exploited for measurements of properties as a function of particle size and for film formation. Oxygen diffusion coefficients can be measured in single-crystal aerosol particles to provide values of bulk diffusion coefficients in the absence of the effects of grain boundary diffusion. Thick superconducting ceramic films can be formed by depositing particles directly from the gas phase onto surfaces.

5. Future Trends

With respect to the general problem of forming complex metal oxides, including superconductors and ferroelectric and ferrimagnetic materials, some of the open questions are as follows:

- For aerosol scientists: How do evaporation, reaction, condensation and nucleation of volatile precursors, reaction intermediates and reaction products influence the chemical composition and morphology of the particles and films?
- For chemists: How can the chemical composition and morphology of particles of existing materials be improved by developing novel precursors? What new materials can be generated using novel precursors?
- For chemical engineers: How do transport processes on a micron-scale such as solvent evaporation, intraparticle transport and intraparticle chemical reaction and heat and mass transport on a reactor-scale influence the morphology and chemical composition of the particles?
- For materials scientists and physicists: What changes in the properties of the powders must be made to

ADVANCED MATERIALS

improve the properties of ceramics formed by processing the powders?

The possibility of producing high quality $YBa_2Cu_3O_7$ has been demonstrated. Powders of other materials with similar characteristics are required for a number of processing schemes for the generation of superconducting ceramic parts and films. Several areas need to be explored in order to increase the number and variety of applications of powders produced by aerosol processes:

- Tl-Pb-Ca-Ba-Cu-O, Bi-Pb-Sr-Ca-Cu-O, and Sb-containing powders produced by aerosol processes may have characteristics that cannot be obtained by other processes. For example, coated and non-equiaxed particles may be useful for the fabrication of bulk ceramics.
- Deposition of superconducting ceramic aerosol particles to form films at higher rates and purities than is currently possible may be feasible.
- The fabrication of bulk superconducting ceramics needs to be studied in conjunction with powder generation by aerosol processes in order to determine the optimum powder generation and processing conditions.

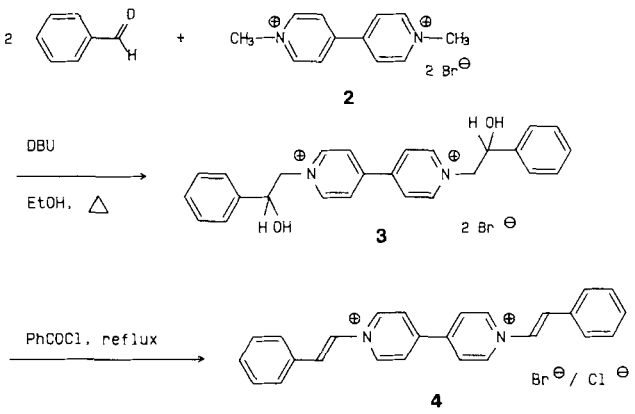
Poly-[*N*,*N*-(1,4-divinylbenzene-β,β′-diyl)-4,4′-bipyridinium dibromide], a Novel Conducting Viologen Polymer**

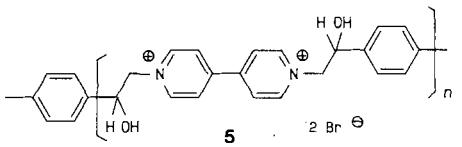
By *Andreas Merz** and *Stefan Reitmeier*

Dedicated to Professor Gottfried Märkl on the occasion of his 60th birthday

The title compound **1** is a new, easily accessible π-conjugated viologen polymer. Properties of particular interest are its conductivity of 1×10^{-3} S cm^{-1} and electroactivity in the potential region from −0.1 to −0.6 V vs. Ag/AgCl.



1



The electrical conductivity of π-conjugated electron rich organic polymers like polypyrrole, polythiophene, and polyaniline is increased by chemical or electrochemical oxidation (p-doping with positive charge carriers).[1] The doping process occurs simultaneously with polymer film formation at the electrode surface during anodic oxidation. On discharging at negative potentials in an electrochemical cell the polymer films become insulating. Polyphenylene and polyacetylene are also electroactive at very negative potentials.[2] The reduction process corresponds to n-doping with negative charge carriers. It was assumed that suitable π-conjugated polymeric viologen structures should be reducible at moderately negative potentials and possibly show conductivity in this potential region.

Methyl viologen **2** displays two reversible redox transitions at −0.57 and −0.92 V.[3] Compound **2** and its homologues have frequently been used as redox catalysts[4] and as electron relays in photocatalyzed water cleavage.[5] Polymeric viologens are also known, with the viologen moiety either as a pendant group on the polymer chain,[6] or as an interconnecting member of the chain.[7]

The orange styryl viologen **4** was prepared as a model monomer in a two step synthesis, following a procedure of *Kröhnke* for the preparation of *N*-alkenyl pyridinium salts,[8] starting from methyl viologen and benzaldehyde and proceeding via the bis-hydrated salt **3** (Scheme 1).[9] The 250 MHz ^{1}H NMR shows that the *E*/*Z* ratio of the styryl units of **4** is 3.6:1. The extended π-system of **4** as compared with **2** is demonstrated by a positive shift of the viologen redox signals and the presence of a third reversible couple which is not likely to be due to the *E*/*Z* isomers.[10]

The same synthetic method is readily applied to the preparation of **1**.[11] Reaction of methyl viologen with 1,4-benzenedialdehyde (1:1) in 90% aqueous ethanol, in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) for 3–4 d at 70 °C gives the polyhydroxy salt **5** as a tan solid in 60% yield. After drying, this is converted to **1** by dehydration in neat benzoylchloride for 10 h at 100 °C.

5

Polymer **1** is obtained as an amorphous black powder. It is paramagnetic, giving a single unresolved ESR signal with $g = 2.009$, a peak to peak width of 5.9 G and a spin density of 5×10^{-17} spins per gram. Elemental analysis shows that the bromide anion has been partially exchanged for chloride which stems from the dehydrating agent. The halogen content is 30% less than calculated for **1** although the C:H:N ratio is correct. The same effect is observed for the hydroxy-polymer salt **5**. The reason for the deviation from the stoichiometric values is not clear at this time, although it may result from the terminal groups or from the irreversible side reaction of some viologen groups. The IR spectrum suggests the presence of water (see[8]) and possibly the benzoate anion. The presence of conjugated viologen structural elements has been confirmed by cyclic voltammetry of 5% of **1** in a

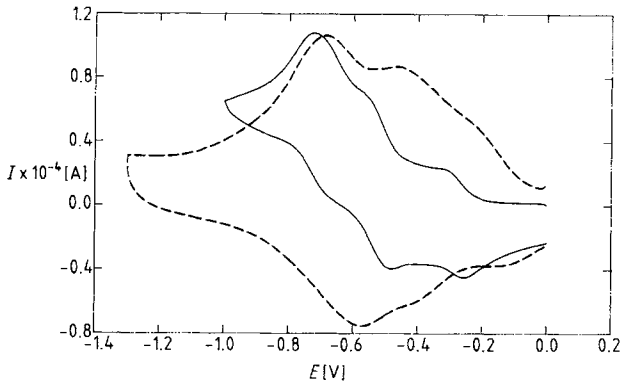

Fig. 1. Cyclovoltammograms of **1** and **4**. (– – –): Voltammogram of **1** embedded in a carbon paste electrode [12] in DMSO/0.1 M Bu_4NClO_4, scan rate 1 mV s^{-1}, E_p(red) = −0.20, −0.46, −0.69 V; E_p(ox) = −0.15, −0.41, −0.58 V. (——): Solution cyclic voltammogram of **4** in DMSO/0.1 M Bu_4NClO_4 on a 0.07 cm^2 Pt disk; scan rate 0.1 V s^{-1}, current scale in this case should be changed to 10^{-5}. Potentials are recorded vs. Ag/AgCl [3]. E_p(red) = −0.31, −0.55, −0.71 V; E_p(ox) = −0.26, −0.48, −0.68 V.

carbon paste electrode[12] (Fig. 1). The voltammogram is very similar to that of **4**. The further positive shift indicates more extended conjugation. The area under the slow sweep voltammogram in Figure 1 corresponds to 1.4 F mol^{-1} for both reduction and oxidation.

Polymer **1** is easily pressed into pellets which have an electrical conductivity[13] of $(1.3 \pm 0.2) \times 10^{-3}$ S cm^{-1}. Neither the ESR spectrum nor the conductivity change on storage in air for two months. Likewise, **1** is stable in water and in many organic solvents. Exposure of the polymer to iodine vapors increases its conductivity by a factor of 2–3. Gaseous SO_2 has no effect. Doping experiments in solvent suspensions with I_2 and $FeCl_3$ for the oxidative process, or with $Na_2S_2O_4$ for the reductive process resulted in almost complete loss of conductivity. Thus, it appears that the necessary conditions for conductivity are produced during the dehydration process without the need for additional doping.

Probing Changes in the Structure and Performance of a Lithium Nickel Oxide Catalyst by in situ X-Ray Diffraction During the High-Temperature Oxidative Coupling of Methane**

By *Ingrid J. Pickering, Peter J. Maddox* and *John M. Thomas**

Heterogeneous catalysts and their precursors are customarily characterized under conditions profoundly different from those that prevail in the actual catalytic reaction. The active solid may possess structural features quite unlike those deduced from measurements conducted at ambient temperatures and pressures. This calls for the increased use of in situ methods for the characterization of heterogeneous

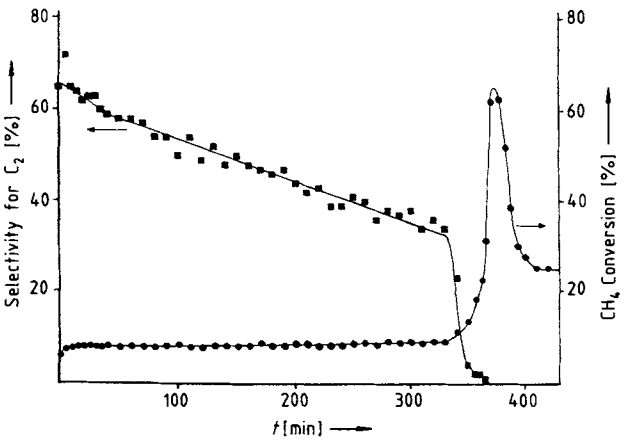

Fig. 1. The changes with time of conversion of methane and selectivity for C_2 hydrocarbons are shown for the duration of the experiment. Percentage conversion of methane is derived as $(100 \times \Sigma n V_{C_n})/V_{CH_4} + \Sigma n V_{C_n}$ and percentage selectivity for ethane and ethene as $(100 \times (2 V_{C_2H_6} + 2 V_{C_2H_4}))/\Sigma n V_{C_n}$ where V_{C_n} is the percentage volume of C_n hydrocarbon product (CO, CO_2, C_2H_4, C_2H_6) in the gas chromatographic analysis. (These values do not take into account any carbon which forms carbonate or other solid phases).

ADVANCED MATERIALS

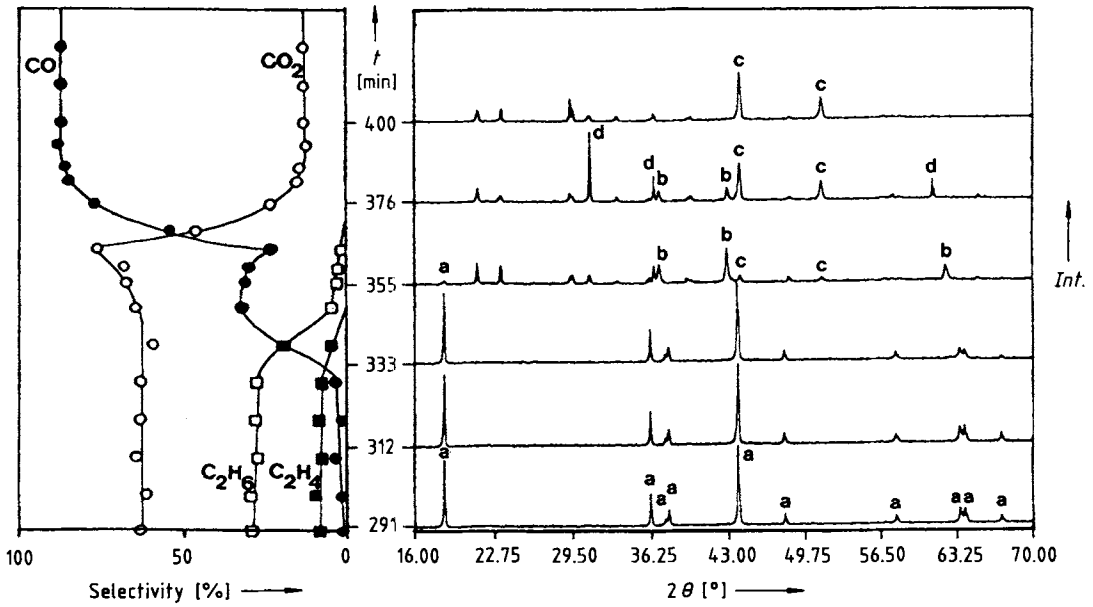

Fig. 2. Variation in selectivities and diffraction patterns as a function of time for the final stages of the reaction. Left: individual percentage selectivities for the various products. Right: corresponding in situ diffraction patterns of the catalyst. The vertical position of the diffraction pattern represents the time at which the scan was commenced, at 16° (2 θ). Diffraction peaks labelled as follows: a: $Li_{0.45\pm0.02}Ni_{0.55\pm0.02}O$, b: NiO, c: Ni metal and d: unknown transient.

catalysts. Here we illustrate the advantages of in situ X-ray diffraction in clarifying the onset and nature of distinct kinds of catalytic action exhibited by a lithium nickel oxide for the oxidation of methane at elevated temperatures.[1, 2]

A sample of 1.01 g of the powdered solid of composition $Li_{0.45\pm0.02}Ni_{0.55\pm0.02}O$ was placed in a porous quartz sample holder in a specially-constructed, resistively-heated, quartz reaction cell fitted with mica windows.[3] The cell was attached to a slightly modified Siemens D500 diffractometer equipped with a rotating anode source (CuK_α radiation), which allowed rapid structural characterization. Under the flow of the reaction gas mixture (composition: CH_4 19.68%, O_2 3.00%, balance N_2; flowrate: 50 mL min^{-1}), the catalyst was rapidly heated to and maintained at 700 °C. A series of diffraction patterns was recorded (2 θ range 16 to 70°), each pattern requiring some 19 min, and concurrently the outlet product gases were analyzed by gas chromatography.

The conversion of methane, and the selectivity for C_2 hydrocarbons during the 7 h catalytic run are shown in Figure 1. After about 330 min the nature of the catalysis changes dramatically (see also expanded version with the appropriate diffraction patterns in Fig. 2). It should be noted that there are three distinct regimes of catalysis associated with correspondingly distinct structural features.

During the initial regime (up to 330 min) the fractional conversion of methane remains essentially constant at ca. 8%; concomitantly the selectivity of C_2 products starts at 65% and gradually drops, for reasons that are at present obscure, to a value of 33% at t = 330 min. The diffraction patterns reveal that a single phase, lithium nickel oxide, functions as the oxidative coupling catalyst. The structure,[4] schematized in Figure 3a, is of the rocksalt type with different cation distributions on alternate close-packed layers.

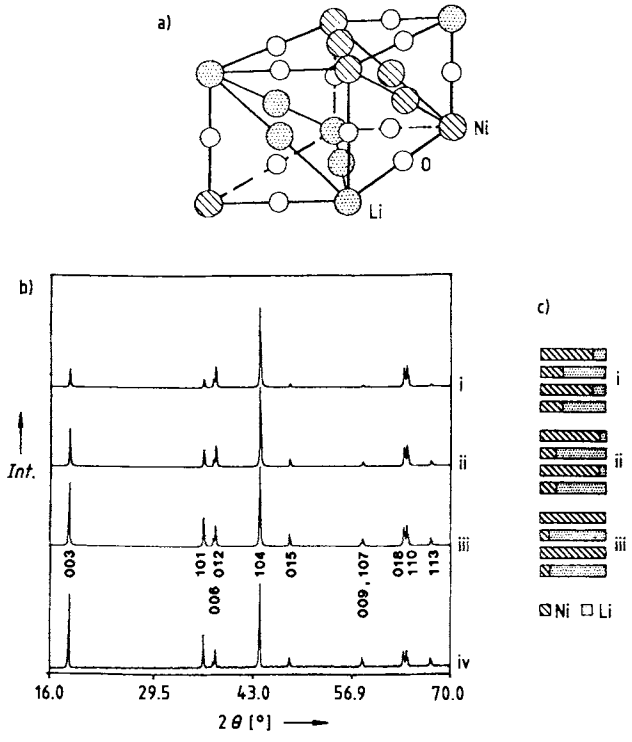

Fig. 3. a) The idealized structure of $Li_xNi_{1-x}O$ for x = 0.5. Its relationship to the rocksalt structure is shown, lithium and nickel ions occupy alternate close-packed layers between the oxygens. b) Diffraction patterns of $Li_xNi_{1-x}O$ for x = 0.43. i, ii and iii are simulated diffraction patterns for increasing order between the layers. Lattice parameters for the simulations are taken from the experimental data (a = 2.905, c = 14.361 Å). iv is the first experimental diffraction pattern collected at reaction temperature (700 °C). c) Representation of the ordering of Li and Ni between the layers. i, ii and iii are the models for i, ii and iii in part b, respectively. i has 20% Li in the predominantly Ni layer, 66% in the other layer; likewise ii 10 and 76%; iii 0 and 86%, i.e. totally ordered.

Diffraction patterns have been simulated (Fig. 3 b, i to iii) for different degrees of ordering[5] of lithium and nickel ions between the layers (represented in Fig. 3c, i to iii). Comparison with the initial diffraction pattern at 700 °C (Fig. 3 b, iv) shows that the lithium ions are essentially fully ordered between the layers. The unit cell is hexagonal, $R\bar{3}m$ with computed cell dimensions of $a = 2.904$ and $c = 14.36$ Å with a slight axial distortion away from the true cubic close packing ($c/a = 4.945$; ideal cubic = 4.899). This distortion is greater than at room temperature ($a = 2.885$, $c = 14.21$ Å, $c/a = 4.925$). The Figures 2 and 3 show that, during the initial period of catalytic activity the lithium nickel oxide structure remains invariant within the limits of our technique. The oxide appears to function as a uniform heterogeneous catalyst in the sense previously elaborated.[6]

In the second regime, 330–360 min, there is dramatic change; at least two crystallographic phases are present as the parent $Li_{0.46}Ni_{0.54}O$ is reduced to its daughter phase NiO (labelled b in Fig. 2). Accompanying the appearance of NiO there is a sharp rise in the degree of conversion of CH_4, and the principal product is CO_2. Production of C_2 hydrocarbons decreases to zero as the Li-Ni-O phase disappears.

In the third and final regime, 360 min and longer, metallic nickel (c in Fig. 2) along with some Li_2CO_3, is the predominant crystallographic phase. It is also noted that new, sharp peaks appear (labelled d); these are as yet unidentified and rapidly disappear (see top diffraction pattern of Fig. 2) before the catalyst is finally converted to metallic nickel and lithium carbonate. In this regime CO is the dominant gaseous product of catalytic reaction, and there is now no longer a uniform heterogeneous catalyst.

In summary, it has been shown that in situ X-ray diffractometry coupled with parallel gas chromatography throws fresh light on the structure of reactive solid catalysts. In the case of the Li-Ni-O system studied here, three distinct regimes could be readily identified each with different gaseous products. Furthermore, although the experimental conditions were not optimized, it was possible to detect the presence of an as yet unidentified transitory solid product as well as those expected on the basis of the known chemistry of the parent, monophasic mixed oxide catalyst. Greater time resolution may be attained with our set-up by using a higher flux of X-rays and a more sensitive detector.

High Resolution Electron Microscopy of the High-T_c Superconductor $Bi_{2+x}Sr_2Ca_{1-x}Cu_2O_{8+\delta}$

By *W. Zhou, A. I. Kirkland, K. D. Mackay, A. R. Armstrong, M. R. Harrison, D. A. Jefferson, W. Y. Liang* and *P. P. Edwards**

The structure of the 85 K Bi-Sr-Ca-Cu-O superconductor has been investigated by means of high resolution electron microscopy combined with image simulation. An ordered one-in-five substitution of calcium by bismuth ions is proposed as the explanation for the observed superlattice formation. This model is consistent with the reports of the recent analytical studies carried out on the same system.

The discovery of high temperature superconductivity in the Bi-Sr-Ca-Cu-O system has demonstrated conclusively that this phenomenon is not confined to compounds containing yttrium and rare-earth elements.[1–4] Several groups have isolated a high-T_c phase in this system and single crystal X-ray[4–6] and neutron diffraction[7] studies have shown both similarities and differences between these new cuprate superconductors and the previously known 40 K and 90 K materials.[4–6] A superstructure has also been observed in these diffraction studies and various structural models for its formation have been proposed.[8–10] Equally important was the indication of additional electron density at the Ca site suggesting a variable Bi:Sr:Ca occupancy.[5, 6] Here the results of high resolution electron microscopy (HREM) and model image simulation of the title compound are presented from which an ordered compositional variation in atomic arrangement, which leads naturally to the superlattice for-

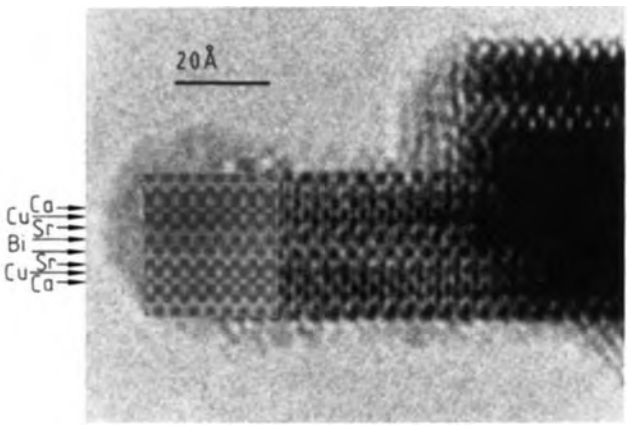

Fig. 1. HREM image of the tip of one crystal a single c lattice vector wide viewed down [110] of the published unit cell together with a calculated image inset (defocus = 950 Å, crystal thickness = 20 Å). The image clearly shows in cross section the metal layers in the order (Bi-Sr-Cu-Ca-Cu-Sr-Bi).

ADVANCED MATERIALS

mation, is proposed. The substitution of Bi on the Ca site also leads to oxygen incorporation and concomitant oxidation.

The crystallites invariably possessed a plate-like morphology and images were readily obtained down the [001] zone axis. These images and electron diffraction patterns confirmed the essentially square 5.4 Å basic unit cell in this projection, and also indicated the pronounced superlattice. Some crystallites were also found to fracture perpendicular to their main cleavage plane or alternatively to curl up at the edges. It was then possible to obtain images in [110] or [100] projections. Figure 1 shows an image of a crystal in its [110] projection and the crystal is only one *c* lattice vector or unit cell wide. No evidence of the superlattice is visible in this projection. It appears that the projected charge density approximation[11] can be used to interpret the image and that the dark dots in the image can thus be correlated with the cation positions, although the oxygen atoms cannot be observed directly. The one-dimensional superlattice can be seen when the crystals are viewed in the [100] orientation, as shown in Figure 2. In this case the image is from the edge of a curled-

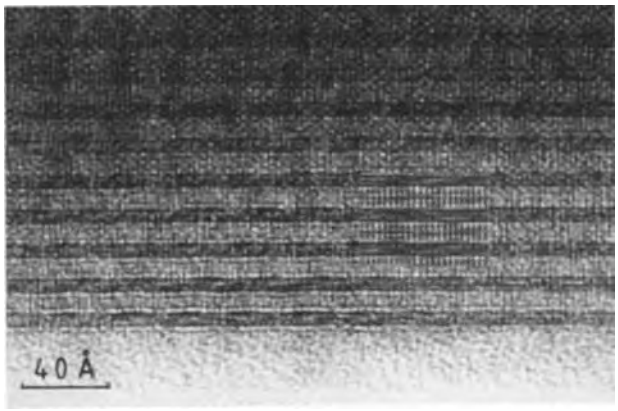

Fig. 2. HREM image of a crystal viewed down the [100] direction, with the one-dimensional superlattice being visible. The model simulation (insert) was calculated for a crystal thickness of 30 Å and an objective lens defocus of −1600 Å.

up platelet crystal some 200–300 Å thick, and clearly shows both the layer-like nature of the material, and a subtle variation of fringe contrast in a direction along the plane of the layers indicating the existence of the superlattice. No drastic variations in the basic arrangement of lattice fringes were observed, implying that a relatively minor effect, such as cation substitution or displacement may be responsible for the superlattice. In general, the superlattice was observed in one dimension as shown in Figure 3a, but a two-dimensional variant was also observed in certain cases (Fig. 3b). The periodicity of the superlattice, whether one- or two-dimensional is predominantly five basic cell repeats, though periods of four and six unit cells were also recorded. In addition, these superlattice vectors have occasionally been observed to be slightly inclined to the basic cell axes. No platelets were obtained which did not exhibit the superlattice.

Two structural models have been proposed[4–6] for this new high temperature superconductor based on single crystal X-ray studies. These models have virtually identical cation distributions, but differ in the arrangement of oxygen ions in the Bi_2O_2 bilayer. In the first,[4] oxygen ions are placed between the sheets of bismuth ions, in an arrangement similar to that found in Aurivillius layered oxides,[12] whereas the second[5–7] has a coplanar arrangement of bismuth and oxygen. The [110] projection is most suitable for comparing the two models, and accordingly images from both were simulated and compared with experimental results. At a focus slightly beyond the optimum both simulations gave a broad overall agreement with the features of the experimental image, although with the oxygens in the same plane as the bismuth the scattered intensity from this plane appeared to be slightly enhanced, and this manifested itself as a more pronounced white fringe between the bismuth-oxygen components and the rest of the structure. The differences between the simulations from the two models were, however, minimal and it was concluded that the scattering from the oxygen ions was insufficient at this value of specimen thickness to distinguish between them. However, with the onset of increased multiple scattering at greater specimen thicknesses differences were expected to occur,[13] but interpretation of images of thick crystals of such strong scatterers is difficult, particularly for those involving inelastic electrons.[14] In addition, there exists the possibility of crystal bending. Consequently no further attempts at image matching were made, although studies of this problem are continuing.

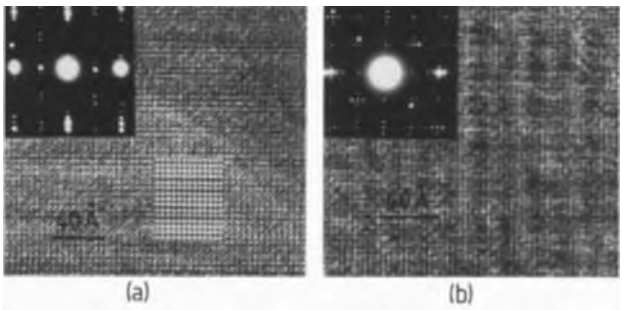

Fig. 3. HREM image of a crystal viewed in the [001] orientation, with insert selected area electron diffraction patterns, a) with one-dimensional superlattice, b) with an apparent two-dimensional superlattice. The inset image simulation in a) was calculated for a crystal thickness of 60 Å and an objective lens defocus of −2200 Å.

This same model was used to simulate images in the [100] projection and again it gave good agreement with the basic image contrast. However, in this projection a superlattice was also visible, which can be seen as a periodic darkening of the overall contrast in a direction perpendicular to the *b* axis (Fig. 2). Image simulations from the basic structure reveal that the darker component represents the Bi_2O_2 layer and the lighter parts the Sr-Ca-Cu-O. This darkening might therefore arise from the inclusion of heavier cations within the Sr-Ca-Cu-O component. Bearing in mind the established tendency of bismuth to replace calcium, it is proposed that this is the origin of the modulating image contrast. Accordingly a model was constructed for such a superlattice and this is shown schematically in Figure 4. Here rows of calcium ions parallel to the [100] axis were replaced by bismuth in

every fifth unit cell. The proposed substitution of the Ca by Bi ions will necessitate a conversion of the square pyramids of oxygen around copper atoms into linked octahedra which effectively constitute a small section of perovskite structure and will also require a local expansion of the structure in the [001] direction. Between the regions of additional bismuth, the layers in the model of Figure 4 suffer a contraction, and, as the regions of excess bismuth are staggered in adjacent layers, the average layer spacing is that of the published structure. Interestingly in this construction, each Bi substituent is accompanied by two oxygen atoms which over-compensate for the increased charge on the bismuth. Thus the resultant stoichiometry is $Bi_{2.2}Ca_{0.8}Sr_2Cu_2O_{8.4}$, giving a nominal average copper valency of +2.33, reminiscent of the copper valency in $YBa_2Cu_3O_7$ superconductors. Images simulated from this model are in good agreement with those obtained experimentally in the [001] projection (Fig. 3). The same model was also used to simulate images in the [100] projection with some displacement/relaxation of the anion lattice at the positions of the inserted oxygen ions as indicated in Figure 4, and the basic superlattice contrast was again obtained. It is therefore concluded that this substitution scheme provides a plausible explanation for both the non-stoichiometry of this material and the observed superlattice. Furthermore, it is assumed that the occasional departure of the superlattice period from five to either four or six unit cell repeats is a means by which the lattice can reduce the strain energy built up by this distortion.

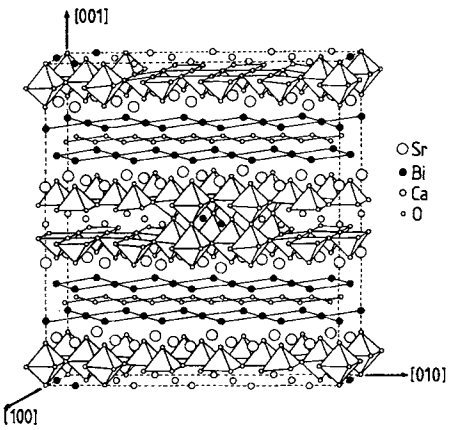

Fig. 4. One superlattice unit cell of the structure model used for the image simulations of Figures 1, 2 and 3. The copper atoms are located at the centers of the square pyramids or octahedra. Unit cell dimensions are $a = 5.4$ Å, $b = 5.4$ Å, $c = 30.7$ Å.

In compositional terms, our model is consistant with the analytical data of *Chippindale* et al.,[15] and would correspond to their predominant phase. Detail differences in cation ratio could well arise from the presence of the superlattice and its variable periodicity, and our structure model can be regarded as an intermediate between two possibly hypothetical end-member phases, namely $Bi_2CaSr_2Cu_2O_8$ and $Bi_3Sr_2Cu_2O_9$. With the general formula $Bi_{2+x}Ca_{1-x}Sr_2Cu_2O_{8+2x}$, the main phase described by *Chippindale* et al.[15] would correspond to $x = 0.143$. On the other hand, their second phase cannot fit easily into this scheme due to the much reduced copper content. This phase, which has a reduced c parameter, may be constructed, however, if a complete Cu-O layer together with a Sr-O layer, were removed, giving the stoichiometry $Bi_{2+x}Ca_{1-x}SrCuO_6$, with $x = 0.286$.

Experimental

Samples with nominal stoichiometry $Bi_{2+x}Sr_2Ca_{1-x}Cu_2O_{8+\delta}$, where $x \approx 0.2$ and $\delta \approx 0.4$, were prepared by reacting Bi_2O_3, $CaCO_3$, $SrO_2/Sr(NO_3)_2$ and CuO in appropriate proportions at 800 °C in air for 20 hours. Samples were tested for superconductivity in the temperature range 10–300 K using both four-probe electrical resistance and field exclusion measurements, and the results in Figure 5 show that a zero resistance state is obtained at 83 K. The samples showed a Meissner effect comparable to those obtained for $YBa_2Cu_3O_{6.9}$ in the same apparatus.

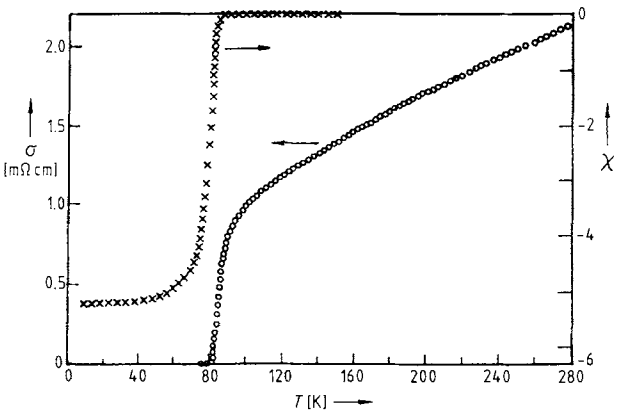

Fig. 5. Variation with temperature of resistivity and AC susceptibility of a pressed pellet of $Bi_{2+x}Ca_{1-x}Sr_2O_{8+\delta}$, where nominally $x \approx 0.2$ and $\delta = 0.4$. The resistivity vanishes at 83 K coinciding with the sharp turn in the susceptibility.

Specimens were prepared for HREM examination by grinding the synthesized material in an agate mortar and pestle in either acetone or liquid nitrogen; the latter being used to embrittle the sample and encourage non-standard cleavage. A drop of the suspension was then placed onto a copper grid coated with a holey carbon film. HREM investigations were carried out with a modified JEOL JEM-200CX instrument [16] operated at 200 kV, with objective lens characteristics $C_s = 0.52$ mm, $C_c = 1.05$ mm and an interpretable point resolution of 1.95 Å at the optimum defocus. Crystals were chosen by examination in the selected-area diffraction mode, and they were oriented such that the beam was parallel to each of the main high symmetry zone axes. After careful correction of residual astigmatism and illumination system misalignments [17], images were recorded at a magnification of ca. 450.000 X. For comparison with experimental images, model-simulated images were computed using the multislice method [18] for [100], [110] and [001] projections of the previously identified basic unit cell over a systematic range of crystal thicknesses and objective lens defocus values.

Polymer Benzo[15]crown-5 Complexes as Sensor Materials for Solvent Vapors—Aromatic Halogenated Hydrocarbons and Polar Solvents**

By *Franz L. Dickert** and *Doris Zeltner*

Dedicated to Professor Gerd Wedler on the occasion of his 60th birthday

For the first time thin layers of polymer-metal complexes with crown ether ligands have been applied as sensor materials for the detection of solvent vapors. The hydrophobic properties of these films enable the detection of even halogenated and aromatic hydrocarbons through conductivity measurements.

The crown ether[1] [15]crown-5 (15C5) forms 1:1 complexes with Mg^{II}, Zn^{II}, Co^{II} and Ni^{II} ions (because they fit well into the cavity of this macrocyclic ligand) and can act as a tetra- or pentadentate ligand.[2, 3] Complexes with the composition $[M^{II}(15C5)\ (S)_2]^{2\oplus}$ have been identified in donor solvents (S). In inert solvents, however, even the usually non-coordinating $ClO_4^{\ominus}$ ion yields inner sphere complexes.[3] The reversible substitution reaction of coordinated anions $X^{\ominus}$ (e.g. $ClO_4^{\ominus}$) by donor molecules [Eq. (a)] has been applied to develop sensor materials for solvent vapors:

$$[M^{II}(15C5)(X)_2] + 2\,S \rightleftharpoons [M^{II}(15C5)(S)_2]^{2\oplus} + 2\,X^{\ominus} \qquad (a)$$

[**] This work was supported by Siemens AG, Central Research and Development (ZFE F1 AMF 32, Dr. *G. Mages*), and the Fonds der Chemischen Industrie.

The formation of a charged complex and anions through the interaction of the initial complex with solvent molecules can easily be detected by conductivity measurements. For practical use formaldehyde resins[4] synthesized from benzo[15]crown-5 (B15C5) are more convenient (§B15C5). These polymer materials form complexes with $Mg^{2\oplus}$ such as **1** in $CH_3OH/CHCl_3$ solution.

Solutions of these polymer complexes are dropped onto interdigital structures to perform conductivity measurements. Stable amorphous films with a thickness of approximately 0.2 μm to 1 μm are obtained after evaporation of the solvent.

The sensor effect consists of two steps. First, an absorption of solvent vapors by the solid macrocyclic layers occurs followed by a chemical reaction according to equation (a). Macrocyclic complexes are very favorable materials for the absorption of different kinds of solvent since these ions have pronounced hydrophobic properties. Strong absorption occurs in the case of protic and aprotic polar solvents such as alcohols, ketones, esters etc. and also for aromatic and halogenated hydrocarbons.

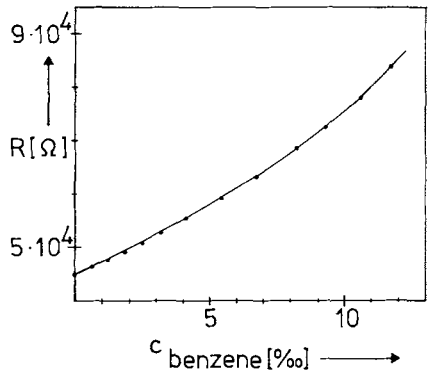

Fig. 1. Dependence of the resistance of the 1:1 complexes of $Mg(ClO_4)_2$ with §B15C5 on an interdigital structure (5 μm electrode distances) on the amount of benzene in the air at 20 °C and 50% humidity.

A typical measurement, e.g. the detection of benzene in the air, is depicted in Figure 1. The resistance of the sensor layers increases parallel with the amount of solvent vapor in the air produced by a gas mixing apparatus.[5] Solvents with no donor properties also result in this sensor effect, since water stemming from the humidity of the air is removed from the sensor layers by the incorporated benzene. Since ionic conductivity is responsible for the described effect, as the ion concentration is diminished according to equation (a) the resistance of the sensor layers increases. The sensitivity of the proposed sensor materials to water vapors can be reduced by increasing the hydrophobic properties of the layers. This can be achieved by the inclusion of cross linking agents such as anisole which enlarge the aromatic ring content in the resins. The addition of ingredients with solvating power such as polyethyleneglycols enables sensors to be designed with characteristic properties. As shown in Figure 2 this procedure can yield a zero slope for certain solvent vapors (e.g. dichloromethane) whereas other solvents (e.g. ethanol) give

a sensor response. Ions other than **1** can also be used. The B15C5 ligand acts in the case of the $K^{\oplus}$ ion as a cap since the ion diameter is larger than the cavity dimension of this crown ether. The application of arrays of these sensors with different characteristic lines makes it possible, in combination

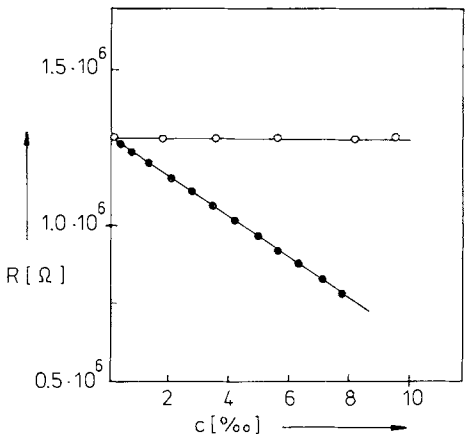

Fig. 2. Dependence of the resistance of the 1:1 complexes of KCl with § B15C5 after the addition of polyethyleneglycol (100 wt.-%, M_r 1000) on an interdigital structure (5 µm electrode distances) on the amount of dichloromethane (○) and ethanol (●) in the air at 20 °C and 30% humidity.

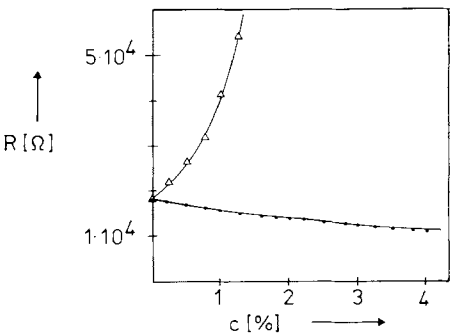
with the methods of pattern recognition,[6–8] to detect organic vapors in the air independent of the humidity. More generally, the selectivity of these sensors can be improved by sophisticated signal processing.

These gas phase measurements can also be applied to detect traces of organic solvents in water. For this purpose a Teflon membrane was applied to separate the sensor element in the gas phase from the water. The solvent vapor is able to penetrate the membrane and a constant vapor pressure of water is obtained in this way. Results for ethanol and dichloromethane are presented in Figure 3. The absorption of the coordinating ethanol [eq. (a)] leads to a decrease in the resistance whereas the opposite effect is observed for dichloromethane as already described for benzene (Fig. 1).



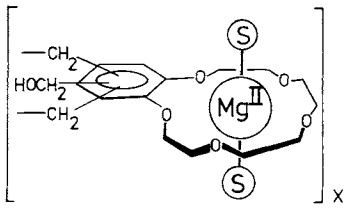


Fig. 3. Dependence of the resistance of the 1:1 complexes of $Mg(ClO_4)_2$ with §B15C5 on interdigital structures (5 µm electrode distances) on the amount of ethanol (●) and dichloromethane (△) in water at 20 °C for a dipping sensor. The sensor element and the water are separated by a permeable Teflon membrane.

The detection limits can easily be determined from the characteristic lines. According to Figure 1, 17 ppm benzene in air or 40 ppm ethanol and 6 ppm dichloromethane in water (Fig. 3) are detectable if a resolution of 10^{-3} for the relative changes in the resistance are assumed.

It is possible to construct low cost equipment for the detection of solvent vapors based on the proposed polymer macrocyclic complexes **1**. The conductivity measurements

1

are easily performed with oscillator circuits incorporating a free running multivibrator. Another possibility is the application of a chemical field-effect transistor (ChemFET).[9] In this method the sensor material is applied to the gate of a ChemFET and electrical contact is realized throuh the use of a perforated electrode[10] which is permeable to gas. In this way compatibility to integrated circuits can be achieved.

Conference Reports

Martensitic Transformations in Bochum

By Norbert Jost *

The European Conference on The Martensitic Transformation in Science and Technology held on March 8.–10. 1989 in Bochum, was a sequence of more or less informal meetings of researchers from western European countries interested in martensitic transformation.** It was organized by *E. Hornbogen* and *N. Jost* from the Institute of Materials at the Ruhr University, Bochum, and *V. Schumacher* from the German Society of Materials (DGM), Oberursel.

The martensitic transformation is a particular type of first order structural phase transformation in crystalline solids. Among its characteristics are its diffusionless nature and the rather large amount of shear displacement associated with the change in crystal structure. Consequently, its onset and course is not only determined by thermodynamic equilibria and nucleation, but also by internal and external shear stresses. It has been found in all types of crystalline materials: ceramics (ZrO_2), polymers (PTFE), and metals (steels, shape memory alloys). The differences in the characteristics of the martensitic transformation from similar transformations in crystalline solids are shown in Table 1.

Table 1. Definition of the martensitic transformation in comparison with some similar solid state reactions.

characteristics / transformation	no diffusion $D \approx 0$	no change in chemical composition $\Delta C \approx 0$	first order transformation 1. Order	large lattice variant shear $\gamma_{\beta\alpha} \gg 0$
martensitic	+	+	+	+
pre-martensitic (and similar)	+	+	○	○
bainitic	○	○	+	+
massive	○	+	+	○

Due to the strong response to the conference announcement two parallel oral sessions in addition to posters were necessary. The topics of the conference were subdivided into four large groups: 1) Fundamentals; 2) Iron Based Alloys, Steels; 3) Shape-Memory Alloys; and 4) Mn-, Ti-, Zr-Alloys and Ceramics.

[**] Conference proceedings will be published by the "DGM-Informationsgesellschaft", Deutsche Gesellschaft für Metallkunde e.V., D-6370 Oberursel, FRG. Editors: E. Hornbogen, N. Jost.

Five invited lecturers summarized recent research interests and 75 contributed papers covered a wide range of more specialized subjects. Additionally, two workshop discussions dealing with "Residual Austenite and Measurement Techniques" and "Future of Shape Memory" were held.

The aim of the conference was to bring together the various interested groups in western European research institutes and industry in order to review the present situation, to assess the prospects, and to define tasks for the future.

For about 3000 years mankind was baffled by the phenomenon of the hardening of steel. About 100 years ago the first successful scientific efforts were made for the scientific clarification of this problem by *Sorby* (1865) in Sheffield. *Adolf Martens* (1850–1914), the ex-president of the Royal Institute for the Testing of Materials, Berlin, gave his name to the main theme of the conference, and an introductory lecture ("*Adolf Martens* and Early Research on Martensite") commemorated the 75th anniversary of his death. This was given by *H. Czichos*, the vice-president of the present Federal Institution for the Testing of Materials (BAM) in Berlin. He recalled some of the highlights of the fundamental work of this great researcher and presented some very interesting original drawings made by *A. Martens* in the 19th century using a specially developed microscope.

The sessions on shape memory alloys (SMA) were led off by three keynote lectures. In the first one, *L. Delaey* (Katholieke Universiteit Leuven, Belgium) gave a review of the potential shape memory alloys. Because SM-effects are not shown in all martensitic alloy systems, all SME "candidate" systems were pointed out, and three groups of technologically important SMA were highlighted. Besides the characteristics of copper- and nitinol based alloys, two recently developed iron based alloys (Fe-Mn-Si and Fe-Ni-Co-Ti) were discussed. The subjects of the second keynote presentation by *R. Gotthardt* (Ecole Polytechnique Federale de Lausanne, Switzerland) were the TEM mobility of austenite-martensite interfaces as well as hysteresis and internal friction. *G. Guenin* (Institut National des Sciences Appliquees, Villeurbanne, France) discussed the two way memory effect in relation to the nucleation and growth of martensite.

The session on the fundamentals of the martensitic transformation was started by a paper by *W. Krauss, S. K. Papi* and *H. Gleiter* (Universität des Saarlandes, Saarbrücken, FRG) in which the mechanism of martensite nucleation was

reviewed. *I. Müller* (Technische Universität Berlin, West) discussed a model for the simulation of shape memory behavior after which the session was concluded by *J. Ortin* and *A. Planes* (University of Barcelona, Spain). They pointed out the thermodynamics of the thermoelastic martensitic transformations in relation to calorimetric measurements.

The second session on shape memory alloys was concerned with thermal and thermomechanical aspects. It was led off by *M. Sade* (a von Humboldt fellow on leave from Centro Atomico Bariloche, Argentina) who gave a report on the thermal and mechanical fatigue of shape memory alloys. The other papers in this session discussed the effect of aging and the thermal and thermomechanical stability of Cu-based SMA.

Many contributions were presented on alloy development and applications, most of them concerned with Ni-Ti alloys. The report of *P. M. Kleinherenbrink* and *J. Beyer* (Univerisity of Twente, Enschede, Netherlands) dealt with the control of the transformation temperatures of Ni-Ti alloys by ternary additions and *T. Duerig* and *K. Melton* (Raychem Corp., Menlo Park, USA) presented details of a very effective way to obtain wide hysteresis in Ni-Ti alloys by the addition of niobium. *J. Beyer, E. J. M. Hiensch* and *P. A. Besselink* from the university of Twente, Enschede, Netherlands reported work on the possibility of the resistance welding of Ni-Ti SMA. The results of this work may be very interesting for the future, especially for new industrial applications of SMA. In the same way this could be said for the "CADSMA", the computer aided design of SMA. A large group of authors from the university of Leuven and *N. V. Proteus* (Kortijk, Belgium) outlined the special problems concerned with construction using SMA. In the next three lectures *P. Tautzenberger* (G. Rau GmbH, Pforzheim, FRG) and *D. Stöckel* (Raychem Corp., Menlo Park, USA) gave an overview of the industrial application of SMA and drew a comparison to the properties of thermobimetals. *J. M. Welter* and *P. Naudot* (Trefimetaux, Serifontaine, France) reported about the development in industrial scale fabrication of Cu-based SMA.

A whole session was concerned with new iron based SMA. It was led off by *M. Sade* who gave a review of the SME in Fe-Mn-Si alloys. *Y. Vanderveken* and his coauthors (Katholieke Universiteit Leuven, Belgium) continued the session with a report on the influence of thermomechanical treatment on the one way effect in Fe-Mn-Si alloys. *P. Donner* and *E. Hornbogen* (Ruhr-Universität Bochum, FRG) described the production of Fe-Mn based SMA by melt spinning and discussed the results in relation to the influence of rapid solidification on the SM behavior. The session was concluded by two papers from *N. Jost* and *K. Escher* (Ruhr-Universität Bochum, FRG) in which the effect of the austenite microstructure on the martensitic transformation and the mechanical properties of Fe-Ni-Co-Ti SMA were analyzed.

The last session on SMA was concerned with special transformation characteristics and hysteresis. It began with a paper by *L. Lu, E. Aernoudt* and *L. Delaey* on the modeling of hysteresis in martensitic transformations after which *J. Stoiber, J. van Humbeeck* and *R. Gotthardt* described the hysteresis effects during martensitic transformation in Cu-Zn-Al SMA. The report of *G. Airoldi* and *G. Riva* (Universita di Milano, Italy) dealt with the stepwise, stress free, martensitic transformation in the Ni-Ti system. The last paper of this session was presented by *L. Manosa* (University of Barcelona, Spain) who had studied the origin of acoustic emission during thermoelastic martensitic transformation.

In addition to these oral sessions 21 posters concerned with SM and a workshop on the future of shape memory held by *E. Hornbogen* gave the participants of the conference the opportunity to discuss more of the fundamental as well as specialized subjects. A systematic survey of shape memory effects and applications in the different fields of engineering was given by *E. Hornbogen* as a basis for the workshop discussion. It can be seen from Table 2 that a large field of applications exist.

Table 2. Systematic survey of shape memory effects and applications in engineering.

technology \ SM effect	one-way	two-way	pseudo-elasticity
connecting, fastening	couplings, pipe connections expanding rivets		seals, spectacle frames
control		valve control, temperature protection greenhouse opener	
motor vehicle		opening of fog lights gear adjustments	high noise absorption
data processing	plug connections for circuits	head/disc system magnetic data memory color changes for optical storage	
engines/ power		rotating machines, solar battery control	
automation	manipulators	robot hands	
medicine	implants (osteosynthesis)	endoscope control	dental braces
clothing	fabric reinforcement		rubber substitute

Besides the sessions on SM, the second large group of contributions was concerned with new developments in steels. It was begun by the keynote paper from *I. Schmidt* (Zahnradfabrik Friedrichshafen AG, FRG) who gave an overview of metastable ferrous austenites and the consequences on fracture and tribology.

The session was continued by *B. Skrotzki* and *E. Hornbogen* (Ruhr-Universität Bochum, FRG) who described a volume fraction vs. temperature function of the martensitic transformation in iron based alloys. *H. Weiland, L. M.*

Matthews and *H. J. Bunge* (Technische Universität Clausthal, FRG) reported work on the texture and microstructure of lath martensite and *H. Berns* (Ruhr-Universität Bochum, FRG) traced the development of new martensitic nitrogen steels, discussing his results with special reference to the technological applications of this steel. *D. Löhe, R. Bartels* and *E. Macherauch* (Universität Karlsruhe, FRG) then dealt with the interaction of dynamic strain aging and the transformation of retained austenite to martensite, after which *K. Ullako* and *J. Pietikäinen* (Helsinki University of Technology, Espoo, Finland) reported their results on the carbon redistribution in low temperature deformed and aged martensite. Fe-Ni-C alloys were the subject of a paper by *X. M. Zhang* (Institute of Metal Research, Shenyang, China) who had studied the effect of plastic deformation on the lenticular martensitic transformation. *T. Abe* and *C. M. Sellars* gave an overview on the effect of thermo-mechanical treatment on the reverse transformation behavior and micro-duplex formation in Fe-Ni alloys. The last lecture of this session was given by *H. Vetters* (Institut für Werkstofftechnik, Bremen, FRG) who discussed the influence of unidirectional and cyclic loading on the martensite formation in austempered ductile iron.

The second session on steels was concerned with the mechanical properties. It began with a paper by *E. Gautier* and coauthors (Laboratoire de Science et Genie des Materiaux Metalliques, Nancy, France) on the transformation plasticity and resulting microstructures for strain induced martensitic transformation in Fe-Ni-C alloys. *Y. Zhang* (on leave from Shangai Iron and Steel Institute, China) reported on reverse austenite and its effect on mechanical properties. The microstructure-strength relationship of low carbon bainite and martensite was discussed by *W. Österle* (BAM, Berlin, FRG), and then *A. Schulz-Beenken* and *H. P. Hougaray* (Max-Planck-Institut für Eisenforschung, Düsseldorf, FRG) reported on a development of high strength martensite. They have shown that the age hardening of coherent intermetallic precipitates is a very effective way to obtain such martensites. In the last paper of the session *J. B. Vogt* and his coauthors (Universite de Lille, France) discussed the influence of nitrogen on the low temperature stress induced martensitic transformation of stainless steel.

In the workshop "Residual Austenite and Measurement Techniques" held by *I. Schmidt* and in five additional posters, interesting aspects on the development of steels were discussed in detail.

The session on transformations in Mn-, Ti-, Zr-alloys and ceramics was led off by *H. Warlimont* and coworkers (Vacuumschmelze Hanau, FRG). They gave an overview of displacive transformation phenomena in high-T_c-superconductors. The lecture by *G. Vogl* and coauthors (Universität Wien, Austria) dealt with the martensitic phase transition and soft phonons in the pure metals Ti and Zr. *M. Humbert* and coworkers (University of Metz, France) explained a simulation model for the texture transformation which occurs during the martensitic $\alpha-\beta$ transformation of Zr sheets. The fractal aspects of the martensitic transformation in Zirconia were discussed by *W. Wunderlich* (MPI-Düsseldorf, FRG) who made special reference to the study of fractal geometry as a new method for the characterization of microstructures. *S. Schmauder* (MPI Stuttgart, FRG) discussed the nucleation of the martensitic transformation of ZrO_2 in the system Al_2O_3-ZrO_2 before *M. Ellner* (MPI Stuttgart, FRG) closed the session by describing the structure of the high temperature phase $Mn_{0.8}Al$ (h) and the martensitic transformation of this phase to Mn_5Al_8.

The last contribution of the conference was the presentation of an educational film by *S. Keller* (Gewerbeschule Hamburg, FRG) and *J. F. Edgar* (Stockport College of Technology, England) in which the crystallographic characteristics of the martensitic transformation in steels were shown with hard sphere models.

The conference was an exciting and important meeting and provided an excellent opportunity for researchers from academic institutions and industry to meet and discuss problems and aspects of martensitic transformation.

Composites and Particle Technology in Las Vegas

By Wolfgang A. Kaysser *

The 118th TMS Annual Meeting and Joint TMS/SME (The Minerals, Metals and Materials Society/Society of Metallurgical Engineering) Exhibition from February 27 to March 2, 1989 in Las Vegas, Nevada, USA confirmed the growing importance of particulate technology as the major production route to new high performance materials. It is increasingly accepted that the required property combinations such as high temperature strength, creep resistance and toughness at low temperatures are not achievable in mono-

Institut für Werkstoffwissenschaften
Pulvermetallurgisches Laboratorium
Heisenbergstraße 5, D-7000 Stuttgart 80 (FRG)

lithic materials and tailored composite microstructures are needed.

Many advanced materials such as intermetallics, ceramic matrix composites and to a lesser extent metal matrix composites suffer from low fracture toughness. New micromechanics models of composite toughening, presented at the conference, require microstructures which permit toughening through the removal of weakly bonded fibers and the bridging of strongly bonded ductile particles. Titanium aluminides are a nice example of attempts to improve the properties of a monolithic base, e.g. Ti_3Al, by introducing stiffening particulates (SiC) which also enhance creep properties, and second phase ductile inclusion (Nb) which results in an increased toughness at lower temperatures. Other intermetallics such as advanced nickel-aluminide alloys have been recognized as potential composite matrix materials for elevated temperature structural applications. The usefulness of monolithic nickel-aluminide single phase material itself, however, is becoming increasingly doubtful due to a combination of limitations in room temperature formability, and creep, oxidation and pest resistance. Reinforced nickel-aluminide alloys should, instead, form a composite with low density, high tensile strength and acceptable creep resistance.

Typical examples of new materials tailored by particulate technology were presented in sessions such as "Light Weight Alloys for Aerospace Applications". Almost all presentations dealt with materials produced from rapidly solidified or mechanically alloyed powders. Major interest focussed in intermetallics on Ti_3Al, TiAl and NiAl compounds or highly modified multiphase Ni-Al composites. In addition, P/M magnesium alloys were shown to be of growing interest because of their low density. Insufficient mechanical performance and corrosion resistance of coarse grained materials has restricted their application up to now. Rapid solidification leads to a substantial refinement of the microstructure, yielding a considerable increase in strength.

Forming methods for materials with rapidly solidified microstructures or composite nature include powder processing, such as particulate liquid infiltration, melt oxidation or mushy state mixing, hot isostatic pressing, forging, rolling and extrusion as well as spray forming or reactive liquid phase sintering. Developments in these processing techniques were emphasized strongly.

Multiphase composites are far from equilibrium, hence, detrimental chemical reactions between the different phases, in particular between the reinforcement and the matrix, can rapidly degrade the strength of the composite. Attempts to solve these problems include variation of the processing parameters to suppress additional intermetallic phases forming at the interfaces, for example in TiB_2/NiAl composites. In most cases coating of the reinforcing phases is necessary to prevent or slow the interface reactions. Coating of SiC fibers or particulates with TiB_2, TiC and Al_2O_3 is used in nickel aluminides and titanium aluminides. Systems such as Ti_3Al and TiB_2 containing coated SiC create a large number of non-equilibrium heterophase boundaries. The prediction of phase stabilities at these interfaces from thermodynamic data and the definition of rules on the time interval of heterophase compatibility from kinetic evaluations (with respect to the mechanical properties) will be of future importance.

Since many of the advanced composites are intended to be used at elevated temperatures, creep becomes a major issue of composite materials characterization. Materials in which the reinforcements are small enough to act as dispersoids, affecting the creep properties, can be treated by the classical microstructural hardening theory. Materials in which reinforcements are large and interact with the matrix elements must be understood in terms of continuum mechanics. Complimentary approaches are needed to understand the creep properties of these materials, for example a mechanics approach that focusses on the load transfer between the matrix and the fiber, and a mechanisms approach that focusses on the interaction of moving dislocations and gliding grain boundaries with larger particles such as fibers. For very high volume fractions of reinforcements the material can almost be locked against creep due to the high constraint levels generated. Lengthy periods of transient response can occur and tertiary behavior can develop due to the failure of the reinforcements. Especially serious consideration was given to superplastic flow in tensile stress loaded metal matrix composites annealed under thermal cycling. The inequality of the thermal expansion coefficients of metal matrix and reinforcement results in very high tensile elongation at low strain rates and low stresses.

It is understood that the expensive powder technology processing of these advanced composites pays off only for elaborate materials designed for the highest performance. This raises the question of the economical viability, i.e. to what extent these materials will be used in applications other than special tasks such as the NASP (National Aero Space Plane) or the former SDI program. It should be noted, however, that the spin-off result of high level targets in materials science for broader applications has been much greater than in other research areas. The use of SiC reinforced aluminum alloys in the pistons of diesel engines in Japan may be nothing other than a first glimpse of the abundant possible applications of these advanced multiphase composites.

The session on the injection molding of powdered metals and ceramics showed the increasingly detailed understanding of this novel powder forming process. Major concerns were the influence of particle size distributions on viscosity, formability and debindering time. Feedstock consisting of spherical 316L stainless steel powder and a polymer binder showed a trend of increasing viscosity with decreasing particle spacing and with a decreasing ratio of particle spacing to particle size. For a number of alloys it is now obvious, however, that second phases forming a liquid during sintering need to be present to achieve full density products after the sintering of the debindered greens. A typical example are injection molded nickel aluminides.

Book Reviews

Corrosion, Thin Films, Glasses, Sensors ...

DECHEMA Corrosion Handbook, Vol. 3. Edited by *D. Behrens*. VCH Verlagsgesellschaft, Weinheim 1988. ix, 282 pp., bound, DM 775.—ISBN 3-527-26654-2

The DECHEMA Corrosion Handbook is a completely new English edition of the DECHEMA Werkstoff-Tabelle and describes the corrosion properties of metallic, inorganic non-metallic, organic and composite materials in different corrosive media. The third volume summarizes the corrosion in acid halides, amine salts, bromides, bromine, carbonic acids and lithium hydroxide, the literature being cited approximately up to 1985.

The general layout of the third volume is identical to the previous ones. Again, the contents are clearly arranged and it is therefore easy for the user to find the desired information quickly. A criticism of the earlier volumes was the rather frequent statement of electrode potentials without any reference system. In the third volume, most of the potentials mentioned in the text, figures or tables refer explicitly to different reference systems (standard hydrogen electrode, standard calomel electrode) although in the chapters concerning bromide (p. 115, 116, Table 12), carbonic acids (Figs. 17, 44, 45) and lithium hydroxide (Fig. 1) the reference system is missing. A list of all reference electrodes used in the Corrosion Handbook, should be included into the introduction, citing their potentials versus the Standard Hydrogen Electrode.

Chapter 1 discusses corrosion properties in acid halides. The introduction to this chapter is very extensive and makes up half of the chapter. Different acid halides are described in detail, including their chemical properties, technical importance and corrosivity with respect to different materials. Then, a detailed description of the corrosion properties of the individual materials with respect to the different acid halides is given. The discussion of the properties of the corrosion system, the medium (introduction), as well as the material is clearly arranged for the reader, despite the overlap in the information provided in the introductory and the later part of the chapter. At the end of this chapter, informative tables summarize the usability of the individual materials in varying concentrations of the different acid halides.

Chapter 2 summarizes the corrosion properties of materials in amines. The short introduction touches only slightly the major importance of amines as inhibitors, and a detailed discussion of the adsorption properties of inhibitors, their technological use and the dangers accompanied with their use (e.g. localized corrosion, if the inhibitor concentration is too low, H-embrittlement in certain solvents) is missing. In the second part of this chapter a detailed description of the corrosion properties of the different materials in solvents containing amines is given. The inhibiting properties of the individual amines are discussed in detail, with special emphasis on their use as vapor-phase-inhibitors in order to inhibit the atmospheric corrosion of Cu and Fe.

Chapters 3 and 4 summarize the corrosion induced by bromides and bromine. In this context, especially the localized corrosion induced by bromides is of importance. The first part of chapter 3 gives a short introduction to the topic, but the determination of pitting potentials by potentiostatic and potentiodynamic experiments is described insufficiently as is the determination of repassivation potentials (although repassivation potentials are mentioned on p. 115). In addition, there is no discussion of the importance of corrosion potentials with respect to pitting potentials nor one on cathodic currents, which have to balance the anodic dissolution of the metal in pits in order to allow pitting corrosion to occur.

Chapter 5 is concerned with corrosion in carbonic acid with special emphasis on the corrosion of Cu and steel in CO_2 containing tap-water. The well written introduction provides the reader with a lot of information concerning the physical properties of CO_2 containing water, water hardness and the electrochemical principles of the corrosion in this system. The general background which is provided in this introduction, is complementary to the detailed description of the individual corrosion properties which are presented in the following part of the chapter. The latter parts are well written, providing lots of information on the corrosion of materials in CO_2 containing media. Techniques mentioned (CERT-test, Fig. 32), should have been explained in more detail for the non-specialist users of the handbook. Figures 44 & 45 discuss pitting corrosion and repassivation, using techniques and terms which have been introduced in chapter 3. It would have been much better to summarize such important techniques and corrosion mechanisms in an individual chapter than to distribute this type of information widely throughout the book. The last chapter is devoted to lithium hydroxide, and is in general well written.

Overall, as a reference book, the third volume of the DECHEMA Corrosion Handbook is highly recommended to anyone working as an engineer or scientist in the corrosion area.

Ionized-Cluster Beam Deposition and Epitaxy. Edited by *T. Takagi*. Noyes Publications, Park Ridge, NJ, USA 1988. viii, 231 pp., bound, US $ 48.—ISBN 0-8155-1168-X

The various techniques for ion-assisted deposition of thin films composed of metals, semiconductors, insulators, magnetic materials, composites etc. are of great importance for application in industrial production as well as for fundamental studies in research laboratories. This volume, of the series Materials Science and Process Technology, deals with the deposition of thin films by means of beams composed of

ionized aggregates of a few hundred to a few thousand atoms rather than individual atoms or molecules. These clusters are formed by the condensation of evaporated atoms during adiabatic expansion through a narrow aperture into a high vacuum region. They are then ionized by electron impact and uniformly accelerated in an electric field between source and substrate surface. A single charge on the cluster is thus used to accelerate many hundreds of atoms. A cluster consisting of 500 atoms has a diameter of the order of 30 Å. The size, charge, and acceleration voltage of the clusters are intimately related with the film formation process.

The author of this book is considered to be the pioneer of the ionized-cluster beam technique. He started the research in this field at Kyoto University (Japan) in 1972. The various activities of the author to promote the spreading of this method throughout the world largely determine also the character of this book. In 60 of the 100 references *T. Takagi* is one of the authors. This unbalanced selection of the material implies that a critical comparison of the ionized-cluster beam deposition with both conventional evaporation and sputter deposition as well as low-energy ion deposition is unfortunately not given. Throughout the entire text the author emphasizes the advantages of "his" technique. In the case of crystalline semiconducting materials, like e.g. Si or GaAs, this point of view is totally misleading, because the quality of thin films prepared by ionized-cluster deposition is far inferior to that of films prepared by either chemical vapor deposition or by molecular beam epitaxy. Unfortunately, most aspects of ionized-cluster beam deposition discussed in this book are treated only qualitatively. A number of misprints and errors should be eliminated in a following edition.

Due to the partiality and the lack of an in-depth treatment of the subject this book is of limited use only. It can, however, serve as an introduction to the field.

Max-Planck-Institut für
Festkörperforschung, Stuttgart (FRG)

Mathematical Approach to Glass. By *M. B. Volf.* Elsevier Science Publishers, Amsterdam 1988. 420 pp., bound, DFL 275.—ISBN 0-444-98951-X

There are different approaches to glass science and technology. One approach is based on chemistry and attempts to answer the question of how the properties of a glass change after the substitution of one component by another. A second approach investigates the structure of the glasses and tries to set up structural models. Of course, structure and properties are related to each other. Glass formation, on the other hand, may also be related to thermodynamic and kinetic arguments, both being of equal importance.

In this book the chemical approach to glass is stressed. The text is essentially based on the finding that the properties of glass are roughly determined by the properties of the constituent atoms or ions and by their bonds. Projected into calculations, this in most cases makes it possible to predict in what way an element will behave when bound to oxygen in an oxide glass. Optimization of properties may then also be possible in a given type of glass. Thanks to the rapid introduction of computer technology ranging from pocket calculators to large computers, the field of applied mathematics in glass is expanding.

The book contains four main chapters. In the first, general ideas and models are described, e.g. models on the chemistry and technology of glass, the chemical model as a theoretical base for the calculations in the chemistry of glass, questions of composition and composition factors, characteristics of mass and volume, activation energy for describing temperature dependencies, and questions of acidobasicity.

The second chapter deals with the affinity of properties, that means, how one property is related to another property. This interdependence of properties is, of course, essential for the approach described in this book.

The third main chapter, on the dependence of properties on composition, contains the known and developed methods, e.g. additivity principles, the methods of *Winkelmann* and *Schott, Gehlhoff* and *Thomas, Huggins* and *Sun, Appen, Gan Fu-Xi, Demkina, Mackenzie* et al., and some regressive and statistical schedules.

The fourth main chapter is the most comprehensive one and discusses the physical dependence of properties. The properties investigated are density, optical properties, permittivity, thermal properties, elasticity, strength, hardness, photoelasticity constant, thermal expansion coefficient, resistance to thermal shock, surface tension, viscosity, electrical properties, and chemical durability. Some supplements and a list of references conclude the book.

This book is of importance to people working in the glass industry and who want to know how a property changes with the change of a component. In most cases the absolute value is not necessary. However, the tendency of the change is more important. This book, of course, has also some value to people who are not so familiar with glasses and their properties and who want to get a feeling of how chemistry influences glass properties. However, there are many anomalously behaving glasses, e.g. borate-containing or mixed alkali glasses. In those cases possible differences between prediction and measurements have to be checked.

Encyclopedia of Materials Science and Engineering, Supplementary Volume 1. Edited by *R. W. Cahn,* Senior advisory Ed. *M. B. Bever.* Pergamon Press, Oxford 1988. xiii, 653 pp., hardcover, US $ 295.—ISBN 0-08-032551-1.

The Encyclopedia of Materials Science and Engineering, published in the spring of 1986, is a comprehensive reference work and source of information for a wide readership, including but not restricted to practitioners in the broad domain of materials. It consists of eight volumes containing 1580 articles, the production of which involved almost 1500 experts all over the world. The Encyclopedia has been well received by reviewers and has been acquired by institutions worldwide.

It is clear that change in some areas is so rapid that publication must be a continuing activity if the Encyclopedia is to

retain its position as an authoritative and up to date systematic compilation of our knowledge and understanding of materials. This is the prime objective of the Supplementary Volumes of the Encyclopedia of Materials Science and Engineering, of which this is the first. The Supplementary Volumes are designed to be used in conjunction with the Main Encyclopedia.

Supplementary Volume 1 contains 113 articles which fall into three categories; articles covering new materials, processing and characterization techniques, models and interpretations, all discovered or developed after the spring of 1985 when the main encyclopedia went to press; articles covering mature topics which for a variety of reasons were not treated in the main encyclopedia; and articles designed to bring the treatment of topics already covered in the main encyclopedia up to date. The later articles are divided into two subsidiary categories.

a) Supplementary articles which are intended to be read in conjunction with the original article of the same, or similar, title in the main encyclopedia; generally a subsidiary phrase such as "recent developments" has been added to the title.

b) Replacement articles which are intended to substitute entirely for the original article and therefore have the title of that article. These articles generally refer to topics in which there have been rapid recent developments: their inclusion does not imply a critical judgement on the original articles.

All articles in Supplementary Volume 1, are furnished with cross-references to relevant articles in the main encyclopedia as well as to other articles in this supplementary volume itself, where appropriate.

As with the Encyclopedia of Materials Science and Engineering itself the careful selection of experts by the two editors has resulted in comprehensive articles. If this standard is maintained in further supplementary volumes the encyclopedia will receive continuously increasing well justified attention and become a must for all libraries covering topics in materials science.

Wolfgang A. Kaysser
Max-Planck-Institut für Metallforschung
Stuttgart (FRG)

Solid State Electrochemistry and its Applications to Sensors and Electronic Devices. By *K. S. Goto*. Elsevier Science Publishers, Amsterdam 1988. x, 454 pp., bound, US $ 119.50.—ISBN 0-444-42912-3.

The title of the book is somewhat misleading, implying that the coverage is much broader than it is in reality. It is in fact restricted to the electrochemistry of solid and liquid (melts, slags) oxides at temperatures in the range 200–2000 °C. The monograph is based on lecture notes of a course given by the author on this specific theme at the Tokyo Institute of Technology since 1971. About 100 "Problems" for discussion and calculations found in the appendix of the book are indicative of this origin.

The book can be divided roughly in two parts, chapters 1–9 "Fundamentals" and chapters 10–13 "Applications". In the course of the first part, which makes up about 60% of the book, a thorough treatment of the following fundamental properties of oxides is given from an electrochemical point of view:

a) Transport properties, diffusion, electronic and ionic conduction in binary oxides and multicomponent systems (chapters 2–5).

b) Thermodynamics of solid state galvanic cells, including the electrochemical Knudsen effusion cell. This is the only location, where the work of *H. Rickert* (erronneously cited throughout as "H. Richert") has been mentioned. His monographs on solid ionic electrochemistry are ignored, as is also the case (with one exception) for the pioneering work of *C. Wagner* (chapters 6–7).

c) Electrochemical kinetics. The chapters 8 and 9 are very useful and overpotential phenomena at the phase boundaries metal/solid oxide as well as metal/liquid-oxide melts are treated thoroughly. The author also introduces the use of the Pt-rotating disc electrode in PbO–SiO_2 melts at 1000 °C.

The final four chapters are devoted to various applications of solid state (sss) devices, with a strong emphasis on oxygen sensors for metallurgy and on MOS-sensors (another name for ISFETS; however, this term is not used in the book). In cooperation with the Japanese steel industry, the author has developed various sensor designs to measure the oxygen activity in molten iron as well as in molten slag. Typical values are 10^{-9} atm and 10^{-8} atm, respectively. Interesting correlations to the carbon content in the iron, the duration of oxygen blasting or the ratio of Fe^{III}/Fe^{II} in the slag have been found. This section is most authoritative, and the predominance of Japanese references is more justified here than in other parts of the book. The work of *Janke* et al. is also adequately discussed. Some parts, however, lie outside the scope "high temperature application" such as those in section 13.3 which include electrochromic displays, coulometric timers or pacemaker batteries. A brief account that electrochemical reactions are relevant to impurity effects and long term behavior (corrosion) of electronic devices, is given in chapter 1, but it is not followed up later in the book.

The typed manuscript has been directly reproduced, unfortunately without line balance, but typing errors are minimal. The price is high, as with many other specialized monographs, but although the variety of the possible subject matter in this area is extremely large, for example, stoichiometry, texture, phases and the result of various combinations, the book is clearly written and a guide in this broad field. It is also clear, that "in the future, many more electronic devices will surely be developed to utilize the physical and chemical properties of solid oxides".

Fritz Beck
Fachgebiet Elektrochemie der Universität
Gesamthochschule Duisburg (FRG)

Handbook of Thin-Film Deposition Processes and Techniques. Edited by *K. K. Schuegraf*. Noyes Publications, Park Ridge, N.J., USA 1988. xvii, 413 pp., bound, US $ 72.—ISBN 0-8155-1153-1

The book gives a thorough account of a large number of thin film deposition processes. Emphasis lies on the techniques which are either already in extensive use in high technology areas, especially in the microelectronics industry, or may be expected to become competitive in the future. Apart from the introduction, which gives a somewhat broader overview, the treatise has been confined to processes in which the films are deposited from the gas phase at pressures ranging from atmospheric to ultra-high vacuum. The techniques treated in this volume can be classified into the following three categories:

1) Chemical methods: They entail chemical vapor deposition (CVD) and its variants, like low pressure chemical vapor deposition (LPCVD) or metal-organic CVD (MOCVD). In these techniques one or several gaseous species react in the vicinity of, or on, the substrate and condense to form a solid film. Apart from the supply of purely thermal energy for reaction initiation a number of additional means are used, leading to higher reaction rates at lower temperatures, such as photochemical vapor deposition (PHCVD) and laser assisted CVD (LCVD). In the former, UV-photons are used to dissociate or excite molecules in the gas phase or on the substrate surface to form a thin film. The latter method either uses a laser beam for the same purpose or for highly localized substrate heating. In electron beam assisted CVD (EBCVD) a high energy electron beam is used instead to dissociate the gas molecules by impact ionization.

2) Physical methods: These include plasma techniques, such as RF and DC sputtering and ion beam deposition, the latter being applied in either of two modes: a) Sputtering mode allowing for a better control over the sputter parameters and a lower operating pressure in the deposition chamber than conventional techniques and b) ion assisted deposition (IAD) in which a beam of ions is directed towards the substrate during the deposition from another source. Conventional vacuum evaporation and electron beam evaporation are not treated in this text, apart from their most advanced application, i.e. in molecular beam epitaxy (MBE). This method offers probably the best control of single crystal growth on a monolayer scale of all deposition techniques in current use. As a result, a number of devices relying on superlattices or quantum well structures have been fabricated, some of which are described in the text. Equally promising is one of the latest developments, namely ionized cluster beam deposition (ICB), in which ionized particles containing typically 100–2000 atoms impinge on a substrate where they spread and eventually condense into a thin film.

3) Physico-chemical methods. They are in essence a combination of the physical and chemical methods mentioned above, the chemical reactions taking place in a plasma generated in a number of ways. Plasma-enhanced or plasma-assisted chemical vapor deposition (PECVD, PACVD) use a plasma generated in a glow discharge. Ions and free radicals produced in the discharge greatly accelerate reaction rates, allowing film deposition at lower substrate temperatures than in purely thermal CVD. Much higher ionizing efficiencies, yielding high deposition rates at still lower substrate temperatures, are offered by electron cyclotron resonance deposition (ECR), in which electrons orbiting in a magnetic field absorb microwave radiation under resonance conditions.

Reactive sputtering, in which a reactive gas is mixed with the inert sputter gas, also belongs to this category.

A special chapter is devoted to plasma and high pressure oxidation of silicon for very large and ultra large scale integration.

Apart from the deposition processes, the book covers a number of other equipment-related topics, such as etching techniques (sputter etching, reactive ion etching, ion beam etching, etc.), resist patterning, including self-development and beam-induced thermal processes.

The book gives a short overview of the physical principles, underlying the various deposition techniques. The basic design and the performance of the deposition equipment are thoroughly outlined. Numerous tables and figures describing the properties and the uniformity of the deposited films are given, enabling the reader to compare the advantages and the limitations of each method. A considerable part of the applications in many chapters has been devoted to silicon technology, in particular to silicon epitaxy, polysilicon, silicides and dielectrics, like silicon oxide, silicon nitride and -oxynitride. The increasing importance of low temperature processing, especially in future ULSI is becoming apparent in view of the many techniques capable of low temperature deposition. III/V-epitaxy and its applications are the leading topics in the chapters on MOCVD and MBE. Other applications include metal films and especially metal-insulator-semiconductor heterostructures, where important advances have been made, particularly by ICB.

The extensive bibliography will be valuable help, especially for newcomers in any of the fields, the references covering the period up to 1986.

In general the book can be recommended to all engineers and scientists wishing to become acquainted with current trends and future outlooks in thin film technology. Since prime importance has been laid on the practical aspects, the production capabilities of the various techniques and their limitations with respect to large scale applications can easily be assessed by the practically minded reader.

4th Int. Conf.
Oarai (Japan)
Contact: O. Nishikawa, The Graduate School of Nagatsuta, Tokyo Inst. of Technol., 4259 Nagatsuta, Midori-ku, Yokohama 227, Japan

9–14 **Zeolites**
8th Int. Conf.
Amsterdam (Netherlands)
Contact: M. Laboushere, 792 Keizersgracht, 1017 EC, Amsterdam, The Netherlands

10 **Bonding and Repair of Composite Materials**
Birmingham (UK)
Contact: John Herriot, Butterworth, P.O. Box 63, Westbury House, Bury St., Guildford GU2 5BH, UK

10–12 **Appl. Organomet. Chem.: an Entry to the New Technology**
The Pines Resort (Australia)
Contact: Dr. A. F. Masters, School of Chemistry, Univ. of Sydney, Sydney, N.S.W. 2006, Australia

10–13 **Magnetic Resonance in Polymers**
9th Spec. Colloq. Ámpere
Prague (Czechoslovakia)
Contact: P. M. M. Secretariat, c/o. Inst. of Macromol. Chem., Czech. Acad. of Sci., 16206 Prague, Czechoslovakia

10–14 **Ion Sources**
Int. Conf.
Berkeley (USA)
Contact: W. O'Connor, Lawrence Berkeley Lab., 50B-2270, Berkeley, CA 94720, USA, Tel. 415-486-6386, Fax 415-486-7000

10–14 **Electron Spectroscopy**
4th Int. Conf.
Honolulu (USA)
Contact: G. E. McGuire, Microelectronics Ctr. of North Carolina, P.O. Box 12889, Research Triangle Park, NC 27709, USA

10–14 **Organic Coatings**
15th Int. Conf.
Athens (Greece)
Contact: Dr. A. V. Patsis, Inst. in Materials Sci., State Univ. of New York, New Paltz, NY 12561, USA

11–14 **Numerical Analysis of Semiconductor Devices and Integrated Circuits**
6th Int. Conf.
Dublin (Ireland)
Contact: J. J. H. Miller, Nase-Code Conf., INCA, P.O. Box 2, Dún Laoghaire, Ireland

12–14 **Solid-State Laser/Optical Fiber Science and Electromagnetic Theory '89**
Top. Mtg./Sino-Japanese Joint Mtg.
Beijing (P.R. China)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

16–21 **Catalysis**
Eur. Conf.
Berlin (West)
Contact: Prof. G. Ertl, Fritz-Haber-Inst. der Max-Planck-Gesellsch., Faradayweg 4–6, D-1000 Berlin

17–20 **Polymer Blends**
Prague (Czechoslovakia)
Contact: P. M. M. Secretariat, c/o. Inst. of Macromol. Chem., Czech. Acad. of Sci., 16206 Prague, Czechoslovakia

18–20 **Polymer Chemistry: Aspects of Radical Polymerization**
Lancaster (UK)
Contact: Dr. J. R. Ebdon, Dept. of Chemistry, Univ. of Lancaster, Lancaster LA1 4YA, UK

18–21 **Integrated Optics and Optical Fiber Communications**
7th Int. Conf. (IOOC-7)
Kobe (Japan)
Contact: P. W. Shumate, Jr., Bell Communications Research, 435 S St., Morristown, NJ 07960, USA

23–24 **Computer-Aided Materials Characterization**
Int. Symp.
Charlotte (USA)
Contact: R. Biederman, Worcester Polytechn. Inst., Worcester, MA 01609, USA, Tel. 508-831-5453/5346

23–28 **Materials and Mechanisms of Superconductivity: High-T_c Superconductors**
Int. Conf. (HTSC-M^{2}S)
Stanford (USA)
Contact: Dr. T. H. Geballe, Dept. of Applied Phys., Stanford Univ., Stanford, CA 94305, USA

24–26 **Micro-Optics/Gradient-Index Optical Imaging Systems**
2nd Conf./8th Top. Mtg.
Tokyo (Japan)
Contact: K. Iga, Tokyo Inst. of Technol., Research Lab. of Precision Machinery and Electronics, 4259 Nagasuta, Midori-ku, Yokohama 227, Japan

24–26 **Composite Structures**
5th Int. Conf.
Paisley (UK)
Contact: Dr. I. H. Marshall, Dept. of Mechanical and Production Eng., Paisley College of Technol., High St., Paisley PA 12BE, UK

25–26 **Computer-Aided Microscopy and Quality Control**
Int. Conf.
Charlotte (USA)
Contact: J. Braun, EG + G Mound Appl. Technologies, Miamisburg, OH 45343-0987, USA, Tel. 513-865-3829

31–2 **Biologically-Engineered Polymers**
Cambridge (UK)
Contact: Royal Soc. of Chemistry, Burlington House, London W1V 0BN, UK

31–3 **Photoacoustic and Photothermal Phenomena**
6th Int. Mtg.
Baltimore (USA)
Contact: J. Murphy, Johns Hopkins Appl. Physics Lab., Johns Hopkins Rd., Laurel, MD 20707, USA, Tel. 301-953-6214

August 1989

2–7 **Pure and Applied Chemistry**
32nd IUPAC Congr.
Stockholm (Sweden)
Contact: Stockholm Convention Bureau, P.O. Box 6911, S-10239 Stockholm, Sweden

13–26 **High-T_c Superconductors**
NATO Adv. Study Inst.
Bad Windsheim (Fed. Rep. Germany)
Contact: R. Kossowsky, Applied Res. Lab., Pennsylvania State Univ., P.O. Box 30, State College, PA 16804, USA

14–17 **Shock Compression of Condensed Matter**
APS Top. Conf.
Albuquerque (USA)
Contact: A. Roach, MS-P 915, Los Alamos Nat. Lab., Los Alamos, NM 87545, USA

14–18 **Hopping Transport**
8th Conf.
Chapel Hill (USA)
Contact: M. Pollak, Dept. of Phys., Univ. of California, Riverside, CA 92521, USA

16–18 **Properties Through Processing**
Amherst (USA)
Contact: H. H. Winter, Dept. Chem. Eng., Univ. of Massachusetts, Amherst, MA 01003, USA

20–24 **Imaging Systems—150 Years of Photography**
Int. Symp. (ISIS '89)
Dresden (German Dem. Rep.)
Contact: Conf. Secretary, ISIS '89, Technische Univ. Dresden, Sektion Physik, Wissenschaftsbereich Photophysik, Mommsenstr. 13, DDR-8027 Dresden, GDR

20–25 **Crystal Growth: Progress in Science and Technology**
9th Int. Conf.
Sendai (Japan)
Contact: Prof. T. Nishinaga, Inter Group Corp., Akasaka Yamakatsu Bldg., 8-5-32, Akasaka Minato-ku, Tokyo 107, Japan

21–24 **Amorphous and Liquid Semiconductors**
13th Int. Conf.
Asheville (USA)
Contact: D. E. Sayers, P.O. Box 8202, North Carolina State Univ., Raleigh, NC 27695-8202, USA

21–25 **Phonons 89**
Heidelberg (Fed. Rep. Germany)
Contact: Inst. f. Angew. Physik II, Univ. of Heidelberg, Albert-Überle-Str. 3–5, D-6900 Heidelberg, FRG

21–26 **Photochemistry**
Int. Conf.
Beijing (P.R. China)
Contact: Prof. S. Wu, Inst. of Photographic Chem., Academia Sinica, Beijing, P.R. China

22–26 **Particles in Gases and Liquids: Detection, Characterization and Control**
2nd Symp. and 20th Annu. Mtg. of Fine Particle Soc.
Boston (USA)
Contact: Dr. K. L. Mittal, IBM U.S. Techn. Education, 500 Columbus Ave., Thornwood, NY 10594, USA, Tel. 914/742-5745

22–26 **Particles in Gases and Liquids: Detection, Characterization and Control**
2nd Symp. and 20th Annu. Mtg. of Fine Particle Soc.
Boston (USA)
Contact: Dr. K. L. Mittal, IBM U.S. Techn. Education, 500 Columbus Ave., Thornwood, NY 10594, USA, Tel. 914/742-5745

27–1 **Supramolecular Organic Chemistry and Photochemistry**
Workshop
Saarbrücken (Fed. Rep. Germany)
Contact: Prof. Dr. H.-J. Schneider, FR Organ. Chem., Univ. des Saarlandes, D-6600 Saarbrücken, FRG

28–31 **Dynamical Processes in Excited States of Solids**
7th Int. Conf. (DPC '89)
Athens (USA)
Contact: DPC '89, Prof. J. E. Rives, Dept. of Physics and Astronomy, Univ. of Georgia, Athens, GA 30602, USA

28–1 **Surface Modification Technologies**
3rd Int. Conf.
Neuchatel (Switzerland)
Contact: The Metallurgical Soc., 420 Commonwealth Dr., Warrendale, PA 15086, USA, Tel. 412-776-9050

28–1 **Magnet Technology**
Int. Conf.
Tsukuba (Japan)
Contact: S. Shimamoto, Japan Atomic Energy Res. Inst., Naka-gun, Ibaraki-ken 311-01, Japan

28–1 **Ferroelectricity**
7th Int. Mtg., (IMF-7)
Saarbrücken (Fed. Rep. Germany)
Contact: Dr. J. Albers, Univ. des Saarlandes, Fachbereich Physik, D-6600 Saarbrücken, FRG

28–1 **Sintering**
7th World Round Table Conf.
Herceg-Novi (Yugoslavia)
Contact: Dr. D. P. Uskoković, Serbian Academy of Sci. and Arts, Knez-Mihailova 35, 11000 Beograd, Yugoslavia

28–1 **X-Ray Optics and Microanalysis**
12th Int. Congr.
Cracow (Poland)
Contact: S. Jasienska, Academy of Mining and Metallurgy, Inst. of Metallurgy, 30-059 Cracow, Poland

28–2 **Photochemistry for High Technology**
Int. Summer School
Leuna-Merseburg (German Dem. Rep.)
Contact: Prof. H.-J. Timpe, Section Chemie, Technische Hochschule für Chemie, Leuna-Merseburg, Gensaerstr., DDR-42 Merseburg, GDR

29–2 **Innovation and Perspectives in Solid Phase Synthesis**
Int. Symp.
Oxford (UK)
Contact: R. Epton, School of Appl. Sci., Wolverhampton Polytech., Wolverhampton WV1 1SB, UK

September 1989

3–5 **Advanced Ceramics and PM Materials, Development and Applications**
Int. New Business and High Tech. Conf.
Jyväskylä (Finland)
Contact: EAMI, Ms. R. Häninen, Reumantie 4, 18100 Heinola, Finland, Tel. 358-10-57062, Fax 358-10-57161

4–6 **Magnetic Recording Media**
Int. Conf.
Rimini (Italy)
Contact: Dr. L. Pareti, MASPEC, Via Chiavari 18, I-43100 Parma, Italy

4–8 **Liquid and Amorphous Metals**
Kyoto (Japan)
Contact: Prof. A. Ueda, Dept. of Appl. Mathematics and Physics, Kyoto Univ., Kyoto 606, Japan

4–8 **Electronic Properties of Two-Dimensional Systems**
Int. Conf.
Grenoble (France)
Contact: J. C. Maan, SNCI-HML, 166x, F-38042 Grenoble Cedex, France

4–8 **High-T_c Superconductivity**
Beijing (P.R. China)
Contact: Prof. Z. X. Zhao, Chin. Acad, of Sci., Inst. of Physics, POB 603, Beijing 100080, P.R. China

4–8 **Electrically and Optically Active Polymers**
21st Europhysics Conf.
Lodz (Poland)
Contact: Dr. J. Ulanski, Polymer Inst., Techn. Univ. of Lodz, Zwirki 36, 90-924 Lodz, Poland

4–8 **Macromolecules 89**
Eur.-Am. Conf. on Functional Polymers and Biopolymers
Oxford (UK)
Contact: Prof. R. Epton, School of Appl. Sci., The Polytechnic, Wolverhampton WV1 1SB, UK

4–8 **Olefin Metathesis and Polymerization**
8th Int. Symp.
Bayreuth (Fed. Rep. Germany)
Contact: Office ISOM 8, Lab. für Anorg. Chem., Univ. Bayreuth, Postfach 101251, D-8580 Bayreuth, FRG

5–7 **Interfacial Phenomena in Composite Materials**
Int. Conf.
Sheffield (UK)
Contact: J. Herriot, Butterworth, P.O. Box 63, Westbury House, Bury St., Guildford GU2 5BH, UK

5–8 **Optical, Electrical and Acoustic Properties**
Kent (UK)
Contact: M. D. Shuttleworth, Plastics and Rubber Inst., 11 Hobart Pl., London SW1W 0HL, UK

5–8 **Polymers, Laminations and Coatings**
TAPPI Conf.
Orlando (FL, USA)
Contact: Mtg. Dept., TAPPI Technology Park, P.O. Box 105113, Atlanta, GA 30348-5113, USA

5–9 **Accelerators in Appl. Res. Technology**
1st Eur. Conf.
Frankfurt (Fed. Rep. Germany)
Contact: K. Bethge, Inst. f. Kernphysik, August-Euler-Str. 6, D-6000 Frankfurt 90, FRG

6–8 **New Materials and Processes for Tooling**
2nd Int. Tooling Conf.
Bochum (Fed. Rep. Germany)
Contact: Ruhr-Univ. Bochum, Unikontakt-Tooling, POB 102148, D-4630 Bochum, FRG

6–9 **Magnetic Materials and Applications (EMMA '89)**
Rimini (Italy)
Contact: L. Pareti, EMMA '89, Istituto Maspec, Via Chiavari 18/A, I-43100 Parma, Italy, Phone 521-95811, Fax 521-96315

7–9 **Biomaterials**
8th Eur. Congr.
Heidelberg (Fed. Rep. Germany)
Contact: Dr. U. Soltesz, Fraunhofer-Institut für Werkstoffmechanik, Wöhlerstr. 11, D-7800 Freiburg, FRG

10–11 **Ceramics in Medicine**
2nd Int. Symp.
Heidelberg (Fed. Rep. Germany)
Contact: Dtsch. Keram. Gesellsch., Frankfurter Str. 196, D-5000 Köln 90, FRG

10–12 **Colloidal Dispersions**
Faraday Discussion 90
Bristol (UK)
Contact: Prof. R. H. Ottewill, School of Chemistry, Univ. of Bristol, Bristol BS8 1TS, UK

10–14 **Optical Communications**
15th Eur. Conf.
Gothenburg (Sweden)
Contact: P. A. Andrekson, Dept. of Optoelectronics, Chalmers Univ. of Technol., S-41296 Gothenburg, Sweden

10–15 **Materials and Fluid Sciences in Microgravity**
Eur. Conf.
Oxford (UK)
Contact: Dr. H. U. Walter, Eur. Space Agency, Microgravity Office, 8–10 rue Mario-Nikis, F-75738 Paris Cedex 15, France

10–23 **Molecular Dynamics of Liquid Crystals**
NATO Adv. Study Inst.
Il Ciocco, Lucca (Italy)
Contact: Prof. C. A. Veracini, Dipartimento di Chimica, Universita di Pisa, Viale Risorgimento 35, I-56100 Pisa, Italy

11–13 **Charge Transfer in Polymeric Systems**
RSC, Faraday Div.
Contact: Dr. J. F. Gibson, Royal Soc. of Chemistry, Burlington House, Piccadilly, London W1V 0BN, UK

11–13 **Holographic Systems, Components and Applications**
2nd Int. Conf.
Bath (UK)
Contact: Inst. of Electronic and Radio Eng., Conf. Dept., Savoy Hill House, London WC2R 0JD, UK

11–13 **Surface Analysis Techniques and Applications**
Manchester (UK)
Contact: E. Wellingham, Conf. Secretariat, Field End House, Bude Close, Nailsea, Bristol BS19 2FQ, UK

13–15 **Microscopy**
150th Anniversary Commemorative Mtg.
London (UK)
Contact: Microscopical Soc., 37–38 St. Clements, Oxford OX4 1AJ, UK

17–22 **Defect Recognition and Image Processing in Semiconductors**
3rd Mtg. (DRIP-3)
Yokohama (Japan)
Contact: Prof. T. Ogawa, Gakushuin Univ., Dept. of Physics, 1-5-1 Mejiro, Toshima-ku, Tokyo 171, Japan

17–22 **Optics and Optical Engineering**
Cambridge Symp.
Cambridge (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham WA 98227, USA

18–22 **Quantum Electronics**
9th Natl. Conf.
Oxford (UK)
Contact: Mrs. M. Sherwen, Rutherford Appleton Lab., Chilton, Didcot, Oxon OX11 0QX, UK

19–21 **High-T_c Superconductors**
Birmingham (UK)
Contact: Dr. C. Greaves, School of Chemistry, Univ. of Birmingham, POB 363, Birmingham B15 2TT, UK, Tel. 021/414-4397

19–21 **Superconductivity and Applications**
3rd Annu. Conf.
Buffalo (USA)
Contact: NYSIS, 330 Bonner Hall, State Univ. of New York, Buffalo, NY 14260, Tel. 716/636-3463

19–22 **Structure and Dynamics of Colloidal Systems**
3rd Eur. Coll. and Interface Soc. Conf. and ILL Workshop
Basel (Switzerland)
Contact: Dr. M. Zulauf, c/o F. Hoffmann-La Roche + Co., ZFE 65–509, CH-4002 Basel, Switzerland, Tel. 0041/616885746, Fax 0041/616919391

20–22 **Structural Adhesives in Engineering**
SAE II '89
Bristol (UK)
Contact: J. Herriot, SAE II '89, Butterworth Scientific Ltd., P.O. Box 63, Westbury House, Bury St., Guildford, Surrey GU2 5BH, UK

20–22 **Manmade Fibers**
Int. Congr.
Dornbirn (Austria)
Contact: Austrian Manmade Fibers Inst., Plossigasse 8, A-1041 Vienna, Austria

21–22 **Fire Retardant Polymers**
Torino (Italy)
Contact: Prof. L. Costa, Dipl. di Chim. dell'Università di Torino, Via P. Giuria, 7, 10125 Torino, Italy

24–28 **Metallization of Polymers**
Int. Colloquium
Montreal (Canada)
Contact: Ed. Sacher, Ecole Polytechnique, Université de Montreal, Quebec H3C 3A7, Canada

25–26 **Additive Approaches to Improved Polymer Performance**
Toronto (Canada)
Contact: Jeff Hood, Stochem. Inc., 106 Summerlea Rd., Brampton, Ontario L6T 4X3, Canada

25–27 **Structure Formation in Polymer Solutions**
22nd Europhysics Conf.
Leuven (Belgium)
Contact: Prof. H. Berghmans, Lab. for Polymer Res., Katholieke Univ. Leuven, Celestijnenlaan 200F, B-3030 Leuven, Belgium, Tel. 16/200656, Fax 16/201215

25–27 **Surface Engineering with High Energy Beams**
2nd Int. Seminar
Lisbon (Portugal)
Contact: Secretariat of ISHT '89 Seminar, Ctr. of Mech. and Mater. of the Tech. Univ. Lisbon (CEMUL), 1096 Lisboa Codex, Portugal

25–29 **Ceramics' 89 "C89"**
4. Int. Conf. Limoges (France)
Contact: Comité Régional D'Expansion Economique du Limousin (CREEL), 27, Boulevard de la Corderi, F-87000 Limoges, France, Tel. 0033/55451830, Fax 0033/55797789

25–29 **Vacuum Solid Surfaces**
IVC-11/CSS-7
11th Int. Conf./7th Int. Conf.
Cologne (Fed. Rep. Germany)
Contact: D. A. Benninghoven, Physikalisches Inst. der Univ. Münster, Wilhelm-Klemm-Str. 10, D-4000 Münster, FRG

25–30 **Epitaxial Crystal Growth**
Int. Conf.
Budapest (Hungary)
Contact: Dr. E. Lendfay, Hung. Acad. of Sci., Inst. for Techn. Physics, Ujpest 1, POB 76, H-1325 Budapest, Hungary

26–28 **Optical Memory**
Int. Symp. (ISOM '89)
Kobe (Japan)
Contact: ISOM '89 Secretariat, Business Ctr. for Academic Soc. Japan, 3-23-1 Hongo, Bunkyo-ku, Tokyo 113, Japan

26–28 **SAMPE**
21st Int. Techn. Conf.
Atlantic City (USA)
Contact: SAMPE, 843 W. Glentana, P.O. Box 2459, Covina, CA 91722, USA, Tel. 818-331-0616

26–29 **Structure and Dynamics of Colloidal Systems**
3rd Eur. Colloid and Interface Conf.
Basle (Switzerland)
Contact: Dr. M. Zulauf, F. Hoffmann-La Roche & Co, ZFE 65-509, CH-4002 Basel, Switzerland

27–29 **Polymer Reaction Engineering**
3rd Berlin Int. Workshop
Berlin (West)
Contact: Prof. Dr. K.-H. Reichert, Inst. f. Techn. Chemie, TU Berlin, Straße des 17. Juni 135, D-1000 Berlin 10

27–29 **New Polymers**
1st Materials Symp.
Regensburg (Fed. Rep. Germany)
Contact: OTTI-Fortbildung, Martin-Luther-Straße 10, D-8400 Regensburg, FRG

30–4 **High-T_c Thin Films and Single Crystals**
Int. Conf.
Ustron (Poland)
Contact: M. W. Gutowski, Inst. of Physics, ON-3 Polish Acad. of Sci., Al. Lotnikow 32/46, PL-02668 Warszawa, Poland

October 1989

1–4 **Interfaces in Condensed Systems Equilibria and Dynamic Phenomena**
Annu. Mtg. Dtsch. Kolloid-Gesellsch. Bochum (Fed. Rep. Germany)
Contact: Prof. Dr. G. H. Findenegg, Physikal. Chem. II, Ruhr-Univ., P.O. Box 102148, D-4630 Bochum 1, FRG, Tel. 0234/700429

1–5 **The Metallurgical Society**
Fall Mtg.
Indianapolis (USA)
Contact: Mtgs. Dept., TMS, 420 Commonwealth Dr., Warrendale, PA 15086, USA

1–5 **Halide Glasses**
6th Int. Symp.
Clausthal (Fed. Rep. Germany)
Contact: Prof. G. Frischat, Techn. Univ. Clausthal, Fak. für Bergbau, Hütten- und Maschinenwesen, Adolf-Römer-Str. 2A, D-3392 Clausthal-Zellerfeld, FRG

2–3 **Makromoleculares Symposium**
Hamburg (Fed. Rep. Germany)
Contact: Prof. Dr. W. Kaminsky, Inst. f. Techn. u. Makromol. Chemie, Univ. Hamburg, Bundesstr. 45, D-2000 Hamburg 13, FRG

2–4 **Electron and Optical Beam Testing of Integrated Circuits**
2nd Eur. Conf.
Duisburg (Fed. Rep. Germany)
Contact: E. Kubalek, Werkstoffe der Elektronik, Univ. Duisburg, Kommandanten-Str. 60, D-4100 Duisburg 1, FRG

2–4 **High Temperature Polymers**
Cleveland (USA)
Contact: Vivian E. Malpass, Ferro Corp., Technical Ctr., 7500 East Pleasant Valley Rd., Independence, OH 44131, USA

2–5 **Materials Week**
Technical Conf.
Indianapolis (IN, USA)
Contact: Technicol Dept. Marketing, ASM Int., Metals Park, OH 44073, USA

4–6 **Fabrication and Characterization of Semiconductor Optoelectronic Devices and Integr. Circuits**
1st Int. Mtg.
Tokyo (Japan)
Contact: Univ. of Tokyo, Dept. of Electronic Eng., Hongo, Bunkyo-ku, Tokyo 113, Japan

8–11 **Organometallic Vapor Phase Epitaxy**
4th Biennial Workshop
Monterey (USA)
Contact: B. Kamperman, TMS, 420 Commonwealth Dr., Warrendale, PA 15086, USA, Tel. 412/776-9050, Fax 412/776-3770

9–10 **Quasicrystals**
DFG-workshop
Bad Honnef (Fed. Rep. Germany)
Contact: Dr. J. Tobolski, Dtsch. Forschungsgem., Bad Godesberg, Kennedyallee 40, D-5300 Bonn 2, FRG

9–11 **Dtsch. Keramische Gesellsch. Jahrestagung 1989**
Coblenz (Fed. Rep. Germany)
Contact: Dtsch. Keramische Gesellsch., Frankfurter Str. 196, D-5000 Köln 90, FRG, Tel. 02203-69069, Fax 2203-69301

10–13 **Ion Beams in Materials Research and Technology**
4th Europhysics Ind. Workshop Bad Honnef (Fed. Rep. Germany) Contact: G. Thomas, Eur. Physical Soc., POB 69, CH-1213 Petit-Lancy 2, Switzerland

11–13 **Materials for Electrochemistry**
Stuttgart (Fed. Rep. Germany)
Contact: Prof. F. von Sturm, Jahnstr. 26, D-8901 Biberbach, FRG

11–13 **Surface Technology Forum**
SURTEC '89
Berlin (West)
Contact: AMK Berlin, M 3/Surtec, Messedamm 22, D-1000 Berlin 19

15–18 **Unconventional Photoactive Solids**
4th Int. Conf.
San Jose (USA)
Contact: Dr. C. G. Willson, IBM Almaden Research Ctr., 650 Harry Road, San Jose, CA 95120, USA

16–19 **High-Tech-Coating**
Congr. and Exhibition
Wiesbaden (Fed. Rep. Germany)
Contact: Demat Exposition Managing, P.O. Box 110611, D-6000 Frankfurt, FRG

17–18 **Optics in Computing**
Int. Symp.
Toulouse (France)
Contact: Secretariat Des Conferences, OPTO-Informatique, ONERA-CERT, BP 4025, F-31055 Toulouse Cedex, France

17–18 **Superconductivity: the Manufacturing Challenge**
Oak Brook (USA)
Contact: K. L. Kammerer, SME, Techn. Committee, Projects Dept., 1 SME Drive, POB 930, Dearborn, MI 48121-0930, USA, Tel. 313/271-1500/542

17–19 **Optical Storage for Large Systems**
4th Annu. Conf.
New York, (USA)
Contact: Rothchild Consult., 256 Laguna Honda Blvd., San Francisco, CA 94116-1496, USA

22–28 **Solid-State and Integrated Circuit Technology**
2nd Int. Conf.
Beijing (P.R. China)
Contact: Continuing Education in Eng., Univ. Extension, Univ. of California, 2223 Fulton St., Berkeley CA 94720, USA

23–24 **Modern Aspects of Superconductivity**
Int. Conf.
Paris (France)
Contact: Dr. R. Suryanarayanan, Lab. de Physique des Solides, 1, Place Aristide Briand, 92195 Meudon, France, Fax 1/45344696

23–24 **High-T_c Superconductors and Crystal Chemistry III**
Bad Honnef (Fed. Rep. Germany)
Contact: Dr. J. Debrus, Physikzentrum, Hauptstr. 5, D-5340 Bad Honnef 1, FRG

The Photosynthetic Reaction Center from the Purple Bacterium *Rhodopseudomonas viridis* (Nobel Lecture)**

By Johann Deisenhofer* and Hartmut Michel*

In our lecture we first describe the history and methods of membrane protein crystallization, before we show how the structure of the photosynthetic reaction center from the purple bacterium *Rhodopseudomonas viridis* was solved. The structure of this membrane protein complex is then correlated with its function as a light-driven electron pump across the photosynthetic membrane. Finally, we draw conclusions on the structure of the photosystem II reaction center of plants and discuss the aspects of membrane protein structure. Sections 1 (crystallization), 4 (conclusions on the structure of photosystem II reaction center and evolutionary aspects) and 5 (aspects of *membrane* protein structure) were presented and written by *H. M.*, sections 2 (determination of the structure) and 3 (structure and function) by *J. D.* We have arranged the manuscript in this way in order to facilitate continuous reading.

1. The Crystallization

1.1. The Background

As in many instances of new scientific developments and technical inventions a chance observation initiated a series of experiments, which ultimately resulted in the elucidation of the three-dimensional structure of a photosynthetic reaction center. In August 1978 I accidently observed the formation of solid, most likely glass-like aggregates, when lipid-free bacteriorhodopsin prepared according to the method of *Happe* and *Overath*[1] (1976) was stored in the freezer. These aggregates are shown in Figure 1 A. From that time on I was convinced that it should be possible not only to produce these solid bodies but also to prepare three-dimensional crystals. The availability of well-ordered three-dimensional crystals is a prerequisite for a high resolution X-ray crystallographic analysis, which – despite the progress made by *Henderson* and *Unwin*[2] (1975) with electron microscopy and electron diffraction on bacteriorhodopsin – was, and still is the only way to obtain a detailed structural knowledge of large biological macromolecules.

At the time I was working at the University of Würzburg as a post-doc in *Dieter Oesterhelt*'s lab, who, in collaboration with *Walter Stoeckenius*, had discovered bacteriorhodopsin[5] and was the first to propose its function.[6] My intention to try to produce well-ordered three-dimensional crystals of bacteriorhodopsin received his immediate support. It turned out that he had already tried to crystallize a modified form of bacteriorhodopsin from organic solvents.

Bacteriorhodopsin, the protein component of the so-called purple membrane, resembles the visual pigment rhodopsin and acts as a light energy converting system. It is part of a simple "photosynthetic" system in halobacteria, and is an integral membrane protein, which forms two-dimensional crystals in the purple membrane. At that time the general belief was that it was impossible to crystallize membrane proteins in three dimensions. With the exception of bacteriorhodopsin there was no information about the three-dimensional structure of membrane proteins, which might

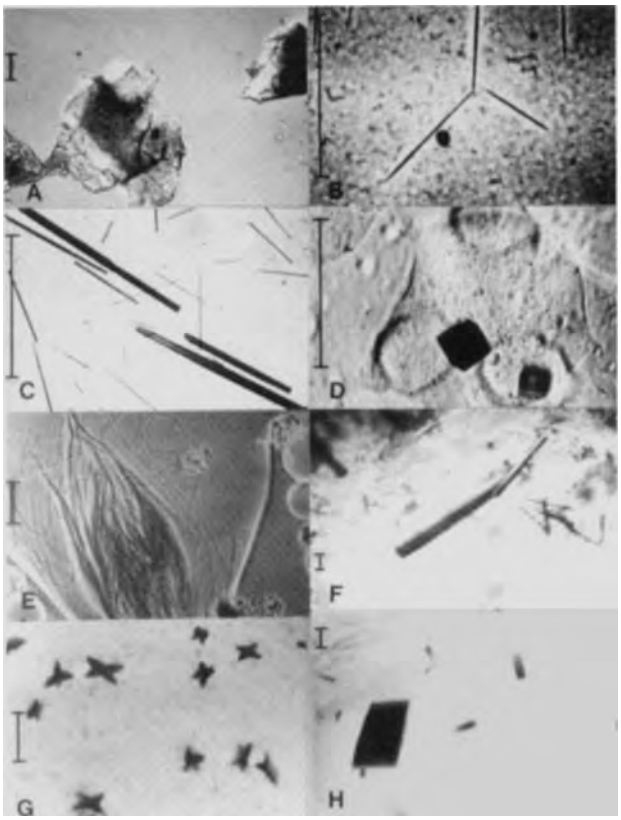

Fig. 1. Optical micrographs showing crystals and aggregates of bacteriorhodopsin and the photosynthetic reaction center from *Rhodopseudomonas viridis*: A) "glass-like" aggregates of bacteriorhodopsin obtained after freezing of lipid-free bacteriorhodopsin; B) rolled up sheets of the two-dimensionally crystalline orthorhombic form of purple membrane (after *Michel* and *Oesterhelt* [3]); C) needle-like crystals of bacteriorhodopsin obtained with sodium phosphate as precipitant; D) cube-like crystals of bacteriorhodopsin obtained with ammonium sulfate as precipitant; E) filamentous aggregates of bacteriorhodopsin and a few cubes (arrows) obtained with ammonium sulfate as precipitant (after *Michel* [4a]); F) hexagonal columns of bacteriorhodopsin obtained in the presence of 3% heptane-1,2,3-triol with ammonium sulfate as precipitant; G) star-like crystals of the reaction center obtained within 2 days (starting conditions: 1 mg protein/ml, 3% heptane-1,2,3-triol, 1.5 M ammonium sulfate) by vapor diffusion against 3 M ammonium sulfate (after *Michel* [4b]); H) tetragonal crystals of the reaction center obtained within 3 weeks (starting conditions as under G) by vapor diffusion against 2.4 M ammonium sulfate (after *Michel* [4b]). In all photographs the bar indicates 0.1 mm.

have provided insights into their various functions, e.g. as carriers, energy converters, receptors or channels.

In our first experiments we tried to decrease the negative surface charge of purple membrane by the addition of long chain amines, and, by subsequent treatment with Triton X100, a detergent, to facilitate rearrangement of the bacteriorhodopsin molecules, which were partly solubilized by the detergent. This procedure may be a way (see Fig. 3) to obtain the type I crystals described below. Within four weeks we obtained the "needles" illustrated in Figure 1 B. Electronmicroscopic studies carried out in collaboration with *Richard Henderson* in Cambridge showed that the "needles" were a new two-dimensionally crystalline membrane form of bacteriorhodopsin. In this new form the membranes are rolled up like tobacco leaves in a cigar.[7]

1.2. A More Systematic Approach

Based on the properties of membrane proteins outlined below, a new strategy was developed.[8] Membrane proteins are embedded into the electrically insulating lipid bilayers. Difficulties are encountered in the handling of membrane proteins because of the amphipathic nature of their surface. It is hydrophobic where the membrane proteins have contact with the alkane chains of the lipids, and it is hydrophilic where the membrane proteins have contact with the aqueous phase (on both sides of the membrane) or with the polar head-groups of the lipids (see Fig. 2). As a result membrane

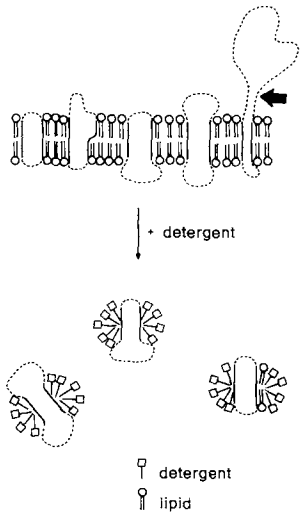

Fig. 2. Schematic drawing of a biological membrane consisting of a lipid bilayer in which membrane proteins are embedded (top), and its solubilization by detergents (bottom). The hydrophilic part of the membrane protein surface is indicated by broken lines (modified after *Michel* [8]).

proteins are not soluble in aqueous buffers or in organic solvents with low dielectric constants. In order to solubilize membrane proteins one has to add detergents. Detergents are amphiphilic molecules which form micelles above a certain concentration, the so-called critical micellar concentration. The detergent micelles take up the membrane proteins and shield the hydrophobic parts of the surface of the membrane protein from contact with water. A schematic drawing of a biological membrane and its solubilization with detergents is presented in Figure 2. The membrane protein in the detergent micelle then has to be purified by chromatographic methods.

Once the protein has been isolated and is available in large quantities, one can try to crystallize it. For membrane proteins, which are merely anchored in the membrane, the most promising approach is to remove the membrane anchor by proteases or to use genetically modified material where the part of the gene coding for the membrane anchor has been deleted. Four examples of highly resolved structures of the hydrophilic domains have already been reported: cytochrome b_5,[9] hemagglutinin[10] and neuraminidase[11] from influenza virus and the human class I histocompatibility antigen, HLA-A2.[12]

There are two possibilities for generating true three-dimensional crystals of really integral membrane proteins:

1) One could think of forming stacks of two-dimensional crystals of membrane proteins. Perpendicular to the membrane the two-dimensional crystals must be ordered with respect to translation, rotation and orientation during or after their formation. In most cases the lipids might still be

present in the form of bilayers and compensate the hydrophobicity of the intramembranous protein surface. Hydrophobic and polar interactions would stabilize the crystals in the membrane planes, whereas polar interactions would dominate in the third dimension (Fig. 3, left). In a reasonable

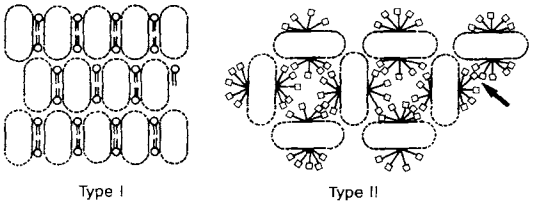

Fig. 3. The two basic types of membrane protein crystals. Type I: stacks of membranes containing two-dimensionally crystalline membrane proteins, which are then ordered in the third dimension. Type II: A membrane protein crystallized with detergents bound to its hydrophobic surface. The hydrophilic surface part of the membrane proteins is indicated by broken lines. The symbols for lipids and detergents are the same as in Figure 2 (after *Michel* [8]).

crystallization procedure one would have to increase both types of interaction at the same time. This seems to be difficult to achieve.

2) The alternative is to crystallize the membrane proteins within their detergent micelles. The crystal lattice will be formed by the membrane proteins via polar interactions between the polar parts of the surface. Figure 3 (right) shows one example of such a crystal. It is immediately clear that membrane proteins with large extramembranous domains should form this type of crystal much easier than those with small polar domains. The size of the detergent micelle plays a crucial role. A large detergent micelle might prevent the required close contact between the polar surface domains of the membrane proteins. One way to achieve a small detergent micelle is to use small linear detergents like octyl glucopyranoside. However, for membrane biochemists, a general experience is that membrane proteins in micelles formed by a detergent with a short alkyl chain are not very stable. An increase in length of the alkyl chain by one methylene group frequently leads to an increase in stability by a factor of two to three. One therefore has to find a compromise.

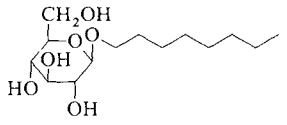
The advantage of the type II crystals is that basically the same procedures to induce supersaturation of the membrane protein solution can be used as for soluble proteins, namely vapor diffusion or dialysis with salts or polymers like polyethylene glycol as precipitating agents. Frequently a viscous detergent phase is formed, which seems to consist of precipitated detergent micelles (see, e.g., Ref. [13]). This phase separation is a serious problem. Membrane proteins are enriched in the detergent phase, and frequently undergo denaturation. In several examples crystals which were already formed are redissolved.

Bacteriorhodopsin, solubilized in octyl glucopyranoside, forms needle-like crystals (Fig. 1 C) when phosphate is used as precipitant (Fig. 1 C) and cubic crystals when ammonium sulfate[3] (Fig. 1 D) is used. The cubic crystals are not very stable, and transform into hairy, thread-like material (Fig. 1 E) after several weeks.[4] In this hairy material bacteriorhodopsin probably forms membranes again.

OmpF-porin, an outer membrane protein from *Escherichia coli*, was also crystallized – after solubilization in octyl glucopyranoside – by *Garavito* and *Rosenbusch*.[14] We received knowledge of this parallel development when *D. Oesterhelt* and *J. P. Rosenbusch* met in China at the end of 1979.

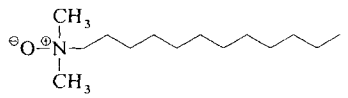
1.3. The Improvement

My opinion regarding the lack of final success with bacteriorhodopsin was always that the detergent micelles were still too large. The use of even smaller detergents was impossible due to insufficient stability of the bacteriorhodopsin in detergents with a shorter alkyl chain or a smaller polar head group. For several reasons, one way out was to add small amphiphilic molecules:[4a, 8] (i) these molecules might displace detergent molecules which are too large to fit perfectly into the protein's crystal lattice in certain positions. (ii) The small amphiphilic molecules are too small to form micelles themselves, but they are incorporated into the detergent micelles. These mixed micelles are smaller than the pure detergent micelles and the curvature of their surface is different. As a result the protein's could come closer together. (iii) Their polar head group is smaller than that of the detergent and less of the protein's polar surface would be covered by the polar part of the mixed small amphiphile/detergent micelle.



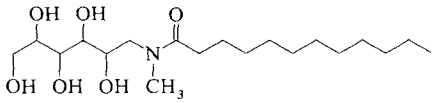
I had a look through the major chemical companies' catalogues and ordered nearly everything which was polar at one end and hydrophobic at the other. In addition I synthesized about 20 amphiphilic compounds, mainly alkylpolyols and alkyl *N*-oxides. These compounds were added during our attempts to crystallize bacteriorhodopsin. Several of the compounds had the effect that hexagonal columns were obtained (see Fig. 1 F), whereas cubes (Fig. 1 D) had been obtained without the additives. The most effective compound was heptane-1,2,3-triol, but it had a slightly denaturing effect on bacteriorhodopsin. The diffraction quality of the bacteriorhodopsin crystals was improved: Using synchroton radiation *H. Bartunik, D. Oesterhelt* and I were occasionally able to achieve a resolution of 3 Å, but only in one direction.

1.4. The Turn to Classical Photosynthesis

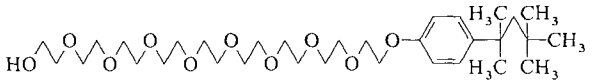


Frustrated from the failure to make a final breakthrough with bacteriorhodopsin, which was partly due to the absence of large extramembranous domains in this protein, I looked for more promising membrane proteins for crystallization. I chose the photosynthetic reaction centers from the purple bacteria *Rhodospirillum rubrum* and *Rhodopseudomonas viridis* and the light-harvesting chlorophyll a/b protein from spinach. I was influenced by the fact that these proteins (or protein-complexes) were said to be already part of a two-dimensional crystalline array in their native environment. As additional benefits they were available in large quantities, could easily be isolated, were colored and denaturation of the proteins was indicated by color changes.

I learnt about the *Rhodopseudomonas viridis* system when *Ernst Wehrli* from the ETH Zürich presented the results of electron microscopic studies during a workshop at Burg Gemen, Germany, in June 1979 (see Ref. [15]). Initially, I received some isolated photosynthetic membranes from him in December 1980. At that time I had moved with *D.*



Oesterhelt to the Max-Planck-Institut für Biochemie at Martinsried near Munich and I was just back from a stay at the MRC in Cambridge where we had carried out X-ray diffraction experiments on the bacteriorhodopsin crystals. We isolated the reaction center using hydroxyapatite chromatography according to a procedure published by Clayton and Clayton in 1978.[16] We tried to crystallize the isolated reaction centers, but without success. I developed a new procedure of isolation using only molecular sieve chromatography and tried again, and met with immediate success. The conditions were nearly identical to those found to be optimal for bacteriorhodopsin. The exception was that I could use *N,N*-dimethyldodecylamine *N*-oxide as detergent instead of octyl glucopyranoside (see Fig. 4). In the presence of 3%



octyl-β-D-glucopyranoside (OG)

N, *N*-dimethyldodecylamine-*N*-oxide (LDAO)

decanoyl-*N*-methylglucamide (DMG)

Triton X 100

Fig. 4. Structural formulas of commonly used detergents: octyl β-D-glucopyranoside, *N,N*-dimethyldodecylamine *N*-oxide, decanoyl *N*-methylglucamide are promising for membrane protein crystallization, whereas Triton X100 is not.

heptane-1,2,3-triol (high melting point isomer) and 1.5 to 1.8 M ammonium sulfate, star-like crystals were obtained upon vapor diffusion against 2.5 to 3 M ammonium sulfate in two days; more regular tetragonal columns with a length of up to 2 mm were formed upon vapor diffusion against 2.2 to 2.4 M ammonium sulfate in two to three weeks (see Figs. 1 G, 1 H). The much smaller polar head group of *N,N*-dimethyldodecylamine *N*-oxide is certainly of importance. Unfortunately, this detergent denatures bacteriorhodopsin. *D. Oesterhelt* generously considered the reaction center as my project.

The crystals turned out to be of excellent quality from the beginning. After a scaling-up of the isolation procedure, a continuous supply of crystals was guaranteed. Initially with the help of *Wolfram Bode* and *Robert Huber*, I could now start collecting the X-ray data. Figure 5 shows a rotation photograph similar to that used for the data collection.

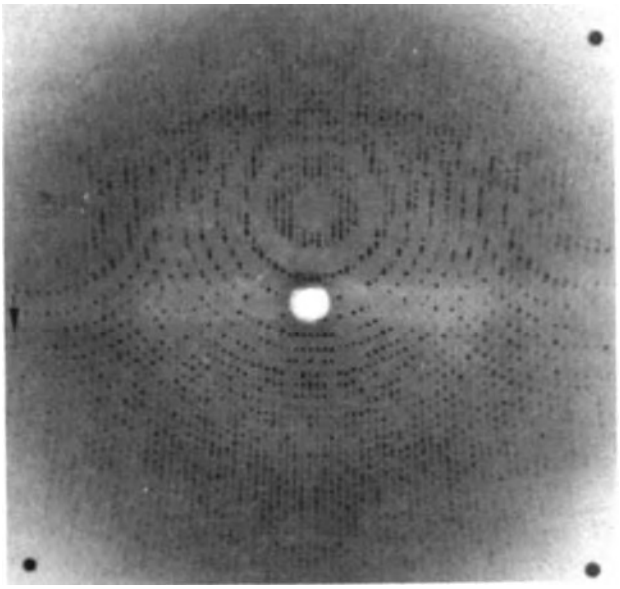


Fig. 5. X-ray diffraction pattern of a single crystal of the reaction center (1° rotation). Exposure time: 20 h, $Cu_{K\alpha}$ radiation, crystal to film distance: 100 mm. The arrow indicates 3.0 Å resolution (after *Michel* [4b]).

2. Determination of the Structure

In spring 1982 I (*J. D.*) joined *H. M.* in order to determine the three-dimensional structure of the reaction center. The tetragonal crystals have unit cell dimensions of $a = b = 223.5$ Å, $c = 113.6$ Å, and the symmetry of space group $P4_32_12$.[4, 17] As it turned out, there is one reaction center with a molecular weight of 145000 Daltons in the asymmetric unit.

2.1. Collection of X-ray Reflection Intensity Data

For data collection we used the rotation method with a rotating anode X-ray generator as the source, and photographic film as the detector.[17] The large unit cell of the reaction center crystals, in combination with the resolution limit of the diffraction pattern at 2.9 Å, limited the rotation interval per film exposure to 0.5°, so that more than two thirds of the reflections on any given film were only partially recorded. However, the long lifetime of the crystals in the X-ray beam at about 0 °C, and their positional stability allowed to add up partially recorded reflections from successive exposures, so that their treatment did not present a serious problem. Nevertheless, it took about three to four months to collect a complete data set. Data collection for the heavy atom derivatives was speeded up by choosing a rotation interval of 0.6° per exposure. A later re-collection of the native data set at the HASYLAB facilities of DESY in Hamburg was carried out at 2.3 Å resolution in rotation intervals of 0.4° by *Irmgard Sinning*, *Gerhard Schertler*, and *H. M.* The most tedious and time consuming task in this type of data collection was the processing of films. *Kunio Miki* and later *Otto Epp* provided invaluable help during that period of the work. We used the computer programs FILME[18, 19] and OSC[20, 21] for film evaluation, and PROTEIN (principal author: *W. Steigemann*) for scaling and merging data.

2.2. Solution of the Phase Problem

To solve the phase problem for the crystal structure of the reaction center we used the method of isomorphous replacement with heavy atom compounds. The experimental part was performed by *H. M.*, the film evaluation and data analysis by myself with support from *Kunio Miki* and *Otto Epp*.

In order to find the heavy atom derivatives, crystals were soaked for three days in 1 mM solutions of the respective heavy atom compounds in a soak buffer similar to the mother liquor. A number of compounds like K_2PtBr_4, $K_2Pt(CN)_4$, $KHg(CN)_2$, K_2HgI_4 and $EuCl_3$ could not be used since they induced the separation of the soak buffer phase into a viscous detergent phase and an aqueous phase. It was established from the beginning that X-ray diffraction no longer occurred on using large heavy atom compounds like $(C_6H_5)_3PbNO_3$ or C_6H_5HgCl, whereas the smaller homologues $(CH_3)_3PbCl$ or C_2H_5HgCl reduced the diffraction to about 6 Å resolution. However, after additional purification of the reaction centers prior to the crystallization the diffraction quality of the crystals was unchanged by the small heavy atom compounds. One compound ($KAuCl_4$) caused a shrinkage of the *c*-axis. Rotation photographs (1°) showing a large part of the 1,*k*,*l* lattice plane were taken and inspected visually for changes in the diffraction pattern. For promising candidates, ca. 50% complete data sets were collected and evaluated.

On average, each heavy atom derivative had nine heavy atom binding sites.[17] The major binding sites were found with the automatic search procedure in the PROTEIN program package. Using five different heavy atom derivatives, we could calculate phases to 3.0 Å resolution, and an electron density map.[17] Phases and map were further improved by solvent flattening.[22]

2.3. Model Building

Map interpretation and model building was done in three stages: First the prosthetic groups in the reaction center were identified. We found the four heme groups, the four bacteriochlorophyll-b molecules, the two bacteriopheophytin-b molecules, and one quinone molecule.[17] Next, the polypeptide chains were built with polyalanine sequence —except in the amino terminal regions of the subunits L, M, and cytochrome where partial amino acid sequences were known[23] and could be used to distinguish between the subunits. At that stage, some use was made of the local symmetry of the subunits L and M. Finally, as the gene sequences of the reaction center subunits were determined[24–26] the model of the protein subunits was completed. The sequence information not only led to an overall verification but also to a number of minor corrections of the polypeptide backbone model, since in the previous model building stage the electron density was not always clear enough to allow determination of the correct number of amino acids.

Our tools for model building were interactive graphics display systems: a Vector General 3400 system (black and white), and later an Evans & Sutherland PS 300 system (color). For both systems we used *Alwyn Jones*' program package FRODO.[27] The model library of this package was extended to include bacteriochlorophyll-b, bacteriopheophytin-b, menaquinone-7, and ubiquinone-1. Frequent use was made of the real-space refinement facility in FRODO which allowed correct incorporation of long stretches of helical structure into the electron density.

2.4. Model Refinement

The reaction center model, with about half of the side chains of the cytochrome subunit still missing, already had the rather low crystallographic *R*-value of 0.359 at 2.9 Å resolution ($R = \Sigma(||F_{obs}| - |F_{calc}||)/\Sigma|F_{obs}|$; F_{obs} and F_{calc} are observed and calculated structure factors, respectively). Crystallographic refinement of the model was started at 2.9 Å resolution, and continued at 2.3 Å resolution. The program packages used for refinement were PROTEIN, EREF,[28, 29] TNT,[30] and again FRODO.

As a result of the refinement the *R*-value was brought down to 0.193 for 95762 unique reflections at 2.3 Å resolution, the refined model consists of 10288 non-hydrogen atoms. Errors in the initial model, e.g. peptide groups and side chains with wrong orientations, were removed. New features were added to the model: a partially ordered carotenoid molecule, a ubiquinone in the partially occupied Q_B binding pocket, a complete detergent molecule (LDAO, see Fig. 4), a candidate for a partially ordered LDAO or similar molecule, seven candidates for negative ions; and 201 ordered water molecules. The upper limit of the mean coordinate error was estimated to be 0.26 Å.[31] A detailed description of refinement and refined model of the photosynthetic reaction center from *Rhodopseudomonas viridis* will be given elsewhere (*J. Deisenhofer, O. Epp, I. Sinning, H. Michel*, to be published).

3. Structure and Function

3.1. Structure Overview

An overall view of the structure of the photosynthetic reaction center from *Rhodopseudomonas viridis* is shown in Figure 6. It is a complex of four protein subunits, and of 14 cofactors. The protein subunits are called H (heavy), M (medium), L (light), and cytochrome; the names H, M, and L were chosen according to the apparent molecular weights of the subunits, as determined by electrophoresis. The core of the complex is formed by the subunits L and M, and their associated cofactors: four bacteriochlorophyll-b (BChl-b) molecules, two bacteriopheophytin-b (BPh-b) molecules, one non-heme iron ion, two quinone molecules, one carotenoid molecule. Structural properties, e.g. the hydrophobic nature of the protein surface, and functional considerations strongly indicate that the subunits L and M span the bacterial membrane. This aspect of the structure will be discussed in Section 5. Each of the subunits L and M contains five membrane spanning polypeptide segments, folded into long helices. The polypeptide segments connecting the transmembrane helices form flat surfaces parallel to the membrane surfaces.

Fig. 6. Stereoview of the overall reaction center of *Rhodopseudomonas viridis*. Protein chains are drawn in smoothed form; green, cytochrome; blue, M-subunit; brown, L-subunit; purple, H-subunit. The atoms of the cofactors are drawn in bright colors: yellow, carbon; blue, nitrogen; red, oxygen; green, magnesium. Smoothed backbone representations of polypeptide chains were produced following an idea of *Richard J. Feldman*, with help from *Marius G. Clore*.

The H subunit contributes another membrane spanning helix with its *N*-terminus near the periplasmic membrane surface. The *C*-terminal half of the H subunit forms a globular domain that is bound to the L–M complex near the cytoplasmic membrane surface. On the opposite side of the membrane the cytochrome subunit with its four covalently bound heme groups is attached to the L–M complex. Both the cytochrome subunit and the globular domain of the H-subunit have surface properties typical for water soluble proteins.

The total length of the reaction center, from the tip of the cytochrome to the H subunit is about 130 Å. The core has an elliptical cross section with axes of 70 Å and 30 Å.

The photosynthetic reaction centers from purple bacteria are the best characterized among all photosynthetic organisms (reviews: Refs. [32, 33]). All of them contain the three subunits H, M, and L; some bacteria lack the tightly bound cytochrome subunit. An example of a reaction center without a bound cytochrome subunit is that from *Rhodobacter sphaeroides*, which was also crystallized;[34, 35] its structure has been shown to be very similar to the reaction center of *Rhodopseudomonas viridis*.[36, 37]

3.2. Subunit Structure

The folding of the polypeptide chains of the four reaction center subunits is shown schematically in Figure 7. As mentioned above, major elements of secondary structure in the subunits L and M are the five membrane spanning helices. A comparison of the polypeptide chain folding in both subunits reveals a high degree of similarity. Structurally similar segments include the transmembrane helices and a large fraction of their connections. In total, 216 α-carbons from the M-subunit can be superimposed onto corresponding α-carbons of the L-subunit with an r.m.s. deviation of only 1.22 Å. The superposition of the subunits is achieved by a rotation of ca. 180° about an axis running perpendicular to the membrane surface; we call this axis the central local symmetry axis. Table 1 lists the helices in both subunits, and Table 2 lists the structurally similar regions in both subunits. Besides the transmembrane helices, called LA, LB, LC, LD, LE, and MA, MB, MC, MD, ME, with lengths between 21 and 28 residues, there are shorter helices in the connecting segments, notably helix de (between transmembrane helices D and E), and helix cd. Subunit M (323 residues) is 50 residues longer than L (273 residues). The insertions in M,

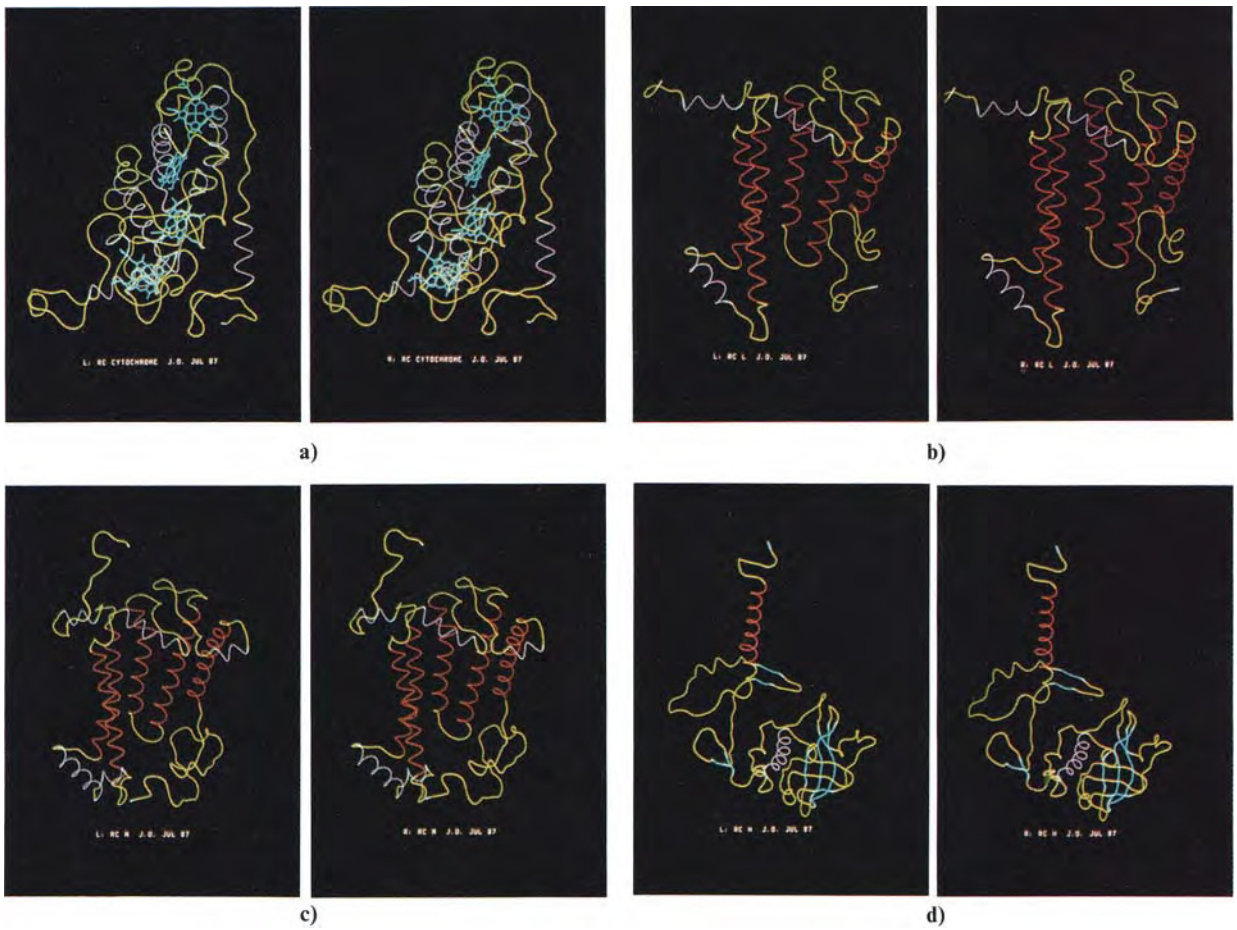

Fig. 7. Stereoview of the smoothed backbone representations of the protein subunits. The secondary structure is indicated in color: yellow, no apparent secondary structure; red, transmembrane helices; purple, other helices; blue, antiparallel β-sheets. a) Cytochrome (with the four heme groups); b) L-subunit; c) M-subunit; d) H-subunit. *N*-termini are marked blue, *C*-termini are marked red.

Table 1. Helical segments in subunits L and M.

Helix	Segment (length)	
	subunit L	subunit M

with respect to L, are located near the *N*-terminus (20 residues), in the connection between the helices MA and MB (7 residues), in the connection between MD and ME (7 residues), and at the *C*-terminus (16 residues). The insertions at the *N*- and *C*-termini make the M-subunit dominate the contacts with the peripheral subunits. The insertion between MD and ME, containing another small helix (see Table 1) is of importance for the different conformations of the quinone binding sites in L and M, and for binding of the non-heme iron (see below).

Table 2. Regions with similar polypeptide chain folding in subunits L and M.

Subunit M		Subunit L	Length
M49–76	→	L29–56	28
M88–96	→	L61–69	9
M100–224	→	L73–197	125
M243–290	→	L209–256	48
M291–296	→	L258–263	6

The H-subunit with 258 residues can be divided into 3 structural regions with different characteristics (see Fig. 7). The *N*-terminal segment, beginning with formylmethionine,[24] contains the only transmembrane helix of subunit H; it consists of 24 residues (H12 to H35). Near the end of the transmembrane helix the sequence shows seven consecutive charged residues (H33 to H39). Residues H47 to H53 are disordered in the crystal, so that no significant electron density can be found for them.

Following the disordered region the H chain forms an extended structure along the surface of the L–M complex, apparently deriving structural stability from that contact. The surface region contains a short helix and two two-stranded antiparallel β-sheets.

The third structural segment of the H-subunit, starting at

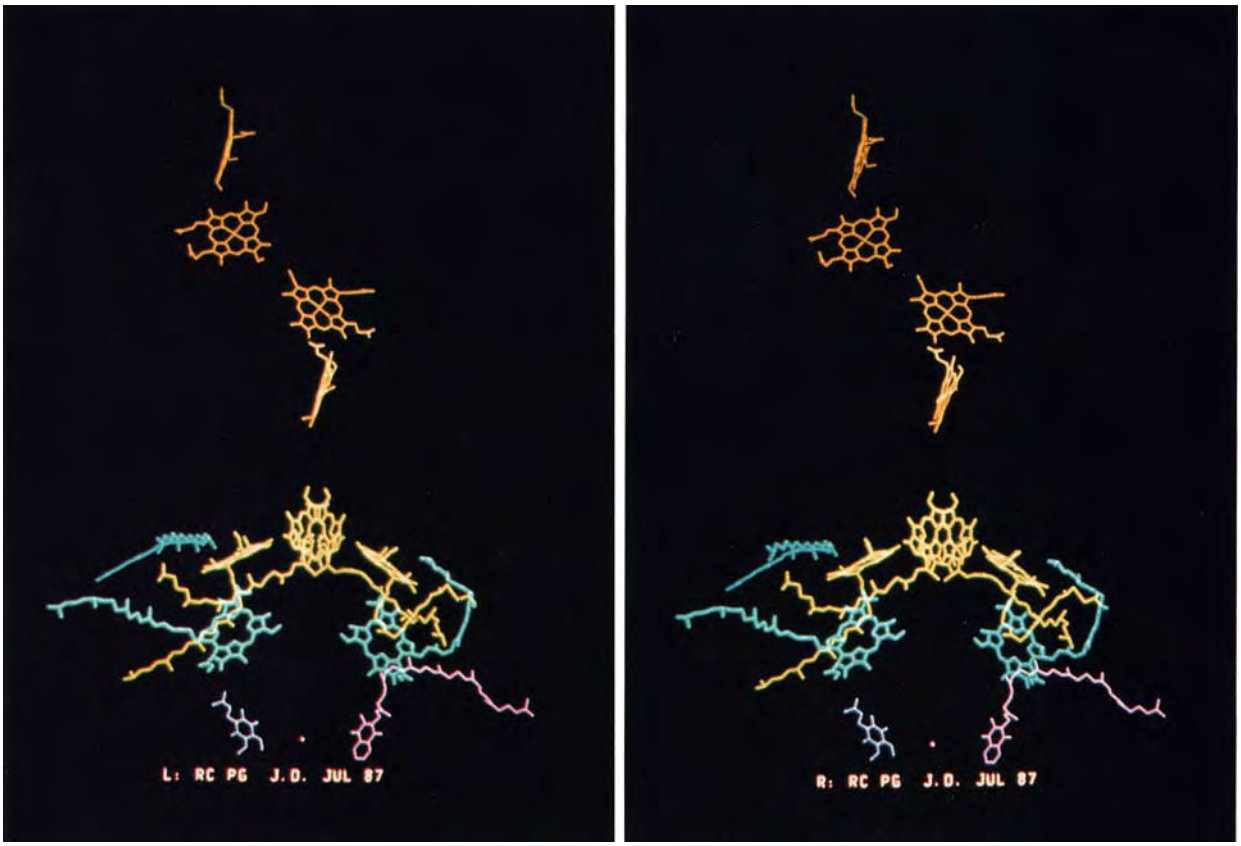

Fig. 8. Stereoview of the cofactors: brown, heme groups; yellow, bacteriochlorophyll-b; light blue, bacteriopheophytin-b; blue, carotenoid (dihydroneurosporene; *I. Sinning, H. Michel*, unpublished results); purple, quinones (right: Q_A, left: Q_B); red dot, non-heme iron.

about H105 forms a globular domain. This domain contains an extended system of antiparallel and parallel β-sheets between residues H134 and H203, and an α-helix (residues H232 to H248). The β-sheet region, the only larger one in the whole reaction center, forms a pocket with highly hydrophobic interior walls. This structural property reminds one of transport proteins like the retinol binding protein[38] and the biline binding protein;[39] however, the strand topology is different. So far, no evidence for a ligand has been found.

With 336 residues[26] the cytochrome is the largest subunit in the reaction center complex. Its last four residues, C333 to C336, are disordered. Also disordered is the lipid molecule-bound to the *N*-terminal cysteine residue.[40] The complicated structure of the cytochrome can be summarized as follows: The structure consists of an *N*-terminal segment, two pairs of heme binding segments, and a segment connecting the two pairs. Each heme binding segment consists of a helix with an average length of 17 residues, followed by a turn and the Cys-X-Y-Cys-His sequence typical for c-type cytochromes. The hemes are connected to the cysteine residues via thioether linkages. This arrangement leads to the heme planes being parallel to the helix axes. The sixth ligand to the heme iron is in three of the four cases a methionine residue within the helix. The iron of heme 4 has histidine C124, located in a different part of the structure, as a sixth ligand. The two pairs of heme binding segments, containing hemes 1 and 2, and 3 and 4, respectively, are related by a local twofold symmetry. From each pair 65 residues obey this local symmetry with an r.m.s. deviation between corresponding α-carbon atoms of 0.93 Å. The local symmetry of the cytochrome is not related to the central local symmetry.

3.3. Arrangement of Cofactors

Figure 8 shows the arrangement of the 14 cofactors associated with the reaction center protein subunits. The four heme groups of the cytochrome, numbered according to the order of attachment to the protein, form a linear chain that points to a closely associated pair of bacteriochlorophyll (BChl-b) molecules. This pair, the so-called "special pair" is the origin of the two branches of cofactors, each consisting of another BChl-b (the "accessory" BChl-b), a bacteriopheophytin-b (BPh-b), and a quinone. The non-heme iron sits between the quinones. The tetrapyrrole rings of BChl-b, BPh-b and quinone molecules approximately follow the same local symmetry that is displayed by the L- and M-chains. The branches of cofactors from the special pair to the BPh-b molecules can be clearly associated with subunits L or M, so that we speak of an L-branch and an M-branch. This is the basis for our nomenclature: BChl-b and BPh-b are called BC_{XY} and BP_X, respectively, where X denotes the branch (L or M), and Y is P for "special pair" or A for "accessory". At

the level of the quinones the situation is more complicated because the subunits interpenetrate here, and the quinone at the end of the L-branch is actually bound in a pocket of the M-subunit and vice versa. Therefore, we prefer the nomenclature Q_A and Q_B with Q_A at the end of the L-branch; Q_A is menaquinone-9, and Q_B is ubiquinone-9.[41] The local symmetry is violated by the phytyl chains of BChl-b and BPh-b, by the different chemical nature and different occupancy of the quinones, and by the presence of a carotenoid molecule near the accessory BChl-b molecule of the M-branch.

3.4. Functional Overview

Our current understanding of the function of the reaction center was developed by combining structural information with information from other experimental techniques, notably spectroscopy, as described in recent reviews.[42-44] Figure 9 shows a schematic view of the reaction center with its

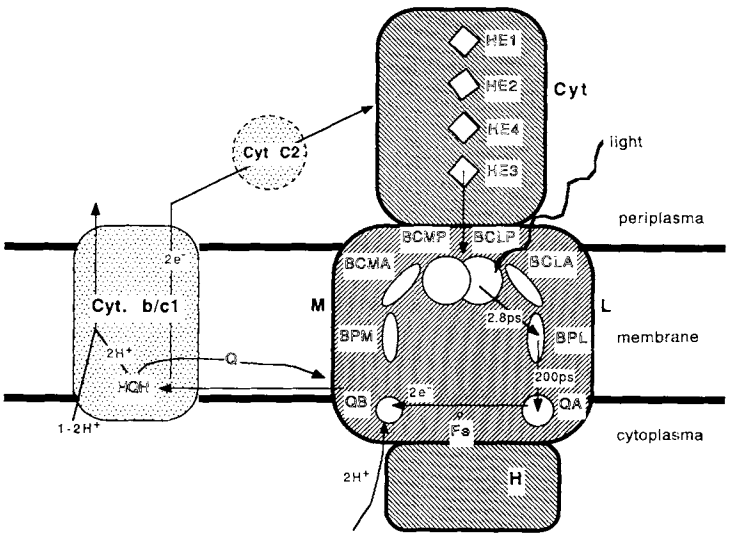

Fig. 9. Schematic view of the reaction center, showing the light-driven cyclic electron flow.

cofactors in the bacterial membrane. The special pair, P, is the starting point for a light-driven electron transfer reaction across the membrane. Absorption of a photon, or energy transfer from light harvesting complexes in the membrane puts P into an excited state, P*. From P* an electron is transferred to the bacteriopheophytin on the L-branch (here: BP_L) with a time constant of 2.8 ps.[45,46] The distinction between the two bacteriopheophytin molecules was possible because they absorb at slightly different wavelengths, and, with a knowledge of the crystal structure, linear dichroism absorption experiments could distinguish between the two chromophores.[47-49]

From BP_L the electron is transferred to Q_A with a time constant of ca. 200 ps. At this point the electron has crossed most of the membrane. Both these electron transfer steps function at very low temperatures (ca. 1 K) with time constants even shorter than at room temperature.[50,51]

From Q_A the electron moves on to Q_B in about 100 μs. The non-heme iron does not seem to play an essential role in this step.[52]

Q_B can pick up two electrons and, subsequently, two protons.[53] In the Q_BH_2 state it dissociates from the reaction center, and the Q_B site is re-filled from a pool of quinones dissolved in the membrane. Electrons and protons on Q_BH_2 (here: HQH) are transferred back through the membrane by the cytochrome b/c_1 complex. The electrons are shuttled via a soluble cytochrome c_2 to the reaction center's cytochrome from which the photo-oxidized special pair is reduced with a time constant of ca. 270 μs. This time constant increases with decreasing temperature down to ca. 100 K, and remains constant for lower temperatures. The whole process can be described as a light-driven cyclic electron flow, the net effect of which is the generation of a proton gradient across the membrane that is used to synthesize adenosine triphosphate, as described by *P. Mitchell*'s chemiosmotic theory. A number of still unsolved problems preclude a complete understanding of the reaction center's function. The nature of the electron transfer steps described above, and their speed and temperature dependence have not yet been explained theoretically. The first step, imposing the question of the role of the bridging BC_{LA}, is a subject of fascinating debate.

One of the greatest surprises in the structure analysis was the symmetry of the core structure, raising the question of the factors leading to the use of only the L-branch of cofactors and of the significance of the apparently unused branch. Further open questions relate to electron transfer between Q_A and Q_B, the role of the non-heme iron, and the function of Q_B as two-electron gate and proton acceptor. Finally, the purpose of the cytochrome, as well as details of the electron transfer from the soluble cytochrome to the cytochrome in the reaction center, and within the four hemes, are yet not fully understood.

3.5. Structural Details in Relation to Function

Here I describe the arrangement of the cofactors and their environment in some detail. Observations relating to open functional questions are emphasized.

Figure 10 shows the BChl-b ring system of the special pair, the primary electron donor of the photosynthetic light reaction. On the basis of spin resonance experiments the existence of a special pair had been postulated some time ago.[54] The two molecules overlap with their pyrrole rings I in such a way that, when viewed in a direction perpendicular to the ring planes, the atoms of these rings eclipse each other. The orientation of the rings leads to a close proximity between the ring I acetyl groups and the Mg^{2+} ions; however, the acetyl groups do not act as ligands to the Mg^{2+} ions. The pyrrole rings I of both BChl-b molecules are nearly parallel, and ca. 3.2 Å apart. Both tetrapyrrole rings, however, are non-planar; planes through the pyrrole nitrogens of each BChl-b form an angle of 11.3°.

The BChl-b molecules of the special pair are arranged with a nearly perfect twofold symmetry. This is illustrated in Figure 11 which shows a view along the twofold axis.[55] The BChl-b rings of the special pair are nearly parallel to this symmetry axis. Further structural elements shown in Fig-

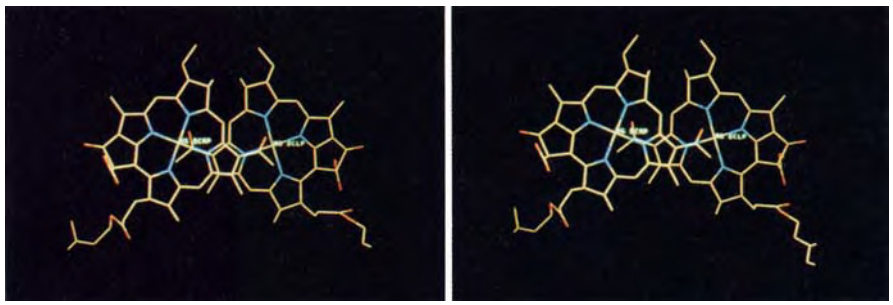

Fig. 10. Stereoview of the special pair with atoms and bonds in color: yellow, carbon; blue, nitrogen; red, oxygen; green, magnesium.

ure 11 that obey the central local twofold symmetry are the histidine residues (L173, M200) acting as ligands to the special pair Mg^{2+} ions, the rings of the accessory BChl-b molecules, the water molecules H-bonded between histidine nitrogen atoms and ring-V carbonyl groups of the accessory

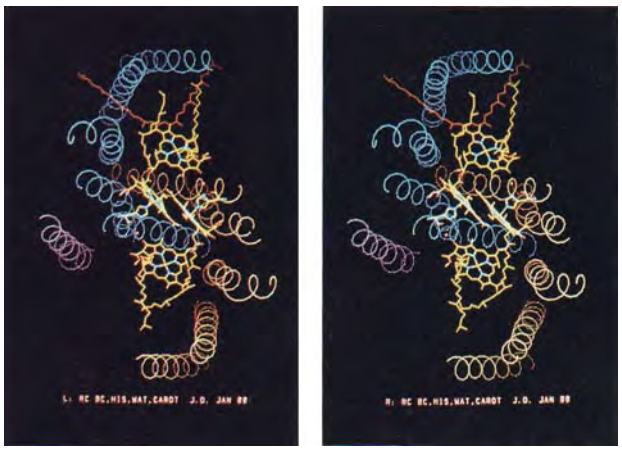

Fig. 11. Stereodiagram of a part of the reaction center (view along the central local twofold axis): special pair with histidine ligands, accessory bacteriochlorophyll-b molecules (BC_{LA} bottom, BC_{MA} top), two water molecules; the transmembrane helices of subunits L (brown), M (blue), and H (purple) are shown in smoothed backbone form.

BChl-b molecules, and the transmembrane helices of subunits L and M. The carotenoid molecule in contact with the accessory BChl-b (BC_{MA}), the side chains of the accessory BChl-b molecules, and the transmembrane helix of the H-subunit are examples of structural elements that break the twofold symmetry. A more subtle deviation from symmetry is the different degree of non-planarity of the two BChl-b ring systems of the special pair. The tetrapyrrole ring of BC_{MP} is considerably more deformed than that of BC_{LP}. This can cause an unequal charge distribution between the two BChl-b systems of the special pair, which in turn can be part of the reason for unidirectional electron transfer.[56]

Even though the tetrapyrrole rings of the BChl-b and BPh-b molecules of the L- and M-branches can be rotated on top of each other using a single transformation with the reasonably low r.m.s. deviation of 0.38 Å between the positions of equivalent atoms, a closer inspection shows considerable differences between the local symmetry operations of the special pair, the accessory BChl-b molecules, and the BPh-b molecules. Optimum superposition of the tetrapyrrole rings of the special pair alone is achieved by a rotation of 179.7°, for the accessory BChl-b molecules by a rotation of $-175.8°$, and for the BPh-b molecules by a rotation of

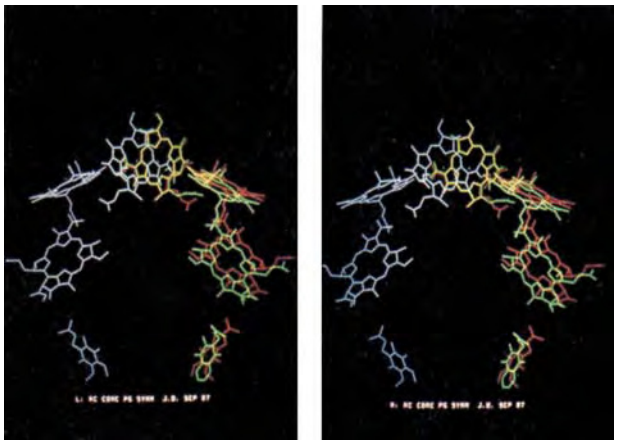

Fig. 12. Stereoview of the cofactors of the M-branch (purple), and of the L-branch (green); the phytyl chains are omitted for clarity. Red: cofactors of M-branch, rotated using a transformation that optimally superimposes the tetrapyrrole ring of BC_{MP} onto that of BC_{LP}.

$-173.2°$. This deviation from twofold symmetry is illustrated in Figure 12, where the cofactors of the M-branch were rotated using the transformation that optimally superimposes the special pair tetrapyrrole rings. It is clear that, due to the imperfect symmetry, interatomic distances and interplanar angles are different in both branches. For example, the closest distance between the atoms involved in double bonds in the special pair, and in BP_L is shorter by 0.7 Å than the corresponding distance between special pair and BP_M. Another example is provided by the angles between the tetrapyrrole rings of the special pair, and those of the accessory BChl-b molecules: the angles for BP_L are about 6° smaller than for BP_M. These structural differences lead to differences in overlap of the orbitals, and are expected to lead to different electron transfer properties in the two branches. This may be another contribution to the unidirectional charge separation in the reaction center.

Yet another observation that may relate to the different electronic properties of the L- and M-branches is the different degree of structural order. The amount of disordered structure, measured by the number of atoms without significant electron density, is larger in constituents of the M-branch than in those of the L-branch. Both phytyl side chains of BC_{MA} and BP_M are partially disordered at their ends; the phytyl chains of BC_{LA} and BP_L have a different conformation and are well ordered. The carotenoid near BC_{MA} may contribute to this difference in phytyl chain structure since its presence prevents an identical arrangement of phytyl chains on both sides.

A measure of the rigidity of the structure are the atomic *B*-values obtained during crystallographic refinement. These

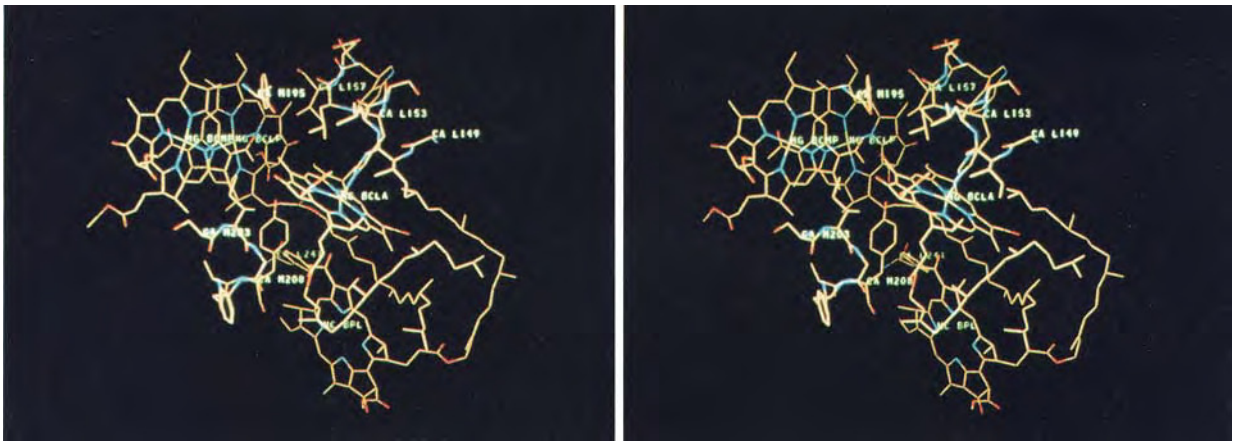

Fig. 13. Stereoview of the special pair, BC_{LA}, BP_L, and selected residues with colored atoms and bonds. Colors as in Fig. 10.

values are higher in the M-branch than in the L-branch. An example is the tetrapyrrole ring of BP_M with an average B value of 21.1 Å^2; in BP_L, B is only 10.3 Å^2.

A major source of asymmetry are the protein subunits L and M surrounding the core pigments. Their overall sequence homology is only 25%.[25] Although key residues like the histidines that are ligands to the Mg^{2+} ions of the BChl-b molecules and to the non-heme iron are strictly conserved, most of the residues in contact with the core pigments are different in the two branches.

I will now describe details of the protein environment of the pigments along the pathway of the electron, and mention additional differences between the branches that may be functionally important. Figure 13 shows a close-up view of the structures that are directly involved in the first step of the light-driven electron transfer reaction: the special pair (P), the accessory BChl-b BC_{LA}, and the first electron acceptor (BP_L). In addition, a few amino acid residues in close contact with these pigments are shown. BC_{LA} is in van der Waals contact with both the special pair and BP_L. The closest approach between the tetrapyrrole rings of the special pair and BP_L is 10 Å (atoms in double bonds). The phytyl chain of BC_{LP} follows a cleft formed by BC_{LA} and BP_L; it is in van der Waals contact with both tetrapyrrole rings.

At first glance this arrangement suggests that the electron should follow the path P → BC_{LA} → BP_L. However, attempts to observe bleaching of the absorption bands of BC_{LA} due to transient reduction failed. Spectroscopic experiments with ultrafast laser systems indicated direct reduction of BP_L from P* without intermediate steps.[45, 46, 50] This result triggered off heated discussions of the mechanism of electron transfer from P to BP_L, and of the role of BC_{LA} in this process. As indicated in Figure 13 with the example of tyrosine M208, it seems plausible that the protein plays an important role, not only as a scaffold to keep pigments in place, but also in influencing functional properties.

Numerous protein-pigment interactions are apparent also for the special pair itself,[57] as shown in Figure 14. These interactions include bonds from N_ε atoms of histidines L173 and M200 to the Mg^{2+} ions of BC_{LP} and BC_{MP}, respectively. Both acetyl groups of the special pair are hydrogen bonded: BC_{LP} to histidine L168, and BC_{MP} to tyrosine M195. A further hydrogen bond is found between the carbonyl oxygen of ring V and the OH group of threonine L248; there is no equivalent hydrogen bond for BC_{MP}.

The special pair environment is rich in aromatic residues: five phenylalanines, three tyrosines, and three tryptophans are in direct contact with the tetrapyrrole rings of the special

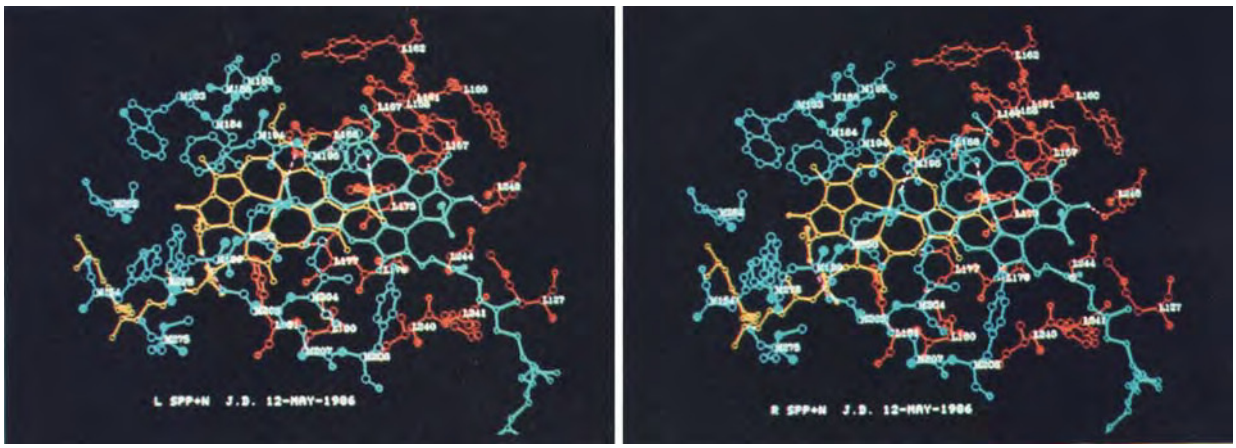

Fig. 14. Stereoview of the special pair and of its protein environment (after *Michel* et al. [57]): brown-red, residues from the L-subunit; blue, residues from the M-subunit; green, BC_{LP}; yellow, BC_{MP}; hydrogen bonds are indicated in purple. The hydrogen bond between serine M203 and BC_{MP} is no longer present in the refined model.

pair. Tyrosine L162 is located between the special pair and the closest heme group (HE3) of the cytochrome, and may play a role during reduction of the photooxidized special pair (P^+) by cytochrome.[57]

Figure 15 shows BP_L, the first electron acceptor, with its protein environment.[57] The BPh-b molecules are held in their places by non-covalent interactions only. In the positions where histidine ligands of BChl-b molecules would be expected, we find leucine M212 in the case of BP_L (see Fig. 15), and methionine L184 in the case of BP_M. BP_L forms two hydrogen bonds to the protein. The one between the ester carbonyl group of ring V and tryptophan L100 has an equivalent in a hydrogen bond between BP_M and tryptophan M127. The other hydrogen bond, between the keto-carbonyl oxygen of ring V and glutamic acid L104 is unique for the L-branch; the residue on the M-side corresponding to glutamic acid L104 is valine M131. Glutamic acid L104 is conserved in all currently known sequences of reaction center L-subunits from purple bacteria. Its position in the electron transfer pathway strongly suggests that it is protonated; otherwise, the negative charge of the ionized glutamic acid side chain would make electron transfer to BP_L energetically highly unfavorable.

As for the special pair, aromatic residues are found in the neighborhood of the BPh-b; the neighborhood of BP_L is richer in aromatic residues than that of BP_M. An especially noteworthy aromatic residue is tryptophan M250 whose side chain forms a bridge between BP_L and the next electron acceptor, Q_A. The M-branch residue equivalent to tryptophan M250 is phenylalanine L216 which, due to the smaller side chain, cannot perform a similar bridging function between BP_M and Q_B.

The environment of the quinone molecules and of the non-heme iron[57] is shown in Figure 16. Instead of the quinone, however, the figure shows the herbicide terbutryne in the Q_B binding pocket. The non-heme iron appears in the center of the drawing, between the binding sites of Q_A and Q_B, very near the central local twofold symmetry axis. It is bound by five protein side chains, four histidines (L190, L230, M217, M264), and glutamic acid M232, whose carboxylate group acts as a bidentate ligand. The iron sits in a distorted octahedral environment with the axial ligands histidine L230 and histidine M264, and equatorial ligands histidine L190, histidine M217, and glutamic acid M232. Histidine L190 and histidine M217 also contribute significantly to the binding of Q_B and Q_A, respectively. The location of the iron and its binding to residues from subunits L and M immediately suggests that a part of the iron's role is to increase the structural stability of the reaction center. It is surprising that its role in electron transfer between the quinones seem to be relatively minor.[58]

The head group of Q_A is bound in a highly hydrophobic pocket; its carbonyl oxygens are hydrogen bonded to the peptide NH groups of alanine M258, and to the N_δ atoms of the histidine M217 bound to iron. As mentioned above, tryptophan M250 forms part of the Q_A's binding pocket; its indole ring is nearly parallel to the head group of Q_A at a distance of 3.1 Å. The isoprenoid side chain of Q_A is folded along the surface of the L-M complex; the last three isoprenoid units are disordered in the crystal. The Q_A binding pocket is well shielded from the cytoplasm by the globular domain of the H-subunit.

The Q_B binding site in the crystals of the reaction center is only partially occupied; the Q_B model is therefore less reliable than the other parts of the structural model discussed above. Nevertheless, the crystallographic data suggest a highly plausible arrangement of the Q_B head group in its pocket; the Q_B side chain remains undefined. Apparently Q_B, similarly to Q_A, forms hydrogen bonds to the protein with its two carbonyl oxygens: one to the N_δ atom of the histidine L190 bound to iron, and a bifurcated hydrogen bond to the OH group of serine L223, and to the NH group of glycine L225. Like tryptophan M250 in the case of Q_A, phenylalanine L216 forms a significant part of the Q_B binding pocket. Major differences between the binding sites of Q_A and Q_B are the more polar nature of the Q_B site, and the presence of pathways through the protein, through which protons may enter the Q_B site. The bottom of the Q_B site is formed to a large part by the side chain of glutamic acid L212. Protons can move from the cytoplasm along a path marked by charged or polar residues to glutamic acid L212 and from there, by an as yet unknown mechanism, to the doubly reduced Q_B^{2-}.

Some herbicides are competitive inhibitors of Q_B binding to reaction centers of purple bacteria. Crystallographic binding studies with the herbicide terbutryne (see Fig. 16), and with *o*-phenanthroline[57, 59] demonstrated binding of these molecules in the Q_B binding pocket, and provided a structur-

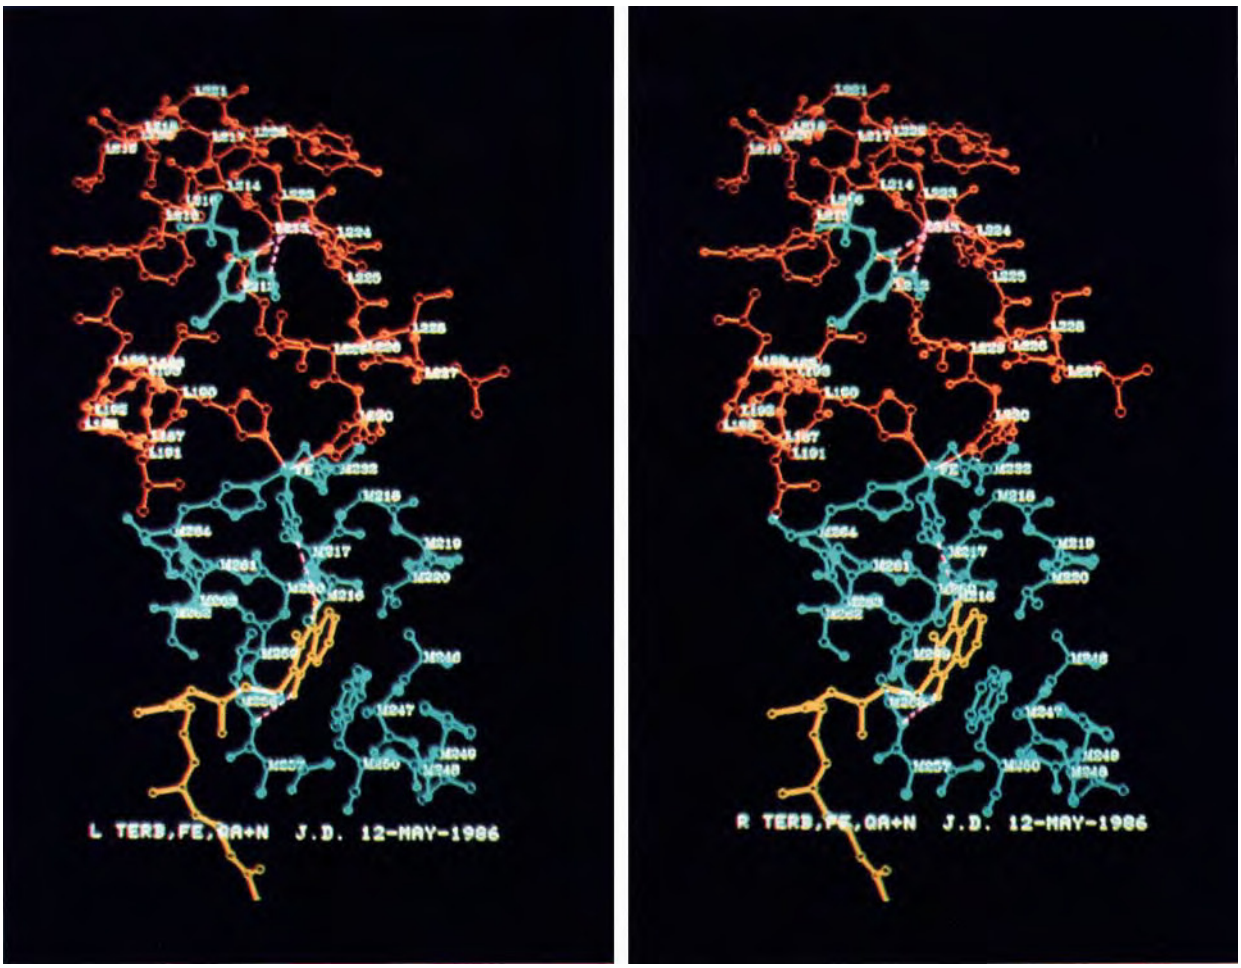

Fig. 16. Stereoview of the primary quinone (Q_A) of the non-heme iron, of the herbicide terbutryne (blue-green) in the Q_B binding pocket, and of the protein environment of these cofactors; colors as in Fig. 14 (after *Michel* et al. [57]).

al basis for understanding mutations that lead to herbicide-resistant *Rps.-viridis*.[60,61] The fact that herbicides which were developed to inhibit photosystem II reaction centers of green plants can also inhibit reaction centers of purple bacteria is one of the many indications of a close structural similarity between these kinds of photosynthetic reaction centers (see also Section 4 and Ref. [62]).

4. The Relation to Photosystem II and Evolutionary Aspects

4.1. Conclusions on the Structure of Photosystem II Reaction Center

The most surprising result of the X-ray structure analysis was the discovery of the nearly symmetric arrangement of the reaction center core formed by the homologous L- and M-subunits together with the pigments. The primary electron donor as well as the ferrous non-heme iron (II) are found at the interface between both subunits. Both subunits are needed to establish the reaction center.

Parallel to our X-ray structure analysis the following results suggesting a close relation between the reaction centers from purple bacteria and photosystem II were or became available: i) Photosystem II reaction center and the reaction center from purple bacteria both possess two pheophytin molecules.[32,63] Upon removal of the quinones or prereduction of them it is possible to trap one electron on one of them.[64,65] ii) Both reaction centers possess a magnetically coupled Q_A–Fe–Q_B complex. iii) The L-subunit of the reaction center of purple bacteria and the D1 protein (which is the product of the psbA-gene and also called Q_B protein, 32 kD-protein or herbicide binding protein) bind the herbicide azidoatrazine upon photoaffinity labeling.[66,67] iv) Weak but significant sequence homologies between the L- and M-subunits of the purple bacteria,[25,57,68–70] and the D1 proteins,[71] and later on also D2 proteins[72–75] of the photosystem II were discovered.

The conclusion to be drawn from the results was obvious: The reaction center of photosystem II from plants and algae had to be expected to be formed by the D1 and D2 proteins with D1 corresponding to the L-subunit and D2 corresponding to the M-subunit. This, however, was at variance with the accepted view[76] that the so-called CP47, a chlorophyll-binding protein with apparent molecular weight of 47000, is the apoprotein of the photosystem II reaction center. Figure 17 compares the amino acid sequences of the L- and M-subunits from two purple bacteria with the D1 and D2 proteins from spinach chloroplasts. Significant sequence homology starts with the glycine-glycine pair (L83, 84, M110,

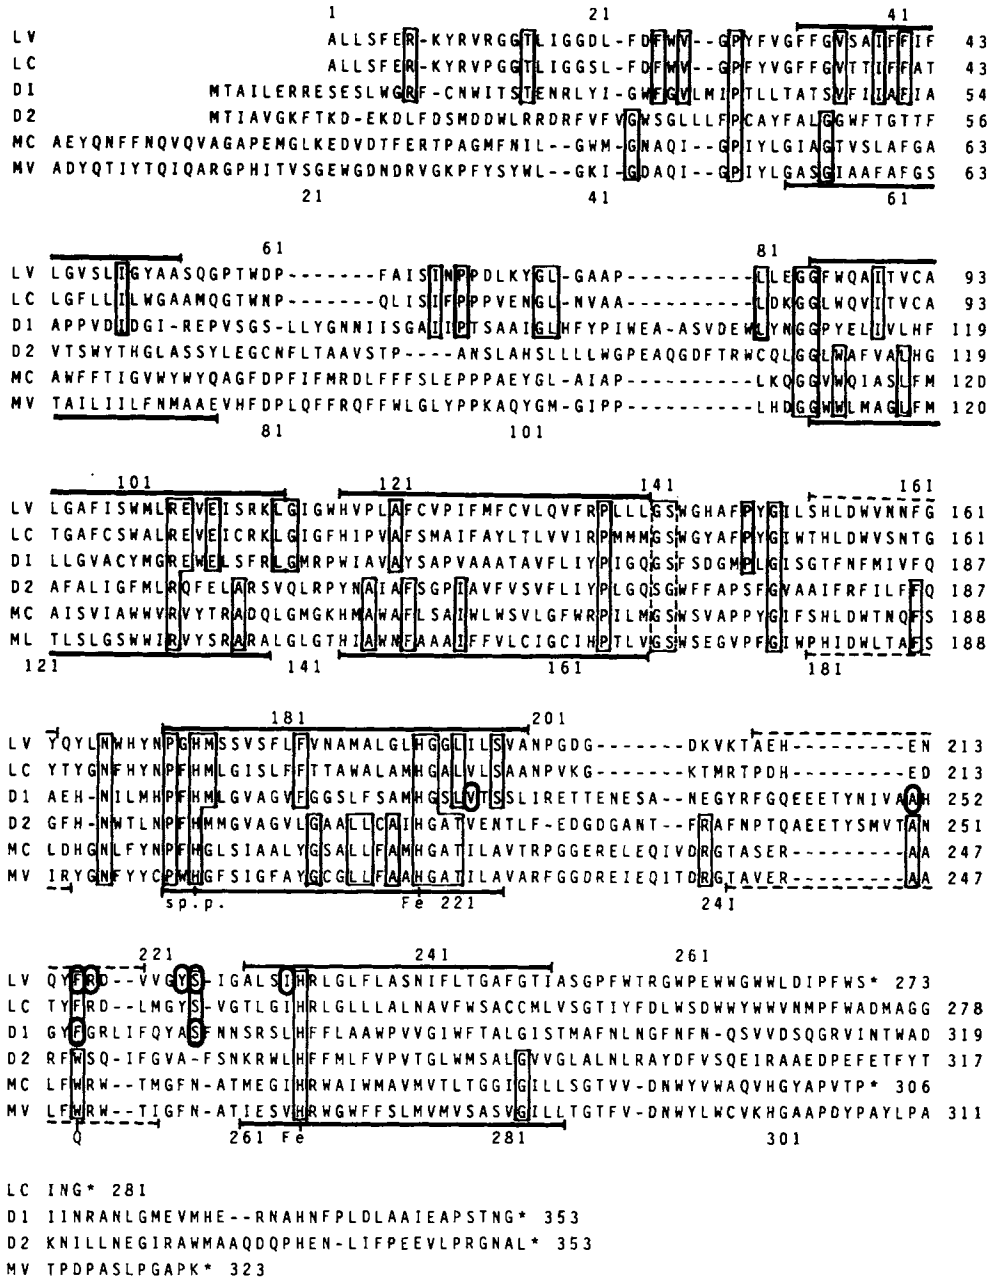

Fig. 17. The amino acid sequences of the L and M subunits of the purple bacteria *Rps. viridis* (LV, MV) [25] and *Rb. capsulatus* (LC, MC) [70] and of the D1 and D2 proteins. Amino acids common to all six subunits, the L subunits and D1, or the M subunits and D2 are boxed. The position of the transmembrane α-helices in the *Rps. viridis* reaction center is indicated by bars above the sequences of the L subunits and below the sequences of the M subunits. The positions of the short α-helices in the connections of transmembrane α-helices C and D, as well as D and E, are indicated by dashed lines. The histidine ligands of the special pair bacteriochlorophyll molecules and of the non-heme iron atom are labeled sp.p. and Fe, respectively. Circles show amino acids known to be mutated in herbicide-resistant reaction centers of purple bacteria or photosystem II (after *Michel* and *Deisenhofer* [62]).

111) at the beginning of the second transmembrane helix. Mainly amino acids of structural importance such as glycines, prolines and arginines are conserved. Part of the amino acids involved in the binding of the pigments and cofactors are also conserved: The histidine-ligands to the magnesium atoms of the special-pair chlorophyll molecules (L173, M200) and to the non-heme iron atom. In the L-subunit and in the D1 protein, a phenylalanine residue (L216, D1-255) and a serine residue (L223, D1-264) are found in the corresponding sequence positions. These residues are involved in the binding of the *s*-triazine herbicides like atrazine and terbutryne, which presumably compete with the secondary quinone Q_B for its binding site. Mutations of these amino acids cause herbicide resistance in the purple bacteria, in plants and in algae. The phenylalanines L216 and D1-255 correspond to tryptophans M250 and D2-254, which form the major part of the binding site of the primary quinone Q_A (see Section 3.5).

Several important differences exist between the reaction centers of photosystem II and those of the purple bacteria: the amino acids involved in the binding of the accessory bacteriochlorophylls in the purple bacteria, and a glutamic acid (M232) which is a bidentate ligand to the ferrous non-heme iron are not conserved. There is no indication of the existence of an analogue to the H-subunit in the reaction center of the photosystem II. The overall structure of the photosystem II reaction center core, however, must be very similar to the reaction center from purple bacteria formed by the L- and M-subunits. Figure 18 shows those helices which are presumably conserved between the reaction center cores of the purple bacteria and photosystem II and the position of the amino conserved between the L- and M-subunits and the D1 and D2 proteins. The identities of amino acids which are found specifically in the L-subunits and the corresponding positions of the D1 proteins, or specifically in the M-subunits and the corresponding positions of the D2 proteins,

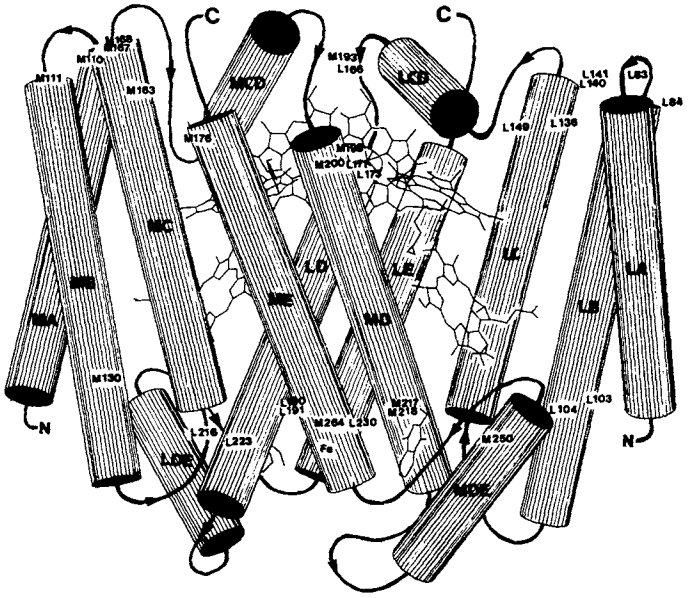

Fig. 18. Column model of the core of the reaction center of *Rps. viridis*. Only helices which are presumably conserved in photosystem II reaction center are shown. The connections of the helices are only indicated schematically. The transmembrane helices of the L (M) subunit are labeled LA-LE (MA-ME) and the major helices in the connections are labeled LCD (MCD) and LDE (MDE). Bacteriochlorophyll molecules of the special pair are at the interface of the L and M subunits between the D and E helices, while the bacteriopheophytin molecules are near the L helices. The binding site for Q_B is between the LDE and LD helices. The location of the amino acids conserved between all L and M subunits and the D1 and D2 proteins, as well as those forming the quinone binding sites, is indicated by their sequence numbers (after *Michel* and *Deisenhofer* [62]).

and are involved in the quinone binding, might be the result of convergent evolution. Their location is also shown.

The photooxidized primary electron donor (P^+) in the reaction center of *Rhodopseudomonas viridis* is reduced by the cytochrome subunit. In the position equivalent to this subunit in the photosystem II reaction center we have to expect the water soluble proteins forming part of the manganese-containing complex which evolves oxygen.

Experimental proof of the existence of a similar reaction center core in photosystem II was the recent isolation of a complex consisting of the proteins D1, D2 and cytochrome b559 from spinach chloroplasts which contains four to five chlorophyll molecules and two pheophytin molecules.[77] It has been shown to be active in electron transport to one of the pheophytins. Recently, evidence has been presented by two groups that a tyrosine residue located on the D1 subunit in the third transmembrane helix is an intermediate electron carrier between the primary electron donor of photosystem II and the oxygen-evolving manganese cluster.[78–80] A topic of speculation at the moment is whether or not the manganese cluster is also bound to the D1 and D2 proteins.

As a result of the work on the bacterial photosynthetic reaction center our entire view on the photosystem II reaction centers from plants and algae has changed.

4.2. Evolutionary Aspects

The sequence similarities discussed above suggest that the reaction centers from purple bacteria and photosystem II are evolutionarily related. A common ancestor possessed an entirely symmetric reaction center with two parallel electron transporting pigment branches across the membrane. This symmetric reaction center was formed by two copies of the same protein subunit encoded by one gene, i.e. was a homodimer. After a gene duplication and subsequent mutations the formation of the asymmetric dimer ("heterodimer") and the use of only one pigment branch for electron transfer became possible. It is an open question whether in evolution this gene duplication occurred only once (before the lineages leading to the purple bacteria and the organisms containing photosystem II split) or twice, after the splitting into these two lineages. In the latter case the specific sequence similarities between L and D1, as well as those between M and D2, would be the result of convergent evolution, whereas the identities of the structurally important amino acids would date back to the original symmetric dimer. Sequence comparisons are in favor of the latter possibility (see Ref. [81]): The similarity of the sequences in the D1 and D2 proteins is much greater than that in the L- and M-subunits. This observation possibly indicates that the gene duplication giving rise to separate D1 and D2 proteins occurred later during evolution than the gene duplication leading to the L- and M-subunits. On the other hand, due to more and stronger interactions with neighboring proteins, the D1 and D2 proteins had less freedom to mutate than the L- and the M-subunits. As a result, sequence comparisons might be misleading.

These evolutionary relationships also indicate that there must be an advantage for reaction centers possessing only one active electron transport chain with two quinones acting in series. There might be rather trivial explanations for the use of only one branch, e.g. an asymmetry in the protein environment can cause an asymmetry in the distribution of electrons in the excited state and subsequently lead to a preferred release of an electron only in one direction. This existing polarity might lead to a faster rate of the first electron transfer step, a minimization of competing reactions, and thus a higher quantum yield for the electron transfer.

A clear advantage of the present day's reaction centers is that the two quinones act in series, and only the released secondary quinone, Q_B, is a two-electron carrier. Consider the situation of the ancient symmetric reaction center: After the first excitation the electron is transferred to the quinone at the end of one pigment branch. The resulting semiquinone is not stable and its electron is lost within a period of seconds. Only if it receives a second electron can it be protonated and energy stored in the form of the quinol. With two identical parallel electron transfer chains the probability for the second electron to be funneled into the same chain to the same quinone as the first electron is only 50%. A possible electrostatic repulsion by the negatively charged semiquinone might even decrease this probability. In a frequent situation the absorption of two photons leads to the formation of two semiquinones in the same reaction center and energy is not stored in a stable way. Clearly, the way out of this dilemma is to switch the two quinones in series and to allow protonation and release only to the final quinone, which is then Q_B in the electron transfer chain, as is observed in the reaction centers of purple bacteria and photosystem II. A considerable increase in the efficiency of light energy conversion must result, especially under poor light conditions.

5. Aspects of Membrane Protein Structure

5.1. The Membrane Anchor of the Cytochrome Subunit

X-ray structure analyses established that the L and M subunits are firmly integrated into the membrane, both possessing five transmembrane helices, whereas the H subunit is anchored to the membrane by one transmembrane helix. The X-ray work showed no indication of any intramembraneous part of the cytochrome subunit. Nevertheless, in the hands of the biochemists it behaved like a membrane protein and aggregated easily. A strange observation during the protein sequencing was that upon Edman-degradation of the isolated cytochrome subunit no *N*-terminal amino acid could be identified after the first degradation, but a normal sequence could be obtained starting with the second amino acid from the *N*-terminus. With the help of *F. Lottspeich, K. A. Weyer* was then able to isolate a modified amino-terminal amino acid, and, in collaboration with *W. Schäfer* to elucidate its structure using mass spectrometry.[40, 82] The result is shown in Figure 19. The *N*-terminal amino acid is a cysteine linked to a glycerol residue via a thioether bridge. Two fatty acids are then esterified to the two OH-groups of the glycerol. The fatty acids are a statistical mixture of singly unsaturated C_{18} fatty acids and singly hydroxylated C_{18} fatty acids. These experiments firmly established that the cytochrome subunit also possesses a membrane anchor, but this is now of a lipid type and not of a peptide type. The membrane anchor is very similar to that of the bacterial lipoproteins (see, e.g., Refs. [83, 84]). The cytochrome subunit of the reaction center is the first cytochrome molecule known to contain such a membrane anchor.

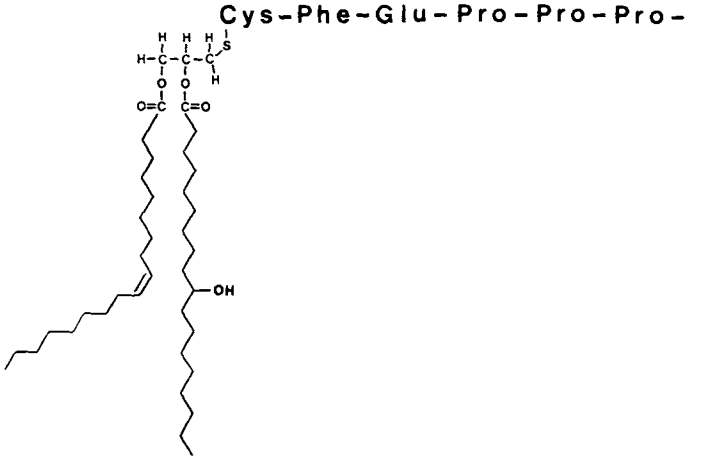

Fig. 19. The *N*-terminus of the cytochrome subunit. Two fatty acids are esterified with the *N*-terminal *S*-glycerocysteine. The fatty acids are a mixture of 18:OH (two isomers) and 18:1 (three isomers) acids roughly in a 1:1 ratio, which are represented by oleic acid and 10-hydroxystearic acid in the figure (after *Weyer* et al. [40]).

5.2. Protein Lipid Contacts

The interaction between lipids and protein occurs at the surface of the proteins. Therefore a closer examination of the surface of the protein complex might be very informative. For this purpose a space filling model of the reaction center is shown in Figure 20a. Carbon atoms approaching the surface of the reaction center are shown as white spheres. A central section perpendicular to the approximate twofold rotation axis can be seen where carbon atoms form the surface of the protein almost exclusively. They are mainly side chain atoms of the amino acids leucine, isoleucine and phenylalanine. This central zone must correspond to the hydrophobic part of the protein surface, which in the membrane is in contact with the alkane chains of the lipids. Approaching the cytoplasmic rim of that central zone a row of nitrogen atoms is seen at the protein surface. These nitrogen atoms are side chain atoms of the basic amino acids arginine and histidine. The role of these basic residues might be to determine the position of the reaction center perpendicular to the membrane via specific interaction between negatively charged phosphate groups of the lipids and the positively charged amino acid side chains of the reaction center protein subunits.

Figure 21 shows the percentage of the "accessible surface area" occupied by carbon atoms, as layers perpendicular to the central twofold rotation axis. The twofold rotation axis runs through the non-heme iron atom near the cytoplasmic side and relates the special-pair bacteriochlorophyll molecules near the periplasmic side of the membrane. Two important conclusions can be drawn from Figure 21: (i) The primary electron donor (special pair), is located in the hydrophobic non-polar part of the membrane, whereas the non-heme iron atom is already in that zone where the protein surface is polar and most likely interacts with the polar head groups of the lipids. (ii) The thickness of the hydrophobic zone perpendicular to the membrane is 30 to 31 Å only. This value is smaller than expected for a lipid bilayer composed of lipids with C_{18} fatty acids.

5.3. Distribution of Amino Acids and Bound Water Molecules

Figure 20b shows the distribution of the strongly basic amino acids arginine and lysine, and of the strongly acidic amino acids glutamic acid and aspartic acid, which at neutral pH possess electric charges at the ends of their side chains. A central zone, where none of these amino acids is found, has a thickness of about 25 Å and is thus slightly thinner than the hydrophobic surface zone shown in Figures 20 and 21. This slight discrepancy is due to two arginine residues and one glutamic acid residue, which are apparently in a hydrophobic environment without counter charges. The role of the positive charges of the arginine side chains seems to be structural. They possibly cancel the partial negative charge at the carboxy-terminal ends of the short helices in the connections of the long D and E transmembrane helices. These short de helices partly intrude into the hydrophobic zone of the membrane and a positive charge seems to be necessary so that the peptide chain can change its direction. The glutamic acid (L104) seems to be protonated and thus neutral, and forms a hydrogen bond with one of the bacteriopheophytin molecules (BP_L)[57] (see also Section 3.5).

Within the L and M subunits the glutamate and aspartate, as well as lysine and arginine residues show an interesting asymmetric distribution with respect to cytoplasmic and periplasmic sides. If one calculates "net charges" for the

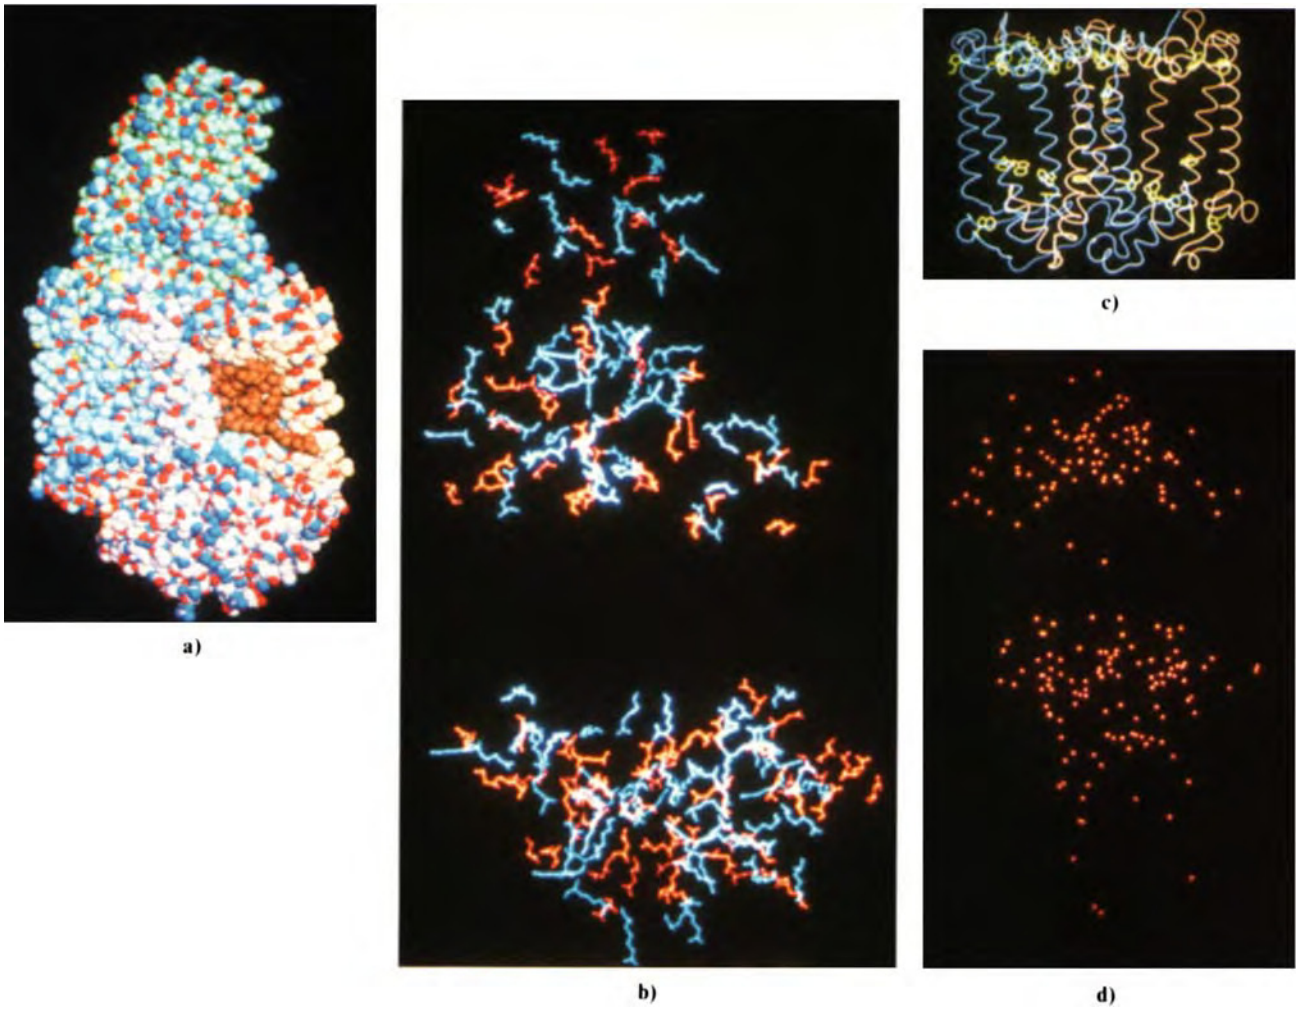

Fig. 20. a) Space-filling model of the photosynthetic reaction center of *Rps. viridis*. Carbon atoms are shown in white, nitrogen atoms in blue, oxygen atoms in red, and sulfur atoms in yellow. The atoms of a bacteriopheophytin molecule visible on the surface are represented in brown. b) Distribution of the "charged" amino acids in the photosynthetic reaction center of *Rps. viridis*. The negatively charged amino acids (aspartic, glutamic) are shown in red, the positively charged amino acids (arginine, lysine) in blue. c) Distribution of tryptophan residues (green) in the L- (brownish) and M-subunits (blue). d) Distribution of bound water molecules in the reaction center. The reaction centers and the L- and M-subunits are always viewed parallel to the membrane.

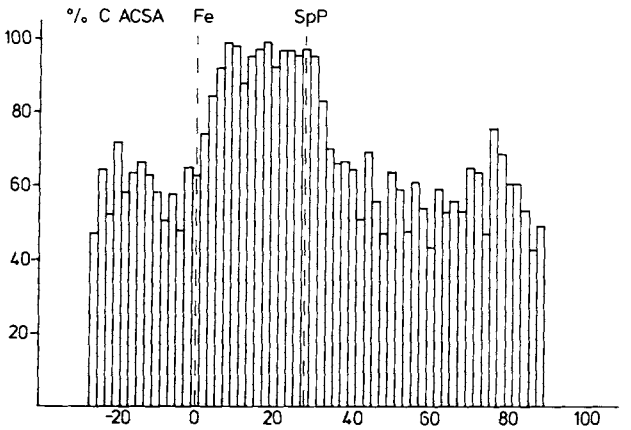

Fig. 21. Percentage of the accessible surface area (ACSA) occupied by carbon atoms; shown for 3 Å-thick layers perpendicular to the noncrystallographic twofold rotation axis, which runs through the ferrous non-heme iron atom (Fe) and the special pair (SpP).

peptide chains on the periplasmic side of the membrane and compares them with the net charges of the cytoplasmic side (assuming that all glutamic acid residues, aspartic acid residues and the carboxy-termini are negatively charged, whereas all the arginine and lysine residues and the amino-termini are positively charged) one finds that the cytoplasmic ends of the transmembrane helices and their respective connections are nearly always less negatively charged than their counterparts on the periplasmic side. This phenomenon is illustrated schematically in Figure 22: As a result the cytoplasmic part of the M-subunit carries four positive net charges and the periplasmic part four negative charges, the cytoplasmic part of the L-subunit two positive charges and the periplasmic part four negative charges. The charge asymmetry becomes even more pronounced if one considers the existence of the firmly bound non-heme iron atom on the cytoplasmic side and the presumed protonation of glutamic acid L104. Thus, these membrane proteins are strong electric dipoles. This result can be correlated with the fact that the interior of bacteria is negatively charged, due to the action of electrogenic ion pumps. This means that the L- and M-subunits are oriented in the membrane in the energetically more favorable manner. Conversely, the combination of the electric field across the membrane, established by the ion pumps, and the anisotropic distribution of negatively and positively charged amino acids in the protein may be one of the factors which determine the orientation of membrane proteins with respect to the inside and outside of the cell.

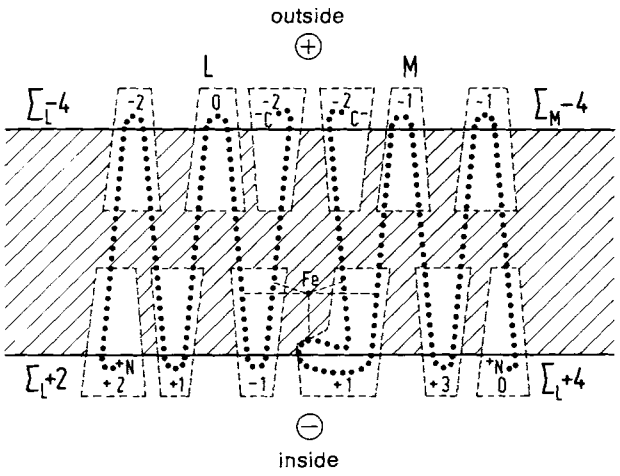

Fig. 22. Schematic drawing of the transmembrane helices and the helix connections of the L and M subunits of the *Rps. viridis* reaction center in the membrane to show the net charges at the ends of the helices and the helix connections. The negatively charged interior of the cell is indicated by the minus sign at the bottom, the positively charged extracellular medium by the plus sign at the top (after *Michel* and *Deisenhofer* [85]).

In the L- and M-subunits the remarkably uneven distribution of the amino acid tryptophan as shown in Figure 20c was quite unexpected. About two thirds of the tryptophans are found at the ends of transmembrane helices or in the helix connections on the periplasmic side. Only a few tryptophan residues are seen in the hydrophobic zone, where they interact with pigments. The residual tryptophans are located in the transition zone between hydrophobic and polar surface or in the polar part of the L- and M-subunits near the cytoplasmic surface. The indole rings of the tryptophans are oriented preferentially towards the hydrophobic zone of the membrane.

Figure 20d shows the distribution of the bound water molecules which have been tentatively identified by X-ray crystallographic analysis. Only five of them are found in the hydrophobic zone of the membrane. A closer inspection shows that they may perform an important structural role. Figure 23 shows one of these water molecules and its probable hydrogen-bonding pattern. It apparently cross-links two transmembrane helices, one from the L-subunit, the other from the M-subunit by donating hydrogen bonds to two peptide oxygen atoms. Another hydrogen bond with an asparagine side chain is possible. Just how much these water molecules contribute to the stability of the structure of the reaction center has still to be clarified.

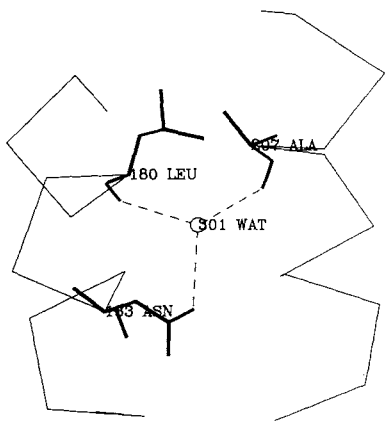

Fig. 23. A firmly bound water-molecule (301 WAT) in the hydrophobic part of the membrane cross-linking two transmembrane helices by forming hydrogen bonds with the peptide oxygen atoms of leucine L180 and alanine M207. Another hydrogen bond with the side chain of asparagine L183 is possible.

5.4. Crystal Packing and Detergent Binding

As outlined in Section 1, the most promising strategy was to crystallize the reaction center within a detergent micelle. According to this concept the crystal lattice should be formed by polar interactions between polar surface domains of the reaction center. This expectation was confirmed by the results of the structural analysis. Mainly the polar surfaces of the cytochrome subunit and the H-subunit are involved in the crystal packing, and only to a minor extent the polar surface part of the M-subunit.

As expected for detergents in a micelle most of the detergent is crystallographically not ordered and, with one exception, cannot be seen in the electron density map: The single transmembrane helix of the H-subunit, two transmembrane helices of the M-subunit, and part of the pigments seem to form a pocket in which one detergent molecule is bound. Its polar head-group apparently undergoes specific interactions with the protein near the cytoplasmic end of the hydrophobic surface zone. Specific binding of this particular detergent molecule might explain why crystals of the photosynthetic reaction center from *Rhodopseudomonas viridis* could be grown only with *N,N*-dimethyldodecylamine *N*-oxide as detergent, but not when octyl glucopyranoside or similar detergents were used.

In collaboration with *M. Roth* and *A. Bentley-Lewit* from the Institut Laue-Langevin in Grenoble the detergent micelle could be made visible by neutron crystallography and H_2O/D_2O contrast variation. A rather flat, monolayer-like ring of detergent molecules surrounding the hydrophobic surface zone of the reaction center became visible. Regions where the detergent micelles are in contact can also be seen. Therefore, attractive interactions between detergent micelles may also contribute to the stability of the protein's crystal lattice. In general, the strategy to crystallize membrane proteins within their detergent micelles[8, 86] now seems to be successful; however, the progress made in crystallizing other membrane proteins has been unexpectedly slow. Well diffracting crystals have only been obtained in the case of bacterial photosynthetic reaction centers and bacterial porins. The necessary fine tuning with respect to the size of the detergent micelle and the size of the polar head group of the detergent is still a formidable task which has to be solved empirically for each individual membrane protein.

We wish to express our sincere gratitude to persons and organizations who helped to make our work possible and successful: Our colleagues Otto Epp, Heidi Grünberg, Friedrich Lottspeich, Kunio Miki, Wolfram Schäfer, Irmgard Sinning, Karl-Alois Weyer and Wolfgang Zinth made important direct contributions as mentioned in the text. Dieter Oesterhelt and Robert Huber, their departments and the whole Max-Planck-Institut für Biochemie provided facilities and a stimulating and supportive atmosphere. Dieter Oesterhelt's backing especially during the intitial, frustrating phases, and the stable environment in the Max-Planck-Gesellschaft allowed us to start a project of unknown duration and outcome. Financially

the project was supported by the Deutsche Forschungsgemeinschaft through Sonderforschungsbereich 143 (Teilprojekt A3 to H.M., Teilprojekt A6 to J.D. and H.M.) and the Max-Planck-Gesellschaft.

A Structural Basis of Light Energy and Electron Transfer in Biology (Nobel Lecture)**

By Robert Huber*

Dedicated to Christa

Aspects of intramolecular light energy and electron transfer are discussed for three protein cofactor complexes whose three-dimensional structures have been elucidated by X-ray crystallography: the light harvesting phycobilisomes of cyanobacteria, the reaction center of purple bacteria, and the blue multi-copper oxidases. A wealth of functional data is available for these systems which allows specific correlations to be made between structure and function and general conclusions to be drawn about light energy and electron transfer in biological materials.

Introduction***

All life on earth depends ultimately on the sun, whose radiant energy is captured by plants and other organisms capable of growing by photosynthesis. They use sunlight to synthesize organic substances which serve as building materials or stores of energy. This was clearly formulated by *L. Boltzmann*, who stated that "there exists between the sun and the earth a colossal difference in temperature ... The equalization of temperature between these two bodies, a process which must occur because it is based on the law of probability will, because of the enormous distance and magnitude involved, last millions of years. The energy of the sun may, before reaching the temperature of the earth, assume improbable transition forms. It thus becomes possible to utilize the temperature drop between the sun and the earth to perform work as is the case with the temperature drop between steam and water ... To make the most use of this transition, green plants spread the enormous surface of their leaves, and, in a still unknown way, force the energy of the sun to carry out chemical syntheses before it cools down to the temperature level of the earth's surface. These chemical syntheses are to us in our laboratories complete mysteries..."[1]

Today many of these 'mysteries' have been resolved by biochemical research and the protein components and their basic catalytic functions have been defined.[2]

I will focus in my lecture on *Boltzmann*'s 'improbable transition forms', namely excited electronic states and charge transfer states in modern terminology, the structures of biological materials involved and the interplay of cofactors (pigments and metals) and proteins. I will discuss some aspects of the photosynthetic reaction center of *Rhodopseudomonas viridis* (see the original publications cited later and short reviews[3-5]) and of functionally related systems, whose structures have been studied in my laboratory: light harvesting phycobilisomes of cyanobacteria and blue oxidases. A wealth of structural and functional data is available for these three systems, which makes them uniquely appropriate examples to derive general principles of light energy and electron transfer in biological materials. Indeed, there are very few systems known in sufficient detail for such purposes.*

We strive to understand the underlying physical principles of light and electron conduction in biological materials with considerable hope for success as these processes appear to be more tractable than other biological reactions, which involve diffusive motions of substrates and products and intramolecular motions. Large-scale motions have been identified in many proteins and shown to be essential for many functions.[12,13] Theoretical treatments of these reactions have to

[***] Abbreviations:
PBS phycobilisomes, light harvesting organelles peripheral to the thylakoid membrane in cyanobacteria, which carry out oxygenic photosynthesis and have photosystems I and II.
PE, PEC, PC, APC phycoerythrin, phycoerythrocyanin, phycocyanin, allophycocyanin, biliprotein components in PBS with covalently attached tetrapyrrole (bilin) pigments.
PS I, II photosynthetic reaction centers in chloroplasts and cyanobacteria.
RBP retinol binding protein.
BBP bilin (biliverdin IXγ) binding protein in *Pieris brassicae*.
Rps. viridis Rhodopseudomonas viridis, bacteriochlorophyll-b containing purple bacterium carrying out anoxygenic photosynthesis.
RC reaction center.
C, H, L, M the four subunits of the reaction center from *Rps. viridis*: the cytochrome c subunit (C), with four hemes displaying two redox potentials (c_{553}, c_{558}) is located on the periplasmic side of the membrane; the L- and M-subunits are integrated in the membrane and their polypeptide chains span the membrane with 5 α-helices each, labeled A, B, C, D, E; they bind the bacteriochlorophyll-b (BChl-b or BC), bacteriopheophytin-b (BPh-b or BP), menaquinone-9 (Q_A), ubiquinone-9 (UQ, Q_B) and Fe^{2+} cofactors; the subscripts P, A, M, L indicate pair, accessory, M-, L-subunit association, respectively; the H-subunit is located on the cytoplasmic side and its *N*-terminal α-helical segment (H) spans the membrane.
P_{680}, P_{960} primary electron donors in PS II and the RC of *Rps. viridis*, respectively, indicating the long wavelength absorption maxima.
P*, D* electronically excited states of P, D (donor), A (acceptor)
LHC light harvesting complexes.
$LH_{a,b}$ light harvesting protein pigment complexes in BChl-a, b containing bacteria.
Car carotenoids.
Sor Soret bands of chlorophyll and bacteriochlorophyll.
PCY plastocyanin, electron carrier in the photosynthetic apparatus of plants.
LAC laccase, oxidase in plants and fungi.
AO ascorbate oxidase, oxidase in plants.
CP ceruloplasmin, oxidase in mammalian plasma.

[*] The structure of the *Rb. sphaeroides* RC is closely related to the *Rps. viridis* RC [6, 7, 151]. A green bacterial bacteriochlorophyll-a containing light harvesting protein is well defined in structure [9] but not in function. In the multiheme cytochromes [10, 11] the existence/or significance of intramolecular electron transfer is unclear.

take flexibility and solvent into account and become theoretically tractable only by applying the rather severe approximations of molecular dynamics[14, 15] or by limiting the system to a few active site residues, which can then be treated by quantum mechanical methods.

Light and electron transfer processes seem to be amenable to a more quantitative theoretical treatment. The substrates are immaterial or very small and the transfer processes on which I focus are intramolecular and far removed from solvent. Molecular motions seem to be unimportant, as shown by generally small temperature dependences. The components active in energy and electron transport are cofactors, which, in a first approximation, suffice for a theoretical analysis, simplifying calculations considerably.

1. Models for Energy and Electron Transfer

To test theories developed for energy and electron transfer appropriate model compounds are essential. Although it would be desirable, these models need not be mimics of the biological structures.

Förster's theory of inductive resonance[16] treats the cases of strong and very weak coupling in energy transfer. Strong interactions lead to optical spectra which are very different from the component spectra. Examples include concentrated solutions of some dyes, crystalline arrays, and the bacteriochlorophyll pair (BC_P) discussed in Section 3.1. The electronic excitation is in this case delocalized over a molecular assembly. A very weak coupling produces little or no alteration of the absorption spectra, but the luminescence properties may be quite different. Structurally defined models for this case are scarce. The controlled deposited dye layers of *Kuhn* and *Frommherz* et al.[17, 18] may serve this purpose and have demonstrated the general validity of *Förster*'s theory, but with deviations.

Synthetic models with electron transfer are abundant and have recently been supplemented by appropriately chemically modified proteins.[19–21] They are well covered in reviews (see, e.g., Refs. [22–29]). Figure 1 shows the essential elements of such models: Donor D (of electrons) and acceptor A may be connected by a bridging ligand (B) with a pendant group (P) embedded in a matrix M.

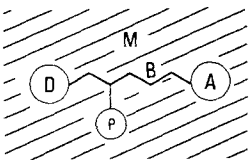

Fig. 1. Determinants of electron transfer models. D: Donor, A: Acceptor, B: Bridge, P: Pendant group, M: Matrix

Models with porphyrins as donors and quinones as acceptors are mimics of the reaction center (RC).[30, 31] Models with peptide bridging ligands[32] merit interest especially in relation to the blue oxidases. The effect of pendant groups (P), which are not in the direct line of electron transfer[22] is noteworthy in relation to the unused electron transfer branches in the RC and the blue oxidases. It is clear, however, that the biological systems are substantially more complex than synthetic models. The protein matrix is inhomogeneous and unique in each case. Despite these shortcomings, theory and models provide the framework within which the factors controlling the transfer of excitation energy and electrons and competing processes are to be evaluated.

1.1. Determinants of Energy and Electron Transfer

The important factors are summarized in Table 1. They may be derived from *Förster*'s theory and variants of *Marcus*' theory[26] for excitation and electron transfer, respectively. These theoretical treatments may in turn be derived from classical considerations or from *Fermi*'s Golden Rule with suitable approximations (see, e.g., Ref. [33]). Excitation and electron transfer depend on the geometric relation between donors and acceptors. Excitation energy transfer may occur over wide distances when the transition dipole moments are favorably aligned. Fast electron transfer requires sufficient electronic orbital overlap. Fast electron transfer over wide distances must therefore involve a series of closely spaced intermediate carriers with low lying unoccupied molecular orbitals or suitable ligands bridging donor and acceptor. Bridging ligands may actively participate in the transfer process and form ligand radical intermediates (chemical mechanism) or the electron may at no time be in a bound state of the ligands (resonance mechanism).[34] The spectral overlap and the 'driving force', for energy and electron transfer, respectively, have obvious effects on the transfer rates and are largely determined by the chemical nature and geometry of donors and acceptors. Nuclear reorganization of donor, acceptor, and the surrounding medium accompanying electron transfer is an important factor but difficult to evaluate, even qualitatively, in a complex protein system; we observe that the protein typically binds donors and acceptors firmly and rigidly, keeping reactant reorganization effects small. Surrounding polar groups may, as a result of their reorientation, slow down rapid electron transfer. However, a polar environment also contributes to the energetics by stabilizing ion pairs ($D^+ A^-$) or lowering activation and tunneling barriers and may thus increase 'driving force' and rate. The energy transfer also depends on the medium and is disfavored in media with high refractive index.

Table 1. Factors controlling the rate of transfer of excitation energy and electrons.

Excitation energy transfer $D^* + A \rightarrow D + A^*$ (very weak coupling)	Distance and orientation (coupling of excited states); Spectral overlap of emission and absorption of D and A; Refractive index of medium
Electron transfer from excited state $D^* + A \rightarrow D^+ + A^-$	Distance and orientation (electronic coupling, orbital overlap);
and from ground state $D^- + A \rightarrow D + A^-$	Free energy change ('driving force'); Reorganization in D and A; Orientation polarization of medium

Processes competing with productive energy and electron transfer from excited states 'lurk' everywhere (Table 2). Quite generally they are minimized by high transfer rates and a conformational rigidity of the cofactors in the protein ensemble.

I will discuss these factors in relation to the biological structures later on.

Table 2. Processes competing with the transfer of excitation energy and electrons.

Excitation energy transfer $D^* + A \rightarrow D + A^*$ (very weak coupling)	Non-radiative relaxation of D^* by photoisomerization and other conformational changes; Excited state proton transfer; Intersystem crossing; Chemical reactions of D^*, A^*, D^+, A^- with the matrix; Fluorescence radiation of D^*
Electron transfer from excited state $D^* + A \rightarrow D^+ + A^-$	Energy transfer; as above; Back reaction to ground state D,A
from ground state $D^- + A \rightarrow D + A^-$	–

2. The Role of Cofactors

The naturally occurring amino acids are transparent to visible light and seem also, with the exception of tyrosine, to be unsuitable as single electron carriers. Tyrosyl radicals have been identified in PS II as excited intermediates Z* and donors D*, which are involved in electron transfer from the water-splitting manganese protein complex to the photooxidized P^+_{680} (for reviews, see Refs. [35, 36]). Their identification has been assisted by the observation that Tyr L162 lies in the electron transfer path from the cytochrome to the bacteriochlorophyll pair (BC_{LP}) in the bacterial RC[37] (see Section 3.2.2.2 and Fig. 10c). A tyrosyl radical is not generated in the bacterial system, because the redox potential of P^+_{960} does not suffice.

Therefore cofactors, i.e. pigments and metal ions, generally serve as light energy acceptors and redox active elements in biological materials.

Figure 2 is a gallery of the pigments and metal clusters which will be discussed further on, namely the bile pigments phycocyanobilin and biliverdin IXγ in the light harvesting

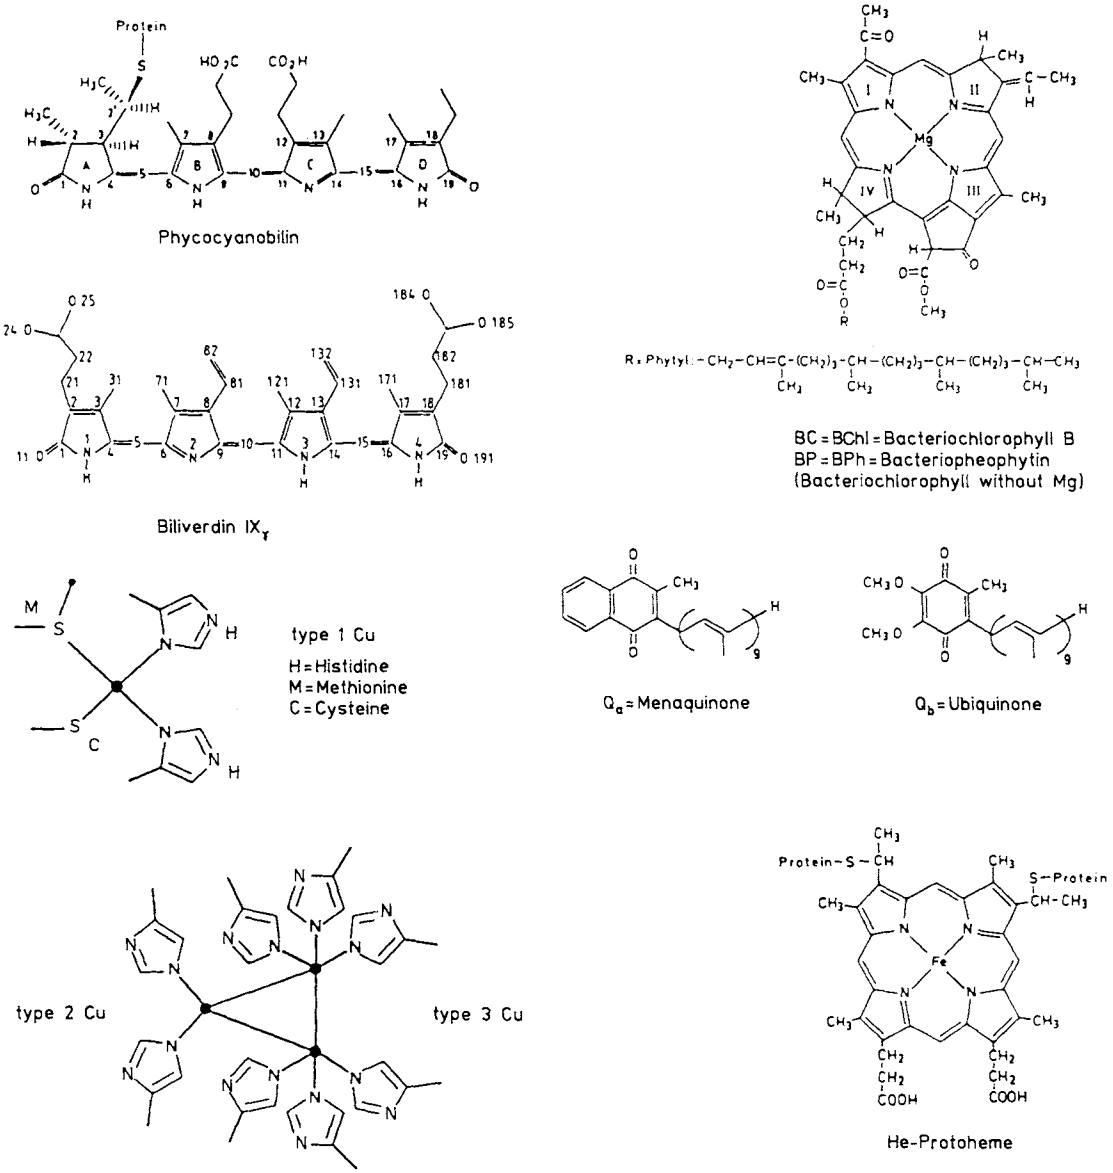

Fig. 2. Cofactors in phycocyanin (PC), bilin binding protein (BBP), ascorbate oxidase (AO) and the reaction center (RC) of the purple bacteria. Phycocyanobilins are covalently bound by thioether linkages to the protein. Biliverdin IXγ is non-covalently bound to the protein BBP. Type-1, type-2, type-3 copper ions are linked to the enzyme AO by coordination to the amino acid residues indicated. Four BChl-b molecules and two 2 BPh-b molecules are bound to the reaction center (RC) of the purple bacteria. A pair of BChl-b serves as the primary electron donor, a menaquinone-9 (Q_A) is the primary electron acceptor and an ubiquinone-9 (Q_B) the secondary acceptor. The four heme groups are bound by thioether linkages to the cytochrome c.

complexes, the BChl-b, BPh-b and quinones in the purple bacterial RC, and the copper centers in the blue oxidases.

The physicochemical properties of these cofactors determine the general features of the protein pigment complexes, whereas the protein part has a decisive influence on the spectral and redox properties.

3. The Role of the Protein

The role of the protein follows a hierarchy in determining the properties of the functional protein cofactor complexes shown in Table 3. The interactions listed in the table are different for the various systems and shall be described separately, except point 1, as there are common features in the action of proteins as polydentate ligands which can be ascribed to a 'rack mechanism'.

Table 3. Hierarchy of protein cofactor interactions.

1. Influence on configuration and conformation of the cofactors by the nature and geometry of ligands (the protein as a *polydentate ligand*)
2. Determination of the spatial arrangements of arrays of cofactors (the protein as a *scaffold*)
3. The protein as the *medium*
4. Mediation of the interaction with other components in the supramolecular biological system

3.1. The Protein as Polydentate Ligand

The 'rack mechanism' was introduced by *Lumry* and *Eyring*[38] and *Gray* and *Malmström*[39] to explain unusual reactivities and spectral and redox properties of amino acids and cofactors by the distortion enforced by the protein.

A comparison of isolated and protein bound bile pigments clearly demonstrates this effect. Isolated bile pigments in solution and in the crystalline state prefer a macrocyclic helical geometry with configuration *ZZZ* and conformation *syn,syn,syn* and show a weak absorption in the visible range and a low fluorescence quantum yield.[40-42] When bound as cofactors to light harvesting phycocyanins, however, they absorb and fluoresce very strongly in the visible range (Fig. 3). The auxochromic shift, essential for the light harvesting functions, is due to a strained conformation of the chromophore, which has configuration *ZZZ* and conformation *anti,syn,anti* stabilized by tight polar interactions with the protein[44-46] (Fig. 4). Particularly noteworthy is an aspartate residue (A87 here) bound to the central pyrrole nitrogen atoms, and conserved in all pigment binding sites. It influences the protonation, charge, and spectral properties of the tetrapyrrole systems. Tight binding is also effective against deexcitation by conformational changes. The structure shown in Figure 3 as representative for the free pigment is in fact observed in a bilin binding protein from insects.[41,42] This protein serves a different function and prefers the low energy conformer. The open chain tetrapyrrole bilins are conformationally adaptable, a property which makes them appropriate cofactors for different purposes.

The cyclic bacteriochlorophyll in the reaction center of purple bacteria is conformationally restrained but responds

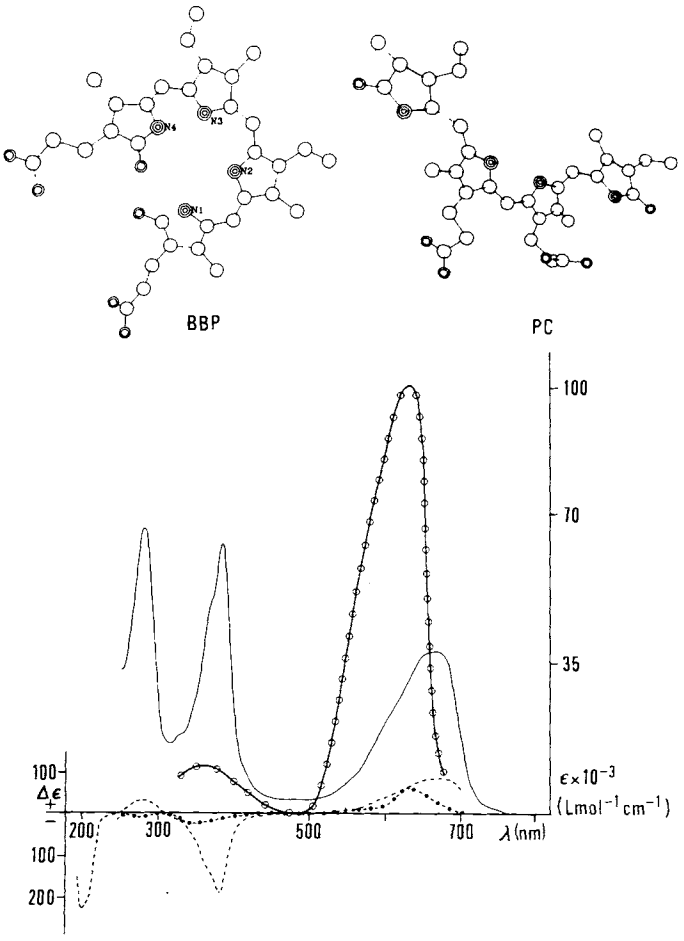

Fig. 3. Tetrapyrrole structures in PC and BBP and the associated optical and circular dichroism spectra [42, 44]. Absorption (———) and CD spectrum (– – –) of BBP; absorption (⊖) and CD spectrum (– · –) of PC.

to the environment by twisting and bending of the macrocycle. This may be one of the reasons for the different electron transfer properties of the two pigment branches in the RC (cf. Section 3.2.2.2). A more profound influence of the protein on the RC pigment system is seen in the absorption spectra, which differ from the composite spectra of the individual components (Fig. 5). The protein binds a pair of BChl-b (BC_P) in such a way that the two BChl-b molecules interact strongly via the pyrrole rings I, the acetyl substituents, and the central magnesium ions.[47] Alignment of the transition dipole moments and proximity of the BChl-b molecules lead to excitonic coupling, which partly explains the long wavelength absorption band P_{960}.[49]

The change in the optical spectra of blue copper proteins compared with those of cupric ions in normal tetragonal coordination is even greater (Fig. 6). The redox potential is also raised, to about 300–500 mV vs. 150 mV for Cu^{2+} (aq).[51] These effects are caused by the distorted tetrahedral coordination of the type-1 copper (a strained conformation stabilizing the cuprous state) and a charge transfer transition from a ligand cysteine $S^- \rightarrow Cu^{2+}$.[39,52]

The examples presented demonstrate the influence of the protein on the cofactors by various mechanisms: the stabilization of unstable conformers and strained ligand geometries and the generation of contacts between pigments leading to strong electronic interaction.

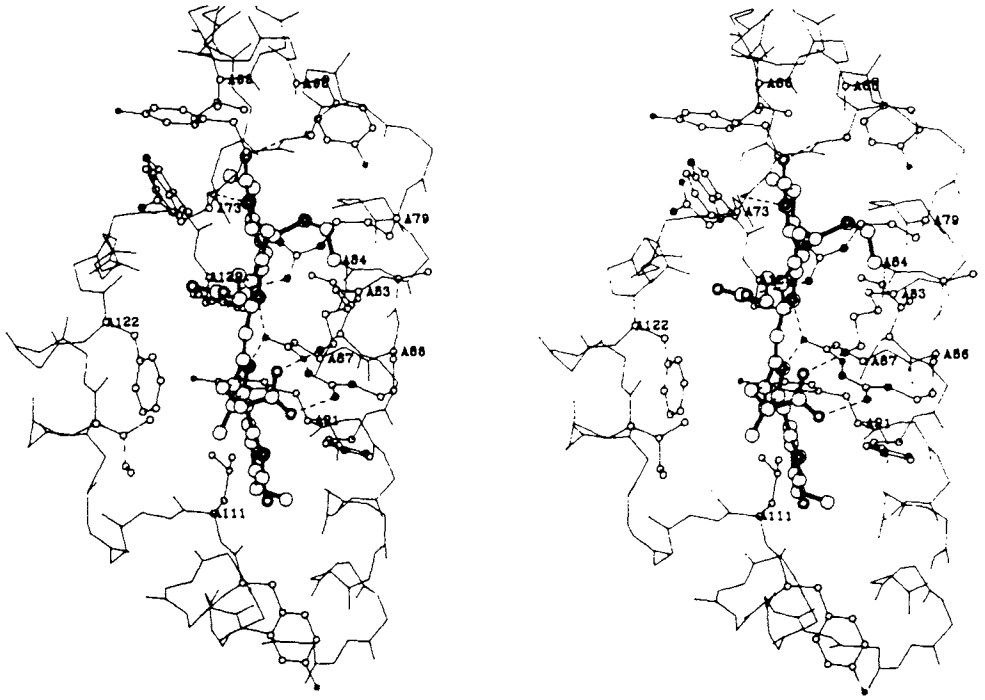

Fig. 4. Stereodrawing of phycocyanobilin A84 (thick bonds) and its protein environment (thin bonds). All polar groups of the bilin except those of the terminal D pyrrole ring are bound by hydrogen bonds and salt links to protein groups [44].

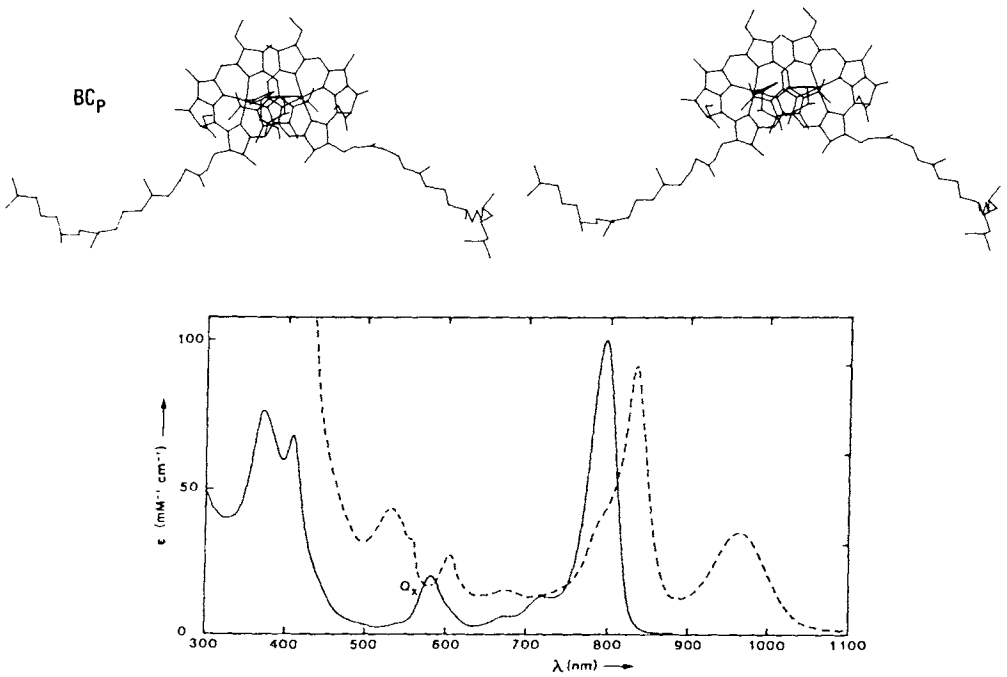

Fig. 5. Stereodrawing of the special pair BC_P in the reaction center (RC) [47] mainly responsible for the spectral alterations and the long wavelength absorption of the RC of *Rps. viridis* (– – –) compared with the spectra of BChl-*b* in ether solution (———) (spectra from Ref. [48]).

The fixation of the relative arrangements of systems of cofactors forms the basis of the energy and charge transfer properties in each system.

3.2. Protein as a Scaffold

3.2.1. Light Harvesting by Phycobilisomes

The limited number of pigment molecules associated with the RC would absorb only a small portion of incident sunlight. The RCs are therefore associated with LHC, which may be located within the photosynthetic membrane or form layers or antenna-like organelles in association with the photosynthetic membrane. Cyanobacteria contain particularly intricate light harvesting systems, the phycobilisomes (PBS), as organelles peripheral to the thylakoid membrane. Compared to PS I and PS II they absorb light of shorter wavelengths and thus use a wider spectral range of sunlight (Fig. 7). The PBS are assembled from components with fine-

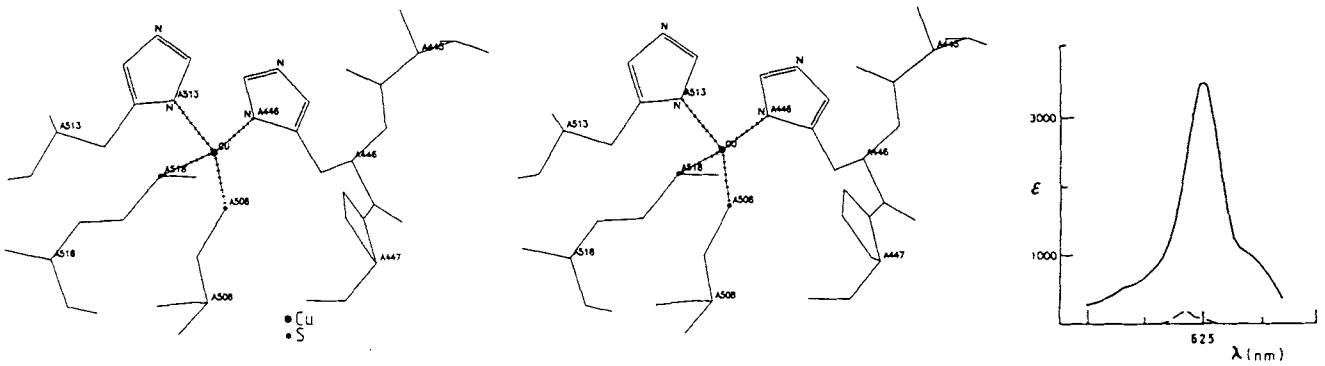

Fig. 6. Stereodiagram of the type-1 copper and its ligands in the ascorbate oxidase (AO). The coordination of the copper is to His A446, His A513, Met A518, Cys A508 [50]. The optical absorption spectra of 'blue' copper in copper proteins (———) are compared with the spectrum of normal tetragonal copper (– – –) (spectra from Ref. [51]).

ly tuned spectral properties such that the light energy is channeled along an energy gradient to PS II.

3.2.1.1. Morphology of the Phycobilisomes

The phycobilisomes consist of biliproteins and linker polypeptides. Biochemical and electron microscopy studies[54–57] led to the model representative of a hemidiscoidal phycobilisome (PBS) in Figure 7. Accordingly, PBS rods are assembled in a polar way from phycoerythrin (PE) or phycoerythrocyanin (PEC) and phycocyanin (PC), which is attached to a central core of allophycocyanine (APC). APC is next to the photosynthetic membrane and close to PS II (for a review, see Ref. [53]). The PC component consists of α- and β-protein subunits, which are arranged as $(\alpha\beta)_6$ disc-like aggregates with the dimensions 120 Å × 60 Å (for reviews, see Refs. 58–63]).

From crystallographic analyses, a detailed picture of the PC and PEC components has emerged.[44–46, 64, 65] The homology in the amino acid sequences suggests that all components have similar structures.

3.2.1.2. Structure of Phycocyanin

The α- and β-subunits of the phycocyanin (PC) (in *Mastigocladus laminosus*) have 162 and 172 amino acid residues, respectively. The phycocyanobilin chromophores (cf. Fig. 2) are linked via thioether bonds to cysteine residues at position 84 of both chains (A84, B84) and at position 155 of the β-subunit (B155).[66] Both subunits have similar structures and are folded into eight α-helices (X, Y, A, B, E, F, G, H: see Fig. 13). A84 and B84 are attached to helix E, B155 to the G-H loop. α-helices X and Y form a protruding antiparallel pair essential for formation of the (αβ) unit.

The isolated protein forms $(\alpha\beta)_3$-trimers with C_3 symmetry and hexamers $(\alpha\beta)_6$ as head-to-head associated trimers with D_3 symmetry (Fig. 8). The inter-trimer contact is exclusively mediated by the α-subunits, which are linked by an intricate network of polar bonds. The inter-hexamer contacts within the crystal (and in the native PBS rods) are made by the β-subunits.[44]

3.2.1.3. Oligomeric Aggregates: Spectral Properties and Energy Transfer

The spectral properties, absorption strength and fluorescence quantum yield of biliproteins depend on the state of aggregation. The absorption spectrum of the (αβ) unit resembles the sum of the spectra of the constituent subunits, but the fluorescence quantum yield is somewhat higher than

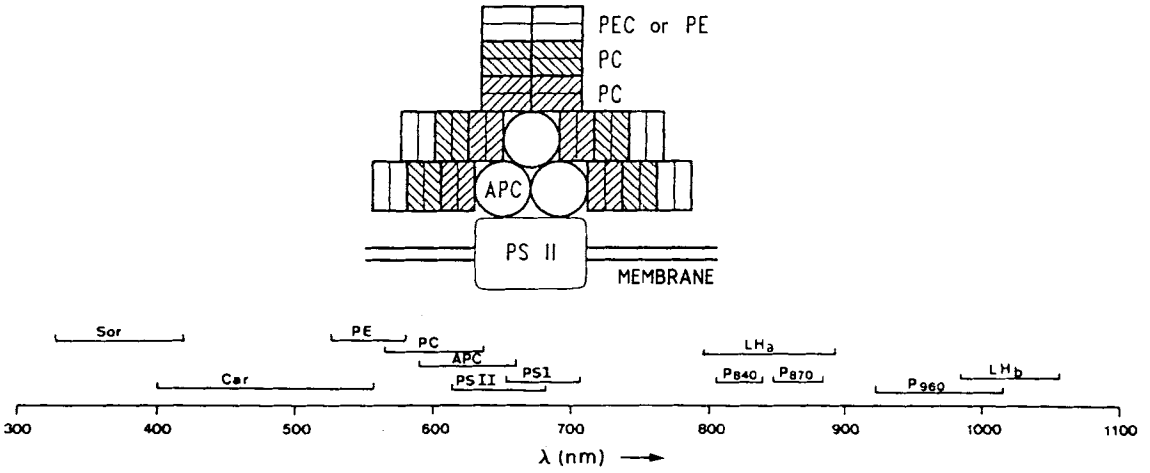

Fig. 7. Scheme of a typical phycobilisome (PBS) with the arrangements of the components and the putative spatial relationship to the thylakoid and photosystem II (PS II; for reviews see Refs. [53, 54]). The component labeled PS II is thought to represent PS II and the phycobilisome attachment sites. The main absorption bands of photosynthetic protein cofactor complexes in photosynthetic organisms are also shown. The PBS components absorb differently to cover a wide spectral range and permit energy flow from phycoerythrocyanin (PEC)/phycoerythrin (PE) via phycocyanin (PC) and allophycocyanin (APC) to PS II (for abbreviations see footnote [***] to the Introduction).

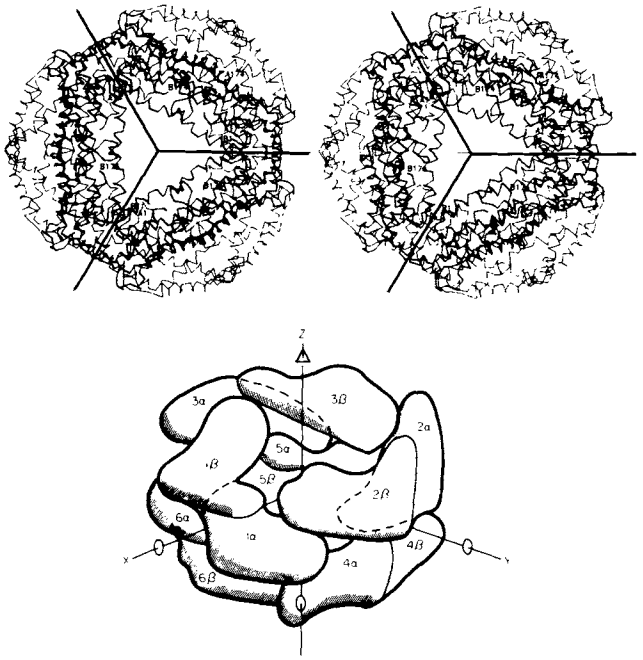

Fig. 8. Stereodrawing of the polypeptide chain fold of an $(\alpha\beta)_6$ hexamer of phycocyanin (PC) seen along the disk axis (top). The scheme (bottom) indicates the packing of subunits in the packing of subunits in the hexamer seen from the side.

the sum of the fluorescence yields of the constituent subunits. Upon trimer formation, the absorption is red-shifted and its strength and the quantum yield of fluorescence are increased[67, 68] (for a review, see Ref. [60]). In the $(\alpha\beta)_6$-linker complexes, the fluorescence is further increased and the absorption spectrum further altered.[69]

These observations can be rationalized by the structure of the aggregates. Formation of $(\alpha\beta)$ units causes little change in the environment of the chromophores. They remain quite widely separated at distances of > 36 Å (Fig. 9a). Upon trimer formation, the environment of chromophore A84 changes profoundly due to approach of chromophore B84 of the related symmetrically bound unit (Fig. 9a, top). In the hexamer (Fig. 9a, middle) the A84 and B155 chromophores strongly interact pairwise across the trimer interface. Furthermore, the molecular structures become more rigid with increasing size of the aggregates, as seen in the crystals of the trimeric and hexameric aggregates.[44, 46] Rigidity hinders excitation relaxation by isomerization and thus increases the fluorescence quantum yield.

The chromophores can be divided into subsets of s (sensitizing) and f (fluorescing) chromophores.[70, 71] The s-chromophores absorb at the blue edge of the absorption band and rapidly transfer excitation energy to the f-chromophores. This transfer is accompanied by depolarization.[72] Excitation at the red absorption edge (f-chromophores), however, results in little depolarization, suggesting that the energy is transferred along stacks of similarly oriented f-chromophores (Fig. 9a, bottom).[73] The assignment of the chromophores to s and f was accomplished by steady-state spectroscopy on various aggregates,[68] by chemical modification guided by the spatial structure,[74] and conclusively by measurement of the linear dichroism and polarized fluorescence on single crystals.[75] Accordingly, B155 is the s-, B84 the f-, and A84 the intermediate chromophore.

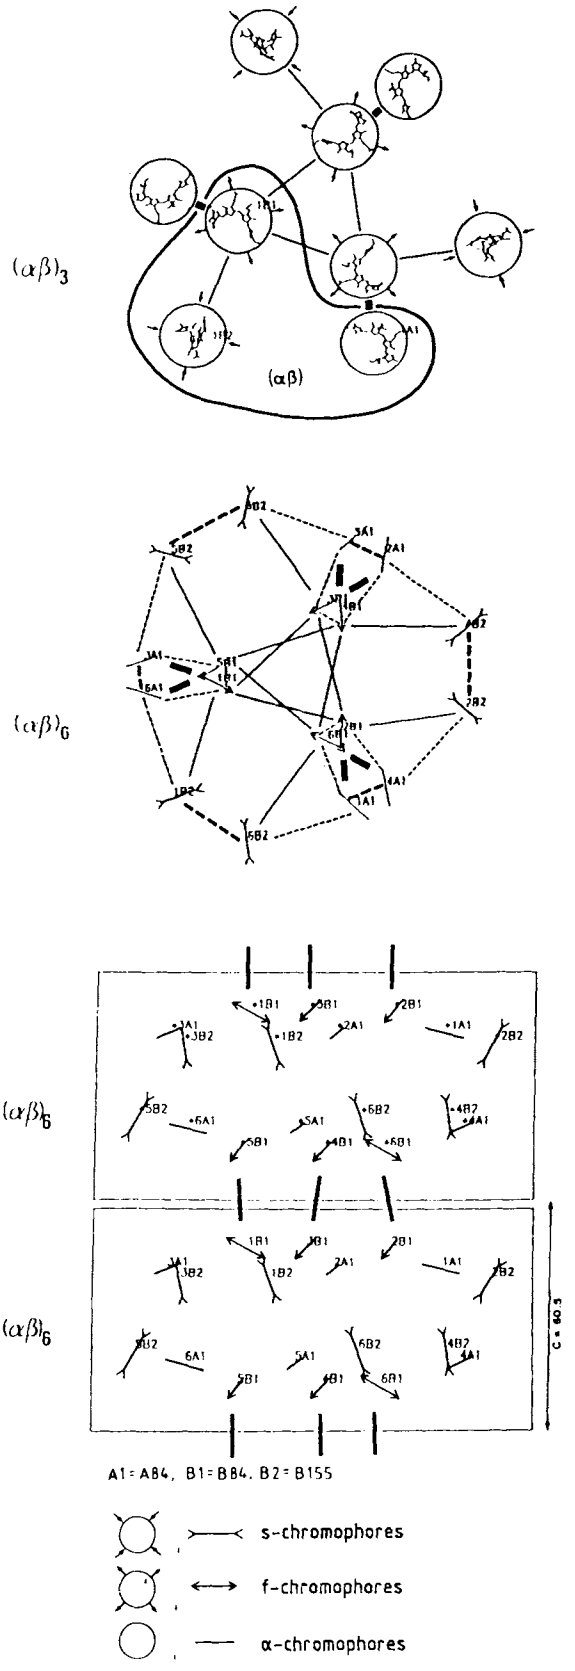

Fig. 9a. Arrangement of chromophores and preferred energy transfer pathways in $(\alpha\beta)_3$ trimers, $(\alpha\beta)_6$ hexamers and stacked hexamers (based on Table 10 from Ref. [44]). For the trimer the detailed structures of the chromophores are drawn, otherwise their approximate transition dipole directions are indicated. For the trimer and hexamer the view is along the disk axis; for the stacked hexamers it is perpendicular. In the stacked hexamers only the inter-hexamer transfers are indicated. The strength of coupling is indicated by the thickness of the connecting lines. Transfer paths within and between the trimers are represented by full and broken lines, respectively.

Light energy is transferred rapidly within 50 to 100 ps from the tips to the core of the PBS (for reviews, see Refs. [60, 73, 76–80]). The transfer times from the periphery to the base are several orders of magnitude faster than the intrinsic fluorescence life-times of the isolated components.[72, 76] The distances between the chromophores within and between the hexamers are too large for strong (excitonic) coupling, but efficient energy transfer by inductive resonance occurs. A Förster radius of about 50 Å has been suggested by *Grabowski* and *Gantt*.[81] The relative orientations and distances of the chromophores as obtained by *Schirmer* et al.[44] were used as basis for the calculation of the energy transfer rates in Figure 9a, which shows the preferred energy transfer pathways in $(\alpha\beta)$ units, $(\alpha\beta)_3$ trimers, $(\alpha\beta)_6$ hexamers and stacked disks as models for native antenna rods. There is very weak coupling of the chromophores in the $(\alpha\beta)$ units. However, some energy transfer takes place, probably between B155 and B84, as indicated by steady-state polarization measurements.[68, 82] Trimer formation leads to strong coupling between A84 and B84, but B155 is integrated only weakly. In the hexamer many additional transfer pathways are opened and B155 is efficiently coupled. Hexamers are obviously the functional units, as the energy can be distributed and concentrated on the central f-chromophores, which couple the stacks of hexamers. Kinetic studies[60, 68, 73, 83] have confirmed the picture of energy transfer along the rods as a random walk (trap or diffusion limited) along a one-dimensional array of f-chromophores. *Sauer* et al.[84] have successfully simulated the observed energy transfer kinetics in PC aggregates on the basis of the structures using *Förster*'s mechanism. The PEC component at the tips of PBS rods is extremely similar to PC.[64, 65] Its short wavelength absorbing chromophore A84 is located at the periphery (cf. Fig. 10a), as are the additional chromophores in PE, which is also a tip component (Fig. 9b).

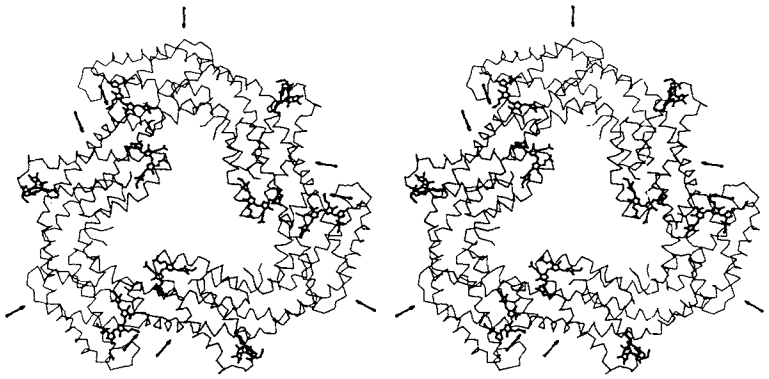

Fig. 9b. Model of the PE $(\alpha\beta)_3$ trimer of phycoerythrin (PE) on the basis of the structure of phycocyanin (PC). The locations of the additional phycoerythrobilins are indicated by arrows.

The phycobilisome rods act as light collectors and energy concentrators from the peripheral to the central chromophores, that is, as excitation energy funnels from the periphery to the center and from the tip to the bottom.

The linker polypeptides determine the functional properties of the aggregates. Some of them are believed to be located in the central channel of the hexamers, where they may interact with B84.

3.2.2. *Electron Transfer in the Reaction Center*[*]

3.2.2.1. *The Composition of the Reaction Center*[**]

The reaction center of *Rps. viridis* is a complex of the four protein subunits C, L, M, H and cofactors arranged as in Figure 10a. The proteins consist of 336, 273, 323, and 258 amino acid residues, respectively.[43, 87, 89] The c-type cytochrome contains four heme groups covalently bound via thioether linkages. The cofactors are four BChl-b (BC_{MP}, BC_{LP}, BC_{LA}, BC_{MA}), two BPh-b (BP_M, BP_L), one menaquinone-9 (Q_A), and a ferrous ion involved in electron transfer. A second quinone (ubiquinone-9 UQ, Q_B), which is a component of the functional complex, is partially lost during preparation and crystallization of the reaction center.

3.2.2.2. *Chromophore Arrangement and Electron Transfer*

The chromophores are arranged in L- and M-branches, which meet at BC_P and are related by an axis of approximate two-fold symmetry.[47] This axis is normal to the plane of the membrane.

While many of the optical properties of the pigment system are rather well understood on the basis of the spatial structure,[49] electron transfer is less well understood. The excited BC_P is quenched by electron transfer to BP_L in 3 ps and then further to the primary acceptor Q_A in about 200 ps, driven by the redox potential gradient between P^*/P^+ (about -760 mV) and Q_A/Q_A^- (about -110 mV). The redox potential of BP/BP^- is intermediate with a value of about -400 mV.[90–99] These functional data are summarized in Figure 10a. General factors controlling the transfer rates have been summarized in Table 1 and are detailed here specifically for the reaction center:

Fast electron transfer requires effective overlap of the molecular orbitals. The orbital interaction decreases exponentially with the edge-to-edge distance of donor and acceptor and is insignificant at distances larger than about 10 Å.[29, 100] In the reaction center the distance between BC_P

[*] A historical background of the development of concepts and key features of the purple bacterial reaction center is given by *Parson* [85].

[**] The arrangement of the reaction center in the thylakoid membranes of *Rps. viridis* as obtained by electron microscopy is described by *Stark* et al. [86].

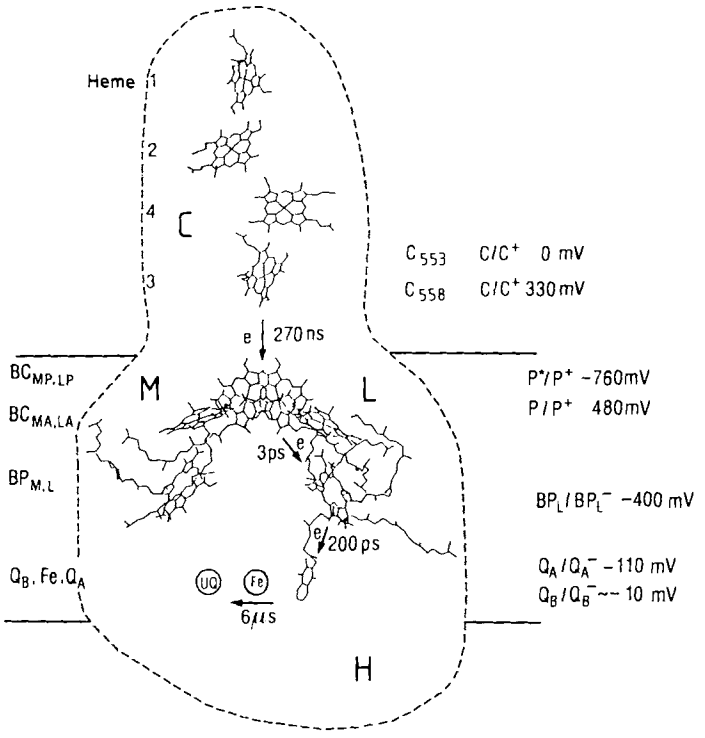

Fig. 10a. Scheme of the structure of the reaction center of *Rps. viridis* showing the cofactor system, the outline of the protein subunits (C, M, L, H), the electron transfer half-times, and the redox potentials of defined intermediates (for references see Section 3.2.2.2; for abbreviations see footnote [***] to the Introduction).

and Q_A is far too large to allow fast direct electron transfer; instead the electron migrates via BP_L. BP_L^- is a spectroscopically and kinetically well defined intermediate. Although located between BC_P and BP_L, BC_{LA}^- is not an intermediate but probably involved in electron transfer by a 'superexchange' mechanism mediating a strong quantum mechanical coupling[101] (for a review, see Ref. [102]). The distance between BP_L and Q_A seems large for a fast transfer. Indeed, in the L branch of the pigment system, this gap is bridged by the aromatic side chain of Trp M250 (Fig. 10b),[37, 88] which might mediate coupling via appropriate orbitals. In addition, the isoprenoid side chain of Q_A is close to BP_L. Electron transfer via long connecting chains by through-bond coupling of donor and acceptor orbitals has been observed[100, 103, 104] but, in the reaction center, there are only Van der Waals contacts.

A second important factor for electron transfer is the free energy change (ΔG), which is governed by the chemical nature of the components, by geometrical factors, and by the environment (solvent polarity). It depends on the ionization potential of the donor in its excited state, on the electron affinity of the acceptor, and on the coulombic interaction of the radical ion pair, which is probably small, as donor and acceptor (BC_P and Q_A in the RC) are far apart. The influence of the environment may be substantial in the stabilization of the radical ion pair by ionic interactions and hydrogen bonds. ΔG is *one* important factor of the activation energy of electron transfer. Also important is the nuclear rearrangement of the reactants and the environment. As the charge on donor and acceptor develops, the nuclear configurations change. These changes are likely to be small in the RC, as the BChl-b macrocycles are relatively rigid and are tightly packed in the protein, and the charge is distributed over the extended aromatic electron system. Reorientable dipolar groups (peptide groups and side chains) may contribute considerably to the energy barrier of the electron transfer. On the other hand, a matrix with high electronic polarizability stabilizes the developing charge in the transition state of the reaction and reduces the activation energy. An alternative picture is that the potential energy barrier to electron tunneling is decreased. Aromatic compounds which are concentrated in the vicinity of the electron carriers in the RC have these characteristics (see Trp M250).

The electron transfer from P* to Q_A occurs with very low activation energy[91, 94, 96, 105–108] and proceeds readily, even at 1 K. Thermally activated processes, nuclear motions, and collisions are therefore not important for the first very fast charge separation steps. There is even a slight increase in rate with decrease in temperature, due either to a closer approach of the pigments at low temperature or to changes of the vibrational levels, which may lead to a more favorable Franck-Condon factor.

The electron transfer between primary and secondary quinone acceptors, Q_A and Q_B, is rather different from the previous processes, because it is much slower (about 6 μs at pH 7 according to *Carithers* and *Parson*[91]) and has a sub-

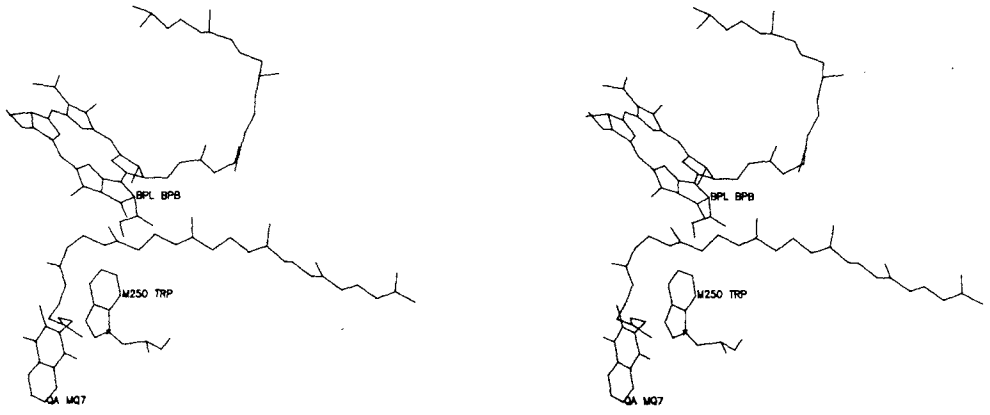

Fig. 10b. Stereodrawing of the arrangement of BP_L, Trp M250 and Q_A in the L-branch of the pigment system of the reaction center.

stantial activation energy of about 8 kcal mol^{-1}. In *Rps. viridis*, Q_A is a menaquinone-9 and Q_B a ubiquinone-9, which differ in their redox potentials in solution by about 100 mV. In other purple bacteria, both Q_A and Q_B are ubiquinones. The redox potential difference required for efficient electron transfer in these cases is generated by the asymmetric protein matrix. The protein matrix is also responsible for the quite different functional properties of Q_A and Q_B. Q_A accepts only one electron (leading to a semiquinone anion), which is transferred to Q_B before the next electron transfer can occur. Q_B, however, accepts two electrons and is protonated to form a hydroquinone, which diffuses from the reaction center (two-electron gate[109]). Q_B is close to Glu L212, which opens a path to the H-subunit and may protonate Q_B. The electron transfer between Q_A and Q_B takes place in an environment which differs considerably from the environment of the primary electron transfer components. The line connecting Q_A and Q_B (the Q_B binding site has been inferred from the binding mode of competitive inhibitors and ubiquinone-1 in *Rps. viridis* crystals[37]) is occupied by the iron and its five coordinating ligands—four histidine residues (M217, M264, L190, L230) and a glutamic acid (M232) residue. His M217 forms a hydrogen bond to Q_A. His L190 is close to Q_B. Q_A and Q_B are separated by an edge-to-edge distance of about 15 Å, which might explain the slow transfer. If electron transfer and protonation are coupled, the observed pH dependence of the electron transfer rate from Q_A to Q_B[110] could be explained, and conformational changes required for proton transfer may generate the observed activation energy barrier. The role of the charged Fe-His_4-Glu complex in the Q_A to Q_B electron transfer is poorly understood at present, as it occurs also in the absence of the iron;[111] its role seems to be predominantly structural.

The cycle of electron transfer is closed by the rereduction of BC_P^* by cytochrome c (subunit C of the reaction center), whereby a distance of about 11 Å between the pyrrole ring I of heme 3 and the pyrrole ring III of BC_{LP} has to be bridged. The transfer time is 270 ns[95] (cf. Ref. [147]); the transfer is considerably slower than the first electron transfer steps. Tyr L162, which is located midway (Fig. 10c), may facilitate electron transfer by mediating electronic coupling between the widely spaced donor and acceptor. The biphasic temperature dependence indicates a complex mechanism in which nuclear motions play a role at high temperatures (for reviews, see Refs. [112, 113]).

The favorable rate controlling factors that have been discussed are a necessary but not sufficient condition for the electron transfer, which competes with other quenching processes summarized in Table 2 and now described in detail for the reaction center:

The transfer of energy from P* back to the light harvesting complex or to other pigments may be favored by orientation and proximity but is disfavored energetically. The special pair BC_P usually absorbs (but not in *Rps. viridis* where the absorption maxima of the RC and the LHC are at 960 and 1020 nm respectively, see Fig. 7) at longer wavelengths than other pigments of the photosynthetic apparatus and thus represents the light energy sink. The natural radiative lifetime of the excited singlet state P* is around 20 ns[107, 114] and may serve as an estimate of the times involved in the other wasteful quenching processes. Clearly, electron transfer is much faster. Non-radiative relaxation of BC_P^* by isomerizations and conformational changes is unlikely, since the cyclic pigment systems are tightly packed in the protein matrix.

The back reaction $P^+Q_A^-$ to PQ_A has a favorable driving force (Fig. 10a) and is temperature independent, but is slow and insignificant under physiological conditions (for a review, see Ref. [94]). The physical basis for this has yet to be explained. It may be related to a gating function of BP_L by its negative redox potential compared to Q_A, to electronic properties of P^+ disfavoring charge transfer, and to conformational changes induced by electron transfer.

The profound influence of the protein matrix on electron transfer in the reaction center manifests itself in the observed asymmetry of electron transfer in the bacteriochlorophyll-b (BC) and bacteriopheophytin (BP) pigments, depending upon whether they belong to the L or the M branch. Only the

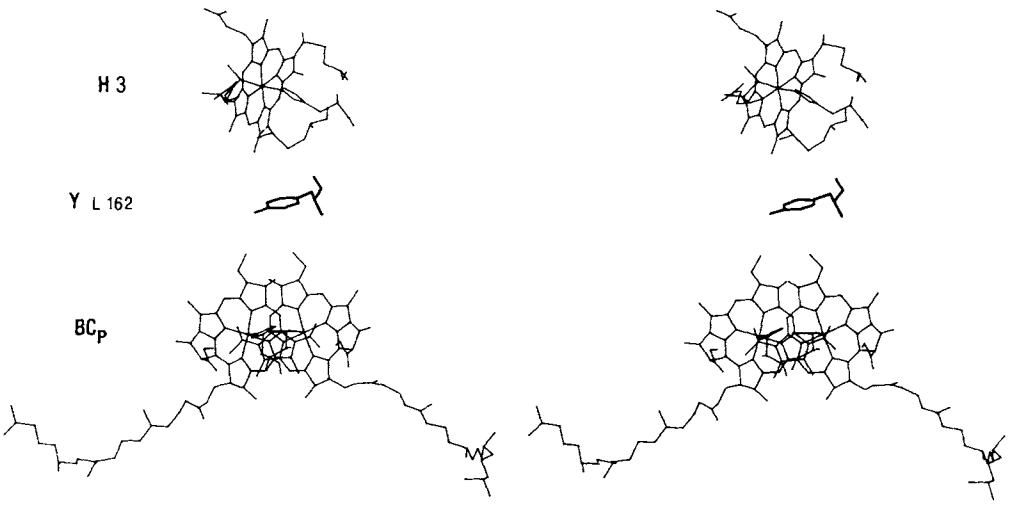

Fig. 10c. Stereodrawing of heme 3 (H3) of the cytochrome c, the special pair BC_P and the intercalating Tyr L162 (Y L162) of the L-subunit [37]. The His and Met ligands to the iron of H3 and the His ligands to the magnesium ions of the BC_P are also shown.

branch more closely associated with the L-subunit is active. An explanation is offered perhaps by the finding that the protein environment of the two branches, although formed by homologous proteins (L and M), is quite different, in particular by virtue of the Trp M250 located between BP_L and Q_A and the numerous differences in the Q_A and Q_B binding sites.[37, 88] Asymmetry is observed in the BC_P due to different distortions and hydrogen bonding of the macrocycles and in the slightly different spatial arrangements of the BC_A and BP. It has been suggested that electron release into the L-branch is thereby facilitated.[115] The M-branch may, however, have influence as a pendant group.

The protein matrix also serves to dissipate the excess energy of about 650 mV[92] of the excited special pair ($P^* Q_A$) compared to the radical ion pair $P^+ Q_A^-$. These processes are probably very fast.

In summary, the very fast electron transfer from BC_P^* to Q_A occurs between closely spaced aromatic macrocycles with matched redox potentials. The protein matrix in which the pigments are tightly held is lined predominantly with apolar amino acid side chains with a high proportion of aromatic residues. The path taken by the electrons is far removed from the water phase.

3.2.3. *The Blue Oxidases*

Oxidases catalyze the reduction of dioxygen by single electron transfers from substrates. Dioxygen requires four electrons and four protons to be reduced to two water molecules. Oxidases must provide recognition sites for the two substrates, a storage site for electrons and/or the means to stabilize reactive partially reduced oxygen intermediates.[116–118]

The 'blue' oxidases are classified according to the distinct spectroscopic properties of the three types of copper which they contain: Type-1 Cu^{2+} is responsible for the deep blue color of these proteins; type-2 or normal Cu^{2+} has no recognizable optical absorption; type-1 and type-2 cupric ions are paramagnetic; type-3 copper has a strong absorption around 330 nm and is antiferromagnetic, indicating coupling of the spin of a pair of cupric ions. The characteristic optical and electron paramagnetic resonance spectra disappear upon reduction.

Studies of the catalytic and redox properties of the 'blue' oxidases have been well documented in several recent reviews (e.g. for laccase,[119] for ascorbate oxidase,[120] for ceruloplasmin[121]). Basically, type-1 Cu^{2+} is reduced by electron transfer from the substrate. The electron is transferred further to the type-3 and type-2 copper ions. The second substrate, dioxygen, is associated with the type-3 and/or type-2 copper ions.

3.2.3.1. *Ascorbate Oxidase, Composition and Copper Arrangement*

Ascorbate oxidase is a polypeptide of 553 amino acid residues folded into three tightly associated domains.[50] It is a dimer in solution; the functional unit, however, is the monomer. Ascorbate oxidase belongs, together with laccase and ceruloplasmin, to the group of 'blue' oxidases.[122]

Structures of copper proteins containing only one of the different types of copper are known: Plastocyanin has a 'blue' type-1 copper, which is coordinated to two histidine residues and the sulfur atoms of cysteine and methionine in a distorted tetrahedral geometry.[123] Cu–Zn-superoxide dismutase contains a type-2 copper, which has four histidine ligands with slightly distorted square coordination.[124] Hemocyanin of *Panulirus interruptus* contains as type-3 copper, a pair of copper ions 3.4 Å apart with six histidine ligands.[125]

In domain 3 of ascorbate oxidase (see Section 4.4) a copper ion is found in a strongly distorted tetrahedral (approaching trigonal pyramidal geometry) coordination with the ligands His, Cys, His, Met as has already been shown in Figure 6. It resembles the blue type-1 copper in plastocyanin. A trinuclear copper site is enclosed between domains 1 and 3 of ascorbate oxidase (Fig. 11a). Four (–His–X–His–) amino acid sequences provide the eight histidine ligands. The trinuclear copper site contains a pair of coppers (Cu 31, Cu 32), each with three histidyl (A108, A451, A507; A64, A106, A509) ligands, forming a trigonal prism. It is the type-3 copper pair; a comparable arrangement is observed in

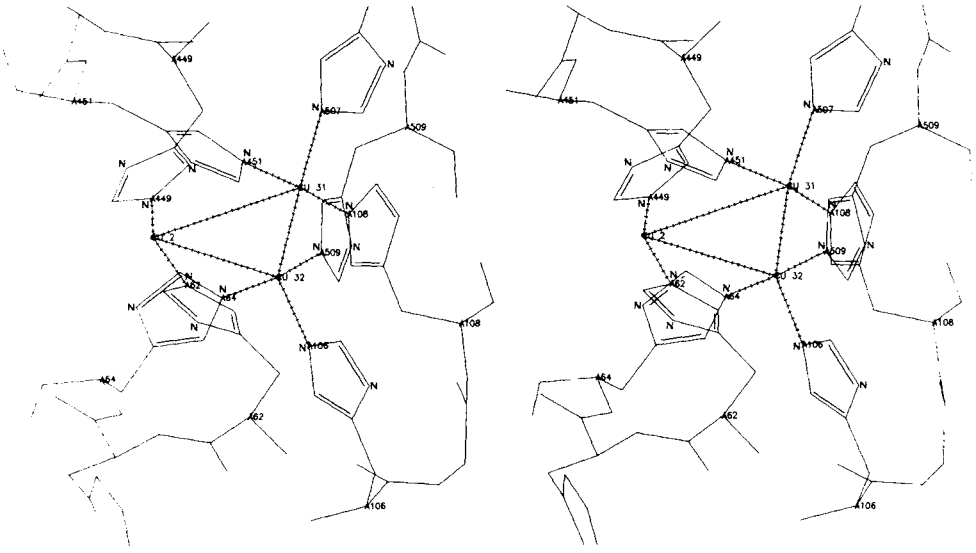

Fig. 11a. Stereodrawing of the trinuclear copper site in ascorbate oxidase. Coordination bonds between the copper ions and the protein residues are marked (dotted lines) [50].

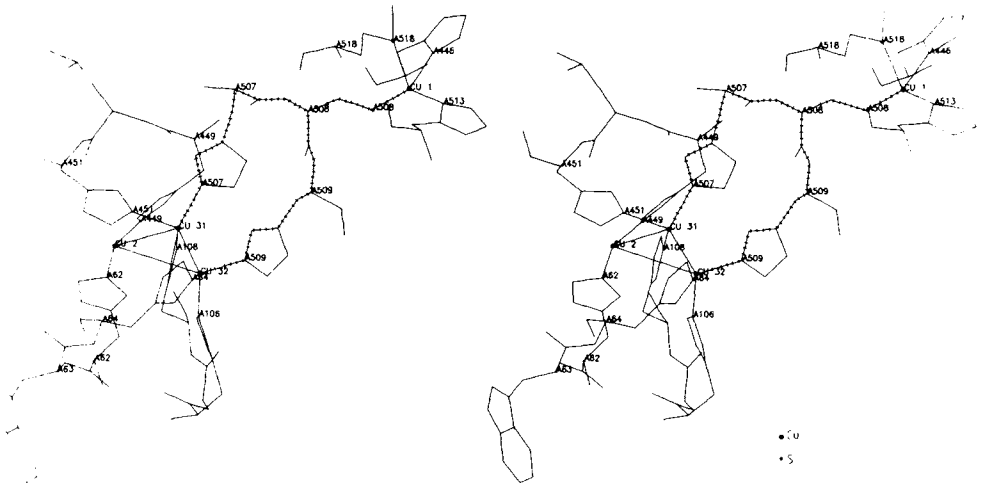

Fig. 11 b. Stereodrawing of the tridentate peptide ligand (–His 507–Cys 508–His 509–) in ascorbate oxidase bridging type-1 copper (Cu 1) and the trinuclear cluster (Cu 31, Cu 32, Cu 2) [50].

hemocyanin. The remaining copper (Cu 2) has two histidyl ligands (A62, A449) and is type-2 copper. The trinuclear copper cluster is the site where dioxygen binds; details of the structure including the presence of exogenic ligands still require clarification. The close spatial association of the three copper ions in the cluster suggests facile electron exchange. The cluster serves as electron storage site and may function as cooperative three-electron donor for the oxygen molecule, to irreversibly cleave the O–O bond.

3.2.3.2. Intramolecular Electron Transfer in Ascorbate Oxidase

Electrons are transferred from the type-1 copper to the trinuclear site. The shortest pathway is via Cys-A508 and His-A507 or His-A509. The (His–X–His–) segment links electron donor and acceptor and thus bridges a distance of 12 Å (Fig. 11 b). The cysteine sulfur and the imidazole components of the bridging ligand have low lying unoccupied molecular orbitals and may favor a chemical mechanism of electron transfer, but the intervening aliphatic and peptide chains are unlikely to form transient radicals and may well participate by resonance. The optical absorption of the 'blue' copper assigned to a cysteine $S^- \rightarrow Cu^{2+}$ charge transfer transition supports the suggested electron pathway.

The putative electron path branches at the C^α atom of Cys A508. Model compounds have shown inequivalence and faster transfer in the N–C direction of amide linking groups.[131] This may apply also to the blue oxidases and cause preferred transfer to A507.

The difference in redox potential between the type-1 copper and the type-3 copper is –40 mV in ascorbate oxidase. Unfortunately, there are no direct measurements of the intramolecular electron transfer rates available. The turnover number serves as a lower limit and is $7.5 \times 10^3\ s^{-1}$ in ascorbate oxidase,[126, 127] indicating a fairly rapid transfer despite the long distance and small driving force. The electron pathway is intramolecular and far removed from bulk water.

The characteristic distribution of the redox centers as mono- and trinuclear sites in the blue oxidases may also be found in the most complex oxidase, cytochrome oxidase (see the hypothetical model of *Holm* et al.[128]) and in the water-splitting manganese protein complex of the photosystem II, which carries out the reverse reaction of the oxidases. For its $(Mn)_4$ cofactor, either two binuclear or a tetranuclear metal center is favored,[129] but mono- and trinuclear arrangements cannot be excluded.

3.3. The Protein as Medium

The boundary between protein as ligand and as medium is fluid. The extreme microscopic complexity of structure, polarity and polarizability of protein media may influence the energy and electron transfer. There are no obvious common structural features in the protein systems discussed except a high proportion of aromatic residues (particularly tryptophans) bordering the electron transfer paths in the reaction center of purple bacteria and in ascorbate oxidase and their wide separation from bulk water by internal location within the protein and the hydrocarbon bilayer (in the reaction center). These effects have been mentioned in Sections 1.3 and 3.2.2.2.

4. Structural Relationships and Internal Repeats

All four protein systems mentioned in the following show internal repetition of structural motifs or similarities to other proteins of known folding patterns. This is a quite common phenomenon and not confined to energy and electron transfer proteins. It is also not uncommon that these relationships often remained undetected on account of the amino acid sequences; in effect this reflects our ignorance of the sequence structure relationships. An analysis of the structural relationships will shed light on the evolution and function of protein systems and is thus appropriate here.

4.1. Retinol and Bilin Binding Proteins

The simplest case is shown in Figure 12, where bilin-binding protein (BBP)[142] is compared with retinol-binding

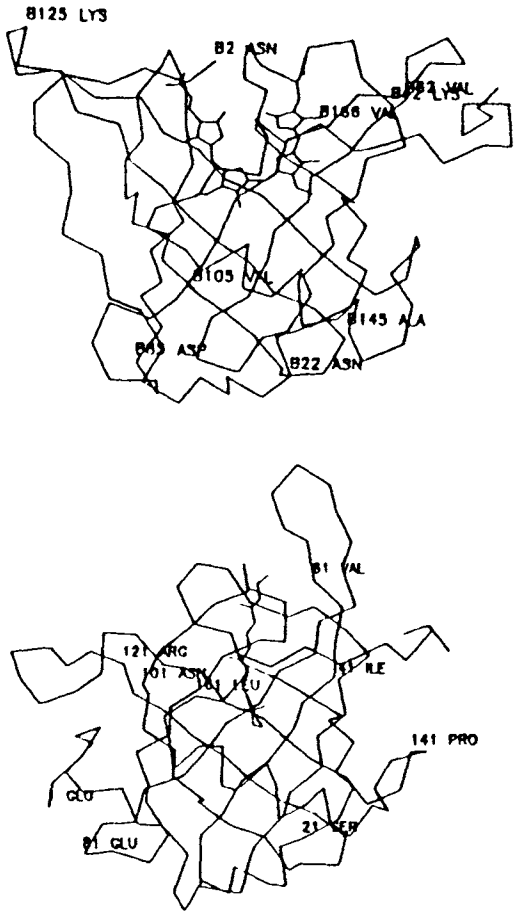

Fig. 12. Comparison of the polypeptide chain folds of bilin-binding protein (BBP) and retinol-binding protein (RBP) with bound cofactors.

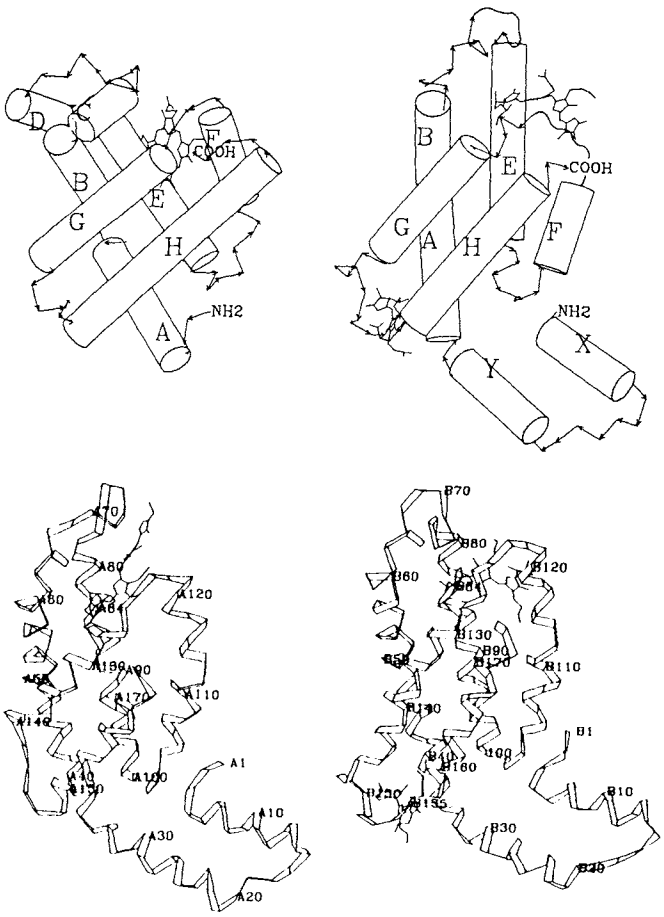

Fig. 13. Polypeptide chain folds of the α- and β-subunits of phycocyanin [44] (lower part, left and right) and comparison of the arrangements of α-helices in myoglobin and phycocyanin (upper part, left and right).

protein (RBP).[130] For the bottom of the β-barrel structure, the structural similarity is obvious, while the upper part, which is involved in the binding of the pigments biliverdin and retinol, differs considerably. The molecule is apparently subdivided into framework and hypervariable segments which determine binding specificity in analogy to the immunoglobulins.[131] This relationship suggests carrier functions for BBP as for RBP, although RBP also serves for pigmentation in butterflies.

4.2. Phycocyanin

In the protein part, phycocyanin (PC) consists of two polypeptide chains α and β which are clearly related in structure (Fig. 13, bottom), and probably originate from a common precursor.

The α-subunit is shorter in the G–H turn and lacks the s-chromophore B155 (see Section 3.2.1.3.). The loss or acquisition of chromophores during evolution may be less important than differentiation of the α and β subunits, which occupy non-equivalent positions in the $(\alpha\beta)_3$ trimer, so that the homologous chromophores A84 and B84 are non-equivalent with B84 lying on the inner wall of the disk. In addition the α and β subunits play very different roles in the formation of the $(\alpha\beta)_6$ hexamer, as has already been shown in Figure 8. Symmetrical precursor hexamers might have existed and could have formed stacks, but would lack the differentiation of the chromophores, in particular the inequivalence and close interaction of A84 and B84 in the trimer. Functional improvement has probably promoted divergent evolution of the α- and β-subunits.

A most surprising similarity was discovered between the PC subunits and the globins shown in Figure 13 (top). The globular helical assemblies A to H show similar topology. The U-shaped extension of phycocyanin formed from the *N*-terminal X,Y α-helices is essential for the formation of the αβ substructure. Comparison of the amino acid sequence after structural superposition reveals some homologies, suggesting divergent evolution of phycobiliproteins and globins;[44] however, what function a precursor of light harvesting and oxygen binding proteins might have had remains a mystery.

4.3. Reaction Center

The reaction center of *Rps. viridis* lacks symmetry across the membrane plane. This is not surprising for a complex which catalyzes a vectorial process across the membrane. However, there is quasi-symmetry relating the L- and M subunits and the pigment system. The structural similarity and the homology of the amino acid sequences of the L- and M-subunits suggest a common evolutionary origin. This relationship is extended to the photosystem II components D1 and D2 on the basis of sequence homology and conservation of residues involved in cofactor binding (for reviews, see

Refs. [132, 133]). The putative precursor was a symmetrical dimer with identical electron transfer pathways. The interaction with the H subunit introduces asymmetry, particularly noteworthy at the *N*-terminal transmembrane α-helix of the H-subunit (H), which is close to the E transmembrane α-helix of the M-subunit, the L-branch of the pigment system, and Q_A (Fig. 14). The improvement of the interaction with the H-subunit, which appears to play a role in the electron transfer from Q_A to Q_B and in protonation of Q_B might have advanced divergent evolution of the L- and M subunits at the expense of the inactivation of the M pigment branch. However, the electron transfer from BC_P to Q_A is extremely fast and not rate-limiting for the overall reaction. The evolutionary conservation of the M branch of pigments may be of functional significance as a pendant group in light harvesting and electron transfer. There are also structural reasons, for its deletion would leave a void.

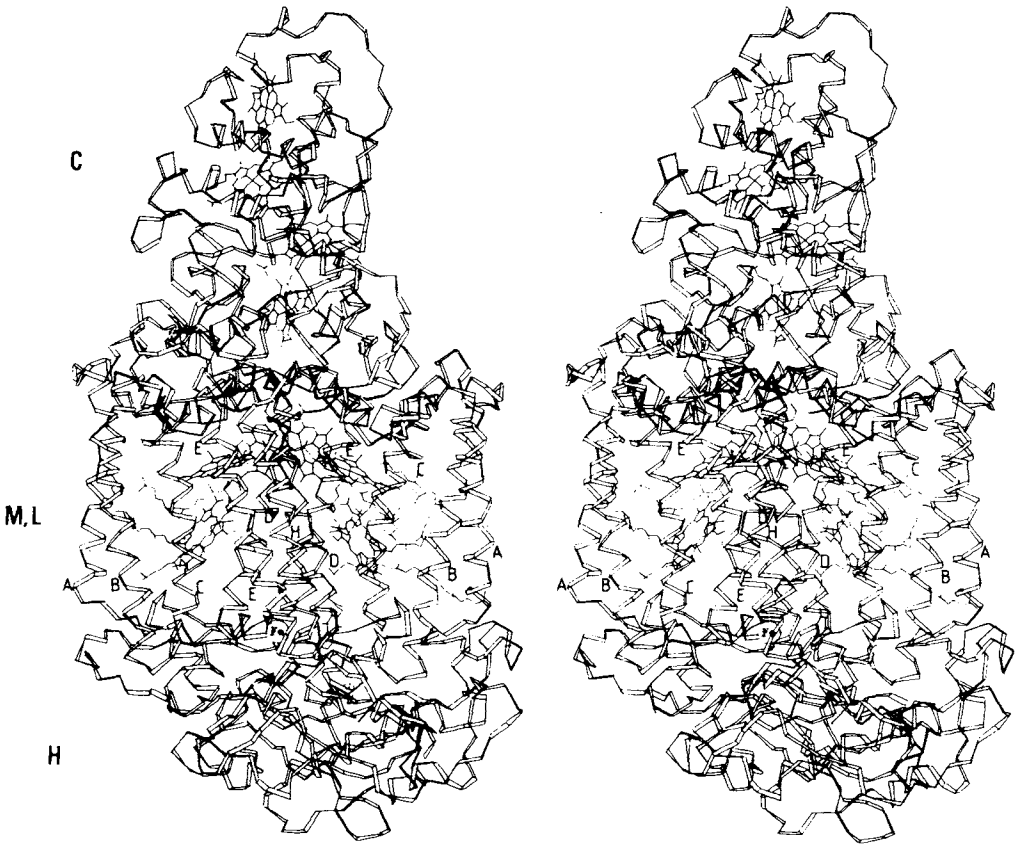

Fig. 14. Stereodrawing of the reaction center of *Rps. viridis* (complete complex of subunits and cofactors). The membrane-spanning α-helices of the L- and M-subunits (A, B, C, D, E in sequential and A, B. C, E, D in spatial order) and the H-subunit (H) are labeled [37] (cf. Fig. 10 a).

The cytochrome subunit (C) contributes to the asymmetry of the L–M complex and shows, in itself, an internal duplication.[37] All four heme groups are associated with a helix-turn-helix motif, but the turns are short for heme groups 1 and 3 and long for heme groups 2 and 4.

4.4. Blue Oxidases

Gene multiplication and divergent evolution is most evident in the blue oxidase, ascorbate oxidase. Figure 15 shows the polypeptide chain of 553 amino acid residues folded into three closely associated domains of similar topology.[50] Although nearly twice as large, they resemble the simple, small copper protein plastocyanin (Fig. 16).[123] In the blue oxidase the domains I and III enclose the trinuclear copper cluster in a quasi-symmetrical fashion, but only domain III contains the type 1 copper, the electron donor to the trinuclear site. A potential electron transfer pathway in domain I is not realized, reminiscent of the M-branch of pigments in the reaction center (cf. Section 3.2.2.2). Similarly to the H subunit in the reaction center, the linking domain II introduces asymmetry in the ascorbate oxidase, which might have promoted evolutionary divergence of domains I and III.

The proteins plastocyanin, ascorbate oxidase, laccase, and ceruloplasmin are members of a family of copper proteins, as indicated by structural relations and sequence homology.[50, 135–137] They provide a record from which an evolutionary tree may be mapped out (Fig. 17). The simplest molecule is plastocyanin containing only a type-1 copper. A dimer of plastocyanin-like molecules could provide the two times four histidyl ligands for the trinuclear copper cluster, representing a symmetrical oxidase. From this hypothetical precursor the modern blue oxidases and ceruloplasmin might have evolved following different paths of gene (domain) insertion and loss or acquisition of copper. In both, the arrangement of the *N*- and *C*-terminal domains, which

Fig. 15. Stereodrawing of the polypeptide chain folds of ascorbate oxidase and exploded view of its three domains from top to bottom [50]. β-strands are indicated as arrows and α-helices as cylinders (produced by the plot program of *Lesk* and *Hardman* [134]).

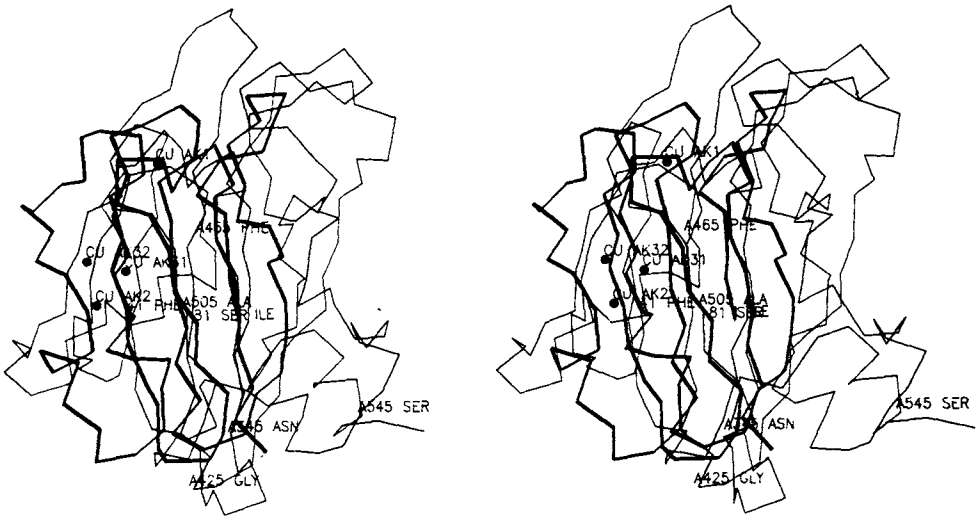

Fig. 16. Stereodrawing and superposition of domain III of ascorbate oxidase (thin lines) and plastocyanin (thick lines). The trinuclear copper site in ascorbate oxidase is buried between domain I (not shown) and domain III.

contain the functional copper cluster, has been preserved. Recombinant DNA technology provides the possibility of reconstructing the hypothetical precursor oxidase. This is under investigation.

5. Implications from the Structure of the Reaction Center for Membrane Proteins in General

The structures of water soluble proteins show a seemingly unlimited diversity, despite their being built from only a few well defined secondary structural elements such as helices, β-sheets and turns and despite their construction from domains and recurring structural motifs. The proteins under discussion provide ample evidence of this. That there seems to be a limited set of basic folds may be related to the evolution of proteins from a basis set of structures and/or to constraints by protein stability and rates of folding. These basic folding motifs do not represent rigid building blocks, however, but adapt to sequence changes and respond to the environment and to association with other structural elements. Adaptability and plasticity (which is not to be confused with flexibility) is related to the fact that the entire protein and solvent system, and not its individual components, must attain the global energy minimum. Water is a good hydrogen bond donor and acceptor and is thus able to saturate polar peptide groups exposed on the surface almost as well as intraprotein hydrogen bonds do (entropic effects excluded).

Membrane proteins face the inert hydrocarbon part of the phospholipid bilayer and must saturate their hydrogen bonds intramolecularly. Only two secondary structures fulfill this condition for the polypeptide main chains, namely the α-helix and the β-barrel. For the assembly of α-helices packing rules have been derived which predict certain preferred angles between the helix axes albeit with a broad scatter. Similarly, the arrangement of strands in β-sheets and β-barrels follows defined rules.[138]

5.1. Structure of the Membrane Associated Parts of the Reaction Center

The reaction center was the first membrane protein whose structure could be determined at atomic resolution. Only the low resolution structure of bacteriorhodopsin was known previously. Both structures have some common features.[139] The structure of the reaction center may permit some conclusions to be drawn about membrane proteins in general. The reaction center contains 11 transmembrane α-helices, which, with 26 residues (H-subunit) or 24–30 residues (L- and M-subunits), have appropriate lengths to span the membrane. The amino acid sequences of these segments are devoid of charged residues (Fig. 18). Few charged residues occur close to the ends of the α-helices. Glycine residues initiate and terminate almost all α-helical segments, both the transmembrane and the connecting α-helices. It is well known from soluble proteins that glycine residues are abundant in turns and often associated with flexible regions of proteins.[12] They may be important for the insertion into the membrane by enabling structural rearrangements. The angles between the axes of the contacting α-helices of the L- and M-complex are 20° to 30°, a packing angle range also preferred by α-he-

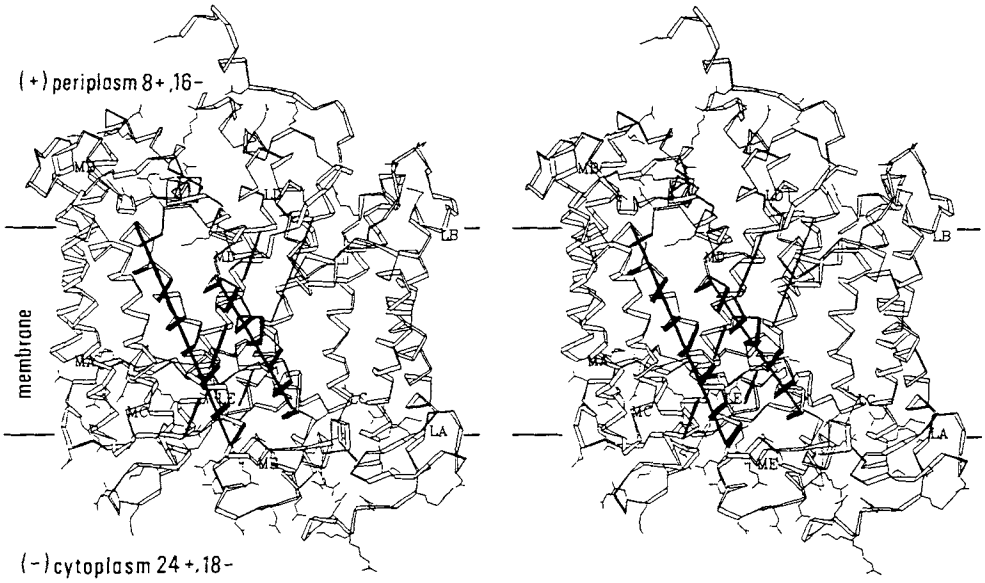

Fig. 18. Stereodrawing of the polypeptide chains of the L- and M-subunits of the reaction center in ribbon representation. The *N*-terminal residues of the membrane-spanning α-helices are labeled (including the prefix M and L) and the tetrahelical motif of the D and E α-helices is marked by shading and lines. The side chains of charged residues are drawn. Asp, Glu, and carboxy-termini are counted as negatively charged, and Lys, Arg and amino-termini are counted as positively charged and added for the cytoplasmic and periplasmic sides [5, 37].

lices in soluble proteins. They have features in common with buried α-helices in large globular proteins, which are also characterized by the absence of charged residues and the preferred location of glycines and prolines at the termini.[140, 141] Furthermore, the D- and E-α-helices of the L- and M-subunits (Fig. 18) find counterparts in soluble proteins. They are associated around the local diad axis and form the center of the L–M module, which binds the iron and the bacteriochlorophyll pair BC_P.

The four D- and E-α-helices of the L- and M-subunits are arranged as a bundle, held together by the iron ion and splayed out towards the cytoplasmic side to accommodate the large special pair. This motif is quite common in water-soluble electron transfer proteins.[142] I will resume this discussion later and suggest appropriate substructures of soluble proteins as models for pore forming membrane proteins.

5.2. Membrane Insertion

The structure of the reaction center is also important regarding our views of the mechanism of integration of membrane proteins into the phospholipid bilayer. The reaction center is composed of components which are quite differently arranged with respect to the membrane: The C-subunit is located on the periplasmic side. The H-subunit is folded into two parts: a globular part located on the cytoplasmic side and a transmembrane α-helix. The L- and M-subunits are incorporated into the phospholipid bilayer. Consequently, cytochrome (the C-subunit) has to be completely translocated across the membrane from its intracellular site of synthesis. In the H-, L-, and M-subunits the transmembrane α-helices are embedded in the bilayer. Only the *N*-terminal segment of H and the *C*-termini and connecting segments of the α-helices located at the periplasmic side of L and M (A–B, C–D) require transfer.

It is interesting to note that only the cytochrome gene possesses a prokaryotic signal sequence, as indicated by the sequence of the gene.[89] Transfer of the large hydrophilic C-subunit may require a complex translocation system and a signal sequence, while H, L, and M may spontaneously insert into the bilayer due to the affinity of the contiguous hydrophobic segments for the phospholipids (for a review of this and related problems see Ref. [143]). A "simple" dissolution still requires transfer across the membrane of those charged residues which are located at the periplasmic side.[37, 88] The increasingly favorable protein lipid interaction which develops with insertion may assist in this process. M and L have considerably more charged residues at the cytoplasmic side (41) than at the periplasmic side (24), providing a lower activation energy barrier for correct insertion. The net charge distribution of the L–M complex is asymmetric, with six positive charges at the cytoplasmic side and eight negative charges at the periplasmic side. As the intracellular membrane potential is negative, the observed orientation of the LM complex is energetically favored (Fig. 18).

The H-subunit has a very polar amino acid sequence at the *C*-terminus of the transmembrane α-helix with a stretch of seven consecutive charged residues (H33–H39)[37, 87] which may efficiently stop membrane insertion. Similarly, there are three to eleven charged residues in each of the connecting segments of the α-helices at the cytoplasmic side of the L- and M-subunits which might stop the transfer of α-helices or α-helical pairs.[144] As an alternative to sequential insertion the L- and M-subunits may be inserted into the membrane as assembled protein pigment complexes, because they cohere tightly by protein–protein and protein–cofactor interactions.

5.3. Models of Pore Forming Proteins

It is not absolutely clear whether the structural principles observed in the reaction center apply also to 'pore' or 'channel' forming α-helical proteins. These could, in principle, elaborate quite complex structures within the aqueous chan-

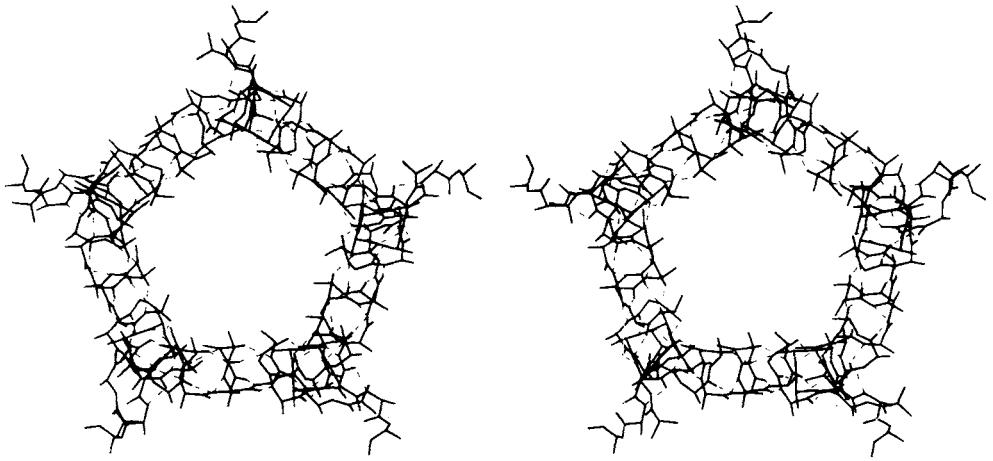

Fig. 19. Stereodrawing of the pentahelical pore in heavy riboflavin synthase [148].

nel,[145] but available evidence at low resolution for gap junction proteins[146] indicates in this specific case a simple hexameric arrangement of membrane-spanning amphiphilic α-helices, whose polar sides face the aqueous channel.

Guided by the observation that rules for structure and packing of α-helices derived for soluble proteins apply also to the reaction center, we may derive models for membrane pore forming proteins from appropriate soluble protein substructures. The penta-helical pore seen at high resolution in the icosahedral multi-enzyme complex riboflavin synthase seems to be a suitable model[148] (Fig. 19). Five amphiphilic α-helices of 23 residues each are nearly perpendicular to the capsid surface. The coiled coil of α-helices has a right-handed twist and forms a pore for the putative import of substrates and export of products. They pack with their apolar sides against the central four-stranded β-sheet of the protein, which mimics the hydrocarbon part of a phospholipid bilayer, and project charged residues into the aqueous channel.

Similar modeling of membrane protein structures may be extended to another class of membrane proteins which have β-structures spanning the outer membrane, the bacterial porins.[149] The β-barrels observed in soluble proteins have four to eight or more strands. The lower limit is determined by the distortion of the regular hydrogen bonds. An upper limit may be given by the possible sizes of stable protein domains. A four-stranded β-barrel with 4 parallel strands duplicated head-to-head with symmetry D_4 is observed in the ovomucoid octamer.[150] The β-strands lean against the hydrophobic core of the molecule and project their (short) polar residues into the channel (which is extremely narrow here).

6. Some Thoughts on the Future of Protein Crystallography

Thirty years after the elucidation of the first protein crystal structures by *Perutz* and *Kendrew* and after steady development, protein crystallography is undergoing a revolution. Recent technical and methodical developments enable us to analyze large functional protein complexes like the reaction center,[37,151] large virus structures (to mention only Refs. [152–154]), protein DNA complexes (to mention only Ref. [155]), and multienzyme complexes like riboflavin synthase.[148]

The significance of these studies for understanding biological functions is obvious and has excited the interest of the scientific community in general.

In addition, it was recognized that detailed structural information is a prerequisite for the rational design of drugs and proteins. As an illustration I chose human leucocyte elastase, which is an important pathogenic agent. On the basis of its three-dimensional structure (Fig. 20)[156] and the criteria of optimal stereochemical fit, potent inhibitors are

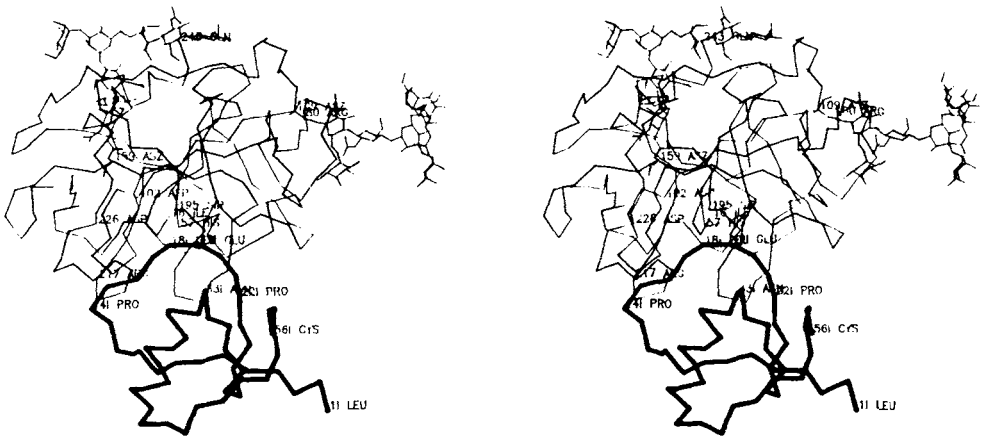

Fig. 20. Stereodrawing of the complex between human leucocyte elastase (thin lines) and turkey ovomucoid inhibitor (thick lines) [156].

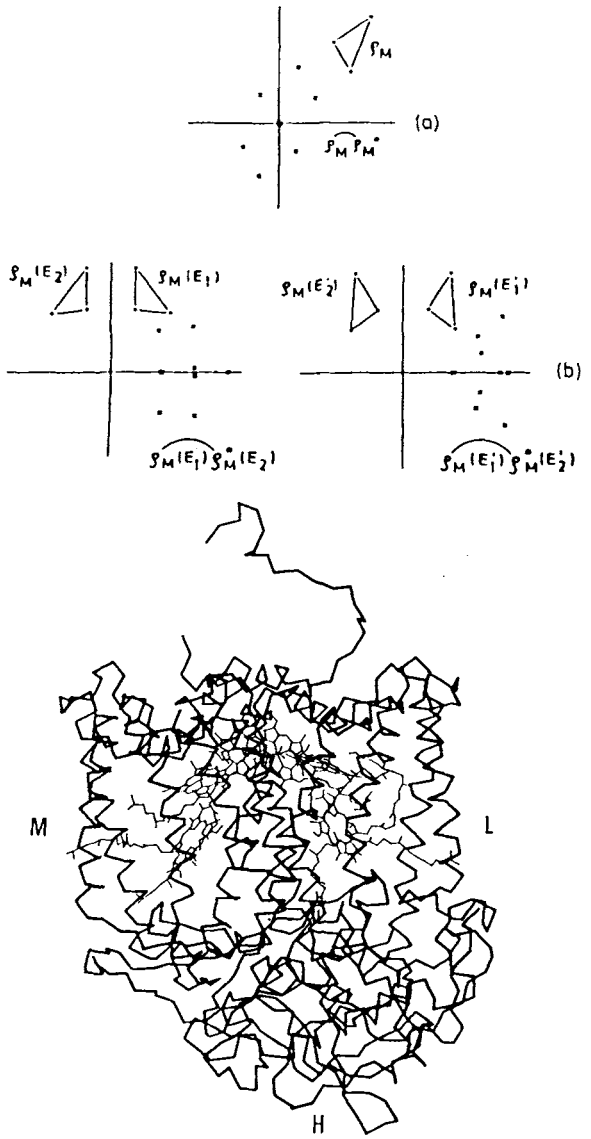

Fig. 21. Faltmolekül construction. Upper part: $\varrho_M\varrho_M^*$ (a) and $\varrho_M(E1)\varrho_M^*(E2)$ (b) are the intra- and intermolecular vector sets of a triangular structure ϱ_M, respectively. Their sum represents the Patterson function. The intramolecular vector set can be constructed from the molecular structure, is located at the origin, and permits the determination of the orientation. From the intermolecular vector set the translation component relative to the mirror plane can be derived. In (b) the intermolecular vector sets corresponding to two different orientations of ϱ_M are shown [164]. Lower part: Drawing of the main chain of the M-, L-, H-subunits and the cofactors which served as search model to solve the phase problem for the crystal structure of the reaction center of *Rb. sphaeroides*. For the calculation all homologous main chain and side chain atoms were included [6].

now being synthesized or natural inhibitors modified by use of recombinant DNA technology in many scientific and commercial institutions. Other, equally important proteins are also being studied. This field especially benefits from the readily available molecular modeling software (e.g. FRODO[157]) and a standard depository of structural data, the Protein Data Bank.[158]

Success *and* the new technical and methodical developments spur protein crystallography's progress. These new developments are indeed remarkable: Area detectors for automatic recording of diffraction intensities have been designed. Brilliant X-ray sources (synchrotrons) are available for very fast measurements and now permit use of very small crystals or radiation-sensitive materials. Their polychromatic radiation is used to obtain diffraction data sets within milliseconds by Laue techniques,[159] and their tunability allows the optimal use of anomalous dispersion effects.[160, 161]

Refinement methods including crystallographic and conformational energy terms provide improved protein models. Methods which allow the analysis of large protein complexes with internal symmetry averaging procedures have been developed[162] leading from blurred to remarkably clear pictures. A priori information of a relationship to known proteins can be used to great advantage as it is possible to solve an unknown crystal structure using a known model of a variant structure by a method discovered and named the 'Faltmolekül' method by my teacher, *W. Hoppe*. It has become a very powerful tool in protein crystallography.

With this last paragraph I wish to pay tribute to *W. Hoppe* who in 1957 laid the foundation to Patterson search methods by discovering that the Patterson function (the Fourier transform of the diffraction intensities) of molecular crystals can be split into sums of intra- and intermolecular vector sets[163] from which orientation and translation of the molecules can be derived when their approximate structure is known (Fig. 21). *Hoppe*'s method has been elaborated, computerized, and reformulated.[8, 165, 166] It provided a shortcut to the crystal structure of the reaction center of *Rb. sphaeroides* which was solved on the basis of the molecular structure of the reaction center of *Rps. viridis* and subsequently refined.[6, 151] The molecular architectures are very similar, although the *Rb. sphaeroides* reaction center lacks the permanently bound cytochrome. The structure solution was independently confirmed using similar methods.[7] With the Faltmolekül method the orientation and location of a molecule in a crystal cell can be determined. The detailed molecular structure and its deviations from the parent model have to be worked out by crystallographic refinement, to which *W. Steigemann* and *J. Deisenhofer* (in his thesis work) laid a foundation in my laboratory.[167, 168]

Recently, NMR techniques have demonstrated their efficiency in the determination of three-dimensional structures of small proteins in solution. In one case a detailed comparison of crystal and solution structures has shown very good correspondence,[169, 170] but further development is called for to extend the power of the method to larger protein structures.

Protein crystallography is the only tool available to unravel in detail the architecture of the large protein complexes described here, and it will continue in the foreseeable future to be the only experimental method that provides atomic resolution data on atom–atom and molecule–molecule interactions. It is such a method which *Emil Fischer* had in mind in 1907 in his 9th Faraday Lecture when pointing out that an understanding of "the precise nature of the assimilation process ... will only be accomplished when biological research, aided by improved analytical methods, has succeeded in following the changes which take place in the actual chlorophyll granules."[171] Yet an ultimate goal for which we all struggle is the solution of the folding problem. The growing number of known protein structures and the design of single residue variants by recombinant DNA technology and their analysis by protein crystallography has brought us nearer to this goal. We are able to study contributions of

individual residues to rates of folding, structure, stability, and function. Also theoretical analysis of protein structures has progressed (to mention only *Levitt* and *Sharon*[172]), but a clue to the code relating sequence and structure is not in sight.[173] Like *Carl von Linné* who 250 years ago created a system of plant classification on the basis of morphology (Genera plantarum, Leiden 1737), we classify proteins according to their shapes and structures. Whether this may lead to a solution of the folding problem is unclear, but it is certain that the end of protein crystallography will only come through it itself.

Acknowledgement

J. Deisenhofer's and my interest in structural studies on the photosynthetic reaction center of *Rps. viridis* was awakened by the establishment of *D. Oesterhelt*'s department in Martinsried in 1980; he brought with him *H. Michel*, with whom a fruitful collaboration on the analysis of the crystal structure of this large protein complex began. Later, other members of my group, *O. Epp* and *K. Miki*, became involved. We had been studying enzymes, proteases and their natural inhibitors, immunoglobulins, and had developed methods to improve data collection, electron density map interpretation, and crystallographic refinement. The tools were available to solve the structure of the reaction center, which was and still is the largest asymmetric protein whose structure has been determined with atomic resolution.

The "eureka" moment of protein crystallography is at the very end when one sees for the first time a new macromolecule with the eyes of a discoverer of unknown territories. To reach this moment much, sometimes tedious work has to be done with the ever present possibility of failure. I am deeply grateful to my collaborators, present and past, for their dedicated and patient work over many years. I mention by name those involved in the studies of the light harvesting cyanobacterial proteins and the blue oxidases: W. Bode, M. Duerring, R. Ladenstein, A. Messerschmidt, T. Schirmer. These projects were collaborative undertakings with biochemists in Switzerland (H. Zuber, W. Sidler), USA (M. L. Hackert) and Italy (M. Bolognesi, A. Marchesini, A. Finazzi-Agro).

Scientific work needs a stimulating environment which was provided at the Max-Planck-Institut für Biochemie and it needs steady financial support, which has been provided by the Max-Planck-Gesellschaft and the Deutsche Forschungsgemeinschaft.

I thank R. Engh, S. Knof, R. Ladenstein, M. Duerring, E. Meyer for their helpful comments on this manuscript.

The Purine Path to Chemotherapy (Nobel Lecture)**

By Gertrude B. Elion*

Introduction

When I joined the Wellcome Research Laboratories in 1944, World War II was in progress. Since the work I am about to discuss covers a period of some 40 years, it may be pertinent to consider the "state of the art" at that time. Our ultraviolet absorption spectra were measured with a Bausch and Lomb spectrograph which had a carbon arc as the light source and photographic plates for recording the amount of light absorbed at each wavelength. There was no paper or ion-exchange chromatography, and purines were isolated and separated as copper and silver salts, or picrates, by fractional crystallization. Tritium and ^{32}P were available, but no ^{14}C or ^{35}S. Geiger counters were used for counting radioactivity; scintillation counters came much later. Some heavy isotopes (e.g., ^{15}N and ^{13}C) were obtainable but required the use of a mass spectrometer, which few laboratories had. The state of knowledge of nucleic acids was rather rudimentary. We knew they contained purines and pyrimidines, but the sequences were not known. The prevailing theory was that there were two purines and two pyrimidines in each tetranucleotide and that these tetranucleotides were strung together in some fashion. However, the nature of the internucleotide linkage had not been established and the helical structure of DNA had not yet been proposed.

In 1940 *Woods*[1] and *Fildes*[2] had put forth the antimetabolite theory to explain the action of sulfonamides on bacteria, suggesting that the sulfonamides interfered with the utilization of a necessary nutrient, *para*-aminobenzoic acid. *Hitchings* theorized that, since all cells required nucleic acids, it might be possible to stop the growth of rapidly dividing cells (e.g., bacteria, tumors, protozoa) with antagonists of the nucleic acid bases. One might hope to take advantage of the faster rate of multiplication of these cells compared with normal mammalian cells and eventually sort out the biochemical differences between various types of cells by the way they responded to these antimetabolites.[3,4] It was my assignment to work on purines, pteridines, and some other condensed pyrimidine systems.

It was, of course, necessary to have some biological systems to determine the potential activities of the new compounds. Essentially nothing was known at that time about the anabolic pathways leading to the utilization of purines for nucleic acid synthesis. A number of catabolic enzymes were known: nucleases, nucleotidases, nucleosidases, deaminases (for guanine, adenine, adenosine, and adenylic acid), xanthine oxidase, and uricase. In 1947 *Kalckar* described the reversibility of nucleoside phosphorylase.[5] The enzymes guanase and xanthine oxidase were useful in our laboratory to examine the purines as substrates or inhibitors of these enzymes.[6,7] However, it was the microorganism *Lactobacillus casei* upon which we mainly relied. It could grow on adenine, guanine, hypoxanthine, or xanthine, provided the pyrimidine thymine was added. It could also synthesize purines and thymine, if given a source of folic acid in the form of liver powder. (The structure of folic acid was not elucidated until 1946 by the *Lederle* group.[8]) *Hitchings* and *Falco* had devised a screening test in which it was possible to determine whether a compound could substitute for thymine[9] or a natural purine[4,10] or inhibit its utilization, and they could also determine whether a compound was a folic acid antagonist.[11,12]

Few chemists were interested in the synthesis of purines in those days and I relied mainly on methods in the old German literature. The transformation reactions were carried out mainly by the methods of *Emil Fischer* and the syntheses from pyrimidine intermediates by the methods of *Traube*. The direct replacement of oxygen by sulfur by the method of *Carrington*[13] also proved to be exceedingly useful for synthesizing the mercaptopurines.[14,15]

In 1950 we reported that 2,6-diaminopurine (DAP) inhibited the growth of *L. casei* very strongly and that the inhibition was reversed specifically by adenine, but not by the other natural purines.[4,16] However, the effects of low concentrations of DAP could also be reversed by folic acid, an attribute which DAP had in common with other diaminopyrimidines and diaminopyrimidine condensed systems.[10] Studies on a DAP-resistant strain of *L. casei* revealed that it grew poorly on adenine as a source of purine. We deduced that adenine and DAP must be anabolized by the same enzyme and that the product of DAP anabolism interfered with purine interconversion.[17] That enzyme was reported by *Kornberg* et al. in 1955 to be adenylate pyrophosphorylase (adenine phosphoribosyltransferase).[18] When tested on mouse tumors and the Ak4 mouse leukemia[19] or tumor cells in tissue culture,[20] DAP proved to be strongly inhibitory. It produced two good clinical remissions in chronic granulocytic leukemia in adults but produced severe nausea and vomiting, as well as severe bone marrow depression, in two other patients.[21] Interestingly, DAP showed activity against vaccinia virus, a DNA virus, in vitro,[22] but its toxicity in animals led us to abandon that possible utility.

Antileukemic Drugs

By 1951 we had made and tested over 100 purines in the *L. casei* screen[23] and discovered that the substitution of oxygen by sulfur at the 6-position of guanine and hypoxanthine produced inhibitors of purine utilization. 6-Mercaptopurine (6-MP) and 6-thioguanine (TG) were tested at the Sloan-Kettering Institute, with whom we had established a

collaboration, and were found to be active against a wide spectrum of rodent tumors and leukemias. Of special interest was the finding by *Clarke* et al.[24] that 6-MP–treated tumors, although they had not regressed completely in the host mouse, were not transplantable into other mice. After some animal toxicology studies by *Philips* et al.,[25] *Burchenal* et al. proceeded rapidly to clinical trial with 6-MP in children with acute leukemia.[26] At that time the only drugs available for the treatment of these terminally ill children were methotrexate (MTX) and steroids and the median life expectancy was between three and four months; only 30% lived for as long as one year. The findings that 6-MP could produce complete remissions of acute leukemia in these children, although most of them relapsed at various intervals thereafter, led the Food and Drug Administration to approve the drug for this use in 1953, a little more than two years after its synthesis and microbiological investigation. A symposium on 6-MP was held at the New York Academy of Sciences in 1954.[27] The addition of 6-MP to the antileukemia armamentarium increased the median survival time to 12 months in these children, and a few remained in remission for years with 6-MP and steroids. This convinced us, as well as many other investigators in the cancer field, that antimetabolites of nucleic acid bases were fruitful leads to follow. Today 6-MP remains one of the dozen or more drugs found useful in the treatment of acute leukemia. With the use of combination chemotherapy with three or four drugs to produce and consolidate remission, plus several years of maintenance therapy with 6-MP and methotrexate, almost 80% of children with acute leukemia can now be cured.

Although we felt we were on the right track in 1952, there were still many unanswered questions. How did 6-MP work? What was the reason for its differential effect on neoplastic cells? How could one improve this differential effect? Reversal studies with 6-MP in *L. casei* did not pinpoint antagonism for any single purine. The inhibition was reversed by hypoxanthine, adenine, guanine, and xanthine.[28] However, studies with a 6-MP–resistant strain of *L. casei* revealed that the strain was unable to utilize hypoxanthine for growth.[29] Again, as with the earlier studies with 2,6-diaminopurine, we concluded that 6-MP and hypoxanthine were anabolized by the same enzyme and that interference with purine interconversions at the nucleotide level was involved.[30] In 1955 (two years after the introduction of 6-MP into clinical use), the enzyme that converts hypoxanthine and 6-MP into their respective nucleotides was identified as hypoxanthine phosphoribosyltransferase (HGPRT).[18] Also in the mid-fifties, the pioneering work of *Greenberg*[31] and of *Buchanan*[32, 33] and their co-workers revealed the pathways of the biosynthesis of purines and the importance of hypoxanthine ribonucleotide (inosinic acid, IMP) as the first purine nucleotide formed in this biosynthetic pathway. It took a number of investigators and a period of years to unravel all of the pathways in which the nucleotide of 6-MP, thioinosinic acid (TIMP), and nucleotides derived from TIMP participated as substrates or inhibitors (Fig. 1).[34]

Our current knowledge of enzyme inhibition constants and the concentrations of the various nucleotides achieved with the therapeutic regimens indicates that the principal modes of action are feedback inhibition of de novo purine synthesis (particularly by methylthioinosinic acid), inhibition of inosinate dehydrogenase, and incorporation into DNA in the form of TG.[35] Selectivity for neoplastic cells probably depends on the levels of the individual anabolic and catabolic enzymes. Catabolic enzyme levels are generally much lower in tumor cells than in normal cells. In addition, mitotic rate, drug transport, and metabolite pool sizes can be responsible for selective toxicity.

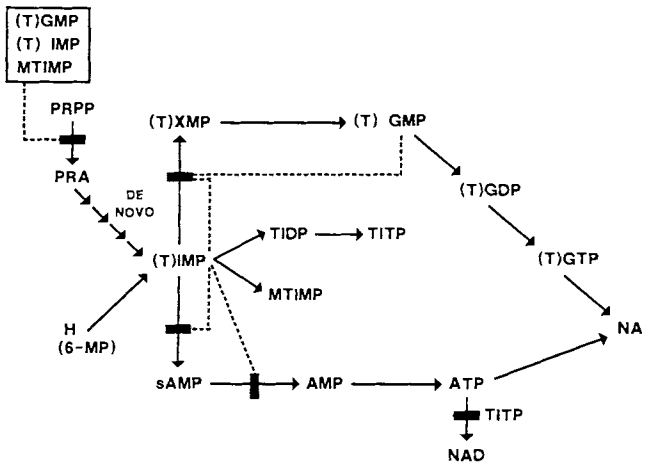

Fig. 1. Pathways in the anabolism of 6-MP and loci of action of the nucleotides derived from 6-MP. In addition, TGDP is converted into dTGDP and dTGTP for incorporation into DNA. MP, DP, and TP are mono-, di-, and triphosphate, respectively. T = thio, M = methyl, G = guanosine, X = xanthosine, PRPP = 5-phosphoribosyl-1-pyrophosphate, PRA = phosphoribosylamine, sAMP = adenylosuccinate.

While these biochemical studies were going on, we studied the metabolic fate of 6-MP, first in mice[36] and then in humans.[37] Pharmacokinetic and metabolic studies were then in their infancy, perhaps because the methodology for separation of metabolites and the counting of radioactive samples as thin films in a flow Geiger counter were so tedious and time-consuming. Nevertheless, using Dowex-1 and Dowex-50 ion-exchange columns and paper chromatography, we investigated the fate of 6-MP in vivo and attempted to discover whether it was possible to modify this metabolism and thus improve the efficacy of 6-MP. We continued to synthesize derivatives of 6-MP and TG and to investigate structure–activity relationships.[38–40] Thioguanine, which we had synthesized earlier than 6-MP, was more active but also more toxic.[25] It was also more difficult to synthesize and, since its mechanism of action appeared to be similar to that of 6-MP, its metabolic fate and clinical activity were explored somewhat later.[41–43] Thioguanine later found its main utility, in combination with cytosine arabinoside, in the treatment of acute myelocytic leukemia in adults.

Studies of the urinary metabolites of 6-MP revealed that extensive metabolic transformations occurred in vivo.[36, 37, 44–46] The single product present in highest amount was 6-thiouric acid, formed by the action of xanthine oxidase on 6-MP. In addition, there were various substances in which the sulfur had been methylated and the methylthio derivative had been oxidized on the sulfur or on the purine ring. A considerable amount of the sulfur had been removed and converted by oxidation into inorganic sulfate, which also appeared as sulfate esters. Very little 6-MP was excreted unchanged.

In an attempt to modify the metabolism of 6-MP, we introduced substituents at the 2- and/or 8-positions of the purine ring and on the ring nitrogens. This led to the loss of antitumor activity, with the exception of the 2-amino-6-mercapto derivative, thioguanine, which we had previously found to have strong antimetabolic activity. Attempts were then made to protect the sulfur from oxidation and hydrolysis by blocking groups which might be removed intracellularly to release 6-MP, hopefully by some tumor-specific enzyme. The most successful compound to emerge from this approach was the *S*-(1-methyl-4-nitroimidazol-5-yl) derivative. This compound, now known as azathioprine (Imuran®), acts as a pro-drug for 6-MP. Because of the proximity of the *ortho*-nitro group, azathioprine is subject to attack by sulfhydryl groups and other nucleophiles[45-49] (Fig. 2). In

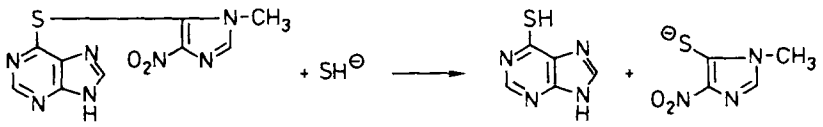

Fig. 2. Reaction of hydrogen sulfide with azathioprine to release 6-MP. Reproduced from [46] with permission.

particular, the glutathione present in red blood cells reacts with azathioprine, releasing 6-MP back into the plasma.[47] This compound had a better therapeutic index in mice bearing adenocarcinoma 755, being as active as 6-MP but less toxic.[50] In patients with leukemia, however, the chemotherapeutic index of 6-MP was similar to that of azathioprine.[51]

Imunosuppression and Transplantation

In 1958 a new horizon appeared. *Robert Schwartz*, working with *William Dameshek* in Boston, investigated the effect of 6-MP on the immune response, based on the rationale that the immunoblastic lymphocyte formed during an immune response closely resembled leukemic lymphocytes. *Schwartz* et al. showed that when 6-MP was administered to rabbits for several days, beginning with the time of injection of a foreign antigen (e.g., bovine serum albumin) the rabbits were unable to mount an antibody response to that antigen.[52] Schwartz and his co-workers worked out the importance of drug dose and timing and showed that 6-MP was most effective when treatment was started at the time of antigen administration.[52, 53] They also demonstrated that animals could be made tolerant to a particular antigen while still retaining immunological reactivity to other antigens.[54] At *Schwartz*'s instigation, we set up an immunological screening test that consisted of measuring the antibody response of mice to sheep red blood cells.[55, 56] It enabled us to identify new active agents and synergistic combinations of drugs and to show that immunosuppression was greater at higher doses of antigen and of drug.

Roy Calne, a young British surgeon, stimulated by the papers of *Schwartz* and his co-workers, decided to examine the effect of 6-MP on kidney transplant rejection in dogs. He obtained a 44-day survival of a kidney from an unrelated donor in a dog given daily doses of 6-MP.[57] This was considerably longer than the expected 9- to 10-day graft survival in control animals. When *Calne* asked us for compounds related to 6-MP which he might investigate, we suggested that azathioprine might have some advantages. The following studies showed azathioprine to be superior to 6-MP for preventing rejection of canine kidney homografts.[58, 59] Successful transplantation of kidneys to unrelated recipients became a reality in man in 1962, with regimens of immunosuppression consisting of azathioprine and prednisone.[60] By 1977, the Kidney Registry had records of 25000 kidney transplants done between 1965 and 1972[61] and the number of transplants done each year has continued to increase.[62, 63] Today the procedure is considered therapeutic rather than experimental, and the importance of histocompatibility matching is recognized.[63] Other organ transplants (e.g., liver, heart, and lung) have likewise become possible. Other immunosuppressive drugs (e.g., cyclosporin) have come into use in recent years, but azathioprine remains a mainstay in kidney transplantation.

The immunosuppressive effects of azathioprine have been studied in a wide variety of immunological systems. The earlier work is reviewed in Ref. [64] and more recent studies in Ref. [65]. Immunosuppressive drugs have also shown utility in the treatment of autoimmune disease. Remissions with 6-MP, thioguanine, and azathioprine have been reported in autoimmune hemolytic anemia, systemic lupus, and chronic active hepatitis.[65] Azathioprine is now an approved drug for the treatment of severe rheumatoid arthritis.[66]

Gout and Hyperuricemia

It was time now to try a new approach to the potentiation of 6-MP activity. Since we knew from metabolic studies that 6-thiouric acid was one of the principal products of 6-MP catabolism, it seemed possible that we could interfere with this oxidation by inhibiting the enzyme responsible for it, xanthine oxidase. In the early days of seeking antimetabolites for the natural purines in our laboratory, xanthine oxidase had been one of the test enzymes. *Doris Lorz* had identified many substrates as well as inhibitors of this enzyme.[7] These compounds had also been tested on *L. casei* and on animal tumors. To test for xanthine oxidase inhibition in vivo, we chose a compound that had no inhibitory effects on bacteria or tumors and was nontoxic, but which was a potent inhibitor of xanthine oxidase. This compound was the hypoxanthine analogue 4-hydroxypyrazolo[3,4-*d*]pyrimidine (allopurinol). When allopurinol was given to mice together with 6-MP, it did indeed inhibit the oxidation of 6-MP and potentiated the antitumor and immunosuppressive properties of 6-MP three- to fourfold.[45, 67, 68] Moreover, the toxicity of 6-MP to mice appeared to be potentiated only twofold, so that the chemotherapeutic index of 6-MP had been in-

creased. Was it possible that the same phenomenon would occur in man? With the collaboration of *Wayne Rundles*, we explored this possibility in patients with chronic granulocytic leukemia, in whom the efficacy and metabolism of 6-MP could be investigated. As had happened in mice, the oxidation of 6-MP to thiouric acid (TU) was inhibited in a dose-related manner and the antileukemic activity of 6-MP was potentiated proportionally.[45, 69–71] Figure 3 illustrates the

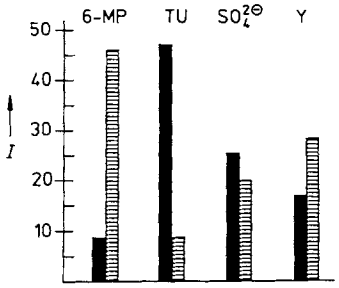

Fig. 3. Radioactive metabolites in the urine following administration of 110 mg of [35S]6-MP to a patient with (▤) and without (■) 300 mg of allopurinol. Reproduced from [71] with permission. Y = other metabolites, I = percent of radioactivity in urine.

fourfold reduction in TU and increase in 6-MP when 300 mg of allopurinol was given together with 110 mg of 6-MP. Later investigations[72] showed that the increased activity of 6-MP was accompanied by a proportional increase in toxicity. Thus, although less 6-MP was required to produce an antileukemic effect, the therapeutic index of 6-MP for leukemia remained unchanged.

Xanthine oxidase is responsible not only for the oxidation of 6-MP, but also for the formation of uric acid from hypoxanthine and xanthine (Fig. 4). Consequently, treatment

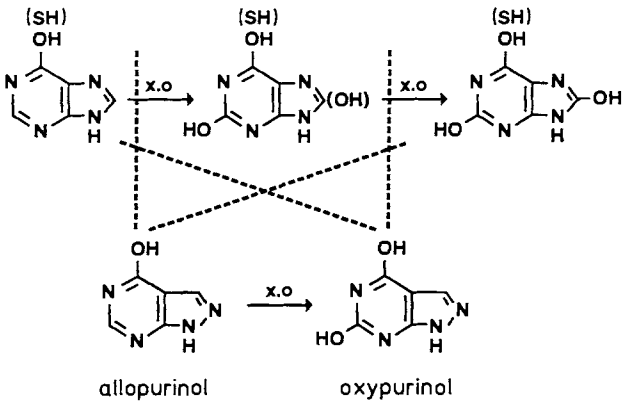

Fig. 4. Pathways in the oxidation of hypoxanthine and 6-MP by xanthine oxidase (x.o.) inhibited by allopurinol and oxypurinol. For 6-MP, the intermediate is 8-hydroxy-6-MP; for hypoxanthine, the intermediate is 2,6-dihydroxypurine (xanthine).

with allopurinol produces a marked decrease in both serum and urinary uric acid.[69, 71, 73, 74] This presented the possibility of a unique approach to the treatment of gout and other forms of hyperuricemia.

It was recognized at the outset that the inhibition of an enzyme like xanthine oxidase in vivo might present some difficulties. First, there was the question as to whether the inhibitor had a sufficiently long half-life in the body to produce a persistent reduction in uric acid production. There was also the possibility that the inhibition would result in an unacceptable accumulation of the intermediates hypoxanthine and xanthine, the latter compound being about as insoluble as uric acid. Moreover, it was possible that more enzyme would be induced by the presence of excess amounts of the intermediates, leading to the need for ever-increasing amounts of inhibitor. Finally, one had to consider carefully the long-term effects of this inhibitor, since gout patients would probably continue to take the drug for life. All of these possibilities were thoroughly examined, first in animals and then in man.

Allopurinol is not only a potent competitive inhibitor of xanthine oxidase but also a substrate,[75] its oxidation resulting in the corresponding xanthine analogue, oxypurinol (called alloxantine, oxoallopurinol, or oxipurinol in early papers), which is also a xanthine oxidase inhibitor (Fig. 4). Oxypurinol also has the unusual property of binding very tightly to the reduced form of the enzyme, thereby inactivating it.[75, 76]. The enzyme activity can be restored by oxidation, which takes place slowly in the presence of air.[76, 77] Allopurinol itself has a short half-life in plasma (about 90 to 120 minutes). However, oxypurinol has a very long half-life of 18 to 30 hours,[75, 78, 79] because it is reabsorbed in the proximal tubule of the kidney.[80] Consequently, steady-state levels of oxypurinol are achieved in a few days and uric acid concentrations can be maintained at the desired level by proper dose adjustment.[80] Because allopurinol is completely absorbed orally, whereas oxypurinol is not, allopurinol remains the ideal pro-drug for oxypurinol.

The fate of the intermediate oxypurines, hypoxanthine and xanthine, turned out to be a fascinating one. These oxypurines do not accumulate in the serum. In fact, their serum levels rise very little during allopurinol treatment[79, 81] for two reasons. First, hypoxanthine and xanthine can be reutilized for nucleic acid synthesis via the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT).[82, 83] The nucleotides formed, IMP and XMP, are the normal intermediates for adenine and guanine nucleotides (AMP, GMP). Second, through a process of feedback inhibition, IMP, AMP, and GMP can reduce the de novo synthesis of purines by inhibiting PRPP-amidotransferase.[84] Thus, the salvage of hypoxanthine and xanthine serves to regulate purine biosynthesis, reducing it when it is excessive. When the oxypurines are not reutilized, they are excreted by the kidney by glomerular filtration, since they are not reabsorbed by the kidney tubule to any significant degree.[85, 86]

Long-term studies with allopurinol in animals and in man have shown that new enzyme is not induced and that allopurinol is a safe and effective drug for long-term treatment.[87] A few percent of patients develop a rash when taking allopurinol. Patients with poor kidney function require lower doses of drug because of the pharmacological properties of oxypurinol and its long half-life.[88]

Allopurinol helps to alleviate several of the clinical problems associated with gout. The hyperuricemia of gout produces deposits of small crystals of uric acid in joints, which result in extreme pain, or large deposits, tophi, which result in gouty arthritis and restricted joint movement. In patients who excrete excessive amounts of uric acid in the urine, urate stones often form in the kidney. With allopurinol it has been possible to prevent and reduce the tophaceous deposits and

to prevent urate stone formation.[74, 81, 87, 89, 90] Likewise, the secondary hyperuricemia associated with the therapy of malignancy can be reduced with allopurinol treatment.[91]

Antiprotozoal Effects of Allopurinol

I would like to digress at this point, to describe another use for allopurinol which materialized about 10 years later, because it typifies the kind of chemotherapeutic selectivity which can be achieved with purine analogues as the result of differences in the specificities of parasitic and mammalian enzymes. The finding by *Joseph Marr* et al.[92] that allopurinol inhibits the replication of *Leishmania donovani* led us into an extended collaboration with *Marr* to discover the biochemical basis for this unexpected activity.[93–101] Leishmaniae and trypanosomes, like many other unicellular parasites, lack the ability to synthesize purines de novo. They do, however, have ample quantities of salvage enzymes which enable them to utilize preformed purines and nucleosides present in the mammalian blood stream. Leishmaniae and trypanosomes have large amounts of the enzyme HGPRT capable of utilizing allopurinol as a substrate to a much greater extent than does the human enzyme.[97] Moreover, the enzyme adenylosuccinate synthetase, which has as its function the conversion of IMP to sAMP, the intermediate for AMP, has a broader substrate specificity than does the mammalian enzyme.[96, 101] The protozoal enzymes consequently convert allopurinol ribonucleotide into the adenylate analogue, 4-aminopyrazolo[3,4-*d*]pyrimidine ribonucleotide, which is then converted into a di- and triphosphate and incorporated into RNA.[93, 94, 98, 100] In the mammalian host this amination does not occur and allopurinol is not incorporated into nucleic acids.[102] The differences in the metabolism of allopurinol by the mammalian host and the trypanosomes are illustrated in Figure 5. Allopurinol has shown activity in the treatment of Leshmaniasis[103] and of Chagas' disease (caused by *Trypanosoma cruzi*).[104]

Allopurinol riboside, a minor urinary metabolite of allopurinol in man, can likewise be converted by leishmaniae in this way,[94] whereas allopurinol riboside is not further metabolized in man.

Antiviral Drugs

In 1968 we decided to return to a path that had intrigued us as early as 1948, the path to antivirals. The antiviral activity of 2,6-diaminopurine (DAP) had been provocative,[22] although its toxicity had been discouraging. Meanwhile, the pursuit of 6-MP, thioguanine (TG), azathioprine, and allopurinol had occupied 20 years. When it was discovered that adenine arabinoside (ara-A) inhibited the growth of both DNA and RNA viruses,[105] the information started a train of thought. Would the arabinoside of DAP (ara-DAP) be equally active? After all, DAP had mimicked adenine in many reactions and could be converted into a nucleoside and nucleotide by adenine-metabolizing enzymes. Moreover, diaminopurine riboside was a poorer substrate for adenosine deaminase than was adenosine. It therefore seemed possible that ara-DAP might persist longer than ara-A, a compound which is rapidly deaminated in vivo.

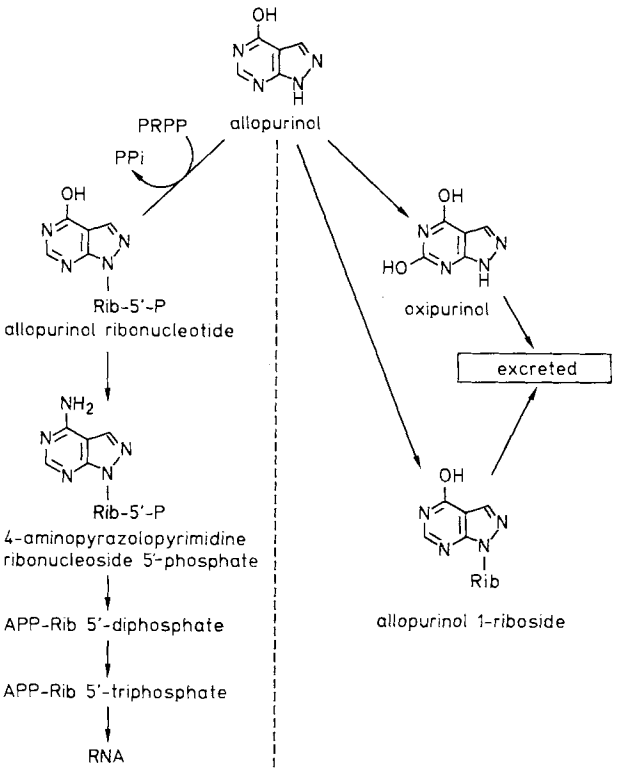

Fig. 5. Metabolic pathways of allopurinol in trypanosoma (left) and man (right).

Diaminopurine arabinoside was synthesized by *Janet Rideout*, and, since we did not have a virus laboratory on site at the time, we sent the compound to our colleague, *John Bauer*, in the Wellcome Research Laboratories in the U.K. for antiviral screening. In a few weeks he informed us that this compound was highly active against both herpes simplex virus and vaccinia virus. Moreover, the compound was less cytotoxic to mammalian cells than ara-A. Thus began our antiviral odyssey. For several years my group pursued studies on the purine arabinosides, exploring structure–activity relationships, seeking better synthetic methods, and doing metabolic studies in mice.[106] *Bauer* and *Collins* studied the activity of these compounds in rabbits and mice.[106] We found that ara-DAP was deaminated to guanine arabinoside in mice and that the guanine derivative (ara-G) was as active an antiviral as ara-DAP. In this respect, ara-G had an advantage over the deamination product of ara-A, hypoxanthine arabinoside, which had very poor antiviral activity. We were not certain whether this advantage was sufficient to warrant the full-scale development of ara-DAP.

In 1970 our laboratories moved to North Carolina and *Howard Schaeffer* joined us as head of the Organic Chemistry Department. He had been studying analogues of adenosine as substrates and inhibitors of the enzyme adenosine deaminase, and he had examined a variety of acyclic side chains on the 9-position of adenine to determine what changes the enzyme would tolerate in a substrate.[107] He found that 9-{(2-hydroxyethoxy)methyl}adenine could still serve as a substrate for adenosine deaminase. This suggested that other enzymes might also recognize such a side chain as a pentose and that nucleoside analogues of this kind might have antimetabolite properties.

When the acyclic adenosine analogue was tested in the antiviral screen, it showed antiherpetic activity in vitro at about twice the concentration of ara-A. The antiviral program now concentrated on the acyclic nucleoside analogues, with the syntheses conducted by *Schaeffer* and *Beauchamp*, the antiviral testing by *Bauer* and *Collins*, and the mechanisms of action, enzymology, and in vivo metabolism by my group.[108, 109] As was the case with the purine arabinosides, the DAP analogue proved highly active on herpes simplex virus in vivo as well as in vitro. However, unexpectedly, the guanine analogue, acyclovir (ACV, acycloguanosine), was over 100 times as active as the diamino compound.[109] Acyclovir is a metabolic product of the DAP derivative, formed by the action of adenosine deaminase and is undoubtedly responsible for the antiviral activity of the diamino compound observed in vivo.[110–112]

Acyclovir

One of the most intriguing aspects of the antiviral activity of ACV is not only its high potency but its unusual degree of selectivity (Fig. 6).[108, 109, 113–115] It is highly active against

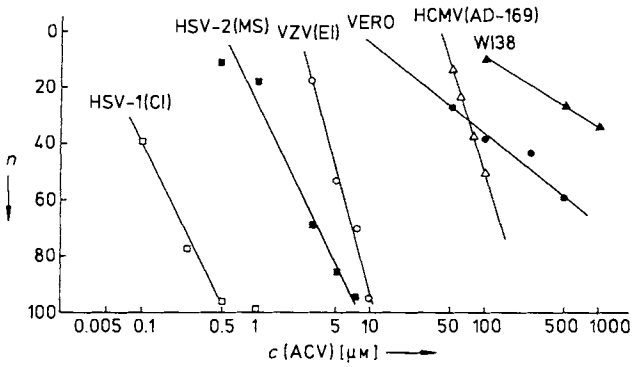

Fig. 6. Dose–response curves of various viruses and cells to ACV. Reproduced from [108] with permission. n = percent inhibition, c = concentration.

herpes simplex virus, types 1 and 2 (HSV-1 and HSV-2), and varicella-zoster (chicken pox) virus. It has activity against several other herpes-type viruses, for example, Epstein-Barr virus (EBV) and pseudorabies virus, but only slight activity against the human cytomegalovirus (HCMV). It is not cytotoxic to the mammalian cells in which these viruses are grown at concentrations hundreds of times greater than those required for antiviral activity. Moreover, the compound is inactive against other DNA viruses (e.g., vaccinia virus) as well as RNA viruses.[109]

We decided that it was highly important to determine the reason for this unusual selectivity, since this would undoubtedly offer exploitable information about the herpes viruses. In order to do these biochemical studies effectively, we set up a virus laboratory in-house with *Phillip Furman* as its head. Radioactive ACV labeled in the 8-position of the guanine with ^{14}C or with ^{3}H in the side chain was synthesized. Vero cells, uninfected or infected with HSV-1, were incubated with both types of radioactive ACV for seven hours. Extracts of these cells were then examined by high-pressure liquid chromatography. The extracts of the uninfected cells showed only the presence of unchanged ACV. In the HSV-infected cells three new radioactive compounds were formed.[108] These products were identified by enzymatic methods as the mono-, di-, and triphosphates of ACV (ACV-MP, ACV-DP, ACV-TP), and this was later confirmed by comparison with authentic synthetic samples.

The enzyme responsible for the conversion of ACV to its monophosphate was laboriously isolated, purified, and identified by *James Fyfe* as a herpesvirus-specified thymidine kinase.[108, 116] While this enzyme had been reported to be formed in herpesvirus-infected cells, it was unexpected that an acyclic nucleoside of guanine could serve as its substrate. A similar enzyme is specified by the varicella-zoster virus. Once the first phosphate has been added, the second phosphate is added by cellular guanylate kinase,[117] while several other cellular kinases can add the third phosphate.[118] Since the cellular thymidine kinase cannot use ACV as a substrate, very little ACV-TP is formed in uninfected cells.[108, 119] The small amount of phosphorylation that occurs in normal cells is due to a 5′-nucleotidase.[120] The pathways for the formation of ACV-TP are shown in Figure 7.

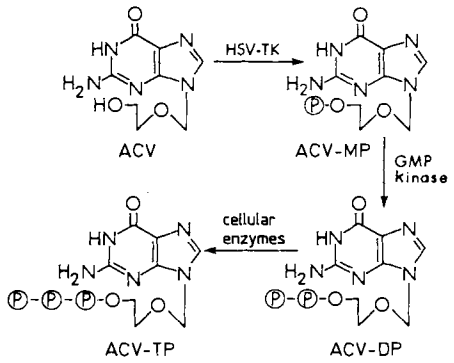

Fig. 7. Pathways for the formation of ACV mono-, di-, and triphosphate. Reproduced from [108] with permission.

When it was apparent that the active antiviral compound was ACV-TP, the interaction of this compound with viral and cellular DNA polymerases was investigated. ACV-TP proved to be a more potent inhibitor of the herpes virus DNA polymerase than of cellular DNA polymerase-α.[121, 122] The quantitative aspects of these differences in the amounts of ACV-TP formation and DNA polymerse inhibition (K_i value) by ACV-TP in virus-infected cells and uninfected cells are illustrated in Figure 8.[123] Moreover, ACV-TP serves as a substrate for the herpes virus DNA polymerase, but chain termination occurs when it is incorporated, because of the absence of the 3′-hydroxyl group needed for chain elongation.[113] Thus, only very small fragments of viral DNA are formed.[124] In addition, ACV-TP not only inhibits but also inactivates the viral DNA polymerase following the formation of the enzyme–template–ACV-MP complex.[125] This inactivation does not occur with cellular DNA polymerase.

The high selectivity of ACV for those herpes viruses that induce a herpes-specified thymidine kinase can thus be explained. This enzyme has proved to be a very useful tool for determining the structural requirements for other potential substrates of this enzyme.[126] Its absence or alteration also explains the resistance of some herpes virus isolates to ACV.[127–129] On the other hand, transfection of cells with

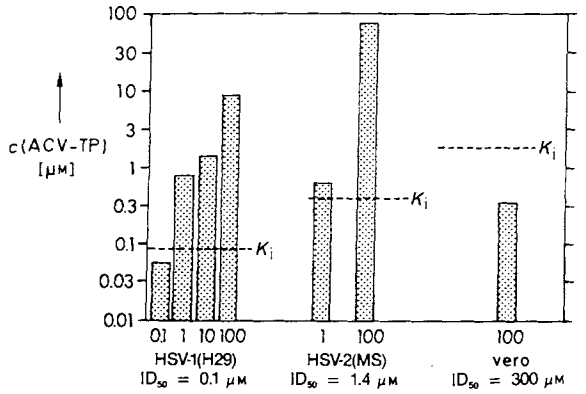

Fig. 8. Amounts of ACV-TP formed in uninfected Vero cells and in HSV-1- and HSV-2-infected Vero cells in the presence of varying concentrations of ACV. Dotted lines represent the K_i values for the individual DNA polymerases. ID_{50} values are concentrations for 50% inhibition of plaque formation. Reproduced from [123] with permission.

a portion of the herpesvirus genome containing the HSV thymidine kinase gene transforms normally resistant cells into ACV-sensitive cells.[130] Resistance to ACV may also result from mutations in the viral DNA polymerase.[127-129]

Epstein-Barr virus and HCMV infection do not induce a specific kinase capable of phosphorylating ACV. However, the DNA polymerase of Epstein-Barr virus is exquisitely sensitive to the small amount of ACV-TP formed in EBV-infected cells.[131] Interestingly, although HCMV-infected cells do not phosphorylate ACV to any extent, they do phosphorylate the closely related ACV derivative, ganciclovir (formerly called BW B759U, DHPG, or 2'NDG), which has an extra hydroxymethyl group on the side chain. Consequently, ganciclovir has proven to be a much better inhibitor of HCMV replication than ACV.[132-134]

Investigation of the pharmacokinetics and metabolism of ACV first in several animal species and then in man revealed that it was a remarkably stable compound. Only two metabolites were found, 9-{(2-carboxymethoxy)methyl}guanine (CMMG) and 8-hydroxyacyclovir.[135] In man, the carboxy derivative CMMG accounted for 9-14% of an intravenous dose of ACV, while essentially none of the 8-hydroxy metabolite appeared in the urine.[136,137] In other species there were somewhat increased amounts of both metabolites.[135,137,138] Acyclovir has a plasma half-life of approximately three hours,[139] so that an intravenous infusion is generally given every eight hours. Because ACV is excreted at about twice glomerular filtration rate and has a limited solubility in water (2.5 mg mL^{-1} at 37 °C), it is administered as a one-hour intravenous infusion rather than as a bolus injection. The compound is also active topically and orally. Although the oral bioavailability is limited, the blood levels attained by oral administration of ACV are adequate for therapeutic efficacy against herpes simplex and varicella-zoster viruses.[140]

The compound is distributed in all body tissues and crosses the blood-brain barrier.[109,135,141] Toxicology studies in mice, rats, and dogs showed the drug to be nontoxic at doses well above those required for therapeutic efficacy.[142]

Acyclovir has now been in clinical use for about eight years and it seems appropriate to mention some of the areas in which it has decreased suffering and saved lives. First episodes of genital herpes infections are characterized by pain, prolonged viral excretion, and slow healing of lesions. Acyclovir, given by either the intravenous or oral routes, produces a significant alleviation of symptoms and decreases the time of viral shedding and time to healing (Table 1).[143]

Table 1. Effect of ACV on first episodes of genital herpes.

Route of application	Median duration in days (ACV/placebo) Virus shedding	Pain	Healing	Ref.
i.v.	2/13	3/7	9/21	[144]
p.o.	1/13	4/8	6/11	[145]
p.o. [a]	3.9/13.4	2.8/3.4	9.5/13.7	[146]

[a] Women only; mean duration.

Recurrent episodes of genital herpes are generally much shorter and less severe than the initial one. Therefore, the benefits of ACV treatment appear to be less dramatic. However, in a study in which patients initiated oral therapy, there was a significant difference in new lesion formation, 23% on placebo, 6.5% on ACV.[147] For patients with frequently recurring genital herpes (e.g., once a month) of several years duration, it has been possible to decrease the frequency of recurrence to a mean of 1.8 episodes during the first year and 1.4 episodes during the second year by oral prophylaxis with ACV.[148] The percentage of patients having no recurrences in a year of oral prophylactic therapy was 45-50%.[149]

Herpes zoster, commonly known as shingles, is caused by a reactivation of latent varicella-zoster virus. It produces severe pain during the acute two-to-three-week episode, as well as a post-herpetic neuralgia months later in about 10 percent of patients. Acyclovir causes a significant decrease in the duration of acute pain but has little effect on the post-herpetic neuralgia.[150] In immunocompromised individuals, herpes zoster can produce serious sequelae in the form of progressive skin dissemination and visceral disease. The latter can be fatal in a small percentage of patients. Intravenous treatment with ACV has effectively prevented this dissemination.[151]

Herpes simplex infections in immunosuppressed individuals is a serious medical problem. Virus continues to be shed for a long time and healing is slow. In two studies that involved 97 immunocompromised patients[152] with a variety of diseases and 34 bone marrow transplant recipients,[153] the effects of intravenous ACV treatment on viral shedding, pain, and time to healing were highly significant (Table 2). In

Table 2. Effect of intravenous ACV on HSV infections in immunocompromised patients.

Patients	Median duration in days (ACV/placebo) Virus shedding	Pain	Healing
All (97)	2.8/16.8	8.9/13.1	13.7/20.1
Bone marrow transplants (34)	3/17	10/16	14/28

bone marrow transplant patients and in leukemic patients, prophylaxis with ACV has made it possible to prevent the reactivation of latent virus during therapy, so that the patients can remain free of herpetic episodes during the period of maximum immunosuppression.[154,155] The treatment of herpes encephalitis, a frequently fatal disease, with intra-

venous ACV has been successful in a large percentage of patients if begun before the patient is comatose.[156, 157]

In addition to the clinical utility of ACV, the lessons learned from its development have proven to be extremely valuable for subsequent antiviral research. In-depth studies of mechanisms of action have led to a better understanding of the enzymatic differences between normal and virus-infected cells and have given impetus to the search for other viral-specific enzymes which are capable of therapeutic application.

Outlook

In my attempt to cover 40 years of research on purines and purine analogues, I have been able to give you only a bird's eye view. However, I hope that I have successfully conveyed our philosophy that chemotherapeutic agents are not only ends in themselves but also serve as tools for unlocking doors and probing Nature's mysteries. This approach has served us well and has led into many new areas of medical research. Selectivity remains our aim and understanding its basis our guide to the future.

Selective Inhibitors of Dihydrofolate Reductase (Nobel Lecture)**

By George H. Hitchings, Jr.*

Introduction

My interest in nucleic acids, their constituents, and their metabolism can be traced to the discovery of adenosine triphosphate in muscle by *Fiske* and *Subbarow*.[1] I had entered Harvard University as a candidate for a Ph.D. degree in 1928 and transferred to Harvard Medical School in 1929. *Otto Folin*, then head of the Department of Biological Chemistry, designated my first predoctoral year to be spent with *Cyrus J. Fiske*, then involved in the momentous discoveries of phosphocreatine and the labile phosphorus compounds of muscle and other tissues. I was soon immersed in the discovery of analytical tools with which to follow the metabolism of adenosine triphosphate.[2]

Other lines of thought coalesced with this interest when I joined Burroughs Wellcome Co. in 1942 as the sole member of the Biochemistry Department. In the meantime, the antimetabolite principle had been expressed by *Woods*[3] and *Fildes*.[4] I saw the opportunity to explore nucleic acid biosynthesis in a new and revealing way by employing synthetic analogues of the purine and pyrimidine bases in a system utilizing these heterocyclic compounds for biosynthesis.

I was able to interest *Elvira Falco*, who was then an assistant in the company's Bacteriology Department. Together we worked out a system using *Lactobacillus casei*, which would grow either with a then unknown "L. casei" growth factor or with a mixture of thymine and a purine (Fig. 1).[5]

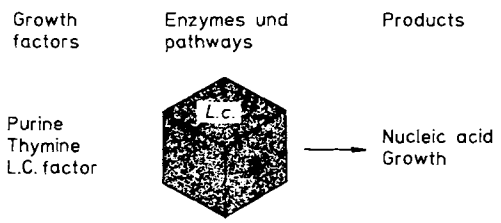

Fig. 1. The use of *Lactobacillus casei* as a black box of enzymes and metabolic pathways concerned with nucleic acid metabolism [9].

This system quickly gave us encouraging results. In a simple screening test for antibacterial activity, analogues were found to inhibit strongly not only the *L. casei* system but pathogenic bacteria as well. We had added toxicity testing in growing rats and other biological screening procedures and were becoming more and more excited by the results.

By 1947 six or seven of us were pursuing this work, and the feeling in the group was, "Now we have the chemotherapeutic agents; we need only to find the diseases in which they will be active." At that point I made two arrangements for collaborative studies, one with Sloan Kettering Institute for antitumor testing using sarcoma 180 (S-180) in mice, and another with outside laboratories for expansion of antibacterial and antimalarial testing. The antimalarial testing was included through the insight of *Peter B. Russell*, also a member of our research group. *Russell* noted the resemblance of a 2,4-diamino-5-phenylpyrimidine to a hypothetical conformation of the antimalarial proguanil. It turned out later that this theory was prescient; the dihydrotriazine is the active metabolite of proguanil.[6]

The next year two leads developed almost simultaneously. *Falco* began a series of selective inhibitors of dihydrofolate reductase (DHFR) with the synthesis of 2,4-diamino-5-phenoxypyrimidine, and *Gertrude Elion* synthesized 2,6-diaminopurine.[7] The latter was among the first four compounds we submitted to Sloan Kettering Institute. It was found to be active in the S-180 test, was taken into clinical trial by *Joseph H. Burchenal*, and gave at least one spectacular remission.[8] This was sufficient to establish cancer chemotherapy as a continuing primary goal of our group. The purine analogue story, which has been a major theme in *Gertrude Elion*'s career, is the topic of her Nobel lecture.[*]

The Discovery of DHFR Inhibitors

The main theme of this essay is the continuing topic of selective inhibitors of dihydrofolate reductase. Biochemical knowledge of the role of folates was developing concomitantly. Figure 2 shows that dihydrofolate is synthesized de novo in prokaryotes (microorganisms), while the higher species of eukaryotes (host) must have the vitamin preformed. I will pick up the story of selective inhibitors of DHFR *in medias res* and carry it forward to current exciting developments.

A short review of our line of research was presented in a symposium honoring *Sir Henry Wellcome*.[9] Several papers[10-12] tell the story of selectivity among 2,4-diaminopyrimidines from its first recognition before 1950 to its confirmation. Proof was developed through inhibitor analysis, sequencing, conformations, induced mitogenesis, computer-assisted conformation studies, and new syntheses based on this type of information.

The earliest proof of the mechanism of action of these compounds is illustrated in Figure 3.[13] The growth of *Streptococcus faecium* was easily inhibited by a diaminopyrimidine when the growth was induced by folate, but it took 500 to 1000 times as much inhibitor when tetrahydrofolate (H_4FA) was supplied. This was correctly interpreted as

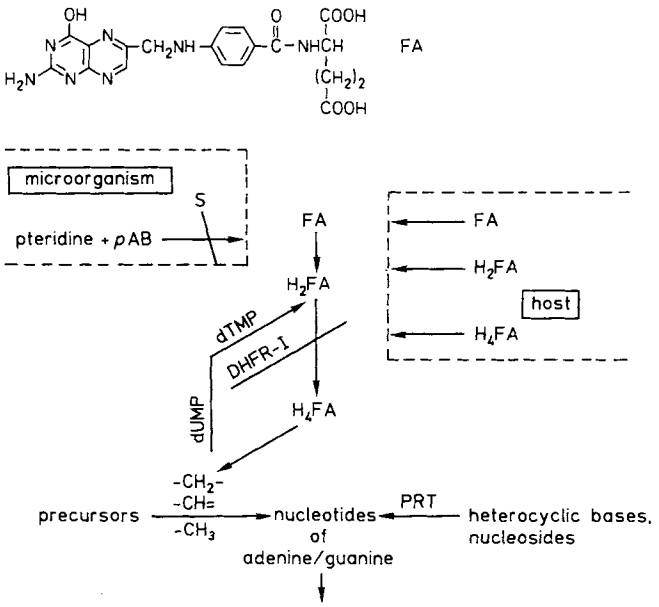

Fig. 2. Folate metabolism. Upper left shows biosynthesis in prokaryotes; upper right shows the uptake of preformed vitamin in mammals. The subsequent utilization for the biosynthesis of nucleic acid components is shown below. The importance of DHFR and the selectivity of its inhibitors takes a central place. FA = folate; H_2FA = dihydrofolate; H_4FA = tetrahydrofolate; dTMP = thymidylate; dUMP = deoxyuridylate; pAB = *p*-aminobenzoic acid; PRT = phosphoribosyl transferase [10].

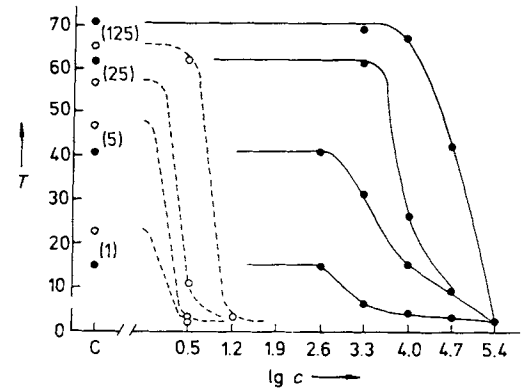

Fig. 3. The concentration (c in 10^{-9} g per 10 mL) of pyrimethamine (Pyr) required to inhibit growth of *Streptococcus faecium* depends on whether FA (○ – – – ○) or a form of H_4FA (●——●) is used in the medium [13]. T = turbidity.

inhibition of the yet unknown enzyme responsible for the reduction of folate to tetrahydrofolate.

By 1950 we had concluded that we were dealing with selective inhibitors of dihydrofolate reductase. From this work it appeared probable that details of fine structure in DHFR vary from species to species and that a given inhibitor may exhibit considerable selectivity as a result of looser or tighter binding to the corresponding enzyme of host or parasite.[14] The full structural analogue methotrexate (MTX) shows little selectivity, while pyrimethamine (Pyr) is highly active against the malarial enzyme and trimethoprim (Tmp) against a bacterial enzyme. Neither has notable toxicity against the rat liver enzyme.

Isolation and characterization of DHFR from various organisms led first to inhibitor analysis (Table 1). This documented unequivocally the different structures of representative dihydrofolate reductases from different sources. This

Table 1. The concentration ($IC_{50} \times 10^8$) of MTX, Pyr, or Tmp required to inhibit the DHFR derived from *E. coli*, rat liver, and *P. berghei* [9].

Inhibitor	Enzyme from		
	E. coli	Rat liver	*P. berghei*
MTX	0.1	0.2	0.07
Pyr	250	70	0.05
Tmp	0.5	3×10^3	7.0

was soon followed by amino acid analyses and sequence determinations.

Concomitantly developing knowledge of the roles of folate derivatives in biosyntheses and metabolism gave a fuller appreciation of the significance of inhibition of DHFR (Figs. 4, 5). The activity of the enzyme is necessary to pro-

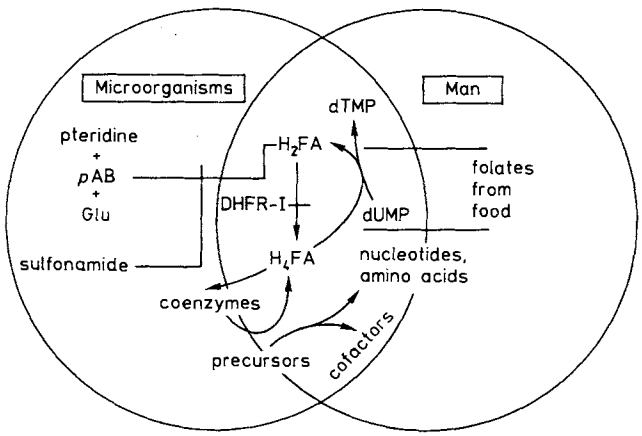

Fig. 4. The metabolic reactions catalyzed by derivatives of H_4FA. GLU = glutamate [12].

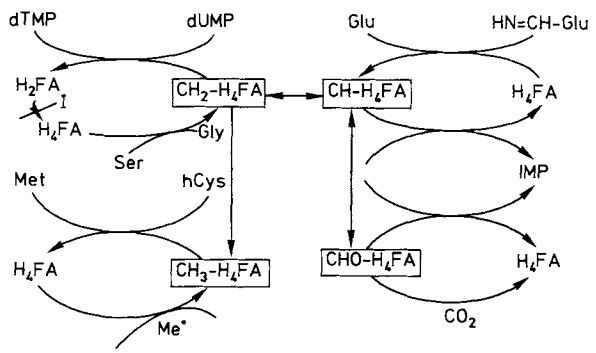

Fig. 5. Details of reactions of specific folate-containing cofactors. Counterclockwise: N^{10}-formyl, N^5,N^{10}-methenyl, methylene, and N^5-methyl tetrahydrofolates. Ser = serine; Met = methionine; IMP = inosinic acid [12].

duce H_4FA initially and to recycle it after its reoxidation in the formation of thymidylate from deoxyuridylate.

Amino acid sequence determinations brought out a full appreciation of the high variability of the basic constituents of this enzyme in a range of species.[15] Between the enzymes of two bacterial species there is only 30 percent homology, and between prokaryotes and eukaryotes only 30 percent. It is only the higher species that exhibit as much as 90 percent homology. *Hitchings* and *Roth* found 16 identities between the enzymes from *Escherichia coli* and those from the mouse tumor L1210.[12] They predicted correctly that study of a wider range of enzymes would reduce the number of identi-

ties. If one takes into account enzymes not in the mainstream, for example, those from protozoa plasmids, the number is even smaller.

The mainstream enzymes (from bacterial and mammalian sources) have similar conformations. That published by *Richardson*[16] may be regarded as the representative type (Fig. 6). Although mammalian enzymes are larger than this

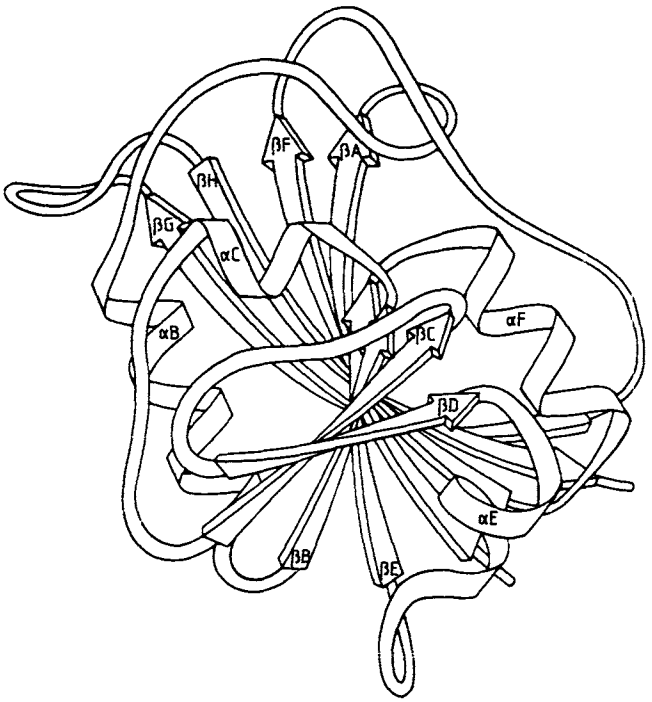

Fig. 6. A graphic illustration of the configuration of DHFR [16].

bacterial enzyme by some 3000 daltons, the extra residues exist as loops that do not greatly alter the main conformation. On the other hand, the enzymes from other types of organism can be so different as to raise doubts about whether they are intrinsically dihydrofolate reductases, or whether their DHFR activity is secondary to some other unknown function (cf. *Matthews* et al.[17]). Figure 7[18] shows some possible origins of Type II DHFR.

If its normal function is:

To reduce H_2FA	To reduce/oxidize other compounds
1. Other intestinal coliforms	1. Pteridine/flavin
2. T4 phage	2. Nonspecific dehydrogenases
3. Anaerobes	
4. Fungi (yeasts)	
5. Protozoa	

Fig. 7. Possible origins of untypical dehydrofolate reductases (DHFR II) [18].

Uses of DHFR Inhibitors

Synergistic Combinations

It is pertinent at this point to refer to some of the applications of selective inhibitors of DHFR. An important application is, of course, the use of co-trimoxazole as an antibacterial. Its creation derived from the knowledge that in combining trimethoprim with sulfamethoxazole, one was creating a sequential blockade of a major biosynthetic pathway in a bacterium or in other prokaryotes (Table 2). The minimal

Table 2. Effect on minimal inhibitory concentration (MIC) of combining one part Tmp with 20 parts sulfamethoxazole [19].

Organism	MIC [μg mL^{-1}] of			
	Sulfamethoxazole		Tmp	
	Alone	Mixture	Alone	Mixture
Streptococcus pyogenes	> 100	1	1	0.05
Streptococcus pneumoniae	30	2	2	0.1
Staphylococcus aureus	3	0.3	1	0.015
Haemophilus influenzae	10	0.3	1	0.015
Bordetella pertussis	50	4	3	0.2
Klebsiella pneumoniae	> 100	4	1	0.2
Klebsiella aerogenes	> 100	4	1	0.2
Escherichia coli	3	1	0.3	0.05
Salmonella typhimurium	10	1	0.3	0.05
Shigella sonnei	10	1	0.3	0.05
Proteus vulgaris	30	3	3	0.15

effects on the host reflect the absence in eukaryotes of the reactions leading to the biosynthesis of dihydrofolate such as occurs in prokaryotic cells.

The strong potentiation that occurs is indicated by the data of Table 2,[19] which show that minimum inhibitory concentrations of one component may be reduced as much as 10- or 20-fold when the second component is also present. Moreover, the combination may be effective against organisms that would not be inhibited by the individual drugs (e.g., *Klebsiella sp.* and *Streptococcus* Group C), where the individual inhibitory concentrations would be borderline or unattainable.

One further illustration of the possible utility of biochemically related inhibitors is given in Figure 8,[20] where the

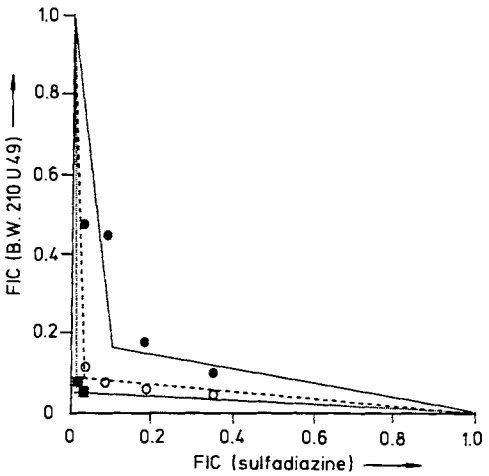

Fig. 8. Fractional inhibitory concentrations (FIC) of B.W. 210U49 and sulfadiazine required for 50 percent inhibition of *P. vulgaris* in the presence and absence of 8-azaguanine: ●—●, no 8-azaguanine; o - - - o, 1 μg mL^{-1}; ■—■, 10 μg mL^{-1} [20].

addition of 8-azaguanine to an already potentiative combination of diaveridine (B.W. 210U49) with sulfadiazine enhances the potency. Such biochemically oriented triple combinations have not been used in a major way, but their potential remains exploitable.

I should like to focus now on the uses of individual DHFR inhibitors.

Trimethoprim and Its Derivatives

Chronologically first, and perhaps still first in importance in cancer chemotherapy, is methotrexate (MTX) from the Lederle Laboratories. Methotrexate had assumed a role in the therapy of acute leukemia as early as 1948[21] and is still of major interest today. As shown in Figure 2, however, it is relatively unselective. Its therapeutic utility depends mainly on differences in uptake, glutamylation, cellular excretion, cellular metabolic balance, and other factors.

Whereas MTX is a close structural analogue of folate, our own "antifols" were significantly different and highly selective. These facts will be brought out by examination of details of the structures and active centers of several enzymes.

For example, the fine structure of the complex of MTX and cofactor in *L. casei* DHFR (Fig. 9)[22] may be contrast-

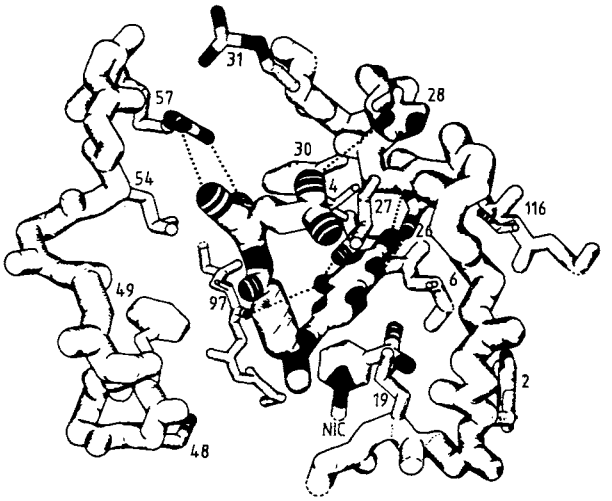

Fig. 9. Schematic illustration of the active site of *L. casei* DHFR showing the binding of MTX and nicotinamide adenine dinucleotide phosphonate [22].

ed with that of Tmp and cofactor in the chicken liver enzyme (Fig. 10).[23] It is obvious that the MTX molecule is much more space-filling than Tmp. Such contrasts are observable in all situations where the small-molecule inhibitors are observed, and the contrasts in the active centers of the enzymes are consistent with the selectivities of the small-molecule inhibitors.

There have been a number of studies of the functions of specific amino acid residues. One of the most cogent was reported by *Kraut* et al.[24] in a paper that combined several experiments. In this study of the *E. coli* enzyme, the replacement of aspartate by asparagine reduced activity to 0.1 % of that of the unaltered enzyme, showing the importance of the ionizable carboxyl group (Fig. 11). The substitution of alanyl for glycyl completely inactivated the enzyme, probably by distorting its conformation. However, substitution of SH for OH (cysteine for serine) had little effect. This type of experiment may provide the background for the synthesis of new and useful inhibitors.

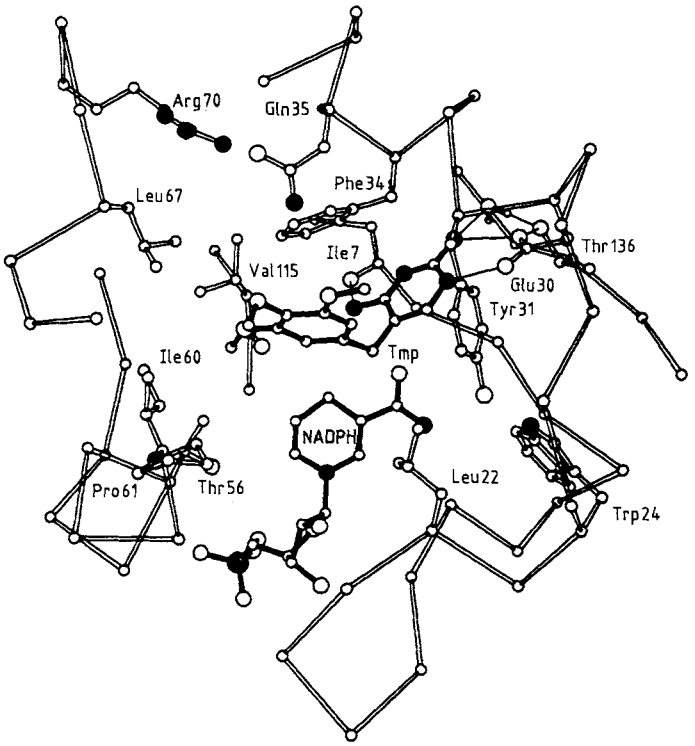

Fig. 10. Schematic illustration of the cofactor in chicken liver DHFR showing the binding of Tmp and nicotinamide adenine dinucleotide phosphonate [23].

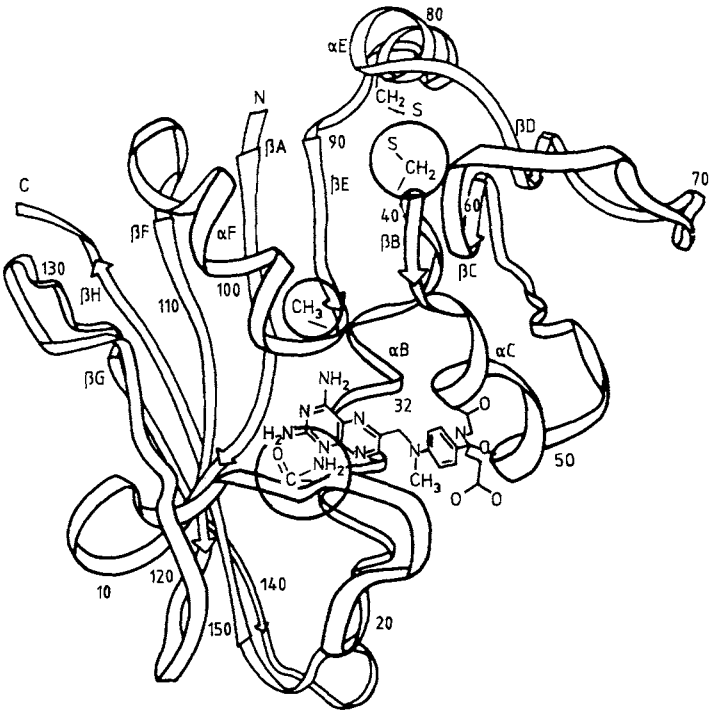

Fig. 11. *E. coli* DHFR with induced specific mutations [24].

An aspect of folate metabolism that appeared relatively late is the identification of the high-molecular-weight derivatives of folic acid as polyglutamates. Since the chain length of most of these exceeds that of the longest form that can be transported into the cell efficiently, most cells contain a pteroylpolyglutamate synthetase. The number of glutamyl residues varies with time and with cell type. The immense

complexities of this situation are only beginning to appear. Nevertheless, it is interesting and instructive to compare the binding constants and kinetic values of polyglutamates in some of the enzymatic reactions involved in folate metabolism (Table 3).[25]

Table 3. Comparison of binding constants (K_m) and kinetic values of polyglutamates in enzymatic reactions in folate metabolism. TS = thymidylate synthase; AICAR TF = AICAR transformylase; GAR TF = GAR transformylase [25].

Enzyme	n	$n/1$	
		K_m	v_{max}
DHFR	5	1	–
Serin-$HOCH_2$-transferase	5	0.0025	–
N^5,N^{10}-CH_2-H_4FA-dehydrogenase	3	< 1	1.7
N^{10}-CHO-H_4FA-synthetase	3	0.01	0.5
N^{10}-CHO-H_4FA-synthetase	5	0.001	0.25
N^5,N^{10}-CH-H_4FA-cyclohydrolase	5	0.5	1.5
T_aS_α	3	0.2	–
T_aS_α	5	0.014	3
AICAR-TF	3	0.01	1
GAR-TF	3	0.8	5

The inhibitor MTX, as well as the tetrahydrofolate, is subject to polyglutamylation. In many cases the ratio of folate polyglutamate to inhibitor polyglutamate is not markedly changed, but it is predictable that among the vast number of possibilities some of the anomalies and some of the therapeutic indices will find solid explanations. A few of the effects of glutamylation on specific biosynthetic enzymes are shown in Table 4.[26]

Table 4. The effect of pentaglutamylation on the binding of MTX to specific tetrahydrofolate-utilizing synthetic enzymes [26].

Enzyme	Folate cofactor	K_i [μM]		K_i(MTX) / K_i(MTX-Glu_5)
		MTX	MTX-Glu_5	
TS	N^5,N^{10}-CH_2-H_4PteGlu$_1$	13.0	0.047	277
	N^5,N^{10}-CH_2-H_4PteGlu$_5$	14.3	0.056	254
AICAR-TF	N^{10}-CHO-H_4PteGlu$_1$	143.9	0.057	2508
	N^{10}-CHO-H_4PteGlu$_5$	40.0	5.89	6.8
GAR-TF	N^{10}-CHO-H_4PteGlu$_1$	80	2.5	32
	N^{10}-CHO-H_4PteGlu$_5$	84	22.0	4

I wish to turn now to the intimate details of the structure of specific enzymes and their exploitation in the synthesis of more active inhibitors. Figure 12[27] shows the fit of Tmp in the DHFR of *E. coli*. In the upper left (residue 57), one can see the guanidino group of arginine. This was exploited by *Lee Kuyper* who replaced the *m*-methoxyl group of Tmp with a series of carboxyalkoxy radicals. The optimum length proved to be five carbon atoms, and the product, the carboxyl amyloxy derivative, bound the enzyme some 50 times more tightly than did Tmp.[28] In the same vein, *Barbara Roth* synthesized a bromoacetoxyphenoxy analogue of Tmp and found that the derivative bound to the histidine-22 residue of the enzyme with a covalent linkage.[29] These examples may be regarded as probes of a vast and exciting future.

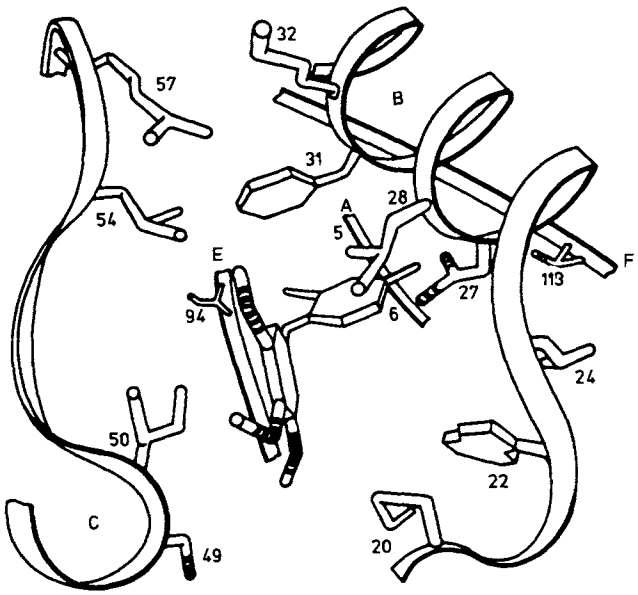

Fig. 12. Fit of trimethoprim (center) in the DHFR of *E. coli* [27].

Lipophilic DHFR Inhibitors

Multiple forms of resistance to antifols appeared soon after work on these inhibitors began. Among these various expressions of resistance (Fig. 13) was a loss of the cellular

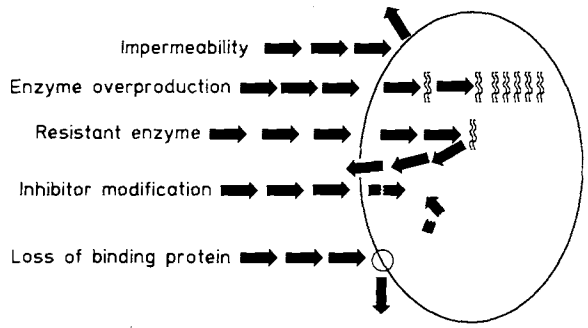

Fig. 13. Mechanisms of resistance to inhibitors of DHFR [18].

transport mechanism, which has stimulated the investigation of lipophilic inhibitors that do not depend on this mechanism for transport into the cell. At present the two potentially useful drugs are trimetrexate and piritrexim (Fig. 14). Exploitation of these inhibitors is in its infancy, but each has exhibited interesting properties of its own. The effects of trimetrexate and MTX are compared in Table 5.[30] Both trimetrexate and piritrexim have shown interesting activities

Inhibitors of other Enzymes

Finally to be mentioned is a selective inhibitor of thymidylate synthase (TS) (Fig. 15). The first of these is 5,8-dideazaisopteroylglutamate (IAHQ) (Fig. 16). IAHQ and specific inhibitors of other biosynthetic reactions involving tetrahydrofolate represent the beginning of a biochemically oriented, improved cancer chemotherapy.[33]

Outlook

I am incredibly blessed to have been involved for well over four decades in a field that continues to become more exciting with every passing year. Figure 17[34] charts the history

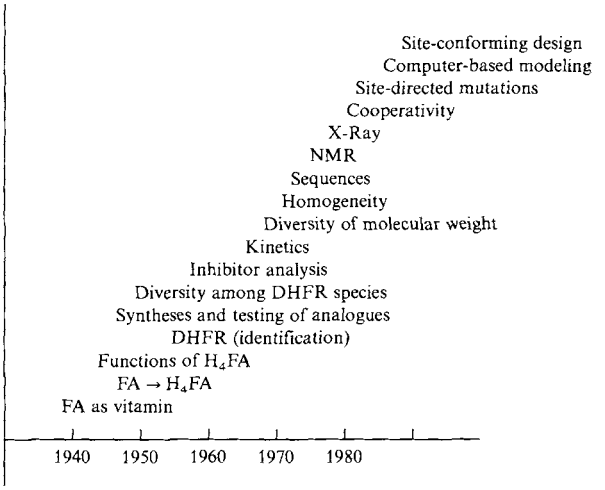

Fig. 17. Accrual of information about DHFR, beginning with untargeted studies in the 1940s and continuing in the 1980s with discovery of new useful compounds and methods of drugs design [34]. The ordinate is a measure of utility in synthetic design.

of increasing knowledge concerning dihydrofolate reductase, beginning with our work in the 1940s. Those early, untargeted studies led to the development of useful drugs for a wide variety of diseases (Fig. 18) and has justified our belief

that this approach to drug discovery is more fruitful than narrow targeting. In 1988 this line of research continues to generate useful new compounds.

I should like to close with a quotation from one of my own papers:[35]

To the biochemical chemotherapist, it is not only a matter of faith, but an obvious fact, that every cell type must have a characteristic biochemical pattern, and therefore be susceptible to attack at some *locus* or *loci* critical for its survival and replication.

I am greatly indebted to Mara Gabriel and Coyla Barry for skillful and energetic work that made completion of this paper possible.

Drugs from Emasculated Hormones: The Principle of Syntopic Antagonism (Nobel Lecture)**

By Sir James W. Black*

In this lecture I want to give an outline of the early stages in the discovery of adrenaline β-receptor antagonists and of the histamine H_2-receptor antagonists. I will end with a brief personal view about future research.

Adrenaline β-Receptor Antagonists

The work that is the theme of this lecture began in the early summer of 1958 when I joined Imperial Chemical Industries' Pharmaceuticals Division. I had gone there to pursue a very clear project that had been developing in my mind for several years. The idea had clinical, therapeutic, physiological, and pharmacological elements.

Clinically, angina pectoris was known to be precipitated by anxiety and emotion just as well as by exercise. Indeed, the initiation of pain by an injection of adrenaline had been used as a diagnostic test. Partial thyroidectomy had been found to relieve severe angina pectoris whether or not associated with hyperthyroidism. At that time, tachycardia seemed to me to be the connecting link in these disorders.

Therapeutically, nitroglycerine could quickly relieve and attack of angina. Nitroglycerine also produced facial flush and headache. The relief of angina was attributed to similar vasodilatation in the coronary arteries. However, the newer, synthetic, selective coronary vasodilators, such as dipyridamole, were clinically ineffective despite the enhanced coronary artery dilatation that they provided. Here was a question mark against the widely practiced industrial strategy of seeking better drugs to increase coronary blood flow for angina.

Physiologically, Smith and *Lawson*[1] had found that hyperbaric oxygen, at two atmospheres pressure, reduced the incidence of ventricular fibrillation associated with occlusion of a coronary artery, even though the oxygen-carrying capacity of the blood had increased by a maximum of only 25%. Might not an equivalently small *decrease* in the myocardial demand for oxygen be just as effective? That was my question.

Myocardial oxygen consumption is determined by the work of the heart and is a function of arterial blood pressure and heart rate. Lowering blood pressure by systemic vasodilatation might dangerously reduce the perfusion pressure and blood flow through disease-narrowed coronary arteries. Indeed, hypotension was known to be able to induce a heart attack. Heart rate, on the other hand, is largely determined by the cardiac autonomic nervous system. Heart rate would thus be reduced by cardiac sympathetic blockade. In addition, there was much discussion in those days about a postulated "anoxiating" action of adrenaline, proposing that the price of rapidly increasing cardiac power was a decrease in cardiac metabolic efficiency.

These clinical, therapeutic, and physiological features of hearts coping with coronary artery disease all seemed to point to the potential advantage of annulling the actions of the sympathetic hormones, noradrenaline and adrenaline, on the heart.

Pharmacologically, the antiadrenaline drugs were a well-recognized class in 1958. All of them showed a pattern of actions similar to those seen by *Dale*[2] with the ergot alkaloids. Characteristically, they reversed the blood pressure rise produced by adrenaline to a fall in pressure, but they did not suppress the associated tachycardia. *Konzett*[3] had shown that isoprenaline, the purely synthetic isopropyl derivative of noradrenaline, produced only the actions such as tachycardia, vasodilatation, and bronchodilatation which the antiadrenaline drugs were not able to suppress. These were the actions of isoprenaline that *Ahlquist*[4] could not explain on the basis of *Cannon* and *Rosenbleuth*'s prevailing hypothesis involving sympathins E and I.[5] *Ahlquist* went on to propose that the wide-spread physiological effects of adrenaline were mediated by two classes of receptors, α and β. In this new classification, the antiadrenaline drugs of the day were α-receptor antagonists and isoprenaline was a selective stimulant of β-receptors.

So I started at I.C.I. with a clear goal – I wanted to find a β-receptor antagonist. I expected this to reduce pulse rates at rest and during exercise and hoped that it would decrease the susceptibility of patients to angina pectoris. The unknown factor for me at that time was the significance of adrenaline's "anoxiating" activity.

John Stephenson was the medicinal chemist assigned to work with me. As no compounds were known to annul the actions of adrenaline on the heart, the program had to be cold-started. The structure of isoprenaline (Fig. 1), the selective β-receptor stimulant, was our only clue. We thought that if N-substitution of adrenaline with an isopropyl group produced a selective *agonist*, then perhaps substitution with a different, larger group might produce a selective *antagonist.* We thought that symmetrical, "doubled-up" analogues of isoprenaline, dibenzylethylamines, might be interesting targets.

We were making compounds and testing them, admittedly without success, when, early in 1959, we read *Powell* and *Slater*'s report[6] about the properties of dichloroisoprenaline (DCI), an analogue of isoprenaline in which the ring hydroxyl groups were replaced by chlorine atoms (Fig. 1). In trying to exploit the bronchodilator properties of isoprenaline by making a long-acting variant, the Lilly group had discovered a compound that intrigued them by displaying – instead of isoprenaline's bronchodilator activity – the

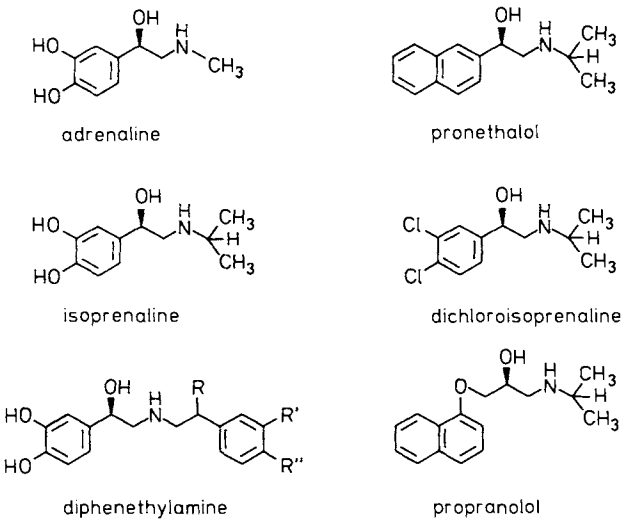

Fig. 1. Chemical structures of adrenaline-related compounds.

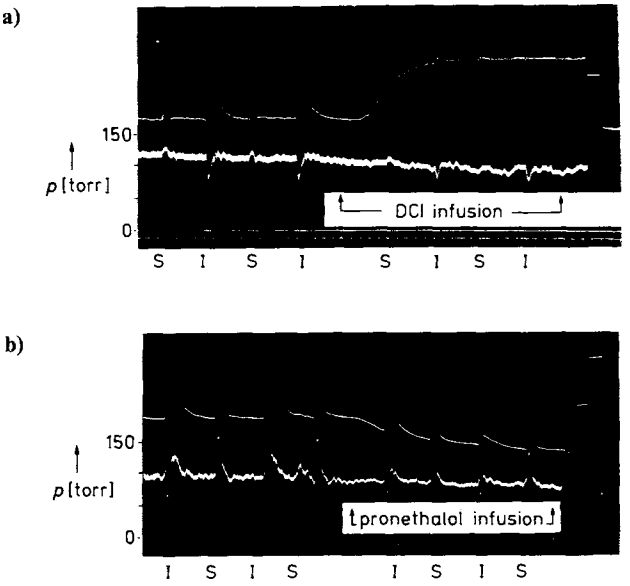

Fig. 2. Effects of a) DCI (100 μg kg^{-1} min^{-1}) and b) pronethalol (100 μg kg^{-1} min^{-1}) infusion upon heart rate and blood pressure responses to injections of isoprenaline (I) (0.4 μg kg^{-1} i.v.) and to sympathetic stimulation (S) (square wave pulses, 10-ms duration, 2.5 V, 15 pulses per second for 30 s) in anesthetized cats. Lower axis shows time markers in one-minute intervals.

opposite property, namely antagonism. Soon afterwards, *Moran* and *Perkins*[7] reported that DCI could annul the inotropic effects of adrenaline on the heart and classified DCI as a β-receptor antagonist. *Stephenson* immediately made some DCI for us to test.

We had started our bioassays using the classical Langendorff preparation, the isolated, spontaneously beating, guinea-pig heart. Isoprenaline is a powerful stimulant of both the rate and force of beating in this preparation, but we measured the amplitude of contractions, which compounded both changes. In this system DCI turned out to be as powerful a stimulant as isoprenaline and so was not at all what we were looking for. We had also developed a technique for simultaneously recording blood pressure and heart rate, in analogue form, in anesthetized animals. Potential antagonists could now be given economically by slow intravenous infusion, and this allowed the effect on a wide range of systems to be monitored. Here, too, the powerful stimulant effects of DCI on heart rate were clearly seen, although there was less hypotension due to vasodilatation than we had expected (Fig. 2). On the basis of these experiments, we decided that DCI was not the lead we needed.

As analytical pharmacologists, what we are allowed to see of a new molecule's properties is totally dependent on the techniques of bioassay we use. The prismatic qualities of an assay distort our view in obscure ways and degrees. Our only defense lies in restless improvement in technique and experimental design, in the hope that collimation of several techniques will improve the reliability of our vision. We would make the change self-consciously today, but then it was intuitive.

We developed a new in vitro assay based on guinea-pig cardiac papillary muscles as a way of measuring the contractile effects of isoprenaline independently of rate changes. Then, we reassessed many early compounds, including DCI. On the new preparation, DCI had no stimulant activities itself but simply antagonized the effects of adrenaline and isoprenaline, although the stimulant activity on pacemaker tissue could be clearly seen in the atrial preparation. We were astonished. Today, we classify DCI as a partial agonist. *Ariens*[8] and *R. P. Stephenson*[9] had introduced the concept of partial agonists a few years earlier but nothing in their writing, as far as I recall, alerted us to expect that the agonist activity of these compounds could be so tissue dependent.

I shall never forget *John Stephenson*'s reaction to this discovery: "We'll make the naphthyl analogue of isoprenaline" (Fig. 1).[35] He had realized immediately that while a fused benzene ring would have similar steric and electronic properties to the two chlorine atoms, there was also the possible advantage of extended π bonding. Compound ICI 38174—nicknamed nethalide for a time, but finally christened pronethalol (Fig. 1)—was conceived in excitement and thrilled us at its birth. Pronethalol was an antagonist without any sign of agonist activity in both atrial and ventricular tissues. In anesthetized animals, pronethalol reduced the resting heart rate and depressed the increments from isoprenaline or stimulation of cardiac sympathetic nerves (Fig. 2b).

Having got over the first hurdle much more easily than I had dared to imagine, I was impatient to tackle the next one. How would someone, restricted by β-receptor blockade, cope with a surge of adrenaline or a burst of exercise? I had always imagined that the combination of *Starling*'s "Law of the Heart" and the buffering capacity of the arterio-venous oxygen difference ought to be able to take up the slack of a reduction in cardiac output. We had developed the noninvasive technique of acceleration ballistocardiography to estimate the force of cardiac contractions in anesthetized dogs (Fig. 3). Adrenaline increased heart rate, aortic blood pressure, and force of contractions. After pronethalol, heart rate and force were reduced and the effects of adrenaline were abolished. However, the vasodilator effects of adrenaline were also blocked, thus exposing the heart to a vasoconstrictor load mediated by the unblocked α-receptors. The heart was able to maintain its output and produced an enhanced rise in blood pressure. This was the experiment that convinced me that the new compound might be more than a laboratory curiosity. In fact, I did notice in these early exper-

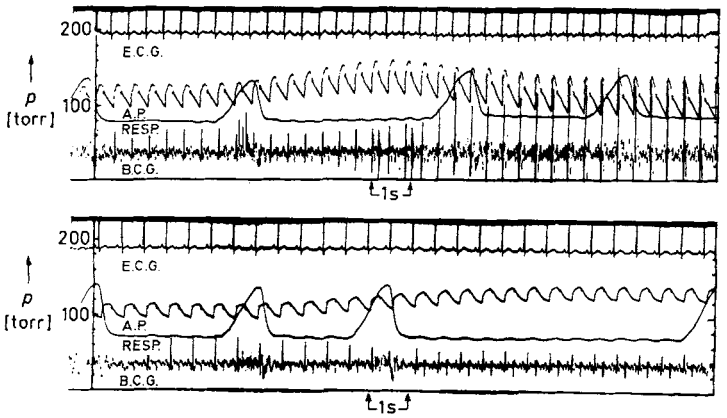

Fig. 3. Cardiac and respiratory responses to adrenaline (1 μg kg^{-1} i.v.) in anesthetized dogs. Top: Before addition of pronethalol. Bottom: 15 minutes after addition of pronethalol. The arrow indicates when adrenaline was administered. E.C.G., electrocardiogram; A.P., aortic blood pressure; RESP, respiration; B.C.G., ballistocardiogram.

iments that the cardiac ballistic action was reduced under load. I noticed also that the time taken from ventricular excitation to the opening of the aortic valves – that is, from the R-wave to the upstroke of aortic pressure – was increased under load. These were tell-tale signs that the cardiac reserve was reduced, but I persuaded myself at the time that this was a reasonable price to pay for the possibility of increasing the work capacity of a heart with restricted coronary flow.

The early clinical studies seemed to confirm that judgment. *Dornhorst* and *Robinson*[10] studied the interaction between pronethalol and isoprenaline in healthy volunteers. Isoprenaline, infused into the brachial artery, produced a large increase in forearm blood flow. However, when repeated after an intraarterial infusion of pronethalol, the first route of administration into man, the vasodilator effect was abolished. Isoprenaline given by slow intravenous infusion increased heart rate, respiratory amplitude, arterial pulse pressures, and forearm blood flow. The subjects in these studies often seemed to get a fear of impending doom and became visibly restless. After pronethalol, all of these effects of isoprenaline were suppressed (Fig. 4). By chance, an athlete and a loafer were the first pair to do maximal exercise after pronethalol. Compared to the control run, the athlete's heart rate at rest and exercise were little changed and his capacity to work was reduced. The loafer's heart rate was substantially reduced by pronethalol at rest and during exercise. He was less distressed by his lower heart rate. The potential benefits of β-adrenoceptor blockade for people with embarrassed hearts was also seen in the first patient with angina of effort. After administration of pronethalol, he was able to do more work before the onset of pain forced him to stop when his heart rate had eventually reached the same level as in the control run (Fig. 5).

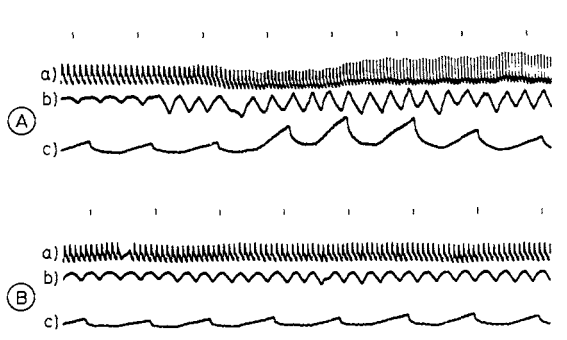

Fig. 4. Effects of intravenous infusion of isoprenaline (10 μg min^{-1}), before Ⓐ and after Ⓑ intravenous infusion of pronethalol (110 mg) on arterial blood pressure (a), respiration (b), and forearm blood flow (c) in a healthy volunteer (reproduced by kind permission from [10]). Time intervals: 10 sec.

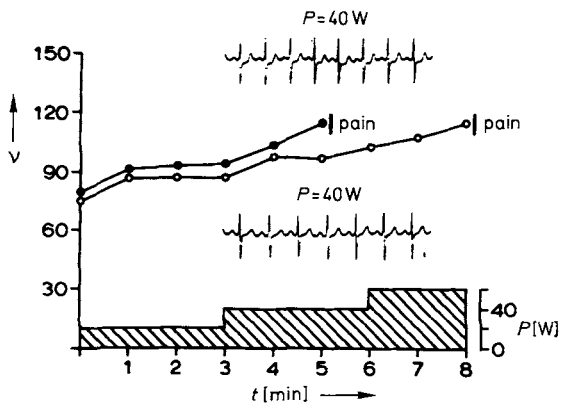

Fig. 5. Effect of pronethalol (250 mg p.o.) on time taken and work exerted before the onset of chest pain in a patient with angina pectoris performing graded exercise on a bicycle. Inserts show the ECG before (top) and after (bottom) administration of pronethalol (reproduced by kind permission from [10]). •, without pronethalol; o, with pronethalol. v = pulse rate.

Pronethalol always seemed to us to be a prototype drug, good enough to answer questions of principle but not good enough to be marketable. So a large chemical group, directed by *Crowther*,[11] was assembled to try to find a more active, safer replacement for pronethalol. The discovery of ICI 45520, propranolol, a naphthyloxy propanolamine derivative, was the result (Fig. 1).

Our bioassays, which had been developed as qualitative screens, had now to be adapted for comparative quantitative bioassay. The isolated, spontaneously beating, guinea-pig right atrial preparation proved to be excellent for these assays. The nature of the surmountable antagonism by propranolol was analyzed by relating the rightward displacement of cumulatively derived dose–response curves to the concentration of antagonist.[34] The linearity and slope of the Schild plot relating these variables indicated the likelihood that adrenaline and propranolol were competing for the same sites. This is the evidence that propranolol can be classified as a *syntopic* antagonist to the native hormones which activate β-adrenoceptors. Note here that I follow *A. J. Clark*[12] in using the term "hormone" very broadly: when one cell secretes a chemical to which another responds physiologically, I define that chemical as a hormone.

Histamine H_2-Receptor Antagonists

In 1964, I went to Smith, Kline & French Laboratories Ltd. to pursue another project that I had been thinking about for some time. Again, the idea had clinical, therapeutic, physiological, and pharmacological implications.

The *clinical* problem was gastric and duodenal ulcers. I had thought a lot about the problem when I worked with

Adam Smith on the effects of 5-hydroxytryptamine on gastric secretion.[13] The immediate cause of ulceration was recognized to be hypersecretion of acid but the nature of the driving stimulus was unknown. The one clear fact was that patients with duodenal ulcers gave an exaggerated secretory response to histamine, the basis of a diagnostic test.

The *therapeutic* problem was that only surgical intervention, partial gastrectomy in those days, was recognized to be effective. The potential value of anticholinergic drugs, like atropine, was obscured by unacceptable side effects. Antacids could be shown to promote ulcer healing but only with clinically unacceptable regimens.

The *physiological* problem was the relationship between gastrin and histamine, both of them powerful stimulants of acid secretion and both synthesized in the mucous membrane of the stomach. *MacIntosh*[14] had proposed that histamine was the final stimulant of secretion when the vagus was stimulated and *Code*,[15] as well as *Kahlson* and *Rosengren*,[16] had extended that idea to gastrin as well, making histamine the *final* common chemostimulant. Mainstream thinking in gastroenterology, however, regarded gastrin as the *direct* hormone of secretion in its own right; thus, the question of the function of histamine in the stomach was unsettled.[17]

The *pharmacological* problem was the selective blocking properties of the antihistamines.[18] The available antihistamines were a diverse group, chemically unrelated to histamine and reminiscent in this respect of the class of adrenaline α-receptor antagonists. They were powerful inhibitors of histamine-induced visceral muscle contractions but had no effect at all against histamine-induced acid secretion, uterine relaxation, or cardiac stimulation. Other effects of histamine, such as vasodilatation, were well known to be insensitive to the antihistamines. The parallels with the spectrum of activity of the antiadrenalines seemed obvious.

In 1964, I had no doubts that histamine had its "β-receptors" and that a new type of selective histamine antagonist could be found. Ambiguity about the physiological role of histamine in acid secretion left me unsure about the clinical value of such drugs. At the very least, however, I expected to answer the physiological question of the gastrin–histamine connection.

The bioassay systems were easily selected. For in vitro assays, guinea-pig ileal muscle was the classical system for studying antihistamines such as mepyramine. Guinea-pig atrial tissue looked like a good assay for mepyramine-refractory histamine responses. The assay for acid secretion was harder to choose. No in vitro assays were available at that time. We chose the Ghosh and Schild method[19] of lumen perfusion of the stomach of anesthetized rats, but the method worked reliably only after it had been substantially modified by *Parsons*, my new colleague.[20]

The chemical program, from the start, concentrated on making analogues and derivatives of histamine. As the whole project was conceived by analogy with the adrenaline β-receptor story, I was particularly anxious to concentrate on varying the imidazole-ring end of histamine. Some of the early ring-substituted compounds turned out to be very important (Fig. 6).[21] Methyl substitution on either of the ring nitrogens produced inactive compounds. Methyl substitution on the 2-position gave compounds that were less active

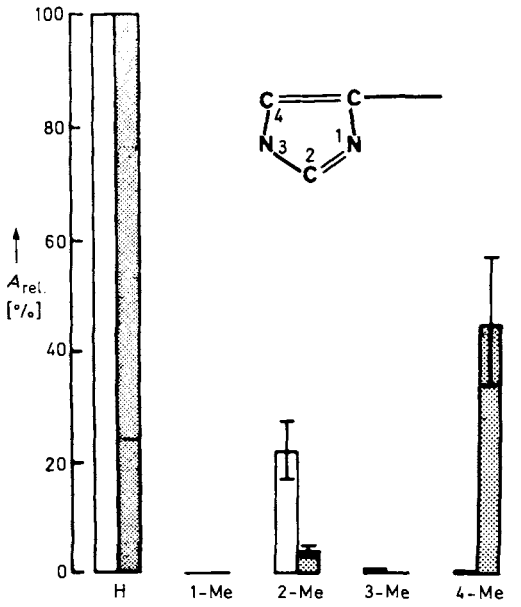

Fig. 6. Selectivity of histamine (H) and several methyl-substituted analogues in the guinea-pig ileum (histamine H_1-receptor assay, □) and right atrium (histamine H_2-receptor assay, ⊠). Activity values, relative to histamine (A_{rel}), were calculated from parallel line assays. Error bars show 95% confidence limits.

than histamine itself but nevertheless showed a clear preference for the ileal assay. However, 4-methylhistamine was exciting for me. Nearly half as active as histamine on the atrial assay, 4-methylhistamine was practically inactive on the ileal assay. We were able to confirm this selectivity in vivo (Fig. 7). In the anesthetized rat preparation, an injection of

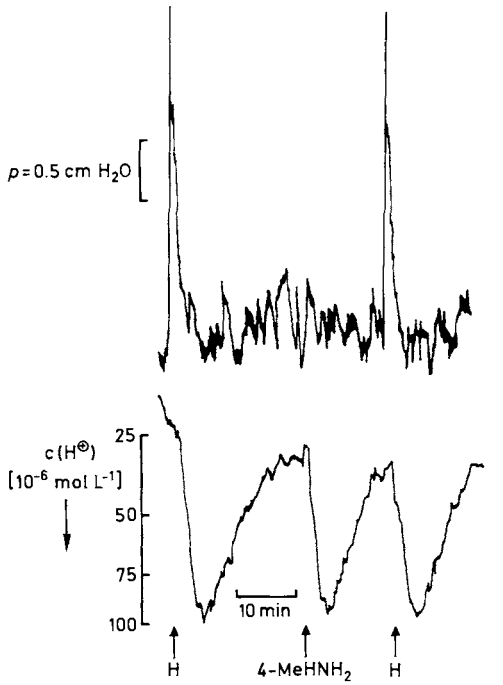

Fig. 7. Effects of intravenous bolus injections of histamine (H, 2 μg kg^{-1}) and 4-methylhistamine (4-$MeHNH_2$, 5 μg kg^{-1}) on secretion of gastric acid (bottom) and stomach wall contraction (top) in an anesthetized rat. c = concentration, p = pressure.

histamine produced a fast, spasmodic contraction of the stomach wall followed by a phasic burst of acid secretion; 4-methylhistamine produced an equivalent output of acid without any muscle contractions. Thus, 4-methylhistamine

was a selective agonist analogous to isoprenaline at adrenergic receptors. This result was the compelling clue which kept us going through several lean years of negative screening.

This observation assumed even greater importance when we compared 4-methylhistamine and 2-methylhistamine with the 1,2,4-triazole analogue of histamine. Using a number of additional assays, both in vitro and in vivo, we found that the triazole analogue was clearly nonselective, whereas 2-methylhistamine was selective for the mepryamine-sensitive responses and 4-methylhistamine was selective for the refractory responses (Fig. 8). When *Ash* and *Schild* proposed

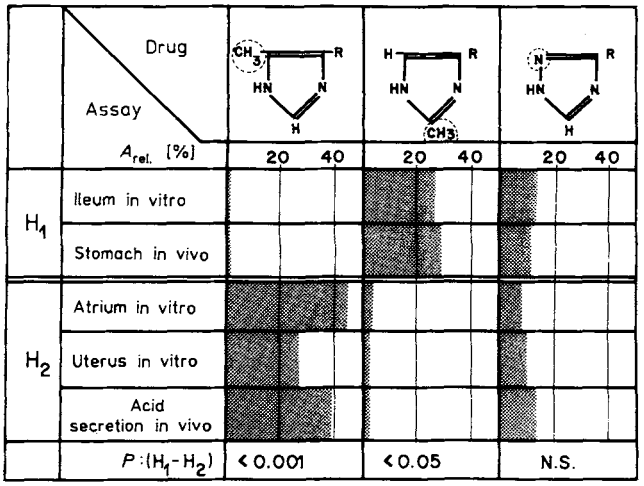

Fig. 8. Selectivity of 2-methylhistamine, 4-methylhistamine, and 1,2,4-triazole analogue of histamine in several in vitro and in vivo, histamine H_1- and H_2-receptor assays. The activity relative to histamine (A_{rel} was calculated from parallel line assays. p (H_1-H_2) = probability value for the difference between H_1 and H_2 results.

in 1966 that the mepyramine-sensitive histamine receptors should be classified as H_1,[22] we used this pattern of bioassay results to argue for the homogeneity of a non-H_1 class of histamine receptor.

A very large number of compounds were made, predominantly ring substitutions and fused-ring heterocycles, all of them inactive. I vividly remember wondering suddenly if the strategy was all wrong. Perhaps we should have spent more time exploring the role of the side-chain amino group. On this suggestion, *Parsons* quickly scanned through the earlier compounds looking for examples of side-chain variations. He came up with N^{α}-guanylhistamine (Fig. 9). This compound was one of the earliest we had tested and had proved to be quite a potent agonist when injected, like histamine, intravenously. However, over the years we had changed the design of the screening assay. A continuous intravenous infusion of histamine was used to produce a stable background of near-maximal acid secretion. A new compound could now be quickly screened by giving a succession of increasing doses intravenously. Even antagonism of very short duration would be detectable. In the new experimental design, the guanidino analogue of histamine now exhibited a small degree of inhibition, about 5% reduction. There it was – a partial agonist! Guanylhistamine on histamine receptors was the analogue of DCI on β-adrenoceptors. However, unlike DCI, the efficacy of histamine had been reduced by modifying the side-chain rather than the ring system.

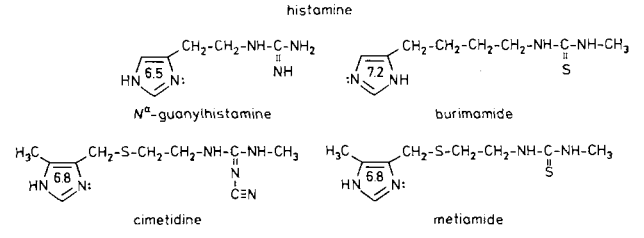

Fig. 9. Chemical structures of histamine-related imidazoles. The numbers inside the rings are pK_a values.

This was the lead that *Ganellin* and his colleagues in chemistry had been waiting for. In one of the early analogues, IPG, the length of the side chain was simply increased from ethyl to propyl. In the rat stomach assay this compound showed good antagonism of histamine without much agonist activity of its own. However, in other species, particularly cat and dog, the compound was nearly a full agonist. Similarly, in the isolated guinea-pig atrial preparation, although much less potent than histamine, the compound achieved a maximum response of about 80% of the histamine maximum. The true nature of this partial agonism could be seen by repeating the dose–response curve in the presence of a nearly maximal concentration of histamine. Only *antagonism* was now seen with the maximum inhibition, about 20%, being equal to the agonist maximum (Fig. 10).

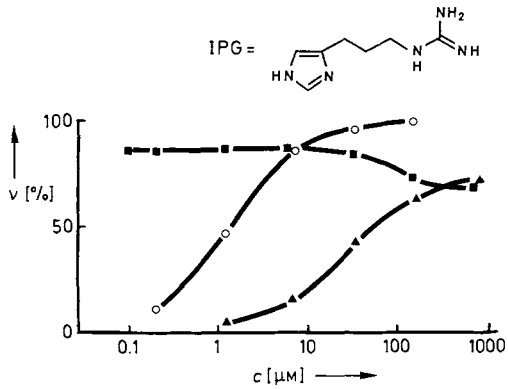

Fig. 10. Effects of cumulative additions of histamine (○), imidazolylpropylguanidine (IPG, ▲), and IPG in the presence of 10 μM histamine (■) on the pacemaker frequency (ν) of the isolated guinea-pig right atrium. Error bars have been removed for clarity (n = 7). ν given in % of the maximum of histamine.

Lengthening the side chain to four carbon atoms and replacing the strongly basic guanidino group by the neutral methyl thiourea group produced burimamide (Fig. 9), the first antagonist of moderate activity which had low enough efficacy to avoid being an agonist in any of our assays. Burimamide, having relatively low potency and poor oral bioavailability, was clearly only a prototype. *Ganellin* saw the way forward. The nonbasic, electron-releasing side chain in burimamide, compared to the basic, electron-withdrawing side chain in histamine, raised the pK_a of the ring and favored the 3*H* tautomer. Inserting the electronegative thioether linkage in place of a methylene and introducing the

4-methyl group to favor H_2-receptor selectivity produced metiamide (Fig. 9), which was much more potent and better absorbed than burimamide. Toxicity associated with thiourea was then eliminated by replacing the thiourea sulfur with a C=N–CN group to produce cimetidine (Fig. 9).

On the atrial assay in vitro, burimamide produced surmountable antagonism, shown by rightward parallel displacement of the histamine dose–response curves. When analyzed by the Schild method, burimamide behaved like a syntopic antagonist to histamine. The estimated dissociation constants (K_B) were found to be independent of the potency of the titrating agonist and also independent of the tissue (atrium or uterus) used for the assay, substantially confirming the syntopic classification (Fig. 11). The high value on the ileum, an H_1 system, disclosed the compound's selectivity. As *Ash* and *Schild*[22] had proposed the notation H_1, we proposed that burimamide should be classed as an H_2-receptor antagonist.

	Atrium	Uterus	Ileum
Histamine	7.8	6.6	288
4-Methylhistamine	7.2		
2-Methylhistamine	6.9		

Fig. 11. Equilibrium dissociation constants (K_B [μM]) for burimamide in guinea-pig right atrium and rat uterus (histamine H_2-receptor assays) and in guinea-pig ileum (histamine H_1-receptor assay) against histamine and its analogues.

The analytical capability to distinguish an antagonist that acts at the same site as the native hormone from one that does not act syntopically – which is a functional antagonist – seems to me to be important in drug research for two reasons. For a defined homogeneous population of receptors, widely disseminated across tissues, the properties of the syntopic antagonist can be generalized. As the mechanism of action of the functional antagonist is unknown, however, its properties have to be identified on a tissue-by-tissue basis. Again, the analytical power of a syntopic antagonist – that is, its ability to prove hormonal involvement in physiological processes – is likely to be greater than for a functional antagonist. Of course, a compound that is a syntopic antagonist at one receptor system can also be a functional antagonist at a different receptor system. However, a possible combination of syntopic and functional properties would be expected to vary between different molecules, and the confusion can be eliminated by building up a class of syntopic antagonists that are chemically distinct but pharmacologically homogeneous. Syntopic antagonists are the best tools that analytical pharmacologists possess.

This problem of the resolving power of a receptor antagonist was seen from the beginning with metiamide. The histamine-induced acid secretion in the rat assay, having reached a plateau, was promptly inhibited when metiamide was given intravenously. Metiamide was found to be equally effective at inhibiting pentagastrin-induced secretion but much less effective against carbachol-induced secretion. Failure to inhibit cholinergically stimulated secretion showed that metiamide was not a nonspecific inhibitor of acid secretion. The ability of metiamide to inhibit the effects of gastrin pointed to potential clinical utility, but it was not at all clear that this result might contribute to a resolution of the gastrin–histamine controversy.

The problem became clear when the interactions between metiamide and the various stimulants were studied quantitatively in dogs with Heidenhain pouches.[23] Metiamide displaced the histamine dose–response curves in parallel to the right, as would be expected for a surmountable, syntopic antagonist (Fig. 12). Carbachol's steep dose–response curves were relatively refractory to inhibition. However, the flatter dose–response curves to pentagastrin were depressed downwards as well as being displaced to the right (Fig. 12).

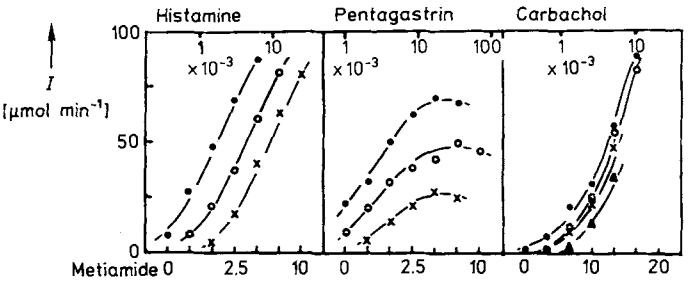

Fig. 12. Effects of intravenous infusion of metiamide against histamine-, pentagastrin-, and carbachol-induced gastric acid secretion in anesthetized dogs with Heidenhain pouches. Doses shown are μmol kg^{-1} min^{-1} for the agonists (upper abscissae); μmol kg^{-1} h^{-1} for metiamide (● = 0, ○ = 2.5, × = 10, ▲ = 20 μmol kg^{-1} h^{-1}). I = acid secretion. Reproduced by kind permission from [23]).

At that time I did not know what to expect if H_2-receptor blockade inhibited gastrin only because histamine was the final common chemostimulant. I could not rule out the possibility that these drugs were functional antagonists of gastrin. Subsequently, when other workers had confirmed the different patterns of inhibition in other species, and with different compounds, an unspecific inhibitory action seemed unlikely. The pattern also became understandable when I was able to model indirect competitive antagonism and applied the model to tyramine, a well-characterized indirectly acting agonist, to show that it was inhibited insurmountably by propranolol, just like the gastrin–metiamide interaction.[24]

When we took the H_2-receptor antagonists into human volunteers, there were no surprises in the patterns of secretory inhibition. However, we did get a surprise, right at the start, with burimamide. We followed the standard clinical practice of giving the volunteers mepyramine before giving them histamine intravenously. Even so, the subjects showed marked skin and conjunctival vasodilatation. The surprise was that treatment with burimamide completely blocked this vasodilatation. In the laboratory, burimamide alone had had no effect on histamine-induced vasodilatation. As both H_1- and H_2-receptors were involved, both antagonists were needed. This finding thus explained the results of *Folkow* et al.[25] of 30 years earlier.

Hormone-Receptor Antagonists in the Future

The histamine project was started by analogy with my experience of the adrenaline project. In retrospect, I think they have some features in common which helped them to

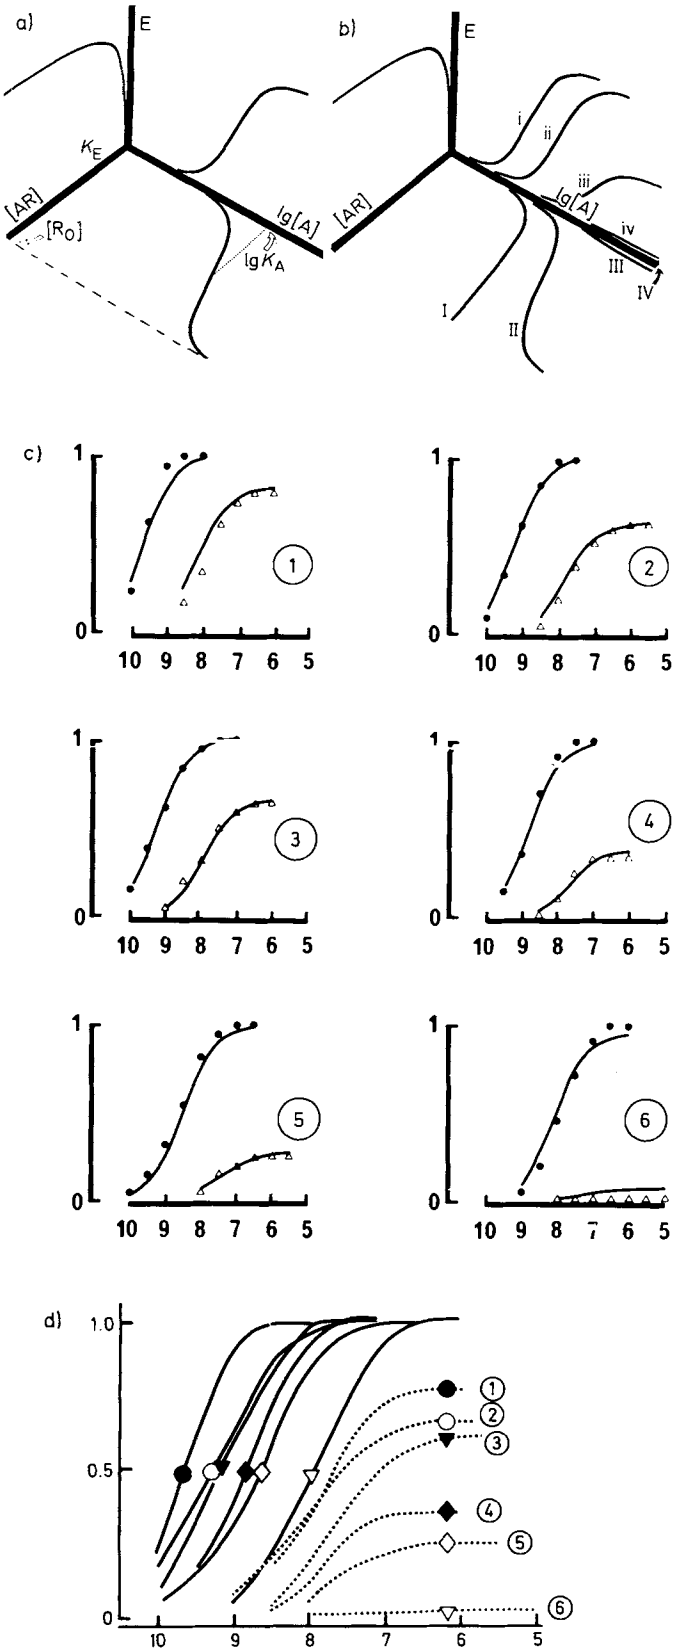

Fig. 13. a) Three-dimensional display of the operational model of agonism [26]. E, pharmacological effect; lg [A], logarithmic concentration of agonist A; lg K_A, log equilibrium agonist dissociation constant; [R_0], operational receptor concentration; [AR], concentration of receptors occupied by A; K_E, concentration of AR required for half-maximal tissue response. The three planes of the figure represent pharmacological effect (right panel), binding or affinity (base panel), and efficacy or transduction (left panel). b) Predictions of the influence of changes in [R_0] on pharmacological effect using the operational model of agonism. Curves I to IV show [R_0] values decreasing successively by tenfold giving rise to effect curves i to iv, respectively. c) Behavior of isoprenaline (●) and prenalterol (△) in guinea-pig tracheal muscle ①, cat left atria ②, rat left atria ③, cat papillary ④, guinea-pig left atria ⑤, and guinea-pig extensor digitorum longus muscle ⑥ [27]. The data has been regressed to the operational model of agonism allowing only [R_0] to vary between tissues. Abscissa: negative log molar agonist concentration [M]. Ordinate: Fractional response to isoprenaline. d) Representation of the model-simulated curves from Figure 13c superimposed on a single pair of axes. ——, isoprenaline; ···, prenalterol. ①–⑥ and axes: see Figure 13c.

succeed. Both started from well-recognized clinical problems at a time when they could be illuminated by specific hypothetical modeling at the laboratory level. The laboratory modeling defined the chemical starting points and the types of bioassay. The clinical problem defined how the newly classified drug should be tested in volunteers and patients. If the intimate coupling of clinical experience and pharmacological modeling has the effect of helping to eliminate wishful thinking in drug research, then the limiting step in the future will be the development and improvement of these models.

Models in analytical pharmacology are not meant to be descriptions, pathetic descriptions, of nature; they are designed to be accurate descriptions of our pathetic thinking about nature. They are meant to expose assumptions, define expectations, and help us to devise new tests.

Traditionally, pharmacological modeling of hormone-receptor systems has been based on the application of the Law of Mass Action to reversible interactions. Therefore, they are all chemical, molar models characterized by thermodynamic parameters. The discovery, often in a homologous series of compounds, that not all agonists could produce the same maximum response (now defined as partial agonists) led to models which had both binding, or affinity, parameters and efficacy, or response-generating, parameters. In both of the studies that I have sketched for you today, chemical modification of a native hormone produced, first of all, selective agonists, then quite separate chemical changes produced partial agonists and finally pure antagonists. The assumption is that partial agonists and antagonists are associated with a relative loss of efficacy – emasculated hormones.

The discovery of partial agonists was, in both studies, crucial to the development of syntopic antagonists. Yet I very nearly, and could quite easily, have failed to discover them. The choice of tissue for the assay was vital. So, why is the expression of efficacy so tissue dependent? How can we try to choose tissues which are most likely to allow us to detect partial agonists?

To illuminate these questions, *Leff* and I developed an operational model of agonism which defined three mutually connected surfaces such that knowing the shape of the function on any two allowed us, syllogistically, to deduce the necessary shape of the function on the third space (Fig. 13a).[26] On the right-hand side of the graphical display of the model is the measured function that relates agonist concentration, on a logarithmic scale (lg [A]), to the tissue effect which it produces. The pharmacological assumption is that the agonist initiates an effect by binding to a receptor (R); then the bound receptor (AR) activates a messenger system that produces the effect. Therefore, the base of the display shows the assumed relationship between agonist concentration and the concentration of bound receptors – the *affinity* relation.

Then, the left-hand panel shows the deduced relation between bound receptor concentration and effect – the *efficacy* relation. The behavior of this model is critically determined by the ratio of $[R_0]$, the total receptor concentration, to K_E, the concentration of bound receptor needed to produce a half-maximal effect. For example, when $[R_0]$ is equal to K_E the agonist can only produce a half-maximal response, thus defining a 50% partial agonist (Fig. 13b).

One of the first uses of the model was to fit simultaneously all of the data which *Kenakin* and *Beek*[27] had got from comparing isoprenaline and prenalterol, a partial agonist at β-receptors, on six different tissues (Fig. 13c). The model of agonism allowed all of the data to be fitted by the theoretical curves shown when only one parameter, total receptor density, was allowed to vary. The concentration of receptors is now known to vary between tissues, so that this seems to me to be an attractive way of accounting for the tissue dependence of a partial agonist's efficacy. Superimposing all the dose–response curves clearly demonstrates that the tissues most sensitive to isoprenaline support the greatest maximum responses to prenalterol and vice versa (Fig. 13d). Practically, therefore, the best way to avoid missing a partial agonist is to measure the potency of the native hormone or full agonist on as many tissues as possible and select assays expressing both high and low efficacy. This seems to be a robust test, relatively insensitive to the mechanisms underlying the differences in sensitivity.

Partial agonists, as empirical facts, have been recognized for many years. Pharmacological modeling of partial agonism and the related concept of efficacy has, however, developed more slowly. Fundamental problems about the nature of efficacy, either as a molar, thermodynamic concept or as a molecular problem in wave mechanics have still to be tackled. However, there seems no doubt about the pragmatic utility in drug research of distinguishing potency changes from efficacy changes in the bioassay of hormone analogues. The discovery of a partial agonist is the vital clue in developing useful syntopic antagonists.

We have gone on to use the model to study the effects of the slope of dose–response curves,[28] functional antagonism,[29] indirect competitive antagonism,[30] dual receptor systems, and receptor distribution when there is a relatively high concentration of transducer molecules.

The dose–response relation can, of course, be broken down into any two necessarily connected steps. Thus, the gastrin dose–response curve of acid secretion can be broken down into the gastrin/histamine-released relation followed by the histamine-released/acid secretion response relation. Two of the relations are known from measurement and the third, the gastrin/histamine-released relation, can be deduced. Using this model, *Shankley* and I were able to make a correct estimate of the K_B of an H_2-receptor antagonist from the family of unsurmountable curves produced by its interaction with pentagastrin, an important piece of evidence linking local histamine release to the physiological action of gastrin.

The approach I have outlined so far has regarded hormones and their conjugate receptors as simple, linear, "command-control" systems. The approach has undoubtedly had some success. Nevertheless, I think if we want to continue to try to develop new drugs by mimicking and manipulating physiological chemical control systems, our ideas will have to become more sophisticated. There is plenty of evidence now that hormone receptors and their dependent messengers are not insulated from each other. Mutually enhancing interactions between any two receptor–messenger systems can occur at many different points, leading to different kinds of physiological advantage.

When one hormone can interact with two allosterically linked receptors on the same cell, the continuous gearing can change the relatively flat concentration–response curve characteristic of the Mass-Action-Law behavior of a one-receptor system into steep curves. This greatly reduces the change in concentration needed to sweep the cellular response through its full range. This could be an advantage for fast-responding cells. When there are two hormones and two receptors, mutual potentiation can lead to threshold changes and pulsing signals and, more importantly, by making the activity of one hormone depend on the other, the convergence changes the type of behavior from obligatory responses to conditional responses, like those of nerve cells, based on summation (Fig. 15).

The rich possibilities of hormonal convergence plus inter-receptor amplification are now being discovered in the area of neuroendocrine secretion. While coexistence of multiple hormones in a single nerve ending does not necessitate co-transmission, there seems as yet no need to doubt it. *Hokfelt* et al., in a recent review,[31] pointed out that the distribution of these hormones was not random. For example, neurones classified as 5-HT-, noradrenaline-, or dopaminetransmitting each had different groups of peptides coexisting in their terminals. Neurobiologists have plenty of ideas about the significance of the very large and rapidly growing number of pharmacologically active substances which have been identified in nervous tissue. However, as an outsider looking in on all their excitement, I sense that my colleagues have problems with the Principle of Parsimony. Neurotransmission involving discrete, microscopic events is unlikely to generate problems with chemical cross talk in the brain at large. So, is there not now an embarrassing number of potential neurotransmitters?

On the other hand, biologists concerned with brain development probably do need an abundance of specific cell markers. *Sperry*'s chemoaffinity hypothesis,[32] one of the earliest attempts to account for the details of pattern development in the embryonic brain, required that cells have individual chemical identification markers almost down to the level of single cells. *Edelman*'s modulation hypothesis[33] – how the composition and density of nerve cell adhesion molecules can be locally regulated by the cells themselves – is chemically much more economical. These molecules subserving cell-to-cell interactions can provide a framework for guiding neurite growth cones. Diffusible growth factors, such as the specific nerve growth factor, can provide a general engine for neural growth into a supporting network. The question that intrigues me, however, is whether the framework and the engine are enough to account for the exquisite fine-tuning of synaptic connections which occurs during brain maturation and for the control of synaptic plasticity now known to be a feature of the mature brain.

I like the idea that these synaptic connections are determined chemotactically. An effective chemotactic address

might then involve the cooperative signaling of two or more chemicals. The possibilities for chemotactic signatures are factorial. If an effective signal involved just three chemicals, then 100 hormones could provide over a hundred thousand different signatures in any one compartment.

As our ideas about hormone–receptor systems become progressively more complicated in terms of multiplex pathways, hierarchy due to cellular conjunctions and biochemical cascades, the reductionist methods of molecular biology would seem to offer modern drug research a way out: simplify the systems by receptor isolation and expression. Molecular biology undoubtedly holds out the promise of the most direct and productive route ever to screening chemicals as hormone receptor reagents. However, once classified at the molecular level, a new reagent will have to be evaluated at the level of tissue complexity to confirm its classification and define its selectivity. These tissue bioassays, such as I have discussed today, may seem old-fashioned but, properly designed, they are arguably the best methods we have for making reliable predictions about clinical outcomes. They have served us well but they need to be continually improved, both technically and in their related operational models, to match our changing ideas. Molecular biology will continue to provide drug research with extraordinary analytical methods and lend a richer texture to our imagination.

These reflections suggest that there will be both great opportunities, and potential dangers, for the development of specific hormone receptor reagents in the future. The limiting factors, however, are likely to be the verisimilitude of our models and the complexity of our bioassays.

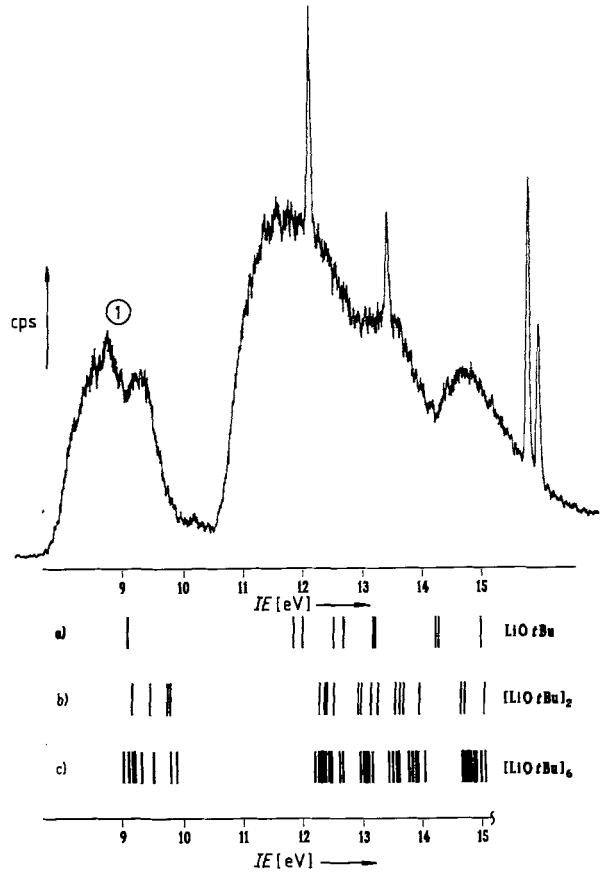
The First PE-Spectroscopic Investigations of Lithium, Sodium, and Potassium *tert*-Butoxide **

By *Manfred Braun,** *Delia Waldmüller,* and *Bernhard Mayer*

Lithium, sodium, and potassium *tert*-butoxide, reagents widely used by several generations of chemists, are monomeric neither in the crystal nor in nonpolar solvents, although this is suggested by the usual formulas $LiOC(CH_3)_3$ **1**, $NaOC(CH_3)_3$ **2**, and $KO(CH_3)_3$ **3**. For example, potassium *tert*-butoxide was found by X-ray structure analysis to exist as a tetramer,[1] whereas, in the case of the corresponding sodium alkoxide, both hexamers and nonamers are present in the crystal.[2, 3] An incomplete X-ray structure investigation of lithium *tert*-butoxide also revealed the possible presence of hexameric aggregates.[4] In THF, the alkoxides **1**–**3** all form tetramers, whereas the lithium alkoxide **1** forms hexameric[5–7] aggregates in benzene, toluene, and cyclohexane.[8] Even in the gas phase (up to ca. 200 °C), the readily sublimable alkoxides do not dissociate to monomers. Thus, mass-spectrometric investigations indicate that, in the gas phase, lithium *tert*-butoxide is present exclusively as the hexamer.[9] Besides hexamers, heptamers of sodium *tert*-butoxide were also found in the gas phase.[2] On the other hand, potassium *tert*-butoxide is tetrameric in the gas phase according to mass spectrometry.[1]

With the goal of studying the "inherent" properties of the aggregated alkoxides **1**–**3**, uninfluenced by a solvent, we have recorded the photoelectron (PE) spectra of these compounds in the gas phase at temperatures between 150 and 180 °C.[10, 11] Figure 1 shows the PE spectrum of lithium *tert*-butoxide and, below it, the orbital energies calculated for aggregates of various size by the MNDO procedure.[12] The characteristic broad double band ① in the region of 8.0 to 9.8 eV presumably arises from molecular orbitals with predominant contributions from the oxygen atoms. This is suggested by a comparison of this PE spectrum with that of *tert*-butyl alcohol, the lowest ionization potential of which lies at 10.23 eV,[13] and confirmed by a comparison of the alkoxide spectrum with the calculated orbital energies (Fig. 1).

The orbital energies of 9.08 eV of the degenerate HOMOs in the monomer (line a), assignable to the nonbonding electron pairs of the oxygen atom, contrast markedly with the spectroscopically observed broad splitting of band ①. This broadening can be explained by the presence of aggregates in the gas phase.[14] For dimeric lithium *tert*-butoxide (line b), the calculations thus predict the existence of four HOMOs that are clearly separated at lower energy from the remaining orbitals. Structure **4**, with a planar four-membered ring, was assumed in these calculations.[15] Since mass-spectrometric investigations have shown that lithium *tert*-butoxide is a hexamer in the gas phase,[9] it was of particular interest to calculate its electronic structure. Structure **5**, in which each oxygen atom is coordinated by three lithium atoms,[16] was used in these calculations. As expected, further splitting was observed in region ① (line c) in comparison with the dimer.[17]



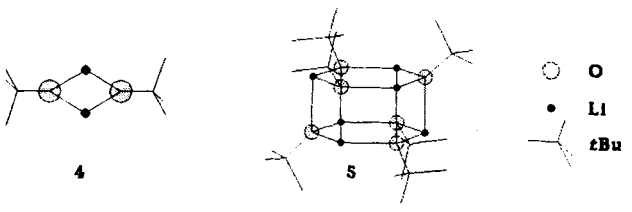


Fig. 1. PE spectrum of lithium *tert*-butoxide in the gas phase and calculated orbital energies [eV] for monomeric, dimeric, and hexameric lithium *tert*-butoxide.

Comparison of the PE spectrum of lithium *tert*-butoxide in the gas phase with those of sodium and potassium *tert*-butoxide (Fig. 2) reveals a clear shift of the lowest ionization potential to lower energies on going from lithium to sodium to potassium (cf. ①, ②, ③).

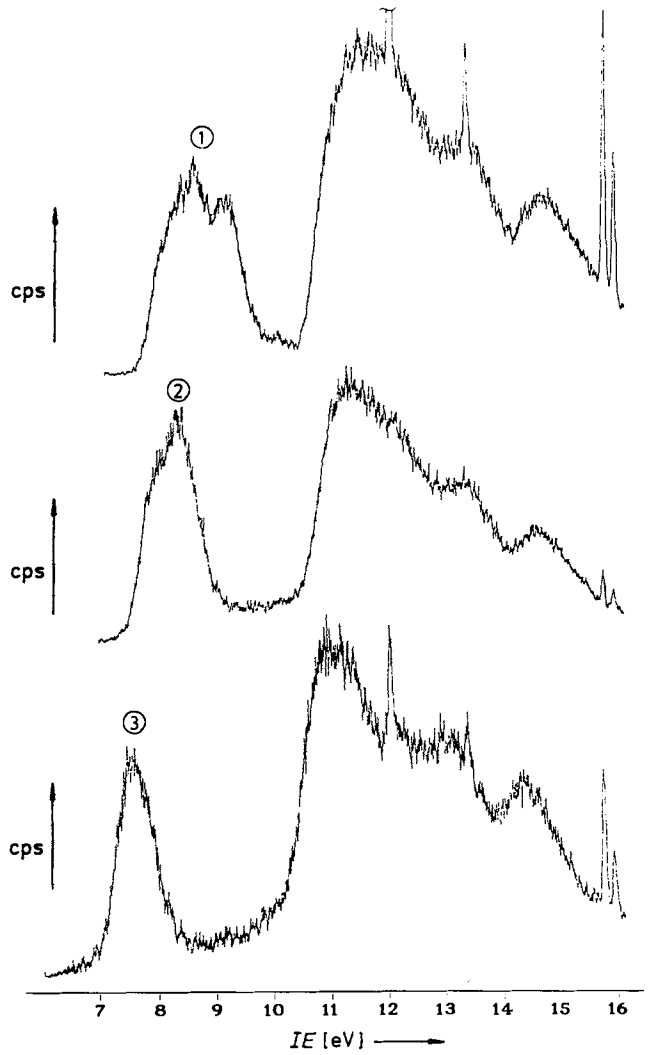

Fig. 2. PE spectra of lithium (top), sodium (middle), and potassium *tert*-butoxide (bottom) in the gas phase.

Assuming that the ionic character of the metal–oxygen bond increases in the order "LiO*t*Bu" < "NaO*t*Bu" < "KO*t*Bu", these spectra appear to support the conclusion that the ionization of alkoxides to their corresponding radical cations becomes easier as the electron density at the oxygen atom is increased. For the hexameric lithium *tert*-butoxide, MNDO calculations give a charge of −0.45 at the oxygen atom; for the monomer, on the other hand, a charge of −0.60 was calculated. Accordingly, a more highly aggregated species should be more difficult to ionize, as has already been shown for hydroxides of lithium, sodium, and potassium by PE spectroscopy.[18] It remains to be determined, however, whether ionization potentials can generally be correlated with a charge separation in alkali metal–heteroatom bonds.

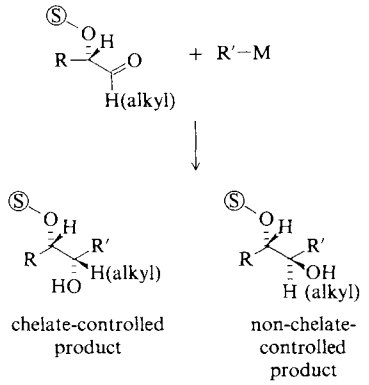
Non-Chelate-Controlled Addition of 1-Bromo-1-lithio-1-alkenes to *O*-Protected Lactaldehydes**

By *Manfred Braun** and *Hellmut Mahler*



In memoriam Hans Musso

Acyclic chiral α-alkoxyaldehydes and α-alkoxyketones react with Grignard reagents[1] as well as with a variety of other organometallic compounds[2] according to *Cram*'s cyclic model[3] to yield preferentially the "chelate-controlled"[4] product (Scheme 1, left). On the other hand, "non-chelate control" (Scheme 1, right), sometimes called "Felkin–Anh selectivity",[5] is generally difficult to accomplish.[4] Recently, additions involving mainly non-chelate control have been realized, for example with weakly Lewis-acidic alkyltitanium reagents[4] and with allylsilanes in the presence of boron trifluoride,[4] as well as by the Cr^{II}-induced

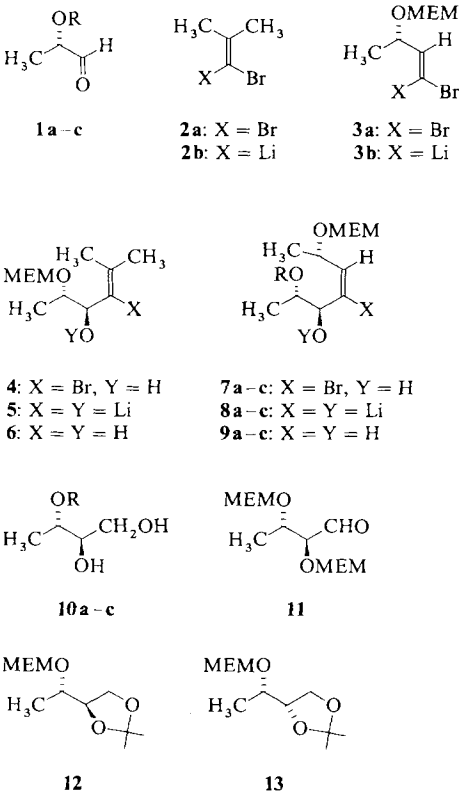
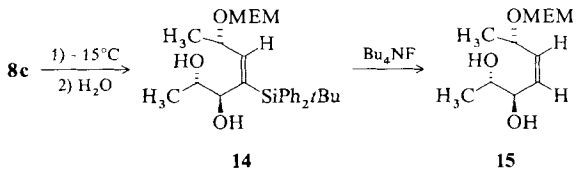
reaction of vinyl and allyl halides.[6] Organolithium compounds add to the above-mentioned carbonyl compounds sometimes with chelate control,[1a, 7] sometimes without any significant selectivity.[8]



Scheme 1. Ⓢ: protecting group. M: e. g., Li, MgX, ZnX, TiX_3.

We have now observed, for the first time, a largely non-chelate-controlled addition of organolithium compounds to *O*-protected lactaldehyde **1a**. Although, owing to its crown-ether-like structure, the (2-methoxyethoxy)methyl (MEM) protecting group of the aldehyde would seem predestined[1b] to direct the addition in the way predicted by *Cram*'s cyclic model, reaction with the lithium reagent **2b**, generated in situ from the dibromoalkene **2a**, results in preferential attack on the *Re* side, yielding the non-chelate-controlled product **4** (yield 86.3%, *de* = 85%). The chiral vinyllithium reagent (*S*)-**3b**, generated analogously from the dibromoalkene (*S*)-**3a**,[9] adds to achiral aldehydes preferentially with *ul* (unlike) topicity[10] (i.e., also from the *Re* side). As expected, in the addition of **3b** to the *O*-protected lactaldehydes **1a–c**, the selectivity can therefore be considerably increased in favor of the non-chelate-controlled products **7a–c** (**7a**, yield 78%, *de* = 91%; **7b**, 79.5/92; **7c**, 83.5/95).



The C–C double bond in the nucleophiles **2b** and **3b** can be cleaved oxidatively to give a hydroxymethylene or a formyl unit; the stereoselective introduction of a $^{\ominus}CH_2OH$ or $^{\ominus}CHO$ synthon with d^1 reactivity[11] is thus possible. To demonstrate this, we transformed the adducts **4** and **7a–c** into the olefins **6** and **9a–c**, respectively, in yields of 89–95% by bromine/lithium exchange at −78 °C (cf. **5** and **8a–c**) followed by protonation. The configuration of the double bond[12] was completely retained in the products. Ozonolysis afforded, after workup with $LiAlH_4$, the diols **10a** (from **6** or **9a**) and **10b,c** (from **9b,c**) in yields of between 78 and 88%. Introduction of a further MEM protecting group into the alkene **9a**, followed by ozonolysis, yields the aldehyde **11** (81%).[13]

Cleavage of the double bond also serves to establish the configuration of the adducts **4** and **7a**. The (2*R*,3*S*)-diol **10a**, prepared from these adducts, was converted into the acetal **12**. To differentiate between the isomers **12** and **13**, reference samples were prepared by addition of methylmagnesium iodide to D-1,2-di-*O*-isopropylideneglyceraldehyde,[14] which occurs with only moderate diastereoselectivity (non-chelate-control), followed by ether formation with MEM-Cl (**12**:*ent*-**13** 69:31). Since these two compounds differ significantly in their ^1H and ^{13}C NMR data,[13] an unambiguous structural assignment of the adducts **4** and **7** was possible.[15]

If the vinyl anion **8c**, generated by bromine/lithium exchange, is not protonated at −78 °C, but instead at −15 °C, O → C migration of the silyl moiety occurs to give quantitatively the vinylsilane **14**, which undergoes fluoride-induced desilylation to yield the olefin **15** with (*Z*) configuration.

1, 7–10: **a**, R = MEM; **b**, R = $SiMe_2tBu$; **c**, R = $SiPh_2tBu$

Since (*S*)-lactaldehyde was used as the starting material, all the products described here are obtained in enantiomerically pure form. Diastereomeric excesses—of the alkenes **9a, b**, for example—can be increased by distillation or column chromatography to *de* > 98%. The (*R*)-lactic esters, also available, afford access to the corresponding enantiomers. The non-chelate control in the reaction of 1-bromo-1-lithio-1-alkenes **2b** and **3b** with *O*-protected lactaldehydes serves to reemphasize that such carbenoids are not only intermediates with unusual structural and spectroscopic properties,[16] but also species with surprising reactivity. The lacking tendency of "ligands" like **1a** to form chelates demonstrates that 1-bromo-1-lithio-1-alkenes do not at all display the typical character of electron-deficient compounds expected for organolithium compounds.

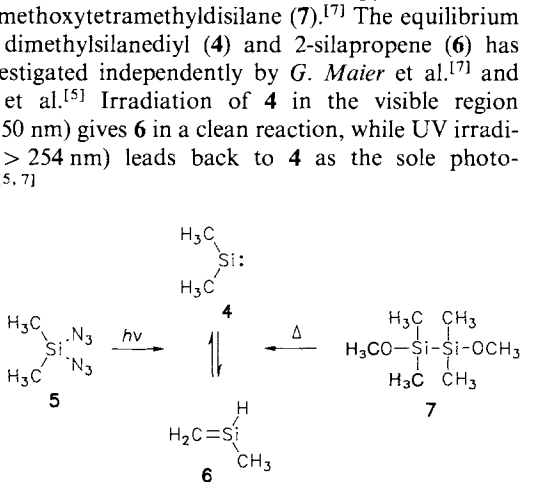
Dimethyldioxasilirane**



By *Andreas Patyk, Wolfram Sander,* Jürgen Gauss,* and *Dieter Cremer**

The reaction of carbenes (**1**) with molecular oxygen yields carbonyl *O*-oxides (**2**), dioxiranes (**3**), or carbonyl compounds and oxygen atoms. These species are powerful oxygen-atom transfer reagents; especially dioxiranes have proved to be useful in preparative organic chemistry.[1] The relative amount of **2, 3,** or oxygen atoms formed depends greatly on the constitution of the carbene and on the reaction conditions.[2]

Whereas the mechanism of carbene oxidation is quite well understood, not much is known about silanediyl oxidation. Recently, *Ando* et al.[3] reported the formation of a silanone *O*-oxide in the oxidation of dimesitylsilanediyl in oxygen matrices at 10 K. The assignment of this species was based on the observation of one IR absorption at 1084 cm^{-1}, which showed an ^{18}O-isotopic shift of 40 cm^{-1}. We have now investigated the reaction of dimethylsilanediyl (**4**) and O_2. In contrast to the observations of *Ando* et al., a dioxasilirane rather than a silanone *O*-oxide is formed as the primary thermal adduct at low temperature.

Silanediyl **4** was generated in argon matrices either by short-wavelength photolysis ($\lambda > 254$ nm, 10 K)[4] of diazidodimethylsilane (**5**)[5, 6] or by flash vacuum pyrolysis (FVP) of 1,2-dimethoxytetramethyldisilane (**7**).[7] The equilibrium between dimethylsilanediyl (**4**) and 2-silapropene (**6**) has been investigated independently by *G. Maier* et al.[7] and *J. Michl* et al.[5] Irradiation of **4** in the visible region ($\lambda_{max} = 450$ nm) gives **6** in a clean reaction, while UV irradiation ($\lambda > 254$ nm) leads back to **4** as the sole photoproduct.[5, 7]

When **5** is irradiated ($\lambda > 254$ nm, 10 K) in argon matrices doped with low O_2 concentrations (0.1–0.5%), the formation of **4** (and traces of **6**) along with a photooxidation product **A** can be monitored by IR spectroscopy.[8] At higher O_2 content (> 2%), **4** is completely oxidized to **A** upon irradiation.

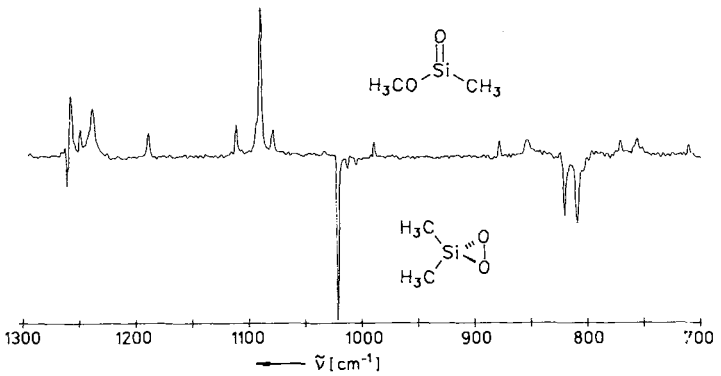
The thermal reaction between unreacted **4** and O_2 (in 0.1–0.5% O_2-doped Ar matrices) is induced by annealing the matrix at 35–42 K. After several hours at this temperature, most of **4** has reacted to give a new product, **B**. The formally spin-forbidden reaction of (singlet) **4** and $^3O_2$ *is—as expected—much slower than the analogous reaction* of triplet carbenes.[2] Compound **A** is not formed in the thermal reaction and **6** does not react with O_2 under these conditions.

Interestingly, thermal adduct **B** is also formed in the gas-phase reaction of **4** and O_2 at high temperature. FVP of disilane **7** (700 °C, 10^{-4} mbar) and trapping of the products in Ar at 10 K produces a mixture of **4** and **6**.[9] If small amounts of O_2 are added in the reaction zone, **4** is almost completely trapped to give a mixture of **A** and **B**. Again, **6** is much less reactive towards O_2 and is not trapped in the gas phase. **B** proves to be photolabile towards visible light irradiation (λ = 436 nm). Photolysis produces **A** as the sole product within several minutes; compound **A** is stable even towards UV irradiation (λ > 220 nm).



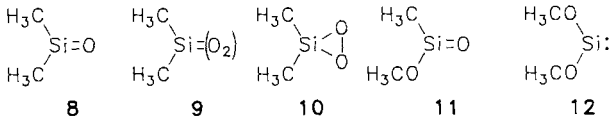


Fig. 1. IR difference spectra showing the photochemistry of **B**, matrix-isolated in a 0.2% $^{16}O_2$-doped Ar matrix at 10 K. Bottom: Bands assigned to **B**, disappearing on irradiation (λ = 436 nm). Top: Bands assigned to **A**, appearing on irradiation.

Table 1. IR-spectroscopic data of **B**, matrix-isolated in Ar at 10 K ($\tilde{\nu}$ [cm^{-1}], Δ, isotopic shift).

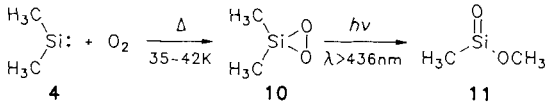
[a] Owing to the presence of three isotopomers in the spectra, not all bands could be assigned. [b] Approximate description on the basis of observed isotopic shifts and by comparison with ab initio calculations. [c] The assignment of the weak bands at 1012.9 and 1005.7 is not definite. [d] Rocking mode.

The IR spectra of **A** and **B** show strong absorptions in the region between 1000 and 1100 cm^{-1}, characteristic of Si–O stretching modes (Fig. 1, Table 1). When the experiments were repeated using $^{18}O_2$, strong isotopic shifts towards lower wave numbers were observed for these bands, which shows that both compounds contain oxygen. Structures for **A** and **B** that have to be considered are dimethylsilanone (**8**), dimethylsilanone *O*-oxide (**9**), dimethyldioxasilirane (**10**), methoxymethylsilanone (**11**), and dimethoxysilanediyl (**12**). Compounds **8**[10] and **12**[11] can be readily excluded by comparison with published matrix IR spectra.

To exclude structures with more than one O_2 molecule added to silanediyl **4**, experiments with mixtures of $^{16}O_2$ and $^{18}O_2$ were performed. If a 1:1 mixture is used, the spectra obtained are exact superpositions of the spectra of the pure $^{16}O_2$ and $^{18}O_2$ isotopomers. Thus, **A** and **B** can only contain one or two O atoms from one O_2 molecule.



The symmetry of **A** and **B** was examined by using a 1:2:1 mixture of $^{16}O_2$, $^{16}O^{18}O$, and $^{18}O_2$. If **A** or **B** contain only one O atom, no additional $^{16}O^{18}O$ isotopomer should be observed. A compound with two equivalent O atoms should give one "mixed" $^{16}O^{18}O$ isotopomer, whereas two different O atoms should lead to two $^{16}O^{18}O$ isotopomers.

Compound **B** gives one mixed $^{16}O^{18}O$ isotopomer together with the "pure" $^{16}O_2$ and $^{18}O_2$ isotopomers in a ratio of 2:1:1. The bands assigned to the $^{16}O^{18}O$ isotopomer are located halfway between the IR bands of the $^{16}O_2$ and $^{18}O_2$ isotopomers (Table 1). This demonstrates that the two O atoms are equivalent; thus, **B** has structure **10**.[12] In contrast, **A** forms two $^{16}O^{18}O$ isotopomers and therefore contains two nonequivalent O atoms. The two new isotopomers can be recognized best in the region between 1090 and 1050 cm^{-1}. Other bands are broadened owing to the presence of the additional two isotopomers. The most reasonable structure for **A**, compatible with both the IR data and the observed absence of photochemistry,[13] is methoxymethylsilanone (**11**).

On the basis of the ^{18}O isotopic shifts, several bands of **10** were assigned (Table 1). These assignments were confirmed by ab initio calculations,[14] which show that the symmetrical Si–O stretching mode (calculated at 1006 cm^{-1}) is—in agreement with the experiment—the strongest band in the IR spectrum of **10**, with calculated isotopic shifts of 21 and 33 cm^{-1} upon incorporation of one and two ^{18}O atoms, respectively. There are only two other vibrational modes in the calculated IR spectrum with similarly strong isotopic shifts: the asymmetric Si–O stretching mode, which is very weak, but should exhibit the strongest isotopic shifts, and the O–O stretching mode, which should lead to a weak but somewhat more intense band than that for the asymmetric Si–O stretching mode. From the ab initio calculations it follows that the observed weak band at 1005.7 cm^{-1} corresponds to the asymmetric Si–O stretching mode. All other assignments given in Table 1 have been made on the basis of the calculated normal modes.

The strong band of silanone **11** at 1090.1 cm^{-1} shows an isotopic shift of −30.9 cm^{-1} in $^{18}O_2$-**11** and is assigned to a Si–O stretching mode.[15] The mixed $^{16}O^{18}O$ isotopomers absorb at 1087 and 1062 cm^{-1}, which are close to the vibrations of the "pure" isotopomers. This demonstrates that the second O atom is not much involved in this Si–O stretching mode. Other bands in **11** that exhibit strong ^{18}O-isotopic shifts are found at 1249.7 (−29.9) and 1238.1 cm^{-1} (−29.4 cm^{-1}).[15] These absorptions are found at higher

wavenumbers than Si–O stretching modes and assigned to the Si=O stretching mode. The splitting of the band can be rationalized by matrix site effects or by the formation of different rotamers in the matrix. The corresponding band in silanone **8** is observed at 1210 cm^{-1} [10] and in dichlorosilanone at 1240 cm^{-1} (^{18}O isotopic shift: -37 cm^{-1}).[16]

4 10 11

The thermal reaction of silanediyl **4** and O_2 at low temperature leads exclusively to dioxasilirane **10**. In contrast, carbenes only give carbonyl *O*-oxides. The difference in the behavior of silanediyls and carbenes becomes clear on the basis of the ab initio calculations. The calculated isomerization barrier of silanone *O*-oxide is just 6.5 kcal mol^{-1},[17] whereas that of carbonyl oxide is 22.8 kcal mol^{-1}.[18] If silanone *O*-oxide is formed in the thermal reaction of **4** and O_2, then it will immediately isomerize to **10** in an exothermic process releasing 63.8 kcal mol^{-1}.[17]

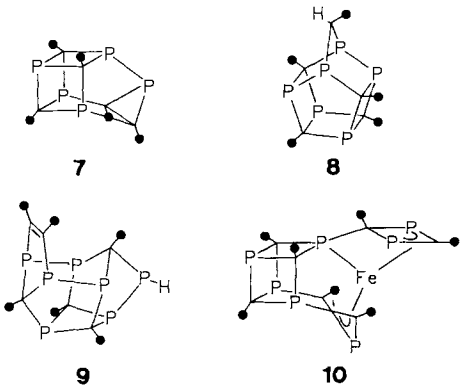
Polycyclic Polyphosphorus Hydrocarbons**

By *Dongqi Hu, Hartmut Schäufele, Hans Pritzkow,* and *Ulrich Zenneck**

The highly efficient synthesis of *tert*-butylphosphaacetylene **1** published by *G. Becker* et al. in 1981[1] provided the foundation for the use of phosphaalkynes in a wide variety of organic and organometallic[2, 3] cycloadditions. With one exception, a maximum of three units of **1** are coupled in the metal-promoted cycloadditions. The exception is the reaction of $TaCl_5$ with **1**, which leads to a complexed tricyclic trimer of **1** as the main product and the $TaCl_6^{\ominus}$ salt of the polycyclic cation $[P_7(CCMe_3)_6]^{\oplus}$ as side product.[4]



The reaction of (η^4-1-methylnaphthalene)(η^6-toluene)-iron **2**[5] with **1** at 0 to 20 °C affords, in addition to **3**, which contains a cyclodimer as ligand, the substances **4** to **6**,[6, 7] the formation of which requires the breaking of PC triple bonds. This finding suggested that more complex products might also be obtained from these systems. Systematic workup of the reaction allowed optimization of the conditions for synthesis of **5**, obtained eventually in 30% yield when **1** and **2** were used in the stoichiometrically required amounts (mole ratio 5:1). Use of a very large excess of **1**, accessible by a new synthetic route,[8] results in reaction of approximately nine moles of **1** per mole of **2** within one day at room temperature. Unreacted **1** can be separated under vacuum from the products.

Besides **3** to **6**, the amounts of which are less than those obtained when a smaller amount of **1** is used, the product mixture yields at least ten other fractions upon medium pressure chromatography (MPLC). When this mixture is heated under vacuum to approximately 100 °C, one obtains, in ad-

[**] Reactive π Complexes of Electron-Rich Transition Metals (SFB 247), Part 9. This work was supported by the Land Baden-Württemberg and the Deutsche Forschungsgemeinschaft (SFB 247). Part 8: D. Hu, H. Pritzkow, H. Schäufele, C. Tolxdorff, U. Zenneck in H. Werner, G. Erker (Eds.), *Organometallics in Organic Synthesis*, Springer, Heidelberg 1989, in press.

dition to the known compounds, the new substances **7** to **10**, which can be isolated in small yields and characterized by X-ray crystal structure analysis.

The pale yellow $(PCCMe_3)_5$ **7** (Fig. 1a) is a polycyclic pentamer of **1**. Its structure may be derived from that of the so far unknown tetraphosphacubane[19a] by replacing a corner with a three-membered ring. A structurally analogous hydrocarbon is known,[9] but neither an organophosphorus compound nor a polyphosphide. The bond lengths and angles[10] of **7**, except for those of the three-membered ring, lie in the range expected for a completely saturated compound. The strikingly small angle C3-P4-C3′ (49.7°) in the three-membered ring is reminiscent of that in the corresponding 1-phosphirane.[11]

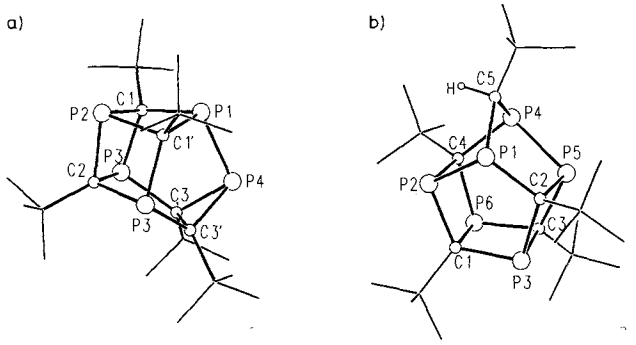

Fig. 1. a) Molecular structure of $(PCCMe_3)_5$ **7**. Selected distances [Å] and angles [°]: P1-P4 2.175(2), C3-C3′ 1.588(7), P-C 1.849–1.902(5); C3-P4-C3′ 49.7(1), P4-C3-C3′ 65.2(4), P1-C1-P2 92.4(1), C1-P1-C1′ 86.1(1), C1-P2-C1′ 84.7(1). b) Molecular structure of $P_6(CCMe_3)_5H$ **8**. Selected distances [Å] and angles [°]: P1-P2 2.196(1), P4-P5 2.203(1), P-C 1.864–1.914(4). The P–C distances in the two five-membered rings of the bases are shorter on average than those between the rings: 1.878 and 1.911 Å. Angles at P: 87.1–88.0 (in C_2P_2), 95.5–103.0 (in C_2P_3); at C: 90.7–92.5 (in C_2P_2), 107.9–117.0 (in C_2P_3).

The almost colorless $P_6(CCMe_3)_5H$ **8** is a heteroanalogue of homopentaprismane[12] (Fig. 1b). Compound **8** is not an oligomer of **1** but instead, as in the case of **4**, **6**, and **9**, a product formed by cleavage and intermolecular exchange of the components of **1**; the number of phosphorus atoms and the number of $CCMe_3$ fragments are therefore different. An additional hydrogen atom is bonded to C5.[13]

$P_7(CCMe_3)_6H$ **9**, which is again pale yellow, may be derived formally from **8** by addition of one more unit of **1** (Fig. 2a). Apart from the charge of the ion $[P_7(CCMe_3)_6]^{\oplus}$ and the additional hydrogen H1 of **9**, these two cage compounds are isomers with markedly different structures.[4, 14]

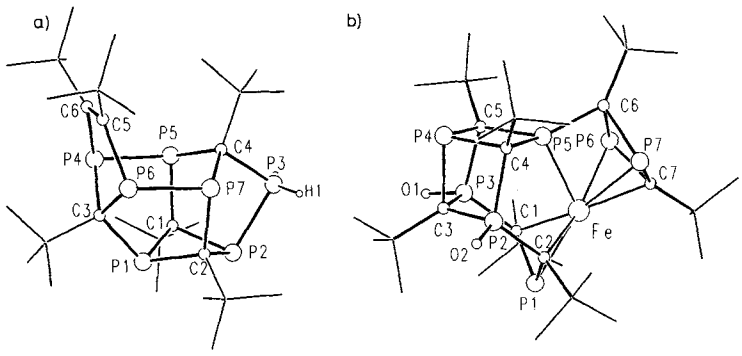

Fig. 2. a) Molecular structure of $P_7(CCMe_3)H$ **9**. Selected distances [Å] and angles [°]: P2-P3 2.154(2), P4-P5 = P6-P7 2.240(1), C5-C6 1.338(6), P-C 1.848–1.904(5); C1-P1-C2 = C1-P2-C2 85.2(5), P1-C1-P2 = P1-C2-P2 87.0(2). b) Molecular structure of (partially oxidized) $(PCCMe_3)_7Fe$ **10** (projection as in Fig. 1a). Selected distances [Å] (some averaged): Fe-P1 2.265(2), Fe-P5 2.281(2), Fe-P6(7) 2.396(2), Fe-C1 2.112(5), Fe-C2 2.131(6), Fe-C7 2.121(5), P6-C6 = P7-C6 1.921(7), P6-C7 = P7-C7 1.780(8), P1-C1 = P1-C2 1.780(7), P2-C2 = P3-C1 1.826(7); the remaining P–C distances are between 1.844 and 1.915 Å.

In **9**, H1 is bonded to a phosphorus atom, in **8** to a carbon atom. Compound **9**, which has a double bond between C5 and C6, displays a near plane of symmetry through C3, C4, P1, P2, and P3. The H atom on P3 can be either above or below this plane; the two positions are occupied roughly to the same extent.

To the best of our knowledge, **9** represents a new type of structure. Consideration of only part of the framework, for example the section C1-C2-C4-P2-P3-P5-P7, reveals some similarities with organopolyphosphanes of the type P_7R_3.[15]

The ligand in the olive-brown iron complex $(PCCMe_3)_7Fe$ **10** (Fig. 2b) is a polycyclic heptamer of **1**. X-ray structure analysis revealed that the substance is partially oxidized at P2 and P3 after workup.[16, 19b] The metal-complex fragment of this paramagnetic cage compound contains 16 valence electrons on iron; P6, C7, and P7 of the four-membered ring, joined to the cage through only a σ bond, form a 1,3-diphosphaallyl ligand, whereas C1, P1, and C2 coordinate as a 2-phosphaallyl ligand. An additional coordination site is occupied by the lone pair of P5. In comparison to other 16-VE complexes of iron, **10** is very stable[17]—presumably because of the chelate effect and the steric shielding of the metal by the *tert*-butyl groups.

The cage portion of **10**, composed of five units of **1**, is remarkably similar to the pentamer **7**. The essential difference is that the atoms of the three-membered ring in **7** serve there as a phosphaallyl ligand and the contact between the phosphorus atoms, which are directly bonded to one another in **7**, is established through the iron atom in **10**. Otherwise, all phosphorus atoms and CR fragments occupy corresponding positions and the bond angles and lengths are very similar.

In view of the large number of possible isomers, it seems reasonable to interpret such structural commonalities in **7** and **10** as a hint of a chemical relationship. Further experimental investigations are necessary to determine whether the analogous eclipsed arrangement of the triphospholyl ligands of **6**,[7] as well as the base five-membered rings of **8**, is a mere coincidence.

Experimental Procedure

1 (11.24 g, 112.4 mmol) and **2** (1.45 g, 5 mmol) were combined in 40 mL of toluene under N_2 at −18 °C and the stirred mixture was allowed to react for 24 h, the temperature rising slowly to room temperature. The toluene and

68.3 mmol of unreacted **1** were removed under vacuum. The residue was extracted into petroleum ether 40/60 and chromatographed several times (column and MPLC: silica gel 60 Merck/5% water; petroleum ether, toluene, THF, and binary mixtures of these solvents). Fourteen colored fractions were isolated. Five have been identified so far, namely, **3, 4, 5, 6,** and **10** (oxygen free [19b], dec. 220 °C).

Heating of the residue under 1 Pa to 100 °C results in complete distillation of **3** and 1-methylnaphthalene. The remaining residue was subjected several times to MPLC, resulting in the isolation of several new fractions. Compound 7 (m.p. 255 °C) crystallized from a brown petroleum ether fraction. Compounds **8** and **9** precipitated as crystalline masses (no sharp melting point) within 14 d from a red-violet petroleum ether solution, the intensity of the color thereby decreasing. The crystals could be separated manually.

When Al_2O_3/5% water was used as the stationary phase in the chromatography and the main components of the mixture were eluted, a brown residue was removed with THF from the top of the column. Concentration of this solution resulted in crystallization of partially oxidized **10**.

The yields of the isolated crystalline compounds **7**–**10** were all about 1%. The NMR spectra of the diamagnetic speices **7**–**9** are very complicated and have not yet been completely analyzed. Compound **10** gives strongly broadened and paramagnetically shifted ^{1}H NMR signals; ^{13}C and ^{31}P NMR signals are not observable.

[19] Notes added in proof (April 17, 1989): a) This gap has been closed in the meantime: T. Wettling, J. Schneider, O. Wagner, C. Kreiter, M. Regitz, *Angew. Chem. 101* (1989); *Angew. Chem. Int. Ed. Engl. 28* (1989), in press; b) Oxygen-free **10** was also confirmed by an X-ray structure analysis. Apart from the two oxygen atoms, the two molecular structures are not significantly different.

The Radical Cation of *N,N'*-Tetramethylene-*syn*-1,6:8,13-diimino[14]annulene. An Experimental Study of the N–N Three-Electron σ Bond**

By *Fabian Gerson,* Georg Gescheidt, Urs Buser, Emanuel Vogel, Johann Lex, Margareta Zehnder,* and *Andreas Riesen*

The N–N three-electron σ bond in radical cations has been the subject of numerous experimental[1–4] and theoretical[5] studies. When such a bond is formed intramolecularly, the N–N distance in the radical cation should be considerably shorter than in the neutral counterpart. This expectation has so far been experimentally borne out solely for 1,6-diazabicyclo[4.4.4]tetradecane (**1**)[1e] and *N,N'*-trimethylene-*syn*-1,6:8,13-diimino[14]annulene (**2**),[2b] because only in the case of these two compounds could the structures of the corresponding radical cations $\mathbf{1}^{\cdot\oplus}$ and $\mathbf{2}^{\cdot\oplus}$ be determined by X-ray crystallography. Here we report an X-ray crystallographic structure analysis performed on the radical cation of *N,N'*-tetramethylene-*syn*-1,6:8,13-diimino[14]annulene (**3**). As will be demonstrated below, $\mathbf{3}^{\cdot\oplus}$ also exhibits a N–N three-electron σ bond. The lengthening of the polymethylene chain on going from $\mathbf{2}^{\cdot\oplus}$ to $\mathbf{3}^{\cdot\oplus}$ leads to an essential change in the "structure" of the two N atoms.

4

2 $n = 3$
3 $n = 4$

The tetramethylene derivative **3**[6] was synthesized from the parent compound **4**[7] by the same procedure as its trimethylene homologue **2**.[2b] In the cyclic voltammogram of **3**,[8] a reversible oxidation wave appears at $E_{1/2} = +0.29$ V (vs. SCE). Accordingly, **3** can be as readily oxidized as **2** ($E_{1/2} = +0.24$ V)[2b] to its radical cation with a variety of reagents ($Tl(OAc)_3$, $AgClO_4$, $(p\text{-}BrC_6H_4)_3NSbCl_6$). The ESR spectrum of $\mathbf{3}^{\cdot\oplus}$ ($g = 2.0035 \pm 0.0001$) at several temperatures is shown in Figure 1. The temperature dependence is due to an interconversion between two equivalent conformations of the tetramethylene chain and a concomitant modulation of the β-proton coupling constants:

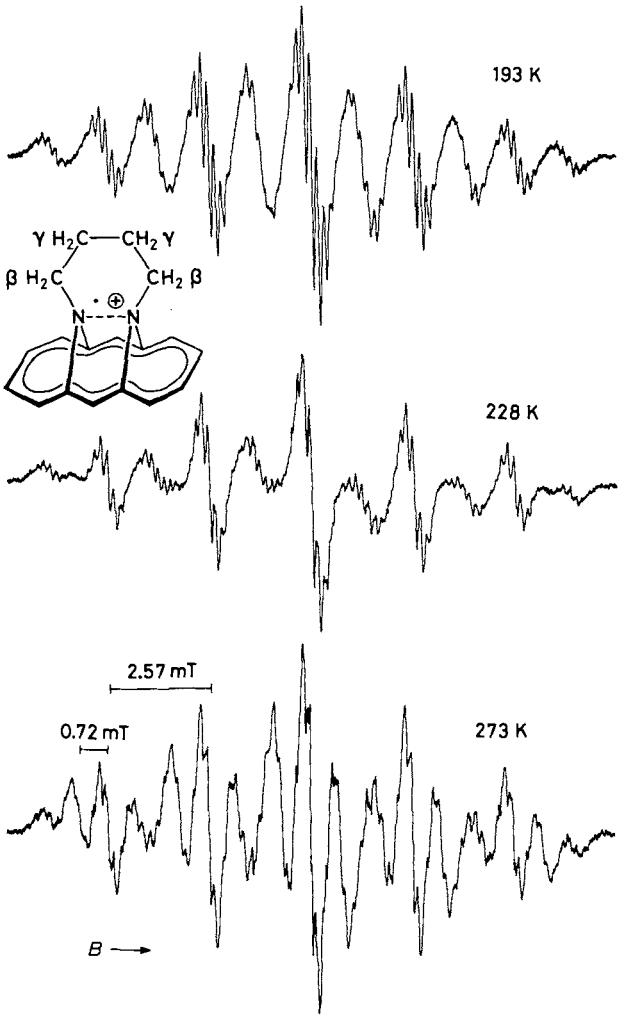

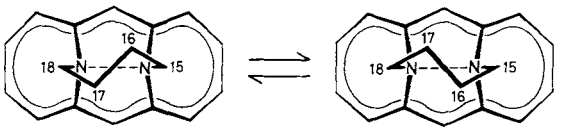

Fig. 1. ESR spectrum of $3^{\cdot\oplus}$ at several temperatures. Solvent, CH_2Cl_2; counterion, $SbCl_6^{\ominus}$.

Although only an average value of 0.72 ± 0.01 mT (fast interconversion) could be exactly measured for these coupling constants, an Arrhenius activation energy E_A was readily calculated for the chain inversion according to a previously described method;[9] simulations of the ESR spectra[10] yielded an E_A value of 22 ± 2 kJ mol^{-1}. A conspicuous spectral feature is the very large coupling constant (a_N = 2.57 ± 0.01 mT) of the two ^{14}N nuclei. It greatly exceeds the corresponding value for $2^{\cdot\oplus}$ (1.685 mT[2]), but it is substantially lower than that for $1^{\cdot\oplus}$ (3.59 mT[1d]). As confirmed by the ENDOR spectra of $3^{\cdot\oplus}$, the protons at the 14-membered π perimeter and the γ protons of the tetramethylene chain give rise to relatively small coupling constants (6H, 0.175 ± 0.005; 4H, 0.150 ± 0.005 mT).

The crystalline perchlorate salt of $3^{\cdot\oplus}$ was prepared by oxidation of **3** with $AgClO_4$ in CH_3CN. Figure 2 gives the mean values of the bond lengths and two selected bond angles in $3^{\cdot\oplus}$ and **3**, as determined by X-ray crystallographic structure analyses.[11] The N–N distance in $3^{\cdot\oplus}$ (218.9 pm) is shortened by 37.1 pm relative to that in **3** (256.0 pm). It compares favorably with the experimentally found N–N bond lengths in $1^{\cdot\oplus}$ (229.5 pm[1e]) and $2^{\cdot\oplus}$ (216.0 pm[2b]), as well as with the analogous value calculated for

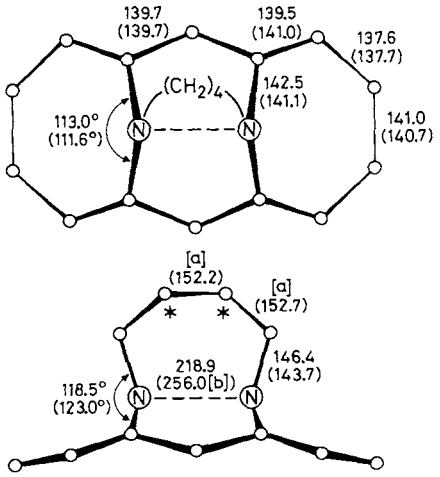

Fig. 2. Mean values for the bond lengths [pm] and two selected bond angles in $3^{\cdot\oplus}$ (**3**). Standard deviations of the bond lengths and bond angles: 0.7 (0.2) pm and 0.4 (0.1)°, respectively. [a] The C atoms, marked here by asterisks, are disordered, because the two conformations of the tetramethylene chain in the asymmetric unit cell are superimposed. [b] No bonding.

$[H_3N\cdots NH_3]^{\cdot\oplus}$ (216.4[5a] and 215.1 pm[5b]). The X-ray crystallographic data thus clearly point to the formation of a N–N three-electron σ bond in $3^{\cdot\oplus}$, a conclusion that could already be drawn from the thermodynamic and kinetic stability of this radical cation and from its large ^{14}N and β-proton coupling constants.

Since the N AOs participating in the N–N three-electron σ bond accommodate almost the entire spin population in $1^{\cdot\oplus}$–$3^{\cdot\oplus}$, the steep rise of the a_N values in the order $2^{\cdot\oplus}$ (1.685 mT) < $3^{\cdot\oplus}$ (2.57 mT) < $1^{\cdot\oplus}$ (3.59 mT) cannot be due to an enhancement of this population, but must be caused by a change in the "character" of the pertinent N AOs. A plot of a_N versus the average C–N–C angles χ[12] in $1^{\cdot\oplus}$ (114.0°[1e]), $2^{\cdot\oplus}$ (119.1°[2b]), and $3^{\cdot\oplus}$ (116.7°) results in an almost perfect straight line with the regression equation (a) (Fig. 3).

$$a_N = (46.18 \pm 0.30) - (0.3736 \pm 0.0026)\,\chi \qquad \text{(a)}$$

The a_N value of 1.35 ± 0.01 mT, obtained by extrapolating χ to 120°, corresponds to two sp^2-hybridized N atoms, each lying in the plane of the three neighboring C atoms. In this

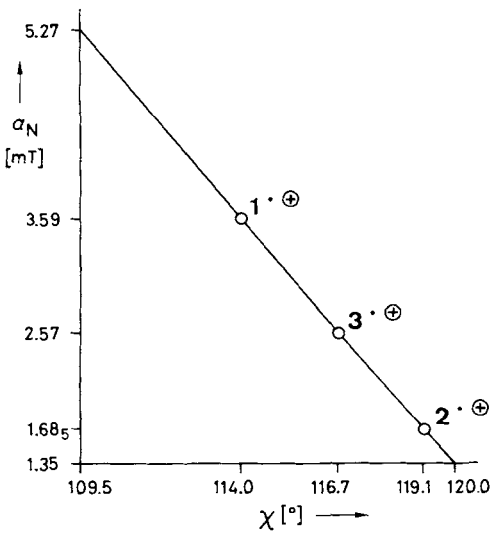

Fig. 3. ^{14}N coupling constants (a_N) versus the average C–N–C angle χ in $1^{\cdot\oplus}$–$3^{\cdot\oplus}$.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0707-0903 $ 02.50/0

case, a three-electron σ bond, formed by N AOs of a pure p character, is perpendicular to the planes of the two "flat" N atoms. The N–N bond in $\mathbf{2}^{\cdot\oplus}$ ($\chi = 119.1°$) approaches such a structure. On decreasing the angle χ, the hybridization of the N atoms changes from sp^2 in the direction of sp^3, and each of them increasingly deviates from the coplanar arrangement with the three neighboring C atoms. The "pyramidalization" of the N atoms enhances the s contribution to the AOs responsible for the N–N bond and thus readily rationalizes the observed rise of the ^{14}N coupling constants with decreasing angle χ: $\mathbf{2}^{\cdot\oplus}$ (119.1°) < $\mathbf{3}^{\cdot\oplus}$ (116.7°) < $\mathbf{1}^{\cdot\oplus}$ (114.0°). In the borderline case, where the two N atoms are sp^3-hybridized ($\chi = 109.5°$), extrapolation yields an a_N value of 5.27 ± 0.02 mT (Fig. 3).

Experimental Procedure

3: Ethyldiisopropylamine (0.52 mL, 3.0 mmol) and 1,4-dibromobutane (0.18 mL, 1.5 mmol) were added to a solution of **4** (312 mg, 1.5 mmol) in 30 mL of toluene in a glass ampoule. After flushing with argon, the sealed ampoule was left standing for 48 h at 150 °C. The reaction mixture was dissolved in diethyl ether, washed three times with water, and dried with magnesium sulfate. Chromatography in pentane on aluminum oxide (particle size 0.063–0.200 mm; column 10 × 2 cm) and recrystallization from diethyl ether afforded 106 mg (27%) of **3** as deep-violet needles (m.p. 130–131 °C).

$\mathbf{3}^{\cdot\oplus}$ $ClO_4^{\ominus}$: anhydrous $AgClO_4$ (16.5 mg, 0.08 mmol) in 2 mL of dry, degassed acetonitrile was added to a solution of **3** (21 mg, 0.08 mmol) in 2 mL of likewise purified acetonitrile. The ampoule was sealed under high vacuum and left standing for several hours at room temperature. Opening of the ampoule and working up the mixture were carried out under argon. Distilling off the solvent, extraction of the residue with dichloromethane, and recrystallization first from dichloromethane and then from nitrobenzene/THF (10:1) gave ca. 4 mg (10%) of red-brown needles of $\mathbf{3}^{\cdot\oplus}$ $ClO_4^{\ominus}$ (m.p. ca. 180 °C), which were stable under argon. Correct elemental analysis [13].

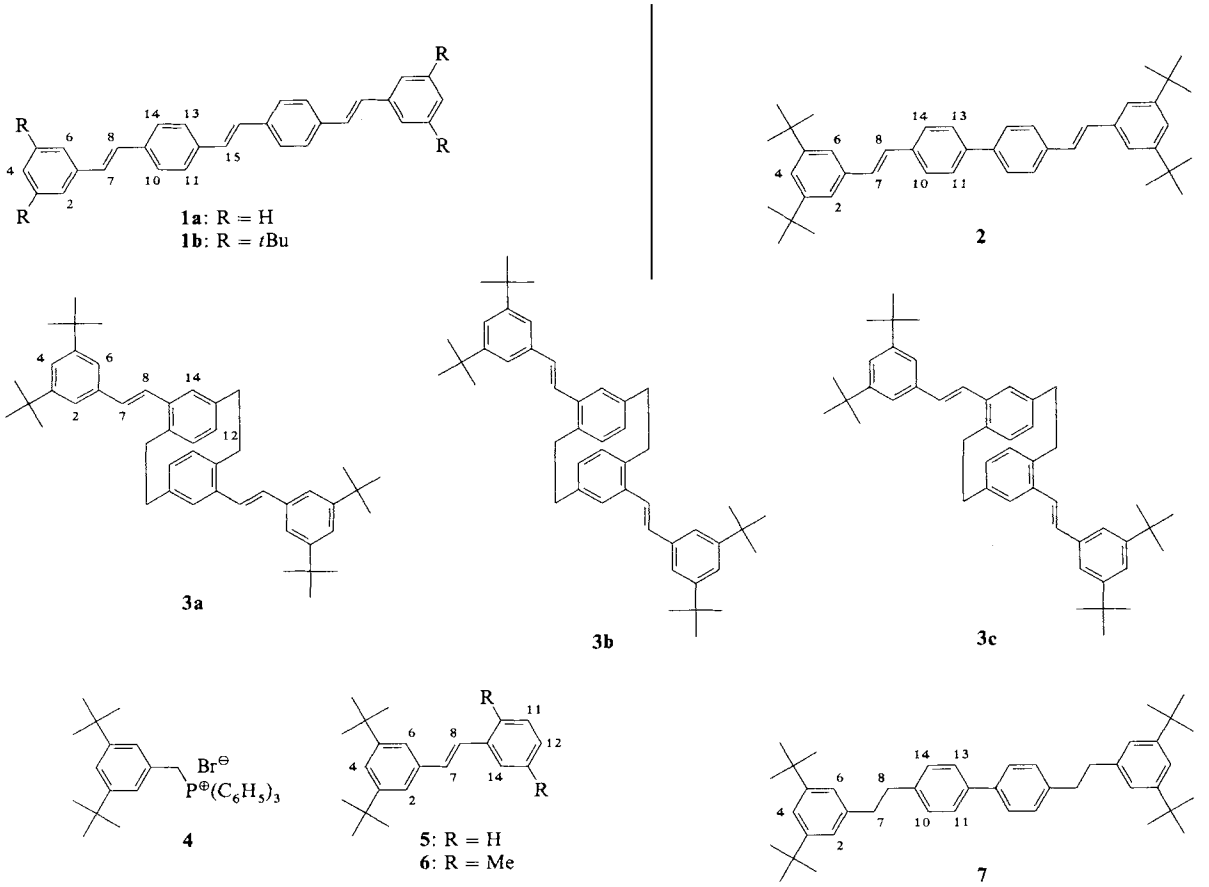
Bis-Stilbene Systems: Reduction to the Tetraanions**

By *Rainer Schenk, Joachim Hucker, Henning Hopf, Hans-Joachim Räder*, and *Klaus Müllen**



Recently, we synthesized a homologous series of soluble oligo-*p*-phenylenevinylenes and studied the dependence of their reduction potentials on chain length.[1] Extrapolation of the results to the analogous polymer compelled us to revise the theoretical concepts[2, 3] used to describe the addition of electrons to linear π systems. However, two questions remain unanswered: What is the maximum number of electrons that can be added to these systems upon reduction? What charge distribution results in a minimization of Coulombic interactions? Using compounds **1**–**3**, in which two stilbene moieties are linked through a vinylene group (**1**) or a single bond (**2**) or interact through space (**3**), we have studied the addition of electrons to polyene chains.

The stilbene systems **1b**, **2**, and **3**[4] were prepared by Wittig reaction of the phosphonium salt **4**[1] (2 equiv.) and, respectively, 4,4′-stilbenedicarbaldehyde, 4,4′-biphenyldicarbaldehyde, and 4,12-[2.2]paracyclophanedicarbaldehyde.[5] The positions of the *tert*-butyl substituents, necessary to increase the solubility of the compounds, were chosen so as to avoid steric perturbation of the π conjugation. For comparison, compounds **5** and **6**[4] were also prepared from **4**. Comparison of the cyclophanes **3** with the stilbene **6** by UV spectroscopy revealed that the longest-wavelength band (**3**, λ = 309, 323 (sh) nm, ε = 46000, 41000; **6**, λ = 297, 317 (sh), 333 (sh) nm, ε = 22200, 17600, 7500) of **3** is shifted bathochromically and has lost fine structure. This finding is in agreement with the observations made for the pair 1,2-bis(*p*-tolyl)ethane and [2.2]paracyclophane and is ascribed to a transannular π, π interaction in the cyclophane system.[6]

Compounds **1b**, **2**, and **3** were reduced with alkali metals in [D_8]THF at −78 °C. The blue to violet products were characterized by ^1H and ^{13}C NMR spectroscopy (see Table 1 and Ref. [7, 8]) as well as by quenching reactions. In each case, trapping with dimethyl sulfate afforded tetramethyl adducts. In agreement with this result, the reduction product of **2** was protonated to give the tetrahydro derivative **7**.[4] Independent of the way in which these structurally related π systems are linked, therefore, reduction yields the alkali-metal salt of the respective tetraanion. This is remarkable, since reduction of **1b**, for example, results in transfer of only

three electrons according to cyclic voltammetry.[11] These tetraanions are all stable at room temperature in the absence of air. For comparison with **1b**,[7] **2**, **3**, and their tetraanions, the stilbenes **5** and **6** were converted into their dianions (see Table 1 and Ref. [7, 8]). Protonation of the latter afforded the corresponding ethane derivatives.

Although the reductions of **1b**, **2**, and **3** were followed by NMR spectroscopy, it was not possible to obtain high-resolution NMR spectra of the intermediate dianions. This was achieved, however, for the more poorly soluble parent compound **1a**.[7]

Structural elucidation of the anions by NMR spectroscopy is hampered by the presence of conformational isomers for $\mathbf{1a}^{2\ominus}/2M^{\oplus}$, $\mathbf{1b}^{4\ominus}/4K^{\oplus}$, and $\mathbf{3}^{4\ominus}/4M^{\oplus}$ (M = Li,K in each case). Conformational isomers were not observed, however, for $\mathbf{1b}^{4\ominus}/4Li^{\oplus}$ and $\mathbf{2}^{4\ominus}/4Li^{\oplus}$. The conformational isomerism is presumably due to slower rotation around the formal single bonds on the NMR time scale because of the higher π-bond order.[9] In each case, rotation of the terminal phenyl units is no longer observed at −20 °C. The number of ^{1}H NMR signals for $\mathbf{1b}^{4\ominus}/4M^{\oplus}$ indicates that the Li salt is only present as a symmetric conformer. The K salt, on the other hand, forms all three possible conformers owing to slow rotation around the formal single bonds C8-C9 and C12-C15.[10] In the case of $\mathbf{3}^{4\ominus}/4M^{\oplus}$, hindered rotation around the formal single bonds C8-C9 (C8′-C9′) can lead to three non-isodynamic conformers **3a–c**, only two of which are centrosymmetric (**3a,b**). The equal intensities of all NMR signals may best be explained by the existence of only *one* non-centrosymmetric structure **3c** with different twisting angles (ca. 0, 180°) with respect to C8-C9 (C8′-C9′).

The two stilbene moieties of $\mathbf{3}^{4\ominus}/4M^{\oplus}$ differ markedly in their ^{1}H and ^{13}C NMR chemical shifts as well as in the coupling constants of their vicinal (olefinic) protons (see Table 1). These effects are due primarily to the conformational isomerism.[10] Even comparison with $\mathbf{6}^{2\ominus}/2M^{\oplus}$ revealed no anisotropic ring-current effects. A shift of charge to the outer styryl units due to electrostatic repulsion within the cyclophane element was not observed.

The calculated π-charge densities q_π in the dianion of **1a** and **1b** decrease in the series $q_\pi(C15) > q_\pi(C7) > q_\pi(C8)$. The additional charge in the tetraanion is localized above all in the terminal double bond, resulting in the series $q_\pi(C7) > q_\pi(C8) > q_\pi(C15)$. As expected based on the correlation of

^{13}C and ^{1}H NMR chemical shifts with π charge densities,[11] H15 in $\mathbf{1a}^{2\ominus}/2M^{\oplus}$ absorbs at highest field, whereas the difference in shifts of H15, H8, and H7 in $\mathbf{1b}^{4\ominus}/4M^{\oplus}$ is significantly smaller. The δ values of $\mathbf{2}^{4\ominus}$ reveal no evidence of "uncoupling" of the stilbene units by twisting around the biphenyl single bond, since the calculated relative charge densities of C7 and C8 are not affected by the twisting. The characterization of all these tetraanions by NMR spectroscopy reveals (also in comparison with $\mathbf{5}^{2\ominus}$ and $\mathbf{6}^{2\ominus}$) the existence of two separate, only slightly perturbed stilbene subunits.

The first two reduction potentials E_1 and E_2 of **1b**, **2**, and **3** were found to be $-1.96/-2.14$, $-2.11/-2.28$, and $-2.30/-2.52$ V, respectively, by cyclic voltammetry (dimethylformamide; NBu_4PF_6 as supporting electrolyte; $T = 288$ K; scan rate 100 mVs^{-1}; potentials vs. SCE, measured using Ag wire as a quasi reference, ferrocene calibration; reversible one-electron transfers in each case). The E_1 and E_{pc} values[12] of **5** and **6**, for comparison, are $-2.39/-2.95$ and $-2.40/-2.95$ V, respectively. The radical anion of **3**—in which the stilbene units interact "more weakly"—thus appears to be less stable than the radical anions of **1b** and **2**, but more stable than those of the reference compounds **5** and **6**. The potential differences $E_1 - E_2$, a measure of the interaction energies of the excess electrons, are 0.18 (**1b**), 0.17 (**2**), and 0.22 V (**3**), and reveal that the interaction of the two charged stilbene units in the dianions of **2** and **3** is small.

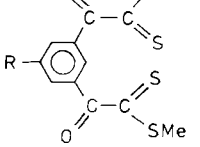
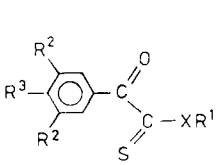
[12] The dianion potentials of **5** and **6** are not half-wave potentials but rather cathodic peak potentials (E_{pc} values), since, under the measuring conditions, the dianion stage is irreversible.

Radical Tri- and Pentaanions of Benzenedi- and Benzenetriglyoxylate Thioesters**



By *Andrzej Sawluk* and *Jürgen Voß**

Although radical monoanions of numerous compounds with π-electron systems have been known for decades,[1] molecular radicals with more than two negative charges have only been described recently: for example, radical trianions of aromatic hydrocarbons having a network of conjugated double bonds, more highly charged ionic hydrocarbons such as the decacyclene hexaanion,[2] or oligoanions of tetramers and pentamers of the phenylene-vinylene type,[3] in which Coulombic repulsion of the electrons is reduced by delocalization.[4] Stabilization may also be achieved, however, by incorporation of functional groups containing atoms with higher polarizability such as sulfur.



We have now found that compounds **1**–**4**,[5–7] which are thiono- and dithioesters of benzenedi- and benzenetrigly-

[**] ESR Investigations on Carboxylic Esters, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. *A.S.* thanks the Konrad-Adenauer-Stiftung for a Promotionsstipendium. Part 10: R. Edler, J. Voß, *Chem. Ber. 122* (1989) 187.

oxylic acid, readily accept several electrons, even though they contain only one benzene ring. This is shown not only by the electroanalytic measurements but also by the ESR spectra.[5] Five maxima ($E_{1/2} = -0.13$, -0.35, -0.59, -1.31, and -1.62 V; cf. Fig. 1) are observed in the differential pulse polarogram of the tris(dithioester) **4**, measured in dimethylformamide (DMF).[10]

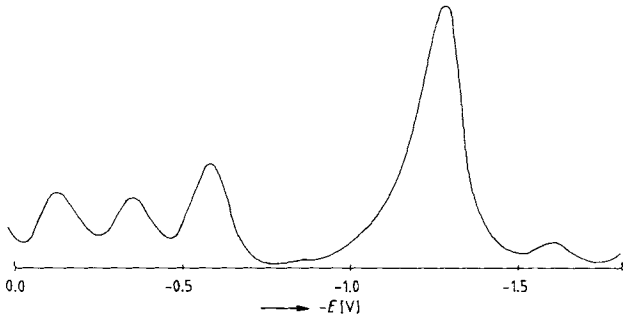

Fig. 1. Differential pulse polarogram of **4**, recorded in DMF/nPr$_4$Br versus Ag/Ag$^{\oplus}$.

The two striking examples in Figure 2 show the completely different ESR spectra of the radical monoanions and the corresponding radical oligoanions obtained by in situ electroreduction at different potentials.[11] We assign the spectrum shown in Figure 2, bottom, to the pentaanion of **4**, because it appears when a cathode potential of -1.0 V, the value at which the corresponding polarographic step begins, is applied to the ESR measuring cell – but, above all, because this assignment provides the only clear explanation of the proton hyperfine structure of the ESR spectrum.

The different spin density distributions arising in the molecule after it accepts one or more electrons result in different coupling constants (Table 1), which can be used to simulate reliably the ESR spectra. In the triply charged radical ions of **1**–**3**, one of the functional groups is capable of bearing two negative charges; in $\mathbf{4}^{\cdot 5\ominus}$, two of the functional groups can each bear two negative charges. These substituents thereby become "diamagnetic", while the benzene ring, with one functional group, contains the unpaired electron. The ESR spectra thus obtained strongly resemble those of the radical anions of *tert*-butyl-substituted thionoesters (e.g., **5a**)[5, 8] and dithioesters (e.g., **5b**, **6**)[9] of phenylglyoxylic acid (compare the ESR spectrum of $\mathbf{5a}^{\cdot\ominus}$, Fig. 3, with that of $\mathbf{1}^{\cdot 3\ominus}$, Fig. 2); on the other hand, the radical monoanions $\mathbf{1}^{\cdot\ominus}$–$\mathbf{4}^{\cdot\ominus}$ exhibit a spin density distribution corresponding to the molecular symmetry. The higher spin density in one thioester group is reflected in the g factors of the radical oligoanions, which are increased by the heavy atom effect of the sulfur atom (Table 1).

Owing to the different alkyl moieties, unsymmetrical radical trianions $\mathbf{2c}^{\cdot 3\ominus}$ exist as two characteristic species, whose overlapping ESR spectra display different coupling constants and g factors (Table 1).

We assume that, in the multiply charged species, each spin label group – defined in terms of the ESR time scale – is coplanar with the ring, so that spin delocalization is possible. By contrast, the other, doubly negatively charged functional groups are twisted out of the ring plane (Fig. 4). For the radical monoanions, such a conformation is also apparently adopted at low temperatures to a certain extent. For instance, on cooling to -49 °C, $\mathbf{2a}^{\cdot\ominus}$ and $\mathbf{3a}^{\cdot\ominus}$ show new ESR spectra, which do not arise by line broadening of the spectra recorded at room temperature. Instead, they resemble much

more strikingly the spectra of the trianions $\mathbf{2a}^{\cdot 3\ominus}$ and $\mathbf{3a}^{\cdot 3\ominus}$ and are due to a different, less symmetric spin density distribution.[5]

Different ESR spectra are also obtained when dithioesters of 4-nitrophenylglyoxylic acid are reduced at different potentials, so that they accept one or more electrons.[5] By contrast, no multiply charged radical anions are detectable for the sulfur-free esters of benzenediglyoxylic esters.[5]

[10] DMF was purified by azeotropic distillation with benzene, dried, and stored over molecular sieves at 4 °C. The potentials are given relative to an internal silver electrode (Ag wire in a 0.1 M solution of tetrapropylammonium bromide in DMF); cf. footnote [b] in Table 1.
[11] The radical ions were generated, as described in [12], by internal electrolysis of 3×10^{-3} M solutions of thioesters in dry DMF (0.1 M in tetrapropylammonium bromide as electrolyte) at a Pt cathode. The ESR spectra were recorded with a Bruker 420 s spectrometer [12].

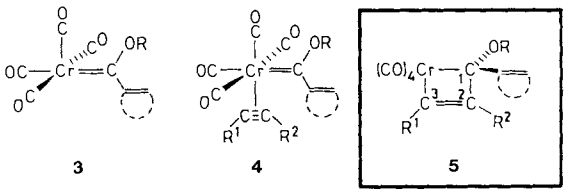
The Mechanism of the Dötz Reaction: Chromacyclobutenes by Alkyne–Carbene Coupling?**

By *Peter Hofmann** and *Martin Hämmerle*

Dedicated to Professor Hans Hofmann on the occasion of his 60th birthday

The reaction of Fischer carbene complexes **1** with alkynes, first described by *Dötz* (Dötz reaction),[1] has proved to be of exceptionally broad preparative value.[2–5] The complexity of this template reaction is revealed by the fact that – depending on reaction conditions and starting materials – roughly ten other types of products have so far been isolated in addition to phenol derivatives **2**.



1 **2**

Although the mechanism of the Dötz reaction and its variants is still largely unknown, all mechanistic proposals start from a *cis* CO dissociation in **1** followed by alkyne coordination to intermediates **3** giving species **4**. Kinetic investigations[6] and studies on tungsten analogues of **1**[7] seem to support this assumption. In a subsequent step, chromacyclobutenes **5** are postulated to be the key intermediates formed[8] by (regioselective) alkyne–carbene coupling at the

metal. It is the stereochemistry of their electrocyclic ring-opening ("mode of rotation" at C1) and of the vinylcarbene complexes thereby formed which was recently suggested to govern the course of further transformations and therefore the chemoselectivity of the overall reaction.[9]

3 4 5

Here we report MO model calculations[10] which demand some modification of these concepts and which are relevant to the stereo- and chemoselectivity of the Dötz reaction. Although planar metallacyclobutenes similar to **5** are known and their structures have been established (**6**,[11] **7**,[12] **8**[13]), analogous ground-state geometries for $Cr(CO)_4$ (d^6-ML_4, isolobal to $CH_2^{2\oplus}$, $CH^{\oplus}$) as metal fragment are unrealistic.

6 $R^1 = R^2 = Ph, SiMe_3$; $R^1 = Ph$, $R^2 = SiMe_3$ 7 8 $R = p$-tolyl

9 10

This is clearly revealed in Figure 1, which shows the computed interaction diagram between a $Cr(CO)_4$ fragment[14] and a C_3H_4 ligand[15] for the unsubstituted, planar model system **9**.

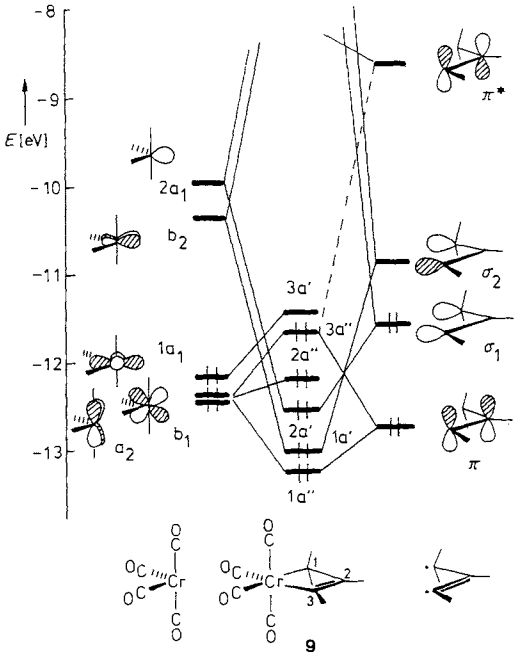

Fig. 1. Interaction diagram between $Cr(CO)_4$ (C_{2v}, "octahedral" fragment) and the C_3H_4 ligand (C_s) for structure **9**. Only the relevant contributions to the molecular orbitals are shown schematically.

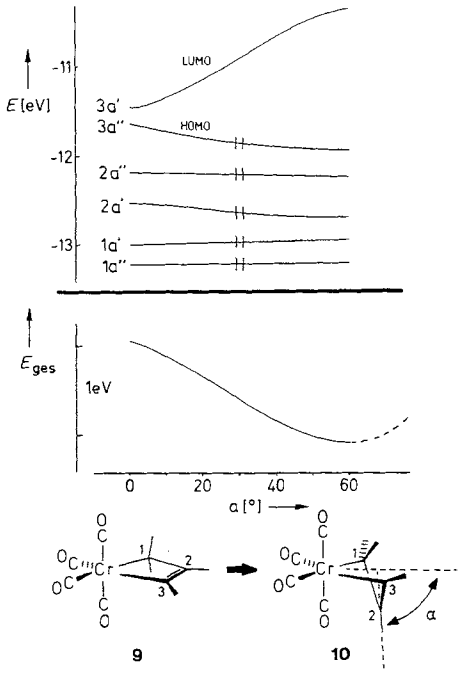
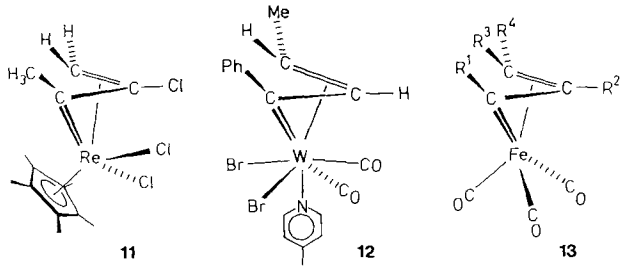
Interaction of the fragment MOs σ_1 and σ_2 with $2a_1$ and b_2 of $Cr(CO)_4$[14] results in the MOs 1a' and 2a' of the two Cr–C σ bonds. The π MO of the C_3H_4 system cannot satisfy the electronic requirements of the chromium center in **9**. Thus, as typical of such cases, an "open-shell" 16-electron system with only a small separation between HOMO and LUMO emerges. The character of the two frontier orbitals of **9**–3a' largely corresponds to the empty x^2-y^2 AO on chromium and 3a'' is mainly localized on C3 of the π MO of the C2–C3 double bond – implies an out-of-plane distortion of the metallacyclobutene ring, that is, a 2nd-order Jahn–Teller stabilization.[14] Figure 2 shows a calculated Walsh diagram and the corresponding total energy for a "ring folding" of **9** (H atoms relaxed). The resulting structure **10**, which is 26 kcal mol^{-1} more stable than **9**, has a large frontier orbital energy separation and an 18-electron configuration. Analogous structure characteristics have been found





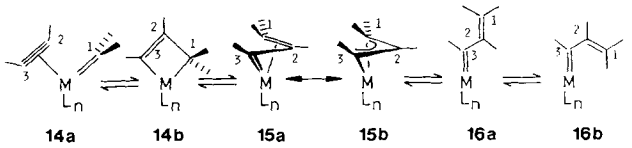


Fig. 2. Walsh diagram and total energy curve for a "folding" of the metallacyclobutene ring of **9** around the C1–C3 axis; H atoms simultaneously relaxed, interatomic distances constant.

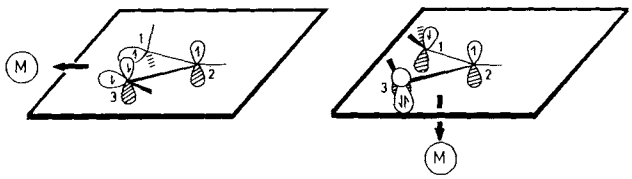
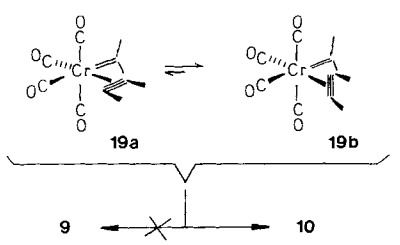
experimentally for **11**[16] and **12**[17] and for representatives of **13**.[18] Thus, within the structural continuum **14**–**16**, $[(CO)_4Cr(C_3H_4)]$, in accord with **15a/15b**, has to be regarded as an η^3-vinylcarbene complex in which the double bond saturates the electron deficiency of chromium intramolecularly. The calculations indicate that the vinyl π system is coordinated relatively loosely to the metal (weak back-bonding). For $ML_n = Cr(CO)_4$, therefore, the isomeric structures **15** (= **10**) and **16a/16b** have similar total energies and, even without complete geometry optimization, are ca. 25–30 kcal mol^{-1} more stable than the most energetically favored structure of **9**! In **10**, unlike **9**, the double bond is no longer localized between C2 and C3; instead, the calculated overlap populations indicate that it resides more between C1 and C2 or is delocalized in the C_3 system. True η^1-vinylcarbene ligands such as those in **16** are known at, for example, $Cr(CO)_5$[19] and $Cp_2Ti(PMe_3)$.[20]

Analogous calculations for Cp_2Ti, $(PH_3)_2Pt$, and $Fe(CO)_3$ as metal fragments correctly reproduce the ground-state geometries found experimentally for **6**, **7**, and **13**: planar metallacyclobutene structures for $Cp_2Ti(C_3H_4)$ and



11 12 13



14a 14b 15a 15b 16a 16b

$(PH_3)_2Pt(C_3H_4)$, η^3-vinylcarbene type for $(CO)_3Fe(C_3H_4)$. In the series d^2-ML_6 (Cp_2Ti in **6**), d^4-ML_5 ([Cp*$ReCl_2$] in **11** and $[W(CO)_2Br_2$(4-picoline)] in **12**), d^6-ML_4 ($Cr(CO)_4$ in **10**), d^8-ML_4 ($Ir(PMe_3)_3Br$ in **8**), and d^{10}-ML_2 ($(PPh_3)_2Pt$ in **7**), the coordination mode of the organic ligand therefore adjusts to the symmetry and occupation of the valence orbitals (the isolobal character) of the respective metal unit and serves as a two-electron donor **17** ("in plane") or a four-electron donor **18** ("out of plane").

17 18

The details of the real structures **11**–**13** (C–C and M–C bond lengths, weight of **15a** versus **15b**, degree of backbonding, etc.) depend on the specific fragment ML_n and on the substitution of the C_3 system. The appreciably lower total energy of **10** compared with **9** means that, in the Dötz reaction, alkyne carbene complexes **4** do not react via chromacyclobutenes **5**. Model calculations on **19**, the η^2-C_2H_2 ligand of which, like ethene,[21] prefers conformation **19b** by ca. 5 kcal mol^{-1}, indeed lead to an energy maximum approximately 23 kcal mol^{-1} above **19a** for the "in plane" alkyne–carbene coupling **19a** → **9** (C_s symmetry), in marked contrast to the exothermic reaction course calculated for Cp_2Ti as metal fragment.[11b] In neither case is the reaction symmetry forbidden.

19a 19b

9 10

Preliminary calculations, even without full optimization of the reaction pathway, reveal, however, that the activation barrier disappears nearly completely for a direct rearrangement of **19b** to **10** (C_1 symmetry). This suggests that alkyne carbene complexes **4**, formed via **3**,[22] should they exist as discrete intermediates at all,[23] may rearrange directly to η^3-vinylcarbene complexes. This mechanism would establish both the regioselectivity of alkyne incorporation and the chemoselectivity of the overall reaction (via *exo*/*endo* or *cis*/*trans* position of the substituents at C1 of intermediates of type **10** and **16**) without a need to invoke chromacyclobutenes **5** and their electrocyclic ring opening.[9] The consequences of the results described here with respect to a mechanistic understanding of the Dötz reaction or of alkyne polymerization with Fischer carbene complexes of tungsten,[24] where intermediates like **5** have also been assumed, are self-evident.

In the case of d^8-ML_3 [13] and d^2-ML_6 [11], for which the coupling products have been isolated, such intermediates are not detectable.

Water Elimination from Phosphorus–Oxygen Compounds: The Formation of 2-Phosphapropene by Thermolysis of Dimethylphosphane Oxide**

By *Hans Bock** and *Martin Bankmann*

Dedicated to Professor Gottfried Märkl on the occasion of his 60th birthday

Unsaturated organophosphorus compounds containing the structural units $-C\equiv P$, $\diagdown C=P-$, $-P=C=P-$, $-C\equiv P\diagup\diagdown$, or $\diagup C-P\diagup\diagdown$ with a wide variety of substituents have recently been synthesized by numerous routes.[1, 2] However, their preparation by thermal dehydration, for example of dialkylphosphane oxides, $R_2HP=O$, which are now being produced on a large scale,[3] has not been reported.[4] The P=O bond, which exhibits a bond dissociation enthalpy of 520 to 720 kJ mol^{-1},[5, 6] is generally regarded as being highly favored energetically; its preferential formation is exploited in the Wittig and Arbusov reactions.[5] Here we report on the gas-phase thermolysis of dimethylphosphane oxide[2, 3] to give 2-phosphapropene [Eq.(1)], which has already been generated by HCl elimination from dimethylchlorophosphane.[1, 2]

(1)

When the decomposition of $(H_3C)_2HP=O$ on quartz wool is followed by PE-spectroscopic real-time analysis,[7] a method that has proved especially valuable for studying reactive molecules in the gas phase, the ionization pattern recorded at room temperature provides no evidence of a hydroxy isomer[8] (Fig. 1, top). The decomposition starts above 770 K, as revealed by the appearance of the characteristic sharp peak at 12.6 eV corresponding to H_2O ionization. Undecomposed dimethylphosphane oxide can be removed by inserting a 230 K cold trap, so that the bands of H_2O and the dehydration product (cf. Ref. [1]: 9.7, 10.0, 12.4, and 14.3 eV) dominate the spectrum. Above 970 K, methane is eliminated ($H_3C-P=CH_2 \rightarrow HC\equiv P+CH_4$), as observed earlier.[1]

The thermal decomposition of dimethylphosphane oxide thus results in water elimination! By carrying out this novel preparation of 2-phosphapropene on finely granulated silica, for example, the reaction can be optimized[2] and even made superior to the HCl elimination from dimethylchlorophosphane, which needs finely tuned reaction conditions and affords only moderate yields.[1] Condensation of the highly reactive 2-phosphapropene in a 77 K cold trap and careful fractional reevaporation allows, for example, the head-to-tail dimer, *trans*-1,3-dimethyl-1,3-diphosphetane, to be characterized by mass and PE spectroscopy,[2, 8] while a viscous, glassy polymeric residue is obtained as the main product.

This surprising dehydration of dimethylphosphane oxide represents an unprecedented type of reaction in organophosphorus chemistry.[5] To rationalize the unexpected observation, a section of the MNDO energy hypersurface has been calculated, which, by appropriate choice of the coordinates

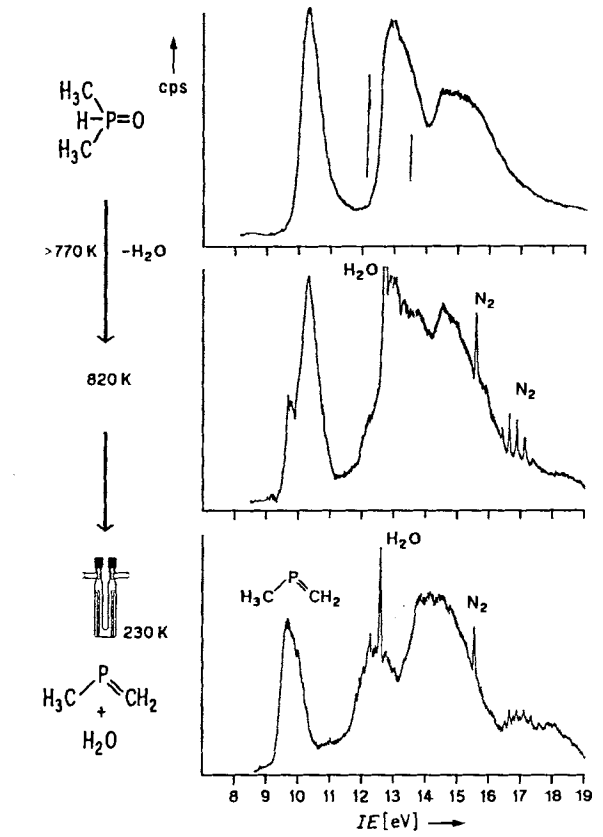

Fig. 1. He(I) PE spectra of dimethylphosphane oxide (top) and its thermolysis products on quartz wool at 820 K, H_2O and $H_3C-P=CH_2$ (middle), as well as the spectrum after removing undecomposed $(H_3C)_2HP=O$ in a 230 K cold trap (below).

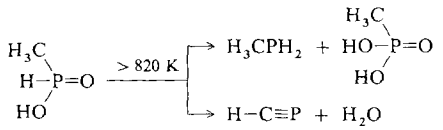
[**] Gas-Phase Reactions, Part 75. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, Hoechst AG, and the Land Hessen. We thank Prof. *K. Kühlein* (Hoechst AG) for donation of chemicals. Part 74: H. Bock, B. Solouki S. Patai; Z. Rappoport (Eds.): *The Chemistry of Organic Silicon Compounds*, Wiley, Chichester 1989, pp. 555–653.



$d(O\cdots H_8)$ and $d(O\cdots H_{12})$ from the total of $(3\times 11-6)=27$ degrees of freedom, contains the two isomers of the starting material, $(H_3C)_2HP=O$ and $(H_3C)_2P-OH$, as well as the two products, $H_3C-P=CH_2$ and H_2O (Fig. 2).[9] With respect to the assumptions introduced, these calculations afford the following speculative insights into the thermolysis pathway: The MNDO enthalpies of formation suggest a relatively shallow potential well for dimethylphosphane oxide, which is considerably deepened by including d-polarization functions in an ab initio basis set (Fig. 2: ○). The barrier for the isomerization $(H_3C)_2P-OH \rightarrow (H_3C)_2HP=O$, calculated by MNDO to amount to approximately 420 kJ mol^{-1}, agrees with reported values.[10] The minimum-energy reaction path crosses the first and highest energy transition state, TS_1, and then follows the slope of the hypersurface to the saddle point TS_2 for the 1,2-HOH elimination at 88-kJ mol^{-1} lower energy (Scheme 1).

Scheme 1. Enthalpy differences ΔH_f from MNDO calculations.

The overall endothermic H_2O elimination is apparently preferred over the energetically more favorable isomerization because of the entropy increase. Considering the numerous approximations and, in particular, the selection among the many degrees of freedom, the reaction profile (Scheme 1) is also in agreement with the experimental result that not even traces of the possible isomerization product $(H_3C)_2P-OH$ are revealed by PE spectroscopy. Under the nearly unimolecular thermolysis conditions (pressure 10 Pa), only the simultaneous elimination of water allows an effective dissipation of the activation energy stored in the "chemically activated" $(H_3C)_2P-OH$.[11]

This type of reaction, in which unsaturated phosphorus(III) compounds are prepared by thermal elimination of water from phosphane oxides, can be extended to other derivatives.[2] For example, methylphosphinic acid, on gas-phase thermolysis at 820 K, only partially disproportionates to methylphosphane and methylphosphonic acid, while phosphaacetylene is formed in approximately the same yield by water elimination.[2]

[8] Vertical ionization energies of $(CH_3)_2HP=O$ with assignment: 10.32 (n_O,$\pi_{P=O}$), 12.9 (σ_{PC}, σ_{PH},σ_{PO}), and >14.5 eV (σ_{CH}). *trans*-1,3-Dimethyl-1,3-diphosphetane: *m/z* 120 ($M^{\oplus}$), 105 ($M^{\oplus}$-CH_3), 92, 77, 75, 57, 45; IE^V = 8.0 ($4b_g$), 9.3 ($6a_g$), 11.3 ($3b_g$, $3a_u$, $5b_u$), 12.9–15.5 eV; ΔH(MNDO) = −274.1 kJ mol^{-1}.

[9] According to the literature, bond enthalpies of four-coordinate phosphorus(v) compounds obtained from MNDO calculations are usually too high, because d-polarization functions are not included in the MNDO parameter set. [cf. M. J. S. Dewar, M. L. McKee, H. S. Rzepa, *J. Am. Chem. Soc. 100* (1978) 3607]. On the other hand, ab initio studies [6], in agreement with the experimental data, indicate that nearly all derivatives HXYPO are 10–60 kJ mol^{-1} more stable than the corresponding tautomers XYPOH. According to the Hammond principle [*J. Am. Chem. Soc. 77* (1955) 334], the transition states of endothermic reactions should be productlike. Therefore, the MNDO results for both the isomerization and the H_2O elimination of the phosphorus(III) derivatives are assumed to satisfactorily approximate this part of the energy hypersurface (Fig. 2). For the phosphorus(v) compound $(H_3C)_2HP=O$, the ab initio total energy [6] also given (Fig. 2: ○) demonstrates that the potential well calculated by MNDO is too shallow.

The "chemically activated" $H_2C=NH$, generated by methyl azide pyrolysis, eliminates H_2 in the subsequent reaction channel and forms HCN at a temperature 500 K lower than after prior isolation in a 180 K cold trap.

Amides Nonplanar Solely by C–N Bond Rotation**

By *Terrence J. Collins** and *José M. Workman*

Because of its central significance, the structural properties of the amide functional group have been studied extensively.[1] As a result of the distinctive bonding features, the C, N, and O atoms and their substituent atoms lie in a planar array for almost all amides, a structural generality having

[*] Prof. T. J. Collins, J. M. Workman

[**] Support by the National Science Foundation (Grant No. CHE-8714720) is gratefully acknowledged.

many notable consequences. Nonplanar amides are rare and arise in organic chemistry primarily when amide groups are constrained by rings.[2] Three separate classes of distinctly nonplanar amide groups bonded to metals have been identified in the last several years.[2, 3] Parameterization of nonplanar deformations was exquisitely defined in the early seventies, allowing amide nonplanarity to be assessed meaningfully in terms of the C–N twist angle and planar-to-pyramidal distortions at carbon and nitrogen.[4]

Deformation by twisting of the C–N bond or by pyramidalization at C are extremely rare. Pyramidalization at nitrogen is the lowest-energy deformation and the dominating occurrence. Here we describe a unique molecule, **2**, with a ligand containing two nonplanar amide groups in which twisting of the C–N bonds is appreciable, but pyramidalization at the N and C atoms is nonexistent.

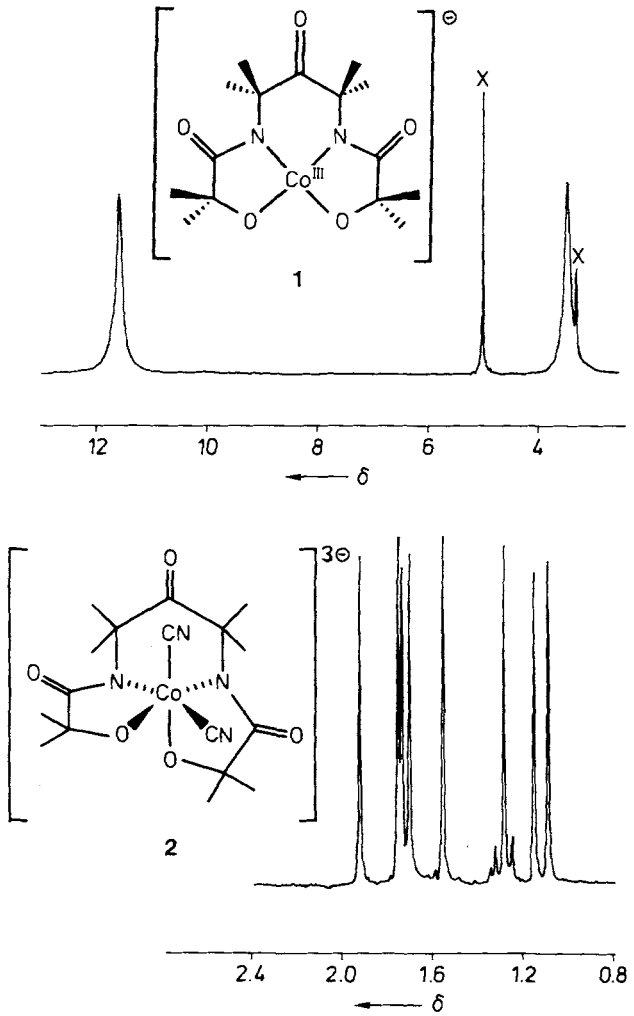

Fig. 1. ^{1}H NMR spectra of **1** (top) and **2** (bottom) (300 MHz, in CD_3OD. ×: solvent peak.

When a CD_3OD solution of the paramagnetic square-planar cobalt(III) complex **1** (Fig. 1), as a sodium salt,[5] is treated with two equivalents of potassium cyanide, the ^{1}H NMR spectrum indicates the formation of a low-symmetry diamagnetic complex, **2**, in which the tetradentate ligand cannot be planar (the two equivalent sets of four methyl groups of **1** are split to eight singlets in **2**; see Fig. 1). The appearance of two ν_{CN} bands in the IR spectrum at 2121 and 2111 cm^{-1} (Nujol mull) is consistent with an octahedral complex containing *cis* CN ligands. Previous experience[2, 3] suggested that the tetradentate ligand can be compatible with a nonplanar octahedral stereoisomer only if the amide groups are distorted. An increase in the IR stretching frequency of the highest amide band (1610 cm^{-1} in **1** to 1654, 1648, 1632 cm^{-1} in **2**) indicates significant amide nonplanarity. The results of an X-ray crystal structure determination[6] for **2** and the Dunitz amide nonplanarity parameters[4, 7] are shown in Figure 2.

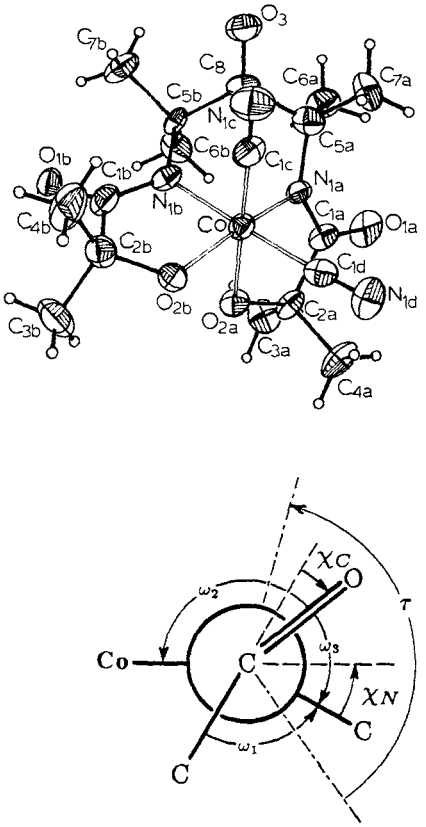

Fig. 2. Top: Molecular structure of **2** [6]. Bottom: Dunitz amide nonplanarity parameters [4]. See also [7].

As expected, both amide groups in **2** are significantly distorted. However, the N atoms remain rigorously trigonal planar ($\chi_{N1b} = -1°$, $\chi_{N1a} = 1°$) with all distortions being accommodated by twisting of the C–N bond ($\bar{\tau}_{N1b-C1b} = 15°$, $\bar{\tau}_{N1a-C1a} = 17°$). As expected,[3a] the amide C atoms remain planar ($\chi_{C1b} = \chi_{C1a} = 1°$). The results suggest that there is $p \rightarrow d\pi$ bonding between the amide N atoms and the Co atom as an additional force holding the amide N atoms planar. This bonding term should be encouraged by the presence of the strong π-back-bonding CN ligands.

[6] Crystal data for NaK_2-**2**·$CH_3OH \cdot 3\,H_2O$: space group $P2_1/c$, $a = 9.869(1)$, $b = 17.323(2)$, $c = 16.083(3)$ Å, $\beta = 94.85(1)°$, $V = 2739.7(7)$ Å^3, $Z = 4$; 1606 independent reflections with $I > 3\sigma(I)$; four-circle diffractometer, $Cu_{K\alpha}$, $3° \leq 2\theta \leq 115°$. Lorentz, polarization, and adsorption corrections and corrections for linear decay were applied to the 3766 independent reflections collected. Anomalous dispersion corrections were applied for Co, K, and Na. The 35 non-hydrogen atoms were located using the SHELXTL Direct Methods programs and the hydrogen atom positions were located. Final cycles of least-squares refinement, which employed anisotropic thermal parameters for non-hydrogen atoms and isotropic parameters for hydrogen atoms, gave $R_1 = 0.053$, $R_w = 0.058$. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England), by quoting the full literature citation.

[7] The twist angle τ and the pyramidalization terms χ_C and χ_N were obtained from the primary torsion angles ω_1, ω_2, and ω_3 as follows: $\tau = (\omega_1 + \omega_2)/2$; $\chi_N = (\omega_2 - \omega_3 + \pi) \bmod 2\pi$; $\chi_C = (\omega_1 - \omega_3 + \pi) \bmod 2\pi$. Here we use the modified twist angle, $\bar{\tau}$: $\bar{\tau} = (\tau) \bmod \pi$ [3a]. $\bar{\tau}$ maximizes at $\pm 90°$ and can be interpreted as the angle between the idealized positions of the $p\pi$ orbitals on C and N. The pyramidalization terms maximize at $\pm 60°$.

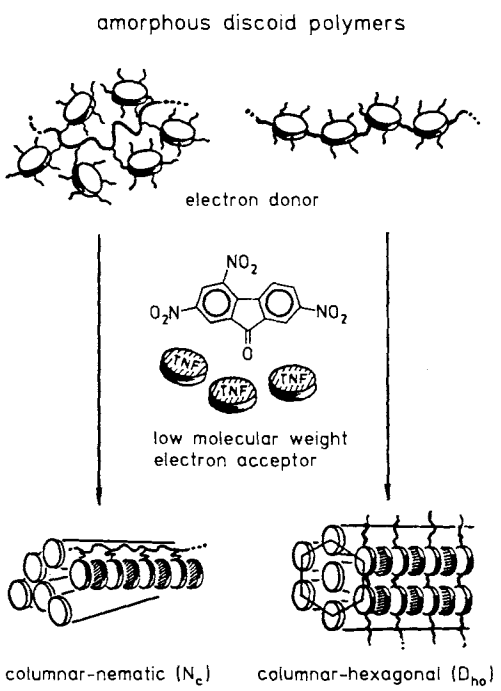

Fig. 1. Schematic presentation of the induction of discotic mesophases in amorphous discoid polymers via charge-transfer interactions with low molecular weight electron acceptors. Left: Side-group polymers. Right: Main-chain polymers. TNF = 2,4,7-trinitrofluorenone as acceptor. D_{ho} = discotic hexagonal ordered (hexagonal long-range order of columns, whose discs are stacked with regular spacings). N_C = nematic columnar (nematic order, i.e., exclusively one long-range orientational order of the columns, whose discs are also stacked with regular spacings). In contrast to the N_C phase, the known discotic-nematic N_D phases [3] do not consist of columns but rather of individual discs ordered in nematic fashion.

Induction of Liquid Crystalline Phases: Formation of Discotic Systems by Doping Amorphous Polymers with Electron Acceptors

By *Helmut Ringsdorf,* Renate Wüstefeld, Elfriede Zerta, Martina Ebert,* and *Joachim H. Wendorff*

Doping of liquid crystals: Structure–property relationships of low molecular weight and polymeric liquid crystals[1] are of current interest, in particular those between molecular structure and properties such as color,[2a] ferroelectricity,[2b] photoreactivity,[2c] and nonlinear optical activity.[2d] These functionalities may be introduced into liquid crystals and also varied not only by chemical synthesis but also by doping.[2a, b, d] It has been found that doping electron-rich discoid polymers with electron acceptors introduces new functional behavior and, moreover, even allows the induction of mesophases in previously non-liquid-crystalline polymers.

Because of charge-transfer (CT) interactions, disc-shaped parts of side-group or main-chain polymers can be arranged in columns, which leads to discotic-columnar mesophases (Fig. 1). Although the functionalization of liquid crystals by doping has been extensively studied,[2a, b, d] induction of mesophases by mixing of non-liquid-crystalline substances has only been established for a few examples of rod-shaped, low molecular weight compounds.[4] Induction of mesophases in amorphous discoid polymers is of special importance since, although numerous amorphous discoid polymers are known,[5] only a few liquid crystalline discotic polymers have been reported.[6, 7]

Polyacrylates[8] and polyesters[9] containing disc-shaped, electron-rich triphenylene units were employed in these induction experiments. The induction agents were fluorenone derivatives[10] with different acceptor strengths: 2,4,7-trinitrofluorenone (TNF) and 2,4,7-trinitrofluoren-9-ylidenemalonodinitrile (TNF-CN). Doping of the polymers was achieved by mixing in solution.[11] The functionalized polymers were characterized by polarization microscopy, differential calorimetry, and X-ray diffraction.[12]

Induction of columnar mesophases in amorphous side-group polymers: The polymethacrylate **1** ($T_g = 30$ °C) and the polyacrylate **2** ($T_g = -6$ °C) were used as amorphous polymers containing electron-rich triphenylene side groups.[5a, 8] When combined with the electron acceptor TNF,[11] these polymers form discotic phases due to CT interactions. Mesophases are obtained after addition of only 25 mol% TNF; they become isotropic at 170 °C (**1**/TNF) and 88 °C (**2**/TNF) (Fig. 2).

Samples containing different amounts of TNF were prepared from **2** (Table 1). Only those with between 20 and 25 mol% TNF exhibit liquid crystalline phases. A mixture containing 10 mol% TNF is amorphous, as is the neat polymer **2**. Mixtures containing high amounts of TNF (molar ratio 2/1 and 1/1) phase-separate during preparation.[11] The enthalpies of clearing are very small (< 0.4 J g^{-1}) for the induced liquid crystalline phases.

The structures of these mesophases were established by X-ray diffraction studies (Fig. 3 and Table 1). The flat plate photograph in Figure 3a shows three reflections. A regular spacing of 3.4 Å between the molecules (triphenylene units, TNF) within the columns can be derived from the sharp, oriented reflection in the wide-angle region.[13] The same value was also found for the intracolumnar spacing in noninduced discotic phases of polysiloxanes containing tripheny-

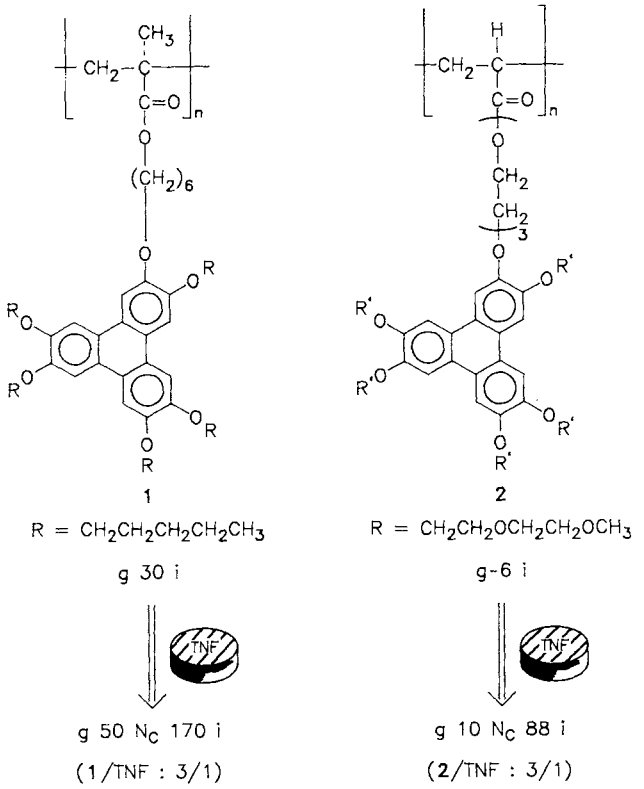

Fig. 2. Induction of nematic-columnar mesophases (N_C) in the amorphous discoid side-group polymers **1** and **2** via CT interactions with the low molecular weight electron acceptor TNF.

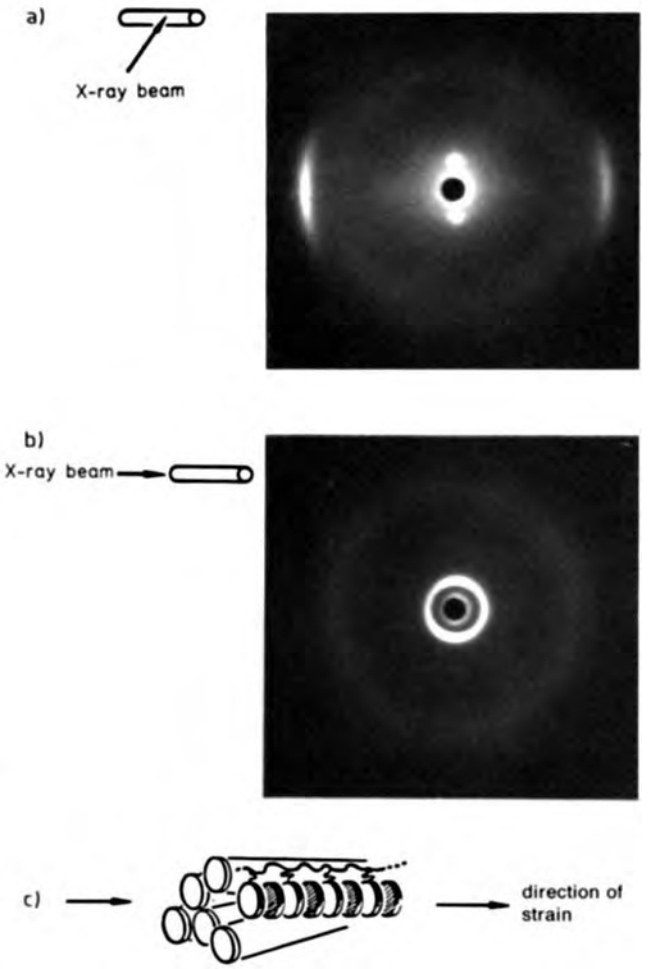
lene side groups.[6e] The weak-intensity halo at 4.2 Å is ascribed to the liquidlike short-range order of the alkyl chains.[14] The strong-intensity small-angle reflection at 16.7 Å is related to ordering of the columns. It is diffuse and higher order reflections are absent. This is evidence against a positional long-range order of the columns as present in, for example, D_{ho} phases. Orientational long-range order of the columns, however, is present because the samples can be macroscopically oriented. These results indicate the existence of nematic-columnar phases (N_C, Fig. 1), which have until now been found for lyotropic[15] but not for thermotropic liquid crystals. Nematic N_C phases align in such a way that the column axes are parallel to the direction of strain (Fig. 3c). The columns and the polymer chain of higher-ordered columnar phases of undoped discotic side-group polymers have also been found to be oriented in the same direction.[6e]

Table 1. Induction of discotic phases in amorphous side-group polymers via CT interactions. Structure and temperature range of mixtures of TNF and the amorphous polyacrylates **1** and **2**.

Polymer	Polymer/TNF [a]	Temperature range [°C]	Phase	Structure: Spacings within the columns [b]	Structure: Spacings between the columns [c]	Halo [d]
2	9/1	g −6 i	amorphous	[e]	[e]	[e]
2	4/1	g 10 N_C 47 i	nematic-columnar	3.40	19.3	4.1
2	3/1	g 10 N_C 88 i	nematic-columnar	3.40	19.0	4.2
2	2/1	(g −7 i)	amorphous	–	–	–
2	1/1	(g −5 i)	two-phase	–	–	–
1	3/1	g 50 N_C 170 i	nematic-columnar	3.42	19.3	4.6

[a] Mole ratio. [b] ±0.03 Å. [c] ±0.3 Å. [d] ±0.1 Å. [e] Nonoriented, diffuse reflections.



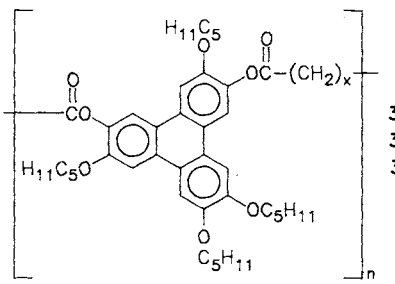


Fig. 3. Flat plate photograph of the nematic-columnar mesophase (N_C) induced in the amorphous side-group polymer **2** for a 4/1 mol ratio of **2**/TNF. X-ray beam impinges perpendicular (a) and parallel (b) to the direction of strain. c) The columns are oriented with the column axes in the direction of strain.

Induction of columnar mesophases in amorphous main-chain polymers: The induction of columnar mesophases in discoid main-chain polymers was studied for the polyester **3c**, which contains triphenylene units in the main chain. The three polymers **3a**,[5] **3b**,[5,6c] and **3c**[5] differ only in the length of the spacer: **3a** and **3b**, with shorter spacers, form D_{ho} phases; the polymer **3c** is amorphous (T_g = 35 °C).

3a, x = 10 : g 50 D_{ho} 220 i
3b, x = 14 : g 60 D_{ho} 150 i
3c, x = 20 : g 35 i

When **3c** is doped with TNF, however, CT complexation increases the interaction between the discs in the main chain, leading to the induction of discotic phases. The phase diagram (Fig. 4) reveals that mesophase induction starts at even

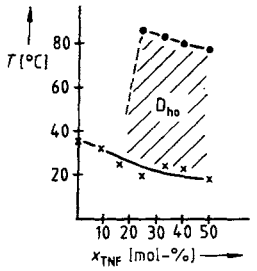

Fig. 4. Phase behavior of mixtures of the amorphous discoid main-chain polymer **3c** and TNF. For amounts of TNF ≥ 25 mol%, higher-ordered discotic phases are induced. For 1/1 and 2/1 mixtures of **3c**/TNF, D_{ho} phases are present. For 1.5/1 (40 mol% TNF) and 3/1 (25 mol% TNF) ratios, the mesophase type could not be determined.

25 mol% TNF. Clearing temperatures decrease slightly (from 83 to 76 °C) with increasing amounts of TNF. Simultaneously, glass transition temperatures decrease from 35 °C for the undoped polymer **3c** to 17 °C, so that the phase width remains constant over the entire doping range (to 50 mol%). Enthalpies of clearing (0.6–1.3 J g^{-1}) are roughly a factor of 10 smaller than for undoped discotic polymers. If a stronger electron acceptor, like TNF-CN, is used instead of TNF, the clearing temperatures increase, for example, for a 2/1 ratio of **3c** to electron acceptor, from 83 °C for TNF to 165 °C for TNF-CN. This shows that the electron acceptor, in addition to inducing mesophases, also strongly influences the mesomorphic temperature range.

X-ray diffraction studies reveal that higher-ordered columnar phases (D_{ho}) are present for the TNF-containing discotic main-chain polymers (Figs. 1 and 5). Such phases are already known for undoped discotic main-chain polymers such as **3a, b.**[6, 7] Thus, the structural features – for example, the values for inter- and intracolumnar spacings of doped and undoped discotic polymers may be compared (Table 2). Figure 5 shows X-ray flat plate photographs of the

3c	2/1	g 22 D_{ho} 83 i	D_{ho}	3.40	26.9	4.4
3c	1/1	g 17 D_{ho} 76 i	D_{ho}	3.41	26.6	4.4
3a [5a]	–	g 50 D_{ho} 220 i	D_{ho}	3.50	20.4	4.2
3b [6b, f]	–	g 60 D_{ho} 150 i	D_{ho}	3.50	21.3	4.2

[a] Mole ratio. [b] ±0.03 Å. [c] ±0.1 Å. [d] Nonoriented, diffuse reflections. [e] Only the Bragg spacings are known so far: 3.40, 21.6/15.5, 4.4 Å; the column spacings cannot be given, since the phase type ($D_?$) is still unknown.

induced mesophases of the polyester **3c** containing 50 and 33 mol% TNF. The sharp wide-angle reflection is assigned to the intracolumnar disc spacings; the sharpness of the reflection indicates a regular arrangement with spacings of between 3.38 and 3.40 Å.

The hexagonal order in the induced D_{ho} phase becomes most evident in the hexagonal pattern of the X-ray photograph in Figure 5b. Values of approximately 27 Å are

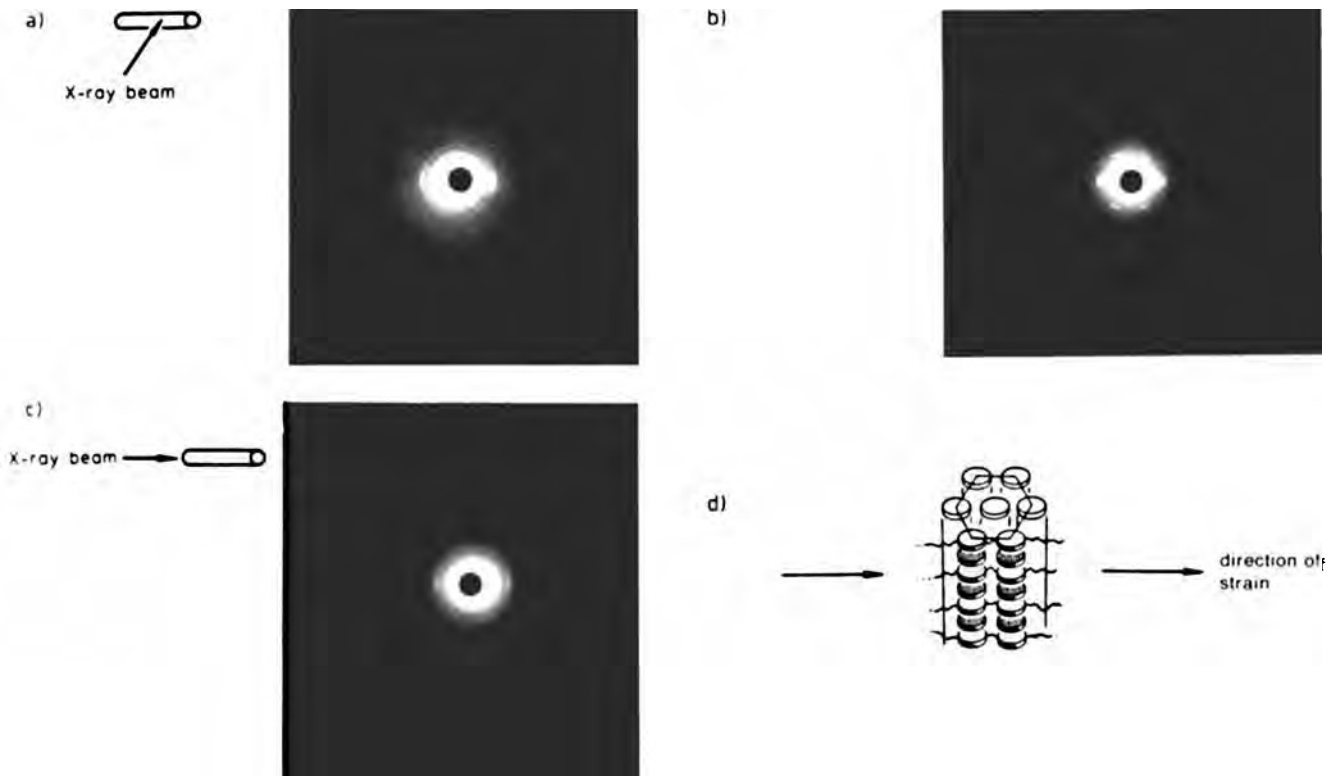

Fig. 5. Flat plate photographs of the hexagonal-columnar mesophase (D_{ho}) induced in the amorphous main-chain polymer **3c** for a 1/1 (a and c) and a 2/1 (b) mole ratio of **3c**/TNF. Impingement of the X-ray beam perpendicular (a, b) and parallel (c) to the direction of strain. d) In contrast to the side-group polymers **1** and **2**, but in analogy to the undoped discotic main-chain polymers [6b, f], the columns are oriented perpendicular to the direction of strain. This means that the polymer chains and not the columns undergo extension upon stretching the polymer.

calculated for the spacing between the columns (= hexagonal lattice constant). These intercolumnar spacings are about 6–7 Å larger than those in noninduced discotic phases of **3a**[5a] (20.4 Å) and **3b**[6] (21.6 Å). Strikingly, they are even larger than the diameter of the hexasubstituted triphenylene discs with extended pentyloxy chains (23–24 Å). Using density measurements to explain this result,[16] a structural model seems likely in which the TNF molecules are not arranged exclusively within the columns but also exist in the side-chain region between the columns.

Induction of columnar mesophases in polymer blends: CT interactions may help to increase the miscibility of polymers, resulting in the formation of one-phase polymer blends.[17] This observation suggested the idea to combine the improved miscibility of polymers due to CT interactions with the induction of discotic mesophases. In the first experiment, TNF and two non-liquid-crystalline discoid polymers containing triphenylene side groups (polyacrylate **2**[8] and polymalonate **4**[18]) were employed (Fig. 6). Polymers **2** and **4** are immiscible. Addition of TNF results not only in miscibility of the two incompatible polymers but also in the formation of columnar mesophases. For a molar ratio of 1/1/1.2 for **2**/**4**/TNF, the polymer blend **5**, in analogy to the polyacrylate **2**/TNF system, exhibits a nematic-columnar N_C phase (temperature range -13 to 89 °C).

Induction and functionalization of liquid crystalline phases: Induction of mesophases by CT interactions opens a wide range of possibilities for polymeric discotic liquid crystals. The synthesis of polymeric as well as low molecular weight[19] discotic liquid crystals is no longer restricted to the classical disc-shaped mesogens. The TNF derivatives used here are nonmesogenic electron acceptors. Furthermore, a greater variety of structures is possible for disc-shaped electron-donor molecules; one possibility is the introduction of normally sterically perturbing functional groups. The type of phase and the phase width may be varied over a wide range by an appropriate choice of polymer system and mixing ratio. Mesophase induction due to CT interactions also opens up a route to liquid crystalline polymer blends. In addition to blends consisting of polymeric discoid donors and low molecular weight acceptors, other combinations are conceivable, such as mixtures of main- and side-chain polymers or of discoid acceptor and donor polymers. Noteworthy is the simultaneous induction of liquid crystalline phases and the introduction of functional behaviors such as color, polarity, and photoreactivity. This approach to functional discotic liquid crystals makes the induction of columnar phases via CT interactions of interest for technical applications in such areas as electrical and photoconductive systems.

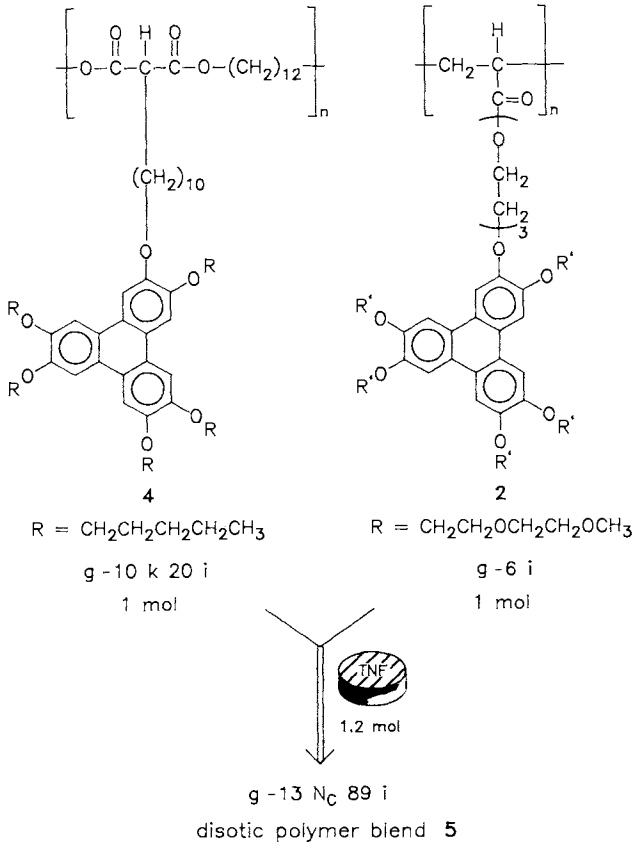

Fig. 6. Induction of discotic mesophases and miscibility in polymer blends via CT interactions with the electron acceptor TNF.

[8] The discoid side-group polymers were obtained by radical polymerization of acrylates and methacrylates in solution. Relative molecular weights of the discoid polymethacrylate **1** from GPC measurements: M_{GPC1} = 3800000 g mol^{-1} (polystyrene (PS) standard, THF, measurement of the refractive index (RI detection)), M_{GPC2} = 4300000 g mol^{-1} (polymethylmethacrylate standard, THF, RI detection): this corresponds to degrees of polymerization P of 3900 and 5500, respectively. Relative molecular weight of discoid polyacrylate **2**: M_{GPC} = 380000 g mol^{-1} (PS standard, $CHCl_3$, UV detection) corresponds to P = 370.

[9] The main-chain polyesters **3a–3c** were each obtained by melt condensation of an isomeric mixture [6a, c] of two triphenylenediacetates and the corresponding 1,ω-dicarboxylic acids (catalyst: *p*-toluenesulfonic acid). **3c**: M_{GPC} = 13000 g mol^{-1} (PS standard, $CHCl_3$, UV detection); corresponds to P = 14.

[10] J. E. Kuder, J. M. Pchan, S. R. Turner, D. L. F. Hinman, *J. Electrochem. Soc. 11* (1978) 1750.

[11] Upon combination of the colorless and yellow solutions, respectively, of the polymer and electron acceptor (in dichloromethane or THF), the color turned red (**3**/TNF) or violet (**1,2**/TNF). The mixtures were stirred for several hours at room temperature. Evaporation of the solvent resulted in separation of a black film, which was dried under oil-pump vacuum for one to two days.

[12] Ortholux II POL-BK (Leitz), microscope used for polarization microscopy investigations; DSC-4 (Perkin-Elmer) calorimeter used for differential calorimetry investigations, heating and cooling rate = 20 K min^{-1} (the melting and clearing temperatures were taken from the peak maxima, the glass transition temperatures were taken from the inflection point of the

curve); X-ray diffraction measurements with nickel-filtered Cu_{K_α} radiation ($\lambda = 0.154$ nm) (oriented samples were obtained by stretching or by applying pressure at a given direction of flow [6b]).

[13] The interplanar separations of many low molecular weight CT complexes containing TNF and polycyclic arenes lie between 3.1 and 3.5 Å; see, for example, L. J. E. Hofer, W. C. Peebles, *Analyt. Chem. 24* (1952) 822.

[14] A M. Levelut, *J. Phys. Lett. 40* (1979) 81.

[15] N. Boden, R. J. Bushby, L. Ferris, C. Hardy, F. Sixl, *Liq. Cryst. 1* (1986) 109.

[16] Taking the hexagonal lattice parameter and the intracolumnar distance (see Table 2), it is possible to calculate the densities ϱ_1 and ϱ_2 for different arrangements of the TNF molecules in the liquid crystalline phase (see Table 3). $\varrho_1 \triangleq$ all TNF molecules are arranged within the columns; $\varrho_2 \triangleq$ no TNF molecule is arranged within a column, that is, all TNF molecules are located in the region between the columns. For the 1/1 mixture, the measured ϱ_3 value agrees with the ϱ_2 value. For the 2/1 mixture, the measured density ϱ_3 is higher than the ϱ_2 value; in this case, the structural arrangement appears to be more complex.

Table 3. Calculated and experimentally found densities of liquid crystalline phases of polymer **3c** with TNF.

3c/TNF	ϱ_1 [gcm^{-3}]	ϱ_2 [g cm^{-3}]	ϱ_3 [g cm^{-3}]
1/1 0.50	1.00	1.04	
2/1 0.57	0.86	1.04

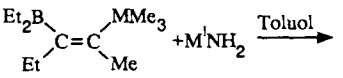
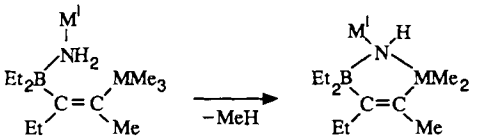
[18] The polymalonate **4** was obtained by Ti^{IV}-catalyzed transesterification of a triphenylene malonate with dodecanediol [5b].

[19] Discotic-columnar phases can also be induced in low molecular weight discoid systems through CT interactions, for example by addition of TNF to non-liquid-crystalline triphenylene derivatives or to discotic-nematic hexaphenylethynylene benzenes: M. Ebert, B. Kohne, K. Praefcke, H. Ringsdorf, J. H. Wendorff, R. Wüstefeld, E. Zerta, unpublished results.



Pentacoordinated Elements of the 4th Main Group with Four Organic Residues

By *Roland Köster, Günter Seidel, Bernd Wrackmeyer,* Klaus Horchler* and *Dieter Schlosser*



Hypervalent species of heavy elements of the fourth main group of the periodic system, especially silicon,[1] are of particular interest because of their importance as starting materials and reactive intermediates (e.g. silicon hydride[2]) in synthesis and because of their biological activity (e.g. silatranes[3]). A coordination number > 4 in the case of silicon, however, has only been documented for compounds with at least two electro-negative substituents on the silicon atom.[1, 4, 5] We report here on the first NMR spectroscopic detection of a long-lived species with a pentacoordinated silicon atom, which has a coordinative Si–N bond besides four organic residues. In addition, the results of NMR investigations on analogous tin and lead derivatives are reported. Whereas an intramolecular Sn–N bond, analogous to that in stannatrane, has been postulated for certain tetraorganostannanes,[6] and pentaorganostannates $[R_5Sn]^{\ominus}$ have already been detected NMR spectroscopically,[7] an increase in the coordination number of lead in tetraorganoplumbanes was hitherto unknown.

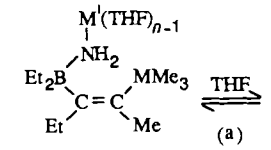
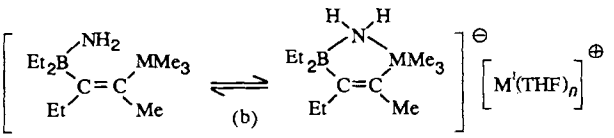
The sodium and potassium aminoborates **2**,[9, 10] which are readily accessible from (*E*)-alkenylboranes **1**[8] by reaction with $NaNH_2$ and KNH_2, respectively, are intermediates in the synthesis of the cyclic compounds **3** and are thus ideal species for investigating intramolecular M–N interactions. **2a** splits off methane already at room temperature, forming an Si–N bond.[11]

1 (1)



2 **3**



a: M=Si, **b**: M=Sn, **c**: M=Pb; M': Na, K

2b reacts similarly,[12a] whereas **2c** does not undergo any simple secondary reaction. Although the cleavage of methane permits assumption of M–N interactions at least for N = Si, Sn, proof of the existence of the anions derived from **2** [(b) in Eq. (2)] with a coordination number of 5 for M is first furnished by the NMR spectra in THF at several temperatures (Table 1).

In coordinating solvents such as THF or upon addition of suitable crown ethers in THF or nonpolar solvents, the equilibrium (a) in Equation (2) can be shifted in such a way that the alkali metal ion $M^{\oplus}$ prefers a coordination other than in **2**. The position of the equilibria (a) and (b) in dilute solutions depends on M' and M and on the temperature, as shown by the δ(M) values measured under various conditions (cf. Table 1). The difference of the $\delta(^{29}Si)$ values in THF (25 °C) for **2a**, M' = Na ($\delta = -18.6$), and **2a**, M' = K ($\delta = -61.0$), typically demonstrates the dependence on the alkali metal. The influence of M is e.g. immediately clear from the fact that the $\delta(^{119}Sn)$ value for **2b**, M' = Na or for **2b**, M' = K, in THF at 25 °C ($\delta = -166.0$) changes only slightly compared to the value at −50 °C ($\delta = -175.6$). Thus, in THF, the Sn–N interaction successfully competes with the M'–N interaction at room temperature, i.e. the coordinative Sn–N bond is stronger than the coordinative Si–N

[a] In [D$_8$]THF (ca. 10%); δ-values versus ext. Et_2O-BF_3 (δ^{11}B), Me_4Si (δ^{13}C), Me_4Si (δ^{29}Si), Me_4Sn (δ^{119}Sn), Me_4Pb (δ^{207}Pb); [coupling constants J(M^{13}C)/Hz], [n.d.] = not detected. [b] **2a**, M′ = Na, K at −60 °C, **2b**, M′ = Na at −80°, **2c**, M′ = Na at −75 °C. [c] Signals in the ratio 2:1; at −20 °C an averaged signal with $^1J(^{119}Sn^{13}C)$ = 308.7 Hz is found. [d] At −90 °C despite satisfactory signal-to-noise ratios no ^{207}Pb-satellite signals are observed; upon further cooling solid **2c** separates, M′ = Na, even from very dilute THF-solutions. [e] At 25 °C: $^1J(^{207}Pb^{13}C)$ = 836.6 Hz. [f] At −50 °C; further measurements in [D$_8$]THF: δ (^{29}Si) (−30 °C) −52.1, (25 °C) −18.6, (25 °C, addition of one equiv. [18]crown-6) −78.8; in toluene δ (^{29}Si) (25 °C) −15.0, (−50 °C) −15.1. [g] At −60 °C; further measurements in [D$_8$]THF: δ (^{29}Si) (−90 °C) −82.4, (25 °C) −61.0. [h] At −50 °C; further measurements in [D$_8$]THF: δ (^{119}Sn) (−30 °C) −175.2, (25 °C) −166.0. [i] At −74 °C; further measurements in [D$_8$]THF: δ (^{207}Pb) (−100 °C) −150.5, (−90 °C) −147.8, (−53 °C) −137.0, (−30 °C) −94.0, (−10 °C) −68.0, (25 °C) ca. −50 (extremely broad), (25 °C, addition of [18]crown-6) no ^{207}Pb-signal; in toluene: δ (^{207}Pb) (25 °C) −56.0. [j] In toluene at 27 °C. [k] $\Delta\delta$M = δM (**2**) − δ(M) (**4**).

bond. **2c**, M′ = Na, in THF at 25 °C, shows only one very broad ^{207}Pb-NMR signals at δ = −50, the position of which is similar to that of the signal in toluene (δ = −56.0). After addition of [18]crown-6 the ^{207}Pb-NMR signal disappears as a consequence of the dynamics of the equilibrium (b). In contrast, the ^{29}Si-NMR signal of **2a**, M′ = Na, in THF (25 °C) is shifted from δ = −18.6 to −78.7 upon addition of the crown ether. It follows from these observations that the strength of the coordinative M–N bond decreases along the series Sn > Si > Pb at room temperature.

The δ(M) values of **2** are clearly influenced by the increase in coordination number of M. The neutral five-membered ring compounds **4** provide the best reference system:[12] one of the anionic equilibrium components of $\mathbf{2}\cdot(THF)_{n-1}$ [Eq. (2)] differs from these merely by an additional methyl group on M and the negative overall charge. $\Delta\delta(^{29}Si)$ [= $\delta(Si_{2a}) - \delta(Si_{4a})$, Table 1] with a value of ca. −100 lies in the same region as $\Delta\delta(^{29}Si)$ for spirocyclic pentacoordinated and tetracoordinated cyanosilicates.[4c] Likewise, $\Delta\delta(^{119}Sn)$ = −291.6 compares very well with the $\Delta\delta(^{119}Sn)$ value of −227 for $[Me_5Sn]^{\ominus}$ and Me_4Sn.[7]

A distorted trigonal-pyramidal environment is expected for pentacoordinated M in **2**, whereby the NH_2 group prefers axial orientation[13] and the olefinic C atom should always be equatorial. The second axial position must accordingly be occupied by a methyl group. Owing to the low activation energy for pseudorotation when the coordination number of M is 5, the signals for the MMe_3 group in the ^{1}H or ^{13}C NMR spectrum do not split down to −95 °C, neither in the case of **2a** nor in the case of **2c**. In the case of **2c** the dynamic behavior is apparent, since ^{207}Pb satellite signals [$^1J(^{207}Pb)^{13}C$)] are no longer observable at −90 °C (other than at −80 °C). In the case of **2b**, the ^{13}C NMR spectrum shows two signals in the ratio 1:2 for the Me_3Sn group at ca. −80 °C. The activation energy for the interchange of the methylene groups is $\Delta G^{\ddagger}_{-75\,°C} = 42 \pm 2$ kJ mol^{-1}. The $^{117/119}$Sn satellite signals of the signal of lower intensity ($SnMe_{ax}$unit) cannot be assigned, whereas for the other signal ($SnMe_{2(eq)}$unit) $^1J(^{119}Sn^{13}C)$ = 450 Hz. Since the mean value for $^1J(^{119}Sn^{13}C_{Me})$ at −20 °C (308.7 Hz) is known it follows that $^1J(^{119}Sn^{13}C)$ = 26 Hz for the axial methyl group. This is in agreement with the expected low s character of the Sn–C_{ax}-hybrid orbital (cf. also with the extrapolated values $^1J(^{119}Sn^{13}C)$ of 441 Hz and 17 Hz for the equatorial and axial methyl groups, respectively in $[Me_5Sn]^{\ominus}$[7]).

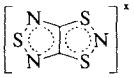
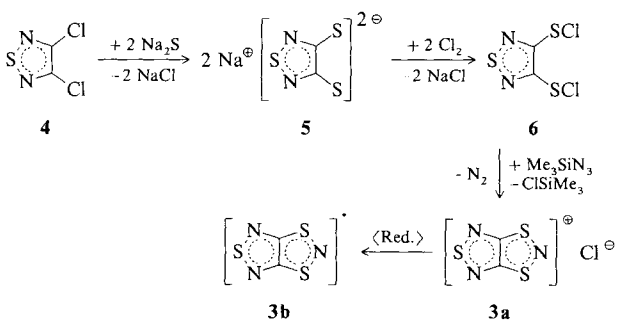
1,3,5-Trithia-2,4,6-triazapentalenyl — a Stable Sulfur-Nitrogen Radical**



By *Gotthelf Wolmershäuser** und *Rudolf Johann*

1,3,2-Dithiazolylium ions **1**[1,2] may be regarded as aromatic 6π-heterocycles. The same holds true for the neutral 1,2,5-thiadiazoles **2**.[3] Upon one-electron reduction the respective radical species are formed.[1,2,4] Owing to their favorable redox potential, their planarity, and the stability of their reduced radical state, benzoannelated derivatives of **1** are suitable building blocks for conductive CT complexes.[2,5]



1 **2**

We were now interested in whether the novel pentalene analogue **3**, in which the two ring systems **1** and **2** are coupled, are also suitable for the synthesis of conductive systems.

3a: x = ⊕
3b: x = ·

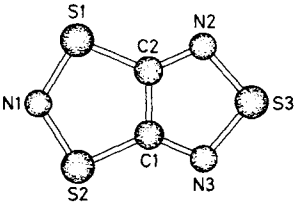
Reaction of the thiadiazole **4** with Na_2S leads to formation of the dianion **5**, which *Rees* et al.[6] had already obtained via another route. By reaction with elemental chlorine, **5** can be converted into the corresponding sulfenyl chloride **6**. As we have already shown, 1,2-disulfenyl chlorides react with trimethylsilyl azide yielding dithiazolylium chlorides.[2] This reaction also takes place in high yields with **6**; **3a**$Cl^{\ominus}$ is obtained as a bright-orange colored solid that is moderately soluble in polar solvents and melts at 195–196 °C with decomposition.

4 **5** **6**

3b **3a**

Treatment of a suspension of **3a**$Cl^{\ominus}$ with sodium dithionite, triphenylantimony or TCNQ-lithium leads rapidly to a deep-blue solution of **3b**. From petroleum ether solutions, which are stable for days even in the presence of air, **3b** crystallizes in the form of black needles. Well-shaped, deep-violet crystals suitable for an X-ray structure analysis are formed upon slow sublimation in a high vaccum.

Information on the structure of **3b** was provided by ESR spectroscopic investigations and an X-ray structure analysis.[7] Of the cell parameters, most striking is the short *b* axis (3.697 Å), from which it follows that the molecules are stacked along this axis. The face normal is inclined about 35.1° to the stacking axis. In the crystal, **3b** has, within the limits of error, C_{2v} symmetry, i.e. the molecules are planar (max. deviation of an atom from the mean plane 0.003 Å; Fig. 1). This result is consistent with findings on the reso-



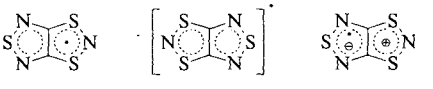


Fig. 1. Structure of **3b** in the crystal. Bond distances [Å] and angles [°]: -C2-C1 1.426(4), N3-C1 1.312(4), S2-C1 1.730(3), N2-C2 1.316(4), S1-C2 1.725(3), S1-N1 1.653(3), S2-N1 1.648(3), S3-N2 1.642(3), S3-N3 1.642(3); N3-C1-C2 114.4(3), S2-C1-C2 113.3(2), S2-C1-N3 132.3(2), N2-C2-C1 114.0(3), S1-C2-C1 114.0(2), S1-C2-N2 132.1(2), S2-N1-S1 116.8(2), S3-N2-C2 106.2(2), S3-N3-C1 106.1(2), N1-S1-C2 97.8(1), N1-S2-C1 98.1(1), N3-S3-N2 99.3(1).

nance-stabilized benzobisdithiazole radical cation (BBDTA$^{\cdot\oplus}$).[8] In the case of benzothiazole (BDTA),[1] on the other hand, the dithiazole ring is slightly bent. In **3b**, the S–N distances in both parts of the molecule are about equal (1.65 and 1.64 Å, resp.), thus indicating single bonds with double bond character (BDTA:[1] 1.65 Å, BBDTA$^{\cdot\oplus}$:[8] 1.62 Å). d(S–N) = 1.62 Å has also been found in the **3b** analogue 1,4-dithia-2,3,5,6-tetraazapentalene.[9] Also the C–C bond(1.426(4) Å) as well as the C–N and the C–S bonds (1.32 Å and 1.73 Å) are best described as single bonds with partial double bond character. Comparison of the bond lengths in **3b** with those in dithiazolylium salts, dithiazolyls and thiadiazoles indicates that the resonance formula **3b′** predominates over that of the formulation **3b‴**. However,

3b′ **3b″** **3b‴**

[*] Dr. G. Wolmershäuser, Dipl.-Chem. R. Johann
Fachbereich Chemie der Universität
Erwin-Schrödinger-Strasse, D-6750 Kaiserslautern (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

the formulation **3b**″ gives an adequate description, particularly if the planarity of the molecule is taken into account.

Whereas relatively short intermolecular S···S contacts are found in other dithiazole radicals (e.g. in BDTA[1] 3.17 Å), in **3b** the shortest intermolecular S···S distance is 3.38 Å; the distance between the molecular planes (3.7 Å) even corresponds to the van-der-Waals distance. Apparently the spin delocalization over the whole molecule makes closer intermolecular contacts unneccessary.

The ESR spectrum of **3b** is consistent with the X-ray structure analysis. In dichloromethane (20 °C) a triplet [a(N) = 11.21 G for N1] of quintets [a(N) = 0.85 G for the equivalent atoms N2 and N3] is observed. The g value is 2.0061. The nitrogen coupling constants of the 1,3,2-dithiazole-2-yls known so far lie between 10.4 and 11.4 G.[10] In contrast, 1,2,5-thiadiazole radical anions with two equivalent N atoms have a(N) values of ca. 5.3 G.[11]

As expected the mass spectrum of **3b** obtained at lower ionization energies shows an intense molecular peak. The IR spectra of **3a** and **3b** are very simple and closely resemble each other. The UV-VIS spectrum of **3b** in dichloromethane shows, besides a broad band at 595.5 nm (blue color), bands at 373.2, 346.3 and 267.7 nm; the longest wavelength band shows vibrational fine structure in nonpolar solvents.

Experimental

5: A solution of Na_2S (906 mg, 11.61 mmol) in 70% ethanol (50 mL) was treated with a solution of **4** (900 mg, 5.81 mmol) in ethanol (5 mL). After 45 min the (now bright orange) solution was evaporated to dryness. The residue was extracted with 2 × 15 mL of ethanol and the combined extracts evaporated to dryness. The dark-orange, glassy solid was dried in a vacuum. Yield: 575 mg (51%). IR (KBr): $\tilde{\nu}$ = 1415(w), 1375(w), 1290(s), 1220(m), 1190(m), 1015(s), 795(m), 605(w) cm^{-1}.

3a: A suspension of finely powdered **5** (700 mg, 3.61 mmol) in carbon tetrachloride (40 mL) was cooled to − 20 °C. Chlorine was passed into the suspension for 10 min. After a further 10 min the reaction mixture was allowed to warm to − 5 °C and, after removal of excess chlorine, centrifuged. The yellow solution was evaporated to dryness and the oily residue taken up in 30 mL of dichloromethane and treated at 20 °C with 0.42 g (3.65 mmol) of trimethylsilyl azide. After completion of evolution of nitrogen (ca. 1 h) the yellow-orange solid was separated off and dried in a vacuum. Yield: 270 mg (38% based on initial amount of **5**). IR(KBr): $\tilde{\nu}$ = 1163(vw), 1005(vw), 895(vw) 827(s), 773(w), 733(s), 549(w), 521(m), 509(s), 421(m), 401(vw) cm^{-1}. M.p 195–196 °C (decomp.).

3b: A vigorously stirred suspension of finely powdered sodium dithionite (1.5 g, 8.6 mmol) in acetonitrile (15 mL) was treated with 100 mg (0.51 mmol) of **3a**. The reaction mixture was covered with a layer of petroleum ether (20 mL). After a few minutes the petroleum ether phase (which was now blue) was replaced by fresh petroleum ether; this procedure was continued until the petroleum ether phase remained colorless. The combined petroleum ether phases were then evaporated to dryness; purification was possible by sublimation in a vacuum. Yield 55.9 mg (68%) black needles. IR(KBr): $\tilde{\nu}$ = 1347(vw), 1214(m), 833(vw), 779(m), 775(s), 680(s), 671(w), 505(m), 485(m) cm^{-1}. Decomposition above ca. 100 °C.

Amide Bond Scission via Bifunctional Activation with Bimetallic Porphyrin Systems with Two Different Metal Centers**

By *Yasuhiro Aoyama**, *Tadahiro Motomura*, and *Hisanobu Ogoshi**

Multicenter interaction is very important for biomimetic catalysts and receptors.[1] It has recently been shown that the metalloporphyrin **1a**, which contains two OH groups enables a bifunctional activation of ketones[2] and a two-point fixation of amino acids.[3] The object of the present study was to develop bimetallic porphyrin systems as a new type of bifunctional catalysts and receptors.[4] We report here that a Rh–Ag system resulting from interaction of $AgClO_4$ with **1a**

1a : R = OH
1b : R = OCH_3
1c : R = H

2

activates amides and esters toward alcoholysis reactions under mild and neutral conditions, as a consequence of intramolecular cooperation of the two metal ions.[5]

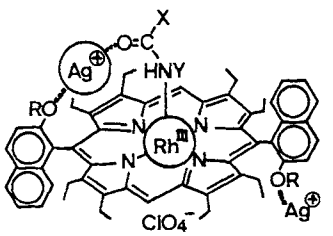
[**] Catalytic Reactions of Metalloporphyrins, Part 5. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture of Japan. – Part 4: Y. Aoyama, K. Midorikawa, H. Toi, H. Ogoshi, *Chem. Lett. 1987*, 1651.



In the presence of $AgClO_4$, the chlororhodium(III) complex of *trans*-5,15-bis(2-hydroxy-1-naphthyl)octaethylporphyrin **1a**[2] promoted the methanolysis of *p*-nitroacetanilide in benzene at 50 °C according to reaction (a) under the following conditions: $[\mathbf{1a}] = 4.0 \times 10^{-6}$ M, $[AgClO_4] = 4.4 \times 10^{-5}$ M, [amide] $= 2.0 \times 10^{-5}$ M, and $[CH_3OH] = 1.3 \times 10^{-3}$ M. The reaction is rather slow (approximate halftime 30 h) and is stoichiometric, since the bis(*p*-nitroaniline) complex **2** formed is no longer active.[6] Under similar conditions, ethyl acetate as substrate underwent ester exchange [reaction (b)]. This reaction is much faster than reaction (a) and is catalytic, since the products do not deactivate the porphyrin catalyst; the yield after 100 h is 2500% based on **1a** under the following conditions:

$$2\,p\text{-}CH_3CONHC_6H_4NO_2 + \mathbf{1a} + 2\,CH_3OH \xrightarrow[AgClO_4]{} \mathbf{2} + 2\,CH_3CO_2CH_3 \quad (a)$$

$$CH_3CO_2CH_2CH_3 + CH_3OH \xrightarrow[AgClO_4]{\mathbf{1a}} CH_3CO_2CH_3 + CH_3CH_2OH \quad (b)$$

$[\mathbf{1a}] = 2.0 \times 10^{-6}$ M, $[AgClO_4] = 4.4 \times 10^{-5}$ M, and [ester] $= [CH_3OH] = 2.5 \times 10^{-3}$ M in benzene at 50 °C. In the absence of $AgClO_4$, reactions (a) and (b) were found to be unmeasurably slow. These reactions are also accelerated by the dimethoxynaphthyl derivative **1b**,[7] although somewhat less effectively than by **1a**. In marked contrast, no reaction takes place with the dinaphthyl derivative **1c** or with the free base of the porphyrin **1a** under otherwise identical conditions, indicating that the central Rh^{III} ion and an OR group (R = H or CH_3) in the same molecule in addition to $AgClO_4$ are essential for the present reactions.

Treatment of **1a**, **1b**, or **1c** with $AgClO_4$ (excess) resulted in a facile anion exchange to give a perchlorate salt of cationic Rh^{III}-porphyrin with concomitant precipitation of AgCl, as in the case of the octaethylporphyrin complex.[8] ^1H NMR spectroscopy of the complexes in C_6D_6 showed that upon interaction with $AgClO_4$ the OCH_3 protons of **1b** and the naphthalene ring protons of **1a** and **1b**, but not of **1c**, undergo characteristic downfield shifts, while the protons of the ethyl groups and *meso* positions remain unaffected; *e.g.*, $\delta(OCH_3) = 3.39$ and 3.24 (two s, each 3H) for **1b** and 3.44 (s, 6H) for **1b**-$AgClO_4$. IR spectroscopy of $CHCl_3$ solutions of **1a** showed a significant shift of ν_{OH} to lower wave numbers upon reaction with $AgClO_4$ ($\nu_{OH} = 3520\ cm^{-1}$ for **1a** and $3440\ cm^{-1}$ for **1a**-$AgClO_4$). These observations can be taken as evidence that excess $Ag^{\oplus}$ ions coordinate with OR groups (R = H or CH_3) of **1a** and **1b**.

3 (R = H, CH_3)

The resulting Rh-Ag-porphyrin forms 1:1 adducts (**3**) with amides (in excess), as evidenced by sharp ^1H NMR signals for bound substrates which are high-field shifted due to the porphyrin ring-current effect:[9] for the *N*-methylacetamide adduct (**3**, X = Y = CH_3) $\delta = -2.70$ (s, 3H, $NHCH_3$) and -0.19 (s, 3H, CH_3CO);[10] for the *p*-nitroacetanilide adduct (**3**, X = CH_3 and Y = *p*-$C_6H_4NO_2$) $\delta = -2.25$ (s, 3H, CH_3CO) and 4.29 (AB q, 2H, $C_6H_4NO_2$ *ortho* to the acetamino group).[11] Considerable high-field shifts for the *N*-methyl and *ortho* *N*-aryl protons ($\Delta\delta \approx 5.5$ and 3.4 ppm, respectively), in the light of the "shielding map" of rhodium porphyrins,[9] suggest that the adducts have a coordinative Rh^{III}-N bond as shown in **3**. An indication of the stability of the adduct **3** comes from the observation of sharp ^1H NMR signals for bound amide without undergoing averaging with those for free amide which is present in excess in the bulk solution; this can be taken as evidence that the exchange between bound and free amide molecules is rather slow at room temperature. Such an adduct with sharp NMR signals could be detected neither in the absence of $AgClO_4$ nor in its presence but with **1c** in place of **1a** or **1b**, indicating that an electrophilic Rh^{III} center and an $Ag^{\oplus}$ ion coordinated with OR groups are essential for the formation of **3**. The prechlorate salt of Rh^{III} porphyrin has been shown to be such a powerful electrophile that it is capable of metalating arenes.

Adduct **3** (X = CH_3, Y = *p*-$C_6H_4NO_2$) is presumably an intermediate of the methanolysis of *p*-nitroacetanilide, since addition of methanol to a solution of **3** leads to facile generation of **2** with concomitant formation of methyl acetate. Nucleophilic attack of methanol on the substrate may be facilitated by an electrophilic *double* activation of the amide bond, both in the leaving group (NHY) and in the carbonyl moiety, by the Rh^{III} and $Ag^{\oplus}$ centers.

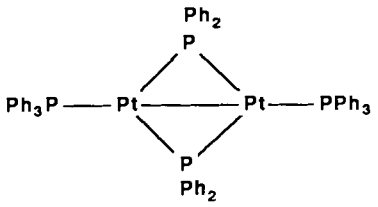
[10] The *N*-Methylformamide adduct (**3**, X = H and Y = CH_3) and acetamide adduct (**3**, X = CH_3 and Y = H) show the corresponding methyl signals at $\delta = -2.79$ (s, 3H, $NHCH_3$) and -0.36 (s, 3H, $COCH_3$), respectively.

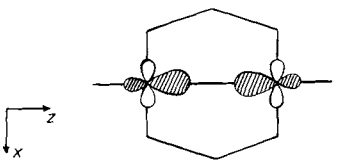
[11] The signals of the *meta* protons could not be identified because of overlap with those of the naphthalene ring protons.



Agostic-type Gold Ligand and Incipient μ_3-PPh_2 Coordination in the $Au_2Pt_2P_6$ "Hammock" Skeleton of the Cluster $[Au_2Pt_2(\mu\text{-}PPh_2)_2(PPh_3)_4][PF_6]_2$

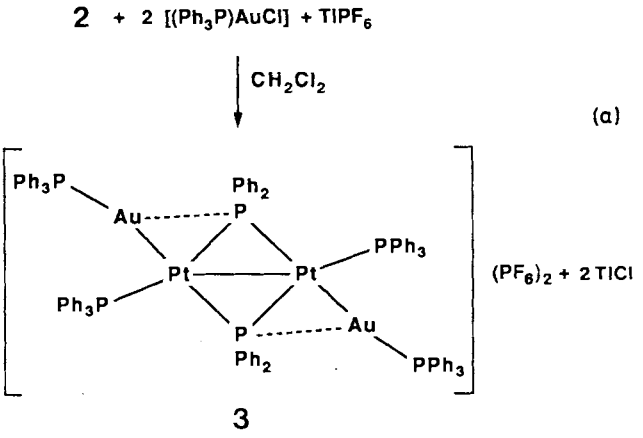
By *Robert Bender, Pierre Braunstein,*[*] *Alain Dedieu,* and *Yves Dusausoy*

The addition of electrophilic metal reagents to electron-rich (neutral or anionic) complexes is a method of choice for the stepwise construction of heterometallic clusters.[1] Thus, for example, the behavior of the metal–metal bond in dipalladium(I)- and diplatinum(I)-complexes such as **1** towards $HgCl_2$ and group 11 electrophiles has recently been the subject of detailed investigations.[2] These 30-electron complex-



1a, M = Pd
1b, M = Pt

2



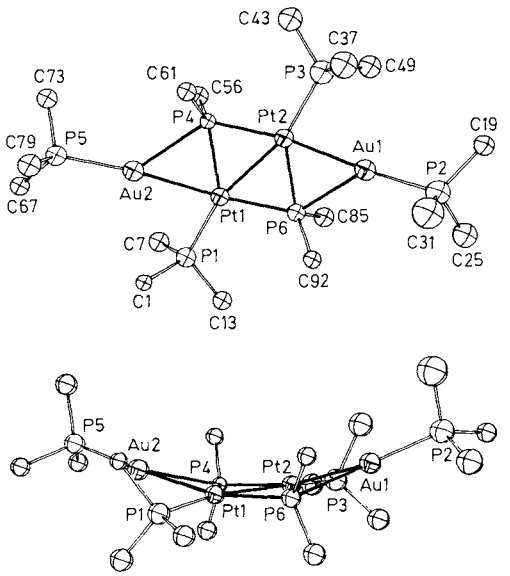
es were found to lead either to "A-frame" clusters through direct involvement of the d^9–d^9 metal–metal bond[2a, b]—more specifically of the HOMO (Scheme 1) formed from the bonding combination of the two d_{z^2} orbitals—or to clusters of higher nuclearity resulting from molecular rearrangements induced by the reactivity of the

Scheme 1. HOMO of complexes of type 1.

M–Cl bond of **1** towards the electrophilic reagent.[2c, d] We have now found that the 30-electron complex **2**,[3] which also contains a d^9–d^9 Pt–Pt bond but no M–Cl bond, reacts with $[Au(PPh_3)]^{\oplus}$ in yet a different manner, leading to an unprecedented raft structure which displays an agostic-type $Au(PPh_3)$ ligand and an incipient triply bridging diphenylphosphido ligand.

Reaction of **2** in CH_2Cl_2 with two equivalents of $[(Ph_3P)AuCl]$ in the presence of $TlPF_6$ resulted in a red solution of **3**[4] and the precipitation of TlCl [Eq. (a)].

3



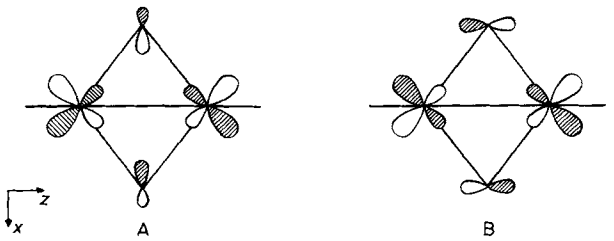


Fig. 1. Views of the molecular structure of the cation of **3**. Only the *ipso* C atoms of the Ph groups are shown. Important bond distances [Å] and angles [°]; Pt1–Pt2 2.660(2), Pt1–Au2 2.667(1), Pt2–Au1 2.634(1), Pt1–P1 2.294(8), Pt1–P4 2.341(7), Pt1–P6 2.301(7), Pt2–P3 2.263(8), Pt2–P4 2.308(7), Pt2–P6 2.315(7), Au1–P2 2.306(8), Au1–P6 2.682(7), Au2–P4 2.629(7), Au2–P5 2.288(8); Au2–Pt1–Pt2 115.5(1), Au1–Pt2–Pt1 117.3(1), Au2–Pt1–P4 62.9(2), Au1–Pt2–P6 65.3(2), Au2–Pt1–P6 165.0(2), Au1–Pt2–P4 164.4(2), Au2–Pt1–P1 82.3(2), Au1–Pt2–P3 80.4(2), P4–Pt1–Pt2 54.5(2), P6–Pt2–Pt1 54.6(2), P4–Pt1–P6 109.5(2), P6–Pt2–P4 110.2(2), P4–Pt1–P1 141.8(3), P6–Pt2–P3 142.4(3), Pt2–Pt1–P1 162.2, Pt1–Pt2–P3 162.3(2), Pt2–Pt1–P6 55.0(2), Pt1–Pt2–P4 55.7(2), P6–Pt1–P1 107.8(3), P4–Pt2–P3 106.9(3), Pt2–Au1–P2 169.6(2), Pt1–Au2–P5 173.3(2), Pt2–Au1–P6 51.6(2), Pt1–Au2–P4 52.5(2), P6–Au1–P2 135.0(3), P4–Au2–P5 132.2(3), Pt1–P6–Pt2 70.4(2), Pt1–P4–Pt2 69.8(2), Pt1–P6–Au1 130.1(3), Pt2–P4–Au2 131.6(3), Pt2–P6–Au1 63.1(2), Pt1–P4–Au2 64.6(2).

Figure 1 shows the molecular structure of the cation of **3** established by an X-ray diffraction study.[5] The $Pt_2Au_2P_6$ skeleton is pseudo-C_2 symmetric with the twofold axis perpendicular to the Pt1, Pt2, P4, P6 mean plane and intersecting the middle of the Pt1–Pt2 bond. The hammock conformation resulting from the slight folding of the $Pt_2Au_2P_6$ raft along Pt1–P4 and Pt2–P6 edges is noteworthy. Thus, the Pt1–Au2–P4, and Pt2–Au1–P6 planes form with the Pt1, Pt2, P4, P6 mean-plane an angle of 15.6 and 17.9°, respectively. The Pt1–Pt2 distance of 2.660(2) Å is longer than that in **2** (2.604(1) Å) and the Pt1–Au2 (2.667(1) Å) and Pt2–Au1 (2.634(1) Å) distances compare with the other known Pt–Au distances.[9]

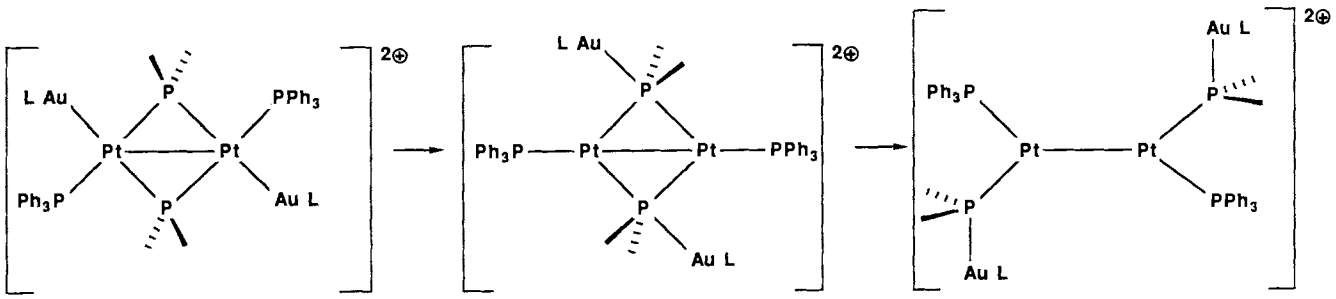
The most remarkable features of **3** are that: (i) addition of $[Au(PPh_3)]^{\oplus}$ to **2** occurs *"externally"* to the $Pt_2(\mu\text{-}P)_2$ core without formation of a $Pt_2[\mu\text{-}Au(PPh_3)]$ unit, in contrast to **1** ; (ii) the relatively short Au1–P6 and Au2–P4 distances of 2.682(7) and 2.629(7) Å, respectively, suggest a bonding interaction between the corresponding atoms and an incipient μ_3-bonding mode for the μ-PPh_2 ligands. The Au1 and Au2 atoms are slightly out of the Pt1–Pt2–P4–P6 mean plane by 0.737(1) and 0.646(1) Å, respectively. The μ_3-bridging of a phosphido group has previously been reported only for Li[10a] or Cu[10b,c] complexes. Note that by virtue of the isolobal analogy between $Au(PPh_3)$ and H, the present structure also suggests that polynuclear systems containing a *bridging phosphane ligand* might exist.

Scheme 2. The two highest occupied orbitals of type 2 complexes.



The unusual bonding in **3** can be easily rationalized through a fragment molecular orbital analysis[11] based on extended Hückel calculations.[12, 13] In this system, the two highest occupied orbitals (A and B, Scheme 2) are now essentially made of the bonding and antibonding combinations of the two d_{xz} orbitals. The bonding combination of the two d_{z^2} orbitals which accounts for the metal–metal bond is at a much lower energy. Hence the orbitals A and B interact primarily with the unoccupied acceptor orbital of the incoming electrophile. Since these two orbitals are polarized outward, away from the metal–metal bond,[17] one expects the attack to occur "externally" to the $Pt_2(\mu\text{-}P)_2$ core. A slight deviation of the Ph_3P–Pt–Pt angle from 180°, as in **3**, does not appreciably modify A and B. It opens on the other hand a reactive channel for the incoming $[Au(PPh_3)]^{\oplus}$ by allowing the two bonding interactions C and D (Scheme 3) to take place. The slight out-of-plane disposition of $Au(PPh_3)$ seems to be governed by electronic rather than by steric interactions: the electrophilic attack in the Pt_2P_4 plane requires a greater deviation of the Ph_3P–Pt–Pt angle from 180°. This in turn destabilizes the d_{xz} orbitals and polarizes them toward the metal–metal bond region,[18] the net result being an overall destabilization of the system and a weakening of its metal–metal bond.

Scheme 3. Bonding interactions between $(Ph_3P)Au$ acceptor orbitals and the orbitals A and B of Scheme 2.

Is the short Au–P distance between the $Au(PPh_3)$ and μ-PPh_2 moieties the result of some bonding interaction? The fragment molecular orbital analysis indeed points to a favorable overlap factor.[19] But the interaction remains rather weak, at least weaker than the interaction of the $Au(PPh_3)$ moiety with the d_{xz} orbitals, owing to an unfavorable energy difference factor (the orbitals of the bridging PPh_2 fragments are at a much lower energy than the d orbitals of the metal framework). That the Au–PPh_3 axis points toward the Pt metal center (P–Au–Pt 171°) rather than halfway between the Pt atom and the phosphido bridge is certainly the best illustration of the domination of the $(Ph_3P)Au$–Pt interaction over the $(Ph_3P)Au$–PPh_2 interaction.

The structure of the cluster **3** is therefore the result of a subtle balance between various possible bonding interactions. It might also be viewed as the result of an agostic-type three-center, two-electron interaction in the $Au(\mu\text{-}PPh_2)Pt$ ring system, somewhat equivalent to the classical M ← H–C agostic interaction. In fact, related M ← Au–C agostic interactions where $Au(PPh_3)$ replaces H have been described.[20] But in **3** the agostic interaction of $Au(PPh_3)$ is with the μ-PPh_2 ligand rather than with the Pt atom. One may conceptually link the two situations by considering them as frozen-in intermediates of the interconversion of the two extremes **4** and **5**.

Calculations, to be detailed elsewhere, indicate that the conversion of **4** into **5** is orbital symmetry allowed. There might however be some spin conservation problems arising from a possible triplet ground state for **5**. On the other hand, the further conversion of **5** into **6** is symmetry forbidden (with retention of the C_{2h} symmetry). The same behavior is displayed by the system which one obtains through the isolobal replacement of $Au(PPh_3)$ by H (or by an alkyl group), an interesting additional feature being that the first step of the migration process corresponds to a reductive elimination at the metal.[21]

[4] A mixture of $[(Ph_3P)AuCl]$ (100 mg, 0.2 mmol) and $TlPF_6$ (70 mg, 0.2 mmol) in CH_2Cl_2 was stirred under nitrogen for 15 min. Complex **2** (128 mg, 0.1 mmol) was added and the resulting red solution was stirred for 2 h. After removal of TlCl by filtration, layering of the solution with hexane (40 ml) and cooling to $-20\,^{\circ}C$ afforded red crystals of **3** in ca. 80% yield. When only one equivalent of $[(Ph_3P)AuCl]$ was used, only **3** and ca. 50% of **2** were recovered.—**3**: $^{31}P\{^1H\}$ NMR (CH_2Cl_2/CD_2Cl_2, H_3PO_4 ext.) $\delta = 228$ (m, $^1J(PPt) = 2190$, $^1J(PPt) = 1550$, $^2J(PP) = 225$, $J(PP) = 68$ Hz, μ-PPh_2), 50.8 (complex m, Ph_3PAu), 26.5 (d with ^{195}Pt satellites, $^1J(PPt) = 4600$, $^2J(PP) = 225$ Hz, Ph_3PPt), -143.4 (hept, $PF_6^{\ominus}$).

[5] Crystal data for **3**: orthorhombic, space group *Pbca*, $a = 31.770(5)$, $b = 24.724(3)$, $c = 23.720(2)$ Å, $V = 18632$ Å^3, $Z = 8$, $\varrho_{calcd} = 1.765$ g cm^{-3}, $F(000) = 9583$, $\lambda = 0.70930$ Å, $\mu(Mo_{K\alpha_1}) = 115.6$ cm^{-1}, intensities of 15140 reflections with $1 < 2\theta < 25^{\circ}$ were measured on a Enraf-Nonius CAD 4 4F diffractometer, $\omega/2\theta$ scan mode with ω scan width $= 0.8 + 0.35 \tan\theta$, $\sin\theta/\lambda_{max} = 0.596$ Å^{-1}, dimensions of crystal selected $0.1 \times 0.1 \times 0.12$ mm. Data reduction was made using the SDP program package with decay correction [6]. Empirical absorption corrections were applied using Difabs [7]. The metal atoms were found by direct methods and the remaining non-hydrogen atoms from subsequent difference Fourier syntheses [8]. All hydrogen atoms were placed in calculated positions and included in the refinement with fixed isotropic thermal parameters ($B = 5$ Å). The structure was refined by full matrix least-squares using 4494 data with $I/\sigma(I) \geq 6$ to $R = 0.057$ and $R_w = 0.062$ with the error in an observation of unit weight of 0.25. Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD-53789, the names of the authors, and the journal citation.

[17] The two d_{xz} orbitals are hybridized out, away from the metal–metal region in order to minimize the out of phase (and hence repulsive) mixing with the σ and π orbitals of the two PPh_2 bridging ligands.

[18] The reversal in the hybridization is induced by the need to minimize the repulsive interactions with the lone pair of the terminal phosphane ligands, which become greater than the repulsive interactions with the orbitals of the bridging ligands.

[19] The overlap between the sp hybrid orbital of $Au(PPh_3)$ with the π orbitals of the PPh_2 fragment amounts to 0.31 (compared with a value of 0.26 and 0.28 for the overlap with the d_{xz} components of A and B respectively (Scheme 2)).

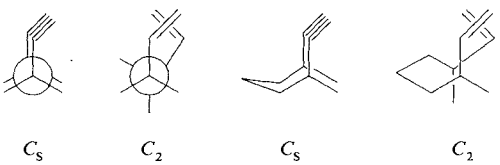
Regiochemistry of the Intramolecular [2+2]-Photocycloaddition of Cyclohexenone to Vinyl Ethers**

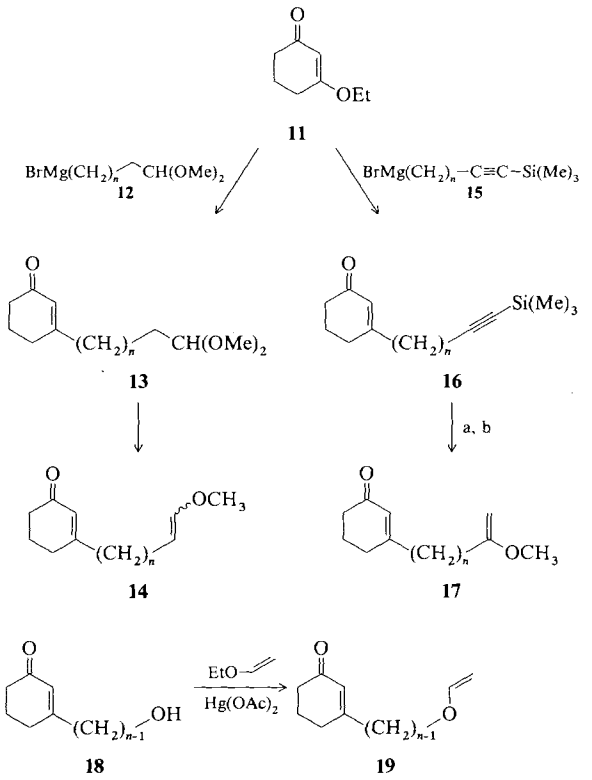


By *Evelyn Fischer* and *Rolf Gleiter**

Dedicated to Professor Margot Becke-Goehring on the occasion of her 75th birthday

The "rule of five" is an empirical rule frequently employed for predicting the regiochemistry of intramolecular [2+2]-photocycloadditions of open-chain, non-conjugated dienes.[1–3] It states that that regioisomer is preferentially formed in which a five-membered ring diradical can be formulated as intermediate. This is illustrated in Scheme 1 for the cyclization of 1,5-hexadiene **1** und 1,6-heptadiene **6**. This rule also applies when one or two double bonds are incorporated in complex systems.[4, 5] Since the rule of five does not satisfactorily explain the stability of the possible intermediates, we proposed a concurrence of electronic and steric effects in the transition state.[6] In the case of **1** the natural sequence of the frontier orbitals should be interchanged by the strong through-bond effect of the ethano bridge with a

Scheme 1.



Scheme 2.

C_2- or C_s-transition state;[6] therefore, the activation energy should be dependent upon electronic factors both in the case of a C_s- as well as a C_2-transition state. The more favorable steric circumstances in the C_2-conformation (Scheme 2, left) should then be decisive for this transition state. In the case of **6** and dienes with longer chains we expect the natural sequence of the π-MOs (π_+, π_-; π_+^*, π_-^*), and, in contrast to the C_2 conformation no electronic contribution to the activation energy for the C_s conformation (Scheme 2, right). Steric effects should be less than in the case of **1** when **6** and dienes with longer bridges are considered. To explore the influence of electronic effects on the intramolecular [2+2]-photocycloaddition we investigated the compounds **14**

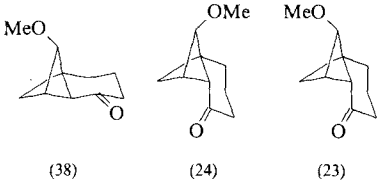
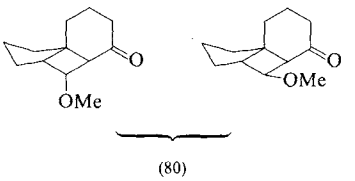
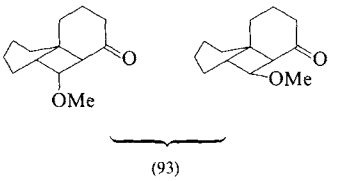
($n = 2$–4), **17** ($n = 2,3$) and **19** ($n = 2,4$) (Scheme 3). Each of these compounds consists of a cyclohexenone moiety whose photochemistry[3b, 7] and photophysics[8] are well documented, and a vinyl ether fragment in which the polarity of the double bond is controlled by the alkoxy group. We assume that an exciplex is formed between the cyclohexenone moiety and the electron-rich vinyl ether moiety in the excited state.

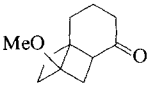
Scheme 3. a) KF. b) $Hg(OAc)_2$, MeOH, $NaBH_4$, NaOH. See text.

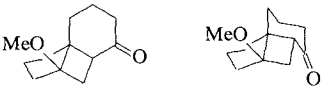
The synthesis of the model compounds **14, 17** and **19** according to conventional methods is outlined in Scheme 3. Irradiation was carried out on 10^{-3} M solutions of the compounds in cyclohexane using a 366-nm interference filter. The product compositions[9] proved to be independent of the presence of a sensitizer (acetophenone, benzophenone); they are listed together with the quantum yields in Table 1. The lifetimes of the respective triplet states τ_{RT} for **14** ($n = 2$–4) and **19** ($n = 4$) quoted in the same table were obtained from the slope of the Stern-Volmer plot ($k_{qT}\tau_{RT}$).[10]

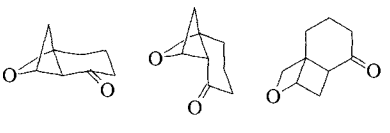


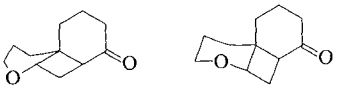




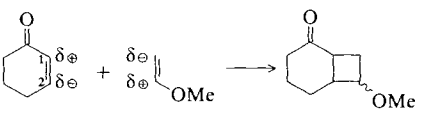








We interpret the results in Table 1 in terms of the polarization of the triplet cyclohexenone and of the vinyl ether moiety shown in Scheme 4.[11, 12] A comparison of the data in Table 1 shows that:



1) Compounds with $n = 3$ furnish only 1,2-bridged head-to-head adducts. The polarization of the enol ether double bond by methoxy groups has no influence on the regioselectivity, but does influence the quantum yield. With compound **17**, $n = 3$, where the polarization favors the head-to-head cycloaddition, the quantum yield is higher (0.71) than in the case of **14**, $n = 3$ (0.46).

2) Dienes with four-membered chains show the same regioselectivity as dienes with $n = 3$. The quantum yields are generally lower than for $n = 3$ and also reflect the polarization of the double bonds [Φ(**14**, $n = 4$) < Φ(**19**, $n = 4$)].

3) When $n = 2$, the regioselectivity is strongly dependent on the polarization of the enol ether double bond. In the case of **14** with $n = 2$, this favors the head-to-tail [2+2]-cycloaddition, and only tricyclo[5.2.1.$0^{1,6}$]decane is formed. However, the quantum yield (0.30) is lower than in the case of **14**, $n = 3$ (0.46), where chain length and enol-ether polarization are opposing each other. If the polarization is reversed (**17**, $n = 2$; **19**, $n = 2$), the quantum yield for the head-to-tail [2+2]-cycloaddition drops to zero.

Table 1. Ratio of head-to-head (□) and head-to-tail [2+2]-cycloaddition (X), quantum yield Φ, lifetime of the triplet state τ_{RT}, and products of the [2+2]-photocycloaddition of **14** ($n = 2,4$), **17** ($n = 2,3$) and **19** ($n = 2,4$).

Starting cpd.	Ratio □ : ×	Φ (τ_{RT}[ns])	Photoproducts (yield in % according to GC)
14, $n = 2$	0:100	0.30 (0.24)	 (38) (24) (23)
14, $n = 3$	100:0	0.46 (0.09)	 (80)
14, $n = 4$	100:0	0.31 (1.1)	 (93)
17, $n = 2$	100:0	0.13	 (75)
17, $n = 3$	100:0	0.71	 (36) (40)
19, $n = 2$	70:30	0.06	 (5) (6) (25)

These results confirm the hypothesis that one of the main reasons for the "rule of five" is to be sought in the through-bond interaction. The absence of an electronic contribution to the activation energy for the C_S transition state with chains where $n = 3,4$ determines the regioselectivity of the cycloaddition;[6] all polarization effects of the substituents are overruled. On the other hand, in the case of compounds with $n = 2$, whose C_S and C_2 transition states experience an electronic activation energy,[6] the polarization of the vinyl ether double bond is decisive for the regiochemistry.

The increased activation energy for $n = 2$ compared to $n = 3,4$ can also be anticipated from the τ_{RT} values: whereas τ_{RT} for **19**, $n = 4$, and **14**, $n = 4,3$ becomes smaller with decreasing chain length, as one would expect for a diffusion controlled process, in the case of **14**, $n = 2$, an increased activation energy seems to outplay the advantage of the short chain and to increase the triplet lifetime.

Deviations from the rule of five can easily be explained in terms of the polarization of the two double bond systems; however, questions remain open, if one does not assume an exciplex,[13] but refers to the stability of possible diradicals.[1-5,14] It can be concluded from the stereochemistry of the products that such diradicals are preferred in which one of the radical centers is located at the carbon atom substituted by the alkoxy group. There would appear to be no preference for C-1 or C-2 (cf. Scheme 4) as second radical carbon atom. On the basis of these considerations one of the questions that arise is why exclusively the secondary product of the six-membered ring radical **20** is formed from **17**, $n = 2$, even though the five-membered ring radical **21** should be more stable. Polarization, however clearly favors **20** over **21**.

21 **17**, $n = 2$ **20**

Oxidative Fluorination of Arenes**

By *Jan H. H. Meurs**, *David W. Sopher*, and *Wolf Eilenberg*

Selectively fluorinated arenes are often biologically active and thus interesting compounds which find many uses as pharmacologically active substances, agrochemicals, or as building blocks for their synthesis.[1] Methods for the selective fluorination of arenes, however, often involve several synthetic steps or are based on the use of highly reactive reagents such as elemental fluorine. We now report the selective oxidative fluorination of some selected phenol and benzene derivatives in an HF/base mixture, in which hydrogen fluoride is present in complexed form.

Hydrogen fluoride/base complexes are well known as reagents for direct fluorination or as sources of fluorine in oxidative fluorination.[2] In the latter case aryl cations or aryl radical cations are formed oxidatively; these react with fluoride ions in situ with formation of the new fluorine–carbon bonds.[3,4] In this way we were able to convert the phenols **1a–e** into the dienones **2a–d** and **2'** in an HF/base mixture in the presence of stoichiometric amounts of lead(IV) compounds or at the anode (Table 1). Without addition of bases no dienones are formed, but only polymers.[5]

1 **2**

The dienones **2a–d** and **2'** are useful intermediates in the synthesis of substituted fluorophenols. For example, hydrogenation of **2a** leads almost quantitatively to *p*-fluorophenol **3**. Numerous nucleophiles undergo a Michael addition with **2a**, whereupon a rearomatization takes place in situ with cleavage of HF. In this way 4-fluoro-3-hydroxybenzonitrile **4**, for example, is accessible in 90% yield. The addition of

Table 1. Conversion of the phenols **1a–e** into dienones in an HF/base mixture.

Phenol	R	Oxidation	HF/		
Base	Yield	Dienone			
				[wt.-%]	[a]
1a	H	PbO_2	HF/H_2O 37/63 (w/w)	12	**2a** [b]
		PbO_2	HF/pyridine 70/30 (w/w)	30(50)	
		PbF_4	9 HF/KF	60(65)	
		Pb_3O_4	9 HF/KF	37(41)	
		$Pb(OAc)_4$	9 HF/KF	42(48)	
		Anode	3 HF/Et_3N	25	
1b	2 Cl	PbO_2	HF/pyridine 70/30 (w/w)	25	**2b**
1c	2 CH_3	$Pb(OAc)_4$	9 HF/KF	10	**2c**
1d	3 CH_3	PbO_2	HF/pyridine 70/30 (w/w)	17	**2d**
1e	4 CH_3	PbO_2	HF/pyridine 70/30 (w/w)	36	**2'** [c]

[a] Determined by GC analysis of the isolated product. [b] Byproduct: benzoquinone. [c] **2'**: 4-fluoro-4-methylcyclohexadienone.

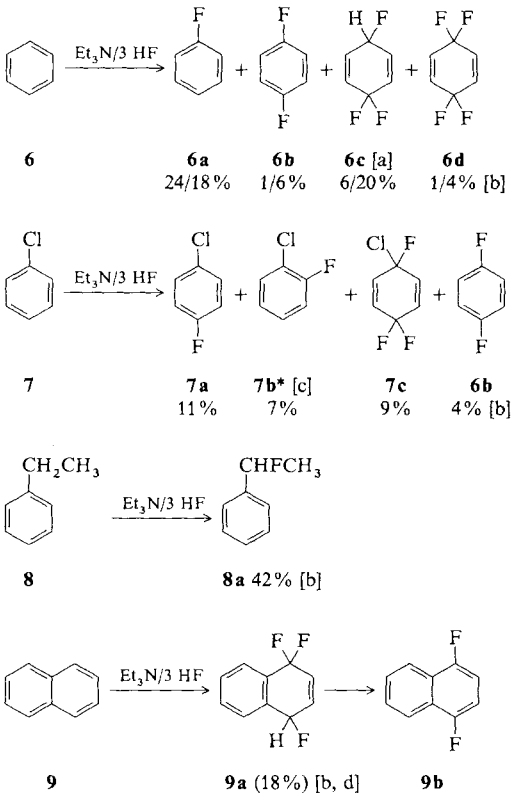
methoxy groups to **2a** leads to **5** in 80% yield; cleavage of HF, however, could not be achieved (Scheme 1).

3 (90%) **4** (90%) **5** (80%)

Scheme 1. [a] Pt 10% on carbon, MeOH, 1 bar H_2. [b] KCN, DMF, 30 min, 20°C; ^{13}C NMR (200 MHz, $CDCl_3$): 157.2, 155.8, 123.4, 119.2, 117.6, 114.8(CN) 100.7. [c] K_2CO_3, MeOH, 4 h, 60°C; ^{19}F NMR (200 MHz, $CFCl_3$): 122.75(2 F, J_{HF} = 8.8 Hz).

Owing to its high oxidation potential, benzene **6** reacts only slowly with PbO_2, and in HF/pyridine 70/30 (w/w) it is converted into **2a** (13%) in 5 d. **6** and other non-activated aromatics such as **7–9** can, however, be readily oxidized in an Et_3N/HF mixture (Scheme 2). In some cases secondary alkylamines (e.g., dipropylamine) or tetraethylammonium fluoride are equally suitable as bases; primary amines lead to electrode passivation.

The system Et_3N/3 HF as electrolyte and source of fluorine, has a series of advantages: it is stable towards oxidation up to over + 2 V/SCE, good electrical conductivity (no addition of supporting electrolytes), and satisfactory dissolution of the substrates that are mentioned here (additional solvent unnecessary). Moreover, it is distillable as azetrope (ratio Et_3N/HF 1/3) and can thus, in principle, be recovered.[6]



The applicability of HF/base complexes in electrochemical fluorination to various classes of substances is presently the subject of further investigation.

Experimental

Oxidation with Pb^{IV} reagents. **2a**: 0.94 g (10 mmol) of **1a** and 4.78 g (20 mmol) of PbO_2 were added with stirring in 20 min at 35°C to 10 mL of HF/pyridine (7/3 w/w) in 50 mL of CH_2Cl_2 (two phases). After 30 min the organic phase was decanted off, washed with 50 mL each of aqueous Na_2CO_3 solution and H_2O, and dried over $MgSO_4$. Subsequent chromatographic purification (silica gel, $CH_2Cl\,CH_2Cl_2$/pentane 1/1 v/v) furnished 0.39 g (30%) of **2a** as a pale yellow solid (highly lachrymatory). ^{13}C NMR (250 Hz; $CDCl_3$): 183.5, 137.0, 131,2, 109.9; ^{19}F NMR (250 MHz, $CFCl_3$): − 98.94.

1b–1e were oxidized analogously using the reagents quoted in Scheme 1. All products afforded correct ^1H NMR/^{13}C NMR data; e.g. ^{19}F NMR ($CFCl_3$, 250 MHz): **2d** − 103.16; **2'**, − 92.03.

Electrochemical oxidation: the electrolyses were carried out in unpartitioned plate cells (3 × 17 cm, electrode separation 1.5–2 mm) of platinum anodes (cathode: Monel) current controlled (5 mA/cm^2) with cell voltages of 3–5 V.

Scheme 2. Anodic oxidation of **6–9**. [a] **6c** can be converted quantitatively into **6b** by base- or acid-catalysis. [b] Conversion: **6**: 60/86%; **7**, 76%; **8**, 63%; **9**, 96%. [c] Experiments with deuterium-labeled compounds confirm attack of the radical cations of **7** in the *o*-position by $F^{\ominus}$. [d] Product unstable: cleavage of HF leads to **9b**.

The electrolyte was pumped through a degassing vessel (evolution of H_2) with the aid of an HF-resistant hose pump (30–50 mL/min).

2a: A solution of **1a** (0.47 g, 5 mmol) in Et_3N/3 HF (14 mL) was electrolyzed up to a charge consumption of 4.5 F mol^{-1} (conversion 90%). The electrode compartments were partitioned by a microporous polyethylene membrane. The reaction mixture was diluted with 50 mL of H_2O, extracted with CH_2Cl_2, and worked up as described above; yield of **2a**: 0.13 g (20%).

6–9 were oxidized analogously; ^{19}F NMR (250 MHz, $CFCl_3$): **7c**, − 92.7, − 103.6. **8a**: − 167.4; **9a**: − 77.3, − 86.6, − 171.5.

The ^{19}F NMR data of all the other compounds are consistent with those quoted in Ref. [7].

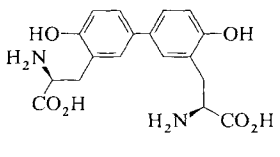
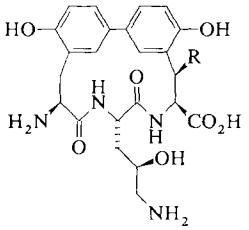
Synthesis of (*S*,*S*)-Diisotyrosine and Its Incorporation in an Ansa Tripeptide**

By *Ulrich Schmidt,* Regina Meyer, Volker Leitenberger,* and *Albrecht Lieberknecht*



In numerous biologically highly active metabolic products of fungi and bacteria, diaminodicarboxylic acids have been found as characteristic building blocks, which – as in plant metabolism – are formed by dimerizing radical oxidation of hydroxylated phenylalanines.

Diphenyl ether structures have been found in the cyclopeptides piperazinomycin,[1] OF-4949 I–IV[2] K-13,[3] bouvardin and deoxybouvardin,[4] RA I–VII[5] and the very complex glycopeptide antibiotics vancomycin, teicoplanin and ristocetin.[6] Isodityrosine **1** was prepared during the synthesis of piperazinomycin,[7] deoxybouvardin,[8] OF-4949,[9–11] and K-13.[11]



Biphenyl structures have been detected in some glycopeptide antibiotics.[6] WS-43708 A (**3a**) and B(**3b**),[12] highly active antibacterial metabolites from *Streptomyces griseorubiginosus* No-43708, contain diisotyrosine **2** (3,3'-(*p*,*p*'-dihydroxybiphenyl-*m*,*m*'-diyl)dialanine) and its β-hydroxy derivative as characteristic building blocks.

3b: R = H

We synthesized diisotyrosine as ether-masked species with four different protecting groups on amino and carboxyl groups (Scheme 1, **11a,b**; for physical data see Table 1).

The biphenyl skeleton was formed from **6** and **8** by Pd^0-catalyzed arylboronic acid-aryl bromide coupling.[13] Key reactions in the synthesis of the amino acid units were condensation reactions of the aldehydes **4** and **9** with (dialkoxyphosphoryl)glycine esters to give didehydroamino acid compounds and their enantioselective and diastereoselective hydrogenation. Since the homogeneous catalyst $[Rh(dipamp)]^{\oplus}$[15] hydrogenates *E*-didehydroamino acid derivatives only very slowly and without high stereoselectivity, we hydrogenated only *Z*-**7a, b** and *Z*-**10a, b** and converted the *Z*-compounds into the *E* compounds by photochemical isomerization. The enantioselectivity or diastereoselectivity of the hydrogenations was greater than 99%. The amino and carboxy protecting groups required on the diisotyrosine for subsequent cyclopeptide synthesis were already introduced during synthesis of the didehydroamino acids with appropriately protected (dialkoxyphosphoryl)glycine.[14]

The ansa-tripeptide **16** was synthesized from the monomethoxy compound **11c** – prepared analogously to **11a, b** – and (*S*)-alanine (Scheme 2). The site of coupling is often crucial for the successful ring closure via ω-aminopentafluo-

Direct Observation of Ground State Splitting in the Chromium(III) Acetate Trimer by Inelastic Neutron Scattering**

By *Upali A. Jayasooriya,* Roderick D. Cannon,* Ross P. White*, and *Gordon J. Kearley*

The electronic states of triangular clusters of paramagnetic ions have been studied extensively.[1] For homonuclear clusters of first-row transition metals bridged by anions, antiferromagnetic coupling predominate **1**, and the Heisenberg model of spin–spin interaction, assuming all three metal ions to be equivalent, leads in every case to an energy level scheme with a multiply degenerate ground state. For example, the Cr_3^{III} triangle in **1** (Fig. 1), is predicted to have a

$[Cr_3O(O_2CCH_3)_6(OH_2)_3]Cl \cdot 5H_2O$ **1**

multiplicity of four.[2] Physical measurements however, imply that in general the degeneracy is lifted by a lowering of symmetry of the metal ion triangle. Temperature-dependent magnetic susceptibility and specific heat data require at least two different coupling constants J(Cr–Cr).[1] Moreover, the low-temperature crystal structure of the chloride salt contains two sets of crystallographically non-equivalent trimer complex molecules.[3] From specific heat data, *Sorai* et al. deduced that both sets are distorted from equilateral geometry, to different extents[4] and more recently *Ferguson* and

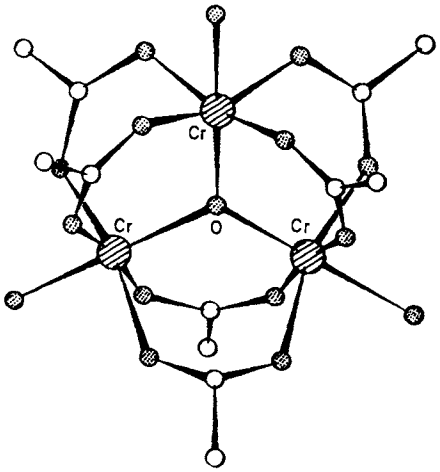

Fig. 1. Structure of the complex cation $[Cr_3O(O_2CCD_3)_6(OD_2)_3]^{\oplus}$.

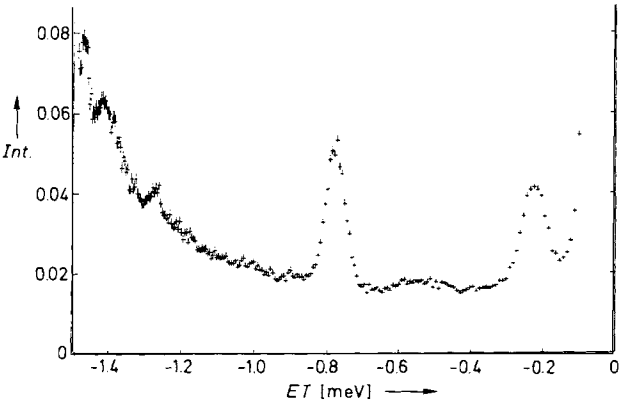

Fig. 2. INS spectrum of $[Cr_3O(O_2CCD_3)_6(OD_2)_3]Cl \cdot 5D_2O$, $T = 1.4$ K, wavelength of incident beam 5.5 Å. Measured on IN5 at the Institut Laue-Langevin, Grenoble. ET = energy transfer, Int. = intensity (in arbitrary units).

Güdel reached the same conclusion from luminescence measurements.[5]

We now report, for the first time, *direct* observation of spectroscopic transitions between the split components of the ground states of these molecules, using inelastic neutron scattering spectroscopy (INS).

The spectrum of the (deuterated) chloride salt is shown in Figure 2. Two well-resolved peaks are seen. The variation in intensity with momentum transfer confirms their magnetic character, and the similarity in intensity is consistent with their originating from two chromophores, present in equal numbers and having equal transition probabilities. Assuming local C_{2v} symmetry, the Heisenberg model interprets each energy as $4|\Delta J| = 4|J_{ca} - J_{ab}|$, where subscript c labels the unique Cr atom and a, b label the two equivalent atoms. We find $\Delta J = 0.778$ and 0.222 meV (6.3 and 1.8 cm^{-1}) for the two sets of complexes in the crystal, in good agreement with previous estimates.[4, 5]

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Combination Effects in Chemical Carcinogenesis. By *D. Schmähl*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. 279 pp., hard cover, DM 128.00.—ISBN 3-527-267-26742-5/0-89573-670-5

This slender and well produced volume summarizes 20 years of work at the Deutsche Forschungsgemeinschaft on the effects of combinations of chemicals on carcinogenesis. While some readers will, understandably, wish that Professor *Schmähl* had attempted to cover all the available information in this area, it must be realized that the large literature, the considerable amount of information of a dubious or unhelpful nature, and the need to present a clear focus on the nature of the interactions, would make this a Herculean task. This volume is a good beginning insofar as it reviews in detail a substantial collection of data of consistently high quality.

Much information on how cancer arises has been accumulated over the past 20 years and is highly relevant to the understanding of chemical interactions in carcinogenesis. The importance of metabolic activation and of the usefulness of genotoxicity tests are considered in some detail in separate chapters. There are no such summaries of the relevance of other factors such as cellular proliferation induced by hormonal mimetic effects or by cytotoxicity followed by regeneration, or by immunotoxicological effects, or by physiological pharmacokinetics, or by cell to cell cooperation. This means that most of the topics are considered from the point of view of what happens when two or more chemicals act together to form tumors, rather than on why it happens.

A further result of focussing the text on the work of a single institute is that some salient features in the development of the subject have been omitted. Thus, in a consideration of the development of tumors in the mouse skin, no mention is made of the classical work of *Berenblum* and *Shubik* which established the importance of multi-agent interactions in the two-stage process. Also no mention is made

of the recent work of *Slaga* and of *Kinsel* that has indicated there may be three stages in the induction of these tumors, each mediated by a separate chemical. Such deficiencies in information limit the value of the book mainly to those who already have a working knowledge of the chemical induction of cancer. It greatly reduces the value of the book all not so well versed in the background of carcinogenesis.

The individual topics in this volume are very well presented, with an abundance of charts and figures to convey the basic data. The interactions described are of major importance in the practical sense, and impinge on many areas of importance to the general human environment. For example, experimental studies on combination effects in inhalation carcinogenesis, the effects of ethanol, interactions between low levels of potent carcinogens that affect the same tissue, combinations of carcinogens and non-carcinogens, interactions between the various components of cancer chemotherapeutic agents used to treat human cancer, interactions between the different components of cigarette smoke, and the all-important subject of the influence of diet, stressing the possibly greater importance of total calories consumed than of fat, are each carefully considered.

Overall, this volume will prove to be of value to those experienced in carcinogenesis, especially in relation to its bearing on the human environment. It will achieve its full potential if it persuades a dedicated group of scientists to attempt to organize the entire literature of interactions in a rational and comprehensive manner.

Chemical Carcinogens. Activation Mechanisms, Structural and Electronic Factors, and Reactivity. Bioactive Molecules Series, Vol. 5. Edited by *P. Politzer* and *F. J. Martin, Jr.*, Elsevier, Amsterdam 1988. xiv, 366 pp., hard cover, HFl 280.00. – ISBN 0-444-43008-3

Since 1978 an "Interdisciplinary Cancer Research Workshop" has been held annually at the University of New Orleans. Following the tenth meeting it was decided to publish a detailed report to mark the first decade of this conference. This book is the result. It consists of 15 chapters dealing with the most important aspects of research on chemical carcinogenesis: 1. Metabolic and chemical activation of carcinogens: an overview; 2. Reactive metabolites of carcinogens and their interactions with DNA; 3. DNA adducts in vitro and in vivo; 4. Carcinogenic halogenated aliphatic compounds; 5. Chemistry, reactivity and carcinogenicity of chloroethers; 6. Carcinogenicity of ethylene and its derivatives: structural considerations; 7. Reactions of vinyl chloride and its metabolites with bases in nucleic acids and the potential biological consequences; 8. Computational studies of olefin and epoxide carcinogenicity; 9. Irregularities of DNA structure and their effects on DNA replication; 10. Nucleic acid alkylation by *N*-nitroso compounds related to organ-specific carcinogenesis; 11. Nitro-polycyclic aromatic hydrocarbons: structural features, genotoxicity, and risk evaluation; 12. Methyl bay region diol epoxides: key intermediates in the metabolic activation of carcinogenic methylated polynuclear aromatic hydrocarbons; 13. Estrogen carcinogenicity: hormonal, morphologic and chemical interactions; 14. Theoretical implications of the k_e carcinogen-screening test; 15. A microspectrofluorimetric study of the cell's multiorganelle detoxification complex and intracellular carcinogen interactions.

The book reports the latest state of knowledge, since all the chapters have been prepared by acknowledged experts in their respective fields. Direct reproduction of the original typescripts has ensured rapid publication. This technique is known to reduce the likelihood of having a good key-word index, a fact which is also confirmed here: the index is less than four pages in length. Thus, "Aflatoxin" is missing, as is "2-Aminofluorene", to give only two examples. Careful scanning of the detailed contents list is therefore needed in order to find a given subject of interest, and it should have been possible to do better than this! Despite this failing the editors have put together a collection of articles which every chemist who is interested in chemical carcinogenesis should have – and their number should increase. The price of the book, however, is rather high.

Angular Momentum: Understanding Spatial Aspects in Chemistry and Physics. By *R. N. Zare*. Wiley, New York 1988. xi, 349 pp., hard cover, $ 39.95. – ISBN 0-471-85892-7

This book by *Richard Zare* is based on the Baker Lectures which he gave in 1980 at Cornell University, and on lectures given to post-graduate students at Stanford University in the following years. It is a gem amongst the excellent books that have emerged over a period of many years from the celebrated Baker Lectures; many chemists will be familiar with *C. K. Ingold*'s "Structure and Mechanism in Organic Chemistry" (1953), and with *Linus Pauling*'s "The Nature of the Chemical Bond", which were products of the early years of this lecture series.

The aim of the book is to give the reader a sound and detailed understanding of angular momentum in atomic and molecular physics. It begins by introducing angular momentum operators and wave functions. Chapter 2 treats the case of coupling between two angular momentum vectors, and Clebsch-Gordan coefficients. Chapter 3 contains a very detailed treatment of rotational transformations. Chapter 4 deals briefly with couplings involving more than two angular momentum vectors (with 6 and 9 *j* symbols), and Chapter 5 describes tensor operators. Finally Chapter 6 treats the energy levels and wave functions of a rigid rotor. The appendix gives some short Fortran programs for numerically evaluating 3, 6 and 9 *j* symbols.

The book is a masterpiece of didactic clarity. By means of numerous carefully set out exercises and examples from atomic and molecular physics, it enables the reader to work systematically through the material, and to gain an effective "practical" understanding of the subject. In this respect the book differs markedly from the many which adopt a more rigidly formal approach to angular momentum theory. *Richard Zare*'s approach is aimed not at theoretical physicists but at experimentalists, spectroscopists and chemists. Nevertheless, theoreticians too would benefit from the many examples of applications. *Zare* develops all the important basic theory needed, and the book is therefore eminently suitable for individual study or for reading in conjunction with a course of lectures. However, nuclear spin is treated very scantily from a chemist's point of view.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0707-0932 $ 02.50/0

To sum up it is appropriate to quote from the preface of "Angular Momentum": "This is not the first book on angular momentum theory, but it differs from others in the emphasis placed on making it a learning text for those with a minimum background in quantum mechanics. It also differs in the choice of examples that are drawn almost entirely from atomic and molecular phenomena. I believe that it is not possible to present this material too simply to anyone learning angular momentum theory for the first time. Consequently, many intermediate steps are left in the text, which, to the initiated, may appear inelegant, if not annoying. At the same time this text serves a secondary purpose of being a reference work; the vast majority of formulas needed to solve any problem in angular momentum theory are contained in this book". It only remains for me to add that the book is strongly recommended as a textbook for students and prospective researchers (and is very sensibly priced!). I hope that it will run into many printings.

Zürich (Switzerland)

Chemiluminescence. By *A. K. Campbell*. Ellis Horwood, Chichester/VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. 608 pp., hard cover, DM 280.00.— ISBN 3-527-26342-X/0-89573-501-6; ISSN 0930-3367.

In separate chapters, the author covers the history of chemiluminescence, detection and quantification, bioluminescence, the need for chemiluminescence analysis, measurement of enzymes and metabolites, ultraweak chemiluminescence, indicators for inorganic ions, an alternative to radioactive labels, energy transfer, and "hills and horizons." Five appendices follow: a glossary, names of luminescent organisms, instructions for finding luminescent organisms, chemiluminescence demonstrations, and commercial sources of equipment.

The book contains a very large amount of information, but concentrated on the biological aspects. The subtitle on the cover "Principles and Applications in Biology and Medicine" is a better description. The historical aspects of the subject are developed in considerable depth, and the tabulation of the numerous units for light in Chapter 2 is particularly helpful. The text and figures are free from typographical errors.

The book unfortunately has a number of faults. In spite of the fact that chemiluminescence is my own specialty, I found the book rather tedious to read. On page 233 we are told that Mexican women use bioluminescent adornments in headwear. The same fact appears in a table on page 240, and again in the text on page 241. Lucigenin appears in a table on page 247 as an indicator of "reactive oxygen metabolites", again on page 302 in a table on limits of detection of oxygen metabolite measurement, with no data entry, and in a third table (page 364) as an indicator of reactive oxygen metabolites O_2^- and $^1O_2$. In most of the tables there is only one bit of information per entry. Aside from redundancies, *Campbell* seems unwilling to allow the reader to use his intelligence and imagination to figure out anything for himself. Half of page 242 is a photographed control experiment that shows absolutely nothing. In the appendix on collecting specimens at night, he gives a useful tip that a squirt of KCl solution will stimulate organisms to emit light, but then spoils it by dutifully itemizing a shovel, a bucket, and a flashlight as necessary equipment for any nocturnal expedition.

The author's enthusiasm for the subject is quite evident, and one is inclined to blame the editors for not showing a more businesslike hand in dealing with numerous artistic literary digressions into topics ranging from children's nursery rhymes to Welsh nationalism. Since footnotes do not appear in the text, it is at times difficult to separate fact from entertaining speculation. The encyclopedic scope of the book is probably best suited for biochemists and medical people with limited background who are interested in entering the field.

The Chemistry of the Quinonoid Compounds. Vol. 2. Parts 1 and 2. Edited by *S. Patai* and *Z. Rappoport*. Wiley, Chichester 1987. Part 1: xiv, pp. 1–878, hardcover, £ 175.00.—ISBN 0-471-91285-9; Part 2: xiv, pp. 879–1711, hardcover, £ 175.00.—ISBN 0-471-91914-4 (2-volume set £ 325.00.—ISBN 0-471-91916-0)

The first "Patai" on quinones appeared in 1974. Since then the preparative chemistry of quinones has been described in "Houben-Weyl" in 1977 and in 1979, whereas a recent account of naturally occurring quinones is available in Volume 3 of Thomson's series. Thus, after nearly 15 years, the new "Patai" presents a much needed survey that covers the broad spectrum of quinone chemistry. These books are timely and most useful for everyone who is concerned with quinonoids in research and teaching.

Chapter 1 is a general introduction into the theoretical chemistry, such as orbital calculations, spectroscopy and reactivity of simple quinones, quinonemethides, quinoneimines and thioquinones. Three chapters on analytical aspects follow: the first one contains numerous references on NMR, IR, and UV/VIS spectroscopy, as well as on chromatographic and electrochemical methods. Unfortunately actual results are mentioned in only a few instances, and the reader will find it necessary to consult the library in order to uncover the essential information hidden in Chapter 2. Some fundamental publications by *Sealy* et al. on ESR/ENDOR spectroscopy appear to have been ignored. Chapter 3 contains numerous data on electron impact ionization mass spectroscopy of anthraquinones, and Chapter 4 deals with the chiro-optical properties (ORD and CD) of chiral quinones that are of interest primarily to the natural products chemist.

The physical chemistry of quinones is described in five chapters. The impressive development in the field of photoelectron spectroscopy is reflected in Chapter 5, which contains a thorough discussion of quantum chemical calculations and many results in tabular form. This chapter also includes three-, four-, and five-membered ring systems as well as heteroquinonoids. Chapter 6 is a more specialized account of the photo-, thermo-, and piezochromism of bianthrones and bianthrylidenes. Chemiluminescence follows in Chapter 7. A comprehensive account of the electrochemistry is given in Chapter 12. An informative review on the reactions and spectroscopic properties of free radicals is found in Chapter 14, which also contains some examples of biochemically important quinonoids.

The remarkable progress in the synthesis of quinonoid compounds is summarized in Chapter 8. More than 500

original articles are covered in 162 pages, and the subjects are properly ordered under methodological subheadings, such as oxidations, annulations, cyclizations and condensations. Organometallic chemistry is covered as well as protective group chemistry with silylated quinones. One third of the chapter deals with the synthesis of naturally occurring quinones, and some of the reactions discussed earlier are repeated here. Nevertheless, this section illustrates the preparative aspects in a very informative way.

The second large chapter on preparative chemistry (Chapter 11, 182 pages, nearly 800 references) summarizes the use of quinones in organic synthesis. Vinylogous additions, reactions at the carbonyl group, cycloadditions, alkylations and substitutions are discussed comprehensively. Numerous examples are given concerning the use of quinones in heterocyclic synthesis. The biochemist will find many hints to analogies of quinone reactions in biological systems. Preparative and mechanistic photochemistry is reviewed in Chapter 13, which contains an orderly arranged survey of the reactions and results, including many tables. A more specialized account of dehydrogenation reactions of quinones in Chapter 23 deals mostly with DDQ. Many interesting examples of allylic and benzylic oxidations are cited.

Chapter 19 illustrates the importance of isotopically labeled quinones in mechanistic and biosynthetic investigations. The detailed, handbook-style listing of various compounds and their synthesis is most appreciated by those concerned with the preparation and use of labeled quinones. However, some of the examples seem to be unnecessary, such as the synthesis of [7-^{14}C]-geraniol and [7α-^{14}C]-methoxycephalosporin. Also the rather extensive description of general tracer methodology is superfluous. Some overlap exists in the contents of Chapters 19 and 22. The latter, entitled "The Biochemistry of Quinones", actually contains a very thorough and informative review of the biosynthesis of quinones, divided into sections on polyketides, shikimate metabolites and isoprenoids. Further sections deal with the metabolization of quinones into other natural products, e.g. aflatoxins, and with the role of vitamin K in blood clotting.

Several classes of quinonoid compounds are discussed under preparative, mechanistic or theoretical aspects in eleven chapters. The chemistry of *o*-quinonoids is presented in a rather lengthy way in Chapter 9. A discussion on *m*-quinones and related non-Kekulé structures follows in Chapter 10. The preparation and reactions of quinone bis- and monoketals is described in a clear style and with many tables in Chapter 15. Chapter 16 deals with quinhydrones and semiquinones, including their metal complexes, and there is a partial overlap with Chapter 14. Again, redox potentials, pK_a values and UV spectroscopic data are listed in tabular form. Some biologically important semiquinones are mentioned.

The synthesis and reactions of heterocyclic quinones are described in Chapter 17, which contains many references to organometallic reagents. Some overlap exists with the contents of Chapter 8, e.g. the synthesis of the mitomycins. The following Chapter 18 on polymerization reactions deals almost exclusively with substituted *p*-quinodimethanes. It includes an extensive compilation of data on the reaction kinetics. The solid state photochemistry of tetrahydronaphthoquinones is described in the rather specialized Chapter 20. *p*-Quinoneimines, which are particularly useful in industrial applications as coloring materials, are discussed in Chapter 21. Azulene quinones and polycyclic quinones, including annulenes and non-benzenoid systems, are found in Chapters 24 to 26, where some overlap exists in the description of the theoretical aspects in Chapters 24 and 26.

In summary, the new "Patai" presents an impressive collection of articles on nearly all aspects of quinone chemistry. More than 4500 references covering the period between 1974 and 1986 have been evaluated. In accordance with the intention of the editors, the literature prior to 1974 is cited very sparingly. Some subjects were not included in the collection: there is no separate chapter on quinone methides. They are mentioned, however, on several occasions throughout the books. One would have liked to see a separate chapter on quinonoid biopolymers and on chemical modifications of various biopolymers by quinones, though some biochemically important reactions are mentioned occasionally.

The text is quite heterogenous with respect to style and density of information. Some very specialized topics are distributed among some broad and general overviews. Eventually, an attempt to achieve more consistency in some chapters might lead to a smaller degree of overlapping. A further suggestion to the editors is that each volume should include a list of abbreviations. As it is now, searching for the meaning of abbreviations used in some chapters can become a time-consuming task. The subject index is not extensive enough, e.g. the key-word "daunorubicin" does not lead to the important data in Chapter 14 (p. 893). The sequence of chapters should be arranged more consistently with respect to the general topics.

Technically, the books are thoroughly prepared. Only a few errors or sloppy formulations were noted (e.g., on p. 495 *c,c*- and *t,t*-2,4-hexadienes... should read: *ZZ*- and *EE*...; p. 1301: 25-iso-caproyl... should read 2*S*-isocaproyl). Very few corrections are necessary in the reaction diagrams and formula schemes (e.g., p. 590, eq. 168: it is not evident from the formulas that the oxidative deamination leads to a 2-keto sugar which is then reduced to the 2-deoxy sugar shown; p. 652, eq. 359: the formula of the butadiene derivative is incorrect in the original paper; p. 681, eq. 452: the formula of homophthalimide is wrong). According to the latest published work, the mechanism of the cytotoxic action of mitomycin on p. 1058 should be revised. Nevertheless, these are minor mishaps which do not at all diminish the value of this important volume. The "Quinone Patai" will find its place in the libraries of most research and teaching institutions. Unfortunately, the high price is prohibitive for purchase by individuals. The list of those who will greatly appreciate these books includes scientists from the fields of physical and synthetic organic chemistry, natural products and pharmaceutical chemistry, and, last but not least, organometallic and biological chemistry.

Martin G. Peter [NB 944 IE]
Institut für Organische Chemie und Biochemie
der Universität Bonn (FRG)

Principles of Organometallic Chemistry. 2nd Edition. By *P. Powell*. Chapman and Hall, London/New York 1988. xv, 415 pp., paperback, £ 13.95. – ISBN 0-412-27590-2. – hard cover, £ 13.95. – ISBN 0-412-27580-5

Anyone who, like this reviewer, was a chemistry student in the early 1970s and was fascinated by the then still young and rapidly developing subject of organometallic chemistry, will clearly remember the first edition of this book, published in 1968 with four authors (*G. E. Coates, M. L. H. Green. P. Powell* and *K. Wade*). That, together with its German translation published in 1972, was almost the only textbook on organometallic chemistry tailored to the needs of students, unless one was prepared to use the two-volume "Coates".

In contrast to that time, there now exists a pleasingly large choice of rival books of varying size and aims, with which this new edition must compete. Of course, the book no longer has a lot in common with the first edition of twenty years ago – apart from its title, little more remains than the subdivision of the contents. Regrettably, however, Chapter 1 ("General Survey") has scarcely been revised. A historical summary of 26 lines, a mini-paragraph (11 lines) on physical properties, an outdated survey of types of bonding, and some very general remarks concerning the stability of organometallic compounds, fail to meet the level of treatment that is nowadays expected of a textbook. Fortunately this chapter is not typical of the rest of the book, and the topics on which it touches are treated in much greater deal and more accurately in later chapters.

The following three chapters (130 pp.) deal with the organometallic chemistry of the elements in Main Groups 1 to 5 and Sub-Groups 1 and 2. After a general discussion of the most important methods of synthesis, arranged according to the groups in the Periodic Table, these chapters deal, at a level and with an amount of detail appropriate for an introductory textbook, with the preparation, structures, reactions and uses of the various classes of compounds. Even such topical matters as the MOCVD (metal organic chemical vapor deposition) technique, arene complexes of Main Group elements, organo-polysilanes, and compounds with low coordination numbers, are briefly covered. The section on "$p_\pi - p_\pi$ Bonding in Compounds of Groups 4 and 5" is outdated, and too short even for an introductory textbook (despite the title, no Group 5 compounds with $p_\pi - p_\pi$ bonds are included).

Next comes a chapter of very heterogeneous content, which is concerned mainly with the chemistry of metal carbonyls and phosphine complexes, while also including the mechanisms of substitution and addition reactions of metal complexes. This is followed by a chapter on the classification of ligands and the treatment of the bonding of π-ligands by MO theory, and a short introduction to complexing by fragment orbitals (although regrettably the isolobal concept is not mentioned). These chapters lead into the organometallic chemistry of the transition metals, classified according to ligand types. The treatment of alkyl and aryl metal complexes is very comprehensive and up-to-date, even including C-H activation. In contrast, the discussion of carbene and carbyne complexes only gives the situation up to about 1975, apart from a mention of the synthesis of vitamin E by *Dötz*; for example, the only mention of a Schrock carbene complex is one structural formula with no related text. An appropriate amount of space (about 100 pp.) is devoted to metal π-complexes, covering the most important aspects, though largely ignoring heteroalkene and heteroarene complexes. A good feature of this section is the discussion of dynamic processes, the understanding of which is greatly helped by the inclusion of figures showing typical NMR spectra.

The book ends with three comparatively short chapters on cluster compounds, on mechanisms of industrial processes which use homogeneous catalysts, and on organoactinides and -lanthanides. The first of these three chapters seems out of place in an introductory book on organometallic chemistry, and the last chapter, with only five pages, does not do justice to the growing importance of this class of compounds. However, the chapter on catalysis is appropriate to the importance of the topic and is up-to-date.

The book declares itself to be aimed at undergraduates. With these readers in mind the author lists selected review articles at the end of each chapter, but no references to original papers. Also at the end of each chapter are a few problems of varying degrees of difficulty, mostly examination questions from British universities. The preface states that a book of answers is available from the publishers.

The right selection of material for an introductory textbook and its proper weighting is no easy task at the present stage of development in organometallic chemistry, and different authors have different approaches. In my view the level of treatment in this book is much more uneven than in other comparable books, and the discrepancies in the extent to which the different chapters are up-to-date have already been mentioned. To the question as to whether the book fills a gap, the answer must be a definite no. If confronted with the choice I would prefer, even for beginners, "Organometallchemie" by *C. Elschenbroich* and *A. Salzer* (also now available in an English translation), which despite its somewhat wider subject coverage gives a clearer, more up-to-date, and better balanced treatment.

Ulrich Schubert [NB 969 IE]
Institut für Anorganische Chemie
der Universität Würzburg (FRG)

Kinetics of Electrochemical Metal Dissolution. (Series: Studies in Physical and Theoretical Chemistry, Vol. 47). By *L. Kiss*, Elsevier, Amsterdam 1988. 260 pp., bound, HFl 200.00.—ISBN 0-444-98964-1

The dissolution and precipitation of metals is the subject of numerous research projects in industry and universities. Thermodynamics gives information as to whether or not a particular reaction can occur. However, it is much more important to know the rate at which a metal is dissolved, e.g. so as to be able to predict the lifetimes of industrial components. Kinetics provides answers to these questions. The appearance of a book dealing specifically with this subject is therefore to be welcomed.

The book is concerned essentially with the uniform dissolution of pure homogeneous metals in solutions of electrolytes. Other types of metal dissolution such as stress crack corrosion (season cracking) or the selective corrosion of alloys are not treated. The book has a logical structure, and at the beginning of each chapter the relevant fundamentals are explained so that the kinetics even of complex electrode reactions can be understood. Much of the cited literature consists of papers from Eastern Europe, some of which are published in Russian. Consequently the English translation of this Hungarian work is of particular interest to readers in the West, enabling them to get an overview of research in those countries on the theme of the book. Published work up to 1983 is covered.

The first chapter deals with equilibria in chemical and electrochemical reactions. The calculation of electrode potentials and potential-pH diagrams is clearly described in textbook style. The author has taken care throughout to ensure that the reader can follow his reasoning, and the book can therefore be recommended as a student text. The second chapter is concerned with the kinetics of electrode processes. The fundamentals of the kinetics are presented clearly and thoroughly. In addition to the penetration and diffusion overpotentials treated here there are, however, other types of overpotentials which, although unimportant for metal dissolution, are certainly important for metal precipitation (e.g. the crystallization overpotential). These could at least have been mentioned briefly. The high level of generality in the formulas and equations means that there are a large number of qualifying statements which require much vigilance on the

part of the reader, especially for complicated reaction equations. These general formulations (e.g. where diffusion and penetration overpotentials are present simultaneously in a reaction with several steps) are made specific to particular situations depending on which is the rate-determining step in the reaction. It would have been desirable to illustrate the relevance of these distinctions for practical situations by giving more examples.

Whereas the fundamentals of metal dissolution are treated in great detail, the dependence of the kinetics of dissolution on the microstructure of the metal surface is unfortunately not discussed. This fails to take account of recent findings that the inhomogeneous nature of real surfaces (points where dislocations meet the surface, grain boundaries, semicrystalline regions, etc.) has crucial effects on the kinetics of metal dissolution. The experimental techniques using rotating disk or disk-and-ring electrodes which are important in electrochemical investigations are thoroughly described. In contrast, however, the various mechanisms of iron dissolution are treated only briefly in relation to their importance, despite the fact that a great deal of detailed work on this topic has been published.

The chapters on the passivity of metals and their transpassive dissolution are well and clearly written. It would also have been of interest to include a more detailed discussion of the effects which the build-up of the passive layer has on the kinetics of dissolution. Treating the transpassivity of metals together with the occurrence of pitting corrosion (p. 173) is of doubtful value, as the two mechanisms are fundamentally unrelated. It would have been better to have included a separate chapter on the kinetics of pitting corrosion.

The final chapter describes the application of kinetics to corrosion calculations, well illustrated by figures. Here again it becomes necessary to distinguish between a number of different cases, showing, for example, the influence of the oxidizing medium or of diffusion processes on calculations of the corrosion current or of the free corrosion potential. The author illustrates very well the usefulness of the polarization resistance for determining corrosion rates, and also details the sort of errors that can arise when the anodic or cathodic partial reactions are no longer controlled purely by ion penetration. The discussion of the different possible types of corrosion protection turns out to be rather brief; however, the book does not set out to cover this topic.

To summarize, this book discusses all aspects of electrode kinetics that are important in the dissolution of pure undeformed metals. Readers who already have some previous knowledge of corrosion will find here a very useful introduction to the kinetics of metal dissolution, a topic which is not covered in such detail in mainstream books in the field.

Ralf Feser [NB 949 IE]
Max-Planck-Institut für Eisenforschung
Düsseldorf (FRG)

Surfactant Science and Technology. By *D. Myers*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xiv, 351 pp., hard cover, DM 88.00.– ISBN 3-527-26695-X/0-89573-339-0

The physical chemistry of surfactant solutions is a topic which continues to attract increasing attention. For this reason the appearance of new textbooks aimed at enabling the reader to enter this field is not unexpected.

In the book reviewed here the author has succeeded well in that aim. The easily readable English text is concisely written, and helps towards a sound understanding of the phenomena described. Although it is not clear why the word "technology" appears in the title, this is, in fact, a good textbook which contains 466 literature references and a bibliography listing 35 books.

The contents are arranged in eight chapters on the following subjects: Overview; The Organic Chemistry of Surfactants; Micellization; Solubilization, Microemulsions and Micellar Catalysis; Surface Activity and the Liquid/Vapor Interface; Emulsions; Foams; Surfactants at the Solid/Liquid Interface.

An exhaustive coverage is not to be expected of a textbook. Thus, for example, rheology is not included at all, and consequently viscoelastic solutions and gels are not treated. Also the phase behavior at the inversion point is not explained in accordance with the most recent findings.

The quality of the book stands out above that of many rapidly produced publications, and it should achieve a wide readership.

ADVANCED MATERIALS

The European Materials Research Society (E-MRS)

Editorial Essay

By Eberhard F. Krimmel*

It was on February 17, 1986, when the European Materials Research Society (E-MRS) was registered at court as a non-profit making learned society with its seat at the "Centre de Recherches Nucléaires" in Strasbourg, France. The history of the Society, however, started many years before when a group of French scientists used to discuss once a year new results and problems of ion implantation, laser and electron beam annealing, etc.

The number of persons participating in the symposia organized by this group of very active scientists continuously increased, the symposia found international recognition and were greatly in demand. Seeing this encouraging development a small circle of scientists from different countries within Europe who were attending one of the symposia in 1982/83 realized that it was time to become organized at the European level. The society to be founded should have an interdisciplinary character and be open to all scientists such as chemists, engineers, physicists, etc., interested and working in research and development within materials science. This nucleus of scientists became the basic unit of the European Materials Research Society. The enthusiasm of the involved scientists, most of them very young scientists, is such that the Society runs on a honorary basis, and although perfectionism is not requested vitality is. The philosophy is that it doesn't matter if a young scientist makes a mistake as not even experienced ones are perfect and in any case mistakes can be corrected!

The categories of membership of the Society are as follows:

First of all there are the ordinary members. These are physical persons active in the domain of materials science and technology or people who contribute to the development of these fields of science. Another catagory concerns sustaining members which are corporate persons such as associations, societies, groups, laboratories, and industrial companies. They must show evidence of supporting activity.

In the United States a society, the Materials Research Society (MRS), was already active with a similar program to that proposed by the European scientists. It was obvious that the American colleagues should be contacted in order to establish international links for the benefit of everybody. Thus, the idea emerged to establish an international federation of autonomous societies having similar structures and aims, all being devoted to materials research and development. These activities concern societies in the USA, Europe, Australia, China, Japan, South America, India, etc.

The E-MRS was founded with the knowledge that over the turn of the century the social future of Europe will depend on the progress that is made in new technologies especially in the development of the materials sciences. These new technologies must also be ecologically beneficial. The aim of the E-MRS is to contribute to this progress by promoting relevant efforts. Chemists, engineers and physicists are scientists who work in different fields and at different levels of a very complex whole. They have to cooperate and intercommunicate to obtain the results which benefit a growing society and which guide the development of our civilization and culture. Thus the E-MRS provides a forum to these scientists for efficient and rapid intercommunication. To this end, the E-MRS organizes conferences, workshops, summer schools, etc. which cover all disciplines of materials science such as ceramics, metals, semiconductors, composites, polymers, and biomaterials. Symposia arranged at short notice on present-day topics, e.g. high-T_c superconductors demonstrate the vitality and quick response of the Society.

In order to emphasize the idea of an unified Europe the main conferences of the E-MRS take place at the seat of the Council of Europe in Strasbourg. Workshops or co-sponsored meetings may be held in other places. The plenary sessions of the main conferences in Strasbourg host the best scientists as speakers on topics which reflect key areas of research on an interdisciplinary level. This years meeting, the largest yet, was attended by 850 people from many nations. Professors Friedel (University of Paris, France) and von Klitzing (Max Planck Institute for Solid State Research, Stuttgart, FRG) led off the extremely strong program of more than 450 lectures, posters and discussion sessions which lasted for four days. The educational potential of the program is always high and therefore special attention has been directed to make it feasible for students to attend the conferences, and publication of conference proceedings and reports serves to disseminate the latest scientific findings to a broad audience.

The interdisciplinary nature of the cooperation and scientific exchange between university and industry R & D efforts is the basis of the E-MRS. Thus the E-MRS coordinates "European Networks" in the field of materials research. At present, 16 Networks covering various fields in electronic and non-electronic materials research and development are in action and more than 200 industrial and university laboratories are involved. Brief details are given in the box.

Also along these lines the E-MRS attaches importance to a fruitful cooperation with other more specialized societies. Such cooperation is already successfully taking place bringing bilateral benefits.

A further topic of activity concerns the critical analysis of the educational situation in the different parts of Europe. The necessity has been recognized of offering, for example, short intensive courses in the various fields of materials science, to individuals not normally having such training possibilities and to other interested parties, including students, to improve their professional skill and to broaden their area of expertise. Up to now more than 10 European intensive courses have already been implemented at the initiative of the E-MRS, exemplified by the Biomaterials course which was part of the Strasbourg meeting.

The E-MRS has been rapidly growing over the last three years and it doesn't take a clairvoyant to see that this will continue. 1992 is coming soon and the importance of materials science is just beginning to be realized.

Eberhard Krimmel studied physics at the University of Tübingen, FRG being awarded a diploma in 1958 in molecular spectroscopy and a Ph.D. in electron interferometry (1961). After a stay of two years at the University of Illinois, Urbana, USA as an Assistant Professor studying radiation damage in metals he started a career with Siemens in Munich, FRG as manager of a research department concentrating on semiconductor and laser technology (1970–1987). From 1982–1985 he was a part-time Professor at the Rand Afrikaans University, South Africa and since 1986 has been an honorary Professor at the University of Frankfurt/Main continuing his interest in semiconductors and ceramics. He was a founding member of the E-MRS (1983) and from 1985–1989 was its Secretary.

An extra large ADVANCED MATERIALS "Materials Science in Britain" is planned for the double issue August/September to coincide with the British Association for the Advancement of Science (BAAS) meeting to be held in Sheffield (UK) September 10.–14. The issue will contain five review articles from top British materials scientists including *B. A. Joyce* "Tailoring Semiconductor Materials to Atomic Dimensions" and *J. M. Thomas* "Catalysts". *R. W. Cahn, G. W. Gray* and *C. J. Humphreys* (amongst others) contribute to the other sections of the journal.

Dichroic Dyes and Liquid Crystalline Side Chain Polymers**

Anisotropic Glasses
Optical Storage
LC-Displays

By Hans-Werner Schmidt*

1. Introduction

Thermotropic liquid crystalline (LC) side-chain polymers have attracted much attention in the last few years. In LC-side-chain polymers, rod-like mesogenic units are attached as side groups to the polymer backbone. The potential of LC-side-chain polymers is based on the unique combination of specific polymer properties with the anisotropic physical properties of conventional low molar mass liquid crystals. The developments in the area demonstrate the practical interest in this new class of materials, especially for optical and opto-electronic applications. Several review articles and books have been published describing the synthesis, characterization, properties and potential applications of LC side-chain polymers.[1]

The reason for the interest in liquid crystalline systems which contain dissolved or incorporated dichroic dyes is that the anisotropic order of liquid crystalline phases causes the molecular orientation of the guest molecules and the anisotropic properties of these guest molecules can be detected. The interplay of the molecular alignment with the different possibilities for macroscopic orientation is the basis for several spectroscopic methods as well as for commercial display applications. For instance, dichroic dye molecules or fluorescent dyes have been used as probes to study order phenomena in different thermotropic and lyotropic systems.

Mixtures of dichroic dyes, dissolved as guest molecules in low-molar-mass liquid crystals, are used in displays operating on the principle of dichroism. The electro-optical effect, a color intensity change, is based on the cooperative alignment of the dye in the host phase and the dependence of absorption on the macroscopic orientation. This effect is schematically demonstrated in Figure 1 for a nematic guest-host system with positive dielectric anisotropy in a typical Heilmeier cell.[2]

In the off-state (left) the nematic phase and the dye molecules are oriented parallel (homogeneously planar) to the glass plates and parallel to the polarization plane of a polarizer. If the transition moment of the absorption of visible light is in the same direction, maximum absorption occurs. In the on-state (right) the molecules are aligned perpendicular to the glass plates by an electric field. As a result, absorption is low. The areas of the display in the on-state appear colorless, while the ones in the off-state are colored. Suitable dichroic dyes for application should have high order parameters, high solubilities, high absorption coefficients and good photochemical stability. A large number of guest-host mixtures have been investigated and correlations between dye structure and properties have been discussed.[3]

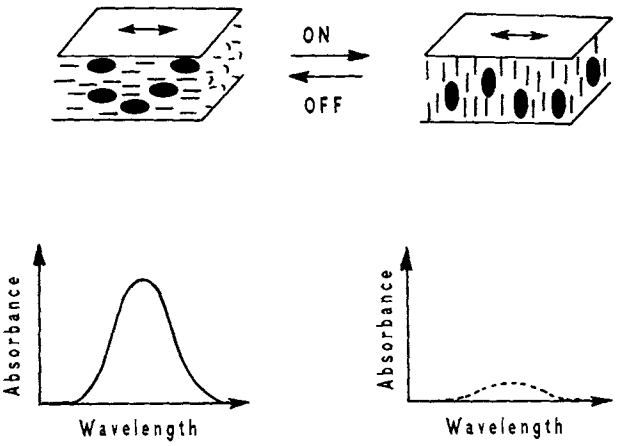

Fig. 1. Schematic representation of the on- and off-states for a guest-host system ($\Delta\varepsilon$ positive) in a Heilmeier cell, and the corresponding absorption spectra. ●: Dichroic dye moiety; ——: mesogenic unit; ↔: polarization plane.

This article focuses on the combination of LC side-chain polymers with dissolved or incorporated dichroic dyes but the results and conclusions are transferable to other types of guest molecules. The structure and properties of different dye containing liquid crystalline systems will be discussed and particular attention is given to copolymers with dichroic dyes and mesogens as side groups. Principal differences to low molar mass guest-host mixtures will be demonstrated and some potential applications of these materials such as dichroic polymer films, media for optical information storage or use as guest components in low molar mass liquid crystals for displays will be discussed.

Kiefer* (Fraunhofer-Institut für Angewandte Festkörperphysik, Freiburg) for fruitful collaboration and to Prof. *H. Ringsdorf* (University of Mainz) for his continuous support.

ADVANCED MATERIALS

2. Dichroic Dyes in Combination with LC-Side-Chain Polymers

Guest-host systems based on LC-side-chain polymers can be classified into three different types. The schematic structures of these types are shown in Figure 2.

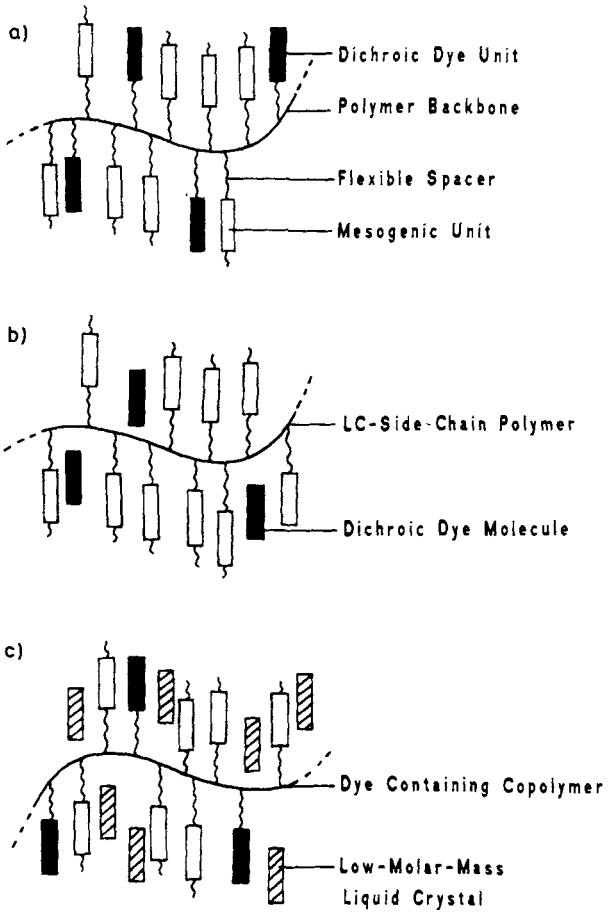

Fig. 2. Schematic structures of host-guest systems in combination with LC-side-chain polymers. a) LC copolymers with dichroic dyes and mesogens as side groups. b) Dichroic dyes dissolved as guests in LC-side-chain polymers. c) Dye containing copolymers as guests in low molar mass LC hosts.

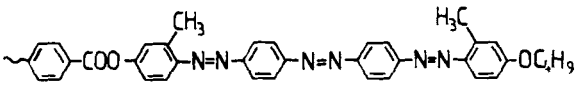
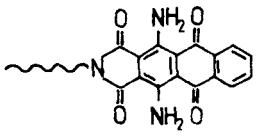
A polymeric guest-host system is a copolymer with dichroic dyes and mesogens as side groups (Fig. 2a). The mesogenic groups as well as the dichroic dyes are covalently attached via flexible spacers to the polymer backbone.[4] This covalent bonding of the mesogenic units and dyes causes significant differences to low-molar mass mixtures. In the case of copolymers, liquid crystalline materials can be prepared with high dye concentrations, but the solubility of dichroic dyes is limited in low molar mass mixtures. In addition, the dye content to the copolymers is independent of the temperature and the type of mesophase. Another important difference is the fact that the order of the liquid crystalline melt does not change for LC-side-chain polymers when they are frozen in the solid state. As a result, the material becomes an anisotropic glass.[5] In contrast to this behavior, the liquid-crystalline order of low molar mass guest-host mixtures is generally destroyed upon cooling by crystallization.



Another approach is the dissolution of dye molecules as guests in LC-side-chain polymers (Fig. 2b).[4d, 5, 6] This approach is limited by the solubility of the dye in the polymer matrix, but is suitable for the use of low dye concentrations. However, it can happen that the dye molecules phase separate and recrystallize above the glass transition temperature.

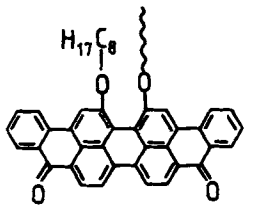
LC-copolymers with dichroic dyes and mesogens as side groups can be dissolved as guest components in low molar mass liquid crystals (Fig. 2c).[4c] The use of dye containing copolymers in mixtures is a general concept which achieves sufficiently high concentrations of dyes which have otherwise very poor solubility in low molar mass liquid crystals. The mesogenic side groups can be regarded as solubility enhancers for the dye moieties. The properties of such guest-host mixtures with respect to possible display applications are discussed in section 6.



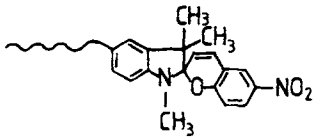
3. Synthesis and LC-Behavior of Dye Containing Copolymers

LC-copolymers with dichroic dyes as side groups can be obtained using the same synthetic procedures as for LC-side-chain polymers. The majority of published copolymers are polyacrylates, synthesized by a free radical copolymerization of mesogenic monomers and monomeric dyes. Another method is the reaction of mesogenic monomers and dyes containing terminal alkene groups with poly(methyl hydrogen siloxane) resulting in a dye containing copolymers with a siloxane backbone. Some functional groups of the dye moiety cause these procedures to fail and other polymerization techniques such as group transfer polymerization, or polycondensation procedures are necessary.

Azo- (mono, bis and tris)-, stilbene-, anthraquinone-, violanthrone-, and spiropyrane-dyes have been investigated in dye-containing LC side chain copolymers.[4] Of particular interest was the preparation of 'black' copolymers which absorb over the entire spectrum of visible light. Such copolymers can be prepared by the attachment of several dyes to one polymer backbone. Examples of dichroic dyes which are covalently attached in LC-side-chain copolymers are the yellow tris azo dye **1**,[4b] the blue anthraquinone dye **2**[4b] and

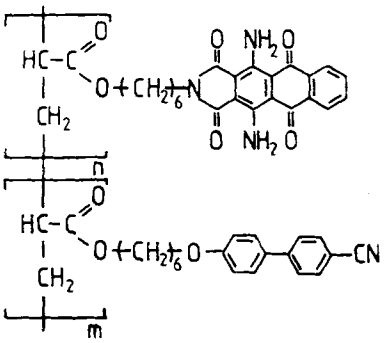


1



2

the violanthrone dye **3**.[7] All three dyes are known to have good photochemical stability and high absorption coefficients. *Cabrera* et al. investigated LC-side-chain copolymers with the photochromic spiropyrane dye **4**.[4e,f]



3

4

The liquid crystalline behavior of the copolymers depends on the dye content and on the molecular structure of the dyes. It was observed that anthraquinone- and spiropyrane-dyes generally destroy the mesophase. In contrast, the tris azo dye **1** increases the clearing temperatures and strongly broadens the mesophase range as the dye content increases. This behavior was found to be independent of the investigated mesogenic side groups in the copolymer. The liquid crystalline behavior of a polyacrylate copolymer **5** with the blue

5

anthraquinone dye **2** and a cyanobiphenyl mesogenic unit as side group will be discussed in more detail. The differential scanning calorimetry (DSC) curve of a copolymer with a dye-content of 2 wt.-% is shown in Figure 3.

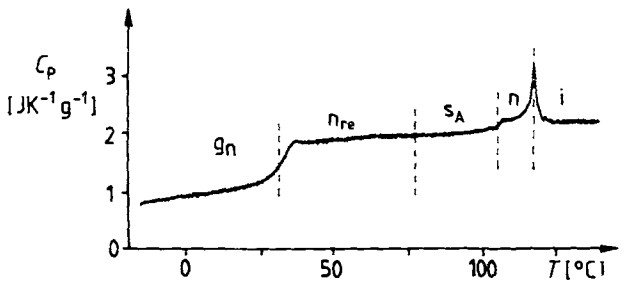


Fig. 3. DSC-heating curve of the anthraquinone-containing LC copolymer **5** (dye content 2 wt.-%). i: isotropic, n: nematic, s_A: smectic-A, n_{re}: reentrant nematic. g_n: nematic glass.

The copolymer has a glass transition at 36 °C and shows several additional endothermic transitions. The following LC behavior was observed using a polarizing microscope. On cooling from the isotropic melt, a nematic phase is formed at 120 °C and at 107 °C a transition to a smectic-A phase is observable. On further cooling a reentrant nematic phase is formed at about 75 °C and becomes a nematic glass below the glass transition temperature. The LC homopolymer without dye has the same phase sequence.[8] With increasing dye content the formation of the smectic-A phase is suppressed and copolymers with more than 10 wt.-% anthraquinone dye are only nematic. The phase diagram for copolymers with a dye content of up to 36 wt.-% is shown in Figure 4. The nematic to isotropic transition is lowered and

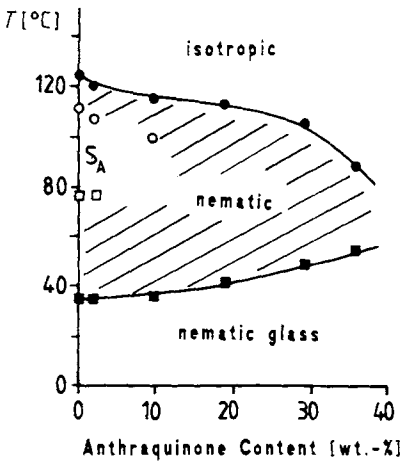

Fig. 4. Influence of the anthraquinone content on the LC behavior of copolymer series **5**. Transition temperatures plotted versus copolymer composition (wt.-% of the dye monomeric unit). ■: glass transition. □: transition reentrant nematic to smectic-A. ○: transition smectic-A to nematic. ●: transition nematic to isotropic.

the glass transition is increased with increasing anthraquinone content. Remarkably the copolymer with 36 wt.-% anthraquinone dye is still nematic. It should be mentioned that similar anthraquinone dyes in low molar mass nematic hosts in general have poor solubilities (below 0.5 wt.-%).

These results demonstrate that it is possible to synthesize liquid crystalline copolymers containing anthraquinone dyes, or other types of dichroic dyes, with very high dye concentrations. These high dye concentrations allow the preparation of thin LC polymer films (down to 1 μm thickness) with adjustable optical densities and absorption properties.

4. Orientational Order in Anisotropic Glasses

The microscopic LC order of side chain polymers can be macroscopically oriented by surface effects, or by magnetic or electric fields in a similar manner to low molar mass liquid crystals. Important is that the macroscopic orientation can

ADVANCED MATERIALS

be transferred to the solid state upon cooling below the glass transition temperature. An optically uniform, transparent, anisotropic glass is obtained. This was demonstrated for nematic as well as smectic glasses. If dye containing LC side-chain copolymers are used, dichroic polymer films are obtained. The oriented films can be prepared between glass plates in a display type cell configuration with a thickness of 0.5 mm to 1 μm (typically 10–20 μm). Uniform films on a substrate are also obtainable by spin coating.

The orientational order of dyes in the anisotropic glasses can be determined from the optical absorbance spectra parallel $A_{\parallel}$ and perpendicular $A_{\perp}$ to the direction of the homogeneous planar orientation (see Fig. 1, on-state). The dichroic ratio R and the order parameter of the dye S_D, characterizing the orientational order of the transition moment of the dyes, are calculated using the following expressions.[3] The order parameters vary from zero for an isotropic system to one for a perfectly aligned system.

$$R = \frac{A_{\perp}}{A_{\parallel}} \qquad S_D = \frac{A_{\parallel} - A_{\perp}}{A_{\parallel} + 2A_{\perp}}$$

As in low molar mass host-guest mixtures the dye structure and type of the liquid crystalline phase have an influence on the order parameter. In Figure 5a the absorption spectra

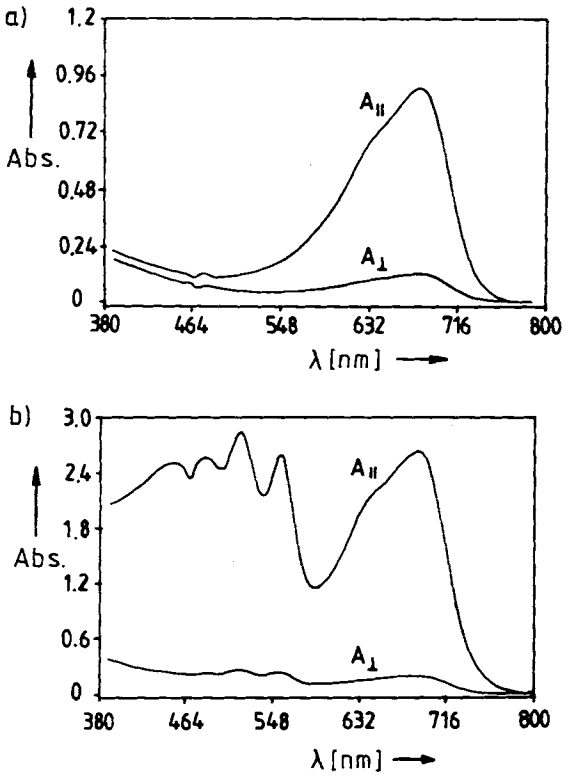

Fig. 5. a) Absorption spectra taken parallel ($A_{\parallel}$) and perpendicular ($A_{\perp}$) to the alignment direction of the anthraquinone containing copolymer **5** in an oriented nematic glass. b) Absorption spectra for a 'black' copolymer with three dyes (yellow tris azo dye, red and blue anthraquinone dyes) in an oriented smectic-A glass.

$A_{\parallel}$ and $A_{\perp}$ for copolymer **5** with the blue anthraquinone dye in the nematic glass are shown. The dichroic ratio is 7.6 and the corresponding order parameter 0.69. The order parameter of the mesogenic side group (0.71) was determined by IR-dichroism measurements, using the vibration of the cyano group attached to the biphenyl unit. The observed S_D values are comparable with those for similar anthraquinone dyes dissolved in low molar mass nematics. Higher dye order parameters are obtainable in smectic glasses, where the host phase has a more ordered structure. The same anthraquinone dye has an order parameter of 0.78 in a smectic-A glass of a polyacrylate with methoxyphenylbenzoate side groups (g 23 s_A 86 n 106 i).

The shape of the dyes and their fixation has also an important influence on the order parameter. The covalently attached rod-like tris azo dye **1** has an order parameter of 0.72 in the nematic glass and 0.84 in the smectic-A glass. For the more plate-like violanthrone dye **3**, which is attached perpendicular to its main molecular axis, lower order parameters were observed as expected. The S_D value in the nematic glass of a polyacrylate with cyanophenylbenzoate side groups (g 32 n 120 i) is only 0.42. In the smectic-A glass (g 30 s_A 93 n 119 i) the order parameter is 0.60.

Figure 5b shows the absorption spectra for a 'black' LC-side-chain copolymer in an oriented smectic-A glass. In this copolymer three dyes are covalently attached to the same polymer backbone: a yellow tris azo dye, and a red and a blue anthraquinone dye. The overall dichroic ratio R for the dyes from 400 to 750 nm is about 10.8.

These examples demonstrate that optically uniform dichroic polymer films, with high dichroic ratios, can be prepared from dyes containing LC-side-chain copolymers. Higher order parameters and dichroic ratios should be obtainable by optimizing the dye structure and the mesogenic side groups.

5. Optical Information Storage with Dye Containing Copolymers

LC-side-chain polymers are considered as one possible organic medium for non-erasable and erasable optical information storage.[9] The interest in this class of materials is based on the various states of order and orientation which they exhibit combined with the possibility of storing defined structures below the glass transition temperature or in highly viscous smectic phases. Storage in low molar mass liquid crystals requires a nematic phase and an additional viscous smectic phase. LC-side-chain polymers allow storage of information in nematic and smectic glasses. Optical storage effects, based on thermal (heat mode)[10] and photochemical (photon mode)[4e,f,11] mechanisms, have been reported for LC-side-chain polymers. Photochemical reactions in cholesteric polysiloxanes doped with benzophenone or carbon black were used for optical write-once storage.[12]

Optical storage based on thermal effects is generally related to a texture change in the LC film. This texture change can be a formation of scattering regions or a defined deformation of the LC-structure with or without the effects of additional external fields. The thermal energy required for a texture change can be generated on the surface or within the active LC film by dye molecules. The latter process has the advantage of higher sensitivity and better resolution. Dye molecules which are either dissolved[10b, 10d] or, like in our work, chemically incorporated into LC-side-chain polymers, can be used for thermal addressing. The covalent fixation of the dye moieties and the possibility of high dye content have additional advantages with respect to the matching of the sensitivity and thermal absorption with the characteristics of the applied laser. This can be done for variable film thicknesses.

As an example, the generation of optical scattering regions in optically clear macroscopically oriented films will be discussed. One possible write-store-erase cycle is schematically shown in Figure 6 for a dye-containing copolymer with a

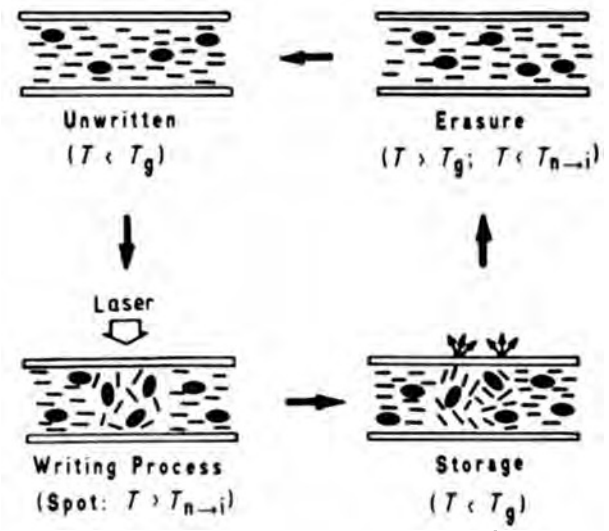

Fig. 6. Schematic representation of a write-store-erase cycle starting from a homogeneous planar oriented nematic glass of a dye-containing copolymer.

nematic phase. The unwritten state is an optically clear, nematic glass with homogeneous planar orientation. The writing process is based on local heating with a focused laser beam above the clearing temperature. On cooling, unoriented light scattering regions can be formed and stored below the glass transition temperature. Erasure is accomplished by heating the material into the nematic phase. The same write-store-erase cycle is possible with copolymers exhibiting a nematic and a smectic-A phase although in this case the information is stored in a smectic glass.

Figure 7 shows laser written scattering lines (width 2–3 mm) written with a He-Ne-laser (4 mW, 633 nm) between crossed polarizers within the macroscopically oriented glass of an anthraquinone dye-containing LC-copolymer.

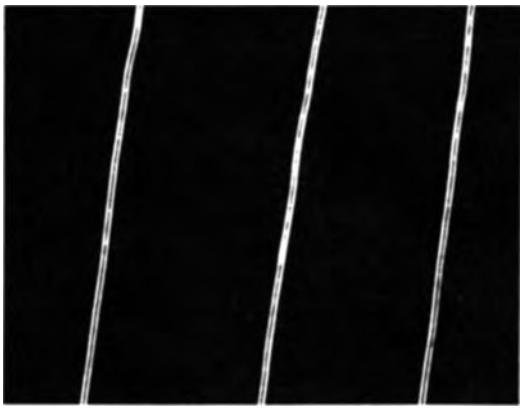

Fig. 7. Scattering lines (width: 2–3 μm) within a homogeneous planar oriented nematic glass (thickness 5 μm) of copolymer **5** (dye content: 10 wt.-%), written with a He-Ne laser (4 mW) at 633 nm. Photomicrograph between crossed polarizers and parallel to the director orientation (IAF, Freiburg).

The series of photographs in Figure 8 demonstrates the storage and erasure process. Figure 8a shows optically isotropic spots with a diameter of 60 μm written with a He-Ne laser in the homogeneous planar orientation of an anthraquinone dye containing copolymer. The information is stored below the glass transition temperature. If the sample is heated for one hour at 50 °C, slightly above the glass transition temperature, reorientation begins and the spot become smaller (Fig. 8b). After heating for an additional hour at 80 °C the spots are completely erased and the original homogeneous planar orientation is again obtained (Fig. 8c).

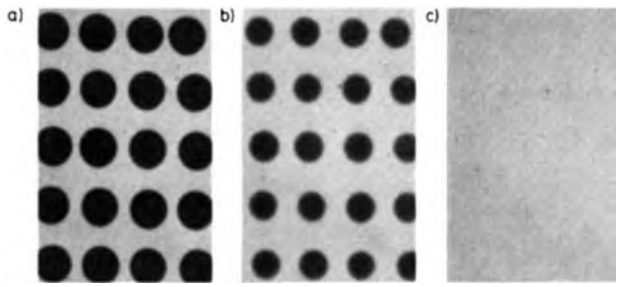

Fig. 8. Photomicrographs between crossed polarizers (45° relative to the director of the macroscopic orientation) of laser written spots on an anthraquinone dye-containing LC-side-chain copolymer (BASF, Ludwigshafen). a) information stored at room temperature. b) sample heated for one hour at 50 °C. c) sample heated for an additional hour at 80 °C.

As mentioned earlier, the writing process is also possible by laser addressing via a conducting IR-absorbing surface. Figure 9 shows a photograph of a cell drawn with a scanning Ne-YAG-laser at room temperature on a homogeneous planar aligned sample of LC-homopolymer with cyanobiphenylene side groups (**5** without the anthraquinone dye). Today, after more than three years, the information is still stable.

Photochemical storage effects in dyes contaning LC-polymers based on the cis-trans isomerization of the azobenzene side groups have been demonstrated by *Eich* et al.[11] and used for reversible digital and holographic optical storage.

ADVANCED MATERIALS

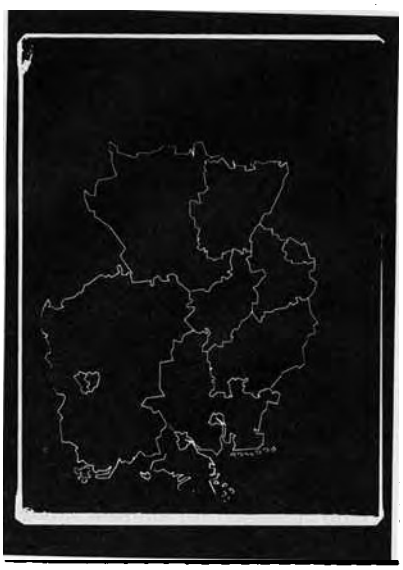

Fig. 9. Outlines of the Federal Republic of Germany and the German Democratic Republic drawn by a Ne-YAG-laser onto a homogeneous aligned nematic LC-homopolymer. Photomicrograph between crossed polarizers and parallel to the orientation of the director. (Cell: 4 cm × 3 cm; thickness: 10 μm; line width: 20–30 μm, IAF, Freiburg).

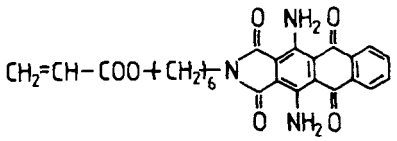
The photochromic and thermochromic behavior of spiropyrane dyes **4** in liquid crystalline polyacrylates and polysiloxanes have been recently described by *Cabrera* et al.[4e,f] The yellow spiropyrane dye was converted by UV-irradiation into its blue merocyanine form. Heating above the glass transition temperature caused the merocyanine side groups to form red dimers. The reverse photoconversion from the merocyanine structures occurred on irradiation with visible light.



The examples discussed above demonstrate that dye-containing LC side chain copolymers can be used in principle as a medium for different modes of reversible optical storage. Studies have to be done on the different systems to further investigate application criteria such as speed, sensitivity, resolution, image density, storage stability, read-out stability, erasability and rewritability.

6. Copolymers as Guests in Low Molar Mass LC-Hosts

Nematic dye-containing copolymers in displays show the same orientation behavior and electrooptical effects as low molar mass host-guest mixtures.[4a] Due to the higher bulk viscosity of the polymers, the response times are longer under comparable conditions. The switching times can be shortened by raising the temperature, applying higher voltages and reducing the cell thickness. Recently, *Kiefer*[13] demonstrated that it is possible to achieve rise times in the order of 25 msec for dye-containing copolymers in thin cells (typically 2 μm) with an applied voltage of 16 V.

A different approach to shortening the switching times is the reduction of the bulk viscosity by adding low molar mass liquid crystals. LC-side-chain polymers are in general miscible with low molar mass liquid crystals if a) the chemical structure of the liquid crystal is similar to the mesogenic side groups and b) if both components have the same mesophase.[14] In the same manner, dye-containing copolymers can be dissolved in low molar mass liquid crystals. The mesogenic side group in the copolymer can be regarded as a solubility enhancer for the dye molecules. The use of dye-containing copolymers as guests is a general concept and is an alternative to the chemical modification of low molar mass dichroic dyes. Several types of dye-containing copolymers were investigated in different nematic low molar mass hosts with respect to the dye solubility, the order parameter S_D and the switching behavior in displays.[4c, 15]

As an example, a mixture of anthraquinone copolymer **5** in a binary nematic host consisting of cyanobiphenyls **7** and **8** (40 mol-% **7**; 60 mol-% **8**) will be discussed. Mixtures with

6

a dye concentration of 1.5wt.-% were prepared. The total polymer concentration in the mixtures can be adjusted by using copolymers with different dye contents. It should be noted that 1.5 wt.-% is not a maximum value, but is already three times higher than the achievable dye concentration of the corresponding dye monomer **6** in the binary host. Dye-containing copolymers can also be dissolved in multicomponent commercial mixtures, which are currently used in LC displays.

7: m = 4 **8**: m = 6

The mixtures have relatively low viscosities. Therefore commercial displays can be easily filled by capillary action and the LC mixture macroscopically aligned into a homogeneous planar orientation by surface effects. The order parameter of the dichroic dye moieties can be determined in the same manner as described in section 4. Figure 10 compares the order parameters S_D of a mixture of copolymer **5** (anthraquinone content 19 wt.-%) dissolved in the binary cyanobiphenyl host, with a mixture of the monomeric dye **6** in the same host. The order parameters S_D are plotted versus the reduced temperature (T_{red}). The reduced temperature is defined by the ratio of actual temperature (K) to the clearing

temperature (K). The value of S_D and the temperature dependence are almost identical for both systems and are not influenced by the polymer fixation of the dye.

Displays filled with copolymer containing host-guest mixtures can be switched by an electric field as shown in Figure 1. As an example, switching conditions and switching times for a mixture of 14.1 wt.-% of an anthraquinone copolymer (dye content 13 wt.-%) in the commercial nematic phase ZLI 1840 (Merck, Darmstadt) are given. The rise time is about 60 msec and the decay time 350 msec in a display (thickness 8.0 μm) at 20 °C and an applied voltage of 7 V. The response times are longer by a factor of 3.8 (rise) and 5.5 (decay) than those measured for host phase ZLI 1840 under the same conditions. It should be noted that a dissolved low molar mass dichroic dye also increases the response times. Additional switching experiments have to be carried out in order to study the influence of the polymer content and of the molecular weight of the copolymers. The results have to be compared with low molar mass host-guest mixtures.

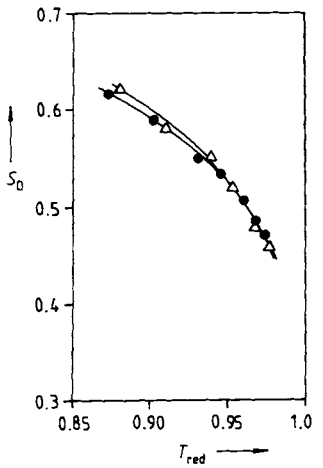


Fig. 10. Order parameter S_D versus T_{red} for the anthraquinone monomer **6** (△) and copolymer **5** (●) in the binary nematic biphenyl host of **7** and **8** (Compositions see [16]).

7. Summary and Outlook

Functional guest molecules incorporated into LC-side-chain polymers lead to polymeric materials which combine the physical and optical anisotropic properties of liquid crystals with the special functions of the guest components. This contribution focused on dichroic dyes, but the results are transferable to other guest moieties. The covalent fixation of the dye to the polymer backbone affords several advantages. Liquid crystalline materials with high dye concentrations were obtained opening the way to the preparation of highly ordered, optical uniaxial films with adjustable thickness and optical density. Thin well aligned LC-polymer films can in principle be used as an active medium for reversible optical information storage and mixtures of dye-containing copolymers in low molar mass liquid crystals can be used in displays. Current developments in the area of ferroelectric chiral smectic-C side-chain polymers will further enhance interest in this area.

Only a small part of the rapidly growing field of LC-polymer materials with specific optical and electrooptical properties has been discussed in this contribution. Combinations of novel polymeric LC-structures with or without special functional guest moieties will certainly lead to a variety of advanced polymeric materials with enormous potential in the areas of integrated optics, non-linear optics, optoelectronics, display and information storage technology.

Production and Application of Rapidly Quenched Materials

Soft Magnetic Materials
Intermetallics
Brazing Alloys

By Hans Warlimont *

1. Introduction

The development of metallic glasses, i.e. amorphous metals produced by rapid quenching from the melt, has an impact on four areas of materials technology:
- substitution of existing materials
- innovation in applications
- instigation of competing material developments
- opening more widely the field of rapid solidification technology

In this overview both ribbon shaped soft magnetic materials and flake shaped hard magnetic materials are included, with emphasis on the former. It should be noted that other rapid solidification processes and products such as rapidly solidified powders, e.g. of aluminum alloys, and the formation of bulk materials by melt-spraying are also being developed and introduced commercially.

Table 1. Commercial applications of cooling wheel based RST.

	Single Roll		Double Roll	Centrifugal Water Cooling Wheel
Form of Product	strip	powder	strip	wire
Materials	amorphous magnetic alloys brazing alloys crystalline brazing alloys	$Fe_{14}Nd_2B$ Al alloys high speed steels hard facing alloys various steels (fibers)	Fe–Si	amorphous
Producers	Allied Signal Metglas Products Hitachi Metals Toshiba TDK VAC SISR I Shanghai CISRI, BMRI Beijing	Delco Remy Allied Signal Metglas Products Marko Materials Fibretech/Ribtec	Kawasaki Steel	Unitika

Table 1 shows a (possibly incomplete) compilation of the major materials, producers and forms of product of rapid solidification technology (RST). Table 2 shows an assessment of the products and applications of RST for 1988 indicating the uncertainty in quantitative data but giving some probable ranges. It should be noted that there are many more pilot productions in operation other than by those companies named in Table 1 and that thin strip casting is being developed on a much larger scale and for a much wider range of products than those comprised in Table 2. In most cases, however, product thickness is larger and cooling rates are lower, and therefore productivity rather than rapid solidification effects are sought.

Table 2. Rapid solidification technology – products and applications 1988.

Products	Applications	Quantities [tons]
amorphous ribbons Fe based	distribution transformers and large chokes	$10^2 \ldots < 10^3$
amorphous ribbons Fe and Co based	inductive components, sensors	$< 10^2$
microcrystalline $Fe_{14}Nd_2B$ powders	bonded permanent magnets	$> 10^2$
amorphous brazing alloys	aerospace	?
microcrystalline Al based powders	aerospace	?
microcrystalline steels	tools, reinforcement	?

2. Power Applications of Amorphous Metals

For this and the following section on the magnetic applications of metallic glasses, recent reviews[1, 2] and publications of conference proceedings[3, 4] should be consulted for details.

Figure 1 shows a comparison of different materials and operating conditions (peak induction $\hat{B}$) with regard to the

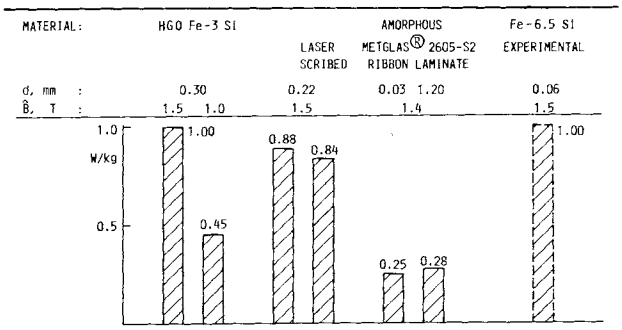

Fig. 1. 60 Hz power loss for typical Fe–Si and amorphous transformer materials.

Prof. Dr. H. Warlimont
Vacuumschmelze GmbH
D-6450 Hanau (FRG)

power loss p_{Fe} in transformers operating at a power grid frequency of $f = 60$ Hz. It is obvious that amorphous metals are substantially superior to the other materials but that progress has been made in the case of silicon steels and operating conditions are also yielding drastic differences. This indicates that economic aspects, such as investment and life cycle costs, will be decisive in the final use of transformer materials. The largest producer of amorphous core transformers in the USA, the General Electric Company, reports that their sales (over the last several years) total just 10000 amorphous core transformers (typically in the 30 kVA power range) but that they expect sales to double in each of the next few years. This should be compared with the total number of 1.2 million transformers sold in the USA annually. Jacksonville Electric Authority in Florida has so far bought 1600 amorphous-metal transformers which have cut power losses by 60%. The transformers are priced about 25% higher than conventional ones.[5]

3. Speciality Magnetic Applications of Amorphous Metals

The drastic reduction of iron loss in amorphous vs. crystalline soft magnetic materials is a major reason for their applications in power transformers. Their low coercivity H_c reduces their hysteresis losses, but their low ribbon thickness $d \lesssim 0.030$ mm and their high electrical resistivity $\rho \gtrsim 130$ μΩcm are still more effective in reducing the eddy current losses, which are proportional to d^2/ρ. This leads to the competitive situation between amorphous metal ribbons and ferrites shown in Figure 2. The ferrites have been improved in the sequence N27, N67, H_{7c4} (commercial designations) but the Co based amorphous ribbons are superior at all frequencies if their ribbon thickness is reduced to $d \simeq 15$ μm which is technically and economically feasible. Apart from lower losses another favorable property of amorphous metal cores with a Z type loop is their high squareness.

Table 3 is a compilation of speciality applications of soft magnetic amorphous metals. They have reached different degrees of importance. The use of amorphous cores in current compensated chokes may be pointed out as a special case. The effectiveness of these chokes in suppressing common mode interference is expressed by the insertion loss as a function of the frequency of the noise spectrum. Figure 3 shows the superiority of amorphous core chokes compared to permalloy and ferrite core chokes which exhibit lower insertion losses and pronounced minima at certain frequencies due to resonance effects.

Table 3. Magnetic speciality applications of amorphous metals.

Field of Application	Specific Application
power supplies	switched mode power supplies: - inverter transformers - chokes for magnetic amplifiers - storage chokes - RF current compensated chokes high repetition rate pulse compressors: - step-up transformers - saturable reactors
other HF circuits	- transformers - chokes
magnetic heads	- audio - data storage
magnetic shielding	- flexible shields
sensors	- magnetic field - position, displacement - force, torque - identification and anti-theft markers

ADVANCED MATERIALS

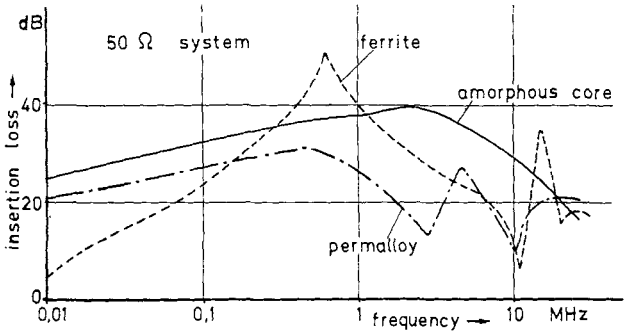

Fig. 3. Insertion loss of common mode interference in current compensated chokes.

4. Rapidly Quenched $Fe_{14}Nd_2B$

The hard magnetic compound $Fe_{14}Nd_2B$ is becoming important among the rare earth bearing permanent magnetic materials because of its high ratio of performance vs. cost. It is produced both by conventional powder metallurgical processing and by RST. To utilize the magnetic material to the full, anisotropic magnets are produced using powder metallurgy. Rapid solidification yields a higher coercivity and a somewhat lower temperature coefficient of the remanence B_r which is useful in some applications, and it allows the production of bonded magnets which are formed more easily yielding in certain cases an economic advantage. Since the material is produced by ribbon formation in the amorphous state, followed by disintegration into flakes and crystallization of the intermetallic compound, the magnetic easy axis is oriented randomly yielding isotropic properties. However, it has been found that uniaxial hot pressing of the flakes induces oriented selective grain growth such that anisotropic properties result. Table 4 gives properties of powders which

Table 4. Properties of rapidly quenched $Fe_{14}Nd_2B$ powders [a].

Type	Remanence B_r [T]	Coercivity ${}_iH_c$ [kA/cm]	$(dB_r/dT)/B_r$ [%/K (25...100 °C]
A. isotropic	0.75	12	− 0.13
B. isotropic	0.80	7	− 0.11
C. anisotropic	0.95	9	− 0.12
E. anisotropic	0.86	10	− 0.17

[a] Magnequench by Delco Remy.

are commercially available. In the present state of evaluation it is to be expected that sintered and rapidly quenched $Fe_{14}Nd_2B$ hard magnetic materials will be supplementing rather than competing with each other.

5. Further Materials Developments and Perspectives

Apart from the soft magnetic amorphous materials and the microcrystalline hard magnetic $Fe_{14}Nd_2B$ compound, other RST materials are beginning to assume commercial importance such as brazing alloys, nanocrystalline soft magnetic alloys and others (Table 2).

Rapid solidification of brazing alloys has yielded two advantageous aspects: a) amorphous and microcrystalline structures impart favorable mechanical properties to brazing alloys; b) supersaturation effects and favorable brazing behavior permit the design of active brazing alloys with technical and economic advantages. Active brazing involves an alloy containing an oxygen getter which eliminates the use of flux media for metal brazing and the need to metallize ceramic parts to be brazed. The resulting simplification of the brazing process is indicated in Figure 4. A typical alloy which was developed for this application is Ag–Cu–Ti.[6]

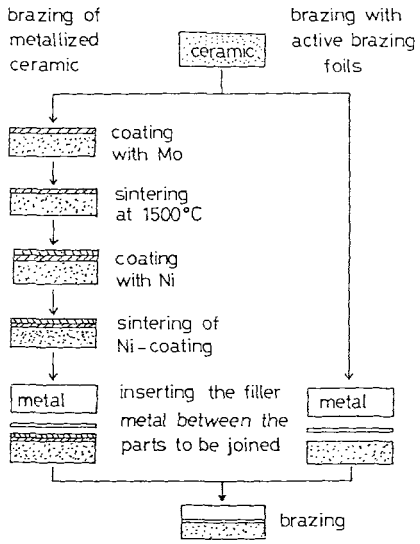

Fig. 4. Comparison of brazing processes for metal-ceramic joints.

A recent development by Hitachi Metals Ltd.[7] has yielded a rapidly solidified soft magnetic material with an extremely low grain size in the nm range. A typical composition

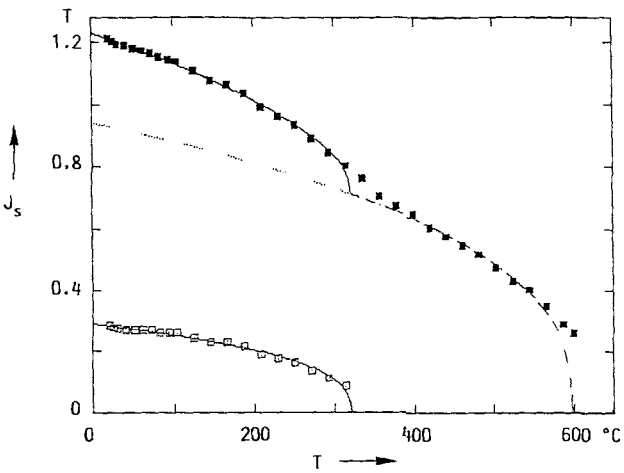

Fig. 5. Magnetization vs. Temperature of rapidly quenched $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ annealed 1 h at 520 °C.

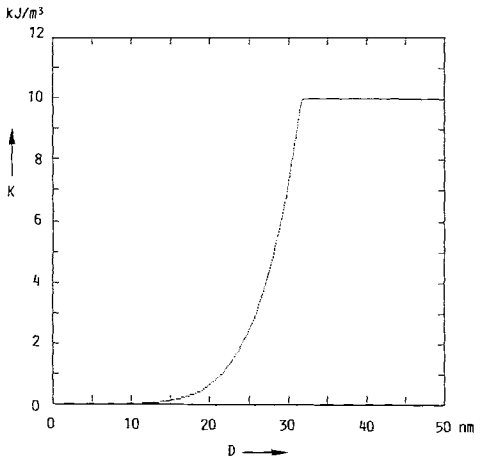

Fig. 6. Computed magnetocrystalline anisotropy K vs. grain diameter D.

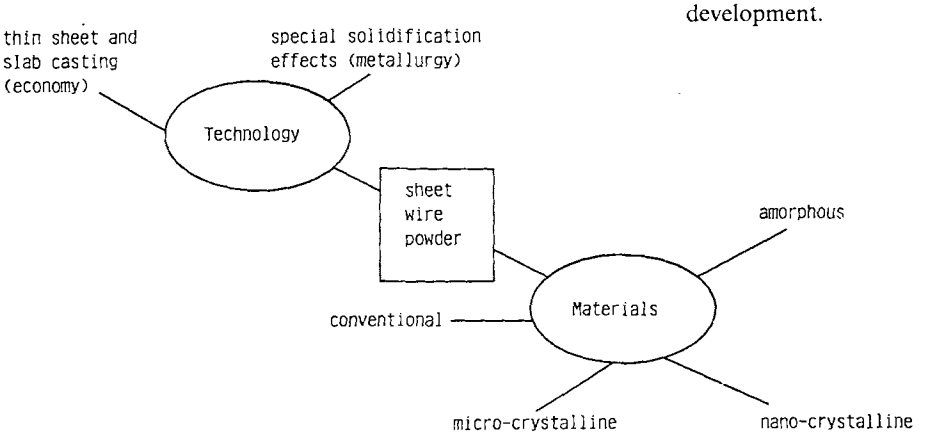

Fig. 7. Perspectives of rapid Solidification technology.

is $Fe_{73.4}Cu_1Nb_{3.1}Si_{13.4}B_{9.1}$. At variance to normal behavior where the coercivity H_c is expected to vary as the inverse of the grain diameter D, this material has a very low coercivity in the same range as that of the best amorphous materials. The explanation was found[8] by first determining the temperature dependence of the saturation polarization shown in Figure 5. It indicates clearly the presence of two ferromagnetic phases with different Curie temperatures which are due to a crystalline Fe–Si rich phase (high-T_c) and probably an amorphous phase (lower-T_c) forming a grain boundary layer. In a second step the magnetocrystalline anisotropy of such a microstructure was computed as a function of grain diameter D, Figure 6. It can be seen that magnetic isotropy prevails up to $D \lesssim 15$ nm. This is one of the essential prerequisites of a low magnitude of H_c. Combined with further favorable magnetic properties such as high B_r and low magnetostriction λ_S and losses p_{Fe} this material is quite promising for a number of applications.

Brazing alloys and nm-range crystalline soft magnetic alloys are just two examples of the versatility and the range of potential developments of rapid solidification technology. In Figure 7 a schematic view of the field is given. One important feature is the technology which allows on one hand for the design of special structural and microstructural effects and on the other, the economy of a one-step process from the melt to the final (or a near-final) product. The second aspect of the application of this technology is the different materials which can be produced possessing a variety of properties. It is obvious that this field has a great potential for further development.

Structure of Anodic Oxide Coatings on Aluminum **

By *Rüdiger Kniep,** *Peter Lamparter* and *Siegfried Steeb*

Porous surface coatings on aluminum are produced by anodic oxidation in acid electrolytes.[1] Pore sizes (10–250 nm) as well as pore densities (10^{12}–10^{15} m^{-2}) are mainly controlled by the anodizing voltage; the thickness of the layers may reach more than 100 μm and is determined by the amount of charge transferred. The remarkably uniform array of the pores in the centers of the almost hexagonally shaped cells makes the films of interest for application in the field of synthetic membranes and as supports for active materials.[2, 3] Furthermore, the coatings are widely used as protective layers which can also be colored by impregnation of the pores with organic dyes or by precipitation of inorganic pigments in the pores.[4, 5] After coloring, the pores are closed by treatment with water or steam. This "sealing" process causes the formation of gelatinous boehmite and amorphous oxide hydroxide by reaction of the pore wall material with water.[6]

The structure of the (amorphous) porous coatings is not clear at present. It is assumed that they are structurally related to the non-porous "barrier-layer" (in direct contact with the metal; thickness 0.1–0.2 μm) which consists of almost pure Al_2O_3 and contains the η- and γ-phases of alumina (spinel-type structures). This assumption is supported by the primary products of crystallization which are formed by thermal treatment of the porous coatings and which were identified as the γ- and γ'-phases of alumina.[7] A recent IR-investigation of dried porous layers[8] is consistent with coordination numbers of four and six (tetrahedral and octahedral) for the aluminum atoms.

In the present work freshly prepared porous coatings were investigated with X-ray and neutron diffraction methods. The aluminum atoms were found mostly to be surrounded tetrahedrally by four oxygen atoms. The close similarities of the radial distribution function (RDF) of the porous layers to that of vitreous silica suggest that the same structural model should be applied for both materials.

Samples for the diffraction experiments were prepared by anodic oxidation of aluminum foils applying the following parameters: bath temperature 12 °C; natural bath convection; current 1.5 A/dm²; voltage 15 V; $Al^{3\oplus}$ content in the bath 5.2 g/l; $H_2SO_{4(total)}$ 200 g/l; $H_2SO_{4(free)}$ 172 g/l. The layers were removed from the metal by treatment with Br_2/MeOH mixtures. The chemical composition of a large number of samples was determined using XFA (Al and S), IC ($SO_4^{2\ominus}$), EDX (Al and S) and TG (H_2O) and yielded a mean brutto-formula of $(5\,Al_2O_3 \cdot SO_3 \cdot 0.66\,H_2O) \cdot 1.33\,H_2O$ with deviations less than one wt-% for the distinct components. The amount of water given inside the brackets of the formula is regarded as the water of constitution (OH-groups) which is released only at temperatures above 470 °C; the amount of water given outside the brackets is regarded as H_2O-molecules (structural water and/or adsorbed water at the pore walls) which is already released between 80 °C and 250 °C.

Figure 1 (a) shows the X-ray structure factors $S^x(Q)$ from angular dispersive X-ray diffraction (ADXD) and from energy dispersive X-ray diffraction (EDXD). Both curves have the same overall shape without sharp reflexes, giving evidence that the anodic oxide coating material is amorphous. In the region of the first peak near $Q = 2$ Å^{-1} the EDXD reflects lower resolution, whereas the high Q-tail of the ADXD curve near $Q = 12$ Å^{-1} we judge to be less reliable. The observation of extended oscillations up to $Q = 23.5$ Å^{-1} demonstrates the power of the EDXD method. The same high-Q oscillations are observed with the neutron structure factor $S^N(Q)$ in Figure 1 (b). At smaller Q, however, S^N is different from S^X where the most drastic difference is the appearance of a large sharp peak in S^N at $Q = 2.8$ Å^{-1} which in S^X shows up only as a small hump. The reduced pair correlation functions $G(R)$, calculated from the structure factors by Fourier-transformation are shown in Figure 2. The restriction of the range, up to only $R = 6$ Å, is justified by the abrupt loss of any correlations in the X-ray curves $G^X(R)$ beyond $R = 4.6$ Å. This signifies that the structural units built up by the aluminum and oxygen atoms in the amorphous phase have a very small extension of maximum of about 5 Å. On the other hand, the neutron curve $G^N(R)$

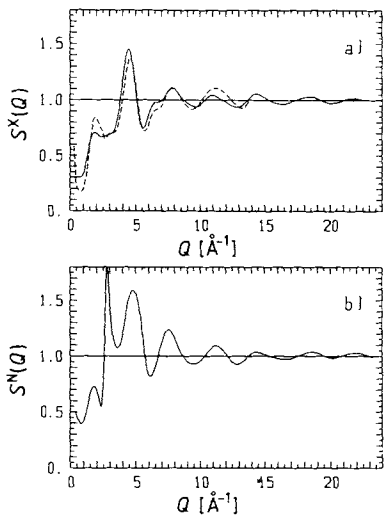

Fig. 1. Amorphous anodic oxide coatings on aluminum. Structure factors $S(Q)$, calculated from a) ADXD (– – –), EDXD (——) and b) Neutron diffraction. $S(Q) = (I(Q) - [\langle b^2\rangle - \langle b\rangle^2])/\langle b\rangle^2$ where $I(Q)$ = coherently scattered intensity per atom; $\langle b^2\rangle$ = mean squared scattering length per atom; $\langle b\rangle$ = mean scattering length (with X-rays depending on Q).

exhibits very extended oscillations up to $R = 20$ Å. Obviously, these extended correlations involve hydrogen atoms which are practically invisible to X-rays. Details of the hydrogen scattering will not be under consideration in this study.

For the identification of the peaks in the $G(R)$ functions in Figure 2 the weighting factors of the ten partial correlation

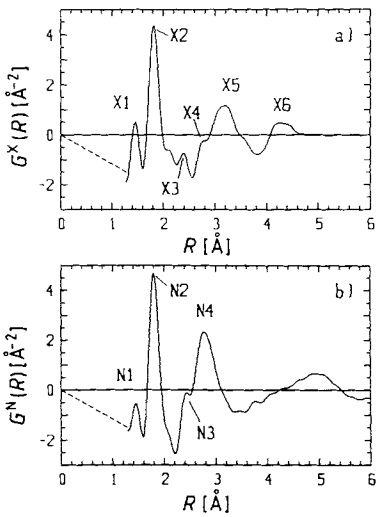

Fig. 2. Amorphous anodic oxide coatings on aluminum. Correlation functions $G(R)$, calculated by Fourier transformation from the structure factors $S(Q)$ in Fig. 1 (a): EDXD; (b): Neutron diffraction; $G(R) = \frac{2}{\pi} \cdot \int Q[S(Q) - 1] \sin QR \, dQ$ where $G(R) = 4\pi R[\varrho(R) - \varrho_0]$; $\varrho(R)$ = pair density distribution function; ϱ_0 = mean number density; R = distance in real space.

functions $G_{i,j}(R)$, (i, j = Al,O,S,H), which contribute to $G(R)$ are listed in Table 1.

The most important information on the short range order in the amorphous coatings is extracted from the main peak of $G(R)$ at $R = 1.80-1.82$ Å (X2 and N2 in Fig. 2) which represents the Al-O nearest neighbors. The almost equal W_{A10} for X-rays and neutrons (Tab. 1) are in accordance

Tab. 1. Weighting factors W_{ij} of the partial correlation functions $G_{ij}(R)$ (i,j = Al,O,S,H). Upper numbers for X-rays; lower numbers for neutrons. $G(R) = \sum_{ij} W_{ij} G_{ij}(R)$, where $W_{ij} = \delta c_i c_j b_i b_j / \langle b \rangle^2$; c_i = atomic concentration; $\delta = 1$ when i = j, $\delta = 2$ when i ≠ j.

	Al	O	S	H
Al	0.176	–	–	–
	0.062	–	–	–
O	0.433	0.266	–	–
	0.418	0.703	–	–
S	0.043	0.053	0.003	–
	0.010	0.035	0.000	–
H	0.011	0.013	0.001	0.000
	– 0.054	– 0.181	– 0.005	0.012

with the equal amplitudes of the corresponding peaks. From the area under the peaks in the radial distribution functions ($RDF^{X,N}(R) = 4\pi R^2 \varrho^{X,N}(R) = RG^{X,N}(R) + 4\pi R^2 \varrho_0$) the coordination number of oxygen atoms around Al is obtained as $4 \leqq Z_{A10} \leqq 5$ depending on the choice of ϱ_0, i.e., the macroscopic density D. According to this method the aluminum atoms are mostly surrounded tetrahedrally by four oxygen atoms. $Z_{A10} = 4$ is obtained using the macroscopic density $D = 2.75$ g cm^{-3} as determined by the Archemedean method. This experimental D-value might be somewhat too small, due to amounts of adsorbed air in the pores of the films. An estimated extrapolation of the densities of amorphous $SiO_2 \cdot Al_2O_3$ materials ($Z = 4.3-4.6$)[9] yields $D = 3.3$ g cm^{-3} for pure amorphous Al_2O_3. The Al-O distance at 1.81 Å in the amorphous porous coatings (Fig. 2) is smaller than the octahedral Al(6)-O distances observed in α-Al_2O_3 (1.86–1.97 Å[10]) and in boehmite (1.88–1.94 Å[11]) and is somewhat larger than the tetrahedral bond lengths Al(4)-O/OH (1.73–1.78 Å) in the isolated dimeric anion $[Al_2O(OH)_6]^{\ominus}$.[12]

According to the significant amount of sulfate in the porous anodic oxide coatings, the peaks X1 (N1) and X3 (N3) in Figure 2 can be attributed to SO_4-tetrahedra. The peaks X1 (N1) at $R = 1.45$ Å correspond to S–O bonds (1.47–1.50 Å) in $SO_4^{2\ominus}$ groups. Its height scales well with the respective W_{SO} in Table 1. The O-O distance along an edge of a SO_4-tetrahedron is expected at $R_{O-O} = \sqrt{8/3}\, R_{S-O} = 2.38$ Å, and shows up at X3 (N3) in the correlation functions. In accordance with W_{O-O} the peak appears higher with neutrons.

In the following we discuss the $G(R)$ curves in Figure 2 on the basis of the structural model for the short range order in the amorphous anodic coatings as presented in Figure 3:

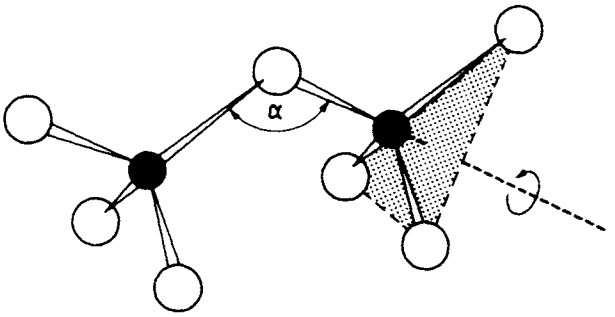

Fig. 3. Short range order in amorphous anodic oxide coatings on aluminum.

Two AlO_4 tetrahedra share a common oxygen corner; the irregular three dimensional structure is then controlled by the possible variations of the angle α, (Al-O-Al), as well as by the conformational statistics resulting from "free" rotation of the tetrahedra around their O-Al-axes. Preferred tetrahedral coordination of aluminum (Al-O 1.81 Å) has already been deduced from the peaks X2 (N2) in Figure 2. The distance between two O-atoms along an edge of a tetrahedron is expected for the case of perfect tetrahedra at $R_{O-O} = \sqrt{8/3}\, R_{Al-O} = 2.95$ Å. We attribute the peaks X4 (N4) at 2.80 Å to this O-O distance which, according to Table 1, appears stronger with neutrons. The average O-O distance along an edge of a tetrahedron in the structure of $K_2[Al_2O(OH)_6]$ is 2.86 Å.[12] With X-rays, a peak X5 appears at larger $R = 3.20$ Å which reflects Al···Al distances resulting from

ADVANCED MATERIALS

corner-sharing AlO_4 tetrahedra; according to Table 1 its contribution is much weaker with neutrons. The angle Al(4)-O(2)-Al(4) of 132° in the isolated dimeric tetrahedral anion $[Al_2O(OH)_6]^{\ominus}$ [12] corresponds with a respective distance Al···Al of 3.18 Å. Larger Al-O as well as O-O distances give rise to the peak X6 around 4.3 Å. Whether the fine structure in $G^N(R)$ in this region is real or is caused by Fourier-ripples cannot be decided presently. It is expected that the broad peaks X5 and X6 are also contributed by non-bonding interactions which reflect the partial substitution of aluminum by sulfur in the amorphous structure.

It should be noted that the short range order in amorphous anodic oxide coatings on aluminum shows close similarities to the short range order reported for vitreous silica.[13-17]

Standardization of the chemical composition $(5\ Al_2O_3 \cdot SO_3 \cdot 0.66\ H_2O) \cdot 1.33\ H_2O$ of the porous anodic oxide coatings to a structural formula $(A)^n[X_{n/2}]$, which in the case of $n = 4$ represents the idealized structure of vitreous silica, leads to $(Al_{0.91}\ S_{0.09})^{[3.39]}\ [O_{3.15/2}\ (OH)_{0.24/2}]$ with the water outside the brackets of the oxide formula not taken into consideration. The coordination number of oxygen atoms around aluminum ($4 \leq Z_{A10} \leq 5$) which is derived from the $RDF^{X,N}$ shows that the oxygen and hydroxyl-groups are not exclusively bound to only two adjacent cations, an observation which is also valid for the structure of vitreous silica.[17]

A final remark should be made concerning the morphology of the almost hexagonally shaped cells (each containing a pore) which has been discussed as an indication of crystallinity of the anodic oxide layers. The isotropic (circular) growth of cells starts at nuclei which are homogeneously distributed over the surface of the aluminum metal. In the course of growth the cells come into contact and develop a homogeneous nearly hexagonal array of cell boundaries which covers the complete coating surface. A pore size near 150 Å and a distance between the pores of about 370 Å was determined from small angle neutron scattering (SANS)[18] studies on a deuterated sample which was prepared under the same anodizing conditions as applied for the materials for the structural investigations.

Experimental

The X-ray diffraction experiments were performed in transmission mode using two different techniques: Angular dispersive X-ray diffraction (ADXD) with a conventional D500-Siemens diffractometer and energy dispersive X-ray diffraction (EDXD) with a laboratory-built set up.[19] The sample material was powdered and filled into a flat container with Kapton-foil windows mounted in a vacuum chamber. With ADXD (EDXD) the scattering could be recorded up to the scattering vectors $Q = 13.5\ Å^{-1}$ ($23.5\ Å^{-1}$), where $Q = 4\pi\sin\theta/\lambda$. Correction methods and normalization to absolute units were applied as described elsewhere.[20, 21] The structure factors $S(Q)$ were calculated according to the Faber-Ziman definition.[22]

The neutron diffraction experiments were performed at the Institute-Laue-Langevin using the instrument D4B up to $Q = 23.3\ Å^{-1}$. The evaluation of the structure factor $S(Q)$ was done essentially as reported elsewhere.[23] However, in the present case the incoherent scattering contribution of the hydrogen in the sample had to be corrected for. This was achieved by fitting a smooth function through the absorption corrected intensity curve in such a way that after the subtraction of the smooth H-contribution the resulting structure factor oscillated properly around one. This smooth function agreed very well with a previously reported[24] hydrogen scattering function. Furthermore, from its intensity an H-content of 10.6 at-% was calculated which corresponds well to the analytical value of 11.4 at-%.

Superconductivity at 7.5 K and Ambient Pressure in Polycrystalline Pressed Samples of β_p-(BEDT-TTF)$_2$I$_3$**

By *Dieter Schweitzer**, *Emil Gogu*, *Hans Grimm*, *Siegfried Kahlich* and *Heimo J. Keller*

Recently, bulk superconductivity at ambient pressure in polycrystalline pressed samples of an organic metal—α_t-(BEDT-TTF)$_2$I$_3$—was observed.[1] This is a remarkable fact because this finding shows that organic superconductors can in principle be used for the production of electronic devices, such as squids, and might even be suitable for the preparation of superconducting cables similar to the high temperature superconductors of the copper oxides.

The polycrystalline pressed samples of α_t-(BEDT-TTF)$_2$I$_3$ were prepared from pulverized single crystals of α-(BEDT-TTF)$_2$I$_3$ and the pressed samples had to be anealed at 75 °C

for one or two days in order to obtain the α_t-phase and to observe bulk superconductivity with an onset temperature of about 9 K.[1] Nevertheless, the superconducting transition was rather broad with respect to single crystals of α_t-(BEDT-TTF)$_2$I$_3$ and zero resistivity was found at 2.2 K. On the other hand, single crystals of (BEDT-TTF)$_2$Cu(NCS)$_2$ show the highest transition temperature known so far among the organic superconductors of 10.4 K,[2] although no bulk superconductivity could be found.[1] The reason for the loss of the bulk superconductivity in the polycrystalline pressed sample compared to the single crystals of (BEDT-TTF)$_2$Cu(NCS)$_2$ is not quite clear, but is probably due to a phase transition of the material during the preparation of the sample under pressure.

Here we report the surprising fact that polycrystalline pressed samples of β-(BEDT-TTF)$_2$I$_3$ show bulk superconductivity with an onset temperature to superconductivity of 9 K, zero resistivity at 3.2 K and the middle of the resistive transition at 7.5 K. In contrast to the polycrystalline samples, single crystals of β-(BEDT-TTF)$_2$I$_3$ show a rather sharp superconducting transition but only at 1.4 K (onset temperature 1.6 K).[3] Under an isotropic pressure of about 1 kbar the single crystals of β-(BEDT-TTF)$_2$I$_3$ show a superconducting transition at 7.5 K.[4, 5] After a pressure-temperature cycling procedure, pressurizing the crystal up to 1 kbar at room temperature and then releasing the helium gas pressure at temperatures below 125 K, superconductivity at 8 K and ambient pressure in β-(BEDT-TTF)$_2$I$_3$ was found.[6, 7] However, this specially prepared superconducting state at 8 K and ambient pressure is metastable because superconductivity at 8 K can only be obtained as long as the temperature of the single crystals does not exceed 125 K. It is therefore very surprising that in the polycrystalline pressed samples of β-(BEDT-TTF)$_2$I$_3$ a stable superconducting state with an onset temperature of 9 K at ambient pressure exists. For this reason we term the polycrystalline pressed samples of the β-phase β_p-(BEDT-TTF)$_2$I$_3$, where the index p indicates the polycrystalline *pressed* material.

Samples of the size $4 \times 1 \times 0.5$ mm^3 were prepared from pulverized single crystals of β-(BEDT-TTF)$_2$I$_3$ (the resulting crystallites from the graining process had typical diameters of 0.1–10 μm) by applying a pressure of about $1.5 \cdot 10^4$ kg/cm^2 to the powder. The β_p-(BEDT-TTF)$_2$I$_3$ samples prepared in this way are mechanically very stable and were not tempered as in the case of the previously reported pressed samples of α_t-(BEDT-TTF)$_2$I$_3$. The conductivity was measured with the usual four point method. Typical room temperature conductivities σ_{300} lie between 5 and 10 $(\Omega\,\mathrm{cm})^{-1}$ and are about a factor of 2 lower than in the polycrystalline pressed samples of α_t-(BEDT-TTF)$_2$I$_3$. Figure 1 shows the typical temperature dependence of the resistivity of polycrystalline pressed samples of β_p-(BEDT-TTF)$_2$I$_3$ as well as of α_t-(BEDT-TTF)$_2$I$_3$. It can clearly be seen that the resistivity characteristics of the samples of β_p-(BEDT-TTF)$_2$I$_3$ differ remarkably from those of α_t-(BEDT-TTF)$_2$I$_3$ samples (and in fact also from the resistivity characteristics of single crystals of β-(BEDT-TTF)$_2$I$_3$).[8] While in the α_t-samples the resistivity decreases as it does in a metal as the sample is cooled from room temperature, in the case of the β_p-(BEDT-TTF)$_2$I$_3$ samples the resistivity first increases slowly on lowering the temperature. At around 220 K, the temperature at which an incommensurate structural modulation in single crystals of β-(BEDT-TTF)$_2$I$_3$ occurs,[9] a maximum in resistivity is observed, and below 220 K again as in a metal the resistivity decreases.

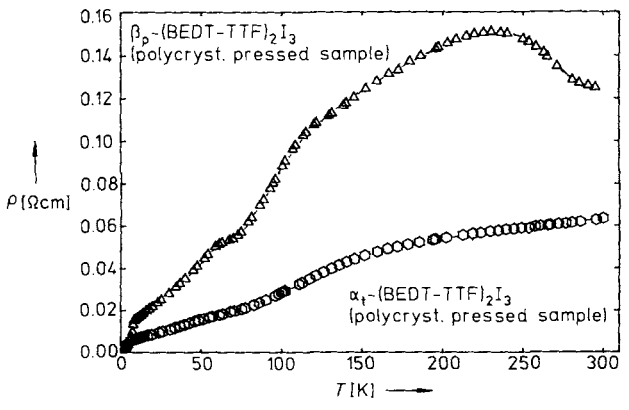

Fig. 1. Temperature dependence of the resistivity of polycrystalline pressed samples of β_p-(BEDT-TTF)$_2$I$_3$ and α_t-(BEDT-TTF)$_2$I$_3$.

Figure 2 shows the resistivity of β_p-(BEDT-TTF)$_2$I$_3$ samples in the temperature range below 16 K. As can be seen the onset of superconductivity lies at around 9 K and zero resistivity is found below 3.2 K indicating a rather broad transition. Nevertheless, the middle of the resistive transition is at around 7.5 K. The onset temperature for superconductivity here in β_p-(BEDT-TTF)$_2$I$_3$ is much higher than that in the single crystals of β-(BEDT-TTF)$_2$I$_3$. The reason for this is not yet clear, but the material probably undergoes a phase transition during the preparation of the polycrystalline samples under pressure. On the other hand, it is clear that the new β_p-phase is not identical with the known α_t-phase indicated by their different resistivity characteristics. In addition, first measurements of the upper critical fields H_{c2} have shown that the polycrystalline pressed samples of the β_p- and α_t-phases have different upper critical fields H_{c2},[10] but these are in both cases much higher than the upper critical field H_{c2} in crystals of α_t-(BEDT-TTF)$_2$I$_3$.[11]

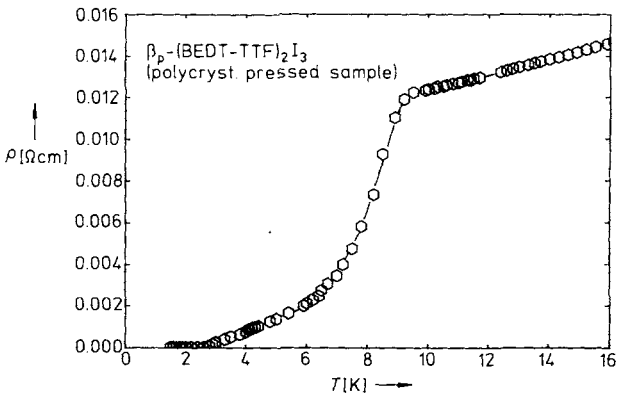

Fig. 2. Temperature dependence of the resistivity of polycrystalline pressed samples of β_p-(BEDT-TTF)$_2$I$_3$ in the temperature range below 16 K.

In order to obtain information on whether the observed superconductivity is a bulk effect of the sample or not, the

ADVANCED MATERIALS

AC susceptibility was measured at a frequency of 3 MHz with a field of about 0.2 Gauss. Figure 3 shows the increase in the resonance frequency of the LC-circuit due to exclusion of the RF-field by diamagnetic shielding currents in the polycrystalline pressed sample of β_p-(BEDT-TTF)$_2$I$_3$. There is clear evidence of an onset of diamagnetic shielding below 6 K (in samples of α_t-(BEDT-TTF)$_2$I$_3$ below 7 K). Here in the polycrystalline sample the onset for the diamagnetic shielding is far above the temperature where the resistivity becomes zero as is usually observed in single crystals of organic superconductors. The signal in Figure 3 which still

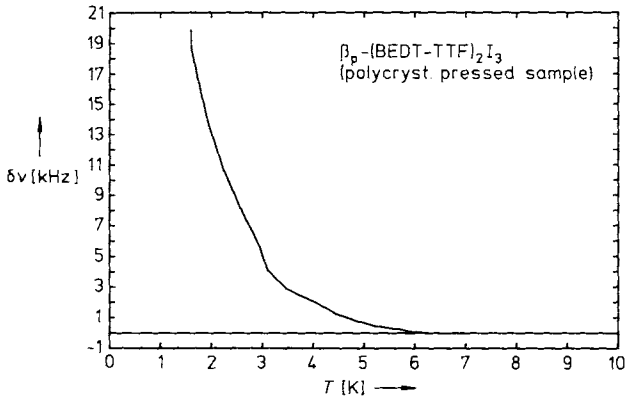

Fig. 3. Increase of the resonance frequency of an LC-circuit (3 MHz) due to exclusion of the RF-field by diamagnetic shielding currents (AC susceptibility) in a polycrystalline pressed sample of β_p-(BEDT-TTF)$_2$I$_3$ caused by cooling the sample from 10 K down to 2 K.

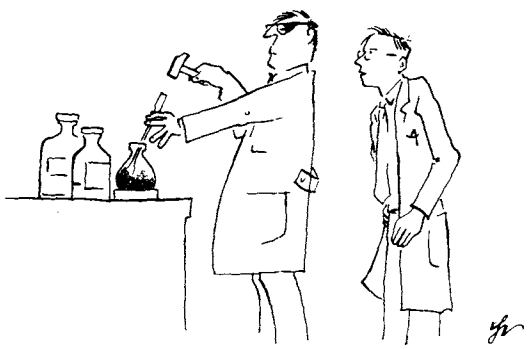
increases on cooling down to 2 K, corresponds to about 50% that expected for a perfect superconductor, indicating a clear bulk effect on the superconductivity in the polycrystalline pressed β_p-(BEDT-TTF)$_2$I$_3$ samples. Nevertheless, the large temperature range in which the frequency shift of the resonance frequency is observed shows that an inhomogeneous distribution of superconducting transitions exists in the sample. A similar broad distribution was already observed in the case of the polycrystalline pressed samples of α_t-(BEDT-TTF)$_2$I$_3$.

It should be mentioned that tempering of the polycrystalline pressed samples of β_p-(BEDT-TTF)$_2$I$_3$ for one or two days at 75 to 90 °C (as in the case of the samples of α_t-(BEDT-TTF)$_2$I$_3$) does not change the physical properties of the samples.



In conclusion, superconductivity at ambient pressure and 7.5 K exists in samples of β_p-(BEDT-TTF)$_2$I$_3$. The superconducting state is stable and the superconductivity is a bulk effect of the sample. Similar to the polycrystalline samples of α_t-(BEDT-TTF)$_2$I$_3$ here again structural phase transitions during the preparation of the samples under pressure seem to play an important role.

As a consequence of the structural phase transition, here in β_p-(BEDT-TTF)$_2$I$_3$, the transition temperature into the superconducting state is increased. This behavior reemphasizes that organic superconductors might also be of interest for industrial applications, as in the preparation of electronic devices polycrystalline materials are easier to use than single crystals. In addition, the discovery of bulk superconductivity in large pressed samples of crystallites of an organic metal of the typical diameter of 1 μm indicates that the observation of superconductivity in conducting polymers should also be possible.

Biomaterials Highlights II

Materials for Biomedical Applications – High Long-Term Success Rates Might Pose New Problems**

By Günther Heimke*

The main influences on the survival rate of implants for a given purpose are:

- the implantation technique and the skill of the surgeon
- the implant material or materials
- the shape of the implant

At a first approximation, the second and third influences are typical engineering aspects. However, as the size, the shape, and the stiffness of an implant can influence the operational procedure, the implantation technique might also be influenced by engineers.

All three major groups of solids have been considered or are used as implant materials: organic solids (like plastics, textiles, even wood, but also ivory and other animal hard tissue) metals, and ceramics.

Plastics are widely used in soft tissue replacements and have stood the test of several decades of service in such different applications as resorbable and non-resorbable sutures, vascular grafts, intraocular lenses, and in many areas of corrective surgery. Their most common applications in orthopedic surgery are the polyethylene sockets in total hip replacements, inlays on the tibial components of total knee protheses and the polymethylmethacrylate (PMMA) bone cement.

The main metallic implant materials are the stainless steels, the Co–Cr–Mo alloys, and some titanium alloys. Today, the application of the stainless steels is essentially confined to temporary implants like bone plates and screws, intramedullary rods, and pins and wires because of their relatively high corrosion rate[1] (more than 75% of all retrieved stainless steel components show evidence of pitting and crevice corrosion). The Co–Cr–Mo alloys have increasingly replaced the stainless steels in all long term (if possible life long) applications like joint replacements and dental implants. In the latter field, these Co based alloys have been substituted almost completely by titanium and some of its alloys. In joint replacements, titanium alloys are also gaining ground.

In spite of being the oldest man made material, the ceramics have been the last group of materials to be considered and tested for implant purposes.[2] Some essentially bioinert oxide ceramics, in particular the highly pure and dense version of alumina ceramic, have found widespread applications for the articulating components in total joint replacements[3] and as dental implants.[4] The fascinating ability of some Ca-phosphate based ceramics, glasses and glass-ceramics (socalled bioactive ceramics) to form a strong bond to bony tissue has not yet be exploited for the fixation of load bearing implants because of the relatively poor mechanical strength and the instability of these materials in the body environment. Trials to overcome these problems by combining them with high strength metals are presently under way.

All of the well established implant materials have stood the test of short and, with the exception of the stainless steels, medium term clinical applications. They have contributed to the considerable increase of survival times and allowed for the use of such devices in younger and younger patients. This, in turn, necessitates the extension of the time of reliable service of all components of such implant systems to much more than ten years. However, all of these implant materials release some matter into their environment.

The presently used plastics and in particular their wear debris have been kept under careful observation without resulting in any alarming finding beyond their influence on the formation and widening of the radiolucencies along adjacent PMMA to bone interfaces. The destruction of the polyethylene sockets of total hip replacements by wear and cold working can be partially counteracted by the use of alumina ceramic for the heads instead of metal.[5] The contribution of the aging of the PMMA bone cement to the increases of the failure rates of total joint replacements has been the main motivation for the attempts to find other modes of implant fixation.

A carcinogenicity test on alumina ceramic was commenced together with the early compatibility studies of this material and proved negative.[6] No reports are yet available which would allow any judgment on medium or long term systemic effects of the bioactive ceramics to be made.

ADVANCED MATERIALS

There is, however, some concern about the long term systemic effects of the corrosion products from metals. Their corrosion rates are estimated to be 0.15 to 0.3 microgram/cm^2/day[7, 8] or about 11 to 22 mg/year for a typical total hip prosthesis. This was confirmed in a paper[9] presented at the recent US Biomaterials Conference. In 24 patients with an average implantation time of 9.8 years, total metal concentrations ranging from 2.6 to 248 microgram/g of dry tissue with an average of 35 microgram/g were found. (For comparison, the total body burden of an average person is less than 10 mg with concentrations in the order of 0.1 nanogram/g.[10])

Of course, the biological effects of the metals used in these alloys differ considerably. Traces of some of them are even needed in normal metabolism, like cobalt in vitamin (B_{12}) synthesis. The concentrations mentioned above, however, are far beyond such limits. Allergies to some of the metals, in particular nickel, cobalt, and chromium, are known and can be avoided by using titanium based materials. Titanium actually is the only metal with a record of several decades of clinical application during which no adverse effects have been reported in spite of the fact that sometimes considerable accumulations of fine Ti particles are seen in the vicinity of such implants.

Until now, there have been not more than ten reports of the occurance of tumors in direct relation to orthopedic implants, but three were published in 1986 and 1987 alone. With the extension of the survival times to the 15 and even 20 years region, information from the epidemiology of human workplace exposure to metal-bearing chemicals and other possible carcinogens with latencies in this order of magnitude must be considered.[10] In the same issue, a group from New Zealand reported on a statistical evaluation of the records of 1358 patients who had received total hip replacements between 21 and 15 years earlier.[11] Using the data of the New Zealand Cancer Registry, they could identify which of these 1358 individuals had developed malignant tumors and compare these numbers with the average rate of tumor occurance in this population. For 298 individuals no data could be made available. They were assumed in the main analysis to be healthy survivers. Table 1 shows the results of this evaluation which is based on a total of 14 286 person-years.

Table 1. The incidence of different kinds of cancer in patients with total hip replacements in comparison to the average population (summarized from [11]), expressed as the ratio of (cases observed in this study)/(cases expected in the average population).

follow-up in years	person years	Type of Cancers (ICD) all	breast (174)	colon & rectum (153 & 154)	bronchus & lung (162)	lymphatic & haemopoietic systems (200 to 208)
Less than 1	1328	1.31	–	0.31	0.71	5.26 $^+$
1 to 2	1293	0.46 *	–	–	0.93	–
2 to 5	3687	0.61 $^+$	0.24	0.38 *	1.16	1.62
5 to 10	5330	0.77 *	0.30 *	0.52 *	0.54	1.38
Over 10	2648	1.60 $^+$	1.01	1.48	1.51	1.66
Total	14286	0.91	0.36 $^+$	0.62 *	0.92	1.68 *
0 to 10		0.74 $^+$	0.22 $^+$	0.41 $^+$		

* p 0.05, $^+$ p 0.01

Generally, a significant decrease in overall cancer incidence up to ten years after operation and a significant increase in those followed for longer than 10 years can be seen. This initial decrease was no longer significant if the 298 individuals of uncertain status at the end of the study were removed from the evaluation.

There is, however, a significant increase overall in the incidence of tumors of the lymphatic and haemopietic systems. The cumulative effect remained significant through the entire study. If the tumors observed in the first two years were excluded, the increase in incidence in the remainder of the study period persisted, but decreased in significance (16/10.57 = 1.51, p = 0.07). The diagnosis for the total hip replacements in these 21 patients was 17 cases of osteoarthritis, two rheumatoid arthritis, and one each with idiopatic aseptic necrosis and Paget's desease.

After discussing many factors which might have influenced their results, the authors point to the fact that the risk of developing a lymphoreticular neoplasm remains small, increasing from 2 per 1000 in the normal population to 6 per 1000 in the study group over 10 years. Nevertheless, the long term biological effects of implants definitly require more detailed attention as their survival times increase.

Along the lines of this warning an Editorial in the January 1989 issue of the British Journal of Bone and Joint Surgery asked its readers to report all cases of malignant tumors along with the necessary details in order to find out if the ten cases reported until now may just be the tip of an iceberg. In addition, animal experiments are presently underway attempting to quantify serveral parameters in order to allow for a more reliable judgement on the risks and to provide possible recommendations to cope with these problems.

Conference Reports

Magnetism in Washington

By Frans Greidanus *

The 1989 INTERMAG (International Magnetics Conference, Washington, USA, March 28.–31.) provided a forum for engineers and scientists to discuss the field of magnetics, from basic research to applications. The sessions included invited and contributed papers, poster sessions, workshops and tutorials. The total number of participants was approximately 800. The diversity of the field was indicated by presentations covering all branches of magnetics and related technologies. Topics discussed included recording heads, superconductivity, microwave components, numerical techniques and field calculations, hard magnets, amorphous magnets, magnetic measurements, recording systems, coercivity mechanisms, domains and domain walls, magneto-optics, magnetic separation and biomagnetism, thin film media, soft magnetic materials, perpendicular recording, and bubble and bloch line memories. Most of the conference took place in six parallel sessions. In the plenary session on March 29. Professor *Iwasaki* from Tohoku University was awarded the 1989 Cledo Brunetti Award for his contributions to the miniaturization of magnetic recording systems.

Also on March 29. a workshop on scanning electron microscopy with polarization analysis (SEMPA) was organized by *J. Unguris* from the National Institute of Standards and Technology (formerly called NBS). SEMPA is a relatively new technology which enables high resolution imaging of magnetic domains by the analysis of the polarization state of electrons reflected from a magnetic surface. In general there was much interest in magnetic domain imaging and related new techniques. Another new tool in this field is the magnetic force microscope. Its possibilities were reviewed in an excellent paper by *Rugar, Mamin, Stern, Fontana, Kasiraj, Mc-Fadyen* and *Lambert* from IBM and optical imaging techniques were reviewed in a paper by *Argyle*, also from IBM.

Materials played an important role at the 1989 INTERMAG conference. Examples are Ba-ferrite as a promising new magnetic recording material, the use of magnetic Co/Pt multilayers for magneto-optical recording, and the application of NdFeB permanent magnets in magnetic imaging devices for clinical applications using NMR.

A substantial number of papers dealt with magnetic recording. Of these about 100 were devoted to magnetic recording, and about 40 to magneto-optical recording. On March 28. a symposium on the status and future of magnetic and magneto-optical disk-drive technologies was organized by Professor *M. Kryder* from Carnegie Mellon University. In this symposium *G. Hughes* (Seagate), *F. Greidanus* (Philips), *D. Rugar* (IBM) and *T. Toshima* (NTT) presented their views. Magneto-optical recording will find its place in the market, but the question whether it will (partially) replace Winchester technology remains to be answered.

An important issue in magneto-optical recording is "direct overwrite." Papers by *Nakao, Sukeda, Ojima, Taka* and *Nishiyama* (Hitachi) and *Greidanus, Jacobs, Spruit* and *Klahn* (Philips) discussed the field-modulation technique. *Kryder, Shieh, Schultz* (Carnegie Mellon), *Meiklejohn* and *Skoda* (MOVID Information Technology) showed real time movies of the writing and erasing of domains with a single laser, operating under different conditions. *Van den Berg* and *Röckelein* (Siemens) proposed two new "direct overwrite" schemes, employing two magnetic layers separated by a thermal insulating layer. It is clear that this subject will attract more attention in the coming years.

Kano, Shono, Kuroda, Koshino and *Ogawa* (Fujitsu) reviewed the possibilities of sputtered garnets for future applications in magneto-optical disks. With garnet layers deposited on Gandolinium Gallium Garnet (GGG) single crystals

[*] Dr. F. J. A. M. Greidanus
Philips Research Laboratories
Eindhoven (Netherlands)

ADVANCED MATERIALS

they have been able to achieve a carrier to noise ratio (CNR) of 60 dB ($v = 0.5$ MHz, $bw = 30$ kHz, $v = 10$ m/s). By depositing the same layers on glass substrates the CNR dropped to 50 dB. Most papers in the session on magneto-optical recording materials were devoted to multilayers (or layered structures) consisting of alternating Co and a non-magnetic metal e.g. Pt or Pd, each individual layer having a thickness of only a few atomic layers. *Ochiai, Hashimoto* and *Aso* (Sony) reported on the magnetic and magneto-optical properties of Co/Pt and Co/Pd ultrathin multilayered films. *Tsunashima, Nagase, Nakamura* and *Uchiyama* (Nagoya Univ.) discussed the possible role of magnetostriction in Pd/PdCo multilayers. *Zeper, Greidanus* and *Carcia* (Philips-Du Pont) were the first to report on thermally written domains and recording experiments in Co/Pt multilayers. In thin (20 nm) films they obtained a CNR of 53 dB ($v = 1.0$ MHz, $bw = 30$ kHz, $v = 5$ m/s). This value approaches the CNR-values obtained in GdTbFe thin films. Multilayers of Co and Pt offer the advantage of increased magneto-optical efficiency in the blue, an important feature for future higher density recording. Furthermore, they are very resistant against corrosion and oxidation and there is no need to apply protective layers. The application of multilayers for magneto-optical recording is an exciting possibility, and increased activitity in this area is anticipated.

In this short report it is impossible to review all subjects discussed at the 1989 INTERMAG. Those who are interested in further information I refer to the contributed and invited papers which will be published in the IEEE Transactions on Magnetics.

Liquid Crystals in Schladming

By Peter Laggner*

One hundred years after the discovery of liquid crystals by the Austrian botanist *Friedrich Reinitzer* was a good time for the VI. European Liquid Crystal Winter Conference (5.–10. March 1989) to be held in Schladming, Austria. This triennial series of 'European' conferences tends to be different from the bigger 'International' conferences as the program is topically confined in order to promote coherent discussion, to reflect the interests of the groups in the organizer's country, and to leave plenty of time and opportunity for less formal interaction.

A specific attraction of this series of conferences is the choice of venue. Previous conferences were held at Les Arcs (France), Madonna di Campiglio (Italy), Garmisch-Partenkirchen (FRG), Bovec (Yugoslavia) and Borovets (Bulgaria) all being winter sports centers. A sport hotel at Schladming this year served this purpose admirably.

The aim of this conference was to bring into fusional contact the two traditionally separate nuclei of liquid crystal research, biology and technology, in order to cross-fertilize the separately developed but related physical and chemical concepts. Thus, under the title "Liquid Crystals in Biology and Technology: Supramolecular Structure, Dynamics and Function" about 130 scientists from 21 nations (not only European) gave 17 lectures (35 min.) and 20 oral contributions (15 min.) and presented 69 posters, representing fields of interest ranging from medical biophysics, chemistry and physics to polymer and display science and technology.

[*] Prof. P. Laggner
Institut für Röntgenfeinstrukturforschung
Österreichische Akademie der Wissenschaften
Steyrergasse 17, 8010 Graz (Austria)

The topics covered in biology included the following: Biomembrane structure and dynamics, polymorphism and dynamics of lipids, Langmuir-Blodgett films, and carbohydrate liquid crystals. Technological topics included amphotropic polymer liquid crystals, chiral main-chain liquid crystals, thermal imaging systems and plastic materials.

An overlap region was presented in the fields of molecular engineering, membrane mimetic chemistry, and drug delivery systems. The first day was devoted to these overlapping topics where concepts from the study of biological membranes combined with synthetic chemistry are used to design devices in the true sense of molecular engineering. *A. Ruaudel-Teixier* (CEN, Saclay, France) and *J. Fendler* (Syracuse University, USA) presented two technically distinct approaches, the LB-film technique on solid interfaces and the BLM (bilayer lipid membrane) technique, where a single membrane of a few nanometers thickness separates two macroscopic aqueous compartments. Both approaches were originally analytical tools in membrane biophysics but are now developing rapidly in the direction of molecular electronics, photonics and sensing devices of ultimate miniaturization. Still in its infancy, as far as marketable products are concerned, this line of research was shown to hold great promise.

Ambitious molecular engineering projects require intelligent chemistry combined with structural information. *L. Feigin* (USSR Academy of Sciences, Moscow) emphasized this point and showed how X-ray small-angle diffraction techniques can provide useful data on the supramolecular architecture of oligo- and multilayer systems of high complexity. Particularly instructive, also in this context, was the

presentation of new X-ray and neutron reflectivity techniques on monolayers at a liquid surface (*J. Als-Nielsen*, Risø National Lab., Denmark). The spectacular achievement of performing the X-ray structure analysis of a single monolayer, can only be realized with high-flux photon sources such as synchrotrons.

The second day's program moved further into the more classical field of lyotropic liquid crystal phase structures and dynamics. An analytical approach to the interpretation of periodic, two-dimensional domain patterns in monolayers under conditions of 'solid-fluid' phase coexistence was presented and discussed in terms of electrostatic and interfacial forces by *R. M. Weis* (Univ. of Massachusetts, Amherst, USA). *P. Fromherz* (Univ. Ulm, FRG) discussed conservative and dissipative instabilities in lipid bilayers which are involved in the formation of different supramolecular structures, such as micelles or closed bilayer vesicles, and in the appearance of oscillatory or solitary waves in a 'fluid-mosaic' membrane containing ion-channel proteins.

A long standing problem of general physico-chemical interest concerns the kinetics and mechanism of phase transitions. This problem was addressed by *B. Tenchov* (Bulg. Acad. of Sci., Sofia, Bulgaria) and *P. Laggner* (Institute for X-ray Fine Structure Research, Graz, Austria) with time-resolved X-ray diffraction studies, using synchrotron X-ray sources, on the specific question of the thermal transitions of lipid bilayers. A wealth of hitherto unavailable information on short-lived intermediate states promises to fill the gap between largely unknown structural mechnisms and the thermodynamic and spectroscopic data which have already reached a high standard but which contain less structural information. Fluorescence spectroscopy on liposomes and LB-films, was reported by *P. Kinnunen* (Univ. Helsinki, Finland) to show indications of regular distribution patterns which might be related to the minimization of steric elastic strain in an assembly of host-guest molecules of different sizes. This phenomenon may be functionally important in biomembranes but also has implications for technological lipid film design.

Deuterium NMR spectroscopy, as a tool to probe molecular interactions at membrane surfaces, was covered by *A. Watts* (Univ. Oxford, U.K.). Being practically nonperturbing and amenable to site-specific labeling, this technique continues to provide new and important information, particularly with regard to lipid-protein interactions. Still with a strong analytical accent in membrane biophysics, but already pointing towards a potential in biosensor development, *L. Tamm* (Biocenter, Univ. Basel, Switzerland) presented studies on monoclonal anti-lipid antibodies and their interaction with fluorescence labeled lipid membranes supported on silicon wafers. Lateral diffusion and domain segregation depending on the thermotropic state of the lipids were analyzed. Similar investigations were extended to other interesting membrane proteins, such as signal peptides which are important components in cellular protein biosynthesis and processing.

Both biologically and technologically important systems were discussed on the third day. *D. Small* (Boston Univ., USA) presented a comprehensive overview on the lyotropic and thermotropic phase behavior of soaps and acid-soap complexes. A profound combination of thermodynamic and X-ray diffraction data linked to the scholarly use of Gibbs phase rule demonstrated the value but also the complexity of physical chemistry in this field. The potential of lipid/bile salt systems, analyzed with respect to their mesomorphic structure and dynamics by NMR and light-scattering techniques as suitable media for controlled drug delivery systems was discussed by *B. Lindman* (Lund Univ., Sweden). Cubic phases formed by monoolein-water were described as particularly promising candidates for systems that can encapsulate both hydrophilic and lipophilic drugs as they are stable under the wide range of conditions required for pharmaceutical purposes.

The chemical and structural aspects of a hitherto rather neglected class of mesogenic substances based upon inositol-derived compounds were reviewed by *K. Praefcke* (Techn. Univ. Berlin, FRG). These discotic carbohydrates form strongly hydrogen-bonded superlattices with thermotropic liquid crystalline behavior and frequently contain hexagonal columnar phases.

Structure-property relationships of liquid crystalline polymers were discussed by *E. Chiellini* (Univ. Pisa, Italy). His presentation focussed on chiral main-chain polyesters produced by the poly-condensation or polyaddition of chiral and non-chiral components. These polymers offer opportunities for the design of materials with specific properties and a wide variety of thermotropic states. The concept of amphotropic liquid crystal polymers was presented by *F. Kuschel* (Univ. Halle, GDR). Here, lyotropic properties are confered to linear polymers by the attachment of alcohol side-chains resulting in comb-like polymeric structures. These structures, which are in principle rather similar to smectic lipid multilayer systems, show stable mesomorphic behavior which can be influenced discretely by variations in main chain flexibility, length and nature of the side chains, and by swelling in water. Apart from being interesting models for the investigation of the intermolecular forces that govern mesomorphism, these systems also show promise as matrix components in pharmaceutical applications.

The last day of the conference was devoted to liquid crystal materials in fields where industrial applications already exist or are imminent. *B. Holcroft* (Thorn-EMI Res. Labs, Hayes, UK) discussed recent advances in the fabrication of thermal imaging films based upon the Langmuir-Blodgett technique. LB films optimized for pyroelectric properties and low thermal conductance of the substrate have been shown to be promising as practical devices for low-light thermal imaging.

Finally *D. Fleischer* (Hoechst AG, Frankfurt, FRG) gave an overview on high performance polymers based upon thermotropic liquid crystals. This presentation highlighted the manifold merits of such materials for extreme applications,

ADVANCED MATERIALS

e.g. in microelectronic devices, in chemical industry, aerospace technology and medicine. He also gave an impression of the many criteria that have to be optimized in industrial high-tech product development.

The framework of lectures complemented well the short contributions and poster presentations. A best-poster award was presented to *G. Hertel, H. Hoffmann* and *J. Kalus* (Univ. Bayreuth, FRG) for their neutron small-angle scattering study on the magnetic field alignment of the nematic phases of surfactants.

On the whole, the attempt to combine biological and technological aspects of liquid crystal research in one conference was well received and stimulated much discussion.

A book of abstracts is available from the author of this report.

Ferromagnetic and High Spin Molecular Based Materials in Dallas

By Joel S. Miller * and Dennis A. Dougherty *

The first symposium focusing on several aspects directly related to high spin and molecular/polymeric ferromagnets convened April 9–12, 1989 as part of the 197th National American Chemical Society meeting in Dallas, Texas, USA. This multidisciplinary meeting brought together inorganic, organic, organometallic, polymer, and physical chemists as well as theoretical and experimental condensed matter physicists from Japan, the USSR, the UK, France, Germany, Italy, Spain, Bulgaria, and the USA. The symposium was comprised of a tutorial and sessions devoted to the preparation and characterization of a 'designer magnet' from organic, organometallic, inorganic, and polymeric materials. This broad interdisciplinary symposium was unusual as it was co-sponsored by the Divisions of Inorganic, Organic, Polymer, and Physical Chemistry of the ACS and additionally supported by the Petroleum Research Fund and Gordon & Breach (Science Publisher). A total of 39 verbal and 25 poster papers were presented and the proceedings will be published as a forthcoming volume of *Molecular Crystals, Liquid Crystals*.

The tutorial session enabled attendees to appreciate the conceptual framework on which the current understanding of cooperative magnetic phenomena in molecular/organic/polymeric systems is based. *D. A. Dougherty* (Caltech) concisely reviewed the key criteria for stabilizing a triplet ground state, the building block of a high spin molecule or polymer. *J. S. Miller* (Du Pont) described the existing paradigms, while the fundamental physics of magnetism were reviewed by *A. J. Epstein* (Ohio State). Models for magnetic order and neutron diffraction aspects were presented by *P. Day* (Institut Laue-Langevin) and insight into the realities of opportunities for molecular based magnets was provided by *R. M. White* (Control Data Corp.). Due to their low density, high molecular weight, and low spin-orbit coupling, competition with existing magnets seems unlikely; however, opportunities might exist in fine particle and magnetooptic recording.

The strategies for designing molecular/polymeric materials with ferromagnetic coupling include: a) unpaired electrons in orthogonal orbitals sharing the same spatial region, b) Heitler-London spin exchange, c) antiferromagnetic coupling of sites with differing S values (ferrimagnet), d) conjugated odd-alternate hydrocarbons, e) polaronic, conjugated block copolymers, and f) configurational admixture of triplet charge transfer excited states. High spin systems demonstrating the feasibility of several of the strategies were discussed and a few high moment materials were described. It was emphasized universally that the rational design of solid state structures remains an art that limits our ability to prepare the secondary and tertiary structures needed to test many concepts in solid state science. Frequently, complex, solvated compositions with undesired or new structure types form instead of the desired phase. Additionally, several polymorphs may form in lieu of the desired structure type. This is particularly crucial for the formation of a bulk ferromagnet as ferromagnetism is a 3-D (bulk) not a 1-D property.

The challenge of rationally controlled spin preferences of small organic molecules was addressed by *J. A. Berson* (Yale), *W. T. Borden* (Univ. Washington), *P. Dowd* (Pittsburgh) and *D. J. Klein* (Univ. Texas at Galveston). While there have been considerable successes, it is clear that for finely balanced systems, present computational methods cannot yet predict the singlet-triplet energy gap to better than a few kcal/mol for modest-sized molecules. A means to experimentally determine the singlet/triplet gap particularly for ground state triplet substances is unavailable, but would be of great value. *H. Iwamura* (Univ. Tokyo) and *K. Itoh* (Osaka City University) have prepared variously substituted extended carbene systems, reaching spin states as high as $S = 5$ in a pentacarbene. The spin coupling capacities of various π topologies were discussed, and the first ferrimagnetically coupled organic molecule was reported by *Itoh*. *Dougherty* described a high spin state ($S = 2$) in a partially localized system, involving ferromagnetic coupling through a cyclobutane ring.

The most extensively characterized organic, organometallic, and inorganic high spin compounds exhibiting magnetic or incipient magnetic order were galvinoxyl [*M. Kinoshita* (Univ. Tokyo)], decamethylferrocenium tetracyanoethenide [DMeFc][TCNE] (*Epstein* and *Miller*) and $Mn^{II}Cu^{II}$[oxamido-*N,N'*-bis(2-benzoato)] · H_2O, [*O. Kahn* (Univ. Paris, South)] and Mn(hexafluoroacetylacetonate)$_2$tetramethyl-*n*-propylnitronylnitroxide [*D. Gatteschi* (Florence)]. Galvinoxyl exhibits strong ferromagnetic coupling (Curie-Weiss $\theta = +19$ K), however, a still to be understood phase transition, which can be suppressed by doping with hydroxygalvinoxyl, occurs at ~ 85 K. The Mn^{II} containing coordination polymers exhibit spontaneous magnetization in accord with ferrimagnetic ordering at 14 and 8.6 K, respectively. The most extensively characterized molecular magnet, [DMeFc][TCNE] [i.e., $\theta = +30$ K, 1 kOe coercive field, α–δ critical constants, and ferromagnetic ordering at 4.8 K confirmed by neutron diffraction], comprises isolated radical cations and radical anions without the benefit of an extended network solid state structure. Substitution of chemically important features of [DMeFc][TCNE] lead to the characterization of several ferromagnetically coupled systems. An additional bulk ferromagnet, however, remains elusive. The extended McConnell model of the configurational admixture of triplet charge transfer excited states appears at present to provide the best understanding of the mechanism of ferromagnetic coupling for this system and enables the prediction of magnetic coupling for related systems.

Based upon this McConnell model several groups have targeted the preparation of radicals to test the model and its special cases. Three-fold or higher symmetry donors containing nitrogen were discussed by *R. Breslow* (Columbia) and *D. A. Dixon* (Du Pont), whereas *L. Y. Chiang* (Exxon) reported on an oxygen containing donor and *F. Wudl* (UCSB), *J. Yamaguchi* (Kyoto), and *J. P. Morand* (Bordeaux) described their successes in preparing sulfur containing donors. *Wudl* also elaborated upon the preparation of 1,3,5,-tris(tricyanovinyl)benzene. In the best characterized system, the six-fold symmetric hexaazaoctadecahydrocoronene system, *Breslow* and *Dixon* noted that distortions to the diamagnetic dication readily occurred and conjectured that this distortion may be circumvented by going to a three-fold symmetric system. Ferromagnetically coupled systems, however, have yet to be prepared with such donors.

Two unusual ferromagnetically coupled high spin polynuclear clusters were reported. *D. C. Johnston* (Iowa) and *D. N. Hendrickson* (UCSD) reported $S = 6$ $[Cr_4^{III}S(O_2CMe)_8(H_2O)_4]^{2\oplus}$ and $S = 14$ $[Mn_8^{III}Mn_4^{IV}O_{12}(O_2CPh)_{16}(H_2O)_4]$, respectively. A microscopic understanding of the mechanism of spin exchange is unknown; however, the 'orbital ordering' mechanism described by *Day* in for example Rb_2CrCl_4 may be applicable. Additionally, a ferromagnetically coupled $S = 9/2$ $Cr^{III}Ni_3^{II}$ cluster was described by *Kahn* and a $S = 12$ $[Mn^{II}$(nitronylnitroxide)$]_6$ ferrimagnetic ring was presented by *Gatteschi* and *Rey*. Novel liquid crystals (*W. Haase*, Darmstadt) exhibiting antiferromagnetic and ferromagnetic order and monomolecular films (*H. M. McConnell*, Stanford) exhibiting long range order captured the imagination of the audience.

The preparation of organic polymers exhibiting high spin if not ferromagnetic order is attracting significant attention. *Iwamura* described materials based on polyacetylenes with radical pendant groups. *A. L. Buchachenko* (Institute of Chemical Physics, USSR), *M. Ota* (Gumna U.), *A. A. Ovchinnikov* (Institute of Chemical Physics, USSR), and *J. B. Torrance* (IBM) described their respective approaches, i.e., silicone based polymers, photooxidation of triarylmethane based polymers, pyrolysis of polyacrylonitrile, polymerization of nitroxyl containing diacetylenes, and iodine oxidation of 1,3,5-triaminobenzene. A reproducibly prepared, well characterized system has been elusive. In post deadline poster contributions *D. W. Wiley* (Du Pont) and *C. J. O'Connor* (Univ. New Orleans) independently reported that prototype dinitroxyl diacetylenes monomers (each crystallizing into two polymorphs) to test the concept of preparing high spin polymer, could not be topochemically polymerized and did not exhibit high spin, ferromagnetically coupled behavior. Theoretical guidance for designing new polymers was additionally described by *N. N. Tyutyukov* (Bulgaria Academy of Science) and *T. Hughbanks* (Texas A & M at College Station).

Clearly the embryonic quest for molecular/polymer based magnetic materials is a thriving area of research. The synthetic challenges are formidable as ferromagnetism, being a bulk and not a molecular property, requires that materials with specific primary, secondary, and tertiary structures be made. The rational design of solids remains an art that limits our ability to prepare such structures.

Nonetheless, several examples of deliberately designed high moment, magnetically ordered materials have been prepared and we look toward a future where ferromagnetic phenomena can be added to the repertoire of physical properties enjoyed by molecular/polymeric materials.

Book Reviews

Microbeams, Surfaces and Sieves

Spectroscopy of Surfaces. Edited by *R. J. H. Clark* and *R. E. Hester*. Wiley, Chichester 1988. xxi, 488 pp., bound US $ 190. – ISBN 0-471-91895-4

This book gives a comprehensive review on the state of the art in selected surface spectroscopies. Except for the chapters by *J. C. Vickermann* on Static Secondary Ion Mass Spectroscopy and by *F. P. Netzer, J. A. D. Matthew* and *E. Bertel* on Electron Excited Surface Spectroscopies, vibrational spectroscopies are discussed. The articles describing the principles and theoretical background of Raman-, IR-reflection absorption-, Inelastic Tunneling- and High Resolution Electron Energy Loss Spectroscopy are comprehensive and clearly written. The book is a good introductory text for advanced graduate students and a useful reference text for researchers in surface and interface science.

The first chapter "Structure and Orientation in Thin Films: Raman Studies with Integrated Optical Techniques" is written by *J. F. Rabolt* and *J. D. Swalen* who pioneered the use of optical spectroscopies to probe organic thin films prepared by Langmuir-Blodgett techniques or by self-assembly through adsorption on a solid surface. They describe the theory of Waveguide Raman Spectroscopy (WRS) starting from basic principles and discuss layered structures to which the technique can be applied. Examples are given to show how different modes of the light beam can be used to emphasize the signal from different layers of the thin films and how polarization dependent measurements are used to determine the molecular structure in thin films. The application to adhesion studies and molecular interactions between thin films is demonstrated for a poly(vinylalcohol)/poly(methylmethacrylate) (PVA/PMMA) composite wave guide.

In chapter two "The Selection Rules for Surface-Enhanced Raman Spectroscopy (SRS)" by *J. A. Creighton* the different physical mechanisms leading to the SERS effect are explained. Their relative contributions to the resulting enhancements are discussed with reference to the spectra of molecular adsorbates at metal-electrolyte and metal-gas interfaces. In a clear and concise way the criteria to distinguish between electromagnetic, resonance and modulated charge transfer enhancement are described and suggestions for further experiments are given. Utilizing the SERS effect to determine the orientation in adsorbed organic films is clearly one of the future applications of the technique.

T. M. Cotton reviews the application of SERS to biological systems in her chapter "The Application of Surface Enhanced Raman Scattering in Biochemical Systems". As an introduction to the subject, she summarizes the theories of electromagnetic and charge transfer enhancement and the experimental aspects of SERS. The biological application of SERS are demonstrated with data obtained for DNA, proteins, lipids and studies of the interaction of dissolved enzymes with coenzymes and substrates. Absolute detection limits in the picogram range have been achieved for aromatic compounds and dyes which make SERS a powerful analytical technique in materials science.

In chapter four *J. C. Vickerman* reviews Secondary Ion Mass Spectrometry (SIMS) and discusses new applications in surface science and materials analysis. Static SIMS applied to the study of thermodynamic quantities in adsorbed layers, and imaging SIMS are two examples in this comprehensive review.

The technique of Inelastic Electron Tunneling Spectroscopy (IETS) for the study of vibrational modes of surface species is free from the normal selection rules other vibrational surface spectroscopies are subject to. In chapter five *N. M. D. Brown* discusses this technique where the adsorbates to be measured are introduced as dopants in the insulator component of a metal-insulator-metal tunnel junction.

Chapter six, written by *F. P. Netzer, J. A. D. Matthew* and *E. Bertel*, is devoted to exited electron spectroscopies in surface science. Whereas Auger-Electron Spectroscopy is routinely used to determine the chemical composition of surfaces, detailed information about the chemical state of the adsorbate and its adsorption site can also be determined from the Auger transitions involving valence electrons and from angular effects. Electron Energy Loss Spectroscopy (EELS) on clean and adsorbate covered surfaces, involving electronic transitions, is discussed in detail. Excellent summaries including illustrative examples are given for Electron Stimulated Ion Desorption (ESD) and Inverse Photoemission Spectroscopy (IPES).

The last two chapters of the book are devoted to vibrational surface spectroscopies, i.e. "High Resolution Electron Energy Loss Spectroscopy" (HREELS) applied to clean and adsorbate covered surfaces is reviewed by *M. A. Chesters* and *N. Sheppard*, and "Infrared Reflection-Absorption Spectroscopy (IRAS) of Adsorbed Molecules" is discussed by *A. M. Bradshaw* and *E. Schweizer*. *Chesters* and *Sheppard* make detailed comparisons of HREELS with IRAS and Raman spectroscopy and emphasize the relative merits of the techniques. This article on HREELS is an excellent introduction to this important technique. *Bradshaw* and *Schweizer* review the use of IRAS on metal and semiconductor surfaces, discuss those factors which are important in the optimization of the IRAS experiment, and compare dispersive and interferometric instruments. The examples given to demonstrate the state of the art in IRAS include hydrogen adsorption on tungsten and silicon surfaces, CO adsorption on Pt(111), K/Pt(111) and stepped platinum surfaces, and the detailed spectroscopic study of surface formate and surface methoxy species.

Like the last article, the book as a whole is not only an excellent introduction to modern techniques in surface science. The many practical hints and comments make it a valuable hand-book in materials science and surface science laboratories.

Michael Grunze
Angewandte Physikalische Chemie
Universität Heidelberg (FRG)

Zeolite Molecular Sieves. By *A. Dyer*. Wiley, Chichester 1988. xi, 149 pp., bound, £ 25.70.—ISBN 0-471-91981-0

Crystalline microporous solids replete with cavities and channels of molecular dimension (3 to 10 Å diameter) are all the rage these days. Not only are they important, as they have been for several decades past, as adsorbents, ion-exchangers and catalysts, they are also promising materials for applications such as second harmonic generation (in laser technology), as the basis of novel microdevices for electro- and photo-catalysis, and potentially as novel membranes in a range of new laboratory-scale and commercially viable fuel cells.

Good books on the fundamentals of zeolite structure and properties exist already, the ones by *Breck* (Wiley, 1974) and *Barrer* (Academic, 1978) and Special Publication No. 23 "The Properties and Applications of Zeolites" (edited by *R. P. Townsend*, the Chemical Society, London, 1980) as well as ACS Symposium Series 218 on "Intrazeolite Chemistry" (Ed. *G. D. Stucky* and *F. G. S. Dwyer*), being particularly noteworthy. There is also a relatively large collection of admirable review articles devoted to various aspects of the science and technology of zeolites which have appeared in the last five years.

This book adds very little to the information already collated in the open literature. It consists of ten brief chapters, the contents of which provide hardly any new items of information and precious few chemical or other surprises. For that reason alone it cannot be recommended as a favored introductory text, which is what it purports to be. In parts the text reads like advertisers copy. Thus, on p. 84, we are told in arid terms that horticultural applications (of clinoptilolite and mordenite) generally use 5 to 10% incorporation of the zeolite into growing media. "The value of this has been shown in the production of tomatoes, bell peppers, house plants and strawberries", and that "obviously ion exchange has a role in these phenomena".

There are a number of misprints. On p. 81 there is talk of "large part mordenite" (not large port) and Figure 80 is labelled 'Tonic' rather than 'Ionic' radius.

More serious, however, is the improper use of figures and micrographs published elsewhere. Figures 42 and 43, for example, appeared in ACS Symposium Series 218 (p. 183, (1983)) and the Springer Series in Surface Science 5 (p. 124, 1986). Had the senior author of these original publications been consulted, and his permission to re-publish sought (a common courtesy), this text would not, as now, be in breach of copyright law.

John M. Thomas

London (UK)

Problem-Solving with Microbeam Analysis. By *K. Kiss*. Elsevier, Amsterdam 1988. 410 pp., hard cover, Dfl 245.00.—ISBN 0-444-98949-8

Microbeam techniques have matured into appropriate methods for the characterization of materials on the micron- and even submicron scale. During the last two decades, instruments such as the electron microprobe and the scanning electron microscope went on the production line and are now in third generation development. Other instruments, e.g. the electron- and ion probes have been constructed and have become commercially available, and, although numerous further instruments have been designed and significant applications have been announced, their ultimate breakthrough has not yet been achieved.

On the other hand, the characterization of microstructures is of high-ranking value in quality assurance and materials research. More and more applications become known, and more commercially available instruments become useful in the guidance of research, especially in high-tech industries. Obviously, each one of these techniques has special capabilities, but none of them are suited to uniquely cope with all the complex problems. Besides, instrument prices in the range of 100 000 to 600 000 US $, and operation costs are very high.

Each technique has its own specific literature, but apart from reviews and proceedings, there exists as yet no survey on the various techniques and their respective fields of application. This book fills this gap and will help engineers, analysts and scientists facing various microanalytical problems to work with those techniques or to select the above mentioned expensive intruments.

Part 1 deals with optical and electron microscopy, X-ray and electron spectroscopy, with ion beam methods as well as Raman and laser techniques. One chapter summarizes those methods especially used for the control of microelectronic devices, another is devoted to the combination of complementary techniques and the last chapter is involved with the strategy of selecting the most suitable technique for solving the problem.

Part 2 includes a great variety of case histories and selected applications of the various techniques. Two entire chapters are devoted to synthetic polymers and microelectronics, a third to miscellaneous problems in metallurgy and corrosion as well as glasses and ceramics, catalysts, fibers, food products, cosmetics and the environment. The numerous examples of failure analysis and trouble shooting reflect the author's wide experience. The book concludes with a bibliography of 829 references, a glossary of acronyms and a subject index with about 1200 keywords.

The advantages and limitations of the individual techniques are evaluated adequately and critically and listed concisely. It is intentional that the finer details of the various methods have been omitted or abridged. However, this reviewer would have wished for some more fundamental information on particular techniques: (i) Optical microscopy is insufficiently described. The principle is mentioned, and some variants such as phase or interference contrast microscopy are discussed briefly, but knowledge of the fundamental figures of merit like spatial resolution, magnification and depth of field are assumed. (ii) X-ray spectroscopy is, in general, based on the Moseley law, and focusing spectrometers fulfill the Rowland condition: no mention is made of either of these two rules. On the other hand, an entire page (p. 54) is spent on artifact peaks called escape-peaks, although the formula $E = E_c - 1.74$ keV would have been self explanatory. (iii) The chapter describing electron spectroscopy in only eleven pages is meagre throughout and in this case a comparison of advantages and limitations is missing. (iv)

The basic modes of operation within microbeam analysis; the recording of line scans, area maps and depth profiles, are certainly not common knowledge and should have been described.

The main emphasis is placed on the methods and applications in the semiconductor and microelectronic industries. Recent innovations like the small-spot ESCA and the LMIS (liquid metal ion source) have been considered and modern analytical electron microscopy is treated in greater detail. On the other hand, there is no mention of the recent development of the STM (scanning tunneling microscope) and the two methods, PIXE (proton-induced X-ray emission) and SXRF (synchrotron X-ray fluorescence), have not even been briefly referred to. Both methods, like RBS (Rutherford backscattering) are dependent on accelerators or storage rings which are scarcely available to the general public, but are very effective.

The literature coverage in both parts of the book is somewhat dated, the mean value lying in the middle of the 70's (only 14% of the citations are dated after 1983) and about 25% of the references are second-rate (sales brochures, internal reports, technical notes, etc.). Some representations are also poor (e.g. Figure 1-74).

Overall, the book is generously illustrated with figures and relatively free of printing errors (Rushka instead of *Ruska*, p. 20; $K_{1,2}$ instead of $K\alpha_{1,2}$, p. 123). However, a great disadvantage is imposed by the great number of figures of poor quality. Of the 306 figures contained in the book, more than half are photographs, mainly included in Part 2, and the majority of these are reproduced badly. This is partly due to bad models, partly to poor quality of the paper – and this at a price which cannot be considered as low. Only the photographic reproduction of Figures 2-35 to 2-38 and the five color photographs is acceptable.

It is for these reasons that the book cannot be recommended without reservations. But since the demand for such a survey is certainly great, the author as well as the publishers should be encouraged to commence with preparations for a revised edition.

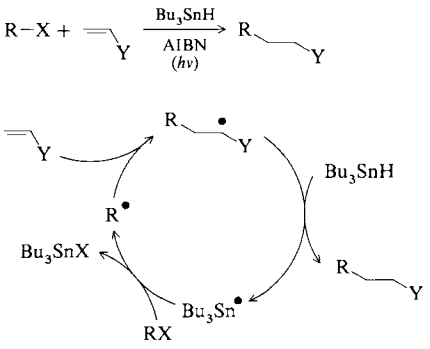
The Stereoselectivity of Intermolecular Free Radical Reactions

New Synthetic Methods (78)



By Bernd Giese*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

The regio- and chemoselectivities of free radical reactions are often high and largely predictable; systematic studies have now shown that the stereoselectivity of free radical reactions can also be directed. Examples involving five- and six-membered cyclic radicals will be used to show how steric and stereoelectronic effects influence the diastereoselectivity of reactions of cyclic radicals with olefins. The temperature, the solvent, and the nature of the radical scavenger used also play a role, so that, if the correct reaction conditions are used, the stereoselectivity of reactions for cyclic reactants can be very high. Lower stereoselectivities are often observed for reactions between acyclic radicals and acyclic alkenes. However, preliminary experiments have indicated that under certain conditions such systems can also react in a stereoselective manner.

1. Introduction

Since the beginning of the present decade, organic synthesis has been enriched by advances in free radical chemistry as chemists have learned how to generate and to trap short-lived radicals in a selective manner.[1] Of particular preparative importance are chain reactions in which the decisive synthetic steps are those involving reactions between radicals and nonradicals. In the case of C–C bond formation via the "tin-method" (Scheme 1) we have shown in detail that the various radicals produced within the chain must have differing selectivities (selectivity condition), but must not lose their high reactivity (reactivity condition).[1, 2]

Scheme 1. AIBN = azobisisobutyronitrile.

It only became possible to use free radical reactions for selective syntheses after mechanistic studies had revealed the effects which influence the reactivity and selectivity of free radicals. *C. Rüchardt* and his co-workers demonstrated the influence of steric effects in free radical chemistry at an early stage.[3] In addition, polar effects (which can today be ex-

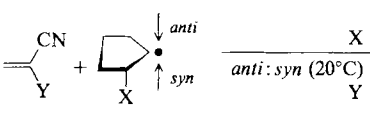
plained in terms of frontier orbital theory[4]) and radical-stabilizing effects play important parts.[5] Regio- and chemoselectivities of radical reactions can be predicted and understood on the basis of these effects.

Less is known about the stereoselectivity of radical reactions. Although the steric course of *intra*molecular reactions, and in particular of cyclization and rearrangement reactions, is known to a large extent,[1, 6] the control of *inter*molecular reactions is still a great problem. Only when this problem is solved will it become possible to use free radicals widely in organic synthesis. This review article will describe the present research situation and indicate some perspectives for the future.

In most carbon-centered free radicals the unpaired electron occupies an orbital which has mainly p-character (i.e., they are π radicals), allowing attack from two sides. Thus, high stereoselectivity requires that the radicals (1) react from preferred conformations and (2) be attacked predominantly from one side. The influence of substituents X on the stereoselectivity in reactions of cyclic radicals **1** and of vinyl radicals **2** has been studied in detail; however, little is presently known about the possibilities for influencing the stereoselectivity of acyclic radicals **3**.

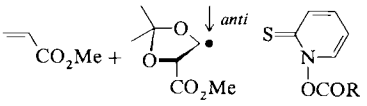
1 **2** **3**



Reactions of five-membered cyclic radicals can demonstrate how *anti*:*syn* stereoselectivity is determined by shielding substituents, since on a time average the highly flexible five-membered ring can be considered to be almost planar. Six-membered cyclic radicals can be used to study the equatorial:axial stereoselectivity. At the end of this article we shall indicate the conditions under which acyclic radicals react in a stereoselective manner.

2. Five-Membered Cyclic Radicals

2.1. Addition Reactions

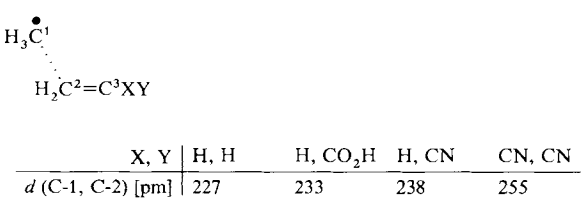


In reactions involving addition to β-substituted radicals, the *anti*:*syn* ratio depends on the substituents of both the radical and the radical trap. In a few cases the solvent can also exert a small influence on the stereoselectivity of the addition. The influence of the substituent X in the cyclopentyl radical **4** on *anti* versus *syn* attack by alkenes has been studied in detail.[7]

An alkoxy substituent shields the *syn* side of the radical **4** only slightly against attack of acrylonitrile (Y = H; 20 °C, CH_2Cl_2; X = OEt, *syn*:*anti* 77:23; O*t*Bu, 80:20): however, the presence of a methyl group leads to a stereoselectivity of 92:8, and an acetamido group directs the attack of α-chloroacrylonitrile nearly completely to the *anti*-side (> 98:2). The ester group in the radical **5** is also sufficient to ensure predominant *anti* addition of methyl acrylate.[8] The sulfur atom of the thiocarbonyl group in **6** also attacks the radical **5** *anti* to the ester group.

X	OEt	O*t*Bu	Me	NHAc
anti:*syn* (20°C)	77:23	80:20	92:8	> 98:2
Y	H	H	H	Cl

4



5 **6**

Substituents on the alkene have a great influence on the stereoselectivity of the C–C bond formation, both the reactivity and the shielding of the alkene playing a role thereby. Thus, the *anti*:*syn* selectivity in addition reactions to the β-ethoxycyclopentyl radical **4**, X = OEt, increases from 72:28 to 90:10 when α-chloroacrylonitrile is replaced by styrene, which reacts 200 times more slowly (Table 1).[7a, 9]

Table 1. Stereoselectivity (*anti*:*syn* attack) of the β-ethoxycyclopentyl radical **4**, X = OEt, in reactions with alkenes (20 °C, CH_2Cl_2) and relative reactivity (k_{rel}) of the alkenes with respect to cyclohexyl radicals (20 °C).

Alkene	*anti*:*syn* Attack	k_{rel}
$H_2C=CClCN$	72:28	31
$H_2C=CHCN$	77:23	3.6
$H_2C=CHCOMe$	86:14	2.0
$H_2C=CHCO_2Me$	88:12	≡ 1.0
$H_2C=CHPh$	90:10	0.15
trans-$NCCH=CHCN$	60:40	41
trans-$MeO_2CCH=CHCO_2Me$	88:12	4.0
$(MeO_2C)_2C=C(CO_2Me)_2$	> 98:2	1.1

When terminal alkenes attack the radical **4**, X = OEt, there is a direct relationship between decreasing reactivity and increasing stereoselectivity. This conforms with the reactivity-selectivity principle[10a] and the Hammond postulate,[10b] according to which the steric shielding of the radical substituent has more effect in the later transition state of the slower reaction. Ab initio calculations[11a] for the addition of methyl radicals to terminal alkenes have demonstrated that the distance between the radical and the olefinic carbon atoms in the transition state increases[11b] as the reactivity of the alkene is increased by electron-withdrawing substituents (Scheme 2).[4] The shielding effect of a substituent on the stereoselectivity should decrease as the distance between the radical and the olefinic C atoms in the transition state increases.

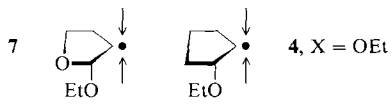
X, Y	H, H	H, CO_2H	H, CN	CN, CN
d (C-1, C-2) [pm]	227	233	238	255

Scheme 2.

This relationship also applies when, as in the case of fumarodinitrile, the alkene carbon atom undergoing attack bears

a small cyano group. On going to the more bulky ester groups, the reactivity effects are compensated by steric effects: the shielding substituents increase the stereoselectivity, so that even in the case of diethyl fumarate the *anti*:*syn* ratio is 88:12. Only the *anti* product can be detected in the reaction with tetraethyl ethenetetracarboxylate, although the reactivity of the latter would lead us to expect the same selectivity as that shown by acrylate esters.[7a, 9]

It is also noteworthy that in the case of the β-ethoxycyclopentyl radical **4**, X = OEt, the stereoselectivity is influenced by the solvent: thus, the *anti*:*syn* ratio for the addition of acrylonitrile at 20 °C increases from 68:32 (cyclohexane) to 76:24 (THF), 77:23 (CH_2Cl_2), and 81:19 (CH_3CN).[7a, 9] This increase in stereoselectivity could be due to better solvation of ethoxy substituent. The introduction of an oxygen atom into the five-membered ring also influences the stereoselectivity of attack, the tetrahydrofuranyl radical **7** reacting somewhat more selectively than the cyclopentyl radical **4**, X = OEt[7a] (Table 2).



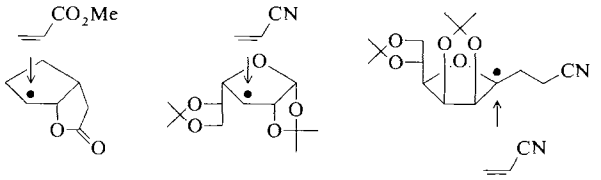


Table 2. Stereoselectivity (*anti*:*syn* attack) in the addition of unsubstituted alkenes to **4**, X = OEt, and **7**.

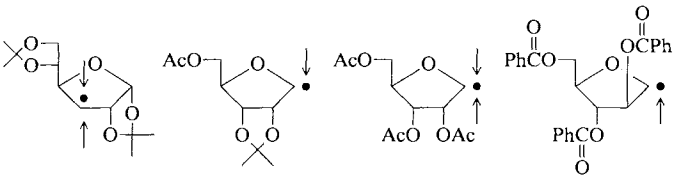
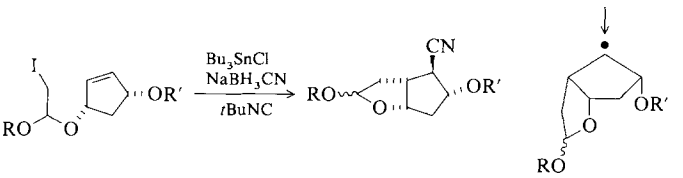
Radical	*trans*-NCCH=CHCN	H_2C=CHCN	H_2C=CHCOMe	H_2C=$CHCO_2Me$
7	64:36	86:14	88:12	93:7
4, X = OEt	60:40	77:23	86:14	88:12



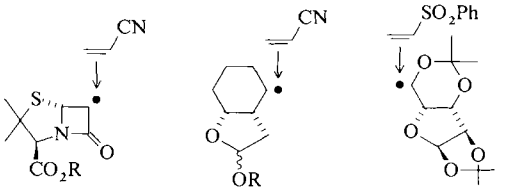
The greater selectivity of the tetrahydrofuranyl radical **7** is probably due to the spatial arrangement of the ethoxy substituent; according to the anomeric effect the ethoxy group in **7** should occupy an axial position and thus be able to shield the *syn* side of the radical more effectively than in **4**, X = OEt. This effect makes it clear that an exact prediction of the stereoselectivity can only be made when the conformations of the radicals are known. How substituents influence conformations will be discussed in the case of six-membered cyclic radicals, for which detailed ESR studies have been carried out.

When more than one substituent is present, the spatial arrangement of the substituents can increase or decrease the stereoselectivity. The presence of a second or third *cis* substituent, as in the radicals **8**–**10**, leads to exclusive *anti* attack even with acrylates or acrylonitrile.[12]



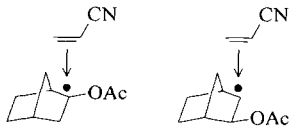
8 **9** **10**

In the glucofuranosyl radical **11**, however, the substituent at C-4 is *trans* to the substituents at C-1 and C-2; this leads to a drastic decrease in the stereoselectivity,[12b] whereby the dioxolane ring annelated at C-1/C-2 shields one side of the radical more strongly than does the alkyl substituent at C-4 (β:α attack of acrylonitrile 73:27).



11 **12** **13** **14**

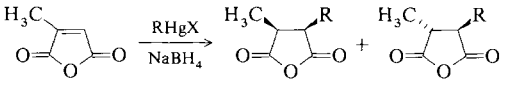
The *cis*-fused dioxolane ring gives the molecule a bent shape. Comparison of the high stereoselectivity observed with radical **12** with the unselective behavior of **13** (β:α attack 50:50) indicates the magnitude of the influence of the annelated ring.[13] However, inversion of the configuration at C-2 suffices to induce a high stereoselectivity (radical **14**; attack from the α side).[14] *Stork* et al. have made use of the high "shape selectivity" in prostaglandin synthesis:[15] in the reaction **15** → **17**, radical **17** is trapped stereoselectively by *tert*-butyl isocyanide.



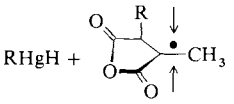
15 **17** **16**

The shape selectivity resulting from the annelation of a five-membered ring also occurs in four- and six-membered cyclic radicals (e.g., **18**–**20**).[13c, 16]

18 **19** **20**



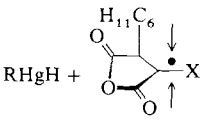
Radicals of the norbornyl type also react in a clearly shape-selective manner. Thus, acrylonitrile attacks not only the norbornyl radical **21**, which is substituted at the radical center, but also the β-substituted norbornyl radical **22** from the *exo* side.[7a, 17]



21 22

2.2. Abstractions

Systematic studies on the influence of substituents on the stereoselectivity of hydrogen abstraction reactions have been carried out. As in addition reactions, a β substituent directs attack to the *anti* side of the radical. Hydrogen abstraction involves the transfer of only a small hydrogen atom, so that, in contrast to the C–C bond-forming reaction, hydrogen abstraction leads to the formation of the thermodynamically less stable products. Thus, in the reaction of methylmaleic anhydride (**23**) with an alkylmercury salt in the presence of $NaBH_4$, the *cis*-product **25** is formed preferably.[18] The five-membered cyclic radical **24**, formed as an intermediate, is subsequently attacked by the alkylmercury hydride.



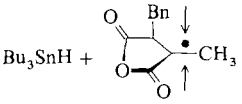
23 25 26

24

R	*n*-C_6H_{13}	*c*-C_6H_{11}	*t*Bu
25:**26**	62:38	89:11	94:6

The degree to which *anti* attack is favored, leading to an increasing amount of the thermodynamically less stable *cis*-product **25**, increases as the shielding substituent R in the radical **24** becomes larger. Not only β but also α substituents influence the stereoselectivity: thus, the *anti*:*syn* stereoselectivity increases in the case of the radical **27** from 70:30 for X = F to 95:5 for X = *t*Bu.[19] The reason for this increase in the stereoselectivity is not yet known.

27



X	F	Ph	*c*-C_6H_{11}	Me	OMe	OAc	*t*Bu
anti:*syn*	70:30	73:27	80:20	89:11	91:9	94:6	95:5

The differences in the shielding of the *syn* and *anti* sides by substituents of varying size are also reflected in the enthalpy of activation and therefore in the temperature dependence of the stereoselectivity. Thus, the difference in the enthalpy of activation for *syn* versus *anti* attack increases from 5 to 9 and 12 kJ mol^{-1} when the β substituent in the radical **24** increases in size from the primary 1-hexyl group to the secondary cyclohexyl and the *tert*-butyl groups, respectively.[20] Variation of the hydrogen donor (alkylmercury hydride, tributyltin hydride, cyclohexane) surprisingly has very little effect on the stereoselectivity. However, variation of the H donor permits the temperature influence on the stereoselectivity to be measured over the range 0–260 °C.[20, 21] As expected, the stereoselectivity decreases with increasing reaction temperature (Table 3).

Table 3. Influence of temperature on the stereoselectivity (*anti*:*syn* attack) of the H transfer by cyclohexylmercury hydride, tributylstannane, and cyclohexane to radical **24** (R = *c*C_6H_{11}).

T [°C]	*anti*:*syn* Attack by $C_6H_{11}HgH$	Bu_3SnH	C_6H_{12}

The influence of the solvent on the stereoselectivity of hydrogen transfer reactions has not yet been studied in detail; however, reactions of the radical **28** with tributyltin hydride in benzene [*anti*:*syn* attack 76:24 (0 °C), 63:37 (80 °C)] and tetrahydrofuran [80:20 (0 °C), 69:31 (80 °C)] indicate that small solvent effects can occur.[20] These are possibly due to variations in the solvation of the tin hydride.

The stereoselectivity of hydrogen transfer and alkene addition can be compared directly using the radicals **4**, X = OEt, **9**–**11**, and **21**.[17, 22] It is found that for five-membered cyclic radicals the shielding effects for hydrogen transfer and for addition to reactive terminal alkenes are similar (Table 4).

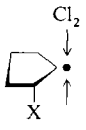

Table 4. Comparison of the stereoselectivities (*anti*:*syn* attack) of free radical addition and D or H abstraction of the radicals **4**, X = OEt, **9**–**11** and **21**.

21	> 95:5	80:20 [b]

[a] Bu_3SnD. [b] RHgH.

The stereoselectivity of halogen transfer to five-membered cyclic radicals is influenced by the same effects that are involved in addition and hydrogen transfer reactions: (1) β substituents favor *anti* attack; (2) attack on annelated systems occurs from the convex side; (3) *exo* attack is preferred in norbornyl systems. β-Chloro and, in particular, β-bromo substituents cause a pronounced *anti* selectivity; thus, the *anti*:*syn* ratio in the chlorination of the β-chlorocyclopentyl radical **29** [98:2 (40 °C), 93:7 (108 °C)] and the β-bromocyclopentyl radical **30** [> 99:1 (40 °C)][23] is much larger than that found for the β-methylcyclopentyl radical **31** [57:43 (104 °C)].[24]

anti:*syn*	98:2 (93:7)	> 99:1	57:43

A coplanar arrangement of the semi-occupied orbital and the carbon-halogen bond would explain this finding. Such a conformational effect is of particular importance in the stereoselectivity of addition in acyclic systems (see Section 4.1). It was possible using the norbornyl radical **32** as an example to show that the stereoselectivity can also depend on the nature of the halogen donor.[25]

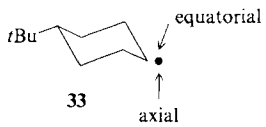
3. Six-Membered Cyclic Radicals

The difference between the axial and equatorial positions is greater in six-membered than in five-membered rings. Thus, the stereoselectivity of six-membered cyclic radicals will be analyzed below with particular reference to the equatorial:axial selectivity.



3.1. Torsional Effects

The stereoselectivity of the 4-*tert*-butylcyclohexyl radical **33** has been studied in detail.[26] "Axial" attack at the radical center of **33** is faster for OH-, D-, Cl-, and Br-transfer reagents than is "equatorial" attack (Table 5).[26, 34] This is reminiscent of the stereoselectivity of nucleophilic attack at the carbonyl carbon in cyclohexanone, which is also sp^2-hybridized. Calculations by *K. N. Houk* et al. have shown that in the transition state for axial attack on cyclohexanone the steric strain caused by the torsional effect is smaller than that for equatorial attack.[27a] Analogous torsional effects may perhaps influence the stereoselectivity of the cyclohexyl radicals.

Table 5. Stereoselectivity (equatorial:axial attack) of the 4-*tert*-butylcyclohexyl radical (**33**) in abstraction and addition reactions.

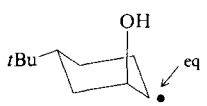
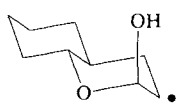
[a] *trans* isomer. [b] *cis*:*trans* mixture 1:1.

33

This torsional effect is counteracted by the 1,3-diaxial interactions which occur in axial attack. The larger the reagent is, the larger will be the influence of these 1,3-diaxial interactions. Thus, the proportion of equatorial attack in the addition of the cyclohexyl radical **33** to alkenes increases from 44 to 88% when an isopropyl group replaces hydrogen at the olefinic carbon atom which is attacked (Table 5).[28]

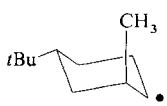


The equatorial:axial ratio also depends on the distance between the reacting molecules in the transition state. This has been demonstrated by force-field calculations,[27b] in which the distance between the radical C atom of the cyclohexyl radical and the methylene group of acrylonitrile is varied continuously. At a hypothetical distance of 207 pm in the transition state, the equatorial:axial ratio is 70:30, whereas at a distance of 247 pm the equatorial:axial ratio is shifted to 43:57.

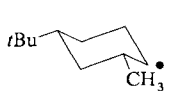


d (C-1, C-2) [pm]	207	217	227	233	238	247
äqu:ax	70:30	64:36	57:43	52:48	48:52	43:57

3.2. Steric Substituent Effects



As in five-membered rings, substituents in six-membered rings in a β position with respect to the radical center lead to an increase in *anti* attack. Axial substituents cause a shift in the direction of axial attack (radicals **34**–**36**)[29] and equatorial substituents direct the reaction towards equatorial attack (radical **37**).[30] Whereas the shielding of the *syn* side of



34

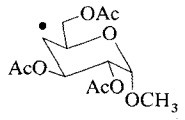
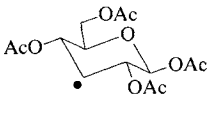
eq:ax 10:90

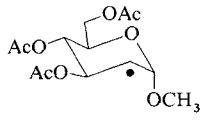


37

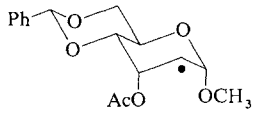


$H_2C=C(CO_2Et)_2$	eq:ax 73:27
$H_2C=CHCN$	eq:ax 79:21
trans-NCCH=CHCN	eq:ax > 97:3
$H_3CCH=C(CO_2Et)_2$	eq:ax > 97:3

the radical by an axial substituent is not surprising, the magnitude of the influence of equatorial substituents on the stereoselectivity is remarkable. The equatorial selectivity increases with increasing size of the substituent at the olefinic carbon atom undergoing attack; thus, even the reaction of fumarodinitrile with the radical **37** leads exclusively to the product of equatorial addition.[30]



A second axial or equatorial β substituent increases the proportion of axial or equatorial attack even further.[12a, 31] A comparison of the stereoselectivity of the carbohydrate radicals **38–41** shows that equatorial substituents are almost as effective as axial substituents when acrylonitrile is the alkene undergoing attack.



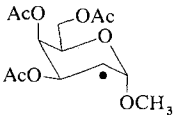
38

39

40

41

Table 6. Stereoselectivity (equatorial:axial attack) in the addition of alkenes to the doubly β-substituted radicals.



Alkene	equatorial:axial **38**	**39**	**40**	**41**
$H_2C=CHCN$	82:18	76:24	55:45	17:83
$H_2C=CHCH_2SnBu_3$	–	85:15	60:40	–
trans-NCCH=CHCN	> 98:2	> 95:5	84:16	52:48

However, fumarodinitrile attacks preferentially in an equatorial manner. This is due to a drastic retardation of axial attack on going from acrylonitrile to fumarodinitrile. While the cyclohexyl radical **33** reacts about ten times faster with fumarodinitrile than with acrylonitrile in both an axial and an equatorial manner, β substituents in the radical reverse this sequence.[31b, 32] Thus, acrylonitrile is three to six times more reactive than fumarodinitrile with respect to equatorial attack on the radicals **38–41.** However, this reactivity difference is even more pronounced for axial attack. The ratio of reactivities of acrylonitrile and fumarodinitrile (k_{AN}/k_{FN}) with respect to axial attack changes by a factor of 200 to 500 on going from the cyclohexyl radical **33** to the carbohydrate radicals **38–41** (see Table 7).[32] This is caused

Table 7. Ratio of the reactivities of acrylonitrile and fumaronitrile ($k_{AN}:k_{FN}$) in equatorial and axial attack on six-membered cyclic radicals.

	33	**38**	**39**	**40**	**41**

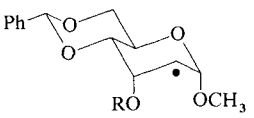
$(k_{AN}:k_{FN})_{ax}$	0.09	> 45	> 40	19	28



by steric effects which increase with the degree of shielding of the olefinic carbon atom undergoing attack. The galactosyl radical **42**[31c] provides a clear example.

42

$H_2C=CHCN$	eq:ax 65:35

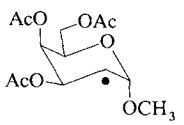
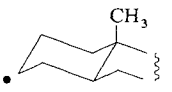
$MeO_2CCH=CHCO_2Me$	eq:ax > 95:5
$H_3CCH=C(CN)_2$	eq:ax > 98:2



The type of substituents at the radical can also influence the stereoselectivity of the reaction: in the reaction of radical **43** with acrylonitrile, the axial versus equatorial selectivity increases from 64:36 via 74:26 and 83:17 to 94:6 on going from the alcohol (R = H) via the ether (R = CH_3) and ester (R = OAc) to the lithium salt (R = Li).[31b, c] The large effect of the lithium salt is due to chelation of the lithium ion by the two axial oxygen atoms of the β substituent of **43**.

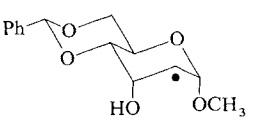
43



R = H	ax:eq 64:36
R = CH_3	ax:eq 74:26
R = OAc	ax:eq 83:17
R = Li	ax:eq 94:6

Axial γ and δ substituents also affect the stereoselectivity, as is shown by the reactions of the galactosyl radical **42** and the steroid radical **44**. For steric reasons the axial γ substituent in **42** favors equatorial attack,[31] whereas the axial δ substituent in **44** favors axial attack[33] (compare the data for **40** and **33**, respectively).

42



Alkene	eq:ax **42**	**40**

$H_2C=CHCN$	40:60	55:45
$H_3CCH=CHCN$	68:32	74:26

As in the case of the five-membered cyclic radical **4**, X = OEt, the stereoselectivity of reaction with the six-membered cyclic radical **45** also increases slightly with increasing polarity of the solvent. The equatorial:axial ratio for attack of acrylonitrile changes from 64:36 in toluene to 76:24 in methanol. This small effect is again probably due to an increase in the solvation of the β substituents.[31c]

45

toluene	eq:ax 64:36

methanol	eq:ax 76:24

Substituents on the six-membered cyclic radical have similar effects on the stereoselectivity of abstraction reactions as on that of addition reactions. However, the torsional effect

can cause the proportion of axial product to be considerably larger in abstraction reactions. The stereoselectivities of deuterium trapping and addition to acrylonitrile are compared in Table 8.[30, 31, 34, 35]

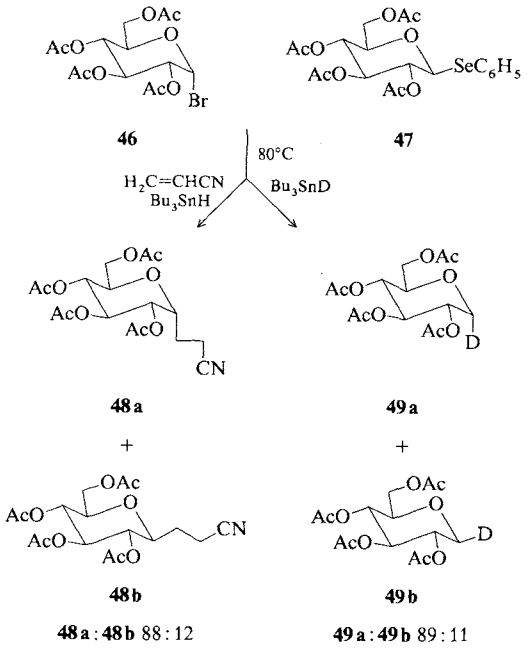

Table 8. Stereoselectivity (equatorial:axial attack) of free radical D abstraction and addition to acrylonitrile of **33** and **37–41**.

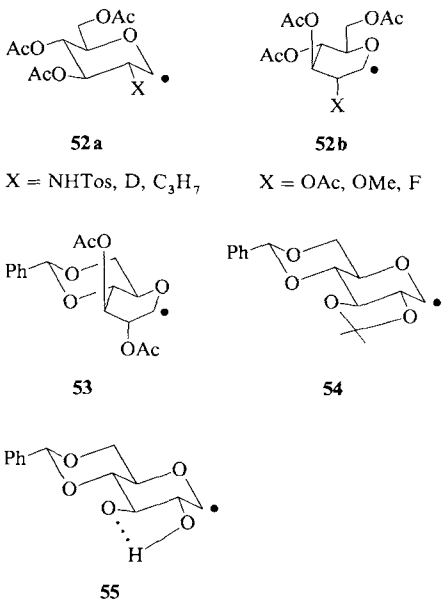
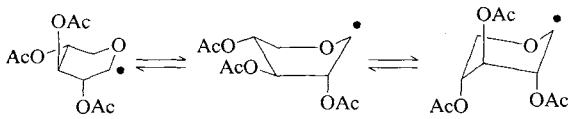
3.3. Stereoelectronic Effects

Glucosyl radicals, in which the radical center is the anomeric carbon atom, yield predominantly α-substituted products. For example, the main products obtained from the α-glucosyl bromide **46** and the β-glucosyl selenide **47** are **48a** in radical addition to acrylonitrile and **49a** in deuterium abstraction from tributyltin deuteride;[31a, 36] the selectivity of the glucosyl radical is independent of whether the radical precursor is an α or β anomer.



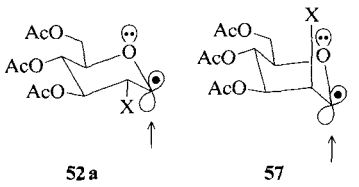
This stereoselectivity is caused by stereoelectronic effects which influence both the radical conformations and the direction of attack on the radicals. ESR studies indicate that the glucosyl radical **50** exists in a slightly distorted $B_{2,5}$ boat conformation, while the mannosyl radical **51** remains in the $^4C_1$ chair conformation of its precursor.[37]

Common to both radicals is the axial arrangement of the neighboring acetoxy group; stabilizing interactions may well exist between the unpaired electron and the neighboring carbon–oxygen bond. This stereoelectronic effect overcompensates the steric repulsion which occurs during the chair–boat interconversion in the glucosyl radical. Analogous conformational changes are not observed in the case of pyranosyl radicals, which have their radical center at C-2 to C-4; thus the radicals **38–40** exist in an only slightly flattened $^4C_1$ chair conformation.[38] The ring oxygen atom adjacent to the radical center of **50** is therefore apparently of critical importance.



According to the frontier orbital theory, this stabilizing effect is due to interaction of the SOMO with the LUMO of the neighboring carbon-oxygen bond. Interaction of the semioccupied orbital with the oxygen lone pair results in a higher SOMO energy, making the SOMO–LUMO stabilization significant.[37] This rationalization is supported by the influence exerted on the conformation of the radicals **52** by the substituent X: only for X = OR or F is the boat form **52b** energetically more favored than the chair form **52a**.[39] Electron-attracting substituents X lower the LUMO energy of the C–X bond and thus increase the stabilizing effect of the SOMO–LUMO interaction. When X = NHTos, D, or C_3H_7, however, only the chair conformer **52a** is observed in the ESR spectrum. In the case of these substituents, the stereoelectronic effect does not suffice to compensate for the increase of the steric strain in the course of the chair–boat interconversion.[39]

The equilibrium between the chair and the boat conformations can also be influenced by ring annelation or by hydrogen bonding. Thus, while the bicyclic radical **53** still exists in a boat form, the annelated five-membered ring in **54** causes the latter to take up a chair conformation. Even the energy of the hydrogen bonds in **55** suffices to suppress the chair-boat interconversion to a large extent.[37]



In the pentopyranosyl radicals the substituent at C-5 is absent; these systems are thus more flexible, and the three radicals **56a–c** can be detected in the ESR spectrum of the

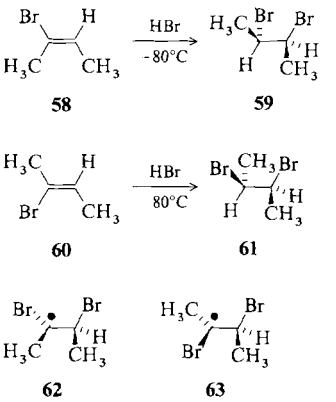
triacetylxylosyl system; in all conformers the carbon–oxygen bond next to the radical center is axial.[40]

56a **56b** **56c**

Not only the conformation but also the direction of attack on substituted oxyalkyl radicals is influenced by stereoelectronic effects. Thus, the glycopyranosyl radicals **52a** and **57**,

52a **57**

which exist in the $^4C_1$ conformation, are attacked axially in both addition and abstraction reactions.



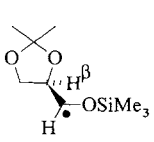
Only in the case of axial attack on the radicals **52a** or **57** is the overlap between the nonbonding electron pair of the ring oxygen atom and the unpaired electron of the radical center (or the newly formed bond) maintained en route to the transition state; only α products are formed.[39] In the case of radicals in the boat conformation **52b**, the stereoselectivity is somewhat smaller. The decrease in stereoselectivity is probably due to the fact that boat conformers are more flexible than chair conformers.[36, 37] There is only a small energy difference between a $B_{2,5}$ boat (e.g., **56a**) and a $^{1,4}B$ boat (e.g., **56b**). According to the stereoelectronic effect, $B_{2,5}$ conformers afford α-products, whereas β products are formed from $^{1,4}B$ conformers. In the xylosyl radicals the selectivity is in fact reversed in favor of the β products, since here, apart from the $B_{2,5}$ boat form **56a**, not only the $^{1,4}B$ boat form **56a** but also the $^1C_4$ chair form **56c** is present.[31b, 41]

4. Acyclic Radicals

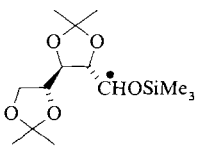
High stereoselectivities are only possible when the radicals (1) react from preferred conformations and (2) are attacked preferentially from one side. Until now only a few experiments have been carried out using acyclic radicals for which both these conditions are fulfilled. However, there are indications as to how the stereoselectivity can be increased.

4.1. Alkyl Radicals

Saturated alkyl radicals can adopt a preferred conformation if, for example, there are stabilizing interactions between the radical center and a neighboring substituent. One example is the free radical addition of HBr to the alkenes **58** and **60**.[42] At −80 °C the products **59** and **61** of *anti* addition are obtained, because the interaction between the radical center and the neighboring carbon–bromine bond locks the intermediate radicals into the conformations **62** and **63**, respectively; these radicals are then attacked *anti* to the shielding bromine atom.



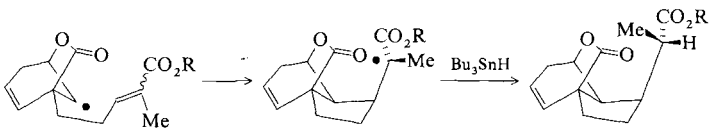
58 **59**



60 **61**

62 **63**

This stereoselectivity decreases when the reaction temperature increases, and disappears at 20 °C.[42] This is perhaps due to the fact that rotation around the central C–C bond can compete with hydrogen abstraction at higher temperatures. The influence of temperature on the rotation of acyclic radicals that exist in a preferred conformation for stereoelectronic reasons is shown by the β coupling constant a(β-H) in the ESR spectrum of the radical **64**.[43] The interaction between the β carbon–oxygen bond and the unpaired electron of the siloxyalkyl radical leads to the preferred conformation **64**. However, the temperature dependence of the β coupling constant shows that rotation around the C–C bond increases as the temperature rises.

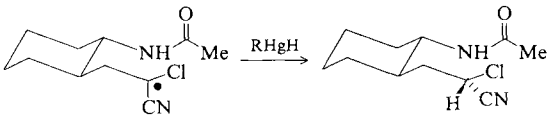


a (β-H)	T [°C]
6.33	−22
6.93	15
7.72	45
8.17	75

64 **65**

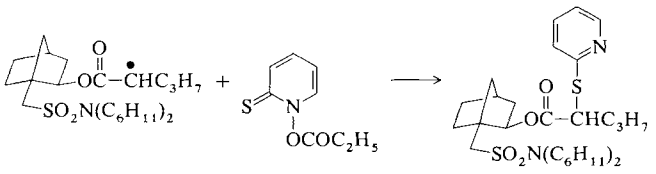
Addition reactions of the radical **64** and the arabinosyl radical **65** at 80 °C afford products in which the diastereomeric excess (*de*) is only just above 30%;[44] higher diastereoselectivity may result at lower temperatures.

Preferred conformations can also be induced by dipole–dipole interactions; thus, the radical **67**, formed from **66**, is trapped with high stereoselectivity by Bu_3SnH to give the product **68** (*de* = 90–94%).[45]



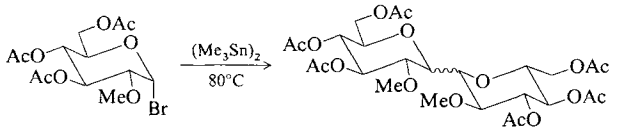
66 **67** **68**

de = 90–94% (80 °C)



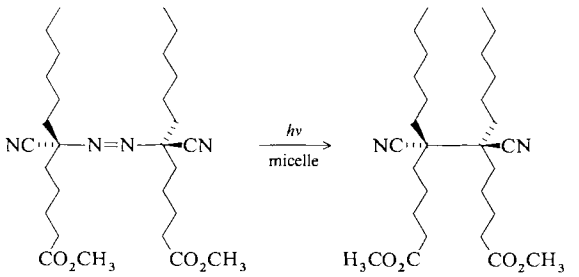
The stereoselectivity does not depend on the configuration of the alkene **66**; the radical center presumably adopts the preferred conformation shown in **67** because of dipole–dipole interactions. The radical will then be attacked from the less shielded side. The radical **69** also affords products

with high selectivity, probably via the conformation shown;[7b] the hydrogen transfer agent in this reaction is an alkylmercury hydride.



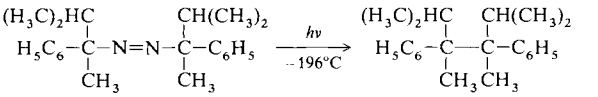
69 **70**
de = 90% (25°C)

The bent shape of the unsymmetrically substituted norbornyl group directs the addition of the radical **71** to the sulfur atom of the thiocarbonyl compound **72**; at −35 °C the product **73** is obtained with a diastereomeric excess of 66%.[46]



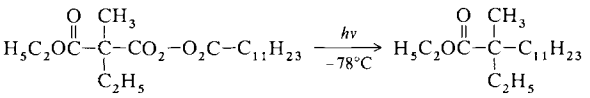
71 **72** **73**
de = 66% (−35°C)

Chiral products can be formed in recombination reactions of radicals that are formed from chiral precursors. However, the stereoselectivity is low in solution: thus, the glucosyl bromide **74** gives the dimers **75** in statistical proportions, although the trapping reactions of corresponding glucosyl radicals with nonradicals can be highly selective.[47]



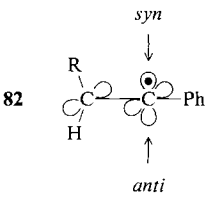
74 **75**

Selective radical–radical recombination reactions do however occur in micelles. This is shown by the photolytic cleavage of nitrogen from the azo compound **76** when the latter is embedded in phospholipid micelles; the reaction occurs with a high degree of retention.[48] The majority of the radicals in the micelle recombine before rotation occurs. These experiments make it clear why the stereoselectivity of radical reactions in enzymes can be different from that in solution.[49]



76 **77**
de = 72% (30°C)

Recombination reactions of radicals in the solid state are often stereoselective: thus, the photolytic cleavage of nitrogen from the azo compound **78** at −196 °C in a matrix affords the dimer **79** with a very high degree of retention,[50] and the photochemical decarboxylation of the diacyl peroxide **80** in the solid state at −78 °C gives the recombination product **81** with 80% retention.[51]



78 **79**

80 **81**

4.2. Vinyl Radicals

In vinyl radicals, rotation around the C=C bond does not occur and substituents can shield the two sides of the π radical to different extents. The hydrogen transfer to the vinyl radical **82** therefore occurs preferably *anti* to the alkyl substituent R with formation of the thermodynamically less stable *cis* alkene.[51]

82

R	*T*[°C]	*anti*:*syn*	H donor
c-C_6H_{11}	0	72:28	RHgH
	80	67:33	
*t*Bu	0	96:4	RHgH
	80	88:12	
Ad	80	> 98:2	Bu_3SnH

The stereoselectivity increases with increasing size of the shielding substituents, so that only formation of the *cis* alkene is observed in the case of the adamantane substituent. The stereoselectivity also depends on the nature of the hydrogen donor: the difference in activation enthalpy between *syn* and *anti* attack increases with decreasing reactivity of the hydrogen donor (see Table 9). However, the influence of the

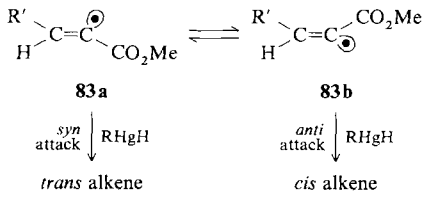


Table 9. Difference in activation enthalpies ($\Delta\Delta H^{\neq} = \Delta H^{\neq}_{anti} - \Delta H^{\neq}_{syn}$) and activation entropies ($\Delta\Delta S^{\neq} = \Delta S^{\neq}_{anti} - \Delta S^{\neq}_{syn}$) in reactions of the vinyl radical **82** (R = *c*C_6H_{11}) with H donors of differing reactivity (k_H).

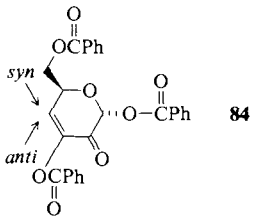
H donor	$\Delta\Delta H^{\neq}$ [kJ mol^{-1}]	$\Delta\Delta S^{\neq}$ [J mol^{-1} K^{-1}]	k_H [L mol^{-1} s^{-1}]
cC_6H_{11}HgH	2.5	1	10^7
Bu_3SnH	4.5	7	10^6
cC_6H_{12}	12	28	1

activation entropies acts in an opposite direction, so that, in the case of the hydrogen donors in Table 9, the isoselective temperature lies at ca. 100 °C.[52b]

Lower selectivities are observed in reactions of σ radicals, since in this case the stability of the two interconverting

σ radicals, the rate at which equilibrium is attained, and the rate of the trapping reaction become important. The influence of the olefinic substituent on the equilibrium position and on the rate of the subsequent reactions acts in opposite directions; in the case of the hydrogen transfer reactions of the radicals **83a** and **83b**, this leads to an actual reversal of the selectivity on going from a *tert*-butyl to an *n*-hexyl substituent.[52a, 53]

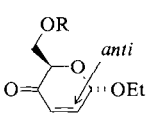


R'	*n*-C_6H_{13}	*c*-C_6H_{11}	*t*-C_4H_9
anti:*syn* (0°C)	34:66	46:54	70:30

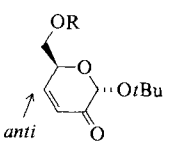
5. Additions of Radicals to Alkenes with Stereogenic Centers

Alkyl radicals without chiral centers can also react in a stereoselective manner when radical traps with stereogenic centers are used. High stereoselectivities have been observed for trapping with chiral alkenes. However, only very little is known about stereoselective abstraction reactions involving radicals in nonenzymatic systems.

5.1. Cyclic Alkenes

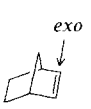


The stereoselectivity of cyclic alkenes and the reactions of cyclic radicals are influenced by steric effects in a similar manner; thus, alkyl radicals add to C-4 of the enolone **84** preferably *anti* to the substituent at C-5.[54] The *anti* selectivity increases with increasing size of the radical.



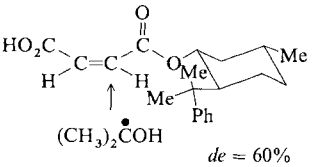
84

Radikal	*n*-$C_6H_{13}^{\bullet}$	*c*-$C_6H_{11}^{\bullet}$	*t*-$C_4H_9^{\bullet}$
anti:*syn* (80°C)	75:25	95:5	> 98:2



The cyclic alkenes **85** and **86** are also attacked preferably in an *anti* manner,[55] and norbornene **87** is attacked almost solely from the *exo* side.[56]

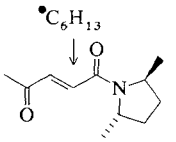
85



86

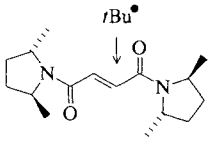
87

5.2. Acyclic Alkenes



There are so far only a few examples of intermolecular radical reactions with acyclic alkenes in which attack is more selective than 3:1. With terminal alkenes no cases of high stereoselectivity are known. It thus appears to be very important that the olefinic carbon atom undergoing attack should bear the chiral substituent. For example, the photochemically produced 1-hydroxy-1-methylethyl radical adds to the chiral maleic ester **88** with a diastereoselectivity of 60%.[57]

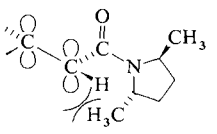
88



de = 60%

The decisive breakthrough occurred with α,β-unsaturated amides.[58] Alkyl radicals add to the alkenes **89** and **90** with diastereoselectivities which increase with decreasing temperature and increasing size of the radicals; even at 20 °C *tert*-butyl radicals add to the fumaric acid diamide **90** with a diastereoselectivity of 96%.[59a]

89



de = 78% (80°C)
87% (20°C)

90

de = 88% (110°C)
96% (20°C)

This high selectivity observed in the amide cases is due to the two stereogenic centers of the amine component. Because of the C_2 symmetry of the amines, the conformation does not change when rotation around the carbon–nitrogen bond occurs. The two methyl groups of the amine component shield the two sides of the alkene to different degrees. This is made clear by formula **91**; the methyl group below the plane of the

91

paper is closer to the alkene than the methyl group directed upwards. The attack on the olefinic C atom that is substituted by the amide group is thus hindered to different degrees by the two methyl groups, and the radical addition is stereoselective.[59b]

These initial experiments with α,β-unsaturated amides make it clear that radical reactions of acyclic systems can indeed be highly stereoselective.

6. Future Prospects

The results obtained in the last few years have shown that cyclic radicals and cyclic radical traps react with predictable and in part high stereoselectivity. Preliminary experiments have shown that the reactions of acyclic radicals with acyclic alkenes can also be stereoselective. However, it must be left to future work to show how preferred conformations of acyclic radicals or acyclic radical traps can be stabilized; both stereoelectronic effects and complexation with metal salts could be of use here. Since stereoselectivities are reflected in differences in activation enthalpies, a reduction of the reaction temperature will also increase the radical selectivity. It is important that the radicals be reactive enough to react at low temperatures. This presupposes, however, that it will be possible to generate radicals at low temperatures under the synthetic conditions required; photochemical techniques, in particular, will be of importance. It would also be desirable to develop alternatives to photochemical generation of radicals. Whether it will be possible to use free radical chemistry for enantioselective syntheses – for example, via chiral metal complexes – remains to be seen. Until now it has not been possible to influence the stereoselectivity of radical reactions with, for example, the chiral ligands of vitamin B_{12}.[60]

The importance of free radical chemistry for organic synthesis will depend on the degree to which stereoselectivity can be controlled. However, the wide use of radicals (for example, in industrial processes) will require the development of methods in which organotin compounds are no longer necessary. It appears to me that this problem can be solved: for example, the method developed by *Barton* et al.[61] using thiopyridine compounds or the use of organocobalt compounds[33,62] make it possible to work without tin. Very recent studies have shown that stannanes can also be replaced by silanes.[63] The use of silanes, in particular, should make possible a wide practical use of free radicals in organic synthesis.

Our own work in this area has been made possible by the generous support of the Deutsche Forschungsgemeinschaft, the VW-Stiftung and the Fonds der Chemischen Industrie. I thank my co-workers, whose names can be found in the list of references, for their hard work and dedication. I am grateful to Prof. Sustmann and Dr. Korth for the ESR studies, Prof. K. N. Houk for help and advice concerning calculations, Prof. H. J. Lindner for X-ray analyses, and Prof. N. A. Porter for extensive and helpful discussions.

Calorimetric Studies of Biopolymers and Aggregates of Phospholipids

By Theodor Ackermann*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

The structural transformations that biopolymers undergo in aqueous solution are complex processes, whose mechanisms can only be explained by the coupling of various partial processes. A spectroscopic analysis of the states of the system often requires considerable effort. In many cases, calorimetric studies have proven to be sufficient for a general characterization of the behavior of the system. These measurements provide information on the stability of the initial state and on the cooperativity of the total process. From the thermodynamic parameters of the system, knowledge on the structure-determining influence of the various types of inter- and intramolecular interactions is obtained. This not only applies to solutions of biopolymers and analogous model substances, but also to solutions of biopolymer complexes with low-molecular-weight ligands and to aqueous suspensions of self-aggregating phospholipids. Possibilities and limitations of the calorimetric methods of measurement are demonstrated for typical examples from the numerous polypeptide and polynucleotide systems and the phospholipid bilayer systems that have been studied. In addition, the special problems involved in carrying out measurements on dilute solutions are pointed out. Here, the latest advances made in measuring techniques are readily apparent.

1. Introduction

The structure of proteins and nucleic acids is characterized by a high degree of molecular order, which is not limited to the covalently bonded atomic building blocks (primary structure). The helix sequences of the secondary structure, stabilized by hydrogen bonds, are a characteristic feature of these biopolymers. The functional diversity of these substances reflects the diversity of the three-dimensional folding pattern (tertiary structure). Hydrophobic interactions, together with other intermolecular interactions, stabilize the aggregation of molecules having defined tertiary structures (quaternary-structure formation). These molecular aggregates, often embedded in the matrix system of the lipid bilayer of biomembranes, are the building elements of biological functional units.

Phospholipids are the most important structural components of biological membranes. Their fatty acid chains are more or less closely packed in the hydrophobic region of the lipid matrix. In the hydrocarbon chains of phospholipid molecules, rotation about the bond between neighboring CH_2 groups is limited. The ideal conformation of this chain is *all trans*. However, this ordered state seldom occurs in membranes. Normally, the CH_2 groups of lipid molecules are in a state characterized by several *gauche-trans-gauche* kinks. In regard to the molecular dynamics of the lipid system, this means that the mobility of the molecular chains in biomembranes is much higher than in the ideal quasi-crystalline lipid bilayer. In an exact description of the state of order of phospholipids, the relative orientation of the neighboring polar head groups must also be considered.

The biological functions of proteins and nucleic acids are optimal only in a narrow temperature range and for an almost constant composition of the surrounding aqueous medium. Any temperature change, as well as any pH shift or change in the solvent composition, leads to a conformational change of biopolymers associated with a reduction in function (denaturation). Examples of this kind of process include the helix–random coil transition of polypeptides and the denaturation of the DNA double helix. The transformation of a polypeptide chain from the ordered helix state to the disordered randomly coiled state is schematically shown in Figure 1. During this conformational change, a variety of different intermediate states can occur in a group of dissolved macromolecules. These intermediate states must be

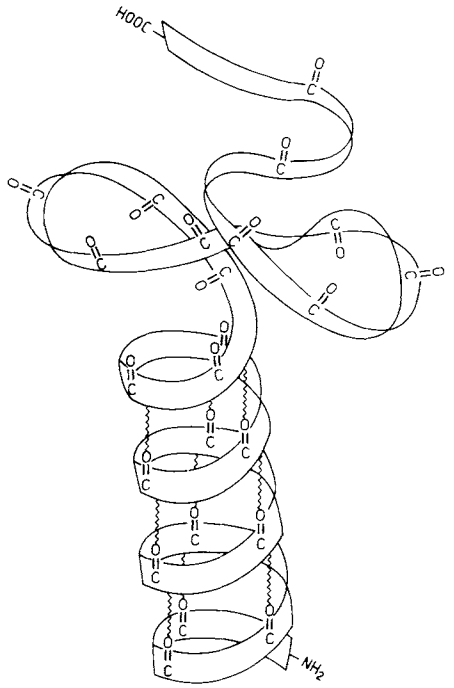

Fig. 1. Helix–random coil transition of a polypeptide chain (schematic).

considered in any statistical thermodynamic theory of helix–random coil transitions.[1-3] Molecular states characterized by a relatively small number of randomly coiled regions between continuous helix sequences are preferred. In the helix–random coil transformation, concerted transitions of connected helix regions to the randomly coiled state take place. The overall process is cooperative and is similar to a phase transition. Therefore, the thermally induced helix denaturation is often compared with a melting process, although it is not a first-order phase transition.

The transition from the ordered helix state to the disordered state is reflected in numerous physical changes when solutions are studied. For example, the optical rotatory power of polypeptide solutions is influenced by the helix–random coil transition. A simple procedure for recording transition curves, in which the degree of helix transformation is represented as a function of temperature, is based on this effect.[4] In measurements on polynucleotide solutions, the helix denaturation curves can be recorded in a similarly easy manner, because base unstacking, which progresses with denaturation, causes a reduction of the hypochromic effect (i.e., increased UV absorption).[5]

Information on the stability of secondary structures with different units can be obtained from denaturation curves. An exact analysis of the combined effects of the various types of weak interactions is only possible if the thermodynamic parameters of the system are known. The most important thermodynamic parameters are the enthalpy of transition and the entropy of transition as well as additional parameters describing the degree of cooperativity of the conformational change. If the observed transformation is coupled with the release of low-molecular-weight ligands, the relevant values for the binding enthalpy and binding entropy must be determined.

Phospholipid bilayer vesicles[6] in aqueous suspension may be considered as lipid-matrix model systems for biological membranes. These lipid systems also change from a quasi-crystalline gel state to a less ordered liquid-crystalline state above a characteristic transition temperature. This transformation, characterized by a reduction in the packing density and increased chain mobility, also takes place within a narrow temperature interval. This cooperative process is called a lipid phase transition.[7] The characteristic transition temperature not only depends on the state of the polar phospholipid head groups, but also on the number of double bonds in the hydrocarbon chains of the lipid and the chain length. The phase transition of lipid bilayers is also influenced by the addition of other components (e.g., cholesterol). In lipid systems with low water content, in addition to the simply structured bilayer vesicles, other more complicated lipid aggregates can also occur. The areas where these "phases" exist can be assigned by a lipid phase diagram. Knowledge of the thermodynamic equilibrium parameters of lipid systems is required for a molecular theoretical interpretation of the phenomena observed in these systems.

There are several methods for determining the thermodynamic parameters of biopolymer solutions and phospholipid systems. Based on studies of simple model systems, several research groups have prepared extensive experimental data which have recently been critically studied and summarized in review articles[8, 9] and data collections.[10] It is not possible to discuss all these data within the framework of this article. Instead, its aim is to present the calorimetric methods described in Sections 4 and 5 as an important procedure for studying biopolymers and phospholipid systems and to exemplify the results obtained with these methods.

2. Degree of Conversion and Enthalpy of Transition

The simplest model system for a biopolymer solution with a temperature-dependent helix–random coil equilibrium is a group of homopolypeptide molecules with the same chain lengths. The peptide units of these molecules are called "segments". If the cooperative interactions are neglected, the state of this system can be described by a two-state equilibrium (segment in α-helix state (B) $\rightleftarrows$ segment in randomly coiled state (A)). The fraction of the segments bound in the helix state is called the degree of helix formation θ.[1-3] The helix formation constant s is the equilibrium constant for process (1).

$$\cdots \text{ABBAA} \cdot \rightleftarrows \cdot \text{ABBBA} \cdots \tag{1}$$

The temperature dependence of the quantity $1-\theta$ is shown in the upper part of Figure 2. The temperature T_m (or

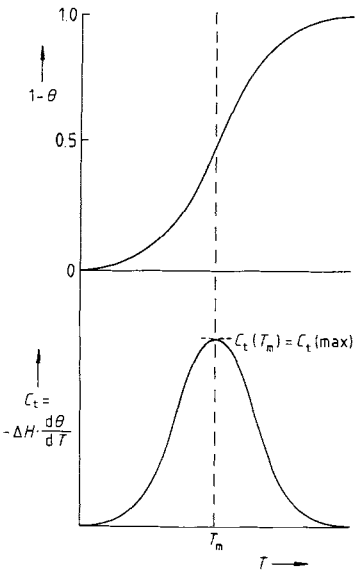

Fig. 2. The temperature dependence of the degree of transformation $1-\theta$ (top) and the conformational excess heat capacity C_t (bottom) of a thermally induced helix–random coil transition according to Equations (3) and (7).

the corresponding ϑ_m of the celsius scale) that is assigned to $\theta = 0.5$ is called the transition temperature. If no cooperative interactions need to be considered, the typical shape of the curve obtained by plotting $1-\theta$ versus T is derived from the temperature dependence of the equlibrium constant s, which, according to the laws of thermodynamics, is expressed by Equation (2).

$$\frac{d\ln s}{dT} = \frac{\Delta H_{v.H.}}{RT^2} \tag{2}$$

In Equation (2), $\Delta H_{v.H.}$ represents the van't Hoff's enthalpy of helix formation or the enthalpy of transition per mole of segmental unit or per mole of lipid. At the transition

point, $s = 1$ and $\theta(1-\theta) = 1/4$. From this and the simplifying assumptions already mentioned,[3] Equation (3) is derived.

$$\left(\frac{d(1-\theta)}{dT}\right)_{T_m} = -\frac{\Delta H_{v.H.}}{4RT_m^2} \tag{3}$$

Based on Equation (3), $\Delta H_{v.H.}$ can be obtained from the slopes of the transition curves recorded by optical methods.

The helix–random coil transition facilitates the addition of solvent molecules to the dissolved polypeptide molecules (solvation). Solvation is an exothermic process. The state of association of the solvent also changes with the state of solvation of dissolved substances. Thus, the overall helix–random coil transition is a process in which endothermic and exothermic partial processes overlap and, except for a relatively insignificant amount, are compensated in the energy balance. Therefore, the molar enthalpy of transition calculated for a peptide segment with an average hydrogen bond dissociation energy[11] of 30 kJ mol^{-1} cannot be significantly greater than 5 kJ mol^{-1}. For a comprehensively studied peptide system (poly(γ-benzyl-L-glutamate)[12,13] dissolved in a mixture of dichloroacetic acid and 1,2-dichloroethane; see Section 7.1), however, a much higher $\Delta H_{v.H.}$ value of approximately 400 kJ mol^{-1} was obtained from the evaluation of transition curves. Apparently, the stabilizing effects of neighboring segments of a peptide chain cannot be neglected, because the formation of a helix sequence is strongly favored by the immediately neighboring segments already in the helix state. This facilitation means that the neighboring segments of a helix sequence in peptide chains change from the helix state to the random state in a concerted process. The influence of this cooperativity is exhibited in the pronounced sharpness of the transition curves.

3. Cooperativity Parameters and Average Cooperative Lengths

Theoretical formulations[1-3,13] allow the derivation of a quantitative relationship for the temperature dependence of the frequencies and neighboring distribution of the segments in the helix and randomly coiled states. This provides information on the average number of united segments still in a helix sequence at temperature T_m. The number N_0 of segments that cooperatively transform to the randomly coiled state at the transition point is called the average cooperative length.[1] When the cooperativitiy is considered, the true molar enthalpy of transition ΔH_t is not used for $\Delta H_{v.H.}$ in Equation (3), but rather the product $N_0 \cdot \Delta H_t$. Equation (4)

$$H_{v.H.} = N_0 \cdot \Delta H_t \tag{4}$$

applies, since, instead of the individual peptide segment, the number of segments (N_0) is used as a molar stoichiometric unit for the conformational change. Evaluation of transition curves that are, for example, determined by measurements of the temperature dependence of optical rotatory power always provides only the product $N_0 \cdot \Delta H_t$. Normally, the average cooperative length N_0 is not known. Often, it cannot be theoretically calculated if there is no exact data on the chain lengths of the polypeptide molecules studied and their influence on the sharpness of the transition curves. In the theory of the helix–random coil transformation, the cooperativity parameter σ should be given central importance. If s is the equilibrium constant for the growth step defined by Equation (1), the product $\sigma \cdot s$ is the equilibrium constant for the nucleation step (5) ($\sigma < 1$). *Applequist*[3] showed that there is a simple relationship [Eq. (6)]

$$\cdots AAAAA \cdot \rightleftarrows \cdot ABAAA \cdots \tag{5}$$

$$N_0 = \sigma^{-1/2} \tag{6}$$

between the cooperativity parameter and the average cooperative length N_0. For example, for $\sigma = 10^{-4}$, $N_0 = 100$. If the value for N_0 is not known, no information on the true molar enthalpy of transition per segment (ΔH_t) can be obtained with the described procedure. However, knowledge of the ΔH_t values is especially important for an understanding of the enthalpy balance that contributes to the stability of secondary structures. Therefore, direct calorimetric procedures should be used to determine ΔH_t values.

The influence of the cooperative interactions discussed here for the helix–random coil transition of a polypeptide system is similarly reflected in the thermally induced denaturation of nucleic acid double-helix sequences. Thus, if chain-length effects are considered, the true enthalpies of denaturation per mole of base pairs (bp) for poly- or oligonucleotides can only be obtained from the different slopes of the so-called melting curves determined by recording UV absorbance of substances with different chain lengths.

The cooperative effect has a particularly dramatic effect on the transition of a lipid bilayer system from the gel state to the liquid-crystalline state. The strong similarities of this change of state with a first-order phase transition lead to the conclusion that this process is highly cooperative. In the physico-chemical characterization of these systems, the exact determination of the true enthalpy of transition can often only be achieved by means of direct calorimetric measurements. Suitable methods for these measurements are explained below.

4. True Enthalpies of Transition and the Conformational Excess Heat Capacity

If the temperature is limited to the relative narrow range of a cooperative conformational transformation, the molar enthalpy of transition ΔH_t can be considered a constant system parameter. Since the total mole number n_g for all segments is given, with the differential mole number change $dn = -n_g d\theta$ and the increase in enthalpy $dH = \Delta H dn$, Equation (7) is obtained, where C_t is the conformational ex-

$$C_t = \frac{1}{n_g}\frac{dh}{dT} = -\Delta H_t \frac{d\theta}{dT} \tag{7}$$

cess heat capacity per mole of segment. The temperature dependence of C_t is schematically represented in Figure 2 (bottom). The symmetric curve shows the proportionality between the value of C_t and the differential quotient $d\theta/dT$.

Since the total enthalpy of transition of the system does not depend on the type of intermediate state, the true molar enthalpy of transition ΔH can be determined by measuring the area under the curve shown in Figure 2 (bottom). Since the transition curve reaches its maximum sharpness at temperature T_m, $C_t(T)$ also has a maximum at this point. Consideration of Equations (4) and (6) gives Equation (8) for T_m.

$$C_t(T_m) = \frac{1}{4\sigma^{1/2}} \frac{(\Delta H_t)^2}{RT_m^2} \tag{8}$$

If the temperature dependence of the heat capacity of a solution of biopolymers is exactly recorded, the parameters ΔH_t and $C_t(T_m)$ can be determined. If these two parameters are inserted into Equation (8), σ and thus N_0 can be calculated based on Equation (6). The prerequisite for an exact determination of the cooperativity parameters is, however, a distortion-free reproduction of the function $C_t(T)$, which can only be achieved if the rate of heating is low and the measuring arrangement is relatively inert to thermal lag effects.

In cases of model substances with uniform primary structures (homopolypeptides and homopolynucleotides) and some transfer ribonucleic acids, the conformational transformation can be reversed by cooling via the same path achieved by heating. In enzyme proteins, deviations from the renaturation equilibrium curve[14] are also rarely observed. In contrast to polypeptides partial renaturation of native DNA samples following thermal denaturation can only be achieved by very slow cooling.[15] Between these two extremes, complete renaturation and nonreversible denaturation, there are numerous hysteresis-like phenomena. The importance of these phenomena in regard to possible information storage effects are discussed in detail by *E. Neumann*.[16] Hysteresis effects are observed during variations of pH values and during thermally induced conformational transformations of several polynucleotide solutions and lipid suspensions. An example of a polynucleotide system with thermally induced hysteresis is the mixed system of poly(deoxyriboadenylic acid)(poly(dA)) and poly(ribothymidylic acid)-(poly (T)).[17] Phosphatide acid systems are lipid systems exhibiting thermal hysteresis.[18] The hysteresis effect is also reflected in the course of the $C_t(T)$ curves. When the equilibrium of hysteresis-free systems is quickly reached, the $C_t(T)$ curves recorded upon heating and cooling must agree. Since the primary objective of thermodynamic measurements is the characterization of changes of state occurring between equilibrium states, it should always be checked whether the system studied goes through a series of equilibrium states during the conformational transformation or whether significant deviations from equilibrium take place. Thus, the development of heating–cooling calorimeters,[19] which make it possible to record $C_t(T)$ curves during heating and cooling, should receive special attention. If the enthalpy area under the $C_t(T)$ curve is constant, the problems related to distortion-free recording of these curves are insignificant if only the ΔH_t values are to be determined.

5. Experimental

The first measurements on solutions of polypeptides[20] and polynucleotides[21] were made with adiabatic recording calorimeters. For special measurements of some samples dissolved in nonaqueous corrosive solvents, glass calorimeter vessels had to be used.[22, 23] In most cases, measurements on aqueous solutions can be done with suitable metal calorimeter vessels (e.g., gold-plated silver vessels[24]). The most suitable method for recording C_t curves is the DSC method (differential scanning calorimetry).[25] The principle of this twin calorimeter method (recording the additional electrical heating power needed for the compensation of the conformational excess heat capacity when heat exchanges with the surroundings are largely excluded) is well-known and described in detail in the latest specialized literature on measuring procedures in calorimetry.[26] However, only some of the specialized types of commercial DSC apparatuses are suitable for measurements on solutions of biopolymers and analogous model substances. Special demands on sensitivity inevitably result from the fact that the major contribution to the enthalpy increase observed in thermally induced conformational transformations is not caused by the structural change of the solute but by the high heat capacity of the solvent. While the increase in enthalpy caused by structural changes strongly contributes to the total heat capacity in the study of homogeneous solid samples (e.g., solid polymer materials), the conformational excess heat capacity for biopolymer solutions is normally no more than one or two percent of the calorimetrically measurable total effect. Thus, the sensitivity for the difference effect to be determined must also be particularly high when the major contribution to the heat capacity caused by the solvent is eliminated by compensation based on the principle of the twin calorimeter. In addition, only instruments with hermetically sealable sample chambers can be used for calorimetric measurements on solutions of biopolymers owing to the volatility of the solvent.

The requirements mentioned are met by the DASM-1M calorimeter (Mashpriborintorg, Moscow, USSR) equipped with gold vessels, which was developed by *P. L. Privalov* et al.[27] An improved version (DASM-4M) is now available. With this type of apparatus, measurements on biopolymer solutions with relatively small concentrations (1–2 mg mL^{-1}) can be made without particular difficulty. The Microcal MC1 (Microcal Inc., Amherst, MA, USA) developed by *J. F. Brandts* et al.[28] is also suitable to make measurements on biopolymer solutions. The Perkin-Elmer DSC apparatus (Perkin-Elmer Corporation, Norwalk, CT, USA) can also be used to study concentrated lipid suspensions (5–10 wt%). However, with this apparatus, the small sample volumes (20 to 25 μL) have a negative influence on the calorimetrically measurable effect. In view of the relatively small number of suitable calorimeters offered, the further development of DSC instruments for the above mentioned purpose would be useful.

Figure 3 shows the construction scheme and the twin vessel unit of a DPSC apparatus (differential power scanning calorimeter) developed in our institute by *M. Grubert*.[29] In Figure 4, as example, a $C_t(T)$ curve of a polynucleotide solution recorded with this type of apparatus is shown.[30] Since the ΔH_t value obtained from the area under the $C_t(T)$ curve corresponds to a small difference effect of two endothermic effects eliminated by compensation, this ΔH_t value cannot be assigned a particularly high degree of relative accuracy. Normally, the ΔH_t values determined with the DSC method are

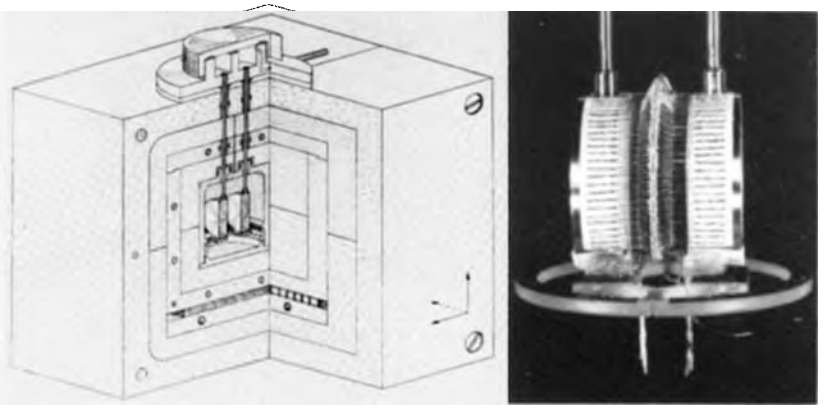

Fig. 3. A construction scheme (left) and twin-vessel unit (right) of a DPSC apparatus (according to *M. Grubert*[29]). The twin-vessel unit fixed to the inlet tubes is surrounded by an adiabatic shield regulated by means of multijunction thermocouples. A constant temperature of the surroundings is maintained by means of a thermostated outer shield with a Peltier battery, which surrounds the adiabatic shield (outer protective end: aluminum block with a pressure-resistant lid; lining of the space between the outer shields: polyurethane-foam fillers).

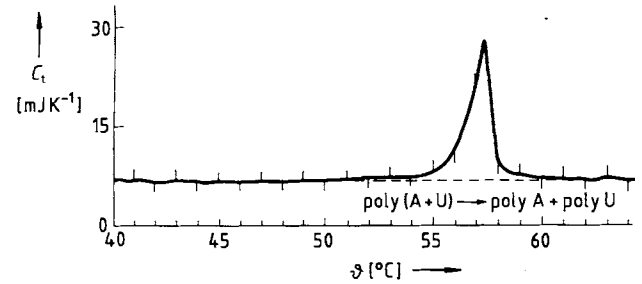

Fig. 4. A $C_t(T)$ curve of a polynucleotide system (equimolar mixture of polyribouridylate and polyriboadenylate in aqueous buffer solution; see Section 6) recorded with DPSC apparatus.

reproducible with an accuracy of $\pm$ 2%. In most cases where thermodynamic data are needed for numerical calculations, this accuracy has proved to be sufficient.

For the thermodynamic characterization of biopolymer systems with ligand binding,[31] direct calorimetric determination of the enthalpy of binding should also be carried out if possible. The LKB mixture calorimeter[32] (model 10700-2; LKB, Broma, Sweden) is suitable for these kinds of experiments. Such measurements have also been made by several research groups.[33]

6. Results from Measurements on Polynucleotide Solutions

Calorimetric measurements on nucleic acids and synthetically prepared poly- and oligonucleotides have been made. The results are summarized in the data collection mentioned previously.[10] Here, several typical examples will be briefly described and explained.

6.1. Deoxyribonucleic Acids

The magnitude of the ΔH_t values per mole of base pairs (mol bp) for the thermally induced denaturation of dissolved deoxyribonucleic acids is approximately 35 kJ/mol bp.[34-37] For a number of different DNA samples, the dependence of ΔH_t values on guanine/cytosine (GC) content has been studied.[38, 39] From the ΔH_t values determined for different T_m values, the entropy of denaturation (ΔS_t values) and the ΔG_t values can be calculated and summarized in a state diagram.[10] With increasing GC content, the ΔH_t values increase (see Fig. 5): that is, they show a T_m dependence that corresponds to the dependence of T_m values on GC content in DNA samples determined by *Marmur* and *Doty*.[5]

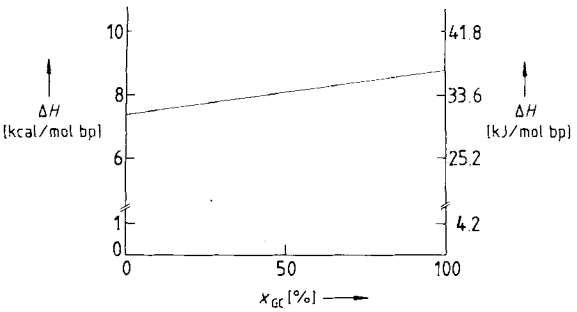

Fig. 5. Dependence of the DNA enthalpy of denaturation ΔH_t on the guanine–cytosine content x of the samples [34, 39].

Exact measured values of the enthalpy of denaturation can therefore be used as an additional analytical criterion for the relative base composition of DNA samples. However, the dependence of ΔH_t values on the GC content is not as pronounced as might be expected in a double helix stabilized solely by hydrogen bonds. From all the ΔH_t values measured on DNA samples, it can be concluded that the hydrogen-bond-enthalpy effect does not contribute significantly to the stabilization of secondary structures and that the double-helix structure is primarily stabilized by means of base stacking. This is understandable if it is considered that solvated single strands are formed during denaturation. The ΔH values for the partial processes of base unstacking listed in Table 2 (Section 9) are approximately 25 kJ/mol bp. The comparison with the value for the enthalpy of DNA denaturation (35 kJ/mol bp) implies that approximately 70% of the total enthalpy effect of the double helix denaturation can be attributed to base unstacking. Thus, the hydrogen-bond systems are of primary importance in regard to the specificity of base pairing, but only of secondary significance for the stability of secondary structures.

In the discussion of ΔH_t values, it is to be noted that the thermodynamic data of dissolved electrolytes are normally related to the standard state of ideal dilution.[40] Calorimetric measurements on polynucleotide solutions of different polynucleotide concentrations have shown that the ΔH_t values of these substances exhibit only a small degree of concen-

tration dependence.[41] The deviations of the ΔH_t^0 values extrapolated to the state of ideal dilution and the measured ΔH_t values from moderately concentrated solutions are within the stated limit of error of $\pm 2\%$. Therefore, the experimentally determined ΔH_t values can be referred to as standard values of first approximation. Up to now, however, this simplified assumption has proven valid only for aqueous polynucleotide solutions.

By means of measurements on selected DNA samples, it was possible to show that the DSC method could also be used in the characterization of highly repetitive sequences in eukaryotic DNA. The repetitive sequences occurring in certain satellite DNAs can be assigned to different discrete peaks in the $C_t(T)$ diagram of the samples studied. From the T_m values determined with this method, the average base composition of the repetitive sequences can be obtained.[42]

6.2. Ribonucleic Acids

The specific transfer ribonucleic acids (tRNAs), which are indispensable for protein biosynthesis, exhibit a characteristic base-pairing pattern (cloverleaf model) and a distinctive tertiary structure (see Fig. 6). Their molecular weights differ

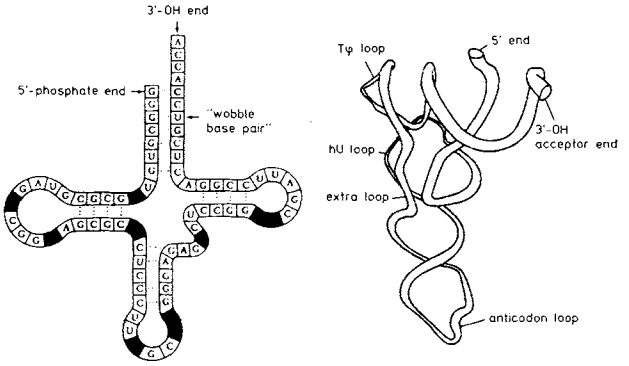

Fig. 6. Simplified drawing of the secondary structure ($tRNA^{Ala}$, left) and the tertiary structure ($tRNA^{Phe}$, right) of transfer ribonucleic acids.

only slightly. However, characteristic differences in the secondary structures of different specific transfer ribonucleic acids can be recognized in the number of base pairs determined by various physicochemical methods.[43] In the largely reversible thermally induced denaturation of dissolved tRNA samples, the endothermic degradation processes of the tertiary and secondary structures overlap.[44, 45] Despite this overlapping of two effects, a significant, nearly linear dependence of the enthalpies of denaturation on the number of hydrogen bonds given by the secondary structure was determined by means of calorimetric measurements on solutions of different specific tRNAs.[46] The ΔH_t value for the denaturation of tRNA samples is approximately 1500 kJ mol^{-1} per mole of tRNA. This value corresponds to an average of approximately 20 base pairs[43] and is thus significantly higher than the calculated values, which were determined using the base-pair denaturation increments listed in Table 2 (Section 9).[46] Based on this, a substantial proportion (approximately 30%) of the total enthalpy of transition of the tRNA sample must be used for the denaturation of the tertiary structures.

Viroids are circular, single-stranded ribonucleic acids (molecular weight of approximately 120000), which as infectious particles lead to a number of plant diseases.[47] Detailed information on the secondary structure of these ribonucleic acids was derived from precise measurements of the temperature dependence of UV absorption of dissolved viroid samples.[48] The model of the secondary structure adapted to the denaturation behavior of the viroid samples[49] is the basis for an estimate of the enthalpy of denaturation, which can be calorimetrically determined using the methods described in this paper. For the CPFV (cucumber pale fruit viroid), enthalpies of denaturation of 3930 ± 150 kJ mol^{-1} were measured with the DPSC method.[50] This value agrees relatively well with the value of 4080 kJ mol^{-1} derived from the model secondary structure. Thus, the model of secondary structure of CPFV suggested by *Riesner* et al.[49] is essentially correct.

6.3. Model Substances (Poly- and Oligonucleotides)

The double helix–random coil transition of equimolar mixtures of complementary homopolyribonucleotides is characterized by a high degree of cooperativity and is easily accessible to studies using the calorimetric methods of measurement described. This is exemplified by the results of measurements on aqueous solutions of polyriboadenylate (poly A) and polyribouridylate (poly U), a system that has been comprehensively studied.[21, 30, 51, 52] The formation and thermally induced degradation of triple helices can be followed relatively well by means of measurements on this system. In Figure 7 $C_t(T)$ curves, recorded at pH 6.8 and a

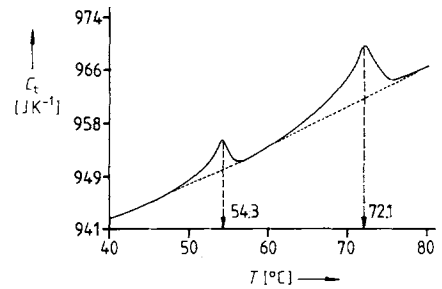

Fig. 7. $C_t(T)$ curve of an equimolar mixture (0.0078 M) of polyriboadenylate (poly A) and polyribouridylate (poly U). The experimental conditions are stated in the text.

$Na^{\oplus}$ concentration of 0.5 mol L^{-1}, are presented. The transition peak at 54.3 °C corresponds to the "disproportionation" (9).

$$2\,\text{poly}(A + U) \rightleftarrows \text{poly}(A + 2U) + \text{poly}\,A \qquad (9)$$

During transformation, a triple helix composed of poly (A + 2U) is formed, accompanied by the release of a molar equivalent of poly A. The pronounced maximum of the heat capacity at 72.1 °C corresponds to a transformation in which the components poly A and poly U are released from the triple-helical complex [Eq. 10]. The model system

$$\text{poly}(A + 2U) \rightleftarrows \text{poly}\,A + 2\,\text{poly}\,U \qquad (10)$$

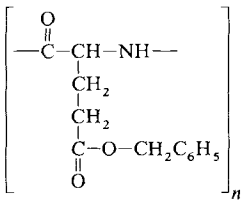
poly(I + C), that is, an equimolar aqueous mixture of polyriboinosylate (poly I) and polyribocytidylate (poly C) has also been largely characterized with calorimetric methods.[53]

From the ΔH_t values of polynucleotide systems, which are related to a double helix denaturation, information on the relative stability of different complementary base combinations can be obtained, because the corresponding entropies of transition differ only slightly.[10] For example, the ΔH_t value[54] of 30 kJ/mol bp determined for alternating poly-d(A-T) fits well into the explanations in regard to the system described in Figure 5. In this context, the experiments on the thermodynamic characterization of the "wobble base pairs" GU postulated by *Crick*[55] (e.g., see Fig. 6, left) should be noted.[56] Using spectroscopic and calorimetric measurements on equimolar aqueous mixtures of poly(A, G) with poly U (also poly(C,U) with poly G), it was possible to show that the ΔH_t value of 28 kJ/mol bp determined for the guanine–uracil base combination differs only slightly from the value for the AU base pair (33 kJ/mol bp). In these cases, the different stabilities of the base combinations are reflected in the different values of the entropies of transition.[56] At the standard temperature of 25 °C, the ribonucleotide secondary structures are also stabilized by the guanine–uracil base combination, although this base combination is characterized by a particularly high dynamic flexibility.[57] The poly A released during transformation based on Equation (9) is not in the randomly coiled form but rather in a partially ordered secondary structure. The enthalpies of transition assigned to the thermally induced degradation of this secondary structure can also be determined with calorimetric measurements.[10] In the determination of enthalpies of transition, the enthalpy changes caused by changes in the secondary structure of single-stranded polynucleotides must in any case be taken into account.

The thermodynamic characterization of oligonucleotide systems[58] is important because these systems provide an especially good basis for the study of the effects of certain base sequences on the relative stability of various secondary-structure elements (e.g., hairpin loops, see Fig. 6). Sequence-specific effects can be better determined by studying short oligonucleotide sequences than by determining the characteristics of polynucleotides. With a suitable set of thermodynamic parameters of oligonucleotides, the stability of certain models of secondary structures (e.g., of viroids) can be approximated. By means of measurements on oligonucleotide systems, it was shown that there is no significant difference between the enthalpies of base unstacking of ribonucleotides and deoxyribonucleotides with identical base pairs.[58] The stabilizing or destabilizing effects of dangling ends on the stability of helix structures can be quantitatively determined by denaturation experiments on solutions of double-helical oligonucleotide complexes.[59] It should be noted that a relatively small slope of the transformation curves is expected even for extremely high degrees of cooperativity, because the average cooperative lengths [see Eq. (4)] cannot be greater than the sequence length of the molecule. For the same reason, only broad and flat $C_t(T)$ curves are obtained from calorimetric measurements on oligonucleotide systems. Thus, the amount of substance used for calorimetric determination in such systems is much greater than the quantity used for measurements on polynucleotide systems. Despite this disadvantage, calorimetric measurements should always be carried out when oligonucleotide systems are studied, provided that there is a sufficient quantity of sample substance. The calorimetrically measured ΔH_t values do not depend on the type of model (two-state model or multistep model) that must be assumed when transition curves are evaluated. A process that corresponds to the simple two-state model exists if the calorimetrically measured total molar enthalpy of transition agrees with the van't Hoff enthalpy of transition $\Delta H_{v.H.}$ derived from the transition curves. This applies, for example, to the deoxyribonucleotide system $d(GC)_3$ ($\Delta H_{v.H.} = 240\ kJ\ mol^{-1}$) studied by *Breslauer* et al.[60] If, on the other hand, $\Delta H_{v.H.}$ is less than the calorimetrically measured total enthalpy of transition, the system goes through a series of intermediate states (for example, rA_7U_7)[61] during the thermally induced helix–random coil transition. Further measured data and experimental details have already been summarized.[58]

6.4. Ligand Binding (Intercalation)

A typical example of an interaction of dissolved biopolymers with low-molecular-weight ligands is the binding of ethidium and acridine dyes to deoxyribonucleic acids. Here, the noncompetitively bound ligands (dye cations) are largely shielded from their surroundings by intercalation.[62,63] In contrast, the competitively (externally) bound ligands can be displaced by competitor salt ions. These types of binding differ in the values of the binding constants; the standard entropy of binding is greater for external binding. In regard to the van't Hoff enthalpies of binding ($-30\ kJ\ mol^{-1}$) derived from the temperature dependence of the binding constants, both types of binding are similar. For the thermodynamic characterization of the binding of dyes to deoxyribonucleic acids, systematic studies with physicochemical methods have been carried out by *H. Zimmermann* and his coworkers.[64] The enthalpies of ligand binding can be calorimetrically determined with a suitable mixing calorimeter and the resulting ΔH values agree relatively well with values derived from binding studies under comparable conditions. This agreement is remarkable, because often difficulties can occur in the calculation of formal standard enthalpies of binding[64] from the temperature dependence of the binding constant owing to the complexity of the binding. Calorimetrically determined formal standard enthalpies of binding are temperature-dependent.[31] This ("apparent") temperature dependence can be primarily attributed to the overlapping of the two binding processes mentioned above and to the effects on the electrolyte equilibria and buffer dissociation equilibria associated with these processes. Detailed discussions of these temperature-dependent binding equilibria have been presented elsewhere.[31,64]



7. Results from Measurements on Solutions of Polypeptides and Proteins

The results from measurements of enthalpies of protein denaturation have been described and summarized in ta-

bles.[65] Some of the most important aspects of these studies are explained here using several examples.

7.1. Polypeptide Systems

Several authors[22, 66] have reported exact calorimetric measurements on solutions of the polypeptide poly(γ-benzyl-L-glutamate) **1** in a mixture of dichloroacetic acid and

1

1,2-dichloroethane. The nonaqueous solvent mixture containing the strongly solvating component dichloroacetic acid was chosen for this model system, because relatively simple assumptions could be made for the polypeptide-solvent interactions (quasi-stoichiometric solvation). This system has already been comprehensively studied by *Zimm, Doty,* and *Iso*[4] and is characterized by the enhanced formation of a polypeptide α-helix (see Fig. 1) when samples are warmed. At low temperatures, solvated polypeptide molecules are largely in the randomly coiled state. Thus, a necessary precondition for helix formation is the release of solvent molecules (dichloroacetic acid) from the polypeptide, thereby making available hydrogen-bond-acceptor and -donator sites. Therefore, the overall process of α-helix formation in this solvent mixture is endothermic. For the thermodynamic characterization of this polypeptide system, all preconditions for the use of the equations developed by *Zimm* and *Bragg*[2] for quantitative determination of the transition curves are satisfied. The optical rotatory power and the heat capacities (measured with a suitable adiabatic calorimeter[23]) of a solution of poly(γ-benzyl-L-glutamate) **1** (0.257 mole per kilogram of solvent) in a mixture of dichloroacetic acid and 1,2-dichloroethane (81:19) result in a temperature curve corresponding to the scheme presented in Figure 2. The enthalpy of transition determined from this data is dependent on the concentration of the dissolved poylpeptide.[22] The ΔH_t value of 3.99 kJ per mole of segment extrapolated to standard ideal dilution agrees well with the ΔH_t value determined from the temperature dependence of the optical rotatory power, where the length of the polymer chain was taken into consideration. From the maximum value of the conformational excess heat capacity, it was possible to calculate the cooperativity parameter σ for this system from Equation (8). A value of $\sigma = 10^{-4}$ was determined for the standard state of ideal dilution. This value agrees well with the value approximated by *Zimm, Doty* and *Iso*.[4] The effects of solvent composition on the magnitude of the ΔH_t values has also been studied.[67] It should be noted that not all polypeptide systems are suitable for a physico-chemical characterization using calorimetric methods. For example, the helix–helix transformation of poly(L-proline) comprehensively studied by *Engel* et al.[68] cannot be induced by a change in temperature ($\Delta H \approx 0$).

7.2. Proteins

The free energy of denaturation of proteins (Gibbs free energy change associated with protein unfolding) is an important parameter for the evaluation of the ability of organisms to live under extreme conditions (thermophilic, psychrophilic behavior).[69] In this context, the determination of enthalpies of denaturation of dissolved proteins is of fundamental importance.[65, 70] The values of the calorimetrically determined enthalpies of denaturation range from 1134 kJ mol^{-1} (pepsinogen, M_r = 38000 g mol^{-1}) to 97 kJ mol^{-1} (tryptophane synthase, α subunit, mutant (Ser 49), M_r = 29000 g mol^{-1}). The numerous interactions between various molecular regions are reflected in the size of the ΔH values. This applies especially to the systems with protein–protein association[71] that have also been thermodynamically characterized (example: tobacco mosaic virus protein TMVP[72]). In the study of association or polymerization of polymer subunits, both positive and negative values for the standard entropies of transition have been found.[72]

Another important aspect of protein thermodynamics is the protein–ligand interaction.[73] Of the numerous ligand binding systems that have been studied, but which cannot be discussed in detail here, five kinds of interactions are particularly noteworthy, namely, the binding of inorganic ions including $H^{\oplus}$ ions, the binding of denaturing agents (e.g., urea),[74] the hapten–antibody interaction,[75, 76] the interaction of proteins (e.g., muscle proteins) with ADP and ATP,[77, 78] and the binding of $NAD^{\oplus}$ and analogous ligands to enzymes (e.g., lactate dehydrogenase from porcine heart muscle).[79]

The interaction between protein subunits[80] and the protein nucleic acid interactions[81] are considered to be especially important. A typical example of the interaction of protein subunits is that between S-peptide and S-protein of ribonuclease S'.[80]

The results from these studies are the basis for the investigation of model concepts on the structure–function relationship of protein systems.

8. Aqueous Lipid Systems

The discussion of thermodynamic parameters of lipid suspensions is limited to the explanation of a few typical examples. For measurements on lipid systems with low water contents, the reader is referred to a recent summary[9] and to the original literature.[82]

8.1. Transition Temperatures, Enthalpies of Transition, and Apparent Molar Heat Capacities

In Table 1 the thermodynamic parameters for 16 different phospholipids, each containing two identical hydrocarbon chains, are summarized. The abbreviations almost always used in the relevant literature[6, 8] (e.g., DSPC for distearoyl phosphatidylcholine) are derived from the trivial names of the fatty acids and of the head-group components linked to the phosphate groups (see footnote to Table 1). The T_m val-

Table 1. Transition temperatures (T_{m1}) and transition enthalpies (ΔH_t) of pretransition as well as transition temperatures, enthalpies of transition, and entropies of transition (T_{m2}, ΔH_2, ΔS_2) of the main transformation of phospholipids with two identical hydrocarbon chains in dilute aqueous suspension (taken from *A. Blume* [9, 83, 84]).

Lipid [a]	T_{m1} [°C]	T_{m2} [°C]	ΔH_t [kJ mol^{-1}]	ΔH_2 [kJ mol^{-1}]	ΔS_2 [J mol^{-1} K^{-1}]

[a] DMPC, dimyristoylphosphatidylcholine; DHPC, 1,2-dihexadecyl-*sn*-glycero-3-phosphocholine; DHPE, 1,2-dihexadecyl-*sn*-glycero-3-phosphoethanolamine; DHPA, 1,2-dihexadecyl-*sn*-glycero-3-phosphoric acid.

ues and the enthalpies of transition (ΔH_2) increase with increasing hydrocarbon chain lengths.

Figure 8 shows, as example, the DSC curves of aqueous suspensions of different phosphatidylethanolamines record-

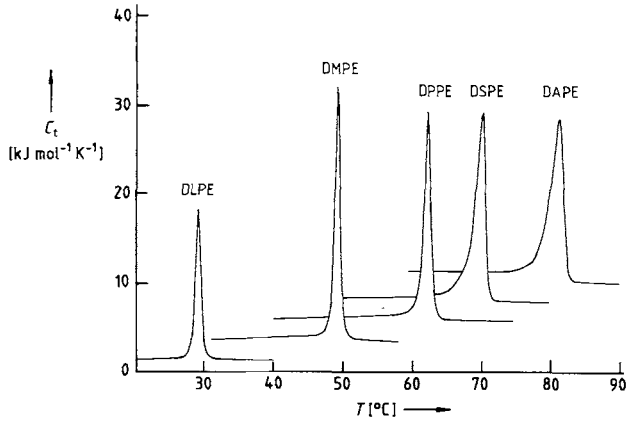

Fig. 8. $C_t(T)$ curve of aqueous suspensions of five phosphatidylethanolamines with different hydrocarbon chain lengths (c = 1 mg mL^{-1}).

ed under identical conditions and at a concentration of 1 mg mL^{-1}. The entropies of transition (ΔS_2) shown in Table 1 vary systematically in an analogous way. The magnitudes of these ΔS values are much lower than the entropies of melting of corresponding long-chain fatty acids or corresponding pure hydrocarbons. This finding clearly shows that the degree of order of the lipid bilayers of liposomes[7] in the liquid-crystalline phase is significantly greater than it is in an isotropic liquid phase. In some lipid systems (e.g., DPPC) a so-called pretransition[6, 85] is observed. Where it was possible to determine enthalpies of transition for this transformation, these values (ΔH_1) are also listed in Table 1. The magnitude of the ΔH_2 values depends not only on the length and degree of saturation of the hydrocarbon chains, but also on the type of phospholipid head groups. As a comparison of the values for distearoyl phosphatidylethanolamine (DSPE) and distearoyl phosphatidylcholine (DSPC) listed in Table 1 shows, the T_m values of phosphatidylethanolamines (PEs) are greater and the ΔH_2 values are smaller than the corresponding values for phosphatidylcholines (PCs) having identical hydrocarbon chain lengths. This finding, which is reflected in the different values of methyl-group increments[84] of ΔH_2 values, indicates that the PE molecules are more closely packed than corresponding PC molecules in the liquid-crystalline phase because of a possible hydrogen-bond linkage of $NH_3^{\oplus}$ head-group components. For quantitative determination of the influence of the size of head groups, *Hinz* et al.[86] made calorimetric measurements on suspensions of different synthetically prepared glycolipids. It is remarkable that for the phospholipids with two different fatty acid chains largely present in biomembranes, a significant dependence of the ΔH_t values on the binding position of these fatty acid chains at the glycerol backbone is observed.[87] Since, for steric reasons, a line joining the three glycerol carbon atoms cannot run parallel to the surface of the bilayer, the effective number of methylene groups in the lipophilic zone is reduced by approximately two units (effective chain shortening effect). Based on this, a lipophilic zone with a largely regular arrangement of hydrocarbon chains with identical effective chain lengths results for MPPC. In contrast, the PMPC bilayer is characterized by a packing of hydrocarbon chains with different effective lengths, resulting in a lower ΔH_2 value. Finally, it should be noted that with the DSC method, the apparent molar heat capacities[88, 89, 95, 96] defined by Equation (11)

$$^{\Phi}C_p = \frac{C_{p,\text{mixture}} - n_{H_2O} \cdot C_{p,H_2O}}{n_{\text{lipid}}} \qquad (11)$$

can be determined and that information on the state of order of lipid molecules can also be derived from these apparent molar heat capacities.[90, 91, 95, 96] Contributions to the apparent molar heat capacities come not only from the excitation of internal degrees of freedom of the molecules, but also from interactions with the surrounding aqueous medium. The negative contributions come from the hydration of the polar groups and the change in the association structure of water[92] caused by hydration. Normally, additional positive $^{\Phi}C_p$ contributions can be attributed to the hydrophobic interaction of nonpolar groups with the bordering regions of the water structure.[93, 94]

8.2. Multicomponent Systems, Lipid–Protein Interaction, and Mixing and Titration Calorimetry

In the formal description of the mixing behavior of multicomponent lipid systems, the methods of classical phase thermodynamics can be used in largely unchanged form.[97] The phase diagrams can be obtained from DSC curves recorded for different mixing ratios.[9] In connection with lipid–protein interactions, the question concerning the state of order of lipid molecules in the immediate surrounding (annulus zone) of integrated membrane proteins is of particular interest.[98] Figure 9 shows, as an example, a set of DSC

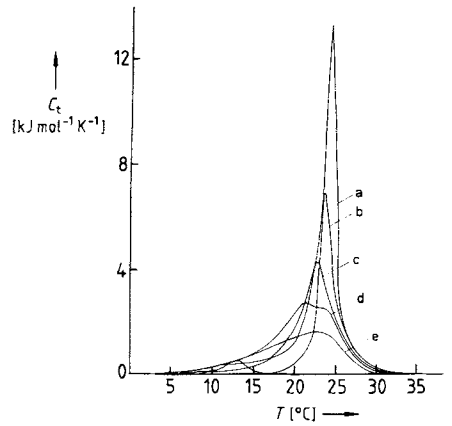

Fig. 9. DSC curve of DMPC–bacteriorhodopsin mixed-vesicle suspensions with the mixture proportions a) ∞, b) 552, c) 316, d) 188, e) 91 (taken from [99]).

curves of aqueous suspensions of vesicles[99, 100] formed from dimyristoyl phosphatidylcholine (DMPC) and bacteriorhodopsin for different values of the mixing ratio. From a comparison of simulated transition curves, based on a simple model, with experimentally determined transition curves, it can be concluded that the state of order of approximately 60 DMPC molecules is influenced by an intercalated bacteriorhodopsin molecule accompanied by a reduction of the individual ΔH_t values of these molecules (approximately 30%). Accordingly, an effective "order effect" beyond the immediate bordering zone can be attributed to the intercalated protein. Similar conclusions are drawn from measurements made in reaction and mixing calorimeters for the characterization of the phospholipid–melittin system.[9]

The investigation of reaction (12) exemplifies measure-

$$DMPA^{\ominus} + OH^{\ominus} \rightleftarrows DMPA^{2\ominus} + H_2O \qquad (12)$$

ments made with a mixing calorimeter.[32, 9] The reaction enthalpy ΔH_{diss} for the $DMPA^{\ominus}$ deprotonation reaction is obtained by subtracting the enthalpy of neutralization from the measured total reaction enthalpy when the dilution enthalpy of NaOH is eliminated by compensation in a twin calorimeter arrangement. From the graphical presentation of the temperature dependence of the ΔH_{diss} values (Fig. 10),

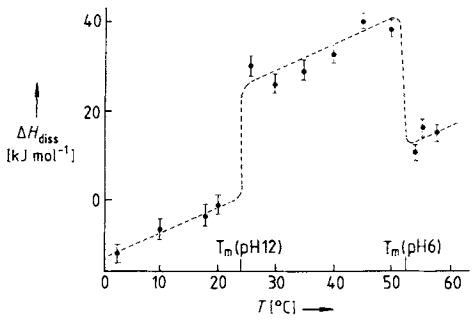

Fig. 10. Temperature dependence of the dissociation enthalpy for the second dissociation step of dimyristoyl phosphatidic acid [9].

three characteristic temperature areas can be recognized. For temperatures below 22 °C, in addition to deprotonation, a change in the angle of inclination of the fatty acid chains takes place (phase transition $L_\beta \rightarrow L_{\beta'}$) between 22 °C and 51 °C, the $L_\beta \rightarrow L_\alpha$ phase transition overlaps the deprotonation;[9] above 51 °C, the experimentally determined ΔH_{diss} values are nearly equal to the enthalpies of denaturation because, in this temperature range, the phase state of lipids does not change. These results are discussed in detail elsewhere.[9]

9. Summary

An opportunity to compare the magnitudes of the ΔH values of different important processes is provided by Table 2. The range of application of calorimetric methods for thermodynamic characterization of biopolymers and suspended lipids is also shown in this table.

Table 2. Magnitude of characteristic ΔH values for different types of structural transformations in biopolymer solutions and aqueous lipid suspensions.

Model substance	Process	Molecular subunit	ΔH [kJ mol^{-1}]	Ref.
Specific transfer ribonucleic acids	Denaturation of the secondary structure	tRNA molecule	1180	[44, 46]
Deoxyribonucleic acid	Double helix–random coil transformation	Base pair	35	[38, 39]
Polyriboadenylic acid	Base unstacking	Nucleotide residue	15	[10]
DNA and ethidium bromide (EB)	Reversal of the "intercalation"	EB molecule	20	[31]
Viroid	Denaturation of the secondary structure	CPFV molecule	3900	[50]
Poly(γ-benzyl-glutamate) in dichloroacidic acid/1,2-dichloroethane	α-Helix formation	Amino acid residue	4	[22]
$(Pro,Pro,Gly)_{15}$	Polyproline II helix-random coil transition	Amino acid residue	2	[10]
Poly(N^5-hydroxypropyl-L-glutamine)	α-Helix-random coil transition	Chain segment	0.5	[10]
Protein	Denaturation	α-Subunit of tryptophan synthase mutant (Ser 49) (M_r = 29000 g mol^{-1})	100	[10, 65, 70]
Phospholipid vesicle in aqueous suspension	Lipid phase transition: gel-liquid-crystalline	DPPC molecule	42	[83]
Phosphatidic acid	Deprotonation (second step)	DMPA molecule or ion	10	[9]

I wish to thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their support of our scien-

tific work. In particular, I would like to thank my former and present co-workers mentioned in the references for their tireless efforts and numerous helpful discussions.

Covalent versus Dative Bonds to Main Group Metals, a Useful Distinction

By Arne Haaland*

Textbooks of inorganic chemistry describe the formation of adducts by coordination of an electron donor to an electron acceptor, often using the amine-boranes, $X_3N \rightarrow BY_3$, as examples. In the Lewis (electron dot) formulas of the compounds, the dative bond in $H_3N \rightarrow BH_3$ and the covalent bond in H_3C–CH_3 are both represented by a shared electron pair. In the simple molecular orbital or valence bond models the wave functions of both electron pairs would be constructed in the same manner from the appropriate sp^3 type atomic orbitals on the bonded atoms: the difference between the covalent and the dative bond becomes apparent only after the orbital coefficients have been analyzed. This may be the reason why many structural chemists seem reluctant to distinguish between the two types of bonds. The object of this article is to remind the reader that the physicochemical properties of covalent and dative bonds may be – and often are – quite different, and to show that a distinction between the two provides a basis for understanding the structures of a wide range of main group metal compounds.

1. Introduction

In his book *The Nature of the Chemical Bond*, probably the most influential book of this century on structural chemistry, *Linus Pauling* classifies chemical bonds as electrostatic, covalent or metallic. In the subsection on covalent bonds in the introductory chapter he represents the bonding in trimethylamine oxide in the following way

1

and adds[1] that the N–O bond "may be considered a sort of double bond consisting of one single covalent bond and one ionic bond of unit strength. A bond of this type has sometimes been called a semipolar double bond. The name coordinate link has also been used, together with a special symbol $\rightarrow$ to indicate the transfer of electric charge from one atom to the other". "We shall not find it convenient to make use of these names or these symbols".

Other chemists have written or edited whole books on electron donor-acceptor adducts, e.g. *E. N. Guryanova* et al.,[2] *R. G. Pearson*,[3] and *V. Gutmann*.[4]

In this article we first discuss the structure of simple molecules containing covalent or dative bonds between atoms of Groups 15, 16 or 17 and metal atoms of Groups 2 and 12–14. Our aim is to bring together information – some of it new, some of it quite old – which highlights the different properties of covalent and dative bonds between the same atom pair, for instance Al and N or Zn and O. In particular we shall be concerned about bond distances. Secondly, we wish to show how the bond distances of intermediate magnitude found in more complicated, polynuclear species may be rationalized in terms of the magnitude of covalent and dative bonding contributions determined by enumeration of canonical forms with localized covalent and dative bonds.

[*] Prof. A. Haaland
Department of Chemistry, University of Oslo,
P.O. Box 1033, Blindern, 0315 Oslo 3 (Norway)

In most of the adducts that we shall discuss, both donor and acceptor are neutral molecules, but we shall include a few species where the donor is a halide ion or the acceptor is a molecular ion with charge +1. Even though solvation of ions like $Mg^{2\oplus}$ or $Al^{3\oplus}$,[5] "secondary bonding" as encountered for instance in the solid trihalides of the heavy Group 15 elements,[6] and hydrogen bonding[7] all involve electron donor acceptor interactions, they are not within the scope of this article.

2. Prototype Covalent and Dative Bonds: Ethane and Amine-borane

H_3C–CH_3 and $H_3N \rightarrow BH_3$ provide convenient prototypes for covalent and dative bonds: The two molecules are isoelectronic, and, at least on paper, one species may be converted into the other by transfer of one proton between the nuclei of the bonded atoms.

It has sometimes been said that "the only difference between a covalent and a dative bond is where you think the electrons come from": When H_3NBH_3 is formed from H_3N and BH_3 the two BN bonding electrons are provided by N, but, since H_3CCH_3 may be formed by coordination of $H_3C^{\ominus}$ to $^{\oplus}CH_3$, it would seem that a distinction between covalent and dative bonds is artificial.

However, regardless of how H_3CCH_3 and H_3NBH_3 have been formed, the molecules differ in the nature of the fragments obtained when the central bonds are broken:

Rupture of the dative bond in $H_3N \rightarrow BH_3$ yields either two species without net charge or spin (H_3N: and BH_3) or two species with both net charge and net spin ($H_3N^{\bullet\oplus}$ and $BH_3^{\bullet\ominus}$). Rupture of the covalent bond in H_3C–CH_3, on the other hand, yields either species with net spin ($H_3C^{\bullet}$) or species with net charge ($H_3C:^{\ominus}$ and $CH_3^{\oplus}$).

Minimum-energy rupture of the central bond in either molecule yields neutral species; rupture of the dative bond in $H_3N \rightarrow BH_3$ proceeds heterolytically, rupture of the covalent bond in H_3C–CH_3 proceeds homolytically.

Since the electron affinities of the halogen atoms are smaller than the ionization energies of the alkali metal

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0992 $ 02.50/0

atoms, minimum energy rupture of the bonds in the gaseous monomeric alkali halides—like the covalent bond in ethane—proceeds homolytically to yield neutral, radical species (atoms).

In the following we shall denote a bond in a neutral diamagnetic molecule as *normal* if minimum-energy rupture in the gas phase or in an inert solvent proceeds homolytically to yield neutral, radical species. The term covers both covalent and ionic bonds as well as bonds of intermediate polarity. We shall use this term rather than the word covalent when discussing very polar bonds and when we wish to make general statements.

We shall define a bond in a neutral, diamagnetic molecule as *dative* if minimum-energy rupture in the gas phase or in an inert solvent proceeds heterolytically to yield neutral, diamagnetic species. The category to which a bond belongs may then be determined experimentally or deduced from measureable quantities like ionization energies and electron affinities.

The C–C bond rupture enthalpy of ethane at 298 K is $\Delta H^0_{dis} = 89.8 \pm 0.5$ kcal mol^{-1}.[8] The bond rupture enthalpy of $H_3N \rightarrow BH_3$ may be estimated to the nearest kcal mol^{-1} from the dissociation enthalpies of seven methylated amine boranes listed in Table 1; $\Delta H^0_{dis}(H_3N \rightarrow BH_3) = 31.1$ $\pm$ 1.0 kcal mol^{-1}.[*] The strength of the prototype dative bond is thus one third the strength of the prototype covalent bond. The difference in bond strength is reflected in the bond distances (Table 2); the covalent C–C bond distance in ethane is 1.533(2) Å by GED[10] (gas electron diffraction); the dative N → B bond distance in H_3NBH_3 is 1.658(2) Å by MW[11] (microwave spectroscopy).[**]

Table 1. Gas phase dissociation enthalpies, ΔH^0_{dis} (in kcal mol^{-1}), of the donor–acceptor complexes of BH_3 and BMe_3 with H_3N and the methylamines $Me_nH_{3-n}N$, n = 1–3.

Donor \ Acceptor	BH_3	BMe_3 [21]
H_3N	31.1 ± 1.0 [a]	13.8 ± 0.3
MeH_2N	35.0 ± 0.8 [b]	17.6 ± 0.2
Me_2HN	36.4 ± 1.0 [b]	19.3 ± 0.2
Me_3N	34.8 ± 0.5 [b]	17.6 ± 0.2

[a] Estimated by us from the other entries in the Table. [b] Calculated from the standard enthalpies of the reactions $2\,Me_nH_{3-n}N \rightarrow BH_3(g) \rightarrow B_2H_6(g) + 2\,Me_nH_{3-n}N(g)$ [19] and the dissociation enthalpy of diborane [20].

While the dipole moment of ethane is, by virtue of its symmetry, zero, the dipole moment of H_3NBH_3[11] is 5.22 D as compared with 1.47 D for free NH_3.[8] The negative pole is undoubtedly at the acceptor. If the electron pair was shared equally between donor and acceptor atoms, corresponding to the transfer of one full electron, $H_3N^{\oplus}$–$B^{\ominus}H_3$, the bond dipole calculated from point charges would be 8.0 D. The observed dipole moment indicates that the electron pair remains more closely associated with the donor than with the acceptor atom.

Table 2. Comparison of the physicochemical data of compounds with covalent and dative bonds.

	H_3C–CH_3	$H_3N \rightarrow BH_3$	Me_3Si–$SiMe_3$	$Me_3P \rightarrow AlMe_3$
ΔH^0_{dis} [kcal mol^{-1}]	90	31 [a]	74 [15]	21 [17]
R [Å]	1.53	1.66	2.34 [16]	2.53(4) [18]
μ [D]	0	5.2		
M.p. [°C]	−183	124		

[a] See footnote to Table 1.

The gross atomic populations obtained by analysis of MOs obtained with a split valence basis indicate that adduct formation is accompanied by transfer of 0.20 $e^{\ominus}$ from N to B.[12] Somewhat surprisingly, the electron density on B appears to be slightly less in the adduct than in free BH_3; the acceptor atom appears to compensate for the acquired electron density by passing a slightly larger negative charge on to its substituent H atoms. Similarly, the donor atom N appears to compensate for the charge transfer to B by extracting a slightly larger negative charge from *its* substituent H atoms: the charge transferred from donor to acceptor originates at the substituents of the donor atom and ends up at the substituents of the acceptor atom. The reader may wonder about the effect of replacing the substituent H atoms on N or B with more or less electron-withdrawing atoms or groups. We shall return to this point in the following section.

H_3NBH_3 is a solid at room temperature. The melting point[13] is about 124 °C and it sublimes at 60 °C/0.001 torr.[14] The melting point of ethane is − 183 °C and the normal boiling point is − 89 °C.[8] The difference is undoubtedly due to strong intermolecular dipole-dipole attractions in the adduct.

Another pair of covalently/datively bonded molecules that are isoelectronic and related through transfer of one proton between the bonded nuclei is provided by Me_3Si–$SiMe_3$ and $Me_3P \rightarrow AlMe_3$ (Table 2). In this case the strength of the dative bond is less than a third of the strength of the covalent bond, and the bond distance is about 10% greater.

3. Inductive Effects

Comparison of the gas phase dissociation enthalpies of complexes of BH_3 and BMe_3 with the methylamines $Me_nH_{3-n}N$, n = 1–3 (Table 1), shows that replacement of three H atoms on the acceptor atom by three Me groups reduces the dissociation enthalpy by about 17 kcal mol^{-1}, i.e. by a factor of 1/2.

If the destabilization were due to increased strain following the introduction of the more voluminous Me groups, introduction of one or more Me groups on N in $H_3N \rightarrow BMe_3$ should lead to still greater destabilization. Instead, it is found that introduction of the first Me group on N *stabilizes* the complex by about 4 kcal mol^{-1} and the second by about 2 kcal mol^{-1}, while the third Me group leads to a small destabilization.

It might be argued that the low dissociation enthalpy of the BMe_3 adducts is the result of high reorganization energy, i.e. that it would take more energy to pyramidalize BMe_3 than BH_3. In fact the molecular force fields indicate that the

[*] This estimate is in reasonable agreement with the dissociation energy D_e obtained by SCF MO calculations with triple zeta plus polarization basis with electron correlation Møller-Plesset calculations to the fourth order, $D_e = 34.7$ kcal mol^{-1}. Correction for zero-point vibrational energies yielded $D_0 = 28.7$ kcal mol^{-1} [9].

[**] As we shall see in Section 9 a *covalent* N–B single bond distance may be estimated to be 1.47 Å, i.e. 0.19 Å shorter than the dative bond in $H_3N \rightarrow BH_3$.

deformation energy of BH_3 is higher than that of BMe_3.[22] We therefore interpret the strong destabilization produced by Me groups on the acceptor atom and the weak stabilization produced by Me groups on the donor atom as an inductive effect due to the greater electron-releasing tendency of the Me group.

If introduction of electron-releasing Me groups on the acceptor atom destabilizes the complex, introduction of electron withdrawing Cl atoms would be expected to stabilize it. As far as we know, the dissociation enthalpy of Me_3NBCl_3 has not been determined. However, the gas phase dissociation enthalpies of $py \rightarrow BMe_3$ (py = pyridine) and $py \rightarrow BCl_3$ are available for comparison. The former, 17 kcal mol^{-1},[23] is similar to that of $Me_3N \rightarrow BMe_3$, while the latter, 38 kcal mol^{-1} [24] is similar to that of $Me_3N \rightarrow BH_3$. In borane complexes the replacement of H atoms on B by Cl atoms appears to have little effect on the dissociation enthalpy.

It is normally assumed that bond distances may serve as indicators of bond strength with the shorter distance associated with the stronger bond. Indeed, the N–B bond distance in $Me_3N \rightarrow BMe_3$, 1.70 ± 0.01 Å by MW,[25] is significantly longer than the bond distances in $Me_3N \rightarrow BH_3$, 1.64 ± 0.01 Å by MW[26] and 1.656(2) Å by GED,[27] and $Me_3N \rightarrow BCl_3$, 1.659(6) Å[28] and 1.652(9) Å[29] by two independent GED studies.

It is noteworthy that the bond distance in $Me_3N \rightarrow BCl_3$ decreases by about 0.06 Å on going from the gaseous to the solid state: two independent crystal structure determinations have yielded N—B = 1.609(6) Å[30] and 1.575(11) Å.[31] Since donor–acceptor bonds are relatively weak, they are relatively easy to compress or elongate. The dipole moment of $Me_3N \rightarrow BCl_3$ in benzene is 6.28 ± 0.02 D.[32] In the crystals, nearest neighbors are aligned with antiparallel N → B vectors. This arrangement stabilizes greater charge transfer, i.e. a stronger dative bond. An early X-ray crystallographic study of our prototype adduct H_3NBH_3 yielded an N–B bond distance of 1.56 ± 0.05 Å,[33] which – although very inaccurate – suggests a shortening of 0.05 Å or more relative to the gas phase.

Before proceeding to allane complexes we pause to take note of H_3BCO, which appears to be the only carbonyl complex of a main group element that is stable under the conditions of normal temperatures and pressures. Molecular orbital calculations indicate that there is considerable back donation of BH bonding electrons into the antibonding CO π-orbital (hyperconjugation).[12] The B–C bond distance is 1.534(10) Å,[34] about 0.04 Å shorter than the covalent $B-C_{sp^3}$ bond distance in BMe_3,[35] and hence only 0.04 Å longer than estimated for a covalent $B-C_{sp}$ bond distance. The gas phase dissociation enthalpy, however, is only 18.8 kcal mol^{-1},[36] or about one fifth of the mean disruption enthalpy of the covalent B–C bonds in BMe_3.[15]

Alane complexes appear to be as sensitive to inductive effects as borane complexes: thus the gas phase dissociation enthalpy of $Me_3N \rightarrow AlCl_3$ is $\Delta H^0 = 47.5 \pm 2.0$ kcal mol^{-1} as compared to $\Delta H^0_{dis} = 30.7 \pm 0.3$ kcal mol^{-1} for $Me_3N \rightarrow AlMe_3$.[37] The bond strength difference is clearly reflected in the N → Al bond distances, 1.96(1) Å by X-ray diffraction in the chloro compound[38] versus 2.10(1) Å by GED in the methyl compound.[37] The dissociation enthalpy of $Me_3N \rightarrow AlH_3$ is unknown, but the N → Al bond distance, 2.063(8) Å by GED,[39] indicates that the compound more closely resembles the $AlMe_3$- than the $AlCl_3$-complex.

In their book on the donor-acceptor bond,[2] *Guryanova* and her coauthors list the dissociation enthalpies of about 700 complexes where both donor and acceptor atoms are main group elements. The entries cover complexes where the acceptor atom is a Group 12 element (Zn), a Group 13 element (B, Al, Ga and In), a Group 14 element (Sn), a Group 15 element (As and Sb) and a halogen atom (Br and I). The donor atoms are Group 15 elements (mainly N and P) and Group 16 elements (mainly O and S). The bond dissociation enthalpies range from 0.2 kcal mol^{-1} to nearly 50 kcal mol^{-1}. The strongest bonds to a given acceptor appear to be formed by N donors. The strongest bonds to a given donor appear to be formed by Al acceptors, followed by B and Ga. Starting with Group 13 the strength of the donor-acceptor bond appears to decrease with increasing group number of the acceptor atom. If the free acceptor carries only hydrocarbon substituents the dissociation enthalpy is less than or equal to 30 kcal mol^{-1} (as in $Me_3N \rightarrow AlMe_3$). If the acceptor atom carries more electronegative substituents, the dissociation enthalpy is higher, and may approach 50 kcal mol^{-1} (as in $Me_3N \rightarrow AlCl_3$). The strength of a donor–acceptor bond between main group elements may be as high as about half the strength of a covalent bond, but often it is much weaker.

4. Dative Bonds and the VSEPR Model

In Figure 1 we compare the structure of the free donor Me_3P[40] and the structure of the free acceptor $AlMe_3$[41]

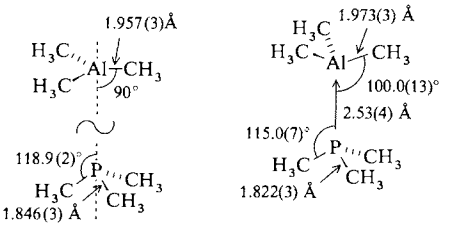

Fig. 1. Structural parameters of free Me_3P [40], free $AlMe_3$ [41] and the adduct $Me_3P \rightarrow AlMe_3$ [18].

with the structure of the adduct $Me_3P \rightarrow AlMe_3$.[18] In free $AlMe_3$ the metal atom is surrounded by three bond electron pairs and the coordination is trigonal planar in agreement with the VSEPR (*V*alence *S*hell *E*lectron *P*air *R*epulsion) model.

As the adduct is formed and a fourth electron pair is introduced (accepted), the Al–C bonds are bent back, and the C-Al-C angles are reduced from 120° to 113°. At the same time the bonds are slightly, but significantly, elongated from 1.957(3) Å to 1.973(3) Å. Both these changes are in the direction predicted from the VSEPR model. It should be noted, however, that after the adduct has been formed the C-Al-C angle remains greater than the tetrahedral angle 109.5°, suggesting that the spatial requirements of the covalent or normal bond pairs (NBP) are greater than the steric requirement of the accepted bond pair (ABP): NBP > ABP.

The P atom in Me_3P is surrounded by three covalent bond pairs (NBP) and one electron lone pair (LP). The structure is pyramidal, in agreement with the VSEPR model, and the C-P-C angle is less than tetrahedral, in agreement with the assumption that the spatial requirement of an LP is greater than that of a NBP.

As the adduct is formed and the lone pair is partially removed (donated), the C-P-C angles increase from 98.6(3)° to 103.4(8)°, and there is a slight but significant decrease in the P–C bond distances from 1.846(3) Å to 1.822(3) Å. Both these changes are in the direction predicted from the VSEPR model. After the adduct has been formed, however, the C-P-C angle remains less than tetrahedral, indicating that the spatial requirement of a donated electron bond pair (DBP) remains larger than that of a covalent bond pair: LP > DBP > NBP.

Similar changes in the structure of the donor have been observed in Me_3PBH_3[42] and Me_3PBCl_3.[43] When Me_3As forms a complex with BH_3 the As–C bond distance decreases from 1.968(3) Å[44] to 1.945 Å[45] and the C-As-C angle increases from 96.1(5)°[44] to 105°.[45]

The structures of the adducts of $AlMe_3$ and $AlCl_3$ with another donor, viz. Me_3N are shown in Figure 2. The structure of the acceptor ($AlMe_3$) in the adduct with Me_3N is very similar to the structure in the adduct with Me_3P and may be rationalized in the same manner. Monomeric $AlCl_3$ is trigonal planar in the gas phase with Al–Cl = 2.064(4) Å.[46] On formation of the adduct the Cl-Al-Cl angle is reduced from 120° to 114° and the Al-Cl bond distance increases to 2.121(4) Å; again the changes are those predicted from the VSEPR model.

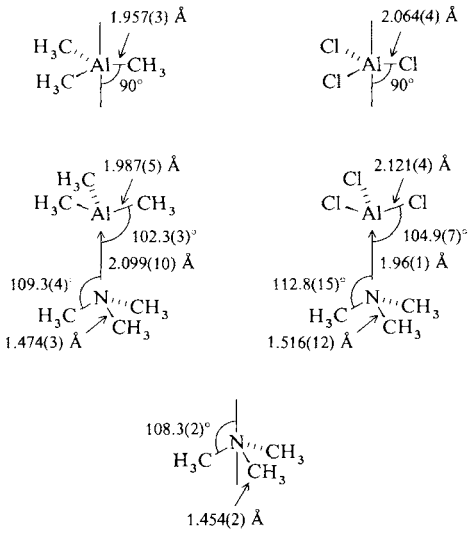

Fig. 2. Structural parameters of free $AlMe_3$ [41], free $AlCl_3$ [46], free Me_3N [47] and the adducts $Me_3N \rightarrow AlMe_3$ [37] and $Me_3N \rightarrow AlCl_3$ [48] (the Al–N bond length was determined X-ray crystallographically [38].

We now turn our attention to the structure of the donor: In free Me_3N the N atom is surrounded by three CBP and one LP. According to the VSEPR model the molecule should be pyramidal and the C-N-C angle less than tetrahedral. The C-N-C angle is, however, found to be slightly greater than tetrahedral, 110.6(6)° by GED[47] and 110.9(6)° by MW,[49] presumably because of steric repulsion between the Me groups. Formation of the adducts with $AlMe_3$ and $AlCl_3$ leaves the C-N-C angle unchanged or slightly decreased while the N–C bond distance *increases* from 1.454(2) Å in free NMe_3 to 1.473(3) Å in the complex with $AlMe_3$ and to 1.516(12) Å in the still stronger adduct with $AlCl_3$.

It appears that while the structural changes in Me_3P could be rationalized in terms of VSEPR, the structural changes in Me_3N on adduct formation are in the opposite direction and must be rationalized in terms of steric repulsion between the atoms and groups bonded to N.[*]

Consideration of steric repulsion between the ligands bonded to the acceptor atom (Al) leads to the prediction that Al–Y bonds should be elongated and Y-Al-Y angles reduced when the adduct is formed. On the acceptor atom VSEPR and steric interactions reinforce one another, on the donor atom they are opposed. When the donor atom is small (N or O), steric factors may prevail.

According to *Gutmann*'s rules on bond length variation,[4] adduct formation should always lead to elongation of bonds to both donor and acceptor atoms. This rule appears to be generally valid for bonds to the acceptor atoms, but is broken for bonds to the donor atom when Me_3P and Me_3As form adducts with boranes or allanes. We presume that it may be broken in other cases when the donor atom is large enough to make steric interaction between the substituents unimportant.

5. 2:1 Amine-Alane Complexes

Both $Me_3N \rightarrow AlH_3$ and $Me_2HN \rightarrow AlCl_3$ will add a second mole of the electron donor. The resulting coordination around Al is trigonal-bipyramidal with the donor atoms in axial positions as expected from the VSEPR model with the additional postulate that NBP > ABP.

The N → Al distances in the 2:1 adducts (Fig. 3) are considerably longer than in the 1:1 adducts, indicating saturation of the acceptor: in $(Me_2HN)_2AlCl_3$,[53] N → Al = 2.059(3) Å compared to 1.96(1) Å in Me_3NAlCl_3[38] (Fig. 2). In $(Me_3N)_2AlH_3$,[54, 55] N → Al = 2.18(1) Å compared to 2.063(8) Å in the 1:1 adduct. The N → Al bonds in

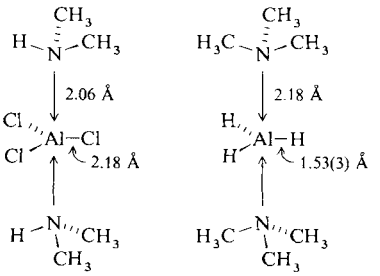

Fig. 3. The structural parameters of $(Me_2HN)_2AlCl_3$ [53] and $(Me_3N)_2AlH_3$ determined by X-ray diffraction [54] and gas-phase electron diffraction [55].

[*] This difference between N and P appears to be carried over to tetraalkylammonium and -phosphonium ions: The mean N–C bond distance in $[Me_4N]F \cdot 4\,H_2O$ is 1.499(2) Å [50], 0.04_5 Å *longer* than in free $(CH_3)_3N$, while the mean P–C bond distance in $[Me_4P][Cu_2Cl_3]$ is 1.779(3) Å [51], 0.06_7 Å *shorter* than in Me_3P. The average of 319 N–C* bond distances (C* = tetrahedral C atom carrying only C and H as additional substituents) in NC_4^+-type ammonium ions is 1.510 Å, 0.04_1 Å longer than the average of 1042 N–C bond distances in NC_3^+-type amines, while the average of 35 P–C* bond distances in C_3PC^*-type phosphonium ions is 1.800 Å, 0.04_5 Å shorter than the average of 23 bond distances in C_2PC^* phosphanes [52].

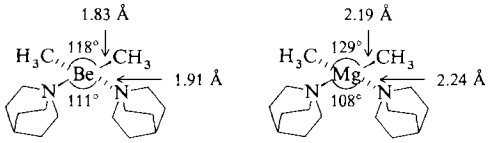
$(Me_2HN)_2AlCl_3$ are about 0.12 Å shorter than in $(Me_3N)_2AlH_3$, again indicating that $AlCl_3$ is a better acceptor than AlH_3. The N → Al bond distances in the 1:1 adducts indicate that $AlMe_3$ is a poorer acceptor than AlH_3; indeed Me_3NAlMe_3 will not add another mole of the base: it appears that 2:1 adducts are as sensitive to inductive effects as the 1:1 adducts.

Both VSEPR and steric considerations suggest that covalent Al–Y bonds should be further elongated on addition of the second donor. Indeed, in $(Me_2HN)_2AlCl_3$, Al–Cl = 2.180(1) Å[53] as compared to 2.121(4) Å in Me_3NAlCl_3.[48]

We are not aware of any observation indicating the existence of 2:1 amine-borane adducts.

6. Some Adducts of Beryllium, Magnesium, Zinc, and Mercury

Quinuclidine forms 2:1 adducts with both dimethylberyllium and dimethylmagnesium. The coordination geometries around the metal atoms as determined by X-ray crystallography[56, 57] are shown in Figure 4.[*] The main features are



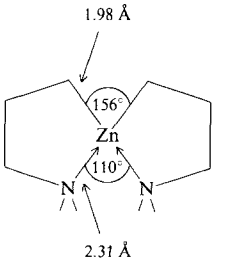


Fig. 4. Structural parameters of the 2:1 adducts of quinuclidine with $Be(CH_3)_2$ and $Mg(CH_3)_2$ [56, 57].

in agreement with the principles already outlined: $BeMe_2$ is linear in the gas phase with R(Be–C) = 1.70 Å;[58] coordination of two donor atoms decreases the C-Be-C angle to 118° and increases Be–C to 1.83 Å. In monomeric, base-free bisneopentylmagnesium the C-Mg-C angle is 180° and R(Mg–C) = 2.13 Å;[59] in the $MgMe_2$ adduct the values are 129° and 2.19 Å.

In each complex the metal atom is surrounded by two covalent electron bond pairs and two accepted bond pairs; the structure is distorted tetrahedral. Even though the datively bonded quinuclidine ligands are more bulky than the covalently bonded Me groups, the C-M-C angles are considerably larger than the N-M-N angles, in agreement with the postulate that NBP > ABP.

The interaction enthalpy between 2,2′-bipyridine and dimethylzinc in toluene is 17.6 kcal mol^{-1}.[60] Since 2,2′-bipyridine presumably acts as a bidentate ligand, this corresponds to a mean N → Zn dissociation enthalpy of 9 kcal mol^{-1}. The Zn–N bonds in the amides $Zn[N(SiMe_3)_2]_2$ are assumed to be single bonds with negligible π-components.[61] The bond energy term[62] is 49 kcal mol^{-1}, i.e. the strength of the covalent bond appears to be four or five times that of the dative bond.

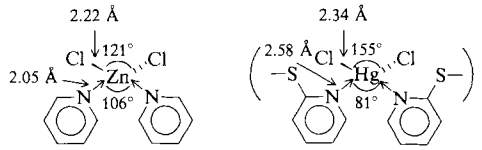
We are not aware of the structure of any simple adduct between a dialkylzinc and an N-centered donor, but the structure of $Zn[(CH_2)_3N(CH_3)_2]_2$ **2** has been determined by

2

both X-ray and GED.[63] The Zn–C bonds are about 0.05 Å longer than in dipropylzinc,[64] the dative N → Zn bonds are 0.50 Å longer than the covalent Zn–N bonds in $Zn[(NSiMe_3)_2]_2$.[61] The weakness of the donor–acceptor interaction is indicated by the large C-Zn-C valence angle and the large N → Zn r.m.s. vibrational amplitude found in the GED study, l = 0.17(3) Å, two or three times greater than the amplitude of the Zn-C bond. The donor–acceptor bonds appear to be about 0.08 Å shorter in the solid phase than in the gas phase.

The structure of the 2:1 complex of pyridine with $ZnCl_2$[65] is shown in Figure 5. The N → Zn bond distance is about 0.25 Å *longer* than the covalent bond distance in $Zn[N(SiMe_3)_2]_2$ but 0.25 Å shorter than the N → Zn bond in **2**; the latter difference is presumably an inductive effect. The Zn–Cl bond is 0.15 Å longer than in gaseous monomeric $ZnCl_2$.[66]

In Figure 5 we also show the coordination sphere of the mercury atom in the related adduct of bis(2-pyridyl) disulfi-



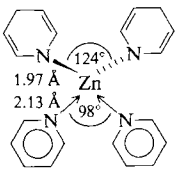


Fig. 5. Structural parameters of $ZnCl_2 \cdot 2$ pyridine [65] and $HgCl_2 \cdot$ bis(2-pyridyl) disulfide [67] in the crystal.

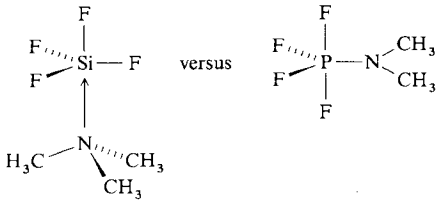
de with $HgCl_2$ in the solid phase.[67] Mercury compounds are known as poorer acceptors than their zinc analogues. The weakness of the interaction is indicated both by the large N → Hg bond distance, more than 0.50 Å longer than the covalent Hg–N bond in the amide $Hg[N(SiMe_3)_2]_2$,[68] and by the large Cl-Hg-Cl angle. The valence angles at the Hg atom are such that a description in terms of sp-hybridization with electron donation into pure p-orbitals may be more appropriate than a discussion in terms of sp^3-hybridization. The elongation of the Hg–Cl bond compared to that in gaseous monomeric $HgCl_2$ is 0.09 Å.[69]

The most interesting N → Zn adduct may be bis(1,4-dihydropyridin-1-yl)-bis(pyridine)zinc, **3**, which is formed from

3

ZnH_2 and four moles of pyridine.[70, 71] In this complex we see for the first time the difference between covalent and dative bonds between the same atom pair demonstrated in the same molecular unit.

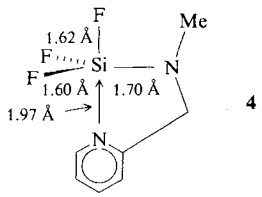


The covalent Zn–N bonds are about 0.15 Å longer than in $Zn[N(SiMe_3)_2]_2$: this elongation is similar to the elongation

[*] In the following we omit estimated standard deviations of less than 0.01 Å or 1°.

of the bonds in $ZnCl_2$ on coordination of two pyridine molecules. The covalent Zn–N bonds in **3** are, however, still 0.16 Å shorter than the dative bonds. The bulks of the four ligands are very nearly equal, and, as expected from VSEPR considerations, the angle subtended by the covalently bonded N atoms (124°) is considerably larger than that subtended by the datively bonded N atoms (98°).

7. Some Adducts of Silicon

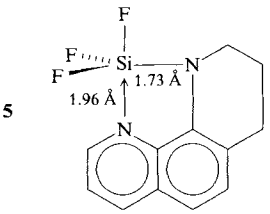


The 1:1 adducts of SiF_4 with the amines $Me_nH_{3-n}N$, n = 0,1,2,3, in argon matrices have been investigated by infrared spectroscopy.[72, 73] The coordination around Si was found to be trigonal bipyramidal with the amine occupying an axial position. A structural chemist has commented:[74] "This conclusion is remarkable. Of the huge range of five-coordinate derivatives known of P and S, all examples with only monodentate groups have the axial sites occupied by the most electronegative ligand...". In other words, why does the N atom in Me_3NSiF_4 occupy an axial position when the N atom in Me_2NPF_4[75] is equatorial (Scheme 1)?

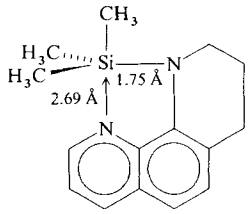
Scheme 1. Structures of Me_3NSiF_4 and Me_2NPF_4.

We suggest that the contradiction is removed if a distinction is made between covalently bonded ligands (F and NMe_2) and datively bonded ligands (NMe_3). If the distinction is made, VSEPR considerations combined with the postulate NBP > ABP lead to the observed structures for both molecules.

The crystal structure of 2-{[methyl(trifluorosilyl)amino]-methyl}pyridine **4** shows that the coordination of Si is trigo-



4



nal bipyramidal.[76] Two F atoms and the covalently bonded amide N atom occupy the equatorial sites, while the axial sites are occupied by the third F and the datively bonded pyridine N atom. The Si–F_{eq} and Si–F_{ax} distances are very similar, 1.603(4) Å and 1.621(5) Å, respectively. The equatorial Si–N distance is 1.70 Å, a normal value for a covalent Si–N bond, the dative, axial N → Si distance is 1.97 Å.

^{19}F-NMR spectra show that axial and equatorial F atoms undergo rapid exchange at room temperature.[76] There is evidence that the exchange proceeds via dissociation of the dative N → Si bond followed by rotation of the SiF_3 group and recoordination of the pyridine N atom. The activation energy (13.2(9) kcal mol^{-1}) determined by line shape analysis[76] is then the sum of the N → Si bond dissociation enthalpy and the barrier to rotation of the SiF_3 group in the uncoordinated intermediate.

Comparison of the axial N → Si bond distances found in the crystal structures of the related compounds **5**[77] and **6**[78] indicates that the dative N → Si bonds are even more

5

6

sensitive to inductive effects than N → Al or N → B bonds: replacement of three F atoms on Si by three Me groups increases the dative N → Si bond distance by 0.73 Å!

The covalent Si–N bond distance appears to increase by 0.02 Å on going from **5** to **6**, but the combined uncertainty is so large that it is doubtful whether the difference is real. A more accurate estimate of the effect on covalent bond distances when three F are replaced by three Me groups, is obtained by comparing the Si–F bonds in SiF_4[79] and Me_3SiF[80] and the Si–C bonds in $MeSiF_3$[80] and Me_4Si:[81] in both cases the bond distances increase by 0.05 Å. The difference between the N → Si bonds in **5** and **6** is thus more than an order of magnitude greater than the elongation expected for covalent bonds.

8. Influence of the Donor Atom and Net Charge

8.1. A Comparison of Donor Atoms

Trimethylaluminum forms stable complexes with a wide range of electron donors. Some D → Al bond distances and gas phase dissociation enthalpies [Eq. (a)] are listed in Table 3.

$$D \rightarrow AlMe_3(g) \rightarrow D(g) + AlMe_3(g) \qquad (a)$$

Table 3. Al–D bond lengths and gas phase dissociation enthalpies of some complexes of $AlMe_3$ and electron donors D.

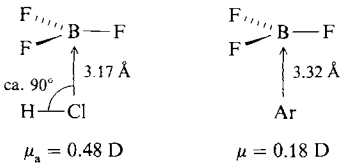
Donor D	R [Å]	ΔH^0_{dis} [kcal mol^{-1}]
Me_3N [37]	2.10	31
Me_3P [17, 18]	2.53(4)	23
Me_2O [17, 82]	2.01(2)	22
Me_2S [83, 84]	2.55(2)	18
Me_2Se [85]	–	16

Complexes of trimethylaluminum with alkyl fluorides or chlorides have not been isolated; the donor–acceptor interaction is obviously not strong enough to compensate for the enthalpy required to produce one mole $AlMe_3$ by dissociation of the dimer, viz. 10 kcal mol^{-1}.[83] It should be noted, however, that Et_3SiF forms a stable complex with $AlEt_3$.[86] The enthalpy required to break the dative F → Al bond is

obviously greater than the enthalpy gained by dimerization of one mole of Et_3Al (9 kcal mol^{-1}[87]).

BH_3 will only form complexes with electron donors in those cases when the donor–acceptor interactions are strong enough to compensate the diborane dissociation enthalpy. No such limitations exist for BF_3 which is monomeric. Gas phase dissociation enthalpies are available for the complexes with Me_3N, Me_2O, Me_3P and Me_2S and the structures of the former two have been determined by GED (Table 4).

Table 4. B–D bond lengths and gas phase dissociation enthalpies of some complexes of BF_3 and electron donors.



Donor D	R [Å]	ΔH^0_{dis} [kcal mol^{-1}]
Me_3N [88, 89]	1.67	27
Me_3P [92]	–	19
Me_2O [90, 91]	1.75(2)	13
Me_2S [93]	–	4

The enthalpy ΔH^0_r of reaction (b) is equal to the sum of

$$D \rightarrow BF_3(s) \rightarrow D(g) + BF_3(g) \qquad (b)$$

the sublimation and dissociation enthalpies. The experimental values are[94] 45 kcal mol^{-1} for $D = Me_3P$ and 20 kcal mol^{-1} for $D = Me_3As$. Subtraction of the dissociation enthalpy of Me_3PBF_3 from the value for Me_3P yields a sublimation enthalpy of 26 kcal mol^{-1} for the adduct. Since the sublimation enthalpy of Me_3AsBF_3 is expected to be greater than that of the P-analogue, it follows from the value $\Delta H^0_r = 20$ kcal mol^{-1} for Me_3As that the dissociation enthalpy of the As-adduct is *negative* (less than -6 kcal mol^{-1}). It seems that in this case intermolecular forces in the crystal are sufficient to stabilize an adduct where the donor–acceptor interaction is repulsive in the gas phase!

The structures of the adducts $HClBF_3$[95] and $ArBF_3$[96] have been determined by microwave spectroscopy (Scheme 2).

Scheme 2. Structural parameters of $HClBF_3$ and $ArBF_3$.

These species are commonly regarded as van der Waals complexes, but may also be described as weak donor–acceptor adducts. Comparison of the Ar → B and Cl → B bond distances, and comparison of the dipole moment of $ArBF_3$ with the dipole moment component μ_a along the Cl → B bond in $HClBF_3$, indicates that Ar is the weaker donor. HCl and Ar are isoelectronic; on paper, HCl may be formed from Ar by withdrawing one proton from the nucleus. The reader may wonder what effect it would have on the donor–acceptor interaction if the proton was completely removed to leave $[ClBF_3]^{\ominus}$. We shall return to such species in Section 8.3.

We have already pointed out that the strongest dative bonds to a given main group acceptor atom are formed by N donors. Beginning with Group 15 the strength of the donor–acceptor bond appears to decrease with increasing group number of the donor atom. With B and Al acceptors the strength of the interaction decreases monotonically with increasing principal quantum number of the valence electrons of the donor atom, but this does not appear to be true for all acceptors.

8.2. Cationic Complexes

Since the introduction of electron-withdrawing substituents on the acceptor atom often leads to a significant increase in the dissociation enthalpy of a donor–acceptor adduct, it is hardly surprising that cationic acceptors form stronger dative bonds than related neutral molecules.

The tetramethyl derivatives of Si, Ge or Sn do not appear to interact with electron donors. Introduction of a Cl atom on Sn leads to the formation of a stable 1:1 adduct with pyridine, the dissociation enthalpy in benzene being 11.0 ± 1.0 kcal mol^{-1}.[97] The interaction enthalpies of Me_3SiCl or Me_3GeCl with pyridine in the same solvent are, however, of the order of -2 kcal mol^{-1} or less.[97]

In striking contrast the dissociation enthalpies of the adducts of the cations $Me_3M^{\oplus}$ with the donor H_2O determined by high pressure mass spectrometry are 30.1 ± 1.9 kcal mol^{-1} for M = Si,[98] 28.6 ± 0.5 kcal mol^{-1} for M = Ge,[99] and 25.7 ± 1.0 kcal mol^{-1} for M = Sn.[100][*]

When $Me_3M^{\oplus}$ is formed from Me_4M by removal of $CH_3^{\ominus}$, a coordination site becomes vacant both in a steric sense since the coordination number has been reduced from four to three, and in an electronic sense since the number of electrons in the valence shell of M has been reduced from eight to six. At the same time the formal charge on the metal atom has increased from zero to +1.

Me_3Al, Me_3Ga and Me_3In are isoelectronic and isoleptic with $Me_3M^{\oplus}$, M = Si, Ge and Sn respectively. Comparison of the dissociation enthalpies of related adducts (Table 5) shows that the introduction of a unit positive charge on the acceptor atom doubles or triples the dissociation enthalpy. Comparison of the dissociation enthalpies of $Et_2O \rightarrow GaMe_3$, $Et_2O \rightarrow GaCl_3$ and $[H(Me)O \rightarrow GeMe_3]^{\oplus}$ indicates that in this series the stabilization accompanying the introduction of a net positive charge on the acceptor is twice as large as the stabilization accompanying the introduction of three electron-withdrawing Cl atoms.

The dissociation enthalpies in Table 5 also show that replacement of an H on the donor atom with a more electron-releasing methyl group invariably leads to stabilization of the adduct, and that the first methyl group introduced has the largest stabilizing effect.

Before we go any further, we note that while the acceptor ability of the cations $Me_3M^{\oplus}$ decreases in the order

[*] In the absence of evidence to the contrary we assume that low-energy rupture of M–O bonds in $[H_2OMMe_3]^{\oplus}$ would proceed heterolytically to yield H_2O and $Me_3M^{\oplus}$, i.e. that the O–M bond is dative according to the definition given above.

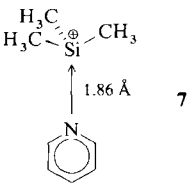


Table 5. Gas phase dissociation enthalpies, ΔH^0_{dis} of cationic and neutral donor–acceptor adducts.

Donor	Acceptor	ΔH^0_{dis} [kcal mol^{-1}]
H_2O	$Me_3Si^{\oplus}$ [98]	30.1 ± 1.9
MeOH	$Me_3Si^{\oplus}$ [98]	39.2
EtOH	$Me_3Si^{\oplus}$ [98]	42.0
Et_2O	$Me_3Si^{\oplus}$ [98]	44.2
Et_2O	Me_3Al [a]	20.2 ± 0.2
H_2O	$Me_3Ge^{\oplus}$ [99]	28.6 ± 0.5
MeOH	$Me_3Ge^{\oplus}$ [99]	35.0
Et_2O	Me_3Ga [101]	12.1 ± 0.2
Et_2O	Cl_3Ga [102]	26.6
H_2O	$Me_3Sn^{\oplus}$ [100]	25.7
MeOH	$Me_3Sn^{\oplus}$ [100]	32.6 ± 1.0
NH_3	$Me_3Sn^{\oplus}$ [100]	36.9
$MeNH_2$	$Me_3Sn^{\oplus}$ [100]	42.1
Me_2NH	$Me_3Sn^{\oplus}$ [100]	44.2
Me_3N	$Me_3Sn^{\oplus}$ [100]	45.6
Me_3N	Me_3In [103]	19.9 ± 0.5

[a] in hexane [17].

$Si^{\oplus} > Ge^{\oplus} > Sn^{\oplus}$, the normal order for neutral molecules is considered to be Sn > Ge > Si.[97]

Both $Me_3Si^{\oplus}$ and $Me_3Ge^{\oplus}$ may be prepared in solution.[104, 105] The structure of **7**, the adduct of $Me_3Si^{\oplus}$ with pyridine, has been determined by X-ray diffraction.[106] The

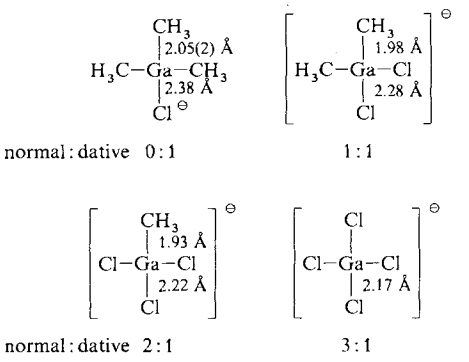
7

mean Si–C distance is not significantly different from the mean Si–C distance in the neutral five-coordinate complex **6**, but the dative N → Si distance is more than 3/4 Å shorter: again we find that the dative bond is more susceptible to inductive/charge effects than covalent bonds. It may be noted that even the very short dative bond in **7** is 0.11 Å longer than the covalent, equatorial Si–N bond in **6**.

8.3. Anionic Complexes

We now turn our attention to adducts where the donor is a negatively charged, monatomic ion. The structure of the anion of $[Me_4As][Me_3GaCl]$ is distorted tetrahedral with a mean Cl–Ga–C angle of 103° and a mean C-Ga-C angle of 115°.[107] The mean Ga–C bond distance (2.05(2) Å) is not accurately determined, but appears to be 0.08(2) Å longer than in free Me_3Ga[108] and 0.05(2) Å longer than in the adduct Me_3NGaMe_3.[109] The Ga–Cl distance (2.38 Å) is 0.28 Å longer than the terminal bond distance in Ga_2Cl_6 (2.10 Å),[110] which may serve as a reference value for a single normal Ga–Cl bond. If it is assumed that the electron affinity of Cl is greater than that of Me_3Ga, it follows that minimum-energy rupture of the Ga–Cl bond in $[Me_3GaCl]^{\ominus}$ would proceed heterolytically to yield Me_3Ga and $Cl^{\ominus}$, i.e. that the Ga–Cl bond is dative, Ga ← $Cl^{\ominus}$, according to our definition. In the following we adopt this description which is in good agreement with the observed bond distances and angles.

In Figure 6 we compare the average bond distances in the ions $[Me_{4-n}GaCl_n]$ (n = 1–4).[107, 111, 112] The two Ga–Cl bond distances in $[Me_2GaCl_2]^{\ominus}$ are indistinguishable, the



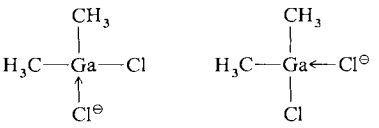


Fig. 6. Average Ga–C and Ga–Cl bond distances in the ions $[(CH_3)_{4-n}GaCl_n]^{\ominus}$ (n = 1, 2, 3 or 4) as determined by X-ray diffraction with $[Me_4As]^{\oplus}$ or $[Me_4Sb]^{\oplus}$ as counterion [107, 111, 112] and the ratio of covalent to dative contributions to the Ga–Cl bonds.

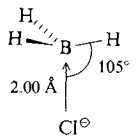
mean value (2.28 Å) is 0.10 Å shorter than the Ga ← $Cl^{\ominus}$ bond distance in $[Me_3GaCl]^{\ominus}$ and 0.18 Å longer than the terminal Ga–Cl distance in Ga_2Cl_6.[110] The bonding may be described in terms of the canonical forms **A** and **B**, where the

Ga atom forms three normal and one dative bond in each. Delocalization (resonance) would yield equal contributions of dative Ga ← $Cl^{\ominus}$ and normal Ga–Cl bonding to each of the two Ga–Cl bonds in the real ion. We note that the observed Ga–Cl distances are reasonably close to the mean of dative Ga ← $Cl^{\ominus}$ and normal Ga–Cl bond distances [(2.10 Å + 2.38 Å)/2 = 2.24 Å] and choose, therefore, to describe the Ga–Cl bonds as intermediate between pure normal and pure dative bonds. This description is consistent with the expected fragmentation behavior of the ion; one Ga–Cl bond (the first) is expected to yield Me_2GaCl and $Cl^{\ominus}$, the other (the second) to yield Me_2Ga and Cl.



Similarly, the bonding in $[MeGaCl_3]^{\ominus}$ may be discussed in terms of three canonical forms, each with three normal Ga–C or Ga–Cl bonds and one dative bond (Ga ← $Cl^{\ominus}$). Delocalization yields normal to dative bonding contributions equal to 2:1, and the Ga–Cl bond distance in the real ion may be estimated from (2 × 2.10 Å + 3.28 Å)/3 = 2.19 Å, versus an observed value of 2.22 Å.

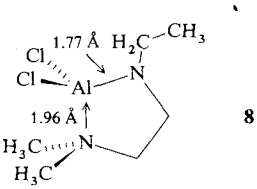
Finally, the Ga–Cl bonds in $[GaCl_4]^{\ominus}$ may be described in terms of 3:1 contributions of normal and dative bonding, and the bond distance estimated from (3 × 2.10 Å + 2.38 Å)/4 = 2.17 Å, equal to the observed value.

All things considered, we feel that the agreement between estimated and observed Ga–Cl bond distances is as good as can be expected for a linear, two-parameter model. If

the standard bond distances $R(Ga-Cl) = 2.12$ Å and $R(Ga \leftarrow Cl^{\ominus}) = 2.40$ Å had been chosen, the four bond distances in Figure 6 and the terminal bond distance in Ga_2Cl_6 would all have been predicted with a deviation of 0.02 Å or less.

The crystal structure of $[Ph_3PNPPh_3][ClBH_3]$ has recently been determined by both X-ray and neutron diffraction (Scheme 3).[113] The $[ClBH_3]^{\ominus}$ ion is pyramidal with a mean B–H bond distance of 1.20 Å and a Cl-B-H angle of 105°.

Scheme 3. Structural parameters of $[ClBH_3]^{\ominus}$.



The authors remark: "The observed bonding parameters are quite normal, except that the B–Cl distance on the anion is anomalously long", and add that this "can be ascribed to incorporation of approximately 19% $(B_2H_7)^{\ominus}$ into the $(ClBH_3)^{\ominus}$ site".

We would suggest that the observed bond distance of 2.00 Å may be quite appropriate for a dative bond from $Cl^{\ominus}$ to B: the difference of 0.38 Å between the dative Ga–Cl bond in $[Me_3GaCl]^{\ominus}$ and the B–Cl bond in $[ClBH_3]^{\ominus}$ corresponds to the difference in the bonding radii of Ga and B. SCF MO calculations on $[ClBH_3]^{\ominus}$ with a 6-31G* basis set yields an optimum structure close to the experimental, and a binding energy relative to BH_3 and $Cl^{\ominus}$ of 19.9 kcal mol^{-1}.[114] In the complex $HCl \rightarrow BF_3$ (see Section 8.1) the B–Cl bond distance was 3.17 Å; as expected $Cl^{\ominus}$ is a better electron donor than HCl.

The covalent B–Cl bond distance in BCl_3 is 1.74 Å.[115] The $[BCl_4]^{\ominus}$ ion in $[NS_2Cl_2][BCl_4]$ is slightly distorted tetrahedral with all B–Cl bond distances close to the mean value of 1.84 Å.[116] Since B, like Ga, can form three covalent bonds to Cl and one dative bond to $Cl^{\ominus}$, delocalization yields covalent to dative bonding contributions equal to 3:1. The estimated bond distance $[(3 \times 1.74\ Å + 2.00\ Å)/4 = 1.83\ Å]$ is in good agreement with the observed value.

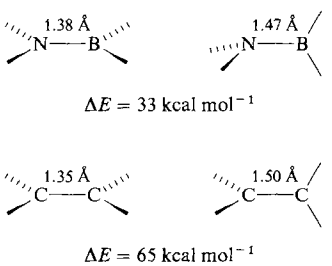
9. Covalent Al–N, Al–O and B–N Bond Distances

The two Al–N bond distances in **8** differ by 0.19 Å.[117] The longest bond, from Al to the four-coordinate N atom, has the same length as the Al–N bond in $Me_3N \rightarrow AlCl_3$ and

8

must be described as a dative bond. About the shorter bond, from Al to the three-coordinate N atom, the authors write: "It has previously been suggested that aluminum-nitrogen bonds that fall at about 1.78 Å are in effect double bonds, with dative nitrogen lone pair to aluminum 3d π-donation,...". We note that the Al–N bond distance calculated from the modified Schomaker-Stevenson (MSS) rule [Eq. (c)][118] is 1.77 Å, and suggest that the shorter Al–N bond should be described as a single covalent bond.

$$R(A-B) = r_A + r_B - 0.085|\chi_A - \chi_B|^{1.4} \qquad (c)$$



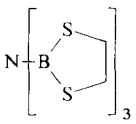
The trisamide $Al[N(SiMe_3)_2]_3$ is monomeric with trigonal planar configuration at Al and $R_{Al-N} = 1.78(2)$ Å.[119] In this species, where Al is tricoordinate, the Al–N bonds may be shortened by dative π-bonding. Comparison with the bond distance quoted above indicates that the effect is modest.

Aluminum trisisopropoxide $Al(OiPr)_3$ is tetrameric in the solid phase.[120] The central Al atom is connected to three terminal Al atoms through double alkoxide bridges. Each terminal Al atom is surrounded by two bridging and two terminal isopropoxide groups. The terminal Al–O distances (1.71 Å) are in good agreement with the covalent bond distance calculated according to the MSS rule[118] (1.72 Å). This covalent bond distance is 0.30 Å shorter than the dative $O \rightarrow Al$ bond distance in $Me_2O \rightarrow AlMe_3$ (2.01(2) Å).

The structure of the monomeric aminoborane, H_2NBH_2, generated by pyrolysis of diborane and ammonia at 500 °C, has been determined by MW spectroscopy.[121] The molecule has a planar ethene-like structure with a N–B bond distance of 1.391(2) Å. This bond may be described as having partial double bond character; a covalent σ-bond plus a dative π-bond. What is the effect of the π-bonding on the bond distance? The author of a recent review[122] surveyed the (dative) bond distances in amine–boranes and adopted N–B = 1.58 Å as reference value for a single (covalent) bond distance. This value would indicate that dative π-bonding in H_2NBH_2 shortens the BN distance by 0.19 Å, which is similar to the difference between single and double CC bond distances.

If the *dative* bond distance in an amine–borane is to serve as expectation value for a single *covalent* bond distance in H_2NBH_2, the logical choice would be the bond distance in H_3NBH_3, B–N = 1.66 Å.[11] Adoption of this value indicates that dative π-bonding in H_2NBH_2 shortens the BN bond by 0.27 Å, which is considerably more than the difference between single and double CC bond distances.

The bonding in H_2NBH_2 has been studied by *ab initio* molecular orbital calculations with a double zeta (DZ) basis (Scheme 4).[123] Complete structure optimization yielded an



Scheme 4. Calculated structural parameters for planar and orthogonal H_2NBH_2 and C_2H_4.

equilibrium B–N bond distance of 1.378 Å, in good agreement with the experimental value. When the π-bond is broken by twisting the BH_2 fragment through 90° into an orthogonal form, the B–N bond distance increases to 1.469 Å and the configuration at N becomes pyramidal.

The energy of this relaxed orthogonal form is 33.3 kcal mol^{-1} above the energy of the planar equilibrium structure. This energy difference appears reasonable when compared to the barrier to internal rotation in $Me_2NBMePh$ obtained by line shape analysis of ^1H NMR spectra, 26.3 kcal mol^{-1}.[124]

MCSCF calculations on the planar and orthogonal forms of ethene[125] (Scheme 4) yield a π-bond energy of 65 kcal mol^{-1}, in good agreement with experimental estimates. It appears that the dative π-bond energy in H_2NBH_2 is about half the covalent π-bond energy in ethene. The C–C distance in the orthogonal form of ethene is that expected for a single bond between two sp^2 hybridized carbon atoms.

In the trisborylamine **9** one B_2N–BS_2 fragment adopts an orthogonal conformation, presumably for steric rea-

9

sons.[126] The corresponding B–N bond distance is 1.47 Å, in agreement with the theoretical value. In the following we shall adopt this as a standard value for a single covalent B–N bond distance. If this value is accepted, it follows that π-bonding shortens the B–N bond in H_2NBH_2 by about 0.07 Å, a third of the difference between single and double CC bond distances.

Coordination of an increasing number of π-donors (amido groups) to the same π-acceptor (B), would be expected to lead to saturation effects. Indeed, the BN bond distance in $B(NHMe)_3$ is 1.432(2) Å.[127, 128]

Hexagonal boron nitride (α-BN) has a graphite-like structure consisting of parallel, planar BN sheets.[129] Each B and N are trigonal planar, the B–N bond distance is 1.446 Å, and the perpendicular distance between the layers is 3.30 Å as compared to 3.35 Å in graphite. The B–N bond distance is slightly, but significantly, longer than in $B(NHMe)_3$, perhaps because each N atom is coordinated to three π-acceptors rather than one.

According to *Gmelins Handbook of Inorganic Chemistry*:[129] "Die Natur der B–N-Bindung ist umstritten. Einerseits ähnelt die BN-Struktur weitgehend der Graphitstruktur, die Bindungslängen C–C und B–N sind nur wenig voneinander verschieden, und die zwischenatomaren Kräfte beider Substanzen liegen in der gleichen Größenordnung." "Die BN-Bindungslänge in der Schichtebene beträgt 1.446 Å und ist damit sehr viel kürzer als die Summe der kovalenten Radien bei Einfachbindung (1.57 Å)". "Es liegt also nahe, für BN eine Resonanzstruktur wie in Graphit anzunehmen. Andererseits weichen gewisse Eigenschaften des BN stark von denen des Graphits ab. So hat BN eine geringe elektrische Leitfähigkeit, ist farblos, und seine diamagnetische Suszeptibilität ist gering, während die des Graphits abnorm groß ist. Diese Eigenschaften des BN lassen sich durch das Vorhandensein von Einfachbindungen erklären."[*]

We note that the B–N bond distance in α-BN is in fact close to our estimate of a covalent single bond distance, 1.45 Å vs 1.47 Å; the contradiction has been removed.

A rough estimate of the strength of a single covalent B–N bond may be obtained by calculating the energy of atomization of hexagonal boron nitride (at 25 °C) [Eq. (d)][130]

$$\Delta E^0_{at}(BN,hex) = \Delta H^0_f(B,g) + \Delta H^0_f(N,g) - \Delta H^0_f(BN,hex) - 2\,RT = 307.3 \text{ kcal mol}^{-1}, \quad (d)$$

and assuming the energy of atomization to be equal to the energy required to break three σ- and one π-bond [Eq. (e)].

$$\Delta E^0_{at}(BN,hex) = 3\,E(B\text{–}N) + E_\pi(B\text{–}N) \quad (e)$$

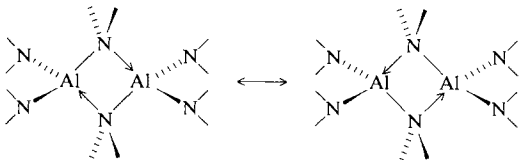
$E_\pi(B\text{–}N) = 33$ kcal mol^{-1} yields the mean B–N single bond energy of $E(B\text{–}N) = 91$ kcal mol^{-1}. An independent, though equally rough estimate based on the energy of atomization of cubic boron nitride (β-BN) yields $E(B\text{–}N) = 92$ kcal mol^{-1}.[**]

Both these values are overestimates; "delocalization energies" or "resonance energies" have been disregarded. We believe $E(B\text{–}N) = 88 \pm 2$ kcal mol^{-1} to be a more realistic estimate. In any case there is little doubt that covalent B–N bonds are as strong as or stronger than covalent C–C bonds: the mean C–C bond energy derived from the energy of atomization of diamond is 85 kcal mol^{-1}. The characteristics of covalent and dative B–N bonds are listed in Table 6.

Table 6. Comparison of covalent and dative B–N bonds.

	Covalent [a]	Dative [b]
E [kcal mol^{-1}]	88 ± 2	31
R [Å]	1.47 ± 1	1.66

[a] Derived from comparison data. [b] Determined on $H_3N \rightarrow BH_3$.



10. Some Polynuclear AlN Compounds

The trisamide $Al(NMe_2)_3$ is dimeric in the solid phase.[132] Each Al atom is surrounded by two bridging and two terminal NMe_2 groups. The terminal Al–N bonds have a length of 1.81 Å and may be described as single covalent bonds. The bridging Al–N bonds are 1.97 Å in length and

[*] "The nature of the B–N bond is controversial. On the one hand the BN and graphite structures are very similar, the difference between the C–C and B–N bond distances is very small, and the interatomic forces in the two substances are of the same order of magnitude". "The B–N bond distance in the sheets is 1.446 Å and thus much shorter than the sum of the covalent radii 1.57 Å". "It is therefore reasonable to assume a resonating (single and double bond) structure as in graphite. On the other hand, some properties of BN differ sharply from those of graphite. Thus, BN has a low electric conductivity, is colorless, and its diamagnetic susceptibility is small while that of graphite is abnormally large. These properties are in agreement with a single bond model".

[**] Cubic BN has a diamond-like structure, each B atom is bonded to four N atoms at a bond distance of 1.56 Å. The enthalpy of the transformation from hexagonal to cubic BN is 0.84 kcal mol^{-1} [131], and the energy of atomization is ΔE^0_{at} (BN, cub) = ΔE^0_{at}(BN, hex) − 0.8 kcal mol^{-1} = 306.5 kcal mol^{-1}. By assuming that the energy of atomization is equal to the energy required to break three single covalent bonds and one dative bond, $\Delta E^0_{at} = 3\,E(B\text{–}N) + E(N \rightarrow B)$, and that $E(N \rightarrow B) = \Delta H^0_{dis}$ $(H_3N \rightarrow BH_3) = 31.1$ kcal mol^{-1}, we obtain $E(B\text{–}N) = 92$ kcal mol^{-1}.

may be described as having equal covalent and dative bonding contributions:

Scheme 5. Canonical structures of $[Al(NMe_2)_3]_2$.

The results of molecular orbital bond index calculations on $[Al(NH_2)_3]_2$ and similar compounds have just been published.[133] The authors note that the bond index of the Al–N terminal bond ist nearly twice the bond index of the bridging Al–N bond and conclude: "This indicates a greater strength for the terminal bonds [...] than previously estimated, the difference arising because the capacity of terminal ligands with lone pair electrons to indulge in dative π-bonding has been underestimated in earlier work". As will be clear from the preceding discussion, we prefer to regard the terminal bonds as single covalent bonds, and the bridging bonds as less than that, viz. as half covalent and half dative. Using the terminal Al–N distance as a reference value for a covalent Al–N bond and the mean of the N→Al bond distances in Me_3NAlH_3 and Me_3NAlMe_3 (2.08 Å) as a reference value for a dative bond distance, we calculate a mean value of 1.95 Å, in reasonable agreement with the observed value of 1.97 Å. A description of each of the four bonds as half covalent and half dative is consistent with the expected fragmentation behavior: two Al–N bonds are expected to break heterolytically to yield the monomeric amides, the next two to break homolytically to yield $(Me_2N)_2Al^{\bullet}$ and $^{\bullet}NMe_2$.

In the following we shall briefly discuss the bond distances in some polynuclear AlN compounds (see Fig. 7). In order to minimize inductive effects we confine ourselves to species with hydrogen and alkyl substituents.

The Al–N bonds in $(H_2AlNMe_2)_3$[132] and $(Me_2AlNMe_2)_2$[134] may also be described as half covalent and half dative. The calculated mean (1.95 Å) is in good agreement with the observed values.

The Al–N bond distance in the cage compounds (HAlN*i*Pr)$_4$[135] and (HAlN*n*Pr)$_6$[136] may be described in terms of 2:1 covalent and dative bonding contributions. From the reference values we calculate a bond distance of 1.90 Å, again in good agreement with the observed values.

Finally, one may describe the bonds in crystalline AlN[137] as 3:1 resonances between covalent and dative bonds. The corresponding calculated bond distance is 1.88 Å. Again, a linear, two-parameter model has been able to reproduce the Al–N bond distances in Figure 7 with a deviation of 0.02 Å or less.

This model is not equally successful in all cases. Thus, the Al–N bridge bonds in $(Cl_2AlNMe_2)_2$ are 1.91 Å,[138] 0.04 Å shorter than calculated from the reference bond distances. The deviation may be interpreted as an inductive effect of the electron withdrawing Cl atoms. But adoption of the Al–N and N→Al distances in **8** as reference values does not lead to improvement, the calculated mean is 1.87 Å, 0.04 Å less than the observed value.

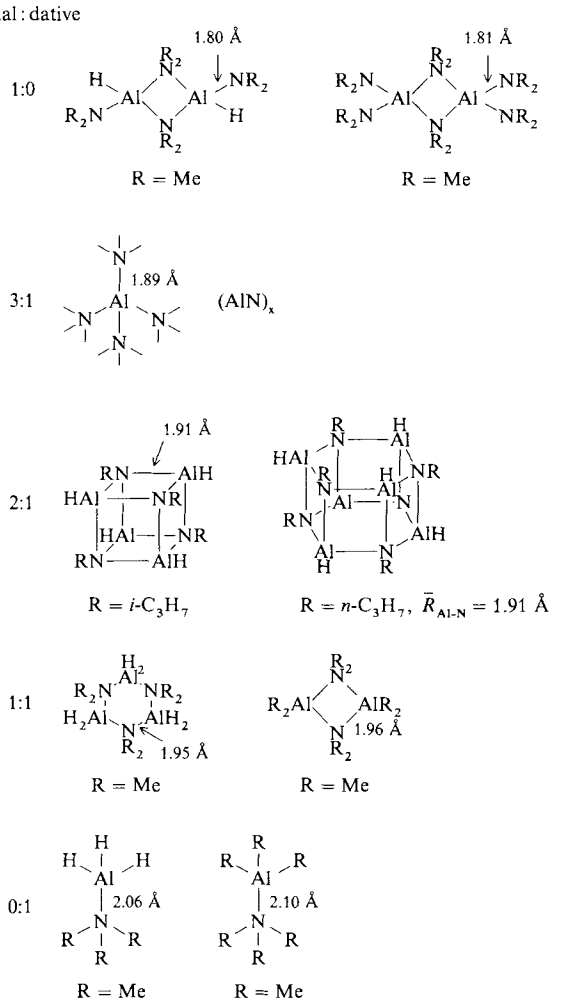


Fig. 7. The structure of some polynuclear AlN compounds and the ratio of normal to dative contributions to the Al–N bonds.

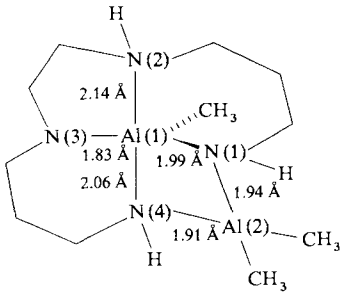
But even in those cases where the model fails in a quantitative way, it remains true that bond distances generally increase with increasing dative bonding contributions. The molecular structures of **10**–**14** have all been determined by



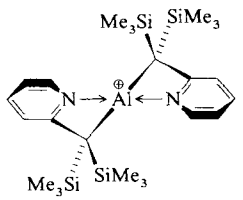
$(Me_2Al)_3(\mu\text{-}PMe_2)_3$ **10**[139] $(Me_2Al)_3(\mu\text{-}OMe)_3$ **11**[140]
$(Me_2Al)_2(\mu\text{-}SMe)_2$ **12**[141] $(Me_2Al)_4(\mu\text{-}F)_4$ **13**[142]
and $(Me_2Al)_2(\mu\text{-}Cl)_2$ **14**[143]

gas electron diffraction. In all these compounds we describe the endocyclic bonds as half dative and half covalent. The Al–P bond in **10** (2.43 Å) is 0.10 Å shorter than in adducts between $AlMe_3$ and phosphanes,[18, 144] and 0.06 Å longer than the bond distance in solid aluminum phosphide, which we would regard as 3/4 covalent and 1/4 dative; we are not aware of any molecule containing what might be described as a single covalent Al–P bond, but expect it to be about 2.32 Å.

The Al–O bond distance in **11** (1.85 Å) is close to the mean of the terminal covalent Al–O distance in tetrameric aluminum trisisopropoxide (1.72 Å)[120] and the dative O→Al distance in $Me_2O \rightarrow AlMe_3$ (2.01(2) Å). The Al–S bond distance in **12** (2.37 Å) is about 0.18 Å shorter than the dative S→Al distance in $Me_2S \rightarrow AlMe_3$,[84] while the Al–F distance in **13** (1.81 Å) is 0.18 Å greater than the normal Al–F distance in gaseous monomeric AlF_3.[145] Finally, the Al–Cl

bond distance in **14** (2.30 Å) is 0.24 Å longer than the normal bond distance in gaseous, monomeric $AlCl_3$.[46]

Before going on to other metals we pause to take note of the dinuclear complex **15**, containing a five-coordinate Al atom,[146] and the cationic complex **16**[147] prepared with $[AlCl_4]^{\ominus}$ as counterion.



15

The five-coordinate Al(1) atom in **15** is trigonal bipyramidal, the four Al(1)–N bond distances range from 1.83 to 2.14 Å. The Al–C and Al(1)–N(3) bonds (1.83 Å) are clearly covalent, the Al(1)–N(2) bond (2.14 Å) clearly dative. As expected the covalently bonded C and N(3) occupy equatorial positions, the datively bonded N(2) an axial position.

Al(1) is bonded to the four-coordinate atom Al(2) through two amido nitrogen atoms, N(1) and N(4). We have seen that when two four-coordinate Al atoms are connected through two amido bridges as in $(Me_2AlNMe_2)_2$, covalent and dative bonding contributions are delocalized to yield four equal Al–N bonds at about 1.95 Å. In **15** the bond distances in the four-membered Al_2N_2 ring range from 1.91 to 2.06 Å.

There are probably several reasons for this variation. Firstly, as we have seen, bond distances to the acceptor atom are expected to increase with increasing coordination number, the mean of the bond distances from N((1) and N(4) to the five-coordinate Al is about 0.10 Å greater than the mean of the bond distances to the four-coordinate Al. Secondly, in compounds of the main group elements with trigonal bipyramidal coordination the bonds to axial ligands tend to be a few hundreths of an Å unit longer than those to equatorial ligands. Finally, we interpret the small but significant difference between the bond distances to the four-coordinate Al(2) (1.935(2) Å and 1.911(3) Å) as an indication that covalent and dative bonding contributions are not completely delocalized over the Al_2N_2 ring: the shortest bond, Al(2)–N(4), and consequently also the Al(1)–N(1) bond appear to be slightly more than half covalent, the longer bonds Al(2)–N(1) and Al(1)–N(4) appear to be slightly more than half dative. We further suggest that the reason for the incomplete delocalization is that it would require energy to increase the covalent contribution to the axial Al(1)–N(4) bond at the expense of the equatorial Al(1)–N(1) bond.

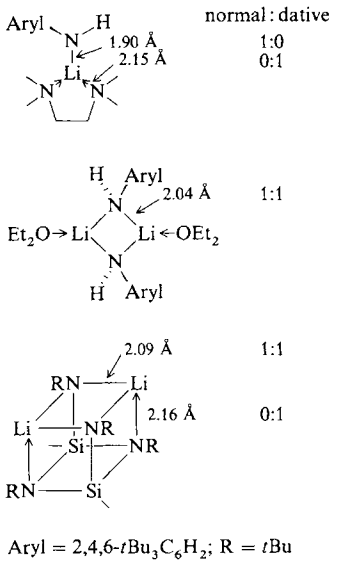
16

Al–C 1.96(2) Å
∢ CAlC 152°
Al–N 1.92(2) Å
∢ NAlN 115°

The mean Al–C distance in the cationic complex **16** is not significantly different from the Al–C bond distances in free $AlMe_3$ or Me_3NAlMe_3, but the dative N→Al distances, 1.92(2) Å, are 0.18 Å shorter than in the latter adduct. It should be noted, however, that even this very short N→Al bond distance is about 0.11 Å greater than the reference value for a covalent Al–N bond that we adopted above.

11. Three-coordinate Lithium Amides

The structure of the adduct of tetramethylethylenediamine and a monomeric Li-amide is shown in Figure 8.[148]



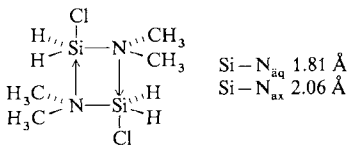


Fig. 8. Bond distances in some three-coordinate lithium amides and the ratio of normal to dative contributions to the Li–N bonds.

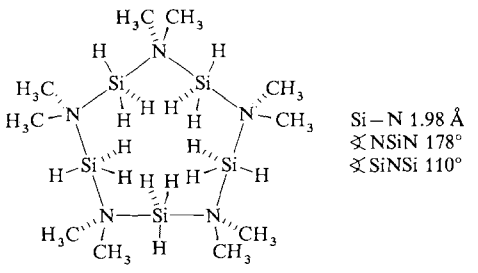
Here again we are able to compare dative and normal bond distances between the same atom pair in the same molecular species: Li–N = 1.90 Å and N → Li = 2.15 Å.

In $[Et_2OLi(\mu\text{-}NHAryl)_2]_2$ (Fig. 8, center) the Li atom is datively bonded to the O atom, while each of the four endocyclic bonds must be regarded as half dative and half normal.[149] The observed Li–N distance is in good agreement with the mean of the pure normal and dative bond distances in the adduct above shown at the top of Figure 8, 2.03 Å. Finally, we turn our attention to the cubic complex at the bottom of Figure 8.[150] The Si atoms are seen to be four-coordinate, and all Si—N distances are of the magnitude expected for covalent bonds. Since the Si–N bonds in the basal plane and the terminal N–C bonds are covalent, it follows that the perpendicular N–Li bonds are dative as indicated. If N is assumed to be capable of forming three covalent and one dative bond, and Li to be capable of forming one normal and two (or more) dative bonds, it follows that since the Li–N bonds in the upper face are all similar, each must be half normal and half dative. The observed mean value, 2.09 Å, is in moderate agreement with the estimated value of 2.03 Å.

12. Two Associated Si Amides



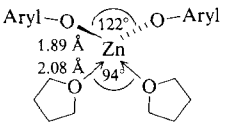
Me_2NSiH_2Cl is monomeric in the gas phase, but dimeric in the solid.[151] The monomeric units in the dimer **17** are held together by two dative N → Si bonds. The coordination around the two Si atoms is trigonal bipyramidal with the datively bonded N atom and the Cl atom in apical positions. The Si–N and N → Si bond distances are comparable to those in the mononuclear adducts **4** and **5** discussed in Section 7.

17

We have seen that when two NR_2 groups bridge two four-coordinate Al or two three-coordinate Li atoms, covalent and dative bonding is delocalized to give four equal bond distances. We suggest that this does not take place in the present compound because it requires energy to increase the covalent bonding contribution to the axial Si–N bond at the expense of the equatorial bond.

Replacement of the Cl atom by a hydrogen atom leads to a radical change of the solid state structure: Me_2NSiH_3 is pentameric in the solid phase as indicated in **18**.[152]

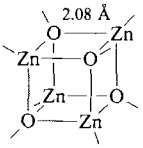
18



The covalently bonded N atom has moved into the apical position formerly occupied by the Cl atom: formation of dimers is prevented by the N-Si-N angle of 180°, the degree of association is now determined by the valence angle at N.

The Si–N bond distances in the ten-membered ring of **18** are indistinguishable. Each of them may be described in terms of equal covalent and dative bonding contributions, though the observed bond distance is somewhat larger than the average of the localized Si–N and N → Si distances in **17** (1.93 Å). We suggest that delocalization is stabilizing in the case of **18** because both N atoms occupy apical positions.

13. Some Zinc-Oxygen Compounds



The Zn atom in the complex **19** formed from $Zn(OAryl)_2$ and two moles of tetrahydrofuran is covalently bonded to two O atoms and datively bonded to two others.[153] The difference between the two bond distances is 0.19 Å.

Solid ZnO has a wurzite structure, each Zn atom is surrounded by four O atoms at an average distance of 1.98 Å.[154] The bonding may be described in terms of equal covalent and dative bonding contributions; the mean of the Zn–O and O → Zn bond distances in **19** is 1.99 Å, in good agreement with the observed value.

19, Aryl = 2,4,6-tBu$_3$C$_6$H$_2$

Tetrameric MeZnOMe has the cubane structure **20**.[155] The external Zn–C bond distance corresponds to a covalent

20

bond. If it is assumed that Zn is capable of forming one more covalent bond and two (or more) dative bonds, it follows that each Zn–O bond in the cube is 1/3 covalent and 2/3 dative. The observed bond distance in **20** is indeed longer than the 1:1 bond in solid ZnO and shorter than the pure dative bond in **19**, but it is significantly longer than the appropriate mean of the bond distances in **19** (2.02 Å), perhaps as an effect of the presence of an electron-releasing methyl group.

14. "Tetrahedral Covalent Radii"

Working with the evidence available at the time when *The Nature of the Chemical Bond*[1] was written, *Pauling* clearly found no reason to distinguish between covalent and dative bonds. He described bonding in solid ZnO, AlN or cubic BN as "covalent bonds with some ionic character". N and O atoms were assigned tetrahedral covalent radii equal to the normal covalent radii determined from the observed bond distances in amines, ethers and related compounds. The "tetrahedral covalent radii" of Zn and the other Group 12 metals were then adjusted to reproduce the observed interatomic distances in oxides and other binary compounds with Group 16 elements. Similarly, the radii of Al and the other Group 13 elements were adjusted to reproduce the observed interatomic distance in nitrides and other binary compounds with group 15 elements.

The observed interatomic distances that we have adopted as reference values for pure, single covalent bonds to four-coordinate metal atoms are consistently shorter than the estimates obtained by adding the "tetrahedral covalent radii" for the two atoms: for Al–N 1.81 Å versus 1.91 Å, for Al–O 1.71 Å versus 1.92 Å, and for Zn–O 1.89 Å versus 1.97 Å. For B–N we have adopted 1.47 Å as a reference value for a single covalent bond to trigonal B; the sum of the "tetrahedral covalent radii" is 1.58 Å.

The reason for the discrepancy is clear. In our terminology the bonds in solid ZnO, AlN or cubic BN are not pure covalent bonds, but bonds of intermediate type with significant dative bonding contributions. The "tetrahedral covalent radii" are therefore incapable of reproducing either of the bond distances in species like **16**, which contain what according to our terminology are *pure* covalent and dative bonds.

We have quoted a few instances where this discrepancy has led investigators to the conclusion that the covalent bonds are shortened by additional π-bonding; there are more instances in the literature.

If the distinction between covalent and dative bonds is made, there arises the need for a new set of covalent radii based on observed pure, single covalent bond distances. In view of the great sensitivity of dative bond distances to inductive effects, it would hardly be profitable to attempt to establish a set of dative bond radii.

15. Conclusion

In this review we have defined a chemical bond as *normal* if minimum-energy rupture proceeds homolytically and as *dative* if minimum-energy rupture proceeds heterolytically. The term normal covers covalent and ionic bonds as well as bonds of intermediate polarity. We have compared the physicochemical properties of chemical bonds between the same atom pair DM where D is a donor element in groups 15, 16 or 17 and M is a main group metal: bonds to transition metals have not been considered. We find that:

1. The strength of a dative, or donor–acceptor, bond is very sensitive to inductive effects, particularly at the acceptor atom. Thus, while $SnMe_4$ does not appear to interact with electron donors such as amines or pyridine, the N → Sn bond rupture enthalpy of pyr → $SnMe_3Cl$ is 11 kcal mol^{-1} and of $Me_3N \rightarrow Sn^{\oplus}Me_3$ 46 kcal mol^{-1}. The variation in bond strength is clearly reflected in bond distances. Thus, while the N → Si bond distances in neutral (five-coordinate) Si^{IV} adducts range from 2.70 to 1.95 Å with increasing electronegativity of the substituents, the N → Si bond distance in pyr → $Si^{\oplus}Me_3$ is 1.86 Å.

2. The available evidence for metals in groups 12, 13 and 14 suggests that the strength of a dative bond rarely exceeds half the strength of an isoelectronic normal bond or a normal bond between the same atom pair.

Again the difference is reflected in bond distances: covalent Si–N distances to four- or five-coordinate Si^{IV} range from 1.70 to 1.80 Å, dative N → Si distances range from 1.95 to 2.70 Å. Normal and dative AlN bond distances in the same molecular unit **8** are 1.77 and 1.96 Å, respectively. Normal and dative LiN bond distances in the adduct at the top of Figure 8 are 1.90 and 2.15 Å, respectively, and the ZnO bond distances in **19** are 1.89 and 2.08 Å.

3. The coordination geometry of the acceptor atom may be predicted from the VSEPR model with the additional postulate that the spatial requirements of a (partially) "accepted" bond pair are less than the spacial requirements of a normal bond pair (NBP > ABP). This means that in five-coordinate trigonal pyramidal adducts the electron donors will occupy the axial positions.

The VSEPR model leads to the prediction that bonds to the acceptor atom will be elongated and the angles between them reduced on coordination of (another) electron donor. Both effects will be reinforced by steric repulsion between donor molecule and acceptor atom substituents.

4. In some molecular species bond distances are found to be equal, though no reasonable Lewis structure in which all are covalent or all dative can be found. Bonding in such species is conveniently described in terms of canonical forms containing localized covalent and dative bonds. Delocalization of bonding (resonance) yields bonds that are intermediate between pure covalent and dative bonds. The covalent or dative contributions to a particular bond in the real molecule may be determined by counting the number of canonical forms in which it is covalent or dative. The lengths of such bonds are generally found to be intermediate between the lengths of a pure covalent and a pure dative bond and to increase with increasing dative bonding contributions. In favorable cases bond distances may be predicted to within two or three hundreths of an Å unit by calculating the appropriate mean of reference values for pure normal and pure dative bond distances.

This approach is particularly useful for describing bonding in symmetric $M_2(\mu^2\text{-}NR_2)$, $M_2(\mu^2\text{-}OR)$ or $M_2(\mu^2\text{-}X)$ fragments; each M–N/O/X bond is half normal and half dative. Similarly, each M–N bond in a symmetric $M_3(\mu\text{-}NR)$ fragment is 2/3 normal and 1/3 dative, and each M–O/X bond in symmetric $M_3(\mu^3\text{-}OR)$ or $M_3(\mu^3\text{-}X)$ fragments are 1/3 normal and 2/3 dative.

We are grateful to the Norwegian Research Council for Science and the Humanities (NAVF) for financial support. We thank. Anne-Lise Ågren for typing – and retyping – the manuscript, and Snefrid Gundersen for preparing the figures. Finally I am grateful to Professors M. F. Lappert, P. Paetzold and P. von R. Schleyer and two anonymous referees for constructive criticism and helpful comments.

The First Heterodinuclear Complexes with Bis(cyclopentadienyl)methane Bridges**

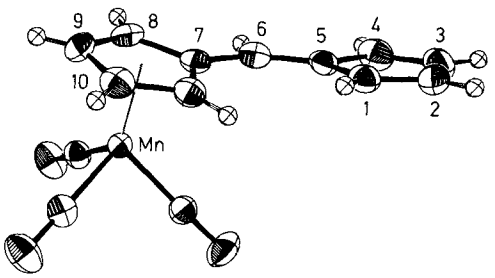
By *Peter Härter,* Günther Boguth, Eberhardt Herdtweck,* and *Jürgen Riede*

Dinuclear complexes have become increasingly interesting because of the possibility that the properties of the two fragments might complement each other, thereby leading to novel reactions.[1] Recent attention has focused on complexes with $(C_5H_4)_2X$ bridges (X = $SiMe_2$ and $(CH_2)_n$, n = 0, 1, 2), for example, since they are particularly stable. However, little is known about the especially interesting heterodinuclear derivatives of this class of compounds owing to the lack of suitable synthetic routes. Only the multistep syntheses of heterodinuclear fulvalene complexes[2] and 1,2-bis(cyclopentadienyl)ethane-bridged complexes[3] have been described. No examples of heterodinuclear complexes of the bis(cyclopentadienyl)methane series have been presented so far. Here we report a simple route to this class of substances.

We have found that the reaction of dilithioferrocene with 6-dimethylaminofulvene to give bis(6-fulvenyl)ferrocene, described by *Mueller-Westerhoff* et al.,[4] can be extended to other complexes containing a lithiated cyclopentadienyl ring. Reaction of tricarbonyl(lithiocyclopentadienyl)manganese **1**[5] with 6-dimethylaminofulvene **2a** or 1-(dimethylaminoethylene)-1 *H*-indene **2b**[6] in THF solution affords, after hydrolysis and chromatographic workup, the new fulvenyl complexes **3a** and **3b**, respectively.

The spectroscopic data for these compounds are consistent with the structures shown. An X-ray structure determination of **3a** confirms this formulation: the bond lengths and angles are typical of $C_5H_5Mn(CO)_3$ derivatives[7] (Fig. 1). The fulvenyl moiety displays the clear alternation of double bonds characteristic of fulvenes. The distance C6–C7 (146.6 pm), as well as the dihedral angle of 16.4° between the two rings, indicates the absence of significant π interaction between the manganese moiety and the fulvenyl moiety.

Reaction of **3a** with "superhydride" ($Li[HB(C_2H_5)_3]$) in THF solution results in quantitative formation of the anionic complex **4**, which precipitates as a pale yellow powder upon addition of hexane to the reaction solution. Further treatment of **4** with freshly prepared tetracarbonyl(iodo)cobalt[8] at −78 °C affords, after warming the reaction mixture to room temperature and extraction with hexane, complex **5** as a reddish-brown oil in 63% yield.



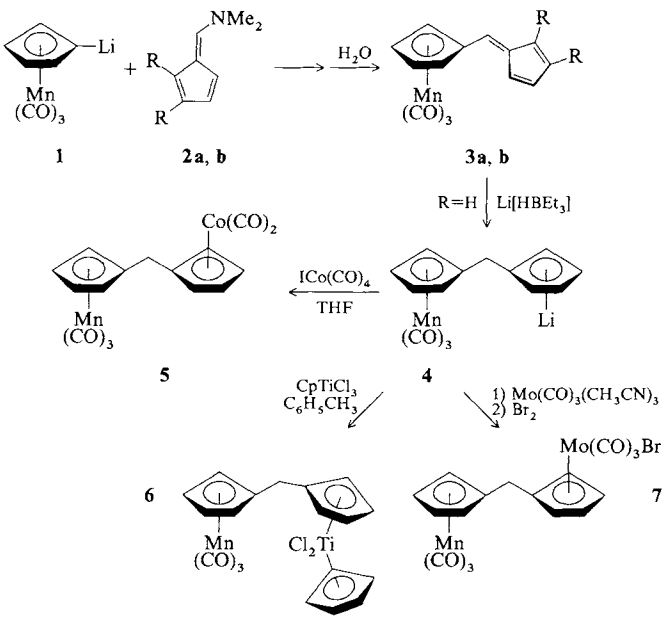


Fig. 1. Molecular structure of the 6-fulvenyl complex **3a** (ORTEP). The complex crystallizes from *n*-hexane in the orthorhombic space group *Pbca*. Selected distances [pm] and angles [°]: Mn–Cp 177.1 (center of the C_5H_4 ring), Mn–CO (average) 179.4(2), C1–C2 132.5(3), C1–C5 147.4(3), C2–C3 145.8(3), C3–C4 133.3(3), C4–C5 145.8(3), C5–C6 135.2(3), C6–C7 146.6(3), C7–C8 142.8(3), C8–C9 140.3(3), C9–C10 140.5(3); C5–C6–C7 128.4(2), dihedral angle Cp–Fulv 16.4. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53895, the names of the authors, and the journal citation.

The IR spectrum of **5** shows CO absorptions at 1944 (E, vs) and 2025 cm^{-1} (A, s), typical of $C_5H_5Mn(CO)_3$ derivatives. The CO vibrational bands of the cobalt moiety are found at 1970 and 2033 cm^{-1} (s). The ^1H NMR spectrum, displaying three groups of lines, corroborates the proposed structure. In a second reaction, **4** was treated with a molar equivalent of trichloro(η^5-cyclopentadienyl)titanium in toluene solution. Extraction of the reaction solution with CH_2Cl_2 afforded complex **6** as a peach-colored, microcrystalline powder. The IR spectrum displays the band pattern typical of $C_5H_5Mn(CO)_3$ derivatives. The proposed structure is supported by the ^1H NMR spectrum. Finally, reaction of complex **4** with tris(acetonitrile)tricarbonylmolybdenum, followed by oxidation with bromine, gives compound **7**.

a, R = H; **b**, R-R = CH=CH–CH=CH

[**] This work was supported by the Stiftung Volkswagenwerk and the Leonhardt-Lorenz-Stiftung.

The ready availability of **3a** opens up a route to other interesting manganese-containing dinuclear complexes. Furthermore, the synthetic strategy described here may be extended to other half-sandwich complexes, since numerous complexes of type **1** are now known.[9]

Experimental Procedure

3a: **1** (2.04 g, 10 mmol) was allowed to react with 4 mL of *n*BuLi (2.5 M *in* hexane) and 1.5 mL of TMEDA in a stirred solution of THF (30 mL) for 1 h at −78 °C. Compound **2a** (1.21 g, 10 mmol) was then added and the reaction mixture was allowed to warm to room temperature. After 5 h of additional stirring, 50 mL of water was added to the mixture. Extraction with diethyl ether and removal of the solvent left a residue, which was chromatographed on kieselgel 60 (activity 2–3) with hexane as eluent. The product (orange band) was obtained with hexane/ether (10:1) in 57% yield (1.50 g). IR (CH_2Cl_2 ν(CO) [cm^{-1}]): 1942 (E, vs), 2024 (A_1, s). ^1H NMR (270 MHz, $CDCl_3$): δ = 4.83, 5.18 (C_5H_4Mn); 6.2 (1H, m), 6.55 (1H, m), 6.60 (1H, m), 6.63 (2H, m). ^{13}C NMR (270 MHz, $CDCl_3$): δ = 83.15, 85.85, 95.73 (C_5H_4Mn), 119.07, 126.72, 130.01, 131.24, 135.52, 145.02 fulvenyl), 224 (CO).

Compound **3b** was obtained in a similar way in 42% yield (1.40 g). IR (CH_2Cl_2, ν(CO) [cm^{-1}]) 1941 (E, vs), 2024 (A_1, s), ^1H NMR (400 MHz, C_6D_6): δ = 7.28 (1H), 7.11 (2H), 7.10 (1H), 6.69 (1H), 6.54 (2H), 4.39 ("t", 2H), 3.93 ("t", 2H).

5: **3a** (280 g, 1 mmol) was treated with 1 mL of "superhydride", $Li[HB(C_2H_5)_3]$ (1 M in THF). The solution turned initially red. After the color had changed to yellow, 10 mL of *n*-hexane was added, the precipitate was filtered off, and the solid (**4**) was washed twice with *n*-hexane and then dissolved in 20 mL of THF. This solution was added to 10 mL of a THF solution of freshly prepared $Co(CO)_4I$ (330 mg, 1.1 mmol) at −78 °C. After the reaction mixture had warmed to room temperature, it was stirred for an additional 1 h. The solvent was then removed in vacuo and the residue extracted with *n*-hexane. Filtration and extraction of the *n*-hexane solution afforded **5** as a reddish-brown oil in 63% yield (250 mg). IR (ν(CO) [cm^{-1}]): 1944 (vs), 1970 (s), 2025 (s), 2033 (s), ^1H NMR (270 MHz, $CDCl_3$): δ = 2.51 (s, CH_2), 3.92, 3.84 (A_2B_2, C_5H_4Mn), 4.35, 4.30 (A_2B_2, C_5H_4Co).

6: $(C_5H_5)TiCl_3$ (220 mg, 1 mmol) was added to a solution of **4** in toluene (20 mL), prepared as described for the synthesis of **5**. The reaction solution was stirred for 2 h at room temperature and then evaporated to dryness. The residue was extracted with 3 × 10 mL of CH_2Cl_2 and the extracts filtered. The filtrate was concentrated until onset of crystallization and then cooled to − 34 °C. The microcrystalline, peach-colored product was collected on a frit and dried under vacuum for ca. 12 h. Yield 270 mg (69%). IR (CH_2Cl_2, ν(CO) [cm^{-1}]): 1933 (E, vs), 2020 (A_1, s). ^1H NMR (400 MHz, [D_6]acetone): δ = 3.71 (s, CH_2), 6.65 (s, Cp), 4.85, 4.97 ("t", C_5H_4Mn), 6.44, 6.72 ("t", C_5H_4Ti). ^{13}C NMR (400 MHz, [D_6]acetone): δ = 30.6, 83.2, 84.6, 105.6, 116.6, 121.0, 124.4, 123.8, 226.

7: $(CH_3CN)_3Mo(CO)_3$ (300 mg, 1 mmol) was added to a solution of **4** in THF (20 mL), prepared as described for the synthesis of **5**, and the reaction mixture was stirred for 2 h at room temperature. It was then cooled to 0 °C and a solution of bromine (50 µL) in 10 mL of THF was added dropwise. The red solution was stirred for 1 h at room temperature and the solvent removed in vacuo. The residue was transferred to silica and eluted with ether. Removal of the ether gave **7** as a microcrystalline red powder (235 mg, 60%). IR (CH_2Cl_2, ν(CO) [cm^{-1}]): 1936 (vs), 1966 (vs), 2022 (s), 2042 (s). ^1H NMR (400 MHz, C_6D_6): δ = 2.80 (s, CH_2); 4.61 ("t", C_5H_4Mo), 4.35 ("t", C_5H_4Mo), 3.95 ("t", C_5H_4Mn), 3.87 ("t", C_5H_4Mn), ^{13}C NMR (400 MHz, $CDCl_3$): δ = 28.02, 82.03, 83.44, 91.39, 95.05, 102.62, 115.95, 224.2, 227.0, 241.2.

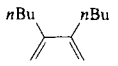
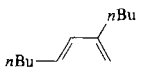
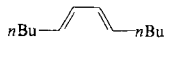
Hydrooligomerization of Alkynes, a New Catalytic Reaction Promoted by $[Co(py)_6]^{\oplus}$ in the Presence of H_2**

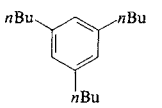
By *Paolo Biagini, Anna M. Caporusso, Tiziana Funaioli,* and *Giuseppe Fachinetti**

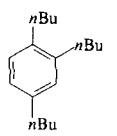
Neutral half-sandwich Co^I complexes of the type $[YCoL_2]$ (Y = η^5-cyclopentadienyl or other 6-electron donor ligand, L = neutral ligand) are among the most effective and widely studied compounds in promoting alkyne cyclotrimerization to give benzenes[1] or co-cyclotrimerization with nitriles[2] or alkenes[3] to give pyridines or cyclohexadienes. Throughout these catalytic cycles the group Y is suggested to remain attached to the cobalt, and neutral organocobalt(III)cyclopentadienes are believed to be the common intermediate species.[4]











The Co^I cationic coordination compound $[Co(py)_6]^{\oplus}$ **1** (py = pyridine) is one of the most reactive known complexes in promoting alkyne cyclotrimerization to yield arenes.[5] It appears, therefore, that the reaction between $[Co(py)_6][BPh_4]$[6] and alkynes in pyridine as solvent results in the formation of new cationic cobaltacyclopentadiene intermediates. We report now that these intermediates react with H_2: conjugated dienes, trienes, or tetraenes are formed in an unprecedented reductive oligomerization of alkynes.

As stated earlier,[5] the reaction of C_2Ph_2 with **1** in pyridine as solvent represents a particular case with respect to other alkynes in that the stoichiometric formation of $[(\eta^6\text{-}C_6Ph_6)Co(C_2Ph_2)]$ and $[Co(py)_6]^{2\oplus}$ was observed. However, when an equimolar amount of C_2Ph_2 (0.6 M in pyridine) was added to a stirred pyridine solution of **1** (0.05 M) under H_2 at atmospheric pressure, the color of the solution changed initially from deep blue to dark brown and gas absorption took place (0.5 moles of H_2 per mole of C_2Ph_2 in 4 minutes at 20 °C). At the end of the gas absorption, the blue color of the solution was restored. This cycle

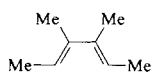
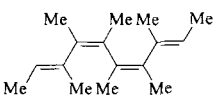
Table 1. The effect of H_2 pressure on the reductive dimerization of 1-hexyne promoted by **1** [a].

P_{H_2} [atm]					
1	2	6	1	20	71
90	26	39	4	4	27

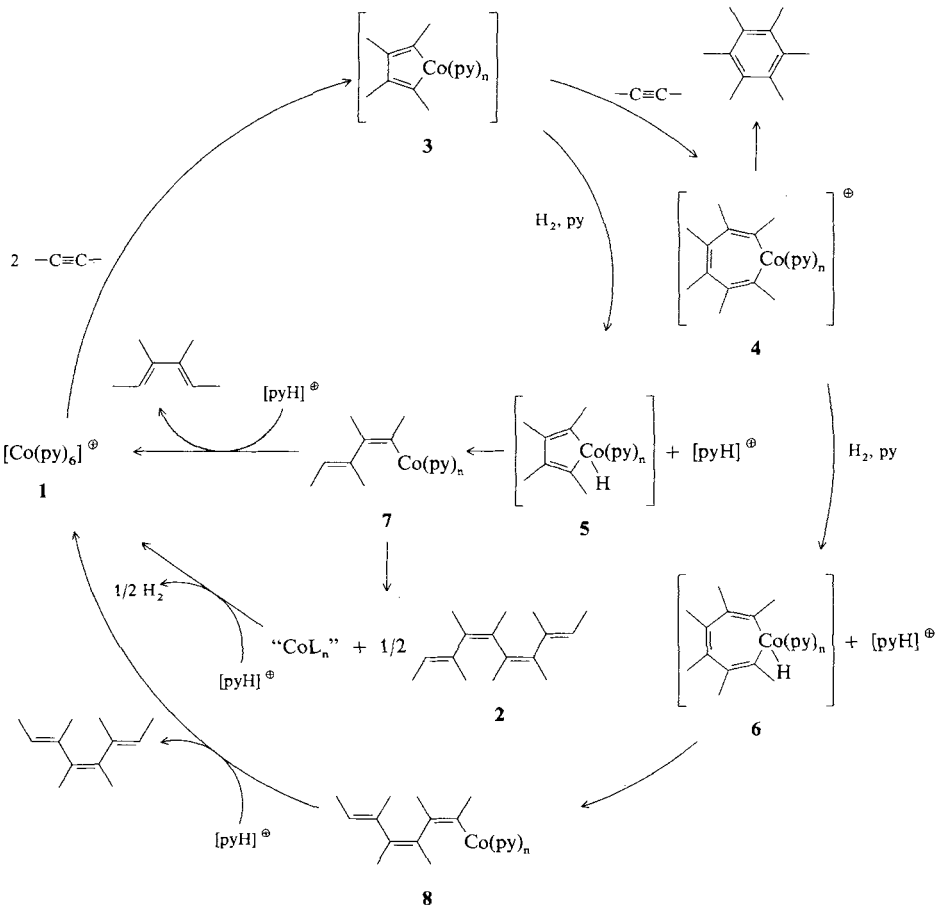
[a] For reaction conditions see text. Numbers refer to percentage product distribution. Conversion of 1-hexyne was > 95% in both cases. Organic products were identified by comparison of their GLC/MS data with those of authentic samples.

was repeated ten times with similar results. Evaporation of the resulting solution to dryness and extraction with Et_2O gave colorless crystals of (*E,E*)-1,2,3,4-tetraphenyl-1,3-butadiene[7] in quantitative yield [Eq. (a)].





$$2\ C_2Ph_2 + H_2 \xrightarrow[\mathbf{1}]{[Co(py)_6]^{\oplus},\ py} \text{(Ph, Ph, Ph, Ph, H, H)} \qquad \text{(a)}$$



Conjugated dienes were also obtained in similar experiments carried out with 1-hexyne (Table 1) or 2-butyne (Table 2); in addition, considerable amounts of aromatic hydrocarbons were formed. Moreover, in the case of 2-butyne, GLC/MS indicated the formation of a linear conjugated triene[8] and of a linear conjugated tetraene. The latter, isolated by fractional distillation, was characterized by ^1H and ^{13}C NMR spectra[9] as **2** (Table 2).

These findings indicate that alkyne cyclotrimerization and hydrogenation to give conjugated polyenes are competing reactions promoted by **1**. Owing to the possible synthetic utility of the formation of conjugated polyenes by reductive oligomerization, we carried out experiments under elevated hydrogen pressure in order to minimize arene formation. Table 2. Reductive oligomerization of 2-butyne promoted by **1** [a].

P_{H_2} [atm]		$C_{12}H_{20}$ (conj. Triene)	 **2**	C_6Me_6
1 [b]	26	9	31	34
90 [b]	41	12	47	–
50 [c]	1	16	81	2

[a] For reaction conditions see text. Numbers refer to percentage product distribution. Conversions of 2-butyne were > 95% in all cases. Diene and hexamethylbenzene were identified by comparison of their GLC/MS data with those of authentic samples. For the identification of triene and tetraene **2** see text. [b] Addition of alkyne to **1**. [c] Addition of **1** to alkyne.

Scheme 1. Proposed mechanism of alkyne oligomerization promoted by **1**.

means of a high-pressure pump, 1-hexyne or 2-butyne, both 0.6 M in pyridine, was injected into a rocking steel autoclave pressurized with 90 atm of H_2 and containing a 0.1 M solution of **1** in pyridine; 30 moles of alkyne per mole of **1** was added over 3 hours at room temperature. GLC analyses of the resulting solutions (Tables 1 and 2) showed that for both alkynes, high hydrogen pressure reduces the formation of aromatic hydrocarbons: high yields of three conjugated dienes were obtained in the case of 1-hexyne, while 2-butyne was converted into a nearly equimolar mixture of diene and tetraene **2**, together with a linear conjugated triene in small amounts.

Although a systematic study of all the reaction parameters has not been made yet, we found a selective hydrotetramerization to occur when catalyst **1** (0.05 M in pyridine) and 2-butyne (1.3 M in pyridine) were added in the reverse order at room temperature under 50 atm hydrogen pressure (Table 2).

As anticipated before, diene and triene formation can be rationalized in terms of the interception by H_2 of cobaltacyclopentadiene or cobaltacycloheptatriene complexes **3** and **4**, respectively (Scheme 1). Presumably, H_2 activation occurs through pyridine-assisted heterolytic cleavage,[10] a step for which the positive charge of cobaltacycle intermediates appears to be an essential requirement. In fact, hydrooligomerization of alkynes is not observed when the neutral Co^I complex $[CoCp(CH_2CH_2)_2]$ is employed in place of **1** under high H_2 pressure. Although the neutral organometallic fragment $CoCp$[1] still promotes cyclotrimerization of alkynes to arenes, variable amounts of olefins and alkanes, depending on experimental conditions, are formed as a consequence of alkyne hydrogenation.

The selective formation of the linear tetraene **2** from 2-butyne is presumably not due to H_2 interception by a cationic cobaltaoctamethylcyclononatetraene. In the absence of H_2, such an intermediate would be expected to reductively eliminate octamethylcyclooctatetraene, which was not found among the products of the cyclooligomerization of 2-butyne promoted by **1**.[5] The selective hydrotetramerization reported here presumably arises from a dimerization of alkadienyl **7** (formed from **3** via **5**) to give **2** and labile Co^0 complexes, which are oxidized back to **1** by the pyridinium cation (Scheme 1). Possible pathways to the diene (via **7**) and the triene (via **4**, **6**, and **8**) are also shown in Scheme 1.

$[\{Ph_2PCH_2C(CF_3)_2O\}NiH(PCy_3)]$: Support for a Nickel Hydride Mechanism in Ethene Oligomerization**

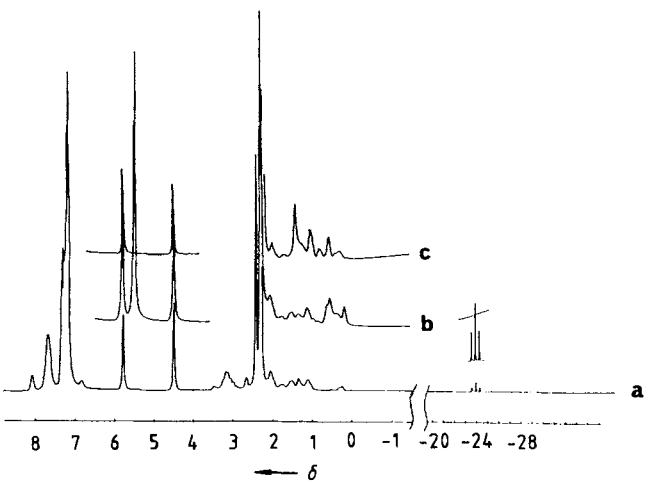
By *Ulrich Müller, Wilhelm Keim,* Carl Krüger,* and *Peter Betz*

Dedicated to Dr. Günther Ohloff on the occasion of his 65th birthday

The selective oligomerization of ethene to give linear α-olefins is carried out industrially in the Shell SHOP process. A capacity of nearly one million tons in 1990 makes this procedure one of the largest applications of transition metals in homogeneous catalysis.[1]

The metallacycloalkane and the metal hydride mechanisms have usually been discussed as C–C bond-forming pathways in oligomerizations.[2–4] In the latter mechanism, metal hydride complexes have been proposed as the catalytically active species. However, attempts to trap and isolate nickel hydride compounds in oligomerizations have met with little success so far. Here we describe the isolation and in situ NMR measurements of nickel hydride complexes which support the hydride mechanism.

The reaction of 3-diphenylphosphino-1,1,1-trifluoro-2-trifluoromethyl-2-propanol **1** with $Ni(cod)_2$ (cod = 1,5-cyclooctadiene) in toluene gives a system that catalyzes the



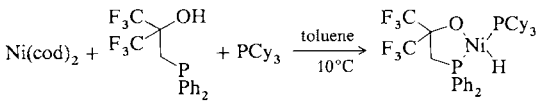


Fig. 1. ^1H NMR spectra of in situ experiments. Spectra: a) $Ni(cod)_2$ plus $Ph_2PCH_2(CF_3)_2OH$ **1**; b) plus ethene after 5 min; c) after 15 min (solvent $[D_8]$toluene at 10 °C).

[+] Crystal structure analysis.

formation of higher olefins from ethene (50 bar) at 50 °C. The C_4–C_{30} oligomers were shown by gas chromatography to be present in a geometric distribution. Linear olefins, 98% of which are α-olefins, predominate to the extent of 99%. Activities of more than 5000 moles of ethene per mole of $Ni(cod)_2$ are attained. When the reaction of **1** with $Ni(cod)_2$ is followed in situ at −10 °C by ^{1}H NMR spectroscopy (Fig. 1, spectrum a), a nickel hydride signal ($\delta = -23.8$) is observed as a triplet.[5]

When ethene is introduced, the hydride signal vanishes immediately and a new signal appears at $\delta = 0.6$, which can be assigned to a nickel alkyl complex (Ni–CH_2; spectrum b). The reaction with ethene was complete after 15 min (spectrum c). Signals at $\delta = 1.12$ and 1.51 indicate the presence of higher nickel alkyl compounds. The presence of the expected α-olefins in the reaction solution could be demonstrated by gas chromatography.

Attempts to isolate the catalytically active nickel hydride complex were unsuccessful. When $Ni(cod)_2$ and **1** were allowed to react in the presence of tricyclohexylphosphane, however, it was possible to isolate complex **2** (Scheme 1).

1 **2**

Scheme 1. Formation of the nickel hydride complex **2**. Cy = cyclohexyl.

An X-ray structure analysis (Fig. 2) confirmed the structure of complex **2**, which has a square-planar configuration

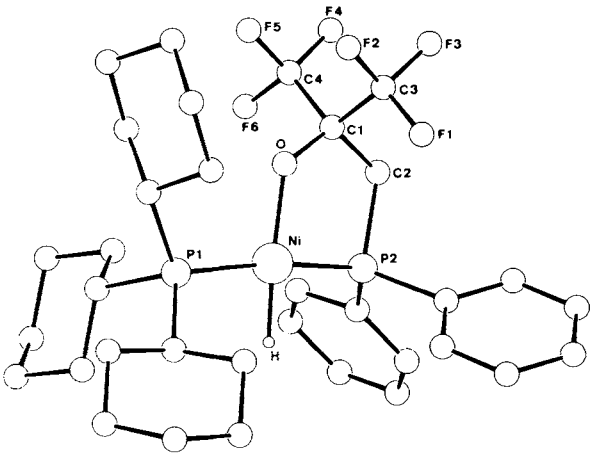

Fig. 2. Molecular structure of complex **2**. Selected bond lengths [Å] and angles [°]: Ni–P1 2.181(1), Ni–P2 2.140(1), Ni–O 1.873(2), Ni–H 1.37(3); P1–Ni–O 99.1(1), O–Ni–P2 87.8(1), P2–Ni–H 89.(1), H–Ni–P1 84(1). Crystal data for **2**: $P\bar{1}$, $a = 10.6169(5)$, $b = 12.0185(6)$, $c = 14.1276(7)$ Å, $\alpha = 102.63(1)$, $\beta = 90.45(1)$, $\gamma = 101.02(1)°$, $V = 1724.3$ Å^3, $Z = 2$, $\varrho_{calcd} = 1.36$ g cm^{-3}, $\lambda = 1.54179$ Å, $\mu = 21.93$ cm^{-1}, $R = 0.044$, $R_w = 0.053$; 7096 unique reflections, 5989 observed with $I > 2\sigma(I)$, 535 refined parameters, residual electron density 0.40 eÅ^{-3}. The positions of the hydrogen atoms, obtained by difference Fourier synthesis, were included in the refinement with fixed isotropic temperature factors ($U(H) = 0.08$ Å^2); all other atoms were refined anisotropically. Further detail of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53678, the names of the authors, and the journal citation.

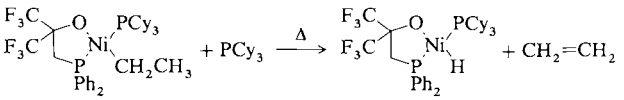

around nickel. The complex is characterized by a large P1–Ni–O angle (99.1(1)°); the chelate ring is folded by 13.5° along the Ni–C2 axis.

Complex **2** does not catalyze the oligomerization of ethene; the PCy_3 ligand presumably blocks the necessary free coordination site. Complex **3** was also isolated. A triplet at $\delta = -24.98$ in the ^{1}H NMR spectrum indicates the coordination of only two phosphorus atoms.

$[\{Ph_2PCH_2C(CF_3)_2O\}NiH(PCy_3)_2]$ **3**

The nickel hydride mechanism would be supported by the trapping and isolation of nickel alkyl complexes in analogy to the reaction shown in Scheme 1. To this end, a solution of $Ni(cod)_2$/**1** in [D_8]toluene was allowed to react with ethene at −20 °C. Addition of PCy_3 led to the formation of a yellow-orange complex, **4**, which could be isolated.

A pseudo triplet in the ^{13}C NMR spectrum of **4** ($\delta = -10.32$) exhibits two C–P couplings with coupling constants of 22.63 and 21.12 Hz, which are in agreement with the presence of two phosphorus atoms coordinated in different fashions to alkyl-substituted nickel. As expected, the methyl C atom gives rise to a singlet at $\delta = 15.29$. In the ^{1}H NMR spectrum, the signals of the Ni–CH_2 group are found at $\delta = 0.2$–0.7. The ^{1}H NMR shift assignments were confirmed on the basis of reference data.[6, 7] When **4** is warmed to room temperature, ethene is lost in a β-hydride elimination step (Scheme 2), resulting in the formation of **2**.

4 **2**

Scheme 2. β-Elimination of ethene from **4**.

Compounds **2** and **4** can serve as models for intermediates in the catalytic cycle and provide important support for the hydride mechanism. The nickel hydrides present in the catalysis solution are rapidly trapped by ethene. The resulting nickel ethyl complex can react further with ethene to give the nickel butyl complex, the nickel hexyl complex, etc. The β-hydride elimination of the nickel alkyl species affords the α-olefins, present in a geometric distribution.

Experimental Procedure

2: $Ni(cod)_2$ (620 mg, 2.25 mmol) was dissolved under argon in 10 mL of toluene in a Schlenk tube equipped with a stirring bar and the resulting solution was cooled to −30 °C. Compound **1** (825 mg, 2.25 mmol) [8] was dissolved likewise in 10 mL of toluene and then slowly added dropwise to the stirred solution of $Ni(cod)_2$. After an additional hour at −10 °C, PCy_3 (659 mg, 2.3 mmol) in toluene was added. The filtered toluene solution contains a nearly quantitative amount of liberated 1,5-cyclooctadiene. The crude yellow-brown product was recrystallized from toluene/petroleum ether (1/10). Yield 1.3 g (62%). ^{1}H NMR ([D_8] toluene): $\delta = 7.7$–6.99 (m, 10H, Ph_2P), 2.97 (d, 2H, CH_2), 2.1–1.2 (m, 33H, PCy_3), −24.85 (dd, 1H, Ni–H).

Complex **3** was prepared in a similar fashion. However, the reaction was performed at 20 °C and twice as much PCy_3 was used. Yield 81%. ^{1}H NMR ([D_8] toluene): $\delta = 7.0$–7.6 (m, 10H, PPh_2), 2.88 (d, 2H, CH_2), 1.2–2.1 (m, 66H, PCy_3), −24.98 (t, 1H, Ni–H).

All new compounds gave correct elemental analyses. The NMR spectra, with detailed coupling constants, are contained in the dissertation of *U. Müller* [9].

Tetra-*tert*-butyltetraphosphacubane: The First Thermal Cyclooligomerization of a Phosphaalkyne**

By *Thomas Wettling, Jürgen Schneider, Oliver Wagner, Cornelius G. Kreiter,* and *Manfred Regitz**

Dedicated to Professor Gottfried Märkl on the occasion of his 60th birthday

The extremely rapid development of phosphaalkyne chemistry has focused above all on cycloaddition reactions and ligand properties.[1] Of particular interest have been the cyclodimerization and cyclotrimerization reactions in the coordination sphere of metals. Thus, *tert*-butylphosphaacetylene **5** can be dimerized, for example, to give cobalt complexes containing diphosphacyclobutadiene (**1**[2, 3]) and diphosphabicyclo[1.1.0]butane ligands (**2**[4]). Complexes with cyclotrimer ligands derived from 1,3,5-triphosphabenzene **3**[5] and its Dewar derivatives **4**[6] are also known.

1 **2** **3** **4**

The use of metal complexes in cyclooligomerization reactions is not always necessary, as shown by the thermal cyclotetramerization of **5**. Although most phosphaalkynes are not particularly thermally stable,[1] the behavior of these species upon heating has not been studied.

When neat phosphaalkyne **5** is heated for a long period of time at 130 °C and the product distilled, pale yellow crystals are obtained which exhibit a high melting point and are stable toward air. Elemental analysis and mass spectrometry revealed that the product is a tetramer of **5**, compound **7**. The stepwise decomposition of the tetramer to the monomer occurs upon electron-collision-induced fragmentation.[7]

The NMR spectra of **7** support a tetraphosphacubane structure with alternating C and P atoms. The $^{13}C\{^1H\}$ NMR spectrum (100.62 MHz, C_6D_6) shows three multiplets at $\delta = -29.07$, 21.57, and 30.64 (Fig. 1). These represent the

[**] Unusual Coordinated Phosphorus Compounds, Part 37. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 36: W. Schnurr, M. Regitz, *Synthesis 1989*, im Druck.

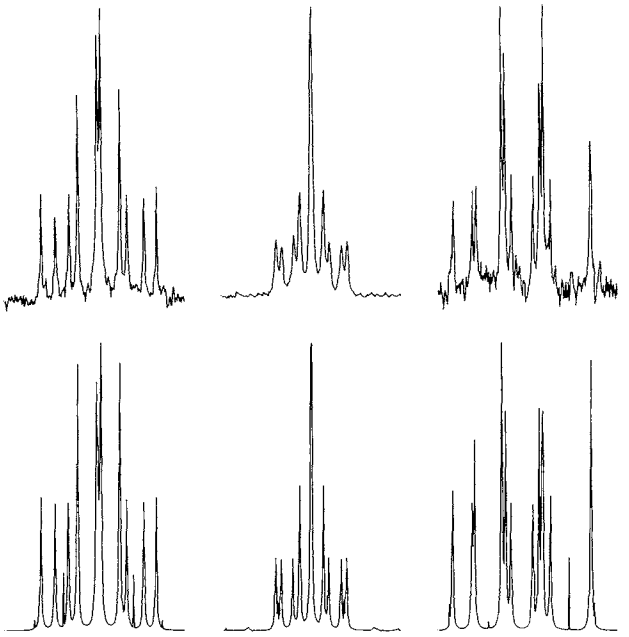

Fig. 1. Measured (top) and simulated (bottom) ^{13}C NMR spectrum of **7** (sequence of the signals from left to right: $C(CH_3)_3$, $C(CH_3)_3$, cage C; see text).

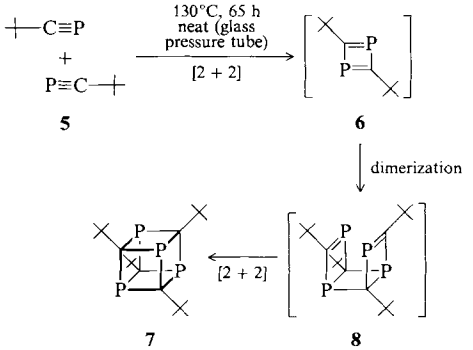

A portions of AX_3Y spin systems, each composed of one ^{13}C and four ^{31}P atoms. Different ^{13}C-induced shifts of the two kinds of phosphorus atoms have to be taken into consideration in calculating the signals.[8] Especially noteworthy is the isotope-induced shift for the spin system containing the cage ^{13}C atom, as revealed by the unsymmetrical appearance of the signal. The separation of the signals due to the two kinds of P atoms is less for the spin system containing the quaternary ^{13}C atom of a *tert*-butyl group or the ^{13}C atom of a methyl group. The $^2J(^{31}P\text{-}^{31}P)$ and the $^nJ(^{31}P\text{-}^{13}C)$ coupling constants (n = 1–5) lie in a narrow range (Table 1).

Table 1. Calculated ^{31}P NMR chemical shifts of the AX_3Y spin systems as well as $^2J(^{31}P\text{-}^{31}P)$ and $^nJ(^{31}P\text{-}^{13}C)$ coupling constants of the $^{13}C\{^1H\}$ NMR signals of **7**.

$\delta(X)-\delta(Y)$	$^2J(^{31}P\text{-}^{31}P)$	$^nJ(^{31}P\text{-}^{13}C)$	$^{n+2}J(^{31}P\text{-}^{13}C)$	n [a]
7.8	8.52	13.43	− 2.05	1
1.3	8.52	10.10	1.49	2
0.3	8.52	6.58	− 0.17	3

[a] n = 1, cage C; n = 2, $C(CH_3)_3$; n = 3, $C(CH_3)_3$.

Unusual is both the strong low-field shift of the phosphorus signals of **7** ($\delta = 257.4$, $CDCl_3$) and the high-field shift of the cage ^{13}C signal ($\delta = -29.07$). Presumably, this reflects a shift of electron density from phosphorus to carbon.

5 **6** **7** **8**

The formation of the pentacyclic system presumably begins with a head-to-tail dimerization of the phosphaalkyne (**5** → **6**), followed by either dimerization to give the tricyclic compound **8** or sterically controlled cycloaddition of two molecules of **5** to **6**,[9] which leads to the same result. The final step, **8** → **7**, is not surprising, since analogous intermolecular phosphaalkene dimerizations are known.[10]

Unequivocal confirmation of the phosphaalkyne tetramer as being tetraphosphacubane **7** was achieved by crystal structure analysis, which revealed a distorted cubelike structure (Fig. 2).

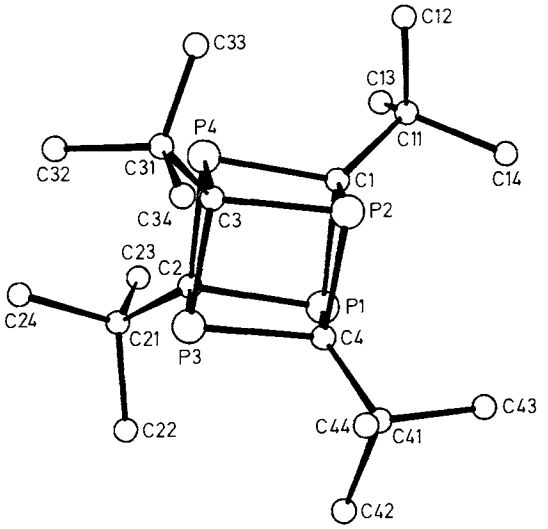

Fig. 2. Molecular structure of **7**: $C_{20}H_{36}P_4$; $P2_1/c$, $a = 9.678(3)$, $b = 14.365(4)$, $c = 17.019(5)$ Å, $\beta = 92.24(2)°$, $T = 20$ °C, $Z = 4$, $\varrho_{calcd} = 1.12$ g cm^{-3}. Enraf-Nonius CAD 4 diffractometer, monochromatic $Mo_{K\alpha}$ radiation, 3089 unique reflections with $2.0 \leq \theta \leq 22.5°$, absorption correction ($\mu = 3.14$ cm^{-1}), full matrix refinement with 2654 reflections [$I > 2\sigma(I)$] and 217 variables. $R = 0.042$, $R_w = 0.037$ [11]. Selected bond lengths [Å] and bond angles [°]: P1-C1 1.880(3), P1-C2 1.886(3), P1-C4 1.877(3), P2-C1 1.883(3), P2-C3 1.891(3), P2-C4 1.882(4), P3-C2 1.881(3), P3-C3 1.875(4), P3-C4 1.886(3), P4-C1 1.885(3), P4-C2 1.876(3), P4-C3 1.875(4); C1-P1-C2 85.4(1), C1-P1-C4 85.7(1), C2-P1-C4 85.6(1), C1-P2-C3 85.5(2), C1-P2-C4 85.5(1), C3-P2-C4 85.7(2), C2-P3-C3 85.0(2), C2-P3-C4 85.5(1), C3-P3-C4 86.1(2), C1-P4-C2 85.6(1), C1-P4-C3 85.9(1), C2-P4-C3 85.2(2), P1-C1-P2 94.2(2), P1-C1-P4 94.3(2), P2-C1-P4 94.1(1), P1-C2-P3 94.2(2), P1-C2-P4 94.3(2), P3-C2-P4 94.7(1), P2-C3-P3 93.9(2), P2-C3-P4 94.2(2), P3-C3-P4 94.9(2), P1-C4-P2 94.3(2), P1-C4-P3 94.4(2), P2-C4-P3 93.9(2).

Comparison of the internal bonding angles of the rings with those of unsubstituted cubanes, which are about 90°,[12] reveals that the C–P–C angles of **7** are on average 4.4° smaller (85.6°), which requires an increase in the P–C–P angles to 94.4°; the exocyclic P–C–C bond angles are 122.2°. The average P–C bond length in the cube is 1.881 Å, the same magnitude as in 1,3-diphosphacyclobutanes.[10]

Experimental Procedure

7: **5** (3.50 g, 35.0 mmol) [13] was stirred with a magnetic stirring bar for 65 h at 130 °C under argon atmosphere in a preheated Schlenk pressure tube. The red, viscous reaction mixture was dissolved in 10 mL of pentane, transferred by pipette to a round-bottomed flask, and evaporated at 25 °C/10^{-2} torr. Kugelrohr distillation of the residue (10 h at 155 °C (oven temperature)/10^{-2} torr) afforded crystalline **7**, which was separated from an oily side product [14] by recrystallization from *n*-pentane. Yield: 280 mg (8%) pale yellow, cube-shaped crystals, m.p. 241 °C [15].

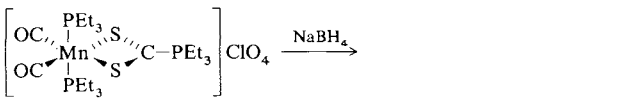
Fehér, *ibid. 101* (1989) 352 and *28* (1989) 339.

A Phosphane–Dithioformate Adduct as a Five-Electron Bridging Ligand $[Mn_2(CO)_6\{S_2C(H)P(cyclo\text{-}C_6H_{11})_3\}_2]$**

By *Daniel Miguel, Jesús A. Miguel, Victor Riera,** and *Xavier Soláns*



Coordinated trialkylphosphoniodithiocarboxylato ligands S_2CPR_3 undergo nucleophilic attack on the carbon atom, thus giving a variety of coordinated 1,1-dithiolato ligands such as xanthates and dithio- and trithiocarbonates.[1]

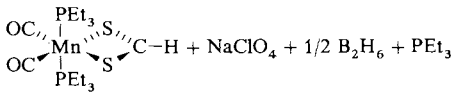
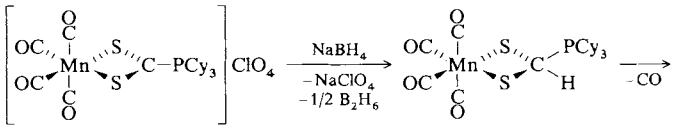
[**] We thank C.A.I.C.Y.T. for financial support.



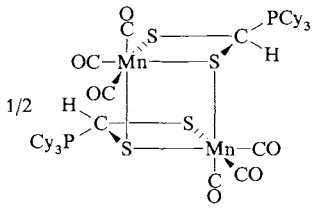
When the nucleophile used in these reactions is the hydride ion, two types of products can be obtained: either the hydride ion displaces the phosphane producing a coordinated dithioformate $^{\ominus}S_2CH$, or the PR_3 group remains attached to the carbon atom and an $^{\ominus}S_2C(H)PR_3$ ligand is formed. The final result seems to depend on both structural and electronic factors.[2, 3] Here we report a preliminary study of hydride additions to coordinated S_2CPR_3 ligands (R = cyclohexyl (Cy, Et)) in octahedral manganese(I) complexes, in which a spontaneous dimerization leads to the formation of a dinuclear Mn^I compound containing two five-electron unsymmetrically bridging $^{\ominus}S_2C(H)PCy_3$ ligands coordinated in an $^2\eta,^1\eta$ fashion.

The reaction of complex **1** [Eq. (a)] with $NaBH_4$ gives a bright red solution of the dithioformate complex **2**, which can be isolated as red crystals. Analytical and spectroscopic data are in good agreement with the structure depicted for **2**



1

(a)



2

in Equation (a). On the other hand, treatment of complex **3**[5] with $NaBH_4$ [Eq. (b)] yields a yellow solution from which the dinuclear complex **4** can be isolated as a crystalline solid.

3

(b)

4

The IR spectrum of **4** shows five $\tilde{\nu}_{CO}$ maxima, in a pattern consistent with an $Mn_2(CO)_6$ grouping, but the available spectroscopic data[4] did not give enough information about the structure of this compound. An X-ray structure analysis was therefore carried out on a crystal of **4**[6] (Fig. 1).

Compound **4** is a dimer in which each $^{\ominus}S_2C(H)PCy_3$ ligand is coordinated to one manganese in an η^2-*S,S'* chelate fashion and one sulfur atom of each ligand serves as a bridge to bind the other manganese atom, thus forming a distorted Mn_2S_2 square with Mn–S distances ranging from 2.379(2) to 2.445(2) Å, values not very different from those found in $[Mn_2(CO)_6(\mu\text{-}SC(SMe)NMe)_2]$.[7] Both manganese atoms are surrounded by a six-coordinate octahedral environment, and the distance Mn1-Mn2 is large enough to prevent any significant interaction between them. The molecule consists of two tricarbonylmanganese units held together by two $^{\ominus}S_2C(H)PCy_3$ bridging ligands and, since no Mn–Mn bond

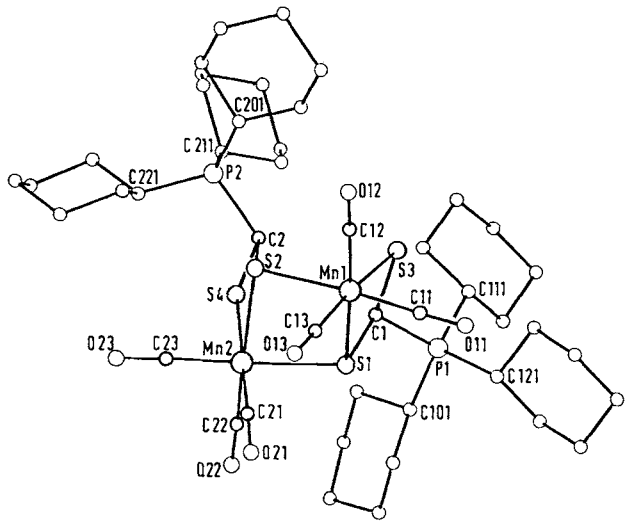


Fig. 1. Molecular structure of the cation of **4**. exists, each bridge must donate five electrons to satisfy the 18-electron rule. The carbonyls on each $Mn(CO)_3$ grouping adopt a *facial* arrangement with C–Mn–C angles very close to 90° and the six $Mn–C_{carbonyl}$ distances are normal. On the other hand, the positions of the sulfur atoms deviate considerably from ideal octahedral coordination, the main deviations being induced by the small bite of the chelate ligands (angles S3-Mn1-S1 = 75.1(1)°, S4-Mn2-S2 = 75.0(1)°).

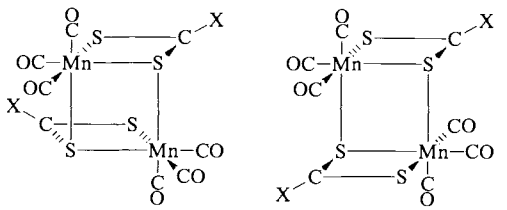
The hydrogens on the central carbons of the ligands, H1 and H2, are close to one manganese and three sulfur atoms, the distances (Table 1) being shorter than the sum of the van

Table 1. Important distances [Å] between the central H atoms of **4** and other atoms. H1 is the H atom on C1, H2 that on C2.



H1-C1 1.06(6), H1-S1 2.36(2), H1-S3 2.39(2), H1-S4 2.55(2), H1-Mn2 3.29(1), H2-C2 1.13(6), H2-S2 2.34(2), H2-S3 2.37(2), H2-S4 2.35(2), H2-Mn1 3.09(1)

der Waals radii of the atoms involved. This implies some degree of interaction between these hydrogens and the manganese and sulfur atoms, which could explain some unusual spectroscopic features, such as the position of the signal of these hydrogens in the ^1H NMR spectrum at lower fields ($\delta = 9.29$) than the range reported for other complexes containing $^{\ominus}S_2C(H)PR_3$ ligands ($\delta = 5.20-6.25$)[3, 8-10] and also the broadening of this signal, which precludes the observation of P–H coupling.

The formation of **4** can be rationalized by a two-step mechanism as shown in Equation (b). First, hydride addition to the carbon atom of the S_2PCy_3 ligand produces the neutral complex $[Mn(CO)_4(S_2C(H)PCy_3)]$, which cannot be isolated. Second, a dimerization, in which a carbonyl ligand on each manganese is displaced by a sulfur atom of the chelate ring of the opposite manganese, yields the final dinuclear product.

As far as we know, **4** is the first complex in which a phosphane–dithioformate adduct acts as a five-electron bridging ligand. However, this kind of dimerization (either spontaneous or thermally induced) has been observed before in other manganese complexes containing 1,1-dithiolato lig-

ands such as S_2CSMe and $^{\ominus}S_2CNR_2$.[7, 11, 12] In the final products of these dimerizations, the two chelate ligands can adopt, in principle, either a *cisoid* (**5**) or a *transoid* (**6**) disposition. However, the factors leading to one or the other geometry are not yet well understood. In the special case of **4**, the intramolecular interactions of the hydrogens with the manganese and sulfur atoms could play a significant role in the adoption of the *cisoid*[13] configuration, since these interactions would not be possible in the *transoid* geometry. However, this kind of hydrogen interaction has been absent in the other dimeric structures (either *cisoid* or *transoid*) reported so far.

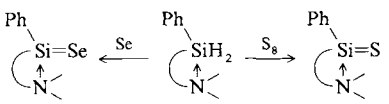
[13] The formation of any significant amount of the *transoid* isomer can be ruled out from spectroscopic data. The carbonyl stretching region of the IR spectra is highly informative: only three active bands (3 A_u) are expected [12] for the centrosymmetric *transoid* structure (point group C_i), whereas six (3 A + 3 B) bands are predicted for the noncentrosymmetric *cisoid* structure (point group C_2). For compound **4**, five bands are observed, probably owing to accidental degeneracy. Since IR and ^1H NMR solution spectra do not change upon crystallization of **4** from the reaction mixture, or upon recrystallization from CH_2Cl_2/hexane, it can be concluded that only very minor quantities of the *transoid* isomer, if any, are produced in the dimerization process.

Formation and Reactivity of Silicon–Sulfur and Silicon–Selenium Double Bonds. The First X-Ray Structure of a Silanethione

By *Prabhat Arya, Jacqueline Boyer, Francis Carré, Robert Corriu,* Gérard Lanneau, Jacques Lapasset, Myriam Perrot,* and *Christian Priou*

Experimental evidence for the existence of multiply bonded silicon compounds has accumulated in the last few years.[1] Compounds containing Si=C,[2] Si=Si,[3] and Si=N[4] double bonds have been isolated. A method of stabilizing them with respect to dimerization is to form adducts with donor molecules or anions.[5, 6]



In 1986, we described the enhanced chemical reactivity of the pentacoordinated functional silane **1** towards carbonyl groups,[7] acyl chlorides,[8] and carboxylic acids.[9] CO_2 reacts with insertion[10] into the Si–H bond of **1** to give silyl formate **2**. Warming **2** at 85 °C decomposes the ester into formaldehyde and the transient silanone **5**, which trimerizes immediately to yield **4**. The silanone **5** has also been trapped[11] with $(Me_2SiO)_3$ to give the eight-membered ring compound **7**.

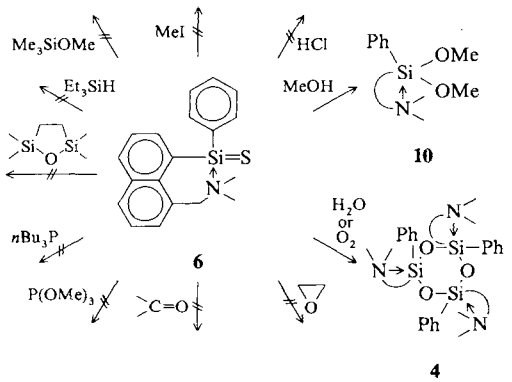
Here we describe the analogous reaction of **1** with CS_2. The unexpectedly easy decomposition of the silyl ester **3** of dithioformic acid at room temperature leads to the formation of the first isolable silanethione, **6**.[1a, 12]



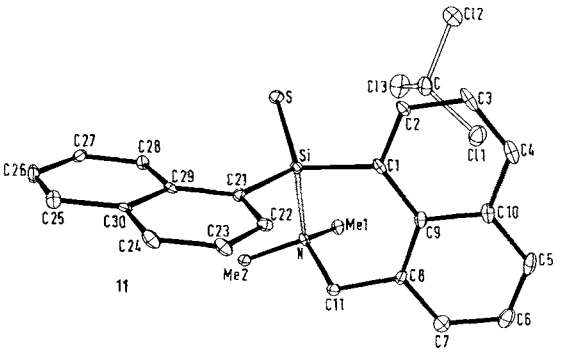
The ^1H NMR spectrum provides the strongest evidence for this structure. Two diastereotopic signals are observed for the methyl groups of the dimethylamino naphthyl substituent and they are clearly deshielded relative to the signals of the parent silane **1**. The IR spectrum exhibits a new band at 645 cm^{-1}.[13] Although **6** is relatively long-lived in solution ($t_{1/2}$: 3 d in $CDCl_3$ at 25 °C), extreme precautions must be taken to avoid exposure to minute amounts of air. The fast oxidation of **6** gives the same trimeric siloxane **4** obtained in the reaction of **1** with CO_2.[10] If the reaction of **1** with CS_2 is performed in the presence of $(Me_2SiO)_3$ no product **8** corresponding to the insertion[1a, 12] of the silanethione **6** into $(Me_2SiO)_3$ is obtained (even after 48 h). However, we observed the formation of the eight-membered ring derivative **7** when the oxidation of **6** was performed in the presence of $(Me_2SiO)_3$; this suggests that the oxidation probably involves the transient formation of silanone **5**. Addition of sulfur to **1** also gives **6**. A small excess of S_8 is necessary to complete the reaction at room temperature, but **6** is the only silicon-containing product. The insertion of sulfur into the Si–H bond normally requires more drastic conditions.[14]

9 **1** **6**

There has been only one report of the transient formation of an $R_2Si=Se$ compound.[15] The addition of Se to **1** gives, similarly to S_8, the monomeric Si=Se species **9**. The reaction is slightly slower than with S_8. Like **6**, compound **9** is extremely sensitive to air. Compound **9** is characterized by a downfield ^{29}Si chemical shift ($\delta = +29.4$) and a high coupling constant with ^{77}Se ($J_{SeSi} = 257$ Hz).

The reactivity of the coordinated Si=S compound **6** with electrophiles and nucleophiles is unexpectedly low. Phosphanes, phosphites, ketones, epoxides, MeI, and HCl are unreactive, as are alkoxysilanes and siloxanes. Methanolysis gives the dimethoxysilane **10**[16] but only if methanol is introduced in a large excess. Hydrolysis leads to the trimer **4**.[10]

The structure of the more bulky silanethione **11**, containing *two* α-naphthyl substituents, has been obtained by X-ray analysis[17] (Fig. 1). The Si–S bond (2.013 Å) is shorter than a Si–S single[18] bond (2.16 Å); an 8% reduction in bond



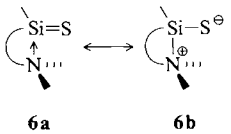


Fig. 1. ORTEP drawing of the molecular structure of **11**·$CHCl_3$. Thermal ellipsoids at the 10% probability level. Important distances [Å] and angles [°]: Si-S 2.013(3), Si-N 1.964(8), Si-C1 1.885(7), Si-C21 1.876(8); S-Si-C1 114.5(3),

length is typical of π-bonded species at silicon. The Si–N distance (1.96 Å), slightly longer than[19] a Si–N σ bond (1.79 Å), supports a very strong association of the aminoaryl substituent with silicon. Generally, the coordinate bond length determined with the same coordinating group lies in the range 2.3–2.6 Å.[20] The silicon center displays a distorted tetrahedral environment with the C1–Si–C21 angle (110°) nearly equal to the Si–Si–N angle (110.9°). The N–Si–C1 angle (96°) and the S–Si–C21 angle (120°) differ considerably, but the sum of the bond angles S-Si-C1, C1-Si-C21, S-Si-C21 is 344.9°, which is intermediate between $sp^2 + p$ (360°) and sp^3 (328.5°). Important to note is the position of the sulfur atom, which is situated outside the plane of the naphthyl–silicon unit, which means that the extra stabilization is not due to aromatic delocalization.

Also noteworthy is the solubility of the internally coordinated silicon compounds **6**, **9**, and **11**. They are insoluble in common organic solvents (CCl_4, Et_2O, THF, benzene, hexane) and only moderately soluble in $CHCl_3$ and CH_2Cl_2, but highly soluble in nucleophilic solvents (DMF, acetone, tetramethylurea, HMPT, $(MeO)_3PO$); the latter solvents are known to have a strong affinity for coordination at silicon.[21]

It is reasonable to expect that the resonance betaine structure **6b** strongly participates in the electronic distribution of **6** and **11**.

6a **6b**

Such a structure would partly explain the unexpectedly low reactivity of the silanethione towards nucleophiles and electrophiles, as well as its low solubility in organic solvents.

Experimental Procedure

Preparation of **6** from **1** and CS_2: The reaction was performed under argon using vacuum line techniques. CS_2 was purified by distillation and repeated freeze/thaw cycles just prior to use. In a typical experiment, 10 mL of CS_2 (12.6 g, 0.16 mol) was added dropwise at room temperature to **1** (2.91 g, 0.01 mol) with stirring. After a 5-min induction period, an exothermic reaction ensued with evolution of gas. After 1 h, the two phases were separated with a cannula. The lower phase was dried in vacuo, giving a yellow-white precipitate, which was dissolved in $CDCl_3$ (freshly distilled). Yield 67%; m.p. 170–171 °C. ^{29}Si NMR (49.69 MHz, $CDCl_3$, TMS int.): $\delta = +22.3$. ^{13}C NMR (62.9 MHz, $CDCl_3$, TMS int.): $\delta = 45.6$, 46.4 ($N(CH_3)_2$), 63.7 (NCH_2), ^1H NMR (62.9 MHz, $CDCl_3$, TMS int.): $\delta = 2.5$, 2.7 (2s, 6H, $N(CH_3)_2$), 4.3 (bd, 2H, NCH_2), 6.9–8.1 (m, 11H, aryl-H). MS (70 eV): *m/z* (rel. int. %): 321(33), 306(100), 245(15), 228(40), 215(20), 167(13), 141(18), 91(11), 84(8), 58(12). MS

(15 eV): *m/z* (rel. int. %): 321(15), 306(100), 245(6), 228(13), 91(2), 84(6), 58(3). FAB-MS (pos.): *m/z* (rel. int. %): 321(10), 306(100), 245(8), 228(30), 215(15), 167(10), 141(12), 91(8), 76(15), 58(8); M_r (calcd) for $C_{19}H_{19}SiSN$ = 321.008. Relative distribution: theoretical 321.008(100), 322.1030(27.838), 323.0999(11.442), 324.1009(2.263); experimental 321(100), 322(27.85), 323(11.74).

Preparation of **6** from **1** and S_8: **1** (0.589 g, 2 mmol) and S_8 (0.088 g, 2.76 mmol) were mixed in degassed $CDCl_3$ (2.5 mL). After 1 h, the NMR spectrum of the yellow solution was recorded. All the starting **1** had been consumed. The spectral data were identical to those of compound **6** isolated from the CS_2 reaction.

Preparation of **9** from **1** and Se: A mixture of **1** (0.5 g, 1.7 mmol) and selenium (0.225 g, 2.8 mmol) in $CDCl_3$ (5 mL) was kept for 30 min at 25 °C and then analyzed spectroscopically. Yield 84%; m.p. >80 °C (dec.). ^{29}Si NMR (49.69 MHz, $CDCl_3$, TMS int.): $\delta = +29.4$ ($J_{SeSi} = 257$ Hz). ^{13}C NMR (62.9 MHz, $CDCl_3$, TMS int.): $\delta = 45.72$, 47.32 (2s, $N(CH_3)_2$), 64.23 (s, NCH_2); ^{1}H NMR (60 MHz, $CDCl_3$, TMS int.): $\delta = 2.6$, 2.8 (2s, 6H), 5.4 (br., 2H), 6.8–8.2 (m, 11H). MS (70 eV): *m/z* (rel. int. %): 369(30), 354 (100), 276(45), 237(30).

$[Mes_2SbCu(PMe_3)_2]_2$: The First Cu^I Antimonide **

By *Alan H. Cowley,* Richard A. Jones,* Christine M. Nunn,* and *Donald L. Westmoreland*

Copper(I) amides and phosphides display an interesting variety of structures which range from dinuclear to octanuclear in character. The Cu^I amides are tetrameric,[1] while all the Cu^I phosphides except $[tBu_2PCu]_4$[2] are coordinated with Lewis bases.[3] Interestingly, the heavier congeners of Cu^I amides and phosphides are unknown. We report here the preparation and X-ray crystal structure of $[Mes_2SbCu(PMe_3)_2]_2$, the first example of an antimonide of a late transition metal (Mes = mesityl).

Dimesitylstibane (Mes_2SbH) was prepared by the reduction of trimesitylstibane[4] with excess lithium, followed by protonation with $[Me_3NH]Cl$. This method avoids the intermediacy of a halostibane. Mes_2SbH is surprisingly stable and does not show any signs of oxidation over a period of weeks. The X-ray crystal structure of Mes_2SbH (Fig. 1),[5] which, to our knowledge, constitutes the first such information for a secondary stibane, revealed that the molecules possess a C_2 axis which bisects the C1–Sb–C1′ angle. Each of the aryl rings is twisted out of the C1–Sb–C1′ plane by an angle of 68.06°. The presence of the Sb-H moiety could not be discerned in the electron density map; however, its identity was confirmed by the detection of a singlet at $\delta = 4.90$ in

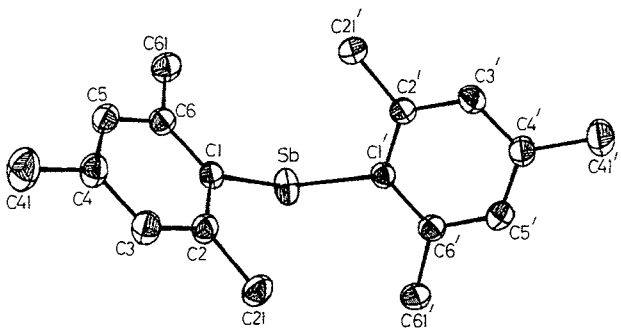

Fig. 1. The structure of Mes_2SbH in the crystal. Selected bond lengths and angles: Sb–C1 2.168(2) Å; C1–Sb–C1′ 101.70(8)°.

the ^{1}H NMR spectrum and a stretching vibration at $\tilde{\nu}_{Sb-H}$ 1887.3 cm^{-1} in the IR spectrum.

Lithiation of Mes_2SbH with *n*BuLi produced Mes_2SbLi, which, upon addition to a THF solution of CuCl and Me_3P, afforded yellow crystalline $[Mes_2SbCu(PMe_3)_2]_2$. Its solid-state structure (Fig. 2)[5] comprises two crystallographically

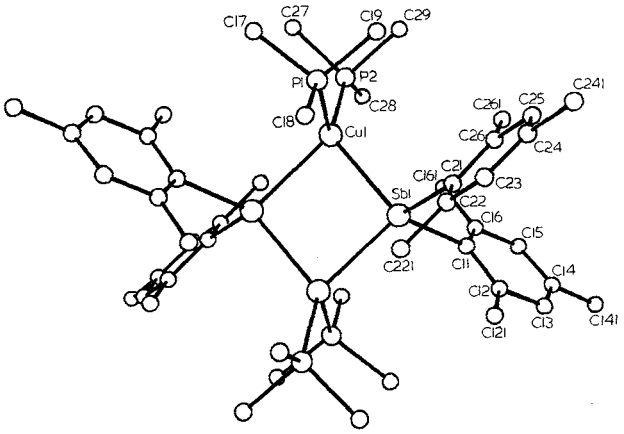

Fig. 2. The structure of $[Mes_2SbCu(PMe_3)_2]_2$ in the crystal [5]. There are two crystallographically independent molecules. Selected bond lengths [Å] and bond angles [°] shown in parentheses (for the second molecule): Sb1–Cu1 2.676(2) (2.661(2)), Sb1–Cu1 2.657(1) (2.681(1)), Cu1–P1 2.288(3) (2.272(3)), Cu1–P2 2.281(3) (2.285(4)), Cu1–Sb1–Cu1' 95.34(5) (94.88(5)), Sb1–Cu1–Sb1' 84.66(4) (85.12(5)), P1–Cu1–P2 105.3(1) (105.4(1)), C11–Sb1–C21 95.2(4) (93.7(4)).

independent molecules with similar dimensions. Both molecules are centrosymmetric and feature a planar Cu_2Sb_2 core of alternating Cu and Sb atoms. The average Sb–Cu–Sb' and Cu–Sb–Cu' angles are 95.11(5) and 84.89(5)°, respectively. Four-coordination of each Cu is achieved by the attachment of two Me_3P ligands. The geometry at both Cu and Sb is distorted tetrahedral. The average Cu–Sb distance is 2.669(2) Å, which is close to the sum of covalent radii for these elements (2.68 Å),[6] but somewhat longer than the only previously measured bond length of 2.554(2) Å in the stibane complex $[(Ph_3Sb)_3CuCl]$.[7] The Cu–Cu separation in the title compound (3.95 Å) precludes any type of bonding interaction between these atoms. The antimonide is moderately stable in the crystalline form in the absence of air. However, surface decomposition occurs in the presence of light. Solutions of the compound decompose in a few hours at 25 °C.

The reaction of Mes_2SbLi with CuCl in the absence of Me_3P resulted in reduction of Cu^I to Cu^0 and formation of the distibane Mes_4Sb_2.[8] Similar observations have been made previously with metal phosphides.[9]

Experimental Procedure

Mes_2SbH: A solution of Mes_2Sb (33 g, 68.8 mmol) and Li powder (2 g, 288.2 mmol) in THF (750 mL) was stirred at 25 °C for 12 h. After filtration of the deep orange solution, solid $[Me_3NH]Cl$ (9.2 g, 172 mmol) was added in one portion. After stirring the reaction mixture for 2 h, the volume was reduced to ca. 200 mL and 500 mL of toluene was added. Filtration through Celite, followed by solvent evaporation, left crude Mes_2SbH as an oily solid. Recrystallization from 3:1 toluene/hexane (−15 °C) afforded a 68% (16.9 g) yield of off-white crystals of Mes_2SbH, m.p. 112–15 °C. X-ray quality crystals were grown from hexane. ^{1}H NMR (300 MHz, C_6D_6, TMS ext.): δ = 2.08 (s, 3H, *p*-Me), 2.31 (s, 6H, *o*-Me), 4.90 (s, 1H, SbH), 6.72 (s, 2H, *m*-H). $[Mes_2SbCu(PMe_3)_2]_2$: Mes_2SbLi was prepared by addition of *n*BuLi (1.5 mL of a 1.6 M solution in hexane) to a solution of Mes_2SbH (0.86 g, 2.38 mmol) in 60 mL of THF at −78 °C. The resulting solution was stirred for 3 h at 25 °C, then added dropwise to a solution of CuCl (0.235 g, 2.37 mmol) and Me_3P (1 mL) in 75 mL of THF at −78 °C. After stirring the reaction mixture at −10 °C for 2 h, the solvent was removed in vacuo. The resulting dark solid was extracted with two 40-mL portions of hexane and filtered through Celite. Concentration and cooling of the solution (−15 °C) afforded a 41% yield (0.51 g) of yellow crystalline $[Mes_2SbCu(PMe_3)_2]_2$, m.p. 160 °C (dec.). X-ray quality crystals were grown from hexane. ^{1}H NMR (300 MHz, C_6D_6, TMS ext.): δ = 0.90 (br, PMe), 2.06 (s, 3H, *p*-Me), 2.47 (s, 6H, *o*-Me), 6.65 (s, 2H, *m*-H). $^{31}P\{^1H\}$ NMR (121.5 MHz, C_6D_6, 85% H_3PO_4 ext.): δ = −34.43(s).

[5] Crystal structure data for Mes_2SbH: monoclinic, space group $C2/c$ (No. 15), $Z = 4$, $a = 13.162(3)$, $b = 9.358(3)$, $c = 13.699(2)$ Å, $\beta = 103.01(2)°$. $V = 1644(1)$ Å^3, $\varrho_{calcd} = 1.459$ g/cm^3, ($Mo_{K\alpha}$, $\lambda = 0.71069$ Å, $\mu = 16.7$ cm^{-1}), 2175 unique data collected (ω-2θ scans, $3.0 \le 2\theta \le 50.0°$), of which 1780 had $I > 3.0\,\sigma(I)$ and were used for structure solution and refinement. $[Mes_2SbCu(PMe_3)_2]_2$: triclinic, space group $P\bar{1}$ (No. 2), $Z = 2$; $a = 12.466(7)$, $b = 12.496(6)$, $c = 20.026(15)$ Å, $\alpha = 75.22(5)$, $\beta = 80.07(5)$, $\gamma = 78.57(4)$, $V = 2932(1)$ Å^3; $\varrho_{calcd} = 1.305$ g/cm^3, ($Mo_{K\alpha}$, $\lambda = 0.71069$ Å, $\mu = 17.8$ cm), 8121 unique data collected (ω-2θ scans, $3.0 \le 2\theta \le 46.0°$), of which 5228 had $I > 3.0\,\sigma(I)$ and were used for structure solution and refinement. Both data sets were collected on an Enraf-Nonius CAD4 diffractometer at 293 K and were corrected for Lorentz, polarization, crystal decay, and X-ray absorption (empirical ψ-scan method). The structures were solved by Patterson syntheses, which located the heavy-atom positions. Refinement (full-matrix least-squares) gave $R = 0.027$ and $R_w = 0.035$ for Mes_2SbH and $R = 0.060$ and $R_w = 0.084$ for $[Mes_2SbCu(PMe_3)_2]_2$. Atoms C(33), C(34), and C(341) of the second molecule of $[Mes_2SbCu(PMe_3)_2]_2$ were refined isotropically; all other non-hydrogen atoms were refined anisotropically. One-Dimensional Metal Chains in a Chiral Environment – The Crystal Structure of Helical Bis(dicarbonylrhodium(I))-3,3'-hexafluoroglutarylbis-(1*R*)-camphorate **

By *Volker Schurig,* Hans Gaus, Peter Scheer, Leonhard Walz,* and *Hans Georg von Schnering*

The propensity of four-coordinate square-planar d^8-transition-metal compounds, for example, dicarbonylrhodium(I)-

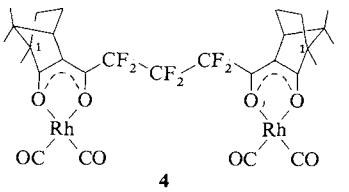
2,4-pentanedionate **1**[1] or $K_2[Pt(CN)_4]Cl_{0.32}(H_2O)_{2.6}$,[2] to form one-dimensional metal chains in the solid state is well established.[2] It has previously been demonstrated that the presence of *chiral* β-diketonate ligands in the inner coordination sphere of the d^8-metal ions Rh^I or Ir^I may efficiently control the degree and mode of molecular stacking. Thus, enantiomerically pure dicarbonylrhodium(I)-3-(trifluoroacetyl)-(1*R*)-camphorate (1*R*)-**2a** crystallizes as a yellow solid devoid of molecular stacking, while the racemate (1*R*/1*S*)-**2a** forms dark dichroic crystals in which the rhodium atoms are linked along a one-dimensional metal chain in a pairwise alternating mode to ligands with -[(1*R*-1*R*-1*S*-1*S*)]$_\infty$- configuration.[3, 4]

1, R = CH_3
3, R = CF_3



(1*R*)-**2a**, M = Rh
(1*R*)-**2b**, M = Ir

The concept of structure control by chiral ligands has subsequently been employed for the engineering of a totally ordered columnar structure consisting of a one-dimensional -[Rh-Rh-Ir-Ir]$_\infty$- metal chain in the solid state simply by mixing the quasi-enantiomers of yellow (1*S*)-**2a** and yellow (1*R*)-**2b** to yield a black quasi-racemate.[5, 6]

We have now synthesized dinuclear bis(dicarbonylrhodium(I)-3,3'-hexafluoroglutarylbis-(1*R*)-camphorate **4** in which two square-planar rhodium(I) entities are linked via a short perfluoroalkyl bridge.

In contrast to the yellow enantiomers of **2a** and **2b**, homochiral **4** forms dark crystals, indicating the formation of a columnar structure. An X-ray structure analysis of **4**[7]

4

showed unexpected features (Fig. 1). Dinuclear **4** does not participate in the bridging of segregated stacks, as might have been expected; instead, both rhodium atoms are incorporated into a single one-dimensional metal chain. This requires the formation of a twisted, helical conformation of **4** in the solid state. In the unit cell *two* independent dinuclear complexes of **4** are observed which differ by *opposite* screw senses of their helical conformations (Rh1-Rh2 (+)-(*P*) and Rh1'-Rh2' (−)-(*M*)) and which are arranged pairwise along the one-dimensional metal chain with the following repetitive sequence (Fig. 1b):

$$\cdots Rh1\text{-}Rh2(P)\cdots Rh1'\text{-}Rh2'(M)\cdots Rh2'\text{-}Rh1'(M)\cdots Rh2\text{-}Rh1(P)\cdots]\cdots_\infty$$

Since all rhodium atoms reside in the homochiral environment of (1*R*)-configurated camphor moieties, the energetically different diastereoisomers (1*R*)-(*P*)-(1*R*) and (1*R*)-(*M*)-(1*R*) (Fig. 2) occur as a result of stereoisomerism in the solid state.[8] Therefore, the one-dimensional metal chains are characterized by two different *intra*molecular metal–metal distances (Rh1-Rh2 (*P*), 3.419 Å; Rh1'-Rh2' (*M*), 3.313 Å) and by three different *inter*molecular metal–metal distances (Rh2$\cdots$Rh1' (*P*/*M*), 4.191 Å; Rh2'$\cdots$Rh2' (*M*/*M*), 3.373 Å, and Rh1$\cdots$Rh1 (*P*/*P*) 3.693 Å). Obviously, there is much stronger interaction between two adjacent (*M*) complexes than between the two (*P*) complexes, and a very weak metal–metal interaction between a (*P*) complex and an (*M*) complex. Despite the high steric constraint imposed by the

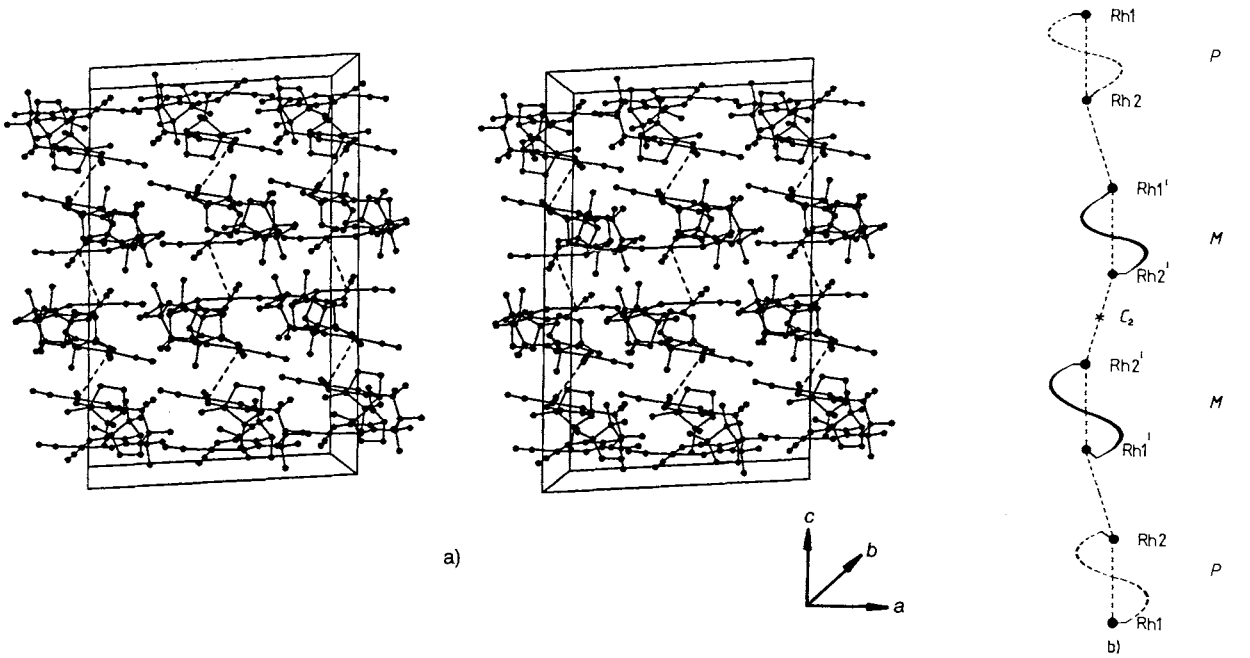


Fig. 1. a) Stereoview of the crystal structure of **4**; b) idealized arrangement of **4** in the one-dimensional metal chain.

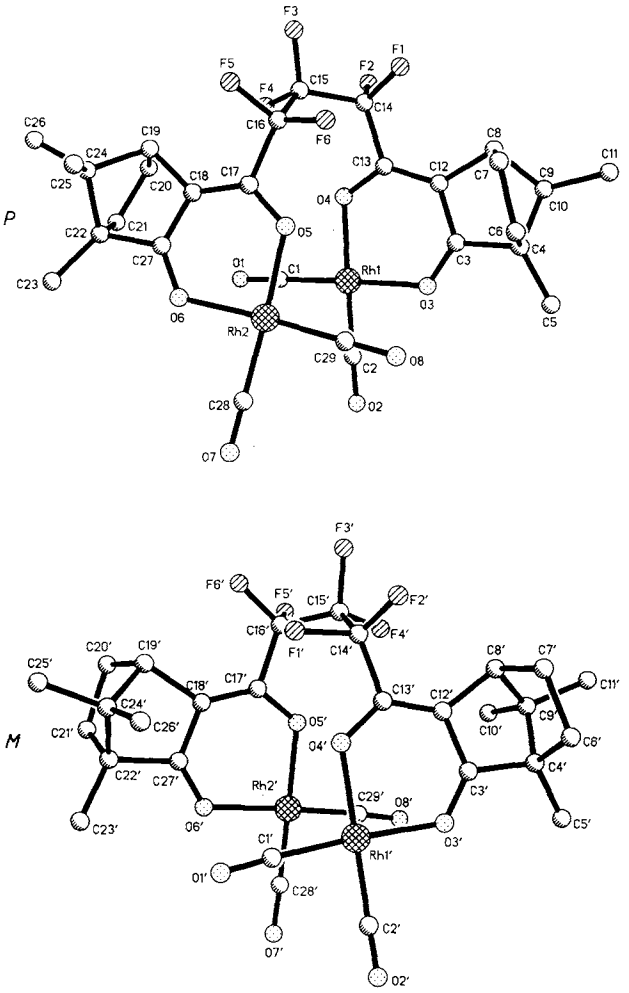

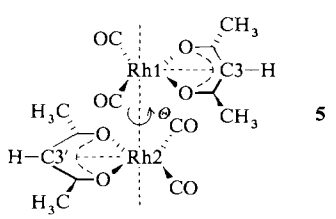

Fig. 2. Molecular structure of (*P*)-**4** (top) and (*M*)-**4** (bottom).

bicyclic camphor moiety, the Rh–Rh distances are comparable to that of planar dicarbonylrhodium(I)-1,1,1-trifluoro-2,4-pentanedionate **3** (Rh-Rh, 3.34 Å),[9] but nevertheless the distances are large with respect to a single Rh–Rh bond (2.50 Å).

In solid **1** the molecules are stacked in an *anti* position (i.e., $\theta = 180°$, interplanar angle C3-Rh1-Rh2-C3′; cf. **5**).[10]

Such nearly *anti* arrangement is observed in the unit cell of **4** between entities with the longest intermolecular metal–metal contact (Rh2 $\cdots$ Rh1′, $\theta = -175.5°$). The other entities exhibit lower interplanar angles (Rh2′ $\cdots$ Rh2′, $\theta = -120.9°$, and Rh1 $\cdots$ Rh1, $\theta = +119.2°$). Because of structural requirements, the intramolecular interplanar angles are much smaller, and different, for the diastereoisomers (1*R*)-(*P*)-(1*R*) (Rh1-Rh2, $\theta = +81.1°$) and (1*R*)-(*M*)-(1*R*) (Rh1′-Rh2′, $\theta = -78.3°$). Since the one-dimensional metal chain is not linear, the planes of the dicarbonylrhodium(I)-β-diketonate entities are not coplanar, but are tilted.[11]

5

In conclusion, the occurrence of opposite helical conformations of **4** (*P* and *M*) in a homochiral environment causes *stereoisomerism in the solid state* and thus deviations from an idealized molecular stacking.[12]

Experimental Procedure

3,3′-Hexafluoroglutarylbis-(1*R*)-camphorate (cf. V. Schurig, *Inorg. Chem. 11* (1972) 736): 3-Bromo-(1*R*)-camphor (6.9 g, 0.03 mol) (recrystallized from ethanol and dried over P_4O_{10}), magnesium powder (0.73 g, 0.03 mol), and diethyl hexafluoroglutarate (4.44 g, 0.015 mol) were refluxed in diethyl ether until most of the metal was consumed. The brown reaction mixture was hydrolyzed with 10% hydrochloric acid, the organic phase separated, and the product freed from volatiles by distillation and sublimation (camphor, ethyl 3-hexafluoroglutarylmono-(1*R*)-camphorate). The residue was chromatographed (dichloromethane/*n*-heptane (5:1, v/v)) on silica. Yield: 2 g (4 mmol, 27%). $[\alpha]_D^{23} + 150$ ($c = 4{,}5$, toluene). MS: *m/z* 509 ($M + 1$) (28%), 508 ($M^{\oplus}$) (100). ^{13}C NMR (25 MHz, $CDCl_3$): $\delta = 213.9, 120.0, 58.0, 49.0, 47.6, 30.2, 26.7, 20.4, 18.7, 8.5$.

4: Equimolar amounts of the ligand and $[(CO)_4Rh_2Cl_2]$ were refluxed in toluene in the presence of an excess of barium carbonate for 24 h. After flash chromatography on inactive neutral alumina, the complex was recrystallized from *n*-hexane at -20 °C. Yield 35%. M.p. 139 °C, red crystals. $[\alpha]_D^{23} + 75$ ($c = 0.4$, dichloromethane). MS: *m/z*: 824 ($M^{\oplus}$) (14%), 796 (48), 768 (100), 740 (30), 712 (26), 682 (13), 610 (12). IR (KBr) [cm^{-1}]: $\tilde{\nu} = 2960, 2935, 2875, 2080, 2015, 1975, 1620, 1490, 1175$. **4** may also be obtained by ligand exchange reaction of 3,3′-hexafluoroglutarylbis-(1*R*)-camphorate and **1** in *n*-hexane.

[11] The angles between the normals of the dicarbonylrhodium(I)-β-diketonate planes are 18.4° for *P* and 11.9° for *M*.
[12] The structure of **4** allows for intentional changes such as *heterochiral* variations ((1*R*,1*S*)-**4** (meso) or (1*R*,1*R*)-**4** + (1*S*,1*S*)-**4** (racemate)) and *heterometallic* combinations (Rh,Ir). If the structural motif of solid (1*R*,1*R*)-**4** is retained, the construction of highly ordered columnar structures with one-dimensional metal chains -[Rh,Ir,Rh,Ir]$_\infty$-, -[Rh,Rh,Ir,Ir]$_\infty$-, or -[Rh,Rh,Rh,Rh,Ir,Ir,Ir,Ir]$_\infty$- can be envisaged, when, for example, iridium is attached to the (1*R*)-configurated ligand and rhodium is attached to the (1*S*)-configurated ligand of **4**. These investigations are currently being pursued.

Isolation, Synthesis, and Absolute Configuration of Filbertone – the Principal Flavor Component of the Hazelnut**

By *Johann Jauch, Dieter Schmalzing, Volker Schurig,* Roland Emberger, Rudolf Hopp, Manfred Köpsel, Wilhelm Silberzahn,* and *Peter Werkhoff*

Chiral, acyclic, aliphatic (conjugated) enones occur in nature as pheromones and flavors. For example, (*E*,6*S*)-4,6-dimethyloct-4-en-3-one, manicone, has been identified in the mandibular gland of the ant *Manica mutica*[1] and (*E*)-5-methylhept-2-en-4-one, filbertone **5**, has been isolated[2] from hazelnut extracts and identified as the principal flavor component of filberts[3] (name synonymous with hazelnut; derived from *St. Philibert*).

The determination of the enantiomeric composition, the assignment of the absolute configuration, and the establishment of a relationship between chirality and olfaction necessitated both the enantioselective synthesis and the quantitative enantiomer separation of **5**. (*E*,5*S*)-Methylhept-2-en-4-one (*S*)-**5** was prepared according to Scheme 1 utilizing the (*S*)-*sec*-butyl chirality pool.

Scheme 1. a) $K_2Cr_2O_7/H_2SO_4/H_2O$; 70 °C/140 torr. b) $LiC{\equiv}CCH_3$/THF; −80 °C, 2 h; allowed to warm in ca. 12 h to +25 °C. c) $LiAlH_4$/THF, 4 h reflux. d) MnO_2/*n*-pentane, 40 h.

Commercially available (*S*)-(−)-2-methylbutan-1-ol **1** was oxidized to (*S*)-(+)-2-methylbutanal **2**,[4,5] which was then coupled with propynyllithium[6] to give (4*R*/4*S*,5*S*)-5-methylhept-2-yn-4-ol **3**. Stereoselective $LiAlH_4$ reduction[7] afforded exclusively (*E*,4*R*/4*S*,5*S*)-5-methylhept-2-en-4-ol **4**, which was oxidized with MnO_2 to (*E*,5*S*)-5-methylhept-2-en-4-one (*S*)-**5** (purity (by GLC) > 98%; overall yield, 20%, with steps a and d not yet optimized).[8]

Whereas racemic and natural **5** had previously been separated by GLC[9] after conversion to the oxime on a diamide phase,[10] the *underivatized* enone can be resolved directly by chiral complexation gas chromatography on nickel(II) bis[3-(heptafluorobutanoyl)-(1*R*)-10-methylcamphorate][11] in 8 min at 50 °C [phase 1] (Fig. 1) and by chiral inclusion gas chromatography on heptakis(2,6-di-*O*-methyl-3-*O*-trifluoroacetyl)-β-cyclodextrin[12] in 12 min at 110 °C [phase 2] (Fig. 2), thus permitting the simple complementary enantiomer analysis of synthetic (*S*)-**5** and *trace amounts* of natural **5**.

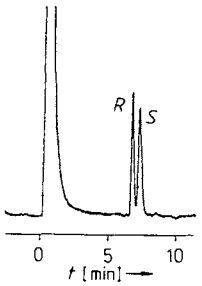

Fig. 1. Enantiomer separation of racemic (*E*)-5-methylhept-2-en-4-one **5** (filbertone) by chiral complexation gas chromatography on nickel(II)bis[3-(heptafluorobutanoyl)-(1*R*)-10-methylcamphorate] in OV-1 (ca. 0.1 m) at 50 °C [phase 1] [11]. Column: 10 m × 0.25 mm (I.D.) fused silica capillary. Carrier: 0.5 bar N_2.

The enantiomeric excess of synthetic (*S*)-**5** was determined on phase 1 and 2 to be *ee* = 92 ± 1% (Fig. 2c). On both phases 1 and 2, the (*S*) enantiomer is eluted as the second peak. Surprisingly, natural **5** exhibits only a rather low enantiomeric excess, varying with the origin of the hazelnuts: *ee* = 54.4% [phase 1], *ee* = 56.2% [phase 2] (Fig. 2a) (filberts from Turkey) and *ee* = 62.5% [phase 1], *ee* = 62.6% [phase 2] (filberts from Italy). Comparison of the elution order of synthetic (*S*)-**5** and natural filbertone established (*S*) configuration for the enantiomer in excess (Fig. 2a and 2c). Thus, it has been shown that **5** isolated from filberts is enriched with the (*S*) enantiomer of varying degree of enantiomeric purity.[9] The observation of differing enantiomeric compositions of natural compounds has a precedent in chiral pheromones (e.g., for *endo*-brevicomin[13]).

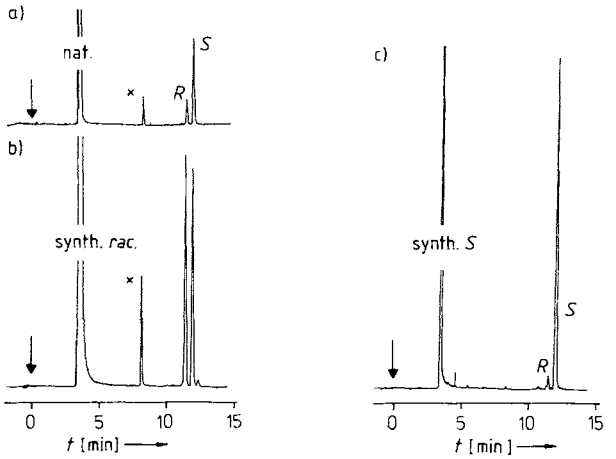

Fig. 2. Enantiomer separation of (*E*)-5-methylhept-2-en-4-one **5** by chiral inclusion gas chromatography on heptakis(2,6-di-*O*-methyl-3-*O*-trifluoroacetyl)-β-cyclodextrin in OV-1701 (0.05 m) at 110 °C [phase 2] [12]. Column: 40 m × 0.25 mm (I.D.) glass capillary. Carrier: 1 bar N_2. a) Natural **5** (filbertone), isolated from filberts [2]; b) racemic **5**, synthesized according to Scheme 1; c) (*S*)-**5**, synthesized according to Scheme 1.

[**] This work was supported by the Fonds der Chemischen Industrie. The identification and isolation of filbertone was performed in Holzminden, its enantiomer separation and the synthesis of the (*S*) enantiomer was carried out in Tübingen. The supply of filberts by *H. Teckenburg*, Schwartau GmbH, Bad Schwartau (FRG), is gratefully acknowledged.

Aided by the efficient analytical enantiomer separation (cf. Fig. 2c), racemization studies on (*S*)-**5** were also performed. No racemization, albeit appreciable thermal decomposition of **5** was observed in the gas phase at 120 °C over 21 days. In the presence of silica no racemization occurred at 22 °C over 21 h, but the *ee* dropped from 92% to 74% in the presence of *basic* alumina at 22 °C over 21 h. These results imply that the low enantiomeric purity of natural filbertone is an inherent property of the natural compound and is unlikely to have been caused by racemization during isolation.[2]

The sensory evaluation of *R*- and *S*-filbertone, separated on phase 2 (Fig. 2b), established a marked olfactory difference between the enantiomers in respect to odor intensity and quality. Also the sensory evaluation of synthetic racemic **5** and enantiomeric (*S*)-**5**, prepared according to Scheme 1, revealed striking olfactory differences. Thus, filbertone represents a new example of the importance of chirality in olfaction, thereby stressing the need to develop efficient chromatographic procedures for stereochemical analyses.[14]

[2] Good quality raw hazelnuts (filberts) (600 g) of a Turkish variety (1988 crop) were ground to a fine slurry in an Ultra-Turrax blender with 1.5 L of distilled water and subsequently transferred into a 10-L round-bottom flask. 4.5 L of distilled water was added and the finely chopped nuts were subjected to a simultaneous steam distillation/extraction procedure with 150 mL of *n*-pentane/diethyl ether (2:1, v/v) for 2.5 h at atmospheric pressure as described by *Likens-Nickerson* (S. T. Likens, G. B. Nickerson, *Proc. Am. Soc. Brew. Chem. 1964*, 5.). The extract was dried over anhydrous sodium sulfate and the organic solvent was removed on a 25-cm × 1-cm Vigreux distillation column. The process was repeated several times, and about 50 mL of an aroma concentrate was obtained from a total of about 5 kg of raw filberts. The aroma concentrates had the characteristic and intense odor of raw filberts. A separation according to the polarity of the volatile components was carried out by adsorption chromatography. The total flavor extract was preseparated on silica gel 60 (70–230 mesh, Merck, Darmstadt) by using a stepwise gradient of increasing amounts of diethyl ether in *n*-pentane. Filbertone was isolated from a medium-polar silica fraction by means of preparative capillary gas chromatography employing a wide-bore fused silica open-tubular column (30-m × 0.53-mm I.D., DB-1/film thickness 1 μm).

The Active Site of Glutathione Reductase: An Example of Near Transition-State Structures**

By *Reiner Sustmann,** *Willi Sicking*, and *Georg E. Schulz**

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

The ubiquitous flavoenzyme glutathione reductase serves an important function in intracellular redox processes by making available free thiols in the form of reduced glutathione.[1] The catalysis proceeds in two separable steps. In the first step investigated here, two electrons are transferred from NADPH to the enzyme, leading to the reduced enzyme as a stable intermediate.

$$H^{\oplus} + NADPH + E_{ox} \rightleftharpoons E_{red}H_2 + NADP^{\oplus}$$

In the second step, glutathione disulfide is reduced.

$$E_{red}H_2 + GSSG \rightleftharpoons E_{ox} + 2\,GSH$$

The active center consists of isoalloxazine (from FAD) and the adjacent disulfide bridge Cys58:Cys63, both of which are buried in the protein. The reducing NADPH binds to the isoalloxazine side of this arrangement and the glutathione being reduced binds to the disulfide side.[2] The geometries have been determined by X-ray structure analysis at resolutions between 2.0 Å and 1.54 Å.[3]

Since the active center is located in a very densely packed, internal region of the protein, which is far apart from all intermolecular contacts with the enzyme crystal lattice[3] and since the enzyme remains active in the crystal, it is safe to assume that the geometry established for the average positions of the non-hydrogen atoms agrees with the geometry of the cellular enzyme to within 0.1–0.2 Å. The mechanism of the reduction is still not known in detail: the important question of whether a hydride transfer or successive one-electron transfers are involved remains unanswered.

Using calculations at the MNDO level that incorporate the most recent PM3 parametrization,[4] we have begun to analyze the interactions in the active center of the enzyme. These calculations are supplemented using perturbation calculations with the PERVAL[5] program, also subjected to PM3 parametrization. The latter allows the direct determination of the interactions of two molecules and the interpretation of the results on the basis of covalent stabilization as well as of polar and noncovalent contributions (closed shell repulsion). The analysis is based on the coordinates of the non-hydrogen atoms obtained from the X-ray structure analysis, complemented with hydrogen atoms introduced with standard bond lengths and bond angles. Since even semiempirical calculations are too unwieldy for FAD and NADPH, only the partial structures important for the reaction, that is, the isoalloxazine ring with and without ribitol and dihydronicotinamide with ribose, were included in the calculations. Hydrogen atoms were placed at the sites of the omitted moieties. The disulfide bridge between Cys58 and Cys63 was treated similarly; the bonds to the remaining protein were replaced by hydrogen atoms. The calculations indeed show that the frontier orbitals of the reactants impor-

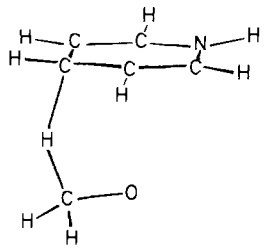
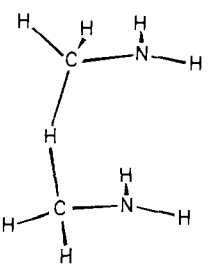
[**] This work was supported by the Deutsche Forschungsgemeinschaft.



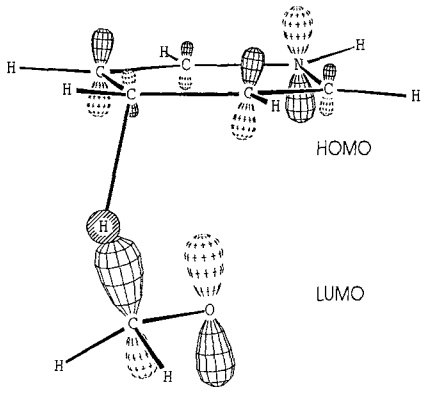
tant for the reaction are localized exclusively in the isoalloxazine and dihydronicotinamide moieties. In addition, the calculations show that the LUMO that is crucial for the reduction of the disulfide bridge is found in the SS bond. These findings are strong evidence that the primary function of the surrounding protein is to hold the reacting molecules in a fixed array.

Here we report on the following aspects of this reaction: (1) the interaction of the dihydronicotinamide of NADPH with the isoalloxazine ring of FAD (see **1**) and (2) the interaction of the reduced isoalloxazine ring with the protein disulfide bridge Cys58:Cys63 (see **5**, bottom). A comparison with the transition-state structures of hydride transfer from dihydropyridine to formaldehyde (see **2**)[6] and from methylamine to the methyleneiminium ion (see **3**),[7] obtained by ab initio calculations, proves useful.

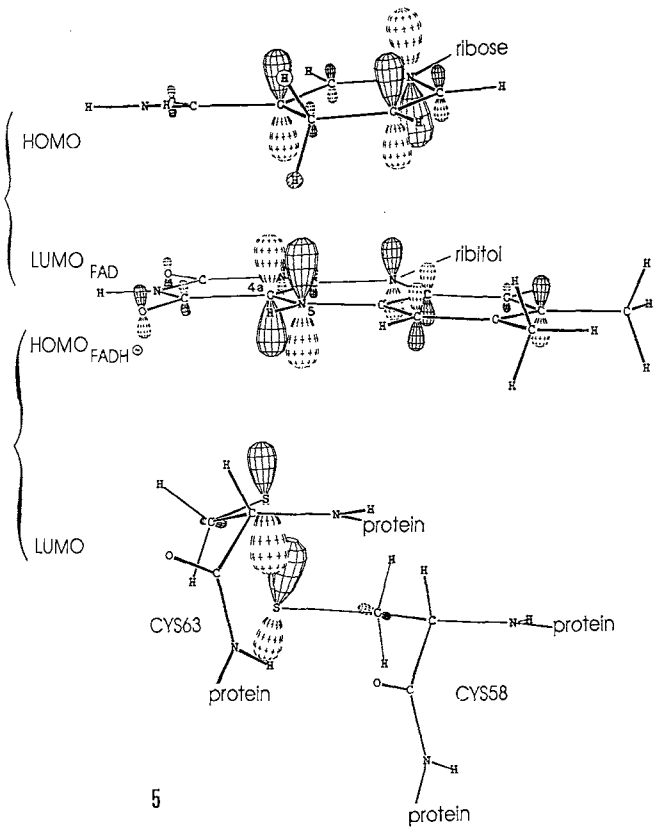


In **1–3**, the X-ray structure of the complex formed between dihydronicotinamide and the isoalloxazine ring of

1



2



3

FAD is compared with the transition structures obtained from the two ab initio calculations. The agreement of **1–3** in the region of the atoms participating in the reaction is striking. It should be remembered, however, that **1** does not represent a transition structure. The calculated interaction of the molecules in complex **1** ($+6.5$ kcal mol^{-1}) is weakly repulsive. The separation of the atoms between which the hydrogen atom is exchanged is 3.2 Å in the enzyme and thus ca. 0.5–0.6 Å larger than in the transition structures **2** (2.70 Å) and **3** (2.55 Å). The question of whether the atoms participating in the reaction adopt a linear arrangement[8] is answered by the ab initio calculations (the atoms lie in a bent arrangement with an angle of ca. 140–150°). The enzyme structure forms a comparable angle of 134°, which is evidence for a similar mechanism. Such an arrangement results in optimal frontier orbital interactions, as is shown in **4** for the dominating $HOMO_{dihydropyridine}$–$LUMO_{formaldehyde}$ interaction (cf. **2**). The PERVAL calculations predict that this interaction accounts for 63% of the total covalent stabilization of the transition state for hydride transfer in **4**. The orientation of the orbitals in **4** serves to emphasize why a nonlinear arrangement is more favorable. In this arrangement, a maximal overlap of the participating orbitals is achieved in proceeding from the starting molecules to the reaction products.

4

The calculated HOMO of the dihydronicotinamide (with ribose) in the enzyme (see **5**, top) has nearly the same structure as that of dihydropyridine (cf. **4**). The LUMO of the isoalloxazine ring (with ribitol) exhibits the largest contribution at the nitrogen atom N-5, which would accept the H atom during hydride transfer. This LUMO nearly agrees with the HOMO of the reduced isoalloxazine moiety $FADH^{\ominus}$ given in **5** (middle). $HOMO_{FADH^{\ominus}}$ and $LUMO_{FAD}$ differ mainly in the contributions of the atoms N-5 and C-4a, the contribution of N-5 being somewhat larger than that of C-4a in $LUMO_{FAD}$. As in **4**, the $HOMO_{dihydronicotinamide}$–$LUMO_{isoalloxazine}$ interaction contributes the most to the

5

covalent stabilization, thus being the dominant interaction. The similarity of the structures **1**–**3** and of their interactions indicates that NADPH and FAD are arranged in a nearly ideal fashion for a hydride transfer to N-5 of the isoalloxazine ring in the enzyme.

In the second step, $FADH^{\ominus}$ transfers reduction equivalents to the disulfide bridge Cys58:Cys63 (cf. **5**, bottom). In this process, the direct nucleophilic attack of the reduced isoalloxazine ring offers an attractive possibility corresponding to the usual proposal of nucleophilic attack on FAD.[9] In such an attack, the nucleophile forms a covalent bond to C-4a of the isoalloxazine. Crystal structure analysis and calculation supports such a mechanism. Especially interesting is the observed unusual conformation of the disulfide bridge,[3] which, in the given fixed position relative to the isoalloxazine ring, leads to an exact orientation of the antibonding LUMO of the bridge toward C-4a, as is shown by the scaled reproduction of the crystal structure of **5**. C-4a of the isoalloxazine ring and the S atoms of the disulfide bridge lie next to each other in a linear fashion, and the energetically nearly degenerate frontier orbitals ($HOMO_{FADH^{\ominus}}$–$LUMO_{Cys58:Cys63}$) result in a strong covalent interaction between C-4a and the sulfur atom of Cys63. Structure **5** serves to emphasize the favorable orientation of the orbitals for back-side attack of C-4a on the disulfide bond. The mechanism can be described as a nucleophilic cleavage of the SS bridge with formation of a covalent bond between C-4a of the isoalloxazine and the S atom of Cys63. Transfer of the proton from N-5 to the S atom of $Cys58^{\ominus}$ and fragmentation by intramolecular nucleophilic substitution to give $Cys63^{\ominus}$ should follow. It is interesting to note that the MNDO PM3 calculation for the interaction of FAD with $Cys63^{\ominus}$, the relative position of which is known from X-ray data, gives a stabilization of -2.6 kcal mol^{-1} and shows no repulsion, although this is usually observed between molecules with closed valence shells. The calculation apparently confirms the spectroscopically established formation of a CT complex[1, 2] between FAD and $Cys63^{\ominus}$.

The MNDO PM3 calculations and the perturbation analysis of the structure of the active site of glutathione reductase show that, in the enzyme, the reaction partners NADPH and FAD, as well as $FADH^{\ominus}$ and Cys58:Cys63, are positioned in such a way that they are localized near the transition state along the reaction coordinates of the hydride transfer and the nucleophilic cleavage of the disulfide bridge, respectively. This positioning eliminates the decrease in entropy required for this reaction and is in agreement with proposals concerning enzyme-catalyzed reactions in general. Furthermore, other mechanisms, such as one-electron transfers, become improbable. Further investigations, which also consider the reduction of glutathione and include some important amino acids in the vicinity of the active center, are in progress.

Are Lithiosulfones Configurationally Stable?**

By *Hans-Joachim Gais,* Gunther Hellmann, Harald Günther, Fernando Lopez, Hans J. Lindner* and *Sigmar Braun*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

According to crystal structure analyses, lithiosulfones **1**[1] have chiral anions even when their α-C atom, bearing different groups, is coordinated in a planar rather than in a tetrahedral fashion.[2] In this respect they differ fundamentally from lithium enolates.[3] This is due to a favored C_α–S conformation in which the two Li-bound O atoms are arranged *gauche* to the lone pair on the α-C atom (cf. Fig. 1 and the formula shown). Earlier H/D-exchange experiments on optically active sulfones **2** have already provided compelling evidence for the chirality of counterion-free α-sulfonyl carbanions and shown that hindered C_α–S rotation, not C_α inversion, is responsible for their observability.[4] Ab initio calculations came to a similar conclusion.[5] According to these results negative hyperconjugation (n_c–$\sigma^*_{SR^3}$) and Coulombic interaction are the dominant mechanisms of stabilization. How stable, however, are the configurations of the lithiosulfones **1**? This important question has remained unanswered so far. In particular, no evidence has been provided for the chirality of **1** in solution.[6] We were also especially interested in whether optically stable lithiosulfones **1** can be generated enantioselectively from optically active sulfones **2**.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Wissenschaftliche Gesellschaft in Freiburg, and the Alexander von Humboldt Foundation (*F. L.*). We thank Dr. *W. Bauer* for the cryoscopic measurements, Dr. *A. Powell* and Dr. *H. Paulus* for the crystallographic data sets, and Dr. *E. Keller* for a version of Schakal-88.

racemization with formation of *rac*-**1a** was observed, even at $-80\,^{\circ}C$. ^1H DNMR measurements on the benzyl-substituted lithio(*phenyl*)sulfones *rac*-**1b** and *rac*-**1c**, in which the exchange of nonequivalent methylene protons was observed in [D_8]THF, gave the following results: *rac*-**1b**, the α-C atom of which should be coordinated in a planar fashion,[2] has an enantiomerization barrier $\Delta G^{\neq}_{215}$ of 9.6 ± 0.2 kcal mol^{-1} ($c = 1.8 \times 10^{-1}$ mol L^{-1}); *rac*-**1c**, the α-C atom of which should be coordinated, by contrast, in a tetrahedral fashion,[2] likewise has a $\Delta G^{\neq}_{215}$ value of only 9.7 ± 0.2 kcal mol^{-1} ($c = 2.8 \times 10^{-1}$ mol L^{-1}).[7] Over a concentration range of 7×10^{-2} to 36×10^{-2} mol L^{-1}, the $\Delta G^{\neq}$ value for *rac*-**1b** does not change, but it increases to 10.1 ± 0.2 kcal mol^{-1} in the presence of four equivalents of hexamethylphosphoric triamide.[8]

Trifluoromethyl sulfones (*triflones*) are ca. 10 pK_a units more acidic than phenyl sulfones.[9] We found that lithiotriflones are also appreciably more configuratively stable than lithio(phenyl)sulfones. Metalation of the optically active triflone (+)-**2d**[10] with *n*BuLi in THF at $-95\,^{\circ}C$ resulted in formation of the optically active lithiotriflone (−)-**1d** with an extrapolated half-life of 30 d at $-78\,^{\circ}C$. The time dependence of the racemization of (−)-**1d** was followed polarimetrically at low temperatures for a concentration range of 5×10^{-3} to 120×10^{-3} mol L^{-1}. It obeys first-order kinetics with a racemization barrier $\Delta G^{\neq}_{239}$ of 17.2 ± 0.1 kcal mol^{-1} ($k_{rac} = 9.40 \times 10^{-4}$ s^{-1}, $t_{1/2} = 12.3$ min).[11] A $\Delta H^{\neq}$ value of 16.7 ± 0.3 kcal mol^{-1} and a $\Delta S^{\neq}$ value of -1.9 ± 1.1 cal K^{-1} mol^{-1} were derived from the temperature dependence (-44 to $-24\,^{\circ}C$) of k_{rac}. A linear relation between α and *t* was also obtained for the racemization of (−)-**1d** in THF in the presence of four equivalents of 1,3-dimethyltetrahydropyrimidine-2(1*H*)-one.[3] In this case, the lifetime of (−)-**1d** ($t_{1/2} = 42$ min at $-34\,^{\circ}C$) is longer. By ^1H DNMR measurements on *rac*-**1d**, the α-C atom of which should be tetrahedrally coordinated,[2] an enantiomerization barrier $\Delta G^{\neq}_{333}$ of 17.8 ± 0.2 kcal mol^{-1} ($c = 3.2 \times 10^{-1}$ mol L^{-1}) was found following the exchange of methylene protons in [D_{14}]diglyme.[8] For the enantiomerization of *rac*-**1e**, the α-C atom of which has been shown to be coordinated in a planar fashion (cf. Fig. 1), the NMR measurements in [D_8]THF gave a $\Delta G^{\neq}_{333}$ value of 16.0 ± 0.2 kcal mol^{-1} ($c = 1.9 \times 10^{-1}$ mol L^{-1}).[7] According to cryoscopic measurements,[12a] **1e** is *monomeric* in THF at $-103\,^{\circ}C$ and concentrations of 7.1×10^{-2} and 13.6×10^{-2} mol L^{-1},[12b, c] and, based on NMR analysis, associated with two molecules of THF. The results of NMR investigations on (−)-**1d** and *rac*-**1d** ([D_8]THF, $-80\,^{\circ}C$, $c = 3.1 \times 10^{-1}$ mol L^{-1}) are in agreement with these findings. Under these conditions, chiral and achiral dimers would have to be present in addition to chiral monomers. There are no differences in the positions of either the ^1H or the ^{13}C NMR signals, and only one species is observed. The appreciably higher acidity of **2d,e** and the greater configurative stability of **1d,e** are in accord with the stabilization of α-sulfonyl carbanions by negative hyperconjugation and Coulombic interaction.[5, 13] Hindered C_α–S rotation is the reason for the observability of chirality in **1e**. This should also be true for **1a–d**, whereby the α-C atoms in **1c–d** might be coordinated in a tetrahedral rather than a planar fashion.[2]

The metalation of (*R*)-**2d** and the protonation of (−)-**1d** occur enantioselectively and with retention of configuration! Reaction of (−)-**1d** ($c = 7.3 \times 10^{-2}$ mol L^{-1}), generated from (*R*)-**2d**[10] and one equivalent of *n*BuLi at $-90\,^{\circ}C$ in THF, with CF_3COOH in THF at $-105\,^{\circ}C$ afforded (*R*)-**2d** (93%) with $[\alpha]^{21}_{365} = +10.9$ ($c = 2.8$, THF).

Are the differences in the stability of deprotonated and lithiated triflones and phenyl sulfones reflexted in C_α–S bonds of different length? To answer this question, crystal structure analyses of (**1e** · TMEDA)$_2$[14a] and **2e**[14b] were carried out.[15] Single crystals of (**1e** · TMEDA)$_2$ were obtained in the usual way by metalation of **2e** with *n*BuLi in *N,N,N',N'*-tetramethylethylenediamine (TMEDA). (**1e** · TMEDA)$_2$ crystallizes as a typically achiral dimer[1] with (*M*) or (*P*) configuration[16] of the two anions, the α-C atoms of which are coordinated in a planar fashion (Fig. 1).

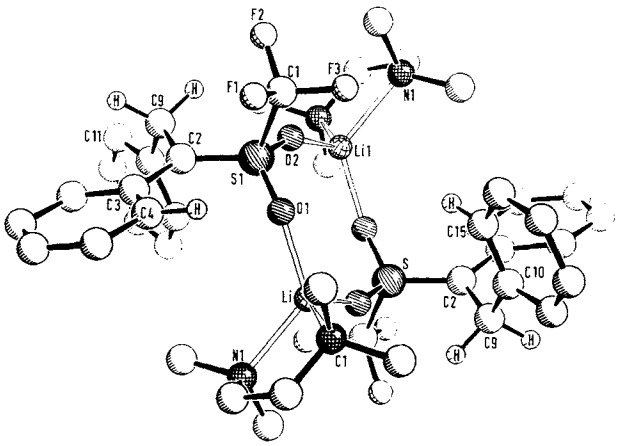

Fig. 1. Molecular structure of one of the two crystallographically independent dimers of (**1e** · TMEDA)$_2$ [17]. Selected bond lengths [Å] and angles [°] for both dimers: S1–O1 1.455(4), S1–O2 1.446(5), C1–S1 1.856(6), C2–S1 1.608(6), C2–C3 1.455(9), Li1–O1 1.920(9), Li1–O2 1.877(9), Li1–N1 2.131(9), Li1–N2 2.099(11); C3–C2–S1 124.1(4), C9–C2–S1 116.6(5), C9–C2–C3 119.2(5) C2–S1–C1 114.9(3); C1–S1–C2–C3 −80.1, C1–S1–C2–C9 96.7. S1–O1 1.445(4), S1–O2 1.459(4), C1–S1 1.823(8), C2–S1 1.611(6), C2–C3 1.480(9), Li2–O1 1.910(12), Li2–O2 1.907(9), Li2–N1 2.132(14), Li2–N2 2.130(11); C3–C2–S1 123.0(4), C9–C2–S1 116.5(5), C9–C2–C3 120.4(5), C2–S1–C1 112.3(3); C1–S1–C2–C3 83.8, C1–S1–C2–C9 −92.6.

Apart from the N atoms of the TMEDA molecules, only the O atoms of the sulfonyl groups are bound to the Li atoms.[18] Bonds do not exist between the Li and the α-C atoms. The anions have the characteristic C_α–S conformation;[1] however, their C_α–S bond is shortened by 11% to 1.609 Å (average value) compared with that in **2e**. It is thus shorter than that in (**1a** · diglyme)$_2$ (1.652 Å),[2b] the α-C atoms of which are also coordinated in a planar fashion, and of the same length as that in [$(CH_2SO_2Ph)Li$ · TMEDA]$_2$.[19] So far, shortenings of the C_α–S bond in metalated sulfones of only ca. 8% have been found.[1] The O–Li distances are of roughly the same length as those in all other lithiosulfones, while the S–O distances are slightly increased. Noteworthy is the fact that the S1–C1 bonds in (**1e** · TMEDA)$_2$ (average 1.839 Å) are no longer than the corresponding bond in **2e** (average 1.853 Å).

Finally, it was important to determine whether the Li atom of monomeric **1e** in solution occupies the same position (*O*-associated) as the Li atoms in (**1e** · TMEDA)$_2$ in the crystal. To this end, ^6Li,^1H heteronuclear NOE experiments[20] were performed on **1e** at 25 °C.[21] For these experiments, a solution of crystalline (**1e** · TMEDA)$_2$ prepared with 95% ^6Li in [D_8]THF ($c = 3 \times 10^{-1}$ mol L^{-1}) was used. On the one hand, 2D NMR experiments using the HOESY pulse sequence[20a, 22] allow one to observe intense correlation peaks for the CH_3 and CH_2 protons of TMEDA, which indicate that, even in [D_8]THF solution, the Li atom is chelated by TMEDA. On the other hand, correlation peaks

for 11-H/15-H ($\delta = 7.38$) as well as for 4-H/8-H and/or 12-H/14-H were observed; the signals of the latter ($\delta = 7.21$ and 7.14, respectively) lie very close to each other.[23] Against expectations, however, no interactions with the diastereotopic CH_2 protons could be obtained in this experiment, despite variation of the mixing time over a range of 2 to 5 s. Therefore, one-dimensional NOE difference experiments were also carried out and, upon irradiation of the resonance frequencies of the CH_2 protons, the expected intensity enhancements were observed. Moreover, the Li,H interactions already appearing in the HOESY spectrum were revealed in the corresponding 1D NOE difference measurements (Fig. 2). Furthermore, despite the small difference in shifts,

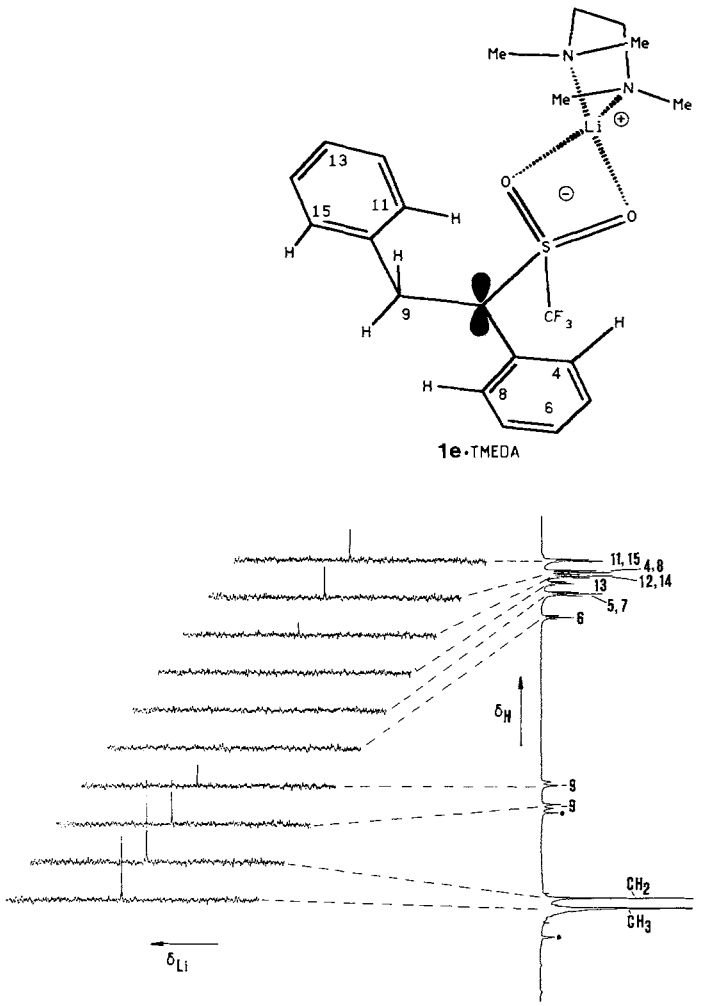

Fig. 2. $^6Li\{^1H\}$ NOE difference spectra of **1e** · TMEDA (see formula for numbering) in [D_8]THF at 298 K. The irradiation in the ^1H NMR spectrum and the resulting ^6Li NMR difference spectra are joined by broken lines. ● = solvent signal.

measurement with decreasing irradiation energy showed that only 4-H/8-H/11-H/15-H, and not 12-H/14-H, exert an NOE on the ^6Li atom. The short Li–H distances found[24] and the other results make a chiral structure of the type shown in the formula for **1e** · TMEDA in THF solution very probable. An (achiral) structure of this type has already been found in an X-ray structure analysis of $[(Me_3Si)_2C\text{-}SO_2Ph]K \cdot [18]$crown-6[25] and in theoretical investigations of $(CH_2SO_2Me)Li$.[5b]

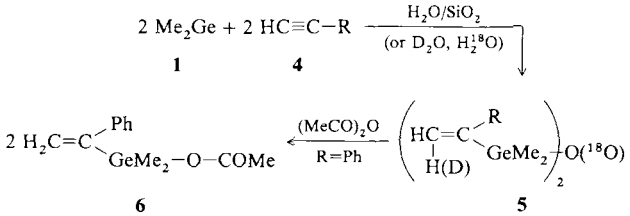
Addition of Free Me_2Ge: to Alkenes and Alkynes on Glass Surfaces in the Presence of Water**

By *Wilhelm P. Neumann,* Hideki Sakurai,* Gilbert Billeb, Hartmut Brauer, Jürgen Köcher,* and *Sabine Viebahn*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

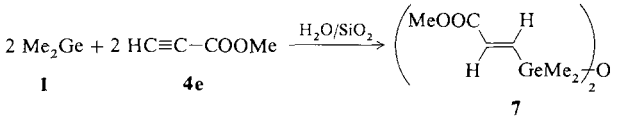
Free Me_2Ge: (dimethylgermanediyl or "dimethylgermylene") **1** undergoes a surprising variety of additions to π systems of alkenes, 1,3-dienes, alkynes, and enones, most of them being regio- or stereospecific.[1] Now we have found that reaction of **1** with conjugated substituted alkenes **2** or with alkynes **4** gives products that contain two Ge atoms and are generated by water adsorbed at the surface of glass or silica gel.



a, X = CN; **b**, X = COOMe; **c**, X = COMe

When we generated free **1** thermally in the presence of acrylonitrile **2a** or other conjugated substituted olefins (**2b, c**) in a glass flask with the usual careful exclusion of air and moisture, we obtained a moderate yield of compounds **3**, the hydrogen contents of which were higher than expected. The additional hydrogens are not contributed via free radical reactions between the partners or with the solvent, as suspected at first. This was established by the lack of influence of cumene and triphenylmethane, as well as of *t*BuBr, which is a powerful scavenger of Ge radicals. Finally, after several difficulties, oxygen was found to be present in the product and structure **3** was established. Compound **3**, a dimer of the adduct expected originally, contains an additional molecule of water. Saturation of the solvent benzene with water did not improve the yields of **3**, and D_2O gave no deuterated **3**. When we added finely powdered glass or silica gel saturated with water and dried at 10^{-3} Torr, however, we obtained nearly quantitatively **3a**; in the same way, reaction with D_2O and with $H_2{}^{18}O$ gave [D_2]**3a** and [^{18}O]**3a**, respectively.

Indeed, water adsorbed at or in the glass[2] is involved stoichiometrically in the reaction. This is evidenced additionally by cross checks: Using a quartz flask after heating it for 4 h at 150 °C/10^{-3} Torr, we found a yield of only 45% instead of 70%. Silylation of its inner surface by means of F_3C-CO-NMe-$SiMe_3$ (MSTFA)/Me_3SiCl over 4 h at 70 °C caused the yield of **3a** to decrease to 35%.



These surprising results required a reinvestigation of the reactions of **1** with alkynes. We had obtained earlier with phenylacetylene **4a** a mixture of unsaturated four-, five-, and six-membered germacycles.[1] Erratically, a minor byproduct with a 1-alkenyl group had been observed (^{1}H NMR), but could not be identified at first. When we now added wet silica gel before starting the reaction, high yields of the new digermoxane **5a** could be obtained instead of the expected products. Alkynes **4b–d** behaved analogously. The structures **5** have been clearly established, also by using $H_2^{18}O$. It should be noted that with **4c**, for example, no product could be detected earlier in the absence of H_2O/SiO_2.

a, R = Ph; **b**, R = Bu; **c**, R = *t*Bu; **d**, R = CH_2OAc

The germoxy group of **5** affords access to new organogermanium compounds, for example to the vinylgermyl acetate **6** starting from **5a** and acetic anhydride. This is additional evidence for the structure of compound **5**.

The structure of the product obtained from methyl acetylenecarboxylate **4e** and **1** was, at first, puzzling. The *E*-olefin **7** was found exclusively instead of the expected 1-alkenyl compound corresponding to **5a–d.**

Elucidation of the mechanism of the participation of adsorbed water thus became a priority task. Compound **1** could react with water in a first step giving the previously unknown hydride $Me_2Ge(H)OH$, which could yield, via hydrogermylation, compounds **3, 5,** and **7**. In the absence of alkene **2** or alkyne **4**, however, water/silica gel and **1** gave only the polygermane $(Me_2Ge)_n$, which we futilely tried to observe.[1] Thus, the intermediacy of a germoxy compound is excluded. An attempted in situ reaction of **1** with methanol led to new ^{1}H NMR absorptions of a hydride XMe_2GeH, but acrylonitrile **2a**, added consecutively, remained unchanged under the standard conditions. Further, no 1-alkenyl structure corresponding to **5** could be observed when phenylacetylene **4a** was hydrogermylated analogously by $Et_2Ge(H)OMe$; instead, the product of an inverse orientation was obtained.[3]

Therefore, the first step is presumably a reaction between **1** and the alkene or alkyne. The resulting intermediate, which

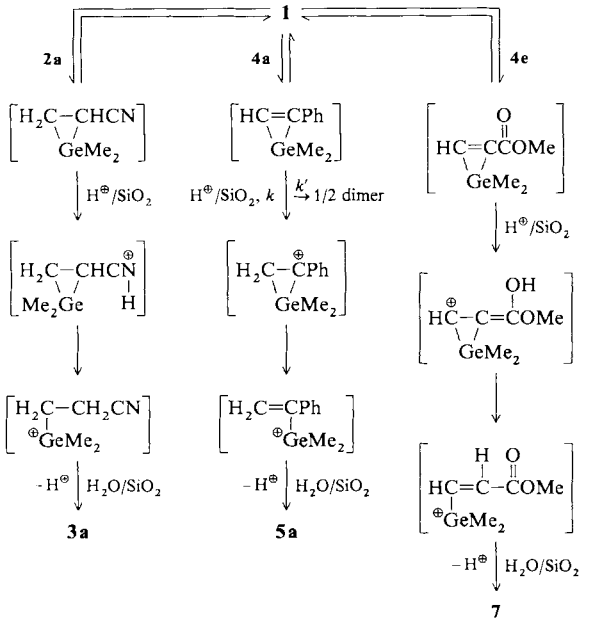
[**] This work was supported by the Fonds der Chemischen Industrie. We are grateful to Dr. *H. Hillgärtner* for very skilfull mass spectrometric investigations.



has not yet been detected directly, has a lifetime sufficient for diffusion to the wall of the flask, where it is stabilized by "reactive water". This term is used in the following way: at the surface of glass, not only (monomeric) H_2O has to be taken into account, but also the products of its reaction with the glass surface [Eq. (a)–(c)].[2]

$$(-\overset{\backslash}{\underset{/}{Si}})_2O + H_2O \rightleftharpoons 2\ -\overset{\backslash}{\underset{/}{Si}}-OH \qquad (a)$$

$$(-\overset{\backslash}{\underset{/}{Si}})_2O + H_2O \rightleftharpoons (-\overset{\backslash}{\underset{/}{Si}})_2O\cdot HOH \quad \text{or} \quad (-\overset{\backslash}{\underset{/}{Si}})_2O^{\oplus}\text{-}H + OH^{\ominus} \qquad (b)$$

$$(-\overset{\backslash}{\underset{/}{Si}})_2O^{\oplus}\text{-}H \rightleftharpoons (-\overset{\backslash}{\underset{/}{Si}})_2O + H^{\oplus} \qquad (c)$$

Protonations of the initially formed intermediates seem to best explain the experimental results. In all cases, the most stable cation is apparently formed and is decisive for the structure of the final product (Scheme 1). Thus, also the structural differences between products obtained with **4a–c** and **4e** can be understood now.

Scheme 1. Proposed mechanisms for the formation of **3a**, **5a** and **7**.

When "reactive water" is lacking, the intermediate decomposes reversibly (**4c**) or dimerizes (**4a**, **4b**[1]), or, in the case of other alkynes, butadienes, or styrene, undergoes rapid insertion forming the corresponding five-membered rings.[1]

We have thus been able to demonstrate that, in the reactions of alkenes and alkynes with **1** to give the new types of compounds **3**, **5**, and **7**, molecules of water, or their products present at and in the glass even after heating,[2] are capable of participating in the reaction in a surprising manner. This "reactive water" generates new products stoichiometrically and completely, when finely powdered glass or silica gel is used. This is probably done by proton donation to unstable intermediates. Our current efforts are directed at the definite identification of the intermediates and at broadening the scope of this new reaction principle.

Experimental Procedures[4]

3: SiO_2 (1.0 g, Celite 545, Nagel & Co.) was heated five times at 150 °C/0.001 Torr in a 50-mL two-necked Duran flask. At room temperature, H_2O (D_2O, $H_2{}^{18}O$) (0.300 mL), 7,7-dimethyl-1,4,5,6-tetraphenyl-7-germa-2,3-benzonorbornadiene [1] (2.0 g, 3.7 mmol), **2** (0.74 mL, 11.1 mmol), and benzene (25 mL) were added. The mixture was heated at 70 °C for 4 h under dry argon. After removal of the solvent at 14 Torr, the residue was stirred twice with 20 mL of pentane and filtered from 1,2,3,4-tetraphenylnaphthalene and SiO_2. The solution was evaporated at 14 Torr. Crude yields (^{1}H NMR) of **3**: 80–85%; rest, $(Me_2Ge)_n$. Equal yields were obtained with 1.5 g of powdered glass of a reaction flask. Without SiO_2, only 50% yields (**3a**) were found. The products were purified by kugelrohr distillation at 0.01–0.001 Torr.

5, **7**: Analogously to **3**, but with 1.0 g of the norbornadiene[1], 0.700 mL of H_2O (D_2O, $H_2{}^{18}O$), 10 mmol of **4**, and 10 mL of benzene, 3.5 h under reflux. Yields of crude products: 90–95%.

Visualization of Chromatographic Separations by NMR Imaging

By *Ernst Bayer*,* *Winfried Müller*, *Martin Ilg*, and *Klaus Albert*

Nuclear magnetic resonance imaging[1, 2] has been very successful in medical diagnosis, since it allows noninvasive observation of liquid and gel-like states as well as of dynamic

[*] Prof. Dr. E. Bayer, Dr. W. Müller, M. Ilg, Dr. K. Albert
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (FRG)

processes. This method has also proved useful in the investigation of exchange, flow, and diffusion processes in chemistry.[3, 4] Liquid chromatography is one of the most common such processes. Chromatographic interactions between eluent and stationary phase in the column cannot be observed in situ. It is therefore impossible to monitor exactly the elution profile and to determine the factors leading to band broadening and other irregularities. Even colored substances, the separation of which led *Tswett* to coin the term chromatography, only provide information on the zone boundaries; they afford no insight into the profile within the column.

^{1}H NMR imaging yields proton images of any desired volume element of a packed column. An unambiguous correlation between position and resonance frequency is achieved with three mutually orthogonal field gradients, which exactly define the positional dependence of the magnetic field. The NMR image is obtained from the signal intensities of the volume elements thus generated. These signal intensities depend on many parameters, such as relaxation times T_1 and T_2, spin density, flow and diffusion phenomena, and chemical shift. Differences in these parameters lead to a high-contrast image. Since these parameters are differently influenced by the interactions between stationary phase, mobile phase, and eluent, it is possible to obtain an image of a chromatogram or a column in either a stationary or a dynamic state. Thus, variations in the packing density along the diameter or length of the column, channel formation, and differences in the degree of wetting can be clearly recognized and subsequently used to develop an optimal method for packing the column. This is of particular importance for preparative columns.

The relaxation times T_1 and T_2 are key factors in imaging, since they provide information on the mobility of the solvent in the stationary phase. Stationary phases of low porosity and large absorption capacity absorb water more strongly than materials having large pores. This is reflected in smaller relaxation times T_1 and T_2 in fine-pored materials, as is shown by the values in Table 1. In the fine-pored gels Sephadex G10 and G15, the mobility of water is highly restricted. In the wide-pored material G100, on the other hand, T_1 and T_2 approach the normal relaxation times of water. Owing to the high polarity of silica gel 60, the mobility of water in this stationary phase is even more restricted than in Sephadex G10. Similar relationships are also observed for other solvents.

Table 1. Proton relaxation times T_1 and T_2 of water in swelled Sephadex gels.

Sephadex	T_2 [ms]	T_1 [ms]
G10	103	490
G15	164	585
G25	305	843
G100	494	2460

Interestingly, a decrease in the relaxation time T_1 is observed along the length of a column from top to bottom, as is shown in Figure 1 for silica columns in a stationary state with acetonitrile and with water as mobile phases. This is ascribed to a denser packing of the silica at the bottom of the column.

Rapid imaging sequences, such as FLASH (Fast Low Angle Shot Imaging),[5] allow the continuous monitoring of a chromatographic process. These sequences are based on the attainment of a dynamic equilibrium magnetization by the use of small flip angles ($\alpha < 90°$). A high transverse magnetization and an only slightly reduced longitudinal magnetization is thereby achieved, so that, even for very short repetition times, high contrast and good signal-to-noise ratios were obtained for measuring times of only a few seconds. This method allows one to monitor a running chromatogram by recording images every 30 s and combining them into a single film.

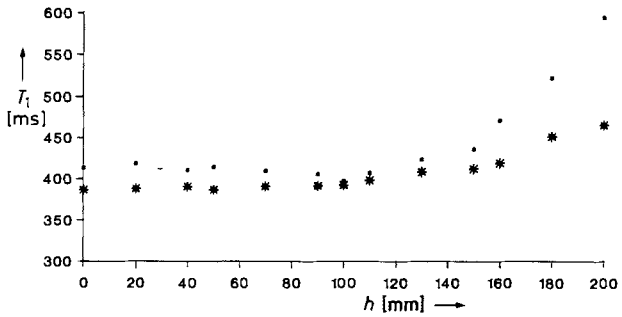

Fig. 1. Relaxation time T_1 in various regions of a silica column. 0 mm is the bottom of the column. Inversion-recovery sequence, Siemens Magneton 1.5 T whole-body system. ■, acetonitrile/SiO_2; *, H_2O/SiO_2.

The development of the profile of the chromatographic bands can be followed in each volume segment of the column rather than merely at the walls. The images thereby obtained allow one to view the elution profile through cross sections or along the length of the column or as a complete set of three-dimensional images (3D FLASH). The separation of both single-component and multicomponent systems has been followed in this way, as shown in Figure 2 (left) for the separation of amavadin, a naturally occurring vanadium(IV) complex,[6, 7] on Sephadex. In this case, the chromatographic bands were followed along a central longitudinal cut through the interior of the column by recording images of a 4-mm-thick slice (see Fig. 2, right). The band broadening and the variation in the elution profile with time are clearly revealed. The analysis of such flow profiles can be carried out even better by chromatographing the diethylenetriaminepentaacetic acid gadolinium complex (Gd-DPTA). This compound is used as a contrasting agent in magnetic resonance tomography at concentrations of 10^{-3} to 10^{-4} M[8] and affords high contrast in this concentration range. The development of the chromatogram was followed continuously and the images were combined into a single

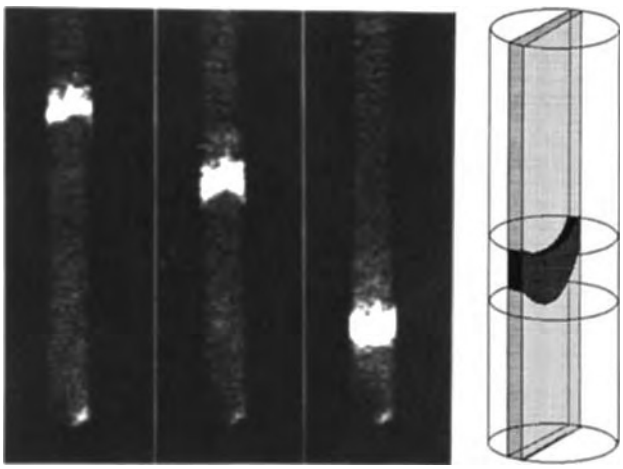

Fig. 2. Left: Fast images of the chromatography of amavadin/H_2O on Sephadex (FLASH sequence, TE = 20 ms, TR = 60 ms) after an elution time of 37 min, 63 min, and 110 min. Right: Schematic drawing of the slice selected in the chromatographic images.

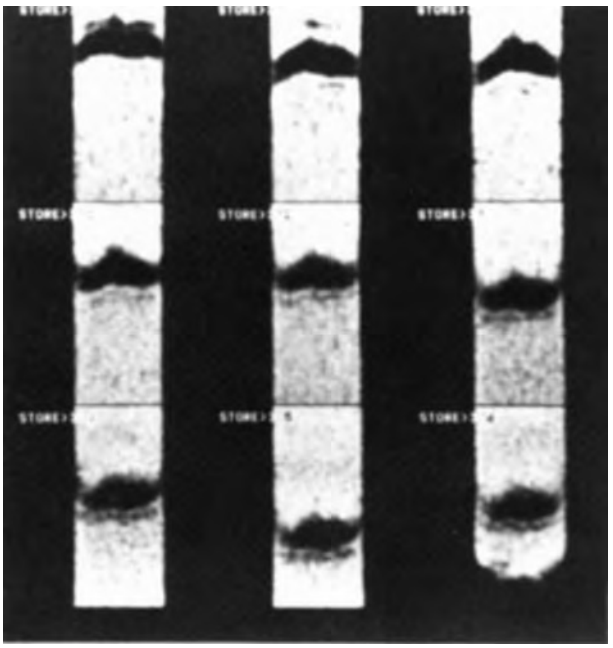

Fig. 3. Development of the elution front (proton image) during the chromatography of Gd-DPTA/H_2O on Sephadex (FLASH, TE = 20 ms, TR = 60 ms). Images from a film [9] at time intervals of 15 min. The images should be viewed along a line, not a column.

film,[9] nine individual images of which are shown in Figure 3.

At the beginning of the column, a parabolic flow profile is formed. This is due to the wall effect; the column packing is less dense at the walls and the interaction between eluent and stationary phase is therefore less strong, allowing a faster band migration. Although the wall effect has been theoretically predicted, in particular with respect to preparative columns, it has not been investigated in situ.[10, 11] This is the first time it has been made visible. Also clearly revealed at the beginning of the chromatogram is the effect of nonuniform sample application. As the elution proceeds, the wall effects become less important and the separation of the individual components is clearly seen. The eluent is observed to move most rapidly through the center of the column. This effect is ascribed to the higher temperature at the center of the column owing to the heat of absorption. The column material has a relatively poor thermal conductivity and cannot transfer the heat rapidly enough to the walls. Still later, band broadening occurs owing to diffusion effects. Also interesting are the contrasts in the column outside the respective elution regions. These differences remain constant with respect to their position during the entire chromatographic separation. We ascribe this to different degrees of wetting of the column material.

In addition to protons, other nuclei, such as ^{19}F, ^{23}Na, and ^{13}C, can also be used in NMR imaging. Because of the low NMR sensitivity of these nuclei, however, the imaging is restricted to larger volume elements with smaller spatial resolution. Nonetheless, mobile and bound sodium ions can be distinguished owing to the effects of their different T_2 relaxation times on the image contrast. A Dowex column loaded with $Na^{\oplus}$ exhibits only weak contrast. Various stages of the elution are shown in Figure 4. Because of the increase in T_2, the now mobile $Na^{\oplus}$ ions are clearly contrasted. In this case, nonuniformities in the column packing, which lead to channel formation, are visible.

These first attempts at following the chromatographic process by means of NMR imaging show that this method

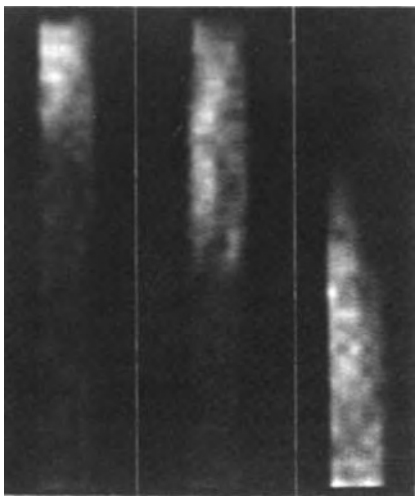

Fig. 4. Flash images (^{23}Na images) of ion exchange on an ion-exchange column during elution with 2 N HCl at time intervals of 40 min (column 30 cm × 3 cm, 3D FLASH, TE = 5 ms, TR = 20 ms).

offers new possibilities for basic investigations. Flow effects, which have so far only been investigated either theoretically or, when experimentally, with concomitant interference in the process, can be studied noninvasively. Optimization of the column packing should be of special value in opening up new applications to preparative chromatography.

The imaging of flow systems in packed and open columns is of interest for many other processes besides chromatography. Imaging allows the observation of chromatographic processes independent of the color of the substances being eluted. Thus, the term chromatography, as coined by *Tswett*, again takes on a general meaning.

So far the resolution of this method has not allowed the diffusion processes in individual particles to be viewed. Model studies on larger particles, however, can be carried out with micro-imaging instruments.[12, 13] Figure 5 shows polystyrene spheres of ca. 500-μm diameter with a planar resolution of 20 μm × 20 μm after swelling in benzene. The

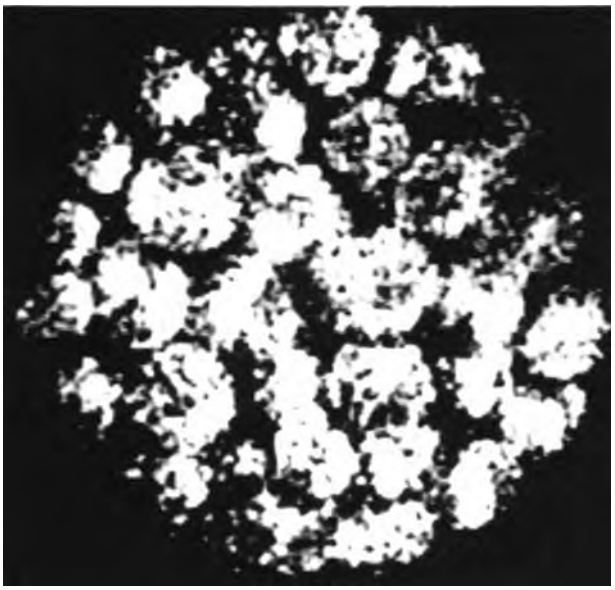

Fig. 5. Micro-image of polystyrene beads in benzene, pixel resolution 20 μm, slice thickness 200 μm (spin-echo sequence, Bruker AM 300 WB instrument). We thank *W. Kuhn*, Bruker Analytische Messtechnik, Karlsruhe-Forchheim, for this image.

distribution of the solvent inside the polymer spheres is revealed by the contrast in brightness. The further development of NMR imaging to include nearly microscopic resolution offers the possibility of numerous applications in polymer chemistry and cell biology.

Insertion of $Cr(CO)_3$ into $As_7^{3\ominus}$ to Form $[As_7Cr(CO)_3]^{3\ominus}$: An Inorganic Nortricyclane-to-Norbornadiene Conversion

By *Bryan W. Eichhorn, Robert C. Haushalter,** and *John C. Huffman*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

The pioneering work of *von Schnering* and co-workers in the development of polyatomic pnictide anions revealed a remarkable family of clusters with unusual structures and properties.[1] Most notable among these compounds are the extensive series of phosphides that include $P_7^{3\ominus}$, $P_{11}^{3\ominus}$, $P_{16}^{2\ominus}$, and $P_{21}^{3\ominus}$.[2] Subsequent studies[3, 4] have shown that the later pnictide elements can adopt structures different from those of the phosphides, such as the square $M_4^{2\ominus}$ (M = Sb, Bi)[5] and the linked bis-trishomocubane $As_{22}^{4\ominus}$.[6] Reactions of these species with transition metals have been virtually unexplored aside from a few examples of transition-metal main-group clusters that include $P_7[FeCp(CO)_2]_3$[7] and the remarkable $^1_\infty[Rb \cdot NbAs_8^{2\ominus}]$.[8] We have been interested in inserting unsaturated transition-metal fragments into various polyatomic p-block cluster anions (Zintl ions) to effect topological rearrangements within the main-group fragment and probe the flexibilities of the cluster frameworks. Thus far, we have isolated and characterized *closo*-$[Sn_9Cr(CO)_3]^{4\ominus}$[9] along with a variety of telluride complexes that include $[Mo_4Te_{16}(en)_4]^{2\ominus}$ (en = ethylenediamine),[10] $[Cr(\eta^2\text{-}Te_2)_2(CO)_2]^{2\ominus}$,[11] and $[Pd(Te_4)_2]^{2\ominus}$.[12] Here we describe the synthesis and structure of $[As_7Cr(CO)_3]^{3\ominus}$, comprising a norbornadiene-related As_7 core derived from the nortricyclic $As_7^{3\ominus}$ ion.

Toluene solutions of $[Cr(CO)_3(\eta^6\text{-mes})]$ (mes = 1,3,5-$Me_3C_6H_3$) react with ethylenediamine extracts of Rb_3As_7[1e] in the presence of three equivalents of 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane (crypt) to form the chromium-arsenide complex **1** [Eq. (a)]. Transparent red-orange crystals of complex **1** can be isolated in good yield from concentrated reaction mixtures at room temperature.

$$[Cr(CO)_3(\eta^6\text{-mes})] + Rb_3As_7 + 3\ \text{crypt} \xrightarrow{\text{en/toluene}} \underset{\mathbf{1}}{[As_7Cr(CO)_3][(Rb \cdot \text{crypt})_3] \cdot 0.5\ \text{toluene}} + \text{mes} \quad \text{(a)}$$

The crystalline solid must be stored at $-20\,^\circ C$ or below and is very air and moisture sensitive in solution and the solid state. Complex **1** has been characterized by energy-dispersive X-ray analysis (EDAX), bulk elemental analysis, solution and solid-state IR spectroscopy, and single-crystal X-ray diffraction.

Compound **1** crystallizes in the space group $P\bar{1}$ with two independent anions, six $(Rb \cdot crypt)^\oplus$ ions, and a toluene solvate molecule in the asymmetric unit (197 heavy atoms);[14] one anion is partially disordered. The structure of the $[As_7Cr(CO)_3]^{3\ominus}$ ion **2** (Fig. 1) contains an opened As_7 cage that is bound in an η^4 fashion to the $Cr(CO)_3$ fragment. The As_7 fragment in **2** bears a striking resemblance to the coordinated norbornadiene ligand in $PdCl_2$(norbornadiene)[15] and represents a new structure type for seven-atom p-block clusters; however, similar P_7 fragments can be identified in the interior of some larger polyphosphorus compounds[1, 2] and certain forms of elemental phosphorus.[16] The As_7 cage in **2** is closely related to the parent $As_7^{3\ominus}$ ion, differing only by the absence of one As–As bond (Fig. 2, left). The site of attachment of the $Cr(CO)_3$ fragment is shown in Figure 2, right. The Cr–As distances in **2** (average 2.67(6) Å) are long in comparison with metal–arsenic distances in related compounds such as $[Cr_2(CO)_6(AsMe)_9]$ (2.44(1) Å)[17] and $[(\mu_3\text{-}As)Cr_2Mn(CO)_{14}]$ (2.38(6) Å).[18] The anion possesses a virtual mirror plane (C_s symmetry). As a result, C13 and C11 are aligned *trans* to As4 and As5, thereby lengthen-

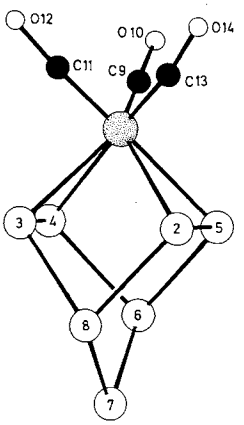

Fig. 1. Ball-and-stick Chem-X [20] representation of **2**. Pertinent distances [Å] and angles [°]: Cr1–As2 2.636(10), Cr1–As3 2.630(11), Cr1–As4 2.685(10), Cr1–As5 2.730(10), Cr1–C9 1.78(5), Cr1–C11 1.67(5), Cr1–C13 1.82(6), C11–O12 1.28(5), C9–O10 1.18(5), C13–O14 1.15(5); C13–Cr1–As4 177(2), C11–Cr1–As5 175(2), C9–Cr1–As2 132(1), C9–Cr1–As3 140(1), Cr1–As4–As6, Cr1–As5–As6 99.5(2) (average), Cr1–As2–As8, Cr1–As3–As8 103.9(1) (average).

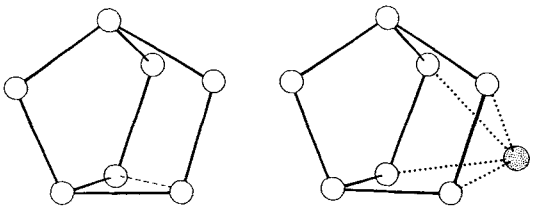

Fig. 2. Two views of the As_7 fragment of **2**. Left: Perspective showing the relationship to the parent $As_7^{3\ominus}$ ion. The separation denoted by the dashed line (3.2 Å) is 0.7 Å longer than in $As_7^{3\ominus}$ (2.49 Å) (see [1e]). Right: Perspective showing the site of attachment of the $Cr(CO)_3$ fragment relative to the parent $As_7^{3\ominus}$ framework.

ing these Cr–As bond distances (average 2.71(2) Å) relative to the Cr–As bond distances to As2 and As3 (average 2.64(2) Å) due to the high *trans* influence of CO. The As–As bond distances occur in two ranges: long contacts for As8–As2,3 and As6–As4,5 (average 2.46(2) Å) and short contacts for As2–As5, As3–As4, and As7–As8,6 (average 2.35(2) Å). The latter distances are typical for bonds to two-coordinate As atoms in polyarsenide cluster anions.[1, 2, 4, 6] The As2–As3 and As4–As5 separations of 3.09(1) and 3.29(1) Å, respectively, reflect a slight asymmetry in the As_7 core but can be considered nonbonding.

A significant amount of electron density has been transferred onto the Cr atom, as evidenced by low CO stretching frequencies in the IR spectrum of **2** [$\tilde{\nu}$(CO) = 1823, 1742, 1706 cm^{-1}] and short Cr–C bond distances (d(Cr,C) = 1.74(8) Å). These values are intermediate between those of $[M_9Cr(CO)_3]^{4\ominus}$ (M = Sn, Pb) and $[Cr(CO)_3(\eta^6\text{-}C_6H_6)]$, as is expected based on ligand donor properties and charge considerations (see Table 1). For electron bookkeeping purposes, it is convenient to consider **2** as a composite of a 14-electron $[Cr(CO)_3]^{2\ominus}$ fragment and a 4-electron-donor (norbornadiene-like) $As_7^{\ominus}$ fragment that satisfies the 18-valence-electron requirement at the Cr center.

Table 1. IR and structural data.

Complex	$\tilde{\nu}$(CO) [cm^{-1}]	d(Cr, C) [Å]	d(C,O) [Å]
$[Cr(CO)_3(\eta^6\text{-}C_6H_6]$ [13a]	1970, 1894	1.83	1.15
$[Sn_9Cr(CO)_3]^{4\ominus}$ [9]	1809, 1703	1.65(7)	1.29(4)
$[Pb_9Cr(CO)_3]^{4\ominus}$ [13b]	1791, 1688	1.76(5)	1.20(7)
$[As_7Cr(CO)_3]^{3\ominus}$	1823, 1724	1.76(9)	1.20(8)

The formation of **1** represents the conversion of a nortricyclic $As_7^{3\ominus}$ cluster into a norbornadiene-like As_7 fragment at a transition-metal center. This transformation closely resembles the organic chemistry occurring at a $(CO)_nCr$(norbornadiene) center (n = 3,4), where norbornadiene-to-nortricyclane conversions are facile.[19] Anion **2** represents the beginning of a growing class of transition-metal pnictide clusters with bare main-group fragments (cf. also Refs. [7, 8]).

Experimental Procedure

Under a He atmosphere a melt of nominal composition Rb_3As_7 (200 mg, ca. 0.26 mmol) was extracted into ethylenediamine (ca. 5 mL), producing a red-orange solution. In a separate reaction vessel, $[Cr(CO)_3(\eta^6\text{-mes})]$ (80 mg, 0.31 mmol) was dissolved in toluene (ca. 1 mL), producing a pale-yellow solution. The toluene solution was added dropwise to the ethylenediamine extract. Three equivalents of crypt (290 mg, 0.78 mmol) were added to the red-orange reaction mixture. No color changes occurred. The mixture was filtered twice and concentrated under vacuum to ca. 3 mL total volume. After 48 h, 320 mg (0.15 mmol) of pale orange red crystals were isolated, washed with toluene, and dried in vacuo (58% crystalline yield based on Rb_3As_7). Elemental analysis calculated for $Rb_6As_{14}Cr_2C_{121}H_{224}N_{12}O_{42}$: As, 24.52; Cr, 2.43; C, 35.95; H, 5.47; N, 3.93. Found: As, 25.06; Cr, 2.48; C, 34.73; H, 5.39; N, 4.02. A disordered en solvate molecule in the crystal lattice, which is typical for cryptated Zintl clusters [3, 9], would explain the high nitrogen content.

Trigonal-Bipyramidal Lanthanoid Complexes with Interstitial Oxygen Atoms**

By Herbert Schumann, Pil Ryul Lee,* and *Jörg Loebel*

Lanthanoid trichlorides react with $K[HB(pz)_3]$ to form the tris(pyrazolyl)borato complexes $[\{HB(pz)_3\}LnCl_2]$,[1]

[*] Prof. Dr. H. Schumann, Dr. P. R. Lee, Dipl.-Chem. J. Loebel

Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12

[**] Organometallic Compounds of the Lanthanoids, Part 49. This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft. Part 48: H. Schumann, R. D. Köhn, F. W. Reier, A. Dietrich, J. Pickardt, *Organometallics 8* (1989) 1388.

$[\{HB(pz)_3\}_2LnCl]$,[1,2] $[\{HB(pz)_3\}_3Ln]$,[1,3] and $[\{HB(pz)_3\}_2Ln(CH_3COCHCOCH_3)]$,[4] in which the tris(pyrazolyl)borato ligands are coordinated to the lanthanoid atom through one nitrogen atom on each of the three pyrazole rings. The pyrazolyl ligand, $C_3H_3N_2^{\ominus}$(pz), and the 3,5-dimethylpyrazolyl ligand, $(CH_3)_2C_3HN_2^{\ominus}$ ($pzMe_2$), however, have two nitrogen atoms capable of coordination; thus, they can be employed as 1,2-μ-bridging ligands in the formation of (η^2-$pzMe_2$) complexes, for example, $[Ni(NO)(pzMe_2)]_2$,[5] and of (η^2-pz) complexes, for example, $[(C_5H_5)_2Ti(pz)_2Ti(C_5H_5)_2]$.[6] X-ray structure analyses of the first pyrazolyl complexes of the inner transition metals, $[(C_5H_5)_3U(pz)]$[7] and $[(C_5Me_5)_2U(pz)_2]$,[8] reveal an η^2 coordination.

We found that lanthanoid trichlorides, $LnCl_3$, react with Na(pz) and $Na(pzMe_2)$ in tetrahydrofuran under inert atmosphere to give organolanthanoid pyrazolates, some of which have complicated formulas. The products could be characterized by elemental analyses and NMR spectra.[9] Traces of water in the reaction mixture result in the incorporation of an $O^{2\ominus}$ ion between the strongly oxophilic lanthanoids. Reaction of YCl_3, $HoCl_3$, $YbCl_3$, and $LuCl_3$ with $Na(pzMe_2)$ thus yielded complexes **1a–4a** as colorless to pink crystals; a molecule of tetrahydrofuran is coordinated to each sodium atom.[10] Extraction of the reaction products with toluene results in replacement of the two tetrahydrofuran molecules coordinated to the two sodium atoms with two 3,5-dimethylpyrazoles (**1b–3b**).[10]

$$3\,LnCl_3 + 11\,Na(pzMe_2) + H_2O \xrightarrow{THF} [Ln_3(\mu\text{-}pzMe_2)_6(\eta^2\text{-}pzMe_2)_3(\mu_3\text{-}O)Na_2(thf)_2] + 9\,NaCl + 2\,H(pzMe_2)$$

Ln = Y (**1a**), Ho (**2a**), Yb (**3a**), Lu (**4a**)

$$3\,LnCl_3 + 11\,Na(pzMe_2) + H_2O \xrightarrow{toluene} [Ln_3(\mu\text{-}pzMe_2)_6(\eta^2\text{-}pzMe_2)_3(\mu_3\text{-}O)Na_2\{H(pzMe_2)\}_2] + 9\,NaCl$$

Ln = Y (**1b**), Ho (**2b**), Yb (**3b**)

The X-ray crystal structure analyses[11] of **2b** and **3a** revealed trigonal bipyramids containing an oxygen atom at the center, three lanthanoid atoms in the equatorial positions, and two sodium atoms at the apical vertices (Figs. 1 and 2). Holmium and ytterbium each are heptacoordinated by four nitrogen atoms of the bridging pyrazolyl ligands, two nitrogens of the terminal pyrazolyl ligands, and the central oxygen atom. In both clusters, the N–N bonds of the bridging pyrazolyl group are not parallel to the sides of the triangle formed by the lanthanoid atoms; thus, in each case, only one of the nitrogen atoms is coordinated to a sodium atom (average distance 248.5 pm in **2b**, 242.9 pm in **3a**). Therefore, together with the THF oxygen atom or a nitrogen atom of the neutral pyrazole ligand, respectively, the sodium atom has a tetrahedral coordination geometry.

Coordination of 3,5-dimethylpyrazole, which is sterically demanding relative to tetrahydrofuran to sodium, forces one of the terminal pyrazole rings in **2b** to lie nearly perpendicular (99.93°) to the plane of the holmium atoms, while the other terminal pyrazole ligands in **2b** and **3a** form angles of only 14.95–33.06° with respect to this plane. One of the bridging pyrazole ligands in **2b** is so strongly tilted that N15 is coordinated to two holmium atoms and N16 exhibits a relatively short distance (236.6(4) pm) to Na1. The nitrogen atoms of the terminal η^2-dimethylpyrazolyl ligands, which exhibit Ln–N distances of 227.5 and 234.8 pm in **3a** and of 230.7 and 239.1 pm in **2b**, are ca. 10 pm closer to the metal atom than those of the bridging ligands (240.2–247.6 pm in **3a** and 243.7–256.7 pm in **2b**). In **2b**, the Na–O distances (272.8(3) and 290.7(3) pm), as well as the Ho–O distances

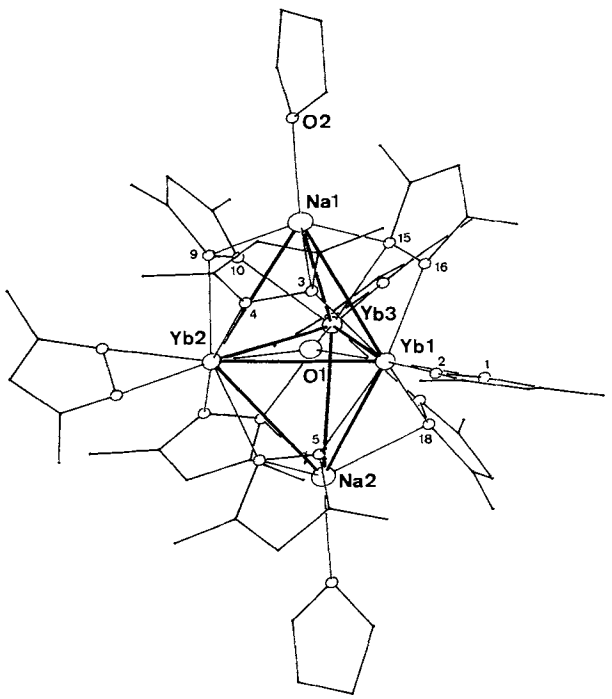

Fig. 1. Molecular structure of **3a**. The N atoms are numbered. For clarity, the C atoms are drawn in a simplified way (H atoms omitted). Selected distances [pm] and angles [°]: Yb1–N1 234.8(5), Yb1–N2 229.8(5), Yb1–N3 244.6(4), Yb1–N5 (243.9(5), Yb1–N16 244.5(4), Yb1–N18 244.8(4), Yb1–O1 213.8(4), Yb2–O1 213.0(4), Yb3–O1 213.2(3), Na1–O1 274.4(3), Na1–O2 227.0(4), Na1–N3 243.5(5), Na1–N4 270.3(5), Na1–N9 240.2(6), Na1–N10 297.6(5), Na1–N15 242.5(5), Na1–N16 274.8(5); Na1–O1–Na2 178.0(2), Yb1–O1–Yb2 120.3(1), Yb1–O1–Yb3 121.3(2), Yb2–O1–Yb3 118.4(2).

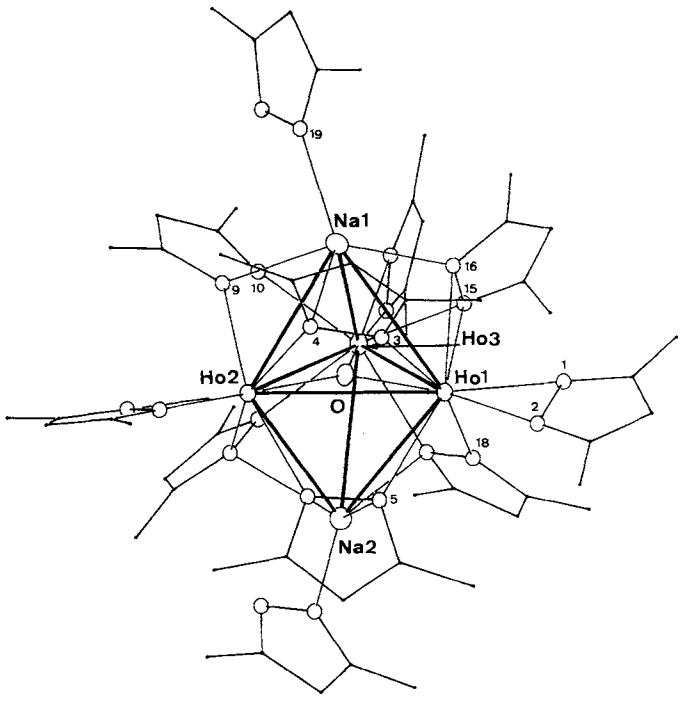

Fig. 2. Molecular structure of **2b**. The N atoms are numbered. For clarity, the C atoms are drawn in a simplified way (H atoms omitted). Selected distances [pm] and angles [°]: Ho1–N1 233.8(3), Ho1–N2 236.8(3), Ho1–N3 244.4(3), Ho1–N5 250.3(3), Ho1–N15 255.5(3), Ho1–N16 256.7(3), Ho1–N18 245.3(4), Ho1–O 217.8(3), Ho2–O 214.2(3), Ho3–O 214.2(3), Na1–O 272.8(3), Na1–N3 278.0(4), Na1–N4 247.6(4), Na1–N9 259.2(4), Na1–N10 283.2(4), Na1–N16 236.6(4), Na1–N19 236.3(5); Na1–O–Na2 174.5(1), Ho1–O–Ho2 123.1(1), Ho1–O–Ho3 111.2(1), Ho2–O–Ho3 125.7(1).

(214.2(3), 214.2(3), and 217.8(3) pm), are significantly different, whereas they are nearly identical in **3a** (274.4(3) and 276.7(3); 213.0(4), 213.2(3), and 213.8(4) pm). Furthermore, the Na–O–Na angle in **2b** (174.5(1)°) deviates more from linearity than in **3a** (178.0(2)°).

The tendency toward higher coordination numbers, together with the strong oxophilicity, leads to the preferential formation of organolanthanoid clusters with a central oxygen atom, as has already been demonstrated in the synthesis of cyclopentadienyllanthanoid alkoxides, whereby complexes **5**, Ln = Y[12] and Gd,[13] were isolated, and in the

$[(C_5H_5)_5Ln_5(\mu\text{-}OCH_3)_4(\mu_3\text{-}OCH_3)_4(\mu_5\text{-}O)]$ **5**

reaction of yttrium with refluxing 2-propanol, which resulted in the formation of **6**.[14] The same tendency to accept

$[Y_5(\mu_3\text{-}O\mathit{i}Pr)_4(\mu_2\text{-}O\mathit{i}Pr)_4(O\mathit{i}Pr)_5(\mu_5\text{-}O)]$ **6**

oxygen from "pure" organic solvents, leading to the formation of oxo-centered clusters, is shown by organouranium compounds like the likewise fortuitously obtained compounds **7**[15] and **8**.[16]

$[\{C_9H_7UBr(CH_3CN)_4\}_2O][UBr_6]$ **7**

$[\{C_5Me_5U[\mu\text{-}(CH_2)P(C_6H_5)_2(CH_2)]\}_2Mg\{CH_2P(CH_3)(C_6H_5)_2\}_2\text{-}(\mu_3\text{-}O)(\mu_2\text{-}O)(\mu_2\text{-}Cl)_2]$ **8**

[10] *Experimental Procedure*: All operations were performed under an argon atmosphere using carefully degassed solutions. **1a**: 3,5-dimethylpyrazolylsodium (1.87 g, 16 mmol) in 50 mL of THF was slowly added to a suspension of YCl_3: (0.97 g, 5 mmol) in 150 mL of THF. The reaction mixture was stirred for 48 h at room temperature and then refluxed for 5 d. After decantation of NaCl and concentration of the solution, colorless crystals of **1a** formed. Yield: 0.85 g (44%). Correct C,H,N analysis. M.p. 270–272 °C. ^{1}H NMR (80 MHz, C_6D_6): δ = 1.27 (m, THF), 2.21 (s, $CH_3(\mu\text{-}pzMe_2)$), 2.37 (s, $CH_3(\eta^2\text{-}pzMe_2)$), 3.20 (m, THF), 5.82 (s, $H(\mu\text{-}pzMe_2)$), 6.40 (s, $H(\eta^2\text{-}pzMe_2)$). ^{13}C NMR (20.1 MHz, C_6D_6): δ = 13.67 (CH_3), 25.45 (THF), 70.60 (THF), 105.23, 110.02, 145.53, 152.23. – **1b**: A reaction mixture containing YCl_3 (0.41 g, 2.1 mmol) and $Na(pzMe_2)$ (0.78 g, 6.6 mmol) in 70 mL of THF was refluxed for 6 d. The solvent was then completely removed in vacuo and replaced by 30 mL of toluene. After filtration of the precipitated NaCl, the solution was concentrated to half of its initial volume, resulting in the formation of colorless crystals of **1b** (0.43 g, 52%). Decomposition point: 230 °C. Correct C,H,N analysis. ^{1}H NMR (80 MHz, C_6D_6): δ = 1.92 (s, $CH_3(H(pzMe_2))$), 2.19 (s, $CH_3(\mu\text{-}pzMe_2)$), 2.36 (s, $CH_3(\eta^2\text{-}pzMe_2)$), 5.60 (s, $H(H(pzMe_2))$), 5.83 (s, $H(\mu\text{-}pzMe_2)$), 6.40 (s, $H(\eta^2\text{-}pzMe_2)$), 9.76 (s, $NH(H(pzMe_2))$). ^{13}C NMR (20.1 MHz, C_6D_6): δ = 11.53, 13.31, 13.45, 103.81, 104.75, 110.09, 144.31, 145.31, 152.24.

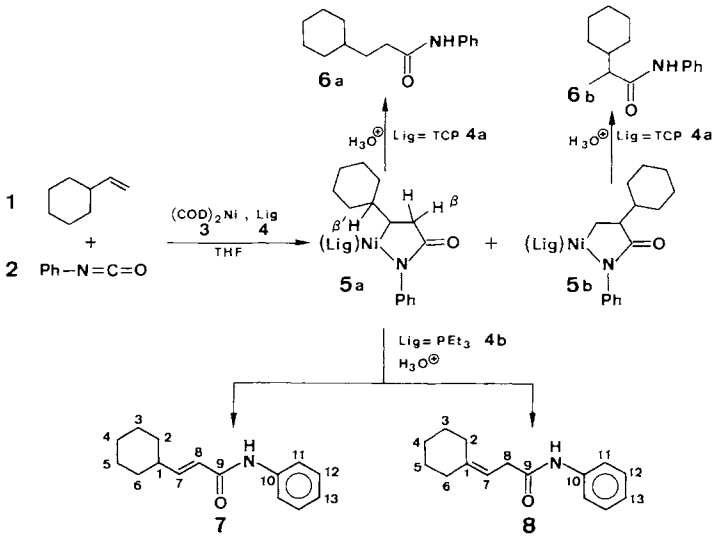
Nickel(0)-Catalyzed Preparation of Isomeric Carboxamides – Ligand-Controlled β-H or β′-H Elimination

By *Heinz Hoberg** and *Dieter Guhl*



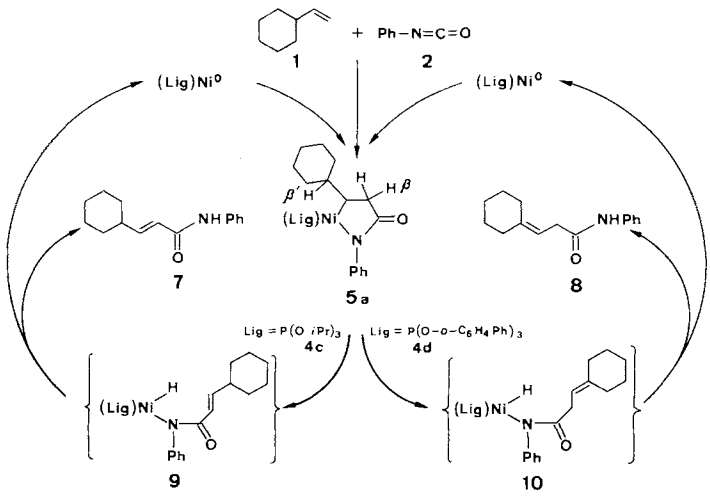
We have presented numerous examples of the diverse ways in which isocyanates can undergo C–C bond forming reactions with C–C multiple-bond systems at nickel(0) complexes, whereby, in addition to stoichiometric reactions, catalytic reactions have become increasingly important.[1] Azanickelacycles formed by oxidative coupling are the proposed intermediates. An important partial step in catalysis is often β-H elimination. It leads to H-Ni amide species which release the unsaturated compound in a reductive elimination step and regenerate the (Lig)Ni^0 starting complex. Until now, only CH groups whose C atoms are part of the azanickelacycle have been employed in the β-H elimination. In principle, however, it should also be possible to involve β-H atoms bound to an exocyclic C atom. Whereas in the first case α,β-unsaturated carboxamides are formed, in the second the β, γ isomers should be obtained.

To determine whether such alternative β-H abstractions are possible in these azanickelacycles, vinylcyclohexane **1** was selected. This alkene contains a tertiary CH bond, the H atom of which exhibits partial "hydride" character; it should therefore be especially well suited as a trial reagent. We have found that, by varying the reaction-controlling ligands **4** and by exploiting steric and/or electronic effects,[2] it is possible to activate selectively the different β-H positions in such a way that the products can be formed with high selectivity and even catalytically.

When a suspension of **1**, phenyl isocyanate **2**, bis(1,5-cyclooctadiene)nickel ($(cod)_2Ni$) **3**,[3] and tricyclohexylphosphane (TCP) **4a** in a molar ratio of 2:1:1:1 in THF at −78 °C is allowed to warm to room temperature (stoichiometric reaction[1]) and then hydrolyzed (2 N H_2SO_4), the saturated carboxamides **6a, b**, derived from the nickelacycles **5a, b**, are obtained in a molar ratio of ca. 95:5. (Scheme 1). The high regioselectivity of the reaction corresponds to that observed for other monosubstituted alkenes.[1] Since isomer **5b**, formed in small amounts, has only one β-H position, the products resulting from it were neglected in this investigation. If the sterically less demanding triethylphosphane **4b** is

[*] Prof. Dr. H. Hoberg, Dipl.-Chem. D. Guhl
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a.d. Ruhr (FRG)

used instead of **4a** in the reaction of **1** with **2** and **3** and the reaction mixture is heated to 50 °C, protonolysis yields, in addition to small amounts of **6a**, the β-H elimination products **7** and **8** in a molar ratio of ca. 1:1 (yield 19%); both products are derived from the coupling product **5a** (Scheme 1).



Scheme 1. Effect of the ligands on the reaction of **1** with **2** at nickel(0) complexes. **6a, b** are products of stoichiometric reaction; **7** and **8** are products of catalytic reaction. Arbitrary numbering in **7** and **8**.

This result clearly demonstrates that ligand **4b** activates the β-H and β′-H positions of **5a** to the same extent for elimination. Control experiments confirmed that the isomeric carboxamides **7** and **8** are formed as a result of different β-H abstraction steps rather than by subsequent isomerization. Neither **7** nor **8** is converted into the other product in the presence of (Lig)Ni^0 or 2 N H_2SO_4.

This stoichiometric reaction can be made catalytic under certain conditions.[1] After four catalytic cycles, the product ratio **7:8** remains constant (1:1) when ligand **4b** is used. Changing the ligand properties allows the product formation to be controlled. Thus, the sterically less demanding triisopropylphosphite **4c** induces β-H elimination at the metallacycle, resulting in an isomer distribution of **7:8** = 95:5. By contrast, the sterically demanding ligand tri-*ortho*-phenylphenylphosphite **4d** activates the β′ position. The product distribution is reversed (**7:8** = 14:86; Scheme 2).

Moreover, the use of ligands **4c, d** gave four of the theoretically expected maximum of ten cycles (based on the amount of **2** employed). We propose the mechanism formulated in Scheme 2 for the formation of carboxamide. The catalytic cycles begin with 1:1 C–C coupling of **1** with **2** at (Lig)Ni^0 to give the central nickelacycle **5a**; the subsequent reactions depend on the ligands used. Ligand **4c** leads to β-H elimination at the nickelacycle with formation of intermediate **9**. Subsequent reductive elimination results in release of **7** and regeneration of the (Lig)Ni^0 starting complex (left-hand cycle in Scheme 2). On the other hand, ligand **4d** activates the exocyclic β′-H position (formation of intermediate **10**); reductive elimination results in release of **8** and makes (Lig)Ni^0 available again for the catalytic cycle (right-hand cycle in Scheme 2).

Scheme 2. Catalytic cycles and product control by the ligands **4c** and **4d**.

The results presented here demonstrate for the first time, to the best of our knowledge, that different β-H positions of a metallacycle can be activated for H elimination with high selectivity by an appropriate choice of ligands. This reaction thus represents a novel variant of β-H elimination, which, in view of the possibility of using different alkenes, promises a wide range of applications in preparative chemistry.

Typical Experimental Procedure

Cyclohexylidenepropionanilide **8** (catalytic): A suspension of **3** (0.38 g, 1.38 mmol), **4d** (0.74 g, 1.38 mmol), and **1** (6.08 g, 55.27 mmol) in ca. 40 mL of THF was placed in a steel autoclave (200 mL) cooled to −30 °C. Compound **2** (1.64 g, 13.8 mmol), as a 1 M solution in THF, was added in a controlled fashion over ca. 8 h to the stirred reaction solution by means of a proportioning pump [4], whereby the mixture was heated simultaneously to +50 °C. After an additional 50 h, the cooled solution was hydrolyzed with ca. 10 mL of 2 N H_2SO_4 and then extracted several times with diethyl ether. The organic phase was dried over $MgSO_4$ and the solvent was then removed. The residue was separated by column chromatography (silica gel 60; eluant, toluene/ether, 1/1). Obtained: 0.17 g (0.72 mmol) **7** (5.2%) and 0.90 g (3.93 mmol) **8** (28.5%). Physical data for **8**: m.p. 101 °C; MS: *m/z* 229 ($M^{\oplus}$); correct elemental analysis IR (KBr): $\tilde{\nu}_{NH}$ = 3250 cm^{-1}, $\tilde{\nu}_{CO}$ = 1650 cm^{-1}. ^1H NMR ($CDCl_3$, 20 °C, 200.1 MHz): δ = 7.94 (s, 1H; NH), 7.51 (m, 1H; 13-H), 7.28 (m, 2H; 12-H), 7.07 (m, 2H; 11-H), 5.34 (t, 1H, $J_{7,8}$ = 7.5 Hz; 7-H), 3.13 (d, 2H; 8-H), 2.16 (m, 4H; 2-,6-H), 1.57 (m, 6H; 3-,4-,5-H). ^{13}C NMR ($CDCl_3$, 20 °C, 50.3 MHz): δ = 170.1 (s; C-9), 146.1 (s; C-1), 137.8 (s; C-10), 128.8 (d, $J_{C,H}$ = 160 ± 2 Hz; C-12), 124.1 (d, $J_{C,H}$ = 161 ± 2 Hz; C-13), 119.7 (d, $J_{C,H}$ = 161 ± 2 Hz; C-11), 113.0 (d, $J_{C,H}$ = 163 ± 2 Hz; C-7), 36.9 (t, $J_{C,H}$ = 128 ± 1 Hz; C-8), 36.0 (t, $J_{C,H}$ = 126 ± 1 Hz; C-6), 28.7, 28.4, 27.6, 26.4 (t, C-2,-3,-4,-5). Cyclohexylacrylanilide **7** (catalytic): amounts of reagents, 0.4 g (1.45 mmol) **3**, 0.30 g (1.45 mmol) **4c**, 6.38 g (58.0 mmol) **1**, 1.74 g (14.6 mmol) **2**; 1 M solution in toluene; solvent 40 mL toluene; reaction time, 17 h. Obtained: 0.076 g (0.33 mmol) **8** (2.2%) and 1.442 g (6.3 mmol) **7** (43.1%). Physical data for **7**: m.p. 125 °C; MS: *m/z* 229 ($M^{\oplus}$); correct elemental analysis. IR (KBr): $\tilde{\nu}_{NH}$ = 3250 cm^{-1}, $\tilde{\nu}_{CO}$ = 1670, 1640 cm^{-1}, $\tilde{\nu}_{C=C}$ = 980 cm^{-1}. ^1H NMR ($CDCl_3$, 20 °C, 200.1 MHz): δ = 8.6 (s, 1H; NH_2), 7.59 (m, 2H; 11-H), 7.24 (m, 2H; 12-H), 7.05 (m, 1H; 13-H), 6.89 (dd, 1H, $J_{7,8}$ = 16 Hz, $J_{7,1}$ = 6.9 Hz, 7-H), 5.98 (dd, 1H, $J_{8,1}$ = 1.2 Hz; 8-H), 2.10 (m, 1H; 1-H), 1.71–0.96 (m, 10H; 2-,3-,4-,5-,6-H). ^{13}C NMR ($CDCl_3$, 20 °C, 50.3 MHz): δ = 165.2 (s; C-9), 151.1 (d, $J_{C,H}$ = 151 ± 1 Hz; C-7), 138.4 (s; C-10), 128.8 (d; C-12), 124.1 (d; C-13), 121.8 (d, $J_{C,H}$ = 157 ± 1 Hz; C-8), 120.3 (d; C-11), 40.3 (d; C-1), 31.8 (t; C-2, C-6), 25.9 (t; C-4), 25.7 (t; C-3, C-5).

Selective 1:3 Coupling of Norbornene and Iodobenzene: A Facile Synthesis of Benzo[*e*]pyrenes with Annelated Cycloaliphatic Moieties**

By *Oliver Reiser, Martin Weber,* and *Armin de Meijere**

Dedicated to Professor Hans-Jörg Sinn on the occasion of his 60th birthday

Palladium(0)-catalyzed coupling of olefins with aryl halides, the so-called Heck reaction,[1] is becoming increasingly important in organic synthesis.[2] Frequent reports of new applications show that the potential of this reaction is far from being exhausted.[3] Under certain conditions, Pd^0-catalyzed coupling of norbornene with bromobenzene, investigated intensively by *Chiusoli* et al.,[4] leads to a 1:2 adduct consisting of a norbornene framework with an annelated dihydrophenanthrene moiety (cf. **10**). With the goal of extending this annelation method to [2.2]paracyclophane-1,9-diene, we allowed the latter to react with iodobenzene under the conditions described by *T. Jeffery*[5] ($Pd(OAc)_2$, K_2CO_3, Bu_4NBr, dimethylformamide (DMF)), which, according to our experience,[6] appeared particularly promising. Instead of 1:2 or 1:4 adducts, however, 1:3 and 1:6 coupling products were obtained. This reaction pathway is not unique to paracyclophanediene; under the same reaction conditions, it is also observed for norbornene **1** (Scheme 1).

1 **2-I** **3**

a, R=H ; **b**, R=CH_3

Scheme 1. a: $Pd(OAc)_2$, K_2CO_3, Bu_4NBr, DMF.

Independent of the relative amounts of reactants, **1** and bromobenzene (**2a**-Br) or iodobenzene (**2a**-I) yielded the norbornane derivative **3a**,[7] containing an annelated 4-phenyl-9,10-dihydrophenanthrene moiety (see Table 1). Even for a threefold excess of **1** over **2a**-X, only **3a** was found. The constitution of **3a** was established on the basis of its ^1H, ^{13}C, and ^1H-^1H correlation NMR spectra[8] and a crystal structure analysis.[9]

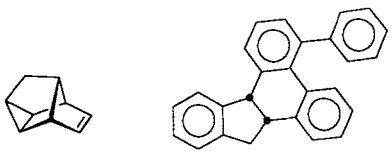

Table 1. Conditions and yields for the Pd^0-catalyzed [a] coupling of norbornene **1** with aryl halides **2**-X (see Scheme 1).

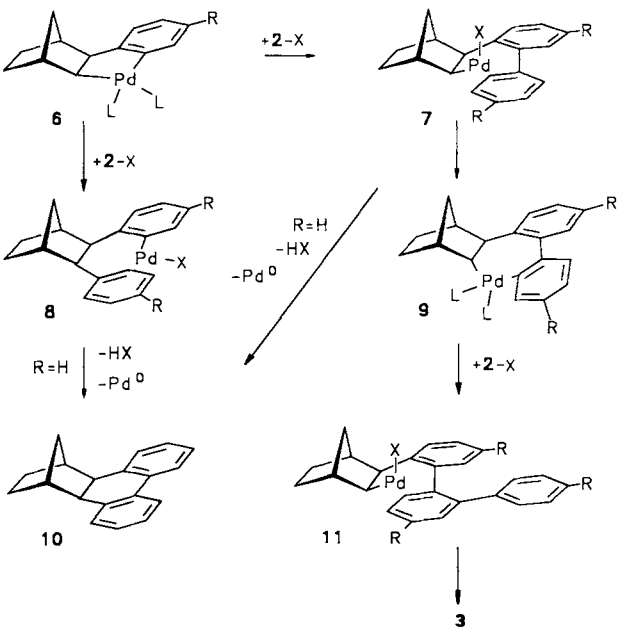
R	X	Equiv. **2**-X	*T* [°C]	*t* [h]	Yield [%] [b]	Conversion of **2**-X
H	Br	0.33	80	12	53	100
H	I	0.33	60	24	46	100
H	I	1	60	12	50	42
H	I	3	60	12	49	36
H	I	3	65	24	66 [c]	23
H	I	3	65	24	83 [d]	85
CH_3	I	1	100	6	30	100

[a] Conditions similar to [6] with 2 mol% $Pd(OAc)_2$. [b] Based on nonrecovered aryl halide **2**-X. [c] Norbornene added as an 18% solution in DMF over 24 h. [d] Norbornene added as a 20% solution in NMP over 24 h; 1 mol% $Pd(OAc)_2$ present. 3 mol% $Pd(OAc)_2$ in NMP added simultaneously over 24 h.



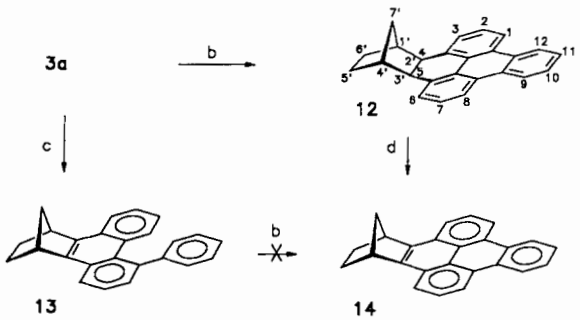
Similarly, reaction with *p*-iodotoluene (**2b**-I) affords compound **3b** as the sole low-molecular product.[7, 8] Based on recovered **2**-X, the yield is up to 53%[10] and even 83% when **1** and additional $Pd(OAc)_2$ (3 mol%), dissolved in *N*-methylpyrrolidone (NMP), are slowly added to a prepared mixture of **2a**-I and the catalyst system in NMP. In the latter case, norbornene **1** is completely consumed, in part in a still unknown competing reaction.

Deltacyclene **4** reacts analogously to **1** (25% yield based on **2a**-I), as does indene, which affords **5** in 35% yield based on **2a**-Br. The products obtained from [2.2]paracyclophanediene have similar structures containing 4-phenyl-9,10-dihydrophenanthrene moieties annelated at the bridges on one side and on both sides.[11]

4 **5**

The reaction of **1** with **2a**-I can be followed by gas chromatography. At no time could even traces of **10**[12] be detected; *Chiusoli* et al.[4] obtained this product with $Pd(Ph_3)_4$/KO*t*Bu/anisol. Although this finding indicates that **10** is not an intermediate on the way to **3a**, it still allows the metallacycle **6**, which is known to be a precursor to **10**, to lead also to **3** (Scheme 2). Whereas **10** could be formed from **7** and **8**,

Scheme 2. Mechanistic possibilities for the domino Heck coupling of iodobenzene with norbornene **1**.



both possible products of the oxidative addition of **2**-X to a Pd–C bond in **6**, by dehydrohalogenation and reductive elimination, **3** can only be formed from **7** (via **9** and **11**). Since the use of $Pd(PPh_3)_4/K_2CO_3$/DMF/Bu_4NBr leads only to **3a**, and not to **10**, and since the addition of **2**-X to the Pd–C_{sp^2} bond in **6** to give **7** should be favored, the formation of **10** in Ref. [4] is presumably due to the more drastic reaction conditions (KO*t*Bu/anisol; 110 °C).

[**] This work was supported by the Stiftung Volkswagenwerk and the Fonds der Chemischen Industrie as well as by Hoechst AG, Hüls AG, and Degussa AG (donation of chemicals). *O. R.* and *M. W.* thank the Studienstiftung des deutschen Volkes for fellowships.

The formation of the 1:3-coupling product **5** from indene and iodobenzene indicates that, in the first step, phenylpalladium iodide adds regioselectively to give *cis*-2-phenyl-1-indanylpalladium iodide.[13]

The domino coupling products of type **3a** offer an easy approach to the synthesis of benzo[*e*]pyrene derivatives containing annelated cycloalipatic moieties, since irradiation of **3a** in cyclohexane in the presence of iodine results in cyclization and dehydrogenation, leading smoothly to **12** (83%).[8] Further dehydrogenation with dichlorodicyanobenzoquinone (DDQ) leads to the norbornene-annelated benzo[*e*]pyrene **14** (85%).[8] If, instead, **3a** is first dehydrogenated to **13** (78%)[8] with DDQ, the photocyclization/dehydrogenation no longer takes place (Scheme 3).

Scheme 3. b: *hv*, cyclo-C_6H_{12}, I_2, N_2, 4 h. c: DDQ, $C_6H_5CH_3$, N_2, Δ, 2 h. d: DDQ, $C_6H_5CH_3$, N_2, Δ, 4 h.

In contrast to benzo[*e*]pyrene, which, like most polycyclic arenes, is only sparingly soluble, the derivative **14** dissolves readily in pentane, hexane, cyclohexane, and other solvents. Although its UV spectrum (maxima at λ_{max} (ε_{max}) = 316.5 (11520), 329.1 (19470), 343.9 nm (25320) and weak long-wavelength absorptions at λ_{max} (ε_{max}) = 365 (1000), 374 (600), 387 nm (1000)) is very similar to that of benzo[*e*]pyrene,[14] it exhibits only weak fluorescence with a quantum yield of 3.5% and emission maxima at 387, 408, and 432 nm.[15]

organosilicon heterocycles.[1] Of particular interest are the recent syntheses of three- and four-membered ring systems by reaction of disilenes with main group six elements O, S, Se, Te.[1,2] The products of reaction of Mes_4Si_2 (Mes = 2,4,6-$C_6H_2Me_3$) with molecular oxygen show unusual structures which present interesting problems in chemical bonding.[2,3] We have now found that Mes_4Si_2 possesses remarkable reactivity toward the group five element phosphorus as well. Tetramesityldisilene reacts with white phosphorus (40 °C, toluene, 24 h) to give an 87% yield of a yellow product having the novel butterfly-like bicyclobutane structure **1**.

1

^{31}P- and ^{29}Si-NMR spectroscopy does not show any phosphorus-rich compound as an intermediate. **1** is a pale yellow solid which is sensitive towards oxygen and moisture. Its composition was confirmed by ^1H, ^{31}P, and ^{29}Si NMR, a high resolution mass spectrum, and an elemental analysis.[4] The ^1H NMR spectrum of **1** exhibits sets of resonance signals for two chemically non-equivalent mesityl groups (*exo* and *endo* groups). The $^{31}P\{^1H\}$ NMR spectrum of **1** shows a singlet with ^{29}Si-satellites at very high field ($\delta = -324.0$), a typical region for phosphabicyclo[1.1.0]butanes with bridgehead P-atoms.[5] In the $^{29}Si\{^1H\}$ NMR spectrum a triplet resonance signal is observed at $\delta = -49.5$. The relative high value of the $J(^{29}Si\text{-}^{31}P)$ coupling constant (77 Hz) is characteristic for known silicon-phosphorus three-membered ring compounds, and is explained by a larger amount of s-character of the Si–P bond than is found in higher cyclic and acyclic Si–P compounds.[6]

1 reacts with $[W(CO)_5(THF)]$ and $[(Ph_3P)_2Pt(C_2H_4)]$ forming the crystalline transition metal complexes **2**, **3**, and **4**; the latter may have a propellane-like structure as shown, or an asterane structure, lacking the P–P bond.

Mes = 2,4,6-$C_6H_2Me_3$

The empirical formulas and structures of the metal complexes **2**–**4** are confirmed by FAB mass spectra as well as by ^1H, ^{29}Si, and ^{31}P NMR spectroscopy.[7] The ^{31}P nuclei of the Ph_3P ligand at Pt in **4** show a typically large $^1J(^{31}P\text{-}^{195}Pt)$ coupling constant (2522.6 Hz), whereas the analogous value for the bridgehead P atoms is much smaller (340.2 Hz). The remarkably low values of the $J(^{31}P\text{-}^{183}W)$ and $^1J(^{31}P\text{-}^{195}Pt)$ coupling constants, taken from the satellite peaks of the $^{31}P\{^1H\}$ NMR spectra,[7] indicates that the σ-donor bonding between the bridgehead P atom and metal includes a much smaller s-orbital contribution at phosphorus than in "normal" transition metal–phosphane complexes.[8] This finding is in accordance with MO calculations indicating that bridgehead P atoms in di-, tri-, and tetraphosphabicyclo[1.1.0]butanes possess donor orbitals with very high p-character [HOMO, HOMO-1].[9] The structure of the complex **3** in the crystal is further corroborrated by the result of an X-ray diffraction analysis (Fig. 1).[10]

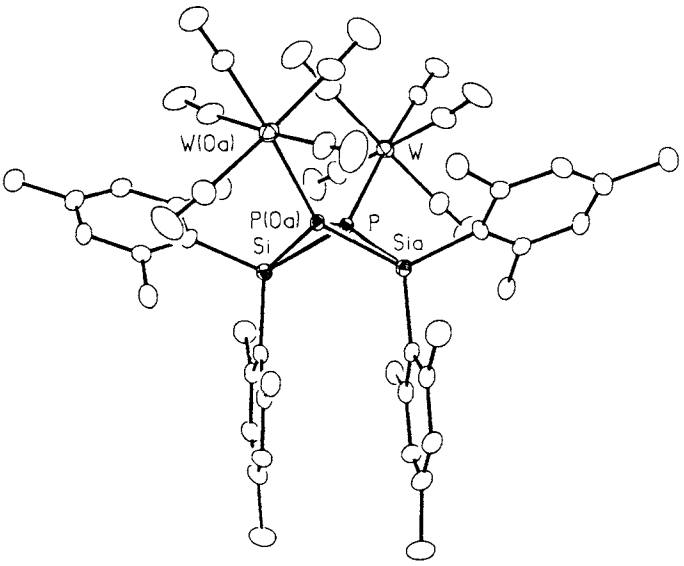

Fig. 1. Crystal structure of **3**. Important bond lengths [Å] and angles [°]: P–P 2.342(2), Si–P 2.267(2) (2.244(2)), P–W 2.560(1), Si–C 1.890(7) (1.873(5)), nonbonding Si–Si 3.244(2), P–Si–P 62.5(1), Si–P–P 58.2(1) (59.2(1)), Si–P–Si 91.9(1), C–Si–C 110.5(3).

The molecule has crystallographically determined, twofold symmetry about an axis perpendicular to the P–P bond. Each P atom lies in the center of a plane generated by the two Si atoms and one W-atom. The dihedral angle between the two three-membered Si–P–P rings is 114.6° and the torsion angle between the two P–W vectors (W–P–P–W) is 30.9°. A remarkable feature in the solid state structure of **3** is the approximately parallel conformation of the *endo*-mesityl groups.

Experimental

1: A solution of Mes_4Si_2 (500 mg, 0.94 mmol) in toluene (10 ml) was treated with white phosphorus (58.2 mg, 0.47 mmol) and the orange solution stirred for 24 h at 40 °C. The orange solution was gradually decolorized to a clear pale yellow solution. After the solution was concentrated to ca. 5 ml, benzene (5 ml) was added and **1** was recrystallized from the hot (60 °C) solvent mixture as pale yellow powder. M.p. 217–218 °C; yield: 516.8 mg (87%).

2,3: 150 mg (0.25 mmol) of **1** dissolved in 5 ml of THF was added to a freshly prepared solution of 118.7 mg (0.3 mmol) of $[W(CO)_5 \cdot THF]$ in THF and the mixture was stirred at 25 °C for 2 h. After removal of volatile components in vacuo the residue was recrystallized several times from a toluene/benzene (1:1) mixture to give **2** as yellow crystals. M.p. 192–197 °C (decomp.); yield: 142.5 mg (56%). Compound **3** was prepared in an analogous manner as **2** [150 mg, 0.25 mmol **1**; 2.5 equivalents $W(CO)_5 \cdot THF$] or by reaction of **2** with 1.5 equivalents of $W(CO)_5 \cdot THF$. Purification of **3** by recrystallization from hot

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0808-1039 $ 02.50/0

benzene gave orange crystals. M.p. 181–185 °C (decomp.); yield: 234.8 mg (70%).

4: A vigorously stirred solution of **1** (200 mg, 0.34 mmol) in toluene (10 ml) was treated with solid $[Pt(PPh_3)_2(C_2H_4)_2]$ (241.9 mg, 0.34 mmol) at 0 °C. Upon addition, the solution immediately turned deep brown. After the solution was allowed to warm to 25 °C and stirred for 2 h the solvent was removed in vacuo. The resulting brown oil was redissolved in benzene (3 ml) and **4** crystallized after 2–8 h as a yellow solid. M.p. 188–194 °C (decomp.); yield: 330.6 mg (74%).

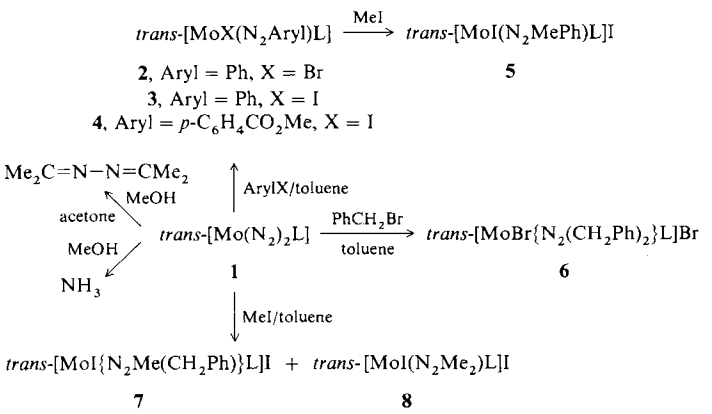
N-Arylation and *N,N*-Dibenzylation of Coordinated N_2 with Organic Halides; Differences in the Reactivity of *trans*-[$Mo(N_2)_2(Me_8[16]aneS_4)$] and Its Phosphane Analogues**

By *Toshikatsu Yoshida,* Tomohiro Adachi, Tatsuo Ueda, Manabu Kaminaka, Nobuyoshi Sasaki, Taiichi Higuchi, Takayuki Aoshima, Izumi Mega, Yasushi Mizobe,* and *Masanobu Hidai**



The direct formation of C–N bonds by reaction of N_2, coordinated to transition metals, with organic compounds has been the subject of intensive studies aimed at the development of new methods for the synthesis of organonitrogen compounds.[1–5] A variety of organic compounds such as RX (R = alkyl, acyl) and acid anhydrides have been found to react with Mo^0-, W^0-, and Re^I-N_2-phosphane complexes to give organo-diazenido and/or -hydrazido complexes. So far, however, no *N*-arylation or *N*-benzylation of coordinated N_2 with arylX and $PhCH_2X$ has been achieved,[2, 3] aside from the indirect *N*-arylation via a diazenido complex $[WX(N_2H)(dppe)_2]$ (dppe = $Ph_2PCH_2CH_2PPh_2$) with the very strong electrophilic aryl fluoride 2,4-$(NO_2)_2C_6H_3F$.[6, 7]

Recently, we have reported on the synthesis of a novel molybdenum(0)-dinitrogen complex *trans*-[$Mo(N_2)_2(Me_8[16]ane\text{-}S_4)$] **1** containing a quadridentate thio-crown ether ligand $Me_8[16]aneS_4$, and on its p_π electron donor properties,[10] which distinguish it from phosphanes. Compared to the phosphane analogues *trans*-[$Mo(N_2)_2(R_2PCH_2CH_2PR_2)_2$] (R = Et, Ph) **1** is very nucleophilic, as manifested by the facile *N,N*-dimethylation of the coordinated dinitrogen in **1** with MeBr under ambient conditions. We have now found the first examples of *N*-arylation and *N,N*-dibenzylation of the coordinated dinitrogen in **1** with the corresponding organic halides to give aryldiazenido and dibenzylhydrazido complexes, respectively. To clarify the difference in reactivity between **1** and the phosphane analogues further, liberation of NH_3 and acetone azine from **1** were also examined.

Reaction of **1** with two molar amounts of PhX in toluene under ambient conditions (no particular irradiation) for 10 h gave the phenyldiazenido complexes **2** (17%) and **3** (26%)[11] together with biphenyl (Scheme 1). When a more activated aryl halide *p*-$IC_6H_4CO_2Me$ was employed, **4** was obtained in a slightly better yield (32%). Formation of the aryldiazenido complexes was confirmed unequivocally by transformation of **3** into the hydrazido complex **5** on treatment with MeI at room temperature and by a single crystal X-ray structure analysis of **4** (Fig. 1).[12]

[**] This work was supported by a Grant-in-Aid for Scientific Research (No. 61125004) from the Japanese Ministry of Education, Science, and Culture, and by the Asahi Glass Foundation for Industrial Technology (*M. H.*). – $Me_8[16]aneS_4$ = 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-tetrathiacyclohexadecane

Scheme 1. L = $Me_8[16]aneS_4$.

The complex **4** adopts a slightly distorted octahedral geometry with four S atoms in the equatorial plane and with the *p*-$N_2C_6H_4CO_2Me$ and I ligands in the *trans* axial sites. The all-up conformation of $Me_8[16]aneS_4$ in **1**[10] was retained during the *N*-arylation. The I ligand lies on the same side as the macrocyclic C atoms with respect to the 4S equatorial plane, while the N_2-*p*-$C_6H_4CO_2Me$ group lies on the opposite side. The complex has crystallographically imposed C_s symmetry with the Mo, S(1), S(9), I, N(1) and N(2) atoms and the phenyl ring as well as the CO_2 group in the symmetry plane. The bond lengths and angles of the MoN_2-*p*-$C_6H_4CO_2Me$ moiety are typical for Mo^{II} and Mo^{IV} organodiazenido complexes.[13, 14] Despite the low yield the observed facile *N*-arylation is remarkable and contrasts sharply with the failure of *trans*-[$M(N_2)_2(dppe)_2$] (M = Mo, W) to react with PhX under similar conditions and with the formation of *trans*-[$MoX_2(dppe)_2$] as sole product under forcing conditions.[15]

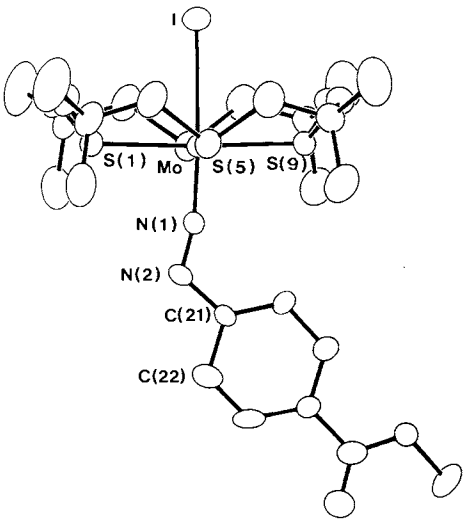

Fig. 1. Crystal structure of **4** (ellipsoids at the 50% probability level). Selected bond distances [Å] and angles [°]: Mo–S(1) 2.435(4), Mo–S(5) 2.443(3), Mo–S(9) 2.440(4), Mo–I 2.925(2), Mo–N(1) 1.775(11), N(1)–N(2) 1.257(15), N(2)–C(21) 1.369(17); S(1)–Mo–S(5) 90.0(1), S(5)–Mo–S(9) 90.0(1), I–Mo–N(1) 176.9(4), Mo–N(1)–N(2) 168.6(10), N(1)–N(2)–C(21) 117.6(11).

N,N-Dibenzylation of **1** with $PhCH_2Br$ also proceeded readily under ambient conditions in toluene to give **6** in 60% yield. A similar reaction of the dppe analogue again failed to give the corresponding diazenido or hydrazido complex, but instead *trans*-[$MoBr_2(dppe)_2$] and bibenzyl.[15] Rather surprisingly, reaction of **1** with MeI in toluene under ambient-conditions gave the *N,N*-benzyl(methyl)hydrazido complex **7** together with the expected *N,N*-dimethylhydrazido complex **8** in a 1:3 ratio. It should be noted that a similar reaction carried out in benzene afforded exclusively **8** in quantitative yield. The formation of **7** may be interpreted in terms of a radical process similar to that confirmed for the *N*-monoalkylation of *trans*-[$M(N_2)_2(dppe)_2$] (M = Mo, W) by alkyl halides.[15] Accordingly, **7** may be produced via an intermediate [$MoI(N_2CH_2Ph)Me_8[16]aneS_4$]. A decisive reaction would be an H abstraction from toluene by a methyl radical formed by an incipient reaction of **1** with MeI together with [$MoI(N_2)Me_8[16]aneS_4$]; the latter would be *N*-benzylated by the benzyl radical thus generated. Apparently the dinitrogen ligand in **1** is reactive enough to be attacked by such a stable radical as $PhCH_2^{\bullet}$.

The high nucleophilicity of **1** is further demonstrated by liberation of NH_3 on treatment with MeOH at 50 °C for 45 h (0.06 mol/Mo atom). If acetone is added to the above system, acetone azine (0.16 mol/Mo atom, 18 h; 0.40 mol/Mo atom, 40 h) is obtained. Although the generation of NH_3 and acetone azine from **1** is not so effective as observed in the corresponding reactions of *cis*-[$W(N_2)_2(PMe_2Ph)_4$] (NH_3 1.01 mol/W atom,[16, 17] $Me_2C=N-N=CMe_2$ 0.88 mol/W atom,[17] 18 h at 50 °C), molybdenum-dinitrogen complexes such as *trans*-[$Mo(N_2)_2(dppe)_2$] and *cis*-[$Mo(N_2)_2(PMe_2Ph)_4$] are known to be completely inactive for such generation of nitrogen compounds under similar conditions.[17] The novel reactivity of the coordinated dinitrogen in **1**, which probably arises from p_π electron donor ability of the crown thioether, seems to provide a basis for elucidating the role of sulfur ligands in the nitrogenase cofactor.

[11] All the new compounds gave satisfactory elemental analyses except **7**, which was characterized by ^1H NMR data. Spectroscopic and physical data: **2**: yellow crystals, m.p. 262–263 °C (dec); IR (Nujol mull): $\tilde{\nu}$(N=N) 1560 cm^{-1}; ^1H NMR: δ = 1.05 (s, 12H, Me), 1.21 (s, 12H, Me), 2.60 (d, J = 11.5 Hz, 8H, CH_2S), 2.92 (d, J = 11.5 Hz, 8H, CH_2S), 7.0–7.3 (m, 5H, Ph). **3**: yellow crystals, m.p. 252–254 °C (dec); IR (Nujol mull): $\tilde{\nu}$(N=N) 1560 cm^{-1}; ^1H NMR: δ = 1.06 (s, 12H, Me), 1.20 (s, 12H, Me), 2.61 (d, J = 12.0 Hz, 8H, CH_2S), 2.98 (d, J = 12.0 Hz, 8H, CH_2S), 7.0–7.3 (m, 5H, Ph). **4**: orange crystals, m.p. 285–287 °C (dec); IR (Nujol mull): $\tilde{\nu}$((N=N) 1540, $\tilde{\nu}$(C=O) 1702 cm^{-1}; ^1H NMR: δ = 1.09 (s, 12H, Me), 1.19 (s, 12H, Me), 2.62 (d, J = 11.3 Hz, 8H, CH_2S), 2.96 (d, J = 11.3 Hz, 8H, CH_2S), 3.82 (s, 3H, CO_2Me), 7.17 (d, J = 8.8 Hz, 2H, Ar), 7.19 (d, J = 8.8 Hz, 2H, Ar). **5**: pale brown crystals, m.p. 278–281 °C (dec); ^1H NMR: δ = 1.20 (s, 24H, Me), 2.87 (d, J = 11.0 Hz, 8H, CH_2S),

3.05 (d, J = 11.0 Hz, 8H, CH_2S), 3.81 (s, 3H, NMe), 7.1–7.4 (m, 5H, Ph). **6**: pink crystals, m.p. 254 °C (dec); ^{1}H NMR: δ = 1.17 (s, 6H, Me), 1.19 (s, 6H, Me), 2.81 (d, J = 11.6 Hz, 4H, CH_2S), 2.93 (d, J = 11.6 Hz, 4H, CH_2S), 4.56 (s, 2H, NCH_2), 7.2–7.4 (m, 5H, Ph). **7**: ^{1}H NMR: δ = 1.18 (s, 12H, Me), 1.23 (s, 12H, Me), 2.86 (d, J = 11.4 Hz, CH_2S), 2.98 (d, J = 11.4 Hz, CH_2S), 3.12 (s, 3H, NMe), 4.56 (s, 2H, NCH_2), 7.15–7.40 (m, 5H, Ph). **8**: pink crystals, m.p. 297–299 °C (dec); ^{1}H NMR: δ = 1.18 (s, 6H, Me), 1.23 (s, 6H, Me), 2.84 (d, J = 11.6 Hz, 4H, CH_2S), 2.94 (d, J = 11.6 Hz, 4H, CH_2S), 3.24 (s, 3H, NMe). The ^{1}H NMR spectra show that the Me_8[16]aneS_4 ligand in **2**–**8** assumes all-up conformation.

[12] Crystal data for **4**: $C_{28}H_{47}N_2O_2S_4IMo \cdot 2\,CH_2Cl_2$, M = 964.18, orthorhombic, a = 23.353(4), b = 13.055(3), c = 13.985(4) Å, V = 4264(2) Å^3, space group *Pnam*, Z = 4, D_c = 1.50 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 14.86 cm^{-1}. Crystal dimension 0.15 × 0.15 × 0.40 mm; intensity data were collected in the range $3 \leq 2\theta \leq 50°$ using the $2\theta/\omega$ scan technique; intensities were corrected for Lorentz and polarization effects. The Mo atom was located by the Patterson map and the other atoms were found by a successive Fourier method, and refined by block-diagonal least-squares procedures. One of solvent molecules (CH_2Cl_2) and the methyl group of the ester were disordered slightly, but could be modeled successfully. At final convergence, $R(R_w)$ = 0.062(0.063), S_w = 1.56 for 2218 unique reflections ($|F_o| \geq 3\sigma(F_o)$) and the final difference map showed no feature above 0.72 eÅ^{-3}. The 7-Norbornadienyl Cation: An NMR/IGLO Validation of its ab initio Structure**

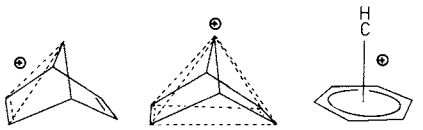
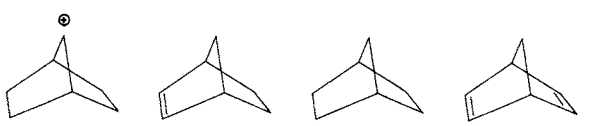
By *Matthias Bremer, Karl Schötz, Paul von Ragué Schleyer,* Ulrich Fleischer, Michael Schindler, Werner Kutzelnigg, Wolfram Koch,* and *Peter Pulay*



In 1960 *Winstein* et al.[1] reported a "world record for anchimeric acceleration".[2] 7-norbornadienyl chloride **1** solvolyzes 10^{14} times faster than 7-norbornyl chloride **2** and even 10^3 times faster than 7-norbornenyl chloride **3**. The exceptional stability of the 7-norbornadienyl cation **4** permitted its preparation (as the $BF_4^{\ominus}$ salt) in SO_2 solution before the days of "super acid".[3] We now present an *ab initio*/IGLO (*I*ndividual *G*auge for *L*ocalized *M*olecular *O*rbitals)[4] study on the 7-norbornadienyl cation **4** – a system important for the understanding of the electronic structure of nonclassical carbocations – which establishes the geometrical consequences of the homoaromatic interactions in **4** and in the related 7-norbornenyl cation **5**.

1 **2** **3**

4 **5**



Of the three structural alternatives considered by *Winstein* for the cation intermediate **4a**–**4c**, the form with the lowest symmetry (C_s), **4a**, was indicated by NMR experiments.[3] The preference for a C_s geometry can be rationalized based on PMO arguments.[5] Tilting C7 toward the C2–C3 double bond results in better overlap and thus higher stabilization than simultaneous interaction with both double bonds in a C_{2v} arrangement. Experimentally, the barrier to bridge flipping **4a** ⇌ **4b** ⇌ **4a** was estimated to be at least 19.6 kcal mol^{-1}.[3b]

4a, C_s **4b**, C_{2v} **4c**, C_{6v}

Our *ab initio* calculations (Table 1) confirm these conclusions. The C_{2v} structure **4b** is found to be 26.6 kcal mol^{-1} (MP2-FC/6-31G*//6-31G*; the "//" means "at the geometry of") less stable than the C_s alternative **4a**. The stabilizations due to the interactions of the double bonds with the positive charges can be evaluated by isodesmic reactions [Equations (a)–(c)].

6 + norbornadiene → **4a** + norbornane (**9**) (**8**)	−20.3	(a)
6 + norbornene → **5** + **8** (**7**)	−15.0	(b)
6 + **9** → **4b** + **8**	+ 6.3	(c)

6 **7** **8** **9**

The large values found for **4a** [Eq. (a)] and for **5** [Eq. (b)] correspond to the solvolysis rate accelerations found experimentally. The situation in **4b** is interesting in view of the qualitative prediction[6] that "longicyclic" interactions in

[**] Support was provided by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, the Convex Computer Corporation and the Regionales Rechenzentrum Erlangen. Most of the IGLO calculations were carried out on the Cyber 205 of the Rechenzentrum of the Ruhr Universität Bochum. We gratefully acknowledge a generous allocation of computer time on the IBM 3090-200 E/VF of the IBM Düsseldorf computer center. The vectorized IBM version of Gaussian 86 was used [18]. We thank *T. Laube* (Zürich) for communicating his results prior to publication.

Table 1. Total Energies [− Hartree] for **4a**, **4b**, **5** and **6–9**.

Level of calculation	**4a**	**4b**	**5**	**6**	**7**	**8**	**9**
3-21G//3-21G	267.29788	267.28200	268.49928	269.67766	269.36909	270.56656	268.16187
6-31G*//6-31G*	268.82076	268.78676	270.02099	271.17676	270.86184	272.06120	269.65251
MP2-FC/6-31G*//6-31G*	269.69686	269.65453	270.90479	272.08861	271.76737	272.97504	270.55095
6-31G*//MP2-FU/6-31G*	268.81849						
MP2-FU/6-31G*//MP2-FU/6-31G*	269.73407						
MP2-FC/6-31G*//MP2-FU/6-31G*	269.69915						

C_{2v} symmetry should be favorable. In contradiction, the isodesmic reaction (c) is *endothermic* by 6.3 kcal mol^{-1} at MP2-FC/6-31G*//6-31G*. The inductive effects of the double bonds are destabilizing.[7, 8] Despite the energy required to achieve the larger structural distortions shown in Figure 1, much greater net stabilization [20.3 kcal mol^{-1}; Eq. (a)] is gained in **4a** than in **4b** due to the bishomoaromatic interactions. Nevertheless, there is some additional stabilization by the second double bond in **4a**.[5, 6] Note the 5.3 kcal mol^{-1} difference in energies between Eqs. (a) and (b). This difference also corresponds to the faster solvolysis rates of **1** over **3**.

5 **4a**

Fig. 1. Structures of the norbornenyl cation **5** and the 7-norbornadienyl cation **4**.

Recently, the IGLO method[4] has been shown[9] to give good to excellent agreement of calculated ^{13}C NMR chemical shifts (based on *ab initio* geometries) and experimental values and thus provides a powerful tool to relate theoretical structures of carbocations to the species actually present in solution.

An advantage of such theoretical methods, for instance IGLO[4] or GIAO,[10] is that chemical shifts for experimentally *inaccessible* species can be readily calculated. It can be applied to the *ab initio* optimized transition structure **4b** as well as to the minimium **4a**. The theoretical methods are in accordance with experiment only for the C_s structure (Table 2; for comparison, results obtained with the GIAO method[10] have been included). As expected,[11] polarization functions (6-31G* basis) are needed to give an accurate description of the geometry resulting from the nonclassical interaction in **4a**. Reoptimization with electron correlation (MP2-FU/6-31G*//MP2-FU/6-31G*) does not lead to significant changes in the geometry or in the calculated chemical shifts. In contrast, the appreciable differences between the geometries of **4a** at 3-21G and at 6-31G* (Table 3) result in large differences between the calculated (IGLO) and experimental ^{13}C NMR chemical shifts (Table 2). This underscores the sensitivity of the chemical shifts as calculated by the IGLO method to geometrical changes in such carbocation systems. Calculated chemical shifts for the C_{2v} structure **4b** (Table 2) deviate widely from experiment. Hence, **4b** can clearly be ruled out as a structural alternative. Good agreement of experiment and theory is also found for the 7-norbornenyl cation **5**. Again, the 6-31G* geometry is a prerequisite for reliable results.

Table 2. Comparison of Experimental and Calculated ^{13}C-NMR chemical shifts (vs. TMS). The level of the calculation is indicated as method/basis//geometry.

[12] After this work was complete, we learned of *T. Laube*'s crystal structure determination of 2,3-dimethyl-7-phenyl-7-norbornenyl cation as $Sb_2F_{11}^{\ominus}$ salt. (Abstract A 32, Chemiedozententagung, Bielefeld 1989; T. Laube, private communication). The C2–C3 X-ray distance (1.381(10) Å) agrees well, but due to the greater degree of classical character, the C2–C7 distances (1.856(10) Å) are larger than the 6-31G* value for **5**. The experimental $\delta(^{13}C)$ values for the 7-phenyl-7-norbornenyl cation [14 b] correspond roughly with our IGLO calculations (Table 2) on the 3-21G geometry of **5** which has a C2–C7 distance of 1.94 Å (Table 3).
[13] We note in this context that IGLO chemical shifts based on the *experimental* geometry of **9** [16] are in poorer agreement with the experimental $\delta(^{13}C)$ values than those calculated using the 6-31G* geometry (Table 2).

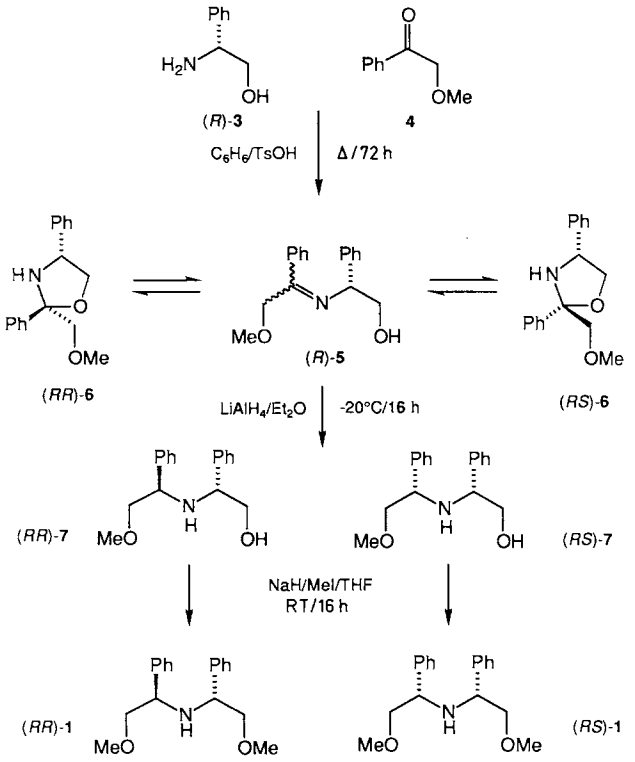
A New Coordinating Chiral Lithium Amide**

By *Donald Barr, David J. Berrisford, Raymond V. H. Jones, Alexandra M. Z. Slawin, Ronald Snaith, J. Fraser Stoddart** and *David J. Williams*

Simultaneous interests in transition state molecular recognition phenomena[1] and lithium polyether[2a] and lithium amide[2b] coordination chemistry encouraged us to examine the potential of chiral lithium amides[3, 4] as enantioselective reagents. Recently, these reagents have been employed (i) as chiral bases to differentiate between enantiomerically-related hydrogen atoms in racemic substrates[5, 6] as well as to discriminate between enantiotopic hydrogen atoms of prochiral substrates,[7–10] and (ii) as chiral complexing agents to effect enantioselective alkylations,[11] carboxylations,[12] aldol condensations,[4, 13] and Michael additions[4] of lithium enolates, aldol-type condensations[14] of toluate carbanions, carbanionic rearrangements[15] of allylic propargylic ethers and asymmetric silylations[3] of certain sulfone anions. No chiral lithium amide utilized hitherto has combined the features which are desirable for wide application, i.e. C_2 symmetry[16, 17] and symmetrically-disposed coordinating groups for the lithium cation.[17, 18] Herein we wish to report on the stereospecific synthesis and characterization of the chiral amine (*R,R*)-**1**[19] and on investigations into the solid-state structure and solution behavior of the lithium amide derived therefrom, the dimer $[(R,R)\text{-}\mathbf{2}]_2$ of (*R,R*)-lithium-di(α-methoxymethylbenzyl)amide.[20]



(*RR*)-**1** R = H $[(RR)\text{-}\mathbf{2}]_n$ R = Li

The new chiral auxiliary (*R,R*)-**1** can be prepared (Scheme 1) in three steps from (*R*)-phenylglycinol (*R*)-**3**.[21] Condensation of (*R*)-**3** with α-methoxyacetophenone **4**[22] affords an equilibrium mixture (in 96% yield) of the diastereoisomeric imines (*R*)-**5** and the diastereoisomeric pair (*R,R*)-**6** and (*R,S*)-**6** of the constitutionally-isomeric oxazolidines.[23] Reduction (H_2/Pd/C) of this mixture has been reported[23] to be unsuccessful. However, we have found that $LiAlH_4$ in Et_2O at low temperature (−20 °C) reduces the mixture in high yield (84%) with modest diastereoselectivity [(*R,R*)-**7**/(*R,S*)-**7** = 70/30].[24] Alternative reducing agents (for example, $NaBH_4$, $BH_3 \cdot C_5H_5N$, $BH_3 \cdot SMe_2$, $Li[CHMeCHMe_2]_3BH$, and $[(CH_3OCH_2$-

Scheme 1. RT = room temperature.

$CH_2O)_2AlH_2]Na$) were less effective and exhibited lower, or even opposite, diastereoselectivities.[25] The diastereoisomeric hydroxyamines (*R,R*)-**7** and (*R,S*)-**7** could be separated by *fractional crystallization* (*n*-hexane/ether) to afford initially (*R,S*)-**7** (17%) and subsequently (*R,R*)-**7** (48%). Both diastereoisomers were *O*-methylated to give (*R,S*)-**1**[26] as an oil (90%), and the C_2-symmetric dimethoxyamine (*R,R*)-**1** as a *crystalline* compound [92%, m.p. 69–70.5 °C (*n*-hexane), $[\alpha]_D = -151.4°$ ($c = 4$, $CHCl_3$)]. The configuration of the newly-generated chiral center in the crystalline compound was determined (Fig. 1) by X-ray structural analysis[27] of a single crystal of the hydrochloride, (*R,R*)-**1**·HCl.

Structural studies on the chiral lithium amide $[(R,R)\text{-}\mathbf{2}]_n$ have been performed[28] in conjunction with the investigations of its suitability and selectivity as a chiral base. Lithiation of (*R,R*)-**1** proceeds under a variety of conditions, and, in non-donor solvents, affords, upon crystallization, a dimeric amidolithium complex,[29] i.e. $n = 2$. This complex has been characterized in the solid state by X-ray crystallography[27] and in solution by NMR spectroscopy and cryoscopy. The crystal structure (Fig. 2) reveals a central, planar Li_2N_2 ring, each Li cation of which is also coordinated by two methoxy groups, one from each amido ligand.[30–34] The geometry at each Li cation is distorted tetrahedral with the largest departures from tetrahedral geometry being for the N–Li–O angles within the five-membered chelate rings.[34–36] There are similar distortions in tetrahedral geometry at each amido nitrogen, being largest within the Li_2N_2 ring. The four-membered Li_2N_2 ring has an atypical structure in which the N–Li bonds (ca. 2.06 Å) associated with one ligand are longer than those (ca. 2.02 Å) associated with the other. Usually, in dimeric amidolithium complexes, N–Li bonds on opposite sides of the Li_2N_2 ring are of near identical lengths.[37] The approximate D_2 molecular symmetry observed in the solid state represents one of the two possible constitutional isomers: the other has C_2 symmetry.[38]

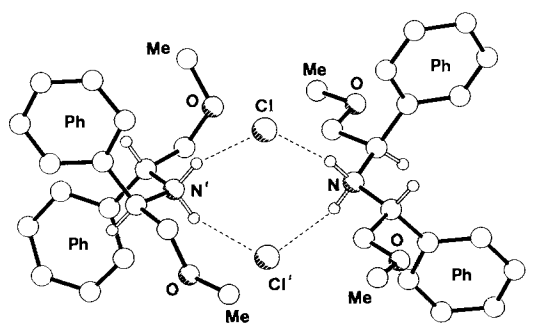

Fig. 1. Structure of (*R,R*)-**1** · HCl in the crystal. Crystal data: orthorhombic, $a = 8.247(2)$, $b = 17.333(5)$, $c = 25.384(6)$ Å, $V = 3629$ Å^3, space group $P2_12_12_1$, $Z = 8$ (2 crystallographically independent molecules), $\varrho = 1.18$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 19$ cm^{-1}, 1887 independent reflections $[|F_o| > 3\,\sigma(|F_o|)$, $\theta \leq 58°]$, $R = 0.10$. The two independent molecules are bridged via hydrogen bonds between the dialkylammonium centers (N and N') and the chloride (Cl and Cl') counterions. Hydrogen bonding geometries: [N ··· Cl] 3.10, [N' ··· Cl] 3.18, [N ··· Cl'] 3.15, [N' ··· Cl'] 3.20 Å. N–H ··· Cl angles in the range, 154–166°.

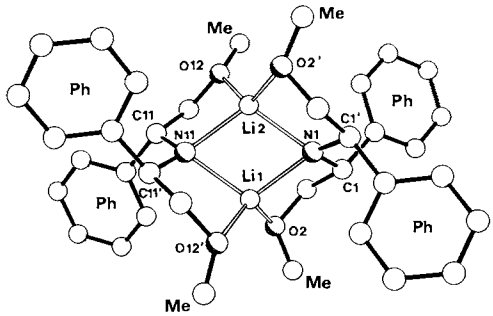

Fig. 2. Structure of $[(R,R)\text{-}\mathbf{2}]_2$ in the crystal. Crystal data: orthorhombic, $a = 10.508(4)$, $b = 15.688(4)$, $c = 20.918(5)$ Å, $V = 3448$ Å^3, space group $P2_12_12_1$, $Z = 4$, $\varrho = 1.12$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 5$ cm^{-1}, 1562 independent observed reflections $[|F_o| > 3\,\sigma(|F_o|)$, $2\theta \leq 116°]$, $R = 0.077$, $R_w = 0.073$. Geometry about the Li_2N_2 ring. Bond lengths [Å]: Li(1)-N(1) 2.061(16), Li(1)-O(2) 1.977(16), Li(1)-N(11) 2.023(17), Li(1)-O(12') 1.996(16), Li(2)-N(1) 2.063(16), Li(2)-O(2') 2.017(14), Li(2)-N(11) 2.024(16), Li(2)-O(12) 1.977(14). Bond angles [°]: N(1)-Li(1)-O(2) 88.0(6), N(1)-Li(1)-N(11) 107.2(7), O(2)-Li(1)-N(11) 123.9(8), N(1)-Li(1)-O(12') 127.5(8), O(2)-Li(1)-O(12') 123.6(8), N(11)-Li(1)-O(12') 89.2(7), N(1)-Li(2)-O(2') 86.8(6), N(1)-Li(2)-N(11) 107.1(7), O(2')-Li(2)-N(11) 127.5(7), N(1)-Li(2)-O(12) 125.5(7), O(2')-Li(2)-O(12) 125.7(8), N(11)-Li(2)-O(12) 87.1(6), Li(1)-N(1)-Li(2) 72.0(6), Li(1)-N(1)-C(1) 105.8(6), Li(2)-N(1)-C(1) 133.7(6), Li(1)-N(1)-C(1') 129.6(6), Li(2)-N(1)-C(1') 107.6(6), C(1)-N(1)-C(1') 107.7(6), Li(1)-N(11)-Li(2) 73.6(6), Li(1)-N(11)-C(11) 133.2(6), Li(2)-N(11)-C(11) 105.7(6), Li(1)-N(11)-C(11') 105.4(6), Li(2)-N(11)-C(11') 130.3(6), C(11)-N(11)-C(11') 108.6. The torsion angles within the Li_2N_2 ring are, within statistical significance, all zero. The transannular Li(1) ··· Li(2) = 2.425(21) Å.

NMR (^{1}H, ^{7}Li, ^{13}C) spectroscopic studies[39] in non-donor solvents (C_6D_6, $C_6D_5CD_3$) from ambient temperature down to ca. −90 °C indicate the presence of a *single, highly symmetrical* lithium amide species. On the basis of cryoscopic measurements[40] in benzene, this species is dimeric. Therefore, there is strong evidence that the observed solid-state structure persists on dissolving in non-donor solvents, thus producing a dimer, $[(R,R)\text{-}\mathbf{2}]_2$, with averaged D_2 molecular symmetry. Knowledge of the existence of $[(R,R)\text{-}\mathbf{2}]_2$ in solution will aid the investigations of substrate deprotonations and subsequent asymmetric electrophilic additions to the derived lithium enolates.[4]

In the case of chiral lithium amides, an appreciation of their coordination chemistry is a prerequisite to understanding their roles in reagent-controlled asymmetric inductions.[41]

Experimental

(*R*)-**5**/(*R,R*)-**6**/(*R,S*)-**6**: (*R*)-phenylglycinol (*R*)-**3** (8.45 g, 98% pure, 60.4 mmol), α-methoxyacetophenone **4** (9.54 g, 95% pure, 60.4 mmol), and *p*-TsOH (115 mg, 0.6 mmol) in C_6H_6 (70 mL) were heated under reflux (N_2) with continuous removal of H_2O. After 72 h, the mixture was cooled to room temperature, diluted with Et_2O (50 mL), cooled to $-5\,^{\circ}C$, and washed sequentially with 5% aqueous $NaHCO_3$ and saturated aqueous NaCl solutions. A standard work-up procedure afforded 15.65 g (96%) of a yellow oil, which was characterized as a mixture of (*R*)-**5**, (*R,R*)-**6**, and (*R,S*)-**6**, *m/z* (CIMS): 270 for $(M + H)^{\oplus}$; ^1H NMR ($CDCl_3$): $\delta = 3.05$ (br s, 2H), 3.43–3.79, 4.14, 4.44, and 4.69 (s and m, 8H), 7.22–7.41 (m, 6H), 7.62–7.71 (m, 2H), cf. Ref. [23a]: ^{13}C NMR ($CDCl_3$) spectroscopy revealed the presence of two resonances at $\delta = 98.7$ and 99.7 characteristic of the diastereoisomerically-related quaternary carbon atoms in the oxazolidine rings of (*R,R*)-**6** and (*R,S*)-**6**.

(*R,R*)-**7** and (*R,S*)-**7**: (*R*)-**5**/(*R,R*)-**6**/(*R,S*)-**6** (15.65 g, 58.2 mmol) in dry Et_2O (50 mL) was added dropwise with stirring to a suspension of $LiAlH_4$ (2.18 g, 57.4 mmol) in dry Et_2O (10 mL) under N_2 at $-20\,^{\circ}C$. After the addition was complete, stirring was continued for 16 h at this temperature. A standard work-up procedure gave the crude product which was eluted on a short SiO_2 chromatography column (*n*-hexane/EtOAc:2/1 v/v) to give a mixture (13.25 g, 84%) of the diastereoisomeric products (*R,R*)-**7** and (*R,S*)-**7**. Fractional crystallization (*n*-hexane/Et_2O (9/1 v/v): solubility 0.1 g mL^{-1}) gave firstly fine needles of (*R,S*)-7 [2.73 g, 17%, m.p. 97.5–98 °C, $[\alpha]_D = -18.3^{\circ}$ ($c = 3$, $CHCl_3$); *m/z* (CIMS): 272 $(M + H)^{\oplus}$; ^1H NMR ($CDCl_3$): $\delta = 2.30$ (br s, 2H), 3.34 (s, 3H), 3.55 (d, 2H), 3.55–3.62 (m, 1H), 3.75–3.82 (m, 1H), 3.85–3.91 (m, 1H), 3.95 (t, 1H), 7.20–7.29 (m, 10H)] and subsequently from the mother liquors, colorless microcrystalline (*R,R*)-7 [7.55 g, 48%, m.p. 77.5–79.5 °C, $[\alpha]_D = -96.1^{\circ}$ ($c = 1.2$, $CHCl_3$); *m/z* (CIMS): 272 $(M + H)^{\oplus}$; ^1H NMR ($CDCl_3$): $\delta = 2.40$ (br s, 2H), 3.32 (s, 3H), 3.29–3.64 (m, 5H), 3.79–3.85 (m, 1H), 7.17–7.22 (m, 2H), 7.24–7.40 (m, 8H)].

(*R,R*)-**1**: (*R,R*)-**7** (4.10 g, 15.1 mmol) in dry THF (12 mL) was added dropwise with stirring over 15 min to a suspension of NaH (500 mg, 80% dispersion in oil, 16.7 mmol) in dry THF (3 mL) under N_2. The mixture was warmed to 40 °C and stirred for 30 min to give a clear solution. This was cooled to $-5\,^{\circ}C$ prior to dropwise addition of MeI (2.20 g, 15.5 mmol) in dry THF (5 mL) within 30 min. The mixture was then allowed to warm up to room temperature and stirred for 16 h. Excess of NaH was destroyed with H_2O and the product was extracted into Et_2O. Flash column chromatography on SiO_2 (*n*-hexane/EtOAc: 2/1 v/v) furnished pure (*R,R*)-**1** (3.96 g, 92%, m.p. 69–70.5 °C, crystallized from *n*-hexane). Alternatively, crystallization of the crude product directly from *n*-hexane (solubility 0.5 g mL^{-1}) afforded pure crystalline (*R,R*)-**1** [3.31 g, 77%, m.p. 69–70.5 °C, $[\alpha]_D = -151.4^{\circ}$ ($c = 4$, $CHCl_3$); *m/z* (CIMS): 286 $(M + H)^{\oplus}$; ^1H NMR ($CDCl_3$): $\delta = 2.30$ (br s, 1H), 3.29 (s, 6H), 3.38–3.57 (m, 4H), 3.64–3.70 (m, 2H), 7.22–7.37 (m, 10H); ^1H NMR (C_6D_6): $\delta = 2.99$ (s, 6H), 3.30 (br s, 1H), 3.35–3.42 (m, 4H), 3.82–3.85 (m, 2H), 7.13–7.34 (m, 10H)]. The hydrochloride (*R,R*)-**1** · HCl was prepared by dissolving (*R,R*)-**1** in methanolic HCl and evaporating in vacuo. Single crystals suitable for X-ray crystallography were obtained by the vapor diffusion method ($CHCl_3$/*n*-pentane).

(*R,S*)-**1**: (*R,S*)-7 (0.35 g, 1.3 mmol) was *O*-methylated in the manner described above for (*R,R*)-**1** to afford (*R,S*)-**1** [0.33 g, 90%, $[\alpha]_D = 0^{\circ}$ ($c = 1-5$, $CHCl_3$); *m/z* (CIMS) 286 $(M + H)^{\oplus}$; ^1H NMR ($CHCl_3$): $\delta = 2.45$ (br s, 1H), 3.34 (s, 6H), 3.51 (d, 4H), 3.94 (t, 2H), 7.14–7.27 (m, 10H)]. (*R,S*)-**1** was characterized as its hydrochloride (*R,S*)-**1** · HCl (m.p. 150.5–154 °C). Single crystals of the hydrochloride, suitable for X-ray crystallography, were obtained by the vapor diffusion method ($CHCl_3$/*n*-pentane).

[(*R,R*)-**2**]$_2$: *n*-BuLi (2.6 mL of a 1.62 M solution in hexane, 4.2 mmol) was added under N_2 to a stirred, chilled suspension of (*R,R*)-**1** (1.20 g, 4.2 mmol) in dry hexane (5 mL). Stirring caused complete dissolution of the amine. After 30 min stirring at room temperature, the mixture was stored at $-5\,^{\circ}C$ for 16 h. The resulting air sensitive, microcrystalline solid was filtered under N_2, dried in vacuo, and characterized as [(*R,R*)-**2**]$_2$ [1.0 g, 82%, m.p. 165 °C dec., Found C 74.4%, H 7.6%, N 4.8%, Li 2.5%, Calc. for $C_{18}H_{22}NLiO_2$ = C 74.2%, H 7.5%, N 4.8%; Li 2.4%; ^1H NMR ($C_6D_5CD_3$): $\delta = 3.10$ (dd, 2H), 3.15 (s, 6H), 3.65 (dd, 2H), 4.08 (br dd, 2H), 7.04–7.10 (m, 2H), 7.16 (dd, 4H), 7.30 (dd, 4H); ^1H NMR (C_6D_6): $\delta = 3.20$ (s, 6H), 3.20–3.23 (m, 2H), 3.79 (t, 2H), 4.27 (br dd, 2H), 7.15–7.23 (m, 2H), 7.31 (t, 4H), 7.47 (d, 4H); ^{13}C NMR (C_6D_6): $\delta = 58.5, 65.3, 81.3, 126.6, 128.3, 128.8, 147.8$]. Single crystals, suitable for X-ray crystallography, were isolated from a sixfold diluted solution in *n*-hexane. The crystals were sealed under N_2 in Lindemann capillary tubes prior to data collection.

Masamune, *ibid. 54* (1989) 1755. By far the most popular chiral lithium amide is (*R,R*)-**II** and its enantiomer (*S,S*)-**II**: see Refs. [3], [6], [7a], [10], [12] and [15]. The chiral amine (*R,R*)-**I** was first reported in 1961 (C. G. Overberger, N. P. Marullo, R. G. Hiskey, *J. Am. Chem. Soc. 83* (1961) 1374; see also Ref. [6]).

(*RR*)-**I** R = H

[(*RR*)-**II**]$_n$ R = Li

[17] While a number of chiral lithium amides possess these structural features (see Ref. [13c]), none have chiral centers that carry large substituents α to the N–Li bond.

[18] Intramolecular coordination not only provides transition-state rigidity but it also enhances lithium enolate-chiral amine complexation. Even in non-chelating achiral systems, the coordinated amine present, after deprotonation, exerts a profound mechanistic effect on the reactivity of a lithium enolate towards, for example, deuterium cations (T. Laube, J. D. Dunitz, D. Seebach, *Helv. Chim. Acta 68* (1985) 1373). Chiral amines, which *lack* extra intramolecular coordinating groups and are present after deprotonation of a substrate, can impart stereoselectivities upon subsequent electrophilic additions to that substrate; cf. Refs. [3], [5], [6], [12], [13a], and [15].

[19] The enantiomer (*S,S*)-**1** [m.p. 65 °C; $[\alpha]_D = 154.1^{\circ}$ ($c = 2.5$, $CHCl_3$)] has also been synthesized (D. J. Berrisford, R. V. H. Jones, D. P. Robinson, and J. F. Stoddart, unpublished results).

[20] Subscript *n* is the aggregation number of the amidolithium complex, i.e. a monomer has $n = 1$, a dimer has $n = 2$, etc.

[21] Both enantiomers of phenylglycinol are commercially-available. (*R*)-**3** and (*S*)-**3** can also be obtained by reduction ($BH_3 \cdot SMe_2$) of (*R*)- and (*S*)-phenylglycine, respectively (A. I. Meyers, J. Slade, *J. Org. Chem. 45* (1980) 2785).

[22] α-Methoxyacetophenone **4** (R. B. Moffett, R. L. Shriner in E. C. Horning (Ed.): *Organic Synthesis, Coll. Vol. 3*, Wiley, New York 1955, p. 562) is commercially available.

[23] M. B. Eleveld, H. Hogeveen, E. P. Schudde, *J. Org. Chem. 51*(1986) 3635. ^{1}H NMR spectrum of the product obtained after *O*-methylation. Direct integration of the mixture of hydroxyamines (*R,R*)-7 and (*R,S*)-7 was less reliable because of accidental equivalence of the resonances for the constitutionally-related protons in the diastereoisomers.

[25] Use of $[(CH_3OCH_2CH_2O)_2AlH_2]Na$/THF/ − 78 °C gave a ratio (*R,S*)-7:(*R,R*)-7 of 4:1.

[26] Solutions of both (*R,S*)-**1** and (*R,S*)-**1** · HCl in various solvents were found to be optically inactive. Unfortunately, a definitive configurational assignment was not obtained from an X-ray crystallographic study of (*R,S*)-**1** · HCl. This is probably attributable to partial rotational disorder within the structure with a pseudo C_2 axis passing through the dialkylammonium center thus producing an apparent flattening of the geometry about the two chiral carbon atoms. Crystal data: monoclinic, $a = 10.602(3)$, $b = 7.152(2)$, $c = 12.275(4)$ Å, $\beta = 103.24(2)°$, $V = 906$ Å^3, space group $P2_1$, $Z = 2$, $\varrho = 1.18$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 19$ cm^{-1}. 926 independent reflections [$|F_o| > 3\,\sigma(|F_o|)$, $\theta \leq 58°$], $R = 0.097$.

[27] Nicolet R3m diffractometer, ω scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structures were solved by direct methods and refined anisotropically. Further details of these structural investigations can be obtained from the Director of the Cambridge Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation for this communication.

[28] For a review of organolithium structural chemistry including amidolithium species, see W. N. Setzer, P. von R. Schleyer, *Adv. Organomet. Chem. 24* (1985) 353.

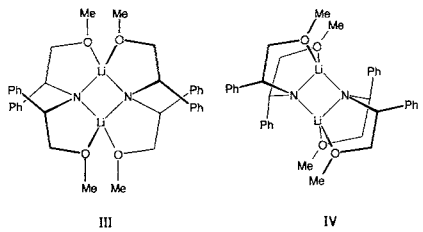
[29] The IR spectrum (nujol mull) of the amidolithium complex [(*R,R*)-**2**]$_2$ contained no bands characteristic of the presence of NH or LiOH. However, brief exposure to (moist) air resulted in the immediate appearance of bands at $\tilde{\nu} = 3550$ cm^{-1} (NH) and 3677 cm^{-1} (OH).

[30] The solid state structure (Fig. 2) is in accord with the structural principles underpinning amidolithium chemistry, i.e. the preferences between rings, stacks, and ladders: D. R. Armstrong, D. Barr, W. Clegg, R. E. Mulvey, D. Reed, R. Snaith, K. Wade, *J. Chem. Soc. Chem. Commun. 1986*, 869; W. Clegg, R. Snaith, K. Wade, *Inorg. Chem. 27* (1988) 3861 and references cited therein. See also Refs. [2b] and [36].

[31] The related complexes $[(PhCH_2)_2NLi \cdot Et_2O]_2$ and $[(PhCH_2)_2NLi \cdot HMPA]_2$ are dimeric ($n = 2$) and in the solid state form Li_2N_2 rings with extra coordination from the added neutral donors (see Refs. [32d] and [36]).

[32] For examples of amidolithium compounds with Li_2N_2 rings that have been characterized by X-ray crystallography, see a) M. F. Lappert, M. J. Slade, A. Singh, J. L. Atwood, R. D. Rogers, R. Shakir, *J. Am. Chem. Soc. 105* (1983) 302; b) L. M. Engelhardt, A. S. May, C. L. Raston, A. H. White, *J. Chem. Soc. Dalton Trans. 1983*, 1671; c) B. Çetinkaya, P. B. Hitchcock, M. F. Lappert, M. C. Misra, A. J. Thorne, *J. Chem. Soc. Chem. Commun. 1984*, 148 ; d) D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, *ibid. 1984*, 285; e) L. M. Engelhardt, B. S. Jolly, P. C. Junk, C. L. Raston, B. W. Skelton, A. H. White, *Aust., J. Chem. 39* (1986) 1337; f) R. A. Wanat, D. B. Collum, G. Van Duyne, J. Clardy, R. T. Depue, *J. Am. Chem. Soc. 108* (1986) 3415; g) D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, D. S. Wright, *J. Chem. Soc. Chem. Commun. 1987*, 716; h) R. A. Bartlett, H. Chen, H. V. Rasika Dias, M. M. Olmstead, P. P. Power, *J. Am. Chem. Soc. 110* (1988) 446.

[33] For recent examples of Li_2N_2 rings in related structures, see D. Colgan, R. I. Papasergio, C. L. Raston, A. H. White, *J. Chem. Soc. Chem. Commun. 1984*, 1708; H. Dietrich, W. Mahdi, R. Knorr, *J. Am. Chem. Soc. 108* (1986) 2462; R. Hacker, E. Kaufmann, P. von R. Schleyer, W. Mahdi, H. Dietrich, *Chem. Ber. 120* (1987) 1533; L. M. Jackman, L. M. Scarmoutzos, B. D. Smith, P. G. Williard, *J. Am. Chem. Soc. 110* (1988) 6058.



[34] In the solid state, intramolecular chelation of the ether oxygen atoms in aza-enolates has been observed to give (i) a four-membered ring (D. Seebach, W. Bauer, J. Hansen, T. Laube, W. B. Schweizer, J. D. Dunitz, *J. Chem. Soc. Chem. Commun. 1984*, 853) and (ii) a six-membered ring (D. Enders, G. Bachstädter, K. A. M. Kremer, M. Marsch, K. Harms, G. Boche, *Angew. Chem. 100* (1988) 1580; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1522).

[35] Alkyllithium chemistry provides many examples of intramolecular chelation (G. W. Klumpp, *Recl. Trav. Chim. Pays-Bas 105* (1986) 1).

[36] In contrast to $[(PhCH_2)_2NLi]_3$, $[(PhCH_2)_2NLi \cdot Et_2O]_2$, and $[(PhCH_2)_2NLi \cdot HMPA]_2$ (donor:$Li^{\oplus}$ ratios 0:1, 1:1, and 1:1, respectively), no evidence has been found for an agostic C–H–M interaction in [(*R,R*)-**2**]$_n$. See D. R. Armstrong, R. E. Mulvey, G. T. Walker, D. Barr, R. Snaith, W. Clegg, D. Reed, *J. Chem. Soc. Dalton Trans. 1988*, 617. This is probably a consequence of the increased neutral donor:$Li^{\oplus}$ ion ratio of 2:1 in [(*R,R*)-**2**]$_n$.

[37] Typically, X-ray crystal structure determinations of Li_2N_2 rings reveal nonequivalence ($a \neq b$) of the N–Li bond lengths. An alternate *abab* cyclic pattern is often observed (Ref. [32]). However, [(*R,R*)-**2**]$_2$ shows a contrasting *aabb* pattern scattered around mean N–Li bond lengths (Fig. 2) that correspond with those reported.

[38] The coordination geometry of the dimeric species could be associated with either D_2 symmetry (**III**) or C_2 symmetry (**IV**). In the dimers **III** and **IV**, the two homotopic amide ligands contain, respectively, homotopic and diastereotopic 5-membered chelate rings.
The coordination geometries and ring distortions are at present being investigated by ab initio and MO calculations on model systems in collaboration with Dr. *D. R. Armstrong* (University of Strathclyde, UK).

III IV

[39] The broad-band decoupled ^{13}C NMR spectrum (63.5 MHz, C_6D_6) shows only seven signals and is therefore not at variance with a dimeric structure [(*R,R*)-**2**]$_2$ possessing averaged D_2 molecular symmetry. This conclusion is supported by variable temperature ^{7}Li NMR spectroscopy (140 MHz, $C_6D_5CD_3$, PhLi as external reference) which (i) reveals a singlet at $\delta = 0.083$ (0.062 M solution) or $\delta = 0.085$ (0.206 M solution) and (ii) produces only slight chemical shift variations on cooling down to − 90 °C. ^{1}H NMR spectroscopy (360 MHz, $C_6D_5CD_3$) reveals a single lithium amide species at ambient temperature which persists on cooling down to − 90 °C. A minor component is also observed in a proportion of < 5% which is independent of concentration (0.062–0.206 M) and temperature. This is unequivocally the parent amine (*R,R*)-**1** resulting from partial hydrolysis of the lithium amide during the experiments. No spectroscopic evidence for constitutional isomerism or aggregation equilibria is observed. We thank Dr. *D. Reed* (SERC NMR Service, University of Edinburgh) for his assistance in obtaining some of these spectra.

[40] Cryoscopic measurements were performed on a sample of [(*R,R*)-**2**]$_2$ in benzene in the concentration range 0.07–0.12 M to give a supramolecular mass of 551 ± 12, i.e. $n = 1.90 \pm 0.04$. The slight variance from $n = 2.0$ cannot arise from an amidolithium dimer-monomer equilibrium since this would be concentration dependent. The low value can be attributed to partial hydrolysis to the parent amine (*R,R*)-**1** prior to or during the measurement (see Ref. [39]).

[41] Efficient asymmetric deprotonation of 4-*tert*-butylcyclohexanone has been demonstrated using [(*R,R*)-**2**]$_n$ in toluene/HMPA. An internal enolate quench with trimethylsilyl chloride gives (*R*)-4-*tert*-butyl-1-[(trimethylsilyl)oxy]cyclohexene in 84% enantiomeric excess.

Platinum Complexes of the Anions $Se_2N_2^{2\ominus}$ and $Se_2N_2H^{\ominus}$; X-Ray Structure Analysis of $[Pt(Se_2N_2H)(PMe_2Ph)_2]Cl$

By *Paul F. Kelly, Ivan P. Parkin, Alexandra M. Z. Slawin, David J. Williams,* and *J. Derek Woollins**

We are actively involved in the preparation of metal–sulfur–nitrogen compounds since they often stabilize otherwise unknown SN anions and, as in the case of **1**

$[Pt(S_2N_2H)(PR_3)_2]X$ **1**

have solid state structures in which both the anions and cations stack.[1, 2] In contrast to SN chemistry the only known SeN heterocycle is Se_4N_4. However, in the light of the extreme stability of **1** we considered that once formed the selenium analogues of **1** would be easily handled and could lead to the development of new SeN chemistry as well as

[*] Dr. J. D. Woollins, Dr. P. F. Kelly, I. P. Parkin, A. M. Z. Slawin, Dr. D. J. Williams
Department of Chemistry, Imperial College of Science and Technology
South Kensington, London SW7 2AY (UK)

having interesting solid state properties. There has recently been a report[3] on the reaction of Se_4N_4 with WCl_6 to give $[WCl_4(NSeCl)]_2$. We have found[4, 5] that S_4N_4 reacts with **2** and **3** to give $[PtCl(S_2N_2H)(PR_3)]/[PtCl(S_3N)(PR_3)]$ and

cis-$[PtCl_2(PR_3)_2]$ **2**

$[Pt(PMe_2Ph)Cl_2]_2$ **3**

$[PtCl_2(PMe_2PH)(S_4N_4)]$, respectively. These observations prompted us to investigate reactions of Se_4N_4 with **2**, PR_3 = ½ $PPh_2CH_2CH_2PPh_2$(dppe), PPh_3, PMe_2Ph, PEt_3, and **3**. Upon refluxing a solution of Se_4N_4 and **2** in xylene at 160 °C, no reaction was observed. (**Caution:** Se_4N_4, being much more unstable than S_4N_4 explodes violently on contact with a metal spatula!)

Reaction of Se_4N_4 with **3** in refluxing $CHCl_3$, however, gave a mixture of products, including **4**,

$[PtCl(Se_3N)(PMe_2Ph)]$ **4**

which we have recently characterized by X-ray crystallography.[6] We have now been able to separate the other major product chromatographically and to identify it by mass spectroscopy as **5**.

$[PtCl(Se_2N_2H)(PMe_2Ph)]$ **5**

Unlike its sulfur analogue, **5** is not especially stable in solution and we have been unable to crystallize it. However, as was the case with the sulfur system, reaction of the crude mixture of **4** and **5** results in displacement of the halogen by phosphane to give **6** which was readily crystallized.

$[Pt(Se_2N_2H)(PMe_2Ph)_2]Cl$ **6**

The X-ray structure of **6** (Figure 1)[7] reveals an essentially planar $P_2PtSe_2N_2$ unit[8] with the expected differences in the Pt–P(1) and Pt–P(2) bond-lengths, reflecting the *trans* influence of the selenium and nitrogen substituents. The lengths of the Pt–P bonds are essentially unchanged from those in the sulfur analogue **1**.[2] The bond-lengths within the $PtSe_2N_2$ ring follow the pattern already observed, i.e. E(2)–N(2) > E(1)–N(1) > E(1)–N(2) (E = S or Se), although the differences are less marked in **6** than in **1**. There is, as expected, a small increase in the Se–Pt–N angle to accomodate the longer bonds in the $PtSe_2N_2$ ring together with a decrease in the readily deformed angles about Se(1) and Se(2); the angles at nitrogen are virtually unchanged on going from **1** to **6**. In contrast to **1** there is no longer approximate C_2 symmetry within the cations in **6**. A consequence of this is a change in the packing of the cations. Whereas in **1** (PR_3 = PMe_2Ph, X = Cl) the structure is comprised of continuous alternately stacked dimer pairs, here discrete pairs of cations pack with their $PtSe_2N_2$ rings parallel and overlapping (Fig. 2) with

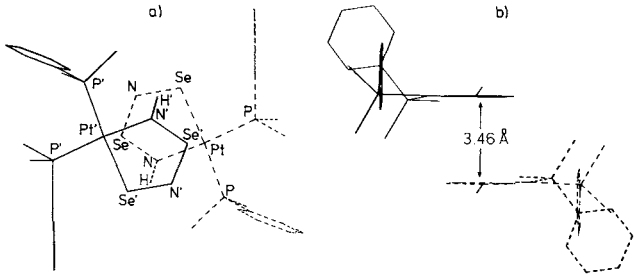


Fig. 2. (a) Plan view of **6** and (b) side view of **6** showing the stacking geometry of the dimer pairs; the Pt · · · Se′/Pt′ · · · Se distance is 3.52 Å.

an interplanar separation of 3.46 Å and a Pt · · · Se1′/Pt′ · · · Se(1) distance of 3.52 Å.[9]

A slightly surprising feature of the structure of **6** is the relative dispositions of the anions and cations. Although the $Cl^{\ominus}$ ion is available for H-bonding, lying adjacent to the N(1)–H group, the N–H · · · Cl geometry is not optimum and, indeed, the $Cl^{\ominus}$ ion lies closer to Se(1) (3.11 Å) than to N(1) (3.19 Å).

Compounds **4**–**6** are the first examples of complexes containing Se–N anions and demonstrate that the $PtSe_3N$ and $PtSe_2N_2$ rings are stable. However, the synthetic strategy described above is not completely satisfactory since Se_4N_4 is extremely hazardous and the yields are low (the overall yield of **6** is ca. 2%). We have therefore developed a new method using liquid ammonia. Thus, addition of $SeCl_4$ to liquid ammonia gives a pale orange solution and a green precipitate [**Caution:** The precipitate can explode violently at room temperature or on addition of water], which, if allowed to warm to room temperature in a pressure vessel, gives Se_4N_4. However, if **2** is added to the mixture in liquid ammonia and the reaction allowed to warm to room temperature under a stream of argon **7** is isolated in up to 70% yield. Compound

$[Pt(Se_2N_2)(PR_3)_2]$ **7**

7 can be protonated to give **8** (ca. 80% isolated yield, quantitatively by NMR). This new "one-pot" synthesis is ex-

$[Pt(Se_2N_2H)(PR_3)_2]BF_4$ **8**

tremely convenient, relatively hazard free, and allows for the preparation of reasonable amounts of metal–selenium–nitrogen compounds which may be of use in the synthesis of new heterocycles. The existence of **4**–**8** suggests that a substantial chemistry of Se–N anions awaits elucidation.

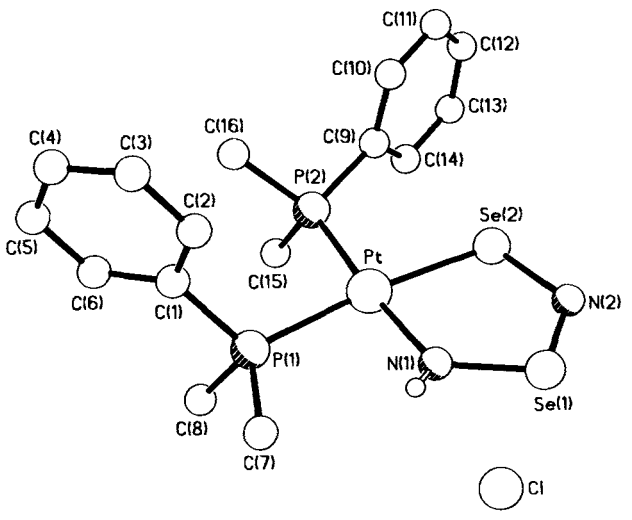

Fig. 1. The structure of **6** in the crystal. Selected bond lengths [Å] and angles: Pt–P(1) 2.305(3), Pt–P(2) 2.260(4), Pt–N(1) 2.021(10), Pt–Se(2) 2.405(1), N(1)–Se(1) 1.758(11), Se(1)–N(2) 1.718(10), N(2)–Se(2) 1.794(11); P(1)–Pt–P(2) 95.4(1), N(1)–Pt–Se(2) 87.1(3), Pt–N(1)–Se(1) 124.6(5), N(1)–Se(1)–N(2) 104.0(5), Se(1)–N(2)–Se(2) 120.6(7), N(2)–Se(2)–Pt 103.6(3).

Experimental

6: A mixture of Se_4N_4 (90 mg, 0.24 mmol) and $[PtCl_2(PMe_2Ph)]_2$ (200 mg, 0.24 mmol) in $CHCl_3$ (25 mL) was heated at $\approx 90\,^{\circ}C$ for ca. 12 h, resulting in a dark solution and a black precipitate. After removal of the solvent in vacuo the residue was extracted with CH_2Cl_2 (30 mL), and the extract filtered through celite, then concentrated and placed on a Bio-beads gel-permeation column and eluted with CH_2Cl_2. The sample resolved into three bands, the slowest moving of which (blue/purple in color) was collected and dried in vacuo to yield a crude mixture of **4** and **5** (17 mg). [At this point **4** and **5** may be separated from each other by preparative thin layer chromatography and the purple species **5** ($R_f \approx 0.2$, CH_2Cl_2 as eluent) identified as $PtCl(Se_2N_2H)(PMe_2Ph)$ by mass spectrometry (m/z 556 ($M^{\oplus}$), 426 ($[Pt(SeN)(PMe_2Ph)]^{\oplus}$) and ^{31}p NMR spectroscopy ($\delta = -26.3$ ppm $^1J(^{195}Pt,^{31}P) = 3178$ Hz).]

The mixture of **4** and **5** was dissolved in THF (20 mL) then treated with PMe_2Ph (1 mL of a 0.03 M solution in THF). Upon addition of the phosphane solution the dark purple color of the mixture immediately turned pale red then yellow/orange. After stirring for 20 minutes the volume of the solvent was reduced to 1 mL in vacuo and the crude product obtained as a pale pink/orange solid by addition of hexane. Crystals suitable for X-ray crystallography were obtained by slow hexane diffusion into a CH_2Cl_2 solution.

7, $PR_3 = \frac{1}{2}$ dppe: $SeCl_4$ (0.60 g, 19.8 mmol) was carefully added in small amounts to liquid ammonia (30 mL) at $-78\,^{\circ}C$ to produce a green solid and a pale orange solution. [$PtCl_2$ dppe] (0.21 g, 3.15 mmol) was added and the suspension stirred for 2 h at $-78\,^{\circ}C$. The solution was allowed to warm slowly to room temperature (ca. 0.5 h) with the ammonia being blown off under a stream of argon to leave a green/orange solid. Extraction with CH_2Cl_2 (50 mL) and filtration through a celite/glass wool plug afforded an orange solution which, on layering with petroleum-ether (50 mL), furnished orange crystals of the product (0.184 g, 74%). Satisfactory elemental analyses and characteristic IR, MS and ^{31}P NMR spectra were obtained ($\delta = 45.7$, 37.1; $^2J(P,P) = 10$ Hz, $^1J(PtP) = 2817$, 2627 Hz).

8, $PR_3 = \frac{1}{2}$ dppe: To a solution of **7**, $PR_3 = \frac{1}{2}$ dppe (0.057 mmol) in 10 mL of THF/benzene (1/1) was added three drops of $HBF_4 \cdot (Et_2O)_2$ (85% in ether, Aldrich). This solution was stirred at room temperature for two hours, by which time the solution had darkened from light orange to green/brown. The solution was evaporated to dryness in vacuo, dissolved in CH_2Cl_2 (5 mL) and layered with *n*-hexane to furnish green crystals of **8**, $PR_3 = \frac{1}{2}$ dppe by slow diffusion (0.040 mmol, 71%, quantitative by ^{31}P NMR). Satisfactory elemental analyses and characteristic IR, MS, and ^{31}P NMR spectra were obtained ($\delta = 48.9$, 36.2; $^2J(P,P) = 10$ Hz, $^1J(Pt,P) = 2698$, 3094 Hz).

Complexes containing other phosphanes were obtained in a similar fashion in overall yields of 25–40%.

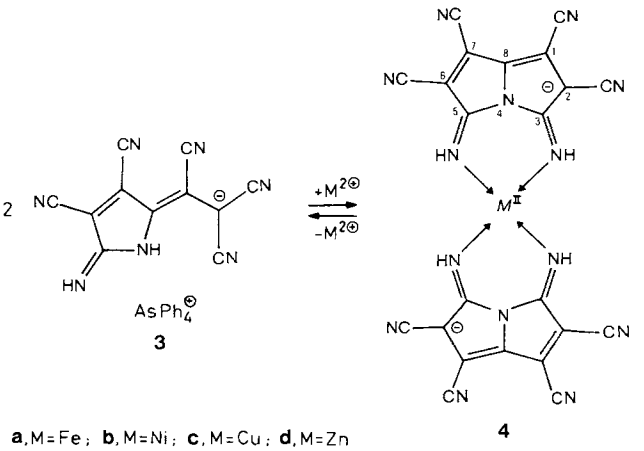
[8] In common with previous studies of **1** the H on N(1) lies significantly out of the PtE_2N_2 plane. We have now observed this feature in a sufficient number of instances for us to be convinced that the effect is real.
[9] In $[Pt(S_2N_2H)(PMe_2Ph)_2]Cl \cdot 0.5\,CH_2Cl_2$ the equivalent interplanar separation is 3.48 Å with Pt ··· S(1)'/Pt' ··· S(1) being 3.50 Å [2].

N-Analogues of Metal Acetylacetonates: Bis(1,2,6,7-tetracyano-3,5-diimino-3,5-dihydropyrrolizinido)metal(II), (Metal = Fe, Ni, Cu, Zn); Crystal Structure of the Copper Derivative**



By *Mario Bonamico, Vincenzo Fares*, Alberto Flamini*, Patrizia Imperatori,* and *Nicola Poli*

The dicyanovinylpyrroles **1** readily cyclize in refluxing aqueous triethylamine to give the pyrrolizine derivatives **2**.[1]

1 **2**

In the course of our studies on the synthesis of metal complexes containing polycyano anions as ligands we have now discovered an analogous metal-promoted reaction of the anion **3**. It affords the corresponding planar symmetric β-diiminometal chelate complexes **4** with exceptional ease.
