Chemical Aspects of Fusion Technology

By Hans J. Ache

Managing thermally controlled nuclear fusion will certainly be regarded one day as one of the most successful accomplishments in nuclear physics. At the same time, however, it will represent a technical achievement unparalleled in the history of science and engineering. This in turn would mean, in retrospect, that decisive contributions had to come from a number of disciplines as diverse as materials and engineering sciences and classical chemistry, and that the same collaboration will have to continue in the future in order to reach the ultimate goal, to construct a reactor capable of producing energy from almost inexhaustible source materials (fuels), such as deuterium and lithium. What is the chemist's role in this development? Similarly as in the development of fission reactors, i.e., the nuclear power plants currently in operation, chemists will have to ensure the existence of a reliable fuel cycle—starting from the availability, storage and reprocessing of the fuel through to the provision for safe storage of the waste. In this review article an attempt will be made to outline the problems associated with these tasks and the approaches to be made by the chemist in solving them.

1. How Does a Fusion Reactor Work?

The underlying principle of nuclear fusion is that atomic nuclei are brought together close enough to fuse despite the repelling electric forces of their two identical charges. In D-T fusion, i.e., the fusion reaction at present standing the best chance of technical realization, this process requires deuterons and tritons with a mean thermal energy of about 10 keV. Consequently, a temperature of ca. 100 million K must be produced in the fuel mixture (plasma) of such a fusion reactor.

Fusion of a deuterium nucleus and a tritium nucleus leads to the production of a He-4 nucleus (α-particle) and a high-energy neutron (14.1 MeV).

$$D + T \longrightarrow {}^4He(3.5\ MeV) + n(14.1\ MeV) \quad (1)$$

The neutron, which carries some 80% of the energy released in the reaction, leaves the plasma without undergoing any major interactions, penetrates the first wall of the reactor, transfers its energy by collisions in the blanket, and produces the tritium necessary to maintain the fuel cycle (Fig. 1) in nuclear reactions with the Li-bearing breeding material in the blanket. This means that 80% of the energy produced in the fusion process is no longer available to maintain the temperature required in the plasma. Consequently, it is imperative that the remaining 20% available

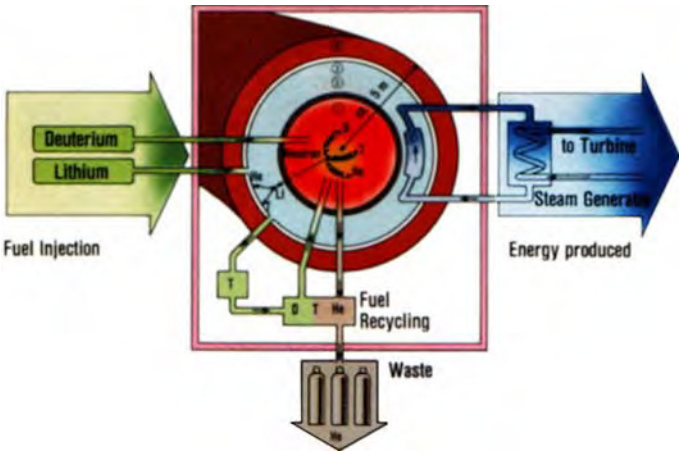

Fig. 1. Schematic diagram of a Tokamak-type fusion reactor (from [1a]): ① = Plasma; ② = First wall; ③ = Blanket; ④ = Magnet coils; ⑤ = Heat exchangers.

as kinetic energy of the α-particles be used most efficiently for plasma heating so as to make up for the heat flow delivered to the outside in the steady-state mode of operation by radiation, thermal conduction, and convection. This is done in the so-called Tokamak reactor,[1] (Tokamak being a russian abbreviation for toroidal magnet chamber), where strong magnetic fields—produced by superconducting magnets—permeate the burning plasma. These magnetic fields are aligned so that the electrically charged plasma particles are compelled to move helically along the magnetic flux lines, thus largely preventing any contact between these particles and the chamber wall and, hence, any heat transport to the wall. The plasma is first heated by induction currents (ohmic heating), a technique which can now attain plasma temperatures of ca. 10^7 K. As this temperature is still one order of magnitude lower than the 10^8 K required for fusion, additional heating techniques are under development, such as the injection of accelerated particles and exposure to electromagnetic waves. In order to keep within tolerable limits the heat release by the plasma through radiation, continuous removal of the helium produced and of any other impurities contained in the plasma chamber must be ensured.

The tritium generated in the blanket by fast neutrons reacting with lithium is extracted in a suitable way, purified, and supplied to the combustion chamber as a fuel together with deuterium. The energy deposited in the blanket by the fast neutrons is extracted by heat exchangers. The heat is used for conventional electricity generation.

2. Preparation of Source Materials

In principle, a number of nuclear reactions can be considered for nuclear fusion. Table 1 lists some of these reactions together with data of importance in practical applications, such as the energy released in the reaction E_2, the required ignition energy E_1 (each expressed in keV as unit of ion temperature), and the ratio of the energy produced in such a reaction relative to the energy required for the reaction to proceed.[2]

Table 1. Fusion reactions.

Reaction	Energy yield E_2 [keV]	Ignition energy E_1 [keV]	E_2/E_1
$D + T \rightarrow {}^4He + n$	17600	10	1760
$D + D \rightarrow {}^3He + n$	3300	50	66
$D + D \rightarrow T + p$	4000	50	80
$D + {}^3He \rightarrow {}^4He + p$	18300	100	183
$p + {}^{11}B \rightarrow 3\,{}^4He$	8700	300	29

There are two parameters in favor of the D–T reaction: on the one hand, the relatively high energy yield associated with it and, on the other hand, the comparatively low ignition energy of 10 keV, which is certainly a very decisive factor for technical implementation.

What about the supplies of source materials required for this reaction? Deuterium is available in sufficient quantities as D_2O/HDO in water; the reserves are good for millions of years, and deuterium can be separated from light water H_2O at relatively little expense. The other fuel, tritium, is the radioactive isotope of hydrogen with a half-life of ca. 12 years. It must be synthesized by means of nuclear reactions, preferably from lithium because of the high cross sections for the appropriate reactions.[3,4] Lithium is also available in sufficient quantities in the crust of the earth and in sea water. The problem is thus reduced to the question of whether sufficient tritium can be produced from lithium, and to whether this can be achieved economically. The nuclear reactions in question are (2) and (3).

$$^6Li + n_{slow} \longrightarrow T + {}^4He \quad (2)$$

$$^7Li + n_{fast} \longrightarrow T + {}^4He + n_{slow} \quad (3)$$

Now, existing fission reactors could be used to irradiate lithium with slow neutrons and produce tritium in this way. This process is actually carried out on a small scale, albeit mainly for military purposes. Normally the source materials used are Li–Al alloys containing a few percent by weight of the highly enriched Li-6 isotope in aluminum. The tritium in this case is driven off at temperatures of ca. 600 K together with the helium produced in the same reaction.[5]

However, in terms of energy, this way of generating tritium would be extremely wasteful, considering that the fission of a ^{235}U or ^{239}Pu nucleus by slow neutrons already releases some 196 MeV of energy [Eq. (4)]. Even if one neutron were available for the Li(n,α)T reaction (2) after each fission, subsequent fusion with deuterium of the tritium atom produced in this way would generate only 17.6 MeV of energy, which is not even 10% of the energy produced in a fission reactor per fission event [Eq. (4)]. Under these circumstances, it would be more reasonable to continue making direct use of the energy produced by fission.

$$^{235}U + n \longrightarrow \text{fission products} + \text{neutrons} + 196\ \text{MeV} \quad (4)$$

It follows, therefore, that a fusion reactor is purposeful only if the tritium is generated directly in it by the fast neutrons produced in the fusion reaction [Eq. (1)]. However, as

only one neutron occurs per fusion, and not all of these neutrons can be expected to be involved in tritium production, nuclear reactions or a sequence of nuclear reactions must be used which are able to generate more than one tritium atom per fast neutron produced in the fusion process. Fortunately, lithium not only contains the Li-6 isotope, which produces tritium with slow neutrons [Eq. (2)], but also the Li-7 isotope, which has an isotopic abundance in lithium of ca. 92.5%. Li-7 reacts with fast neutrons in accordance with Equation (3), giving rise not only to a tritium atom, but also to a slow neutron, which can undergo another reaction, this time with Li-6, producing more tritium as shown in Equation (2). Consequently, the tritium yield may be increased considerably and a tritium breeding factor, i.e., a ratio of tritium produced to tritium consumed, in excess of 1 may be achieved.

Attaining a tritium breeding factor clearly in excess of unity is decisive for a fusion reactor. Hence, one of the first and foremost tasks for chemists, and especially radiochemists, was to provide the cross-sections of all nuclear reactions possible with these potential breeding materials as a function of neutron energy, which are required to calculate the tritium breeding factor. Many thousands of measurements had to be carried out for reliable predictions to be made of the suitability of a compound as a blanket material, the greatest difficulties being encountered especially in measurements of the energy and angular distribution of nuclear reactions producing secondary neutrons. Earlier reports frequently showed discrepancies in the findings published by various laboratories. However, it has meanwhile been possible to clear up most of them.

The database now available can be regarded as quite reliable, allowing neutron physicists to calculate a variety of blanket concepts, i.e., various arrangements of the blanket material.[6] These have shown that breeding factors considerably in excess of unity can be achieved in pure lithium as the blanket material. A detailed assessment of the influence of existing uncertainties in the relevant cross-sections on the determination of the tritium breeding factor led to a final uncertainty of only 2–6% in the tritium breeding factor.[7]

Should the use of "breeding" materials other than elemental Li, such as Li-silicates, Li-titanates, etc., result in the number of neutrons not being sufficient because of competing reactions of the neutrons with other elements, so that a breeding ratio in excess of unity could not be guaranteed, so-called neutron multipliers will have to be considered; these are elements which undergo nuclear reactions with fast neutrons and thereby produce several neutrons. The elements beryllium and lead, in particular, would be eligible for this purpose.

Although it may thus seem possible to maintain a fuel cycle, it must be emphasized here that not too many neutrons are available for tritium production and that the tritium produced must be handled very economically.

3. Fuel Cycle in a Tokamak Reactor

Whereas the fundamental considerations for the production of tritium could be treated quite independently of the type of reactor involved, the fuel cycle can be discussed only with reference to a specific type of reactor. The first energy-producing fusion reactors, as provided for in the European Fusion Program,[8] will be based on the Tokamak principle[1] (Fig. 1), i.e. the fusion of deuterium and tritium in a plasma. Two parameters are decisive for the ignition and maintenance of the plasma: the product of plasma confinement time and plasma density, and the temperature (Fig. 2). According to *Lawson*,[9] certain minimum levels of these parameters must be ensured for ignition to take place reliably and for the thermonuclear fire to be maintained. Since helium is produced in the fusion, the plasma becomes "diluted," which decreases the product of confinement time and density; consequently, helium must be removed in order to maintain the thermonuclear fire.

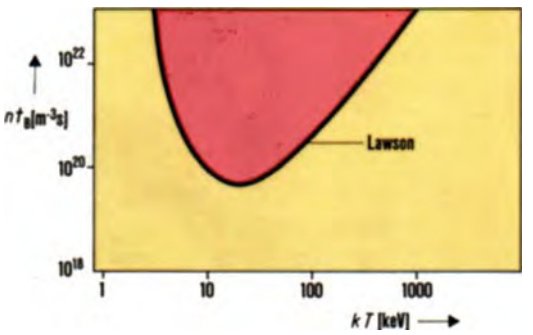

Fig. 2. Lawson diagram: The product of plasma density, (n), and plasma confinement time, (t_B), is plotted as a function of the ion temperature, kT, of the particles in the plasma. The orange area indicates the range in which a thermonuclear fire can be maintained. "Dilution" of the plasma [formed according to Eq. (1)] leads to "extinction" of the plasma. The burnup is thereby limited.

The burnup, i.e., the amount of helium produced, must not exceed a certain level, which may vary between 2% and 20%, depending on the design of the plasma chamber. This implies a continuous throughput through the plasma chamber, coupled with a continuous separation of helium from the unspent fuel mixture. A schematic diagram of such a fusion reactor is shown in Figure 1.

According to the law of conservation of momentum, the energy released as kinetic energy in reaction (1) is distributed in the ratio of 1 :4 between the α-particle (^{4}He) and the neutron. It is imperative that the majority of the α-particles with two positive charges be prevented from leaving the plasma, as their kinetic energy is required to maintain the high plasma temperature needed for the fusion process. This objective can be achieved to a large extent, but not completely, by the method of magnetic confinement used in the Tokamak principle.

The neutrons produced in the fusion process can leave the plasma, pass through the first wall and release their energy in the breeding blanket, where tritium is produced. This energy, and the energy released in the ^{6}Li(n,α)T and ^{7}Li(n,nα)T nuclear reactions, the latter of which contributes some 12% to the total energy, is "extracted" by means of a coolant, probably water. Of course, it cannot be ruled out in this process that the tritium produced in the

blanket will diffuse into the water. Such an exchange must also be taken into account in the cooling of the first wall.

The complete fuel cycle in a fusion reactor is shown in Figure 3. A distinction can be made between an inner and an outer fuel cycle: combustion in the plasma, exhaust pumping, exhaust purification, and tritium recovery from the impurities, plus downstream hydrogen isotope separation and storage in the inner fuel cycle; tritium generation in the blanket, tritium extraction and purification in the outer fuel cycle; finally, the recovery of tritium from the coolant must also be considered.

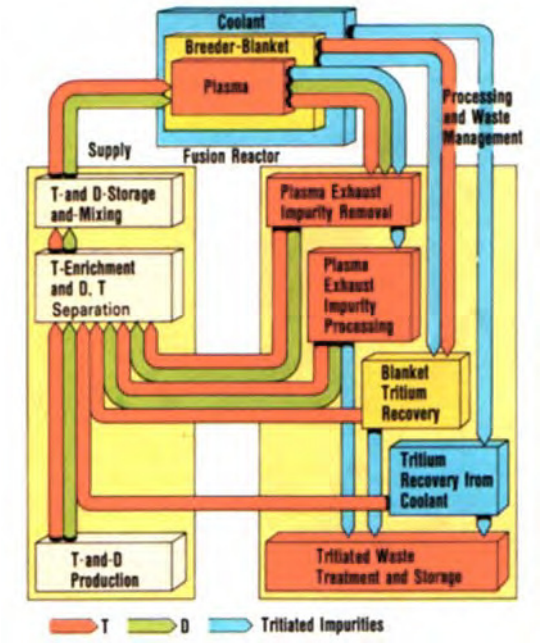

Fig. 3. Fuel cycle in a fusion reactor.

Model calculations have been carried out in order to assess the tolerable rate of total tritium losses in the system on the basis of a tritium breeding factor given by the blanket concept, and to detect those points at which losses are particularly important.[10,11] First of all, the minimum tritium breeding factor (B_{min}) required to maintain the fuel cycle had to be determined [Eq. (5)]; it is a function of the tritium loss in the system (V) and the radioactive decay of the tritium inventory ($\lambda\tau$), where λ is the decay constant of tritium and τ is the average retention time of the tritium in the system.[10]

$$B_{min} = 1 + V + \lambda\tau \tag{5}$$

The retention time, τ, (in days) is given by the tritium inventory divided by the daily tritium consumption. The total loss not due to decay can be subdivided into the losses arising in the different subsystems [Eq. (6)].

$$V = (1-f)\,V_B + V_K + (1/A - 1)\,V_R \tag{6}$$

V_B = loss in T production from the blanket; V_K = loss in T recovery from the cooling water; V_R = losses in plasma exhaust purification; f = fraction of T transferred to the cooling water in the blanket; A = T burnup in the plasma; $(1/A-1)$ = factor taking into account the fact that, for a given quantity of fuel, more runs through the system or purification steps are necessary at low burnup than at high burnup.

If $V_B \approx V_K \approx V_R$, the total loss is largely determined by $(1/A-1)\,V_R$, i.e. the losses arising in plasma exhaust purification seem to play a major role. This is explained by the fact that a given quantity of fuel required to produce energy in a power reactor will need more cycles or purification steps at low burnup than at high burnup. V_R is thus weighted by the factor of $(1/A-1)$, which is already 49 at $A = 2\%$ (Table 2). Let us explain the situation once more: If 90 g of tritium is burnt in the NET (*N*ext *E*uropean *T*orus) reactor per day, 1.8 kg of tritium must be purified each day at a burnup of 5%, whereas it would be only 0.45 kg per day at a burnup of 20%. Obviously, considerably higher tritium losses would arise in the former case. At a given breeding factor of $B \leq 1.1$ and a burnup of 5%, including radioactive decay, the losses in plasma purification can be estimated to be in the region of less than 0.1%.

Table 2. Relation between T-burnup and T-loss in the cycle [Eq. (6)].

A	$(1/A-1)$
0.1	9
0.05	19
0.02	49

For the chemist, this poses the following questions: What possibilities are there for increasing the burnup? How can losses in plasma exhaust purification be kept low enough? Or, even better, how can both objectives be met? As mentioned in Figure 2, the burnup factor is limited first by the dilution effect of the helium produced. But that is not all.

In addition to the uncharged fast neutrons produced in fusion, a considerable number of charged and uncharged helium and hydrogen particles which have escaped magnetic confinement impinge upon the "first wall" surrounding the plasma. The estimated flux in an energy producing reactor is 10^{14}–10^{15} neutrons $cm^{-2}\ s^{-1}$ and ca. 10^{16} charged or neutral hydrogen and helium particles.[12] This

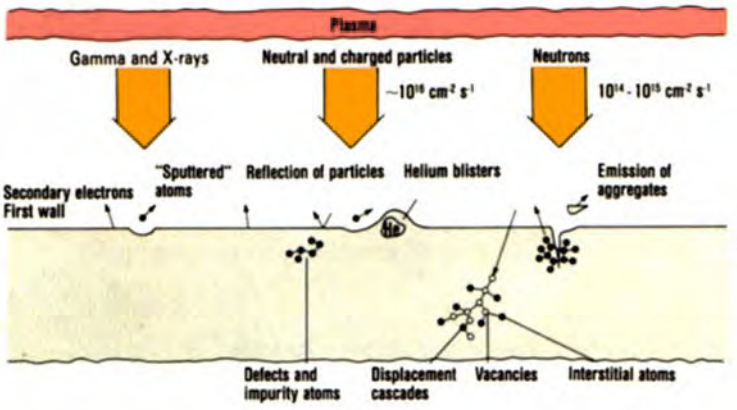

Fig. 4. Summary of the events occurring in the plasma-wall interaction.

irradiation of the first wall is certainly one of the most difficult problems in fusion and has not yet been solved satisfactorily. The interaction of these particles with the first wall may give rise to a number of chemical and physical processes, sputtering, etc., all of which will cause wastage and embrittlement of the material of the wall (Fig. 4).[13]

In addition to these materials problems, sputtering will introduce impurities into the plasma. A particularly critical situation in maintaining the fusion process arises if the plasma gas is contaminated by elements of higher atomic numbers, since their presence results in increased energy diffusion from the plasma. As a consequence, additional energy will have to be supplied to the plasma from the outside or, in other words, the ignition temperature in the plasma must be raised, as can be seen from Figure 5, where the ignition temperature is plotted as a function of the concentrations of various elements.

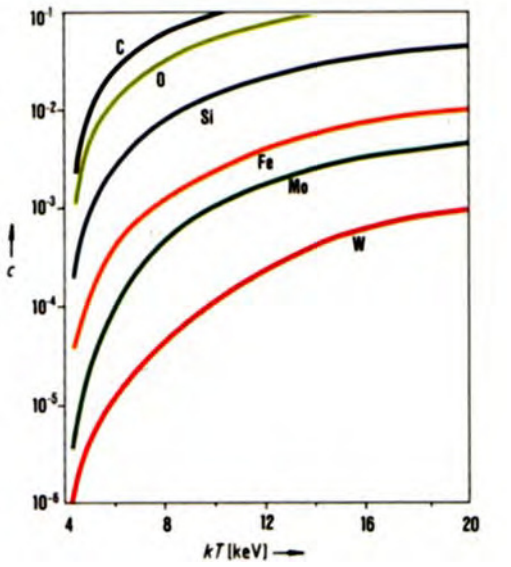

Fig. 5. Relationship between the ignition temperature kT and the impurity concentration c [atomic fraction] in the plasma for various heavy elements.

The additional burdening of the plasma with these impurities, which, like helium, must be removed continuously, means that the burnup will be decreased beyond the limit set by the dilution with the helium produced in the fusion process. If this contamination of the plasma could be prevented, it would be possible to increase the burnup and in this way also reduce the tritium losses in the plasma exhaust purification by reducing the number of cleaning steps.

In the present concept implemented already, e.g., in such experimental reactors as TFTR, TEXTOR, and JET,[14] the plasma chamber, which, at least according to current designs, would be made of stainless steel or alloys of elements of high atomic numbers, because of the extremely large mechanical and thermal stresses, is covered with a protective coating of materials of low atomic numbers, for which preferably graphite or C–H films with an H/C ratio of 0.4 can be used.[15]

4. Chemistry of the First Wall

Two aspects of the wall protection are of particular interest to chemists: what about the uptake of hydrogen in carbon? Is it possible that a tritium inventory is built up in the graphite or in the C–H films, which would create difficulties in plasma ignition, especially in the early phase, because of the adsorption of fuel in larger quantities? What kinds and what volumes of impurities get into the plasma?

These aspects have been the subject of numerous studies,[16] which have shown that hydrogen, unless it is reflected by the graphite surface, is retained in the graphite until a saturation concentration of 0.4 H/C has been reached. If more hydrogen is made available at temperatures of 900–1200 K, hydrogen is released again as H_2. When the graphite was implanted with hydrogen up to saturation, bombardment with deuterium released first pure H_2, then HD and, finally, after saturation, D_2.[17] This aspect is significant especially if the plasma chamber had been carburized, i.e., the carbon had been applied to the first wall by means of a glow discharge in a mixture of CH_4 and H_2 (Fig. 6).[18] In this case, there is again a carbon

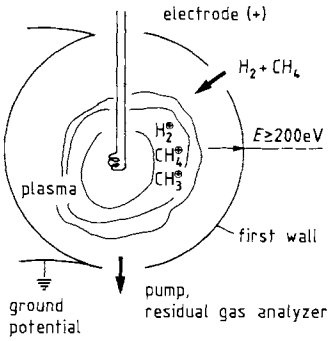

Fig. 6. Method of carburization to produce a protective carbon coating on the first wall. The plasma discharge in a mixture of CH_4 and H_2 produces a deposition of carbon films on the first wall.

layer saturated with hydrogen in a ratio of H/C ≈ 0.4. If a D–T mixture is used to ignite a fusion reactor prepared in this way, it may well be that the fuel is unduly diluted in the initial stage by H_2 released from the bombardment of the wall with D or T. It has therefore been proposed to choose the composition of the C–H film in such a way that its hydrogen isotope composition corresponds to the fuel mixture, which might be achieved, e.g., by a glow discharge in mixtures of CD_4 and T_2.[19] In addition, the diffusion of tritium into the inner layers of graphite was also of interest, as this could have led to an undesirable increase in the tritium inventory in the first wall. These studies, all of which were conducted to improve our knowledge of the chemical and physical bonding of hydrogen in graphite or, even better, in carbon, and which also included Raman and photoelectron spectroscopic as well as secondary ion mass spectrometric studies, resulted in a number of empirical models, which also took into account migration through the pores into the inner regions of the graphite. Such models for graphite are summarized schematically in

Figure 7.[16] They allow the T inventory bound in the graphite to be estimated, and show that this quantity can be considered as unimportant compared to the overall T-inventory.

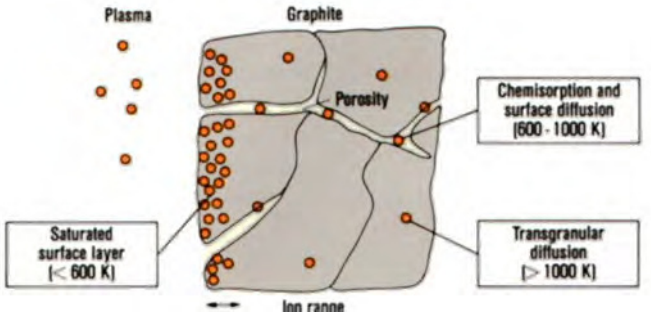

Fig. 7. Schematic diagram of the uptake of hydrogen in graphite (from [16]): Graphite produces a surface coating saturated with hydrogen (H/C = 0.4). If more hydrogen is supplied, this will be incorporated, while simultaneously releasing a corresponding amount of hydrogen already present.—Diffusion of hydrogen into the pores and transgranular diffusion on a larger scale occur only at higher temperatures.

From the results of the above experiments it was to be expected that there is no serious tritium storage during the plasma burning time, when the temperature of the graphite layer is ca. 1500 K. As a realistic upper limit, the tritium inventory bound in the graphite of the plasma chamber walls in the NET reactor is assumed to be ca. 10^{18} tritium atoms/cm^2, which adds up to a negligible quantity of 10^{25} tritium atoms for a total surface area of 10^7 cm^2.[20]

Strictly speaking, however, these conclusions relate only to the processes arising in the interaction between hydrogen and the solid graphite matrix. More recent studies have shown that the erosion to be expected to occur in graphite plates is due in approximately equal parts to physical sputtering, chemical sputtering by hydrogen, chemical reactions with oxygen, and a combination of various other effects.[21] Oxygen contamination can never be absolutely excluded in a plant as complicated as a fusion reactor. Physical sputtering leads to the formation of graphite deposits on large surface areas in the reactor, and the entrainment of large quantities of tritium in these deposition layers e.g., bound by co-deposition cannot be ruled out. In this connection it should also be pointed out that physicochemical quantities, such as the solubility of hydrogen in graphite at temperatures of ca. 1500 K, are still unknown and need to be studied before any final statements can be made about the hydrogen storage capacities of graphite or similar materials.

The release of tritium as T_2 is not the only possibility resulting from an interaction between hydrogen and a graphite surface saturated with hydrogen. In addition to the absorption and desorption of hydrogen, also the products formed as a consequence of the reactions between energetic hydrogen particles and carbon are of interest, as they result in contamination of the plasma. Studies on the reactions of thermal and energetic hydrogen atoms or ions with graphite and with carbon films (H/C = 0.4) have shown that the chemical erosion of carbon includes the production of hydrocarbons,[22,23] especially of methane or

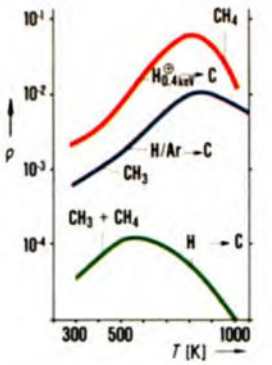

Fig. 8. Reactions of thermal and energy-rich hydrogen with graphite (from [24]): Thermal hydrogen produces mainly CH_3; energy-rich hydrogen produces CH_4; ρ = reaction yield per H atom, T = target temperature.

methyl radicals. Figure 8 shows a plot of the hydrocarbon yield as a function of the target temperature T for several kinetic energies of the impinging particles, atomic hydrogen or hydrogen ions. It can be seen that, in an equilibrium state, i.e. in the presence of a surface saturated with hydrogen (H/C = 0.4) the yield of CH_4 upon irradiation with hydrogen ions of 0.4 keV energy is 4×10^{-2} CH_4 per $H^{\oplus}$ at 800 K.[24] The desorption of H_2 is always roughly two orders of magnitude higher, under otherwise unchanged conditions. It would be extremely important to find materials in which the formation of hydrocarbons and, hence, the contamination of the plasma and also erosion is diminished. However, for the time being it must be assumed, as has been borne out by experiments in JET, that the plasma exhaust will contain 10% of the tritium bound to methane at a burnup of 5%, which leaves it to the chemists' creative imagination to find ways of purifying the exhaust and recovering the tritium, and do all this at a loss of less than 0.1%.

5. Chemistry of the Internal Fuel Cycle—Tritium Recovery

Regarding the plasma exhaust purification process, the chemist is presented with the following tasks: firstly, the process should be so designed that it proceeds effectively and as quickly as possible at the lowest possible temperature so that diffusion losses are avoided and, secondly, the process should not involve any appreciable formation of tritiated waste, and thus not cause any loss of tritium.

Irrespective of the first wall being covered with a protective coating or not, as described in Section 4, methane must in any case be considered as a possible impurity in the plasma gas. However, it certainly will not be the only impurity. First and foremost, outgassing of various materials at the high operating temperatures encountered will also cause compounds other than methane, e.g., CO, CO_2 and H_2O, to enter the plasma. Moreover, in a machine as large and complicated as this, minor leakages can never be excluded entirely, which means that minute quantities of nitrogen and oxygen will penetrate into the plasma chamber, thus probably causing further contamination of the plasma with nitrogen compounds such as nitrogen oxides and ammonia.

A suitable purification procedure must therefore provide for all these components of the plasma exhaust. Moreover, the hydrogen flux resulting from this process must not contain more than 100 ppm of He and 1 ppm of other impurities, since otherwise there will be difficulties in downstream low-temperature rectification of the hydrogen isotopes.

Since such quantities as the daily throughputs of tritium and deuterium, the volume of blanket material and the like are also of importance in choosing the process techniques, the operating conditions assumed in the NET concept will serve as a basis for the following discussions.

NET is the successor to JET (Joint European Torus) and will serve as a basis for the construction of a demonstration machine (DEMO).[7] While the JET program is primarily geared to resolving problems in the physics sector, the NET program is designed to generate a burning plasma and, concomitantly, to serve as a test-bed for the more important reactor components, such as the first wall, blanket, and the tritium generation and purification systems. DEMO is planned to be a reactor capable of generating energy and breeding its own tritium, albeit as yet not optimized economically.

A peak power of 747 MW has been estimated for NET with a duty cycle of 0.8, which corresponds to plasma burning times of ca. 1000 s interrupted by down-times of ca. 250 s. At an availability of 100%, this results in a tritium consumption of 91 g and a deuterium consumption of 60.8 g per day. At a burnup of 5%, i.e., if the respective burning of tritium and of deuterium in the plasma is to be limited to 5%, this means a daily througput of 1824 g of tritium and 1217 g of deuterium.[25] These quantities must be purified daily.

5.1. Primary Purification of the Plasma Exhaust

There are essentially four techniques[26] which can be applied to separate hydrogen from the impurities in the inner fuel cycle, each of them raising interesting questions for the chemist.

5.1.1. Palladium-Silver Membranes

The first of these techniques is based on the application of palladium-silver membranes, which are permeable to hydrogen at elevated temperature (>600 K), while retaining impurities.[27] The major advantage of this technique, which is shown schematically in Figure 9, lies in its continuity; however, two critical problem in particular arise from the application of this technique to fusion technology:

1. Embrittlement of the palladium–silver alloy by helium (produced as tritium decays within the membrane) and by frequent temperature changes, as are required when the purification system is started up and turned off.
2. Reversible or irreversible coating of the membrane surface with substances which impede the passage of hydrogen (membrane poisoning).

While the mobility of helium and, hence, outgassing from the membrane, is considered to be sufficient at the operating temperature of the membrane, it is not yet known what maximum contamination of potential poisons to the phase transit reaction is tolerated by the membrane. For carbon monoxide, for example, it was observed that, up to concentrations of 8.2×10^{-3} mol L^{-1}[28] and even higher contents of other gases, such as ammonia, carbon dioxide, and nitrogen, there was no reduction in the flow of hydrogen; methane does not impair the membrane surface even at concentrations up to 40%.[29] More extensive (surface) studies must be carried out in this area in order to gain a better understanding of these poisoning phenomena and, thus, embark on specific further developments in the production of these membranes.

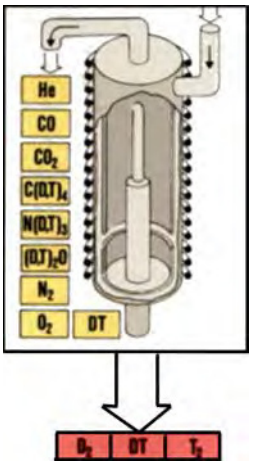

Fig. 9. Schematic diagram of the removal of impurities from the plasma exhaust by means of the Pd/Ag membrane. Advantage: continuous process; disadvantages: the waste stream contains T, embrittlement with changes in temperature, poisoning by certain compounds.

A fundamental problem associated with membrane techniques is the possibility of obtaining a hydrogen flow free from impurities, but not a flow of impurities free from hydrogen. That is, the recovery of tritium from the flow of impurities in a second process step is indispensable.

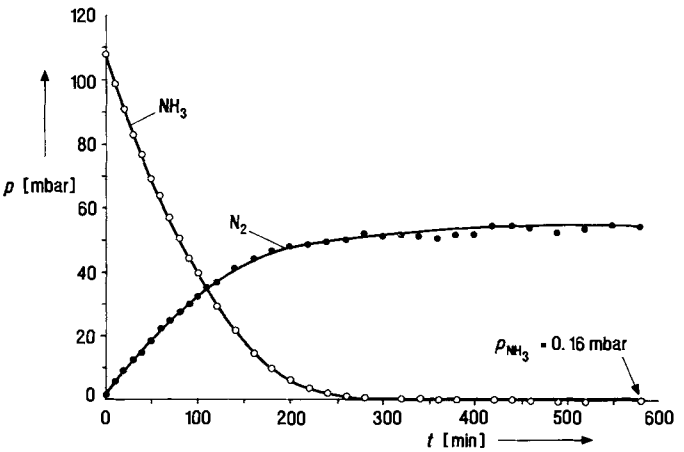

Fig. 10. Catalytic decomposition of ammonia on the surface of a Pd/Ag permeator [29].

A special advantage associated with the use of palladium–silver membranes is the catalytic decomposition of ammonia, one of the expected impurities in the reactor exhaust, on the surface of the permeator. This reaction has been observed and quantified in connection with experiments performed on the decomposition of ammonia by transition metal catalysts.[29] Figure 10 shows typical curves for the concentrations of ammonia and nitrogen while a helium/ammonia mixture is being circulated, and Figure 11 shows the dependence of the decomposition rate on pressure as determined from the experiments. Hydrogen is separated simultaneously, thus shifting the chemical equilibrium of reaction (7)

$$2\,NH_3 \rightleftharpoons N_2 + 3\,H_2 \qquad (7)$$

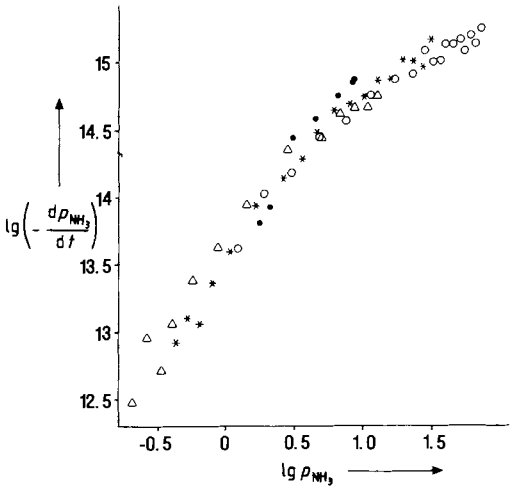

Fig. 11. Kinetics of ammonia decomposition in a Pd/Ag permeator [29]. Initial pressure p [mbar] of NH_3: ○ = 108.1, * = 60.4, ● = 49.7, △ = 32.9. dp_{NH_3}/dt in molecules $cm^{-2}\,s^{-1}$.

in the direction of the elements. As shown in Section 5.2, tritium bound to nitrogen and deuterium can be recovered in the same way.

An arrangement for the separation of deuterium and tritium from the reactor exhaust, which would be suitable for NET, would be a bundle of 250 or 300 palladium–silver tubes of ca. 1.6 mm diameter and roughly 40 cm long, which would be operated at ca. 600 K and an inlet pressure not exceeding 1 bar. The hydrogen partial pressure on the outlet side could be kept below 1 mbar, thus allowing the hydrogen isotopes to be separated as quantitatively as possible in the very first process step.[25]

5.1.2. Hot Metal Getters

The second method of hydrogen separation uses hot metal getters. Purifying various gases is possible, in principle, by selective getter reactions in specific solids. Thus, various metals such as uranium, titanium, and zirconium or some of their alloys react, partly at high temperatures, with hydrocarbons, carbon oxides, ammonia, nitrogen, hydrogen, water, and oxygen in irreversible reactions producing carbides, nitrides and oxides, and in reversible reactions producing hydrides,[30–35] as is shown schematically in Figure 12. The reactivity depends very much on temperature,

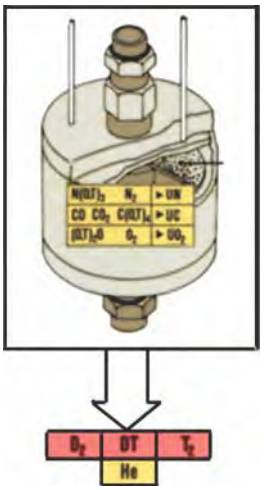

Fig. 12. Schematic diagram of the removal of impurities from the plasma exhaust by means of hot metal getters. Advantages: continuous method, irreversible retention of nitrogen, carbon, and oxygen, negligible retention of hydrogen at higher temperatures; disadvantages: requires high temperatures, produces large amounts of waste.

the state and size of the surface area, and the composition of the getter material. Figure 13 shows the coexistence lines for thermodynamic equilibrium of uranium and titanium with their respective hydrides, and, for a zirconium–aluminum alloy commercially available as ST 101 getter material,[36] a pressure limit for hydrogen above which the material will embrittle at the respective temperature due to reaction with hydrogen. It should be noted that the logarithmic pressure scale in Figure 13 covers more than 10 orders of magnitude.

Whereas uranium no longer produces hydride above 650 K at the hydrogen partial pressures under discussion

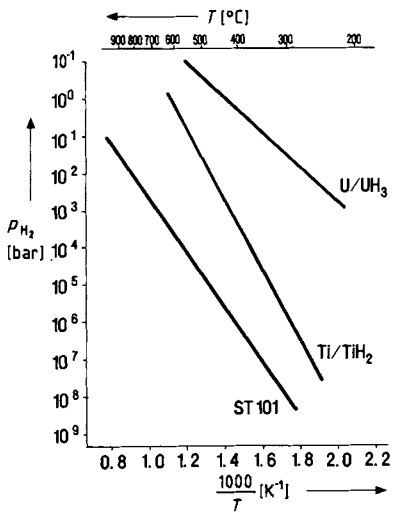

Fig. 13. Hydrogen equilibrium pressures as a function of temperature in various metal/metal-hydrogen systems [29].

($p_{H_2} \leq 0.1$ bar) and thus no longer binds any hydrogen (aside from its sparing solubility), in the case of titanium this is true only for temperatures above 850 K; the zirconium-aluminum alloy would even have to be used at temperatures above 1200 K in order to minimize the hydrogen inventory of the getter and avoid embrittlement.

The lower temperature limit for the formation of uranium carbide from hydrocarbons or carbon oxides is estimated to be around 1100 K[32,37] for kinetic reasons and, especially, because of the rate of diffusion of the reaction product into the interior of the solid. Similar temperatures apply for titanium and zirconium-aluminum alloys.[38,39] Also ammonia and nitrogen are converted into metal nitrides only above ca. 900 K.[38,39] The metal oxides are, by comparison, produced relatively easily by reaction with water or oxygen: in the case of uranium, e.g., the oxide formed on the metal surface at only 450 K does not act as a protective coating for the base metal. The reaction with water may also lead to formation of uranium hydride, independently of the partial pressure and the temperature.[32]

When using these hot-metal getters in fusion technology it must be borne in mind that prolonged use, e.g., of uranium, leads to saturation by the nitride, carbide, etc., which reduces the efficiency of the getter; normally, this point is reached when about 10% of the uranium metal has been used. This means that the getter must be replaced periodically, thus giving rise to considerable amounts of radioactive waste. Since uranium is relatively expensive and is pyrophoric when finely distributed, it should as far as possible be replaced by other getter materials, e.g. zirconium-aluminum alloys (SAES getters) or zirconium-cobalt alloys. Therefore, in the search for suitable substitutes, of primary interest regarding the potential systems are the determination of physicochemical data, such as hydrogen solubility, diffusion constants, phase diagrams, and the kinetics and thermodynamics of their reactions with hydrogen, carbon, oxygen, and nitrogen. In particular, a knowledge of the kinetics of formation and decomposition of these compounds is of decisive importance in deciding whether a material can be used as a getter or not. Moreover, getter-poisoning by certain compounds or elements also plays a role, which, in turn, necessitates surface chemistry studies being carried out in order to elucidate the reactions occurring under these conditions. The advantage of plasma gas purification by getters without a further tritium recovery step, as would be required in the use of Pd/Ag membranes, is offset by the disadvantage that most of these getters require high temperatures, thus raising problems of tritium diffusion to the outside. Current efforts are claimed at finding getter materials which are already effective at low temperatures. Furthermore, this technique requires separation of the helium before the hydrogen isotope mixture can be separated by low-temperature rectification.

5.1.3. Molecular Sieves

The third method is based on the adsorption of impurities on molecular sieves at temperatures around 300 K and 75 K, respectively,[40,41] as shown schematically in Figure 14. Although this method is rather simple in principle, it is a batch process also requiring subsequent separation of the helium, which can be achieved by conversion of the tritium into uranium tritide and pumping off the unbound helium. The impurities adsorbed in the molecular sieve are pumped off periodically at elevated temperatures and need to be processed further (see Section 5.2).

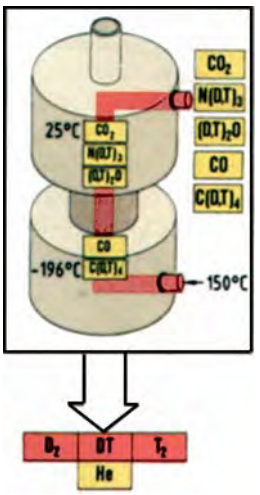

Fig. 14. Schematic diagram of the removal of impurities from the plasma exhaust by means of molecular sieves. Advantage: proven technique; disadvantages: the waste stream contains T, batch process.

A problem associated with the use of adsorbers, such as zeolites, is the possibility of an isotope exchange between the tritium adsorbed, e.g., as water, and the residual water content in the zeolites, which cannot be removed even at higher temperatures.[42] To what extent this process may result in an undesirable increase in the tritium inventory in the adsorber is presently the subject of numerous investigations.

5.1.4. Selective Freezing

The fourth method makes use of selective freezing of the plasma exhaust in cryopumps,[26,43] which are also used to pump off the plasma. In order to achieve CH_4 separation down to the 0.1 ppm level required for subsequent removal of the hydrogen isotopes, temperatures of <45 K are necessary; the corresponding temperature for the separation of N_2 and CO is 28 K. Calculations have shown that also significant quantities of DT and T_2 are frozen out together with these impurities,[26] which means that the impurities separated need to be reprocessed, as in the molecular sieve and Pd/Ag membrane methods. Estimates have shown that approximately ten times more DT/T_2 enters the waste stream to be reprocessed than is the case with the Pd/Ag membrane.

5.2. Recovery of Tritium from the Plasma Exhaust Impurities

As explained in Section 5.1.1, separation of the plasma exhausts by means of the Pd/Ag membrane technique pro-

duces a gas stream containing not only the impurities that have been removed from the plasma, but also slight quantities of tritium as DT or T_2. According to a quantitative estimate, this stream will amount to 1–6% of the plasma exhaust stream. Further purification by the membrane technique does not seem to be feasible because of the increased hazard of membrane poisoning as a result of the high concentration of impurities. Consequently, other methods will have to be envisaged for the reprocessing of such a stream and the recovery of tritium from its tritium-bearing components.

A similar stream of impurities arises upon regeneration of molecular sieves if the plasma exhausts are purified by cryoadsorption (see Section 5.1.3) or cryopump techniques are used. The decisive aspect to be borne in mind when selecting the methods for recovery of tritium from the impurities is, as also in exhaust purification itself, the minimization of tritium losses into the open, i.e., in cooling systems, laboratory or reactor spaces, and also in the form of radioactive waste. Consequently, first and foremost, diffusion must be minimized and, since this is determined by the temperature, also the temperature must be kept as low as possible in all reactions; secondly, the catalysts and getters etc. must be chosen especially from the point of view of their regenerability, so as to limit the accrual of radioactive waste. That is, the complex composition of the reactor exhaust so far as a simple and quantitative recovery of deuterium and tritium is concerned, requires a sophisticated combination of a variety of physicochemical processes. Even the sequence of possible steps is in no way trivial. In principle, only a minimum number of process steps should be sought for, at temperatures as low as possible and involving a minimum of radioactive inventory; not only are high decontamination levels in the process exhaust called for, but also minimization of secondary wastes.

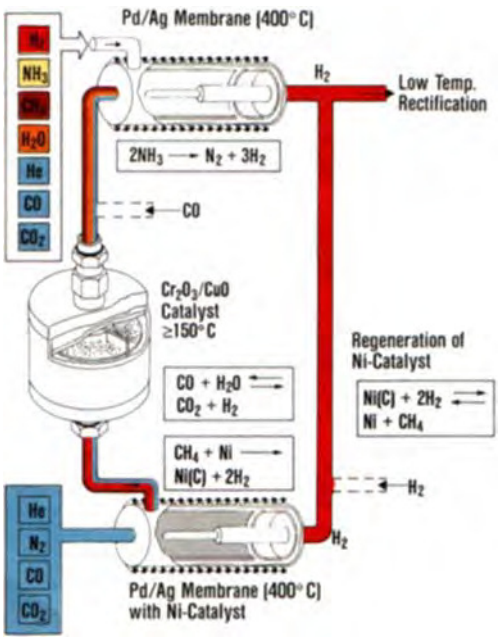

Fig. 15. Flowsheet for the removal of impurities from the plasma exhaust by means of a combined Pd/Ag membrane-catalyst-Pd/Ag membrane (cracking) process [42].

Recently,[29] a combination of several process steps was reported which seems to optimally fulfill the requirements regarding lowest possible process temperatures and minimum accrual of waste. The flowsheet is shown in Figure 15.

Since the reactor exhaust consists mainly of unburnt deuterium and tritium, the most reasonable first process step must surely be the removal of the bulk of these two species. Because of the advantages of low operating temperature (ca. 650 K), the very low stationary tritium inventory, the high efficiency of tritium removal, and, especially, the high purity of the product, this is done in the concept discussed here by means of a palladium/silver permeator, which is so dimensioned that the hydrogen content can be reduced to 1%.[25] At the same time, the small amounts of ammonia to be expected in the reactor exhaust are catalytically converted into the elements on the palladium/silver tubes, and the hydrogen reaction product is removed together with the main process gas.

In general, the concentration of impurities is low at the inlet of the permeator, which makes poisoning rather unlikely. It is known that water does not reduce the permeation rate.[29,44] The permeability in the presence of higher concentrations of CO is decreased only at temperatures below 575 K. The concentrations of both compounds are coupled via the reactions (8), (9) and (10).

$$2\,CO + 2\,H_2 \rightleftharpoons CH_4 + CO_2 \quad (8)$$

$$CH_4 + H_2 \rightleftharpoons CO + 3\,H_2 \quad (9)$$

$$CO + H_2O \rightleftharpoons H_2 + CO_2 \quad (10)$$

Molecular oxygen is not expected to arise, because of the large excess of hydrogen and because of the catalytic activity of palladium in the generation of water. Consequently, the removal of hydrogen in the Pd/Ag permeator will shift the thermodynamic equilibrium in the direction of carbon dioxide production.

Water present in the exhaust can be catalytically reduced by means of CO, which would have to be added, on

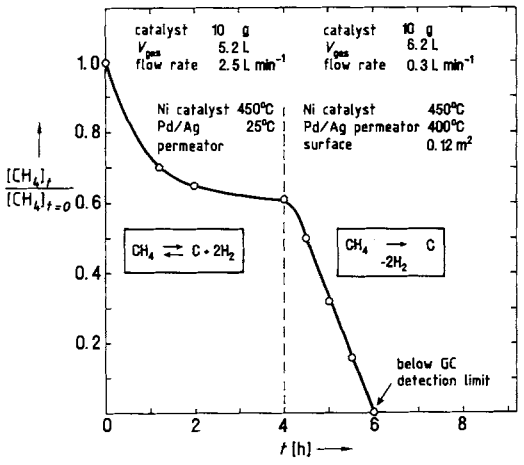

Fig. 16. The methane cracking reaction in a closed circuit at 450°C on a nickel catalyst, first without (left) and then with hydrogen removal by a Pd/Ag membrane (right) [29].

a Cr_2O_3/CuO bed at about 420 K. The final process step is the conversion on a bed consisting of palladium/silver permeator and nickel/aluminum oxide catalyst.

Figure 16 shows the results of equilibration experiments[29] which were run in a closed loop with a mixture of 40 vol.% methane (0.093 mol) in helium on a 10 g nickel/aluminum oxide catalyst at 720 K. It follows from Figure 16 that the mixture can be thermodynamically equilibrated within four hours.

Calculation of the methane equilibrium concentration as a function of pressure and temperature using thermodynamic standard data (Fig. 17) gives an excellent agreement

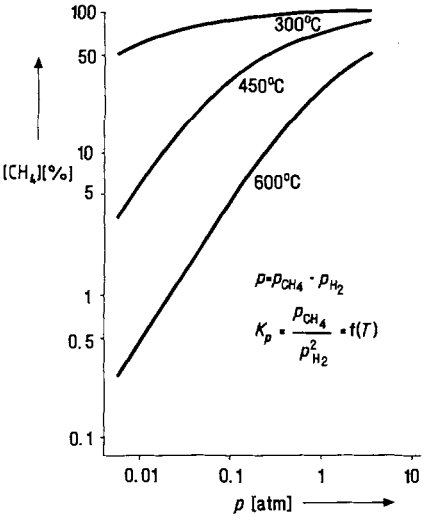

Fig. 17. Methane equilibrium concentrations at various temperatures as a function of the total pressure [29].

of the value calculated at 720 K for $p = 580$ mbar with that measured in the experiment described above. As the temperature of the catalyst is raised or lowered, the methane concentration follows the calculated curve, that is the reaction is reversible. A palladium/silver permeator integrated into the circuit and operated at ca. 675 K allows selective removal of the hydrogen produced, thus shifting the equilibrium to methane concentrations below the limit of gas chromatographic detection (Fig. 16). Because of the reversibility of the reaction, the carbon deposited on the catalyst during methane decomposition can be reconverted into methane by reaction with hydrogen at temperatures of 720–770 K.

This direct combination of cracking reactions and hydrogen permeation is likely to produce very high decontamination levels. Furthermore, no sizable amounts of waste, at least of waste which cannot be regenerated should be formed in this process, and thus loss of tritium ought to be minimized.

The hydrogen recovered and purified in one of the methods described above (decomposition of NH_3 and CH_4, reduction of H_2O with CO) can be decomposed into its isotopes either by cryogenic distillation,[45] thermodiffusion, or by means of gas chromatographic techniques.[46,47]

A fourth method of tritium enrichment by photochemical dissociation of tritiated trifluoromethane or similar compounds using laser radiation is still in the early stages of development and will therefore not be covered in greater detail here.[48] The basic principle of this technique is the excitation of the molecule, by means of a pulsed CO_2 laser, to such a level that it dissociates into CF_2 and TF. The reactive TF can be removed from the hydrocarbon stream by well-known techniques.

Also the question of tritium storage has largely been solved. In all modern techniques the tritium gas is converted at relatively low temperatures into a solid metal hydride (metal tritide) [Eq. (11)],[49] the metals used being preferably uranium, zirconium, and titanium. At higher temperatures, these metal hydrides again decompose into tritium and metal.

$$M + \frac{x}{2} T_2 \rightleftharpoons MT_x \qquad (11)$$

For instance, under equilibrium conditions, the tritium pressure across the UT_3/U system is 3.5×10^{-4} torr at 350 K and ca. 5×10^2 torr at 670 K.

The kinetics of hydride formation and decomposition, and the influence of gaseous impurities, such as air, or that of the decay of tritium (according to $T \xrightarrow{\beta^-} {}^3He$) producing ^3He, have been studied in great detail. One of the important considerations is that these metal tritides are stable under the usual storage conditions; thus, e.g., for zirconium hydride in air an ignition temperature between 720 and 830 K was observed, whereas uranium hydride is more pyrophoric.

The tritium stored in this way can now be released again as a gas and, after having been mixed with deuterium in a 1:1 ratio, can be fed back into the plasma chamber of a Tokamak reactor, where it can be ignited at high temperature (ca. 10^8 K). The rates of feeding the fuel and extracting the plasma gases are determined by the rated power of the reactor and the burnup of tritium and deuterium.

6. Blanket Chemistry

The blanket serves three purposes; firstly, it must not only accommodate the energy of the fusion neutrons, whose kinetic energy amounts to some 80% of the fusion energy, but also the energy released in the exothermal neutron capture reactions (such as $^6Li(n,\alpha)T$), which contributes another 12% to the total fusion energy, and convert this energy into heat to be removed from the blanket in a way suitable for further use. Secondly, it, i.e. its lithium part, represents the target material, with which the neutrons produced in the fusion reaction undergo nuclear reactions, to furnish the fuel required for fusion, namely tritium. Finally, the blanket also serves, at least in part, as a shield for the immediate environment of the fusion reactor, including the relatively sensitive superconducting magnets, against neutron radiation.

These criteria result in the following boundary conditions for the proper choice of blanket material:

1. It must enable a tritium breeding factor in excess of 1 to be achieved.

2. Extraction from the blanket of the tritium bred should be easy. It should be possible to minimize the tritium inventory in the blanket.
3. It may neither react with the material of the vessel nor with the coolant transferring the thermal energy from the blanket, e.g., to a steam generator.

As already mentioned in Section 3, the second part of the fuel cycle concerns the extraction of tritium from the breeding blanket, the purification of the tritium bred and its introduction into the plasma. An assessment, for this external fuel cycle, of the tritium breeding ratio vs. the losses and the retention time in the same way as made for the internal fuel cycle [Eq. (5)], and under the assumption that the losses can be restricted to 0.1%, as in the inner cycle, should give rise to the expectation that this time, the radioactive decay should play a more important role because of the expected longer retention time of the tritium in the blanket and especially if larger quantities are transferred to the cooling water ($f \geq 0.5$). For the chemist, this raises the problem of investigating those parameters for the potential breeder materials which determine the retention time and thus also the tritium inventory in the breeder blanket. In principle, two types of blankets are under consideration:[50]

1. The "liquid" blanket consisting of lithium metal or the eutectic lithium–lead mixture.
2. The solid blanket, for which mainly lithium compounds can be used, such as lithium silicates, titanates, aluminates, etc.

6.1. Liquid Metal Blankets

Let us first consider the case of a "liquid" blanket. In this category, only the so-called liquid metal blankets consisting of pure lithium metal or the eutectic lithium–lead mixture, $Li_{17}Pb_{83}$ (m.p. 508 K), must be seriously taken into account.[50,51] For both these materials a breeding factor in excess of unity has been predicted. Various methods of tritium extraction have been proposed for this type of blanket. The successful development of an extraction technique, however, requires that the fundamental physicochemical data be known, such as the solubility or distribution equilibria of the compounds to be extracted between the phases involved in extraction. Hydrogen is known to be dissolved in metals generally on an atomic basis. Its distribution between the metal and the gas phases is determined by the Sievert equation [Eq. (12)], K_S being defined by Eq. (13).

$$S = K_S p^{1/2} \tag{12}$$

$$\lg K_S = A + \frac{B}{T} \tag{13}$$

where S = solubility of hydrogen in the metal in atom-ppm (appm). K_S = Sievert's constant (appm torr$^{-1/2}$), p = hydrogen partial pressure (torr), A and B are constants (B is related to the dissolution energy).

The first task for the chemist, therefore, was to clarify whether this relation also applies under the conditions of fusion technology, i.e., at extremely low tritium concentrations and high temperatures. Investigations showed[52,53] that the equation (12) does indeed apply under all conditions related to fusion. At the same time, it was observed that the solubility of hydrogen in $Li_{17}Pb_{83}$ is several orders of magnitude lower than it is in pure Li metal.[53] This is due to the fact that the Li activity responsible for the solubility of hydrogen is largely reduced in the mixture as compared to pure Li. To illustrate these differences, let us assume that 1 appm of hydrogen is dissolved in each of these materials at 773 K; this results in an equilibrium partial pressure of hydrogen over Li metal of 2×10^{-11} torr, while, in the case of the Li–Pb mixture, it is already 4×10^{-2} torr.[54] From this standpoint it would seem much simpler to extract tritium from the $Li_{17}Pb_{83}$ mixture than from lithium metal.

Despite the relatively high solubility of tritium in lithium metal, recent mass spectrometric investigations[55] have drawn attention to a possibility of separating tritium from lithium by high-temperature distillation. Experiments have shown that the tritium compounds formed at temperatures above 1300 K are mainly those of the LiT and Li_2T types, whose equilibrium partial pressures are a factor of 40 and more above that of T_2 over the metal. It should therefore be possible to remove the tritium from the Li metal by high-temperature distillation outside the blanket (in a secondary circuit).

Another method of T extraction could make use of the freezing out of tritium in a cold trap at 78 K.[51] However, as the solubility of tritium in lithium is still very high at that temperature (estimates range between 200 weight-ppm (wppm) and 2700 wppm), the tritium inventory in a lithium blanket of 1630 m^3 typical for an energy producing power reactor would still be unrealistically large (160–2200 kg), and it is for this reason that the application of this technique is no longer under serious consideration.

More opportunities are thought to lie in the application of getters for the extraction of tritium from Li metal.[51] The passage of liquid lithium over a bed of porous getter materials is under discussion. Various metals such as yttrium and cerium and their alloys are at present under investigation regarding their gettering capabilities.[56] For removal of tritium from and regeneration of the getters, they are removed from the lithium stream and heated in a vacuum. The problems associated with this technique, and relevant exploratory studies still to be carried out will be dealt with in greater detail in the discussion of Li–Pb blankets.

Another technique is tritium extraction into a salt melt.[57] In this case, the liquid lithium metal is brought into close contact with a melt of LiF–LiCl–LiBr, with which Li metal is not miscible, outside the blanket at 445 °C. Since tritium has a much higher solubility in the salt melt than in the metal, this method of extraction can reduce the tritium concentration in Li metal to less than 0.5 wppm, i.e., at an assumed blanket volume of 1630 m^3, the tritium inventory in the blanket would represent an acceptable level of ca. 400 g. However, one grave disadvantage of this method is the presence of halogen ions in the blanket material and the associated hazard of enhanced corrosion of the structural materials.

The extraction of tritium from the Li–Pb alloy, $Li_{17}Pb_{83}$, can be achieved by techniques similar to those employed in the extraction of tritium from Li metal.[26] One major advantage is the considerably higher tritium equilibrium partial pressure over the metal mixture. Therefore, the tritium can conceivably be removed by simply pumping off the gas phase over the metal phase or by permeation through suitable membranes.[58] However, there is still the drawback of the equilibrium pressure not being established fast enough for practical application, because of the relatively slow kinetics of the diffusion process. Efforts are under way to accelerate this process by scrubbing the tritium in the Li–Pb alloy with helium gas in a countercurrent flow process.[59] At present, this is believed to be the most promising process.

As in the extraction of tritium from Li metal, in this case also the removal of tritium by means of suitable getters is under discussion; given the low solubility of T in $Li_{17}Pb_{83}$, this technique should be easier than with lithium metal.[57] Yttrium for example has a solubility for tritium at 500°C which exceeds that of $Li_{17}Pb_{83}$ by a factor of 2×10^5; i.e., if 1800 t of blanket material (tritium equilibrium partial pressure, 10^{-4} torr) is brought into contact with only 20 kg of yttrium getter, only 1.3 g of tritium would remain in the blanket, while 6.7 g of tritium would be taken up by the getter, provided that there is always enough time for the equilibrium to adjust. The use of getters has so far always failed because very little is known about the compatibility of the getter materials envisaged, such as U, Zr, Ti, and their alloys, with the Li–Pb mixture. Also the kinetics of the tritium uptake by the getters is largely unknown, although this is a factor of decisive importance for their practical application. Furthermore, very little information is available about the extent to which the effectiveness of getters is influenced by the presence of impurities such as O, N, C, etc. in the Li–Pb mixture.

6.2. Solid Blankets

In the case of solid blankets, mainly ceramic materials, such as lithium compounds of the type Li_2O, γ-$LiAlO_2$, Li_5AlO_4, Li_2SiO_3, Li_2TiO_3, Li_2ZrO_3, and Li_4SiO_4 are to be used. In all these cases, perhaps with the exception of LiO_2, neutron multipliers, such as beryllium, will be required to achieve a breeding factor >1. Once again the chemists contribution to this field primarily concerns the determination of the physicochemical data of these materials, as these are most important both in the successful planning of tritium extraction and in the selection of the structural material that comes into contact with the blanket. Criteria influencing the choice of material in this case are, inter alia, the rate of tritium release and the expected tritium inventory in the blanket, which is determined by the tritium adsorbed, dissolved and bound to defects, and by the thermal stability. All these parameters are summarized schematically in Figure 18. Especially the fraction of tritium bound to defects is likely to depend very strongly on structural changes of the material in the radiation field.

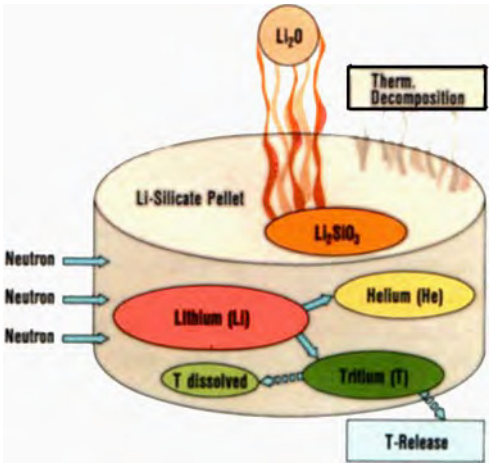

Fig. 18. Schematic diagram of the thermal decomposition of the blanket material (Li_2SiO_3) and of the processes associated with the generation and release of tritium.

Of particular interest in this connection[60] are the studies in which the production and the release of the tritium generated in the $^6Li(n,\alpha)T$ reaction in Li_2O has been monitored. In the author's opinion, the tritium may initially be present in Li_2O both as a neutral atom as well as a positively or a negatively charged ion (Fig. 19). The neutral

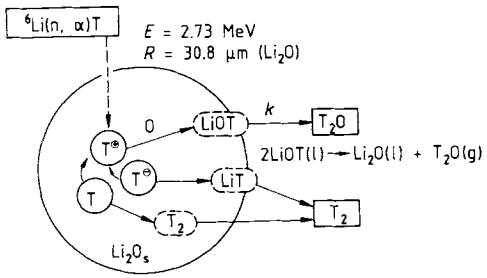

Fig. 19. Schematic representation of the reactions associated with the generation of tritium and its subsequent release in Li_2O [60].

particles produce molecular T_2, which diffuses out of the crystal, while the positively charged tritium on the surface produces first LiOT and then T_2O. Consequently, the negatively charged tritium should produce LiT as an intermediate stage on the surface, and then finally T_2. The rate-determining step in the release of T_2O at low temperatures ($T<570$ K) is the dissociation of LiOT on the surface, whereas, at higher temperatures, it is the diffusion of $T^{\oplus}$ which determines the course of the reaction. In agreement with numerous other findings it can be summarized that the transport of tritium inside the compounds under investigation is determined by diffusion at fusion-related temperatures. Some of these findings are reproduced in Figure 20,[61] where the diffusion constant is plotted as a function of temperature for a variety of possible breeder materials. It follows, e.g., that the diffusion constant of tritium is several orders of magnitude higher in the liquid blanket materials than in the ceramics, as was to be expected.

These studies also revealed that the activation energy for the diffusion is relatively high,[62] that, e.g., in β-Li_5AlO_4 particles with a diameter of 200 μm an average retention time of 4 s was measured at 1273 K, whereas at 873 K it was a factor of 100 greater. However, as there will always be temperature gradients, because of the geometry of the blanket, clear differences in tritium retention in various regions of the blanket must be expected, which must be taken into account in calculating the tritium inventory.

A factor of decisive importance with regard to the suitability of a ceramic material as a blanket material is its low solubility for hydrogen. Although data on the diffusion of hydrogen isotopes in ceramic blanket materials have been published by several groups of authors (see Fig. 20),[61,63]

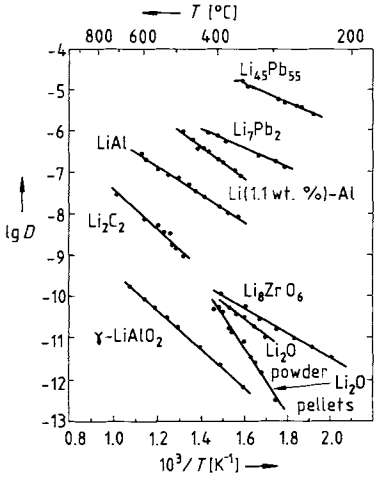

Fig. 20. Diffusion constant D [$cm^2\ s^{-1}$] of tritium as a function of temperature in a number of potential blanket materials [61].

very little has thus far been reported about the physical solubility of tritium in such materials.[64] One main reason for this lack of information obviously lies in the basic difficulties of measuring these quantities.

More recent volumetric measurements, and measurements with radioactive tracers,[65] indicate very low solubilities of ca. 10^{-5} mol hydrogen/mol Li_2SiO_3 at temperatures between 720–820 K. The results are reproduced in Figure 21 together with the hydrogen solubilities in some other solids.[65] The measurements also showed, however, that impurities in these ceramics may lead to clearly different results. Very little is known at present about the effects of radiation induced defects on the solubility.

The diffusion measurements available to date seem to favor a lower blanket operating temperature of 570–600 K, i.e., a temperature at which a sufficiently rapid hydrogen transport may be expected. The upper temperature limit is given by another property of these materials, namely their property of losing their porosity, or of sintering, at higher temperatures.[50] This normally occurs at temperatures above 0.8 T_m, T_m being the temperature of the absolute melting point. Above this temperature the thermal sintering process begins, generally between 1070–1570 K. Since it is known that radiation effects can lead to the so-called closure of porosity even at low temperatures, detailed investigations must be carried out in the future into the influence of radiation on the thermal stability of these compounds. At present, very little is known about these effects, nor about the question as to what extent radiation-induced defects may influence the diffusion of tritium, or what kind of barriers they represent to T diffusion.

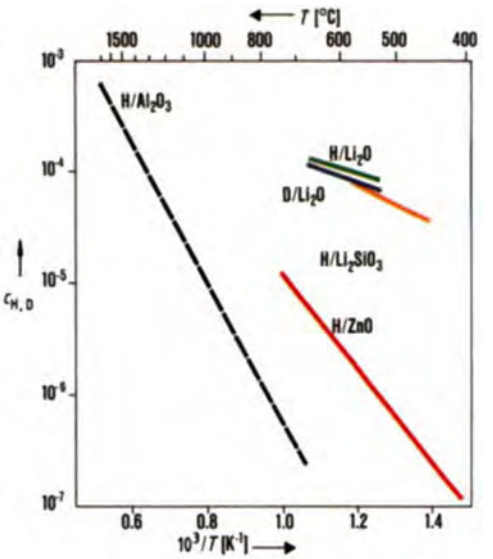

Fig. 21. Hydrogen solubility c [mole fraction] as a function of temperature in various ceramics [65].

As far as the process of thermal release is concerned, the rate-determining step is the diffusion of tritium through the interior of the solid, as has been explained above (Fig. 19). In this connection it should be pointed out that in studies in which T was produced in the reaction $^6Li(n,\alpha)T$, this tritium occurred as HTO if the reaction took place in oxygen-bearing compounds,[60] whereas it was found as HT in oxygen-free compounds.[66] Since the range of the recoil tritium particle generated in the nuclear reaction is very short, and since tritium cannot be expected to diffuse through the interior of the solid as HTO, it may be concluded that the reaction between the "hot" recoil T particles and their environment has only very little influence on the form in which tritium leaves the solid. Especially at the high temperatures prevailing in the blanket, there will be surface reactions between the tritium compound and the blanket materials which will determine the final chemical form of the tritium extracted or released.

A conclusive answer to the question of whether and with what efficiency tritium can be extracted from various blanket materials, can best be found by appropriate exploratory experiments. Such experiments are at present under way in various places. The results so far have been quite encouraging. For instance, a research team from the Argonne National Laboratory has been able to show in a neutron irradiation experiment conducted in the Oak Ridge research reactor that more than 99.9% of the theoretical amount of tritium to be expected can be extracted as tritium gas from a solid Li ceramic at temperatures between 860 and 920 K.[93]

In a ceramic blanket, extraction of tritium by means of the propellent gas flow (helium) seems to be the simplest method.[25,67] Separation of the tritium, which, as has been

borne out in the Argonne experiments, is present as T_2, perhaps together with small amounts of HTO, can be achieved by a variety of processes, whereby similar considerations apply as for the methods used in plasma exhaust purification (Section 5).[26] One such process is based on the catalytic combustion of tritium to produce HTO or T_2O and its subsequent condensation in a cold trap or on a molecular sieve.[68] The water arising must be decomposed either by reduction on a hot metal bed (uranium)[69] or—as has recently been proposed—electrolytically, before the hydrogen mixture can be subjected to isotope separation.

The reduction step with uranium is expensive and gives rise to waste problems, as has been mentioned in Section 5.1.2. The electrolysis of tritiated water with a high specific activity of T, however, raised a number of problems, for which a solution was found only recently in the development of new types of electrolysis systems. In conventional electrolysis systems using aqueous KOH as the electrolyte, the tritium–hydrogen exchange, e.g., would result in considerable tritium enrichment in the electrolyte, thus increasing the tritium inventory to unduly high levels. In addition, there would be the problems of waste disposal and tritium recovery from the electrolyte. More recent developments in this field therefore depart from a particularly compact design with extremely low electrolyte volumes.[70] In a different type of electrolyzer using solid electrolytes, such as synthetic polymers, there is the problem of radiation-induced damage to these membranes, and no satisfactory solutions have as yet been found for long-term operation.

Another modern development, high-temperature electrolysis,[71] uses an inorganic solid electrolyte of stabilized ZrO_2-ceramics (Fig. 22), which remains in place and undergoes no change during operation of the electrolytic plant. The plant can be run at 370–1270 K. The water vapor supplied is decomposed on the cathode side of the electrolysis membrane under the influence of the applied voltage.

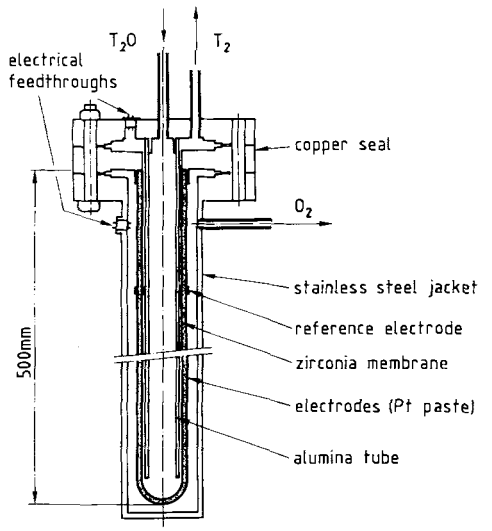

Fig. 22. Schematic representation of a high-temperature cell for the electrolysis of tritiated water [71].

With regard to the thermal stability of blanket materials, there is not only the question already dealt with of changes in porosity as a function of temperature, but also the problem of thermal decomposition of the compounds and the associated formation of aggressive products which could contribute to corrosion in the structural materials. Such studies[72–75] have been and are being carried out with Knudsen effusion cell mass spectrometers, which allow the species generated at higher temperatures to be identified and quantified (vapor pressure). The compounds to be studied are heated to a precisely set high temperature in the Knudsen cell and the gaseous species are fed into the ionizing chamber of the mass spectrometer, ionized, and measured. A vapor-pressure curve measured in this way for Li over Li_2SiO_3 as a function of temperature is shown, for example, in Figure 23.[76]

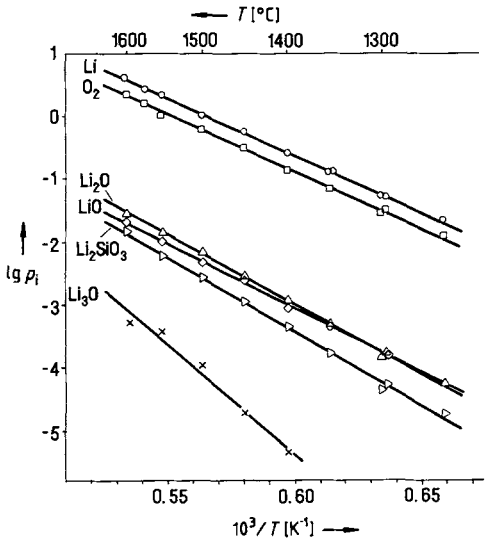

Fig. 23. Partial saturation vapor pressures p_i [Pa] over Li_2SiO_3 as a function of temperature [76].

The other purpose of the blanket is to transform the kinetic energy of the neutrons produced during fusion into heat, and to transport this heat to a steam generator. This requires a coolant, which probably will be water, because of its widely known advantages. Another possibility would be helium gas.

6.3. Tritium Removal from the Coolant

The problem associated with the use of water is that, because of the low solubility of tritium in most blanket materials, which is one of the very reasons for this choice of material, the equilibrium partial pressure of the tritium over the liquid or solid blanket will be relatively high. This means that there will be substantial diffusion of tritium through the walls of the pipes into the cooling water at the blanket temperatures of more than 600–800 K. The extent of this diffusion will be illustrated by way of an example: for a hydrogen concentration of 1 appm in the lithium metal, the equilibrium partial pressure of hydrogen over the metal is 2×10^{-11} torr at 770 K. *Sievert*'s constant for stainless steel (SS 316) is 9.1, which leads to a diffusion of

4×10^{-5} cm^3 of hydrogen per hour (at STP) through a wall area of 1 m^2 at a wall thickness of 1 mm. This corresponds to ca. 10^{-4} Ci of tritium per hour.[54] In the case of $Li_{17}Pb_{83}$, where the partial pressure of the oxygen is considerably higher under the same conditions (4×10^{-2} torr), the same line of reasoning will lead to a diffusion of 1.8 cm^3 or 4.8 Ci per hour (at STP). Naturally, this equilibrium partial pressure will not be attained if the tritium gas over the blanket is continuously extracted or removed by means of helium gas. However, it must be assumed that considerable quantities of tritium will probably enter the cooling water, and will have to be removed periodically; in addition to this, there is the cooling water used for cooling the first wall, into which also major amounts of tritium are going to diffuse (Fig. 24). Other tritium-bearing aqueous solutions arise during decontamination of the exhaust air from rooms and boxes by oxidation of the tritium.

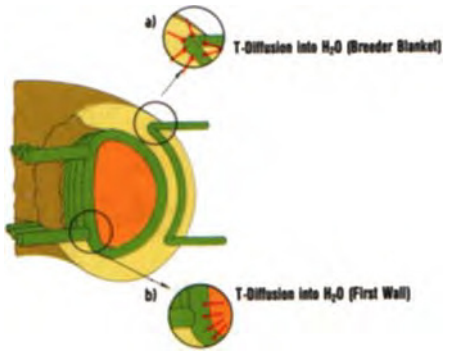

Fig. 24. Schematic diagram of tritium diffusion into the cooling water. a) Tritium diffusion into the cooling water of the breeding blanket (heat decrease); b) tritium diffusion into the cooling water of the first wall.

At present, only very crude approximations of the permeation of tritium into the cooling water can be made. In a power-producing reactor, an equilibrium permeation rate into the cooling water of 10^2–10^4 Ci of tritium per day is generally assumed. It has been suggested that the tritium concentration in the cooling water should be limited to 2–10 Ci per liter, which could be achieved by the detritiation of ca. 1000 liters per day for the cooling water volumes assumed above. Various methods are available for this purpose. Fractional distillation of water, a step used in water treatment or as the final process step in the production of heavy water, where the dilution factor (the ratio D/H or T/H in the water) is between 10^{-1} and 10^{-2}, cannot be used for the depletion of tritium in cooling water because the dilution factor in this case will be below 10^{-7}. Consequently, more effective enrichment processes must be used before the tritium-enriched hydrogen stream is subjected to cryogenic fractionation. Three of the procedures studied most intensively in this connection will be briefly discussed here.

The first process is *v*apor *p*hase *c*atalytic *ex*change (VPCE),[77] in which the catalytic exchange is brought about in the countercurrent flow [see Eq. (14)] at operating

$$HTO_{gas} + H_2 \overset{cat.}{\rightleftharpoons} H_2O_{gas} + HT \qquad (14)$$

temperatures of ca. 500 K, i.e., with superheated steam. The advantage of the method lies in the fact that the catalyst is not inactivated by liquid water. On the other hand, there is the disadvantage that the process needs to be run in several cascades, thus requiring a relatively extensive system including repeated evaporation, superheating, and condensation of the water, and involving a considerable consumption of energy.

The second process is *l*iquid *p*hase *c*atalytic *ex*change (LPCE)[78] on a hydrophobic catalyst [Eqs. (15) and (16)].

$$HTO_{liquid} + H_2O_{gas} \overset{cat.}{\rightleftharpoons} H_2O_{liquid} + HTO_{gas} \qquad (15)$$

$$HTO_{gas} + H_2 \overset{cat.}{\rightleftharpoons} H_2O_{gas} + HT \qquad (16)$$

In the process, tritium is exchanged between tritiated water and gaseous hydrogen in a countercurrent flow process.

The third process is *c*ombined *e*lectrolysis–*c*atalytic *ex*change (CECE). In this case, as shown in Figure 25, the cooling water is supplied to the column containing the hydrophobic catalyst. It exchanges with the tritium-bearing hydrogen stream generated in the electrolyzer, whereby tritium is further enriched in the water [Eq. (17)].

$$HT + H_2O_{liquid} \overset{cat.}{\rightleftharpoons} HTO_{liquid} + H_2 \qquad (17)$$

The tritium-enriched liquid water enters the electrolyzer, where it is dissociated again. Part of the tritium-bearing hydrogen stream enters the low-temperature rectification column, while the remainder, as described above, is passed to the catalytic column for exchange with the tritiated water. The hydrogen stream is burnt with oxygen at the head of the exchange column.

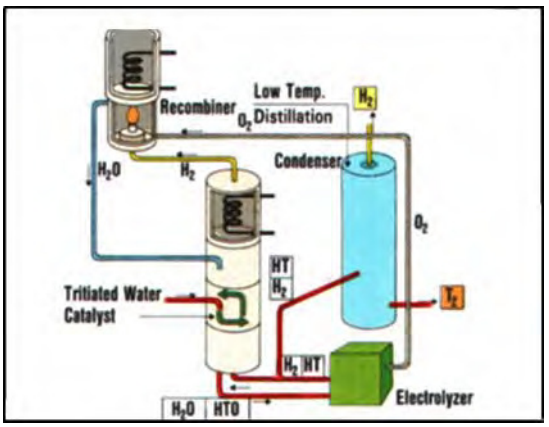

Fig. 25. Schematic diagram of tritium enrichment by the CECE method [79].

Prerequisite for the successful application of the latter two processes was the development of a hydrophobic catalyst,[29,80] which also had to meet stringent criteria of stability, abrasion resistance, radiation stability, and relative insensitivity to impurities because of the problems associated with the waste management of material contaminated with tritium. Catalysts of this kind, which work on a Pt–carbon–teflon basis, have been known for some time. Specific further development of these materials has enabled catalysts

to be developed which fully satisfy the aforementioned criteria.

Other procedures which have been proposed for the separation of tritium from aqueous solutions are based on the application of lasers, e.g., the process of selective dissociation of the C-T bond in trifluoromethane, in which case a transfer of the tritium bound in the water to the trifluoromethane gas must first be achieved,[48] or the photochemical dissociation of tritiated water in the presence of solid-state catalysts such as Pt on TiO_2, which are distributed as colloids in the aqueous phase.[81] The catalytic reduction of tritiated water by carbon monoxide (water-gas reaction) is also envisaged.

However, if the diffusion of larger quantities of tritium into the coolant must be reckoned with, the choice of procedure will depend on the respective characteristic retention time of tritium or on the tritium inventory in the individual systems. In this respect, the CECE process is likely to surpass all other procedures, except perhaps the laser separation.

7. Analysis

The analytical problems arising in the fuel cycle of a fusion reactor have been hinted at very briefly under the headings of the different systems. Thus, in the case of plasma exhaust purification, aside from plasma diagnostics, concentration assays of the tritiated impurities must carried out quickly and, whenever possible, under flow conditions. Conventional methods may be employed for this purpose, such as mass spectrometry, FT-IR spectrometry and laser Raman spectrometry, but they will all have to be adapted to special conditions, especially for on-line operation.[82]

Determination of the properties of materials, diffusion, etc. requires the use of thermochemical methods such as thermogravimetry, X-ray diffraction, electrochemical Knudsen effusion cell mass spectrometry and, in particular, techniques of surface analysis, such as ESCA and Auger spectroscopy, and secondary ion mass spectrometry, to study the reactions largely proceeding on the surfaces of getters.[83] Quality control, e.g., in the production of blanket materials, is achieved in the usual way by optical spectrometry (AAS, AES, AFS, etc.) and also by X-ray fluorescence and neutron activation analysis.

Difficulties arise, however, in the continuous checks for impurities in a liquid metal blanket, for which no methods are as yet available that have been tested under realistic conditions. As already mentioned in Section 6, one important aspect in the choice of the blanket is its compatibility with the structural materials surrounding it. In a liquid metal blanket there is also the influence of impurities on the aggressiveness of the blanket material towards the structural material, which may lead, e.g., to locally enhanced corrosion. There is. therefore, the urgent need to monitor continuously for such impurities as nitrogen, hydrogen, oxygen, and carbon in the liquid metal blanket.

For hydrogen and carbon, monitors have been proposed[84] which are based on the principle of the diffusion of these impurities through suitable membranes at elevated temperatures. As is seen in Figure 26, such an in-line hydrogen monitor consists of an α-Fe membrane, which, at an operating temperature of 350°C, permits the diffusion of hydrogen, which is then pumped off in a controlled way. The resultant hydrogen partial pressure is measured.

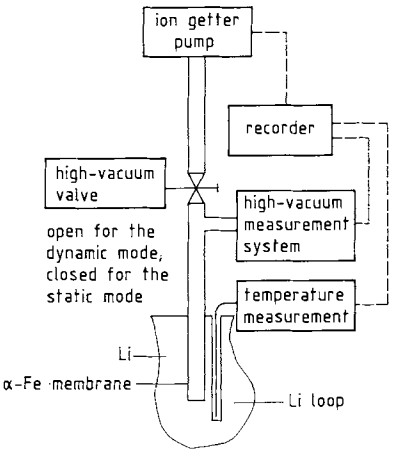

Fig. 26. Schematic diagram of the in-line hydrogen monitor [84].

In the carbon monitor, the carbon likewise diffuses through an α-Fe membrane, but at a temperature of 500°C. The iron oxide coating on the inside oxidizes the diffusing carbon to CO, which is determined by flame photometry either in this form or after catalytic conversion into CH_4.

The in-line oxygen and nitrogen monitors,[84] which are still at the experimental stage, are based on the electrochemical principle. A measuring setup of this kind is outlined in Scheme 1 for the case of oxygen, and in Scheme 2 for the case of nitrogen.

$$\mathrm{Li(O)\ //\ \overset{\text{solid electrolyte}}{ZrO_2\cdot MgO}\ //\ \overset{\text{reference electrode}}{In-In_2O_3}}$$

or

$$\mathrm{Li_{17}Pb_{83}(O)\ //\ (ZrO_2-MgO\ or\ ThO_2-Y_2O_3)\ //\ In-In_2O_3}$$

Scheme 1. Measuring set-up of an in-line oxygen monitor.

$$\left.\begin{matrix}\mathrm{Li(N)}\\ \text{or}\\ \mathrm{Li_{17}Pb_{83}(N)}\end{matrix}\right\}\ \mathrm{//}\ \overset{\text{solid electrolyte}}{(AlN)}\ \mathrm{//}\ \overset{\text{reference electrode}}{(Cr-Cr_2N)}$$

Scheme 2. Measuring set-up of an in-line nitrogen monitor.

In both cases the problem is the lack of compatibility of the solid electrolytes with the liquid metals, Li or $Li_{17}Pb_{83}$, which leads to rapid decomposition. The development of more resistant systems will pose major problems to electrochemists.

8. Safety Aspects in Fusion Reactor Operation

As unavoidable as the diffusion of tritium into the cooling water will be the release of non-negligible quantities into the glove-box atmosphere, in which many of the processes described here will have to be carried out, and, of course, into the environment of the fusion reactor.

Removing tritium from a glove-box atmosphere no longer poses any problems. The procedure is based on the catalytic combustion of hydrogen and subsequent adsorption of the water onto suitable materials.[26] Another method, which has already been used for test purposes, employs the catalytic addition of hydrogen to a carbon–carbon double bond in suitable organic compounds, such as linoleic acid.[85] In this case, the glove-box atmosphere is pumped in a countercurrent flow through a linoleic acid solution containing a platinum catalyst. From the waste disposal point of view, however, the addition to a solid compound would be preferable. Consequently, certain types of organometallic compounds have been proposed which might act as getters for T_2 or HT. In this case, the tritium is expected to attach to a carbon–carbon double bond or triple bond in the compound, with this step being catalyzed by a heavy metal atom present in the molecule.[86] However, investigations with these compounds showed that, in the presence of oxygen, the same catalyst also promotes the oxidation of tritium to water, thus destroying the advantage of the method, which is the immobilization of tritium in a solid form without producing the radiologically more dangerous intermediate product, water. As a consequence, these materials surely cannot be used for the detritiation of the exhaust air from rooms, for which so far the conventional method of catalytic combustion of tritium and subsequent absorption in molecular sieves is foreseen.

It would be worthwhile, however, to find a catalyst able to induce an effective combustion of small quantities of tritium in air at room temperature, because it is uneconomical, although still required at the present time, to maintain a large catalytic bed at elevated temperatures. Some recent studies[87] have already improved our understanding of the kinetics controlling the oxidation of tritium to tritiated water with atmospheric oxygen; progress has been made in the development of catalysts meeting the required specifications on the basis of platinum/Al_2O_3, palladium/kaolin and palladium/zeolite. However, they have not yet reached the stage of development for use as reliable emergency purification systems. In all these processes, the water produced is subsequently adsorbed on molecular sieves.

Monitoring the tritium activity in the reactor building as well as the amount of tritium released into the environment with the exhaust air requires detectors which can measure maximum concentrations of tritium as HTO of 5×10^{-10} g T per m^3 of air, which is the maximum permissable exposure level for working in controlled areas, up to 10^{-12} g/m^3 in controlled areas outside reactors which is the maximum permissible exposure level for personnel not under occupational surveillance.

The most sensitive technique in use at the present time operates in the batch mode and is based on the catalytic combustion of the gaseous, tritium-bearing substances encountered, such as T_2, HT, etc., the adsorption of the HTO produced, and the measurement of its amount by liquid scintillation spectrometry.

Continuous monitoring for gaseous T-compounds, especially of HT or T_2 in the presence of γ-radiation and in the presence of radioctive noble gases, such as Kr-85, Xe-133, etc., is possible with most monitors now commercially available. The simplest versions consist of three ionization chambers in a sandwich structure and work according to the principle of anticoincidence counting.[88] The smaller inner chamber is dimensioned so as to be just large enough to absorb quantitatively the soft β-radiation from tritium (< 0.018 MeV). It is permeated by the gas stream to be monitored. The more energetic radiation or external γ-radiation emitted by the other radioactive noble gases (fission product gases, etc.) penetrates the wall of this counting chamber and is registered in one of the two closed outer counting chambers. Only signals resulting from the inner counting chamber, which are not coincident with signals from one of the outer counting chambers, are due to the decay of tritium and are registered.

Depending on their design, the dynamic range of such detectors is between 10^{-2} and 10^{7} μCi m^{-3} in the presence of γ-radiation and radioactive noble gases, and thus includes the permissible concentration of 5×10^{-3} Ci of HT or T_2 in controlled areas. Another type of detector[89] is based on the following principle: The pulse rise time in a proportional counter is a function of the speed at which the electrons (β-particles) arrive at the counting wire. The shorter the range of the β-particles the smaller will be the fluctuations in their arrival time. If one plots the observed relative count rate as a function of the pulse rise time (Fig. 27), two clearly different regions are found, in which only the signals registered under A are due to the decay of tritium and will be registered. When using counters of this type with a volume of 3 L, 2×10^{-8} g m^{-3} or 2×10^{-1} μCi m^{-3} of tritium can be detected in the presence of comparable Kr-85 activities.

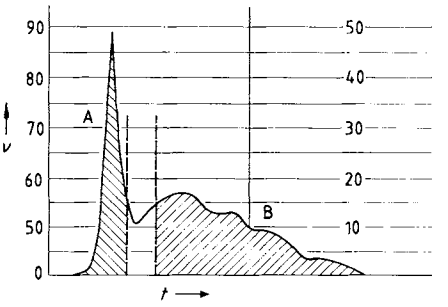

Fig. 27. Relative count rate ν vs. pulse rise time t in a Berthold-type tritium monitor [89]. Background: 1000 cpm (counts per minute); T: 300 cpm; measuring time 20 min; relative flowrate air/methane = 1/4.

In this connection, reference should also be made to the need to detect tritium separately in all its forms, because its radiological toxicity depends strongly on its presence, e.g., as HT or T_2 or as the much more dangerous HTO or T_2O.[90]

The radiological toxicity of tritiated water is roughly a factor of 25000 greater than that of HT or T_2, because most of the inhaled tritium is exhaled again, and the permeability of human tissue is lower for HT than for HTO.

In the tritium flow monitors used so far, a selection of the tritium compounds was achieved by a two-chamber system in which one chamber measured the bulk tritium, while the other measured only tritium present as HT or T_2,

after water had been removed in an upstream molecular sieve.[88] A more recent discovery[88] makes use of the property of Nafion, a polymeric fluorohydrocarbon, whose permeability for water is up to a factor of 10^4 higher than it is for hydrogen. The principle of such a monitor can be seen from Figure 28. It consists of two concentric cylinders with a partition wall made of Nafion. The gas stream under investigation, which contains HTO, HT, and possibly radioactive noble gases, flows into the inner cylinder, HTO enters the outer cylinder through the membrane and is scavenged into a separate detector, while HT and the noble gases are measured in a conventional T-detector, as explained above.

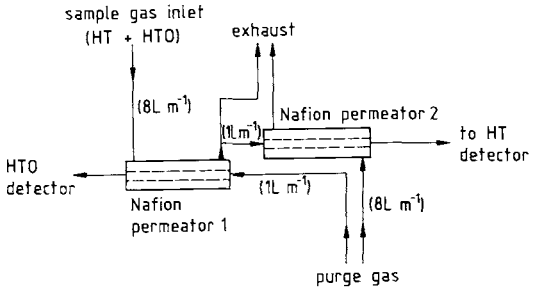

Fig. 28. Schematic diagram of a tritium monitor for simultaneous measurement of tritium gas and tritiated water [88].

A very decisive factor in the operation of a fusion reactor will be the minimization of tritium losses to the environment. As has been discussed above in more detail, this is necessary, on the one hand, for economic reasons. On the other hand, however, the acceptance of this new way of generating energy will also depend on our ability to ensure that radioactive contamination of the environment is minimized by the retention of tritium in a fusion reactor, e.g., by a system of in-depth containments. According to current technical experience in this sector[91] it would seem possible to limit the escape of tritium into the atmosphere to 2 g of tritium annually during the normal operation of a fusion reactor. On this basis, a maximum radiation dosage under the most adverse conditions and for the most highly exposed person permanently staying at a distance of 1 km from the reactor would be 1.5 mrem/a. The average exposure level for those living within a radius of 50 km from the reactor would then be 0.001 mrem/a. These levels correspond to some 0.75 and 0.005%, respectively, of the average natural radioactive dose of 200 mrem/a in the Federal Republic of Germany and are clearly well below the local variations in dose levels due to natural radioactivity.[90]

Chemists must, however, devote special attention also to those measures which can contribute to a minimization of tritium-bearing and tritium-contaminated wastes. In designing flowsheets and selecting the methods available for each process step, the handling of radioactive wastes and their disposal must also be taken into account. In addition, the decontamination of surfaces contaminated with tritium is of special importance, particularly if one considers the huge dimensions of the components of a future fusion reactor. Consequently, chemists will also have to develop new and more effective methods of surface decontamination, which in turn demands a better knowledge of the chemical processes leading to contamination.

The fusion reactor will not only produce tritium but also a number of other radioactive products arising as a consequence of the irradiation of structural and blanket materials with neutrons.[90,92] The amount of radioactivity generated in this way will depend largely on the elemental (and isotopic) compositions of the materials used. It is to be expected that it will be possible, in the course of future developments, to manufacture materials containing mainly those isotopes of the elements used which, like the Mo isotopes of masses 95, 96 and 97, will produce only limited amounts of radioactive nuclides or, at least, no long-lived radionuclides upon neutron irradiation. Another important factor will be the use of blanket material of extremely high purity; this will lead to a substantial reduction in the radioactivity produced by neutron bombardment of the impurities. It should also be pointed out that, in contrast to the radioactive wastes arising in fission reactors, in the case of fusion reactors no long-lived α-emitters are produced.

The influence of the material of the first wall on its specific activity is shown in Figure 29. If current commercial steel grades, such as AISI 316 are used, the activity inventory will be roughly 10^{10} Ci after five full-load years, with a loading of the first wall of 10 MW per year and m^2.[90] This corresponds to the activity inventory of a fission reactor of the same electric power. If low-activation materials are used, such as a vanadium-chromium-titanium alloy (V15Cr5Ti), this inventory is already one order of magnitude lower. Further development in this direction seems to be possible.

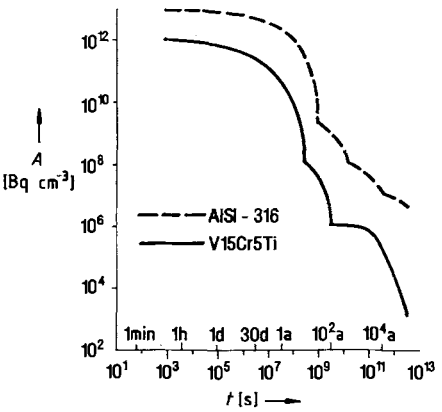

Fig. 29. Specific activity A of the first wall of a fusion reactor for two different wall materials as a function of time [90].

9. Concluding Remarks

An attempt has been made in this article to outline the problems that chemists have been faced with, and will be facing, in the development of fusion technology. These problems will continue to make very great demands on the capabilities of chemists. The challenge is great but not insurmounable given the possibilities and facilities of modern chemical research and process engineering.

The author would like to express his deep gratitude to his staff at the Institute for Radiochemistry, and especially to Drs. Penzhorn, Ihle, Glugla, Albrecht and Willin, for their enthusiasm and valuable assistance in drafting the manuscript and to Ms. Pfennig for her help in reviewing the manuscript and compiling the references.

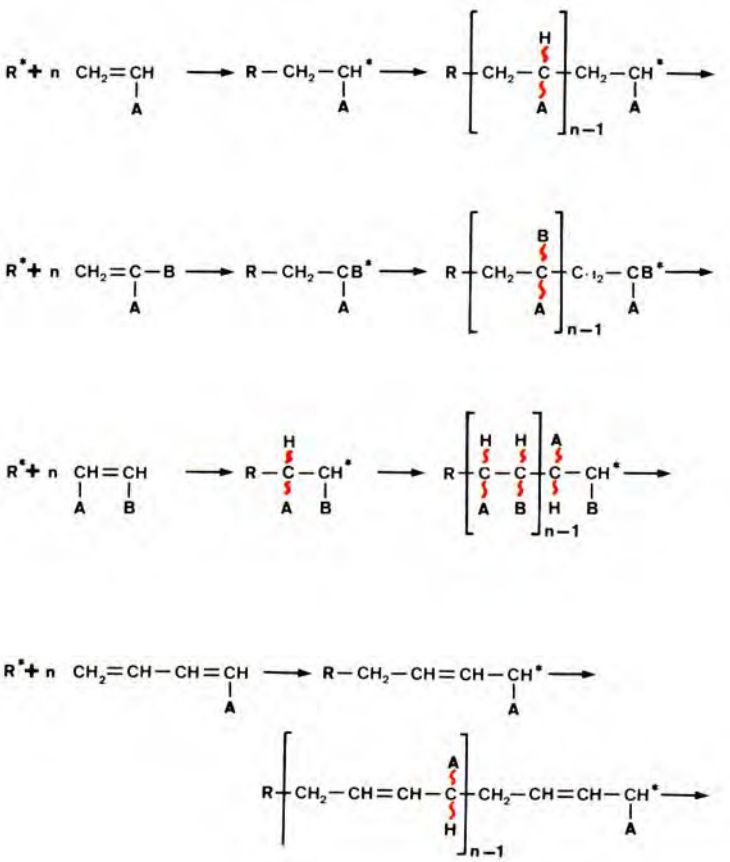
Main-Chain Chirality and Optical Activity in Polymers Consisting of C–C Chains**

By Günter Wulff*



Main-chain chirality is the optical activity resulting from the configurational or conformational arrangement in the main chain of a polymer. The chirality of the most important types of structures has been investigated on the basis of systematic considerations of symmetry. This has led to the surprising result that even in polymers derived from 1-substituted or nonsymmetric 1,1-disubstituted olefins (the technologically most important polymers) several types of chiral structures exist, which are expected to result in optical activity if a particular enantiomer is favorably formed. By carrying out an asymmetric cyclopolymerization, it has been possible to obtain certain structural types in the form of optically active copolymers or homopolymers (e.g., copolymers of styrene with methyl methacrylate, or even the homopolymer of styrene). Another new group of optically active polymers consists of the atropisomeric helical polyisocyanides, poly(trityl methacrylates), and polychlorals. Optically active polymers are already used as adsorbents for the chromatographic separation of racemic mixtures. Further applications are likely to emerge.

1. Introduction

Polymers consisting of C–C chains are mainly obtained by polymerization of unsaturated monomers (e.g., ethylene, 1-substituted or 1,2-disubstituted olefins, butadiene, or substituted 1,3-dienes). Polymers formed from 1-substituted olefins are usually termed, according to the nature of the substituents, polyolefins, vinyl polymers, or polyacrylates; those formed from 1,1-disubstituted olefins are called polyolefins, vinylidene polymers, or polymethacrylates. For the substituted monomers, as can be seen from Scheme 1, each propagating step during the polymerization results in the formation of a new stereogenic center[***] with four different substituents. This holds good for free radical, anionic, cationic, or coordination polymerization. With increasing degree of polymerization the number of possible diastereomers rises rapidly.

Following the discovery of stereoregular polymerization using Ziegler–Natta catalysts,[5] the stereochemistry of such chains was studied in great detail (for reviews see, e.g., Refs. [6–9]; an excellent review article on this topic by *Farina*[10] has been published recently). The tacticity of polymer chains (i.e., the uniformity of successive configurational arrangements in the main chain[11]) is now well known, thanks mainly to NMR spectroscopic studies.[6–10]

On the other hand, it was still not certain whether polymers could show optical activity as a result of chirality due to the configurational arrangements in the main chain (known as main-chain chirality). While evidence for such phenomena was subsequently found for 1,2-disubstituted olefins and certain substituted dienes,[12–14] until recently it was thought that, for polymers based on 1-substituted and nonsymmetric 1,1-disubstituted olefins, main-chain chirality would not give rise to optical activity.[15–19] These latter types of polymers are by far the most important classes of polymeric materials, both technologically and scientifically. Optical activity in such polymers was only observed for

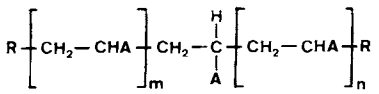
[**] On the Chirality of Polyvinyl Compounds, Part 8. Part 7: [1].

[***] An atom bearing several substituents is described as *stereogenic* if interchanging two of its substituents results in a stereoisomer (such an atom is said to form a stereocenter). Notations such as chiral C atom or chiral center, which have been used customarily up to now, should be avoided [2–4].

polymers obtained from 1-substituted olefins bearing an optically active side chain (for reviews on optically active polymers in general see, e.g., Refs. [10, 15–24]).

Only recently has optical activity arising from the main-chain configuration been shown to occur for polymers of 1-substituted and nonsymmetric 1,1-disubstituted olefins.[25–30] Furthermore, it has been possible to synthesize a completely new type of optically active polymer, whose chirality results from a sort of atropisomerism in the main chain. In this manner one can obtain polymers with a predetermined single-handed helical structure.[31–36]

The considerable delay in investigating the chirality of vinyl polymers was due to the special stereochemical features associated with very long chains. Firstly, it is not always possible to determine the symmetry properties of such systems in a simple way, and secondly, stereoregular polymers with complicated tacticity can be synthesized only with difficulty. Moreover, the relationship between chirality and optical activity is more complex for polymers than for low-molecular-weight substances. For many chiral polymers, even pure enantiomers, optical activity is not expected for fundamental reasons.



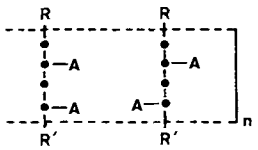
In the present survey, the symmetry properties of polymers consisting of C–C chains will be systematically reviewed in Section 2, in which the relationship between chirality and optical activity in polymers will also be discussed. Section 3 will deal with the different types of optically active polymers known so far. The problem of atropisomerism in polymer chains will be discussed in detail in Section 4. The treatment will be limited throughout to polymers whose optical activity results from chirality due to the configuration or conformation in the main chain. Polymers with optical activity arising from the configuration of side chains (for reviews see Refs. [10, 17, 20, 21, 37, 38]) and optically active polymers with heteroatoms in the main chain[10, 17–21, 39, 40] are not included.

The main emphasis in this article will be on polymers of 1-substituted and 1,1-disubstituted olefins, since a significant amount of new information has recently been gathered on these polymers.

2. Symmetry Considerations for Polymers Consisting of C–C Chains

2.1. Statement of the Problem

Symmetry properties are more difficult to recognize in polymer chains made up of uniformly repeating units than in low-molecular-weight compounds. The macromolecule usually contains stereocenters, either at each carbon atom of the chain or at alternate carbon atoms, each of which bears four different substituents. In the vinyl polymer **1**, for example, two of the substituents are the group A and the hydrogen atom. The other two substituents consist of the chain ends of different length.



1

Optical activity is not expected to result from this structure alone, since, on the one hand, stereocenters with two different, but very long, substituents (e.g., in natural fats) show practically no optical rotation and, on the other, for each stereocenter in the chain there is one on the other side of the chain with the opposite configuration. This implies that the chain residues of differing length in **1** are exchanged; $n > m$ instead of $n < m$. Any optical activity found must therefore be caused by other structural features.

In addition to this fundamental problem there exists another one of a more practical nature. Whereas compounds of low molecular weight are in general uniquely defined with regard to their constitution and configuration, leaving the conformation as the sole variable about which one must make assumptions, this is not the case for macromolecules. The existence of structural defects in the chains, of differences in the chain ends, and of a distribution of molecular weights, as well as the fact that the configuration is almost never completely uniform, even in stereoregular polymers, forces one to use simplified models. (For a discussion of the need to use models in dealing with real molecules, see *Mislow* and *Bickart*[41].)

2.2. Selection of Suitable Models

At first, the macromolecules are assumed to possess an ideal stereoregular structure: i.e., they are made up of repeating units with identical constitution and configuration. Such ideal stereoregular polymers are usually described by specifying the smallest regularly repeating configurational unit (called an *n*-ad).[6–11] For the well-known stereoregular vinyl polymer types, namely, isotactic and syndiotactic, these units are termed the *meso* diad and the racemic diad, respectively.[*]

2 **3**

For ideal stereoregular polymers the following two models, which have also been used in previous work,[10, 15, 16, 28, 30] will be employed here:

a) A very long finite chain with identical chain ends;
b) An infinite (i.e., unlimited) chain. This is a useful model for true high polymers and has been shown to be particularly valuable for stereochemical considerations. In this case all the units of a stereoregular polymer are

[*] Throughout this article macromolecular formulas are shown in the normal Fischer projection, since chains of known absolute configuration are dealt with. This differs from the IUPAC Macromolecular Division's recommendations [11], which suggest that for polymers the 90°-rotated Fischer projection should be used. Furthermore, for greater clarity the carbon atoms of the chain are represented by dots, and the hydrogen atoms are omitted. Different substituents on the main chain are denoted by A, B, D, and E. The substituents themselves are regarded as having rotational symmetry with respect to the substituent-to-chain axis.

exactly identical, and there are no longer any end groups.

Considerations of symmetry in both these models are based on the conformation with the highest symmetry, which is usually the zigzag chain conformation. For the sake of simplicity, the normal Fischer projection will usually be employed here.

For the finite chain model a, with identical chain ends, the chirality can be determined in the usual manner by point group symmetry considerations, although for long chains this is often not easy. For the infinite chain model b, the symmetry properties of stereoregular polymers can be described using the one-dimensional space group (line group), since this model involves a three-dimensional body having periodicity in one direction. This method of describing the polymer chain has been used mainly in calculations related to spectroscopic studies.[16,42-48] When using space groups it is necessary to take into account, in addition to the symmetry operations of the point groups, translational and other symmetry operations combined with translation (glide planes, transverse mirror planes, and screw symmetry axes).[46-50] A one-dimensional space group is chiral if it contains neither a mirror symmetry plane nor a glide plane of symmetry.[16]

For symmetry considerations an infinite chain can be replaced by a ring, which may be regarded as an endless chain with a finite number of units.[51,52] *Farina, Peraldo,* and *Natta*[16] have applied this principle very successfully to determine the symmetry properties of complex stereoregular polymers, especially polymers of 1,2-disubstituted olefins and 1,3-dienes. In these studies they placed the *n*-ads in a ring containing the corresponding number of units. The ring, assumed to be planar, together with its substituents, has symmetry properties comparable to those of the infinite chain model b, but can be described in terms of point group symmetry. An example is the triad in a stereoregular homopolymer of a vinyl monomer; this triad is represented as the three-membered ring structure **4** (in this case the CH_2 groups do not contribute to the symmetry properties and are omitted from the ring representation). The triads **5a-f**, shown as Fischer projections (Fig. 1), are equivalent and describe the same stereoregular polymer chain in the infinite chain model (in this case, only the repeating configurational unit without end groups is shown).

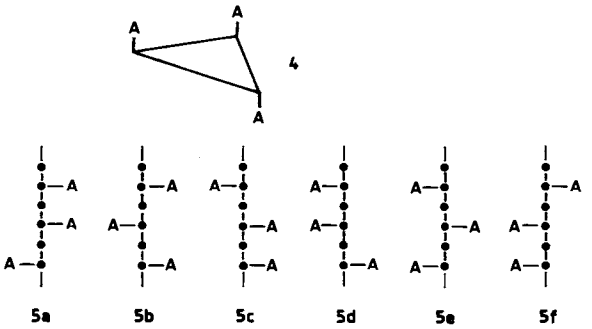


Fig. 1. Different triad representations for the same stereoregular polymer (the triads 5 form an infinite chain).

2.3. Types of Chiral Polymers

2.3.1. Stereoregular Homopolymers

Here we shall discuss polymers of 1-substituted olefins (CH_2=CHA) and of nonsymmetric 1,1-disubstituted olefins (CH_2=CAB), which have the same symmetry properties. Since polymers of symmetric 1,2-disubstituted olefins (ACH=CHA) have comparable symmetry properties, they can also be treated here.

It has long been recognized that the usual types of stereoregular homopolymers of these monomers, namely, the isotactic and syndiotactic polymers, are achiral.[6-10,15-21] For the finite chain model it can be seen that the isotactic chain **6** (Fig. 2) possesses a mirror plane and is therefore a *meso* form. (The difference between R and CH_2-R at the chain ends is neglected here.) The tertiary carbon atoms of the chain can be assigned an absolute configuration in which, in addition to A and H, the substituents are the two chain ends of different lengths. If, for example, one assigns to carbon atom a) the (*R*) configuration and then considers a tertiary carbon atom on the other side of the chain, the chain end that was previously the shorter one now becomes the longer and, accordingly, one obtains the (*S*) configuration for b). In an isotactic chain, therefore, one-half is (formally) in the (*R*) configuration and the other half in the (*S*) configuration.

The mirror symmetry in isotactic polymers can be eliminated[25,26] if, starting near the middle of the chain, substituents are switched to the opposite side of the chain with respect to the Fischer projection (**7**). The stereogenic centers in the chain now have continuous sequences of either (*R*) or (*S*) configuration. Since each section of the chain is strictly isotactic, we have proposed to describe such structures as "inverse biblock isotactic".[25,26] Structure **7** has only a twofold axis of symmetry and can therefore be regarded as chiral. A structure of this type cannot be represented by the infinite chain model. In high polymers with such structures optical activity is not expected solely on the basis of configurational effects. One needs to determine experimentally, by synthesizing model compounds, the upper limit of molecular weight for which optical rotation can occur, in certain cases as a result of the formation of a chiral long-range ordering (e.g., a single-handed helix).[53]

Syndiotactic polymers **8**, as represented by the infinite chain model, possess a glide mirror plane and translational mirror planes perpendicular to the chain axis. Thus the syndiotactic chain is achiral.

The above conclusions pertaining to symmetry also apply to isotactic polymers **9** and syndiotactic polymers **10** obtained from 1,2-disubstituted olefins (ACH=CHA), which are accordingly achiral.[16]

As was mentioned previously, isotactic and syndiotactic polymers have structures which can be characterized in terms of *meso* and racemic diads **2** and **3**, respectively. For longer structural units such as triads, a triad characteristic of an isotactic polymer also exists, in addition to the triads **5**. Placed in a ring (see **4**), such a triad gives rise to mirror symmetry. Similarly, investigation of the possible tetrads and pentads reveals only achiral configurations. Only for a

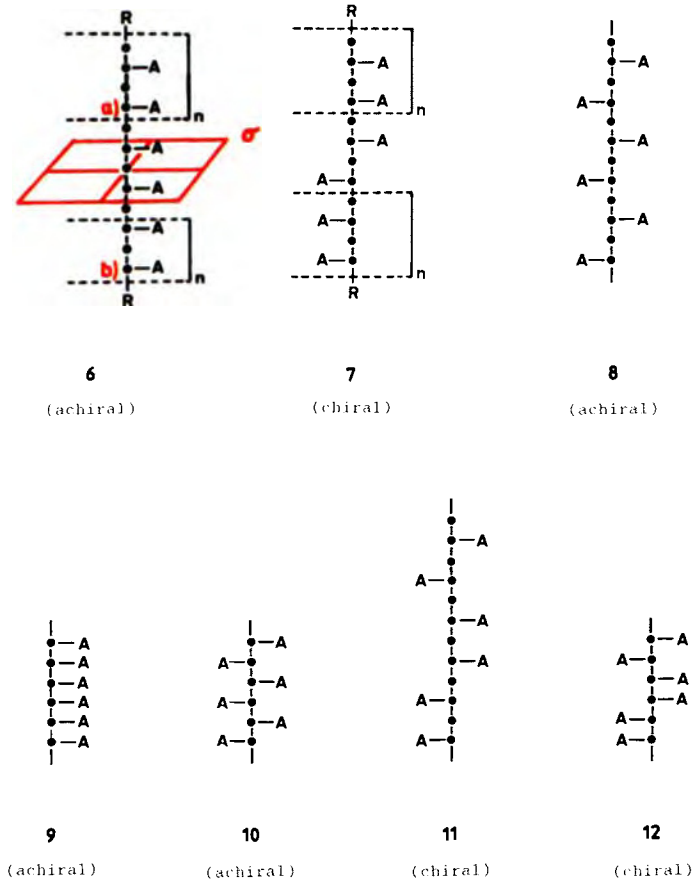

Fig. 2. Chiral and achiral homopolymers: **6** and **9** isotactic; **8** and **10** syndiotactic; **7** inverse biblock isotactic; **11** and **12** have chiral hexads.

regularly repeating structural unit made up of six monomer units is one of the eight possible hexads (see **11**) chiral, with C_2 symmetry. When arranged in a six-membered ring, the hexad has symmetry properties similar to those of the hexitols, of which only chiroinositol is chiral. This conclusion is also true for vinyl and vinylidene compounds and for the triads in polymers of symmetrically 1,2-disubstituted olefins **12**.[10,16] When longer structural units (heptads, octads) are considered, the number of possible chiral structures increases.

2.3.2. *Stereoregular Copolymers*

In stereoregular copolymers a much greater proportion of the structures are chiral. However, for the simplest cases of the alternating copolymers of 1-substituted olefins, the possible diads **13** and **14**, as well as all the conceivable tetrads, are achiral (Fig. 3). This also holds good for the corresponding homopolymers of nonsymmetric 1,2-disubstituted olefins.[54]

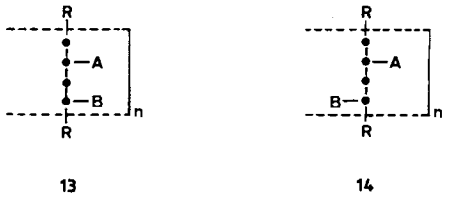

Fig. 3. Achiral diads in copolymers.

Of the three possible triads **15**–**17** with the sequence AAB, one structure is chiral and asymmetric,[25] namely, **17**. Figure 4 shows the three possible configurations in the ring form. In the asymmetric triad **17** the chirality is determined by the diad which carries the A substituents. Although the carbon atom with the B substituent is in a chiral environment (i.e., it is "chirotopic"[3]), it does not constitute a stereogenic center in this triad (compare **17a** and **17b**).

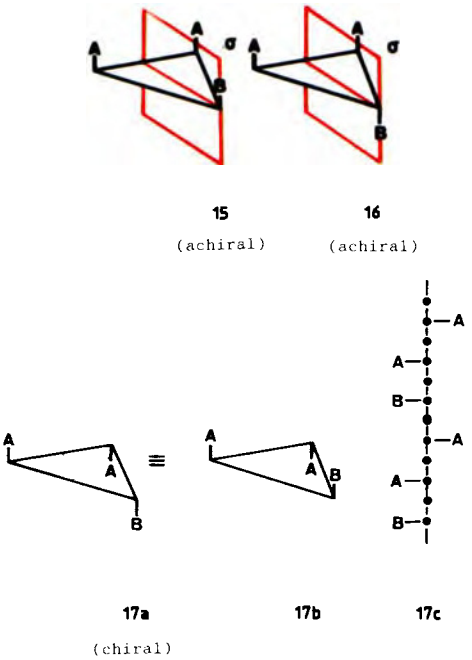

Fig. 4. Possible triads with the sequence AAB.

All four possible triads **18**–**21** (Fig. 5) in a stereoregular terpolymer are chiral and asymmetric. Of the five possible tetrads with the sequence AABB, three (**22**–**24**) are chiral (Fig. 6). Chiral polymers having this type of symmetry

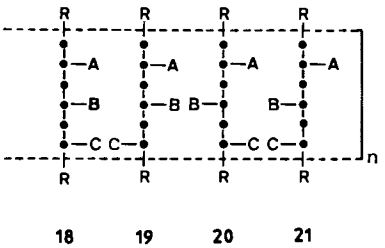

Fig. 5. Chiral terpolymers.

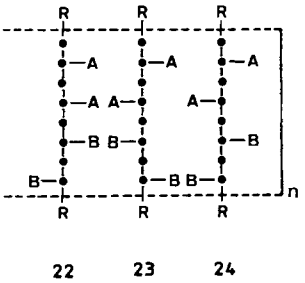

Fig. 6. Chiral tetrads.

(without the CH_2 groups of **22**–**24**) can in principle also be obtained by alternating copolymerization of ACH=CHA with BCH=CHB.

When the investigation of the symmetry properties of stereoregular copolymers further includes tetrads with other arrangements of the substituent (e.g., A_3B) or different substituents (A, B, D, E) or includes longer structural units (pentads, hexads, etc.), the proportion of chiral configurations is greatly increased. For example, for tetrads made up of three or four different monomers with different substituents, all the possible configurations in a stereoregular polymer are chiral.

2.3.3. Chiral Polymer Structures Resulting from Breakdown of Translational Symmetry

In the foregoing section chiral structures in stereoregular polymers were identified mainly by putting the repeating units into a ring structure. In other cases they can be derived in a more straightforward manner by introducing intermediate units along the chain to remove the mirror symmetry in the direction perpendicular to the translational axis (see Fig. 7).

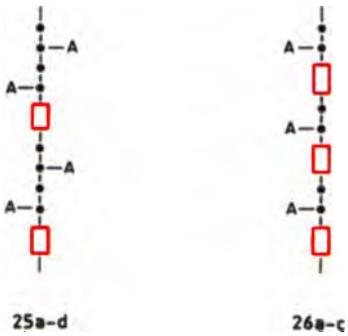

Fig. 7. Removal of translational symmetry by inserting intermediate groups. Intermediate units in **25a**, one or more comonomer units; in **25b**, atactic homopolymer; in **25c**, heteroatoms; in **25d**, double bonds. Intermediate units in **26a**, double bonds; in **26b**, 1,2-disubstituted comonomers; in **26c**, heteroatoms.

An achiral, syndiotactic polymer **8** can be converted into a chiral chain by separating the A–A structural units from each other (**25**). In the chain **17c** such a separation has been achieved by introducing a comonomer unit with the substituent B. It is especially easy to obtain polymers of this type by introducing heteroatoms into the chain to afford chiral polyesters, polyamides, polyethers, polyimines, etc. (which will not be discussed further here). Since in the case of the copolymers **17c**, the carbon atom bearing the substituent B is not decisive for the chirality, the AA diads can also be separated from each other by chains of any comonomer which can be either stereoregular or atactic.[29] This gives rise to a very important question with regard to the optical activity of homopolymers: Do chiral chains result when AA diads of a given absolute configuration (e.g., (*S*,*S*)) are separated from each other by atactic sequences of the same monomer, and could, for example, polystyrene be optically active under these circumstances?

A detailed statistical analysis of all possible arrangements in polymers of this type shows that, in fact, 25–50% of the stereogenic carbon atoms in the diads are present in chain segments which could contribute to the optical activity of the polymer.[57] The occurrence of chiral arrangements with uniform absolute configurations in these partially atactic polymers is due to the fact that each stereogenic center of the diads has one adjacent center with a uniquely predetermined absolute configuration, whereas the configuration of the stereogenic center on the other side changes in a random manner. Thus, in addition to polymers with chiral hexads **11**, it is also possible to obtain chiral homopolymers when diads with a uniform absolute configuration are distributed within a polymer chain which is otherwise atactic (**25b**). (The arrangement in the hexad **11** can also be described by means of chiral diads separated from each other by a monomer unit with alternating absolute configuration.) However, the optical rotation exhibited by such polymers is noticeably smaller than for other types of chiral polymers.[57]

As shown in **25** and **26**, many different ways of separating the diads have already been known for some time; important contributions to this problem have been made by *Arcus*,[15] *Schmitt* and *Schuerch*,[58] and *Natta* and *Farina*.[16,59] Polymers that have been particularly well studied are those of 1,2-disubstituted olefins (and also of cyclic olefins). Thus, when a comonomer CH_2=CHB or even ethylene is used to achieve the separation in such syndiotactic polymers, the chiral structures **27** and **28** can be obtained (Fig. 8). It should also be possible for structural elements of the type shown in **28** to be formed in the polymerization of 1-substituted olefins, if some head-to-head linkages occur. This provides another possible route for obtaining optically active, albeit nonregular, homopolymers from 1-substituted olefins.[25]

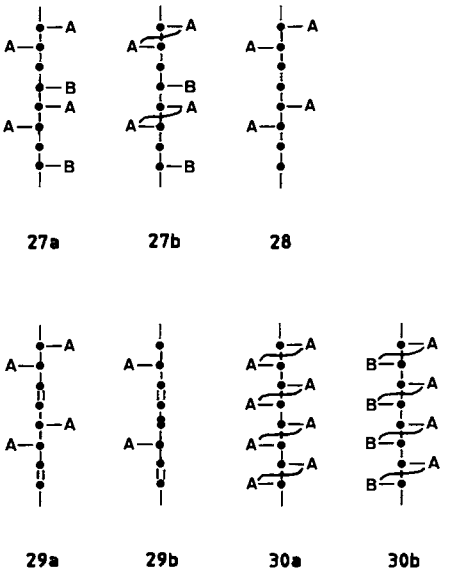

Fig. 8. Types of chiral structures resulting from elimination of the translational symmetry.

A double bond is also suitable as an intermediate unit in **25** (see **25d**). From 1,4-A_2-butadienes one can construct chiral polymers with structures of the type **29a**, while from 1-A-butadienes chiral polymers like **29b** are obtained.

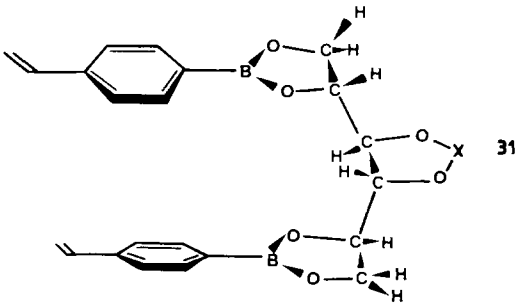
The mirror planes perpendicular to the translational axis in syndiotactic polymers from 1,2-disubstituted olefins can also be eliminated by forming a ring structure, as shown in **30a**. In this case no intermediate unit is introduced; instead, the two chain substituents on a stereogenic carbon atom are nonequivalent because one of the neighbors is in the same ring structure while the other is outside. The existence of this type of structure has been verified particularly for the case of two different substituents (**30b**).[13,16] For clear representation of the stereochemical situation, one can also put the structural units of **27**–**30** (Fig. 8) into a ring structure.[16]

2.3.4. Atactic Polymers

Atactic polymers contain chiral centers with equal numbers of (*R*) and (*S*) configurations distributed in a random sequence along the chain.[11] In this case only the finite chain model can be used, and a detailed analysis is best carried out using statistical methods. Clearly, the model for such a chain will be chiral, but molecules of this kind do not in fact show optical activity. In 1984 *Green* and *Garetz*[60] calculated the probability of finding both enantiomers of a diastereomer in a sample of an atactic polymer. They found that, with a degree of polymerization (X_n) of 70 or greater, the molecules of an atactic polymer in principle must be present as pure enantiomers, since the number of possible diastereomers is far greater than the total number of molecules present. This leads to the paradoxical conclusion that, in a polymerization carried out under achiral conditions, pure enantiomers are formed. According to *Green* and *Garetz*, optical activity in such cases is not observed owing to intermolecular compensation of the rotational contributions from the different diastereomeric species.[60] However, it should be pointed out that the arrangement in atactic polymers is cryptochiral (i.e., the model of the molecule is chiral, but the substance is in actuality achiral)[41] and therefore even a single chain of this polymer is not expected to show optical activity.

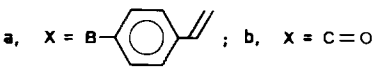
3. Polymers with Optical Activity Caused by Chirality of the Main-Chain Configuration

3.1. Polymers of 1-Substituted and Nonsymmetric 1,1-Disubstituted Olefins



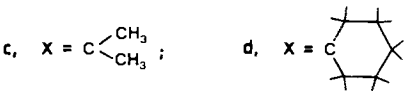
3.1.1. General Considerations

The initial attempts to synthesize optically active polymeric vinyl compounds were made at a time when the types of chain configurations necessary for chirality were not yet clear. Based on the negative results obtained in these experiments[61,62,65–67] it was assumed that polymers of 1-substituted olefins could not be obtained in forms exhibiting optical activity due to main-chain chirality.[15,17–19,61]



The discussion in Section 2 has shown that a great many structures in this class of polymers are indeed chiral. One only needs to consider how structures such as **11**, **17**–**24**, **25a**, or **25b** can be prepared as single enantiomers. In all these cases, if there is a predominance of one absolute configuration, optical activity is expected to occur. Admittedly, though, these structures are not very easy to synthesize.

3.1.2. Asymmetric Copolymerization



Of the chiral structures deduced in Section 2, the copolymer of the type **17c**, with an asymmetric triad, should be most easy to obtain in practice. In this case, the deciding factor for optical activity is the configuration of the diad carrying the substituent A. An attempt was therefore made to link two monomer units to a chiral template molecule to give, for example, **31**, followed by copolymerization with another monomer. A suitable chiral template is D-mannitol, to which 4-vinylphenylboronic acid was bonded at the 1,2 and 5,6 positions. The 3,4 position contains a five-membered ring, which stabilizes the spatial conformation of the molecule.[25,27,29]

31

a, X = B ; b, X = C=O

c, X = C(CH$_3$)$_2$; d, X = C

The template monomer (e.g., **31d**[29]) was subjected to free radical polymerization with various comonomers and, after splitting off the template, a soluble linear copolymer with a molecular weight of about 100000 was obtained.

The polymers obtained using a comonomer ratio of 1:1 show a very pronounced optical rotation in some cases, with $[\alpha]_{365}^{30}$ values from −56.0 to +145 [degree dm^{-1} g^{-1} cm^3] (see Table 1). Notwithstanding their different directions of rotation, both the positively and negatively rotating polymers possess the same absolute configuration. For example, polymer No. 10 with 4-vinylbenzaldehyde as the comonomer gave, after reduction with $LiAlH_4$, a polymer which had a structure corresponding to that of copolymer No. 6 obtained using 4-vinylbenzyl alcohol as comonomer. Both these polymers showed almost the same negative optical rotation value.[68] Similar relationships were also observed in other cases. Circular dichroism studies have shown that the positive rotations are caused by large Cot-

Table 1. Optical rotation values for copolymers of **31d** with various comonomers, measured after splitting off the template molecules [29, 68, 69]. The free-radical-initiated copolymerization, with the comonomers in a molar ratio of approximately 1:1, was continued until 10–20% of the monomers had reacted.

No.	Comonomer	$[\alpha]_{365}$ [degree $dm^{-1} g^{-1} cm^3$]
1	Methacrylonitrile	− 56.0
2	Methyl methacrylate	− 33.8
3	Styrene	− 23.0
4	3-Methylstyrene	− 18.8
5	4-Methylstyrene	− 7.7
6	4-Vinylbenzyl alcohol (4-hydroxymethylstyrene)	− 7.0
7	4-Chlorostyrene	+ 1.5
8	4-Nitrostyrene	+ 20.7
9	4-Vinylbenzonitrile (4-cyanostyrene)	+ 27.0

11	2-Vinylnaphthalene	+ 56.0
12	4-Vinylstilbene	+ 145

ton effects arising from the conjugated chromophore of the comonomer. Presumably the comonomers are forced by the chiral diads into an asymmetric conformation, a phenomenon already documented in the case of polymers bearing chiral side chains.[38]

The detailed copolymerization behavior of **31d** with methyl methacrylate is illustrated by the copolymerization diagram in Figure 9, in which the composition of the polymer is plotted as a function of that of the comonomer mixture. It can be clearly seen that the template monomer is preferentially incorporated into the polymer. The diagram also shows the optical rotation values of the resulting polymers. The specific rotation value reaches its maximum of about −80° when the copolymer contains about 25 mol% of **31d**.[27,29]

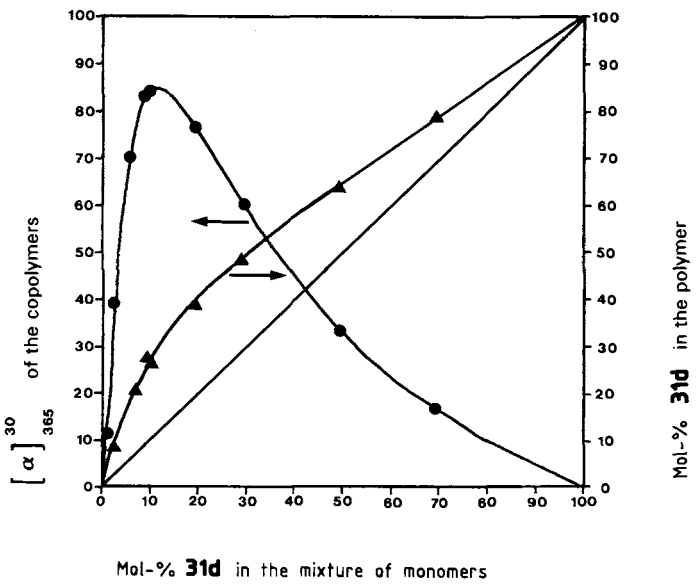

Fig. 9. Constitution of copolymers of **31d** with methyl methacrylate (Table 1, No. 2) and their optical rotation after splitting off the template molecules. The composition of the monomer mixture is plotted as the abscissa.

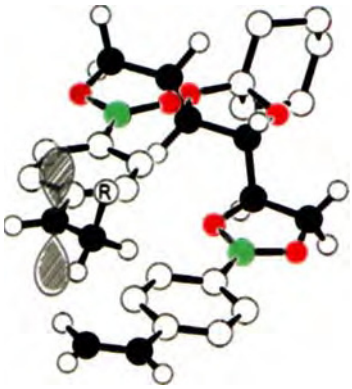
More detailed studies on the mechanism of this asymmetric copolymerization have shown[29] that **31d** undergoes a cyclopolymerization; i.e., the two double bonds in **31d** are incorporated into the polymer chain one after the other through the formation of a 19-membered ring. Figures 9 and 10 show the crucial step after the addition of the growing "macroradical" to **31d**. The benzyl radical thus generated can only react with the second double bond in the conformation shown in Figures 10 and 11. A further monomer can then only react from below, resulting in the formation of an (*S,S*) distyryl diad. For a different conformation of the first double bond one obtains an (*R,S*) diad, which is a *meso* form and does not contribute to the optical activity.



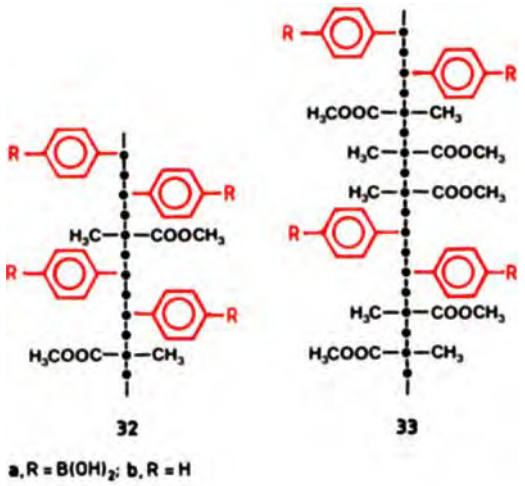


Fig. 10. Possible arrangement of the styryl radical from **31d** after reacting with a free radical R* according to a ball-and-stick model. For clarity the carbon atoms of mannitol and the vinyl group are shown in black and the hydrogen atoms of the phenyl ring and the cyclohexyl group are omitted (boron, green; oxygen, red).

Fig. 11. The CPK space-filling model of the same intermediate as in Fig. 10 shows that after the reaction of this free radical with the second double bond a further monomer unit can only add from below (boron, green; oxygen, red).

After the template molecules are split off, copolymers of methyl methacrylate with **31d** contain the idealized structure **32a**, or, in the case of an excess of the comonomer, the structure **33a**.

Boric acid can be quantitatively removed from these polymers using $AgNO_3/NH_3$, resulting in styrene–methyl methacrylate copolymers **32b** or **33b**, which are especially suitable for ^1H and ^{13}C NMR studies.[29,70] The structure

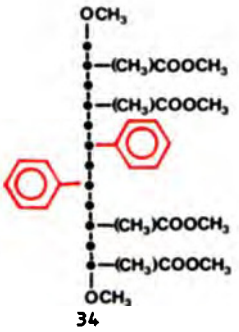

Fig. 12. Optically active copolymers **32**, **33** and an optically active model compound **34**. For **33**, a portion of the chain in which the configurations of the methacrylate units are randomly arranged is shown. The same is true of the methacrylate units in **34**.

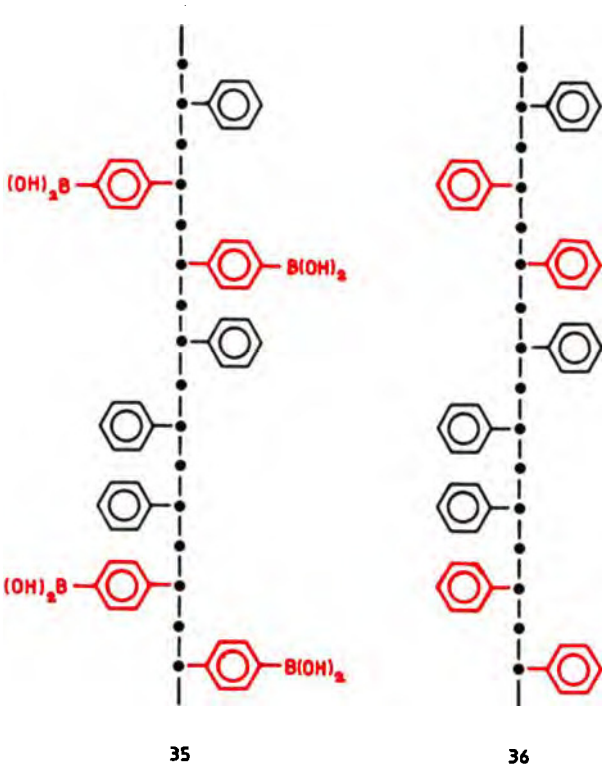
and absolute configuration of the polymers **32b** and **33b** have been unambiguously determined by comparison of their NMR and circular dichroism spectra with those of newly synthesized model compounds (e.g., **34**).[29,71] The polymer chains, as predicted from conformational analysis, do in fact contain (*S,S*) distyryl diads, along with a certain amount of (*R,S*) *meso*-diads.

Polymers of the types **32b** and **33b** can be subjected to various functionalization reactions,[1] namely, nitration, bromination, chloromethylation, or acetylation at the *para* position of the distyryl diads, as well as reduction of the ester groups. In an analogous manner modified materials can be obtained from methacrylonitrile-based copolymers. These reactions afford a wide variety of optically active, soluble polymers bearing different functional groups with optical activities arising from main-chain chirality.

3.1.3. Optically Active Homopolymers

In a number of cases optically active homopolymers could also be obtained; however, their specific optical rotation values (reported for the polymers based on methacrylate,[22,72–75] vinylcarbazole,[76,77] *m*-tolylvinylsulfone,[78] and benzyl[79]) were quite small. The structure and mechanism of formation of such polymers are still unclear. In some cases the optical activity was attributed to chiral conformations, since configurational chirality in the main chain did not appear to be possible.

A systematic synthesis of homopolymers made up of chiral hexads **11** would probably be difficult. On the other hand, polymers of the type **25b** have now been prepared.[57] For this purpose **31d** was copolymerized with styrene: after splitting off the 3,4-*O*-cyclohexylidene-D-mannitol used as a template, an optically active 4-vinylphenylboronic acid–styrene copolymer **35** was obtained, with a specific optical rotation $[\alpha]_{365}^{30} = -35$ [degree dm^{-1} g^{-1} cm^3]. Quantitative deboronation of **35** gave the styrene homopolymer **36**, with a specific optical rotation $[\alpha]_{365}^{30} = -3$ [degree cm^{-1} g^{-1} cm^3] (Fig. 13). The homopolymer synthesized by this method contains asymmetric distyryl diads of uniform configuration within an otherwise atactic styrene polymer. It is thus the first example of an optically active homopolymer of this class with defined structure and configurational main-chain chirality.



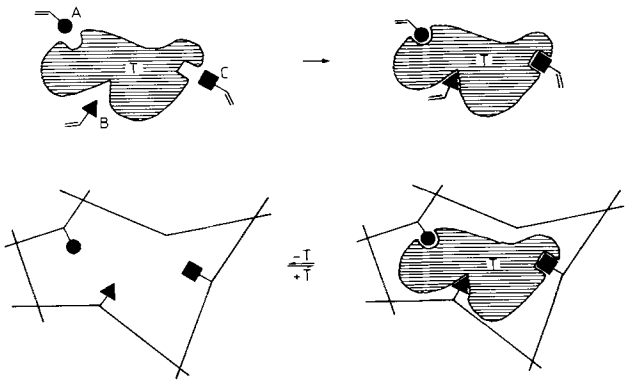


Fig. 13. The optically active co- and homopolymers **35** and **36** (portion of the chain).

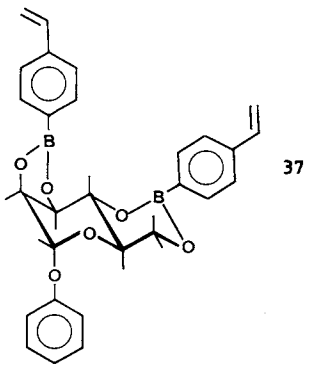
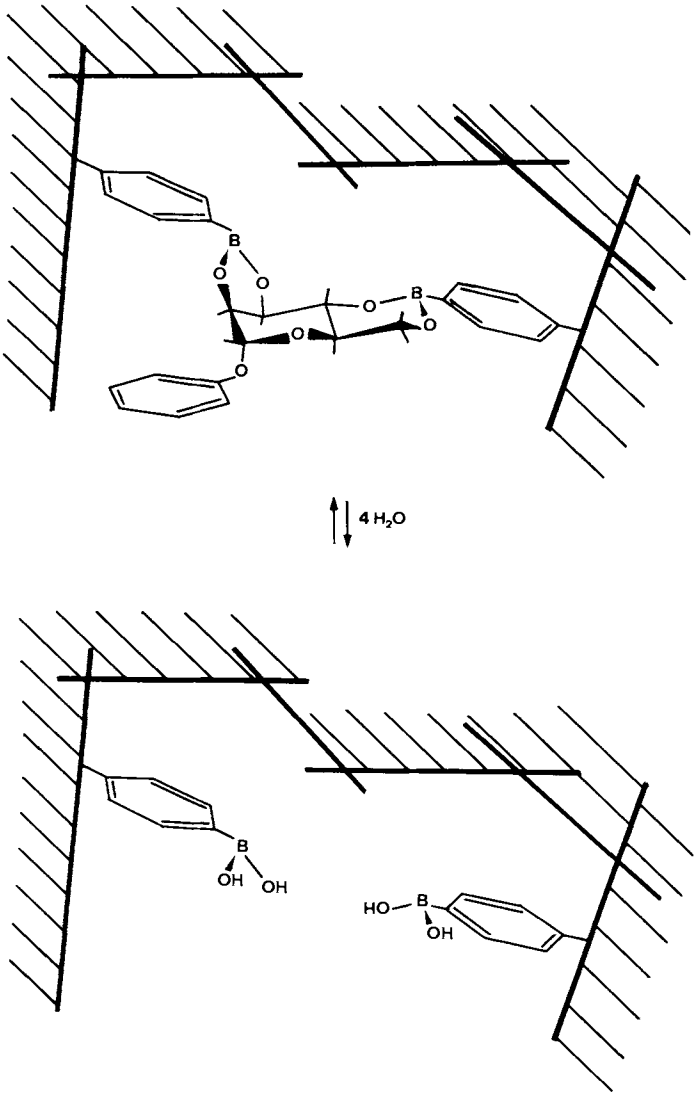
3.1.4. Branched and Cross-linked Polymers



Quite apart from chirality due to the configurational arrangement of substituents along the main chain of linear polymers, it should be possible for branched polymers to generate asymmetric configurations at branching positions arising from the different lengths of the chains. However, up to now no examples are known.

On the other hand, we have been successful in obtaining chiral arrangements in cross-linked polymers.[80–83] For this purpose polymerizable vinyl monomers containing functional groups were attached to suitable optically active template molecules, which were subsequently copolymer-

Scheme 2. Schematic representation of polymerization in the presence of a template (T).



ized, in the presence of solvents and relatively large concentrations of cross-linking agents, to give macroporous polymers. Removal of the template molecules (see Scheme 2) left behind chiral cavities in the polymer, the cavity shape and the arrangement of the functional groups being determined by the template molecules. An example is the polymerization of the monomer **37**, where phenyl-α-D-

37

mannopyranoside acts as a template to which two molecules of 4-vinylphenylboronic acid are linked as diesters of boronic acid. After polymerization and removal of the template (Scheme 3), chiral cavities are left behind, each with two boronic acid groups. Polymers of this type are optically active. The optical activity is measured for a suspension of the polymer in a solvent having the same refractive index as the polymer, a technique which was developed for other types of insoluble polymers. Figure 14 depicts the incorporation of the template into the polymer. The asymmetry of the cavities can be recognized from the excellent racemate resolution ability for the template compound. For the present system α values (the ratio K_D/K_L of the solvent/polymer partition coefficients for the L and D forms) greater than 4.5 were obtained.[83]

The chirality of the cavities is stabilized by means of the cross-linking points in the polymer chain. This chirality can arise from the configuration of the cross-linking points as well as from asymmetric conformations of the polymer chain which are stabilized by cross-linking. In the case of **37**, the chiral configurations of the linear portions of the chain do not contribute to the asymmetry of the cavity.

Scheme 3. Schematic representation of the removal of the template molecule phenyl-α-D-mannopyranoside from a highly cross-linked copolymer of **37**.

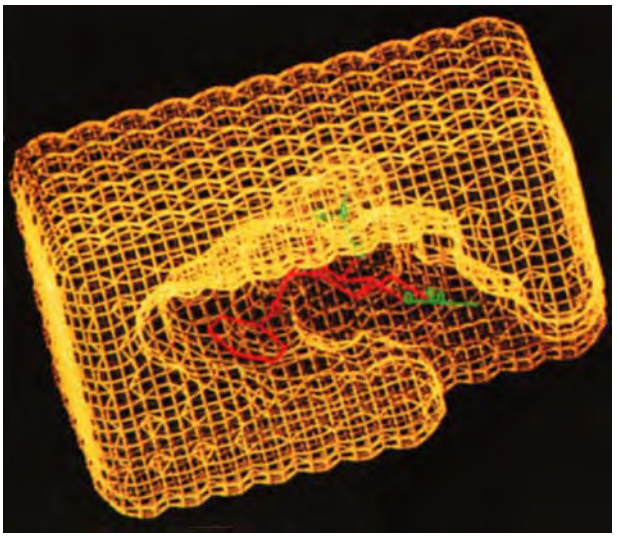


Fig. 14. Computer-generated representation of the imprinting caused by phenyl-α-D-mannopyranoside as a template (see Schemes 2 and 3).

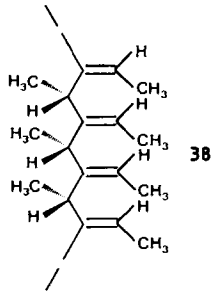
This method of molecular inprinting has now been extensively applied with many different templates, and numerous other research groups have reported important applications based on this principle. (Further details are described in several recent review articles.[85-88])

3.2. Polymers of 1,2-Disubstituted Olefins

In contrast to vinyl polymers, optically active polymers with main-chain chirality obtained from 1,2-disubstituted olefins have been quite systematically studied.[10, 15-21] Three principal methods have been used for asymmetric induction during polymerization:

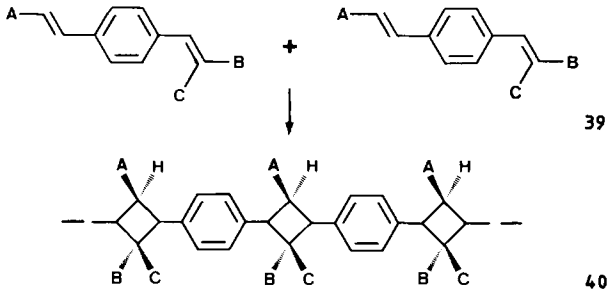
a) During copolymerization, monomers with optically active substituents that can be subsequently removed have been used. In this case the substituent controls the stereochemistry of each step during chain growth.
b) Polymerization can be carried out in the presence of an optically active catalyst. This method cannot, however, be applied to free radical polymerization with optically active initiators.[61, 62]
c) Another possibility involves polymerization in a chiral medium such as an optically active solvent or clathrate-forming compound.



Using (*S*)-(−)-α-methylbenzyl methacrylate and maleic anhydride (method a, structural type **27b**), *Beredjick* and *Schuerch*[12] were the first to obtain optically active polymers consisting of C–C chains with main-chain chirality. Several more examples have been reported in recent years.[89-93] *Natta, Farina* et al.[13] succeeded in obtaining polymers of the type **30b** (thought to be predominantly in the *threo*-diisotactic configuration[10]) with strong optical activity by cationic polymerization of benzofuran in the presence of an optically active catalyst.

3.3. Polymers of Substituted 1,3-Dienes

Natta and co-workers[14, 46] carried out the anionic polymerization of methyl sorbate using an optically active initiator and thereby obtained the first optically active homopolymer consisting of C–C chains with main-chain chirality (the structures of the 12 possible regular stereoisomers are given in Ref. [10]). A polymer with a chiral structure of the type **29b** was obtained[95] by asymmetric polymerization of 1,3-pentadiene (here A = CH_3). The γ-radiation-induced polymerization of dienes immobilized in a chiral host lattice (e.g., perhydrotriphenylene[96, 97] or deoxycholic acid[98, 99]) has proved to be a better method. It appears that in these cases the asymmetric induction by the chiral host lattice could be a through-space effect.[97] Optically active polymers have also been obtained by the free radical polymerization of 2,4-pentadienoic acid in the presence of (*S*)-(−)-α-phenylethylamine.[100]



3.4. Other Structural Types

Two optically active polymers with special structures should be mentioned here. The first was obtained by polymerization of optically active (*R*)-2,3-pentadiene using π-allylnickel iodide. Of the four possible structures, the predominant one is thought to be **38**.[101]

38

In the second instance *Addadi, Lahav* and co-workers[102, 103] photopolymerized unsaturated dicarboxylic acid derivatives of the type **39** in the crystalline phase (Fig. 15). They used achiral monomers which, however, could be obained as a chiral crystal modification. The photopolymerization gave optically active cyclobutane derivatives with the structure **40**, with a relatively low degree of polymerization.

39

4. Chiral Conformations and Atropisomers

4.1. General Considerations

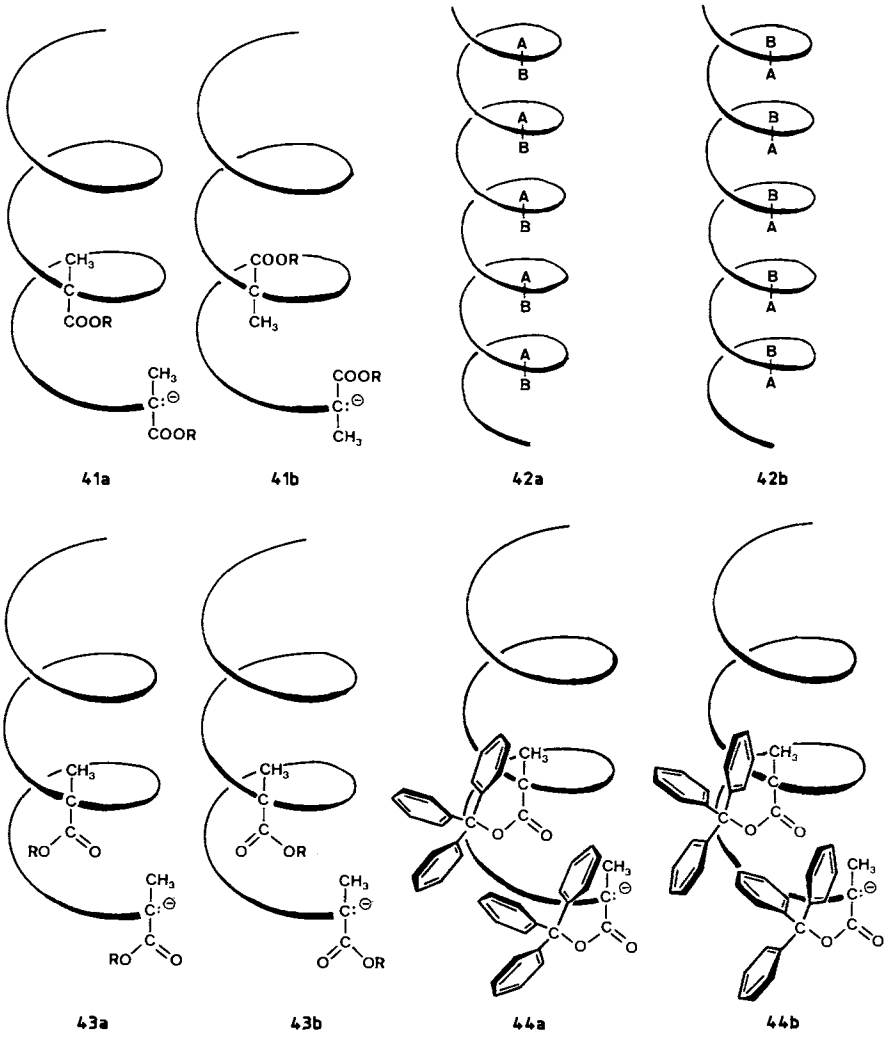
In contrast to the assumptions made regarding molecular models in Section 2, real polymer molecules in solution constantly undergo rapid conformational changes; they exist, for example, as random coils or in partially regular helical conformations.[10, 104-106] (For reviews on helical molecules and helicity see Refs. [107, 108].) The probability of finding achiral conformations is vanishingly small, and therefore in practice all real chain molecules (even polyethylene) are present in chiral conformations. However, these chiral conformations do not in general produce measurable optical activity, since conformations with positive and negative optical rotations are present in equal amounts (i.e., the polymers are "stochastically achiral").[41]

In the crystalline phase many isotactic polymers are present in helical form.[10, 47, 109] The helices can have either right-handed or left-handed structures, the two forms (en-

antiomorphic conformations) having equal energy. When helices of this kind (e.g., in polypropylene) are formed, they do not possess C_2 symmetry, since all the substituents are oriented along one direction of the helix (unidirectional helix).[10, 109] In principle, under chiral conditions it may be possible to produce helices with predominantly one screw sense in the crystalline phase or other solid phase and thus to obtain a solid with optical activity (see, e.g., Refs. [110, 111]). However, for high-molecular-weight polymers of this kind the optical activity should be lost immediately and completely upon dissolving or melting, since the conformational equilibrium results in the formation of helices with both the screw senses in equal amounts (in addition to random components). In solution, however, a one-screw-sense helicity in chains with achiral substituents can be induced by a pendant optically active catalyst[112] or through the presence of a small number of optically active substituents.[38, 113a] Helices with a single screw sense can be formed even when the stereogenicity of the optically active substituents is due to an isotope effect, e.g., H and D.[113b]

A different case arises when an isotactic polymer chain possesses bulky substituents which impose severe steric hindrance. Now it becomes possible to stabilize the helix by these groups. As a result, there is no longer any conformational equilibrium at room temperature, or perhaps even at higher temperatures. For every individual chain only one type of helix occurs. Following the success of *Nolte, Drenth* and co-workers with polyisocyanides,[31, 32] of *Vogl* et al.[35] with polychlorals, and of *Okamoto, Yuki, Hatada* and co-workers[33, 34] with poly(trityl methacrylate), there have been considerable developments in obtaining optically active polymers with stable, one-screw-sense helices derived from achiral monomers. This type of isomerism can be described as atropisomerism, since it is a form of conformational isomerism in which particular isomers are stabilized by rotational hindrance about single bonds.

The particular case of poly(trityl methacrylate) illustrates the complexity of the stereochemical problems associated with the formation of such helices. The helix is actually formed during the polymerization reaction (Fig. 16). Under achiral conditions left-handed (*M*) and right-handed (*P*) helices are formed in equal amounts, but with optically active catalysts mostly or exclusively one of these two is formed in certain circumstances. If one considers a single step during the chain growth, the monomer molecule with a prostereogenic center can add to the growing *M*-type helix in either the (*R*) or the (*S*) configuration. The two intermediate states **41a** and **41b** are diastereomers.



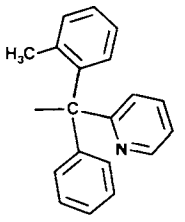


Fig. 16. Schematic representation of the stereochemical situation during the growth of an (*M*) trityl methacrylate helix. For clarity the carbanion, instead of the ester enolate is shown in each case. Structures **41a** and **41b** show the incorporation of a monomer unit in the (*R*) and (*S*) configuration, respectively, while **42a** and **42b** show the identities of the completed helices so formed, **43a** and **43b** show the two preferred conformations of the ester group, and **44a** and **44b** show the two helical forms of the trityl propeller.

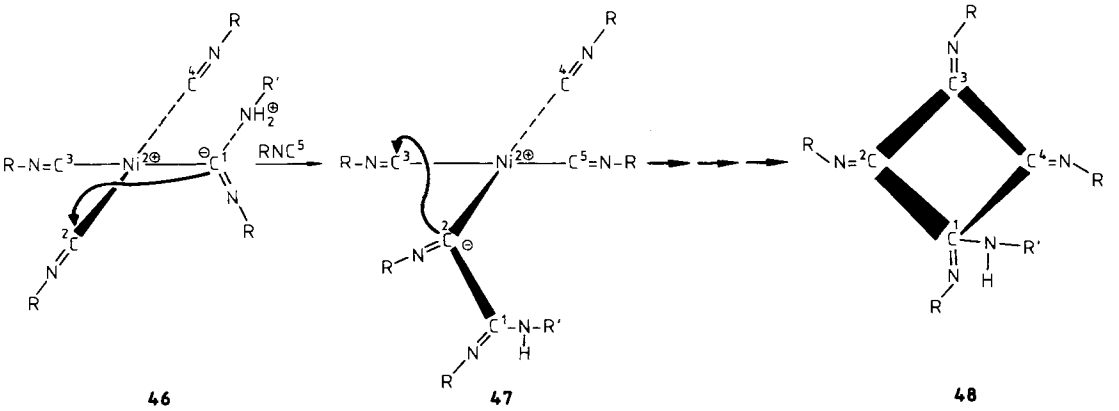
Studies on oligomers suggest that the monomer always adds to the helix in the same configuration.[63,64,114] However, in the completed helix of a high polymer, where the influence of the end groups can be neglected, the two configurations *M*(*R*) and *M*(*S*) are indistinguishable, and they no longer constitute diastereomers (cf. **42a** and **42b**). An analogous situation exists for the *P*-type helix.

These conclusions are only valid if the substituents on the polymer chain can be assumed to have rotational symmetry with respect to the substituent-to-chain axis. However, this is not the case for poly(trityl methacrylate). Conformational analysis shows that the ester groups can have two different conformations in the helix, namely, **43a** and **43b**. Examination of CPK space-filling molecular models suggests that the rotation about the bond linking the carboxyl carbon to the polymer-chain carbon is partially or completely restricted and that for steric reasons all the groups must have the same conformation.

One must also take into consideration that the trityl group, which is in the propeller form, should have the same sense of helicity (i.e., (+) or (−)) in all the trityl groups, and that this sense is already established during the polymer growth reaction (**44a** and **44b**). (For the stereochemistry of molecular propeller forms see Ref. [115a], and for the preferred conformation of the trityl group see Ref. [115b].) Consequently, for the actual growth reaction in the presence of an optically active catalyst, each growth step has a total of 16 possible diastereomeric intermediate states. Steric considerations suggest that one of these is preferred. It is not yet known to what extent the side groups (ester and trityl group) retain conformational mobility, which would enable them to rearrange into the most thermodynamically stable configuration after the helix has been formed. In the completed polymer itself there are a total of four possible diastereomeric *d,l* pairs which could occur (as atropisomers or conformers).

The situation becomes further complicated when the propeller consists of three different "blades", as *Okamoto* et al.[116] recently reported for polymerization of a methacrylate containing the optically active propeller structure **45**. Owing to the occurrence of both planar and point chirality,[115a] in addition to the propeller chirality, the propeller structure **45** alone has eight possible diastereomeric *d,l* pairs.[115a] As a result, a single enantiomer of **45** gives rise to a total of 32 possible diastereomeric configurations for the helices in the polymer. Thus, in this case, a complete determination of the configuration and conformation of the helix will not be easy.



45

4.2. Chiral Atropisomeric Polymers

4.2.1. Helical Polyisocyanides

Polyisocyanides **48**, also termed poly(carbonimidoyls) or polyiminomethylenes (see Refs. [32, 36, 117–119] for reviews), have a structural type which is highly unusual in polymers, with each carbon atom of the chain having a double bond to a nitrogen atom. This brings about a restricted rotation about the C–C single bonds of the chain and hence results in the formation of stable, rigid helices.[120a] *Nolte, Drenth* et al.[31] have succeeded in separating the right- and left-handed helices of poly(*tert*-butyl isocyanide) chromatographically, using a polymer prepared from optically active (*S*)-*sec*-butyl isocyanide as the stationary phase. Circular dichroism studies and calculations using *Tinoco*'s exciton theory suggest that the negatively rotating polymers have a *P*-type helix and the positively rotating polymers an *M*-type helix.[36a]

The polymerization of isocyanides takes place, for example, in the presence of Ni^{II} salts (Fig. 17). In this case, a planar $[Ni(CNR)_4]^{2\oplus}$ complex (**46**) is initially formed. The reaction itself is initiated by attack from a nucleophile such as an amine, which increases the nucleophilicity of the carbon in **46** sufficiently to allow the attack of an adjacent coordinated isocyanide ligand (**47**). The reaction then continues as a succession of insertion steps in the same direction around the Ni center (the so-called merry-go-round mechanism).[32]

46 **47** **48**

Fig. 17. Mechanism of polymerization and helix formation in polyisocyanide **48** (cf. Fig. 18) [36].

This leads readily to the formation of a very tight helical structure (**48a**, Fig. 18), since the isocyanide units on the nickel ion are in the desired geometrical arrangement. The insertion reaction can proceed in either a clockwise or a counterclockwise direction, giving rise to right- or left-handed 4_1 helices, respectively. In principle the substituent can be in either the *syn* or the *anti* position during the growth process. It is assumed that all the substituents during the chain growth are in fact oriented in the same direction; hence, in this case, the helical polymers resulting from either the *syn* or the *anti* configuration would be identical.[120b]

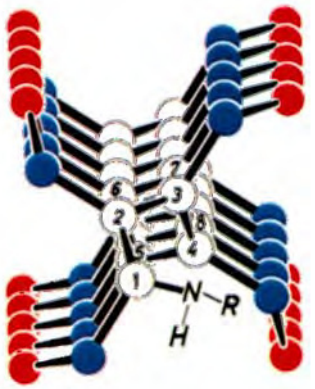


Fig. 18. Stereo view of the helix of **48** (cf. Fig. 17). The computer drawing of the helix was prepared according to data obtained from *R. J. M. Nolte*, Nijmegen, and *W. Drenth*, Utrecht.

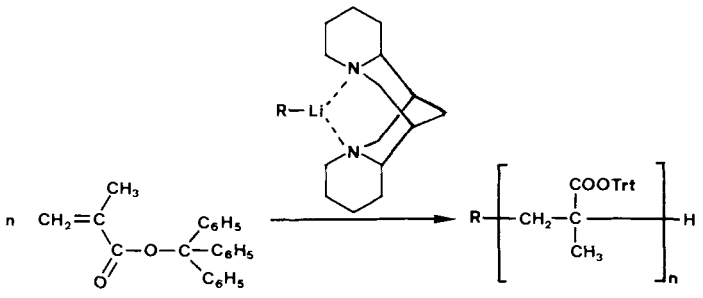
It has recently been found[36a, 121] that use of an optically active amine as the initiating nucleophile results in the formation of a one-screw-sense helix with an optical yield of up to 85%. It is also possible, in the presence of small amounts of slowly polymerizing optically active isocyanides, to convert the achiral isocyanide into a nearly uniform homopolymer with a high degree of optical enrichment.[36a, 122]

4.2.2. *Helical Poly(trityl methacrylates)*

By anionic polymerization of trityl methacrylate in toluene at −78 °C using a butyllithium/(−)-sparteine complex (initiator/ligand complex), *Okamoto* et al.[33] obtained helical poly(trityl methacrylates) showing large positive optical rotation values (Fig. 19 and Table 2). When the very bulky trityl group was replaced by a methyl group, the optical rotation completely disappeared and highly isotactic poly(methyl methacrylate) (*meso* form) was obtained. The



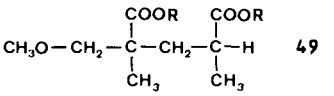


Fig. 19. Polymerization of trityl methacrylate to give helical polymers using alkyllithium/(−)-spartein.

49

Table 2. Helical polymers of methacrylate monomers; polymerizations of $CH_2=C(CH_3)COOR$ were carried out in toluene at −78 °C. Abbreviations: DPEDA = *N,N'*-diphenylethylenediamine; DDB = 2,3-dimethoxy-1,4-bis(dimethylamino)butane; Li-(*R*)-PAN = lithium-(*R*)-*N*-(1-phenylethyl)anilide; TMEDA = *N,N,N',N'*-tetramethylethylenediamine.

[a] Optical rotations measured in THF for the THF-soluble component. Results given for *R* = **45** are for initial rotation at −78 °C, and final rotation after quenching the reaction with methanol and allowing the reaction mixture to stand at −20 °C.

chirality must therefore be attributed to a type of atropisomerism which is stabilized by the trityl group.[123] By using other optically active ligands in the initiator complex—e.g., (*R,R*)-(−)-2,3-dimethoxy-1,4-bis(dimethylamino)butane ((−)-DDB)[124a]—it has also become possible to obtain a poly(trityl methacrylate) showing negative optical rotation (see Table 2).

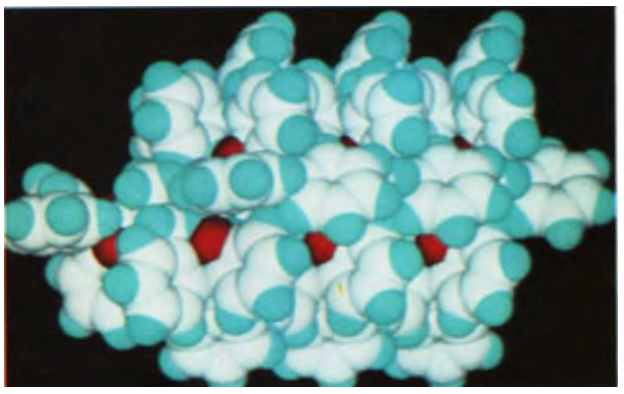
Optically active polymers can also be prepared using an optically active initiator, lithium (*R*)-*N*-(1-phenylethyl)anilide, although in this case the specific rotation is smaller.[124b] The diphenyl(2-pyridyl)methyl group[125, 126] and the optically active propeller group (+)-phenyl(2-pyridyl)(*o*-tolyl)methyl **45**[116] have also been used as bulky ester groups. The methacrylic ester of **45** has some unusual properties. Polymerization of the optically active monomer at −78 °C, even without the introduction of a chiral ligand into the achiral initiator, gives a polymer with strong positive optical rotation. After quenching the reaction with methanol and allowing the product to stand at −20 °C, it is slowly converted into a polymer showing negative optical rotation (see Table 2). This behavior is unaltered when (+)-DDB is introduced as the ligand during the polymerization. Apparently, the initial product, formed under kinetic control, is subsequently converted into the thermodynamically more stable form by an alteration of the conformation of the side chains[116] (see Section 4.1 with regard to the several possible isomeric forms in this case).

Relatively little is known regarding the mechanism of formation of helical poly(trityl methacrylates). It is well known that during polymerization under achiral conditions both types of helices are formed simultaneously and can be separated chromatographically on optically active poly(trityl methacrylate) as stationary phase.[127] Further details have been obtained from studies on the oligomers formed during the early stages of the polymerization.[63, 64, 114] In contrast to high polymers, isotactic oligomers at this stage do not form *meso* compounds. One can therefore study the absolute configuration following the

first addition steps. Thus it was possible for the first time to obtain optically active oligomers ($X_n = 1$–4) of trityl methacrylate and of methyl methacrylate (after transesterification of the oligomers).[63] The extent of asymmetric induction during the first addition step in the presence of (−)-spartein was only 20 to 40% depending on the reaction conditions.[114] The two enantiomers thus formed undergo further reaction at different rates, yielding oligomers with an isotacticity of over 90%.

The stereochemistry of the addition of the monomer at the chain end is controlled firstly by the last chiral center in the chain (backbone control) and secondly by the chiral ligands of the initiator complex (chelate control). In order to study the influence of the former factor, pure samples of the four possible "dimers" ((+) and (−) *threo* and (+) and (−) *erythro*), e.g., (+) form of **49**, were synthesized and, after deprotonation with lithium diisopropylamide (LDA), were used as initiators.[114] In the presence of an achiral chelating agent, the (+) and (−) forms of **49** gave polymers exhibiting opposite optical rotations (see Table 2). However, addition of (−)-sparteine was found to control completely the direction of optical rotation of the resulting polymer.

There is some evidence that the helix contains four monomeric units per turn.[63] The rate of reaction increases markedly after the formation of oligomers with $X_n = 4$ and $X_n = 8$.[63,64] Beyond $X_n = 9$, the stereochemistry of further chain growth is controlled by the preformed helix (in a manner similar to the helix control mechanism[128a]). Accordingly, the growing end of a preformed single-handed helix incorporates only one antipode of a racemic monomer.[127b] Figure 20 shows a computer-generated representation of the structure with four monomeric units per turn of the helix, in one of its possible conformations. The severe crowding of the substituents is clearly evident.



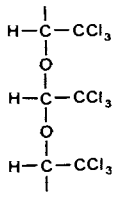


Fig. 20. Computer-generated representation of helical poly(trityl methacrylate) with four monomer units per turn and all trityl ester groups in the same configuration (this is one of eight possible structures).

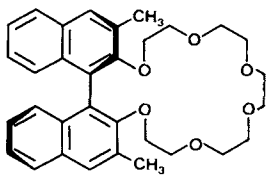
4.2.3. Helical Polychlorals

Although polychlorals **50** are not C–C polymers, they will be mentioned briefly here, since their symmetry properties are similar to those of the polyvinyl compounds. Using optically active anionic initiators, *Vogl* and co-workers[35,36b,128,129] were able to obtain insoluble polymers of chloral. Films of these polymers show an extremely large optical rotation, with $[\alpha]_D$ values up to +3000°. Here again it is assumed that the helices are present in only one screw sense. The insolubility of the polymers presents considerable obstacles for further detailed studies.



50

4.3. Optical Activity Caused by Flexible Chiral Conformations in the Main Chain

Contrary to atropisomers which are stabilized by large sterically crowded groups, one-screw-sense helical conformations of the chain in common polymers may be only stable in the solid phase or are stabilized by chiral catalysts, head groups, or side groups. Although unambiguous examples of the first case are not yet known, the polymerization of propylene in the presence of (*S*)-ethylenebis(tetrahydroindenyl)zirconium dichloride and methylalumoxane $(MeAlO)_n$ in toluene produces a highly isotactic polypropylene.[110,111] It has been shown, by studies during the early stages of the polymerization, that the oligomers in this polymerization are optically active and are essentially isotactic.[130a,b]

Cram and *Sogah*[112a] polymerized various esters of methacrylic acid (methyl, *tert*-butyl, benzyl) anionically in the presence of optically active binaphthyl crown ethers (e.g., **51**) to give oligomers ($X_n = 4.8$–12) which at first, in

51

the presence of the initiator,[112b] showed considerable optical activity. After removal of the catalyst, however, the optical rotation became considerably smaller, a fact which was attributed to an unwinding of the helices in the chain.[112] It appears that the helicity in this case is caused solely by the anchored catalyst and that the remaining optical rotation in these oligomers could be due to configurational effects, as in the case of optically active oligomers of methyl methacrylate[63] and propylene.[130]

5. Outlook

In this survey it has been shown that, contrary to previous assumptions, even the technologically most important polymers (i.e., those based on 1-substituted and nonsymmetric 1,1-disubstituted olefins) can exist in optically active forms. One of the factors that can give rise to optical activity in these polymers is the configurational arrange-

ment of the stereogenic centers along the main chain. Chirality due to the main-chain configuration is by no means unusual. In fact, when all conceivable structures are taken into consideration, it occurs very frequently. However, because of cryptochirality, atactic polymers, in particular, cannot occur in optically active forms, even when enantiomers of a single type are present. In stereoregular polymers, on the other hand, many optically active structures are conceivable; some of these have been realized experimentally and show very strong optical activity in some cases. In addition to optically active vinyl and vinylidene polymers with configurational main-chain chirality, further new groups of optically active polymers have been synthesized with optical activity arising from helical, atropisomeric structures.

The immediate objectives of the present investigations are essentially of scientific interest directed towards a general and deeper understanding of the stereochemistry of polymers. In addition, a very interesting question arises: Does optical activity in enantiomerically pure or enriched polymers introduce new interesting properties, leading to novel practical applications? Despite the very short time since the synthesis of these materials, some interesting applications have already begun to emerge.

Optically active poly(trityl methacrylate),[131-135] polychloral,[136] and cross-linked polymethacrylates prepared through the template approach[137-139] have been successfully used as adsorbing media for chromatographic separation of racemates. Chromatographic columns consisting of poly(trityl methacrylate) supported on silica gel[132] are now commercially available. Further emerging applications of these materials include their use as chiral reagents in asymmetric synthesis, as chiral catalysts or model enzymes, and as components of membranes and vesicles. For such applications selectivity can sometimes be considerably enhanced by the combination of side-chain chirality with main-chain chirality.[140]

The physical properties of pure optically active forms of polymers can differ considerably from those of racemates, as has been observed in the case of poly(α-methylbenzyl methacrylates).[141] There is particular interest in these materials for possible applications based on their piezoelectric, ferroelectric, or nonlinear optical properties. In particular, at the present time the nonlinear optical properties of optically active polymers are being thoroughly investigated in several laboratories. Generally speaking, interactions of electromagnetic fields with substances showing nonlinear optical properties generate new fields with altered phase, frequency, and amplitude as well as other characteristics of propagation. Materials of this kind are used to an increasing extent for the construction of optical switches and elements for signal processing, for positioning and guiding of laser beams, and for second harmonic generation in lasers.[142]

The use of polymers instead of inorganic or organic crystals offers several advantages. They are mechanically stable, can be easily produced and processed, and can be readily modified to introduce functional groups giving rise to high nonlinear optical coefficients.[142-144] More challenging is to obtain a noncentrosymmetric phase structure of the polymers, which is necessary for achieving nonlinear effects. For this purpose oriented rodlike molecules can be used in thin layers.[145] Helical, optically active polymers could also be used. Noncentrosymmetric arrangements can also be obtained in bulk using liquid crystals exhibiting the chiral smectic C-phase.[146] Since, in this case, the polymers have to be chiral and optically active, this offers an important application of the polymers described in this article.

Special thanks are due to my co-workers who have been involved with me in research on this topic and who, through their commitment and their ideas, have contributed to an important share of these results. We received financial support from the Deutsche Forschungsgemeinschaft, the Minister of Science and Research in the State of Nordrhein-Westfalen, and the Fonds der Chemischen Industrie. In preparing this review I have benefited from detailed discussions with K. Mislow (Princeton), M. M. Green (New York), M. Farina (Milan), Y. Okamoto (Osaka), and R. Bareiss (Mainz). The computer graphics in Figures 14 and 19 were obtained with the help of Dr. Hövel (Bayer AG, Leverkusen) and those in Figures 10, 11, and 18 were produced with the help of Dipl.-Chem. T. Stach, Düsseldorf, to both of whom I express my sincere thanks. Thanks are also due to Dr. P. K. Dhal, Düsseldorf, for his help in the preparation of this manuscript.

[55] In this case the new term "chirogen" for the designation of chiral partial structures could be used, a chirogen is a stereocenter that is not identical with its mirror image [56].

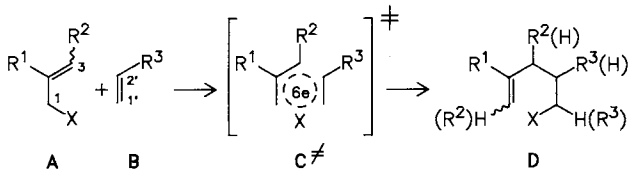
Intramolecular, Stoichiometric (Li, Mg, Zn) and Catalytic (Ni, Pd, Pt) Metallo-Ene Reactions in Organic Synthesis

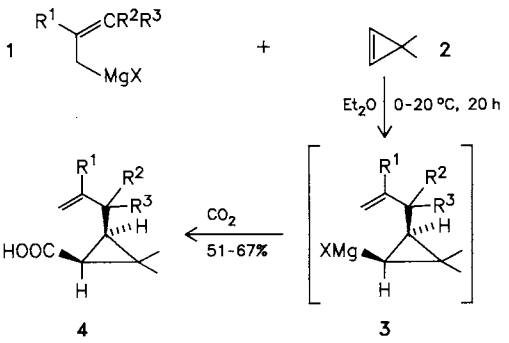
New Synthetic Methods (75)



By Wolfgang Oppolzer*

Dedicated to Professor Elias J. Corey on the occasion of his 60th birthday

Metallo-ene reactions, hardly recognized until very recently, have experienced a breathtaking development when applied in an intramolecular sense. Efficient regio- and stereoselective magnesium-ene cyclizations have served as a cornerstone for numerous syntheses of structurally diverse natural products (e.g., sesquiterpenes of marine or plant origin, alkaloids, fragrances, insect defense compounds, and a fungitoxin). A brilliant example is the synthesis of the elusive odorant (+)-khusimone which outshines 20 years of work in the field of tricyclovetivane synthesis. Palladium-, platinum-, and nickel-catalyzed versions of the metallo-ene reaction are in a comparatively early stage of exploration, but, nevertheless, reveal intriguing potential. Hence an almost 100% stereospecific C–O→C–Pd→C–C chirality transfer permits simple and selective, *cis*- or *trans*-annelation processes. The mild cyclization conditions are compatible with various functional groups, such as nitrogen moieties, which offer interesting perspectives for the preparation of heterocycles (e.g., alkaloids) difficult to obtain by other methods. Carbon monoxide insertion reactions of the cyclized σ-metal intermediates were shown to afford annelated cyclopentanones and cyclopentenones with concomitant stereocontrolled formation of four carbon–carbon bonds. These and other observations, highlighted in this article, provide a platform for further extensions and applications of this powerful method in organic synthesis.



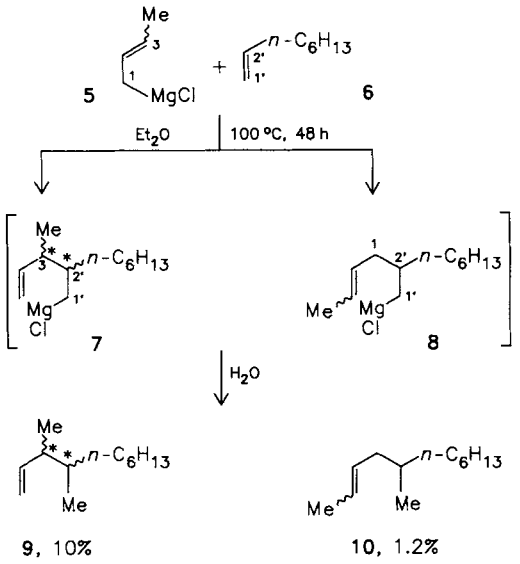
1. Introduction

The ene reaction, discovered 45 years ago by *Alder* et al.,[1] usually involves the thermal reaction of an olefin containing an allylic hydrogen (ene) with an electron-deficient unsaturated compound (enophile) to form 1:1 adducts via a cyclic 6e transition state (e.g., **A** + **B** → **C**$^{\neq}$ → **D**, X = H, Scheme 1).

Scheme 1. X = H: ene reaction. X = M: metallo-ene reaction.

Starting in 1970, *Lehmkuhl* et al.[2] systematically studied the analogous addition of allylic Grignard reagents **A**, X = MgCl, to alkenes or alkynes. Kinetic measurements showed negative activation entropies of $\Delta S^{\neq} = -18$ to -24 cal K^{-1} mol^{-1}.[2b] Further evidence for a concerted suprafacial reaction via transition state **C**$^{\neq}$, X = MgL_n, was provided by the addition of 2-alkenylmagnesium halides **1** to 3,3-dimethylcyclopropene **2**; subsequent carboxylation with CO_2 yielded *cis*-2-allylcyclopropanecarboxylic acids **4**[2c] (Scheme 2). Given that the configuration of a cyclopropyl-magnesium bond is stable and is carboxylated (CO_2) with retention,[3] it follows that the allyl unit and the metal are transferred to the same face of the cyclopropene **2** to furnish intermediate **3**.

R^1, R^2, R^3 = Me, H; X = Cl, Br



Scheme 2.

This more than formal analogy with the classical ene process has prompted us to classify transformations like **A** + **B** → **D**, X = metal, as metallo-ene reactions. Indeed, closely related additions of allylzinc,[4] -aluminum,[5] and -boron reagents[6] to (strained) alkenes, acetylenes, allenes, and enol ethers have appeared in the literature since 1971.

Despite the extensive work of *Lehmkuhl*, the magnesium-ene reaction has received virtually no attention as a strategic tool in organic synthesis. Problems of low regio- and stereoselectivity and low overall efficiency may limit the applicability of the bimolecular reactions, as exemplified by the addition of crotylmagnesium chloride to 1-octene[2a,d] (Scheme 3).

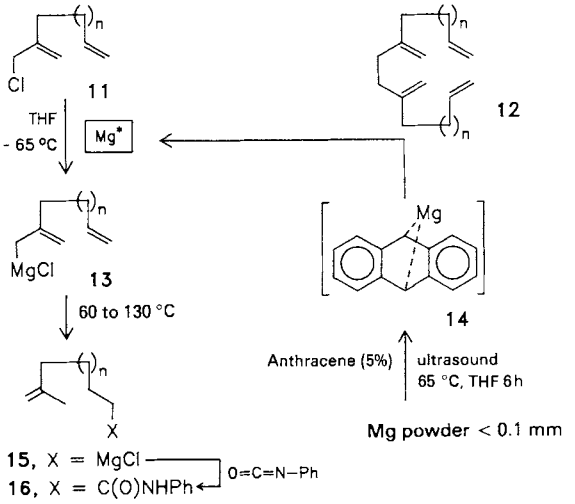
Scheme 3.

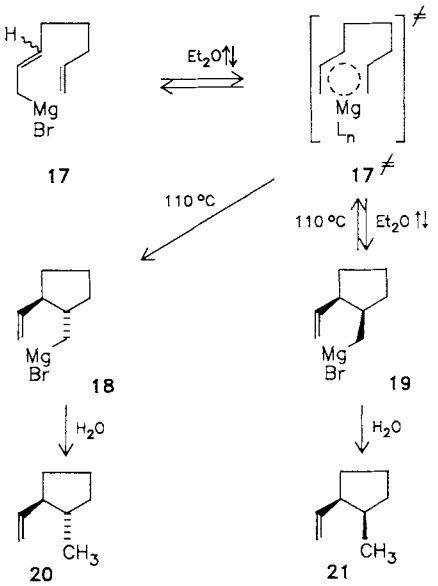


In contrast, similar to intramolecular [4+2] cycloadditions[7] and ene reactions,[8] intramolecular versions of the metallo-ene process may be regio- and stereoselective, entropically favored, and thus more efficient. This holds for two different modes of cyclization (Scheme 4) in which the enophile is linked by a suitable bridge, either to the terminal carbon atom (C-3, type I) or to the central carbon atom (C-2, type II) of the metallo-ene unit.

Scheme 4. Type I: The bridge Y links the enophile to C-3 of the metallo-ene. Type II: The bridge Y links the enophile to C-2 of the metallo-ene.

Essential for the practicality of such processes was, furthermore, a convenient preparation of the 2-alkenylmetal precursors **E** and **G**. In particular, the conventional treatment of allylic halides with Mg turnings in Et_2O frequently led to coupling products: e.g., **11** → **12** (Scheme 5).

Magnesium, activated by evaporation[9] or, much more conveniently, by sonication with anthracene (5%),[10] usually accomplished the metalation of 2-alkenyl chlorides (e.g., **11**) at −65°C in THF without significant coupling.[11] The resulting, clean, alkali-metal- and alkali-halide-free solutions of Grignard reagents **13** are compatible with the thermal cyclization/trapping sequence **13** → **15** → **16**.[11] This easy preparation of the starting 2-alkenylmagnesium chlorides, as well as the propensity of the cyclized alkylmagnesium intermediates **F** and **H** for further functionalizations and cyclizations involving the metalated and the two olefinic sites, offers a considerable potential in organic synthesis.

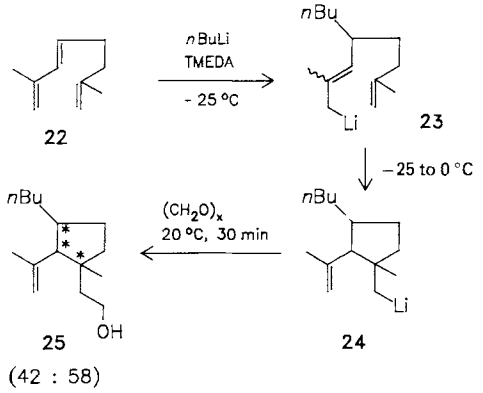


Scheme 5. The yield of **16**, n = 2, was 69% based on **11**.

2. Intramolecular Magnesium- and Lithium-Ene Reactions

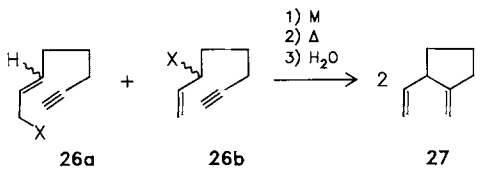
2.1. Type-I Reactions

2.1.1. Initial Studies



The first encouraging example of an intramolecular type-I magnesium-ene reaction dates back to 1972. As described by *Felkin* et al.,[12a] 2,7-octadienylmagnesium bromide **17** cyclized in boiling Et_2O to give, after aqueous workup, selectively *cis*-1-methyl-2-vinylcyclopentane **21** in 67% yield. Heating the solution of the transient Grignard product **19** to 110°C (sealed tube, 24 h) furnished, after hydrolysis, mainly the thermodynamically more stable *trans*-cyclopentane **20** (**20** : **21** = 11 : 1), indicating the re-

Scheme 6.



versibility of the cyclization **17** ⇌ **19** at a higher temperature.[12b] It is worth noting that **17** could be obtained in situ from 1,3-butadiene, *n*PrMgBr and $[(PPh_3)_2NiCl_2]$ (2 mol%) and that **18** and **19** were also trapped by D_2O or acetone. The conversion **17** → **19** → **21** was also reported in a patent.[12c]

Two years later, the transformation of the isoprene dimer **22** to **25** (mixture of stereoisomers) was observed and interpreted as a conjugate addition of *n*BuLi to diene **22** followed by a (surprisingly smooth) intramolecular lithium-ene addition **23** → **24**.[13]

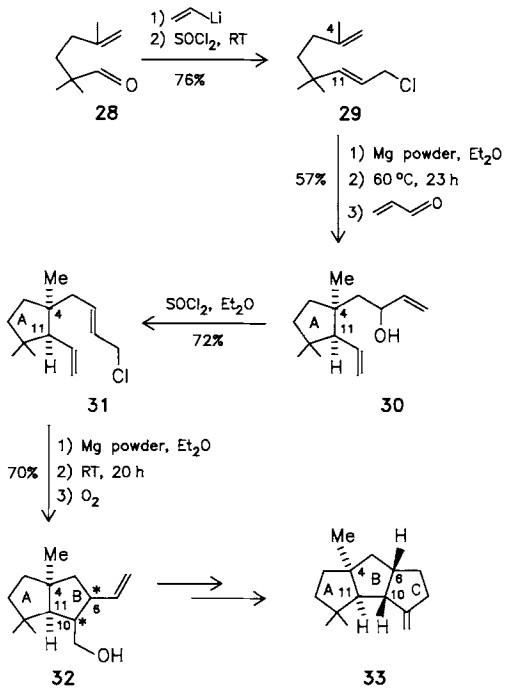
Scheme 7. The yield of **25** was 58% based on **22** (two stereoisomers).

A comparative study demonstrated the relative efficiency of a metalation/cyclization/hydrolysis reaction sequence to give **27** from enynyl bromides and phenyl ethers **26a** and **26b**.[14] These reactions obviously involve intramolecular zinc-, magnesium-, and lithium-ene additions to a terminal acetylene unit (Scheme 8, Table 1).

Scheme 8.

Table 1. Cyclizations of alkynes **26a** and **26b** to give **27** via intramolecular metallo-ene reactions.

X	Metal M	Solvent	*T* [°C]	*t* [h]	Yield **27** [%]
Br	Zn	THF	20	2	43
Br	Mg	Et_2O	[a]	2	15
OPh	Li	THF	50	2–24	50



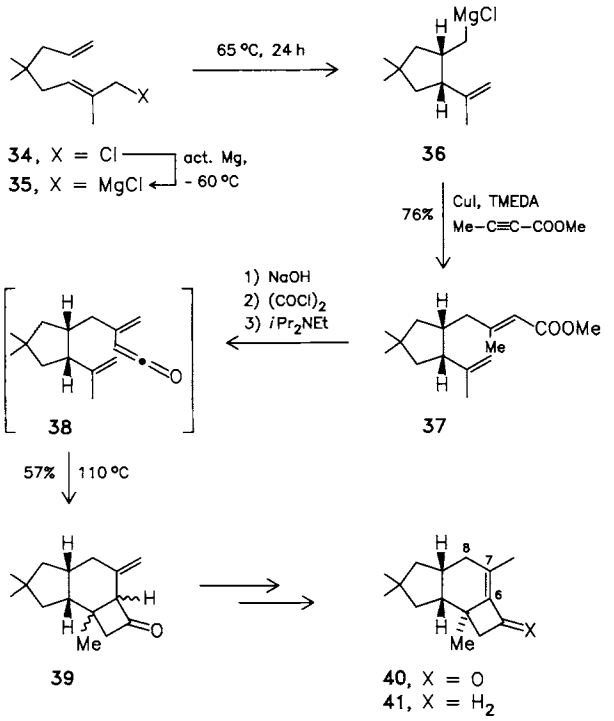
[a] Heated under reflux.

Also the cyclization of 1 : 2 adducts of allyl Grignard derivatives to 1,3-butadiene or isoprene giving divinylcyclohexylmethylmagnesium halides (mixtures of stereoisomers) has been ascribed to an intramolecular magnesium-ene process.[2e]

2.1.2. *Applications to Syntheses of Natural Products*

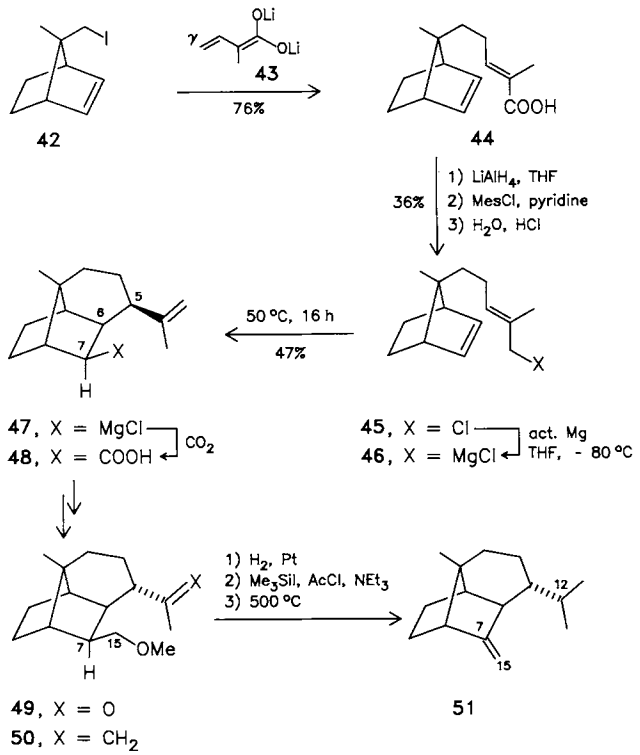
After these more or less isolated reports it was the challenge of natural product synthesis which spurred the most relevant exploration and extensions of the intramolecular magnesium-ene reaction. Its strategic role in synthesis is also illustrated by the following examples.

The synthesis of $\Delta^{9(12)}$-capnellene **33**, published in 1982,[15] addressed the issue of rendering this process iterative to assemble polycyclopentanoid systems (Scheme 9).



Scheme 9.

Thus, in the first key step **29** → **30**, the sterically congested bond between C-4 and C-11 was formed with high stereochemical control. Trapping of the cyclized Grignard intermediate with acrolein set the stage for the second magnesium-ene cyclization which occurs at room temperature. Scavenging the bicyclic magnesium-ene product with oxygen furnished alcohol **32** as a 3 : 2 mixture of stereoisomers. This kinetically derived lack of diastereoselection was of minor importance since the remaining closure of ring C was accomplished by an intramolecular aldolization with thermodynamic control over the configuration at C-6 and/or at C-10. Hence, the mixture **32** was channeled efficiently into the pure *cis-anti-cis*-triquinane **33**.

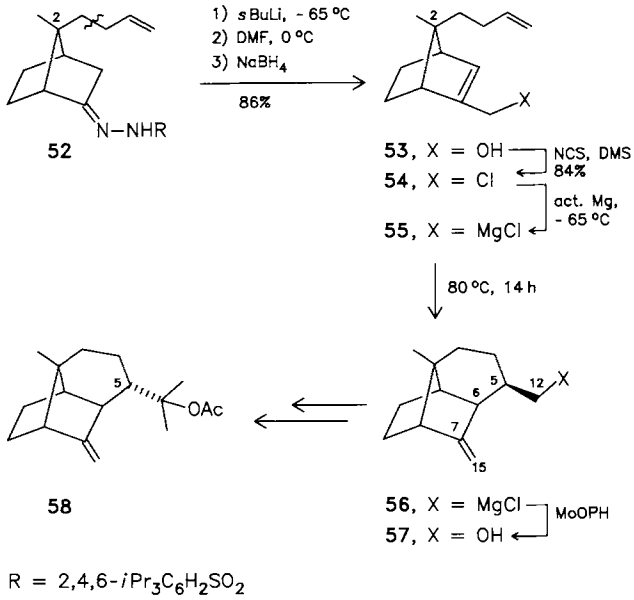


Highly diastereocontrolled formation of a *cis*-1,2-disubstituted five-membered ring was again observed in the key step **35** → **36** of the synthesis of (±)-6-protoilludene **41**[16] (Scheme 10).

Copper-promoted trapping of the cyclized organomagnesium species **36** by 1,4 addition to methyl 2-butynoate furnished the conjugated ester **37** in *one* synthetic operation from **34** (76%). The thus generated 1,2-*cis*-disposed functionalities in **37** were ideally suited to form the remaining six- and four-membered rings simultaneously by an intramolecular vinylketene/alkene cycloaddition (**38** → **39**). The carbonyl group in **39** (chromatographically

Scheme 10.

purified), furthermore, directed the olefin bond into the 6(7) position (instead of the otherwise favored 7(8) position). Although the [2+2] addition (**38**→**39**) did not show the desired high stereoselectivity, this approach to the protoilludene skeleton **39** in only two or three synthetic operations from the readily available acyclic dienyl chloride **34** exemplifies the *general* potential of magnesium-ene cyclizations when coupled with cycloaddition processes.

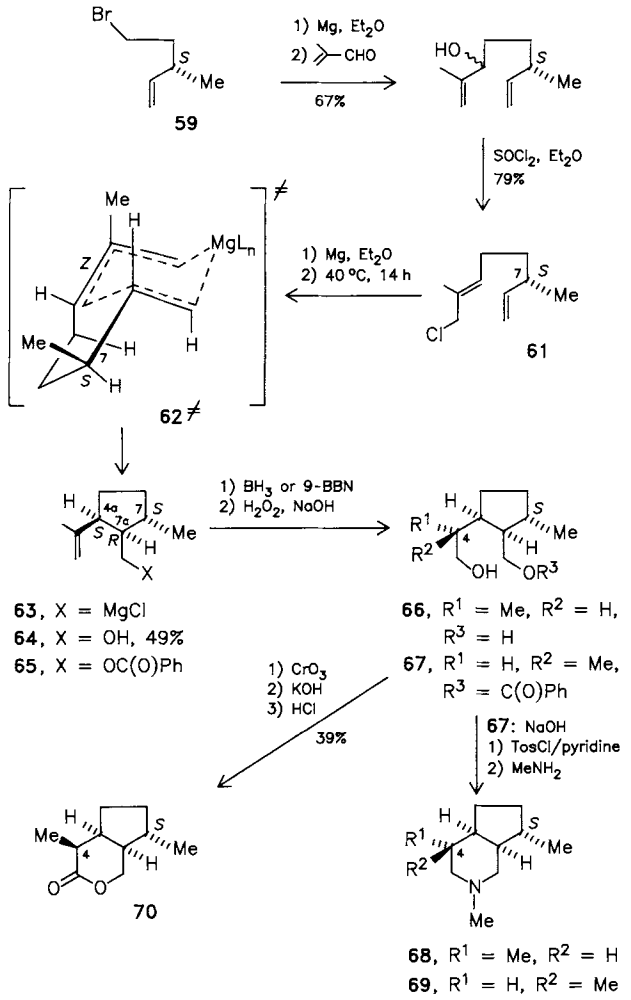


Scheme 11.

Another approach to an unusual sesquiterpene, sinularene **51**,[17] involves the diastereocontrolled formation of a six-membered ring by a magnesium-ene process (Scheme 11).

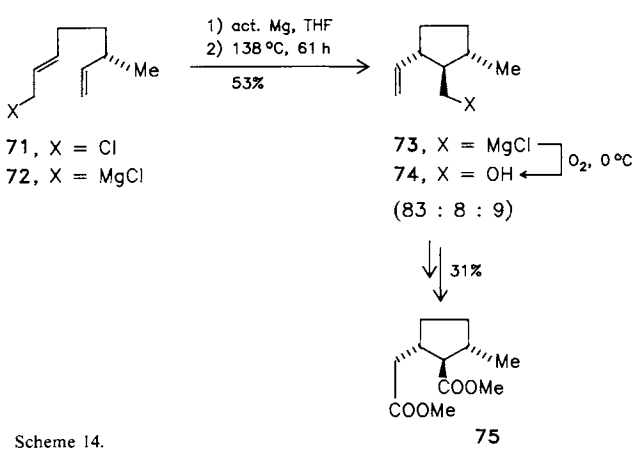
Thus, selective γ-alkylation of the dianion **43** by the iodide **42** gave the (*E*)-carboxylic acid **44**, which was converted into allylic chloride **45**. Successive treatment of **45** with activated magnesium, heating to 50 °C, and CO_2 trapping led to the formation of the bond between C-5 and C-6 and that between C-7 and C-15, giving the crystalline carboxylic acid **48** (47% overall yield) in a single operation. In this case, however, the kinetically controlled *cis* relation of magnesium-donor and -acceptor sites in **47** required an epimerization at C-5 (KOH treatment of **49**) to give, via a final ester pyrolysis, the target molecule **51**.

A related synthesis of 12-acetoxysinularene **58**[18] differs in that the magnesium-ene unit is part of the norbornene skeleton which carries the enophilic chain at C-2 (Scheme 12).



Scheme 12. NCS = *N*-chlorosuccinimide, DMS = dimethyl sulfide, MoOPH = MoO_5-pyridine-hexamethylphosphoramide complex.

Hence, by reversing the relative positions of the reaction partners, the bond between C-5 and C-6 was closed in the key step **55**→**56** with simultaneous formation of both the methylene group and the C-12 Mg functionality. Accordingly, one synthetic operation provided alcohol **57** in 62% yield from chloride **54**. (Again, the initial *cis* relation of C-12 and C-7 was altered thereafter by an epimerization at C-5.)

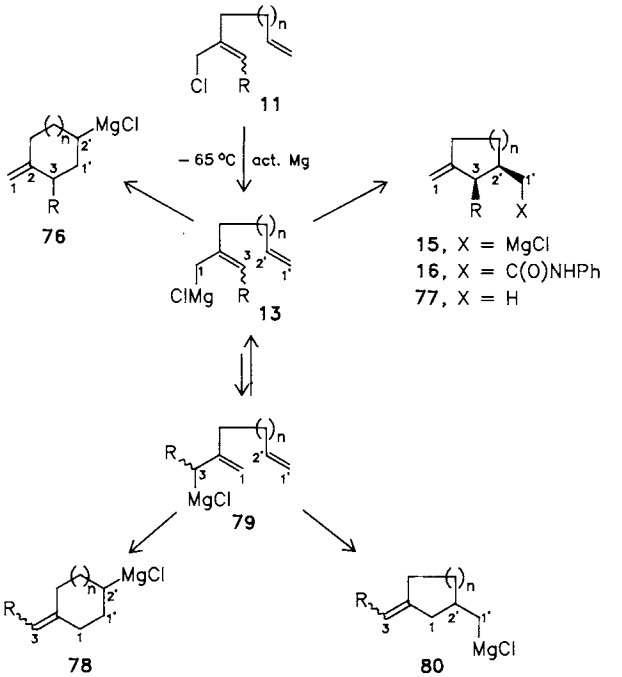


The stereodirecting bias of a preexisting stereogenic center on the intramolecular magnesium-ene reaction is illustrated by the enantioselective syntheses of (+)-α-skytanthine **68** and (+)-δ-skytanthine **69**, as well as of (+)-iridomyrmecine **70**[19] (Scheme 13).

Bromide **59**, easily accessible in 94% enantiomeric purity via an asymmetric 1,4 addition of vinylcopper to a chiral *O*-crotylenoate, was converted into the allylic chloride **61**. Metalation of **61** with commercial Mg powder and

Scheme 13. 9-BBN = 9-borabicyclo[3.3.1]nonane.

heating of the resulting solution under reflux followed by oxidative trapping of **63** with MoOPH at −78 °C yielded an 88.4/5.9/3.0/1.4 stereoisomer mixture of cyclized alcohols (58%). The major isomer **64**, isolated by flash chromatography (49% from **61**), has the desired (4a*S*,7a*R*) configuration. This result is consistent with a favored transition state **62**≠ (with the C-7 methyl group oriented toward the convex face) assuming that 2,3-substituted 2-alkenylmagnesium halides react in their (*Z*) form (cf. Section 2.2.1). Stereoconvergent control over the remaining center C-4 was achieved by hydroboration(BH_3)/oxidation of the free alcohol **64** to give diol **66** which was cyclized to give (+)-skytanthine **68**; alternatively, hydroboration(BBN)/oxidation of the benzoate **65** furnished predominantly the C-4-epimer **67** which was transformed into either (+)-δ-skytanthine **69** or (+)-iridomyrmecine **70**.



Scheme 14.

Whereas all foregoing applications rely on a kinetically determined stereoselectivity of magnesium-ene cyclizations, it is apparently a thermodynamic control which governs the cyclization **72**→**73** at 138 °C over 61 h to give, after oxidative quenching with O_2, an 83 : 8 : 9 mixture of stereoisomers. The major all-*trans* alcohol **74** was converted into the dimethyl ester of *trans,trans*-boschnialic acid **75**[20] (Scheme 14).

2.2. Type-II Magnesium-Ene Cyclizations

2.2.1. Systematic Investigations

This version, in which the enophilic chain is attached to the central atom C-2 of the magnesium-ene moiety was not described until 1982 (see Scheme 15). A systematic investigation dealing with the efficiency as well as the regio- and stereoselectivity of this reaction[21] (Scheme 15, Table 2) involved heating 2-alkenylallylmagnesium chlorides **13** followed by quenching of the cyclized Grignard reagents with phenyl isocyanate (Table 2, entries 1–5) or water (entry 6).

Scheme 15.

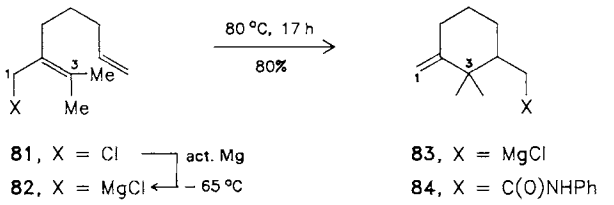


Table 2. Intramolecular type-II magnesium-ene reactions **11**→[**13**→**15**]→**16** or **77**.

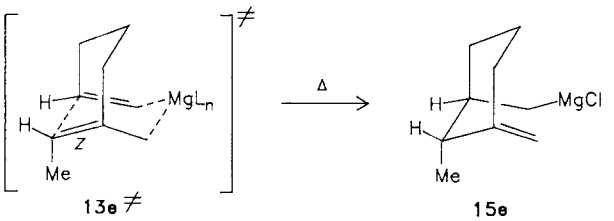
Entry		n	R	*T* [°C]	*t* [h]	Product	Yield [%]
1	**a**	1	H	130	23	**16a**	71
2	**b**	2	H	80	17	**16b**	72
3	**c**	3	H	130	17	**16c**	71
4	**d**	3	CH_3	130	23	**16d**	40 [a]
5	**e**	2	CH_3	80	17	**16e**	86
6	**f**	2	n-C_6H_{13}	80	17	**77f**	81

[a] 20% of noncyclized dienylanilide isolated.

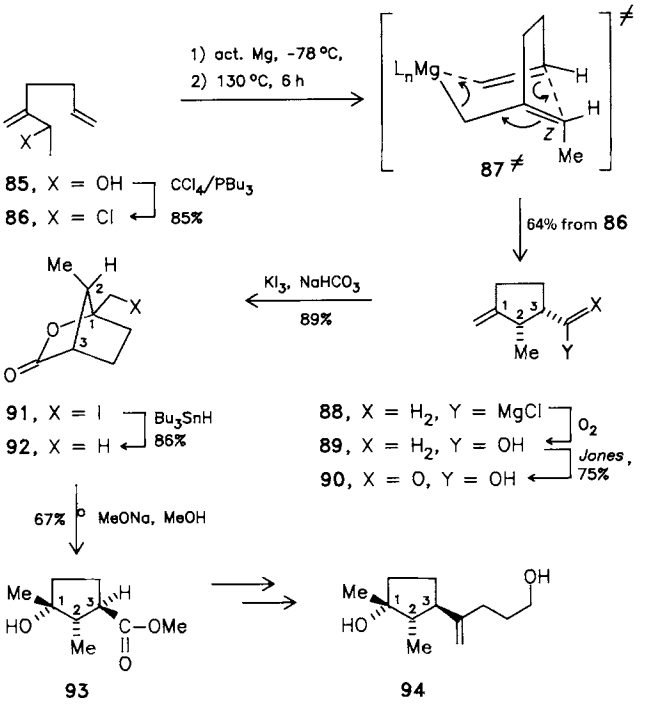


It is worth noting that a six-membered ring (entries 2, 5, 6) was formed more readily than a five-membered (entry 1) or a seven-membered ring (entries 3, 4), reflecting the counterplay of entropic and angle-strain factors.

This study also revealed an astonishing *regioselectivity* insofar as only products **16** or **77** (but no isomers derived from **76** or **78**) were observed, regardless of the distance between the reactive units. Accordingly, the magnesium was transferred to the distal site C-1′ of the *enophile* and the new C–C bond was formed at the proximal C-2′ site. As to type-II cyclizations of nonsymmetrically substituted *magnesium-ene* species (entries 4–6), a rapid 1,3-metal migration, **13**⇆**79**,[22] leaves two possibilities: C–C bond formation with either the more or less substituted ene terminal C-3 (**13**→**15**) or C-1 (**79**→**80**) of which only the former regiochemistry was observed. Also the 3,3-dimethyl-substituted magnesium-ene component of **81** underwent C–C bond formation only to C-3 (generating a quaternary center) to give **84** (80%, Scheme 16).

Scheme 16.

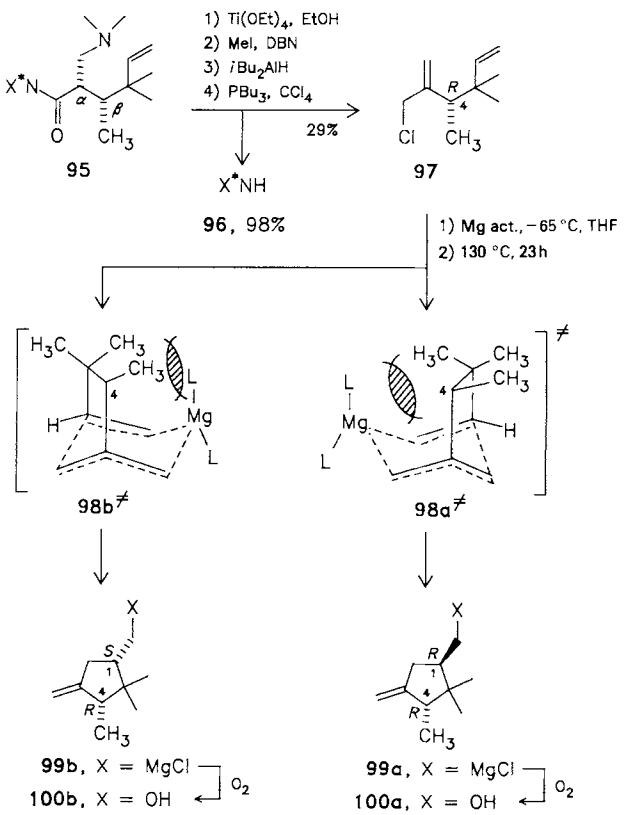
Focusing on the *stereochemistry* it is interesting to note that only *cis* isomers **16** and **77** were observed; this indicates highly selective olefin "insertion" into a (*Z*)-ene unit **13** (Scheme 17) which is in a rapid equilibrium with (*E*)-**13** (via the 1,3-Mg shift **13**⇆**79**; see Scheme 15).



Scheme 17.

2.2.2. *Applications to the Syntheses of Natural Products*

The above-mentioned type of stereocontrol is exploited in a synthesis of the fungitoxin (±)-chokol-A **94**[23] (Scheme 18).

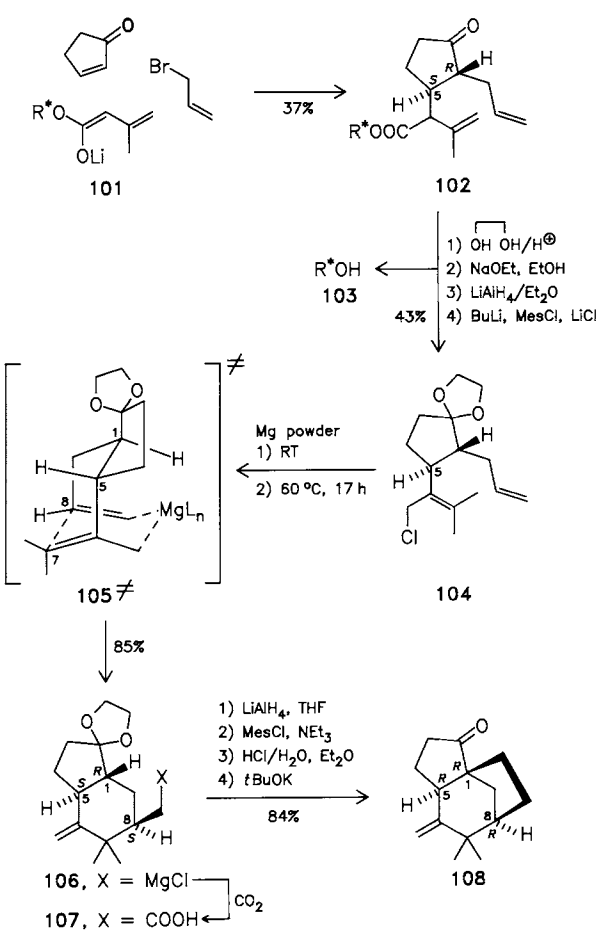


Alcohol **85** (easily prepared from 1-hexen-5-one in two steps) efficiently gave allyl chloride **86** (CCl_4/PBu_3; 85% yield). The metalation/cyclization/oxidation step **86**→**87**≠→**88**→**89** (described in detail) furnished *cis*-cyclopentylmethanol **89** (64% from **86** together with 2% of its *trans* epimer and 6% of a positional isomer derived from **80**); **89** was then oxidized to *cis*-carboxylic acid **90**. Iodolactonization/reduction, **90**→**91**→**92**, assured the desired *cis* disposition of the C-1-hydroxyl and C-2-methyl groups

Scheme 18.

in **93**. Basic methanolysis of lactone **92**, accompanied by C-3 epimerization, furnished the *trans*-related 3-methoxycarbonyl substituent, which was transformed into the pentenol side chain of **94**.

By contrast, no diastereoselectivity was found in the type-II magnesium-ene cyclization/oxidation **97**→**98**≠→

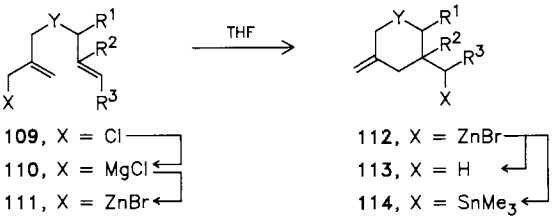


Scheme 19. DBN = 1,5-diazabicyclo[4.3.0]non-5-ene.

99 → **100**, which afforded the carrion beetle defense compound β-necrodol **100a** together with its C-1 epimer **100b** (61%, 1:1 mixture).[24] This is not surprising since transition states **98a**$^{\neq}$ (→ **100a**) and **98b**$^{\neq}$ (→ **100b**) suffer similar steric crowding due to the *gem*-dimethyl substitution (Scheme 19).

Nevertheless, **95**, obtained in enantiomerically pure form via a methylcopper addition/Mannich reaction of a chiral *N*-crotonoylsultam, provided (4*R*)-**97**, which yielded, after separation from **100b**, optically pure β-necrodol **100a**, thus enabling an assignment of the absolute configuration of the natural product.

A culmination of the type-II magnesium-ene cyclization methodology is its ideal application to the regio-, diastereo-, and enantioselective synthesis of the otherwise elusive, odoriferous norsesquiterpene (+)-khusimone **108**[25] (Scheme 20).



Scheme 20.

Conjugate addition of a chiral dienolate **101** to cyclopentenone, coupled with an enolate trapping by allyl bromide, chromatography, and crystallization, directly gave enantiomerically pure **102** (37% from cyclopentenone), which was readily converted into allylic chloride **104**. Slow addition of **104** to Mg powder (Merck) in THF, heating the solution at 60 °C for 17 h, and quenching with CO_2 gave, after crystallization, bicyclic carboxylic acid **107** (85% from **104**). No regio- or stereoisomer of **107** was found in the mother liquor. This particularly strong influence of the preexisting centers C-5 and C-1 in **104** on the generation of the stereogenic center C-8 conforms with the sterically least congested transition state **105**$^{\neq}$. Hence, the magnesium-ene step provided the thermodynamically unstable, sterically encumbered 7,7-dimethyl-6-methylene moiety with perfect control over the chirality at C-8.

2.3. Type-II Zinc-Ene Cyclizations

The thermal type-II cyclizations of olefinic allylzinc bromides **111** show interesting possibilities; the latter were prepared in situ from chlorides **109** via transmetalation of the Grignard intermediates **110** with $ZnBr_2$ (1.5 equiv.). Quenching of the cyclized alkylzinc species with H_2O (→ **113**) or $ClSnMe_3$ (→ **114**) provided oxygen and nitrogen heterocycles[26] (Scheme 21, Table 3).

Scheme 21.

Table 3. Intramolecular type-II zinc-ene reactions **111** → **112** → **113** or **114** in THF.

Entry		Y	R^1	R^2	R^3	*T* [°C]	*t* [h]	Product	Yield [%] [a]
1	**a**	O	H	H	H	80	23	**114a**	57
2	**b**	O	H	H	CH_3	80	45	**113b**	80
3	**c**	O	H	CH_3	H	130	22	**113c**	50
4	**d**	O	C_6H_5	H	H	80	48	**113d**	76 [b]
5	**e**	OCH_2	H	H	H	80	24	**114e**	62
6	**f**	O	$-(CH_2)_3-$		H	130	22	**113f**	0
7	**g**	NCH_3	H	H	H	80	24	**114g**	64

[a] Based on **109**. [b] 2:1 *trans/cis* mixture.

Analogous attempts to cyclize the allylmagnesium chlorides **110** failed, except for the transformation **110g** → **114g** (76%). On the other hand, the less nucleophilic zinc derivatives **111** cyclized readily at 80 °C, even with a terminally methyl-substituted alkenyl unit (although at 130 °C, entry 3); however, the reaction failed with a cyclohexenyl enophile unit (entry 6).

2.4. Conclusions

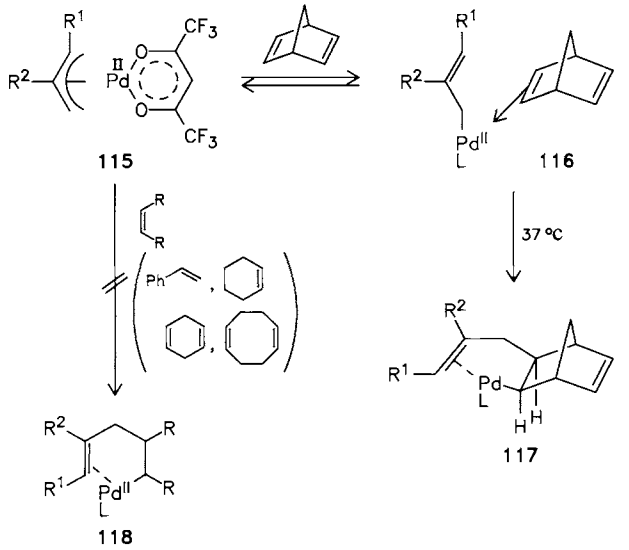
The following trends can be seen from the available evidence.

Ring size: The ease of cyclization decreases in the following order relative to the size of the developing ring:

type I: $5 > 6 \gg 7$
type II: $6 > 5 \approx 7 \gg 8$

Regioselectivity: Carbon–carbon bonds are preferentially formed between the proximal sites of ene and eno-

phile in the type-I process and between the more substituted ene terminal and the proximal enophile site in the type-II version.



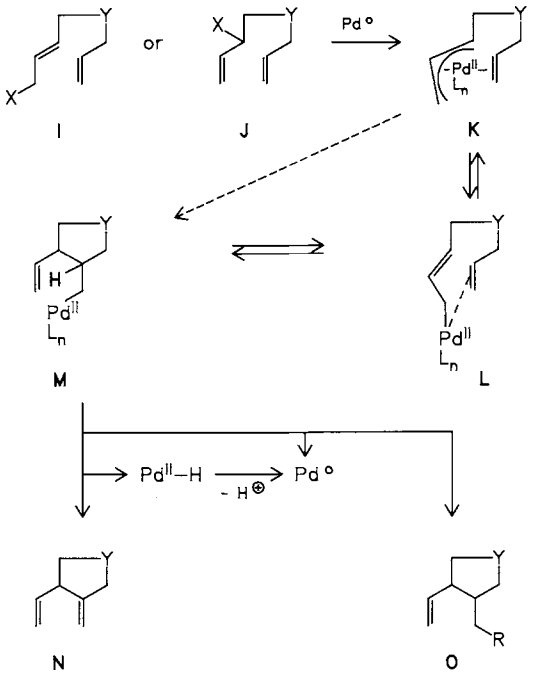
Stereoselectivity: Type-I cyclizations usually furnish, under kinetic control, predominantly five- and six-membered rings carrying *cis*-disposed magnesium-donor and -acceptor units even when a quaternary center is generated. 2,3-Dialkyl-substituted allylmagnesium moieties react preferentially in their (*Z*) form, inducing a *cis* relation of the C-3 substituent and the magnesium acceptor site in type-II cyclization products. However, the stereoselectivity of type-I and type-II magnesium-ene cyclizations can be greatly diminished by severe steric hindrance, for example, by critically placed *gem*-dimethyl groups (cf. **31**, **98**).

Limitations: The above examples involve only terminal (or strained, cf. **46**) olefinic enophile units since intramolecular insertions of 1,2-dialkyl, trialkyl, and cyclic alkenes into allylmagnesium compounds could not be achieved. Furthermore, attempts to apply these cyclizations to the preparation of pyrrolidines have so far failed. Nevertheless, type-II cyclizations of allylzinc derivatives show potential in overcoming some of these limitations.

3. Palladium-, Nickel-, and Platinum-Catalyzed Intramolecular Metallo-Ene Reactions

3.1. Palladium-Catalyzed Metallo-Ene Reactions

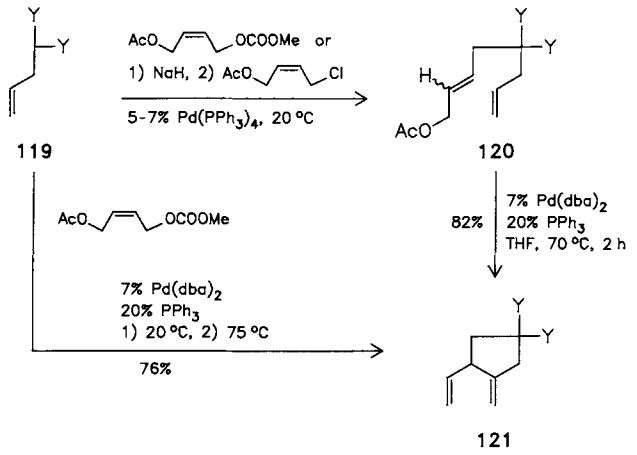
As a more interesting concept to circumvent these and other constraints of magnesium-ene cyclizations, we envisaged the exploration of *catalytic* intramolecular palladium-ene reactions. Indeed, stoichiometric amounts of allylpalladium complexes **115** and norbornadiene have been reported to undergo rapid, reversible formation of the σ-allyl complexes **116**, which at 37 °C yielded the *cis*-insertion products **117**[27] (Scheme 22).



Scheme 22. L = hexafluoroacetylacetonate.

Similar stoichiometric additions of allylpalladium species to norbornene[28] and 1,3-dienes[29] are also known, whereas simple olefins (e.g., styrene, cyclohexene, 1,4-cyclohexadiene, and 1,5-cyclooctadiene) did not undergo this reaction.[27]

3.1.1. Type-I Cyclizations

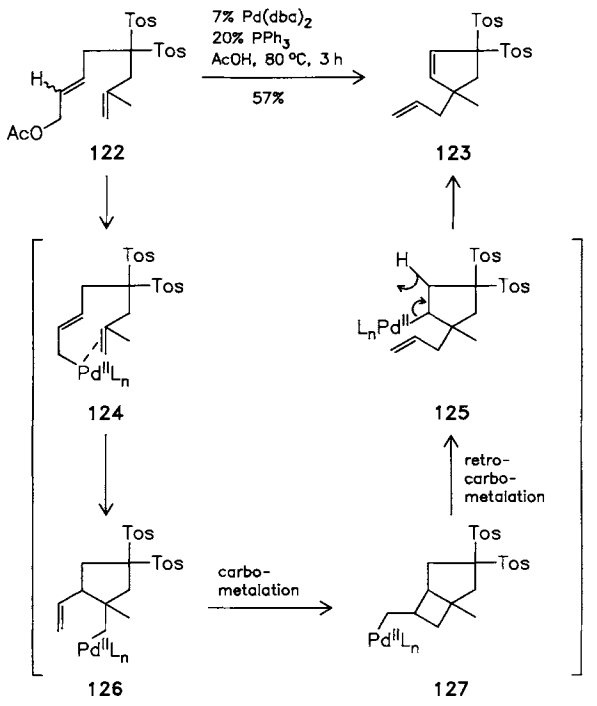


However, we assumed that the intramolecular ene process **L** → **M** would be entropically favored and that a subsequent irreversible β-elimination **M** → **N** would withdraw the ene product **M** from the equilibrium **L** ⇆ **M**.[30a] A further option is insertion/reductive elimination **M** → **O**.[30b] The thereby regenerated Pd^0 should continue the catalytic cycle by oxidative addition to allyl derivatives **I** or **J** (e.g., X = OR), thus providing in situ the olefinic allylpalladium intermediates **K** (Scheme 23).

Scheme 23.

Acetoxydienes **120** were readily obtained, predominantly as their (*E*) isomers, via $Pd(PPh_3)_4$-catalyzed alkylation[31] of disulfones **119a** (Y = SO_2Aryl) or malonates **119b** (Y = COOMe) with 4-acetoxy-2-butenyl methyl carbonate. Heating diene **120a** (Y = Tos) with $Pd(dba)_2$ (0.07 equiv.)/PPh_3 (0.2 equiv.) in THF at 70 °C gave the expected cyclized 1,4-diene **121a** in 83% yield. Even more conveniently, product **121a** was obtained (76% yield) in *one* operation from **119a** via Pd^0-catalyzed alkylation/cyclization[30] (Scheme 24, Table 4, entry 2).

Solvent effects significantly influence this novel ene process, as illustrated by the cyclization of the malonate **120b** (→ **121b**). Whereas no reaction took place in toluene, dichloromethane, or *N,N*-dimethylformamide, the rate and yield increased on proceeding from THF (20%) to methanol (65%) to acetic acid (77%, entries 3–5).[30] Interestingly, the presence of the phosphane turned out to be indispensable for the transformation **120b** → **121b**.

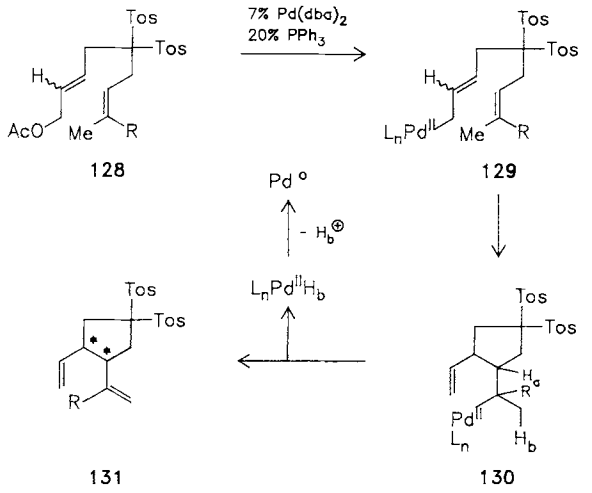


Scheme 24. dba = dibenzylideneacetone.

Table 4. $Pd(dba)_2/PPh_3$-catalyzed cyclizations **120** → **121**.

Entry		Y	Solvent	T [°C]	t [h]	Yield **121** [%]
1	**a**	Tos	THF	70	2	82
2 [a]	**a**	Tos	THF	one-pot [a]		76
3	**b**	COOMe	THF	80	40	20
4	**b**	COOMe	MeOH	80	8	65
5	**b**	COOMe	AcOH	80	1.5	77

[a] One-pot reaction from **119a**.

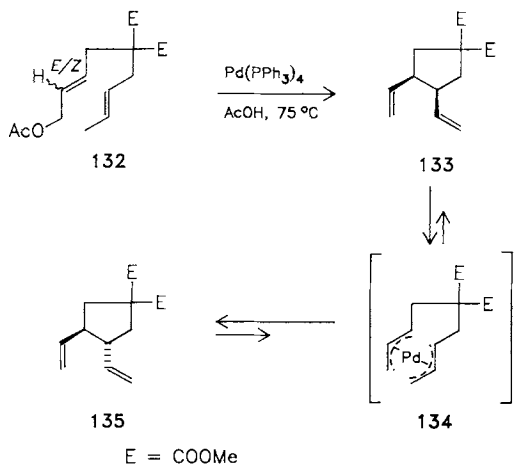


Intramolecular insertion of a 1,1-dialkylalkene into an allylpalladium unit (**124** → **126**) proceeded under the usual conditions as illustrated by the cyclization **122** → **123**[32] (Scheme 25).

Scheme 25.

It appears that the cyclized alkylpalladium intermediate **126**, unable to undergo β-elimination, carbometalates the adjacent vinyl group to give the transient **127**, which undergoes retro-carbometalation/β-elimination **127** → **125** → **123**.

In striking contrast to 8-alkyl-substituted 2,7-dienylmagnesium halides, which did not cyclize (cf. Section 2.1), the allylpalladium unit of **129** inserted readily into a terminally mono- and even dimethyl-substituted olefinic bond to give the transients **130** (Scheme 26, Table 5).



Scheme 26.

Table 5. $Pd(dba)_2/PPh_3$-catalyzed cyclizations **128** → **131**.

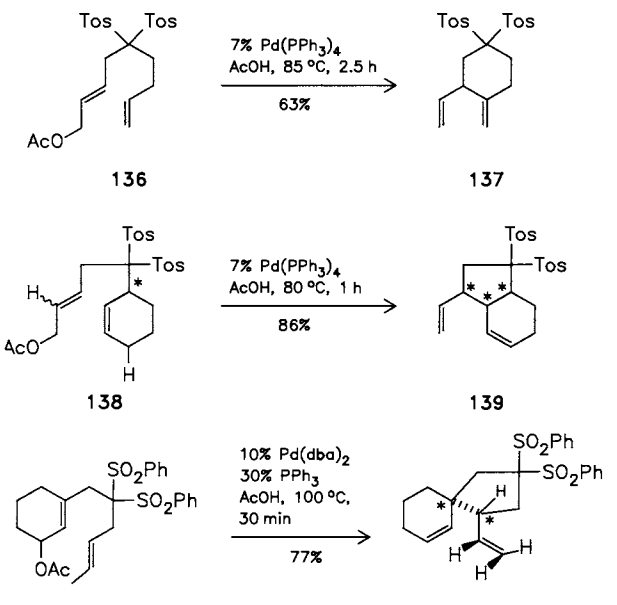
Entry		R	Solvent	T [°C]	t [h]	Yield **131** [%]
1	**a**	H	THF	75	15	80
2	**a**	H	AcOH	75	1.5	91
3	**b**	Me	THF	85	40	40
4	**b**	Me	AcOH	75	1.5	71

The efficient Pd^0-catalyzed cyclizations (AcOH, 75 °C, 1.5 h) of acetoxydienes **128a** and **128b** furnished, in each case, a single 1,5-diene product, **131a** (91%) and **131b** (71%), respectively. It follows that the cyclic alkylpalladium intermediates **130** eliminate the exocyclic H_b prefer-

Scheme 27.

Table 6. Stereochemistry of $Pd(PPh_3)_4$-catalyzed cyclizations **132** → **133** + **135**.

Entry	**132** $E:Z$	Equiv. $Pd(PPh_3)_4$	t [h]	Yield [%] **133** + **135**	**133** : **135**
1	0 : 100	0.05	5	70	36 : 64
2	60 : 40	0.05	5	67	36 : 64
3	60 : 40	0.07	2	26 (80) [a]	32 : 68
4	60 : 40	0.10	24	52	10 : 90



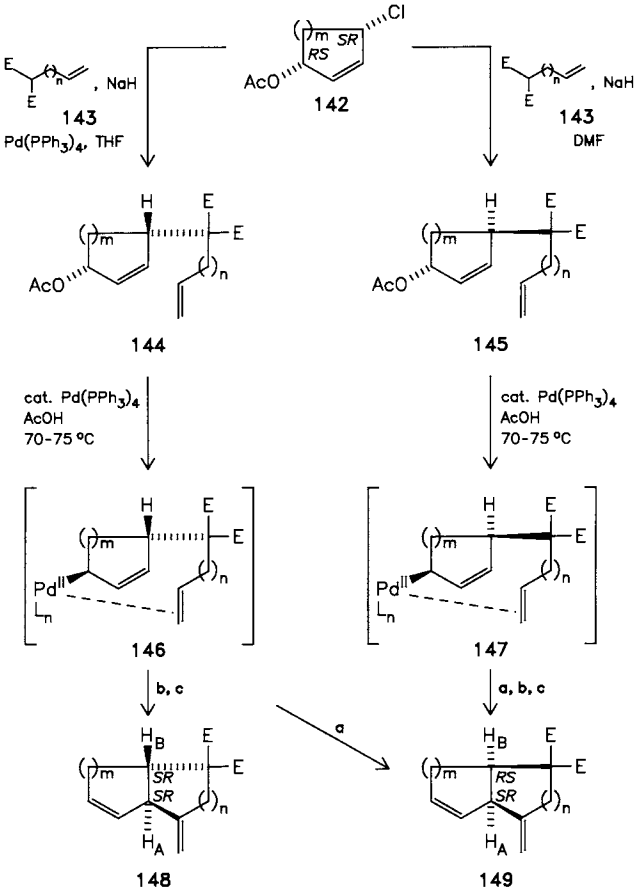
[a] Yield in parentheses based on recovered **132**.

entially over H_a in agreement with the conformational constraints of a *syn* β-elimination process. Again, acetic acid proved to be a better solvent than THF (cf. entries 1, 2 and 3, 4).[30]

The cyclization **132** → **133** + **135** showed a kinetically controlled 2 : 1 preference for the formation of the *trans*-divinylcyclopentane (independent of the ene *E*/*Z* configuration (cf. Scheme 34); the ratio increased to 9 : 1 when more catalyst and a longer reaction time were employed[32] (Scheme 27, Table 6).

This useful predominance of the thermodynamically more stable *trans* product **135** (entry 4) presumably involves a palladium-catalyzed "Cope-type" equilibration (**133** ⇆ **134** ⇆ **135**).

As expected, $Pd(PPh_3)_4$ also proved to be a suitable catalyst for intramolecular palladium-ene reactions (Scheme 28).



Scheme 28.

Conversion **136** → **137** illustrates the feasibility of this method for six-membered ring formation. Acetoxydiene **138**, containing a cyclic enophile unit, furnished stereoselectively the bicyclic product **139** in 86% yield.[30]

The palladium-ene unit may also be part of a ring, as shown by the stereoselective formation of a spiro system (**140** → **141**).[32a,33]

Stereochemically even more striking are the cyclizations depicted in Scheme 29 and Table 7.

Scheme 29.

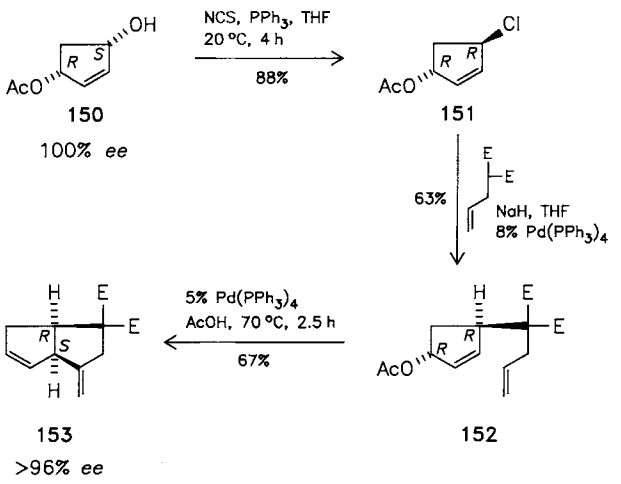


Table 7. Stereocontrolled syntheses of bicyclo[4.3.0]-, [4.4.0]-, and [5.3.0] ring systems by Pd-catalyzed cyclizations of acetoxydienes **144** and **145** (in AcOH).

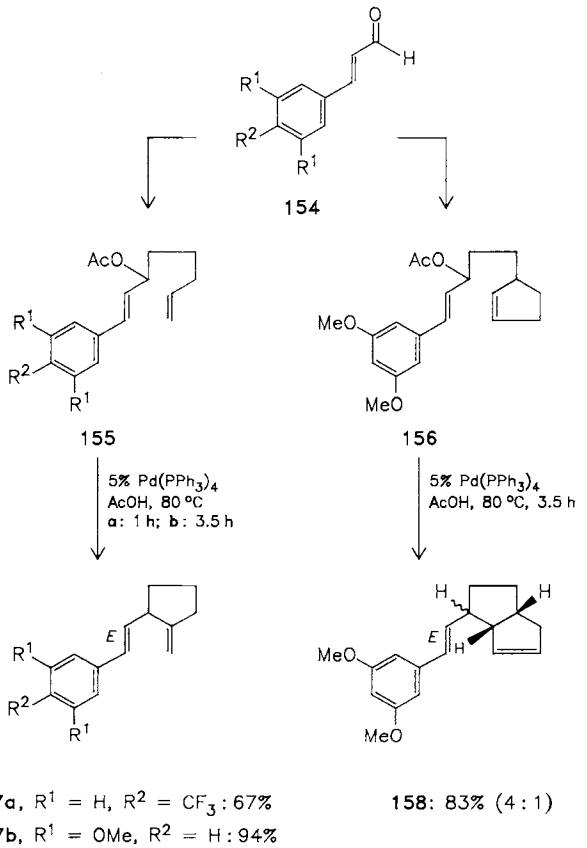
Entry [a]	Starting material	m	n	t [h]	Yield **149** + **148** [%]	**149** : **148**
1	**145a**	2	1	1.1	84	≥98 : ≤2
2	**144a**	2	1	4	55	≥98 : ≤2
3	**145b**	2	2	3	60	>99 : <1
4	**144b**	2	2	3	69	5 : 95
5	**145c**	3	1	4	73	99 : 1
6	**144c**	3	1	1.8	80–92	2 : 98

[a] Entries 1–4: 7 mol% $Pd(PPh_3)_4$, 75 °C. Entry 5: 10 mol% $Pd(PPh_3)_4$, 70 °C. Entry 6: 5 mol% $Pd(PPh_3)_4$, 70 °C.

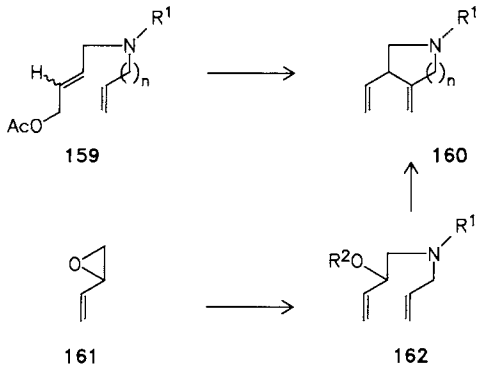


Comparison of entries 1 and 2 shows that the *trans*- or *cis*-olefinic cyclohexenyl acetates **145a** or **144a**, respectively, gave the same *cis*-annelated hexahydroindene **149a**.[30] However, the conversion **144a** → **149a** is significantly slower, presumably due to the relatively slow *trans*/*cis* isomerization **146** → **147**. It appears that, in initially formed **146a**, coordination of the Pd atom with the *trans*-disposed enophile is highly unfavorable, which prevents its conversion to **148a**. However, a longer bridge or a larger preexisting ring should permit allylpalladium/olefin coordination even in the *trans* intermediates **146**. Indeed, the *trans*-acetoxydiene **145b** furnished exclusively the *cis*-fused octahydronaphthalene **149b**, whereas the *cis*-acetoxydiene **144b**

gave, with 95% stereospecificity, the *trans*-annelated product **148b** (entries 3, 4).[33,34] This interesting C-O→C-Pd→C-C chirality transfer also provides selective routes to *cis*- or *trans*-fused octahydroazulenes **149c** or **148c**, respectively (entries 5, 6).[32,34] These findings confirm that the olefin inserts predominantly into the σ-(or π-)allylpalladium unit *cis* relative to the Pd atom (i.e., in a suprafacial manner).

Scheme 30.

Scheme 30 exemplifies the analogous enantiospecific preparation of a hexahydropentalene **153** from a readily available, optically pure hydroxy acetate **150**.[32,34]



Scheme 31.

The *gem*-disulfone and malonate functionalities described above facilitate the preparation of the "palladium-ene" precursors **I** (Scheme 23) and can be readily removed or modified but they *are not essential* for the cyclization process. Thus, 3-acetoxy-substituted 1,7-octadienes **J** (e.g., **155**, **156**) containing simple carbon bridges are very readily accessible and undergo smooth Pd-catalyzed cyclizations[32] (Scheme 31).

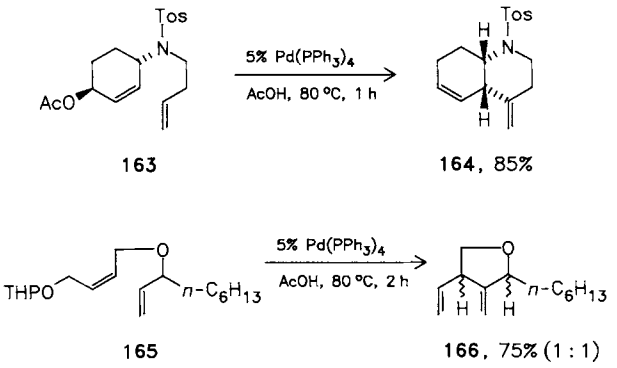
Only products **157** and **158** containing an (*E*)-olefinic bond were found, indicating the ene-type reaction of (*E*)-allylpalladium intermediates.

Catalytic Pd-ene cyclizations may also open new perspectives in alkaloid synthesis, as shown by the smooth formation of pyrrolidines and piperidines.[33,35]

Scheme 32.

Table 8. Synthesis of pyrrolidines and piperidines by Pd^0-catalyzed cyclizations **159**→**160** and **162**→**160** (AcOH, 80 °C, 5 mol% $Pd(PPh_3)_4$).

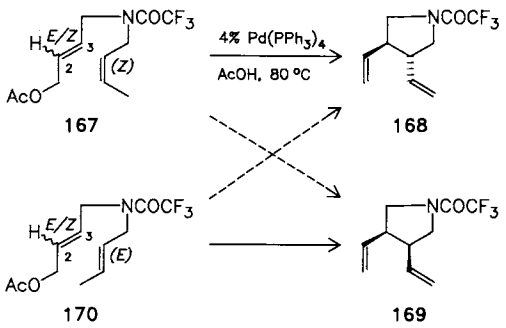
Entry	Starting material	R^1	R^2	n	*t* [h]	Yield **160** [%]
1	**159a**	CH_2Ph	—	1	3	72
2	**159b**	$COOCH_2Ph$	—	1	1	69
3	**159c**	Tos	—	1	0.5	72
4 [a]	**159d**	Tos	—	2	4	77
5	**162e**	C(O)Ph	C(O)Ph	1	0.5	81
6	**162f**	Tos	H	1	3.5	78



[a] 7 mol% of $Pd(PPh_3)_4$ used.

Scheme 32 and Table 8 illustrate the cyclizations of "palladium-ene" precursors **I** (**159**, entries 1-4) and **J** (**162**, entries 5, 6) containing a nitrogen atom as part of the bridge. The leaving group in **162** can even be a simple hydroxyl group (entry 6).[35]

Stereospecific formation of the *cis*-fused octahydroquinoline **164** (85%) is depicted in Scheme 33, which also shows the conversion of diallyl ether **165** to a 1:1 *cis*/*trans* mixture of tetrahydrofurans **166** (75%).[35]



It is worth noting that the initial oxidative addition of Pd^0 to **165** proceeded with selective substitution of the allylic acetal group whereas the allylic ether moieties remained intact.

Pd^0-catalyzed cyclizations of (*E*,*Z*)-, (*Z*,*Z*)-, (*E*,*E*)-, and (*Z*,*E*)-*N*-trifluoroacetamides **167** and **170** (Scheme 34, Table 9) again represent the insertion of terminally methyl-

Scheme 33. THP = tetrahydropyranyl.

substituted olefinic bonds into (*E*)-allylpalladium components followed by β-elimination of a methyl hydrogen atom[35] (Scheme 34, Table 9).

Scheme 34.

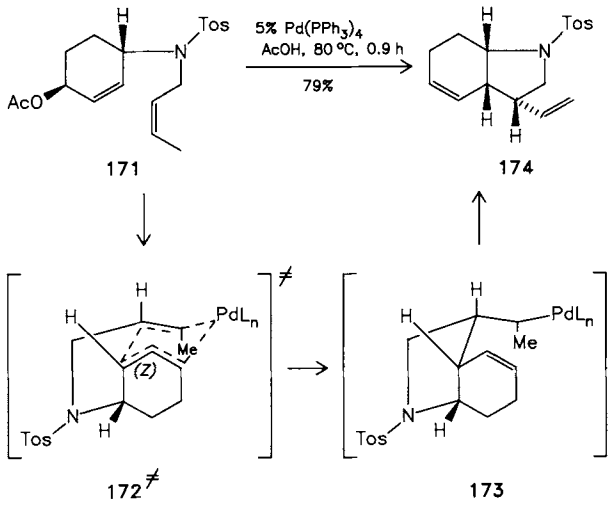


Table 9. Pd^0-catalyzed cyclizations **167** → **168** + **169** and **170** → **168** + **169**.

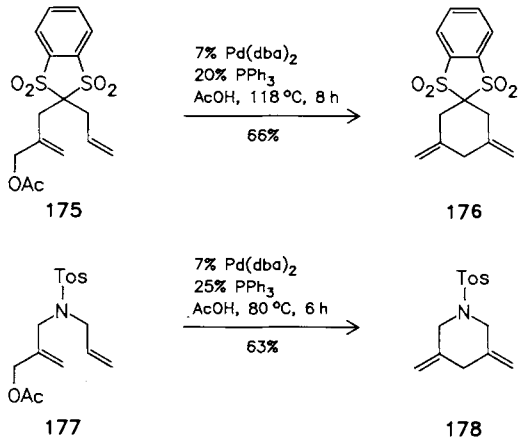
Entry	Starting material	*E/Z* C-2–C-3	*t* [h]	Yield **168** + **169** [%]	**168** : **169**
1	**167**	*E*	0.6	76	88 : 12
2 [a]	**167**	*E*	20	75	88 : 12
3	**167**	*Z*	1.9	59	91 : 9
4	**170**	*E*	2	67	28 : 72
5 [a]	**170**	*E*	52	62	30 : 70
6	**170**	*Z*	2.5	51	30 : 70

[a] 10 mol% of [polymer-C_6H_4-$P(C_6H_5)_2]_4Pd$ (Fluka).

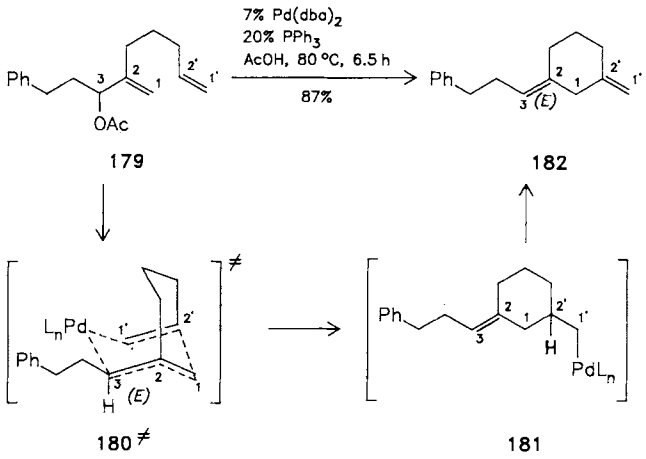
Entries 2 and 5 exemplify the use of a polymer-supported palladium(0)-phosphane catalyst which may offer, in general, practical advantages for carrying out palladium-catalyzed ene-type cyclizations.[36] As to the *stereochemistry*, dienes **167**, containing a (*Z*)-enophile, gave, under kinetic control, predominantly the *trans*-divinylpyrrolidine **168** (≈8 : 1, entries 1–3), whereas dienes **170**, containing an (*E*)-enophile, afforded, less selectively (2.5 : 1), the *cis* product **169** (entries 4–6). This stereochemical outcome was independent of the *E/Z* configuration of the allyl acetates **167** and **170** in agreement with an (*Z*)-→(*E*)-allylpalladium isomerization prior to the insertion (indeed, isomerizations (*Z*)-**167** → (*E*)-**167** and (*Z*)-**170** → (*E*)-**170** were observed under the cyclization conditions).



By contrast, if the (*Z*) configuration of the allylpalladium unit (e.g., in **172**$^{\neq}$) is enforced by incorporation into a ring, only *cis*-substituted insertion products are expected, as confirmed by the annelation **171** → **174**[35] (Scheme 35).

Scheme 35.

3.1.2. *Type-II Cyclizations*

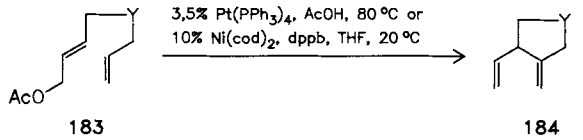


Scheme 36 illustrates the feasibility of carrying out catalytic type-II palladium-ene cyclizations, for example, the transformation **175** → **176** (118 °C, 8 h, 66% yield).[33,37] Cyclization of **177** proceeded under milder conditions (80 °C, 6 h) to give piperidine **178** (63%).[37]

Scheme 36.

Also, dienyl acetate **179** (readily prepared from 6-hepten-2-one and lacking the disulfone moiety) was easily transformed into (*E*)-1,4-diene **182** (87%)[33,37] (Scheme 37).

This regiochemistry parallels that of stoichiometric additions of allylpalladium complexes to norbornadiene,[27] but was subject to uncertainty in view of the relatively fast 1,3-Pd migration[31] (formally analogous to the equilibrium **13** ⇆ **79**; Scheme 15, Section 2.2.1). Accordingly, the conversion **179** → **182** demonstrates a new stereocontrolled access to exocyclic trisubstituted alkenes involving C–C bond formation at the less substituted allylpalladium ter-



Scheme 37.

minal and thus showing a regio- and stereochemistry *opposite* to the type-II magnesium-ene process (Scheme 15, **13** → **15**).

3.2. Platinum- and Nickel-Catalyzed Reactions

The above concept of catalytic metallo-ene cyclizations (Scheme 23) may also be extended to platinum and nickel. Norbornene has already been reported to undergo stoichiometric, bimolecular addition of a preformed allylnickel complex followed by carbomethoxylation of the adduct,[28a] as well as a nickel-catalyzed allylation/rearrangement/elimination.[38] Allylnickel/olefin insertions are apparently involved in Ni-catalyzed polymerizations and oligomerizations of 1,3-butadiene[39] such as the dimerization to 1-methylene-2-vinylcyclopentane.[40]

Scheme 38. cod = 1,5-cyclooctadiene; dppb = *P,P'*-tetramethylenebis(diphenylphosphane).

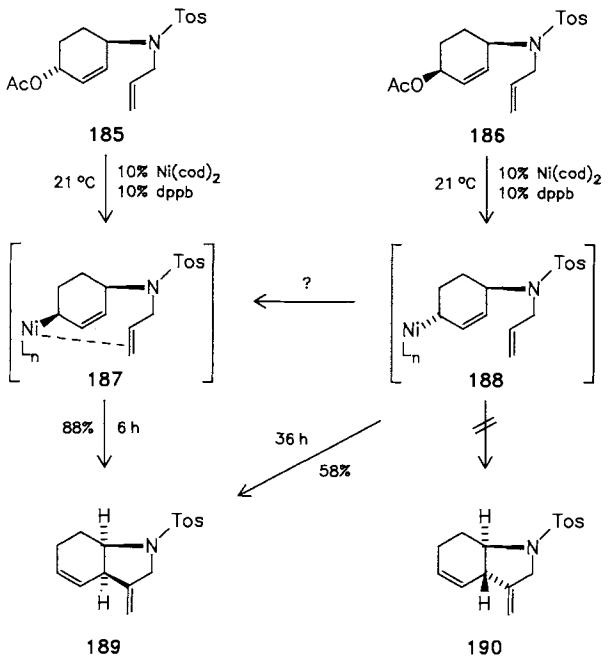


Table 10. Pt^0- and Ni^0-catalyzed cyclizations **183** → **184**. Pt^0 catalysis: 3.5 mol% $Pt(PPh_3)_4$, AcOH, 80 °C. Ni^0 catalysis: 10 mol% $Ni(cod)_2$, dppb, THF, 20 °C.

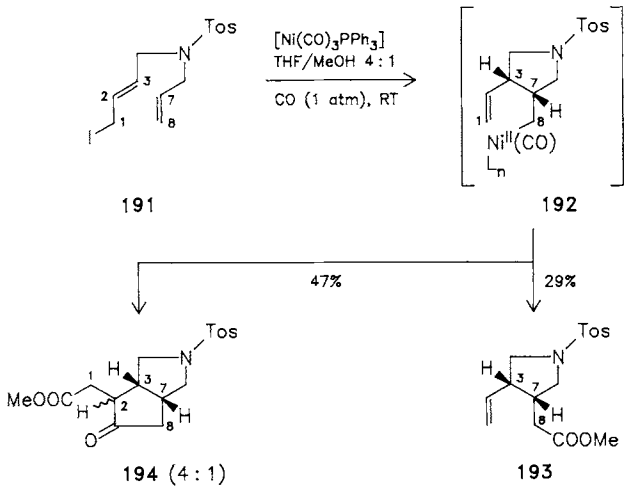
Entry		Y	Cat.	Solvent	T [°C]	t [h]	Yield [%]
1	**a**	$C(SO_2Ph)_2$	Pt^0	AcOH	80	5	85
2	**a**	$C(SO_2Ph)_2$	Ni^0	THF	20	3	83
3	**b**	N–Tos	Ni^0	THF	20	12	76
4	**c**	$N–CPh_3$	Ni^0	THF	20	0.7	92

Heating dienyl acetate **183a** with 3.5 mol% of $Pt(PPh_3)_4$ in acetic acid at 80 °C furnished the expected cyclopentane **184a** in 85% yield[33,41] (Scheme 38, Table 10, entry 1).

The feasibility of Ni^0 complexes as catalysts for intramolecular metallo-ene reactions was, despite the encouraging precedents, not straightforward and depended strongly on their ligands. Systematic studies showed a 1:1 mixture of $Ni(cod)_2$/dppb to catalyze (10 mol%) the allylation/elimination **183** → **184** at 20 °C in THF with a synthetically useful efficiency (76–92%, entries 2–4).[33,41]

The catalyst [Ni(cod)dppb], formed in situ, induced smooth conversion of monocyclic *trans*-acetoxydiene **185** to the *cis*-fused 3-methylene-hexahydroindole **189** (88%), which is also formed much more slowly (58%) from the *cis*-precursor **186**[41] (Scheme 39).

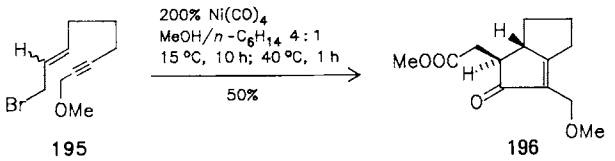
Scheme 39.



This indicates a preferred *cis*-allylnickel/olefin insertion **187** → **189** analogous to the closely related palladium-catalyzed annelations **146a** or **147a** → **149a**.

Coupling of an intramolecular nickel-ene process with a methoxycarbonylation should regenerate a Ni^0 species to continue the catalytic cycle analogous to the originally envisaged sequence **I** or **J** → **K** → **L** → **M** → **O** (Scheme 23).

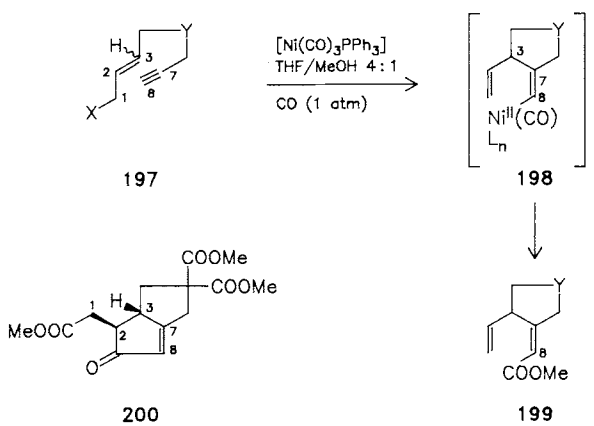
Tricarbonyl(triphenylphosphane)nickel[42] (25 mol%), a stable, easy to handle solid (versus the highly volatile and toxic $Ni(CO)_4$) readily catalyzed the conversion of dienyl iodide **191** (THF/MeOH 4:1, 1 atm CO, room temperature) to the monocyclic *cis*-substituted pyrrolidine **193** (29%) and the bicyclic compound **194** (47%, 4:1 mixture of isomers, Scheme 40).[41]



It thus appears that the nickel-ene process **191** → **192** is stereoselective and that **192** forms a *C*-acylnickel intermediate which inserts either methanol (→ **193**) or the internal olefinic bond giving, after final methoxycarbonylation, ketoester **194**. It is interesting to note that both insertion pathways are preferred over a β-elimination of **192**.

Direct β-elimination cannot interfere with allylnickel/alkyne insertion–carbonylation sequences. Very recently, the

Scheme 40.



bicyclization of (*E*)- and (*Z*)-**195** to **196** (50%), promoted by 200 mol% of $Ni(CO)_4$ at 40°C, has been reported[43] (Scheme 41).

Scheme 41.

Use of 25 mol% of the more practical $[Ni(CO)_3PPh_3]$ catalyst under CO (1 atm, THF/MeOH 4:1, room temperature) resulted in exclusive monocyclization of enynyl iodide **197a** to **199a**[41] (Scheme 42, Table 11, entry 1).

This unusual stereocontrolled approach to an exocyclic trisubstituted olefinic bond is consistent with a suprafacial allylnickel/acetylene insertion **197** → **198**. Malonate **197b** yielded, under similar reaction conditions, the monocyclic ester **199b** (41%) and the bicyclic diester **200** (36%) in a stereospecific manner (entry 2). Bicyclization (→ **200**, 62%) was more prominent when starting with bromide **197c**, which required a higher reaction temperature (entry 3).[41]

Scheme 42.

Table 11. $[Ni(CO)_3PPh_3]$-catalyzed intramolecular allylation/carbonylation of alkynes **197** → **199** (+ **200**). 20–25 mol% catalyst, 1 atm CO.

Entry		*E/Z* of **197**	Y	X	*T* [°C]	*t* [h]	Yield **199** [%]	Yield **200** [%]
1	**a**	*E*	N–Tos	I	RT	20	69	–
2	**b**	*E*	$C(COOMe)_2$	I	RT	20	41	36
3	**c**	*Z*	$C(COOMe)_2$	Br	[a]	[a]	14	62

[a] 48 h at RT then 12 h at 50°C.

3.3. Conclusions

Intramolecular metallo-ene reactions may be catalyzed not only by complexes of Pd^0 but also by those of the other d^{10} transition metals, Pt^0 and Ni^0. Nickel(0) requires an inert atmosphere and a more subtle choice of ligands but provides *cis*-diastereoselectivity in the cyclization step (proceeding at room temperature in THF) and offers numerous possibilities in synthesis when combined with CO-insertion reactions. The stereochemical evidence cited above is not consistent with radical (cf. Scheme 29) or metallocyclic intermediates (cf. Scheme 34), but is in agreement with a suprafacial σ-allylmetallo-ene type process or a direct π-allylmetal/alkene(alkyne) insertion pathway. The compatibility of this reaction with nitrogen atoms as part of the bridge offers interesting perspectives for alkaloid syntheses.

4. Summary and Outlook

Stoichiometric, intramolecular metal-ene reactions (M = Li, Mg, Zn) involving terminal or strained alkene enophile units have served extensively as a cornerstone in efficient syntheses of natural products. Most of this work centers on allylmagnesium/alkene cyclizations because of their diastereoselectivity, the accessibility of the starting materials, and the propensity of the cyclized Grignard intermediates to be trapped by a vast array of electrophiles. On the other hand, the use of Mg is incompatible with several functionalities (e.g., certain heteroatoms) in the acyclic precursor. Zinc-ene cyclizations seem to surmount some of these limitations.

However, d^{10}-transition-metal-catalyzed versions promise, at the moment, an even wider range of possibilities. The need to maintain the catalytic cycle by continuous regeneration of the zerovalent metal limits, however, the functionalizability of the metalated center in the cyclized intermediate. For the same reasons, the readily accessible starting materials may contain various functional groups which are compatible with the reaction conditions and which may be of value for the syntheses of complex heterocycles such as alkaloids. The suprafacial nature of the process permits a useful C–O→C–Pd→C–C chirality transfer.

The exploration of this field is still in its infancy and has focused mainly on the palladium-catalyzed process which is easier to carry out and apparently more versatile (e.g., regarding the substitution pattern of the enophile unit) than the less expensive nickel-catalyzed version. Already,

complementary regio- and stereoselectivities of intramolecular magnesium-, palladium-, and nickel-ene type processes have been recognized which may be put to advantage in organic synthesis.

The future will supply more insight into the mechanisms; nevertheless, the depicted rationalizations have proved to be of predictive value. The range of synthetically useful insertion reactions which are to regenerate the catalytic species will certainly be expanded, as will the nature of the metal, ligands, and starting materials. In particular, the application and development of chiral ligands for achieving asymmetric metallo-ene cyclizations is a considerable challenge. Finally, strategic use for the synthesis of naturally occurring or new structures, difficult to obtain by other methods, is expected to reveal the realistic and full potential of the transition-metal-catalyzed versions.

It is a privilege to acknowledge the crucial contributions of my co-workers whose names are cited in the appropriate references. We thank the Swiss National Science Foundation, Sandoz AG, Basel, and Givaudan SA, Vernier, for generous support of this work.

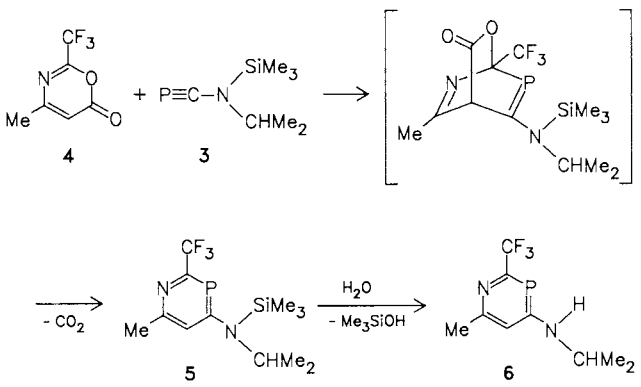
A Stable Amino-Substituted Phosphaalkyne**

By *Rolf Appel** and *Michael Poppe*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

The stabilization of phosphaalkynes[1a] at room temperature requires the use of bulky organic groups such as isopropyl, methylcyclohexyl, methylcyclopentyl, neopentyl,[1b] *tert*-butyl,[2] tri-*tert*-butylphenyl,[3] adamantyl,[4] or triptycyl.[5] Phosphaalkynes containing small groups[6] or heteroatoms, such as F–C≡P[7] or $(CH_3)_3Si$–C≡P,[8] are unstable and can only be characterized spectroscopically. The existence of stable bromo-, hydroxy-, or amino-substituted phosphaalkynes, described in the literature,[9] has been questioned.[10]



We have now found that the stable amino-substituted phosphaalkyne **3** is formed by NaOH-induced elimination of hexamethyldisiloxane from the adduct of tris(trimethylsilyl)phosphane with isopropyl isocyanate. According to the elemental analysis and spectroscopic data, **1** is a tautomeric mixture **1a**, **b**.[11] The ^{31}P NMR spectrum shows two resonances at $\delta = -123$ (broad) and -151 (broad) in a ratio of 1:9. In the ^{13}C NMR spectrum, the quaternary C atom is characterized by the resonance at $\delta = 160.1$ (d, $^1J_{CP} = 43.2$ Hz); a phosphaalkene isomer could not be detected.

Mechanistically, the formation of **3** from **1** can be explained in terms of the intermediary formation of the non-isolable 1-aza-3-phosphaallene **2**, which rearranges very rapidly to the phosphaalkyne. Analogies are known from carbodiimide chemistry.[12]

The empirical formula $C_7H_{16}NPSi$ for **3** was established by the elemental analysis and the high-resolution mass spectrum. The ^{31}P NMR spectrum displays a singlet at $\delta = -140$; the alkyne C atom gives rise to a doublet at $\delta = 154$ ($^1J_{CP} = 18.3$ Hz) in the ^{13}C NMR spectrum. These data are in agreement with the observation that P and C atoms of phosphaalkynes absorb at higher field than P and C atoms of phosphaalkenes.[2]

Constitutional isomers of **3** with phosphacarbodiimide or cyanophosphane structure can be ruled out by the ^1H NMR and IR spectra. In the IR spectrum of **3** (neat), neither a cumulene nor a C≡N stretching vibration is present. Instead, one observes a strong absorption at $\tilde{\nu} = 1588$ cm^{-1}, which may be assigned to the P≡C stretching vibration. For *t*Bu–C≡P and F–C≡P, characteristic IR absorptions at 1533 cm^{-1} and 1660 cm^{-1}, respectively, have been reported.[2,7] In the ^1H NMR spectrum, the protons of the trimethylsilyl group give rise to a singlet at $\delta = 0.04$ and the proton of the isopropyl group gives rise to a septet of doublets at $\delta = 2.7$ ($^3J_{HH} = 6.6$ Hz; $^4J_{HP} = 2.8$ Hz) due to coupling between the protons of the methyl groups and the P atom.

Further structural proof is provided by the [4+2] cycloaddition with an electron-poor heterodiene.[13] As expected, **3** reacts with the oxazinone **4**[14] to give the 1,3-aza-λ^3-phosphinine **5**, which, owing to its ready hydrolysis, can only be isolated in pure form as the NH compound **6**.

The phosphaalkyne **3** is stable both in pure form and in solution; a solution of **3** in toluene can be heated under reflux for 10 min without apparent change (^{31}P NMR). Upon contact with air, the initially colorless liquid turns first yellow then orange.

Experimental Procedure

1: Tris(trimethylsilyl)phosphane (14.5 g, 58 mmol) and isopropyl isocyanate (6.4 g, 75 mmol) were stirred in 20 mL of ether for 3 d. After removal of all volatiles under oil-pump vacuum, the residue was distilled. B.p. 38–40°C/10^{-4} torr. Yield: 16.9 g (87%, based on tris(trimethylsilyl)phosphane) of a colorless, spontaneously flammable liquid. ^1H NMR (400 MHz, C_6D_6): $\delta = 0.30$–0.33 (27 H, $Si(CH_3)_3$), 1.15 (d, 6 H, $J_{HH} = 6$ Hz, $N(CH_3)_2$), 3.98 (sept, 1 H, $^3J_{HH} = 6$ Hz, NCH); ^{13}C NMR (23 MHz, C_6D_6): $\delta = 0.9$, 1.1, 1.5 ($Si(CH_3)_3$), 24.2 (s, $(CH_3)_2$), 53.8 (d, $^3J_{CP} = 27.7$ Hz, NC), 160.1 (d, $^1J_{CP} = 43.2$ Hz, CP). ^{31}P NMR (32.4 MHz, C_6D_6, H_3PO_4 ext.): $\delta = -151.2$, -123.1. MS (70 eV, 70°C): *m/z* 335.1687 ($M^{\oplus}$).

Gerhard-Domagk-Strasse 1, D-5300 Bonn 1 (FRG)

[**] Low-Coordinate Phosphorus Compounds, Part 71. Part 70: R. Appel, N. Siabalis, *Phosphorus Sulfur*, in press.

3: Finely ground NaOH (ca. 1 g) was added to a solution of **1** (7.1 g, 21 mmol) in 15 mL of tetraglyme. At the end of the reaction, the solution was deep red. All components that were volatile at room temperature were condensed under high vacuum in a trap cooled to −78°C. Repeated condensation from the trap afforded pure **3**. Yield: 2 g (56%) of a colorless liquid, b.p. 39–40°C/1.5 torr. ^{1}H NMR (90 MHz, C_6D_6): $\delta = 0.04$ (s, 9 H, $Si(CH_3)_3$), 1.13 (d, 6 H, $^3J_{HH} = 6.6$ Hz, $(CH_3)_2$), 2.7 (sept., d, 1 H, $^3J_{HH} = 6.6$ Hz, $^4J_{HH} = 2.8$ Hz, NCH). ^{13}C NMR (23 MHz, C_6D_6): $\delta = -1.47$ (s, $Si(CH_3)_3$), 21.06 (s, $(CH_3)_2$), 48.62 (d, $^3J_{CP} = 6.6$ Hz, NC), 153.9 (d, $^1J_{CP} = 18.31$ Hz, PC). ^{31}P NMR (32.4 MHz, C_6D_6, H_3PO_4 ext.): $\delta = -140$; IR (KBr, neat, selected absorption): $\tilde{\nu} = 2930$ (s), 1588 (vs), 1251 cm^{-1} (vs). MS (70 eV, 150°C): 173.0789 ($M^{\oplus}$), molecular weight (cryoscopic in benzene): 169.

5/6: **3** (560 mg, 3.2 mmol) and **4** (580 mg, 3.2 mmol) were heated together without solvent at 70°C for 45 min, resulting in the evolution of gas and the formation of **5**. ^{1}H NMR (90 MHz, C_6D_6): $\delta = 0.15$ (s, 9 H, $Si(CH_3)_3$), 1.18 (d, 6 H, $^4J_{HP} = 6.6$ Hz, $(CH_3)_2$), 2.42 (d, 3 H, $^5J_{HP} = 2$ Hz, CH_3), 3.95 (m, 1 H, NCH), 6.72 (d, 1 H, $^3J_{HP} = 2.8$ Hz, Aryl-H). ^{19}F NMR (84.6 MHz, C_6D_6, $CFCl_3$ ext.): $\delta = -66.8$ (d, $^3J_{FP} = 38.6$ Hz). ^{31}P NMR (32.4 MHz, C_6D_6, H_3PO_4 ext.): $\delta = 133.8$ (q, $^3J_{PF} = 38.6$ Hz). Compound **5** is hydrolyzed by even traces of water with cleavage of the Si-N bond to give **6**, b.p. 55°C/10^{-4} torr. Yield: 325 mg (43% based on **3**) of a yellow oil. Appropriate spectroscopic data were obtained for **6**.

Synthesis of the Novel Ring Systems 1,2,3,4-Oxazadisiletidine and 1,3,4,2,5-Dioxazadisilolidine**

By *Gregory R. Gillette, Jim Maxka*, and *Robert West**

The reactions of disilenes[1] have led to the isolation of many novel cyclic organosilanes.[2] Here we report the reactions of tetramesityldisilene **1** (Mes = 2,4,6-$Me_3C_6H_2$) with nitrosobenzene and nitrobenzene to yield the title compounds **2** and **3**, which, to the best of our knowledge, represent the first examples of these structures for organosilicon compounds (Scheme 1).

Scheme 1.

The addition of a blue solution of nitrosobenzene in C_6D_6 to a yellow solution of **1** in the same solvent resulted in slow decolorization of the solution. A single new product was observed in the ^{29}Si-NMR spectrum having resonances at $\delta = 27.2$ and 9.75.[3] The colorless solid obtained after work-up gave spectral data consistent with the structure of the [2+2] cycloadduct **2**.[4] To further characterize **2** an INEPT-INADEQUATE ^{29}Si-NMR experiment was conducted to determine the coupling constant between the two nonequivalent silicon atoms.[5] The spectrum obtained for **2** is shown in Figure 1 (top). The value of 108 Hz for the coupling constant in **2** is larger than the usual 80–90 Hz for $^1J_{Si-Si}$ in organodisilanes and implies a larger amount of s character in the Si–Si bond of **2** than is found in typical disilanes. The $^1J_{Si-Si}$ of **2** is similar to that for the isoelectronic 1,2-dioxadisiletane[6] and may be indicative of unusual bonding in these ring systems.

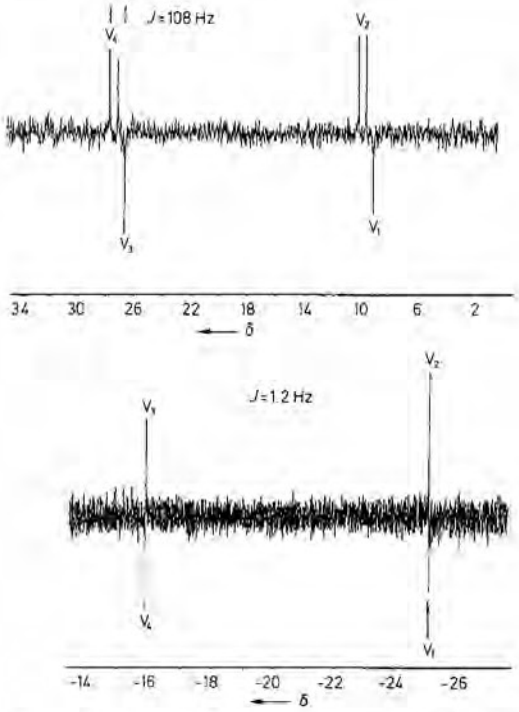

Fig. 1. Top: INEPT-INADEQUATE ^{29}Si-NMR spectrum for **2**, $J = 108$ Hz. Bottom: INEPT-INADEQUATE ^{29}Si-NMR spectrum of **3**, $J = 1.2$ Hz.

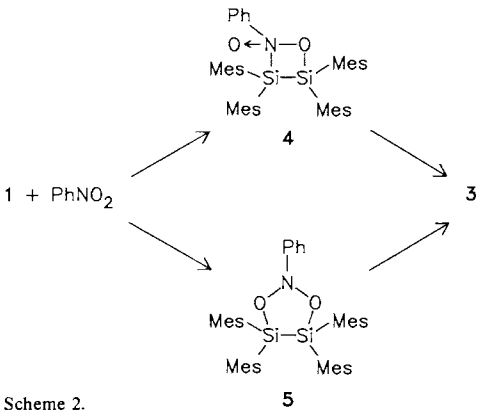

Addition of nitrobenzene to a solution of **1** in C_6D_6 resulted in immediate decolorization of the yellow solution. Analysis of the solution by ^{29}Si-NMR spectroscopy showed that only one product was formed with ^{29}Si resonances at $\delta = -15.8$ and -24.9. The colorless solid obtained after work-up gave analytical data consistent with structure **3**,[7] although the *N*-oxide **4** could not be excluded.[8] The INEPT-INADEQUATE ^{29}Si-NMR spectrum of the product is shown in Figure 1 (bottom). The ob-

[**] Dedicated to Professor *Hans Bock* on the occasion of his 60th birthday. This work was supported by the Air Force Office of Scientific Research Air Force Systems Command, USAF (contract No. F49620-86-0010) and by the 3M Company.

served value of 1.2 Hz for the coupling constant is in the range of known $^2J_{(Si-O-Si)}$ values (1–4 Hz)[9] and is consistent with structure **3**. As further proof of the structure **3**, we found that **2**, when oxidized with 1 equiv. of *m*-chloroperbenzoic acid at −78 °C also yields **3**.

With the structure of **3** established as the 1,3,4 isomer, the question remains as to how it is formed. Two possible pathways can be envisioned (Scheme 2): a [2+2] cycloaddition of $PhNO_2$ with **1** would lead to the *N*-oxide **4**, while

Scheme 2.

[3+2] addition would lead to the 1,3,2-dioxazolidine isomer **5**. Preliminary studies of the reaction at low temperature indicate that **5** may be a precursor to **3**.[10] Further studies are necessary in order to determine the mechanism of this rearrangement.[11]

[3] All spectra were recorded on a Bruker AM 360 (71.55 MHz for ^{29}Si) spectrometer using either the INEPT or INEPT-INADEQUATE pulse sequences and complete proton decoupling. Chemical shifts (δ-values) are reported in ppm from a tetramethylsilane external reference.

[4] Experimental procedure for **2**: A solution of nitrosobenzene (50 mg, 0.46 mmol) in 1 mL C_6D_6 was added to a solution of **1** (250 mg, 0.46 mmol) in 1 mL C_6D_6. The yellow solution slowly decolorized after addition. The benzene was removed in vacuo and the residue was recrystallized from hexane (5 mL) to yield the colorless solid **2**. Yield: 176 mg (59%), m.p. 280–284 °C; correct elemental analyses. MS: calcd. ($M^{\oplus}$) 639.3340, found 639.3347 (2.45%); ^1H-NMR (270 MHz, C_6D_6): δ = 7.85 (d, 2H), 7.38 (d, 1H), 7.30 (t, 2H), 6.84 (s, 4H), 6.82 (s, 4H), 2.73 (s, 12H), 2.61 (s, 12H), 2.28 (s, 6H), 2.24 (s, 6H).

[5] For a discussion of the INEPT-INADEQUATE experiment as applied to ^{29}Si NMR, see: H. B. Yokelson, A. J. Millevolte, B. R. Adams, R. West, *J. Am. Chem. Soc. 109* (1987) 4116.

[6] M. J. Michalczyk, R. West, J. Michl, *J. Chem. Soc. Chem. Commun. 1984*, 2525–26. The magnitude of $^1J_{Si-Si}$ for 1,2-dioxadisiletanes ranges from 96–98 Hz.

[7] Experimental procedure for **3**: To a solution of **1** (400 mg, 0.75 mmol) in C_6D_6 at room temperature was added 76 µL (0.75 mmol) of nitrobenzene. The yellow solution immediately decolorized upon addition. The benzene was removed in vacuo and the residue was recrystallized from hexane to yield the colorless solid **3**. Yield: 310 mg (63%), m.p. 257–260 °C; correct elemental analyses; MS: calcd. ($M^{\oplus}$) 655.3289, found 655.3322 (100%); ^1H NMR ($CDCl_3$): δ = 7.08 (t, 2H), 6.86 (d, 2H), 6.72 (t, 1H), 6.69 (s, 4H), 6.68 (s, 4H), 2.28 (s, 12H), 2.23 (s, 6H), 2.20 (s, 6H), 2.06 (s, 12H).

[8] The IR spectrum did not distinguish unambiguously between **3** and **4**.

[9] G. Pfisterer, H. Dreeskamp, *Ber. Bunsenges. Phys. Chem. 73* (1969) 654; R. K. Harris, B. J. Kimber, *J. Magn. Reson. 17* (1975) 174.

[10] Reaction of **1** with 1 equiv. of $PhNO_2$ at −50 °C yields one new product according to ^{29}Si NMR having a resonance of δ = 0.64 (C_7D_8). After the solution is warmed to room temperature the peak at +0.64 ppm vanishes and is replaced by two new peaks at δ = −15.8 and −24.9, the same chemical shifts as were found for **3**.

[11] Recently we have learned, by private communication from Prof. *M. Weidenbruch*, that the addition of an isocyanate to tetra-*tert*-butyldisilene proceeds with a similar rearrangement to give an analogous five-membered ring product. Editorial note: see M. Weidenbruch, B. Flintjer, S. Pohl, W. Saak, *Angew. Chem. 101* (1989) 89; *Angew. Chem. Int. Ed. Engl. 28* (1989) 95.

$[(Me_3Si)_2CHGe]_6$, the First Hexagermaprismane**

By *Akira Sekiguchi, Chizuko Kabuto,* and *Hideki Sakurai**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Highly symmetrical polyhedral alkanes, such as tetrahedrane, cubane and prismane, have been the subject of considerable interest because of their unusual physical and chemical properties.[1] The synthesis of polyhedranes consisting of framework of atoms other than carbon is also intriguing as a challenging synthetic target as well as from being of theoretical interest. Theoretical calculations, limited to polyhedral silicon compounds at present, suggest that hexasilaprismane is the most stable valence isomer of H_6Si_6.[2] The replacement of the silicon atoms by germanium, should not alter this situation.[2] In this respect, it was of particular interest to prepare silicon or germanium analogues of prismane. We describe herein the synthesis of the first hexagermaprismane, **2**, as well as its X-ray crystal structure analysis.

For the synthesis of strained molecules, such as hexagermaprismane, it is of prime importance to choose an appropriate protecting group. After several unsuccessful attempts, we have found the bis(trimethylsilyl)methyl group to be best suited for hexagermaprismane [Eq. (a)]. A solu-

$$\underset{\mathbf{1}}{(Me_3Si)_2CHGeCl_3} \xrightarrow[Li]{THF} \underset{\mathbf{2}}{[(Me_3Si)_2CHGe]_6} \qquad (a)$$

tion of bis(trimethylsilyl)methyltrichlorogermane **1** (2035 mg, 6.02 mmol) in THF (20 mL) was added dropwise to a stirred suspension of lithium powder (153 mg, 21.9 mmol) in THF (10 mL) at −78 °C under argon.[3] The color of the solution turned deep dark-brown. The reaction mixture was stirred for an additional 6 h at −78 °C and then overnight at room temperature. The reaction mixture was concentrated and then carefully chromatographed on silica gel with hexane (R_f = 0.75), to afford yellow-orange crystals of the hexagermaprismane **2** (166 mg, 12%). After isolation and purification, the prismane **2** was unexpectedly stable to atmospheric oxygen and moisture, although it partially decomposed upon heating to 200 °C.

The prismane structure of **2** was deduced on the basis of the following spectroscopic properties: the FD mass spectrum contained the $M^{\oplus}$ cluster in the range *m/z* 1388–1402 in agreement with that calculated for $C_{42}H_{114}Si_{12}Ge_6$. The molecular weight was determined as 1375 (calcd. 1390.8) by vapor pressure osmometry. Correct elemental analyses were also obtained. The ^1H, ^{13}C and ^{29}Si NMR spectra are fully consistent with the highly symmetrical structure: ^1H NMR (200 MHz, C_6D_6): δ = 0.62 (s, 18H, $SiMe_3$), 1.37 (s,

[**] Chemistry of Organosilicon Compounds, Part 252.—Part 251: H. Sakurai, K. Ebata, K. Sakamoto, Y. Nakadaira, C. Kabuto, *Chem. Lett. 1988*, 965.

1H, Si_2CHGe); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 4.08, 29.8$; ^{29}Si NMR (40 MHz, C_6D_6): $\delta = -1.95$.

An absorption maximum at 280 nm ($\varepsilon = 3.22 \times 10^4$, hexane), tailing into the visible region (~ 500 nm), was observed in the electronic spectrum. The prismane **2** exhibits thermochromism. Crystals of **2** reversibly change color from pale yellow at -196 °C to intense orange at 200 °C.

The X-ray structure determination unequivocally established the prismane structure of **2** (Fig. 1). Because of a limited data set, there is some uncertainty in the positions of the methyl substituents.[4] However, the prismane structure consisting of six germanium atoms was determined with sufficient accuracy to discuss its geometrical features.

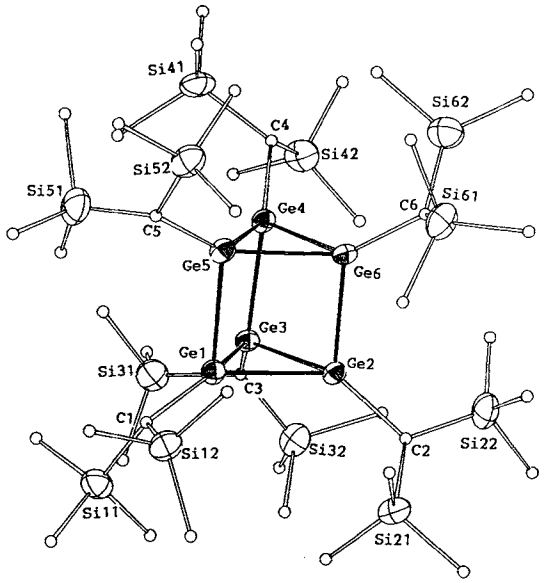

Fig. 1. Crystal structure of **2** (ORTEP). Selected bond lengths [Å] and angles [°]: Ge1-Ge2 2.584(6), Ge1-Ge3 2.580(6), Ge2-Ge3 2.580(5), Ge4-Ge5 2.579(6), Ge4-Ge6 2.579(5), Ge5-Ge6 2.578(6), Ge1-Ge5 2.526(6), Ge2-Ge6 2.516(6), Ge3-Ge4 2.523(4); Ge2-Ge1-Ge3 60.0(1), Ge1-Ge2-Ge3 60.0(1), Ge1-Ge3-Ge2 60.1(1), Ge5-Ge4-Ge6 60.0(2), Ge4-Ge5-Ge6 60.0(2), Ge4-Ge6-Ge5 60.0(2), Ge2-Ge1-Ge5 89.9(2), Ge3-Ge1-Ge5 88.5(2), Ge1-Ge2-Ge6 89.8(2), Ge3-Ge2-Ge6 91.4(1), Ge1-Ge3-Ge4 91.4(2), Ge2-Ge3-Ge4 88.5(2), Ge3-Ge4-Ge5 88.6(2), Ge3-Ge4-Ge6 91.2(2), Ge1-Ge5-Ge4 91.3(2), Ge1-Ge5-Ge6 89.7(2), Ge2-Ge6-Ge4 88.7(2), Ge2-Ge6-Ge5 90.3(2).

The molecule has D_{3h} symmetry. The prismane skeleton is constructed from two regular triangles (Ge-Ge 2.578(6)–2.584(6) Å, av. 2.58 Å and Ge-Ge-Ge 60.0(2)–60.1(1)°, av. 60°) and three regular squares (Ge-Ge 2.516(6)–2.526(6) Å, av. 2.52 Å and Ge-Ge-Ge 88.5(2)–91.4(2)°, av. 90°). All the Ge-Ge bonds are considerably longer than the Ge-Ge bond lengths in other polygermanes (2.374–2.465 Å). It is surprising that the bond lengths in the triangles are longer than those in the squares, since calculations for C and Si prismanes have predicted the opposite trend[2] as was found in the structures of the carbon analogues.[5]

[3] Compound **1** was prepared by the reaction of bis(trimethylsilyl)methylmagnesium chloride with tetrachlorogermane in ether in 80% yield. B.p. = 112–115 °C/10 torr; ^1H NMR ($CDCl_3$): $\delta = 0.40$ (s, 18H, $SiMe_3$), 1.07 (s, 1H, Si_2CHGe); MS: m/z 323 ($M^{\oplus} - Me$); Correct CH-analyses.

[4] Fairly good crystals were obtained from a hexane/ethanol solution. The crystals belong to the orthorhombic space group *Imm*2 ($Z = 4$). However, the crystals contained hexane and became opaque immediately upon loss of solvent. Even when the crystal was sealed in a glass capillary under an atmosphere saturated with solvent, data collection was not possible. Crystals for X-ray analysis were obtained from benzene/ethanol solution. Although most of the crystals were twinned, we were able to find one single crystal of size $0.1 \times 0.1 \times 0.3$ mm. Since the crystal gradually decomposed in the X-ray beam, the data were measured at a high speed ($2\theta - \omega$ scan mode, ω-scan speed 8°/min) on a Rigaku AFC5-R diffractometer with a rotating anode (50 kV, 200 mA) using graphite monochromatized $Mo_{K\alpha}$ radiation. A total of 3016 reflections within $2\theta = 30°$ with significant intensity were collected. The direct structure determination was rather complicated because of the pseudosymmetry about the Ge atom positions on the crystal axes as well as insufficient data. The correct solution was finally obtained by combining use of the Negative Quartet Invariant method. The final R factor was 0.084 for 1966 reflections with $F_0 \geq 3\sigma(F_0)$ ($R = 0.098$ for all reflections). Crystal data of **2**: $C_{42}H_{114}Si_{12}Ge_6$, $M_r = 1390.8$, $a = 22.456(5)$, $b = 25.858(8)$, $c = 13.042(7)$ Å, $\beta = 102.30(3)°$, $V = 7399.2(52)$ Å^3, space group $P2_1/n$, $Z = 4$, $\rho_{calcd} = 1.25$ g/cm^3, $Mo_{K\alpha} = 25.9$ cm^{-1}. Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Energie, Physik, Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-53423, the names of the authors, and the journal citation.

K_4P_3, a Compound Containing the Radical Anion $P_3^{4\ominus}$ **

By *Hans Georg von Schnering,* Martin Hartweg, Ute Hartweg,* and *Wolfgang Hönle*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

The alkali metals M form many compounds with phosphorus, which exhibit differing structures and properties[1] and have been particularly well characterized for $M : P \leq 1$. As early as 1956, however, there was evidence, from the work of *Korte* and *Klemm*,[2,3] for the existence of other well-defined compounds between K_3P and KP although they could not be unambiguously identified. This is due, to a considerable extent, to the exceptional stability of yellow K_3P_7,[4] which is the only detectable intermediate in the thermal decomposition of K_3P. We have now synthesized and characterized one of the intermediate phases, the compound K_4P_3.

Sufficient quantities of pure K_4P_3 are obtained only if an excess of potassium is used in the synthesis from the elements (K, P_{red}, $K : P = 1.5$–2.0; 400 °C, Nb- or Solidex ampoule; glove box with integrated gas purification; < 0.1 ppm H_2O; < 1 ppm O_2). Although the crystals of K_4P_3 are partly embedded in potassium or in green-reflecting K_3P

Naturforsch. B43* (1988) 561.

after the reaction, they can be easily isolated by mechanical separation. For K : P ratios of ca. 1.5, another phase, in addition to K_4P_3, is produced as a black, micro-crystalline powder, from which K_4P_3 can also be readily separated. Up to now, stoichiometric reactions have led to mixtures of other phases. This explains why marked quantities of K_4P_3 are observed, in almost all cases, in the synthesis of K_3P. The excess alkali metal is apparently necessary to compensate for the high decomposition pressure and losses through reaction with the wall of the reaction vessel.

K_4P_3 forms blue-black, metallically gleaming platelets, which are very air- and moisture-sensitive. **Caution**: reaction products having K : P > 1 have a tendency to undergo **explosive decomposition** upon grinding even under an inert atmosphere with the formation of a potassium mirror on the wall of the mortar. This tribochemical reactivity increases with aging of the product under the influence of light. Samples, which have been carefully sealed in Schlenk-tubes, often explode after several weeks of storage. Whether these properties are attributable to K_4P_3 or to traces of other compounds is, as yet, unclear. However, the electronic structure of K_4P_3 suggests that it is responsible for this behavior.

The crystal structure of K_4P_3 was determined from single crystal data.[5] K_4P_3 crystallizes in the W_3CoB_3 type of structure[6] (Fig. 1). Characteristic is the bent P_3-chain with relatively short bond lengths (d_{P-P} = 218.3 pm) and a large

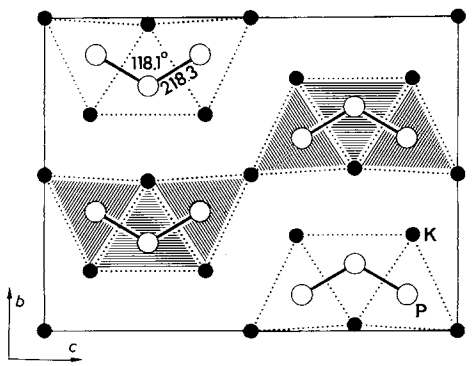

Fig. 1. Projection of the K_4P_3 structure on (100). The hatched structural units are displaced by $a/2$ with respect to each other. d_{P-P} in pm.

bond angle (P-P-P = 118.1°) (compare, e.g., $P_3^{5\ominus}$ in LaP_2: 222.0 pm/107.5°[7]). Each P atom lies in the center of a trigonal prism built up of 6 K atoms with tricapped rectangular faces, such that the terminal P atoms are coordinated by 8K + 1P and the central P atom by 7K + 2P (d_{K-P} = 332.1–336.3 pm). Figure 1 shows the characteristic condensation of three prisms and their further connection to form a two-dimensional, infinite, corrugated, layered structure. Noteworthy is the relationship with the structure of K_4P_6,[8] in which trigonal prismatic coordinated P atoms are assembled as isolated $P_6^{4\ominus}$ rings. According to the simple electron-transfer model of *Zintl* and *Klemm*,[9] K_4P_3 contains the 19-valence electron $P_3^{4\ominus}$ radical anion. It is the first triatomic 19-electron system, without the involvement of a second-row element, to be isolated and is isoelectronic and topologically directly comparable to $S_3^{\ominus}$, ClO_2 and the $O_3^{\ominus}$ radical of the alkali metal ozonides.[10] The tribochemical lability mentioned above is consistent with this picture.

The expected paramagnetism of K_4P_3 could be detected. The temperature dependence is, however, complex and does not follow the simple Curie-Weiss law (Fig. 2), un-

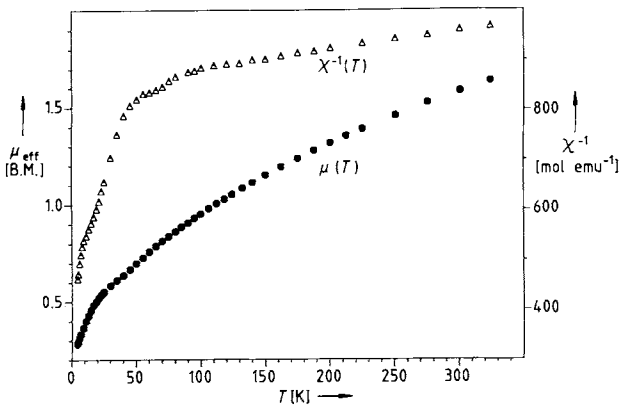

Fig. 2. Variation of the reciprocal magnetic susceptibility χ^{-1} (△) and the effective magnetic moment μ_{eff} (●) with temperature T.

like, for example, the above-mentioned ozonides.[10] At 300 K, an effective magnetic moment of $\mu = 1.6$ B.M. is attained but the temperature dependence of the curve does not lead one to expect a convergence at the expected value for $S = 1/2$ ($\mu = 1.74$ B.M.). On the contrary, the dependence of the reciprocal magnetic susceptibility χ^{-1} upon the temperature T shows a gradient typical for a doublet state ($S = 1/2$) only in the range $50 < T < 100$ K. Above 100 K, χ^{-1} exhibits, with good precision, the behavior of a quartet state ($S = 3/2$). Initial quantum mechanical calculations[11] (Hartree-Fock, SCF) show that the lowest-lying doublet and quartet states have almost the same energy so that a $^2\Gamma \rightarrow {}^4\Gamma$ excitation seems to be possible even at low temperatures. The first doublet-doublet transition is expected at ca. 10000 cm^{-1}. ESR measurements (300 K, powder sample, 0.2 mg) showed a signal at $g = 2.02$ with linewidth ca. 80 G but with only 15–20% of the expected intensity (cf. $S_3^{\ominus}$: $g = 2.028$; 160 G[12]). The loss of intensity could be explained either by the occurrence of a quartet state or by high electrical conductivity. Because of the extreme sensitivity of the compound one can not exclude the possibility of a partial decomposition of the substance, particularly upon weighing out small quantities. For this reason, quantitative statements will have to await the results of further investigations.

Two of the three possible normal vibrations of the P_3 moiety are observed in the FIR spectrum at 300 K, the asymmetric stretch at 438 cm^{-1} and the deformation at 163 cm^{-1}. This represents a shift of ca. 30–40 cm^{-1} to higher wave numbers compared with other P-P stretching frequencies which is in accord with the increased P-P bond-order.

$Na_xMg_{5-x}Ga_9$, a New Intermetallic Phase as a Link Between Zintl Phases and Metals

By *Reinhard Nesper**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Binary compounds of the alkali metals with the elements of group 13 such as NaTl belong to the classical Zintl phases,[1] i.e., they are compounds with defined compositions.

In contrast, the ternary compounds of the alkali or alkaline earth metals with group 13 elements often exhibit a phase width, with which the dependence of bonding relationships upon the valence-electron number can be studied. The binary phases NaGe,[2] Na_7Ga_{13},[2,3] $Na_{22}Ga_{39}$,[4] Mg_5Ga_2,[5] Mg_2Ga,[6] MgGa,[7] $MgGa_2$[8] and $MgGa_5$[9] are known border members of the ternary system Na/Mg/Ga. In the course of systematic studies of this system, we have discovered the new ternary compound $Na_xMg_{5-x}Ga_9$, which is not a derivative of the binary phases. The compound exhibits, typical for intermetallic compounds, a phase width $2 \leq x \leq 3$.

The synthesis was carried out by heating a mixture of the pure elements in welded niobium ampoules to 1100 K and then cooling over a period of 24 h. The product has a metallic luster and is both air- and moisture-sensitive. The compound is not ductile but hard and brittle, resembling in this respect the classical valence compounds and Zintl phases. The compound exhibits, however, a specific resistance of $\rho(300\ K) \simeq 10\ \Omega$ cm, which lies within the range of resistances found for metals and increases with rising temperature. $Na_xMg_{5-x}Ga_9$ gives an X-ray powder pattern which is distinctly different from those of the binary phases $NaGa_4$, Na_7Ga_{13}, $Na_{22}Ga_{39}$, MgGa and $MgGa_2$. Single-crystal photographs show predominantly the Laue symmetry $6/mmm$ (Table 1), which is modulated by composition-dependent superstructures.

$Na_xMg_{5-x}Ga_9$ crystallizes in a new structure type, in which the Ga-atoms form a three-dimensional framework of linked icosahedra and Friauf polyhedra (truncated tetrahedra, cf. Fig. 1). These two types of polyhedron are typical for intermetallic phases. The Ga framework is not significantly influenced by the superstructure and the cation positions within the framework are all localized unambiguously. The mean distances between the Ga atoms of the icosahedra are similar (2.69–2.73 Å), while that of Ga5 in the Friauf polyhedra is ca. 0.1 Å longer (2.81 Å). Although these distances are somewhat longer than the sum of the covalent radii ($2r_{cov} = 2.52$ Å), quantum mechanical calculations have shown that this effect does not necessarily lead to the loss of countable local bonds. In related aluminides, whose electronic structures follow, to a large extent, the valence rules according to quantum mechanical calculations,[10] bonds which are about 0.2 Å longer than $2r_{cov}$ are also found.

The superstructure results essentially from changes in the region of the six-fold tube. A further Ga atom is located here, which is terminally bound to the icosahedron and shows a significant elongation of its electron density (Fig. 2). This nonuniformity can be well described by three different Ga positions (Ga1, Ga1′ and Ga1″), each of which is bound in a different manner to the neighboring Ga atoms. Thus, by combination of the positions Ga1, Ga1′ and Ga1″, limiting cases for the local chemical bonding can be

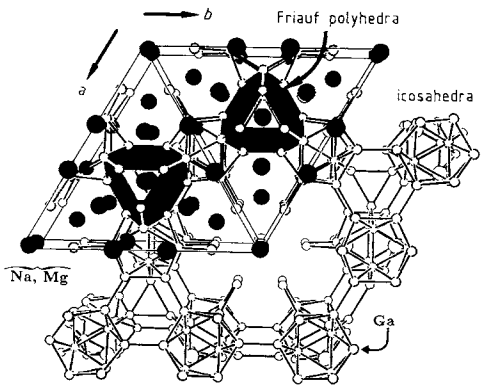

Fig. 1. Projection of the hexagonal structure of $Na_xMg_{5-x}Ga_9$ along the c-axis [14]: Ga, open circles; Na, Mg, full circles; Friauf polyhedra, black; metal atoms outside of the unit cell are not shown.

Table 1. $Na_xMg_{5-x}Ga_9$; structural parameters: space group $P6/mmm$-D_{6h}^1 (No. 191), $Z = 6$, $a = 15.43(1)$, $c = 8.998(6)$ Å; single-crystal structure solution: four-circle diffractometer, 461 reflections hkl, $R_w(aniso) = 0.056$ [13]. The relatively large standard deviations of the occupation factors of the split positions are attributed to strong correlation of the closely-neighboring positions in the structure refinement. This does not, however, alter the fact that split positions are present.

formulated, in which one, two or three bonds per Ga atom are attained (Ga1, one bond: Ga1-Ga2; Ga1′, two bonds: Ga1′-Ga1′, -Ga1′; Ga1″, three bonds: Ga1″-Ga1″, -Ga1″, -Ga2′; cf. Fig. 2). Mean distances of 2.60–2.83 Å are also obtained for these limiting cases.

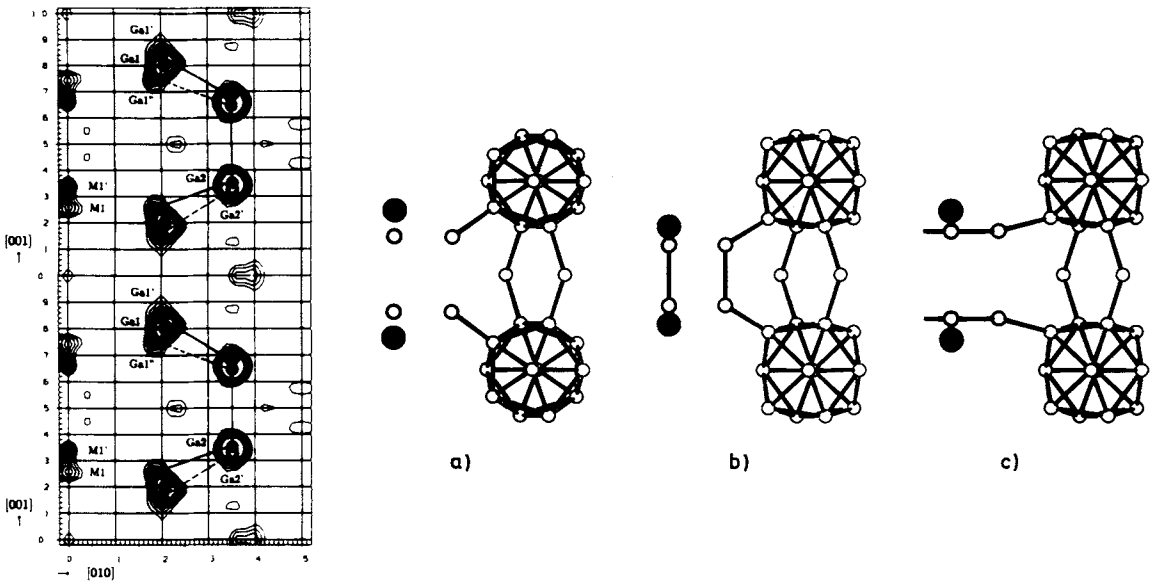

Fig. 2. Electron density of the plane (0*yz*). The distribution of the electron density of Ga1 can be described by three positions, which have bond orders of one, two and three to the neighboring Ga atoms (cf. a, b, c; Ga: open circles; Na, Mg: full circles).

The differentiation between Na and Ga exclusively on the basis of the crystallographic data is, in this case, not possible. The distances M–Ga lie in the range 3.2 to 3.5 Å and give coordination numbers of 10 to 12 for all M atoms except for M1 and M1′, which have only six neighbors. A decision between Na–Ga and Mg–Ga contacts is not possible on this basis. If one, however, sets the requirement that the balance of charge between the Ga polyanions and the cations has to be satisfied locally as is found, for example, in Zintl phases, then all the positions cannot be occupied by Mg atoms. In order to analyze the electron balance using the Zintl-Klemm concept,[11] the icosahedra were treated as *closo*-polyhedra as described by *Wade*.[12] The icosahedron is coordinated in the first coordination sphere by four metal atoms, only half of which are at its disposal ($M_{4/2}Ga_{12}^{2\ominus}$). The X_{12} framework of the Friauf polyhedron can be understood in terms of classical, two-electron two-center bonds.[10] Since the polyhedron is linked to three icosahedra, only three Ga-atoms, each of them four-bonded, remain per formula unit. They are not part of the icosahedra. Accordingly, the following electron balance can be written for the basic framework:

$$6\,Na^{\oplus} + 1.5\,Ga_{12}^{2\ominus\ \text{icosahedron}} + 3\,Ga^{\ominus\ \text{Friauf}}$$

The charge required for the basic framework is already satisfied by six of the metal positions even if these are occupied only by Na atoms. A variable charge for the remaining atoms (Na or Mg) can only be compensated on the local level by the bond order of Ga1 (Ga1′, Ga1″).

A further metal position (M1) lies in the center of the large tube and is a direct neighbor of Ga1. Depending on the occupancy of this position (Na or Mg), Ga1, Ga1′ and Ga1″ receive differing amounts of transferred charge, to which the different bonding situations are correlated. Consequently, Ga1 can be formulated as a 7e-, 6e- or 5e-species according to (1b)$Ga^{4\ominus}$, (2b)$Ga^{3\ominus}$ and (3b)$Ga^{2\ominus}$. The observed displacements of the electron density with formation of the superstructure(s) indicate those positions which represent different bonding situations.

The phase width of $Na_xMg_{5-x}Ga_9$ includes the formulas with $2 \le x \le 3$, as revealed in this structural chemical study. $Na_xMg_{5-x}Ga_9$ possesses the typical properties (silver metallic luster, electrical conductivity) and the typical structural building blocks of intermetallic phases. Nevertheless, its bonding can be understood in terms of classical valence rules and the Zintl-Klemm concept.[11] These findings are supported by experimental and quantum mechanical studies of related ternary aluminides.[10]

Enantioselective Reduction of α,β-Unsaturated Carboxylates with $NaBH_4$ and Catalytic Amounts of Chiral Cobalt Semicorrin Complexes**

By *Urs Leutenegger, Andrew Madin,* and *Andreas Pfaltz**

Chiral C_2-symmetric chelate ligands having the structure type of semicorrins **1**–**3** are readily accessible in enantiomerically pure form starting from pyroglutamic acid.[1] The substituents at the two chirality centers can be varied quite easily and are held firmly in position by the rigid ligand skeleton in immediate proximity to the coordination center of the ligand. Semicorrins of this type therefore appeared to offer ideal prerequisites for use in enantioselective catalysis with chiral metal complexes. As a first example of a metal-catalyzed process that proceeds enantioselectively under the influence of chiral semicorrin ligands, we have investigated the cyclopropanation of olefins with diazo compounds. With copper complexes of the ligand **3** as catalysts we obtained enantioselectivities of up to 97% *ee*.[1] We now report on the enantioselective reduction of α,β-unsaturated carboxylates with sodium borohydride in the presence of cobalt-semicorrin complexes as catalysts.

1 R = CH_2OSiMe_2tBu
2 R = CH_2OEt
3 R = CMe_2OH

Our studies in this direction were stimulated by the work of *Fischli* et al.,[2] who had shown that α,β-unsaturated carbonyl compounds can be reduced selectively at the CC double bond with optical yields between 0 and 33% with zinc/acetic acid and cobalamine as catalyst.[3] In our case, sodium borohydride in ethanol/dimethylformamide (DMF) proved to be the better choice as reducing agent.[4] The ester **4a** employed as test substrate[2] is virtually inert to this reagent at room temperature in the absence of a catalyst (<5% conversion after 48 h). In the presence of catalytic amounts (1 mol-%) of the semicorrin complex formed in situ from $CoCl_2$ and the ligand **1**, on the other hand, a smooth, remarkably uniform reduction to the optically active ester (+)-**5a** is observed, which proceeds to completion at room temperature within 1–2 d (crude product: >99.8% **5a** according to GC).[5] The enantiomeric purity of the product was reproducible at 94% *ee* in a series of experiments.[6] The other substrates investigated so far, with the exception of the phenyl-substituted derivatives **4d** and **6d**, react with similarly high enantioselectivity (cf. Table 1). The (*E*)- and (*Z*)-isomers each afford products of opposite configuration. Ethyl geranate **4b** and the (*Z*)-isomer **6b** are selectively reduced at the conjugated CC double bond, whereas the isolated double bond remains untouched. Upon work-up, the ligand **1** forms a (catalytically inactive) cobalt-bis(semicorrinate) complex, and can be recovered in good yield by decomplexation with acetic acid.

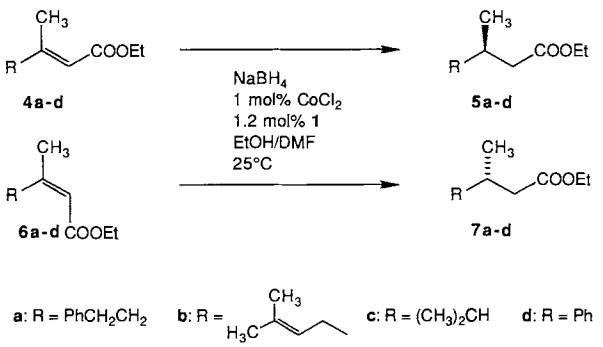

Table 1. Enantioselective reduction of the α,β-unsaturated carboxylates **4a**–**d** and **6a**–**d** [5].

Starting compound	Product	Yield [%] [a]	Enantioselectivity [% *ee*] [b]	Configuration [c]
4a	(+)-**5a**	97	94	*R*
6a	(−)-**7a**	95	94	*S*
4b	(+)-**5b**	95	94	*R*
6b	(−)-**7b**	94	94	*S*
4c	(−)-**5c**	84 [d]	96	*S*
6c	(+)-**7c**	86 [d]	90	*R*
4d	(+)-**5d**	95	81	*S*
6d	(−)-**7d**	97	73	*R*

[a] Product isolated after column chromatography. [b] Estimated accuracy ± 1%. Determined by ^{1}H-NMR spectroscopy with Eu(hfc)$_3$ after reduction to the corresponding alcohol with $LiAlH_4$ and acetylation [2]. The *ee* values of **5a**,**b** and **7a**, **b** were checked by HPLC analysis (Techsil 5 μ; pentane/AcOEt 5:1) of the corresponding (*R*)-1-(1-naphthyl)ethylamides [7]. [c] Assignment based on optical rotation; for **5a**, **7a**: according to Ref. [2]; **5b**, **7b**: [8]; **5c**, **7c**: [10]; **5d**, **7d**: [11]. [d] Loss of substance because of volatility of the product.

The method described here for the enantioselective reduction of α,β-unsaturated carboxylic acid esters can be carried out very easily on a laboratory scale. It has numerous possible applications in organic synthesis; e.g. isoprenoid chains, as occur inter alia, in the vitamins E and K_1, can be synthesized stereoselectively in this way[7,8] (cf. the reactions **4b**→**5b** and **6b**→**7b**). The enantioselectivities lie in the same range as in the catalytic hydrogenation of structurally related α,β-unsaturated carboxylic acids and allylic alcohols with the Ru^{II}-BINAP catalysts developed by *Nojori* et al.[7] In contrast to the enantioselective catalytic hydrogenation with chiral rhodium- and ruthenium-phosphane complexes,[7,9] which afford high optical yields only in the presence of a free carboxy, amide or hydroxy function in the proximity of the CC double bond, in the reduction with cobalt-semicorrin complexes, carboxylic esters can be used. The mechanism of the cobalt-catalyzed reaction and its applicability to other classes of substrates are presently the subject of further investigations.

[3] Examples of enantioselective cobalt-catalyzed hydrogenations of α,β-unsaturated carbonyl compounds with H_2 (7–50% *ee*) are also known: S. Takeuchi, Y. Ohgo, J. Yoshimura, *Chem. Lett. 1973*, 265; Y. Ohgo, S. Takeuchi, Y. Natori, J. Yoshimura, *Bull. Chem. Soc. Jpn. 54* (1981) 2124.
[4] No reaction was observed with molecular hydrogen (2–100 atm, 25–100°C). In the presence of Zn/AcOH or Zn/NH_4Cl the cobalt-semicorrin complex was decomplexed.
[5] *Procedure:* A solution of the α,β-unsaturated ester (9.2 mmol) in EtOH (3.7 mL) under N_2 was treated successively with $CoCl_2 \cdot 6H_2O$ (0.092 mmol dissolved in 1 mL of EtOH), **1** (0.11 mmol in 1.9 mL of EtOH; color change from bluish-violet to dark blue), and $NaBH_4$ (18 mmol in 5.5 mL of DMF; color change to brown). The slightly turbid reaction mixture was degassed under high vacuum by repeated freezing and thawing, and finally stirred for 48 h at ca. 25°C in a vacuum-tight, sealed ampule fitted with Teflon stopper. After addition of H_2O, the mixture was extracted with methylene chloride and the organic phase washed three times with water to remove DMF. The yellow, crude product was purified by flash chromatography [12] (silica gel, 2 × 15 cm; hexane/Et_2O 15:1).
[6] On using the ligand **2** the *ee* value of **5a** was 90%. The ligand **3** does not form a cobalt complex under the reaction conditions (presumably for steric reasons).

Nickel Complexes Containing Sterically Demanding Thiolate Ligands: $[Ni_8S(SC_4H_9)_9]^{\ominus}$, a Mixed-Valence Nickel Sulfide Thiolate Cluster, and $[Ni_4(SC_3H_7)_8]$, a Homoleptic Nickel Thiolate**

By *Thomas Krüger, Bernt Krebs,* and *Gerald Henkel**

In terms of their complex chemistry, numerous metalloproteins belong to the class of metal thiolates or metal sulfide thiolates. Prominent examples are the metallothioneins, the iron-sulfur proteins, and the nitrogenases (cf., e.g., Ref. [1]). The investigation of the structure and function of these biomolecules has been accompanied over the past two decades by an unprecedented development of the chemistry of iron, copper, zinc, molybdenum, cadmium, and mercury complexes containing sulfur ligands (cf., e.g., Ref. [2]).

Nickel was recently added to the list of biologically important elements; partial sulfur coordination has been reported for the nickel centers in certain enzymes.[3] The catalytic activity of nickel-containing hydrogenases and CO dehydrogenases appears to be related to the redox properties of the nickel center; metal oxidation states of +1 to +4 have been discussed.[3–5]

The known mixed nickel sulfide thiolate complexes, like the homoleptic nickel thiolates, contain the metal in its divalent form (cf. Ref. [6] and references cited therein). The synthesis of the mixed-valence compound **1** has now demonstrated for the first time that sterically demanding ligands such as 2-methyl-2-propanethiolate are capable of stabilizing unusual oxidation states of nickel in complexes with complete sulfur coordination.

Complex **1** is prepared by reaction of $NiCl_2$ with NaS*t*Bu in methanol and is obtained, after addition of Ph_4PBr, as black needles of the complex salt **2**.[7]

$[Ni_8S(StBu)_9]^{\ominus}$ **1**
$[Ph_4P][Ni_8S(StBu)_9] \cdot MeOH$ **2**
$[Ni_4(SiPr)_8]$ **3**

According to an X-ray structure analysis,[8] crystals of **2** contain, in addition to undistorted $Ph_4P^{\oplus}$ ions and solvate molecules, two symmetry-independent octanuclear anions **1** having the novel $Ni_8(\mu_6\text{-}S)(\mu_2\text{-}SR)_9$ framework. The

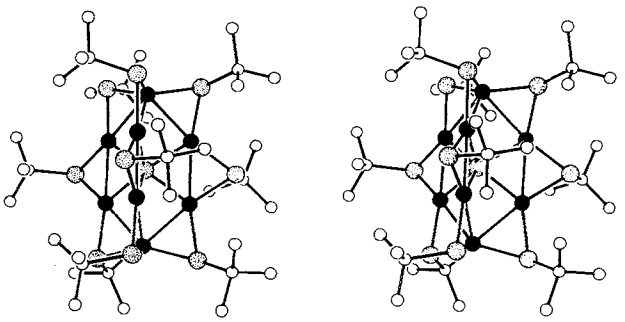

Fig. 1. Stereoscopic view of the structure of **1** in crystals of **2** (hydrogen atoms omitted). Nickel, black; sulfur, dotted; carbon, white.

structure of **1** (H atoms omitted) is shown in Figure 1. The central Ni_8S_{10} unit of **1** is given in Figure 2. Six nickel atoms (Ni^P, black) form a trigonal prism, whose triangular faces are capped by two further nickel atoms (Ni^K,

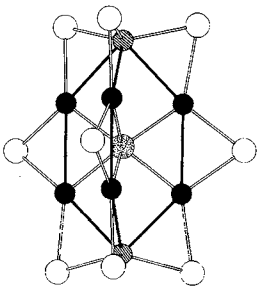

Fig. 2. Schematic drawing of the Ni_8S_{10} framework of the complex anion **1**. Nickel, black and hatched; sulfur, dotted and white. For details see text.

hatched). The average oxidation state of the metal centers is +1.25 and can be formally ascribed to six $Ni^{\oplus}$ and two $Ni^{2\oplus}$. The diamagnetic behavior of **1** (symmetry C_3, slightly distorted) indicates a delocalized electron system, so that an assignment of integral oxidation states to individual metal centers is problematical. Indeed, in addition to unusually short distances between the capping nickel atoms (hatched) and their neighbors (black; average 2.471 Å), we observe three further short distances between the nickel atoms of opposite triangular faces of the metal prism (average: 2.444 Å), which we ascribe to nickel–nickel bonds. Moreover, all nickel pairs with short distances also have thiolate bridges, resulting in a total of nine (μ_2-SR) functions (white). The edges of the triangular faces of the prism have an average length of 3.122 Å and are not

bridged by ligands. With a total of 114 skeletal electrons in the Ni_8S_{10} framework, a "magic" electron count[9] is achieved.

The center of the nickel prism is occupied by a unique sulfur atom (dotted) bonded simultaneously to six nickel atoms. This represents the first example of the stabilization of a sulfide ion in a complex, in which it is encapsulated by six equivalent metal atoms. The $(\mu_6\text{-S})Ni_6$ fragment represents a slightly distorted portion of the structure of hexagonal NiS. The average $(\mu_6\text{-S})$–Ni bond length is 2.179 Å. Thus, despite the high coordination number of the sulfur atom, this length is even slightly shorter than the average (SR)–Ni^k bond length of 2.196 Å. In contrast, the average (SR)–Ni^p bond length is only 2.157 Å.

Just as unusual as the oxidation state of the nickel centers is their coordination. The ligands are arranged in such a way that each nickel atom is surrounded by three sulfur atoms in a nearly trigonal-planar fashion. The deviation of the capping nickel atoms from the plane of the sulfur atoms is very large (0.439 Å), presumably due to the bonds to the three metal neighbors. A similar effect is not observed for the nickel atoms of the central metal prism, because their direct metal neighbors lie in the same plane as the sulfur ligands. In this case, the deviation is only 0.095 Å.

The reaction of $(Et_4N)_2[NiBr_4]$ with NaS*i*Pr in acetone or acetonitrile does not result in the formation of a mononuclear nickel thiolate ion, even when a large excess of thiolate is used; only the cyclic, neutral complex **3**, isolated as black crystalline material is formed instead.[7] According to the X-ray structure analysis,[8] **3** is a tetranuclear molecule (idealized D_{4h} symmetry) with a cubane-like Ni_4S_8 framework (Fig. 3). An analogous condensation

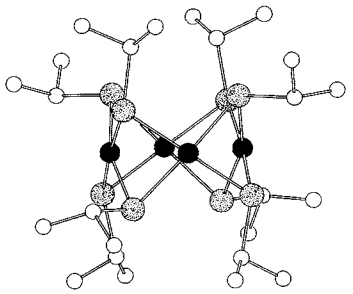

Fig. 3. Crystal structure of **3** (hydrogen atoms omitted). Nickel, black; sulfur, dotted; carbon, white.

is observed for the nickel thiolates $[Ni_4(SC_5H_9NMe)_8]$[10] and $[Ni_4(SC_6H_{11})_8]$.[11] All three compounds share a common feature: they all contain ligands of the secondary thiolate type (2-propanethiolate, *N*-methylpiperidine-4-thiolate, cyclohexanethiolate). The preferential formation of tetranuclear, neutral nickel thiolate complexes might therefore be due to specific chemical properties of secondary thiolate ligands.

Heterogeneous, Metathesis-active Schrock-type Carbene Complexes by Reaction of Carbyne Tungsten(VI) Complexes with Silica Gel**

By *Karin Weiss** and *Georg Lössel*

We have recently reported the preparation of heterogeneous, bimetallic metathesis catalysts by reaction of Fischer-type carbene or carbyne tungsten(0) complexes with the reduced Phillips catalyst, a silica gel-Cr^{II} compound.[1-3] The carbene and carbyne complexes presumably undergo a [2+1]-cycloaddition of the W=C or W≡C bond to the surface Cr^{II} atoms; the complexes exhibit no reactivity towards silica gel. As an extension of this study, we have now investigated the activation of Schrock-type carbyne tungsten(VI) complexes by reduced Phillips catalyst.

In homogeneous solution, the carbyne tungsten(VI) complexes exhibit varying degrees of metathesis activity, depending on the other ligands at the W center. Thus, for example, $[Cl_3(dme)W{\equiv}C\,t\text{Bu}]$[4] (dme = dimethoxyethane) catalyzes the metathesis of linear and cyclic olefins at

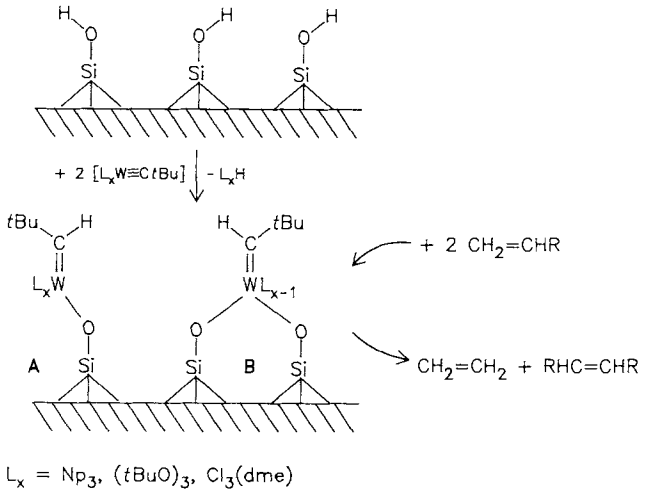
[**] Investigations of Polymerization and Metathesis Reactions, Part 15. This work was supported by the Deutsche Forschungsgemeinschaft. Part 14: [3].

room temperature,[5,6] while $[(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$[4] (Np = neopentyl) shows no metathesis activity. We tested whether the metathesis activity of the carbyne complex $[(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$ could be enhanced by reaction with reduced Phillips catalyst as described below. The carbyne complex was stirred with an equimolar (Cr : W) quantity of the reduced Phillips catalyst [Merck silica gel 7733, activated with O_2 at 800 °C, reduced with CO at 350 °C, ca. 1% Cr^{II}, preparation as described in Ref. [7]] suspended in hexane at 0 °C. After 2 h, the bimetallic catalyst was collected by filtration, washed with hexane and dried in vacuo. For comparison, the reaction of silica gel, which had been subjected to the same preparative steps as the reduced Phillips catalyst, with the exception of Cr-doping, with the carbyne complex was also investigated. In each case, $[(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$ was quantitatively adsorbed.

The metathesis activity of the two products was tested by reaction with 1-octene in hexane at 69 °C. The metathesis of 1-octene affords tetradecene C_{14} and ethylene C_2 [Eqn. (a)]

$$\underset{C_8}{2\,C_6H_{13}CH{=}CH_2} \overset{cat}{\rightleftharpoons} \underset{C_{14}}{C_6H_{13}CH{=}CHC_6H_{13}} + \underset{C_2}{H_2C{=}CH_2} \qquad (a)$$



The results showed, surprisingly, that the product derived from the carbyne complex and silica gel has greater catalytic activity (Fig. 1b) than the bimetallic catalyst (Fig. 1c). We therefore conclude that $[(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$ is activated by reaction with the silica gel and not by reaction with the surface Cr atoms of the reduced Phillips catalyst. After reaction with the carbyne complex, the Phillips catalyst no longer exhibited polymerization activity indicating that $[(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$ had reacted with the surface Cr atoms. Thus, in the case of the reduced Phillips catalyst, the SiOH groups and the chromium atoms compete for reaction with the carbyne complex.

The activation by silica gel can be explained by reaction of the carbyne complex with the Si–OH protons. *Schrock* et al.[8] have shown that carbyne tungsten(VI) complexes react with Brønsted acids HX to give carbene tungsten(VI) complexes; this reaction is generally used for the synthesis of Schrock carbene complexes. In the reaction with excess HX, the anion $X^{\ominus}$ may displace one of the ligands (e.g., $t\mathrm{BuO}^{\ominus}$) from the W center [Eqn. (b)].

$$[(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}] + 2\,\mathrm{HX} \longrightarrow [\mathrm{X}_2(t\mathrm{BuO})_2\mathrm{W}{=}\mathrm{CH}t\mathrm{Bu}] + t\mathrm{BuOH} \qquad (b)$$

X = PhO, Cl, RCOO etc.

The surface SiOH protons of silica gel could react with the carbyne tungsten(VI) complexes to give either a "one-legged" surface anchored carbene complex (Scheme 1, structure **A**) or, via ligand displacement, to afford a "two-legged" surface anchored complex (Scheme 1, structure **B**). The surface carbene W^{VI} complexes are both coordinatively unsaturated and in each case the electrophilic character of the W center is further increased by the coordination of SiO groups.

L_x = Np_3, $(t\mathrm{BuO})_3$, $Cl_3(dme)$

Scheme 1. Reaction of carbyne tungsten(VI) complexes with silica gel to form heterogeneous carbene tungsten(VI) complexes.

The synthesis of heterogeneous carbene tungsten(VI) complexes can be extended to $[Np_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$ and $[Cl_3(dme)\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$. The quantity of HCl produced in the reaction between $[Cl_3(dme)\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$ and silica gel was determined acidimetrically. One mol of HCl is eliminated per mol of carbyne complex suggesting that the adsorbed carbene complexes have the structure **B**.

The solid-state ^{13}C NMR spectrum of the product from $[(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$ and kieselgel exhibited resonances at $\delta = 28.8$ and 73.9 (tBuO) and 31.9 ($=\mathrm{C}(\mathrm{C}CH_3)_3$). Carbene tungsten(VI) complexes exhibit similar chemical shifts in solution. We have, until now, been unable to detect the signal for the carbene carbon atom, perhaps because of splitting into several rotational side bands.

The metathesis activity of the heterogeneous carbene complexes was tested by reaction with 1-octene at 69 and 122 °C. Their activity was compared with that of the analogous carbene and carbyne complexes in homogeneous solution (Table 1, Fig. 2). Of the complexes tested, only the heterogeneous carbene complexes proved to have high catalytic activity. Thus, for example, the system SiO_2/$[Np_2\mathrm{W}{=}\mathrm{CH}t\mathrm{Bu}]$ had a turnover rate of 830 mol 1-octene per mol W at 122 °C. In contrast, the carbene and carbyne complexes in solution had smaller turnovers or showed no activity at all. Raising the reaction temperature generally led to an increase in the rate of reaction.

Schrock[9] and *Osborn* et al.[10] have shown that metathesis-inactive carbene tungsten(VI) complexes can be activated by the addition of Lewis acids or by substitution of

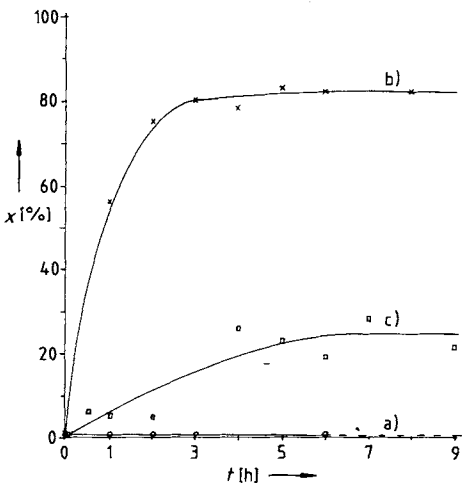


Fig. 1. Metathesis of 1-octene with $(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}$ at 69 °C; x = turnover of 1-octene; molar ratio 1-octene : W = 10^4 : 1. a) in hexane solution; b) carbyne complex, fixed on silica gel; c) carbyne complex, fixed on reduced Phillips catalyst.

Table 1. Metathesis of 1-octene with hetero- and homogeneous carbene and carbyne tungsten(VI) complexes. x = turnovers per minute (mol 1-octene/mol W). Starting concentration 1-octene : W = 10^4 : 1.

	Turnover [%] at 69 °C	at 122 °C
a) Heterogeneous catalysts		
$SiO_2/[Cl_2W{=}CHtBu]$	30	200
$SiO_2/[(tBuO)_2W{=}CHtBu]$	60	140
$SiO_2/[Np_2W{=}CHtBu]$	260	830
b) Homogeneous catalysts		
$[Cl_3(dme)W{\equiv}CtBu]$	5	50
$[(tBuO)_3W{\equiv}CtBu]$	1	5
$[Np_3W{\equiv}CtBu]$	0	0
$[(tBuO)_2(PhO)_2W{=}CHtBu]$	0	0

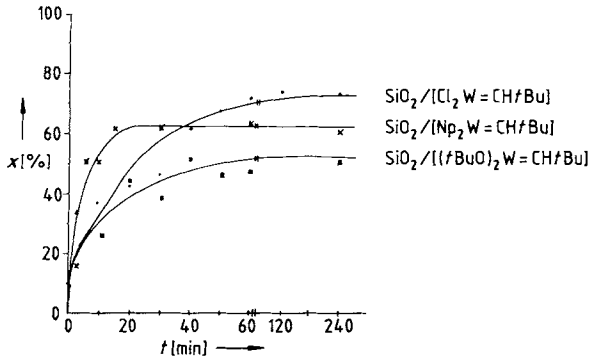

Fig. 2. Metathesis of 1-octene with heterogeneous carbene tungsten(VI) complexes at 122 °C; x = turnover of 1-octene; molar ratio 1-octene : W = 10^4 : 1.

the alkoxy ligands by strongly electron-withdrawing perfluoroalkoxy or imido ligands. In this way, the electronegative character of the W center is increased, favoring addition of olefins to the W=C bond so that metathesis can more readily occur. A similar effect is clearly also achieved by coordination on the SiO_2 surface.

The heterogeneous carbene complexes can be stored at −30 °C for several weeks without loss of catalytic activity. After one week at 20 °C, $SiO_2/[Np_2W{=}CHtBu]$ still had its original activity.

Alkene isomerization becomes significant only when the molar ratio W : 1-octene becomes greater, i.e. with decreasing 1-octene concentration. A similar behavior has been observed for the heterogeneous bimetallic catalysts prepared from carbene or carbyne tungsten(0) complexes and the reduced Phillips catalyst.[1-3]

Carbene tungsten complexes in high oxidation states have long been postulated to be the catalytically active species in the metathesis of olefins by heterogeneous tungsten catalysts.[11] The results reported here support this theory and make it possible to study these catalysts systematically.

A *trans*-Dimethyl Derivative of Octahedral Ti^{IV}: Alkylation and Arylation of Ti^{IV}-Schiff Base Complexes**

By *Carlo Floriani,* Euro Solari, Fabio Corazza, Angiola Chiesi-Villa,* and *Carlo Guastini*

The chemistry of the titanium–carbon bond is still having a major impact in organometallic chemistry for both metal-induced stoichiometric[1,2] and catalytic transformations.[3b] Many of its characteristics are, however, associated with the presence of cyclopentadienyl ligands at a tetrahedrally coordinated metal center.[3c] Since the chemical behavior of the Ti–C bond towards substrates is largely affected by the steric and electronic constraints imposed by the ancillary ligands, we turned our attention to a rigid ligand, such as salen [salen = *N*,*N*′-ethylenebis(salicylideneiminato) dianion], whose use has many precedents, almost exclusively in the organometallic chemistry of cobalt(III).[4] Several organic derivatives of early transition metals with tetradentate ligands have been reported recently.[5,6] $[Ti(salen)Cl_2]$ **1**[7] seemed to be an excellent starting material for the preparation of organometallic derivatives.

[**] This work was supported by the Fonds National Suisse de la Recherche Scientifique (S. N. F. 2.131-0.86).

The alkylation and arylation reactions were much more complex than expected because of the presence of electrophilic sites in the salen ligand. Depending upon the nucleophile and the solvent, the reaction can follow three different pathways a)–c) to form complexes **2**–**4** (Scheme 1). The reaction is influenced by a considerable number of variables, of which the polarity of the solvent is probably the major factor determining the reaction pathway. Alkylation of **1** using LiMe in benzene led to the dimethyl derivative **2**,[8] whose structure is shown in Figure 1.[9] The structure shows a nearly *trans* arrangement of the two methyl groups ($C1_{Me}$–Ti–$C2_{Me}$ 154.9(6)°). The Ti–C bond distances,[3] as well as the structural parameters for the [Ti(salen)] moiety, are in the usual ranges.[7b] **2** is a red crystalline solid, which is stable in the solid state but undergoes decomposition in solution at room temperature. This instability might be due to the self-labilization of two alkyl groups *trans* to each other.

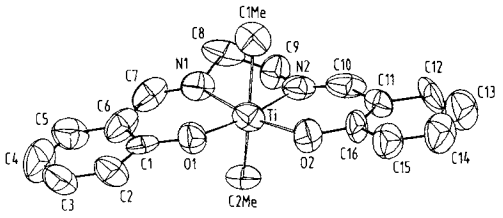

Fig. 1. Molecular structure of **2**. Bond lengths [Å]: Ti–O1 1.83(1), Ti–O2 1.86(1), Ti–N1 2.14(1), Ti–N2 2.15(1), Ti–C1Me 2.15(2), Ti–C2Me 2.15(1); bond angles [°]: O1–Ti–O2 110.9(4), N1–Ti–N2 76.5(6), N1–Ti–O1 86.5(5), N2–Ti–O2 86.1(5), N1–Ti–O2 162.6(5), N2–Ti–O1 162.8(5), C1Me–Ti–C2Me 154.9(6).

When the reaction was carried out using either CH_3MgI or LiMe in THF, reduction to titanium(III) was observed. When **1** was reacted with PhMgBr in THF, complex **3** was isolated and structurally characterized.[10] **3** is much more thermally stable than **2**, both in the solid state and in solution. Reduction of **1** was also observed using MesMgBr (Mes = 2,4,6-$Me_3C_6H_2$) in THF. When the same reaction was carried out in toluene or dioxane,[11] **4** was isolated. The structure of complex **4** is shown in Figure 2.[12] One of the mesityl groups is bonded to the metal atom (Ti–C 2.142(3) Å), while the other is bound to one of the imino carbon atoms. The titanium atom has a pseudo-square pyramidal coordination, with the metal atom lying 0.487(1) Å out of the N_2O_2 plane of the salen ligand, which is distorted due to alkylation at the imino carbon atom. The alkylation leads to the trianionic [salenMes] ligand, and would account for the significant differences observed between the two Ti–N and Ti–O bond lengths. Additionally, the ^{1}H NMR spectrum shows the inequivalence of the mesityl groups, and of the two *o*-methyl substituents of the mesityl group attached to the metal atom.[11]

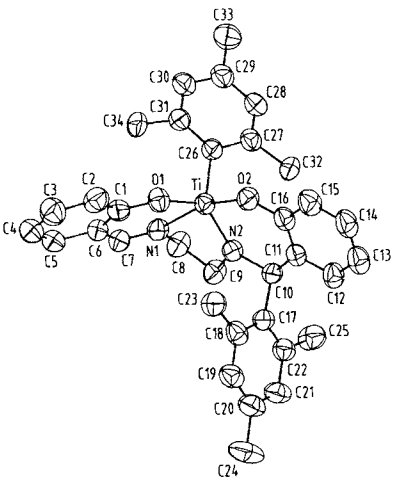

Fig. 2. Molecular structure of **4**. Bond lengths [Å]: Ti–O1 1.874(3), Ti–O2 1.822(3), Ti–N1 2.151(3), Ti–N2 1.927(3), Ti–C26 2.142(3); bond angles [°]: O1–Ti–O2 100.5(1), N1–Ti–N2 76.4(1), N1–Ti–O1 81.7(1), N2–Ti–O2 89.6(1), N1–Ti–O2 162.2(1), N2–Ti–O1 132.7(1).

The results raise the question of whether complexes **3** and **4** have a diaryl metal complex as a common precursor. The formation of **3** can then be readily explained by homolytic cleavage of a Ti–C bond. Migration of an alkyl group to the imino functionality may account for the formation of **4**. The thermal decomposition of **2**, as followed by ^{1}H NMR spectroscopy, clearly shows migration of one of the methyl groups to the imino carbon atom. We cannot, however, exclude a direct alkylation at the imino group. Although this has not been observed in the alkylation of cobalt(III) complexes,[4] the electrophilicity of the imino groups is significantly higher in **1**.

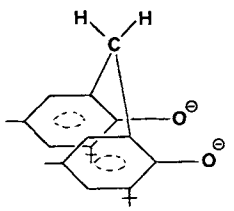
[8] *Experimental procedure* for **2**: To a suspension of **1** (3.25 g, 8.44 mmol) in benzene (200 mL) was added a solution of LiMe (16.88 mmol) in Et_2O dropwise at room temperature. The very insoluble complex **1** dissolved completely giving a red-brown solution. After 2 h, LiCl was filtered off, and the solution allowed to stand for 24 h to give **2** (1.80 g, 50.5%). Crystals suitable for X-ray analysis were obtained by recrystallizing **2** from toluene to give **2**·C_7H_8. ^{1}H NMR (CD_2Cl_2): $\delta = -0.25$ (s, 6H), 4.31 (s, 4H), 7.02 (m, 4H), 7.35 (s, 4H), 8.37 (s, 2H).

[9] **2**: orthorhombic, space group $P2_12_12_1$, $a = 22.795(2)$, $b = 14.734(1)$, $c = 6.849(1)$ Å, $V = 2300.3(4)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.26$ g cm^{-3}, $F(000) = 920$, $\lambda(Mo_{K\alpha}) = 0.71069$ Å, $\mu(Mo_{K\alpha}) = 3.88$ cm^{-1}; crystal dimensions $0.19 \times 0.31 \times 0.72$ mm^3. The structure was solved by the heavy atom method and refined anisotropically for all non-hydrogen atoms except for the toluene carbon atoms. The methyl carbon atom of toluene was found to be statistically distributed over two positions and was isotropically refined with site occupancy factors of 0.5. All hydrogen atoms, apart from those in the disordered methyl groups, were placed in geometrically calculated positions and introduced into the final refinement as fixed contributors ($U_{iso} = 0.08$ Å^2). 882 unique observed reflections [$I > 2\sigma(I)$] collected at room temperature ($6° < 2\theta < 46°$) were used, $R = 0.038$ [13].

[10] *Experimental procedure* for **3**: A solution of PhMgBr (14.07 mmol) in THF (11.7 mL) was added to a suspension of **1** (2.71 g, 7.04 mmol) in THF (70 mL). **1** dissolved giving a green-blue solution. After adding dioxane (2.5 mL, 30.0 mmol) and allowing the solution to stand at room temperature for 5 h, magnesium salts crystallized and were removed by filtration. After 2 d green-blue crystals of **3**·1.5 thf had formed (2.28 g, 70%). $\mu_{eff} = 1.77$ BM at 294 K. The solid state structure shows a pseudooctahedral coordination for titanium with the Ph group *trans* to the THF molecule; the salen ligand forms the equatorial plane.

[11] *Experimental procedure* for **4**: A solution of MesMgBr (21.0 mmol) in THF (18.6 mL) was added to a suspension of **1** (4.05 g, 10.5 mmol) in dioxane (100 mL) at room temperature. A green solution formed with an insoluble white solid. The solid was removed by filtration, and the solution allowed to stand for 24 h at room temperature to give yellow-orange crystalline **4**·$C_4H_8O_2$ (4.14 g, 65%). The reaction in toluene gave solvent-free **4** (70%) without any reduction to titanium(III) (green solution). ^{1}H NMR of **4** (from toluene) (C_6D_6): $\delta = 1.60$ (s, 3H), 2.03 (s, 3H), 2.12 (s, 3H), 2.43 (s, 3H), 2.49 (s, 6H), 2.70 (m, 1H), 3.17 (m, 1H), 3.39 (m, 1H), 4.29 (m, 1H), 6.30–7.25 (a series of multiplets, 12H), 7.28 (s, 1H).

[12] **4**: monoclinic, space group $P2_1/n$, $a = 12.804(1)$, $b = 26.566(3)$, $c = 10.014(1)$ Å, $\beta = 95.27(1)°$, $V = 3391.9(6)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.255$ g cm^{-3}, $F(000) = 1360$, $\lambda(Cu_{K\alpha}) = 1.54178$ Å, $\mu(Cu_{K\alpha}) = 24.56$ cm^{-1}; crystal dimensions $0.21 \times 0.21 \times 0.65$ mm^3. Solution of the structure as for **1** (see [9]). The hydrogen atoms, partly located by difference methods, partly placed in calculated positions, were introduced as fixed contributors into the final refinement ($U_{iso} = 0.12$ Å^2). 3625 unique observed reflections [$I > 2\sigma(I)$] collected at room temperature ($6° < 2\theta < 130°$) were used, $R = 0.057$. The intensities were corrected for absorption [13].



[13] Further details of the crystal structure investigation are available from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England) on quoting the full literature citation.

A Sensitive Spectroscopic Probe for Monitoring Changes in the Coordination Sphere of Titanium: Eight-Membered Dioxatitanacycles and Their Organometallic Derivatives**

By *Carlo Floriani,* Fabio Corazza, William Lesueur, Angiola Chiesi-Villa* and *Carlo Guastini*

Is there a method for efficiently monitoring changes in the coordination sphere of a metal ion via spectroscopy? One possibility is to enclose the ion in a heterocycle and to study changes in the structure and their dependence upon changes in the metal coordination sphere. The 2,2′-methylenebis(6-*tert*-butyl-4-methylphenolato) dianion (MBP) proved to be a suitable probe for these effects in organotitanium chemistry.

MBP can also act as an oxo matrix for anchoring organometallic functionalities and as a O⌒O′ bidentate ligand which can adapt its interaction with the metal atom to changes in the coordination sphere and can form very stable metallacycles. Additionally, MBP contains methylene hydrogen atoms which may be influenced by the proximity of a metal atom.

[**] This work was supported by the Fonds National Suisse de la Recherche Scientifique (S.N.F. 2.131-0.86). We thank Prof. *V. Bertolasi* for the collection of X-ray data for complex **5** and Dr. *S. Pastor* (Ciba-Geigy) for helpful discussions.

We report the synthesis of functionalizable eight-membered dioxatitanacycles and some of their organometallic derivatives emphasizing the relevance of the use of the ancillary ligand MBP. The importance of organotitanium compounds with oxo ligands in organic synthesis,[1,2] organometallic chemistry[1-3,4a] and catalysis[4b] is well known.

The reaction of $TiCl_4$ with $MBPH_2$ in *n*-hexane proceeded with spontaneous evolution of HCl to give red crystals of [(MBP)TiCl$_2$] **1**.[5] **1** is fairly soluble in a large number of organic solvents. The boat conformation of the metallacycle **1** in the solid state is shown in Figure 1.[6] The structure exhibits some interesting structural peculiarities: the Ti–O bond distances are exceedingly short in agreement with a very high Ti–O bond order (probably > 2).[3b] Accordingly, the oxo ligands must be considered to be donors of more than two electrons, and the Ti–O bond order and the electron donation from the oxo ligand to titanium should vary with the coordination number of the metal.[3] The coordination number of the metal was increased either by replacing one chlorine by a Cp ligand [Cp = η^5-C_5H_5], or by adding a monodentate ligand to **1**. Reaction of $MBPNa_2$ with $CpTiCl_3$ gave [CpTiCl(MBP)] **2**[7] while the addition of a monodentate ligand L to **1** [L = *t*BuNC, THF] led to the adducts [(MBP)TiCl$_2$L] **3**, L = RNC and **4**, L = THF. Preliminary crystallographic results show that complex **2** has a similar boat structure to **1** with the Cp ligand in a pseudo-axial position; the Ti–O bond distance in **2** (Ti–O 1.82(2) Å) is significantly longer than that in

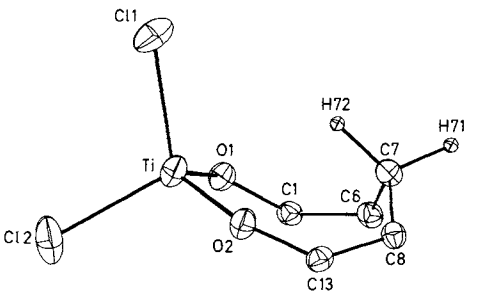

Fig. 1. Molecular structure of [(MBP)TiCl$_2$] **1** (ORTEP, 50% probability ellipsoids). Bond lengths [Å] and angles [°]: Ti–Cl1 2.215(2), Ti–Cl2 2.206(2), Ti–O1 1.760(4), Ti–O2 1.742(4); O1–Ti–O2 106.5(2), Cl2–Ti–O2 108.1(2), Cl2–Ti–O1 110.6(2), Cl1–Ti–O2 111.0(2), Cl1–Ti–O1 111.1(2), Cl1–Ti–Cl2 109.5(1), Ti–O1–C1 143.6(4), Ti–O2–C13 155.8(4).

1.[9] The ^{1}H NMR resonances of the CH_2 group proved to be an excellent probe for the detection of metallacycle formation and are very sensitive to changes in the metal coordination sphere within the metallacycle.[10] The two protons appear as a singlet in the free phenol, but give rise to a pair of well-separated doublets in the metallacycle. The separation of the two doublets, which ranges from 0.34 in **1**, to 0.72 in **2**, 1.03 in **3**, and 1.13 ppm in **4**, increases with increasing coordination number of the metal. It is as yet unknown whether this variation is due to a change in the conformation of the metallacycle in solution, since **2** has a boat conformation in the solid state, while [Cp_2Zr(MBP)], which exhibits two doublets separated by 1.07 ppm, has a solid-state chair conformation.[9] It is however clear that changes in the coordination sphere of the titanium atom are revealed by a change in the separation of the two doublets in the ^{1}H NMR spectrum. Thus, the interaction of a substrate with the metal center can be observed during

metal-assisted reactions. Reaction of **1** with LiMe or LiPh led to the thermally stable organometallic compounds [(MBP)$TiMe_2$] **5**[11] and [(MBP)$TiPh_2$] **6**.[12] An X-ray structural analysis[13] of **5** showed that it also has a boat conformation (Fig. 2). The molecule has a plane of symmetry containing the $TiMe_2$ and CH_2 groups. The structural parameters are very similar to those of **1**. The ^1H NMR at room temperature shows the non-equivalence of the two methyl groups and of the two methylene protons. The separation of the two doublets ($\Delta\delta = 0.17$) and the short Ti–O bond distance (1.799(3) Å) are as expected for tetracoordinate titanium.

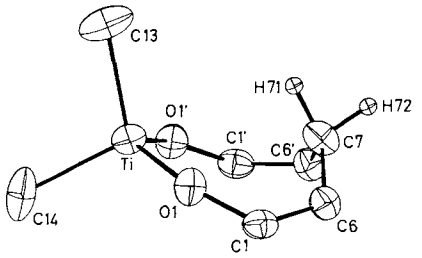

Fig. 2. Molecular structure of [(MBP)$TiMe_2$] **5** (ORTEP, 50% probability ellipsoids). Bond lengths [Å] and angles [°]: Ti–O1 1.799(3), Ti–C13 2.090(9), Ti–C14 2.030(10); O1–Ti–O1′ 112.7(2), C13–Ti–C14 105.8(5), C14–Ti–O1 109.0(1), C13–Ti–O1 110.0(1), Ti–O1–C1 145.7(3). Atoms marked (′) are generated by the transformation $x, 1/2-y, z$.

[5] *Procedure* for **1**: $TiCl_4$ (6.5 mL, 61.8 mmol) was added dropwise to a solution of $MBPH_2$ (21.0 g, 61.8 mmol) in *n*-hexane (300 mL). The resulting red solution, on standing at room temperature for 12 h, gave red crystals of **1** (yield 24.9 g, 88.0%). ^1H NMR (200 MHz, CD_2Cl_2): $\delta = 7.22$ (d, 2H, Ph), 7.03 (d, 2H, Ph), 4.08 (d, 1H, $J_{HH} = 14.4$ Hz, CH_2), 3.74 (d, 1H, $J_{HH} = 14.4$ Hz, CH_2), 2.34 (s, 6H, Me), 1.47 (s, 18H, *t*Bu). Some titanacycles containing other heteroatoms are described in [4b].

[6] Structure of **1**: triclinic, space group $P\bar{1}$, $a = 9.704(1)$, $b = 12.938(2)$, $c = 9.514(1)$ Å, $\alpha = 92.45(1)$, $\beta = 94.0(1)$, $\gamma = 85.97(1)°$, $V = 1187.8(3)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.279$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.71069$ Å, $\mu(Mo_{K\alpha}) = 5.97$ cm^{-1}: crystal dimensions $0.08 \times 0.45 \times 0.78$ mm^3. The structure was solved by the heavy atom method (Patterson and Fourier synthesis) and refined by full-matrix least-squares. For 1427 unique observed structure amplitudes [$I > 2\sigma(I)$, no correction for absorption] collected at room temperature on a Philips PW 1100 diffractometer in the range $6 < 2\theta < 46°$ the *R* value was 0.038 (unit weights). All the hydrogen atoms were located in a difference Fourier map and introduced as fixed contributors in the final stage of refinement [14].

[7] *Procedure* for **2**: Solid $CpTiCl_3$ (10.71 g, 48.83 mmol) was added to a suspension of $MBPNa_2$ (48.83 mmol) in benzene (300 mL) and the mixture gently heated. The resulting suspension was kept at room temperature for 12 h, then heated and filtered while hot to remove NaCl. **2** crystallized upon concentration of the solution (yield 15.0 g, 63.0%). ^1H NMR (200 MHz, CD_2Cl_2): $\delta = 7.04$ (d, 2H, Ph), 6.91 (d, 2H, Ph), 6.83 (s, 5H, Cp), 4.16 (d, 1H, $J_{HH} = 13.6$ Hz, CH_2), 3.44 (d, 1H, $J_{HH} = 13.6$ Hz, CH_2), 2.24 (s, 6H, Me), 1.31 (s, 18H, *t*Bu).

[8] *Procedure* for **3**: *t*BuNC (0.33 mL, 2.95 mmol) was added to a solution of **1** (1.35 g, 2.95 mmol) in *n*-hexane (80 mL). The color changed from red to deep-red. The solution was cooled to 4 °C for 48 h to afford deep-red microcrystalline **3** (yield 1.50 g, 94%). IR: $\tilde{\nu}$(CN) (nujol) = 2223 cm^{-1}, $\tilde{\nu}$(CN) (C_6D_6) = 2211 cm^{-1}; ^1H NMR (200 MHz, CD_2Cl_2): $\delta = 7.09$ (d, 2H, Ph), 6.95 (d, 2H, Ph), 4.52 (d, 1H, $J_{HH} = 13.9$ Hz, CH_2), 3.49 (d, 1H, $J_{HH} = 13.9$ Hz, CH_2), 2.26 (s, 6H, Me), 1.55 (s, 9H, *t*BuNC), 1.41 (s, 18H, *t*Bu).

[9] C. Floriani et al., unpublished.

[10] Detailed conformational studies have been carried for a number of heterocycles with phosphorus, silicon and boron in the same diphenoxo skeleton; see: S. D. Pastor, J. D. Spivack, R. K. Rodebaugh, D. Bini, *J. Org. Chem. 49* (1984) 1297; S. D. Pastor, J. D. Spivack, *J. Heterocycl. Chem. 20* (1983) 1311; P. A. Odorisio, S. D. Pastor, J. D. Spivack, L. Steinhuebel, R. K. Rodebaugh, *Phosphorus and Sulfur 15* (1983) 9; *ibid. 19* (1984) 285; H. S. Rzepa, R. N. Sheppard, *J. Chem. Res. 5* (1988) 102 and references cited therein.

[11] *Procedure* for **5**: A suspension of **1** (1.55 g, 3.36 mmol) in pentane (50 mL) at −30 °C was reacted with a solution of LiMe (6.72 mmol) in Et_2O. The yellow solution was warmed to room temperature and LiCl removed by filtration. The resulting solution gave, on cooling at −30 °C for 12 h, yellow crystalline **5** (yield 0.61 g, 43.6%). ^1H NMR (200 MHz, C_6D_6): $\delta = 6.99$ (d, 4H, Ph), 3.38 (d, 1H, $J_{HH} = 14.2$ Hz, CH_2), 3.21 (d, 1H, $J_{HH} = 14.2$ Hz, CH_2), 2.11 (s, 6H, *p*-Me), 1.60 (s, 18H, *o*-*t*Bu), 1.38 (s, 3H, Me), 1.36 (s, 3H, Me).

[12] *Procedure* for **6**: **1** (3.70 g, 8.70 mmol) was added to a solution of LiPh (17.5 mmol) in Et_2O (100 mL) at room temperature. The resulting solution was allowed to stand for 12 h, then evaporated to dryness. The resulting solid was dissolved in pentane (50 mL) and LiCl removed by filtration. The pentane solution, upon cooling to −30 °C, gave crystalline green **6** (yield 1.79 g, 38.0%). ^1H NMR (200 MHz, CD_2Cl_2): $\delta = 8.02$ (m, 4H, Ti-Ph), 7.25 (m, 6H, Ti-Ph), 7.19 (d, 2H, Ph), 7.04 (d, 2H, Ph), 3.68 (d, 1H, $J_{HH} = 14.5$ Hz, CH_2), 3.56 (d, 1H, $J_{HH} = 14.5$ Hz, CH_2), 2.31 (s, 6H, *p*-Me), 1.59 (d, 18H, *t*Bu).

[13] Structure of **5**: orthorhombic, space group *Pnma*, $a = 11.982(2)$, $b = 23.753(5)$, $c = 8.375(1)$ Å, $V = 2383.6(7)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.161$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.71069$ Å, $\mu(Mo_{K\alpha}) = 3.69$ cm^{-1}; crystal dimensions $0.21 \times 0.27 \times 0.40$ mm^3. The structure was solved by the heavy atom method (Patterson and Fourier synthesis) and refined by full-matrix least-squares. For 1631 unique observed structure amplitudes [$I > 3\sigma(I)$] collected at room temperature on a CAD4 diffractometer in the range $4 < 2\theta < 54°$ the *R* value was 0.080 (unit weights). Most of the hydrogen atoms were located in a difference Fourier map and introduced as fixed contributors in the final stage of refinement. All calculations were carried out using SHELX 76 [14].

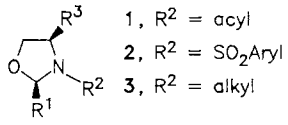
3-Arylsulfonyloxazolidines as Chiral Templates; Asymmetric Synthesis of 2-Substituted 2-Hydroxycyclohexanecarbaldehydes from 2-Hydroxymethylenecyclohexanone**



By *Inga Hoppe, Dieter Hoppe,* Christian Wolff, Ernst Egert,** and *Regine Herbst*

Enantiomerically pure mono- and bicyclic 3-acyloxazolidines are suitable as chiral templates for asymmetric synthesis.[1–4] Our attempts to use **1** more generally for intra- and intermolecular reactions at R^1 and R^2, however, revealed serious disadvantages to this approach:[5] (1) changing stereoselectivities in the condensation step;[4–6] (2) lack of stability toward several organometallic reagents; (3) low tendency for crystallization and difficult NMR-spectro-

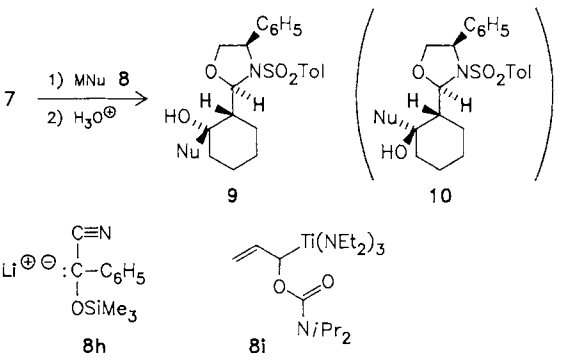
scopic structural elucidation owing to slowly interconverting amide rotamers.



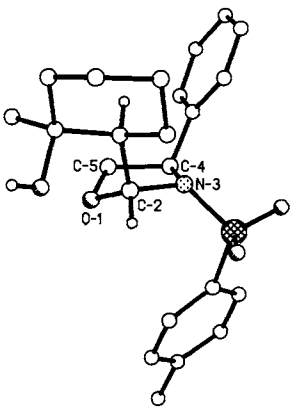
R^1 = alkyl, alkenyl, aryl; R^3 = alkyl, phenyl

We have now found that the 3-arylsulfonyloxazolidines **2** are not only free of these limitations but also have further advantages. We present here the first example of their application in enantioselective synthesis. (*R*)-*N*-(4-Toluenesulfonyl)phenylglycinol **4** undergoes acid-catalyzed condensation with 2-hydroxymethylenecyclohexanone **5** to give a single crystalline *cis*-oxazolidine **7** (yield 71%); less than 5% of the other three possible diastereoisomers are present in the crude product.[7] The *cis* selectivity of formation observed for 3-alkyloxazolidines **3**[8] thus remains valid. In addition, the formation of a third stereogenic center is induced in the cyclohexane ring. We assume that this is the result of an intramolecular *anti* addition of the OH group in the intermediary (*E*)-enamide **6**.

Tol = *p*-tolyl

The addition of widely differing nucleophiles MNu **8** to the keto group of the six-membered ring usually leads to diastereoisomerically pure adducts **9** (Table 1); only the reduction of **7** with diisobutylaluminum hydride (DIBAH) or sodium borohydride affords, in addition to **9a**, a second diastereoisomer, presumably **10a** (99%, 43:57, and 72%, 48:52, respectively).

The configuration of the methyl adduct **9b**—(1′*R*,2*R*,2′*S*,4*R*)—was determined by an X-ray structure analysis.[12] Noteworthy is the pyramidal configuration of N-3 (sum of angles 344.5°; Fig. 1) and the fact that the aryl moiety of the sulfonyl group covers the "bottom face" of the five-membered ring.



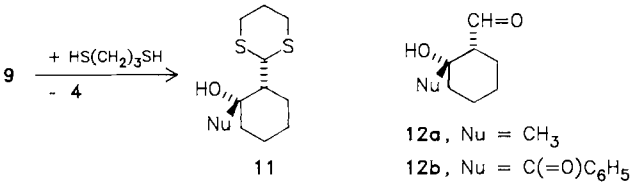


Fig. 1. Molecular structure of **9b**. The five-membered ring adopts an envelope conformation, with O-1 lying 50 pm outside the plane formed by the four other ring atoms.

Table 1. Yields, melting points, and optical rotations for the synthesized oxazolidines **9** and *ent*-**9**.

Starting material	MNu	Product **9** [a, b]	Nu	Yield [%] [c]	M.p. [°C] [d]	$[\alpha]_D^{20}$ [e]
7	$Zn(BH_4)_2$ **8a**	**9a**	H	99	60 (decomp.)	−563
7	$ClMgCH_3$ **8b**	**9b**	CH_3	89	171	−112.8
ent-7	$ClMgCH_3$ **8b**	*ent*-**9b**	CH_3	91	171	+113.0
7	$BrMgC_6H_5$ **8c**	**9c**	C_6H_5	80	161	− 79.4
7	$BrMgCH{=}CH_2$ **8d**	**9d**	$CH{=}CH_2$	95	55	− 96.7
ent-7	$Li^{\oplus}CH_2{=}C(O^{\ominus}){-}OtBu$ **8e**	*ent*-**9e**	CH_2CO_2tBu	70	169	+ 80.4
ent-7	$Li^{\oplus}(CH_3)_2C{=}C(O^{\ominus}){-}OMe$ **8f**	*ent*-**9f**	$C(CH_3)_2CO_2Me$	50	147	+ 95.6
ent-7	Li–C(OMe)=CH_2 [9] **8g**	*ent*-**9g**	C(OMe)=CH_2	52	56 (decomp.)	+ 86.3
ent-7	**8h** [10]	*ent*-**9h** [f]	(C=O)Ph	67	181	+ 56.4
ent-7	**8i** [11]	*ent*-**9i**	(*Z*)-$CH_2CH{=}CHOCb$ [g]	68	71	+ 45

[a] All products **9** were obtained in analytically pure form (C ±0.3, H ±0.3). [b] A second diastereomer could not be detected in any case by ^1H NMR spectroscopy, ≥95% *ds*. [c] After chromatographic purification. [d] From ether/petroleum ether. [e] CH_2Cl_2, $c = 1$. [f] Isolated and characterized as $OSiMe_3$ derivative. [g] OCb = (C=O)N*i*Pr_2.

The amino acetals **9** correspond to (2-substituted) 2-hydroxycyclohexanecarbaldehydes **12**. As we showed by converting *ent*-**9b** and *ent*-**9h** into the enantiomerically pure dithianes *ent*-**11b** (85%) and *ent*-**11h** (80%), respectively, the removal of the chiral auxiliary occurs smoothly with 1,3-propanedithiol, even for dehydration-sensitive derivatives.[3]

The method described here allows the general and simple synthesis of enantiomerically pure aldehydes of type **12**; usually, diastereoisomer separations of the intermediates are not required. The good crystallizability of **9** simplifies purification, when necessary in specific cases. Functionalized nucleophiles, such as enolates (**8e**, **8f**), synthetic equivalents of acylanions, **8g**[9] and **8h**,[10] and of homoenolates (e.g., **8i**[11]), also react facilely, thereby allowing the synthesis of bicyclic compounds in subsequent reactions. The enantiomers *ent*-**11** are also accessible with the L-valinol congener (*ent*-**7**, $(CH_3)_2CH$ instead of C_6H_5).

Experimental Procedure

7: 4-Å molecular sieves (10 g) and methanesulfonic acid (0.15 g) were added sequentially to a solution of **4** (2.91 g, 10 mmol) and **5** (1.26 g, 10 mmol) in 50 mL of dichloromethane. The reaction mixture was stirred slowly for 24 h at 20–25 °C; solid potassium carbonate (0.4 g) was then added and the solids were filtered off, followed by removal of the solvent under vacuum. Crystallization from ether and chromatography of the mother liquor on silica gel with ether/pentane (1:1) afforded 2.84 g (71%) **7**, $R_F = 0.13$, m.p. 144 °C, $[\alpha]_D^{20}$ −136.1 (CH_2Cl_2, $c = 1$). *ent*-**7**, $[\alpha]_D^{20}$ +136.0, was obtained in the same way from *ent*-**4**. Selected spectroscopic data. ^{1}H NMR ($CDCl_3$): $\delta = 3.82$ and 3.90 (ABX, $J_{gem} = 9.1$ Hz, $J_{cis} = 7.3$ Hz, $J_{trans} = 5.8$ Hz, 5-H_2), 4.75 (dd, 4-H), 5.73 (d, $J = 8.5$ Hz, 2-H). ^{13}C NMR ($CDCl_3$): $\delta = 54.6$ (C-1′), 62.1 (C-5), 71.1 (C-4), 91.5 (C-2), 209.9 (2′-C=O); IR (KBr): $\tilde{\nu} = 1660$ (C=O), 1355 and 1165 cm^{-1} (NSO_2).

ent-**9b**: A 2 M solution of methylmagnesium chloride in THF (3 mL, 6 mmol) was added to a solution of *ent*-**7** (2.00 g, 5.00 mmol) in THF below −70 °C and the resulting mixture was stirred for 24 h in an acetone/dry ice bath. The solution was then warmed to room temperature and the solvent removed under vacuum. The residue was worked up with dichloromethane/saturated ammonium chloride solution. Crystallization from toluene/ether and chromatography of the mother liquor on silica gel with ether/pentane (1:1) afforded 1.89 g (91%) *ent*-**9b**, $R_F = 0.15$. A second diastereomer could not be detected. ^{1}H NMR ($CDCl_3$): $\delta = 1.25$ (s, 2′-CH_3), 2.25 (s, OH), 3.87 and 4.00 (ABX part, $J_{gem} = 9.0$ Hz, $J_{cis} = 7.8$ Hz, $J_{trans} = 7.1$ Hz, 5-H_2), 5.63 (d, $J = 8.5$ Hz, 2-H). ^{13}C NMR ($CDCl_3$): $\delta = 29.5$ (2′-CH_3), 21.4 (C-4′), 24.7 (C-5′), 25.2 (C-6′), 40.8 (C-3′), 47.4 (C-1′), 62.0 (C-4), 70.77 (C-2′), 70.84 (C-5), 90.4 (C-2).

ent-**11b**: A solution of *ent*-**9b** (208 mg, 0.50 mmol), 1,3-propanedithiol (0.080 mL, 0.80 mmol), and methanesulfonic acid (15 mg) in dichloromethane (2.5 mL) was refluxed under argon for 3 h and, after cooling, neutralized with potassium carbonate (40 mg). Chromatography on silica gel with ether/pentane (1:5) afforded 98 mg (85%) *ent*-**11b**, m.p. 68 °C (pentane), $[\alpha]_D^{20}$ +63.4 (CH_2Cl_2, $c = 1.5$). *ent*-**11h**: Yield 80%, m.p. 99 °C, $[\alpha]_D^{20}$ +1.96, $[\alpha]_{436}^{20}$ −91.5 (CH_2Cl_2, $c = 1$).

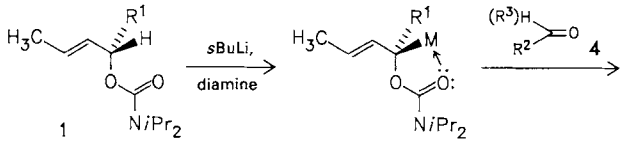
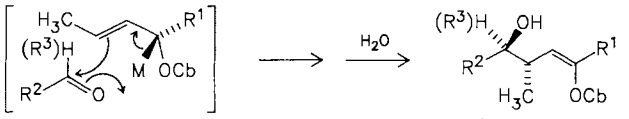
Asymmetric Homoaldol Reaction by Enantioselective Lithiation of a Prochiral 2-Butenyl Carbamate**



By *Dieter Hoppe** and *Oliver Zschage*

Enantiomerically pure *secondary* 2-alkenyl carbamates such as **1a** are deprotonated by alkyllithium-TMEDA with retention of configuration to give the corresponding chiral lithium derivatives **2a**·TMEDA.[1] The latter are configurationally stable below −70 °C and thus of preparative value. After metal exchange with tetra(isopropoxy)titanium, which also occurs with retention, the titanium complex **3a** adds to aldehydes **4** with 1,3-chirality transfer in the allyl moiety—coupled with enantiofacial differentiation at the carbonyl group (transition state **A**)—to afford, after aqueous work-up, the optically active homoaldol adducts **5**.[1–3]



Nonracemic 1-unsubstituted enol carbamates such as **6**, valuable building blocks for the synthesis of diastereoisomerically pure γ-lactones,[4,5] are not accessible in this way, since their synthesis requires (prochiral) *primary* alkenyl carbamates like **1b** as starting materials. We have now found a surprisingly simple approach to generate (*R*)-**2** by deprotonation of **1b** in the presence of an enantiomerically pure diamine as complex-forming agent. Second-order asymmetric induction[6] results in the crystallization of only one enantiomer of **2b**, as a diamine complex, from a solution of the configurationally labile, racemic lithium

1–3: a, $R^1 = CH_3$; b, $R^1 = H$ — 2, M = Li · diamine; 3, M = $Ti(OiPr)_4^{\ominus}\ Li^{\oplus}$

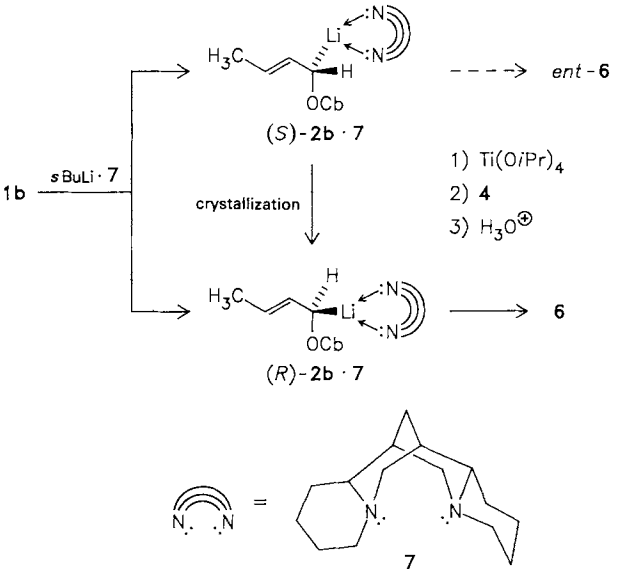
A — 5, $R^1 = CH_3$; 6, $R^1 = H$

Cb = $C(=O)N(iPr)_2$

4,6: a, $R^2 = CH(CH_3)_2$, $R^3 = H$; b, $R^2 = CH_3$, $R^3 = H$; c, $R^2 = (CH_2)_3CH_3$; $R^3 = H$; d, $R^2 = R^3 = CH_3$

compound *rac*-**2b**. The solid product is then transmetalated to give the configurationally stable titanium derivative **3b**, which adds enantioselectively to aldehydes and ketones.

Reaction of (*E*)-2-butenyl carbamate **1b** with a solution of equivalent molar amounts of *sec*-butyllithium and (−)-sparteine[7] **7** below −70°C in pentane/cyclohexane results, within only a few minutes, in the crystallization of a lithium complex. Upon addition of four equivalents of tetra(isopropoxy)titanium,[8] the complex goes into solution; subsequent reaction with achiral aldehydes **4a–c** or with acetone (**4b**) gives the diastereomerically pure adducts **6a–d** in 90–95% yield and with 80–84% enantiomeric excess[9] (see Table 1).



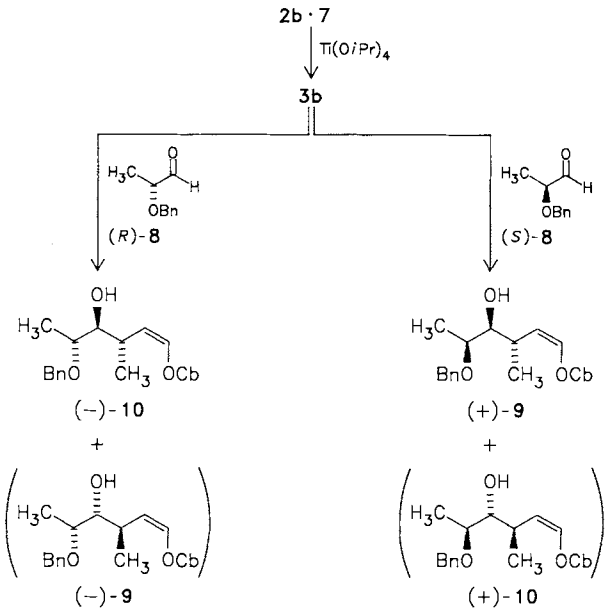


Table 1. Yields, enantiomeric excesses, and optical rotations for the homoaldol adducts **6**, **9**, and **10**.

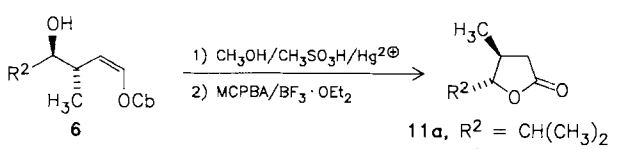
Product	R^2	R^3	Yield [%]	*ee* [%]	$[\alpha]_D^{20}$ [a]
6a [5a]	$(CH_3)_2CH$	H	95	83	+15.2
6b [5a]	CH_3	H	95	80	+22.0
6c [4a]	*n*-C_4H_9	H	92	82	+ 5.1
6d [4b]	CH_3	CH_3	93	84	+48.0
(+)-**9** [5b]	(*S*)-$CH_3CH(OBn)$	H	90 [b]	>95	+33.0
(−)-**10** [5b]	(*R*)-$CH_3CH(OBn)$	H	79 [c]	>95	− 9.8

[a] Methanol, $c = 2.0$–2.5. [b] Besides 4% (+)-**10**. [c] Besides 14% (−)-**9**.



The same reaction with (*S*)-2-benzyloxypropanal (*S*)-**8** leads to formation of the diastereoisomers[5b] (+)-**9** and (+)-**10** (95:5, yield 94%), whereas with (*R*)-**8** the enantiomers (−)-**9** and (−)-**10** are obtained in almost the opposite ratio (15:85, yield 93%).[1b,10] The configuration at C-3 and C-4 of the diastereoisomers formed in excess, (+)-**9** and (−)-**10**, which is related to that of **3** through the transition state **A**,[1] leads to assignment of an (*R*) configuration to the reacting titanium species **3b**.[11] The average enantiomeric ratio attained for **6**/*ent*-**6** (91:9) reflects the minimal diastereoisomeric ratio of the sparteine complexes (*R*)-**2b**·**7**:(*S*)-**2b**·**7** in the reaction mixture.

The same result is obtained when the racemate *rac*-**2b**·DME (DME = dimethoxyethane) is first generated and (−)-sparteine **7** is then added (92% **6a** with 82% *ee*). On the other hand, in experiments in which crystallization did not occur, **6a** was obtained in the same yield but with maximally 20% *ee*.

Thus, the following interpretation is compelling: the enrichment of (*R*)-**2b**·**7** is the consequence of a second-order asymmetric induction;[6] i.e., the diastereoisomeric complexes (*R*)- and (*S*)-**2b**·**7** are configurationally labile in solution and equilibrate through an epimerization; (*R*)-**2b**·**7** is removed from the equilibrium by crystallization and, as a solid, is configurationally stable. The transmetalation with $Ti(OiPr)_4$ apparently occurs directly with the solid. Thus, it is not possible to determine whether **1b** is deprotonated by *s*BuLi·**7** with enantiotopic differentiation—although this was our original conception.

Methanolysis and Grieco oxidation[4a] of **6** afford the optically active lactones **11**. We obtained (+)-**11a**[12] in 87% and (+)-**11c**[12] (Quercus lactone A)[13] in 90% yield.

6 — 11a, $R^2 = CH(CH_3)_2$; 11c, $R^2 = (CH_2)_3CH_3$

This method offers a fundamentally new and very simple route to nonracemic allyllithium derivatives. Thus, (*R*)-**2b** should be of interest not only as a chiral homoenolate reagent but also (after ozonolysis[14] of **6**) as an *anti*-selective propanal enolate equivalent that adds with good reagent-controlled stereoselectivity.[15]

Experimental Procedure

A ca. 1.4 M solution of *sec*-butyllithium (2.2 mmol) in cyclohexane/isopentane was added to a solution of (−)-sparteine (**7**) (2.2 mmol) in pentane (7 mL) and cyclohexane (1 mL) [16] cooled in a dry ice/acetone bath. **1b** (2.0 mmol) [4b] in 2 mL of pentane was then added to the stirred solution. After 10 min, the precipitate formed on the wall of the flask was brought into suspension by removing the flask briefly from the cooling bath (internal temperature max. −60 °C!) and the flask was cooled once again at −70 °C. After 30 min, 8.8 mmol of tetra(isopropoxy)titanium was added and, after another 30 min, 2.5 mmol of the carbonyl compounds **4** or **8**. After stirring for 4 h, the reaction mixture was allowed to warm to 0 °C and 2 N hydrochloric acid and ether (40 mL each) were added, followed by the usual workup. Purification was accomplished by flash chromatography on silica gel with ether/pentane (1:8 to 4).

[7] (−)-Sparteine has already been used for chiral modification of "cations" of organometallic compounds containing *achiral* "carbanion" moieties: see, for example, M. Guetté, J. Capillon, J.-P. Guetté, *Tetrahedron 29* (1973) 3659. It is important to note that the asymmetric induction in that case is caused by the orientation of the starting materials with respect to the cation. Thus, the direction and extent of the asymmetric induction cannot be predicted. Application to a chiral Grignard compound gave only a slight enantiomeric exess (7% *ee*), cf. S. Harvey, P. C. Junk, C. L. Raston, G. Salem, *J. Org. Chem. 53* (1988) 3134.

[9] Determined by ^{1}H NMR spectroscopy in ca. 0.2 M $CDCl_3$ solution with 10–40 mol% of tris[(3-heptafluoropropylhydroxymethylene)-d-camphorato]europium(III) [Eu(hfpc)$_3$]. The 1-H signal of **6** is shifted 0.2–0.5 ppm downfield compared with that of *ent*-**6**.

[10] For the problem of double stereodifferentiation in the addition of chiral organometallic compounds, see R. W. Hoffmann, J. Lanz, R. Metternich, G. Tarara, D. Hoppe, *Angew. Chem. 99* (1987) 1196; *Angew. Chem. Int. Ed. Engl. 26* (1987) 1145, and references cited therein.

[11] In control experiments, the lithium complex **2b**·**7** also gave **6a** (62% *ee*) in excess in addition to α adducts and the γ-*syn* diastereomer. This demonstrates that the metal exchange with Ti(O*i*Pr)$_4$ occurs with retention.

[12] **11c**: $[\alpha]_D^{20}$ +52.1 (methanol, $c = 1$). The optical purity of 62%, determined by comparison of the optical rotation with that of the natural product [13a], is presumably incorrect, since the transformation of **6c** (83% *ee*) cannot be accompanied by racemization. **11a** (83% *ee*): $[\alpha]_D^{20}$ +31.8 (methanol, $c = 2.5$).

[16] The crystallization of (*R*)-**2b**·**7** is induced by cyclohexane. It is still not clear whether the cyclohexane is incorporated into the crystal lattice or only serves as a crystallization seed. As we have shown for **6a**, after addition of cyclohexane, *n*-butyllithium in hexane can also be used for the deprotonation, giving the same results.

Retention of Configuration in the Non-Darwinian Evolution of Cytochrome c

By *Shosuke Kojo**, *Koushi Fukunishi*, and *Ikuyo Tsukamoto*

Cytochrome c from eukaryotes characteristically has two sulfide bonds between the cysteine residues of the apoprotein and the hemin group. Acid hydrolysis of cytochrome c affords the prosthetic group hemin c **1**, whose structure is shown in Figure 1. Since cytochrome c is distributed in a wide range of organisms, it has been especially useful as a probe for the study of molecular evolution, particularly with regard to changes in the amino acid sequence.[1,2] These studies are related to the idea of non-Darwinian,[3] i.e., neutral evolution,[4] in which variations in homologous proteins are attributed to a genetic drift without selective advantage. Thus, for example, the cytochrome c of a horse differs from that of baker's yeast in 45 of the ca. 110 amino acid residues.[5] This number is very large, considering that, in many cases, even a single amino acid alteration is sufficient to cause a dramatic change in the function of the protein.

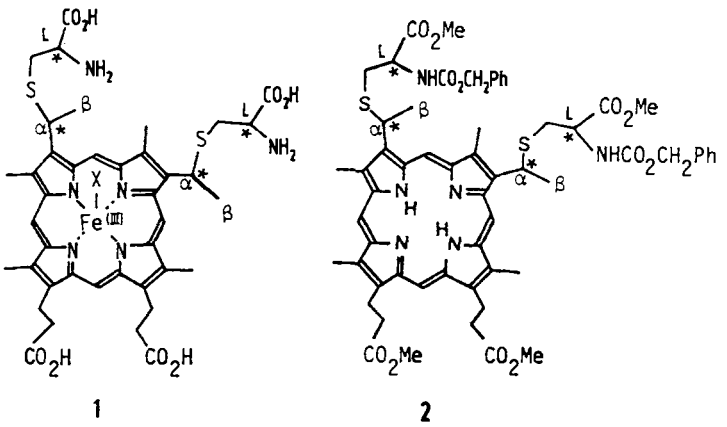

Fig. 1. Hemin c **1** and bis(*N*-benzyloxycarbonyl)porphyrin-c tetramethylester **2**. The chiral carbon atoms are indicated by asterisks. The letter L indicates that the cysteinyl group is the L-isomer. X represents a ligand; in compound **1**, X = Cl.

Cytochrome c is located in a respiratory system, whose origin is very old. Furthermore, its fundamental reaction mechanism has not changed during biological evolution.

Accordingly, some structural similarities are expected to be exhibited by the various cytochrome c forms even after considerable neutral evolution. Such similarities must be closely related to the function of the protein, which transports electrons from cytochrome c_1 to cytochrome oxidase in the mitochondrial membrane. The functional similarity of eukaryotic cytochromes c is demonstrated by the fact that many of them react equally rapidly with beef heart cytochrome oxidase in spite of them having considerable differences in the amino acid sequence.[6] In order to exhibit this functional similarity in interaction with neighboring proteins, cytochrome c must retain its redox potential and molecular properties, such as size and charge distribution as well as the environment and orientation of the active site. The retention of the redox potential is, as is already well-known, ensured by the presence of sulfide bonds and of similar ligands bound to the iron atom of the hemin group. The retention of the molecular properties is expected to be dependent on the configuration of the two chiral α-C atoms bearing the sulfide bonds. As shown by X-ray studies,[2] the small protein of cytochrome c just covers the porphyrin ring, one edge of which even projects into the solvent. For this reason its molecular shape (especially in the vicinity of the active site) is assumed to be strongly influenced by the configuration of the two chiral C atoms at the junction of the hemin group and the apoprotein. Since the hemin group contains two chiral carbon atoms, four diastereomers are possible.

We have developed a chemical method[7] to investigate this stereochemical problem and have established unambiguously that hemin c **1** of horse cytochrome c consists of a single isomer.[1] A mixture of the four diastereomers of **1**[8] was prepared and converted into the tetramethylesters **2**[9] (Fig. 1). The four components of **2** were separated by HPLC. We also prepared isomers of **1** starting from D- or D,L-cysteine, and used these compounds to check for racemization of the cysteine part of **1** using HPLC; no racemization was found. Moreover, cytochrome c was converted to **2** via stereospecific reactions and its HPLC chromatogram compared with that of the chemically prepared diastereomers. This showed that horse cytochrome c contained only one of the four possible diastereomers.[7] The same method was applied to cytochrome c from chicken, tuna and *Saccharomyces cerevisiae*. All of these cytochromes c were shown to have the same stereochemistry at the chiral carbon atoms as the horse cytochrome c. Although only a limited number of examples is available, these results strongly suggest that the configuration in the positions α- to the sulfide bonds is retained during the evolution of eukaryotic cytochrome c and that this—as mentioned above—may be essential for the retention of protein function. In other words, neutral evolution was apparently only possible if the stereochemical requirements were fulfilled.

Model of a Solvent-Shared Ion Pair with N-H···C Hydrogen Bonds between Amine and Carbanion—Crystal Structure of [Fluorenyllithium·2 Ethylenediamine]$_\infty$**

By *Stefan Buchholz, Klaus Harms, Michael Marsch, Werner Massa,* and *Gernot Boche**

In the majority of organolithium compounds $Li^\oplus$ is bound directly to C or heteroatoms (N, O, S) of the carbanion ("contact ion pairs").[1] In a few exceptional cases $Li^\oplus$ is chelated by two 12-crown-4[2] or tetramethylethylenediamine (TMEDA) molecules.[3] Herein we report on the solid state structure of [fluorenyllithium·2 ethylenediamine]$_\infty$ **1**.[4] The ethylenediamine (EDA) ligands in this complex form a network structure with the fourfold coordinated $Li^\oplus$ ions in which the "naked" fluorenyl anions are embedded; the structure is stabilized by N-H···C hydrogen bonds (Fig. 1).[5]

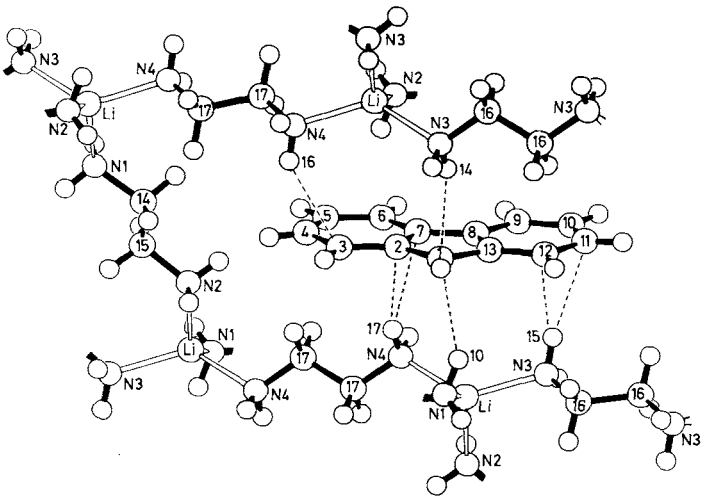

Fig. 1. Section of the crystal structure of [fluorenyllithium·2 ethylenediamine]$_\infty$ **1** [8] with N-H···C hydrogen bonds <280 pm. Two of the three crystallographically different EDA molecules lie on inversion centers. Important bond lengths [pm]: C1-C2 139.9(4), C2-C3 142.6(5), C3-C4 136.3(6), C4-C5 139.6(6), C5-C6 139.9(6), C6-C7 138.7(4), C7-C8 143.6(4), C8-C9 141.7(4), C9-C10 137.7(5), C10-C11 139.8(5), C11-C12 138.0(4), C12-C13 141.4(4), C13-C1 142.7(4), C14-C15 152.0(4), C16-C16′ 152.9(4), C17-C17′ 151.9(4), C14-N1 148.4(4), C15-N2 148.0(4), C16-N3 146.9(4), C17-N4 146.7(4), Li-N1 207.1(5), Li-N2 209.8(5), Li-N3 208.0(5), Li-N4 207.7(5), Li···C13 403.6(6), Li′-C2 406.0(6), Li′···C3 407.5(7); N-H···C hydrogen bonds with H···C distances <280 pm: C1-N3′ 331.1(4), C1-H14′ 250(4), H14′-N3′ 87(4), C7-N4 332.9(4), C7-H17 259(3), H17-N4 90(3), C1-N1 342.9(5), C1-H10 257(3), H10-N1 97(3), C3-N4′ 349.5(4), C3-H16′ 274(3), H16′-N4′ 90(3), C12-N3 350.8(4), C12-H15 271(3), H15-N3 95(3), C2-N4 357.0(4), C2-H17 269(3), H17-N4 90(3), C11-N3 359.4(9), C11-H15 267(3), H15-N3 95(3); bond angles [°]: N1-Li-N2 126.2(3), N1-Li-N3 101.2(2), N1-Li-N4 102.5(2), N2-Li-N3 103.5(2), N2-Li-N4 99(2), N3-Li-N4 127.5(3); N-H···C hydrogen bonds: C1-H14-N3 156(3), C7-H17-N4 140(3), C1-H10-N1 148(2), C3-H16′-N4′ 141(3), C12-H15-N3 142(2), C2-H17-N4 166(3), C11-H15-N3 164(2); torsion angles [°]: N1-C14-C15-N2 175.5(2), N3-C16-C16′-N3′ 180, N4-C17-C17′-N4′ 180.

Each $Li^\oplus$ ion is surrounded by four EDA molecules, which are present in antiperiplanar conformation (torsion angles 180, 180 and 175.5°). The N-Li-N bond angles (99.0 to 127.5°) are closer to the tetrahedral angle than in a

chelate.[9] $Li^{\oplus}$ is not bound to a C atom of the fluorenyl anion, the shortest distance Li–C13 is 403.6 pm (in the solid state structure of the contact ion pair fluorenyllithium·2quinuclidine[10] the following Li–C distances were found: 233.3, 247.1 and 279.4 pm). In contrast, the fluorenyl anion **1** exhibits hydrogen bonding with the amine hydrogen atoms of the EDAs, of which only those with H···C distances <280 pm are shown in Figure 1. The bonds H14–C1 (250 pm), H10–C1 (257 pm) and H17–C7 (259 pm), in particular, are significantly shorter than the sum of the van-der-Waals radii of H and C (290 pm).[11] According to semiempirical calculations[10, 12] C1 exhibits the highest charge density, that of C7 also being high. Up to now the presence of H bonds to carbanions was mainly concluded from kinetic investigations;[13] spectroscopic detection was possible in only a few cases.[14] Investigations by *Seebach* et al.[15] and *Tamm* et al.[17] show the significance of N–H bridged amide, ester, and ketone enolates, which were prepared by deprotonation with lithium amides, in alkylation or deuteration (degree of deuteration up to <1%). *Dunitz* and *Seebach* et al. first found an N–H···C bond X-ray crystallographically in the lithium enolate $[t\mathrm{BuC(OLi)CH_2}\cdot\mathrm{TriMEDA}]_2$.[15b]

Our findings are in agreement with the UV/VIS spectrum of fluorenyllithium in ethylenediamine, from which the presence of N–H···C hydrogen bonds had already been concluded;[18] the absorption maximum $\lambda_{max}=368$ nm[19] is shifted hypsochromically compared to that of the solvent-separated ion pair ($Fl^{\ominus}$, THF, $Li^{\oplus}$, −30°C, $\lambda_{max}=373$),[20] and the contact-ion pair ($Fl^{\ominus}$, $Li^{\oplus}$, THF, 25°C) absorbs at 349 nm.[19]

Marcus[21] recently made a distinction between "solvent separated", "contact" and "*solvent shared*" ion pairs. In a solvent-separated ion pair each ion has its own solvent shell, whereas in a solvent-shared (solvent-bridged) ion pair both ions share the solvent molecules. The solid state structure of **1** is thus a model for a solvent-bridged ion pair. In this case in particular it is also to be expected that the N–H bonds participating in H-bonds are additionally polarized by the $Li^{\oplus}$–N interaction and thus better hydrogen bond donors. Solvent-shared ion pairs of the type described here should therefore be of general importance in polar organometallic compounds in solvents which contain N–H or O–H groups.

The position of the bridging hydrogen atom was calculated; an assumed N–H distance of 101 pm gives H···C contacts of 262 and 273 pm. The H···C distances measured by us, however, are not to be compared with these. Namely, if the H atom in an N–H···C hydrogen bond is localized X-ray crystallographically too short a N–H and thus too long a H···C distance is expected to result [16]. The measured N–H distance, e.g. in the N3–H14···Cl hydrogen bond in **1**, is only 87 pm. Review: D. Seebach, *Angew. Chem. 100* (1988) 1685; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1624.

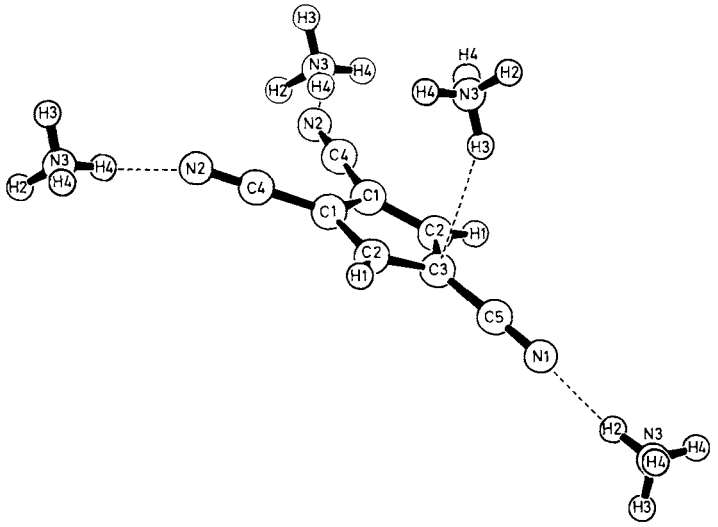
years,[1] very little information is available about their ammonium equivalents (carbanions with ammonium counterions).[2] Herein we report on the crystal structure of ammonium 1,2,4-tricyanocyclopentadienide **1**.[3]



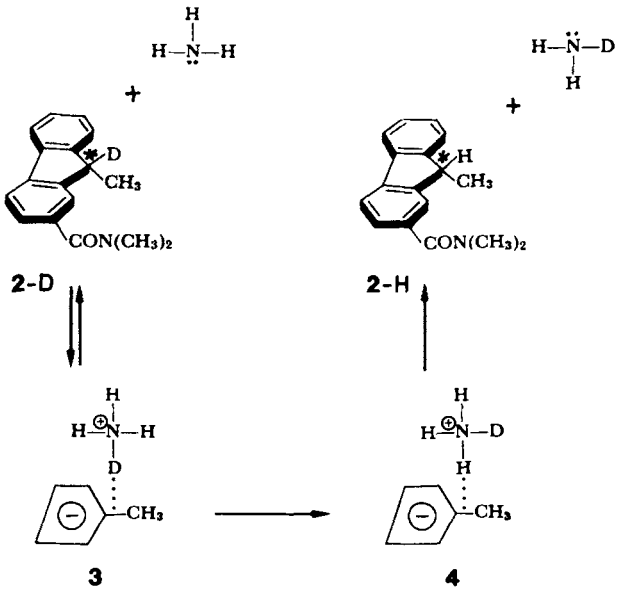


Fig. 1. Section of the crystal structure **5** of ammonium 1,2,4-tricyanocyclopentadienide **1** [8], showing the interactions of a 1,2,4-tricyanocyclopentadienide ion with the four nearest ammonium ions (atoms with the same numbers are symmetry equivalent); cation and anion lie on crystallographic mirror planes, that of the anion being perpendicular to the ring plane. Important bond lengths [pm]: C1-C1′ 142.9(2), C1-C2 139.0(3), C2-C3 141.6(2), C1-C4 142.0(3), C4-N2 115.3(2), C3-C5 142.2(4), C5-N1 114.8(3); hydrogen bonds [pm]: N3···N1 291.2(3), H2···N1 195(4), N3-H2 97(3), N3···N2 295.4(2), H4···N2 206(2), N3-H4 90(2), N3···C3 341.8(3), H3···C3 258(4), N3-H3 98(4); important (bond) angles [°]: ring plane-C1-C4 2.8(2), ring plane-C3-C5 3.6(2), ring plane-C4-N2 4.7(1), ring plane-C5-N1 4.7(2), ring plane-N2-N3 5.45(2), ring plane-N1-N3 5.06(2); hydrogen bond angles [°]: N3-H2···N1 171(3), N3-H4···N2 174(2), N3-H3···C3 144(3).

As shown in Figure 1, each nitrile N-atom is bound via a hydrogen bond to an $NH_4^{\oplus}$ ion, and each $NH_4^{\oplus}$ ion forms three hydrogen bonds to nitrile N-atoms and one hydrogen-bond to a cyclopentadienide C-atom (C3).

The N-H···N hydrogen bonds are almost linear (N3-H2···N1 171(3)°; N3-H4···N2 174(2)°), and the H···N distances are markedly shorter (H2···N1 195(4), H4···N2 206(2) pm) than the sum of the van-der-Waals radii of H and N (275 pm).[9] The N atoms of the $NH_4^{\oplus}$ ions participating in the N-H···N bridges lie "below" the five-membered ring plane[10] (N3 47.4(5), N3′ 52.2(8) pm), so that the nitrile groups are also bent "downwards" (distances to the ring plane: C4 7.0(4), N2 16.4(0.4), C5 9.0(6), N1 18.4(7) pm). The CN bond lengths in the nitrile groups (115.3(2) pm) are almost exactly as long as in acetonitrile (115.7 pm[11]), and are thus consistent with the crystal structure of [(α-cyanobenzyllithium·TMEDA)$_2$·benzene][12] and underscore the chiefly inductive stabilization of a negative charge.

Also remarkable about the structure of **1** is the hydrogen bonding of an $NH_4^{\oplus}$ ion to a C atom of the 1,2,4-tricyanocyclopentadienide (N3-H3···C3).[13] The bond angle is 144(3)°, and the distances N3-H3 and H3···C3 are 98(4) and 258(4) pm, respectively. The H3···C3 distance corresponds to the H···C distances measured for [fluorenyllithium·2ethylenediamine]$_\infty$.[14] The H-bond to C3 is consistent with the results of an MNDO calculation, according to which C3 (−0.196) has a much higher negative charge than C1 (−0.130) and C2 (−0.032).

Cram explained the high degree of D/H exchange with retention compared to the racemization found in the reaction of the optically active fluorene derivative **2**-D with NH_3 (0.3 mol L^{-1} NH_3 in THF at 145°C: $k_{ex}/k_{rac}=148$!) in terms of deuterium (hydrogen) bonding of $NDH_3^{\oplus}$ to the fluorenyl anion (see Scheme 1; similar observations were made with propyl and dipropylamine as bases).[15a]

Scheme 1. D/H exchange with retention (predominant) in the reaction of the optically active **2**-D with NH_3 [15a].

Whereas the N-D···C bridge in **3** leads back to the optically active **2**-D, on rotation of the $NDH_3^{\oplus}$ ion about an N-H axis an N-H···C bridged ion pair **4** is obtained from which **2**-H is formed by proton transfer with retention. Hydrogen bonds also play a decisive role in the isoracemization example: PhEtCDCN in THF/1.5 M *t*BuOH with tripropylamine as base: $k_{ex}/k_{rac}=0.05$!); the tertiary amine takes the $D^{\oplus}$ ion on a "conducted tour" from one side of the molecule via a nitrile N···$DN^{\oplus}Pr_3$ bridge (!) to the other, without $D^{\oplus}$ wandering into the solvent.[15b] The crystal structure of **1** may tentatively be regarded as a suitable solid-state model for both D/H exchange reactions in solution. In the sense of the correlation principle[16] the solid state structure of **1** represents the initial phase of proton transfer from N3 to C3 (or the final phase of the deprotonation of the corresponding CH acid by NH_3), and the observed structure can be assigned to a point on the reaction coordinate.

A New Oxygen Sensor Based on the Thermoelectric Power of Solid Solutions of Nb_2O_5 and Bi_2O_3**

By *A. V. Chadwick, W. Zhou,* and *J. M. Thomas**

There is a growing general demand for sensitive sensors, especially those like some of the biosensors in commercial use that can function at relatively low temperatures. Moreover, in view of its potentially pervasive practical importance, a new, robust material suitable for monitoring the partial pressure of oxygen is of particular interest.

Currently favored oxygen sensors of inorganic type are often based on solid electrolytes, such as alkaline-earth stabilized zirconia (ZrO_2(Ca)) in which anion vacancies abound. An electrochemical concentration cell is used,[1] and this requires a reference pressure of oxygen for its operation. Many other non-stoichiometric mixed oxides are potentially viable oxygen sensors, one example being the stabilized δ-phase of Bi_2O_3, which is said[2] to be a 'thermogalvanic' oxygen gauge. There are, however, other inorganic oxygen sensors, e.g., semiconductors, which do not require a reference system.

During the course of an extensive study[3–6] of the solid-state structural and catalytic chemistry of solid solutions derived from Bi_2O_3, we have discovered what appears to be a powerful new oxygen sensor; and which, because it entails measurement of thermoelectric power, dispenses with the need for a reference pressure of oxygen. It consists of a dilute solid solution (1:60) of Nb_2O_5 in Bi_2O_3, which has the previously recognized structure of the β-phase of Bi_2O_3[7] (Fig. 1).

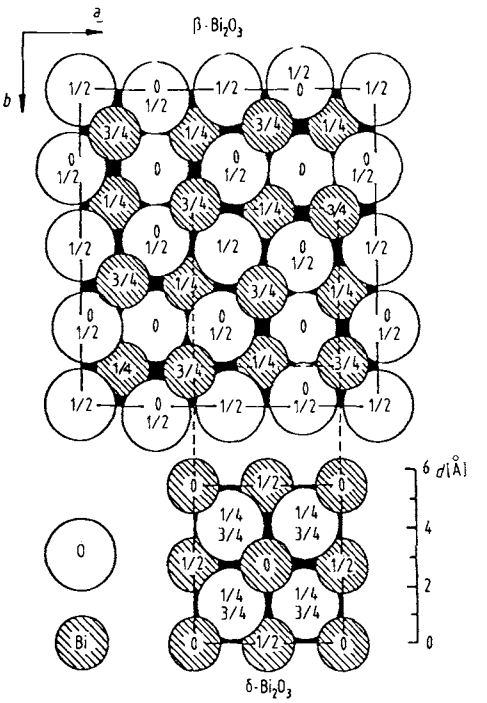

Fig. 1. Schematic representations of the crystal structures of β- (above) and δ-Bi_2O_3 (below). The β-phase may be regarded as a distorted form of the δ-phase which, in turn, may be regarded as the fluorite structure with a quarter of the normal $O^{2\ominus}$ sites left vacant.

For an essentially ionic solid, the thermoelectric power θ, defined as the ratio of the voltage difference ΔV to the temperature difference ΔT between two faces of a sample in a temperature gradient, has two components.[8,9] One is the so-called homogeneous thermoelectric power arising from the thermo-migration of ions, thereby generating a separation of charge; the other, heterogeneous component arises from the temperature dependence of the crystal-electrode contact potential. The usual arrangement[10] employed for recording θ entails the following cell (Scheme 1).

inert metal, O_2 (M = Pt, Au, etc.)	metal oxide (the sensor)	O_2, inert metal (M = Pt, Au, etc.)

Scheme 1.

The comprehensive relationship between θ and the various transport parameters and concentration of point defects is rather complicated.[6] But for a purely anionic conductor there is a simple dependence between θ and the oxygen pressure p_{O_2} [Eq. (a)]

$$\theta \sim \frac{1}{4}\frac{R}{F}\ln p_{O_2} \qquad \text{(a)}$$

where R is the gas constant and F the Faraday constant. The origin of the factor of 1/4 is the equation (b),

$$\frac{1}{2}O_{2,g} + 2e^{\ominus}_{M} \rightleftharpoons O^{2\ominus}_{\text{surface of metal oxide}} \quad (b)$$

from which it can be seen that one electron equates with one quarter of an O_2 molecule.

Previous studies[8,9] of the thermoelectric power of the stabilized δ-phase of Bi_2O_3 in the system $Y_2O_3 \cdot Bi_2O_3$ show that the solid solutions are purely ionic, and plots of θ versus $\ln p_{O_2}$ do indeed have the expected slope $1/4(R/F)$ with θ itself being essentially temperature dependent. We find that the thermoelectric power of the δ-phase of pure Bi_2O_3 exhibits ionic behaviour for $p_{O_2} > 2 \times 10^{-3}$ atm, but not so at lower pressures.

In the present study, samples of $Nb_2O_5 : Bi_2O_3$ (1:60) were prepared as pressed pellets (ca. 1 mm thick, 13 mm diameter) by mixing the pure component oxides and sintering in air at 1023 K for prolonged periods. Gold foil sheets (0.01 mm thick) were pressed onto the faces of a sample and the sandwich so formed was placed between the platinum electrodes of a conductivity cell. The temperature at each face was determined by Pt-Pt/13% Rh thermocouples spot welded to each electrode. The thermocouple EMF at each electrode was monitored with a digital voltmeter and the voltage across the sample was measured with a high impedence electrometer.[10] The pressure of air in the cell could be varied from 10^{-8} to 1 atm. The sign convention used is that θ is positive if the polarity of the hotter electrode is positive. Initial experiments showed that ΔV versus ΔT plots passed through the origin so that rapid measurements of θ could be determined from a single value of ΔT. Additional measurements of conductivity were taken using AC techniques. The sample was annealed in the cell at 1000 K for ca. 12 h to ensure a good electrical contact between it and the electrodes.

The conductivity measurements showed a transition at 900 K, decreasing by two orders of magnitude with decreasing temperature, which indicates the change from high temperature δ-phase to low temperature β-phase. The transition was very slow when the sample was held a few degrees above or below 900 K and it took several hours for the conductivity to reach a constant value.

The plot of θ versus $\ln p_{air}$ for a sample in the δ-phase at 1033 K (Fig. 2) is very similar to that observed for pure Bi_2O_3 showing a slope of $1/4(R/F)$ at high p_{air}, suggesting predominantly ionic conduction. The plot reverses slope at low p_{air}. With the β-phase, however, the results were very unusual. A typical plot for θ versus in $\ln p_{air}$ is shown in Figure 2 for a sample at 768 K. The slope is $4.7(R/F)$ and the results were reversible and characterized by a rapid response (the voltage settles after a few seconds on cycling p_{air}). Similar results were observed down to 573 K.

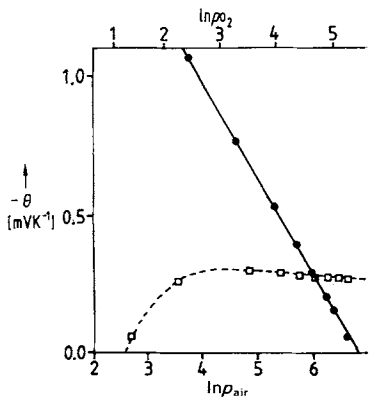

Fig. 2. The dependence of the thermoelectric power θ on air pressure p [torr] for $Nb_2O_5 : Bi_2O_3$ (1:60). Empty squares: δ-phase at 1033 K; filled circles: β-phase at 768 K.

We do not know the origin of the observed dependence of θ on $\ln p_{air}$ in the β-phase. The exponent of 4.7 is too large to be explained on the basis of any simple reaction involving gaseous O_2 and defects. The phenomenon is presumably associated with the generation of electronic carriers either within the sample or at the sample-electrode interfaces.

Although the origin of the observations for the β-phase is at present unclear, the magnitude, speed and reproducibility of the changes in thermoelectric power with varying p_{air} points to potential application in oxygen monitoring. The enhanced response of $Nb_2O_5 : Bi_2O_3$ solid solutions make them attractive materials as oxygen sensors, and worthy of future investigation.

Investigation of the Tautomerism of ^{15}N-Labeled Hydroporphyrins by Dynamic NMR Spectroscopy**

By *Martin Schlabach, Helmut Rumpel,* and *Hans-Heinrich Limbach**

The problem of the mechanism of the thermal- and light-induced tautomerism of porphyrin, P (Fig. 1, top left) and its derivatives is of current interest.[1-10] Information about the different reaction pathways shown in Figure 1 (top left) has mainly been obtained from dynamic NMR studies of kinetic HH/HD/DD isotope effects[4,5] and of solid state effects,[8] as well as from theoretical studies.[10] Unfortunately, it has not yet been possible so far to significantly increase or decrease the reaction barrier by variation of the chemical structure,[2,5,7] a technique which

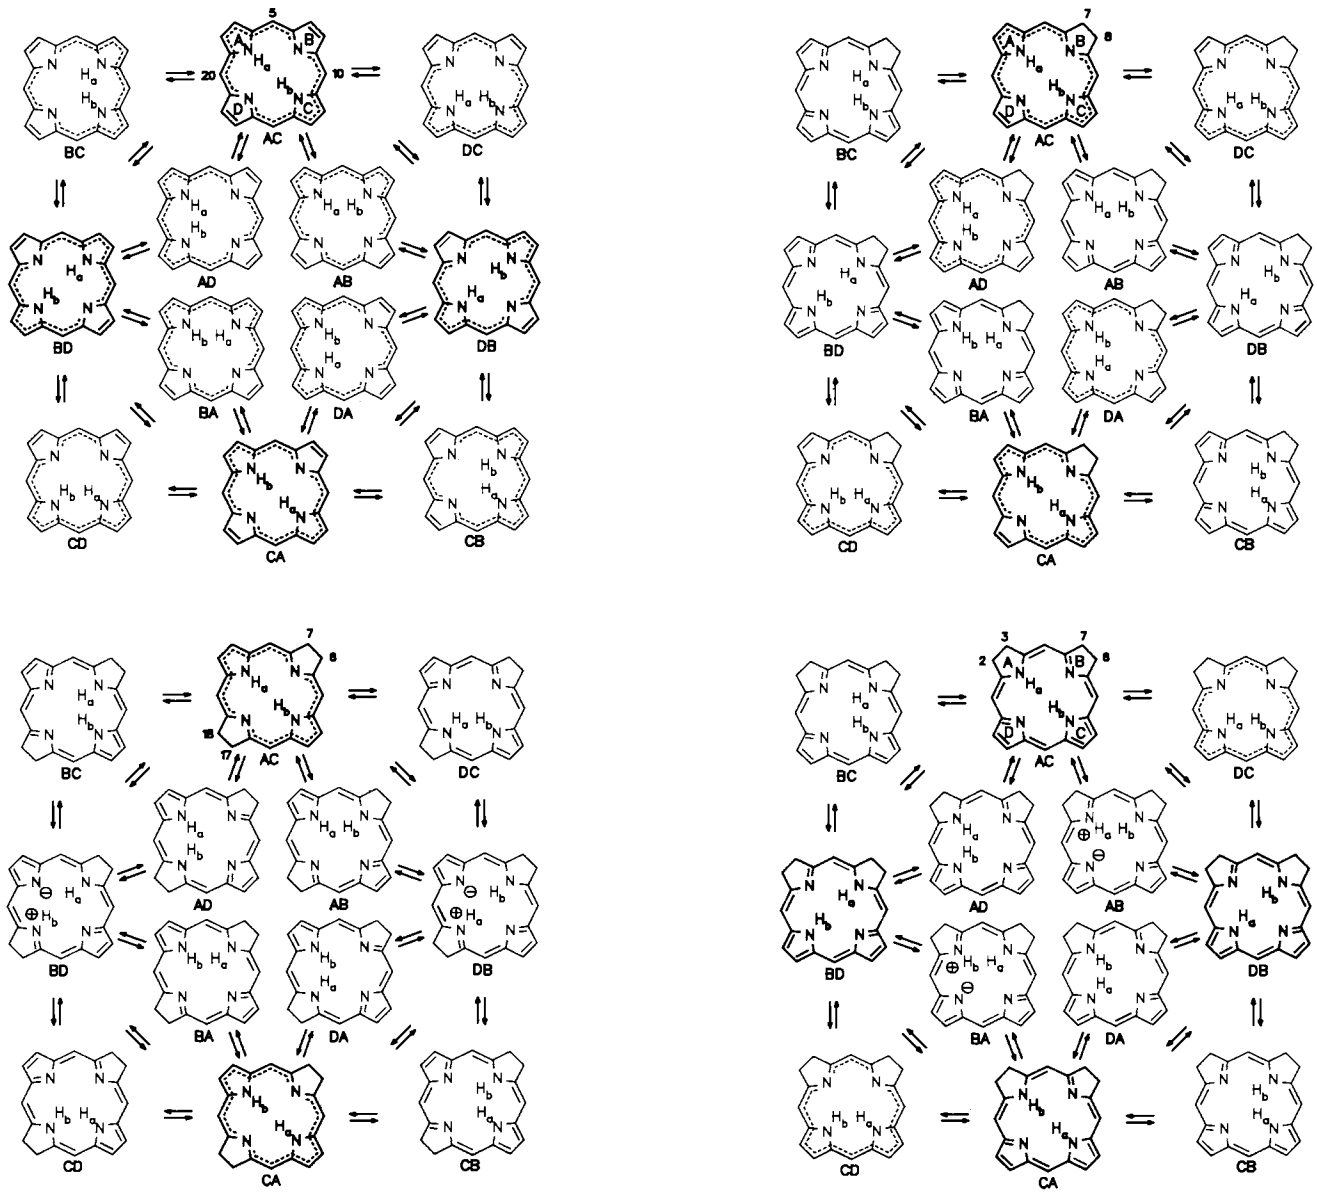

Fig. 1. Proton transfer pathways in the parent compounds porphyrin (formerly porphine [27]) (top left), chlorin (top right), bacteriochlorin (bottom left), and isobacteriochlorin (bottom right). The different pyrrole rings are labeled clockwise with the capital letters A to D. The nitrogen atoms in these rings are labeled as N-21, N-22, N-23 and N-24. The various tautomers are represented here, in a way similar to that proposed in [18], by the pairs XY, with X, Y = A–D. X refers to the pyrrole ring on which the inner proton H_a is located and Y characterizes the location of H_b. All tautomers XY and YX are degenerate with exception of the case where one proton is substituted by deuterium. Tautomeric structures which have been spectroscopically assigned are boldfaced. The dashed lines indicate, as usual, "aromatic" 18 π electron delocalization pathways [3, 7]. Only one zwitterionic structure is shown for the tautomers BD and DB and for AB and BA in Figures 1c and 1d.

usually provides interesting insights into reaction mechanisms. We show here that this goal can be achieved by specific hydrogenation of the pyrrole rings of porphyrins, which leads to the biologically important hydroporphyrins chlorin, C (Fig. 1, top right), bacteriochlorin, Bc (Fig. 1, bottom left) and isobacteriochlorin, iBc (Fig. 1, bottom right).[11–22] Although some evidence for tautomerism[1a] and phototautomerism[21] of chlorins, and for phototautomerism of isobacteriochlorins[22] has been reported, the proton transfer processes occurring in these compounds have not yet been characterized. The different reaction dynamics of hydroporphyrins observed here can be explained by the gain or loss of aromatic resonance energy during the different reaction steps shown in Figures 1. In particular, we have performed ^{1}H NMR line shape analyses of the ^{15}N-labeled hydroporphyrins TPC,[23] TPBc,[24] and TPiBc[25] dissolved in organic solvents.

The ^{1}H NMR spectra of TPC in $C_2D_2Cl_4$ contain only one signal at $\delta \approx -1.5$ ppm for the two inner protons H_a and H_b. This δ-value signifies that TPC experiences an aromatic, porphyrin-type ring current.[28] As shown in Figure 2, the signal is split at room temperature into a ^{1}H-^{15}N doublet. These results are consistent only with the presence of the two degenerate tautomers AC and CA which exchange slowly at room temperature within the NMR timescale. For the case of fast exchange, the signal should exhibit a triplet structure as found for other ^{15}NH$\cdots{}^{15}$N $\rightleftharpoons$ ^{15}N$\cdots$H^{15}N proton transfer systems.[4, 29] In fact, a doublet→triplet interconversion is observed at elevated temperatures (Fig. 2, top).[30] The rate constants were obtained by line shape analysis [Eq. (a)].[31]

$$k_{AC\rightarrow CA} \cong 10^{11.8} \exp(-61.3\ \mathrm{kJ\ mol^{-1}}/RT) \qquad \text{(a)}$$

Thus, the energy of activation of the tautomerism increases to about 20 kJ mol^{-1} upon hydrogenation of one

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0101-0077 $ 02.50/0

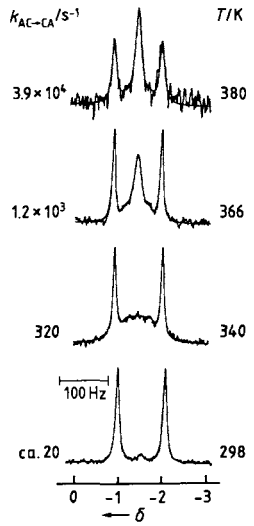

Fig. 2. Superposed experimental and simulated 90.02 MHz ^{1}H NMR spectra of 95% ^{15}N-enriched TPC [23], dissolved in $C_2D_2Cl_4$, as a function of temperature T. 4 μs $\pi/2$ pulses, 2 kHz spectral width, 2.1 s repetition time, 2000 scans on average.

pyrrole ring of porphyrin, an effect which can be explained by the loss of the aromatic resonance energy during the course of the reaction AC→CA.

The ^{1}H-^{15}N doublet of the inner protons of TPBc dissolved in [D_8]toluene appears at $\delta \approx -1.25$ ppm. Thus, this compound also experiences a porphyrin-type ring current. This finding confirms the model of the aromatic electron delocalization pathways[3,7] indicated in Figure 1 by dashed lines. In contrast to TPC, however, the TPBc ^{1}H-^{15}N doublet does not show any sign of conversion into a triplet even at 140°C. Thus, the process AC→CA must be much slower in TPBc than in TPC. This is understandable because not only is aromatic resonance energy lost during the interconversion AC→CA (Fig. 1, bottom left), there is also the additional energy required for charge separation, when the formally zwitterionic intermediates BD and DB are formed.

The greatest surprise is, however, provided by the temperature dependent signals of the inner protons of TPiBc, shown in Figure 3. At −100°C, two exchange broadened

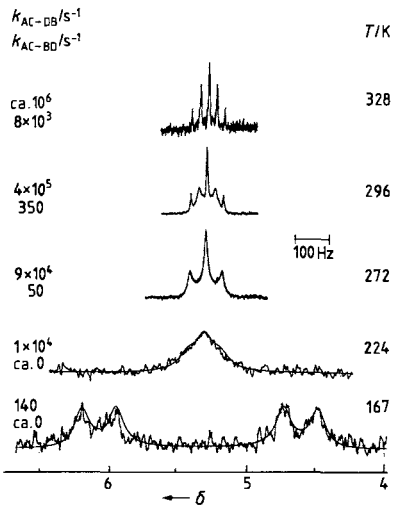

Fig. 3. Superposed experimental and simulated 400.12MHz ^{1}H NMR spectra of 95% ^{15}N-enriched TPiBc [25], dissolved in [D_8]toluene, as a function of temperature T. 3 μs $\pi/2$ pulses, 7 kHz spectral width, 2.1 s repetition time, 8000 scans on average.

^{1}H-^{15}N doublets[32] of equal intensity are observed at $\delta = 4.6$ and 6.1. This low-field shift of the inner proton signals indicates that the porphyrin-type ring current is largely suppressed in TPiBc.[28] The observation that H_a and H_b are inequivalent[33] can only be explained by the presence of the degenerate non-aromatic *trans*-forms AC, DB, CA and BD (Fig. 1, bottom left). As the temperature is raised, however, coalescence of the H_a and H_b doublets into a single exchange-broadened triplet is observed (Fig. 3, middle). These signal changes are expected for the processes AC→DB (and CA→BD). The processes AC→BD (and CA→DB) would not render H_a and H_b equivalent but would lead to two ^{1}H-^{15}N triplets at $\delta = 4.6$ and 6.1. It is, however, surprising that the latter processes are not completely suppressed but lead at higher temperatures to a triplet→quintet interconversion of the ^{1}H-^{15}N signal (Fig. 3, top). The rate constants were obtained by line shape analysis [Eqs. (b) and (c)].[34]

$$k_{AC\rightarrow DB} \cong 10^{10.3} \exp(-27\,\mathrm{kJ\,mol^{-1}}/RT) \quad (b)$$

$$k_{AC\rightarrow BD} \cong 10^{11.1} \exp(-49.2\,\mathrm{kJ\,mol^{-1}}/RT) \quad (c)$$

^{1}H NMR spectra of deuterated and partly deuterated TPiBc showed that both processes are affected by major kinetic HH/HD/DD isotope effects. In addition, preliminary experiments using the ^{15}N CP/MAS NMR technique[8a-f] indicate that the process AC→DB also takes place in the solid state. These results establish TPiBc as the first intramolecular proton transfer system characterized by two symmetric double minimum potentials of unequal height.

The finding that in TPiBc the process AC→DB is much faster than the process AC→BD could perhaps be explained in terms of weak hydrogen bonds between the rings A and D and between C and B although there is no evidence at present for such phenomena in this class of compounds.[12,15,16] The assumption of a step-wise rather than a concerted reaction mechanism provides, however, a more plausible explanation of the experimental results. According to Figure 1 (bottom right), one expects the process AC→DC in TPiBc to be assisted by a considerable gain of resonance energy in the two transition states separating the aromatic *cis*-intermediate DC from the non-aromatic *trans*-tautomers AC and DB. Such a stabilization is neither expected for pathway AC→BD nor for the concerted proton transfer steps. Further experimental and theoretical studies are, however, necessary in order to confirm the first experimental indications for a stepwise reaction mechanism for the tautomerism of porphyrins obtained in this work.

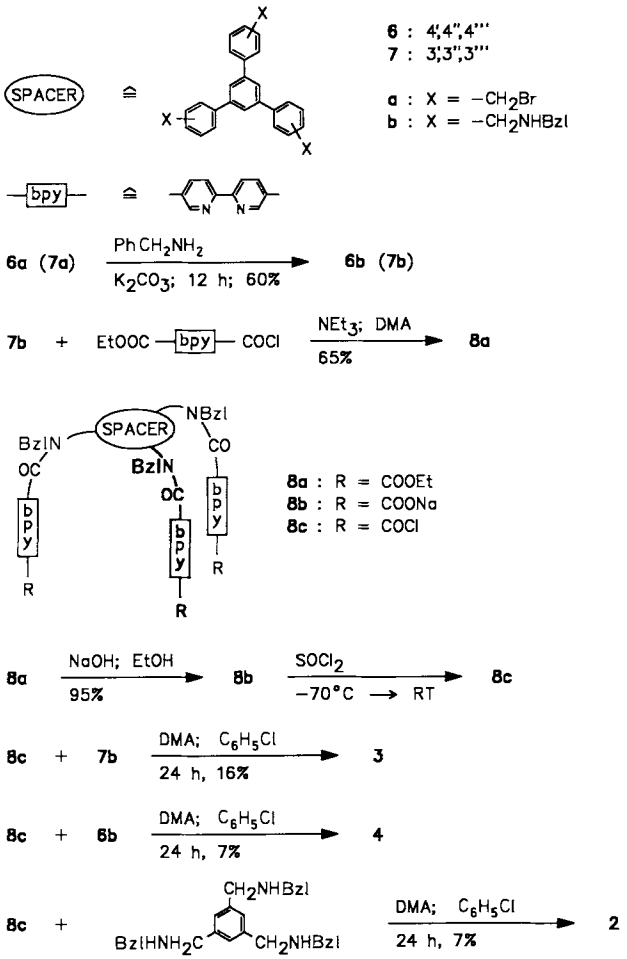
[30] Intermolecular proton transfer would lead to breakdown of the ^{1}H-^{15}N splitting pattern [29].
[31] The activation parameters were obtained from a total of 16 spectra of TPC in $C_2D_2Cl_4$ and [D_8]toluene in the temperature range 298 to 406 K; no solvent effects were observed.
[32] In monodeuterated TPiBc, these signals are sharp at -100°C due to a kinetic HH/HD isotope effect which indicates that the broadening in the bottom spectrum of Figure 3 stems from proton transfer and not from slow rotational diffusion [6].
[33] We tentatively assign the signal at $\delta = 4.6$ to H-21 and the signal at $\delta = 6.1$ to H-23. For the atomic numbering scheme see legend to Figure 1.
[34] $k_{AC \rightarrow DB}$ was obtained from 7 spectra between 170 and 280 K, $k_{AC \rightarrow BD}$ from 4 spectra between 270 and 320 K. Note that the line shape of the outer proton signals, which are not shown here, is sensitive only to the process AC→DB and not to the process AC→BD.

Selective Molecular Recognition of Trihydroxybenzenes**

By *Frank Ebmeyer* and *Fritz Vögtle**



The complexation of organic molecules in nonaqueous media is currently being intensively investigated.[1] We report here on the synthesis and complexation properties of the macrobicyclic compounds **2**–**4**,[2] which exhibit a remarkable selectivity for phenolic substrates, in particular trihydroxybenzenes. Although the bipyridine ligand **1**, synthesized in 1986, strongly complexes small metal cations,[3] it does not bind organic molecules. The successive expansion of the host cavity with the C_3-symmetric spacers introduced by us[4] leads to the new complex-forming molecules **2**–**4** having larger cavities.

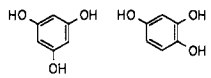
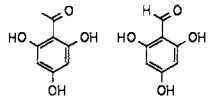
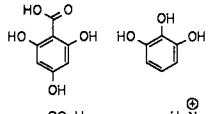
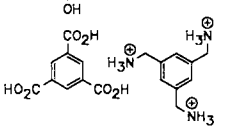
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie and by Bayer AG, Leverkusen, BASF AG, Ludwigshafen, Hoechst AG, Frankfurt, and Degussa AG, Hanau (donation of chemicals). *F. E.* thanks the Stiftung Volkswagenwerk for a Kekulé Stipendium. We thank Dr. *J. Peter-Katalinić* (Physiologisch-chemisches Institut der Universität Bonn) and Finnigan/MAT (Bremen) for FAB mass spectra, Dr. *G. Eckhart* and *C. Schmidt* for EI mass spectra and NMR spectra, respectively, Dipl.-Chem. *Ch. Seel* for the drawings, and Mrs. *A. Bail* for assistance.

Attempted transfer of the reaction conditions used in the cyclization to **1**[3] to the expanded tris(bipyridine) compound **5** (containing the 4′,4″,4‴-triphenylbenzene spacer) was unsuccessful. Only upon employing the *meta*-substituted spacer—under modified conditions[5]—was the large-cavity compound **3** obtained in 16% yield.[6] The macrobicyclic compounds **2** and **4** with conical cavities[8] were obtained similarly, in yields of 7% each (Scheme 1).









Scheme 1. Bzl = benzyl, DMA = dimethylacetamide.

The new ligands, hexadentate in the cavity,[9] are tailor-made for incorporating complementary trifunctional guest molecules. However, attempts to form inclusion complexes with tricarboxylic acids such as 1,3,5-benzenetricarboxylic acid or the tris(ammonium) salt of 1,3,5-tris(aminomethyl)benzene as guests (dichloromethane as solvent) were unsuccessful. On the other hand, several trihydroxybenzenes were complexed. The guest substances, which are insoluble in dichloromethane, dissolved after addition of the host compounds **2**–**4**; the ^{1}H NMR spectra of the filtered solutions display signals of host *and* guest molecules. The simple pattern of the guest signals—not split in the 400 MHz spectrum—indicates a symmetrical complexation.[10]

Integration of the NMR absorptions reveals a 1 : 1 stoichiometry of the host–guest complexes, even when starting with nonstoichiometric ratios of host and guest molecules. A 1 : 3 stoichiometry was found for the guests picric acid (2,4,6-trinitrophenol) and nitrophloroglucinol (1,3,5-trihydroxynitrobenzene), which do not fit into the cavities of **2**–**4**. The complexation of the phenolic guests is selective. As shown in Table 1, only certain trihydroxybenzenes are complexed, but not structurally related compounds or the isomer pyrogallol (1,2,3-trihydroxybenzene). These findings reflect a marked guest selectivity found earlier in other studies.[11]

Table 1. Host/guest selectivities (+, complexation; −, no complexation). Host concentrations ca. 2×10^{-3} mol L^{-1}; solvent CD_2Cl_2, 25 °C.

Guest	2	3	4
	+	+	−
	+	+	+
	−	−	−
	−	−	−

Selectivity is also observed upon varying the host compounds: whereas neither the host **1** nor its open-chain precursor **8a** complexes phloroglucinol and 1,2,4-trihydroxybenzene, these compounds are indeed complexed by **2** and **3** (but not by the isomer **4**). This finding supports the notion of hydrogen bonding between host and guest in a suitably sized cavity. In agreement with this, the hosts **2**, **3**, and **4** also discriminate between phloroglucinol derivatives: even a small structural change such as the introduction of a methyl or a carboxyl group results in loss of complexation.

A gravimetric method[12] revealed an appreciable association constant of 11 000 ± 2000 (in dichloromethane) for

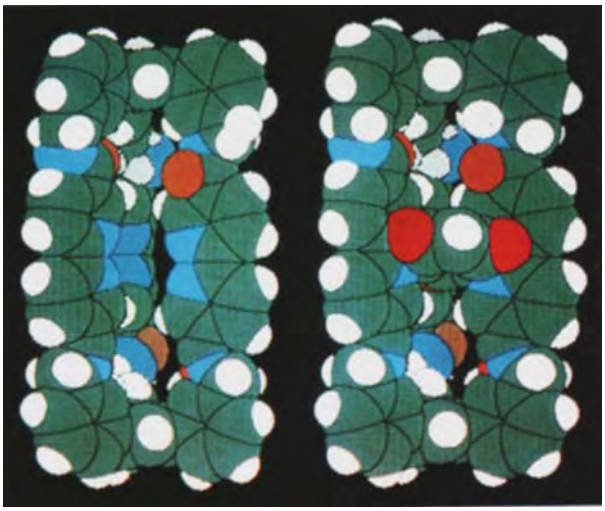


Fig. 1. Left: Host molecule **3** with empty cavity. Right: Space-filling model of the phloroglucinol complex of **3**; the phloroglucinol guest molecule lies perpendicular to the plane of the page between the three bipyridine units of the host **3** [16].

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0101-0080 $ 02.50/0

the complex of **3** with phloroglucinol; this high value can be explained by the formation of multiple hydrogen bonds between host and guest in the cavity. The exact fitting of the guest into the interior of the "receptor molecules" **2–4** is supported not only by the marked host/guest selectivities and the high association constants, but also by the fact that irradiation of the resonance of the bipyridine protons results in a small but significant NOE effect (−0.5%) for the guest protons.

Compounds **1–4** illustrate that the cavity of host compounds can be changed selectively with respect to size and shape by variation of the spacer, allowing the direct synthesis of selective complex-forming molecules.[13] The conical shape of the cavity, the high selectivity in the molecular recognition of trihydroxybenzenes, and the stabilization of phenolic guests toward oxidants[14] have hardly been achieved so far in a synthetic "receptor molecule".[15]

A Silicogermanate with a Si : Ge Ratio ≥ 2 —an MFI Zeolite of Novel Composition**

By *Zelimir Gabelica** and *Jean-Louis Guth*

The pore volume, acidity and sorptive properties of zeolites can be modified and controlled by substitution of the framework atoms. We report herein results dealing with the substitution of Si by Ge in pure Si-bearing zeolites. A series of crystalline, microporous solids containing Si and Ge in an MFI type tetrahedral framework have been synthesized under hydrothermal conditions in the presence of $Pr_4N^{\oplus}$ ions as structure directing agents, over the whole pH range in the absence of alkali metal or ammonium cations. The unit cell composition of these solids, after removal of included organics, is $Si_{96-x}Ge_xO_{192}$, where $x \leq 34 \pm 4$. It is concluded that such a framework is built up from the 5-1 secondary building units (SBU) in which at least two tetrahedral centers are occupied by Ge. Such a high degree of substitution of Si by another tetravalent element has, until now, not been observed for an MFI type structure. Our method opens new pathways for preparing other highly substituted zeolites.

Both amorphous (glasses) and crystalline solid solutions are known in the binary system SiO_2–GeO_2.[1-2] In contrast to the open zeolitic structures, these phases, which were obtained at high temperature (>700 °C), are not microporous. The frameworks of the natural zeolites[3] and of most of the synthetic molecular sieves[4] contain Si and Al atoms in the tetrahedral positions. Framework substitution by other tetravalent and trivalent elements is also well-known.[4] Recently, a series of zeolite structures containing only Si were reported.[5,6] In the case of Si-MFI, the incorporation of $Ti^{4\oplus}$ in the framework has been reported but the degree of substitution was very low (ca. 2.5 wt.%).[7] Substitution of Si by Ge was, until now, not reported; clearly, this could only be achieved when a trivalent element (e.g., $Al^{3\oplus}$) was present in the framework.

The novel (Si,Ge)-MFI zeolites are obtained by heating an aqueous solution of the Si and Ge reactants at 60–220 °C in the presence of a structure directing agent such as $Pr_4N^{\oplus}$. The crystallization time depends markedly on temperature, pH and the presence of fluoride ions. Typically, a mixture having the molar composition $GeCl_4$–SiO_2–HF–$0.5\,Pr_4NBr$–$8\,CH_3NH_2$–$35\,H_2O$ is heated in the presence of MFI seeds for 15 h at 180 °C in PTFE coated autoclaves. The resulting solid, as identified by X-ray diffraction, has an MFI type structure. The unit cell composition, after calcination in air at 550 °C for 10 h, is $Si_{63}Ge_{33}O_{192}$, as determined by atomic absorption and spot EDX analysis of individual crystallites.[8] In neutral or acidic media, other oxides, which contain most of the Ge, coprecipitate with the

MFI zeolite. In very basic media, the formation of soluble germanates also limits the extent of Ge incorporation in the zeolite. Moreover, if the basic pH value is adjusted by alkali metal or ammonium hydroxides, the corresponding germanates precipitate together with MFI crystallites, whose frameworks consist mostly of Si. These problems can be avoided by adjusting the pH to about 10 using short chain alkyl amines such as CH_3NH_2. Under these conditions, pure (Si,Ge)-MFI crystals can be synthesized in good yield with a wide range of compositions. A further addition of fluoride ions, which are known to advantageously reduce the mobilizing effect of $OH^{\ominus}$ ions,[9] reduces the crystallization time considerably. The crystal size of the silicogermanate zeolite increases with decreasing pH, provided that $F^{\ominus}$ ions are present. At pH 10–11, Si-MFI precipitates in Ge-free media, as tiny elongated platelets ($10 \times 3 \times 0.5$ μm), whereas the habitus of the Ge-rich phases is nearly isometric ($6 \times 4 \times 4$ μm for $x = 33$).

The freshly prepared silicogermanate crystals are orthorhombic but become monoclinic at room temperature (±20°C), provided that the included organic molecules are first removed by heating to 500°C in air. The monoclinic-orthorhombic transition temperature increases linearly with increasing Ge content (Fig. 1). For conventional

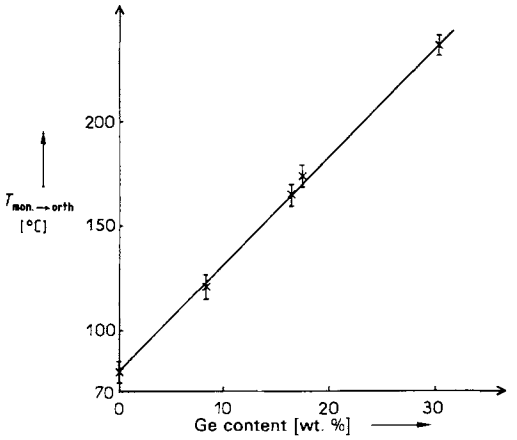

Fig. 1. Dependence of the orthorhombic-monoclinic phase transition temperature upon Ge content for calcined MFI samples. The samples were prepared at pH 10–11. Data were collected by temperature-dependent X-ray structure analysis.

MFI zeolites in which Si is substituted by a trivalent element (Al, B, ...), the opposite is observed, i.e., the transition temperature decreases with increasing substitution.[10] The lattice constants and the unit cell volume also increase with increasing substitution (Table 1).

Table 1. Dependence of the lattice constants and the unit cell volume upon the Ge content x for the monoclinic phase.

x [wt. %]	a [Å]	b [Å]	c [Å]	β [°]	V [Å^3]
0	13.379	20.098	19.878	90.58	5345
17.1	13.428	20.137	19.939	90.58	5391
32.8	13.455	20.180	19.968	90.51	5428

Differential thermal analysis (DTA) has been used to detect organic templates in MFI frameworks.[11,12] Using DTA, we were able to detect $Pr_4N^{\oplus}$ ions, whose decomposition temperature in the MFI framework is different from that of $Pr_4N^{\oplus}F^{\ominus}$ ion pairs.[12] Since they are not expected to occur in regular TO_2 frameworks containing only tetravalent elements, their presence indicates the formation of framework defects of the type $T\text{-}O^{\ominus}$. The stronger acidic character of Ge, compared to Si, reduces its tendency to (poly)condense into regular Ge-O-T framework bridges, especially in basic media. Upon thermal decomposition of the $Pr_4N^{\oplus}$ ions, the formation of an increasing number of T-O-T bridges results in a marked decrease in the number of $T\text{-}O^{\ominus}$ defects. This phenomenon was studied by comparing the high resolution solid-state MAS ^{29}Si NMR spectra of the freshly prepared and calcined Si-MFI and (Si,Ge)-MFI phases (Fig. 2). As expected, the calcined

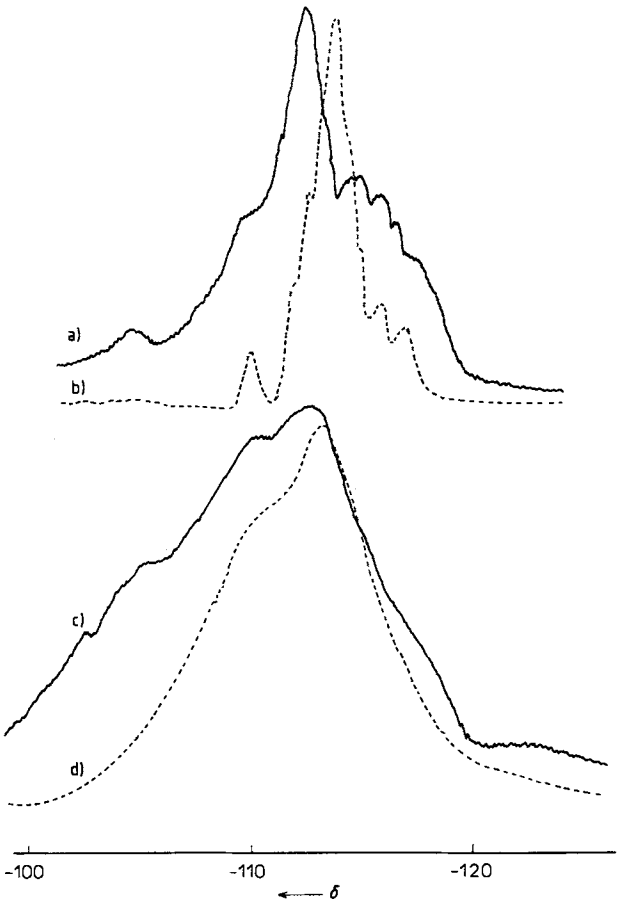

Fig. 2. High resolution solid-state MAS ^{29}Si NMR spectra (Bruker MSL 300 MHz spectrometer) a) untreated Si-MFI; b) its calcined form; c) untreated (Si,Ge)-MFI (Si : Ge ≈ 2); d) its calcined form.

phases show better resolved spectra. The signals are also narrower for the pure Si-MFI than for the silicogermanate zeolite, especially in the high field region. When Ge is present in T sites, the increasing number of Si(nGe) configurations results in a spectral broadening in the low field region (Ge is less electronegative than Si). The presence of defect groups, which are characterized by an NMR resonance at $\delta \approx -105$[13] was not clearly detected. Nevertheless, the shoulder observed between $\delta = -108$ and -110 for both freshly prepared and calcined (Si,Ge) phases suggests the presence of Si(nGe) framework configurations in these zeolites.

Our investigations allow germanium to be added to the already wide range of elements which can occupy T sites in MFI frameworks. The unexpectedly high Ge contents exceed the degrees of Si substitution achieved up to now. The upper limit of the Si:Ge ratio of about 2 can be understood on the basis of the assumption that the formation of Ge-O-Ge linkages is avoided; they have also not been detected in solution.[14] Consequently, a pure Ge-MFI zeolite is expected to be difficult to synthesize.

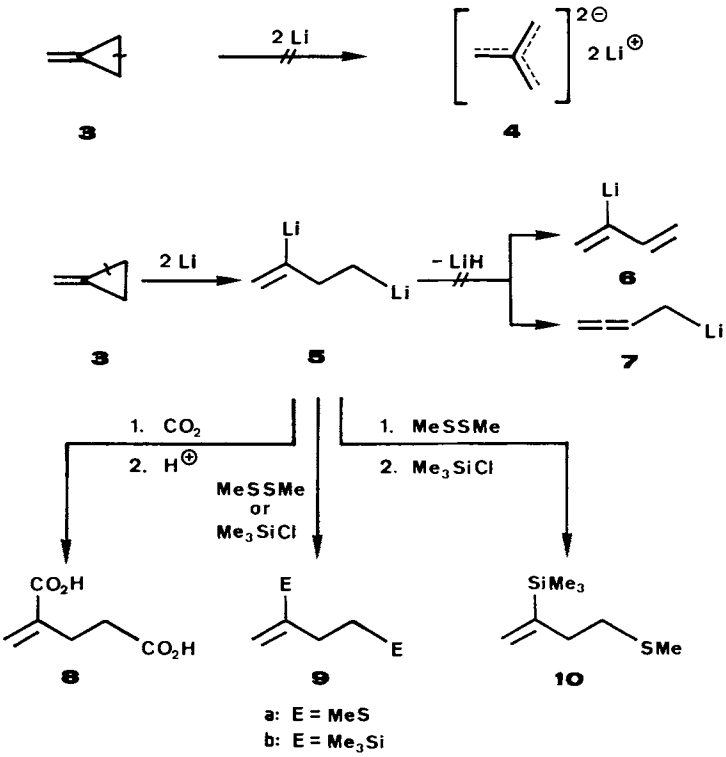
Stable Open-Chain 1,3-Dilithium Compounds by Reaction of Methylenecyclopropanes with Lithium Powder: 2,4-Dilithio-1-butenes**

By *Adalbert Maercker** and *Klaus-Dieter Klein*

Dedicated to Professor Gerhard Hesse on the occasion of his 80th birthday

Polylithium organic compounds[1] can be prepared by reductive cleavage of a cyclopropane σ bond with lithium, provided that a resonance-stabilized system is formed; for example, the dilithium "semibullvalenediide" **2** is obtained by treatment of semibullvalene **1** with lithium in



1 **2**

THF or dimethyl ether at −78°C.[2] The homologous barbaralane reacts analogously, that is, again with formation of a bis(allyllithium) compound.[3]

[**] Polylithium Organic Compounds, Part 9. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.—Part 8: A. Maercker, F. Brauers, W. Brieden, M. Jung, H. D. Lutz, *Angew. Chem. 100* (1988) 413; *Angew. Chem. Int. Ed. Engl. 27* (1988) 404.

We have now found that methylenecyclopropane **3** also reacts smoothly with lithium powder, both neat at its boiling point (10°C, 1 h) and in diethyl ether at room temperature (1/2 h). However, cleavage of the weakest cyclopropane bond to form the extremely stable, Y-delocalized trimethylenemethane dianion **4**[4] does not occur. Instead, the 2,4-dilithio-1-butene **5**, combining both vinyl and homoallyl character, is the sole product (Scheme 1).

Scheme 1.

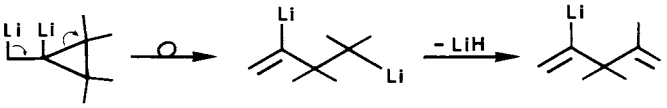
Derivatization of **5** with carbon dioxide, dimethyl disulfide, and chlorotrimethylsilane leads to formation of the expected products **8** (50%), **9a** (53%), and **9b** (67%), respectively, which were characterized by NMR spectroscopy and mass spectrometry (Table 1); dimethyl sulfate affords 2-methyl-1-pentene in 68% yield. Since the two anionic centers of **5** differ in their reactivity, the reaction can also be carried out stepwise with two different electrophiles, for example, first with one equivalent of dimethyl disulfide and then with chlorotrimethylsilane. The formation of **10** (Scheme 1, Table 1) in 25% yield proves that—as expected—the homoallyl position is more reactive than the vinyl position. This is further supported by the tandem reaction with methanol and chlorotrimethylsilane, which gives mainly 2-trimethylsilyl-1-butene[7] (33%). However, the presence of traces of 2-lithio-1-butene **11** always has to be taken into consideration, since still unreacted **3** is in part metalated by **5**.

Compound **5** is remarkably stable toward diethyl ether as solvent, a property already observed for 1,3-dilithiopropane[8] and, as in that case, presumably due to a doubly bridged structure.[9] However, in contrast to 1,3-dilithiopropane,[8] which rapidly eliminates lithium hydride (half-life period of 1 h at room temperature), **5** does not display such reaction behavior at all—neither 2-lithio-1,3-butadiene **6** nor its tautomer **7** (Scheme 1) could be detected. It was therefore possible to carry out detailed NMR studies on the orange-red solution of **5** (Table 1). However, no conclusions could be drawn regarding association and bridging, since the $^{6}Li,^{13}C$ coupling constants could not be derived from the spectra. The appearance of several signals in the ^{6}Li NMR spectrum recorded between -20 and $-80\,^{\circ}C$ is not compelling evidence against a doubly bridged structure, but might also indicate the simultaneous presence of different aggregates. Unfortunately, the crystals obtained so far have not been suitable for an X-ray structure analysis.

The reaction of 2,2-dimethylmethylenecyclopropane **13** with lithium powder under the same conditions, yielding **17**, provided clues as to the mechanism of cleavage of **3** with lithium (Scheme 2). The formation of **17** indicates that, before ring-opening occurs to give **16**, the initially formed radical anion **14** reacts with a second lithium atom to give the 1-lithiomethylcyclopropyllithium **15**. As a cyclopropylcarbinyllithium derivative, **15** then undergoes the known[10] anionic rearrangement with ring-opening to form the primary homoallyllithium derivative **17**.[11]



Scheme 2.

Experimental Procedure

Approximately 10% of a solution of **3** (8.0 g, 0.15 mol) [12] in 50 mL of diethyl ether was added dropwise, initially at room temperature, to a suspension of lithium powder (2.5 g, 0.36 mol, 2% sodium) in 50 mL of diethyl ether, the reaction being carried out under argon. After the reaction had begun—the reaction solution turned yellow and began to reflux—the remaining solution of **3** was added at ice-bath temperature so as to avoid partial evaporation of **3** (b.p. 10°C). The reaction mixture was then stirred for 1/2 h at room temperature and the excess lithium was filtered off under inert gas. Yield: 70–75% **5**; very stable (half-life period of decomposition, 27 d at room temperature).

[11] The corresponding tetramethyl derivative of **3**, on the other hand, leads only to a monolithium compound, since, after ring-opening, the initially formed product eliminated lithium hydride. The reason for this secondary reaction might be the formation of a tertiary homoallyllithium center occurring for the first time:

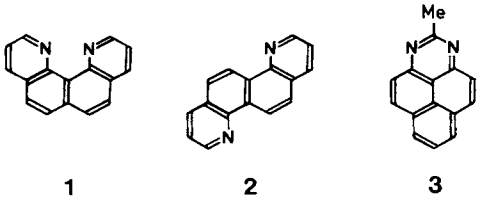
Structures of Quino[7,8-*h*]quinoline and Quino[8,7-*h*]quinoline**



By *Claus Krieger, Ian Newsom, Michael A. Zirnstein,* and *Heinz A. Staab**

Recently, we described a new type of "proton sponge", quino[7,8-*h*]quinoline **1**.[2] The two nitrogen atoms of **1** are mutually oriented as in 1,8-bis(dimethylamino)naphthalene ("proton sponge"); in contrast to the earlier "proton sponges", however, **1** lacks the hydrophobic shielding of the basic centers and thus of the hydrogen bond in the *mono*protonated cation, which was responsible for the low

[**] New "Proton Sponges", Part 8.—Part 7: H. A. Staab, M. Höne, C. Krieger, *Tetrahedron Lett. 29* (1988) 1905.

rate of proton transfer observed for the "proton sponges" known so far. Accordingly, **1**, whose basicity constant is eight powers of ten larger than that of quinoline, is also a kinetically active base.[3]

1 **2** **3**

The first synthesis of **1**, reported in 1950, began with the nitration of benzo[*h*]quinoline, whereby the authors thought they had obtained 10-nitrobenzo[*h*]quinoline; the corresponding amine was then converted by Skraup reaction into a compound which they held to be **1**.[4] In fact, the nitration afforded a mixture of products, from which the desired 10-nitro compound was not obtained but probably instead the 7-nitro compound. Therefore, the compound formed in the Skraup reaction was presumably a structural isomer of **1**, the quino[8,7-*h*]quinoline **2**.[5] In 1967, *Buu-Hoï* et al.[6] reported the synthesis of **1** from 1,8-bis(acetamido)naphthalene by double Skraup reaction. Upon repetition of this procedure, we found that neither MS nor NMR data were in agreement with the structure **1**, but instead were in complete agreement with the suggestion of *Sauvage* et al.,[7] made at the time of our studies (1985), that this reaction does not yield **1** but, rather unexpectedly, 2-methyl-1,3-diazapyrene **3**. In addition, however, we obtained a further compound (m.p. 219–221 °C) in this reaction in small yield; its elemental analysis, mass spectrum [*m/z* 230 (100%, $M^{\oplus}$), 202, 115 (5, $M^{2\oplus}$)] and ^{1}H NMR spectrum [$\delta = 7.60$ (dd, 2H; 3-H), 8.05 (d, 2H; 5-H), 8.35 (dd, 2H; 4-H), 9.10 (dd, 2H; 2-H), 9.45 (d, 2H; 6-H); $CDCl_3$, 80 MHz] established the structure of a quinoquinoline. Based on the synthetic route, we first suspected **1**. However, the number of lines in the fully decoupled ^{13}C NMR spectrum, containing only three signals for quaternary C atoms, indicated the presence of **2**. Its formation is apparently, as in the earlier attempts to synthesize **1**, due to the preferred introduction of the nitrogen functions into the synthetic precursors in the 1,5 instead of the desired 1,8 positions of the central "naphthalene system".

The decade-old uncertainties concerning the synthesis and structural assignment of **1** and **2** could now be resolved by X-ray structural analysis of the two compounds. Furthermore, the structure of **1** was of particular interest because of its "proton sponge" properties.[2]

Evaporation of a solution of **1** in acetone afforded crystals containing 1/2 molecule of water per molecule of **1**. Figure 1 shows the molecular structure of **1** viewed from above the quinoquinoline system. The bond lengths around the periphery of the molecule and, in particular, the alternations of these bond lengths, largely correspond to the bonding in other quinoline systems (e.g., **2**; see below). Noteworthy in the inner region, characterized by the close proximity of N(1) and N(12), is the increase in the central external angle of the "naphthalene unit" (125.4°), which results in an increase in the N···N distance to 272.8 pm. Despite the interaction between these nitrogen atoms, there is only a very slight deviation of the molecule from

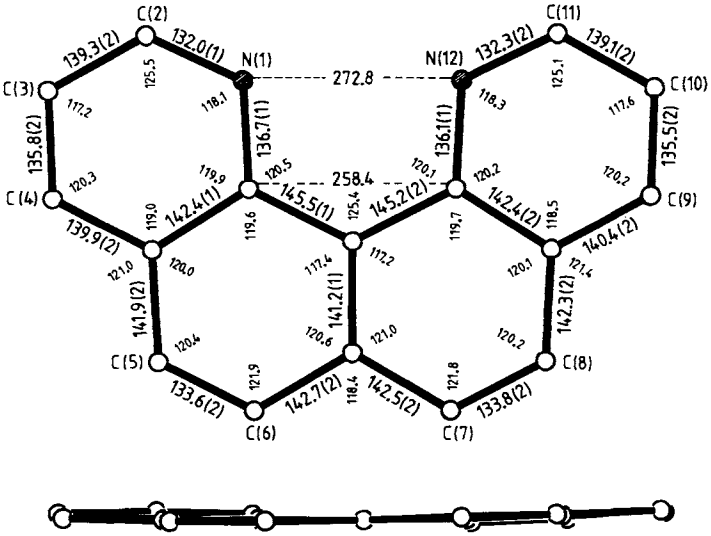

Fig. 1. Molecular structure of **1** viewed from above the plane of the quinoquinoline (above) and from the side (bottom). The upper part of the figure shows bond lengths [pm] and angles [°] (standard deviation of the last decimal place in parentheses). Tetragonal space group $I4_1/a$, $a = 1446.0(2)$, $c = 2213.9(4)$ pm; $Z = 16$, $\rho_{calcd} = 1.373$ g cm^{-3}; 2860 measured reflections, 1854 with $I \geq 2.00\sigma(I)$ observed; structural solution by direct methods (MULTAN), $R = 0.046$ [8].

planarity, as shown in the side view (Fig. 1, bottom): the largest deviations from the "least-squares plane" through the ten "naphthalene" C atoms are 13 and 12 pm for C(2) and C(3), respectively; the two nitrogen atoms lie only 7 pm above and 6 pm below this plane. Since, owing to interactions between the basic groups, all other strong "proton sponges" (e.g., 1,8-bis(dimethylamino)naphthalene, corresponding to **1**) exhibit a strong steric deformation of the free base, which is reduced by the N···H···N hydrogen bond upon protonation,[1] the largely planar structure of **1** is very surprising. This planarity is undoubtedly due to the incorporation of the nitrogen atoms into the tetracyclic aromatic system. Figure 2 shows the crystal packing of **1** · 1/2 H_2O in the projection along the *c* axis.

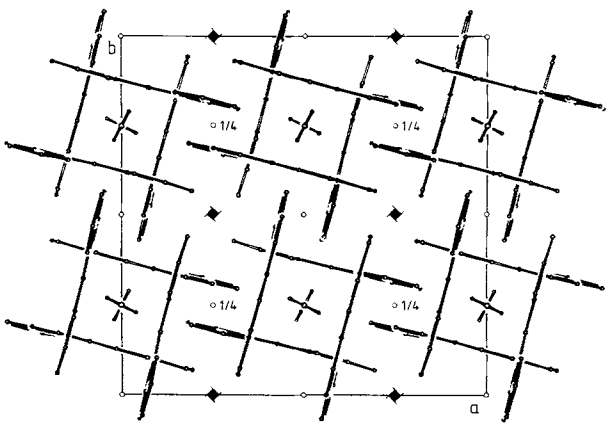

Fig. 2. Crystal packing of **1** · 1/2 H_2O in the projection along the *c* axis.

ing of **1** and also reveals the positions of the molecules of crystal water on the $\bar{4}$ axis. Because of the large separation from the nitrogen atoms of **1** and the unfavorable arrangement referred to the "lone pairs" of these atoms, the water molecules do not engage in specific hydrogen-bond interactions with **1**.

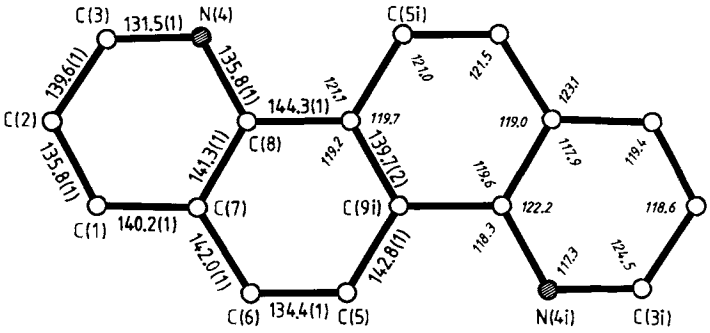

Fig. 3. Molecular structure of **2** as viewed from above the quinoquinoline plane with bond lengths [pm] and bond angles [°] (standard deviations of the last decimal place in parentheses). Monoclinic prisms from ethanol/water, space group $P2_1/c$, $a=450.5(1)$, $b=971.7(2)$, $c=1233.5(2)$ pm, $\beta=93.29(2)°$, $Z=2$, $\rho_{calcd}=1.418$ g cm^{-3}; 1354 reflections, 976 observed with $I \geq 2.00\sigma(I)$; structure solution by direct methods (MULTAN), $R=0.037$ [8].

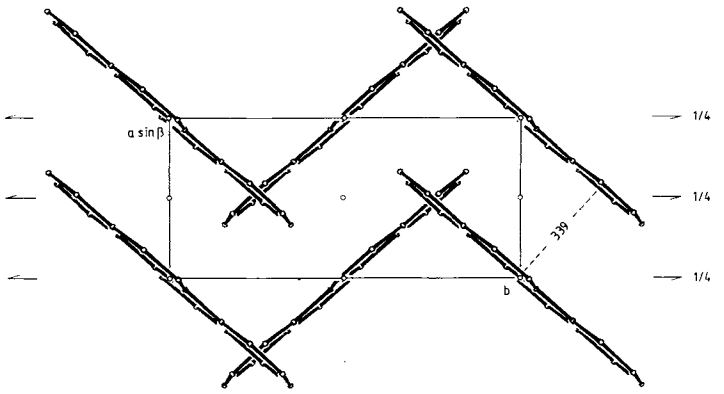

Fig. 4. Crystal packing of **2** in the projection along the *c* axis.

Figure 3 shows the molecular structure of **2** viewed from above the tetracyclic ring system. The bond lengths and bond angles of the centrosymmetric molecule do not deviate significantly from those of other quinoline compounds. The molecule is nearly perfectly planar with maximal deviations of 2 pm [for C(6) and N(4)] for the least-squares plane formed by the 18 ring atoms. The crystal packing (Fig. 4) shows the "herring-bone pattern" often observed for polycyclic aromatic compounds. The molecules are stacked along the *a* axis, the stacking axis forming an angle of 41.4° with the plane of the molecules; the interplanar distance between neighboring molecules within the stack is 339 pm.

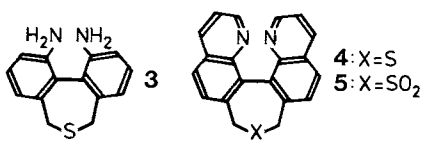
Benzo[1,2-*h* : 4,3-*h'*]diquinoline ("1,14-Diaza[5]helicene"): Synthesis, Structure, and Properties**



By *Heinz A. Staab,* Michael A. Zirnstein,* and *Claus Krieger*

Our synthesis of quino[7,8-*h*]quinoline **1** provides a "proton sponge"[1] whose basic centers, as well as the N···H···N hydrogen bond (in the cation formed by protonation of **1**), are not hydrophobically shielded by *N*-alkyl groups.[2] In the preceding communication, we described the molecular structure of **1**.[3] In the same way that **1** is related to 1,8-bis(dimethylamino)naphthalene, the actual "proton sponge"[4] benzo[1,2-*h* : 4,3-*h'*]diquinoline **2** is related to 4,5-bis(dimethylamino)phenanthrene, whose synthesis, structure, and "proton-sponge" properties we have also described.[5] Whereas a largely planar structure was found for **1**,[3] compound **2**, whose basic structure is that of a [5]helicene, should display strong helical deformation. This should be reflected in the N···N distance, the preferential orientation of the nitrogen "lone pairs", and thus the N···H···N hydrogen bond in the monocation **2a** derived from **2**.

1 **2** **2a**

To synthesize **2**, 1,11-diamino-5,7-dihydrodibenzo[*c*,*e*]-thiepin **3**, synthesized earlier by us,[5] was converted into 7,9-dihydrothiepino[3,4-*h* : 6,5-*h'*]diquinoline **4** (24% yield) in a double Skraup reaction (glycerol, arsenic acid, conc. sulfuric acid; 30 min, 145–150°C). Oxidation with trifluoroperoxyacetic acid in trifluoroacetic acid (2 h, 0–20°C) led to the *S*,*S*-dioxide **5** in 72% yield. A variant of the Ramberg–Bäcklund rearrangement[5,6] with KOH and CCl_4 in *t*BuOH (3–5°C, then 2.5 h, 40°C) resulted in conversion of **5** into the desired **2** (m.p. 271–273°C; 13% yield, 16% re-

isolation of **5**). The structure of **2** was established by correct elemental analysis, mass spectrum [*m/z* 280 (100%, $M^{\oplus}$), 279 (24), 252 (24), 140 (11, $M^{2\oplus}$); high-resolution MS: $M^{\oplus}$ 280.0997 corresponding to $C_{20}H_{12}N_2$] and ^{1}H NMR data [$\delta=7.59$ (dd, $J=8.1$ and 4.2 Hz, 2H; 3,12-H), 8.10 and 8.12 (AB, $J=8.5$ Hz, 2H each; 5,10- and 6,9-H), 8.19 (s, 2H, 7,8-H), 8.43 (dd, $J=8.1$ and 1.7 Hz, 2H; 4,11-H), 8.56 (dd, $J=4.2$ and 1.7 Hz, 2H; 2,13-H; 500 MHz, [D_6]dimethyl sulfoxide (DMSO)].

[**] New "Proton Sponges", Part 9.—Part 8: [3].

The molecular structure of **2**, which has C_2 symmetry in the crystal, is shown in Figure 1. Bond lengths and angles (Fig. 1, top) do not reveal any unusual features in comparison to planar **1** or its isomer.[3] The middle of Figure 1 shows the considerable helical deviation of the planar arrangement; this is seen even more clearly in the side view along the central bond C(17)–C(17i) (Fig. 1, bottom). The consequence of this helical deformation is an increase in the N···N distance to 270.5 pm, which is only slightly shorter than the N···N distance in planar **1** (272.8 pm). Figure 2 shows the lattice packing of **2**, which is present as a racemate.

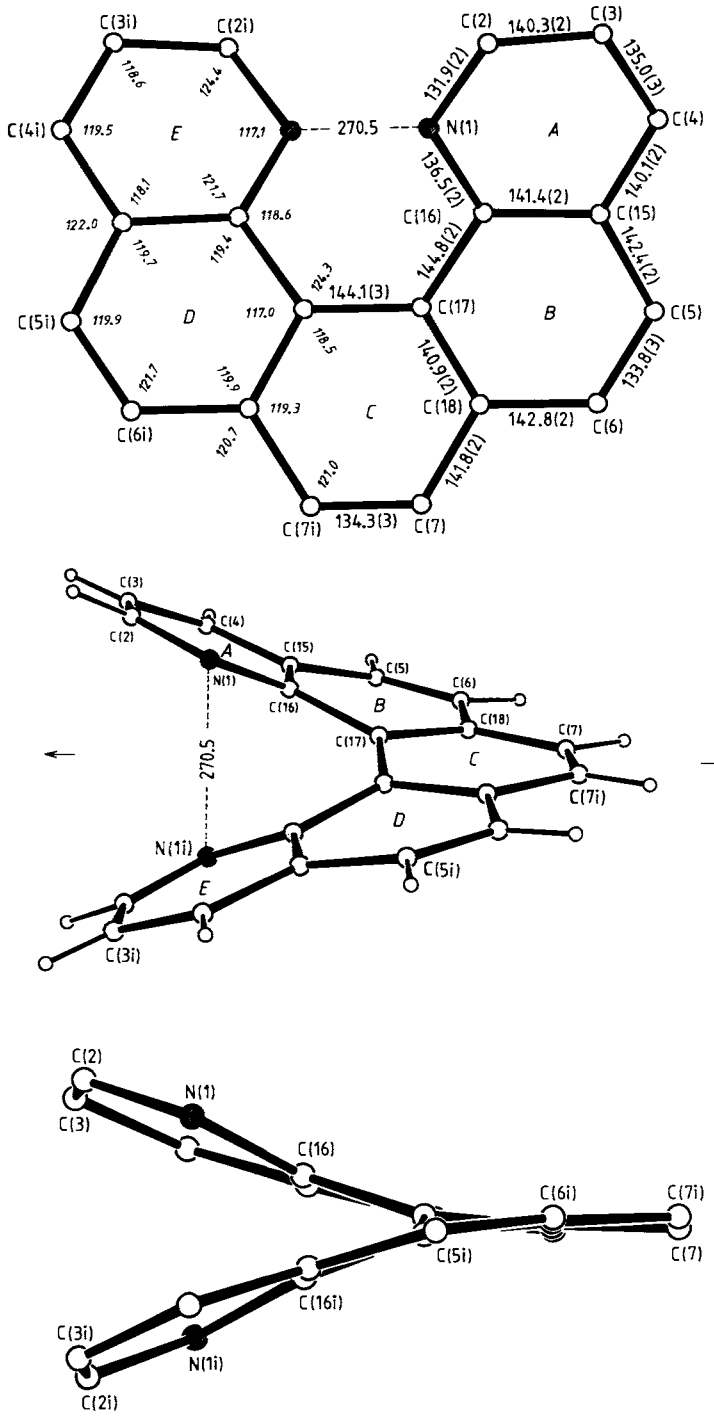

Fig. 1. Molecular structure of **2** viewed from above the average plane of the central six-membered ring C (top), from the side of and somewhat above the pentacyclic system (middle), and from the side along the central C(17)–C(17i) bond (bottom); bond lengths [pm] and valence angles [°] (standard deviations of the last decimal place in parentheses) are given above. Crystal of **2** from ethyl acetate, space group $C2/c$; $a = 1213.0(3)$, $b = 905.8(2)$, $c = 1279.2(3)$ pm, $b = 106.28(2)°$; $Z = 4$, $\rho_{calcd} = 1.380$ g cm^{-3}; 1613 symmetry-independent reflections to $\sin\theta/\lambda = 6.8$ nm^{-1}, 910 observed with $I \geq 2\sigma(I)$ [7]. The structure was solved starting from that of [5]helicene [8] by placing the molecule on the twofold axis and optimizing its position by variation of the y coordinate and rotation around the twofold axis; $R = 0.039$.

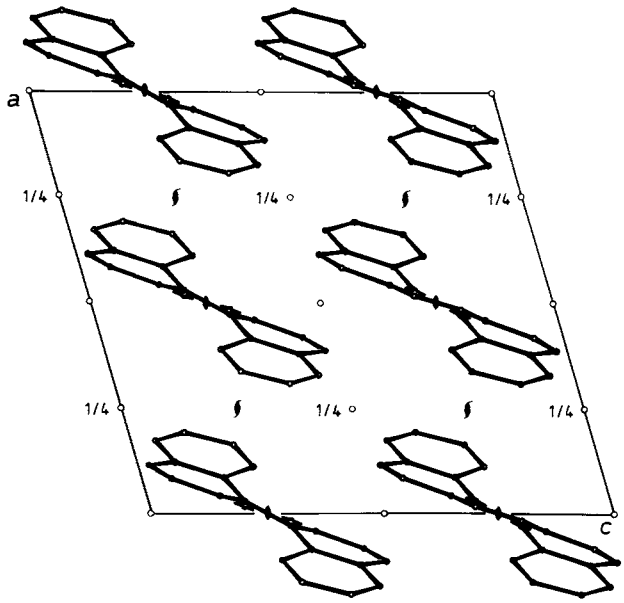

Fig. 2. Crystal lattice packing of **2** (racemate) in the projection along the b axis.

Upon addition of 70% perchloric acid in excess to **2** in dichloromethane, a perchlorate is formed which can be recrystallized from methanol/water (3:1) (64% yield; m.p. ≥ 320 °C, dec.). The elemental analysis and the ^{1}H NMR spectrum [$\delta = 8.28$ (dd, $J = 7.8$ and 4.7 Hz, 2H; 3,12-H), 8.44 and 8.49 (AB, $J = 8.4$ Hz, 2H each; 5,10-H and 6,9-H), 8.59 (s, 2H; 7,8-H), 9.15 (dd, $J = 8.0$ and 1.6 Hz, 2H; 4,11-H), 9.59 (dd, $J = 4.6$ and 1.6 Hz; 2,13-H), 23.89 (br. s, 1H, N···H···N); 500 MHz, [D$_6$]DMSO] confirm the expected presence of the *mono*cation **2a**. Compared to **2**, all signals in **2a** are shifted downfield by the protonation. Most noteworthy is the chemical shift of the hydrogen-bond proton (to almost $\delta = 24$!). Although we find a strong downfield shift for all N···H···N hydrogen bonds in the "proton sponges", the value found for **2a** shows that here the anisotropy effect of the helical aromatic bonding system is additionally important.

^{1}H NMR spectroscopic determination of the signal intensities in transprotonation experiments with 1,8-bis(dimethylamino)naphthalene[1] gave a pK_a value of 10.3 ± 0.2 for **2**. In these experiments, only averaged signals were found for **2** and **2a**, so that, in this case, the rate of proton transfer is rapid relative to the time scale of the NMR method. This is not true for typical "proton sponges", whose basic centers and N···H···N hydrogen bonds are hydrophobically shielded by *N*-alkyl groups.[1] The behavior of **2**/**2a** is in complete agreement, however, with that of **1**/**1a**. Thus, **2** is also an example of a kinetically active "proton sponge". That the basicity constant of **2** is nearly two powers of ten smaller than that of **1**,[2] although the N···N distance in **2** (270.5 pm) is somewhat shorter than

in **1** (272.8 pm)[3], is presumably due to the helical structure of **2** (see Fig. 1, middle). This structure nearly removes the destabilizing "lone-pair" interaction of the nitrogen atoms in the free base and, for **2a**, hinders the formation of an N···H···N hydrogen bond along the favored direction of the nitrogen "lone pairs".

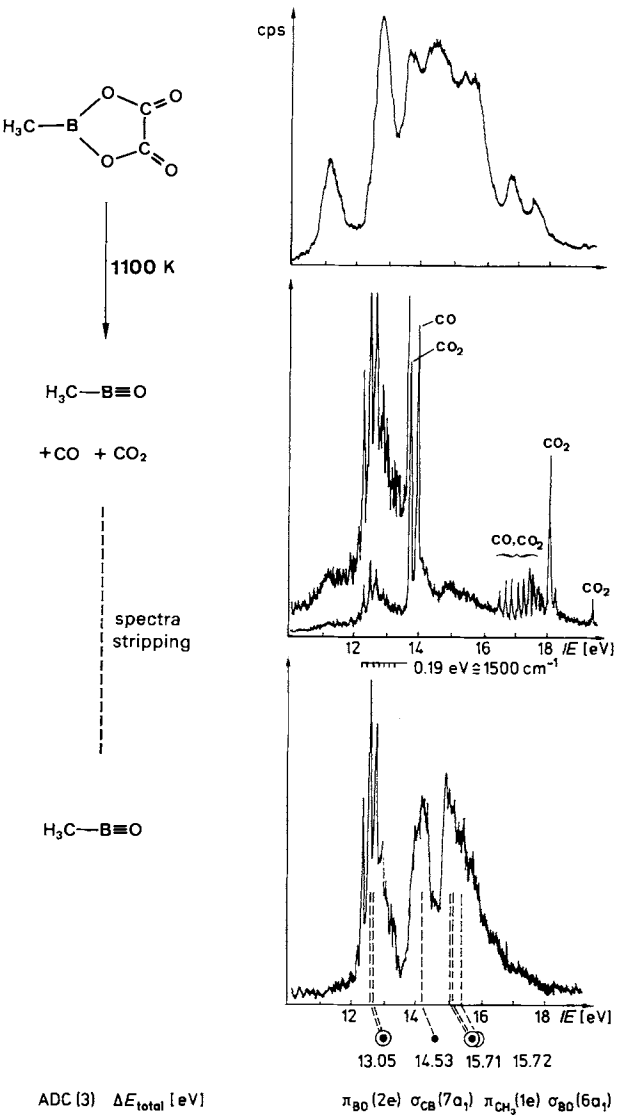
Methylboron Oxide, $H_3C-B{\equiv}O$**

By *Hans Bock,* Lorenz Cederbaum,* W. von Niessen, Peter Paetzold,* Pavel Rosmus,* and *Bahman Solouki*

Dedicated to Professor Heinz Georg Wagner on the occasion of his 60th birthday

Organoboron oxides (organo(oxo)boranes) RBO are kinetically unstable with respect to their cyclic trimers[2-4] and, therefore, in contrast to the isoelectronic iminoboranes RBNR[5] and methyleneboranes $RBCR_2$,[6] they were previously unknown. The title compound is of particular interest with regard to its electron distribution; containing 16 valence electrons, it should thus have a linear CBO framework[7] and can be compared with numerous well-known compounds, such as $H_3C-C{\equiv}CH$ and $H_3Si-C{\equiv}CH$[8] as well as $H_3C-C{\equiv}N$.[9]

Methylboron oxide was generated by pyrolysis of 2-methyl-1,3,2-dioxaborolane-4,5-dione at 1100 K, optimized by PE-spectroscopic real-time gas analysis[1] (Fig. 1), and the PE spectrum of the "pure" compound (Fig. 1, bottom) was obtained by digital subtraction ("spectra stripping") of the ionization patterns of the thermodynamically favored fragmentation molecules CO and CO_2.[10] The radical cation states were assigned on the basis of the total energy differences determined from a highly-correlated calculation according to the algebraic diagrammatic construction(3) procedure (ADC(3) procedure).[11]



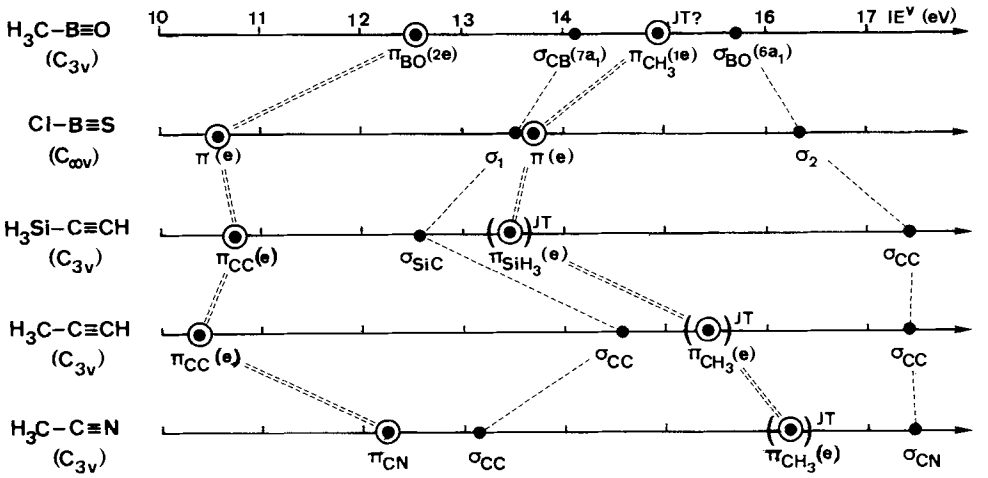


Fig. 1. He(I) PE spectra of 2-methyl-1,3,2-dioxaborolane-4,5-dione at 330 K (top), of its pyrolysis products at 1100 K (middle), and—after digital subtraction of the ionization patterns of CO and CO_2—of methylboron oxide (bottom) [10]. Assignment of the six radical cation states in the measuring range on the basis of ADC(3) total energy differences [11].

A comparison of the radical cation states of $H_3C-B{\equiv}O$ with equivalent states[12] of the iso(valence)electronic molecules $Cl-B{\equiv}S$,[4] $H_3Si-C{\equiv}CH$,[8] $H_3C-C{\equiv}CH$,[8] and $H_3C-C{\equiv}N$[9] (Scheme 1) corroborates the ADC(3) assignment (Fig. 1) and furthermore provides, on the basis of first- and second-order perturbation arguments, insights into its electron distribution (JT: center of gravity of Jahn-Teller-split bands).

The sequences of the radical cation states of the iso(valence)electronic molecules $H_3C-B{\equiv}O$ and $Cl-B{\equiv}S$ are, as expected, in agreement and therefore support the independently made assignments.[4, 11] The lower π(e) ionization energies can be explained by the differences in the effective nuclear charges $Z_{eff}(S) < Z_{eff}(O)$, and the larger π and σ splittings by the differences $Z_{eff}(Cl-S) < Z_{eff}(O-C)$ as

[**] Gas-Phase Reactions, Part 70. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der chemischen Industrie, and the State of Hessen. Part 69: [1].

Scheme 1.

well as the thereby increased second-order perturbations ($\Delta E \approx 1/\Delta Z_{eff}$).[12] An analogous argument, $Z_{eff}(Si) \ll Z_{eff}(C)$, allows a comparison with and among the H_3Si- and H_3C-acetylene derivatives, for which the "hyperconjugative" π_{CC}/π_{EH_3} interactions can be estimated from the ionization energies by means of the following equation:[8, 12]

$$\beta^{\pi}_{CC/EH_3} = \sqrt{(IE_1(HC{\equiv}CH) - IE_1)(IE(e, H_3EEH_3) - IE_1)}$$

$$\beta^{\pi}_{CC/CH_3} = -2.1\ \text{eV} \gg \beta^{\pi}_{CC/SiH_3} = -1.4\ \text{eV}$$

Omitting first-order perturbation corrections[8, 12] for $H_3C-B{\equiv}O$, the following value is obtained:

$$\beta^{\pi}_{BO/CH_3} = \sqrt{(\approx 13.4 - 12.5)(14.3 - 12.5)} \approx -1.3\ \text{eV}$$

This hyperconjugative interaction parameter is in agreement with the observed small π splitting $\Delta\pi(e) = 2.5$ eV (cf. Scheme 1: $H_3C-C{\equiv}CH$ 5 eV; $H_3Si-C{\equiv}CH$ 2.7 eV). Extremely close comparability exists with H_3CCN due to the isoelectronic relationship between $B{\equiv}O$ and $C{\equiv}N$: the first two vertical ionization energies differ from each other only by $\Delta IE_1 \approx 0.3$ eV and $\Delta IE_2 \approx 0.9$ eV; the π interaction, $\beta^{\pi}_{CN/CH_3} \approx -1.8$ eV[9] is larger by 0.5 eV.

The comparison of the radical cation states (Scheme 1) thus provides the following clues: The C_{3v} molecule $H_3C-B{\equiv}O$ contains, according to chemical parlance, a "true BO triple bond"[5] and its ionization pattern, cum grano salis, is identical with that of the isoelectronic $H_3C-C{\equiv}N$.[13] The two compounds are also similar with respect to the vibrational fine structure ($\tilde{\nu}^{\oplus} \approx 1500\ \text{cm}^{-1}$; H_3C-CN, $\tilde{\nu}^{\oplus} \approx 1430\ \text{cm}^{-1}$[9]) visible in the first ionization band (Fig. 1) and due presumably to an H_3C deformation. MNDO calculations[14] predict a largely balanced charge distribution

$$H_3C^{+0.19}-B^{-0.06}{\equiv}O^{-0.13}$$

and a negative enthalpy of formation $\Delta H_f \approx -90$ kcal mol^{-1}. In view of the experimentally determined (Fig. 1: generation temperature $T \approx 1100$ K) thermodynamic stability of $H_3C-B{\equiv}O$, the kinetic instability of organoboron oxides[2] is presumably caused by the energetically favored oligomerization, for example, to give six-membered ring compounds $(RBO)_3$, and it should be possible to isolate derivatives with bulky alkyl or aryl groups.

[13] Starting from the structure in the gas phase (determined by electron diffraction), the following MNDO eigenvalues were calculated for H_3CCN: −12.8 eV (2e), −14.1 eV ($4a_1$), −15.5 eV (1e), and −18.5 eV ($3a_1$) (cf. Scheme 1). The resulting charge distribution

$$H_3C^{+0.20}-C^{-0.11}\equiv N^{-0.08}$$

leads to a dipole moment $\mu=2.6$ D ($\mu_{exp}=3.9$ D [9]).

[14] MNDO geometry optimization for $H_3C-B\equiv O$ gave $d_{CB}=153$ pm, $d_{BO}=118$ pm, $d_{CH}=111$ pm and $\sphericalangle HCB=110°$, and $\mu=2.4$ D as dipole moment. The eigenvalues −13.6 eV (2e), −14.4 eV ($4a_1$), −15.6 eV (1e), and −17.7 eV ($3a_1$) reflect the ionization pattern despite differing Koopmans' defects [11] (cf. also 4-31-G ab initio results G. Raabe, W. Schlieker, W. Strassburger, E. Heyne, J. Fleischhauer, *Z. Naturforsch. B42* (1987) 1027).

The Structure of Hexaaminobenzene**

By *David A. Dixon,* Joseph C. Calabrese,* and *Joel S. Miller**

The quest for molecular organic ferromagnets has culminated in the characterization of the complex $[Fe^{III}(C_5Me_5)_2]^{\oplus}[TCNE]^{\ominus}$ as a bulk ferromagnet.[1,2] Totally p-orbital based ferromagnets require stable radical cations or anions with D_{2d} symmetry or with a rotation axis of three or greater,[2] such as hexaaminobenzene **1**.[3] Donor-acceptor systems based on substituted $\mathbf{1}^{\oplus}$ have yet to be characterized as exhibiting ferromagnetic behavior;[4] however, this high symmetry, low ionization potential donor is of fundamental interest. Herein we report the X-ray structural analysis and redox properties of **1**.

Hexaaminobenzene was prepared by a literature route from 1,3,5-triamino-2,4,6-trinitrobenzene.[3b] Crystals suitable for single crystal X-ray diffraction[5] were obtained from nitromethane under an inert atmosphere. The molecule has six identical CNH_2 groups (Fig. 1). The geometrical parameters are given in Table 1. A packing diagram is depicted in Figure 2. The crystal packing is dominated by weak intermolecular NH···N interactions such that the nitrogen lone pair is positioned between adjacent hydrogens of nearby molecules. This results in an arrangement in which each molecule is surrounded by twelve other molecules in three different orientations. The vibrational spectrum of **1** is quite simple, consistent with its high molecular symmetry. Characteristic infrared absorptions (Nujol; for IR data in KBr see [3a]) are given in Table 2.

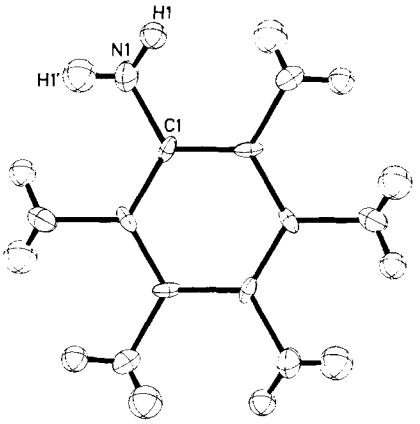

Fig. 1. ORTEP drawing of **1** (50% ellipsoids).

Unlike hexaazaoctadecahydrocoronene, which exhibits four reversible one-electron oxidations,[6,7] **1** exhibits only one reversible one-electron oxidation at −0.11 V (vs. SCE in $MeNO_2$) corresponding to $\mathbf{1}^{\oplus}e^{\ominus} \rightleftharpoons \mathbf{1}$. Although an irreversible oxidation to $\mathbf{1}^{2\oplus}$ occurs at ca. +0.56 V, chemical oxidation has not yet led to crystalline solids suitable for single crystal X-ray analysis.

Table 1. Bond lengths and angles for **1** (see Fig. 1 for the numbering scheme).

Ab initio molecular orbital calculations were carried out with the program GRADSCF[8] on a CRAY-XMP/24 computer using both the minimal STO-3G basis set[9] and the 6-31G* (N) basis set (168 orbitals).[10] The geometry of **1** was gradient optimized[11] and force fields were calculated analytically.[12]

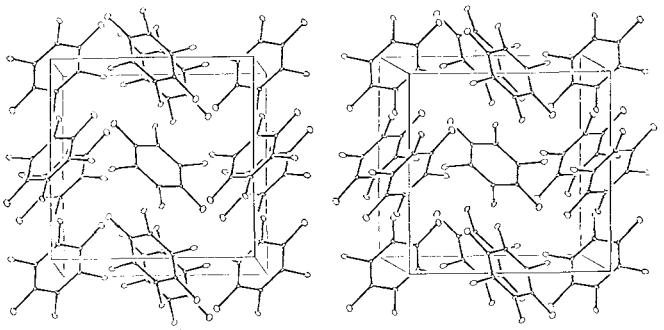

Fig. 2. Stereoview of a unit cell of **1** (hydrogens omitted for clarity).

The calculated metric parameters for **1** are given in Table 1. The structure was initially calculated with exact D_{3d} symmetry using the STO-3G basis set. This structure is not an energy minimum, but has a negative direction of curvature characterized by an imaginary frequency of 93i cm^{-1}; i.e., it is a transition state. When the structure was reoptimized following the direction of negative curvature, a minimum energy structure with S_6 symmetry was obtained. This S_6 structure is 0.2 kcal/mol lower in energy at the Hartree-Fock level and 0.4 kcal/mol lower at the MP-2 level with the STO-3G basis set[13] than the D_{3d} structure. The S_6 structure has the NH_2 groups rotated by 13° away relative to the D_{3d} structure about the C–N bond axis. Consistent with the small energy difference, the geometry parameters for the two structures are essentially the same. We reoptimized the S_6 structure with the much larger 6-31G* (N) basis set. The calculated C–C bond distance is only 0.009 Å longer. The calculated C–N distance is in even better agreement and is 0.006 Å shorter than the experimental value. The experimental N–H bonds are too short compared to the theoretical values, a well-known phenomenon.[14] The calculated values for θ(CCC) and θ(CCN) are 120 ± 1.0°, consistent with the experimental results. The NH_2 groups are calculated to be more pyramidal than the experimental values. This is not surprising considering the difficulty in assigning the hydrogen positions in the crystal structure. With the 6-31G* (N) basis set, the NH_2 groups are even further twisted away from the D_{3d} structure with CCNH torsion angles of 11° and 52° giving an average twist of 21° for the NH_2 groups. The calculated rotation away from the D_{3d} structure about the C–N bond is consistent with the observed values considering the errors in the positions of the hydrogens (Fig. 1). The STO-3G structure is in good agreement with the 6-31G* (N) structure except that the C–N and N–H bond distances are too long with the smaller basis set.

The vibrational frequencies calculated with the STO-3G basis set need to be scaled in order to account for basis set deficiencies, correlation effects and anharmonicity.[15] Scale factors of 0.8 to 0.9 are typical and a value of 0.82, based on comparing our calculated spectra with the experimental one, was used. Scaled and unscaled values with the calculated infrared intensities are presented in Table 2 together with their symmetry assignments. At this level of calculation, the intensities are only given for qualitative comparison. Twelve bands between 3370 (scaled) cm^{-1} and 3210 (scaled) cm^{-1} corresponding to the N–H stretches were calculated. The scaled positions of the most intense N–H stretches agree with the experimental values. The agreement is best for the lower frequency bands.

The scaled bands at 1629, 1482 and 1196 cm^{-1} are predicted to be intense in the IR and correspond to motions of the NH_2 groups, e.g., scissoring, and to C–C ring stretches and deformations. The most intense IR band in this region is the one at 1482 cm^{-1} according to both theory and experiment. There are three Raman bands in this same spectral region. The broad band observed at 1625 cm^{-1} is probably due to two overlapping e_g bands calculated at 1650 and 1596 (scaled) cm^{-1} with possibly some contribution from the intense a_u (IR-active) band at 1629 cm^{-1}. The most intense IR band (predominantly NH_2 motion) is calculated to be at 940 cm^{-1} and a less intense band is predicted at 827 cm^{-1}. This latter band has a significant component of C–N bond motion. The experimental intensities for this pair are reversed. We also calculate an intense a_u band at 894cm^{-1} (scaled) with I = 145 km/mol involving significant motion of the NH_2 group. The Raman band at 890 cm^{-1} is a combination of an a_g band (ring deformation) and an e_g band (NH_2 group motion). The Raman bands near 830 cm^{-1} could be due to the very strong IR-active e_u band at 840 cm^{-1}. The weak Raman band at 720 cm^{-1} is of a_g symmetry, as is the most intense Raman band at 579 cm^{-1}. The a_g band at 579 cm^{-1} is the symmetric C–N stretch.

The Structure of the Tetracation of Hexaazaoctadecahydrocoronene, A Simple Substituted Benzene

By *David A. Dixon,* Joseph C. Calabrese, Richard L. Harlow,* and *Joel S. Miller**

The molecular and electronic structure of benzene and its derivatives have fascinated chemists for many years. Due to the high symmetry of benzene, the dication of benzene or of highly symmetrical benzene derivatives was postulated[1] to play the role of the degenerate triplet cationic species in *McConnell*'s model[2] for organic ferromagnets. *Breslow* et al.[3a-c] and *Praefeke* et al. [3d] have synthesized the highly symmetric derivative (D_{3d} point group) hexaazaoctadecahydrocoronene **1** and have generated its dication.[3a-c]

[**] We are indebted to *W. Marshall, R. S. McLean, D. Wipf,* and *C. Vazquez* for assistance in obtaining physical measurements and preparing samples and to *P. J. Krusic, M. D. Ward,* and *E. Wasserman* for stimulating discussions.

In the solid state, the dication exhibits a singlet ground state as observed by magnetic susceptibility and EPR measurements consistent with the X-ray structures of several $\mathbf{1}^{2\oplus}$ salts which show a distorted structure with C_{2v} symmetry.[4] Other EPR studies suggest that the spin of the ground state of materials containing $\mathbf{1}^{2\oplus}$ can be strongly dependent on the environment.[3c] **1** can be further oxidized to yield $\mathbf{1}^{4\oplus}$ as shown by cyclic voltammetry.[3b,4] We have succeeded in crystallizing $\mathbf{1}^{4\oplus}$ as the salt $[\mathbf{1}][SbF_6]_4\cdot MeCN$[5] and herein report the first structural determination of a benzene derivative in the +4 oxidation state.

The salt crystallizes in the monoclinic space group $C2/m$[6] and the tetracation lies on a $2/m$ site in the asymmetric unit. In Table 1, the heavy atom bond distances for $\mathbf{1}^{4\oplus}$ are compared with those of **1**.[4] The structure of $\mathbf{1}^{4\oplus}$ (Fig. 1) is only slightly distorted from the idealized D_{3d}

[a] C_B: C atoms of benzene ring; C_H: aliphatic C-atoms.

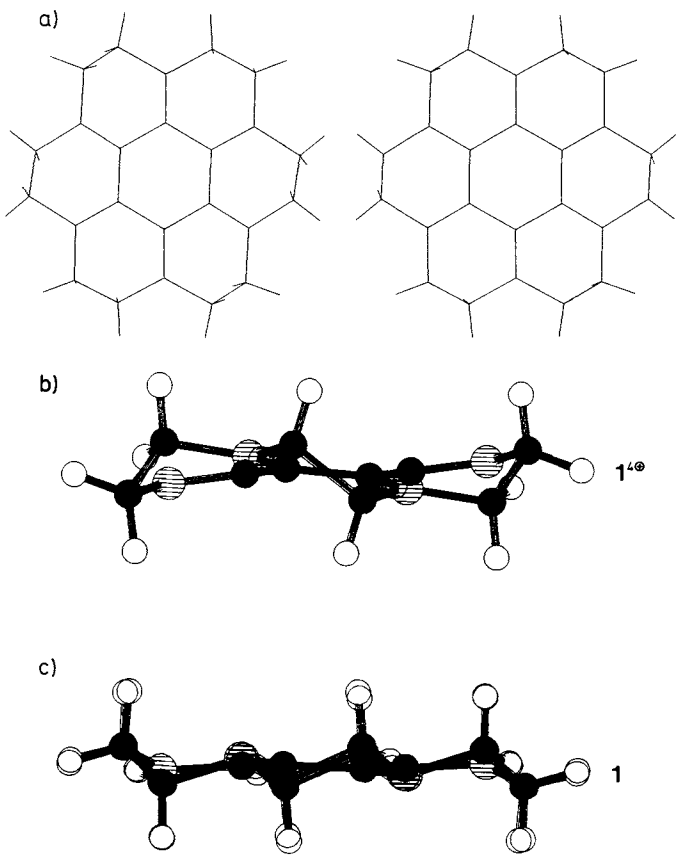

Fig. 1. Structure of $\mathbf{1}^{4\oplus}$ in crystals of **1** $[SbF_6]_4\cdot MeCN$. a) Stereoview down the approximate 3-fold axis of $\mathbf{1}^{4\oplus}$. b) Side view of $\mathbf{1}^{4\oplus}$. c) Side view of **1**. Note the higher planarity of **1** compared to $\mathbf{1}^{4\oplus}$.

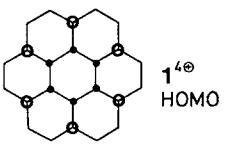
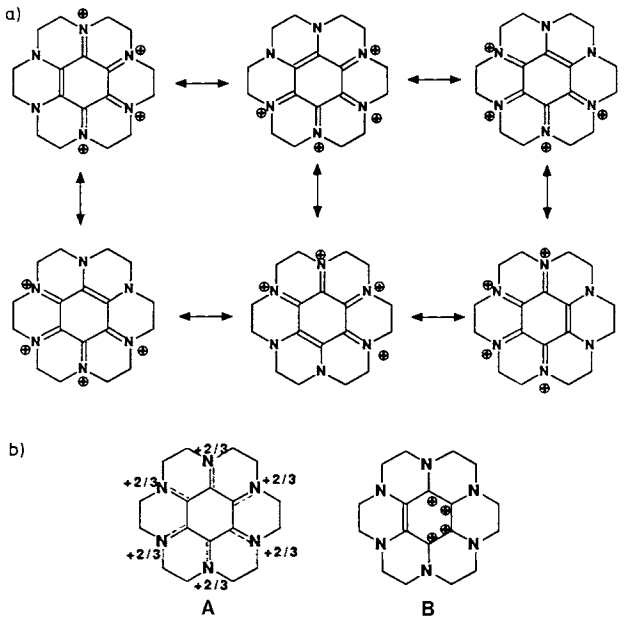
symmetry. All the C_B–C_B bond distances are equal within experimental error as are the C_B–N bond distances. The C_B–C_B bond distances are 0.04 Å longer in the tetracation as compared to the neutral molecule, whereas the C_B–N bond distances are 0.10 Å shorter in the tetracation. Both the N–C_H and C_H–C_H bond distances are 0.03 Å longer in the tetracation. The $(C_B)_6N_6$ central region of the tetracation is significantly nonplanar as compared to the planarity of the moiety in **1** (Fig. 1b, c). The average C_B and N displacements from the C_6 least squares plane are 0.053 and 0.245 Å in $[HAOC]^{4\oplus}$ as compared to 0.013 and 0.116 Å for HOAC.



The "π orbitals" of **1** can be formally generated by adding the benzene π orbitals (Scheme 1, left) to the orbitals of the N lone pairs (Scheme 1, right). The exact mixing

Scheme 1. Left: π-orbitals of benzene. Right: orbital scheme for the nitrogen lone-pairs, obtained by linear combination of the N-atom orbitals. The energy scales, left and right are different.

depends on a variety of factors such as overlap, electron repulsion, etc. Although the HOMO of **1** is degenerate, it has significant electron density on both C and N. Thus, when four electrons are removed from **1**, remixing of the orbitals could occur, leading to an e^2 occupancy and a triplet state for $\mathbf{1}^{4\oplus}$. Magnetic susceptibility measurements showed, however, that $\mathbf{1}^{4\oplus}$ is diamagnetic between 2 and 320 K with no evidence for a triplet state contribution.



The geometry of $\mathbf{1}^{4\oplus}$ was gradient optimized[7] as a singlet with the STO-3G basis set[8] and represents an energy minimum as shown by analytical second derivative[9] calculations.[10] Even though the charge is redistributed, the HOMO for $\mathbf{1}^{4\oplus}$ is nondegenerate, and is predominantly an out-of-plane p orbital on C_B and N (Scheme 2). The

Scheme 2. Out-of-plane p orbitals on C_B and N, which dominate in the HOMO of $\mathbf{1}^{4\oplus}$.

LUMO is a degenerate pair of orbitals. The calculated bond distances for HAOC and $[HAOC]^{4\oplus}$ are listed in Table 1. The calculated C_B–C_B bond distance in $\mathbf{1}^{4\oplus}$ is 0.04 Å longer than the average experimental value. The other calculated bond distances in $\mathbf{1}^{4\oplus}$ are 0.012–0.034 Å longer than the experimental values and show the identical trends found when comparing the experimental **1** and $\mathbf{1}^{2\oplus}$ geometry parameters.[4] (The expanded calculated external C_H–C_H and C_H–N bond distances allow the calculated internal C_B–C_B and C_B–N bond distances also to be longer.) The calculations also show the increase in nonplanarity of the $(C_B)_6N_6$ moiety in going from **1** to $\mathbf{1}^{4\oplus}$ that was observed experimentally (see Fig. 1b, c).

The calculated charge distribution for $\mathbf{1}^{4\oplus}$ shows C_B with a charge of 0.19 $e^{\ominus}$ and N with a charge of -0.17 $e^{\ominus}$. The group charges for the C_H groups are 0.37 $e^{\ominus}$. These can be compared to the charges in **1** of 0.06 $e^{\ominus}$ on C_H, -0.28 $e^{\ominus}$ on N and 0.11 $e^{\ominus}$ on the C_H groups. Clearly the largest change in the charge distribution is on the external portion of the molecule. The charge removed from C_B and N is approximately equal. Considering the excess charge on the C_H groups, most of the charge was removed from the nitrogen region rather than from the benzene ring. This is consistent with the modest lengthening of the C_B–C_B bond distances as compared to the dramatic decrease in the C_B–N bond distances which is approaching the C–N bond distance found in protonated imines (1.29 Å).[11] This is also consistent with the coefficients in the LUMO of $\mathbf{1}^{4\oplus}$ being larger on N than on C_B. From the above results, the most important resonance structures for $\mathbf{1}^{4\oplus}$ are shown in Scheme 3.[12] Note that the charges are on the nitrogen atoms (as in **A**) rather than on the carbon atoms (as in **B**).

Scheme 3. a) The most important resonance structures of $\mathbf{1}^{4\oplus}$. b) **A** = charge distribution in $\mathbf{1}^{4\oplus}$ derived from the resonance structures; **B** = charge distribution in $\mathbf{1}^{4\oplus}$ based on the $(4n+2)\pi$-electron rule.

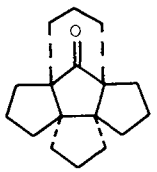
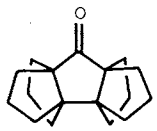
[12] Although the $(4n+2)$ π-electron counting rule can be applied to substituted benzenes, it is inappropriate to apply it to the structure of $1^{4\oplus}$ for determining the charge distribution. The $4n+2$ rule would place four positive charges in the benzene ring, whereas the excess positive charges are clearly found in the regions of the nitrogens.

From Tetraspiranes to Bispropellanes**



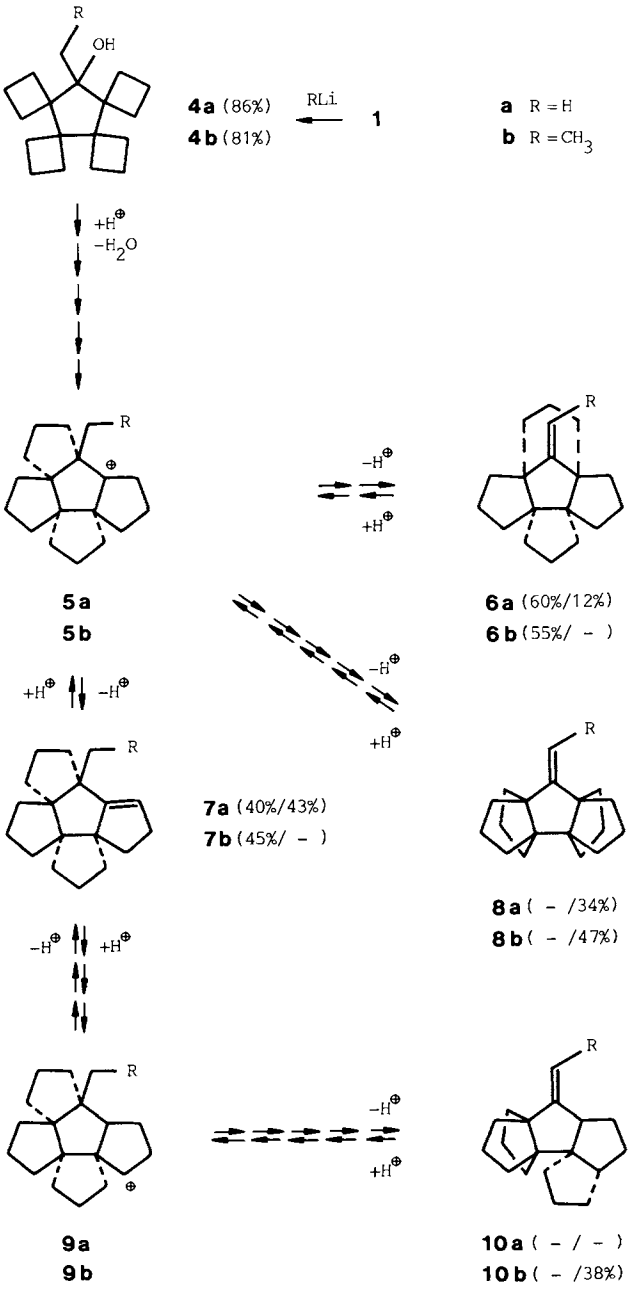
By *Lutz Fitjer** and *Ulrike Quabeck*

In memoriam David Ginsburg



Upon reaction with acid the tetraspiroketone **1** rearranges via a fivefold 1,2-shift to the pentacyclic ketone **2** ($\Delta H_f = -53.1$ kcal mol^{-1}).[1] Formation of the isomeric bispropellanone **3** ($\Delta H_f = -53.1$ kcal mol^{-1})[1] is not observed even if equilibrium conditions are maintained. We have now found that the relative stabilities of **2** and **3** can be altered to such an extent by replacement of the carbonyl oxygen by alkylidene groups that rearrangements of the corresponding tetraspiranes (**4a,b**) to bispropellanes (**8a,b**) are possible.

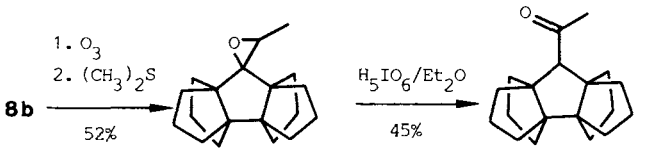
1



2

3

Evidence of this was afforded by force field calculations[2] on **6a,b**, **7a,b** and **8a,b** as potential products of a rearrangement of **4a,b** via **5a,b** (see Scheme 1). **8a** ($\Delta H_f = -5.80$ kcal mol^{-1}) and **8b** ($\Delta H_f = -13.07$ kcal mol^{-1}) are so distinctly favored over their isomers **6a** and **7a** ($\Delta H_f = -2.32$ kcal mol^{-1} and -3.82 kcal mol^{-1}) and **6b** and **7b** ($\Delta H_f = -5.80$ and -5.86 kcal mol^{-1}) respectively, that we have prepared **4a** and **4b** and used them in rearrangement experiments.



We obtained **4a** (m.p. 110–111 °C, yield 86%[3] and **4b** (m.p. 25–27 °C, yield 81%)[3] by reaction of the tetraspiroketone **1**[1] with methyl- and ethyllithium, respectively. For the rearrangement we chose conditions favoring the kinetically and thermochemically controlled reactions A and B, respectively. In the case of reaction A, 0.38 molar benzolic solutions of **4a** and **4b** were heated together with 2 gram equivalents of Nafion NR 50[4] at 70 °C for 30 min, and, in the case of reaction B, 0.10 molar benzolic solutions with 40 gram equivalents of Nafion NR 50 at 70 °C for 6 h. Reaction A afforded, in the case of **4a** and **4b**, mixtures of **6a** (m.p. 202–206 °C, 60%)[3] and **7a** (m.p. 118–121 °C, 40%)[3] and **6b** (m.p. 182–184 °C, 55%)[3] and **7b** (liq., 45%),[3] respectively. Reaction B in the case of **4a** furnished a mixture of **6a** (12%), **7a** (43%) and **8a** (m.p. 176–178 °C, 34%)[3] and in the case of **4b** a mixture of **8b** (m.p. 121–123 °C, 47%)[3] and **10b** (m.p. 156–160 °C, 38%).[3] The formation of **10b** was unexpected, as this requires involvement of the secondary carbenium ion **9b** as intermediate and could be associated with a considerably higher activation energy than all the other products.[5] All rearrangement products were separated by thin-layer chromatography on silica gel doped with silver nitrate[6] in dichloromethane.

[**] Polyspiranes, Part 18. Rearrangement Cascades, Part 13. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Parts 17 and 12: L. Fitjer, A. Kanschik, M. Majewski, *Tetrahedron Lett. 29* (1988) 5525.

The structures of **6a** (C_s), **7a** (C_1), **8a** (C_{2v}) and **10b** (C_1) were deduced from the number and multiplicity of their ^{13}C-NMR signals. The structures of **6b** (C_1) and **7b** (C_1) could be assigned on the basis of the coupling patterns of their vinyl proton signals (**6b**: $\delta = 5.32$, dd, $J = 1.6$ and 3.3 Hz, 1H; **7b**: $\delta = 4.94$, q, $J = 8.0$ Hz, 1H). **8b** (C_s) was identified by comparison of its ^{13}C-NMR spectrum with that of **8a**. Attempts to oxidatively cleave the double bond of **8b** have thus far failed. Ozonolysis afforded the epoxide **11** (m.p. 145°C, 52%),[3,7] while an attempted subsequent cleavage with periodic acid in anhydrous ether[8] furnished the ketone **12** (m.p. 155°C, 45%).[3]

11 12

These findings show that suitably substituted tetraspiranes can be used for the synthesis of bispropellanes. The realizability of such transformations had already been predicted by *Ginsburg*.[9] A verification of the equilibria via equilibration experiments with **6a,b**, **7a,b**, **8a,b** and **10b** has not yet been carried out. The route to trispropellanes, however, would appear open.

Disilene *versus* Silanediyl ("Silylene") Additions to CN and NCO Bonds**

By *Manfred Weidenbruch,* Bolko Flintjer, Siegfried Pohl,* and *Wolfgang Saak*

Despite bulky ligands, which are necessary for the stabilization of the SiSi double bond ("embedded double bonds"), disilenes are more reactive than alkenes bearing sterically less demanding substituents, and, in some cases, undergo reactions atypical for CC double bonds.[1] For example, alkenes do not undergo [2+2]-cycloadditions with nitriles.[2] We have now found, however, that tetra-*tert*-butyldisilene **3**, formed on photolysis of hexa-*tert*-butylcyclotrisilane **1**,[3] reacts smoothly with tri-*tert*-butylsilyl cyanide **4**[4] to give the 2,3-disila-1-azetine **5**.

In contrast, nitriles RCN with smaller substituents R react with **2** to give preferentially azasilirenes **6**, which spontaneously undergo σ-dimerization to give 1,4- or 1,3-diaza-2,5-disila-1(6),3-cyclohexadienes **7**.[5] Formation of the intermediates **6** could be confirmed indirectly by the analogous reaction with phosphalkynes, from which stable phosphasilirenes are isolable.[6] Apparently the bulky

tBu_3Si group prevents addition of **2** to **4** to give the ring-strained **6** (and its dimerization to **7**) and thus favors the [2+2]-cycloaddition to give **5**. The formation of **5** by addition of **2** to **4** (→ **6**) with subsequent silanediyl insertion in the Si–C or Si–N bond cannot be completely ruled out. However, such insertion reactions only take place at higher temperatures[7] and should, in this case, be further impaired by the bulky substituents.

The spectroscopic data contribute very little to an elucidation of the constitution of **5**,[8] for the C=N stretching vibration, which normally appears between 1560 and 1605 cm^{-1} in the case of SiC=NSi compounds,[5] is not ob-

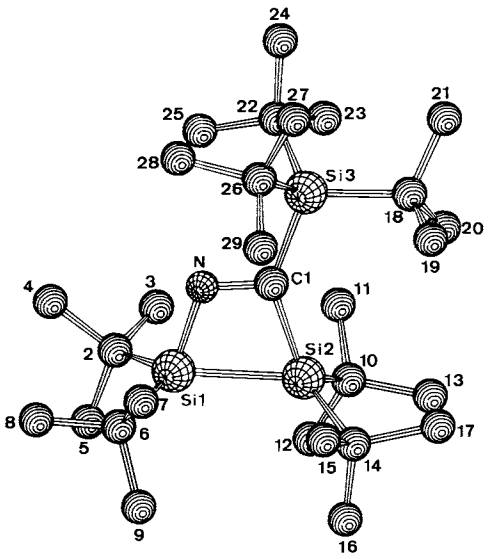
[**] Silicon Compounds with Strong Intramolecular Steric Interactions, Part 34. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 33: M. Weidenbruch, A. Schäfer, H. Marsmann, *J. Organomet. Chem. 354* (1988) C 12.

served. An X-ray structure analysis of **5**[9] (Fig. 1), on the other hand, revealed some especially informative features: The four ring atoms and the exocyclic Si atom lie exactly in a plane. The steric crowding of the molecule not only forces a stretching of all ring bonds but also leads to a substantial widening of the Si2–C1–Si3 angle to 144°. As expected, the smallest bond angles inside the ring occur at the Si atoms.



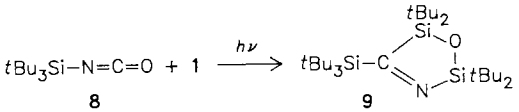


Fig. 1. Crystal structure of **5** (without H atoms). Selected bond lengths [pm] and angles [°] (standard deviations): Si1-Si2 179.8(2), C1-N 130.4(3), C1-Si2 199.6(3), C1-Si3 195.4(3); Si1-N-C1 109.7(2), N-C1-Si2 104.8(2), C1-Si2-Si1 69.5(1), N-Si1-Si2 75.8(1), Si2-C1-Si3 143.9(1).

Less unambiguous from the mechanistic standpoint is the photolysis of **1** in the presence of tri-*tert*-butylsilyl isocyanate **8**,[4] which we have investigated as first example for the reaction behavior of **3** (or also of **2**) towards cumulated double-bond systems. Here again a compound is isolated which is formally composed of **3** and **8** in a ratio of 1:1. The obvious assumption that the product[10] is formed by [2+2]-cycloaddition of **3**, either at the CO or at the CN double bond,[11] is disproved by the X-ray structure analysis[9] (Fig. 2), which rather indicates that multiple cleavage and recoupling of bonds leads to formation of the 3-aza-1-oxa-2,5-disilacyclopent-3-ene derivative **9**. The

8 **9**

formation of **9** not only requires rupture of the CO bond and insertion of the oxygen between two Si atoms, but also migration of the bulky tBu$_3$Si group from the N atom to the C atom. All the more astonishing is that the rearrangement takes place under the mild reaction conditions chosen here. Attempts to trap intermediates with other isocyanates have so far failed.

West et al.[12] recently found that the reaction of the stable tetramesityldisilene with nitrobenzene is initiated by a [2+3]-cycloaddition of the Si=Si bond to the oxygen atoms of the nitro group at which, as in the case of **9**, a rearrangement with formation of the disiloxane finally takes place. This can be regarded as indicative of a similar reaction of **8** with **3**.

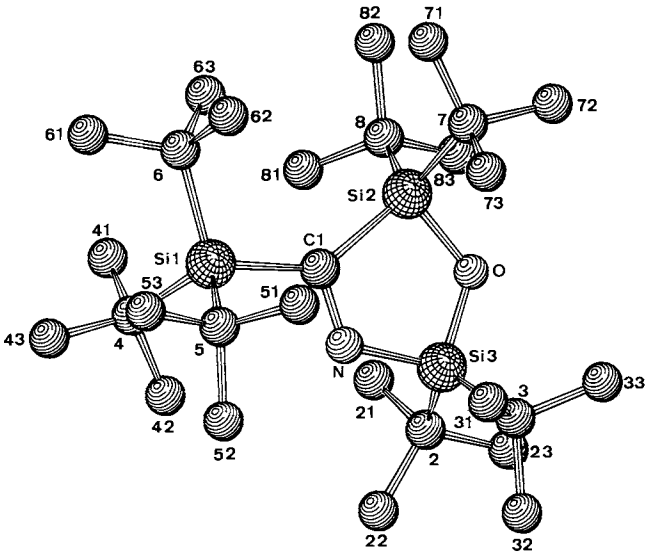

Fig. 2. Crystal structure of **9** (without H atoms). Selected bond lengths [pm] and angles [°] (standard deviations): C1-Si2 202.2(3), Si2-O 166.2(2), O-Si3 165.6(2), Si3-N 177.4(2), N-C1 129.0(3), C1-Si1 196.7(3); C1-Si2-O 93.8(1), Si2-O-Si3 118.4(1), O-Si3-N 99.2(1), Si3-N-C1 118.5(2), N-C1-Si2 110.1(2).

Experimental

5: A solution of **1** (0.65 g, 1.53 mol) and **4** (1.00 g, 450 mL) in 70 mL of *n*-hexane was irradiated with a mercury high-pressure lamp (Heraeus TQ150) until the initially yellow solution was almost colorless. The residue remaining after removal of *n*-hexane by distillation furnished, after repeated recrystallization from *n*-pentane, 0.35 g of crystalline **5** (30% yield, based on **3**). Additional **5** remained unpurified in the mother liquor (NMR signals).

9: Analogously to the synthesis of **5**, a solution of **1** (0.85 g, 2.0 mmol) and **8** (1.40 g, 5.9 mmol) in 60 mL of *n*-hexane afforded 0.32 g (20%) of crystalline **9**. Similarly as in the case of **5**, according to an NMR analysis additional **9** remained unpurified in the mother liquor.

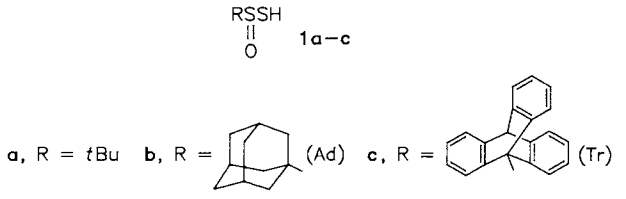
Thiosulfinic Acids: a New Class of Chiral Organosulfur Compounds**

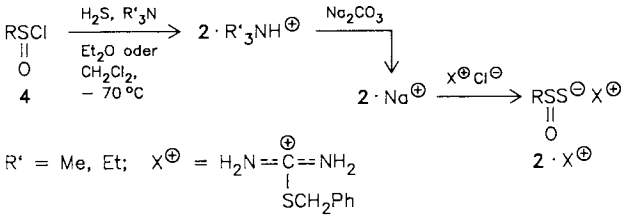
By *Marian Mikołajczyk,* Piotr Łyżwa, Józef Drabowicz, Michał Wieczorek,* and *Grzegorz Bujacz*



Dedicated to Professor Friedrich Cramer on the occasion of his 65th birthday

The well-known sulfinic acids RSO_2H[1,2] are effectively achiral because their anions are symmetrical and therefore achiral. Replacement of one of the two oxygen atoms in this anion by sulfur formally leads to the thiosulfinic acids RSOSH **1**, for which both the acid and its anion are chiral. However, to the best of our knowledge this class of organosulfur compounds has not yet been described. The only known compounds, which may be regarded to be formally derived from thiosulfinic acids, are the thiosulfinates RS(O)SR,[3] which were also obtained in optically active form.[4]

Scheme 1.



The chiral thiosulfinate anion can be described by three mesomeric forms (Scheme 1). Therefore, protonation could lead to three tautomeric forms of the acid **1** and the reaction with an electrophile $E^{\oplus}$ could result in the formation of three isomeric products.

[**] This work was supported by the Polish Academy of Sciences and the Ministry of National Education (CPBP 01.13 and RP.II.10).

We now report the first synthesis and characterization of the relatively stable salts of thiosulfinic acids **1a–c**, whose stability may be due to the sterically demanding substituents at the central sulfur atom.

Reaction of the sulfinyl chlorides **4a–c** with hydrogen sulfide and trialkylamines at −70°C in ether or dichloromethane gave, in high yields (75–87%), the ammonium salts of the acids **2**. For ease of characterization these salts were converted first into sodium and then into *S*-benzylthiuronium salts. ^{1}H and ^{13}C NMR spectra of the salts thus obtained are consistent with the thiosulfinic acid structure (Table 1).

Table 1. Selected ^{1}H and ^{13}C NMR data for salts of the thiosulfinic acid **1**.

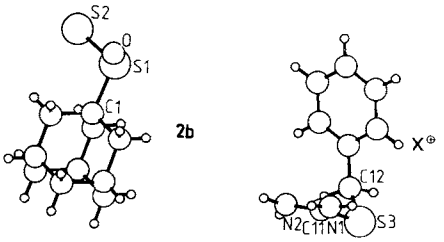
2a · $Me_3NH^{\oplus}$ [a]: ^{1}H NMR (60 MHz, TMS_{int}, $CDCl_3$): $\delta = 1.15$ (s, 9H; Me_3C), 2.80 (s, 9H; Me_3N); $^{13}C\{^1H\}$ NMR (22.63 MHz, $CDCl_3$): $\delta = 22.74$ (Me_3C), 43.53 (Me_3N), 52.7 (Me_3C–)

2b · $X^{\oplus}$ [b]: ^{1}H NMR (60 MHz, TMS_{int}, CD_3OD): $\delta = 1.7$–2.5 (m, 15H; Ad), 4.40 (s, 2H; CH_2Ph), 4.85 (s, 4H; NH_2), 7.40 (s, 5H; Ph); $^{13}C\{^1H\}$ NMR (38.93 MHz, $CDCl_3$): $\delta = 30.65$, 36.61, 43.89 (Ad), 36.75 (CH_2Ph), 66.33 (C-1 of Ad), 128.08, 129.48, 129.72, 130.07 (Ph), 138.04 ($C(NH_2)_2$)

2c · $Na^{\oplus}$ [c]: ^{1}H NMR (300 MHz, TMS_{int}, CD_3OD): $\delta = 5.34$ (s, 1H; H10), 7.21–7.35 (m. 6H), 7.59–7.66 (m, 3H), 8.54–8.57 (m, 1H), 8.98–9.01 (m, 2H); $^{13}C\{^1H\}$ NMR (38.93 MHz, CD_3OD): $\delta = 56.16$ (C10), 75.56 (C9), 123.90, 124.22, 125.29, 143.64, 143.87, 148.29, 149.67

[a] We have not been able to isolate an analytically pure salt because of slow decomposition. [b] m.p. 135–140°C (from ethanol); correct C,H,S,N analyses were obtained. [c] **2c** · $Et_3NH^{\oplus}$; m.p. 223–225°C (from chloroform/*n*-pentane); we have not been able to isolate the analytically pure salt because of facile oxidation to the corresponding thiosulfonate.

A final proof of the structure was provided by an X-ray structure analysis (Fig. 1) of the *S*-benzylthiuronium salt of adamantanethiosulfinic acid **2b**.[6] It showed a slightly distorted tetrahedral arrangement of the substituents (carbon, oxygen, sulfur and lone electron pair) around the central sulfur atom in the anion under discussion. The S1–O and S1–S2 distances of 1.536 and 2.025 Å suggest delocalization of the negative charge in the anion.



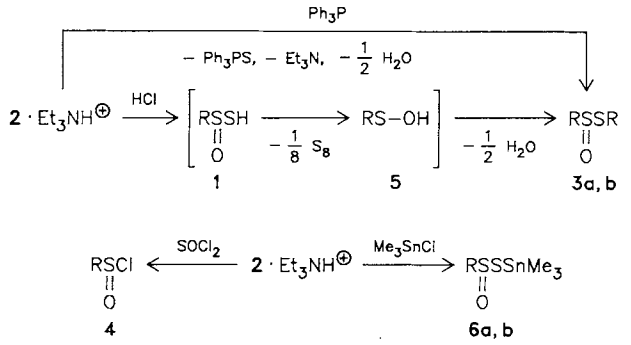


Fig. 1. Molecular structure of **2b** · $X^{\oplus}$. Important bond lengths [Å] and bond angles [°]: C1–S1 1.845(3), S1–O 1.536(2), S1–S2 2.025(9), C11–S3 1.759(3), C11–N1 1.302(4), C11–N2 1.318(4), C12–S3 1.826(3); S2–S1–O 109.70(8), S2–S1–C1 104.74(8), O–S1–C1 103.12(9), N2–C11–S3 120.9(2), N1–C11–S3 116.9(2), N2–C11–N1 122.2(2).

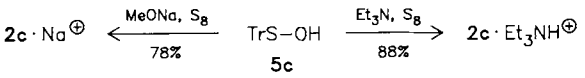
Some chemical reactions of the triethylammonium salts of **2** are summarized in Scheme 2.



Scheme 2.

The free acids **1a** and **1b** obtained upon acidification undergo a fast and almost quantitative conversion into the thiosulfinates **3a** and **3b** via the sulfenic acids **5a** and **5b**. The only exception is triptycenethiosulfinic acid **2c**, which gives, after elimination of sulfur, the stable triptycenesulfenic acid **5c**.[7] The conversion of the triethylammonium salts of **2a** and **2b** into **3a** and **3b** may also be achieved by using triphenylphosphine as a desulfurization agent. Triethylammonium salts of **2** react with thionyl chloride to give the sulfinyl chlorides **4** in high yields (60–77%). Trimethyltin chloride reacts with the ammonium salts of **2a** and **2b** to give the stannyl derivatives **6a** and **6b**[8]. Their thiolo-structure was supported by a strong IR absorption band at 1050 cm^{-1} characteristic for the S=O grouping.

Taking advantage of the fact that the sulphenic acid **5c**[7] is stable, we also found that it reacts easily with elemental sulfur in the presence of triethylamine or sodium methoxide to give the corresponding salts of **2c**.

This reaction resembles the well-known addition of elemental sulfur to dialkyl phosphites to afford monothiophosphates[9].

Experimental Procedure

2b · $Na^{\oplus}$: Triethylamine (0.46 g, 4.55 mmol) in ether (5 mL) was added to a solution of **4b** (0.5 g, 2.28 mmol) in dry ether (30 mL) at −70°C, after which hydrogen sulfide (0.08 g, 2.28 mmol) was passed through the reaction mixture. After stirring for 5 min at −70°C, triethylammonium chloride was filtered off and the ethereal solution shaken with a solution of sodium hydrogen carbonate (0.12 g, 1.13 mmol) in water (5 mL). The aqueous phase was washed with ether (2 × 10 mL) and evaporated under vacuum to give **2b** · $Na^{\oplus}$ as a white powder. Yield 0.35 g (74%).

2b · $X^{\oplus}$: *S*-Benzylthiuronium chloride $X^{\oplus}Cl^{\ominus}$ (0.49 g, 2.42 mmol) in water (10 mL) was added to a solution of **2b** · $Na^{\oplus}$ (0.5 g, 2.42 mmol) in water (10 mL) at 5°C. After 12 h at 5°C, the precipitate of **2b** · $X^{\oplus}$ was collected by filtration and recrystallized from ethanol. Yield: 0.55 g (69%); m.p. 135–140°C.

Self-Reduction of $[Ph_4P][Nb(SCH_2CH_2CH_2S)_3]$ with Formation of a Nb_2^{IV} Complex**

By *Kazuyuki Tatsumi,* Yoitsu Sekiguchi, Michiyo Sebata, Akira Nakamura,* Roger E. Cramer,* and *Thomas Chung*

The usefulness of dithiolate ligands lies partly in their ability to form transition metal complexes of diversified structural types with varying nuclearity. In spite of this advantage, the relevant chemistry of group 5 metals has not been well developed. We have recently reported the syntheses and characterization of anionic tris(dithiolato) complexes $[M(SCH_2CH_2S)_3]^{\ominus}$, $[M(SCH_2CH_2CH_2S)_3]^{\ominus}$, and $[M(SCH{=}CHS)_3]^{\ominus}$, M = Nb^V and Ta^V.[1] The 1,2-ethanedithiolato complexes undergo an unusual intramolecular rearrangement in DMF, in the presence of a trace amount of water, methanol or phenol, yielding $[MS(SCH_2CH_2S)(SCH_2CH_2SCH_2CH_2S)]^{\ominus}$.[2] In this reaction, the pentavalent metal oxidation state is retained. In contrast, in the case of the homoleptic 1,3-propanedithiolato complex of Nb^V, an interesting self-reduction was found to take place in acetonitrile to give an Nb^{IV}–Nb^{IV} binuclear complex, which in turn afforded another binuclear species when treated with methanol.

When a concentrated acetonitrile solution of $[Ph_4P][Nb(SCH_2CH_2CH_2S)_3]$ **1** was allowed to stand at room

temperature under Ar for approximately one month, the color of the solution changed from reddish-orange to red. During this time, the characteristic UV-VIS absorption bands of **1** [$\lambda_{max}(\varepsilon)$: 344 (15000), 403 (11000), 482 sh (6500)] were replaced by three new bands. From this solution, we isolated a red crystalline powder (70% yield), which was formulated as $[Ph_4P]_2[Nb_2(SCH_2CH_2CH_2S)_5]$ **2** on the basis of elemental analysis and the IR and NMR spectra.[3a,b] Treatment of **2** with methanol led to the formation of another binuclear complex **3** containing methoxy groups as dark-red crystals.[3a,c] The UV-VIS spectra of **2** and **3** are rather similar but are distinguishable, and the conversion **2** → **3** was observed to occur spontaneously. Both **2** and **3** are diamagnetic and moderately air- and moisture sensitive. Treatment of **1** with methanol did not, however, lead to formation of **3** and only an uncharacterizable powder precipitated.

$$[Ph_4P][Nb(SCH_2CH_2CH_2S)_3] \xrightarrow[CH_3CN]{1\ month} [Ph_4P]_2[Nb_2(SCH_2CH_2CH_2S)_5]$$

1 **2**

$$\xrightarrow[MeOH]{} [Ph_4P][Nb_2(OMe)_3(SCH_2CH_2CH_2S)_3]$$

3

A single crystal X-Ray structural analysis[4] showed that **3** consists of discrete phosphonium cations and binuclear niobium anions. The ORTEP plot for the anion is shown in Figure 1. The two niobium atoms are bridged by one

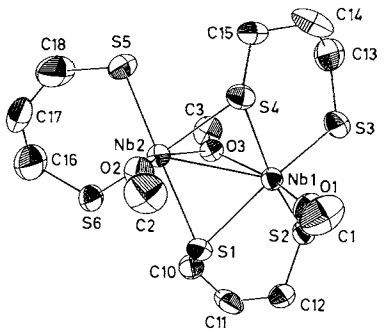

Fig. 1. The structure of the complex anion of **3** shown with 50% probability ellipsoids. Selected bond distances [Å] and angles [°]: Nb1–Nb2 2.901(1), Nb1–S1 2.537(2), Nb1–S2 2.494(2), Nb1–S3 2.457(2), Nb1–S4 2.516(2), Nb2–S1 2.568(2), Nb2–S4 2.564(2), Nb2–S5 2.464(2), Nb2–S6 2.459(2), Nb1–O1 1.860(4), Nb1–O3 2.091(3), Nb2–O2 1.846(4), Nb2–O3 2.088(4); S1–Nb1–S2 85.7(1), S4–Nb1–S3 91.3(1), S5–Nb2–S6 91.1(1), Nb1–O3–Nb2 87.9(1), Nb1–S1–Nb2 69.2(0), Nb1–S4–Nb2 69.6(0), Nb1–O1–C1 156.6(5), Nb2–O2–C2 158.7(5).

oxygen and two sulfur atoms, to provide a rare example of a triply bridged Nb^{IV} dimer. The metal–metal distance of 2.901(1) Å indicates the presence of a single bond, which accounts for the diamagnetism of **3**. The Nb^{IV}–Nb^{IV} bond length is comparable with those found in the related binuclear species $[Nb_2X_4(\mu\text{-}S)(\mu\text{-}S_2)(C_4H_8S)_4]$ (X = Cl, 2.844(2) Å; X = Br, 2.830(5) Å),[5] the semiconductor $Nb(S)(S_2)$ (3.037(3) Å),[6] and the quadruply-bridged Nb^{IV} dimer $[Nb_2Cl_4(\mu\text{-}Cl)_4(PMe_3)_4]$ (2.833(1) Å);[7] in contrast, the complex $[Cp_2Nb_2(CO)_4(\mu\text{-}S)_3]$ has a very long metal–metal distance (3.555(1) Å).[8] The more-common doubly-bridged Nb^{IV} dimers also exhibit differing Nb–Nb distances, e.g., $[Nb_2Cl_4(\mu\text{-}OMe)_2(OMe)_2(MeOH)_2]$ (2.781(1) Å),[9] $[Nb_2Cl_2(\mu\text{-}S)_3(NCMe)_4]$ (2.864(3), 2.872(3) Å),[10] and $[Cp_4Nb_2(\mu\text{-}S)_2]$ (3.2340(8) Å).[11]

The three dithiolates cause an asymmetry in the structure of **3** with two of them acting as half-bridging ligands and one as a terminal ligand.[12] Although the two pseudo-octahedrally coordinated niobium atoms are nonequivalent, their local coordination environments are similar. The oxygen and niobium atoms are nearly coplanar, with a maximum deviation (dev.) of 0.01 Å from the least-squares plane to which the S1–S2–S3–S4 (dev. 0.04 Å) and S1–S4–S5–S6 (dev. 0.07 Å) planes are perpendicular (89.5° and 89.4°, respectively). The dihedral angle between the two S_4 planes is 118.0°. Nb(1) is displaced by 0.23 Å out of the first S_4 plane towards the terminal methoxy group, while Nb(2) lies 0.24 Å out of the second S_4 plane. The Nb–O1 and Nb–O2 bonds are shorter than expected for a single bond, possibly due to $O\text{-}p_\pi\text{-}Nb\text{-}d_\pi$ donation. The Nb–S(terminal) distances resemble those in **1** (2.442(4)–2.466(4) Å), but the S–Nb–S bite angles are notably larger than those in **1** (83.9° av.) and $[Nb(SCH_2CH_2S)_3]^{\ominus}$ (81.9° av.).

The room temperature ^1H NMR spectrum of **3**[3c] shows three singlet peaks (1:1:1) for the methoxy protons and two complicated multiplets (1:2) for the dithiolate protons. This implies that the asymmetric structure is retained in solution and that the coordination geometry is rigid. For **2**, according to the ^1H NMR spectrum,[3b] the coordination mode of one dithiolate differs from that of the other four. It is possible that one dithiolate occupies a bridging position and the others terminal positions.

In the formation of **2**, the reduction of Nb is probably induced by reductive elimination of a dithiolate ligand from **1**. It should be noted here that neither $[Nb(SCH_2CH_2S)_3]^{\ominus}$ nor $[Ta(SCH_2CH_2CH_2S)_3]^{\ominus}$ gave a reduced dimer under similar conditions. In the case of the Ta^V complex, the reduction potential of −1.59 V ($E_{1/2}$ vs. SCE, quasi-reversible, in DMSO) lies well below that of **1** (−1.25 V, quasi-reversible),[1b] so that its propensity for resisting self-reduction is understandable. The reduction potentials of $[Nb(SCH_2CH_2S)_3]^{\ominus}$ (−1.20 V) and **1** are, however, very similar. Therefore, the different behavior of the two Nb^V chelates must be due to other factors, e.g., the chelate ring size. 1,2-Ethanedithiolate, which forms smaller rings than 1,3-propanedithiolate, is perhaps less well-suited for occupying a bridging or a half-bridging position in Nb^{IV} dimers, and/or is less likely to be eliminated as a cyclodithiaalkane.

[3] a) All manipulations were carried out under argon using water-free solvents. **2** and **3** gave satisfactory elemental analyses. b) **2**: red crystalline powder; ^1H NMR (400 MHz, $CDCl_3$, room temperature): δ = 1.91 (quintet, 8H, $SCH_2CH_2CH_2S$), 2.30 (quintet, 2H, $SCH_2CH_2CH_2S$), 2.67 (t, 16H, $SCH_2CH_2CH_2S$), 3.13 (t, 4H, $SCH_2CH_2CH_2S$); UV/VIS (DMF): $\lambda_{max}(\varepsilon)$ = 316 sh, 391 (16000), 470 (4100) nm; far-IR (Nujol mull): 363 (w), 345 (w), 331 (m), 311 (m), 292 (m), 283 (m), 263 (w) cm^{-1}. We have not yet been able to develop a rational synthesis for **2**. For instance, when an acetonitrile solution of **1** was refluxed for one day, formation of **2** was observed, but a large amount of uncharacterizable powder also precipitated. c) **3**: dark-red crystals; ^1H-NMR (400 MHz, $CDCl_3$, room temperature): δ = 2.29 ppm (m, 4H, $\mu\text{-}SCH_2CH_2CH_2S$), 2.36 (m, 2H, $SCH_2CH_2CH_2S$), 2.8 (m, 4H, $\mu\text{-}SCH_2CH_2CH_2S$), 3.15 (m, 4H, $SCH_2CH_2CH_2S$), 3.4 (m, 2H, $\mu\text{-}SCH_2CH_2CH_2S$), 3.57 (s, 3H, $\mu\text{-}OCH_3$), 3.74 (m, 2H, $\mu\text{-}SCH_2CH_2CH_2S$), 3.85 (s, 3H, OCH_3). The signals of the dithiolate protons were tentatively assigned on the basis of sequential decoupling experiments. UV/VIS (DMF): $\lambda_{max}(\varepsilon)$ = 316 (6600), 379 (11000), 460 (1400) nm; far-IR (Nujol mull): 423 (m), 354 (m), 336 (w), 317 (m), 297 (w), 287 sh, 263 (w) cm^{-1}.

[4] A single crystal of **3** was mounted in a glass capillary and sealed under argon. Monoclinic, space group $P2_1/n$, $a=18.593(4)$, $b=14.558(5)$, $c=15.894(3)$ Å, $\beta=105.99(2)°$, $\rho_{calcd}=1.505$ g cm^{-3}, $Z=4$, $\mu(Mo_{K\alpha})=5.45$ cm^{-1}. X-ray data were collected on a Syntax $P\bar{1}$ diffractometer in the $\theta/2\theta$ mode using graphite-monochromated $Mo_{K\alpha}$ radiation. The data were corrected for Lorentz and polarization effects, and an empirical absorption correction was applied. Of the 8831 measured reflections ($3<2\theta<50°$), 5343 observed reflections with $F_0^2>3.0\sigma(F_0^2)$ were used for the structure analysis. The structure was solved by MULTAN 80 and the standard Patterson heavy atom technique and refined to $R=0.0448$ and $R_G=0.0475$ using the SHELX 76 program. The phenyl rings of $Ph_4P^{\oplus}$ were treated as semi-rigid bodies, while the other non-hydrogen atoms were described anisotropically. A difference Fourier map after the final cycle of refinements showed a maximum residual peak of 0.8 e/Å^3 in a phenyl ring. Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD-53344, the name of the authors, and the journal citation.

BOOK REVIEWS

Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for qualified book reviewers are welcome. Publishers should send prospects or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Bundesrepublik Deutschland. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Organometallic Chemistry. An Overview. By *J. S. Thayer*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xii, 170 pp., hard cover, DM 68.00.—ISBN 3-527-26196-6/0-89573-121-5

This book is written for people with a reasonably good background in chemistry who may be interested in learning something about organometallic chemistry. Since the very definition of an "organometallic" compound is neither uniform nor completely consistent, the author has chosen to include in the "metal" portion of "organometallic" any element whose electronegativity is less than that of carbon. This definition will include elements (boron, silicon, germanium, phosphorus, arsenic and tellurium) that are often termed "metalloids".

After a brief introduction to the concept of organometallic chemistry and its nomenclature and historical development, the classification of organometallic compounds used in this book is explained. This is based on the type of bonding as follows: ionic metal–carbon bond (with a metal cation and a carbanion), electron-deficient (when an electron pair on a single carbon is shared with two metal atoms), covalent, and synergistic (involving interaction of π-electrons of an olefin—or nonbonding electrons on a divalent carbon atom—with empty orbitals on metal atoms). Chapter 2 (11 pages) describes the general methods of synthesis of the metal–carbon bond, including those using elemental metals as well as metal compounds. Chapters 3 (8 pages) and 4 (8 pages) deal with ionic and electron-deficient metal–carbon bonds, respectively. Metal–carbon σ-bonds are discussed in Chapters 5 to 7 (41 pages), divided into the reactive metals (e.g. Zn, Cd, Ga, most transition metals, many derivatives of Be, Mg and Al), the heavy metals (those of the last two rows of the Periodic Table, with relatively high electronegativities, including Hg, Ir, Tl, Sn, Pb, Sb, Bi, Pt and Au), and the metalloids (B, Si, Ge, P, As, Se, Te and higher-valent Br and I). The organization of these chapters is clear, and provides the reader with a rapid and concise view of the essential features. They cite specific literature references (up to 1985), as well as general books and reviews. Synergistic metal–carbon bonds are discussed in Chapters 8 to 10 (29 pages), including mononuclear compounds of divalent carbon, mononuclear complexes of unsaturated hydrocarbons, and polynuclear compounds. These chapters are again well presented, although additional references should have been cited in Chapter 10. To show the role of polynuclear complexes in catalysis and surface sciences, the classical reviews by *Muetterties* and *Krause* (*Angew. Chem. Int. Ed. Engl.* 1983) or by *Muetterties, Rhodin* et al. (*Chem. Rev.* 1979) would have been most appropriate (rather than a series of *nine* articles by *Maught* in *Science* 1983). The importance of organometallic compounds in biology is very well illustrated in Chapters 12 to 14 (32 pages), including pharmaceutical and biochemical uses, toxicological and biocidal aspects, and environmental occurrence and transformation. These chapters are most welcome, and will convince the reader of the broad scope of organometallic chemistry. Thus, for example, Vitamin B_{12} coenzyme was shown in 1961 to con-

tain a Co–C bond, making it the first organometallic compound known to be formed as a product of biological metabolism; or again, the first report that methylmercuric compounds can be generated by the action of microorganisms on inorganic mercury compounds appeared in 1968. Chapter 14 (5 pages) serves as a postscript, in which selected topics and papers which appeared during the preparation of the preceding chapters are mentioned. This includes synthetic aspects, compounds involving metal–metal multiple bonding, and organometallic compounds in the environment, with references up to 1986. A subject index (6 pages), an author index (6 pages) and a compound index (10 pages), all very useful, conclude the book.

Despite obvious omissions (the late *R. S. Nyholm* and *J. Lewis* should have been cited for their pioneering work on carbonyl and metal–metal bonded complexes), and some awkwardly drawn figures (e.g. erroneous perspective in Figs. 6.1 and 9.2, ring unsaturation not shown in Fig. 10.1, inconsistent representation of the carbonyl ligands in Fig. 10.3), this book is very well written and presented.

The author has emphasized topics such as organometalloid chemistry, and industrial and biological applications, which should attract the interest of a broader audience. It therefore represents a useful addition to the many monographs already available in this area, and will certainly be very helpful to beginners in organometallic chemistry, who will be further encouraged by the conciseness of the book (170 pages). More advanced students or researchers will find more detailed information in, for example, "Organotransition Metal Chemistry" by *A. Yamamoto* (Wiley, New York 1986) or in "Organometallchemie" by *Ch. Elschenbroich* and *A. Salzer* (B. G. Teubner, Stuttgart 1986).

Finally, the publisher should be complimented for the high quality at the reasonable price of 0.40 DM/page for a hard-cover book.

Inorganic Mass Spectrometry. Edited by *F. Adams, R. Gijbels,* and *R. Van Grieken.* Wiley, Chichester 1988. xi, 404 pp., bound, £ 57.50.—ISBN 0-471-82364-3

The editors of this book, who together head the Center for Microanalysis and Trace Analysis at the University of Antwerp, deserve credit for having satisfied a long-felt need for an up-to-date review on inorganic mass spectrometry; it is published as Volume 95 in the series "Chemical Analysis". As the editors themselves state in the introduction, the book appears at a time when there is considerable renewed interest in inorganic mass spectrometry (MS) in research, development and applications, and the indications of a rapid growth in its importance to the analytical chemist are unmistakable.

The first chapter (*I. Cornides*, 16 pp., 87 references) gives a chatty and amusing account of the historical background to the inorganic mass spectrometry of solids. Chapter 2 (*G. Ramendik, J. Verlinden* and *R. Gijbels*, 68 pp., 267 references) is a detailed and accurate report on spark source MS (SSMS). The principle of the method and the instrumentation are described, with an appropriately detailed treatment of the physical background. In addition to the main area of application of this method in multielement analysis of bulk samples, its capabilities for microanalysis, local analysis and depth profile analysis are discussed.

Chapter 3 (*W. W. Harrison*, 40 pp., 93 references) is concerned with glow discharge MS (GDMS), a method whose application to analysis is still quite new. It offers a very informative means for directly analyzing conducting and semiconducting solids, and commercial instruments using this method are now available. The article only covers the literature up to 1985, and is therefore not completely up-to-date, especially with regard to applications. Also the advantages of the method are a little over-generalized in places, and the disadvantages are rather played down. It turns out that a more complete and up-to-date review article on GDMS, with *W. W. Harrison* as one of its authors, has already been published elsewhere this year, which suggests that publication of the book has been delayed.

Secondary ion MS (SIMS), a method with a particularly high sensitivity, has been used for many years in surface analysis. Chapter 4 (*A. Lodding*, 48 pp., 103 references) describes the latest instrumental developments in the method, and the resulting application possibilities, including imaging SIMS. An impressive and concise account of the current state of techniques and knowledge in SIMS is presented; altogether the chapter is an excellent introduction and overview for the non-specialist.

The following chapter on laser microprobe MS (*A. H. Verbueken, F. J. Bruynseels, R. Van Grieken* and *F. Adams*, 124 pp., 303 references) is much concerned with minute details. The extent of this is apparent from such trivial statements as that the effects of electrostatic lenses are governed by the laws of ion optics, or that with the help of a computer one can easily undertake even tasks that are lengthy and laborious when carried out manually. However, when the applications are reached the information content improves, although even here the overview of the topic tends to become lost in the wealth of detail, leaving the impression that less quantity would have resulted in better quality.

Chapter 6 (*A. L. Gray*, 44 pp., 38 references) deals with MS using an inductively coupled radiofrequency plasma as the ion source (ICP/MS), giving in a relatively modest amount of space an excellent introduction and review. The basic principles and the design and functioning of the instrument are described fully in an easily understandable and very clearly presented way. With regard to the applications and the special sample introduction techniques needed, the capabilities of the method are convincingly shown using well chosen examples with detailed explanations.

Chapter 7 (*K. G. Heumann*, 76 pp., 232 references) gives a clear, precise and comprehensive account of the principles and applications of the isotope dilution method. The description of the applications is very detailed and even includes procedural rules, and consequently this contribution offers much more than just an introductory survey. This approach seems to be well justified, since the isotope dilution method can in principle give sufficient accuracy in any isotope-specific measurement problem, and it is therefore of prime interest in this context.

The eighth and last chapter (*R. Gijbels* and *F. Adams*, 18 pp., 55 references) gives an assessment of trends for the future development of inorganic MS.

The currently topical theme of MS on sputtered neutral particles (SNMS), which offers better quantitative measurements together with better depth resolution than is possible with other methods for surface and depth profile analysis, has unfortunately not been covered in this mono-

graph. Furthermore, it can be seen just by scanning the list of contents that the individual methods have received very unequal treatment as regards length, without there being, in the introduction for example, any indication of the reasons for this or of the editors' aims. The suspicion that is thereby raised, that this is a rather heterogeneous collection of review articles of different sorts, is reinforced when reading the book. The individual contributions vary greatly in breadth of coverage and in depth and quality of treatment, and also in the extent to which they are up-to-date.

As is only to be expected from a collection of individual articles, there can be no uniformity of style and presentation in this book, and it cannot offer the majority of readers a balanced treatment of the different methods included. It would certainly have helped if the editors had exercised a tighter coordination of the individual contributions, although the resulting delay in publication would have made the book less up-to-date. Its appearance should nevertheless be welcomed, as it has at present no competitor in the analyst's bookshelves, and the numerous references give rapid access to the original papers.

Arzneimittel—Fortschritte 1972 bis 1985. Edited by *A. Kleemann, E. Lindner* and *J. Engel.* VCH Verlagsgesellschaft, Weinheim 1987. xiv, 1517 pp., bound, DM 540.00.—ISBN 3-527-26329-2

This book is a supplementary volume which updates and extends the five-volume work "Arzneimittel—Entwicklung, Wirkung und Darstellung", by *Ehrhart* and *Ruschig,* which was published in its second edition in 1972. In twenty chapters by numerous experts the book deals with the progress made in pharmaceutical chemistry in the thirteen years from 1972 to 1985.

The volume begins with a short survey of drug design by *J. K. Seydel,* which in 51 pages summarizes the theory of structure-activity relationships, continuing up to molecular modelling and computer graphics.

In the second chapter (59 pp.) on enzyme inhibitors *H. Tschesche* reports on reversible proteinase inhibitors, including the renin- and angiotensin-converting enzyme inhibitors and the microbial α-glucosidase inhibitors, but makes no reference whatever to irreversible enzyme inhibitors such as α-difluoromethylornithine (see, for example, C. Walsh, *Tetrahedron 38* (1982) 871-909). However, some of these enzyme inhibitors are discussed later, along with mechanisms, when antihormones are treated in Chapter 18.

In the third, quite short, chapter (36 pp.) *T. Y. Shen* and *P. Davies* summarize the latest developments in the area of anti-inflammatory agents and the most important methods for synthesizing them.

In Chapter 4, which is also short (28 pp.), *J. A. Vida* reports on progress in psychotropic drugs, from the neuroleptics to the anxiolytic drugs.

Next, in Chapter 5 (281 pp.), several groups of authors in turn deal with new cardiovascular drugs. A short section on sympathomimetics and positive inotropic substances is followed by a very detailed discussion of the cardiac glycosides. Next antihypertensives are discussed; in addition to the pure α_1-adrenoreceptor antagonists such as Prazosin, Ketanserin is also included. After covering the centrally acting α_2-adrenoreceptor agonists of the clonidine type, the new dopamine agonists such as Fenoldopam are briefly discussed, followed by drugs with direct myogenic vasodilatory activity such as Hydralazine and Minoxidil. Also included under this class of substances is the new, very interesting potassium dilator BRL-34915, although the mechanism of its activity was not clarified until after the chapter was written.

The tables that follow listing substances with activity on the renin-angiotensin system illustrate the large number of similar and highly active ACE inhibitors that are currently being developed, and they also give evidence of the beginning of the very active phase of development in the area of renin inhibitors and angiotensin-II antagonists. Next comes a brief description of the chemical syntheses of most of the cardiovascular drugs that are listed here. The section which follows gives a survey of the development of beta-receptor blockers, with tables giving in each case the important intrinsic sympathomimetic activity (ISA). In the discussion of anti-anginal and anti-hypertensive drugs (23 pp.), the very important calcium antagonists and their syntheses are unfortunately only treated very briefly. The sections that follow summarize developments in vasoactive drugs and nootropics.

In Chapter 6 (21 pp.) *D. Bormann* and *R. Muschaweck* report briefly on developments in diuretics, but they fail to mention, in addition to the usual sulfonamide diuretics, the aldosterone antagonists of the spironolactone-spirorenone type; these are, however, discussed in Chapter 9 on steroid hormones.

In Chapter 7 (28 pp.) *A. Novakova-Banet, H. Feier, J. Müller* and *H. Zilg* discuss blood factors and clotting, and also fibrinolytics (although the plasminogen activators were not yet known at the time), and finally blood substitutes.

Chapter 8 (42 pp.) by *E. Granzer* deals with lipid regulators, briefly describing Compactin and Mevinolin, and also their use with advantage in combination with bile acid binding resins such as Cholestipol.

The first part of Chapter 9, by *W. König*, consists of more than 200 pages on regulatory peptides, and is a small monograph in itself. The treatment of the topic ranges from Somatostatin via ANF (atrial natriuretic factor), the encephalins and insulin, through to the interleukins and tumor necrosis factors (TNF); even structure-activity relationships are discussed for the important peptides. In the careful and accurate review of progress in steroid hormones by *U. Stache* in Chapter 9, Part 2 (41 pp.), the only important development missing is that of the aromatase inhibitors for future treatment of breast and prostate carcinomas, which had already emerged at the time of the review; however, this is briefly covered in Chapter 18.

The discussion of oral hypoglycemic drugs in Chapter 10 (18 pp.) by *W. Hitzel* and *R. Weyer* includes, in addition to stimulators of endogenic insulin synthesis, a brief account of some new substances such as Acarbose and Sorbinil which reduce the blood glucose level.

In Chapter 11 (87 pp.) *G. Beck* gives an overview of developments in prostaglandins, thromboxanes and leukotrienes, and assesses their likely future applications in fertility control, and in the treatment of gastric ulcers, and more especially of cardiovascular disease. Data on the new thromboxane-synthetase inhibitors and thromboxane antagonists, together with the 5-lipoxygenase inhibitors and leukotriene antagonists are summarized in short tables.

In Chapter 12 (33 pp.) *U. Achterrath-Tuckermann, G. Dressen, M. Mollière* and *J. Engel* report on progress in

respiratory drugs. In addition to the antitussives and β_2-stimulators there is a brief account of the anti-asthmatic/anti-allergic drugs, but surprisingly the very important cromoglycic acid disodium salt (Intal), although mentioned briefly in the text, does not appear in the corresponding table. In the discussion of the latest developments the potentially very important PAF antagonists are mentioned only in a single sentence, and the thromboxane antagonists are not mentioned at all, despite the fact that they might have a very important role in asthma therapy, as well as the leukotriene antagonists which are discussed in some detail.

In Chapter 13 (30 pp.) *J. Szelenyi* and *H. Schickaneder* describe the most important anti-ulcer drugs, from antiacids via histamine-H_2 antagonists to the new K^+-H^+-ATP-ase inhibitors.

Chapter 14 (118 pp.) by *W. Schröck* on antibiotics is confined to a detailed discussion of antibiotics of the β-lactam, aminoglycoside, macrolide and peptide types; all other antibiotics, e.g. tetracyclins, are either omitted or dealt with in Chapter 15 by *H. Plümpe* (65 pp.), which covers compounds with antiparasitic activity; here the latest developments in treatments against protozoa and in anthelmintics are described, including the remarkable results obtained using Praziquantel.

In Chapter 16 (33 pp.) *M. Plempel* and *J. Stetter* summarize progress on new antimycotics, and in Chapter 17 (27 pp.) *J. Hilfenaus* describes developments in antiviral agents, continuing up to Aciclovir as an inhibitor of the viral thymidine kinase; this chapter was written before work related to the AIDS virus came into prominence.

In the report on anti-tumor agents (Chapter 18, 72 pp.) *W. P. Brade* and *U. Niemeyer* discuss the cytostatic drugs, including the new platinum complexes. They then describe progress in hormones and antihormones, and discuss, amongst other topics, the biosynthesis of oestrogen and the aromatase inhibitors—including the irreversible "suicide inhibition", mention of which was omitted from Chapter 2 on enzyme inhibitors. The LHRH analogs such as Buserelin, which are also interesting in this context, receive only a brief mention here, but they were discussed earlier in Chapter 9 on regulatory peptides.

In Chapter 19 (66 pp.) a group of authors examine progress in immune stimulation and immune suppression. After discussing the immune system and how it can be stimulated by muramyl dipeptides and substances such as Levamisol or Azimexon, special attention amongst immunosuppressives is given, as expected, to cyclosporin, which represents a notable therapeutic breakthrough in this field.

In the 20th and last chapter (11 pp.), *H. G. Schwick* gives an overview of antibody serums and vaccines, without, however, mentioning monoclonal antibodies.

Leaving aside the many gaps and omissions in the material covered—e.g. chemotherapeutic compounds such as the highly effective gyrase inhibitors are missing—one finds that in many of the chapters the literature cited extends only up to 1981 or 1983, and only a few of the articles list references to work published in 1985 and 1986.

Looking at the volume as a whole, many of the chapters give very good summaries of the topics covered, and there are only a very few printing errors. Moreover, most of the authors have tried to give fair evaluations of other pharmaceutical products in addition to those made by their own firms, and to give them their rightful place.

It remains a mystery why this work, which is aimed at all scientists working in the pharmaceutical field, has been written and published in German, with the exception of the two chapters by English-speaking authors (Chapter 3 by *Chen* and *Davies* and Chapter 4 by *Vida*); this limits its readership to those who can read German texts, and these are relatively few in international terms. It inevitably limits the distribution of the work, and this in turn makes the price so high as to be prohibitive for many. For these reasons such works should in future, as a general principle, be published only in English, and it should further be borne in mind that all publications on progress in the pharmaceutical field must compete with, for example, the series "Annual Reports in Medicinal Chemistry", which is good value for money and is nearly always very up-to-date.

Schering AG, Berlin

Ions in Solution: Basic Principles of Chemical Interactions. By *J. Burgess*. Ellis Horwood, Chichester/Halsted Press, New York 1988. 191 pp., bound, £ 15.95.—ISBN 0-7458-0172-2/0-470-21059-1

Following the comprehensive monograph "Metal Ions in Solution" (Ellis Horwood, Chichester 1978, 480 pp.), the same author has now written a shorter version on the same topic, which nevertheless includes additional material and has been updated. It is aimed mainly at chemistry students, and is accompanied by two audio-cassettes (obtainable from the Royal Society of Chemistry, Distribution Centre, Letchworth SG6 1HN, Great Britain).

The contents of the book are conveniently arranged in 13 chapters. The first half deals with all the important aspects of the solvation of ions, the main emphasis being on a detailed description of the behavior of metal cations in aqueous solution. After an introductory chapter which is devoted to the dissolution of salts and the hydration of metal cations and of simple and complex anions, the second chapter introduces solvation numbers, and describes how these can be determined by NMR spectroscopy or by measuring ionic mobilities. Chapter 3 describes the types of information that can be obtained from X-ray and neutron diffraction measurements on electrolyte solutions (radial distribution functions, ion-solvent distances), and Chapter 4 gives an account of the use of spectroscopic and thermochemical methods to determine the strength of intermolecular ion-solvent interactions.

This is followed in Chapter 5 by a description of the Brønsted acid/base behavior of aqua-metal ions, their hydrolysis, and their polymerization to form polynuclear bridged aqua-complexes, and their stability constants are discussed in Chapter 6. An appropriate amount of attention is given here to selective cation solvators such as coronands, cryptands and naturally occurring crown ethers (valinomycin, monactin, monensin). Concluding this half of the book, Chapter 7 deals with the redox potentials of the aqua-metal ions and of the complexes derived from them by ligand exchange.

The second half of the book is concerned with kinetic and thermodynamic aspects of ion solvation. The first topics treated are solvent exchange reactions between solution and solvento-metal ions (Chapter 9), complex formation between solvento-metal ions and polydentate open-chain or macro(poly)cyclic ligands (Chapter 10), associative and dissociative substitution in complex ions (Chapter 11), and redox reactions involving an "inner sphere" and "outer sphere" electron transfer mechanism (Chapter 12).

The 13th and last chapter, "Past, Present and Future", summarizes the current state of research and the developments to be expected in a few selected areas of the chemistry of ions in solution (e.g. direct NMR spectroscopy of metal ions, the synthesis and applications of new highly selective macrocyclic ligands, and the importance of activation volumes for determining reaction mechanisms). At the end of the book is a useful glossary with definitions of frequently used terms, a bibliography which should encourage further reading, and a brief subject index. The book is well written from a teaching standpoint, and contains 77 tables and 93 figures. It was apparently based on a series of lectures and a workbook accompanied by audiocassettes. The sections of the book dealing with complex formation by metal ions in solution, and with the kinetics of solvent exchange between solvated metal ions and the bulk of the solvent—topics on which the author has himself made significant research contributions—are especially good.

Unfortunately a few printing errors that could confuse beginners in the field have crept in: incorrect formulas are given for ethylenediamine tetraacetate and hexamethylphosphoric acid triamide (p. 13) and for the metabisulfite ion (p. 71).

This book provides valuable, though quite demanding, reading for both the beginner and the advanced student wishing to become acquainted with the chemistry of ions in solution.

Architecture of Eukaryotic Genes. Edited by *G. Kahl.* VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xiv, 518 pp., bound, DM 195.00.—ISBN 3-527-26835-9/0-89573-809-0

This book contains a summary of the symposium on "Chromatin Structure of Plant Genes", which took place in Frankfurt/Main in 1986. Accordingly it consists of 27 individual articles based on the main lectures of the symposium, arranged under seven topic areas. Eight articles are concerned with structure and function of genes within plants or obtained from plants, while 17 articles describe, for genes from higher eukaryotic organisms other than plants, principles of structure and function that have been intensively studied, and may be generally applicable; a final article deals with the nucleosome fine structure of the lower eukaryotic organism *Saccharomyces cerevisiae*. At the beginning is an article on the structural and topological polymorphism of DNA, which is relevant to all types of organisms. The book concludes with an attempt at a general perspective on current trends in research on chromatin structure and chromatin activation in plant cells.

With the arrangement of topics adopted here the reader is first familiarized with the general DNA structure, and particularly with the organization, sequences and activity of expression signals in plant genes, then with higher level regulation mechanisms. Next comes a chapter on the properties of the DNA binding proteins in the chromatin and the structure of their genes, followed by an overview of protein-DNA interaction effects in the chromatin. Next is a chapter of central importance which describes the relationships between chromatin structure and expressional activity for a few particular genes, followed by another dealing with the transcriptional activity of the DNA and its dependence on the degree of methylation of its regulator sequences, with several examples. The last two topics covered are the long-range geometrical structure of the chromatin in the nuclear matrix, and the genetic and physical mapping of high molecular weight chromosomes.

Obviously a book dealing with such a wide range of topics in areas where intensive research is continuing can only present a snapshot of the situation, which is all that is intended, and it therefore cannot be expected to be up-to-date and complete in every detail. Instead the value of the book lies more in the insights which the individual articles give for specialists in neighboring areas, and in the very useful drawing together of these different topics under the general theme of chromatin structure and gene expressional activity, in a form which, to the best of my knowledge, is new and unique. Some of the individual articles are structured along the lines of reviews, and so have the inherent disadvantage that for the specialist their topicality lasts only until the next review article appears; others consist of summaries of the authors' own researches, and these can serve as examples for the application of similar ideas to other genes and organisms.

Because of the variety of material contained in the book, and its relatively advanced level, which in some cases is even highly specialized, the potential readership extends from the advanced student with some previous knowledge of molecular genetics, who wishes to study the organization of DNA in chromatin and the structural and mechanistic dynamics involved when genes are activated, to the specialist in a particular area who wants to have a collection of reviews of related areas at hand for consulting when needed. Both these groups of readers will be able to obtain an overview from this book, and the plentiful references provided will enable them to follow this by reading up on individual topics in greater depth. The book is also of undoubted value to the university teacher preparing specialist lectures on eukaryotic molecular genetics, and he will also find here reviews to help in course planning, and specific examples to use in his lectures. Whilst I anticipate that those buying their own copy of the book will be limited to specialists in the field, it is beyond question that it should be available in the library of every molecular genetics laboratory, both for the general education of those working in the area, and to provide reviews of the specialist topics covered.

der Universität Erlangen-Nürnberg (FRG)

Solvents and Solvent Effects in Organic Chemistry. 2nd edition, revised and enlarged. By *C. Reichardt.* VCH Verlagsgesellschaft, Weinheim 1988. 534 pp., bound, DM 108.00.—ISBN 3-527-26805-7

It was not until the last few decades that values of the acidities, basicities and reactivities of organic compounds determined by mass spectrometry showed that many properties that had formerly been attributed to the reactants are to a large extent determined by the solvents. The study of solvent effects has therefore come to occupy a central role in the whole of (organic) chemistry. For this reason alone the first edition of this book, published in 1979, was assured of success, which was further increased by the excellent preparation and presentation of the material.

The many new results and the greatly extended knowledge that have been gained in this field during the last eight years (including publications up to the beginning of 1987) have been incorporated into this considerably enlarged new edition, maintaining the same high standard. Since new facts and views concerning the solvents themselves have also come to light, the title has been extended to take account of this.

The original division into seven chapters has been retained, but the relative emphases have shifted considerably. The book begins with a chapter on "Solute-Solvent Interactions" (45 pp., 303 references), in which those currently held concepts that are of general validity are summarized. In addition important effects such as solvophobic interactions and micelle formation are discussed. "Classification of Solvents" (26 pp., 171 references) deals with their classification according to their various physical and chemical properties (e.g. acids and bases). Also included here are specific solvation effects, and recent attempts using multivariant statistical methods (chemometrics) to arrive at a rational classification of solvents.

The chapter on "Solvent Effects on the Positions of Homogeneous Chemical Equilibria" (41 pp., 229 references) covers not only the classical effects on acid-base and keto-enol equilibria (including the most recent data, with also gas phase data for comparison), but also solvent effects on conformational, valence isomerization and electron transfer equilibria. The next chapter on "Solvent Effects on the Rate of Homogeneous Chemical Reactions" (171 pp., 769 references) has undergone the greatest enlargement, as is evident from the remarkably large bibliography alone. Qualitative observations, quantitative measurements and theories are discussed, with examples from a very wide range of reaction types, and effects produced by external pressure, molecular sieve action and liquid crystalline reaction media are described.

The important topic "Solvent Effects on Absorption Spectra of Organic Compounds" (53 pp., 434 references) has also been updated to the latest situation. In addition to the classical effects on UV-VIS and IR spectra, solvent effects on ESR and NMR spectra are also described. The final chapter "Empirical Parameters of Solvent Polarity" (66 pp., 287 references) has been rewritten because of the large number of new papers that have been published. The description of the now well-known Y, Z and E_T scales has been enlarged to include also some newer characteristic quantities, and properties specific to the solvents, e.g. acceptor and donor properties. The comparison of different empirical scales and the detailed discussion of the controversial multiparameter relationships is especially helpful.

There is a welcome addition in the form of an appendix which contains numerous tables listing the properties of solvents, methods for purification, and areas of use in spectroscopy and synthesis; information on toxicities is also included.

It can already be seen from this brief description of the contents of the book that one could scarcely imagine any other monograph which would treat the whole field of solvent effects so comprehensively without becoming unacceptably long. One gets the impression that the literature has been very carefully reviewed and evaluated. The well chosen examples enable the reader to quickly understand each type of problem, and the detailed bibliography allows him to extend his reading both in breadth and depth. Anyone wishing to learn about solvent effects or to investigate them, or who wishes to find typical examples of effects on equilibria and reactions, will find this book to be good value. For these reasons it belongs not only in every library but also at the chemist's bench, and an economical paperback edition of the book would be a very welcome addition.

Siegfried Hünig [NB 937 IE]
Institut für Organische Chemie
der Universität Würzburg (FRG)

Zur Konformation des Cyclohexans. (Ostwalds Klassiker der exakten Wissenschaft, Band 274.) By *H. Sachse* and *E. Mohr*. Akademische Verlagsgesellschaft Geest & Portig, Leipzig 1987. 152 pp., paperback, DM 21.00.—ISBN 3-321-00025-3

In 1885 *Adolf von Baeyer* assumed in his strain theory that all cycloalkanes had a planar ring of carbon atoms. This view was challenged five years later by *Hermann Sachse*, who proposed non-planar chair and boat structures for the important case of cyclohexane. He also correctly recognized the possibility of chair inversion in cyclohexane, yet overestimated the strain requirements, and concluded that inversion could not occur at room temperature. This led him to describe the *cis*- and *trans*-cyclohexane-1,4-dicarboxylic acids as conformational rather than configurational isomers. As a corollary of this, he further concluded that for monosubstituted cyclohexanes one should expect two stable and separable isomers with axial and equatorial orientation of the substituent respectively. Since this could not be backed by experiment, and probably also as a consequence of the eminent authority of *von Baeyer*, the work of *Sachse* gained no recognition and fell into oblivion for many years to come. It was not until 25 years later (1915), long after *Sachse*'s premature death in 1893, that *Ernst Mohr* again took up the cyclohexane problem, and made it clear that "no objection whatsoever" could be raised against *Sachse*'s ideas regarding the non-planar structure of cyclohexane, provided the inversion barrier is low enough. A breakthrough in favor of the non-planar structure of cyclohexane eventually came from the firm conclusion reached by *Mohr* in 1922 that *both* stereoisomers of decalin should exist, followed almost immediately (1923) by *Walter Hückel*'s experimental verification of this prediction. On this matter, *Mohr* had engaged in a controversy with *Richard Willstätter*, one of *von Baeyer*'s former students and late supporter of a planar structure of cyclohexane, who shortly earlier (1921) had declared *trans*-decalin could not be made due to excessive strain.

The present booklet is preceded by an introduction by editor *Horst Remane*, describing some elements of conformational analysis (9 pages): present-day significance, some basic facts, historical developments. Biographical details and an account of the scientific achievements of *Hermann Sachse* and *Ernst Mohr* follow (13 pages). Mention is made here of both pioneers' grave personal lives overshadowed by serious illness. *Sachse* died at an age of only 31, *Mohr* at 53. The central part of the book is, of course, taken up by the reprints of *Sachse*'s two key publications and three relevant papers by *Mohr*:

1) H. Sachse: Über die geometrischen Isomerien der Hexamethylenderivate, *Berichte der Deutschen Chemischen Gesellschaft 23* (1890) 1363–1370.
2) H. Sachse: Über die Konfigurationen der Polymethylenringe, *Zeitschrift für Physikalische Chemie 10* (1892) 203–241.

3) E. Mohr: Die Baeyersche Spannungstheorie und die Struktur des Diamanten, *Journal für Praktische Chemie 98* (1918) 315–353.
4) E.Mohr: Zur Theorie der *cis—trans*-Isomerie des Decahydronaphthalins, *Berichte der Deutschen Chemischen Gesellschaft 55* (1922) 230–231.
5) E. Mohr: Zwei spannungsfreie Cycloheptanmodelle, *Journal für Praktische Chemie 103* (1922) 316–328.

The original papers are annotated with comments by the editor, which make up the last 13 pages, including an author index.

Some critical comments follow concerning the editing of the little book. The introductory section on fundamentals of conformational analysis appears somewhat drab and outdated. The origin of the rotation barrier in ethane (p. 8) is actually pretty clear (R. M. Pitzer, *Acc. Chem. Res. 16* (1983) 207). It is rather disconcerting to detect just in *this* text that the characterization of the stationary points of the inversion process of cyclohexane has not been gotten right (p. 10, Fig. 5).

The editor has taken much care in supplementing the old nomenclature by more recent conventions, but in my view has gone a little too far, as the present historical context demands a tender approach indeed. For example, on page 14 it is noted *expressis verbis* "... Jod [Iod, H. R.]"; *un peu de trop*, it seems to me! Again, wherever the name "Hexamethylen" occurs in the original papers, and this happens frequently, of course, the reader is invariably and relentlessly instructed that the glorious modern term is "Cyclohexan". In favor of the editor, let us assume that the editing program of a computer has performed its stubborn task here! I found the alteration of "Benzol" in the original papers to "Benzen" very irritating, since even modern German usage on the whole still prefers the old "classical" variant. The editor had indeed better avoided this inept interference, especially since he ultimately refrained from introducing the new word in the titles of the cited publications (see, for example, the bizarre situation on p. 82, ref. 12).

As the original papers have not been directly reproduced, but have instead been newly type-set and annotated, some errors have naturally crept in here and there. For example, in connection with note [5] on p. 30 the proper spelling is "Kohlenstoffatom*e*." It is to be hoped that the numerous analytical relationships in *Sachse*'s second paper have not suffered; one error at least is perceptible in the first expression on p. 54. In Fig. 1 and, more particularly, Fig. 2 of the first paper by *Mohr*, the perspective is wrong, while Figs. 4, 6 and 20 are turned upside-down.

On p. 144 it is stated in note [42] that the twist forms of cyclobutane interconvert by pseudorotation. In actual fact, this process is to be referred to as a ring inversion, since the planar four-membered ring allows only a single type of non-planar deformation (normal coordinate), which necessarily cannot be degenerate. A pseudorotatory degree of freedom corresponds to a double degeneracy, which is only possible in rings with five or more members.

Despite all this criticism, it is to be welcomed that the publishers of the series "Ostwalds Klassiker" have devoted a volume to the history of elucidation of the cyclohexane structure, and thereby also to the core of conformational analysis. The booklet is recommended to everyone interested in the history of the development of basic concepts of modern chemistry, especially as the price is within reach of even small purses.

Paving the Way ...

ADVANCED MATERIALS has made a successful start. In 1989 it will continue to be part of ANGEWANDTE CHEMIE but may be subscribed to separately and will be available in its own specially designed cover,[*] which shows an idealized picture of a microfabricated structure of a kind commonly used in microelectronics. The decision to pave the way for ADVANCED MATERIALS to become a journal in its own right has been made in response to many requests by scientists and engineers from various disciplines other than chemistry, bearing witness to the accuracy of the message conveyed in the first editorial in May last year:

Modern science and technology rely on specialists. Nevertheless, the complexity of many problems is all too often an obstacle to gaining a deeper understanding of physical and chemical phenomena. In particular, the development of advanced materials and new technologies requires the joint efforts of many specialists from a variety of disciplines. The nature of ceramics, polymers, composites and other new materials is such that successful processing must integrate the individual steps of molecular and microstructural design, engineering, testing and manufacturing. The once common distinction between the product, its function in a system, and the material from which it is made has lost its meaning in a context wherein new materials are created on demand to serve special requirements. This implies that a multidisciplinary team of experts is more likely to be successful in the development and application of advanced materials than are individual researchers working within the limits of their special field.

It is always surprising to see that despite the diversity of all the materials in use and under development, the concepts, phenomena and transformations involved in making and using ceramics, metals, polymers and composites are strikingly similar. Important features are phase equilibria, phase transformation mechanisms, defect structures, flow and fracture mechanisms, structures of crystals and glasses and their relationships, internal boundaries and their contribution to macroscopic behavior, the motion or confinement of charge carriers, the statistical mechanics of assemblies of subsystems; these features not only serve to characterize the individual materials in which they were first studied, but also determine the behavior and performance of other materials which at first sight are totally unrelated.

It is this intellectual relationship between the phenomena that are seen in different materials and between the seemingly distinct features that are found in the same material, which has given birth to *Materials Science* as a discipline in its own right. One of the most challenging tasks is to provide the link between the thinking of the chemist who considers materials mainly in terms of structure and dynamics on the atomic and molecular scale and the concepts of the physicist whose models are often based on the continuous nature of matter. Moreover, materials science integrates important aspects of engineering in so far as certain properties of materials arise solely from the process of manufacturing owing to the physical and chemical methods of handling. The latter is most obvious in modern polymer materials where the supermolecular structure of the constituent chain molecules is entirely determined by the processing methods.

Recent years have witnessed an unprecedented explosion of new structural materials. Today the place of technological change due to the availability of more and more specialized high performance materials is rapid. We are only beginning to realize the opportunities provided by the new materials. In addition to changing the engineering landscape, advanced structural materials have also altered traditional policies regarding materials. Historically, national interests in materials have centered around the problem of shortages of supply of certain "critical" ores and minerals. The potential of the new materials such as high performance composites goes far beyond substitution. They provide performance and manufacturing advances which cannot be achieved with traditional metals and they are often the key for new technologies. Therefore, an active governmental role in accelerating the development and commercialization of such materials is seen in all major industrialized countries.

ADVANCED MATERIALS

Advanced materials are now ranked together with microelectronics and biotechnology as the most promising "high-tech" industries of the future. With the rise of materials science as a recognizable discipline, many new journals covering different aspects of the field have been founded, all of them publishing either original papers or long, in-depth reviews. In addition, there exist series of books, a plethora of monographs and even an encyclopedia for this new discipline. What the materials community is still lacking is a truly international journal that concomitantly provides stimulating short reviews comprehensible to the many subgroups of the discipline and highly topical short communications that are of interest to more than one discipline; such a journal should also present highlights from the recent original literature, conference reports, book reviews, information about funding programs and materials science institutes, as well as other important news, i.e., all those ingredients that make a journal enjoyable and timely. ADVANCED MATERIALS is intended to serve this purpose.

The program is illustrated best by presenting the authors and titles of the reviews published in the first six issues:

H. Möhwald
Controlling the Microstructure of Monomolecular Layers

J. G. Bednorz, K. A. Müller
Perovskite-Type Oxides—the New Approach to High-T_c Superconductivity (Nobel Lecture)

W. A. Kaysser, G. Petzow
Advanced Materials by Powder Metallurgy

M. T. Reetz
Anionic Polymerization of α-Activated Olefins

J. W. Rabalais et al.
From Carbon Beams to Diamond Films

D. Haarer, A. Blumen
Polymeric Photoconductors—New Concepts

H. Yanagida
Intelligent Materials—A New Frontier

R. Schöllhorn
From Electronic/Ionic Conductors to Superconductors: Control of Material Properties

Z. Yoshida, T. Sugimoto
New Donors of Molecular Organic (Super)Conductors

M. Antonietti
Microgels—Polymers with a Special Molecular Architecture

H. Inokuchi
New Organic Superconductors

Thus ADVANCED MATERIALS covers all aspects of materials science, but especially genuine new materials and methods for their preparation, modification and investigation; important theoretical concepts are also discussed. Attention is always focused on an interdisciplinary approach. The key question is, what does the physicist want to know from the chemist and vice versa, and what do both have to communicate to the materials scientists? ADVANCED MATERIALS is planned to stimulate fruitful discussions and to promote cooperation between scientists from different disciplines.

Finally, it is important to note that ADVANCED MATERIALS now accepts short communications for publication (see Notice to Authors on the following pages). With this addition to the publishing program ADVANCED MATERIALS features

- editorial essays
- short reviews
- short communications
- highlights from the literature ("research news")
- news from the materials science scene
- book reviews
- conference reports
- conference calendar

and serves the needs of a rapidly growing materials science and engineering community. It should help to pave the way for fruitful cooperation.

ADVANCED MATERIALS

Notice to Authors

1. General Information

ADVANCED MATERIALS appears monthly as part of Angewandte Chemie and publishes short review articles, communications, research news, conference reports, book reviews, a conference calendar and correspondence. Contributions for all sections must be submitted in English. Manuscripts (original and one copy) should be submitted to the following address:

ADVANCED MATERIALS
Postfach 101161
D-6940 Weinheim
Federal Republic of Germany

Authors of review articles and communications will receive immediate acknowledgement of receipt of their manuscript.

2. Type of Contributions

2.1. Review Articles

Review articles should deal with topics of current interest in any area of materials science and engineering, and should be written in such a way that they are comprehensible to the large and heterogeneous readership of ADVANCED MATERIALS. Rather than an assemblage of detailed information with a complete literature survey, a critically selected treatment of the material is desired; unsolved problems and possible developments can also be discussed, applicational aspects should be highlighted. Although review articles are generally written upon invitation, unsolicited manuscripts are also welcome provided their contents are in keeping with the character of the journal; in any case, authors wishing to write a review article should contact the editor as early as possible.

A review article should be clearly structured. A *lead-in* (maximum length half a page of manuscript), which should not be a mere summary of the article, but rather an "appetizer," must precede the text itself; this should arouse the readers' interest—particularly those not familiar with the area. The first section of the review article itself, the *introduction*, should primarily introduce the nonspecialist to the subject in as clearly and lively a way as possible. A review article should conclude with a section entitled *summary and outlook*.

Length: A review article should consist of a manuscript having up to 15 pages of pure text (A4 format, *double* spacing, ca. 60 typewriter strokes per line); footnotes and literature citations, tables, formulas, schemes, and figures, in a number appropriate to the text and topic should be submitted on separate sheets. If a longer article is planned, the agreement of the editor should be sought as early as possible. Short review articles (8–10 manuscript pages of pure text) are *highly welcome* and are generally published more rapidly.

2.2. Communications

Communications are short notes describing preliminary or complete results of experimental or theoretical studies covering all branches of materials science and engineering including materials related chemistry and physics. A communication must be of general interest with respect to its significance, novelty, or wide applicability; it must at least contribute to the development of an important area of research and should be written in such way that the nonspecialist is able to recognize the significance the author attaches to his results. Contributions which do not satisfy these criteria will not be accepted for publication even if they are factually and formally beyond reproach. In reaching a decision the interest of the reader, and not that of the author, is paramount. *Therefore, the first paragraph of a communication should give a short explanation of what is being reported, why the investigation was undertaken, and what findings have been made.*

Usually, the quality of each communication is assessed by two independent referees. In general, a decision to accept or reject a communication will be made within four to six weeks; the result is then communicated to the author immediately. Authors who are requested to alter their manuscripts should send the revised version within three months to the editorial office; otherwise, a communication could be considered to have been withdrawn.

Justification: A short text justifying why a preliminary communication should appear in ADVANCED MATERIALS must accompany the manuscript. The justification should facilitate making a decision to either accept or reject the article.

Length: Inclusive of all literature citations, footnotes, and tables, a communication should consist of a manuscript of not more than six pages (A4 format, *double* spacing, ca. 60 typewriter strokes per line); a limited number of figures and formulas may be added. Longer communications will be accepted only if their quality warrants special consideration; otherwise, they will be returned immediately.

Only publications that have already been published or are in the press should be cited; copies of publications in press should be submitted along with the manuscript. Unpublished results and lectures should only be cited for exceptional reasons. Details that could be of importance to the referees, but that are unlikely to be of interest to the reader, can be submitted as an enclosure.

2.3. Research News, Conference Reports and Book Reviews

Research news, conference reports and book reviews are usually written on invitation. Suggestions for research results to be highlighted, conferences to be covered and books to be reviewed and for authors are welcome.

3. Manuscript Preparation

To prepare their manuscript formally beyond reproach, authors are requested to carefully study comparable articles in a recent issue of the journal; this is conducive to a speedy handling of a manuscript. American spellings should be used throughout: consult *Webster's Third New International Dictionary of the English Language*, G. and C. Merriam, Springfield MA, 1965. Useful, general hints for preparing manuscripts are to be found in such books as

The ACS Style Guide. American Chemical Society, Washington 1986; *The Chicago Manual of Style*, 13th edition, University of Chicago Press, Chicago 1982. H. F. Ebel, C. Bliefert, W. E. Russey, *The Art of Scientific Writing*, VCH Verlagsgesellschaft, Weinheim 1987.

Review articles should be divided into sections and subsections (1. ..., 1.1. ..., 1.1.1. ...) which are to be provided with headings. The section numbers should be referred to in cross references.

Communications should not be divided into sections. However, experimental details should be summarized separately under the heading *Experimental Procedure*. The literature references and footnotes should have as little text as possible.

Manuscripts should be typed on one side of A4 format paper using *double spacing* and ca. 60 typewriter strokes per line; a ca. 3-cm margin should be left free at the top, bottom, and left-hand side of each page, and a ca. 2-cm margin on the right-hand side. Italics are designated by single underlining, bold type by double underlining.

3.1. First Page

Both the title, *which should be as succinct as possible*, and the *full* fore- and surnames of the authors should be typed using lower and upper case letters. An asterisk after the name of the author to whom correspondence should be sent refers to a footnote at the bottom of the same page where the respective address can be found. This footnote contains the names of the authors with their academic titles. If necessary, a second footnote on this page should contain the series title and series number as well as the reference of the last article in the series. In addition, this footnote should also contain, if necessary, the names of institutions, companies, and individuals who have supported the work.

3.2. Nomenclature, Symbols, and Units

The rules and recommendations of the International Union of Pure and Applied Chemistry (IUPAC) and the International Union of Pure and Applied Physics (IUPAP) should be adhered to.

3.3. Abbreviations and Acronyms

Abbreviations and acronyms should be used sparingly and consistently. Where they first appear in the text they should—apart from the best known exceptions—immediately follow the complete term in parentheses. In review articles where a number of abbreviations and acronyms occur these can be explained in a footnote on the first page.

3.4. Chemical Formulas

Chemical formulas should be sketched with stencils or prepared with a printer using a computer graphics program. Formulas should be numbered consecutively with Arabic numerals and Roman lower case letters; these are to be doubly underlined in text, e.g., 1, 2a. Abbreviations such as Me, Et, *n*Br, *i*Pr, *s*Bu, *t*Bu, and Ph (not ϕ) may be used in formulas; however, their use should be consistent.

3.5. Equations

Mathematical, physical and chemical equations should if possible be numbered consecutively with Roman lower case letters in parentheses. Greek letters and special characters must be clearly recognizable (if necessary, an annotation should be supplied in the margin, e.g., Greek small case psi); in addition, it must also be evident whether a symbol should lie on the line or appear as a sub- or superscript, whether it should be in italics or boldface.

3.6. Figures

Originals are required if line drawings or photographs (sharply defined, high-contrast, without masking screen, black-and-white) are used. All figures are to be numbered with Arabic numerals in the sequence in which they are referred to in the text and are to be supplied with a comprehensive legend. Color photographs can be reproduced.

Formulas and figures should be capable of being reduced either to widths of 5–8 cm or 14–17 cm. *Symbols and captions must be 1.5–2.0 mm large after the reduction process.* Insofar as possible, all lettering should roughly have the same size.

3.7. Tables

Tables should be provided with a brief title and should only be subdivided by three horizontal rules (head rule, neck rule, foot rule). Tables having only one or two columns and columns having only one or two entries are to be avoided. For footnotes in tables, Roman lower case letters set in square brackets are to be used. All tables are to be numbered using Arabic numerals in the sequence in which they are referred to in the text.

3.8. Literature References, Footnotes

References to literature or to footnotes in the text are to be set in square brackets (e.g., [1], [2a, b], or [1–3]). References and footnotes are to be numbered *consecutively* and arranged at the end of the manuscript. Mode of citation: forenames (initials) and surnames of all authors, abbreviated form of the title of the journal (singly underlined; abbreviated according to *Chemical Abstracts Service Source Index*, volume number (singly underlined), year of publication in parentheses, page number (on which the publication begins). Example: a) B. Müller, A. Smith, Angew. Chem. 95 (1983) 24; Angew. Chem. Int. Ed. Engl. 22 (1983) 19; b) C. von Zeta, J. Chem. Soc. Chem. Commun. 1983, 5312. When citing a book, its title should be underlined. Example: B. Müller in A. Smith (Ed.): Chemistry, An Introduction, publisher, publisher's location and year of publication, page number.

4. Galley Proofs and Reprints

The author to whom correspondence should be addressed will receive two galley proofs of both the German and the English versions of an article; one copy of *each* version should be corrected and returned immediately together with the duly completed forms for ordering complimentary (30 for review articles, 25 for communications) and extra reprints.

Advanced Ceramics for Biomedical Applications

Bioinert Ceramics
Bioactive Ceramics
Glass and Oxide Ceramics
Implant Devices

By Günther Heimke*

1. Introduction

The broad exploration of the possible improvement of hard tissue replacements by the application of ceramic materials was initiated by *Hulbert*[1] and *Hench*[2] in the late 1960's. It was soon realized that, from the large number of ceramic materials, only a few have a combination of properties which made them reasonable candidates for uses in reconstructive surgery. These few have been grouped into two main categories according to the reactions they provoke in the surrounding bony tissue: The one does not or nearly not influence the adjacent tissue biochemically. Therefore, it was termed "bioinert". The materials in the other group were found to have a really fascinating ability; they can bond to living bony tissue in the sense of a gluing effect, but without the addition of an adhesive. They are called "bioactive" materials.

From the point of view of the introduction of these ceramics into medicine it might be called a happy coincidence that, at about the time these materials became available to implantology, some inadequacies of the previously used materials and material combinations were realized: In the mid 1960's, total hip replacements had become a standard treatment after the introduction of polymethylmethacrylate (PMMA) as the so-called bone cement.[3] By 1970, increased reoperations stimulated efforts to find the causes for the failures. In the early 1970's, it was widely agreed that the soft tissue layer, which separates the surface of the PMMA along most parts of the interface from the normally proliferating bony tissue, is the weakest link in this chain.[4] It was also recognized that polyethylene wear particles contributed, among other things, to a thickening of the soft tissue layer and, therefore, to implant loosening. In dentistry, a direct correlation exists between the thickness of the soft tissue interlayer, the mobility of the implant, the pocket depth of the gingiva surrounding the implant, and the probability of implant failure.[5] At that time, it was generally assumed that a basic cause for the formation of the soft tissue interlayer was the chemical instability of the materials used, mainly the stainless steels, cobalt-based alloys, and the PMMA. This instability resulted in solution products (metal ions or monomers) disturbing the highly sensitive differentiation processes necessary for undisturbed bone formation.

The particular type of ceramic biocompatibility raised hopes of avoiding such soft tissue interlayers and thereby achieving direct anchorage of implant devices. Soft tissue free implant fixation was termed osseo-integration. For joint replacements, the low friction and high wear resistance of alumina ceramics offered an additional advantage.

2. Bioinert Ceramics

The main representative of the bioinert materials is the high purity, high density alumina ceramic. Other oxide and mixed oxide ceramics have also been tested for their biological responses but were found only to approach the compatibility and the other favorable combination of properties of the alumina ceramic.[6, 7]

Soon after the early publications several groups extended and detailed the studies of these new materials in different directions: *Boutin*[8] immediately commenced clinical trials and, thus, was the first to insert a hip prosthesis containing an alumina ceramic component into humans, and *Griss* and *Heimke*, as summarized in a review,[9] began detailed studies of the tissue reactions and the possibilities for cement-free anchorage of hip joint components.

Their initial experiments, in which the test pieces were placed in the bony tissue under nearly load-free conditions, confirmed the high degree of tissue compatibility of high-purity alumina and the adequacy of the definition of the term "bioinert" given in Table 1. It was recognized that the reorganization of the bony tissue adjacent to an alumina implant follows exactly the same sequence of reactions characteristic of fracture healing. Further experi-

Table 1. The concept of a bioinert material.

Requirement	Result
"Nothing goes into solution": leakage of ions or other matter from the implant into the surrounding tissue below detectability by the cells and without any systemic effects	No biochemical influence on cell differentiation and proliferation No biochemical information to the cells about the presence of the implant
Strong and fast absorption of molecules contained in body fluent so that the surface of the implant is completely covered (coated) by the body's own matter	No enzyme reactions The implant is "camouflaged" against the host's immune system No foreign body reactions

[*] Prof. Dr. G. Heimke
Department of Bioengineering
Clemson University
301 Rhodes Eng. Res. Center
Clemson, SC 29634-0905 (USA)

ments with fully functional total hip replacements in sheep and dogs revealed the influence of an incompletely stable initial implant fixation and enabled the design criteria to be defined, allowing for a stable and reliable anchorage of the joint components in the adjacent bony tissue. Simultaneously, alumina wear particles were tested biologically as well as the carcinogenicity of this material.[9]

The essential biomechanical requirement for fracture healing is to avoid any shear motion along the interface. In addition to fracture healing, however, it was found that, for maintaining the close bone contact with such a bioinert prosthesis, it is essential to preserve this condition of motionlessness along the interface concerned for the entire lifetime of the prosthesis.

Basically, there are only two mechanical situations allowing for a motionless contact: the load-free situation and an orientation of the interface perpendicular to the forces acting along this interface. Thus, all load-bearing implants must present to the adjacent bony tissue sufficiently large interfaces that are transmitters of mostly pure pressure. Surfaces along which the forces are mainly transmitted parallel (resulting in shear along the interface) are separated by a soft tissue interlayer from the surrounding bone and therefore cannot contribute to osseo-integration and load transmission. Figure 1 summarizes this concept schematically. Clinical experience has shown that the requirement of perpendicularity of the forces meeting the interface allows for a deviation of up to $\approx 15°$.

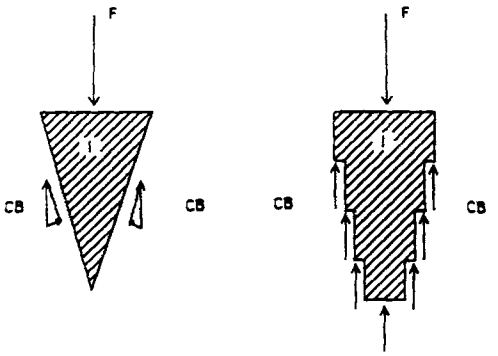

Fig. 1. Schematic representation of the shape dependence of the forces (F) acting along the interfaces of implants (I). Left: large tangential component resulting in shear along the interface; right: pure pressure at the surfaces of the steps, avoiding tangential movements along these surfaces (CB = cancellous bone).

The validity of the concept of the purely stress-and-strain-field controlled tissue reactions along the interface to implants of a bioinert material like Al_2O_3 ceramic was confirmed by the discovery of the "load-line-shadow effect" by *Büsing* et al.,[10] in 1979. The essentials of this effect are schematically described in Figure 2.

According to the previously described requirements for close bone contact, such contact could not be expected along mainly tangentially loaded interfaces such as the cylindrical surfaces of the Tübingen dental implants shown in Figure 3. However, evaluation of the tissue surrounding two implants, which had been in situ and functioning well for many years and which became available for inspection because of an accident the patient suffered, revealed a close bone apposition not only along the pressure transmitting interfaces (the surfaces of the steps connecting the cylinders of different diameters) but also along the cylindrical, mainly tangentially loaded areas. Because of the interlocking effect, due to the presence of the lacunae, and because of the much higher stiffness of the implant as compared with the surrounding, mostly cancellous bone,

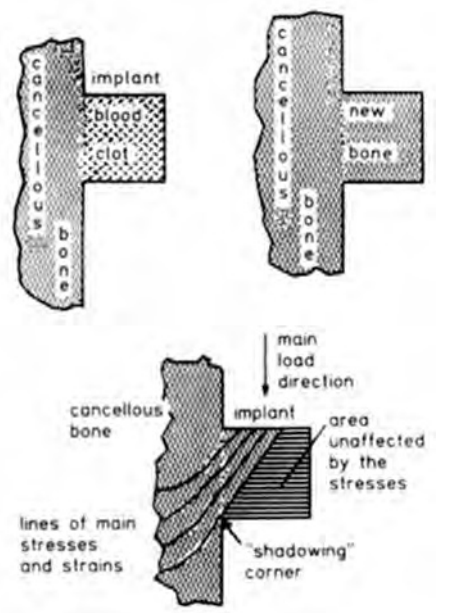

Fig. 2. The Load-Line-Shadow Effect. Top left: after press-fitting the implant, the lacunae are filled with a blood clot. Top right: during the healing-in phase the blood clot serves as a scaffold for new bone formation, filling the lacunae homogeneously. Bottom: After loading, the bony tissue reorganizes according to the stress and strain field present, resulting in an area of decalcification where no stresses are acting, the area which is "shadowed" from the load lines.

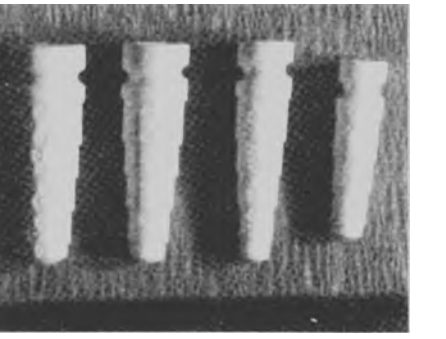

Fig. 3. Frialit Dental Implant, Tübingen type, made of medical grade alumina ceramic. Note the stepped shape of the intraosseous portion with lacunae along the cylindrical surfaces. The grooves parallel to the axis are for additional rotational stabilization. The circular groove around the coronal part is to accommodate the margin of the gingiva.

ADVANCED MATERIALS

the relative movements created by all load changes are accommodated by the elastic deformation of these bony structures some distance from the surface of the implant rather than by shear movements along the interface. Thus, an interdependence exists between the shape of the implant and the reactions of the bony tissue surrounding it. To achieve a stable and reliable osseo-integration, the shape of the implant must be chosen so that the stress and strain field created by its insertion allows for remodeling reactions resulting in a close bone contact along as many interfaces as possible.

3. Bioactive Ceramics

A fascinating bond formation was observed between bony tissue and some Ca-phosphate containing glasses and glass ceramics. It was studied in detail by *Hench* et al.[2] and *Blenke* et al.[11] Some time after the insertion into bony tissue, the formation of a silica rich zone along the interface was observed from which some sodium, calcium and phosphate ions had obviously leached out. It was hoped that this zone would act as a diffusion barrier, preventing the leaching out of these ions from continuing. The mechanical strength of the interface in tension or shear was tested after the animals were sacrificed; high forces were needed and the samples mostly ruptured inside the glass or the bone. This mechanically strong bond was found after a healing-in period during which the condition of motionlessness along the interfaces, as in fracture healing, was observed. It was maintained under loading conditions as long as the forces transmitted through the interfaces concerned were mainly perpendicularly oriented, as was the case in the early experiments of *Hench* et al.[2] Along mainly tangentially loaded interfaces, however, the bond could not be maintained reliably. It appears that the silica-rich layer is disturbed again and again by shear forces, resulting in a continuation of the leaching process.

A similarly strong attachment of bony tissue had been observed with some Ca-phosphate ceramics by the mid-1970's. The details of bonding, however, were found to be very different from the bond to the glasses. A summary of information gained after the first decade was given by *Jarchow*[12] and *de Groot*.[13] The main representatives of these bioactive ceramics are hydroxylapatite $Ca_{10}(PO_4)_6(OH)_2$, which, with some variations, is identical with the mineral phase of bony tissue and tricalciumphosphate $Ca_3(PO_4)_2$; this can, with some approximation, be regarded as the dehydrated version of hydroxylapatite. Both materials have been tested biologically in dense and porous versions.

If inserted into bony tissue, a layer of body deposited hydroxylapatite covers most of the implant surface relatively early during the healing-in period. The crystals immediately underneath appear to have lost much of their integrity; organic matter can be detected down to a depth of several crystal layers along grain boundaries.[14] In areas not in contact with bony tissue, the initial resorption processes which also precede the deposition of the bony layers do not cease. The influences of the chemical and phase compositions, crystal structure, and ceramic processing parameters on the tissue responses have been evaluated by several groups. Dense hydroxylapatite and tricalciumphosphate ceramics were found to be relatively stable in the bony environment; for the porous versions, different resorption rates have been found.

The present state of knowledge about the reactions of these bioactive materials in the body environment can be presented in the following three statements:

a) The initial flexural strength cannot be increased to much more than 100 MPa for the Ca-phosphate ceramics and to 200 MPa for the glasses.[15]
b) In the body environment the strength is reduced considerably by corrosion and fatigue.
c) The bond of bony tissue to dense hydroxylapatite can withstand several years of functional loading by shear forces.

4. Clinical Applications of Ceramics in Medicine

The low mechanical strength of the bioactive ceramics and its further reduction by fatigue excludes their uses in most of the load bearing applications. A clinical trial in which the low mechanical strength is believed to be compensated by pre-compressing the hydroxylapatite ceramic of cylindrical dental implants is, with some various after early failures from other reasons, still in progress.[13]

Many attempts have been made to compensate for the poor mechanical properties of these bioactive materials by coating them onto high strength substrates in order to use the bone bonding ability of the bioactive ceramics for the

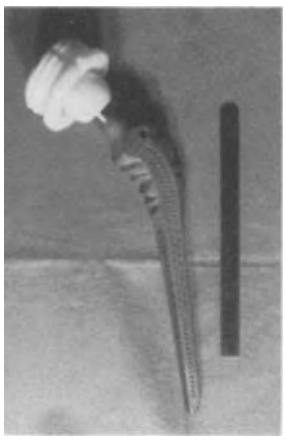

Fig. 4. Frialit Total Hip Replacement System: the cylindrical socket is made of the alumina ceramic as specified in the last column of Table 2. Its threads with asymmetrical cross section are designed for load transmission predominately by pressure. The BMO (biomechanically optimized) stepped stem is made of a TiAlFe alloy.

fixation of joint replacements and other load bearing implants. As the instability of the glasses and glass-ceramic under shear loading was already realized in the late 1970's, much hope concentrated on more or less dense hydroxylapatite coatings. However, here too, the lack of stability of this material in body environment is a fundamental problem, and all experts in this field agreed nearly unanimously during the 3rd World Biomaterials Congress in Kyoto, Japan, in April 1988 that even the best coatings of this kind will not last for more than about six years. They might contribute to the early healing process, but such coatings cannot replace mechanical fixation means like those shown in Figure 4 in long term implants.

The clinical applications of these bioactive materials are, therefore, confined to load-free or nearly load-free situations such as alveolar ridge augmentations, filling of periodontal defects, filling of cysts and other cavities, or corrections in the field of maxillofacial surgery.

The highly dense and pure alumina ceramic has been used in several high load-bearing applications for nearly two decades. No other ceramic has such a favorable combination of properties. The high-strength zirconia ceramics are multiphased, with at least one phase having reduced corrosion resistance. The essential properties of the medical-grade versions of the alumina material had been standardized during the 1970's (ISO 6474, ASTM F 603-83, DIN 58835). Extended clinical experiences have shown, however, that further improvements are necessary to extend the safety margin. The combination of properties that has been reached with a specially tailored material is shown in Table 2 and compared to the standard values.

Table 2. Properties of medical-grade alumina ceramics.

Property	Ceramic according to ISO 6474 ASTM F603-83 DIN 58835	Frialit Bioceramic
Density [g cm^{-3}]	> 3.9	> 3.98
Alumina content [%]	> 99.5	> 99.9
SiO_2 and alkali metal oxides [%]	< 0.1	< 0.05
Microstructure, average grain size [μm]	< 7	< 2.5
Microhardness [MPa]	23000	23000
Compressional strength [MPa]	4000	4000
Flexural strength [MPa]	> 400	> 450
Young's modulus [MPa]	380000	380000
Impact strength [cm MPa]	> 40	> 40

Corrosion resistance [mg m^{-2} d^{-1}]	< 0.1	< 0.1

4.1. Applications in Orthopedic Surgery

In orthopedic surgery the first ceramic implants whose design takes full account of the stress and strain field controlled bone reactions are the cylindrical sockets of the Frialit Total Hip Replacement system shown in the upper part of Figure 4. They are combined with a ball of the same ceramic fixed on a metal stem. Their clinical trial commenced in 1974. They have now stood the test of more than 14 years of clinical application. The first generation of these sockets and balls had been combined with metal stems which are still anchored with bone cement. Extended further animal experiments led to the design of stems with specially shaped steps and lacunae,[16] shown in the lower part of Figure 4. These stems are made of a vanadium-free high strength TiAlFe alloy tailor-made for medical applications.[17] This now completely cement-free implantable system has stood the test of more than six years of applications in many clinics.

One other hip replacement system with alumina ceramic sockets which also takes approximate account of the design rules mentioned above was introduced into clinical trials shortly afterwards. These ceramic sockets have also proved to be satisfactory.[18]

As already mentioned, some years earlier *Boutin* had commenced the application of alumina ceramic in hip surgery.[8] His design, however, closely followed the shape of plastic cups designed for cement fixation and did not take account of the design rules discussed above. Some years later *Chiari* et al. tested such sockets experimentally and *Plenk* found them to be separated from the bone by a soft tissue layer along most of the interface.[19]

Relatively early alumina ceramic implants were used in tumor surgery of the proximal femur and in the upper arm, but without convincing results.[20] Similarly, early attempts to introduce alumina ceramic components in knee surgery have not led to large scale applications.[21] Extended experiments with ceramic on ceramic articulating knee replacements never reached the state of clinical trials.[22] It was not until the introduction of total knee replacements with anchoring portions and femoral condyles of alumina ceramic and an articulating tibia plateau layer of polyethylene, and of ankle joints with a similar material combination, that ceramic components found clinical application in this part of the lower extremities.[23]

The discovery of a considerable reduction of the polyethylene wear debris in the combination of alumina ceramic balls with polyethylene sockets,[24] as compared to metal balls in the same application, led to large scale uses of this combination in Europe. Long term follow-up studies in many clinics have confirmed that this combination results in a reduction of the polyethylene wear debris by a factor of two.

4.2. Alumina Ceramics in Dentistry

The application of Degussit, a dense alumina ceramic, to dental implantology and other fields of medicine was suggested by *Sandhaus* as early as 1964.[25] The first ceramic dental implant system fully taking into account the remodeling ability of bony tissue was designed by *Schulte* and *Heimke* in 1975 and subsequently tested on a strictly

experimental basis with a detailed follow-up of each single implant. In 1977, following the presentation of the early, two years' results, eleven other clinics of the German speaking countries participated in this clinical study. In 1980 the results achieved were summarized in a special symposium. It was not until this survey was undertaken that these implants were made available to the dental practitioners. A detailed interim report has been prepared.[26]

This implant system (an example of such an implant is shown in Figure 3) allows immediate replacement of an extracted tooth, thus preventing the atrophy of the alveolar ridge with all its later difficulties. It can also be used as a so-called late implant in the already healed and even partially atrophied jaw. A variation of the original design takes special account of this application.[27]

Scientifically, all the different studies (e.g. histology) on retrieved implants, different types of mobility tests, and detailed studies of the gingival attachment either confirmed the initial design rules or, like the discovery of the load-line-shadow effect, even contributed to a more detailed understanding of the load-pattern-controlled tissue reactions around bioinert implants. In addition, the observation of full preservation of the shape of the alveolar ridge around such immediate implants after more than twelve years opens a new regime of dental care with the possibility of considerably improving public health.

A surprising point of view is also worth mentioning, amplifying the statement about dental care. From the definition of the term "bioinert" given in Table 1, mentioning the adsorption properties for body molecules, one would have expected a tendency for increased plaque formation with such ceramic implants. However, experience has shown beyond any doubt that the opposite is true: these implants cause much less plaque formation than metal implants or natural teeth.

The follow-up of all implants inserted in the Tübingen clinic (now more than 1000) has yielded more than one million items of data, which have been computerized and evaluated after five and ten years from all relevant points of view. The average success rate of these implants, if applied within their regime of indications, was 92.5% after five years, and remained so in the ten year analysis.[28]

Besides the *Sandhaus* implant already mentioned, there are other dental implant systems utilizing either alumina ceramic or alumina single crystals. None, however, meet the biomechanical requirements for osseo-integration of bioinert implants. Rather, all of them merely duplicate more or less the shape of the previous metallic implant designs. Therefore, many of these implants are separated from the surrounding bony tissue by soft tissue interlayers having different thicknesses. This soft interlayer, of course, results in implant mobility which, in turn, creates some mechanical irritation of the gingiva surrounding it and increases the probability of infection and implant loss.[5] There exists, however, no large-scale or long-term statistical evaluation on any of these implant systems.

4.3. Applications of Ceramics in ENT and Maxillofacial-Surgery

In the field of ears, nose and throat (ENT) surgery the transmission of forces is of minor importance for most of the large-scale applications. Thus, the bioactive ceramics have found some applications here.

Middle-ear implants of alumina ceramic replacing all or part of the ossicular chain (see Fig. 5) were tested and introduced clinically by *Plester* and *Jahnke*.[29] Almost simultaneously, *Reck*[30] evaluated a Ca-phosphate containing glass-ceramic for the same purpose and reported the formation of a thin bony membrane between the plate of these implants and the tympanic membrane. However, some concern exists about the building of a bony bridge between the bone around the oval window and the shaft of the implant because of its bioactivity. This same danger exists for hydroxylapatite implants suggested for this application.[31] The alumina and the glass ceramic ossicular chain replacements have now stood the test of up to nine years of clinical use.

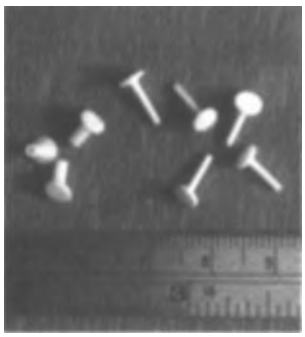

Fig. 5. Frialit middle ear implants of different shapes for easy adjustment to the individual situation.

Porous tricalciumphosphate ceramics were considered as filling material for different kinds of bone defects by many authors. *Zöllner* et al. used a relative stable material of this kind for the reconstruction of the mastoid and adjacent bone walls.[32] They confirmed the good bone bonding ability of this material, gave indications about its slow degradation, and demonstrated that such materials must not be used in positions immediately below the skin because of the danger of dehiscences.

The same group designed, tested clinically and introduced the alumina ceramic trachea supporting ring shown in Figure 6.[33] It is to replace the cartilage around the trachea if it has to be removed in tumor surgery.

Orbital support plates of alumina ceramic have been tested and clinically introduced by *Frenkel* et al. in the late 1970's.[34]

Many attempts have been made to improve the results of some branches of plastic surgery by the insertion of ceramic spacers. Examples are the attempts of *Swart* and *de*

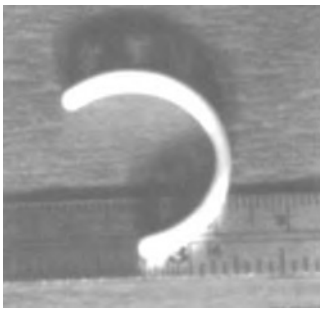

Fig. 6. Frialit trachea supporting ring.

Groot to change the jaw bone geometry with hydroxylapatite ceramic[35] and of *Wilson* with a bioactive glass.[36]

5. Final Remarks

Of all the ceramic materials considered for implant applications, only a few were found to meet the very severe requirements. The highly dense and pure alumina ceramic has stood the test of more than a decade of clinical use in different fields of surgery, and could eventually find large scale applications in several areas. Only one of the bioactive glasses has reached the state of routine application as ossicular chain replacement. Several Ca-phosphate ceramics have stood the test of nearly ten years of application in dentistry, in particular in alveolar ridge augmentations to improve the stabilization of total dentures.

In spite of the basic, still unsolved problem of its limited stability in the body environment, many attempts are still being made to elicit the favorable biological response to the Ca-phosphate ceramics for the fixation of bone replacements. Increasingly sophisticated composites and multilayer systems are being designed and tested. However, the more complicated the systems become, the higher the probability of failure and the greater the effort necessary to arrive at a well founded decision to commence clinical trials.

One more point needs to be considered: the present day success rates achieved with the already well established systems are to be regarded as the standard that any new system must surpass. Because one is dealing with humans, extremely strong evidence must exist and clearly indicate a high probability of a considerable improvement over existing systems before any clinical trial can be considered at all. Furthermore, any judgement about the success of an intended improvement cannot be given until at least five years of a closely controlled clinical series have been completed.

Surface Chemistry with the Scanning Tunneling Microscope

Surface Imaging
Surface Spectroscopy
Surface Modification
Nanolithography

By Jürgen P. Rabe*

1. Introduction

The Scanning Tunneling Microscope (STM) is a new tool in surface science, which allows for a variety of very local investigations on a preselected area of the sample. Its essential feature is a fine tip which is brought into close proximity to the sample (gap ≤ 1 nm) and whose position normal as well as parallel to the surface is controlled very accurately on an atomic length scale, i.e. ≤ 0.1 nm. The particularly precise control of the normal coordinate is accomplished by the accurate measurement of the gap width by means of the electron tunneling current between tip and sample. With this original concept[1,2] semiconductor surfaces have been imaged in ultra high vacuum (UHV) with unprecedented resolution,[3-5] local work function images have been obtained,[6] and soon it was realized that one can also get important local electron spectroscopic information with the STM,[5,7-10] including, e.g., the superconducting energy gap.[11,12]

The requirements for a sample to be investigated are sufficient electrical conductivity, sufficient flatness, and limited mobility of surface atoms or molecules. There is no requirement for any degree of order, rendering the method applicable to the study of individual defects or, e.g., metallic glasses.[13] Important for the general applicability of STM to materials science and surface chemistry is the fact that the method itself does not require UHV. Indeed, atomic resolution images have been obtained in fluid environments such as cryogenic liquids,[14,15] air,[16] water[17] and electrolytes.[18] Also solvents, oils and even greases have been used.[19,20] The only condition is that neither the electrical conductivity nor the viscosity of the fluid is too large. The advantages of the fluid environment include protection of air sensitive materials like GaAs, increased stability of the tunneling gap and a higher experimentally accessible tip voltage range.[19] Moreover, surfaces can be imaged under chemically active solutions such as electroplating solutions[18] or etchants.[21]

The STM can, however, not only be used for the characterization of surfaces but with the same instrument one can also manipulate surfaces on a scale as small as subnanometers.[22-24] Of possible technological relevance in this context is nanolithography with the STM[25-27] and, possibly, even the ability to write and read information into and from single molecules.

Other types of imaging based on related concepts have also been introduced, having in common that a fine tip is scanned across the surface and some strongly distance dependent interaction is measured while scanning. Examples of these "Scanning Tip Microscopies" are Surface Potentiometry,[28,29] Atomic Force Microscopy[30] and Scanning Thermal Profilometry,[31] the latter two being also applicable to nonconducting surfaces. However, these methods will not be discussed here any further.

While most of the early STM work was performed on clean semiconductor surfaces in UHV, this field will only be briefly mentioned here. The interested reader is referred to other reviews[32-34] and the proceedings of the three International Conferences on Scanning Tunneling Microscopy.[35-37] Also the application of STM to nonconducting samples, either coated with an ultrathin conducting film[38-40] or replicated[41] will not be discussed in detail here. This review will, however, cover surface chemistry, imaging of organic molecules at surfaces and surface modifications with the STM.

2. The Method

Electron tunneling is a common phenomenon on the atomic scale, which allows electrons to penetrate into classically forbidden regions in space. The probability of finding an electron at increasing distances away from a nucleus decreases exponentially outside an atom. If one brings an atomically sharp metallic tip close (≤ 1 nm) to an electrically conducting surface a tunneling current will flow when a small potential difference (of the order of 1 V or less) is applied between the two. To a first approximation, the current depends exponentially on the gap width, decreasing by about one order of magnitude for every Ångstrom of increase in gap spacing. It is this very high sensitivity to the gap width which makes the tunneling current a suitable signal to control the gap by means of a feedback loop. The accuracy can be better than 0.01 nm.

If the tip is now scanned across the surface while the current is sensed, a topograph of the surface can be obtained in two ways. In the constant current mode[1,2] the tip height is adjusted with the feedback loop maintaining a constant current. The image is obtained as a map of the tip height $z(x, y)$ versus the lateral coordinates x and y (Fig. 1). Alternatively, in the constant height mode[42] the tip is

[*] Dr. J. P. Rabe

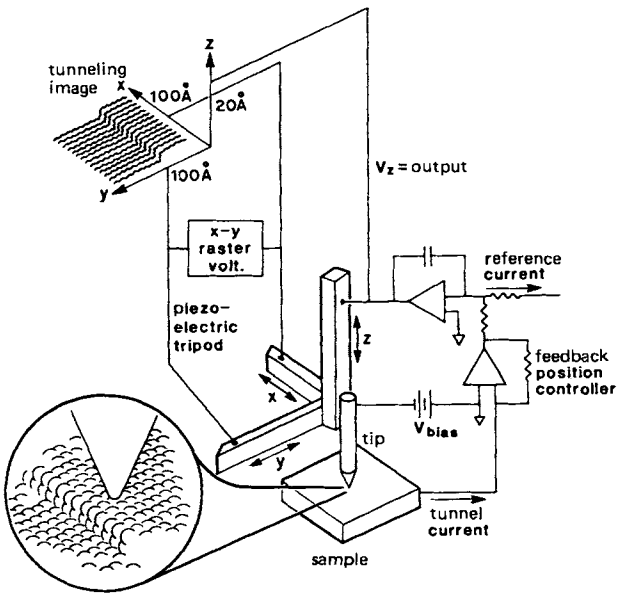

Fig. 1. Schematic illustration of the Scanning Tunneling Microscope [32]. The tunnel current from tip to sample, induced by V_{bias}, is maintained constant by an electronic feedback system (right), which controls the tip position normal to the sample surface via the z-leg of the piezoelectric tripod. A record of the z-leg feedback voltage, as the x-y tripod legs raster scan the tip laterally, constitutes a tunneling image, which is a form of replica of the sample surface (inset at bottom).

scanned at constant height and the current $I(x, y)$ is recorded as a function of x and y. In the latter case the limiting frequency of the feedback loop must be smaller than the frequency of current variations due to atomic structure. The feedback loop serves only to maintain the average current constant.

Common to all the published instrument designs are piezoelectric elements as x-, y- and z-translators. After the initially devised tripod[1,2] the simpler single tube[43] arrangement became widely used as a compact and fast scanner. Sample positioning, originally achieved with a piezoelectric walker ("louse")[1,2] has been simplified by differential springs, levers[44] or, elegantly, with a piezoelectric translator relying on the moment of inertia.[45] While external vibration isolation was essential in the earlier instruments, newer designs are often so small and rigid that it became less important or even obsolete.[46] Also the operating temperature range has been increased to extend from 4.2 K to 350 K.[11,46]

An essential feature of the STM is the tip. Different materials have been used, including W, Pt/Ir, Au and carbon. Also, tips have been prepared according to different procedures, e.g. mechanically ground or electrochemically etched. For use under liquid, they have been coated with glass or polymer, leaving only the last few microns bare. However, it appears that many results are fairly independent of the particular tip preparation recipe. On the other hand, since the formation of the outermost cluster of atoms on a macroscopic tip is usually not well controlled, some variation in instrumental resolution is observed even with equal tip preparation. Also the tip may change during scanning. In an attempt to obtain tips controlled to an atomic level, they have been reproducibly prepared and subsequently characterized in a field ion microscope.[47]

A theory of the STM[48,49] has been developed, based on the transfer Hamiltonian of *Bardeen*.[50] Assuming an ideal tunneling geometry (tip on flat) the tunneling current was found to be proportional to the local density of states (LDOS) of the surface at the center of curvature of the tip and at the Fermi energy. In the constant current mode the STM image then represents simply a contour of constant LDOS. In the usual case of an extended Fermi surface the image gives basically the contour of constant total charge density. In an attempt to determine how the LDOS is reflected in STM images the apparent size of an adsorbed atom has been studied as a function of bias for several different atoms.[51–53]

3. Conductor Surfaces

Gold was one of the first surfaces studied with the STM.[1,2,54–57] While the early studies in UHV revealed monoatomic steps and corrugation due to surface reconstructions, later also atomic corrugation of the close packed Au (111) surface was reported in both UHV and air.[58] Furthermore, hills on evaporated gold films, typically about 2 nm high, have been observed under a number of fluids, including glycerol, silicone- and paraffin-oil as well as several greases.[20]

The hexagonal reconstruction of Pt (100) has been imaged in UHV at terraces and domain boundaries.[59,60] Silver films on mica, exhibiting (111) surfaces, can be atomically flat across terraces several tens of in diameter. Atomic resolution images in air reveal, however, not the silver lattice but a larger lattice, possibly from a semiconducting surface layer of about monolayer thickness.[61]

While aluminum in air forms too insulating an oxide for STM imaging, niobium, on the other hand, forms a surface oxide layer which is sufficiently conducting for stable tunneling. Films prepared by vapor deposition at room temperature are fairly rough, but deposition at elevated substrate temperature gives considerably smoother films.[62]

Highly oriented pyrolytic graphite (HOPG) is a semimetal, which has been imaged at atomic resolution in UHV[63] and in a variety of fluids, e.g., air,[16] water,[17] electrolytes[18] and liquid helium.[15] It forms large (diameter ≈ 1 μm) atomically perfect, flat terraces, which are chemically inert; moreover, the spatial variation of the LDOS is very pronounced, resulting in high contrast images with a resolution of about 0.2 nm. However, attempts to use HOPG as a well characterized substrate to image monomolecular adsorbates on it with the STM suffered from its excessive inertness. In this context, defects may be of importance and have therefore been investigated in some de-

ADVANCED MATERIALS

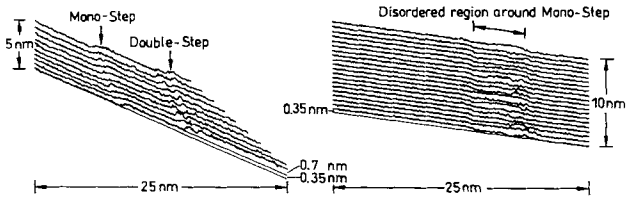

Fig. 2. STM images of mono- and bilayer steps on graphite in the constant current mode [64].

tail[64] (Fig. 2 and 3). Amorphous carbon, on the other hand, forms very flat films with grain sizes of the order of some nanometers[40,65] The problem of adhesion of adsorbates (e.g. a polymer) to graphite is also of interest in carbon fiber composites technology. Interestingly, carbon fiber surfaces can be imaged with the STM at atomic resolution.[64]

The first atomic resolution STM images were obtained on a silicon (111) surface in UHV with its 7×7 reconstruction ,[3] and it was also this surface which gave early electron spectroscopic results.[5,8-10] Experiments on freshly prepared silicon surfaces in air are, however, only possible for a limited time due to the formation of an insulating oxide surface layer.[66] In an attempt to avoid the oxide formation under ambient conditions a chemical preparation is required, which terminates dangling silicon bonds. For hydrogen terminated silicon atomically flat surfaces have been observed.[67] Other semiconductor surfaces investigated in detail include GaAs (110)[68] and, e.g., several low index faces of the group IV semiconductors Si, Ge and Sn.[69]

While direct local electron spectroscopic studies with the STM proved very successful in UHV, they appear more difficult in air or under liquids. Nevertheless, there also it is the electronic surface structure which is sensitively probed. An example of this is charge density waves in TaS_2. While STM images of native TaS_2 are dominated by a charge density wave state,[14,70] titanium doping systematically perturbs this electronic feature so that the surface structure can be imaged directly (Fig. 4).[71,72] It is expected that systematic studies of chemically modified surfaces will also lead to a better understanding of STM images.

Generally speaking, it appears easier to obtain atomic resolution images of semimetals or semiconductors than of simple metals. This has been attributed to the smeared-out electronic wavefunction in the case of metals

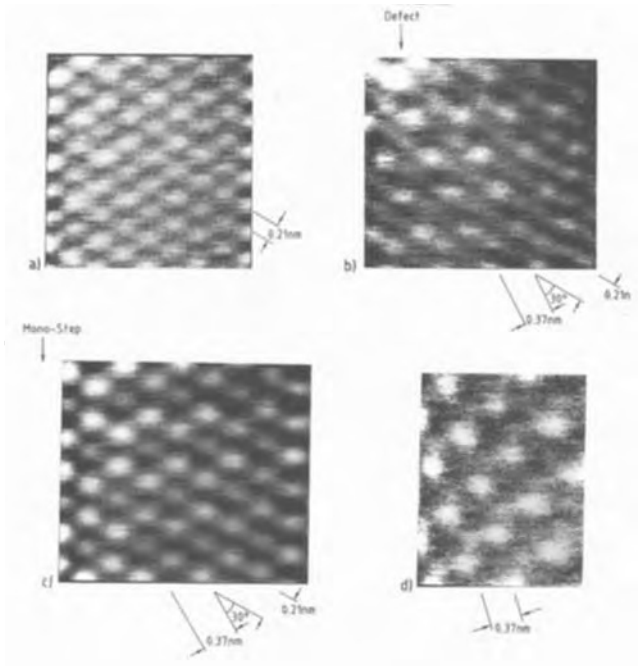

Fig. 3. STM images in the constant height mode [64]. a) Highly oriented pyrolytic graphite (HOPG). b) $\sqrt{3} \times \sqrt{3}$ R 30° superstructure near localized defect on graphite. c) Inverse $\sqrt{3} \times \sqrt{3}$ R 30° structure next to graphite step. d) $\sqrt{3} \times \sqrt{3}$ R 30° structure dominating STM image close to a defect. Intensity of superstructure relative to graphite image decays away from the defect over some 3 nm.

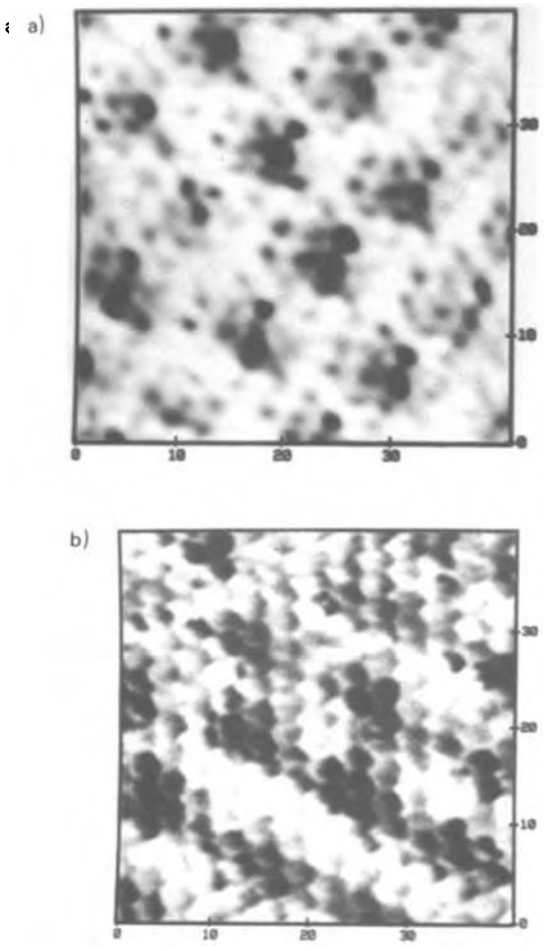

Fig. 4. Gray scale image of $Ti_xTa_{1-x}S_2$ recorded in the constant current mode [72]. The sample surfaces were covered with oil to improve the image stability. a) $x = 0.06$; The gray scale in this image (black minimum to white maximum) is 0.43 nm. b) $x = 0.1$; The gray scale in this image, 0.29 nm, is significantly smaller than in (a). The tip bias voltages are +8 mV and +9 mV, respectively, the tunneling current is 2.1 nA. x- and y-axes markings are in 0.1 nm.

and the large spatial variation of the LDOS of semiconductors, where higher contrast, higher resolution images and also more detailed spectroscopic information are obtained. In fact, the fairly high contrast in the atomic resolution images of the noble metals is difficult to interpret. Clearly, semiconductor surface studies in UHV have to date made by far the largest contribution of STM to high resolution microscopy and spectroscopy, partly since STM is well suited for these studies and partly since these surfaces had already been extensively investigated by other techniques.

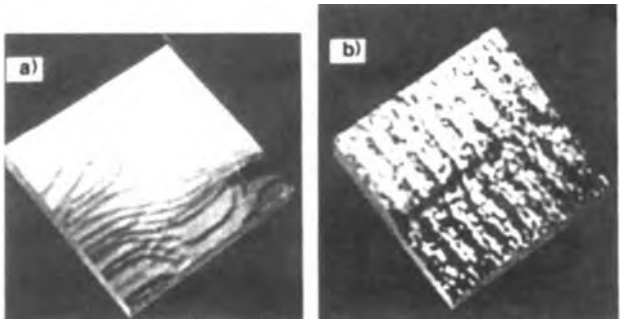

Fig. 5. STM images of the TTF-TCNQ surface [73]. a) A 200×200 nm^2 area. The surface is terraced, with steps approximately 1 nm high. b) A 10×10 nm^2 area in which rows of molecules are seen at a step.

The first molecularly resolved image of an organic conductor has been obtained on tetrathiafulvalene tetracyanoquinodimethane (TTF-TCNQ) crystals,[73] revealing monomolecular steps and the unit cell on the crystal surface (Fig. 5). Also some features in the STM image could be reproduced by simulations in which contours of constant electron density were calculated from the molecular orbitals that are involved in conduction (Fig. 6). These results suggest that the STM will also be a useful tool for the investigation of the electronic properties of organic conductors.

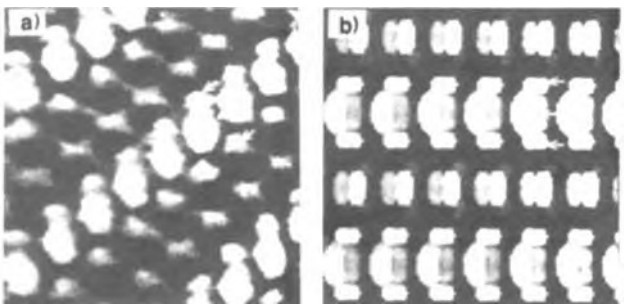

Fig. 6. Comparison of an experimental STM image and a theoretical simulation of the TTF-TCNQ surface [73]. a) A 2.5×2.5 nm^2 scan with a total height range of 0.9 nm. Lighter regions are higher. Arrows indicate a row of triplets of balls assigned to individual TCNQ molecules. b) A 2.5×2.5 nm^2 simulated image. Arrows indicate a row of TCNQ molecules along the *b* direction.

4. Organic Adsorbates

For an adsorbate to be imaged with the STM it is necessary that 1) the underlying substrate is sufficiently flat, 2) molecular mobility is not too high, and 3) the current through the molecule is sufficient. A number of atomically flat substrates such as graphite, suitably prepared gold and silver or silicon are available. However, the fact that some of these substrates can be imaged at atomic resolution in a variety of fluid environments indicates that in these cases the mobility of the environments adsorbates is too high for them to appear on the images in any way other than noise. On the other hand, adsorbates bonded chemically to a surface can be imaged. Moreover, their interaction with the substrate can be studied by imaging the electronic structure of the substrate close to the adsorbate. An example is the band bending around oxygen adsorbed on GaAs (110),[74] which reaches as far as 5 nm away from the adsorbate. Another example is a defect such as an adsorbate on graphite, which results in a superlattice appearing superimposed on the STM image of graphite and decaying away from the defect.[64, 75]

Clear examples of atom resolved surface chemistry are the imaging of chemical bond formation after adsorption of NH_3 on Si (001)[76] and a mapping of the reactivity of dangling bond states on Si (111)-(7 × 7).[77] For NH_3 as an adsorbate it was found that Si rest atoms are more reactive than Si adatoms and that center adatoms are more reactive than corner adatoms. Probing dangling bond states on both clean and NH_3-exposed surfaces revealed interactions and charge transfer between sites, influencing surface reactivity (Fig. 7).[77]

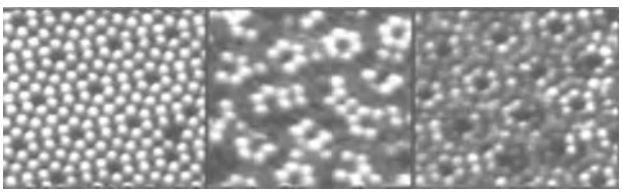

Fig. 7. Topographs [77] of the unoccupied states of a) a clean Si (111)-(7 × 7) surface (tip voltage = 0.8 V), b) partially reacted surface (tip voltage = 0.8 V), and c) partially reacted surface (tip voltage = 3.0 V).

Highly resolved images of organic adsorbates have been obtained on an ordered (3 × 3) superlattice of coadsorbed benzene and carbon monoxide on a rhodium (111) surface (Fig. 8).[78] While images on the close packed monolayer are very stable, for submonolayer coverage diffusion increases and it is observed that an individual molecule changes places during the STM scan of one image.

A similar situation is encountered for phthalocyanines on copper (100). While it appeared difficult to image a single phthalocyanine molecule on silver,[79] regular arrays of these molecules on Cu (100) could be observed and under

ADVANCED MATERIALS

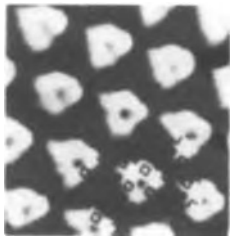

Fig. 8. STM image of an ordered (3 × 3) superlattice of coadsorbed benzene and carbon monoxide on rhodium (111) [78]. At tip voltage < 0.5 V a nominally threefold structure with a depression in the center is observed. According to the superimposed mesh based on the LEED model, the lobes appear to be localized between, rather than over, the underlying metal atoms.

some circumstances atomic scale features were observed, which agree well with Hückel molecular orbital calculations.[80] Attempts to image multilayers gave neither regular structures nor very high resolution, indicating that in this case the conductivity of the layer may be too small to allow for a nondestructive observation.

Studies on larger organic molecules have also been reported, including a whole single virus,[81] fatty acid salts,[82] lipid/protein membranes,[83] DNA,[84] several synthetic polymers such as phthalocyaninato-polysiloxane[64], poly-octadecylmethacrylate and poly-methylmethacrylate[85] and a liquid crystalline material,[86] all on graphite.

However, the interpretation of these experiments is difficult, since the tunneling distances are rather large and also the intrinsic conductivities often appear too small to explain the current densities used in the experiments. Here there may be significant surface conductivity due to adsorbed water and salts, which are always present in biological preparations. As a matter of fact, molecularly resolved images of macroscopically thick paraffin have been reported to be of varying quality, depending on the ambient humidity.[84] Another issue is the notoriously poor adhesion of adsorbates to graphite. While it may be enhanced around defects in the substrate, it is necessary to distinguish those defects carefully from an adsorbate.[64] It appears that this has not always been done. The interpretation is further complicated if one takes into account a deformation of the molecule during scanning.[87] In conclusion, while apparently several polymers have been imaged with the STM, clearly more work is necessary to understand the situation as well as in the case of the inorganic conductors.

5. Surface Modification with the STM

The STM setup also provides a means of modifying surfaces on an atomic scale and imaging the effect immediately afterwards. This is achieved by raising the tip voltage for a short time (e.g. 100 ns) to a value of the order of 4 V. However, the processes involved are not fully understood. For a germanium surface it was suggested that a transfer of tip material to the sample may occur.[22] For graphite immersed in an organic liquid (phthalates) it was argued that individual organic molecules had become selectively attached to the substrate.[23] On the other hand it was observed that similar modifications could be obtained without these specific molecules (Fig. 9).[24] For metallic glasses it has been suggested that local melting is responsible.[88] Though lithography on a nanometer scale has been shown to be possible,[25-27] more understanding is necessary to control the modifications better. This includes their dimensions as well as their stability, which, e.g. due to diffusion, can be limited to a time scale of hours.[24, 89]

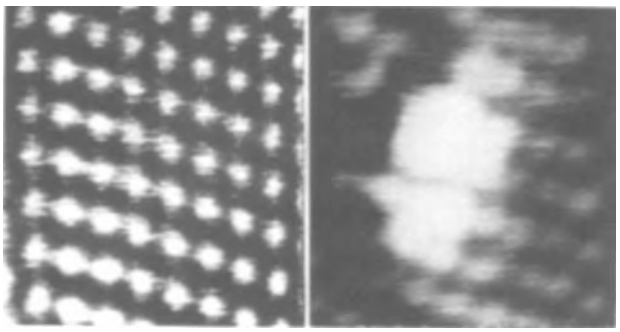

Fig. 9. STM images of highly oriented pyrolytic graphite (HOPG) in air in the constant height mode [24]. Tip voltage 100 mV, tunneling current 2 nA. Left: Atomic resolution image, representing for a flat terrace of about 1 μm diameter, before applying a voltage pulse. Right: Same area after applying a 100 ns pulse of 3.5 V. The surface has been modified on an area of about 0.5×1.0 nm^2.

6. Outlook

The STM is not only a microscope, local electron spectrometer and lithographer, it quite generally provides very locally injected low energy electrons for analytical or manipulative purposes. For example, the tunneling electrons can cause local excitations which then may decay radiatively. The corresponding light can be analyzed spectroscopically, leading to an optical spectroscopy with molecular spatial resolution.[90] Indeed, the STM appears to be close to what *R. P. Feynman* had asked for in 1960:[91] A machine, capable of storing and reading information on a small scale, say 100 atoms. Today it is envisioned that the miniaturization of computing may lead to a molecular electronics: single molecules acting as diodes, switches or molecular wires. Here the STM may provide the means to address the particular molecule.

Research News

Aluminum-rich Metallic Glasses

An enormous variety of metallic liquid solutions have been converted by rapid quenching from the melt into metallic glasses. They fall into two large groupings: (1) M + m, where M is a metal and m a metalloid, and (2) M + M', where only metals are present. In both categories, one or both M's most commonly are transition metals. Group-1 glasses often contain two or more distinct metalloids, whereas up to now studies of group-2 glasses have been restricted to binary systems. The total solute content has rarely been less than 15 at.%, and ≈20 at.% is more common.

Of the many hundreds of alloy systems in which melt-quenched metallic glasses have been recorded since the sport was invented in 1959, none include aluminum, although a few instances have been recorded of *partial* vitrification of rapidly quenched aluminum melts containing Si, Ge, Cu, Ni, Cr or Pd as solute—i.e., a small amount of glassy phase coexisted with a larger amount of metastable crystalline phase. Aluminum has always been regarded as a solvent inimical to glass formation.

It is therefore an occasion for surprise that within a few months, two teams in different countries, working quite independently of each other, have discovered similar families of aluminum-rich alloys that can be completely vitrified by rapid quenching from the melt. *Inoue, Ohtera, Tsai* and *Masumoto* in Sendai, Japan, were the first to publish;[1] they were followed five months later by *He, Poon* and *Shiflet*[2] in Charlottesville, Virginia. Both teams used single-roller melt-spinning (the most usual method used for research purposes nowadays): in this technique, a jet of molten alloy is directed at an angle at the circumference of a rapidly spinning copper wheel, and a narrow quenched ribbon is generated. In thework discussed here, the ribbons were 15–30 μm thick and 1–2 mm wide.

The two groups both made glasses always containing *two* solutes, one being a rare earth metal and the other a transition metal. The Japanese effort was entirely concentrated on the Al-Y-Ni system: the investigators found that *both* solutes were necessary to make a glass. Figure 1 shows the range of compositions in this system which gave fully amorphous ribbons: one Al-Y-Ni alloy examined by the American investigators is also included in this figure (in the lower left part). The Americans also studied a variety of other ternary aluminum alloys, in all of which the solutes were combinations of a rare earth and a transition metal. these included individual compositions in the Al-Ce-Fe, Al-Gd-Fe, Al-Ce-Ni, Al-Ce-Co, Al-Y-Co, Al-Ce-Rh and Al-Y-Ni systems. All of these had total solute contents of only 10–13 at.%, and it is noteworthy that the most interesting mechanical properties in the American study were found for the most dilute alloy, $Al_{90}Ce_5Fe_5$.

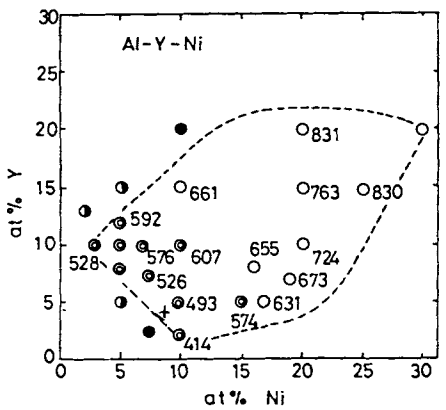

Fig. 1. Compositional range of melt-spun Al-Y-Ni alloys: ◎ amorphous, ductile; ○ amorphous, brittle; ◑ amorphous plus crystalline; ● crystalline. The numbers give the crystallization temperatures [°C] (from reference [1]). The cross in the lower left part gives a composition of an amorphous Al-Y-Ni alloy found by *He* et al. [2].

None of the numerous theoretical criteria which have been proposed to interpret glass-forming ability (GFA) of different alloy combinations and compositions[3] will help us here: for some of them (e.g., a criterion based upon the volume change on melting) we lack the experimental information that would enable us to check their applicability; for others we are faced by the difficulty that the criteria are applicable only to binary alloys. However, a very recent study[4] from the Virginia group, on Al-Fe-Gd glasses, has established that there is no deep eutectic anywhere in the glass-forming region and that the reduced glass-forming temperatures, $T_r > T_x/T_m$ (where T_x, T_m are crystallization and melting temperatures, respectively) are abnormally high (0.65–0.70); the reason is unknown. High T_r always favors glass formation, but the normal route to a high T_r is via depression of T_m at deep eutectics. These glasses, therefore, are anomalous.

The most thoroughly researched criterion for high GFA is undoubtedly the degree of mismatch in atomic size between solvent andsolute, and this criterion also appears to have the widest applicability.[3] For binary alloys, this criterion was studied in great detail by *Egami* and *Waseda*,[5] who established a functional relationship between the disparity in atomic volumes and the minimum solute concentration needed for a glass to be made in that alloy system: the larger the disparity, the smaller the minimum solute concentration needed. This quantified the well established

principle that crystallization of a melt is inhibited if it contains atoms differing widely in size.

Egami and *Waseda*'s analysis is not directly applicable to ternary alloys, but it is interesting to note that the rare earth solute atoms are always larger than the aluminum solvent, while the transition metal atoms are smaller. By way of example, atomic volumes for two of the new aluminum glasses (in Å^3) are: Al 16.6, Ce 34.4, Fe 11.8;—,Y 33.0, Ni 10.9. The implication is that a mixture of small and large solute atoms is particularly favorable for stabilizing a liquid/amorphous structure and discouraging crystallization. This conclusion is consistent with one of the few earlier studies that looked systematically at ternary glasses: *Ohnuma* et al.[6] examined a range of Co-B-TM alloys, where various transition metals were partially substituted for boron. It was found that the total solute content needed to achieve vitrification was the smaller, the larger the size of the transition metal atom: in general, the larger the disparity between the size of the solvent (cobalt) atom and the sizes of the (larger) transition metal and (smaller) boron solutes, the easier it was to make a glass.

The practical interest of the new glasses lies in their strength. *He* et al. found tensile strengths in the range 670–940 MPa, while *Inoue* et al. reported values in the range 730–1140 MPa for various compositions in their single alloy system. These strengths greatly exceed the strengths of even the best precipitation-hardened crystalline aluminum alloys (300–500 MPa) and the possibility of using ribbons of some of the new alloys as reinforcing fibers in composites at once presents itself. Advantages include in particular the low density of the fibers, their ductility which offers the prospect of enhanced intrinsic ductility in composites incorporating them, as well as good corrosion resistance. Drawbacks include a relatively low Young's modulus (up to 71 GPa), somewhat lower than for crystalline aluminum alloys, and rather low crystallization temperatures, 250–370°C for the compositions of greatest interest. However, this is still higher than the limiting temperature of use for organic fibers such as Kevlar.—The *Wall Street Journal* for October 6 carried a report of an interview with a staff scientist of Allied-Signal Corporation which is the principal commercial manufacturer of metallic glasses. This scientist very reasonably doubted whether the new glasses could be used as massive constructional materials, but made no reference to use in composites. The Virginia authors, also interviewed, expressed the belief that the aluminum glasses have a rosy future in the aerospace industry.

Research on metallic glasses, which excited a steadily high level of interest during the 1970s and early 1980s,[7] has shown signs of abating recently. Perhaps the new aluminum glasses will inject a new vitality into this field: certainly many questions related to the formation, properties and crystallization of these glasses deserve to be addressed.

Conference Reports

High-Temperature Superconductors in Strasbourg ...

The symposium on preparation and applications of high-temperature superconductors at the European Materials Research Society (E-MRS) conference on November 8–10, 1988 in Strasbourg, France attracted more than 200 scientists from Europe and overseas. Thirty-eight lectures, 15 of which were invited, and over 100 posters were presented in ten sessions. Most presentations discussed the structure of $YBa_2Cu_3O_7$ and Bi- and Tl-based superconductors, including the effect of substitutions and impurities. Other areas of interest were the preparation and characterization of thin film superconductors as well as bulk and thin film properties and their measurement by a variety of techniques such as X-ray photoelectron spectroscopy, Raman spectroscopy, nuclear magnetic resonance, etc. In addition, practical applications such as a Meissner-Ochsenfeld motor constructed by AEG engineers were presented during one of the two poster sessions.

A new phase in the Y-Ba-Cu-O system, namely $Y_2Ba_4Cu_8O_{16}$, which was reported at the Interlaken meeting earlier this year to be present in some thin films, can

now be prepared in bulk form, as *E. Kaldis* (ETH Zürich) explained during his presentation. This so-called 248-phase has a T_c of 80 K. The critical current density is comparable to that in the 123-phase, but the 248-phase shows a significantly improved oxygen stability.

A number of presentations discussed the preparation and properties of Bi-Sr-Ca-Cu-O and Tl-Ba-Ca-Cu-O superconductors. In both systems two superconducting phases with $T_c > 77$ K exist. While in the Tl-system it is possible to isolate the high-T_c and low-T_c phases, this is not so in the Bi-based system. The formation of the low-T_c phase apparently proceeds much faster here than the high-T_c phase. Larger fractions of the high-T_c phase are observed after reaction times of 50 to 100 hours, while the low-T_c phase appears after only a few hours of sintering. In several presentations the stabilizing effect of Pb doping on the high-T_c phase in Bi-Sr-Ca-Cu-O was discussed. From X-ray spectra it would appear that the Pb enters the structure on the Bi sites, as *S. Amelinckx* (Univ. of Antwerp) reported. Other dopants, e.g. Nd, Sm or Gd, seem to reduce the amount of high-T_c phase in the Bi-Sr-La-Cu-O system, as shown on a poster by *M. Raveau* et al. (Univ. of Caen).

H. J. Scheel (Univ. of Geneva) summarized the activities on crystal growth of oxide superconductors. Impurities at a level as low as 0.1 wt.% interfere significantly with crystal growth, so the starting materials should be at least of 99.99% purity. Even though many groups are working on crystal growth of high-T_c superconductors, there are still no large untwinned single crystals of good quality available. One reason for this is insufficient knowledge of the phase diagrams under certain conditions, such as oxygen partial pressure, CO_2 content, etc. Even at this symposium dominated by materials scientists, a conspicuous lack of phase equilibria studies was apparent.

While the current carrying capability in sintered bulk high-T_c superconductors remains a problem because of small coherence lengths, anisotropy and granularity (*R. Flükiger*, Kernforschungszentrum Karlsruhe), the situation with thin film superconductors looks more promising. A large number of groups presented papers on the preparation and characterization of high-T_c superconducting thin films. A wide variety of methods, such as sputtering, thermal- and laser-evaporation, molecular beam epitaxy, etc., were employed to produce superconducting films, and a general distinction was made between in-situ processing and post-anneal processing. In-situ processing takes place in the presence of activated oxygen at relatively high pressures during deposition. Post-anneal processing requires additional oxygen annealing to crystallize the films following deposition. The primary advantage of in-situ processing over post-anneal processing, in addition to the fact that no additional oxygen annealing is necessary, is the lower substrate temperature (500 to 700 °C as compared to 800 to 900 °C, respectively), which helps to avoid film-substrate reactions. A further problem with films made by post-anneal processing is their high surface roughness which makes electronic applications of these films difficult or impossible (*A. Kapitulnik*, Stanford Univ.). An interesting approach was presented by *H.-U. Habermeier* (Max-Planck-Institut für Festkörperforschung, Stuttgart). He exposed his films to an oxygen plasma during deposition as an alternative to furnace annealing and showed it to be an excellent tool to restore the oxygen content of the films, even at temperatures as low as 300 °C. The most commonly used substrates were single crystalline $SrTiO_3$ and MgO, but also films deposited on yttria-stabilized zirconia, Al_2O_3, sapphire, $LiNbO_3$, and Si were discussed. In view of potential applications, in particular applications in connection with semiconductor devices, these substrates are of primary interest.

In conclusion, there were no sensational reports, and no spectacular new T_c records were announced; the fax machine in the conference office certainly did not run hot as it did at the Interlaken meeting at the beginning of the year. However, this does not mean that no progress was made in the field of high-T_c superconductors, only that the hectic phase of the research and development disappeared —at least for the time being. The dust of previous stampedes towards higher T_c has settled to make room for serious, systematic work towards a more complete understanding of these novel materials.

... and Colorado Springs

After the conference on Critical Currents in High-T_c Superconductors held in Snowmass Village in August of last year, Colorado was, once again, the site of a major superconductivity conference. This time it was the Conference on the Science and Technology of Thin Film Superconductors that took place on November 14–18, 1988 in Colorado Springs, Colorado, USA. Over 200 scientists and engineers from around the world attended this conference, which was organized by the U. S. Department of Energy (DOE), the Solar Energy Research Institute (SERI), the National Institute of Standards and Technology (NIST) (formerly National Bureau of Standards, NBS), The Naval Research Laboratory (NRL), and the Lawrence Berkeley Laboratory (LBL). Thirty-six invited and contributed papers, and more than 40 posters were presented on thin film deposition techniques, characterization, theory, device design and ap-

plications as well as bulk material studies related to thin films. In addition to the technical presentations, a set of short courses was offered during the first day of the conference to bring the audience up to date with current research in the area. The courses, organized by Lawrence Berkeley Laboratory's Superconductivity Research Center for Thin Film Applications, were given by such prominent scientists as *S. Wolf* (NRL), *J. R. Kwo* (AT&T Bell Labs.), *J. Clarke* (UC Berkeley), and others. The topics ranged from an introduction to superconductivity, through fabrication and characterization of superconducting thin films, to superconducting electronics applications. These short courses were quite a success, since they offered the scientists involved in the preparation of films some insight into the problems engineers encounter when designing devices based on these films.

The technical presentations started off with representatives of DOE, NRL, and NIST giving overviews of the activities at their respective government agencies. Especially impressive was the budget increase for basic energy science at the DOE from \$ 12.4 million in the fiscal year 1987 to \$ 36.7 million in 1989.

Presentations during the first two days of the conference focused on film preparation and characterization. Among methods commonly used to deposit superconducting films were thermal and electron beam co-evaporation, laser ablation, dc- and magnetron sputtering, including multitarget sputtering, molecular beam epitaxy (MBE), metalorganic chemical vapor deposition, etc. A much discussed preparation technique was the laser ablation or laser enhanced deposition technique. A pulsed excimer laser beam is directed on a target mounted in a vacuum chamber under the heated substrate. The emitted atoms or molecules from the target collect on the substrate and form the film. Laser fluxes in the range of 0.1 to 5 J cm^{-2} were reported. The advantage of this method is quite obvious: a relatively simple arrangement is sufficient to produce films of 0.1 μm thickness in only a few minutes. The not very uniform coverage of the substrate by this method is an inherent problem which could be overcome, e.g. by a scanning set-up or a similar technique. A post-deposit oxygen annealing step can be avoided by plasma-assisted laser deposition, as *H. S. Kwok* (State Univ. of New York (SUNY), Buffalo) reported. The plasma between target and substrate is produced by a low pressure dc oxygen discharge. In addition to being a "one-step" process, this method is compatible with semiconductor processing since substrate temperatures as low as 400°C are sufficient. *J. R. Kwo* (AT&T Bell Labs.) used her MBE apparatus with a reactive oxygen species excited by a microwave plasma contained in a flow tube reactor. In this case, the substrate temperature was 550°C. *R. H. Hammond* (Stanford Univ.) also used a microwave cavity to produce atomic oxygen during film deposition. Using an oxygen partial pressure versus temperature diagram determined by *R. Bormann* (Univ. of Göttingen), he compared the film deposition and cooling conditions which he used with the data published by other groups.

Preparation of superconducting thin films made by a new method, electron beam flash evaporation, was discussed during the short courses as well as in several talks and posters. As with the laser ablation method, the flash evaporation process convinces by its simple approach. Small pellets (approx. 0.2–0.5 g) of the oxide components are evaporated to completion by a high-intensity electron beam from a water cooled copper hearth. It takes 30 to 40 s to completely evaporate a 0.3 g pellet, as reported by *P. R. Broussard* (NRL), and depending on the experimental set-up, the evaporation of one pellet results in a film thickness contribution of about 20 nm according to the information on the poster of *M. F. Davis* et al. (Univ. of Houston). No deposition-rate measuring schemes and complex feed-back circuits are required for this method. The stoichiometry of the films is very close to that of the pellet, even when large substrates are coated. The method has been used successfully for the preparation of both $YBa_2Cu_3O_x$ and $Bi_2Sr_2CaCu_2O_y$ superconducting films. Best results were obtained with Bi-based films deposited on MgO substrates, showing zero resistance critical temperatures of 85 K after short post-deposition annealing at 865°C in oxygen. Reproducibility of the films varies considerably among the different groups and the methods employed. Very reproducible films, however, resulted from the so-called "BaF_2 process", first used by *P. M. Mankiewich* (AT&T Bell Labs.). In this process, metallic Y and Cu together with BaF_2 are co-deposited in the presence of oxygen. The films are amorphous and insulating. Post-deposition annealing in wet oxygen is required to convert the films into superconductors with critical temperatures near 90 K. Even though post-deposition annealing is necessary to obtain superconductive films, these films are highly reproducible and are very robust and generally withstand the rough treatments with water and solvents during lift-off lithography. Many researchers reported on efforts to produce films by a one-step or in-situ process, i.e. a deposition procedure not requiring post-deposition oxygen annealing to produce a superconducting film. Common to all reported procedures are the relatively low substrate temperatures of 500 to 700°C as compared to conventional multistep processing requiring post-deposition annealing at 800 to 900°C. A development towards lower deposition temperatures is of course favorable in view of electronic applications that might require common processing steps for superconductors and semiconductors.

Throughout the entire meeting the issue of the determination of the substrate temperature came up repeatedly. The substrate temperature is one of the most crucial deposition parameters for all film preparation methods, yet in many cases not very accurate statements as to the real substrate temperature could be made, since many experimenters measure the temperature of the heating block rather than that of the substrate itself. According to one study,

ADVANCED MATERIALS

however, there can be a temperature difference of as much as 30 K between heater block and substrate surface, which led *R. H. Hammond* to conclude that the thermal contact between heater and substrate is of extreme importance.

Substrate materials commonly used in the preparation of superconducting films were $SrTiO_3$, MgO, cubic ZrO_2 (YSZ), and sapphire, all dielectric materials. Single crystalline $SrTiO_3$, which has only a 0.5% lattice mismatch with $YBa_2Cu_3O_7$, is the preferred substrate for achieving epitaxial films exhibiting the highest critical current density measured to date (of order 10^6 A cm^{-2} in zero field at 77 K). Because of their high dielectric losses, neither $SrTiO_3$ nor MgO is a suitable substrate material for microwave applications. Here the recently discovered $LaGaO_3$ and $LaAlO_3$ provide excellent microwave properties (low dielectric constant, low loss tangent) and are easier and less expensive to produce than $SrTiO_3$. Structure and lattice constants are favorable for growing epitaxial films of perovskite related superconductors. *R. W. Simon* (TRW) showed dielectric measurements confirming the desirable microwave properties of $LaAlO_3$ substrates. He speculated that $BaZrO_3$ might also turn out to be a good substrate material; an indication thereof could be the successful use of ZrO_2 buffer layers used on some $YBa_2Cu_3O_7$ films. *Simon* encouraged researchers to focus on new substrate materials; there is "no reason to be married to $SrTiO_3$", as he put it, "since this material has nothing to offer except high prices and bad high frequency properties". *H. S. Kwok* described films made by plasma-assisted laser deposition on dielectric, semiconducting, and metallic substrates. Especially interesting were his critical current measurements of films deposited on stainless steel. J_c of these flexible films decreased by as much as 20% from an initial value of about 1000 A cm^{-2} by repeated bending. *J. Tate* (Technische Universität München) showed that the films deposited by thermal co-evaporation on Si substrates had a 100 Å amorphous SiO_2 layer between substrate and $YBa_2Cu_3O_7$ film. The motivation for depositing films on semiconducting substrates was, of course, with a view to potential electronics applications, but the Munich group also argued that "if you can make films on Si, you can make them on anything".

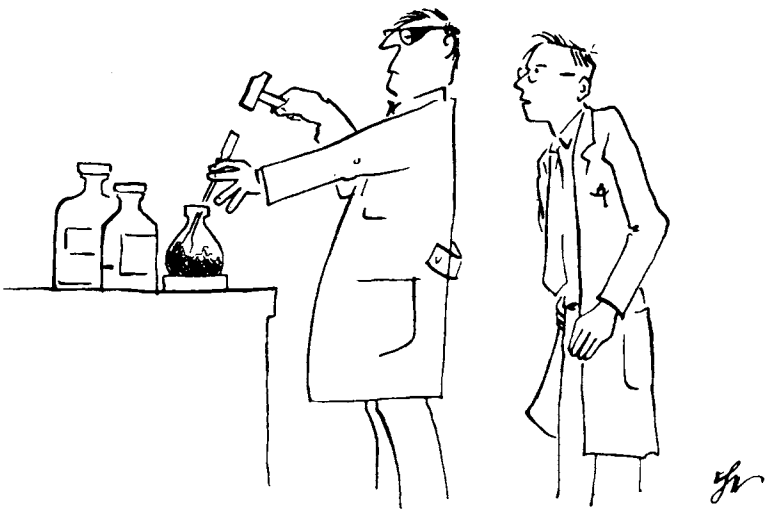
The critical current density of superconducting films, apart from T_c the single most important parameter for any application, was most often measured by the four-point method. *S. Wolf* emphasized the need for a uniform standard in determining the critical current density. The ASTM standard of 1 μV cm^{-1} now used in many publications was really designed for long wires. As a better standard for short samples, the $\varrho < 10^{-11}\Omega$ cm specific resistivity criterion was suggested. The even more stringent criterion of $\varrho < 10^{-14}\Omega$ cm is being used by the Fermilab for their magnet wire. Since in many cases the critical current density is measured by less stringent criteria due to small samples and insufficient measurement resolution, it is important for comparison toinclude the measurement criterion along with the value of the critical current density.

Talks presented during the third day of the conference centered around Josephson junctions as well as electronics and microwave applications of thin film superconductors. *J. Przybysz* (Westinghouse R&D Center, Pittsburgh) gave an excellent overview of his group's effort to build Josephson shift registers. These and other digital elements are required for high speed signal processing, e.g. in microwave electronics, radar technology etc. There are essentially two ways to obtain superconducting digital circuits. One approach consists of using persistent current loops that are coupled to shift a single bit to the next loop; the other approach is first building logic gates from Josephson switches and then assembling shift registers and other circuits with these gates. The fastest Josephson shift register to date is a Fujitsu one-bit shift register operating at 2.3 GHz—still slower than the current state of the art GaAs technology. However, the Josephson shift register has the potential to reach 60 to 100 GHz clock frequencies, much higher than can be hoped for with GaAs circuits. One drawback with Josephson electronics is that in many cases the semiconductor-based measuring equipment stops working well before the limit of the former is reached.

R. Koch (IBM, Yorktown Heights) showed recent developments on SQUIDS made by magnetron sputtering Tl-Ba-Ca-Cu-O films on cubic zirconia and $SrTiO_3$ substrates, followed by annealing and patterning by photolithography. In addition he reported on voltage noise power measurements in thin film stripes. He showed that voltage noise power does not follow a square law, as would be expected for resistive noise, but varies almost linearly with the voltage. Such a behavior suggests that the noise is created by the motion of thermally excited flux vortices across the sample. Among other applications discussed were photodetectors for visible and infrared wavelengths, superconducting transmission lines for analog signal processing, voltage standards and an analog-to-digital converter based on a high-speed superconducting counter.

Interesting thoughts on the benefits of using the proximity effect with high-T_c superconductors were presented by *V. Z. Kresin* (LBL). A combination of an A 15 superconductor with a high-T_c superconductor would effectively raise T_c of the A 15 material. This combination could be useful in utilizing the good current carrying capabilities of metallic superconductors at higher temperatures. The T_c in the high-T_c superconductor of such a combination is lowered by the same token; but that can be useful in some cases, e.g. measuring normal state properties at low temperatures as done in fermiology. There is no experimental evidence for the proximity effect in high-T_c superconductors since very good quality films are required for these studies.

The last conference day was devoted to the "Colorado Superconductivity Shootout", an opportunity to compare thallium versus bismuth versus yttrium superconducting compounds. The basis for the "shootout" was a series of talks given by six speakers who then formed a panel to lead the subsequent discussion. The best aspects of



Tl-superconductors were presented by the inventor himself, *A. M. Hermann* (Univ. of Arkansas, Fayetteville). He pointed out the high current density in both bulk and thin films of Tl-based superconductors, as well as their excellent thermal and chemical stability. Bi-superconductors were defended by *R. J. Soulen* (NRL) and *N. G. Dhere* (SERI). Finally, *R. Simon* (TRW) presented a line-up of the three classes of high-T_c superconductors together with Nb as the representative for the conventional superconductors, much in the style of Consumer Report Charts on VCRs or automobiles. Although each material has advantages in specific areas, there were no overall winners or losers. The common consensus was that more effort is necessary to tame and understand these materials more thoroughly before selecting the superior superconductor.

During the following panel discussion, the toxicity of Tl-compounds was a prominent topic. *D. S. Ginley* (Sandia National Laboratories) stressed, as he had done during his talk on Tl-films earlier in the conference, that Tl is not exceptionally toxic. The problem is not the toxicity but the question of how to handle the substances. Tl, which accumulates in soft tissues, has a half-life of 20 to 30 days in the body; however $BaCO_3$, which is about 100 times less toxic than Tl, accumulates in bone marrow and thus remains inside the body considerably longer than Tl. The toxicity of Tl is quite well documented in a Johnson & Matthey summary sheet that includes data on skin absorption, lethal doses, etc.

The Conference on the Science and Technology of Thin Film Superconductors was in fact an exciting and important meeting, just as the organizers promised in their announcement. As a result of the very specialized focus on thin film superconductors, the number of attendees was manageable and it was not necessary to organize concurrent sessions, certainly a point that increased the efficiency of this meeting. The conference provided an excellent opportunity to meet researchers from industry as well as national laboratories and academic institutions, and to discuss a wide spectrum of problems ranging from preparation techniques through methods of characterization to circuit design using superconducting switching elements. In today's over-abundance of superconductivity conferences, this conference was well worth attending.

Call for Short Communications · Call for Short Communications · Call for Short Communications

... doesn't melt, won't dissolve, just can't be broken down — let's send it to ADVANCED MATERIALS!

ADVANCED MATERIALS from now on welcomes short communications from all over the world, from academia and from industry, from chemists, physicists and materials scientists, provided they are in keeping with the program outlined in the editorial on page 107. Authors who are interested in submitting short communications (up to six pages of doublespaced manuscript together with an appropriate number of figures and/or formulas) should prepare their manuscripts in accordance with the "Notice to Authors" (see page 109).

Conference Calendar

February 1989

13–17 **Plasma Processing in Semiconductor Materials**
Bristol (United Kingdom)
Contact: Dr. S. Pringle, Dept. of Extramural Studies, The Univ., Queens Rd., Bristol BS8 1HR, UK

15–17 **Solid-State Circuits,**
36th IEEE Int. Conf.
New York (USA)
Contact: L. Winner, 301 Almeria Ave., Coral Gables, FL 33134, USA

19–22 **Adhesion,**
12th. Annu. Mtg.
Hilton Head Island (USA)
Contact: D. Hunston, NBS, Polym. Div., Gaithersburg, MD 20899, USA

21–24 **Recent Advances in Drug Delivery**
Salt Lake City (USA)
Contact: K. Knutson, Univ. of Utath, Dept. of Pharmaceutics, CCCD, 421 Wakara Way, Suite 318, Salt Lake City, UT 84108, USA

21–26 **Optical Fibers and their Applications,**
5th Symp.
Warsaw (Poland)
Contact: R. S. Romaniuk, IPI Warsaw Univ. of Technol., Nowowiepska 15–19, PL-00-665, Warsaw, Poland

26–3 **Microlithography,**
Symp. and Exhibition (Micro '89)
Santa Clara (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham, WA 98227, USA

27–1 **Microphysics of Surfaces, Beams and Adsorbates,**
3rd Top. Mtg.
Salt Lake City (USA)
Contact: R. B. Hall, Exxon Research & Eng., Rt. 22E, Annandale, NJ 08801, USA

27–3 **Superconductivity,**
Gordon Conf.
West Coast (USA)
Contact: A. Sleight, E. I. Du Pont de Nemours, Experimental Station 356/301, Wilmington, DE 19898, USA

27–3 **High-Temperature Superconducting Oxides: Processing & Related Properties,**
TMS Annu. Mtg.
Las Vegas (USA)
Contact: The Metallurgical Soc., 420 Commonwealth Dr., Warrendale, PA 15086, USA

March 1989

1–3 **Technical Ceramics,**
2nd Int. Congr. and Exhibit. (Techkeram 2)
Wiesbaden (Fed. Rep. Germany)
Contact: Demat Exposition Managing, P.O. Box 110611, D-6000 Frankfurt, FRG

5–10 **Liquid Crystals,**
6th Eur. Winter Conf.
Schladming (Austria)
Contact: P. Laggner, Inst. für Röntgenfeinstrukturforschung of the Austrian Acad. of Sci., Steyrergasse 17, A-8010 Graz, Austria

6–8 **Crystal Structure, Microstructure and Properties of Minerals and Ceramic Materials,**
Int. Colloq.
Bochum (Fed. Rep. Germany)
Contact: Prof. O. W. Flörke, Ruhr-Univ. Bochum, Inst. für Mineralogie, P.O. Box 102148, D-4630 Bochum, FRG

6–8 **Lithium Battery Technology & Applications,**
4th Int. Seminar
Deerfield Beach (USA)
Contact: S. P. Wolsky, Ansum Enterprises Inc., 950 De Soto Rd., Suite 3B, Boca Raton, FL 33432, USA

6–9 **Advanced Materials**
MRS Industry-Univ. Conf.
Denver (USA)
Contact: Dr. Fred Smith, Adv. Mater. Inst., Colorado School of Mines, 1500 Illinois, Golden, CO 80401, USA

6–9 **Condensed Matter Division,**
Eur. Phys. Soc.,
9th Gen. Conf.
Nice (France)
Contact: J. P. Latteuorte, Lab. de la Metiere Condensee, Univ. de Nice, F-06034 Nice, Cedex, France

6–10 **Quantum Wells for Optics and Optoelectronics; Picosecond Electronics and Optoelectronics,**
Top. Mtg.
Salt Lake City (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

8–9 **Molecular Chemistry of Solid-State Electronics**
London (United Kingdom)
Contact: The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG, UK

9–10 **The Martensitic Transformation in Science and Technology**
Bochum (Fed. Rep. Germany)
Contact: Dtsch. Ges. Metallkd., Adenauerallee 21, D-6370 Oberursel FRG

9–11 **Makromolekulares Kolloquium**
Freiburg (Fed. Rep. Germany)
Contact: Prof. H. Finkelmann, Inst. für Makromol. Chemie der Univ., Stefan-Meier-Str. 31, D-7800 Freiburg, FRG

11–14 **Surface Finishing '89**
Brighton (United Kingdom)
Contact: Inst. of Metal Finishing, Exeter House, 48 Holloway Head, Birmingham B1 1NQ, UK

12–14 **High-Tech-Materials and Finishing**
Berlin (West)
Contact: Technik + Kommunikation-Verlag GmbH, Ritterfelddamm 82 h + i, D-1000 Berlin 22

12–25 **Diffusion in Materials,**
NATO Adv. Study Inst.
Aussois (France)
Contact: A. L. Laskar, Phys. and Astron. Dept., Clemson Univ., Clemson, SC 29631, USA

13–14 **Regio Macro II**
Basel (Switzerland)
Contact: Prof. M. Mutter, Inst. für Org. Chem., Univ. Basel, St. Johanns-Ring 19, CH-4056 Basel, Switzerland

15–17 **Confocal Microscopy/3-D Image Processing in Microscopy,**
1st Int. Conf./2nd Int. Conf.
Amsterdam (Netherlands)
Contact: Bureau PAOG, Congr. Office, Tafelbergweg 25, NL-1105 BC, Amsterdam, Netherlands

15–17 **Intelligent Materials,**
Int. Workshop
Ibaraki (Japan)
Contact: T. Kurino, The Soc. of Nontraditional Technol., Toranomon Kotohira-Kaikan Bldg. 3F, 1-2-8 Toranomon, Minato-ku, Tokyo 105, Japan

20–22 **Mechanical Properties of Materials at High Rates of Strain,**
4th Int. Conf.
Oxford (United Kingdom)
Contact: J. Harding, Eng. Sci. Dept., Univ. of Oxford, Parks Rd., Oxford OX1 3PJ, UK

20–22 **Refractory Metals and Silicides**
Eur. Workshop
Houthalen (Belgium)
Contact: R. De Keersmaecker, IMBE, Kapeldreef 75, B-3030 Leuven, Belgium

20–23 **Surface Science,**
Interdisciplinary Conf.
Liverpool (United Kingdom)
Contact: P. Weightman, Liverpool Univ., Oliver Lodge Lab., Oxford St., P.O. Box 147, Liverpool L69 3BX, UK

27–31 **Aerospace Sensing,**
Tech. SPIE's Symp.
Orlando (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), Technical Program Committee, P.O. Box 10, Bellingham, WA 98227, USA

28–31 **Aluminum-Lithium**
5th Int. Conf.
Williamsburg (USA)
Contact: Al-Li-V, School of Eng. and Applied Sci., Thornton Hall, Univ. of Virginia, Charlottesville, VA 22901, USA

29–31 **Neutron and X-Ray Scattering: Complementary Techniques**
Canterbury (United Kingdom)
Contact: Dr. R. J. Newport, Univ. of Kent, Physics Dept., Canterbury, Kent CT2 7NR, UK

30–31 **Colorado Microelectronics**
Colorado Springs (USA)
Contact: CMC '89 Conf. Secretary, Microelectronics Research Lab., Univ. of Colorado, Colorado Springs, CO 80933-7150, USA

30–14 **High-T_c Superconductors,**
Exp. Workshop
Miramare (Italy)
Contact: Int. Ctr. for Theoretical Physics, P.O. Box 586, I-34100 Trieste, Italy

April 1989

1–6 **Superconductivity,**
2nd World Congr.
Houston (USA)
Contact: R. D. Kane, World Congr. on Superconductivity, P.O. Box 27805, Houston, TX 77227-7805, USA

3–5 **Modern Practice in Stress and Vibration Analysis**
Liverpool (United Kingdom)
Contact: Meetings Officer, Inst. of Physics, 47 Belgrave Sq., London SW1X 8QX, UK

3–6 **Low Energy Ion Beams,**
5th Conf.
Guildford (United Kingdom)
Contact: Meetings Officer, Inst. of Physics, 47 Belgrave Sq., London SW1X 8QX, UK

3–7 **Copolymerization and Copolymers in Dispersed Media**
Lyon (France)
Contact: I. Guillot/C. Pichot, Lab. des Materiaux Organiques, BP 24, F-69390 Vernaison, France

3–7 **High Temperature Materials '89**
Gaithersburg (USA)
Contact: J. W. Hastie, National Bureau of Standards, Gaithersburg, MD 20899, USA

4–7 **Electrochemical Processing of Semiconductors**
Berlin (West)
Contact: W. Pieth, Free Univ. of Berlin, Inst. of Phys. Chem., Takustraße 3, D-1000 Berlin 33

4–14 **Phase Transition in Soft Condensed Matter,**
NATO Adv. Study Inst.
Geilo (Norwegen)
Contact: G. Jarret, Inst. for Energy Technol., Dept. of Physics, P.O. Box 40, N-2007 Kjeller, Norwegen

6–7 **Modeling in Crystal Growth from the Melt,**
NATO Workshop
Parma (Italy)
Contact: G. Müller, Inst. für Werkstoffwissenschaften 6, Martensstraße 7, D-8520 Erlangen, FRG

10–12 **Bayreuther Polymer Symp.,**
Bayreuth (Fed. Rep. Germany)
Contact: BPS '89, Lehrstuhl Makromolekulare Chemie II, Univ. Bayreuth, Postfach 101251, D-8580 Bayreuth, FRG

10–13 **Microscopy of Semiconducting Materials,**
MRS 6th Oxford Conf.
Oxford (United Kingdom)
Contact: Administrator, Royal Microscopy Soc., 37/38 St. Clements, Oxford OX4 1AJ, UK

11–13 **Catalysis by Well Characterized Materials**
Liverpool (United Kingdom)
Contact: Prof. R. W. Joyner, Leverhulme Ctr. for Innovative Catalysts, Univ. of Liverpool, Grove St., P.O. Box 147, Liverpool L69 3BX, UK

17–26 **Ceramics and Composite Materials,**
Spring College in Mater. Sci.
Trieste (Italy)

Contact: Int. Ctr. for Theoretical Physics, Spring College in Mater. Sci. 1989, P.O. Box 586, I-34100 Trieste, Italy

18–19 **Industrial Water-Soluble and Water-Swellable Polymers**
Manchester (United Kingdom)
Contact: The Registar (Mid-Career Training), UMIST, P.O. Box 88, Manchester M60 1QD, UK

23–28 **Nondestructive Testing,**
12th World Conf. (WCNDT '89)
Amsterdam (Netherlands)
Contact: B. de Jong, RAI Organisatie Bureau Amsterdam bv, Europaplein 12, 1078 GZ Amsterdam, Netherlands

23–27 **American Ceramic Society,**
91st Annu. Mtg. and Expo.
Indianapolis (USA)
Contact: Dr. K. M. Nair, Electronics Dept., E.I. du Pont de Nemours Co., Inc., 3181 Buffalo Ave., Niagara Falls, NY 14302, USA

24–28 **Optical Science and Engineering,**
2nd Int. Congr.
Paris (France)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham, WA 98227, USA

24–28 **Lasers and Electro-Optics,**
LEOS-IEEE-OSA Conf. (CLEO '89)
Baltimore (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

24–28 **MRS Spring Mtg.**
San Diego (USA)
Contact: J. B. Ballance, MRS, 9800 McKnight Rd., Suite 327, Pittsburgh, PA 15237, USA

25–27 **Hot Isostatic Pressing of Materials**
Antwerpen (Belgium)
Contact: Hot Isostatic Pressing Conf., c/o K. VIV, Jan van Rijswijcklaan 58, B-2018 Antwerpen, Belgium

26–28 **Joining Ceramics, Glass and Metal**
3rd Int. Conf. (CGM '89)
Contact: Dtsch. Gesellsch. Metallkd., Adenauerallee 21, D-6370 Oberursel, FRG

May 1989

1–3 **Tunable Solid State Lasers,**
Top. Mtg.
North Falmouth (USA)
Contact: Optical Soc. of America (OSA), 1816 Jefferson Pl. NW, Washington, DC 20036, USA

1–5 **Scanning Microscopy,**
Salt Lake City (USA)
Contact: O. Johari, Scanning Microscopy Int., P.O. Box 66507, Chicago, IL 60666, USA

4–6 **The Solid State—Dynamics and Kinetics**
Annu. Mtg. Dtsch. Bunsen-Gesellsch. für Phys. Chem.
Siegen (Fed. Rep. Germany)
Contact: Dtsch. Bunsen-Gesellsch., Carl-Bosch-Haus, Varrentrappstr. 40/42, D-6000 Frankfurt am Main 90, FRG

7–12 **High-T_c Superconductor Technologies**
175th Mtg. Electrochem. Soc.
Los Angeles (USA)
Contact: S. Raider, IBM T. J. Watson Research Ctr., P.O. Box 218, York Town Heights, NY 10598, USA

7–12 **Fundamentals of Adsorption,**
3rd Int. Conf.

Reaction Mechanisms in Heterogeneous Catalysis; C–H Activation as a Case Study

By Wilhelm F. Maier*

Heterogeneous catalysis is changing from an empirical art to an exact science. The various methods for the analysis of solids and surfaces, constantly refined by materials science and surface science, seem to be almost unlimited. The increasing availability of atomic resolution microscopy as well as synchrotron radiation allows the characterization of catalyst particles, surface structures, surface processes and surface intermediates. We have learned to determine the surface structure sensitivity of catalytic reactions. Thermodynamic and kinetic data of catalytic reactions are now determined routinely. Isotopic exchange and labeling experiments provide information about reactant-catalyst interactions. How much have we learned through these techniques about the nature or mechanism of heterogeneously catalyzed reactions? The following article attempts to summarize the progress and the problems encountered in mechanistic studies of C–H bond formation and activation in a hydrogen atmosphere as an example for the present state of the understanding of reaction mechanisms in heterogeneous catalysis.

1. Introduction

The activation and formation of carbon–hydrogen (C–H) bonds on surfaces are fundamental processes in heterogeneously catalyzed reactions. C–H activation is most commonly associated with functionalization and refining of hydrocarbons. The reverse process, C–H bond formation, is a central step in dihydrogen addition and hydrogenolysis reactions. Although C–H activation and hydrogenation are connected by microscopic reversibility, they have traditionally been treated separately. The astronomical number of publications concerned with these reactions prevents a comprehensive review. Secondary literature represents the most helpful source of information for the chemist.[1–3]

[*] Prof. Dr. W. F. Maier
Fachbereich 8 Chemie der Universität/Gesamthochschule
Schützenbahn 70, D-4300 Essen 1 (FRG)

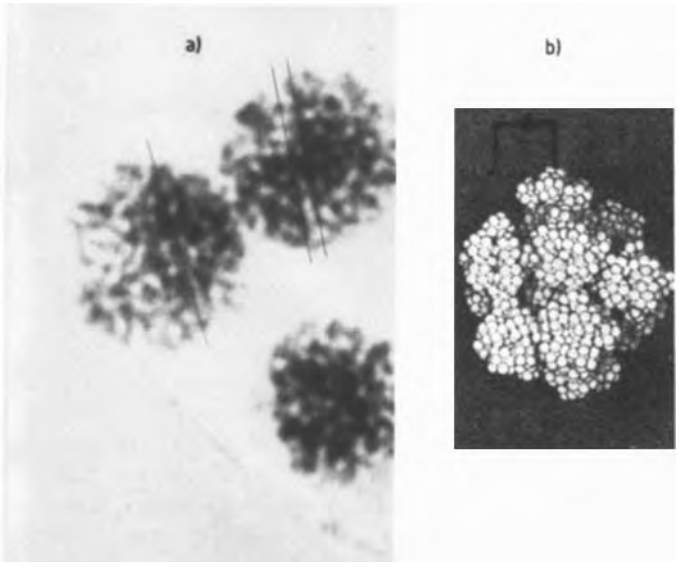
2. General Aspects

Heterogeneously catalyzed reactions with hydrogen are surface reactions with three principal reaction partners: the organic molecule, hydrogen, and the catalyst surface. Although the effects of the structure of the organic molecule and of the reaction and process conditions[4] on the catalytic process are understood, empirical procedures still dominate in catalyst preparation and development.[5] Process catalysts, prepared by empirical recipes of a proprietary nature, often contain multiple additives of unknown function. The catalytic reaction, however, is still a molecular process and it is unlikely that all the additives participate in the catalytic process itself. More likely is that additives and pretreatment procedures chemically or morphologically modify the catalyst to provide a maximum concentration of active sites.[6] An understanding of the effect of modifiers on the surface and bulk structure of a catalyst

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0202-0135 $ 02.50/0

may therefore go hand in hand in hand with a molecular understanding of the active site structure.

It was hoped that organometallic chemistry would bring about this molecular understanding through the synthesis of well defined homogeneous analogues of the active site. Well known examples of homogeneous catalysts are Wilkinson's catalyst and its analogues for olefin hydrogenation. Deuteration reactions of olefins with Wilkinson type catalysts cleanly produce [D_2]alkanes,[7] in contrast to the mixture of isotopic isomers generated by heterogeneous catalysis.[2] Despite a wide range of applications and catalyst variations, there is no indication of a strong impact of this homogeneous catalyst upon the understanding of heterogeneous hydrogenation catalysis.[8] Mild, homogeneous activation of C–H bonds in alkanes[9] is achieved by reactive organometallic intermediates. Despite some theoretical insight into the mechanism of the homogeneous processes,[10] there is no evidence for an analogy with heterogeneously catalyzed C–H activation reactions. Organometallic chemistry has become a distinct field of chemical research which has opened up new avenues in heterogeneous catalysis, such as heterogenized homogeneous catalysis. This apparent lack of correlation between heterogeneous and homogeneous catalysis may largely be attributed to the dominating mononuclearity of organometallic compounds, which is in strong contrast to the rather large metal clusters encountered in heterogeneous catalysis. However, an analogy between homogeneous and heterogeneous catalysis is perhaps possible in the area of metal cluster chemistry. *Schmid* et al. observed not only the preferred formation of clusters of 13 and 55 atoms, they also obtained evidence for the formation of structured super clusters via the combination of 13 atom clusters (Fig. 1b).[11] Pd super clusters of this type might be present in heterogeneous Pd-catalysts.[6] Some structural order, similar to that found in Schmid's clusters, is recognizable in the TEM-picture of the Pd super clusters of a heterogeneous catalyst (Fig. 1a). The distance between the layers in these clusters is about 50 Å, which corresponds to a particle diameter of about 60 Å. We have observed similar super clusters on various Pd catalysts, such as Pd on SiO_2, TiO_2 and Al_2O_3, indicating that super cluster formation may be a general phenomenon for certain metals. These analogies between homogeneous clusters and heterogeneous catalysts suggest that metal cluster chemistry may eventually redeem the promises of organometallic chemistry with respect to heterogeneous catalysis. At present, however, we have to recognize that organometallic chemistry has not yet contributed significantly to the understanding of classical heterogeneous catalysis.



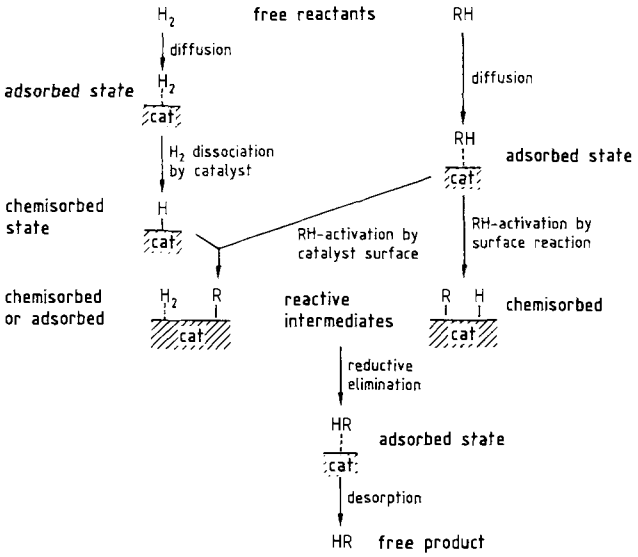


Fig. 1. a) TEM picture of Pd super clusters of a Pd/Al_2O_3 catalyst (magnification from Fig. 1B in [6]), b) postulated super cluster from homogeneous cluster chemistry [11]. Recognizable orientation in a) is marked with lines.

3. Reaction Conditions—Thermodynamic and Kinetic Aspects

Understanding of heterogeneously catalyzed reactions must be based on mechanistic studies of heterogeneous catalysis. Mechanistic studies in heterogeneous catalysis commonly determine thermodynamic and kinetic data as well as investigate isotopic exchange. Despite many decades of such research there is still little precise knowledge about the catalytic process itself. A problem in such mechanistic studies is that the reaction conditions chosen have to be examined carefully before meaningful conclusions can be drawn. Scheme 1 shows a simplified summary

Scheme 1. Summary of the processes involved in heterogeneously catalyzed reactions of hydrocarbons with hydrogen.

of the processes involved in C–H activations of alkanes with heterogeneous catalysts.

Depending on reaction conditions, any one of the steps in Scheme 1 may be rate determining. Activation barriers for C–H activation, commonly determined without knowledge of identity of the rate determining step, have contributed little to our mechanistic understanding. It is commonly accepted that activation barriers below 3 kcal mol^{-1} are indicative of diffusion control or hydrogen activation as the rate limiting step, conditions which do not contribute to the understanding of the reaction. Useful

data for mechanistic studies therefore require reaction conditions, under which the hydrocarbon itself is involved in the rate determining step, which is often indicated by higher activation barriers (>3 kcal mol^{-1}) and first and zero order reactions in hydrocarbon and hydrogen respectively. Such conditions ensure minimal residence time of the organic reactant on the catalyst surface and little interference by secondary surface processes. Appropriate reaction conditions can be readily achieved in gas phase flow reactors by using high hydrogen and low hydrocarbon partial pressures. The importance of controlling the reaction conditions is demonstrated by the dependence of the isotopic distribution of the products upon the concentration of adsorbed hydrogen and upon whether the reaction proceeds with a reaction-controlled or diffusion-controlled rate limiting step.[12]

Higher activation barriers (>3 kcal mol^{-1}) and positive and zero reaction orders in reactant and hydrogen, respectively, indicate that oxidative addition (chemisorption or adsorption of the hydrocarbon) or reductive elimination (desorption) is the rate determining step. Evidence for oxidative addition as the rate determining step has been found in the H/D exchange of 2,2-dimethylpentane on Rh.[13]

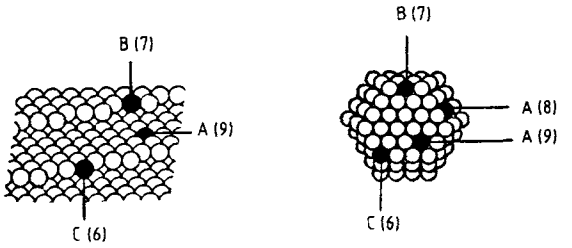
However, high activation barriers do not guarantee reaction rate control. First order reaction rates in hydrogen with activation barriers comparable to the condensation enthalpies of the reactant, the solvent, or water (commonly between 6 and 15 kcal mol^{-1}) are consistent with desorption of "surface-condensed" molecules being rate determining.[14] In this model the rate is determined by the formation of free surface sites for hydrogen chemisorption by desorption of adsorbed material (monolayers of water, solvent, or reactant).[14]

In addition to these problems of interpretation, kinetic studies, especially of olefin hydrogenation reactions, are often plagued by catalyst poisoning of still unknown origin.[15] Further difficulties result from lack of knowledge of the actual reaction temperature, since the temperature at the catalytically active center can exceed the average reactor temperature by up to several hundred degrees.[16]

The H/D exchange reactivity of those alkanes which are capable of forming olefinic or allylic intermediates (linear and cyclic alkanes) on Pt is inversely proportional to the vapor pressure, indicating a dependence on the concentration of adsorbed hydrocarbon.[17] Such a dependence of the C–H activation rate on the surface concentration of adsorbed hydrocarbons is supported by the vapor pressure dependent adsorption of saturated and unsaturated hydrocarbons on Rh-black (nonporous) under H/D exchange conditions.[13] Since adsorption is a purely physical process, this reaction follows the Langmuir/Hinshelwood formalism with physisorbed and not chemisorbed reactants.

4. Which Catalyst Properties are Important for Catalysis?

4.1. Surface Interactions



The chemical nature of the metal catalyst affects the activity and the selectivity of hydrogenation[2] and C–H activation reactions. However, the exact function of the metal catalyst in these reactions is still unclear. It was found that hydrogenation, dehydrogenation, and exchange reactions occur with spillover hydrogen (migration of dissociated hydrogen from the catalyst metal particle onto the support)[18] indicating that the metal is not necessarily part of the actual reaction. What then is the function of the noble metal particles in the catalytic reaction?

4.2. Surface Carbonization

Before we can address the metal surface itself, we have to consider surface carbonization. Carbonaceous residues rapidly form on catalyst surfaces during the catalytic reaction and cause variable deactivation due to surface blocking. It was never clear whether the catalytic reactions are happening on the exposed metal surface or on top of a rapidly forming carbonaceous overlayer. In 1950, *Beek* concluded that surface deposits are not involved in the reaction.[19] Carbonaceous residues were found to be catalytically inactive for hydrogen reactions.[20] Such insensitivity of the catalytic reaction to carbonaceous residues is observed in practice, where lower levels of carbonization on process catalysts do not seem to affect catalytic activity or selectivity. Cyclohexene and ethylene hydrogenation occur despite a rapid buildup of a carbonaceous overlayer so dense that direct interaction of the reactant with the Pt surface is essentially impossible.[21,22] It was suggested that the reaction occurs on top of the overlayer and that the carbonaceous overlayer material is part of the catalytically active site.[21] In the case of ethylene hydrogenation, the carbonaceous layer was shown to consist mainly of alkylidynes, which were proposed as direct mediators of the catalytic activity. This view was opposed by later studies on Pd catalysts, where the buildup and removal of surface alkylidynes is unrelated to the catalytic reaction itself and the carbonaceous materials, such as alkylidynes, were considered to be uninvolved bystanders in the catalytic process.[23] Similar insensitivity to carbonaceous buildup was found in the activity and selectivity of H/D exchange reactions of hydrocarbons on Rh black.[24] It was concluded that carbonaceous surface species are not required as part of the catalytically active site on catalyst surfaces. Catalytic reactions seem to be insensitive to the presence of carbonaceous deposits indicating that the reactions might not differentiate between an exposed metal surface and a carbon covered surface.[13] Only catalyst deactivation by extensive carbonization can be considered to be a true effect of carbonaceous material.

4.3. Surface Structure

There are only a few principally different sites on the surface of a face centered cubic crystal: terrace atoms on (111) or (100) surfaces (characterized by nine or eight nearest neighbors respectively); all surfaces with higher Miller Indices contain additional surface steps and kinks (characterized by seven or six nearest neighbors respectively). The same type of surface atoms are also present on metal particles (Scheme 2). A principal difference between step or

Scheme 2. Similar surface atom types on flat surfaces and particles of FCC metals. Atom types are characterized by the numbers of nearest neighbors in parentheses. A = on (111) or (100) terraces; B = on steps or edges; C = on kinks or corners.

kink atoms on plane surfaces and on metal particles is the degree of surface curvature. Especially for small particles surface curvature can be expected to affect the electronic and steric interaction of the surface with the reactant. Surface reactions which are influenced by the types of surface atoms are termed surface structure sensitive. Such sensitivity of catalytic reactions to the surface structure of the metal particles of the catalyst suggests that the ideal catalyst would be a material with the right surface structure rather than an empirical mixture of ingredients.

4.3.1. Analysis

Although surfaces of well defined structure are routinely prepared for surface science studies by the cutting of single crystals, their direct use in catalysis would be costly and unpractical. Whereas heterogeneous catalysts have metal surface areas of several $m^2\ g^{-1}$, single crystal surfaces have only a few cm^2 of surface area and their use outside of UHV-chambers is hampered by surface contamination and rearrangement in the first atomic layer. Direct application of the insights achieved by surface science studies to catalysis is also limited by the idealized conditions required for single crystal studies, which usually differ greatly from the conditions used in catalysis. Although the number of exposed surface atoms can be measured by various adsorption techniques, there is no relationship between this number and the number of active sites on the catalyst surface. There is general agreement that the catalytic intermediates are very unstable and very few in number.[25] An upper limit of 10^{-4} active sites/surface atom (steady state concentration) can be estimated based on data obtained during the study presented in ref. [13]. Whether the concentration of reactive intermediates is controlled by unique arrangements of the surface atoms or simply controlled by thermodynamic factors with all surface atoms as potential active sites is not clear. The direct study of catalytic reactions by surface science techniques[26] is therefore also limited by the low steady state concentration of reactive intermediates, which is orders of magnitude below the accuracy attainable in the preparation of defined surfaces. (The commonly attainable precision in the cutting angle leads to a concentration of defect sites of > 1% on the single crystal surface.) The importance of such surface imperfections has recently been demonstrated by *Poelsema, Lenz* et al. on nearly defect-free surfaces.[27] They found that H_2 dissociation occurs on the step atoms of Pt-surfaces, H_2 activation on terrace surfaces is therefore directly dependent on the defect concentration. This evidence for the high structure sensitivity of hydrogen activation on Pt seems to question the results of all previous structure sensitivity studies.

In spite of the mentioned difficulties, there are practical methods for generating catalysts with preferred surface orientations. The preparation of oriented Pd-catalysts of high catalytic selectivity has been achieved by epitaxial growth of Pd on a suitable support. Figure 2 shows the (111) orientation of a Pd film on sapphire and the (100) orientation of a Pd film on tungsten foils. As expected, these oriented Pd film catalysts show high *cis*- and semi-hydrogenation selectivities for the reduction of alkynes.[28]

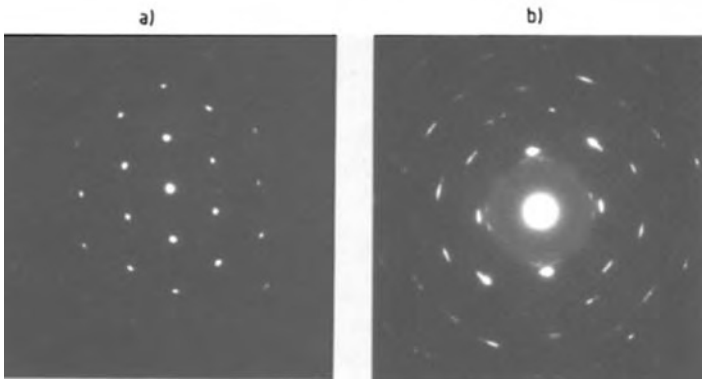


Fig. 2. Electron diffraction pattern of epitaxial Pd-films (thickness 100 nm) show a) the preferred (100) orientation of Pd on W foil and b) its preferred (111) orientation on sapphire.

Sophisticated transmission electron microscopy (TEM) studies allow the characterization of supported metal particles on practical catalysts,[29] but the wide distribution of particle sizes and shapes on a supported metal catalyst renders a detailed analysis of the surface composition of "real" catalysts impractical. Tunneling electron microscopy does allow the atomic characterization of selected portions of the surface, but there is still too little experience with this method for it to have an impact on our understanding of heterogeneous catalysis.

Nevertheless, simple geometric considerations predict that with increasing particle size the number of terrace type surface atoms increases while the number of step and especially kink type sites decreases.[17] The surface of idealized particles has a maximum step atom concentration for particles having an intermediate dispersion (= ratio of surface atoms to total number of atoms) of 30–60%,[30] while the surface of smaller metal particles is dominated by kink-type atoms. Investigations on the influence of catalyst dispersion on catalytic activity and selectivity are not only worthwhile, but are also the only methods currently available which give information about the surface structure sensitivities of catalytic reactions under real reaction conditions. These studies are normally conducted under standardized conditions using several, well characterized catalysts with widely differing dispersions. Additional complications in the interpretation of results are caused by the dependence of the work function on metal particle size, especially for very small particles. It is not yet possible to separate the effect of surface structure from particle size

effects. The increasingly metallic character of larger metal particles may affect catalytic reactions just as much as the changes in surface structure associated with these size changes. Further complications are caused by the morphological instability of supported or dispersed metal particles under the reaction conditions with respect to particle migration, fusion, reconstruction and crystallization processes. Pd and Ni based catalysts[31] are, because of their tendency to form β-hydride phases, especially prone to such morphological changes, which make conclusive analyses of particle size or surface structural effects difficult. The improved selectivity of Rosenmund,[32] Lindlar,[28,33] and other Pd catalysts[6] after empirical catalyst pretreatment with a modifier has been explained in terms of morphology changes caused by the modification process.

Figure 3 shows how the size of the Pd crystallites of a Pd/C catalyst in its untreated form increases after catalyst modification with the Rosenmund treatment and after

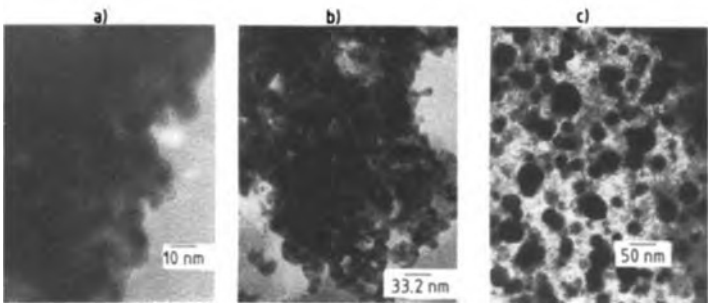

Fig. 3. TEM pictures showing the increase of Pd-particle size of a Pd/C catalyst. a) Untreated catalyst. b) Catalyst after Rosenmund treatment. c) Deactivated catalyst.

deactivation.[28] In this case deactivation can be attributed to loss of metal surface area and not catalyst poisoning. The problems of morphological instability, associated with heterogeneous Pd catalysts, were overcome by the use of epitaxial Pd-film catalysts on tungsten foil (see Fig. 2). The orientation of these Pd film catalysts increases with use, an effect associated with the orienting influence of the tungsten carrier material.[28]

4.3.2. Surface Structure Sensitive Reactions

The surface structure sensitivity of a catalytic reaction is commonly determined as the dependence of the reaction rate or selectivity on catalyst dispersion. Knowledge of the sensitivity of catalytic reactions to surface orientation[34] or particle size can be used for the rational improvement of heterogeneous catalysts.[28] Many examples of reactions exhibiting sensitivity to the surface structure of single crystals are known.[26] Based on several studies, *Boudart* et al. classified C–H bond breaking and forming as surface structure insensitive reactions and C–C bond forming and breaking as surface structure sensitive reactions.[35] However, many of the studies upon which the conclusions are based must be interpreted with caution; they neither cover the whole dispersion range from bulk metal to 100% dispersion nor do they report that reaction conditions have been applied which assure that the catalytic reaction is the rate determining step as discussed in Section 3. Hydrogenation reactions best illustrate the controversial nature of this new field. In spite of reaction rates that are zero order in reactant and first order in hydrogen, sensitivity of the rate of hydrogenation to metal dispersion was reported for supported Pd catalysts.[36,37] A moderate structure sensitivity was detected for propene hydrogenation on silica supported Pd catalysts.[36b] 1-Butyne hydrogenation is most rapid on low dispersed Pd catalysts while 1-butene hydrogenation is rather insensitive to Pd dispersion.[37a] On the basis of Pd particle size analysis, edge (step) type surface atoms seem to correlate with the isomerization of (+)-apopinene on dispersed Pd and Pt catalysts.[37b] These observations are in contrast with the generally accepted surface structure insensitivity of hydrogenation reactions. Structure insensitivity was observed in studies of cyclohexene hydrogenation over a limited dispersion range[38] as well as in the hydrogenation of ethylene on defined single crystal surfaces.[39] These discrepancies may be due to experimental conditions as well as to the special nature of ethylene or cyclohexene, which are not at all representative for the conformationally demanding higher olefins. A generalization of surface structure classifications of hydrogenation reactions in the absence of more reliable data seems premature.

There have been few studies on the structure sensitivity of H/D exchange of saturated alkanes. C–H activation of *n*-hexane is most effective on low dispersed (< 10%) Rh[24] and Pt[17] catalysts, and there is little change in turnover frequency at higher dispersions (> 10%). Although it was concluded that terrace surfaces are most effective for C–H activation, a simple particle size effect (e.g. work function) cannot be excluded. Structure sensitivity of rate and isotopic distribution of *n*-hexane exchange on Rh has been observed.[24] H/D exchange of *n*-hexane on Pt single crystal surfaces of (111) and (10,8,7) orientation shows no sensitivity of the reaction rate or isotopic distribution to the surface structure.[40] This was interpreted as structure insensitivity of the exchange reaction,[40] although the data are also consistent with terrace atoms being the active sites,[17] since terrace type surface atoms dominate on both crystal faces (see Section 4.3.1).

5. Hydrogen

While chemisorbed hydrogen on most group 8–10 metal surfaces is dissociated and located in the threefold hollow between the surface atoms,[41] little is known about the nature of the hydrogen in the catalytically active site. Nothing is known about the reactivity of this 'stable' surface hydrogen relative to "top on" bound or bridging hydrogen atoms for surface reactions with organic reactants.

6. Isotopic Exchange Reactions of Hydrocarbons

The structure of the organic reactant is known to influence both the rate and selectivity of C–H bond formation and activation. The most useful tool for probing C–H bond activation and formation mechanisms have been isotopic exchange experiments with deuterium [Eq. (a)].[42]

$$C_nH_m + q\,D_2 \xrightarrow{\text{catalyst}} C_nH_{m-q}D_q + q\,HD \qquad (a)$$

Here the number of deuterium atoms introduced into the hydrocarbon and their distribution are believed to be characteristic of the type of interaction (i.e. type of surface intermediate) between the catalyst and the hydrocarbon. Such experiments are carried out under low conversion conditions to ensure a single interaction of the reactant molecule with the catalyst. Large D_2/hydrocarbon ratios minimize hydrogen dilution (reintroduction of already exchanged H-atoms). Suitable reaction conditions are most readily attained in gas phase flow experiments. Analysis of the products by GC-MS provides information about the total conversion (reaction rate) and the isotopic distribution of the exchanged hydrocarbon.

Branched alkanes are less reactive than linear and cyclic alkanes.[17] Within these classes, the extent of conversion of an alkane correlates with its boiling point and the amount adsorbed with its vapor pressure.[13,17] This indicates that the overall conversion is largely controlled by the steady state surface concentration, while the relative reactivity of different classes of alkanes depends on the ease of formation of reactive surface intermediates (Scheme 4).

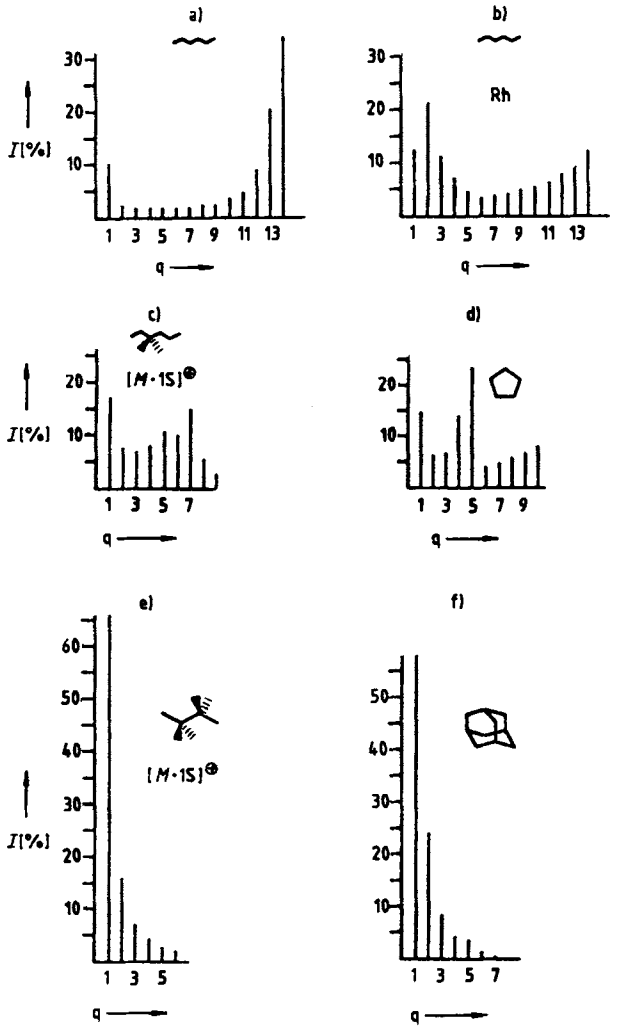

Fig. 4. Representative isotopic distributions ($M^{\oplus}$-peak) from H/D exchange experiments on group 8–10 catalysts at low hydrocarbon conversion. a) *n*-Hexane, b) *n*-hexane on Rh, c) 3,3-dimethylhexane, d) cyclopentane, e) 2,2,3,3-tetramethylbutane, f) adamantane. The distribution b) is typical for Rh. I = relative intensity, q = number of deuterium atoms in the hydrocarbon [cf. Eq. (a)].

The isotopic distribution of alkanes after exchange with deuterium, are obtained from the corrected MS pattern of the parent ion. There are some distinct and reproducible exchange patterns (Fig. 4) attributable to certain structural features of the hydrocarbon or the chemical nature of the catalyst. These patterns seems to provide direct information about the catalyst-hydrocarbon interaction.

6.1. Mono and Perdeuteration Maxima

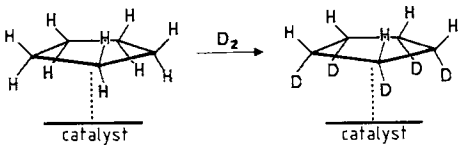
H/D exchange reactions of straight chain hydrocarbons on various group 8–10 metal catalysts produce an isotopic distribution which is characterized by distinct mono and perdeuteration maxima (Fig. 4a).[17,24,43] This type of exchange selectivity has been studied in detail with *n*-hexane and other hydrocarbons on Pt catalysts.[17] In monodeuterated *n*-hexanes the deuterium was located at the terminal position as shown by high resolution ^2H NMR.[17] This assignment is also in agreement with the decreasing relative concentration of the D_1-maximum from *n*-pentane to *n*-heptane found in simple competition experiments, which correlates with the decreasing concentration of terminal C–H bonds.[17] It has been postulated that the activation of terminal C–H bonds leads to surface alkyl ligands which are more likely to reductively eliminate than to undergo additional C–H activations. Secondary C–H bond activation must therefore be the initiator of the multiple exchange processes leading to poly- and perdeuterated products, an interpretation which is also supported by steric arguments.[17] Earlier studies had already shown that the polydeuteration of quaternary centers does not proceed very effectively.[44] Perdeuteration maxima in side chains with three or more adjacent C–H bonds point to the formation of allylic intermediates. For example, the H/D exchange of 3,3-dimethylhexane (Fig. 4c) produces a D_7-maximum localized in the propyl side chain, while the methyl groups show only little D_1-exchange and the ethyl group a statistical distribution for D_1–D_5.[45] A rapidly converting olefin-allyl intermediate, postulated earlier as the most effective mechanism for polydeuteration of alkanes,[17] seems to be confirmed.

Polydeuteration via quaternary centers appears to proceed through metallocyclic α,γ- or α,δ-bound intermediates.[46] These intermediates seem to form more readily if the C–H-bonds activated are secondary rather than primary.[17] In compounds such as 2,2-dimethylbutane or 3,3-dimethylpentane, where allylic intermediates can not form due to the hydrocarbon structure, indications of the formation of vinyl-type intermediates have been obtained.[17] The presumably facile interconversion of σ- and π-vinyl groups in α,α,β-intermediates (see Scheme 4) is believed to be responsible for the direct formation of *trans*-hydrogenation products from alkynes.[2,14] Further evidence for vinylic intermediates has been obtained from mechanistic studies of olefin hydrogenation reactions.[47]

Competition experiments of *n*-hexane with various amounts of 4-methyl-2-pentene provide further evidence for the importance of π-olefin intermediates in polydeuter-

ation reactions. At very low olefin concentrations the 2-methylpentane produced shows a perdeuteration maximum while for *n*-hexane perdeuteration decreases with increasing olefin concentration.[17] Further evidence for olefinic intermediates was provided by high resolution ^2H NMR studies of the H/D exchange product of cyclopentane.[48]

The dominance of a D_1-product with a lack of significant formation of D_2- and higher deuterated isomers after exchange of compounds such as methane, tetramethylbutane (Fig. 4e) and adamantane (Fig. 4f) also support this mechanism.[24] The lack of polydeuteration in adamantane shows that the propagation of C–H activation requires the presence of planar π-bonded intermediates. Further evidence for the importance of planar π-bonded intermediates is provided by the D_2-product formed in H/D exchange experiments of norbornane,[44] where the formation of planar allylic intermediates is impossible due to the rigid structure.



6.2. Dideuteration Maxima

The selective formation of D_2-maxima in the H/D exchange of saturated hydrocarbons on Rh catalysts is attributed to the chemical nature of the metal catalyst (Fig. 4b). A ^2H NMR study indicates that this D_2-maximum in *n*-alkanes is due to the formation of olefinic intermediates and not α,α-adsorbed species.[24] The same conclusion was arrived at independently by *Kemball* et al. for the origin of the D_2-maximum in cyclopentane exchange on Ni[48] and Rh[49] catalysts. It points to a high preference of Rh over other metals to form surface olefins as reactive intermediates in alkane exchange reactions. This preferred formation of D_2-alkanes is temperature and surface structure sensitive, particularly at low temperatures and low dispersions.[24] A decrease in the activation barrier for H/D exchange of *n*-alkanes was found for Rh-foil relative to dispersed Rh. Hydrocarbons which are not capable of forming olefinic intermediates (such as adamantane and tetramethylbutane) show no dependence of the activation barrier on dispersion. This has been interpreted as evidence for a concerted activation of adjacent C–H bonds with formation of olefinic intermediates on the surfaces of low dispersed Rh particles.[24]

6.3. Semideuteration Maxima

Another deuteration selectivity is the formation of semideuteration maxima for cyclic hydrocarbons, a selectivity observed on various metal catalysts (Fig. 4d). Semideuteration is most prominent in cyclopentane but still detectable in cyclohexane and cycloheptane.[17,50] These partial deuteration maxima are attributed to selective exchange on one side of the ring (Scheme 3).[51]

While rapid exchange on one ring side may proceed through the olefin-allyl conversion (see Section 6.1), there must also be an activation barrier for the ring flip. There is increasing perdeuteration with increasing temperature which is indicative of a higher energy intermediate or transition state. A vinylic intermediate has been suggested[17]

Scheme 3. Model to explain the preferred semideuteration in H/D-exchange reactions of cycloalkanes.

rather than the previously proposed roll-over mechanism.[44]

6.4. Olefin Deuteration

Many of the peculiar aspects of olefin deuteration have been discussed elsewhere.[2] For the content of this article it is important to recognize that deuteration of terminal olefins does not give the simple D_2-hydrocarbon expected from a *cis* addition of deuterium to the double bond, but results, in addition to varying amounts of polydeuterated isomers,[2] in a distribution of D_1, D_2 and D_3 isomers in a ratio of about 1:2:1 (Fig. 5). Since this ratio is not influenced by the extent of conversion or by the partial pressure of deuterium, intermolecular hydrogen exchange and C–H activation must be involved in the hydrogenation mechanism. ^2H NMR spectroscopy has provided evidence for the preferred allylic activation of adsorbed olefins as the origin of the D_1 and the D_3 products supporting the preference, postulated in Section 6.1, for allylic over vinylic intermediate formation in the catalytic process.[17] There appears to be only a small difference in the relative stability of allylic and vinylic intermediates. Allylic intermediates seem to form more readily if secondary C–H bonds are involved. The higher C–H bond energy of the methyl group may be responsible for the more facile exchange of the internal vinyl hydrogen (preferred formation of a vinyl or α,α,β-intermediate, see Scheme 4) in the H/D-exchange of propene.[47]

Above: on a heterogeneous Pt catalyst: below: deuterium atoms in the gas phase after reaction with microwave plasma generated in a microwave discharge. (For a more detailed discussion of Figure 5 see Section 8.)

6.5. Reactive Intermediates, A Summary

It can be concluded that surface alkyl, olefin, and allyl ligands are catalytic intermediates in efficient H/D exchange processes. Vinylic and metallocyclic intermediates are also formed but apparently dominate only when the formation of allylic or olefinic intermediates is hindered. Alkylidenes and alkylidynes are not important intermediates in the catalytic exchange processes. This is most likely due to their higher kinetic or thermodynamic stability. Scheme 4 shows the relative importance of these reactive surface species.

Scheme 4. Surface intermediates ordered according to relative stability

Although there is some mechanistic understanding of C–H bond activation and formation processes, the desired molecular understanding of these heterogeneously catalyzed reactions has not been attained. There is still no convincing evidence for the successful identification and characterization of the above mentioned reactive intermediates in heterogeneously catalyzed reactions. Stable surface intermediates such as alkylidynes have been characterized with appropriate techniques but, as explained above, they are not involved in the catalytic process. Interpretations of reaction mechanism are therefore still speculative in nature and have increasingly been based on homogeneous organometallic analogues with an emphasis on covalent bonding. Multiple functionality is thus attributed to the transition metal surface. It is believed to simultaneously activate C–H and H–H bonds, and to serve as a mediator for the reactive intermediates determining the product composition. Although there is little doubt that hydrocarbon conversion on catalysts like zeolites is controlled by carbocations as reactive intermediates,[52] the question of whether radicals, charged, or covalently bonded species are the reactive intermediates in metal catalyzed reactions has not been resolved. This question may be ambiguous considering the change in electronic nature of such intermediates when interacting with the band structure of the metal surface. In fact, the catalytic activity of overlayers of carbonaceous material,[21] of gold films on platinum single crystal surfaces[53] and of spillover hydrogen,[18] suggests that catalysis may not require the presence of exposed catalyst metal surfaces.

7. Catalysis on Silica Overlayers

To investigate the true function of exposed transition metal surfaces in the catalytic reaction, transition metal film catalysts with and without a silica overlayer were compared.[54,55] It was expected that D_2 or H_2 would diffuse through the overlayer and become activated at the transition metal surface (see Scheme 5). The activated hydrogen could then diffuse back to the gas-surface interface in a process similar to hydrogen spillover.[18] Activated hydrogen on the oxide surface was expected to exhibit characteristic catalytic properties different from those of hydrogen on the exposed transition metal surface. Identification of such differences would allow the characterization of metal and of hydrogen spillover catalysis.

Scheme 5. Schematic representation of an overlayer catalyst with the related reaction processes.

The catalysts for these investigations were prepared by thin film deposition techniques on catalytically inactive single crystal silicon wafers. While the Pt/Si as well as the SiO_2/Pt/Si films were found to be catalytically active, SiO_2/Si films were catalytically inactive confirming the importance of Pt. The thin film catalysts were analyzed for composition and trace metal exposure using depth profiling procedures with secondary ion mass spectrometry (SIMS), Rutherford backscattering spectrometry (RBS), and Auger electron spectrometry (AES). All analytical techniques indicated that the silicon dioxide film is continuous, of uniform thickness, and uncontaminated by platinum. Impregnation of the SiO_2 surface of the catalytically inactive SiO_2/Si film with allyl platinum at readily detected concentrations of 10^8–10^{14} Pt atoms per cm^2 led to catalytically inactive materials. This excludes activity due to undetectable trace contamination of the SiO_2 surface with Pt. To exclude other alternative explanations for the observed catalytic activity such as cracks or pores in the silica overlayer, the following control experiments were conducted:

1. A 19 nm Pt layer was deposited on a Si surface through a mask so that the Pt surface was surrounded on all sides by a narrow frame of uncovered Si. The complete surface was then layered with silica. Since the catalytic activity per cm^2 Pt of the masked film was the same as that of an unmasked film, it could be excluded that the activity is purely due to edge effects.
2. Scanning electron microscope pictures show no visible cracks or pores.
3. The relative conversions in competitive deuterations of *n*-hexane and *n*-octane are independent of the presence and thickness of the silica overlayer and correlate with vapour pressure and not with hydrocarbon diffusion rates which supports the absence of small cracks or pores.

4. Subsequent deposition of SiO_2 or Au to fill cracks and pores does not decrease the catalytic activity.
5. SIMS does not show an increase in carbon content at the Pt-SiO_2 interface in used films; a carbon layer is normally formed immediately on the surface of Pt catalysts.

All these data suggest that there is no exposed Pt on the thin film catalysts indicating that the catalysis is happening on the silica surface itself. It was reported that H/D exchange reactions on overlayer catalysts show isotopic exchange patterns very similar to those on catalysts with exposed transition metal surfaces.[54] Activation barriers for these reactions are also very similar on both catalysts, while the catalytic activity decreases exponentially with increasing thickness of the silica overlayer. Similar catalysis on overlayered and exposed Pt films was also observed in hydrogenation-dehydrogenation studies with cyclohexene.[55]

Although all reaction and analytical data were consistent with catalysis on the outer silica surface, there was still a chance that cracks may be opening at higher reaction temperatures due to the different expansion coefficients of the individual layers. Since the analyses of the catalyst films are performed at room temperature, such temperature dependent crack openings would not be detected. *Cis*-semihydrogenation of 2-hexyne, a reaction most selective on Pd, was chosen to examine this possibility. While 2-hexyne hydrogenation on Pd under gas phase flow conditions produces *cis*-2-hexene with a selectivity of greater than 90%, the selectivity decreases to 68% *cis*-hexene on silica covered Pd films at lower temperatures. However, upon raising the temperature above 200 °C these silica covered Pd films gave the >90% *cis*-hydrogenation selectivity indicative of exposed Pd.[56] Control experiments with exposed Pd films showed high *cis*-semihydrogenation selectivity (>90%) over the whole temperature range studied. It must therefore be concluded, that on SiO_2/Pd/Si cracks are opening at higher temperatures and closing again at lower temperatures. Consequently it cannot be excluded that the observed catalysis at elevated temperatures is fully or partly due to direct metal hydrocarbon contacts. However, the fact that catalysis is still observed at lower temperatures on the SiO_2/Pd/Si films still supports the hypothesis that a transition metal hydrocarbon interaction is not required to achieve catalysis.

8. The Connection between Deuterium Atom Reactions and Catalysis

If the transition metal is not accessible to the organic reagent, then the following explanation is the only one consistent with the data presented. Deuterium or hydrogen diffuse through the silica overlayer and are activated (dissociated) at the transition metal surface. The hydrogen atoms diffuse back through the overlayer to the silica surface where they act as catalytically active sites. Such an interpretation is not unreasonable. Spillover hydrogen on silica and alumina has been shown to react with alkanes and olefins;[18] atomic hydrogen on alumina converts benzene to cyclohexane.[57] As early as 1912, *Langmuir* had noted that hydrogen atoms adsorbed on glass surfaces have a long-lived reactivity.[58] Surface diffusion of deuterium atoms on SiO_2 has an activation energy of ca. 15.0 kcal mol^{-1} [61] to 25 kcal/mol[60], on Al_2O_3 28 kcal/mol;[61] while the adsorption energy for H and D atoms on quartz is 12 kcal mol^{-1}.[62] This indicates significant bonding between the hydrogen atom and the silica surface. *Chen* and *White* obtained evidence for 4 states of spillover deuterium on Al_2O_3.[63] The active sites of these overlayer catalysts may therefore be similar, but not necessarily identical with adsorbed hydrogen atoms on silica surfaces.

Further support for such interpretations was obtained in a study which compared the isotopic distributions of hydrocarbons after gas phase and surface reactions with dissociated deuterium atoms generated by a microwave discharge.[64] On heterogeneous catalysts, deuteration of olefins is dominated by a D_2 maximum with varying amounts of polydeuterated isomers (see Fig. 5). It was found that the isotopic distribution of saturated hydrocarbons obtained from the reaction of mono-, di-, tri- and tetrasubstituted alkenes with deuterium atoms in the gas phase is identical to that obtained in deuteration reactions of olefins on Pt, while a slightly higher tendency to polydeuteration was observed on Pd catalysts.[64] The data suggest that the reactive intermediates in heterogeneously catalyzed olefin hydrogenation reactions behave like gas phase radicals, which supports the unimportance of distinct surface metal bonds in the reactive intermediates in such catalytic processes.

However, when saturated hydrocarbons such as *n*-alkanes or cycloalkanes are reacted with the deuterium atoms in the gas phase the polydeuteration maxima observed with Pt catalysts are not reproduced. A distinct D_1 maximum is observed in all cases with statistical fall-off to higher deuteration. No trace of the D_{14} maximum for *n*-hexane, the D_5 and D_{10} maxima for cyclopentane, or the D_7 maximum for 3,3-dimethylhexane was found in the gas phase reactions indicating that these maxima require either the presence of an exposed transition metal surface or at least the presence of a surface per se. However, the lack of a D_5 maximum for cyclopentane after exchange on atomically dispersed Pt (Fig. 6) indicates that this semi-

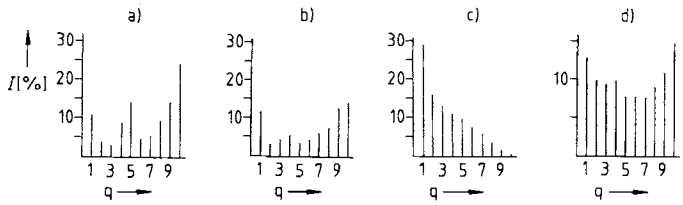


Fig. 6. Isotopic distribution ($M^{\oplus}$ ion) of cyclopentane after exchange with deuterium which was activated as follows: a) on a Pt film; b) on highly dispersed Pt; c) by microwave plasma in the gas phase; d) by microwave plasma in the gas phase in the presence of Al_2O_3.

deuteration maximum may be surface structure sensitive and require the presence of metal clusters. Figure 6 shows how different approaches to the activation of the deuterium for the reaction with cyclopentane affect the isotopic product distribution.

To test for the influence of the surface on the isotopic product distribution, the gas phase reactions were carried out in the presence of inert-membranes separating the deuterium atom flow from the hydrocarbon flow. It was hoped that deuterium atoms would diffuse through the membrane and react with the alkanes on the other side to form exchanged alkanes with per- or polydeuteration maxima.[64]

The expected perdeuteration maxima were obtained for cyclopentane and cyclohexane when a membrane of inert alumina or silica was placed between the gas phase streams of D atoms and cyclic alkanes. Increased polydeuteration was also observed in H/D exchange reactions of acyclic hydrocarbons, although no perdeuteration maxima were observed. Control experiments in the absence of the hydrogen-dissociating plasma showed no exchange.[64] Therefore, perdeuteration maxima in hydrocarbons are not useful as mechanistic tracers for the interaction of metal surface atoms with the substrate.

9. Summary and Outlook

Despite the obvious importance of catalytic C–H bond formation and activation, an understanding of such catalytic processes on the molecular level has not been reached. However, several important findings can be summarized. An exposed transition metal surface is not required for the hydrogenation of olefins or the C–H activation of alkanes. The primary function of group 8–10 transition metals in the catalysis of hydrogen reactions with C–H bond formation and activation is to dissociate (activate) hydrogen, the secondary function is to provide metal specific selectivity. The dissociated hydrogen seems to represent the catalytically active site. Since the concentration of dissociated hydrogen is highest at the hydrogen dissociation sources, i.e. the metal particles, exposed transition metal surfaces are the most effective catalyst surface for these types of reaction. The similar product distributions from the reactions of gas phase deuterium atoms and from heterogeneous catalysis in a deuterium atmosphere suggests a chemistry arising from surface radicals.

In spite of its complexity, heterogeneous catalysis is slowly changing from an empirical art to an understandable science. Modern analytical techniques are largely responsible for this transition. One of the most urgent problems in heterogeneous catalysis is the development of methods which allow the determination of the surface concentration of active sites and the identification and characterization of true reactive intermediates in catalytic processes. Solid state chemistry, materials science and surface science are important related areas for heterogeneous catalysis as are the empirical knowledge collected in catalysis research and chemical engineering and the mechanistic understanding of organic chemistry. A molecular understanding of heterogeneous catalysis requires a multidisciplinary approach and future progress will largely depend on the ability of the scientists to select the right combination of methods. Only such a molecular understanding of catalytic processes will provide insight into the controlling factors of chemical processes on heterogeneous surfaces.

This article was only made possible through the experimental contributions of my graduate students. Work on C–H activation was started with Carlito B. Lebrilla with contributions by Gene C. Lau and Susan B. Chettle. Major breakthroughs were achieved by the work of Jeffrey M. Cogen, Alan B. McEwen, and Judith G. Ulan with contributions from Felicia A. Etzkorn. I owe much to the continuing enthusiasm, engagement, skills, and many creative as well as aggressive discussions of these coworkers. I am also grateful to the invaluable contributions of materials scientists, who are coauthors of many of our papers.

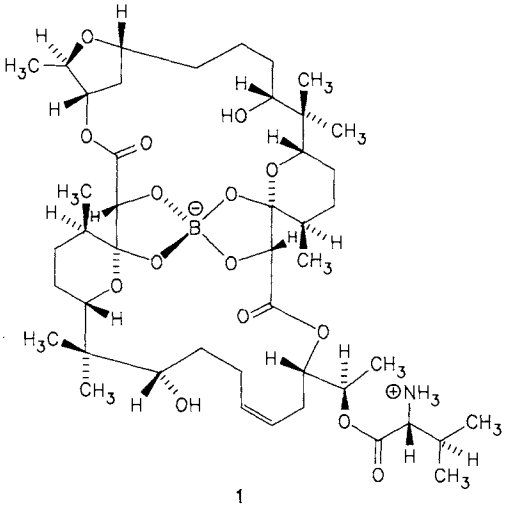
Biosynthetic Studies on Antibiotics



By Heinz G. Floss* and John M. Beale*

The intricacies of the synthetic chemistry executed by living cells in the assembly of complex organic natural products can be probed in great detail by stable-isotope labeling in conjunction with sophisticated 2D and multiple-quantum NMR methods of analysis. Mechanistic details are revealed by unraveling the "cryptic" stereochemistry of biosynthetic reactions with the aid of stereospecific isotope labeling. Analysis of blocked mutants and cloning of biosynthetic genes provides new tools for the study of biosynthetic pathways and for the exploitation of the chemical capabilities of living organisms.

1. Introduction

Living cells manage to elaborate a bewildering variety of organic molecules. Many of these are of ubiquitous or widespread occurrence in living organisms and are essential to the "conduct of business" of living cells. These are often called "primary metabolites"; they make up or are involved in the formation of the structural, functional, energy-producing, or information-containing molecules of living cells. Many other organic compounds are found in nature which are produced by a more limited range of organisms, sometimes only a few species. These are often called "secondary metabolites", a term which unfortunately has suggested to many biochemists that these compounds are secondary in importance. Some of these compounds serve more subtle and specialized functions in the survival of an organism in its overall environment, often relating to communication with other organisms, maintenance of symbiotic relationships, or defense against predators, but for the majority of these compounds no functions are (as yet) known. Many of these natural products are useful to man, for example, as drugs (antibiotics, alkaloids) or as flavoring or coloring agents; others may be detrimental, like toxins, poisons, or irritants.

The structures of organic natural products range from extremely simple ones, like formic acid, the defense and protective agent of certain ants and nettles, to very complex structures, like boromycin **1** (Fig. 1),[1,2] a boron-containing antibiotic produced by *Streptomyces antibioticus* containing 45 carbon atoms and 16 chiral centers. The synthetic prowess of living cells has been a challenge to generations of synthetic organic chemists; the desire to duplicate in the laboratory some of the chemistry carried out by nature has been one of the major driving forces for the development of new synthetic methodology. The chemistry executed by living cells in the course of such natural product syntheses is even more remarkable when one considers the constraints under which it has to be carried out: all reactions have to take place at room temperature, at neutral pH, at normal pressure, and in an aqueous environment! The desire to unravel the secrets of this chemistry has been the motivation of many bioorganic chemists who

1

Fig. 1. Boromycin **1**.

study the biosynthesis of such organic natural products. Beyond suggesting new approaches to the chemical total synthesis of complex organic molecules (biomimetic chemistry), the insights gained from such biosynthetic studies may lead to improved methods for the production of natural products which are of commercial value. They may suggest means of interfering with the formation of natural products which are detrimental to man, and they may allow the structural modification of natural products, for example, by diverting the biosynthetic machinery into producing analogues of the normal natural products from analogues of the biosynthetic precursors or intermediates, and by exchange of genetic information between different organisms. However, quite apart from these potential practical payoffs, biosynthetic studies on natural products generate fundamental knowledge which helps us understand how living organisms have evolved to become highly refined synthetic organic chemists and how the products of these synthetic labors help the organism maintain and improve its position within a particular ecosystem.

2. Experimental Approaches to Biosynthetic Studies

A multitude of different approaches are used to study the biosynthesis of natural products.[3] The majority of these involve the feeding of variously isotope-labeled pre-

[*] Prof. H. G. Floss, Prof. J. M. Beale
Department of Chemistry, University of Washington
Seattle, WA 98195 (USA)

cursors or intermediates to an intact organism to assess the role of the compound tested in a biosynthetic pathway. Such studies may be complemented or followed up by experiments with cell-free systems or, ultimately, purified enzymes. An alternative line of attack on biosynthetic problems involves the use of blocked mutants and, more recently, techniques of molecular genetics (e.g., the cloning of biosynthetic and regulatory genes).

In a classical tracer experiment[4] the putative precursor or intermediate is labeled with a radioactive isotope (e.g., ^{14}C or tritium) and administered to the biological system producing the metabolite under investigation. The proximity of the precursor–product relationship is assessed by examining the percentage incorporation, the percentage specific incorporation, or the dilution factor. Unless the values are very low (less than 0.01% incorporation) or very high (over 10% incorporation), it is often difficult to draw definitive conclusions from these values alone. Therefore, such experiments usually have to be followed up by a chemical degradation of the metabolite under investigation in order to determine whether the radioactivity is located specifically in the expected position.[5] An alternative is the labeling of the precursor in remote positions with two radioactive isotopes (e.g., ^{14}C and tritium) followed by an assessment of whether the ratio of the two isotopes remains constant during the metabolic transformation. Multiple labeling with two radioactive isotopes can also be used to probe specifically for the retention of certain hydrogen atoms relative to the backbone of the molecule in the transformation of a precursor to a product. However, most of these questions can now be probed more easily and/or more definitively by stable-isotope labeling followed by analysis of the product by mass spectrometry or NMR spectroscopy. The unique advantage of radioactive tracer experiments is their great sensitivity; this makes them the method of choice in those cases where the rate of synthesis of a metabolite is very low (e.g., in many experiments with intact higher plants) or where the amounts of metabolite produced are very small (e.g., in studies on the biosynthesis of many vitamins, cofactors, hormones, or pheromones). However, more often in contemporary natural products biosynthesis work, studies with radioactive tracers are used as a prelude to stable-isotope feeding experiments.

The use of stable-isotope labeling in conjunction with mass spectrometry and particularly high-field NMR spectroscopy has become one of the most incisive tools of research in natural products biosynthesis.[6] The power of this approach stems from the fact that the analytical methodology not only indicates the presence or absence of the isotope, but also reveals its distribution within a molecule and between individual molecules of a population. Thus, potentially, an enormous amount of metabolic information can be extracted with sophisticated spectroscopic techniques from the products of such stable-isotope labeling experiments. Tagging of a precursor with a single stable-isotope label (e.g., ^{13}C in a single position of a molecule) allows the fate of the labeled atom to be traced through a metabolic reaction sequence. The ^{13}C NMR signals corresponding to the atom or atoms in the product that originate(s) from the labeled atom of the precursor will show an increased intensity in the ^{13}C NMR spectrum. The fate of bonds can be traced through a metabolic reaction sequence by placing two stable isotopes at the two ends of the bond (e.g., two ^{13}C atoms at the two ends of a carbon–carbon bond) such that the ^{13}C NMR signal for each of the carbons is split into a doublet by coupling to the neighboring ^{13}C nucleus. The administered precursor is diluted by unlabeled material either synthesized endogenously from the available nutrients or administered externally together with the labeled sample. If the bond between the two stable isotopes is broken during the metabolic conversion, the stable isotope in each terminus will be diluted with a large excess of unlabeled material. If a bond is subsequently reformed, the probability of reconnecting the two stable isotopes in the same molecules becomes very small. Hence, the coupling between the two nuclei is lost. Retention of the coupling in the final product indicates that the two nuclei must have originated from the same molecule, strongly suggesting that the bond between them has never been broken.

Multiple stable-isotope labeling, first introduced into studies of natural products biosynthesis by *Seto* et al.[7] and by *Battersby* et al.[8] can also be used to distinguish between intra- and intermolecular processes in group-transfer and rearrangement reactions. In relatively simple cases, mass spectrometry may serve as the analytical tool to distinguish between intra- and intermolecular labeling, but with more complex molecules, NMR spectroscopy is usually the method of choice. In addition to the coupling analysis, which can be used with two magnetically active nuclei, intramolecular double labeling with two isotopes can also be detected if one isotope is magnetically active and the other exerts an isotopic shift on its NMR signal. In this way, the presence of deuterium can be detected by the α- or β-deuterium isotope shift on a ^{13}C NMR signal[9] and the presence of ^{18}O can be detected by the (smaller) α-^{18}O effect.[10] With these techniques, the retention of specific oxygen, hydrogen, or nitrogen atoms relative to the backbone of the precursor molecule can be probed definitively.

Key precursors, like glucose[11,12] or glycerol,[13] labeled uniformly with ^{13}C (90–99% enrichment in every carbon) can be used for mapping of metabolic pathways to a product in cases where it is not evident from the structure or from simple specific feeding experiments which metabolic route(s) is (are) involved in the construction of a particular metabolite. Extensive analysis of the homonuclear coupling patterns of the product from such a feeding experiment reveals which assemblies of carbon atoms in the product have been derived intact from the precursor molecule. Since the various pathways of primary metabolism lead to predictable coupling patterns, the involvement of certain metabolic routes (e.g., shikimate pathway, pentose phosphate shunt, Krebs cycle) can be inferred. Such experiments, particularly when applied to complex molecules, require the detailed analysis of often very complex second-order and/or overlapping coupling patterns, necessitating the extensive use of modern 2D and multiple-quantum NMR techniques. The amount of metabolic information that can be extracted from such experiments is usually proportional to the degree of sophistication of the

NMR analysis of the product. Hence, it is not surprising that many state-of-the-art 2D NMR techniques have been quickly adopted or modified for biosynthetic experiments (e.g., INADEQUATE,[14,15] triple-quantum INADEQUATE,[16] COSY,[17] and 2D heteronuclear correlation).[18] 2D NMR techniques have also been developed for the stereochemical analysis of stereospecifically deuterium-labeled natural products, as exemplified by the work of *Vederas* et al.[19] and *Gould* et al.[20]

Once the basic building blocks of a natural product have been identified, the studies often turn to a more detailed analysis of the biosynthetic reaction sequence and mechanistic aspects of biosynthetic transformations. Analysis of the stereochemistry of these transformations often provides mechanistic information, allows a discrimination between alternative pathways, or sometimes provides evidence for or against the involvement of a particular enzyme.[21] Since the majority of biochemical reactions take place at centers, usually carbon atoms, that are not a priori chiral, these studies usually rely on the synthesis of stereospecifically isotope-labeled substrates and the evaluation of their fate in the biosynthetic reaction sequence. Again, the isotope used in such studies may be radioactive (e.g., tritium) or stable (e.g., deuterium).

More detailed information is obtained by further studies with crude cell-free extracts or, eventually, individual purified enzymes. Even the use of a crude cell-free system has an advantage over that of whole cells in that one can be reasonably certain that an administered precursor will reach the site of synthesis. In a whole-cell experiment, nonincorporation of an administered compound may be due to permeability barriers which prevent its uptake by the cell. Studies with purified individual enzymes ultimately provide definitive mechanistic information on specific reaction steps. They also may shed light on the regulation of a biosynthetic pathway. However, one has to realize that studies at the enzymatic level can be quite involved and labor-intensive; therefore, many biosynthetic investigations are not carried all the way to this stage.

An altogether different approach to biosynthetic studies involves the use of genetic techniques. The preparation of mutants blocked in the synthesis of the metabolite under investigation in conjunction with assays for cosynthesis, in vivo or in vitro complementation, may reveal the minimum number of steps involved in a biosynthetic sequence. Chemical analysis of these mutants can establish the structures of intermediates, thus ultimately allowing the construction of a biosynthetic pathway. This approach has been extensively used to unravel the routes of primary metabolism. Its application to the study of secondary metabolites is more difficult because loss of the biosynthetic ability in this case does not result in a nutritional requirement. Thus, the selection of blocked mutants is more difficult, having to rely usually on the analysis of large numbers of colonies for some identifiable marker (e.g., loss of a pigment or loss of antibiotic activity). Nevertheless, the approach has been used successfully in natural products biosynthesis, particularly in the study of various antibiotics.[22-24] With the further development of systems for the genetic manipulation of organisms producing secondary metabolites, we are now beginning to see the impact of modern methods of molecular biology on such biosynthetic studies. Already, a number of antibiotic biosynthesis genes have been cloned, including those for entire pathways,[25] and a few have been sequenced. These genes are used to study the regulation and genetic control of antibiotic biosynthesis, to isolate biosynthetic genes from other organisms[26] and to construct genetically engineered organisms producing new hybrid antibiotics.[27,28] The next few years are likely to see a dramatic increase in the use of genetic approaches to the study of natural products biosynthesis, and these can be expected to be very incisive, particularly when combined with more traditional chemical and biochemical approaches.

In the following we will highlight some of these methods and approaches used in the study of natural products as we discuss various projects, most of which have been or are being conducted in our laboratory in the field of antibiotic biosynthesis.

3. Hydroaromatic Compounds—The Formation of Cyclohexane Rings

A number of antibiotics contain partially or fully reduced benzene rings which are evidently derived via the shikimate (**2**, Fig. 2) pathway, raising the question how a metabolic pathway designed to produce aromatic systems has been diverted into generating hydroaromatic struc-

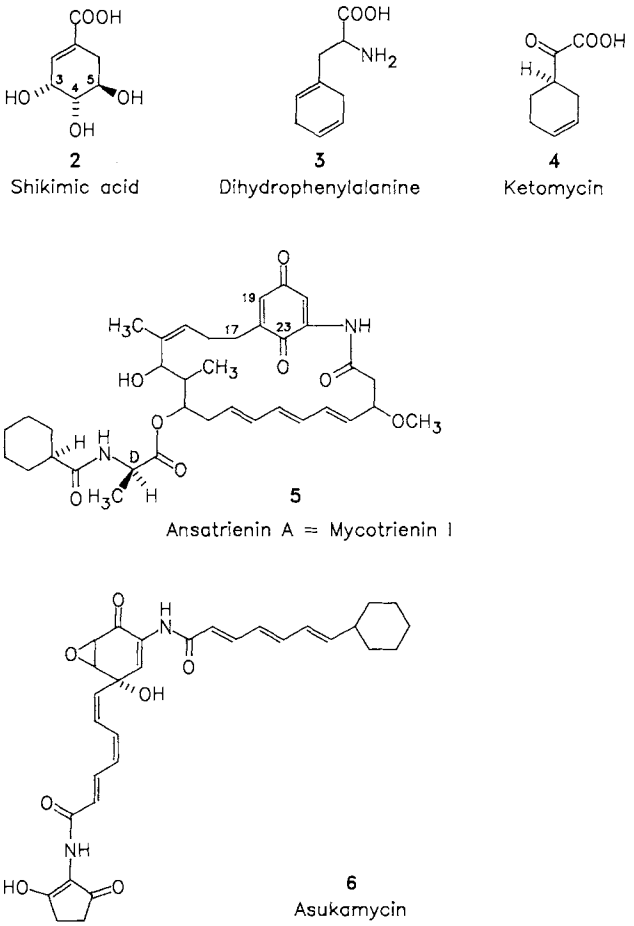


Fig. 2. Shikimic acid **2** and some of its hydroaromatic metabolites.

tures To obtain information on the mode of formation of these reduced aromatic ring systems, we have studied a number of examples (see Fig. 2) including the unconjugated cyclohexadiene system in dihydrophenylalanine **3**[29] and the cyclohexene ring in ketomycin **4**.[30]

Cyclohexane rings are found in two antibiotics, ansatrienin (mycotrienin) **5**, isolated from *Streptomyces collinus*[31-33] and *S. rishiriensis*,[34-36] and asukamycin **6**, isolated from *S. nodosus* var. *asukaensis*[37,38] (Fig. 2). Shikimate-derived cyclohexane rings are also found in the ω-cyclohexyl fatty acids of thermophilic acid bacteria and other bacteria,[39-42] e.g., ω-cyclohexylundecanoic acid **12** (see Fig. 4). In ansatrienin **5** the cyclohexane ring is present as a cyclohexanecarboxylic acid which is linked via a D-alanine residue to the macrocyclic lactam ring, whereas in asukamycin **6**, as in the ω-cyclohexyl fatty acids, the cyclohexane ring is attached to the end of a hydrocarbon chain. It seemed likely that in both the latter cases the cyclohexane ring also originates from cyclohexanecarboxylic acid which, in the form of its CoA ester, serves as the starter unit for a polyketide chain. The experimental evidence supports this notion, both in the case of the ω-cyclohexyl fatty acids and in that of asukamycin **6**. For example, feeding experiments with ^{13}C-labeled acetate and malonate clearly established the polyketide origin of the two olefinic hydrocarbon chains in **6**.[43] Cyclohexane[*carboxy*-^{14}C]carboxylic acid was incorporated into both asukamycin **6**[43] and ansatrienin **5**;[44] degradation of labeled **5** showed that essentially all the label was confined to the cyclohexylcarbonyl moiety. Further studies showed that the cyclohexane rings in both **5** and **6** are derived via the shikimate pathway and not by reduction of a benzene ring (no incorporation of labeled phenylalanine or benzoic acid).[43,44] Degradation of ansatrienin **5** derived from [U-^{14}C]shikimic acid showed that all seven carbon atoms of the precursor are incorporated to give rise to the seven carbon atoms of cyclohexanecarboxylic acid (Fig. 3). Consistent with this finding was the inefficient incorporation of labeled **3** into **5**.[44]

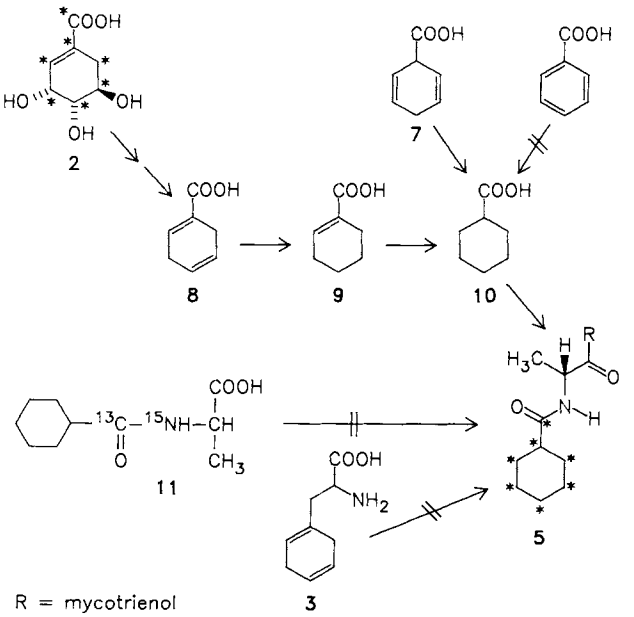

Fig. 3. Formation of the *N*-(cyclohexylcarbonyl)alanine moiety of ansatrienin **5** (mycotrienin) from shikimic acid **2**.

To obtain further information on the steps leading from shikimic acid **2** to cyclohexanecarboxylic acid, we have started to trace this sequence backwards. Good incorporation of 1,4-cyclohexadiene[*carboxy*-^{14}C]carboxylic acid (^{14}C-labeled **8**) into both ansatrienin **5**[44] and asukamycin **6**[43] suggested conversion of **2** to this unconjugated diene followed by sequential reduction of the two carbon-carbon double bonds. However, this conclusion was rendered questionable when it was observed that 2,5-cyclohexadiene[*carboxy*-^{14}C]carboxylic acid (^{14}C-labeled **7**) was incorporated into both antibiotics with comparable efficiency. Obviously, *Streptomyces* species have the ability to reduce carbon-carbon double bonds somewhat indiscriminately. The case for the intermediacy of the 1,4-diene **8** was strengthened, however, by the finding that ansatrienin A **5** is accompanied in the fermentation by a small amount (2 to 3%) of an analogue containing the 1-cyclohexenecarboxylic acid moiety (**9**) in place of cyclohexanecarboxylic acid.[44] The late steps in the reaction sequence from shikimic acid **2** to the cyclohexylcarbonyl moiety of **5** can therefore be written as shown in Figure 3.

Feeding experiments with ^{15}N-labeled D- and L-alanine showed that the D isomer was the more immediate precursor of the D-alanine moiety in ansatrienin **5**. It was also concluded that the incorporation of cyclohexanecarboxylic acid **10** into **5** involves the stepwise attachment of first alanine and then the acid moiety to the macrocycle rather than preassembly of cyclohexylcarbonylalanine **11**. The latter, doubly labeled with ^{13}C and ^{15}N in the amide linkage, gave incorporation of the components but no incorporation of the intact compound.[44]

The biosynthesis of cyclohexanecarboxylic acid raises the question of the stereochemistry of processing of intermediates in the pathway from shikimic acid **2**, i.e., the cryptic stereochemistry of formation of the symmetrical cyclohexane ring. This problem was addressed by two groups, that of *Okuda* in Tokyo and our own. Both laboratories used the same basic principle, asymmetric labeling of the cyclohexanecarboxylic acid moiety via a precursor carrying a stable isotope and conversion to a derivative containing an auxiliary chiral center followed by NMR analysis. Investigating the biosynthesis of ω-cyclohexylundecanoic acid **12** (Fig. 4), *Furukawa* et al. fed D-[6-^{2}H$_2$]glucose to *Curtobacterium pusilum*.[45] The resulting fatty acid was degraded by microbial oxidation with *Candida tropicalis* to cyclohexanecarboxylic acid **10**, which was further derivatized by reaction with phenyllithium to give cyclohexyl phenyl ketone **13**, followed by asymmetric reduction with (−)-*N*-methylephedrine/*N*-ethylaniline/$LiAlH_4$ to give (*S*)-α-cyclohexylbenzyl alcohol **14**. NMR analysis of **14** in the presence of a lanthanide shift reagent allowed the determination of the deuterium distribution between the hydrogens at C-2 and C-6 as well as between the equatorial and axial positions. The results of this analysis established the axial hydrogen at C-2 (as defined by the authors; C-6 of **10** in Fig. 7) as the primary site of labeling with 66% deuterium enrichment. The two hydrogens at C-6 each contained 5% deuterium and the remaining positions less than 2% each. The authors interpreted this result to indi-

cate reduction of the carbon-carbon double bond of shikimic acid by *syn* addition of hydrogen on the *Re-Re* face.[45] Implicit in this interpretation is the assumption that the primary site of labeling in shikimic acid **2** is at C-2.

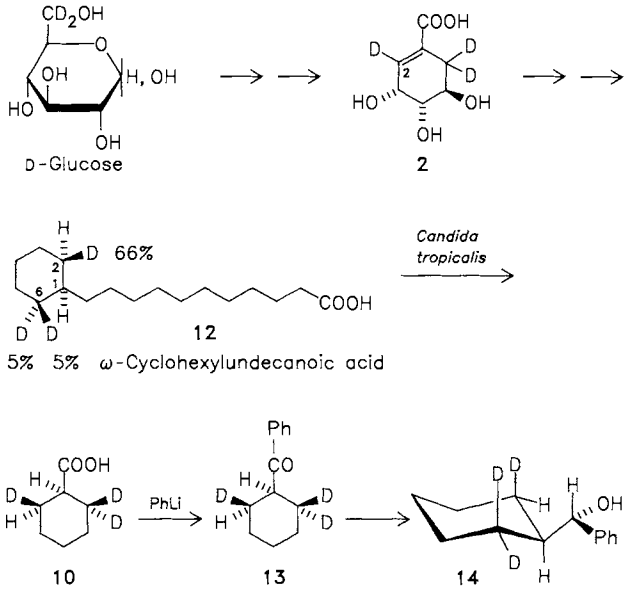

Fig. 4. Stereochemical analysis of cyclohexane ring formation in ω-cyclohexylundecanoic acid (**12**) biosynthesis [45].

In our own approach,[46] we synthesized a sample of [2-^{13}C]shikimic acid by the procedure of *Fleet* et al.[47] Starting from 10 g of D-[1-^{13}C]mannose, optically active D-(−)-[2-^{13}C]shikimic acid was obtained in 17–18% yield. A sample of this material was fed to *S. collinus* and the resulting ansatrienin **5**, showing one labeled position in the cyclohexane ring, was degraded to cyclohexylmethanol **15**, which was then derivatized with (*S*)-mandelic acid to give **16** (Fig. 5). The ^{13}C NMR spectrum of this derivative showed a chemical shift difference of $\Delta\delta = 0.05$ ppm between the signals for C-2 and C-6 of the cyclohexane ring, only one of which was enriched. An unambiguous assignment of these ^{13}C NMR signals, as well as of the ^{1}H NMR signals at these two carbon atoms, was made by synthesizing an authentic sample of (1*R*,2*R*)-[2-^{2}H]cyclohexylmethanol **15** (systematic numbering) by the route shown in Figure 6. Analysis of the (*R*)- and (*S*)-mandelate esters of this sample revealed that in the (*S*)-mandelate derivative C-2 (the *pro-R* carbon) resonates at higher and C-6 (the *pro-S* carbon) at lower field. A deuterium-decoupled 2D ^{1}H,^{13}C correlation spectrum[19] of the same samples revealed the proton assignments at these carbon atoms. Based on this analysis it was concluded that the ^{13}C in the biosynthetic sample resided exclusively in the *pro*-6*S* position. Hence, the steric course of the processing of shikimic acid **2** to cyclohexanecarboxylic acid **10** in the biosynthesis of ansatrienin **5** is the same as in the biosynthesis of cyclohexyl fatty acids such as **12**.[46] However, it was also found that the small amount of the 1-cyclohexenecarboxylic acid **9** accompanying the cyclohexanecarboxylic acid **10** in the hydrolysis of this biosynthetic sample of **5** carried the ^{13}C label not at C-2 but at C-6 (see **9**, Fig. 5). Hence, the process is more complex than a direct *Re-Re* reduction of the carbon-carbon double bond of **2**. By the route of *Fleet* et al.,[47] we also synthesized samples of **2** deuterated at C-2 and stereoselectively deuterated at C-6, and fed these to *S. collinus*.[48] Deuterium from C-2 was effectively incorporated and occupies the 6*R* (axial) position in the resulting cyclohexanecarboxylic acid, consistent with the results of *Furukawa* et al.[45] However, absolutely no deuterium from C-6 of **2** was incorporated; hence, the reaction sequence must include two steps involving hydrogen abstraction from C-6. A hypothetical pathway rationalizing these results is shown in Figure 7.

4. Formation of Antibiotic Sugar Components

4.1. 2,6-Dideoxyhexoses

2,6-Dideoxyhexoses are found as sugar components of a wide variety of antibiotics. Two examples, studied in our laboratory, are chlorothricin **20** (see also Fig. 12)[49-53] and granaticin **19** (see also Fig. 28).[54-60] Chlorothricin is an unusual macrolide (see Section 5.1) containing two glycosidically linked 2-deoxy-D-rhamnose moieties **22**, to one of which is attached a modified 6-methylsalicylic acid. Granaticin, a member of the benzoisochromane quinone family (see Section 7), contains a 2,6-dideoxyhexose in a rather unusual double linkage to the aromatic aglycone (**21**). In both instances the origin of the deoxyhexose moiety was readily traced to glucose.

Feeding experiments with [3,4-^{14}C,1-^{3}H]- and [3,4-^{14}C,2-^{3}H]glucose and *S. violaceoruber* gave granaticin **19** without a decrease in the $^{3}H/^{14}C$ ratio,[61] pointing to intact incorporation of glucose and retention of both H-1 and H-2 in the process. In contrast, H-3 and H-5 are eliminated in the conversion, as shown by feeding experiments with correspondingly double-labeled glucose samples. Tritium from C-6 of glucose is incorporated into granaticin, with 80% residing in one or both of the *C*-methyl groups. Notably, tritium from C-4 of glucose is also efficiently incorporated and resides again almost exclusively in one or both of the *C*-methyl groups, as evidenced by recovery of 90% of the tritium in the acetic acid obtained by a Kuhn-Roth oxidation. Taken together, these results leave little doubt that the intact glucose molecule, with the exception of H-3 and H-5, gives rise to the deoxyhexose moiety **21** of granaticin **19** (Fig. 8). This conversion must involve removal of the oxygen functions from C-6 and C-2 of glucose and is accompanied by migration of H-4 to C-6 of the sugar.

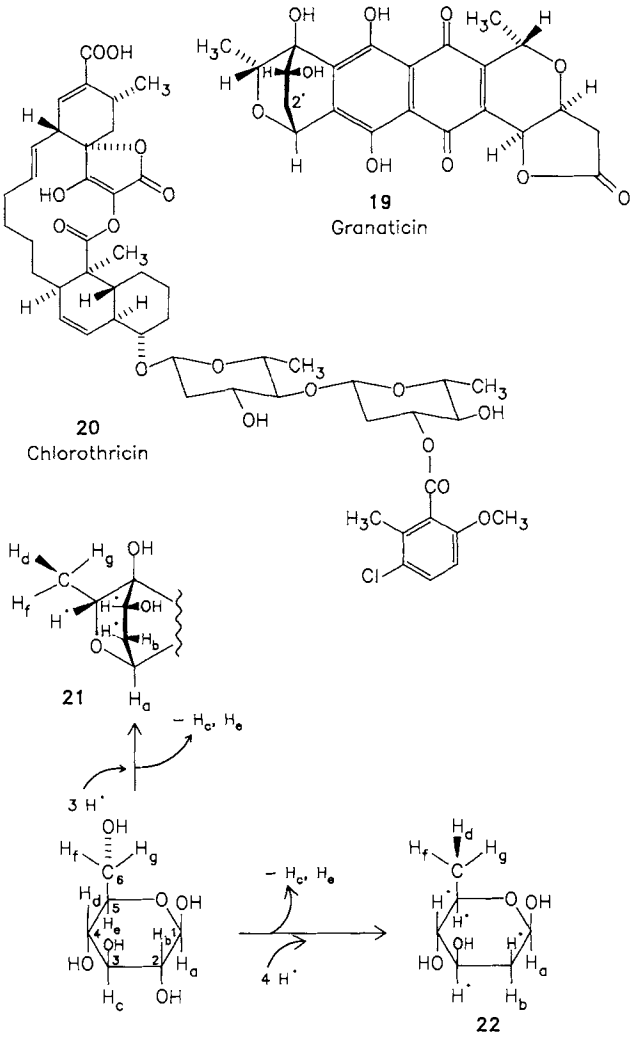

Fig. 8. Fate of glucose hydrogens in the conversion to the 2,6-dideoxyhexose moieties **21** and **22** of granaticin **19** and chlorothricin **20**, respectively.

Analogous results were obtained on formation of the two deoxyhexose moieties **22** of chlorothricin **20**. Early radiotracer experiments[62] had shown significant incorporation of ^{14}C-labeled D-glucose into **20** with about 30-35% of the total radioactivity of the antibiotic located in the two sugars. In further experiments,[63] glucose labeled with ^{14}C at C-6 and with tritium in various positions was fed to *S. antibioticus* and the resulting chlorothricin was degraded by methanolysis and alkaline hydrolysis to methyl 2-deoxy-α-D-rhamnoside,[49] which was analyzed for the change in $^{3}H/^{14}C$ ratio relative to the precursor. The results (Fig. 8) showed complete retention of the hydrogens in positions 2 and 6 and predominant retention of the hydrogen from C-1 (67%). The hydrogens at C-3 and C-5 were almost completely lost. About one-third of the tritium from C-4 of glucose was retained, but was shown by a Kuhn-Roth oxidation to be located not at C-4 but rather at C-6 of the deoxy sugar.

Loss of H-5 of the hexose and transfer of H-4 to C-6 as a hydride are typical of the reaction catalyzed by TDP-glucose oxidoreductase,[64] which converts TDP-D-glucose into TDP-4-oxo-6-deoxy-D-glucose. To probe further for the involvement of this enzyme in the first step of the

transformation of the glucose skeleton to that of 2,6-dideoxyhexoses, we elucidated the steric course of the hydrogen transfer from C-4 to C-6 of the hexose moiety. We had earlier determined the steric course of this reaction with the partially purified enzyme from *E. coli* using as substrate a mixture of unlabeled TDP-D-glucose and (6*R*)- or (6*S*)-TDP-D-[4-^{2}H,6-^{3}H]glucose.[65] The precursor was labeled in such a way that every tritiated molecule also contained deuterium. If the migration of deuterium from C-4 to C-6 is intramolecular, a chiral methyl group will be formed at C-6, and if the process is stereospecific, one enantiomer of the chiral methyl group will result predominantly or exclusively. Degradation of the resulting TDP-4-oxo-6-deoxyglucose by Kuhn-Roth oxidation followed by chirality analysis of the acetic acid generated from C-6 and C-5 of the sugar by the method of *Cornforth* et al.[66] and *Arigoni* et al.,[67] using an adapted procedure,[68] showed that the methyl group was indeed chiral. The precursor of 6*S* configuration had produced predominantly a methyl group of *R* configuration and the 6*R* isomer had produced predominantly an *S* methyl group,[65] showing that H-4 replaces the 6-hydroxyl group with inversion of configuration at C-6 (Fig. 8).

The stereochemical results on the TDP-glucose oxidoreductase reaction led to the proposal of a plausible model for the events in the active site of this enzyme during the catalytic process (Fig. 9). The carbohydrate moiety must be bound in a conformation placing H-5 and the 6-hydroxyl group in a *syn* orientation. A sandwich-like arrangement of the carbohydrate ring and the pyridine nucleotide cofactor, with the C-4 atoms of both moieties juxtaposed on each other, aided by two bases mediating proton transfers, one near the 4-hydroxyl group and one near H-5 and the 6-hydroxyl group, allows for transfer of H-4 to C-6 via the pyridine nucleotide with a minimum of motion.

Intramolecularity and migration of H-4 with the same stereochemistry was demonstrated for the formation of the methyl group in the 2-deoxy-D-rhamnoside moieties **22** of chlorothricin **20**[63] and in the deoxyhexose portion **21** of granaticin **19**[61] (Fig. 8). In these cases, (6*R*)- and (6*S*)-D-[6-^{14}C,4-^{2}H,6-^{3}H]glucose were fed to cultures of *S. antibioticus* and *S. violaceoruber*, respectively. Chlorothricin **20** was degraded to methyl 2-deoxy-α-D-rhamnoside, which was then subjected to Kuhn-Roth oxidation to carve out the methyl group and the attached carbon as acetic acid for chirality analysis, whereas granaticin **19** was subjected directly to Kuhn-Roth oxidation. The results leave little doubt as to the role of TDP-glucose oxidoreductase as the key enzyme in the formation of the deoxyhexose moieties of **19** and **20**. We have since demonstrated the presence of TDP-glucose oxidoreductase in cell-free extracts from both organisms and have shown that the enzyme activity is low during the growth phase and rises dramatically at the beginning of the antibiotic production phase.[69]

While in all the features examined so far the pathways to the 2,6-dideoxyhexose moieties of **19** and **20** were found to be identical, a difference was seen when we examined the steric course of replacement of the 2-hydroxyl group of glucose by hydrogen. This was done by feeding D-[2-^{2}H]glucose to *S. antibioticus* and to *S. violaceoruber*. Again, the resulting chlorothricin was degraded to methyl 2-deoxy-α-D-rhamnoside, which was then analyzed by deuterium NMR spectroscopy. The single signal in the spectrum appeared at the chemical shift of the equatorial hydrogen at C-2. Hence, deuterium occupies the 2*R* position and the replacement of the 2-hydroxyl group of glucose by a hydrogen occurs with inversion of configuration at C-2[70] (Fig. 8). The resulting granaticin was analyzed by ^{1}H NMR spectroscopy and found to be deuterated exclusively in the *pro*-2′*S* position. Hence, the newly introduced hydrogen occupies the *pro*-2′*R* position, having replaced the oxygen from C-2 of glucose with retention of configuration[61] (Fig. 8). It therefore appears that different pathways may be involved in the formation of the 2,6-dideoxyhexose moieties **21** and **22**, which differ in stereochemistry and thus perhaps also in mechanism.

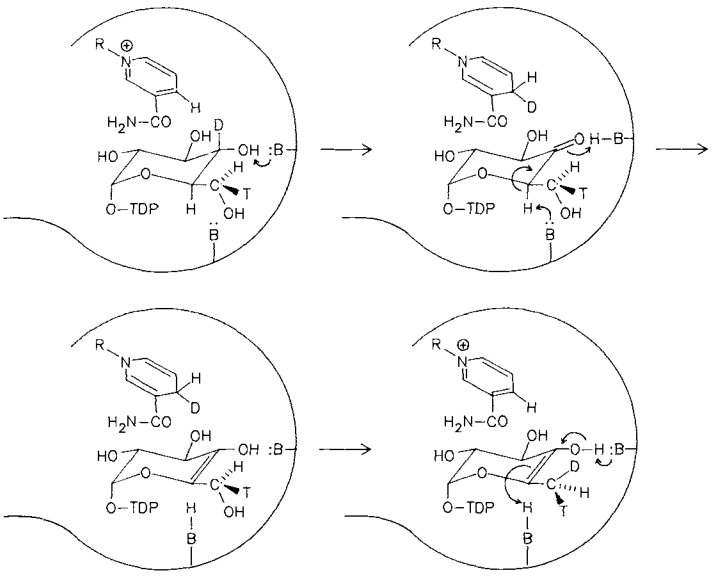

Fig. 9. Proposed stereochemical mechanism of the TDP-glucose oxidoreductase reaction [61, 65].

4.2. Spectinomycin and the Stereochemistry of the Inositol 1-Phosphate Synthase Reaction

Having available in (6*R*)- and (6*S*)-[4-^{2}H,6-^{3}H]glucose **23** a rather sophisticatedly labeled precursor designed specifically to probe for the stereochemistry and mechanism of the TDP-glucose oxidoreductase reaction, we decided to examine the formation of one more antibiotic, spectinomycin **24** (Fig. 10).[71,72] This unusual aminoglycoside, a metabolite of several *Streptomyces* species,[73,74] inhibits protein synthesis at the ribosomal level by selectively inhibiting initiating ribosomes.[75] The compound is used clinically for the treatment of gonorrhea as well as for veterinary purposes. Spectinomycin was chosen as a target because, as shown by earlier workers, it arises from two molecules of glucose,[76,77] both of which undergo stereochemical changes at C-6. One molecule of glucose gives rise to the 4,6-dideoxyhexose moiety making up ring C of the antibiotic, whereas the other is cyclized to *myo*-inositol, which is subsequently incorporated into the actinamine moiety (**25**) making up ring A of the antibiotic. In the

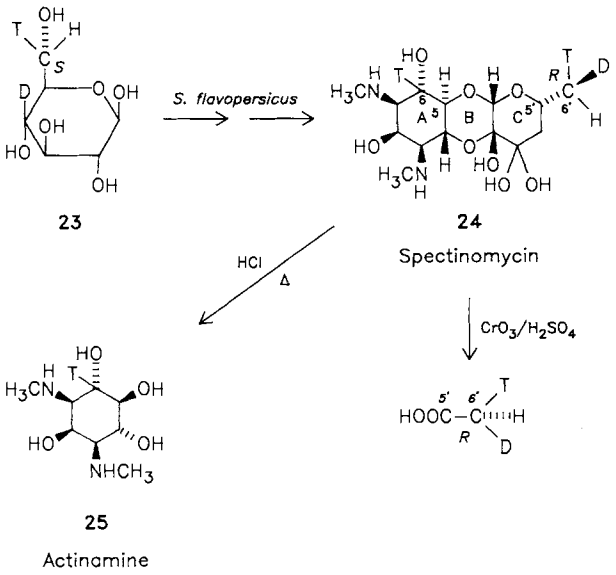

Fig. 10. Biosynthesis and chemical degradation of spectinomycin **24**.

latter conversion, C-1 and C-6 of glucose ultimately give rise to C-5 and C-6, respectively, of spectinomycin **24**.[77,78]

A high degree of incorporation of tritium from C-4 of glucose into the 6'-methyl group of spectinomycin suggested the involvement of the TDP-glucose oxidoreductase reaction in the formation of the 4,6-dideoxyhexose moiety of **24** as well.[78] Feeding experiments with (6*R*)- and (6*S*)-[6-^{14}C,4-^{2}H,6-^{3}H]glucose followed by Kuhn–Roth oxidation of **24** then showed that, as in all the other cases examined, the oxidoreductase reaction involves intramolecular transfer of H-4 to C-6, replacing the 6-hydroxyl group with inversion of configuration (Fig. 10).

Degradation of another aliquot of the samples of **24** from these two feeding experiments showed that the actinamine moiety of this antibiotic had been formed with predominant retention of the pro-6*S* hydrogen and loss of the pro-6*R* hydrogen of glucose (Fig. 10). This result was surprising because the stereochemistry of the cyclization of glucose 6-phosphate **26** to *myo*-inositol 1-phosphate **29** with the enzymes from rat testes and rat mammary gland had been studied earlier by *Kirkwood* et al.,[79] who reported that the reaction proceeds with loss of the pro-*S* hydrogen. Since *myo*-inositol has been firmly established as a precursor of the actinamine moiety of spectinomycin, this observation suggested that either the earlier results were incorrect or the stereochemistry of the *myo*-inositol synthase reaction is not uniform in different organisms. In collaboration with *Frank* and *Mary Loewus* of Washington State University, we therefore examined the steric course of the reaction catalyzed by the enzymes from beef testes and from pollen of *Lilium longiflorum*.[80] In both cases the cyclization proceeded with the same stereochemistry as observed for spectinomycin biosynthesis in *Streptomyces flavopersicus*, that is, with predominant loss of the pro-*R* and predominant retention of the pro-*S* hydrogen. The observed stereochemistry is consistent with the mechanistic classification of this enzyme as an aldolase[81] and with the general stereochemistry deduced for enzymatic aldol condensations.[82] Based on these stereochemical results, a mechanism was proposed in which a single basic group on the enzyme, positioned near C-1 and O-5 (in the substrate) and C-6 (in the product) mediates sequentially four proton transfers (Fig. 11). The first of these is abstraction of a hydrogen from the 1-OH group and subsequent addition of the hydrogen to O-5, thereby mediating the hemiacetal ring opening of glucose 6-phosphate **26**. Rotation around the C-4/C-5 axis, placing C-6 in proximity to C-1, is followed by dehydrogenation at C-5 to ketone **27**. Inspection of models indicates that binding of the substrate in a conformation that places the phosphorus of the phosphate group in an extension of the C-4/C-5 axis allows for this conformational reorientation without detaching the molecule from its essential binding sites on the enzyme. Abstraction of the pro-*R* hydrogen from C-6 by the same base followed by transfer of this hydrogen to the carbonyl oxygen at C-1 then sets the stage for the aldol condensation to form the C-6/C-1 bond in **28**. Reduction of the C-5 carbonyl group completes the sequence. This mechanism makes one prediction, namely that the enzyme should utilize the β rather than the α anomer of glucose 6-phosphate **26**. This prediction has recently been confirmed by *Sherman* et al.[83]

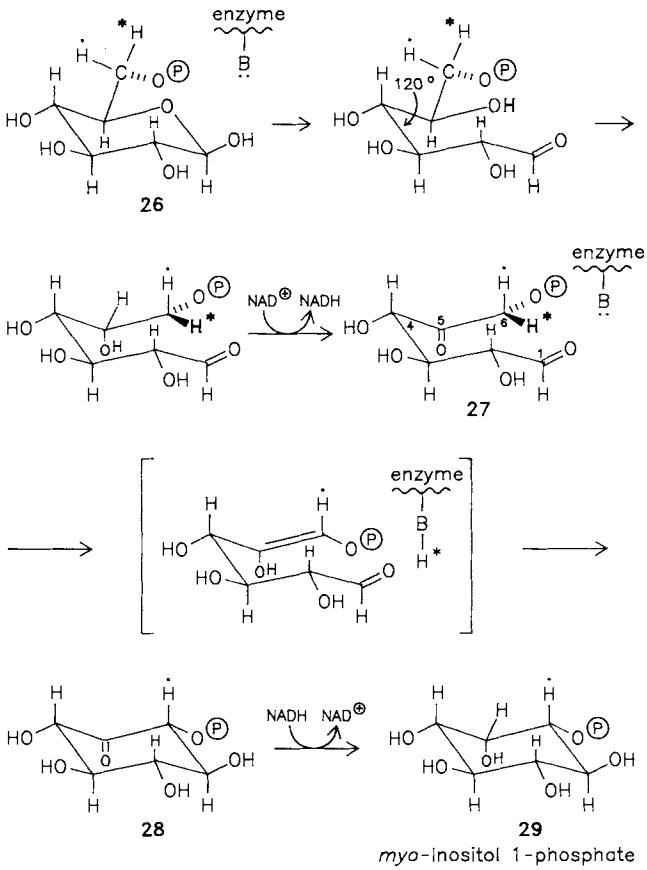

Fig. 11. Proposed stereochemical mechanism of the *myo*-inositol 1-phosphate synthase reaction [80].

5. Unusual Macrolides

In addition to the classical macrolide antibiotics,[84] exemplified by the 14-membered macrocyclic lactone tylosin

and the 16-membered erythromycin, Streptomycetes elaborate a number of "unusual" macrolides, which do not fit the standard structural, and therefore presumably biosynthetic, pattern of the classical compounds. Three of these, chlorothricin **20**, boromycin **1**, and aplasmomycin **31**, were the subject of biosynthetic studies in our laboratory.

5.1. Chlorothricin

Chlorothricin **20** (Fig. 12), isolated from cultures of *Streptomyces antibioticus*,[49] is an antibiotic inhibiting the anaplerotic CO_2 fixation catalyzed by pyruvate carboxylase.[85] Moreover, mode-of-action studies have pointed to an interaction between chlorothricin and the membrane phospholipids of *Bacillus subtilis*.[86] The mechanism of action of chlorothricin is clearly quite different from that of other macrolide antibiotics. Its structure is also quite different.[50–53] The aglycone of chlorothricin (chlorothricolide) represents a novel macrocyclic ring system incorporating a *trans*-octahydronaphthalene structure and a tetronic acid moiety spiro-linked to a cyclohexene ring.

Early radioactive tracer experiments carried out both in our laboratory and in that of *Pape* in Münster clearly established incorporation of acetate into both the aglycone and the acyl moiety, consistent with a polyketide origin of both these structural elements (see Fig. 12).[62] The distribution of the label between these two moieties was determined by methanolysis of **20**,[49] which produced the aglycone as its methyl ester as well as methyl 2-deoxy-D-rhamnoside and its derivative containing the 3-acyl moiety of **20**. The acyl moiety, but not the aglycone, was also efficiently labeled by the methyl group of methionine. The aglycone, on the other hand, was significantly labeled by propionate carrying ^{14}C in any of the three carbon atoms.[62]

Complete analysis of the ^{13}C NMR spectrum of chlorothricin[87] was followed by feeding experiments with specifically ^{13}C-labeled precursors.[63] These studies demonstrated unequivocally the origin of the acyl moiety from four acetate units and one methyl group of methionine, the latter providing the methoxy carbon. Formation of this portion of the molecule presumably proceeds via 6-methylsalicylic acid, which is further modified by chlorination and methylation. The 29 carbon atoms of the aglycone moiety represent ten acetate and two propionate units arranged in a contiguous chain starting with an acetate unit (C-29 and C-21) (Fig. 12). The two propionate units occupy positions 1, 2, 27 and 19, 20, 28 in the chain, and in one of these the branching methyl group has been oxidized to a carboxyl group (C-28).

It was not evident from the initial results with single-labeled acetate samples that C-25 and C-26 were also acetate-derived. However, chlorothricolide derived from [1,2-$^{13}C_2$]acetate showed coupling between the signals for C-25 and C-26 with $^1J_{C,C}=91.5$ Hz, typical of carbons in a tetronic acid structure. Thus, C-25 and C-26 arise from a single acetate unit. We propose that C-25 was initially directly linked to C-1 (**30**), belonging to the terminal unit of the polyketide chain.[63] In the subsequent processing of the polyketide, a Baeyer–Villiger oxidation then converts the C–C bond into an ester linkage (Fig. 13). Support for this proposal comes from the subsequent isolation of antibiotics, the tetrocarcins[88,89] and the kijanimycins,[90–92] in which the original C–C bond is retained in the form of an acyltetronic acid structure.

These results left the origin of three carbon atoms, C-22, C-23, and C-24 of the aglycone moiety, unaccounted for. Among a number of radioactive potential precursors tested,[63] succinic acid showed good incorporation into the aglycone; in particular, the two center carbon atoms were

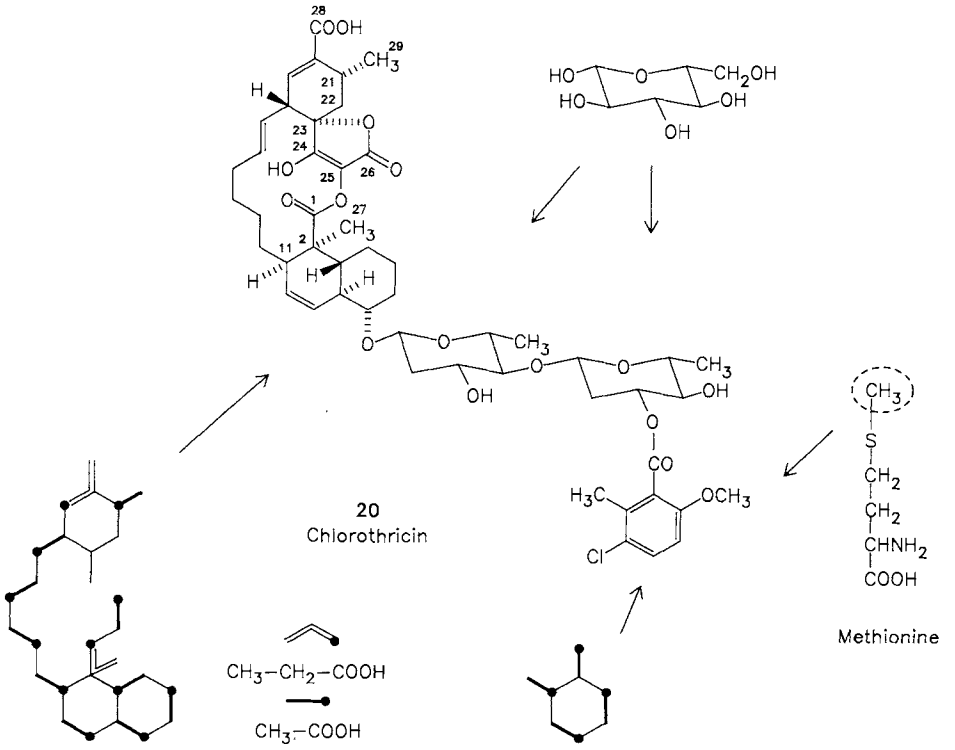

Fig. 12. Biosynthetic origin of chlorothricin **20**.

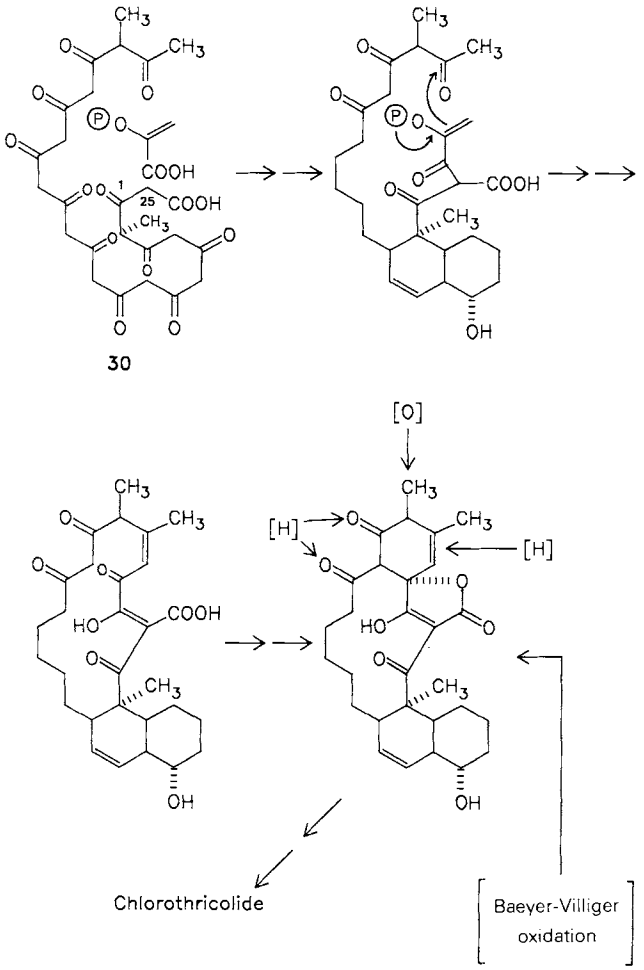

Fig. 13. Proposed biosynthesis of the chlorothricin aglycone, chlorothricolide.

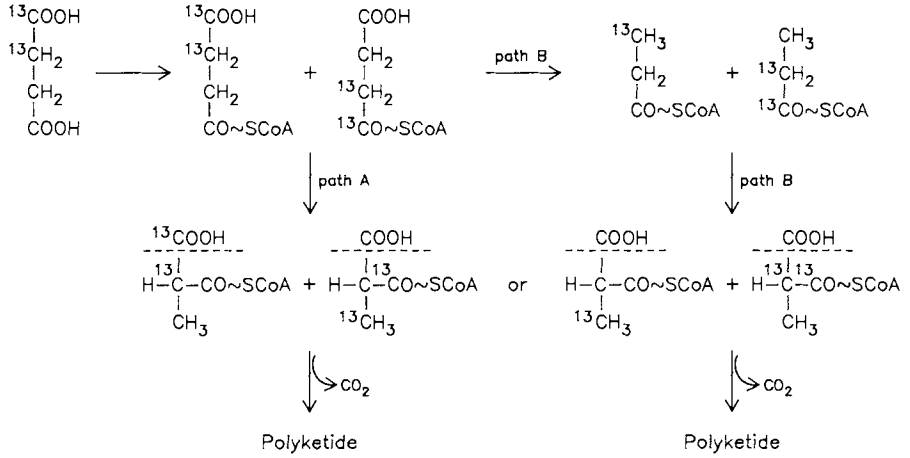
used very efficiently. This led us to speculate that C-22, C-23, and C-24 may arise from the Krebs cycle intermediate oxalacetic acid, which would be incorporated with loss of the β-carboxyl group. However, this mechanistically attractive idea was quickly disproved when it was found that [1,4-$^{13}C_2$]succinic acid labeled exclusively the two carbon atoms arising from C-1 of propionate, but not C-24.[63] Following detailed scrutiny of a number of further compounds it was concluded that [2-^{14}C]glycerol might be a specific precursor. This notion was confirmed unequivocally by synthesizing and feeding [U-$^{13}C_3$]glycerol containing 99 atom% ^{13}C in each carbon atom. Extensive analysis of the coupling pattern of the resulting chlorothricolide showed the expected incorporation via acetyl-CoA into the acetate-derived carbons as well as some incorporation into the propionate-derived units, reflecting entry of acetyl-CoA into the Krebs cycle. Most importantly, however, C-22, C-23, and C-24 were all labeled and showed the expected coupling pattern for incorporation of an intact glycerol molecule. C-23 was coupled to both C-22 and C-24 as confirmed by a carbon-carbon decoupling experiment.[70] Glycerol is a symmetrical molecule in which the two hydroxymethyl groups are in an enantiotopic relationship and therefore distinguishable by an enzyme. Glycerol kinase, the enzyme mediating entry of glycerol into cellular metabolism, phosphorylates the pro-*R* hydroxymethyl group, which thus gives rise to C-3 of triose phosphates, phosphoglycerate, phosphoenolpyruvate, and ultimately pyruvate and lactate. To determine the "orientation" in which glycerol is incorporated into the three-carbon moiety of chlorothricolide, we synthesized and carried out feeding experiments with (2*R*)-[1-$^2H_2$]glycerol. The deuterium NMR spectrum of the resulting chlorothricolide methyl ester cleanly showed two signals, corresponding to the hydrogen of the propionate-derived methyl group, C-27, and to the *pro-R* hydrogen at C-22. Consequently, C-3 of glycerol gives rise to C-24 of chlorothricin and C-1 to C-22. The stereospecific retention of only one hydrogen at C-22 is consistent with intermediate formation of a double bond between C-21 and C-22 which is then reduced stereospecifically. The compound actually condensing with the polyketide portion to give the tetronic acid structure is almost certainly not glycerol itself, but rather a metabolite of it. On mechanistic grounds, we propose that the actual substrate is phosphoenolpyruvate. A plausible mechanism for the formation of chlorothricolide is shown in Figure 13.

An attempt was made to probe further the proposed mechanism by tracing the fate of the methyl hydrogens of acetate into chlorothricolide. This is commonly done by feeding experiments with sodium [2-^{13}C,$^2H_3$]acetate and analysis of the product by ^{13}C NMR spectroscopy for the deuterium-induced isotope shifts of the ^{13}C NMR signals. The α-deuterium shift is best observed with simultaneous ^{1}H and ^{2}H broadband decoupling to remove splitting by deuterium.[93] Alternatively, one may label the precursor with ^{13}C in the adjacent carbon position and detect deuterium through the β-deuterium shift which is relayed through two bonds.[9] Since the deuterium isotope shifts are additive, they allow not only detection of the presence of deuterium in a given position, but also determination of how many atoms of deuterium are attached to a particular carbon. Surprisingly, the chlorothricolide derived from sodium [2-^{13}C,$^2H_3$]acetate showed no deuterium in any of the acetate-derived positions. The only deuterated carbon was the propionate-derived methyl group, C-27, which carried two atoms of deuterium. Therefore, complete washout of deuterium from the methyl group of acetate must occur during the incorporation of the acetate units into the polyketide, possibly by extensive carboxylation/decarboxylation of acetyl-CoA.

On the other hand, acetyl-CoA seems to enter the Krebs cycle with retention of the deuterium to produce propionate units containing dideuterated methyl groups. From proffered [2-^{13}C,$^2H_3$]acetyl-CoA, one turn of the Krebs cycle will produce succinyl-CoA containing two atoms of deuterium at C-3, which upon rearrangement in the methylmalonyl-CoA mutase reaction will produce methylmalonyl-CoA monodeuterated at C-2. Further turns of the cycle will introduce at most one atom of deuterium into C-3 of the propionate units. The observed presence of two atoms of deuterium in this position can be explained in two ways. If succinyl-CoA and free succinate are in equilibrium, then one-half of the succinyl-CoA molecules will end up dideuterated at C-2, producing methylmalonyl-CoA with two deuterium atoms in the methyl group. Alternatively, a new, heretofore unsuspected pathway may op-



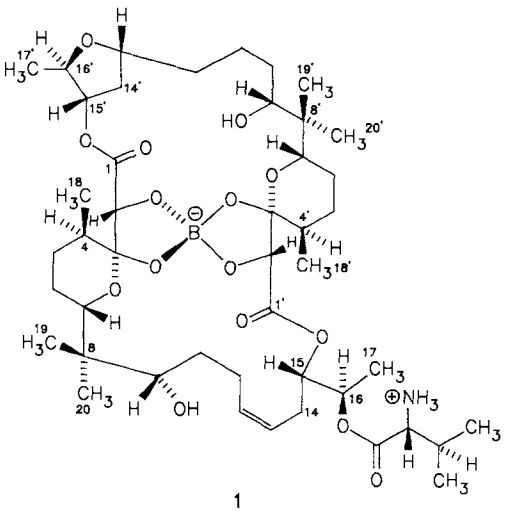


Fig. 14. Use of [1,2-$^{13}C_2$]succinic acid to distinguish two possible pathways to propionate units in polyketides. Prediction for path A: no ^{13}C-^{13}C one-bond coupling. Prediction for path B: ^{13}C-^{13}C one-bond coupling, C-1/C-2 and C-19/C-20.

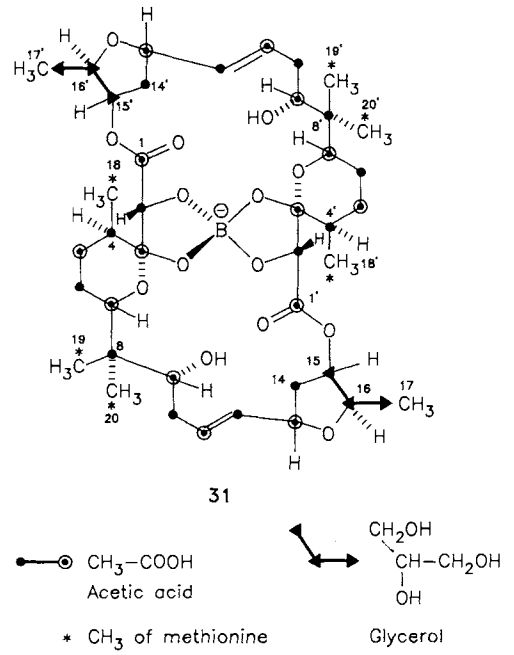
erate, in which succinyl-CoA is directly decarboxylated to propionyl-CoA followed by carboxylation to methylmalonyl-CoA. As a probe to distinguish between these two possibilities, we synthesized a sample of [1,2-$^{13}C_2$]succinic acid. In the cell, this compound is metabolized to a 1:1 mixture of [1,2-$^{13}C_2$]- and [3,4-$^{13}C_2$]succinyl-CoA. Via the direct decarboxylation pathway (path B, Fig. 14), these would produce propionate units labeled in all three carbon atoms and showing coupling between C-1 and C-2. On the other hand, via the methylmalonyl-CoA mutase reaction (path A) the result would be propionate units which are also labeled in every carbon but show no one-bond coupling. Feeding of this precursor to the chlorothricin fermentation gave chlorothricolide in which the propionate-derived carbons were enriched but clearly showed no one-bond coupling. Therefore, direct decarboxylation of succinyl-CoA does not contribute significantly to the formation of propionate units in this polyketide synthesis.



5.2. Boromycin and Aplasmomycin

Among the thousands of organic natural products there are only a handful which contain boron. The first of these to be discovered was the ionophoric antibiotic boromycin **1** (Figs. 1 and 15), a metabolite of *Streptomyces antibioticus*.[1,94] Its structure, elucidated by chemical degradations and an X-ray analysis[1,2] is that of a macrocyclic dilactone consisting of two carbon chains of identical carbon-carbon connectivities folded around a boron atom. In addition, a D-valine moiety is attached to one of the chains through an ester linkage. The antibiotic activity of boromycin **1** against gram-positive bacteria, certain fungi, and protozoa[95] is due to interaction with the cytoplasmic membrane resulting in the breakdown of the permeability barrier for potassium ions.

A second boron-containing ionophore, aplasmomycin **31** (Fig. 15), was isolated from a strain of *Streptomyces griseus* obtained from a sample of sea mud from the Sea of Japan.[96] Its structure[97-99] is similar to that of boromycin but lacks the D-valine moiety. In addition, the two macrolide chains in aplasmomycin have identical structure and the same configuration at every pair of chiral centers. Thus,

1

31

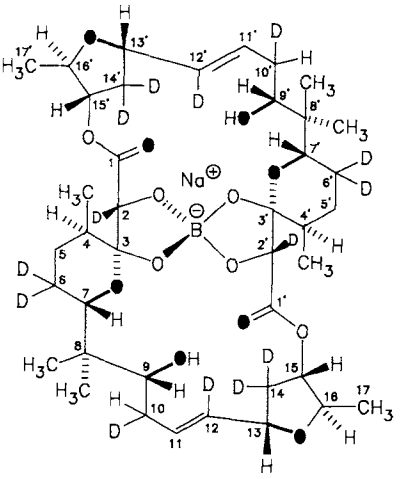
Fig. 15. Biosynthetic building blocks of aplasmomycin **31**. For comparison: boromycin **1**.

the ^{13}C NMR spectrum of this compound of 40 carbon atoms shows only 20 signals, which were readily assigned.[100] The conformations of **1** and **31** both in the crystal[97, 101] and in solution[100, 102, 103] are similar and, interestingly, they change little upon removal of the boron.

The biosynthesis of boromycin **1** and aplasmomycin **31** naturally has to be viewed in the context of that of classical macrolide antibiotics. The latter are formed by a version of the polyketide pathway in which one-carbon or two-carbon branches arise by substitution of propionate or butyrate units in place of acetate chain-extension units (cf. Ref. [84]). Based on this precedent, one would predict that the four methyl branches at C-4, C-4′, C-16, and C-16′ arise by incorporation of propionate units and the two geminal dimethyl branches at carbons 8 and 8′ arise by substitution of isobutyrate for acetate units. However, an alternate mode of biosynthesis was proposed by *Birch* et al.[104] at the time the first classical macrolide antibiotics were discovered. This envisioned construction of the contiguous polyketide carbon chain entirely from acetate units and introduction of the methyl branches by *C*-methylations (i.e., by transfer of methyl groups from *S*-adenosylmethionine). Feeding experiments with ^{13}C-labeled acetate or malonate and with [*methyl*-^{13}C]methionine immediately revealed that the origin of the carbon framework of both **1** and **31** follows the model of *Birch* rather than the path of classical macrolide biosynthesis (Fig. 15). C-1/C-1′ through C-14/C-14′ of each chain represent seven acetate units; three methyl groups in each chain, C-18/C-18′, C-19/C-19′, and C-20/C-20′, are derived from the methyl group of methionine; and the starter units, C-15/C-15′, C-16/C-16′, and C-17/C-17′ are not labeled by either acetate, methionine, or propionate.[105, 107] Complementary results on the biosynthesis of boromycin **1** were obtained by *Pape* et al. in Münster.[108]

The D-valine moiety of **1** was found to originate from D-valine as the immediate precursor. L-Valine is incorporated, but only via conversion to the D form with loss of the α-hydrogen. This was demonstrated unequivocally by showing predominant retention of deuterium in the incorporation of D-[2-^{2}H]valine and complete loss of deuterium from the corresponding L isomer.[105] This finding was surprising in view of the fact that the D-amino acid moieties of various peptide antibiotics originate from the free L-amino acid rather than the D-amino acid as the immediate precursor.[109–111] In those cases epimerization at the α-carbon occurs only after binding of the amino acid to the synthase at some stage during product assembly.[109–112] A different mechanism is evident in boromycin biosynthesis. An attempt was made[113] to achieve the directed biosynthesis of analogues of boromycin containing different amino acids in place of D-valine by feeding other D-amino acids in labeled form. However, except for a minimal incorporation of radioactivity from D-leucine, no formation of amino acid analogues of boromycin was evident.

Since the boromycin fermentation gave poor yields and inefficient incorporation of labeled precursors and since the NMR spectra of **1** are rather complex, we turned to the simpler system aplasmomycin **31** in order to unravel further details of the biosynthesis of this unusual macrodiolide system. Feeding experiments with ^{14}C-labeled pyruvate and lactate suggested that these compounds were only incorporated via metabolism to acetate. Glycerol was a very efficient precursor, which, as shown by a feeding experiment with [1,3-$^{13}C_2$]glycerol, not only labels both the acetate units (via metabolism to pyruvate and acetyl-CoA) and the methionine-derived methyl groups (via phosphoglyceric acid, serine, and the tetrahydrofolate system), but also specifically the starter unit (Fig. 15). A 3.5-Hz two-bond coupling between the signals for the highly enriched carbon atoms 15 and 17 unequivocally demonstrated that the three carbon atoms of the starter unit arise from an intact molecule of glycerol.[107]



Starter units for the initiation of polyketide chains are generally thioesters of carboxylic acids; hence, instead of glycerol itself, a closely related metabolite is a likely candidate. Since the starter unit apparently is not formed via lactic or pyruvic acid, lactaldehyde or methylglyoxal were considered as possible intermediates because they could give rise to thioesters of pyruvic or lactic acid without going through the free acid. However, both compounds were ruled out by the stereochemical experiments discussed below and by the fact that [3-^{13}C]lactaldehyde and [3-^{13}C]methylglyoxal were incorporated exclusively into the carbon atoms derived from C-2 of acetate, but not into the starter unit.[114] The possibility was examined that serine might be the starter unit or a more immediate precursor of it. However, a feeding experiment with D,L-[3-^{13}C]serine gave incorporation only into the methionine-derived methyl groups (via the tetrahydrofolate system) and into the carbon atoms derived from C-2 of acetate (via acetyl-CoA).

We then decided to determine how the glycerol molecule is oriented in the starter unit and which hydrogens are retained in the transformation by feeding experiments with [1,1,3,3-$^{2}H_4$]-, (2*R*)-[1,1-$^{2}H_2$]-, and [2-$^{2}H_1$]glycerol. The aplasmomycin **31** from [2-$^{2}H_1$]glycerol contained no deuterium at all as revealed by mass spectrometry. The other two aplasmomycin samples showed nearly identical deuterium NMR spectra, revealing predominant labeling (38–39% enrichment) at C-17/C-17′, but no significant deuterium enrichment at C-15/C-15′. Hence, C-1 of glycerol, the *pro-R* hydroxymethyl group, which is phosphorylated by glycerol kinase, gives rise to C-17/C-17′ of aplasmomycin **31** whereas C-3 gives rise to C-15/C-15′. Only the hydrogens from C-1 of glycerol are retained and become part of the methyl group of the starter unit.[114] In addition, deuterium is incorporated into the methionine-derived methyl groups and to a very small extent into the acetate-derived portion of the molecule.

The above results set the stage for some further experiments on stereochemical aspects of the formation of the methyl groups of aplasmomycin **31**. All four methyl groups of each polyketide chain are labeled by C-1 of glycerol; C-17/C-17′ by direct incorporation of glycerol, C-18/C-18′, C-19/C-19′, and C-20/C-20′ via conversion of C-1 of glycerol to C-3 of serine and then to the methyl group of methionine. The steric course of the transfer of the latter to the polyketide backbone was probed by feeding experiments with (*methyl-R*)- and (*methyl-S*)-[*methyl*-$^{2}H_1$,^{3}H]methionine.[115] Kuhn–Roth oxidation of the resulting aplasmomycin samples gave radioactive acetic acid containing the chiral methyl groups from C-18/C-18′, C-19/C-19′,

and C-20/C-20′. Chirality analysis of these acetic acid samples[66-68] showed that the methyl group of methionine had been transferred to the polyketide chain with inversion of configuration. This result conforms to the steric course established for the majority of *S*-adenosylmethionine-dependent methyltransferases studied to date[116,117] and suggests a direct transfer of the methyl group from the sulfur of the substrate to the acceptor carbon in an S_N2 process. However, when serine stereospecifically labeled with deuterium and tritium at C-3 was used in feeding experiments, both the 3*R* and the 3*S* isomer produced aplasmomycin containing racemic methyl groups. Thus, the conversion of the methylene group of serine to the methyl group of methionine must be accompanied by complete racemization. Therefore, if a sample of glycerol chirally tritiated and deuterated at C-1 is fed to the cultures and the resulting aplasmomycin degraded by Kuhn-Roth oxidation, any chirality observed in the resulting acetic acid should be due entirely to C-17/C-17′, whereas the methionine-derived methyl groups would only contribute racemic acetic acid. When this experiment was carried out with (1*R*,2*R*)-[1-$^2H_1$,^3H]glycerol, the acetic acid from the degradation showed an *F* value of 35,[*] corresponding to *S* configuration with 52% *ee*. That the methionine-derived methyl groups were indeed racemic was confirmed by degradation of another sample to give a fragment containing only the latter methyl groups, but not C-17/C-17′. Kuhn-Roth oxidation of this material produced racemic acetic acid. The contribution of the methionine-derived racemic methyl groups to the chirality of the acetic acid from the Kuhn-Roth oxidation of aplasmomycin **31** can be estimated based on the earlier experiments with deuterated glycerol, and correction for this contribution indicates that the C-17/C-17′ methyl groups have *S* configurations with 84% *ee*.[114] The finding that the methyl group of the starter unit generated from (1*R*,2*R*)-[1-^2H,^3H]glycerol has high chiral purity and *S* configuration again rules out the involvement of the methylglyoxal synthase reaction as well as the pyruvate kinase reaction in the formation of the starter unit from glycerol. Pyruvate kinase would have generated a methyl group of *R* configuration,[118] whereas methylglyoxal synthase would have produced a racemic methyl group.[119]

Further information on the mode of assembly and modification of the polyketide chain of aplasmomycin **31** was obtained by determining the fate of the methyl hydrogen and carboxyl oxygen atoms of acetate during the biosynthesis. This was done using the isotope-shift methodology[9,10,93] and precursors intramolecularly double labeled with ^{13}C and ^2H or ^{13}C and ^{18}O. Aplasmomycin derived from [2-^{13}C,$^2H_3$]acetate was analyzed by ^{13}C NMR spectroscopy with simultaneous ^1H and ^2H broadband decoupling. The results, summarized in Figure 16, showed the incorporation of one atom of deuterium each at C-2/C-2′, C-10/C-10′, and C-12/C-12′ and two atoms of deuterium each at C-6/C-6′ and C-14/C-14′. Notably, no deuterium was present at C-4/C-4′ and only one deuterium atom at C-10/C-10′. The origin of the oxygen atoms was similarly probed with [1-^{13}C,$^{18}O_2$]acetate. The ^{13}C NMR spectrum of the aplasmomycin derived from this precursor showed isotopically shifted satellites for the signals at C-1/C-1′, C-7/C-7′, C-9/C-9′, and C-13/C-13′. Notably, C-3/C-3′ showed no isotopically shifted signal, indicating that the oxygen of the pyran ring is contributed by C-7/C-7′ and that, surprisingly, the other oxygen at C-3/C-3′ does not originate from the carboxyl group of acetate.[114]

31

Fig. 16. Origin of hydrogen and oxygen atoms of aplasmomycin **31** from acetate and glycerol. D = deuterium from [2-^{13}C,$^2H_3$]acetate; ● = ^{18}O from [1-^{13}C,$^{18}O_2$]acetate. Heavy lines connect the ^{18}O to the carbon from which it originated. C-17 and C-17′ are deuterated from (2*R*)-[1,1-$^2H_2$]glycerol.

A number of conclusions can be drawn from these results. The ^{18}O enrichment at C-1/C-1′ is as high as in the other labeled positions, suggesting that the lactone functions are formed directly from a carboxyl-activated derivative rather than from a carboxyl group obtained by hydrolysis of an activated intermediate (e.g., a thioester). In the latter case only half as much ^{18}O should have been retained at C-1/C-1′ as in the other positions. Methylation of the polyketide chain (both at C-4/C-4′ and C-8/C-8′) at the β-diketone stage seems plausible on mechanistic grounds. Methylation at C-4/C-4′ prior to removal of the C-5/C-5′ oxygen via a 4,5-ene intermediate would account for the lack of deuterium retention at C-4/C-4′. For the C-10/C-10′ to C-14/C-14′ segment, the retention of only one atom of deuterium at C-10/C-10′ implies removal of the C-11/C-11′ oxygen function via a 10,11-ene intermediate. Since the final product contains an 11,12 double bond and C-13/C-13′ initially is at the carbonyl oxidation level, a double bond shift seems a plausible possibility.

By process of elimination, the choice of the polyketide starter unit is narrowed down to phosphoglyceric acid or phosphoenolpyruvate as the two most likely candidates. These compounds have not been encountered before as polyketide starter units or, for that matter, as thioesters, and further verification of this tentative conclusion is highly desirable. Unfortunately, in view of the impermeability of cell membranes to phosphate esters this cannot be done by in vivo feeding experiments, but has to await the availability of a cell-free system. The finding that the oxygen of the tetrahydrofuran ring originates from C-13/C-13′

[*] The F value (see Ref. [68]) is an experimental measure of the configuration and optical purity of a chiral methyl group: F = 79 corresponds to 100% *ee R*; F = 50 to a racemate; F = 21 to 100% *ee S*.

rather than C-16/C-16′ is intriguing; it points to a displacement of the original oxygen at the center carbon of the starter unit. A plausible sequence of events is outlined in Figure 17, implying phosphoenolpyruvate as the starter moiety, but alternatives are certainly conceivable.[114]

6. Formation of Some Unique Structural Elements in Antibiotics—mC_7N and C_5N Units

6.1. Background

The antibiotic asukamycin **6**[37,38] (Fig. 2), in addition to the cyclohexane ring, contains two other unique structural elements. One is a C_5N unit in the form of a molecule of 2-amino-3-hydroxycylopent-2-enone amide-linked to a short polyketide chain. The same structural unit is present in the closely related manumycin **44**[120,121] (see Fig. 24) and in reductiomycin **46**[122] (see Fig. 26) as well as in a number of other recently discovered antibiotics.[123-127] Until recently, nothing was known about its biosynthesis.

The other unique structural element present in asukamycin **6** as well as manumycin **44** and ansatrienin **5** (Fig. 2) consists of a six-membered carbocyclic ring, usually aromatic or quinoid, carrying an additional carbon and a nitrogen substituent in a 1,3 (*meta*) arrangement. This so-called mC_7N unit was first recognized as a structural element of the ansamycin antibiotic rifamycin B **35** (Fig. 18), not derived by the polyketide pathway.[128,129] It is present in all the ansamycins and in ansamitocin **34** (Fig. 18) as well as in structurally quite different antibiotics such as the mitomycins (see **36**, Fig. 18).[130] Other compounds contain mC_7N units which were proposed to be of similar biosyn-

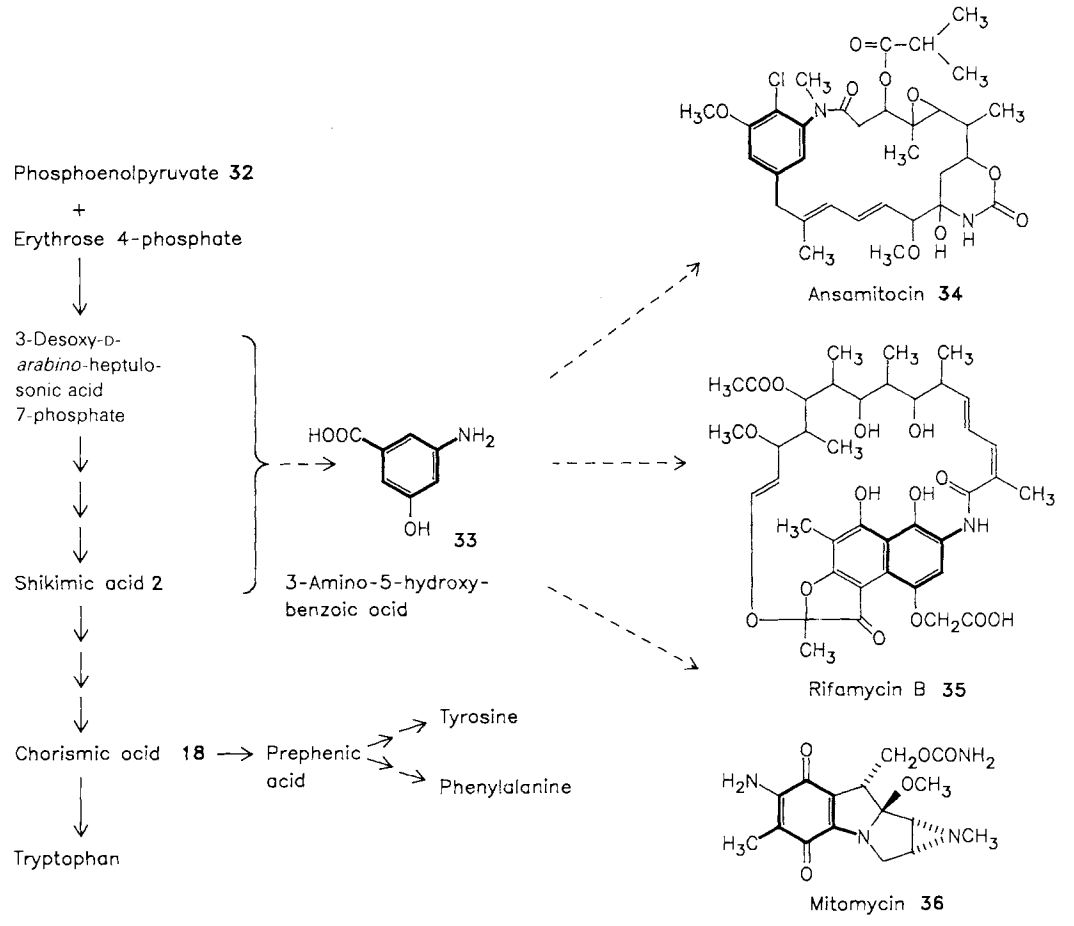

Fig. 18. Origin of the mC_7N units in rifamycin B **35**, ansamitocin **34**, and mitomycin **36**. The framework of the mC_7N unit is shown in heavy lines.

thetic origin:[131] e.g., the aminocyclitol valienamine, which is present in validamycin[132] and in the β-glucosidase inhibitor acarbose **42**[133] (see Fig. 22).

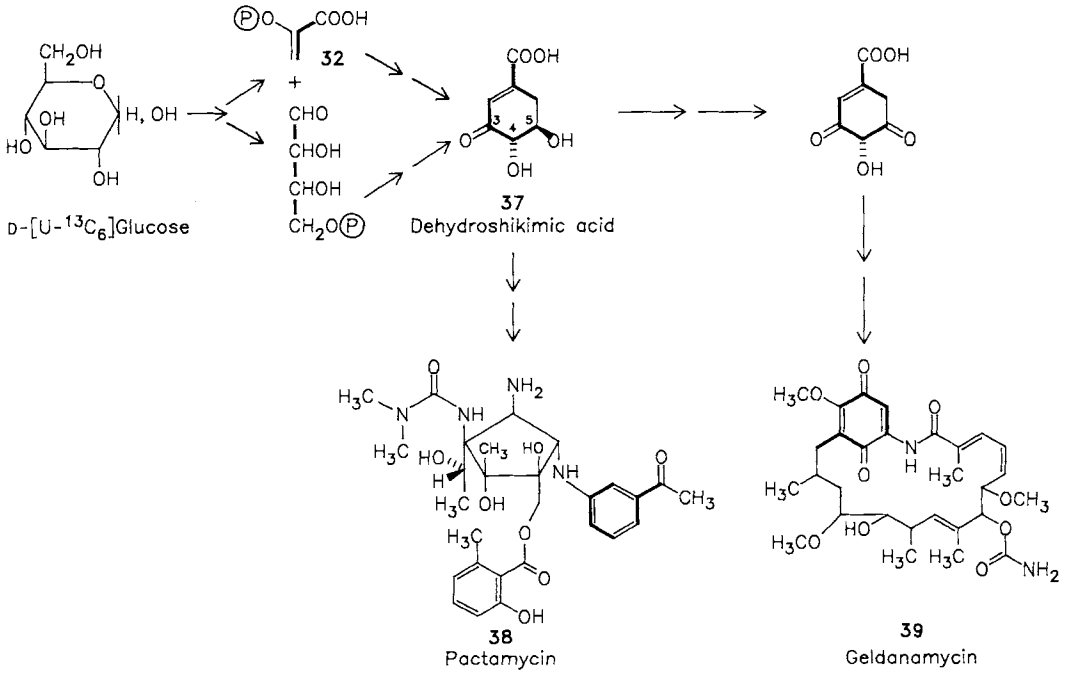
Feeding experiments with a variety of labeled precursors[130, 134–137] established a labeling pattern in the mC_7N unit of ansamycins and mitomycin **36** closely resembling that for shikimic acid. Yet, all attempts to demonstrate incorporation of labeled shikimic acid[134, 136, 138] or, in the case of mitomycin, also of dehydroquinic acid[137] were unsuccessful. These negative results may either reflect poor uptake of shikimic acid or indicate that the branch-off point for formation of the mC_7N unit is earlier in the shikimate pathway.

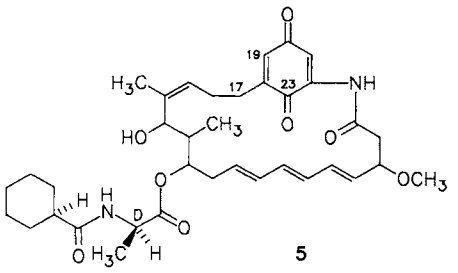
An important breakthrough was the demonstration by *Nüesch* and *Ghisalba* through genetic studies and by *Rickards* and co-workers through feeding experiments that 3-amino-5-hydroxybenzoic acid is a specific and proximate precursor of the mC_7N unit in rifamycin **35**[139] and its relative actamycin,[140] ansamitocin **34**,[141] and mitomycin **36**.[142] However, this leaves still unexplained how 3-amino-5-hydroxybenzoic acid is formed via the shikimate pathway. *Hornemann* et al.[137] established by degradation of mitomycin samples from various specifically labeled precursors that the nitrogen is attached to the carbon atom corresponding to C-5 of shikimic acid rather than to that corresponding to C-3. This finding was rather surprising, since it ruled out a straightforward transamination of 3-dehydroshikimic acid. This was confirmed by *Rinehart* et al.[143] who analyzed the ^{13}C–^{13}C coupling pattern in the mC_7N unit of geldanamycin **39**, an ansamycin antibiotic, biosynthesized from D-[U-$^{13}C_6$]glucose (Fig. 19). In contrast, the same experiment with pactamycin **38**[144] (Fig. 19), which contains a structurally more unusual mC_7N unit, revealed attachment of the nitrogen to the carbon corresponding to C-3 of shikimic acid or dehydroshikimic acid **37**,[12] indicating different pathways to the mC_7N units in these two compounds.[143] Consistent with this difference, the mC_7N unit of pactamycin **38** is formed via 3-aminobenzoic acid rather than 3-amino-5-hydroxybenzoic acid **33**. *Rinehart* et al. proposed (Fig. 19) that the mC_7N unit of pactamycin **38** is formed via transamination of dehydroshikimic acid **37** at C-3, whereas **33**, which gives rise to the other mC_7N units, is formed by oxidation of dehydroshikimic acid to the 5-oxo analogue followed by transamination at C-5.[143]

6.2. Naphthomycin and Ansatrienin

In our own studies on the biosynthesis of mC_7N units, we first focused on two ansamycin antibiotics, ansatrienin **5** (cf. Fig. 2) and naphthomycin A **40**, also a metabolite of *Streptomyces collinus*[145] (Fig. 20). The naphthomycins represent a small group of closely related antibiotics, whose structures were elucidated by chemical and spectroscopic means[146–150] and whose antibiotic activity is due to vitamin K antagonism.[145] As would be expected, the ansa chains of both types of compounds are derived from acetate and propionate units by the polyketide pathway.[148, 151, 152] Consistent with the results of *Rickards* and co-workers[140, 142] was our observation of very efficient and specific incorporation of 3-amino-5-hydroxy[*carboxy*-^{13}C]-benzoic acid into naphthomycin A **40** (64% enrichment at C-27)[152] as well as ansatrienin **5** (48% enrichment at C-17).[44, 152]

The site of attachment of the nitrogen to the shikimate-pathway-derived carbon skeleton was determined by feeding experiments with [U-$^{13}C_3$]glycerol and ^{13}C–^{13}C coupling analysis of the products.[153, 154] Glycerol as substrate has the advantage over D-[U-$^{13}C_6$]glucose that it is more





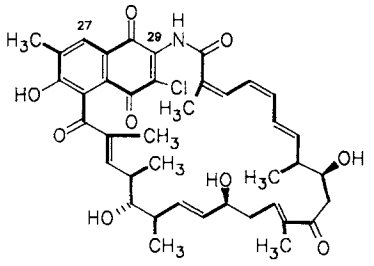


Fig. 19. Pactamycin **38** and geldanamycin **39**, the ^{13}C–^{13}C coupling patterns in their mC_7N units after feeding experiments with D-[U-$^{13}C_6$]glucose [12, 143], and a hypothesis for the formation of their mC_7N units via the shikimate pathway [143]. ^{13}C–^{13}C coupling is indicated by heavy lines connecting carbons.

Naphthomycin A

Fig. 20. Naphthomycin A **40** and the enrichment and ^{13}C-^{13}C coupling pattern in a sample biosynthesized from [U-$^{13}C_3$]glycerol (cf. caption to Fig. 19).

efficiently utilized, even in the presence of other carbohydrates as carbon source; in addition, the coupling pattern of the products is not altered by metabolism of the substrate through the glycolytic pathway. Nevertheless, the products from feeding experiments with this precursor usually show very complex coupling patterns which require extensive use of 2D NMR techniques for analysis. Particularly useful is a triple-quantum version of the 2D INADEQUATE experiment which we developed for this purpose.[155] This experiment specifically detects assemblies of three directly coupled ^{13}C nuclei which share a unique triple-quantum-coherence frequency (see Section 6.3 and Fig. 23). The naphthomycin A **40** derived from [U-$^{13}C_3$]glycerol (Fig. 20) showed the expected couplings in the polyketide moiety; in addition, the mC_7N moiety contained two three-carbon assemblies derived intact from glycerol and one aromatic carbon, C-29, carrying the nitrogen, which was enriched but did not show significant coupling to neighboring carbons. Completely analogous results were obtained for ansatrienin **5**. This identifies the assembly of the mC_7N unit in **40** and **5** as being identical to that in mitomycin **36** and geldanamycin **39**; i.e., the nitrogen is attached to the carbon corresponding to C-5 of a shikimic acid molecule.

The presence in ansatrienin **5** of a shikimate-derived cyclohexanecarboxylic acid moiety in addition to the mC_7N unit offered the unique opportunity to test the proposition that the lack of incorporation of shikimic acid **2** into the mC_7N unit is due to impermeability of the cells. Conclusive evidence that shikimic acid labels only the cyclohexanecarboxylic acid moiety but not the mC_7N unit came from an experiment in which D-[2-^{13}C]shikimic acid was fed to *S. collinus*. The ^{13}C NMR spectra of the resulting **5** revealed approximately 5% enrichment in C-6 of the cyclohexane ring, but no significant enrichment (less than 0.2%) in C-19 or C-23, the two possible sites of labeling in the mC_7N unit.[46] It is therefore clear that, at least in the case of ansatrienin biosynthesis, the lack of incorporation of shikimic acid into the mC_7N unit is not due to permeability problems.

We conclude that the formation of 3-amino-5-hydroxybenzoic acid **33** must branch off at a much earlier stage in the shikimate pathway. To accommodate all the known facts about the biosynthesis of the mC_7N unit of the mitomycin, ansamycin, and ansamitocin antibiotics, we propose the pathway for the formation of 3-amino-5-hydroxybenzoic acid **3** shown in Figure 21. It had already been

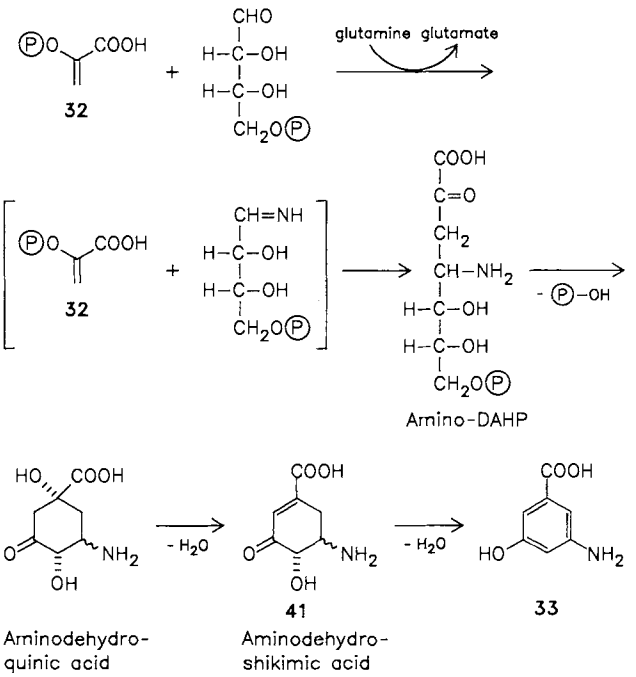

Fig. 21. Proposed mode of formation of 3-amino-5-hydroxybenzoic acid **33**, the precursor of mC_7N units.

suggested by *Hornemann* et al.[137] that the 4-deoxy-4-amino analogue of 3-deoxy-D-*arabino*-heptulosonic acid 7-phosphate (DAHP) is the precursor of the mC_7N unit. We are proposing that this compound ("amino-DAHP") is formed by an enzyme similar to DAHP synthase, but carrying an additional subunit which can hydrolyze glutamine. The nascent ammonia thereby produced reacts with the aldehyde group of erythrose 4-phosphate to form an imine. Condensation of the imine with phosphoenolpyruvate would then produce the amino analogue of DAHP. This notion is supported by the finding of *Jiao* et al.[156] that the most efficient source of the nitrogen of rifamycin is the amide nitrogen of glutamine. The amino analogue could then be carried through the next two stages of the shikimate pathway, possibly by the normal enzymes, to give the 5-amino analogue of 3-dehydroshikimic acid, which by enolization and dehydration would produce 3-amino-5-hydroxybenzoic acid. Obviously, this scheme is at the moment entirely speculative and awaits experimental scrutiny.

6.3. Acarbose

The α-D-glucosidase inhibitor acarbose **42** (Fig. 22)[133,157] is a pseudotetrasaccharide containing an unsaturated cyclitol moiety, valienamine, and a 6-deoxy sugar attached to a molecule of maltose. Valienamine is also a component of the antibiotic validamycin A;[132,158,159] it represents an mC_7N unit which had been proposed to arise in the same manner as the mC_7N unit of the ansamycins and mitomycins.[131] On the other hand, the substitution pattern of valienamine differs substantially from that of other mC_7N units, suggesting the possibility of a different biosynthetic origin. In collaboration with the group of *Pape* we examined this question by feeding [*carboxy*-^{13}C]-3-amino-5-hydroxybenzoic acid and 3-aminobenzoic acid to cultures of *Actinoplanes sp.* SN 23/29. NMR analysis of the resulting **42** showed no detectable incorporation of label from either precursor.[160] Hence, it does indeed appear that a different pathway is operating in the formation of the mC_7N unit of acarbose. To obtain more information, we carried out a feeding experiment with [U-$^{13}C_3$]glycerol. The analysis of the resulting **42** by a variety of multiple-quantum 2D NMR techniques revealed the labeling and coupling pattern shown in Figure 22. Particularly informative was the triple-quantum 2D INADEQUATE spectrum (Fig. 23). A strong signal indicated the presence of a contiguous array of three ^{13}C nuclei representing C-6, C-1, and C-2 of the valienamine moiety. The remaining four carbon atoms of this mC_7N unit are derived from glycerol as two C_2 units. This coupling pattern is in accord with formation of the valienamine moiety by cyclization of a heptulose which, in turn, arises by two successive transfers of C_2 units by transketolase onto a triose phosphate (Fig. 22). *Rinehart* et al.[161] have independently demonstrated the same mode of formation for the valienamine moiety of the antibiotic validamycin.

6.4. Asukamycin and Manumycin

Manumycin **44** (Fig. 24), a metabolite of *Streptomyces parvulus*,[120,121,162] and asukamycin **6** (cf. Fig. 2)[37,38] both contain an mC_7N unit and a C_5N unit connected by short polyene chains ending in carboxyl groups which are amide-linked to the nitrogens of the mC_7N and C_5N units. The polyketide origin of these polyene chains has been demonstrated for manumycin **44** by *Thiericke* and *Zeeck*[163] and for asukamycin **6** in our laboratory.[43] As shown in Figure 24, one polyketide chain in both antibiotics is initiated by the exocyclic carbon of the mC_7N unit, which presumably therefore at one point must have had the oxidation state of a carboxyl group. The other polyketide chain in manumycin is initiated by an acetate unit and in asukamycin by cyclohexanecarboxylic acid (see Section 3), both presumably in the form of their coenzyme A esters.

6.4.1. Origin of the mC_7N Unit

In light of the origin of the mC_7N units of the ansamycin and mitomycin antibiotics from 3-amino-5-hydroxybenzoic acid **33**, we fed this compound, labeled with ^{13}C in the carboxyl group, both to *Streptomyces nodosus* subspecies *asukaensis* and to *Streptomyces parvulus*. No significant incorporation of ^{13}C was seen into either asukamycin **6** or manumycin **44**.[164] Similarly, 3-amino[*carboxy*-^{13}C]-benzoic acid **43** was not significantly incorporated into manumycin, although addition of larger quantities of 3-aminobenzoic acid to the fermentation resulted in the formation of a new compound containing a simple benzene ring in place of the six-membered ring of **44**.[165] Feeding experiments with ^{13}C-labeled acetate indicated specific incorporation of two molecules of acetate into the mC_7N units of **6** and **44** in a tail-to-tail fashion (Fig. 24), labeling four of the seven carbon atoms of this moie-

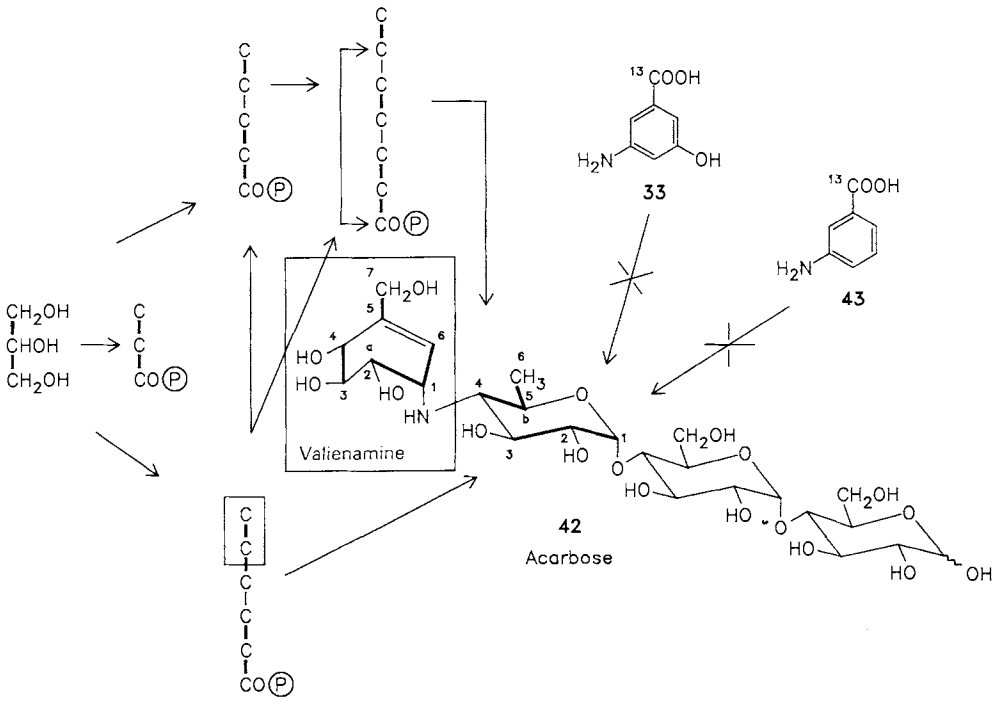

Fig. 22. Acarbose **42** and its ^{13}C-^{13}C coupling pattern and mode of formation from [U-$^{13}C_3$]glycerol.

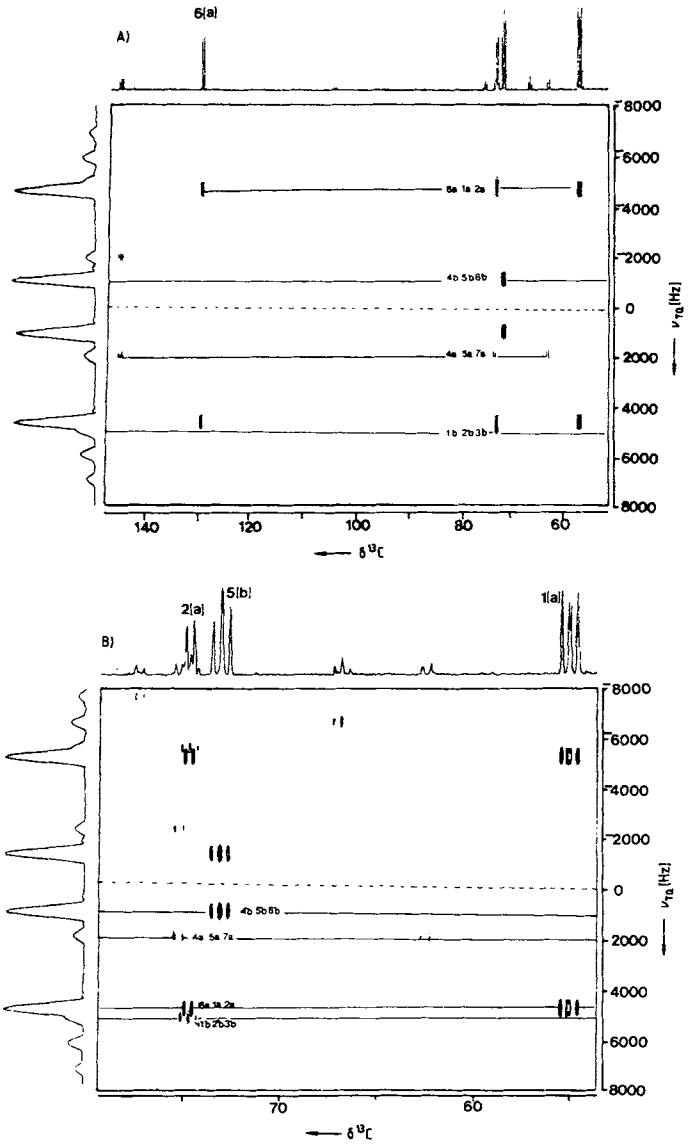

Fig. 23. Triple-quantum 2D INADEQUATE spectrum of acarbose **42** biosynthesized from [U-$^{13}C_3$]glycerol. A) Full 121.5-MHz spectrum. B) F2 expanded spectrum. The spectra are symmetrical around the $\nu_{TQ} = 0$ axis (dotted line). Signals sharing the same TQ frequency arise from contiguously coupled arrays of three ^{13}C nuclei. Some of the weaker signals, e.g., 4(a)5(a)7(a), arise from statistical coupling across one of the bonds, as confirmed by the double-quantum 2D INADEQUATE spectrum. The carbons in the valienamine moiety are indicated by "a", those in the 6-deoxy sugar moiety by "b".

ty.[163, 164] No such incorporation of acetate into the mC_7N unit is predicted via the shikimate pathway; hence, these results suggest a completely different origin of these mC_7N units. To probe for the origin of the remaining three carbon atoms, we again carried out experiments with [U-$^{13}C_3$]glycerol. Extensive analysis of the coupling patterns in the resulting **6** and **44** revealed that an intact glycerol molecule is incorporated into C-1, C-2, and C-3, albeit at somewhat lower enrichment than the incorporation of acetate into the other four carbon atoms of the mC_7N unit.[164] This pattern is indeed different from that predicted for glycerol incorporation via the shikimate pathway (i.e., two contiguously coupled three-carbon segments plus one enriched carbon atom without significant ^{13}C–^{13}C coupling). The latter pattern was, however, seen in the cyclohexane ring and the attached carbon of asukamycin **6**.

The tail-to-tail connection of two molecules of acetate in the mC_7N unit of asukamycin and manumycin suggests origin of those four carbon atoms from a four-carbon dicarboxylic acid generated via the Krebs cycle. This notion is supported by a feeding experiment with [1,4-$^{13}C_2$]succinic acid which gave low but specific incorporation into C-6 and C-7 of asukamycin.[166] The relatively low enrichment obtained with this precursor is in all likelihood due to extensive metabolism of succinate via the Krebs cycle. A more proximate precursor of the three glycerol-derived carbon atoms of the mC_7N unit has not yet been identified. However, a feeding experiment with D,L-[1-^{13}C]serine gave no detectable incorporation into either C-1 or C-3 of **6**. Similar results have been obtained with **44**.[167]

It is evident from the results described here that, again, the pathway operating in the formation of the mC_7N unit of these antibiotics is entirely different from that leading to the biosynthesis of the ansamycin and mitomycin antibiotics on the one hand and the valienamine moiety of acarbose **42** and validamycin on the other. However, considerable additional work is necessary to unravel the detailed features of this new pathway. The origin of another mC_7N unit, a structural element of the antibiotic kinamycin, has been studied by *Gould* et al. In this case the mC_7N unit was found to originate from acetate by the polyketide pathway.[168] All these studies taken together clearly indicate that the biosynthetic similarities among the various mC_7N units do not extend as far as some of the structural comparisons had originally suggested.

6.4.2. Origin of the C_5N Unit

Inspection of the structure of the C_5N unit of manumycin **44** and asukamycin **6**, the 2-amino-3-hydroxycyclopent-2-enone moiety, immediately reveals that it contains all the carbon, hydrogen, nitrogen, and oxygen atoms of 5-aminolevulinic acid **45** minus one molecule of water. Working with the asukamycin fermentation, we therefore tested the notion that the C_5N moiety arises by an intramolecular cyclization of **45**.[169]

In agreement with this idea, [2-^{14}C]glycine gave specific incorporation of up to 20% whereas [1-^{14}C]glycine gave nine times lower incorporation under comparable conditions. Intact incorporation of C-2 of glycine with the attached nitrogen was demonstrated by feeding [2-^{13}C,^{15}N]glycine and observing splitting of the ^{13}C NMR signal for C-2 of the 2-amino-3-hydroxycyclopent-2-enone moiety at $\delta = 115.4$ into a doublet by the attached ^{15}N. [1,4-$^{14}C_2$]Succinic acid was incorporated rather poorly (specific incorporation 0.3 to 0.6%), possibly reflecting the Krebs cycle activity in this organism, but the feeding experiments with [1,2-$^{13}C_2$]acetate and [U-$^{13}C_3$]glycerol (Fig. 24) support the notion that C-3, C-4, C-5, and C-1 of the C_5N unit arise from succinic acid. Two molecules of acetate are incorporated into these four carbon atoms in a tail-to-tail fashion, the carboxyl groups giving rise to C-1 and C-3. Finally, feeding experiments with 5-amino-[5-^{14}C]levulinic acid showed significant incorporation (specific incorpora-

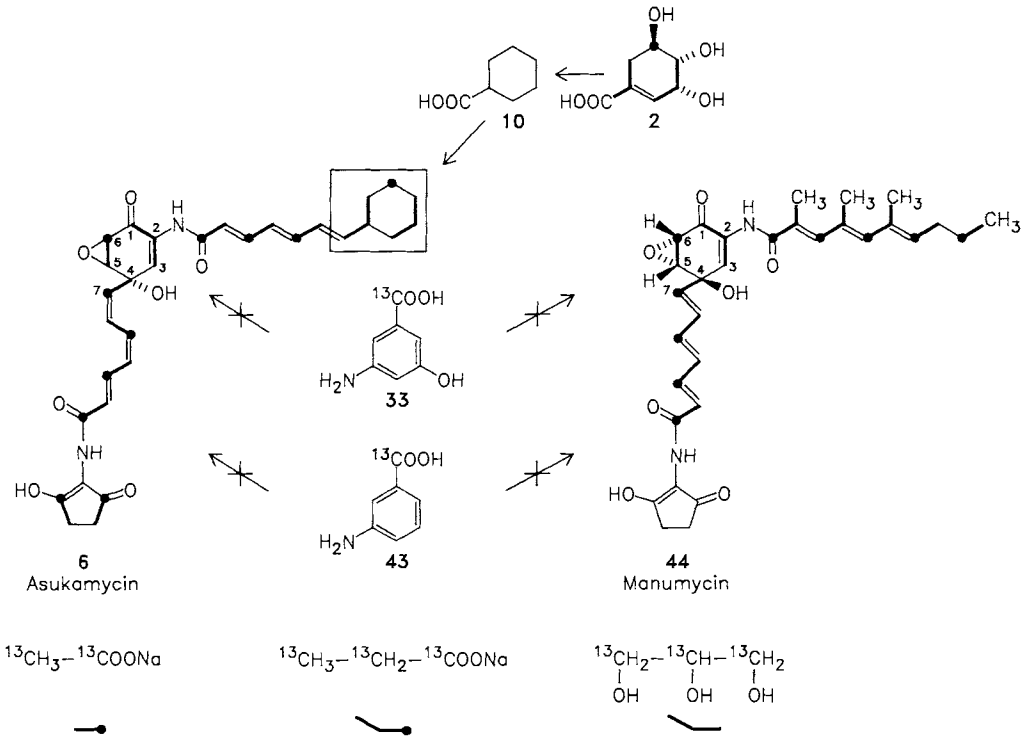

Fig. 24. Biosynthetic labeling patterns of asukamycin **6** and manumycin **44**.

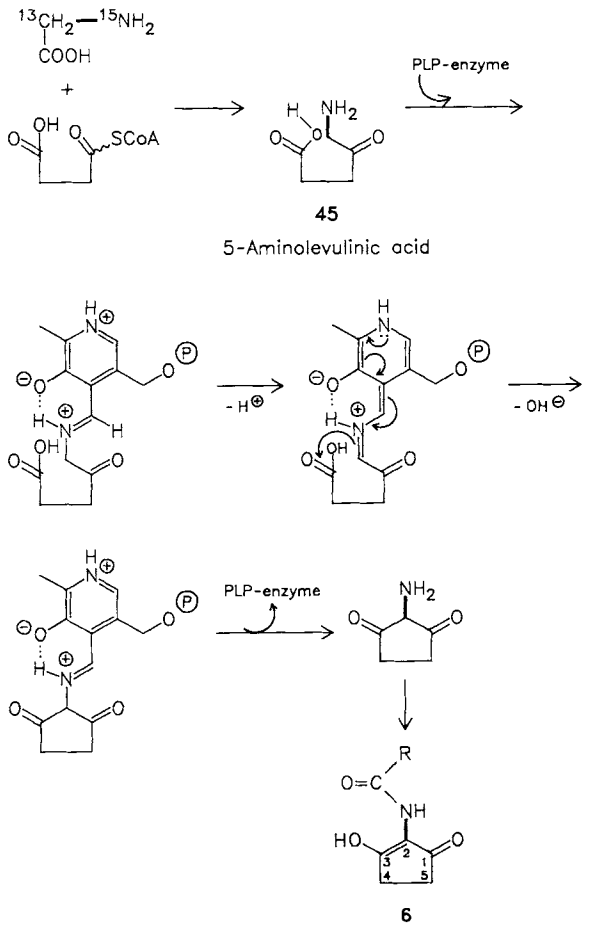

Fig. 25. Proposed mechanism for the formation of the C_5N unit in asukamycin **6** from 5-aminolevulinic acid **45**.

tion of 0.2 to 2.2%) despite the fact that this compound inhibited asukamycin formation and underwent extensive decomposition during the fermentation.

On the basis of these results, we suggested[169] that the 2-amino-3-hydroxycyclopent-2-enone moiety is formed from one molecule each of succinyl-CoA and glycine, with decarboxylation of the latter, via 5-aminolevulinic acid **45**, which then undergoes an intramolecular cyclization. Figure 25 shows a plausible mechanism for this reaction, invoking pyridoxal phosphate (PLP) catalysis to generate a carbanion at C-5 which attacks the carboxyl carbon.

6.5. Reductiomycin

We wanted to verify the biosynthetic origin of the C_5N unit established in asukamycin **6** in another example and we chose for this the antibiotic reductiomycin **46** (Fig. 26). The structure of this antibiotic, a metabolite of *Streptomyces xanthochromogenus*, was the subject of some controversy,[122,170,171] which was settled in favor of structure **46** by total synthesis.[172] Feeding experiments with ^{14}C-labeled precursors gave results similar to those obtained on the C_5N unit of asukamycin **6**.[173] [2-^{14}C]Glycine, but not [1-^{14}C]glycine, was efficiently incorporated into **46**, and both [1,4-$^{14}C_2$]succinic acid and 5-amino-[5-^{14}C]levulinic acid were incorporated significantly but less efficiently than [2-^{14}C]glycine. Unequivocal proof for the direct origin of the 2-amino-3-hydroxycyclopent-2-enone moiety from an intact molecule of 5-aminolevulinic acid **45** was ascertained by feeding experiments with a sample of the latter doubly labeled with ^{13}C in positions 4 and 5. The ^{13}C NMR spectrum of the resulting sample of **46** showed labeling exclusively in C-1, C-2, and C-3 of the

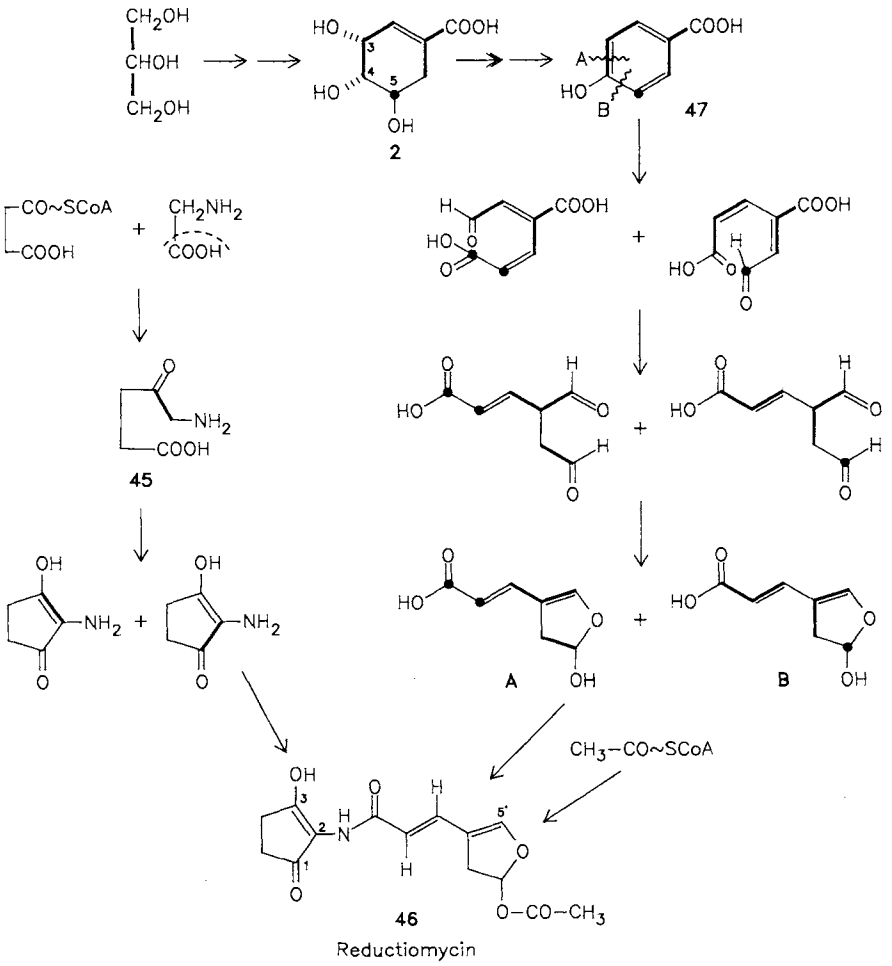

Fig. 26. Biosynthesis of the antibiotic reductiomycin **46**. **A** and **B** are the products formed by cleavage of **47** at A and B, respectively.

C_5N moiety. C-2 was twice as heavily enriched as C-1 and C-3; in half of the labeled molecules, C-2 was coupled to C-1 and in the other half to C-3. The patterns of incorporation of [1,2-$^{13}C_2$]acetate and [U-$^{13}C_3$]glycerol are fully in accord with formation of the C_5N unit by intramolecular cyclization of 5-aminolevulinic acid **45**.[173]

The origin of the remaining nine carbon atoms of **46** was less obvious. Inspection of the structure suggested the possibility that the entire nine-carbon assembly, including the acetoxy group, could be derived by a ring cleavage of tyrosine or a derivative thereof followed by a Baeyer–Villiger oxidation. However, this notion was quickly dismissed when it was found that [1-^{14}C]tyrosine was not at all incorporated and that [1,2-$^{13}C_2$]acetate gave high enrichment and coupling in the acetoxy group. The origin of the remaining seven carbon atoms making up the dihydrofuranylacrylic acid moiety was again probed in a feeding experiment with [U-$^{13}C_3$]glycerol.[173] The incorporation of three C_2 units from glycerol into the three acetate/succinate-derived portions of the molecule was readily detected. However, the seven carbon atoms of the dihydrofuranylacrylic acid moiety showed a very complex coupling pattern. By a 2D INADEQUATE experiment and subsequent spectral simulation, this was unraveled as a superimposition of two coupling patterns, each present in half of the labeled molecules (Fig. 26). One (cf. **B**) contained two intact molecules of glycerol and a single enriched but not coupled carbon and the other (cf. **A**) contained one C_3 segment, one C_2 segment, and two single enriched, but not coupled, carbon atoms. The coupling pattern in **B** is immediately reminiscent of a biosynthesis via the shikimate pathway. Cleavage of a molecule of shikimic acid **2** between C-4 and C-5 would give the observed pattern. Pattern **A** would result from a cleavage of shikimic acid between C-3 and C-4. The results thus suggested that the dihydrofuranylacrylic acid moiety might arise by aromatic ring cleavage of a symmetrical compound formed from shikimic acid **2**. A logical candidate would be 4-hydroxybenzoic acid **47** or the corresponding aldehyde. When this notion was tested by feeding 4-hydroxy-[*carboxy*-^{13}C]benzoic acid to *Streptomyces xanthochromogenus*, **46** was obtained which contained 64% ^{13}C exclusively in the expected position, C-5'.[173] Further experiments suggest that the ring cleavage occurs at the stage of the corresponding aldehyde.

7. Benzoisochromane Quinone Antibiotics

7.1. Background

In 1947 *Brockmann* and *Pini*[174] reported the isolation of a deep red, crystalline pigment from cultures of an Actinomycete. This compound, actinorhodin **55**, was the first

member of a sizable family of antibiotics sharing the common structural element of a disubstituted tricyclic benzoisochromane skeleton **48** (Fig. 27).[175] Additional common structural features are oxygen functions at C-11 and C-13, a quinone function in one of the aromatic rings and the absence of an oxygen function at C-9. The hydrogens at the two common chiral centers, C-3 and C-15, are in a *trans* relationship. Streptomycetes can elaborate either compounds of 15*R* (A series, actinorhodin, kalafungin) or 15*S* configuration (G series, granaticin, the nanaomycins, and the naphthocyclinones). At least in one case[176] the same culture has been observed to produce members of both enantiomeric series.

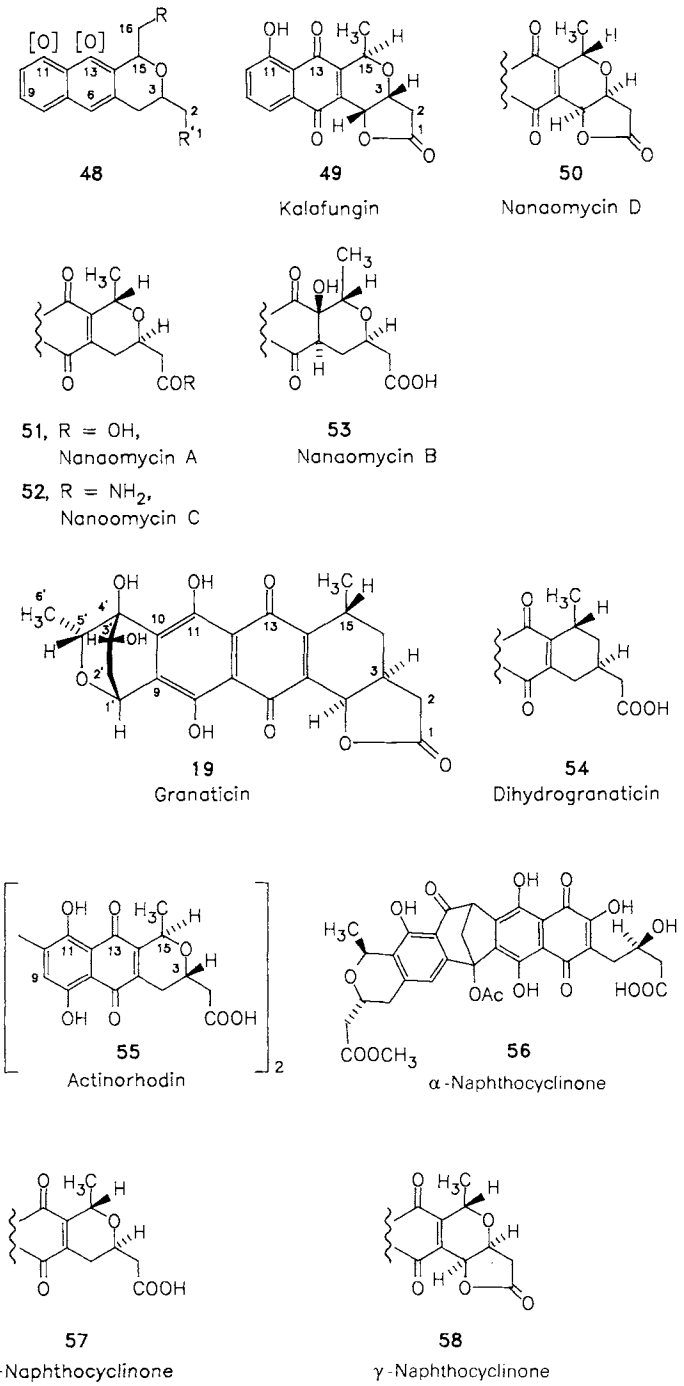

Fig. 27. Some benzoisochromane quinone antibiotics, sharing the common structural element **48**.

As reviewed earlier,[177] the benzoisochromane quinone antibiotics can be categorized into simple monomers, C-16-modified monomers, carbohydrate-modified monomers, and dimers. The simple monomers are represented by kalafungin **44**, a metabolite of *Streptomyces tanashiensis*,[178,179] and the nanaomycins **50**–**53** isolated from *S. rosa* var. *notoensis* (Fig. 27).[180–186] Most of these compounds show pronounced activity against gram-positive bacteria and mycoplasmas, as well as good antifungal activity;[181] nanaomycin A **51** has been approved for use in Japan as an anti-ringworm agent in cattle. Carbohydrate-modified monomers are represented by granaticin **19** and its congeners. These were first isolated from *S. olivaceus*,[54] but have also been obtained from various other *Streptomyces* species.[55–58] The structure of granaticin **19** (Fig. 27) was determined by spectroscopic methods[59] and by a single-crystal X-ray analysis.[60] Granaticin co-occurs with, among other congeners, its analogue dihydrogranaticin **54**, which does not contain a lactone ring.[57]

The simplest of the dimeric benzoisochromane quinones, actinorhodin **55** (Fig. 27)[187–189] from *S. coelicolor*, is a very deeply colored pH indicator, red in acid, blue at an alkaline pH. More highly modified dimers are the naphthocyclinones, which were isolated from cultures of *S. arenae* and whose structures were deduced by extensive spectroscopic studies[190–192] and by an X-ray analysis.[193] The quantitatively prevalent compound is α-naphthocyclinone **56** (Fig. 27) which lacks two carbon atoms in the "eastern" portion of the molecule compared to all the other naphthocyclinones.

7.2. Formation of the Polyketide Backbone

Feeding experiments with ^{13}C-labeled acetate and malonate have demonstrated unequivocally that the basic skeleton of the benzoisochromane quinone antibiotics is constructed from eight acetate/malonate units via the polyketide pathway, giving rise to the labeling patterns shown in Figure 28 for nanaomycin A **51**,[182] actinorhodin **55**,[194] and granaticin **19**.[61,195] The biosynthetic labeling pattern has been used in two instances to settle subtle structural uncertainties. *Ōmura* and co-workers placed the hydroxyl group in nanaomycin A at C-11 rather than C-8, because it is attached to a carbon enriched by [1-^{13}C]acetate,[182] and we showed that the two monomeric units in actinorhodin **55** are connected through C-10 labeled by the methyl group of acetate.[194] A feeding experiment with [1,2-$^{13}C_2$]acetate also established that all eight acetate units of **55** are incorporated intact into each monomer unit.[194] In the case of α-naphthocyclinone **56**, ^{13}C-labeled acetate and malonate gave the enrichment pattern shown in Figure 29, clearly indicating origin of this molecule from two polyketide chains plus one additional acetate moiety giving rise to the acetoxy group.[196] The involvement of two polyketide chains follows in particular from the finding that two directly connected carbons in the center of the molecule are both derived from C-2 of acetate.

Further information on the mode of polyketide assembly was sought in the case of granaticin **19** by following the fate of the methyl hydrogens and the carboxyl oxygens of acetate through the biosynthetic sequence.[197] Analysis of

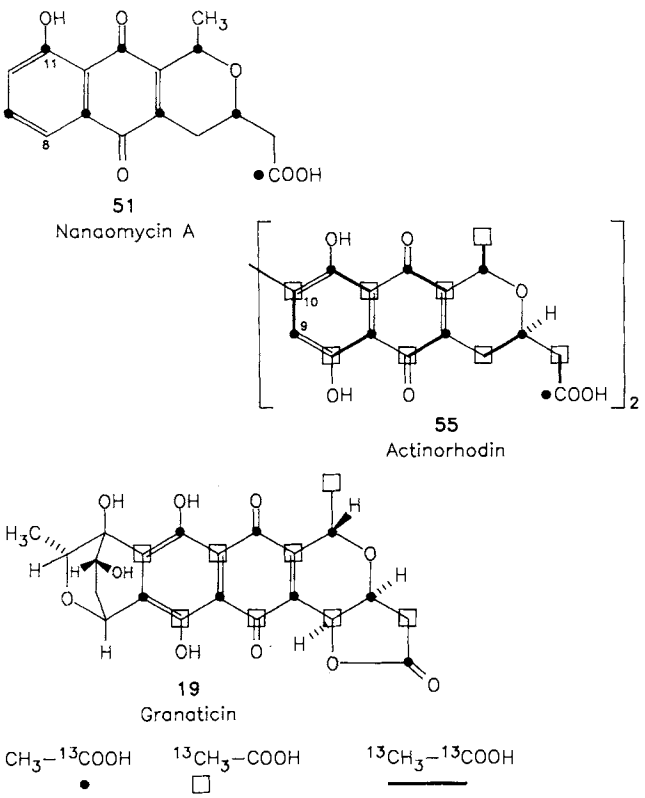

Fig. 28. Labeling and coupling pattern in benzoisochromane quinones after feeding experiments with ^{13}C-labeled acetate.

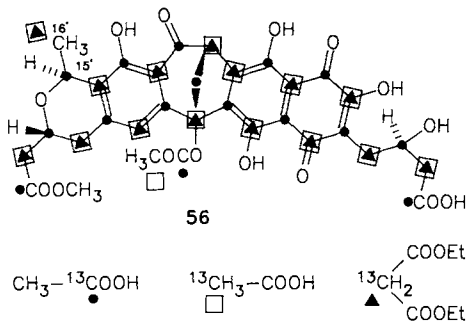

Fig. 29. Labeling pattern of α-naphthocyclinone **56** after feeding experiments with ^{13}C-labeled acetate and malonate.

a sample of **19** biosynthesized from [2-^{13}C,$^{2}H_3$]acetate by $^{13}C\{^{1}H,^{2}H\}$ triple-resonance spectroscopy showed the incorporation of one atom of deuterium each at C-2 and C-4 (Fig. 30). C-16 carried a maximum of two, not three, atoms of deuterium. These findings suggest that C-2 of the polyketide chain goes through the intermediate stage of a methine carbon, resulting in replacement of one of the original deuterium atoms by a normal hydrogen atom. The finding of only two rather than three atoms of deuterium in the methyl group of the starter unit is intriguing. It could have a trivial explanation—e.g., rapid equilibration between acetyl-CoA and malonyl-CoA—but it also would be consistent with the idea that the starter unit might be malonyl-CoA rather than acetyl-CoA. The resulting polyketide would have to be decarboxylated stereospecifically prior to release from the synthase.

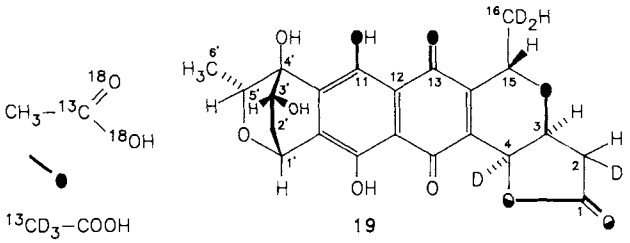

Fig. 30. Fate of the methyl hydrogens and the carboxyl oxygens of acetate in the biosynthesis of granaticin **19**.

The fate of the acetate oxygens was probed in an experiment with [1-^{13}C,$^{18}O_2$]acetate followed by ^{13}C NMR analysis of the product by the ^{18}O shift method. This experiment showed incorporation of ^{18}O at C-1, C-11, and C-13 and into the oxygen of the pyran ring (Fig. 30). The ^{18}O shift from the pyran ring oxygen was only observed on the ^{13}C NMR signal for C-3, not that for C-15, demonstrating that this oxygen is provided by the C-3 carbonyl group of the polyketide. The ^{18}O distribution between the carbonyl and the lactone oxygen at C-1 was not determined, because the granaticin sample was derivatized to the methyl ester of dihydrogranaticin **55** (Fig. 27) for NMR analysis. The ^{18}O enrichment at C-1 of this derivative was about half that in the other three positions, consistent with loss of half the ^{18}O during esterification. This result indicates the retention of only one atom of oxygen at the original C-1 of granaticin **19**. Hence, the formation of the lactone ring of granaticin from a free carboxyl group involves no loss of ^{18}O.[197]

7.3. Formation of the Sugar Moiety of Granaticin

In granaticin **19** the basic polyketide-derived skeleton is modified by the attachment of a six-carbon moiety to the aromatic system in an unusual, rigid [2.2.2] arrangement. Structural inspection of this additional six-carbon moiety identifies it as a 2,6-dideoxyhexose, and, in accord with this view, its origin was readily traced to glucose.[61] Details of the conversion of glucose to this dideoxyhexose moiety were discussed in Section 4.1.

An interesting problem is posed by the attachment of the sugar moiety, presumably in the form of TDP-4-oxo-2,6-dideoxyhexose **59**, to the aromatic ring system, since the process is completely regiospecific. This regiospecificity may be due to recognition of the substitution pattern at the opposite end of the aromatic moiety by the enzyme generating the first C–C bond to the sugar moiety. In this case the first bond formed may be the *C*-glycosidic linkage between C-1 of the sugar and C-9 of the aglycone (path A, Fig. 31). Alternatively, the first bond to the sugar moiety may be formed at the stage of an aromatic precursor not yet oxygenated at C-8 (path B, Fig. 31). This would imply that the first bond is formed by an aldol condensation between C-4 of the sugar and C-10 (activated by the 11-hydroxyl group) of the aromatic precursor. Hydroxylation at C-8 and closure of the *C*-glycosidic bond then completes the structure. In view of findings (see Section 7.6) that the stereochemistry in the pyran ring can be altered without

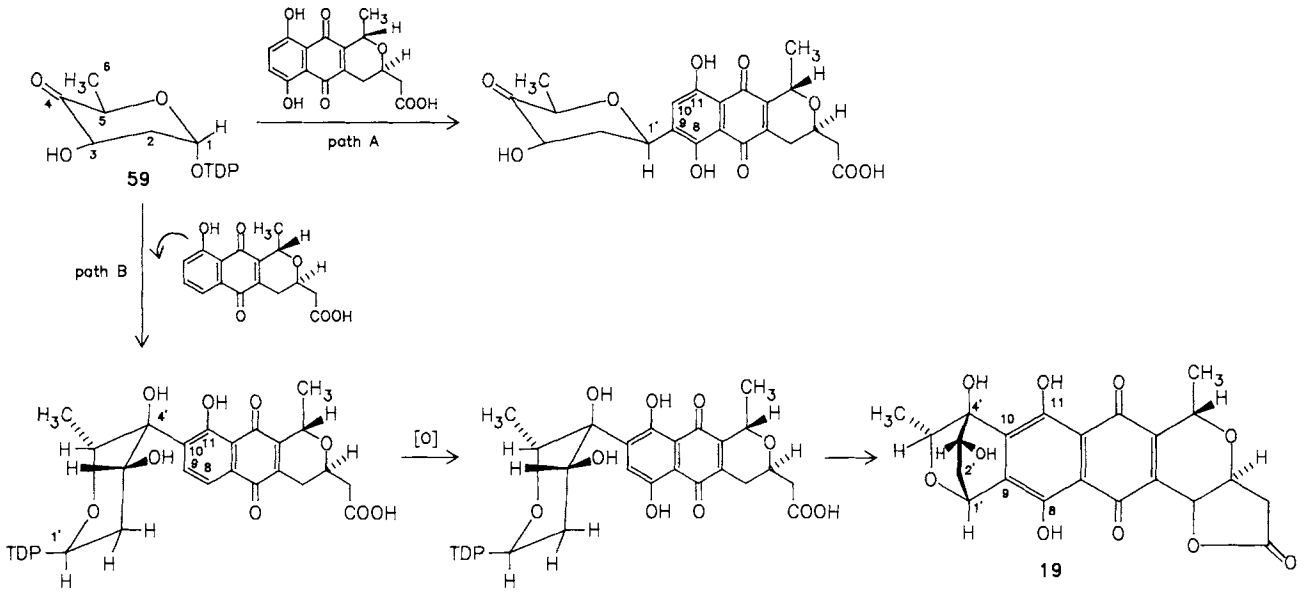

Fig. 31. Possible mechanisms for the attachment of the sugar moiety to the aromatic core of granaticin **19**.

losing the regiospecificity of sugar attachment, we favor the second possibility (path B).

7.4. Biosynthetic Interrelations among Benzoisochromane Quinone Antibiotics

Biosynthetic relations among the various nanaomycins were studied by *Ōmura* et al.[198] Using the fatty acid synthase inhibitor cerulenin[199] to inhibit de novo polyketide formation, they incubated cultures of *S. rosa* var. *notoensis* with individual nanaomycins and monitored their transformation, or lack thereof, to other nanaomycins. These experiments revealed that the biosynthetic reaction sequence was conversion of nanaomycin D to A to E to B (Fig. 32). All three conversions were also demonstrated in cell-free systems[201,202] and the enzyme catalyzing the first of these, nanaomycin D reductase, was purified and studied in some detail.[201,202] The epoxidation of nanaomycin A to E is catalyzed by a mixed function oxygenase requiring NADPH and oxygen.[200] Nanaomycin B synthase, catalyzing the reductive epoxide opening of nanaomycin E to B requires NADH or NADPH and is the first example of an enzyme catalyzing a reductive epoxide ring opening.[200] Nanaomycin D reductase, catalyzing the conversion of nanaomycin D to A, is a flavoprotein of molecular weight 68000 daltons containing FAD. It requires NADH as the reducing agent.[225] The reaction as catalyzed by this enzyme is essentially irreversible and a number of other benzoisochromane quinones, but not granaticin, can serve as substrate in place of nanaomycin D. It is well known[57,61,184,203] that the lactone forms of benzoisochromane quinone antibiotics and their ring-open dihydro forms are readily interconverted chemically under either reducing (lactone to dihydro) or oxidizing (dihydro to lactone) conditions. A likely mechanism for this interconversion is shown in Figure 33. The only redox reaction in the system is the interconversion of the quinone and the hydroquinone form. The hydroquinone of the lactone is then in equilibrium with the quinone of the ring-open dihydro form. *Ōmura* et al.[202] presented evidence, consistent with this view, that nanaomycin D reductase is in fact an NADH dehydrogenase using quinones as facultative electron acceptors.

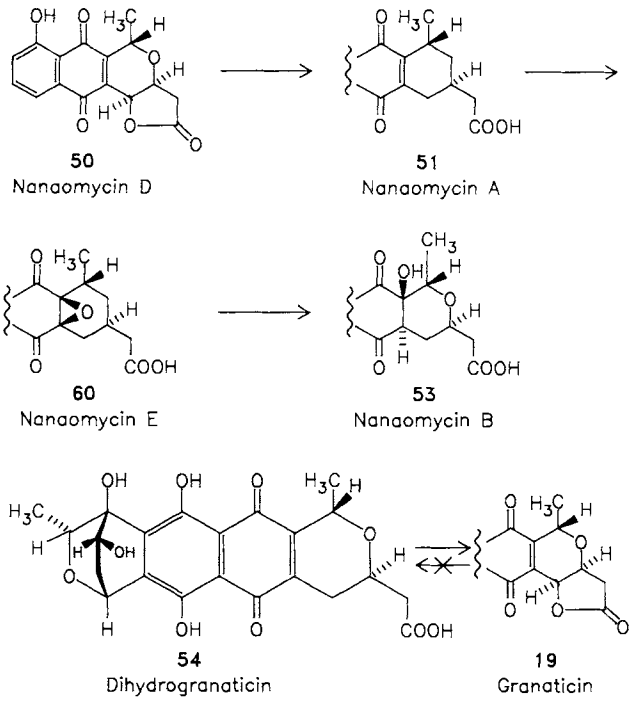

Fig. 32. Biosynthetic interrelations in the nanaomycin and granaticin series.

The finding that in the nanaomycin series the biosynthetic sequence proceeds from the lactone **50** to the ring-open dihydro form **51** is in marked contrast to the situation in the granaticin series. Here the biosynthetic se-

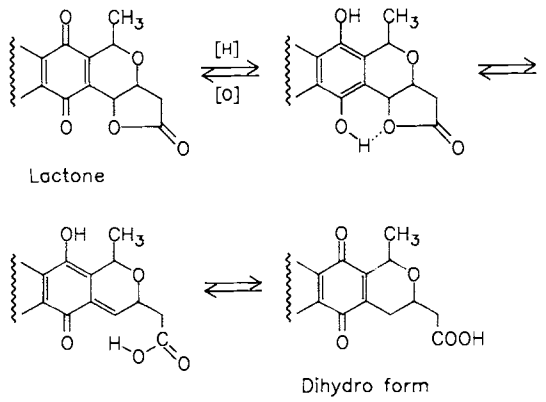

Fig. 33. Mechanism of the interconversion of benzoisochromane quinone lactones and their ring-open dihydro forms.

quence clearly proceeds from dihydrogranaticin **54** to granaticin **19** (Fig. 32). This was established by following the time course of the appearance of the two compounds in the fermentation[57,61] and by observing unidirectional conversion of **54** to **19** in cerulenin-inhibited cultures[197] and in cell-free extracts of *S. violaceoruber*.[61] Consistent with the mechanism shown in Figure 33, the enzymatic reaction is dependent on oxygen but no ^{18}O is incorporated into the product when the conversion is carried out in an atmosphere of $^{18}O_2$ gas.[61]

A detailed study has been made of the interconversions among naphthocyclinones in *S. arenae*.[204] The individual naphthocyclinones were prepared in ^{14}C-labeled form by biosynthesis from sodium [1-^{14}C]acetate and were then fed individually to cultures of *S. arenae*. The distribution of radioactivity among the various naphthocyclinones was analyzed after 6 h and 24 h of metabolism. The biosynthetic relationships established by these experiments are summarized in Figure 34. The main biosynthetic reaction sequence (**58** → **57** → **64** → **56**) parallels that seen in the nanaomycin series (**50** → **51** → **60** → **53**, Fig. 32) rather than that found for granaticin (**54** → **19**, Fig. 32). The lactone, γ-naphthocyclinone **58**, undergoes reductive ring opening to β-naphthocyclinone **57**, which is then epoxidized to **64**. Side reactions lead to δ-naphthocyclinone **62** and to the chlorohydrin **63** of β-naphthocyclinone. However, the main route of metabolism involves conversion of the epoxide and/or chlorohydrin of β-naphthocyclinone to α-naphthocyclinone **56** and further to α-naphthocyclinone acid, the end product of the pathway. This reaction has chemical precedent; both β-naphthocyclinone epoxide **64** and the chlorohydrin **63**, upon photolysis and hydrolysis of the product, give α-naphthocyclinone **56**. A likely mechanism, involving extrusion of C-15′ and C-16′ as acetaldehyde has been proposed.[192,204] The conversion of **57** to **62** is rather obscure, and nothing is known about the source of the additional three carbon atoms. Finally, the "monomer" **61** (Fig. 34), a degradation product of the naphthocyclinones,[190,191] and the corresponding "dimer" **65** were fed in radiolabeled form. The monomer was incorporated into the naphthocyclinones about four times more efficiently than the dimer. This suggests that **61** may serve as a precursor of the "western half" of the naphthocyclinones and

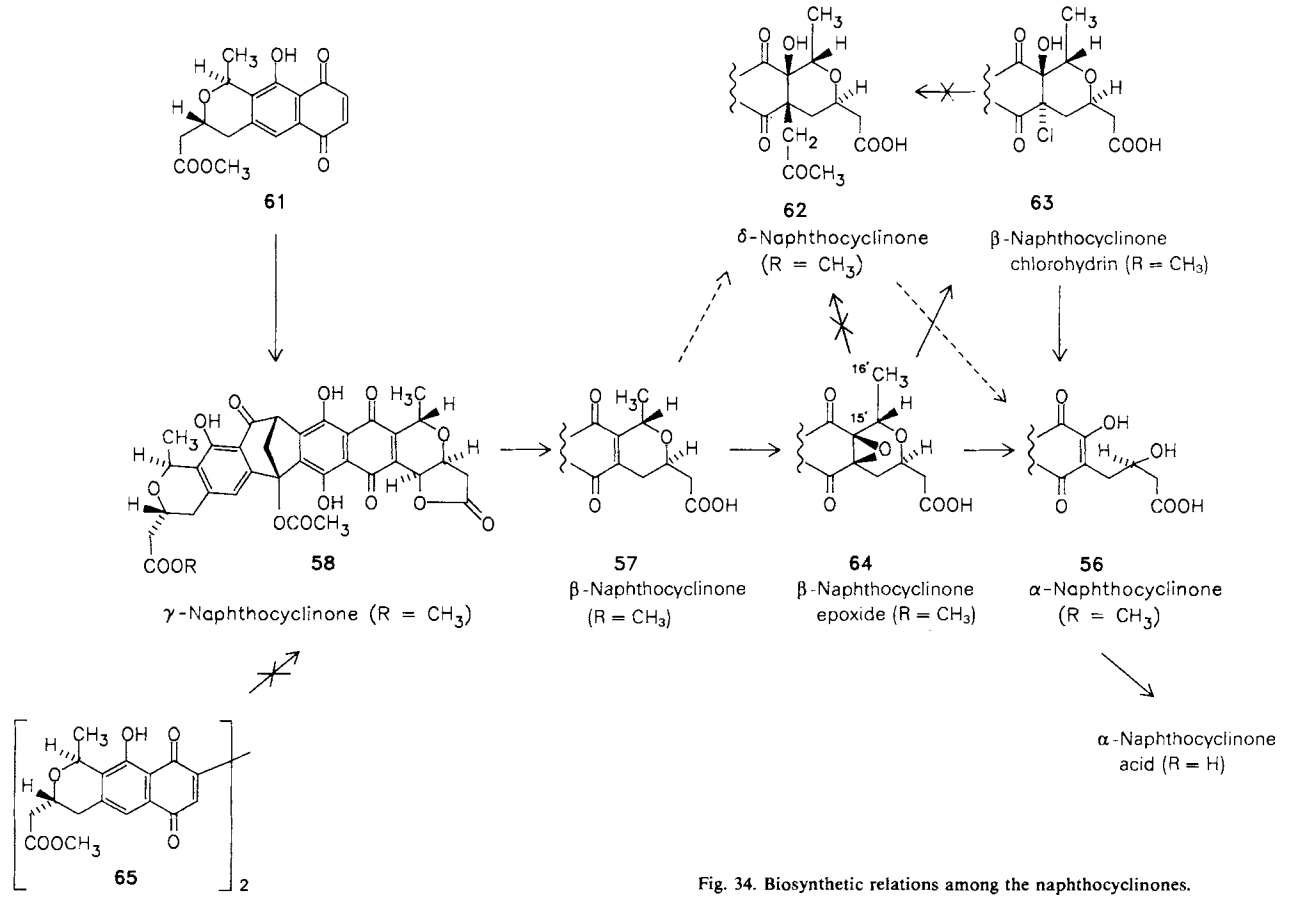

Fig. 34. Biosynthetic relations among the naphthocyclinones.

that the dimerization occurs either at the stage of a product derived from **61** or involves **61** and another monomeric unit to give an unsymmetrical dimer unit. However, more data are needed to draw definitive conclusions on this point.

7.5. Mapping of the Actinorhodin Biosynthetic Pathway by Analysis of Blocked Mutants

As a result of the extensive studies of *Hopwood* et al.,[205] *Streptomyces coelicolor* is today the genetically best-characterized member of the genus *Streptomyces*. Following the establishment of an extensive gene map for this organism, *Rudd* and *Hopwood*[206] isolated 76 mutants of *S. coelicolor* blocked in the biosynthesis of the antibiotic actinorhodin **55**. To select for these mutants, they exposed the colonies briefly to ammonia vapor, making use of the fact that **55** turns dark blue at an alkaline pH; nonproducing mutant colonies do not show this color change. Genetic mapping of these blocked mutants (*act* mutants) showed that all the biosynthetic genes are located in a narrow cluster on the *S. coelicolor* chromosome. The 76 *act* mutants were ordered into seven classes based on several criteria, primarily a cosynthesis assay. This assay involves growing two different mutant colonies next to each other on an agar plate; a mutant blocked late in the biosynthetic pathway (a "secretor" will accumulate a biosynthetic intermediate which diffuses into the surrounding agar and can be converted by a mutant blocked earlier in the pathway (a "converter") into **55**, giving rise to a blue zone in the converter colony where it borders the secretor.[206] The cosynthesis assay allowed ordering of the seven mutant classes in the following biosynthetic sequence:

$$\xrightarrow{\text{I}} \xrightarrow{\text{III}} \xrightarrow{\text{VII}} \xrightarrow{\text{IV}} \xrightarrow{\text{VI}} \xrightarrow{\text{V}} \text{actinorhodin } \mathbf{55}$$

The class *II* mutants cannot be assigned a position in the sequence; in all likelihood they are regulatory mutants. Mutants of classes I and III do not secrete diffusible intermediates; hence, they must be blocked very early in the biosynthetic pathway.

Mutants in classes VII, IV, VI, and V served as secretors in the cosynthesis assay, and our laboratory set out to isolate the biosynthetic intermediates from mutants representing these four classes (Fig. 35). The fractionation of culture extracts was guided by a modification of the cosynthesis assay, in which filter paper discs carrying fractions to be tested were placed on a lawn of a converter mutant. The intermediates in members of two classes (VII and VI) could be detected in the crude extract but were too unstable for isolation.[207] Class V, a very large mutant class, turned out to be genetically heterogeneous and yielded, from members of two subclasses, two compounds which were active in the cosynthesis assay, **70** and **49** (kalafungin) (Fig. 35).[208,209] Based on these structures as well as

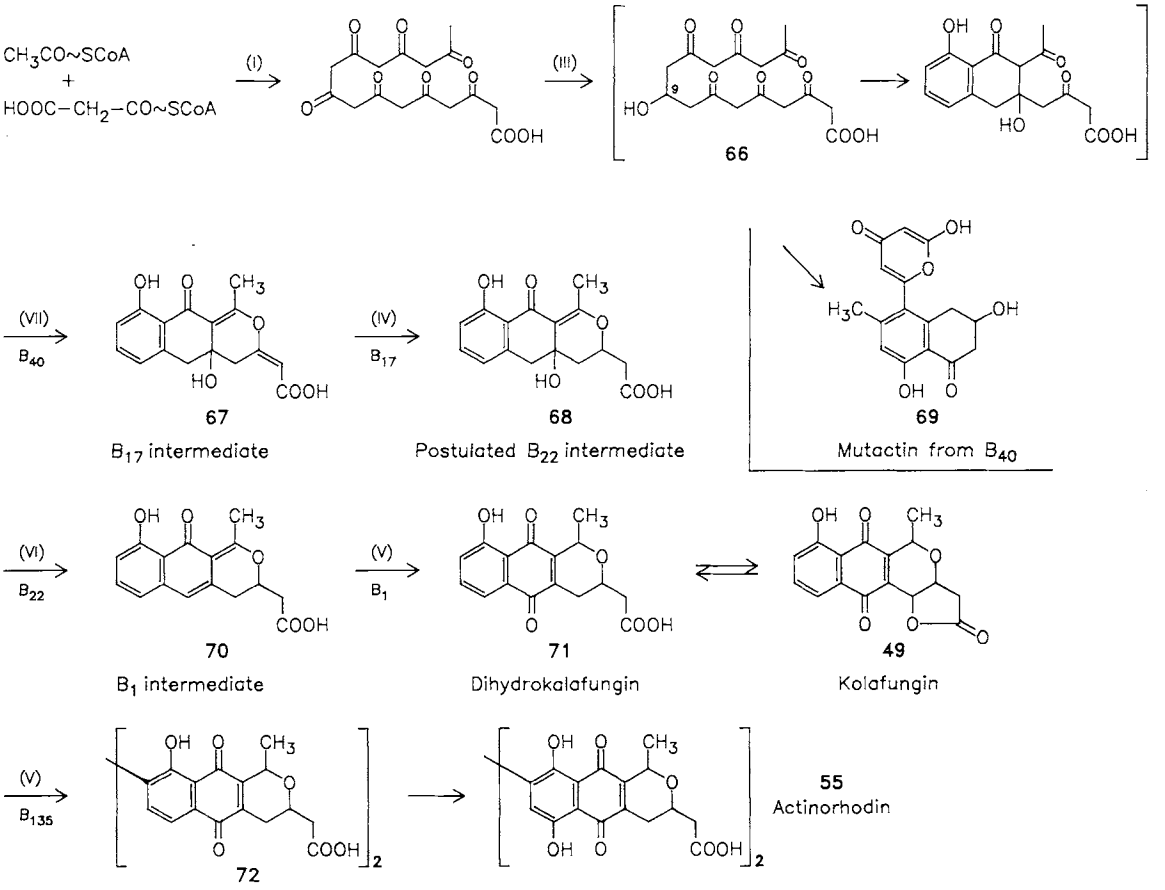

Fig. 35. Actinorhodin (**55**) biosynthesis intermediates isolated from blocked mutants, and their arrangement in a hypothetical pathway of actinorhodin formation.

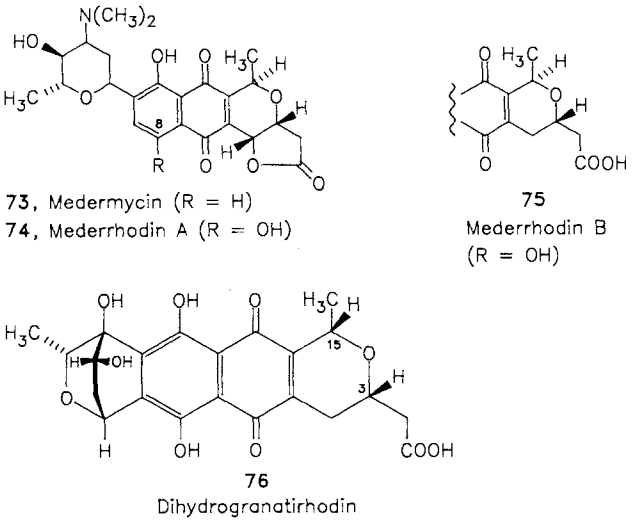
that of compound **67** from mutant B_{17} (class IV), on the feeding experiments discussed earlier, and on mechanistic extrapolations, the hypothetical pathway for actinorhodin biosynthesis shown in Figure 35 was postulated. In particular, it is proposed that the dimerization occurs at the stage of dihydrokalafungin **71** or kalafungin **49** and that the introduction of the 8-hydroxyl groups is the terminal step of the reaction sequence. This accounts for the complete regiospecificity of the process without the need for an enzyme which is very discriminating as to the exact structure and stereochemistry at a remote site of its substrate.

The class VII mutant, B_{40}, produced copious amounts of a novel 16-carbon compound, mutactin **69** (Fig. 35), which, although not a precursor of **55**, is clearly related to the biosynthetic pathway. Its structure, established by X-ray crystallography and spectroscopic analysis,[210] can result from a different mode of cyclization of the presumed open-chain polyketide precursor **66** of actinorhodin after its reduction at C-9. Remarkably, mutactin **69** may be present as the racemate as suggested by both the X-ray structure and the absence of an optical rotation. A feeding experiment with [1,2-$^{13}C_2$]acetate revealed formation of **69** from eight intact molecules of acetate with a coupling pattern corresponding entirely to that seen in actinorhodin **55**. It is not at all obvious how the enzymatic reduction of a carbonyl group in a nonsymmetrical molecule can ultimately lead to a racemic product or how the resulting chiral center, if formed stereospecifically, can be racemized in a subsequent reaction. Mutactin **69** is also formed in traces by wild-type *S. coelicolor*, but not by *act* I and *act* III mutants, which lack the polyketide synthase and polyketide reductase, respectively, suggesting that mutactin formation shares these two enzymes with the actinorhodin biosynthetic pathway.

7.6. New Hybrid Antibiotics

Following the isolation and characterization of the *act* mutants and the finding that all the actinorhodin biosynthetic genes are contained in a cluster, *Malpartida* and *Hopwood*[211] succeeded in cloning the entire pathway. They constructed a plasmid, pIJ2303, carrying a DNA insert containing all the actinorhodin biosynthetic genes as evidenced by the fact that introduction of this plasmid restored synthesis of **55** in all *act* mutant classes and conferred the ability to synthesize **55** on a different organism, *S. parvulus*, which does not normally produce the compound. Further subcloning led to the construction of a series of plasmids containing various segments of the actinorhodin biosynthetic gene cluster.

Availability of the actinorhodin biosynthetic genes made it possible to examine whether new natural products could be generated by gene transfer between different *Streptomyces* strains producing different antibiotics. Obviously, to maximize chances of success one wants to start with strains producing relatively similar compounds. Therefore, in collaboration with the group of *Ōmura*, *Hopwood* and coworkers transformed the medermycin-producing *Streptomyces* AM-7161 (wild-type) with plasmids carrying some or all of the actinorhodin biosynthetic genes. Three transformants, each a recipient of a plasmid containing a gene which is lacking in class V *act* mutants of *S. coelicolor*, produced, in addition to medermycin **73**, one or two new compounds, mederrhodin A **74** and its ring-open dihydro derivative, mederrhodin B **75** (Fig. 36).[212,213] Mederrhodin A **74** has the same structure as medermycin **73** but carries the additional hydroxyl group at C-8 characteristic of actinorhodin **55**. In a similar collaboration with our laboratory, *Hopwood* and co-workers transformed the wild-type of the granaticin-producing *S. violaceoruber* and a nonproducing mutant with plasmids carrying some or all of the actinorhodin biosynthetic genes. A new compound, dihydrogranatirhodin **76** (Fig. 36), was produced by the transformant of the wild-type carrying pIJ2303. This compound has the same structure as dihydrogranaticin **54** (see Fig. 27) but the opposite configuration (actinorhodin stereochemistry) at either C-3 or C-15.[212]



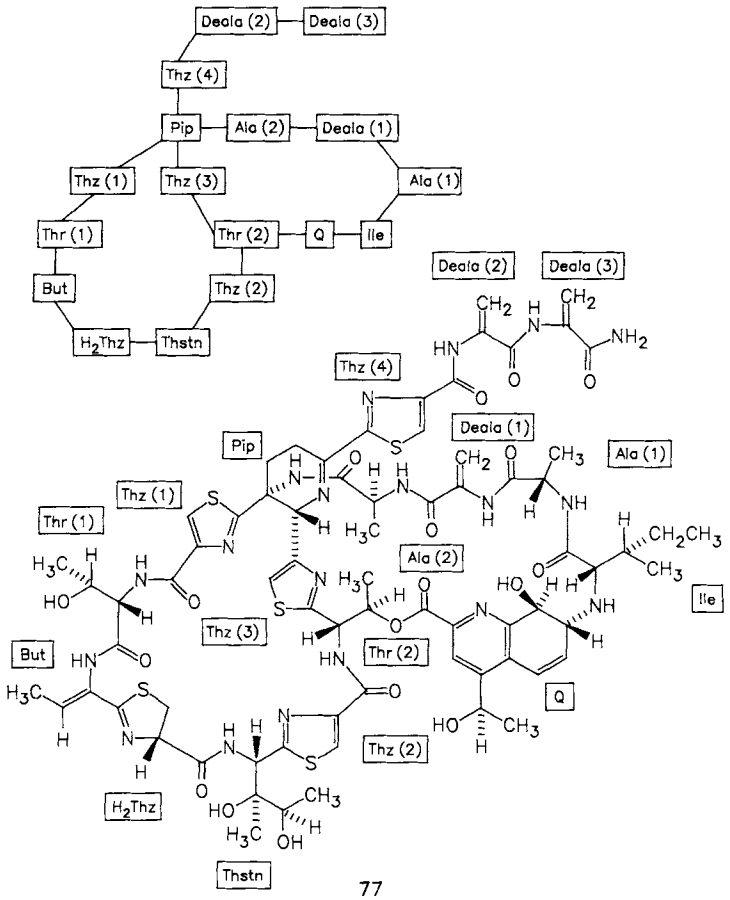


Fig. 36. Medermycin **73** and some new hybrid antibiotics in the benzoisochromane quinone series generated by genetic engineering.

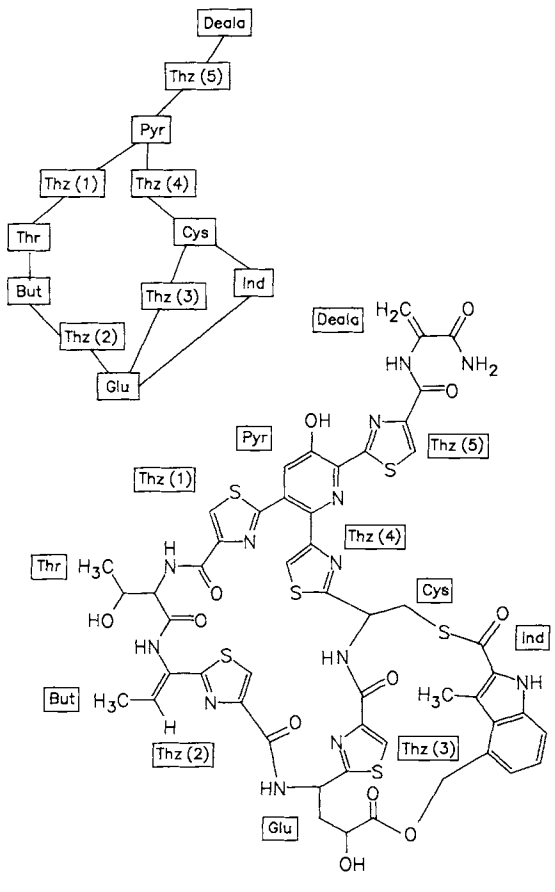
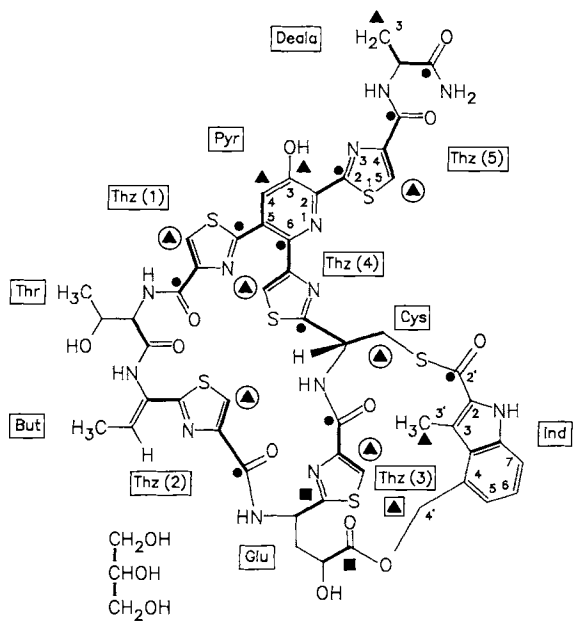


Dihydrogranatirhodin and the mederrhodins represent the first examples of the formation of new hybrid antibiotics by specific interspecies gene cloning. Although the structural modifications achieved are small, they demonstrate the feasibility of this approach; its potential and scope remain to be explored in further work.

8. Thiopeptide Antibiotics

Thiostrepton **77** (Fig. 37)[214–217] and nosiheptide **78**, also called multhiomycin,[218–220] are highly modified sulfur-rich peptide antibiotics. They belong to a family of about 20 known structures containing thiazole rings, which are called thiopeptide antibiotics. Their structures were elucidated by a combination of chemical degradations and X-ray crystallography. Most compounds in this family share a common architecture characterized by a macrocycle incorporating four thiazole and one pyridine or reduced pyridine ring, a side chain consisting of another thiazole and one or two dehydroalanine moieties, and an extra loop of more variable structure. Consistent with this common architecture, **77** and **78** share a common mode of

77



78

action in their activity against gram-positive bacteria; both bind to the 50S ribosomal subunits,[221,222] thereby inhibiting the functions of elongation factors Tu and G.[222] Resistance to these antibiotics is due to methylation of a distinct site on the 23S rRNA by a specific methylase, resulting in the inhibition of antibiotic binding.[222] Nosiheptide **78** is used commercially in Europe and has been approved for use in Japan as a feed additive to increase weight gains in chickens;[223] thiostrepton **77** is not used commercially but is employed extensively as a research tool in molecular biology. Both **77** and **78** contain a number of unusual structural features which caused us to investigate their biosynthesis.

8.1. Biosynthesis of Nosiheptide

Since nosiheptide **78** is evidently a modified peptide, the incorporation of a variety of ^{14}C-labeled amino acids was tested in a series of preliminary feeding experiments with *S. actuosus*. These showed efficient incorporation of L-[U-^{14}C]threonine, L-[U-^{14}C]cysteine, L-[U-^{14}C]serine, L-[*methyl*-^{14}C]methionine, and L-[3'-^{14}C]- and D,L-[7a-^{14}C]tryptophan, but not of L-[U-^{14}C]alanine and L-[1'-^{14}C]phenylalanine.[224] In preparation for further, definitive experiments with ^{13}C-labeled precursors, the 51 signals in the ^{13}C NMR spectrum of nosiheptide **78** were unambiguously assigned. The signal assignments started from the earlier work of *Lukacs* and co-workers[218] and are based on chemical shift theory, multiplicity, ^{1}H-^{13}C correlations, long-range couplings, NOE effects, and multiple-quantum spectroscopy on multiply ^{13}C-enriched samples.[225-227]

Fig. 38. Labeling and coupling pattern in nosiheptide **78** after feeding experiments with various stable-isotope-labeled precursors.

The labeling and coupling patterns observed in **78** after feeding experiments with various ^{13}C-labeled precursors are shown in Figure 38. Specific labeling of the dehydroalanine moiety by L-[3-^{13}C]serine and D,L-[1-^{13}C]serine but not by D,L-[3-^{13}C]cysteine indicates that the dehydroalanine moiety specifically arises by dehydration of serine.[228] This parallels the origin of the dehydroalanine moieties of berninamycin as demonstrated by *Pearce* and *Rinehart* et al.[229,230] The five thiazole rings would be predicted to arise from a molecule of cysteine plus the carboxyl group of another acid or amino acid. This expectation is confirmed by the finding that D,L-[3-^{13}C]cysteine labels C-5 in all the thiazole rings as well as C-3 in the cysteine moiety. C-1 of the cysteine precursor serine, fed as the racemate, labeled the carbon atoms attached to C-4 of the five thiazole rings as well as C-2 of thiazole-4 (see Fig. 38). The same carbons that were enriched by C-3 of cysteine were also labeled by L-[3-^{13}C]serine.[224,228]

The two biosynthetically most unusual structural elements of **78** are the pyridine moiety and the indolecarboxylic acid moiety (Fig. 38). C-6 of the pyridine moiety is provided by the cysteine making up thiazole-4. The remaining four carbon atoms come from two molecules of serine which are connected tail-to-tail (i.e., through their C-3 atoms). This follows from the specific labeling of C-3 and C-4 of the pyridine ring by C-3 of serine and of the C-2 atoms of thiazole-1 and thiazole-5 by C-1 of serine.[224,228] The two serine moieties could be incorporated into the pyridine ring either intact or in the form of glycine and a C-1 unit following breakdown by serine hydroxymethyltransferase. An attempt to distinguish between these two possibilities by feeding experiments with [U-$^{13}C_3$]glycerol followed by coupling analysis gave incomplete results. Figure 38 shows the ^{13}C–^{13}C connectivities that were definitively established; however, a number of expected couplings were not seen, presumably due to the low enrichment of the sample.[224] On the other hand, recent experiments with L-[1,2-$^{13}C_2$]- and L-[2,3-$^{13}C_2$]serine have shown unequivocally that the two serine moieties are incorporated intact.[227] This would be consistent with a mechanism proposed by *Bycroft* et al.[231] which postulates that the pyridine ring arises from two molecules of dehydroalanine.

The incorporation of radioactive tryptophan into **78** suggested origin of the indolecarboxylic acid moiety in some way from that amino acid. It was found that C-3 of serine labeled both C-3′ and C-4′ of the indolecarboxylic acid moiety. Serine can give rise to the methyl group of methionine via the tetrahydrofolate pathway. However, feeding experiments with [*methyl*-^{13}C]methionine enriched nosiheptide **78** in only one carbon, C-4′, and C-1 of serine specifically labeled C-2′, the carboxyl group of the indolecarboxylic acid moiety. This led to the formulation of a specific hypothesis (Fig. 39) for the formation of the indolecarboxylic acid moiety through cyclization of tryptophan by bond formation between the carboxyl carbon and C-2 of the indole ring, followed by excision of the α carbon and the nitrogen of the side chain, methylation at the 4 position of the indole, and hydroxylation of the methyl group.[228] To test this postulate, we prepared a sample of L-tryptophan carrying ^{13}C at 50% enrichment in the 2 position of the indole ring and at 90% enrichment in the carboxyl group. The labeled indole was prepared by chemical synthesis and was then condensed with [1-^{13}C]serine using tryptophan synthase as the catalyst. ^{13}C NMR analysis of the nosiheptide resulting from the feeding of this precursor showed enrichment exclusively in C-2 and C-2′ of the indolecarboxylic acid moiety and coupling of these two signals to each other with the expected intensity ratios of the coupled and noncoupled signals. This result demonstrates unequivocally that the indolecarboxylic acid moiety arises by a rather unusual rearrangement of tryptophan (Fig. 39). In this process the two hydrogens of the side-chain methylene group of tryptophan are retained, as was demonstrated in a feeding experiment with D,L-[3-^{13}C,$^{2}H_2$]tryptophan.[227] Nonincorporation of ^{14}C- and ^{13}C-labeled 4-methyltryptophan into nosiheptide indicates that methylation of tryptophan is not the first step in the reaction sequence leading to the indolecarboxylic acid moiety.[224,227,228]

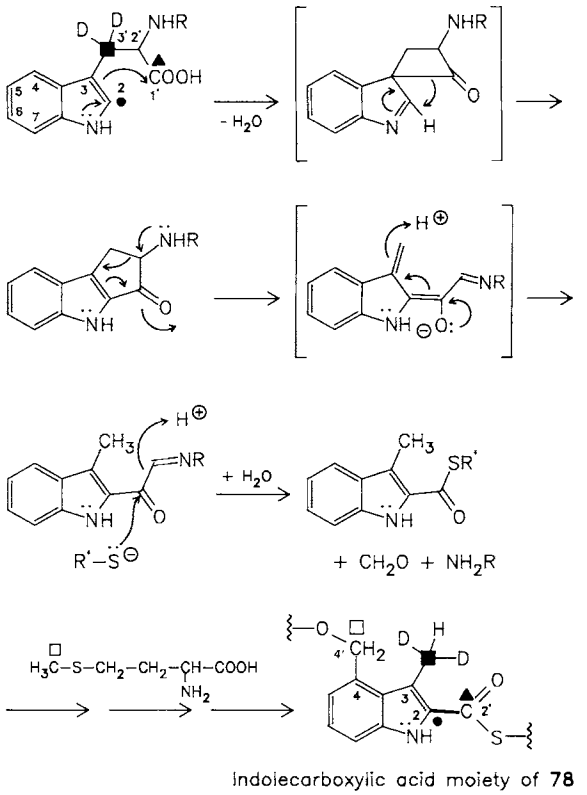

Fig. 39. Formation of the indolecarboxylic acid moiety of nosiheptide **78** from tryptophan, and a possible mechanism of this transformation. ■, ▲, ●, □: ^{13}C label.

The results obtained so far are consistent with formation of nosiheptide **78** by extensive modification of a primary peptide precursor which should have the following sequence:

H_2N-Ser-Cys-Thr-Thr-Cys-Glu-Cys-Cys-Cys-Ser-Cys-Ser-OH

Closure of the macrocycle by formation of the pyridine ring would involve connecting Ser-1 and Ser-10. Whether the tryptophan residue giving rise to the indolecarboxylic acid moiety is also part of the primary peptide, and how it would be linked to this, or whether it is attached at a later

stage remains to be established. Inhibition experiments with chloramphenicol suggest that the assembly of the primary peptide precursor is a nonribosomal process[227] and should thus be mediated by an enzyme as template in analogy to the biosynthesis of other peptide antibiotics.[232]

8.2. Biosynthesis of Thiostrepton

The biosynthesis of thiostrepton **77** in *S. azureus* largely follows similar lines as that of nosiheptide **78** (Fig. 40). In the studies on **77** we were greatly aided by the detailed ^{1}H and ^{13}C NMR analysis of this compound carried out by *Hensens* et al.,[233,234] although, based on the analysis of multiply labeled samples, several signal assignments had to be changed.[227] D,L-[3-^{13}C]Cysteine labeled five sites corresponding to the C-5 of the thiazole and dihydrothiazole rings (Fig. 40). The same carbon atoms were labeled by C-3 of serine. In addition, the latter compound labeled C-3 of the three dehydroalanine moieties, C-3 and C-4 of the piperidine ring, and C-3 as well as the methyl group of the quinaldic acid moiety. The latter methyl group was also the only position labeled by L-[*methyl*-^{13}C]methionine.

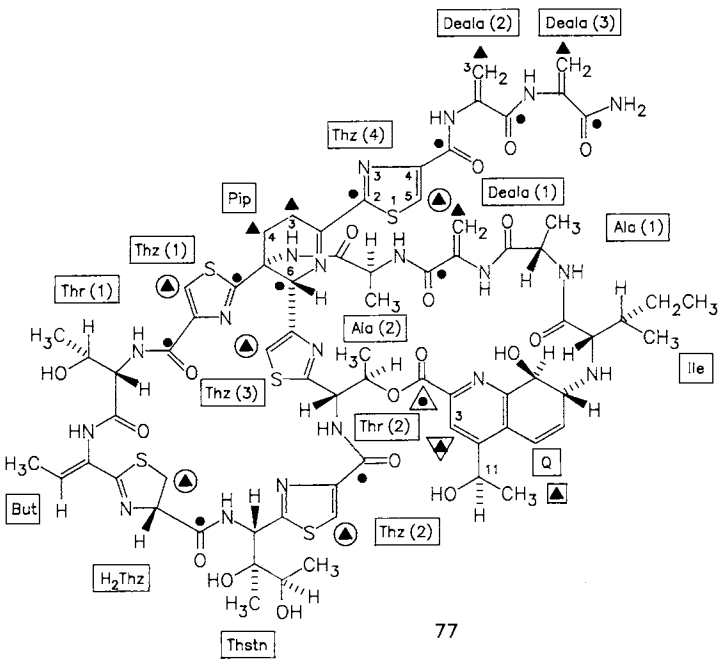

Fig. 40. Labeling pattern in thiostrepton **77** after feeding experiments with various stable-isotope-labeled precursors.

D,L-[1-^{13}C]serine labeled eleven sites, namely all the carbonyl groups attached to the thiazole and dihydrothiazole rings and the carbonyl groups of the dehydroalanine and quinaldic acid moieties as well as C-6 of the piperidine ring and C-2 of thiazole-1.[235] Experiments with L-[1,2-$^{13}C_2$]- and L-[2,3-$^{13}C_2$]serine demonstrated intact incorporation of all the serine molecules, except for the labeling of the quinaldic acid methyl group.[227,236] Finally, L-[*carboxy*-^{13}C]tryptophan labeled exclusively the carbonyl group of the quinaldic acid moiety.[235] It follows that in all likelihood the dehydroalanine moieties, the thiazole rings, and the piperidine ring in thiostrepton have the same origin as in nosiheptide.

The quinaldic acid moiety evidently arises by an expansion of the indole ring of tryptophan. The carbon skeleton of tryptophan can account for all the carbons of the quinaldic acid moiety except the methionine-derived methyl group. The ring expansion resembles that established for the formation of quinine-type alkaloids from tryptophan in higher plants;[237] i.e., C-3 of the tryptophan side chain (see Fig. 39 for numbering) should give rise to C-3 of the quinaldic acid and C-2 of the indole ring should give rise to C-11 of the quinaldic acid. Interestingly, D,L-2-methyl-[3'-^{13}C]tryptophan was efficiently incorporated and specifically labeled C-3 of the quinaldic acid moiety.[236] Hence, in this case methylation of tryptophan seems to take place before its further modification and/or incorporation into the peptide. In accord with this notion, we have demonstrated formation of 2-methyltryptophan in *S. azureus* both by trapping experiments and in a cell-free system.[238]

The steric course of the incorporation of the methionine methyl group into the quinaldic acid moiety in **77** was examined by feeding experiments with samples of methionine carrying a chiral methyl group. The resulting thiostrepton **77** was subjected to Kuhn–Roth oxidation and the tritiated acetic acid was analyzed for its chirality. Surprisingly, (*methyl-R*)-methionine produced a methyl group of *R* configuration and (*methyl-S*)-methionine gave a methyl group of *S* configuration in **77**.[239] It was also shown with [methyl-$^{13}C^{2}H_3$]methionine that all three methyl hydrogens are retained.[238] Thus it appears that the transfer of the methyl group proceeds with net retention of configuration. This is in contrast to the majority of methyltransferases studied so far (see Section 5.2). However, we have recently encountered another example of a methyl transfer with net retention of configuration in the biosynthesis of the antibiotic thienamycin which also contains a methyl group in the form of a hydroxyethyl function.[240] It seems likely that methyl transfer with net retention of configuration involves a two-step process.

8.3. Genetics of Nosiheptide and Thiostrepton Biosynthesis

Our longer term goal in the studies on nosiheptide and thiostrepton biosynthesis is to develop in parallel both the bioorganic chemistry and the genetics of formation of these antibiotics. This may eventually allow the production of new hybrid structures based on the knowledge and methods developed in these studies. The rationale for choosing this group of compounds for such studies is that they represent biologically very potent molecules and are therefore obvious targets for structure modification. However, their complexity severely limits the possibility of structure modification by chemical means. On the other hand, they should be ideal subjects for biological structure modification: they share the same overall architecture but are made up of somewhat different building blocks which one might be able to exchange. Also, they share a common

mode of action, reducing the likelihood that newly created hybrid antibiotics would kill the producing organism.

The genetic studies on *S. actuosus* and *S. azureus* are being carried out in collaboration with the laboratory of *W. R. Strohl* at Ohio State University. The overall strategy is based on the observation that in the cases examined the cluster of antibiotic biosynthesis genes also contains the resistance gene.[241-243] Hence, we are cloning size-fractionated partial digests of the parent DNA into a suitable plasmid, which is used to transform a sensitive organism. Selection for thiostrepton or nosiheptide resistance and for an additional marker on the plasmid then isolates the resistance gene plus additional biosynthetic genes from the cluster surrounding the resistance gene. The DNA inserts in the reisolated plasmids can be used to probe further into the biosynthetic gene cluster of the parent DNA. Biosynthetic genes from *S. azureus* will be used to transform *S. actuosus* and vice versa and the transformants will be analyzed for the appearance of new compounds. Hopefully, as more information develops about the biosynthetic pathway, it can also be used to select more directly for specific biosynthetic genes.

9. Conclusion and Outlook

The foregoing review of our work on the biosynthesis of antibiotics has given a glimpse of the multitude of different approaches and techniques that are used today in unraveling the metabolic pathways leading to secondary metabolite formation. The study of natural products biosynthesis has undergone several dramatic changes over the last few decades. The ready availability of isotopically labeled compounds starting in the late 1940s opened up the possibility of undertaking biosynthetic studies. The advent of Fourier transform NMR spectroscopy dramatically expanded the scope of such investigations by providing a tool with which far more definitive information could be gained with much greater ease than was possible before. Another revolution of the field is clearly in the making with the rapid development of the molecular biology of secondary metabolite formation. The incorporation of genetic approaches into biosynthetic studies promises to add yet another dimension to this field. It has the potential of bringing us closer to an understanding of fundamental questions as to how nature manages to elaborate this bewildering array of organic chemicals, and why. In addition, it may lead to exciting practical advances in the formation and production of commercially important natural products.

We acknowledge with pleasure the contributions of a large number of enthusiastic and dedicated co-workers, whose names are mentioned in the appropriate references. Our studies were made possible by financial support from the National Institutes of Health (Grant AI 20264), and we were greatly aided by the services of the Los Alamos Stable Isotope Resource (supported by NIH grant RR 02231 and by the Department of Energy), by the Purdue University Biological Magnetic Resonance Laboratory (supported by NIH grant RR 01077), and by the Ohio State University Campus Chemical Instrument Center. Finally, we thank Kay B. Kampsen for her skill and patience in typing this manuscript.

Gas Chromatographic Determination of the Enantiomeric Composition of Epoxy Alcohols**

By *Wilfried A. König,* Sabine Lutz, Gerhard Wenz, Günther Görgen, Christoph Neumann, Andreas Gäbler,* and *Wilhelm Boland*

Dedicated to Professor Kurt Heyns on the occasion of his 80th birthday

Chiral 2,3-epoxy alcohols, which are extremely useful building blocks in organic synthesis, are especially attractive since they are readily accessible by enzyme- and transition-metal-catalyzed processes from simple precursors[1,2] and by EPC syntheses (EPC = enantiomerically pure compounds) from natural products.[3] Of particular interest is the preparation of smaller functionalized epoxy alcohols (C_3–C_{10}) since these can be converted regio- and stereospecifically into important natural products.[4]

Ring-opening reactions of 2,3-epoxy alcohols with nucleophiles (also hydrides) have S_N2 character and proceed under mild conditions; they count among the best methods for the synthesis of two adjacent, stereochemically uniform sp^3 carbon centers.

However, the problem of an accurate determination of the enantiomeric excess (*ee*) of 2,3-epoxy alcohols has not yet been resolved satisfactorily, at least in the range of *ee* > 97%. The most commonly used method, the preparation of the diastereomeric esters with α-methoxy-α-trifluoromethylphenylacetic acid (MTPA ester, "Mosher ester")[5] is relatively insensitive[6] and, like all derivatizations with chiral reagents, involves the danger of falsifying the results by kinetic resolution or insufficient enantiomeric purity.

We now report on the gas chromatographic separation of enantiomeric epoxy alcohols using glass capillary columns coated with peralkylated α-cyclodextrins as stationary phase.[7] Perpentylated and perhexylated α-cyclodextrin[8] proved to be exceptionally enantioselective towards trifluoroacetylated hydroxy compounds.[8] The trifluoroacetylation, which is achieved in a few minutes at room temperature,[9] leads, in the case of epoxy alcohols, without racemization to highly volatile derivatives which are eluted with short retention times from the columns (Figs. 1 and 2). The separation results for a selection of epoxy alcohols are given in Table 1. In all cases where optically active

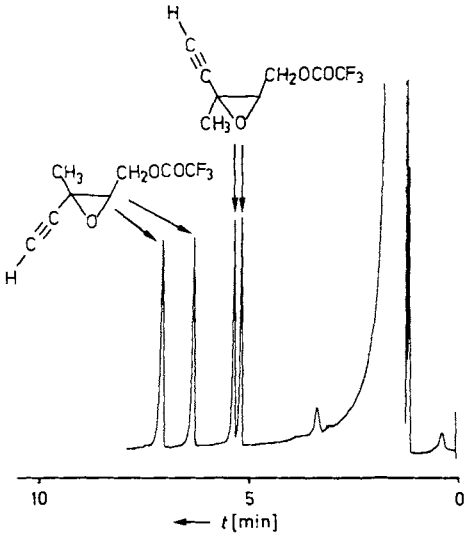

Fig. 1. Separation of the enantiomers of (*E*)- and (*Z*)-2,3-epoxy-3-methyl-4-pentyn-1-ol after trifluoroacetylation on a 38-m glass capillary coated with perhexylated α-cyclodextrin at 60°C and hydrogen (1 bar) as carrier gas.

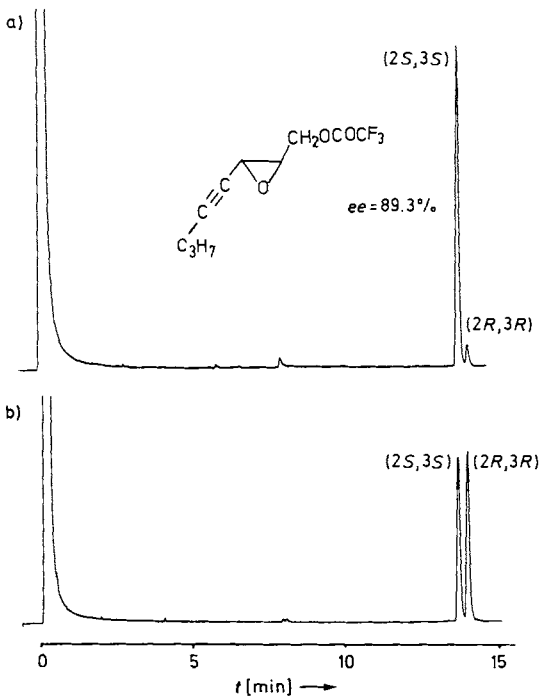

Fig. 2. a) Determination of the enantiomeric excess after trifluoroacetylation of a sample of (*E*)-2,3-epoxy-4-octyn-1-ol prepared by asymmetric epoxidation with L-diethyl tartrate as chiral reagent [2]. 40-m glass capillary coated with perpentylated α-cyclodextrin, at 80°C and hydrogen (1 bar) as carrier gas. b) Chromatogram of the racemate for comparison. *ee* value determined by electronic integration.

Table 1. Separation factors α for some gas chromatographic separations of epoxy alcohol enantiomers on hexakis-2,3,6-tris-*O*-pentyl)-α-cyclodextrin (I; 40-m glass capillary) and hexakis(2,3,6-tris-*O*-hexyl)-α-cyclodextrin (II, 38-m glass capillary).

Epoxy alcohol (trifluoroacetyl derivative)	α	Column	Column temp. [°C]
2,3-Epoxypropan-1-ol	1.110	I	45
2,3-Epoxy-2-methylpropan-1-ol	1.130	II	50
3,4-Epoxybutan-2-ol [a]	1.04/1.02	II	40
(*Z*)-2,3-Epoxypentan-1-ol	1.075	II	60
(*Z*)-3,4-Epoxyhexan-1-ol	1.139	II	60
(*E*)-3,4-Epoxyhexan-1-ol	1.096	II	60
(*E*)-2,3-Epoxy-3-methyl-4-pentyn-1-ol	1.121	II	60
(*Z*)-2,3-Epoxy-3-methyl-4-pentyn-1-ol	1.029	II	60
(*E*)-Epoxycinnamyl alcohol	1.103	II	100
(*Z*)-Epoxycinnamyl alcohol	1.020	II	100
(*E*)-4,5-Epoxyhexan-1-ol	1.030	I	60
(*E*)-2,3-Epoxyheptan-1-ol	1.020	II	60
(*E*)-2,3-Epoxy-4-octyn-1-ol	1.019	I	60

[a] Four stereoisomers.

epoxy alcohols are separated (2,3-epoxypropan-1-ol, (*E*)-2,3-epoxyheptan-1-ol, (*E*)-2,3-epoxy-4-octyn-1-ol (Fig. 2)), the (2*S*)-isomers were eluted before the (2*R*)-isomers. A remarkable finding is that not only the epoxy derivatives of allyl alcohols can be resolved but also compounds in which epoxy function and hydroxy function are separated by up to three carbon atoms.

Thus, a simple and reliable method is now available for checking the enantiomeric composition in asymmetric epoxidations even for enantiomeric excesses >98%.[10]

[9] Approx. 0.1 mg of the sample was dissolved in 0.2 mL of dichloromethane. After addition of 0.05 mL of trifluoroacetic anhydride the solution was allowed to stand at room temperature for 10 min. The anhydride was then removed in a stream of nitrogen and the sample taken up in dichloromethane.
[10] Capillary columns with perpentylated α-cyclodextrin will be commercially available in the near future from Macherey-Nagel (Düren).

Tellurobenzaldehyde by Staudinger-Chalcogenation of the Ylide Benzylidenetriphenylphosphorane**

By *Gerhard Erker** and *Regina Hock*

The heavier analogues of ketones and aldehydes $R^1R^2C{=}X$ (X = Se, Se, Te) are characterized by enhanced π- and n-donor properties as well as increased π-acceptor ability.[1] Because of the resulting changes in chemical reactivity, these chalcogenocarbonyl compounds are of fundamental interest. In order to study systematic variations of characteristic properties, it is important that $R^1R^2C{=}X$ compounds be available for all the chalcogen elements X. Synthetic routes to thioketones and (sometimes extremely reactive) thioaldehydes have long been known.[2–4] Recently, several simple methods were described for preparing highly reactive selenoaldehydes.[3c, 5] To our knowledge, free telluroaldehydes, which are probably even less stable, have not yet been generated and characterized by subsequent chemical reactions.[6] For the generation of a telluroaldehyde, we have now successfully employed a synthetic method that has in the past been very useful for a preparation of selenoaldehydes.[3c]

Non-stabilized phosphorus ylides $Ph_3P{=}CHR$ react with elemental selenium to furnish selenoaldehydes [RCH=Se], which, for example, can be trapped in situ with 2,3-dimethylbutadiene to give 3,6-dihydro-2*H*-selenapyrans (e.g., **3c**). We have now prepared the 3,6-dihydro-2*H*-thiopyran derivative **3b**[7b] analogously, via intermediate thiobenzaldehyde generated from $Ph_3P{=}CHPh$ **1** and sulfur at 50°C. This reaction can be used to synthesize tellurobenzaldehyde as well [Eq. (a)], provided that the

(a)

3a, X = O; **b**, X = S; **c**, X = Se; **d**, X = Te

chalcogen has first been activated. Tellurium powder (99.0%, Merck) was treated with triphenylphosphine in toluene for 12 h at 105°C. Then, 2,3-dimethylbutadiene was added. Finally, a solution of the ylide **1** in toluene was added dropwise at 105°C. The reaction mixture was fil-

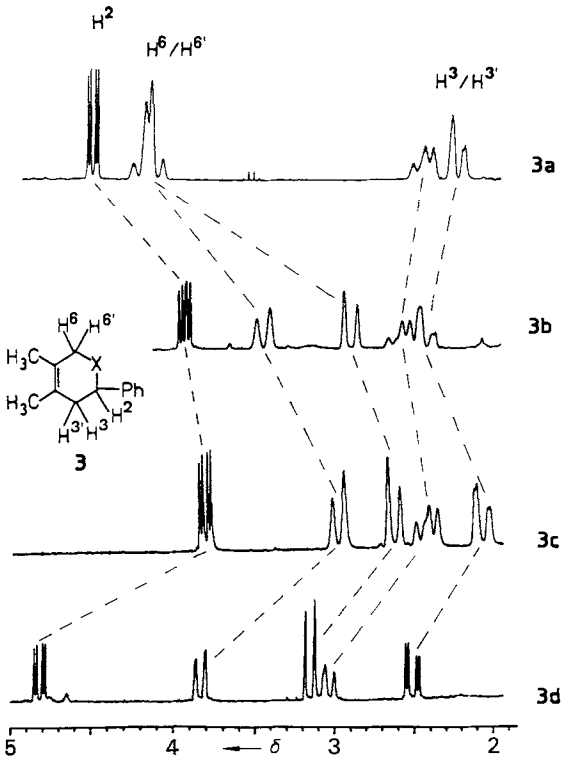

Fig. 1. Comparison of characteristic sections from the 200-MHz ^{1}H NMR spectra of the compounds **3a–d** [7].

Am Hubland, D-8700 Würzburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Alfried Krupp-Stiftung.

tered, the solvent was removed in vacuo, and the residue extracted with hexane. 3,6-Dihydro-4,5-dimethyl-2-phenyl-2*H*-tellurapyran **3d** was separated from triphenylphosphane and stilbene (see below) by chromatography (silica gel/hexane). The "Diels-Alder adduct" **3d** of the in situ generated tellurobenzaldehyde **2** was isolated in 11% yield.

The rather sensitive tellurium compound **3d** was characterized by MS and NMR spectroscopy.[7d] Figure 1 shows, for comparison, characteristic sections of the ^{1}H NMR spectra of the four 3,6-dihydro-2*H*-chalcogenapyrans **3a–d**.

In the absence of an added scavenger, **2** reacts with **1** to give stilbene [Eq. (b)]. Due to the low thermal stability of

$$\underset{\mathbf{1}}{2\,Ph_3P{=}CHPh} \xrightarrow[100\,^\circ C]{Te_{cat}} 2\,Ph_3P + PhHC{=}CHPh \qquad (b)$$

the resulting Ph_3PTe[8] product, the stepwise ylide-alkylidene coupling reaction can also be achieved using a catalytic amount of tellurium. In a typical experiment, 5 g (14 mmol) of **1** and 0.18 g (1.4 mmol) Te in 100 mL toluene were heated for 6 hours at 100 °C. Chromatographic analysis of a sample revealed the formation of *cis*- and *trans*-stilbene in a 1:9 molar ratio. Fractional crystallization from acetone/methanol (1/7) yielded *trans*-stilbene (61%) and triphenylphosphane (70%).[9]

The Solid-State Structure of $Me_2B-O-BMe_2$**

By *Horst Borrmann, Arndt Simon,* and *Heinrich Vahrenkamp**

Diboroxanes R_2BOBR_2 **1** are isoelectronic with allenes R_2CCR_2. The question of whether this isoelectronic relationship also results in isosterism, i.e., whether diboroxanes can have a linearly coordinated oxygen atom, has not yet been answered. Electron diffraction and X-ray structural analyses of three monomeric diboroxanes gave bond angles at oxygen of 144–166°,[1] with the larger bond angles presumably being due to steric rather than electronic effects, as is also found for the disiloxanes. In contrast, the results of complete IR spectroscopic analyses for diboroxanes with R = vinyl (in all three states) and R = Me (**1a**, in the solid-state) are in agreement with a linear B-O-B arrangement.[2]

$Me_2B-O-BMe_2$ **1a**

Compound **1a**, which crystallizes at −16 °C, thus offered the chance, via a structure determination, to finally clarify the situation. The X-ray structural analysis[3] was carried out at −160 °C on crystals which had been grown in glass capillaries on the diffractometer using the Bridgman method.[4] The surprising result is shown in Figure 1.

1a is, as predicted, centrosymmetric, however not so because of the presence of a linear B-O-B skeleton but because it is dimeric in the solid state. **1a** therefore appears to be the first boron-oxygen compound for which aggregation through formation of a BOBO four-membered ring has been observed.[5] The two B-O bond lengths are very different. The bond length within the ring (158 pm) is longer than all those which have been found for BX_4 compounds (143–156 pm),[6,7] while the exocyclic bond length (138 pm) is almost identical with those of BX_3 compounds (137 pm)[7] or monomeric diboroxanes (136 pm).[11] Figure 1

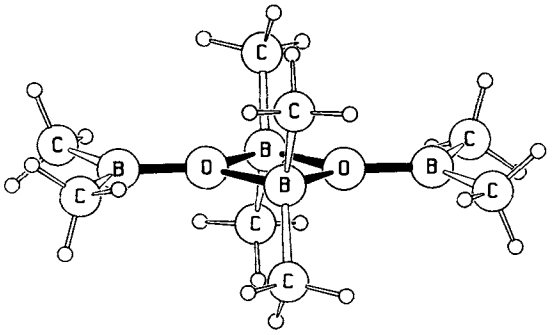
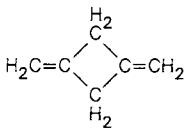
[**] We wish to thank Mr. *P. Behrens* for valuable assistance.





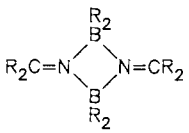


Fig. 1. Molecular structure of dimeric **1a** (small circles = H atoms). Bond lengths [pm]: B-O 158.0(1) (endocyclic), 137.7(1) (exocyclic), B-C 156.3-159.5(1); bond angles [°]: in the ring: O-B-O 86.1(1), B-O-B 93.9(1); external: B-O-B 133.2(1), O-B-C 119.8(1).

shows not only the centrosymmetry but also the two mutually perpendicular major planes of the molecule, whose aesthetically appealing form more than compensates for the nonappearance of a linear monomer.

Despite being dimeric, solid **1a** still represents an interesting example of isosterism since allene also forms a dimer **2**, the molecular geometry of which, as determined by STO-3G calculations,[8] corresponds in all details with that of dimeric **1a** (C-C distances 131 and 154 pm, angles in ring 87 and 93°). The same is true for dimeric alkylideneiminoboranes **3**, of which $[Me_2BNCHPh_2]_2$[9] has structural parameters which are almost identical with those of **1a** (B-N 159 pm, N-C 127 pm, angles in ring 87 and 93°).

2

3

The fact that **1a** is monomeric in the liquid and gas phases indicates that the enthalpy of formation for the dimer is low. The low temperature ^1H NMR spectrum of **1a** in solution shows a splitting of the signals, which was originally attributed to the bent form of the molecule.[10] This result must now be reinterpreted as being due to dimer formation at low temperature in solution. As shown in Figure 1, the monomer conformation,[1a] as determined by electron diffraction, remains almost unchanged upon formation of the dimer;[11] only one B-O bond is lengthened to a considerable extent.

The greater tendency of the diboroxane to dimerize, as compared to other R_2B-O compounds could perhaps be explained by a synergic effect. The formation of the B-O-B linkage means, firstly, that the electronic saturation of the two boron atoms through p_π-p_π interaction with the one oxygen atom is insufficient, and secondly that more negative charge is localized on the oxygen atom due to the inductive effect of the two boron atoms. The diboroxane is therefore both a stronger Lewis base and a stronger Lewis acid than a simple alkoxyborane. If the substituents are small enough, as in the title compound, an energetically favorable intermolecular saturation of the Lewis basicity and acidity is possible.

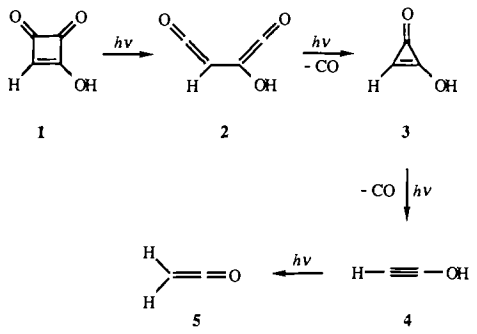
Ethynol: Photochemical Generation in an Argon Matrix, IR Spectrum, and Photoisomerization to Ketene**

By *Remo Hochstrasser* and *Jakob Wirz**



Ethynol (hydroxyacetylene) has been considered as a possible constituent of flames, planetary atmospheres, and interstellar clouds.[1a] Several quantum mechanical calculations have led to the prediction that the isolated molecule is kinetically stable with respect to the highly exothermic tautomerization to ketene.[1] Recently, *Schwarz* and coworkers provided the first experimental proof for the existence of ethynol[2] and related molecules[3] by tandem mass spectrometry. Further evidence for ynols is limited to rather tentative assignments of some IR bands observed after cryogenic trapping of products formed by flash vacuum pyrolysis.[4] Several unsuccessful attempts to generate matrix-isolated ethynol have been reported recently.[5] Acetylene diolate salts are well-known as products of oxocarbon chemistry[6a] and have been characterized recently by matrix IR spectroscopy.[6b] Ynolate ions are gaining interest as reactive species for synthesis.[7]

In the course of our investigations of keto-enol tautomerism,[8] we were searching for photochemical methods to generate ethynol under conditions suitable for its spectroscopic identification as well as for the study of its reaction kinetics in solution. We found that irradiation of 3-hydroxycyclobutene-1,2-dione (semisquaric acid) **1** in an argon

matrix cleanly yields ethynol **4** in three photochemical steps.

Semisquaric acid **1** was synthesized by the procedure of *Serratosa* et al.[9] Deuterated samples were obtained by exchange in D_2O. Selective isotopic enrichment was achieved by exploiting the different exchange rates; exchange at carbon required several days. A sample of **1** was sublimed from a small quartz container at ca. 100 °C, while a steady stream of argon was condensed on a CsI sample window at a temperature of 23 K. The resulting matrix was cooled to 12 K and irradiated with pulses from a KrF excimer laser (248 nm, 20 ns, ca. 10 mJ cm^{-2}).[10] The irradiation was interrupted repeatedly in order to monitor the progress of the reaction by IR spectroscopy. Usually, 15 to 25 spectra were recorded in the range from 3630 to 630 cm^{-1} for each sample. With an instrumental resolution of 0.2 cm^{-1}, the peaks were generally well separated and sufficiently sharp for a base-line correction by graphical interpolation to be carried out with negligible ambiguity to obtain the absolute absorbances of the bands.

In the initial stages of the irradiation, complex product mixtures formed, which were analyzed as follows. Peaks belonging to the same compound were identified on the basis that their absorbance ratio remained constant throughout the sequence of spectra. This could best be determined graphically by a pairwise comparison of peak intensities. Curved lines resulted, if the selected bands were due to different compounds. Smaller, but still quite pronounced deviations from linearity were observed when a pair of bands belonged to the same compound, but to different sites in the matrix; it is well-known that IR-bands of matrix-isolated molecules often exhibit site splitting. Finally, if the chosen pair of peaks corresponded to the same compound in the same site, the points accurately followed a straight line through the origin. Other criteria, such as the band splitting patterns and changes of site population observed upon slight warming of the matrix, were used to distinguish between independent components and different matrix sites for a single component. In this way, five independent reaction components were identified. Figure 1 shows the change in intensity of one characteristic peak of each of the five components with increasing irradiation time. The curves represent concentration profiles with arbitrary units, since the extinction coefficients are unknown. The different induction periods and the corresponding displacements of the concentration maxima of the intermediate products indicates that the components are formed sequentially.

The first photolysis product of **1**, 2-hydroxy-1,3-butadiene-1,4-dione (hydroxybiketenyl) **2**, exhibits two very strong, relatively broad carbonyl bands at 2112 and 2135 cm^{-1}. The strongest bands of the next product, 2-hydroxy-

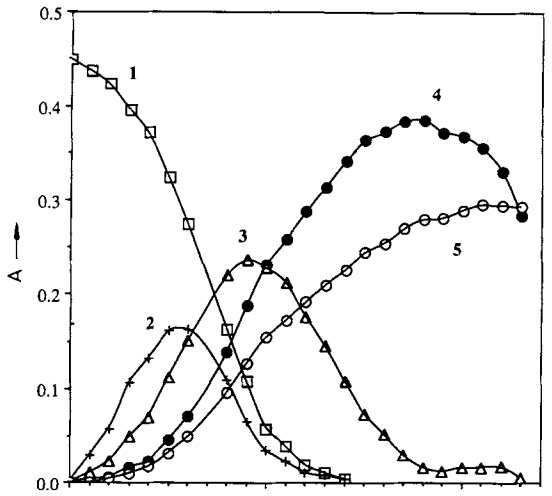

Fig. 1. Concentration profiles of the components **1** to **5**, plotted as the absorbance (A) of one characteristic band each: **1**, 1351.8; **2**, 2112.2; **3**, 1857.2; **4**, 3501.3; **5**, 2147.1 cm^{-1}. The abscissa orders the spectra chronologically, but approximately represents a logarithmic scale of the irradiation dose, as the irradiation times were increased considerably towards the end of the reaction. The full abscissa range corresponds to a dose of ca. 10^4 laser pulses (100 J cm^{-1}).

cyclopropenone **3**, are the C=O stretch at 1857 cm^{-1} and the C=C stretch at 1650 cm^{-1}. Ethynol **4** and its deuterium-substituted isotopomers each exhibit five bands above 630 cm^{-1} (Table 1). Work to determine the bending vibrations ν_6 to ν_9 in the spectral range below 630 cm^{-1} is in progress; the values 599, 523, 383, and 346 cm^{-1} may be quoted as preliminary results for HCCOH. The IR spectra of matrix-isolated ketene **5** and its mono- and dideutero derivatives are well-known.[11]

The photochemical valence isomerization and decarbonylation of cyclobutenediones[12] to cyclopropenones[13] and of the latter to yield acetylenes[14] are well-known reactions. We have obtained an authentic precedent for a reaction sequence of the type **1**→**2**→**3**→**4** under our conditions of matrix isolation by photolyzing 3,4-dimethylcyclobutenedione.[15] Analysis of the sequential spectra gave results analogous to those obtained with **1**. In this case two of the three expected intermediates, dimethylcyclopropenone[15] and 2-butyne, are known compounds which we identified unambiguously by independent synthesis and matrix isolation.

The observed IR bands leave no doubt that compound **4** retains both the OH/D and the CH/D groups of **1**; moreover, the band at 2198 cm^{-1} is characteristic for an unsymmetrically substituted alkyne. The stretching bands of **4**, apart from the OH-stretch, lie at much the same frequencies as those of fluoroacetylene.[17] A heuristic approach would be to consider the OH-stretching vibration as localized and to treat **4** as a quasilinear isotopomer of fluoroacetylene (OH ≙ ^{17}F, OD ≙ ^{18}F). This very simple model works amazingly well. The wave numbers of the H/D–C, C≡C, and C–O stretching bands (Table 1) obey both the Redlich-Teller product rule[18a] and the Decius-Wilson sum rule[18b] quite well and are reproduced within ±5 cm^{-1} by the following force field (f/N m^{-1}): 580 (H/D–C), 1400 (C≡C), 920 (C–O), and −40 for the cross terms H/D–C≡C and C≡C–O. The agreement with the frequencies and intensities predicted for ethynol by recent ab initio calculations[1a,5] is as good as can be expected.[19]

The spectrum of the matrix after the disappearance of components **1** to **3** is shown in Figure 2. Apart from bands

Table 1. Wavenumbers ($\tilde{\nu}$/cm^{-1}) and relative intensities (%) of the fundamental bands of **4** and its mono- and dideuterated derivatives in the range 3630 to 630 cm^{-1}.

due to CO, CO_2, and H_2O, all significant absorptions can be assigned to either the intermediate ethynol **4** or the final product ketene **5**. The final reaction is very slow; presumably ethynol exhibits very little absorption at the irradiation wavelength of 248 nm.[10] Nevertheless, we maintain that the conversion to ketene is a photo-induced reaction of isolated ethynol. The rate of the isomerization **4**→**5** was independent of the water content of the matrix, which varied greatly from sample to sample. Furthermore, in deuterated samples the isotopic purity was retained through to the end product **5**. This excludes the possibility that the isomerization **4**→**5** is caused by a reaction with adventitious water in the matrix.

This work has provided conclusive evidence for the identification of ethynol and suggests that hydroxycyclopropenones could be suitable precursors for the photochemical generation of hydroxyacetylenes in solution. The two weak IR bands at 2230 and 1155 cm^{-1}, which were tentatively assigned to ethynol by *Lasne* and *Ripoll*,[4a] do not agree with our data, but we cannot exclude the possibility that the discrepancy is due to the different media.

Well-Resolved ESR Spectra of Arenecarboxyl Radicals in Solution**

By *Hans-Gert Korth,* Wolfgang Müller, Janusz Lusztyk,* and *Keith U. Ingold*

Dibenzoyl peroxide and related bis(arenecarbonyl) peroxides **1** are the most widely used initiators of free-radical processes. Their thermal and photochemical decomposition yields primarily arenecarboxyl radicals (arenecarbonyloxyl radicals) **2**.[1] The molecular and electronic struc-

1 **2**

a, Aryl = C_6H_5

tures of these radicals are currently under active investigation[2] as are the kinetics of their reactions.[3] Elucidation of the structures of the radicals **2** would be greatly aided if high resolution ESR spectra could be obtained. Benzoyloxyl **2a** has been observed by ESR in the solid state at very low temperatures[4,5] and this radical along with two *para*-substituted derivatives have been detected in solution at room temperature using time-resolved ESR spectroscopy.[6] In all these cases, the spectra were too poorly resolved to reveal any hyperfine splittings (HFS) by ring substituents. Earlier attempts to detect benzoyloxyl radicals by conventional ESR spectroscopy using continuous UV photolysis of dibenzoyl peroxide in suitable solvents have met

[**] Issued as NRCC No. 29827.

with no success,[7] presumably because of the high reactivity of the radicals[3] and/or other experimental problems.

We have recently reported[8] that carbonyloxyl radicals of the type $ROCO_2^{\circ}$, $RCH{=}CHCO_2^{\circ}$, and $RC{\equiv}CCO_2^{\circ}$, which we had earlier found to be relatively resistant to decarboxylation using UV/VIS absorption spectroscopy,[8,9] gave well-resolved ESR spectra in solution at low temperatures. The observations encouraged us to reevaluate the continuous UV photolysis of bis(arenecarbonyl) peroxides in solution as a source of $ArylCO_2^{\circ}$ radicals **2** that would be detectable by ESR spectroscopy. Once the critical conditions were worked out,[10] good first-derivative ESR spectra of $ArylCO_2^{\circ}$ were obtained for a wide variety of peroxides **1**[11] (see Table 1 and Fig. 1).

Table 1. ESR parameters for the radicals **2** in cyclopropane solution [a].

2

2	R	T [°C]	g	Hyperfine splitting [mT] a(o-H)	a(others) [b]

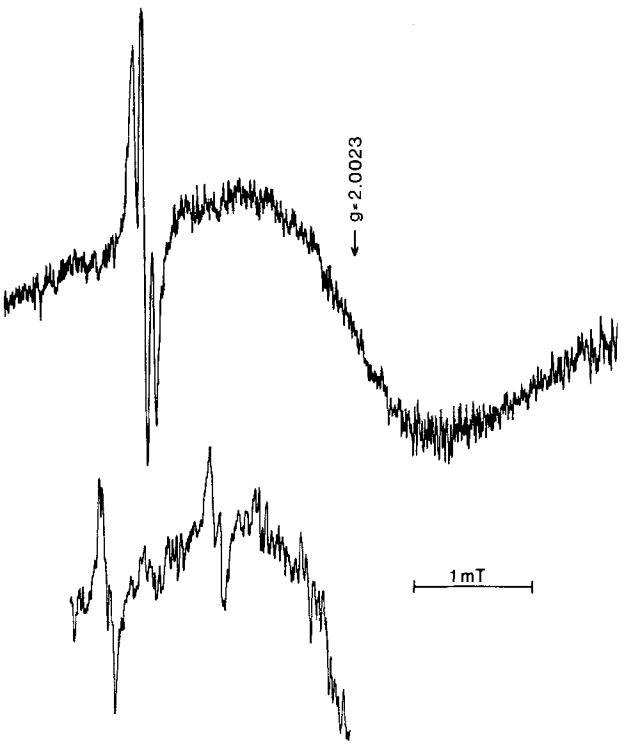
f	3-Cl	−120	2.01236(4)	0.065(2) (2H)	
g	2-F	−124	2.01164(4)	0.081(3) (1H)	0.840(5) (1F)
h	2-Cl	−120	2.01093	0.123(3) (1H)	0.390(5) (1Cl)

[a] Numbers in parentheses indicate the probable error in the last digit. [b] Experimental line widths were 0.02–0.03 mT. The upper limit for any additional, unresolved HFS was ≤0.02 mT. [c] g = 2.0117 [4], 2.0123 [6]. [d] From carbonyl-[^{13}C]-labeled peroxide, **1a**.



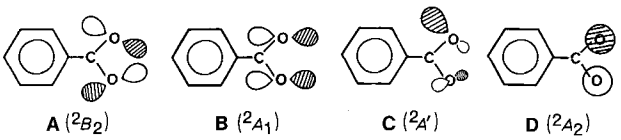


Fig. 1. ESR spectra of the benzoyloxyl radical **2a** at −120°C (top) and the 2-fluorobenzoyloxyl radical **2f** at −124°C (bottom) in cyclopropane. Microwave power: 15 mW.

The g-factors of our radicals **2** vary between 2.0109 and 2.0124 and thus lie in the range characteristic for carbonyloxyl radicals[4–6,8] and, in the only case where a direct comparison is possible, there is satisfactory agreement with the literature data.[6] The ESR signal of the benzoyloxyl radical **2a** (Fig. 1, top) shows HFS by just two equivalent hydrogen atoms in a 1:2:1 pattern. The same triplet pattern with virtually identical HFS is observed also with the *para*-substituted radicals, **2b**, **2c**, and **2d** and with the *meta*-substituted radical **2e**, which clearly indicates that the interaction of the unpaired electron with the two *ortho* protons is responsible for the triplet splitting. This is further confirmed by the spectra of the two *ortho*-substituted radicals **2f** (Fig. 1, bottom) and **2g**, which exhibit a doublet splitting by the *ortho* hydrogen and doublet and quartet splittings by the fluorine and chlorine substituents, respectively.

The lower energy states of the benzoyloxyl radical are the coplanar structures **A**–**D**, in which the unpaired electron resides almost exclusively in oxygen p-type orbitals; both theoretical[2] and experimental[4,5] evidence favor the

$^2B_2$ electronic configuration **A** as the ground state. Our observation of a coupling between the unpaired electron and the two *ortho* hydrogen atoms, or an *ortho* hydrogen and *ortho* halogen atom, support an in-plane orientation of the SOMO with the interaction occurring by a through-space mechanism. That is, our results are consistent with the σ-electronic structures **A**–**C** but inconsistent with the π-structure **D**.[12]

The ^{13}C HFS of 1.33 mT found for the carboxyl-[^{13}C]-labeled benzoyloxyl radical **2a** confirms the minor contribution of this carbon atom (ca. 1% 2s spin density) to the SOMO. Virtually the same ^{13}C HFS has been found for this radical in single crystals[13] and for the $Me_3CC{\equiv}C^{13}CO_2^{\circ}$ radical in solution.[8]

INDO calculations using AM1-UHF-optimized geometries are in accord with the experimental findings (see Fig. 2). The ground state appears to have a planar configuration with unequal C–O bond lengths. There is little spin density on either the carboxyl carbon or in the aromatic ring, with the highest spin density being found at the *ortho* positions. The INDO calculations overestimate the ^{13}C

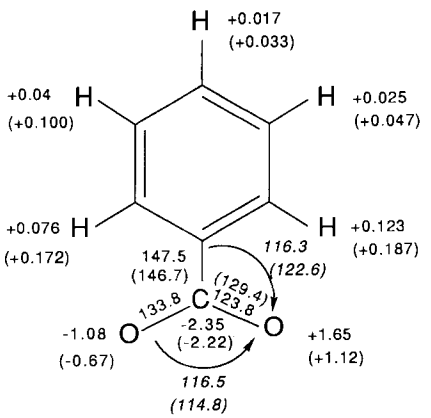

Fig. 2. Optimized AM1-UHF geometry (bond lengths in [pm], bond angles in [°]) and INDO hyperfine splittings ([mT]) of the benzoyloxyl radical **2a**. Data for C_{2v} geometry are given in parentheses.

HFS of the carboxyl carbon but they underestimate the ^{17}O HFS (the calculated isotropic ^{17}O HFS is 3.35 ± 0.5 mT, based on measurements for single crystals[5]). If the $CO_2^{\ominus}$ moiety is forced to adopt a C_{2v} geometry with equal C-O bond lengths, the INDO calculated ^1H HFS values increase while the ^{17}O HFS values decrease, thus moving these HFS values further from their experimental values. This behavior[14] may indicate an unsymmetrical equilibrium structure like **C** for this and other carbonyloxyl radicals.[15] However, because there is very little s-spin density on all the atoms of these radicals, the semiempirical calculations may not be adequate for a reliable assignment of a symmetrical or an unsymmetrical ground state structure.[16]

[9] J. Chateauneuf, J. Lusztyk, B. Maillard, K. U. Ingold, *J. Am. Chem. Soc. 110* (1988) 6727.
[10] Very dilute solutions of **1** (typically 1-3 mg, to avoid crystallization) in cyclopropane (ca. 0.5 mL) were sealed in 4 mm o.d. quartz tubes and photolyzed directly in the cavity of a Varian E-104 EPR spectrometer with the focused UV light from a 1 kW Hg/Xe lamp at ca. -120°C, using microwave power levels of 10-20 mW. We failed to detect any ESR spectra of radicals **2** on photolysis of **1**, Aryl = 4-$MeOC_6H_4$, 4-PhC_6H_4 and C_6F_5.
[11] We thank Dr. *J. Chateauneuf* for providing us with some of the bis(arenecarbonyl) peroxides **1**.
[12] A σ-electronic structure is further supported by the fact that the *g*-values for the 2-halobenzoyloxyl radicals **2f** and **2g** are lower than those of the other radicals **2**. The *g*-values of benzyl radicals, which have a π-electronic structure, are increased by *ortho* halogenation; see A. Berndt in H. Fischer (Ed.): *Landolt-Börnstein, New Series*, Springer, Berlin 1977, Vol. II/9b, p. 543; 1988, Vol. II/17c, p. 173.
[13] R. A. Merrill, *Ph. D. Thesis*, Yale University 1986. We thank Professor *J. M. McBride* for bringing this work to our attention.
[14] INDO calculations on other carbonyloxyls yield the same result.
[15] The experimental evidence which favors the symmetrical (C_{2v}) $^2B_2$ configuration **A** was obtained from the anisotropic ^{17}O HFS of $C_6H_5CO_2^{\ominus}/CD_3^{\ominus}$ radical pairs in a single crystal of $C_6H_5CO_3CD_3$ at 7-25 K [5, 13].
[16] High-level ab initio calculations on various carbonyloxyl radicals are in progress.

Octabromocyclohexaarsenate, $[As_6Br_8]^{2\ominus}$**

By *Ulrich Müller** and *Heike Sinning*

Organocyclopolyarsanes $(RAs)_n$ with various ring sizes have been known for some time (see, e.g., Refs. [1-4]). We have now prepared the first halogeno-cyclopolyarsane $[As_6Br_8]^{2\ominus}$.

With the intention of binding the $Cr(CO)_5$ fragment to the ion $[As_2SBr_5]^{\ominus}$,[5] we added solid $PPh_4[As_2SBr_5]$ to a solution of $[Cr(CO)_5(THF)]$ in THF (molar ratio 2.6 : 1). As the reaction mixture was stirred, $PPh_4[As_2SBr_5]$ slowly dissolved with gas evolution and a yellow powder precipitated, which contained, apart from sulfur, some chromium, very little carbon, and no bromine. The powder was removed by filtration and the filtrate cooled to -5°C to afford yellow crystals of $(PPh_4)_2[As_6Br_8]$. The first of the three crystal fractions also contained some $Cr(CO)_6$; yield 80%. We are currently investigating whether other halogen substituted polyarsanes can be synthesized by this method.[15] The carbonylchromium compound apparently acts as a reducing agent in the reaction. Further knowledge about the course of the reaction and about the other products will require more detailed studies. Although cyclopolyarsane complexes such as $[(PhAs)_6Mo(CO)_4]$[6] and $[(PhAs)_nMo_2(CO)_6]$ (n = 8, 9, 10)[7] are known, we have, up to now, not detected a corresponding complex with the $Cr(CO)_5$ fragment.

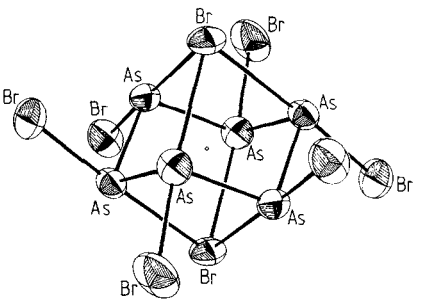

Fig. 1. Molecular structure of the anion of $(PPh_4)_2[As_6Br_8]$ (with 50% probability thermal motion ellipsoids at 20°C). Bond lengths [pm] and angles [°]: As-As 243.0 to 246.5(3), As-Br(terminal) 243.2 to 248.4(4), As-(μ_3-Br) 293.6 to 299.4(3); As-As-As 97.7 to 100.5(1), As-As-Br 87.2 to 89.9(1), Br-As-(μ_3-Br) 174.4 to 176.7(1).

The X-ray structural analysis[8] showed that $(PPh_4)_2[As_6Br_8]$ contains the $[As_6Br_8]^{2\ominus}$ ion, the structure of which is shown in Figure 1. The ion can be regarded as being an As_6Br_6 molecule with two additional $Br^{\ominus}$ ions. The As_6 ring has a chair conformation with the bromine atoms in equatorial positions. As_6Br_6 thus has the same structure as As_6Ph_6.[4] The average As-As bond length of 245.2 pm lies in the range found for polyarsanes[3,4,6,7,9] and polyarsenides.[10,11] The two other $Br^{\ominus}$ ions lie above and below the As_6 ring, each being bonded to three As atoms. The coordination geometry of each As atom can be described as a trigonal bipyramid in which one equatorial position is occupied by a lone pair of electrons and the axial positions by bromine atoms.

The separations between the $[As_6Br_8]^{2\ominus}$ ions are large because of the bulky cations; there are no intermolecular As···Br contacts. The IR and Raman spectra are consistent with the mutual exclusion rule for the point group D_{3d}. Seven IR and seven Raman bands were observed in the region between 100 and 300 cm^{-1}[12] (expected numbers: ten IR and eleven Raman bands[13]). Because of the near correspondence of the As-As and As-Br stretching frequencies at 270 cm^{-1},[14] considerable vibrational coupling is to be expected so that an exact assignment of the individual bands can only be achieved with difficulty.

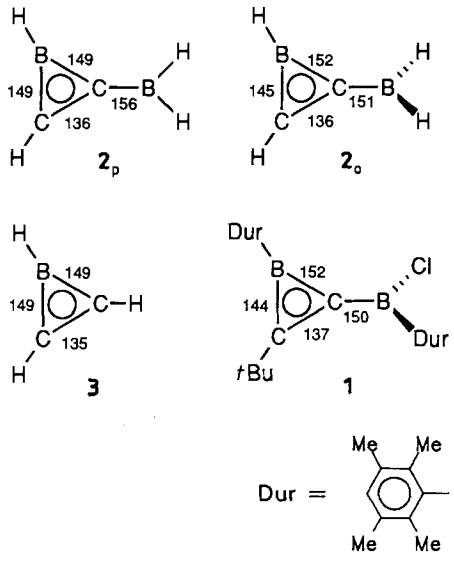
The Structure of a *C*-Borylborirene with Strong C–B Hyperconjugation**



By *Andrea Höfner, Bernd Ziegler, Werner Massa,* and *Armin Berndt**

C–Y hyperconjugation in **A** leads, as illustrated by the resonance formulas **B** and **C**,[1] to shortening of the CX bond, lengthening of the CY bond and a decrease in the YCX angle.

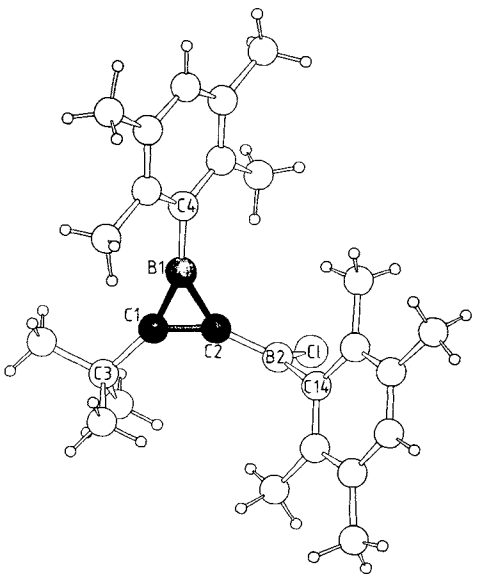
The geometrical consequences of C–C hyperconjugation for carbocations were recently verified on the basis of the crystal structure of the 3,5,7-trimethyl-1-adamantyl cation.[3,4] The results of a crystal structure analysis of the *C*-borylborirene **1** presented here confirm the geometrical consequences of C–B hyperconjugation in a neutral molecule, which were predicted by ab-initio calculations.[5]

According to ab-initio calculations by *von Schleyer* et al.[5] (3-21G//3-21G), the bond lengths in the planar *C*-borylborirene $\mathbf{2}_p$ are very similar to those of the unsubstituted borirene **3**,[6,7] whereas those in the orthogonal *C*-borylborirene $\mathbf{2}_o$ differ greatly from those of $\mathbf{2}_p$ and **3** (compare the bond lengths [pm] in the structural formulas). The BCB angle in $\mathbf{2}_o$ is 11.5° smaller than in $\mathbf{2}_p$.[8] The

reason for this structural distortion[9] is C–B hyperconjugation, which according to the calculations[5] also leads to a stabilization of ca. 10 kcal mol^{-1} for $\mathbf{2}_o$ with respect to $\mathbf{2}_p$.

With the X-ray structural analysis of the *C*-borylborirene **1**, we have found an almost orthogonal conformation and structural parameters which are in good agreement with those calculated for $\mathbf{2}_o$.

1[10] was synthesized from *tert*-butyl(trimethylstannyl)acetylene and 1,2-dichloro-1,2-diduryldiborane(4).[12] A similar procedure has been used to prepare the (liquid) *tert*-butyl substituted analogue of **1**.[11] The result of an X-ray structural analysis[14] of **1** is shown in Figure 1.



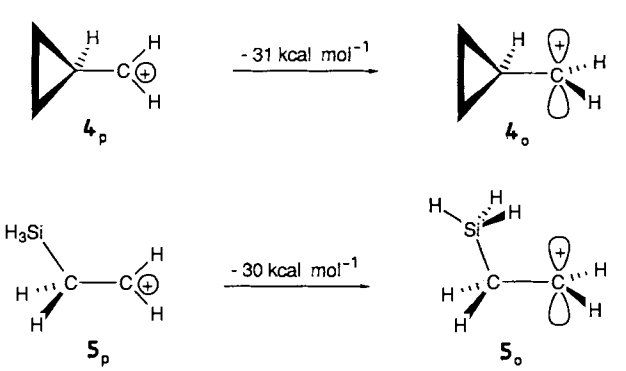


Fig. 1. Molecular structure (SCHAKAL program) of **1** projected approximately on the plane B1,C1,C2. Important bond lengths [Å] and angles [°]: C1-B1 144.3(4), C1-C2 136.7(4), C2-B1 151.6(4), C2-B2 149.8(5), C1-C3 150.6(4), B1-C4 154.8(4), B2-Cl 178.4(4), B2-C14 156.3(4); C1-B1-C2 54.9(2), B1-C1-C2 65.3(2), B1-C2-C1 59.8(2), C1-B1-C4 157.1(3), C2-B1-C4 147.9(3), B1-C1-C3 159.0(3), C2-C1-C3 135.7(3), B1-C2-B2 146.3(3), C1-C2-B2 153.8(3), C2-B2-C14 124.6(3), C2-B2-Cl 116.7(2), C14-B2-Cl 118.3(2); C1-C2-B2-C14 −95.5(6), C1-C2-B2-Cl 91.1(6).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The B1,C1,C2 plane forms an angle of 85° with the C1,B2,C14 plane. The duryl rings are twisted by 49 and 88° with respect to the B1,C1,C2 and C2,B2,C1 planes. The C1C2 bond of 137 pm in the three-membered ring is considerably longer than the CC double bonds in cyclopropenes (130 pm[15]) but the same as that in the tri-*tert*-butylcyclopropenium ion.[16] The BC bond lengths in the three-membered ring of 144 and 152 (av. 148) pm are markedly shorter than the value of 155 pm calculated for the BC single bond in borirane.[6] The bond lengths in the borirene indicate delocalization of the two π-electrons.

The B1,C2,B2 angle in **1** (146.3°) is very similar to that calculated for $\mathbf{2}_o$ (145.7°),[5] unlike that for $\mathbf{2}_p$ (157.2°).[5] The different BC bond lengths in the ring of **1** and the exocyclic BC bond length of 150 pm, which is very short for a BC single bond, are in good agreement with the data calculated for $\mathbf{2}_o$, and therefore represent evidence for pronounced hyperconjugative interaction in orthogonal *C*-borylborirenes. Hyperconjugation is normally found only in charged systems.[17] The strong hyperconjugation in neutral *C*-borylborirenes is due to a combination of structural units which are most effective in this interaction, i.e., a strained three-membered ring (cf. **4**[18]) and atoms of low electronegativity (cf. **5**;[19] in **1** and **2** it is the boron atom with negative π-charge).

Bromoselenates(II,IV), a Novel Type of Mixed Valence Compounds**

By *Bernt Krebs,** *Erhard Lühers,* and *Frank-Peter Ahlers*

Compounds of the chalcogens in the oxidation state +2 with chlorine, bromine and iodine are markedly less stable than the corresponding Se^{IV}- and Te^{IV}-compounds. Thus, the dominating species among the haloselenium and -tellurium anions were hitherto the long known hexahaloselenates(IV) and -tellurates(IV) $[XY_6]^{2\ominus}$ and the polynuclear species $[X_3Y_{13}]^{\ominus}$, $[X_2Y_{10}]^{2\ominus}$ and $[X_2Y_9]^{\ominus}$ (X = Se; Y = Cl, Br and X = Te; Y = Cl, Br, I), which are formed as degradation products of the tetrameric molecular halides X_4Y_{16}.[1,4e] Only recently was it also possible to prepare pure haloselenate(II) and -tellurate(II) anions and to isolate them in the form of the crystalline salts. The anions $[SeBr_4]^{2\ominus}$, $[Se_2Br_6]^{2\ominus}$, $[TeCl_4]^{2\ominus}$, $[TeBr_4]^{2\ominus}$ and $[TeI_4]^{2\ominus}$ could be characterized by structural analyses.[2-5] The same holds for further novel anions such as $[Se_3Br_8]^{2\ominus}$,[4b,c,6] $[Se_4Br_{14}]^{2\ominus}$,[6,7] $[Se_5Br_{12}]^{2\ominus}$,[4b,c,6] and $[Te_4I_{14}]^{2\ominus}$.[4b,c,6]

Exploiting the dissociation equilibria (a) and (b) already shown to be effective in the synthesis of pure haloselen-

$$\tfrac{1}{4}\,Se_4Br_{16} \rightleftharpoons SeBr_4 \rightleftharpoons SeBr_2 + Br_2 \qquad (a)$$

$$2\,SeBr_2 \rightleftharpoons Se_2Br_2 + Br_2 \qquad (b)$$

Wilhelm-Klemm-Strasse 8, D-4400 Münster (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Minister für Forschung des Landes Nordrhein-Westfalen, and the Fonds der Chemischen Industrie.

ates(II) in organic solvents we have now found access to a remarkable new class of mixed valence compounds in which selenium is present in the oxidation states +2 and +4. The anions **1**–**3** have been prepared and isolated in the form of the deep-red to reddish-black crystalline salts **1a**–**3a**, and have been characterized by X-ray structure analyses and vibrational spectra.

$[Se^{II}Se^{IV}Br_8]^{2\ominus}$ **1** $[Se^{II}_2Se^{IV}Br_{10}]^{2\ominus}$ **2** $[Se^{II}_3Se^{IV}Br_{12}]^{2\ominus}$ **3**

$[(C_2H_5)_4N]_2[Se_2Br_8]$ **1a** $[(nC_3H_8)_4N]_2[Se_3Br_{10}]$ **2a**
$[(C_6H_5)_4P]_2[Se_4Br_{12}]\cdot CH_2Cl_2$ **3a**

When bromides are added to the solutions of $SeBr_4$ in weakly polar organic solvents, nucleophilic addition reactions lead to the formation of complex reaction mixtures from which the mixed valence bromoselenates can be isolated. Of importance for their formation is the presence of $Br_3^{\ominus}$, since, on the one hand, it leads (with "neutralization" of the oxidation potential of Br_2) to a shift of the $SeBr_4$/$SeBr_2$ equilibrium (a) to the right, and, on the other, catalyzes the $Br^{\ominus}$-transfer (cf. Ref. [2]). Possible formal modes of reaction are the addition of $Br^{\ominus}$ to $SeBr_4$ to give bromoselenates(IV) followed by addition of $SeBr_2$ molecules to the selenate(IV) (or the substitution of $SeBr_4$ groups by $SeBr_2$ groups) or, conversely, the addition of $SeBr_4$ to initially formed bromoselenates(II). The reaction conditions

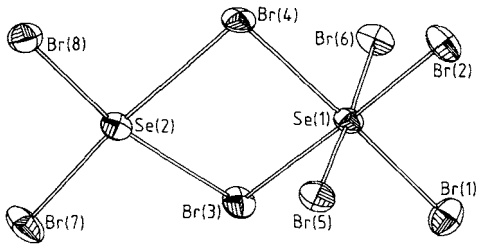

Fig. 1. Structure of **1** in the crystal of **1a** [8]. Important bond lengths [Å] and angles [°]: Se(1)-Br(1) 2.496(2), Se(1)-Br(2) 2.471(3), Se(1)-Br(3) 2.706(3), Se(1)-Br(4) 2.648(2), Se(1)-Br(5) 2.535(4), Se(1)-Br(6) 2.596(4), Se(2)-Br(3) 2.817(2), Se(2)-Br(4) 2.889(2), Se(2)-Br(7) 2.379(3), Se(2)-Br(8) 2.435(2), Se(1)···Se(2) 4.044(3); Br(1)-Se(1)-Br(2) 92.6(1), Br(7)-Se(2)-Br(8) 96.1(1), Br(3)-Se(1)-Br(4) 86.8(1), Br(3)-Se(2)-Br(4) 80.2(1) (cf. also [4c, 7]).

for reproducible synthesis of pure products by precipitation can be optimized by variation of reaction time, solvent, concentration, temperature, and counterion. As shown by an X-ray structure analysis,[8] **1** (Fig. 1) consists of a $Se^{IV}Br_6$ octahedral moiety and a square planar $Se^{II}Br_4$ moiety coupled via a common edge. As in all other haloselenates(II) the Se electron pairs not participating in bonding are stereochemically active in the sense of a ψ^2-octahedral $Se^{II}Br_4E_2$ coordination geometry. The Se^{II}–Br bridge bonds (average 2.853 Å) are very much longer than the terminal bonds (2.407 Å). The dihedral angle between the planar $Se^{II}Br_4$ moiety and the basal plane of the $Se^{IV}Br_6$ octahedron is 34°. In the $[Et_4N]_2[Se_2Br_8]$ salt prepared independently by *Hauge* et al.[7] the anion is much more strongly folded: the corresponding dihedral angle is 57°.

In the exactly centrosymmetric **2** (Fig. 2) the asymmetry of the $Se^{II}Br_4$ structural unit is even more pronounced ($Se-Br_{bridge}$ 2.970, $Se-Br_{term}$ 2.349 Å). Here we have the first example of a second $SeBr_2$ molecule being added to the $Se^{IV}Br_6$ octahedron in the *trans* position, and the resulting equatorial planes subtend an angle of 22°.

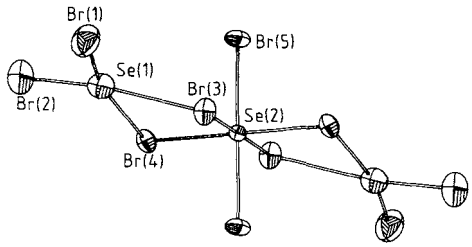

Fig. 2. Structure of **2** in crystals of **2a** [8]. Important bond lengths [Å] and angles [°]: Se(1)-Br(1) 2.338(2), Se(1)-Br(2) 2.360(2), Se(1)-Br(3) 2.943(2), Se(1)-Br(4) 2.997(2), Se(2)-Br(3) 2.557(1), Se(2)-Br(4) 2.570(1), Se(2)-Br(5) 2.549(1), Se(1)···Se(2) 4.042(3); Br(1)-Se(1)-Br(2) 99.5(1), Br(3)-Se(1)-Br(4) 76.7(1), Br(3)-Se(2)-Br(4) 91.9(1).

The structure of **3** (Fig. 3) is particularly noteworthy. In the first place, two $SeBr_2$ molecules are coordinated via *cis*-edges to the central $Se^{IV}Br_6$ octahedron; a third $SeBr_2$ unit bridges one of the $Se^{IV}BrSe^{II}$ four-membered rings such that a short Se–Se distance of 3.335 Å results between Se(4) and Se(2), indicating a bonding interaction. Se(2) thereby completes the square planar coordination geometry of Se(4). The $[Se_4Br_{12}]^{2\ominus}$ ions in **3a** are linked via unusually short Br–Br contacts of 3.116 Å between Br(6) and Br(9) to give polymeric associates.

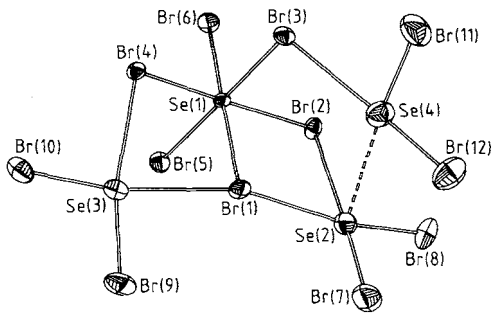

Fig. 3. Structure of **3** in crystals of **3a** [8]. Important bond lengths [Å] (all standard errors 0.003 Å): Se(1)-Br(1) 2.756, Se(1)-Br(2) 2.592, Se(1)-Br(3) 2.575, Se(1)-Br(4) 2.515, Se(1)-Br(5) 2.512, Se(1)-Br(6) 2.396, Se(2)-Br(1) 2.898, Se(2)-Br(2) 2.981, Se(2)-Br(7) 2.355, Se(2)-Br(8) 2.348, Se(3)-Br(1) 2.982, Se(3)-Br(4) 3.036, Se(3)-Br(9) 2.327, Se(3)-Br(10) 2.339, Se(4)-Br(3) 3.056, Se(4)-Br(11) 2.293, Se(4)-Br(12) 2.332, Se(1)···Se(2) 4.146, Se(1)···Se(3) 4.051, Se(2)-Se(4) 3.335.

The average Se–Br bond lengths (Figs. 1, 2 and 3) are significantly longer than those of two-electron two-center bonds, both in the case of Se^{II} as well as Se^{IV} (cf., e.g., Ref. [2]). This is consistent with a three-center four-electron model (with only one bonding MO per linear Br–Se–Br unit). As in other halochalcogenates a clear correlation between the *trans* oriented bonds is, in agreement with this model, also recognizable in **1**, **2** and **3**.[9]

The structural data of the diamagnetic compounds indicate that they belong to the Class I compounds of the Robin-Day classification,[10] i.e. that no significant valence exchange takes place. The different coordination geometries are clear indications of the different selenium valencies; as in the pure bromoselenates(II) the Se···Se distances are greater than 4 Å and thus rule out direct exchange contacts. The colors of the anions, which are darker with increasing degree of condensation, differ very little from those of the pure Se^{II} and Se^{IV} compounds; the exact measurement of the UV-VIS spectra, which presents diffi-

culties because of the equilibria present in solution, is currently being investigated.

Due to the reversibility of formation of the mixed valence bromoselenates, i.e. of their decomposition into stable $[SeBr_6]^{2\ominus}$ and $SeBr_2$, their preparative application as source material for the rather labile $SeBr_2$ in the pure state is conceivable.

Experimental

1a: A solution of $SeBr_4$ (0.88 g, 2.2 mmol) and Et_4NBr (0.46 g, 2.2 mmol) in CH_2Cl_2 (50 mL) was heated under reflux for 45 min. After cooling to 5°C, orange-red $[Et_4N]_2[Se_2Br_{10}]$ precipitated out, which, after a few hours' contact with the mother liquor, underwent decomposition, leading thereby to formation of deep-orange-red, crystalline **1a**. This is stable in moist air for a few days. Yield 22%; correct C,H,N analysis. M.p. 130°C. Raman: $\tilde{\nu}$=249 (s), 215 (vs), 153 (s), 111 (w) cm^{-1}; IR: 198 (vs) cm^{-1}.

2a: 0.98 g (2.45 mmol) of $SeBr_4$ and 0.65 g (2.45 mmol) of nPr_4NBr were dissolved at 40°C in 60 mL of CH_2Cl_2, and the solution kept at this temperature for 30 min, and then cooled to −20°C. After 2 h, reddish-black $[nPr_4N]_2[Se_5Br_{12}]$ began to precipitate which, after 2 d at −20°C, redissolved. Deep dark-red crystalline **2a** was then formed. This is air-stable for a few days. Yield 24%, correct C,H,N analysis. M.p. 121°C. Raman: $\tilde{\nu}$=265 (vs), 190 (s), 175 (s), 153 (m), 125 (s) cm^{-1}; IR: 264 (s), 206 (vs), 115 (m) cm^{-1}.

3a: 1.0 g (2.5 mmol) of $SeBr_4$ and 1.05 g (2.5 mmol) of Ph_4PBr were dissolved in 45 mL of CH_3CN at 35°C. After cooling to 20°C the solution was evaporated down under vacuum to 25 mL; after a few hours, deep-dark red **3a** crystallized at 20°C. Yield 18%; correct C,H analysis. M.p. 168°C (decomp.). Raman: $\tilde{\nu}$=255 (m), 226 (s), 163 (vs) cm^{-1}; IR: 176 (s) cm^{-1}.

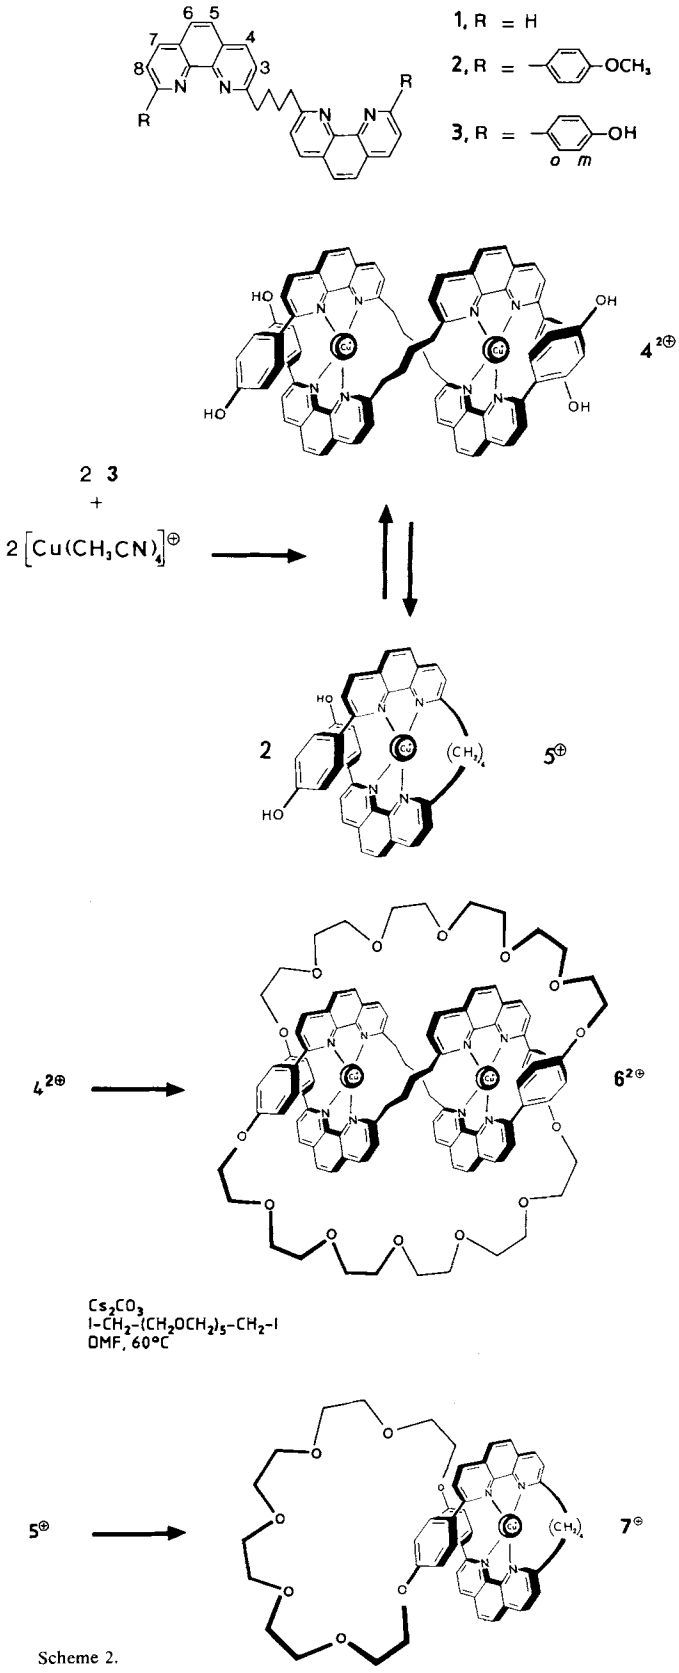
A Synthetic Molecular Trefoil Knot**

By *Christiane O. Dietrich-Buchecker* and *Jean-Pierre Sauvage**

The synthesis of molecular knots has been a long-standing quest in chemistry.[1,2] Discussions about their hypothetical properties can be found in relatively old literature.[3] Such topologies are abundant in Nature since duplex circular DNA can be converted into highly knotted forms,[4] making the synthesis of knots an even more challenging problem for the chemist.

Recently, we have developed an efficient way of interlacing and interlocking molecular threads (formation of catenanes, Scheme 1, top) by taking advantage of a three-dimensional template effect around a transition metal.[5,6] We have now extended our synthetic concept to two transition metal centers connected by two bis-chelate molecular links (Scheme 1, bottom).



Scheme 1. Templated synthesis of interlocked macrocyclic ligands, the catenands. The function of the transition metal center is to gather two linear fragments $\mathbf{A}_1$ and to entwine them, leading to $\mathbf{B}_1$. After cyclization of $\mathbf{B}_1$ using the proper connections, $\mathbf{C}_1$ is formed. Its demetalation affords the catenand $\mathbf{D}_1$. Bottom: Strategy towards a trefoil knot using two transition metal centers as templating species. Two coordinating molecular threads $\mathbf{A}_2$ are interlaced on two transition metal centers, forming a double helix $\mathbf{B}_2$. After cyclization to $\mathbf{C}_2$ and demetalation, a knotted system $\mathbf{D}_2$ is obtained.

An important prerequisite for the success of such an approach is the formation of a helicoidal dinuclear complex. Of utmost importance is the stability of the double helix $\mathbf{B}_2$, which has to be stable under the conditions of the cyclization to $\mathbf{C}_2$. The choice of the chemical link between the two chelating subunits of each $\mathbf{A}_2$ fragment is thus crucial. Besides the chemical stability, steric parameters and flexibility are factors that also have to be examined. In particular, in the reaction of $\mathbf{A}_2$ and the transition metal ion (●), the formation of $\mathbf{B}_2$ has to be favored over that of polymeric complexes or that of the mononuclear complex by folding up of $\mathbf{A}_2$ on one metal center. Dinuclear helicoidal molecular architectures have been reported previously.[7-12] After many attempts with various linkers, we found that compounds with two 1,10-phenanthroline

moieties connected via their 2-positions by a $-(CH_2)_4-$ tie, do indeed form a double helix when complexed to two copper(I) centers. Furthermore, by introducing appropriate functional groups at the 9-positions we have been able to make a molecular trefoil knot of the D_2 type according to the strategy depicted in Scheme 1 (bottom). The precursors used and the synthetic reactions are shown in Scheme 2.

Scheme 2.

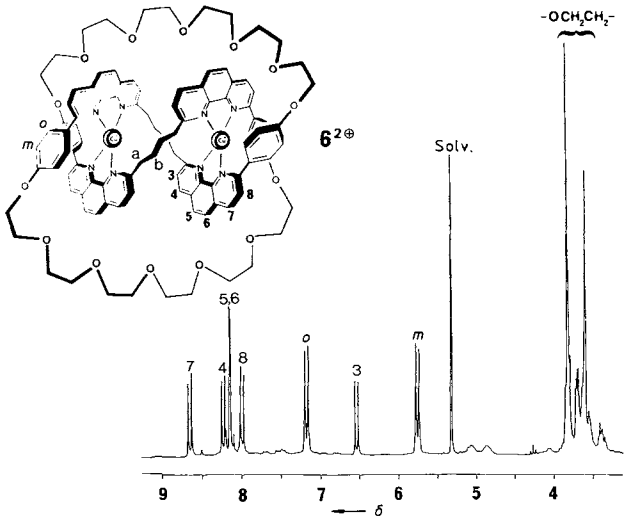
1 was prepared in 86% yield by reaction of $Li(CH_2)_4Li$[13] with 1,10-phenanthroline (large excess) in diethyl ether at 0°C under experimental conditions resembling those previously reported for the preparation of 2,9-disubstituted-1,10-phenanthroline derivatives.[14] Addition of *p*-lithioanisole to a suspension of **1** in ether at +2°C followed by water hydrolysis and MnO_2 treatment led to **2** in 83% yield. Demethylation of **2** to **3** was carried out quantitatively under drastic conditions: HCl-pyridine at 210°C.[14b, 15] The double-helix complex $\mathbf{4}^{2\oplus}$ was prepared as a deep-red solid by addition of stoichiometric amounts of $[Cu(CH_3CN)_4]BF_4$ in CH_3CN to a solution of **3** in dimethylformamide (DMF). ^{1}H-NMR studies using the model compound **2** and copper(I) clearly show that the double-helix complex is formed together with considerable amounts of the mononuclear complex **2**-$Cu^{\oplus}$, indicating that crude $\mathbf{4}^{2\oplus}$ is probably contaminated by a large fraction of $\mathbf{5}^{\oplus}$. The complex mixture containing $\mathbf{4}^{2\oplus}$ was allowed to react under high dilution conditions[5] with two equivalents of the diiodo-derivative of hexaethyleneglycol, $ICH_2(CH_2OCH_2)_5CH_2I$,[16] in DMF at 60°C in the presence of Cs_2CO_3 (large excess). After work-up and repeated chromatographic purification (SiO_2; CH_2Cl_2/CH_3OH), the main compound isolated as its $BF_4^{\ominus}$ salt (24% yield) was shown to be the mononuclear complex $\mathbf{7}^{\oplus}$[17] formed by ring-closure of $\mathbf{5}^{\oplus}$, confirming that indeed the reaction between **3** and $[Cu(CH_3CN)_4]^{\oplus}$ leads mainly to $\mathbf{5}^{\oplus}$. In addition to $\mathbf{7}^{\oplus}$, a small amount (3% yield) of a slightly more polar copper(I) complex could be purified and isolated. This compound turned out to be the knotted system $\mathbf{6}^{2\oplus}$.

From a tetrafunctional double helicoidal precursor, several 2+2 connections are possible, the most probable ones being those depicted in Scheme 3.

Scheme 3. Some possible cyclization pathways for a tetrafunctionalized dinuclear helicoidal complex. With 1,10-phenanthrolinecopper(I) based systems, the most probable connections correspond to reaction PR + QS, leading to the desired knot.

$\mathbf{6}[BF_4]_2$ is a dark-red crystalline solid (needles) with a high resolution mass spectrum (FAB) showing a molecular peak at 1816.74 (calculated molecular weight for $\mathbf{6}^{2\oplus}$ = 1816). The ^{1}H-NMR spectrum of $\mathbf{6}^{2\oplus}$ is reproduced in Figure 1.[18]

Since $\mathbf{6}^{2\oplus}$ contains a double helix wound round two Cu^{I} ions, it is chiral. This can indeed be demonstrated in the presence of *Pirkle*'s reagent.[19] Clear splitting of peaks is observed for most aromatic signals even after addition of a small amount of chiral reagent.



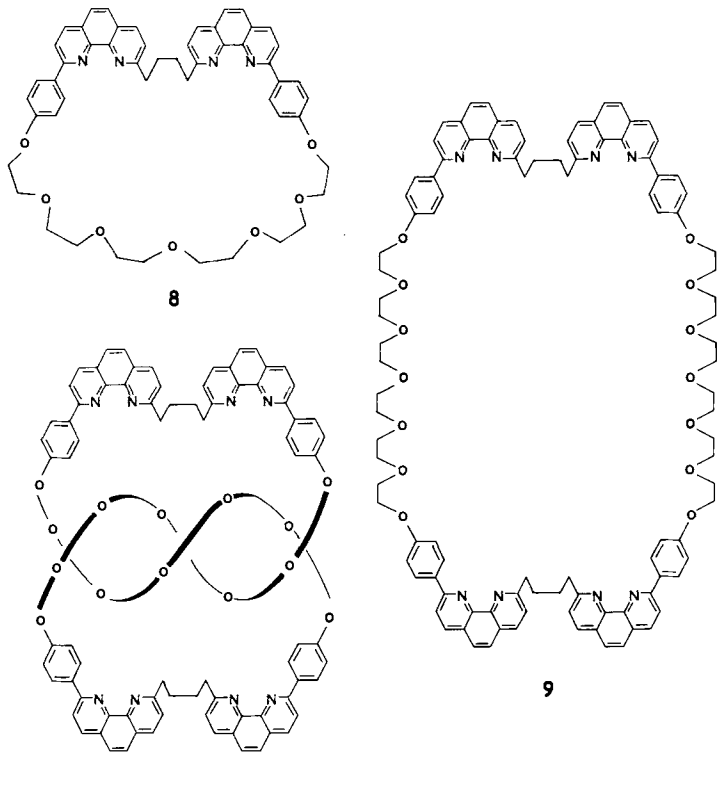


Fig. 1. ^{1}H-NMR spectrum (200 MHz) of $\mathbf{6}^{2\oplus}$ (5 mg $\mathbf{6}[BF_4]_2$ in 0.5 mL CD_2Cl_2. The $-(CH_2)_4-$ bridge shows two multiplets at $\delta = 0.5$ ($(CH_2)_b$) and 1.6 ($(CH_2)_a$).

Quantitative demetalation of the various copper(I) complexes by aqueous KCN leads to the corresponding free ligands (Scheme 4). A crystalline 43-membered ring **8** is obtained from $\mathbf{7}^{\oplus}$. It has been fully characterized. Demetalation of $\mathbf{6}^{2\oplus}$ affords the free trefoil knot **10** as a glass.

Very small amounts (ca. 0.5%) of **9**, the unraveled topological isomer of **10**, were isolated by careful chromatography of samples obtained by demetalating impure fractions from the chromatographic purification of $\mathbf{6}^{2\oplus}$. The comparison between the two isomers **9** and **10** is indeed a strong indication for the knotted topology of **10**. Both compounds have almost identical mass spectra (FAB): molecular peaks appear at nearly the same value (1690.9 for **10** and 1691.4 for **9**; calculated: 1690). Moreover, the general pattern and the various fragmentations of both compounds are strikingly similar.

By contrast, the ^{1}H-NMR spectra of **9** and **10** are remarkably different (Fig. 2). As expected, the spectra of **8** and **9** (Fig. 2a, b) are almost superimposable, whereas **10** leads to an extremely different spectrum with broad and

Scheme 4.

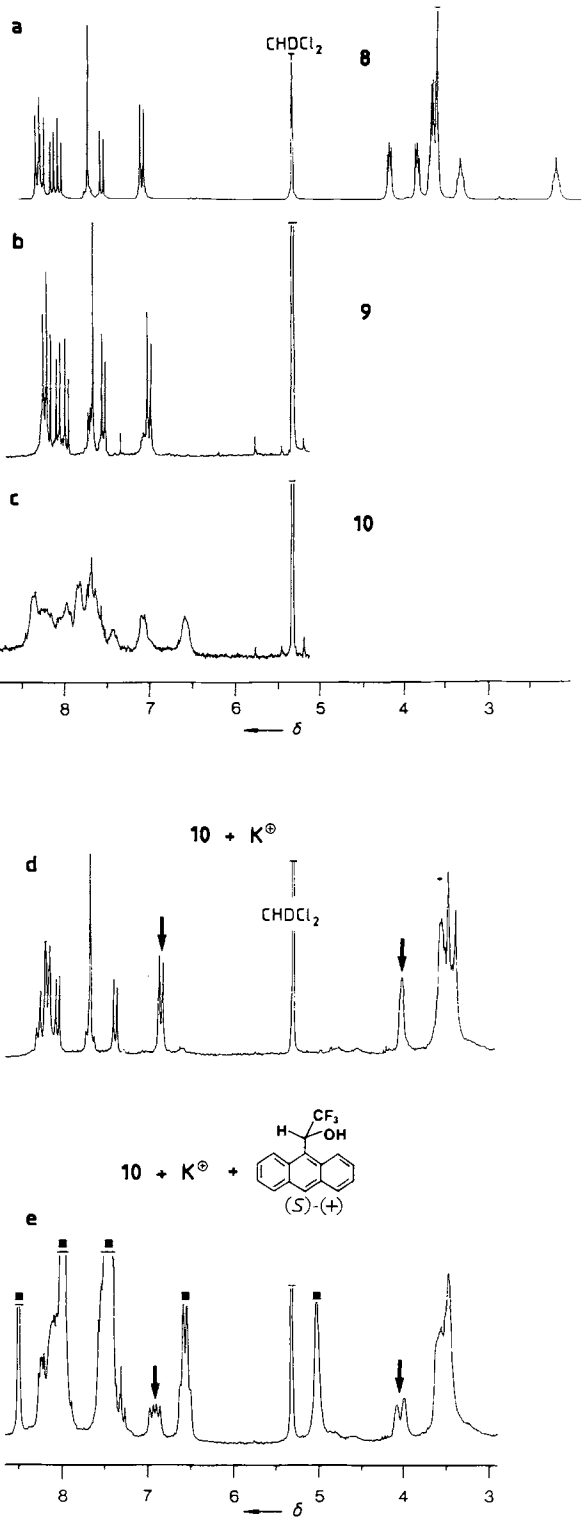

Fig. 2. a–c) 200-MHz ^{1}H-NMR spectra of **8**, **9** and **10**. d) ^{1}H-NMR spectrum of **10** after addition of KPF_6 (excess). e) Same spectrum as (d) but in the presence of *Pirkle*'s reagent; signals indicated by black squares.

poorly resolved signals spanning between $\delta = 6.5$ and 8.5 for the aromatic protons. The interconversion

$$6^{2\oplus} \underset{Cu^{+}}{\overset{CN^{\ominus}}{\rightleftharpoons}} \mathbf{10}$$

was shown to be perfectly reversible. It could be monitored by ^{1}H NMR spectroscopy and thin-layer chromatography, proving that the broad ^{1}H NMR spectrum of **10** was not due to the presence of impurities but rather that it reflects the raveled nature of its organic skeleton undergoing slow conformational changes.[20]

Unexpectedly, addition of KPF_6 to **10** leads to a drastic change in its ^{1}H NMR spectrum (Fig. 2c, d): both signal sharpening and chemical shift changes are observed. This is good evidence that $K^{\oplus}$ interacts with **10** via its O donor atoms. $K^{\oplus}$ complexation by either **8** or **9** was also detected under the same conditions, as indicated by chemical shift changes in the $-(CH_2O)-$ region in the presence of KPF_6. For the two latter complexes, no splitting of peaks was observed even after addition of large amounts of *Pirkle*'s reagent, in agreement with the achiral structure of **8** and **9**. In sharp contrast was the behavior of the $K^{\oplus}$ complex of **10**. Surprisingly large splitting of peaks was observed upon addition of *Pirkle*'s reagent, both for a $-(CH_2)-O-$ signal around $\delta = 4$ and in the aromatic region ($\delta H_m = 6.9$). This is indeed a clear demonstration that the molecular system is chiral, which is in agreement with the topological chirality of a trefoil knot.

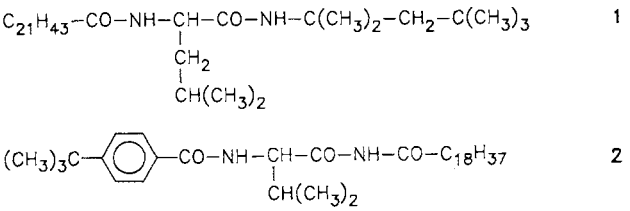
[20] High temperature ^{1}H NMR spectra recorded in [D$_6$]DMF. Indeed, the whole spectrum was well resolved with sharp signals at normal chemical shifts ($\delta = 7.3$ to 8.6) above 140°C.

Temperature Dependent Inversion of Elution Sequence in the Resolution of α-Amino Acid Enantiomers on Chiral Diamide Selectors

By *Katsunori Watabe, Rosita Charles,* and *Emanuel Gil-Av**



Stereoselectivity in chiral chromatography is measured by the resolution coefficient α, which also specifies the order of elution of a pair of enantiomers on a phase (selector) of given handedness.[1] On many selectors, the sequence of elution of the enantiomers of a given class of compounds was found to be consistently linked to their configuration.

In all studies carried out thus far, resolution has been found to decrease with increasing temperature. The Gibbs-Helmholtz relationship (a)[2] predicts, however, that if $\Delta\Delta H^0$ and $\Delta\Delta S^0$ are non-zero, have the same sign and are temperature independent (the general case), resolution will vanish ($\ln\alpha = 0$) at the isoenantioselective point $T_{iso} = \Delta\Delta H^0/\Delta\Delta S^0$. Thereafter, peak, reversal and improved resolution should result, as the temperature continues to be raised. This behaviour, which is known for achiral compounds,[3] had not been observed till now for enantiomers on chiral selectors.[4,5] The detection of such a peak inversion in chiral systems was of fundamental interest and of importance for understanding the influence of temperature, $\Delta\Delta H^0$ and $\Delta\Delta S^0$ on the stereoselectivity in the chromatographic separation of enantiomers.

$$\ln\alpha = \frac{\Delta\Delta S^0}{R} - \frac{\Delta\Delta H^0}{R}\frac{1}{T} \qquad \text{(a)}$$

It was observed in 1985[6] that the enantiomers of *N*-acetyl-valine-*tert*-butylamide were eluted at 170°C from a diamide phase in the reversed order as compared to a series of *N*-TFA-α-amino acid *tert*-butylamides, which had been studied previously.[7] Thereupon we investigated[8] the temperature dependence of the resolution coefficients for *N*-docosanoyl-L-leucine-(1,1,3,3-tetramethylbutyl)amide **1** (up to 220°C) and *N*-*para*-*tert*-butylbenzoyl-L-valine octadecylamide **2** (up to 200°C), coated on whisker-walled glass capillaries of 2–8 m length (up to 40000 plates). The selectands examined were optically enriched *N*-acyl-*tert*-butylamides of α-amino acids (Fig. 1), *N*-TFA isopropyl

2

esters of α- and γ-amino acids and *O*-pivaloyl *N*-TFA 2-amino alkan-1-ols (Fig. 2).

The plots in Figure 1 (for phase **1**) demonstrate that all curves for diamide selectands, except for the proline derivative, have a linear branch which crosses the $\ln\alpha = 0$ line and then shows inversion of the order of elution in agreement with the Gibbs–Helmholtz equation. The isoenantioselective points lie in the range 130–150 °C. Corresponding measurements on phase **2** confirmed these results. Re-examination of previous results[7] indicated similar behavior of diamide selectands on other diamide phases.[9] Recently, evidence for the occurrence of the inversion phenomenon for additional classes of compounds[10] and other selectors[11] was reported by other groups.

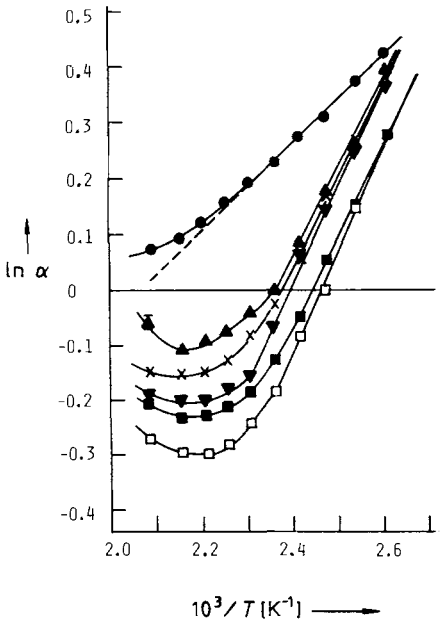

Fig. 1. Plots of $\ln\alpha$ versus $1/T$ for *N*-TFA-amino acid *tert*-butylamides on phase **1**. ● = proline, ▲ = alanine, × = α-aminobutyric acid, ▼ = leucine, ■ = valine, □ = *N*-acetylvaline *tert*-butylamide.

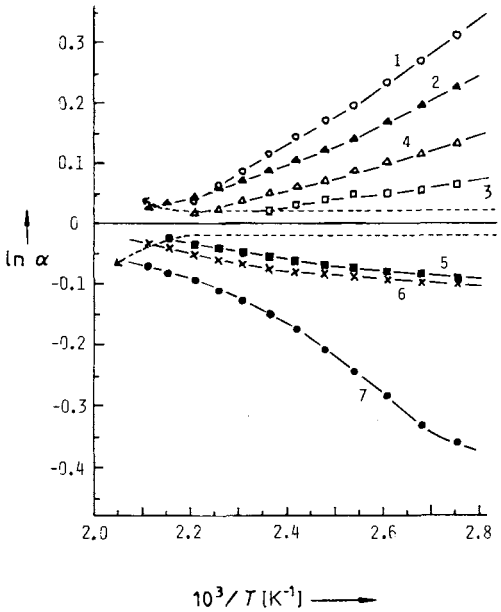
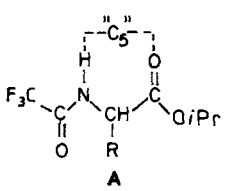
Previous failure to observe inversion would appear to be due largely to high T_{iso} values, at which the phase or the selectand might be unstable. In addition, the capacity ratios (k') decrease strongly with increasing temperature. Consequently, the term $k_2'/(k_2'+1)$ in the equation (b) for the peak resolution factor

$$R = \frac{\sqrt{N}}{4}\,\frac{\alpha-1}{\alpha}\,\frac{k_2'}{k_2'+1} \qquad \text{(b)}$$

becomes smaller so that for a detectable separation larger minimal α values are required. The dotted lines in Figure 2 delimit schematically the region which widens with rising temperature, in which, for a given plate number N, the peaks cannot be separated and the α values are undeterminable. Furthermore, the thermodynamic parameters might not remain constant at higher temperatures, leading to non-linearity of the Gibbs–Helmholtz plots.[2, 12]





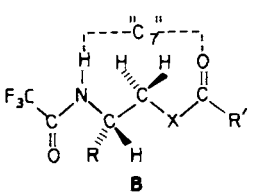


Fig. 2. Plots of $\ln\alpha$ versus $1/T$ for *N*-TFA-amino acid isopropylesters (1, 2, 3, 4, 6) and *O*-pivaloyl *N*-TFA-amino alcohols (5, 7) on phase **1**. 1 Alanine, 2 glutamic acid, 3 aspartic acid, 4 phenylglycines, 5 2-aminoheptan-1-ol, 6 γ-amino-δ-methylheptanoic acid, 7 leucinol. Separation is not possible in the region between the dotted lines.

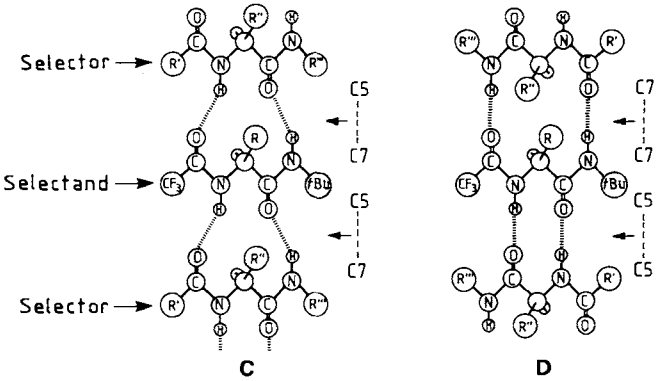
A combination of these effects might explain the deviation from linearity of the curves in Figure 2 for *N*-TFA-amino acid esters and derivatives of 2-aminoalkan-1-ols on phase **1**. The corresponding plots show departures from linearity and merge into or approach the non-resolution zone at the maximum temperatures used.

The plots that exhibit inversion (Fig. 1) have a non-linear part with an inflexion point, after which the curve approaches the x-axis. The simultaneous occurrence of two resolution mechanisms with opposite enantioselectivities could explain the observed shape of the curves. It is known[14] that compounds that differ in the type of association which they form with the diamide phase can exhibit opposite orders of elution for the enantiomers. Thus, the *N*-TFA isopropyl esters of α-amino acids, which present a "C_5" moiety (**A**) to the phase, have $\alpha > 1$, whereas *N*-TFA-γ-amino acid esters and the 2-amino alkan-1-ol derivatives, which have a "C_7" moiety (**B**), have the opposite order of elution ($\alpha < 1$) (Fig. 2).

A



B

X = CH_2, R' = O*i*Pr
X = O, R' = *t*Bu

On the other hand, a phase may form associates of opposed stereoselectivity with the *same* selectand. Thus, the

N-TFA-*tert*-butyl amides of α-amino acids can intercalate between a diamide solvent in either a parallel (**C**) or an antiparallel (**D**) fashion (Scheme 1). The resulting hydrogen bonded structures and the orientation of the asymmetric centers towards each other are not the same. For each of these two modes of intercalation there should be a corresponding $\ln\alpha$ vs. $1/T$ plot analogous, respectively, to the curves with $\alpha > 1$ and $\alpha < 1$ of Figure 2. Superimposition of such individual contributions to the total resolution, if of appropriate magnitude, could lead to an overall curve, as found experimentally, i.e., a linear branch, inversion and an inflexion point.

R = CH_3, C_2H_5, $CH(CH_3)_2$, $CH_2CH(CH_3)_2$,

R' = n-$C_{21}H_{43}$, p-$(CH_3)_3C$-C_6H_4,

R'' = $CH_2CH(CH_3)_2$, $CH(CH_3)_2$

R''' = $C(CH_3)_2CH_2C(CH_3)_3$, n-$C_{18}H_{37}$,

Scheme 1. Parallel (**C**) and antiparallel (**D**) intercalation of an *N*-TFA-L-α-amino acid *tert*-butylamide in a diamide selector, with hydrogen bonding of type "C_5-C_7" (**C**) and "C_7-C_7" + "C_5-C_5" (**D**).

The proposed explanation is supported by the behavior of the *N*-TFA-*tert*-butyl amide of proline. This diamide selectand cannot intercalate between the phase molecules, as shown in Scheme 1, and indeed, behaves quite differently from the other diamide selectands (see Fig. 1). It should be emphasized that such a double mechanism of resolution (Scheme 1) is not a condition for the observation of inversion, but it might shift the T_{iso} point into a favorable range.

In conclusion, the sense of the stereoselectivity of a chiral selector-selectand system is not to be considered a constant property, but is temperature dependent. This is of particular importance for the determination of configuration from chromatographic data. In many cases, however, inversion of the order of elution cannot be observed, largely because of too high T_{iso} points. It is noteworthy that a temperature dependent inversion of the chirality of the products of certain stereoselective reactions has been observed[15, 16] and was interpreted analogously in terms of the Gibbs-Helmholtz relationship involving the thermodynamic parameters of the relevant transition states.[16]

[12] Dilution of diamide selectors by apolar solvents causes an increase of the resolution coefficients of the *N*-TFA α-amino acid esters [13]. This has been ascribed to dissociation of the hydrogen bonded network of the selector and to the higher stereoselectivity of the non-associated form. A similar change could occur on raising the temperature, leading to an upward curvature of the Gibbs-Helmholtz plot and implying that $\Delta\Delta H^0$ and/or $\Delta\Delta S^0$ depend on the temperature.

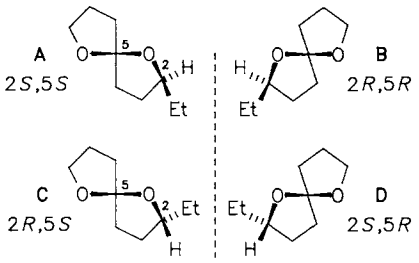
Evidence for a Temperature Dependent Reversal of the Enantioselectivity in Complexation Gas Chromatography on Chiral Phases**

By *Volker Schurig,** *Joachim Ossig*, and *Rainer Link*

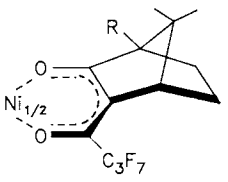
A temperature dependent reversal of the enantioselectivity (i.e., of the sign of $\Delta_{R,S}(\Delta G^0)$) of a defined, non-racemic stationary phase (selector) in the chromatographic separation of a chiral substrate (selectand) has been predicted on the basis of the temperature term in the Gibbs-Helmholtz relationship (a)[1]

$$RT\ln(K_R/K_S) = -\Delta_{R,S}(\Delta G^0) = -\Delta_{R,S}(\Delta H^0) + T\Delta_{R,S}(\Delta S^0) \quad (a)$$



$$T_{iso} = \Delta_{R,S}(\Delta H^0)/\Delta_{R,S}(\Delta S^0) \quad (b)$$

(where **R** arbitrarily represents the enantiomer which is eluted after its **S** antipode from a chiral column). When $\Delta_{R,S}(\Delta G^0) = 0$ ($K_R = K_S$, no enantiomer separation), the isoenantioselective temperature T_{iso} [Eq. (b)] is reached. At T_{iso}, peak coalescence ('of the third kind'[2]) occurs; below it the order of elution is governed by $-\Delta_{R,S}(\Delta H^0)$ and above it by $\Delta_{R,S}(\Delta S^0)$). At the coalescence temperature T_{iso} (no enantiomer separation) the sign of enantioselectivity will change.[3]



The first gas chromatographic evidence for a temperature dependent reversal of the enantioselectivity of a chiral stationary phase was obtained by *Watabe, Charles* and *Gil-Av* in a hydrogen-bonding selectand-selector system.[4] Here we report a further example which was observed by enantioselective coordination in complexation gas chromatography and is characterized by a low value of T_{iso}. In the gas chromatographic separation of the enantiomers of (*E*)-2-ethyl-1,6-dioxaspiro[4.4]nonane **1b** on nickel(II)-bis[3-(heptafluorobutanoyl)-(1*S*)-10-methylenecamphorate]

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We wish to thank Prof. *E. Gil-Av*, Rehovoth, Israel, for communicating his results prior to publication.

1a = A + B
1b = C + D

2a, R = CH_3
2b, R = $CH{=}CH_2$

2b[5] the coordination interaction ($K_{mean}=(K_C+K_D)/2$) steadily decreases between 30°C and 150°C. No separation of the enantiomers **C** and **D** is observed between 70°C and 90°C. At 60°C **D** is eluted after **C** whereas at 140°C **C** is eluted after **D** (Fig. 1). Most important is the observation that enantiomer discrimination increases with increasing temperature above the coalescence region (Fig. 2), although the total coordination interaction decreases, as expected. Thus, the requirement of the Gibbs-Helmholtz equation of an increase of $+\Delta_{D,C}(\Delta G^0)$ above T_{iso} is fulfilled. Unfortunately, because of the decrease of the selectand-selector coordination at higher temperatures and the configurational lability of the chiral spirocenter of **1**, which causes characteristic interconversion profiles[2,6] (cf. Fig. 2), investigations could only be carried out up to 150°C.

The determination of the Gibbs-Helmholtz parameters of the enantioselective association between **1b** and **2b** from relative retention data[2,7] revealed a linear relationship between $R\cdot\ln(K_D/K_C)$ and 1/T (measured at five degree intervals between 50 and 65°C) with $-\Delta_{D,C}(\Delta H^0)=0.62$ kcal mol^{-1} and $\Delta_{D,C}(\Delta S^0)=-1.75$ cal mol^{-1} K^{-1},[8] from which $T_{iso}=354$ K (80°C) is calculated[9] (Fig. 3); this value is in agreement with the experiment (Fig. 2). Peak coalescence is observed for the enantiomers **A** and **B** of the (*Z*) diastereomer **1a** at 60°C.

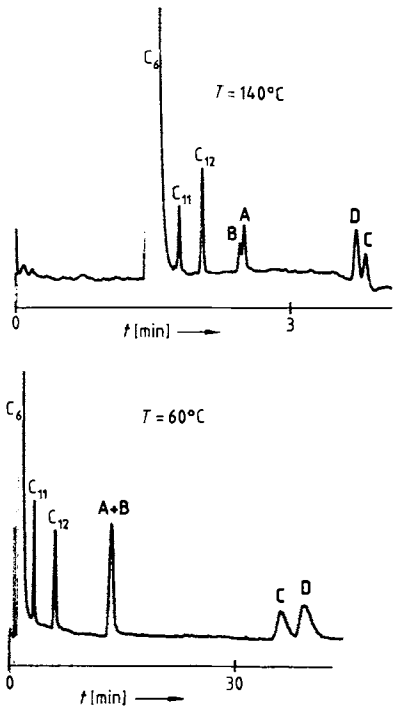

Fig. 1. Temperature dependent reversal of the enantioselectivity of **2b** (ca. 0.15 M in OV-101) in the separation of **1b** (enriched in the **D** enantiomer) by complexation gas chromatography. Column: 25 m × 0.25 mm fused silica capillary, 0.2 μ stationary phase, carrier gas: N_2. C_6 = *n*-hexane (solvent), C_{11} = *n*-undecane, C_{12} = *n*-dodecane.

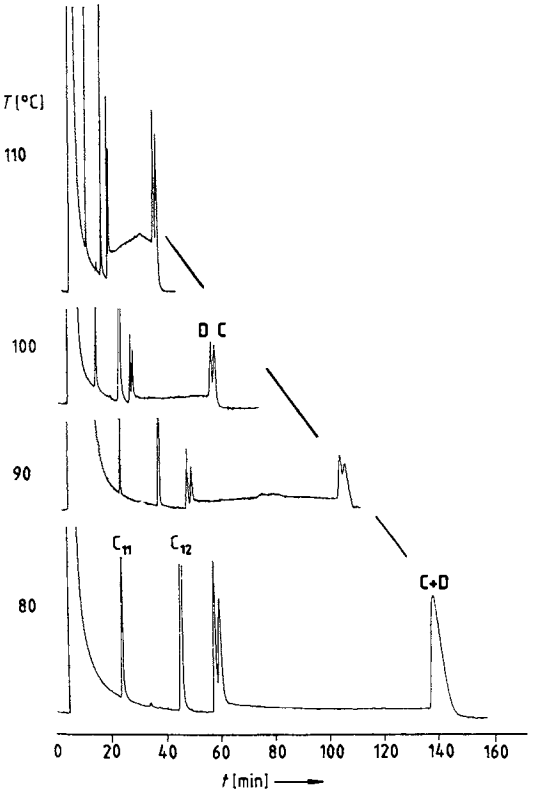

Fig. 2. Peak coalescence ('of the third kind') for the enantiomers **C** and **D** of **1b** (racemic) in complexation gas chromatography on **2b** (0.1 M in OV-101) at 80°C and increase of enantiomer discrimination with increasing temperature. Column: 34.2 m × 0.25 mm glass capillary, carrier gas: 1.0 bar N_2. C_{11} = *n*-undecane, C_{12} = *n*-dodecane.

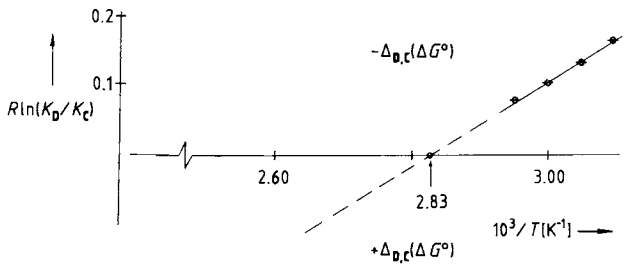

Fig. 3. Extrapolation to determine the isoenantioselective temperature T_{iso} for the separation of **1b** on **2b**. $R\cdot\ln(K_D/K_C)$ (T[°C]): 0.165 (50); 0.136 (55); 0.104 (60); 0.080[5] (65).

The findings could well be of considerable importance for the understanding of mechanistic aspects of enantioselectivity in chromatography, in particular, and of enantiomer recognition in chiral environments, in general. The influence of temperature on the discrimination of enantiomers will now have to be considered in rationalizing chiral recognition. In complexation gas chromatography, exceptions[2] to the rules correlating the absolute configurations of structurally closely related selectands with their

order of elution from chiral selectors[10] as well as unsatisfactory enantiomer separation for particular selectands[11] may well be due to the temperature dependence of the enantioselectivity, particularly for temperatures close to T_{iso}. It is intriguing to realize that above T_{iso}, preferential recognition of one enantiomer is not caused by stronger binding to a non-racemic matrix but is due to the higher degree of disorder in the resulting chemical interaction.

[8] The enantioselective selectand-selector system **1b** and **2b** shows some unusual features which are not fully understood at present. Although the temperature-dependent reversal of the elution order of **1b** on **2b** is fully reproducible, $-\Delta_{D,C}(\Delta G^0) = RT \cdot \ln(K_D/K_C)$ almost doubled at, e.g., 60°C with increasing time of operation of the column, while K_{mean} remained essentially unchanged. Also, an excessive peak-broadening, reaching a maximum at T_{iso} has been observed both for the racemic mixture and the single enantiomers.
[9] Recently, in a careful study of the temperature dependence of the separation of **1a** and **1b** on **2a** (1*R*) in SE-54 polysiloxane in five degree intervals between 80 and 120°C, T_{iso} values as high as 200°C have been extrapolated for these *Z*/*E* isomers [7].

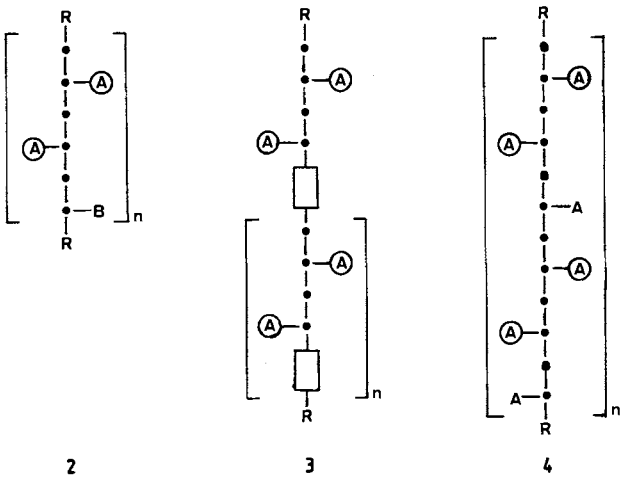
[11] Thus, isopropyloxirane is not resolved on **2a** at 60°C (T_{iso}) [2]. Besides, it also shows a temperature dependent reversal of the elution sequence: V. Schurig, D. Wistuba, unpublished.

Can Polystyrene be Optically Active?**



By *Günter Wulff** and *Pradeep K. Dhal*

Dedicated to Professor Kurt Heyns on the occasion of his 80th birthday

The question, as to whether polymers based on vinyl monomers can exhibit optical activity arising from a chiral configuration of the main chain (main chain chirality) has long been a subject of discussion. The conclusion of this debate, after consideration of all the commonly encountered and well-known structures of both homo- and copolymers, revealed that they are not expected to exhibit any such characteristics.[2] Careful symmetry considerations have shown recently that, particularly in the case of copolymers, several chiral structures are possible which should be able to exhibit optical activity.[1,3] By copolymerizing the mannitol derivative **1** with different comonomers and subsequent cleavage of the mannitol template, optically active copolymers (e.g., poly(4-vinylphenylboronic acid-co-styrene)) consisting of asymmetric triads of type **2** were obtained.[4-6]

1

2 **3** **4**

In this example, the diads having A substituents (4-vinylphenyl boronic acid residues incorporated via the mannitol derivative **1**) are decisive for chirality (in this case, the diad has the (*S*,*S*)-configuration).[6] The carbon atoms bearing B substituents do not represent stereogenic centers and essentially serve to separate the chiral diads from one another. Therefore, this spacer can also be composed of a relatively long chain fragment (stereoregular or atactic) of comonomer units (see **3**).[1,6] This gives rise to the question of whether a chain fragment consisting of an atactic sequence of homopolymer could fulfill the requirements of a spacer for the diads as well. If this were so, it would be possible to prepare, for the first time, optically active vinyl homopolymers possessing well-defined main chain chiral configurations.

In order to address this question, a systematic model study was carried out for all possible partial chain structures. We analyzed to what extent the asymmetric arrangement at the centers of the diad, which originally had a defined absolute configuration, is retained upon introduction of intermittent atactic units. The following essential simplifications were introduced:

a) Chain fragments consisting of one, two, or three monomer units with a statistical distribution of all possible configurations, were considered to serve as appropriate bridging groups between the diads in **3**.

[*] Prof. Dr. G. Wulff, Dr. P. K. Dhal
Institut für Organische Chemie und
Makromolekulare Chemie der Universität
Universitätsstrasse 1, D-4000 Düsseldorf (FRG)

[**] On the Chirality of Polyvinyl Compounds, Part 9. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie. Part 8: [1].

b) Two stereocenters on each side of the investigated center were taken into account in determining the asymmetry of the centers in the tactic diads. Moreover, it was assumed that the arrangement of these four neighboring stereocenters would mainly govern the rotational contributions arising from the asymmetric center. The remaining parts of both chains were regarded as being identical (see Fig. 1).

c) It was assumed that identical partial structures within the chain would bring about optical rotations of the same sign for the entire molecule.

Although the introduction of these simplifications is not free from problems, in our opinion this approach is adequate for the assessment of possible effects.

Inspection of chain structures in the light of the above model reveals that, for a separating unit consisting of varying number of monomers, at least 25% of all the centers of the diads are stereogenic and chirotopic (asymmetric) and could contribute to the optical rotation. As an illustration, all possible partial structures for a polymer chain with two monomeric units in the spacer are shown in Figure 1. By taking the central carbon atom (one of the centers of the diad, in the box) as reference, it is evident that in formulas **c** and **e** this center is chirotopic but not stereogenic and that in formulas **d** and **f** it is stereogenic but not chirotopic (pseudo-asymmetric). In the arrangements **a**, **b**, **g**, and **h**, the central carbon atom is stereogenic and chirotopic (asymmetric). However, the structural arrangements in formulas **b** and **h** are mirror images of each other. Consequently, only the central stereogenic centers in the diastereomeric arrangements **a** and **g** (i.e., 25% of all centers) are expected to contribute appreciably to the optical rotation (same or opposite sign). Similar results are obtained when three or more monomeric units are present in the atactic part of the spacer. In contrast, if a single monomeric unit constitutes the separating component, half of the centers of the diads should be chirotopic and stereogenic (asymmetric). This type of chain configuration corresponds to the earlier discussed homopolymer type consisting of chiral hexads **4**.[1, 2c, 3]

From the above analysis, it appears that for chain structures of type **3** with separating units consisting of atactic homopolymer fragments, optical activity, albeit to a moderate extent, can be expected. The synthesis of this structure involved copolymerization of the monomer **1** with styrene in various molar ratios (see Table 1), whereby removal of the 3,4-*O*-cyclohexylidene-D-mannitol template yielded optically active copolymers with optical rotations in the range $[\alpha]_{365}^{30} = -28°$ to $-36°$ (Fig. 2). Quantitative deboronation using $AgNO_3/NH_3$ in acetone[6] resulted in the formation of the homopolymer **6a** containing distyryl

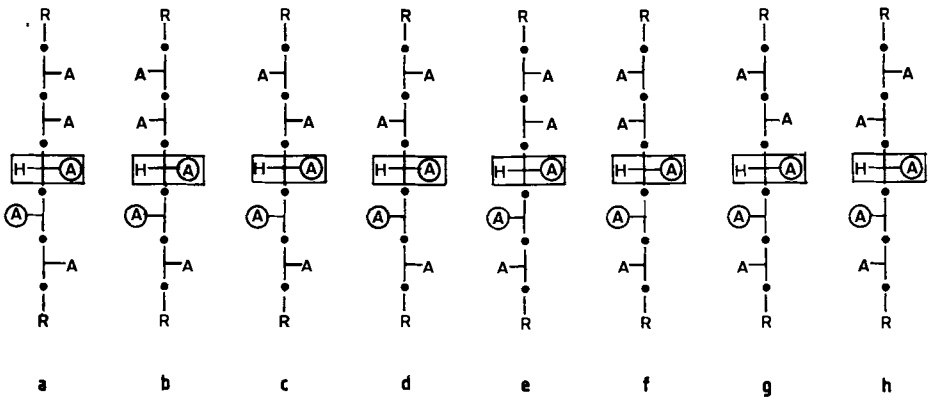


Fig. 1. Chain fragments consisting of a tactic diad of defined absolute configuration (in circles) with statistical distribution of all possible configurations in the atactic part. The center under consideration is indicated by a box. Two neighboring stereocenters on either side are taken into consideration. The separating atactic component consists of two or more monomeric units.

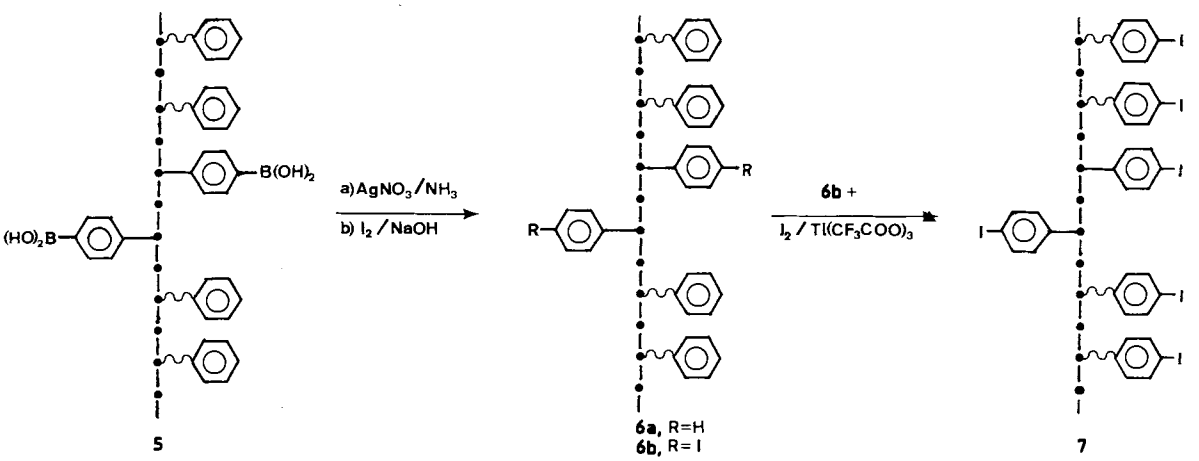

Fig. 2. Preparation of optically active homopolymers.

diads of known absolute configuration in an otherwise atactic polystyrene. As can be seen from Table 1, for certain compositions, distinct optical rotations were observed. Since the boric acid residues could be removed quantitatively, the possibility of any contribution from residual 4-(dihydroxyboryl)styryl diads to the observed optical activity can be ruled out. Furthermore, the circular dichroic (CD) spectrum of the polymer **6a** ($\lambda = 217$ nm, $[\Psi] = -245°$) does not resemble that typically found for 4-(dihydroxyboryl)-styryl diads[7] ($\lambda = 234$ nm, $[\Psi] = -2656°$) as in the case of **5**, but clearly resembles that of the distyryl diads ($\lambda = 217$ nm, $[\Psi] = -2395°$) present in the deboronated copolymers of **1** with methacrylonitrile.

Reduction in the optical activity of **6a** to one tenth of the value compared with the copolymer **5** could be explained in the following manner:

a) Approximately 25% of the total (S,S)-diads of **5** only contribute to the optical activity of **6a**.
b) The diastereomeric arrangements **a** and **g** might result in optical rotations of opposite sign.
c) The molar rotational contributions of chain segments bearing comonomer units are likely to be significantly higher than the corresponding homopolymers (**a** and **g**).

Using an analogous procedure, optically active poly(4-iodostyrene) was prepared. **5** was converted first to an optically active poly(styrene-co-4-iodostyrene) **6b** by replacing the boric acid residues with iodine.[8] This copolymer was subsequently subjected to thallium(III) trifluoroacetate catalyzed iodination[9] to produce the desired poly(4-iodostyrene). These homopolymers also showed distinct optical activity for particular compositions.

Table 1. Optical activity of co- and homopolymers (in THF). Polymer **5** was synthesized by radical copolymerization of **1** with styrene in various molar ratios followed by removal of the template [6]. Further details of the modification of **5** are outlined in the text and Fig. 2. The molecular weights of the polystyrene samples **6a**, as determined by GPC measurements using a polystyrene standard, were found to lie in the range $\overline{M} = 30000$–35000 [a].

Experiment No.	Mole fraction of **1** in monomer	in polymer	$[\alpha]_{365}^{20}$ [°] **5**	**6a**	**6b**	$[\alpha]_{436}^{20}$ [°] **7**

5	0.35	0.47	−28	−0.5	−24	−1

[a] Representative physical data and elemental analyses for the polymers: polystyrene **6a** (No. 2): $\alpha_{measured} = -0.012 \pm 0.002°$ ($c = 0.32$), elemental analysis: calcd. C 92.26, H 7.74, found C 92.34, H 7.69; **6a** (No. 3): $\alpha_{meas.} = -0.011 \pm 0.002°$ ($c = 0.35$), found C 92.08, H 7.82; poly(4-iodstyrene) **7** (No. 2): $\alpha_{meas} = -0.015 \pm 0.002°$ ($c = 0.38$), calcd. C 41.77, H 3.06, found C 41.80, H 2.77; **7** (No. 3): $\alpha_{meas.} = -0.015 \pm 0.002°$ ($c = 0.33$), found C 41.88, H 2.70.

It has thus become possible, for the first time, to synthesize optically active homopolymers with well-defined structures based on 1-substituted olefins. The observed optical activity unequivocally originates from the chiral configurations in the main chain. Homopolymers with low optical activity, e.g., of the methacrylate type (for a concise survey see Ref. [1]) reported in the past have always remained ambiguous with respect to their structures and mechanisms of formation. As the possibility of a configurational chirality in the main chain was not conceivable, in some cases the optical activity of these polymers was attributed to a chiral conformation.

A Polyhedral Oligogermane: 4,8-Dibromo-octa-*tert*-butyltetracyclo[3.3.0.0^{2,7}.0^{3,6}]octagermane**

By *Manfred Weidenbruch**, *Fred-Thomas Grimm*, *Siegfried Pohl*, and *Wolfgang Saak*

In spite of much interest in inorganic rings and cages,[1] examples of these types of compound for the heavier elements of the fourth main group are restricted to the few bi- and polycyclic silicon compounds reported in the last few years. In addition to derivatives of bicyclo[1.1.0]tetrasilane[2] and bicyclo[2.2.0]hexasilane,[3] the first polycyclic oligosilanes have recently been reported.[4] Although an octasilacubane[5] has also been synthesized, it has yet to be structurally characterized.

In contrast, bi- and polycyclic oligogermanes have not previously been reported. In the early literature, the reductive dehalogenation of trichlorophenylgermane was reported to afford a compound of composition $(PhGe)_6$, which, at that time, was believed to be a hexagermabenzene derivative.[6] With the benefit of modern knowledge, a polyhedral germane would appear more likely.[7]

We now report the synthesis of a polycyclic oligogermane via a simple route. Treatment of germanium tetrabromide with *tert*-butyllithium gave a mixture of dibromodi-*tert*-butylgermane and 1,1,2,2-tetrabromo-1,2-di-*tert*-butyldigermane **1**[8] in 20% yield in each case. Reaction of the latter with excess naphthalene/lithium [Eq. (a)] afforded a

$$4\,t\mathrm{BuBr_2Ge{-}GeBr_2}t\mathrm{Bu} + 14\,\mathrm{C_{10}H_8/Li} \longrightarrow \underset{\mathbf{1}}{} \qquad \text{(a)}$$

$$t\mathrm{Bu_8Ge_8Br_2} + 14\,\mathrm{LiBr} + 14\,\mathrm{C_{10}H_8}$$

[**] Compounds of Germanium and Tin, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 3: M. Weidenbruch, K. Schäfers, S. Pohl, W. Saak, K. Peters, H. G. von Schnering, *Z. Anorg. Allg. Chem.* (in press).

mixture consisting of unreacted **1** and two other germanium compounds. The mass spectrum of the major product (crude yield 50%, HPLC) showed it to contain a skeleton of eight germanium atoms. The X-ray structural analysis[10] (Fig. 1) confirmed this, showing that **2** is 4,8-dibromo-octa-*tert*-butyltetracyclo[3.3.0.0^{2,7}.0^{3,6}]octagermane. Both enantiomers of the chiral molecule are present in pairs in the unit cell. Only four signals, instead of eight, were observed for the *tert*-butyl protons in the ^{1}H NMR spectrum[9] of **2**, which is in accord with the C_2 molecular symmetry. Not only does **2** exhibit exceptional thermal stability it is also air and moisture stable.

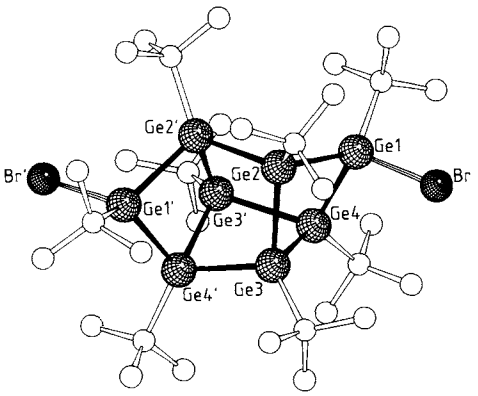

Fig. 1. Molecular structure of **2** (H atoms omitted). Selected bond lengths [pm] and angles [°] (standard deviations). The numbers marked with dashes indicate symmetry equivalent atoms. Ge1-Ge2 247.8(1), Ge1-Ge4 244.3(1), Ge2-Ge3 254.2(1), Ge2-Ge2' 246.1(1), Ge3-Ge4' 249.5(1), Ge-C 201.3 (ave.); Ge2-Ge1-Ge4 86.1(1), Ge1-Ge2-Ge3 87.9(1), Ge2-Ge3-Ge4 83.9(1), Ge1-Ge4-Ge3 90.1(1), Ge2'-Ge2-Ge3 94.3(1), Ge2-Ge3-Ge4' 103.8(1), Ge3-Ge4-Ge3' 82.5(1), Ge1-Ge4-Ge3' 103.6(1). Interplanar angles [°]: Ge2-Ge1-Ge4/Ge2-Ge3-Ge4 143.9, Ge4-Ge3-Ge4'/Ge4-Ge3'-Ge4' 141.8.

The absence of cyclotetragermanes in the reaction mixture suggests that these compounds, which are presumably the initial products of reaction (a), are subject to a spontaneous condensation reaction. The results reported here are in agreement with those of ab-initio calculations on bicyclo[2.2.0]hexagermane,[11] which predicted that the two fused four-membered rings are almost unstrained. The formation of an octagermacubane from **2** is not possible, since, in addition to the reductive elimination of the two bromine atoms, the cleavage and re-formation of a Ge–Ge bond is required.

Experimental procedure

Naphthalene/lithium (4.1 mmol) in THF (60 mL) was added to **1** (0.68 g, 1.18 mmol) in benzene (60 mL) and the resulting mixture stirred for 12 h at room temperature. The solvent was removed, the residue extracted with *n*-pentane, and the extract filtered to remove LiBr. Naphthalene was removed by vacuum sublimation. The resulting residue contained (HPLC analysis) 48% **2** and 15% **1**. Pure **2** was obtained by preparative HPLC (Nucleosil column, eluent *n*-hexane) followed by recrystallization from *n*-pentane.

Residual Enantiomerism and Chromatographic Resolution of a 1,1,2-Triarylalkene**

By *Silvio E. Biali,* Zvi Rappoport,* Albrecht Mannschreck* and *Nikola Pustet*

1,1,2-Triarylalkenes exist in a chiral "propeller" conformation in which the three rings are twisted in the same sense.[1,2] The rotational behavior of molecular propellers is generally analyzed in terms of "flip" mechanisms involving correlated rotation of the rings and leading to helicity reversal.[3] In these mechanisms, as applied to alkene propellers,[4] the rings which flip pass through a plane perpendicular to the plane of the double bond, whereas those rings that do not flip pass through the plane of the double bond. According to the number of rings that flip, these mechanisms are dubbed three-, two-, one- or zero-ring flip. We have shown previously that the rotational mechanism of lowest activation energy (threshold mechanism) which leads to enantiomerization of the sterically hindered stable enol[5] 1,2,2-trimesitylethenol **1** and its acetate **2** is the three-ring flip.[4]

$Mes_2C{=}C(OH)Mes$ **1** $Mes_2C{=}C(OAc)Mes$ **2**

$Mes_2C{=}C(OAc)(2,4,6\text{-}Me_3\text{-}3\text{-}OMe\text{-}C_6H)$ **3**

Mes = 2,4,6-$Me_3C_6H_2$

The activation barriers for the three-ring flip of **1** and **2** are relatively low (77.0 and 79.5 kJ mol^{-1}, respectively)[4] and therefore the resolution of **1** and **2** at room temperature is precluded. Moreover, since the three-ring flip exchanges pairs of diastereotopic groups in all three rings, the higher energy flip processes cannot be followed by NMR spectroscopy. However, the preference for a low en-

ergy enantiomerization via a three-ring flip raised an interesting possibility. If one of the mesityl rings is rendered dissymetric, e.g. by replacement of one of the mesityl protons by another substituent ("tag"), the compound should exist in four stereoisomeric forms (two enantiomeric pairs) due to the helicity and because the tag can lie either above or below the plane of the double bond. The three-ring flip will then result in *diastereomerization* (D) but not in enantiomerization (E), which requires both helicity reversal and "tag inversion" with respect to the C=C plane. Under conditions of fast three-ring flip the compound should exist in two residual enantiomeric forms (see Fig. 1)[6] which can

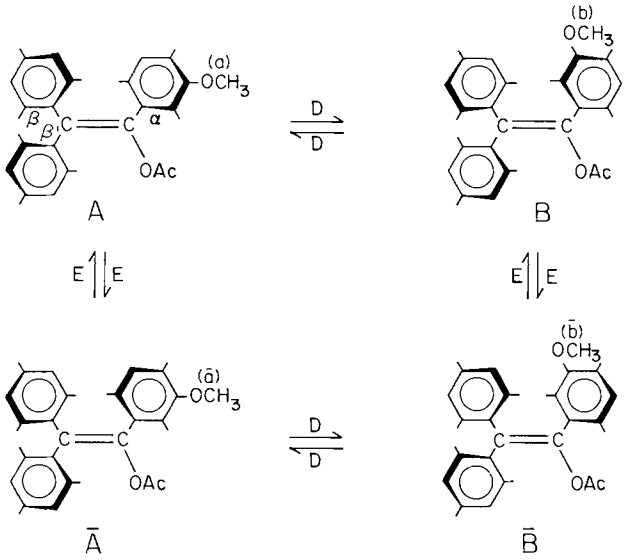

Fig. 1. Diastereomerization (D) and enantiomerization (E) of **3**. Dashes over capital letters denote enantiomers and over lowercase letters enantiotopic sites.

be interconverted only by a non-flip process, i.e., by passage of the tagged ring through the plane of the double bond. The barrier for this interconversion should be higher than that for the three-ring flip and, provided that it is sufficiently high, the lifetimes of the residual isomers should be long enough to enable resolution. The racemization barrier of a sample enriched in one enantiomer will then be the non-threshold rotational barrier for the process, in which the ring bearing the tag passes through the plane of the double bond. In order to investigate these possibilities, compound **3**, a derivative of **2** in which one aromatic proton of the α-ring is replaced by OMe, was chosen. The acetate group was chosen since we encountered difficulties in crystallization of its parent enol **4**. The choice of the *meta*-OMe substituent was based on three considerations. First, the height of the barriers are mainly determined by steric interactions between the *ortho*-methyl groups of the three rings in the ground and transition states, so that the presence of a *meta* substituent should not affect the barrier for the threshold mechanism in the absence of buttressing effects. Second, it is expected that the diastereomeric ratio will not differ appreciably from 1:1 and therefore both diastereomers could be detected in the NMR spectra under slow exchange conditions. Third, since the chemical shift of the OMe signal is very different from the other chemical shifts, this group should allow easy monitoring of the diastereomerization process.

Compound **3** was synthesized in two steps from dimesitylketene via the enol intermediate **4**[7] [Eq. (a)].

$$Mes_2C{=}C{=}O \xrightarrow[2)\ H^{\oplus}]{1)\ ArylMgBr} \underset{\mathbf{4}}{Mes_2C{=}C(OH)Aryl} \xrightarrow{Ac_2O/py} \mathbf{3} \qquad \text{(a)}$$

Aryl = 2,4,6-Me_3-3-OMe-C_6H

For a frozen propeller conformation, **3** should exist in four stereoisomeric forms. In Figure 1 the two diastereomeric forms (two pairs of enantiomers) are designated A and B; dash over a letter designates the other enantiomer. The OMe groups in A and B are designated a and b, respectively, and the corresponding enantiotopic sites in $\bar{A}$ and $\bar{B}$ are labelled ā and b̄. In the ^1H NMR spectrum ($C_6D_5NO_2$, room temperature), **3** displays 21 signals for the Me, AcO and Aryl-H groups and two OMe signals in the ratio of ca. 1.08, in agreement with the presence of two pairs of diastereomers in solution. This ratio increased to 1.15 upon raising the temperature to 378 K. In addition, some of the signals (including those for OMe) broadened and eventually coalesced. From the frequency difference between the two OMe signals ($\Delta\nu = 76$ Hz at 200 MHz) at slow exchange and the coalescence temperature ($T_c = 388$ K), a barrier of 79.5 kJ mol^{-1} was calculated for the diastereomerization of **3** using the Gutowsky–Holm approximation[8] and the Eyring equation. We ascribe this diastereomerization process, which exchanges the OMe groups a ⇌ b and ā ⇌ b̄, to a three-ring flip, by analogy with the isomerization of **2**. The equality of the rotational barriers for **2** and **3** indicates that the buttressing effect of the OMe substituent has little or no influence on the threshold barrier. The analogy with **2** suggests that the enantiomerization barrier must be higher than 79.5 kJ mol^{-1}. At 422 K (60 MHz) five Me, one AcO, one MeO and three Aryl-H signals are observed. The number of Me and Aryl-H signals is lower than expected for the residual isomers (nine Me and five Aryl-H signals). This high temperature spectrum can be explained either by a fast passage of both the β- and β′-rings through the plane of the double bond (a topomerization process), by a rapid rotation of the α-ring through the plane of the double bond (an enantiomerization process), or by simply assuming poor resolution of the pairs of *ortho* and *meta* signals for the β- and β′-rings at 60 MHz. Since the latter explanation seemed highly likely, we attempted the resolution of **3** by chromatography on an optically active column.

In principle, if the rotation of the rings is slow on the chromatographic time scale, *both* racemates should be resolved. In practice, using an optically active column of triacetylcellulose,[9] which has been used successfully for the separation of other helical compounds,[10] with EtOH/H_2O (96/4) as eluent, we observed rather erratic behavior; sometimes both racemates and sometimes a single (residual) racemate were resolved. As soon as an enriched solution was detected in the polarimetry cell, the flow through the column was stopped, the cell thermostated at 290 K and the racemization of the sample followed by polarimetry over the course of two half lives. The experimental racemization rate constant ($k = 2.4 \times 10^{-4}\ s^{-1}$) gives a racemization barrier $\Delta G^{\neq}$ of 91 kJ mol^{-1}. Since k(racemization) = $2k$(enantiomerization), the barrier for the enantiomerization process is 92.7 kJ mol^{-1} (at 290 K). This value most probably corresponds to a [β,β′]-two-ring flip process in which the α-ring passes through the plane of the double bond. Interestingly, the energy difference between

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0202-0200 $ 02.50/0

the three-ring flip and the enantiomerization barrier process is only 13.2 kJ mol^{-1}. This energy difference is reminiscent of the energy difference of 15.5 kJ mol^{-1} between the three-ring and the [α,β]-two-ring flip found for trimesitylethylene.[11] Not surprisingly, the energy required for the simultaneous introduction of two rings into the C=C plane is greater than twice that for one ring, as can be concluded from a calculation of the energy barrier for the zero-ring flip in the less crowded 1,1-diphenylethylene.[12] Finally, we would like to point out that, in retrospect, Adams' classical resolution of substituted styrenes[13] represents also the separation of residual enantiomers, provided that the twist angle Aryl–C=C differs from 90° in the ground state conformation of styrene.

In summary, we have shown that a suitably substituted triarylalkene propeller can be resolved into its residual enantiomers. Two rotational barriers were measured for **3**, a low energy diastereomerization barrier corresponding to a three-ring flip and a higher energy enantiomerization barrier corresponding probably to a [β,β']-two-ring flip.

Experimental Procedure

To a Grignard reagent prepared from 1-bromo-3-methoxy-2,4,6-trimethylbenzene [14] (2.45 g, 10.7 mmol) and magnesium (0.26 g, 10.8 mmol) in dry THF (35 mL) was added dropwise dimesitylketene[5,15] (3 g, 10.7 mmol) in dry THF (15 mL). After heating for 3 h at reflux, the mixture was poured onto HCl/ice and extracted with ether. The organic phase was separated, dried ($MgSO_4$) and the solvent was evaporated, leaving an oil, which according to NMR consisted mainly of **4**. Crude **4** was acetylated by refluxing for 5 h with Ac_2O (6 mL) in pyridine (21 mL). The mixture was poured into water and the resulting solid was treated with active charcoal and recrystallized three times from ethanol to afford analytically pure **3**, m.p. 122°C.

LiSrN—A Three Dimensional Structural Arrangement of Corner and Edge Sharing Orthorhombic Bipyramids, $NLi_{2/2}Sr_{4/4}$**

By *Gerhard Cordier, Axel Gudat, Rüdiger Kniep,* and *Albrecht Rabenau**

As part of our investigations related to the work of *Juza* et al.[1] on the phase relations and crystal structures of intermediate compounds in the lithium-metal-nitrogen ternary system,[2] we have prepared the compound LiSrN as metallically-lustrous single crystals. The product was obtained from the reaction of lithium nitride[3] with strontium (1 : 1 molar ratio) under a nitrogen atmosphere (1 atm) in a tantalum ampoule at 700°C; the melt was cooled to room temperature over a period of 12 hours. "LiSrN" was previously reported to have been prepared in 1970[4] and was indexed from X-ray powder diagrams as tetragonal ($a = 11.08$ Å, $c = 13.40$ Å). However, these powder diagrams have now been shown to actually correspond to a mixture of the phases LiSrN and Li_4SrN_2.[5] Our single crystal structure analysis of LiSrN reveals that it is in fact tetragonal but with $a = 3.924(3)$ Å and $c = 7.085(4)$ Å).[6]

The stoichiometric phase LiSrN is an isotype of the YCoC structural type which was first determined in 1986 by X-ray powder methods.[7] That the extent of occurrence of this very simple structural type is not restricted to the ternary transition metal carbides, but is also found in the realm of the main group elements, makes it of interest to examine more closely its structural features.

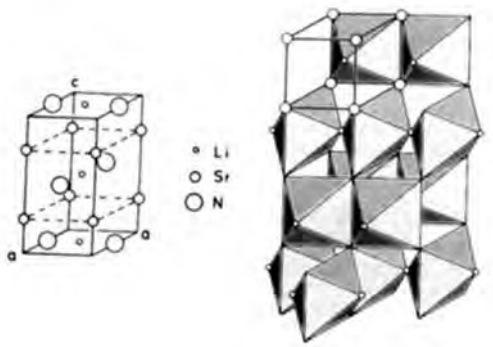

Fig. 1. LiSrN: unit cell (left) and a section of the structure assemblage (right, polyhedral representation). Explanation in text.

The metal cations (Fig. 1) are arranged as in the known cesium chloride structure. The anion occupies the center of two opposing faces of the cube (compressed here in one direction); along [001], the face centers are alternately occupied, each being turned 90° with respect to the other, thus resulting in the longer *c*-axis.[6] If one considers the crystal structure of LiSrN from the viewpoint of coordination polyhedra, then for each nitrogen atom an orthorhombic-bipyramidal environment (*mmm* symmetry) results. Lithium atoms occupy the apices of the flattened bipyra-

mids with a bond length (Li–N 1.962 Å) which is comparable with the axial bond distance (Li–N 1.938 Å) of the hexagonal-bipyramidally coordinated nitrogen atoms in Li_3N[8] and lies within the order of magnitude of the sum of the covalent single bond radii (Li–N 1.98 Å). In this way, extended chains of $[LiN]^{2-}$ result (cf. $[CoC]^{3-}$ in YCoC[7]) and are turned 90° with respect to one another in their sequence along [001]. The equatorial planes of the coordination bipyramids of the nitrogen atoms are composed of strontium atoms having tetrahedral coordination (Sr–N: 2.643 Å, Sr–N–Sr 95.85° and 84.15°).

The three-dimensional polyhedral framework (Fig. 1, right) consists of linear chains of lithium atom apex-shared bipyramids and linear chains of Sr–Sr edge-sharing bipyramids, which are bonded to each other through the common Sr corners without structural distortion. By this mode of connection ($NLi_{2/2}Sr_{4/4}$), the distance between the apical lithium atoms of the bipyramids (2×1.962 Å) corresponds exactly to the length of two unshared parallel edges (Sr···Sr) in the equatorial planes. One cannot generate this structural assembly with regular coordination octahedra, whereby the distance between two apical atoms is longer than the length of an edge by a factor of $\sqrt{2}$. A *c/a* ratio of 2.0 leads to a tetragonal-bipyramidal coordination (4/*mmm* symmetry) for the "interstitial" position; the *c/a* ratios of 1.880 and 1.804 for YCoC[7] and LiSrN, respectively, characterize their orthorhombic distortions.

Intramolecular Diels–Alder Reaction of Vinylsulfonic Acid Esters

By *Eva Bovenschulte, Peter Metz,** and *Gerald Henkel*

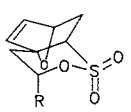
The intramolecularization of the Diels–Alder reaction has notably increased the synthetic potential of this cycloaddition, often making it easier to overcome reactivity, regiochemical, and stereochemical problems.[1] Moreover, the intramolecular variant makes it possible to control the configuration of up to four new chiral centers by an asymmetric center in the bridge which joins the diene and dienophile moieties.

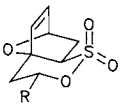
As part of a project concerned with the enantioselective synthesis of both enantiomers of nonactic acid[2] and its homologues, the monomeric building blocks of the macrotetrolide antibiotics,[3] we have investigated the intramolecular Diels–Alder reaction of the vinylsulfonic acid esters **3**.

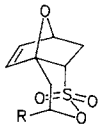
a, R = Me; **b**, R = Et; **c**, R = *i*Pr

The hydroxyalkylfurans **2** required for the synthesis of **3** are obtainable in good yields by lithiation of furan and subsequent alkylation with epoxides **1**.[4] With equimolar amounts of furan, *n*BuLi and **1**,[4] some double alkylation was observed; this side reaction can be completely suppressed by use of a slight excess of furan. **1a** and **1b** were employed as racemates; with (*R*)-**1c**[5] accessible in three steps from L-valine, the simple transition to an enantioselective synthesis should be demonstrated.

When the alcohols **2** are esterified with vinylsulfonic acid chloride,[6] the vinylsulfonates **3** are obtained which undergo a highly diastereoselective intramolecular Diels–Alder reaction already at room temperature to give the sultones **4**. No further diastereomers could be detected ^{1}H- or ^{13}C-NMR spectroscopically, even in the crude products. The sequence of the reaction steps—first, intermolecular esterification, and then intramolecular cycloaddition[7]—was confirmed for **4a** by spectroscopic characterization (^{1}H-, ^{13}C-NMR) of the labile intermediary sulfonate **3a**. The relative configurations of the tricyclic compounds **4** (*exo*-adduct, equatorial R) could be derived from the ^{1}H-NMR spectra, and in the case of **4a** unequivocally established by a crystal structure analysis.[8]







The high dienophilicity of vinyl sulfonates, which had already been observed in some intermolecular Diels–Alder reactions,[9] is underscored by the finding that the acrylate of **2a** (**2a** + acrylic acid chloride, Et_3N, THF 12 h, 25°C; 95% yield) does not cyclize even after heating in toluene at reflux for three days.

Results of MNDO[10,11] and MMPMI[10,12] calculations suggest a thermodynamic control of the relative configurations of **4** (Table 1).

If one assumes that the four possible diastereomers **4**–**7** are in equilibrium with one another by a reversible cycloaddition[9,13] of **3**, an almost exclusive formation of the *exo*-adduct **4** (**4** : **5** approx. 97 : 3) follows from the relative heats of formation listed in Table 1.

[†] Crystal structure analysis.

Table 1. Calculated heats of formation E_{rel} [kcal mol^{-1}] (relative to **4**) of the sultones **5**–**7** diastereomeric with **4** using MNDO [10, 11] (**a**, **b**) and MMPMI [10, 12] (**c**).

	 **5**	 **6**	 **7**
a	2.1	5.7	6.6
b	2.2	6.1	8.3
c	2.0	4.3	7.2

The conversion of the sultones **4** into actic acids and the extension of the title reaction to further 1,3-dienes are currently under investigation.

Experimental

2: The procedure given in Ref. [4a] was modified in that 1.4 equivalents of furan were employed.

1.20 g of (*R*)-**1c** [5] ($[\alpha]_D^{20} = +3.38$ (pure)) afforded, after Kugelrohr distillation at 60°C/0.5 mbar, 1.60 g (75%) of (*S*)-**2c** (correct MS high resolution) with $[\alpha]_D^{20} = -36.5$, $[\alpha]_{365}^{20} = -125.4$ (in each case $c = 0.54$ in $CHCl_3$). In an analogous way *rac*-**1a** furnished 65% *rac*-**2a** [4], while *rac*-**1b** afforded 74% *rac*-**2b** [4b].

4: A 0.24 M solution of the alcohol **2** in THF was treated with 2 equivalents of Et_3N. After cooling to 0°C, 1 equivalent of freshly distilled vinylsulfonic acid chloride **6** was added dropwise. After 1.5 h stirring at 0°C in the case of *rac*-**2a** and *rac*-**2b**, or 12 h stirring at room temperature in the case of the sterically stronger shielded alcohol (*S*)-**2c**, the reaction mixture was poured onto ice, saturated with NaCl and extracted three times with Et_2O. The combined organic phases were washed once with 2 N HCl and once with saturated $NaHCO_3$ solution, and then dried over $MgSO_4$. If the solvent is removed in vacuo at 0°C, the vinylsulfonic esters *rac*-**3a** and *rac*-**3b** can be isolated; their cyclization, however, already starts at room temperature and, is complete after maximally 3 h. If, the solvent is removed in vacuo at 40°C bath temperature, cycloaddition to give *rac*-**4a** and *rac*-**4b** takes place spontaneously. In the reaction of (*S*)-**2c**, no formation of (*S*)-**3c** was observed by thin-layer chromatography, and (+)-**4c** was isolated directly after removal of the solvent in vacuo even at 0°C. The crude sultones **4** were recrystallized from ether.—*rac*-**4a**: 3.69 g (90%) from 2.40 g *rac*-**2a**, m.p. 124°C; *rac*-**4b**: 2.00 g (92%) from 1.33 g *rac*-**2b**, m.p. 124°C; (+)-**4c**: 829 mg (87%) from 600 mg (*S*)-**2c**, m.p. 135°C, $[\alpha]_D^{20} = +17.3$, $[\alpha]_{365}^{20} = +38.7$ (in each case $c = 0.30$ in $CHCl_3$). Correct C,H analyses were obtained for **4a**–**c**.

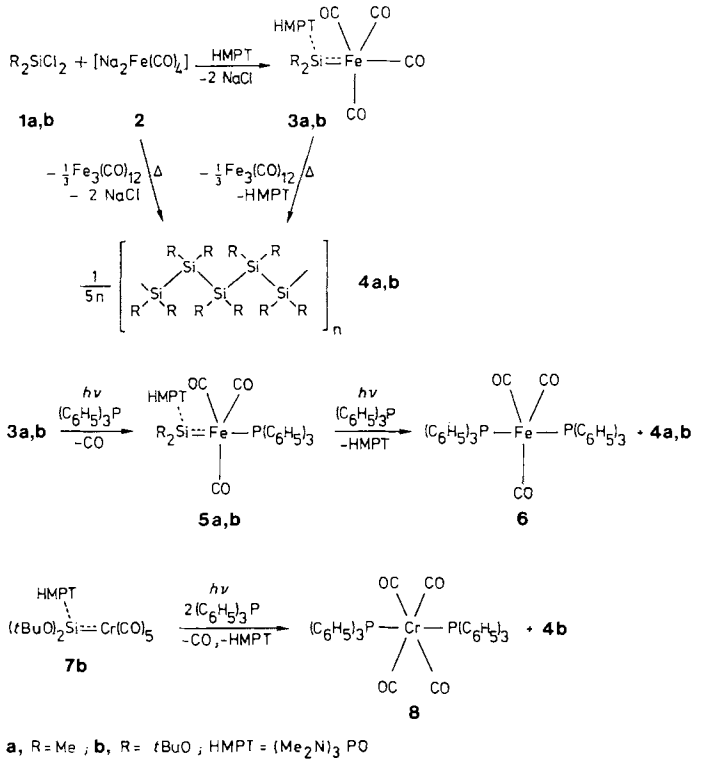
Identification of $[(OC)_4Fe{=}Si(CH_3)_2 \cdot \{(H_3C)_2N\}_3PO]$ as Intermediate in the Formation of Polysilanes from $(H_3C)_2SiCl_2$ and $[Na_2Fe(CO)_4]$**

By *Christian Zybill,* Dallas L. Wilkinson, Christian Leis,* and *Gerhard Müller*



Polysilanes are being used to an increasing extent as precursors for semi-conductors in electronics and optics and also for the preparation of ceramics.[1] These polymers are synthesized conveniently by coupling reactions of dichlorosilanes with sodium. More recently, the reactions of suitable monomers in the presence of transition metal compounds have attracted growing interest. For example, $C_6H_5SiH_3$ is catalytically converted by $Cp_2Zr(CH_3)_2$ into chain polymers with molecular weights of ca. 1500.[2–4] Until now, however, the mechanism of this reaction has been a matter of controversy, particularly with regard to the role of silanediyl (silylene) complexes as possible intermediates.[5]

Using the system **1a/2**, we have now been able to prepare the polysilane **4a** and, via a trapping reaction with HMPT (hexamethyl phosphoric triamide) at −45°C, to isolate the silanediyl complex **3a**. The polysilane **4a** can also be prepared by thermal decomposition of **3a**. The photolysis of **3a** in the presence of $(C_6H_5)_3P$ proceeds stepwise, yielding first the mono(phosphane) complex **5a** and then the bis(phosphane) complex **6** with concomitant formation of polysilane. The latter reaction can also be successfully carried out for the analogous *tert*-butoxy compounds **3b** and **7b**. The polymerization products were spectroscopically characterized in each case. A cryoscopic molecular weight determination for a sample derived from the thermal decomposition of **3a** gave $M_n = 550 \pm 10$.

3a is a coordination compound of the dimethylsilanediyl ligand, which is of great interest, particularly with regard to its reactivity. This complex has been thoroughly investigated spectroscopically (^{29}Si NMR: $\delta = 92.4$); the CO ligands are fluctional at room temperature and rotation about the Fe–Si bond is unhindered. A single crystal X-ray structural analysis[6] showed an axial coordination of the silanediyl ligand to the $Fe(CO)_4$ fragments (Fig. 1), which can also be inferred from the IR data. The crystal contains two crystallographically independent molecules, which exhibit only slight structural differences. The silicon atom has a distorted tetrahedral coordination geometry

with the HMPT molecule being only weakly bound to silicon via the oxygen atom (Si-O, 1.731(4) and 1.736(4) Å for the two independent molecules). The Fe-Si bond lengths are 2.279(2)/2.292(2) Å (compare: Si-O 1.730(3), Fe-Si

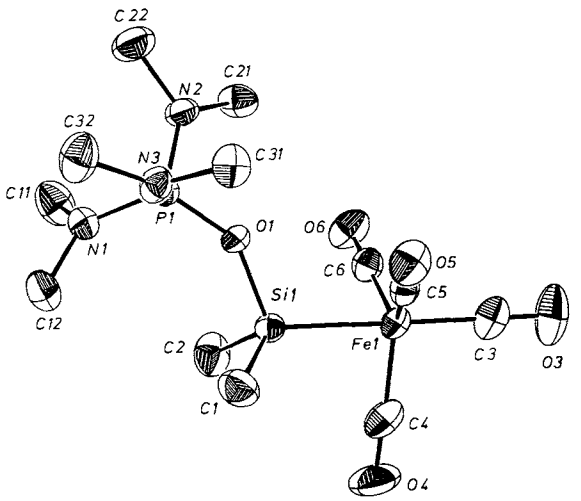

Fig. 1. Molecular structure of one of the crystallographically independent molecules of **3a** (ORTEP, 50% probability thermal motion ellipsoids, H atoms omitted). Important bond lengths [Å] and angles [°] for both molecules: Fe-Si 2.279(2)/2.292(2), Si-O 1.731(4)/1.736(4), Fe-C3 1.789(7)/1.782(7), Fe-C4 1.775(7)/1.734(7), Fe-C5 1.751(6)/1.762(7), Fe-C6 1.757(6)/1.743(6), Si-C1 1.871(6)/1.852(6), Si-C2 1.875(6)/1.862(6); Fe-Si-O1 110.4(1)/109.6(1), Fe-Si-C1 115.5(2)/116.8(2), Fe-Si-C2 115.4(2)/115.6(2), O1-Si-C1 103.8(2)/101.8(2), O1-Si-C2 102.7(2)/103.8(2), C1-Si-C2 107.7(3)/107.6(3).

2.289(3) Å in **3b**[5a]). Thus, replacing the *t*BuO substituents at silicon by methyl groups has surprisingly little effect on the structure of the silanediyl ligands. The results presented here provide evidence for the role of silanediyl complexes as intermediates in the polymerization of $(CH_3)_2Si$ units with the system **1a**/**2**. However, a more detailed understanding of this reaction, which can be both thermally and photochemically initiated, must await the results of further studies. Alternative mechanisms, are also plausible.[2-4, 7]

Experimental

3a: **1a** (0.75 g, 5.8 mmol) (distilled from K_2CO_3) was added dropwise to a solution of **2**·1,5 dioxane (2.0 g, 5.8 mmol) in THF (100 mL) at −45°C. After addition of HMPT (5 mL), the reaction mixture was stirred for a further 2 h, then filtered to remove NaCl. The solvent was removed in vacuo and the tarry residue re-extracted into THF (15 mL). Crystals of **3a** were obtained by cooling. **3a** can also be purified by column chromatography on a water cooled silica gel column with THF as eluent. The fast-moving, almost colorless fraction was collected. Yield 0.72 g (40%).

3a: ^{29}Si NMR (53.54 MHz, C_6D_6): $\delta = 92.4$ ($^2J(^{31}P,^{29}Si) = 17.5$ Hz); ^{1}H NMR (270.17 MHz, C_6D_6): $\delta = 0.77$ (s, 6H, H_3C–Si), 1.90 (d, 18H, $^3J(^{31}P,^1H) = 4.6$ Hz, H_3C–N); ^{13}C NMR (67.94 MHz, C_6D_6): $\delta = 11.00$ (H_3C–Si), 26.39 (d, $^2J(^{31}P,^{13}C) = 4.6$ Hz, H_3C–N), 218.87 (CO). Correct elemental analyses (C, H, N). **3b**: see [5a, c].

4 (from **1** and **2**): A mixture of **2**·1,5 dioxane (1.32 g, 3.8 mmol) and **1a** (5 mL) or **1b** (5 mL) in 50 mL THF was heated under reflux for 1 h. The reaction mixture was extracted into THF and the extract absorbed on a 10 cm Florisil column. $Fe_3(CO)_{12}$ was eluted with THF after which the Florisil was extracted with THF. Removing the solvent in vacuo afforded **4a** (121 mg) or **4b** (154 mg).

4a: ^{29}Si NMR (C_6D_6): $\delta = -22$ (br.); ^{1}H NMR (C_6D_6): $\delta = 0.2$ (br.); IR (KBr): no Si–O bands; MS (EI): masses up to *m/z* 420 observed, basis peak *m/z* 57; cryoscopic molecular weight determination in dioxane; $M_n = 550 \pm 10$. Correct elemental analyses (C, H). **4b**: ^{29}Si NMR (C_6D_6): $\delta = -91.2$ (br.); ^{1}H NMR (C_6D_6): $\delta = 1.2$ (br.).

4 (from **3**): 1 g of **3** was heated in 30 min to 120°C in vacuum and the temperature maintained at this value for 10 min. After cooling, the polysilane was extracted into THF. Yields: **4a**, 120 mg; **4b**, 80 mg.

5: A solution of **3a** (0.93 g, 3 mmol) or **3b** (1.54 g, 3 mmol) in THF (100 mL) was irradiated at −70°C in the presence of $(C_6H_5)_3P$ (787 mg, 3 mmol) for 2 h using a high-pressure Hg lamp. Removal of the solvent in vacuum afforded **5a** or **5b** in quantitative yield.

5a: ^{1}H NMR (C_6D_6): $\delta = 0.7$ (s, 6H, CH_3), 2.5 (d, $^3J(^{31}P,^1H) = 10.5$ Hz, H_3C–N), 7.0–7.3 (br, 15H, C_6H_5). **5b**: ^{1}H NMR (C_6D_6): $\delta = 1.7$ (s, 18H, *t*BuO), 2.5 (d, $^3J(^{31}P,^1H) = 10.5$ Hz, 18H, HMPT), 7.0–7.3 (br., 15H, C_6H_5); ^{31}P NMR (C_6D_6): $\delta = 87.8$.

6: Further irradiation of **5** at −40°C in the presence of $(C_6H_5)_3P$ (molar ratio 1:2) gave the phosphane complex **6** and the polysilane **4**, which was separated on Florisil as described above. Yield of **6**: 81%.

6: ^{1}H NMR (C_6D_6): $\delta = 7.1$ (br., 18H); 7.5–8.0 (m, 12H); ^{31}P NMR (C_6D_6): $\delta = 95.2$. Correct elemental analyses (C, H).

8: The synthesis of **8** from **7b** [5c] was carried out similarly to the synthesis of **6**: Yield: 79%.

8: ^{1}H NMR (C_6D_6): $\delta = 7.1$ (br., 18H), 7.5–8.0 (m, 12H); ^{31}P NMR (C_6D_6): $\delta = 79.6$. Correct elemental analyses (C, H).

Bis[(cyclooctane-1,5-diyl)di(pyrazol-1-yl)borato]cobalt: a Polypyrazolylborate Complex with Two Agostic Hydrogen Bonds**

By *Swiatoslaw Trofimenko, Joseph C. Calabrese,* and *Jeffery S. Thompson**

In this communication, we report on the synthesis and coordination chemistry of a novel polypyrazolylborate ligand, (cyclooctane-1,5-diyl)di(pyrazol-1-yl)borate $\mathbf{1}^{\ominus}$, prepared from 9-borabicyclo[3.3.1]nonane (BBN), pyrazole (Hpz), and potassium pyrazolide. This ligand is similar to the well-known dialkyl(pyrazol-1-yl)borate ligands $\mathbf{2}^{\ominus}$ in having two pyrazolyl groups bonded to the boron atom, but differs in that the alkyl substituents are part of a rigid bicyclic ring system. The results presented herein demonstrate that the Co^{II} coordination chemistry of $\mathbf{1}^{\ominus}$ is different from that of the ligands $\mathbf{2}^{\ominus}$[1-4] since it acts as a tridentate ligand binding through the two pyrazolyl nitrogen atoms and an agostic hydrogen bond to the metal ion.

$\mathbf{1}^{\ominus}$

$[R_2B(pz)_2]^{\ominus}$ $\mathbf{2}^{\ominus}$
$\mathbf{2a}^{\ominus}$, R = Me; $\mathbf{2b}^{\ominus}$, R = Et; $\mathbf{2c}^{\ominus}$, R = *n*Bu

Compounds containing agostic C-H-M bonds have been of great interest because of the proposed role of such interactions in addition/elimination reactions between alkanes and transition metal ions and in olefin polymerizations.[5-8] Although the ligand $\mathbf{2b}^{\ominus}$ provided some of the early examples of agostic hydrogen bonding in Mo chemistry, because of the scorpioid curling of its pseudoaxial ethyl group toward the metal ion, it has the disadvantage of exchange processes among the coordinated methylene hydrogen atoms and of inversion of the $B(pz)_2$-M ring at higher temperatures.[2-4] The new ligand $\mathbf{1}^{\ominus}$ has a single, fixed C-H bond directed towards the metal ion.

Metal complexes with $\mathbf{1}^{\ominus}$ were prepared in a straightforward manner, similar to the procedures used to prepare other polypyrazolylborate ligands and complexes.[1] Although the ligand is prepared as its potassium salt, it is more easily handled as the thallium salt Tl(**1**). Both the thallium salt and the cobalt complex **3**, have a sharp band in the IR spectrum indicative of an agostic bond:[5] 2766 cm^{-1} for Tl(**1**) and 2690 cm^{-1} for **3**. The color of **3** is not deep purple, like that of the known tetrahedral complexes **4**[2] and **5**,[3] but rather pale yellow-red, resembling, in that respect, the octahedral Co^{II} complexes.

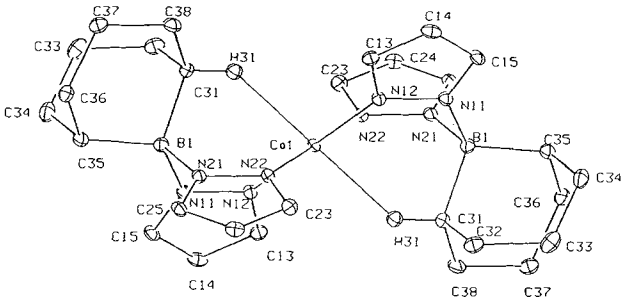

Fig. 1. Molecular structure of **3**. Selected bond lengths [Å]: Co-N12 1.925(3), Co-N22 1.920(3), Co-H31 2.166, Co-C31 2.942(4).

An X-ray structure determination[9] confirmed the pseudooctahedral structure involving two agostic C-H-M bonds (Fig. 1). The 2.166 Å Co-H distance compares well with the previously reported distance of 2.26 Å in the structually more complicated molecule **6**.[10] **3** contains a Co^{II} ion in a rare square planar arrangement with the four pyrazolyl groups, but also with apical agostic hydrogens. In solution, and especially on heating, **3** develops a reddish-purple color, that may be due to partial detachment of the C-H-M bonds and possibly a twist of the two $\mathbf{1}^{\ominus}$ ligands towards a tetrahedral geometry. However, on crystallization, the original material is recovered.

The ligand $\mathbf{1}^{\ominus}$ clearly imposes an unusual coordination geometry upon the Co^{II} ion, unlike that observed with other polypyrazolylborate ligands.[11] The present work, together with our other recent publications,[12] broadens the range of compounds that can be prepared with this growing class of polypyrazolylborate ligands through proper choice of substituents on both the pyrazole ring and the boron atom.

Experimental

K(**1**): Pyrazole (30.4 g, 0.44 mol) and dry KOH pellets (11.2 g, 0.2 mol) were stirred and refluxed in toluene (500 mL) in a 1 L flask. Water was removed by means of a Dean-Stark trap. When all of the water had been removed, 400 mL of a 0.5 M solution of 9-borabicyclo[3.3.1]nonane in THF was added

dropwise at such a rate that THF distilled over slowly. The evolution of hydrogen gas was followed by means of a wet-test meter. When the addition was complete and 5 L of hydrogen had evolved, the slurry was concentrated to approximately 400 mL, cooled slightly, and diluted with hexane to 1 L. A white precipitate formed. The solution was filtered while hot. The white precipitate was then washed with hexane and air-dried to afford K(**1**) as a white solid (54 g, 93% yield), which was used to prepare the other metal derivatives.

Tl(**1**) and [Co(**1**)$_2$] **3**: these compounds were prepared by adding an aqueous solution of $TlNO_3$ or $Co(NO_3)_2$ to a methanolic solution of K(**1**). The precipitated products were isolated by filtration, washed with water, then with methanol, and air-dried. The materials were recrystallized from toluene. Correct elemental analyses (C, H, N) were obtained.

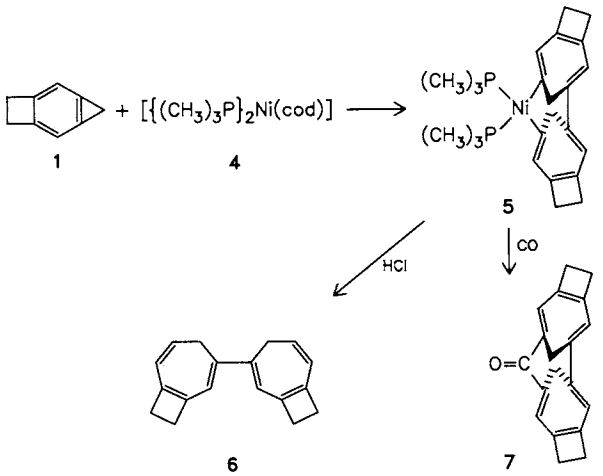
Structure, Deformation Electron Densities, Photoelectron Spectra, and Reactivity of 3,4-Dihydro-1*H*-cyclobuta[*a*]cyclopropa[*d*]benzene**

By *Dieter Bläser, Roland Boese,* Waldemar A. Brett, Paul Rademacher, Harald Schwager, Amnon Stanger,* and *K. Peter C. Vollhardt**

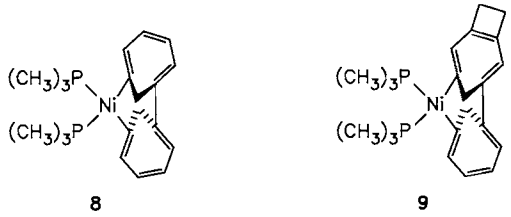
The title compound **1**[1] ranks among the most strained fused benzenes known.[2] Simple resonance pictures suggest increased double bond character[3] at the sites of ring fusion in **1** compared to that observed in 1*H*-cyclopropabenzene **2** and 1,2-dihydrocyclobutabenzene **3** and thus also suggest unusual reactivity in ring-opening transformations.

1 **2** **3**



Interestingly, however, MNDO[4] calculations reveal that the energies of the frontier orbitals and the size of their coefficients at the sites of ring fusion in **1** are very similar to those found in the model systems **2** and **3**, indicating that, should attack by a metal be frontier-orbital-controlled, any observable rate differences may be attenuated. A theoretical estimation of the enthalpies of hydrogenation of the respective double bonds gave values of −48.6 (**2**), −22.3 (**3**), and −51.9 (cyclopropene bond in **1**) kcal mol^{-1}.[4c] Clearly (and not surprisingly) conversion of the cyclopropene (and not cyclobutene) carbons in **1** is favored thermodynamically, but (and in conflict with expectation) not much more than the cyclopropene bond of **2**.

Preliminary experiments showed that **3** is not attacked by (η^4-1,5-cyclooctadiene)[bis(trimethylphosphane)]nickel **4** (THF, 20–60 °C, 3 d); the only new products are metallic nickel and $Ni[P(CH_3)_3]_4$. In contrast, addition of **1** (2 equiv.)[5] to **4** (pentane, −78 to 20 °C, 3 h), resulted cleanly in the extremely air-sensitive metallacycle **5** (79%)[6]—a reaction that proceeded in a manner completely analogous to that of **2** to give **8**.[5a,f] The assignment of the *anti*-conformation of **5** is tentative and follows by analogy with the structure of the metallacycle **8** that has been proven by an X-ray analysis.[5f] Like **8**,[5a,f] compound **5** is hydrolyzed by HCl to **6** and carbonylated by CO to **7**.[7]



A competition experiment (**1** : **2** : **4** = 8 : 8 : 1, pentane in preparative, [D_8]THF in analytical ^{1}H-NMR runs carried out to 30% and 100% completion) gave results completely irreconcilable with a simple bond-fixation analysis but

[**] This work was supported by the Director, Office of Energy Research, Office of Basic Energy Sciences, Materials Science Division of the U.S. Department of Energy (Contract No. DE-AC03-76 SF 00098) and by the National Institutes of Health (CA 20713). *H. S.* was the recipient of an Otto-Hahn fellowship and a Max-Planck Institute for Coal Research (Mülheim) fellowship (1986–1987), *A. S.* acknowledges a Dr. Chaim Weizmann fellowship (1985–1987).

gratifyingly consistent with the calculations: not only were all possible coupling products **5**, **8**, an **9** formed, but incorporation of the less strained building block **2** was in fact dominant (in all cases, **5** : **8** : **9** = 1 : 4 : 4)! Assuming that the relative reactivity of **1** and **2**, respectively, is the same in the two consecutive (presumably η^2)[5c,8] metal complexation steps, its value would be approximately 1 : 2.

The reactions of the substrates **1** and **2** with **4**, with or without added ligands, are in excellent agreement with direct (perhaps HOMO controlled)[4b] attack of the arene on **4** (or its η^2-1,5-cyclooctadiene isomer bearing an open coordination site) followed by 1,5-cyclooctadiene dissociation, inhibited strongly at low concentrations of the aromatic substrate, less so when these are high. To shed light on the unexpectedly low reactivity of **1**, an X-ray analysis[10] was carried out at 100 K (Fig. 1) and the result compared with those for **2**[9a] and **3**.[9b]

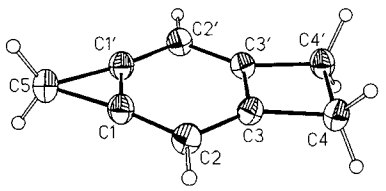

Fig. 1. Crystal structure of **1** (ellipsoids correspond to the 50% probability surface) [10] at 100 K. Distances [Å] and angles [°] (maximum standard deviations 0.001 Å and 0.1°, respectively), values after a libration correction [11] in parentheses: C1–C2 1.385 (1.388), C2–C3 1.405 (1.407), C3–C4 1.522 (1.524), C1–C5 1.508 (1.510), C1–C1′ 1.349 (1.353), C3–C3′ 1.402 (1.406), C4–C4′ 1.579 (1.583); C1–C2–C3 109.2, C1′–C1–C2 170.2, C1–C5–C1′ 53.2, C2–C3–C4 142.2, C3–C4–C4′ 86.7, C1′–C1–C2 126.3, C5–C1–C1′ 63.4, C2–C3–C3′ 124.4, C3′–C3–C4 93.3.

In **1**,[12] the bonds of the cyclopropene ring are 0.015–0.022 Å longer than those in **2**, and the bonds of the cyclobutene ring are 0.003–0.020 Å longer than in **3**. The largest differences in the bond distances of **1** and **2** are found for the bonds C1–C2 and C1′–C2′ (0.022 Å). The corresponding bond angle at C2 and C2′ is extremely small (109.2°), reduced by 4.0° and 6.8°, respectively, compared to those in **2** and **3**. Thus, there is an additive expansion effect of the double annelation in **1**, the reasons for which may be gleaned from the electron density maps (Fig. 2a).

Consistent with the assumption that the deviations of the electron density maxima from the direct C–C connections is a measure of strain (Fig. 2b), the cyclopropene ring pushes its electrons more strongly (0.27 Å) into the π-system than its cyclobutene counterpart (0.10 Å). The electron densities are moved into the exocyclic direction with respect to the bonds C1–C2 and C2–C3, a result of the intracyclic shifts of the annelated bonds. This shift is smaller with respect to C1–C2 (0.04 Å) than that with respect to C2–C3 (0.15 Å). The extent of this effect is also evident in the bond angles that can be assigned to the electron density maxima (Fig. 2b). In the cyclopropene moiety the "outside" angle is 98° instead of 53.2° for the nucleus–nucleus connection, that associated with the annelating carbon 170.2° instead of 141°; in the case of the four-membered ring the latter value is 130° instead of 142.2°. Even the smallest bond angle in the benzene nucleus is widened from 109.2° to 117°.

The X–X deformation electron density map perpendicular to the molecular plane in the C_2-axis reveals a π-contribution by its elliptical shape along the distances C1–C1′ and

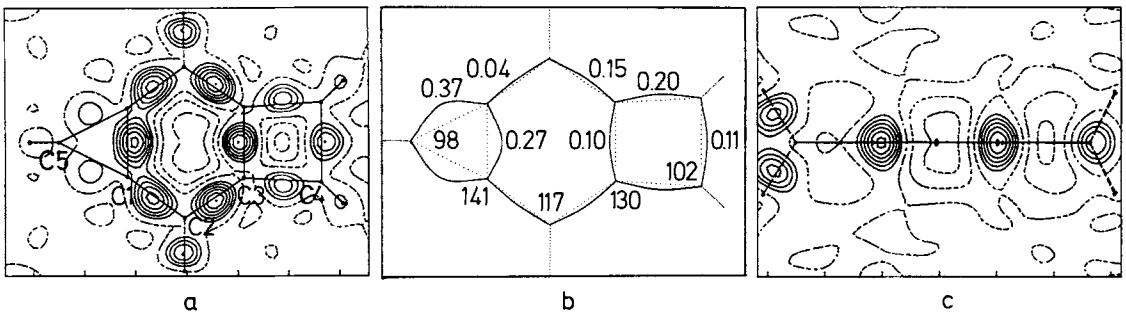

Fig. 2. a) Contour lines of the X–X deformation electron densities in the molecular plane of **1**. Unbroken lines: positive values and zero, distance 0.05 e/Å^3; broken lines: negative values, distance 0.1 e/Å^3. b) Electron density maxima shifts (decimal points in Å) of the internuclear distances (dotted); the unbroken lines lead in every case from nucleus to nucleus via the electron density maximum. The quoted angles [°] refer to the direct electron density maximum-nucleus-electron density maximum connections. The estimated standard deviations are 0.02 Å and 1°, respectively. c) Contour lines of the X–X deformation electron density lines perpendicular to the molecular plane in the C_2-axis of the molecule (edge view; left cyclopropene part, right cyclobutene part). Other details as in Fig. 2a.

C3–C3′, respectively, compared to the radial distribution along the single bond C4–C4′ (Fig. 2c). To counter the effects of the doubly induced strain, the system undergoes expansion, thus avoiding an even greater displacement of the electron density maxima from the direct internuclear connections.

That the structure of **1** is unusual is also reflected in its photoelectron spectrum.[13] Thus, not only are the first two ionization bands (π_2, π_3) shifted to lower energies, but their splitting (0.84 eV) is noticeably larger than those in **2** (0.66 eV) and **3** (0.54 eV).[14] Most importantly, and in contrast to 1,2,4,5-dicyclobutabenzene,[15] their average value (8.72 eV)[13] is ca. 0.1 eV lower than that estimated assuming a simple additive effect of the two annelated rings (C_6H_6 9.25 eV, **2** 9.15 eV, **3** 8.93 eV), consistent with the observed expansion of the aromatic ring. Ab initio calculations[16] indicate an overall stabilizing effect of this deformation, the sum of the heats of formation of benzene and **1** being lower than that of **2** and **3**.

2,4,6-Triisopropylphenylcopper, a New Tetranuclear Organocopper Aggregate with Unsymmetrically Bridging σ–π Bonded Aryl Ligands**

By *Dominique Nobel, Gerard van Koten**, and *Anthony L. Spek*

In organic synthesis, there are many widely-used reactions which employ organocopper reagents or in which organocopper species are important intermediates; the Ullmann and Castro reactions are typical examples.[1] However, the available structural information for organocopper species is limited, owing to their high reactivity and to the difficulties encountered in preparing pure compounds and in growing single crystals.[2] Earlier results from this laboratory demonstrated that it was possible to isolate stable, well-defined aryl copper complexes when a coordinating function was introduced in the ring at the *ortho*-position(s). A similar stabilizing effect arises when steric hindrance is introduced near the metal–carbon bond. Representative structures are those of pentameric mesitylcopper **1**,[3] which contains three-center two-electron bonded mesityl ligands, and of monomeric 2,4,6-triphenylphenylcopper **2**,[4] which possesses a two-center two-electron σ-bonded aryl group.

[2,4,6-$Me_3C_6H_2Cu$]$_5$ **1** 2,4,6-$Ph_3C_6H_2Cu$ **2**

Herein, we report on the synthesis, characterization and reactivity of the new organocopper compound 2,4,6-triisopropylphenylcopper **3**, whose structure features an unsymmetrically bridging 2,4,6-triisopropylphenyl ligand, a novel

bonding situation which provides the missing link between the two extremes represented by **1** and **2**.

[2,4,6-iPr$_3$C$_6$H$_2$Cu]$_4$ **3**

Compound **3** is conveniently prepared by the reaction of 2,4,6-iPr$_3$C$_6$H$_2$Li and CuBr in ether at 243 K, and can be isolated as a pale yellow, air and moisture sensitive solid. Crystals of **3** are thermally stable (decomp. 215°C) and dissolve readily in aprotic organic solvents including pentane. A cryoscopic molecular weight determination for **3** in benzene gave a concentration-independent molecular weight of 613 which is higher than that expected for the monomer (M = 266.9). This result, which indicates a degree of association of ca. 2.3, is good evidence for the presence of aggregated species in solution. At 198 K, the ^{1}H NMR spectrum of **1** ([D$_8$]toluene, 200 MHz) exhibits two equally intense sets of signals for the *ortho*-isopropyl substituents, with the CH resonances at δ = 4.47 and 3.50 and those of the CH$_3$ groups at δ = 1.79 and 1.04. At the same temperature, the ^{13}C NMR spectrum (50.32 MHz) shows not only signals attributable to two different *ortho*-isopropyl groups and a single *para*-isopropyl substituent, but also six separate signals for the carbon atoms of the aromatic rings. These ^{1}H and ^{13}C NMR data indicate that in **3**, although all the aryl ligands are equivalent, the molecular structure must possess a particular symmetry. On raising the temperature of the solution, spectral changes occur which are consistent with the occurrence of intermolecular exchange processes. For example, in the ^{1}H NMR spectrum, the sets of resonances attributed to the *ortho*-isopropyl groups coalesce at ca. 273 K, and at 293 K afford two broad signals at δ = 3.88 (CH) and 1.29 (CH$_3$).

A single crystal X-ray structural analysis[5] (Fig. 1a) showed that **1** exists in the solid state as a tetranuclear aggregate with (crystallographic point group $\bar{4}$) containing a slightly distorted square planar Cu$_4$ array (characterized by Cu–Cu distances of 2.445(1) Å and a Cu–Cu–Cu angle of 89.86(3)°) with each Cu–Cu edge bridged by the C_{ipso} of a 2,4,6-triisopropylphenyl unit.

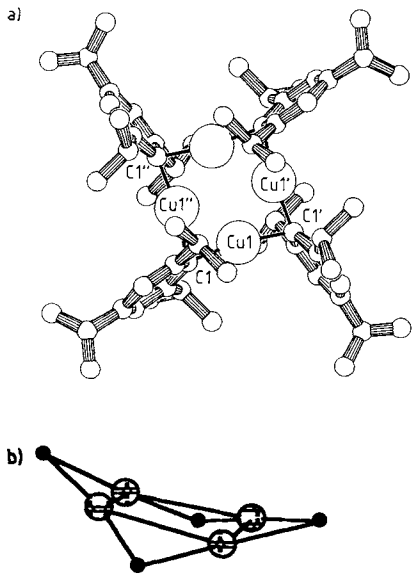

Fig. 1. a) Crystal structure of **3**. Selected bond lengths [Å] and angles [°]: Cu1–Cu1′ 2.445(1), Cu1–C1 1.958(7), Cu1″–C1 2.018(7); Cu1″–Cu1–Cu1′ 89.86(3), C1–Cu1–C1′ 169.8(3). b) Schematic representation of **3** showing the puckering of the Cu$_4$C$_4$ ring.

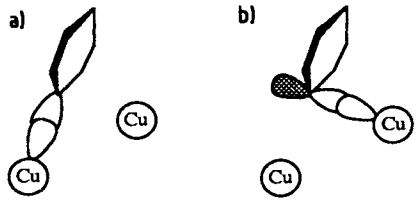
The resultant eight-membered Cu$_4$C$_4$ ring is distinctly puckered (Figure 1b) with the four Cu atoms and the four C_{ipso} atoms alternately situated ±0.0660(2) and ±0.578(7) Å, respectively, above and below the mean Cu$_4$ plane. The bridging mode of the aromatic rings is highly unsymmetrical, as illustrated both by the significant differences between the Cu1–C1 (1.958(7) Å) and Cu1″–C1 (2.018(7) Å) bond lengths and by the 67.4(3)° angle between the aromatic plane and the Cu1–Cu1″ vector.

A possible rationale for this geometry is that the aromatic C_{ipso} atom is σ-bonded to one copper center (Cu1) but π-bonded to the other (Cu1″); this is shown schematically in Figure 2. This bonding description is supported by



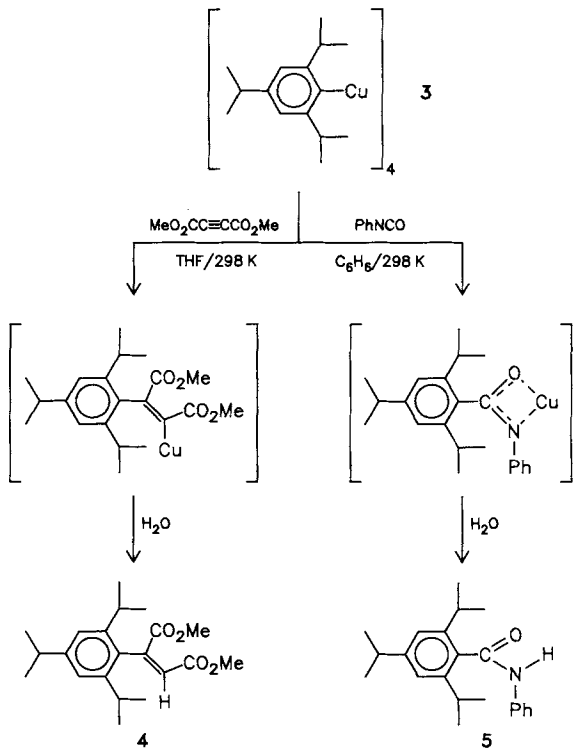


Fig. 2. Molecular orbitals involved in the σ- and π-interactions of **3**.

the almost linear C_{ipso}–Cu–C_{ipso} arrangement with an angle of 169.8(3)°. Consequently, the cluster might be best described as resulting from the association of four monomeric iPr$_3$C$_6$H$_2$Cu units having two-center two-electron bonds, whereby stabilization is provided by an interaction of the electron-rich π-orbital of C_{ipso}, perpendicular to the plane of the aryl ring, with an empty orbital of a neighboring copper atom.

These features in **3** and those found in complexes such as **1** and **2** confirm that steric factors can greatly affect the bonding mode of organic groups in organocopper com-

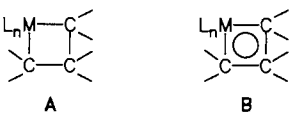
pounds: an increase of the steric requirements of the *ortho*-substituents (e.g., Ph > *i*Pr > Me) in arylcopper complexes results in an increased tendency to form two-center two-electron Cu-C bonds which are shielded by the *ortho*-substituents, thus hindering interactions with other mononuclear units (e.g. in **2**).

The peculiar bonding mode found in **3** is reflected in its unusual reactivity towards electrophilic substrates, such as dimethylacetylene dicarboxylate (DMADC) and phenyl isocyanate. At ambient temperature, both substrates insert into the Cu-C bond of **3** affording, after hydrolysis, the corresponding alkene **4** or amide **5** in quantitative yield.

The alkyne insertion reaction is normally only exhibited by hetero cuprate reagents (i.e., RCuMX species, M = Li, MgX),[6] while the isocyanate reaction is unprecedented for organocopper reagents. Preliminary experiments involving the *tert*-butyl analogue of **3** indicate a similar diverse reactivity. It can be anticipated that the sterically demanding *ortho-tert*-butyl groups would result in this compound being dimeric or even monomeric. However, its high instability has until now hampered the growth of crystals suitable for an X-ray analysis.

Experimental

3: A diethyl ether solution of triisopropylphenyllithium (1.0 M, 32 mL) was added at 233 K to a stirred suspension of CuBr (4.5 g, 31.3 mmol) in Et_2O. The reaction mixture was stirred for 1 h and the solvent removed in vacuo. The pale yellow residue was recrystallized from pentane to give **3** as yellow prisms in 50% yield. ^{1}H NMR (298 K, [D$_8$]toluene): $\delta = 1.21$ (d, 6H, *p*-CH(CH_3)$_2$, $^3J = 6.9$ Hz), 1.29 (d, 12H, *o*-CH(CH_3)$_2$, $^3J = 6.5$ Hz), 2.74 (sept., 1H, *p*-C*H*(CH$_3$)$_2$, $^3J = 6.9$ Hz), 3.88 (sept, 2H, *o*-C*H*(CH$_3$)$_2$, $^3J = 6.5$ Hz), 7.01 (s, 2H, Aryl-H). ^{13}C{^{1}H} NMR (298 K, [D$_8$]toluene): $\delta = 24.09$ (*p*-CH(*C*H$_3$)$_2$), 27.40 (*o*-CH(CH$_3$)$_2$), 34.96 (*p*-*C*H(CH$_3$)$_2$), 41.77 (*o*-*C*H(CH$_3$)$_2$), 120.86 (*m*-C), 136.17 (Cu-C), 152.58 (*p*-C), 167.00 (*o*-*C*H(CH$_3$)$_2$).



Reactions with DMADC and PhNCO: To a solution of **1** (0.26 g, 1 mmol) in benzene was added two equivalents of DMADC or PhNCO. After stirring for 1 h, the reaction mixture was poured into a 10% aqueous NH_4Cl solution. The organic layer was dried and the solvent removed in vacuo to afford a pale yellow solid which was recrystallized from pentane. **4**: m.p. 378 K. ^{1}H NMR ($CDCl_3$): $\delta = 1.16$ (d, 6H, *o*-CH(CH_3)$_2$, $^3J = 6.8$ Hz), 1.21 (d, 6H, *o*-CH(CH_3)$_2$, $^3J = 6.8$ Hz), 1.25 (d, 6H, *p*-CH(CH_3)$_2$, $^3J = 6.9$ Hz), 3.24 (sept, 1H, *p*-C*H*(CH$_3$)$_2$, $^3J = 6.9$ Hz), 3.89 (sept, 2H, *o*-C*H*(CH$_3$)$_2$, $^3J = 6.8$ Hz), 3.60 (s, 3H, OCH_3), 3.61 (s, 3H, OCH_3), 5.95 (s, 1H, HC=C), 7.03 (s, 2H, Aryl-H). FD-MS: *m/z* 346 (5%, $M^{\oplus}$), 331 (9, $M^{\oplus} - Me$), 286 (100, $M^{\oplus} - HCO_2Me$). **5**: m.p. 456 K. ^{1}H NMR ($CDCl_3$): $\delta = 1.26$ (d, 12H, *o*-CH(CH_3)$_2$, $^3J = 6.8$ Hz), 1.28 (d, 6H, *p*-CH(CH_3)$_2$, $^3J = 6.9$ Hz), 2.92 (sept, 1H, *p*-C*H*(CH$_3$)$_2$, $^3J = 6.9$ Hz), 3.10 (sept, 2H, *o*-C*H*(CH$_3$)$_2$, $^3J = 6.8$ Hz), 7.06-7.68 (8H, Aryl-H and NH). FD-MS: *m/z* 323 (5%, $M^{\oplus}$), 231 (100%, $M^{\oplus} - PhNH$).

Reactions of Mono- and Dinuclear Metal-Alkylidyne Complexes with Phosphaalkynes: C≡P and C≡Mo Metathesis**

By *Anthony F. Hill, Judith A. K. Howard, Thomas P. Spaniol, F. Gordon A. Stone** and *Jürgen Szameitat*

Transition metal-mediated alkene- and alkyne-metathesis processes are considered to proceed via the cycloaddition of metal-carbon and carbon-carbon multiple bonds to form, often transiently, metallacyclobutanes **A** or metallacyclobutadienes **B**, respectively.[1,2] Guided by the isolobal analogy,[3] which relates the frontier orbitals and valence electrons of the fragments CR, P and d^5-ML_5 (M = Mo or W, L = ligand), we have addressed the question of cycloaddition and metathesis in reactions of a phosphaalkyne with both mononuclear and heterobinuclear metal-alkylidyne complexes.

Treating *t*BuC≡P **3**[4] with the alkylidynemolybdenum complex **2**, prepared from **1** and K[$H_2B(pz)_2$],[5] affords, in quantitative yield, the neopentylidynemolybdenum compound **4**. A plausible intermediate in this transformation is

Aryl = *o*-$H_3COC_6H_4$; X = OCH_3; pz = pyrazol-1-yl

the 1-phospha-3-molybdacyclobutadiene **5**, which may either retro-eliminate **3** or afford the phosphaalkyne **6**. The instability of the latter would then drive the process towards the observed quantitative formation of **4**.

We have so far been unable to isolate a mononuclear metal complex structurally akin to **B**. However, our extensive studies of the reactions of bi- and trinuclear metal-alkylidyne complexes with alkynes have led to the discovery of many dimetal compounds of type **7** which may be

7

regarded[6a,7] as metallacyclobutadienes stabilized by 'complexation' with metal–ligand fragments.[3,8] Accordingly, the bimetallic p-tolylmethylidyne complex **8**, which reacts with PhC≡CPh[7c] to yield such an 'Fe(CO)$_3$' coordinated tungstacyclobutadiene **9**, was treated with **3**. In this manner, complex **10** was isolated and fully characterized in-

8

9 **10** **11**

Cp* = η^5-$C_5(CH_3)_5$; Tol = p-$H_3CC_6H_4$

cluding an X-ray diffraction study.[9] The latter established the structure shown in Figure 1, which may be viewed as a 1-phospha-3-tungstacyclobutadiene moiety coordinated to an Fe(CO)$_3$ group.[6b]

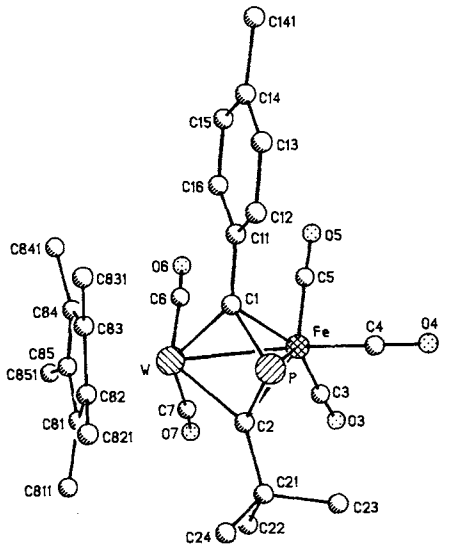

Fig. 1. Molecular structure of complex **10**. Bond lengths [Å]: C(1)-Fe 2.11(2), C(1)-P 1.76(2), C(1)-W 2.18(2), C(2)-Fe 2.14(1), C(2)-P 1.77(1), C(2)-W 2.22(1), Fe-P 2.34(1), W-Fe 2.720(2).

Despite the displacement (0.649 Å) of the W atom from the plane defined by C(1), C(2) and P, the close similarity between the bonds between P and C(1) [1.76(2)] and C(2) [1.77(1) Å], both clearly multiple in nature, indicates that considerable electron delocalization occurs within the ring. The gross structural features of **10** are directly comparable with those of **9** and attest to the validity of the isolobal replacement of RC≡CR and P≡CR units in **9** and **10**, or alternatively 'P' and d^5-ML$_5$ groups in relating **10** to the recently reported compound **11**.[10]

Experimental

2: A suspension of **1** (6.50 g, 10.0 mmol) and K[$H_2B(pz)_2$] (1.90 g, 1.02 mmol) in Et_2O (100 mL) was stirred for 3 h, filtered through a plug of alumina (3 × 3 cm) and then freed of solvent under reduced pressure to provide yellow microcrystals of **2** (5.04 g, 93%). IR (Et_2O): $\tilde{\nu}$(CO) = 1919 cm^{-1}; $^{13}C\{^1H\}$ NMR: δ = 281.3 (t, J(PC) = 26 Hz, C≡Mo), 235.6 (t, J(PC) = 16 Hz, CO); $^{31}P\{^1H\}$ NMR (85% H_3PO_4, external): δ = 161.2.

4: Diethyl ether (3 mL) and **3** (70 mg, 0.70 mmol) were condensed onto solid **2** (0.35 g, 0.55 mmol) at −78 °C. The mixture was warmed to room temperature, stirred for 18 h and freed of volatiles in vacuo. The residue was chromatographed on silica gel at −40 °C eluting with Et_2O. Removal of solvent from the major yellow eluate provided microcrystals of **4** (0.27 g, 84%). IR (Et_2O): $\tilde{\nu}_{max}$(CO) = 1912 cm^{-1}; $^{13}C\{^1H\}$ NMR: δ = 312.7 (t, J(PC) = 24 Hz, C≡Mo), 235.5 (t, J(PC) = 15 Hz, CO); $^{31}P\{^1H\}$ NMR: δ = 161.0.

10: A solution of **8** [7c] (0.21 g, 0.34 mmol) in THF at −78 °C was treated with **3** (60 mg, 0.60 mmol). The mixture was stirred at −5 °C for 10 min, and then freed of volatiles in vacuo. The residue was crystallized from toluene/hexane (1/3) to afford dark green crystals of **10** (0.13 g, 52%). IR (hexane): $\tilde{\nu}_{max}$(CO) = 2040vs, 1985 s, 1975 vs, 1911 m cm^{-1}; $^{13}C\{^1H\}$ NMR: δ = 222.9 (WCO, J(WC) = 142.3 Hz), 219.8 (WCO, J(WC) = 129.7 Hz), 214.3 (FeCO), 152.0 (CP, J(CP) = 61.8, J(WC) = 54.8 Hz), 123.0 (CP, J(PC) = 55.3, J(WC) = 51.1 Hz); $^{31}P\{^1H\}$ NMR: δ = 177.2.

[5] Complex **1** was prepared using a procedure described by A. Mayr, A. M. Dorries, G. A. McDermott, D. Van Eugen (*Organometallics 5* (1986) 1504). The salt K[$H_2B(pz)_2$] was obtained as reported by S. Trofimenko (*Inorg. Synth. 12* (1970) 100).

[6] a) More conventionally, these compounds are formulated as heterobinuclear metal complexes in which the metal–metal bonds are spanned by μ-C(R)C(R′)C(R″) fragments (R, R′, R″ = alkyl or aryl groups). b) The WC_3- and WC_2P four-membered rings in **9** and **10** are necessarily nonplanar because of the relatively large radius of W compared with C or P. Hence the bonding of the Fe(CO)$_3$ group to these rings may be better described in terms of a σ bond involving the tungsten atom and η^3 coordination from the C_3 or C_2P fragments to the iron. However, the isolobal principle [3] is useful in relating the species concerned.

[7] In these species, M = Mo or W, L = η^5-C_5H_5 or η^5-C_5Me_5, and M′L$_n$ may be the groups Fe(CO)$_3$, Co(η^5-C_5Me_5), Rh(η^5-C_9H_7) (C_9H_7 = indenyl) or W(CO)(η-MeC_2Me)$_2$. See a) J. C. The recently accomplished stabilization of *cyclo*-P_6 (hexaphosphabenzene) as middle deck of the triple decker complex **A**[1]

$[(\eta^5\text{-}C_5Me_5)Mo(\mu,\eta^6\text{-}P_6)Mo(\eta^5\text{-}C_5Me_5)]$ **A**

aroused hope that *cyclo*-As_6 (hexaarsabenzene) might possibly be stabilized in the same way.

Indeed, after initial difficulties[2] we have now been able to carry out such a stabilization. Complex-stabilized *cyclo*-As_6 (**2**) can be generated both thermally (**1** and As_4 as starting compounds) as well as photochemically[3] ($MoAs_3$-tetrahedranes **3** as starting compounds).

cis-$[(\eta^5\text{-}C_5Me_4R)(CO)Mo(\mu,\eta^2\text{-}As_2)]_2$ **4a, b**

a, R = Me; b, R = Et

In addition to the triple-decker complexes **2**, in the thermal process the complexes **3a**,[2,4] **3b** are formed, in the photochemical process the dinuclear complexes **4a**,[2] **4b**; the framework of **4** consists of two As_2Mo_2 tetrahedra with common Mo–Mo edge.[2,5] The complexes **2a, b** form brownish-red, air-stable crystals which are virtually insoluble in pentane, sparingly soluble in benzene, and only moderately soluble in dichloromethane (in all cases, however, **2b** dissolves better than **2a**). The ^1H NMR spectra[6] show, as in the case of **A**,[1] a distinct upfield shift for the CH_3 groups (ring current effect of *cyclo*-As_6?).

The crystal structure analysis of **2b**[7] shows that both five-membered rings and the As_6-ring are planar and parallel (Fig. 1). In contrast to the As_5-middle deck distorted by Jahn–Teller effects[8] (As–As = 2.389(2)–2.762(3) Å) in the 27 valence electron (VE) triple-decker **5**,[9] within the limits of error a regular arsenic hexagon is found in the 28 VE triple-decker **2b**. The mean As–As distance (2.35 Å) lies almost exactly between the values for an As–As single bond (e.g. As_4 = 2.44 Å[10]) and As=As double bond (ca. 2.24 Å[11]); in the case of **3a**[4] and Rb_4As_6 (planar six-membered ring),[12a] the mean value is 2.37 Å, in the case of **6**[13] it is 2.44 Å. The Mo–Mo distance[8] in **2b** (2.639(1) Å) is almost identical to that in **A** (2.647(1) Å)[1] and to other M–M distances in triple-decker complexes with a *cyclo*-P_6 middle deck.[1b] The same holds for the mean Mo–C distances and the mean As–As–Mo angle (64.2°; P–P–Mo = 64.8° in **A**[1]). The increase in size of the *cyclo*-E_6 middle deck on going from E = P (**A**[1]) to E = As leads to a decrease in the mean Mo–E–Mo angle in the $Mo(E_6)Mo$ framework (hexagonal bipyramid) (E = P: 62.8° in **A**[1]; E = As: 58.7° in **2b**).

Fig. 1. Crystal structure of **2b**. Experimental

Thermal procedure: A solution of 2.0 g (7.58 mmol) of $Mo(CO)_6$ in 80 mL of xylene was treated with an equivalent amount of HC_5Me_4R (R = Me, Et) and the mixture stirred under reflux for 24 h. The hot mixture was then treated with a hot solution of 3.5 g (11.7 mmol) As_4[2] (prepared in 350 mL of xylene under reflux). After 30 hours' refluxing, ca. 1/3 of the solvent was distilled off and the remaining mixture then treated with a freshly prepared hot solution of 1.5 g (5.0 mmol) of As_4 in 150 mL of xylene and stirred for a further 30 h under reflux. The reaction solution (containing small amounts of insoluble material) was evaporated down to ca. 50 mL (oil-pump vacuum), treated with 10 mL of silica gel (activity grade II), and dried under vacuum until freely flowing (black-brown powder). Upon subsequent chromatographic separation (35 × 3 cm column, filled with silica gel and petroleum ether (30–75 °C boiling range)), 497 mg (16%) of **3a** [517 mg (16%) of **3b**] was eluted as a yellow fraction with petroleum ether. With petroleum ether/toluene (10/1), 249 mg (9%) of **2a** [328 mg (12%) of **2b**] was eluted as a brownish-yellow fraction; finally, with petroleum ether/toluene (3/1), 10–20% of **1** was eluted. The yields quoted for **2** and **3** refer to 80% conversion.

Photochemical procedure: A solution of 0.28 mmol (143 mg) of **3a** [147 mg of **3b**] in 120 mL of toluene was heated to reflux in a Duran glass apparatus and irradiated with a 150-W mercury high-pressure lamp for 60 min with concomitant passage of N_2. After addition of ca. 3 mL of silica gel, the reaction mixture was evaporated to dryness and chromatographed (25 × 2 cm column). Elution with petroleum, to which toluene was added portionwise up to 20% by volume, afforded 67 mg (52%) of **2a** [66 mg (50%) of **2b**, recrystallizable from hot heptane] as a brownish-yellow fraction, which was followed

Pyrones as Substrates for Palladium-Catalyzed [4+3] Cycloadditions**

By *Barry M. Trost** and *Stephan Schneider*

The schizophrenic behavior of pyrones is illustrated by their reacting as 4π electron partners towards olefins[1] and as 2π electron partners towards dienes.[2,3] The reactivity of trimethylenemethane-palladium complex as an equivalent of an electron-rich 4π-electron partner[4,5] (i.e., equivalent to an electron-rich diene) suggests that pyrones should participate as 2π-electron partners with this reactive intermediate. In contrast to such a prediction, we wish to report that either a [2+3] or a [4+3] cycloaddition may be observed depending upon the pyrone substitution, and that the latter represents the first example in which pyrone behaves as a 4π-electron substrate towards a 4π-electron reactant.

The commercially available methyl coumalate **1** reacts with 2-trimethylsilylmethylallyl acetate **2** in the presence of 5 mol% of the Pd^0 complex **3** formed in situ by reaction of one equivalent of palladium acetate with six equivalents of triisopropyl phosphite and two equivalents of *n*-butyllithium in *n*-hexane [Eq. (a)].[6] Surprisingly, an approximate

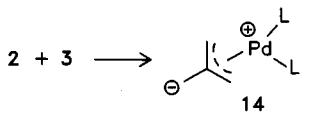
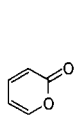
[**] We thank the National Science Foundation and the National Institutes of Health, the Institute of General Medical Sciences, and the Deutsche Forschungsgemeinschaft (postdoctoral fellowship for *S. S.*).

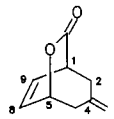


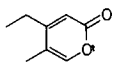
6.83; **5**: $\delta = 4.88$, 7.22), and of the proton adjacent to the ring oxygen atom (**4**: $\delta = 5.27$; **5**: $\delta = 5.47$) provide ready diagnosis of the structures of the cycloadducts. Placing the carbomethoxy group at the 3-position of the pyrone provides exclusive five-membered ring formation [Eq. (b)] to give cycloadduct **6** with a carbon skeleton reminiscent of the iridoids.[8]

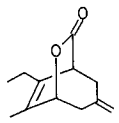
(b)

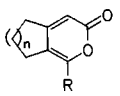
6

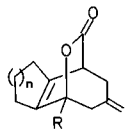


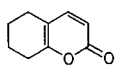


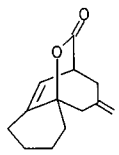


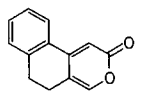


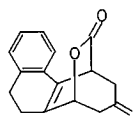






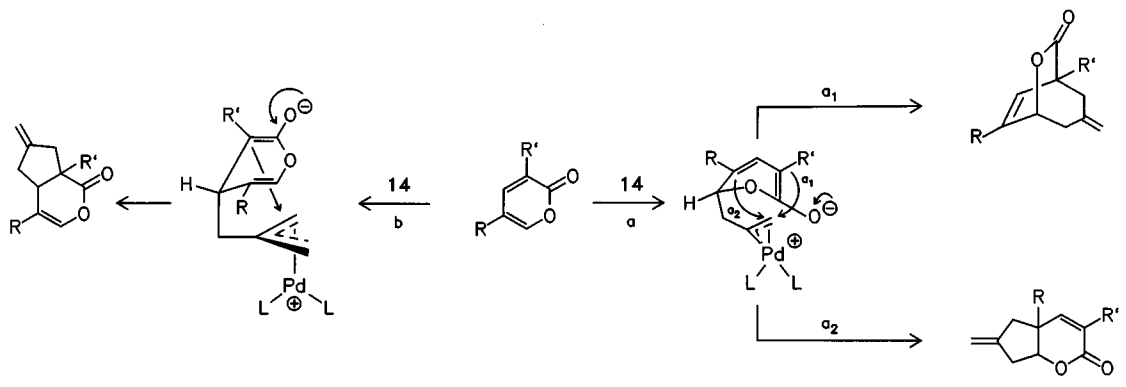






On the other hand, pyrone itself undergoes exclusive [4+3] cycloaddition to give **7** (see Table 2). Alkyl substituted and aryl substituted pyrones also lead only to [4+3] cycloadducts (**8**–**13**) normally in excellent yields. We attribute the low yield of **12** to the strain involved in bridging the positions 5 and 9 of the 3-methylene-6-oxa-7-oxobicyclo[3.2.2]non-8-ene nucleus by a $(CH_2)_4$-chain. Steric hindrance is a less likely cause for the low yield of **12**, for **9** is formed in excellent yield, even though the 4,5,6-trisubstituted pyrone starting compound is sterically more crowded. Pyrones bearing a 6-methylthio substituent[9] or a 4-methoxy substituent[10] failed to undergo cycloaddition.

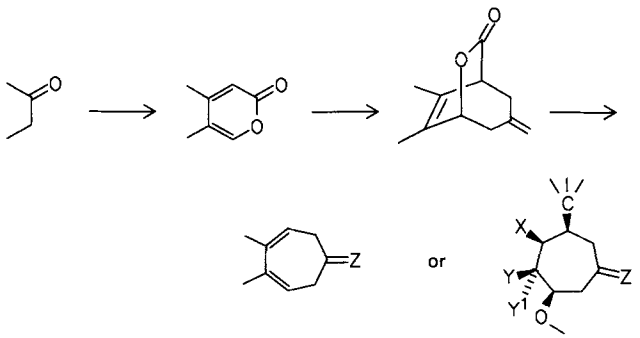
14



To understand why the trimethylenemethane–PdL_2 complex **14** (formed from **2** and **3**) diverges from its normal reactivity as an equivalent of an electron-rich diene, we suggest that this cycloaddition is a two step process[11] as depicted in Scheme 1. Nucleophilic attack by the TMM–PdL_2 complex at the 6-position is generally favored to generate the thermodynamically most stable dienolate (path a). The normal preference for such dienolates to react at the α-position then leads to the seven-membered ring products (path a_1). On the other hand, the incorporation of a strong anion stabilizing group at the 5-position ($R = CO_2CH_3$) increases the anionic nature of this carbon with the resultant partitioning along path a_2 becoming competitive with path a_1. When R′ is a strong electron-withdrawing group, charge effects appear to control the position of initial attack favoring path b which can only lead to [2+3] cycloadducts.

Table 2. [4+3] Cycloadditions [a].

Pyrone derivative	Cycloadduct [7]		Yield [%]
		7	70[b]
		8	89[b]
		n = 1, R = CH_3	9	86[c]
		n = 2, R = H	10	90[d]
		n = 3, R = H	11	92[e]
		12	23[b]
		13	90[b]



[a] General procedure: Reactions normally performed with 1 mmol of pyrone (1 M concentration in benzene) and 1.4 eq of 2-trimethylsilylmethylallyl acetate with 500 μl of the catalyst solution (generated by treating 0.25 mmol of palladium acetate in 1.8 ml of benzene with 1.50 mmol of triisopropyl phosphite and 320 μl of a 1.56 M hexane solution of *n*-butyllithium) at 80° in a sealed reaction vessel.

Synthetically, this [4+3] cycloaddition appears to be a most useful and general approach to seven-membered rings (see Scheme 2).[12, 13] The endocyclic double bond becomes a useful functional group for diastereocontrolled functionalization (such as a *cis*-hydroxylation) and the lactone bridge represents a *cis*-1,4-substitution of oxygen and carbon. Loss of carbon dioxide to form cycloheptadienes

Scheme 1. Proposed reaction routes to explain the products **4**–**13** obtained in the reactions according to Equation (a).

is also possible. The ready availability of the pyrones from ketones[14] enhances the value of this approach for the stereocontrolled construction of seven-membered rings.

Scheme 2. Seven-membered rings from ketones via pyrones and possible functionalizations.

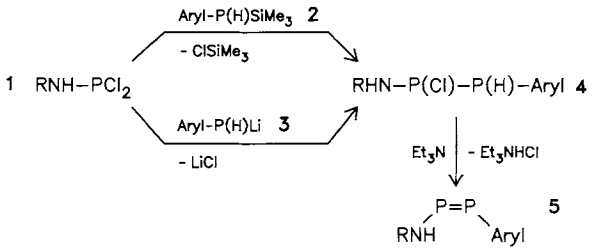
[14] The 2-pyrones were synthesized first by classical formation of the 2-ethoxymethylene ketones followed by addition of ethyl lithioacetate and cyclization with 1–2% sulfuric acid in acetic acid. For some recent synthetic work, see Ref. [9] and H. Stetter, H. J. Kogelnick, *Synthesis 1986*, 140.



Synthesis, Structure, and Reactivity of Diphosphenes having a *cis*-Configuration

By *Edgar Niecke,* Berthold Kramer,* and *Martin Nieger*

In contrast to the diazene system (E = N), for which, depending on the substituents, both the *trans*-form **I** and the *cis*-form **II** may be thermodynamically favored,[1] stable[2] *cis*-diphosphenes **II** (E = P) were previously unknown.[3] We now report the synthesis of the first stable diphosphenes with a *cis*-configuration.

As has been shown by various synthetic studies, diphosphenes are accessible via β-elimination of hydrogen halides from suitably substituted diphosphane precursors.[4] We applied this synthetic method to diphosphanes having secondary amino substituents. Thus, reaction of the dichlorophosphanes **1a**[5] and **1b–d** with either the silylphosphane **2**[6] or the lithium phosphide **3** afforded the diphosphanes **4**. The base-induced elimination of hydrogen chloride from **4** gave the *cis*-diphosphenes **5**.

Aryl = $C_6H_2tBu_3$

R = *t*Bu (a), Adamantyl (b), CEt_3 (c), $C_6H_2iPr_3$ (d)

The structures and compositions of compounds **5a–d** and of the precursors **1b–d** have been determined on the basis of elemental analyses, mass and NMR spectral data, and X-ray structural analyses for **5a**, **b**. The intermediates **4a–d** were characterized by ^{31}P NMR spectroscopy.

The ^{31}P NMR signals of **5a–d** exhibit significant shifts to higher field ($\Delta\delta = 100$–200 ppm) compared with those of the known *trans*-1-aminodiphosphenes, $R'R''N–P=P–C_6H_2tBu_3$.[7] Conclusive proof of the *cis*-configuration was provided by X-ray structural analyses for **5a** and **5b** (Fig. 1).[8] The molecules, whose basic frameworks (without Me groups) have approximate C_s symmetry, have the *cis*-configuration with respect to the PP bond with the four atoms P(1), P(2), N(1) and C(11) lying in a plane (torsion angle N(1)-P(1)-P(2)-C(11) 0.6(2)° for **5a**, 0.5(2)° for **5b**).

The coplanarity of the substituents at the N atom makes possible a p–π interaction with the PP double bond, which might be responsible for the relatively short PN bond lengths (164.5(4) and 165.2(5) pm for **5a** and **5b**) and the large angles at P(1) (109.9(2) and 109.2(2)°, respectively). Unlike the amino group, the aryl substituent is twisted out

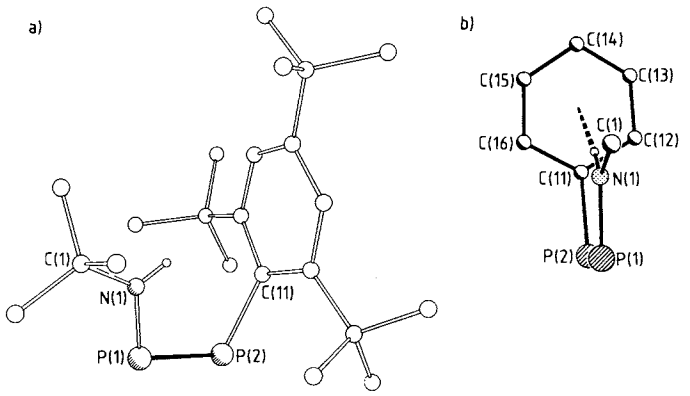

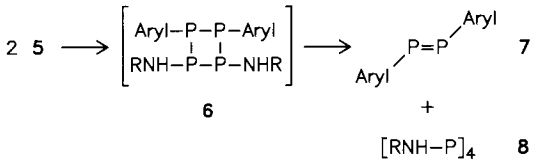

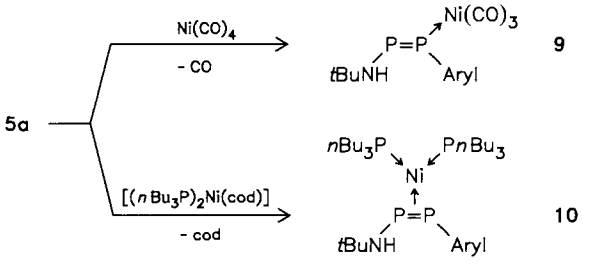

Fig. 1. a) Molecular structure of **5a**. Important bond lengths [pm] and angles [°] (for **5b** in parentheses): P(1)-N(1) 164.5(4) [165.2(5)], P(1)-P(2) 203.8(2) [204.4(2)], P(2)-C(11) 186.2(4) [185.5(5)]; N(1)-P(1)-P(2) 109.9(2) [109.2(2)], P(1)-P(2)-C(11) 102.0(2) [102.2(1)], C(1)-N(1)-P(1) 129.5(3) [127.8(3)]; torsion angle N(1)-P(1)-P(2)-C(11) 0.6(2) [0.5(2)]. b) View of the basis framework along the PP axis.

of the plane of the π-system with an angle between the PPN plane and the plane of the arene ring of 90°. The bond lengths P(2)-C(11) (186.2(4) and 185.5(5) pm for **5a** and **5b**), the angles at P(2) (102.0(2) and 102.2(1)°) and the PP bond lengths (203.8(2) and 204.4(2) pm) lie within the ranges normally found for diphosphenes.[3] Particularly noteworthy is the distance of the amino proton from the centroid of the arene ring (**5a**, 264 pm; **5b**, 270 pm) which suggests a weak attractive interaction between the proton and the aromatic π-system.[10] To what extent an interaction of this type is responsible for the stabilization of the *cis*-form of **5** with respect to the *trans*-form remains an open question.

The crystalline diphosphenes **5a-d** are practically indefinitely stable in the solid state under an inert atmosphere. In solution, they decompose within a few days at ambient temperature or a few hours at 60°C to give the *trans*-diphosphene **7**[2b] and the cyclotetraphosphane **8**. The latter two compounds can be regarded as being the products of the cycloreversion of the head to head dimer **6**.

Like their *trans*-analogues, the *cis*-diphosphenes react with transition metal compounds to furnish η^1- or η^2-complexes. This was demonstrated by the reaction of **5a** with nickel compounds to give the diphosphene complexes **9** and **10**.

Experimental

1b-d: 39 mL of 15% *n*BuLi solution in hexane (10% excess) was added dropwise to a solution of 50 mmol of adamantyl-NH_2, Et_3CNH_2 or $C_6H_2iPr_3NH_2$ in ether (20 mL). The reaction mixture was stirred for 1 h at 25°C after which it was added dropwise to a solution containing three molar equivalents of PCl_3 (14 mL) in ether (40 mL) at −60°C. The solution was allowed to warm to 25°C and the solvent removed in vacuum. The residue was extracted into pentane and LiCl was removed by filtration. The product was purified by distillation or recrystallization. **1b**: 9.4 g (74%), m.p. 25-27°C; **1c**: 9.7 g (61%), b.p. 56-57%/0.25 torr; **1d**: 11.9 g (74%), m.p. 48-50°C. MS: *m/z* 253 (**1b**$^{\oplus}$, 12%); 216 (**1c**$^{\oplus}$, 7%); 320 (**1d**$^{\oplus}$, 14%). ^{31}P NMR ($CDCl_3$): δ(**1b**) = 165.8; δ(**1c**) = 156.6; δ(**1d**) = 155.8.

5a, b: A solution of **2** (10 mmol) in *n*-hexane (30 mL) was reacted with 20 mmol of **1a** [5] or **1b** in *n*-hexane (20 mL) at 0°C. The solution was allowed to warm to 25°C and was stirred for a further 2 h. The diphosphanes **4a** and **4b** are formed as pairs of diastereomers. ^{31}P NMR (C_6D_6): δ(**4a**) = −60 (−49) (J(P,H) = 174 (213) Hz), 133 (122) (J(P,P) = 173 (263) Hz); δ(**4b**) = −59 (−49) (J(P,H) = 170 (212) Hz), 133 (121) (J(P,P) = 170 (260) Hz). The solution containing **4a** or **4b** was treated with one molar equivalent of Et_3N. After removal of the amine hydrochloride by filtration, the solution was cooled to 80°C to afford **5a** or **5b**. **5a**: 3.04 g (40%), m.p. 117-123°C; **5b**: 2.7 g (29%), m.p. 187-192°C. MS: *m/z* 379 (**5a**$^{\oplus}$, 30%); 457 (**5b**$^{\oplus}$, 1%). ^{31}P NMR (C_6D_6): δ(**5a**) = 377, 214 (J(P,P) = 526, J(P,H) = 12 Hz); δ(**5b**) = 375, 213 (J(P,P) = 524.5, J(P,H) = 12.7 Hz).

5c, d: To a solution of **1c** or **1d** in ether (30 mL) was added dropwise a solution containing an equimolar amount of **3** in ether (20 mL) at −50°C. The stirred solution was allowed to warm to room temperature and most of the solvent was removed under vacuum. The residue was extracted with hexane and LiCl removed by filtration to afford a solution containing **4c** or **4d** (mixtures of diastereomers). ^{31}P NMR: (C_6D_6): δ(**4c**) = −62.3 (−51.2) (J(P,H) = 178 (212.5) Hz), 136 (121.3) (J(P,P) = 175 (267) Hz); δ(**4d**) = −62.8 (−49.4) (J(P,H) = 180 (214) Hz), 142.1 (119.6) (J(P,P) = 179 (270) Hz). **4c** and **4d** were converted to the diphosphenes **5c** and **5d** as described for **4a, b**. **5c**: 0.85 g (20%), m.p. 134-137°C; **5d**: 1.85 g (35%), m.p. 112-115°C. MS: *m/z* 421 (**5c**$^{\oplus}$, 23%), 525 (**5d**$^{\oplus}$, 6%). ^{31}P NMR (C_6D_6): δ(**5c**) = 379.0, 212.3 (J(P,P) = 527.2, J(P,H) = 13.1 Hz); δ(**5d**) = 379.7, 209.3 (J(P,P) = 523, J(P,H) = 13.6 Hz).

9: $Ni(CO)_4$ (5 mmol) was added to a solution of **5a** (5 mmol) in toluene (50 mL). Gas evolved and the color of the solution changed from light-yellow to red-brown. After warming to 25°C, the solution was reduced to one quarter of its volume in vacuum. Addition of Et_2O (20 mL) and cooling to −30°C afforded the analytically pure complex **9**. Yield, 2.12 g (80%), m.p. 112-115°C (decomp.). MS: *m/z* 520 ($M^{\oplus}$, 5%). IR (C_6D_6): $\tilde{\nu}$ = 2085, 2040, 2012 cm^{-1}. ^{31}P NMR (C_6D_6): δ = 164, 341 (J(P,P) = 561 Hz).

10: A solution of **5a** (5 mmol) in toluene (30 mL) was treated with [(*n*$Bu_3P)_2$Ni(cod)] (5 mmol) (cod = 1,5-cyclooctadiene) and *n*Bu_3P (200 mg) dissolved in toluene (7 mL). The color became cherry-red. After the reaction was complete, the solution was cooled to −80°C to afford **10** as a deep-red solid. **10** decomposes in solution within a few hours at 25°C. ^{31}P NMR ([D_8]toluene, 203 K) Aryl$P^A P^K$NHCMe$_3$·Ni(*n*Bu_3P^M*n*Bu_3P^X): δ(A) = −55.1, δ(K) = 85.2, δ(M) = −3.9, δ(X) = 4.6; J(A,K) = 427, J(A,M) = 10, J(A,X) = 47.5, J(K,M) = 30.5, J(K,X) = 30.5, J(M,X) = 3.2 Hz.

A Tetraborylphosphonium Ion with a Spiroheterocyclic Structure**

By *Matthias Driess, Pascal Frankhauser, Hans Pritzkow,* and *Walter Siebert**

Dedicated to Professor Ernst Otto Fischer on the occasion of his 70th birthday

Boron–phosphorus compounds with organic substituents have been far less thoroughly investigated than the corresponding boron–nitrogen compounds.[1] σ^3- or σ^4-coordinated boron and phosphorus atoms are present in phosphinoboranes $(R_2P-BR_2)_n$, n = 1–4.[2] Phosphonioborates, R_3P-BR_3 ("phosphaneboranes"), contain B and P atoms with coordination numbers of 4. To the best of our knowledge, examples of BP compounds with λ^5-phosphorus and λ^3,σ^3-boron atoms have not previously been reported. This category of compounds includes the *P*-borylphosphoranes R_2B-PR_4 and *P*-borylphosphonium ions $[R_2B-PR_3]^{\oplus}$.

We report here on the formation of the tetraborylphosphonium ions **3a**, **b** as the first compounds with λ^5,σ^4-phosphorus and λ^3,σ^3-boron atoms. The spirocyclic structure of the phosphonium ion, with tetrahedral coordination at the phosphorus atom, was determined by a crystal structure analysis of **3b**.

Compound **3a** was obtained for the first time as a colourless solid in 17% yield in the synthesis of the C_2B_2P derivative **2** from the diborylethene **1** and $P(SiMe_3)_3$.[3] By reacting **1** and $P(SiMe_3)_3$ in a ratio of 2:1 at 140°C, the yield of **3a** was increased to 64%. The use of bulky $N(iPr)_2$ groups on the boron atoms is essential for the kinetic stabilization of the spirocation of **3**. Other derivatives of **3**, for example with $R = NMe_2$ or NEt_2, could not be obtained.

3a is soluble in CH_2Cl_2 and $CHCl_3$, but not in toluene and THF. The ionic structure of **3a** was confirmed, following substitution of $Cl^{\ominus}$ with the non-coordinating $[BPh_4]^{\ominus}$ ion (→ **3b**), by comparison of the ^{31}P NMR chemical shifts: **3a** and **3b** have almost identical δ-values (−190.5 and −187.3, respectively).

The high field positions of the ^{31}P NMR signals of **3**, which are unusual for phosphonium salts, can be explained by the electropositive character of the boron atoms next to phosphorus. Other indications for this phenomenon were reported some time ago.[4] The electropositive character of the boron atoms in **3** is comparable to that of hydrogen atom substituents $[MePH_3^{\oplus}Cl^{\ominus}: \delta(^{31}P) = -156]$.[5]

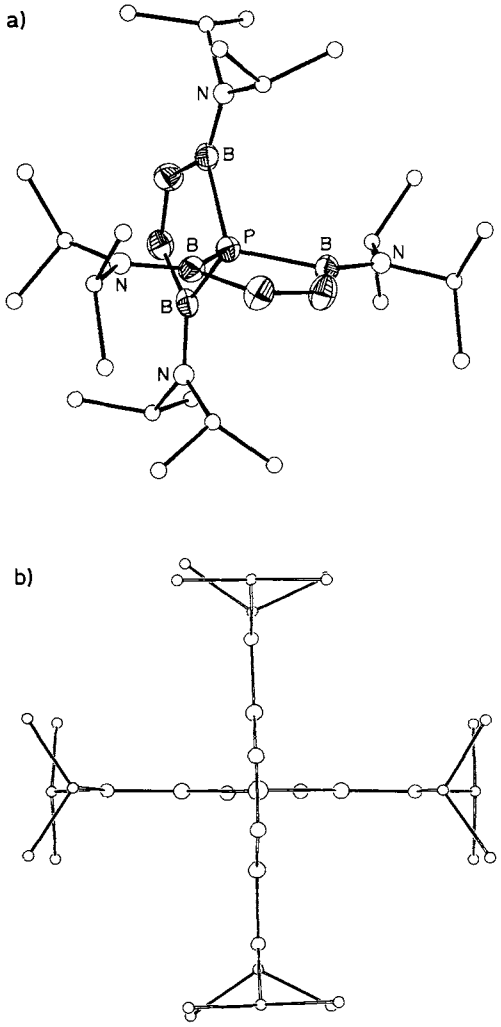

Fig. 1. Cation of **3b**. a) Structure in the crystal. Selected bond lengths [Å] and angles [°]: P-B 1.957–1.961(5), B-C 1.548–1.568(7), C-C 1.330, 1.334(6), B-N 1.357–1.374(7); B-P-B 93.0, 93.5, P-B-C 103.8–104.5(3), B-C-C 118.9–119.6(4). b) Projection in the direction of the S_4-axis.

In contrast, phosphorus atoms in tetraorganophosphonium compounds exhibit low field resonances.[6] For a phosphorane with a P–Cl bond, an even greater shielding

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

of the ^{31}P nucleus can be anticipated. The ^{11}B spectra of **3a**, **b** show a signal at $\delta = 41.9$ ($b_{1/2} = 479$ Hz), and in addition, a signal at $\delta = -3.73$ in the spectrum of **3b** for $[BPh_4]^{\ominus}$. The ^1H NMR spectrum of **3a** exhibits a doublet at $\delta = 7.65$ for the olefinic protons, for which the coupling constant ($|^3J_{PH}| = 16.7$ Hz) is on average 11 Hz greater than for **2**.[3] This points to the greater s-character of the boron–phosphorus bond in **3**. Due to the BN π-bond, the two *i*Pr groups of the $N(iPr)_2$ unit are inequivalent.

An X-ray structural analysis also confirms the ionic structure of **3b** in the solid state (Fig. 1a).[8] The cation has approximately D_{2d} symmetry (Fig. 1b). The C_2B_2P rings are planar (maximum deviations from the best planes 0.008 and 0.019 Å) and lie perpendicular to each other (90.9°). The phosphorus atom has distorted tetrahedral coordination, for which the B-P-B angle inside the ring is considerably less (93–94°) than that between the rings (116–119°), but 4–5° larger than in 2,5-dihydro-2,5-bis(diisopropylamino)-1*H*,1,2,5-phosphadiborole.[9] The bond lengths are in good agreement with those of the *P*-phenyl substituted C_2B_2P derivatives,[9] although in these compounds the ring is not planar.

Experimental

3a (1,1'-Spirobi[2,5-bis(diisopropylamino)-2,5-dihydro-1*H*-1,2,5-phosphoniadiborole] chloride): A mixture of **1** (5.16 g, 16.17 mmol) [10] and $P(SiMe_3)_3$ (2.02 g, 8.08 mmol) was heated at 140°C for about 5 hours, until no more Me_3SiCl distilled over. The molten reaction mixture gradually solidified. The crude product was extracted twice with petrol ether then dissolved in CH_2Cl_2. After filtering off a yellow, insoluble compound, **3a** was obtained at −30°C as a colorless powder. Yield: 2.9 g (5.16 mmol, 64%); m.p. 273°C (decomp.).—^1H NMR (200 MHz, CD_2Cl_2): $\delta = 1.01$ (d, 24H, $J_{HH} = 6.9$ Hz), 1.28 (d, 24H), 3.27 (d sept, 4H, $^4J_{PH} \approx 1$ Hz), 3.40 (d sept., 4H, $^4J_{PH} = 2.9$ Hz), 7.65 (d, 4H, $^3J_{PH} = 16.7$ Hz). ^{13}C NMR (50 MHz): $\delta = 21.38$ (s, CH_3), 25.28 (s, CH_3), 47.13 (d, $^3J_{PC} = 6.5$ Hz, NCH), 60.20 (d, $^3J_{PC} = 11$ Hz, NCH), 159.3 (br., BC). MS (DCI (field desorption + chemical ionization), CH_4): *m/z* 562 (3%, $M^{\oplus}$), 546 (3%, $[M - Me - H]^{\oplus}$), 519 (6%, $[M - iPr]^{\oplus}$), 43 (100%, $iPr^{\oplus}$).

3b: A solution of **3a** (320 mg, 0.57 mmol) in CH_2Cl_2 (10 mL) was mixed with $Na[BPh_4]$ (340 mg, 0.99 mmol) and the reaction mixture stirred for 1 h. The insoluble components were filtered off and the solvent removed in a vacuum. **3b** was crystallized from a little acetonitrile at −30°C. Yield: 398 mg (0.47 mmol, 83%).

$LiBH_4(NaBH_4)/Me_3SiCl$, an Unusually Strong and Versatile Reducing Agent**

By *Athanassios Giannis** and *Konrad Sandhoff*

Metal borohydrides MBH_4 (M = Li, Na, 1/2 Ca, 1/2 Zn) are amongst the most important reducing agents in organic chemistry.[1,2] Their reactivity is strongly influenced by the following factors: a) the solvent,[2] b) the metal ion M,[2] and c) the presence of catalysts such as $B(OMe)_3$,[3] *B*-methoxy-9-borabicyclononane,[3] or halides[4,5] of cobalt, nickel, iridium, osmium, copper, platinum and titanium. Despite the variation of these parameters, the range of functional groups that can be reduced by metal borohydrides is very limited. We now report a method which makes it possible also to reduce amino acids, carboxylic acids, amides, nitriles, nitroalkenes, and sulfoxides with alkali metal borohydrides in good yields.

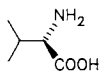
We found that the addition of Me_3SiCl makes possible the reduction of α-amino acids with $LiBH_4$ in THF (Nos. 1–4 in Table 1). When optically pure α-amino acids were used, optically pure β-amino alcohols were obtained. This inspired us to investigate the use of $LiBH_4/Me_3SiCl$ as a reducing agent for other functional groups. Thus, simple carboxylic acids are reduced to alcohols (No. 5), while primary, secondary and tertiary amides (Nos. 6–8) and nitriles (Nos. 10–12) afford the corresponding amines. High yields were obtained in all cases. Dimethyl sulfoxide was reduced to dimethyl sulfide (No. 9), the dipeptide derivative Fmoc-L-Phe-L-Ala-OMe (No. 14) gave the corresponding amino alcohol, and *N*-benzyloxycarbonyl-6-amino-1-hexanol was converted into 6-amino-1-hexanol (No. 15). Similar results were obtained with $NaBH_4$ (Nos. 6, 8, 9, 11, 12, 14 and 15 in Table 1). Because of its good solubility in THF and the milder reaction conditions, $LiBH_4$[6] is, however, the reducing agent of choice.

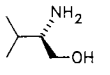
The strength of this new system is demonstrated by the smooth reduction of the nitrostyrene derivative (No. 13) on a preparative scale (100 mmol) to afford the corresponding amine. Other methods for the reduction of conjugated nitroalkenes, such as $LiAlH_4$ reduction or catalytic hydrogenation, are unsatisfactory; far better results have been obtained using diborane in the presence of $NaBH_4$[7] or $BF_3 \cdot OEt_2$.[8]

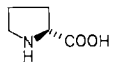
We suggest that in reductions using $LiBH_4(NaBH_4)/Me_3SiCl$ in THF, a borane THF complex is formed [Eq. (a)] which, with the assistance of excess Me_3SiCl, acts as the reducing agent.

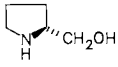
$$LiBH_4 + Me_3SiCl \xrightarrow{THF} LiCl + Me_3SiH + BH_3 \cdot THF \qquad (a)$$

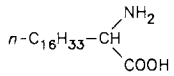
The addition of Me_3SiCl makes it possible to carry out reductions with $LiBH_4$ or $NaBH_4$ which are either very slow or do not occur in its absence. The reaction mechanism, the use of other alkylhalogenosilanes,[9] and the suitability of the method for other functional groups remain to be investigated.

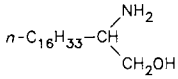


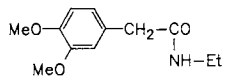


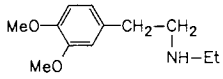


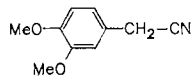


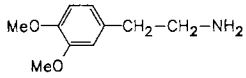


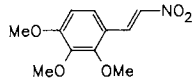


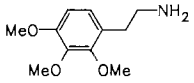


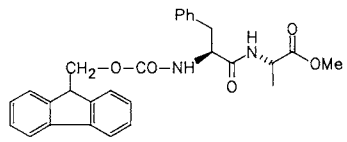


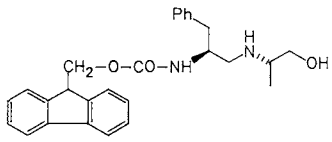












Typical procedures

Me_3SiH is formed in all reactions. It should therefore be ensured that this volatile silane (b.p. ~ 10°C) can escape from the reaction vessel.[10]

Table 1. Reductions with $LiBH_4(NaBH_4)/Me_3SiCl$.

No.	Starting material	Product [a]	Method [b]	Yield [%]
1			A	91
2			A	88
3			A	94
4			A	85
5	Ph–COOH	Ph–CH_2OH	A	92
6	Ph–CO–NH_2	Ph–CH_2–NH_2	A B	91 89
7			A	90
8	HCO–NMe_2	Me_3N	A B	72 [c] 71
9	Me–SO–Me	Me–S–Me	B	60
10	Ph–CN	Ph–CH_2–NH_2	A	90
11			B	90
12	Me–CN	Me–CH_2–NH_2	A B	75 [c] 70
13			A	91
14			A [d] B	60 55
15	Ph–CH_2–O–CO–NH–$(CH_2)_6$–OH	H_2N–$(CH_2)_6$–OH	A B	95 88

[a] All new compounds gave satisfactory C,H analyses and appropriate spectra. [b] A: $LiBH_4$ as reducing agent; B: $NaBH_4$ as reducing agent. [c] Isolated as the hydrochloride. [d] Purified by flash chromatography (silica gel, chloroform/methanol).

Reaction 1 in Table 1: A solution of Me_3SiCl (8.64 g, 80 mmol) was added under argon to a solution of $LiBH_4$ (0.87 g, 40 mmol) in THF (20 mL) over the course of 2 min. A precipitate of LiCl formed. L-valine (2.34 g, 20 mmol) was added portionwise to the mixture within 5 min. After stirring for 24 h at room temperature, 30 mL of MeOH were cautiously added and the volatiles removed by distillation. The residue was treated with 20% KOH solution and extracted three times with 50 mL portions of CH_2Cl_2. The organic phases were combined, dried over Na_2SO_4, and the solvent evaporated to afford L-valinol which was spectroscopically pure (^1H NMR). Yield after Kugelrohr distillation 1.87 g (91%), $[\alpha]_D^{24} = +14.7$ (neat).

Reaction 11 in Table 1: $NaBH_4$ (4.56 g, 120 mmol) was added to a solution of Me_3SiCl (26.04 g, 240 mmol) in THF (100 mL) and the mixture refluxed for 3 h under argon. A solution of 3,4-dimethoxybenzylcyanide (10 g, 56.4 mmol) in THF (50 mL) was then added over the course of 10 min. The solution was refluxed for a further 10 h. After cooling, 100 mL MeOH were cautiously added and the volatiles removed in vacuo. The residue was taken up in dilute HCl and washed with ether. The aqueous solution was treated with excess dilute NaOH and then repeatedly extracted with CH_2Cl_2. The organic extracts were combined, dried over Na_2SO_4, and the solvent evaporated to afford 2-(3,4-dimethoxyphenyl)ethylamine (pure by ^1H NMR). Yield after kugelrohr distillation 9.16 g (90%).

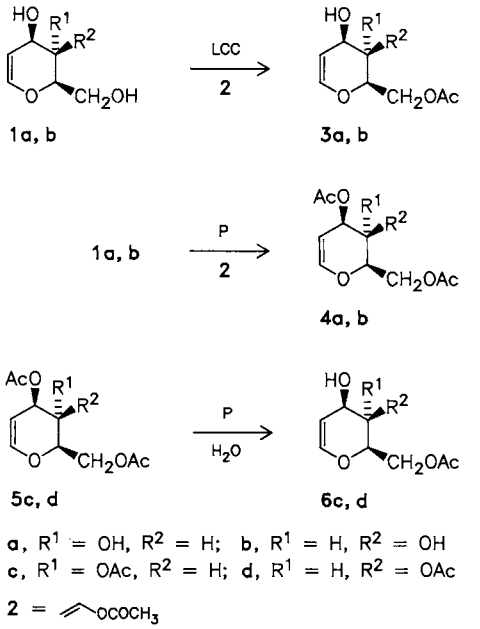
Enzymatic Synthesis of Selectively Protected Glycals**

By *E. Wolfgang Holla**

Glycals and their esters are versatile chiral building blocks.[1] They can be obtained in good yields from the corresponding saturated carbohydrates;[2] however, because of their overfunctionalization with hydroxyl groups and because of the absence of strategically valuable functional groups such as C=C and C=O bonds, these are in many cases unsuitable for direct conversion into the target molecules. The directed chemical linkage or transformation of glycals such as **1a** and **1b** at the hydroxyl groups usually requires tedious, multistep protection and deprotection procedures. Regioselective acetylations of D-glucal **1a** and D-galactal **1b** and deacetylations of the triacetates **5c**, **5d** have so far never been reported.[3] This prompted us to investigate lipase-catalyzed acetyl transfer reactions [Eq. (a)–(c)].[4]



$$Gly(OCOR')_{n+x} + x\,H_2O \rightleftharpoons Gly(OCOR')_n(OH)_x + x\,R'COOH \quad (a)$$

$$Gly(OH)_{m+y} + y\,R'COOR'' \rightleftharpoons Gly(OH)_m(OCOR')_y + y\,R''OH \quad (b)$$

$$Gly(OH)_{m+y} + y\,R'COOCH{=}CH_2 \longrightarrow Gly(OH)_m(OCOR')_y + y\,CH_3CHO \quad (c)$$

In the present communication we report some novel, efficient and facile enzymatic syntheses of partially protected as well as fully hydroxyl-differentiated glucals and galactals.

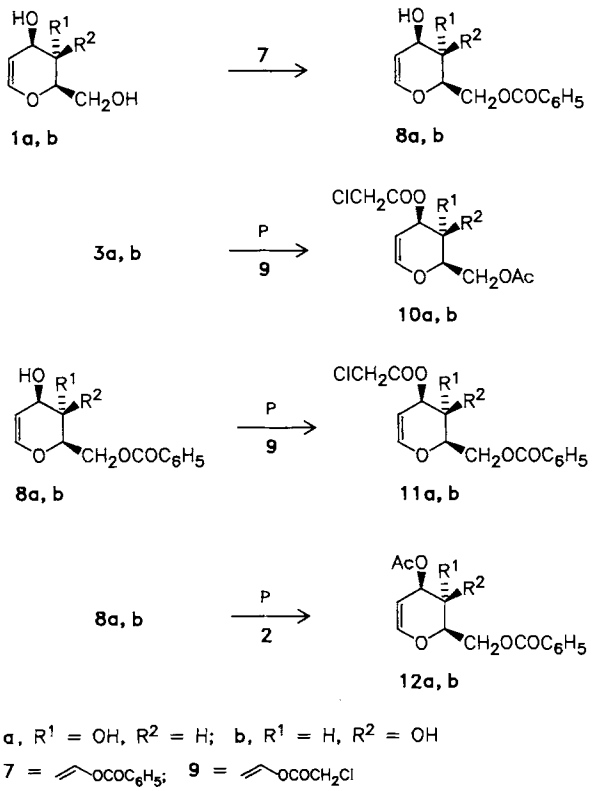
Of primary interest was the realization of enzymatic transacetylations in nonaqueous organic media. Reversible transesterifications [Eq. (b)], however, generally result in unsatisfactory conversions. This problem can be overcome by using vinyl esters[5] [Eq. (c)]. An especially suitable reagent for irreversible enzymatic acetyl transfer is the inexpensive vinyl acetate **2**. For carrying out the reactions the glycals are either stirred with the enzyme in pure **2** at room temperature or are previously taken up in small amounts of a cosolvent and finally treated with **2** and the lipase (Table 1). The enzymes employed are commercially available lipases from *Candida cylindracea* (LCC) and *Pseudomonas fluorescens* (P).[6] Especially suitable for the selective acetylation of the primary hydroxyl groups of **1a** and **1b** are the *Candida lipases* (Scheme 1, Table 1). Thus, the reaction of **1a** in **2**/ethyl acetate in presence of the lipase OF afforded, in 24 hours, 6-*O*-acetyl-D-glucal **3a** in 90% yield. The galactal derivative **3b** was obtained by dissolving **1b** in a little water, addition of **2** and lipase S-VII, and stirring the resulting mixture for 45 minutes. With lipase P, on the other hand, the 3,6-di-*O*-acetyl derivatives **4a** and **4b** were obtained in 92% and 75% yield, respectively.

Scheme 1. Lipase-catalyzed acetylations and deacetylations.

Table 1. Enzymatic acetyl transfer reactions with D-glucal **1a**, D-galactal **1b** and 3,4,6-tri-*O*-acetyl-D-glucal **5c**.

Starting Cpd.	Enzyme [6] [a]	Reaction conditions [b]	Product	Isolated Yield [%] [c]
1a	OF, 0.4 g	**2** [d], 24 h	**3a**	90
1b	S-VII, 0.8 g	**2** [e], 45 min	**3b**	93
1a	P, 0.25 g	**2** [d], 48 h	**4a**	92
1b	P, 1.0 g	**2** [e], 20 h	**4b**	75 [f]
5c	P, 1.0 g	buffer [g], 5–7 h	**6c**	90

[a] The quoted amounts of enzyme refer to 1.0 g of starting compound; the enzymes can be used several times. [b] All reactions at room temperature. [c] After flash chromatography. [d] 20–25 vol-% ethyl acetate. [e] 1–4 vol-% water, 2 g of powdered molecular sieve 4 Å. [f] Approx. 10% of regioisomer found. [g] 10 mL 0.25 M potassium phosphate buffer, pH = 7.



After completion of the reactions the insoluble enzymes can be recovered by membrane filtration and used again in further transformations.[7]

Especially interesting with regard to the regiochemistry is the deacetylation of tri-*O*-acetyl-D-glucal **5c**. The lipase-P-catalyzed ester cleavage in weakly buffered solution without pH-control affords 4,6-di-*O*-acetyl-D-glucal **6c** in 90% yield. In the case of the tri-*O*-acetyl-D-galactal **5d**, on the other hand, the formation of a complex mixture of **6d** and several di- and monoacetates is observed.

For the synthesis of completely hydroxyl-differentiated glycals we investigated the enzymatic transfer of benzoyl and chloroacetyl groups[8] by using vinyl esters **7** and **9**, respectively (Scheme 2, Table 2). Lipase AY-20 and, contrary to expectation, lipase P are suitable for the selective benzoylation of the 6-hydroxy groups of **1a** and **1b** with **7**. With tetrahydrofuran or water as cosolvent, the monobenzoates **8a,b** are obtained in about 70% yield.[9] Regioselective chloroacetylation of **3a,b** and **8a,b** with **9**/lipase P and acetylation of **8a,b** with **2**/lipase P gave the completely differentiated glycals **10a,b**, **11a,b**, and **12a,b** in good yields.[10]

Postfach 800320, D-6230 Frankfurt am Main 80 (FRG)

[**] I am grateful to Frau *A. Weber* for carrying out some of the preparative work.

Scheme 2. Lipase-catalyzed synthesis of completely hydroxyl-differentiated glycals.

Table 2. Enzymatic acylations (benzoylation, chloroacetylation and acetylation) of glycals.

Starting Cpd.	Enzyme [6] [a]	Reaction conditions [b]	Product	Isolated yield [c] [%]
1a	AY-20	**7** [d], 6 h	**8a**	70 [e]
1b	AY-20	**7** [f], 8 h	**8b**	67
1b	P	**7** [f], 10 h	**8b**	66
3a	P	**9** [g], 2–3 h	**10a**	83 [e]
3b	P	**9** [g], 6 h	**10b**	80 [e]
8a	P	**9** [g], 1–2 h	**11a**	82
8b	P	**9** [g], 6 h	**11b**	80
8a	P	**2**, 5 h	**12a**	92
8b	P	**2** [g], 8 h	**12b**	80

[a] One gram of enzyme used per gram of starting compound; the enzymes can be used several times. [b] All reactions at room temperature. [c] After flash chromatography. [d] 30–40 vol-% tetrahydrofuran. [e] 5–10 vol-% regioisomer found. [f] 5–10 vol-% water, 3 g of powdered molecular sieve 4 Å. [g] 20–30 vol-% dimethoxyethane.

Our results show that the enzymatic acetylations and chloroacetylations of glucal **1a** and galactal **1b** as well as the lipase-catalyzed benzoylations first described by us provide versatile and efficient routes to useful monosaccharide synthetic building blocks.

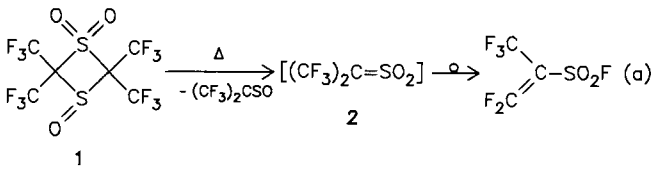
[9] For comparison: Treatment of **1a** with 1 equivalent of C_6H_5COCl/pyridine at 0°C gave **8a** in only 29% yield [3c].
[10] Acyl-group migrations were not observed in any of the reactions. All the given structures are consistent with the spectroscopic data.

Bis(trifluoromethyl)sulfene $(CF_3)_2C{=}SO_2$, Isolated as Adduct

By *Uwe Hartwig, Hans Pritzkow, Klaus Rall,* and *Wolfgang Sundermeyer**

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

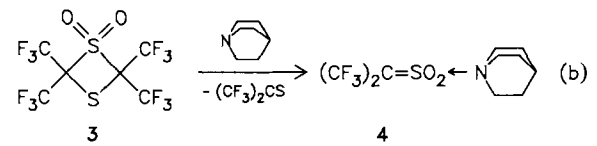


Sulfenes $R_2C{=}SO_2$ (thione *S,S*-dioxides) have so far not been isolated but only detected as unstable intermediates by (in most cases) cycloaddition reactions.[1] Of particular interest for investigations on the synthesis and stabilization of small reactive molecules are compounds with double bonds between main group elements of the second and third periods. Such species containing, for example, C=Si,[2] N=Si[3] and $C{=}SF_4$ bonds[4] have been isolated or stabilized as adducts[2,3] and characterized by structural analyses.

In reactions previously carried out with α-H-sulfonyl chlorides in the presence of suitable tertiary amines no symmetrically substituted sulfenes $R_2C{=}SO_2$ could be isolated, but, after further reaction, only sulfonylsulfenes,[1] as was recently demonstrated by us with the isolation of the amine-stabilized species **A**.[5,6]

$XCH_2{-}SO_2{-}C(X){=}SO_2{\leftarrow}N(CH_2CH_2)_3CH$ **A**,
X = H, Cl, Br, CF_3

A completely different route now led to the successful synthesis of bis(trifluoromethyl)sulfene **2**, namely via the symmetrical cleavage of 1,3-dithietane *S*-oxides.[7] The thermolysis of tetrakis(trifluoromethyl)-1,3-dithietane 1,1,3-trioxide **1**[8] already gave an indication of the existence of **2** [Eq. (a)], as did also the reaction of the corre-



[*] Prof. Dr. W. Sundermeyer, Dr. U. Hartwig, Dr. H. Pritzkow, Dipl.-Chem. K. Rall

1 2

sponding 1,1,3,3-tetroxide with tertiary amines[9] and the isolation of cycloaddition products of **2** generated in situ.[10]

On the other hand, when tetrakis(trifluoromethyl)-1,3-dithietane 1,1-dioxide **3** is allowed to react with quinuclidine as tertiary amine in acetonitrile [Eq. (b)] not only is the dimer of hexafluoroacetone formed but also the bis(trifluoromethyl)sulfene-quinuclidine adduct **4**, which precipitates as colorless crystals in 74% yield [m.p. 181°C (de-

3 4

comp.)]. The 90 MHz ^{19}F NMR spectrum shows the same unusual shift [$\delta = -47.8$ (s) in CD_3CN] typical for the $F_3C-C=SO_2$-group with partial negative charge on the sulfene C-atom, as was already observed for the product of the reaction of the 1,1,3,3-tetroxide analogue of **3** with tertiary amines[9] and in the case of the (2,2,2-trifluoromethylsulfonyl)trifluoromethylsulfene-quinuclidine adduct.[6]

An X-ray structure analysis of **4**[11] showed that **2** was stabilized by coordination of a quinuclidine molecule to the SO_2-group (Fig. 1). The S–N distance (1.91 Å) is longer

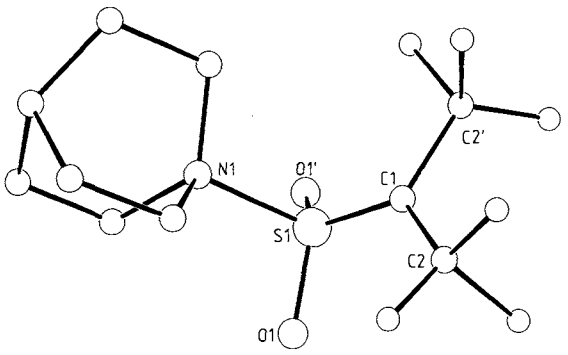

Fig. 1. Structure of **4** in the crystal. Important bond lengths [Å] and angles [°]: S1-N1 1.907(7), S1-C1 1.663(9), S1-O1 1.429(5), C1-C2 1.445(12); S1-C1-C2 120.2(5), C2-C1-C2' 118.5(9), O1-S1-O1' 118.3(4), N1-S1-O1 100.3(2), N1-S1-C1 107.0(4), O1-S1-C1 114.1(2).

than an S–N single bond, whereas the C–S distance (1.66 Å) is only slightly longer than an isolated C=S double bond. The mass spectrum, elemental analysis and the product of hydrolysis quinuclidinium-1,1,1,3,3,3-hexafluoropropane-2-sulfonate[12] likewise confirm the constitution of this first symmetrically substituted sulfene adduct **4**.

The analogous reaction with tetrafluoro-1,3-dithietane 1,1-dioxide **5** [Eq. (c)] proceeds completely differently. Instead of the expected difluorosulfene-quinuclidine adduct which, like **4**, should be soluble in polar aprotic solvents, only a product soluble in water and methanol is formed, the ^{19}F NMR spectrum of which shows two triplets at $\delta = -65.7$ and -78.8 of equal intensity and with the same coupling constant. The product, which formed colorless crystals (m.p. 124°C), was finally unequivocally identified as (quinuclidinodifluoromethylthio)difluoromethanesulfinate **6** by an X-ray structural analysis (Fig. 2).[13]

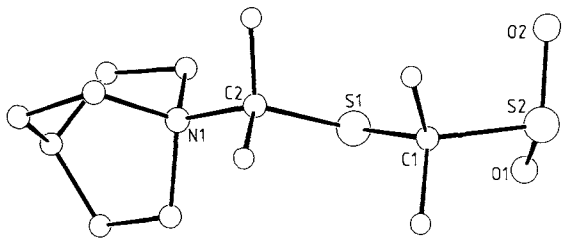

Fig. 2. Structure of **6** in the crystal. Important bond lengths [Å] and angles [°] (the values for each of the independent molecules are given): S1-C1 1.810(4), 1.820(4), S1-C2 1.798(4), 1.821(4), S2-C1 1.884(4), 1.897(4), S2-O1 1.476(3), 1.467(4), S2-O2 1.465(3), 1.441(4), C2-N1 1.514(5), 1.505(5); C1-S1-C2 98.3(1), 98.0(1), C1-S2-O1 97.2(1), 97.7(2), C1-S2-O2 101.9(2), 101.3(2), O1-S2-O2 111.5(1), 112.9(2), S1-C1-S2 108.2(2), 107.8(2), S1-C2-N1 112.1(2), 111.7(2).

The C–N distance corresponds to a single bond, so that one can speak here of an internal tetraalkylammonium salt in which the charges are separated by five bonds, whereas in the "inverse" fluorosulfene-trimethylamine adduct[14] only three bonds separate the positively and negatively charged centers.

Other than in the case of **3**, in the case of **5** the nucleophilic attack of the amine did not take place at the sulfur atom but at the carbon atom. As was expected, but hitherto not confirmed experimentally, the $C-SO_2$ bond is ruptured thereby, and not the electron-richer C–S bond.—The apparently nonpolar $C=SO_2$ bond (in sulfenes) is first polarized by steric and electronic effects of the substituents: usually as $R_2\overset{\ominus}{C}-\overset{\oplus}{S}O_2$, so that nucleophiles attack at the sulfur atom; if however the polarization is $R_2\overset{\oplus}{C}-\overset{\ominus}{S}O_2$, the nucleophilic attack takes place "inversely" at the carbon atom.[14–16]

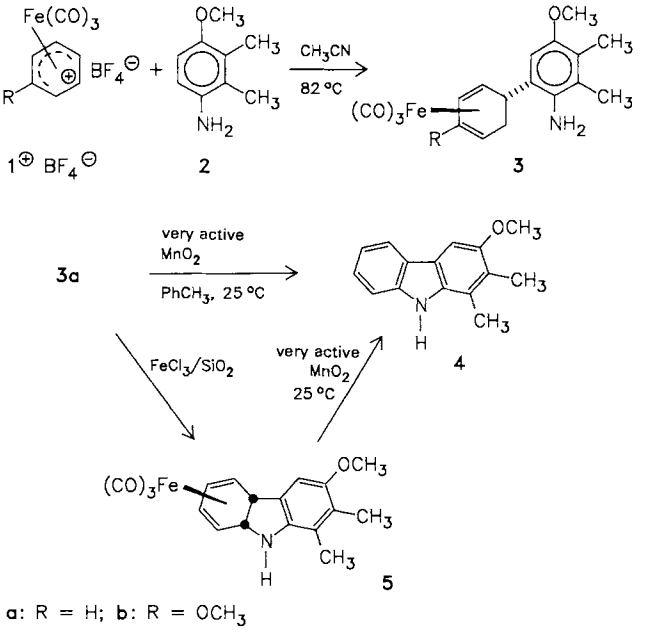
Highly Selective Oxidations of $Fe(CO)_3$-Cyclohexadiene Complexes: Synthesis of 4b,8a-Dihydrocarbazol-3-ones and the First Total Synthesis of Carbazomycin A**

By *Hans-Joachim Knölker*, Michael Bauermeister, Dieter Bläser, Roland Boese,* and *Jörn-Bernd Pannek*

Tricarbonyl(η^5-cyclohexadienylium)iron cations $\mathbf{1}^{\oplus}$ are very useful reagents for regio- and stereoselective C–C bond formation. They afford a wide range of 5-*exo*-substituted tricarbonyl(η^4-cyclohexadiene)iron complexes[1] in the electrophilic substitution of electron-rich aromatic systems such as indole, pyrrole, furan, and aniline.[2,3] Furthermore, some 5-*exo*-substituted cyclohexadiene iron complexes bearing a hydroxy or an amino group in the side chain have been observed to undergo oxidative cyclizations to give fused ring systems.[3,4]



Our intention is to use a methodology of consecutive iron-induced C–C and C–N bond formation for the total synthesis of pharmacologically active heterocyclic natural products. Here we report a very direct route to tricyclic carbazole alkaloids and a stereoselective access to various metal-complexed dihydrocarbazole derivatives including the hitherto unknown 4b,8a-dihydrocarbazol-3-one **7**.

The iron complexes **3** were prepared stereoselectively from the cations $\mathbf{1}^{\oplus}$ and the amine **2** by modified literature procedures[3] (**3a**, 95%; **3b**, 64%) (Scheme 1). However, the described cyclization procedure (reaction with iodine in pyridine)[3] was ineffective for our highly donor substituted compounds. We found that employment of milder oxidizing agents leads to a very reagent-sensitive and selective reaction furnishing either the aromatized cyclization products (e.g., **4**) or the corresponding iron-complexed dihydro derivatives (e.g., **5**) depending on the reaction conditions. This method opens up the way to a very direct synthesis of many naturally occurring carbazole alkaloids which are oxygenated in the 3- or in the 2- and 6-position.[5] We envisaged an application in the total synthesis of the carbazomycins, which are the first antibiotics with a carbazole skeleton.[6]

[**] Transition Metal-Diene Complexes in Organic Synthesis, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft. We wish to thank Dr. *V. Wray*, Gesellschaft für Biotechnologische Forschung (GBF), Braunschweig-Stöckheim, for recording the COSY spectra and Dr. *K.-H. Geiss*, BASF Aktiengesellschaft, Ludwigshafen, for nonacarbonyldiiron.

Using the methodology described above, 4-deoxycarbazomycin B **4** has been synthesized in two steps from the cation $\mathbf{1a}^{\oplus}$ (Scheme 1). Reaction of **3a** (see above) with

Scheme 1.

very active manganese dioxide[7] afforded, in 28% yield, **4**, whose spectral data were identical with those reported by *Nakamura* et al. for the natural product.[6,8] An extensive investigation of the oxidative cyclization of **3a** showed that the scope of this reaction is much larger than originally anticipated. The one-pot transformation of **3a** to the carbazole **4** involves cyclizing dehydrogenation, aromatizing dehydrogenation and demetalation. This mechanism is supported by the isolation of the intermediate iron-complexed 4a,9a-dihydro-9*H*-carbazole **5** as a by-product in the cyclization of **3a** to **4** using $FeCl_3$ supported on silica gel[9] or 10% Pd/C at 80°C (Scheme 1). This strategy thus provides access to the interesting 4a,9a-dihydro-9*H*-carbazole skeleton[10] without additional annelated rings. The structure of **5** has been confirmed by an X-ray analysis (Fig. 1).[11] Single crystals of **5** exhibit optical anisotro-

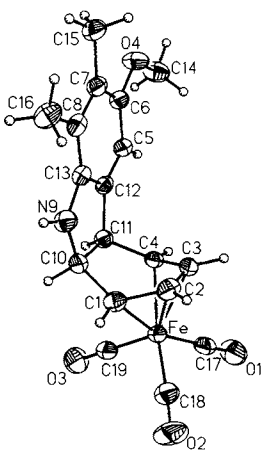

Fig. 1. Molecular structure of **5** [11]. Selected bond lengths [Å]: Fe-C1 2.106(3), Fe-C2 2.060(3), Fe-C3 2.063(2), Fe-C4 2.111(2), C1-C2 1.426(4), C2-C3 1.398(4), C3-C4 1.423(3), C4-C11 1.512(3), C1-C10 1.515(3).

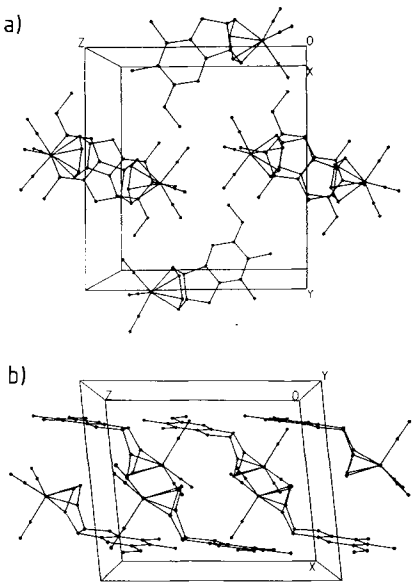
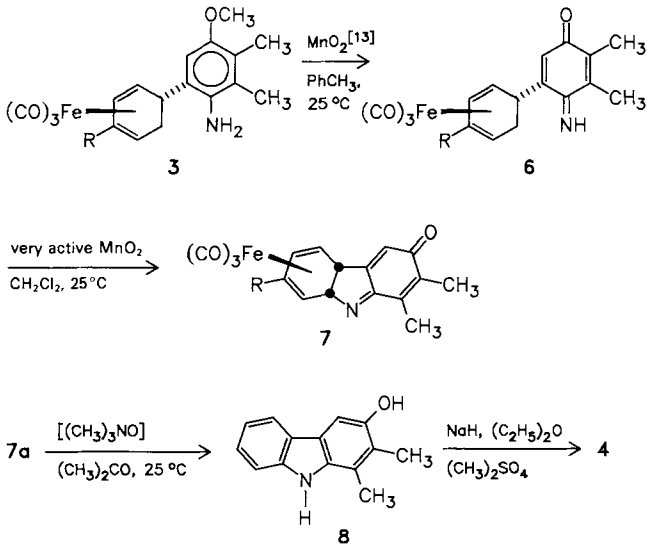
pism. Rotation of these columnar crystals by 90° about the longitudinal axis results in a colour change from red to yellow. This interesting feature can be explained by the crystal packing (Fig. 2). When looking at the plane of the aromatic rings (Fig. 2a), which are arranged in parallel layers, the crystals appear red. Orthogonal to this direction (Fig. 2b) the crystals appear yellow. With very active manganese dioxide[7] **5** is smoothly converted into **4** (Scheme 1).





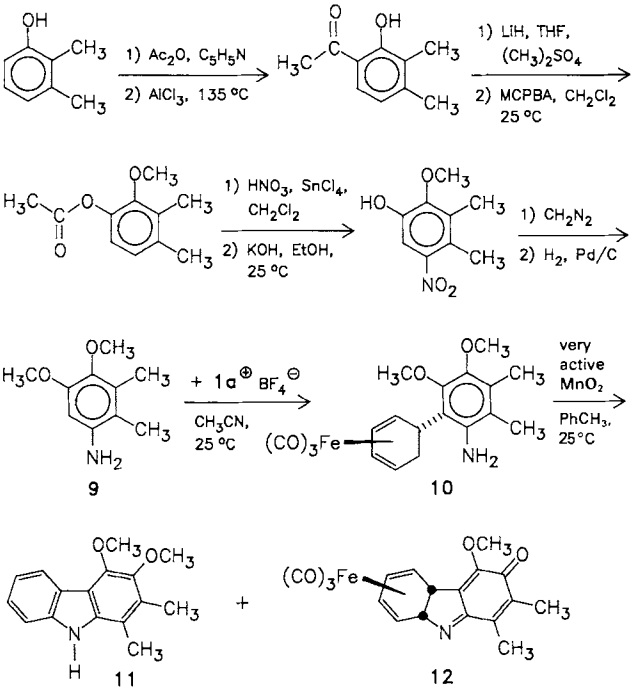


Fig. 2. The unit cell in crystals of **5** [11]. a) View perpendicular to the aromatic rings, b) side view (rotated by 90° about the *z* axis.

An even more striking example for the synthetic flexibility of these cyclizations is the first synthesis of the 4b,8a-dihydrocarbazol-3-ones **7** (Scheme 2). Selective oxidation of the complexes **3** using commercial MnO_2[13] gave the non-cyclized iminoquinones **6a** (60%) and **6b** (67%). The iminoquinones **6** are readily cyclized in a regio- and stereoselective manner to afford the novel iron-complexed 4b,8a-dihydrocarbazol-3-ones **7a** (90%) and **7b** (71%) again using very active manganese dioxide.[7] Structural assignments for **7** are based on ^1H, ^{13}C and COSY NMR spectra, and an X-ray crystal structure determination for **7a**.[1] The complexes **7** are stable at room temperature for at least several months, in contrast to the analogous 2,3-dihydroindol-5-ones, which are reported to undergo immediate ismerization to the 5-indolyl alcohols.[15] Upon demetalation of **7a**, however, rearrangement to the 3-carbazolyl alcohol **8** (93% yield) occurs instantaneously (Scheme 2). Methylation of **8** yields again 4-deoxycarbazomycin B **4** (96%). Due to the cleaner course of the iminoquinone-cyclization this route to the aromatized carbazoles is much better (48% overall yield of **4**) than the direct oxidative cyclization of the complexed amine **3a** (28% yield). Taking advantage of the tricarbonyliron fragment as a protecting group for the diene should allow exploitation of the iminoquinone reactivity in Michael and cycloaddition reactions.

Scheme 2.

Scheme 3.

Finally, to demonstrate the utility of these reactions in alkaloid synthesis, we completed the first total synthesis of the antibiotic carbazomycin A **11** (Scheme 3). The required amine **9** was prepared in eight steps from 2,3-dimethylphenol (28% overall yield). Subsequent C–C bond formation with **1a** to give the complex **10** (84% yield) and cyclization using very active manganese dioxide[7] (25% yield) afforded carbazomycin A **11**, the spectral data of which (UV, IR, ^1H NMR, ^{13}C NMR) are in full agreement with those of the natural product.[6] The isolation of the iron-complexed iminoquinone **12** as a byproduct in 17% yield indicates that the imonoquinone-cyclization could also be used for the synthesis of **11**.

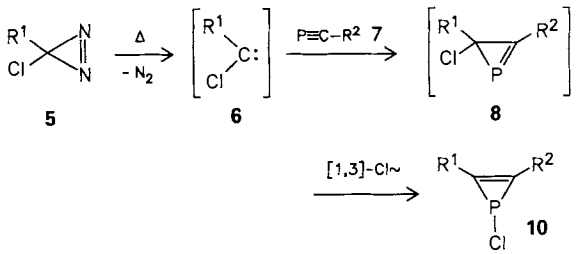
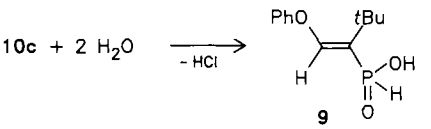
2-Chloro-2*H*-phosphirene/1-Chloro-1*H*-phosphirene Isomerization by [1,3]-Chlorine Shift**



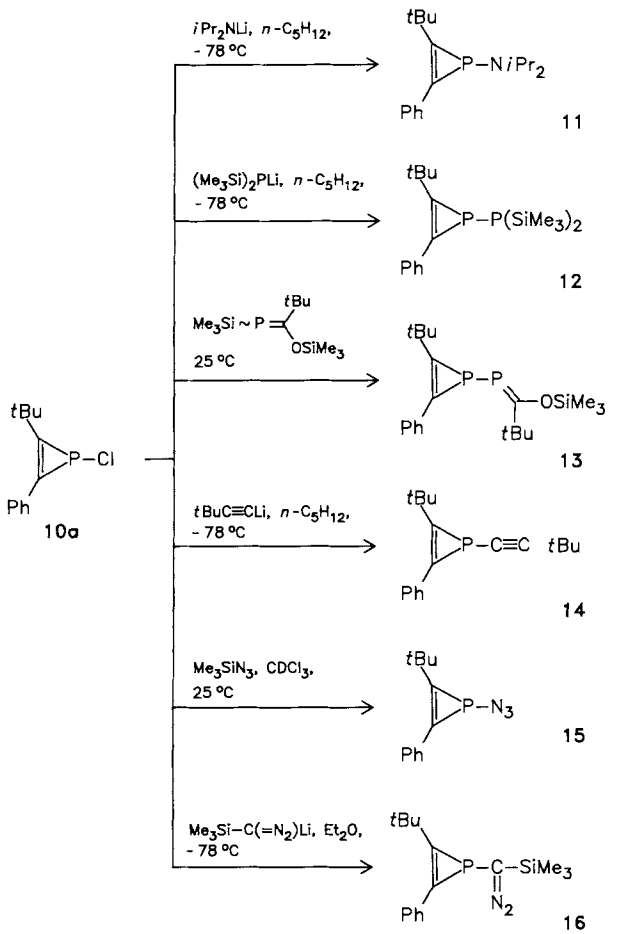
By *Oliver Wagner, Michael Ehle,* and *Manfred Regitz**

2*H*-Azirines **1** are stable and useful building blocks in heterocyclic synthesis.[1] In contrast, the 1*H*-azirines **2** are antiaromatic and short-lived, and consequently their existence could hitherto only be demonstrated by trapping reactions.[2] The energy gradient between the two azirine systems clearly manifests itself in unidirectional isomerizations (**2**→**1**).[3] We have now found exactly the opposite situation in the case of unsaturated three-membered ring systems with phosphorus as heteroatom: 2*H*-phosphirenes **3**[4] are converted by a substituent-shift from carbon to phosphorus into 1*H*-phosphirenes **4**.[5]



1 **2** **3** **4**

When chlorocarbenes **6** are generated from diazirines **5**[6] by thermal elimination of N_2 in presence of phosphaalkynes **7**,[7] subsequent work-up by distillation affords the 1-chloro-1*H*-phosphirenes **10** as stable, colorless oils.[13] Their constitution was confirmed by elemental analyses, the relatively high-field position of the ^{31}P-NMR signals and the occurrence of two ^{13}C-NMR signals characteristic for olefinic three-membered ring carbon nuclei (Table 1).



5 **6** **8** **10**

The constitution of **10c** was additionally confirmed by the result of hydrolysis in aqueous ether, which led with ring-opening and cleavage of the P-Cl bond to the phosphonous acid **9** [colorless crystals, m.p. 87 °C; IR (KBr): $\tilde{\nu}=2900$ (POH), 2400 cm^{-1} (PH); ^{1}H NMR ($CDCl_3$): $\delta=1.39$ (s, 9H, *t*Bu), 7.21 (m, 6H, phenyl- and olefin-H), 7.35 (d, $^1J_{PH}=568$ Hz, PH), 9.88 (br., 1H, POH); ^{13}C NMR ($CDCl_3$): $\delta=29.8$ [d, $^3J_{PC}=4.5$ Hz, $C(CH_3)_3$], 34.2 [d, $^2J_{PC}=6.9$ Hz, $C(CH_3)_3$], 119.5 (d, $^1J_{PC}=125.8$ Hz, C*t*Bu), 153.9 (d, $^2J_{PC}=31.3$ Hz, COPh); ^{31}P NMR ($CDCl_3$): $\delta=29.2$].

9

As primary products of the previously unknown intermolecular carbene addition to P-C triple bonds[8,9] only the 2-chloro-2*H*-phosphirenes **8** are conceivable; but these

16: yellow oil, not distilled; IR: $\tilde{\nu} = 2040$ cm^{-1} (C=N_2); ^1H NMR (C_6D_6): $\delta = 0.27$ (s, 9H, $Si(CH_3)_3$), 1.39 (s, 9H, *t*Bu); ^{13}C NMR (C_6D_6): $\delta = -1.1$ [d, $^3J(P,C) = 3.0$ Hz, $Si(CH_3)_3$], 29.1 [s, $C(CH_3)_3$], 30.3 (d, $^1J(P,C) = 63.5$ Hz, P–C=N_2), 32.8 [d, $^2J(P,C) = 6.5$ Hz, $C(CH_3)_3$], 120.6 (d, $^1J(P,C) = 48.9$ Hz, =CPh), 138.4 (d, $^1J(P,C) = 56.2$ Hz, =C*t*Bu); ^{31}P NMR (C_6D_6): $\delta = -178.8$

[a] Unless otherwise stated IR spectra as film, ^1H- (200 MHz), ^{13}C- (50.2 Hz) and ^{31}P-NMR spectra (80.8 MHz) in $CDCl_3$ [TMS (int) and 85% H_3PO_4 (ext), respectively with b.p. data from Kugelrohr distillations.

cannot be isolated because of a rapid 1,3 chlorine shift to give compounds **10**. Resolution of the P=C double bond in **8** in favor of the C=C double bond in **10** is only understandable if the latter have no antiaromatic character. This in turn requires that the halogen does not lie in the plane of the three-membered ring.[10]

The chlorine substituent in **10** readily undergoes nucleophilic replacement. Reactions of **10a** with a series of nucleophiles (Scheme 1)—some at 25°C, some at −78°C—led to a broad spectrum of novel, functionalized 1*H*-phosphirenes (**11–16**); like **10a–g** they are sensitive to hydrolysis.

That the unsaturated three-membered ring of **10a** remains intact in all substitution reactions is already shown by the positions of the ^{31}P- and ^{13}C-NMR signals of the products (Table 2), which are comparable with those of the signals of **10**. Investigation of the reactivity of **11–16** will show whether such compounds have similar synthetic potential as the corresponding substituted cyclopropenes.

Experimental

10a: The solution of **5a** (0.48 g, 2.5 mmol) [6] in excess **7a** (2.0 g, 20 mmol) [7] was heated to 80°C for 30 min in a pressure Schlenk tube (protective shield). The deep-brown reaction solution was cooled to room temperature, the excess pressure equalized, unconsumed **7a** removed at 25°C/10^{-2} mbar (and recovered in a cooling trap at −200°C), and the residue purified by Kugelrohr distillation [150°C (furnace temperature)/10^{-2} mbar]. Yield: 0.36 g (63%) of colorless oil.

13: The solution of **10a** (0.45 g, 2.0 mmol) in excess (2,2-dimethyl-1-trimethylsiloxy-1-propylidene)trimethylsilylphosphane [11] was stirred for 6 h at room temperature (^{31}P-NMR monitoring; the crude solution contained the *E*/*Z* isomers in the ratio 5:1) [12]. After addition of 3 mL of pentane and cooling to −78°C, (*E*)-**13** precipitated out. Yield: 0.37 g (49%) of yellow, amorphous powder, m.p. 49°C.

All the new compounds gave correct elemental analyses.

Organoselenium Chemistry I. Functional Group Transformations. By *A. Krief* and *L. Hevesi*. Springer, Berlin 1988. xi, 221 pp., hardback, DM 186.00.—ISBN 3-540-18629-8

Selenium, whose discovery is ascribed to *Berzelius* in 1817, was during the 19th century already being mentioned occasionally in reports of organic compounds and organic reactions. It moved into the limelight of organic synthesis in the early thirties of the present century, with the discovery by *H. L. Riley* that α-CH_2 groups in olefins and ketones can be oxidized using selenium dioxide. At about the same time *O. Diels, L. Ruzicka* and others observed the dehydrogenating effect of elemental selenium, which at that time was used especially for converting steroids to phenanthrene derivatives or chrysene. The mid-seventies saw the beginning of a blossoming of organoselenium chemistry which continues today. On the one hand more and more organic molecules possessing selenium-containing skeletons or functional groups became accessible, while on the other hand various selenium reagents for carrying out especially mild or highly specific transformations were discovered. This work is associated particularly with the names of *N. D. Jones* and *K. B. Sharpless*.

The present-day importance of organoselenium chemistry has naturally led to the publication of numerous reviews and monographs on selenium compounds, and to these is now being added the work by *Krief* and *Hevesi*, which is to consist of two volumes. The authors' aim is to give an account of the most common selenium reagents, and the breadth and limits of their usefulness in organic synthesis.

The first volume, published in 1988, deals with actually or formally possible single stage processes involving selenium-containing intermediates, which cannot or need not be isolated. The second volume will treat processes with two or more stages involving selenium-containing intermediates. In addition there is to be a section on the preparation of the most important selenium reagents.

The introduction to Volume I deals with the occurrence of selenium and its compounds in nature, and with toxicity, biochemical functions, and some industrial and ecological aspects. This is followed by ten chapters on selenium compounds in organic synthesis, arranged according to the different oxidation states of selenium (-2 to $+6$). The contents of the individual chapters are best summarized by listing the chapter headings: Reactions involving hydrogen selenide, selenols and related compounds; Reactions of metallic or amorphous selenium with organic molecules; Reactions involving selenium oxides and their derivatives; Reactions using selenenyl halides and related compounds; Reactions involving benzeneseleninic anhydride and related compounds; Reactions using benzeneseleninyl halides; Reactions using perseleninic acids; Selenium dioxide oxidations; Reactions of imidoselenium compounds; Reactions involving selenium oxychloride and selenium tetrahalides.

As well as the synthetic methods themselves, the mechanistic aspects necessary for understanding them are briefly covered. The style of the book combines fluency and brevity with a high information content; the clearly presented reaction schemes and a comprehensive keyword index are especially good features. However, in the descriptions of the syntheses one often feels the lack of a critical evaluation, and especially of comparisons with other known methods for carrying out the same transformations. The book is definitely not a substitute for a comprehensive review of organoselenium chemistry, such as is contained in the two volumes on selenium and tellurium compounds published in 1986 and 1987 in the series "The Chemistry of Functional Groups (editors *S. Patai* and *Z. Rappoport*), but it will nevertheless be a valuable aid to the preparative chemist, and especially to the natural products chemist.

Nitrile Oxides, Nitrones and Nitronates in Organic Synthesis. Novel Strategies in Synthesis. By *K. B. G. Torssell*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xii, 332 pp., hardback, DM 115.00.—ISBN 3-527-26641-0/0-89573-304-8

The second volume in the series "Organic Nitro Chemistry" treats some further functional N–O derivatives such as nitrile oxides, nitrones and alkyl and silyl nitronates with the isoxazoles derived from them and their hydrogenated forms. The synthesis, reactivities and applications of the compounds are described.

After an introductory discussion of general aspects (Chapter 1, pp. 1–47: dipolar character, 1,3-dipolar addition, physico-chemical properties of the isoxazoles, stereo- and regiochemical considerations, asymmetric induction), the first part of the book (Chapters 2 and 3, pp. 55–89) deals with the synthesis and chemistry of nitrile oxides and nitrones. Since there are already several excellent review articles covering this field, a condensed survey is given here. (However, for the nitrile oxides there is no mention of the elegant synthesis from nitromethyl derivatives and Ph_3P–CCl_4 reported in 1983 by *Furukawa, Hashimoto* and *Nishiko*). Next comes a review (Chapter 4, pp. 95–122) of the synthesis, properties and reactions of alkyl and silyl nitronates, which are of interest as reagents in the nitro-aldol reaction (Henry reaction) as well as 1,3-dipoles.

The largest part of the book is Chapter 5 (pp. 129–270), which is concerned with the use of nitrile oxides, nitrones

and nitronates, and of their cycloaddition intermediates the isoxazoles, isoxazolines and isoxazolidines, in the synthesis of a wide range of types of compounds. As the author emphasizes under "Concluding Remarks" (p. 255), this chapter is intended as an extension of *A. I. Meyers* classic work "Heterocycles in Organic Synthesis", published more than 13 years ago, in relation to the isoxazoles and their hydrogenated derivatives and precursors. Cycloaddition of nitrile oxides, nitrones and nitronates to olefins and acetylenes gives isoxazole derivatives, whose reductive reactivation offers a useful and generally applicable route to a wide variety of hydroxy, carbonyl and amino compounds, and also to alkylated hydrocarbons, which can then be used as versatile building blocks for syntheses. Syntheses described here include: 2-nitroalcohols, α-cyanoketones, 2-cyanoalcohols by 3-H abstraction from isoxazoles, the Woodward-Olofson peptide synthesis, ketone anellations, 1,3-carbonyl shifts, β-polyketones (polyketides), 2-isoxazolines as masked aldols, other α,β-unsaturated carbonyl compounds, β-acylated acrylic esters, 1,4-diones, furans, 3(2*H*)-furanones and pyrones, pyrrole and indole derivatives, aziridines and 1-azirines, pyrazoles, imidazoles, oxazoles and isothiazoles. Next the synthesis of further heterocycles by ring transformations via the side-chains of isoxazoles is described; heterocycles accessible by this method are pyridines, pyrimidines, pyridazines, oxazines, quinolines and quinoxalines, azetidines, and condensed heterocyclic systems. Other syntheses dealt with are those of cyclopentane derivatives (e.g. rethrolones, prostaglandin precursors, terpenoids), 1,3-aminoalcohols, alkaloids (including syntheses by intramolecular cycloaddition), glycosides, amino acids and macrocycles.

In order to include also the most recent publications in this rapidly developing field, an addendum (pp. 271–300) has been provided, covering the literature from December 1985 to August 1987. Topics here include MCSCF calculations on the mechanism of 1,3 dipolar cycloadditions, FMO theory of the addition of nitrones to cumulenes, and syntheses of *D*-2-desoxyriboses, numerous alkaloids, diterpenes (e.g. Forskolin), flavonoids, ring strained nitrones, pheromones, and aryl- and heteroaryl-*C*-glycosides.

The book contains a total of 1806 literature citations, and a bibliography in Chapter 1 lists all relevant review articles covering the different subject areas dealt with. A large amount of information is collected together in the many tables. In a field where many excellent review articles have already been published, the author of this monograph has skilfully filled existing gaps in information on the synthesis and applications of nitrile oxides, nitrones and nitronates, and has at the same time provided a wide-ranging survey of new synthetic strategies based on the latent functional isoxazoles and their reduced forms obtained by these methods.

The high information content of this commendable monograph is, however, unfortunately reduced by the fact that some of the structural formulas are of poor quality (most of them are too lightly drawn, heteroatoms are badly placed, double bonds are depicted too narrowly, bonds are crooked, in stereochemical representations the arrowed bonds can scarcely be made out; consequently some of the reaction schemes lose much of their clarity, e.g. on pages 27, 56, 66, 77, 112, 178, 184, 209, 216, 226, 245, 276, 277 and 281). Despite these inadequacies in the formulas, the monograph can be thoroughly recommended to chemists with interests in synthesis, heterocyclic compounds and natural products as a rich source of information.

ADVANCED MATERIALS

Advanced Materials R & D—Planning for the Future

Editorial Essay

By James Economy*

1. Introduction

One of the major questions confronting materials scientists concerns their future role with respect to the emerging technologies of the 21st century. Today, we hear of many activities among the various nations of the world directed at achieving leadership in future industrial technologies through major commitments in advanced materials R&D. In Japan, seven specific areas in materials R&D were identified by the Ministry of International Trade and Industry (MITI) in the early 1980's and large joint industrial programs were established to carry out leading edge research in these areas.[1] In the USA, emphasis is being placed on more effectively coupling the materials research efforts in the universities and the national laboratories to industry. In Europe a number of activities can be identified; e.g., in Germany the government is beginning to foster closer interactions between the large chemical giants and the Max Planck Institute for Polymer Research in Mainz, while in France close collaborations between CNRS and industry are in place. As a backdrop, a number of the global technology companies have been acquiring key materials industries such as composites fabricators or advanced metal alloys manufacturers with the intent of better participating in these obvious growth areas.

One might ask which of these approaches if any provides a reasonable probability of fulfilling the hopes and anticipations of the countries or organizations who have committed significant resources to these activities? Stated somewhat differently, can one predict future needs with sufficient accuracy to lay out and justify an advanced materials program with the necessary effort and continuity to address the future technologies of the 21st century? Clearly the track record of industry has not been very good in the past two decades in developing new materials let alone in addressing the short-term needs for those industries which are dependent on advanced materials for their new product lines. Part of the problem lies in the fact that the chemical and metal companies who traditionally have provided most of the initiative to new materials development have dramatically changed their posture in the past twenty years. Thus, most of the metal industries have either sharply reduced or eliminated their R&D and that which remains tends to focus on very near term goals. Much of the chemical industry has emphasized forward integration into high value added markets where their skills in materials may provide significant leverage. On the other hand, many of the major industries such as electronics, aerospace, automotive etc. who have critical needs for new or improved materials for the most part still depend on the traditional materials suppliers who are actively pursuing the above indicated goals. Unfortunately, many of the R&D managers in the materials dependent industries are trained more in the needs and opportunities of the particular industry rather than in the synthesis and development of the advanced materials upon which the future of their industry may depend. Hence, programs on new materials development may not be as readily supported in such environments. Other factors that may be cited which work against the successful pursuit of advanced matrials R&D in the USA include the preoccupation of high level management with potential takeovers and the demands on R&D management to demonstrate an early return on investment in materials research.

In this paper, I first look at the field of advanced materials from a historical perspective and then examine closely two industrial R&D efforts with which I was directly involved. In the first case, the research was directed at development of new materials for diversification of the company into new areas, while in the second example, work on new materials was aimed at meeting the internal

needs of the corporation. These two approaches are discussed in terms of their respective risks and payoff and then a number of generalizations are drawn concerning future directions for advanced materials research.

2. Historical Perspective (early 1900's–1960)

In spite of the current enthusiasm for R&D on advanced materials, a strong perception exists among many industrial leaders that the field is mature and that there are very few new materials with significant commercial value remaining to be discovered. In addition, recent experiences with the time required for development of new materials suggest that it takes far too long and is too risky bringing a new material to the marked place. Although these views are undoubtedly correct for a number of materials categories, the danger lies in the tendency to generalize them to the whole field of advanced materials. In this section, I would like to explore some of the sources for these perceptions and also describe why industrial scientists of an earlier era were indeed more successful in the commercial development of advanced materials.

When one examines the development of new materials prior to 1960, one can identify certain distinct patterns to these discoveries. Thus in the early 1930's when *Carothers* and his team were laying the foundation for the field of condensation polymers, they came up with the unexpected discovery that melts of aliphatic polyesters could be melt-drawn into filaments and then cold-drawn to achieve much higher strengths. The implications were undoubtedly obvious to the researchers and especially management that they had an alternative to silk and within several years a material (Nylon) had been selected, optimized and scaled-up to a semi-works facility. This also was the first example of melt-spun filaments, and required significant innovation in the design of the spinning system.

In an earlier era, *Acheson*'s work on the reaction of SiO_2 with carbon may have yielded the anticipated SiC, however what was unexpected was the very high hardness of the material. Its potential use as an abrasive must have been immediately obvious and within a short period of time, *Acheson* proceeded to scale up the reaction for commercial development.

In the early 1950's, the discovery of linear polyethylene by several groups of workers in different laboratories appears again to have been fortitous, but at least two of the groups recognized the significance almost immediately and within five years one of them, Phillips Petroleum, had put a 50 million pounds per year facility on stream. In fact, Phillips sold the know-how for such a plant to a number of other companies and undoubtedly quickly recouped its initial investment. Certainly, the earlier development of high pressure, branched polyethylene permitted easy identification of markets for the linear polyethylene with its greatly improved thermal resistance and stiffness.

These three examples, although taken from quite different periods of time, have a number of points in common which appear to characterize many of the major developments in commodity materials such as polymers (see Table 1 for a listing of the major commodity polymers). In each of these cases, there were readily identifiable markets which could be addressed almost immediately. Potential existed for low cost routes to the product and high level management had the technical background to commit resources for rapid scale-up in a timely way. To a considerable extent, one can understand why investment in industrial R&D during the period of 1930 to 1960 proved to be highly profitable. However, by 1960, it was becoming clear that it was unlikely that there would be any new commodity polymers and greater attention was focussed on specialty polymers. In fact from our vantage point today, the commodity polymers listed in Table 1 can only be considered as a mature field since the last one was introduced over 30 years ago. It is noteworthy that a significant industrial R&D effort continues on these polymers but it is directed primarily at improvements in the product and/or process. This kind of incremental research appears to have had significant payoffs in recent years — witness the recent progress in the manufacture of polyolefins.

Dr. Economy received his BS from Wayne State University (1950), his PhD from the University of Maryland under Professor W. J. Bailey (1954) and was a research associate at the University of Illinois (1954–1956) with Professor C. S. Marvel. He worked at Allied Chemical as a general research leader on polyolefin research from 1956–1960. From 1960–1975 he was Manager of Chemistry and of the Research Branch in the R&D Division of the Carborundum Co. From 1975–1989, he was Manager of the Polymer Science and Technology Department in the Research Division of IBM. Just now, in February 1989, he joins the faculty of the University of Illinois as Professor and Head of the Materials Science and Engineering Department. He has carried out research on high temperature polymers, flame resistant materials, high performance composites and advanced materials for microelectronic devices. He has received a number of distinguished awards including the AIC Chemical Pioneer Award (1987), ACS Phillips Medal (1985), the Southern Research Burn Institute Award (1976), Schoelkopf Medal (1972), and 14 IR 100 Awards for Outstanding Technical Developments in American Industry. He has published over 150 technical papers and received more than 70 US patents. He has served on numerous government committees and was chairman of the Polymer Division of the American Chemical Society (1985). He is a member of the National Academy of Engineering, the National Materials Advisory Board (since 1984) and is the USA representative to IUPAC's Macromolecular Division (since 1985).

During the late 1950's the US Government began to pursue a more aggressive role in stimulating R&D on advanced materials to fill specific needs such as advanced military hardware, aerospace applications and nuclear reactors. Incentives in the form of large government grants were made available to encourage industry and university scientists to pursue these goals.

Another phenomenon which could be traced back to that particular era was the desire of many companies to diversify from their traditional businesses into areas with high growth opportunities such as plastics. If done properly, this kind of diversification could be extremely effective at insuring the long term stability of a company. However, the chief executive officer (CEO) often lacked the technical expertise or intuitive skills necessary to manage these new businesses and in such an environment high level decision making could lead to disastrous consequences or at least to delays on critical decisions. In the late 1960's, this problem would be further exacerbated by a new generation of CEO's drawn primarily from the financial ranks.

Undoubtedly the most dramatic change during this period was the dominating role assumed by the US government in defining its advanced materials needs. From an industrial viewpoint it was easy to focus on these government needs with the expectation of financial support by the government followed by the potential for a wider commercial development. As shown in Table 2, the needs of the Department of Defense (DOD) encompassed a wide range of exciting materials opportunities. It was only natural that many of the best scientists from industry and academia would be attracted to these areas, especially with the added inducement of financial support. Thus, this intrusion by the US government into the traditional market driven R&D of the past tended to focus attention of industrial R&D toward developments where potential for commercialization either might not exist or was much further off in the future.

In recent years another factor acting to further complicate development of new materials has been the increasing level of sophistication and complexity of the new specialty materials. This increased complexity has unfortunately been more than matched by the large number of advanced techniques available for characterizing these materials. However, the investment in such tools and skilled personnel can be prohibitive, particularly for mid-size industries.

3. R&D at Carborundum Co. (1960–75)

Let me now consider the research program that I managed at the Carborundum Company, since it illustrates effectively a number of the issues raised in the previous section. As described in a recent paper,[2] the R&D work on advanced materials at Carborundum was highly successful from a technical viewpoint. Over 30 new materials were

discovered and brought to the level of scale-up and test marketing. In Table 3 is provided a partial list of the materials developed during my tenure at Carborundum. The success of the program is best illustrated by the fact that eight of the materials are commercially available today, while work continues on at least six of the others. Considering the relatively small size of the group (30–40 people) it is all the more remarkable that so many materials could be developed and marketed in such a short period of time. There were indeed many novel features with respect to the organization and operations and these are discussed in detail elsewhere.[2] I do not intend to review the achievements of the group, but rather to focus on those features which greatly complicated commercial development. One point that is immediately obvious from an examination of Table 3 is that most of the materials were developed primarily in response to the general goals defined by the US Government.

To better illustrate the problems confronting researchers during that era it is instructive to review one of the programs in Table 3, namely, that on the aromatic polyesters of *p*-hydroxybenzoic acid (PHBA). Today, this class of polymers is being pursued aggressively by a number of companies with the anticipation that their use as engineering plastics will provide a major advance over metals such as aluminum or steel. Of particular interest here is the examination of key decisions made that critically influenced the directions of the program.

As shown in the chronology in Table 4, this program had its beginnings in early 1963, when the homopolymer of PHBA was successfully prepared for the first time and shown to be processible by sintering or metal forming techniques. This was followed by the successful synthesis in 1966 of the copolymers of PHBA which could be melt-processed at about 400 °C but still retained their properties to well over 300 °C. Our studies were prompted by the rather large DOD effort on high-temperature polymers initiated in the late 1950's. At the time most of the DOD effort was directed at heterocyclic and related ladder-like polymers that could be processed from solution into coatings and fibers and might have use at temperatures up to 800 °C. In our approach we had realized from a study on carbon fibers that the thermal oxidative stability of carbon was limited to 400 °C. Hence, it was clear that no carbon based polymer would have utility much above that temperature. We therefore undertook to look at potentially low cost polymers that were fabricable by melt or solid state processing with the idea that such systems would have far broader utility.

In early 1970 we commercially introduced the homopolymer of PHBA (Ekonol) as a material which could be fabricated by metal forming techniques such as plasma spraying or high energy forging. This was followed in 1972 by the copolymer of PHBA with biphenol terephthalate (Ekkcel) which was commercialized as an injection molding grade polymer with a use temperature in excess of 300 °C.

Table 4. The aromatic polyester strategy.

1963–1966	Discovery of the homopolymer of PHBA (1963) Discovery of copolymers of PHBA/BPT (1966)
1970–1972	Introduction of Ekonol/Ekkcel to market
	• Also developed high modulus fiber • Purchased Three Plastics Co. • Far east joint venture with Sumitomo Chemical • Metco markets Ekonol as plasma spray powder
	however
	• Acquisitions don't work out • Market for Ekkcel develops too slowly
1974–1978	Carborundum comes under financial duress
	• Tries to decommit from Ekonol • Cuts back effort on Ekkcel • Fiber is forgotten • Is acquired by Kennecott
	however
	• Metco holds Carbo to Contract on Ekonol • Dartco licenses Ekkcel • Sumitomo continues work on fiber
Today Program is Highly Successful	
	• Carborundum still manufactures Ekonol—very profitable • Dartco has 20,000,000 lb/yr plant on stream—Xydar (Ekkcel) • Sumitomo introduces Ekonol fiber (1985) • Many companies poised to introduce similar polymers
	however
	• Large potential may lie elsewhere • Fundamental understanding lags

To help accelerate commercialization of these new materials the Carborundum Co. acquired several US plastics companies (total value ca. $ 30 million) and also established a joint venture with Sumitomo Chemical in the Far East on these new polymers. In the meantime, in 1971, we also demonstrated that the copolymer could be melt drawn into a high modulus filament with properties similar to the Aramid fibers. Of more immediate importance, the Metco Co. began to make significant progress in marketing the Ekonol resin as a plasma spray powder. However, other than for that application, the markets for these materials developed very slowly in the ensuing three or four years. As it turned out, the acquisitions were not particularly good fits and contributed little to the commercialization of these new polymers.

In the meantime, the CEO of Carborundum began to explore other more direct routes to diversification that did not require as much commitment in time and resources, and the momentum to the materials R&D effort began to disappear. In fact by the late 1970's, attempts were made to license the polyester technology and to decommit from prior sales agreements. Fortunately, the Dart Corporation had identified an important use for the injection moldable polyester, Ekkcel, for high temperature cookware, and went ahead and licensed the technology from the Carborundum Co. By 1983–1984 they had made sufficient pro-

ADVANCED MATERIALS

gress to justify putting a 20 million lb plant on stream to manufacture the polymer under the trade-name Xydar. In the case of Ekonol, although Carborundum tried to decommit from manufacturing the polymer. Metco held them to an earlier agreement to supply the powder. Fortunately, for Carborundum, the use of Ekonol became and has continued to be a highly profitable specialty polymer. Subsequently, the Carborundum Co. was purchased by Kennecott which was acquired by SOHIO which was then taken over by British Petroleum.

There are several lessons to be gleaned from this brief narrative. First of all, the discovery, optimization, scale-up and test marketing of these new polymers was readily achieved within five to seven years, and this was true for practically all of the materials listed in Table 3. The next step which involved a much larger commitment of financial resources required a high level management better skilled in the nuances of the new technology and able to make key decisions in a timely fashion. Certainly our CEO was sufficiently committed that he acquired several engineering plastics companies with the intent that they would accelerate the use of these new polymers. Since these were already profitable organizations the risk in the acquisitions was minimal and at least created a very desirable image. Unfortunately it turned out that the product lines and skills base of these acquisitions were far removed from the potential uses of our new materials. Undoubtedly, the most serious problem was the absence of a clear market need which typified the developments described earlier in the "Historical Perspective". In retrospect, it is clear now that we should have been able to distinguish the needs of the market place from the wish list of government agencies.

4. Polymer R&D at IBM (1975-present)

Let me turn now to consider in some detail a different approach to advanced materials research in industry and one with which I have been involved with since 1975 at IBM. Here, the primary goal is to develop new or improved materials for the advanced devices currently in development in the operating divisions. There is however, a unique constraint, namely, these materials must be developed, optimized and available in reproducible quantities from a vendor within two to four years. This relatively short time represents the lead time normally provided in the design and development of a new device.

It is instructive to reflect on the environment within IBM when I first jointed the company in 1975, since the attitude toward development of new materials and especially polymers was and is typical of many industries whose product lines depend on development of new or improved materials. The group that I inherited and which included a number of excellent scientists, was accustomed to working closely with the operating divisions in a response

mode to solve problems with materials that were provided by various vendors. At the time it was clear that there were needs within IBM for advanced polymers for the many new devices under development within the company (see Table 5). It was equally apparent that the traditional suppliers of new polymers were not particularly motivated to develop such systems primarily because of the very small volumes needed for many of the applications (< 1000 kg/yr). Yet these new materials were critical for the next generation of devices planned for the 1980's.

Hence, through the late 1970's, the polymer group was restructured to include a much stronger component dedicated to polymer synthesis. And by the early 1980's, the group was positioned to begin to make significant contributions to the advanced technologies of IBM. In fact, from 1982 to the present, the polymer group has on average successfully transferred two new materials each year to the operating divisions for use in a wide range of advanced devices. Some of these developments represented modifications of existing materials while others were at the leading edge of advanced materials development. By closely coupling our synthetic scientists with the device designers in the divisions, we were able to make modifications in the material adjusting in real time to the frequent design changes. As can been seen in Figure 1, this kind of internal

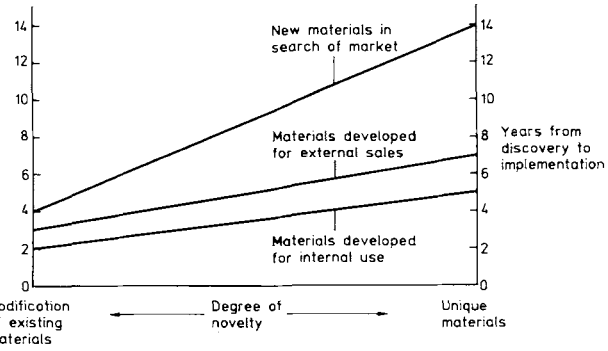

Fig. 1. Time scale for new materials development.

collaboration greatly reduces the time from conception to implementation as compared to similar research carried on by a typical vendor.

The need to conceive of, optimize and make available advanced materials within a two to four year time period has led us to challenge the scientists in our department in a unique fashion. First of all, it is essential that we pursue synthetic studies directed to what are perceived as the longer range needs. Toward that end, the scientists in the group are encouraged to spend ca. 50% of their time on basic studies in relevant areas. This aspect of their performance is measured primarily by the quality of their external publications and presentations. As specific needs emerge from the operating divisions, our scientists are able to draw upon this accumulated knowledge base to design solutions tailored to the specific needs. To further facilitate the transfer of advanced materials, we carry out studies to test the compatibility of these materials with device processing. Obviously, a critical part of the technology i.e., the design of the recipes used in device fabrication resides with the development groups in the divisions. We also have established a Synthetic Development Laboratory whose main role is to develop the optimum synthetic route, provide development quantities to the divisions and identify and work with vendors to provide commercial lots. Typically our involvement continues well into the development cycle and includes detailed characterization of the optimized material and establishment of materials specifications.

The success of the above approach is illustrated not only by the excellent track record in technology transfer to IBM's operating divisions over the past seven years, but also by the many scientific breakthroughs generated by our group (see Table 6). The scientific advances indicated here have either been cited as part of the five to six major scientific achievements of IBM's Almaden Research Center from the past three years or have been the basis for major external scientific awards.

Table 6. Significant polymer science and technology contributions from IBM's Almaden Research Center during the past three years.

Ordering in semiflexible polymers

Nature of monolayer films at surfaces
Mechanism of adhesion in polyimides
Measurement of attractive/repulsive forces at surfaces
Surface tunneling microscopy of gold atoms vs. organics on gold
FT Raman spectroscopy
Ab initio calculations of polymer conformations and properties
Polysilane conformations

An important component to the success of the polymer group in IBM has been the continuity of the effort over the past decade. To meet the increasing needs of the operating divisions the group has been increased from 25 people in 1975 to the present figure of ca. 60. In addition, we support between 24–27 post-doctoral scientists and host five to seven professors on sabbatical each year. The presence of these scientists greatly enhances our ability to address the basic aspects of a given problem while still focussing our attention on the short-term needs.

5. Conclusions and Recommendations

From the previous discussions in this paper, one can draw a number of conclusions concerning the future opportunities in advanced materials research.

1. The polymer materials research program at IBM represents a particularly effective model for industries which depend on the availability of advanced materials. In our group, requirements for a given application of the polymer are clearly understood and the scientist can make the incremental changes in a timely way to match the device needs. Obviously, other industries besides the information industry can greatly benefit from internal research groups whose charter includes designing the new materials which will be pivotal to their future product lines. This does not argue that joint efforts by major chemical companies and large users of polymers should not be pursued on optimizing polymers for specific uses. However, if the materials dependent industry has a core of scientists trained in the synthesis and processing of materials as relates to the company's need, then that group can take a leadership role in the interactions with the traditional materials suppliers.
2. The role of high level management is critical for those new materials programs which require significant investment. It is essential that such management be technically astute and be able to commit the resources of the company in a timely way. One can usually identify the presence of such management in those organizations which maintain an excellent track record on commercializing new materials. The converse hardly needs further discussion. It should be noted that in programs such as the one at IBM, the decision to scale-up a new material is not as expensive because of the smaller amounts involved and such decisions are made at an intermediate level of managements.
3. A number of companies are committing significant R&D resources to work in specific areas such as conducting polymers, non-linear optical materials, toughened ceramics, high-T_c superconductors, diamond films etc. with the expectation that the eventual payoff justifies the investment. Experience teaches us that programs which still require major technical breakthroughs can be stifled through early commitment of large resources. Typically, breakthroughs in these areas depend

on talented scientists working in small groups who understand and address the problem in its entirety. A commitment of larger resources aimed at increasing the likelihood of success often works in the opposite direction since the effort to be effectively managed is broken up into a series of interrelated tasks which are readily managed through PERT charts.

4. Recent attempts by the US Government to stimulate industrial R&D by building up efforts in universities and/or the National Laboratories does not address the critical problems confronting much of US industry. There is absolutely no substitute for industrial scientists who are effectively interfaced with the needs of the particular industry and its markets and have available to them the latest techniques to probe and address the future needs in materials.
5. It is essential that universities undertake to train high quality materials scientists skilled in synthesis and processing of new materials. It should be obvious that the development of new materials tailored to specific needs or-equally as important the unexpected discovery of materials with unique properties lies primarily within the purview of the clever scientists trained effectively in synthesis and processing of materials.

Finally, let me return to the question posed in the opening of this article; namely, can one organize an advanced materials R&D effort which addresses the opportunities of the 21st century? I would argue that for industry, the primary emphasis should be directed at fulfilling the perceived materials needs of the next two to five years as discussed in conclusion "1". Such an approach will not only impact the company's immediate needs, but hopefully would have sufficient latitude to permit for unexpected breakthroughs which address longer range opportunities. With respect to planning and implementing a materials R&D effort for the 21st century, past experience shows that it is extremely difficult to identify needs of the next five to seven years let alone 10–15 years from now. Thus, one must think in terms of national or even international programs to establish an infrastructure which 1) attracts talented young people into the science programs of our universities, 2) provides for continuity of high risk research in all sectors of the R&D establishment, and 3) places responsibility for commitment of funds and resources by the government and industry in the hands of technically astute leaders. In this way one can greatly increase the potential for successful development of advanced materials critical to high technology industries of the 21st century.

Magneto-Optical Recording and Data Storage Materials**

Rare-Earth Transition-Metal Alloys
Thermomagnetic Writing
Lorentz Microscopy

By Frans J. A. M. Greidanus* and Stefan Klahn

Amorphous rare-earth (RE) transition-metal (TM) alloys are used for magneto-optical (MO) recording a rapidly developing technology, which combines the possibility of achieving high bit densities with practically unlimited erasability and rewritability. During the last years new insights, relating material properties to recording performance, have been obtained. New experimental techniques, such as the observation of magnetic contrast in the electron microscope, have made a major contribution to the understanding of domain formation processes. The RE-TM alloys have been most successful in recording applications until now. In these materials the RE-TM composition determines both the compensation and Curie temperatures and has a strong impact on the recording characteristics. Improvements in deposition techniques and the application of dielectric layers resulted in carrier-to-noise ratios of 61 dB. Despite major improvements, problems related to corrosion and structural relaxation, which lead to long-term instabilities, have not yet been solved completely. Another important topic is the so-called direct-overwrite problem, which will be discussed in relation to the material properties.

[**] We wish to thank our colleagues at the Philips Research Laboratories in Eindhoven and Hamburg, in particular *Ben Jacobs* and *Peter Hansen*, who have made a large contribution to our understanding of magneto-optical materials.

1. Introduction

In the past ten years the development of optical recording technology has led to products for various applications, such as the Compact Disc video and audio systems and the write-once DOR (Digital Optical Recording) system, which are now on the market. The availability of relatively cheap and mass-produced solid-state lasers made these developments possible. The driving forces behind these developments were the considerable advantages of optical recording over other storage techniques. Readout is done by a laser focussed through a substrate on the storage layer, providing a non-contact technique insensitive to dust and fine scratches on the substrate. A second advantage is the possibility of achieving high bit densities (10^8 bits cm^{-2}). This value compares favorably with other existing technologies, as can be seen in Figure 1.

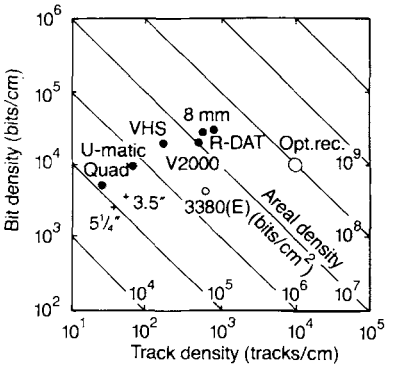

Fig. 1. Areal density for various recording systems. ●: helical scan, +: flexible disc, ○: rigid disc (courtesy of *S. B. Luitjens*).

In the history of optical recording three phases can be distinguished: 1) The oldest type of optical-storage systems are the replicated discs, used in the Compact Disc video and audio system. These are designed for the distribution of prerecorded information. 2) The second class is formed by write-once media. Here the writing process is based on the absorption of energy from a focussed laser beam, modulated according to the information to be recorded. The available commercial systems are based on the formation of holes in a reflective layer. 3) The latest class of optical systems, which is at present the subject of intensive research and development, employs media which can be erased and rewritten innumerable times. Here several different physical principles are being followed. Well known is the use of a reversible crystalline-to-amorphous phase transition in the recording film to store the information. A second method is based on a thermo-magnetic effect to write, and a magneto-optical (MO) effect to read out the information. In this review article we will focus our attention on the materials for this latter technique.

The principles behind MO recording have been known for years. However, it was not until the mid sixties that a record and playback system employing a laser beam was suggested. Writing of domains in a magnetic material by heating it locally above the Curie temperature was suggested in 1958 by *Mayer*,[1] long before an optical memory was envisioned. *Mayer* employed a focussed electron beam or the point of a heated needle. The first observation of an MO effect is even older and dates from 1846[2] when *Faraday* observed that polarized light passed through a fluid in a strong magnetic field changes its polarization state. Ever since this phenomenon has been designated as the Faraday effect when it refers to the transmitted beam, whereas it is called the Kerr effect when it refers to the reflected beam.

The first proposal for employing a laser both for writing (high power) and reading (low power) dates from 1965, when *Chang* et al.[3] discussed a memory based on $Gd_3Fe_5O_{12}$ (GdIG). Since then several other materials, such as MnBi, EuO, CoPt and $CoFe_2O_4$ have been suggested and investigated with respect to their applications as an MO memory layer. The most important development, however, was started by *Chaudhari* et al.[4] in 1973, with the observation that amorphous GdCo-layers possessing perpendicular anisotropy are suitable for MO recording. This discovery was the start of a series of exploratory studies in the rare-earth (RE) transition-metal (TM) binary and ternary alloy system with regard to their potential for MO data storage. These studies led, e.g., to the systems GdTbFe and TbFeCo which are the most suitable materials known today. To a large extent this is due to a steady increase in the signal-to-noise properties over the years as can be seen in Figure 2.

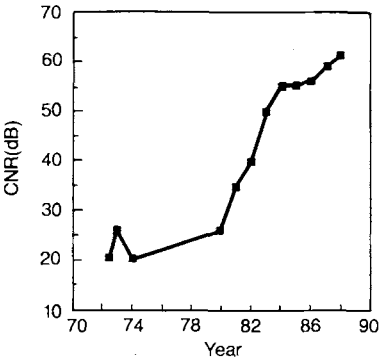

Fig. 2. Maximum reported carrier-to-noise ratio for MO recording (measured for a domain length of 1.5 μm at 1 MHz and 30 kHz bandwith) versus year of publication.

2. Magneto-Optical Recording

The principle of optical readout of domains in a perpendicular MO layer is shown in Figure 3a. The change of the polarization direction when linearly polarized light is reflected from a magnetic surface is shown here. Phenomenologically, MO effects can be described by assigning to

ADVANCED MATERIALS

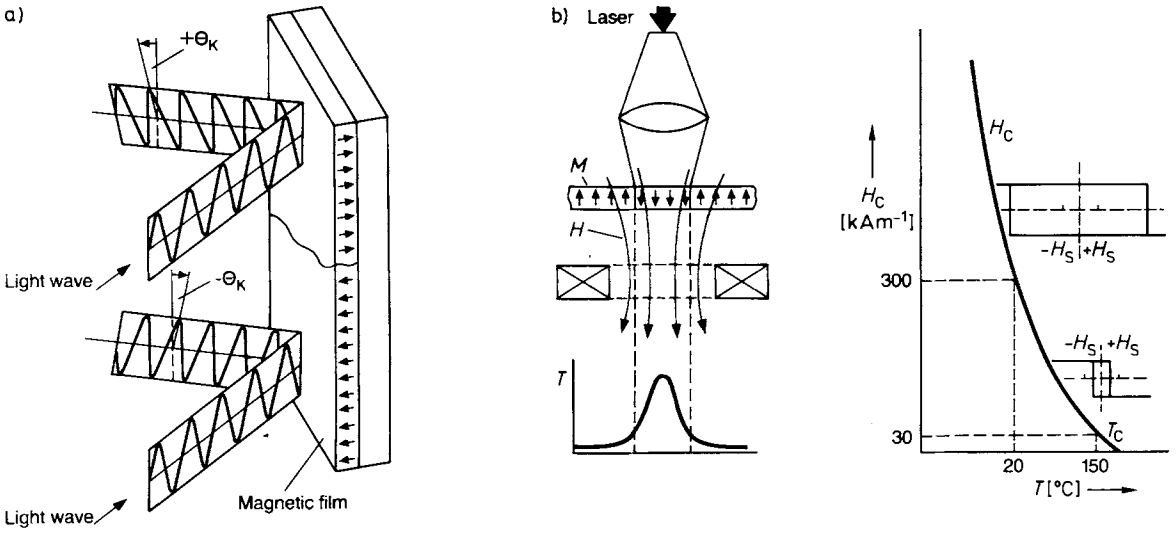

Fig. 3. a) Principle of MO reading. b) Principle of thermomagnetic writing.

the medium a dielectric tensor with non-zero off-diagonal elements. This is equivalent to introducing two different complex indices of refraction for right- and left-handed circulary polarized light. Microscopically these effects find their origin in the spin–orbit interaction, which couples the spin moment and the motion of the electron. The optical properties are influenced by the electron motion. The sign of the angle through which the polarization is rotated depends on the direction of the magnetization vector with respect to the propagation direction of the light. For practical materials the magnitude of the Kerr rotation is fairly small (typically 0.2–0.3°). Consequently the signals arising from the modulation of the polarization state of the reflected light are very small. Nevertheless, they can be detected with a good carrier-to-noise ratio (CNR) if sources of noise in the readout can be made sufficiently small.

Several schemes for thermomagnetic writing exist. With Curie point writing, the MO layer is heated above its Curie temperature and the magnetization is reversed in an applied magnetic field. A second method can be employed in materials in which the coercive field is a decreasing function of temperature. Upon heating, the magnetization can be reversed in an applied field larger than the coercive field of the layer at the elevated temperature, but smaller than the coercive fields in the remaining non-heated area of the film. In this way a domain can be written thermally, as illustrated in Figure 3b. This method is referred to as threshold writing when applied to ferromagnetic films and as compensation-point writing when applied to ferrimagnetic films. In general domains of the order of the diffraction limited diameter of the laser spot, which is about 1 μm, can be written, although it is possible to write substantially smaller domains, as will be discussed in Section 5.

The discs employed for MO recording consist of a glass or polycarbonate substrate coated with a photo-polymerized lacquer with pregrooves. On top of this a stack of optical layers containing the MO layer is deposited. Information can be written in a disc and read out with a special recorder using polarizing optics.[5]

3. Magneto-Optical Materials

In addition to a large Kerr rotation there are several other requirements a material has to satisfy in order to be suitable as a recording medium for thermomagnetic writing with optical readout. These requirements are:

1) Perpendicular magnetic anisotropy
2) High coercivity at room temperature
3) High magneto-optical figure of merit, $R\theta_k^2$, where θ_k is the Kerr rotation and R the reflectivity of the MO film
4) Switching characteristics matched to the available laser power ($T_c < 600$ K) and the available magnetic field strength (< 50 kA m^{-1})
5) Low media and write noise
6) Low deposition temperatures and high deposition rates
7) Long-term stability

The classes of materials which enable all these requirements to be fulfilled at the same time, are limited. The best candidates at present are the ferrimagnetic amorphous RE-TM alloys. Several compositions, mostly containing Gd and/or Tb as the RE atom and Fe and/or Co as the TM atom, were suggested and have been studied in the past. Among these, GdTbFe and TbFeCo are probably the most suitable materials. In the remaining part of this section we

will discuss how the requirements 1-7 can be fulfilled in the system $(Gd,Tb,Dy)_x(Fe,Co)_{100-x}$ with $(15 < x < 30)$.

1) Perpendicular anisotropy can be achieved by proper deposition conditions and composition. The origin of the perpendicular anisotropy in amorphous alloys is an anisotropic short-range ordering process during deposition. Mechanisms of magnetic anisotropy are magnetostriction, bond orientational anisotropy and single-ion (spin-orbit coupling) anisotropy.[6] Typical values for the anisotropy constant involved are $K_u = 10^4$ J m^{-3} for Gd based alloys and $K_u = 10^5$ J m^{-3} for Tb and Dy based alloys.

2) The absolute value of the magnetization of $Gd_{24}Tb_1Fe_{75}$ is shown in Figure 4 as a representative example. The RE and TM sublattices have opposite magnetization directions and the temperature dependence of the "sublattice" magnetizations differs as well. Because of this the resulting total magnetization becomes zero at a temperature which is called the compensation temperature, T_{comp}. At this temperature the coercive field, which is about proportional to $1/M_s$, diverges. The Kerr rotation is caused chiefly by the Fe sublattice and has a non-zero value at T_{comp}. By adjusting the position of T_{comp} a few tens of degrees below or above $T_{ambient}$, which can be achieved by choosing the proper composition, very high coercivity values, implying high domain stability, can be achieved.

3) The Kerr rotation for the RE-TM is only moderate, with typical values of 0.2–0.3°. However, the shot noise limited CNR measured during a recording experiment is not proportional to the Kerr rotation angle, θ_k, but to the MO figure of merit $R\theta_k^2$. By depositing a suitable optical enhancement layer, it is possible to increase the Kerr rotation at the expense of the reflectivity and thus increase the figure of merit. In this way a satisfactory CNR can be obtained.

4) The power necessary for switching the magnetization is determined both by the thermal properties of the MO layer stack and substrate and by the Curie temperature of the MO layer. As an example, T_c versus composition, x, is shown for the four binary systems GdFe, GdCo, TbFe and TbCo in Figure 5.[7] It can be seen that by a proper choice of composition, T_c can be adjusted. However, other requirements, such as a proper positioning of T_{comp}, should be achieved as well. Therefore it is necessary to use ternary systems in which T_c is adjustable by the Fe/Co ratio. In practical systems T_c is between 450 K and 500 K and T_{comp} is determined by the RE-TM ratio.

5) As the RE-TM-alloys are amorphous no crystal-grain boundaries are present. Therefore very low media-noise levels are achieved. By choosing proper RE-TM compositions, the write noise caused by imperfectly written domain patterns can be reduced to the level of the media noise.

6) The amorphous RE-TM alloys can conveniently be deposited with vapor deposition and sputtering techniques. In mass production lines, magnetron sputtering is preferred as it enables high deposition rates and does not necessitate substrate cooling.

The structure, and thus the magnetic properties, such as coercivity and anisotropy, as well as the stability against oxidation of the films, is very much dependent on the preparation parameters.[8] RE-TM films prepared with magnetron sputtering at low argon pressures (0.6 Pa) and short substrate-target distances (60 mm) are very dense and smooth, whereas films prepared at high argon pressures (2.5 Pa) and large substrate-target distances (120 mm) exhibit a porous microstructure with voids and a pronounced columnar structure. The films deposited under the latter conditions are much less stable against oxidation and show reduced anisotropy constants compared to the former. The target technology of RE-TM targets is a current is-

ADVANCED MATERIALS

sue. One problem is the brittleness of the RE-TM alloys, another the homogeneity of the deposited films. The magnetic properties of the films are very dependent on the composition, e.g. the compensation temperatures change with 40 K to 100 K per atom percent RE. Therefore MO discs should have a homogeneity better than 0.5 atom percent, which requires homogeneous targets with almost equal distributions of the sputtered atoms. The distribution of the sputtered atoms depends on the preparation technique of the target, e.g. casting of an alloy or hot pressing of powders.

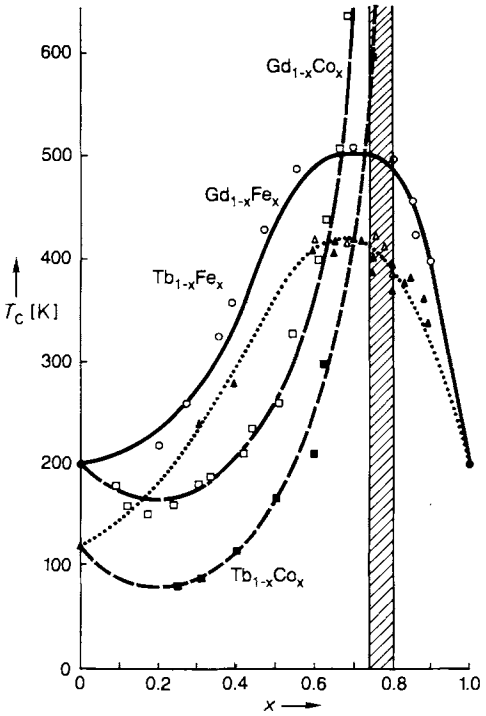

Fig. 5. Curie temperature versus composition for amorphous binary alloys (for references see *P. Hansen* [7], Fig. 2). The shaded area indicates the range of compensation temperatures in the vicinity of room temperature of these alloys.

7) One of the most serious disadvantages of the amorphous RE-TM alloys is their susceptibility to corrosion and oxidation.[9] Therefore long-term stability can only be achieved in a suitable multilayer structure in which the MO layer is covered by protection/passivation layers. Such a structure is shown in the inset of Figure 6. From the substrate side the MO layer is protected by means of a dielectric layer, which can be e.g. AlN or Si_3N_4. Apart from acting as a protection layer, this layer also serves as the optical enhancement layer discussed under 3). On the back side the MO layer is protected by means of a metallic layer, e.g. Al, which also serves as a reflector. Aging experiments on such a structure are also shown in Figure 6. In general several mechanisms contribute to the degradation of MO-layers: oxidation, corrosion, structural relaxation and crystallization. Degradation affects the following magnetic properties: magnetic anisotropy, saturation magnetization, coercive field, and compensation temperature.

The inset shows a typical trilayer stack. (a) substrate, (b) dielectric enhancement layer, (c) MO layer, (d) metal reflector, (e) organic protection layer.

4. Thermomagnetic Writing

It is of vital importance to have insight into the physics of the thermomagnetic writing process in amorphous RE-TM layers, since irregularities in the written domains cause the so-called write noise, which is often the main noise contribution in practice. For this reason, several recent theoretical papers dealing with the thermomagnetic writing process have appeared.[10–12] Several models have been worked out, starting from computer simulations,[10] or applying a "bubble-like" phenomenological description.[11,12] In the latter case the stability of the domain is given by the following equation:

$$F = \frac{\partial}{\partial r}(E_W + E_H + E_D) = F_W + F_H + F_D,$$

where E_W is the domain-wall energy, E_H the magnetic-field energy, E_D the demagnetizing energy, F_W, F_H and F_D the corresponding forces and r the domain radius. The resulting domain diameter can now be calculated by equating the total force, as given above, to the coercive force F_c. Of course, the proper temperature dependences of the magnetic properties, at the end of the laser pulse, have to be taken into account in the calculation.

Experimental observations of the dynamics of domain formation processes have been scarce hitherto.[13] However, very advanced techniques to study laser-written domains, using Lorentz microscopy, have recently become

available.[14, 15] An example is shown in Figure 7. In this case the MO layer was deposited on a specially prepared silicon wafer disc, with 100 μm by 100 μm windows with 10 nm thick Si_3N_4 membranes. On top of this Si_3N_4 layer the MO layer was deposited and protected with a thin Al/SiO_x layer. On this MO disc domains were written with a laser beam under various conditions. After recording, the silicon wafer was cut into pieces each containing a single window. These specimens were investigated in the electron microscope, using a special operation mode, called Lorentz microscopy. In this way it was possible to visualize magnetic contrast and to obtain images of the laser-written domains.

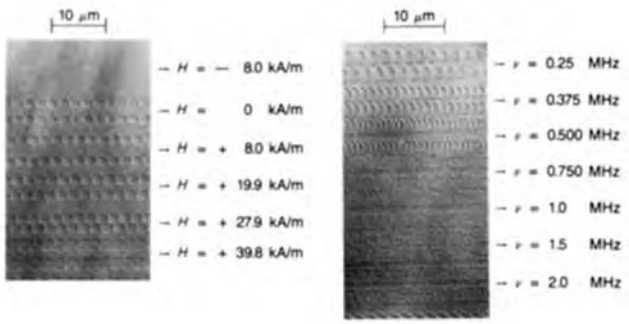

Fig. 7. Lorentz microscopy images of thermomagnetically written domains. Left: Dual tracks, written with laser modulation for various applied fields. Right: Dual tracks, written with magnetic-field modulation for various frequencies.

5. Direct Overwrite

The usual way to write data on an MO disc is to heat the MO layer locally in a fixed applied field. The information to be recorded is supplied by modulating the laser beam. The main drawback of this method is that information already recorded cannot be overwritten. Whole sectors or tracks have to be erased before new information can be recorded. Several solutions to this problem have been suggested. *Shieh* et al.[16] suggested a method for a direct-overwrite technique, utilizing the demagnetizing field of the MO layer itself. The use of exchange-coupled magnetic double layers may also offer interesting possibilities in this respect.[17] The most obvious and direct way to solve the direct-overwrite problem is to modulate the applied field.[18] Using this method, the MO layer is heated continuously by the laser, while the applied magnetic field is switched with a high frequency and modulated according to the information to be recorded. In this way old information can be overwritten, just as in conventional magnetic recording.

By switching the applied field while rotating the disc, overlapping domains of different polarity are written, leaving only a crescent. Because the dimensions of this crescent in the tangential track direction are only determined by the disc velocity and switching frequency of the applied field, domains much smaller than the laser spot can be written. In Figure 7 it can be seen that it is feasible to write domains as small as 0.25 μm in the writing direction in a $Gd_{15}Tb_{6.5}Fe_{78.5}$ layer. Apart from the direct overwrite feature and the possibility of obtaining very high recording densities, magnetic-field modulation offers two other advantages in MO recording. First the quality of the coded signals is improved, as the laser is on continuously and consequently there is no influence of a thermal history when writing a domain. Secondly, influences of compositional variations over the disc surface on the length of written domains, which is apparent in the case of laser modulation, are less critical when writing with magnetic-field modulation. This is due to the fact that the domain length in this case is only determined by the switching frequency of the applied field and the disc velocity.

The use of magnetic-field-modulation methods in MO recording requires the use of special magnetic heads which are capable of generating relatively high fields at large distances, which can be switched at high frequencies. It has recently been shown[19] that it is feasible to design heads which meet all the requirements.

6. Future Materials

Although it is possible to employ amorphous RE-TM compounds for MO recording there is a continuous search for materials with improved properties. The focus is mainly on an increased MO figure of merit and improved chemical stability. Another important development is the future availability of compact solid-state lasers operating at shorter wavelengths than 800 nm. A continuous shift towards blue wavelengths is expected in the future.

Giant MO effects have recently been found in uranium compounds at low temperatures.[20] It has not yet been possible to find room temperature ferromagnets with such high figures of merit, albeit that materials with higher Kerr rotations than the RE-TM materials are known. The material with the highest Kerr rotation at room temperature known today is the Heusler alloy PtMnSb discovered at our laboratories.[21] Despite several attempts, it has not yet been possible to induce perpendicular anisotropy in this material, which is essential for its applications. In PtMnSb the high Kerr rotation value is found at 720 nm. This could become a disadvantage in the future when recording at shorter wavelengths is expected.

Magnetic oxides, such as ferrites and garnets, show unsurpassed chemical stability. This can be combined with high MO figures of merit as has been shown e.g. by the work of *Martens* et al.[22] on Co-ferrite. One of the problems with the oxides is the presence of recording noise. CNR values comparable to those obtained for the RE-TM alloys have not been reported yet. Another drawback for the application of magnetic oxides is the necessity of using

high temperature deposition techniques. Nevertheless research is being continued at several laboratories and progress may be expected.

Very interesting MO effects have been found in metallic, artificially layered structures.[23,24] This is a new field but the possibility for "atomic engineering" in these materials may provide yet unknown and unexpected phenomena.

7. Summary and Outlook

In this article we have discussed materials for MO recording and their application in rewritable recording systems. After a long period of intensive research the RE-TM alloys can be adjusted to satisfy all the requirements for suitable MO materials. This has been made possible by new insights in the physics of the recording processes, combined with advanced preparation techniques. The requirement of direct overwrite, which is expected to be essential for practical applications, will have an impact on further developments in the RE-TM alloy system. Lorentz microscopy pictures show that extremely small domains can be written in a controlled way in these materials allowing for very high recording densities. Unfortunately the resolution during readout is limited by the spatial extent of the laser spot which is about 1 μm at the present wavelength of 800 nm.

The main disadvantage of the present materials is their moderate MO performance and chemical instability. Although some practical solutions to these problems have been found, these drawbacks are the driving force in the search for completely new classes of materials. Magnetic oxides and metallic multilayers offer some interesting prospects here. All these efforts are worth pursuing, because MO recording may develop as the future recording technology, combining the advantages of both magnetic and optical recording.

A Novel Monolithic Thin-Film Electroluminescent Device with Extrinsic Memory

Flat display panels are a part of many portable consumer products. Their visual performance is inferior to that of cathodic ray tubes: the luminance of liquid crystal displays (LCDs), the leading flat display technology, is very low, and, in the conventional line-by-line addressing mode, their contrast decreases with increasing panel size. Electroluminescent (EL) display devices are an interesting alternative to LCDs. Figure 1 shows the structure of a standard thin-film(TF) EL device. The active ZnS-Mn layer is sandwiched between two dielectric Y_2O_3 layers.[1,2] Electroluminescence is excited by an alternating field of some 10^6 V cm^{-1}, applied between the metallic and the transparent electrode.

In principle the visual performance of emissive display panels is independent of screen complexity and addressing mode. In practice, the average luminance decreases with

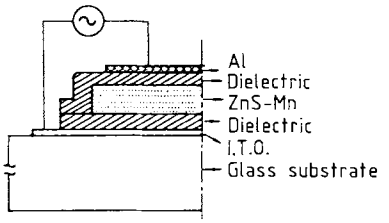

Fig. 1. Cross section of a standard TFEL structure (schematic). See also [7].

increasing screen size: in the line-by-line addressing mode, the time during which each pixel is excited is reduced to T/N, where the period T is determined by the operating frequency of the panel and N is the number of lines. This decrease in luminance can be compensated for by higher excitation currents, but the current density supported by the thin-film electrodes is limited. This practical limitation of screen size and complexity in EL panels can be overcome with the use of memory devices. An EL device with memory shows bistable behavior and remains in the ON or OFF state until the device is switched. Thus, for a static image on a display screen, no periodic refreshing of the screen is required. Standard ZnS-Mn EL devices have been shown to exhibit intrinsic bistability,[3] but the hysteresis margin is low and fades with aging of the device. Moreover, high EL efficiency and a large hysteresis margin cannot be obtained simultaneously. Consequently, this intrinsic memory effect cannot be used in display panels.

EL devices with extrinsic memory were proposed thirty years ago by *Kazan*.[4] The memory effect is produced by electrical coupling between a photoconductive (PC) layer and the EL device. A TFPCEL device can be switched ON either electrically (excitation of the EL layer) or optically (excitation of the PC layer). Due to the optical emission of the EL layer, the PC layer becomes photoconductive. The device remains thus in the ON state until the ac voltage which excites electroluminescence is switched OFF.

The first TFPCEL devices were developed ten years ago.[5] The photoconductive CdS layer was deposited on a separate transparent substrate, thus requiring an additional interconnecting step in producing a display panel. Moreover, due to the ohmic behavior of CdS layers, the dark switching voltage is inconveniently large and difficult to control. Electrical switching of such a TFPCEL display panel would be practically impossible.

Two french physicists, *P. Thioulouse* of the Centre National d'Etudes des Télécommunications (CNET, Bagneux) and *I. Solomon* of the Ecole Polytechnique (Palaiseau) have developed a device which solves both problems:[6–8] the TFEL device and PC layer are integrated on the same substrate, and the whole device can be switched ON electrically.

The original feature of this device is the choice of the PC-layer material, an amorphous hydrogenated silicon–carbon alloy (a-$Si_{1-x}C_x$:H), which can be deposited with high reproducibility in a conventional glow-discharge plasma reactor. Figure 2 shows the structure of the new TFPCEL device. Stoichiometric Ta_2O_5 is deposited by reactive magnetron sputtering on the ITO-coated glass substrate. Chlorine-free ZnS–Mn is deposited by electron beam evaporation. The photoconductive a-$Si_{1-x}C_x$:H layer has $n^{\oplus}$-i-$n^{\oplus}$ structure and can be grown in a single run. Due to carrier-injection from the $n^{\oplus}$ into the i-layer, the dark conductivity of the i-layer is strongly non-ohmic and governed by the density of states at the Fermi-level which can be adjusted by variation of the carbon content.[9]

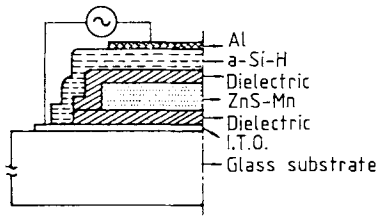

Fig. 2. Cross section of the new TFPCEL device (schematic). The photoconductive a-$Si_{1-x}C_x$:H layer has $n^{\oplus}$-i-$n^{\oplus}$ structure; its dark conductivity is therefore governed by space-charge limited conduction. This non-linear current–voltage characteristic favors electrical switching of the device [7].

The new device exhibits a combination of properties very favorable for application in display panels with high resolution: electrical switching is possible (Fig. 3) with a memory margin sufficiently large for large-size panel applications; the picture elements (pixels) have very sharp edges without the need for an additional photolithographic step; luminance (about 650 cd m^{-2}) and contrast are high, whereas the sensitivity of the PC layer to ambient light is rather low and can be adjusted by a proper choice of deposition conditions. No degradation of the memory effect was observed after more than 2000 hours of opera-

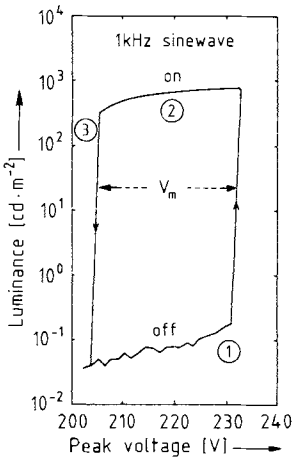

Fig. 3. Luminance vs. voltage characteristics of the new TFPCEL device operated in the dark with a 1 kHz sine waveform. The device is switched ON electrically (1) and remains in the ON (emitting) state (2) until the peak-to-peak voltage is decreased below the threshold value (3). The memory margin V_m is of the order of 25 V [7].

tion. The device is monolithic, and the addition of the PC layer to the conventional TFEL device requires only one additional step: the deposition of an amorphous silicon alloy using a well-known industrial deposition technique. The simplicity of the new device is an important difference to LCD panels driven by a-Si:H thin-film transistors, a very complex technology. The new TFPCEL structure, although still a prototype, clearly has the potential for use in highly complex display panels, and its high switching speed is compatible with TV applications.

Conference Reports

Intermetallic Phases

The first German symposium on intermetallics ("Intermetallische Phasen: Grundlagen—Einsatzmöglichkeiten—Herstellung") was held on November 24–25 in Bad Nauheim as a joint meeting of the Deutsche Gesellschaft für Metallkunde (DGM) and the Verein Deutscher Eisenhüttenleute (VDEh). It was attended by materials scientists and engineers—nearly half of them from industry—mostly from Germany, Switzerland and Austria. The symposium was composed of four main sessions:

- fundamentals
- structural materials for high-temperature applications and lightweight materials
- functional materials
- processing technology

and three workshop discussions dealing with the production of engine parts, the boundary conditions for intermetallic materials research, and the prospects of intermetallics for high-temperature applications. The aim was to bring together the various groups in research institutes and industry which are studying intermetallic phases, or are interested in applying intermetallics, in order to review the present situation, to assess the prospects and to define tasks for the future. In this symposium only invited lectures were given, and proceedings are not published.

The introductory lecture was given by *H. J. Engell* (Max-Planck-Institut für Eisenforschung, Düsseldorf) who explained that intermetallic phases occupy a position intermediate between metallic alloys and ceramics with respect to atom bonding and crystal structure. This results in the particular properties of intermetallics which make them promising for high-temperature applications and as functional materials. *E. Parthé* (Univ. of Geneva) discussed the crystal structures of intermetallics and showed that complex crystal structures—e.g. those of the Laves phases—result from the stacking of simple basic structures, planes or columns, which allows the prediction of new structures. The first paper by *J. Hünecke* and *H. Wever* (Tech. Univ. of Berlin) discussed constitutional disorder and its temperature dependence with respect to the β′-Hume-Rothery phases and the $B8_2$ phases NiSb and Ni_3Sn_2. The second paper by *J. Hünecke, H. Wever* and *G. Frohberg* outlined the diffusion mechanisms in intermetallics and applied the analysis to phases of types B2, DO_3, $B8_2$, $L1_2$ and A15. The session on fundamentals was concluded by a review by *P. A. Beaven* (GKSS-Forschungszentrum, Geesthacht) on the possibilities for the ductilization of intermetallics, and in particular the effects of composition, i.e. stoichiometry, macroalloying, microalloying, and of processing were discussed.

The session on structural materials for high-temperature applications was led off by an introductory lecture by *G. Sauthoff* (Max-Planck-Institut für Eisenforschung, Düsseldorf). First an overview was given on the criteria for the selection of phases for high-temperature applications, and on the nickel aluminides and titanium aluminides which are already a subject of materials developments, and are now beginning to be introduced commercially in the USA and Japan. Then some less common phases were described which are of special interest for applications at temperatures above 1000°C and are a subject of current research. Figure 1 shows some examples.

The oxidation and hot gas corrosion behavior was reviewed by *L. Singheiser* (Asea Brown Bovery, Mannheim). In particular the effects of alloying elements, of impurities

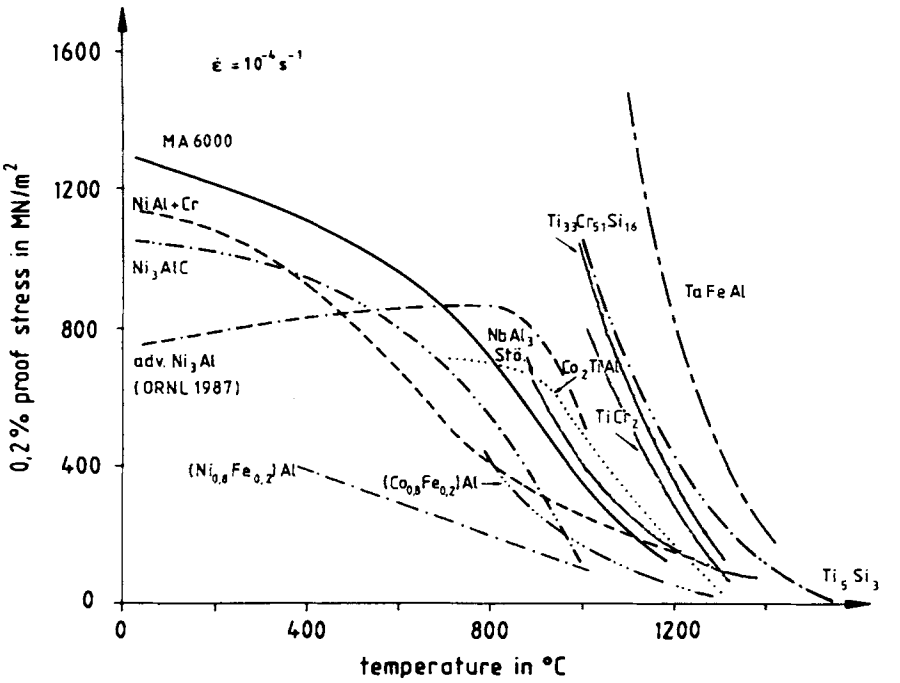

Fig. 1. 0.2% proof stress as a function of temperature for various phases and alloys (Machon, Sauthoff, Frommeyer et al., 1987).

in the atmosphere, and of evaporation of oxides were discussed, and the potential of various phases was evaluated. The creep behaviour of intermetallic phases was analyzed by *G. Sauthoff* and it was shown that the observed behavior can be described by the familiar constitutive equations. Then the possibilities for increasing the creep strengths were discussed, and examples were given with respect to B2 phases and other less common phases. The fatigue behavior was the subject of a paper by *A. Gysler, G. Lütjering* and *I.-G. Park* (Tech. Univ. of Hamburg-Harburg), who have studied the high-temperature fatigue of Al–Mn alloys with large volume fractions of Al_6Mn, in particular crack growth and the effects of atmosphere. As regards lightweight materials, *K.-H. Matucha* (Metallgesellschaft, Frankfurt) reported a current materials development based on Mg_2Si which aims at applications in conventional heat engines. *R. Wagner* (GKSS-Forschungszentrum, Geesthacht) reported work on intermetallic materials based on TiAl, Ti_3Al and Ti_5Si_3. In particular, metallurgical processing and the effects of alloying on microstructure and properties were discussed, and it was shown that both TiAl and the multiphase materials are promising for applications at temperatures up to 1000°C. Nickel aluminides were reviewed by *G. Frommeyer* (MPI für Eisenforschung, Düsseldorf). Ni_3Al and NiAl were discussed with respect to elasticity, plasticity, strengthening and alloying, and the resulting properties were shown.

The session on functional materials was led off by *H. Warlimont* (Vakuumschmelze, Hanau), who reviewed the various functional intermetallics—soft magnetic materials, hard magnetic materials, magnetostrictive materials, superconducting materials, shape-memory materials—with respects to processing and properties. In addition, the commercial importance and the economic potential of these intermetallics was emphasized. Magnetic rare-earth intermetallics were the subject of the paper by *W. Rodewald, W. Fernengel* and *B. Wall* (Vakuumschmelze, Hanau). In particular the properties were discussed and the production techniques were described. Superconducting A15 phases were discussed by *R. Flükiger* (Kernforschungszentrum Karlsruhe) with special reference to the effects of order and stoichiometry on the critial temperature, and a comparison was drawn to the Chevrel phases and the superconducting oxides.

The last session, on processing technology, began with a paper by *W. A. Kaysser* and *R. Laag* (MPI für Metallforschung, Stuttgart) on the fundamentals of powder metallurgy. Methods of powder production were described, the deformability and creep behavior of the powder particles was analyzed, and densification by hot isostatic pressing or hot extrusion was discussed. The report by *H. Grewe* and *W. Schlump* (Krupp Forschungsinstitut, Essen) dealt with the production of components of intermetallics by powder metallurgy. There is evidently a potential for near-net-shape-processed turbine components, the most promising phases being TiAl, Ti_3Al and related materials. The metallurgy of intermetallics was discussed by *G. Frommeyer* (MPI für Eisenforschung, Düsseldorf), with special reference to induction melting and electron-beam melting on the one hand and melt spinning and melt atomization on the other hand. The dependence of the process parameters on the thermodynamic properties of the respective systems was outlined, and examples were given. The thermo-mechanical treatment and forming of intermetallics was discussed by *C. Hartig* (Techn. Univ. of Hamburg-Harburg) with special reference to TiAl-based materials. The basic

principles were outlined and results from current research were presented.

The lectures gave rise to lively discussions which were continued during the breaks and the "Hessen Vesper" party. These many discussions and the workshop results were summarized by *H. Mecking* (Tech. Univ. Hamburg-Harburg) in his concluding remarks in the following way.

- The excellent and perfectly organized programme was a well-balanced presentation of the various aspects of intermetallics and offered a nice opportunity to "look over one's fences".
- This meeting is to be repeated, i.e. there should be a second symposium on intermetallics within two years, with more time for discussions.
- There are three stages of materials development. The first and traditional stage has been development by trial and error, with fundamental research lagging behind applications. The second stage is the optimization of existing materials on the basis of fundamental principles, e.g., as in the case of steels. The third stage is to derive concepts for the development of new materials, which is also the aim of this symposium, and which is supported by research programs of the Federal Ministry of Research and Technology (BMFT) and the German Research Society (DFG). However, the present projects for the development of new intermetallic materials have not been preceded by the necessary fundamental research, and in particular the physical mechanisms which control the plasticity and brittleness of the intermetallics have not yet been analyzed. Thus, much more fundamental research is necessary for achieving new materials developments.
- This fundamental research has to be concentrated on smaller groups of intermetallics, because the whole spectrum of intermetallics is much too broad and divergent. In view of high-temperature applications such a smaller group could be the aluminides and perhaps some silicides.
- Intermetallics have a wide-ranging potential for a variety of applications depending on the particular phases. Materials development on the basis of intermetallics is high tech—even though it may be less fascinating than space research—and must be continued.

Biomaterials, Bioelectronics .

Only some months after its foundation the European Institute of Technology (EIT) held its first conference on biotechnology in Verona on 7–8 November 1988. In the opening session *J. M. Marcum,* the president of the EIT, outlined the goals for the EIT in general and for this conference in particular. One of the major tasks defined by the leading companies in chemistry and electronics which have set up the EIT is to act as a mediator between industry and university.

The strategy of the EIT, which is to support and monitor existing centers for the three areas of interest, information technology, materials technology and biotechnology, rather than to set up new groups, seems to be promising and flexible. The EIT will also foster liaison between different groups and catalyze contacts with potential industrial partners.

To define its own position and to initiate first contacts between industry and university the EIT invited more than 40 speakers to Verona. Nine topics, covering the broad range from basic research in biotechnology up to current scientific work with direct commercial applicability, were chosen for this conference, including a special session dealing with the organization and management of research. The first session ranged from the different possibilities for inducing overproduction in plant cell cultures (*G. Kochs* and *H. Grisebach,* University of Freiburg, FRG) up to transgenic plants (*S. Altenbach,* Plant Cell Research Institute, Dublin, USA), and gave an impression of the future importance of these methods. *K. Mosbach* (University of Lund, Sweden) presented interesting results on the production of synthetic enzyme complexes. The method he calls "molecular imprinting" offers a new promising practical approach for the synthesis of selective new materials for purification procedures. The use of enzymes from thermophilic bacteria (*M. Rossi,* University of Naples, Italy) which retain their activity even in mixtures with water-miscible organic solvents could soon become of industrial importance. The wide range of advanced techniques for the isolation of biotechnologically produced substances on a technical scale was described by *M. R. Kula* (KFA Jülich, FRG), *C. R. Lowe* (University of Cambridge, UK) and *M. A. Vijayalakami* (University of Compiègne, France). Concluding with the session on "Genetic and Plasmid Stabilization", the first day offered a program of high "information density" to all participants, covering all current problems in biotechnology.

The second day was devoted to more interdisciplinary sessions, on themes such as "protein engineering" and

"bioelectronics and biomaterials". Here I will focus attention especially on the latter topic. Biosensor research is clearly the dominant theme in this area. *I. J. Higgins* (Cranfield Institute of Technology, UK) reviewed the rapid development in the field of biosensors during the last few years. He expects protein engineering to make important advances in improving the stability of the biological components of biosensors, the most serious problem in current biosensor research. *Higgins* also reported on basic approaches to the development of biochips and biocomputers. He and others believe that bacteriorhodopsin will play an important role in that field. However, this work is still in its infancy, and it could take several more years to achieve a real breakthrough. *M. Thompson* (University of Toronto, Canada) gave a comprehensive overview of the problems of chemoreception and its role in biosensor development. The talk by *I. Karube* (Tokyo Institute of Technology, Yokohama, Japan) illustrated the steady progress being made in Japanese biosensor research and its industrial applications. This again reinforced the impression that Japanese leadership in the field of semiconductor-based biosensors is unchallenged. *M. T. Flanagan* (University College, London, UK) described the rapid evolution in the field of optical biosensors and the impressive achievements of his group in this technology. Thin films of trivalent metal phosphates have been developed by his group as new materials for optical waveguides. The cheap production of such films, their excellent structural integrity, and the ease of immobilizing proteins on their surfaces, could lead to wide use of such materials in the field of optical biosensors.

A special session of the conference was devoted to "research planning and training in biotechnology". National institutions such as the "Lund Science Park" (*S. J. Holm*, Lund, Sweden) provide a unique opportunity for scientists to offer their results to industry. Whereas such "technology parks" (usually in the neighbourhood of a university) work more on a local level, organizations such as GBF (*I. Klein*, Braunschweig, FRG, and EUREKA (*K. Draxler*, Vienna, Austria), aim to coordinate research projects on an international level. The EIT will also operate in this way. If the nearly perfect organization of this conference by *M. Chopplet* (EIT, Paris, France) can be extended into the EIT's work as mediator and communicator between industry and university, this institution will provide new leadership in this field.

der Universität München (FRG)

The 1988 Fall Meeting of the Materials Research Society in Boston

The MRS held its Fall Meeting, approximately the 15th in its history, in Boston from 28 November to 3 December. 24 symposia, each lasting three or four days, incorporating more than 2000 papers in total, plus the traditional lunchtime symposium on 'Frontiers of Materials Research', constituted the main agenda. The printed program, incorporating abstracts to all papers, occupies 644 folio pages. The list of authors' names alone, just short of 5000, printed in very small type in three columns, fills 18 pages. In addition to the main programme, 27 short technical courses were on firm offer, at prices ranging from $ 320 to $ 770, with a further possible 23 courses on 'sale or return'. In addition, Prof. *Thurow* of the Massachusetts Institute of Technology delivered a lecture telling his compatriots what their country needed to do to maintain technological leadership, and Prof. *Jacques Friedel* of Paris gave a lecture of reminiscences to mark the occasion of his receipt of the MRS's annual award for distinguished materials scientists.

About 4000 participants crowded the two linked hotels which housed the Meeting (not all authors of multi-author papers were present), many spilling off at intervals to drink gallons of Coca-Cola, view the extensive exhibition of equipment and books or to consult the in-house employment exchange put on offer by the American Institute of Physics for the MRS. (This offers an indication of the type of jobs favored by MRS members.) The total membership of the MRS is now over 8000. Two peculiarities certainly help the MRS to recruit new members: all those who paid the $ 165 registration fee were automatically registered as MRS members for the coming year, and all (except students with their reduced fee) were entitled to a free subscription, not only to the Society's *Bulletin* but also to the *Journal of Materials Research* published by the Society.

The Society, which only twelve years ago was run on a part-time and shoestring basis by a single industrial scientist, now has 18 full-time headquarters staff, most of whom seemed to be in Boston being kept extremely busy. Certainly the symposia were faultlessly organized: timekeeping was so precise that it was possible, for those nippy on their feet, to run from one symposium to another to hear a particular paper. The Meeting as a whole was masterminded by a triumvirate of scientists; these selected the symposium topics (which are proposed by enthusiasts

among the membership), and each of the approved symposia was then organized by two, three or four scientists, aided by funds provided by several corporate and government sponsors, distinct for each symposium. (The funds provided are used, inter alia, to contribute to some of the costs of invited speakers and some others.) The MRS as a whole has also enrolled some 150 corporate sponsors who make it possible to keep the subscription at its modest level (US $ 50.00), so that many can afford to join.

Most of the symposia will be published in the form of volumes of camera-ready text. When this fall's publishing program is complete, the MRS will have published 144 full symposium proceedings in seven years. Some of the symposia publish only slim volumes of extended abstracts: this is entirely understandable with regard to the high-T_c superconductor symposium, which (as in previous years) will provide extended abstracts together (in due course) with an optional purchase of edited videotapes. It is less easy to understand why the symposium on 'Fractal Aspects of Materials' as in previus years only offers extended abstracts: perhaps the fractal dimension of the papers is such that an abbreviated view provides the same intellectual outline as a full paper would!

One third of the symposia were more or less closely linked to microelectronics concerns, though the titles did not always make this explicit: Advances in Materials, Processing and Devices in III-V Compound Semiconductors; Laser and Particle-Beam Modification of Chemical Processes on Surfaces; Chemical Perspectives of Microelectronic Materials; Thin Films—Stresses and Mechanical Properties ... and several others. Increasing attention to the chemical aspects of microelectronic technology has been noticeable in the last few Meetings, and this tendency has also extended to some other symposium fields (e.g., Graphite Intercalation Products—Science and Applications, which has been a favored field for several years). Generally speaking a new field is initially tried out in a first symposium; if the response is good, the topic may be repeated in a later Meeting, and some fields (such as Laser Annealing of Semiconductors, not represented this year) become hardy near-perennials.

After a slow start, polymers are moving into the limelight: in 1988, two symposia covered liquid-crystal polymers and rigid-rod polymers, and other topics such as diffusion in polymers were treated in earlier years. Some topics which cover a physics-chemistry spectrum are apt to be treated by a more physical approach: this is true, for instance, of the 1988 symposium on Pore Structure and Permeability of Cementitious Materials.—Metals have always been the poor relations at MRS Meetings, at least in their massive form (metallic thin films get plenty of attention!) In 1988, the third in a series of excellent symposia on High-Temperature Ordered Intermetallic Alloys was held; these alloys are of great longterm interest for aviation, both airframe and engine uses, and for some terrestrial uses as well. These symposia, like all MRS symposia, owe their inception to the advocacy of a few committed members. Perhaps in due course sufficient metallurgically inclined members will propose suitable symposium topics to improve the balance. But perhaps the apparent imbalance is as it ought to be, since MRS symposia have always tended to favor fields located in the gaps between the well established major sciences. Indeed, this sense of neglected interstices could be said to have been the reason for the creation of the MRS in the first instance.

Conference Calendar

March 1989

9-10 **The Martensitic Transformation in Science and Technology**
Bochum (Fed. Rep. Germany)
Contact: Dtsch. Ges. Metallkd., Adenauerallee 21, D-6370 Oberursel, FRG

9-11 **Makromolekulares Kolloquium**
Freiburg (Fed. Rep. Germany)
Contact: Prof. H. Finkelmann, Inst. für Makromol. Chemie der Univ., Stefan-Meier-Str. 31, D-7800 Freiburg, FRG

11-14 **Surface Finishing '89**
Brighton (United Kingdom)
Contact: Inst. of Metal Finishing, Exeter House, 48 Holloway Head, Birmingham B1 1NQ, UK

12-14 **High-Tech-Materials and Finishing**
Berlin (West)
Contact: Technik + Kommunikation-Verlag GmbH, Ritterfelddamm 82 h + i, D-1000 Berlin 22

12-25 **Diffusion in Materials,**
NATO Adv. Study Inst.
Aussois (France)
Contact: A. L. Laskar, Phys. and Astron. Dept., Clemson Univ., Clemson, SC 29631, USA

13-14 **Regio Macro II**
Basel (Switzerland)
Contact: Prof. M. Mutter, Inst. für Org. Chem., Univ. Basel, St. Johanns-Ring 19, CH-4056 Basel, Switzerland

13-15 **Mikroelektronik**
Baden-Baden (Fed. Rep. Germany)
Contact: VDE-Zentralstelle Tagungen, Stresemannallee 15, D-6000 Frankfurt 70, FRG

15–17 **Confocal Microscopy/3-D Image Processing in Microscopy,**
1st Int. Conf./2nd Int. Conf.
Amsterdam (Netherlands)
Contact: Bureau PAOG, Congr. Office, Tafelbergweg 25, NL-1105 BC, Amsterdam, Netherlands

15–17 **Intelligent Materials,**
Int. Workshop
Ibaraki (Japan)
Contact: T. Kurino, The Soc. of Nontraditional Technol., Toranomon Kotohira-Kaikan Bldg. 3F, 1-2-8 Toranomon, Minato-ku, Tokyo 105, Japan

20–22 **Mechanical Properties of Materials at High Rates of Strain,**
4th Int. Conf.
Oxford (United Kingdom)
Contact: J. Harding, Eng. Sci. Dept., Univ. of Oxford, Parks Rd., Oxford OX1 3PJ, UK

20–22 **Refractory Metals and Silicides**
Eur. Workshop
Houthalen (Belgium)
Contact: R. De Keersmaecker, IMBE, Kapeldreef 75, B-3030 Leuven, Belgium

20–23 **Eurocomposites and New Materials,**
Conf. and Exhib.
Bordeaux (France)
Contact: EACM, 2 Place de la Bourse, F-33076 Bordeaux Cedex, France

20–23 **Surface Science,**
Interdisciplinary Conf.
Liverpool (United Kingdom)
Contact: P. Weightman, Liverpool Univ., Oliver Lodge Lab., Oxford St., P.O. Box 147, Liverpool L69 3BX, UK

20–24 **Am. Phys. Soc. Mtg.**
St. Louis (USA)
Contact: W. W. Havens, Am. Phys. Soc., 335 E. 45th St., New York, NY, 10017; Tel. 212-6827341

27–31 **Aerospace Sensing,**
Tech. SPIE's Symp.
Orlando (USA)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), Technical Program Committee, P.O. Box 10, Bellingham, WA 98227, USA

28–31 **Aluminum-Lithium**
5th Int. Conf.
Williamsburg (USA)
Contact: Al-Li-V, School of Eng. and Applied Sci., Thornton Hall, Univ. of Virginia, Charlottesville, VA 22901, USA

29–31 **Neutron and X-Ray Scattering: Complementary Techniques**
Canterbury (United Kingdom)
Contact: Dr. R. J. Newport, Univ. of Kent, Physics Dept., Canterbury, Kent CT2 7NR, UK

30–31 **Colorado Microelectronics**
Colorado Springs (USA)
Contact: CMC '89 Conf. Secretary, Microelectronics Research Lab., Univ. of Colorado, Colorado Springs, CO 80933-7150, USA

30–14 **High-T_c Superconductors,**
Exp. Workshop
Miramare (Italy)
Contact: Int. Ctr. for Theoretical Physics, P.O. Box 586, I-34100 Trieste, Italy

April 1989

1–6 **Superconductivity,**
2nd World Congr.
Houston (USA)
Contact: R. D. Kane, World Congr. on Superconductivity, P.O. Box 27805, Houston, TX 77227-7805, USA

2–4 **Solar Energy**
Int. Conf.
San Diego (USA)
Contact: Dept. of Mechanical Eng., San Diego State Univ., San Diego, CA 92182-0191, USA

3–5 **Molecular Electronics**
Bangor (Wales)
Contact: Prof. H. Block, Center for Molecular Electronics, School of Industrial Science, Cranfield Institute of Technology, Cranfield, Bedford MK43 OAL, UK

3–5 **Modern Practice in Stress and Vibration Analysis**
Liverpool (United Kingdom)
Contact: Meetings Officer, Inst. of Physics, 47 Belgrave Sq., London SW1X 8QX, UK

3–6 **Low Energy Ion Beams,**
5th Conf.
Guildford (United Kingdom)
Contact: Meetings Officer, Inst. of Physics, 47 Belgrave Sq., London SWIX 8QX, UK

3–7 **Copolymerization and Copolymers in Dispersed Media**
Lyon (France)
Contact: I. Guillot/C. Pichot, Lab. des Materiaux Organiques, BP 24, F-69390 Vernaison, France

3–7 **High Temperature Materials '89**
Gaithersburg (USA)
Contact: J. W. Hastie, National Bureau of Standards, Gaithersburg, MD 20899, USA

4–7 **Electrochemical Processing of Semiconductors**
Berlin (West)
Contact: W. Pieth, Free Univ. of Berlin, Inst. of Phys. Chem., Takustraße 3, D-1000 Berlin 33

4–7 **Refractories and High Temperature Materials**
Swansea (United Kingdom)
Contact: Inst. of Ceramics, Shelton House, Stoke Rd., Shelton, Stoke on Trent ST4 2DR, UK

4–14 **Phase Transition in Soft Condensed Matter,**
NATO Adv. Study Inst.
Geilo (Norwegen)
Contact: G. Jarret, Inst. for Energy Technol., Dept. of Physics, P.O. Box 40, N-2007 Kjeller, Norwegen

5–7 **Insulating Films on Semiconductors**
6th Int. Conf.
Garching (Fed. Rep. Germany)
Contact: F. Koch, Physik-Dept. E 16, Techn. Univ. München, D-8046 Garching, FRG

6-7 **Modeling in Crystal Growth from the Melt,**
NATO Workshop
Parma (Italy)
Contact: G. Müller, Inst. für Werkstoffwissenschaften 6, Martensstraße 7, D-8520 Erlangen, FRG

10-12 **Bayreuther Polymer Symp.,**
Bayreuth (Fed. Rep. Germany)
Contact: BPS '89, Lehrstuhl Makromolekulare Chemie II, Univ. Bayreuth, Postfach 101251, D-8580 Bayreuth, FRG

10-12 **British Liquid Crystal Society**
Annu. Conf. 1989
Sheffield (United Kingdom)
Contact: Dr. D. A. Dunmur, Dept. of Chemistry, Univ. of Sheffield, Sheffield S3 7HF, UK

10-12 **Microstructure of Materials in Packaging Technology**
51st WE-Heraeus-Seminar
Bad Honnef (Fed. Rep. Germany)
Contact: Dr. V. Schäfer, WE-Heraeus-Stift., Heraeusstr. 12-14, D-6450 Hanau, FRG

10-13 **Microscopy of Semiconducting Materials,**
MRS 6th Oxford Conf.
Oxford (United Kingdom)
Contact: Administrator, Royal Microscopy Soc., 37/38 St. Clements, Oxford OX4 1AJ, UK

11-13 **Catalysis by Well Characterized Materials**
Liverpool (United Kingdom)
Contact: Prof. R. W. Joyner, Leverhulme Ctr. for Innovative Catalysts, Univ. of Liverpool, Grove St., P.O. Box 147, Liverpool L69 3BX, UK

17-19 **Metals and Materials 89**
Guildford (United Kingdom)
Contact: Inst. of Metals, 1 Carlton House Terrace, London SW1Y 5DB, UK

17-20 **Rare Earth Materials**
5th Biliteral Symp. (FRG/USSR)
Bad Honnef (Fed. Rep. Germany)
Contact: Dr. J. Debrus, Physikzentrum, Hauptstr. 5, D-5340 Bad Honnef 1, FRG

17-21 **Metallurgical Coating**
Int. Conf.
San Diego (USA)
Contact: B. D. Sartwell, Naval Research Lab., Code 4675, Washington, DC 20375, USA, Tel. 202-767-4800, Fax 202-767-5301

17-26 **Ceramics and Composite Materials,**
Spring College in Mater. Sci.
Trieste (Italy)
Contact: Int. Ctr. for Theoretical Physics, Spring College in Mater. Sci. 1989, P.O. Box 586, I-34100 Trieste, Italy

17-29 **STM Basic Concepts and Applications**
NATO Adv. Study Inst.
Erice (Italy)
Contact: Dr. H. Rohrer, IBM Research Div., Zürich Research Lab., Saumerstr. 4, CH-8803 Rüschlikon, Switzerland

18-19 **Industrial Water-Soluble and Water-Swellable Polymers**
Manchester (United Kingdom)
Contact: The Registar (Mid-Career Training), UMIST, P.O. Box 88, Manchester M60 1QD, UK

19-21 **Particle Characterization**
4th Eur. Symp.
Nürnberg (Fed. Rep. Germany)
Contact: Prof. Dr. K. Leschonski, Techn. Univ. Clausthal, Inst. f. Mechan. Verfahrenstechn. u. Umweltverfahrenstechn., Leibnizstr. 15, D-3392 Clausthal-Zellerfeld, FRG

23-27 **American Ceramic Society,**
91st Annu. Mtg. and Expo.
Indianapolis (USA)
Contact: Dr. K. M. Nair, Electronics Dept., E.I. du Pont de Nemours Co., Inc., 3181 Buffalo Ave., Niagara Falls, NY 14302, USA

23-28 **Nondestructive Testing,**
12th World Conf.
(WCNDT '89)
Amsterdam (Netherlands)
Contact: B. de Jong, RAI Organisatie Bureau Amsterdam bv, Europaplein 12, 1078 GZ Amsterdam, Netherlands

24-28 **Optical Science and Engineering,**
2nd Int. Congr.
Paris (France)
Contact: Soc. of Photo-Optical Instrumentation Eng. (SPIE), P.O. Box 10, Bellingham, WA 98227, USA

24-28 **Lasers and Electro-Optics,**

Garmisch-Partenkirchen (Fed. Rep. Germany)
Contact: VDE-Zentralstelle Tagungen, Stresemannallee 15, D-6000 Frankfurt 70, FRG

8–11 **SAMPE**
34th Int. Symp. and Exhib.
Reno (Italy)
Contact: SAMPE, 843 West Glentana, P.O. Box 2459, Covina, CA 91722, USA, Tel. 818-331-0616

8–12 **High Temperature and Wear Resistant Materials in a World of Changing Technology**
12th Int. Plansee Seminar
Plansee (Austria)
Contact: Metallwerk Plansee, A-6600 Reutte, Austria

9–11 **Coatings and Sensors for Acoustic and Electromagnetic-Optical Applications**
Univ. Park. (USA)
Contact: V. K. Varadan, Dept. of Eng. Sci. and Mechanics, Penn. State Univ., 227 Hammond Bldg., Univ. Park, PA 16802, USA

10–11 **Polyimides**
Montpellier (France)
Contact: Prof. M. Abadie, LEMD/MAO-USTL, F-34060 Montpellier Cedex 1, France

16–19 **Modern Developments in Materials Science and Technology,**
Annu. Mtg. Dtsch. Gesellsch. Metallkd.
Karlsruhe (Fed. Rep. Germany)
Contact: Dtsch. Gesellsch. Metallkd., Adenauerallee 21, D-6370 Oberursel, FRG

16–19 **Rare-Earth Magnets and Their Applications**
10th Int. Workshop
Kyoto (Japan)
Contact: Dr. C. Herget, Sparte Anorg. Chemie, Th. Goldschmidt AG, P.O. Box 101461, D-4300 Essen 1, FRG

22–24 **Sol-Gel-Gläser**
52nd WE-Heraeus-Seminar
Bad Honnef (Fed. Rep. Germany)
Contact: Dr. V. Schäfer, WE-Heraeus-Stift., Heraeusstr. 12–14, D-6450 Hanau, FRG

22–24 **Werkstoffanalytik,**
Wien (Austria)
Contact: Prof. Dr. M. Grasserbauer, Inst. für Analytische Chem. der Tech. Univ. Wien, Getreidemarkt 9, A-1060 Wien, Austria

22–24 **Glastechnische Tagung**
Stuttgart (Fed. Rep. Germany)
Contact: Dtsch. Glastechn. Gesellsch., Mendelssohnstr. 75–77, D-6000 Frankfurt am Main, FRG

22–25 **Clustering and Aggregated State of Matter**
Strasbourg (France)
Contact: Prof. E. Constantin, Groupe de Recherche de Spectrométrie de Masse Interlab., Dept. de Chim., 1 rue Blaise Pascal, 67008 Strasbourg Cedex, France

22–25 **Graphite Intercalation Compounds,**
5th Int. Symp. (ISGIC-5)
Berlin (West)
Contact: Dr. F. W. Froben, Fachbereich Physik, Freie Univ. Berlin, Arnimallee 14, D-1000 Berlin 33

24–26 **Advances in the Stabilization and Controlled Degradation of Polymers,**
11th Int. Conf.
Luzern (Switzerland)
Contact: Dr. A. V. Patsis, Inst. in Materials Sci, State Univ. of New York, New Paltz, NY 12561, USA

25–26 **Quantitative Methods in Assessment of Structural Defects**
Kansas City (USA)
Contact: A. P. Berens, Univ. of Dayton, Research Inst., 300 College Park Ave., Dayton, OH 45469, USA

29–31 **Cross-linked Polymers,**
3rd Int. Conf.
Luzern (Switzerland)
Contact: Dr. A. V. Patsis, Inst. in Materials Sci, State Univ. of New York, New Paltz, NY 12561, USA

30–2 **E-MRS Spring Mtg.**
Strasbourg (France)
Contact: P. Siffert, Ctr. de Recherches Nucléaire, Lab. PHASE, F-67037 Strasbourg, Cedex, France

31–2 **Applied Surface Analysis,**
11th Symp.
Cleveland (USA)
Contact: J. Grant, Research Inst., 300 College Park, Dayton, OH 45469-0001, USA

31-2 **Thermogravimetry and Thermal Engineering,**
6th Biennial Conf.
Budapest (Hungary)
Contact: I. Benko, MATE, House of Technol. III. 318, P.O. Box 451, H-1372 Budapest, Hungary

June 1989

5–7 **CONIMAT' 89**
1st Int. Convention for the Technology Transfer of New Materials
Strasbourg (France)
Contact: Adhesion Et Associes - CONIMAT', 9, rue de L'Ancienne Mairie, 92100 Boulogne, France, Tel. 48 25 26 04, Fax. 46 03 86 26

6–9 **Chemistry of Functional Dyes,** Int. Symp. (ESTech '89) Osaka (Japan) Contact: Prof. T. Kitao, General Secretary of the Symp., Kinki Chem. Soc., Japan 1-8-4, Utsubo honmachi, Nishi-ku, Osaka 550, Japan

12–15 **Narrow-Gap Semiconductors and Related Materials,** Int. Conf. Ogunquit (USA) Contact: D. G. Seiler, Phys. Dept., Univ. of North Texas, P.O. Box 5368, Denton, TX 76203, USA

18–21 **Colloid & Surface Science,** 63rd ACS Div. of Colloid & Surface Chem. Symp. Seattle (USA) Contact: J. Berg, Dept. of Chemical Eng. BF-10, Univ. of Washington, Seattle, WA 98105, USA

18–23 **Ceramic Materials and Production Methods** 1st Conf. of the Eur. Ceramic Soc. and Fair Maastricht (Netherlands) Contact: Mrs. L. M. J. Bos, P.O. Box 1630, 6201 BP Maastricht, Netherlands

19–21 **Composites** Asia-Pacific 89 Adelaide (Australia) Contact: The Secretariat, Techsearch, Composites Asia-Pacific '89, P.O. Box 2471, Adelaide S.A. 5001, Australia

20–22 **SAMPE** 3rd Int. Electronics Conf. Los Angeles (USA) Contact: M. Smith, Business Director, SAMPE, P.O. Box 2459, Covina, CA 91722, USA, Tel. 818-331-0616

21–23 **Chemically Modified Surfaces,** Midland (USA) Contact: W. T. Collins, Dow Corning Corp., Mail Stop C41C00, Midland, MI 48686, USA

21–23 **Electronic Materials** Cambridge (USA) Contact: The Metallurgical Soc., 420 Commonwealth Dr., Warrendale, PA 15086, USA

Stiff-Chain Polymers—Structure, Phase Behavior, and Properties

By Matthias Ballauff*

Most of the industrial plastics used up to now consist of flexible macromolecules in which the repeat units are joined together in a nonlinear fashion by rotating bonds. Stiff-chain polymers, which in the ideal case have a rodlike shape, have received much less attention. The reason for this is that such polymers usually exhibit an exceedingly low solubility. Very often, they are absolutely insoluble and do not melt. However, in recent years these polymers have aroused technical interest because high-modulus fibers and moldings can be fabricated from them. These favorable mechanical properties are directly related to the nearly parallel arrangement of the rodlike macromolecules in the solid state which is achieved through spinning or extrusion from a liquid crystalline (nematic) state. It is therefore evident that a thorough understanding of the phase behavior and the structure is required for a universal technical utilization of these materials. The great variety of methods used in polymer science today has led to a deeper understanding of stiff-chain polymers. Experimental results together with theoretical modeling of the phase behavior have direct implications for the practical use of these macromolecular materials.

1. Introduction

Today, synthetic polymers represent a class of ubiquitous materials, for they may be molded easily into arbitrary shapes and used for a multitude of purposes. The almost inexhaustable varieties of molecular architecture constantly lead to new applications. However, the great potential of macromolecular materials has so far only been partially exploited, since mostly flexible polymers have been used, i.e. chain molecules in which the successive units are assembled by rotating bonds and form angles different from 180°. In contrast to this, stiff-chain polymers are derived from rigid monomer units connected in a collinear fashion. Their technical development and use has only just begun. This delay can be traced back to the low solubility of these polymers and to the necessity of using exotic solvents. In addition to this, the melting point is very high and in many cases the materials do not melt at all. This renders investigations in solution or in the melt by conventional physicochemical techniques a very difficult task. The processing of stiff-chain polymers is very often impossible for the same reasons. The ultimate cause for these problems lies in the rodlike shape of the macromolecules: because of their coil-like nature, flexible macromolecules may assume a vast number of conformations in the melt or in solution. Hence, melting or dissolving a flexible coil is accompanied by a substantial gain in entropy. In contrast, stiff-chain polymers experience no alteration in shape regardless of the state of their aggregation. Hence, dissolution in a solvent or melting requires cleavage of numerous intermolecular contacts, but leads only to a minor gain in entropy.

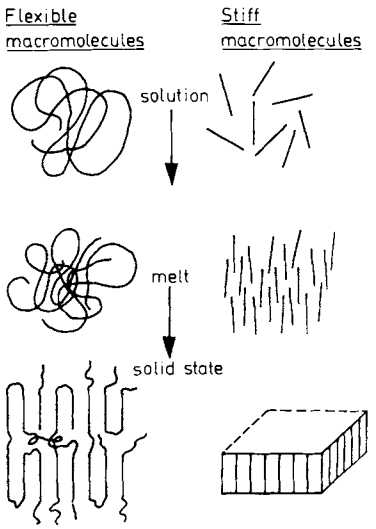
This brief overview clearly demonstrates that great difficulties are encountered both in the processing and in the scientific investigation of stiff-chain polymers. Despite such unusual problems, this class of polymers has recently attracted unusual interest from the scientific and engineering communities. The underlying reasons for this development best emerge on comparing the phase behavior of stiff and of flexible macromolecules (Fig. 1).



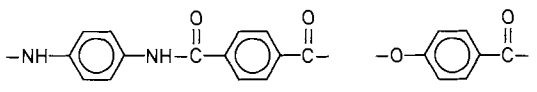


Fig. 1. Schematic comparison of the phase behavior of flexible and stiff macromolecules.

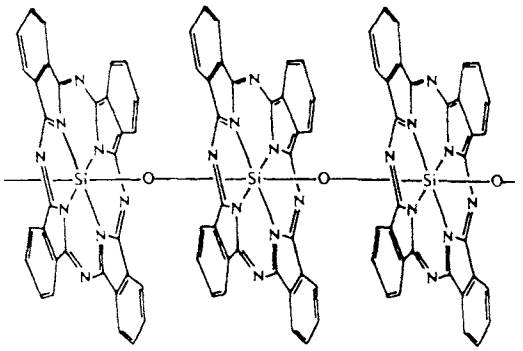
Flexible macromolecules assume a coiled conformation both in the melt as well as in solution. When the concentration of the dissolved macromolecules exceeds a critical value the coils overlap and form entanglements. If the degree of polymerization and the overlap are large enough these entanglements will govern the dynamics of such systems.[1] Furthermore, it is evident that solutions and melts from flexible macromolecules in equilibrium will be isotropic, i.e., there will be no preferred direction in the system. Complete crystallization from such a melt would require the disentanglement of all coils and adoption of a special conformation allowing the packing in the crystal. This qualitative argument already leads to the conclusion that flexible polymers can normally be transformed only into the semicrystalline state from the melt, if crystallization from the melt takes place at all. Figure 1 shows the typical lamellar morphology of the crystalline regions with the interdispersed amorphous phase. This arrangement has far-reaching consequences for the mechanical properties of these systems.

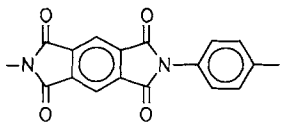
Stiff-chain polymers, depicted as rods in Figure 1, lead to an entirely different phase behavior. In contrast to flexible polymers there is no formation of entanglements. At higher concentrations, however, interaction between the rods leads to a constraint of rotation. The consequences of this effect on the dynamics of such a solution can be treated quantitatively.[1] Still higher concentrations are followed by an increase of parallel alignment of the rods due to steric effects. If the concentration exceeds a certain critical value that is a function of the axial ratio, i.e., the ratio of length to the diameter of the rods, a spontaneous transition to an ordered, liquid crystalline system takes place.[2,3] The ordered domains thus generated may be aligned by external fields or by flow processes, whereupon macroscopically oriented solutions or melts are formed. The strong steric interaction between the rods, which already causes partial alignment and liquid crystalline order in solution, will lead to a well-ordered, parallel arrangement of the macromolecules in the solid state. Under certain conditions, e.g., by spinning from liquid crystalline solutions, macroscopic order may be achieved in these systems and preserved upon transition to the solid state.

Thus, the discovery that poly-(*p*-phenyleneterephthalamide) **1** forms liquid crystalline solutions from which high modulus fibers may be spun was the major incentive for scientific and corporate research on stiff-chain polymers.[4,5] The unusual mechanical properties of these materials mainly derive from the high alignment of the rodlike molecules and the absence of an amorphous phase, which limits the mechanical strength of flexible polymers. A great number of stiff-chain polymers forming liquid crystalline melts or solutions[6,7] have now been synthesized and investigated. It is the goal of this review to demonstrate the interrelation of the phase behavior of stiff-chain polymers with their molecular architecture. The discussion is not restricted to liquid crystalline phases deriving from these systems (see Ref. [6] for a detailed discussion of liquid crystal polymers) but deals rather with the phase behavior in the entire accessible range of temperature. This requires first a discussion of how a rod-shaped structure of a macromolecule may be achieved. The typical phase behavior of stiff-chain polymers is discussed next using the polyester **2** of *p*-hydroxybenzoic acid as a well-investigated example. After this the molecular architecture necessary to lower the melting point below the temperature of thermal decomposition for the observation of liquid crystalline phases is discussed. The subsequent section is devoted to the experimental determination of chain stiffness. Then a short survey of the theory of the nematic phase is given. A central point of this discussion is the predictive power of theoretical models with regard to the phase behavior of stiff-chain macromolecules used in practice. A final section deals with the properties and possible applications of these materials.



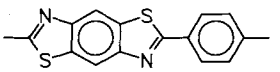
1 2

2. Molecular Architecture of Stiff-Chain Polymers



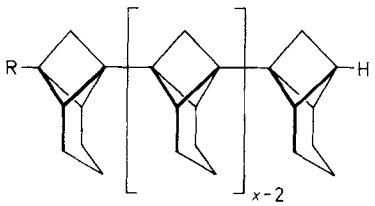
Already mentioned in Section 1, flexible polymers are usually built up by a sequence of nonlinearly linked units. Stiffness of the polymer chain is effected through building up the chain from anisometric groups. The rodlike shape may now be realized by a linear, rigid connection of these monomers or by the steric interaction of the neighboring

monomer. The polyphthalocyaninatosiloxanes **3** exampls of the latter building principle.[8]



3

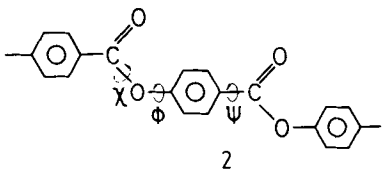
Here the flexible siloxane chain is forced into a stretched conformation by the steric repulsion of the densely packed phthalocyanine rings. In contrast to this the stiffness of the polyimide **4** follows from the molecular configuration of the repeat units in which planar rings are joined together by a C–N bond to a phenyl group.



4

5

This bond is also located in the plane of the imide ring and parallel to the long axis of the polyimide molecule. Rotations about this C–N single bond do not affect the stiffness of the whole macromolecule. A similar, ladder-like structure is realized in the poly-*p*-phenylenebenzodithiazole **5**.[9]



Chain stiffness can also be realized with cycloaliphatic structures of suitable geometry. The polypropellanes **6** recently introduced by *Schlüter*[10] may serve as examples. Here, as in the case of the polyimides **4**, the rotation around the C–C single bond connecting the repeat units does not result in a deviation from the rodlike shape.

6

In addition to this, chain stiffness can be introduced into flexible polymers by helical supramolecular structures. This building principle is very often found in biopolymers such as DNA,[11] Xanthan[12] or in a number of polypeptides. Here, extraordinary stiffness may be effected by winding up several helical strands.

In all the examples dealt with up to now, the extended shape is evident from the molecular architecture, whereas the discussion of chain stiffness in *p*-linked fully aromatic polyesters and polyamides is more complicated. Repeat units as in the polyester **2** (cf. Fig. 2) are only linear if there is no free rotation about the C(O)–O bond (angle χ),

2

Fig. 2. Definition of the torsion angles in the repeat unit of the polymer **2** for the calculation of the chain conformation within the framework of the rotational isomeric state model (cf. Fig. 14) [15–17, 87, 88].

i.e., if the ester group is planar. Rotations around the other framework bonds (torsion angle ϕ and ψ) do not lead to deviations from rodlike shape, since subsequent units may be assumed, to a first approximation, to be collinear. The analysis of the conformation of the polyester segment shown in Figure 2 by *Flory* et al.[15–17] indeed leads to the conclusion that the ester group (and also the amide group) is planar, and the oxybenzoyl unit and the analogous unit of the polyamides will exhibit a high stiffness. This analysis, however, does not take into account the influence of substituents in the *o*-position to the carboxy group[18] on the conformation. This point will be discussed further in Section 5.

3. Poly(4-oxybenzoate) as Example

In this section the polyester **2** of *p*-hydroxybenzoic acid (see Fig. 2) will be discussed as a well investigated example of a stiff-chain polymer. First experiments leading to the synthesis of this polymer were carried out as long ago as the end of the last century. Hence these investigations are among the oldest experiments in polymer science. *Schiff* in 1882[19] and *Klepl* in 1883[20] reported the isolation of oligomers from the products obtained upon reaction of *p*-hydroxybenzoic acid with $POCl_3$ or upon heating the monomer. *Emil Fischer* and *Karl Freudenberg*[21] synthesized the pure oligomers of *p*-hydroxybenzoic acid and of vanillic acid up to the tetramer. In the course of this work they found that the solubility of the products decreases strongly with increasing degree of polymerization. Starting from the acetoxybenzoic acids, *Gilkey* and *Caldwell*[22] succeeded in synthesizing the polymers of *m*- and *p*-hydroxybenzoic acid. The first systematic study of the polyester poly-(*p*-oxybenzoyl) **2** was conducted by *Economy* et al.,[23] who also investigated the structure by means of electron- and X-ray diffraction. A major improvement in the synthesis and subsequent characterization of the products with regard to their molecular weight was achieved by *Kricheldorf* and *Schwarz*.[24–26] On the basis of the latter works *Lieser*[27a] succeeded in 1983 in determining the phase behavior and the unit cells of the individual modifications of the polyester **2** by electron diffraction. According to *Lieser* **2** forms two orthorhombic modifications I and II at room temperature (see Fig. 3; cf. also Refs. [27b, c]).

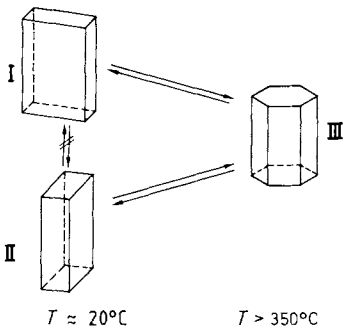


Fig. 3. Schematic representation of the unit cell of modifications I–III of the polyester **2** [27a]: The mixture of two orthorhombic modifications I and II at room temperature transforms reversibly into the pseudohexagonal modification III.

Both modifications are transformed through a first-order transition at 330°C into a pseudohexagonal phase III. Cooling down to room temperature again leads to a mixture of modifications I and II together with structures containing a number of defects.[27a] The fact that I cannot be transformed into II and vice versa suggests that the asymmetric macromolecules have different directions in the two phases.[27a] Since no macroscopically oriented samples suitable for X-ray scattering have been obtained up to now, this problem still remains unsolved. Investigations on the polycondensation with the help of small-angle X-ray scattering and electron microscopy show that the chains are sufficiently mobile even in the crystal structure, especially in phase III, and thus are sufficiently reactive, i.e. the macromolecules have enough reactivity that the polymerization will proceed mainly in the solid state.[28] A further point of interest is that poly(*p*-thiobenzoyl) exhibits the same phase behavior as poly-(*p*-oxybenzoyl) **2**.[29]

The absence of a melting process in the case of **2** renders the fabrication of this polymer by the usual methods employed in plastics technology impossible. Molding can be achieved only by high-energy forging. This problem, which is typical for stiff-chain polymers, may be circumvented in some cases, e.g. poly(*p*-phenyleneterephthalamide) **1**, which is sufficiently soluble in concentrated sulfuric acid. However, it is obvious that processing from such aggressive solvents gives rise to a number of technical problems. Molding directly from the melt is certainly the less costly alternative. An overview of the concepts for lowering the melting point of stiff-chain polymers, based on examples, is given in the next section.

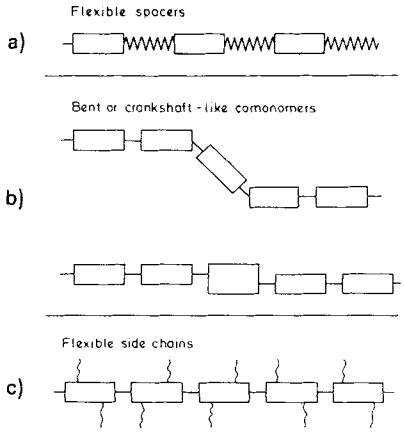
4. Concepts for Improving the Solubility and for Lowering the Melting Points of Stiff-Chain Macromolecules

In principle the melting points of stiff-chain polymers can be lowered by the following modifications of the structure:

1) Insertion of flexible comonomer units ("spacers") like *n*-alkylene chains.[30,31] However, this strongly reduces the rigidity of the resulting macromolecules. These polymers are flexible coils in solution and will not be discussed in further detail here.

2) Inclusion of bent units of different size. This leads to a disturbance of the crystal structure and a lowering of the melting point.[32,33]

3) Appending of flexible side chains onto the stiff main chains. Here the side chains act like a bound solvent, which lowers the interaction between the main chains, and leads to a large increase in entropy when dissolving or melting the polymer.[34–38]



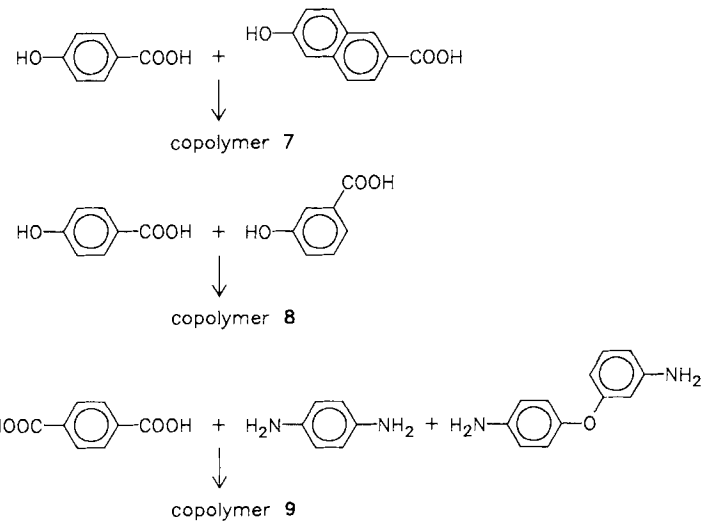


Fig. 4. Concepts for improving the solubility and meltability of stiff-chain polymers: a) insertion of flexible spacers between the rigid, mesogenic units; b) insertion of bent or crankshaft-like comonomers; c) appending of flexible side chains to the rigid, linear main chain.

4.1. Copolymers

Because of the increased interest being shown in stiff-chain macromolecules in industry for the fabrication of high-strength fibers, numerous copolyesters and copolyamides have been synthesized from relatively easily accessible fully aromatic hydroxycarboxylic acids and bisphenols and have been patented. Scheme 1 shows three selected examples which should serve as models for illustrating the main features of such polymers.

The first system shown, the copolyester **7** ("Vectra", Hoechst-Celanese)[39–41] consisting of 2-oxy-6-naphthoyl and *p*-oxybenzoyl units, exemplifies the disturbance of

Scheme 1. Selected copolymer systems.

crystallization by comonomer units of different size, which leads to a crankshaft-like structure along the polymer chain. The copolymer **8** of *p*- and *m*-hydroxybenzoic acids[24,42–46] consists of a sequence of linear and bent units of approximately equal size. It is especially suitable for structural investigations, since the phase behavior of poly(*p*-oxybenzoyl) **2** is already well-known (cf. Section 3). The third example, the copolyamide **9**[47–49] can assume a coiled or a stretched conformation. This is due to the 3,4′-linkage of the diaminodiphenyl ether, in which the 60° bend of the ether bond can be straightened out again by the *m*-linkage. Thus, the influence of intermolecular interactions on the conformation of the chain can be studied directly. A further example of technical importance is provided by the copolyester of *p*-hydroxybenzoic acid, terephthalic acid and 4,4′-biphenyldiol ("Xydar", Dartco).

The main problems concerning the synthesis and phase behavior of stiff-chain copolymers will now be discussed using results based on the second system (copolymer **8**) of Scheme 1. Later on, a comparison with the results of the other two systems will follow. Despite the inclusion of units along the chain which disrupt crystallization, the melting point of these materials may still exceed 300°C. This fact together with the low solubility leads to a number of problems during polycondensation in the melt. In general, two methods are used to circumvent these problems: the activation of the hydroxy groups by acetylation ("acetoxy method"; Fig. 5, top) or by silylation ("silyl method";

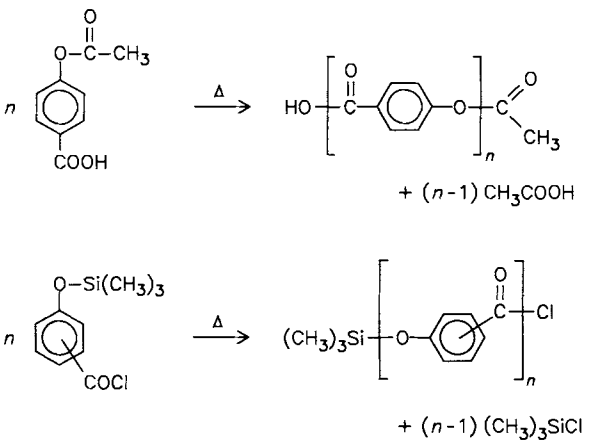

Fig. 5. Methods for polycondensation of aromatic polyesters: acetoxy method (above) and "silyl method" (below).

Fig. 5, bottom).[25,28] An important point during the polycondensation process is to maintain homogeneity at least in the early stage. Otherwise block copolymers instead of statistical copolymers may result. Since the copolymers **8** exhibit sufficient solubility in $CHCl_3$ up to a content of 40% of the linear *p*-component, a sequence analysis by means of ^{13}C NMR spectroscopy in solution is possible. This shows that the monomer units are distributed at random along the chain.[42,43] In the case of insoluble products a sequence analysis may be achieved in special cases by means of wide-angle X-ray scattering of solid oriented samples. This method of analysis has been developed by *Blackwell* et al.[49–51] and by *Bonart* et al.[52–54] and has been applied to a number of copolymer systems. In this treatment the intensity of the meridional reflections of samples with sufficient orientation[55] is compared to results of model calculations which explicitly simulate the deviation from a random sequence of the monomeric units. Using this method it has been shown that copolymer **7** is a statistical copolymer (see Ref. [51]). A similar analysis of the 3,4′-linked copolyamide **9** showed that it assumes a stretched conformation in the solid state.[49] This finding demonstrates the strong steric interaction of the chains in ordered systems which leads to a stiffening of systems which in themselves are flexible. Thus, the present results lead to the conclusion that statistical copolymers may be obtained if the conditions of polycondensation are well-defined. Also, the analysis shows the chains to adopt a stretched conformation in the solid state.

Another point of interest is the crystallinity of these copolyesters and -amides as well as the kind of distortion exerted by the bent or crankshaft-like comonomer onto the crystal lattice of the linear component. In principle, this poses the question of crystallization in random copolymers. A number of studies of this problem have been carried out on copolymer **7** by *Windle* et al.,[56] who have formulated the concept of "non-periodic layer crystallites" (NPL).[56–58]

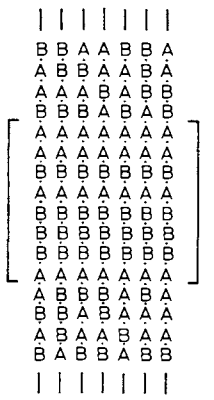

Fig. 6. "Non-periodic layer crystallite" (NPL) model of *Windle* et al. [56–58] for the crystallization of stiff-chain copolymers of the monomers A and B. The NPL crystallite marked in the figure by parentheses is built up by juxtaposition of parts of the chains having the same sequence of monomer units.

Here, the formation of small crystallites is modeled by putting together parts of the chains in the same sequence (see Fig. 6). In this model semicrystallinity thus may be brought about through lateral juxtaposition of parts of the chains having the same shape. The probability of finding a given fixed sequence of congruent units decreases strongly with the length of the sequence. Therefore these NPL crystallites will have a rather limited size. These ideas have been further developed by *Windle* et al.[57,58] A comparison with experimental results gave first hints that such ordered regions do indeed exist (cf. discussion of experimental findings in Refs. [57] and [58]).

The high crystallinity of copolyester **8** can be explained without the NPL concept, since investigations by X-ray[43] and electron diffraction[44] have shown that the modifications of the polyester **2** of *p*-hydroxybenzoic acid (see Section 3) can incorporate an appreciable number of bent *m*-

units. As is obvious from wide angle X-ray measurements[43] (cf. Fig. 7), even an amount of 10% hardly broadens the reflections. Electron diffraction studies[44] can supplement this information by more detailed information on the kind of defects. Only if the content of bent *m*-units is 30% or greater is the crystallinity disturbed considerably.

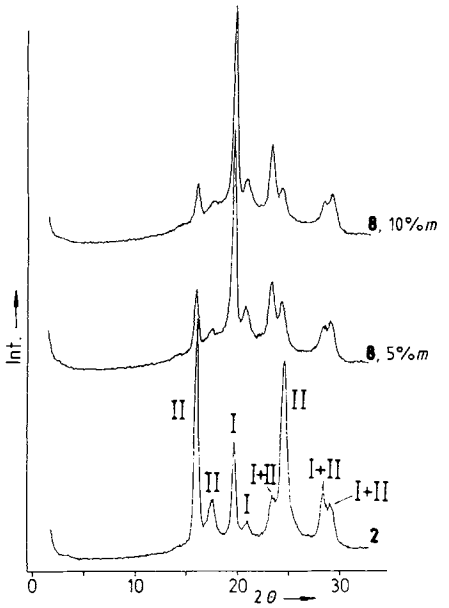

Fig. 7. X-ray diffractograms [43] of the polyester **2** of *p*-hydroxybenzoic acid and of the copolyester **8** containing 5% and 10% *m*-hydroxybenzoic acid at room temperature. The roman numerals I and II indicate the two orthorhombic low-temperature modifications I and II of **2** [27a] (cf. Fig. 3).

Having discussed the phase behavior of the materials at room temperature, the question now is how the disturbance of the comonomer units affects the phase behavior at elevated temperature. Figure 8 shows the diffractograms of copolymer **8** with 10% *m*-units at room temperature and above the temperature of the first order transition.[59,60] It is obvious that both modifications I and II have been transformed into modification III, the pseudohexagonal packing of the chains of which could be demonstrated with electron diffraction photographs[44] of oriented samples. Cooling the sample down to room temperature again leads to a mixture of I and II, as observed in the case of the homopolymer **2**. Rapid cooling, however, allows phase III to supercool down to room temperature if the disturbance by *m*-units ($\geq 30\%$) is strong enough.[59,60]

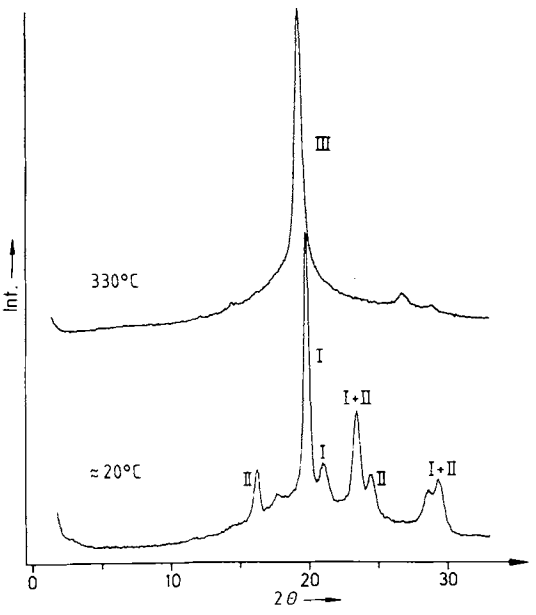

Fig. 8. X-ray diffractograms of copolyester **8** containing 10%. *m*-hydroxybenzoic acid at room temperature and at 330°C. The diffractograms demonstrate that both low-temperature modifications I and II (cf. Fig. 3) are transformed into the high temperature modification III.

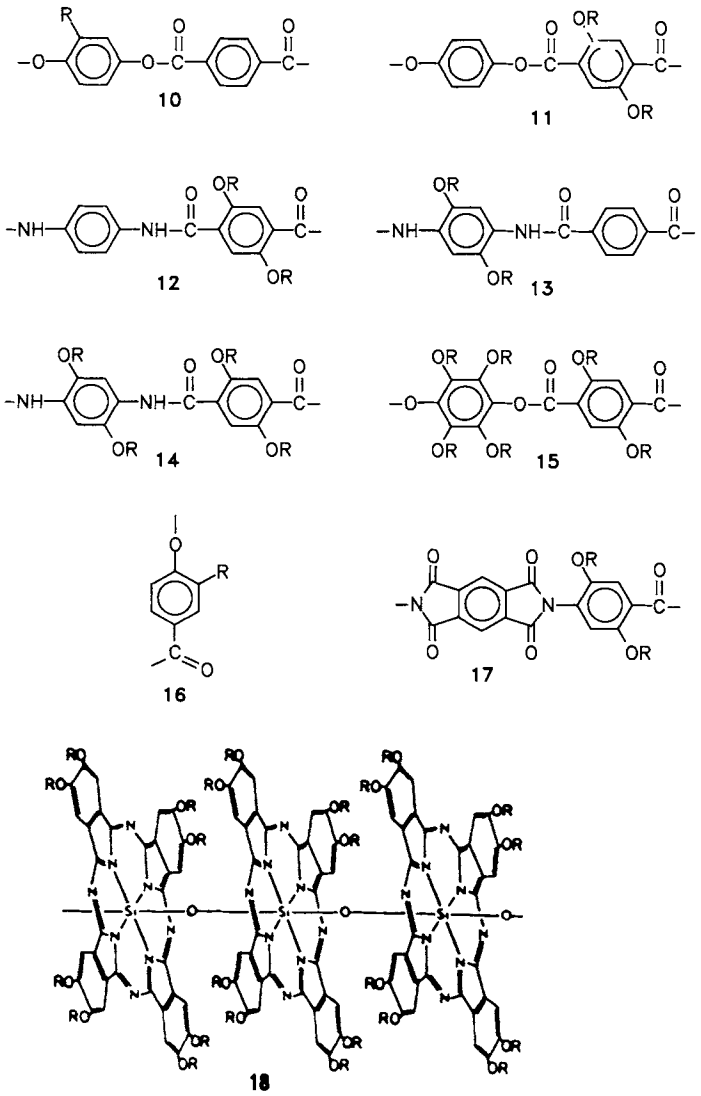
All the results obtained on copolyester **7** up to now by X-ray studies (powder and fiber diagrams)[50,56,61] lead to the following conclusions: at room temperature there is a mixture of an amorphous phase and a strongly disturbed, probably pseudohexagonal phase.[61] The amount of the ordered phase, which could be compared with modification III of the polyester **2**, increases upon annealing. Raising the temperature diminishes the crystalline part and above 300°C there is only an amorphous melt. *Windle* et al.[56,62] investigated this phase by polarization microscopy and came to the conclusion that it is a biaxially nematic phase. Up to now only *Finkelman* et al.[63] have succeeded in providing direct evidence of a thermotropic biaxial nematic phase in liquid crystalline polymer with the mesogenic units in the side-chain. Similarly, *Ebert, Hermann-Schönherr Wendorff, Ringsdorf* and *Tschirner* have reported convincing evidence for a biaxial nematic phase in a stiff- chain polyester with flexible side chains.[64] Since there are no comparable conoscopic[*] observations on fully oriented samples of polyester 7, the above conclusion drawn by *Windle* et al. is only indirect and needs confirmation by further investigations.



So far only a few measurements have been carried out on the glass transition in copolymers of the type **7**–**9**. Measurements of the glass transition temperature T_g of the copolyester **8** as a function of its composition show[43] that T_g does not increase but becomes smaller on increasing the amount of *p*-hydroxybenzoic acid. This unexpected result becomes plausible when the great number of defects in the orthorhombic or the pseudohexagonal structures is taken into account. Thus, at comparatively low temperatures a rotational motion of chain segments may be induced even if the free volume available is rather small, whereas an increase in mobility of non-linear segments would necessitate a much higher free volume. ^{2}H NMR spectroscopic investigations on the copolymers discussed here[65–67] would be very helpful, since the present results are not yet conclusive regarding the mechanism of motion. However, as already stated by *Wendorff* et al.,[68] this phase, especially the high-temperature modifications of the polyester **2** and of the copolymers of type **8**, may be compared with plastic crystals or highly ordered smectic phases, i.e., with systems characterized by positional long range order in which the molecules have certain rotational degrees of freedom above the glass temperature.

4.2. Stiff-Chain Macromolecules with Flexible Side Chains

The third concept delineated in Figure 4 for improving the solubility and lowering the melting point of stiff-chain polymers consists in the attachment of flexible side chains to rigid main chains. In contrast to the foregoing concepts, the stiffness of the main chain is fully preserved. During the process of melting or upon dissolution these side chains can adopt a vast number of configurations as in the case of flexible coils. To a first approximation these side chains act like a solvent bound to the main chain; by variation of the length and number of side chains per repeat unit the amount of "bound solvent" may be changed continuously.[37] The concept has already been realized in the case of helical polypeptides like poly(γ-benzylglutamate) and related polypeptides, where the phenyl group of the glutamic acid bears long *n*-alkyl substitutes.[13] In spite of the high degree of stiffness of the main chain these comb-like polymers are sufficiently soluble in organic solvents.

The first comb-like polymer of this kind based on stiff-chain polyesters was introduced by *Lenz* et al. in 1983.[34,69] It is the polyester **10** (Scheme 2) of terephthalic acid and 2-*n*-alkylhydroquinone. In accord with the above considerations the melting point decreases continuously with increasing length of the side chains. This enables the observation of liquid-crystalline phases over a conveniently accessible temperature range. In the meantime a series of these comb-like polymers[34,36,38,64,69-80] (see Scheme 2, systems **10**–**18**) have been studied, and in all cases a strong increase in solubility and a marked decrease in melting point have been reported. This enables polycondensation not only in the melt but also in solution. Furthermore, the materials obtained can be purified by precipitation from solution. In some cases the solubility is high enough to allow a characterization by the standard methods usually employed for flexible macromolecules.

Scheme 2. Stiff macromolecules with flexible side chains. R = $(CH_2)_nH$.

The most important results obtained with these systems will be discussed in the following using polyester **11** as example.[38,70,71] As is obvious from the wide angle X-ray patterns[71] measured at room temperature (see Fig. 9), polyesters **11** exhibit a high degree of crystallinity. Further-

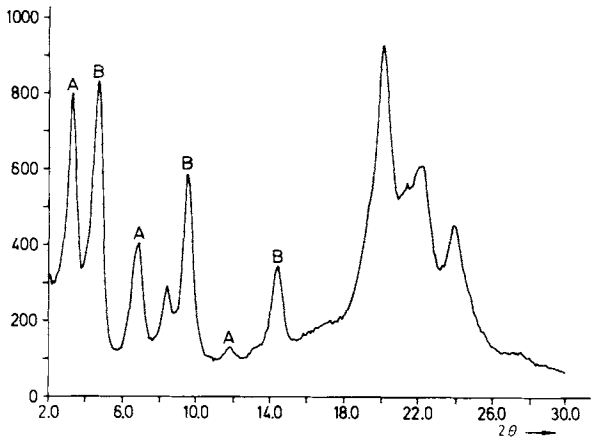

Fig. 9. X-ray diffractogram of the polyester **11**, R = $(CH_2)_{16}H$, at room temperature [71]. The reflections termed A and B originate from the layered structures A and B. Ordinate: Intensity.

more, the strong Bragg reflections marked A and B in the diffractogram in the region of small angles indicate, together with their higher orders, the formation of two layered modifications referred to in the following as A and B. A plot of the layer spacings for the modifications A and B versus the number of carbon atoms in the side chains (Fig. 10) demonstrates that the length of alkyl groups is decisive for the build-up of the structure.[71] For both modifications the intercept is, within the limits of error, the same. Its value approximately matches the diameter of the main chains; only the slope of the curve is different. In most of the systems presented in Scheme 2 three phase transitions of first order are observed:[38] at low temperatures there is an increase of disorder of the packing of the side chains which may be compared to the transition from the crystalline to the solute phase in the *n*-alkanes. Raising the temperature further leads to the mesophase and finally to the vanishing of liquid crystalline order and the formation of an isotropic melt. In the case of the polyester **11** one observes nematic mesophases for short side chains ($2 \leq n \leq 6$). If the side chains are long enough ($n \geq 8$), the modification A already present in the solid state (cf. Fig. 9)

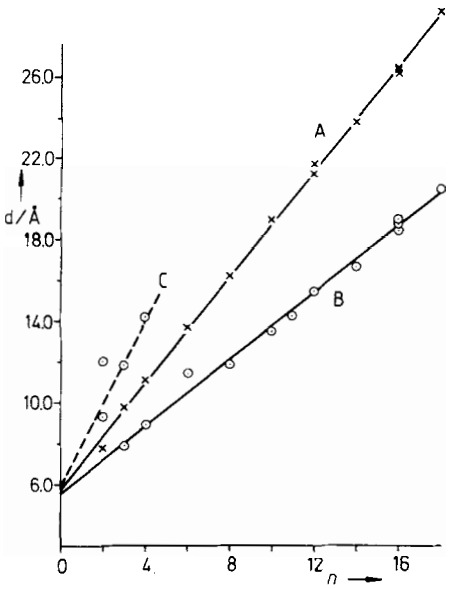

Fig. 10. Plot of the Bragg distances d calculated from the reflections A and B (see Fig. 9) versus n, the number of carbon atoms in the side chains of the polyester **11**. The modifications A and B differ with regard to the increment per CH_2 group. As expected the extrapolation to $n=0$ leads for both modifications to a value approximately corresponding to the diameter of the main chain. A third modification C is detectable only for short side chains [71].

remains stable also in the liquid crystalline phase. This is obvious from the strong Bragg reflections and their higher orders[38,70,71] (cf. Fig. 11).

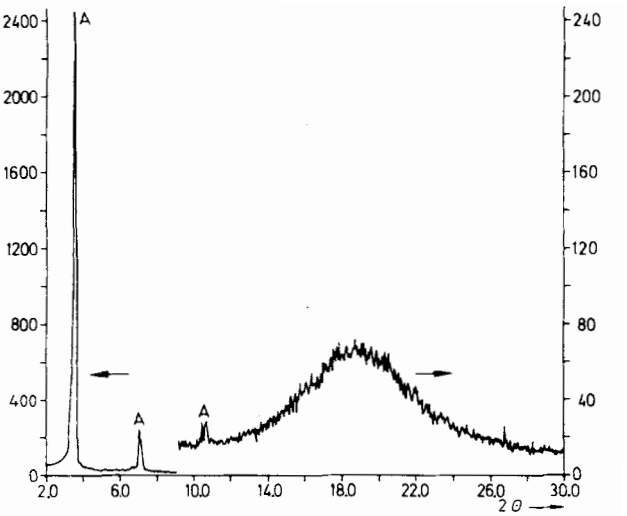

Fig. 11. X-ray diffractograms of the mesophase ($T=120$°C) of the polyester **11**, R = $(CH_2)_{16}H$ [71]. The strong Bragg reflection together with its higher orders is clearly visible. The halo in the wide angle region indicates liquid-like short-range order. Ordinate: Intensity.

This mesophase, first observed in the polyester **11**[38] also occurs in the polyamides **12**,[70,72] **13**[70,72] and **14**.[72] However, in contrast to the polyesters, in the case of these polyamides there is a strong correlation of the main chains through hydrogen bonding between amide bonds.[70,72,73]

Similarly to the systems discussed previously, the polyesters **10** form mesophases with a layered structure if the length of the chains is more than 12 C atoms; for shorter side chains, nematic mesophases are observed.[69] The polyimides **17**[75,76] can also be converted into layered mesophases whose Bragg distance lies near to that of the B modification of the polyester at high temperature.[76] Finally, the polyesters **16** of the 3-*n*-alkyl-4-hydroxybenzoic acid also form such layered structures in the mesophase if the side chains are long enough.[79] Hence, the formation of this mesophase is a general phenomenon that has not yet been observed in low molecular weight liquid crystals. The structural data available so far for the polyesters and amides **11**–**13** suggest an intercalated arrangement of the side chains,[70,71] since the layer spacings are much smaller than the overall breadth of the molecule:

Only when both phenyl rings of the repeat unit are substituted with side chains, as in the polyamides **14**, do the layer spacing and the breadth of the molecules (assuming a fully stretched conformation of the side chains) approximately coincide.[72] The model depicted in Figure 12 is nat-

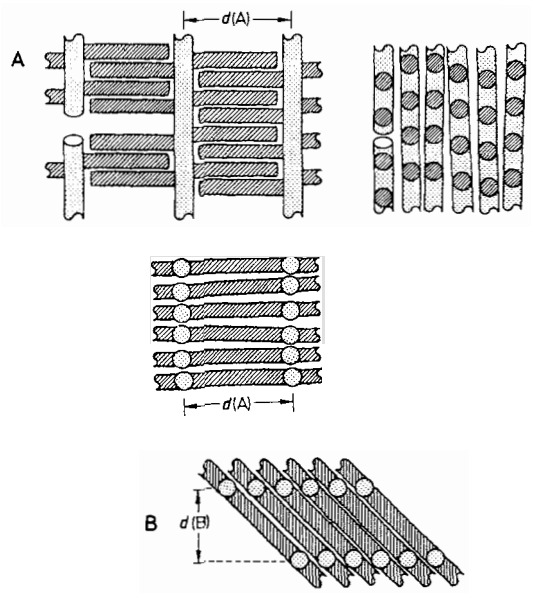

Fig. 12. Model [71] of the molecular structure of modifications A and B of the polyester **11**: The dependence of the layer spacing on the length of the side chains (see Fig. 10) leads to the proposition of an intercalated arrangement of the side chains. The absence of additional reflections in the diffractogram (Fig. 11) shows that there is no strict correlation of distances between main and side chains. The model is an idealized picture of the molecular arrangement of the side chains, the packing of which will exhibit an increasing number of defects with rising temperature [71].

urally idealized, for the packing of the side chains will exhibit an increasing number of defects with rising temperature. X-ray measurements conducted on polyimides **17** have shown that there are well-defined intermediate phases in this process. In these phases a part of the order of the side chains is preserved.[76] This becomes evident upon examining the X-ray diffractograms of the polyimide **17** at different temperatures[76] (Fig. 13).

The highly crystalline low-temperature modification is first transformed into an intermediate-temperature phase. The presence of only a few remnant reflections in the wide-angle region points to a high number of defects in the packing of the side chains. A further rise in temperature is finally followed by the formation of a mesophase in which

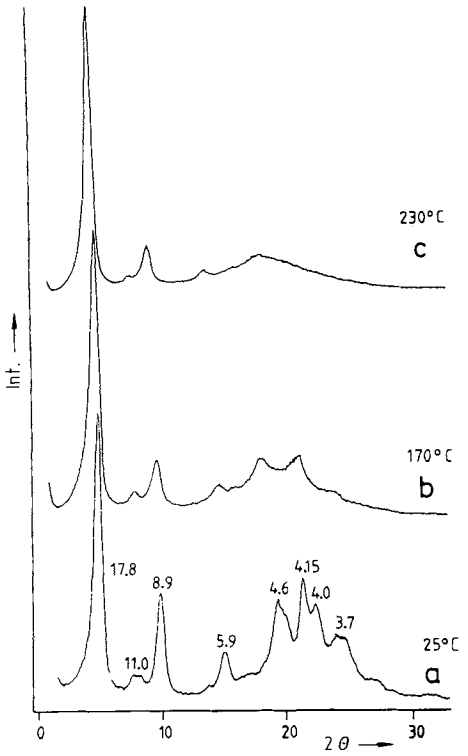

Fig. 13. X-ray diffractogram of polyimide **17**, R = $(CH_2)_{14}H$, as a function of the temperature [76]. a) Low-temperature modification; b) medium temperature modification with disarranged packing of the side chains; c) high-temperature modification (mesophase).

the long range order of the alkyl chains is no longer present. These conclusions are supported by results from ^2H NMR spectroscopic measurements on the polyimide **17**.[82]

The above mentioned organization of the rigid macromolecules with flexible side chains in the solid state and in the mesophase (liquid crystalline state phase) has important consequences for the dynamics of such systems. Thus, it could be shown by ^2H NMR experiments that the layered mesophase of the polyester **11** only partially aligns in magnet fields even if the field strength is very high (7 Tesla).[81,82] The result is corroborated by measurements of the diamagnetic susceptibility of such systems using a SQUID magnetometer.[83] This method utilizes the high sensitivity of a superconductivity coil with a semiconducting contact towards minute changes of the magnetic field in order to determine the magnetic susceptibility. If the tensor of the diamagnetic susceptibility of the polymer molecule is known, these measurements allow the determination of the degree of order and alignment present in the system.[84] Mesophases with layered structures of the polyester **11** orient only slowly whereas nematic phases (see above) of **11** bearing shorter side chains can be oriented to a high degree.[83]

These first experiments on orientation in a magnetic field reveal an important difference regarding the dynamics of nematic and smectic phases, which are also detected in low molecular weight liquid crystals: mesophases with layered structures have higher viscosities than the corresponding isotropic phases, whereas nematic liquid crystals generally exhibit a lower resistance to flow than the isotropic phase.[85] This can be demonstrated for polyester **11** by determination of the viscosity in the isotropic nematic and the layered mesophase.[86] The viscosity determined in the same system is thus unequivocally related to the microscopic organization of the macromolecules.

From the results discussed in this section concerning the structure of stiff macromolecules with flexible side chains it becomes obvious that the initial concept of the side chains being a "bound solvent" is indeed correct. For all the systems present in Scheme 2 there is a drastic decrease of the melting point and a marked increase of the solubility. For side chains of adequate lengths a new phenomenon, the formation of layered structures (see Fig. 12) occurs. By this peculiar arrangement an efficient packing of the molecules is achieved through separation of main and side chains.

5. Experimental Determination of Chain Stiffness

The determination of the shape, i.e. of the conformation of a macromolecule in the melt and in solution is one of the classical problems of polymer physics. Therefore, in the last 50 years a number of methods for determining the form of polymers have been developed. However, all these methods—except neutron scattering—require dissolution of the macromolecules. Due to their good solubility, flexible polymers could be studied by these methods with high precision. Hence, the shapes and conformations of flexible polymers are well known, whereas very little can be stated yet about the conformations of stiff macromolecules. This is due to the difficulties encountered in bringing stiff-chain polymers into solution. Before discussing these problems in more detail, an important chemical obstacle must first be mentioned.

The first requirement for chain stiffness is the correct structure of the chain, especially when the polymer has a ladder-like structure. A single open imide ring in the polyimide **17** would disrupt the rodlike character at this position and hence reduce chain stiffness considerably. Therefore polycondensation has to be conducted in such a manner that the formation of imide rings proceeds to practically 100% conversion, and open-structured intermediates like the polyamide acids in the preparation of the polyimides should be circumvented, if possible, in the case of polyimide **17** this can be achieved by reaction of pyromellitic anhydride with imidazole-blocked, substituted *p*-phenylene diisocyanates.[75,76] The synthesis of stiff-chain polymers with ladder-like structures thus requires a high standard regarding the completeness of reaction. In any case the degree of conversion should be checked by model reactions.

Once the problem of structure faults along the chains is solved, chain stiffness and conformation may be described in terms of three of the models presented schematically in Figure 14:

1) by *Flory*'s rotational isomeric state model (RIS),[87,88] in which the chain conformation and shape are described using molecular parameters (conformational energies, torsional angles) (cf. Fig. 2);

2) by the Kuhn model,[87,89] which idealizes the chain by a sequence of rods of length l_K (Kuhn length) held together by entirely flexible joints;
3) by the worm-like chain model of *Kratky* and *Porod*.[90] Here the chain is represented by a continuously bent stick or worm. Chain stiffness is characterized by the persistence length a; for very long chains[90] $2a = l_K$.

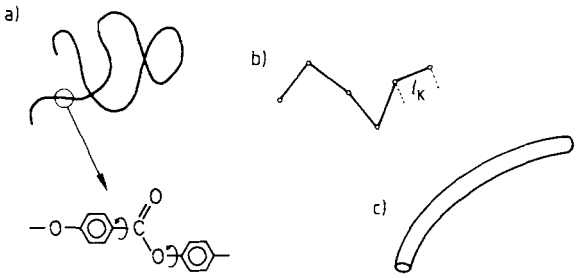

Fig. 14. Models for describing chain stiffness in polymers: a) RIS model (*Flory* [87, 88]); b) The Kuhn model [88, 89], l_K = Kuhn length; c) the —Kratky-Porod worm-like chain model [90] (see text).

The experimental determination of parameters necessary for the description in terms of the RIS model requires in most cases involved measurements of the depolarized light scattering of the electric and magnetic birefringence and the dipole moment of carefully chosen oligomers (cf. Refs. [15–17, 87, 88]). Very often these data are not available. Therefore in this context we only discuss methods for determining the Kuhn length or the persistence length of dissolved macromolecules. For this purpose the following methods are suitable:

1) Scattering methods[11,12,87,91–98] (light, X-ray, and neutron scattering)
2) Depolarized light scattering[87,98–101]
3) Electric and magnetic birefringence[87,101]
4) Flow induced birefringence[102]

Of these methods the scattering methods certainly give the most information with a minimum model assumptions. Therefore, a brief description of these methods and their data evaluation for assessment of chain stiffness will be given here. First the intensity of the light, X-ray, or neutron beam scattered by a solution of macromolecules is determined as a function of polymer concentration c_2 and the scattering angle θ. This experimental scattering intensity $I_{exp}(c_2, s)$ [$s = (4\pi/(\lambda)\sin(\theta/2)$] is then extrapolated to vanishing concentration.[93] Then the data are plotted in the following way:

$$\lim_{c_2 \to 0} \frac{Kc_2}{I_{exp}(s, c_2)} = \frac{1}{M_w I_n(s)} = \frac{1}{M_w}\left(1 + \frac{\langle R_g^2 \rangle}{3} s^2 + \cdots\right)$$

$$s\langle R_g^2 \rangle^{0.5} \ll 1$$

where M_w is the weight-average molecular weight, $\langle R_g^2 \rangle$ is the Z-average of the radius of gyration,[93] K is a constant depending on the radiation used and the system, and $I_n(s)$ is the structure or form factor of the single molecule.[103] The function $I_n(s)$ is normalized to 1 for $\theta = 0 : (I_n(0) = 1)$. The radius of gyration $\langle R_g^2 \rangle$ obtained from the slope of the above plot[93] in the region of small angles gives a measure of the spatial dimensions of the molecule. From the latter quantity the Kuhn length l_K may be calculated if the molecular weight distribution is known (see Ref. [11]).

If the polydispersity is not known with sufficient accuracy the determination of l_k becomes uncertain since the molecular weight distribution strongly influences this quantity.[91] As has been demonstrated by *Schmidt*[14] this problem may be overcome in an elegant way by combined measurements of the static and the dynamic light scattering, where the latter method yields additionally the hydrodynamic radius of the chain. Since this quantity only depends on the weight average of the degree of polymerization the polydispersity as well as the stiffness of the dissolved chains may be inferred in an unambiguous way.[14]

Further information is accessible from the form factor $I_n(s)$, the determination of which very often requires measurements of the X-ray and neutron scattering, since the range of s accessible in light scattering is too small in most cases. Figure 15 shows a reduced Kratky plot $I_n(s \cdot a)(s \cdot a)^2$ versus $s \cdot a$ for wormlike chains of differing stiffness.[11] For a better comparison the reduced variable $s \cdot a$ has been used instead of s. The parameter n indicated on the curve is the ratio of the length of the chain L to the persistence length a. Small length values of $n = L/a$ thus indicate high stiffness, whereas higher values of n characterize flexible macromolecules.

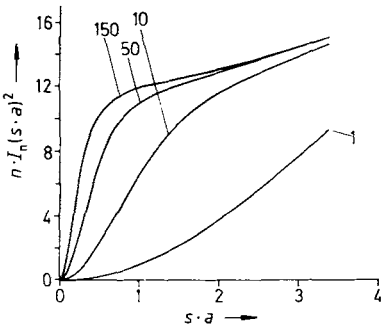

Fig. 15. Form factors of Kratky-Porod worm-like chains in a reduced plot (after [11]) a: persistence length, l: contour length of the macromolecule, $n = l/a$: number of persistence lengths per molecule is thus a measure of chain stiffness, i.e. $n \approx l$: great stiffness, $n \geq 100$: flexible coil (see detailed discussion in [11]).

In the case of flexible chains ($n = 200$) first a strong increase of $I_n(s)$ is observed, followed by a plateau-like region, and finally a practically linear region. Stiff chains, however, show only a weak upward curvature. A comparison of Figure 15 with experimentally obtained form factors may thus lead to an estimate of the chain stiffness. A problem in this comparison of experimental results with the above calculations is the finite diameter of the polymer chains leading to additional interferences not being taken into account in the above worm-like chain model of *Kratky* and *Porod*.[11] This effect is seen from a downward curvature of $I_n(s)s^2$ at higher values of s. The importance of this problem for a correct interpretation of $I_n(s)$ has been demonstrated recently by *Rawiso, Duplessix*, and *Picot*[104] using polystyrene as an example.

Whereas numerous measurements of the chain stiffness of polypeptides[24] and other biopolymers[12,92] have now been reported, only a few data are available on the synthetic systems discussed in Section 4. Thus, a compilation of persistence lengths obtained from typical polyamides in sulfuric acid[101] by methods 1)-4) (see above) contains results differing by one order of magnitude. This can be traced back mainly to the strong tendency for association of stiff chain macromolecules and the uncertainty regarding the molecular weight distribution. Consequently, there has been no quantitative study yet to assess the influence of fluctuations of the angle χ (cf. Fig. 2) on the RIS calculations of *Flory* et al.[15-17] *Birshtein*[105] has demonstrated theoretically that this effect may considerably reduce the persistence length. An experimental verification obtained from polydiacetylene in solution has been reported recently by *Allegra, Brückner, Schmidt* and *Wegner*.[106] First measurements on the soluble polyphthalocyaninatosiloxanes **18** unequivocally demonstrate the rodlike character of this polymer in agreement with the considerations given in Section 2.[107]

All the methods discussed above only allow the determination of chain stiffness and conformation of the single molecules in solution. The form factor of macromolecules in the melt or solid state can only be determined by neutron scattering on a mixture of protonated and deuterated molecules. Numerous such studies have been carried out on flexible macromolecules,[108] whereas to the best of the authors knowledge neutron scattering has not yet been applied to the systems discussed in Sections 4.1 and 4.2. The strong stiffening of chains through interactions with neighboring chains in the condensed phase has so far been demonstrated only by *Blackwell* et al.[49] on copolyamide **9** (Scheme 1, cf. Section 4.1).

6. On the Theory of Nematic Phases

As shown in Sections 4.1 and 4.2, stiff-chain macromolecules may form nematic as well as mesophases with a layered structure. In the course of this discussion it became evident that the arrangement of the chains is mainly determined by an efficient packing in space. In this section these considerations shall be discussed in more detail when dealing with the theory of nematic phases.

There are presently two fundamentally different approaches to the statistical mechanical description of nematic phases: 1) the Maier-Saupe theory[109] and its further development by *Luckhurst* et al.,[10] in which only the anisotropic attractive interactions between the rods are taken into account; 2) theories which are based on the repulsive interaction (excluded volume) and only introduce the attractive part of the potential afterwards.[111] Since it is well established today[112] that the structure of liquids is determined by repulsive interactions—i.e. by the form of the molecule—only theories which explicitly take this fact into account should come under discussion.

The statistical mechanics of ordered systems has been developed by the pioneering work of *Onsager*[113] and *Flory*.[114,115] Both authors were able to show by different methods that solutions of long rodlike molecules will spontaneously form nematic phases above a certain concentration. The fundamental concept of *Onsager* is depicted in Figure 16.[116] Consider a system of hard rods of length l and a square base with the length of the edges given by d. If the rods are aligned parallel to each other their volume is given by ld^2; this value coincides with the excluded volume of one molecule at dense packing. In dilute solution the excluded volume is of the order of l^2d. The volume fraction in solution at which the excluded volume of two rods is no longer negligible thus results in the ratio of d^2l to $l^2d = d/l$. Therefore it follows that the minimum volume fraction necessary for the formation of an ordered phase is proportional to the reciprocal axial ratio $x = l/d$ of the rods.

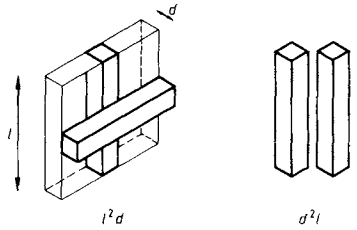

Fig. 16. Onsager theory of the isotropic to nematic phase transition: excluded volume of two rods in dilute solution (left) and in bulk (right).

This result can be quantitatively derived by the Onsager theory.[113] An important point of this statistical-mechanical treatment of a gas of long rods is the assumption that particles with different orientation may be treated as different thermodynamic components. Using this theory it was shown for the first time that systems without attractive interaction can only form ordered phases by steric repulsion. A major problem of Onsager's theory however, is the restriction of the calculation to purely binary interactions. Hence, the range of validity of this theory is confined to highly dilute solutions.[117] In addition to this shortcoming, the excluded volume per particle is overestimated in the frame of the Onsager theory. Hence the quantitative validity of the results derived therefrom has been doubted.[118]

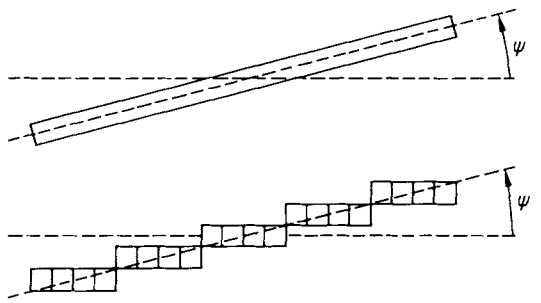

Fig. 17. Rendition of a rod in the lattice model of *Flory* [114, 115].

In contrast to Onsager's theory, the lattice model of *Flory* enables calculation over the entire range of concentration. The rod which forms an angle ψ with the preferred axis is represented in a cubic lattice by splitting up into submolecules[108] (see Fig. 17). By this artifice the partition

function can be calculated by the standard methods of lattice statistics. *Khokhlov* and *Semenov*[119] recently showed that the Flory theory reduces to the result of the so-called "decoupling approximation" by *Parsons*[120] at higher orientation; at vanishing concentration, the partition function of the Onsager theory is obtained.

The statistical-mechanical treatment of systems by rods over the entire range of concentration furthermore allows the calculation in the case of thermotropic nematic liquid crystals.[121-123] Thus, ordering transitions in condensed phases, in which attractive forces must also be taken into account may be dealt with in the framework of this model. Central to this extension of theory is the fact first put forward by *Flory* and *Ronca*[121] that only anisotropic dispersion forces matter. This can be explained in the following way: in dilute solution parallel alignment of two rods leads to more mutual contacts than a perpendicular arrangement; thus, ordering is favored if only binary interaction is considered. However, in condensed matter parallel alignment of molecules is not followed by an increase of interaction because cleavage of contacts between the two probe rods may be counteracted by formation of contacts with other rods. Hence, only anisotropic dispersion forces (Maier-Saupe interaction[109]) can directly promote ordering.

The above ideas are supported by a semiquantitative calculation of the so-called characteristic temperature of these anisotropic dispersion forces from optical and thermodynamic data.[124] Hence the nematic to isotropic transition temperatures of the homologous series of rod-shaped molecules[125, 126] can be described by a virtually constant characteristic temperature T^* which can be related directly to molecular parameters.[122, 123]

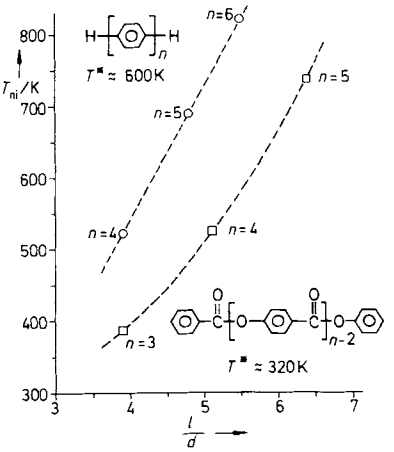

Fig. 18. Nematic-isotropic transition temperatures T_{ni} of two homologous series of rodlike molecules as a function of axial ratio l/d [122, 123]. The characteristic temperature T^* is a measure of the strength of the anisotropic dispersion forces [124].

Furthermore, the data in Figure 18 demonstrate the marked increase of the nematic-isotropic phase transition temperatures with increasing axial ratio, thus indicating directly and unambiguously the importance of the steric interactions between the rod-like molecule for the stability of the ordered phase.

A further advantage of the Flory theory lies in its applicability to a number of polymeric systems. This will be demonstrated in the following with flexible side chains already introduced in Section 4.2, while the second deals with mixtures of flexible and stiff macromolecules.

Stiff macromolecules with flexible side chains can be treated in the framework of the lattice model of *Flory* by introducing the main chain according to the Scheme shown in Figure 17 and appending the side chains in the sense of the Flory-Huggins statistics[127] for flexible chains. The details of this calculation have been described elsewhere[37] and will not be discussed here. The most important result of this theory is the finding that flexible side chains do indeed act to a good approximation like a "bound solvent" and shift the transition from the isotropic to the anisotropic solution to higher polymer concentrations.

An extension of this theory to thermotropic systems through introduction of anisotropic dispersion forces and free volume as indicated above[128] allows a direct comparison with the results obtained on stiff macromolecules with flexible side chains which form nematic phases (see Section 4.2). The experimental results on these systems again lead to the conclusion that flexible side chains are comparable to a solvent affixed to the rods. The above theory corroborates this concept also for the thermotropic systems under consideration here. The side chains weaken the steric as well as the attractive interaction between the main chains. These effects cause a continuous decrease of the transition temperature between nematic and isotropic phase, as observed experimentally on low molecular weight model systems[129] as well as on the polymers discussed in Section 4.2. Mesophases with layered structure observed in these systems with long side chains cannot be dealt with by this theory since the separation of main and side chains in the layers is not included in the model.

A further example for the broad applicability of the Flory model is given by the treatment of blends of stiff and flexible polymers, which is discussed in the following.

Mixtures of flexible polymers have been in use technologically for some time, and have been the subject of many scientific investigations in recent years.[130] The phase behavior and the compatibility of these systems can be described to a good approximation in terms of the Flory-Huggins theory,[127, 130, 131] which gives the following expression for the free energy of the mixture:

$$\Delta F_n/RT = \frac{\phi_1}{x_1}\ln\phi_1 + \frac{\phi_2}{x_2}\ln\phi_2 + \phi_1\phi_2\chi$$

The quantities ϕ_1 and ϕ_2 denote the volume fractions of the polymeric components and x_1 and x_2 their number of segments. The interaction parameter χ is a function of temperature and concentration in general.[131] However, this equation only holds true for isotropic systems. If there is liquid crystalline order in one phase the Flory-Huggins theory is no longer applicable. As has been demonstrated by *Flory*[132] demixing already occurs in purely athermal systems, i.e., when $\chi = 0$. Hence, the reason for this phase separation is of solely entropic nature. The ordered nematic phase formed during demixing excludes the flexible com-

ponent with high selectivity. This prediction could be fully verified for a number of ternary systems consisting of a flexible and a stiff polymer dissolved in a common solvent.[133]

An extension of the Flory model to include thermotropic mixtures of stiff and coiled macromolecules shows[134] that in this case incompatibility also results. This effect is more pronounced with increasing molecular weight of both compounds. Figure 19 illustrates this effect using as example the mixture of short-chain polystyrene and low molecular weight *p*-butyl-*N*-(*p*-ethoxybenzylidene)aniline, which typically forms thermotropic liquid crystals.[135]

In the isotropic phase both components are fully miscible. Cooling leads to an isotropic phase containing most of the polymer whereas the coexisting nematic phase has only a very small content thereof. The calculated phase diagram in Figure 19 (bold lines) shows that theory is in qualitative agreement with the experimental results of *Kronberg* et al.[134] All results given herein lead to the conclusion that mixtures of stiff and flexible polymers are incompatible upon formation of an ordered phase. For an isotropic mixture, however, the expression by *Flory* and *Huggins* is still valid, demixing is caused by an unfavorable enthalpic interaction. The realization of such a compatible mixture of a stiff chain and a flexible polymer (molecular composite) is of great technical interest since the favorable mechanical properties of composites could be obtained without having to tolerate internal surfaces as are formed by incorporation of glass and carbon fibers in conventional composite materials. Theoretical considerations[136] suggest that this goal may be achieved using the stiff macromolecules with flexible side chains introduced in Section 4.2.[136]

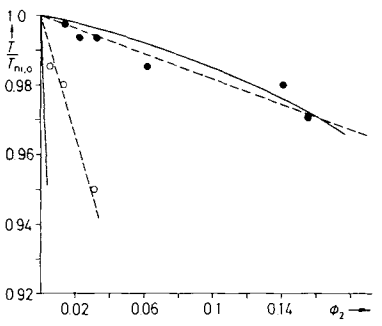

Fig. 19. Phase diagram of a mixture of oligomeric polystyrene (weight average molecular weight 4000) and the low molecular weight *p*-butyl-*N*-(*p*-ethoxybenzylidene)aniline, which forms nematic liquid crystals. Circles: experimental data of *Patterson* et al. [135] (open: nematic phase, filled: isotropic phase); bold curve: theoretical phase diagram [134].

7. Properties

The foregoing sections have shown that chain stiffness in macromolecular systems can cause the formation of highly ordered structures in solution, in the melt and in the solid state. The concepts introduced in Section 4 facilitate access to systems which are sufficiently soluble and melt undecomposed. In this section a brief overview of the technical application of such systems will be given.

As already mentioned in the introduction, the discovery of liquid crystalline order in solutions of poly-*p*-phenyleneterephthalamide **1** and the possibility of spinning this material from such solutions to high modulus fibers was the starting point for the intensive technical fabrication of stiff-chain macromolecules.[4,5,41,137,138] These fibers have a specific modulus higher than steel and exhibit a high thermal stability and a small thermal expansion coefficient.[138] The excellent mechanical properties are mainly traced back to the high orientation along the fiber axis. A short heat treatment at temperatures around 300 °C can even improve these mechanical properties. Since thermal polycondensation is rather slow in these systems the observed improvement must be mainly due to an increase of orientation and crystallinity. Fibers spun from poly-(*p*-phenylbenzodithiazole) **5** dissolved in polyphosphoric acid and subjected to a subsequent heat treatment[138] have an even higher modulus. All systems discussed up to this point require the use of strong mineral acids as solvent. In contrast, the copolyamide **9** (Scheme 1) can be spun from *N*-methylpyrrolidone (cf. Section 4.1,[47,48]) and obviates the use of mineral acids.

The aromatic polyesters introduced in Section 4 may be processed from the thermotropic mesophase if the content of disrupting units along the chains (Section 4.1) or the number of flexible side chains (Section 4.2) is high enough. Thus, aggressive or expensive solvents are no longer required making these materials interesting candidates for a wide spectrum of technical applications. Here also a heat treatment leads to considerable improvement in the mechanical properties.[139] In contrast to the polyamides, polycondensation in the solid-state plays an important role in this process.[138] Important copolyesters already produced in large-scale quantities are "Vectra" (Hoechst-Celanese) (cf. **7**) and "Xydar" (Dartco), which is the copolyester of terephthalic acid, *p*-hydroxybenzoic acid and 4,4'-biphenyldiol (cf. Section 4.1 and Ref. [138]). High-strength fibers can be spun from these materials. In addition to this the lower viscosity of the nematic phase[85] facilitates processing from the melt. The main areas of application of these stiff-chain polyamides and polyesters are as fibers for the fabrication of offshore cables, bullet resistant vests, rubber reinforcement tires, i.e., in all areas where high strength and light weight are required. Thermotropic polyesters have the advantage of being processable at temperatures below thermal decomposition. In addition to this they exhibit high flame resistance, small thermal expansion coefficients and small shrinkage upon cooling to room temperature, thus enabling the molding of intricate parts such as are needed for instance in microelectronics. Special properties such as the high transparency for microwaves and the high heat-deflection temperature make "Xydar" suitable for microwave ovenware. The insolubility in common organic solvents and the higher temperatures at which these materials can still be used allow their use in chemical equipment. This list, which is far from complete, already gives an idea of the numerous applications of these new materials. One problem, however, is the poor compressive strength. The mechanical properties measured perpendicular to the preferred direction are considerably poorer than those determined along the chain direction.

Fillers can improve these properties to a certain extent.[138] It seems, however, that a more fruitful way to solve this problem is a better control of structure and morphology in the solid state (see Section 4).

In conclusion, stiff-chain polymers are a very interesting class of new materials, both from the scientific point of view as well as from the point of view of possible applications. The potential of these promising polymers is still far from being exhausted and there will be more important developments in this field in the near future.

The author is indebted to Prof. Dr. G. Wegner and Dr. G. Lieser for stimulating discussions and critical revision of the manuscript. Financial support of the Bundesminister für Forschung und Technologie, Project "Steife Makromoleküle" is gratefully acknowledged.

Theoretical Chemistry en route to a Theory of Chemistry

By Anton Amann* and Werner Gans*

Quantum mechanical and classical aspects are of equal importance in chemistry, and theoretical chemistry must be able to deal with this situation. Classical quantities with which a chemist has to deal include, for example, the temperature and the chemical potential of a substance, and chirality, knot-type and tertiary structures of molecules. Classical concepts of this type are no more consequences of traditional quantum chemistry than is the theory of complex chemical processes (for example adsorption, heterogeneous catalysis) and macroscopic systems. Algebraic quantum mechanics affords a general framework for the discussion of classical quantities and large systems. There are other independent approaches for the theoretical treatment of chemical problems; these can be summarized by using the keywords "fractals", "chaotic motion", "quasicrystals" and "knot theory". The relationships between these four research topics and their connection with algebraic quantum mechanics, as well as their importance for theoretical chemistry, were discussed at a NATO Workshop in 1987 (see Ref. [1]). In an extended theoretical chemistry, the notion of "molecules" will not play a role as central as it does in quantum chemistry. In the theory of large systems in particular, the introduction of complementary approaches appears to be appropriate; the term "molecule" as used by the chemist does not appear either in the description of disordered systems by means of fractals or in the thermodynamic limit of algebraic statistical mechanics.

1. Introduction

The last great advance in theoretical chemistry was due to the introduction of quantum mechanics; quantum chemistry, with the help of which it is now possible to carry out extremely accurate calculations of molecular properties, developed parallel to the development of computer technology. However, many other equally important aspects of chemistry have been forgotten by theoretical chemists; these include the term "substance", classes of compounds, and states of aggregation as well as attempts to understand chirality or macroscopic properties of large systems from a theoretical point of view. The contact with traditional theoretical areas of chemistry, such as thermodynamics and chemical kinetics, is very small; due to the great variety of chemical reactions the quantum-chemical treatment of kinetic problems is still in its infancy. In the course of time, quantum chemistry has seen the development of a large number of models (MO, VB, Hückel, "coupled electron pair approximation" (CEPA), and many others) which, although they all have a quantum-mechanical basis, are always adapted to a specific situation and often contain approximations which are dictated more by computational possibilities than by physical or chemical intuition. Important aspects of quantum mechanics are thus lost, and models are much less than a theory (and at best a good caricature) of a physical or chemical system. Models (e.g., the Ising model, the Debye-Hückel model for solvation shells of ions, electronegativity models) are useful or stimulating for the scientist's everyday work, but they are by definition never correct or incorrect.

A theory, however, makes a serious claim to represent the truth, and is characterized by three aspects:

- a mathematical formalism (guarantees the absence of contradictions)
- a clearly defined area within which it is valid ("universe of discourse", i.e., much more than a specific situation)
- an interpretation

In the case of quantum mechanics, these are the Hilbert space formalism, the restriction to the forms in which molecular matter is organized, and an interpretation which allows the chemist to deal in the same fashion with large and small systems.

Since quantum mechanics as a theory is highly developed, it has a considerable regulating influence; this refers generally to the formal requirements which a theory must fulfill. Above all however, other—as a rule classical—theories and observables should be compatible with quantum mechanics in a particular and well-specified sense. The development of theories takes place on many levels, so that in Section 3, four modern research areas which are of importance for theoretical chemistry will be presented. In Sections 2 and 4 we shall list reasons why numerical quantum chemistry, which with its molecular view of the world of chemistry is so successful in many ways, cannot deal with all those phenomena which require a theoretical explanation. The choice of topics dealt with in Section 3 is certainly not exhaustive, but it should indicate the direc-

tion in which theoretical chemistry must progress if it is to create order and establish correlations in the rich area of chemical phenomenology.

2. Classical Quantities in Chemistry

Chemistry contains an enormous amount of empirical knowledge, which was originally collected and interpreted without the theoretical background of quantum mechanics. Most of the terms used by chemists are either related to terms from classical physical theories or are taken directly from these. Some examples are temperature, chemical potential, chirality, knot types in polymers (e.g., a DNA molecule) and nuclear frames of molecules.

Quantum mechanics in its original codification by *von Neumann* (Hilbert space quantum mechanics)[2] has only little in common with the terms mentioned above. It is not able to describe the quantities of classical physics (see the appendix to this section). However, in his later publications, dealing with the theory of operator algebras, *von Neumann* himself laid the foundations for the extension of the formalism of quantum mechanics.

Classical quantities or observables are characterized by the fact that they have dispersion-free expectation values in *each* state of the system under consideration. As is well-known, this is not true for the quantum mechanical observables (operators) position $\boldsymbol{Q}$ and momentum $\boldsymbol{P}$, whose properties are determined by Heisenberg's uncertainty principle: $[\boldsymbol{Q},\boldsymbol{P}] = \boldsymbol{QP} - \boldsymbol{PQ} = \mathrm{i}\hbar\boldsymbol{I}$, i.e., $\boldsymbol{Q}$ and $\boldsymbol{P}$ do not commute. Classical observables, however, commute not only with one another but also with all other observables which are present in the system. If the set of observables is extended on mathematical grounds to form an algebra, one says that the classical observables lie in the center of this algebra (for details see appendix). If an algebra of observables consists only of the center, the result is a completely classical theory; classical point mechanics, for example, can be thus described (the Koopman formalism[3]). Classical theories and quantum mechanics are of comparable importance in chemistry; the non-existence of classical quantities would in any case be contrary to the chemist's experience.

In general, chemical systems can be characterized by the observables (what do we see?) and their dynamics (what happens as time progresses?). We shall use the example of the chirality of molecules to show how it is possible by including systems with (infinitely) many degrees of freedom (and by a corresponding generalization of quantum mechanics: see appendix) to obtain classical observables, and also to show the consequences for the possible states of the system.

Chiral molecules, e.g., the amino acid alanine, are always dextro- or laevorotatory (D,L; *R*,*S*; +/− according to the preferred terminology). If $\boldsymbol{\Psi}_\mathrm{D}$ and $\boldsymbol{\Psi}_\mathrm{L}$ denote the corresponding ground state vectors, the rules of Hilbert space quantum mechanics also allow the existence of their superposition $\boldsymbol{\Psi}_0 \stackrel{\mathrm{def}}{=} 1/\sqrt{2}\,(\boldsymbol{\Psi}_\mathrm{D} + \boldsymbol{\Psi}_\mathrm{L})$. The totally symmetric (pure) ground state described by $\boldsymbol{\Psi}_0$ has, however, not been detected experimentally. It may exist, but if so it is short-lived and unstable. An experimental method for its detection has been suggested by *Quack*.[4] It must be remembered that $\boldsymbol{\Psi}_0$ has nothing to do with the clearly existent racemate, which is described by a density operator. A suggested solution to the problem presented here is as follows: the fiction of an isolated molecule should be discarded. Each molecule is in fact coupled to the radiation field, and the inclusion of the radiation field (a system consisting of an infinite number of bosons) leads to a qualitatively completely new discussion of the molecular system. An important keyword is the "infrared singularity". The conceptually clearly posed problems of this approach have not yet been solved in all mathematical details. The following (simplified) picture[5,6] results: if the energy difference of the two lowest eigenvalues of the molecular Hamiltonian operator is small enough (the corresponding eigenstates are then almost degenerate), two ground states exist for the complete system (molecule plus radiation field). These are interconvertible via space inversion and are thus chiral. The corresponding chiral state vectors lie in different sectors (see appendix) and thus may not be superposed. The condition of the near-degeneracy of the molecular eigenstates is important; it is fulfilled for alanine, but not, for example, for the potentially chiral ammonia isotopomer NHDT. The transition from alanine to NHDT thus represents a kind of qualitative jump. Alanine is characterized by a classical chirality observable, which commutes with all other observables and has the dispersion-free values of +1 or −1, depending on whether the state under study is laevo- or dextrorotatory. In contrast, NHDT and ammonia behave as isolated molecules, even when coupled to the radiation field, i.e., the totally symmetric state described by $\boldsymbol{\Psi}_0$ does exist. "Chiral" states for ammonia are not forbidden by the rules of quantum mechanics and have been prepared in the course of molecular beam experiments; they are non-stationary states corresponding to the chemist's "pyramid".

The instability of the totally symmetric ground state of a chiral molecule is perhaps also due to other effects, e.g. collisions with neighboring molecules. If the state described by $\boldsymbol{\Psi}_0$ is to be prepared experimentally, all effects of this type must be excluded. An interesting aspect of this discussion is provided by the non-inversion-invariant terms in the Hamiltonian operator, which correspond to the "weak neutral current in atomic nuclei" (cf. [4]). The coupling of molecules to their environment, and in particular to the radiation field, is, however, interesting and important in its own right, and not merely because of the chirality problem; it is responsible for the formation of the chemist's "quasi-molecules" with partially classical properties.

The chirality (of molecules) is an example of a classical observable; another is the temperature (of substances). Superpositions between thermal equilibrium states at different temperatures are thus forbidden.[7] The knot type of a (DNA) molecule is also conceptually a good example of a chemically relevant classical observable: superpositions of molecules with different knot patterns (see Section 3) are not observed experimentally. The knot type of a molecule is clearly and unequivocally determined (dispersion-free), but it is still completely unclear how to arrive at the corresponding classical observable. However, the examples of

chirality and temperature (among others) show that it is possible to derive classical observables with the help of the extended quantum-mechanical formalism even without resorting to ad hoc rules. In these two cases the large (infinite) number of degrees of freedom of the radiation field or of the macroscopic thermodynamic system plays a vital role in the emergence of the relevant classical observable.

Appendix

The basis for the following discussion is the Hilbert space $\mathscr{H}$ of the state vectors Ψ, on which a scalar product is defined. Observables such as the position Q and the momentum P are always described by (self-adjoint) linear operators, i.e., linear maps of the Hilbert space into itself. In the case of quantum mechanics it can be shown that to each non-trivial operator A on $\mathscr{H}$ there exists a state vector $\Psi \in \mathscr{H}$ such that the expectation value $\langle \Psi, A\Psi \rangle$ is not dispersion-free, i.e., $\langle \Psi, A^2\Psi \rangle \neq \langle \Psi, A\Psi \rangle^2$. (An operator is called nontrivial if it is not a scalar multiple of the unit operator I on $\mathscr{H}$). Traditional quantum mechanics, which allows all (bounded) linear operators on $\mathscr{H}$, thus has no room for dispersion-free (= classical) observables, and all operators have the remarkable property which is known from the Heisenberg uncertainty principle for position and momentum operators Q and P: $[Q,P] = QP - PQ = i\hbar I$, i.e., for each nontrivial operator A on $\mathscr{H}$, there is always an operator B, such that $[A,B] = AB - BA$ does not vanish, i.e. A and B do not commute.

A *-algebra of operators is closed under addition and multiplication of elements as well as multiplication by (complex) scalars and the formation of the adjoint of an operator, $A \rightarrow A^*$. The set $\mathscr{B}(\mathscr{H})$ of all linear (bounded) operators on a Hilbert space $\mathscr{H}$ is a *-algebra: this is the algebra of observables in traditional quantum mechanics. In generalized (algebraic) quantum mechanics, any possible *-sub-algebras of the algebra $\mathscr{B}(\mathscr{H})$ are permitted as algebras of observables. It is obvious that not all elements (operators) of an algebra of observables describe physically relevant quantities.[8-10]

If $\mathscr{M}$ is an algebra of observables of a physical system, its classical observables[8-12] are found in the so-called center $\mathscr{Z}(\mathscr{M})$ of $\mathscr{M}$, $\mathscr{Z}(\mathscr{M}) \stackrel{\text{def}}{=} \{A \in \mathscr{M} \mid AB = BA \text{ for all } B \in \mathscr{M}\}$. The center thus contains those operators of $\mathscr{M}$ which commute with *all* operators. $\mathscr{Z}(\mathscr{M})$ is usually only a part of $\mathscr{M}$, but if $\mathscr{Z}(\mathscr{M}) = \mathscr{M}$ the algebra $\mathscr{M}$ is referred to as commutative. Classical mechanics has such a commutative algebra of observables, and in particular there is no uncertainty principle for position and momentum.[8,9]

The existence of classical observables in an algebra of observables $\mathscr{M}$ has consequences for the structure of the Hilbert space: it splits up into sectors which are separated by a so-called superselection rule. The sectors are indexed by the possible dispersion-free values of the classical observables, and the superselection rule has the consequence that transition probabilities of the form $|\langle \Psi_l, A\Psi_k \rangle|^2$, $\Psi_l \in \mathscr{H}_l$, $\Psi_k \in \mathscr{H}_k$, $\mathscr{H}_l$, $\mathscr{H}_k$ = different sectors of $\mathscr{H}$, vanish for *all* observables $A \in \mathscr{M}$. Thus the state vector $\Psi = c_l\Psi_l + c_2\Psi_k$, c_1, $c_2 \in \mathbb{C}$ (after normalization) formed formally according to the normal superposition principle for states does not correspond to a pure state but to a mixture $\langle \Psi | A\Psi \rangle = |c_l|^2 \langle \Psi_l | A\Psi_l \rangle + |c_2|^2 \langle \Psi_k | A\Psi_k \rangle$, $A \in \mathscr{M}$. The vector Ψ describes for example a racemic mixture (an ensemble), but not a superposition of chiral states of a single molecule. In other words: classical observables restrict the universal validity of the superposition principle for state vectors.[9]

3. New Theoretical Concepts in Chemistry

The extension of quantum mechanics described in Section 2 thus offers the possibility of describing large systems and classical properties. However, various theoretical approaches for the description of macroscopic objects and systems with a large number of degrees of freedom have developed which are independent of quantum mechanics. As far as chemically relevant systems are concerned, considerable progress has been made recently through the introduction of theoretical concepts such as "fractals", "quasicrystals", and "chaotic motion for strongly coupled systems". These concepts are not completely independent of one another; the stochastic moment plays an important role, but not in the sense that symmetry is completely destroyed. Self-similarity and scaling invariance are the notions connecting these three areas, and there exist relations to the theory of critical exponents of phase transitions.[13,20]

In the following sections, these three areas will be described, together with examples of their application.

3.1. Fractals

Fractals have been known as mathematical objects for many years, though not under this name;[14] however, they were first introduced into science in the 1970's.[15-17] A characteristic of a fractal object is that the standard methods for determining its length and area fail; there exists no yardstick with which a fractal can be measured and which would give a finite value. When a fractal is enlarged or reduced in size, the same pattern is still found, so that we speak of scale- or dilation-invariance and refer to fractals as self-similar structures.

The properties described above can be seen very clearly from the so-called Sierpiński lattice (Fig. 1), in which the self-similarity is generated according to the following procedure: the starting point is an equilateral triangle whose sides are 2 units long, and this triangle contains three smaller upright triangles with sides of unit length. A further, smaller equilateral triangle standing on an apex is now placed into each of these upright triangles: thus the sides of the initial three smaller triangles are each divided into two, and the original pattern is obtained, but three

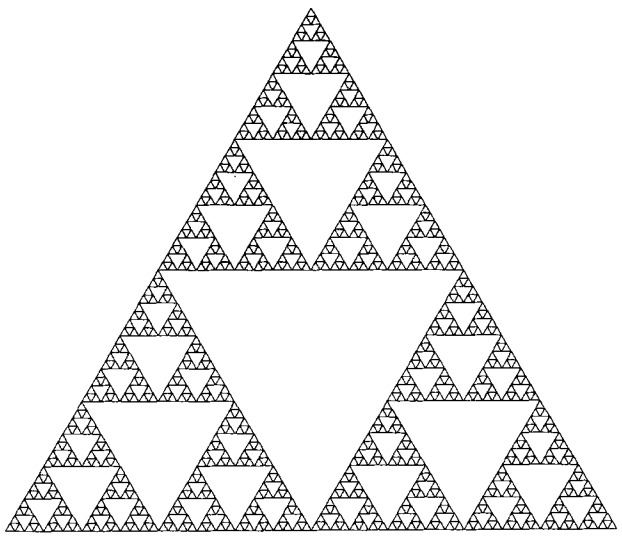

Fig. 1. The Sierpiński lattice after the sixth iteration.

times on half the scale. Iteration of this procedure N times gives the Nth stage of the Sierpiński lattice. The Sierpiński lattice itself is obtained by an infinite number of iterations and is to be understood as part of an infinite hierarchy of triangles of ever increasing size, since the same pattern must recur for each scale. In contrast to the so-called regular lattices, i.e., those with unit cells such as crystal lattices, the Sierpiński lattice is no longer translation-invariant. This has consequences: in the case of regular (two-dimensional) lattices the number of lattice points in a sphere of radius R is proportional to R^d with $d=2$. A similar power law, $N(R) \sim R^{\tilde{d}}$, applies for the Sierpiński lattice, but here $\tilde{d}=\ln 3/\ln 2=1.584$, i.e., it is smaller than the dimension d of the embedding space and is in particular non-integral. The number $\tilde{d}$ is called the *fractal dimension* of the lattice and is a universal characteristic of a given object. A second characteristic dimension of the Sierpiński lattice, to which we shall refer later, should be mentioned, namely its *spectral* dimension $\tilde{d}$. It is more difficult to derive than the fractal dimension determined from the self-similarity[18] and reflects the connectivity properties of the lattice. The inequality $\tilde{d} \leq \tilde{d} \leq d$ applies; only in the case of regular lattices are all dimensions equal.

The strict self-similarity, determined in the case of the Sierpiński lattice by the procedure followed in its construction, must be replaced by statistical self-similarity when natural objects are to be characterized by fractal dimensions. When such an object is enlarged or reduced in size, the structure obtained is not exactly the same but is similar, so that it is not possible solely on the basis of the structure observed to state the scale range concerned (scale-invariance). *Mandelbrot*[15] has listed many fractals observed in nature: coastlines, island archipelagos, lung alvaeoli, trees, mountains, etc. However, in contrast to the situation in mathematics, there are upper and lower bounds to self-similarity in nature, and scale invariance is present only within a certain range.

Chemically and physically interesting applications of fractals for the description of highly irregular structures have been described for aggregation phenomena,[19] percolation problems,[20] in heterogeneous catalysis,[21] for diffusion in disordered materials,[22] and for polymers.[23]

Aggregation clusters with fractal structures are known in particular for metal deposition under diffusion-controlled conditions or for aerosol formation (Fig. 2).

Figure 3 shows a percolation cluster. Such structures are formed in forest fires (at the time when the fire has just reached from one end of the forest to the other), in phase transitions in dilute magnets, in the transition liquid/glass, in polymer gel formation etc.[24] at a certain critical concentration p_c; a fractal is present at exactly this moment.

Extremely rough, fissured, and porous surfaces play an important role in heterogeneous catalysis. It is possible with the help of monolayers of adsorbed molecules of different (effective) diameters as yardsticks, to determine the fractal dimension of, for example, activated charcoal: $\tilde{d} \approx 2.78$. This indicates that many active centers lie close together, so that the surface becomes volume-like.[21,25]

Extremely disordered materials, e.g., glasses, can also be considered as fractals and simulated on a computer as deterministic fractals, since the fractal dimension $\tilde{d}$ is a statistical property. So-called anomalous time laws are found for chemical reactions in glasses; for long times t, the relaxation occurs according to a stretched exponential function (Kohlrausch-Williams-Watts law) [Eq. (a) for the "target annihilation" problem ($\phi(\tau)=1/e$)] or according to an algebraic decay law [eq. (b) for bimolecular reac-

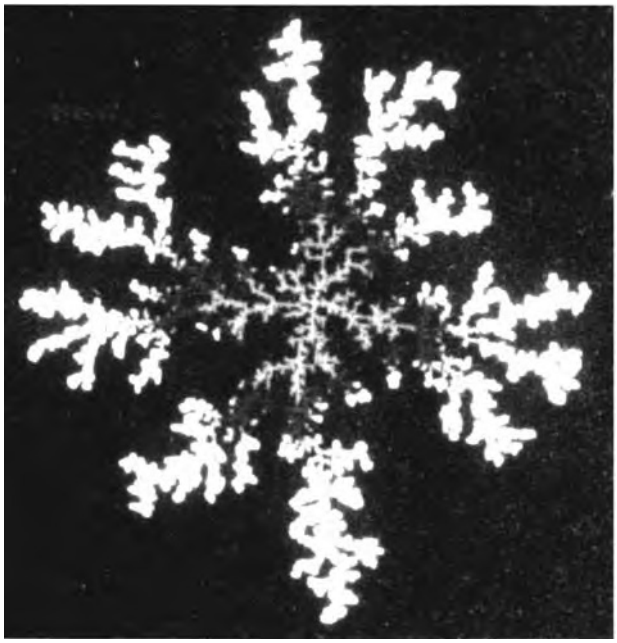

Fig. 2. Diffusion-controlled aggregate on a 600×600 square lattice. The different shadings show the development of the aggregate.

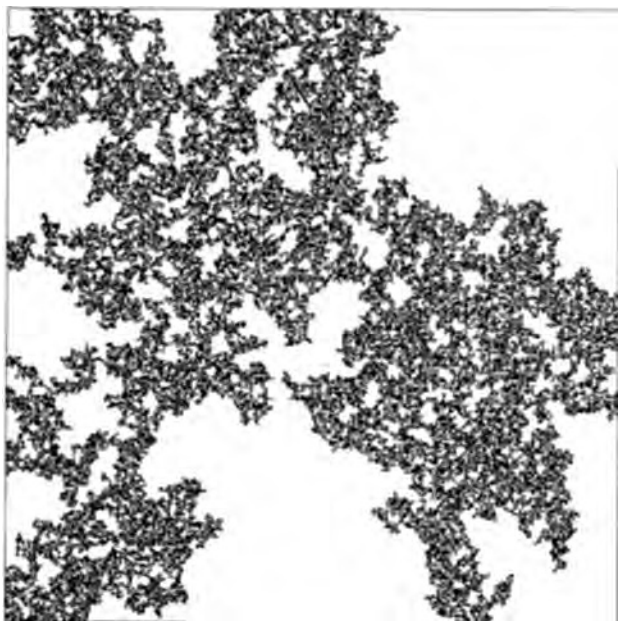

Fig. 3. Percolation cluster at the critical concentration $p_c \approx 0.593$ on a 500×500 square lattice.

$$\phi(t)=\exp[-(t/\tau)^{\alpha}] \qquad \alpha, \tau > 0, \qquad t > \tau \tag{a}$$

$$\phi(t) \sim t^{-\gamma} \qquad 0 < \gamma < 1 \tag{b}$$

tions].[22,26] The exponents α and γ in these decay functions ϕ are related to the spectral dimensions $\tilde{d}$ and not to the fractal dimension $\tilde{d}$; they reflect the connectivity of the lattice on which the particles follow their random paths. The second rate law (b) can in addition be interpreted as a temporal fractal, i.e., $\phi(bt)$ with $b>0$ behaves just as does $\phi(t)$ but on a different time scale determined by b, and there is no characteristic time for the process.

3.2. Spectra of Systems with Strongly Coupled Degrees of Freedom—Chaotic Motion in Molecules?

The rotatory, vibratory, and electronic degrees of freedom are strongly coupled in highly excited molecular states. The resulting spectra appear very "complicated", and the normal characterization of the energy levels by means of quantum numbers is impossible because of the coupling of the degrees of freedom. Although in principle the exact Hamiltonian operator incorporating all interactions could be written down, statistical methods are used in the analysis of such complex spectra, as in nuclear physics.[27] Of particular interest is the question as to whether the numerous, apparently randomly distributed energy levels form clusters for various values or whether they repel one another. A long sequence of random numbers within a certain interval, for example, forms a considerable number of clusters. If the distribution of the spacings S to the nearest neighbors are considered in units of D, the mean distance between the random numbers, the result is a Poisson distribution [Eq. (c), Fig. 4].

$$P_P(S)=(1/D)\exp(-S/D) \qquad (c)$$

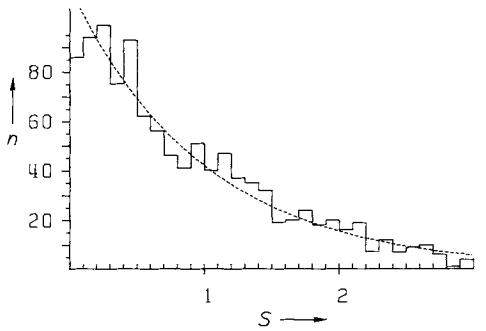

Fig. 4. Distribution of the energy level distances S for two uncoupled quartic oscillators [dotted line = Poisson distribution according to Eq. (c)]. n = number of cases with spacing S.

If this procedure is applied to "simple" spectra, i.e., low-energy spectra with quantum number characterization of the energy levels, a Poisson distribution of the nearest neighbor spacings is also obtained, i.e., smallest distances and cluster formation are allowed.

The Poisson distribution cannot, however, be fitted to the distribution of the distances to the nearest neighbor energy levels in the case of spectra from highly excited states with coupled degrees of freedom, since very small distances between the levels no longer occur. With the assumption of linear repulsion between the energy levels (see, e.g., Ref. [27]) a different distribution function is obtained, namely the Wigner distribution[28] [Eq. (d)].

$$P_W(S)=(\pi S/2D^2)\exp[-\pi S^2/4D^2] \qquad S\geq 0 \qquad (d)$$

In many cases, this function reproduces the distribution of the nearest neighbour spacings quite well (Fig. 5).

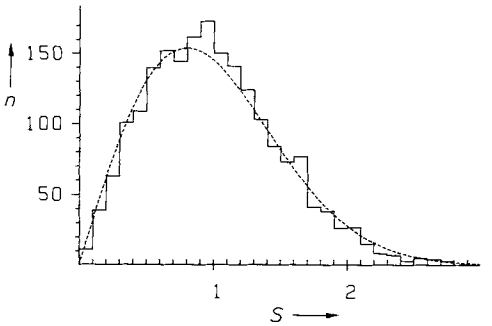

Fig. 5. Distribution of the energy level distances S for two strongly coupled quartic oscillators [dotted line = Wigner distribution according to Eq. (d)].

Between the extreme cases of Figures 4 and 5, there is a large transitional range, which will be of great interest to spectroscopists and theoreticians; it will hopefully be possible to use the spectra to obtain basic information on the dynamics of the systems under consideration.

The simplest systems in classical mechanics are integrable systems where the number of constants of the motion is equal to the number of degrees of freedom. However, when a non-integrable part is added to the Hamilton function (simple example: a rotator kicked periodically by a certain force) there no longer exist any constants of the motion (except for the energy). Integrable systems do not always possess periodic, closed orbits in phase space; it is possible that in the course of time a trajectory almost fills (in the sense of measure theory) an energy shell in phase space (ergodic behavior). Nevertheless, trajectories with neighboring initial conditions remain close together, and such a motion is referred to as regular. Non-integrable systems, in contrast, can exhibit so-called chaotic behavior, which means that trajectories which originally lay close together diverge exponentially; small variations of the initial conditions lead to a completely different behavior of the system, and such a motion is called chaotic or irregular.[29-31]

Regular and irregular systems differ however not only in their dynamic behavior but also in their relationship to quantum mechanics. Integrable systems can be quantized semiclassically;[32] the energy levels of the corresponding quantum system can be characterized by quantum numbers, and Poisson statistics governs their spectra. Model studies using harmonic or quartic oscillators have shown[33] that for the case of strong coupling in an approximate quantum treatment the energy levels of the spectrum repel one another, so that Wigner statistics must be used (fractal concepts can also be applied[34]). In this type of spectra, the semiclassical limit $\hbar\to 0$ yields a chaotic classical system. This does not however mean that one is al-

lowed to speak of "quantum chaos", since for quantum systems there is no criterium analogous to the difference between regular and chaotic trajectories in the classical case. However, one has become accustomed to speaking of regular and irregular spectra, in analogy to the dynamics of the corresponding classical systems.

Thus the difference between Poisson and Wigner distribution of the spacings between neighboring energy levels in spectra cannot serve as a measure for the chaotic behavior of quantum systems. *Kolmogorov* and *Sinaĭ*[35] have introduced an entropy, the Kolmogorov-Sinaĭ (KS) entropy, as a characteristic invariant for classical dynamical systems; it is strictly zero for regular motion, but has values >0 for chaotic motion; for completely random systems without a deterministic part, its value is ∞. Attempts to adapt this concept to dynamic systems of quantum mechanics have been made previously, in particular in connection with irregular spectra;[36,37] however, difficulties always occurred because of the intrinsic non-commutativity of the quantum mechanical algebra of the observables. A very promising approach to extending the KS entropy to the non-commutative, i.e., quantum mechanical, case has been made by *Connes, Størmer, Narnhofer* and *Thirring*.[38] It was shown that the KS entropy of a dynamics implemented by a Hamiltonian operator with a discrete spectrum vanishes; thus, from this point of view, Hamiltonian systems with discrete spectra are not chaotic. A non-vanishing KS entropy occurs, for example, in the dynamics on algebras which are encountered in algebraic statistical mechanics: these algebras, the so-called type-III W*-algebras,[39] are also non-commutative, but, for example, possess no smallest (one-dimensional) projectors, unlike the algebra of observables of standard quantum mechanics.

3.3. Quasicrystals

Translation invariance in planar and spatial structures implies that certain symmetry elements are excluded. For this reason, there are no fivefold rotation axes in the crystallographic groups of three-dimensional space. Thus, the discovery in 1984 by *Schechtman* et al.[40] of five- and tenfold symmetry axes in diffraction diagrams of aluminum-manganese alloys was even more sensational. As is often the case in science, mathematicians had already suggested a solution. *Penrose*,[41] *de Bruijn*,[42] and others had been studying so-called quasi-periodic lattices since the 1970's. These are lattices without translational symmetry, though they are not completely disordered patterns. Figure 6 shows a planar Penrose pattern which is built up from two different types of rhombus.

The sections of equal length are all parallel to the sides of a regular pentagon. As mentioned above, these patterns do not show translation invariance, but the pattern is self-similar in that an area (e.g., a pentagon with its surroundings) of diameter D occurs again with the same arrangement and a diameter somewhat larger than $2D$.[41]

Quasicrystalline structures are non-translation-invariant images of translation-invariant structures in spaces with a Euclidean dimension greater than three. They can be obtained by projection of a translation-invariant regular lattice in a higher-dimensional space. A three-dimensional quasicrystal is constructed by placing a three-dimensional (hyper)plane in a higher-dimensional (e.g., six-dimensional) lattice and projecting all those lattice points which lie at a certain distance T (where T is, for example, the length of the unit cell of the regular lattice) from the plane onto this plane. According to the position of the plane (rational or irrational slope) in the higher-dimensional space, one obtains a regular or quasi-periodic lattice in three dimensions. The compatibility of the fivefold symmetry with that of the higher-dimensional lattice determines whether fivefold point symmetries can occur in the quasicrystal. Representations Δ higher than three-dimensional of point groups G, which are not compatible with the translational symmetry of three-dimensional lattices, can be induced by subgroups of G according to the well-known Frobenius procedure.[43] The hyperplane (i.e. the three-dimensional space) must be situated in the higher-dimensional lattice in such a way that the representation Δ leaves the hyperplane invariant.[44]

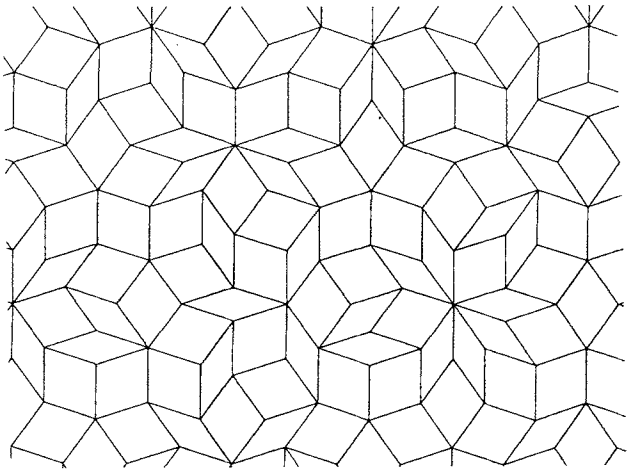

Fig. 6. Planar Penrose built up from two different types of rhombus.

In the alloy system Al-Mn-Si, there exists a normal crystalline phase which can be converted into a quasicrystalline phase by means of a small deformation. This phase transition corresponds to a change in the position of the hyperplane in higher-dimensional space.[44]

3.4. Knot Theory

The final topic is not so closely related to physical chemistry as are the three previous ones, but it has led to discussions between biochemists and mathematicians; some aspects of knot theory also make this field an interesting one for theoretical chemistry.

DNA molecules can be knotted under the influence of topoisomerases and by recombination. The first evidence of the existence of various types of knot was found on electrophoresis plates: differently knotted DNA molecules with the same nucleotide sequence wander at different rates. It is now possible to obtain excellent electron microscope pictures of knotted DNA molecules. This is made possible by coating the DNA strand by a layer of RecA protein.[45] In this way, the strand thickness is increased

from 10 Å to 100 Å, and the manner in which the strands cross each other can be clearly determined (Fig. 7).

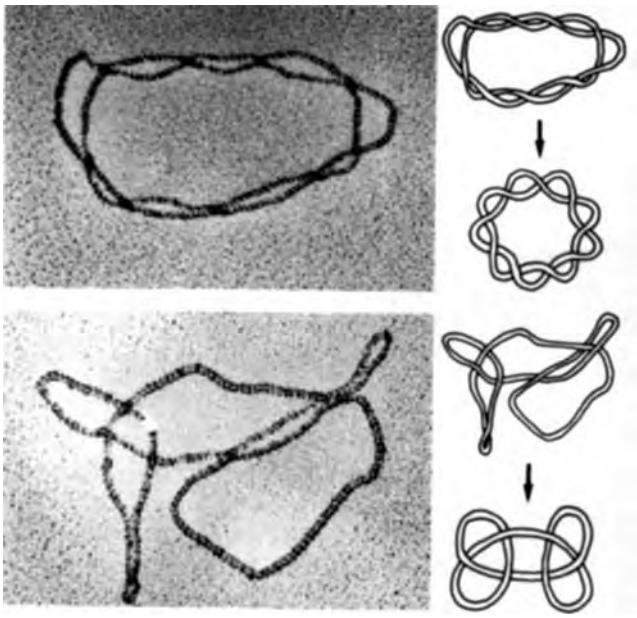

Fig. 7. Left: electron microscope pictures of knotted DNA strands; right: schematic diagrams of the real and ideal knots.

Knot theory, in mathematics, is a part of topology, i.e., one can deform knots without their undergoing any "essential" change (see Fig. 8). The study of knots was initiated by the physicist *P. G. Tait*,[46] he was interested in smoke rings and the Thomson (Kelvin) atomic theory. The main mathematical task is to find the characteristic topological invariants for knots and, because of the number of forms which a knot can assume, to define a notion of equivalence. Two knots which can be interconverted by means of an invertible differentiable map, which leaves the orientation of the space invariant, are said to be equivalent ("ambient isotopic").[47] For example, the two knots in Figure 8 are equivalent.

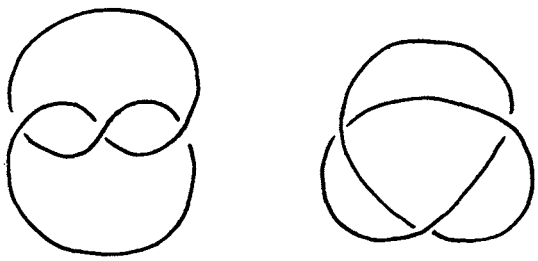

Fig. 8. Two different representations of the trefoil knot [55].

The question of equivalence becomes more difficult, however, as the number of crossing-points in the knot increases.

An invariant for knots, the so-called Alexander-Conway polynomial Δ_K, was introduced in 1928. A finite polynomial with integral coefficients in the variables $t^{1/2}$ and $t^{-1/2}$ is assigned to each oriented knot; equivalent knots lead to the same polynomial. The polynomial corresponding to the trefoil knot in Figure 8 is given by Equation (e).

$$\Delta_K(t) = t - 1 + t^{-1},\ t \in \mathbb{R} \qquad \text{(e)}$$

However, the Alexander-Conway polynomials very often assign the same invariant to inequivalent knots, e.g. the mirror images of the chiral trefoil knot. This problem was first solved only a few years ago by *Jones*,[48] who introduced new polynomials, which can distinguish between the "antipodes" of chiral knots, as invariants. *Interestingly, the Jones polynomials were discovered in the course of studies of a particular type of operator algebras which occur in algebraic quantum mechanics.* In addition, there was found to be a direct relationship between knot theory and mathematical structures in lattice models of algebraic statistical mechanics (Ising-like models, Yang–Baxter equation, see, e.g., Ref. [49]) and with group theory (braid groups).

There are several review articles on the present role of knot theory in chemistry which are worth reading, including those written by *Walba*,[50] *Wasserman* and *Cozzarelli*,[51] *Sumners*,[52] and the corresponding articles in Ref. [1]. Enzymes can be classified according to the type of knot and the chirality they produce from unknotted circular molecules, and the modes of reaction of differently knotted DNA molecules also differ. The knot type of a molecule is a classical observable in the sense of Section 2. As indicated above, there are indeed mathematical connections with quantum-mechanical structures, but at present there is no concrete indication as to how an observable "knot type" could be obtained in the center of an observable algebra.

All the concepts presented here are relevant to chemistry; the relationship between them can be seen from the importance of the terms "self-similarity", "random processes", and "operator-algebraic methods", and "large" systems are often studied. Numerical quantum chemistry is in the process of treating clusters, defect crystals, and polymers, since, thanks to the new generation of computers, the required calculation capacity is now available. However, theoretical chemistry is not bound to the molecular picture and must in future take much more account of very different levels of description, because both the language of the chemist and the theoretical foundation provided by quantum mechanics must be taken seriously. The following section will describe the relationship between the purely molecular and other, just as legitimate, points of view.

4. Do Molecules Exist?

The molecular viewpoint which is dominant in chemistry today has its roots in the period at the beginning of this century when, for example, *Wilhelm Ostwald* underwent "conversion" to atomism and thus to the molecular picture. The idea that it is possible and necessary to relate *all* the phenomena of chemistry to the properties of elementary entities is one shared by very many natural scientists. This way of thinking has resulted in great achievements and in much practical insight. In addition, the contribution of quantum chemistry to the confirmation of the "correctness" of quantum mechanics should not be underestimated

(e.g., the exact calculation of the dissociation energy of the H_2 molecule[53]). However, both quantum mechanics, on the one hand and chemical phenomenology, on the other, make it clear that the molecular point of view is *not the only possible one*:

- Quantum-mechanics is a holistic theory; thus coupled systems (e.g., electrons and nuclei in a molecule) form an inseparable unit. The state of the whole system cannot be reconstructed from the states of the partial systems. Thus, for example, in a discussion of macroscopic systems which consist of many molecules the restriction of the global state to one single molecule is no longer a pure state (but a mixed state represented by a density operator). Since, however, only pure states describe individual single molecules, the usual notion of "molecule" disappears in this case. In addition "molecules" in a macroscopic system are so strongly coupled via Einstein-Podolsky-Rosen correlations[9, 54] that also from this point of view it is no longer possible to speak of discrete molecules.
- According to chemical intuition, molecules contain a nuclear framework, i.e., the positions of the nuclei relative to one another are fixed. This intuition is taken into account in quantum chemistry by the Born-Oppenheimer "approximation". A superselection rule in the sense of Section 2 (with the classical observable "nuclear framework") applies to molecules with different frameworks, though it is by no means as strict as, for example, the superselection rules for charge or chirality. The Born-Oppenheimer picture of a molecule is often sufficient for the chemist's purposes, but cannot be maintained in precision spectroscopy. For a molecule such as ammonia the fiction of the nuclear framework collapses.[5, 6] Experiment (microwave spectroscopy) and quantum chemistry are in agreement, yielding a totally symmetric ground state for NH_3. A conventional rationalization of this fact is that the molecule exists in two pyramidal forms which interconvert by means of "tunneling". However, neither theory nor experiment support this rationalization: ground states in quantum mechanics are stationary and do not vary with time. Pyramidal states of NH_3 can be prepared experimentally, but are not eigenstates of the Hamiltonian operator and are thus not stationary.
- If an object, e.g., the surface of a heterogeneous catalyst or a disordered solid, is described as a fractal, the molecular picture has been left behind, since molecules are not self-similar or scale-invariant. Ordered crystal structures always possess a smallest unit, the unit cell, from which the crystal is built up by translation. The scale-invariance of fractal structures does not permit the occurrence of such smallest units. That both descriptions, the fractal and the molecular, are mutually exclusive but complementary is thus not only a question of magnitude but becomes evident through the completely different symmetry laws of the two points of view.

"Matter consists of molecules, and molecules consist of the nuclear framework and electrons": this idea is of great value for chemistry, but it is not universally applicable. There are situations in which completely different theoretical concepts and approaches must be applied.

5. What is Theoretical Chemistry and What is Its Purpose?

The most important aspects of theoretical chemistry, as they have been presented here, can be summarized by the following theses:

1. The theory of chemistry must be much more than a collection of models. Models are useful or useless according to the situation, but can never be right or wrong.
2. Theoretical chemistry takes its concepts from various sources. The contribution of quantum chemistry is important, but is by no means the only one.
3. Theoretical research cannot orient itself *solely* to the molecular picture of matter. Complementary approaches exist, for example, for scale-invariant fractal structures or in algebraic quantum mechanics of large systems.
4. Theoretical chemistry naturally has good contacts with applications. The actual purpose of the theory is, however, to understand phenomena and interrelationships in a qualitative manner. This qualitative understanding is just as "exact" as quantitative (numerical) statements.

A theory which is intended to help the science of chemistry, which is so rich in phenomenology, must be extended on various levels of knowledge; it must provide clear, universally valid concepts which are of sufficient clarity and longevity that chemists in laboratories can also profit from them.

For kindly providing the Figures for this article, we wish to thank: A. Blumen, J. Klafter, G. Zumofen (Figs. 1-3), T. Zimmermann (Figs. 4, 5), P. Kramer (Fig. 6) and A. Stasiak (Fig. 7). Special thanks are due to K. Lendi for critically reading the manuscript.

The Structure of Lithium Compounds of Sulfones, Sulfoximides, Sulfoxides, Thioethers and 1,3-Dithianes, Nitriles, Nitro Compounds and Hydrazones

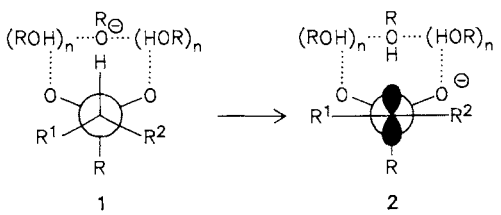
By Gernot Boche*

Acceptor-substituted lithio compounds $LiA-CR^1R^2$, in which the acceptor A is an RC(O), $N\equiv C$, RSO_2, RS(O)NR, RSO, RS, O_2N, or $RC(N-NR_2)$ group, have long played an important role in organic synthesis. Their significance has grown still further in the last fifteen years, as one has increasingly learnt to employ them successfully in chemo-, regio-, diastereo- and enantioselective reactions. Remarkably, little if anything was known of the structures of these compounds. It is therefore not surprising that interest in the structures of this class of compounds has greatly increased in recent years. In the following review, we shall summarize recent research into the structures of the lithio compounds of sulfones, sulfoximides, sulfoxides, thioethers and 1,3-dithianes, nitriles, nitro compounds, and hydrazones. Crystal structure determinations from recent years are central to this study. They are supplemented by solution studies and by calculations of structures. Structural similarities and differences between the individual states of aggregation are pointed out wherever possible, as is also the relationship between structure and reactivity.

1. Introduction

There can be no class of compounds for which a greater discrepancy exists between their importance in modern organic synthesis and the lack of knowledge about their structures than organometallic compounds. A new synthesis using these reagents can be found in practically every issue of any of the respected journals and is usually characterized by high chemo-, regio-, diastereo- or enantioselectivity. At the same time, the course of the reaction can often only be understood by the IOC method ("intuition of the organic chemist"). This state of affairs is unacceptable in the long term; firstly, because of the fundamental interest in knowing the structure of organometallic compounds, and secondly, because a knowledge of the structure-reactivity relationships for this class of compounds could well be of further help to the synthetic chemist.

It is therefore pleasing that in recent years structural aspects of organometallic chemistry, especially of organolithium compounds, have become the subject of growing interest, along with purely synthetic aspects.[1] Solution NMR spectroscopic studies by *Jackman* et al.,[2] and X-ray structural analyses by the groups of *Seebach* and *Dunitz*, have contributed substantially to an understanding of the structures of synthetically important enolates, ester-enolates and amide-enolates;[3] part of this work has been the subject of a review.[3a]



The following sections will report on the progress that has been made in recent years for lithio compounds of sulfones, sulfoximides, sulfoxides, thioethers and 1,3-dithianes, nitriles, nitro compounds and hydrazones, largely with the aid of X-ray structure determinations. The question as to what extent the results of solid-state investigations agree with those for solutions and with calculations ("gas-phase") will be given particular consideration. Additionally, we shall discuss the extent to which a knowledge of the structure allows the reactivity (selectivity) to be understood.

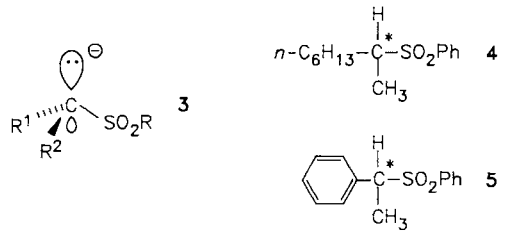
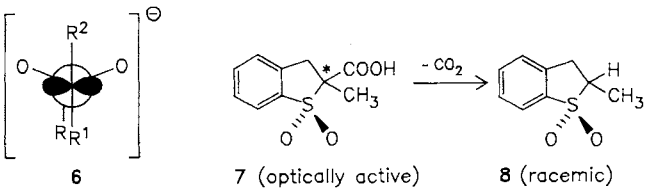
2. Monolithium and Dilithium Compounds of Sulfones

2.1. Monolithium Compounds



The remarkable fact that acyclic sulfones having a chiral α-carbon atom largely retain their configuration upon H/D exchange has led to numerous experimental[4-37] and theoretical[38-43] studies of the structures of the intermediate α-sulfonyl "carbanions". As early as the sixties, e.g., *Corey* et al.[15,19,20] concluded from their elegant studies of the deprotonation (and also decarboxylation and retro-aldol reactions) of chiral acyclic sulfones that the reaction should occur as outlined in Scheme 1.



Scheme 1.

The leaving group (a proton in **1**) adopts a *gauche* orientation with respect to the two O atoms of the sulfone group. Cleavage of the proton then leads to a planar, chiral "carbanion" **2** (if $R^1 \neq R^2$), in which the lone pair of electrons on the anionic α-carbon atom is *gauche* to the two sulfonyl O atoms. Therefore, the chirality of an α-sulfonyl "carbanion" should not be due to the tetrahedral configuration at the α-C atom, as would be the case in **3**. If the anionic C atom were non-planar (or nearly planar, and

rapidly inverting), then upon H/D exchange of the optically active sulfones **4** and **5** the two $k_{exchange}/k_{racemization}$ ratios (k_e/k_r) should not be approximately equal (41 and 44 respectively), since the phenyl ring in **5** favors a planar α-carbon atom far more than does the *n*-hexyl group of **4**.[20] In this case, the achiral conformation **6** can be excluded. In contrast, decarboxylation of the optically active carboxylic acid **7** affords racemic **8**. Since the sulfone group is incorporated in a five-membered ring, the only intermediate "anion" that can be formed is an achiral one of type **6**.[20]

3 **4** **5**

6 **7** (optically active) **8** (racemic)

Corey and *Lowry*[19] were also able to show that protonation or deuteration of the "anion" **2** occurs from the same side as deprotonation. From their results, these authors also inferred an increased barrier to rotation about the C_α–S bond in α-sulfonyl "carbanions".[15,19,20]

Extensive spectroscopic investigations have been carried out by *Chassaing*, *Marquet* et al.[29,30,32] including a ^{13}C NMR study of lithium compounds **9**–**13**,[29,30] which gave the following results (Table 1):

Table 1. C,H coupling constants [Hz] for the α-C atom of **9**–**13** [29, 30].

	^1J(C,H)	Δ^1J("anion"–sulfone)
$PhSO_2CHPhLi$ **9**	168	+30
$CH_3SO_2CHPhLi$ **10**	163	+23
$tBuSO_2CHPhLi$ **11**	160	+21
$tBuSO_2CHLi$ **12**	142	+ 4
$PhSO_2CHLi$ **13**	139	0

In the benzylic "anions" **9**–**11**, the coupling constants $^1J_{C-H}$ for C_α are very large, in agreement with a nearly planar configuration at this C atom, and the authors assume a "very loose" C–Li bond.[29] By contrast, in the non-benzylic "anions" **12** and **13**, and in others of this type, the change in the coupling constant relative to that of the corresponding sulfone is considerably smaller, so that hybridization "between sp^2 and sp^3" is proposed, and with it a non-planar α-C atom.

These results lead to the interesting conclusion that for a sulfone group it appears to be irrelevant whether the negative charge to be stabilized is situated on a planar or on a pyramidalized α-C atom.

IR spectroscopic studies of $PhSO_2CH_2Li$[32] indicated an increase in the S–C_α and a decrease in the S–O force constants relative to the corresponding values for methylphenyl sulfone. The S–C_α bond should therefore be shortened in the "anion", and the S–O bond lengthened.

The results of 3-21G and 3-21G* (with consideration of the d-orbitals of sulfur) calculations carried out by *Wolfe* et al.[41] on α-sulfonyl carbanions (without a counterion) are in accord with the *gauche* conformation **2**. In **2**, the decisive interaction for stabilization, i.e., that between the n_C-orbital and the σ^*_{S-R}-orbital, is conformationally especially favorable.

Bond lengths (pm) for dimethyl sulfone $CH_3SO_2CH_3$ **14** and its anion **15** were calculated using 3-21G*,[41] and are presented in Table 2. The experimental values for **14** are given in parentheses.[44]

Table 2. 3-21G* bond lengths [pm] in **14** and **15** [41]; experimental values in parentheses [44].

	$H_2\overset{\ominus}{C}$–S	H_3C–S	S–O
$CH_3SO_2CH_3$ **14**	—	175.6 (177.1)	143.8 (143.5)
$CH_3SO_2\overset{\ominus}{C}H_2$ **15**	161.8	179.7	146.2

Thus, calculations for anion **15** also show a marked shortening of the S–C_α bond relative to the S–CH_3 bond of sulfone **14**, while the S–O bond is only negligibly lengthened.

For further elucidation of α-sulfonyl "carbanion" structures the following questions must be answered, and to do so requires the results of X-ray structure investigations.

1. What are the bond lengths and angles in the carbanion moiety? In particular, which is more favored, a chiral conformation as in **2**, with a planar α-C atom, or one with a pyramidalized α-C atom?

2. Where is the Li atom located? Although this question has been ignored in most studies to date, the IR spectroscopic investigations mentioned above[32] were interpreted in terms of lithium being bound simultaneously to the two oxygen atoms and to the anionic α-C atom. 3-21G* calculations for $LiCH_2S(H)O_2$,[42] however, gave a four-membered (C–S–O–Li) ring as the only energy minimum. We shall now show how a series of crystal structure investigations has led to a unified picture of the structure of "α"-lithiosulfones.

The first X-ray structure determination of an α-sulfonyl "carbanion",[45] that of α-(phenylsulfonyl)benzyllithium-tetramethylethylenediamine **16** was published by *Boche* et al.[46] Shortly afterwards, and independently, a paper by *Gais* appeared,[47] on (phenylsulfonyl)methyllithium-tetramethylethylenediamine **17**.

$[PhSO_2CHPhLi \cdot TMEDA]_2$ **16** $[PhSO_2CH_2Li \cdot TMEDA]_2$ **17**

TMEDA = tetramethylethylenediamine

Since the solid-state structures of **16** and **17** concur in their fundamental details, only that of **16** is shown in Figure 1.

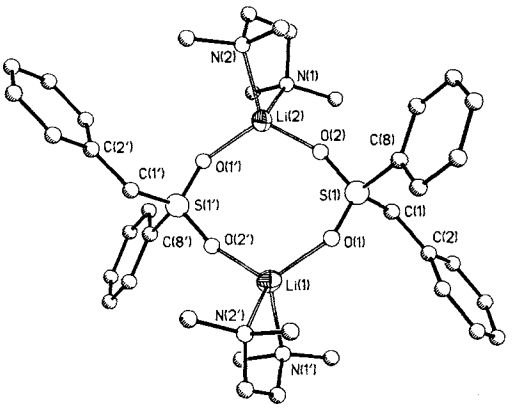


Fig. 1. Crystal structure of **16** [46].

16 and **17** crystallize as dimers, with the Li, S, and O atoms forming a flat, chair-like eight-membered ring. The sulfur atoms lie above and below the plane of the Li and O atoms. Thus, there is no Li–C bond, so that, in the solid state at least, these compounds cannot be called α-lithio sulfones![48]

The C(1)–S(1) distance of 164.1 (161.0) pm in **16** (**17**) is considerably shorter than the corresponding bond length in sulfones (mean value of 58 bond lengths: 180.6 pm[51]). This agrees with the qualitative evidence from the IR analysis,[32] and also with the results of calculations[41] (see Table 2). In sulfene and in thioformaldehyde, in which CS double bonds occur, the CS distances are 161.0(4)[52] and 161.08 pm,[53] respectively. However, in contrast to the IR spectroscopic evidence, the S–O bond lengths of 146.5 and 146.0 pm in **16** and **17**, respectively are only marginally longer than those found in sulfones (mean value of 53 bond lengths: 143.4 pm;[51] methyl phenyl sulfone 145.9 pm;[54] dimethyl sulfone 143.5 pm[44]). This agrees with the results of 3-21G* calculations (see Table 2).

The X-ray structures of lithiosulfones **18**–**22**, also determined in the groups of *Boche* and *Gais*, corroborate the picture found in **16** and **17**. Dimers are formed, independent of the complex ligands TMEDA or diglyme, linked together by an eight-membered (S–O–Li–O–S–O–Li–O) ring; no bond is formed between the Li atom and C_α; the C_α–S bond is shortened considerably, and the S–O bond slightly lengthened.

$[PhSO_2CH(CH{=}CH_2)Li \cdot Diglyme]_2$ **18**[55]

$[PhSO_2CH(SiMe_3)Li \cdot TMEDA]_2$ **19**[56]

$[PhSO_2C(CH_3)_2Li \cdot Diglyme]_2$ **20**[57]

$[PhSO_2C(CH_3)PhLi \cdot TMEDA]_2$ **21**[57]

$[CH_3SO_2CHPhLi \cdot TMEDA]_2$ **22**[58]

The conformation around the C_α–S bond and the configuration of the anionic α-C atom deserve special attention, because of their relevance to the solution stereochemical studies mentioned previously. Table 3 lists the torsion angles α(β) between the A(B) substituent on C_α and the R substituent on the neighboring S atom, for lithiosulfones **16**–**22**. The sum of the angles $|\alpha|+|\beta|$ is a measure of the pyramidalization of C_α, while the γ-values[59a] express the divergence of the unshared electron pair on C_α from the ideal *gauche* conformation. In the Newman projection **A**, the molecule is viewed from the α-C towards the S atom.

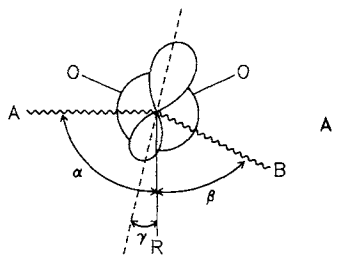

Table 3. Torsion angles α (β) [°] between the substituents A (B) on C_α and R on S; the sum of the angles $|\alpha|+|\beta|$ [°], and γ-values [59a] for lithiosulfones **16**–**22**. For definition of the angles see **A**.

α-Lithiosulfone	A	α	B	β	$\lvert\alpha\rvert+\lvert\beta\rvert$	γ [59a]
16 [a]	H	—	Ph	70	180 (?)	20 (?)
22	H	−109	Ph	73	182	18
19 [59b]	H	−76	$SiMe_3$	94	170	9
21	CH_3	−89	Ph	80	169	4.5
17	H	−81	H	81	162	0
18	H	−78	$CH{=}CH_2$	76	154	1
20	CH_3	−66	CH_3	73	139	3.5

[a] In **16**, the position of the benzylic H atom (A) could not be located sufficiently accurately [46].

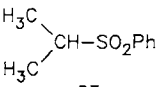
From the numerical values of α and β in the individual compounds, it can be deduced that the substituents A and B are arranged by and large such that the lone pair of electrons adopts a *gauche* conformation to the two O atoms on sulfur. The solid-state structural data for α-sulfonyl "carbanions" **17**–**22** thus confirm that this conformation is the most thermodynamically stable, a conclusion which had also been reached on the basis of kinetic studies on chiral sulfones, such as **4** and **5**, in solution. Calculations ("gas phase") for **15** have also revealed a preferred *gauche* conformation.

Remarkably, however, apart from the Me_3Si substituted lithiosulfone **19**, only the phenyl substituted compounds **21** and **22** (and presumably also **16**) are largely planar. **17**, **18**, and especially **20** have a pyramidalized α-C atom (see the $|\alpha|+|\beta|$ values in Table 3). That this should be so for **18** is particularly surprising, considering the allylic position of the α-C atom. In (**16**), **19**,[59b] **21**, and **22**, a larger deviation from the ideal *gauche* conformation than in **17**, **18** and **20** is also observed (see the γ-values in Table 3).

How is the configuration at C_α and the conformation around the C_α–S bond of these α-sulfonyl "carbanions" to be understood? In the phenyl-substituted compounds (**16**), **21** and **22**, the flattening is doubtless connected with partial stabilization of the negative charge by p_π–p_π interactions with the phenyl ring. The conformation around the C_α–S axis is thought to be caused by van der Waals repul-

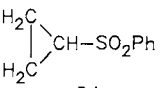
sion between the phenyl ring and the neighboring oxygen atom. Van der Waals interaction with the oxygen atoms is also thought to be responsible for the increase in pyramidalization observed between the CH_2 compound **17** and the $C(CH_3)_2$ compound **20**. The ease with which the configuration changes in **16**–**22** can therefore only mean that the energy difference between planar and pyramidalized α-C atoms in lithiosulfones is small.

Bors and *Streitwieser* came to exactly this conclusion in a comprehensive theoretical study of the structures of $CH_3SO_2CH_2^{\ominus}$, $CH_3SO_2CH_2Li$ and $LiCH_2SO_2CH_2Li$.[43] They used the 3-21G*+ basis set, which is extended relative to 3-21G*[41] and thus better describes the situation of the electrons on the anionic α-C atom. In order to test whether stabilization of a negative charge by a neighboring sulfonyl group could possibly be due to a p_π–d_π interaction, the 3-21G+ basis set was also used; this program neglects the d-orbitals on sulfur.



As far as the configuration at the anionic α-C atom in $CH_3SO_2CH_2^{\ominus}$ is concerned, 3-21G*+ led to a planar configuration, while 3-21G+ yielded a pyramidalized C_α in which the H atoms are bent out of the plane by 18.3°. Nevertheless, the energy difference between a planar and a pyramidalized α-C atom is not very large as shown by the energy of $CH_3SO_2CH_2^{\ominus}$ (3-21G*+), in which the H atoms on C_α are each bent out of the plane by 20° (away from the O atoms); it is a mere 0.57 kcal mol^{-1} less stable than the planar form! These calculations also show that from an *energetic* point of view, there is no reason to assume p_π–d_π conjugation between the lone pair of electrons on C_α and the sulfonyl group. Calculations of bond lengths, proton affinities, and electron densities gave the same result, which can only mean that the n_{C^-}–σ^*_{S-R} interaction is crucial for stabilization of the negative charge.[43]

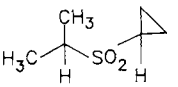
The increased barrier to rotation about the C_α–S bond in α-sulfonyl "carbanions",[15,19,20] which *Corey* and coworkers deduced from the results of H/D exchange experiments, has also been verified by calculations.[43] The *gauche* conformation corresponding to **2**, with the lone pair on C_α lying between the O atoms of the RSO_2 group, represents a minimum on the potential hypersurface of $CH_3SO_2CH_2^{\ominus}$. Upon rotation through 90°, the energy rises by 14.33 kcal mol^{-1}; optimization of this "90°-conformation", assuming C_S-symmetry, yields a value that is increased by 9.31 kcal mol^{-1}.



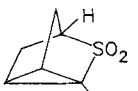
The question of whether a negative charge is better stabilized by an acceptor substituent X when the α-C atom is planar, or when it is pyramidalized, was first investigated with the aid of the "cyclopropyl effect". If stabilization occurs predominantly by delocalization and π-bond formation, a cyclopropyl compound C_3H_5–X should be less acidic than the corresponding isopropyl compound iC_3H_7–X, despite the fact that cyclopropane itself is more acidic than propane.[60] This is because the exocyclic "π-bond" in the three-membered ring "anion" confers additional strain on the latter; methylenecyclopropane is 13.5 kcal mol^{-1} more strained than cyclopropane.[61] Indeed, cyclopropyl ketones and other cyclopropylcarbonyl compounds show considerably reduced kinetic[25] and thermodynamic[31] acidity compared to the corresponding isopropyl compounds. The planarity of enolates as well as the double bond character of their C–C bonds, and the single bond character of the C–O bonds have been confirmed by X-ray structural data.[3]

Remarkably, with cyclopropyl and isopropyl sulfones application of this criterion led to contradictory results. *Zimmerman* et al.[8] (measurements in ether and hydrocarbons), and *Cram* et al.[21] (measurements in DMSO) reported that the equilibrium acidities of **23** and **24**, for instance, are approximately equal.

In H/D exchange experiments ($k_{H,rel}$ for exchange of 30% RH in CH_3OH/CH_3ONa (0.22 M) at 53.2°C), *De Boer* et al.[25] found cyclopropyl sulfone **24** to have a 34-fold higher acidity than **23**. Similar observations were made by



23

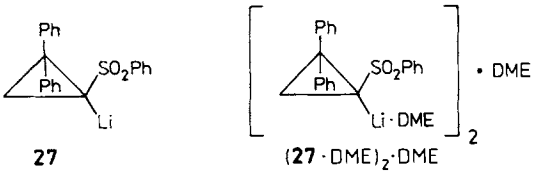


24

Kirmse et al.:[35] in *intra*molecular competitive H/D exchange of **25** (D_2O, 0.5 M NaOD, 74°C), the cyclopropyl H is 213 times more acidic than the isopropyl H.

In **26**, the cyclopropyl H adjacent to the SO_2 functionality is 145 times more acidic than the other H atom adjacent to the sulfone group (at 35°C).[35]

25



26

Completely different results have been reported by *Bordwell* et al.[28,31] As shown by Table 4, methyl sulfones, and the related methylsulfoximide and methyloxosulfonium ion, are more acidic than the corresponding cyclopropane derivatives. In addition, a comparison of cyclopropyl sulfones with the appropriate isopropyl sulfones shows that the latter are the more acidic.[31]

Table 4. The cyclopropyl effect on the equilibrium acidities K_a of sulfones and related compounds in DMSO [28, 31].

X	pK_a (H_3C-X)	pK_a (C_3H_5-X)	ΔpK_a
$\overset{\oplus}{S}(O)(NMe_2)Ph$	14.4	20.9 ± 0.3	6.5 ± 0.3
SO_2CF_3	18.8	26.6	7.8
$S(O)(NSO_2Ph)Tol$	24.5	28.8 ± 0.2	4.3 ± 0.2
SO_2Ph	29.0	> 32	> 3

The causes of this discrepancy for sulfones and related compounds are not known at present. One could deduce from the data in Table 4 that, "like enolate and nitronate ions, α-sulfonyl carbanions are planar",[31] but this has been repeatedly disproved by the structural studies on α-sulfonyl "anions" described above. The tetrahedral configuration of the α-C atom in 2,2-diphenyl-1-(phenylsulfonyl)cyclopropyllithium **27**, is utterly contrary to the data in Table 4, and to their interpretation. **27** crystallizes as a dimer with three molecules of dimethoxyethane (DME), (**27**·DME)$_2$·DME[62] (Fig. 2).

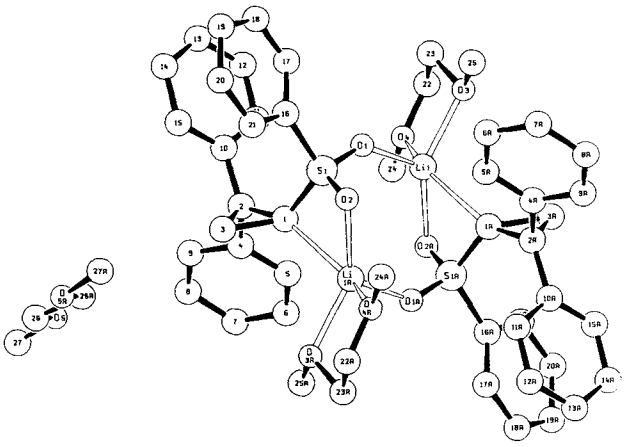


Fig. 2. Crystal structure of (**27**·DME)$_2$·DME [62].

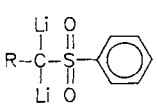
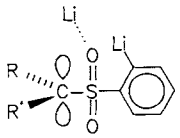


As in the crystal structures of the lithiosulfones **16**–**22**, the Li and sulfonyl O atoms are linked in such a way as to produce the typical (S-O-Li-O-S-O-Li-O) eight-membered ring. Each Li atom is bound to one DME molecule, with an additional molecule of DME cocrystallizing outside the "dimer". The most striking feature is that the $PhSO_2$ group is bent 61.7(5)° out of the plane of the cyclopropane ring. The bond between the Li atom and C_α (C1–Li1A 244.0(14) pm) is unique for lithiosulfones, and may be attributable to the high charge density in the exocyclic "anion" orbital. The bond axis C1–Li1A forms an angle of 24.9(6)° with the plane of the three-membered ring. Compared with the n_C–$\sigma^*_{S\text{-}C}$ interaction, a p_π–d_π interaction (delocalization) should therefore be of secondary importance in the stabilization of α-sulfonyl "anions".[34,63]

A glance at the literature shows how different **27** is from other cyclopropyl "anions" in which the charge is stabilized by delocalization. Because of the additional strain exerted by the double bond, cyclopropyl ester-enolates, for example, are highly reactive compounds even at −78°C, and can only be handled using special techniques.[64–66] The nitronate of nitrocyclopropane cannot be trapped with an electrophile (except in H/D exchange reactions), let alone be analyzed spectroscopically.[67] In contrast, 2,2-dimethyl-1-(phenylsulfonyl)cyclopropyllithium is—quite in accordance with the findings quoted above—stable even at 80°C in THF/DMSO.[21] Remarkably, we also found a tetrahedral α-C atom in the cyanocyclopropyl "anion" **64**. This agrees with the observation that, nitrile groups stabilize a negative charge predominantly by induction, and like the sulfone group not by delocalization (see Section 6).



Thus, the X-ray crystal structures of lithiosulfones **16**–**22** and **27** published in the last three years, quantum mechanical calculations, and earlier kinetic and NMR spectroscopic studies provide a largely consistent picture of the structures of this class of compounds. The structure of a monomeric lithiosulfone is not known to date. It would also be interesting to know the C_α–S and S–O bond lengths in a lithiosulfone forced to adopt a conformation around the C_α–S axis which is rotated 90° from the optimum *gauche* conformation, e.g., that derived from **8**.

2.2. Dilithium Compounds

Dilithium derivatives[68] of sulfones have also been known for some time, and play a role in synthetic chemistry.[69] In systematic studies using reactions and NMR spectroscopy, *Gais* et al.[70] were the first to show that on synthesis of these compounds from sulfones or lithiosulfones and *n*-butyllithium the α,α-dilithio compounds **28** are not the only possible products.

28a: R = $CH{=}CH_2$
28b: R = Ph
28c: R = $SiMe_3$

29a: R = $CH{=}CH_2$, R' = H
29b: R = Ph, R' = H
29c: R = $SiMe_3$, R' = H
29d: R R' = $CH{=}CH{-}CH_2{-}CH_2$
29e: R = R' = $SiMe_3$

Reactions of phenyl sulfones, for instance, lead to the formation of α,*o*-dilithiosulfones **29** as well; in addition, the transformation **29** → **28** is observed. Thus, the α,α-"dianion" **28a** is only formed from the α,*o*-"dianion" **29a**, which is the initial product,[70a] upon raising the temperature. **29b** and **28b** behave similarly.[70c] The α,*o*-"dianion" **29c** is not formed; only the α,α-isomer **28c** is observed.[70b] In the case of **29d** and **29e** the α,α-compounds cannot be formed.[70c]

The most notable aspect of NMR studies of the α,*o*-dilithium compounds **29a**, **29d** and **29e** is the spectroscopic similarity of their α-C atoms to those of the corresponding α-monolithiosulfones. As X-ray structure determinations on monolithiosulfones **16**–**22** have shown, the Li atom is bound to the sulfonyl O atoms, not, however, to the α-C atom. *Boche* et al.[71] have also found exactly this bonding situation in **29e**, which crystallizes as an ether solvated, dimeric α,*o*-dilithium compound (Fig. 3).

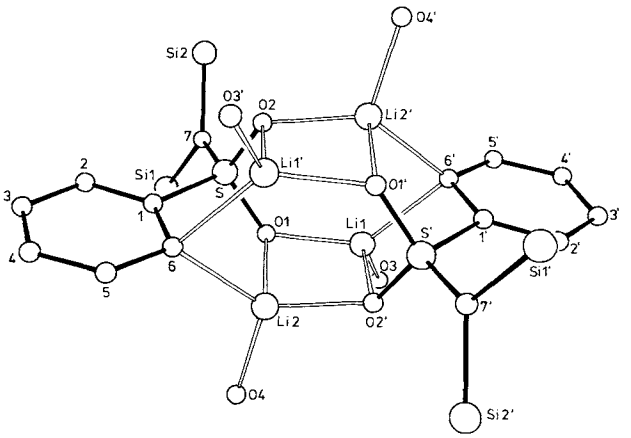


Fig. 3. Crystal structure of (**29e**)$_2$·4 Et_2O [71].

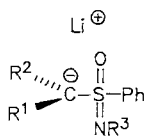
Figure 3 shows the characteristic (S-O-Li-O-S-O-Li-O) eight-membered ring of monolithiosulfones. The C_α-S bond is shortened to 163.7 pm, the lone pair of electrons on C_α adopts a *gauche* conformation with respect to the sulfonyl O atoms (rotated by ca. 18.5°), and the α-C atom is slightly pyramidalized.



Additionally, **29e** represents an example of an *ortho*-lithium compound that is stabilized by coordination of an RSO_2 group. This type of structure was previously unknown.[72] Each Li atom is bound to an anionic phenyl C atom and to a sulfone O atom, giving rise to a five-membered (C-C-S-O-Li) ring, which is favorable for complex formation. A further coordination site on the lithium is occupied by an O atom of the sulfone group of the second "molecule", leaving a fourth coordination site vacant for the O atom of an ether molecule.

Regio- and stereocontrolled reactions of organolithium compounds, e.g., *ortho* lithiation and other reactions in which "complex-induced proximity effects" play a role, are currently of much synthetic significance.[73] RSO_2 substituents act as strongly directing groups in these reactions.[73b]

Recently, *Gais, Günther, Lindner* et al. have reported[74] the X-ray structure and the results of NMR spectroscopic studies for the α,α-dilithium compound dilithiotrimethyl(phenylsulfonylmethyl)silane **28c**. The crystal structure differs from those of the monolithium compounds **16**-**22** and **27** and from that of the α,*o*-dilithium compound **29e** in several respects. In **28c**, six "dianions" are aggregated to form $(\mathbf{28c})_6 \cdot Li_2O \cdot 10\,THF$. Most importantly, however, there are three different dianionic α-C atoms, each of which is bound to at least two Li atoms; obviously, the double negative charge on C_α must also be stabilized by Li-C bonds! (A similar bonding situation has also been observed for a dilithiated nitrile, see Section 10.2.) In the absence of Li_2O, **28c** crystallizes as $(\mathbf{28c})_4 \cdot 7\,THF$, whose structure has also been determined. Because of its solubility in THF, $(\mathbf{28c})_4 \cdot 7\,THF$ is amenable to multinuclear NMR spectroscopic studies. ^1H, ^{13}C, and ^6Li NMR data showed that also in solution one C atom is bound to two different Li atoms.

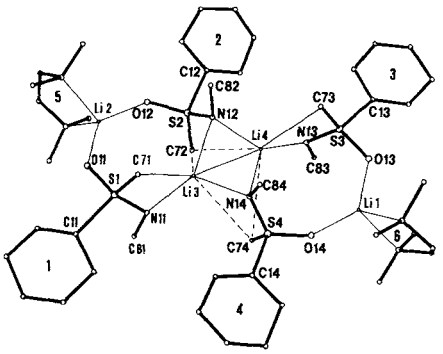
3. Lithium Compounds of Sulfoximides

Far less information is available on the structures of lithium compounds of sulfoximides (e.g., **30**) than for the related lithiosulfones, despite the fact that the former are of interest in asymmetric synthesis,[75] on account of the chiral center at sulfur.

30a: $R^1 = R^2 = H$, $R^3 = Me$
30b: $R^1 = R^2 = [^{13}C]Me$, $R^3 = Me$
30c: $R^1 = H$, $R^2 = R^3 = SiMe_3$

The first structural clues came from a ^{13}C NMR spectroscopic study by *Chassaing* and *Marquet*.[30a] On the basis of the $^1J_{CH}$ coupling constants of **30a** in THF, they concluded that the configuration of the α-C atom is pyramidalized, as in the corresponding α-sulfonyl "carbanion". The sulfoximide acidity measurements made by *Bordwell* and coworkers[28,31] are summarized in Table 4, together with the sulfone acidity measurements that were discussed in detail previously (see Section 2.1). As will be shown below, it can be assumed that an $RS(O)(NSO_2R')$ substituent, like an RSO_2 group, stabilizes a negative charge by n_C-σ^*_{S-C} interaction. For both the $RS(O)(NSO_2R')$ and RSO_2 groups, however, it remains unclear how the data in Table 4 and the conclusions drawn from them can be reconciled with this fact.

Detailed structural information was provided by the X-ray structure analysis of the sulfonimidoyl compound $((S)\text{-}\mathbf{30a})_4 \cdot 2\,TMEDA$, which was published by *Gais* et al. (Fig. 4).[76]



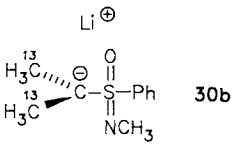


Fig. 4. Crystal structure of $((S)\text{-}\mathbf{30a})_4 \cdot 2\,TMEDA$ [76].

In contrast to the α-sulfonyl "carbanions" described in Section 2.1, **30a** does not crystallize as a dimer, but rather as a tetramer. The Li atom and the (*S*)-(*N*-methyl-*S*-phenylsulfonimidoyl)methanide moiety each occur in two different coordination environments. Li1 and Li2 are each coordinated to TMEDA and to the O atoms of two different "carbanions" (O13,O14 and O11,O12, respectively), a pattern equivalent to that found in α-sulfonyl "carbanions". Each of the other two Li atoms (Li3 and Li4), which are separated by only 278(5) pm, is coordinated to three N atoms of a sulfoximide group (N11,N12,N14 and N12, N13,N14, respectively), and to an "anionic" C atom (C71 or C73) with a mean Li-C distance of 249(5) pm). Thus, the Li-C bond in $((S)\text{-}\mathbf{30a})_4 \cdot 2\,TMEDA$ fundamentally differentiates this structure from those of the α-sulfonyl "carbanions" **16**-**22**, in which only Li-O bonds were observed!

The authors also discern a contact between the other two "anionic" C atoms (C72 and C74) and Li3 and Li4, respectively. The mean Li-C distance of 323(4) pm is, however, so large that it can hardly represent a bonding interaction. The S-CH_2 distances (mean value 164(2) pm) are shortened relative to the S-C distances in *S*-methylsulfoximides (mean value for nine compounds: 174 pm), though not to the same extent as in α-sulfonyl "carbanions" (see Section 2.1). Since the position of the H atoms on the "anionic" C atom could not be determined, nothing can be said about the configuration of this carbon, or about the conformation about the C-S axis.

Some information concerning the structure in solution ([D_8]-THF) was obtained using the ^{13}C-labeled compound **30b**.

30b

A diastereotopomerization of the two $^{13}CH_3$ groups was observed, caused either by rotation around the C–S bond, if the configuration of the "anionic" C atom is planar, or by rotation and inversion if it is pyramidal. The $\Delta G^{\neq}_{70°C}$ value for the topomerization is 9.2 ± 0.2 kcal mol^{-1}. It was, however, not possible to determine which mechanism is responsible for the topomerization. Preparatively, it is significant that even at $-70°C$ α-sulfonimidoyl "carbanions" of type **30**, $R^1 \neq R^2$, are not configurationally stable. It is interesting that an asymmetric elimination, with which 1-alkenylsulfoximides have been synthesized with a high degree of induction, was explained in terms of this configurational lability.[77]

30c could be crystallized without donor ligands, as the tetramer $(\mathbf{30c})_4 \cdot 2C_6H_{12}$.[78] The crystal structure is depicted in Figure 5 together with a partial structure showing the atom numbering scheme.

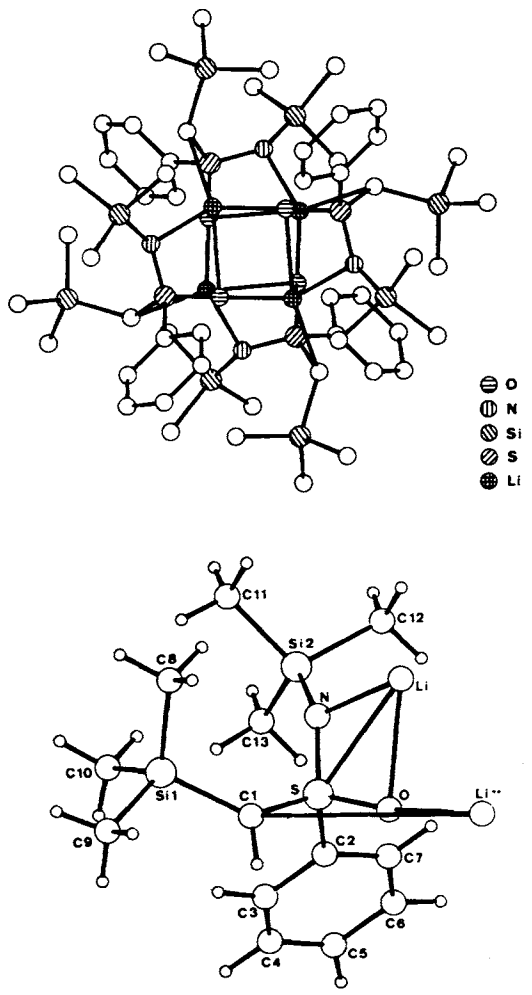

Fig. 5. Top: crystal structure of $(\mathbf{30c})_4 \cdot 2C_6H_{12}$; bottom: partial structure of $(\mathbf{30c})_4 \cdot 2C_6H_{12}$ with numbering scheme [78].

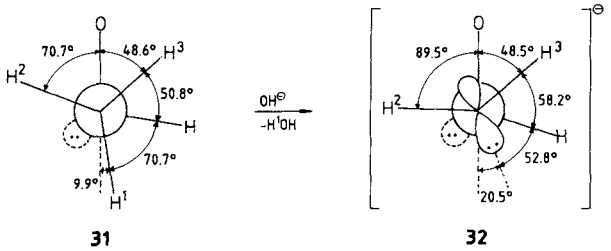
$(\mathbf{30c})_4 \cdot 2C_6H_{12}$ is composed of two *R,R*- and two *S,S*-**30c** diastereomers. A Li_4O_4 cube forms its center. Each Li atom is pentacoordinated to the O and C (!) atoms of one sulfonimidoyl anion, to the N and O atoms of a second, and to the O atom of a third. Two molecules of cyclohexane, derived from the solvent, are also present in the crystal lattice. $(\mathbf{30c})_4 \cdot 2C_6H_{12}$ is readily soluble in hydrocarbons, undoubtedly because the polar core, with its Li and C, N, and O atoms, is well-shielded by the eight trimethylsilyl and four phenyl groups. The configuration at C1 is of particular interest. C1 projects 17 pm out of the plane defined by its substituents S, Si1, and H1, so that C1 is markedly pyramidalized—in accordance with the results of the ^{13}C NMR spectroscopic studies on α-sulfonimidoyl "carbanions" mentioned above.[30] The conformation about the C1–S bond is such that the S–C2 bond lies approximately *anti* to the 243.08 pm long C1–Li** bond. The C1–S bond is—as in $((S)\text{-}\mathbf{30a})_4 \cdot 2$TMEDA—shortened relative to that in the sulfoximide, in this case to 163.7(4) pm.

Here, too, it is likely that a stabilization by n_C–σ^*_{S-C} interactions, in a way similar to that in α-sulfonyl "carbanions",[41,43] is responsible for the observed configuration and conformation. In contrast to the α-sulfonyl case, however, α-sulfonimidoyl "anions" also exhibit bonding between the Li atoms and the "anionic" C atoms. This could be connected with the lower acceptor ability of the sulfonimidoyl group compared to the sulfone group, and with the greater donor character of the O atoms in α-sulfonyl "carbanions" compared to the O and N atoms in α-sulfonimidoyl "carbanions".

The $^1J_{CH}$ coupling constant for the anionic C atom in $(\mathbf{30c})_4 \cdot 2C_6H_{12}$ (in $[D_{12}]$cyclohexane) is 5 Hz larger than that for the corresponding non-lithiated sulfoximide. This points to a hybridization between sp^2 and sp^3 in solution as well, a finding which is in agreement with the crystal structure of $(\mathbf{30c})_4 \cdot 2C_6H_{12}$, and with earlier NMR spectroscopic studies.[30] In THF, which has better solvating properties, Δ^1J_{CH} is significantly larger (15.0 Hz). A different, THF-solvated aggregate must be responsible for this, with a nearly planar "anionic" C-atom and perhaps with no contact to the Li lithium.



It is clear that, in contrast to the lithiosulfones, quite some work still remains to be done to better understand the structures of lithiosulfoximides and their reactions, particularly with respect to chiral induction.

4. Lithium Compounds of Sulfoxides

Because they contain a chiral $R^3S(O)$ group, α-sulfinyl "carbanions" $R^1R^2C{-}S(O)R^3M$ have in recent years proved to be important synthetic building blocks, as is demonstrated by a wealth of publications.[79,80] Almost all of these are also concerned to some extent with the structures of the "α"-lithiosulfoxide reagents.

The first clues to the structures of α-sulfinyl "carbanions" were provided by *Wolfe*, *Buncel* et al., who observed selectivity in the H/D exchange of the diastereotopic methylene protons of benzyl methyl sulfoxide (0.25 M NaOD in D_2O, 75°C).[81a,d] This study has been confirmed several

times, and applied to other sulfoxides,[81b] and was corroborated by *Wolfe* et al. using 3-21G* calculations. The quintessence of these studies is summarized in Figure 6.

31 **32**

Fig. 6. Newman projections of the energetically most favorable conformations of $H_3C-S(O)H$ **31** and its anion $H_2\overset{\ominus}{C}-S(O)H$ **32**, formed by reaction with $OH^{\ominus}$ [81b, c].

H^1, which has a virtually antiperiplanar arrangement with respect to the S-O bond, is cleaved from the sulfoxide $H_3C-S(O)H$ **31**, because the α-sulfinyl carbanion which is thus formed most closely resembles the optimum structure of $H_2\overset{\ominus}{C}-S(O)H$ **32**. The conformation about the C-S axis in **32**, in which the lone pair of electrons on the α-C atom is rotated 20.5° away from the position antiperiplanar to the S-O bond, represents a compromise between maximization of the $n_C-\sigma^*_{S-O}$ and $n_C-\sigma^*_{S-H}$ stabilization as well as minimization of lone pair repulsion.[81d] The configuration of the "anionic" C atom is strongly pyramidalized, with the substituents (H^2 and H^3) bent *towards* the O atom. A counter ion was not included in these calculations.

Further clues to the structures of α-sulfinyl "carbanions", particularly with regard to the position of the counter ion (usually lithium) were derived from reactions with electrophiles.[32, 79a, 82–86] Electrophiles containing oxygen (H_2O, D_2O, CO_2, RCHO, R_2CO and $(CH_3O)_3PO$) react with "α"-lithiosulfoxides in THF with retention of configuration, while CH_3I reacts with inversion (though an exception to this inversion with CH_3I has recently been observed[87]). *Biellmann* et al.,[83] *Durst* et al.,[84] and *Chassaing* and *Marquet*[85] concluded from this that the Li atom in the "α"-lithiosulfoxide is bound to the sulfoxide O and to the α-C atom, and that the stereoselectivity is connected with the ability of the electrophile to form a complex with lithium (Fig. 7).

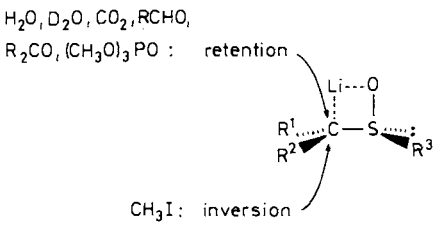


Fig. 7. "Ion-pair" model of "α"-lithiosulfoxides, and diastereofacial differentiation [83–85].

The *n*-BuLi in THF required to form the "α"-lithiosulfoxide is also led to the sulfoxide through complexation of the lithium with the sulfoxide O atom.[87]

Extensive IR, Raman, and ^{13}C NMR spectroscopic studies of lithiosulfoxides have been published by *Chassaing* and *Marquet*.[29, 30, 32] From the C,H coupling constants in **33**, **34** and **35**, they concluded that the α-C atoms in the benzylic anions **33** and **34** are largely planar, while the α-C atom in **35** is hybridized "between sp^2 and sp^3" (see Table 5).

Table 5. C,H coupling constants for the α-C atom of **33**, **34** and **35** [29, 30].

	^1J(C,H)	Δ^1J("anion"-sulfoxide)
$CH_3SOCHPhLi$ **33**	160	+20
*t*BuSOCHPhLi **34**	161	+23
*t*BuSOCH$_2$Li **35**	147.5	+10

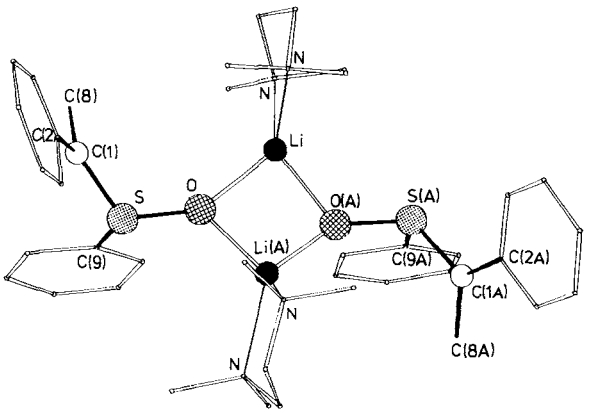
According to a similar study, "α"-lithiothiacyclohexane 1-oxides are planar at C_α.[90] Finally, the topomerization of the α-H atoms in **36a–c** (Table 6) showed that these compounds are configurationally stable only at low temperatures, and that the counter ion has an influence on the rate of topomerization.

Table 6. Coalescence temperature of the signals of the two H atoms on C_α, and ΔG^+ values for the topomerization, for **36a–c** [32].

	$T_{coal.}$ [°C]	ΔG^+ ($T_{coal.}$) [kcal mol^{-1}]
$PhSOCH_2Li$ **36a**	−5	13.6
$PhSOCH_2K$ **36b**	−47.5	10.7
$PhSOCH_2K$ + [2.2.2]Cryptand **36c**	−66	10.7

The force constants derived from the vibrational spectra indicate a shortening of the C-S bond and a lengthening of the S-O bond.[32] A chelate structure, as depicted in Figure 7, was deduced from the presence of C-Li and O-Li stretching vibrations.[32] However, on the basis of ^{13}C NMR spectroscopic studies of fluoro(phenylsulfinyl)methyllithium, *Seebach* suggested that the Li atom might be bound only to the sulfinyl O atom.[91]

The first crystal structure of an α-sulfinyl "carbanion", that of (**38b**)$_2$·2TMEDA, was published by *Boche* et al.[92] The dimer is linked together through a (Li-O-Li-O) four-membered ring (Fig. 8).



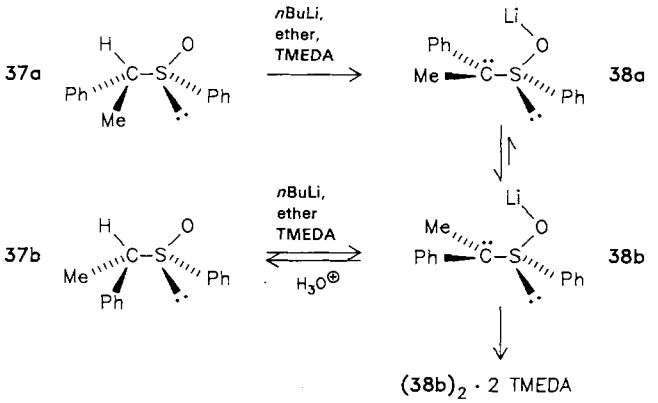


Fig. 8. Crystal structure of dimeric (**38b**)$_2$·2TMEDA [92].

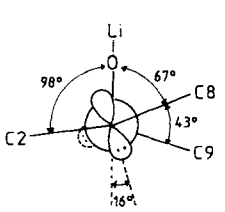
The diastereomer $(\mathbf{38b})_2 \cdot 2$TMEDA is produced from a *ca.* 1:1 mixture of the two diastereomeric α-methylbenzyl sulfoxides **37a**, **b** with *n*-BuLi in ether/TMEDA. The phenyl rings at C1 and S are oriented *trans* to one another (torsion angle C2,C1,S,C9 = 152(1)°). Since protonation of **38** in ether solution yields only **37b**, and since the protonation of α-sulfinyl "carbanions" proceeds stereoselectively (see above), then presumably only one diastereomer is present in solution, i.e., that also observed in the crystalline state, **38b**. From the stereoselectivity of sulfoxide deprotonation with *n*-BuLi in ethereal solvents (see above), one might also have expected formation of the isomeric lithio sulfoxide **38a**. The topomerization data (see Table 6) suggest, however, that in solution at room temperature, **38a** will be rapidly converted into the obviously more thermodynamically stable **38b**.

The C1–S distance of 163(1) pm is distinctly shorter, and the S–O distance of 158(1) pm is somewhat longer than the corresponding bonds in sulfoxides (dimethyl sulfoxide 180 pm and 147 pm, respectively)[93]—a quantification of the vibrational spectral data.[32] Since the torsional angle C1,S,O,Li is 12(2)°, the Li atom does not lie exactly in the C1,S,O plane. The C1–Li distance is extraordinarily large, (400(3) pm), so that one can no longer speak of a C–Li bond (C–Li bonds are shorter than *ca.* 250 pm).[1] This distinguishes the bonding situation of the Li atom found in $(\mathbf{38b})_2 \cdot 2$TMEDA from that which is expected (see Fig. 7). Little can be said about the role of the TMEDA ligands here, since no other lithiosulfoxide structures are known at present.[164] But $(\mathbf{38b})_2 \cdot 2$TMEDA, at least, is not an α-lithiosulfoxide!

The configuration of the anionic C1 atom and the conformation about the C1–S axis of $(\mathbf{38b})_2 \cdot 2$TMEDA deserve particular attention (Fig. 9).



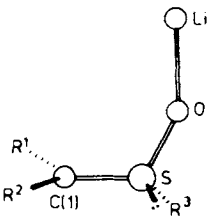


Fig. 9. Configuration of C1 and conformation along the C1–S bond in $(\mathbf{38b})_2 \cdot 2$TMEDA [92].

As can be seen, C1 is non-planar and projects 12(1) pm out of the S–C2–C8 plane; the substituents at C1 are bent *towards* the O atom (and thus also towards the Li atom). A planar benzylic α-C atom had been predicted on the basis of ^{13}C NMR spectroscopic data (see Table 5). The lone pair of electrons at C1 is bent *ca.* 16° away from the antiperiplanar position to the S–O bond, thus reducing repulsion between the two unshared pairs of electrons. The benzylic C1 atom in $(\mathbf{38b})_2 \cdot 2$TMEDA must be more nearly planar than the nonbenzylic C_α of the system $H_2\overset{\ominus}{C}-S(O)H$ **32** used in model calculations (Fig. 6), and should bear less charge. After allowing for this, the calculated structure[81b,c] of the α-sulfinyl anion moiety and that found in the solid state agree surprisingly well, especially considering that the calculations dispense with the Li atom. It is possible that the crystal structure of $(\mathbf{38b})_2 \cdot 2$TMEDA may even offer an explanation of why it is possible to disregard Li in the calculations. Since there is no C–Li bond in $(\mathbf{38b})_2 \cdot 2$TMEDA, the configuration of C_α and the conformation about C_α–S can hardly be significantly affected by the counter ion.

It would be presumptuous, on the basis of a single crystal structure of one α-sulfinyl "carbanion",[164] to attempt to deduce the structures of the entire class of compounds in a variety of media (the molecular weight has yet to be determined). Neither can one explain the observed diastereofacial differentiation, nor the diastereoselectivity of reactions with electrophiles, especially since these are not very pronounced, and exceptions have already been referred to.[87] Nonetheless, some insights can be attained, which—with all due caution—are discussed below.

38b–43

	R^1	R^2	R^3
38b	CH_3	Ph	Ph
39	H	Ph	CH_3
40	H	Ph	*t*Bu
41	H	S-*p*-Tolyl	*p*-Tolyl
42	H	H	*p*-Tolyl
43	H(Ph)	Ph(H)	Ph

Fig. 10. Bonding relationships of C1, S, O and Li in $(\mathbf{38b})_2 \cdot 2$TMEDA [92], and their extrapolation to the structures of **39**–**43**.

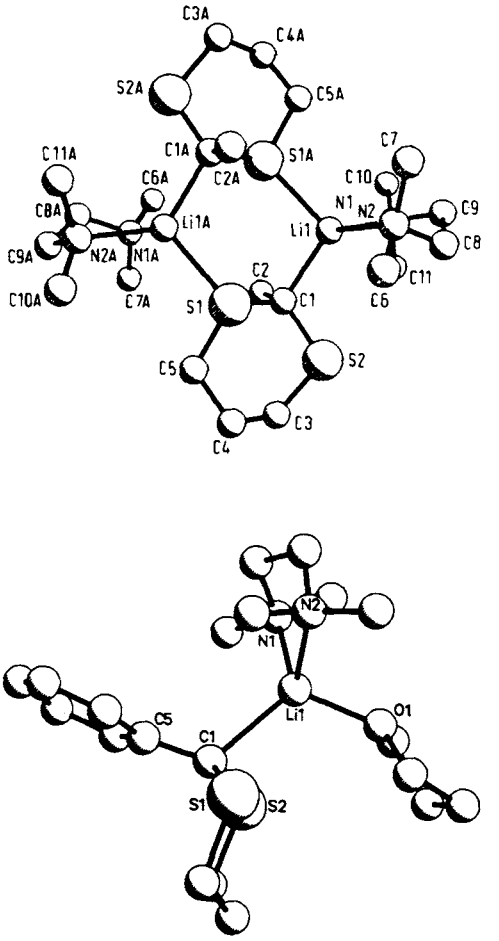
1. It can be seen from Figure 10 that the diastereofacial differentiation found in many cases, which had led to the "ion-pair" model (Fig. 7), is also in accord with the crystal structure of $(\mathbf{38b})_2 \cdot 2$TMEDA. Thus, for O-containing electrophiles, there exists the possibility of forming a complex with lithium with the reaction therefore occurring from the corresponding side.

2. If one assumes that, as in **38b**, the "large" substituents in lithiobenzylmethyl sulfoxide **39** and lithiobenzyl-*tert*-butyl sulfoxide **40** avoid one another, so that the configurations and conformations in these compounds are comparable with those in $(\mathbf{38b})_2 \cdot 2$TMEDA (Fig. 10), then the findings of *Ohno* et al.[80e,87] can be understood as follows. Methyl iodide approaches the methyl compound **39** from the face *away* from O and Li, as is normal, but with the *tert*-butyl compound **40**, steric hindrance from the *tert*-

butyl group is so great that CH_3I favors the otherwise unusual face with the O-Li bond.[164] The fact that lithiobenzylphenyl sulfoxide reacts with CH_3I to form a 1 : 1 diastereomeric mixture agrees with this; apparently when R^3 = Ph, both faces are equally favored.[92]

3. If **41** has the assumed structure, then the diastereoselectivity upon reaction with benzaldehyde found by *Gennari, Scolastico* et al.[94] can also be understood; the O···Li coordinated benzaldehyde approaches in such a manner as to undergo minimal interaction with the *p*-tolyl-S group. Similarly, it is clear why **42**, which is unsubstituted at the anionic C atom, does not react diastereoselectively,[95] although why a certain selectivity is found for the corresponding ZnCl compound is unclear.[96] The fact that the products of the reaction of **43** with benzaldehyde suggest the presence of various diastereomeric lithiosulfoxides could be due to the experimentally proven reversibility of this addition reaction.[97]

Conclusion: just as one swallow does not make a summer, one can not, of course, draw a complete picture of this class of compounds from *one*[164] crystal structure of a lithiosulfoxide. We are further still from understanding the stereoselective reactivity of lithiosulfoxides with electrophiles. It is pleasing, however, that the crystal structure of (**38b**)$_2$·2TMEDA is in overall agreement with the models derived from calculations as well as from selective reactions and spectroscopic data. It remains to be seen if and how structural studies on further lithiosulfoxides will consolidate and refine the current picture.[164]



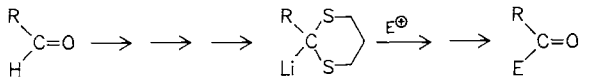


Fig. 11. Crystal structures of (**44a**)$_2$·2TMEDA [99] (top) and **44b**·TMEDA·THF [50a] (bottom).

5. Lithium Compounds of 1,3-Dithianes and Thioethers

5.1. Lithium Compounds of 1,3-Dithianes

Even in the early stages of the "carbanion era", lithiodithianes **44** found extensive use as Umpolung reagents.[98]

44a: R = CH_3
44b: R = Ph

It is therefore not surprising that even at the beginning of the eighties *Amstutz, Dunitz, Seebach* et al. had already carried out X-ray structure determinations of 2-lithio-2-methyl-1,3-dithiane **44a**, which crystallizes as (**44a**)$_2$·2TMEDA,[99] and of 2-lithio-2-phenyl-1,3-dithiane **44b**, which crystallizes as **44b**·THF·TMEDA[50] (Fig. 11).

(**44a**)$_2$·2TMEDA consists of three *trans*-linked six-membered chairs and two Li-TMEDA five-membered rings. The 33 pm difference between the C-Li and S-Li bond lengths corresponds approximately to the difference in the covalent radii of C and S (27 pm). The lithium atom therefore exhibits comparable interactions with the α-C atom of one dithiane ring and the S atom of the other. It is not entirely clear whether the equatorial position of lithium has steric grounds or whether it is due to electronic factors, as was assumed earlier;[100] however, since the methyl group is the smallest of the three substituents on the dithiane ring, it should occupy an axial position for steric reasons.[99] With THF instead of TMEDA, lithiodithiane **44a** also exists as a dimer (**44a**)$_2$·4THF in the solid state.[101] However, there is chemical evidence for a temperature-dependent monomer-dimer equilibrium in THF solution. According to cryoscopic measurements, monomeric **44a** is the major component in THF at low temperatures. Interestingly, TMEDA in THF associates with **44a** only to a small extent, as is also demonstrated by the melting point.[101] The ^{13}C NMR spectrum confirmed the dominant presence of monomeric **44a** at low temperatures.[102]

In contrast to (**44a**)$_2$·2TMEDA, **44b**·THF·TMEDA occurs as a monomer in the solid state. The Li atom is coordinated to the α-C atom, and also to one TMEDA and one THF molecule. The phenyl group in the unmetalated dithiane occupies an equatorial position, but in **44b**·THF·TMEDA it is axially oriented, as was also shown by trapping experiments in solution. At the same time, the plane of the benzene ring is twisted through 90°, whereby the optimum conformation for conjugative charge stabilization is attained. The benzylic α-C atom is, nevertheless, clearly pyramidalized (Fig. 12).

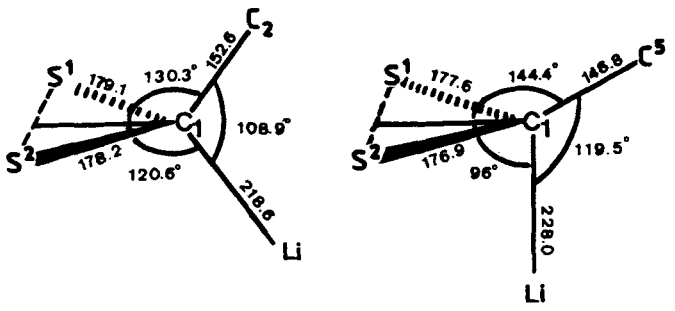

Fig. 12. Bond lengths and configuration at C1 for $(\mathbf{44a})_2 \cdot 2$TMEDA (left) and **44b**·THF·TMEDA [50a] (right).

As shown in Figure 12, the angle of 130.3° between the S1-C1-S2 bisector and the C1-C2 axis in $(\mathbf{44a})_2 \cdot 2$TMEDA changes to "only" 144.4° in **44b**·THF·TMEDA (here the C1-C5 axis). Together with the change in the C-Li bond length and in the angle of the C-Li bond to the bisector (see Fig. 12), this seems to indicate a transition towards a π-complex structure[49] for **44b**·THF·TMEDA. Compared to the differences in reactivity, however, and to the pK_a difference of eight units between the corresponding acids,[50a] these changes appear minor. The conclusions originally drawn[50a] from deformation density distributions about the nature of the C-Li bonds in $(\mathbf{44a})_2 \cdot 2$TMEDA and **44b**·THF·TMEDA were corrected in a later publication.[50b] The crystal structure data leave the question of the ionic nature of the C-Li bond open. On this point the authors adopt the viewpoint of *Streitwieser* et al.:[103] "operational criteria to distinguish charge transfer from polarization effects are difficult to devise, particularly within the limitations of working with real compounds".

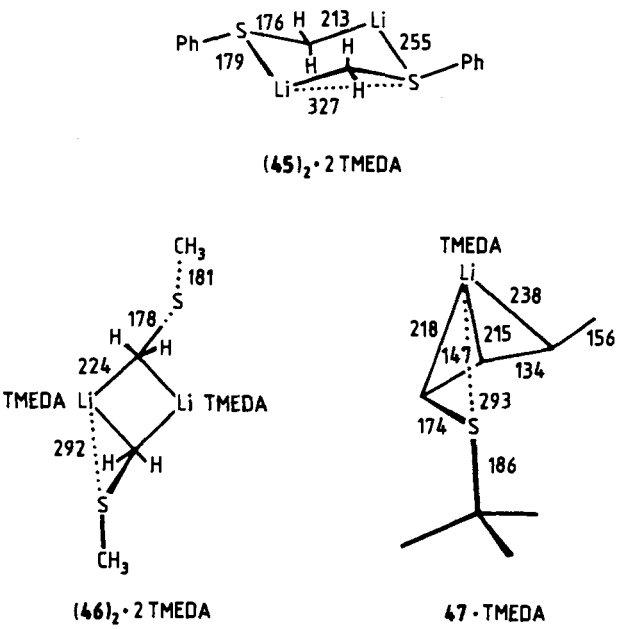
5.2. Lithium Compounds of Thioethers

Up till now, crystal structure data have been obtained for the following α-lithiothioethers (Fig. 13): (phenylthio)methyllithium **45** as $(\mathbf{45})_2 \cdot 2$TMEDA,[50b] (methylthio)methyllithium **46** as $(\mathbf{46})_2 \cdot 2$TMEDA,[50b] and (*E*)-1-(*tert*-butylthio)-2-butenyllithium **47** as the monomeric TMEDA complex, **47**·TMEDA.[104]

$(\mathbf{45})_2 \cdot 2$TMEDA displays similarities to the lithiodithiane $(\mathbf{44a})_2 \cdot 2$TMEDA, but shows differences as well. Both form dimers with a six-membered ring, but in $(\mathbf{45})_2 \cdot 2$TMEDA the Li-C distance, for instance, is shorter than in $(\mathbf{44a})_2 \cdot 2$TMEDA (213.0, compared with 218.6 pm), while the Li-S bond length is longer (255.4, compared with 251.9 pm). Since the phenyl rings in $(\mathbf{45})_2 \cdot 2$TMEDA occupy equatorial positions, each S-phenyl bond lies antiperiplanar to the C-Li bond. If, as in the anomeric effect, this results from an interaction involving the lone pair of electrons on C_α and the $\sigma^*_{S\text{-phenyl}}$ orbital, then $C_{methylene}$-S (175.9 pm) should be shorter and C_{phenyl}-S (179.2 pm) longer than the corresponding bonds in CH_3-S-aryl molecules. Indeed, the Cambridge Structural Database gives mean values of 182.1 and 176.8 pm, respectively, which confirm these expectations.

Strangely, methylthiomethyllithium **46** dimerizes through a (Li-C-Li-C) four-membered ring to give $(\mathbf{46})_2 \cdot 2$TMEDA. There is no obvious explanation for the difference between this and $(\mathbf{45})_2 \cdot 2$TMEDA. The difference in energy between the six- and four-membered rings is probably only small. Although this difference "will doubtless soon be explained using semi-empirical or ab initio calculations",[50b] this has not yet happened.

The four-membered ring in $(\mathbf{46})_2 \cdot 2$TMEDA is folded along the Li-Li axis by 22°. Each C atom in the ring is five-fold coordinated, to two H atoms, two Li atoms and one S atom. The H-C-H and H-C-S bond angles are all close to the tetrahedral angle (between 103.3 and 109.2°), so that C_α can be described as sp^3-hybridized.



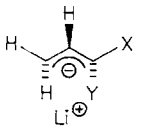


Fig. 13. Crystal structures of lithiothioethers.

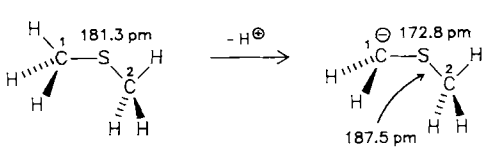
The structure of lithiated 2-butenyl-*tert*-butyl sulfide **47**·TMEDA is of particular importance, since organometallic compounds of this type (i.e., also those with heteroatoms other than sulfur) are important as heterosubstituted allyl anion synthons.[105] Its reactions suggest a *cis* (*syn*) configuration for the "6π-electron, 4 atom" system.[106] The structure of such an "anion" was until now, however, unknown.

The following structural features are characteristic. The Li atom is bound to all three C atoms of the allyl moiety, as well as to the TMEDA N atoms (see Fig. 13). On the basis of the distance between Li and S (293 pm), there appears to be no interaction between them. The S atom lies in the plane of the allyl C atoms, and adopts a *cis* (*syn*) configuration, in agreement with the conclusions reached from trapping experiments.[106] The Li atom lies above and the *tert*-butyl group below the plane of the allyl C atoms. The *t*Bu-S bond is exceptionally long; at 186 pm, it is the longest known to date. The cause of this is again probably the n-σ* interaction mentioned above for **45**. The bond lengths in the allyl moiety are not appreciably different from those in allyl thioethers: C2-C3 134 (134 pm), and C1-C2 147 (149) pm.

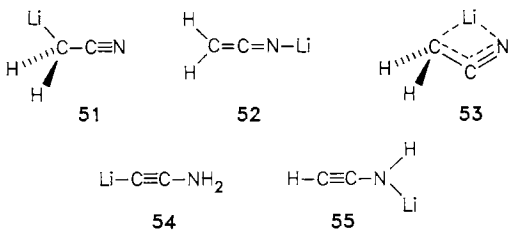


Can we use this structure to say anything about the α/γ-selectivity in reactions of such compounds with electrophiles? If **47**·TMEDA is a model of the reactive species, then the position of the Li atom, more or less in the center of the allyl group, shows that the counter ion cannot be crucial for α/γ selectivity. The structure accords far better with a situation in which all possible parameters, such as solvent, counter ion, coordination partner, temperature, electrophile, etc., are able to influence the course of the reaction.[105] Understanding such complexity is at present beyond the capabilities of the chemist.

48a: X = H, Y = SH
48b: X = SH, Y = H

The crystal structure of **47**·TMEDA was also compared with model calculations for *cis*(*syn*)-**48a** and *trans*(*anti*)-**48b**. The *cis*(*syn*) isomer is the more stable. Using 3-21G this extra stability amounts to 6.8 kcal mol^{-1}, while with 3-21+G‖3-21G it is 6.5 kcal mol^{-1}. The C1-C2-C3-Li moiety largely corresponds with that calculated for allyllithium,[107] with the allyl group as an η^3-ligand, and with an ionic bond to lithium. Interestingly, in both isomers the position of the Li atom is affected only negligibly by the position of the S atom, indicating the absence of a covalent Li-S bond; however, electrostatic interactions are also conceivable. Like the H atoms in allyllithium, the substituents are bent out of the C1-C2-C3 plane;[107] the inner ones away from lithium, the outer ones remaining largely in the plane, and H2 towards lithium. The most notable difference between the crystal structure of **47**·TMEDA and the calculated ("gas-phase") structure of **48** is the greater asymmetry in the coordination sphere of the Li atom in **47**·TMEDA. In the solid state, the difference between C1-Li and C3-Li distances is 20 pm, while the calculated values differ by only 10 pm. The C-C bonds also differ considerably between the two structures. While in **47**·TMEDA they amount to 147 and 134 pm, in **48a** they lie only 1.4 pm apart. Although it is not clear at present what determines these differences, the "reproduction" of the solid state structure by the calculations is on the whole satisfying and encouraging.

The question of how an RS group stabilizes an adjacent negative charge was first studied by *Wolfe* et al.[41, 108] On moving from dimethyl sulfide **49** to the anion **50**, their calculations show a shortening of the C1-S bond and a lengthening of the S-C2 bond, in keeping with the experimental data for lithiosulfides (see above).



49 **50**

According to *Wolfe*, the participation of a sulfur d-orbital plays an important role here. Renewed investigations by *von Schleyer, Houk* et al.[109] concluded, however, that d-orbitals are only important in determining the geometry, and not the energy.

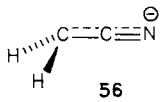
6. Lithio Compounds of Nitriles

There is no doubt that the extent of application of cyano-stabilized "carbanions" in synthesis[110] is inversely related to the knowledge of their structures. Only recently have these compounds become known in more detail. A comprehensive article by *von Schleyer, Moffatt* et al., which appeared in 1986, is concerned with structural calculations for monomeric, dimeric, tetrameric, solvated and non-solvated, lithium (and also sodium and magnesium) compounds of this type.[111] Calculations were also carried out for anions without counter ions. Some of the earlier experimental results, which are summarized in Ref. [111], and some of the calculated data will now be briefly discussed.

In principle, metalated monomeric nitriles can occur as *C*-metalated species **51**, *N*-metalated species (ketenimine derivatives) **52**, bridged compounds **53**, and in the case of acetonitrile also as the acetylene derivatives **54** and **55**. These alternatives were originally inferred from IR and NMR spectroscopic studies,[112] but were later revised in favor of ion-pair equilibria.[113]

51 **52** **53**

54 **55**



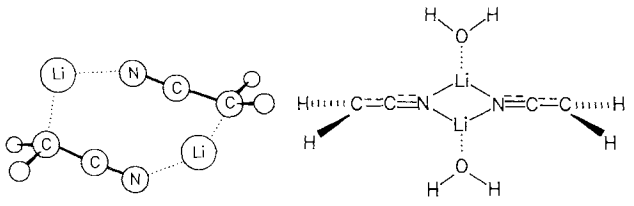
As well as these structural variants, one must—as always with organometallic compounds—take aggregation into consideration. *Das* and *Wilkie*,[114] for example, found that $LiCH_2CN$ is tetrameric in DMSO, and that LiCH(Ph)CN is dimeric in DMSO and in dimethoxyethane. In contrast, *Bauer* and *Seebach* observed dimeric $LiCH_2CN$ in THF between −108 °C and room temperature, and monomeric LiCH(Ph)CN at −108 °C.[101b, 115]

According to calculations at the (MP2/6-31+G*//6-31+G*) level, the anion $CH_2CN^{\ominus}$ **56** has a non-planar α-C atom, although the inversion barrier of 0.3 kcal mol^{-1} is minimal.

It is remarkable that on going from CH_3CN to $CH_2CN^{\ominus}$ **56**, the CN bond is only negligibly lengthened (Table 7).

Of the lithiated monomers, the most stable is the bridged species **53**, followed by the ketenimine derivative **52**, which is higher in energy by 9.7 kcal mol^{-1} (MP2/6-31G*//6-31G*) or 5.8 kcal mol^{-1} (6-31G*//6-31G*). Table 7 lists important bond lengths for both molecules.

Here, too, the comparatively short C-N bonds are clearly apparent.



56

Table 7. Calculated bond lengths [pm] for CH_3CN, **56**, **53**, and **52**.

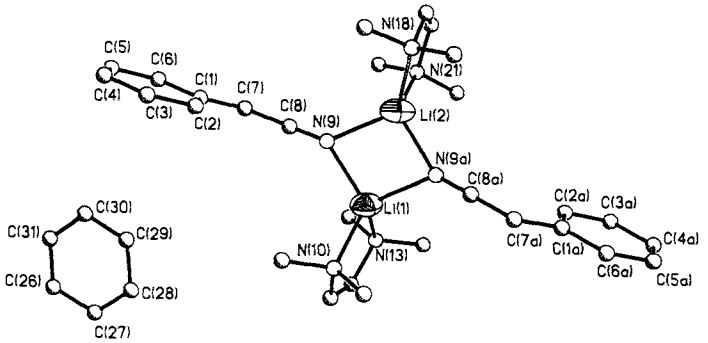
	CH_3CN [a]	**56** [a]	**53** [b]	**52** [b]
CN	113.55	116.22	116.5	118.0
CC	146.87	139.27	139.8	133.0

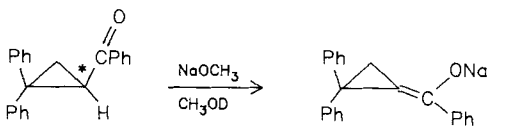
[a] 6-31+G*//6-31+G*. [b] 3-21G//3-21G.

Finally, the molecular weight determinations mentioned above also prompted calculations for dimeric structures; because of the size of the molecules, this had to be carried out using MNDO. Various considerations[111] led to the conclusion that in the absence of solvation the eight-membered ring dimer **57** ought to be most favored, while in ethereal solvents, and in the solid state, the di-solvated four-membered ring dimer **58** (with H_2O as the proven[107b] model for ethereal solvents) should occur.

57 58

What does the structure look like in reality? The first answer to this question was provided by the structure of α-cyanobenzyllithium, which crystallizes as $(\mathbf{59})_2 \cdot 2\text{TMEDA} \cdot C_6H_6$ (Fig. 14).[116]





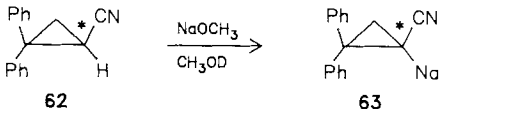


Fig. 14. Crystal structure of $(\mathbf{59})_2 \cdot 2\text{TMEDA} \cdot C_6H_6$ [116].

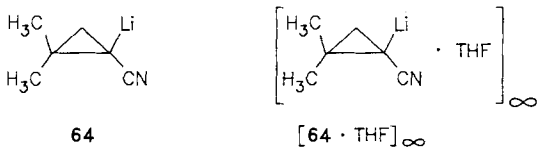
59 is the first lithionitrile to have yielded crystals that could be examined by X-ray crystallography. The co-crystallization of benzene (closest distance to the lithium compound: 378 pm) appears to be decisive here, since $LiCH_2CN$ and LiCH(Ph)CN have long been known as solids. The structure found in the solid state and that determined by MNDO-calculations[111,117] should therefore be the same as that indicated by the molecular weight determination[114,115] in solution at room temperature. Furthermore, the small difference in the heats of formation between $(\mathbf{59})_2 \cdot 4NH_3$ and $2\,[\mathbf{59} \cdot 3NH_3]$ $(-2NH_3)$ of only ca. 5 kcal mol^{-1} (MNDO)[117] suggests that **59** is a monomer[101b,115] in THF at −108 °C for entropy reasons. It is interesting that in lithionitrile **59**, too, the Li atom has no contact with the "anionic" C_α-atom, so that this is not an α-lithio compound either! To what extent the TMEDA ligands are responsible for this cannot be said at present. However, it appears that they are not important, as indicated by the crystal structure of the lithioaminonitrile **83**, in whose case the Li atoms are complexed with the O atoms of ether molecules (see Section 10.1). At −35 °C, the hydrogen atoms at C-7 and C-7a of $(\mathbf{59})_2 \cdot 2\text{TMEDA} \cdot C_6H_6$ could be located, and the sum of the bond angles at C7 (360°) and C7a (359.5°) determined. These atoms are therefore planar, which on the basis of their benzyl "anion" character and the inversion barrier in anion **56** of only 0.3 kcal mol^{-1}, is quite plausible.

The bonding situation in the almost linear C-C-N unit of **59** ($\sphericalangle$ = 178.4(1.0)°) is of particular interest. The C7-C8 and C8-N9 distances are 137.8(8) and 117.9(8) pm, respectively (mean values). The C-N distances calculated for **56** (116.22), **53** (116.5) and **52** (118.0 pm) therefore agree satisfactorily with those found in **59**. In nitriles, such as acetonitrile,[118] the C-N distance (115.7 pm) is only slightly shorter; in comparable ketenimines such as $Ph_2C{=}C{=}N{-}C_6H_4{-}p\text{-Br}$, by contrast, one finds shorter C-C, and above all significantly longer C-N bonds (133.0 and 124.0 pm, respectively),[119] in accordance with IR spectroscopic data.[116] The structural similarity of the lithium "keteniminate" **59** to normal ketenimines is hence considerably less than that of a lithium enolate to enol ethers, for which the pairs of C=C and C-O distances are almost identical.[120] The reason for this is probably a different mode of stabilization of the negative charge. While a carbonyl group acts predominantly via delocalization, in the nitrile group the (inductive) field effect also plays a considerable part. The "cyclopropyl effect" illustrates this difference splendidly. The comparatively less acidic (−)-(*R*)-(2,2-diphenylcyclopropyl)phenyl ketone **60**, for example, shows a k_R/k_E value of 1, on H/D exchange (0.1 M $NaOCH_3$ in CH_3OD).[121] The low acidity and complete racemization result from the additional strain that the planar enolate **61** introduces into the three-membered ring.



60 61

62 63

In the optically active nitrile **62**, a comparable experiment (1.0 M $NaOCH_3$ in CH_3OD) gives a contrasting k_R/k_E value of 1.2×10^{-4}, corresponding to 99.9 percent retention of the therefore at least strongly pyramidalized cyclopropyl "anion" **63**.[122,123] It was left to an X-ray structure determination to show that a nitrile group can also stabil-

ize a negative charge when the anionic α-C atom has a fully tetrahedral configuration. Figure 15 shows the structure of 1-cyano-2,2-dimethylcyclopropyllithium **64**, which crystallizes as $[\mathbf{64}\cdot THF]_\infty$.[124]

64 $[\mathbf{64}\cdot THF]_\infty$

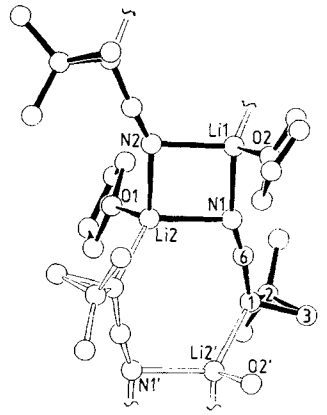


Fig. 15. Crystal structure of $[\mathbf{64}\cdot THF]_\infty$ [124].

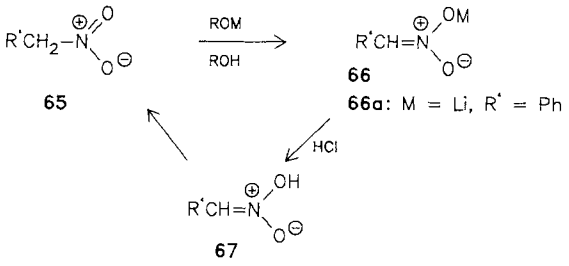
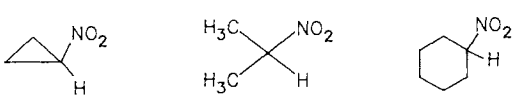


First, one observes that each Li atom is bound to the N atoms of two nitrile groups, producing the (Li-N-Li-N) four-membered ring also found in **59** (and calculated for **58**). The CN group, however, is no longer situated on a planar α-C atom, but on a tetrahedral one; it lies at an angle of 57.6° to the plane of the three-membered ring. At the same time, the anionic C atom possesses a short (214.3 pm) C-Li bond. This coordination, which leads to a genuine α-lithionitrile, is probably due to the high electron density in the exocyclic, "anionic", three-membered ring orbital, as is the case in the cyclopropylsulfonyl "anion" $(\mathbf{27}\cdot DME)_2\cdot DME$. The consequence of this is that, in addition to the (Li-N-Li-N) four-membered ring, one observes the (C-C-N-Li-C-C-N-Li) eight-membered aggregation pattern that was also predicted (see **57**). The C-Li axis is severely bent (51.8°) out of the plane of the cyclopropyl ring. The C1-C6 (140.0 pm) and C6-N1 (117.8 pm) bond lengths are not very different from those in cyclopropanecarbonitriles (e.g., cyclopropane-1,1,2,2-tetratetracarbonitrile: CC, 144.2 pm; CN, 115.0 pm).[125] This, together with the marked displacement of the nitrile group out of the plane of the three-membered ring, accords well with the importance of the (inductive) field effect in the stabilization of a negative charge by this acceptor substituent.[34]

It is also remarkable that the C2-C3 bond opposite to the nitrile group is shorter (147.3 pm) than either of the two adjacent bonds (C1-C2 150.0 pm; C1-C3 152.2 pm). This situation is expected for acceptor-substituted cyclopropanes if the 3*e'* Walsh-orbital can interact with an acceptor π*-orbital.[126, 127] This seems, therefore, still to be the case, even for the cyanocyclopropyl anion **64**.[128]

Conclusion: Although only two crystal structures of lithiated nitriles are available,[159] these, together with the solution studies, give a unified picture of the nature of lithionitrile structures, and of how a nitrile group stabilizes a negative charge. The (inductive) field effect is of great importance here. Once again, the agreement between calculations and solid-state structures should be particularly stressed, since not only the correct C-N bond lengths, but also the tetrahedral configuration of the cyanocyclopropyl "anion"[129] and the four- and eight-membered coordination rings were found both theoretically and experimentally.[159, 165]

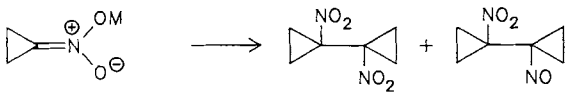


7. Lithiated Nitro Compounds

Although the "nitronate" structure **66** of nitro-"carbanions" is not really in question, until recently no simple member of this class of compounds had been structurally characterized. The formation of nitronates[130-132] has, however, been known since the end of last century, as has their protonation to give nitronic acids **67**,[133] which isomerize to the more stable nitro compounds **65**.

65 **66** **66a**: M = Li, R' = Ph **67**

Recent NMR investigations by *Bradamante, Pagani* et al.[34] are in agreement with the supposed structure of nitronates. Extensive information concerning their applications in synthesis is also available.[134] Nitro compounds and nitronates are of particular importance in substitution reactions that proceed with electron transfer.[135] The kinetic and thermodynamic acidity of nitro compounds has been intensively researched, since nitro compounds are deprotonated astonishingly slowly, given their high acidity.[136, 137] The much greater acidity of nitro compounds in hydroxylic solvents, such as alcohol and water, compared with that in non-hydroxylic solvents such as dimethyl sulfoxide is also noteworthy, as is the extraordinarily low acidity of nitrocyclopropane **68** as compared to **69** and **70**[138] (Table 8).

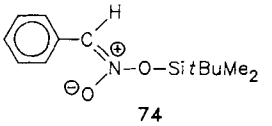


68 **69** **70**

Table 8. Equilibrium acidities pK_a of the nitro compounds **68**, **69**, and **70** in CH_3OH/H_2O (1/1) and in DMSO [137b].

	CH_3OH/H_2O (1/1)	DMSO
68	> 18	26.9 ± 0.2
69	8.85 ± 0.02	16.89 ± 0.05
70	10.07 ± 0.01	17.90 ± 0.05

The generally higher acidity of nitro compounds in hydroxylic solvents is attributed to stabilization of the nitronate by hydrogen bonding.[137a-c,e]



The lower acidity of the cyclopropane derivative **68** corroborates the assumption of a "nitronate" structure **71** for the corresponding "anion", in which an exocyclic C=N double bond gives rise to additional strain.[137b] However, except for H/D exchange, the nitronate **71**, which was generated using a wide variety of bases, could not be trapped by any of the many electrophiles tried.[67] Instead, under the reaction conditions used, **71** rapidly "dimerizes" to furnish **72** and **73**.[67] Therefore, several possible explanations for the reactivity and for the structure of **71** have been discussed.[67,139] The calculated acidity of nitrocyclopropane also does not conform to the pattern found for other CH-acids.[140]

71 **72** **73**

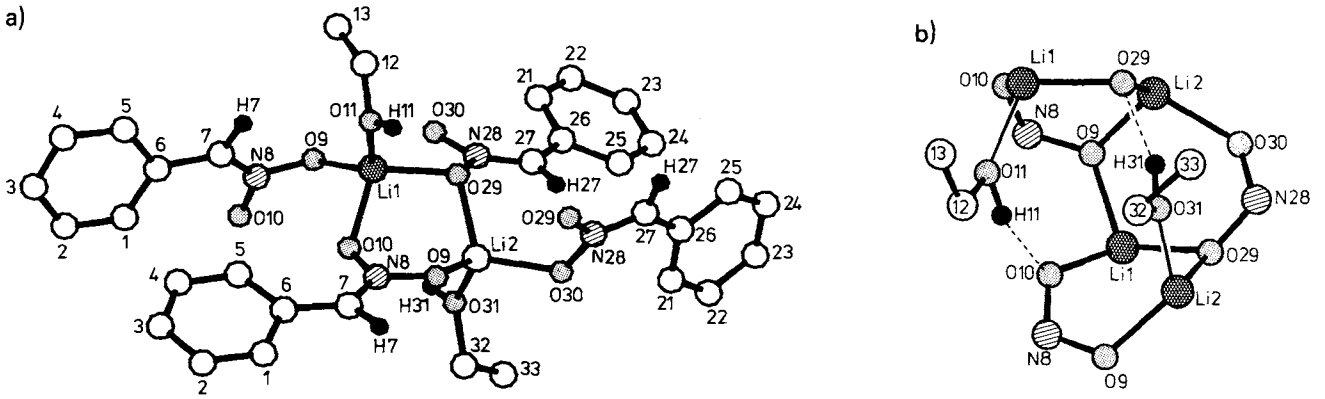
Boche et al. have recently reported the crystal structure of α-nitrobenzyllithium **66a**, which was synthesized from phenylnitromethane **65a** and lithium ethanolate in ethanol, and which crystallizes with ethanol as a polymeric aggregate [**66a**·EtOH]$_\infty$ (Fig. 16).[141] Each Li atom is bound to an O atom of three different nitronates and to an ethanol O atom. This gives rise to six-membered (Li-O-N-O-Li-O) rings, which are annelated through common Li and O atoms to form an endless, ribbon-like structure, which is additionally stabilized by hydrogen bonding. Once again, then, this is not an α-lithio compound! The best plane through C7, N8, O9 and O10 in the nitronate moiety is rotated by 15.2° with respect to the plane through C1-C6. This twisting, and the marked increase in the C1-C6-C7 (126.8(5)°), C6-C7-N8 (126.5(5)°) and C7-N8-O10 (124.7(5)°) bond angles beyond 120°, ensure weaker van der Waals repulsion between H1 and O10 (separation 236 pm). Similar bond angles were found in **74**.[142]

The C7-N8 bond in the nitronate [**66a**·EtOH]$_\infty$ (129 pm) is much shorter than the corresponding bond in uncharged nitro compounds, while the N8-O9 and N8-O10 bonds (133 and 130 pm) are longer. In 1,2-diphenyl-3-nitrocyclopropene, for example, CN 151.8, NO 121.4 and 121.7 pm are found.[143] The C7-N8 bond length in [**66a**·EtOH]$_\infty$ is approximately the same as that in the silyl nitronate **74** (130.2 pm).[142] If and how this finding can be applied to cyclopropyl nitronate **71** is not at present clear,[67,139] but the low acidity of nitrocyclopropane **68** and the high reactivity of nitronate **71** are probably connected with it.

74

The ethanol included in the crystal, and its hydrogen bonds to the nitronate O atoms (see Fig. 16b), confirm the explanation proposed for the increased acidity of nitro compounds in hydroxylic solvents.[137] As in the solid state, hydrogen bonding should also stabilize the nitronate in solution.

The solid-state structure of [**66a**·EtOH]$_\infty$ could perhaps serve as a model for the protonation of nitronates in solution to give nitronic acids. It is tempting to regard the hydrogen bonds, in the sense of the correlation principle,[144] as representing the initial stage in this reaction, and the structure of the fragment composed of phenylmethyl nitronate and ethanol as one point on the reaction pathway.[145] However, structural correlations of this type gain reliability only after statistical evaluation of a large number of structures containing a comparable structural fragment, so that the single finding in [**66a**·EtOH]$_\infty$ must be corroborated by further examples.



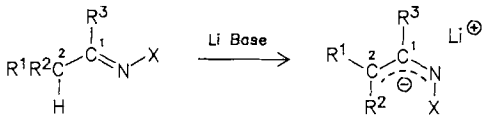


Fig. 16. a) Section of the crystal structure of [**66a**·EtOH]$_\infty$. b) Partial structure showing the hydrogen bonds.

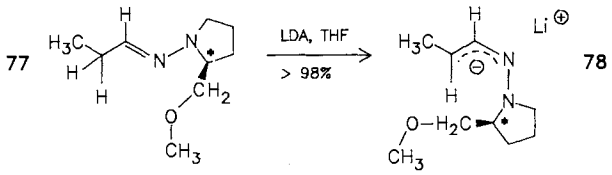
8. Lithium Compounds of Hydrazones

Lithiohydrazones **76a** belong to the large group of 1-azaallyl "anions" **76** (metalloenamines, alkylidenamine-"anions", aza-enolates).

They are prepared from hydrazones **75a** (where X can also be an N-heterocycle) by deprotonation with lithium bases. Metalated alkylidenamines **76b**, oximes **76c**, and



75 76

a: X = NR^4R^5; b: X = R; c: X = OH; d: X = OR

oxime ethers **76d** are obtained in an analogous manner from **75b**, **75c**, and **75d**, respectively. These 1-azaallyl "anions" are all of great importance in modern organic synthesis.[146] Numerous experimental[146-148] and theoretical[149] investigations into both the structures of 1-azaallyl "anions" **76** and their selective reactions with electrophiles E-X have been carried out, prompted by the practically quantitative asymmetric inductions that have been obtained using chiral 1-azaallylmetal reagents in the past fifteen years.[146-148] An excellent review of research into the structures of 1-azaallyl "anions" up to 1987 has been published by *Collum* and *Kallman*.[150] For reasons of space we have to limit ourselves here to structural studies on lithio compounds of hydrazones **76a**, with occasional references to the general situation in 1-azaallyl "anions", especially since the most recent results concern the former.

A great variety of possible structures exists for lithiohydrazones **76a**. The Li atom can be η^1-N bound, for example, whereby the lithium can interact either with the sp^2-orbital, in the plane of the azaallyl atoms, or perpendicular to them, with the p-orbital. In addition, η^1-C^2, η^3-C^2C^1N, and η^4 bonding with the Li ion are also conceivable; in the last of these the second N atom is also bound to Li. As far as the 1-azaallyl atoms C^2, C^1 and N are concerned, *E* and *Z* configurations are possible at both C^2C^1 and C^1N.

In a systematic study of the stereochemistry of lithiohydrazones **76a**, using ^1H NMR spectroscopy and trapping reactions with electrophiles E-X, *Enders, Newcomb, Bergbreiter* et al.[151] found a clear preference for the E_{CC} and Z_{CN} configurations. The stereochemistry does, however, depend on the solvent. Thus, deprotonation of the chiral propionaldehyde-SAMP (= (*S*)-1-amino-2-(methoxymethyl)pyrrolidine)hydrazone **77** with lithium diisopropylamide (LDA) in THF leads to the E_{CC}-Z_{CN}-lithiohydrazone **78** in >98% yield.

77 78

In the presence of HMPT, both configurations are altered. While the CC configuration could be determined by ^1H NMR spectroscopy, the only evidence for the CN configuration came from trapping reactions with electrophiles E-X. Very little can be said about the conformation(s) around the N-N bond, or about the position of the Li atom, and its mode of bonding to the 1-azaallyl anion moiety. In terms of these findings, the model **79** (Fig. 17) would appear to be most appropriate. Lithium is η^3-bound to the 1-azaallyl anion atoms, and also intramolecularly chelated to the ether oxygen.

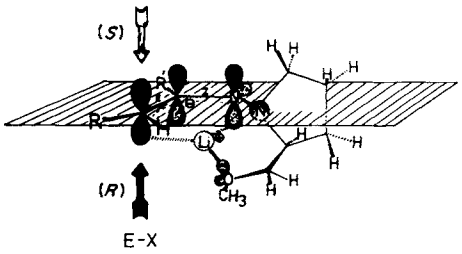


Fig. 17. Model structure **79** of a lithio-SAMP-hydrazone [146f, 151].

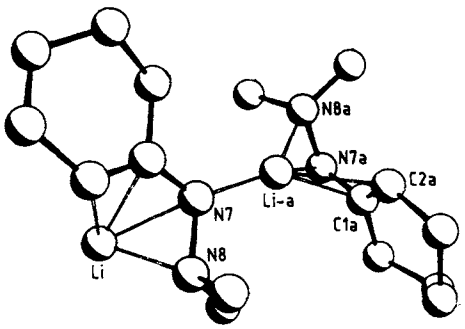
The first crystal structure[152] of a lithiohydrazone was published by *Collum, Clardy* et al.[153] in 1984. The lithiated cyclohexanone dimethylhydrazone **80** crystallizes as the polymer $[\mathbf{80}]_\infty$; the solvent (THF) is not incorporated into the crystal. Figure 18 shows a section of the structure.



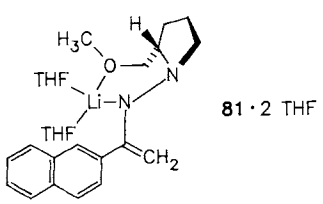


Fig. 18. Crystal structure of the asymmetric unit of lithiated cyclohexanone dimethylhydrazone $[\mathbf{80}]_\infty$ [153].

Remarkably, Li displays two different modes of bonding to the neighboring anions; to one it is bound in an η^1-N manner (N7), while to the other an η^4 bonding mode (N8a, N7a, C1a, C2a) is observed. An osmometric molecular weight determination in THF indicated a degree of aggregation of three or four. In a later paper,[154] the initial assumption that aggregates of **80** reacted with electrophiles E-X was revised in favor of reaction of a bis-solvated monomer. Kinetic studies had revealed the presence of an equilibrium tetramer $\rightleftharpoons$ 4[monomer·2solvent].

According to NMR studies, the crystals of lithiated, chiral 2-acetylnaphthalene-SAMP-hydrazone **81** contain two molecules of THF per molecule **81**;[155] a molecular weight determination in THF revealed the presence of a monomer.[101b]

81·2 THF

Recently, an X-ray structure determination of **81**·2THF was carried out.[156] As Figure 19 shows, **81**·2THF occurs

as a monomer in the solid state so that one can assume the situation in the solid to be a useful model for that in THF solution.

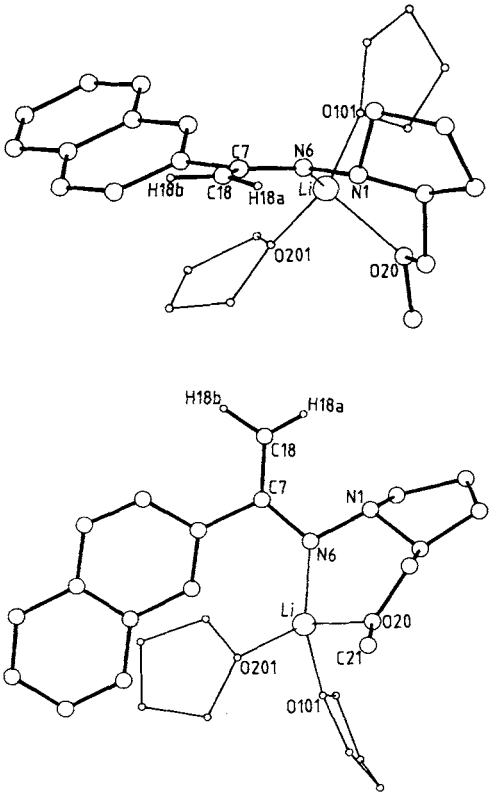

Fig. 19. Two views of the crystal structure of **81**·2THF [156].

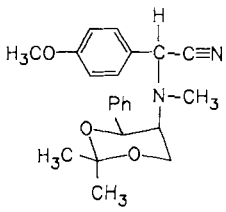
In **81**·2THF, the N1–N6–C7–C18 atoms are almost planar (torsion angle −0.52(0.41)°), with the N–N bond lying *syn*-periplanar to the C–C "double bond" (C7–C18 137.2(2) pm). Theoretical[149] and solution[151] studies also show the *syn* configuration to be favored. The N6–N7 bond (136.9(2) pm) is somewhat shortened relative to that in enamines (138–142 pm).[157] The sum of the angles at N6 is 356.4°, indicating slight pyramidalization and therefore a high degree of sp^2 character. As Figure 19 bottom, in particular, shows, the lithium atom is η^1-bound to this nitrogen atom; intramolecular chelation to the methoxy group bends it 17.5(4)° out of the 1-azaallyl plane, so that it lies 59(4) pm below this plane (see Fig. 19, top). The structure of **81**·2THF thus agrees with the models of related compounds put forward by *Whitesell* et al.[158] and *Meyers* et al.[147] One can imagine asymmetric electrophilic substitutions of E–X with this and other chiral 1-azaenolates proceeding, as suggested,[146f] by a lithioretentive S_E2' mechanism; the actual course of the reaction is at present, however, unclear.

9. Summary and Prospects



The structural studies presented in this article are based largely on X-ray structure investigations carried out in the last five years. This report can not, therefore, be more than an instantaneous picture of a field that is being intensively researched. A first review was justified, however, by the wealth of new results already now available.

It is necessary to be aware of the limitations introduced by the fact that the new data are derived predominantly from crystal structures, and that TMEDA is frequently involved as a complex ligand. In addition, one must also realize that there is no *one* structure for organolithium compounds anyway, since in solution, i.e., in various solvents, at least some deviation from a given crystal structure must be expected. Furthermore, solid state structures of "anions" can not be identical if the "ligands" (solvent molecules, TMEDA etc.) are different. Nonetheless, it is encouraging to realize that the crystal data often agree very well with those in solution and with calculated structures. Thus, a unified picture of lithiated sulfones can now be drawn, to which some ten X-ray structure determinations have made an important contribution. With lithiated nitriles, too, the situation is now somewhat better understood, even though only two crystal structures are known at present. With lithiated, chiral sulfoximides and sulfoxides,[164] several more crystal structure determinations will have to be performed. Because of their importance in reactions exhibiting chiral induction, it is natural to wish to understand this induction in terms of the structures of the lithium compounds. As with lithiated hydrazones, however, there are at present only the beginnings of an understanding of the structures; we are still very far away from understanding the often very selective reactions that occur with chiral induction. (Indeed, this is the case for reactions of organometallic reagents with electrophiles in general.) This is a field which will occupy chemists for some time to come. With lithiated 1,3-dithianes and thioethers, too, open questions remain, while lithiated nitro compounds show how much just one structure can explain, where there had previously only been strong indications.

10. Supplement

10.1. Structure of the Lithium Compound of Aminonitrile 82

Figure 20 shows the structure of the lithio compound **83** of aminonitrile **82**; **83** crystallizes as $[(\mathbf{83})_2 \cdot OEt_2]_\infty$.[160]

Without going into the details of the structure of $[(\mathbf{83})_2 \cdot OEt_2]_\infty$,[161] it should be emphasized that the (Li–N–Li–N) four-membered ring that is found in the lithionitriles $(\mathbf{59})_2 \cdot 2TMEDA \cdot C_6H_6$ (Fig. 14) and $[\mathbf{64} \cdot THF]_\infty$ (Fig. 15), is present here as well. This clearly shows that the "complex ligands" TMEDA, THF, and diethyl ether do not have a critical influence on the formation of this characteristic structural feature of lithionitriles. The

structural elements in $[(\mathbf{83})_2 \cdot 2OEt_2]_\infty$, i.e., ether, ketal, and amine, obviously do not disturb formation of the (Li-N-Li-N) four-membered ring in the solid state

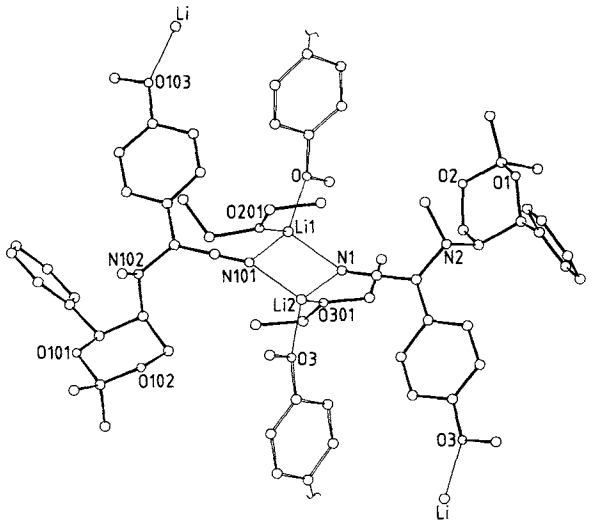


Fig. 20. Crystal structure of $[(\mathbf{83})_2 \cdot OEt_2]_\infty$ [160].

either.[165] Since Li1 and Li2 of $[(\mathbf{83})_2 \cdot 2OEt_2]_\infty$ are coordinated to the *p*-methoxyphenyl oxygen atoms of two further "anions", the dimer becomes a polymer.

10.2. The Structure of the Dilithium Compound of Trimethylsilylacetonitrile 84

Figure 21 shows the structure of the dilithium compound **84** of trimethylsilylacetonitrile, which crystallizes as $(\mathbf{84})_{12} \cdot 6OEt_2 \cdot C_6H_{14}$ from ether hexane.[162]

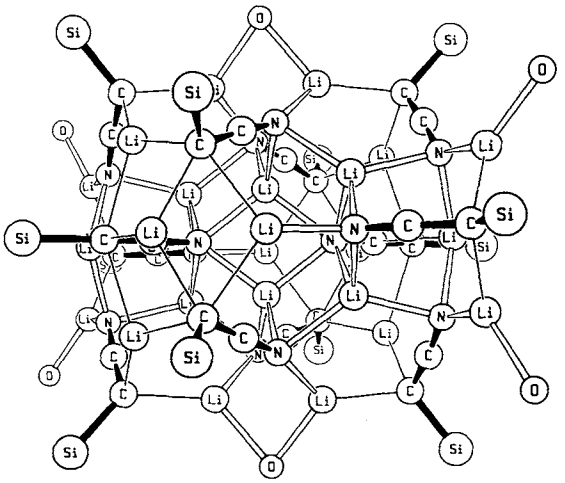

Fig. 21. Crystal structure of $(\mathbf{84})_{12} \cdot 6OEt_2$ · hexane (hexane, methyl and ethyl groups omitted) [162].

The dilithio compound **84** (as $(\mathbf{84})_{12} \cdot 6OEt_2 \cdot C_6H_{14}$) has a structure that is completely different from those of the monolithio compounds $(\mathbf{59})_2 \cdot 2TMEDA \cdot C_6H_6$, $[\mathbf{64} \cdot THF]_\infty$ and $[(\mathbf{83})_2 \cdot 2OEt_2]_\infty$. In **84**, 12 "dianions" are bound together with 24 Li atoms and six diethyl ether molecules to form an aggregate of unusual size (hexane lies outside of this unit). In the interior, one finds primarily N and Li atoms, while a hydrophobic shell composed of the C_2H_5 groups of the ether molecules and the CH_3 groups of the Me_3Si groups surrounds the whole (for reasons of clarity, these 12 C_2H_5 and 36 CH_3 groups are omitted in Figure 21). In contrast to the monolithio compounds (with the exception of $[\mathbf{64} \cdot THF]_\infty$, for which the cyanocyclopropyl "anion" represents a special case; see Section 6), in $(\mathbf{84})_{12} \cdot 6OEt_2 \cdot C_6H_{14}$ there are strong interactions between the α-C and Li atoms. Thus, there are three groups of Me_3Si-C-CN dianions. The α-C atom of the first group binds to two lithium atoms, while those of the second and third groups bind three; the third group is distinguished from the second by the cyano C atom also being bound to a Li atom. There is therefore an unmistakeable structural relationship between the dilithionitrile **84** and the dilithiosulfone $(\mathbf{28c})_6 \cdot Li_2O \cdot 10THF$ (see Section 2.2),[74] at least as far as the high degree of aggregation and the C-Li bonds are concerned.

The author offers his warmest thanks to the coworkers named in the literature references, for their patient and skilful handling of the sensitive crystals synthesized and investigated in Marburg. Representative of them all are Michael Marsch, who has an exceedingly skillful and fortunate hand with crystallizations and insertion of the crystals into the X-ray capillary tubes, and Dr. Klaus Harms, who carried out the measurements and calculations. Special thanks are due to the Deutsche Forschungsgemeinschaft, who supported our research as part of the Schwerpunktsprogramm "Reaction control by non-covalent interactions: quantification of the influence on structure, reactivity and selectivity", and in the Sonderforschungsbereich 260, "Organometallic compounds as selective reagents in organic chemistry". Without this support, our research would not have been possible.

[48] Li-C bonds are in fact found in other "benzyllithium" compounds. Thus, for example, the Li atom in the polymeric benzyllithium-triethylenediamine complex bridges three C atoms (corresponding to C1, C2, and C3 in Fig. 1) [49], while in the monomeric dithiane·**44b**·THF·TMEDA (see Fig. 11) one finds a C-Li bond to the benzylic C atom [50]. As in other benzyllithium compounds with strong acceptor substituents A ((**38b**)·2TMEDA, A = –(O)SPh, Fig. 8; (**59**)$_2$·2TMEDA C_6H_6, A = –C≡N, Fig. 14; **66a** C_2H_5OH, A = NO_2, Fig. 16), the absence of a C-Li bond in **14** is therefore probably the result of the coordination saturation of the $Li^{\oplus}$ ion by heteroatoms of the acceptor substituent, and of the lower electron density at the benzylic, anionic C atom.

[87] This can be inferred from a recent article on benzylmethyl sulfoxide and benzyl *tert*-butylsulfoxide by *Ohno* et al. [80e], which contains a critical examination and a detailed discussion of the stereochemistry of H/D exchange and of deprotonation with *n*-BuLi in THF, as well as the reaction of lithium derivatives of methyl or benzyl *tert*-butylsulfoxide with D_2O, R_2CO, or CH_3I. It was found that in the methylation reaction, the lithio compounds of the two sulfoxides in THF exhibit different diastereofacial selectivities. In lithio-*tert*-butylsulfoxide, CH_3I attacks from the *same* side as D_2O and R_2CO! The role of the medium, which had been recognized earlier [88, 89], is emphasized as well. In THF, D_2O attacks from the same face as e.g., R_2CO but upon H/D exchange ($OD^{\ominus}$, D_2O, CH_3OD) it does so from the opposite face. This has been explained in terms of $OH^{\ominus}$ in D_2O/CH_3OD approaching from the side away from the sulfoxide atom, where rapid deuteration (protonation) then also occurs. Complexation of the base, $OH^{\ominus}$; with the sulfoxide atom via the counter ion, $M^{\oplus}$ in D_2O is less important than that of *n*-BuLi in THF.

[117] According to MNDO calculations, the dimer $[PhCH(CN)Li \cdot 2\,NH_3]_2$ has a structure corresponding to **59**. It is ca. 5 kcal mol^{-1} more stable than $2\,PhCH(CN)Li \cdot 3\,NH_3 - 2\,NH_3$: S. Schröder, Universität Marburg 1986.

[118] C. C. Costain, *J. Chem. Phys. 29* (1958) 864. Interestingly, in nitrile complexes such as CH_3CN-BF_3, the C–N bond length is shortened to 113.5 pm (B. Swanson, D. F. Skriver, J. A. Ibers, *Inorg. Chem. 8* (1969) 2182), so that in **59**, in which the nitrile nitrogen atom is coordinated to two Li atoms a similar effect could be partly responsible for the short C–N bond length.

[159] The crystal structure of a third lithionitrile, i.e., that of $[\mathbf{83})_2 \cdot 2OEt]_\infty$, is reproduced in Section 10, and fits into this picture.

[160] M. Marsch, K. Harms, G. Boche, P. Gerdes, D. Enders, unpublished.

[161] In connection with the structure of $[(\mathbf{83})_2 \cdot 2OEt_2]_\infty$, it is interesting that in reactions of **83** with α,β-unsaturated carbonyl compounds (Michael addition), one isomer is formed preferentially (*de* between 82 and >98%), so that high diastereofacial differentiation and diastereoselectivity are present.

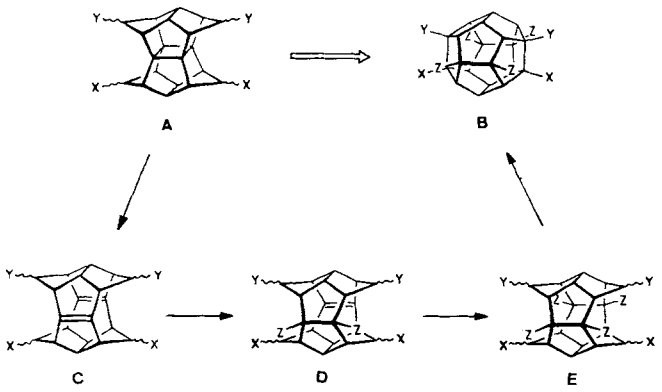
[163] Recent review: D. Seebach, *Angew. Chem. 100* (1988) 1685; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1624.

[164] If the solid state structure of α-(*tert*-butylsulfinyl)-α-methylbenzyllithium-pentamethyldiethylenetriamine is a model for the reacting species in solution one easily recognizes the difficulties for an electrophile like CH_3I to approach the anionic C atom from the side opposite to the -OLi bond (M. Marsch, K. Harms, G. Boche, unpublished results, Universität Marburg, 1989).

[165] In contrast to the structures of $(\mathbf{59})_2 \cdot 2TMEDA \cdot C_6H_6$, $[(\mathbf{83})_2 \cdot 2OEt_2]_\infty$ and also $[\mathbf{64} \cdot THF]_\infty$ in the case of $[LiCH(CN)_2 \cdot HMPA]_\infty$ instead of the (Li-N-Li-N) four-membered ring a (Li-O-Li-O) ring is formed. Each Li atom is additionally bound to two N atoms of two malonodinitrile anions, K. Jens, J. Kopf, N. P. Lorenzen, E. Weiss, *Chem. Ber. 121* (1988) 1201. HMPA with its strong oxygen donor atom apparently makes the difference.



[166] A monomeric potassiosulfone has been described recently, H.-J. Gais, J. Vollhardt, C. Krüger, *Angew. Chem. 100* (1988) 1108; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1092. Monomeric lithiosulfones should exist, e.g., in very dilute THF solutions, M. J. Kaufman, S. Gronert, D. A. Bors, A. Streitwieser, Jr., *J. Am. Chem. Soc. 109* (1987) 602.

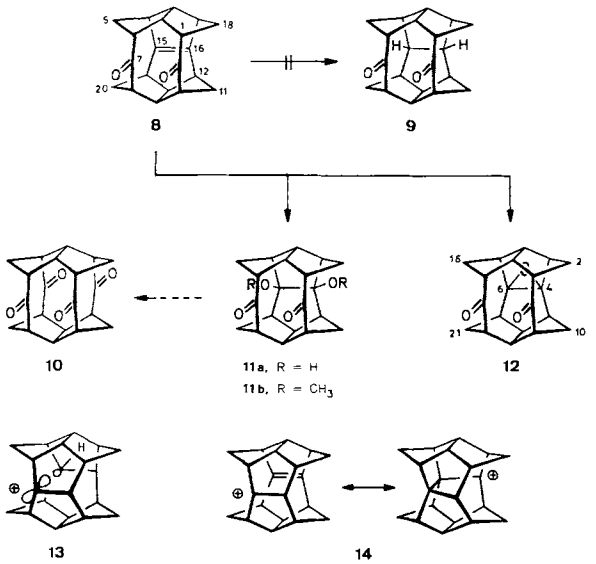
The Pagodane Route to Dodecahedranes: Chemistry and Structure of Bissecododecahedranes**

By *Georg Lutz, Dieter Hunkler, Grety Rihs,* and *Horst Prinzbach**

The energy-rich $C_{20}H_{20}$ hydrocarbon [1.1.1.1]pagodane **A** (X = Y = H)[1] can be converted into dodecahedrane **B** (X = Y = Z = H) catalytically[2] as well as stepwise (via **C**, **D** and **E**).[3] The yields of these procedures, yet encouraging in view of the ready availability of the starting materials, remain unsatisfactory for several reasons:[1] persistence of intermediates (e.g. **7**; cf. **13**, **14**),[4] "hyperstability",[3,5] particularly at the mono-ene step **D**, and the conditions necessary for the final dehydrogenative C–C bond formation **E** → **B**.[3,6] Limits drawn by this step **E** → **B** regarding a variable substitution of the pagodane and (seco)dodecahedrane frameworks[4] are the subject of this communication. Several promising ways out of this dilemma by functionalization of the four methylene positions (X, Y) are conceivable, and will be outlined in the two directly following communications.[7,8]

According to force-field (MM2) calculations, the unsaturated bissecododecahedranes **1** and **6** have olefin strains (OS)[5] of −11.4 and −13.9 kcal mol^{-1}, respectively.[3] However, whereas the diene **1** can be smoothly hydrogenated to the mono-ene **6**, the latter resists all attempts at hydrogenation, but can be epoxidized and cyclopropanated. The check remained to be made, whether bisseco intermediates **E** (X, Y = H) with four and two Z-substituents, respectively, can be prepared from **1** and **6**, and whether such Z-substituents survive dehydrogenative C–C bond formation[6] to give **B**.



Diene **1** is rapidly oxidized by $KMnO_4$ (homogeneous solution in acetone/H_2O/CH_2Cl_2, −35 to 0°C, 2 h); with excess reagent the only product, according to thin-layer chromatographic monitoring formed in almost quantitative yield, is not the ene-diol **2a** or the tetrol **5a** but the octacyclic ene-dione **8**.[9] Under more drastic conditions, **8** reacts slowly with further reagent (to give, inter alia, lactones; besides the hydroperoxide **7a**), without tetrol **5a**, diol-dione **11a** or tetrone **10** being detectable (TLC, ^{1}H NMR, MS monitoring). The ene-diol **2a** is, however, obtainable selectively (>80%) by reaction of **1** with OsO_4 (1.2 equivs.) in benzene, since the very slowly formed osmate half-ester, identified ^{1}H-NMR spectroscopically, precipitates (total conversion after 2 d at 20°C). **2a** can be liberated from the latter with $LiAlH_4$; it is acid-labile: even traces of HCl catalyze rapid isomerization to give mainly **7b**.[1] This tendency for transannular C–C bond formation also manifests itself upon treatment with acetic anhydride/pyridine (20°C) with preferential formation of **7c,d** (together with some **2b**). Double etherification leading to **2c,d** (NaH, CH_3I or $PhCH_2Br$, 20°C, 1 d) is slow but unproblematical (>90%). The double bond in **2a** cannot be

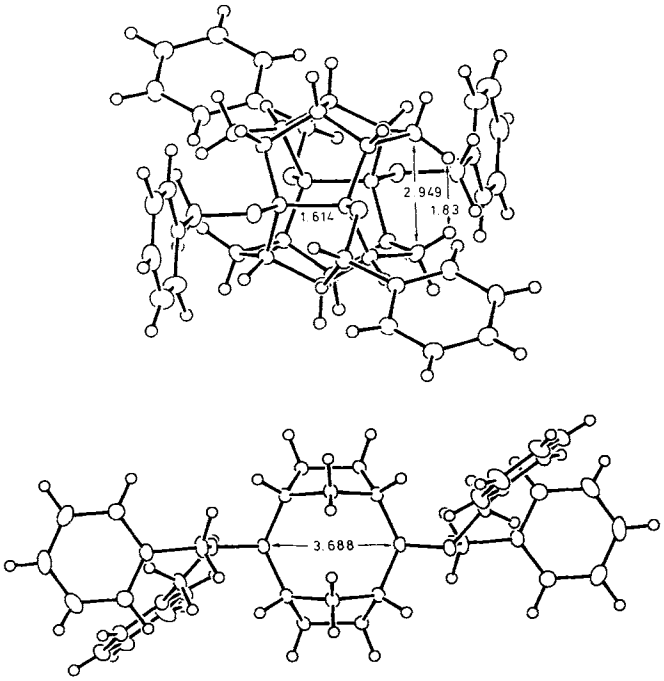
hydrogenated (to give **4a**) (Pd/C, Pt or N_2H_2), but can be epoxidized with *m*-chloroperbenzoic acid to give **3a** (95%). Both $KMnO_4$ (acetone/CH_2Cl_2, 20°C) and RuO_4 (CCl_4, 20°C) effect uniform glycol-cleavage of **2a** to give the enedione **8** (>95%). Hydroxylation of **2c,d** to the fourfold substituted bisseco compounds **5b,c**, on the other hand, is again selective (80–85%) via the osmate half-ester sparingly soluble in benzene (2 equiv. OsO_4, 20°C). Analogously to **2a**, **5b,c** can be converted into the more soluble D_{2h} symmetric tetraalkoxybisseco compounds **5d,e**. In the case of **5b,c** acid-catalyzed acetalization with 2,2-dimethoxypropane is again not possible without noticeable competition by transannular processes; in contrast, the reaction of **5c** with di-*tert*-butyldichlorosilane (1.5 equiv. 50°C, 2 d) in the presence of the BEMP-iminophosphorane base (2-*tert*-butylimino-2-diethylamino-1,3-dimethylperhydro-1,3,2-diazaphosphinane)[10] to give **5f** proceeds rather selectively (85–90%).

Not unexpectedly, the hyperstable bisseco-ene **6** is not oxidized by $KMnO_4$ (under various conditions); as in the case of **2a**, *cis*-hydroxylation (to **4a**) can only be achieved with OsO_4 in benzene, followed by $LiAlH_4$-reduction of the sparingly soluble osmate half-ester (>90%). Rather surprising and preparatively disadvantageous is the sensitivity of the saturated diol **4a** to transannular reactions, as known for **2a** and manifested, inter alia, in the very low-yield esterification to **4b** (25%); double alkylation to **4c,d** is practically quantitative, as in the case of **5b,c**. Thus, the prevailing transannular C–C bond formation to give nonacycles **7** in the case of the highly homoconjugated diene **1** is obviously a dominating process not only in the bisseco-enes **2** and **6**, but also in the saturated bisseco-compounds **4** and **5** (in the reaction of **6** with chlorosulfonyl isocyanate, e.g., **7e** is formed (ca. 60%)—presumably favored by the effective overlap between the empty p orbital and the opposite bridgehead C,H sp^3 orbital in cations of the type **13**.[11] A plausible intermediate is the cation **14** stabilized by hyperconjugation and generated from **1** by protonation and from **7f** by hydrolysis under superacidic conditions;[12] it is stable at room temperature for several hours.

The enedione **8** is another hyperstable olefin (*OS* according to MM2 calculations: −14.7 kcal mol^{-1}); even under drastic conditions it is not hydrogenated to **9**, but is smoothly oxidized to **12** by *m*-chloroperbenzoic acid. The dihydroxydione **11a**, sought for as precursor for the tetraketone **10**, and not observed in the oxidation of **8** with RuO_4 or $^1O_2$, is isolated in the form of the derivative **11b** (in moderate yield) from **5b** and RuO_4.

The tetrabenzyloxy derivative **5e** allowed an X-ray crystallographic examination of a first saturated bissecododecahedrane (Fig. 1).[14] In the crystal, the four substituents are arranged in such a way that a center of symmetry is preserved; their strain contribution is manifested, inter alia, in the length (1.614(4) Å) of the C–C bonds flanked by (almost orthogonally oriented) benzyloxy groups, and



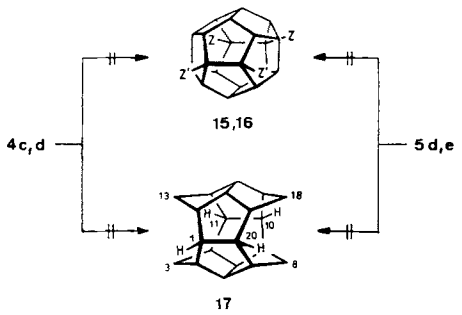


Fig. 1. Crystal structure of **5e** (distances in Å).

the torsional angle O-C1-C20-O of 4.2°. Considering the degree of substitution, there is a good overall agreement with the results of force field calculations.[3] Thus it is demonstrated that, with the bulging of the framework to 3.688 Å, the internal hydrogen atoms of the methylene positions are compressed to a distance (1.83 Å) considerably (ca. 0.5 Å) smaller than twice their van-der-Waals radius. As expected on the basis of force field calculations,[3, 15] this H–H distance is also smaller (ca. 0.1 Å) than in a dimethylsecododecahedrane.[16]

The hope that the OR substituents in the bissecododecahedranes **4** and **5** would survive the drastic conditions of dehydrogenation to the doubly and quadruply substituted dodecahedranes **15** (Z = H, Z′ = OR) and **16** (Z = Z′ = OR), respectively, through steric protection by the vicinal hydrogen atoms, was not realized: under multiple sets of dehydrogenative and hydrogenative conditions (Pd/C mixtures, 1–15 atm H_2, 170–250°C) the $C_{20}H_{22}$ nonacycle **7g**,[1] known to be stable under these conditions, is formed in consistently high yields (90%). That even in the case of the benzyl ethers **2d** and **5e** the respective glycols **2a** and **5a** and also the diol **7b** were not isolable, emphasizes the significance of heterolysis in these bridgehead positions;[13] that also the still unknown, saturated bisseco parent hydrocarbon **17** was not obtained is once more an indication for the high rate of the dehydrogenative olefina-

tion (formation of **2**, **6**) relative to the dehydrogenative C–C bond formation in such bisseco intermediates (**4**, **17**).

Under mild hydrogenative conditions (CH_2Cl_2, room temperature, Pd/C ca. 4 d), the very sparingly soluble tetrol **5a** arises from **5c**.

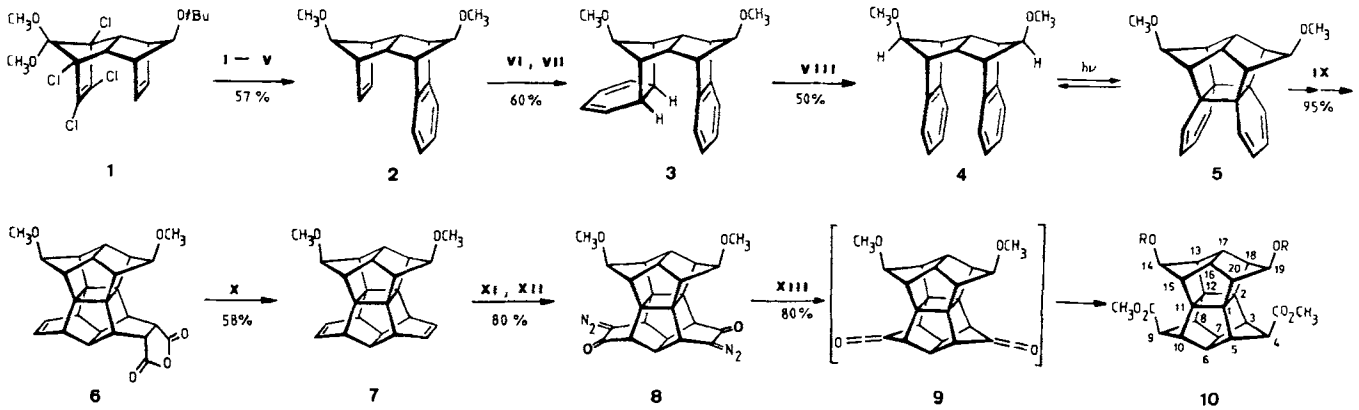
The Pagodane Route to Dodecahedranes: Total Synthesis and Chemistry of 4,9,14,19-Tetrasubstituted [1.1.1.1]Pagodanes**

By *Johann-Peter Melder, Hans Fritz,* and *Horst Prinzbach**

Dehydrogenative C–C bond formation en route from pagodanes to dodecahedranes via bisseco- or secododecahedranes necessitates conditions which previously incorporated functional groups cannot survive.[1] A broad spectrum of such substituents would, on the other hand, tolerate a variety of methods established for the formation of C–C bonds between sp^2- or sp^2- and activated sp^3-C centers (**A** → **B** and **C** → **B**, respectively).[2] In close analogy to



the preparation of the unsubstituted $C_{20}H_{20}$-pagodane (and of 4-*syn*,9-*syn*-disubstituted precursors[3]), we have developed the syntheses outlined in Schemes 1 and 2 for pagodanes appropriately functionalized in the four methylene positions (C-4, C-9, C-14, C-19).[4] An alternative protocol based on intramolecular functionalization is described in the directly following communication.[5,6]

Starting compound for the total synthesis is the C_{12}-diene **1**, an isodrin analogue, which is prepared in a ca. 40% yield from molar amounts of 7-*tert*-butoxynorbornadiene and tetrachlorocyclopentadienone-dimethyl ketal.[7] In this route to the *anti,anti*-dimethoxy-*syn,syn*-diester **10a**, condensed to 17 one-pot reactions (for ca. 40 functional changes), but not yet optimized in all individual steps (yield ca. 6% based on **1**; 85% per one-pot reaction!), an increased loss of material must be tolerated in the dehydrogenating aromatization **3** → **4** because of cleavage of etheral bonds in addition to the usual C—C homolysis. The steric shielding of the "inner" hydrogen atoms in **3** is presumably intensified by a "buttressing effect" of the CH_3O groups—which, however, influences only insignificantly the UV absorption of the face-to-face dibenzo com-

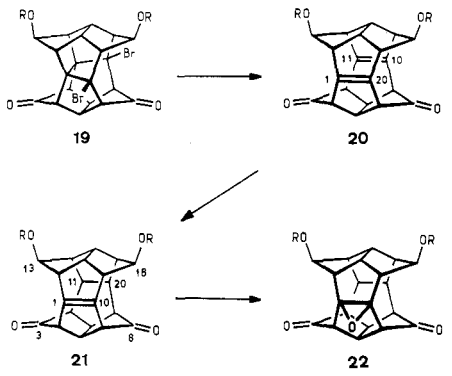
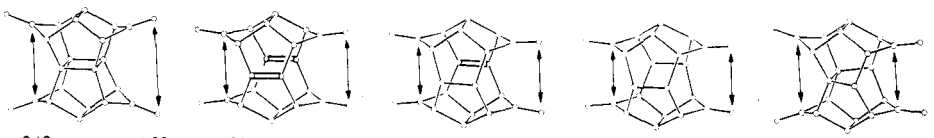
pound **4**[8] [(isooctane): $\lambda_{max}(\varepsilon)=287$ (330), 264 (1230), 257 (910), 228 (3440) nm] and the photoequilibrium established (ca. 3:1)[3,10] with the "*o,o-syn*-dibenzene" **5** [(isooctane): $\lambda_{max}(\varepsilon)=290$ (2400), 255 (2350), 215 (1830) nm] on irradiation at 254 nm. The CH_3O residues sterically hinder the domino-Diels–Alder addition **5**→**6**: the reaction with maleic anhyride (MA) requires rather drastic conditions (100°C), but without posing problems by thermal retrocleavage to give **4** [$t_{1/2}$(150°C)=30 min].[11] Despite this drawback for *exo* attack, *endo* addition still cannot compete.[12] The relatively low yield in the oxidative degradation **6**→**7** under similar drastic conditions as in **3**→**4** presumably has the same causes (C–O as well as C–C cleavage). The stereoselectivity of the addition of methanol to the ketene intermediates (**9**) is reduced: the photolysis of the bis(diazo)diketone mixture of C_2-**8** and C_s isomer (not shown here) in methanol furnished a 9:1 mixture of the *syn,syn*- and *syn,anti*-dimethyl esters **10a** and **11a**, respectively, in better than 90% yield; the products were separated by crystallization. The methyl ether groups in **10a** and **11a** can be readily cleaved with iodotrimethylsilane (TMSI). The quantitatively isolated, sparingly soluble dihydroxy diester **10b** is oxidized to the *syn,syn*-diketo diester **12** by pyridinium chlorochromate (PCC) with only minute loss of material.

Pagodane-4,9,14,19-tetrone **18**, the prototype of [1.1.1.1]pagodanes with four sp^2-hybridized bridge atoms, was obtained via the route depicted in Scheme 2: the mixture **10a/11a** can be converted into the *anti,anti*-dimethoxydione **14a** in 70% overall yield according to the method of *Trost* et al.,[13] whereby **11a** reacts much slower and only the bisthiomethylated intermediate **13a** needs to be isolated. In the case of **14a** the ether cleavage with TMSI (as carried out in the case of **10a**) to give the diol-dione **14b** turned out to be problematic. The diacetate **14c** is therefore prepared by treatment of **14a** with HBr/glacial acetic acid/acetic anhydride (110°C) (yield ca. 50%). Subsequent acetalization (**15a**), acetate hydrolysis (**15b**) and oxidation affords the D_{2h}-symmetrical, very sparingly soluble and extremely hygroscopic tetrone **18**. Upon heating in methanol/*p*-tosylOH, **16** equilibrates with **17** (ratio 2:3). From **18**, under the same conditions, the same mixture of **16**/**17** is formed.



Concerning the opening of the four-membered ring and the stability of the functional groups under the conditions required[1,5] preliminary results for **14a** can be quoted: the

Scheme 2. I: TMSI/$CHCl_3$, 95%. II: PCC/CH_2Cl_2, 90%. III: LiN(*i*Pr)$_2$/CH_3SSCH_3/THF, −78°C, 88%. IV: KOH/$HO(CH_2)_2OH$, reflux; NCS/MeOH, 100%. V: conc. HCl/CH_2Cl_2, 88%. VI: HBr/HOAc/Ac_2O, reflux, 52%. VII: MeOH/*p*-TosylOH, 92%. VIII: PCC/CH_2Cl_2, 89%.



photoaddition of bromine to give **19a** is achieved in at least 80% yield, while the bromine elimination to give **20a** is almost quantitative. Bisseco-diene **20a** upon irradiation ($\lambda=254$ nm) undergoes a rapid [2+2] cycloaddition (**14a**), rapidly adds bromine (**19a**), and is slowly hydrogenated by N_2H_2 (**21a**). Not unexpectedly, the latter is stable towards

further hydrogenation, but is oxidized under standard conditions to the bisseco epoxide **22a**. The reactivity of the carbonyl groups in bisseco-frameworks is reduced:[14] In contrast to **14a**, compounds **20a–22a** cannot be condensed with phenylhydrazine or hydroxylamine. This cage effect can even be useful, e.g., in that the preparatively important cleavage of the two protecting methyl groups in **21a** with TMSI to give the diol **21b** is achieved without interference by the side reactions observed in the case of **14**, thus opening up an efficient entry to bisseco-tetrones.

a, R = CH_3; b, R = H

Force field (MM2) calculations[15] for **18**, the bisseco-dodecahedrane-tetrones **23–25**, and the hydrogenolysis product **26** (Scheme 3), reveal the following differences compared to the respective hydrocarbons (values in parentheses) of possibly preparative importance:[16] 1) the cleavage **18** → **23** is considerably exothermic; 2) the olefin strain in **23** (+9.7 kcal mol^{-1}) and **24** (+8.7 kcal mol^{-1}) is distinctly positive, and 3) ΔH_f^0 is more negative for **24** than for **26**. Accordingly, the four sp^2-hybridized bridge atoms should facilitate the thermal cleavage **18** → **23** as well as hydrogenation to **25**, and on the other hand should impair the detrimental competition by transannular C–C bond formation (**26**) frequently observed in the parent frameworks.

The Pagodane Route to Dodecahedranes: 4,9,14,19-Tetrasubstituted [1.1.1.1]Pagodanes by Intramolecular Functionalization**

By *Rolf Pinkos, Grety Rihs,* and *Horst Prinzbach**

Functionalization of the pagodane framework at the secondary positions 4, 9, 14 and 19 should open up a productive route to symmetrically highly functionalized pentagonal dodecahedranes. Concomitant with the development of a total synthesis,[1] our activities have been directed to the use of *syn,syn*-substituents X, selectively incorporated into readily accessible pagodanes **A** and bissecododecahedranes **C** and **E**, for the functionalization (Y) of the respective opposite methylene groups (**B**, **D**, **F**). In view of the limitations for the type of substitution (X, Y) as caused by the ring-opening conditions **B** → **D**,[2] a protocol with four-membered ring opening preceding functionalization (**A** → **C** → **D** → **F** or **A** → **C** → **E** → **F**) was to be followed. Depending on the transannular distance *d*, a functionalization via seven- or eight-membered transition states should be advantageous.

Fundamental limitations of this procedure are exemplified for the *syn,syn*-diester **1**: the opening of the lateral four-membered ring bonds a to give the bisseco-diene **4**[3] (**B** → **D**) according to the proven procedure[2] becomes complicated in so far as the α-ester position on the open side of the dibromide **3a** is brominated relatively rapidly (**3b**). In addition, during the 1,4-bromine elimination **1** is partly re-formed from **3a** (yield of **4** ca. 75% based on conversion of **1**). The diimide-reduction of **4** proceeds much more slowly than in the case of the ester-free diene,[2,4] but furnishes selectively the ene diester **5**. In the epoxidation of **4** with peracids under normal conditions, side reactions occur, which, however, can be avoided by the use of benzoylperoxycarbamic acid (100% **6**).

With increasing bulging of the carbon skeleton in going from **1** ($a = 1.583$ Å) via **4** (2.59 Å) to **5** (2.96 Å), the transannular distances *d* between methylene and ester-bearing C atoms decreases from 3.60 to 3.30 and 3.22 Å, respectively (MM2 calculations; cf. Scheme 3 in Ref. [1] and the distance of 2.949 Å for **5e** in Fig. 1 of Ref. [4])—with drastic consequences for the reactivity of the *syn*-ester groups: transformations, which in the case of **1** (to **2a**–**2h**[5]) were generally unproblematical and highly efficient, are, in the case of **4**, **5** and **6**, extremely retarded and unselective or even impossible without previous epimerization at the α-C atoms—due to steric interactions and poor solvation of the tetrahedral intermediates. Very informative in this context is the X-ray structure analysis[6] of the *syn,syn*-diepoxy diester **6** (Fig. 1). Unlike **1**,[5] **6** crystallized in the C_s symmetrical ester conformation. With a molecular diameter of

2.935 Å, the distance between substituted and opposite methylene C atoms (3.611 Å in **1**) is now only 3.228 Å; the distance between the carbonyl C atoms and the respective

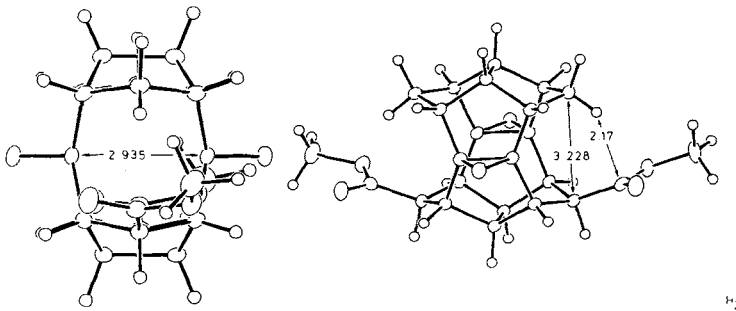

Fig. 1. Crystal structure of **6** (distances in Å).

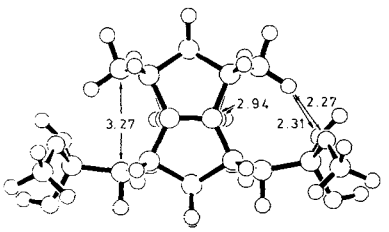
syn-H atoms (2.17 Å; average 2.41 Å in **1**) is considerably less than the sum of the van-der-Waals radii.[7]

The extent of steric compression associated with the tetragonalization of the carbonyl centers in the diesters **4**–**6** becomes evident in the simulated structure (MM2) of the bishydrate **7** (Fig. 2) derived from the ene-diester **5**: the increase in strain of 36.6 kcal mol^{-1} compared to that in **5** reflects the extreme steric pressure between the *syn*-methylene hydrogen atoms and the opposite oxygen atoms located at a distance (2.27 and 2.31 Å) much smaller than the sum of their van-der-Waals radii.

7



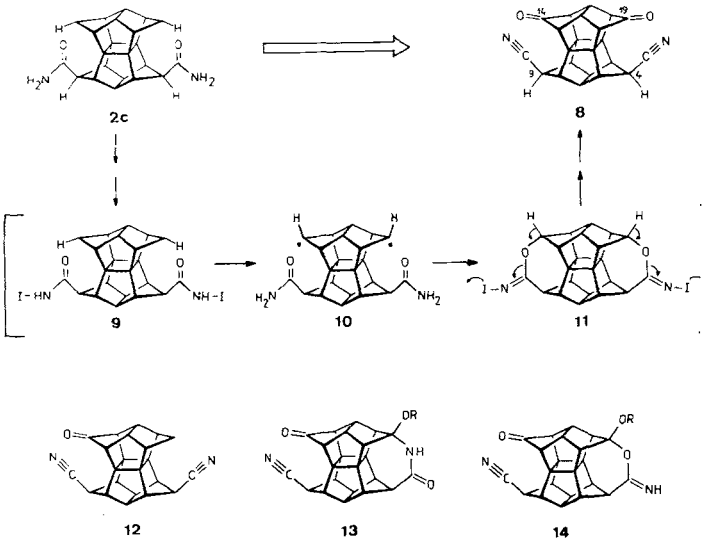


Fig. 2. MM2-simulated structure (SCHAKAL) of the bis-ester hydrate **7** (distances in Å).

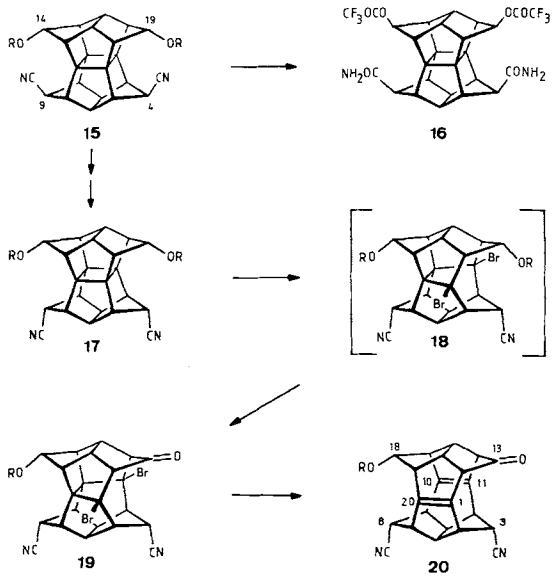
A consequence of this drastically reduced reactivity of *syn*-oriented substituents in bisseco pagodanes with regard to the above schematized alternatives for methylene functionalization implies that the variation of the X residues required for the introduction of the Y functions is not possible at the stage of the bisseco structures **C** or **E** but must be brought about at the stage of the pagodanes **A**. Thus only such X residues can be considered which are stable or are appropriately modified under the conditions of the opening reactions **A**→**C** or **B**→**D**.



A twofold intramolecular, mechanistically remarkable functionalization of the type **A**→**B**, which proved highly valuable for the entire program, was realized—after unsatisfactory results with *inter alia*, the bishypoiodide **2e** and the dinitrite **2f**[8]—in a variant of the Barton reaction[10] with the *syn,syn*-dicarboxamide **2c**. By irradiation of a ca. 10^{-3} M solution of **2c** in CH_2Cl_2 in the presence of 12 equiv. I_2, after complete conversion and simple work-up (crystallization), the C_s-symmetrical 14,19-dioxopagodane-4-*syn*,9-*syn*-dicarbonitrile **8** can be reproducibly isolated in over 90% yield (for 2 mmol quantities; ca. 95% per function). From the mother liquor, two additional products can be separated chromatographically in variable amounts from other components and identified as ketodinitrile **12** and lactam **13**; the latter is differentiated from iminolactone **14** mainly by ^{13}C-NMR data. The sequence of the numerous intermediates in going from **2c** to **8** is not yet clear; the bisiodamide **9**, the diradical **10** and the bisiodoiminolactone **11** are merely guides. The unusual efficiency of both abstraction of ε-hydrogen atoms and ketone formation[10] is understood in terms of the rigid structure and the very favorable atomic distances.[11]

Starting from **8**, the functional groups and the stereochemistry at positions 4(9) and 14(19) in the [1.1.1.1]pagodane framework can be varied selectively. By twofold, acid-catalyzed nitrile hydrolysis of **8** (HCl/HOAc, reflux, 12 h), the previously reported[1] 4-*syn*,9-*syn*-pagodanedicarboxylic acid is obtained, by twofold *exo*-specific reduction with $NaBH_4$ (ethanol, 20°C) the all-*syn*-dihydroxydinitrile **15a** in quantitative yield. The spanning of the C4(19)- and/or C9(14)-positions by diatomic bridges as postulated in **11** as well as **13** and **14**—striven for en route to homologous dodecahedranes and according to force field calculations with increasing bulging of the skeletal frameworks (**B**→**D**→**F**) accompanied by decreasing strain—sets the scene for twofold epimerization at C14(19) in **15a**: the product isolated quantitatively from its solution in $CF_3CO_2H/CHCl_3$ (1:1, 20°C, 3 d) and, according to ^{1}H-NMR monitoring formed via several intermediates, is (tentatively) assigned the structure as *anti,anti*-bis(trifluoroacetoxy)-*syn,syn*-dicarboxamide **16**. The double epimerization at C-4(9) in **15a** to give the thermodynamically more stable 14-*syn*,19-*syn*-dihydroxy-4-*anti*,9-*anti*-dinitrile **17a** proceeds slowly because of strong kinetic preference for *exo*-protonation of the carbanions and is accomplished quantitatively by heating in *t*BuOH/*t*BuONa in a sealed tube (160°C, 1 h).

The effects of specific framework substitution upon the two-step opening of the four-membered ring (**B**→**D**), essential for advancement of the project,[12] have also been checked on **15b** and **17b**.[1] In the case of all-*syn*-**15b** the photoaddition of bromine under various conditions was so slow relative to several competing processes that a complex product mixture is present already after minimal conversion. **17b** under standard conditions (CH_2Cl_2/CH_3CN

(10:1), 15 equiv. Br_2), selectively furnishes the dibromoketone **19b** (yield ca. 85%); a preparatively very useful[13] stereofacial selectivity manifests itself in the regiospecific cleavage of the *syn*-ether on the "open" side of the dibromide **18b**. The elimination of bromine from **19b** to give the bisseco-diene **20b** proceeds almost without competition.

a, R = H; **b**, R = CH_3; **c**, R = $COCH_3$

The Pagodane Route to Dodecahedranes: Polyfunctionalized Pentagonal Dodecahedranes and Dodecahedrenes**

By *Johann-Peter Melder, Rolf Pinkos, Hans Fritz,* and *Horst Prinzbach**

An early defined goal in our quest for pentagonal dodecahedranes with pagodanes as central intermediates[1] is the modification of the outer dodecahedrane sphere with diverse substitution patterns.[2] Single and, in some cases, double and triple substitution of the parent dodecahedrane

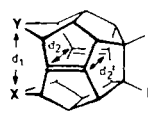
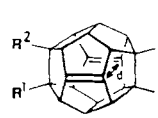
Wörth* for MS analyses, Mrs. *M. Lutterbeck* and *M. Froom*, *G. Leonhardt* and *J. Leonhardt* for supplying starting materials, *G. Fehrenbach* for graphical work, and Dr. *W.-D. Fessner* and Dr. *L. Knothe* for helpful discussions.



hydrocarbon has been reported by the *Paquette* group.[3] With the elaboration of highly efficient protocols for the activation of the 4,9,14,19-positions in the pagodane precursors, the scene was set for the preparation of pentagonal dodecahedranes **N**–**S** (Scheme 1) with four to eight skeletal positions being substituted.[4,5] The reliability of the force-field calculations[6] as to structural details is well established by X-ray analyses of relevant frameworks,[5,7,8] whilst the ΔH_f^0-, E_{str}- and olefin strain (*OS*)-data have to be taken as merely qualitative. The following points are essential: 1) the X–Y distances (d_1) of 2.8–3.0 Å in the bisseco- and monoseco-frameworks are favorable for *p/p* overlap; 2) the C–C bond formations bisseco→seco and seco→dodecahedrane are exothermic—except in the case of the dienes (**A**, **G**) and three-membered ring-enes (**D**, **K**); 3) the olefin strain for the monoseco-olefins **G**, **H** and **K** is positive, the hydrogenations **H**→**I** and **K**→**M** should therefore be possible; 4) the pyramidalization at the sp^2 centers in the case of the dodecahedrenes **N**, **O** and **Q** is of considerable but preparatively not necessarily limiting[9,10] order of magnitude. A general prerequisite for the realization of the individual projects is that the $2\sigma \rightarrow 2\pi$ cleavage of the respective pagodanes to give the bisseco-dienes **A** and the conversion of the latter into the differently saturated bisseco compounds **B**–**F** can be achieved with sufficient selectivity. For a given choice of X and Y in **A**–**F**, C–C bond formation methods can be employed (inter alia a–e) which require (and tolerate) quite different functional groups and, conducted irreversibly, should also overcome thermodynamically more or less unfavorable situations (e.g. **A**→**G**→**N**, **D**→**K**→**Q**).

Here we report a first preparative entry to four-, six- and eightfold functionalized pentagonal dodecahedranes of types **P** (**12a**–**d**, **13**), **R** (**15a**–**d**, **16**) and **S** (**18a**, **b**) and of dodecahedrenes of type **O** (**19a**, **b**) as highly versatile representatives using the Aldol variant (a). Homologous dodecahedranes are a subject of the following communication.[11]



Starting material for all dodecahedranes presented here is the readily accessible dimethyl dioxopagodane-*syn,syn*-dicarboxylate **1**[4,5] or the bisseco-diene **4** derived from **1**. The opening of the four-membered ring in **1** leading to **4** via photobromination to give **2** and subsequent elimination of bromine was a priori not unproblematical: the addition of Br_2, already retarded by two keto[12] or two ester residues, proceeds so slowly under the concerted influence of these four functional groups, that (faster) subsequent bromination on the seco side of the dibromide **2** to give the tribromide **3** cannot be avoided.[13] This complication, however, has been satisfactorily solved: **3** can be obtained almost exclusively from **1**, when conversion is restricted to ca. 50% (yield ca. 95%; with increasing conversion, additional bromination products are formed) and can be separated easily and practically free of losses from **1** by filtration over silica (due to the high degree of substitution, **3** is not very susceptible to hydrolysis). Furthermore, the bromine substituent on C-4 is also eliminated (largely with retention) under the conditions of diene formation (Zn, NaI, Na_2SO_3, dimethylformamide (DMF), 140°C, 10 min);[5] besides diene **4** (ca. 90% isolated as crystals), at most traces of **1** are formed. Considerable steric compression on the seco side of **3** becomes evident, inter alia, from the hindered rotation of the *syn*-ester group on C-4; C_s symmetry is already destroyed at room temperature (cf. footnote [7] in Ref. [5]). The $[\pi_2+\pi_2]$ photocycloaddition, usually rapid in besseco-dienes, is not tangled by the C=O functions

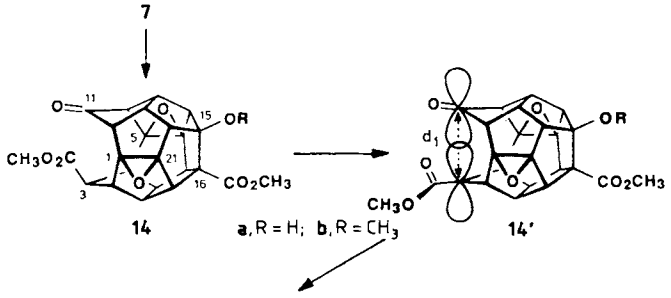
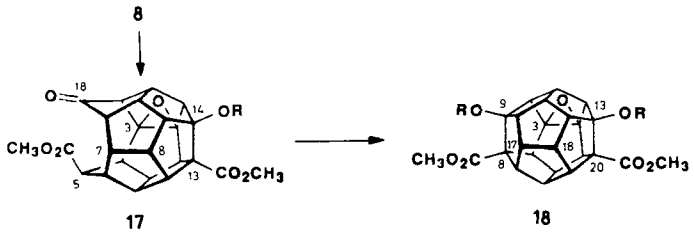
Scheme 1. Energy and structure data of model frameworks calculated for X = CH_2, Y = CO, Z = CH_2, R^1 = H, R^2 = OH; ΔH_f^0, E_{str}, *OS* [kcal mol^{-1}]; *d* [Å]; pyramidalization at the olefinic centers (pyr) [°].—The following methodologies are considered for the ultimate bond formations: a) Aldol addition (X = CHA, Y = C=O); b) pinacol addition (X = Y = C=O); c) Michael addition (X = CHA, Y = C=CHA); d) nucleophilic substitution (X = CHA; Y = CHL); e) oxidation (X = Y = CA$^{\oplus}$). A = acceptor group, L = leaving group.

in **4** (π/π distance ≥ 2.7 Å; $\lambda_{max}(CH_3CN) = 216$ nm ($\varepsilon =$ 1300), 270 (sh, 90), 314 (sh, 60)); upon acetone-sensitized excitation, **1** is formed quantitatively. For the unsaturated ε-ketoesters **5** and **6** differences compared to the diketo[12] and diester analogues[5] are manifest in the lability of the products derived from epoxidation and hydrogenation. The oxidation of **4** with *m*-chloroperbenzoic acid (*m*-CPB) (1.5 equiv., room temperature, CH_2Cl_2) leads selectively to the epoxyene **5**; oxidation of the latter to the diepoxide **7** (3.0 equiv., yield at least 80%) necessitates considerable thermal activation (rapid at 80°C), but is complicated in that **7** undergoes changes under the given conditions (as also on the TLC silica plates; acid catalysis). The hydrogenation of **4** with a large excess of diimide (hydrazine, HgO, 25 equiv., 0°C) ends with the hyperstable monoene **6**, which, however, after ca. 50% conversion is increasingly accompanied by secondary products (not **9**). Epoxidation of **6** furnishes **8**, which reacts further when *m*-CPB is used. That **4** is more reactive than **5** and **6** (cf. *OS* of −10.1, −10.6 and −12.3 kcal mol^{-1} for **A**, **B** and **D**, respectively) may reflect partial compensation of the hyperstability by destabilizing π/π interaction in **4**.[12]



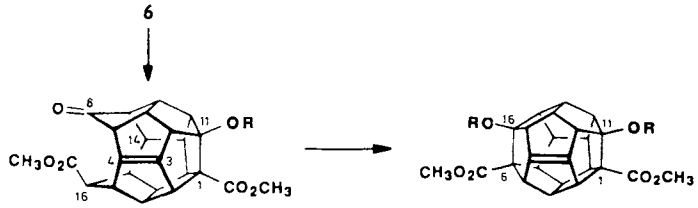
With the bisseco ε-ketoesters **4**–**8**, five substrates of the series **A**–**F** are available. For **P**-dodecahedranes initially sought after (e.g. **12a**), the appropriate precursor (**9**) is lacking. A detour is, however, offered by the reaction sequence **B**→**H**→**I**→**P**. In the case of the ε-keto ester **6** a

small enthalpy gain with moderate increase in strain is expected from model considerations for transannular bonding leading to β-hydroxyester **10a** (**B**→**H**, $\Delta\Delta H_f^0 = -3.0$ kcal mol^{-1}, $\Delta E_{str} = +6.9$ kcal mol^{-1}). Other than the hyperstable **6**, **10a** should undergo hydrogenation to give **11a** (cf. **H**→**I**, $OS = +6.1$ kcal mol^{-1}). The transformation of **11a** to the fourfold functionalized dodecahedrane **12a** (cf. **I**→**P**, $\Delta\Delta H_f^0 = -18.3$, $\Delta E_{str} = -8.4$ kcal mol^{-1}) is especially advantageous from energetic and stereoelectronic arguments. Indeed, this sequence from **6** to **12a** can be effected in a one-pot reaction not yet analyzed in detail: after prolonged reaction of **6** with hydrazine/HgO in large excess (25 equiv.) at 60°C, **12a** (dimethyl 11,16-dihydroxyundecacyclo[9.9.0.0^{2,0}.0^{3,7}.0^{4,20}.0^{5,18}.0^{6,16}.0^{8,15}.0^{10,14}.0^{12,19}.0^{13,17}]icosane-1,6-dicarboxylate) arises in 30–40% yield; it can be separated chromatographically from further, in part not yet fully characterized components (inter alia, **10a**, **11a**, **19a**) and crystallized from CH_2Cl_2/CH_3OH (colorless crystals, m.p. >320°C). Dimethyl ether **12b**, dicarboxylic acid **12c** and diacetate **12d** are first derivatives.[14] **10a** in the meantime (see below) has been selectively prepared from **6** under acid-catalysis conditions. An entry to **12a** almost free of losses (yield >90% based on **6**) is now opened up via hydrogenation to **11a** (Pd/C, CH_3OH, 20°C). The elimination of the OR- or CO_2R-functionalities in **12a**—exemplary also for **15a,b**, **18a,b** and **19a,b**—is now intensively studied as entry to 1,6-disubstituted dodecahedranes, their variation primarily under the aspect of olefin formation. The bislactone **13**, for example, is a potential precursor of a dodecahedradiene (cf. **21**) and prototype of annelated dodecahedranes.



A gain in enthalpy with moderate increase in strain is likewise predicted for the cyclization of the bisseco-diepoxide **7** via the seco-diepoxide **14a** to the diepoxydodecahedrane **15a** (dimethyl 9,13-dihydroxy-2,18-dioxatridecacyclo[10.10.0.0^{1,3}.0^{3,10}.0^{4,8}.0^{5,22}.0^{6,20}.0^{7,17}.0^{9,16}.0^{11,15}.0^{13,21}.0^{14,19}.0^{17,19}]docosane-8,21-dicarboxylate) (cf. **E**→**L**→**R**): $\Delta\Delta H_f^0$ (ΔE_{str}) **E**→**L**/**L**→**R** = −3.0 (+6.4)/−3.5 (+5.9) kcal mol^{-1}. Our expectations were again fulfilled: Upon acid

catalysis (stirring over silica, CH_2Cl_2, 25 °C) from **7** dodecacycle **14a** slowly emerges (yield ca. 80%) and from the latter—with sufficient kinetic distinction for selective isolation of **14a**—the eightfold functionalized dodecahedrane **15a**, which crystallizes from CH_2Cl_2/CH_3OH as colorless crystals (m.p. > 320 °C, yield ca. 20%). The dimethyl ether **15b** is exclusively formed on addition of NaH (excess) and 3 equiv. CH_3I to a solution of **7** in anhydrous THF (room temperature). The β-hydroxy ester **15a** was converted into **15c**, **d**. The bislactone **16** is valuable, inter alia, as intermediate en route to the diepoxydodecahedradiene (cf. **23**).

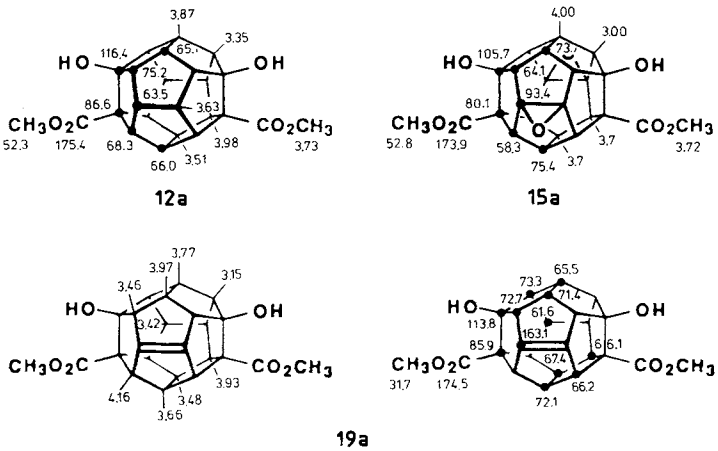


15a: $R^1 = H$, $R^2 = CH_3$
15b: $R^1 = R^2 = CH_3$
15c: $R^1 = R^2 = H$
15d: $R^1 = COCH_3$, $R^2 = CH_3$

The formation of the two C–C bonds in going from the bisseco-epoxide **8** via **17a** to the epoxydodecahedrane **18a** (dimethyl 9,13-dihydroxy-2-oxadodecacyclo[10.9.0.0^{1,3}.0^{3,10}.0^{4,8}.0^{5,21}.0^{6,19}.0^{7,17}.0^{9,16}.0^{11,15}.0^{13,20}.0^{14,18}]heneicosane-8,20-dicarboxylate) should profit from considerable driving force (cf. **F**→**S**: $\Delta\Delta H_f^0 = -22.4$, $\Delta E_{str} = -2.5$ kcal mol^{-1}). Indeed, **8** reacts slowly on SiO_2 (CH_2Cl_2, 25 °C) to give **17a** and then further to give **18a**, and reacts very rapidly with NaH/CH_3I (THF, 25 °C) to give **18b** (in each case colorless crystals from CH_2Cl_2/CH_3OH, m.p. > 320 °C.

The preparation of the dodecahedrenes **19** from the bisseco-ene **6** via **10** as intermediates was considered promising on the basis of energy criteria (cf. **H**→**O**: $\Delta\Delta H_f^0 = -6.4$, $\Delta E_{str} = +3.4$ kcal mol^{-1}). Such highly pyramidalized olefins are normally extremely reactive. Here the chances for isolation should, however, be improved by the special steric situation on the outer molecular sphere and by the type of substitution.[9] **6** changes only very slowly (ca. 50% conversion after 3 d) on SiO_2 (CH_2Cl_2, exclusion of oxygen, 25 °C); the steps leading to **10a** and to **19a** are kinetically so different that the comparably little oxygen-sensitive **10a** can be highly enriched and isolated by chromatography/crystallization in a yield of 95% based on conversion. Stirring of **6** over NaH (anhydrous THF, exclusion of oxygen, 25 °C) leads, after a few minutes, quantitatively to the Na_2-salt **19c** (with not absolutely water-free THF to the diol **19a**), while stirring over NaH/CH_3I (anhydrous THF, 25 °C) leads to the dimethyl ether **19b**. Ca. 10^{-2} M THF solutions of **19a** remain unchanged for days at room temperature; on heating under reflux, oligomeric (dimeric?) material separates out. The dodecahedrene **19a** (dimethyl 11,16-dihydroxy-undecacyclo[9.9.0.0^{2,9}.0^{3,7}.0^{4,20}.0^{5,18}.0^{6,16}.0^{8,15}.0^{10,14}.0^{12,19}.0^{13,17}]icosa-8-ene-1,6-dicarboxylate crystallized from CH_2Cl_2/CH_3OH is, as expected, sensitive towards oxygen; it is oxidized to **18a** with *m*-CPB, and is hydrogenated to **12a** over Pd/C.

C_{2v} symmetry is established for **12a** by five ^{1}H and seven ^{13}C, for **15a** by four ^{1}H and seven ^{13}C NMR framework signals, C_s symmetry for **18a** and **19a** by nine ^{1}H and twelve ^{13}C NMR framework signals each, all having appropriate intensities (Fig. 1); the assignment of the signals is confirmed by COSY, NOE and selective decoupling experiments. In the case of **18a** and **19a** the vicinal H,H coupling constants on the epoxide and ene sides, respectively, are 7–8 Hz, on the opposite sides 10–11 Hz. The ^{13}C NMR signals of the substituted quaternary C atoms generally



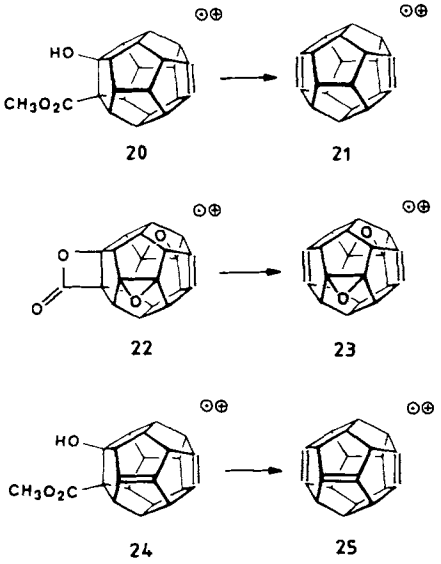


Fig. 1. ^{1}H and ^{13}C NMR data of **12a**, **15a** ($CDCl_3$) and **19a** ([D_8]THF).

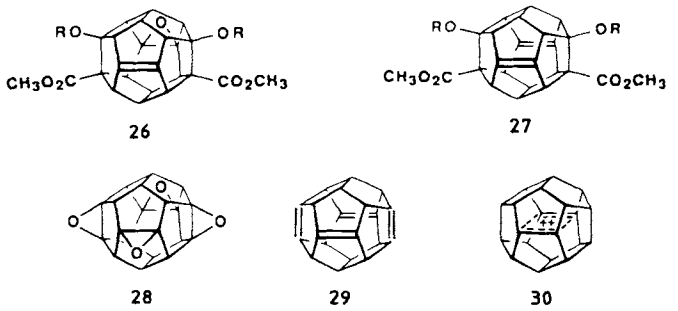

have similar chemical shifts as the signals in singly OH/CO_2R substituted dodecahedranes ($\delta = 116.0$ for C–OH, $\delta = 84.5$ for C–CO_2R[3]); those of the olefinic C atoms in **19a** are, partly also due to the substituents, shifted downfield compared to those in the planar bicyclo[3.3.0]octa-

1(5)-ene[15] (146.0 ppm) and those in the highly strained 10-selenatricyclo[3.3.3.$0^{3,7}$]undec-3(7)-ene[16]) ($\delta = 150.7$, cf. **10a**: $\delta_{C-4} = 145.2$, $\delta_{C-3} = 163.4$). In line with comparatively low strain in the saturated dodecahedranes are the C,H coupling constants (e.g. 134–140 Hz in the case of **12a**).

Information with regard to the stability of even multiply unsaturated dodecahedranes (cf. **27/29**) is provided by the EI mass spectra for **12**, **15**, **18** and **19**. The singly and doubly—and with limitations triply—unsaturated dodecahedrane radical cations resulting from elimination of the vicinal substituents are generally represented by relatively intense signals. Typical examples are the following: The ene radical cation **20** (*m/z* 332, 100%), which is formed from **12a**$^{\odot\oplus}$ (*m/z* 408, $M^{\oplus}$, 8%) via the successive expulsion of H_2O (*m/z* 390, 14%), CO (*m/z* 362, 42%) and CH_2O, and the diene radical cation **21** (*m/z* 256, 45%) from **20** via the same type of fragmentation. **15a**$^{\odot\oplus}$ (*m/z* 436, 9%, $M^{\oplus}$) first eliminates CH_4O from both sides (*m/z* 404 (100%), 372 (52%), cf. bislactone **16**), then CO_2 (diepoxyene **22**, *m/z* 328, 30%, and diepoxydiene **23**, *m/z* 284, 42%). **19a**$^{\odot\oplus}$ (*m/z* 406, 10%, $M^{\oplus}$) decays to the diene radical cation **24** (*m/z* 330, 74%) and triene radical cation **25** (*m/z* 254, 25%). Primarily subtle conformational differences between the ecliptically fixed vicinal pairs of substituents in **12**, **15**, **18** and **19** might be responsible for the varying degradation of the substituents.

Fourteen of the eighteen model frameworks depicted in Scheme 1, including four of the six dodecahedrane types, are represented by fully characterized compounds. Good

chances are seen for the now imminent thermodynamically unfavorable conversions of the type **D** → **Q** (**5** → **26**) and even **A** → **N** (**4** → **27**) whereby complexation of the vicinal hydroxy/ester functions can possibly be helpful. Such thermodynamically critical cases will also be explored in the meantime by S_N2 substitution in *syn,syn*-bisseco-diesters and -dinitriles with very good *anti,anti* leaving groups (Scheme 1, d, X = $CHCO_2CH_3$, CHCN; Y = CHI, $CHOCOCF_3$). Speculations are allowed on the stability and the bonding situation of rather exotic representatives such as the D_{2h} species **28** and **29** and the dication **30**.[7]

[9] According to MM2 predictions the CC double bonds in the parent systems dodecahedrene **O** and dodecahedradiene **N** ($R^1 = R^2 = H$) respectively are strongly pyramidalized towards tetrahedral coordination with angles of 46.5° and 45.6° (for comparison: 63.4° for edges of the dodecahedrane **P**), but still flat enough that their reactivity ought to be kinetically reduced by the flanking methine groups. According to the olefin strain criteria reported by *Maier* and *Schleyer* [6], with calculated *OS* values of 18.3 and 18.0 (diene strain = 36.3 kcal mol^{-1}) these species should be manageable at low temperature.

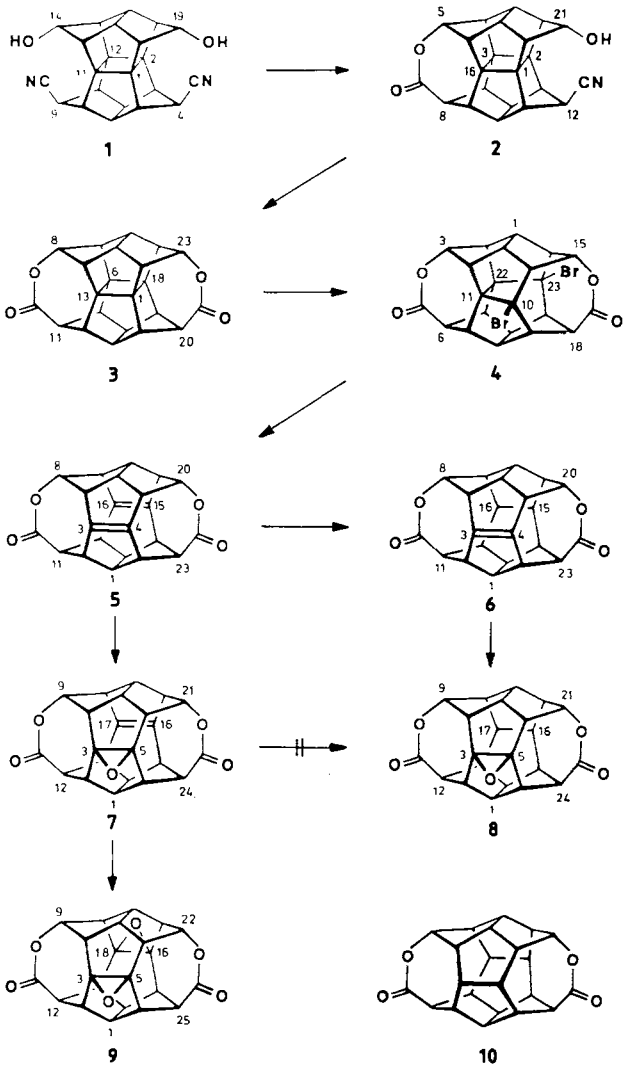
The Pagodane Route to Dodecahedranes: Polyfunctionalized Homologous Dodecahedranes and Dodecahedrenes**

By *Rolf Pinkos, Johann-Peter Melder, Hans Fritz,* and *Horst Prinzbach**

In memoriam Hans Musso

Our route to functionalized dodecahedranes[1] can be utilized for the homologization of the pentagonal framework by one,[2] two (or more) similar or different "bridges" and thus for the construction of novel poly(hetero)cyclic skeletons featuring more or less spherical surfaces and varying molecular diameters (cf. Fig. 29 in Ref. [3]). For a series of model frameworks with diatomic bridges—selected for their correspondence with the skeletons in Ref. [1]—energy and structure data are presented in Scheme 1. In spite of the deficiencies of such MM2 calculations[4] several preparatively significant conclusions are realistic in comparison with the non-homologous counterparts.[1] 1) The trends in energy and structure parameters within and between the seco-monohomologous (**A**–**D**) and the bishomologous dodecahedranes (**E**–**H**) resemble very closely that of the bisseco series in Ref. [1]; 2) for the mono-homologues (**I**–**M**) the consequences of the CH_2CO bridge are only minor when set gainst the seco analogues in Ref. [1]; 3) in the seco-series **A**–**D** the steric requirements for X-Y connecting bond formation (to give **I**–**M**) are therefore favorable; 4) for the homologous dodecahedradienes **E** and **I** strong transannular π/π interactions but different reactivities are to be expected.[5]



Scheme 1. Energy and structure data of model frameworks, calculated for R = S = CH_2CO, X = CH_2, Y = CO; ΔH_f^0, E_{str}, olefin strain (OS) [kcal mol^{-1}]; *d* [Å]; pyramidalization at the olefinic centers (pyr) [°].

In this communication we present bis- and monohomologous dodecahedranes of types **E**, **F**, **H** and **I**–**M**,[6] with COO units as diatomic bridges. Four and two five-membered rings, respectively, of the pentagonal dodecahedrane skeletons are herein replaced by seven-membered lactone rings. From previous work it could be inferred that tetrafunctionalized pagodanes **N** can be singly or doubly bridged to give **O** and **P**, respectively, and that the latter could be converted into the dienes **A** and **E**, respectively, by proven methodology.[7]

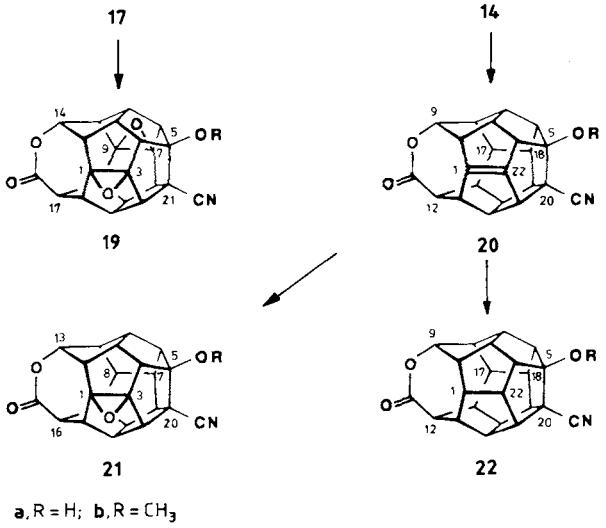
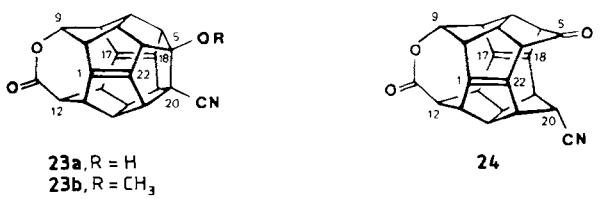
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and BASF AG. We thank Dr. *D. Hunkler* for NMR analyses, Dr. *J. Wörth* for MS analyses, Mrs. *M. Lutterbeck* and *M. Froom*, *G. Leonhardt* and *J. Leonhardt* for supplying starting materials, *G. Fehrenbach* for graphical work, and Dr. *W.-D. Fessner* and Dr. *L. Knothe* for helpful discussions.

Starting material is generally the dioxo-pagodane-*syn,syn*-dicarbonitrile (**N**, X = CHCN, Y = CO) or the all-*syn*-14,19-dihydroxy-4,9-dicarbonitrile **1** obtained therefrom in quantitative yield.[8] The latter is converted rapidly and uniformly into the monolactone **2** (**O**) on treatment with conc. acetic acid under reflux;[9] the cyclization to the more highly strained bislactone **3** (**P**) is relatively slow and unselective: after ca. 70% conversion (based on **2**, 40 min) the yield of **3** is ca. 40% (as alternative, double dehydration of the all-*syn*-dihydroxydicarboxylic acid prepared via **1** is investigated[10]).



The conversion of bislactone **3** into the bishomologous dodecahedradiene **5** turned out to be straightforward: photobromination **3**→**4** under standard conditions[7] furnished dibromide **4** almost exclusively (ca. 95% isolated) even after quantitative conversion. The absence of competing bromination at the 11(20) positions can be attributed to only slight stabilization of the potential radical centers by the—for this purpose unfavorably oriented—α-carbonyl groups. Elimination of Br_2 to give **5** (**E**), in principle in competition to the re-formation of **3**, is also rapid and quantitative under proven conditions (Zn/NaI, Na_2SO_3, dimethylformamide (DMF), 150°C). The dodecahedradiene **5** (9,21-dioxaundecacyclo[11.11.0.0^{2,11}.0^{3,7}.0^{4,24}.0^{5,20}.0^{6,18}.0^{8,17}.0^{12,16}.0^{14,23}.0^{15,19}]tetracosa-3,15-diene-10,22-dione), with only slight pyramidalization of the olefinic centers, is quite persistent towards oxygen and can be crystallized from CH_2Cl_2 (m.p. >320°C; $\tilde{\nu}_{C=O}$ = 1720 cm^{-1}). The strong transannular π/π interaction expected for a transannular distance of (possibly somewhat more than) 2.7 Å manifests itself in a long wavelength UV absorption (CH_3CN, λ_{max} = 255 nm (sh, ε = 110)), in a quantitative [$\pi_2+\pi_2$]-photocycloaddition (leading to **3**) and quantitative bromine addition (leading to **4**). Also typical for structure **5**, which is rather similar to that of the bissecododecahedradienes, is the electrochemical oxidation to a radical cation and a dication.[11] The behavior of this "flattened" dodecahedradiene under diverse hydrogenation conditions is consistent with expectations based on calculations: with diimide the reaction always comes to an end at the stage of the dodecahedrene **6** (**F**); the saturated, clearly more strained bishomododecahedrane **10** (**G**) is not attained even under drastic conditions. Oxidation of **5** with *m*-chloroperbenzoic acid or peroxycarbamic acid is surprising in that the second oxidation step is so rapid that even with equivalent amounts of oxidizing agent considerable amounts of diepoxide **9** (**H**) are found besides monoepoxide **7** (TLC, ^{1}H NMR). Oxidation of **6** to **8** with peroxycarbamic acid at 40°C (CH_2Cl_2) is rapid and free of competition. **7** cannot be hydrogenated to **8**.

The ε-ketonitrile **11**, which is obtained in quantitative yield from the monolactone **2**, was an obvious precursor for monohomologous dodecahedranes (**I**–**M**) (Aldol-route[11]). The conversion of **11** into the secohomododecahedradiene **13** (**A**) is more laborius insofar as **12**, the product of a regiospecific addition of bromine on the lactone side of **11**, undergoes further unselective bromination. The loss of material remains limited, however, if the bromination is stopped at ca. 50% conversion, whereupon **12** can be cleanly separated by chromatography (>90%). Dehalogenation to **13** is quantitative. In **13**, with its almost parallel CC double bonds ($d \geq 2.7$ Å, λ_{max}(CH_3CN) = 306 nm (ε = 70), 271 (sh, 220), 260 (sh, 250), 223 (1040)),



$[\pi_2+\pi_2]$-photocycloaddition (acetone, to give **11**) and bromination (to **12**) again proceed uniformly. Qualitative differences compared to the diene **5** are manifest in the analogous derivatization reactions: under the hydrogenation conditions effective in the case of **5**, **13** reacts only extremely slowly; with a very large excess of diimide ($N_2(CO_2K)_2$, CH_3CO_2H, CH_2Cl_2/CH_3OH, 0°C, 14 h), however, **14** (**B**) is formed quantitatively. The latter proves to be hyperstable—no **18** (**C**)—but is oxidized by peroxycarbamic acid ($CHCl_3$, 60°C) to **16**. At room temperature, the diene **13** is converted quantitatively into the monoepoxide **15**, which, at 70°C, is further oxidized very slowly to the diepoxide **17** (**D**) (>80% isolated). Presumably, with increasing bulging of the molecular framework, i.e., with decreasing (increasing) d_1 (d_2) distances, destabilizing interactions between C=O and C≡N become effective. Hydrogenation of **15** to **16** cannot be achieved.

As in the case of the analogous pentagonal dodecahedranes the prognosis for cyclization of the seco precursors (**14**→**20** (**B**→**K**), **16**→**21** and **17**→**19** (**D**→**M**)) was promising. First examples have been realized: under reversible (I, *tert*-butyl alcohol, potassium *tert*-butoxide, THF, 20°C) as well as irreversible (II, NaH/CH_3I, THF, 40°C) reaction conditions, **17** was uniformly transformed (>95% isolated) into homologous diepoxydodecahedranes **19a** (**b**), and **14**, equally selectively, into the homologous dodecahedranes **20a** (**b**). The latter, inspite of (presumably) considerable pyramidalization of the olefinic C atoms, are virtually insensitive to oxygen and can be isolated in the crystalline state. As expected, the olefin **20a** (5-hydroxy-11-oxo-10-oxaundecacyclo[11.9.0.0^{2,9}.0^{3,7}.0^{4,22}.0^{5,20}.0^{6,18}.0^{8,17}.0^{12,16}.0^{14,21}.0^{15,19}]dodeca-1(22)-ene-20-carbonitrile) is hydrogenated to **22a** (**L**); peracid oxidation leads quantitatively to **21a**.

The cyclization **13**→**23** (**A**→**I**) should be considerably endothermic. In preliminary experiments carried out reversibly (conditions I) as well as irreversibly (II), neither **23a** nor **23b**, but only *anti*-nitrile **24**, i.e. rapid and quantitative epimerization at C-20, was observed. That no H/D exchange takes place in **24** under analogous conditions underscores the importance of *syn*-orientation for the CN or COOR substituents in the (bis)seco substrates—possibly an essential for the preparation of the pentagonal dodecahedranes.[1]

Exemplary for the diverse (bis)homologous dodecahedranes, the ^1H and ^{13}C NMR data of **5** (C_{2v}), **19a** (C_s) and **20a** (C_1) are given in Figure 1. COSY, NOE and selective decoupling experiments have allowed complete assignment of all signals. Inter alia, the geometrical consequences of the homologization of the dodecahedrane framework, indicated by the d (d') distances (Scheme 1), are reflected in chemical shifts, especially of the olefinic signals. Besides the generally intense $M^{\oplus}$ signals, the EI mass spectra feature no significant signals for pentagonal dodecahedranes that could result from CO_2 eliminations; with **22a** as so far singular exception: *m/z* 345 ($M^{\oplus}$, 85%), 302 ($M^{\oplus}-HOCN$, 100%), 274 ($M^{\oplus}-HOCN-CO$, 86%), 258 ($M^{\oplus}-HOCN-CO_2$, 32%).

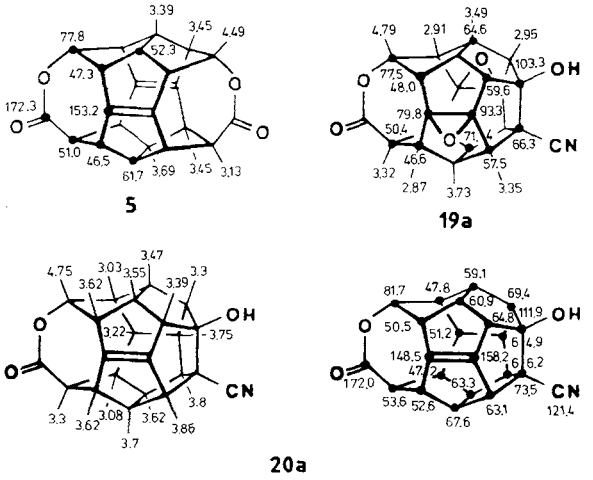


Fig. 1. ^1H and ^{13}C NMR data of **5**, **19a** ($CDCl_3$) and **20a** ($CDCl_3$/[D_6]dimethyl sulfoxide.

The results of this and the preceding communication open up a preparative entry to variously modified, saturated and unsaturated dodecahedranes: Our routes to tetrafunctionalized pagodanes[1] are efficient, the mode of substitution can be deliberately varied, and the methods for the ultimate C–C bond formations can be adjusted to the respective thermodynamic situation. The first steps of our pagodane synthesis[14] have already been performed on the kg scale[15] and we hope that appropriately equipped institutions will assist us in lifting subsequent steps to this scale.

Do Any AB_n Molecules Have Anomalous Shapes? ν_3 of TiF_4 and TiF_3 and Their Relevance to the Shape of TiF_2**

By *Ian R. Beattie,* Peter J. Jones,* and *Nigel A. Young*

Recent experimental work suggests that all discrete molecular first-row transition-element dichlorides are linear in the ground electronic state. We now find that an IR band previously assigned to matrix-isolated TiF_3 is due to TiF_4. Further, the band assigned to TiF_2 is due to TiF_3. The reported bond angle of 120° for "TiF_2" can thus be explained by the presence of trigonal-planar TiF_3. "TiF_2" was a key molecule in the proposals for nonlinearity of AB_2 species. We question whether there is unambiguous evidence of anomalous shape for any high-temperature AB_n molecule.

In 1979 *Drake* and *Rosenblatt*[1] summarized the experimental data on the structures of metal dihalide and trihalide molecules. The dichlorides (MCl_2) of the first-row transition series and calcium were assigned a linear configuration, which is in agreement with recent work.[2,3] For the difluorides (MF_2), those of Ca, Sc, Ti, and V were assigned as nonlinear, the remainder as linear. For ScF_2 and VF_2 (which are both monoisotopic) the bond angles were estimated[4] by analogy with those of neighboring molecules. Thus CaF_2[5] and TiF_2[6] represent key experimental points in the assignment of nonlinear structures to these MX_2 species.

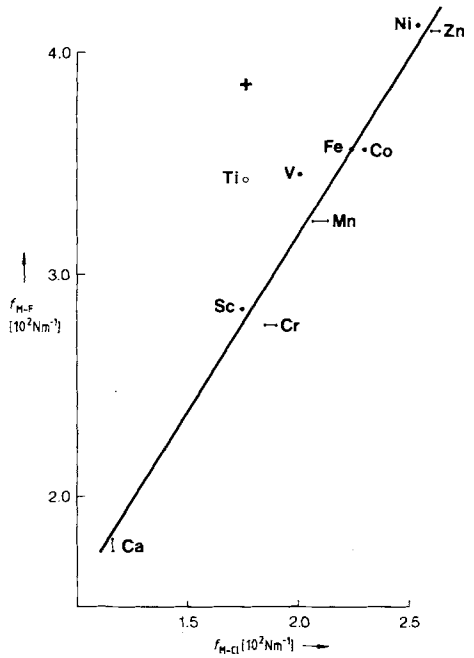

Fig. 1. Plot of f_{M-F} versus f_{M-Cl} for MX_2 molecules in argon matrices.

In Figure 1 we plot the Simple Valence Force Field bond-stretching force constants f_{M-F} and f_{M-Cl} for the MX_2 molecules isolated in argon matrices. The calcula-

tions are based on the reported experimental[2-7] values of ν_3 and assume that the MX_2 molecule is linear and symmetrical. If the molecule is nonlinear, our calculation will yield an apparently lower force constant than that which would be obtained using the correct molecular geometry. This rather crude approach to the bonding in these molecules leads to a roughly linear relationship between f_{M-F} and f_{M-Cl}. The straight line on the graph is based on a least-squares plot *including the origin* but omitting the titanium point, which is well removed from the line.

Matrix isolation studies of lower-valent fluorides are fraught with difficulty (notably the occurrence of ^{19}F in 100% abundance, which makes even the *formula* of the species isolated open to question). Figure 1 suggests the force constant value for TiF_2 may be in error. Allowing the molecule to bend to 120° moves TiF_2 even further from the line, to the point designated + in Figure 1. In view of the importance of TiF_2 in valence theory we have studied the vapors over heated TiF_3 and TiF_4.

In our experiment, vaporization of TiF_4 (prepared from titanium and fluoride) at ca. 100°C followed by cocondensation of the vapors with argon or neon (Fig. 2) gave IR spectra almost identical in frequency and intensity pattern to those assigned to TiF_3.[6] Using a Perkin Elmer 983 G infrared spectrometer at 0.5-cm^{-1} resolution, we did not observe any additional bands in the 1000- to 200-cm^{-1} region. Similar results were obtained by heating TiF_3 (Alfa Inorganics).

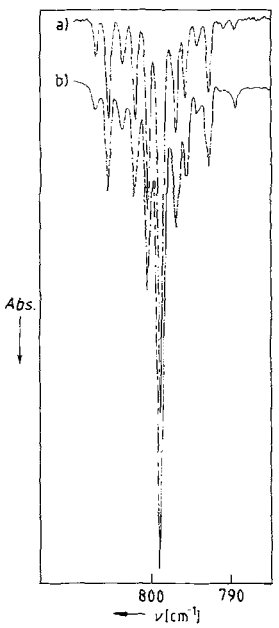

Fig. 2. Comparison of the IR spectra of a) TiF_4 in neon and b) TiF_3 in neon [6].

A mass spectrometric study[8] has shown that TiF_4 sublimes unchanged. Further, TiF_4 was the *only* vapor species identified from the initial heating of commercial TiF_3 at 708 K. If the TiF_3 was held at 848 K for sufficient time to avoid "swamping the mass spectrometer with TiF_4,"[8] some TiF_3 could be observed. The authors also report univariant vaporization for the two-phase region $Ti+TiF_2$, again with *only TiF_3 and TiF_4 identified as vapor species.*

We conclude that the band originally assigned to TiF_3[6] was ν_3 of TiF_4. The reported spectrum of TiF_2 was generated by heating "commercially available" TiF_3 and passing the vapors (i.e., TiF_4) into a cell containing elemental titanium at 940 or 1100°C. By contrast, the mass spectrometric studies[8] show that up to 1025 K (the limit of these experiments) the vapors would contain *only* TiF_4 and TiF_3. In our experiment, passing TiF_4 vapor (from commercial TiF_3) over titanium metal at ca. 800–850°C, followed by matrix isolation in argon, led to an IR spectrum showing a sharp, intense new band at 740 cm^{-1} (together with the band at 792 cm^{-1} due to TiF_4). *There were no other intense bands in this region of the IR spectrum.* The 740-cm^{-1} band was ca. 60% of the intensity of the TiF_4 band. Under high resolution this band showed titanium-isotope fine structure, the frequencies agreeing to better than 1 cm^{-1} with those assigned[6] to TiF_2. *Our results, combined with the earlier mass spectrometric data, identify the 740-cm^{-1} band as due to TiF_3, not TiF_2.*

We further find that matrix isolation of the vapors from recently sublimed TiF_3 (heated rapidly to ca. 850°C) gave bands at 740 cm^{-1} (TiF_3) and 792 cm^{-1} (TiF_4) in roughly equal proportions. It is thus clear that TiF_3 both disproportionates and sublimes unchanged on heating, a not unexpected behavior for halides in this region of the periodic table.[9]

For trigonal-planar TiF_3 the isotope intensity and frequency pattern calculated for ν_3 (neglecting the in-plane deformation) is *identical* to that calculated for TiF_2 with a bond angle of 120°. The angle calculated[6] for "TiF_2" in an argon matrix is 119.5°, while in neon, where there are at least two sites, angles of 125.4° and 123.4° are given.

There are many theories of why certain high-temperature molecules adopt anomalous geometries. However, the evidence for such distortions is in many cases not definitive. Electron-diffraction molecular-scattering patterns are averaged over all thermal vibrations *and* all species in the vapor; the precise interpretation of electric deflection data on such molecules is open to question, as is that derived from ESR measurements in matrices.[10] IR isotope shift data for matrix-isolated species become insensitive as the mass of the central atom increases. For "TiF_2" the isotope shift between ^{46}Ti and ^{50}Ti in argon was 2.1 cm^{-1} *less* than that calculated for a linear molecule (which was why it represented a key observation). CaF_2 is another key molecule, but here the difference between the observed isotope shift (^{40}Ca, ^{44}Ca in krypton) and the calculated shift for a linear molecule is less than 1 cm^{-1}.[15]

Observation of the totally symmetric stretching vibration in the IR spectrum has been used as a criterion of geometry, notably for compounds of the heavier elements where the symmetric stretch and the antisymmetric stretch approach one another in frequency. In such cases *partial* isotopic substitution ($^{16}O/^{18}O$; $^{35}Cl/^{37}Cl$) can lead to unambiguous identification of both ν_1 and ν_3.[11] Even in these cases, however, great caution is necessary, as may be seen by reference to elegant papers by *Lesiecki* and *Nibler* et al.[12]

Where a lowering of symmetry results in the resolution of a degeneracy (T_d to *any* lower symmetry; D_{3h}, with loss of the C_3 axis, e.g., to C_{2v}), the observation of additional bands coupled with partial isotopic substitution can lead to assignment of the point group. However, *Beattie* et al.[13] produced evidence that $ThCl_4$ had T_d symmetry in neon, but a lower symmetry in krypton, illustrating the possibility that matrix gases may cause a change of geometry. In the case of T-shaped UO_3[14] one could imagine a trigonal-

planar gas-phase molecule being distorted along a coordinate towards $UO_2^{2\oplus}O^{2\ominus}$ in a matrix.

There are many careful and very difficult experiments in the literature. The purpose of this communication is to question how many of the results on high-temperature molecules lead to *unambiguous* determination of the shape of the *free molecule*.

tBu$_2$P–P=PBrtBu$_2$ · LiBr and the Formation of tBu$_2$P–$\ddot{\text{P}}$

By *Gerhard Fritz,* Tilo Vaahs, Holm Fleischer,* and *Eberhard Matern*

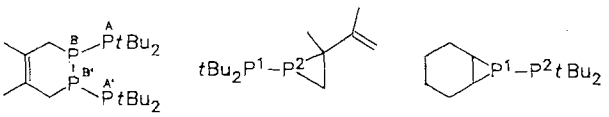
Although complexes having terminal phosphanediyl (phosphinidene) ligands—formed via phosphole complexes—are well-known,[1] all efforts to isolate a free phosphinidene have been unsuccessful up to now. Thus, for example, free phosphinidenes could not be detected in the thermolysis of 7-phosphanorbornadienes or of $(PMe)_5$.[2] Attempts to form free phosphinidenes via decomplexation of terminal phosphinidene complexes have also failed.[2] Apparently, what is lacking is a suitable precursor, from which phosphinidenes can be generated at sufficiently low temperatures.

We have now found that the reaction of **1**[3] with **2** affords yellow, toluene-soluble crystals of **3**.[4] The formulation of **3** as the LiBr adduct of a P–P ylide took into account the ^{31}P NMR spectroscopic data, which were consistent with multiple bond character for the P^2–P^3 bond, and the increased coordination number at P^3.

$$(t\text{Bu}_2\text{P})_2\text{PLi} + \text{Br–CH}_2\text{–CH}_2\text{–Br} \longrightarrow$$

1 **2**

$$t\text{Bu}_2\text{P}^1\text{–P}^2\!=\!\text{P}^3\text{Br}t\text{Bu}_2\cdot\text{LiBr} \xrightarrow{20\,^\circ\text{C}} \text{P}_n(\text{P}t\text{Bu}_2)_n$$



3 **4, 5**

The LiX adduct of a C–P ylide $Ph_3\overset{\oplus}{P}\text{–}\overset{\ominus}{\ddot{C}}RR'\cdots LiX$ can be understood in analogous terms.[5] **3** resembles the lithiated ylides $(R_2CLi\text{–}PR_3)X$ of *H. Schmidbaur* and *W. Tronich*[6] and the 1,1,3,3-tetraphenyl-1λ^5,2λ^3,3λ^5-triphosphenyl cation[8] and triphosphenium ions[7] described by *A. Schmidpeter* et al. A crystal structure analysis of **3** was, until now, not possible.

Compound **3** decomposes upon warming to 20 °C with quantitative formation of tBu$_2$PBr, LiBr, and the cyclophosphanes **4** ($n=3$) and **5** ($n=4$).[9] The formation of these compounds suggests that 2,2-di-*tert*-butyl-1,1-diphosphanediyl, **6**, is the intermediate in this reaction. Therefore, we attempted to obtain evidence for the intermediacy of **6** by trapping reactions. Decomposition of **3** in 2,3-

$t\text{Bu}_2\text{P–}\ddot{\text{P}}$ **6**

dimethyl-1,3-butadiene at ambient temperature gives rise to the compounds **7** and **8**; the cyclophosphanes **4** and **5** are no longer formed. The formation of **7** is favored with respect to **6** and suggests the presence of $t\text{Bu}_2\text{P–P=P–P}t\text{Bu}_2$ as a reactive intermediate.[10] The decomposition of **3** in cyclohexene led to **9**,[10] but in this case, the major products were the cyclophosphanes **4** and **5**.

7 **8** **9**

The reaction of **3** with dimethylbutadiene to give **8** is analogous to the conversion of terminal phosphinidene complexes to vinylphosphirane complexes.[1] The formation of **9** from **3** and cyclohexene is directly comparable to the reaction of phosphinidene complexes with olefins.[1]

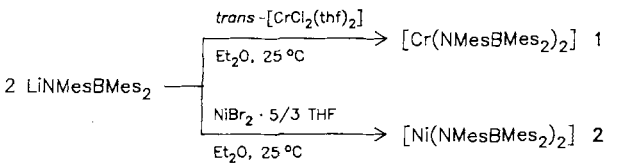
[9] Since one of the $PtBu_2$ groups in **4** is *trans* to the others, only three signals, rather than four, are observed in the ^{31}P NMR spectrum. $\delta = 67$ (1P), 47 (2P). The signal at $\delta = -163$ (3P, high field shift typical for three-membered ring compounds) consists of two overlapping signal patterns for the three exocyclic P atoms. MS: *m/z* 528.2631 ($M^{\oplus}$), 471.1945 ($M^{\oplus} - t$Bu). **5** crystallizes from the reaction mixture at -20°C. ^{31}P NMR: $\delta = 63$ (P_{subst}), -43 (P_{ring}), $^1J_{PP} = -329$ Hz. MS: *m/z* 708.3562 ($M^{\oplus}$), 559.2389 ($M^{\oplus} - P$tBu), 533.1407 ($M^{\oplus} - 3t$Bu). Compounds **4** and **5** are known from the decomposition of $tBu_2P-P(SiMe_3)-P(SiMe_3)_2$ [G. Fritz, T. Vaahs, *Z. Anorg. Allg. Chem. 553* (1987) 85]. They are formed at 65 °C (15 h) with preferred cleavage of $P(SiMe_3)_3$ [side product, $tBuP(SiMe_3)_2$] suggesting the intermediacy of **6**.

[10] For the trapping reactions, **1** was dissolved in 2,3-dimethyl-1,3-butadiene or cyclohexene. **2** was then added at 0°C and the solution stirred at 20°C for 5 d. In each case, a clear orange solution formed which gradually became cloudy as LiBr precipitated. Quantities for **7** and **8**: 0.5 g (1.21 mmol) **1**, 0.22 g (1.21 mmol) **2**, 10 mL 2,3-dimethyl-1,3-butadiene; for **9**: 1.0 g (2.42 mmol) **1**, 0.44 g (2.42 mmol) **2**, 15 mL cyclohexene. ^{31}P NMR (spectrum of the reaction solution): **7**: $\delta = 45.3$ (P^A), -48.7 (P^B), $J_{BB'} = -277$, $J_{AB} = -329$, $J_{AB'} = 65$, $|J_{AA'}| \leq 1$ Hz. **8**: $\delta = 34.5$ (d, P^1), -189.0 (d, P^2); $J_{12} = -233$ Hz. **9**: $\delta = 65.5$ (d, P^2), -225.0 (d, P^1), $J_{12} = -220$ Hz. The formation of **7** can be compared with the reaction of $tBuP=P-SiMe_3$ [from $tBuClP-P(SiMe_3)_2$] with 2,3-dimethyl-1,3-butadiene [G. Fritz, H. Fleischer, *Z. Anorg. Allg. Chem.*, in press] as well as the reactions of $tBu_2P-P=PtBu$ [from $tBu_2P-P(SiMe_3)-PCltBu$] and $tBu_2P-P=P-SiMe_3$ [from $tBu_2P-P(Cl)-P(SiMe_3)_2$] with cyclopentadiene [G. Fritz, T. Vaahs, *Z. Anorg. Allg. Chem. 552* (1987) 34].

$[M(NMesBMes_2)_2]$ (M = Cr, Ni): Stable, Distorted, Two-Coordinate d^4 and d^8 Complexes**

By *Ruth A. Bartlett, Hong Chen,* and *Philip P. Power**



Many three-coordinate complexes are now known for a wide range of transition metals.[1,2] However, except for d^{10} complexes, stable, two-coordinate transition-metal species are extremely rare. Currently, the range of such compounds is confined to the metals Mn,[3-6] Fe,[6,7] and Co[6,7] involving a few bulky alkyl[3,4] and amide[5,6] groups for Mn and silylamide ligands only for Fe and Co.[6,7] Divalent nickel silylamides such as $[Ni\{N(SiMe_3)_2\}_2]$ appear to be unstable,[8] and homoleptic Ni^{II} alkyls appear to be unknown. Similarly, no homoleptic, monomeric amide or alkyl derivatives have been described for Cr^{II}, although higher-coordinate base-stabilized Cr^{II} alkyls and amides have been reported.[9]

Recently, we have shown that borylamide ligands, $^{\ominus}NRBMes_2$ (R = Ph or Mes), are effective in achieving a low coordination number in Mn by preventing association.[5] This is a consequence of both the large ligand size and the significantly reduced nitrogen lone pair availability for bridging. We now describe the synthesis and structural characterization of the complexes $[M(NMesBMes_2)_2]$ (**1**, M = Cr; **2**, M = Ni), the first[10] neutral two-coordinate derivatives of Cr^{II} and Ni^{II}.

[**] This work was supported by the National Science Foundation and the Petroleum Research Fund.

The complexes **1** and **2** were synthesized in moderate yield by reaction of the lithium borylamide $LiNMesBMes_2$[5] and *trans*-$[CrCl_2(thf)_2]$ or $NiBr_2 \cdot 5/3\,THF$ (Scheme 1).[11]

Scheme 1. Mes = 2,4,6-trimethylphenyl.

The chromium complex, **1**, was obtained as green crystals (m.p. 195 °C) from hexane and has the X-ray crystal structure[12] shown in Figure 1. A key feature is the N1-Cr-N2 angle of 112.3(3)°, which is far from the expected linear or near-linear configuration. There are Cr···C10 and Cr···C37 contacts of about 2.39 Å, which are much shorter than that previously observed (2.536(5) Å) in the manganese analogue, $[Mn(NMesBMes_2)_2]$ **3**, even though Cr and Mn have similar metallic radii.[5] In addition, the angles between the B1-C10 and B2-C37 bonds and the respective mesityl planes (10.2 and 15.2°, respectively) indicate moderately strong Cr···C interactions. The asymmetry of the B-C bonds and the N-B-C angles within each ligand support this view. Two other structural

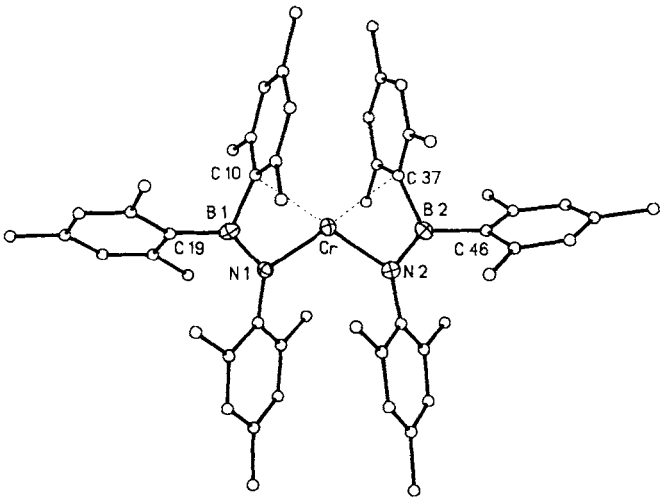

Fig. 1. Crystal structure of **1** [12]. The hydrogen atoms and solvent hexane molecule have been omitted for clarity. Selected bond distances [Å] and angles [°]: Cr-N1 1.980(7), Cr-N2 1.988(7), N1-B1 1.373(13), N2-B2 1.381(12), B1-C10 1.647(14), B1-C19 1.598(14), B2-C37 1.646(14), B2-C46 1.624(14), Cr···C10 2.383(15), Cr···C37 2.391(15); N1-Cr-N2 112.3(3), Cr-N1-B1 98.8(6), Cr-N2-B2 96.8(6), N1-B1-C10 113.1(8), N1-B1-C19 128.7(9), C10-B1-C19 118.1(8), N2-B2-C37 115.4(8), N2-B2-C46 129.4(9). Angle between Cr-N1-C10 plane and Cr-N2-C37 plane = 18.7°.

features merit comment. First, the twist angles between the boron and nitrogen planes are 11.1° for both ligands. This, together with the average B-N distance of 1.377(13) Å, shows that both B-N bonds have an undiminished p-p π interaction.[5] Second, the dihedral angle between the Cr-N1-C10 and Cr-N2-C37 planes is 18.7° whereas an angle closer to 90° might be expected for a quasi-tetrahedral

configuration. Thus, the structure of **1** is nearer to distorted square planar than it is to the distorted tetrahedral type seen in **3** or the almost linear geometry seen in **2**. Square-planar coordination is, of course, known for a number of d^4 complexes, for example, *trans*-$[Cr\{N(SiMe_3)_2\}_2(thf)_2]$.[9]

The structure of the dark red nickel complex **2** (m.p. 165 °C) is shown in Figure 2. The main features of interest are the wide, almost linear, N1-Ni-N2 angle of 167.9(1)° and a possible Ni···C19 interaction at 2.611(3) Å. These two parameters are in sharp contrast to the deviations found in **1**. The relatively minor distortions from linearity could be due to crystal packing. Nevertheless, some asymmetry is evident in the B-C bonds and the N-B-C angles. The asymmetries, however, do not mirror the wide N-Ni-N angle or the long Ni···C contacts. The short B-N distances and the low (13.5°) twist angles between the B and N planes indicate that the B-N double bond is preserved.

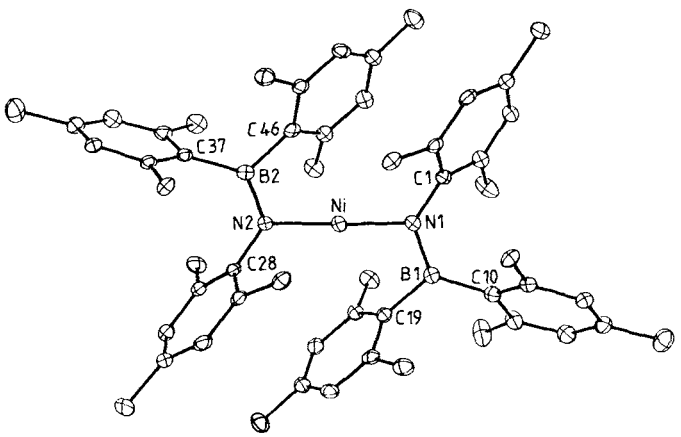

Fig. 2. Crystal structure of **2** [12]. Hydrogen atoms omitted for clarity. Selected bond distances [Å] and angles [°]: Ni-N1 1.867(2), Ni-N2 1.865(2), N1-B1 1.411(4), N2-B2 1.412(4), B1-C10 1.595(3), B1-C19 1.617(4), B2-C37 1.596(3), B2-C46 1.619(4), N1-C1 1.424(4), N2-C28 1.428(3), Ni···C19 2.611(3), Ni···C46 2.703(3); N1-Ni-N2 167.9(1), N1-B1-C10 125.6(3), N1-B1-C19 111.9(2), N2-B2-C37 126.0(3), N2-B2-C46 112.8(2).

The differences between the structures of **1** and **2** are probably both steric[13] and electronic in origin. The smaller size of nickel favors a wide N-M-N angle. The large size of chromium permits closure of this angle and the d^4 electron configuration is probably responsible for the quasi-square-planar geometry. Also, the nickel center is more electron rich than chromium and has less tendency to achieve a higher electron density through structural distortion. Possible supporting evidence comes from a comparison of the average B-N distances in **1** (1.377(12) Å) and **2** (1.412(4) Å). It can be argued that the value for **2** is longer because the more electron-rich nickel center can donate electron density more effectively into the B-N π* orbital than chromium. More conclusive evidence awaits the synthesis and spectroscopic characterization of complexes involving a wider variety of ligands and transition metals. An alternative explanation is that, owing to the larger size of Cr, the ionic character of the Cr-N bond in **1** is greater than that of the Ni-N bond in **2**. Thus, the negative charge on the nitrogens in **1** is greater, which leads to a stronger B-N π interaction.

The absorption spectra of **1** and **2** were recorded in toluene at ambient temperature. For **1**, two absorptions were seen at $\lambda = 16030$ ($\varepsilon = 252$) and 12530 cm^{-1} (77). This result is consistent with the X-ray structure but does not rule out other conformations in solution. The more intensely colored **2** has three absorptions at $\lambda = 28985$ ($\varepsilon = 1200$), 23060 (1100), 17480 cm^{-1} (914). In the absence of comparative data for other complexes it is difficult to draw many structural conclusions from these spectra. Magnetic measurements (using the Evans method)[14] for **1** and **2** at 25 °C support a high-spin configuration for **1**. No paramagnetically shifted peaks could be detected for **2** nor could different environments for the mesityl groups be distinguished.

Two Ferrole Isomers in Equilibrium: Experimental Confirmation of an Old Hypothesis**

By *Miklos Tasi, Anne K. Powell,* and *Heinrich Vahrenkamp**

After 30 years of extensive investigations of the chemistry of alkyne iron carbonyl compounds, almost 100 ferracyclopentadienyl iron complexes are now known.[1] Numerous structural and spectroscopic studies have confirmed the idea that in diiron complexes of type **A** the ferracyclopentadienyl unit acts as a π-ligand towards the $Fe(CO)_3$ fragment.[1,2] On the basis of these investigations, it was also assumed that only a low energy barrier exists for the site exchange of the ferrole ring (**A** ⇄ **C**) and that this process passes through a transition state **B** of C_{2v} symmetry.[3] The only evidence for a dynamic behavior of ferroles until now was, however, the earlier observation[3a] that optically active oxy- and hydroxy-substituted ferroles racemize at higher temperatures.

We have now been able to detect the reversible interconversion of two isomeric ferrole complexes. Heating the μ_3-azoalkane-bridged triiron cluster $[Fe_3(CO)_9(N_2Et_2)]$[4] in the presence of excess phenylacetylene in petrol ether at 110°C for 10 min afforded the two isomers **1a** and **1b** in 18 and 57% yield, respectively. Brown **1a** and red **1b** were separated by chromatography with hexane on silica gel and were characterized spectroscopically[5] and by crystal structure analyses.[6] Both clusters contain an almost linear triiron skeleton (Fe–Fe–Fe angles 162 and 167°). The central iron atom is bound to both the μ-azoalkane and the μ-butadienediyl ligands, which adopt the most favorable arrangement with respect to each other whereby they are located on opposite sides of the clusters. The FeC_4 rings in both compounds are almost planar (largest deviations from the best plane being 9 and 11 pm, respectively). Characteristically, the bonding mode of the CO group on the central iron atom—bridging in **1a** and terminal in **1b**—adapts itself to the location of the butadienediyl ligand.

Since the two iron atoms bound to the butadienediyl ligand in **1** are located in different environments (without taking the C_4 ligand into account), a flip-flop process for the ferrole rings as in **A** ⇄ **C** should be readily detectable. The thermal treatment of **1a** and **1b** shows that this process does in fact occur. Heating the pure isomers in solution led to equilibrium mixtures of **1a** and **1b**; at 90°C, the ratio **1a**/**1b** was ca. 3/7 and at 110°C, 1/10. From the temperature dependence of the equilibrium constants, an isomerization enthalpy of 90±20 kJ mol^{-1} could be estimated. The uncertainty in this value is largely due to the fact that the compounds slowly decompose above 90°C. For the same reason, an accurate kinetic study of the isomerization reaction was also not possible.[7]

Although a large number of ferrole complexes having the two iron atoms in different environments are known,[1] for none of them was an isomerization as in **A** ⇄ **C** observed.[8] Apparently, one of the isomers is always decidedly favored with respect to the other, since the bonding situation in these complexes calls for a π-interaction between the more electron-rich iron atom and the ferracyclopentadienyl ring.[1,3b] The occurrence of the isomerization for **1a** and **1b** may be regarded as a further demonstration of the ability of polymetallic compounds to undergo charge delocalization. Thus, in the ferrole-like clusters **1**, two of the carbonyl ligands of the basic ferrole structure (see **A** and **C**) have been replaced by the $Fe(CO)_3(N_2Et_2)$ group, which is bound to the ferrole unit through iron–iron and iron–nitrogen bonds. Since systems with metal–metal bonds are known to be capable of delocalizing electron density,[9] and since the azo ligand is also known to act as an electron reservoir,[10] it is possible that these two factors contribute to a balancing of the charge in the ferrole unit, whereby the isomerization process becomes more facile.

Our observations are in accord with the arguments for the possible isomerization of ferrole compounds.[3b] In particular, the data are in agreement with the proposed transition state **B** with C_{2v} symmetry and also with a stepwise folding over of the two ends of the butadienediyl moiety (flyover bridge, C_2 symmetry). The fact that in **1a** as in **1b**, the phenyl groups are bound to the iron-complexed inner C atoms of the C_4 ligand suggests that the butadienediyl unit migrates without intermediate C–C bond-making and bond-breaking, which rules out, for example, a transition state with a μ_2-η^4-cyclobutadiene ligand.

The chemical objective of this investigation, which led to the complexes **1**, is the construction of organic molecules within the ligand spheres of clusters. In this respect, the controlled elimination of CO or $Fe(CO)_n$ groups from **1** might offer access to new C–N bond-forming reactions.

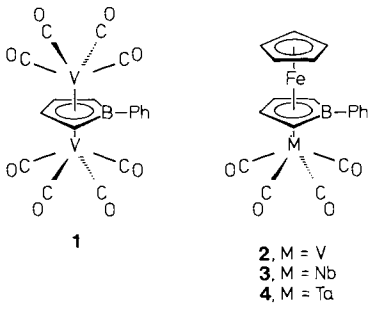
The 30-Electron Rule for Triple-Decker Complexes —Vanadium, Niobium and Tantalum Complexes as Illustrative Examples**



By *Gerhard E. Herberich,* Ingeborg Hausmann,* and *Norbert Klaff*

The number of valence electrons in the triple-decker complexes thus far isolated[2] lies between 26 in $[(\mu\text{-}\eta^6\text{-}C_6H_6)(VCp)_2]$[3] and 34 in $[(\mu\text{-Cp})(NiCp)_2]^{\oplus}$.[4] *R. Hoffmann* et al. have demonstrated in a definitive treatise on the MO scheme of triple-decker complexes that closed electron shells are achieved with 30 and 34 valence electrons;[5a] this conclusion has often been cited as the 30/34e rule. Wade's cluster rules[5b] lead to a narrower statement for triple-decker complexes: the magic number of valence electrons is 30.[5c]

The many triple-decker sandwich complexes with one or two outer Cp ligands often have a valence electron count deviating from 30.[2] For instance, in the case of vanadium the 26e systems $[(\mu\text{-}\eta^6\text{-}C_6H_6)(VCp)_2]$[3] and $[(\mu\text{-}\eta^6\text{-}P_6)\text{-}\{V(C_5Me_4R)_2\}_2]$ (R = Me, Et)[3] are known, but no 30e systems. On the other hand, it can be seen from the general MO scheme for triple-decker complexes that: a rigid 30e rule should apply when strong σ-donor-π-acceptor ligands such as carbon monoxide are present in the outer complex fragments. As illustrative examples for this assertion, we describe here some 30e complexes containing $M(CO)_4$ fragments, where M is an element of the fifth subgroup (vanadium, niobium, tantalum).

1-Phenyl-2,5-dihydro-1*H*-borole reacts with $V(CO)_6$ in hexane with dehydrogenative complexation to give red, crystalline **1**. The electrophilic stacking of the hydride **5**[6] with $V(CO)_6$ in hexane affords red needles of **2**. The complexes **1** and **2** are the first 30e triple-decker complexes of vanadium. The higher homologues **3** and **4** are obtained as deep-red needles by electrophilic stacking of sodium borataferrocene **6**[6] with **7** or **8**, respectively[7] in THF; they are the first triple-decker complexes of niobium and tantalum.

The new complexes[8] are sensitive to light and extremely sensitive to nucleophilic degradation.[1] In the IR spectrum they show the typical pattern of three CO bands for $M(CO)_4$ groups with highly perturbed local C_{4v} symmetry (Table 1). Their NMR data, with ^{11}B and ^{13}C NMR signals

at comparatively high field, confirm the presence of a bridging 1*H*-borole ligand; the AA'BB' system in the ^1H NMR spectrum shows the small coupling constant $N = {}^3J_{23} + {}^4J_{24}$ of only 3.9–4.2 Hz which is typical for the triple-decker structure.[9] The closely related triple-decker

$[NMe_3Ph][(\mu\text{-}\eta^5\text{-}C_4H_4BPh)\{Cr(CO)_3\}(FeCp)]$ **9**

complex **9** has been characterized by X-ray crystallography;[10a] here again, as in the case of the molybdenum and tungsten homologues,[10b] the outer carbonyl ligands enforce a 30e configuration.

Experimental

1: A mixture of 1-phenyl-2,5-dihydro-1*H*-borole (2.0 g, 14 mmol) and $V(CO)_6$ (1.00 g, 4.6 mmol) in hexane (20 mL) was heated to 55°C for 16 h. Filtration and chromatographic work-up (silica gel, −20°C) of the hexane filtrate afforded a yellow zone containing 7.3 mg (32 μmol; 0.7%) of $[V(CO)_4Cp]$ and a second, carmine-red zone, from which 9.6 mg (21 μmol; 0.9%) of red crystals of **1** were obtained by threefold crystallization. M.p. 68°C, decomp. 74°C, soluble even in pentane, light-sensitive in solution.—^1H NMR (80 MHz, [D$_6$]acetone): δ=7.66 (m, 2H$_o$), 7.36 (m, 2H$_m$+H$_p$), 5.72 (m, H-3,4), 4.29 (m, H-2,5); $N = {}^3J_{23} + {}^4J_{24}$=4.2 Hz. ^{11}B NMR (32.08 MHz, $CDCl_3$, ext. $BF_3 \cdot OEt_2$): δ=21.

2: A solution of **5** (345 mg, 1.32 mmol) [6] in hexane (100 mL) was treated with a solution of $V(CO)_6$ (361 mg, 1.65 mmol) in hexane (25 mL) at −25°C and the mixture stirred for 7 d at room temperature. Chromatographic work-up (Al_2O_3 with 7% water, −35°C) afforded a first runnings of $V(CO)_6$ with pentane, then a red zone with pentane/toluene (1/1), from which 228 mg (0.54 mmol; 41%) of red needles of **2** were obtained after removal of the eluent and crystallization from hexane at −30°C. M.p. 140°C (decomp.), light- and air-sensitive, soluble even in pentane.—^1H NMR (80 MHz, $CDCl_3$, int. TMS): δ=7.72 (m, 2H$_o$), 7.34 (m, 2H$_m$+H$_p$), 4.08 (s, Cp), 4.48 (m, H-3,4), 3.43 (m, H-2,5); $N = {}^3J_{23} + {}^4J_{24}$=4.0 Hz. ^{11}B NMR (32.08 MHz, $CDCl_3$, ext. $BF_3 \cdot OEt_2$): δ=11.4. ^{13}C-NMR (67.88 MHz, $CDCl_3$, −70°C): δ=255 (br., CO), 140.9 (s, C$_i$), 132.5 (dm, $^1J_{CH}$=155 Hz, C$_o$), 127.4 (dd, $^1J_{CH}$=158 Hz, C$_m$), 126.9 (dt, $^1J_{CH}$=159 Hz, C$_p$), 68.6 (dm, $^1J_{CH}$=177 Hz, Cp), 66.6 (d, $^1J_{CH}$=165 Hz, C-2,5), 65.0 (d, $^1J_{CH}$=183 Hz, C-3,4).

3: A solution of the salt 7 (prepared from 2.00 g (3.62 mmol) of $[Na\{O(CH_2CH_2OMe)_2\}_2][Nb(CO)_6]$ and 0.72 g (7.3 mmol) of CuCl [7]) in 250 mL of Et_2O was treated dropwise at −70°C with a solution of **6** (prepared from 0.85 g (3.25 mmol) of **5** by deprotonation with NaH [6]) in 120 mL of Et_2O and the mixture stirred for ca. 12 h at room temperature. Filtration,

$NaBH_4$ Reduction of Ketones in the Solid State

By *Fumio Toda,* Koji Kiyoshige,* and *Minoru Yagi*

Previously we reported that Baeyer-Villiger oxidations of ketones with *m*-chloroperbenzoic acid proceed much faster in the solid state than in solution.[1] We have now found that reductions of ketones with $NaBH_4$ also proceed in the solid state (Table 1). In addition, the formation of 1 : 1 inclusion complexes can be exploited to carry out regio- and enantioselective reductions leading to products such as **2a** and **4**, which are of interest as synthetic building blocks but only accessible with difficulty by other routes.

A mixture of the ketone and a tenfold molar amount of $NaBH_4$ was finely powdered using an agate mortar and pestle and kept in a dry box at room temperature for five days, being stirred once a day. The reaction mixture was extracted with ether, and the dried ether solution was evaporated to give the corresponding alcohol in the yields shown in Table 1. Almost the same results were obtained by shaking the mixture for a day using a test-tube shaker.

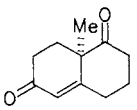

Table 1. Reduction of simple ketones in the solid state by $NaBH_4$.

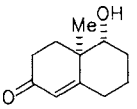
Ketone	Alcohol	Yield [%]
Ph_2CO	Ph_2CH-OH	100
trans-PhCH=CHCOPh	*trans*-PhCH=CHCHPh (OH) + $PhCH_2CH_2CHPh$ (OH)	100 (1 : 1)
		100
		53
PhCHCOPh (OH)	*meso*-PhCH–CHPh (OH OH)	62
$PhCH_2COPh$	$PhCH_2CHPh$ (OH)	63
		21
		92
$PhCOCONiPr_2$	$PhCHCONiPr_2$ (OH)	24



Treatment of a 1 : 1 inclusion complex[2,3] of (*R*)-**1** and (*R,R*)-**5** with $NaBH_4$ in the solid state for 3 days gave (*R,R*)-**2a** of 100% *ee* ($[\alpha]_D$ −192.8 (c = 0.24, benzene)) in 54% yield. The corresponding reaction of a 1 : 1 complex of (*S*)-**1** and (*S,S*)-**5** gave (*S,S*)-**2a** of 100% *ee*. Treatment of the racemic diketone **1** with (*R,R*)-**5** results in selective formation of an inclusion complex with (*R*)-**1**; decomposition of the complex gives (*R*)-**1** of 100% *ee*. Since the hydride attacks the carbonyl carbon at the 7-position from the side opposite the methyl group,[4] (*R*)-**1** should give (*R,R*)-**2a** of 100% *ee*, as was found. The IR spectrum and $[\alpha]_D$ value of the product were comparable to those of an authentic sample ($[\alpha]_D$ −203 (c = 1.545, benzene)) prepared by biological reduction of *rac*-**1**.[5]

The enone moiety of (*R*)-**1** is presumably masked by forming a hydrogen bond with the hydroxyl group of (*R,R*)-**5**, so that the other carbonyl group is reduced selectively. When the reduction of (*R*)-**1** is carried out in the presence of (*R,R*)-**5** in a suspension in water, the diol **2b** is obtained as a mixture of diastereomers.

(R)-(−)-3

(R,R)-(−)-4

(R,R)-(−)-5

It is not easy to prepare even racemic alcohol *rac*-**2a**. Recently, a preparative synthesis of *rac*-**2a** by selective reduction of *rac*-**1** with $NaBH_4$ in $MeOH/ClCH_2CH_2Cl$ (1:1) at −78 °C was reported.[4] A more complicated preparative method is the MnO_2 oxidation of *rac*-**2b**, prepared by reduction of *rac*-**1**.[6] The above-mentioned biological method is also complicated.[5]

Similar reduction of a 1:1 complex[3] of (*R*)-**3** and (*R,R*)-**5** with $NaBH_4$ in the solid state gave (*R,R*)-**4** of 100% *ee* ($[\alpha]_D$ −98.2 (c = 0.3, benzene) in 55% yield. The $[\alpha]_D$ value is comparable to that recorded for an authentic sample ($[\alpha]_D$ −97 (c = 1.415, benzene) prepared by a biological method.[7]

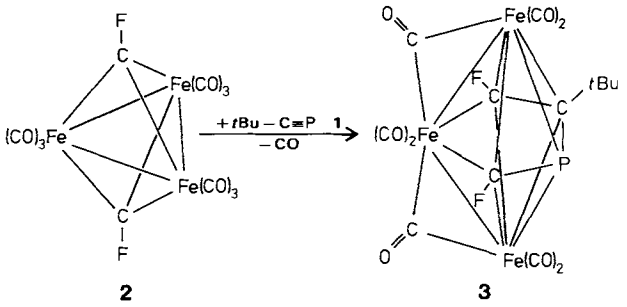
Formation of a Phosphaferracyclopentadiene Ring by Coupling of a Phosphaalkyne with Two Fluoromethylidyne Ligands**



By *Dieter Lentz** and *Heike Michael*

The coordination chemistry of the phosphaalkyne *t*BuC≡P **1**[1] has been extensively investigated in the last few years.[2] Other reactions that have been reported recently for **1** include its cyclodimerization and cyclotrimerization,[3] [2+2]-, [3+2]- and [4+2]-cycloadditions,[4] dimerization with insertion of CO,[5] as well as a reaction with a Fischer-type carbene complex.[6]

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft and the BASF AG (donation of pentacarbonyliron). We thank Prof. *J. Fuchs* for assistance with the crystal structure investigation and Dipl.-Chem. *L. Turowsky* for providing the compound *t*BuC≡P.

In the course of our investigations of the reactivity of $[Fe_3(CO)_9(\mu_3\text{-}CF)_2]$ **2**[7] towards alkynes,[8] we have discovered a novel type of reaction. Thus, reaction of **1** with **2** proceeds with coupling of both CF ligands to the phosphaalkyne to afford the five-membered phosphaferra heterocycle of complex **3**.

2 **3**

The ^{19}F NMR spectrum of **3** exhibits two doublets and the ^{31}P NMR spectrum contains a doublet of doublets (Table 1).

Table 1. Spectroscopic data for the compounds **3** and **5a-c**.

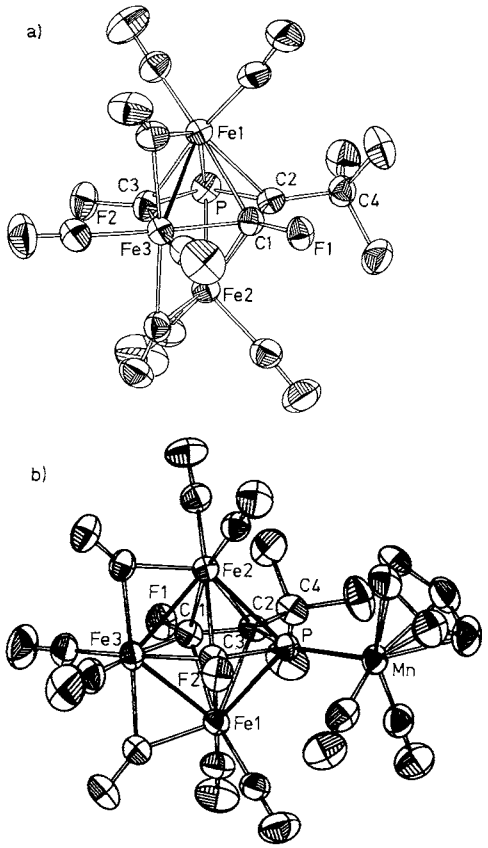
An X-ray structure analysis[9] showed that **3** has a pentagonal bipyramidal cluster skeleton (Fig. 1a). The five-membered Fe-C-P-C-C ring is completely planar (maximum deviation 0.4 pm) with the two F atoms and the central C atom of the *t*Bu group also lying in this plane (maximum deviation 0.8 pm). The near equality of the two C-P bond lengths indicates extensive delocalization of the electrons in the five-membered ring. Assuming that the phosphorus atom contributes three skeletal electrons, the cluster **3** conforms with the Wade rules,[10] which predict this type of *closo* structure for 16 skeletal electrons. A carbon analogue of **3**, $Fe_2(CO)_8[Fe(CPh)_4]$ (i.e., with CPh instead of P) was synthesized by *Hübel* et al. in 1959[11a] and was structurally characterized[11b] some years later.



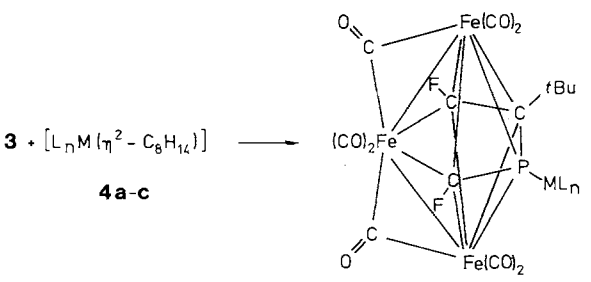


Fig. 1. a) Molecular structure of **3**. b) Molecular structure of **5b**. Important bond lengths [pm] and angles [°] for **3/5a**. Fe2-Fe3 245.13(7)/245.3(1), Fe1-Fe3 245.35(6)/245.9(1), Fe3-C1 199.9(4)/200.4(4), Fe3-C3 196.9(3)/196.1(5), Fe2-C1 212.4(4)/212.1(5), Fe2-C3 209.7(4)/208.9(5), Fe2-C2 230.0(4)/226.7(4), Fe2-P 242.9(1)/244.5(2), Fe1-C1 215.1(4)/211.6(5), Fe1-C3 209.7(4)/210.7(4), Fe1-C2 224.2(4)/229.9(4), Fe1-P 241.8(2)/241.6(2), C1-C2 143.4(5)/143.4(6), C1-F1 137.9(4)/138.2(5), C3-P 180.8(4)/180.1(5), C3-F2 138.5(4)/139.0(5), C2-P 180.2(3)/181.1(4), C2-C4 155.0(5)/155.7(6), Fe-CO_{term} 178.1(4)-181.8(4)/177.2(5)-180.8(5), Fe3-μ-CO 205.5(5), 205.9(4)/203.5(5), 207.2(5), Fe2-μ-CO 188.7(4)/189.2(5), Fe1-μ-CO 188.4(4)/187.6(5), Mn-P —/217.2(2), Mn-CO —/178.0(5), 178.5(5), Mn-C_{Cp} —/213.1(6)-215.2(6); Fe2-Fe3-Fe1 87.48(3)/87.48(4), C1-Fe3-C3 77.8(2)/76.7(2), Fe3-C1-C2 127.5(3)/129.3(3), C1-C2-P 114.7(3)/112.7(3), C2-P-C3 91.3(2)/91.5(2), P-C3-Fe3 128.7(2)/129.6(3), Fe2-P-Fe1 88.79(4)/88.64(5), Mn-P-C2 —/141.8(2), Mn-P-C3 —/126.6(2), Mn-P-Fe1 —/130.97(6), Mn-P-Fe2 —/137.54(6), P-Mn-CO —/91.1(2), 93.6(2).

Since the phosphorus atom in **3** occupiés the apex of a distorted square based pyramid (Fig. 1a), it should be possible to coordinate a further metal ligand fragment (ML_n) in this position provided that the P atom possesses a nonbonding pair of electrons. Thereupon, we reacted **3** with the chromium compound **4a** and with the manganese complexes **4b** and **4c** (Cp* = C_5Me_5) to afford the clusters **5a**-**c**, in which **3** is bound as a ligand to the ML_n fragment of **4**. This bonding situation results in a marked low field shift for the ^{31}P resonances and a decrease in the magnitude of the F-P coupling constants.

a, $L_nM = (CO)_5Cr$; **b**, $L_nM = Cp(CO)_2Mn$; **c**, $L_nM = Cp^*(CO)_2Mn$

The crystal structure of **5b**[9] showed that the cluster skeleton of **3** hardly changes upon coordination to the $MnCp(CO)_2$ fragment (Fig. 1b). Without exception, the differences between the bond lengths and angles of **3** and **5b** are very small. Like **3**, **5b** has a planar Fe-C-P-C-C ring (maximum deviation 2.5 pm) with the ring substituents lying in the plane (maximum deviation 12 pm).

Experimental

3: **1** (120 mg, 1.2 mmol) and **2** (300 mg, 0.62 mmol) were dissolved in *n*-pentane (250 mL) in a photolysis apparatus under an Argon atmosphere. The solution was irradiated for 30 min using a high pressure mercury lamp (Philipps HPK 125 W, pyrex glass filter), then filtered through a thin layer of silica gel (Woelm 63-200 μm). After removal of the solvent under vacuum, the product was dissolved in the minimum volume of pentane and the solution cooled to −20°C to afford deep-green crystals of **2**. Yield: 220 mg (64% based on **2**), m.p. 142-143°C.

5a: **3** (30 mg, 0.06 mmol) was stirred with **4a** (37 mg, 0.12 mmol) in *n*-pentane (20 mL) for 2 h at room temperature. The reaction solution was filtered through a thin layer of silica gel (Woelm 63-200 μm). After removal of unreacted starting material by elution with pentane, **5a** was eluted with CH_2Cl_2. Hexane (50 mL) was added to the eluate and the solution was concentrated on a rotary evaporator until the onset of crystallization. Cooling to −78°C afforded **5a** as yellow-green crystals. Yield: 13 mg (30% based on **3**), dec. >70°C.

5b: A solution of **3** (112 mg, 0.2 mmol) and **4b** (58 mg, 0.2 mmol) in *n*-hexane (50 mL) was heated under reflux for 3 h. The reaction solution was filtered through a thin layer of silica gel (Woelm 63-200 μm). Unreacted starting material was eluted with hexane. **5b** was obtained by elution with CH_2Cl_2. The solvent was removed using a rotary evaporator and the residue extracted into *n*-pentane. Cooling to −20°C afforded dark-green crystals of **5b**. Yield: 57 mg (40%), m.p. 138-139°C.

5c: Analogous to **5b**. Yield: 26 mg (18%), dark green crystals, m.p. 162-163°C.

Microstructure of a Discotic Polymer as Revealed by Electron Diffraction and High-Resolution Imaging

By *Ingrid Gisela Voigt-Martin,* Heinz Durst, Volker Brzezinski, Herbert Krug, Willi Kreuder,* and *Helmut Ringsdorf*

Electron microscopy has become a powerful tool to obtain atomic-level as well as molecular-level information.[1] It has recently been applied to study the microstructure and defects in smectic liquid crystals[2–5] without resorting to staining methods which are liable to cause artifacts.

Polymeric liquid crystals are well suited for such investigations because they are nonvolatile and their mesophases can be frozen in below their glass transition temperatures.[6] This allows detailed structural investigations because both the microstructure and defects in polymeric liquid crystals are retained in the glassy state. The smectic layers exhibit well-defined undulations and contain single and multiple dislocations.[5]

Recently, polymers with disclike mesogens as side groups[7] or in the main chain[8,9] have been described. They exhibit a discotic columnar structure as elucidated by X-ray investigations.[10] For low-molecular-weight compounds such liquid-crystalline microstructures have been known since 1977.[11] These compounds contain flat, rigid discs (e.g., triphenylene) and several flexible alkyl chains.[12] In discotic main-chain polymers[8] around ten to one hundred of such molecular discs are linked via flexible alkyl spacers (Fig. 1).

The polymer **1a**[8] shows an ordered, hexagonal columnar mesophase (D_{ho}) in complete analogy to its low-molecular-weight model compound **1b**. The mesophase width is even broader than for the hexakis(pentyloxy)triphenylene **1b**.[13] In contrast to **1b**, which crystallizes on cooling, the D_{ho} microstructure of the polymer can be frozen in below the glass transition temperature $T_g=60$ °C (Fig. 2).

The electron diffraction pattern (primary diffraction) indicates a hexagonal microstructure. The diffraction spots are sharp and show both first- and second-order reflections (Fig. 3). The measured lattice spacing is $d=18.1$ Å, from which a hexagonal lattice constant of $a=20.9$ Å could be calculated in agreement with the values obtained by X-ray studies (17.7 Å and 20.4 Å, respectively[10]).

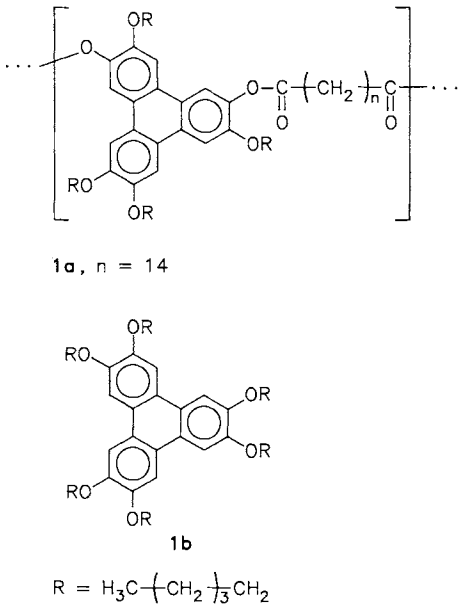

Fig. 1. Schematic representation of a repeating unit of the discotic polymer **1a** and structure of the model compound **1b**.

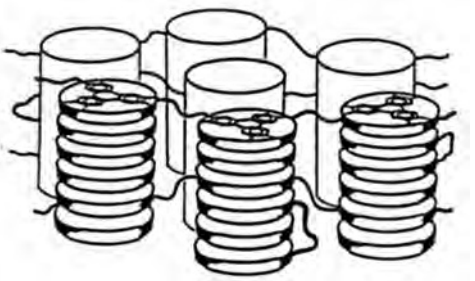

Fig. 2. Schematic representation of the D_{ho} mesophase of the polymeric triphenylene derivative **1a**.

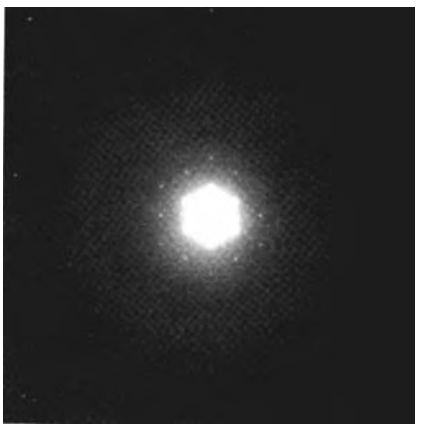

Fig. 3. Electron diffraction of the discotic polymer **1a**; D_{ho} phase viewed along the column axis.

The spots are arranged in a hexagon, but they are not arced as in the X-ray pattern of the same polymer.[10] Two explanations can be put forward. Firstly, the electron beam probes a very small area of about 2 μm in diameter, within which the orientation is apparently almost perfect. In contrast to this, X-rays probe about 1 mm^2, so that an average orientation is obtained. Secondly, the thickness of the film

for electron microscopy is of the order of several hundred angstroms only. This corresponds roughly to one hundred molecular triphenylene discs stacked on top of one another (see Fig. 2). This, in turn, is the typical correlation length within the columns of discotic liquid crystals.[17] The thin-film technique enables almost undisturbed columns to be observed which extend through the whole thickness of the polymer films.

While diffraction techniques give important general information regarding molecular packing, it is difficult and often impossible to elicit details regarding defects and correlation distances from them without making massive assumptions. The reason is that phase information is always lost in a diffraction pattern so that the Fourier transform contains amplitude information only. Phases can be reintroduced mathematically but this involves assumptions or additional information. An alternative approach is to apply high-resolution direct imaging. This method allows the observation of molecular structures. In Figure 4 the two-

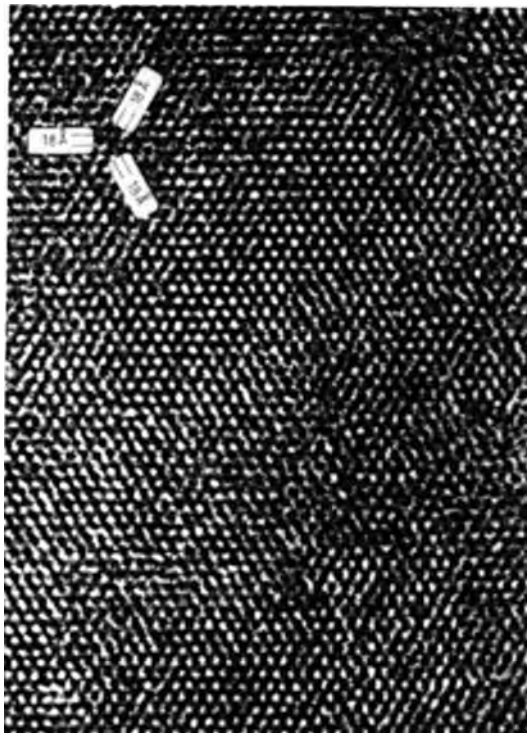

Fig. 4. Bright-field high-resolution electron micrograph of the discotic polymer **1a**. Middle: D_{ho} phase viewed along the column axis. Lower half: Tilted domain.

dimensional hexagonal packing of the molecular columns of the discotic liquid-crystalline polymer **1a** is shown for the first time. The single columns of the packed triphenylene discs (cf. Fig. 2) can be resolved and their distance (ca. 18 Å) is in agreement with the values obtained from electron diffraction (see Fig. 3) and X-ray diffraction.[10] In the same specimen other domains were observed with a slight tilt angle between the local column axis and the beam axis. This high-resolution direct imaging involves special techniques and is—in contrast to inorganic materials—difficult to apply to beam-sensitive samples like this polymer. For comparison, the computer-treated image is shown in Figure 5.[16] In the context of investigations of ultrathin films[18] these electron-microscopic images stimu-

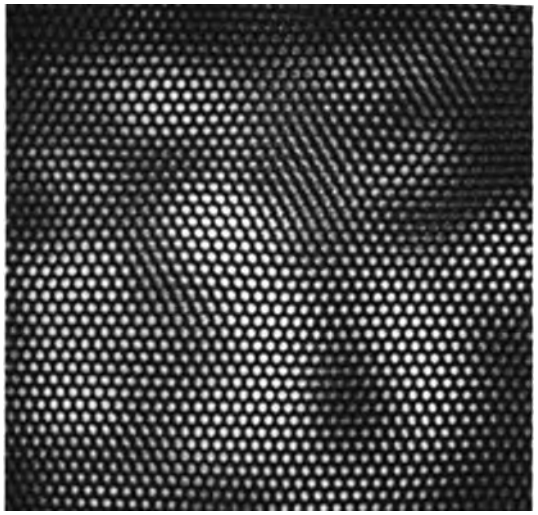

Fig. 5. Computer-treated high-resolution electron micrograph of discotic polymer **1a** (cf. Fig. 4).

late provocative ideas regarding applications in the fields of electronics and optoelectronics.[19] The submicrometer structures in the systems applied so far are still roughly a hundred times larger than those in the discotic polymer **1a**. For instance, in the field of information storage one can envisage addressing such regularly ordered nanometer structures. Configurations similar to scanning tunnel electron microscopy could be applied for implanting electrons into single columns of ordered discotic polymers. Furthermore, these columns are densely stacked π systems surrounded by paraffinic chains, which give an insulation against the six columns in the immediate neighborhood, so that they might act as molecular conductors. The predominant conductivity[20] across the thin film might be further increased by doping with electron-acceptor molecules.[21]

Experimental Procedure

In order to study the mesophase of polymer **1a** by electron microscopy, 400-Å films were prepared by spreading a polymer solution in chloroform (30/100 w/v) on a water surface. The dried film was sandwiched between two carbon films and transferred onto copper grids for electron microscopy. Orientation was obtained by annealing in a magnetic field of 1.5 T just below the D_{ho}→isotropic phase transition temperature. The magnetic field direction was chosen to be in the film plane, so that the columns are oriented perpendicular to the film, as is to be expected from the known anisotropy of the magnetic susceptibility of a similar low-molecular-weight discotic compound [17]. Finally, the film was cooled to ambient temperature and thus the orientation was frozen in. The production and interpretation of a high-resolution electron micrograph is not a trivial matter. It is particularly difficult in the case of beam-sensitive samples, where special cryogenic methods combined with the low-dose technique have to be developed and applied [3]. In order to understand the difficulties regarding interpretation of the electron micrographs, it is necessary to explain the physics involved without detailed reference to the mathematics, which is related elsewhere [15].

Imaging involves a two-stage process, mathematically expressed by two Fourier transforms. The first involves the production of an electron diffraction pattern (primary diffraction) in reciprocal space from the object in real space (first Fourier transform). Subsequently, in a second Fourier transformation, an image is produced from the diffraction pattern. It is important to realize that the objective lens of the microscope produces a phase shift so that the expression for the phases and amplitudes in reciprocal space is modified by an oscillating microscope transfer function which depends on the defocus value [4], as well as on manipulations in reciprocal space involving the objective aperture. In order to image objective details having certain spatial frequencies, therefore, a very specific transfer function must be chosen. In the low-angle range which is relevant for these samples, the band width is very narrow and only a very small range of frequencies is transferred. Furthermore, because of the rapidly oscillating transfer function, higher-order re-

flections may have suffered a phase change so that the information in the appropriate frequency range is transferred with reversed contrast.

The second stage in image analysis involves image reconstruction, where the electron micrograph now serves as object. Filtering of Fourier frequencies in reciprocal space (secondary diffraction pattern) is performed generally with the aid of a computer. The various stages of frequency filtering are very complex and must be treated with careful consideration of the physics involved. Otherwise, artifacts can easily be introduced. The safest way to guard against this is to compare the original image (which must be of very high quality) with the computer-treated image, and to ensure that defects have not been introduced which were not in the original. Details regarding these procedures will be published elsewhere [16].

On the Formation of "Free Radicals" from Alkylcobalt Complexes**

By *Bernd Giese,* Jens Hartung, Jianing He, Ottmar Hüter,* and *Andreas Koch*

Alkylcobaloximes of type **1** are becoming of increasing importance in organic synthesis, since their photolysis generates radicals which can be used for both carbon-carbon[1] and carbon-heteroatom bond-forming reactions.[1c,2] Preparatively useful reactions include cyclizations[1a] and intermolecular additions to olefins,[1b-d] which, depending on the reaction conditions and the substituents, afford alkanes **2** and/or alkenes **3** (H_2dmg = 2,3-butanedionedioxime).

On the basis of ESR measurements, it has been concluded that alkyl radicals generated from alkylcobaloximes in a matrix still undergo an interaction with the Co^{II} complex **5**.[3] By carrying out reactivity and selectivity studies on alkylcobaloximes in organic solvents, we have now been able to show that C-C bond formation involves the reaction of free radicals that do not differ from those generated from other radical sources.

In order to determine the reactivity, the hexenylcobaloxime **9** was photolyzed in the presence of various quantities of CCl_4 at 26°C using a 300 W sun lamp. From the ratio of the products **12** and **7** and the known rate of cyclization of the hexenyl radical **10**,[4] the rate of abtraction of chlorine from CCl_4 could be determined as $6.9 \times 10^3\ M^{-1}\ s^{-1}$. This value agrees remarkably well with the literature value for the hexenyl radical, which was generated from the corresponding azo compound.[5]For intermolecular addition reactions with the alkene **16**, the reaction rates for the intermediates generated by reduction of the cyclohexylmercury salt **13**[6] and by photolysis of the cyclohexylcobaloxime **14** were also identical within the limits of experimental error (Table 1). Since the mercury salt gives rise to uncomplexed radicals, these reactivity experiments lead to the conclusion that free radicals are formed in the photolysis of cobaloximes.

These findings were supported by stereochemical studies. Thus, in the cyclization of the 1-methylhexenylcobal-

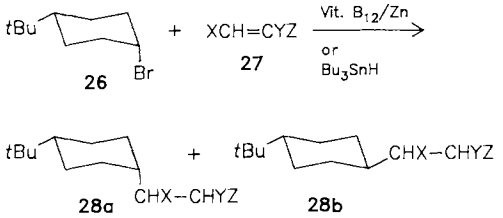
oxime **17**, formation of the *cis*-disubstituted cyclopentane is favored (**18a** : **18b** = 78 : 22, 26°C) and, independent of their configuration, the *tert*-butylcyclohexylcobaloximes **19a** and **19b** react with CCl_4 to afford the chlorides **20a** and **20b** in the ratio 77 : 23. These stereoselectivities correspond with those of free, uncomplexed radicals.[7]



According to these results, the C–C coupling products **2** and **3** are formed via the free radical **4** in the photolysis of the cobaloxime **1**. The question remains as to whether the "adduct cobaloxime" **6** is an intermediate in this reaction. In order to answer this question, we prepared independently the cobaloximes **23** from the corresponding bromides **21** and the Co^I complex **22**.[8] Photolysis of **23** affords the alkanes **24** and the alkenes **25** in a ratio which depends on the substituent X and the solvent. The data show that the photochemical reaction of the cobaloxime **14** (≅ **1**) with alkenes (Reaction Ⓐ) and the irradiation of the adduct cobaloxime **23** (≅ **6**) (Reaction Ⓑ) have identical product ratios. The amount of alkanes **24** in the product mixture increases with increasing electron withdrawing character of the substituent X and upon changing from an aprotic to a protic solvent. Furthermore, when the experiments were carried out in CH_3OD a deuterium atom was incorporated. This indicates an ionic cleavage of the cobalt–carbon bond in the formation of alkanes. The alkenes **25** are formed by elimination of hydridocobaloxime from the cobaloxime **23**.[9]

X	Solvent	Reaction Ⓐ **24** : **25**	Reaction Ⓐ *E* : *Z* (**25**)	Reaction Ⓑ **24** : **25**	Reaction Ⓑ *E* : *Z* (**25**)
CO_2Et	CH_2Cl_2	0 : 100	20 : 1	0 : 100	20 : 1
	CH_3CO_2H	58 : 42	20 : 1	58 : 42	20 : 1
CN	CH_2Cl_2	29 : 71	1.4 : 1	23 : 77	1.1 : 1
	CH_3CO_2H	90 : 10	2.4 : 1	88 : 12	2.0 : 1

Uncomplexed free radicals are also involved in the vitamin B_{12} catalyzed C–C coupling of alkyl halides with alkenes. This is shown by the reaction rates of the alkenes **16** when the cyclohexyl radical is generated by the method of *Scheffold* et al.[10] from cyclohexyl bromide **15**, vitamin B_{12}, and Zn (Table 1). Furthermore, the stereoselectivity is independent of whether the radical intermediate is prepared from *tert*-butylcyclohexyl bromide with vitamin B_{12} or with tributylstannane.

The proof of the occurrence of uncomplexed radicals presented here is important for the design of syntheses us-

Correlation of the Dynamic Behavior of *n*-Alkyl Ligands of the Stationary Phase with the Retention Times of Paracelsin Peptides in Reversed Phase HPLC

By *Bettina Pfleiderer, Klaus Albert, Klaus D. Lork, Klaus K. Unger, Hans Brückner,* and *Ernst Bayer**

In reversed phase high performance liquid chromatography (RP-HPLC), the retention of substances and the selectivity of the separation are influenced by the following properties of the basis gel: chemical structure and surface of the basis gel, and the nature, chain length, and density of the hydrophobic ligands. In this study, we have determined the mobility of *n*-alkyl ligands on silica gel using ^{13}C CP/MAS NMR spectroscopy and have correlated this with the unusual retention behavior of paracelsin peptides on these RP carriers. The natural mixture of sequence-analogous eicosapeptides (Scheme 1) which was used is of great interest because of its antibiotic and membrane active properties, such as hemolysis of erythrocytes and voltage dependent ionic conductivity in liquid bilayer membranes.[1–3]

Scheme 1. Structure of the paracelsin peptides **A**–**D**. Ac = Acetyl; Aib = α-aminobutyric acid (2-methylalanine), Pheol = phenylalaninol; all chiral components have the L configuration.

RP materials with *n*-alkyl chain lengths $1 < n < 20$ were prepared by reacting LiChrospher (Si 100, 10 μm) with the appropriate *n*-alkyldimethylchlorosilane.[4] The ligand density was 3.5 ± 0.2 mol m^{-2}.

Since changes in the mobility of *n*-alkyl groups are revealed by the relaxation behavior of the carbon atoms, they can be characterized through determination of the spin-lattice relaxation times T_1[5] or the relaxation times in the rotating coordinate system $T_{1\rho H}$.[6] We chose the $T_{1\rho H}$ values of the protons as a measure of the mobility of the alkyl chains, since $T_{1\rho H}$ gives information about rates of motion in the kHz range,[6] and because relatively small changes in the mobility result in large changes in the $T_{1\rho H}$ times. In contrast, the T_1 times, which are sensitive in the MHz range, exhibit only small differences.[7] In the range of slow molecular motions, the $T_{1\rho H}$ values are averaged completely by ^{13}C-^1H dipolar interactions.[8] However, the high mobility of the alkyl chains, which exhibit liquid-like behavior, and the additional rapid rotation of the probe at the magic angle (MAS, $\nu_{rot} = 4000$–5000 Hz) lead to a drastic reduction in the dipolar interactions, so that averaging by spin diffusion does not occur in these systems. This phenomenon has been observed by *Alemany* et al. for highly mobile molecules.[9, 10]

Solid-state NMR spectroscopy on C_8 and C_{18} phases has shown that the total mobility of the C_{18} chain is smaller than that of the C_8 chain.[11] For a more thorough investigation, materials with n = 4, 5, 6, 8, 10, 12, 14, and 18 were selected for $T_{1\rho H}$ measurements using ^{13}C CP/MAS NMR spectroscopy. Figure 1 shows the dependence of the relaxation times $T_{1\rho H}$ of the terminal methyl groups of the stationary phase upon the alkyl chain length n. Analogous behavior was observed for the (n − 1) and (n − 2) methylene groups of the respective *n*-alkyl ligands. Surprisingly, a maximum in the $T_{1\rho H}$ value of ca. 80 ms occurs for a chain length of n = 6–8. The $T_{1\rho H}$ values of the alkyl chain carbon atoms of the C_4 and C_8 phases are given for comparison in Table 1. In the case of the C_8 phase (and also the C_5 and C_6 phases), they increase in the direction of the terminal methyl group, whereas in the C_4 phase they are practically identical for all positions.

The temperature dependence of the relaxation times revealed that an increase in the $T_{1\rho H}$ values corresponds to a higher mobility of the *n*-alkyl chain. Thus, the relatively small $T_{1\rho H}$ values of the C_4 phase indicate a low motional

C_8 phase	56.2	62.5	61.8	71.8	71.8	64.7	78.0	86.3

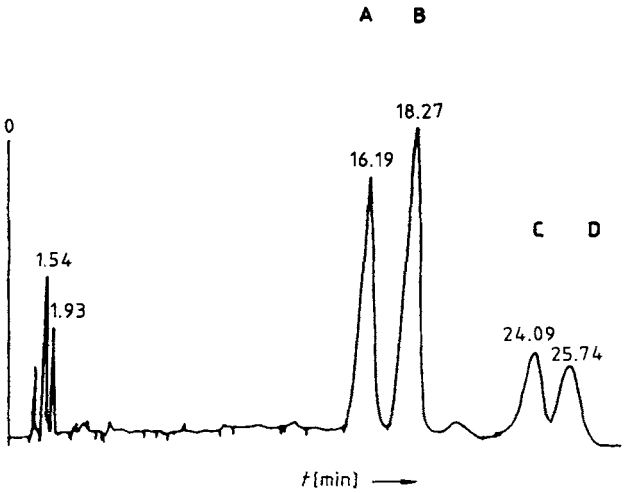

Fig. 2. HPLC chromatogram of the natural mixture of paracelsin peptides **A**, **B**, **C**, and **D**; t = retention time. Chromatographic conditions: column: 250 mm × 4.6 mm; stationary phase: LiChrospher RP-8, Si 100 (Merck), 5 μm; eluent: acetonitrile/methanol/water (39/39/22); UV detection at $\lambda = 206$ nm; $T = 303$ K; flow rate: 1 mL min^{-1}; quantity injected: ca. 20 μg peptide mixture in 20 μL methanol.

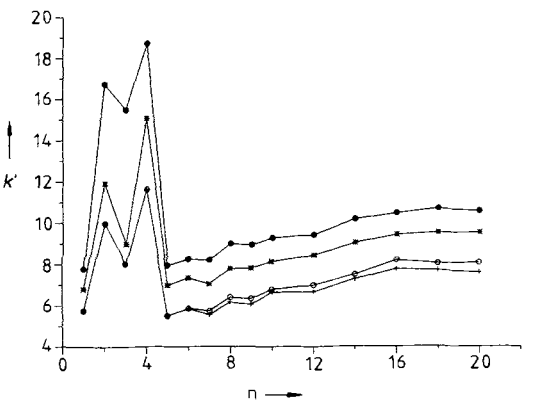

Fig. 3. Dependence of the capacity factors k' of the paracelsin peptides **A** (+), **B** (○), **C** (*), and **D** (●) on the alkyl chain length n; k' is defined as $(t - t_0)/t_0$, where t_0 = retention time of water. Chromatographic conditions as in Fig. 2, but with LiChrospher, Si 100 (Merck), 5 μm, chemically modified with *n*-alkyldimethylchlorosilanes, n = 2–20, as stationary phase.

freedom for all the carbon atoms of this phase, and the maximum of the methyl $T_{1\rho H}$ value at n = 6–8 means that the mobility of the terminal methyl group is highest for chains of these lengths. The mobility becomes increasingly restricted for chains with n > 10 and approaches that found for n = 4. A similar behavior, albeit without a pronounced maximum, has been found in relaxation time measurements on RP phases in suspension.[12] The strength of the dependence of the mobility upon the chain length is influenced by the solvating ability of the suspending liquid.[13, 14]

The mobility of the *n*-alkyl ligands reflects their conformational behavior. Suitable sensors for the determination of conformation are, for example, peptides and proteins, for which the conformation influences the interaction with the stationary phase. A connection between the retention of peptides in RP-HPLC and their conformational behavior has been found by *Houghten* and *Ostrech*.[15] The HPLC elution profile of the paracelsin peptides **A**–**D** (see Scheme 1) on a C_8 phase showed that a complete separation of the compounds is possible, in spite of the extremely small structural differences (only one CH_2 group more from **A** to **B** and from **C** to **D**).

This finding led to a systematic investigation of the dependence of the retention of paracelsin peptides on the alkyl chain length n. In this manner, an unusual behavior was detected (Fig. 3). Maxima in the retention, and therefore also in the capacity factors k', occur for n = 2 and 4. Beyond n = 5, the retention times increase only slightly and are comparable with that retained for a C_1 phase. The same behavior, although less pronounced, was observed also when binary eluents (methanol/water 85/15 *v/v*) were used. It was also found that the retention times of the peptides decrease on going from n to (n + 1) when n is an even number.

Comparing the dependence of the methyl $T_{1\rho H}$ values of the stationary phase and of the capacity factors k' of the paracelsin peptides upon the chain length n shows that a maximum in the retention corresponds to a minimum in the mobility of the *n*-alkyl chain. This can be explained by the assumption that the low mobility of the alkyl chains of the C_4 phase reflects a conformation (preferably a *trans-gauche* conformation) which facilitates a maximum steric interaction with the paracelsin peptides.

A comparison of the parcelsin components **B** and **C** is illustrative for the separation behavior. The replacement of Ala by Aib in position 6 and of Leu by Val in position 9 (cf. Scheme 1) leads to isobaric peptides of nominal atomic mass 1921. Nevertheless, the k' values of **C** are considerably larger than those of **B**. This can be explained by the fact that the (formal) removal of a CH_2 group from position 9 of **B** (replacement of Leu by Val) and its introduction in position 6 (replacement of Ala by Aib) leads to a more lipophilic peptide which interacts more strongly with the RP phase. The interaction with the stationary phase is favored by the remarkably stable helical conformation of the paracelsin peptides, which has been detected by circular dichroic measurements and by temperature dependent ^{13}C NMR spectroscopy.[1] A predominantly α-helical structure is assumed, in analogy with the crystal structure of the paracelsin analogue alamethicin.[16] In contrast, protected homopeptides of Aib have 3_{10} helical structures.[17–19]

From the α-helical projection[20] of the paracelsin peptides, it can be seen that the amino acids in positions 6 and 9 lie on the same side of the helix. If a horizontal interaction of the peptide helix with the stationary phase is assumed, the alkyl side chains of these amino acids point directly towards the relatively rigid alkyl chains of the C_4 phase; this leads to optimum interaction and thus to maximum k' values for the paracelsin peptides on the C_4 phase.

Much Less Strained Cubane Analogues with Si, Ge, Sn, and Pb Skeletons**

By *Shigeru Nagase**

Polyhedral carbon compounds such as tetrahedrane (C_4H_4), prismane (C_6H_6), and cubane (C_8H_8) have long formed interesting synthetic targets in organic chemistry;[1] among these, cubane is especially intriguing because of its high O_h symmetry and high strain.[2] There is currently considerable interest in replacing the carbons in these compounds by heavier homologues such as silicon in the expectation of unprecedented physical and chemical properties.[3]

As we have demonstrated in a recent theoretical study on persilatetrahedrane,[4] polyhedral silicon compounds consisting of only fused three-membered rings possess high strain and are subject to "bond stretch" isomerism.[5,6] In contrast, we have shown that they become significantly less strained than the corresponding carbon compounds as the number of fused four-membered rings increases.[7] Thus, persilacubane **1**, having six fused four-membered Si rings, is much less strained than cubane.[7,8] Indeed, the first polyhedral silicon compound, a persilacubane derivative (**1** with tBuMe$_2$Si instead of H) was recently synthesized and its novel properties were investigated.[9]

1, X = Si
2, X = Ge
3, X = Sn
4, X = Pb

We report now ab initio calculations of the structures and strain of still heavier cubane homologues, pergermacubane **2**, perstannacubane **3**, and perplumbacubane **4**. Geometries were fully optimized at the Hartree-Fock (HF) level with the GAUSSIAN 82 program[10] by using the ab initio effective core potentials[11] and the double-zeta (DZ) basis sets[12] augmented by a set of six d-type polarization functions[13] on each heavy atom.

Table 1. Optimized bond lengths and ionization potentials (I_p) of cubane and its homologues **1**–**4** of O_h symmetry [a].

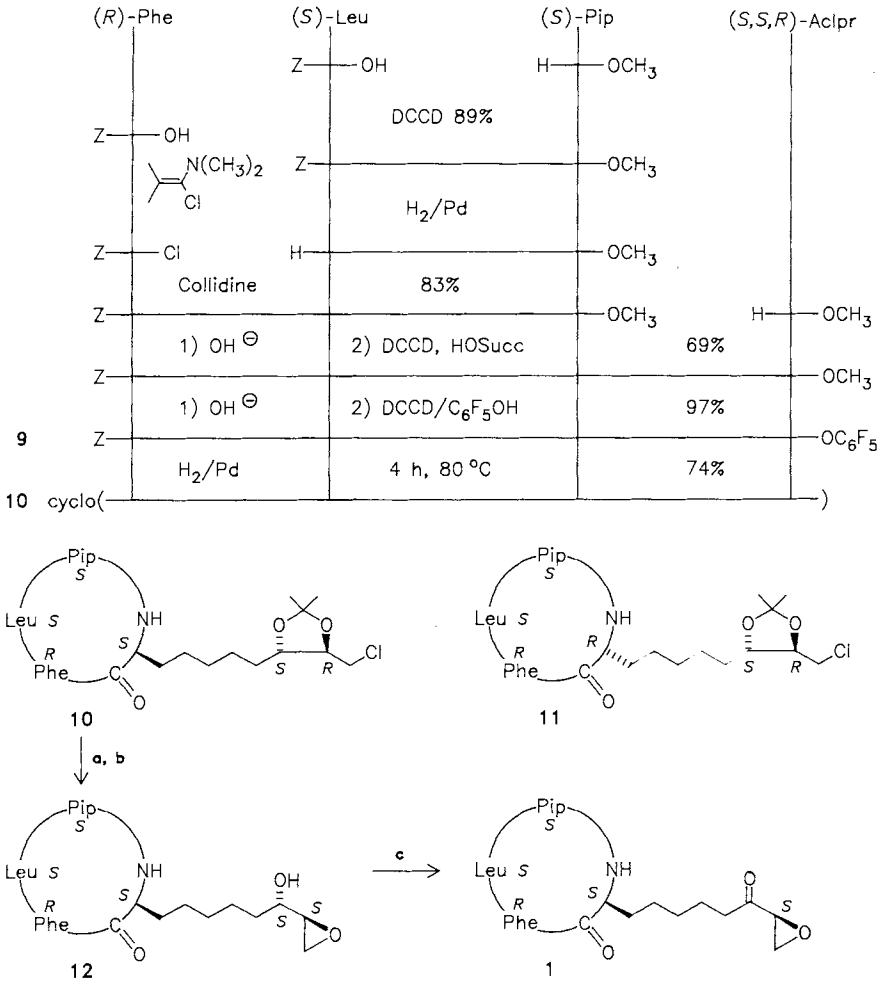
	C_8H_8 [b]	**1**	**2**	**3**	**4**
d_{X-X} [Å]	1.559	2.382	2.527	2.887	2.949
d_{X-H} [Å]	1.081	1.477	1.542	1.714	1.744
I_p [eV] [c]	10.4	8.3	7.7	7.1	6.6

[a] The total energies are −34.78608 (**1**), −33.85480 (**2**), −30.72293 (**3**), and −31.25989 (**4**) a.u. [b] HF/6-31G* values taken from [7]. For the electron diffraction values of d_{C-C} (1.575 Å) and d_{C-H} (1.100), see A. Almenningen, T. Jonvik, H. D. Martin, T. Urbanek, *J. Mol. Struct. 128* (1985) 239. [c] Based on Koopmans' theorem.

Table 1 shows the optimized structures of **1**–**4** together with the ionization potentials. The Si–Si, Ge–Ge, Sn–Sn, and Pb–Pb bond distances in the cubic skeletons are only ca. 0.02–0.04 Å longer at the HF/DZ+d level than those in the four-membered rings of cyclotetrasilane (2.363 Å), cyclotetragermane (2.508), cyclotetrastannane (2.867), and cyclotetraplumbane (2.908). The bond distances in the strain-free molecules X_2H_6 were calculated to be 2.344 (Si), 2.480 (Ge), 2.839 (Sn). and 2.868 (Pb) Å.

The Si–Si bond distances of 2.382 Å in **1** compare favorably with the values of 2.38–2.45 Å in the X-ray structure of the derivative Si_8R_8 synthesized recently:[9] the somewhat longer bond distances and slightly distorted cubic structure (∢SiSiSi = 87–92°) in this derivative are most likely ascribable to the presence of the bulky tBuMe$_2$Si groups.

$$X_8H_8 + 12\,H_3X{-}XH_3 \longrightarrow 8\,HX(XH_3)_3 \qquad \text{(a)}$$



1–**4**

X = Si, Ge, Sn, Pb

Table 2 summarizes the strain energies calculated from the so-called homodesmotic reactions (a).[14,15] It should be noted that the strain energy of 99.1 kcal mol^{-1} calculated for **1** agrees reasonably well with our previous HF/6-31G* value of 93.5 kcal mol^{-1}.[7]

Scheme 2. (*S,S,R*)-Aclpr = 8,9-*O*-isopropylidene-protected amino-10-chloro-8,9-dihydroxydecanoic acid. a) oxalic acid/dioxane/H_2O, 80°C, 12 h; b) K_2CO_3/CH_3OH, RT, 4 h; c) DCCD/DMSO/dichloroacetic acid.

on the other hand—which is also catalyzed by 4-pyrrolidinopyridine—this inversion of configuration is of secondary importance,[12] because the configurationally stable ring is quickly closed. Hydrolysis of the isopropylidene compound **10** and epoxide formation yielded **12**, which reacts with DMSO/DCCD to give the epoxyketone **1**. The NMR spectrum, mass spectrum and α_D^{20} value were identical with those of the natural product.

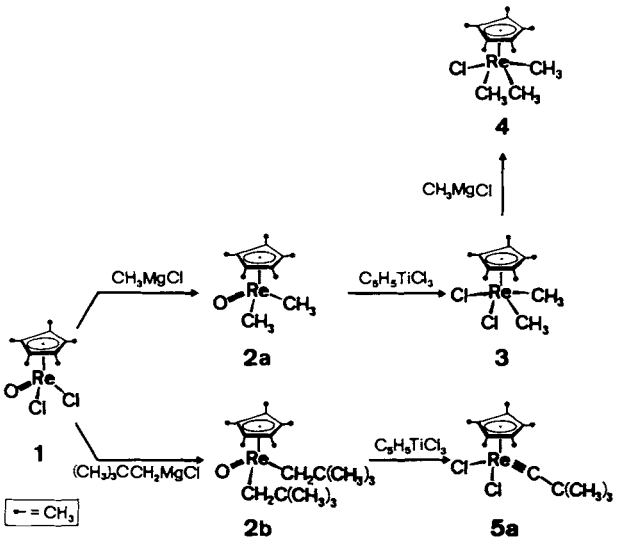
Alkyl and Alkylidyne Complexes of Rhenium**



By *Josef K. Felixberger, Paul Kiprof, Eberhardt Herdtweck, Wolfgang A. Herrmann,* Ralf Jakobi,* and *Philipp Gütlich**

Because of its great variety of oxidation states, the element rhenium allows the fixation of many different types of ligand in stable complexes, and the catalytic activity of some rhenium complexes is based on the readily achieved,

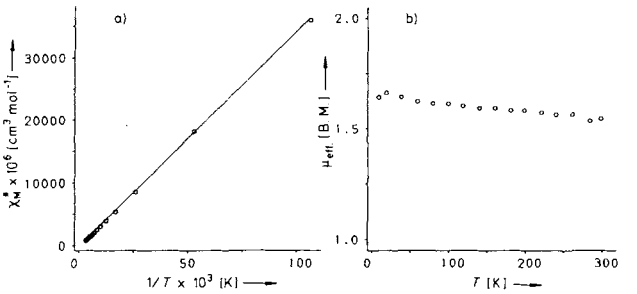
reversible change in the metal oxidation state.[1] Whereas methylrhenium(VII) oxide CH_3ReO_3[2] is an effective catalyst for the metathesis of olefins,[3] the sterically less readily accessible d^0-Re^{VII} complex $(\eta^5\text{-}C_5Me_5)ReO_3$, and in particular its reduced derivative **1** (d^2-Re^V), are suitable precursors for the preparation of model compounds for these reactions. We now report on stepwise alkylation and halogenation reactions, which afford new alkylidyne complexes of rhenium in high oxidation states, and which can be expected to be applicable to other organometallic oxides.

Scheme 1.

As shown in Scheme 1, the oxodichloride **1** can be converted into the known dimethyl derivative **2**[1] using methylmagnesium chloride (75% yield). The selectivity of the reaction is demonstrated by the fact that methylation at the ReO group does not occur. A less direct route involving a chlorination step allowed the synthesis of alkyl(halogen) derivatives without changing the metal oxidation state. Thus, reaction of the oxophilic chlorinating agent trichloro(η^5-cyclopentadienyl)titanium(IV) with **2a** yields the isolable intermediate *dimethyl* product **3**, which can be selectively methylated to afford the otherwise inaccessible *trimethyl* derivative **4** (Scheme 1). The analogous *tetramethyl* compound can be obtained by further reaction with the Grignard reagent, but is more easily prepared by exhaustive methylation of $(\eta^5\text{-}C_5Me_5)ReCl_4$.[4] Thus, the complete series of compounds $(\eta^5\text{-}C_5Me_5)Re(CH_3)_nCl_{4-n}$ (n = 0–4) is now available.

Although the alkylation and chlorination of **1** and **2** described here can in general be extended to higher alkyl derivatives, further, special reactions of the products cannot be excluded. An example with interesting preparative consequences is provided by the neopentyl compound **2b**. Once again, the organotitanium(IV) reagent proved to be suitable for the intended oxygen-chlorine exchange, but this reaction was followed by oxidation of the metal center with concomitant elimination of neopentane (GC and ^1H NMR detection). The isolable final product, obtained in 65% yield, was the blue, paramagnetic alkylidyne-Re^{VI} complex **5a** (Scheme 1), whose identity was confirmed by elemental analysis, vapor pressure osmometry, mass spectroscopy, and ESR spectroscopy. The ESR spectrum of **5a** (toluene solution) exhibits a sextet signal pattern ($I = 5/2$; $^{185}Re/^{187}Re$, $\langle g\rangle = 2.050$, $\langle A\rangle = 233 \times 10^{-4}$ cm^{-1}; **5b**, $\langle g\rangle =$ 2.074, $\langle A\rangle = 196 \times 10^{-4}$ cm^{-1}; **5c**, $\langle g\rangle = 2.104$) and thus corresponds with that expected for a d^1 spin system of hexavalent rhenium. Unlike those of **5a** and **5b**, the ESR spectrum of **5c** shows a singlet. Obviously the unpaired electron in this complex does not couple with the rhenium atom. The paramagnetic nature of **5a** was confirmed by magnetic measurements. The complex follows almost precisely the Curie law (Fig. 1a) and the effective magnetic moment closely approaches the theoretical value for a d^1 system of 1.73 B.M. (Fig. 1b). This means that the central atom is indeed present in a higher oxidation state (Re^{VI}) and that the electron density at the carbyne carbon atom (formally a trianion) is very high.[5]



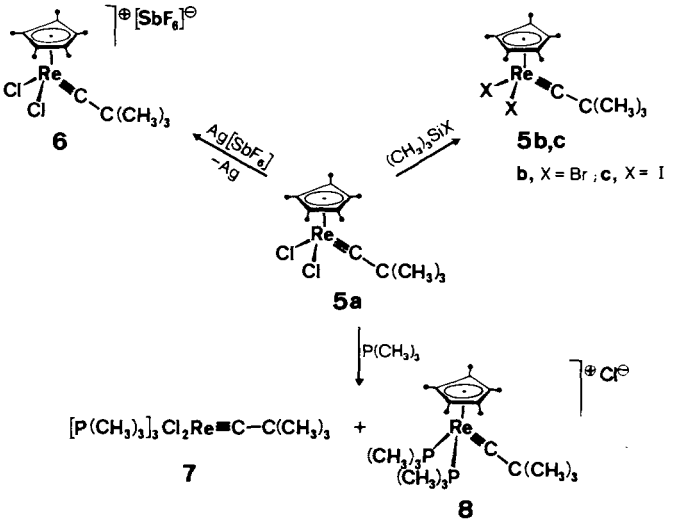


Fig. 1. Results of magnetic measurements on **5a**. a) χ_M^* as a function of reciprocal temperature. **5a** closely follows the Curie law ($\chi_M^* = C/T$, C = Curie konstant = 0.344(1) cm^3 mol^{-1}). b) Effective magnetic moment μ_{eff} as a function of temperature (cf. text).

As shown in Scheme 2, **5a** is converted by trimethylsilyl halides $(CH_3)_3SiX$ (X = Br, I) into the thermally stable, paramagnetic derivatives **5b** (green) and **5c** (brown). A structural assignment for the solid state was based on a single crystal X-ray analysis of the bromo compound **5b**[6] (Fig. 2). The Re–Cl distance of 167(1) pm is extremely short, as is typical for a rhenium–carbon triple bond length of ca. 173 pm.[7] The sequence of atoms Re≡C–C is almost linear (173(1)°). Two bromine atoms and the centrally coordinated C_5Me_5 ligand complete the distorted tetrahedral coordination geometry (Fig. 2).

Scheme 2.

The new alkylidyne complexes **5a–c** undergo reversible one-electron oxidations (**5a**: $E_{1/2} = 0.71$ V, CH_2Cl_2 solution, vs. Ag/AgCl). As would be expected from the cyclo-

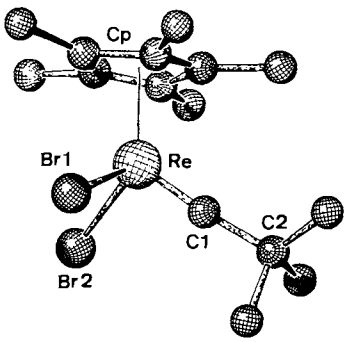

Fig. 2. Molecular structure (SCHAKAL) of the paramagnetic alkylidyne complex **5b** at 23°C. The complex crystallizes from *n*-hexane in the orthorhombic space group $P2_12_12_1$. Selected bond lengths [pm] and angles [°]: Re-C1 167(1), Re-Br1 248.9(1), Re-Br2 248.7(1), Re-Cp* 205; Br1-Re-Br2 93.50(5), C1-Re-Br1 98.0(3), C1-Re-Cp 125, Re-C1-C2 173(1) [Cp: center of ligand $C_5(CH_3)_5$].

voltammetric data, **5a**, for example, is oxidized by silver hexafluoroantimonate ($E^0 \approx 1.00$ V) in dichloromethane to afford the cationic, diamagnetic alkylidyne complex **6** with formation of silver. Apart from signals for the *tert*-butyl group and the ring ligands, the ^{13}C NMR spectrum of **6** (Table 1) shows the particularly characteristic alkylidyne resonance at $\delta = 338.0$ ($CDCl_3$).[8]

In addition to the oxidation of **5a** to **6**, which formally contains heptavalent rhenium, its reduction to give rhenium(V) complexes is also possible. The addition of a threefold molar amount of trimethylphosphane to the intense blue solution of **5a** in toluene furnishes the complexes **7** (15% yield, orange crystals) and **8** (50%, yellow, fluffy precipitate); see Scheme 2. The elemental analysis and spectral data of **7** are consistent with the formula shown in Scheme 2. The ^1H and ^{31}P NMR spectra are in accord with a meridional arrangement of the PMe_3 ligands, which can give rise to two structural isomers. The ^{13}C NMR spectrum (Table 1), which exhibits a quartet for the carbyne carbon atom ($^2J_{C,P} = 13.5$ Hz), shows that the three phosphane ligands have a *cis* arrangement with respect to the carbyne moiety. The ^1H NMR spectrum of **8** shows, besides the resonances of the $(\eta^5\text{-}C_5Me_5)Re{\equiv}CCMe_3$ fragment, signals for two chemically equivalent PMe_3 ligands. Elemental analysis, NMR data, and electrical conductivity ($\Lambda = 57.0$ S cm^2 mol^{-1}; $c = 0.22$ mmol L^{-1}, CH_2Cl_2, 20°C) corroborate the formulation of **8** as an ionic alkylidyne complex of pentavalent rhenium. The oxidation product of the reaction is a methylphosphorus(V) chloride (NMR detection).

Upon passing oxygen through a solution of **5a**, cleavage and derivatization of the alkylidyne ligand occurs affording **1**, its dimer, and, as organic products, pivalic anhydride and pivaloyl chloride (GC/MS/IR detection).

Compounds **5** and **6** represent the first examples of alkylidyne cyclopentadienyl complexes of rhenium in high oxidation states; analogous complexes having rhenium in low oxidation states have been known for some time.[7a,9] The complexes **5** are also the first monomeric 17-electron carbyne complexes, which were previously thought of as unstable molecules.[10] Because of its free coordination site and high oxidation state of the central atom as well as the resulting electrophilicity of the metal, the coordinatively unsaturated alkylidyne complex **6** in particular appears to be a promising model for investigations of alkyne metathesis. Some data for the new compounds are collected in Table 1.

Experimental Procedure

2b: A suspension of **1** (3.50 g, 8.6 mmol) in THF (50 mL) was added dropwise to a solution of $(CH_3)_3CCH_2MgCl$ (25 mmol) in THF (50 mL) at −70°C. After stirring for 15 min, the solution was allowed to warm to room temperature and then stirred for a further 1 h. 1,4-Dioxane (2.20 mL, 25 mmol) was added and the solvent removed under vacuum. The resulting residue was extracted into *n*-hexane and the solution filtered to remove $MgCl_2 \cdot$ 1,4-dioxane. **2b** was purified by column chromatography on silylated kieselgel at 15°C with *n*-hexane as eluent. Yield: 3.30 g (80%); brown needles.

3: A solution of **2a** (368 mg, 1.00 mmol) and $(\eta^5\text{-}C_5H_5)TiCl_3$ (220 mg, 1.00 mmol) in toluene (20 mL) was stirred at room temperature for 15 h. After removing the solvent in vacuum, the residue was suspended in CH_2Cl_2

Table 1. Spectroscopic data for the new organorhenium complexes **2b** and **3**–**8** [a, b].

[b] Solvent: C_6D_6 (**2b**, **4**), CD_2Cl_2 (**3**), $C_6D_5CD_3$ (**5**), $CDCl_3$ (**6**, **7**, **8**); spectra at +25°C. The ^1H NMR spectra of **3** and **4** show strong temperature dependence (singlet/triplet spin equilibria, d^2 configuration). ^1H NMR: 400 MHz, ^{13}C NMR: 100 MHz, ^{31}P NMR: 109.4 MHz. [c] H_3PO_4 as external standard.

and then adsorbed on silylated kieselgel 60. **3** was eluted with toluene as a brown band. Yield: 225 mg (60%), red-brown crystals.

4: A suspension of **3** (422 mg, 1.00 mmol) in toluene (10 mL) was added dropwise to a solution of CH_3MgCl (1.00 mmol) in THF (20 mL) at −70°C. The reaction mixture was allowed to warm to room temperature and stirred for 1 h to afford a brown solution, which was chromatographed on silylated kieselgel 60 at 15°C with *n*-hexane as eluent. Yield: 200 mg (40%), brown crystals.

5a: A solution of **2b** (2.40 g, 5.00 mmol) and $(\eta^5\text{-}C_5H_5)TiCl_3$ (2.20 g, 10.0 mmol) in toluene (75 mL) was heated under reflux for 18 h. After removal of the solvent in vacuum, the crude product was purified by column chromatography on silylated kieselgel. **5a** was eluted with *n*-hexane as a broad, blue band. The eluate (ca. 500 mL) was concentrated to ca. 150 mL and cooled to −78°C to afford crystals of **5a**. Yield: 1.50 g (65%), blue needles.

5b/5c: A stirred solution of **5a** (462 mg, 1.00 mmol) in CH_2Cl_2 (5 mL) was reacted with 4.0 mmol of $(CH_3)_3SiX$ (X = Br, I) at room temperature for 20 h. The solution was adsorbed on silylated kieselgel and purified by column chromatography on the same material (25 × 1 cm, 15°C). **5b** and **5c** were eluted with *n*-hexane as green and brown bands, respectively. Yields: 210 mg (40%) **5b**, green needles and 225 mg (40%) **5c**, brown needles, after recrystallization from *n*-hexane.

6: A solution of **5a** (230 mg, 0.50 mmol) in CH_2Cl_2 (5 mL) was combined with a solution of $Ag[SbF_6]$ (150 mg,. 0.50 mmol) in CH_2Cl_2 (5 mL) at −78°C. After stirring for 30 min at room temperature, a green-blue solution had formed. Yield 260 mg (75%) after filtration and recrystallization of the soluble components from $CHCl_3$.

7/8: A solution of **5a** (462 mg, 1.00 mmol) in toluene (10 mL) was reacted with $P(CH_3)_3$ (310 µL, 3.00 mmol) at −78°C. Warming to 25°C furnished a brown solution of **7** and a white precipitate of **8**. After stirring for 1 h at 25°C, the solution of **7** was filtered and then purified by chromatography on silylated kieselgel (30 × 1 cm, 15°C). **7** was eluted with toluene as a narrow brown band. Yield: 85 mg (15%), orange crystals (from *n*-hexane/ether). **8** was extracted from the residue with THF as a yellow solid. Yield: 290 mg (50%).

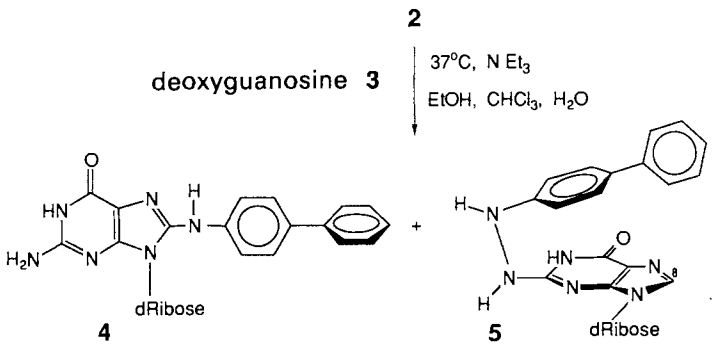
Synthesis of *O*-Acetyl-*N*-(4-biphenylyl)hydroxylamine ("N-Acetoxy-4-aminobiphenyl"), an Ultimate Metabolite of Carcinogenic 4-Aminobiphenyl, and Its Reaction with Deoxyguanosine**

By *Michael Famulok, Ferdinand Bosold,* and *Gernot Boche**

One possibility for the conversion of mutagenic and carcinogenic amines such as 4-aminobiphenyl[1] into an ultimate carcinogen consists in *N*-oxidation to *N*-(4-biphenylyl)hydroxyl amine ("*N*-hydroxy-4-aminobiphenyl") **1**[2] followed by *O*-acetylation to the title compound **2** ("*N*-acetoxy-4-aminobiphenyl").[3] Although the carcinogenicity of aromatic amines has been known since 1895,[4] **2** is the first metabolite of a mutagenic and carcinogenic aromatic amine activated by an *N*-acetoxy group,[5] which was isolated. Herein we report on the synthesis of **2** and its reaction with deoxyguanosine **3**.

1



2

Although **2** is thermally labile and decomposes within an hour above 10°C it can be subjected to an elemental analysis (C,H,N) and ^{13}C NMR spectroscopic characterization. Proof for the *O*-acetyl structure is afforded in particular by the carbonyl band at $\tilde{\nu} = 1755$ cm⁻¹; in contrast, the isomeric *N*-acetyl compound (hydroxamic acid) absorbs at 1642 cm⁻¹.

Reaction of **2** with deoxyguanosine **3** in ethanol/chloroform/water at 37°C leads to the two adducts **4** and **5** in 6% and 3% yield respectively.[6] The isolation of **4** and **5** is therefore important, because **4** and (very small amounts of) **5** were also found upon feeding dogs with 4-aminobiphenyl (ABP) and subsequent enzymatic cleavage of the DNA (from the epithelium of the bladder). The yield of **5** was apparently too small to be able to quote experimental data which unequivocally confirm its structure.[7] **4** has also been obtained together with two unidentified products upon reaction of *O*-acetyl-*N*-(4-biphenylyl)-*N*-trifluoroacetylhydroxylamine with **3** in sodium citrate buffer (pH

7.0) and ethanol at 50°C.[8] The assumption that **2** is the reactive species in this reaction is confirmed by our findings.[9]

Experimental

2: A suspension of 4.00 g (21.6 mmol) of **1** in diethyl ether (50 mL) and triethylamine (2.9 mL, 21.6 mmol) cooled to −40°C was treated with a solution of acetyl cyanide [10] (1.50 g, 21.6 mmol) in diethyl ether (30 mL) and the mixture vigorously stirred for 2 h between −40° and −10°C. After extraction with ice-water the aqueous phase was extracted at 0°C with 50 mL of CH_2Cl_2, the organic phases combined, dried with $MgSO_4$, and the solvent removed in a rotary evaporator at 0°C. The residue was rapidly dissolved at room temperature in 100 mL of ether/petroleum ether (1/1) and 20 mL of CH_2Cl_2 and recrystallized at −30°C. The bright yellow crystals of **2** were dried at −20°C. Yield 3.98 g (81%); correct elemental analysis (C,H,N). ^{1}H NMR (400 MHz, $CDCl_3$, 230 K): δ = 2.27 (s, 3H), 7.15 (d, 2H), 7.38 (t, 1H), 7.47 (t, 2H), 7.58 (2d, 4H), 8.90 (N−H, 1H). ^{13}C NMR (400 MHz, $CDCl_3$, 230 K): δ = 19.3, 116.9, 126.7, 127.0, 127.7, 128.7, 136.7, 140.1, 145.4, 170.8. IR (Nujol): $\tilde{\nu}$ = 3245, 1755, 1223 cm^{-1}.

Reaction of **2** with **3**: **2** (909 mg, 4.00 mmol) was treated with a solution of **3** (1.07 g, 4.00 mmol) and triethylamine (455 mg, 4.50 mmol) in 70 mL of ethanol/$CHCl_3$/water (7/3/4) at 37°C. After 1 h the solvent was removed; the adducts **4** and **5** were first separated over a silica gel column with $CHCl_3$/ethanol (7/3) and then by preparative HPLC [11]. Yield (after silica gel chromatography): **4**: 112 mg (6%); ^{1}H NMR ([D$_6$]DMSO, 400 MHz: the data agree with those quoted in Ref. [7a]. ^{13}C NMR: δ = 38.4, 61.2, 71.2, 82.8, 87.2, 112.1, 117.6, 125.9, 126.5, 126.6, 128.7, 132.2, 140.0, 140.3, 143.1, 149.5, 153.0, 155.9. MS (FD): *m/z* 434 (100%, $M^{\oplus}$), 318 (61%, $M^{\oplus}$ − dRibose + H). IR (KBr): $\tilde{\nu}$ = 3329, 2927, 1680, 1562, 1356, 1024, 960, 764, 698 cm^{-1}; **5**: 55 mg (3%); ^{1}H NMR ([D$_6$]DMSO, 400 MHz): δ = 2.12 (m, 1H), 2.42 (m, 1H), 3.47 (m, 2H), 3.76 (m, 1H), 4.28 (m, 1H), 4.91 (s, OH), 5.21 (s, OH), 5.95 (dd, 1H), 6.35 (s, 2H, −NH−NH−), 7.37 (d, 2H), 7.37 (t, 1H), 7.40 (s, 1H), 7.48 (t, 2H), 7.65, 7.66 (2d, 4H), 8.24 (s, 1H, NH); the singlet of H-8 of the deoxyguanosine part of **5** (δ = 7.40) is shifted markedly upfield compared to that of **3** ([D$_6$]DMSO, 300 MHz, δ = 7.94) and other purine nucleosides and nucleotides (see C. J. Pouchert, J. R. Campbell: *The Aldrich Library of NMR Spectra, Vol. 8*, Aldrich Chemical Company, Milwaukee 1974). This suggests a folded conformation for **5** in which the biphenyl moiety lies above the guanine part of the molecule and thus provides for the shielding of H-8. A similar folded conformation was found for methotextrate in an unpolar solvent (P. Faupel, V. Buss, *Angew. Chem. 100* (1988) 422; *Angew. Chem. Int. Ed. Engl. 27* (1988) 423). ^{13}C NMR: δ = 61.8 (t, ^1J(C-H) = 140.0 Hz), 70.7 (d, ^1J(C-H) = 149.9 Hz), 82.0 (d, ^1J(C-H) = 163.5 Hz), 87.2 (d, ^1J(C-H) = 147.2 Hz), 125.0 (s), 126.5 (d, ^1J(C-H) = 159.5 Hz), 126.6 (d, ^1J(C-H) = 159.7 Hz), 127.0 (s), 127.4 (d, ^1J(C-H) = 212.6 Hz), 127.4 (d, ^1J(C-H) = 162.6 Hz), 128.3 (d, ^1J(C-H) = 162.4 Hz), 128.9 (d, ^1J(C-H) = 161.7 Hz), 138.3 (s), 139.0 (s), 139.6 (s), 148.8 (s), 155.4 (s); the C-2 signal of the dRibose moiety is covered by DMSO signals. MS (FD): *m/z* 434 (100%, $M^{\oplus}$), 318 (78%, $M^{\oplus}$ − dRibose + H); IR (KBr): $\tilde{\nu}$ = 3334, 2924, 1658, 1522, 1487, 1333, 1086, 1049, 764, 698 cm^{-1}. UV: λ_{max} = 251, 216 nm.

1 2 3

dro-2,2'-bibenzoxazole as was previously assumed, but affords, instead, 5a,6,11a,12-tetrahydro[1,4]benzoxazino[3,2-*b*][1,4]benzoxazine **1**. Exposure of an air-saturated solution of **1** in an inert solvent (e.g., cyclohexane) to long wavelength light ($\lambda \geq 260$ nm) leads to the formation of 2,2'-bibenzoxazole **2**; when the photolysis is performed with short wavelength light ($\lambda < 260$ nm), [1,4]benzoxazino[3,2-*b*][1,4]benzoxazine **3** is formed additionally.

In order to study the mechanism of this photooxidation reaction in more detail, we prepared derivatives and analogues of **1**, for example, the compound 5,5a,6,11,11a,12-hexahydro-5,6,11,12-tetramethyl-quinoxalino[2,3-*b*]quinoxaline **4** which has not yet been described in the literature.

4

5

R = CH_3

Compound **4** exhibits very surprising photochemical properties. Irradiation of a nitrogen-purged solution of **4** in cyclohexane with light of wavelength $\lambda = 254$ nm yields the oxalic acid orthoamide **5** in 11% chemical yield along with other, as yet uncharacterized photoproducts. **5** is a stable compound and can be recrystallized from ethanol. It absorbs similarly to **4** in the UV and has an unstructured fluorescence spectrum. An X-ray structure analysis[2] (Fig. 1) showed that **5** has a [4,4,4]-propellane structure with the molecule lying with C1 and C10 on a crystallographically exact threefold symmetry axis (symmetry position x,x,x); the molecular symmetry is D_3. The difference electron density map showed additional maxima which were assigned to a disordered solvent molecule (ethanol), whose presence was also indicated by the elemental analysis.

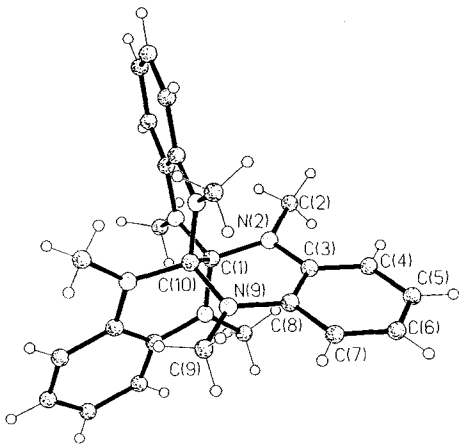

Fig. 1. Molecular structure of **5**. Selected bond lengths [pm] and angles [°]: C1-C10 157.9(7), C1-N2 144.5(3), C10-N9 145.1(3), C2-N2 145.0(5), C3-C4 138.9(5), C4-C5 138.5(7), C5-C6 134.8(8), C6-C7 137.8(6), C3-C8 141.7(5); N2-C1-C10 107.2(2), C1-N2-C2 121.6(3), N2-C3-C8 120.0(3), C1-C10-N9 107.4(2).

Nothing is known about the mechanism of the photoreaction **4** → **5**. To the best of our knowledge, **5** is the first orthoamide derivative of oxalic acid with the substitution pattern of a hexaminoethane.

Experimental Procedure

4: *N,N'*-dimethyl-N,N'-ditosyl-*o*-phenylenediamine [3] (88 g, 0.2 mol) was heated in a mixture of H_2SO_4 (80 mL) and H_2O (8 mL) for 5 h, after which the solution was poured into 300 mL of ice water [4]. The resulting solution was allowed to flow under N_2 into 1 L of NaOH (6 M) and the free amine was steam distilled under N_2 into a light-protected receiving flask. After ca. 3 L of liquid had been collected, 19.2 g of a 30% aqueous solution of glyoxal (0.1 mol) was added to the amine-water emulsion with rapid stirring. After stirring for a further 48 h, the crude product was collected by filtration, washed with H_2O, and dried. Yield: 19 g (65%), m.p. 160–164°C. Recrystallizing three times from 2-propanol (1 g/50 mL) under N_2 afforded colorless crystals of **4** (14.3 g, m.p. 167–169°C). ^{1}H NMR (80 MHz, $CDCl_3$): $\delta = 2.98$ (s, 12H, CH_3), 4.28 (s, 2H, CH), 6.5 (m, 8H, arylH); UV (C_6H_{12}): λ_{max}/nm (logε) = 312 (4.11), 257 (4.14), 227 (4.81). Correct elemental analysis.

5: A solution of **4** (1 g) in p.a. cyclohexane (1.3 L) was photolyzed (48 h) in a Rayonet reactor under N_2 using 16 lamps ($\lambda = 254$ nm). After removal of the solvent on a rotary evaporator, the mixture was separated chromatographically (Al_2O_3, cyclohexane/diisopropyl ether 3/1). It yielded 520 mg of unreacted **4** and, after recrystallization from ethanol, 53 mg (11%) of **5** as colorless crystals, m.p. 272–273°C. MS: $m/z = 426$ ($M^{\oplus}$); ^{1}H NMR (80 MHz, $CDCl_3$): $\delta = 2.7$ (s, 18H, CH_3), 6.5–6.85 (m, 12H, arylH); UV (C_6H_{12}): λ_{max}/nm (logε) = 316 (4.38), 310 (4.34), 250 (4.33, sh), 227 (4.99); fluorescence: $\lambda_{max} = 347$ nm (line width 50 nm). Correct elemental analysis.

(*t*BuSiP)$_4$—The First Silaphosphacubane**

By *Marianne Baudler,* Guido Scholz, Karl-Friedrich Tebbe,* and *Magda Fehér*

Although a large number of phosphorus-silicon heterocycles having various molecular frameworks are already known,[1,2] a silaphosphane with a cubane structure has yet to be reported. We have now prepared the first silaphosphacubane, *closo*-tetrakis(*tert*-butylsilylphosphane) **1**, and

[**] Contributions to the Chemistry of Phosphorus, Part 192. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie. Part 191: M. Baudler, C. Block, H. Budzikiewicz, H. Münster, *Z. Anorg. Allg. Chem.*, in press.

wish to report here on its unexpected formation and remarkable molecular structure.

After having successfully synthesized several organotris(phosphino)silanes $RSi(PH_2)_3$ (R = Me, Et, *i*Pr, Ph),[3] we found that phosphination of the trichlorosilane **2** with $LiAl(PH_2)_4$[4] (1,2-dimethoxyethane (DME), −40 °C) does not lead to the *tert*-butyl compound **3**, but instead affords **4**, **5**,[5] PH_3, and small quantities of other compounds which were not further characterized. The course of the reaction is obviously determined by the bulky *tert*-butyl group. In contrast to **4**, compound **5** is not stable in the reaction mixture at room temperature and upon removal of the solvent. Under these conditions it undergoes rearrangement to afford a mixture of more highly condensed Si–P compounds, from which **1** may be obtained in analytically pure form by extraction with *n*-hexane; the reaction can be described in an idealized manner by the following equation: [6]

The silaphosphane **1** forms colorless, tetrahedral, or platelike crystals (m.p. 323–324 °C, dec., sealed tube) which are stable under an inert atmosphere and moderately soluble in hydrocarbons, THF, and monoglyme. Compound **1** is sensitive to oxidation and hydrolysis, particularly in solution. Apart from the signal group for the $M^{\oplus}$ ion (*m/z* 464–469), the mass spectrum (15 eV, 100 °C) shows only a low-intensity signal group for the ion $(M-t\mathrm{Bu}+\mathrm{H})^{\oplus}$. The ^{31}P NMR spectrum (*n*-hexane, 25 °C, 121.497 MHz) exhibits a singlet at $\delta = -177.0$ with ^{29}Si satellites and the $^{1}H\{^{31}P\}$ NMR spectrum (300.135 MHz) a singlet at $\delta = 1.01$. The ^{29}Si DEPT NMR spectrum (THF/[D_8]THF, 25 °C, 59.628 MHz) consists of an AX_3Y system with $\delta = -28.5$ and the calculated coupling constants $^{1}J_{SiP} = +37.6(1)$ Hz, $^{3}J_{SiP} = -12.6(3)$ Hz, and $^{2}J_{HP} = +23.8(1)$ Hz. One band is observed in the IR spectrum at 413 (s) with a shoulder at 380 cm^{-1} and in the Raman spectrum three bands (with splittings) appear at 375 (s), 402 (m), and 439 (vs), which can be assigned to the stretching vibrations of the Si–P skeleton. All these findings are consistent only with the presence of the symmetrical cage compound 2,4,6,8-tetra-*tert*-butyl-1,3,5,7-tetraphospha-2,4,6,8-tetrasilapentacyclo-[4.2.0.$0^{2,5}$.$0^{3,8}$.$0^{4,7}$]octane **1**. The exact molecular parameters were obtained from an X-ray structure analysis[7] (Fig. 1).

Two different molecules of symmetry $\bar{4}$ (S_4) and 23 (*T*) are present in the crystal in the ratio 6:2; their structural parameters differ only slightly (Table 1). The cage, which is highly distorted compared with a cube, is composed of a larger P_4 tetrahedron and a smaller Si_4 tetrahedron. The bond angle at silicon is considerably larger than that of a corner of a cube, while that at phosphorus is correspondingly smaller, which results in the phosphorus atoms being displaced outwards. The *tert*-butyl substituents have a staggered arrangement. The silicon–carbon bonds in the molecule of $\bar{4}$ symmetry point almost exactly in the direction of the diagonal of the phosphorus–silicon cage, while those of the molecule with symmetry 23 lie precisely in this orientation.

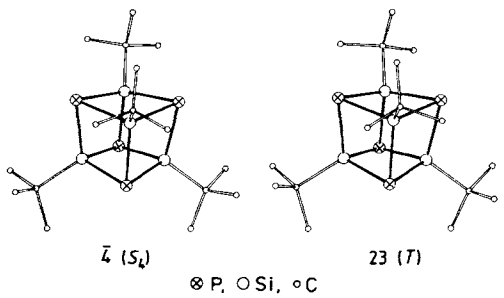

Fig. 1. Molecular structures of **1** in the crystal.

Table 1. Selected interatomic distances [pm] and angles [°] for the two different molecules of **1** [mean values (S_4) and values (*T*)].

Distance	S_4	*T*	Angle	S_4	*T*
P-Si	228.1(2)	227.8(3)	P-Si-P	101.61(7)	101.62(9)
P···P	353.6(3)	353.1(4)	Si-P-Si	77.03(31)	77.02(9)
Si···Si	284.1(8)	283.6(4)	P-Si-C	116.5(15)	116.5(2)
Si-C	189.4(6)	190.3(7)	Si-C-C	109.6(7)	106.2(5)
C-C	151.8(19)	155.6(10)	C-C-C	109.3(8)	112.5(5)
			P-Si-C-C	−174.9(5)	−173.2(4)
				− 56.1(5)	
				+ 63.5(5)	

Compound **1** is most likely formed by intermolecular condensation of four-membered ring compounds with alternating Si and P atoms and reactive PH and SiCl groups, which can be detected as intermediates using ^{31}P NMR spectroscopy. The remarkable thermal stability of **1** compared to the related heterophosphacubane $(PhSnP)_4$[9] can be attributed to the similar covalent radii of phosphorus and silicon and to the bulky *tert*-butyl substituents.

A Novel Trimeric Chiral Copper(I) Thiophenolate with Intramolecular Coordination**

By *D. Martin Knotter, Gerard van Koten,* Hendrik L. van Maanen, David M. Grove,* and *Anthony L. Spek*

To date only a few structures of copper(I) thiophenolates, either with or without discrete donor ligands, have been elucidated and none of these structures have a potentially chelating group on the thiophenolate ring.[1] Here, we wish to present results concerning the synthesis, structural characterization, and unusual properties of a copper(I) thiophenolate, **1**, whose thiophenolate ligands have a 1-(dimethylamino)ethyl group in the *ortho* position. In this type of thiophenolate we can anticipate formation of a six-membered metallacycle through intramolecular chelation of the chiral CH(Me)NMe$_2$ group. Consequently, the complex may exhibit new and interesting behavior.

The 2:1 reaction of optically pure, chiral 2-[(*R*)-1-(dimethylamino)ethyl]thiophenol with Cu_2O in ethanol affords in high yield the copper(I) thiophenolate **1**.

$$6\,HSC_6H_4\{CH(Me)NMe_2\}\text{-}o + 3\,Cu_2O \xrightarrow{\text{ethanol, reflux}} 2[CuSC_6H_4\{CH(Me)NMe_2\}\text{-}o]_3 + 3\,H_2O$$

[**] This work was supported in part (*A. L. S.*) by the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organization for Scientific Research (NWO).

Compound **1** is a yellow, air-sensitive solid which is readily soluble in most organic solvents and which was found by cryoscopy to be trimeric. Recrystallization from THF affords the crystalline solvate **1**·THF, which has a melting point of 148°C with no visible decomposition.

Spectroscopic characterization of **1** included IR (absence of the SH band at 2600 cm^{-1} found in the parent thiophenol), UV/VIS, and ^{1}H NMR spectroscopy. In its electronic spectrum, **1** (solid) shows an absorption maximum at 400 nm. Furthermore, **1**·THF shows an emission maximum at 556 nm and the crystals show intense triboluminescence when mechanically disrupted; green flashes are clearly visible even in broad daylight.

The 200.13-MHz ^{1}H and 50.32-MHz ^{13}C NMR spectra of **1** (solvent free) in [D$_8$]toluene are temperature dependent. At 358 K the ^{1}H NMR spectrum of **1** shows only one thiophenolate ligand pattern with chemical shifts that are consistent with a noncoordinated amine substituent.[2] At a lower temperature (233 K) four ligand patterns are present in a 9:2:2:2 ratio, ascribable to the presence of two trimeric species in a 3:2 ratio: a major symmetric one with ligand pattern intensity 9 and a minor asymmetric one with three separate ligand patterns with 2:2:2 intensity. The number of methyl groups present in this ^{1}H NMR spectrum and the corresponding ^{13}C NMR spectrum at 233 K is clear evidence for coordination of nitrogen to copper in both species.

To help elucidate the structural aspects and geometry of trimeric **1** in solution, a single-crystal X-ray analysis of **1**, obtained from THF solution, was carried out[3] (Fig. 1a).

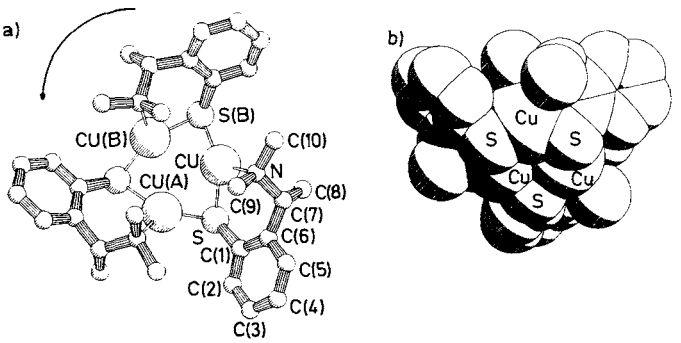

Fig. 1. a) Structure of **1** in the crystal (excluding disordered THF). Important bond lengths [Å] and angles [°]: Cu-S 2.231(2), Cu-S(B) 2.186(2), Cu-N 2.077(7), Cu-Cu(A) 2.828(1); N-Cu-S 101.6(2), S(B)-Cu-N 129.3(2), S-Cu-S(B) 128.4(1), C1-S-Cu 107.5(3), Cu(A)-S-C1 109.9(3), Cu-S-Cu(A) 79.63(7). The molecule has a crystallographic threefold rotation axis. Arrow indicates the "left-hand turn" of the chelating arms. b) Space-filling model of compound **1** showing the "open" S_3 side.

The crystal structure of **1** shows a unit cell containing two independent trimeric molecules and two disordered THF molecules. Each trimeric molecule has a central Cu_3S_3 six-membered ring of chair conformation and C_3 symmetry, comprising alternate copper and sulfur atoms; the amine substituent of each thiophenolate ligand is *N*-coordinated to a neighboring copper atom. In this way each copper atom is trigonally coordinated (2 S, 1 N) and each sulfur is tetrahedrally coordinated (2 Cu, 1 C_{aryl}, lone pair). All aromatic groups are equatorially bound to sulfur with respect to the Cu_3S_3 ring. Furthermore, all chelate rings are identical. The copper–sulfur bond lengths and the distance between copper atoms are typical for bridged copper–sulfur compounds.[4] The Cu–N distance is short, though in the expected range.

One striking result of the C_3 symmetry of this molecule and the equatorial coordination of the aryl groups is that the Cu_3S_3 ring has an S_3 side which is "open" and a Cu_3 side, with Cu···Cu distances of 2.828(1) Å, which is shielded by the organic groups (Fig. 1b). The whole molecule is chiral and the CH(Me)NMe_2 group of the chelating ligand shows a left-hand turn in which the *C*-methyl group is positioned axially with respect to the aromatic ring.[5] The alternative "right-hand turn" conformation was not detected by NMR and we assume that this conformation, which places the *C*-methyl group in an equatorial position is sterically unfavorable.

This solid-state structure of **1** in which all ligands are equivalent appears to correspond to the major species present in solution at low temperature. The minor asymmetric species, with which the major species is interconvertible at higher temperatures, is almost certainly also a trimer. We believe this trimer to be derived from the symmetric form by inversion of one S atom whereby one aromatic ring assumes an axial position with respect to the Cu_3S_3 ring. The interconversion of these two isomers, as seen in the ^1H NMR spectra is probably an intramolecular process; there is no concentration dependence either of the cryoscopic molecular weight in benzene or of the isomer ratio determined from low-temperature ^1H NMR spectra. The postulated S inversion is well known for thioethers[6] but is new for d^{10} metal thiolates, and the proposed asymmetric structure bears analogy to that of $[B_3(SR)_3]$.[7]

Compound **1** is the first characterized metal thiophenolate with a chelating group in the *ortho* position. Due to this chelating group we have been able to isolate a trimeric, neutral copper(I) thiophenolate—this is quite remarkable since neutral species in this type of chemistry are rare and trimers were until now unknown.[1] Because the sulfur and nitrogen atoms are in fixed positions with respect to one another, compound **1** may be used as a chiral tridentate sulfur ligand in the way thio-[9]crown-3 ethers have been used.[8] Another direction we are exploring is the use of **1** as a chiral template for the synthesis of higher-order cuprates.[9]

Experimental Procedure

1: A mixture of Cu_2O (4.38 g, 30.6 mmol) and 2-[(*R*)-1-(dimethylamino)ethyl]thiophenol (7.73 g, 42.6 mmol) in 100 mL of ethanol was refluxed for 20 h under a nitrogen atmosphere. Excess Cu_2O was removed by filtration and the clear yellow ethanol solution evaporated in vacuo to afford the yellow solid product. Recrystallization from a saturated THF solution was carried out by slow cooling over two days from 68 to 14°C in a 3-L Dewar flask initially filled with 68°C water. **1**·THF was obtained as pale yellow needles (m.p. 148°C). Yield: 8.03 g (78%). Crystals of the solvate were dissolved in pentane and the solvent removed in vacuo to afford solvent-free **1**.

[**] Heterocycles as Ligands, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. *P. Sartori* for helpful discussions and support.—Part 3: [7].

a C_2 fragment by a BN unit. In contrast to the borole dianions[1,3] and pyrroles,[4] which are closely related through similar ring structures, the exocyclic BN compounds **3** and **4a** have so far not been used as ligands; the reason for this may be connected with unsolved problems in their synthesis.[5]

The synthesis of the trihydro(tetramethylpyrrolyl)borate ligand **4b** at the complex center by borylation of the corresponding azacyclopentadienyl complex is conceivable. For the synthesis of the decamethylferrocene analogue iron(II) trihydro(tetramethylpyrrolyl)borate **6** we allowed the tetramethylpyrrole adduct **5**[7] instead of the inaccessible 1,1'-diazaferrocene to react with $Me_2S \cdot BH_3$. The sandwich compound **6** thus obtainable in good yields is readily soluble in dipolar aprotic solvents and is air-stable in the solid state. As expected, the ^{13}C NMR shift of the coordinated C atoms in **6** ($\delta = 98.56$, 86.97) differs very little from the corresponding values of the starting compound **5**;[7] the ^{11}B NMR spectrum ($\delta = -20.23$ (q), $^1J_{B,H} = 94.84$ Hz) shows the analogy between the ligands **4b** and the pyridine-borane adducts.[8] Stepwise cleavage of the BH_3 groups of **6** to give bis(tetramethylpyrrolyl)iron, visible in the mass spectrum as most intense peak, could not be reproduced preparatively.

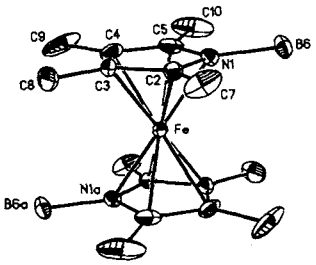

Fig. 1. Molecular structure of **6** with thermal ellipsoids drawn at the 50% probability level (without hydrogen).

Upon determination of the crystal structure of **6**[9] disorders similar to those already established by *Seiler* and *Dunitz* for ferrocene,[10a,b] nickelocene[10c] and ruthenocene[10d] were observed. Cobaltocene is also disordered in the crystal, so that disorders can be regarded as a characteristic feature of the metallocenes. Upon refinement with anisotropic temperature factors (Fig. 1), better referred to here as anisotropic displacement parameters (ADPs),[13] the displacements are neither compatible with a temperature oscillation nor with a rotational disorder, even in lower symmetries. Rather, on assuming centrosymmetry, there are disorders in which the rings are each arranged around a shifted and rotated C_5 axis. This is illustrated for **6** in Figure 2; all atoms were freely refined with good convergence and with the same R value, using in each case

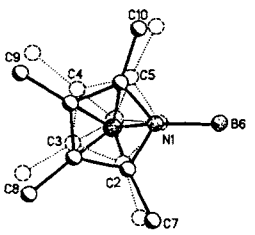

Fig. 2. Presentation of the disorder of **6**; the atoms drawn in unbroken and in broken lines are each refined with 50% occupation factors.

isotropic displacement factors and 50% occupation factors. Therefore an analysis of the ADPs with the THMA program[14] was not necessary. The bond lengths within each of the "half molecules" are comparable with those that were also obtained in the refinement with ADPs, which will be discussed further.

On the basis of the isosteric principle **6** could also be isostructural with decamethylferrocene **7**.[15] In the crystal, **7** has D_{5d} symmetry in the space group *Cmca*, whereby the fivefold axes of the molecules are orthogonal. This could also be true in the case of **6** if boron and nitrogen lie on the crystallographic mirror plane. We found, however, that **6** is monoclinic (Laue symmetry $2/m$) and has the space group $P2_1/n$. The fivefold axes in the refinement with ADPs are tilted at 85.1°, thus resulting in the lower symmetry of **6**. The molecular geometry of **6** is changed slightly compared to that of **7**,[15] despite the isosteric relationship of the two compounds, since the exocyclic BH_3 group in the ligand **4b** does not compensate the smaller radius of the nitrogen atom compared to the carbon. Thus, the projection of the coordination center onto the ring plane is shifted in the direction of the nitrogen atom relative to the geometrical center of the ring. Hereby, the bonds to C2 and C5 ($\bar{d}$(Fe-C2,5) = 2.029 Å) as well as the iron-nitrogen bond (d(Fe-N1) = 2.004(1) Å) are shorter than the mean value of the Fe-C bond in **7** ($\bar{d}$(Fe-C) = 2.050 Å); this is compensated by the marked expansion of the bonds to C3 and C4 ($\bar{d}$(Fe-C3,4) = 2.077 Å) in the sense of a distance lying in the expected range d (Fe-C_4N(center)) of 1.655 Å. In a similar way, the relative expansion of the C3-C4 bond (1.432(3) Å) essentially equals the shortening of the C-N bonds ($\bar{d}$(N1-C2,3) = 1.398 Å), so that the mean value of the ring bonds in **6** ($\bar{d}$ = 1.41 Å) almost agrees with that in **7** ($\bar{d}$ = 1.42 Å). The B-N bond (d(N1-B6) = 1.599(2) Å) is noticeably longer than the mean value of the exocyclic C-C distances both in **6** ($\bar{d}$ = 1.49 Å) and in **7** ($\bar{d}$ = 1.50 Å); this makes the BH_3 groups protrude out more from the ring plane of the ligand in the direction away from the coordination center. Hereby, the mean plane of the atoms C(7-10)B6 forms an angle of 1.8° with the mean ring plane C(2-5)N1.

The shift of the ligand **4b** relative to the molecular axis of **6** thus corresponds to that of the borole dianion.[16] However, due to the ratio of the radii, this ligand is shifted in the opposite direction, which is probably also true in the case of the hitherto unknown ligand **3**. In contrast, in the diazaborolide complexes of iron[17] the proximity of the heteroatoms in the ring leads to an equalization of the difference in the radii and to central coordination. The structure of iron(II) trihydro(tetramethylpyrrolyl)borate **6** thus demonstrates possibilities and limitations of the use of the isosteric principle in the construction of sandwich complexes.

Experimental

6: A mixture of **5** (0.63 g, 1.15 mmol) and $Me_2S \cdot BH_3$ (0.05 mL, 6.9 mmol) in benzene (20 mL) was stirred for 10 min. After addition of 40 mL of pentane the resulting precipitate was purified by recrystallization from CH_2Cl_2/ether. Yield 301 mg (80%), bright orange crystals.—^1H NMR (60 MHz, [D_6]benzene, TMS int.): $\delta = 2.0$ (s, 12H; C(2,5)-CH_3), 1.38 (s, 12H, C(3,4)-CH_3), BH_3 not ovserved.—^{11}B NMR (25.71 MHz, CD_2Cl_2, $BF_3 \cdot Et_2O$ ext.): $\delta = -20.23$ (q, $^1J(^{11}B,^1H) = 94.84$ Hz).—$^{13}C\{^1H\}$ NMR (75.43 MHz, CD_2Cl_2, TMS int.): $\delta = 98.56$ (C2,5), 86.97 (C3,4), 10.18 (C2,5-CH_3), 7.97 (C3,4-CH_3).—MS (70 eV): m/z 328 ($M^{\oplus}$, 15%), 314 ($M^{\oplus} - BH_3$, 54), 300 ($M^{\oplus} - 2BH_3$, 100), 285 ($M^{\oplus} - 2BH_3 - CH_3$, 23) and further fragments.

Structural Diversity in Iodoantimonates; the Anions $Sb_3I_{11}^{2\ominus}$, $Sb_5I_{18}^{3\ominus}$ and $Sb_6I_{22}^{4\ominus}$**

By *Siegfried Pohl,* Rainer Lotz, Wolfgang Saak,* and *Detlev Haase*

The trihalides of the heavy elements of the fifth main group can react as Lewis acids with halide ions to give anions of various degrees of condensation (see, e.g., Ref. [1]). Thus, on reaction with iodide, SbI_3 forms iodoantimonates in which Sb^{III} is generally coordinated with distorted octahedral geometry.

[**] This work was supported by the Fonds der Chemischen Industrie.

Besides the antimonates $Sb_2I_9^{3\ominus}$ and $[SbI_4^{\ominus}]_\infty$ mentioned in Ref. [2], the SbI_3-rich anions $Sb_6I_{22}^{4\ominus}$,[3] $Sb_8I_{28}^{4\ominus}$,[4,5] $[Sb_2I_7^{\ominus}]_\infty$,[5] and $[Sb_3I_{10}^{\ominus}]_\infty$[4,6] have recently been prepared, some of them having the same formula but different structures. We have now been able to isolate three novel iodoantimonates, namely salts **1**–**3**:

$[Cu(CH_3CN)_4]_2Sb_3I_{11}$ **1** $(Me_4N)_3Sb_5I_{18}$ **2** $[(C_5H_5)_2Fe]_4Sb_6I_{22}$ **3**

The compounds **1** and **2** are obtained upon reaction of CuI and Me_4NI respectively with SbI_3 in acetonitrile. **3** is prepared according to equation (a), likewise in acetonitrile; the ferrocene employed in this reaction is not oxidized completely.

$$6(C_5H_5)_2Fe + 3I_2 + 6SbI_3 \longrightarrow [(C_5H_5)_2Fe]_4Sb_6I_{22} + 2/3(C_5H_5)_2FeI_3 + 4/3(C_5H_5)_2Fe \quad \text{(a)}$$

3

All three compounds were characterized by X-ray structure analyses.[7] The $Sb_3I_{11}^{2\ominus}$ ion of **1** forms three face-sharing octahedra (Fig. 1), comparable in this respect to the suboxide $Cs_{11}O_3$.[8] The anions $Sb_5I_{18}^{3\ominus}$ (Fig. 2) and $Sb_6I_{22}^{4\ominus}$ (Fig. 3), on the other hand, consist of edge-sharing octahedra. The anion of **3**, like other iodoantimonates,[4] corresponds to a section from a layer of the CdI_2 structure. It thus has a structure other than the ion of the same composition in **4**[3] (see below).

$[Fe(1,10\text{-phen})_3]_2Sb_6I_{22}\cdot 2CH_3CN$ **4**

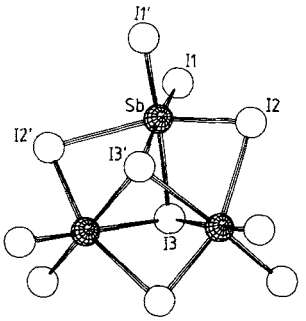

Fig. 1. Structure of the anion of **1** in the crystal. Distances [pm]: Sb-I1 278.2(2), Sb-I2 297.7(3), Sb-I2' 346.4(3), Sb-I3 335.6(2). The disorder of I2 derived from the crystallographic point symmetry (D_3) is not shown here for sake of clarity (I2 lies next to the twofold axis of rotation).

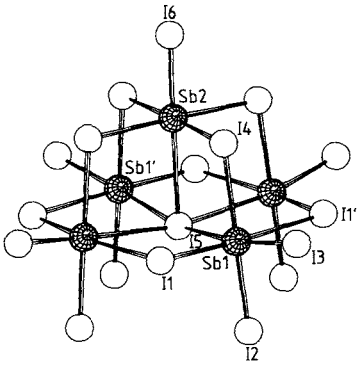

Fig. 2. Structure of the anion of **2** in the crystal (C_s symmetry). Distances [pm]: Sb1-I1 281.0(2), Sb1-I1' 354.8(2), Sb1-I2 289.1(2), Sb1-I3 277.0(2), Sb1-I4 316.9(2), Sb1-I5 341.8(1), Sb2-I4 302.8(2), Sb2-I5 354.7(4), Sb2-I6 272.4(5).

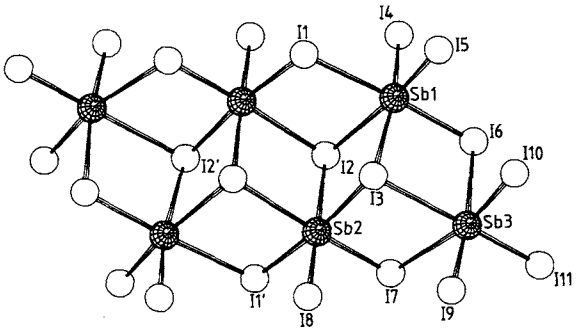

Fig. 3. Structure of the anion of **3** in the crystal (C_i symmetry). Distances [pm]: Sb1-I1 326.3(1), Sb1-I2 331.1(1), Sb1-I3 346.9(1), Sb1-I4 278.4(1), Sb1-I5 281.2(1), Sb1-I6 288.0(1), Sb2-I1' 298.0(1), Sb2-I2 336.9(1), Sb2-I2' 327.9(1), Sb2-I3 311.6(1), Sb2-I7 284.8(1), Sb2-I8 280.7(2), Sb3-I3 336.5(2), Sb3-I6 348.9(2), Sb3-I7 352.9(2), Sb3-I9 276.4(2), Sb3-I10 279.0(2), Sb3-I11 278.6(2).

The stereochemistry of the individual Sb^{III} atoms is similar in all three compounds: in the distorted SbI_6 octahedra the almost linear I-Sb-I units oriented perpendicular to each other can, according to *Rundle*[9] be described by four-electron three-center bonds. Within such a three-center bond the distances, as a measure of the bond strengths, can in some cases be very different. Thus, they vary from symmetric arrangements (I-Sb in each case 302.8 pm, see I4-Sb-I4' in **2**) through to strongly asymmetric groups (e.g. I5-Sb2-I6 in **2** with 354.7 and 272.2 pm). These variations are accompanied by deviations of the I-Sb-I angle from 180° by up to 20° (I2-Sb-I2' angle in **1**: 159.0°). Possibly a slight stereochemical influence of the non-bonding electron pair of antimony(III) is also reflected in these distortions. The structure of $Sb_5I_{18}^{3\ominus}$ also contains approximately linear Sb-I-Sb units (see Sb1-I5-Sb1' in Fig. 2). Comparable groupings have already been found in the anion $(PhSbI_2)_4I^{\ominus}$[10] and in the central Sb_6I_6 twin cube of **4**.[3] In all cases the Sb-I distances indicate that iodine, in contrast to Sb as central atom in linear units, forms only weak, almost symmetrical bonds with the two neighboring atoms. Due to the flexibility of the Sb-I bonds, a large number of different linkages are possible for the SbI_6 octahedra, thus enabling an optimal fit of the anions to the "spatial requirements" of the respective cations. The result is the observed structural diversity, which is not limited to the iodoantimonates—and not even to the fifth main group elements. Thus, the different forms of Te_4I_{16}[11] correspond in the coupling of the octahedra to the different $Sb_6I_{22}^{4\ominus}$ ions (see above). Such a conformity of the structures can be an indication that the species $Te_3I_{11}^{\oplus}$, $Te_5I_{18}^{2\oplus}$ and $Te_6I_{22}^{2\oplus}$ isoelectronic with $Sb_3I_{22}^{2\ominus}$, $Sb_5I_{18}^{3\ominus}$ and $Sb_6I_{22}^{4\ominus}$ respectively are likewise stable and isolable with suitable anions.

Experimental

1: 0.19 g (1 mmol) of CuI and 0.75 g (1.5 mmol) of SbI_3 were dissolved with heating in 80 mL of CH_3CN. Within ca. 6 days at −18°C bright red prisms of **1** crystallized out in ca. 85% yield. The compound rapidly loses acetonitrile. The elemental analysis was therefore only satisfactory regarding the ratio Cu : I : Sb.

2: The compound (orange-red prisms) was always obtained in admixture with $(Me_4N)_3Sb_2I_9$ and $(Me_4N)_4Sb_8I_{28}$ upon using the same procedure as for **1**; see also Ref. [5].

3: 0.09 g (0.5 mmol) of ferrocene, 0.06 g (0.25 mmol) of I_2 and 0.25 g (0.5 mmol) of SbI_3 were successively dissolved with heating in 150 mL of CH_3CN. Within 1 day at room temperature black compact crystals separated out in 82% yield; satisfactory C,H,Fe,I analysis.

Synthesis and Structure of a Binuclear *syn*-Coordinated μ-Cycloheptatrienyl Hydrido Complex with Hindered C_7H_7 Rotation**

By *Hubert Wadepohl,* Wolfgang Galm,* and *Hans Pritzkow*

Dedicated to Professor E. O. Fischer on the occasion of his 70th birthday

(η^6-Cycloheptatriene)metal complexes, like the (η^4-cyclopentadiene) compounds[1] with two fewer ring carbons, have an activated methylene *exo*-CH bond.[2,3] In such compounds, the *endo*-hydrogen also exhibits enhanced reactivity: at elevated temperature a shift from the methylene group to a vinylic ring position is observed. Whereas the unsubstituted η^4-C_5H_6 complex **1** does not rearrange at 100°C,[3] $[(\eta^6\text{-}C_7H_8)Cr(CO)_3]$ **2** displays a [1,5]-sigmatropic shift of the *endo*-hydrogen atom.[4] We have already ex-

[**] This work was supported by the Land Baden-Württemberg, (Forschungsschwerpunkt No. 40, "The Chemistry of Isolated and Complexed π Systems").

ploited the activation of the *exo*-CH bond in **1** in the synthesis of the (μ-η^4:η^1-cyclopentadi*enylidene*) complexes **4a**, **4b**, following reaction (a).[5,6]

Whereas both methylene CH bonds were finally cleaved in this reaction, the analogous reaction of **2** with **3b** led to the heterodimetallic complex *syn*-(μ-η^4:η^3-cycloheptatri*enyl*)(μ-hydrido)(tricarbonyl)chromium(η-pentamethylcyclopentadienyl)cobalt **5** [Eq. (b)].

2 **3b** **5**

$[Cp^*Co(CO)]_2$ ($Cp^* = \eta^5$-C_5Me_5) was formed in a side reaction; thus the yield of red-brown **5** amounted to only 15–25%. In contrast to the reaction of complex **1**, the formation of **5** from **2** cannot be explained by an attack of the incoming reagent[7] at the *exo*-CH bond of the methylene group. Instead, attack at the chromium atom leads to a change in the hapticity of the seven-membered ring. Loss of ethene and a hydrogen shift then leads to **5**. The hydrogen shift is reversible; thus, complex **2**, together with $[Cp^*Co(CO)_2]$, was formed upon reaction of **5** with CO (1 bar, room temperature, THF).

An X-ray crystal structure was obtained of **5** to clarify the coordination geometry of the cycloheptatrienyl ring.[8] Complex **5** has approximately C_s symmetry (Fig. 1). The

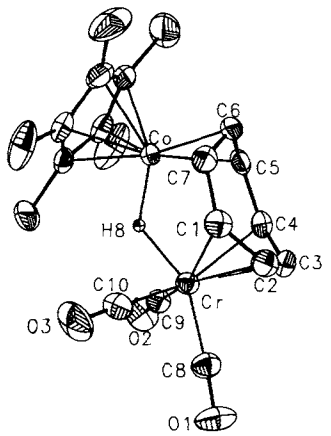

Fig. 1. Molecular structure of **5**. Selected bond lengths [Å] and angles [°] with standard deviations in parentheses: Cr-Co 2.899(1), Cr-H8 1.69(2), Cr-C1/4 2.300(4), Cr-C2/3 2.166(3), Cr-C8 1.817(3), Cr-C9 1.841(3), Cr-C10 1.857(4), Co-H8 1.54(3), Co-C6 1.945(3), Co-C5/7 2.071(4), Co-C(Cp*) 2.052(4)···2.089(3), C1/4-C2/3 1.393(5), C1/4-C7/5 1.447(5), C5/7-C6 1.408(6); Co-Cr-C8 174.3(1), Cr-H8-Co 127(1), C8-Cr-H8 150.0(8).

noncrystallographic mirror plane is comprised of both metal atoms, the hydrido ligand (H8), a carbonyl group (C8–O1), and the carbon atom C6 of the C_7H_7 ligand. On the distorted pseudo-octahedral-coordinated chromium atom there are two carbonyl groups in *cis* positions and one in a *trans* position to Co and thus to the CrHCo bond. The bond lengths in the C_7 ring can be interpreted in terms of (η^4-diene)chromium and (η^3-enyl)cobalt units, joined to each other by relatively long (1.45 Å) C–C bonds. The cycloheptatrienyl ring has a boat conformation (the dihedral angle between the η^4-diene and the η^3-enyl planes is 59°). The chromium, the cobalt, and the bridging hydrogen atom (H8) make up a 3c-2e MHM′ system.[9] Thus, both metals attain an 18-valence-electron configuration. Until now, CrHCo three-center bonds had not been investigated by structural analysis. In contrast to other complexes with a *syn*-M(μ-η^4:η^3-C_7H_7)M′ structure,[10] **5** has a large metal–metal distance (2.899 Å). This is attained by a shift of the chromium atom towards C2 and C3, rather than by a more pronounced folding of the C_7H_7 ring. Hence, Cr–C2/C3 bonds are shorter than Cr–C4/C5 bonds.

To our knowledge, until now it had not been possible to freeze out the rotation of the cycloheptatrienyl ring in *syn*-M(μ-C_7H_7)M′ complexes on the NMR time scale,[10,11] although this has been achieved with *anti*-M(μ-C_7H_7)M′ structures. However, in the ^1H and ^{13}C NMR spectra of **5**, measured at temperatures of approximately 200 K, we observed the expected signal patterns for a rigid μ-η^4:η^3-C_7H_7 structure. The ^1H resonance of the central proton (H6) of the enyl unit of the bridging ligand is shifted upfield of the outer protons H5 and H7 by $\Delta\delta \approx 1$. Normally, the reverse order is observed in η^3-allyl complexes,[12] which is also the case for *anti*-[$(CO)_3Fe(\mu$-η^4:η^3-$C_7H_7)Mo(CO)_2Cp$] **6**.[13a] Similar high-field shifts in $[Cp(CO)_2Mo(\eta^3$-$C_7H_7)]$ and $[(CO)_3Co(\eta^3$-$C_7H_7)]$ ($\Delta\delta \approx 1.5$) have been attributed to the boat conformation of the seven-membered ring.[14] An analogous explanation for *syn*-M(μ-η^4:η^3-C_7H_7)M′ complexes like **5** seems reasonable. In numerous examples with a similar folding of the ligand, however, the average ^1H NMR shifts of fluxional μ-η^4:η^3 cycloheptatrienyl ligands are at a lower field ($\delta(C_7H_7)_{mean} \approx 4.2$ to 3.5)[10,11] than in **5** ($\delta(C_7H_7)_{mean} = 2.92$).

In the literature[10b] the different rotational energy barriers for *anti*- and *syn*-M(μ-1-4-η^4:5-7-η^3-C_7H_7)M′ complexes have been explained by the p_π–p_π orbital overlap between the localized η^4-diene and η^3-enyl ring fragments. Thus, measurements of the bond lengths between these fragments and the torsion angles C3-C4-C5-C6 and C2-C1-C7-C6 should provide useful evidence for this overlap. For instance, these come to 1.49 Å and 61°, respectively, in **6**[13b] (*anti* structure, high rotational barrier), 1.43 Å and 0/34°, respectively, in *syn*-[(μ-CO)(μ-η^4:η^3-C_7H_7)-$\{Fe(CO)_2\}_2]^\ominus$,[10a] and 1.45 Å and 22/24°, respectively, in *syn*-$[(CO)_2Rh(\mu$-η^4:η^3-$C_7H_7)Fe(CO)_3]$[10b] (both low rotational barriers). However, the observed geometry of **5** (C1/4-C7/5 1.45 Å, torsion angles 0, 8.7°) shows that the mentioned structural parameters in the solid state cannot be correlated with the molecular dynamics in solution without further evidence.

Experimental Procedure

A solution of **2** (280 mg, 1.23 mmol) and **3b** (320 mg, 1.28 mmol) in 40 mL of petroleum ether was heated at 60–80°C for 6 h. The solvent was removed from the resulting green solution in vacuo, and the dark residue was redissolved in 20 mL of toluene. Red-brown crystals of **5** were obtained from solution at −25°C, which were recrystallized from toluene several times. Yield: 80 mg (15%) of red-brown prismatic crystals, dec. > 180°C. By further solvent concentration and cooling (−25°C), unreacted **2** and $[Cp^*Co(CO)]_2$ could be isolated.

5: IR (THF): $\tilde{\nu}$(CO) = 1957.5 (vs), 1878 (vs) cm^{-1}. ^1H NMR (200.1 MHz, [D_8]toluene), T = 350 K: δ = 2.92 (s, 7H, C_7H_7), 1.54 (s, 15H, Cp^*), −10.18 (s, 1H, bridging H); T = 200 K: δ = 4.07 (br. s, 2H, H2,3), 2.68 and 2.58 (each br. s, 2H, H1,4 and H5,7), 1.55 (br. s, 1H, H6), 1.38 (s, 15H, Cp^*), −10.13 (s, 1H, bridging H). $^{13}C\{^1H\}$ NMR (50.3 MHz, [D_8]toluene), T = 300 K: δ = 237.9 (CO), 93.7 (C_5Me_5), 68.2 (br, C_7H_7), 8.9 (C_5Me_5); T = 190 K: δ = 238.2 and 238.4 (CO), 93.2 (C_5Me_5), 83.6, 66.6, 59.5, 56.5 (C_7H_7), 8.7 (C_5Me_5). EI-MS (70 eV): m/z (%) 422 (9, $M^\oplus$), 394 (5, $[M-CO]^\oplus$), 366 (6, $[M-2CO]^\oplus$), 336 (92, $[M-3CO-2H]^\oplus$), 250 (27, $[Cp^*Co(CO)_2]^\oplus$), 222 (18, $[Cp^*Co(CO)]^\oplus$),

194 (100, $[Cp^*Co]^{\oplus}$), 193 (10), 192 (60), 133 (36), 92 (35, $[C_7H_8]^{\oplus}$), 91 (80, $[C_7H_7]^{\oplus}$), 59 (16, $Co^{\oplus}$), 52 (38, $Cr^{\oplus}$). Correct C,H analysis.

Selective Hydrogenation of Esters to Alcohols with a Catalyst Prepared from Rh_2O_3, $Sn(n\text{-}C_4H_9)_4$, and SiO_2: Evidence for Site Isolation**

By *Abdellah El Mansour, Jean P. Candy,* Jean P. Bournonville, Osmar A. Ferretti,* and *Jean-Marie Basset**

A new generation of bimetallic catalysts exhibiting unusual activities and/or selectivities can be obtained via the reaction of organometallic compounds of main-group elements, in particular group IV, with supported group VIII transition metals.[1] We report here that the reaction of $Sn(n\text{-}C_4H_9)_4$ with Rh_2O_3/SiO_2 results in a $Rh/Sn/SiO_2$ catalyst which is more active and much more selective than Rh/SiO_2 for the hydrogenation of ethyl acetate to ethanol. Our results indicate the ability of tin atoms to isolate rhodium atoms from their neighbors. The concept of real (or apparent) site isolation of rhodium by zinc atoms has been recently advanced by *Ichikawa* et al.[2] to explain the selective hydroformylation of ethylene on a $Rh/Zn/SiO_2$ catalyst.

Catalyst **B** (Rh_2O_3/SiO_2),[3] obtained by oxidation of catalyst **A** (Rh/SiO_2), reacts with $Sn(n\text{-}C_4H_9)_4$ to give catalyst **C** in a two-step process (Table 1). Between 25 and 150 °C

Table 1. Amount of gases evolved (mol C_4/mol Sn) during the preparation of catalyst **C** from $Sn(n\text{-}C_4H_9)_4$ and catalyst **B** (Sn/Rh = 2/1).

T[°C]	1-C_4H_8	2-(*E*)-C_4H_8	2-(*Z*)-C_4H_8	$\sum C_4H_8$	$\sum C_4H_{10}$	H_2O
50	0.12	0.05	0.02	0.19	0.20	–
100	0.56	0.24	0.14	0.94	0.74	–
150	0.70	0.30	0.20	1.20	1.07	–
200	1.44	0.42	0.48	2.34	1.35	+
300	1.45	0.60	0.44	2.49	1.42	+

ca. 1 mole of butane and 1 mole of butene are evolved per mole of stannane. Above 150 °C, mostly butenes and water are produced. The amount of butenes and butane evolved at 300 °C is close to the expected value of four C_4 molecules per tin atom, indicating that the surface does not contain any significant amount of hydrocarbon residue. This result was confirmed by the IR spectra of the catalyst taken in situ at various temperatures. The $\nu_{C\text{-}H}$ and $\delta_{C\text{-}H}$ bands centered at ca. 2800–3200 and 1200–1600 cm^{-1}, respectively, which are intense at 25 °C, almost disappear under vacuum at ca. 200 °C. At the end of the reaction the final ratio butane/butenes is close to 0.5/1 which agrees fairly well with reaction (a).

$$Rh_2O_3 + 4\,Sn(n\text{-}C_4H_9)_4 \longrightarrow Rh_2Sn_4 + 11\,C_4H_8 + 5\,C_4H_{10} + 3\,H_2O \quad (a)$$

The mass balance data (Table 1) suggests that the reaction occurs in two steps: below ca. 150 °C rhodium(III) would not be reduced since equimolar amounts of *n*-butenes and *n*-butane are formed. At this stage the presence of a partially alkylated Sn–Rh bimetallic complex, $[(Rh^{III}\text{-}O)_xSnBu_y]$ ($x+y=4$), can be postulated. Above ca. 150 °C this complex would decompose under partial vacuum with concomitant reduction of Rh^{III} and Sn^{IV} to give Rh^0 and Sn^0 (catalyst **C**). After treatment of **C** under H_2 at 500 °C, X-ray photoelectron spectroscopic measurements confirmed the presence of Rh^0 and Sn^0 (Table 2).

Table 2. Binding energies [eV] of Rh($3d_{5/2}$, $3d_{3/2}$) and Sn($3d_{5/2}$, $3d_{3/2}$) electrons in various rhodium, tin, and rhodium-tin samples.

Sample	Rh		Sn		Ref.
	$3d_{3/2}$	$3d_{5/2}$	$3d_{3/2}$	$3d_{5/2}$

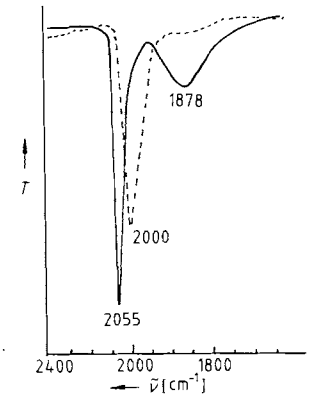
[**] The authors would like to express their thanks to Dr. *J. C. Bertolini, R. Gallezot, J. L. Duvaux*, and *I. Mutin* for helpful discussions regarding X-ray photoelectron spectroscopy and STEM experiments. *J.-M. B.* would like to express his best thanks to Prof. *W. A. Herrmann* for his kind hospitality in Munich and for helpful discussions.

The particles obtained in **C** are bimetallic as demonstrated by STEM (scanning transmission electron microscopy). Their Sn/Rh ratio was the same as that of the starting materials, at least for Sn/Rh < 2. (The tin X-ray emission peak was always associated with that of rhodium.) The chemisorption properties of these bimetallic particles are drastically modified with respect to those of supported rhodium. Whereas Rh/SiO_2 chemisorbs ca. 1 mole of CO and 0.53 mole of H_2 per mole of rhodium atoms (25 °C, 100 mbar of CO or H_2), the bimetallic Rh/Sn (1/1) chemisorbs only 0.4 mole of CO and 0.05 mole of H_2 per mole of rhodium atoms (under the same conditions). IR spectroscopy of CO chemisorbed on catalyst **C** brings supplementary information. With Rh/SiO_2 two strong bands at 2055 and 1878 cm^{-1} are reasonably assigned to the terminal carbonyl and bridging carbonyl, respectively[5] (Fig. 1). With $Rh/Sn/SiO_2$ only one band is observed at 2000 cm^{-1}, which is also reasonably assigned to a linear carbonyl; the band ascribed to a bridging carbonyl is no longer present (only an extremely small shoulder at ca. 1850 cm^{-1} is observed possibly due to traces of bridging CO on $Rh/Sn/SiO_2$).



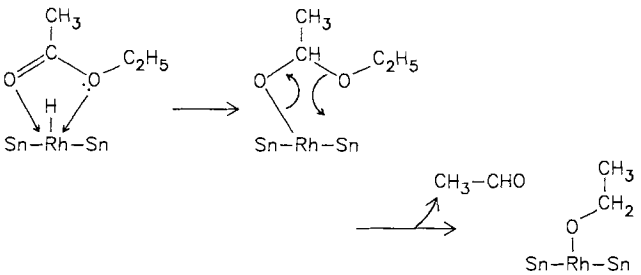


Fig. 1. IR spectrum of CO adsorbed on Rh/SiO_2 (—) and $Rh/Sn/SiO_2$ (---). T = transmission.

The new catalyst **C** exhibits a very high chemoselectivity in the hydrogenation of ethyl acetate to ethanol (Table 3). As the ratio Sn/Rh increases from 0/1 to 0.2/1, the conversion of ethyl acetate decreases sharply, whereas the selectivity of ethanol formation increases significantly. Above an Sn/Rh ratio of 0.2/1 both the conversion of ethyl acetate and the selectivity of ethanol formation increase with tin content to reach values higher than 95% for an Sn/Rh ratio higher than unity, whereas Rh/SiO_2 gives CH_4, C_2H_6, CO, and CO_2, corresponding to a completely unselective C–C or C–O bond cleavage. $Rh/Sn/SiO_2$ with Sn/Rh = 1.7/1 exhibits a very high chemoselectivity for the C(O)–O bond cleavage of the ester group (Table 3). The drastic difference in the nature of the catalysts **A** and **C** is also evident from the variation of apparent activation energy, which decreases from 75.2 kJ mol^{-1} for pure Rh/SiO_2 to 46 kJ mol^{-1} for $Rh/Sn/SiO_2$. The concept of site isolation accounts quite well for a mechanism where the ester could be coordinated to a single rhodium atom; H transfer to the carbon atom of the carbonyl group is followed by a kind of concerted reaction leading to acetaldehyde[6] and rhodium alkoxide (Scheme 1). In agreement with this concept is the absence of C–C bond breakage, which is known to occur on metallic ensembles.[7]

Table 3. Catalytic activity r and selectivity S_i of various $Rh/Sn/SiO_2$ catalysts in the hydrogenation of ethyl acetate to ethanol. $T = 543$ K; H_2/AcOEt = 9/1; $p = 5$ MPa.

Scheme 1. Proposed mechanism of hydrogenation of ethyl acetate on catalyst **C**.

In conclusion, the concept of rhodium site isolation by tin atoms, which may account for the high chemoselectivity of **C**, is supported by three experimental facts: Tin decreases sharply the amount of H_2 and CO chemisorbed on rhodium in agreement with the partial coverage (or poisoning) of catalytically active rhodium atoms by inactive tin atoms. Tin suppresses the presence of bridging carbonyls, in agreement with a possible isolation of rhodium atoms from their neighbors. It is possible that other factors may be superimposed, such as an electronic effect of tin which increases slightly the electron density on rhodium.

Experimental Procedure

Rhodium was grafted on silica (Aerosil, 350 m^2 g^{-1}) by cationic exchange between $[RhCl(NH_3)_5]^{2\oplus}$ ions and $Si-O^{\ominus}NH_4^{\oplus}$ groups at pH 10. The $Si-O^{\ominus}NH_4^{\oplus}$ groups were obtained by exchange between $Si-O^{\ominus}H^{\oplus}$ groups and $NH_4^{\oplus}$ ions in ammonia solution. $[RhCl(NH_3)_5](OH)_2$ was obtained by contact of $[RhCl(NH_3)_5]Cl_2$ with an anionic exchange resin (IRA 400) in aqueous solution. The surface complex obtained by this route was decomposed by calcination at 300 °C in flowing dry air and then reduced in flowing hydrogen at 300 °C to give catalyst **A**. This catalyst contains 1 wt% of rhodium. **A** could be transformed into **B** by treatment with dry O_2 at 25 °C for 1 h. The particle size of **B** was in the range of 1.0–1.5 nm as determined by electron microscopy.

Adsorption of a given amount of $Sn(n\text{-}C_4H_9)_4$ in *n*-heptane on **B** [3] was achieved at 25 °C for 15 min. Various concentrations of $Sn(n\text{-}C_4H_9)_4$ at this stage could govern the final Sn/Rh ratio, at least for Sn/Rh ratios lower than 1.7/1. After removal of the solvent under vacuum (10^{-4} torr, 16 h), the solid was progressively heated in a closed vessel at 50, 100, 150, 200, and 300 °C. Qualitative and quantitative analysis of the gas phase was carried out after each plateau. Blank experiments carried out under the same conditions between $Sn(n\text{-}C_4H_9)_4$ and a silica pretreated at 25 or 200 °C did not show any significant reaction. The amount of tin that could react with **B** was proportional to the rhodium content up to an Sn/Rh ratio of ca. 1.7/1. $Rh/Sn/SiO_2$ catalysts with various tin contents were prepared (Table 3). Prior to catalytic measurements, the samples were treated "in situ" under flowing hydrogen (5 MPa, 8 mole of H_2 per gram of catalyst per hour at 100 °C (1 h), 250 °C (1 h), and 450 °C (2 h)). The hydrogenation of ethyl acetate was carried out in a conventional fixed-bed flow-differential reactor at 270 °C under 4.5 MPa of H_2 and 0.5 MPa of ethyl acetate. The contact time was varied between 2.2 and 40 h^{-1}. Activity (r) can be defined as the number of moles of ethyl acetate transformed per gram of catalyst per hour. Selectivity (S_i) can be defined

as the ratio of the carbon weight in product i to the total carbon weight in all the products.

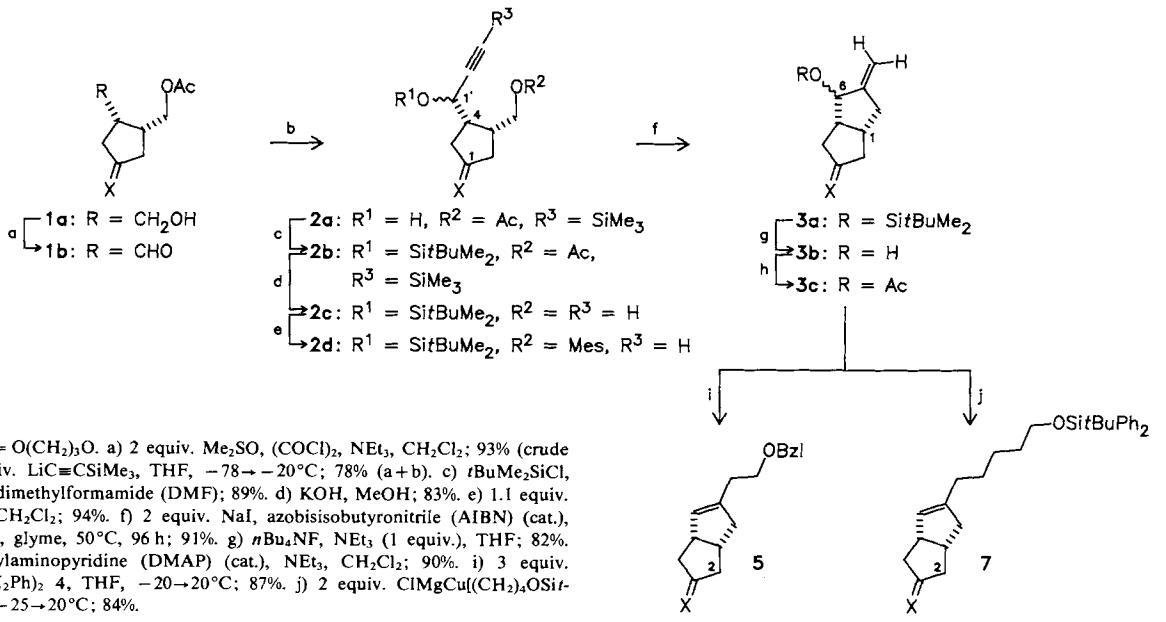
Flexible Syntheses of Optically Active Isocarbacyclins**



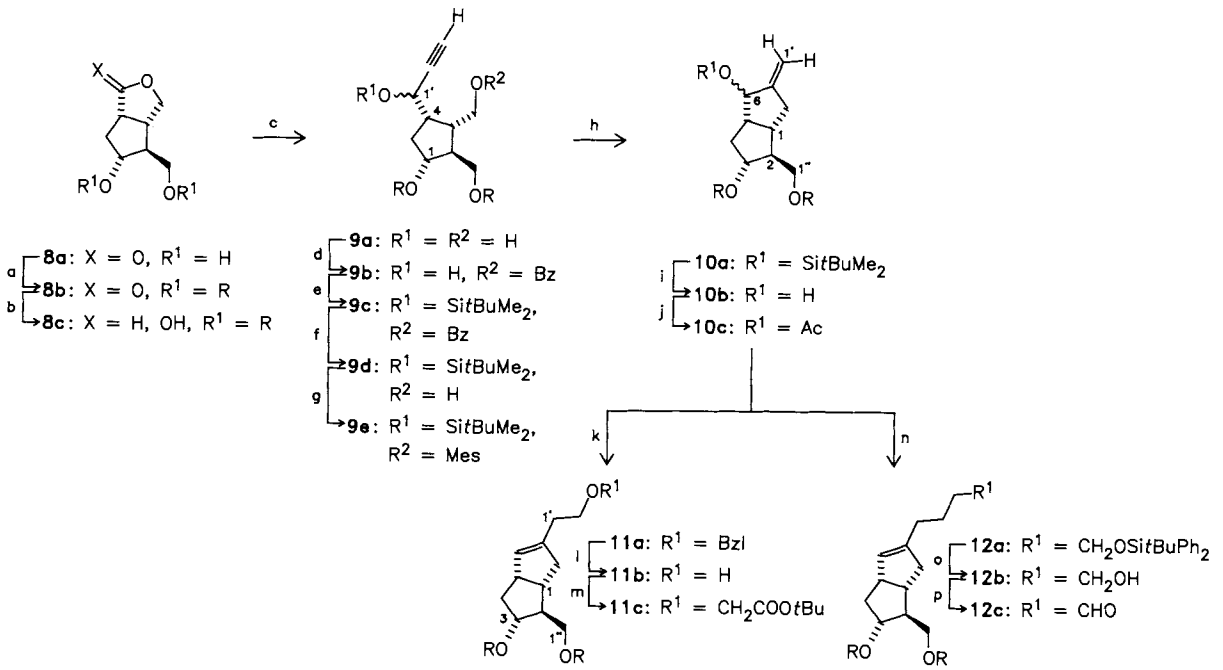
By *Horst Hemmerle* and *Hans-Joachim Gais**

Great hopes are placed on stable analogues of the hemostase regulator prostacyclin[1a] for the therapy of vascular diseases.[1b] The most promising compound aside from carbacyclin[1b] is isocarbacyclin **15a**[2] (see Scheme 3). Its biological activity is determined not only by the sense of chirality but also the structure of both side chains. For example, the derivative **15b** is characterized by strong inhibition of platelet aggregation *and* oral activity;[3b] its analogue with a triple bond between C13 and C14 and an ethyl instead of a methyl group on the alkyne C of R is possibly even more potent.[4a] Syntheses appropriate for the attainment of compounds of the type **15** must therefore be enantioselective and flexible with regard to *both* side chains.[3] We now describe two novel entries to **15** which fulfill these conditions.

The skeletal framework, the upper side chain and the 6,9α double bond of **15** are established starting from **1** or **8** by radical 5-*exo*-*dig*-cyclization[3f,5] and γ-substitution with cuprates[6] (see Schemes 1 and 2).[7] The lower side chain is then generated by proven methods[1b,3,4] (see Scheme 3); one central building block, **10c**, already contains the requisite hydroxymethyl group, in the case of the other, **3c**, it is missing and must be incorporated at a later stage. We have already described optimized routes with enzyme-catalyzed asymmetric key steps for the synthesis of the starting compounds (−)-**1a**[8] and (+)-**8a**.[9–11]

The synthesis of the allylic acetate **3c** begins with the oxidation of the alcohol **1a** to the aldehyde **1b** and its addition to lithium(trimethylsilyl)acetylide (Scheme 1). The alkynol **2a** is obtained as a diastereomeric mixture ((1′*R*)-**2a** : (1′*S*)-**2a** = 3 : 1); C-4 epimers were not formed. Silylation, selective cleavage of the trimethylsilyl and acetyl groups and subsequent mesylation furnished the mesylate **2d**. The primary iodide[12] generated in situ from **2d** was cyclized in a radical reaction by the tin method[13] to give **3a** in 91% yield. This was then converted into **3c**.

3c reacts smoothly with the cuprates **4** and **6** to give the bicyclic alkenes **5** and **7**, respectively, which were isolated in yields of 87% and 84%, respectively. The transformation **3c** → **5** can also be achieved with stable benzyloxymethylmagnesium chloride[15] in the presence of 10 mol-% CuI.



Scheme 1 [14]. X = $O(CH_2)_3O$. a) 2 equiv. Me_2SO, $(COCl)_2$, NEt_3, CH_2Cl_2; 93% (crude yield). b) 1.1 equiv. $LiC{\equiv}CSiMe_3$, THF, −78 → −20°C; 78% (a+b). c) $tBuMe_2SiCl$, imidazole (ImH), dimethylformamide (DMF); 89%. d) KOH, MeOH; 83%. e) 1.1 equiv. $MeSO_2Cl$, NEt_3, CH_2Cl_2; 94%. f) 2 equiv. NaI, azobisisobutyronitrile (AIBN) (cat.), 2 equiv. nBu_3SnH, glyme, 50°C, 96 h; 91%. g) nBu_4NF, NEt_3 (1 equiv.), THF; 82%. h) Ac_2O, dimethylaminopyridine (DMAP) (cat.), NEt_3, CH_2Cl_2; 90%. i) 3 equiv. $ClMgCu(CH_2OCH_2Ph)_2$ **4**, THF, −20 → 20°C; 87%. j) 2 equiv. $ClMgCu[(CH_2)_4OSitBuPh_2]_2$ **6**, ether, −25 → 20°C; 84%.

Racemates of bicyclic compounds of the type **5** and **7** have already been converted into *rac*-**15b** and *rac*-**15a** (R = *n*-C_5H_{11}), respectively.[3b,c] The attachment of the lower side chain would be shortened still further by a selective deprotonation of **5** and **7** (X = O) at C-2 with chiral bases.[16]

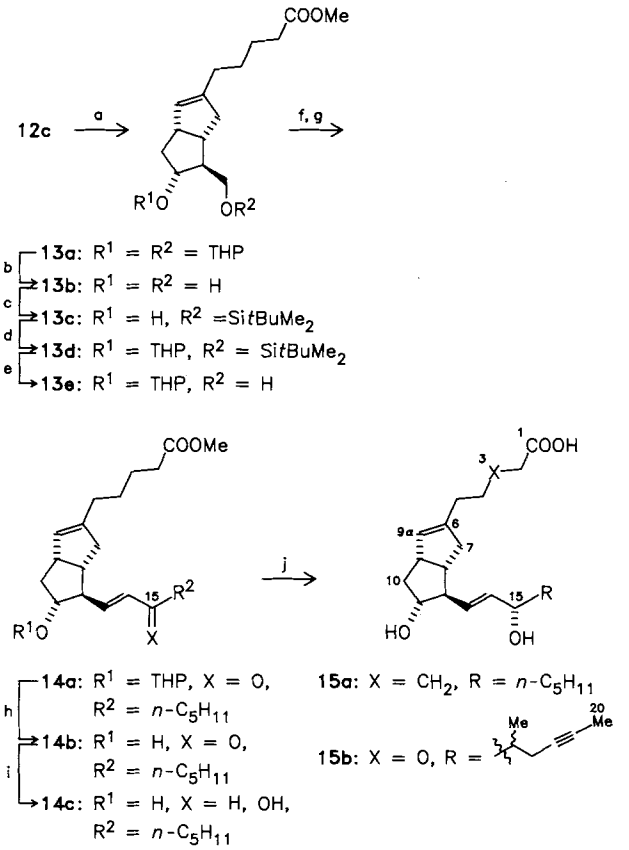
Scheme 2 [14]. R = tetrahydropyranyl (THP). a) Dihydropyran, THF, pyridinium *p*-toluenesulfonate (PPTS) (cat.); 95%. b) 1.1 equiv. iBu_2AlH, THF, $-78\rightarrow-20$°C; 95%. c) 3 equiv. BrMgC≡CH, THF; 96%. d) 1.1 equiv. BzCl, pyridine, −30°C; 74%. e) $tBuMe_2SiCl$, ImH, DMF; 97%. f) KOH, MeOH, 0°C; 71%. g) 1.1 equiv. $MeSO_2Cl$, NEt_3, CH_2Cl_2, −30°C; 95%. h) 2 equiv. NaI, AIBN (cat.), 2 equiv. nBu_3SnH, glyme, 50°C, 96 h; 82%. i) nBu_4NF, NEt_3 (1 equiv.), THF; 87%. j) Ac_2O, DMAP (cat.), NEt_3, CH_2Cl_2; 91%. k) 2 equiv. **4**, THF, $-25\rightarrow20$°C; 92%. l) Na, EtOH, NH_3, THF, −78°C; 82%. m) 10 equiv. $BrCH_2COOtBu$, nBu_4NHSO_4, NaOH; 74%. n) 3 equiv. **6**, ether, $-25\rightarrow20$°C; 95%. o) nBu_4NF, NEt_3 (1 equiv.), THF; 92%. p) SO_3·pyridine, Me_2SO, NEt_3; 94%.



For the synthesis of the allylic acetate **10c** functionalized on C-2 (Table 1), the lactone **8a** was converted into the hemiacetal **8c**, from which the diastereomeric alkynediols **9a** ((1′*S*)-**9a** :(1′*R*)-**9a** = 6 : 1) were prepared by reaction with three equivalents of bromomagnesium acetylide (Scheme 2); C-4 epimers were not found. The diastereomeric ratios of **2a** and **9a** indicate opposite asymmetric inductions for the acetylide additions to **1b** and to the aldehyde in equilibrium with deprotonated **8a**. The mesylate **9e** was then obtained from **9a** by protective group manipulations and mesylation in the way shown in Scheme 2. The radical ring closure of the primary iodide generated in situ from **9e** leads smoothly to the formation of **10a** in 82% yield.

The flexibility of our concept for the generation of upper side chains is demonstrated by the reactions of **10c** with the cuprates **4** and **6** to give the two alkenes **11a** (92%) and **12a** (95%), respectively, with the double bond in the correct position for **15**.

The following findings for the synthesis of the alkenes **5** (**11a**) and **7** (**12a**) are still important: Despite greater steric hindrance, the intermediary alkyl radical generated from (1′*S*)-**2d** [(1′*S*)-**9e**] cyclizes in the same way as its epimer formed from (1′*R*)-**2d** [(1′*R*)-**9e**], *and* both C-6 epimeric acetates **3c** (**10c**)[17] react with the cuprates **4** and **6** with substitution, whereby regiomers were not detectable NMR spectroscopically in any of the cases.

In order to obtain the intermediate compound **11c** with the upper side chain of **15b**, the benzyl ether **11a** was cleaved in the usual way to give the alcohol **11b**, which was then treated with *tert*-butyl bromoacetate to give **11c**.[4] The compound **13a** with the upper side chain of **15a** was obtained from **12a** via the alcohol **12b** and the aldehyde **12c** (Schemes 2 and 3).

Scheme 3 outlines by way of example the routine path leading to the linking of the lower side chain of **15a** to

Scheme 3 [14]. a) Ag_2O, NaOH, EtOH, H_2O; $H_3O^{\oplus}$; CH_2N_2; 85%. b) MeOH, PPTS (cat.); 93%. c) $tBuMe_2SiCl$, ImH, DMF; 86%. d) Dihydropyran, PPTS (cat.); 91%. e) nBu_4NF, NEt_3 (1 equiv.), THF; 92%. f) SO_3·pyridine, Me_2SO, NEt_3; 93% (crude yield). g) 3 equiv. $(MeO)_2PO-CH_2-CO-(CH_2)_4Me$, NaH, glyme, 0°C; 65% (f+g). h) MeOH, PPTS (cat.); 92%. i) 10 equiv. 2,6-*t*Bu-4-Me-$C_6H_2OAliBu_2$, toluene, $-78\rightarrow-10$°C; 87%. j) NaOH, MeOH, H_2O; $H_3O^{\oplus}$; 95%.

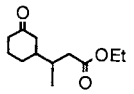
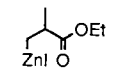
Copper(I)-Promoted Michael-Addition Reaction of Organozincs of Esters, Nitriles, and α-Amino Acids**

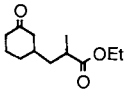
By *Yoshinao Tamaru,* Hiroto Tanigawa, Tetsuji Yamamoto,* and *Zen-ichi Yoshida**

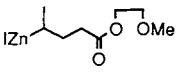
The Michael addition reaction is one of the most important methods to construct desired molecules. Classically it is the reaction of soft α-carbonyl carbanions with electron-deficient olefins.[1] Development of copper-promoted 1,4-addition of hydrocarbon groups has greatly expanded the scope of this reaction.[2] Although we are still short of a general method to conduct Michael addition with such carbanions as those remote from carbonyls by more than two carbons, two precedents have been reported. One is the reaction of β-zinc esters[3a] and the other is that of β-, γ-, and δ-zinc nitriles and esters,[3b,c] the latter being reported very recently during preparation of this manuscript.

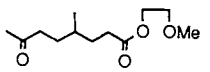
Here we report that organozincs[3d-f] bearing electrophilic functionalities (ester,[4] nitrile, α-amino acid) essentially at any positions more remote than the β-position serve as Michael donors and add to α,β-unsaturated aldehydes, ketones, and esters in the presence of trimethylsilyl chloride[5] and cuprous cyanide.[6]

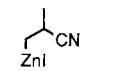


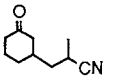


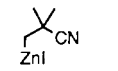


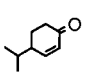


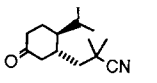


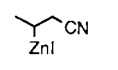


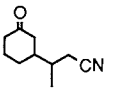


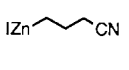


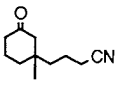


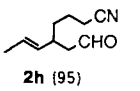


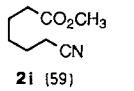


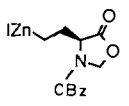


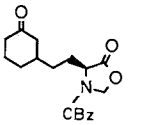


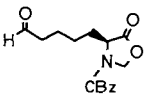












Some representative results are summarized in Table 1 and Scheme 1. The following points deserve comment:

1. The results of runs 1 and 2 indicate that the position of the methyl group of the starting iodoesters does not change during the reaction. This regiochemistry is in sharp contrast to the Michael addition reaction of β-zinc esters developed by *Kuwajima* et al.[3a] and also to our previous observation on the reaction of **1a** and **1b** with aldehydes.[4d] These two reactions only provide 3-substituted 2-methylpropionic esters (e.g., a product like **2b**) through a rearrangement via a common intermediate **3** (Scheme 2).[7] The same is valid in the reactions of the nitrile series (runs

[**] This work was supported by the Ministry of Education, Science and Culture (Japan). It was presented at the 56th Annual Meeting of the Chemical Society of Japan (April 1988). Abstract II, p. 1758. We are indebted to Dr. *Y. Ito* and Dr. *T. Hayashi* and to *Y. Matsumoto* (Kyoto University) for the determination of *ee* values and helpful discussion.

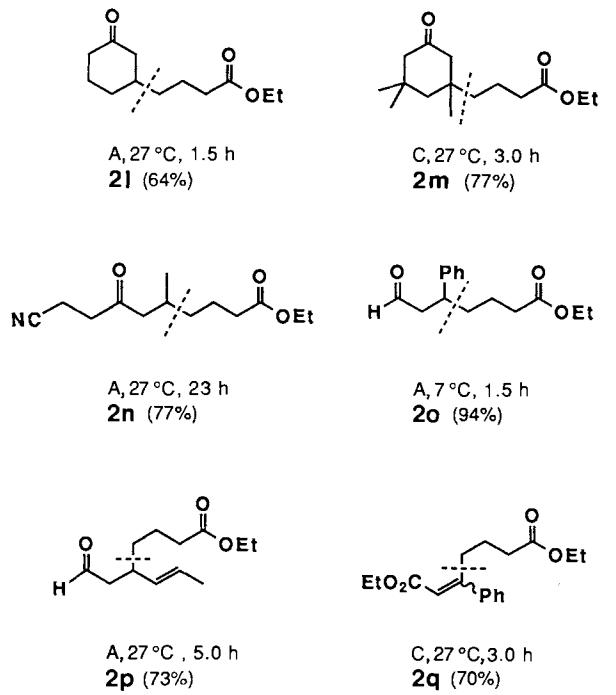

Table 1. Michael addition of organozincs of esters, nitriles, and α-amino acids.

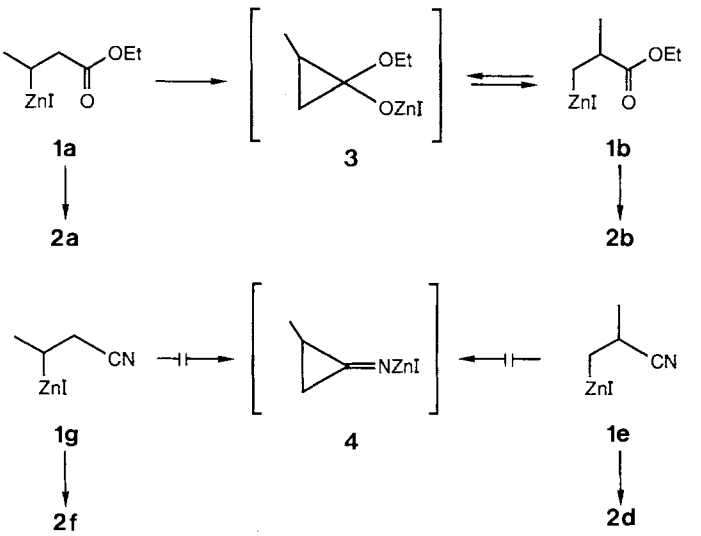
Run	Michael donor [a]	Acceptor	Reaction conditions [b]	Product (yield [%]) [c]
1	 **1a**		B, 7 °C, 1.5 h	 **2a** (78) [d]
2	 **1b**		B, 7 °C, 1.5 h	 **2b** (70) [d]
3	 **1d**		A, 27 °C, 4.0 h	 **2c** (76)
4	 **1e**		B, 7 °C, 10 h	 **2d** (70) [d]
5	 **1f**		B, 0 °C, 40 h	 **2e** (54)
6	 **1g**		B, 7 °C, 5.0 h	 **2f** (62) [e]
7	 **1h**		B, 7 °C, 19 h	 **2g** (70)
8	**1h**		B, 27 °C, 4.0 h	 **2h** (95)
9	**1h**		C, 0 °C, 16 h	 **2i** (59)
10	 **1i** [f]		B, 0 °C, 15 h	 **2j** (71) [d]
11	**1i** [f]		B, 7 °C, 6.0 h	 **2k** (70) [g]

[a] For the generation of **1**, see [6]. [b] CuCN/HMPA ratio in equivalents: A, 0.05/1.0); B, 0.35/1.5; C, 1.0/1.5. [c] Yields are for the homogeneous products purified by column chromatography over silica gel and based on the unsaturated carbonyl compounds. [d] Diastereomeric ratio was not determined. [e] Diastereomeric mixture (1 : 1) was obtained. [f] The starting iodide was prepared according to the literature procedure: D. H. R. Barton, Y. Hervé, P. Potier, J. Thierry, *J. Chem. Soc. Chem. Commun. 1984*, 1298. CBz = benzyloxycarbonyl. [g] $[\alpha]_D^{20} = +101$ ($c = 0.34$, $CHCl_3$).

4–6) in which no isomerization via **4** (Scheme 2) is observed.



2. The reaction of the present organozinc-Cu^I system with 2,4-hexadienal results in specific 1,4-addition. The sole products were **2h** and **2p** without any traces of 1,2- or 1,6-addition products. The formation of **2g** and **2m** in reasonable yields from highly substituted and hence unreactive ketones as well as a highly *trans*-selective addition (run 5) may be valuable aspects of the reaction. Furthermore, the successful reactions with olefinic (run 9) and acetylenic esters (e.g., to give **2q**) clearly indicate the wide scope of the reaction.

Scheme 1. Reaction of ethyl 4-(iodozinca)butyrate **1c** with α,β-unsaturated ketones, esters, and aldehydes. For the reaction conditions (A, B, C) and yields, see footnotes [b] and [c] in Table 1.

3. The reaction is not confined to β- and γ-esters and nitriles. Their higher homologues react with similar effectiveness.[8] Among these, the β-zinc esters and nitriles proved to be by far the least reactive.[4d,9] For example, neither **1e** nor **1g** reacts with 3-methyl-2-cyclohexenone even under forcing conditions (C: 7 °C, 20 h; cf. run 7).

4. Most importantly, the results in runs 10 and 11 suggest that the reaction opens a new and efficient route to the

Scheme 2. Possible isomerizations of organozinc compounds.

syntheses of chiral amino acid derivatives. The product **2k** was obtained in more than 99% *ee*.[10]

[6] The zinc iodides **1a–i**, prepared in situ by the reaction of the corresponding iodide with 1.05–1.10 equivalents of Zn–Cu couple in dioxane/HMPA (60°C, 3–5 h) [4], were successively treated at the temperature indicated in Table 1 and Scheme 1 with CuCN and trimethylsilyl chloride (2 equivalents) and then with an α,β-unsaturated carbonyl compound (0.7 equivalents). The reaction was monitored by gas chromatography using biphenyl as an internal standard. For the stoichiometries of CuCN and HMPA and the reaction conditions for Michael addition, see Table 1.
[7] The cyclization of **1a** and **1b** to **3** seems to proceed only at higher temperatures and in the presence of a silylating agent. As a matter of fact, 1-ethoxy-1-(*tert*-butyldimethylsiloxy)cyclopropane was obtained in 65–70% isolated yield by heating a mixture of *tert*-butyldimethylsilyl chloride and ethyl 3-(iodozinca)propionate in tetrahydrofuran/*N*,*N*-dimethylacetamide at 60°C for ca. 12 h (unpublished results). Note that in the present reaction **1a** and **1b** were exposed to trimethylsilyl chloride at ambient temperature or below, while the reactions of **1a** and **1b** with aldehydes only proceed in the presence of trimethylsilyl chloride at higher temperatures (ca. 60°C) [4d].
[8] Under conditions B (7°C, 3 h), δ- and ε-zinc nitriles reacted with 2-cyclohexenone to furnish the corresponding 1,4-addition products in 70 and 92% isolated yields, respectively.
[9] The low reactivity of these β-zinc esters and nitriles may primarily be ascribed to the electron-withdrawing effect of the carbonyl and cyano groups.
[10] The *ee* values were determined by means of HPLC with a chiral stationary phase column (Sumipax OA-1100, *n*-hexane/1,2-dichloroethane/ethanol = 100/20/1), using racemic **2k** as a reference.

BOOK REVIEWS

Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for qualified book reviewers are welcome. Publishers should send prospects or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Bundesrepublik Deutschland. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Introduction to Microscale High-Performance Liquid Chromatography. Edited by *D. Ishii*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xiv, 208 pp., bound, DM 118.00.—ISBN 3-527-26636-4; 0-89573-309-5

The editor of this book and author of several of the chapters is amongst the leading advocates of microcolumn techniques in HPLC. Although several monographs on the use of narrow bore columns have already appeared in the last few years, this technique still generates only marginal interest, despite the continuing growth in the application of HPLC with columns of 2 to 5 mm internal diameter. The advantages of narrowing the cross-section are a reduction in the amount of eluent needed, an increase in the solute concentration at the peak maximum, the possibility of more easily combining HPLC with mass spectrometry, and an increase of 30 times in permeability when open capillaries are used, allowing the use of longer columns. Even for LC it can be shown theoretically that with capillary columns several hundred thousand plates can be achieved. However, with the narrow capillary columns, of the order of 10 μm diameter, which theory indicates are needed for LC, the sample injection volumes are limited to a few nL. Furthermore, the peak volumes are so small (1 to 10 nL) that when using photometric detectors it does not appear possible to achieve high detection sensitivities. "Thus, the apparatus must be designed by each laboratory." This quotation from the book sums up the whole range of problems.

The book gives a good overview of the capabilities and problems of microcolumn techniques using open or irregular packed capillaries, and "semimicro" columns with diameters of less than 1.5 mm. The problems of choosing a suitable sample introduction system, detector and connection methods (eliminating dead volume so far as possible) are explained, and various solutions to these problems are described and amplified by examples of the chromatograms obtained (effects of time constants, etc.). Regrettably, in one of the most important figures (Fig. 2-3), which is intended to illustrate the advantages of microcolumns, such as enhanced detection sensitivity, the curves do not agree with the legends. It is sufficient here to point out that

columns with larger diameters can be more heavily loaded (in volume *and* mass), resulting in similar trace detection sensitivities. Consequently it only makes sense to use columns with smaller diameters to improve the detection sensitivity when the amount of sample available is very limited.

Examples of applications are included so as to illustrate the capabilities of microcolumn techniques. The critical reader will notice that many of the compounds in the separation examples are condensed arenes, chlorinated biphenyls, phthalic acid esters, tocopherols, etc.—all of which are compounds with very large molar extinction coefficients. In other examples (Figs. 7-58 to 7-66) columns with internal diameters in the conventional range (2.1 to 4.6 mm), packed with very small particles (average diameter $<5\,\mu m$), have been used. In English-speaking usage (and in this book) columns such as these are also often referred to as "microcolumns". However, in the introduction a clear distinction is made between the two sorts of microcolumns, namely those with small column diameters, and those that have normal diameters but are packed with small particles. This book is concerned only with techniques using small diameter microcolumns. It is recommended as reading for anyone interested in these techniques and wishing to put them to practical use.
