In contrast to **1**, the anion **3**[2] is stable in boiling aqueous amines, but it isomerizes promptly in the presence of a metal(II) ion at room temperature to yield the title compounds **4** (ca. 95%): the pyrrole proton attacks the adjacent nitrile nitrogen atom, and the intramolecular metal-promoted reaction proceeds with formation of the C–N bond. It is not possible to isolate the metal-free β-diimino anion, since demetalation reverses the reaction and regenerates the anion **3**.

The structure **4**, or the equivalent mesomer with the negative charge on C-6, is supported by the ^{13}C NMR spectrum of the zinc(II) compound **4d** and the X-ray crystal structure analysis of the copper(II) compound **4c** (Fig. 1).

The ESR and electronic spectra of **4c** in solution (see *Experimental*) resemble those of copper(II)-tetraazaporphy-

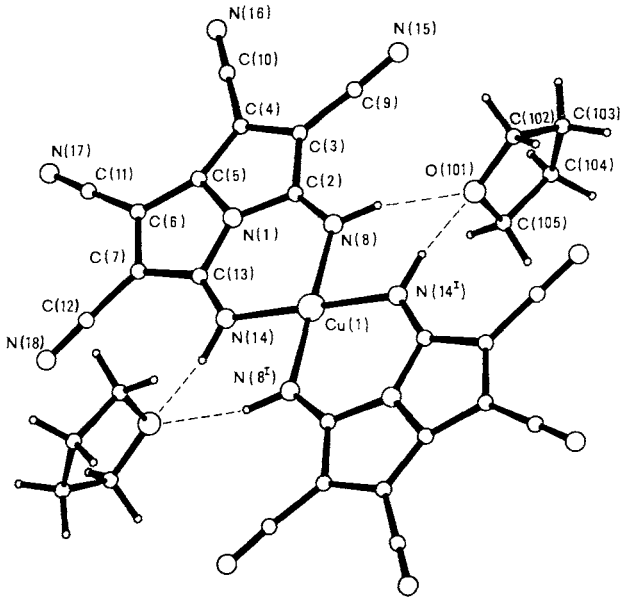

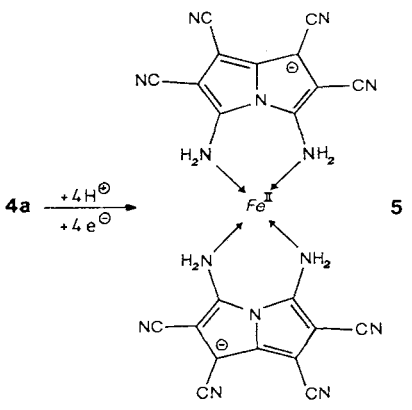

Fig. 1. Crystal structure of $Cu(C_{11}N_7H_2)_2 \cdot 2\,C_4H_8O$ **4c** · 2 THF. The labeling of the C and N atoms is identical with that of the free anionic ligand already reported [2]. *Pbca*; $a = 13.233(2)$, $b = 10.754(2)$, $c = 21.411(4)$ Å. $R = 0.054$ (1075 reflections). The copper atom completes its octahedral, tetragonally distorted coordination with two N(15) nitrogen atoms (at 2.82 Å) from two crystallographically equivalent complex units. Selected bond lengths [Å] and angles [°]: Cu–N8 1.984(5), Cu–N14 1.995(5), C2–N8 1.289(8), C13–N14 1.285(8), N1–C2 1.375(8), N1–C13 1.380(8), N1–C5 1.375(8), C2–C3 1.453(9), C7–C13 1.444(8), C3–C4 1.409(8), C6–C7 1.395(9), C4–C5 1.388(9), C5–C6 1.399(9); N8–Cu–N14 92.1(2), C2–N1–C13 133.7(5), C2–N8–Cu and C13–N14–Cu 126.2(4). Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD-53844, the names of the authors, and the journal citation.

rins.[3] In spite of this analogy, **4c** does not exhibit any solid state collective properties: it is a paramagnetic insulator and the extra electronic band at low energy in the reflectance spectrum arises from the transition $d_{xy} \rightarrow d_{x^2-y^2}$ confined in the chromophore CuN_4N_2.[4]

The iron(II) complex **4a** is easily reduced to the β-diamino species **5**. Therefore, **5** might undergo a Schiff condensation

with an appropriate dicarbonyl compound to yield conjugated, dianionic tetraazaannulenes, suitable for the synthesis of molecular materials.

Experimental

4b, 4c (M = Ni and Cu, resp.): A solution of **3** (0.50 g; 0.81 mmol) in acetone (50 mL) was treated with either a solution of $NiCl_2 \cdot 6\,H_2O$ (0.90 g) in water (5 mL) or a solution of $CuCl_2 \cdot 2\,H_2O$ (0.70 g; excess) in acetone (20 mL). The color immediately turned from violet to blue, and after concentration the complex **4** · 2 $(CH_3)_2CO$ separated as air-stable black (**4b**, M = Ni) or purple (**4c**, M = Cu) microcrystals (0.25 g; yield ca. 95%). Recrystallization from THF/water (9/1) afforded THF-adducts instead of acetone-adducts, as indicated by IR spectra and elemental analysis (C, H, N, O, M). **4**, characteristic IR bands (Nujol, cm^{-1}): $\tilde{\nu}$ = 3290 (m, N–H), 2220 (w, C≡N), 2210 (s, C≡N), 1640 (vs, C=N–H). Crystals of **4b** · 2 S (S = THF, acetone, EtOH) have a metallic luster; their color depends on S (purple, black and golden, respectively). The electronic transitions responsible for this behavior are not resolved in the reflectance spectra; single crystals have been grown for both reflectivity and X-ray diffraction studies. – Electronic and magnetic properties of **4c** · 2 THF: electronic spectrum in solution (THF, λ[nm], $(10^{-3}\,\varepsilon)$): 646(54), 613(52), 387(24); the reflectance spectrum shows an additional band at 950 nm; μ_{eff} = 1.85 BM at 290 K; electron paramagnetic resonance parameters (hfs in gauss units): $g_\parallel = 2.22$, $g_\perp = 2.03$, $A_\parallel = 187.5$, $A_\perp = 23$, $\langle a \rangle = 81.3$.

4d (M = Zn): this complex, which is very soluble in polar solvents, and very labile towards water, was characterized ^{13}C-NMR spectroscopically. The sample was prepared in a dry-box: A solution of 0.060 g (0.23 mmol) of $NaC_{11}N_7H_2$ (= **3**, Na instead of $AsPh_4$) in dried C_2D_5OD (1.5 mL) was treated with excess anhydrous $ZnCl_2$. The resulting blue solution was filtered into an NMR tube (∅ = 5 mm); 0.1 mL of a solution of $Cr(acac)_3$ in C_6D_6 (1.5×10^{-4} M) was added as relaxation reagent. The spectrum can be fully assigned taking into account: i) the molecular symmetry (C-8 will give the least intense peak); ii) the electronic deshielding effect (C-3, between two nitrogen atoms, will fall at lowest field), and iii) the relaxation agent effect, which will be more pronounced on the external groups (C≡N groups) of the molecule, increasing the intensity of their signals: δ = 156.9 (C-3), 125.5 (C-8), 112.4 and 110.2 (C≡N), 109.8 (C-1), 94.7 (C-2). Addition of $As(C_6H_5)_4Cl$ (0.105 g; 0.25 mmol) in water (3 mL) to the previous ethanolic solution causes the quantitative precipitation of **3** (0.14 g).

4a (M = Fe), **5**: **4a**, which is insoluble in THF was obtained in quantitative yield by reaction of **3** with anhydrous $FeCl_2$ (excess) in THF. If commercial $FeCl_2 \cdot 4\,H_2O$ is used protonation and reduction (probably at the expense of $Fe^{2\oplus}$) of the β-diimino ligand into a β-diamino ligand occur, giving **5**; this was filtered off and, after crystallization from CH_3CN/THF (1:1) under N_2, golden, moisture-sensitive crystals of composition **5** · 4 THF were obtained. A preliminary single-crystal X-ray analysis shows that this complex is six coordinated with a *trans*, tetragonally distorted, FeN_4O_2 chromophore (electronic spectrum in solution (CH_3CN, λ[nm], $(10^{-3}\,\varepsilon)$): 1040 (4.3), 880 (5.4), 730 (4.9), 617 (29), 588 (25). – The bis-β-diamino structure of **5** is supported by the IR data: the strong band of **4a** at 1640 cm^{-1}, which is due to a C=N–H stretching vibration, is absent in **5**, and the band in the N–H stretching region has two maxima (3180, 3270 cm^{-1}) indicating the presence of NH_2 groups (see also Ref. [5]).

Tri-*tert*-butyl(trimethylsilyl)tricyclo[1.1.0.0^{2,4}]-butane – a Second Tetrahedrane Derivative**

By *Günther Maier** and *Dieter Born*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

Tetra-*tert*-butyltetrahedrane,[2] which was first synthesized some eleven years ago is thus far the only unequivocally identified compound with a tetrahedral C_4 ring framework.

[**] Small Rings, Part 67. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. – Part 66: [1].

This molecule owes its astonishing stability to a "corset effect",[2] which should also occur when the *tert*-butyl substituents are replaced by other bulky groups. This is in fact the case, as is demonstrated here for the example of tri-*tert*-butyl(trimethylsilyl)tetrahedrane **1**. In spite of the high ring strain, this molecule is stable up to 180 °C(!).

The synthesis of **1** was accomplished starting from the diazo compound **4**,[3a] the chemistry of which is unexpectedly diverse.[3b] Upon irradiation [route (b)], **4** fragments exclusively via the carbene **5** to the two acetylenes **6** and **7**.[3a] Flash thermolysis [route(c)], on the other hand, proceeds less cleanly: aside from the two acetylenes,[3a] trimethylsilyl cyanide **16** and tri-*tert*-butylazete **13**—recently described for the first time by *Regitz* et al.[4]—are also formed as cleavage products. Presumably **4** isomerizes upon heating, firstly via the betaine **8**[5a] or the diazabenzvalene **9** to the Dewar-diazabenzene **10**,[5b] which in turn serves as precursor for the azete **13** and trimethylsilyl cyanide **16**, which is in thermal equilibrium with trimethylsilyl isocyanide **17**.[6]

The thermolysis of **4** proceeds somewhat differently, both without solvent or in solution (e.g. in benzene) [route(d)]. In either case **4** isomerizes to a green compound, which, according to its spectroscopic data, has the structure **14** (whether the trimethylsilyl group is *syn* or *anti* is undecided). The formation of **14** can be explained as follows: the isonitrile **17**, which is in equilibrium with **16**, reacts with the azete **13**, present in comparable concentration, via **15**[7] to give the stable end product **14**. The reaction course discussed for the thermal excitation of **4** is supported by the isolation of the two carbonyliron complexes **11**[8] and **12**, which are formed upon heating **4** in the presence of nonacarbonyldiiron.

How does one get from the diazo compound **4** to the tetrahedrane **1**? Several experiments were necessary in order to find this out. At an earlier stage it emerged that the cyclobutadiene **2** is formed in the CuCl-catalyzed thermal decomposition of **4** [route(a)]. If, after the elimination of nitrogen, dimethyl acetylenedicarboxylate is added to the reaction mixture, the corresponding Diels-Alder adduct of **2** can be isolated.[2c, 9] Maleic anhydride and citraconic anhydride react similarly. Using the same reaction procedure with nonacarbonyldiiron leads to the cyclobutadiene complex

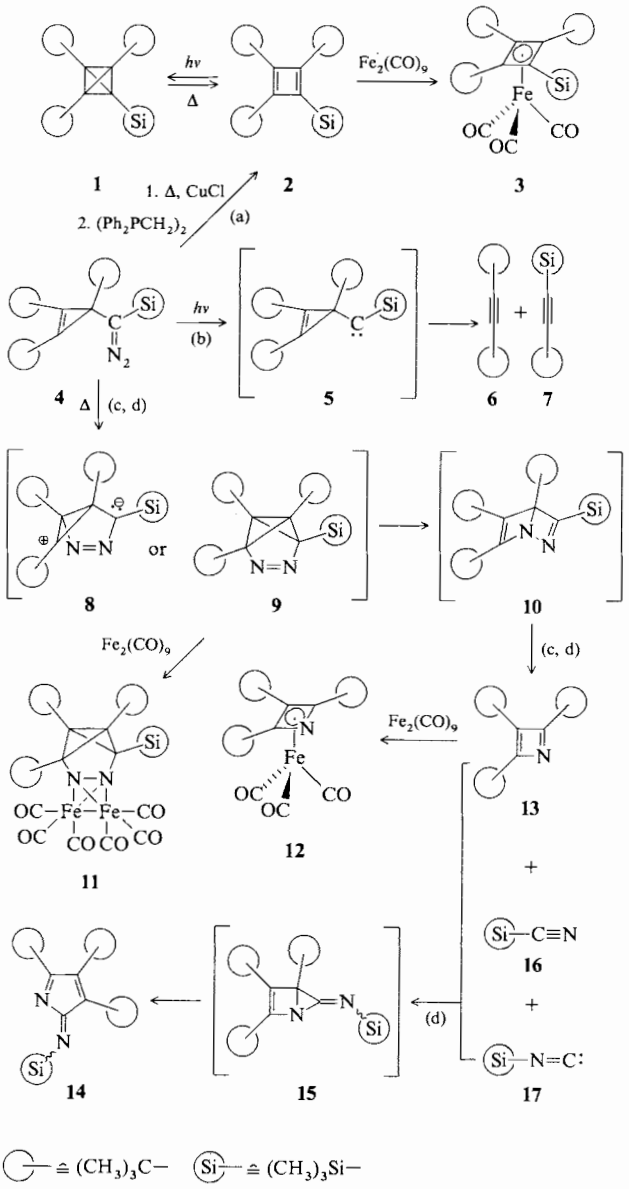

Table 1. Reaction conditions, yields, and NMR spectroscopic data of the compounds **1, 2, 3, 11, 12**, and **14**. NMR: δ values relative to TMS. **1, 3, 11** and **14** furnished correct elemental analyses.

3.[8] On the other hand, all attempts to obtain the free cyclobutadiene **2** directly from the reaction mixture failed. **2** is presumably present as a CuCl complex under the mentioned conditions. Only after addition of ethylenebis(diphenylphosphane)[10] can **2** be isolated. The structure of tri-*tert* butyl(trimethylsilyl)cyclobutadiene **2** is unequivocally confirmed by the data in Table 1.

Upon irradiation of **2** in cyclohexane or diethyl ether ($\lambda \geq 300$ nm), quantitative isomerization to the tetrahedrane **1** occurs. This second, spectroscopically confirmed[8] tetrahedrane derivative is thermally even more stable (higher barrier for the retroisomerization to the cyclobutadiene) than tetra-*tert*-butyltetrahedrane. Whereas the latter rearranges into the respective cyclobutadiene at 135 °C, **1** melts without decomposition at 162 °C to give a colorless liquid, which is converted upon reaching 180 °C with red coloration into the cyclobutadiene **2**. Since the "corset effect" in **1** is not stronger than in the tetra-*tert*-butyl analogue (longer C–Si bond), one gets the impression that the trimethylsilyl group may stabilize the tetrahedrane structure also by electronic effects.[11]

Experimental

2: A solution of 320 mg (1.00 mmol) of the diazo compound **4** in 5 mL of CH_2Cl_2 was added to 500 mg (5.06 mmol) of CuCl at 0 °C. After 14 h the mixture was warmed to room temperature and the resulting red solution added to 400 mg (1.00 mmol) of ethylenebis(diphenylphosphane) in 10 mL of CH_2Cl. The reaction mixture was heated under reflux for 2 h, the solvent evaporated off in a stream of argon, and the liberated cyclobutadiene **2** sublimed at 3×10^{-2} torr in an air-bath at about 120 °C (cf. Table 1).

1: A solution of **2** (50 mg, 0.17 mmol) in [D_{12}]cyclohexane (0.4 mL) was irradiated in a sealed NMR tube for 4 d ($\lambda \geq 300$ nm; 200W Hg high-pressure lamp). The solution was colorless during the course of irradiation, and only the signals of **1** could be observed in the ^{13}C-NMR spectrum. Chromatography on basic aluminum oxide with pentane as eluent, followed by sublimation (30 °C, 3×10^{-2} torr), afforded pure tetrahedrane **1** (cf. Table 1).

[10] Using this reagent, *Krebs* et al. have succeeded in liberating the first kinetically stabilized cyclobutadiene from its $PdCl_2$ complex: H. Kimling, A. Krebs, *Angew. Chem. 84* (1972) 952; *Angew. Chem. Int. Ed. Engl. 11* (1972) 932; A. Krebs, H. Kimling, R. Kemper, *Justus Liebigs Ann. Chem. 1978*, 431.

[11] Examples: own works cited in [1]. Theoretically, σ-donor-π-acceptor substituents can stabilize three-membered rings. J. D. Dill, A. Greenberg, J. F. Liebman, *J. Am. Chem. Soc. 101* (1979) 6814; T. Clark, G. W. Spitznagel, R. Klose, P. von R. Schleyer, *ibid. 106* (1984) 4412; D. Cremer, E. Kraka, *ibid. 107* (1985) 3811. This effect is also to be expected from a trimethylsilyl group.

p-Quinodimethane Analogues of Tetrathiafulvalene

By *Yoshiro Yamashita,* Yasuo Kobayashi,* and *Tsutomu Miyashi*

2,2′-Bis(1,3-dithiole) derivatives containing quinodimethane structures are promising electron donors for "organic metals", since the extended conjugation decreases the Coulombic repulsion.[1] However, the parent compound, 2,2′-*p*-quinobis(1,3-dithiole) **1**, was hitherto unknown, and the reported examples of derivatives as neutral donors were limited to the dibenzo derivatives **2a, b**,[2] although some dication salts were known.[3] We report here on a simple synthesis of **1** and its derivatives, and on their properties.

Aramaki, Sendai 980 (Japan)

We recently found the usefulness of the Wittig-Horner reaction of 2-dimethylphosphono-1,3-benzodithiole **3a** with conjugated 1,4-diketones for the preparation of 2,2′-bis(1,3-dithiole) donors.[4] We have now used the Wittig-Horner reaction of **3b**, which was synthesized by a similar method as that for **3a**,[5] to prepare **1**. In this case, a cyclopentadiene adduct of *p*-benzoquinone **4** was used as a diketone and after introduction of the 1,3-dithiole rings the cyclopentadiene was removed by a retro-Diels-Alder reaction, since the direct reaction of *p*-benzoquinone with **3b** gave a complex mixture of products without formation of **1**.

Thus, a solution of **3b** in dry THF was treated with 1.1 equivalents of *n*-butyllithium at −78 °C under nitrogen, and after stirring for 5 min, 0.43 equivalent of **4** was added. The solution was then stirred at −78 °C for a further 10 min and allowed to warm to room temperature, whereupon the bis(1,3-dithiole) derivative **5** was obtained in 27% yield. Thermolysis of **5** at 200 °C under reduced pressure furnished, via a retro-Diels-Alder reaction, dark red crystals of **1** in 54% yield.[6] The benzo derivatives **6a, b** were prepared analogously by reaction of the Diels-Alder adducts of 1,4-naphthoquinone and the corresponding methyl compound, respectively with cyclopentadiene. The dibenzo derivative **7** could be synthesized in 74% yield by direct Wittig-Horner reaction of **3b** with 9,10-anthraquinone. The dibenzotetrathiafulvalene (TTF) analogue **2a** could be prepared by a retro-Diels-Alder reaction of **8**, which was obtained in 73% yield by reaction of **3a** and **4**. **9a, b** and **10** were prepared similarly. The decomposition temperatures of the new donors are listed in Table 1. The TTF analogues **1** and **6a, b** are air sensitive, whereas the dibenzo analogues **2a, 7, 9a, b,** and **10** are stable towards air.

The oxidation potentials of the donors (Table 1) were measured by cyclic voltammetry. The values for the donors with quinoid structures are lower than those of TTF measured under the same conditions (0.28, 0.64 V vs. SCE); the parent compound **1**, in particular, is an extremely strong electron donor. This may be due to the fact that the quinoid structures form a new aromatic sextet upon oxidation.

Table 1. Decomposition temperatures and oxidation potentials [a] of the donors.

Donor	$T_{dec.}$ [°C]	$E_{1/2}$ [V]
1	230–245	−0.11, −0.04
6a	160–170	0.00
6b	190–194	−0.04
7	320–325	+0.25 [b]
9a	260–270	+0.18
9b	243–248	+0.15
10	314–317	+0.24
5	168–170	+0.17
8	260–265	+0.37

[a] 0.1 M Et_4NClO_4 in MeCN, Pt electrode, scan rate: 100 mV s^{-1}; *E* vs. standard calomel electrode (SCE). [b] Irreversible. Calculated as E_{pa} (anodic peak potential) − 0.03 V.

Other characteristic features are that the difference between the first and second oxidation potentials of **1** is very small and that two-electron oxidation waves are observed in the other new donors. Accordingly, the donors with quinoid structures form dications more readily upon oxidation, due to the decreased Coulombic repulsion. With tetracyanoquinodimethane (TCNQ), the donors **1, 6a, b, 2a,** and **9a, b** gave charge-transfer complexes which exhibit good conductivities (Table 2).

Table 2. Properties of charge-transfer complexes with TCNQ.

Donor (D)	T_{dec} [°C]	Molar ratio [a] D:A	σ[S cm^{-1}] [b]
1	> 400	3:4	5.3×10^{-4}
6a	> 360	2:3	2.9×10^{-2}
6b	> 400	2:3	1.9×10^{-2}
2a	250–253	1:1	4.1×10^{-3}
9a	245–249	3:5:3 H_2O	1.9×10^{-2}
9b	220–225	1:1.8:H_2O	2.2×10^{-2}

2-Isocyanato-2-alkenoates – Synthesis and Reactions**

By *Franz Effenberger,* Christan Baumgartner,* and *Jürgen Kühlwein*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

Very few data have been quoted in the literature about 2-isocyanato-2-alkenoates; they have been detected spectroscopically as reaction intermediates,[1a, b] and in two cases have even been isolated.[1c] α-Isocyanatoacrylic acid esters have on one occasion been presumed as intermediates in the thermolysis of ethyl 1-isocyanatocyclobutane-2-carboxylate,[2a] and on another their formation and their spectroscopic detection – likewise in thermolysis reactions – have been reported in a patent.[2b]

1

In the perrhenate-catalyzed decomposition of α-azidocarboxylic acid derivatives such as **1**[3] we could successfully replace acetic anhydride by other acylating reagents, thereby providing easy access to a series of interesting *N*-substituted α,β-didehydroamino acid esters.[4a]

[*] Prof. Dr. F. Effenberger, Dr. C. Baumgartner, Dr. J. Kühlwein
Institut für Organische Chemie der Universität

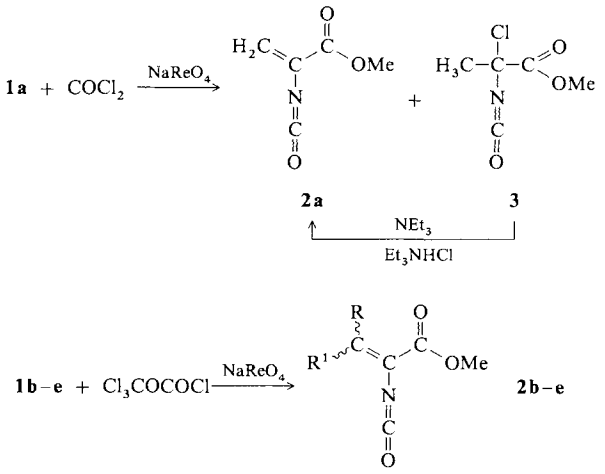
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The results which we have now found with phosgene and diphosgene as "acylating reagent" in this decomposition reaction, although hoped for, are still surprising: as reaction products, the 2-isocyanato-2-alkenoates **2** were obtained in very good yields (Table 1).[4]



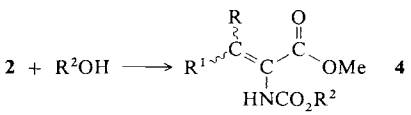


Table 1. R and R^1 in **1** and **2** and yields of **2**.

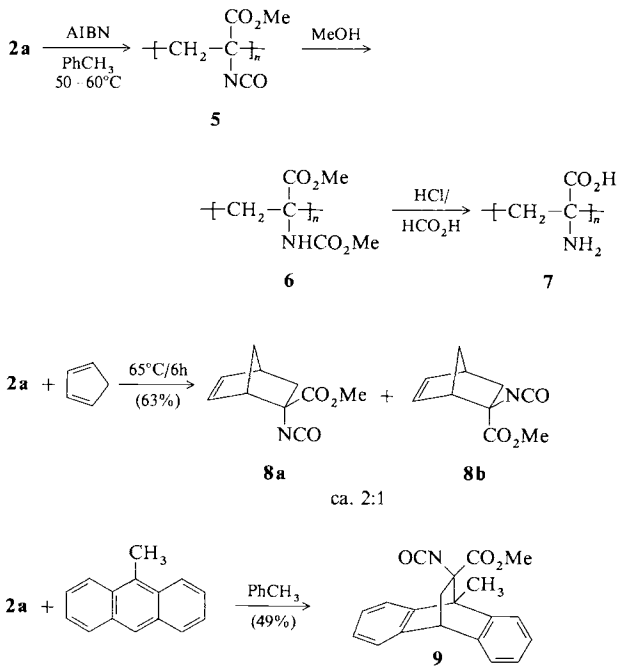
	R	R^1	Yield of **2** [%]
a	H	H	69
b	H	Me	88
c	Me	Me	82
d	H	*n*Pr	80
e	H	Ph	53



Whereas the substituted esters **2b–e** could be isolated and worked-up by distillation without any problem, the synthesis of pure α-isocyanatoacrylate **2a** at first presented great difficulties, because it was always formed in a mixture with its—distillatively—inseparable HCl-adduct **3**, and because it is exceptionally reactive, and easily polymerizes. However, the addition product **3** could be completely converted into the acrylate **2a** by careful extrusion of HCl with triethylamine in diethyl ether, so that **2a** was obtained in 69% yield—referred to **1a**—in this way.

As expected, all usual addition reactions to the isocyanato group of the compounds **2** could be carried out, which, e.g., upon using appropriate alcohols (*tert*-butyl alcohol, benzyl alcohol) yield directly the urethane-protected dehydroamino acids **4**, which are of special interest in peptide chemistry.

R^2 = *t*Bu, $PhCH_2$

The acrylic ester **2a**, which, besides the isocyanato group, has an activated and sterically unhindered C—C double bond, provides access to further, versatile reactions. In the presence of azoisobutyronitrile (AIBN) radical polymerization leads to the polymers **5**; with methanol these yield the polymeric urethanes **6**, which can be hydrolyzed to the poly(α-aminoacrylic acid) **7**. We have no explanation for the astonishingly low degree of polymerization of **5** (n = 14–15).[5] The properties of **7** are almost identical with the properties of the poly(α-aminoacrylic acid) obtained by hydrolysis of the *N*-acetyldehydroalanine polymers.[6]

That the acrylic ester **2a** is also suitable as dienophile for Diels-Alder reactions is demonstrated by the reactions with cyclopentadiene to give **8** and with 9-methylanthracene to give **9**, whereby **2a** proves to be distinctly more reactive than *N*-acetyldehydroalanine.[7] The cycloadducts **8a,b** can be further converted by alcohol addition into urethane-protected cyclic α-amino acids and by acid hydrolysis into the corresponding free cyclic α-amino acids.[8]

The previously reported reactivity sequence for Diels-Alder reactions with anthracenes is confirmed in the reactions of **2a** with anthracenes: no cycloadducts were obtained at temperatures up to 115 °C, neither with anthracene nor with 9-methoxyanthracenes. Higher reaction temperatures are not possible because of the thermolability of **2a**.

Experimental

2a: Phosgene was passed into a cold mixture of sodium perrhenate (1.0 g, 3.66 mmol) and methanesulfonic acid (0.2 g) in ethyl acetate (500 mL). After addition of 64.5 g (0.5 mmol) of **1a** and of 300 mg of hydroquinone, phosgene was condensed into the mixture such that it was always present in excess. The mixture was then heated at 70–80 °C until completion of evolution of gas, cooled down, and the whole liquid distilled rapidly under high vacuum into a cooled receiver. After evaporation of the ethyl acetate, distillation at 50 °C/12 torr furnished 69 g of a mixture of **2a** and **3** in the ratio 1:2. At 0 °C, 125 mL of diethyl ether were added, then a solution of triethylamine (in equimolar amount to **3**; 31.0 g, 310 mmol) in 125 mL of diethyl ether was added dropwise at 0 °C. After removal of precipitated triethylamine hydrochloride by filtration, the filtrate was evaporated and distilled at 44.5 °C/12 torr. Yield: 43.6 (69%) of **2a** as a colorless, viscous liquid. ^1H NMR ($CDCl_3$): δ = 3.93 (s, 3H, CH_3), 5.82, 5.50 (each s, each 1H, =CH). Correct elemental analysis (C,H,N).

A Polymeric Technetium Compound of the Composition $[Tc_2O_3(C_5Me_5)]_n$

By *Basil Kanellakopulos,* Bernd Nuber, Konstantinos Raptis*, and *Manfred L. Ziegler**

Dedicated to Professor Margot Becke on the occasion of her 75th birthday

The tricarboxylrhenium complex **1**[1] reacts with H_2O_2 to give the trioxo-complex **2**, which has proved to be an interesting and versatile starting compound for exploring the remarkable chemistry of rhenium in high oxidation states.[1] So far it has not been possible to carry out an X-ray structure analysis of **2** itself; however, the structure of one of its derivatives is already known, namely that of **3**, which forms discrete molecules. This might also be assumed in the case of **2**.

$[(\eta^5\text{-}C_5Me_5)Re(CO)_3]$ **1** $[(\eta^5\text{-}C_5Me_5)ReO_3]$ **2**

$[(\eta^5\text{-}C_5Me_4Et)ReO_3]$ **3** $[(\eta^5\text{-}C_5Me_5)Tc(CO)_3]$ **4** $[(C_5Me_5)Tc_2O_3]_n$ **5**

In the reaction of the tricarbonyltechnetium complex **4** with perhydrol it has now been shown that the technetium species **4** behaves differently than its rhenium homologue **1**. Elemental analysis, mass spectra, and, above all, an X-ray structure analysis yielded the empirical formula $C_{10}H_{15}Tc_2O_3$ for the product **5** in a polymeric structure. It is clear from Figure 1 that, in **5**, two Tc atoms are bridged by three μ-oxo ligands and the coordination of the Tc atoms is in each case completed by a C_5Me_5 ring (= Cp*). These Cp* rings are, however, concomitantly a component of the neighboring units, so that the above mentioned empirical formula results. The planes of the Cp* rings and of the oxo-bridge ligands are, crystallographically exactly parallel to one another, i.e. a kind of polydecker structure is formed (distances: Cp*-O_3 planes 297.3(3), Tc-O_3 plane 93.4(3), Tc-Cp* plane 204.0(4) pm). A striking feature is the unusually short distance (186.7(4) pm) between the two Tc atoms coupled by the three μ-oxo ligands (distance between the Cp*-bridged Tc atoms 407.7(4) pm); the shortest Tc–Tc distance recorded so far is 213(1) pm. Shorter metal–metal distances are found only in binuclear chromium complexes[5] with a minimum of 182.8(2) pm in $[Cr_2(2\text{-}MeO\text{-}5\text{-}MeC_6H_3)_4]$.[6]

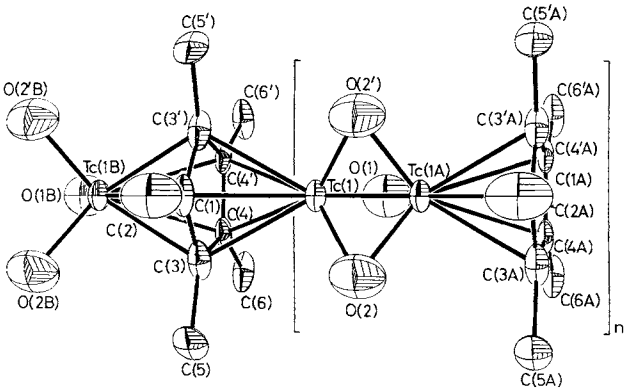

Fig. 1. Section of the polymer **5** in the crystal. The vibration ellipsoids are drawn at the 50% probability level. **5** is viewed along one of the mirror planes. Important bond lengths [pm] and angles [°]: Tc1–O1 190(2), Tc1–O2 185(2), Tc–C_{Ring} 238(2); Tc1–O1–Tc1A 58.8(8), Tc1–O2–Tc1A 60.7(6), O1–Tc1–O2 97.5(5), O2–Tc1–O2' 96.3(9).

Formally, the two technetium centers must be assigned on oxidation number of +3.5. This would mean that the ground state has the relatively rare $\sigma^2\,\pi^4\,\delta^1$ configuration and thus a bond order of 3.5.[7] This bond order together with the three μ-oxo ligands makes the extremely short Tc–Tc distance understandable.

The spectroscopic data are fully consistent with the results of the X-ray structure analysis. Thus, in the EI mass spectrum the molecular peak is clearly visible at m/z 381.6 (18%), and the Tc–O stretching vibrations appear in the IR spectrum at 909 (symmetric) and 880 cm^{-1} (antisymmetric). In the ^1H NMR spectrum the methyl protons are observed at $\delta = 1.606$.

Experimental

A solution of **4** (180 mg, 0.57 mmol) in C_6H_6 (15 mL) was treated with 5 mL of 30% H_2O_2 and the mixture stirred at room temperature. The initial concentration of **4** first started to decrease after 24 h. After 3 days, **4** could no longer be detected. After separation of the phases the organic phase was dried with Na_2SO_4 and freed of oily reaction products by chromatography (silica gel 60, 30 × 20 cm, C_6H_6). Subsequent elution with C_6H_6/diethyl ether (1/1) gave a yellow zone. After slow evaporation of solvent from the eluate (ca. 12 h), **5** was recovered in the form of needle-shaped yellow crystals. Yield: 25.0 mg (16.0%). ^{99}Tc 51.6% (calcd. 51.94%). EI-MS fragmentation (relative intensity [%] in parenthesis): $Cp^{*\oplus}$ (100); $Cp^*Tc^{\oplus}$ (36); $Cp^*TcO_3^{\oplus}$ (0.0); $Cp^*Tc_2O_3^{\oplus}$ (18). The corresponding relative intensities for **2** under similar conditions are 100, 35, 100, and 0.0%.

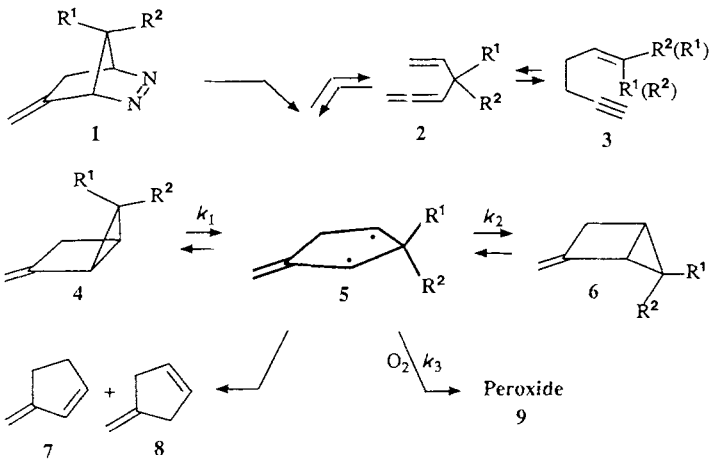
Energy Wells of Diradicals; 4-Methylene-1,3-cyclopentanediyl**

By *Wolfgang R. Roth,* Frank Bauer, Karsten Braun,* and *Rolf Offerhaus*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

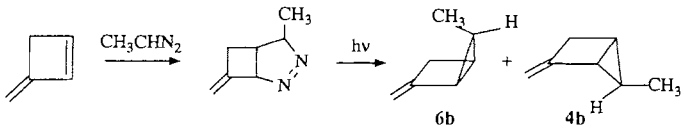


The recombination of free radicals is a collision-controlled process requiring very little activation enthalpy.[1] In the analogous intramolecular reactions the situation is far less clear, and older concepts of substantial barriers[2] have been contradicted.[3] Systematic investigations of resonance stabilized diradicals have revealed a marked dependence of the recombination barrier on the structure (see Scheme 1), which

Scheme 1. Energy wells of diradicals in kcal mol^{-1} [2].

has been explained in terms of the conformational stability of the diradicals.[4] Determination of the recombination threshold of the title compound **5** (Scheme 2) enables a critical test of this hypothesis.

In the systems outlined in Scheme 1 interaction of the unpaired electrons requires a considerable rotation of the respective orbitals, which is possible only with more or less great sacrifice of resonance stabilization. In the case of 4-methylene-1,3-cyclopentanediyl **5** the situation is completely different. Here, recombination leads to a three-membered ring, whose Walsh orbitals still allow an interaction with the



Scheme 2. **a**: $R^1 = R^2 = H$; **b**: $R^1 = H$, $R^2 = CH_3$; **c**: $R^1 = R^2 = CH_3$

exocyclic double bond even in the transition state of the reaction. The recombination enthalpy should therefore be distinctly smaller than in the homologous 2-methylene-1,4-cyclohexanediyl (see Scheme 1).

5 is accessible thermally starting from **1**,[5,6] **2**[7] and **4** or **6**,[8] and, in the case of **1** also photochemically. According to ESR investigations by *Dowd*[5] **5** has a triplet ground state. Our interest turned to the equilibrium **4** ⇌ **5** ⇌ **6**, which we have tried to detect by the mutual rearrangement **4b** ⇌ **6b**. The substrates were synthesized analogously to that of the parent compound[8a] by addition of diazoethane to methylenecyclobutene and photolysis of the resulting pyrazolines (Scheme 3). The structure of the gas-chromatographically separated isomers is confirmed by the spectroscopic data.[9]

Scheme 3.

The mutual rearrangement **4b** ⇌ **6b** was carried out in pentane at six temperatures between 20 and 60 °C. The resulting rate constants of the first order reactions (Table 1)

enabled calculation of the activation parameters (Table 2). For the determination of the energy well of the diradical **5** we chose the dimethyl derivative **5c**, since, in this case, the rearrangement to **7** and **8** is suppressed. The thermolysis of **4c** and **6c** led exclusively to **2c** and its secondary product **3c**. The rate of this reaction was investigated in the gas phase between 175 and 237 °C and 206 and 286 °C, respectively. The respective first order rate constants (Table 1) were ascertained by matching the reaction course simulated in Scheme 2 with the experimental data (Marquardt optimization[10]). The resulting activation parameters are listed in Table 2.

Tabelle 2. Activation parameters [a].

Reaction	E_a [kcal mol^{-1}]	A [s^{-1}]	$\Delta H^{\neq}$ [kcal mol^{-1}]	$\Delta S^{\neq}$ [cal K^{-1} mol^{-1}]
4b → **6b**	23.6 ± 0.5	$(1.7 \pm 1.4)10^{13}$	23.0 (40 °C)	0.94 (40 °C)
6b → **4b**	24.5 ± 0.3	$(2.8 \pm 1.5)10^{13}$	23.9 (40 °C)	− 0.02 (40 °C)
4c → **2c**	35.8 ± 0.2	$(4.2 \pm 1.7)10^{13}$	34.8 (206 °C)	0.85 (206 °C)
2c → **3c**	35.2 ± 0.1	$(1.1 \pm 0.3)10^{11}$	34.2 (244 °C)	− 11.0 (244 °C)

[a] All error data refer to a confidence limit of 95%.

In order to demonstrate the influence of the methyl groups on the ring opening, the thermolysis of the parent compound **4a** (= **6a**) was also investigated for comparison. As the data in Table 2 show, these differ negligibly from those of the dimethyl compound.

When the thermolysis of **4c** is carried out in the presence of oxygen, the diradical **5c** can be trapped as peroxide.[11] If one assumes that the diradical reacts collision-controlled with oxygen in analogy to the reaction of free radicals, then the rate of this reaction can be described with equation (a),[12]

$$k_3 = N_A(\sigma_a + \sigma_b)^2/4\,(8\pi kT/\mu)^{1/2}\ \mathrm{Lmol^{-1}\,s^{-1}} \qquad (a)$$

where N_A is the Avogadro number, σ_a and σ_b the collision cross-sections of the reacting molecules,[13] k the Boltzmann constant, and μ the reduced mass. Should the formation of the peroxide proceed via the triplet state an additional spin statistical factor[14] would have to be taken into account, which, however, only influences the entropy but not the enthalpy of the energy well. A singlet $\rightleftharpoons$ triplet equilibrium[15] would have the same effect. A definite statement can be made at the moment therefore only about the recombination enthalpy. The rate of formation of peroxide is—assuming a steady-state for **5**—described by equation (b).

$$k_{per} = k_1\left(1 - \frac{k_2}{k_2 + k_3[O_2]}\right) \qquad (b)$$

With this relationship, k_1 and k_2 can be determined from the dependence of the formation of peroxide on oxygen only, if the measurements are carried out in the non-linear range of the function. As the data in Table 1 show, this does not apply in the present case; owing to the limits of the apparatus used, we could only measure trapping rates up to $\leq$ 750 torr oxygen pressures. We have therefore assumed that k_1 is, to a good approximation, described by the corresponding rate konstants ($k_{\mathbf{4b,6b}}$) of the monomethyl compound. In view of the influence of the methyl substitution on the ring-opening reaction being only slight (see above) this assumption may not lead to any serious error. The resulting activation parameters for k_2 (see Table 2) clearly indicate that the oxygen pressure required for a direct determination of k_1 is ca. 1000 atm.

As already mentioned above, the available data do not allow a decision whether the determined energy well refers to the singlet or the triplet state. With a value of 2.4 kcal mol^{-1}, the well is in fact much smaller than in the case of the analogous 2-methylene-1,4-cyclohexanediyl (9 kcal^{-1}) and is practically identical with that of the parent compound (2.3 ± 0.2 kcal mol^{-1}[16]). *Closs* et al. have obtained this value from ESR measurements at low temperatures, where the reaction seems to be the result of a tunnel mechanism ($A = 10^8$ s^{-1}). Consistent with the observed A factor ($A = 5.9 \times 10^{13}$ s^{-1}) such a mechanism is ruled out under our conditions.

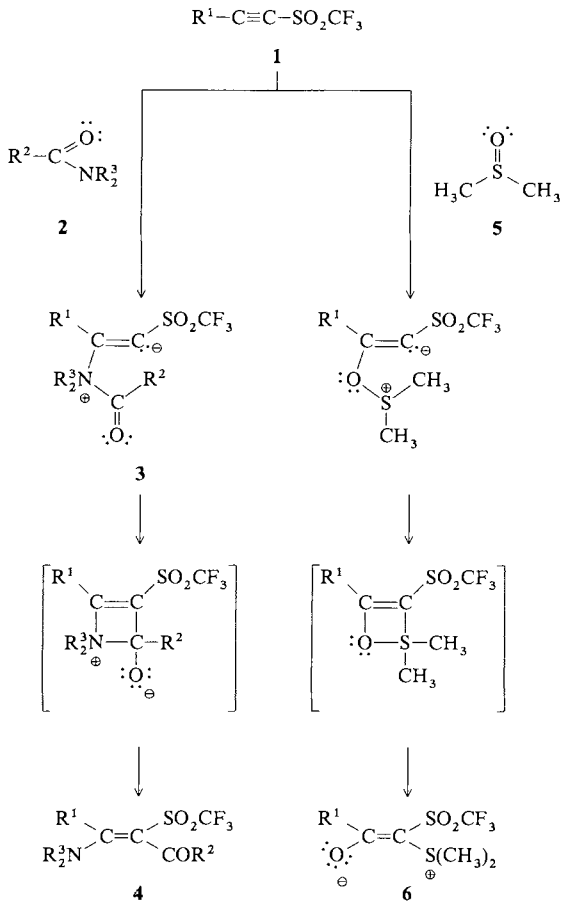
Addition of Carboxamides to Alkynyl Trifluoromethyl Sulfones**

By *Michael Hanack*,* and *Bärbl Wilhelm*



The trifluoromethylsulfonyl group is one of the strongest electron-withdrawing functional groups.[1] Olefins and alkynes bearing this substituent are highly reactive, e.g. in [4 + 2]- and 1,3-dipolar cycloadditions,[2] and are therefore of great preparative interest. We have recently reported a novel, improved method for the synthesis of alkynyl trifluoromethyl sulfones **1** from sodium acetylides and trifluoromethanesulfonic anhydride.[3] In related studies we have also investigated the addition of nucleophiles to **1**, which occurs

[*] Prof. Dr. M. Hanack, Dipl.-Chem. B. Wilhelm

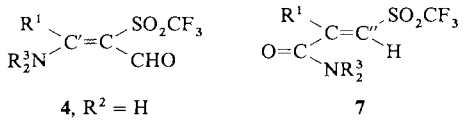
Auf der Morgenstelle 18, D-7400 Tübingen (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.



considerably more easily than in the case of comparable systems such as acetylenecarboxylic acid esters.[3,4]

On attempting to add sulfinic acids dissolved in dimethylformamide **2a** we observed an unusual addition of **2a** to the triple bond of phenylethynyl trifluoromethyl sulfone **1a** (Scheme 1). This addition is applicable to alkynyl trifluoromethyl sulfones in general: Table 1 shows the products of the reaction with several substituted carboxamides **2** and dimethyl sulfoxide (DMSO) **5**.

Scheme 1. Mechanism of the addition of carboxamides **2** and of DMSO **5** to alkynyl trifluoromethyl sulfones **1**. R^1,R^2,R^3 see Table 1.

According to the spectroscopic data, not only the structure **4** but primarily also the structure **7** had to be taken into consideration for adducts of **1a–d** and **2a–d**.

4, $R^2 = H$ **7**

In the case of **4a**,[5] for example, a singlet is observed at $\delta = 7.71$ in the ^1H NMR spectrum. This would rather point to an olefinic than to an aldehydic proton. The ^{13}C off-resonance NMR spectrum shows a singlet at $\delta = 188.7$, which could be assigned to both the carbon atom C′ in **4a** as well as to the carbonyl carbon atom in **7a** ($R^1 = C_6H_5$, $R^3 = CH_3$). A doublet appears at $\delta = 158.0$, which may arise from the aldehyde carbon atom in **4a** or from the carbon atom C″ in **7a**. In the IR spectrum the carbonyl vibration is observed at $\tilde{\nu} = 1642\ cm^{-1}$, i.e. at exceptionally low field for an aldehydic carbonyl group.

For an unequivocal elucidation of the structures of the adducts we allowed the sulfone **1a** to react with ^{13}C-labeled dimethylformamide **2a**. Due to the labeling, a doublet now appears at $\delta = 157.9$ in the ^{13}C off-resonance spectrum of the product. This rules out the structure type **7**, since the labeled carbon atom would then have to give rise to a singlet in the ^{13}C off-resonance spectrum of **7a***. Hence, the structures **4a–i** are unequivocally verified. The substituents R^3 on the nitrogen atom of the formamide adducts **4a–i** show different chemical shifts, i.e. their magnetic equivalence is removed. This is due to the interaction of the aldehyde hydrogen atoms with the lone pair on the nitrogen atom. All the addition products are sterically uniform.

Reaction of the trifluoromethyl sulfones **1a–d** with the formamides **2a–d** is quantitative. Other activated alkynes e.g. phenyl phenylethynyl sulfone, diethyl acetylenedicarboxylate and ethyl phenylpropiolate do not react with dimethylformamide **2a**, even at elevated temperatures. Owing to the low carbonyl activity, the acetamides **2e–g** are less reactive towards **1** than the formamides **2a–d** (Table 1). All

1c/5	**6b**	n-C_4H_9	–	–	90
1e/5	**6c**	c-C_6H_{11}	–	–	94

attempts to initiate reaction of **1a** with tetramethylurea or *N,N*-diethylurethane met without success. The addition of DMSO **5** to acetylenedicarboxylates is well known.[6] By way of comparison, **5** reacts much more readily with the alkynyl trifluoromethyl sulfones **1a,c,e**: even at room temperature the stable ylides **5a–c** are formed in quantitative yield[7] (Table 1).

Our results (Scheme 1) confirm a mechanism which has already been proposed[6] for the addition of DMSO **5** to acetylenecarboxylates. The structure of the acid amide adducts **4** would suggest a mechanism comparable to that for the addition of **5**: the nitrogen atom of the acid amide **2** attacks at the β-carbon atom of the alkynyl trifluoromethyl sulfone **1**, and the resulting zwitterion **3** is stabilized by cyclization and subsequent rupture of the carbon-nitrogen bond to give **4**. If this mechanism is involved in the addition, as suggested by the stereochemical uniformity of the products **4**, the latter must have *E*-configuration.

Experimental

Mixtures of the alkynes and carboxyamide **2** or dimethyl sulfoxide **5** were stirred at room temperature for 1 to 2 d. After aqueous work-up, the formamide and dimethyl sulfoxide adducts **4a–i** and **6a–c** were purified by flash chromatography (hexane/ethyl acetate); the acetamide adducts **4j–m** crystallize from the reaction mixture in analytically pure form. All the products separate

out as colorless to yellowish crystals which are stable towards air at room temperature.

A Systematic Entry to Butterfly-Type $[M_4(CO)_{12}(\mu_4\text{-XY})]$ Clusters**

By *Harald Bantel, Bernhard Hansert, Anne K. Powell, Miklos Tasi,* and *Heinrich Vahrenkamp**

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

Cluster expansion with organometal building blocks is an indispensable strategy for the systematic synthesis of multinuclear clusters.[1, 2] We are presently investigating the use of cluster-bound ligands of the type XY (X,Y = RC,RN,C,N,O) for controlling and altering the activity of such complexes[3]. Trinuclear complexes containing these ligands are fairly readily accessible, whereas their tetranuclear counterparts are largely unexplored. The unusual chemistry which, e.g., the exposed C-ligands in the clusters $[(Fe_4(CO)_{13}(\mu_4\text{-C})]$[4] and $[HFe_4(CO)_{12}(\mu_4\text{-CH})]$[5] exhibit makes further preparative and reactivity studies appear worthwhile. The clusters **1** provide simple and ideal examples for such studies; the alkyne-[6] and nitrile-complexes[7] of **1** have long been known, while the azoalkane complex[8] was first reported only recently. The current thermal methods[1] with $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$ as fragment sources have proven unsuitable for the expansion of such clusters with $M(CO)_3$ building blocks. However, photochemical reactions[9] with $Fe_2(CO)_9$ and $Ru(CO)_5$ provided access to the tetranuclear clusters **2a** in 45%, **2b** in 42% and **2c** in 64% yield.[10]

$$\underset{\mathbf{1}}{[M_3(CO)_9(\mu_3\text{-XY})]} \xrightarrow{\text{"M(CO)}_3\text{"}} \underset{\mathbf{2}}{[M_4(CO)_{12}(\mu_4\text{-XY})]}$$

a: M = Fe, XY = Me_2C_2; **b**: M = Fe, XY = PhCN;
c: M = Ru, XY = Et_2N_2

Hitherto, only **2b**[7b] had been isolated, albeit in very small yields, and structurally characterized; the Ru-analogue[11] of **2a** was first reported somewhat earlier. The new compounds **2a** and **2c** were characterized by their spectra[12] and by structural analyses.[13] All these clusters are of the butterfly type, in which the ligand XY is located in the groove of the bicyclobutane-like folded M_4 unit.

A comparison of the structures of **2a**, **2b** and **2c** (Fig. 1) not only shows the dependence of the M_4XY skeletal geometry on the electron number of the ligand XY, but also its variability at constant electron number. Thus in **2a**, with its 4e alkyne ligand, a 60e cluster with seven skeletal electron pairs is present, which, in agreement with the Wade rules has the *closo* octahedral geometry. **2b** and **2c** are 62e clusters with eight skeletal electron pairs, since nitrile, like azoalkane, is a 6e ligand. As expected, both clusters have an open M_4XY skeleton, which however cannot be easily derived from a *nido*[7]-polyhedron. **2b** can be regarded as a capped trigonal bipyramid (with the C atom as "cap"). **2c** is best described as an *arachno*-D_{2d} dodecahedron whose vacant positions lie above the two Ru_2N_2 rectangles, a feature observed here for the first time. To a close approximation all three clusters **2** reveal the geometry of the starting cluster **1**, to which an $M(CO)_3$ has been added sideways.

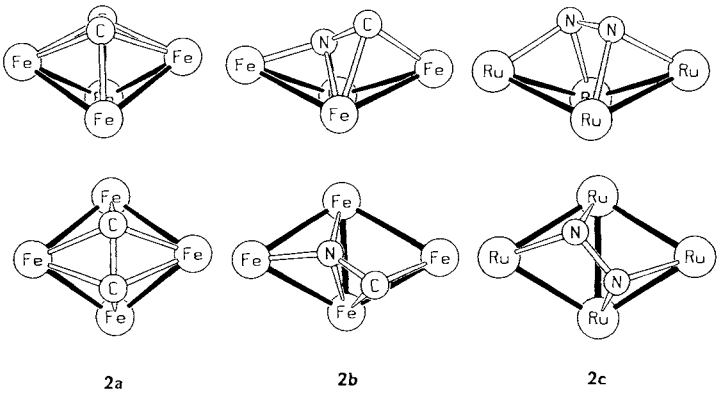

Fig. 1. Two views each of the molecular skeletons of **2a–2c**. Bond lengths in the XY ligands: **2a**, C–C 144(1); **2b**, C–N 135(1); **2c**, N–N 146(1) pm. Dihedral angle between the two M_3 units: **2a**, 115°; **2b**, 135°; **2c**, 124°.

Despite entirely different orientation of the XY ligand to the M_4 unit, all three complexes show a similar expansion of the formally X–Y multiple bond to almost the length of a single bond (Fig. 1). The weakening of this bond (reduction by coordination[3]) should correspond to a markedly modified reactivity of the XY ligands, which in **2b** and **2c** might also be increased by their exposed situation. Photochemical cluster expansion can – as long as the ligand is photochemically stable – be used generally, e.g., with other organometal

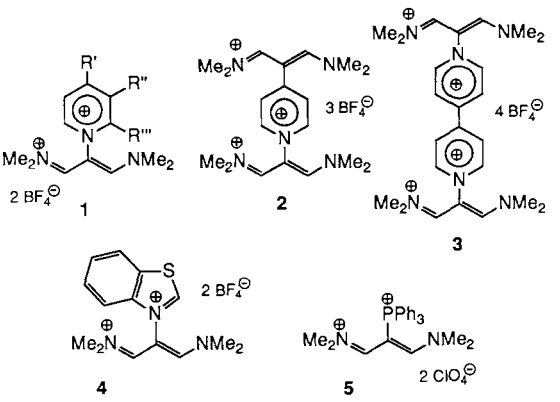
Di(1-pyridinio)- and Di(1-bipyridindiio)-dihydrodibenzotetraaza[14]annulenes**



By *Florian Adams, Rudolf Gompper,** and *Eckardt Kujath*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

Derivatives and metal complexes of porphyrin[1-4] and thus of the structurally related phthalocyanine[2-5] have attracted great interest for some time as redox catalysts (inter alia for fuel cells), synthetic oxygen storage systems, molecular metals, and discotic mesophases. Porphyrins which are coupled covalently with an electron acceptor (quinone,[6] ferrocene,[7] viologen,[8] arene[9]) have recently gained special importance as models for light-induced electron transfer. The use of such systems as molecular shift registers has also been proposed.[10] Tetraaza[14]annulenes (cf. Refs. [2, 4, 11, 12]) have properties similar to those of porphyrins and phthalocyanine. Interest therefore attaches to new derivatives of these three classes of compounds because, inter alia, metal complexes of such systems which bear cationic substituents basically fulfill all the prerequisites for organic superconductors.[13] Two compounds of the porphyrin and porphyrazine series,[14] which approximate the Little models, have been investigated as catalysts for the photoreduction of water. We report here on the synthesis of dibenzotain two pyridinio- or bipyridindiio-moieties and thus are prospective redox systems for the investigation of light-prospective redox systems for the investigation of light-induced electron transfer and as models for organic superconductors.

Hitherto, only diazepines had been obtained in reactions of vinamidinium salts (which can easily be prepared with a large variety of substituents) with 1,2-diamines.[15,16] We have now found that tetraaza[14]annulenes **11** can be prepared from the 2-(1-pyridinio)vinamidinium salts **1**–**3** as well from the 2-phosphonio-vinamidinium salt **5**[17] and *o*-phenylenediamine. The 2-(1-pyridinio)-vinamidinium salts **1** and **3** (for physical data of the new compounds see Table 2) and the benzothiazoliovinamidinium salt **4** were prepared in good yields according to the method described by *Lloyd* et al.[15] for **1a** (R′ = R″ = R‴ = H)[15,18] by reaction of the corresponding *N*-carboxymethylpyridinium salts with dimethylformamide/phosphorus oxide chloride. The *N,N*′-bis(carboxymethyl)-4,4′-bipyridinediium dibromide employed for the synthesis of **3** was obtained by hydrolysis of the dimethyl ester, which in turn was prepared by reaction of 4,4′-bipyridine with methyl bromoacetate; the method of *Michaelis* and *Hill*[19] did not lead to the desired compound. No salt **1**, R″,R‴ = H, R′ = Me, could be isolated upon reaction of *N*-carboxymethyl-γ-picolinium chloride with dimethylformamide/phosphorus oxide chloride; **2** was formed directly.

As a new derivative of viologen, **3** can be reversibly reduced to a radical trication and a dication (see Table 1). Position 2 in vinamidinium salts carries a negative partial charge. It is therefore surprising that the (reversible) reduction of **3** proceeds more easily than that of methylviologen

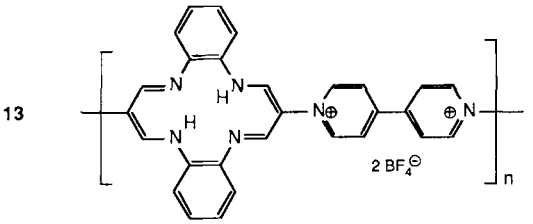
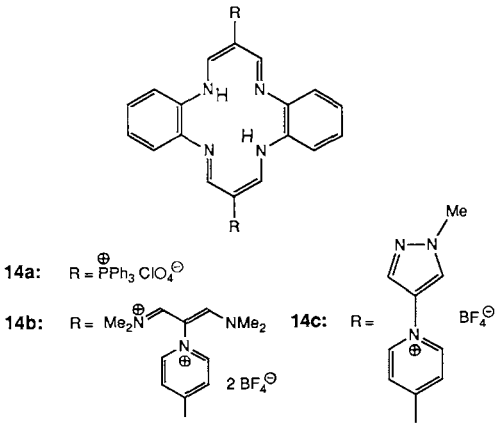
Table 1. Redox potentials of **1g**, **3**, **9**, **11k**, **12k-Ni**, **12k-Cu** (cyclovoltammetry in (i) DMF, (ii) CH_3CN/0.1 M n-BuN_4PF_6, Pt-electrodes versus Ag/AgCl/3 M NaCl).

Cpd.	E_1 [V]	E_2 [V]	K_{com}
1g	− 0.49	− 0.12	1.9×10^6 (ii)
3	− 0.27	0.05	2.7×10^5 (ii)
9	− 0.86	− 0.45	8.9×10^6 (i)
11k	− 0.59	− 0.25	5.8×10^5 (i)
12k-Ni	− 0.59	− 0.24	8.6×10^5 (i)
12k-Cu	− 0.60	− 0.25	8.6×10^5 (i)



($E_1 = -0.67$ V, $E_2 = -0.26$ V; cf. Ref. [20]). One would have rather expected a similarity with **9** and bipyridinediylides[20] ($E_1 \approx -0.8$ V, $E_2 \approx -0.6$ V). In contrast, the reduction of **1g** takes place in the normal range.

Reaction of **1a** with malononitrile in the presence of Hünig base affords the orange colored ylide **6**, which should attract attention for applications in the area of nonlinear optics. Upon heating a mixture of **1a** and 2,3-dimethylbenzothiazolium tetrafluoroborate under analogous conditions the blue cyanine dye **8** is obtained. The noval viologen derivatives **9** and **10** are obtained on reaction of **3** with sodium hydroxide and methylhydrazine, respectively. Heating of **1a** with p-phenylenediamine in methanol leads to **7** and not to a polymeric condensation product.



By reaction of the vinamidinium salts **1a–h** with o-phenylenediamine (**1i** reacts only under template conditions, see below), it was possible to prepare the dipyridiniodibenzotetraaza[14]annulenes **11**, which are comparable with the pyridinio-[21] and bipyridinio-substituted porphyrins.[22] **11k** is formed upon reaction of **11g** with trimethyloxonium tetrafluoroborate.

Especially interesting is the reaction of **3** with o-phenylenediamine. A practically insoluble product is formed, which, on the basis of an elemental analysis and the IR spectrum, is ascribed the structure **13**. The compounds **11** are red, whereas **13** is black.

Reaction of the phosphoniovinamidinium salt **5**[17] with o-phenylenediamine leads to formation of the [14]annulene derivative **14a**. — Of the two vinamidinium systems in **2**, only that in position 4 reacts with o-phenylenediamine, and there results the red salt **14b** in which the pyridinium ring is coupled to the [14]annulene ring via C-4 and not as in **11** via the N atom. The signals of the protons of the dimethylamino groups appear in the ^{1}H NMR spectrum of **14b** at $\delta = 2.65$ and 3.38 and thus at almost the same field as in the spectrum of **1a** (2.47, 3.40). The electronic spectrum of **14b**, like that of **1a**, shows an intense absorption maximum at 306 nm; no maxima are found in this region in the spectra of **11**–**14b** reacts with methylhydrazine (in excess) to give the dark red pyrazole derivative **14c**.

Like other dihydrodibenzotetraaza[14]annulenes,[11,23] the pyridinio derivatives **11** can be converted into their Ni-, Cu-, Co- and Fe-complexes **12** by heating with metal(II) acetates in dimethylformamide; the complexes are also formed on reaction of **1** with o-phenylenediamine in the presence of the metal acetate (cf. Ref. [24]). **12i** can be prepared only in this way. The electronic spectra of **12** show bathochromic shifts of the longest wavelength absorption maxima and of the Soret bands[23,25] at 350–400 nm compared to those of **11**.

The complexes **12** have practically the same (cyclovoltammetrically determined) redox potentials (see Table 1) as the metal-free compound **11k**, and both differ very little in this respect from methylviologen.[20] The measurement of the electrical powder conductivity[26] (4-electrode measurement, 1800 kp) shows that the complexes **12** investigated are insu-

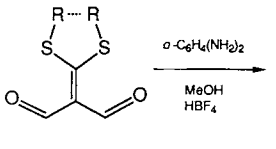
Di(4-pyridinio)-, Di(2-benzothiazolio)-, Di(2-[1,3-dithiolylio])- and Diformyltetraaza[14]annulenes and Tetraaza[14]annulenylene-Homologous Tetrathiafulvalenes **

By *Florian Adams* and *Rudolf Gompper**

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

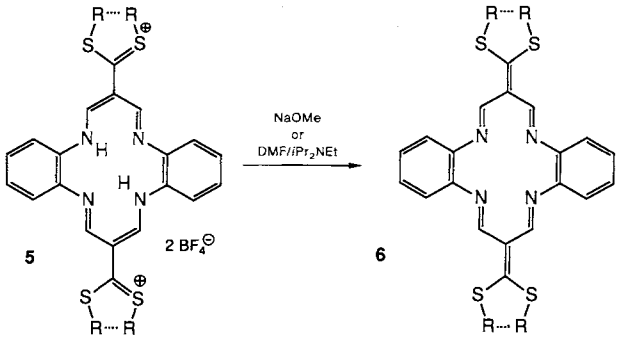
Tetrathiafulvalene (TTF) (cf. Refs. [1,2]) and bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF or ET)[2,3] still have special importance as donors for the production of synthetic metals and organic superconductors, even though a whole series of derivatives, vinylogues, phenylogues, and pentalenylene homologues[4] of TTF have been sythesized in the meantime (cf., e.g., Refs. [2,3]). Metal complexes of cyclic π-electron systems such as porphyrin, phthalocyanine and dihydrodibenzotetraaza[14]annulene, bearing cationic substituents of the cyanine dye type, should according to *Little* et al.[5] have superconducting properties. As models for such compounds we have prepared 7,16-di(1-pyridinio)- and -(1-[4,4'-bipyridindio])-5,14-dihydrodibenzotetraaza[14]annulenes and some metal complexes thereof.[6] In these compounds, the (bi)pyridinio moieties are bound via the N atom to the fourteen-membered ring; an NH deprotonation could therefore only lead to zwitterions. In the case of 5,14-dihydrodibenzotetraaza[14]annulene derivatives, whose cationic substituents are attached to the ring via a C atom, the deprotonation should however lead to 7,16-bis(methylene) derivatives of tetraaza[14]annulenes, which stem from the 7,16-dihydro isomers ($C^{7/16}H$ form instead of $N^{5/14}H$ form). Ni-complexes of tetrahydro derivatives of such compounds are already known.[7] If the methylene groups were part of a 1,3-dithiole ring then such compounds would be dibenzotetraaza[14]annulene homologues of TTF. They should have interesting redox and complexation properties.

a: M = H, H ; **b**: M = Ni, Cu, Co



In the previous communication[6] we have only described such compounds in which two carbocation or phosphonium centers are coupled with the fourteen-membered ring (see **14** therein). A system **2a** (for physical data of the new compounds see Table 1), in which the benzothiazole rings carry the positive charges, can be obtained from the benzothiazoliovinamidinium salt[8] **1** by reaction with *o*-phenylenediamine. If the reaction is carried out in the presence of metal(II) acetates the metal complexes **2b** are formed. Deprotonation of **2a** with sodium methoxide yields the desired orange 7,16-bis(methylene)-7,16-dihydrodibenzotetraaza[14]annulene in 86% yield (the FAB mass spectrum[9] shows the required molecular mass of 582). It can be regarded as a [14]annulenylene homologue of the electron-rich 2,2'-bi(3-methyl-2,3-dihydrodibenzothiazolylidene).

Tetraaza[14]annulenylene-homologous tetrathiafulvalenes **6** are obtained by deprotonation of the dithiolylium salts **5**, which in turn are prepared by heating the methylenemalonaldehydes **4**[10] with *o*-phenylenediamine in the presence of tetrafluoroboric acid-ether in methanol. A nickel- and a copper-complex can be prepared from **6e**.



6b does not react with *p*-tetracyanoquinodimethane. This is understandable on the basis of the cyclovoltammogram of **6b** (irreversible oxidation at 0.75 eV). **6a, b, f** react with iodine to give black complexes whose elemental analyses correspond approximately to the composition $\mathbf{6} \cdot (I_3)_{1.7}$ and which have only insignificant powder electrical conductivi-

An interesting further entry to tetraaza[14]annulenes of the structural type **2/3** and **5/6** is opened up by the diiminium salt **8a**, which can be obtained in 75% yield from the vinamidinium salt **7**[12] and *o*-phenylenediamine. **8a** can be condensed with 1,4-dimethylpyridinium tetrafluoroborate or 2,3-dimethylbenzothiazolium tetrafluoroborate to give the tetraaza[14]annulenes **8b** and **8c**, respectively. Hydrolysis of **8a** affords the dialdehyde **8d**, which can be converted into the metal complex **8e**. As the syntheses of **8b, c, e** indicate, **8a, d** could be valuable starting materials for further interesting tetraaza[14]annulene derivatives.

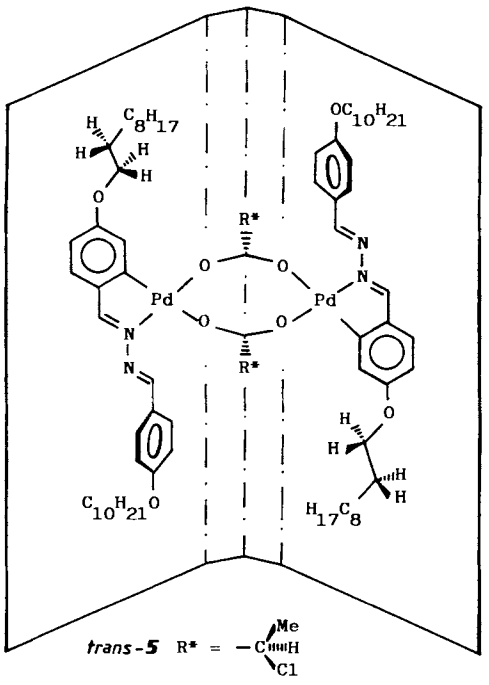
A Novel Approach to Ferroelectric Liquid Crystals: the First Organotransition Metal Compound Displaying This Behavior **

By *Pablo Espinet, Jesús Etxebarría, Mercedes Marcos, Joaquina Pérez, Angel Remón*, and *José Luis Serrano*

Ferroelectric liquid crystals (FLC) are nowadays a major area of interest in mesogenic materials, both in basic and applied research. They are based on rodlike organic molecules with chiral centers in one of the terminal chains.[1-3] Recently, some fully organic mesogens having a "pseudo"-discotic core and helical structure have been reported[4] as a novel molecular type which could be used to obtain chiral mesogens. We have described some *ortho*-palladated dimers $[Pd_2(C,N)_2(\mu\text{-}X)_2]$ derived from the alkylidenamines $R-C_6H_4-N=CH-C_6H_4-R'$;[5] when X = acetate the molecules have a rigid roof-shaped chiral structure; however, only one of the derivatives displayed liquid crystal behavior (monotropic). We report here that similar compounds containing *ortho*-palladated azines display S_C mesophases and advantageously enable the introduction of chirality centers by means of chiral carboxylates (Scheme 1), which can

Scheme 1. Synthesis of **5** and its phase diagram. K = crystalline; S_C^* = chiral smectic C phase; S_A = smectic A phase; I = isotropic liquid; R = $H_{21}C_{10}O$.

give rise to FLC behavior. Three novel aspects may be noted: i) the unprecedented molecular shape; ii) the new way of introducing chirality; and iii) the presence of metal atoms in the molecule.



On refluxing with $Pd(OAc)_2$ in acetic acid,[6] the azine **1** was *ortho*-metalated only in one ring to give **2**.[7] Treatment of **2** in acetone with HCl (Pd/HCl = 1/1) gave **3**. Removal of the Cl bridges in **3** with $AgClO_4$, and addition of the optically active propionate **4** furnished the complex **5** in which two asymmetric carbon atoms have been introduced.

As shown by ^{1}H NMR spectroscopy, compound **5** consists of a mixture of *trans*-$\Lambda R,R$ (34%), *trans*-$\Delta R,R$ (34%) and *cis*-*R,R* (32%) isomers[8] (Fig. 1). A roof-shaped *trans* complex is chiral; since the formation of **5** is not enantioselective, *trans*-**5** must be a 1:1 mixture of Λ and Δ enantiomers. When, in addition, the two carboxylate bridges are non-racemic, the enantiomers are converted into two non-racemic diastereomers: *trans*-$\Lambda R,R$ and *trans*-$\Delta R,R$. A roof-shaped *cis* complex is not chiral on its own; the chirality introduced by the (*R*)-2-chloropropionate ligands leads to *cis*-*R,R* as the third diastereomer present in the mixture.

The hydrogens attached to the asymmetric carbon atoms of the propionato ligands give rise to distinct ^{1}H NMR signals in the three diastereomers (see Fig. 1). The two *trans* diastereomers, each containing two homotopic propionato

ligands, give rise to two overlapped quartets at $\delta = 4.481$ ($^3J_{H,H} = 6.7$ Hz) and 4.467 ($^3J_{H,H} = 6.7$ Hz); the *cis* diastereomer, which contains two diastereotopic propionate ligands, gives rise to two additional quartets at 4.65 ($^3J_{H,H} = 6.7$ Hz) and 4.23 ($^3J_{H,H} = 6.7$ Hz) ppm.

The phase sequence and transition temperatures of **5**, studied by differential thermoanalysis and optical microscopy, are given in Scheme 1. Complex **5** possesses an enantiotropic stable smectic C phase (S_C^*) between 102 and 119 °C. A preliminary study of the physical properties of the compound concentrated on its electrooptic switching behavior.[9] When the temperature of the sample was decreased below 119 °C (entering the S_C^* phase), the material began to respond to an electric field. If the applied field is a square wave of the order of 1 Hz, the switching occurs uniformly over the sample between two states that cannot be brought to extinction between crossed polarizers. Under these conditions, the switching behavior was analyzed by recording on a digital oscilloscope the light intensity of a He–Ne laser transmitted through the sample between crossed polarizers and oriented so as to give maximum contrast. Figure 2a shows the electro-optic response of a sample region of about 2 mm^2 for a driving square voltage of ± 17 v and 0.5 Hz. The sample thickness was 11 μm. As can be seen, the optical response is about three orders of magnitude slower than that of calmitic S_C^* phases.[12] This is due to the high viscosity of the material, presumably caused by the molecular shape, which gives rise to a higher correlation between the molecules than in the calamitic case. The voltage dependence of the rise time τ is shown in Figure 2b. The parameter τ was taken as the time required for a change of transmission from 10% to 90% of the difference between the two transmission levels. Within the field region investigated[10] (11 to 17v) the results obtained fit well to a law $\tau \sim 1/U$ that is characteristic for the switching behavior of FLC.[11]

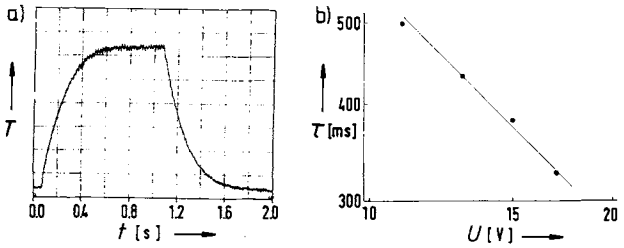

Fig. 2. a) Electrooptic response of complex **5** at a square wave voltage of ± 17v and 0.5 Hz. The sample thickness was 11 μm and the temperature 103 °C. T = transmission in arbitrary units. b) Log-log plot of the voltage dependence of the rise time of **5** at 103 °C.

[7] 45 min., Pd/azine = 1/1; **2** showed a S_C phase in the range of 117.0 to 142.8 °C.
[8] Note on the nomenclature of the isomers: *cis*/*trans* refers to the orientation of the ligands relative to the (Pd-carboxylato)$_2$ ring, R describes the absolute configuration of the 2-chloropropionato ligands, Δ/Λ is used in analogy to the D/L nomenclature in octahedral complexes (see, for example, E. J. Corey, J. C. Bailar, Jr., *J. Am. Chem. Soc. 81* (1959) 2620) to distinguish the two isomers of *trans*-(*R*,*R*)-**5**.
[9] The cell used for the measurements was made of SnO_2-coated glass plates on which a thin film of nylon 6/6 was deposited. One of the plates was rubbed unidirectionaly in order to stretch the nylon film and create an anisotropic aligning surface. The material in the isotropic phase was then introduced into the cell by capillary action and cooled down slowly (0.2 °C/min) into the S_A phase. Fairly good alignment was achieved over the whole sample area.
[10] The higher field region could not be studied in further detail because the material partially deteriorates when subjected to moderate electric fields.

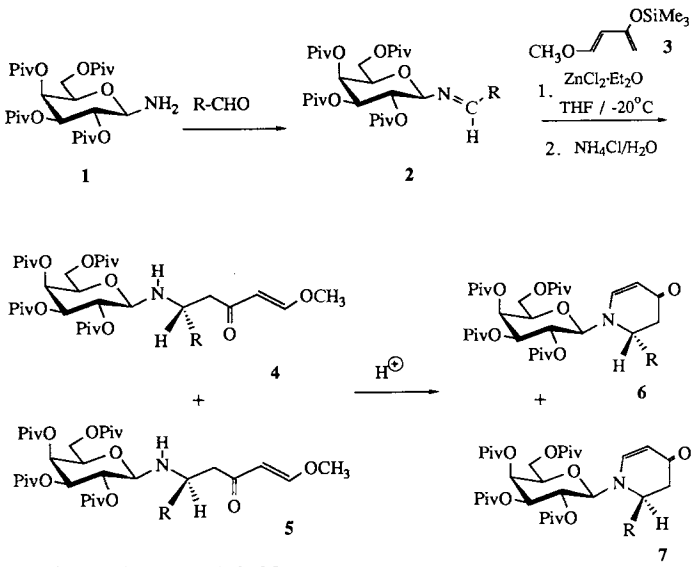
Carbohydrates as Chiral Templates: Stereoselective Tandem Mannich-Michael Reactions for the Synthesis of Piperidine Alkaloids**



By *Horst Kunz** and *Waldemar Pfrengle*

Dedicated to Professor Helmut Ringsdorf on the occasion of his 60th birthday

O-Acyl-protected glycosylamines, particularly the 2,3,4,6-tetra-*O*-pivaloyl-β-D-galactopyranosylamine **1**,[1,2] are effective chiral auxiliaries in Strecker[1] and Ugi syntheses[2] of α-amino acids. Schiff bases **2** prepared from **1** and aldehydes, moreover, react as heterodienophiles with isoprene in aza-Diels-Alder reactions in the presence of zinc chloride at 5–20 °C, whereby chiral piperidine derivatives are formed with moderate diastereoselectivity (diastereomeric ratio ≤ 10:1).[3] An analogous reaction of the Schiff base **2d** (formed from pyridine-3-carbaldehyde and **1**) with 1-methoxy-3-trimethylsiloxybutadiene **3**,[4] first carried out for configurational assignment, turned out on closer examination to be a reaction sequence involving a Mannich reaction followed by a heteroanalogous Michael reaction and a condensation step. Since stereoselective Mannich reactions have thus far rarely been described in the literature[5] we have investigated this reaction sequence in more detail.

Aldehydes react with **1** in the presence of silica gel and a molecular sieve almost without anomerization to give the Schiff bases **2**. Conditioned by a delocalization of the C=N π-electrons in the σ* orbital of the ring C–O bond, the compounds **2** prefer a conformation in which the ring C–O bond is almost perpendicular to the plane of the double bond.[2]

In the presence of zinc chloride the Schiff bases **2** react highly selectively with the silyl dienol ether **3** in tetrahydrofuran at −20 °C to give the Mannich bases **4/5**. The diastereomeric ratios lie in the range 20–50:1 (Scheme 1 and Table 1).

Scheme 1. Piv = $(CH_3)_3C$–CO.

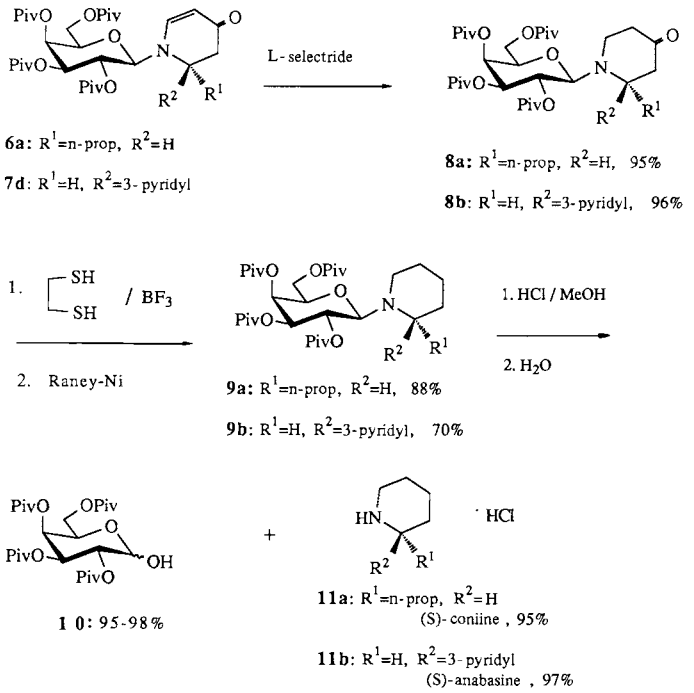
If the reaction is stopped after 2–12 h (T.L.C. control) with aqueous ammonium chloride solution, the Mannich compounds **4/5** can be isolated, or, in the case of the propyl derivative **4a**, detected thin-layer chromatographically. If, on the other hand, direct hydrolysis with 1 N HCl is used for work-up then the subsequent Michael addition occurs immediately followed by elimination of methanol, and the dehydropiperidones **6/7** can be isolated in high yields (≥ 90%) (Table 1).

The diastereoselectivity of these tandem Mannich-Michael reactions is fully dictated by the introductory Mannich reaction, since the Mannich bases **4/5** and the cyclization products obtained from them with dilute HCl show identical diastereomeric ratios. Direct acid hydrolysis of the reaction mixtures furnishes the piperidones **6/7** in the same diastereomeric ratio as the bases **4/5**.

In the case of **2a–2c** one equivalent of zinc chloride suffices for starting the reaction, whereas in the case of **2d** two equivalents of Lewis acid are required. It seems to be a consequence of this fact that the Mannich reaction of **2d** is stereochemically different from that of **2a–2c**, as demonstrated in the conversion of **6a** and **7d** into known piperidine alkaloids. This conversion is initiated by the reduction of the C=C double bond of **6a**[6] and **7d**[7] with L-selectride.[8]

Table 1. Diastereoselective tandem Mannich-Michael reaction of the Schiff bases **2** with 1-methoxy-3-trimethylsiloxy-1,3-butadiene in tetrahydrofuran at −20 °C according to Scheme 1.

Schiff-Base	R	Main diastereomer	Yield [%] **4(5)/6(7)** [a]	**6(7)** [b]	Diastereomeric ratio **6:7** (= **4:5**) [c]	Pure diastereomer	Yield (%)
2a	*n*-Propyl	**4a/6a**	−/90	96	97.5:2.5 (*S*):(*R*)	**6a**	81 [d] [6]
2b	*p*-Chlorphenyl	**4b/6b**	82/−	95	98:2 (*R*):(*S*)	**6b**	90 [e]
2c	2-Furyl	**4c/6c**	36/60 [e]	95	96:4 (*R*):(*S*)	**6c**	60 [e]
2d [f]	3-Pyridyl	**5d/7d**	57 [7]/−	90	4:96 (*S*):(*R*)	**7d**	86 [e] [7]



[a] After hydrolysis with aq. NH_4Cl. [b] After hydrolysis with 1 N HCl. [c] HPLC direct from the crude product. [d] Crystallization from *n*-hexane. [e] Isolation by flash chromatography in petroleum ether/acetate mixtures. [f] Reaction requires 2 equivalents $ZnCl_2$.

The *N*-galactosylpiperidones **8a** and **8b** thus formed are converted via their dithiolanes and desulfurization with Raney-Ni into the *N*-galactosylpiperidines **9a** and **9b**, respectively. Treatment of the compounds **9** with HCl in methanol leads to almost quantitative detachment of the enantiomerically pure alkaloids (*S*)-coniine **11a** and (*S*)-anabasine **11b**, respectively, from the carbohydrate template (Scheme 2). The tetrapivaloylgalactose **10** can be recovered almost completely thereby and reconverted into the starting auxiliary.

On comparing the optical rotations with the data quoted in the literature it is found that the natural (*S*)-coniine **11a** and the natural (*S*)-anabasine **11b** are obtained in enantiomerically pure form in this way. The complexing and chiral properties of the carbohydrate are crucial for the opposite, but in both cases very effective, stereoselection in the depicted Mannich syntheses **4a/5d**. For the reaction with **3**,

Scheme 2.

the Schiff bases **2** require activation by the Lewis acid. This coordinates the nitrogen and, simultaneously and in a favorable way, also the carbonyl oxygen of the pivaloyl moiety in (*Z*)-position. The Mannich reaction of this complex is thought to be initiated by liberation of the latent nucleophilicity of the silyl dienol ether **3**. The interaction of the silyl residue of **3** with a chloride ligand on the zinc—which is essential for this liberation—takes place in the case of **2a** (and **2b** and **2c**) *in front* of the plane of the C=N double bond (Formula **A**), whereby the (*S*)-diastereomer **4a** of the precursor of coniine **11a** is formed. **2d** requires two equivalents of zinc chloride for the reaction with **3**. The first is bound to the pyridine nitrogen and thus inactivated; only the second activates the C=N double bond. The zinc chloride coordinated to the more nucleophilic pyridine nitrogen should activate the silyl dienol ether **3** via its consequently more nucleophilic chloride ligands (Formula **B**). In this case, **3** is introduced *from the free back side* of **2d** and the (*S*)-configurated precursor **5d** of anabasine **11b** is formed. This

A **B**

hypothesis (reaction via **A, B**) awould explain the opposite stereochemical course of the two enantioselective syntheses of the piperidine alkaloids and the high stereocontrol of the Mannich reactions.

Carbohydrates as Chiral Templates: Stereoselective Synthesis of β-Amino Acids**

By *Horst Kunz** and *Dirk Schanzenbach*

Chiral β-amino acids are of interest as constituents of antibiotics[1] and as synthetic building blocks, especially for β-lactam antibiotics.[2] In contrast to the numerous stereoselective methods for the synthesis of α-amino acids,[3] comparably few examples of methods for the symmetric synthesis of β-amino acids have been described in the literature.[4] High inductions are reported for $TiCl_4$-catalyzed reactions of the Schiff bases of valinates with silylketene acetals[5] and for a similar reaction of benzylidenaniline with the silylketene acetal of *N*-methylephedrine propionate.[6] In both cases however, *N*-substituted β-amino acids are obtained whose *N*-substituent (in the former case[5] it is the inducing group) cannot be removed at a later stage. We report here on the asymmetric synthesis of *N*-unsubstituted β-amino acids in which concomitantly high yields, very high inductions and the cleavage and recovery of the chiral auxiliary group are achieved. The basic principle of this synthesis is the effective diastereoselective Mannich reaction of Schiff bases **1** of 2,3,4,6-tetra-*O*-pivaloyl-β-D-galactosylamine.[7]

The silyl ketene acetals **2**, which are prepared in the usual way from lithium ester enolates by silylation and are distilled, react with the Schiff bases **1** in the presence of zinc chloride at −78 °C to −30 °C within 24 h to give the *N*-galactosyl-β-amino acid esters **3** (Scheme 1, Table 1).

Scheme 1. Piv = $(CH_3)_3C$-CO.

[**] This work was supported by the Fonds der Chemischen Industrie.

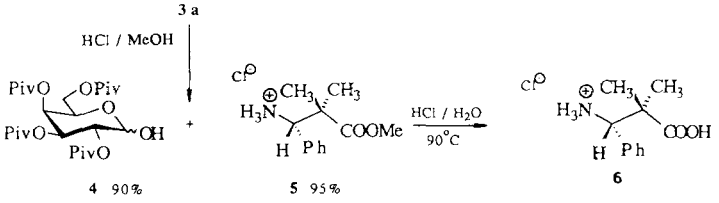

Table 1. Diastereoselective synthesis of *N*-galactosyl-β-amino acid esters **3** according to Scheme 1.

Ester	R	R′	*T* [°C]/*t* [h]	Yield [%]	(*S*):(*R*) [a]	$[\alpha]_D^{22}$ [b]
3a	C_6H_5	CH_3	−30/24	89	150:1	+16.5
3a	C_6H_5	CH_3	+30/1	90	70:1	
3b	C_6H_5	C_2H_5	−30/24	82	5:1	+13.1
3c	3-Cl-C_6H_4	CH_3	−30/24	89	200:1	+10.2
3d	2-Cl-C_6H_4	CH_3	−30/24	92	1:80 [c]	+14.2
3e	4-F-C_6H_4	CH_3	−30/24	88	105:1	+13.3
3f	2-Naphthyl	CH_3	+30/72	90	10:1	+15.4
3g	*n*-C_3H_7	CH_3	−30/24	83	250:1	+11.8

[a] Analytical HPLC (Diode array detection) on RP-18 columns in acetonitrile/water. [b] $c = 1$, $CHCl_3$. [c] The reversal of the diastereoselectivity is deceptive of the residues R, only 2-chlorophenyl has a higher priority than R'_2-C-COOMe.

The diastereoselectivity of the reaction in conversions of the silylketene acetal of methyl isobutyrate (**2**, R′ = Me) is in each case very high. The diastereomeric ratio (70–250:1) is determined directly by HPLC analysis of the reaction solution after hydrolysis with ethylenediamine tetraacetic acid (EDTA) solution. A marked stereoselectivity is still always observed even when the reaction is carried out at + 30 °C, which is necessary in the case of **1f**. In the 100-MHz ^{13}C NMR spectrum the major diastereomers of the aromatic products **3a–f** all show a signal at $\delta \approx 86.3$ for the anomeric C and a signal at $\delta \approx 71.5$ for the β-C of the amino acid moiety. In the case of the aliphatic derivative **3g** the corresponding signals appear at $\delta = 89.5$ and 59.7. The sterically demanding α-diethyl branched derivative **3b** is formed with only moderate selectivity.

In order to determine the absolute configuration of the major diastereomers, the phenyl derivative **3a** was converted into the known[8] free amino acid **6**. The removal of the β-phenyl-β-alanine ester derivative[9] from the carbohydrate template can be achieved almost quantitatively with HCl in methanol, and the auxiliary can be re-isolated in ≥ 90% yield (Scheme 2).

Scheme 2.

Comparison of the optical rotation values[10] with those quoted in the literature for the (*R*)-compound show that the (*S*)-configurated β-amino acid **6** is obtained in high enantiomeric purity by the synthesis described here. It can be concluded, therefore, that all β-amino acid derivatives prepared according to Scheme 1 are preferably formed with (*S*)-configuration. The direction of the asymmetric induction in this β-amino acid synthesis is accordingly identical to that observed in the previously described tandem Mannich-Michael reaction for the synthesis of coniine.[7]

The method presented here enables the synthesis of chiral β-amino acids in high yields and with high diastereomeric excess, and the releasing of β-amino acids without *N*-substituents from the auxiliary. The preparative scope of this method is even considerably greater when one realizes that the opposite enantiomers of the chiral β-amino acids can be obtained in the same way with 2,3,4-tri-*O*-pivaloyl-α-D-arabinopyranosylamine, as could already be demonstrated in the meantime in Ugi and Strecker syntheses.[11]

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Solids and Surfaces: A Chemist's View of Bonding in Extended Structures. By *R. Hoffmann*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim 1988. x, 142 pp., hard cover, $ 24.95.—ISBN 0-89573-709-4/3-527-26905-3

Extended structures have become increasingly fashionable for study in the last two decades. Much progress has occurred towards determining and understanding chemical and physical properties of compounds of this type, whether they be solids, surfaces, or macromolecules. Theoretical models of electronic structure in such systems have also developed beyond the treatment of small molecules or small unit cells. Most recently, theoretical aspects of solid state chemistry have moved beyond the purely conceptual, e.g., as in the Zintl-Klemm rules, towards more quantitative descriptions, which have been around in solid state physics for some decades. "Solids and Surfaces: A Chemist's View of Bonding in Extended Structures" by *Roald Hoffmann* is an effective attempt to translate the language of band theory for chemists. True to his style over the years, his descriptions are highly pictorial and intuitive—an extremely useful complement to the mathematical formulation in the physics literature. Given this, one can contend that this book also teaches physicists the particular point of view of chemists for looking at such problems.

The book begins by setting up the vocabulary of band theory, i.e., Bloch functions, *k*-space, etc., in order to develop the ideas behind the construction of energy band diagrams. Such dispersion curves have no analog in molecular orbital theory, and so "to retrieve a local, chemical, or frontier orbital language in the solid state," Prof. *Hoffmann* introduces the connection between density-of-states diagrams (DOS) and molecular orbital energy level schemes—something which "chemists can sketch..., intuitively." Local descriptions fall naturally by partitioning the DOS into various components, either via atomic orbital or bond orbital contributions. COOP (crystal orbital overlap population) diagrams provide another interpretative tool that gives "a way to find bonds in the bands that a fully delocalized calculation gives." In the remainder of the book, he develops and extends these ideas using numerous examples studied in his research group over the last several years, e.g., $ThCr_2Si_2$, Chevrel phases, the NiAs → MnP transition, as well as surface structural problems involving Ni(100) with CO, and various transition metals with the methyl group. Within these examples, Prof. *Hoffmann* introduces the ideas of Peierls distortions, frontier orbital approaches, and the significance of the Fermi level, including its influence over surface reactions.

As mentioned in the preface, the material in this monograph has already appeared in two review articles, one in *Angewandte Chemie*, the other in *Reviews of Modern Physics*. One may therefore question the need for such a book. In addition, a number of other publications exist that discuss chemical bonding and electronic structure from both physical and chemical points of view. Yet, "Solids and Surfaces", through its numerous examples, combines the ideas of bonding and reactivity in molecules with those of both solids and surfaces—topics which may be too cumbersome and excessive for even a single review article.

Prof. *Hoffmann*'s self-assessment of this material is also true—the language of solid state physics is much more extensive than what is presented in his book. Yet, it represents an excellent first step for students and other chemical researchers who are not well versed in the language of electronic structure in the solid state. It may also be a valuable companion text to one which provides more quantitative descriptions for those who are interested in more of the details.

The Chemistry of Sulphones and Sulphoxides. Series: The Chemistry of Functional Groups. Edited by *S. Patai, Z. Rappoport* and *C. Stirling*. Wiley, Chichester 1988. xvi, 1210 pp., bound, £ 235.00.—ISBN 0-471-91588-2

In the well-known and very useful series "The Chemistry of Functional Groups", the first volume of which appeared 25 years ago (also edited by *S. Patai*), we now have for the first time a comprehensive account of the chemistry of sulfoxides and sulfones. This not only fills a gap in the series, but also remedies a more general deficiency, as there is no recent monograph of comparable scope and standard on these classes of compounds. Such a publication was long overdue, as sulfoxides and sulfones have come to occupy an important and established place in the repertoire of organic chemistry; this is clearly shown, for example, by Chapters 12 and 16 on sulfinyl carbanions and asymmetric syntheses, Chapters 13 and 14 on rearrangement reactions, or Chapters 22 and 23 on electrochemical and electron transfer reactions.

The editors have succeeded in engaging eminent experts as authors for the individual chapters, and in addition they have, of course, the experience needed to bring the separate contributions together so as to form a consistent whole. Not surprisingly, therefore, the result is an excellent book—a handbook in the true sense, and not merely a collection of essays.

The first six chapters (165 pages altogether) deal with the theoretical and physical-chemical aspects of sulfoxides and sulfones, and also with their analysis—a very useful chapter from a practical standpoint. A separate chapter on the chirality of sulfoxides, a topic of great importance to the preparative chemist, is also included here. Next there are three substantial chapters dealing in turn with the preparation of open-chain sulfones (*K. Schank*, 68 pp.) and sulfoxides (*J. Drabowicz, P. Kielbasinski*, and *M. Mikolajczyk*, 146 pp.), and of the corresponding heterocycles (*U. Zoller*, 104 pp.). The latter chapter, in accordance with the author's own field of research, includes an especially detailed account of the unusual three-membered ring systems.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1989 0570-0833/89/0808-1070 $ 02.50/0

After two further chapters on substituent effects, hydrogen bonding and complex formation, the chemical reactions are then treated in a total of 435 pages. The chapters by *S. Oae* and *Y. Uchida* and by *G. H. Posner* on α-sulfinyl and α-sulfonyl carbanions as useful CC bond-forming reagents are of particular interest for the synthetic organic chemist; these reagents have proved to be extremely useful for asymmetric syntheses. Other chapters that are mines of information on reactions useful for preparative work are those on rearrangement reactions (*S. Bravermann*, 94 pp.)—here one thinks of the important Pummerer reaction—on reduction reactions (*J. S. Grossert*, 43 pp.), which includes a description of the interesting Julia reaction for preparing carbonyl compounds from sulfones, and on sulfinyl and sulfonyl radicals (*C. Chatgilialoglu*, 34 pp.). The last of these chapters contains, for example, (though rather inconspicuously) the SO_2 extrusion reaction which is important in cyclophane chemistry.

The numerous literature references extend up to 1987 in a few chapters, but in general only up to 1986; the long time required to produce such a book makes it very difficult to achieve a degree of topicality better than this.

This volume is, of course, essential to every library. Because of its exceptionally high quality I would also like to recommend individual organic chemists (not only sulfur chemists) to buy it, but of course the price is almost prohibitive.

Computational Chemistry. An Emphasis on Practical Calculations. (Series: Studies in Physical and Theoretical Chemistry, Vol. 56). By *M. D. Johnston*. Elsevier, Amsterdam 1988, xviii, 680 pp., hard cover, HFl 245.00/paperback, HFl 245.00. – ISBN 0-444-42962-X/0-444-42963-8

This book is apparently based on the author's lecture notes of an introductory course on data processing for chemistry students. Its contents are arranged in a clear didactic sequence as follows: 1) basic considerations and concepts in electronic data processing, with the emphasis on personal computers (algorithms, structured programming, user-friendliness, sorting programs, text processing, preparation of tables, data banks, main-frame computers and networks, basic PC equipment, programming languages); 2) various useful application-orientated programs in analytical and numerical mathematics (factorization of rational functions; Horner scheme; useful formulas for differentiation and angular functions; complex numbers; matrices, determinants, vectors, systems of linear equations); 3) programming numerical and graphical problems of chemistry in BASIC (graphical representation of 2D and 3D functions, contour plots, simple molecular graphics, some special functions, searching for stationary points, numerical differentiation and integration, Monte-Carlo integration, matrix routines, diagonalization, differential equations, curve-fitting, regression analysis, minimization); 4) an extensive collection of useful programs for the chemist, varying greatly in length (some up to 2000 lines in length, including a molecular graphics program, a graph-plotting package, a matrix package, simplex minimization, a fast Fourier transform program, a titration curve program, and NMR spectrum simulation). Each section concludes with questions to test the reader's understanding and a few exercises.

The text is written in an easy, one might even say casual, style, such as one might use when lecturing to students so as to hold their attention. This is indeed necessary in the early part of the book, which sometimes contains long-winded general observations expressed in sentences of little factual content ("textbooks are an invaluable source of basic information"; "select the best method for the problem at hand"; "write expressions so that it is best for the actual calculation").

The teaching strategy of the book is based on illustrating the methods and enabling the reader to learn and understand by applying them himself. The theoretical background to the methods used and the programs listed is explained later (though not always adequately). This very pragmatic approach should please chemists who are not keen on theory, but it is not to everyone's taste.

The author expresses the view that some first-hand programming experience is needed in order to make effective use of the computer and pre-written programs (however, the assertion that "if you can program, the computer is your servant; otherwise you are the computer's slave" is rather an exaggeration). While it is true that programming experience is best gained by working through examples of well-written programs, the reproduction in the book of many pages of computer code appears of limited value. Would it not have been possible to supply a diskette to go with the book? Many of the comments reflect the personal tastes of the author too strongly, and should be read with a measure of skepticism ("FORTRAN is not suitable for use with microcomputers"; "In going from microcomputers (i.e. PCs) to minicomputers we gain little, if anything"; "The mouse is one of the silliest inventions which has ever captured the fancy of anyone").

The book contains much of value for a good introductory course, but there is not much on the subjects of data banks and text processing. Incidentally, it has been prepared using a *very* basic word-processing system (no special characters, no line justification, no word breaks); also the typed pages are not free of typographical errors. Students, for whom the book is no doubt intended, will surely not pay the horrendous price for this level of quality. Comparable books are available at considerably lower prices.

Two-Dimensional NMR Methods for Establishing Molecular Connectivity. A Chemist's Guide to Experiment Selection, Performance and Interpretation. By *G. E. Martin* and *A. S. Zektzer*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xviii, 508 pp., hard cover, DM 126.00. – ISBN 3-527-26858-703-5/0-89573-703-5

In view of the flood of books on two-dimensional NMR spectroscopy during recent months and years, the appearance of each new book prompts one to ask whether it has a particular appeal, either with respect to the range of topics covered or the readership to which it is addressed. The book "Two-Dimensional NMR Methods for Establishing Molecular Connectivity", by *G. E. Martin* and *A. S. Zektzer*, published by VCH Verlagsgesellschaft, does in fact display such a special quality. It concentrates on a clearly defined subject area, giving a very detailed account of two-dimensional pulsed NMR methods for revealing connectivities of the two elements hydrogen and carbon, the main emphasis being on applications to organic natural products with molecular mass less than 1000. In NMR spectroscopy connectivity information is, in chemists' language, information about the molecular constitution of a compound. Questions relating to

stereochemistry or conformation are therefore excluded completely from the discussion. In accordance with this, methods for measuring such structure-related NMR parameters as coupling constants or cross-relaxation rates are not included.

The organization of the book falls clearly into seven chapters. In the introductory chapter the principles of 2D NMR spectroscopy are briefly described, and practical information and advice is given on the processing of the data, presentation of the spectra and planning of experiments (including pulse width calibration). Chapter 2 is devoted to H-H connectivities, and includes a detailed description of the basic COSY experiment and six variants of it. The chapter concludes with an account of multiple quantum NMR spectroscopy. In Chapter 3 methods for determining H-C connectivities are described. A full account of all the methods, from the first selective SPT experiments through to the most sensitive present-day pulse sequences with ^1H detection, is given. Chapter 4 is devoted to relayed experiments, including homo- and heteronuclear, single and multiple relayed experiments, and the related TOCSY experiment. Chapter 5 then deals with ^{13}C-^{13}C connectivities, with a strong emphasis on the INADEQUATE experiment. The latest variants with ^1H detection are also treated. Finally, Chapter 6 presents spectroscopic problems of structure determination in organic molecules, and solutions to these are provided in Chapter 7.

The main emphasis of the book is on the fifty or so pulse sequences that are described. The discussion of these is supported by an excellent survey of the literature, with a comprehensive bibliography which covers not only the first publication on each pulse sequence and the modifications subsequently introduced, but also many published applications. The authors give details of experimental conditions which they have themselves tested and found to give good results, and the majority of the spectra shown are their own. In many of the examples spectra recorded on the same compound using different methods are shown and discussed in order to compare the information given by each method. This gives the user a valuable impression of the advantages and disadvantages of the various methods. The descriptions of the pulse sequences include explicit information on phase cycles, although regrettably these are incorrect in some cases. Readers must therefore be warned against using these pulse sequences uncritically; instead they should compare them with the original papers.

The book does not aim to give a rigorous theoretical understanding of the pulse sequences, and the reader who is unfamiliar with "spin gymnastics" will experience some difficulty in understanding the discussions. Inevitably, therefore, certain expressions are used, such as "passive transfer", without their meaning being fully explained.

The numerous figures illustrating the techniques described are an important feature of the book. However, it is incomprehensible why the labeling of the spectra is so sparse and frequently illegible, often making the search for the spectral details discussed in the text a laborious task. The poor quality and often inadequately small scale of the figures is especially annoying in Chapters 6 and 7 which contain the spectroscopic problems. Also cross peaks are sometimes missing, so that one is forced to read the solution to the problem.

In summary it can be said that this book offers a detailed, excellently researched and unbiased account of 2D NMR methods for determining molecular constitution. For the NMR practitioner it provides very useful information and advice on planning experiments and interpreting spectra, illustrated by interesting examples from natural products chemistry. One is willing to forgive the less than perfect quality of the figures and the errors that are probably unavoidable in view of the large amount of material included.

Activation Analysis with Charged Particles. Ellis Horwood Series in Analytical Chemistry. By *C. Vandecasteele*. Ellis Horwood, Chichester/Halsted Press, New York 1988. 171 pp., hard cover, $ 29.95. – ISBN 0-7458-0175-7/0-470-21204-7

In contrast to neutron activation analysis (NAA), charged particle activation analysis (CPAA), mainly using protons, but also deuterons, tritons, and nuclei of helium-3 and helium-4, has found little use up to now in elemental trace analysis; consequently it has no chance of becoming a universal routine method. Nevertheless CPAA, which has very high sensitivity, can be used as a complementary method with NAA and other trace analysis methods in special types of problems. It offers higher sensitivity than the other methods, and also eliminates ambiguity in some cases, for determining light elements such as H, Be, B, C, N and O down to ppb concentrations, especially in ultra-pure metals and semiconductors. However, the acceleration of the particles for CPAA requires very expensive equipment such as a Van de Graaf generator or a cyclotron (for protons and deuterons with energies of 2 to 20 MeV), and sometimes causes complex nuclear reactions which necessitate subsequent radiochemical separation. Consequently it has great disadvantages compared with NAA and atomic spectroscopy for determining medium and heavy elements, e.g. in geochemical or biological matrices, and only in rare cases is it sensible to use it for such analyses.

The author of this first monograph on the theory, experimental requirements and applications of CPAA, who has considerable practical experience in this field, is well aware of the limitations of the method. About a half of the book is taken up by general matters, including introductions to the theoretical basis, descriptions of accelerators and irradiation techniques, the relevant nuclear reactions and data on these, and the procedures needed for calibration and avoidance of errors. In the chapters that follow describing applications to trace analysis, the practical importance of CPAA in each of the areas covered is clearly reflected by the numbers of publications cited. The most important chapter, "Determination of Light Elements", has 85 references. That on "Determination of Medium and Heavy Elements in Metals and Semiconductors" – where irradiation by protons is still the most important experimental method – has 42 references. "Analysis of Geological, Environmental and Biological Samples" has 14 references, as does the more academic "Activation Analysis using Heavy Ions". In all the chapters the literature up to the present date is covered very thoroughly and described in clear language, thus giving students, teachers and those interested in using the method an excellent picture of the capabilities of CPAA, although only a few experts will ever be able to use the method in their own laboratories. The main value of the book therefore lies in the information on when it is appropriate to use CPAA, and where to turn for help in such cases.

Industrielle Organische Pigmente. Herstellung, Eigenschaften, Anwendung. By *W. Herbst* and *K. Hunger*. VCH Verlagsgesellschaft, Weinheim 1987. xiv, 637 pp., hard cover, DM 320.00. – ISBN 3-527-26319-5

The chemistry, properties and methods of use of organic dyes and pigments as colorants for textiles, paper, leather and similar substrates have already been the subject of numerous monographs, and have also to varying degrees found their way into many organic chemistry textbooks, and thus even into undergraduate courses. However, this is not true of the second large group of organic coloring media, namely those pigments that are used mainly in the manufacture of printing inks, paints and varnishes, and as colorants for plastics. In view of the continual growth in the technological and economic importance of this latter group of products, and also the scientific problems which they present, the appearance now of a substantial and comprehensive monograph on this subject is very much to be welcomed; the book deals with all the different types of industrially manufactured pigments, mainly from the practitioner's point of view.

The general part of the book (190 pp.) begins by defining the book's subject of organic pigments, as distinct from inorganic pigments and organic dyes, then goes on to give a brief classification of the different types of pigments according to their chemical structures. The chemical and physical properties of each group, and their important behavioral characteristics when in use (e.g. color shade and strength, fastness, crystallinity, polymorphism, particle size distribution, coloring behavior), are described, together with the relevant test methods. Next the reader learns about the different areas of application of organic pigments.

The main part of the book contains a tersely written, but nevertheless almost exhaustive, description of the large class of the azo pigments (230 pp.), e.g. mono- and bis-azo, naphthol-AS, benzimidazolone, and metal complex pigments, followed by polycyclic pigments (134 pp.), such as the phthalocyanines, the quinacridones, the dioxazines, the perylene and perinone derivatives, and other types related to these in the wider sense. In every case the structures, synthetic methods, properties and applications are described, and the various commercially available products are summarized.

A further section (12 pp.) deals with the environmental aspects and toxicology of pigments, and with relevant legislation. The book ends with a set of formula schemes describing the synthetic methods used for making the most important pigments (32 pp.), together with a reference table of pigments and a subject index.

Because of its comprehensiveness, and the convenient arrangement and competent treatment of the material, the book is an almost ideal information source both for the practitioner in the field and for the reader about to enter it. The important aspects of the synthesis and applications of organic pigments are dealt with very fully, in a clear style and with a rational sub-division of the material. The excellent layout is a considerable aid to the reader, and it is a pleasure to open the book. The price seems an acceptable one for the readership envisaged by the authors, but the same does not apply for university departmental libraries or others interested in the topic.

In the reviewer's opinion, specialists in other fields who want to try something new could usefully consult this book. For example, a solid state physicist or materials scientist who, in his own studies (unrelated to pigments), wishes to investigate a range of different chemical structures, could hardly find a greater variety of easily prepared, crystallizable substances with well-defined structures than the pigments described here. To summarize, in this book by *W. Herbst* and *K. Hunger* we now have a standard work which will hold its place in the literature for a long time to come.

Wolfgang Lüttke [NB 981 IE]
Organisch-Chemisches Institut
der Universität Göttingen (FRG)

Advanced Inorganic Chemistry. 5th Edition. By *F. A. Cotton* and *G. Wilkinson*. Wiley, Chichester 1988, xvii, 1455 pp., hard cover, $ 44.95. – ISBN 0-471-84997-9

Eight years after the publication of the previous edition there is now a new "Cotton & Wilkinson" in its original English version. For a book which is aimed not only at advanced students but at everyone with interests in modern inorganic chemistry, this time interval is just about long enough for the most recent developments to be treated at a textbook distance. This already highlights one of the undoubted merits of the concept followed since the appearance of the first edition in 1962; the evidence of the authors' own productive research activities (more than 1000 scientific papers by *F. A. Cotton*) guarantees a careful selection and critical appraisal of results from the current literature.

What, then, can long-standing "subscribers" to this work and first-time readers expect to find? The manuscript deadline was mid-1987, and consequently the new superconducting materials are represented only by five lines tucked away in the chapter on copper oxides and one literature citation (*Whangbo* and *Williams*). For reasons of space, only citations later than 1979 are included, and one therefore needs to refer to previous editions for work published earlier. Although the text itself contains very few printing errors, the citations themselves are marred by some repeated annoying mistakes in German names (e.g. *Hüttner, Sherer*).

The overemphasis in "Cotton & Wilkinson" on transition metal and coordination chemistry at the expense of Main Group element and molecular compounds is perceived as such especially in the German-speaking world and is still clearly detectable despite the claim to the opposite in the book's blurb. This is apparent both from the choice of literature references and from the (too scanty) list of contents. A short introduction to coordination geometry and ligand classification is followed by a systematic treatment of the elements of the Periodic Table and their compounds; the enlarged section on Main Group elements is essentially due to the new system of classifying complex ligands under the respective coordinating atoms. In this section, moreover, the treatment is not always up-to-date; for example, the description of the photoreactivity of chlorophyll is identical to that in the third edition of 1972, and has therefore long been outdated.

In the transition metals section the compounds of the 4d and 5d elements are particularly strongly represented; furthermore, the comprehensively discussed topics of systems with metal-metal, metal-carbon and metal-hydride bonds, homogeneous catalysis, reaction mechanisms and bioinorganic chemistry are almost entirely concerned with transition metal compounds.

The still rapidly expanding field of organo-transition metal chemistry (metal carbonyl clusters, complexes containing C-ligands, catalysis) has been given increased emphasis compared with previous editions. The chapter which appeared in the fourth edition as "Transition Metal to Carbon Bonds in Synthesis" has now been given the more explicit title "Oxidative-Addition and Insertion Reactions". It would have been desirable to include a comprehensive review of the photo-

chemistry of organometallic and coordination compounds, a topic which has become increasingly important in the last few years.

The relatively small increase in size of about 60 pages compared with the previous edition gives a total of 1455 pages, still just about compact enough for convenient use. This modest increase has been achieved at the cost of excluding some "theoretical" material; as the authors note tersely in the preface, "something had to go". The original conception of "Cotton & Wilkinson" thus becomes even more strongly evident, one aspect being a consistent emphasis on experimental facts, especially on structural information, as opposed to interpretations and theoretical models; as the preface puts it, "theories come and go". However, in actual work (or examination) situations such maxims are scarcely helpful; models, even though they may change with time, are indispensable for the development of chemical knowledge (as is the process of disproving them). The approach adopted by the authors follows the current trend in the USA towards more "descriptive" chemistry; however, the book is by no means devoid of necessary theoretical discussions and popular concepts. For example, one finds the planarity of silyl amines explained in terms of unoccupied silicon d-orbitals (illustrated by a diagram), isolobal and valence electron rules are used throughout, and the coordination geometries of the elements are classified according to their not always meaningful oxidation states.

Thus "Cotton & Wilkinson" can only be recommended to the student in combination with a textbook such as "Holleman & Wiberg" in which the emphasis is on fundamentals and Main Group element chemistry; a recent serious alternative is "Greenwood & Earnshaw", which covers both fields equally well. Furthermore, using "Cotton & Wilkinson" as a work of reference has taken a certain amount of getting used to; it is true that, in contrast to the still inadequate contents list, the subject index has been enlarged by 50% compared with the previous edition, but the mixing of names with chemical formulas now results, for example, in "RHgX" being listed between "Rhenium" and "Rhodium". To sum up, however, "Cotton & Wilkinson" in this new edition will maintain, and may further extend, its unique standing as a classic work amongst the available literature for students and teachers of inorganic chemistry; being more ambitions than a conventional textbook, but now deliberately omitting the treatment of basic elementary material, this edition provides a selective "eight-year review", a bonanza of information on important results and developments which could otherwise easily be overlooked in the general deluge of publications.

ADVANCED MATERIALS

Materials Science and Engineering in Britain

Editorial Essay

By Colin Humphreys*

Mankind is poised to move into a revolutionary era: the age of new materials. For example, materials scientists are designing novel liquid crystals which will enable television sets of the future to be thin and light, so that they can be hung on a wall like a picture. We can make superconductors in which an electric current will circulate for ever with no battery required to keep it going: well known recent developments in materials chemistry have led to higher critical temperature superconductors which may ultimately result in cheaper electricity and ultrafast levitating trains. We can make materials which store information so compactly that the entire contents of the Encyclopaedia Britannica can be contained within the space occupied by this full stop →. (see Fig. 1) We can make semiconductor lasers so thin that one

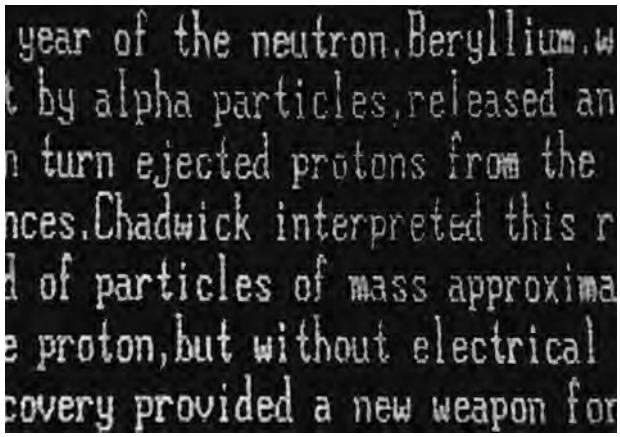

Fig. 1. A portion of the Encyclopaedia Britannica written in AlF_3 using an electron beam. The beam has a diameter of only 0.5 nm and each letter is composed of a double row of dots 4 nm in diameter. Each dot is a hole etched through the 50 nm thick AlF_3 specimen directly using the electron beam. At this scale of lithography the entire contents of the Encyclopaedia Britannica could be written on a pinhead. The potential for information storage, molecular filters, etc. is clear. The nanometer scale lithography was performed using a 100 keV electron beam in a computer controlled VG HB 501 scanning transmission electron microscope.

million of them can be stacked side-by-side within the thickness of a one penny coin, and the color of the laser light emitted can be chosen simply by varying the laser layer thickness: such lasers are being used in the latest generation of compact disc players. Laser surgery, using novel lasers developed by materials scientists, is enabling the blind to see and artificial heart valves, made from advanced materials, are giving life to some who would otherwise be dead.

Many readers of this article will require artificial hip joints in the future. Twenty years ago the average lifetime of an artificial hip joint was only three years. Today the average life time is ten years, and current research on advanced materials has improved the lifetime of the next generation of artificial hip joints to thirty years. Since the cost of an artificial hip joint is only £ 100, and the cost of the operation is about £ 3000, these recent developments in materials science and engineering are not only of benefit to the patient but also to the financial benefit of the health service. Research into artificial skin is in progress, and longer term research into an artificial pancreas so that diabetics would no longer need to inject insulin is also underway.

Novel materials are essential for use in protecting our environment in, for example, solar cell technology or in catalytic converters.

The main force driving developed nations into the age of new materials, however, is not the desire for improved health care nor for a better environment, it is that for economic growth. The economic growth argument was concisely summarized in an issue of Scientific American entirely devoted to advanced materials which stated: "Advanced materials are essential to the future growth of the aerospace, electronic device, automobile and other industries. Progress in materials science sets ultimate limits on the rate at which key sectors of the economy can grow."

For the above reason, the importance of new and improved materials is clearly recognized in developed countries. *George Keyworth*, President *Reagan*'s former chief scientific advisor, stated: "Materials science is probably the most important subject in the US today." In Japan, the Ministry of International Trade and Industry (MITI) has targeted three key areas for massive research and development: new materials, new electronic devices and biotechnology, and top of the list is new materials. In the Japanese government's Basic Technology for Future Industries Program there are eleven major projects, seven of which are in the area of new materials. About two years ago the UK government set up the Advisory Council on Science and Technology (ACOST) to advise it on priorities in science and technology. ACOST has recently identified new materials as a key enabling technology.

Materials research is a strategic research area which is essential for future industries and in which research discoveries can be transformed into market place products in a peri-

[*] Prof. C. J. Humphreys
Chairman, Materials Science and Engineering Commission,
Science and Engineering Research Council (UK)
and Head of Department of Materials Science and Engineering
University of Liverpool,
P.O. Box 17, Liverpool L69 3BX (UK)

od of typically three to twenty years. Our competitors have already realized this and overseas governments have selected new materials for priority funding in order to make their future industries competitive, to improve their future balance of trade and to reduce their future unemployment. For example, the US government invests well over £ 700 million per annum in materials research, and the Japanese government invests an estimated £ 500 million per annum. On the other hand, the UK government invests only about £ 60 million per annum in materials research of which about £ 20 million is allocated to the Science and Engineering Research Council (SERC). Last year the annual increase in spending of the Japanese government on materials research in the civil sector exceeded the total spending of the UK government in this area. With such a massive funding discrepancy in materials research between the UK and our competitors it is essential that the UK makes the best use of its limited resources, and that it invests more heavily. The UK has been slow to wake up to what has been happening in materials research in Japan, the USA and parts of Europe (notably West Germany and France). However there are now clear signs that Britain is increasingly aware of the strategic importance of materials research.

Perhaps the first evidence of this increased awareness was the decision of the SERC (which funds science and engineering research in all UK universities and polytechnics) to set up in 1987 a panel to study the funding of materials science and engineering by the SERC. The panel, chaired by Dr. *Peter Day*, reported in January 1988 that although much UK materials research is of the highest standard internationally, many areas are in rapid decline. The panel presented evidence that the funding levels are totally inadequate. Their report also stated that the administration of materials research within the SERC was very fragmented, with materials research being funded by the Physics Committee, Chemistry Committee, Materials Committee, Process Engineering Committee, etc. As a result of this report, and of further consultations, the SERC under its Chairman, Professor *Bill Mitchell*, decided to reorganize totally its funding of materials research and the Materials Science and Engineering Commission of the SERC was established in September 1988.

The Mission Statement of the Commission has recently been drawn up and is as follows:

The Commission will promote excellence of research and training in both the science and engineering of materials. It will take an integrated view of materials research from synthesis through processing to demonstrator projects. It will seek to maintain and enhance the world class materials research record of the UK. It will encourage the creation of new materials and facilitate the competitive exploitation of materials by British industry in international markets.

The breadth of the Commission can be seen from the titles of the seven committees it controls: ceramics and inorganic materials, polymers and composites, metallic and magnetic materials, semiconductors, superconductors, molecular electronics, and medical engineering and sensors. The Commission and each of its seven committees is multidisciplinary and contains chemists, physicists, materials scientists, electrical engineers, etc. Roughly half the Commission members are from universities and polytechnics and half from industry. The inherited budget of the Commission was about £ 15 m p.a., but in its first year of operation this has been increased to £ 20 m p.a. The increase is a very welcome first step to what is required.

The Commission will determine a coherent SERC strategy for the support of materials research and it will take a leading rôle in identifying national priorities in materials research. In addition to having research priority areas, the Commission fully recognizes that unpredictability is part of the fascination of research, and that many major breakthroughs have been unexpected and unplanned: it will therefore have a balance between funding priority areas and funding high quality research in any area and it will respond quickly and flexibly to the unexpected.

The Commission is very keen on fostering links with Europe and internationally in general. It has already held small scientific meetings with France, Italy and Japan. As we move into the highly competitive age of new materials, the SERC Materials Science and Engineering Commission will do its utmost to ensure that UK universities and polytechnics are at the leading edge of materials research, and that the results are transferred to industry and to medical care.

Professor Colin Humphreys obtained a B.Sc. from Imperial College, London in 1963 and a Ph.D. from Cambridge in 1967. From 1966 to 1985 he was a Research Fellow and then Lecturer in the Department of Metallurgy and Materials Science, University of Oxford. He was appointed the Henry Bell Wortley Professor of Materials Engineering and Head of the Department of Materials Science and Engineering at the University of Liverpool in 1985 and from January 1, 1990 his new address will be at the Department of Materials Science and Metallurgy, University of Cambridge. He is a Member of the Electron Diffraction Commission of the International Union of Crystallography, and a Council Member of the Science and Engineering Research Council (SERC) and of the Institute of Metals. His main research interests are electron diffraction and microscopy, semiconductors, superconductors and nanometer scale electron beam lithography. He was published over 160 papers. In 1988 he became the first Chairman of the newly formed Materials Science and Engineering Commission of the SERC.

Advanced Catalysts: Interfaces in the Physical and Biological Sciences

Heterogeneous Catalysis
Molecular Sieves
Biocatalysis
Catalyst Design
Abzymes
Ribozymes

By John M. Thomas*

1. Introduction

It has been established that catalytic materials, one way or another, now account for some 25% of the gross national product (GNP) of the USA. But catalysts have long played a central rôle in the economy of civilized nations. The ancient Greeks and Romans, for example, used biological catalysts (enzymes) for the production of wine and its conversion to vinegar and for the transformation of starch into sugar. They also used alkalis as inorganic catalysts to produce soaps from fats and oils. Nowadays, much of the food we eat and the medicines we take, many of the fabrics and building materials that keep us warm, and almost all the fuels that transport us by road, sea or air are produced by heterogeneously catalyzed reactions. The current world production of ammonia, required as an agricultural fertilizer, is about 120 million tonnes per annum. Owing to the expanding need to feed mankind, this figure is increasing at some 6% per annum. Vitamins and drugs, herbicides and pesticides, as well as a range of foodstuffs including margarine are all the products of catalysis. Catalysts are the cornerstone of the chemical industry, which, in contrast to many other sectors of the (UK) economy, continues to flourish (Figs. 1 and 2).

Most of the catalysts used for commercial processes are heterogeneous, being composed either of metals or alloys (usually supported on high area oxides), of oxides or sulfides, or of microporous, microcrystalline aluminosilicates known as zeolites. Increasingly, biocatalysts such as enzymes, immobilized on high-area solid supports, as well as appropriate micro-organisms are utilized for the production of certain key foodstuffs and pharmaceuticals (Table 1).[3]

The first patent encompassing heterogeneous catalysts was taken out by an Englishman named *Peregrine Phillips* who, in 1831, described how sulfuric acid could be manufactured by passing sulfur dioxide and oxygen over finely divid-

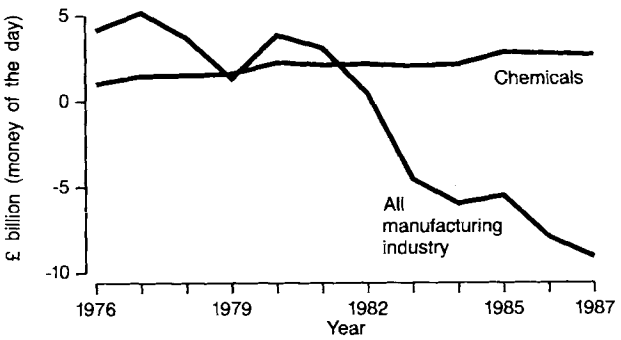

Fig. 1. U.K. Trade balance in chemicals and all manufacturing industry [1].

Table 1. Current industrial scale applications of immobilized biocatalysts [3].

Application	Enzyme	Microorganism
Steroid conversions	11-β-hydroxylase (EC 1.14.15.4)	*Curvularia lunata*
	Δ¹-dehydrogenase (EC 1.3.99.4)	*Arthrobacter simplex*
Glucose isomerization	Xylose (glucose)-isomerase (EC 53.15)	*Actinoplanes sp.* *Arthrobacter sp.* *Bacillus coagulans* *Streptomyces sp.*
Raffinose hydrolysis	α-D-galactosidase (EC 3.2.1.22)	*Mortierella vinaceae*
Starch saccharification	Glucoamylase (EC 3.2.1.3)	*Aspergillus niger*
Lactose hydrolysis	β-D-galactosidase (EC 3.2.123)	*Aspergillus niger*
6-APA from penicillin	Penicillin acylase (EC 3.5.1.11)	*Eschericia coli*
Optical resolution of α-amino acids	Amino acylase (EC 3.5.1.14)	*Aspergillus oryzae*
L-aspartic acid from fumaric acid	Aspartase (EC 4.3.1.1)	Eschericia coli (EC 3.5.2.2)
L-malic acid from fumaric acid	Fumarase (EC 4.2.1.2)	*Brevibacterium ammoniagenes*
D-phenylglycine from D,L-phenylhydantoin	Hydantoinase (EC 3.5.2.2)	*Bacillus brevis*
Acrylamide from acrylonitrile	Nitrilase (EC 3.5.5.1)	*Corynebacterium sp.*
L-phenylalanine	Transaminase (EC 3.6.1.58)

[**] Based on the Presidential Address to the Chemistry Section, British Association for the Advancement of Science, Sheffield, September 1989.

I am grateful to *Barnaby Smith* for his help in preparing this paper and to the Laura Ashley Foundation for the award (to B. S.) of a school-leaver fellowship. Support from the Science and Engineering Research Council is also appreciated.

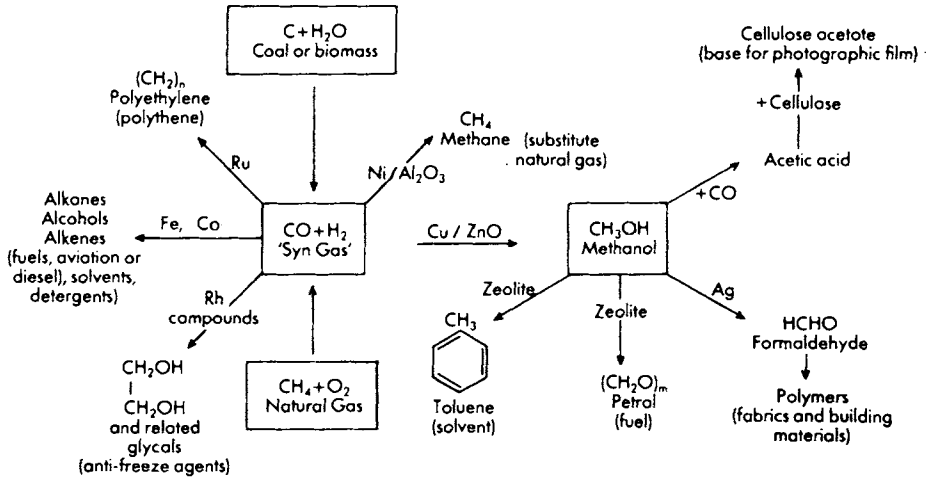

Fig. 2. Synthesis gas (abbreviated 'syngas') is a mixture of carbon monoxide and hydrogen and may be produced either by oxidizing coal or by burning methane. A wide variety of products can be generated from 'syngas' using the appropriate catalyst. Fischer-Tropsch catalysts such as Fe or Co (extreme left) promise to provide (from coal as primary feed-stock) exceptionally clean fuels [2].

ed platinum supported on clay. Platinum continues to play a pivotal rôle in modern catalysis; it serves to isomerize (reform) linear hydrocarbons, such as those initially produced by the (zeolite-catalyzed) cracking of oil, to their branched and aromatic analogs, many of which have high octane ratings. Platinum, and its congener rhodium, also finely divided and supported on alumina and ceria, are the center pieces of the automotive exhaust catalysts, which reduce emissions of undesirable gases into the environment (Table 2). Some forty million auto-exhaust catalytic units were installed on light vehicles in 1988 alone. Over a third of the world's available platinum is now used in auto-exhausts. Platinum is also of central importance in electro-catalysis which is a primary feature of the fuel cell, where electricity is generated directly by the electro-chemical combustion of hydrogen or methanol.

Table 2. Decrease in emission rates per mile driven since the introduction of auto-exhaust catalysts in the USA.

Pollutant	Percentage Decrease
Carbon Monoxide	86
Nitrogen Oxides	56
Hydrocarbons	84

2. Mechanisms of Catalysis

Much mystery still surrounds our knowledge of how heterogeneous catalysts function. The auto-exhaust catalysts that convert nitric oxide, carbon monoxide and hydrocarbons to harmless products, are less complicated than other multiphasic and multicomponent inorganic catalytic solids. The situation is also less complicated for the so-called uniform heterogeneous catalysts in which all, or almost all, of the atoms in the bulk of the solid participate directly, or are implicated indirectly, in the catalytic processes of the overall reaction.

Examples of uniform catalysts are zeolites, silico-aluminophosphates (SAPO's) – see later – as well as certain clays and pillared clays. In all these cases, the active sites are uniformly distributed in the bulk of the solid. Because of the microporosity of these structures, however, the active sites are accessible only to gaseous reactant species of the requisite size and shape. Uniform heterogeneous catalysts, primarily because their structures may be elucidated by the traditional techniques (especially X-ray crystallography) applicable to the study of bulk solids, are therefore very well characterized in comparison with heterogeneous catalysts consisting of supported or multiphasic solids.[4, 5] Detailed discussions of how catalysts function have been given elsewhere.[4, 6]

The zeolitic and SAPO-based catalysts frequently function in a dual manner. First, they provide, at specific (active) sites within the accessible pores, protons that are effectively the catalytic agents. Second, their well-defined porosity, in which the apertures in the form of cages and channels – at the internal surface of which the active sites are situated – permit access to those reactants that are of the requisite size. This shape-selectivity for the reactants, is often accompanied by a similar shape-selectivity for the products, since only those generated species that are small enough are able to diffuse out from the interior of the catalyst.

Uniform heterogeneous catalysts possessing zeolitic character are much more akin to enzymes in their mode of action than to the multiphasic inorganic solids, typified by the ammonia synthesis catalyst (which consists of iron and the oxides of potassium, silicon, aluminum and combinations thereof[7]) or by the iron–potassium based industrial cata-

lysts for the conversion of ethylbenzene to styrene. This catalyst has recently been shown[8] by in situ X-ray diffraction study to contain Fe_3O_4, $KFeO_2$ and $K_3Fe_{22}O_{34}$.

Paradoxically, much more is known about the structure of the active sites in enzymes than those in metallic or oxide catalysts, even though their overall structures and constituent parts are substantially more complicated than those of the metals and oxides in extensive industrial and laboratory-scale use. Enzymes generally have active sites which consist of pockets, or clefts, the lining of which contain the crucial set of amino acids, in the right sequence and conformation required to 'process' the reactant species.[4]

3. Trends in the Design of New Catalysts

In addition to the logical extensions and improvements that are being pursued for existing catalysts, there is also intense activity focused on the creation of radically new ones. Not only are there advances occurring in heterogeneous catalysis, which has hitherto dominated the commercial scene, there are nowadays significant developments in biocatalysis, in homogeneous catalysis and in the evolution of fundamentally new types of catalysts. Some of these are rooted in the inorganic, inanimate world, others very firmly in the biological and animate.

3.1. New Heterogeneous Catalysts

Table 3 highlights the areas currently attracting considerable attention both at the fundamental and applied level.

Table 3. Current trends in the evolution of heterogeneous catalysts.

Tailored Solids
Development of stereoselective catalysts based on pretreated metals (e.g. Ni, Pt) and on immobilized transition-metal complexes.
Membrane (e.g. metal alloy) catalysts for single-stage synthesis.
Molecular sieves in which cage and channel dimensions are controlled.
Development of new oxide-based solids capable of the sacrificial loss of structural oxygen for selective oxidation of hydrocarbons
Schottky-junction (metal on oxide) catalysts [a]
Fine-tuning of Fischer-Tropsch catalysts (based on Fe, Co, Ru) so as to generate ultra-clean hydrocarbons from CO + H_2 mixture derived from coal.
Photocatalysts
Design and preparation of solids, the electronic band-gap of which are engineered (as in the fields of semiconductor physics and opto-electronics)
Quantum solids (ultra fine particles in 20 to 500 Å diameter range) with and without enclathration.
Electrocatalysts
New designs and components for fuel cells (for energy generation).
Derivatized electrodes (for sensors and other analytical purposes).

[a] See J. C. Frost's discussion on junction effects in catalysts for methanol synthesis (*Nature London 334* (1988) 577).

Stereoselective catalysts, which are capable of producing an enantiomeric excess of a given species from a prochiral precursor, are of growing importance. Chirality, after all, holds sway in living processes and is hence of enormous relevance in the quest for catalysts needed for the generation of pharmaceuticals. Until about the early 1960s, access to enantiomerically enriched compounds from prochiral reactants was thought to be realizable only by biological or enzymatic methods.[9] However, at least a decade earlier, some fascinating Japanese work[10] had indicated that a special preparation consisting of metallic palladium supported on silk served as a heterogeneous catalyst for the asymmetric reaction involving the hydrogenation of oximes and ketones. Since that time Ziegler-Natta catalysts for the asymmetric polymerization of olefins, as well as specially modified Raney-nickel heterogeneous catalysts, have been used extensively for asymmetric conversions. Of late so-called Lindlar catalysts,[10, 11] in which the surface of the palladium is modified by the deliberately added lead 'impurities', have been extended to encompass Pd-Pb alloys, which function as efficient means of effecting stereoselective hydrogenations for the synthesis of insect sex pheromones.[12]

The scope for tailoring metal catalysts by pre-adsorbing upon their surfaces bulky organic molecules which create prochiral cavities for the incoming reactant is obviously considerable. *Wells* et al.[13] have re-examined the Orito reaction[14] in which platinum, modified by the presence of presorbed cinchonidine (a member of the cinchona alkaloids), becomes active for the stereoselective hydrogenation of an α-ketoester (e.g. methyl pyruvate) to an optically active product (e.g. *R*-(+)-methyl-lactate, Fig. 3). My colleagues

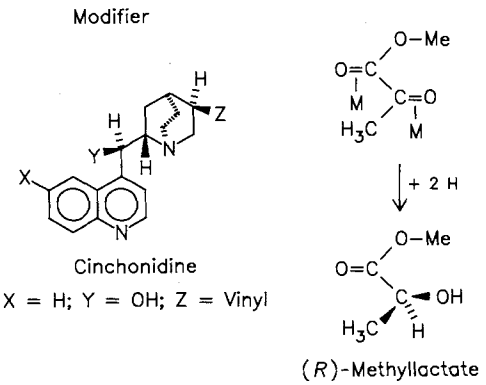

Fig. 3. Cinchonidine preadsorbed on a platinum catalyst favors the hydrogenation of a co-adsorbed α-ketoester to the optically active *R*-methyl lactate [13].

and I[15] have explored, by computer graphics (see Fig. 4), the way in which this stereoselective process might proceed. The plausible assumption here is that cinchonidine forms an ordered, well spaced out array of interstices in the sorbed layer. The interstices permit ingress of the methyl pyruvate in a preferred fashion so as to pre-ordain the formation of a given stereo product.

Membrane catalysts such as those based on palladium or on binary alloys of palladium with one of a dozen or more other metals – Al, Ti, Ni, Cu, Mo, Ru, Rh, Ag, In, W, Re and

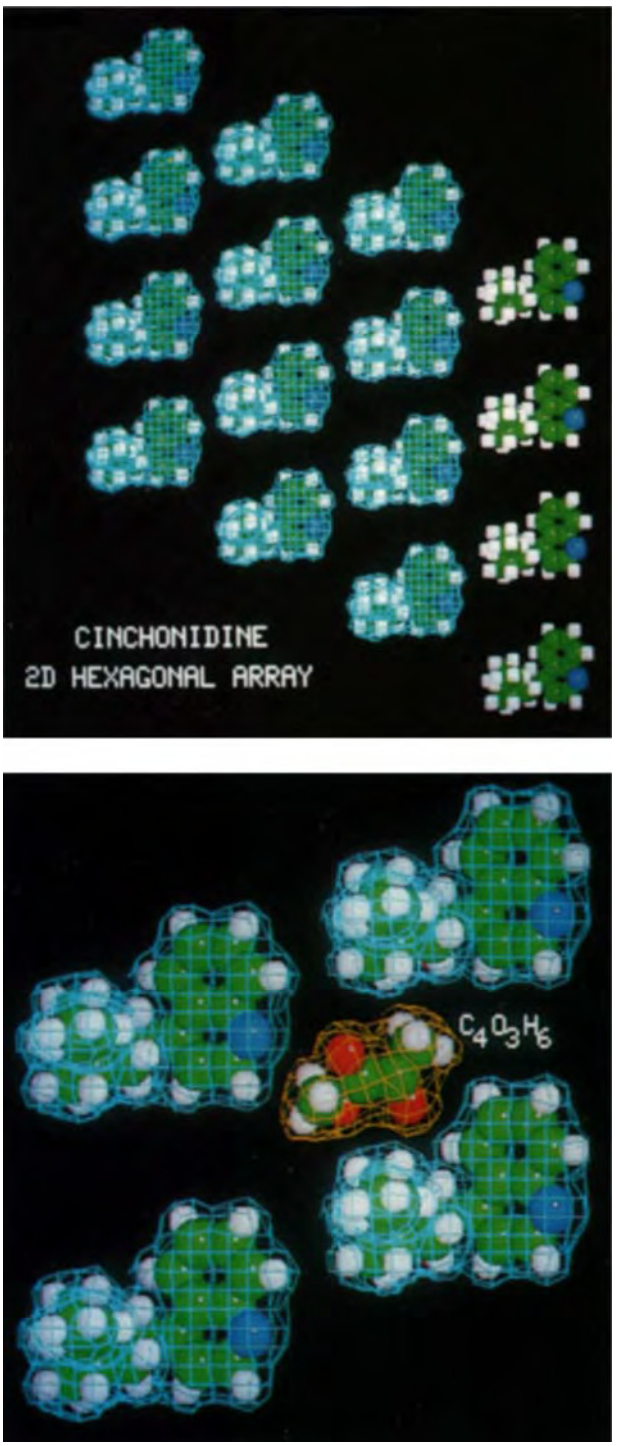

Fig. 4. (a) Schematic illustration of the way in which cavities in the ordered monolayer of cinchonidine (on a platinum surface, which is not shown) may serve as centers where a prochiral reactant may be stereo-preferentially adsorbed as in (b). This preordains the production of an enantiomeric excess of the methyl lactate formed by catalytic reduction on the modified metal surface. (After *Barnaby Smith* et al. [15]).

Pt – are permeable to hydrogen but not to the organic compounds which are to be hydrogenated. Hydrogen transfer through such membrane catalysts which are in the form of foils or thin-walled tubes, provides a new method of influencing the addition or removal of hydrogen. The Soviet scientist *Gryaznov*[16] has carried out pioneering studies of this new type of catalyst, which has already been brought to commercial use in the one-stage production of vitamin K_4, as shown in Figure 5.

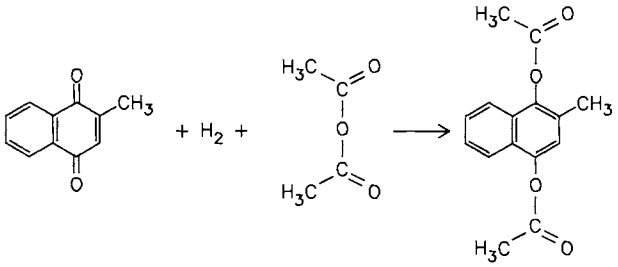

Fig. 5. One-stage production of Vitamin K_4 on a permeable palladium membrane catalyst [16].

Palladium-based binary alloys consisting of yttrium have also recently been used,[17] as membrane catalysts, for the production of hydrocarbons from synthesis gas ($CO + H_2$ mixtures). Recognizing that palladium surfaces are remarkably efficient catalysts for the trimerization of acetylene to benzene[18] and the synthesis of thiophene[19] from adsorbed acetylene and sulfur[20] (see Fig. 6), it ought to be

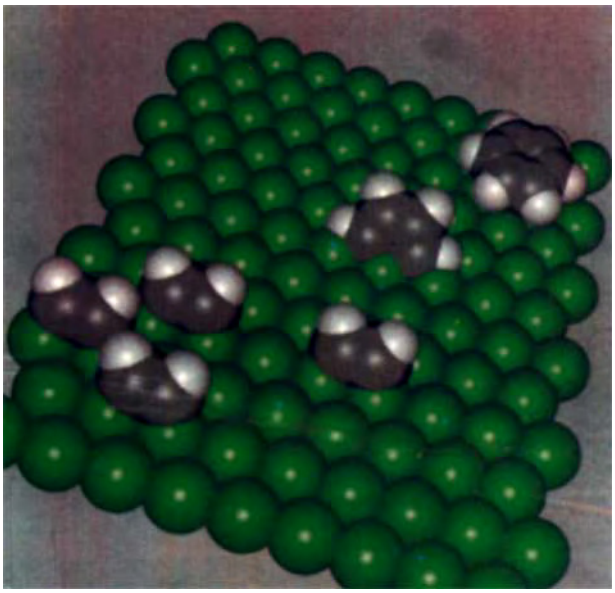

Fig. 6. Schematic illustration, after *Gellman* [19], showing how a close-packed surface of palladium metal catalyzes the trimerization of acetylene, via intermediates, to benzene.

feasible to so design a system, consisting of a membrane catalyst based on this metal, capable of selectively synthesizing partially hydrogenated aromatic and heterocyclic compounds.

Molecular sieve catalysts are already widely used[4, 20–23] in the hydrocracking of oil and petrol, in the synthesis of

petrol from methanol, in alkylations and isomerizations; and their increasing rôle in laboratory-scale synthesis and conversions continues to expand.[23–25] A selection[25–27] (taken from other publications) of interesting catalytic reactions, of value in the production of fine chemicals, is shown in Figure 7.

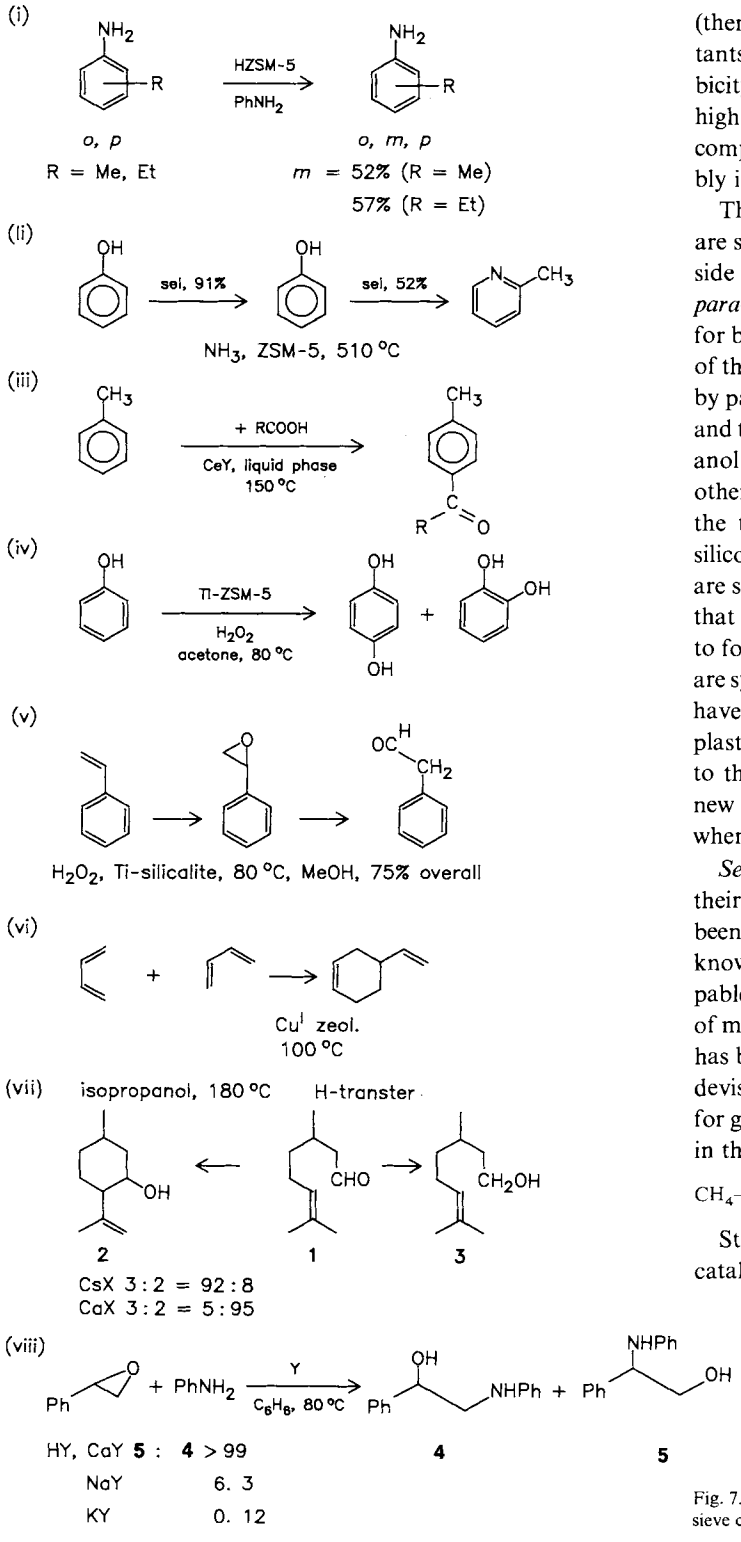

Fig. 7. A selection of some of the organic reactions catalyzed by molecular sieve catalysts. (After *Van Bekkum* [25] and *Thomas* and *Theocharis* [24])

These and other reactions, for which the appropriate microporous solid catalyst has yet to be developed, are or will be rendered possible through the special characteristics of zeolitic solids viz: a sharp, well-defined pore-size distribution; good thermostability; adjustable Brønsted or Lewis acidity; a wide range of exchangeable cations of different radius or polarizability; adjustable size and morphology (thereby allowing scope to modify diffusion times of reactants and products); adjustable hydrophilicity or hydrophobicity (according to whether the Si/Al ratio is low (1.0) or high (> 20) respectively) an ability to accommodate metal complexes, some of which are so bulky as to require assembly inside the cavities and channels.

The channel dimensions of the well-known zeolite ZSM-5 are such that, when methanol is catalytically dehydrated inside its pores, only monocyclic aromatics (benzene, toluene, *para*-xylene, etc.) are produced. The channels are too small for bicyclics such as naphthalene to form. This is the essence of the synthesis of petrol from natural gas – methane, which by partial oxidation is first converted to a $CO + H_2$ mixture and then, catalytically, over a copper-based catalyst to methanol – now operating in New Zealand.[30] By assembling another type of molecular sieve, known as SAPO-34, in which the tetrahedrally-coordinated framework constituents are silicon, aluminum and phosphorus, the channel dimensions are significantly smaller than those of ZSM-5 (see Fig. 8) so that it is not now possible for even the monocyclic aromatics to form. Instead olefins such as propene and other α-olefins are synthesized. This is an important advance as the α-olefins have a variety of end uses: components of solvents, textiles, plastics, plasticizers and surfactants. More details pertaining to the general principles of the design of new zeolites and new AlPO-based molecular sieve catalysts are given elsewhere.[4, 31, 32]

Selective oxidation catalysts, especially those that release their own structural oxygen in a sacrificial fashion, have been known for some time. Of late, however, an increased knowledge of the solid-state chemistry of solids that are capable of accommodating large, steady-state concentrations of mobile vacancies created by the loss of structural oxygen has been acquired. This will make it increasingly possible to devise novel solids capable of catalyzing reactions that have, for good reasons, been regarded as very difficult to cope with in this way. One such example is:

$$CH_4 \xrightarrow{(O)} C_2H_6 + C_2H_4 + C_2H_2 + \text{other products}$$

Strenuous efforts will continue to be made to devise new catalysts for other reactions in which there is an abundance

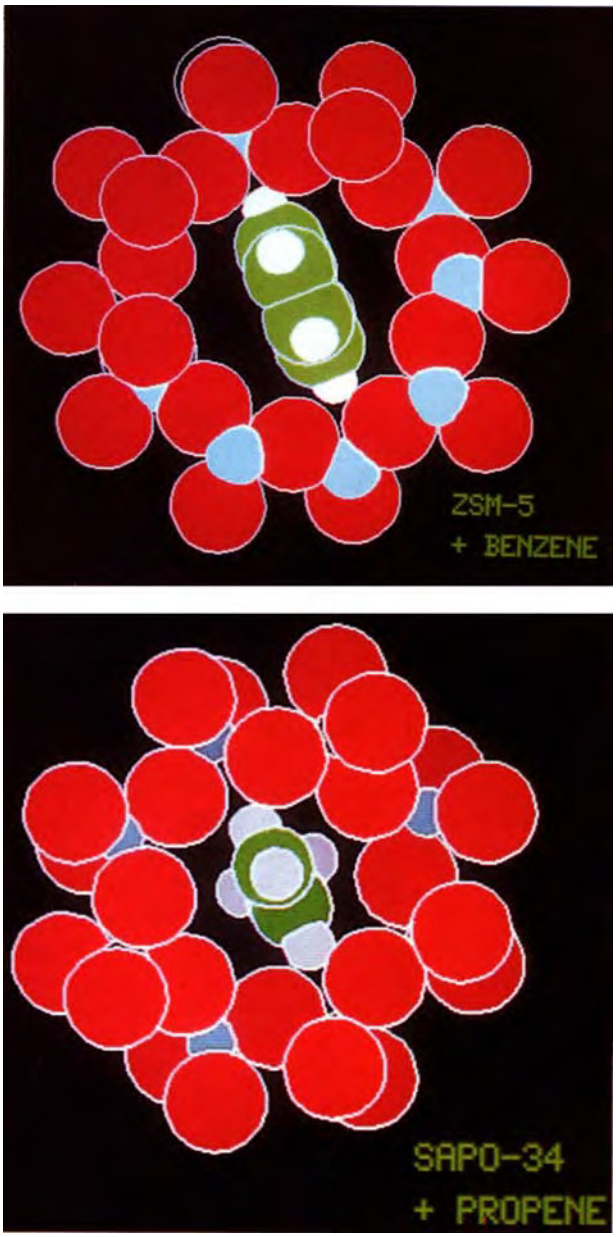

Fig. 8. When methanol is catalytically dehydrated over a molecular sieve (acid) catalyst, the nature of the products is governed by the dimensions of the channels. (a) Over a ZSM-5 catalyst, the channels are large enough to permit the formation of benzene. (b) Over a SAPO-34 (acid) catalyst, which has smaller pores, the dehydration yields only alkenes such as propene. (After *Yan Xu* and *Barnaby Smith*, unpublished).

of reactants e.g. nitrogen to nitrates, carbon dioxide to formates and fossil material to more useful hydrocarbons. Insofar as producing clean hydrocarbons (for fuels or packaging material) is concerned, there in renewed interest in Fischer-Tropsch catalysis based on iron, cobalt or ruthenium. Thus, coal or natural gas, when gasified to $CO + H_2$ mixtures, can be satisfactorily purged of sulfur, nitrogen and other environmentally harmful heteroatoms. Using catalytic systems such as the Shell middle distillate process, which by Fischer-Tropsch catalysis converts the $CO + H_2$ mixtures to a suite of hydrocarbons of controllable ranges of molecular weight, an abundance of high-quality hydrocarbons is created. Recognizing that world coal supplies will persist for many more centuries, this is an important development.

One may expect that, with our increased knowledge of the factors that influence the magnitude of the electronic band gaps of solids, and the preparative requirements for their production, important developments are likely in the field of photocatalysis. With the practice of band-gap engineering, well established in the design and preparation of solids for specific optoelectronic purposes, it would be surprising if new photocatalysts were not developed in the near future. In this connection, the realization that very finely divided solids (such as the binary III–V and II–VI semiconductors) possess band gaps larger than those of their bulk analogs offers further scope for the preparation of new photocatalysts, especially when they can be stabilized by enclathration inside zeolitic or analogous hosts.

3.2. New Homogeneous Catalysts

Whilst it is not the aim of this review to encompass homogeneous catalysts, a few comments are in order since renewed efforts are now underway to improve methods of immobilizing homogeneous catalysts on inert, durable and large surface area solids. The performance of all homogeneous catalysts could, in principle, be improved by anchoring them on to an appropriately derivatized microporous solid. More often than not, however, the support tends to diminish the effectiveness of the dispersed catalyst, either by reducing its turnover frequency or its selectivity. The supreme advantage that immobilization confers, whether it be on inorganic[33] or polymeric[34] supports, however, is the ease of separating product from reactant.

Some of the materials that ought to be relatively easy to tether to an appropriate solid surface are the metal complexes. And it is these very materials that have recently shown extraordinary efficiency as entioselective catalysts in the important field of chiral synthesis. The work of *Noyori*[9] and others[35, 36] testifies to the significance of asymmetric reactions generally. Among other things, we note that impressive entioselectivities, rivaling those attained via the use of enzymes, have been achieved using metal-complexes.

It is convenient to illustrate the strategy employed by reference to the recent elegant work of *Pfaltz*,[35] who has introduced transition-metal semicorrins, schematized in Figure 9. The C_2-symmetry of these transition-metal complexes ($M = Co^{II}$, Ni^{II}, Pd^{II} or Cu^{II}, as well as other ions) is readily apparent. The chirality elements are dictated by the size and nature of the R groups, which are in close proximity to the coordination center.

With the aid of Figures 10 and 11 we see how these semicorrin complexes function as enantioselective catalysts. Assuming that the transition state of the enantioselectivity-

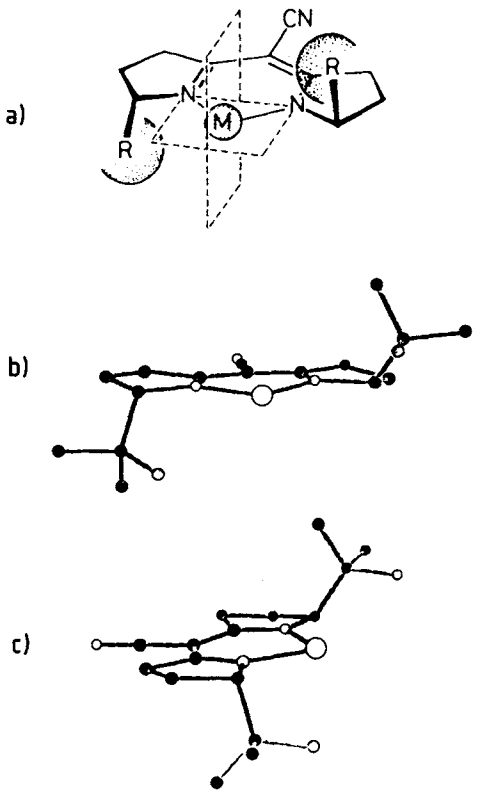

Fig. 9. The C_2-symmetry of the semicorrin ligand is illustrated in (a). The two substituents, R, at the stereogenic centres are held in close proximity to the coordination center (metal M) by the rigid framework of the semicorrin ligand. (b) and (c) represent molecular models when R is a $C(OH)(CH_3)_2$ group. (After *Pfaltz* [35]).

determining step resembles the hypothetical π-complex depicted in Figure 10, the observed selectivity may be ratio-

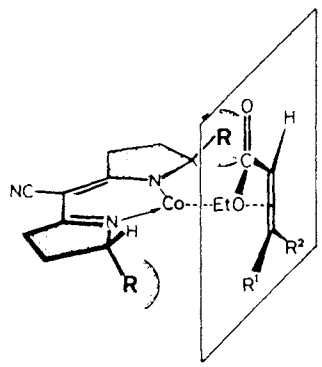

Fig. 10. The transition state for the (semicorrinato) cobalt-catalyzed reduction of α,β-unsaturated carboxylic esters is thought [35] to be of this kind.

nalized in the following manner. The ester group occupies a sterically unencumbered site of the coordination sphere, whereas the olefinic H-atom is placed in a sterically more crowded environment (Fig. 11 A). However, the transition structure leading to the opposite enantiomer (Fig. 11 B) is

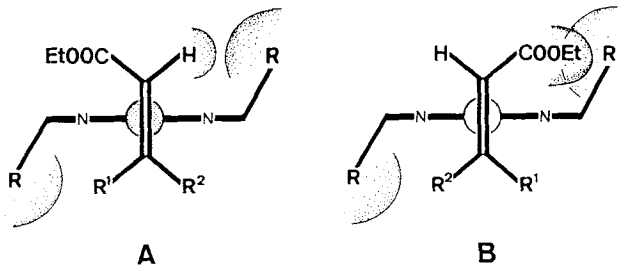

Fig. 11. Illustration of the possible origin of enantioselection. For steric reasons the transition state, represented by B, is forbidden, and that shown in A is likewise preferred [35].

expected to be considerably destabilized owing to steric repulsion between the ester group and the adjacent substituent of the semicorrin ligand.

When such elegant design can be introduced to fashion powerful homogeneous catalysts of this kind, there will be a great incentive to devise a 'tea-bag' version[37] of the immobilized catalyst, where the active catalyst may rattle around in its (molecular) container, be accessible to the reactant, and from which product may be washed away so as to regenerate the original catalyst.

3.3. Enzyme Catalysis

It has long been recognized[38, 39] that enzymes have great potential as catalysts for use in synthetic organic chemistry; and their importance in this, and other contexts, is underlined by the processes enumerated in Table 1. Increasingly, a number of small-scale syntheses of materials used in analytical procedures (such as derivatized, biological sensors), in research and as chiral building blocks (synthons) for the production of pharmaceuticals and fine chemicals, is under development. An important trend is the change in technology for the production of enzymes – partly because of improved methods from classical microbiology, and partly because of the viability of genetic engineering, in particular site-selective mutagenesis – for their stabilization and manipulation now makes these catalysts practical for far broader use than hitherto in large-scale synthetic organic chemistry.[38]

The main impetus for biotransformation studies, using enzyme catalysts as center pieces, has been the continued growth in demand for enantiomerically pure compounds. In this context, advantage is taken of the high stereospecificity of the actual reactions catalyzed. Advantage is also taken of the regioselectivity of enzyme-catalyzed reactions. Examples may be found in the selective esterification of dicarboxylic acids, the selective hydrolysis of compounds containing ester functions (e.g. sugar esters) and the selective reduction of compounds containing multiple carbonyl groups.[39]

For the materials scientist, one of the significant messages here is that enzymology is now playing a growing rôle in governing the strategies for the modification of materials

derived from fermentation synthesis. Another is the exigent need to evolve more satisfactory means of immobilizing some of the several dozen or so commercially available and useful enzymes, as well as the many more that have recently come to light but which are not yet so readily obtainable.

3.4. Trends in Biocatalysis

Because most enzymes operate effectively under mild conditions (pH usually between 6.5 and 8.5 and at around room temperature) it is often possible to assemble complex systems containing multiple enzymes operating in sequence or in parallel to achieve multi-step processing of the reactants. The work of *Knowles* and *Whitesides* et al.[40] on the synthesis of ribulose 1,5-diphosphate (RuDP), an important substrate in plant biochemistry constitutes a nice example. The point of chief technical interest here is the final conversion of 6-phosphogluconate to RuDP. The kinase that converts ribulose-5-phosphate to RuDP is oxygen sensitive. Thus, the in situ regeneration of NAD from NADH required in the conversion of 6-phosphogluconate to ribulose-5-phosphate cannot be carried out using an oxygen-based regeneration system. The regeneration is, however, conveniently carried out anaerobically using the α-ketogluconate/glutamate dehydrogenase system. This part of the synthesis requires the cooperative action of four enzymes: 6-phosphogluconate dehydrogenase and 5-phosphoribulokinase for the principal conversions, and glutamate dehydrogenase and acetate kinase for in situ regeneration of cofactors.

It may be seen, therefore, that multi-enzyme 'cocktails' constitute a useful way of producing novel biocatalysts. However, there are other ways forward; and these are summarized in Table 4.

Table 4. Current topics and trends in biocatalysis.

Use of:	(i) Multi-enzyme systems (ii) 'Whole cells' and micro-organisms, (e.g. Bacteria such as *Methylococcus capsulatus* (Bath) and baker's yeast).
Antibodies as enzymes (abzymes) [a].	
RNA as enzymes (ribozymes) [b].	
Genetic and chemical modification of enzymes (protein engineering).	
Man-made (miniature) enzymes.	

[a] See P. G. Schultz et al. *Angew. Chem. Int. Ed. Engl. 27* (1988) 1172; *Angew. Chem. 100* (1988) 1227. [b] See T. R. Cech, *Nature 339* (1989) 507, for a discussion of the idea that RNA molecules may exhibit catalytic activity.

It is often not necessary to extract an enzyme or a collection of enzymes from the living cell. The latter may be used as such; and whole cell catalysts are nowadays in quite common use, either in their suspended or immobilized state, on an inert solid (often derived from a heat-treated clay). In microbial biotechnology, one uses the microbes as such to catalyze a highly specific chemical change. Both ICI[41] and Shell[42] have put to good industrial use the microbial catalytic conversion (fermentation) of benzene and some of its derivatives to *cis*-3,5-cyclohexdiene-1,2-diol (Fig. 12).

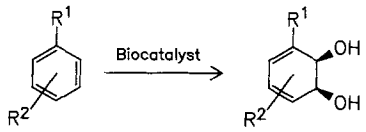

Fig. 12. The process of dioxygenation of substituted benzene (where R_1 and R_2 may, for example, be CF_3 and H respectively) is catalyzed using soil bacteria [42].

Certain enzyme systems, operating in vivo, catalyze hydrooxylations, epoxidations and related oxidation reactions with selectivities unparalleled by any other procedure. They are of great value in the oxidative functionalization of steroids and other hydrocarbons (using fungal systems).

There is a bacterium, known as *Methylococcus Capsulatus* (Bath),[43] a soluble methane monooxygenase, that converts methane to methanol at room temperature. Its mode of action, in particular its regio- and stereo-selectivity, when catalyzing the conversion of cyclohexanes consists of at least three components.

Though other microorganisms have been used to catalyze the (bio) reduction of ketones, it has recently been reported[45] that baker's yeast efficiently catalyzes the reduction of $Cr(CO)_3$-complexed aromatic ketones. Increased enantiomeric excess, over that achieved by other catalysts, and kinetic resolution of planar chiral complexes is feasible with the yeast (Fig. 13).

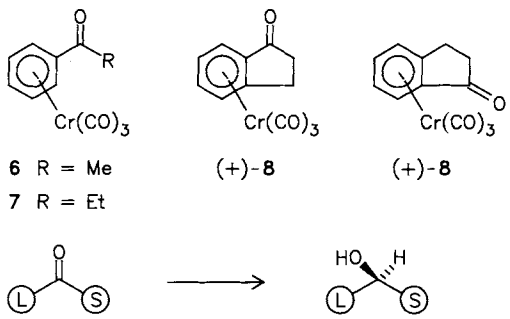

Fig. 13. Aromatic ketones, such as those shown in (1) to (3) when complexed with chromium carbonyl, undergo enantioselective reduction using baker's yeast [45]. The (*S*)-alcohol is always obtained preferentially, indicating that the reduction follows the so-called Prelog rule (Scheme 1; the large substituent L represents the aromatic group)

Abzymes (or catalytic antibodies) have appeared on the scene very recently. Their existence arises because of a question posed more than a decade ago: Can antibodies be made to serve as enzymes? (The term abzymes is a hybrid of *ant*i*b*odies and en*zymes*).

Nature, it is believed, utilizes no more than about 30 to 40 thousand enzymes to effect all the bewildering range of coupled processes responsible for the teaming manifestations of

life. So far as practical applications—outside of life cycles—are concerned, the limitation of enzymatic catalysis is that there are so few enzymes compared with the enormous numbers of scientifically important chemical reactions which one seeks to catalyze. Antibodies, like enzymes, are proteins. Their structural features complement, in a literal sense, those of the antigenic sites of intruder species. They have the ability to recognize foreign substances, and are of breathtaking diversity. The immune system, which is where antibodies are generated, is able to make over a 100 million different kinds of antibodies.

Both antibodies and enzymes exert their influences in much the same way: by binding to other molecules. The question therefore naturally arises: Can one capitalize upon the similarity of antibodies and enzymes (as molecular recognizers) to make the former act as biocatalysts? If so, the door is opened to an almost limitless range of new catalysts. However, antibodies, in their normal rôle, do not catalyze chemical transformations. The way in which they have been recently 'cultured' to function as catalysts, is by feeding the immune system with a stable structural analog of the transition-state through which a particular reactant molecule must pass to be transformed. The antibody will then bind that 'transition state' and its precursor, enabling the free energy with which antibodies bind to their targets to be harnessed in a catalytic process. This kind of abzyme chemistry is in its infancy. But it is already clear that it has a major rôle to play in biological and medical science.

Rationally modified enzymes may be produced by means of site-directed mutagenesis. Such enzymes possess significantly different surface charges, pH-activity profiles and (often) high catalytic activities as well as altered specificities compared with their parental analogs. The serine protease subtilisin (from *Bacillus amyloliquefaciens*)[46] has been 'engineered', by site-directed mutagenesis so as to effect all the above-mentioned changes. The human enzyme called tissue-type plasminogen activator has recently been modified by mutagenesis so as to increase its effectiveness in dissolving blood clots. These are pointers for directions that may be taken in the design and assembly of rationally modified enzymes, i.e. to go from the so-called wild to the mutant state.

There is a radically different route that may also be followed, and that entails the assembly of a miniature enzyme, rivaling the performance of the parent which it mimicks. *Bender* et al.[47] have constructed a miniature biological catalyst (see Fig. 14) which has a performance that closely matches that of chymotrypsin. Chymotrypsin itself is a large (MW 24,800 Daltons) and complicated (245 amino acids) enzyme, the function of which is to catalyze the hydrolysis of a variety of esters and amines. From an X-ray analysis of its structure, the constituents of its active site—the lining, as it were, of the pocket into which the reactant falls upon being bound by the catalyst—were determined. This reveals which chemical constituents are essential for the catalytic action. But an engineered miniature catalyst must also be efficient in capturing the reactant: it has to possess accessible pockets of the right size to accommodate the reactant but not too securely, for the reasons given earlier. *Bender* et al. took advantage of the carbohydrates known as cyclodextrins, which are themselves the products of enzymatic decomposition of starch. The α, β, and γ-cyclodextrins have, respectively, six, seven and eight sugar units (Fig. 14) and on a molecular scale they are like truncated cones or bottomless empty buckets. They also have remarkable receptor properties for a range of guests. It is also rather easy to graft small side-groups on to their rim. The net result is an artificial or miniature enzyme, provided the side-groups that are grafted onto the rim are those present, in the right sequence, at the active site in chymotrypsin itself.

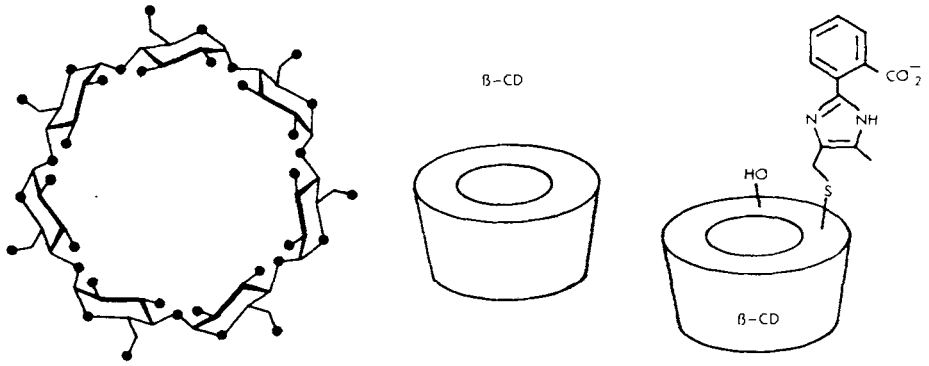

Fig. 14. A miniature enzyme, which rivals the performance of chymotrypsin, has been fashioned by *Bender* et al. [47], from a β-cyclodextrin, which consists of seven sugar units and serves as the receptacle to accommodate (recognize) the substrate molecule. The functional groups grafted on to the rim of the cyclodextrin are the same as those that line the active site of the chymotrypsin. The nature of the active site was determined by X-ray crystallography as in the classic study of lysozyme by *Phillips* [48].

The future of catalysts rests, quite clearly, not on the use of one family of structures, or on one type of catalytic system. It is instead bound up with a rich diversity of disciplines that incorporate major strands of endeavor ranging from solid-state science (physics and chemistry) on the one hand,

through to biological, and medical science (encompassing microbiology and enzymology) on the other. The materials scientist and chemical engineer confronted with the task of evolving new systems for catalytic conversion needs to be a polymathic individual capable of roaming freely, and with discrimination, through this vast field of endeavor.

Materials for the Next Millenium

By Ernest D. Hondros* and Edward Bullock*

Consumption Trends
Technico-Economics
European Performance
Materials Development

1. Introduction – The Materials Spectrum

The materials that make up the things which surround our daily lives and which are taken so much for granted are the product of a highly sophisticated and interactive chain of processes. The mineral-based materials in particular, extracted from the earth as raw ores are converted into alloys, composites and fine ceramics by techniques which call on the utmost ingenuity of man. The complexity of the basic, interactive, scientific disciplines involved in the production of modern, advanced materials is illustrated in Figure 1. The whole spectrum from the minerals in the earth to the formed material component, which has been finely tuned to closely specified properties to meet the requirements of a particular application, is shown.

The intricacy and breadth of such an interdependent chain of processes has evolved over many centuries to meet the immediate needs of society. Progress in materials utilization has largely determined the advance and ascendancy of soci-

ADVANCED MATERIALS

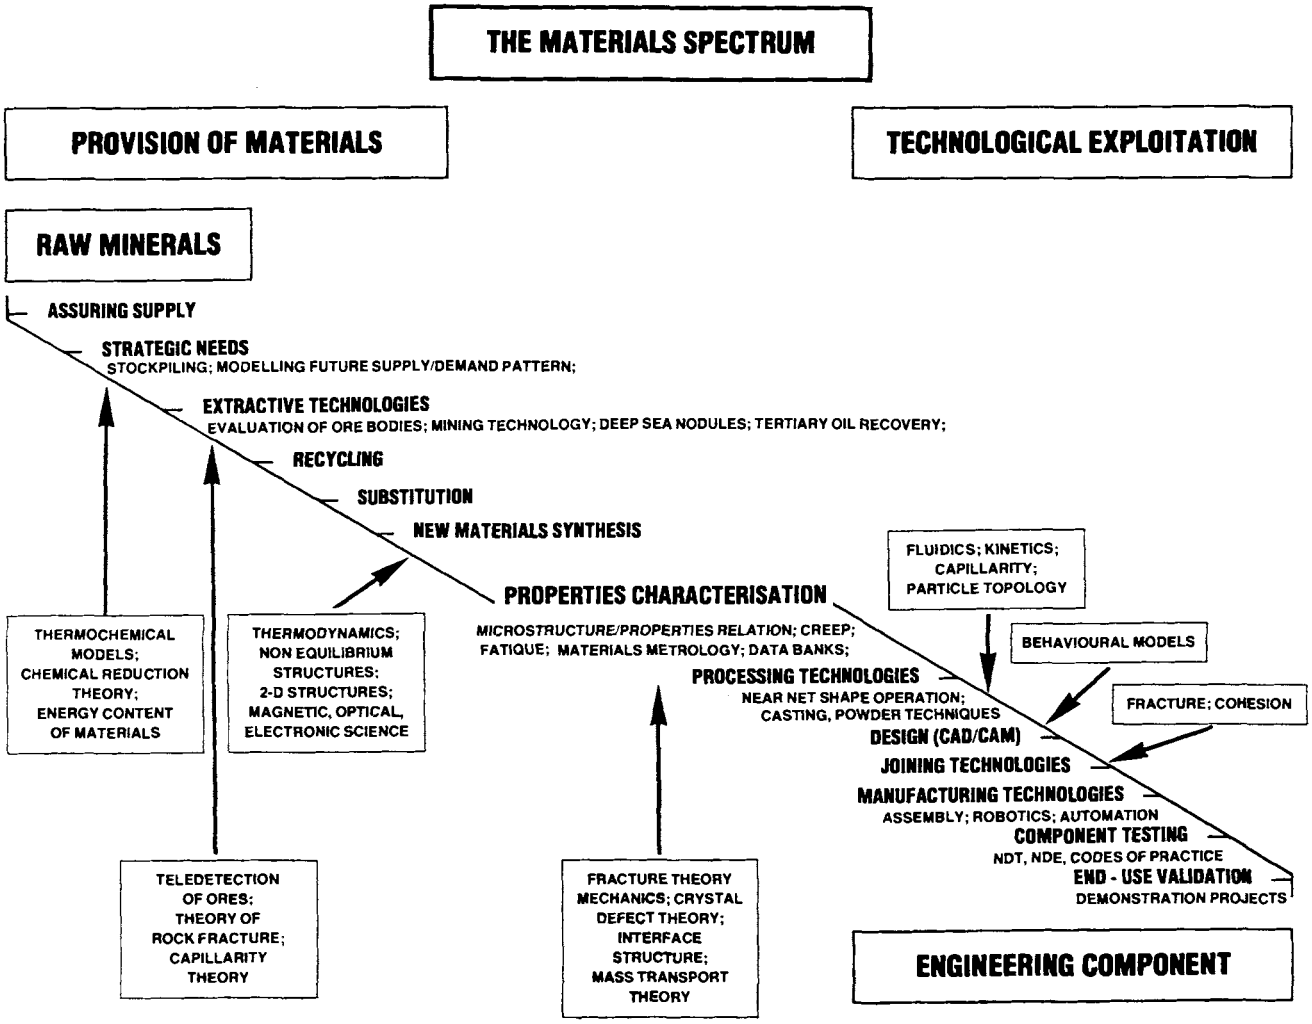

Fig. 1. The materials spectrum.

eties and has always been an issue of high priority. This situation still pertains today and will continue into the future.

As the complexity of materials processes has increased, so too has the volume of use, from the first, relatively insignificant fabrication of artifacts in the Stone Age, through the increasing demands of the Bronze and Iron Ages and accelerating during the last century to the prodigious levels of today. Concurrent with this massive expansion in volume has come a wide diversification in material types as conventional materials are developed to their physical limit and new materials are sought. Thus today in the industrially developed countries, the consumption of iron and steel, and of lead and copper have reached the top of the "S" curve of growth rate with time, while relatively new materials such as plastics, aluminum and composites are growing rapidly, and highly innovative materials, typically engineering ceramics and intermetallics are in the initial stage of slow development prior to mass exploitation.

The trend towards diversity will continue as current high growth rate materials reach their limits and saturate (including perhaps aluminum by the end of the century) to be replaced by new materials. Furthermore, as the demands for materials performance become more exacting, materials will become increasingly tailored to specific performance needs so that the trend will be for the use of combinations of highly specialized materials, each developed for a specific function within the operating system.

2. Materials Consumption Trends – The Global Responsibility

The staggering increase in utilization of the physical resources of the world, quantified in Figure 2 for the US, has led to wide concern that with such continuous growth in materials consumption, there is a danger of global exhaustion.

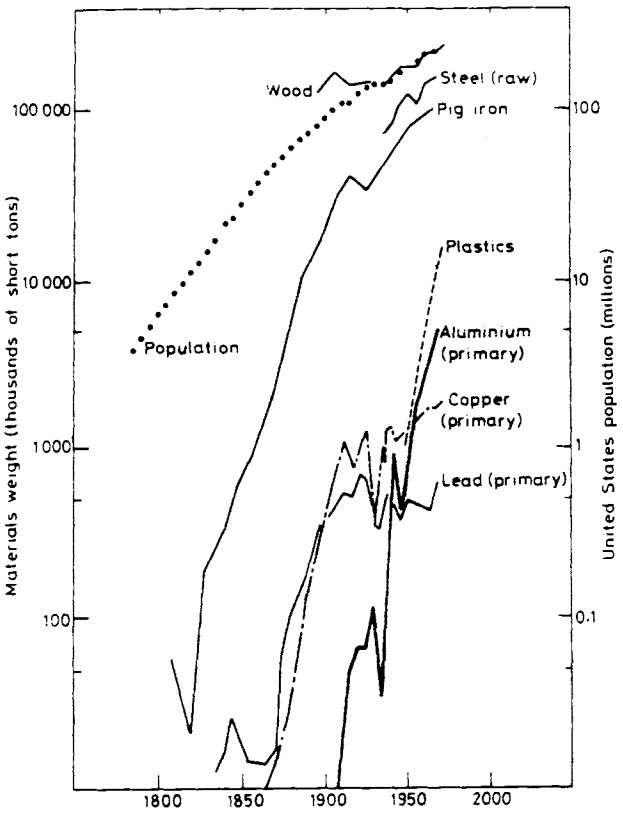

Fig. 2. Growth in usage of industrial materials in the USA compared with population growth.

Such anxieties have preoccupied the attention of strategic economic planners. There have also been signs of alarm among the industrial nations on the continuity of supply of primary materials from third world countries. The significance of the problem can be seen in Table 1 which shows the

Table 1. Import dependence of raw materials by trading areas.

	(% of consumption)			
	EEC	USA	Japan	COMECON
Aluminum	61	85	100	28
Copper	90	14	94	4
Chromium	100	91	98	2
Cobalt	100	98	100	68
Iron Ore	79	36	99	5
Lead	76	13	78	3
Nickel	100	70	100	13
Manganese	100	98	98	3
Tin	87	83	98	
Titanium	100			
Tungsten	99	52		
Zinc	91	57	74	9

amount of some principal metals imported in the form of ores and concentrates as a percentage of consumption. Among the major trading blocs, the dependence on external supplies of raw materials is most critical for Japan. The position of America is somewhat better than for example, the European Community, but nevertheless there has been considerable concern in regard to the more vulnerable strategic metals such as chromium, cobalt, tungsten and manganese, and especially fears that politico-economic movements in the Third World could produce serious restrictions to supply.

The problems of whether the growth in demand in goods and services can continue, and what constitutes the physical limit, have been the source of much agitated public debate in the past years. This was expressed perhaps in its most sensational form in the deliberations of the "Club of Rome" which led to many popular books, presenting the alarmist vision of declining natural resources.

This matter is central to any forecast of the shape of the next millenium in terms of the materials infrastructure. For this reason many analytical methodologies have been applied to the problem of forecasting the demand for raw materials throughout the world in the next century. Indeed, many of the forecast scenarios have appeared alarming.

The analysis we refer to is that of *Malenbaum*[2] who presented the outlook for demand in terms of two component elements – *the intensity of use* and *the total output of final goods and services*. He found that the intensity of use of most materials has been declining in recent years, with the exception of aluminum. The forces giving rise to a declining pattern of intensity of usage, especially in the richer waste producing countries, originate partly from technological developments, from substitutions among the raw materials and from shifts in the types of final product that consumers expect. This development, the decline in the intensity of usage, symbolizes a conscious slackening of Man's consuming appetite for raw materials.

Typical results of this type of analysis are shown in Figure 3 for three elements, chromium, tungsten and cobalt in which the intensity of usage per unit of (GDP) is plotted versus time. This indicates at least saturation in intensity of usage and even in some cases a significant reduction. The broad outcome of this analysis is that by the turn of the century the world will be consuming a volume of raw materials two to three times greater than in the previous quarter of a century. In most cases the ratios are closer to a factor of two. Compared with forecasts of equivalent ratios of five to ten made according to other models, this is an optimistic forecast.

In contrast to earlier anxieties, this represents a hopeful vision of Man and society working in close symbiosis with nature and leading to the reduction in the rates of materials consumption. It represents a conscious trend to limit the consumer appetite of Man. Since analyses of this type were made, there has been time to check on their validity and they appear to be closer to the true pattern of events. This model then is a salutary change from the Doomsday Doctrine, which suggests Man's helplessness in the face of resource exhaustion or of the deterioration of the environment. Given a certain measure of global political stability, this level of demand in raw materials can be met through existing reserves for some hundreds of years.

ADVANCED MATERIALS

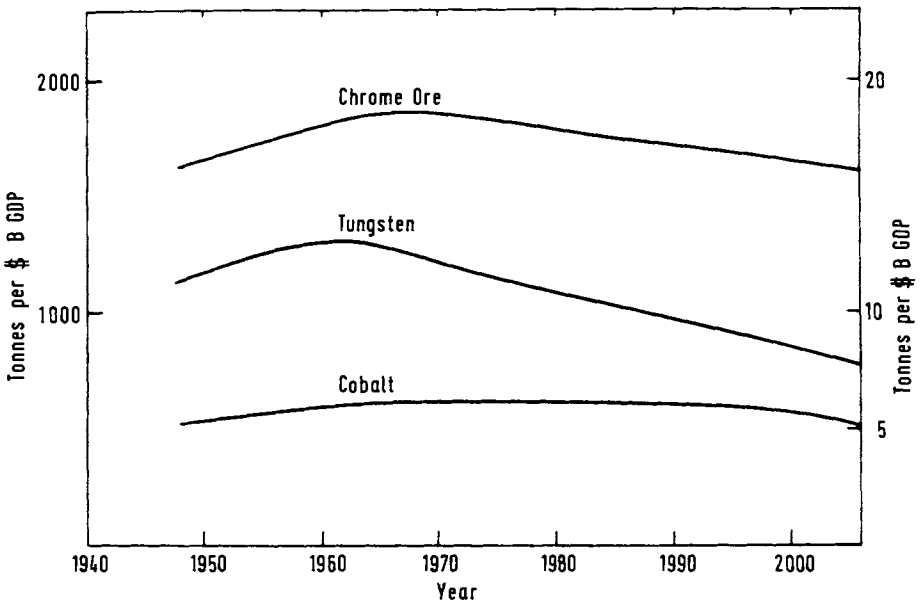

Fig. 3. Changes in intensity of use per unit GDP with time, for chromium, tungsten and cobalt.

Incidently, one conclusion from the above is that the setting of materials science and technology research objectives in terms of the substitution for scarce or unavailable materials is not a tenable assumption.

3. Materials and Future Technologies

It is now widely recognized that materials play an underpinning rôle to the major industries; they provide a substantial framework for the mechanical, chemical, building, process engineering and transport sectors. Hence, the existing euphoria about materials is partly a recognition of the fact that materials represent the rate determining step in the emergence of future technologies and for the competitivity of many existing technologies.

This is illustrated in a dramatic form in the outcome of a survey carried out by the Japanese[3a] to determine the measures that will be necessary to cope with the future requirements in industry, energy, natural resources and the environment. The question was posed as part of a systematic study of the necessary conditions for satisfying human expectations for a stable and prosperous future society. Many distinguished men and women of learning were involved in this "Delphic" type of forecasting methodology, an approach which can be considered as a process of iteration towards a consensus in games of clairvoyance. The outcome of this study, presented in Table 2, is a summary of the principal science and technology innovations for which future realization is expected. The vast amount of information collated and displayed in a chronological manner shows clearly that materials developments per se are some of the high priority items; however, the important observation is that in a large number of items in the forecast it is the materials *factor* which is implied as the rate determining step. In other words, to realize the major technological developments indicated in the table there will be a concurrent need to develop materials with specific functions.

Table 2. Technology Development Forecast (Japan).

2006	Forecasting earthquakes within one month.
2005	Super conductors with critical temperature of liquified nitrogen (77 K).
2004	Means of converting cancerous cells into normal cells.
2003	Steel production from nuclear energy.
2002	Submersible cargo ships: Aircraft and automobiles using hydrogen fuel.
2001	Drugs for arteriosclerosis.
2000	Large scale environmental purification technologies.
1999	Chemical agents for treating clotted cancer growths.
1998	Direct aluminum refining technology (direct reduction). Earthquake prediction through sea-bed crust activity.
1997	Deep sea extraction of metallic nodules. Large scale commercial nuclear fuel reprocessing plant.
1996	Engineering laboratory in space. Three dimensional memory devices.
1995	Deep sea (several hundred metres) drilling technologies. Disposal of high level radioactive wastes by solidification techniques.
1994	Super LSI – 10^9 devices per chip.
1993	Super computer (high speed devices): High efficiency thermoelectric conversion.
1992	Advanced robots for complex working environments.
1991	Long range meteorological forecasting.
1990	Large area amorphous silicon solar cell.
1989	Satellite prospecting (minerals, fishing, agricultural).

It is remarkable that in most of the categories involved in this forecast, technologies are cited which clearly depend on materials developments – thus materials related technologies are destined to be crucial in those innovations that will compose the fabric of the industries and societies of the next millenium. It seems clear that, whether in connection with

the equipment for deep sea mining or for realizing thermonuclear fusion or for replacing diseased human organs or developing large area solar conversion cells, the critical step in the realization of all these innovations will be the advent of the materials precursor.

From such a broad recognition of the rate determining rôle of materials technologies, most of the industrialized countries have recently launched programs with central government support in order to stimulate growth in materials innovations. As early as 1980 the USA in its National Materials and Minerals Policy Act highlighted the critical importance of minerals and materials to the national economy, defence and standard of living and urged the government to intervene in areas where there is a potential for high "payoff" technology. At the same time, Japan has galvanized its institutions into action and has mobilized behind advanced materials, including fine ceramics, polymers, amorphous metals and composite materials. The same note is being struck in many places and at different levels of action—in fact with a strangely repetitive beat. In the UK the *Collyear* report recommended a program of the order of a hundred million pounds over five years in new materials, equally financed by industry and government. In Germany, the German Federal Ministry for Research and Industry (BMFT) has implemented a large materials research program, to continue over about ten years, with links between the universities and the public sector in order to procure close collaboration. In France the Materials Mission has been published which is aimed at the establishment of a mobilization program to double government investment. Similarly there have been materials proposals in the Netherlands, in Belgium, more recently in Italy and currently in Spain and Portugal. In the European Community programs, materials is the pivot of the new Institute of Advanced Materials, shaped from the materials R & D activities of two establishments (Petten and Ispra) of the Joint Research Centre. Finally, materials R & D will feature strongly in collaborative cost-shared programs and in the next phase of the BRITE program, materials innovations will be closely linked with the technological end-use, particularly in the manufacturing and processing industries.

4. A Sectorial Approach

The types of materials that should be developed in the coming years in Europe are those linked to the industries in which Europe has an economic and trading ascendancy. The materials must be closely interlinked with the manufacturing industries. Hence, it might be instructive to take a glimpse at the world competitive market position of the European Community. Figure 4 shows graphically the European position. We see that the European Community has a high market share (30–40%) in a number of very high output industrial sectors, such as the chemistry sector, electrical engineering, motor manufacturing, mechanical engineering

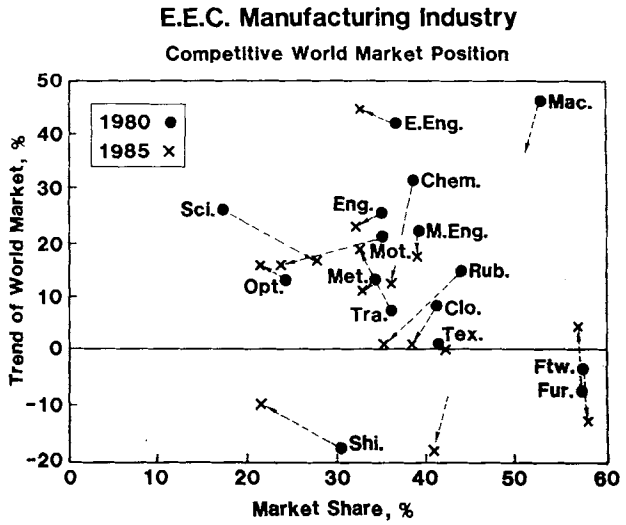

Fig. 4. EEC manufacturing industries competitive world market position.

as well as in clothing and textiles. The next point to note is the ominous drift towards a lower market share in high volume industries, in all cases except the chemical sector, mechanical engineering and textiles. The only sector which is showing a highly significant growth is that of scientific instruments, hardly a volume market. We note for example the large decline in the motor manufacturing industry, in shipping as well as in the rubber industries.

This can be compared with the Japanese position in the world market place (Fig. 5). Consistent with a total Japanese economy which is lower in volume than that of the European Community, many industrial sectors in Japan have a lower world market share. However, the targeted increases in the important sectors, notably electrical engineering, general engineering and metallurgical products are clear.

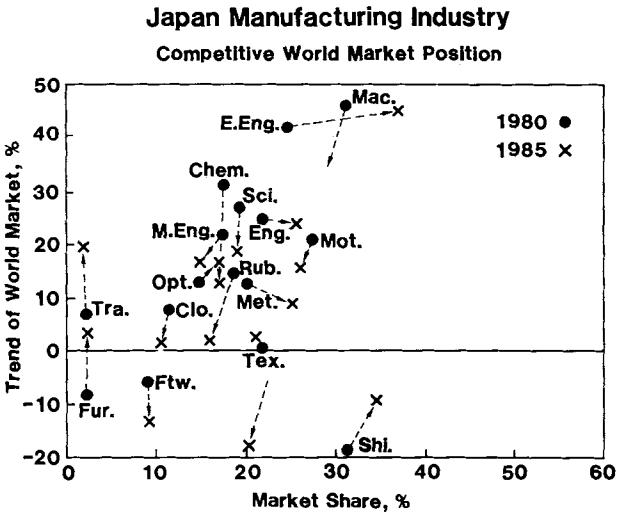

Fig. 5. Japanese manufacturing industries competitive world market position. (E.-, M.-Eng. = Electrical, Mechanical Engineering; Mot. = Motors; Rub. = Rubber; Opt. = Optics; Met. = Metals; Tra. = Tractors; Clo. = Clothing; Tex. = Textiles; Ftw. = Footware; Fur. = Furniture; Shi. = Shipping; Mac. = Machines; Chem. = Chemicals; Sci. = Science).

ADVANCED MATERIALS

The broad findings of this enquiry are that in the major sectors, although the EC and the USA hold the largest part of the world market, the EC's rate of growth is low and Japan is catching up very quickly. In all of the industrial sectors, it was noted that either the USA or Japan has the most important R & D expenditure.

Looking at it in this competitive way, which we must, the overall position is that Europe has to work harder and invest in more R & D in order to retain its market position in nearly all of the industrial sectors. This gives us a wide field of choice. The materials innovations in Europe in the coming years have to underpin a wide variety of industries, in particular those related to electrical and mechanical engineering.

5. Technico-Economic Aspects

In the western world, outside the defence sector, the future materials scene will be determined not only by the innovation and the competence of the materials scientists, but also by market forces – by the technico-economic aspects. This latter field is complex and usually neglected by the scientists. However, in a forward look such as this, it must be emphasized that the future does not depend only on the genius of the scientist and inventor.

As an example, consider the introduction of new ceramic materials into the engines of the future. We are all aware of the euphoria about advanced ceramics, and more recently, this earlier hyper-enthusiasm has been toned down to more realistic levels. Figure 6 shows an example from a worldwide

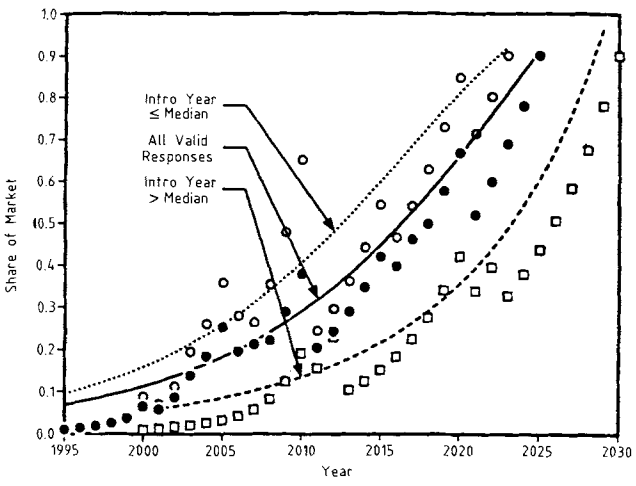

Fig. 6. Usage of ceramics in heat engines – forward look.

"Delphic" survey[3b] on the introduction of ceramics into heat engines. This was a wide, very subtle survey and the results can be treated with respect. They show the market penetration curves for ceramic engine components such as light-duty engine valves and heavy duty engine piston caps. These show reasonably good penetration prospects. The ceramics are considered to make improvements in performance through reduced fuel consumption, increased power density, reduced inertia for light duty engines and improved durability and heat insulation for heavy-duty engines.

The above scenario is highly speculative: it means that the model *could* apply, not that it is bound to apply. The realization of the above depends critically on market factors. Cost is the primary barrier; there will be a price premium for the first few years and this should inhibit manufacturers from introducing new ceramics. Are the technical advantages worth the extra cost? This is what the manufacturer has to decide – to take the risk that the public is sufficiently appreciative of the benefits.

This question throws up the whole complex subject of the strategic commitment to manufacturing among industrial firms. Enlightened industrialists are aware that in their companies, a "higher charge against the present is necessary to ensure a long term future", to quote the words of *Malpas*,[4] ex-director of B.P. research. These considerations will be essential in the introduction of advanced materials into the technologies of the next millenium. This is illustrated in the model for funds flow, (Fig. 7)[4] for a typical advanced mate-

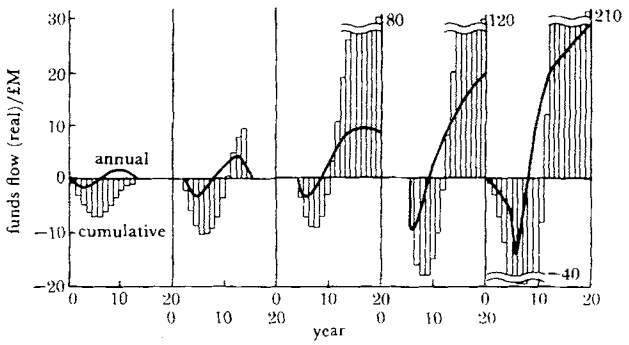

Fig. 7. Model for funds flow in a typical advanced materials business venture.

rials business venture. The first two projects represent relatively low investment; they have poor discounted cash-flow rates over the first ten years of the project life – however, they represent a sort of learning curve, leading to development markets – they are a cheap entry route into the "megabuck" business ventures, which although requiring heavy capital funding, indicate more attractive return rates. The projects 3 to 5 will be embarked upon only with the experience and "comfort factor" based on the earlier, loss making projects.

These are the vital considerations for a business with a positive strategy of long term investment, which applies in particular to high risk ventures on advanced materials.

6. The Conceptual Trends

For the materials innovations of today and the future, if there exists one grand design or overriding idea it is the

following: all materials innovations are in the direction of incorporating a greater knowledge content per unit weight of material. This important concept is shown in Figure 8, which

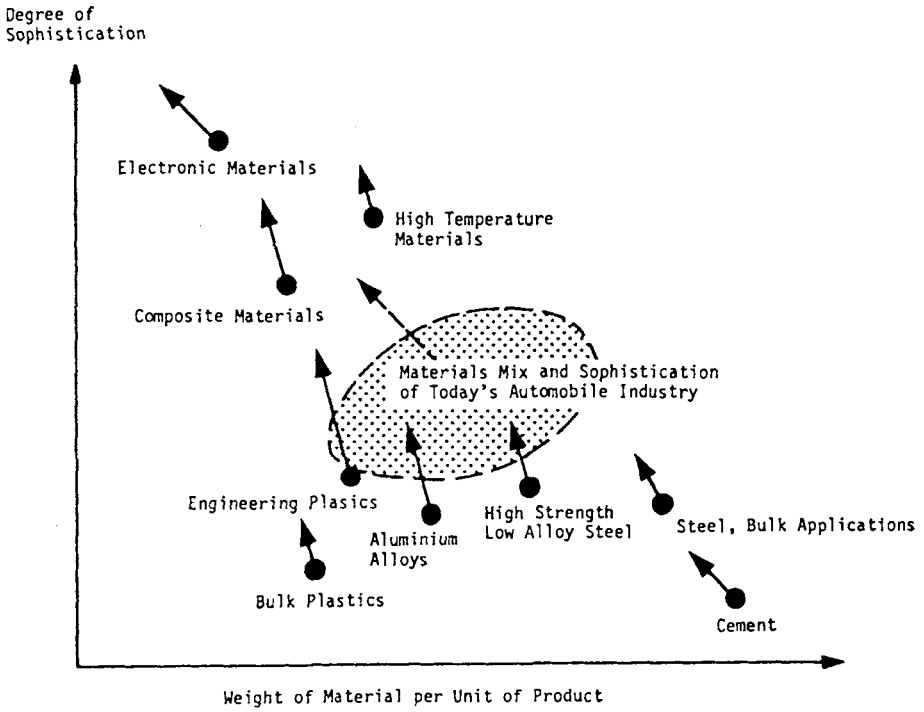

Fig. 8. Heuristic model correlating quantity of material in a given product and "information" attached to the material and its use.

is a heuristic model indicating the time dependent movement between the quantity of material in a product and information content of the material. This is derived from the work of *Altenpohl*.[5] On the diagram, each point indicates the trend for the future. In short this means that the materials innovations are increasingly incorporating a higher level of intellectual sophistication. This is consistent with the notion of the development of goods and manufactured products which have a high added value. The trend holds, whether it is for highly exotic materials for electronics applications or for bulk materials such as cement, where we see the vector moving towards improved macro-defect free cements.

Again, if we can discern a grand conception in the *means* for innovating materials for the future, it is in the ambition to design materials architectures with specific properties from basic building blocks. We are still a long way off from this, yet there are strong indicators and promising overtures in the production of two dimensional modulated structures at an atomic level which have highly specific and unique electronic properties. This grand design is the approach to the subject in terms of matter in extremely small assemblages, either two dimensional or three dimensional, these assemblages procuring properties that are completely different from those of the macroscopic forms. For example, a new type of strengthening has been suggested for an artificially produced material consisting of alternate layers of pure metals where the thickness of the layer is below a hundred nanometers. If the layers are so thin, it may not be possible for a Frank-Read source to operate in either layer, in which case the mode of plastic deformation will be by single dislocation movement.

For the development of materials for the next millenium, there are a number of conceptual trends, which can be considered as a collection of the accumulated thinking and experience among materials scientists. Here, specific themes which may exert a significant influence on materials development over the next two decades are highlighted.

7. Highlighted Themes of Future Significance

7.1. High Knowledge Content Structural Materials

In this category, the materials enable the engineering concept to be realized: the materials supply a supportive rôle. They find their value in that they permit the engineering structure to fulfil its functions and in this sense they are used to contain, to connect, to control or to display an engineering device. Here we are concerned with designing complex engineering structures to operate over a longer and more reliable lifespan, that is, we try to avoid over-design. We are concerned essentially with the benefit that is available through the incremental improvement of existing materials.

Material advances here are aimed to procure economic benefit through, for example, improved performance in the development of hexagonal boron nitride for hard coating applications or improved durability in an attempt to reduce the rates of corrosion, wear and fatigue. For example, in a recent survey[5b] it was found that in the USA some 4% of the gross national product is lost through the fracture of materials and structures.

7.2. Materials with Specific Functions

Here we are concerned with materials which in themselves constitute part of a potentially useful scientific phenomenon. They are now increasingly being referred to as 'functional' materials and their applications are typically in electronics, and optical and magnetic products. Thus, whereas in 1959 the number of transistors on a semiconductor chip was one, the increase over the last two decades has been of such enormous magnitude that in the near future we expect to have a hundred million tiny transistors on a single chip. In addition to this planar silicon technology, there are opportunities in newer, faster materials such as those provided by compounds of group III elements in the periodic table (gallium, aluminum, indium) with group V elements (antimony, arsenic, phosphorus) which offer new potential properties for opto-electronic and microwave applications. In the field of fiber optics, the traditional electric current in copper for transmitting messages is being replaced by laser light moving in a tiny glass fiber. The power of this new technology is such that each fiber can transmit the equivalent of a complete Encyclopedia Brittanica in one minute. The research opportunities here are obvious: improved fiber and better light carriers.

This is of course a very extensive and rapidly moving technological field with a large industrial infrastructure. The future will see new materials for such micro-electronics applications involving rapidly evolving techniques of fabrication, as in wafer production, epitaxial growth, sputter deposition, oxidation and diffusion of impurities, ion implantation and surface analysis techniques.

7.3. Improved Conventional Volume Materials

In spite of the slackening in the rate of consumption of traditional metals and steel in particular, these materials as well as common cement will be required in greater volumes in the future, both for advanced applications and in the more common aspects of Man's daily life such as in building materials. In particular, hydraulic cements are energy-cheap and today we see efforts being directed towards improving the strength of cement through a close study of porosity, rheology and the nature of the particle packing.

Newly innovated cements are already available, such as those known as macro-defect free cements which owe their improved strength to the removal of macroscopic voids, giving rise to cements with a bending strength of up to 70 MPa compared with the normal low strength of Portland cement of 5 MPa. In fact, a research team at ICI[6] has shown that by using combinations of high alumina cement and a copolymer of vinyl acetate and vinyl alcohol, strengths of up to 150 MPa may be achieved.

7.4. Property Design by Microstructure and Microchemistry Control

The marked influence that very small changes in chemistry or microstructure can have on bulk properties has long been recognized and exploited, as in the traditional addition of carbon to iron to make steels with highly tunable properties. In the last decade the importance of highly localized micro-environments, both chemical and structural, has been increasingly appreciated especially in the leverage effect they have on bulk mechanical properties. Examples abound; segregation to grain boundaries in metals, low melting grain boundary phases in structural ceramics, local defect populations especially in surfaces creating sites for fracture initiation, all factors controlling materials degradation and failure. Fortunately the phenomena are not exclusively deleterious and numerous opportunities to tailor the micro-environment for benefit are currently exploited; the addition of rare earth elements at trace levels to enhance the stability of corrosion protective scales on metals, the development of mechanically alloyed microstructures to enhance alloy strength, and the influence of boron in reducing brittleness in intermetallic alloys are examples.

The engineering of the micro-environment of materials has only recently begun, but is firmly founded on the basic principles that properties are in general determined by interfacial atomic interactions and that in a complex material, integrity is dependent on weakest link failure. Future exploitation of these ideas opens a promising field for materials advances, and already interesting innovative materials are emerging. Just one such example is given by the recent development of nano-crystalline structures. This novel idea of *Gleiter*[7] and his coworkers is to construct a material from nano-crystalline assemblages. This is tantamount to the production of a new state of matter, intermediate between a

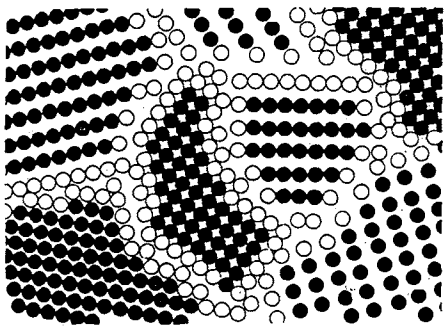

Fig. 9. Microstructural model of nanocrystalline materials.

polycrystal and a glass. The structure of the nano-crystalline metal made by evaporation on to a cold substrate followed by compaction of the fine powder is shown in figure 9. The crystal grains are so small that almost half the atoms in the metal occupy intergranular sites. As a result of the presence of a large proportion of matter in grain boundary sites, diffusion creep can operate even at low temperatures where the mass transport occurs along the grain boundary regions.

7.5. Synthesis of Non-Equilibrium Structures

The introduction of means that prevent lower free energy or ground state structures and compositions from being formed in alloys provides new opportunities for materials synthesis and property processing. More generally, the study of non-equilibrium phenomena is throwing up ideas of fundamental importance for the formation of metallurgical microstructures. The mixing of chemical species to produce alloys and ceramics has up to now been constrained by equilibrium thermodynamics – the rigid, inescapable laws of classical theory. In effect, metallurgists and solid state scientists have had to put up with a sort of tyranny of the constitutional phase diagram. By varying the processing conditions, in particular by imposing cooling rates exceeding $10^6\,^{\circ}C\,s^{-1}$, important constitutional changes can be introduced so that the retained metallurgical phases have compositions outside their equilibrium limits.[8] The resulting non-equilibrium phases may be crystalline or glassy. Such glassy materials often have unusual combinations of chemical and physical properties including strength, hardness, electric response, catalytic ability and corrosion resistance.

Already such materials have been aimed at applications, especially where combinations of extreme hardness and high corrosion resistance are required, as in cutting devices. Since these materials combine magnetic softness with mechanical hardness, they are useful for tape-recording heads. In particular ferromagnetic glasses are very easily magnetized, because magnetic domain walls move through them with ease and they therefore make excellent electric power transformers, with markedly reduced core losses. Figure 10 compares the energy losses in transformers of various sizes made by various companies. The decreases achieved by using metallic glass are quite dramatic. This is an area with enormous economic potential – it has been calculated that the introduction of metallic glass cores in the 40 million power distribution transformers in the USA could make a potential saving of a thousand million dollars per year.

7.6. "Two-Dimensional" Phenomena

Surfaces and interfaces have long been regarded as critical regions with a fundamental importance for many solid state phenomena of technological application. Catalysis, corrosion and adhesion are some examples of surface controlled phenomena. In the past decade we have seen many advances in methods for modifying surfaces in order to control such properties. Future trends in the surface sciences of relevance to materials technologies will be the exploration of physical and chemical phenomena on and just below and just above the surface, that is, in zones with an extremely small third dimension.

Thus the introduction of ion implantation techniques, with cascade ion mixing and continuous or pulsed laser heating introduces possibilities for obtaining new types of surface phases. Alloy compositions can be produced with extended solid solubilities and with these one may manipulate basic engineering properties. A wide range of properties can be modified by these treatments. An important example of this is an improvement in wear resistance in a titanium/aluminum/vanadium alloy used for artificial hipjoints. The incorporation of nitrogen can increase the lifetime of this joint by a factor of 400.

A completely different class of "2-D" phenomena is emerging for atomically layered structures which are grown on specially prepared surfaces. By using well controlled vapor deposition and other techniques for thin film deposition, a totally new area of *artificially structured materials* is being opened up which holds great promise for the discovery of new basic phenomena. Thus for modulated metallic alloys, unusual elastic, magnetic and superconductor properties have been observed. The field of greatest interest is in optoelectronic devices made from layered structures, the chemical composition being modulated from layer to layer.

7.7. Computerized Materials Information Systems

An important future trend in the materials science is the development of computerized information systems of increasing complexity. In typical first and second generation database services they are generally specialized on a single subject, making them important for use by experts in that subject field. Already the total number of publicly available

databases of European origin is somewhat over 800. These are mostly bibliographic databases and in the non-scientific fields.

In the case of materials information systems for engineering the complex nature and high costs have hitherto hindered the construction and exploitation of factual databases of the second and third generation type aimed at the professional engineer. The future will see the development of factual data banks as an everyday tool for the materials engineer who will have access to a comprehensive, reliable and up to date data base on engineering materials.

Related to this is the trend in future materials processing now referred to as "intelligent processing" in which sensors embedded in the material while it is being formed, or non-intrusive sensors such as ultrasonic beams, will feed back information at the microstructural level during dynamic forming. Based on the physical model for the process, the computer in turn should make the adjustments or changes necessary to ensure a defect free final shape.

7.8. Micro Non-Destructive Evaluation

The value of the non-destructive evaluation of defect structures in metals, for component acceptance, for integrity evaluation of structures, welds, components in operation etc., is long established and considerable attention is being devoted to extend these techniques to the monitoring of large scale plant. The major challenge for the future will be to adapt this technology to new materials such as engineering ceramics which have intrinsically much higher defect sensitivity and have inherently high flaw population densities, arising from processing constraints. Here, critical flaw sizes are of the order of tens of micrometers. While workers in the ceramics processing technologies struggle to achieve higher reliability using finer powders, better particle size distributions and ultra-clean conditions, inevitably a proportion of a production product will contain defects of significant size, discontinuities, porosity or surface cracking, which may be detected only if the appropriate technique can be developed.

A number of possibilities are under investigation, developed from the acoustic and thermal non-destructive testing (NDT) principles of metal testing methodologies. For example, acoustic microscopy shows promise in surface crack detection and the resolution obtained using the scanning acoustic microscopy (SAM) and scanning electron acoustic microscopy (SEAM) is of the necessary order. At the current stage of development, the correct interpretation of even simple images requires a high degree of expertise and offers a major challenge to the developers of computer image identification.

8. Conclusions

The main points of this study are as follows:

- materials will increasingly grow in importance as a basic enabling technology – determining the development and innovation of other important future technologies in a variety of industrial sectors – transport, communication, etc.
- at a global level, there should be no fear of a collapse in supply of conventional materials, especially metals due to over-consumption.
- there are efforts and planning at a European level to stimulate materials R & D, to fill technology gaps and to strengthen the declining industrial sectors; here R & D cooperative networks are recognized as important.
- for making new materials into market products, innovation is necessary but not sufficient: technico-economic considerations (e.g. investment decisions) are paramount.
- a number of conceptual trends in future materials R & D can be discerned, based on the development of materials with higher "intellectual density."

Tailoring Semiconductor Crystals to Atomic Dimensions**

Molecular Beam Epitaxy
GaAs Thin Films
Film Growth Dynamics
Quantum Wells/Wires
Superlattices

By Bruce A. Joyce*

This article provides an introduction to the growth by molecular beam epitaxy (MBE) of semiconductor structures which have dimensions of the same order as interatomic distances in solids. The basic process technology is first described, followed by a brief account of surface reaction mechanisms involved in the growth of GaAs from an atomic beam of Ga and molecular beams of As_4 and As_2.

From the study of growth dynamics using electron diffraction techniques it is shown how reduced dimensionality structures can be grown and some indication is given of the effects of quantum confinement on material properties. Finally, some recent modifications of MBE based on flux interruption are described.

1. Introduction

It has become possible to fabricate semiconductor structures having dimensions of the same order as interatomic distances in solids. They are usually referred to as low dimensional systems. The movement of electrons in these structures is constrained because their dimensions are less than the electron wavelength and as a result they exhibit properties very different from those of the bulk material. The electronic confinement can be in one, two or three dimensions to produce layers, wires and dots respectively and the effects are already being exploited in novel electronic and opto-electronic devices, of which the quantum well laser is perhaps the best known example.

In this short article I will describe the technique of molecular beam epitaxy (MBE) which is one of the two major fabrication methods used to prepare low dimensional systems, indicate how the necessary levels of control and understanding have been achieved, and illustrate some of the reduced dimensionality structures which can be grown directly.

Particular thanks on this occasion are due to *Jon Gowers* for permission to use his micrograph of the superlattice which was grown by *David Hilton*. I also wish to thank *Steve Pringle* of VG Semicon for providing the material for Figure 1.

2. Molecular Beam Epitaxy (MBE) – The Process

The fundamental principles of MBE were established over twenty years ago, first for silicon and subsequently for III–V compounds such as gallium arsenide (GaAs). The subject has been extensively reviewed.[1-5] In this technique atomic or molecular beams are formed from Knudsen effusion cells and allowed to impinge on to a heated substrate under ultra high vacuum (UHV) conditions of $< 10^{-10}$ torr. If the conditions are correct a single crystal epitaxial film grows on the substrate, which is typically a single crystal semiconductor wafer approximately 5 cm in diameter. The cells are maintained at room temperature for gaseous sources or heated to produce an adequate vapor pressure for solid phase source material. Typical source pressures are in the range of 10^{-2} to 10^{-3} torr, which allows operation in the molecular flow, or collision-free regime, so that the first collision of a beam molecule is with the substrate. Under these conditions the molecular flux at the substrate is given by:

$$J_i = [a p_i / \pi d^2 (2\pi m_i k T)^{1/2}] \cos\theta \quad (1)$$

where J_i is the flux per unit area at a distance d from the source, which has an orifice of area a and contains molecules (atoms) of mass m_i having an equilibrium vapor pressure p_i at a temperature TK. θ is the angle between the beam and the substrate surface normal. The flux is regulated by a fast-acting shutter operating in front of each aperture.

A microcomputer is used to controll cell and substrate temperatures and all of the shutter operations, enabling any predetermined growth sequence to be achieved. Since the beams are neutral and collimated (by the aperture geometry) they are necessarily divergent and usually non-axial with respect to the substrate. To obtain uniform growth rate and composition (in the case of alloy films) over a large substrate area, the substrate stage is rotated at speeds between 0.03 and 2.0 Hz. For the growth of high quality films a substrate surface free of crystallographic and other defects and clean on an atomic scale (< 0.01 monolayers (ML) of impurities) must be prepared. This usually involves free etching by an oxidative process which removes any carbon and leaves the surface covered with a protective volatile oxide which is subsequently removed by thermal desorption in the vacuum chamber.

Experimental systems which can provide the required levels of control have become rather complex, but Figure 1 illustrates schematically the important features. The basis is

ADVANCED MATERIALS

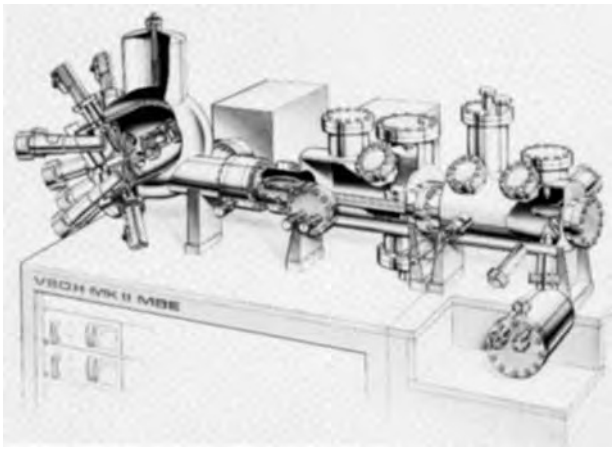

Fig. 1. Schematic illustration of an MBE system for the deposition of III–V compounds.

a two or three chamber stainless steel UHV system, usually ion- or cryo-pumped and incorporating large areas of liquid nitrogen cooled panels. An interlock system to enable the substrate to be introduced into the growth chamber without breaking the vacuum is essential if films having high quality electrical and optical properties are to be prepared.

In situ analytical facilities usually include a quadrupole mass spectrometer for residual gas analysis and a reflection high energy electron diffraction (RHEED) arrangement for assessment of surface structure and growth dynamics (see section 4). This consists of a 10–50 keV electron gun and a fluorescent screen, using a forward scattering geometry with the electron beam at a very shallow angle (1–3°) to the substrate surface. In addition, an Auger electron spectrometer may be incorporated to determine surface composition and purity. Some or all of these analytical facilities may be housed in a separate analysis/preparation chamber mounted between the sample insertion interlock and the growth chamber.

In the remainder of this article I will concentrate on films of III–V compounds, principally GaAs prepared from solid (elemental) sources, since most of our understanding of growth mechanisms and most areas of application relate to these materials, but the same basic principles apply to silicon, germanium and II–VI compounds.

3. MBE of III–V Compounds – The Basic Chemistry

The source materials used are usually elemental, and all of the group III elements produce monoatomic beams. Group V sources are rather more complex, since direct evaporation produces tetraatomic molecules (P_4, As_4, Sb_4), but dimeric molecules can be obtained by passing the tetramer flux through a high temperature stage at the front of the Knudsen cell. Dopants used are beryllium for p-type and silicon for n-type, both of which evaporate as monomers.

Growth is initiated by bringing the substrate to the appropriate temperature (typically in the range 500–700 °C) in a beam of the Group V element to prevent thermal dissociation and then opening the shutter of the group III element source. A typical growth rate is 1 μmh^{-1}, which corresponds approximately to 1 ML s^{-1}, or a flux of 5×10^{14} atoms $cm^{-2}\,s^{-1}$. The group V element flux may be between three and ten times greater, but the growth rate is entirely determined by the group III element flux.

The experimental arrangement of MBE is unique amongst epitaxial thin film preparation methods in that it allows direct in situ reaction kinetic measurements to be made using the technique of modulated beam relaxation spectroscopy (MBRS). The basic experiment is very simple; a neutral, thermal atomic or molecular beam is directed at a substrate surface and the desorbing flux detected mass spectrometrically. The problem of distinguishing between background signals and those produced by desorbing species is solved by (mechanically) modulating either the incident beam or the desorbing flux and examining the mass spectrometer signal for a correlated response. By correct choice of data acquisition and signal processing methods[6] it is possible to evaluate a wide range of kinetic parameters, including (i) thermal accommodation coefficients of molecules interacting with the surface, i.e. the nature of kinetic energy exchange processes between the surface and the incident species (ii) surface lifetimes and the energies of binding states (iii) sticking coefficients, or residence times which are long compared to the modulation frequency and (iv) orders of chemical reactions.

A good example of the power of the technique comes from its application to the interaction of Ga and As_4 beams on a GaAs(001) surface to form GaAs.[7] The presently accepted model for this is shown in Figure 2. The As_4 molecules are

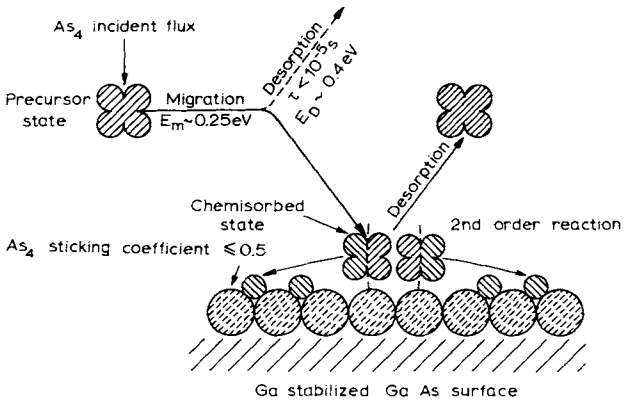

Fig. 2. Model of the growth chemistry of GaAs from molecular beams of Ga and As_4.

first adsorbed into a weakly bound mobile precursor state, in which the activation energy of migration is approximately 0.25 eV. An activation energy of desorption of ≈ 0.4 eV can be determined from the temperature dependence of the sur-

face residence time of an As_4 molecule. A crucial finding is that the sticking coefficient of As_4 never exceeds 0.5, even when the Ga flux is much higher than the As_4 flux, or when the surface is completely covered with a monolayer of Ga atoms (as in Fig. 2). Furthermore, the desorption rate is second order with respect to the incident flux. These results are explained by postulating a pairwise dissociation of As_4 molecules chemisorbed on adjacent Ga atoms, so from two As_4 molecules four As atoms go to form GaAs, while the remaining four desorb as an As_4 molecule. By contrast, in growth from As_2 the basic process for As incorporation is simple first order dissociative chemisorption on surface Ga atoms.[8]

These models are well over ten years old, but they have received some very recent experimental support from *Tsao* et al.[9] These workers also found a maximum As_4 sticking coefficient of 0.5, at which point the surface reconstruction changed from As-stable to Ga-stable. In addition, they were able to show that the chemical reaction was not the rate determining step in the growth of a GaAs film, which is an important factor in the discussion of growth dynamics (see section 4).

4. The Dynamics of Film Growth

Before embarking on a discussion of growth dynamics it is important to establish the basic concepts of the surface structure of GaAs, which can be monitored by the in situ RHEED facility. In general, semiconductor surfaces either relax by bond rotation on reconstruct, i.e. display a lower symmetry than that produced by a simple termination of the bulk lattice. In III–V compounds the form of the reconstruction is related to surface composition and stoichiometry, which can be illustrated by the GaAs(001) surface. It is a polar orientation and is ideally terminated by a complete layer of Ga or As atoms, but in practice it forms a series of surface structures, ranging from the Ga-rich 4×2, though an intermediate 3×1 to an As-stable 2×4, where $(n \times m)$ relates the surface unit cell to that of the bulk (1×1) and indicates the increase in the periodicity in two orthogonal $\langle 110 \rangle$ directions at the surface. In addition to displaying the surface symmetry the RHEED pattern can also be used to evaluate surface morphological properties such as the presence of steps, facets, antisite disorder etc.[10]

A further and extremely important application of RHEED is the direct in situ study of film growth dynamics. This has been made possible by the discovery and development of the RHEED intensity oscillation technique.[11, 12] The primary observation is that damped oscillations occur in the intensity of all features of the RHEED pattern immediately following the start of growth. Typical results for the growth of GaAs and AlAs(001) oriented films on GaAs(001) substrates are shown in Figure 3, taken using the specular spot on the 00 rod. The steady state period corresponds precisely to the growth of a single molecular layer, i.e.

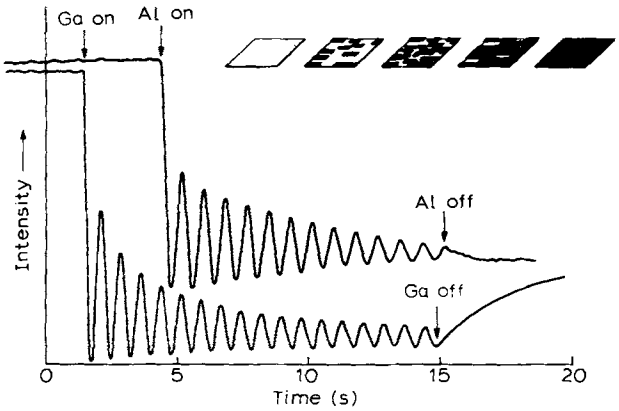

Fig. 3. Intensity oscillation of the specular beam in the RHEED pattern from AlAs and GaAs(001) 2×4 surfaces during growth. Inset shows the growth of a molecular layer in a two-dimensional mode.

a complete layer of Ga(Al) + As atoms, equivalent to $a_0/2$ in the [001] direction.

The feature common to all explanations of this oscillatory intensity response is that it occurs as a direct result of the changing surface topography associated with a layer-by-layer (two-dimensional) growth mode. On the basis of 2-D growth and a single scattering diffraction process it is a straightforward matter to construct a growth model which accounts for the RHEED results. We will deal with the specular spot for simplicity, but similar arguments can be applied to all features. If we relate intensity changes with surface roughness effects on an atomic scale, we can assume that the equilibrium surface is smooth, corresponding to a high specular intensity. When growth commences, 2-D centres are formed randomly on the surface, leading to a decrease in specular intensity (i.e. an increase in diffuse scattering). This is the expected result for a single scattering process, since the wavelength of the electrons is typically 0.1 Å whilst the GaAs monolayer step height is 2.83 Å i.e. the wavelength is more than ten times smaller than the size of the scattering centers, thus producing diffuse scattering. This will be a maximum at half-layer coverage ($\theta = 0.5$) and a minimum at the start of each layer ($\theta = 1$). The development of a monolayer is illustrated in the inset to Figure 3. In fact this model is greatly oversimplified, because electron diffraction is a multiple scattering process, but the basic tenet is correct; the oscillatory response is a manifestation of a layer-by-layer 2-D growth mode which implies significant adatom migration on the surface. In reality an intensity maximum seldom corresponds to monolayer completion because its position in the monolayer depends strongly on diffraction conditions (azimuthal and polar angles). Fortunately conditions can be chosen which ensure correspondence between intensity maxima and monolayer completion. The complexities introduced by diffraction effects have been treated extensively elsewhere[12] and need not concern us further here. The decay of the oscillations is particularly important, however, since it represents a change of growth mode from 2-D nucle-

ation to step propagation. As a result of the growth front becoming distributed over more than one layer, brought about by a second layer starting before the previous one is complete, a steady state terrace width, or step distribution is eventually established. This occurs when the mean step separation equals the surface migration distance of the group III adatoms. Under these conditions there are no intensity oscillations since statistically the surface morphology does not change during growth.

These growth mode changes which occur as a consequence of the surface migration of adatoms can be exploited in a rather simple way to establish quantitative data for the migration processes.[13] The method involves the use of a vicinal surface, which means preparing a substrate so that its surface plane is a few degrees away from a singular surface, i.e. a surface with an exact low index orientation, (001) say. To minimize its free energy, a surface of this type will break up into a formation of exact (001) terraces separated by monomolecular steps (of height $a_0/2$ in the case of III–V compounds). The mean step-free terrace width l, is given by $l = a_0/2 \tan\alpha$, where α is the angle of misorientation. As an example for $d \approx 2°$, $l \approx 80$ Å. If the migration length of the group III element is λ, for $\lambda > l$ the step edge will act as the major sink for migrating adatoms and there will be no two dimensional (2-D) growth on the terrace. Since RHEED intensity oscillations occur only as the result of 2-D growth, they will be absent for this growth mode. If, however, growth conditions are varied to the point where $\lambda < l$, 2-D growth will be re-established on the terraces and oscillations will be observed. It is consequently comparatively straight forward to study λ as a function of growth conditions. It must be emphasized, however, that in the present context surface migration refers to the transport of group III adatoms in a weakly bound precursor state before their final incorporation in a lattice site; it is migration related to growth, not surface dissociation.

Ideally, the measurements should be performed by systematically varying the extent of misorientation and hence terrace width, but in practice it is simpler to use a single substrate with a fixed misorientation and vary the migration length by changing growth parameters. A typical data set obtained by varying the substrate temperature at fixed As_2 and Ga fluxes is shown in Figure 4. The inset illustrations demonstrate the changing growth modes as the temperature changes. Clearly, as the temperature rises the migration length increases to the point where it equals the terrace width, and the RHEED intensity oscillations disappear. If surface migration is assumed to be isotropic, it is possible to determine values of the migration coefficient D_0 and the activation energy E_d using the relationships:

$$\lambda^2 = 2\,D\tau \tag{2}$$

and

$$D = D_0 \exp(-E_d/kT) \tag{3}$$

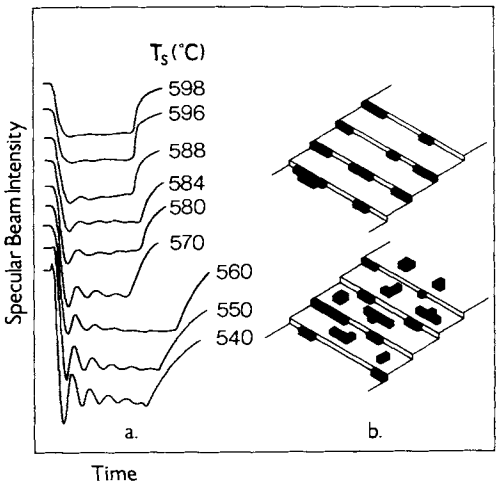

Fig. 4. Data set showing the transition from oscillation to constant response in the RHEED specular beam intensity as a function of substrate temperature, with constant gallium flux, for the growth of GaAs. Inset illustrates layer-by-layer and step propagation modes on the terraces formed from the vicinal surface.

Here λ is the mean displacement (terrace width), D the migration coefficient at a temperature T and τ the surface lifetime in the precursor state. There are some detailed analytical difficulties, but the basic principles appear to be valid.

5. Quantum Wells, Superlattices and Quantum Wires

We have seen that the fundamental growth mode on a singular surface is layer-by-layer and this enables quantum wells and superlattices to be grown. In a quantum well, a layer of one material, say GaAS, is sandwiched between two layers of material of greater band gap, say (Al,Ga)As, a III–V alloy in which some fraction of Ga is substituted by Al. More complex alternating structures are known as multiple quantum wells (MQWs). When the layers are sufficiently thin (typically < 20 Å) to allow electron coupling between them, the structure is referred to as a superlattice. Detailed consideration of the transport and optical properties of such structures are outside the scope of this article, but an excellent review has been written by *Kelly* and *Nicholas*.[14] It will perhaps be useful however to discuss briefly one example here. In semiconductors the recombination of electrons and holes causes the emission of radiation. In a quantum well structure the energy of this radiation increases (the wavelength decreases) as the well thickness is reduced. This is a quantum shift brought about by the confinement of the electrons in the well to two dimensions. The actual wavelength of emitted light is a function of the well width and this has been used to fabricate MQW lasers with emission characteristics quite different from those based on the equivalent bulk materials.

Some idea of the perfection with which two dimensional structures can be grown may be obtained from electron microscopy and this is illustrated in Figure 5. This is a cross

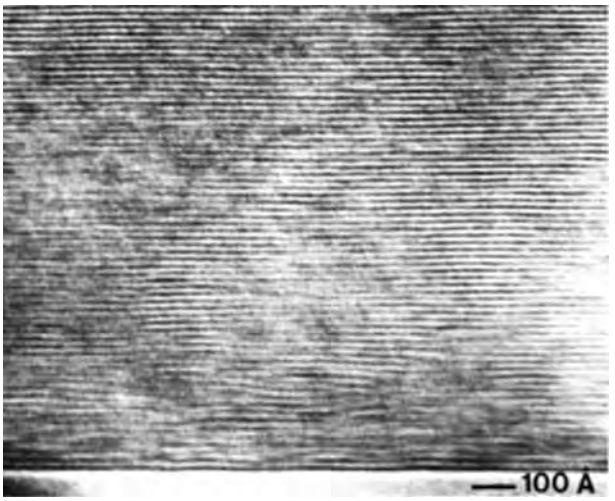

Fig. 5. Transmission electron micrograph of a GaAs (3 ML)/AlAs (3 ML) superlattice.

sectional transmission electron micrograph (TEM) of a GaAs-AlAs superlattice composed of alternate layers each 3 ML (8.5 Å) thick. It is evident that averaged over the thickness of the cross section, interfaces on a scale of < 1 ML can be produced. Similar conclusions can be drawn using X-ray diffraction and photoluminescence techniques.

Quantum well wires are low dimensional structures with quantum confinement in two dimensions. Most attempts to fabricate them have relied on high resolution lithography, but the lateral dimensions achieved have been rather too large to produce significant separation of sub-band energies. A new approach has been made possible by control of the growth mode on vicinal planes, following the principles discussed in section 4. By restricting growth to the step propagation mode and growing alternate fractional monolayers of, say, GaAs and AlAs on a GaAs(001) substrate tilted typically 2° towards (110), vertical columns of GaAs and AlAs can be grown on the terraces, which are ≈ 80 Å in width.

There is already evidence[15, 16] of some success in the growth of these structures, although it is clear that as yet they are far from ideal. Simulation studies indicate that poor quality at low substrate temperatures results from a significant amount of two-dimensional cluster formation due to restricted surface diffusion, whilst high temperature degradation is brought about by enhanced thermal fluctuations in the step edge structure.

6. Growth Process Modifications

Finally, we may consider some recently developed modifications to the growth process, which were introduced with the idea of growing more "perfect" interfaces in heterojunctions, quantum wells and superlattices, i.e. maximizing areas of single composition in the interface plane, or minimizing the number of layers normal to the plane in which compositional variations occur. They all rely on interruption of one or other or both (anion and cation) fluxes.

If growth is stopped by shutting off the group III element flux whilst maintaining constant the substrate temperatures and group V element flux, the intensity of the specular spot in the RHEED pattern recovers almost to its pre-growth value, provided correct diffraction conditions are chosen. The "recovery" or relaxation, occurs in two stages (fast and slow) and obeys an expression of the form:

$$I = A_0 + A_1 \exp(-t/\tau_1) + A_2 \exp(-t/\tau_2) \quad (4)$$

where τ_1 and τ_2 are the temperature dependent time constants of the fast and slow stage respectively. It seems probable that during the fast stage singly coordinated atoms on the peripheries of two dimensional growth centers break away to reform into more highly coordinated sites. The slow step then results from adatom clusters evolving to form the maximum number of nearest neighbor bonds.

This is the basis of the simplest modification, known as interrupted growth,[17] where the shutter controlling the cation flux is closed for periods of up to 60 s. This results in a lower step density and is more successful for lower binding energy, faster diffusing species, and it is also important for the interruption to occur close to monolayer completion. The other two modifications, known as atomic layer epitaxy (ALE)[18] and migration enhanced epitaxy (MEE)[19] both involve periodic interruptions of each flux during growth. It is claimed that as well as improving interface morphology, both techniques produce high quality material at lower substrate temperatures than is possible by conventional growth, but it is a claim which remains to be fully substantiated. It appears that both ALE and MEE depend on rapid relaxation during a short interruption period which occurs very close to monolayer completion.

It is reasonable to conclude that semiconductor structures of atomic dimensions, at least in one direction, can be reliably fabricated using MBE or one of its related alternatives. Some success has been achieved in control over two dimensions on the same scale, but much work remains to be done before successful exploitation can be claimed. Control over all three dimensions is still very much in the "ideas" stage.

Structure-Directed Synthesis of New Organic Materials**

Unnatural Products
Molecular LEGO
Solvent Sensors
Zeolitic Macropolycycles
Diels-Alder Reactions

By Franz H. Kohnke, John P. Mathias, and J. Fraser Stoddart*

1. Preamble

The time has now been reached when the chemist can make almost anything the living world has produced. Natural product synthesis has dominated the conceptual advances in synthetic organic chemistry for more than a century now. Yet, although the deep significance and fundamental importance of natural products and the life processes that sustain and characterize them are clear, they are arguably only an infinitesimally small part of the chemical scene. Compounds which are wholly unnatural comprise an infinite variety of structures which can only be conceived and constructed thanks to the knowledge, imagination, and expertise of the chemist. The reasons for making unnatural products come from many quarters – they include evaluating chemical theories, both old and new, synthesizing exotic compounds, which, more often than not have symmetry appeal, and preparing materials with some particular structural form that might perform some highly desirable physical, chemical, or biological function.

The manufacture and manipulation of structures at a molecular level raises[1] "the possibility of maneuvering things atom by atom." The prospect is one of performing physical feats on a truly microscopic scale. The question is how to construct advanced materials that express their properties at a molecular level and then to gain access to these properties, i.e. how do we make molecules and speak to them?

Recently, rigid molecular lines or strips, with nanometer scale dimensions and composed of polyacenequinone units, have been prepared[2] by repetitive Diels-Alder reactions. Their synthesis is attractive because they could provide a range of new materials capable of forming organized monolayers and molecular electronic devices of different sorts. Artificial cell bilayer membranes, and molecular barriers and sensors all rely[3] upon the formation of surface structures with the appropriate electronic characteristics. The prospect[4] that the parent polyacenes and their cyclic analogs – the cyclacenes – constitute materials with "the possibility of possessing interesting condensed phases including high temperature superconductivity and ferromagnetism" is particularly tantalizing.

Although synthetic strategies based on a repetitive Diels-Alder methodology, involving bisdienes and bisdienophiles,[5] have much to commend themselves in the synthesis of ladder polymers, there is a need to avoid ill-defined mixtures of compounds containing molecules of differing molecular weights and different stereochemistries that are not particularly amenable to purification by chromatography or by any other means.

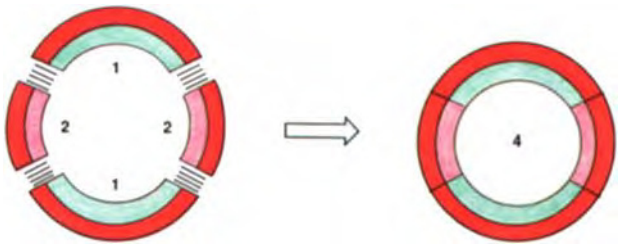
[**] We are most grateful to Dr. *N. S. Isaacs* (University of Reading) for performing all the high pressure reactions, Dr. *J. D. R. Thomas* (University of Wales College of Cardiff) for conducting the chemical sensing experiments, Mr. *P. R. Ashton* and Dr. *N. Spencer* (University of Sheffield) for recording FABMS and NMR spectra, respectively, and to Dr. *D. J. Williams* and Miss *A. M. Z. Slawin* (Imperial College London) for carrying out the X-ray crystal structure determinations. The research was supported by the University of Sheffield, the Science and Engineering Research Council, and the Ministry of Defence in the UK, and by the University of Messina in Italy. One of us (*J. F. S.*) acknowledges the award of a Research Fellowship from the Leverhulme Trust and thanks Dr. *Peter Mitchell* and Prof. *Jean-Marie Lehn* for useful discussions.

Recently, we have shown[6] that certain bisdienes and bisdienophiles, containing bicyclic ring systems, will undergo repetitive Diels-Alder reactions at their diastereotopic π-faces in a highly controllable manner,[7] not only with complete diastereoselectivity being expressed with respect to each component, but also with very high mutual diastereoselection occurring between the components, i.e. their relative reaction orientations are pre-determined. The implications of this discovery is that there are inherently simple ways of making apparently complex unnatural products from appropriate substrates. Since the pure compounds can be obtained without the need to use reagents or catalysts and result from information pre-programmed into the substrates and carried over into the products, we have referred[8, 9] to this as a form of *structure-directed synthesis*, i.e. the outcome of the reactions is dictated either by the structures of the substrates (i.e. the control is kinetic) or by the structures of the products (i.e. the control is thermodynamic). In this review, we shall outline how the principle of structure-directed synthesis can be applied to the precise and stepwise construction of new organic materials.

2. Molecular Belts

The synthesis (Scheme 1) of the macropolycycle dubbed[6] kohnkene **4** from "intelligent" substrates[10] – the bisdienophile **1** and the bisdiene **2** – is now well documented.[6, 7] The power of the synthetic approach is a double-barrelled one: a) It can be executed in discrete steps since one bisdienophile **1** will undergo cycloadditions with two bisdienes **2** under relatively mild conditions to give (78%) a discrete 2:1 adduct **3**, which can be characterized and then coaxed, under much more forcing conditions, to react remarkably efficiently (36%) in a belt-forming manner with a second bisdienophile **1**. b) Treble diastereoselectivity is expressed every time a Diels-Alder reaction occurs, such that only one product is formed after each cycloaddition step, e.g. none of the other nine configurational diastereoisomers of the 2:1 adduct **3** have been observed. It would appear that the stereoelectronic information pre-programmed into the bisdienophile **1** and the bisdiene **2** is transmitted in a domino-like fashion through all the intermediate Diels-Alder adducts to the final macropolycycle **4**. Although it has been strongly implied in the literature (see reference[7] for a discussion) that this kind of molecular recognition between bicyclic diastereofacial dienes and dienophiles is a transition state phenomenon (i.e. kinetic control is operative), the proposal remains to be vindicated or otherwise in the context of the synthesis of kohnkene **4**. Be this as it may, the practical outcome is clear: the synthetic chemist can create[7] molecular materials that are rigid, ordered, and large without having to resort to complicated multistep syntheses using expensive reagents or exotic catalysts. In this respect, unnatural product synthesis is reminiscent of prebiotic chemistry where – it has been argued[12] – certain key, relatively simple, chemical compounds served



Scheme 1. The construction of kohnkene **4** from the bisdienophile **1** (blue) and the bisdiene **2** (pink) via the 2:1 adduct **3** by a stereoelectronically-programmed set of Diels-Alder reactions – leading to the formation of new cyclohexene rings (yellow) – followed by its conversion into dideoxykohnkene **5** and [12]collarene **8** via the symmetrical (?) and unsymmetrical octahydro[12]cyclacene derivatives **6** and **7**, respectively (O = solid red). In the macropolycyclic hydrocarbons, benzenoid rings are gray/black and 1,4-cyclohexadiene rings are yellow/green. Reagents and conditions: i, PhMe, reflux, 12 h; ii, CH_2Cl_2, 10 kbars, 55–60 °C, 200 h; iii, $TiCl_4$, $LiAlH_4$, THF, room temp., 18 h; iv, HCl, Ac_2O, reflux, 16 h; v, Li/NH_3, Et_2O, EtOH, – 78 °C, 45 min.

ADVANCED MATERIALS

as the building blocks for the elaboration of apparently complex biomolecules, or their biosynthetic precursors. With special structural elements of vitamin B_{12} in mind, *Eschenmoser*[11] has commented on the fact that "these outwardly complex structural elements are found to self-assemble with surprising ease under structurally appropriate preconditions". He goes on to add that "the amount of external instruction required for their formation turns out to be surprisingly small in view of the complexity of these structural elements." The prospect that the chemist might be able to create an unnatural world, using the same concepts and principles that the living world relied upon in the beginning, is an extremely exciting one indeed.

The making of kohnkene **4** has an aspect of molecular 'LEGO' about it. The rigid curved structures of the component bisdienophiles **1** and bisdienes **2**, coupled with the exclusive manner in which they interact and react with each other, dictates that a molecular-belt compound has to be the outcome. Scheme 2 is an attempt to capture visually how one

Scheme 2. A diagrammatic representation of the treble diastereoselectivity exhibited by each Diels-Alder reaction between two (blue on the concave surface) bisdienophiles **1** and two (pink on the concave surface) bisdiene **2** units in the construction of kohnkene **4**. The convex surfaces, which carry the oxygen atoms, are featured in red.

doubly "intelligent" substrate, i.e. **1**, can recognize another doubly "intelligent" substrate, i.e. **2**.

Unnatural product synthesis[13] will increasingly provide incentives for major conceptual developments in the art and science of chemical synthesis, as it relates to organometallic and inorganic materials, as well as to organic ones. A recent convincing illustration is provided by the structural features of self-assembly, cooperativity, and self-self recognition that characterize[14] the new polynuclear double-stranded helicates (trimers, tetramers, and pentamers) incorporating poly(bipyridine) strands and copper(I) cations.

One of the additional challenges in synthesizing an unnatural product is to uncover a property or demonstrate a function for the new material. X-Ray crystallography of kohnkene **4** not only reveals[6] that it is a belt-like molecule with the six oxygen atoms pointing outwards, but that the rigid cavity is of the appropriate dimensions to include a benzenoid substrate oriented orthogonally (Fig. 1) between the aromatic rings at 6 and 12 o'clock with an interplanar separation of 7.9 Å. Indeed, when a piezoelectric quartz crystal was coated with kohnkene **4**, detection of aromatic vapors

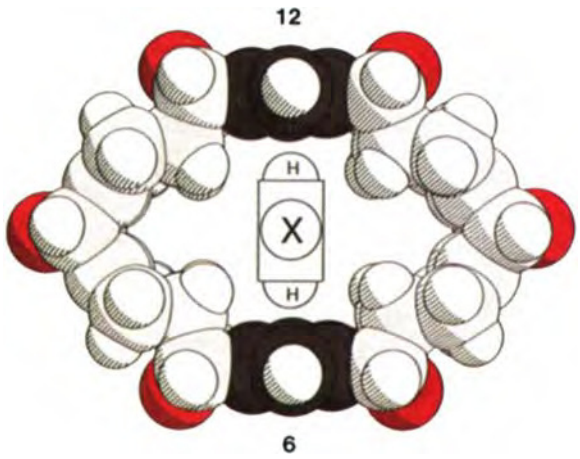


Fig. 1. Space-filling representation of the X-ray crystal structure of kohnkene **4** showing the proposed model for the rapidly-reversible inclusion of monosubstituted benzene derivatives (center) – the relative response of the piezoelectric quartz crystal is in the order, X = NO_2 > Br > Cl > H – involving stabilizing edge-to-face interactions with the aromatic rings at 6 and 12 o'clock in **4** (H = white, C = gray/black, O = red).

was achieved.[15] The response of the detection system is illustrated by a typical recorder trace for nitrobenzene (Fig. 2), the substrate for which kohnkene **4** is particularly

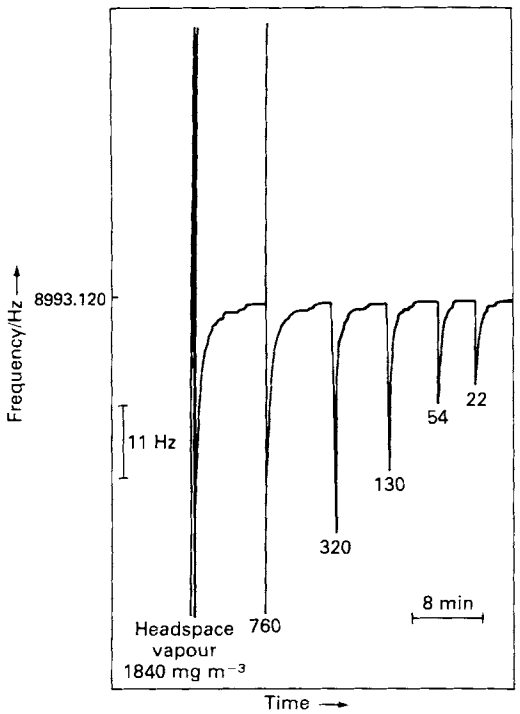

Fig. 2. A typical recorder trace of a calibration for nitrobenzene vapor using a piezoelectric quartz crystal (gold electrode) coated with kohnkene **4**. Reproduced from *Anal. Proc.* 26 (1989) 14, by permission of the publishers.

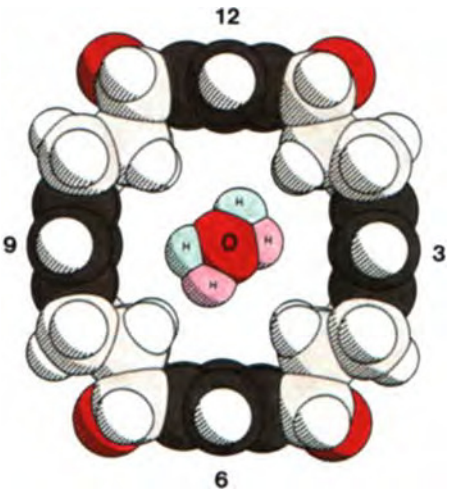
sensitive. Whatever the precise mechanism by which nitrobenzene vapor is adsorbed on to a surface of solid kohnkene **4**, the reversible association produces a change in the mass of the quartz crystal which can be monitored by changes in the

frequency of its oscillation. This extremely sensitive technique for monitoring gaseous products[16] represents one of the most immediate applications of new organic materials with zeolitic properties.

The model proposed in Figure 1 for the interaction of a monosubstituted benzene derivative with kohnkene **4** involves edge-to-face stabilizing interaction[17] between the substrate and the aromatic rings at 6 and 12 o'clock. In the case of nitrobenzene, the electron-withdrawing nitro group would only serve to enhance any stabilization through edge-to-face interactions involving slightly electron deficient – or δ^+ – hydrogen atoms on the substrate molecules and the π-electron systems of the two aromatic rings in kohnkene **4**. The dideoxy derivative **5**, obtained[18] on deoxygenation of kohnkene **4** ranks as an equally sensitive but much more universal type of sensor for a range of aromatic vapors including those of toluene, 2-nitrotoluene, 3-nitrotoluene, benzene, chlorobenzene, bromobenzene, and nitrobenzene.[15] X-Ray crystallography (Fig. 3) shows that the interplanar distance between the planes of the aromatic rings at 6 and 12 o'clock is 9.6 Å, whilst that between the planes of the aromatic rings at 3 and 9 o'clock is marginally less at 8.9 Å. The most striking feature of the solid state structure is that a disordered water molecule is positioned within its Celtic-cross like cavity such that its hydrogen atoms are more than 2.7 Å away from any potentially interactive sites within the rigid hydrophobic cavity. Attempts to reach (Scheme 1) [12]beltene[19] **9** and [12]cyclacene[20] **10** have so far only proved to be partially successful. Dehydration of dideoxykohnkene **5**, under conditions of thermodynamic control, led, not to the highly symmetrical octahydro[12]cyclacene derivative **6**, containing two benzene and two anthracene units, but rather to the much less symmetrical isomer **7** comprised of one benzene, one anthracene, and two naphthalene units. The isomer **7** was converted by means of a Birch reduction into [12]collarene **8** with six 'insulated' benzene rings. Apart from [12]cyclacene **10**, all the other hydrocarbons, i.e. **7**–**9**, in Scheme 1 are characterized by π-electron systems which are localized or delocalized in a plane perpendicular to that of the macropolycycle. Exploiting their coordination chemistry towards transition metals might uncover some novel organometallic materials.



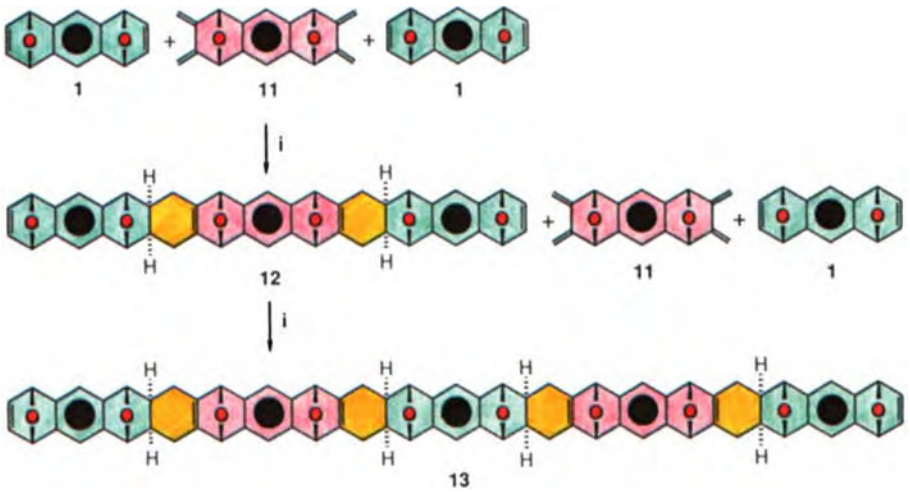


Fig. 3. Space-filling representation of the X-ray crystal structure of dideoxykohnkene **5**. In the disordered water molecule, which is included in the middle of **5**, half the molecules have their hydrogen atoms located in positions shaded pink and half in positions shaded blue (H = white, C = gray/black, O = red).

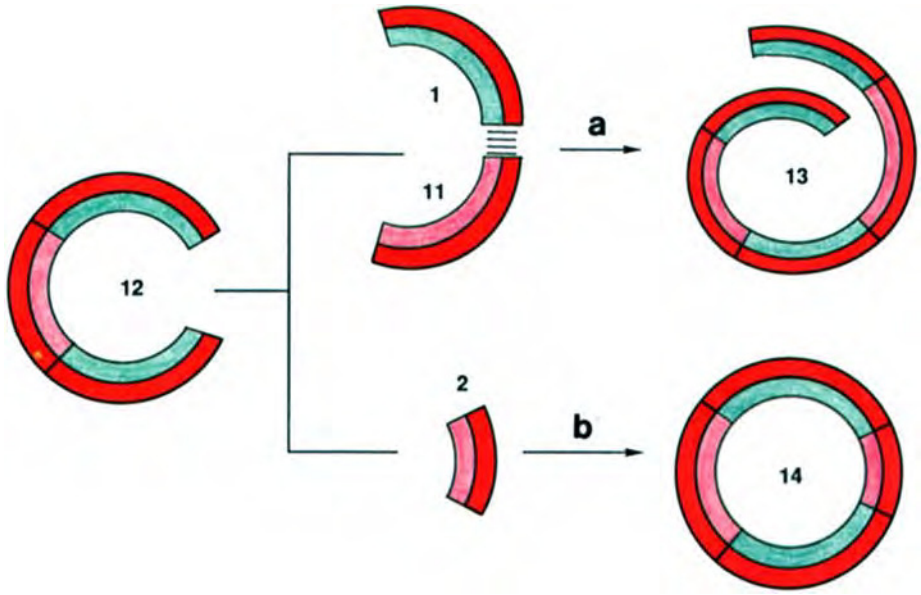
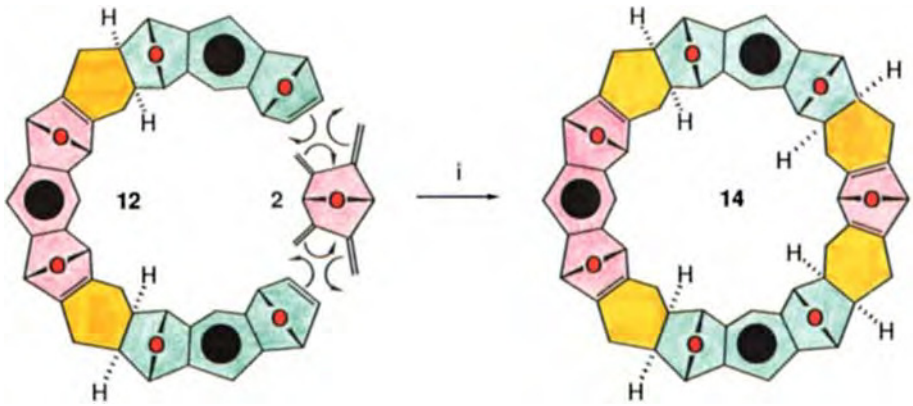
3. Molecular Strips



The power of any synthetic approach to new materials lies ultimately in its generality. One might ask – is it possible to replace **1** and **2** by other bisdienophiles and bisdienes and still



Scheme 3. The construction of the 2:1 adduct **12** and the 3:2 adduct **13** with the all-*syn* configurations from the bisdienophile **1** (blue) and the extended bisdiene **11** (pink) by repetitive Diels-Alder reactions. The newly-formed cyclohexene rings are highlighted in yellow (O = solid red). Reagents and conditions: i, CH_2Cl_2, 10 kbars, 50 °C, 6 days.

ADVANCED MATERIALS

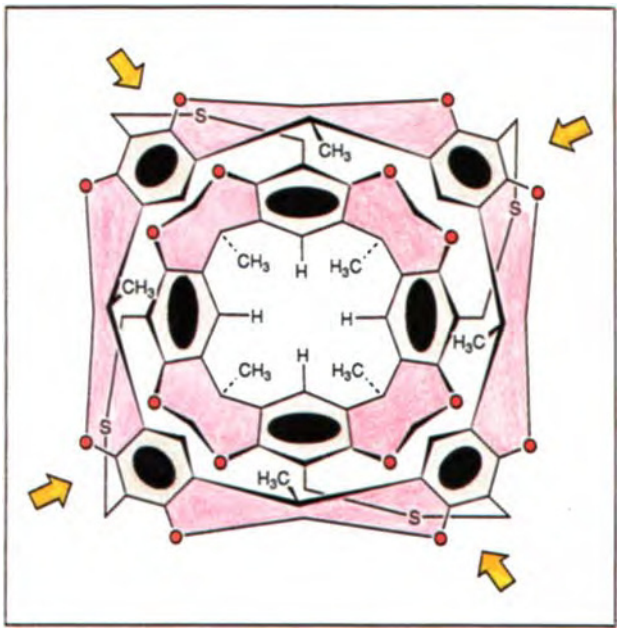
retain stereoelectronic control of the repetitive Diels-Alder reactions? The answer is by and large – yes, but the outcome is a little different.[8] Instead of constructing molecular belts, one obtains (Scheme 3) using **1** and the extended bisdiene **11** in place of **2**, molecular strips in the form of a 2:1 adduct **12** and a 3:2 adduct **14**, which coils up like a spring – at least, so ^{1}H NMR spectroscopy in solution indicates. In Scheme 4 an attempt is made to rationalize what might be happening in this series of repetitive Diels-Alder reactions. The bisdiene **11** is obviously too large to fit into the 'gap' in the 2:1 adduct **12** and so the route to the 3:2 adduct **13** is an inevitable outcome. However, despite the fact that a [16]cyclacene derivative has not been isolated, the [14]cyclacene derivative **14**, resulting from reaction of the 2:1 adduct **12** with the smaller bisdiene **2** (Scheme 5) is formed with remarkable ease. These preliminary observations hold out the promise that it should be possible to construct molecular strips of varying sizes and shapes in a highly controlled manner. Considerable thought and effort has already been invested[2–4] in the applications to materials science of rigid molecular lines and strips.

Scheme 4. A diagrammatic representation of the construction by repetitive Diels-Alder reactions of a) the 3:2 adduct **13** from three bisdienophile **1** (blue on the concave surface) and two extended bisdiene **11** units (pink on the concave surface) and of b) the [14]cyclacene derivative **14** from the bisdiene **2** unit (pink on the concave surface) – both having the 2:1 adduct **12** as a common intermediate. The convex surfaces, which carry the oxygen atoms, are featured in red.

Scheme 5. The construction of the [14]cyclacene derivative **14** by two stereoelectronically-programmed Diels-Alder reactions from the bisdiene **2** and the 2:1 adduct **12**. Fragments derived from bisdienophile **1** units are shown in blue and those derived from bisdiene (**2** and **11**) units are shown in pink. Cyclohexene rings, resulting from Diels-Alder reactions, are highlighted in yellow (O = solid red). Reagents and conditions: i, PhMe, reflux, 17 h.

4. Molecular Cages

The relatively recent construction of carcerands[21]—hollow container-like molecules (Fig. 4), which can imprison smaller molecules to form so-called carceplexes—raises the prospect of new organic materials with exciting properties and exotic applications,[13, 21] e.g. slow release biodegradable molecular encapsulants for pharmaceuticals and agrochemicals or metabolism-resistant molecular shells, containing radiation-emitting guests, attached to immunoproteins for use in cancer therapy. Incarcerated molecules inside soluble carcerands[21] give very unusual NMR spectra. They indicate that the inside of the carcerand is a new phase—the incarcerated molecules plus 'vacuum'—whose properties are a function of the degree of occupancy of the interior of the carcerand by the imprisoned molecules. At the end of their recently-published communication, *Sherman* and *Cram*[22] speculate: "The carceplexes represent a new state of matter whose guest-mobility with respect to the host is subject to design, and whose physical properties are subject to molecular level manipulation. Several potential applications of carceplexes to materials science problems are envisioned, and are being examined."



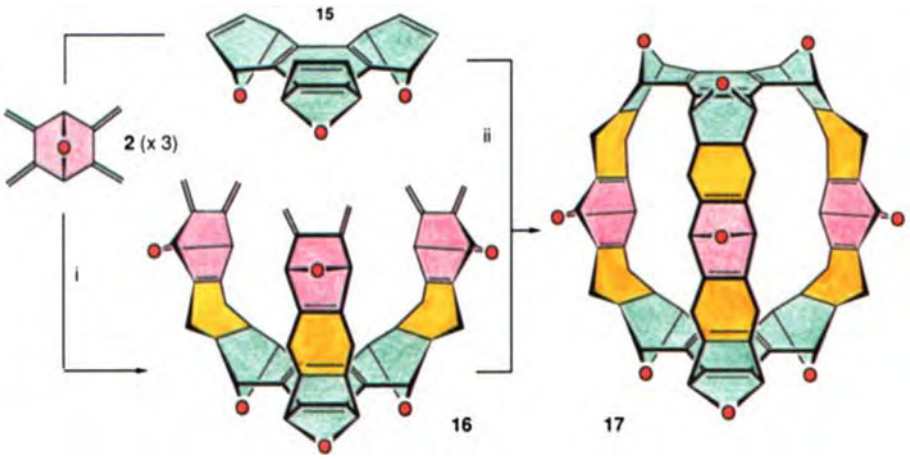


Fig. 4. Looking through the portals along the four-fold axis of the structural formula of *Cram*'s carcerand which is shaped like an American football. The arrows indicate the four carbon–sulfur bonds formed during the last step of the synthesis which brings together two cavitands each composed of alternating resorcinol (gray/black) and 8-membered acetal rings (pink) (O = solid red).

The recognition[23] that the basic carcerand topology is such that its atoms can be assembled on a minimal surface, may assist in the design and syntheses of other organic molecules. However, incentives for designing and synthesizing new materials come from many quarters. The cage compound **17**, which we have called[9] trinacrene after an old name (Trinacria) for Sicily, can be constructed via the 3:1 adduct **16** in two steps from the bisdiene **2** and the all-*syn* trisdienophile **15** (Scheme 6). The synthesis of trinacrene **17**, relying on repetitive Diels-Alder reactions as it does, is once again one that can be performed under tight stereochemical control. It is within the realms of possibility to adapt structure-directed approaches of this kind towards rational and total syntheses of carbon clusters,[24] including the C_{60} compound (Fig. 5) which has been christened buckminsterfullerene or footballene.

Scheme 6. The construction of trinacrene **17** via the 3:1 adduct **16** by a stereo-electronically-programmed set of Diels-Alder reactions from the bisdiene **2** (pink) and the all-*syn* trisdienophile **15** (blue). Newly-formed cyclohexene rings are highlighted in yellow (O = solid red). Reagents and conditions: i, PhMe, reflux, 16 h; ii, CH_2Cl_2, 10 kbars, 50 °C, 6 days.

ADVANCED MATERIALS

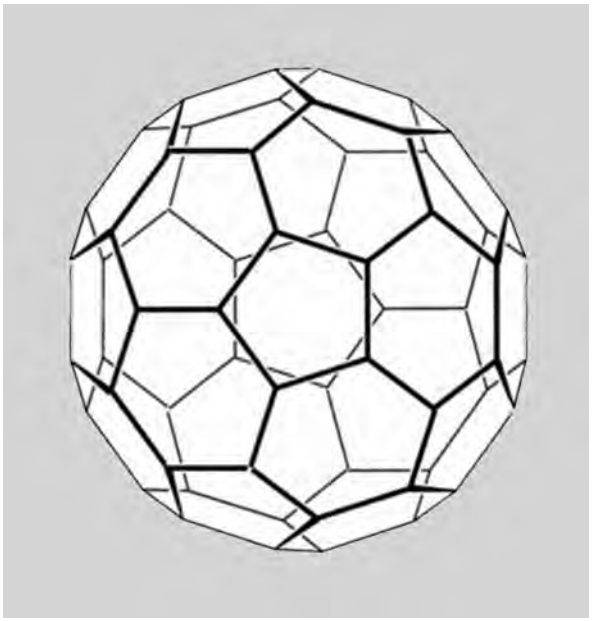

Fig. 5. The structural formula of buckminsterfullerene or footballene, a C_{60} species composed of 12 pentagonal and 20 hexagonal rings in the shape of a pentagonal dodecahedron.

neering may seem rather bizarre, but, actually, the notion that mechanical and electronic devices can operate at a molecular level has already been demonstrated in biological systems. For example, the smallest known[26] rotatory mechanical devices – either natural or artificial – are the bacterial ion-driven flagellar motors, which are unique to the fields of biology and engineering.

The form and function of unnatural products is infinite. As invention, rather than discovery, becomes more and more the hallmark of chemical research, unnatural products with form and function will result. Natural products serve only to reveal some of what is possible and they certainly do not have a monopoly on the means of realizing the possibilities. If you want to reach for the sky (Fig. 6) then wings – but without feathers – might be all you need to help you on your way.

Received: June 2, 1989

Fig. 6. Birds in flight – natural and unnatural forms functioning.

5. Outlook

The structure-directed synthesis of unnatural products is set to undergo rapid development during the next few years. It will provide a relatively straightforward means for the creation of a vast number of very large, organized, and functional structures. Opportunities beckon presently for the production of molecules with form – that look like ball bearings, beads and threads, belts, cages, chains, chimneys, clefts, coils, collars, knots, ladders, nets, springs, stacks, strips, washers, and wires – and concurrently and subsequently for molecules with function – that work like abacuses, capacitors, catalysts, circuits, clocks, conductors, dynamos, membranes, motors, nuts and bolts, resistors, screws, semiconductors, sensors, shuttles, superconductors, and switches.[25] Some of these postulated developments in molecular engi-

Metal Organic Chemical Vapor Deposition (MOCVD) Perspectives and Prospects**

High Purity Semiconductors
Heteroepitaxy
Low-Dimensional Structures
Precursors for III–V Growth
Electronic Ceramics
Thin Films

By John O. Williams*

1. Introduction

This paper reviews the progress that has been made over the past decade in the use of metal organic chemical vapor deposition (MOCVD) for the preparation of high purity, epitaxial layers of a wide range of semiconductor materials: it also considers an extension of the technique to the preparation of thin film electronic ceramics and archetypal high temperature oxide superconductors.

It is now over a decade since the pioneering work of *Manasevit* and coworkers[1, 2] gave rise to the remarkable interest subsequently shown in processes that use metal-organic compounds for the production of semiconductor materials. Since 1981 four international conferences have been held on the topic,[3] numerous workshops have been organized and nowadays, for certain key III–V materials systems (and to a lesser extent narrow band gap II–VI analogs), MOCVD or metal organic vapor phase epitaxy (MOVPE) is an accepted production technique yielding novel electronic and optoelectronic devices.[4–6] In many of these cases, MOVPE compares favorably with molecular beam epitaxy (MBE) and for certain materials particularly those containing phosphorus, MOVPE can produce superior materials. MOVPE is capable of producing thin layered structures – the so-called quantum wells and superlattices – and the technique can be used for atomic layer epitaxy (ALE)[7] and in the preparation of layered crystals (LC).[8]

One area where MOCVD has not developed to the same extent as MBE is the in situ monitoring of the deposition reactions. Despite recent progress[9, 10] our understanding of the basic processes occurring in MOCVD is not very advanced and monitoring techniques are only currently being developed unlike in the case of, for example, reflection high energy electron diffraction (RHEED) in MBE to monitor and control atomic layer deposition.[11] In addition, since compounds are used as precursors in MOCVD, a great effort has to be expended in order to achieve the required levels of high purity and safety/convenience of the growth process. Many innovative preparation and purification routes have been developed[12, 13] for the most common precursors and over the past two years, safer and less toxic chemicals have been studied as alternative starting materials.[14, 15] With an improved understanding of the growth mechanisms, we can look forward to a period of considerable innovation in the use of the MOCVD technique and it is interesting to note

[**] I would like to thank members of the UMIST Solid State Chemistry Group and the UK JOERS Consortium on InP-based materials for numerous stimulating discussions. The financial support of the SERC, US Air Force, Thorn EMI CRL, Air Products Ltd. and Johnson Matthey Ltd. is also gratefully acknowledged.

ADVANCED MATERIALS

that this is already happening in the fields of both electronic ceramics e.g. $PbTiO_3$[16, 17] and high-T_c oxide superconductors of the family $YBa_2Cu_3O_x$ (x:6 to 7).[18, 19]

2. Attainment of High Purity in Semiconductor Materials

Most advances in semiconductor devices rely on the availability and subsequent doping of high purity materials. In recent years there have been significant advances in this field. MOCVD has its own difficulties in this area additional to those of other conventional preparative techniques since the precursors that are used do not lend themselves to ready purification: they are often pyrophoric, hazardous chemicals. It is now possible to analyze directly the metal organic precursors for elemental impurities at the ppb level using variants of inductively coupled plasma (ICP) analysis.[20]

Parallel studies to characterize impurities in the grown epitaxial layers by such techniques as secondary ion mass spectrometry (SIMS) and low temperature photoluminescence (PL) allow correlation between impurities in the starting materials and those in the epitaxial layers.[21–23] This relationship may be illustrated by reference to some recent work on the growth of GaAs. Two batches of trimethyl gallium (TMGa) were used with the same, high purity, arsine source. The ICP analysis of the TMGa showed different amounts of common impurities as shown in Table 1. The

Table 1. ICP analysis for impurities in TMGa1 and TMGa2*.

Elements	TMGa1	TMGa2
Si	0.2 ppm	0.05 ppm ND
Zn	0.6 ppm	0.3 ppm ND
Sn	< 0.5 ppm ND	0.5 ppm ND
Mg	0.05 ppm	0.05 ppm ND
Mn	< 0.05 ppm ND	0.05 ppm ND
Fe	< 0.3 ppm ND	0.3 ppm ND

* ND = not detected

level of Si and Zn, recognized n- and p-type impurities respectively in GaAs, is lower in source TMGa2 than in TMGa1. The electrical characteristics of GaAs grown from TMGa2 and arsine are much improved over those from TMGa1 and the same arsine. The low temperature (77 K) electron mobility and concentration are higher and lower, respectively, and for TMGa2 the lowest carrier concentration and highest mobility are obtained at the lower growth temperature of 600 °C (Figure 1). This low growth temperature can

be adventitious for good morphology and crystallinity of the epilayers. The electrical properties are dominated by the Si and the activated incorporation of this impurity is consistent with doping studies using disilane.[24]

A similar situation is observed in the case of InP preparation by MOCVD where Si is again found to be the dominant impurity in the highly purified organometallic precursor, trimethylindium (TMIn). The presence of this impurity in the grown layers has been confirmed by depth profiling studies and analysis of low temperature photoluminescence spectra.[21] Figure 2a shows the electron concentration as a function of depth through the InP epilayers grown with increasing temperatures. The corresponding silicon profile in SIMS is shown in Figure 2b. Low temperature (4 K) PL spectra confirm the presence of donors, and measurements in a magnetic field (where the donor related transitions are resolved) indicate the presence of S and Ge impurities in addition to the Si. Removal of Si yields extremely high quality InP material with theoretical values of electron mobility and concentration reached for epilayers ca. 10 μm in thickness. Indeed, one of the highest reported electron mobility values for InP ca. 400.000 $cm^2 V^{-1}$ at 60 K has been reported for MOCVD material using purified TMIn.[25] The two examples cited are for binary materials. There have also, as a result of this success with GaAs and InP, been significant improvements in the purity of ternary and quaternary materials. This will not be covered in this review, but the interested reader is referred to the recent literature.[26]

3. Heteroepitaxy

Heteroepitaxy describes the situation where an epitaxial layer of one material is grown upon another in strict crystallographic registry. In addition to providing considerable fundamental scientific interest such materials combinations have enormous technological significance. Table 2 summarizes the properties of a few simple heteroepitaxial systems which are prepared by MOCVD. The list is confined to binary and elemental materials although, as we shall see later in sections 4 and 5, systems including ternary and quaternary materials may also be classified as heteroepitaxial.

Table 2. Simple heteroepitaxial systems.

Material	Crystal Structures	Unit Cell dimension a_0/pm	Lattice Mismatch $[\Delta a/a]_0 \times 10^2$	Band Gap /eV
GaAs (e)	sphalerite (fcc)	0.565331	+4.09	1.35
Si (s)	diamond	0.543072		1.14
GaAs (e)	sphalerite (fcc)	0.565331	−3.68	1.35
InP (s)	sphalerite	0.586928		1.29
ZnSe (e)	sphalerite (fcc)	0.56670	+0.24	2.67
GaAs (s)	sphalerite (fcc)	0.565331		1.35

(e) epitaxial layer; (fcc) face-centered cubic; (s) substrate: $[\Delta a/a]_0$ is the measurement for a stress free epitaxial layer and is defined as $(a_0 - a_s)/a_s$ where a_s is the unit cell dimension of the substrate.

It is instructive to consider these pairs of materials in turn. Since Si dominates the commercial semiconductor market, there has been interest in preparing GaAs on Si. There appear to be significant advantages if this could be done properly including: the relative cheapness of Si substrates as compared to GaAs, the better thermal conductivity of Si with relevance to power devices, the ability to combine high speed GaAs devices with high density Si circuits and the possibility for fabrication of GaAs opto-electronic devices in combina-

ADVANCED MATERIALS

tion with Si integrated circuits. However, two major difficulties arise. First the two materials differ in the symmetry of their respective crystal structures, and second, the unit cell dimensions differ leading to a "lattice mismatch" at the interface between epilayer and substrate. The symmetry difference (sometimes referred to as different color symmetry) leads to the formation of anti-phase boundaries (APB) when growth proceeds on substrate surfaces of particular orientations with catastrophic consequences for electrical behavior at the interfaces. Because of these difficulties it is now accepted that any devices made in the GaAs/Si system and relying on the GaAs must utilize material well away from the interface unless the APBs and other defects can be eliminated. Furthermore, these limitations are likely to preclude the development of devices that utilize both Si and GaAs simultaneously. Considerable progress has been made recently in the MOCVD growth of GaAs on Si without necessarily employing buffer layers to accommodate the lattice mismatch.

Preparation of Si surfaces prior to growth is a prerequisite and a complex series of nucleation and crystal growth steps appear necessary for the preparation of GaAs with acceptable crystallinity. Figure 3 illustrates how surface preparation, nucleation and growth temperature affect the crystallinity of GaAs grown on accurately oriented (100)Si substrates. Experiments to reduce interfacial defects have also been carried out employing substrate surfaces deviating from (100) orientation and good properties obtained at 4° off towards (110).[27] In addition to the problems encountered in the GaAs/Si system the other two pairs of materials referred to in Table 2 suffer the disadvantage of possible interdiffusion of elements with catastrophic consequences if it occurs to an appreciable extent. The situation is worst for ZnSe/GaAs since Zn acts as a p-type dopant in GaAs and Ga as an n-type dopant in ZnSe. Excellent quality ZnSe has been grown on (100)GaAs surfaces by reduced and atmospheric pressure MOVPE.[28] Room temperature photoluminescence is observed indicating the low concentrations of shallow and deep centers, but the structural, electrical and optical properties are highly dependent on epilayer thickness and the distance away from the interface. The X-ray and PL data for ZnSe epilayers grown on GaAs and varying in thickness from 0.5 μm to 8.0 μm are given in Figure 4. In the thinnest layers, deep center emission appears in the PL and in the X-ray data the ZnSe diffraction maxima are shifted to lower 2θ values. SIMS analysis on the ZnSe reveals the presence of Ga diffusion from the substrate (Fig. 4c) and cross sectional transmission electron microscopy (Fig. 4d) confirms the defective nature of the interface. It is unlikely that the ZnSe/GaAs interface can be made sufficiently good to support efficient devices relying on optical/electronic properties. However, the ternary $ZnSe_{0.95}S_{0.05}$ grown on GaAs[29] offers a lattice-matched system, and studies following MOCVD growth indicate that its properties are superior to those of ZnSe/GaAs and adequate to support devices. The distortion at the interface of ZnSe/GaAs renders the structure tetragonal as opposed to cubic[30] and this has been

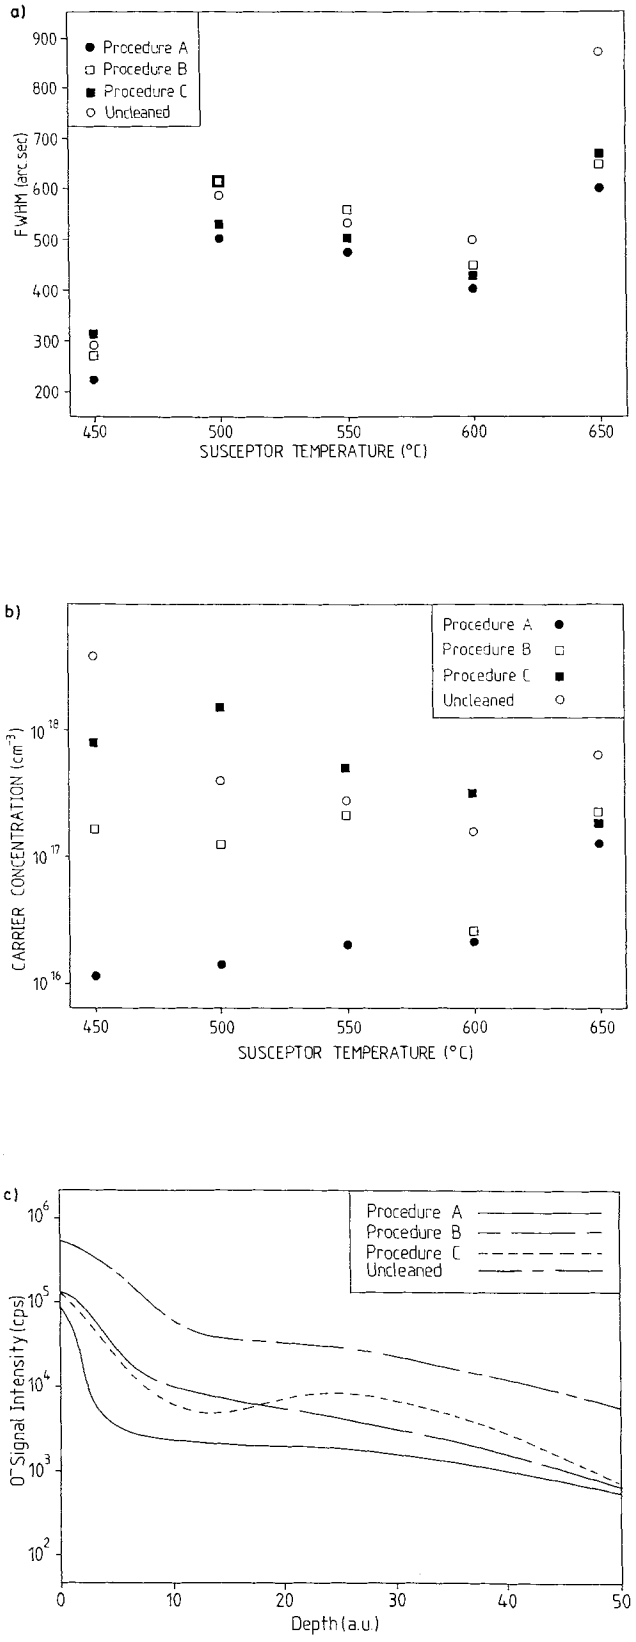

Fig. 3. a) X-Ray rocking half widths vs. susceptor temperature for each Si(100) surface. b) Background carrier (electron) concentration vs. susceptor temperature. c) Dynamic SIMS spectra showing surface oxide thickness for each Si(100) surface.

confirmed recently by electron spin resonance studies of Mn-doped ZnSe using the $Mn^{2\oplus}$ ions to probe the local symmetry.[31]

GaAs has been grown successfully on InP substrates[32] and efficient devices such as solar cells and MESFETS have been fabricated. As with the other two heteroepitaxial systems these do not rely on charge carrier transport across the interface or on optical generation of carriers in that region. We can, therefore, conclude that in these three heteroepitaxial systems we have important building blocks for the development of integrated opto-electronic devices that will combine important electronic and optical functions on a common substrate i.e. Si, GaAs or InP.

4. Ternary and Quaternary Materials

Figure 5 shows how the band gap of III–V materials varies with the lattice constant and composition. Such diagrams are often referred to as phase diagrams and they aid the crystal grower in his choice of material system appropriate to a particular electronic/optical requirement. (The term band gap engineering is commonly used to describe this approach). The tie-lines represent ternary compositions e.g., $Ga_{1-x}In_xAs$ and $InAs_{1-y}P_y$ and areas on the diagram contained within points of four binary compounds represent quaternary materials e.g., $Ga_{1-x}In_xAs_{1-y}P_y$. It is apparent that one particular ternary composition will have the same lattice constant as a binary compound and this may be found by drawing vertical lines through the binary point to intercept the tie-line for that particular ternary e.g. $Ga_{0.47}In_{0.35}As$ is lattice matched to InP (dotted line). Similarly, a range of quaternary compositions e.g. $Ga_{1-x}In_xAs_{1-y}P_y$ with $0 < x < 1$ and $0 < y < 1$ will be matched to InP and will be represented by the same vertical dotted line. Almost the entire range of III–V direct band gap, ternary and quaternary materials have been prepared by MOCVD. For many of these the problem of compositional uniformity both within the bulk and across the surface of the grown layers has been solved and lattice matching is achieved with good morphology and crystallinity of the grown layers. One of the most important III–V ternary systems is $Ga_{1-x}Al_xAs$/GaAs and the other is $Ga_{1-x}In_xAs$/InP. The "AlGaAs" system is unique in that lattice-matching to GaAs is retained for a wide range of x values since the radii of Al (1.43 Å) and Ga (1.41 Å) are similar. In contrast only one composition of "InGaAs" is lattice-matched to InP. Double crystal X-ray rocking curve analysis confirms that a

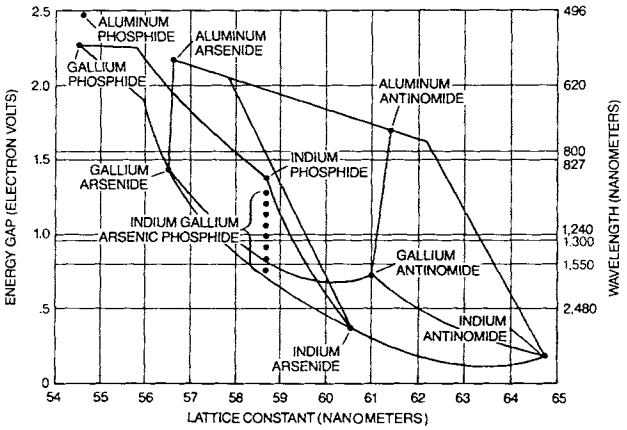

Fig. 5. Band-gap engineering of a semiconductor can be done by varying the elemental components of the semiconductor alloy in a controlled way. Here the energy across the band gap is plotted against the lattice constant, or the dimension of the basic unit of the crystalline lattice. The lines that connect points on the graph show how the band gap and the lattice constant vary for mixtures of the binary compounds to which the points correspond. Such mixtures are ternary compounds. For example, the ternary compound gallium aluminum arsenide can be made to have any band gap between about 1.4 and 2.2 electron volts by varying the ratio of gallium to aluminum between the band-gap extremes represented by gallium arsenide and aluminum arsenide. Materials of differing composition that have roughly the same lattice constant, such as these two binary compounds, can be deposited in alternating layers to create a single crystal lattice. Operating wavelengths for three important optical communications systems are 800, 1300 and 1550 nm [55].

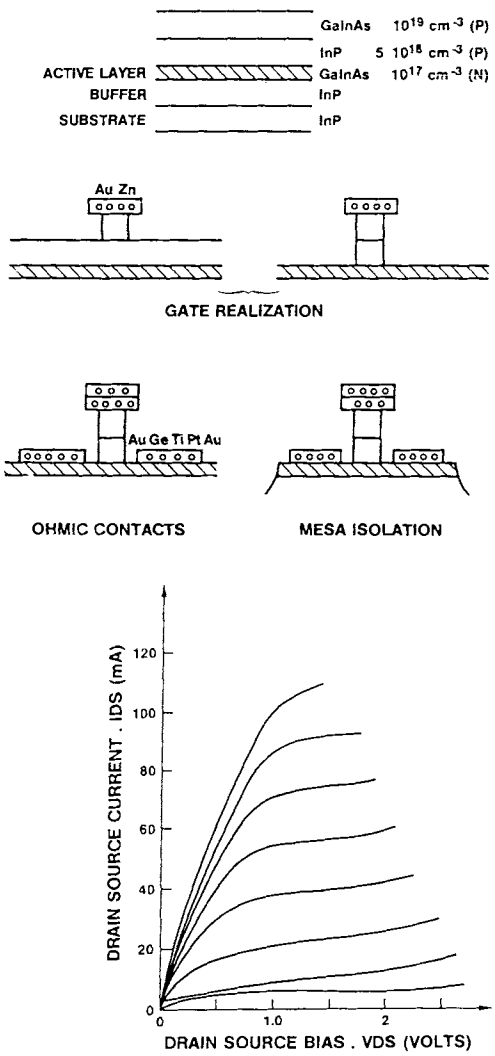

Fig. 6. (Top) Schematic diagram of the JFET fabrication process. (Bottom) JFET DC characteristics.

lattice mismatch $[\Delta a/a]_0$ of less than 8×10^{-5} may be routinely obtained with a full width at half maximum (FWHM) of < 40 arc/sec for this system. Several device structures including junction field effect transistors (JFETs) and double heterostructure pindiodes have been fabricated with excellent characteristics. Figure 6 gives details of the structure, fabrication, uniformity and characteristics of a typical JFET structure grown by MOCVD.[33]

The quaternary system $Ga_{1-x}In_xAs_{1-y}P_y$ covering the entire composition range has also been prepared by MOCVD[34] and the field has been reviewed recently.[6] There are also important advances presently being made with ternary and quaternary materials containing antimony.[35]

Over the past three years, *Dupuis* and collaborators have made significant advances in the fabrication of low threshold, high efficiency $Al_{1-x}Ga_xAs/GaAs$ double heterostructure injection lasers directly on Si substrates.[36] As mentioned in section 3, this is another example of heteroepitaxy but in this work, the lattice mismatch has been accommodated by the preparation of Si/Ge buffer layers. Four types grown by MBE have been used (i) single Ge layers (1 μm thick) deposited on Si (ii) a single Ge layer grown on Ge/Si strained layer superlattice, (iii) a Ge layer deposited on linearly graded Ge/Si alloy buffer layer, (iv) a combination of (ii) and (iii). It is found that the best device performance is obtained using procedure (i)[37] and this work illustrates the sophistication of layered structures that can be prepared by a combination of MBE and MOCVD.

5. Low-Dimensional Structures and Devices

Over the past decade there has been considerable progress in the study of low dimensional structures prepared by both MOCVD and MBE. It is not my intention in this review to compare the two techniques and the task of presenting a comprehensive account of 'LDS/LDD' is an impossible one because of the enormity of the subject area. I shall, therefore, be highly selective in my choice of topics and will attempt to address particular materials problems. The interested reader is referred to three recent excellent reviews which cover other aspects.[38, 39, 54]

Initial studies dealt with the "AlGaAs/AlAs" or "AlAs/GaAs" quantum well and multiple quantum well structures. Here GaAs acts as the well material and AlAs or AlGaAs as the material in the barrier layers. Lasers operating in the red spectral region ca. 850 nm are now in commercial use. A particularly interesting structure is that of a graded refractive index separate confinement heterostructure single quantum well laser (GRINSCH SQW laser). The laser consists of a 500 nm GaAs buffer layer, 1 μm $Al_{0.6}Ga_{0.4}As$ cladding, 340 nm graded "AlGaAs" confinement region within an 8 nm thick GaAs SQW active layer, 500 nm $Al_{0.6}Ga_{0.4}As$ cladding and 100 nm GaAs contact layer. This type of laser gives continuous wave (CW) operation at room temperature with a broad area threshold current density of ca. 300 Acm^{-2} and a single longitudinal mode operation at 843 nm with a peak width of less than 1 nm.[32]

The advent of devices such as high electron mobility transistors (HEMTs) based on a two dimensional electron gas (2 DEG) formed in the "AlGaAs"/GaAs system has further emphasized the dimensionality of these thin layer structures. Figure 7a is a schematic diagram of a typical heterojunction structure grown by MOCVD. The two dimensional electron gas is formed in the undoped GaAs layer just below the thin ca. 15 Å undoped "AlGaAs" layer and sustains a high electron mobility in two dimensions (Figure 7b). The doping in the upper "AlGaAs" layer is achieved using selenium. A

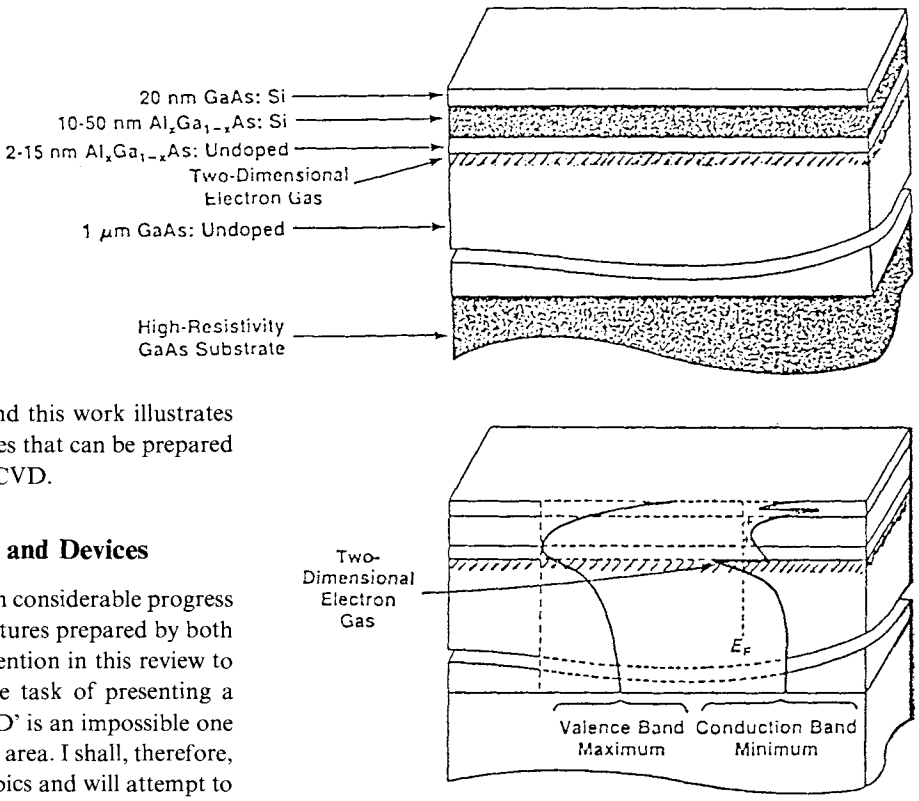

Fig. 7. a) Cross section of a modulation doped heterojunction. b) Energy band diagram for structure of (a). The two dimensional electron gas formed in the structure is ideal for the conducting channel of a FET.

ADVANCED MATERIALS

HEMT structure requires good doping uniformity, low carrier concentration in undoped material and sharp interfaces. These requirements can be met by MOCVD. Multiple quantum well structures in InP-based ternary and quaternary materials have also been prepared by MOCVD. Figure 8 shows the actual structure grown and the corresponding photoluminescence spectra for the GaInAsP/InP system. It should be noted that each quaternary well yields a PL emission peak which shifts to lower wavelengths as the well width decreases.

Examination of Figure 8 allows us to understand the concept of strained layer superlattices (SLS) and pseudo-

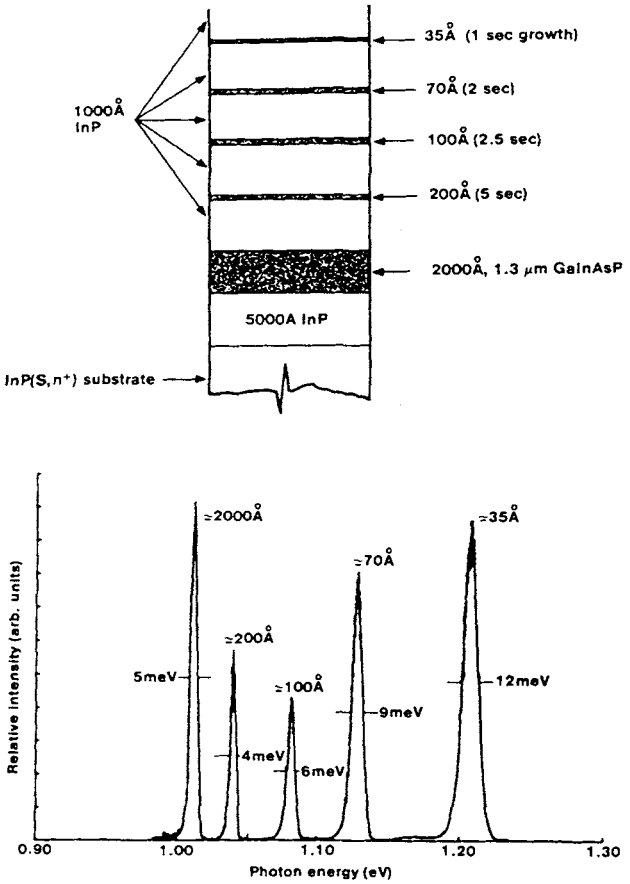

Fig. 8. a) GaInAsP/InP quantum wells grown to assess epitaxy and interface quality. b) Photoluminescence spectrum of a GaInAsP multiquantum well sample, emission from each of the four different wells and from the bulk epitaxial material can be observed. $T = 4.2$ K, 25 mV, 40 mW, 0.18 W cm^{-2}.

morphic structures. It has been shown that dislocations in ternary materials grown on binary semiconductors can be confined to the interfacial regions when the layers are thin ca. ≤ 200 Å.

Furthermore, the effective lattice-matched composition of the ternary can be achieved by growing successively thin layers of different binary compounds of the required thickness. Thus, the composition $Ga_{0.47}In_{0.53}As$ can be built up of GaAs and InAs layers of appropriate relative thickness. In a similar way, the quaternary of a given composition can be equivalent to two ternaries, neither of which is lattice-matched to the substrate. Typical materials combinations that have been grown successfully by MOCVD are indicated in Table 3. In order to achieve uniform compositions and sharp interfaces, careful control of reactor geometry is required.

6. Novel Precursors for III–V Growth

Conventional group III organometallic and group V hydrides used as precursors for MOCVD suffer severe disadvantages despite the fact that good quality epitaxial layers can be produced in the majority of cases. These disadvantages arise from the toxic and hazardous nature of arsine and phosphine, for example, and the pyrophoric nature of TMGa and TMIn. TMIn suffers further limitations due to its crystalline nature which can severely reduce the levels of compositional uniformity that can be obtained in several ternary and quaternary systems.

Another important consideration when preparing complex systems is the relative thermal behavior of a pair of group III and/or group V precursors. Arsine and phosphine, for example, decompose in the gas phase and, as far as is known, at GaAs and InP substrate surfaces, with very different rates. Such considerations have prompted several research groups worldwide to seek alternative precursors. Table 4 lists alternative precursors for arsine that have been

Table 4. A selection of alternative As precursors used with TMGa to produce GaAs.

Compound	Vapor Pressure	GaAs n_{77K}/cm^{-3}	electrical data Ref μ_{77K}/cm^2 V^{-1} s^{-1}
Trimethylarsine (TMAs)	235 Torr at 20 °C	p ~ 10^{17}	–
Triethylarsine (TEAs)	5 Torr at 20 °C	n ~ 5×10^{15}	13.000
Diethylarsine (DEAs)	0.8 Torr at 18 °C	n ~ 3×10^{14}	64.000
Tertiarybutylarsine (TBAs)	96 Torr at −10 °C	n ~ 1×10^{15}	53.000
Phenylarsine	2 Torr at 20 °C	n ~ 1×10^{15}	40.000

examined in recent years for GaAs growth by MOCVD. With most of these reagents carbon incorporation is a major problem and hitherto only two precursors, tertiarybutylarsine (TBAs) and phenylarsine (PAS) have shown real promise. Both of these are liquids under normal conditions. GaAs with relatively high electron mobilities (ca. 40.000 $cm^2 V^{-1} s^{-1}$ at 77 K) and low donor concentration for nominally undoped material ($n \leq 1 \times 10^{15} cm^{-3}$) has been reported.[14] For the case of InP growth, liquid tertiarybutylphosphine (TBP) has also shown promise.[15] It may be no accident that these liquid precursors, with hydrogen atoms linked directly to the group V element, yield epitaxial layers relatively free of carbon impurities, in contrast to those precursors that contain no group V–H bonds, e.g. trimethyl- and triethylarsine (TMAs and TEAs respectively). It appears that As–H and/or As–H_2 units are required in order to react with methyl radicals from TMGa to form GaAs without resulting in carbon formation, although final details await mechanistic investigations currently underway in several laboratories. PAS is also being used to grow InAs.

From time to time in the MOCVD field, there has been interest in developing adduct precursors or "magic compounds" where the group III–group V bond has already been formed.[40] Thermal dissociation would simply detach side groups leaving behind the III–V binary compounds, a process that would be safe and cheap. However, progress in this area has been disappointing for several reasons. First, the adducts cannot be purified sufficently: second, they require the presence of other group III or group V sources in order to produce stoichiometric material and third, they cannot alone provide ternary and quaternary materials of variable composition.

7. Crystallography – Controlled Growth

The manufacture of the current generation of electronic devices with features of the order of several microns involves complex etching and lithographic processes which are both inefficient and time consuming. Therefore, considerable interest is being shown in local or selected area deposition where the semiconductor material is deposited only where it is required, e.g. in the active region. There have been several approaches to achieving selected area deposition using MOCVD. One has involved "photo-assisted" deposition using, for example, laser radiation and capitalizing on photonic or thermal effects to deposit the desired material. Several review articles have appeared covering these aspects.[41, 42] A much more recent and novel approach is to use precursors selectively to deposit on particular surfaces but not on others. The acronym CODE, compound and orientation dependent epitaxy, has been used to describe this technique.[46] Such growth surfaces would vary in their composition and/or structure and crystallography. It is also desirable to use MOCVD to overgrow contoured substrates in order to isolate component function, and for interfacing. The work of *Hersee* et al.,[43] *Demeester* et al.,[44] *Yoshikawa* et al.,[45] *Scott* et al.[46] and *Garrett* and *Thrush*[47] covering both GaAs and InP based systems should be consulted for further details. Much of this work has been concerned with the ability of MOCVD to deposit over mesa-type structures and into channels of given crystallography.

Such capabilities would assist in the fabrication of buried heterostructure lasers, waveguides and active/passive waveguide interfaces by single step epitaxy. A common technique to study the behavior over contoured substrates is to employ a multi-heterostructure growth technique to follow the time evolution of the growing surfaces, i.e. to grow a superlattice whose individual layer thickness is much less than the total thickness of the grown layer. Although the precise distortion of the growth process introduced by the creation of the superlattice is uncertain, some general preliminary conclusions can be drawn in relation to the preference for growth on certain crystallographic planes in the InGaAs/InP and AlGaAs/GaAs systems: (i) InGaAs is reluctant to nucleate on either (111)A or (111)B surfaces, whereas InP grows on all available crystal planes. AlGaAs/GaAs on the other hand nucleates on (111)A surfaces but not on (111)B surfaces. (ii) For both systems nucleation and growth on (100) and (110) surfaces appears to be better than for (111) surfaces. Clearly, the growths are controlled by surface free energies, preferential adsorption, differential sticking coefficients etc. and it will be interesting to see the results of controlled experiments involving, for example, different precursors for the group III elements.

8. Electronic Ceramics and Oxides

Over the past two years, there has been growing interest in the so-called high-T_c oxide superconductors typified by the composition $YBa_2Cu_3O_{7-x}$ where $0.1 < x < 0.2$.[48] Superconducting transition temperatures around 90 K have been obtained for compressed, polycrystalline samples prepared by sintering and annealing the constituent oxides in specific proportions. In addition, other compositions based on Bi, Tl, Sc etc. have shown promise.[49] In order to be compatible with electronic and other types of device structures and the complete range of processing technologies it is desirable to prepare these materials as thin films. There have been various reports of successes using, for example, vacuum evaporation, sputtering, MBE, spray pyrolysis and screen printing. MOCVD has also been used with variable success.[50] Hitherto, metal chelate precursors such as 2,2,6,6-tetramethyl-3,5-heptanedione (thd) derivatives have been used, but the process has been unreliable and the thermal growth has to be followed in most cases by either a high temperature treatment or an annealing process under controlled conditions. The main difficulties arise from the choice of precursor and substrate material and these have not been optimized. In general, the following conditions are typical:

ADVANCED MATERIALS

(i) precursors kept at ca. 150 °C to 300 °C
(ii) substrate materials such as MgO or yttrium stabilized zirconia
(iii) growth temperatures in the range 600–900 °C
(iv) subsequent annealing in O_2 or high temperature treatment at ca. 900 °C
(v) reduced pressure operation (10–100 Torr) with heated lines from precursor containers to the growth chamber.

Thin films of "YBCO" have been obtained with preferred orientation (*c* axis normal to film plane) and variable composition, exhibiting superconducting transition temperatures over the range 30 to 80 K. Recently, we have improved the compatibility of precursors by using fluorinated β-diketones of the three metals Y, Ba and Cu and this appears also to improve the reproducibility of the MOCVD process.[51] We have demonstrated control over the composition as measured by energy dispersive X-ray analysis (EDAX) and the perovskite structure can be obtained by careful choice of processing temperature and substrate material/orientation. Future work in this area should address the understanding of the basic deposition process in order to remove the empiricism currently prevailing, and photo-assisted techniques should be investigated.

Four years ago, we proposed MOCVD routes for the preparation of electronic ceramic and ferroelectric oxides typified by $PbTiO_3$ and $Pb(La,Zr)TiO_3$. In recent years this has proven possible for $PbTiO_3$, in particular, using alkoxide and β-diketone derivatives of Pb and Ti and some success has been obtained with $Pb(La,Zr)TiO_3$. In addition, the work of *Brierley* et al.[52] using a range of precursors has demonstrated the preparation by MOCVD of $PbTiO_3$ and $Pb(Sc,Ta)O_3$ thin films. The stoichiometry and thickness of the films may be controlled by adjusting the temperatures of the precursors, the flow rate of the carrier gas and the deposition time. As with the "YBCO" system, post-growth heat treatments and/or annealing are necessary to achieve the required crystalline structure (phase). The reader could well ask what are the advantages of MOCVD for these two materials systems. The main one overcomes the inability of sputtering to maintain stoichiometry in these complex oxides and the other removes the need with spray pyrolysis to perform the deposition sequentially in order to build up film thickness. Also in this context, our experiences with laser ablation from single targets of $PbTiO_3$ and/or $Pb(La,Zr)TiO_3$ have demonstrated that it is extremely difficult to retain film stoichiometry and obtain the pervoskite phase.[53]

9. Conclusion

In this review, I have attempted to cover certain materials aspects of MOCVD. What is readily apparent is the tremendous versatility of the MOCVD processes and their applicability to the preparation of a wide range of important materials systems. Thin film epitaxial structures of widely varying but controlled compositions and thicknesses can be prepared with complete certainty and we appear to be confined at present only by the limited range and purity of available precursors. We are also beginning to understand the fundamentals of the growth processes that involve complex combinations of gas phase and surface phenomena. Progress in this area will remove the empiricism currently dominating our quest for better and novel starting materials. The entire field appears to have an exciting future and should contribute to the development of advanced materials for many years to come.

Siloxane Copolymers with Laterally and Terminally Attached Mesogenic Side Chains**

By *G. W. Gray**, *J. S. Hill* and *D. Lacey*

In view of the demand for liquid crystal polymers of different types[1] with certain specific physical characteristics, many workers have considered how this could be met through synthesizing copolymers containing two or more terminally attached mesogenic side chains, and tuning the properties of the polymers by variation of the type and ratio of the side chains. In this way, using the smectic-depressing properties of a lateral methyl substituent, a nematic side-chain polysiloxane with a proportion (but only up to 32%) of terminal cyano-groups and positive dielectric anisotropy was first produced.[2]

Acrylate polymers containing mesogenic groups attached laterally to the backbone were first reported by *Finkelmann*,[3] and analogous polysiloxanes have since been reported by *Gray* et al.[4] and *Keller* et al.[5] These are predominantly nematic materials, and by synthesizing a series of novel siloxane copolymers containing varying amounts of terminally *and* laterally attached mesogenic groups, we now show that a further degree of flexibility is provided for the development of liquid crystal polymers with defined physical characteristics for applications in areas such as integrated optics,[6] optical storage,[1,7] gas liquid chromatography,[1] and NCAP displays,[8] e.g. nematic polysiloxanes containing 80–85% of cyanosubstituted side chains, and having a range of dielectric properties of technological interest.

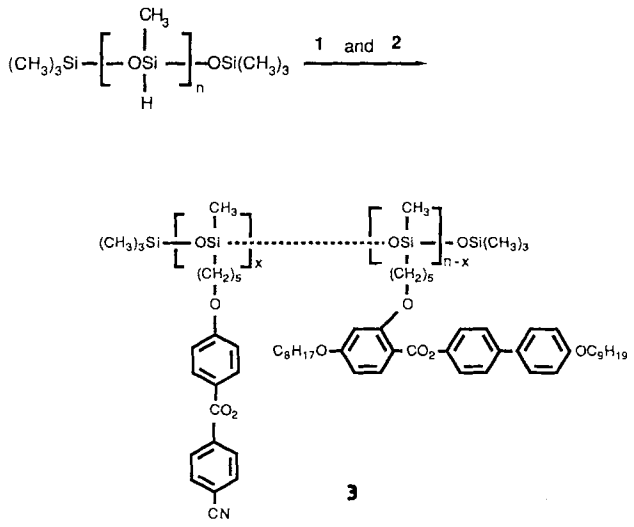
Experimental

For the precursor of the *terminally* attached moiety we chose the alkene **1**, which gives a crystalline smectic homopolymer with relatively high melting and clearing points. Most laterally attached polysiloxanes which have been prepared to date are nematogenic and have a glass transition. We chose as the *lateral* comesogenic precursor the alkene **2** which has been prepared in our laboratories, and gives a typically low T_g, low T_{N-I} homopolymer.



The synthesis of those compounds using standard procedures is shown in scheme 1.

Scheme 1.

The copolymers were prepared by hydrosilylation of the alkenes in toluene at 70 °C for 18–24 h (Scheme 2), using poly(hydrogenmethylsiloxane) obtained from Wacker Chemie (DP ~46, $\gamma \sim 2.2$); a 1.1 molar excess of the mixture of alkenes was used, with platinum divinyltetramethyl disiloxane as the catalyst. Purification was effected by repeated precipitation of the polymers from dichloromethane solution with 3:2 v:v methanol:ether, and subsequent centrifugation. The pure polymers were dried in vacuo in the isotropic state.

ADVANCED MATERIALS

Scheme 2.

The relative proportions of the mesogenic side chains in each polymer were determined by ^{1}H NMR. The terminal-lateral ratio in each copolymer was found to be greater than the ratio of the alkene precursors used in the feedstock for the original reaction. This implies that the overall rate of hydrosilylation is greater for the terminal than for the lateral mesogen, and is probably explained by the greater steric hindrance to the approach of the lateral moiety to the reaction site.

The thermal properties of the polymers were determined by differential scanning calorimetry and optical microscopy. The results are summarized in Table 1, and a graphical illustration of these results is given in Figure 1.

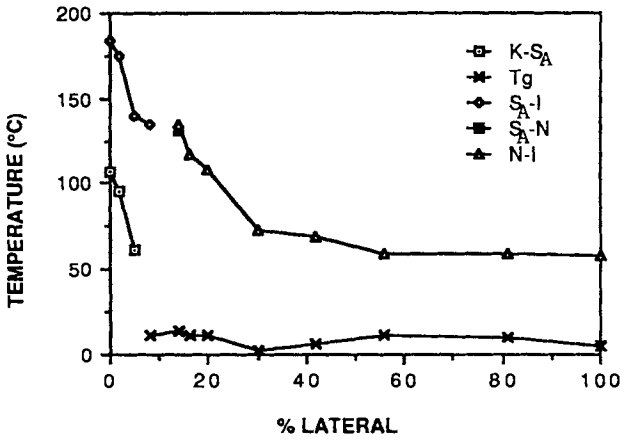

Fig. 1. Thermal properties of siloxane copolymers w.r.t. the proportion of laterally attached mesogens.

The main features of this copolymer system are summarized below.

(a) The introduction of only small amounts of the lateral side-chain component into the predominantly terminally cyano-substituted polymer has been shown for the first time to have very striking effects, whereas introduction of small amounts of the terminal side-chain component into the predominantly laterally substituted polymer has very little effect.

(b) Very low concentrations (2–5%) of the laterally attached side chain decreased both T_m and T_{S-I}, and with $\geq 8\%$, glass transitions were observed.

(c) On increasing the lateral side-chain content to 14%, a narrow range nematic phase appeared to be introduced (DSC) above the S_A phase, and with $\geq 16\%$, the polymers exhibited nematic phases only.

(d) The marked increases in the isotropization temperatures ceased with $\geq 30\%$ of lateral side-chain component, and the T_{N-I} values became fairly constant. Apart from minor fluctuations, the T_g values remained about the same for $\geq 8\%$ of lateral side-chain component.

X-ray diffraction studies (University of Bristol) and dielectric studies (University of Swansea) are currently being undertaken on these copolymers.

Through this system, we have demonstrated the possibility of tuning the thermal and mesomorphic properties of conventional siloxane polymers with terminally attached side chains by the introduction of a laterally attached comesogenic component. This is exemplified by the introduction of a glass transition, and the change from a purely smectic to a purely nematic polymer system.

At the same time, we have shown that one may introduce both small and large (up to 70%) amounts of mesogenic side chains containing cyano-groups into a laterally attached side chain polymer so that the dielectric properties may be changed considerably without significantly affecting the thermal properties of the original polymer.

This method of using mixed lateral-terminal side-chain copolymers to tune properties may be extended to other side-chain liquid crystal polymer systems such as polyacrylates and condensation polymers.

Polymers with a High Refractive Index and Low Optical Dispersion

By *Hans-U. Simmrock, Alfred Mathy, Ligia Dominguez, Wolfgang H. Meyer** and *Gerhard Wegner*

Materials for use in optics are usually characterized in terms of their refractive index n_D and their Abbe number ν_D which describes the wavelength dependence of the refractive index, the optical dispersion ($\nu_D = (n_D - 1)/(n_F - n_C)$ where n_D, n_F and n_C are the refractive numbers of the material at the wavelengths of the spectral lines of Na, F and C respectively).

In the n_D vs. ν_D diagram the regime of materials which combine high refractive indices with high Abbe numbers used to be exclusively occupied by inorganic glasses. Transparent polymers range from $n_D = 1.33$ to $n_D = 1.73$. However, polymers with high n_D values usually have low ν_D values and vice versa. For example, the data corresponding to two optically extreme polymers are: $n_D = 1.675$ and $\nu_D = 19$ for poly-*N*-vinylcarbazole and $n_D = 1.345$ and $\nu_D = 83$ for Teflon FEP (Fig. 1). Thus, the combination of high refractive index with low optical dispersion in polymers appeared until now to be unachievable.[1]

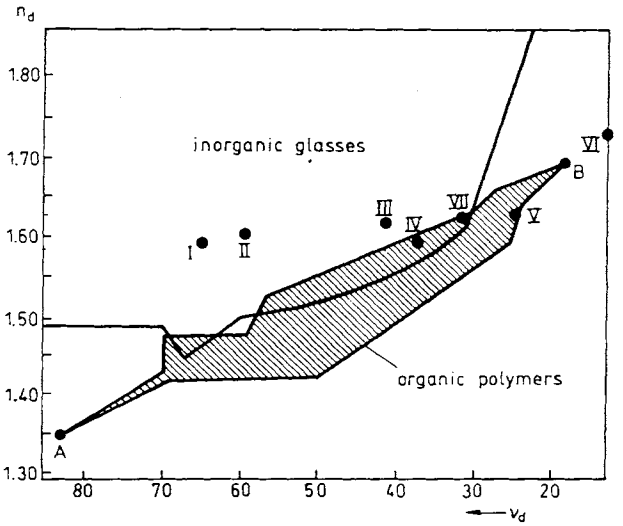

Fig. 1. Refractive indices and optical dispersion of ionenes and other materials: n_D vs. ν_D diagram. I, II, III, IV, V, VI and VII: Ionenes are defined in Table 1. A: Teflon FEP, B: Poly-*N*-vinylcarbazole.

Numerous efforts have been made in the past to extend the polymer regime towards higher indices and lower dispersion. We report here a successful approach using polyelectrolytes, in which the optical parameters can be adjusted by varying the structure of the polymer *and* by the proper choice of the counterions.[2] We use polyelectrolytes of the type **1**, which are also known as "Ionenes" (Io), with the main chain segments R^1, R^2 and the side chains R^3, R^4 being organic moieties (e.g. aliphatic groups), and X = monovalent (q = 1) or divalent (q = 0.5) counterions. The solid state properties of such polyelectrolytes are usually scorned as being "salt-like". Indeed, ionenes with R^1 and R^2 being relatively short aliphatic segments, due to their high charge density, are highly crystalline materials with physical and chemical properties resembling those of inorganic salts.[3]

1 $\quad \dagger R^1-N(R^3)_2-R^2-N(R^4)_2\dagger_n 2 \cdot n \cdot q \cdot X$

However, ionenes where R^1 and R^2 are larger organic components with low charge density have more polymer-like properties. They can be processed from the melt or from solution to form glassy films with excellent optical transmission in the visible and near-UV (Fig. 2). In such ionene glasses ionic conductivity has been recently demonstrated.[4]

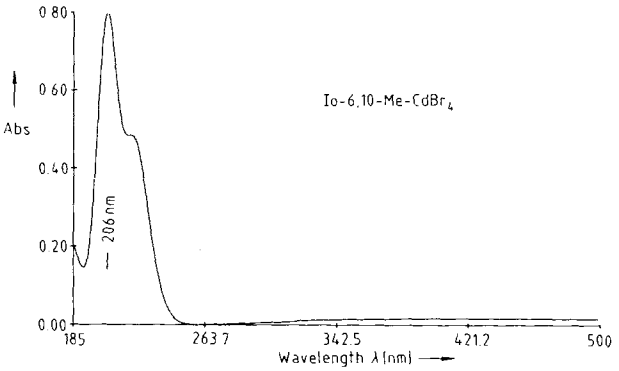

Fig. 2. UV-VIS-Absorption spectrum of a typical ionene-film (thickness: 1 μm; Io-6, 10-Me-$CdBr_4$ defined as in Table 1).

Recrystallization can be suppressed and long-term stability of the glassy state can be obtained by introducing a certain amount of irregularity along the polymeric structure such as in copolymers ($R^1 \neq R^2$) by using isomeric mixtures and by combining rigid and flexible chain segments. By these means the thermal behavior and the processibility of the materials can also be greatly influenced. For example: the glass transition temperature of Io-10-Et-BF_4 ($R^1 = R^2 = (CH_2)_{10}$; $R^3 = R^4$ = ethyl; X = BF_4) is $-22\,^\circ C$, while that of Io-Do,Pip-Me-$CdBr_4$ ($R^1 = -CH_2-CH=CH-CH_2-$; $R^2 = -cyclo\text{-}NC_5H_9-(CH_2)_3-cyclo\text{-}C_5H_9N-$; $R^3 = R^4$ = methyl; X = $CdBr_4$) is $+191\,^\circ C$. The thermal properties and relaxation phenomena in glassy ionenes have recently been discussed in detail elsewhere.[4]

ADVANCED MATERIALS

In contrast to ordinary polymers the counterions in polyelectrolytes provide an additional parameter by which the material properties can be influenced. With respect to the optical properties of ionenes the choice of counterion, turned out to be decisive: Due to the relatively simple structure of the polymer backbone a refractive index without counterions of only about 1.5 can be expected, while by the proper choice of X n_D can be shifted to 1.7 and higher.

Different counterions can be introduced into ionenes by metathetical ion exchange in solution following one of the experimental procedures described in detail elsewhere.[5] By these means materials with purities better than 99% with respect to the counterions can be obtained. Another possible method for counterion exchange in the glassy material are concentration or electrochemically driven diffusion processes.

For the optical measurements about 1 μm thick transparent films were obtained by spincoating from dimethylformamide (DMF) solutions. The optical parameters of the films were determined with a prism coupler as described in detail by *Ulrich* and *Torge*.[6, 7] The prism coupler can be used to determine the refractive index and the thickness of a light-guiding thin film. Both parameters can be obtained simultaneously and with good accuracy (n_D better than $\pm$ 0.0005) by measuring the coupling angles at the prism and fitting them to a theoretical dispersion curve. Using laser light of different wavelengths, the wavelength dependence of the refractive index and thus the Abbe-numbers can also be determined.

The optical parameters of a selection of different ionenes are compiled in Table 1 and displayed in Figure 1.

Obviously, with refractive indices between 1.58 and 1.72 and Abbe-numbers up to 65 the ionenes have intruded into the regime of inorganic glasses. When comparing ionenes with polymers with identical backbone structures but different counterions the influence of the polarizability of X on the refractive index can be substantiated: e.g. Io-6,10-Me-$CdBr_4$ exhibits an $n_D = 1.5858$, while the corresponding ionene combined with the more polarizable CdI_2Br_2 exhibits an $n_D = 1.6250$.

Similarly, the absorption of the counterions plays a rôle in the dispersion: a couterion absorbing in the UV such as $CdBr_4$ gives rise to a relatively low dispersion, whereas a counterion absorbing closer to the visible such as CdI_2Br_2 gives rise to a higher dispersion.

With the determination of the optical parameters by the prism coupler method the applicability of polyelectrolyte glasses as waveguiding material has been demonstrated. Since the choices are so manifold for the backbone structures and the counterions, a great variety of materials with tailor-made optical and other physical as well as chemical properties can be made. Therefore, the application of this class of materials in optics appears to be very promising.

Gauge Theory – A New Outlook on Solid State Dynamics

By Stanley Clough *

Occasionally in science a new outlook arises which radically changes perceptions and genuinely deserves the overworked description "breakthrough". Such an event has occurred recently in the recognition of the fact that the dynamics of condensed matter must be described by gauge theory.[1-3] A consequence has been to throw new light on the hitherto dark and mysterious relationship between the quantum and classical descriptions of solid state dynamic processes. A sound basis is provided for classical models and attention is now focused on new phenomena which can be expected when neither pure quantum nor pure classical descriptions are appropriate. The most important consequence however, is that the incorrect procedure and concepts which have been commonly used are highlighted.

One of the problems about understanding the properties of materials is the need to choose either a quantum mechanical or classical description, when the relationship between the two descriptions can be quite obscure. This is in spite of the existence of phenomena which are clearly quantum mechanical at low temperature but better described classically at high temperatures. A hybrid theory which would encompass both regimes has never existed. Its non-existence has even been part of a dogma which insists that only the mysterious Copenhagen interpretation links the two types of theory. It is as if we had to use two different languages in the north and the south of a country with no guidance about what to do in the middle. Nature, we were told, is like that. Now it appears that nature is more sensible. We were leaving out key features called symmetry breaking and *Berry*'s phase. Now the two languages are revealed as different dialects of the same language and one merges smoothly into the other. The hybrid theory that spans both quantum and classical regimes exists. It is gauge theory.

Berry's discovery was that there are two ways in which the phase of an eigenfunction can advance, not one as previously supposed. Quantum mechanics had been structured to handle the motion of one system but not two, and the phase associated with one system driving another had been overlooked. Not for the first time, science had mistaken a special case for the general one. The analysis of most problems of condensed matter involves a decomposition of the whole sample into two parts, a subsystem whose motion is to be described and a thermal heat bath where the effect of the latter on the former is crucial to the description. Regarding the subsystem to be isolated leads to a set of eigenstates and eigenvalues for the subsystem with the latter controlling the evolution of the phase of the wave function. When the interaction with the heat bath is switched on, the state of the subsystem changes and a new way in which the phase of its wave function can change comes into play.

The idea which makes these statements tangible is symmetry breaking. In order to swim a spherical creature must deform to create a paddle. In the same way, the symmetry of an isolated system is broken when it interacts, and one or more new coordinates are created through the interaction. Symmetry breaking is a common occurrence throughout physics and is usually discussed by means of a schematic diagram like Figure 1. This represents a potential energy surface with the shape of the bottom of a wine bottle, i.e., a central maximum surrounded by a circular trough. Superimposed on the central maximum is a deep minimum which

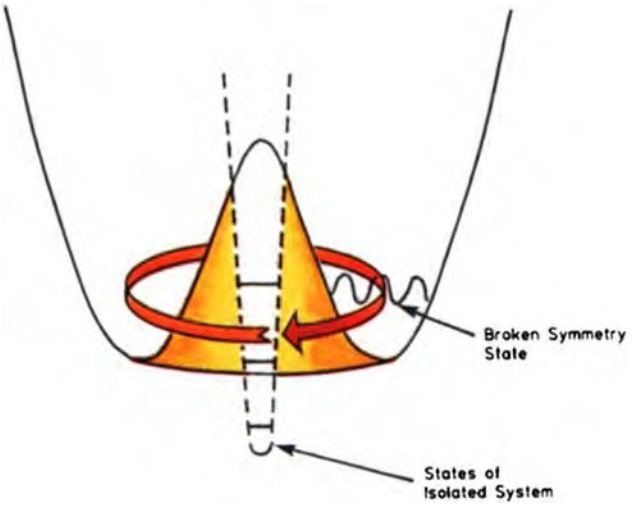

Fig. 1. A schematic representation of symmetry breaking and the consequent appearance of a new quasi-classical coordinate. An isolated system is represented by the central minimum. The state of a thermally interacting system is described by a wave packet in the circular trough, combining both quantum and quasi-classical features, the latter arising from the *Berry*'s phase associated with motion around the trough.

represents the isolated system with its set of energy levels. When the interaction with the surroundings is turned on, the symmetry breaks and the wine bottle potential comes into play. The state of the subsystem is now a wave packet located in the circular trough and the new coordinate generated by the interaction is the position in the trough. The interacting environment drives the wave packet around the trough and this is the motion which leads to the acquisition of *Berry*'s phase. The dynamics therefore require specification of the wave packet as a linear combination of the states of the isolated system, and also the driven motion around the trough. At high temperatures the wave packet is a mixture of many states of the isolated system, averaging out the quantum motion, and the wave packet becomes localized so that its motion in the trough acquires a classical particle-like character. In this way there is a smooth progression from the almost pure quantum behavior of a weakly driven system at low temperature, when the energy levels determine the dynamics, to the quasi-classical behavior of a thermally driven system at high temperature. In the light of this description it is easy to see how earlier discussions, which attempted to describe the temperature dependence only in terms of the states of the isolated system (being unaware of the symmetry breaking, the motion associated with the new coordinate(s) and *Berry*'s phase) were handicapped.

The history of gauge theory and how it finally arrived in solid state physics is an interesting story. Its origin is the most radical idea of the century, *Einstein*'s geometrization of gravitation in his theory of general relativity. *Newton*'s force of gravity was replaced by a curvature of space into time. The notion that other forces might be represented (or replaced) by curved spaces was immediately taken up by *Weyl* in 1919 in the first gauge theory which was an example of an idea before its time. Its somewhat unhelpful name dates from this period. The problem was that no other space could be imagined into which the xyz space could be curved. It was not until the advent of quantum mechanics, when the phase of a wavefunction could be identified as a kind of additional particle coordinate in an intangible "internal" space, that the nature of the curvature in *Weyl*'s theory could be recognized. Two sub-spaces may be said to be curved into each other if a displacement through one entails a shift in the other. Thus moving a clock in a gravitational field results in a change of its time rate because space-time is curved. The gravitational field determines the magnitude of the effect and is a measure of the curvature. Similarly, a quantum particle moving in a region in which the external xyzt space time is curved into the "internal" space, experiences a change in the internal coordinate, i.e. the phase of the wave function. This provided a brilliantly simple description of electromagnetism and the foundation for particle physics theories. However, gauge theory became associated with the intangible "internal" spaces and its application to the more mundane problems of condensed matter was overlooked.

The wave function of a charged particle moving through a space–time vector dr experiences a phase change q (A. dr) where A is the electromagnetic vector potential. Thus electromagnetism can be recognized as a gauge theory arising from the existence of a very simple internal charge space. The six components of the electromagnetic field, E_x, E_y, E_z, B_x, B_y and B_z represent the curvature of the internal space into xyzt measured in the planes xt, yt, zt, yz, zx, and xy, respectively. The internal charge space is experienced only by particles carrying electric charge and can be visualized as a circle of values between 0 and 2π. All electromagnetism follows from this. The curvature is due to the presence of other charges, so that the interaction between charges occurs as each charge modifies the curvature of the space through which other charges move.

The elaboration of the theory for more complex internal spaces laid the foundation for theories of the nuclear forces between fundamental particles, which resulted later in the spectacular successes of the electro-weak theory for the unified electromagnetic and weak nuclear interactions, and quantum chromodynamics for the strong interaction. In these theories the curvature is quantized with the appearance of exchange particles like the photon in electromagnetism. A further element in the argument was required to account for the mass of the exchange particles associated with the weak interaction. This crucial element is symmetry breaking.

Solid state physics remained largely isolated from these developments of the 60's and 70's. There were warning signals that it had adopted some false concepts, but there were also standard explanations which covered up the contradictions. Then in 1984/5 the term *Berry*'s phase (or the topological phase) began to be heard and to become very common in titles in Physical Review Letters. *Berry*'s innovation[1] was to consider the evolution of the wave function of a driven system rather than a dynamically isolated one. He showed that it acquired an extra phase (*Berry*'s phase) dependent on the geometry of the driven trajectory. *Simon*[2] saw at once that this phase was a consequence of the trajectory of the driven system occurring on a curved space, and *Wilczek* and *Zee*[3] recognized the mathematical structure of gauge theory. It had finally arrived in solid state physics.

It should have been no surprise. Most problems in the solid state require a division into a subsystem P and its thermal environment Q. If subsystem P drives subsystem Q then the coordinates of the two subspaces P and Q cannot remain pure. The spaces are curved into each other and the curvature replaces the forces which each exerts on the other. Space Q acts as an "internal" space for P, and vice versa. The interaction of such systems is described by gauge theory. This means that the differential momentum operator $\partial/\partial x^P$ is replaced by the covariant derivative $D = ((\partial/\partial x^P) + iA)$. This is the prescription for differentiating on a curved x^P surface. A is a vector potential which describes (through the derived field) the curvature of the surface. It depends on the state of the interacting subsystem Q and therefore allows one subsystem (the heat bath) to drive the other (the system under examination). The curvature introduced by the inter-

action changes the space of the isolated system and is responsible for symmetry breaking.

The story so far can be summarized by saying that gauge theory is the universal description for forces between interacting systems. To understand its importance for condensed matter science, it is necessary to appreciate the bad state the latter has fallen into because of the lack of awareness of curvature. Briefly, solid state physics exists in curved spaces which have been treated as flat. Some of the consequences of curvature have been introduced in an ad hoc way and some left out. Naturally this has caused confusion. The confusion has been concealed by a set of concepts which have been developed to make physical sense out of false theoretical structure. Gauge theory with symmetry breaking blows away this conceptual smoke-screen and replaces the rather abstract mysteries by a much simpler set of ideas.

The simplest example of solid state dynamics which illustrate these matters is the hindered rotation of symmetrical molecular groups like CH_3 or NH_4 in crystals. At low temperature these exhibit clear quantum mechanical tunneling motions and at high temperatures their rotation can be described in terms of classical hopping between the wells of the hindering potential. The discrete quantum phenomena at low temperature can be accounted for by the cyclic boundary condition $\psi(\Phi) = \psi(\Phi + 2\pi)$, where Φ is the rotation coordinate. This is normally justified by the statement that the wavefunction must be single valued. In fact it only applies to the special case where the group is dynamically isolated. If it interacts with the environment so that the two move together in a correlated way then the boundary condition takes the form $\psi(\Phi) = \psi(\Phi + 2\pi)\exp(iy)$ where y is connected with the movement of the environment. The phase factor y is *Berry*'s phase and for a methyl group it is connected with the thermally activated rotation rate. At low temperatures y is small and the effect of the boundary condition is to allow only a small number of rotational states. For the methyl group these are three in number known as A, E^a and E^b, the latter pair being degenerate. The energy difference between the A and E levels is the tunnel splitting. This determines the frequency whose reciprocal specifies a time during which an additional phase y is acquired. At higher temperatures the root mean square value of y grows. When it is of the order π, the boundary condition has lost its restrictive character and a broad band has replaced the discrete levels. In short, thermal broadening has occurred clearly related to the rate of driven rotation. The magnitude of the broadening becomes identifiable as the reciprocal of the correlation time for the driven rotation as assumed in purely classical theories.

The intervention of the environment in defining $\Phi + 2\pi$ relative to Φ curves the one dimensional Φ space which may be regarded as being changed from a flat circle into a helix. This symmetry breaking is the key to an understanding of how classical mechanics can emerge from quantum mechanics. Symmetry breaking is an inevitable consequence of interactions, as for example, when two previously spherical atoms form a chemical bond. Methyl rotation is just the simplest example but the conclusions apply quite generally. The effect of the environment breaks the symmetry of the isolated system, introduces new coordinates which are embryonic versions of the classical ones, and as the fluctuations of the environment come to dominate, a smooth transition from quantum to classical behavior occurs.

How has solid state physics managed so long without these concepts? Without the broken symmetry and its quasi-classical coordinate and associated *Berry*'s phase, the attempt has been made to explain quantum damping or motional broadening only in terms of the levels in the central minimum of Figure 1. The observable broadening now attributable to *Berry*'s phase was wrongly accounted for by life time broadening of the levels due to incoherent transitions between them, though how the rate of thermal transitions between levels could be measured in thermal equilibrium was not explained. Since vibrational excitation clearly has nothing to do with rotation, it led to a curious doctrine of separation. This supposed there to be two kinds of concept, quantum and classical, and asserted that no theory should contain both. Thus rotation is a classical concept, along with torque, and according to this doctrine should not figure in a quantum theory. This made the absence of driven rotation into a principle, which was reassuring but wrong. In the central minimum there is no motion clockwise or anticlockwise because time-reversal symmetry remains unbroken, but the quantum motion can be described as a kind of bidirectional motion, both clockwise and anticlockwise simultaneously. It was then argued that the Copenhagen interpretation meant that the apparent bidirectional motion was to be interpreted statistically as either clockwise or anticlockwise rotation. This introduced rotation but it had nothing to do with the broadening and nothing to do with the lattice. Using such devices, a conceptual gap was concealed for many years. The new insights of gauge theory solve many problems simultaneously and carry the weight of established success in relativity, electromagnetism and particle physics. The new developments represent a long delayed achievement of a unified approach to interactions across the whole of Physics.

ADVANCED MATERIALS

Imaging Organic Molecules with the Scanning Tunneling Microscope

By Jürgen P. Rabe*

Atomic resolution has become a common feature in Scanning Tunneling Microscopy (STM) of inorganic semiconductor surfaces, both in vacuum and in a number of fluid ambients. A review has been given recently in this journal.[1] Moreover, the physics involved in the imaging process for these materials is well enough understood to allow detailed electron-spectroscopic investigations on an atomic scale to be performed. For organic materials, however, the method is much less developed. Clearly, this cannot be attributed to a lack of interest but rather to the characteristics of organic systems; above all the lack of electrical conductivity. In an attempt to circumvent this particular problem the imaging of single organic molecules as they are adsorbed on a conducting substrate has been attempted, since in this case the distance required for the probing electrons to tunnel is minimized. However, for these systems another typical feature of organic materials, molecular mobility, may still remain a problem. To date, due to these difficulties, only few systems have successfully been imaged by STM and it is this lack of experimental data which contributes to a third problem, namely the lack of a good understanding of the contrast mechanism in STM imaging of organics. Therefore, it is of particular interest that recently a number of new organic systems have been imaged.

In Figure 1 an STM image of Cu-phthalocyanine on Cu(100) is shown as obtained under ultra-high vacuum conditions by *Lippel* et al.[2] It shows isolated Cu-phthalocyanine molecules adsorbed flat with two different rotational orientations. Notably, studies of the same adsorbate on Ag(111), Au(111) and Si(111) 7×7 surfaces gave considerably less clear and stable images, indicating that the STM can resolve the internal structure of a flat isolated molecule, provided that the interaction between adsorbate and substrate is strong enough to sufficiently reduce molecular motion. The important question of contrast generation is also addressed by the authors. They interpret their images as representing the charge distributions of free molecule states near to the Fermi level. Like in the case investigated earlier[3] of benzene and carbon monoxide coadsorbed on Rh(111), the authors favor this explanation rather than an adsorbate induced change of the local work function.

In Figure 2 another high resolution STM image obtained by *J. K. Spong* et al.[4] is shown: The adsorbate layer at the interphase between a conducting solid substrate (graphite) and a liquid crystalline ambient (5-nonyl-2-*n*-nonoxylphenylpyrimidine). This example is representative of a whole

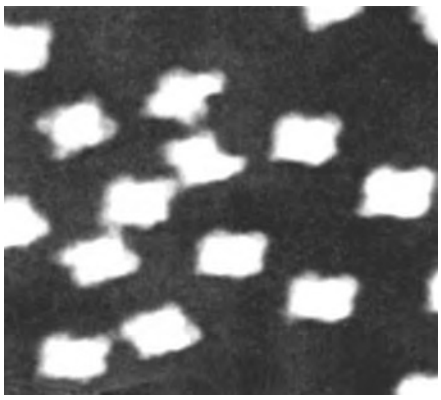

Fig. 1. STM image of Cu-phthalocyanine on Cu(100), as obtained by *P. H. Lippel* et al. [2]. The isolated molecules are adsorbd flat with two different rotational orientations. The scan dimensions are 15 nm × 15 nm.

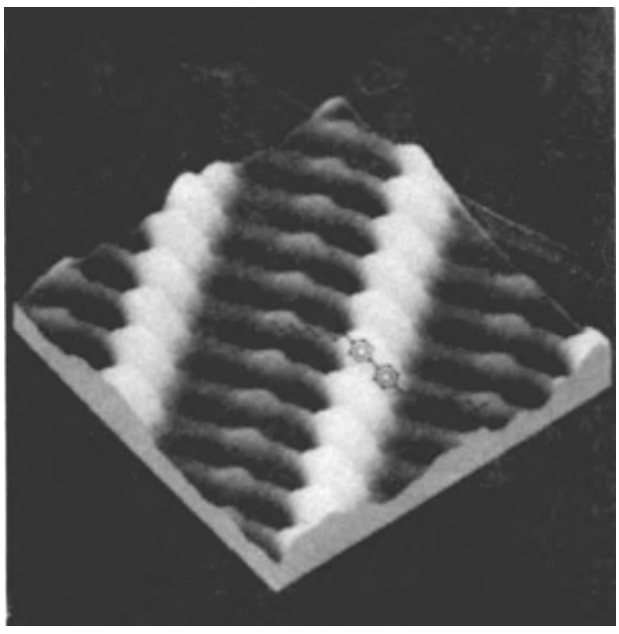

Fig. 2. Three dimensional display of an STM image of 5-nonyl-2-*n*-nonoxylphenylpyrimidine on graphite, as obtained by *J. K. Spong* et al. [4]. The scan dimensions are 4.3 nm × 5.2 nm. The image has been unit cell averaged.

class of liquid crystalline materials on graphite.[4, 5] Evidently, the molecules are imaged as they are adsorbed flat on graphite, quite like the phthalocyanine rings on copper. However, in this case no isolated molecules, but rather an ordered array is imaged. The intermolecular interaction within the monolayer may stabilize the position of any particular molecule, thereby reducing molecular motion sufficiently for STM imaging. The contrast is attributed in this case to the modulation of the local work function of the substrate by the polarizable molecular adsorbates. Indeed, functional groups which are electronically as dissimilar as benzene and cyclohexane can have similar contrast when imaged by the STM. This is explained by their comparable polarizability. However, it should be noted that alkane residues also have similar polarizabilities but give a different contrast in the STM. Obviously, the issue of contrast generation still remains a matter of debate.

A quite general way to reduce molecular motion is to increase the number of segments per molecule interacting with the substrate, a feature typical in polymer adsorption. Interestingly, high resolution STM images of DNA and double stranded RNA have recently been obtained by *T. P. Beebe* et al.[6] and *G. Lee* et al.[7] Both groups could resolve, minor and major grooves of the double helices adsorbed on graphite. However, the pitch periodicity was found to vary considerably. This can be attributed to the combined forces of the surface, partial dehydration and possibly intercalation with ionic species. To draw conclusions about the contrast mechanism is very difficult in these cases, since the samples were prepared by allowing buffer solutions of DNA and RNA to evaporate on graphite and the STM investigation was performed in air immediately after the last amounts of water were observed to evaporate. It cannot be excluded, therefore, that traces of electrolyte may contribute to the conductivity. Furthermore, it should be mentioned that due to the thickness of the molecule it is more complicated to interpret high resolution images of this material, than it was in the examples given before.

Our understanding of the processes involved in imaging organic adsorbates is considerably improving. This is both stimulating and encouraging for those working in this research area.

Phase Equilibria under Stress

By Robert W. Cahn*

Ever since the Phase Rule was first formulated more than a century ago, it has been recognized that hydrostatic pressure is a variable that must affect phase equilibria; the normal neglect of this variable in the construction of ordinary metallurgical equilibrium diagrams is merely a recognition that atmospheric pressure is minimal, and a flourishing research field is centered upon the investigation of new polymorphs and new transition temperatures under large pressures. Nevertheless, in the last few years the whole field has been given a quite new impetus by a small group of thermodynamics theorists who have examined the whole issue afresh.

Before we look at these new developments, let us dispose of some of the other ways in which an applied stress can affect phase dispositions. Here the major interest attaches, not to hydrostatic pressure but to uniaxial stress – a simple tension or compression. One important category is that of martensitic transformations, as in ordinary carbon steel. Here, a phase transforms by combining a macroscopic shear with more complex localized strains. When a cubic crystal transforms, it can typically form 24 crystallographically equivalent orientations or variants. An applied stress in the elastic range will favor a few of these orientations, or even a single one, over all the others. This has often been experimentally confirmed (e.g. by *Kochendörfer* and *Müller*,[1] who in this way created virtually a single crystal of a martensitic phase). This same phenomenon is crucially involved in the much studied family of shape-memory alloys, which return to an 'imprinted' shape on gentle heating.[2]

Again, when a single crystal of a cubic disordered phase is cooled so as to create a non-cubic superlattice, then a very small applied compression can pick out one of the, e.g., three

ADVANCED MATERIALS

possible variants to the complete exclusion of the others: this was demonstrated for the ordering transition of CuAu (cubic → tetragonal) by *Arunachalam* and *Cahn*.[3] More recently, those who study superalloys, the family of materials used in the construction of jet engines, have found that internal stresses within a two-phase alloy, resulting from a slight mismatch between the lattice parameters of the two epitactically intergrown 'coherent' phases, can modify the shapes of the dispersed phase particles. This effect can be substantial enough to cause dangerous deterioration of creep resistance. A very recent example of such an observation[4] refers to a dispersion of a phase with B2 order in a matrix with a Heusler ($L2_1$) type of order. The disperse particles form an array of tiny parallel cuboids, but on prolonged annealing a structural change takes place, a population of dislocations arises which winds down the internal stresses and the microstructure changes radically. The topic has been more generally treated by *Johnson* et al.[5]

The most recent work of this kind is also in some ways the most surprising. The long established and practically very important theory of Ostwald ripening—the coarsening of large precipitates at the expense of small ones in a nonuniform dispersion—has proved to be vulnerable. *Johnson* et al.[6] have shown that coherent misfit stresses can drastically alter the kinetics of Ostwald ripening, and can even lead to an inversion of the process, in the sense that smaller particles will grow at the expense of larger ones. One impatiently awaits experimental verification!

All of these diverse phenomena seem peripheral: in all of them, the orientation or morphology of a phase is affected by stress, but the volume fractions and compositions of the constituent phases should not at first sight be affected. A phase equilibrium is altered only when these two linked variables are changed. This is the issue addressed by the seminal work of my American namesake, *John Cahn*, and his French collaborator *Larché*.[7] They consider in quantitative detail the situation of a coherent two-phase solid in which the kind of elastic mismatch referred to above arises. In fact, as they show, both the magnitude of the lattice parameter mismatch and the detailed geometry of the two phases affect the Gibbs free energy of each phase. What this implies is that the Gibbs free energy of each phase is affected by the amount and morphology of the other phase. However, the classical tangent construction (see Figure) in which the composition and volume fraction of each phase is determined by drawing the common tangent in an isothermal plot of the Gibbs free energies of the two phases, depends on the absolute nature of these free energy plots. If the free energy of phase *A* of a certain composition depends on the volume fraction and disposition of phase *B*, then the tangent construction loses its validity. This has a striking consequence: in a binary alloy, a two-phase field is not what we are used to. Conventionally, all alloys within a two-phase field at a given temperature consist of differing proportions of two phases which always have the same compositions. Where the new theory of coherent stress-sensitive equilibria is valid, the compositions

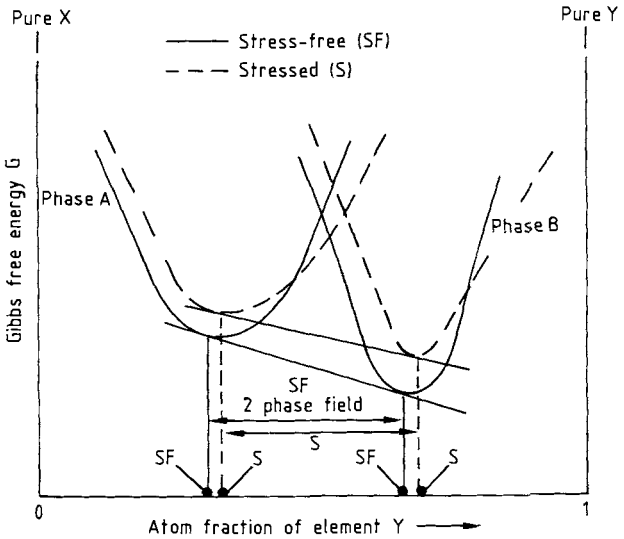

Fig. 1. Schematic diagram of the possible effect of non-hydrostatic stress (internal and external) on the free energies of two coexisting phases in the absence or presence of stress. Stress modifies the two-phase field. Only under very special conditions can the common tangent construction of free energy curves be used to depict phase equilibria in non-hydrostatically stressed solids [11].

of the two constituent phases change as the two-phase field is traversed, and the ordinary lever rule can no longer be employed to compute the volume fractions of the two phases. Somewhat similar ideas were put forward the same year[8] by the Russian theorist *Roitburd* (who is now settled in America).

These radical ideas due to *Cahn* and *Larché* have been further developed recently by two Americans, *Johnson* and *Voorhees*,[9, 10] who are making the running in this field at present. One of their conclusions is that a sort of catastrophic instability may arise so that more than one stable state is possible for the same two-phase alloy when it is subject to self-generated internal stress. The theory has also been applied to the practically important case of elastically stressed heteroepitaxial thin films,[11, 12] where the crucial rôle of coherency stresses in affecting electronic properties has been recognized for some time. The theoretical treatments have focused on elastic self-stresses (i.e., those due to lattice mismatch); the possible rôle of externally applied stresses has still to be addressed. It is clear that theory has run a long way ahead of experimental verification; it is possible that systematic experiments involving intentionally applied external stresses might go some way towards testing the theorists' predictions. Such experiments may also reveal parallels between the older work outlined at the beginning of this article and the more recent theories.

In parallel with the metallurgical literature, indeed somewhat ahead of it in point of time, has been a vigorous debate within the geological/mineralogical community concerning the rôle of non-hydrostatic stresses in phase equilibria in rocks. Phenomena such as pressure solution phenomena, crystallization under stress (the geologists call this recrystallization), shear transformations in rocks such as quartzite,

and diffusion under applied stress, and special phenomena such as the growth of Dauphiné twins in quartz crystals, are all of interest in particular to petrologists, and there has been much disagreement about the magnitude and even the sign of some of these effects. One of the leaders of this community, the Australian rock-mechanics expert *Mervyn Paterson*, some years ago wrote a masterly overview[13] of the whole field (he calls it non-hydrostatic thermodynamics) in which he sought to inject rigor into what had sometimes been a hand-waving discussion. *Paterson* does discuss coherent transitions, e.g., the α/β transition in quartz, but not from the viewpoint later developed by *Cahn, Larché, Johnson* and *Voorhees*. He is concerned here by such matters as the change in transition temperature occasioned by a uniaxial stress and how that change depends upon the crystallographic direction of that stress in a highly anisotropic crystal. It may be that the time is now ripe for a convergence of the metallurgists' and geologists' approaches.

Networks Composed of Rigid Rod Polymers

By Matthias Ballauff*

The physics and chemistry of networks of rubbers is a subject of long-standing interest in polymer science. To illustrate the tremendous technical importance of this field it suffices to mention the tire industry. Considerable profit is made from the advantageous properties of materials exhibiting rubber elasticity. All network polymers used for technical purposes are composed of flexible macromolecules, and the physics of rubber elasticity has been developed based on the fact that flexible chains are crosslinked.[1, 2] In two recent publications[3, 4] *Vilgis, Boué* and *Edwards* for the first time set up a theory of rubber elasticity for networks composed of rigid rod polymers.

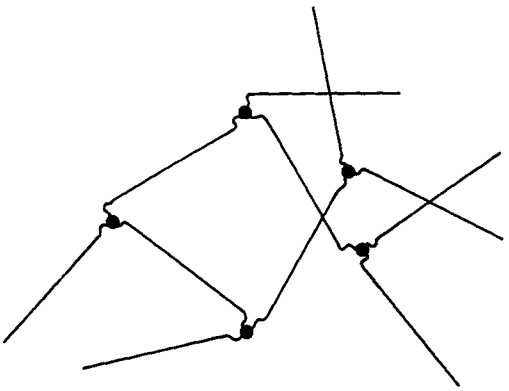

Fig. 1. Schematic representation of a network of rods connected by flexible hinges.

Figure 1 schematically depicts a rubber consisting of rods connected by flexible hinges. The first question to be asked when looking at Figure 1 is what is the degree of freedom of such a structure? More than one hundred years ago *Maxwell*[5] showed that there is a limiting functionality m_c (or an upper critical dimension) given by $m_c = 2\,d$ with d being the space dimension. This can be exemplified by considering two-dimensional networks in a simple square lattice configuration (see Fig. 2).

The functionality is four in this case which exactly corresponds to the limiting functionality in two dimensions

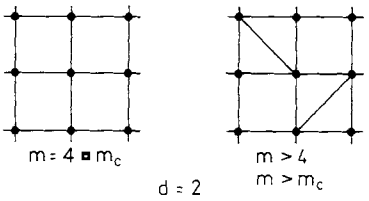

Fig. 2. Critical functionality for two dimensional networks: $m = 4 = m_c$: network can be deformed by shearing (left hand side); $m > 4$, i.e., $m > m_c$: rigid network (right hand side).

($d = 2$). This network can be deformed by shearing. If one increases the functionality beyond four by putting down rods on some diagonals (see Fig. 2) the lattice becomes entirely rigid and the elasticity is no longer of entropic nature but of a purely energic nature, i.e., deformation of this network requires the bending and elongation of bonds. The same

[*] Dr. M. Ballauff
Max-Planck-Institut für Polymerforschung
Postfach 3148
D-6500 Mainz (FRG)

argument applies in three dimensions in the case of simple cubic topology. Here the limiting functionality is $m_c = 6$.

The above named authors succeeded in elaborating a theory of rubber elasticity for rigid rod networks with $m < m_c$. The method applied is rather involved and will not be discussed here. The principal result of the calculation is shown in Figure 3.

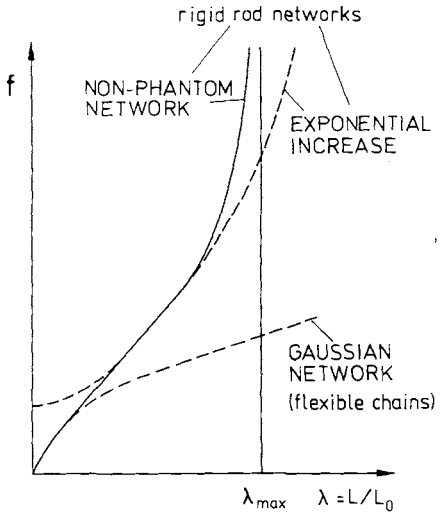

Fig. 3. Theoretical stress–strain relation of a rod network.

Here the stress per unit area f is plotted as a function of strain λ, where λ denotes the linear extension divided by the length at rest ($\lambda = L/L_0$). At low extensions the behavior resembles the results found for conventional networks.[1,2] At larger deformations the stress–strain relation crosses over to an exponential increase. Here obviously the rod-like nature of the chains within the network comes into play. It has to be noted that these results were derived for phantom networks, i.e., for systems without entanglement constraints. The authors also succeeded in including the latter effect into the model. Here theory predicts a maximum deformation at which the stress, as a function of strain, will diverge. This maximum deformation is a function of the concentration at the formation of the rod network. The physical argument leading to this divergence is again quite obvious: Due to the entanglement constraint the rods cannot move through each other but exert a mutual steric hindrance. With increasing extension of the network more and more rods will intersect and decrease the number of degrees of freedom of the system until the critical strain is reached.

This theory is the first attempt to tackle the problem of rigid rod networks. It is a mean-field approach and treats only isotropic systems. Such networks can be synthesized by simultaneous polymerization and cross-linking reaction. A totally different situation arises if cross-linking is effected in ordered liquid crystalline solutions or melts of rod-like polymers. Here the cross links would fix the liquid crystalline order even when the solvent is removed or the temperature is raised beyond the point of phase stability. This obviously provides numerous opportunities to design a whole class of new polymeric materials. The present work by *Vilgis, Boué* and *Edwards* thus could become an example for an interesting technical development preceded by theoretical ideas.

STOP PRESS: Interdisciplinary scientists sought: The Royal Society of Chemistry is inviting nominations for its 1989 Interdisciplinary Awards. The aim of the awards is to draw attention to the importance of interdisciplinary studies, particularly those of public interest, involving chemistry and one or more other science and to reward and publicize such work.There are no age or nationality restrictions but nominees should be domiciled in the UK or Republic of Ireland.

The closing date for nominations is *2 October 1990*. Further details from Dr. J. F. Gibson, RSC, Burlinton House, London WIV 0BN (UK).

Neuchatel Switzerland: The Third International Conference on Surface Modification Technologies will be held at CSEM (Centre Suisse d'Electronique et de Microtechnique) Neuchatel, Switzerland from August 28 to September 1, 1989. The Conference is jointly sponsored and organized by the Minerals, Metals, Material Society (TMS), USA, the Metallurgical Society of AIME, and the CSEM. General Meeting Information is available from M. Karl; TMS, 420 Commonwealth Drive, Warrendale, PA 15086, USA, Tel. 412-776-9050.

Conference Reports

Joining Ceramics, Glass and Metal in Bad Nauheim

By Graham Partridge*

The third international conference on joining ceramics, glass and metal was held from 26.–28. April 1989 in Bad Nauheim, a spa town in the Federal Republic of Germany. This is a very pleasant town (although it rained for much of the period of the conference. Normally, this could be expected in England but, somehow it is assumed that the Germans would do better, even with the weather). The conference itself was held in the Kurhaus (Congress Center) which is very well equipped for conferences of this type. Furthermore, the many hotels meant that no delegate need be more than a few minutes away from the Kurhaus.

The conference was organized by the Deutsche Gesellschaft für Metallkunde (DGM), together with the Deutsche Glastechnische Gesellschaft (DGG), the Deutsche Keramische Gesellschaft (DKG) and the Deutsche Verband für Schweisstechnik (DVS) and was the third in a series of conferences targeted at technical developments in joining ceramic, glass and metal. The conferences are held at four-yearly intervals which permits significant developments to take place in this broad, important field between meetings.

For convenience the conference was divided into four themes, namely

Active brazing
Diffusion bonding
Friction welding, Reaction bonding and other joining methods
Properties and testing

Oral papers were presented in each group, including an initial plenary paper by an appropriate expert on the particular theme. In addition, poster contributions reinforced and expanded the technological areas covered.

During the course of the conference, three short (1 h 20 m) workshops were held in parallel on the themes of

Active brazing/Testing methods
Diffusion bonding/Interlayers
Design of bonded systems/Applications

A total of 232 participants were recorded as attending the conference. As would be expected, more than 50% were from the Federal Republic of Germany although the majority of the European countries were well represented and there were also participants from as far afield as Australia, China and Japan. Interestingly, no attendees from the USA were recorded.

The technical sessions were always well attended (in spite of the attractions of Bad Nauheim) and the poster area was crowded during poster discussion periods. The workshops attracted 50–60 participants each and the discussions were lively and informative.

The standard of oral presentation and of the posters was high. This presented a problem for many of the speakers and poster designers since the conference was held in English with no facilities for parallel translation. It says a great deal for those who spoke and who discussed their posters in what was not their native language that they were able to make their points well and answer questions put to them. Each oral presentation allowed time for a few questions following the paper.

Inevitably, there was some overlap in the chosen themes, for example, property determinations were presented in all sessions.

The following review covers highlights (in the author's opinion only) and does not hope to cover all the many and varied aspects of this highly stimulating international conference.

1. Active Brazing

The papers in this session were concerned with brazes which contained titanium. The presence of Ti enabled the braze to wet and bond to the ceramic surface. It was shown

[*] Mr. G. Partridge
GEC Engineering Research Centre
P.O. Box 30, Lichfield Road, Stafford ST17 4LN (UK)

by *M. Nicholas* that wetting became progressively more difficult in the series oxide–nitride–carbide–boride although good wetting was not always essential to achieve a good bond, especially if pressure were applied across the join. Shear strengths of bonds involving ceramics were seen to be generally stronger with the strongest ceramics.

A number of presentations covered the difficulties of brazing ceramics to metals where a wide disparity in thermal expansion coefficients leads to high stress in the join and ceramic. The use of interlayers, such as Mo and Cu was shown to be beneficial in reducing stress levels and leading to strength improvements in the joins. Mo appeared to be particularly beneficial for SiC and Si_3N_4 (*E. Lugscheider* et al.) and useful for Graphite to stainless steel (*P. Jacquot* et al.). Design of the joints was important—a high ratio of ceramic to metal thickness in the join influenced residual stress in the ceramic and decreased shear strength (*Weise* et al.) and the use of a ductile metal filler was also helpful.

2. Diffusion Bonding

The diffusion bonding of ceramics to metal, resulting from interactions at the ceramic-metal interface at elevated temperatures was discussed by a number of lecturers covering a range of ceramic to metal systems. The plenary lecture was given by *J. J. Klomp* and he set the scene admirably. It is clear that diffusion bonding requiring transport of metal can lead to reaction products which may be disadvantageous. Ideal contact surfaces are not generally available and pores produced in the contact zones are removed by creep and vacancy diffusion. Bonding time and pressure are helpful in this respect (*B. Gibbesch* et al.) as applied to Nb and Cu bonds to sapphire. It was noted by *B. Derby* that joint strength and toughness had to be clearly distinguished when characterising the mechanical properties of diffusion bonds between ceramic and metal. Comparison of brazing and diffusion joins of SiC to metal was made by *Batfalsky* et al. who indicated that diffusion joins should be capable of higher temperature operation. Diffusion barriers and interlayers such as copper were often necessary (*J. Schiepers, J. P. Krugers* et al.) to enable expansion mismatches to be tolerated. Silicides which influence bond integrity were formed at the ceramic interface. The use of hot isostatic pressing for joins of Si_3N_4 to steel was shown to be advantageous (*M. Corbiere* et al.) and tungsten was the preferred "stress relieving material" adjacent to the ceramic. The use of TiH_2 powder interlayers, sintered simultaneously during Al_2O_3–Ti bonding (*S. Prech*) was interesting and further development of Cu to Al_2O_3 bonds was discussed by *W. Wlosinki* et al.

3. Friction Welding, Reaction Bonding and other Joining Methods

This section covered aspects of less well known methods for joining ceramics to metals. *D. Hann*, in his plenary address, covered a number of tasks which engineers must undertake in developing a reliable join, with particular emphasis on the problems occurring in lapped joins. As with a number of other applications discussed in other presentations, finite elemental analysis was seen to be useful in determining stresses which were strongly influenced by the geometry and thickness of the bonded parts. Shear strength testing was said to give general, relative information but other tests were also necessary to give critical information. *G. Partridge* et al. dealt with the joining of glass-ceramics directly to metals, either in bulk joining processes or by coating application and this latter aspect was amplified by *Ashcroft* et al. in a poster presentation. Generally, these forms were matched in expansion, so stresses were low. The development of unusual crystal phases in the glass-ceramic at the interface were discussed and problems arising from the competing diffusion processes of bond development (essentially via the metal oxide layer) and crystallization of the precursor glass were outlined. *W. Schaefer* et al. discussed bonding of high temperature zirconia electrochemical cells using a variety of joints (glass, welding, clamping) in the overall stack. Aluminophosphate mortars were described by *A. Hesse* et al. to join reaction bonded SiSiC and it was seen that the mortar itself was the weak link in the bonded assembly. Friction welding (*Weiss* et al.) was an unusual technique successfully used to join ceramic to metal. Initially metallization of the ceramic was seen to occur as the bond developed. The use of nickel foil, converting to nickelous oxide at the interface was shown to be a useful way of joining MgO to itself or to metals (*K. Atarashiya* et al.) and also for joining Al_2O_3 to Ti-6Al-4V alloys (*Y. Ito* et al.).

4. Properties and Testing

The plenary paper by *G. Gnirss* et al. discussed the properties of ceramic to metal joins with respect to design considerations and further looked at failure mechanisms in the joins. The general experience was that the bonding zone or adjacent ceramic were the weakest points and the lifetime of components was determined by creep and fatigue controlled sub-critical crack growth as well as temperature and time dependent degradation within the bonding zone. Optimization of the bonding process requires new bonding media, reduction of thermally induced stresses and improvement in the reproducibility of high quality ceramics. To some extent this latter might be met by improvements in powder processing and by composite developments. *M. Turwill* et al. discussed joining of ceramics to metals for various applications generally with reasonably close thermal expansion matching of the ceramic and metal parts. Finite element analysis of stresses in joins was discussed by *B. T. J. Stoop* et al. and *K. J. Ferenc* et al. It was found by *Stoop* that both tensile and shear stresses are maximum in the ceramic in the vicinity of the ceramic-metal interface. Elementary bending theory may also be used to determine residual thermal stress distributions in an asymmetrical ceramic/solder/metal plate as shown

by *O. T. Iancu* et al. The determination of stress in a ceramic to metal join is not easy. Optical methods using polarized light cannot generally be used owing to lack of transparency. However, in some cases X-ray diffraction techniques (*B. Ergermann* et al.) can be employed to determine residual surface stresses and triboelectric effects or light emission under stress may also be used (*H. Teodorescue* et al.).

In many cases ceramic to metal joins may be subjected to environmental conditions likely to cause weakening. *K. Suganamu* et al. discussed stress corrosion failure, in particular, the influence of water on Si_3N_4 joins where stress corrosion of the Si_3N_4 itself can take place. However, the results obtained showed that the joins can maintain high integrity over a long period of time. Several workers addressed the bonding of copper to Al_2O_3, an important bond in the microelectronics field. Fracture toughness values of K_{ic} up to 4 MPa $m^{1/2}$ were obtained by *L. J. Bostelaar* et al. and *A. Otszyna* et al. showed that the bonds to α-Al_2O_3 were stronger than those to β-Al_2O_3. *N. Klein* et al. also showed that thermal cycling led to deterioration in the Cu to Al_2O_3 bond owing to shear stresses in the join, but control of the crystallite orientation in the Al_2O_3 could beneficially influence thermal endurance.

The majority of the papers and posters presented have been drawn together in a volume entitled "Joining Ceramics, Glass and Metal", edited by *W. Kraft* and published by the DGM.

The conference was highly successful and provided not only an excellent venue for the dissemination of research results but also the opportunity to meet fellow workers in this wide and disparate field.

Magnetic and Magneto-Optic Thin Films and Multilayers in San Diego

By Ernesto Marinero* and Takao Suzuki*

The spring meeting of the Materials Research Society (MRS) in San Diego, April 24th to 29th, 1989, was host for two major symposia dealing with magnetic and magneto-optical materials. The symposium on "Growth Characterization and Properties of Ultrathin Magnetic Films and Multilayers" comprised 11 invited talks and 42 contributed papers over three and a half days and provided a unique and interactive forum in which to discuss recent advances in low dimensional magnetism, diluted magnetic semiconductors, epitaxial overlayers and the utilization of in situ and ex situ techniques to characterize their microstructure and electronic and magnetic properties. The other symposium on "Materials for Magneto-Optic Data Storage" was the first dedicated entirely to materials aspects of the rapidly emerging magneto-optic data technology. This symposium lasted for two days and was particularly successful in providing a well balanced forum between the industrial applications of the technology and fundamental materials research. Thirty seven papers were presented, including outstanding invited lectures, which covered the entire spectrum of materials issues relating to magneto-optical recording media. This included the magneto-optic active layers, dielectric layers and substrates. Emphasis was placed, in particular, on rare earth transition metal amorphous films, such as TbFeCo, GdTbFeCo, from the fundamental as well as the applicational point of view.

Growth, Characterization and Properties of Ultrathin Magnetic Films and Multilayers

The study of ultrathin magnetic structures is a rapidly expanding field of materials research whose growth is synergistically driven by an increasing appreciation of the degree to which the magnetic properties depend on interfacial processes and by the utilization of growth techniques which permit the fabrication of multilayer structures with novel electronic and magnetic properties. Equally important is the fact that atomic level control of the microstructure of these layers offer new opportunities to elucidate the physics of magnetism, to rigorously test theoretical models and, in some cases, to synthesize new materials.

The symposium opened with an invited talk by *Roy Richter*, General Motors (GM) who presented recent theoretical results on the temperature dependence of the spin anisotropy of a monolayer of Fe. Changes in the magnitude of the perpendicular anisotropy as a function of temperature were attributed to changes in the Fe monolayer band structure. *Mayer* and *Gutierrez* (Johns Hopkins) presented experimental results on Fe(110)/Ag(111) superlattices (SL) grown by molecular beam epitaxy (MBE). No out-of-plane magnetization was observed for this particular system. *Krebs* (NRL), on the other hand, found that Fe(001)/Ag(001) superlattice grown on thick Ag(001)/ZnSe(001) substrates exhibited strong perpendicular anisotropy for Fe layers < 3 ML. The importance of interface roughness was highlighted by *Albert Fert* (University Paris-Sud) who reported

on the measurement of giant magnetoresistance in Fe(001)/Cr(001) SL. This roughness leads to electron scattering processes at the Fe/Cr interface, and the increase in magnetoresistance for Cr < 20 Å is ascribed to a change from parallel to antiparallel orientations for the magnetization of neighboring Fe layers. In turn, the interface electron scattering is enhanced by the antiparallel orientation. Similar effects are predicted for other transition metals.

Growth of Fe (Nd, Dy, Y) SL's was reviewed by *Teruya Shinjo* (Kyoto University) who observed that for Fe < 20 Å, the Fe/Nd SL is amorphous and exhibits perpendicular anisotropy. For thicker Fe layers (30 Å) bcc ferromagnetic structures are obtained with in-plane magnetization. The growth of hcp Fe/Ru superlattices was reported for the first time by *Maurer* et al. (CNRS) with evidence for strong interactions through the Ru layers. Co/M (M = Pd, Au, Cu) SL's were also discussed and *Hoving* (Philips) pointed out significant magnetic differences between Pd/Co single crystals and polycrystalline multilayers. In particular, the anisotropy is perpendicular in the single crystal only for Co thickness of 1–2 ML vs. 8 Å for the polycrystalline system. In the case of Co/Au, *Lee* (University of Michigan) reported a transition from out to in-plane anisotropy for Co ~ 20 Å.

In situ techniques to characterize magnetic properties of thin film systems are rapidly developing. *Dan Pierce* (NIST) described the SEMPA technique (Scanning Electron Microscopy with Polarization Analysis) which permits domain imaging with intensity directly proportional to the magnetization and resolution presently ~ 400 Å. He speculated that the STM would be the ultimate magnetic tool of sensitivity to spin could be derived. An elegant demonstration of the use of STM to study ultrathin films was given by *P. N. First* (NIST) who showed images of 0.1 Å Fe layers grown on GaAs which exhibited 3D growth of 20–30 Å diameter islands at 300 K. Similarly, spin-resolved photoemission and Brillouin scattering are powerful tools to study spin-split electronic band structure as reported by *Guntherodt* (Aachen) for the case of Fe/Ni. *Eric Kay* (IBM Almaden Research Center) utilizing secondary electron spin-polarization analysis, showed that 0.1 ML of an adsorbate can alter the Curie point by as much as 30% in the case of permalloy thin films.

A combination of spectroscopies and in situ magnetic measurements were utilized in the MBE growth of Fe/Ag, Fe/Ni and Ni/Fe by *Heinrich* and collaborators (Simon Fraser University). They showed, for example, that in the case of Fe/Ni, Ni grows bcc (RHEED, REELFS) up to 6 ML. A structural transformation occurs for thicker layers giving rise to large magnetic anisotropies which from FMR studies are attributed to growth defects. The effect of strain on magnetic properties was discussed by *Farrow* (IBM) for the case of LaF_3/Dy/LaF_3 and by *Florczak* (University of Minnesota) for epitaxial (100) Fe films.

The use of ex situ techniques such as EXAFS, X-ray scattering and TEM were described by *Cargill* (IBM Watson Research Center) and *Li* (Arizona State University) to study microstructural properties of thin films. FMR and NMR studies have been applied by *de Gronckel* (Eindhoven) to Co/Pd multilayers to investigate the behavior of the anisotropy as a function of Co and Pd thickness. The spin-echo NMR studies indicate that as the Co layer thickness is decreased, structural changes take place that result in an expansion of the Co lattice. The observed magnetic changes are attributed to this structural transformation.

Werner Keune (University of Duisburg) presented results on UHV CEMS (Conversion Electron Mössbauer Spectroscopy) of fcc Fe(100) films on Cu(100) and showed that the para-, ferro- and antiferro-magnetic properties strongly depend on growth temperature. These results were discussed in terms of thickness dependent lattice relaxation.

A search for an experimental manifestation of the universality hypothesis was described by *Pescia* (Julich) who utilized spin-polarized electron scattering to measure the order parameter in < 3 ML Fe films on Au(100). It is found that although the Curie temperature exhibits a thickness dependence, the critical exponent β of the power law $M \sim (1 - T/T_c)^{\beta}$, is essentially independent of thickness. M is the order parameter. This is explained by the fact that as long as the film is thin enough, the system remains two-dimensional and therefore has a single set of critical exponents which are independent of the strength of the interaction.

Furdyna (Notre Dame), *Gunshor* (Purdue University) and *Jonker* (NRL) reviewed recent progress on diluted magnetic semiconductors (DMS). A typical material set belonging to this class are the $A_{1-x}Mn_xB$ alloys (where A = Zn, Cd and B = Se, Te). *Furdyna* indicated that DMS multilayer structures may be grown with pronounced field-dependent effects. Examples of such structures include, multiple quantum well structures in which the wells consist of a DMS material, or magnetic field-induced SL's. *Gunshor* reported on the intercalation of ZnTe monolayers in ZnSe/MnSe quantum wells which dramatically altered the optical emission due to excitonic self-trapping at Te sites. *Jonker* described ongoing work at NRL on Fe and Co-based DMS materials, indicating that their properties (magneto-optic, electronic) are strongly influenced by the ground state of the magnetic ion used and the energy levels it introduces relative to those of the host semiconductor. The electron-ion and ion-ion exchange parameters for the Fe- and Co-based materials are significantly larger than for the Mn-based counterparts.

In summary, the symposium was an excellent event in which the structural, electronic and magnetic properties of ultrathin magnetic materials were discussed. It brought together a dynamic collection of leading materials scientists from Europe, Japan and the USA, and it is apparent that state-of-the art growth and characterization techniques are widening our understanding of magnetic phenomena at an atomic level.

Materials for Magneto-Optic Data Storage

In the keynote talk, *M. Kryder* of Carnegie Mellon University reviewed the current status of the magneto-optical

recording media based on amorphous rare earth (RE)-transition metal (TM) thin films. He pointed out that to maximize Kerr rotation, anisotropy, corrosion resistance and reflectivity, the sputtering conditions should be selected to produce so-called Zone T featureless films. *F. Lin* of IBM Almaden Research Center described in his invited talk the property requirements for the magneto-optic active and dielectric layers that are needed in order to realize high performance recording and reliable data storage. He emphasized the importance of understanding the micromagnetics and controlling the regularity of the written domains in order to achieve a high carrier to noise ratio (CNR).

While the properties of TbFeCo media appear adequate for today's MO storage devices, their rather weak magneto-optic activity at shorter wavelengths (less than 500 nm) may restrict their extension to high storage densities. One approach that has been taken in order to overcome this disadvantage involves alloying TbFeCo with a light rare earth element such as Nd and Pt which both have enhanced M-O activity due to their highly spin polarized 4f states. However, the origin of this enhancement was challenged in a paper by *D. Weller* of Siemens. He presented a systematic study using XPS and Kerr spectroscopy, to characterize in situ RE-FeCo films deposited in ultra high vacuum. His main conclusion is that the 4f-excitations of RE ions are not expected to contribute more than few tenths of a degree to Kerr rotation.

The study of the magneto-optic and magnetic properties of multilayered and exchange coupled films as candidates for higher MO activity has been gaining in interest. *D. J. Sellmyer*, University of Nebraska, and *C. Falco*, University of Arizona, discussed in detail the origin of perpendicular magnetic anisotropy and magneto-optic properties in Fe/Nd, Dy/Co, Pd/Co and other alloy systems of RE-TM. *Sellmyer* concluded that single-ion anisotropy is the major contributor except in Gd. *Falco* discussed the structure of multilayered films made by MBE in conjunction with those made by sputtering. *P. F. Carcia* of E.I. du Pont presented a paper on the wavelength dependence of Kerr activity in Co/Pt multi-layer films. The enhancement in Kerr rotation at short wavelength was shown to be due to the high M-O effect in the very thin Co layers. *S. D. Bader* of Argonne National Laboratory presented an invited talk on surface magneto-optic Kerr effect (SMOKE) of ultrathin ferromagnetic films. The result showed a dramatic example of a metallic reflector enhancement effect due to the nonmagnetic Au underlayer.

Another approach for enhancing magneto-optic activity is to use exchange coupled two-layered films. In such a film structure, optimization of Kerr rotation can be done in one layer and magnetic properties in the other. *R. Gambino* of IBM Thomas Watson Research Center and *H. Wakabayashi* of IBM Almaden Research Center discussed the mechanism for exchange coupling in CoPd/TbFeCo and Co/TbFeCo films. *Gambino* pointed out that properly designed exchange coupled films appear to provide a viable approach to high density storage media. Further extensive discussion was given on multi-layered films of TbFe, Cu/Co and Pd/Co in papers presented by *Krishnan* of CNRS, and *England* of the University of Arizona.

Bi-substituted garnet films are attracting increasing attention due to their very high Faraday activity. The Faraday signal at about 500 nm is almost one order of magnitude larger than the MO activity for RE-TM films with similar thickness. However, a large readback noise results from grains and surface roughness in these polycrystalline films. *M. Gomi* (Tokyo Institute of Technology) discussed the possibility for controlling the grain boundary structure so as to provide better domain regularity and less domain noise by using additives such as W at concentrations of less than 1 atom-%. *K. Shono* of Fujitsu presented data on the recording performance of (Bi-Dy) substituted garnet disks where 57 dB and 54 dB at 5 and 1.4 μ bit length, respectively, were achieved. Such results are encouraging for the eventual use of these materials as a future high density storage media. In addition to these technology oriented talks, *P. Wigen* of the Ohio State University described evidence for partially spin polarized Bi^3 in $Bi_3Fe_5O_{12}$ where a moment of 0.25 μ_B is formed at the Bi ion sublattice while the moment on the tetrahedral iron sublattice decreases by 0.5 μ_B.

Dielectric layers are important for MO recording media because they provide the optical enhancement of Kerr rotation and protection from oxidation for the MO active layers. The dielectric layers for these purposes require a high refractive index, stability to the environment and low internal stress. *K. Hashima* of Mitsubishi Electric Co. described a new dielectric material based on AlGeN which exhibits high refractive index (2.4–2.5) with a very small internal stress (less than 10^9 dyne/cm^2).

Polycarbonate (PC) is the most widely used substrate for MO disks. However, PC can have relatively large optical retardation depending on injection molding conditions and it also absorbs water which alters the mechanical tolerances of the disk. *Y. Togami*, Mitsui Petrochemical Ind. Co., and *M. Yamazaki* of Nippon Zeon Co. described the properties of amorphous polyolefins which overcome these drawbacks.

The oxidation and corrosion behavior of TbFeCo has been a key concern because of the high reactivity of Tb. *A. Lee* of the University of Arizona discussed the interaction of H_2O on UHV clean TbFeCo surfaces using AES, XPS and RBS. Also, *D. Majundar* of Eastman Kodak Co. described the effect additive elements such as Pt and Zr have on the oxidation in TbFeCo. Both papers suggest that such additives can reduce the reactivity of TbFeCo films.

Besides these materials oriented talks, the symposium also covered a key performance disadvantage of MO technology; that is, the lack of direct overwrite capability. *N. Imamura* of TOSOH Co., and *N. Ohta* of Hitachi discussed the current status of the direct overwrite technology. *O. Ishii* of NTT presented the new approach of the direct overwrite using a magnetic head for writing and a laser beam for reading in a two-layered film.

The symposium "Materials for Magneto-Optic Data Storage" was a very successful and exciting meeting.

ADVANCED MATERIALS

Book Reviews

Sol-Gel, Drug Release, Superconductors and Liquid Crystals

Sol-Gel Technology for Thin Films, Fibers, Preforms, Electronics and Specialty Shapes. Edited by *L. C. Klein*. Noyes Publications, New Jersey, USA 1988. xxi, 407 pp., bound, US$ 72.–ISBN 0-8155-1154-X

Sol-gel technology has been a popular subject in materials science and engineering for some four decades. Its promise for the preparation of controlled and homogeneous compositions and for the fabrication of various forms such as powders, fibers, coatings and monoliths has made it the potential answer for many of the problems which have been identified by people working with the processing of ceramics and glass. The technology has proved difficult to apply to some of the more classical sectors of ceramics such as powder and monolith preparation but notable successes have been achieved particularly where precise performance is required in components of limited dimensions (films, coatings, fibers).

The present book performs the valuable function of summarizing the technical advances that have been made in the subject to the end of 1987. In 17 chapters contributed by 27 authors and co-authors drawn from the United States, from Europe and from Japan, sol-gel technology is reviewed with emphasis on examples where progress in applications has been achieved. The editor has been successful in building the book around a logical arrangement which allows the different sectors of the technology to be systematically treated; there is throughout an emphasis on processing methods and on applications and this together with the concentration on topics where commercial success has been reached or can be foreseen, makes the book a valuable and instructive guide for those wishing to find their way in what has become a complex subject.

The opening section of the book contains three introductory chapters which review the preparation of glass using sol-gel methods, the contribution which has been made by molecular dynamics theory to the understanding of the sol-gel process and the subject of phase transformations in gels; in the latter, emphasis is given to the differences that can be identified between the behavior of gel derived and conventional glasses.

The second part of the book relates to the preparation of coatings and thin films by the sol-gel process. As pointed out in the opening chapter on film preparation, such coatings directly exploit the advantages of the sol-gel process; they have reached commercial application in large quantities and they in fact predate much of the fashionable interest of recent years. Specialized treatments of anti-reflective films and of oxynitride films are given in separate chapters. The third part of the book describes the use of sol-gel methods for the preparation of fibers by drawing, blowing or by unidirectional freezing. Following a review of such developments, more detailed treatments are given of the aluminoborosilicate system and of the preparation of continuous fibers.

The fourth section of the book describes the use of sol-gel procedures for monolith formation. The treatment is in terms of glass products and this indeed reflects a general tendency in the book; where appropriate, discussions are included of the polycrystalline products which can stem from sol-gel methods but the major attention is given to glasses and amorphous systems. This section also includes descriptions of thermal insulation, of the manufacture of ultrapure glass and of particulate gels and glasses. The book concludes with a section devoted to specific applications of the technology. Following a short chapter on the fabrication of electronic ceramics, there are treatments of superionic conducting systems (both glass and crystalline, with emphasis on sodium and lithium conductors) of the fabrication of hollow glass microspheres and of filters and membranes.

The editor is to be congratulated on having assembled a timely and authoritative text around a subject which has caused a certain degree of confusion. The emphasis on practical aspects and on applications will be of particular value for those who are trying to clarify the precise contribution to be expected from this much debated technology.

Richard Brook
Max-Planck-Institut für Metallforschung
Stuttgart (FRG)

Controlled Release of Drugs: Polymers and Aggregate Systems. Edited by *M. Rosoff*, VCH Verlagsgesellschaft, Weinheim, 1989, xi, 315 pp., bound, DM 132.–ISBN 3-527-26797-2

This book is the first in a designated series intended to provide topical reviews in various areas of controlled release technology as well as from other pertinent disciplines where advances may contribute to the field of controlled release. The series itself is designed to consolidate, across a wide breadth of topics, a rapidly expanding primary literature database; each volume within the series supposedly allowing substantial review of specific current areas while emphasizing the more subjective exploration of ideas and speculation for future directions from the authors of each chapter. The overall goal of such a strategy is to provide a relevant overview of controlled release issues, problems and progress aiming at broad readership, practical utility and volume longevity. To achieve this the editors of each volume have collected an impressive set of advisory editors to assure and

endorse coherency of content as a whole as well as accuracy and quality within each chapter.

Chapters 1, 2 and 9 deal specifically with issues concerning the use of polymeric materials as matrices for the controlled release of drugs while the remaining six chapters are devoted to dispersed or aggregated system technology – emulsions, dispersions, liposomes, liquid crystals, micelles and microemulsions. I was pleasantly surprised to find so much information compiled on "organized systems" – those utilizing organizing principles which are involved in the field of lyotropic liquid crystals – directed towards controlled release technologies. In this sense, I find the term "aggregated" used in the title to be misleading as, in my opinion, lyotropic liquid crystals "organize" instead of "aggregate". It is, in fact, this organization which is critical to their use in controlled release technology. Aggregation is correctly applied in terms of microcapsules and microspheres. However, were it aggregation per se that compelled lyotropic phases to form and transform, I would believe that the anisotropy so critical to function would not exist. This may be a matter of semantics.

This is one of the few books on controlled release I have read where nine different approaches to the same problem are uniquely presented – each in the style, interests, and scope of each author with little discontinuity or repetition. Each author starts and ends his reviews and discussions within the bounds of his assigned topic which I find refreshing. In addition, each author makes an attempt to break the reader in gently to the topic at hand with short but generally adequate introductions to developments and concepts within each chapter. In this way and considering the effective, relatively straight-forward method with which theory, concept, and applications are developed and focused, the volume qualifies well as a text for newcomers to the field, persons in neighboring fields, and graduate students exposed to these ideas for the first time.

Specifically with regard to the text, chapter 1 addresses the development of models for drug release from various porous polymer matrices. Models for the classical cases of steady-state flow-through and diffusion-controlled release from macro-porous membranes are presented. Closer analyses of tortuosity, corrugation, percolation models, admittedly borrowed originally from other fields, along with various simulation procedures using Monte Carlo and other numerical methods are well formulated and digestible for the neophyte. Microporous systems, where drug and pore size are comparable, are also analyzed at length and in general concepts are well formulated and adequately presented within the constraint of the chapter length.

Chapter 2 discusses controlled drug release from biodegradable polymers. Starting from a review that contrasts polymeric controlled release with conventional drug therapies, the author continues to describe and develop ideas within the scope of biodegradeable polymer matrices. Matrix erosion and resulting release profiles for diffusion-controlled, reservoir and hydrogel devices as well as enterically-coated and covalently-bound drug matrices are addressed. A short overview of the various factors affecting polymeric biodegradation, both chemically and physically, is also given. In addition, factors considered in biodegradable device formulation, administration, and evaluation are briefly presented. Finally, mechanisms of the chemical degradation of polymers currently in use are outlined. Again, the information supplied is stimulating and heavily referenced.

Chapter 3 moves away from polymer matrices to discuss dispersed systems for injectable (parental) drug carrier systems. Materials and device formation techniques for microspheres and microcapsules are given, following an introduction to parental systems and their degradation. The author then moves on to non-polymeric dispersions – liposomes, nonionic surfactant vesicles (niosomes) and loaded erythrocytes as alternative parental vehicles. Two last sections deal with parental emulsions and nanoparticles (polymeric). I enjoyed the review and was satisfied with the content and referenced material.

Chapter 4 discusses liquid crystals and their role in dispersion stabilization and briefly, drug delivery applications. I was excited to see such a chapter because of the applicability of such molecular dynamics and organization to controlled release. However, I soon became bogged down in differentiating arrays of photomicrographs and phase diagrams that the chapter barely has room to detail. Although I did get a lot out of most sections qualitatively (liquid crystal nomenclature and properties, emulsifier associations and stabilization issues), I felt that the sections on l.c. phase behavior and applications to drug delivery lacked sufficient detail and significance and detracted from the quality of the majority. This is particularly clear after reading other chapters dealing with emulsion stabilization by other methods where applications are much more fully discussed. More importantly, I could not discriminate after all was said and done, if liquid crystals had any future in drug delivery or if they should better be left alone. Aside from these issues, I found the content of this chapter, for the most part, interesting.

Chapter 5 goes on to describe and support the weaknesses from Chapter 4 (which may indicate that Chapter 4 was an essential and fully adequate foundation to build upon). The concepts of multiple emulsions, their construction and stability, are fully detailed and referenced. Transport mechanisms for solutes, although not well understood, are developed for both micelles and facilitated transport. A final section on the in vivo administration of emulsions as parental drug delivery systems highlights current interests and levels of understanding for these systems.

Chapter 6 is structured much like Chapter 5 except that it deals with microemulsions. Two differences are notable in this interesting and well written account: namely, that unlike emulsions, microemulsions form spontaneously without external agitation, and that, unlike emulsions, the pharmaceutical value of microemulsions has not yet been adequately

assessed. The authors detail very effectively the requirements and stability of microemulsions and then explain that very little has been done in drug delivery with these systems. From the optimistic description of the basic research undertaken it seems like a ripe research opportunity.

Chapter 7 details liposomal formulations from a more commercial perspective with emphasis on macromolecular drug delivery. An array of materials and methods for the construction of liposomal vehicles having various properties are first described rather extensively. Issues concerning the various routes to delivery are reviewed, touching briefly on trouble-shooting clearance and RES uptake problems. Finally, a short section mentions the specific case of liposomes as macromolecular carriers. Issues in formulation stability and internalization by cells were not addressed to any significant extent. Nevertheless, the chapter gives a very current, well-informed review of a topic that has received much attention in the last decade.

Chapter 8 presents data on the inclusion of nucleic acids into reverse micelles. DNA and RNA of various sizes and types are shown to be solubilized into reverse micelles much smaller than the dimensions of the DNA and RNA themselves. This chapter could have been formatted more effectively in the same style as all others chapters but was instead kept in a classical journal format: Introduction, Experimental, Results, Discussion. It seems to be one of the few mistakes made by the editor. Not only is this format inappropriate for this type of literature review of applied techniques, but reader appeal becomes problematic for anyone unfamiliar with this type of work due to the less-generalized, non-conceptualized style of presentation. Not that this detracts from the quality of the data presented; it simply makes it less comprehensible. Data from spectrometric studies (UV and CD) of the inclusion of biopolymers of DNA and RNA into reverse micelles are given and explained. How this relates to controlled release drug delivery issues is mentioned in a small, speculative section at the end of the chapter.

Chapter 9 returns to polymeric matrices with a well presented review of transdermal delivery systems and models, problems in the development of these systems, and explanations about what can be done to deliver more drugs with this strategy. Less attention is paid to actual materials as is to the design of devices for specific functions, characteristics, and properties, e.g., skin or device rate control and skin permeability enhancement for desired kinetics of delivery. Strategies include diffusion and rate controlling membranes for desired release parameters, examples from current commercial products, and factors to consider in future designs. Modeling analysis include skin depot effects, permeability measurements and predictions, and rate control. This chapter is easy to read and understand and presents most essential and pertinent considerations for transdermal delivery.

Universität Mainz (FRG)

Superconductors: The Breakthrough. By *R. M. Hazen*, Unwin Hyman Ltd., London, 1988, xxviii, 271 pp., bound, £ 12.95. – ISBN 0-04-440288-0

A review of this book from 1988 is still worthwhile just in case someone has missed it. In writing this book in such a popular style the author is running the risk of having his leg pulled by colleagues, not least for employing such a modest title. However, he should be congratulated most warmly for doing so.

This is the story of the discovery of superconductivity at temperatures above the boiling point of nitrogen, the temperature above which commercial exploitation of the effect becomes a viable proposition.

The Preface, Foreword and the first Prologue all give a historical overview and set the scene, explaining the reason for, and the potential importance of the research in the area up until the first indications of success in January 1986 from *Bednorz* and *Müller* at IBM Zürich (who were eventually awarded the Nobel Prize in Physics for their work).

The book is structured in three main sections. The first details the work in the laboratory of Prof. "*Paul*" *Chu* in Houston where the complex-metal oxide synthesis work was done and where, by switching ingredient elements from the original *Bednorz/Müller* recipe ($T_c \sim 30$ K) possibly the first indications of superconductivity above 77 K were seen. One has to say possibly, because, after the initial announcement of the IBM team there were many groups from many nations suddenly devoting their full resources to the problem.

The second section follows the work in which the author was directly involved, that of solving the structures of the two crystalline phases, work carried out at the National Geophysical Lab. in Washington DC in collaboration with *Chu*. The interactions of the multidisciplinary teams are highlighted and even espionage, betrayal and unethical publishing are hinted at.

The third section describes the intense excitement which was generated by the race to be recognized as the pioneer of high-T_c superconductivity above the all important 77 K which culminated in the New York meeting of the American Physical Society which has become known as the "Woodstock of Physics" where representatives of the various competing groups came together resulting in the most memorable scientific meeting in years.

An erroneously spelt erroneous, along with a few other minor defects are counteracted by pictures of the important participants and by lines such as "A good X-ray peak has a silhouette that soars like a futuristic skyscraper; our peaks looked more like melting igloos" which emphasize humorously the sort of problems and disappointments which were overcome on the way to success while bringing a smile to the lips of the more knowing.

The book is written with a humor which can be appreciated both by the scientist and the more general public and a good effort is made to explain enough of basic physics and chemistry to capture the attention of the non specialist, to

involve him in the excitement of discovery and to keep him reading to the end.

Anyone with an ounce of the scientist romantic in him will love a story which rivals Star Wars for fantasy and Gone With The Wind for romance. It is the sort of book which brings science to the attention of the general public and gives it a good name.

Side Chain Liquid Crystal Polymers. Edited by *C. B. McArdle*. Blackie and Son Ltd., London 1989. 448 pp., bound, £ 75.–ISBN 0-216-92503-7 (USA: 0-412-01761-X)

This book presents an overview of thermotropic side chain liquid crystalline polymers, one of the rapidly growing innovative fields in liquid crystalline materials research. The book is made up of clearly structured contributions from acknowledged experts in the field. Within 14 chapters, theoretical concepts, structural and synthetic aspects, characterization methods and properties, and a discussion of potential applications are covered. Since the book is exclusively dedicated to thermotropic side chain liquid crystalline polymers it is certainly more than an extension to the existing reviews.

In an introductory chapter the editor *McArdle* summarizes the scope and potential for thermotropic side chain liquid crystalline polymers, focusing on applications based on electro-thermo-optical effects. The second chapter on the physical principles of the polymers is written by *M. Warner* and the syntheses and different structural principles of liquid crystalline polymers containing mesogenic side groups are covered by *Percec* and *Pugh*. The authors not only describe the 'classical' side chain systems, but also novel types of structural modifications. The following chapter by *Gray* deals in detail with the synthesis and properties of side chain liquid crystal polysiloxanes. The placing of liquid crystalline polysiloxanes into a separate chapter is questionable, as it overlaps and repeats some parts of the previous chapter. *Le Barny* and *Dubois* describe the scope and potential of chiral smectic C liquid crystal side chain polymers, which are currently under extensive investigation because of their potential applications. The following three chapters 6–8 summarize the characterization of side chain liquid crystalline polymers. The chapter by *Noel* covers, with well chosen examples, macroscopic structural characterization, by DSC, optical microscopy, miscibility studies and X-ray methods. The chapters on dielectric relaxation spectroscopy (*Haws, Clark* and *Attard*) and on NMR methods used to study molecular order and motions (*Böffel* and *Spiess*) treat the theoretical background and give experimental results. The contribution on cholesteric side chain polymers (*Shibaev* and *Freidzon*) discusses especially their optical properties and demonstrates features of cholesteric materials. Side chain liquid crystalline elastomers are described by *Gleim* and *Finkelmann*. The properties of side chain liquid crystalline polymers in an electric and a magnetic field are summarized by *Haase*. Chapters 12 and 13 are concerned with two potential applications of side chain liquid crystalline polymers; as optically nonlinear media (*Möhlmann* and *van der Vorst*) and as materials for optical data storage (*McArdle*). Both contributions also cover theoretical aspects and compare side chain liquid crystalline materials with low molar mass liquid crystals and inorganic materials. The last chapter by *Janini, Laub, Purnell* and *Tyagi* treats theoretical aspects as well as experimental results concerning the use of side chain liquid crystalline polysiloxanes as the stationary phase in gas-liquid chromatography.

The book demonstrates the interactions which are necessary in such an interdisciplinary research area. All chapters are distinctly structured and well written. Figures, formulas and tables are uniform and clearly incorporated within the text. The more general introductions into each specific topic and the extensive up to date (1988) literature references are very valuable. However, the organization of the chapters is not entirely convincing. In addition, more specific cross references to other chapters would be helpful. Nevertheless, the book is highly recommended to academic and industrial researchers in the field of liquid crystals and is also of general interest to physicists and chemists working in linear and nonlinear optics, optoelectronics and molecular electronics.

Mechanical Testing of Composites

Zwick offer a wide range of Universal Testing Machines from 2 kN to 500 kN, for tensile, compression and flexural tests, plus:

- High Resolution Dual Strain Sensor Transducers (Temperature −70° to +270° C)
- Strain Measurement for thread and composite fibre bundles
- Transverse Strain Measurement for Poissons Ratio
- Compression and stabilising rigs
- Temperature Chambers (−150° to +400° C)

In addition, machine control and data storage is fully PC compatible.

Zwick is your reliable partner for testing composites in aerospace or any other high-tech industry

The Active Sites in Manganese-Containing Metalloproteins and Inorganic Model Complexes

By Karl Wieghardt*

Manganese is an essential trace element, forming the active sites of a number of metalloproteins. Several metalloproteins contain two or more manganese ions per subunit. The structural properties of these enzymes and the experimental evidence for their proposed structures are described. Parallel to the efforts of biochemists, who are seeking to understand the function of these enzymes on a molecular level, inorganic chemists have been investigating the coordination chemistry of bi- and polynuclear complexes of manganese which contain O,N donor atoms and a variety of bridging O,N ligands. A large number of such complexes have been synthesized, their X-ray structures determined and their magnetic and spectroscopic properties studied in detail. In some instances the electronic and spectroscopic properties of these model compounds are amazingly similar to those of the biomolecules. This has led to a deeper understanding of the structure and sometimes of the function of the metalloproteins. Research on manganese metalloproteins with polynuclear active sites represents a fascinating example of interdisciplinary cooperation between physicists, biochemists and inorganic chemists.

1. Introduction

Manganese is an essential trace element. Typical defficiency symptoms in human beings are growth disorders, bone deformations, abnormalities in membrane formation and defects in the connective tissues. The amount of manganese in a grown man (75 kg) is only about 10–20 mg, in comparison to the 3–4 g of iron.[1] Plants and many bacteria also require minute amounts of manganese for a healthy existence. In its divalent form manganese can be an enzyme activator or, alternatively, it can form the active site of the metalloprotein.

Up to now relatively few manganese-containing metalloproteins have been isolated pure and structurally sufficiently well characterized to determine the nature of the active sites. The resolution of a single crystal X-ray determination is rarely sufficient to reveal the bonding characteristics of the manganese center (ca. 1.8–2.2 Å is required). The exact coordination geometry of the manganese atom in the protein is, however, required to give a deeper understanding of the respective functions of the enzymes.

When manganese is in the relevant physiological oxidation states +II, +III, +IV (and possibly +V) with "normal" coordination of the oxygen and nitrogen atoms from the protein (possible coordination numbers being 4, 5 and above all 6), it forms a paramagnetic centre: Mn^{II} high spin (h.s.) d^5-electronic configuration (five unpaired electrons), Mn^{III} d^4 (h.s.) (four unpaired electrons), Mn^{IV} d^3 (three unpaired electrons), Mn^{V} d^2. This means that such metalloproteins can be investigated particularly well using physical methods. For example:

1) Electron spin resonance (ESR) spectroscopy: very sensitive and informative for Mn^{II}[2] and for polynuclear complexes in which the manganese ions are in different oxidation states (mixed valence complexes, e.g. $Mn^{II}Mn^{III}$ or $Mn^{III}Mn^{IV}$).

2) Electron spectroscopy (UV-VIS spectroscopy):[3] particularly informative in the case of Mn^{III} and Mn^{IV} complexes due to (d-d) and charge-transfer (CT) absorption bands in the visible region.

3) Measurement of the magnetic susceptibility: allowing the study of the coupling of the electrons in neighboring manganese centers and thereby yielding an estimate of the distance between them.

4) Resonance Raman spectroscopy: affording information about the first coordination sphere of the Mn atoms.

5) X-ray absorption spectroscopy (EXAFS: *e*xtended *X*-ray *a*bsorption *f*ine *s*tructure, XANES: *X*-ray *a*bsorption *n*ear *e*dge *s*tructure): likewise giving information about the nature of the surrounding atoms and the oxidation state of the manganese ions.

However, each of these methods gives limited structural information only. Frequently, the combination of spectroscopic results on biomolecules and available knowledge of the spectroscopic and coordination properties of low molecular weight manganese complexes can lead to reasonable and likely structural proposals. On the other hand, in many cases spectroscopic results are obtained which are not understood by comparison with those of known manganese complexes. Here the coordination chemist needs to synthesize new relatively simple model complexes whose structures must be established in order to study their spectroscopic properties. Comparison of these results with the properties of the metal centers in biomolecules can then give information as to whether more such complexes are needed or if it is necessary for the biochemist to modify his proposed structure. This interdisciplinary cooperation between theoretical, physical and inorganic chemists on the one hand and biochemists on the other has over the last two or three decades been coined "bioinorganic chemistry".

For the inorganic chemists, in this context, metalloproteins with two or even more manganese atoms per subunit are particularly interesting. These Mn atoms can be relatively close to one another (Mn–Mn distance < 6 Å) and, consequently, inorganic chemists can conceive the

Postfach 102148, D-4630 Bochum (FRG)

biomolecule as a binuclear complex where the two Mn centers are ligated by a very large chelating ligand, namely the apoprotein. These metalloproteins are described in the first part of this review. Emphasis is laid on the structural aspects of their active sites and the evidence for published proposals, which are often based on a comparison of the spectroscopic properties of the metalloprotein with those of the synthesized model complexes whose structural and electronic properties are well defined. In the second part the chemistry of these manganese complexes is discussed and its relevance to biochemistry demonstrated. The characteristics of the model complexes[4] are discussed in order to show their enormous potential in determining the nature of the active sites of metalloproteins.

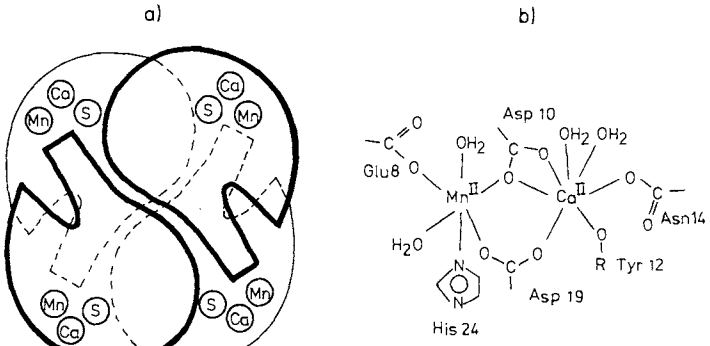

Fig. 1. a) Schematic representation of concanavalin A tetramers. The manganese and calcium binding sites are given as well as the saccharide binding site (S) near the metal atoms [6f]. b) Structure of the metal centers in concanavalin A.

2. Biomolecules with Binuclear Active Sites

2.1. Concanavalin A

This manganese and calcium metalloprotein belongs to the lectin group. It is a vegetable protein that was first isolated from jack beans, *Canavalia enisformis*;[5] subsequently animal forms were also found in mammalian cells. Its biological function is unknown but it has specific binding sites for small carbohydrates (α-D-mannopyranose, α-D-glucopyranose). Its activity is regulated by the coordination of divalent metal ions (the apoprotein does not have a large affinity for these molecules).

An X-ray structure determination, in which the resolution of the three-dimensional electron density was 2.0 Å, revealed the structure of the active site of concanavalin A, schematically illustrated in Figure 1.[6] It consists of four similar subunits at pH > 7, with a molecular weight of 25500 per unit. It forms dimeric species at pH < 6. To each subunit is bound a Mn^{II}-(S1 'transition metal binding site') and a calcium ion (S2 'calcium binding site'), which are 4.25 Å apart. The two metals are symmetrically and unsymmetrically bridged by the carboxylate groups of the aspartic acid moieties 19 and 10, and each binds two H_2O molecules. The N atom from the imidazole ring from Histidine 24 and an O atom from the $-CO_2^{\ominus}$- group of glutamate 8 are also coordinated to the Mn^{II} center; it is therefore in an octahedral environment ($MnNO_5$ coordination).

As well as being bound to the previously mentioned bridging carboxylate ligands the $Ca^{2\oplus}$ is also ligated by a carboxylate group and a phenolate group from aspartinate 14 and tyrosinate 12 and the second O atom of the asymmetrically bridging carboxylate group from aspartate 10: it exhibits a seven coordinate environment (distorted octahedral +1 coordination; CaO_7). The binuclear complex can be regarded approximately as two octahedra connected by a common edge. The structure of the apoprotein is also known, the subunits probably exhibit a different conformation than in the protein.

The metal binding sites S1 and S2 show different affinities for the divalent metal cations. This makes it feasible to selectively exchange the more weakly bound $Ca^{2\oplus}$ ion for divalent transition metal cations. The reaction of the apoprotein with Mn^{II} in the presence of methyl-α-D-mannopyranoside (α-MDM) leads to a ternary complex, which contains *two* manganese ions per subunit. The ESR spectra[7] of the Ca/Mn form without bound α-MDM (SCMPL form) and the metabolized Mn_2^{II} form with two Mn^{II} ions and bound α-MDM (SMMPL form) are completely different at 77 K. The SCMPL form shows a six-line spectrum (separation 92 G) at $g = 2.0$ typical for a Mn^{II} ion octahedrally coordinated by oxygen atoms, whereas a series of overlapping signals each split into eleven lines due to hyperfine coupling (altogether at least 32 resonances were observed) were found at $g = 1.927$ (77 K) for the SMMPL form. The hyperfine splitting was only 47 G, half the value of the SCMPL form (Fig. 2). The coordination of the two Mn^{II} ions in the SMMPL form is therefore different, and the spin systems are antiferromagnetically coupled: $H = -2JS_1S_2$ ($S_1 = S_2 = 5/2$) with a

Karl Wieghardt was born in Göttingen in 1942. He studied chemistry in Hamburg and Heidelberg from 1962–1967. After graduation he remained in Heidelberg studying under the supervision of Prof. Hans Siebert, receiving his doctorate in 1969. He spent the following years carrying out postdoctoral research with Prof. Siebert, and finally with Prof. A. G. Sykes in Leeds (1972). On returning to Germany he first took up an appointment as Lecturer at the University of Heidelberg (1974–1975) and then as Professor at the Technical University of Hannover (1976–1980) before accepting the offer of a chair in chemistry at the University of Bochum. Prof. Wieghardt's research interests include inorganic reaction mechanisms (redox chemistry), complex chemistry with macrocycles, preparative coordination chemistry, and bioinorganic chemistry.

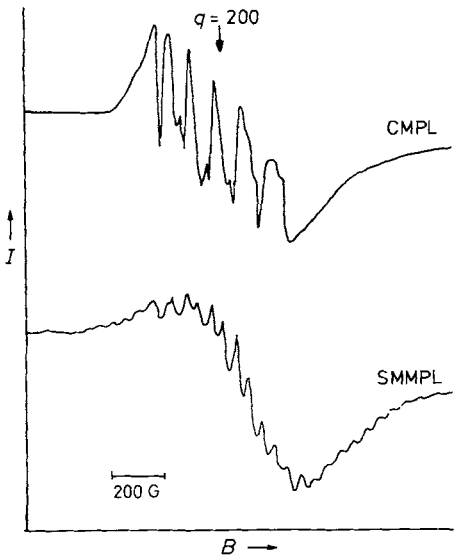

Fig. 2. X-band ESR spectra of the CMPL and SMMPL forms of concanavaline A at 77 K. CMPL is the $Ca^{2\oplus}/Mn^{II}$-containing form *without* an additional bound saccharide. The SMMPL form contains *two* neighboring Mn^{II} centers and a bound saccharide (α-MDM) [7]. B = magnetic field strength; I = first derivation of the ESR signal; g = 2.00.

spin exchange coupling constant of $J = -0.9\ cm^{-1}$ (weak antiferromagnetic coupling). The intensity of the signal of the SMMPL form decreases considerably between 1.4 and 4 K because the ground state ($S = 0$) is reached, in contrast to the SCMPL signal which remains strong ($S = 5/2$ ground state). These results were confirmed by measuring the magnetic susceptibility of the apoprotein (to obtain the diamagnetic correction) and the two differing manganese-containing forms of concanavalin A.[7b]

2.2. Further Metalloproteins with Neighboring Mn^{II} Ions

The enzymes to be described below are structurally less well characterized; no X-ray structural analyses are available to date. They all contain at least two metal cations of which one or both can be Mn^{II}. In vivo these cations can be $Mg^{2\oplus}$, $K^{\oplus}$ or $Ca^{2\oplus}$, but in vitro they can be replaced by Mn^{II}, making an ESR investigation possible. Metalloproteins which bind several metal ions and which can be investigated using Mn^{II} ions as a probe, include: pyruvate-kinase,[42] *S*-adenosylmethionine-synthetase,[8] phosphoribosylpyrophosphate-synthetase,[43] enolase,[12] inorganic pyrophosphatase,[44] and carbamylphosphate-synthetase.[45]

Some of these enzymes will be described in more detail since they demonstrate the use of ESR spectroscopy in structural investigations.

S-Adenosylmethionine-synthetase,[8] which is isolated from *Escherichia coli*, requires two metal cations (in vivo $Mg^{2\oplus}$ and $K^{\oplus}$) per enzyme subunit (it is a tetramer in its active form) to achieve optimum activity. It binds two Mn^{II} ions per subunit in the presence of a nucleotide substrate (adenylimidophosphate) or of pyrophosphate product. In the absence of nucleotides only one Mn^{II} ion per subunit is coordinated. The two Mn^{II} centers in the ternary complex must be located next to each other since weak spin exchange coupling is observed in the ESR spectrum.[8d] This coupling is caused by a magnetic superexchange through at least one bridging ligand. There are two different Mn binding sites per subunit; one is formed from the ligands of the protein component, the other can only be used if nucleotides or pyrophosphates are present. The second binding site for the Mn^{II} ion is thought to be in the phosphate component of the nucleotide. The two sites in the ternary complex are bridged by either the α-phosphoryl group of the nucleotide or by a functional group (carboxylate?) from another part of the protein.

Glutamine-synthetase, which is also isolated from the *Escherichia coli* shows very similar characteristics. It consists of twelve identical subunits and catalyzes different reactions, including the biosynthesis of glutamine from glutamate, ammonia and ATP.[9] In vivo, the enzyme requires two Mn^{II} cations to achieve catalytic activity. In the absence of ATP two Mn^{II} ions are bound at two different sites, S_1 and S_2 with differing affinities. The first $Mn^{2\oplus}$ ion is coordinated at S_1 within the protein in the absence of the substrate (a nucleotide), inducing thereby a conformational change, the second $Mn^{2\oplus}$ then occupies the S_2 site and facilitates a connection between the second $Mn^{2\oplus}$ in S_2 and the incoming substrate nucleotide. ESR investigations have shown[9h] that the distances between the S_1 and S_2 sites vary between 8 and 10 Å according to the nucleotide bound. The manganese containing enzyme with a Mn^{II} in the S_1 only was treated with a Cr^{III} containing nucleotide,[10] which acts kinetically as a 'dead end' inhibitor of the enzyme activity. The electronic interaction between the paramagnetic Cr^{III} ion in S_2 and the Mn^{II} (d^5 h.s.) in S_1 was investigated.[9h] Using the dipolar electronic spin relaxation theory of *J. S. Leigh*[11] the distance between S_1 and S_2 can be estimated from the spin-spin interaction.[11] Figure 3 shows the current proposal for the active site in glutamine synthetase in the presence of a Co^{III}-ATP complex.

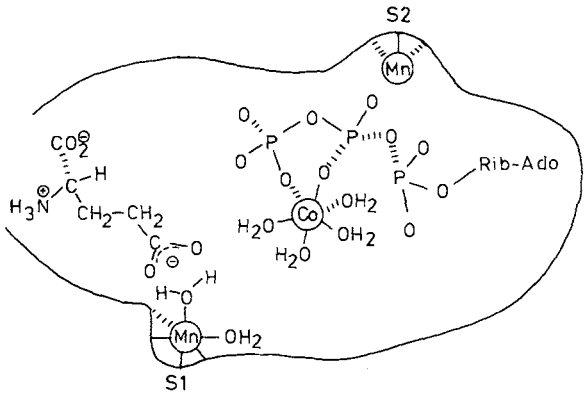

Fig. 3. Current proposal for the manganese binding site in glutamine synthetase in the presence of Co^{III}-ATP [1c].

Different binding sites for two $Mg^{\oplus}$ and Mn^{II} per subunit were discovered in a *yeast enolase* (phosphoenolpyruvate-hydratase) from *Escherichia coli 4.2.1.11*.[12] Additional Mn^{II} binding sites were also detected by ESR spectroscopy when the ratio $[Mn^{II}]/[enolase]$ was > 2. Weak spin-spin exchange interactions ($J = -0.0043\ cm^{-1}$) indicate that these sites must be near a Mn^{II} center that is strongly bound to the protein.

Finally, a manganese-containing catalase from *Thermophilium album*, a thermophilic bacteria, has been isolated. It has a molecular weight of 141 000[13] and is tetrameric with 1.4 ± 0.4 Mn^{II} ions per subunit. It is not clear if this enzyme contains one or two manganese centers per subunit. The enzyme is colorless; no absorption band has been found in the visible region, which may indicate the presence of Mn^{II} rather than Mn^{III} ions.

2.3. Metalloproteins with Mn^{III} Centers

Among the best characterized manganese containing proteins of this type are the superoxide dismutases (SODs), catalases and pseudocatalases.[14] The former catalyze the decomposition of $O_2^{\ominus}$-radicals [Eq. (a)] and the latter two the decomposition of H_2O_2 [Eq. (b)].

$$2\,O_2^{\cdot\ominus} + 2\,H^{\oplus} \rightarrow H_2O_2 + O_2 \qquad (a)$$

$$2\,H_2O_2 \rightarrow 2\,H_2O + O_2 \qquad (b)$$

These SODs are red and contain only one Mn^{III} ion per subunit. The metal ion is surrounded by N- and O-donor atoms from the amino acids of the polypeptide chain. The Mn^{III} ions are substantially more firmly bound than the Mn^{II} in the metalloproteins described in Sections 2.1 and 2.2. They show no ESR signals but a characteristic absorption spectrum with an intense maximum in the visible region ($^5E_g \rightarrow {}^5T_{2g}$ in O_h symmetry).

The SOD isolated from *Thermus thermophilus HB8* has been structurally characterized by X-ray diffraction.[15] It consists of four similar subunits. The resolution (2.4 Å) was good enough to allow the first coordination sphere of the Mn^{III} ion to be determined.[15b] Figure 4 shows the active

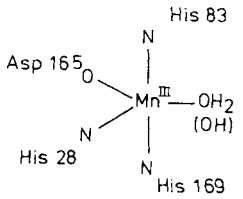

Fig. 4. Schematic representation of the active site of the superoxide dismutase from *Thermus thermophilus* bacteria.

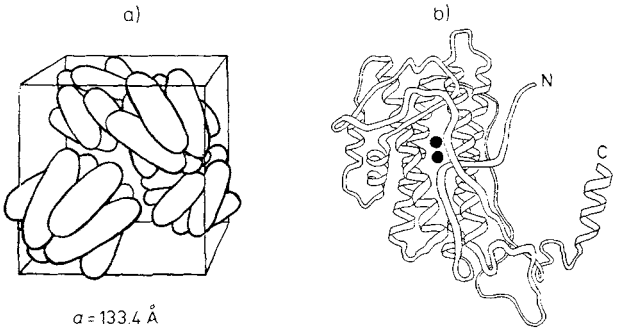
site; four donor atoms (three N atoms, and one carboxylate-O atom) from the protein and a coordinated H_2O molecule (or $OH^{\ominus}$) give the Mn center a trigonal bipyramidal coordination geometry.

2.3.1. The Catalase from Thermus Thermophilus (HB8 strain)

Unlike all other known catalases, this catalase is very heat resistant. It consists of two Mn^{III} ions per subunit (MW = 33 000–37 000) and is a hexamer. A red single crystal was subjected to an X-ray analysis.[16] Figure 5 shows schematically the arrangement of the six subunits and a sketch of one subunit, in which the two neigboring Mn^{III}



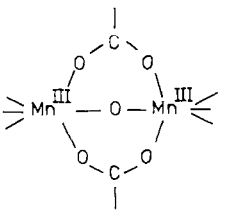


Fig. 5. Catalase from *Thermus thermophilus* (HBB strain): schematic representation a) of the quarterary structure of the hexamer in the crystal, b) a subunit. The black circles represent two manganese atoms separated by 3.6 Å [16].

centers can be clearly seen (Mn · · · Mn 3.6 Å). Due to the low resolution (3 Å) it is not possible to clearly establish the nature of the first coordination sphere of the metal centers. The manner in which the bridging ligands connect the two Mn centers is, therefore, also uncertain.

Each subunit consists of a polypeptide chain of about 300 amino acids; the sequence being unknown. Four large parallel α-helices of 25–30 amino acids form most of the quarternary structure of a subunit. The Mn ions are situated in the center of the four α-helices. This metalloprotein belongs to the group of four α-helix proteins, to which the iron-containing protein hemerythrin[17] also belongs. In this protein two Fe^{III} ions form a μ-oxo-bis(μ-carboxylato)diiron(III) structural unit to which N atoms from histidine moieties are bound. The structural relationship between some iron-containing[18] and some manganese-containing proteins will be encountered frequently further on. The duality of Fe^{III} and Mn^{III} is often referred to in the literature, since in some cases a metalloprotein can be reconstituted from the apoprotein using either Fe^{III} or Mn^{III}. Sometimes even the enzymatic activity is retained.

Interestingly, the electronic spectrum of this form shows an intense absorption band at 450 nm with a shoulder at 500 nm. As I will show later (Section 4.2) these bands are characteristic of the μ-oxo-bis(μ-carboxylato)dimanganese(III) structural unit (Scheme 1).

Scheme 1.

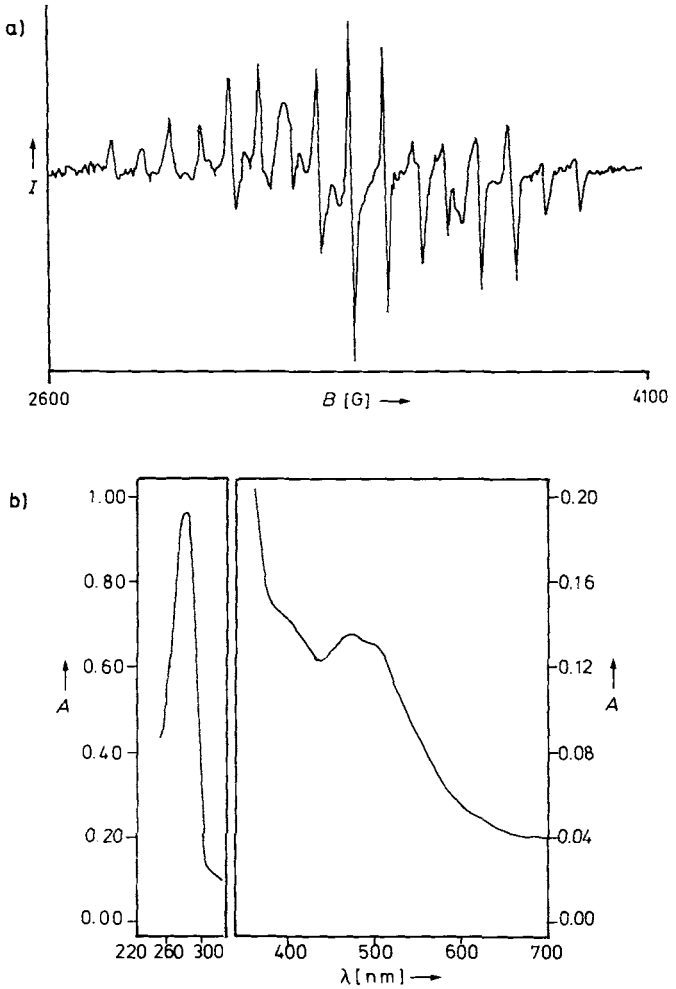
Khangulov et al. have shown in an elegant piece of work[16d,e] that a series of more complicated but also more informative ESR spectra are observed, if the Mn_2^{III} form is changed to Mn_2^{II}, $Mn^{II}Mn^{III}$ and $Mn^{III}Mn^{IV}$ forms by external reductants or oxidants. Particularly diagnostic is the ESR spectrum of the mixed valence form $Mn^{III}Mn^{IV}$, which shows a sixteen line pattern (50–70 K). This is characteristic for a strongly antiferromagnetic coupled (Mn^{III} $S = 2$, Mn^{IV} $S = 3/2$) oxo-bridged dimer with a $S = 1/2$ ground state.

2.3.2. The Pseudocatalase from Lactobacillus Plantarum

In concentrated solutions this catalase is pink. It has a molecular weight of 172000 and consists of five similar subunits (MW 34000), which each have two Mn^{III} ions.[19] The term pseudocatalase was introduced in order to indicate that the catalase activity is not inhibited by azide or cyanide ions, unlike in the case of other known catalases. The use of the prefix 'pseudo' has been criticized because it could imply that the catalase activity is impaired, disrupted or different, and this is not the case.

The existence of two manganese centers in close proximity was first concluded from the electronic spectrum (Fig. 6b).[61] In the visible region, a band was observed at 470 nm with shoulders at 398 and 500 nm. The molar absorption coefficient (ca. 1.3×10^3 L mol^{-1} cm^{-1}) are distinctly larger than they would normally be for monomeric octahedral Mn^{III} complexes. The synthesis of simple model complexes showed that such absorption bands are typical of complexes with the structural unit μ-oxo-bis(μ-carboxylato)dimanganese(III) or μ-oxo-bis(μ-carboxylato)manganese(III)-manganese(IV).[81,82]

This more 'indirect' evidence was recently confirmed by the discovery of a 16-line ESR spectrum of the biomolecule (Fig. 6a).[20] The manganese ions therefore form a mixed valence $Mn^{II}Mn^{III}$ or more likely a $Mn^{III}Mn^{IV}$ unit. In acid solution the manganese ions disproportionate, forming substitutionally labile Mn^{II}, which leaves the active site as $Mn(OH_2)_6^{2\oplus}$.



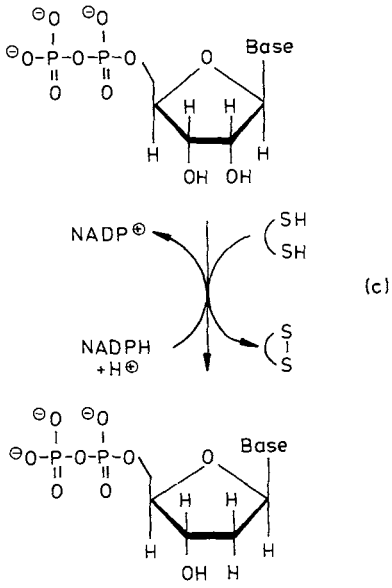


Fig. 6. Pseudocatalase from *Lactobacillus plantarum*: a) ESR spectrum at 6 K (6–10 μM [Mn]) [20]. b) Electronic spectrum at pH = 7.0 (left: 0.88, right: 17.52 mg enzyme per mL) [19]. *A* = absorption.

2.3.3. Ribonucleotide Reductase (RR) from Brevibacterium Ammoniagenes

The reduction of ribonucleotides to the corresponding 2'-deoxyribonucleotide, the building block of DNA, is one of the most important reactions for the existence and propagation of all life forms.[21] This enzymatically controlled reaction is shown in Equation (c). It appears simple enough, but the mechanistic details are by no means fully understood.

(c)

Three RR-enzymatic systems have been characterized, of which those containing iron but no heme groups are of great interest, because the active site consists of μ-oxo bridged Fe^{III} centers.[18]

Auling et al.[22] have recently shown that there is also a manganese-containing RR which was isolated from the gram-positive *brevibacterium ammoniagenes* (ATCC 6872). The enzyme consists of two protein subunits, namely a nucleotide binding protein B1 (MW = 80000) and the catalytically active protein B2 (MW = 100000). The latter is composed of two polypeptides (MW 50000) which are both necessary for enzymatic activity.

The manganese content has not yet been determined, but the electronic spectrum displaying two absorption maxima in the visible region (455 and 485 nm) is again typical of the μ-oxo-bis(μ-carboxylato)dimanganese(III) structural unit. The spectrum is shown in Figure 7 (the molar absorption coefficients are not known).

2.3.4. Further Metalloproteins with Probable Binuclear Mn_2^{III} Active Sites

The chemist is trained to determine the composition of a purified compound by an elemental analysis before describing its physical or chemical properties. This is trivial. How-

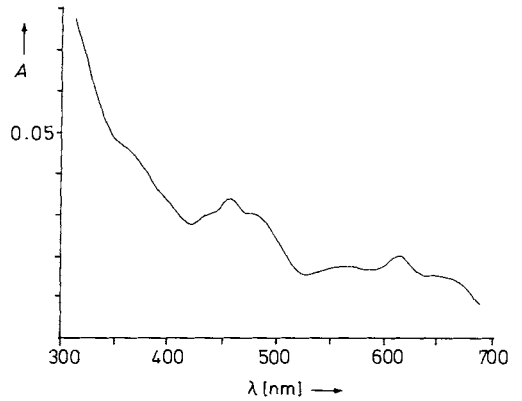

Fig. 7. Electronic spectrum of ribonucleotide reductase from *Brevibacterium ammoniagenes* at pH = 6.6 [22].

ever, the biochemist faces a series of problems in the process of purification to homogeneity of a new metalloprotein, which can often put into question the value of elemental analyses.

1) The isolation and purification of a metalloprotein is a complex multistep process. The metal content is very small and can only be determined by modern spectroscopic methods such as atomic absorption spectroscopy, ICP atomic emission spectroscopy (ICP inductively coupled plasma) or in the case of Mn^{II} containing proteins, quantitative ESR spectroscopy. Mn^{II} ions are kinetically labile and the stability constants of the binding sites are often quite small. Consequently, Mn^{II} ions are frequently washed out during the purification procedure or replaced by other divalent cations ($Ca^{2\oplus}$, $Mg^{2\oplus}$, $Fe^{2\oplus}$ etc.), which are inadvertantly introduced by the chemicals used.

2) The redox potential of the manganese cations in the oxidation states +II, +III and +IV are often close to one another. Thus, during isolation unintended changes in oxidation states can result in a formerly inert Mn center in higher oxidation state being washed out as labile Mn^{II} ions.

3) Binuclear manganese complexes tend to undergo pH dependent disproportionation reactions such as that shown in Equation (d). This process is discussed in more detail later in Section 4.2.

$$2\,Mn_2^{III} \rightarrow Mn^{II}Mn^{III} + Mn^{IV}Mn^{III} \qquad (d)$$

This reaction can again be the cause of too small a Mn content, since the Mn^{II} centers can leave the enzyme's active sites during purification.

4) Finally, sometimes even the qualitative determination of the nature of the metal in the active site can be a problem. The coordination chemistry of Fe^{III} and Mn^{III} is so similar in aqueous medium that unintended substitution of one metal cation by accidental presence of the other metal cation can lead to the wrong description of a metalloprotein. For instance:

One source of the so called *purple acid phosphatase* are the tubers of the sweet potatoes from Japan (Kokei No. 14 or Kontoki). This metalloprotein was originally described as a manganese-containing enzyme.[23] The MW is 110000 with two subunits (MW 55000). It was estimated to have one Mn^{III} ion per molecule of enzyme. *Averill* et al. have recently shown that this is probably an error.[24] They obtained a higher purity grade, with 14-fold higher activity, by slight modifications of the original purification procedure and have shown that there are two Fe^{III} ions per molecule enzyme and only traces of manganese. Purple acid phosphatase from uteroferrin and bovine spleen has a binuclear Fe^{III}–O–Fe^{III} active site.[18] However, in the present case it has been suggested that the enzyme from sweet potatoes has a mononuclear active Fe site.[24] It is conceivable that the Japanese group actually had a manganese form of the enzyme in their hands, whereas the American scientists purified an iron form. I think it highly improbable that iron was mistaken for manganese or vice versa by one or other group; more likely the duality of these two trivalent cations is the cause of the discrepancy.

In a further example, I would like to point out that the analytically determined manganese content could possibly be wrong. In 1984, *Reinards, Altdorf* and *Ohlenbusch* reported a manganese superoxide dismutase, which they purified from the procaryotic microorganism *Acholeplasma Laidlawii*.[25] It has a MW of 41500 and is formed from two subunits. The manganese content was given as 0.51 ± 0.05 Mn atoms per subunit (atomic absorption spectroscopy). The published electronic spectrum, however, appears to be remarkably like that of the spectrum of a μ-oxo-bis(μ-carboxylato)dimanganese(III) structural moiety. This would lead to the conclusion that the active site of this SOD is a binuclear Mn_2^{III} complex. Further investigation of this enzyme will be of interest.

3. The Active Site of Photosystem II

One of the fundamental processes in biology is the visible light driven oxidation of water, which occurs in a complex molecular 'apparatus' in the thylakoid membrane of chloroplasts of green plants, in algae and in some cyanobacteria. This 'apparatus', called photosystem II (PS II), has a manganese-containing active site which can oxidize coordinated water molecules[49] to oxygen [Eq. (e)].

$$2\,H_2O \rightarrow O_2 + 4\,H^{\oplus} + 4\,e^{\ominus} \qquad (e)$$

The manganese is the essential component, but $Ca^{2\oplus}$ and $Cl^{\ominus}$ ions are also necessary for the activity of PS II ($F^{\ominus}$ ions for example are effective inhibitors). Large acetate concentrations likewise inhibit O_2 evolution, but this effect is reversible; the activity is regenerated once the acetate ions have been washed out.[69]

From elemental analysis it appears that four manganese centers make up the active site;[40] whether all four are involved in the redox process is not clear. The arrangement of these four[37] manganese ions relative to one another in PS II and the mechanism of the water oxidation have been intensively investigated for many years. There have been many, in part controversial, suggestions and our understanding of the mechanism at the molecular level is still far from perfect.

I am not going to describe the spatial arrangement of PS II or the details of the photochemistry,[32,33] the electron[41] and proton transport.[46] These aspects are covered in many excellent reviews, of which only a selection is cited.[26–38]

The recent review of *Renger*'s in this Journal is particularly comprehensive in this respect.[26]

I would now like to briefly outline some features of our knowledge of the structure of the active site and some ideas for the reaction mechanisms involved in photosynthesis.

From *Joliot*'s[47] observation that periodic O_2 evolution occurs from dark-adapted chloroplasts when they are irradiated with a series of short light flashes, *Forbush, McGloin* and *Kok* have identified five states (oxidation states) during water oxidation.[48] These have been designated, S_0–S_4. In each case the absorption of one quantum of light raises the oxidation level by one unit (releasing one electron each time) and drives the system from S_0 to S_4. In the step $S_4 \rightarrow S_0$, O_2 is finally evolved and the S_0 state is regenerated (Fig. 8a).

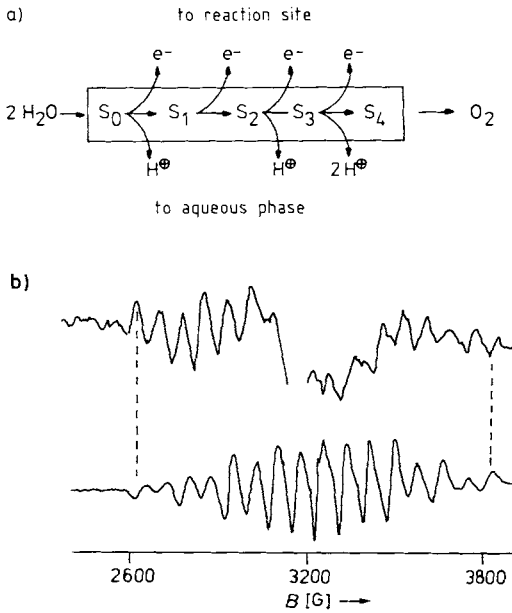

Fig. 8. a) The S-state model for water oxidation in photosynthetic membranes. b) Comparison of the ESR spectra of PS II membranes (top, at 300 K, cooled to 200 K and measured at 10 K in the dark) with that of the mixed-valence $Mn^{III}Mn^{IV}$ analogue of the borato complex **11** (Fig. 14) [61] (bottom).

The stoichiometry and sequence of the movement of protons in the cycle has been investigated by *Förster* et al.[46] *Dismukes*,[41a,b] in a pioneering observation, showed that the PS II particles are ESR active in the S_2 state. The discovery of a complex 16- to 19-line spectrum at $g = 2.0$ (Fig. 8b) and later a further signal at $g = 4.1$ [41e–k] as well as the recently discovered tyrosine radical[50] has given a large impulse to clearing up the nature of the active site. The derivation of its structure from ESR measurements, whose reproducibility under different experimental conditions and in different laboratories is not discussed here (this is a problem!), depends critically on the development of the theory of paramagnetic polynuclear manganese centers.

The only method that to date has been able to probe directly the surroundings of the manganese atoms in PS II is EXAFS spectroscopy. The method was developed for this problem bei *Klein* et al.[51] The interpretation of the spectra obtained from PS II particles in the states S_0, S_1, S_2 and recently S_3[52] proves the following:

1) The oxidation level of the manganese cluster increases stepwise from S_0 to S_2, without the structure significantly changing; the transition from S_2 to S_3 does *not*, however, bring about a change in oxidation state at the manganese center.[54] This is an important result, because up to now it has been assumed that the four electrons came successively from the manganese cluster. An organic radical must arise somewhere in the $S_2 \rightarrow S_3$ transition (oxidized histidine?).[55]

2) The first coordination sphere of all Mn atoms consists of oxygen and/or N atoms (probably more O atoms than N atoms).

3) No chloride coordination was found within 2.2 Å of the Mn atoms. The activity of PS II is $Cl^{\ominus}$ dependent and coordination of $Cl^{\ominus}$ has often been discussed but not experimentally proven. The EXAFS spectra can not exclude the possibility that there is a Mn · · · Cl distance >2.2 Å.

4) Of great significance is the observation of a Mn · · · Mn distance at 2.7 Å and probably another Mn · · · Mn distance at 3.3 Å.[51–53]

The most recent EXAFS measurements from *Cramer* et al.[53] with polarized, synchroton radiation on orientated chloroplasts shows that the manganese cluster has a Mn · · · Mn vector of 2.7 Å and a further one of 3.3 Å arranged almost vertically to the membrane. The authors conclude that the active site could be made up from two differing binuclear units, one with two μ-oxo bridges and connected to the other with carboxylato bridges. Alternatively, however, an unsymmetrical tetranuclear structure is conceivable.[39]

Figures 9, 10 and 11 give three speculative suggestions for the structure and reaction mechanism; these reflect current knowledge and have been particularly stimulating to the in-

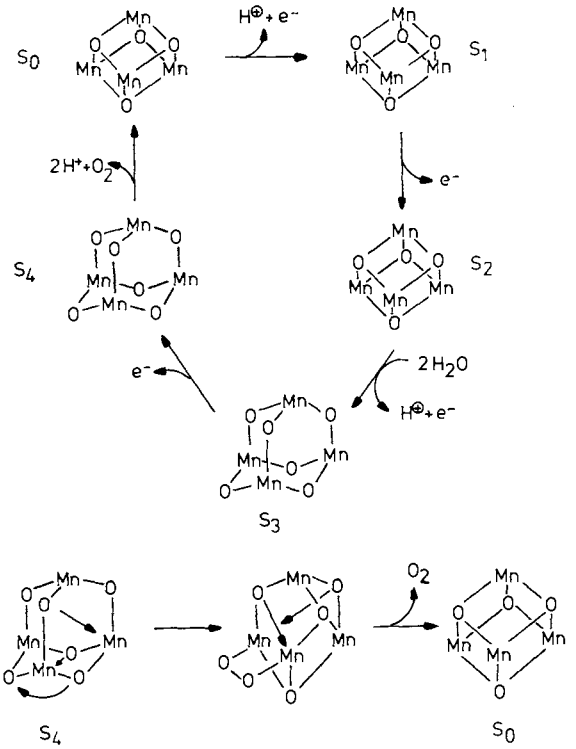

Fig. 9. Speculative reaction mechanism for the water oxidation in PS II, in which a structural change is proposed to take place between the regular cubane framework $\{Mn_4O_4\}$ and the adamantane skeleton $\{Mn_4O_6\}$ (after *Brudvig* and *Crabtree* [56]).

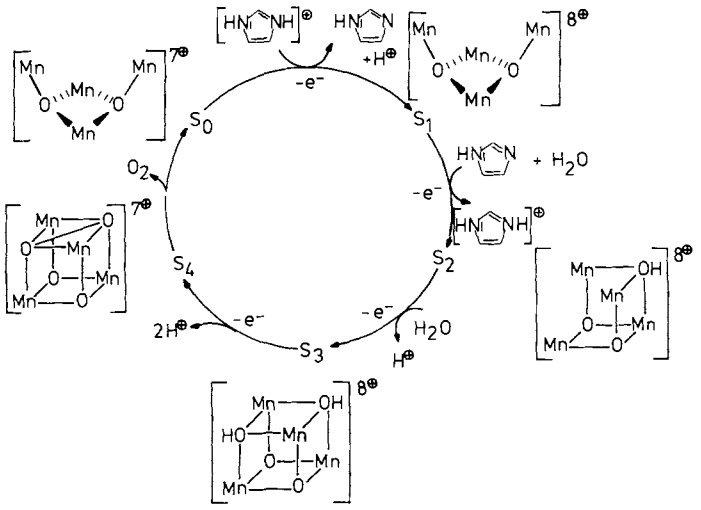

Fig. 10. Speculative mechanism for water oxidation in PS II with $\{Mn_4O_2\}$ and $\{Mn_4O_3\}$ structural units (after *Vincent* and *Christou* [57]).

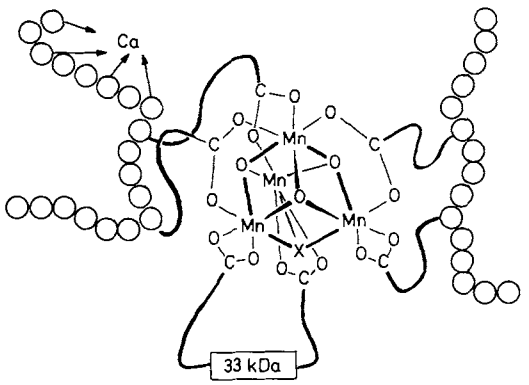

Fig. 11. Structural proposal from *Dismukes* [36a] for the active site of PS II. The circles symbolize polypeptide chains which have carboxylato groups available for bonding (the amino acid sequence is known); X is a μ_3-Cl bridge (Mn–Cl 2.6 Å). At the bottom a protein subunit (MW 33000) is sketched, which has two carboxylato groups bound to the Mn center. This protein component can be easily removed, making two Mn centers very labile.

organic chemist. Mechanistically, the minimal model, in which two H_2O ligands are oxidized at a binuclear center (*Witt* et al.,[32] *Renger*,[59] *Vänngard* et al.,[49] *Kambara* et al.[58] etc.) is still just as reasonably valid as the more complex schemes introduced by *Brudvig* and *Crabtree*[56] on the one hand and by *Vincent* and *Christou*[57] on the other. *Dismukes*' model[36] (Fig. 11) is an aesthetically pleasing combination of experimental facts, thoughtful deduction, and a lot of imagination. Thus, the mechanism could be like this but also quite different. These suggestions have been strongly influenced by more recent developments in the inorganic coordination chemistry of manganese, whereby the synthesis of low molecular weight bi-, tri- and tetranuclear complexes of manganese has stimulated many ideas.

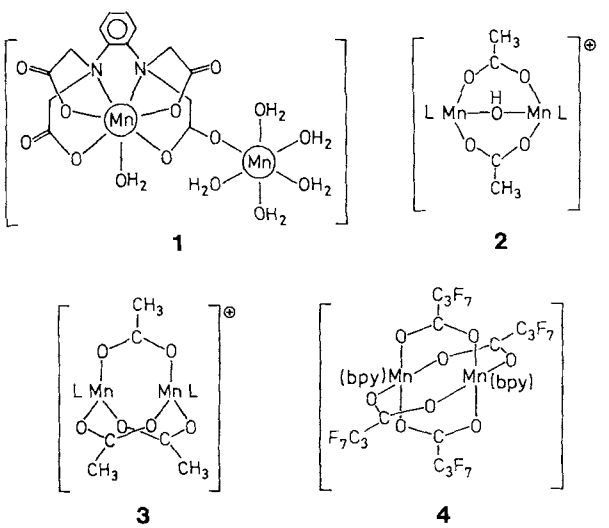
4. Model Complexes of Manganese[60, 68]

In all the previously described biomolecules, the manganese ions were bound by O and N donor atoms from within the protein. Functional groups include, for example, carboxylato, alkoxy and phenoxy groups and the imidazole N atom from histidine. Sulfur coordination was not observed in any of our examples. Consequently, I shall describe the classical coordination chemistry (Werner type) of manganese with O and N ligands.

Complexes of Mn^V in an octahedral environment were until recently unknown. The occurrence of this high oxidation state in biological systems has not been established as yet, but due to recent preparative results it can be no longer viewed as being as exotic as it was several years ago. *Buchler* et al.[62] and *Hill* et al.[63] prepared the first diamagnetic nitridoporphyrinatomanganese(v) complex. Its structure has been determined by X-ray diffraction and has a fivefold MnN_5 coordination geometry. A very reactive oxochloroporphyrinatomanganese(v) complex with octahedral coordination of the Mn^V ion[64] has also been reported. Electrochemical and spectroelectrochemical investigations of the $Mn^V \equiv N$ unit have been published recently.[65] *Okawa* et al.[66] reported a synthesis of a probable octahedral, paramagnetic complex ($\mu_{eff} = 2.83\ \mu_B$) $K[MnL_2]$ (L is the trianion of *N*-(2-hydroxyphenyl)salicylamide), which can be recrystalized without decomposition from water. Once more it is demonstrated that 'unusual' oxidation states can be stabilized readily by the correct choice of suitable ligands. *Calvin*[67] and *Brudvig*[56] have therefore quite rightly considered Mn^V as a possible oxidation state in PS II.

4.1. Binuclear Mn^{II} Complexes

Carboxylato groups show a pronounced inclination to bind to manganese in either a monodentate or a bidentate manner; in the latter case with the formation of a symmetrical μ-carboxylato bridge. These complexes model the bonding characteristics of biomolecules with two neighboring Mn^{II} ions, since polypeptides often have unbound $-COO^{\ominus}$ groups, which can be utilized in coordination to metal ions. Figure 12 shows four structural types, which have all been characterized by X-ray crystallography. Complexes **1**,[70] **2**,[71] **3**[72] and **4**[73] contain one to four bridging acetate



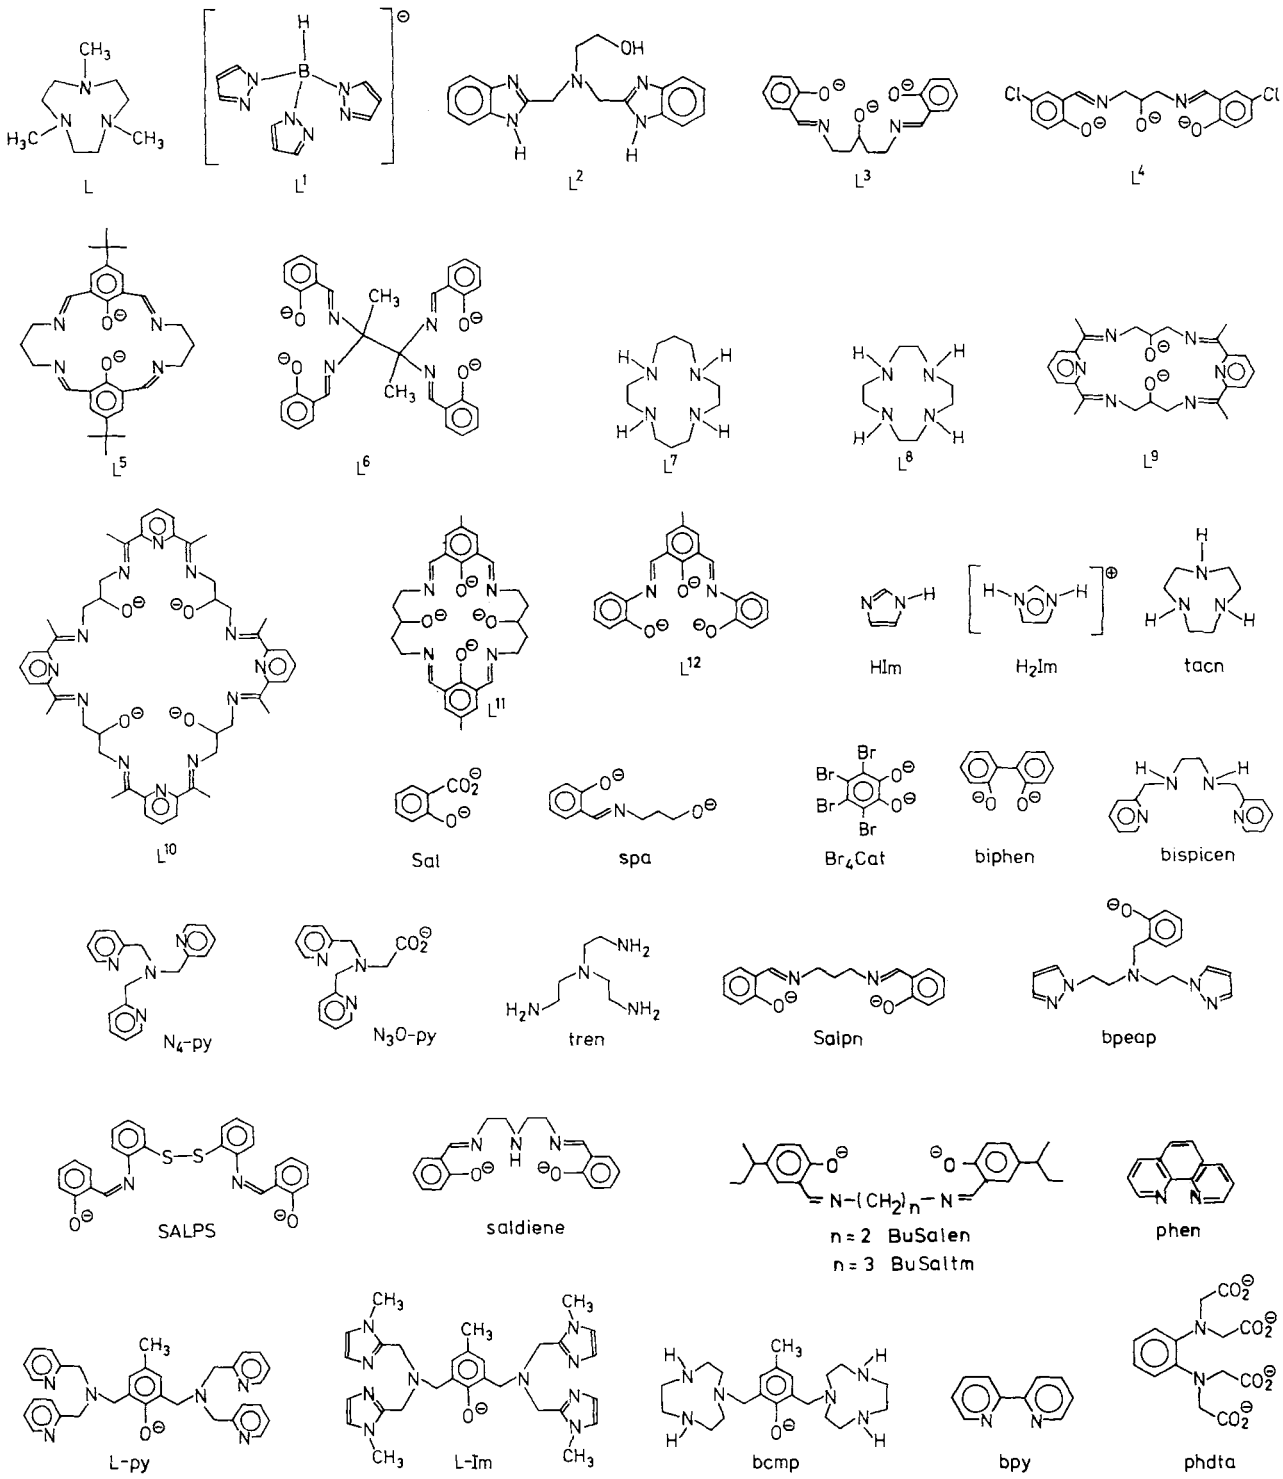


Fig. 12. The binuclear Mn^{II} complexes **1**–**4**. For ligands see Scheme 2. The counterions in **2** and **3** are $PF_6^{\ominus}$ and $BPh_4^{\ominus}$, respectively.

Scheme 2. O, N ligands and their abbreviations.

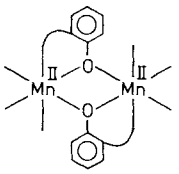
ligands. Their Mn · · · Mn distances and magnetic properties are listed in Table 1. Intramolecular weak antiferromagnetic spin exchange coupling of both high spin Mn^{II} ions is observed, occurring either through space in **3** and **4** or via a superexchange mechanism in **2**. Interestingly, the OH bridged species **2** shows the strongest coupling, i.e. μ-OH groups are good mediators for the superexchange mechanism, whereas carboxylato groups are rather poor in this respect.

A further potential ligand for Mn^{II} is the phenoxy group from tyrosine in the polypeptide. Phenoxy groups frequently link two metal ions in simple molecular complex chemistry. The complexes **5**,[74] **6**[75] and **7**[76] (Fig. 13) are examples of this; **5** and **6** have been structurally characterized by X-ray diffraction. In both cases the two octahedra are edge-linked and have relatively short Mn · · · Mn distances. In each case weak antiferromagnetic coupling is observed (Table 1).

Compounds **6**, **7** and **8**[78] show complex ESR spectra with distinct hyperfine splitting. Instructive discussions have been reported by *Hendrickson* et al.[76] and *Dismukes* et al.[78] ESR spectroscopy is a good method for distinguishing between monomeric and dimeric structures, if the spin ex-

change coupling constant J is substantially larger than the ^{55}Mn hyperfine coupling constant a.[77] The separation of the signals for a dimer is then $a/2$, half the value of the corresponding monomeric species. These investigations confirm and extend the argument for use of ESR measurements for biomolecules with two neighboring Mn^{II} ions.

The complex **8** is particularly interesting, because it serves as a functional model for the catalases from *Lactobacillus plantarum* and *Thermus thermophilus*. It decomposes H_2O_2 catalytically, the initial rate being proportional to $[H_2O_2]^2$.[8] An analogous but monomeric Mn^{II} complex is inactive. The first step in this reaction is proposed as being the formation of a μ-oxo-bridged dimanganese(III) intermediate, which then reacts with a further molecule of H_2O_2, releasing O_2 and thus being reduced [Equations (f) and (g)].



$$H_2O_2 + Mn^{II}_2 + 2\,H^{\oplus} \rightarrow Mn^{III}_2 + 2\,H_2O \qquad (f)$$

$$Mn^{III}_2 + H_2O_2 \rightarrow Mn^{II}_2 + O_2 + 4\,H^{\oplus} \qquad (g)$$

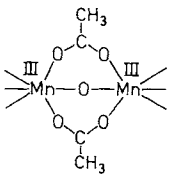
Fig. 13. The binuclear μ-aryloxo or μ-alkoxo bridged Mn^{II} complexes **5**–**8**. For ligands see Scheme 2.

In order to study spin-spin interactions, some binuclear Mn^{II} complexes were studied, containing coordinated organic radicals. This is a very important aspect, since in PS II the transition from the ESR active S_2 state to the ESR inactive S_3 state does not involve a change in oxidation state at the manganese centers. This means that an organic radical must extinguish the ESR signal in the S_3 state. Examples include the manganese complexes with catechol and semiquinone ligands.[79, 80] The semiquinone complex with structure A or B[79] shows, in solution, that the coordination of paramagnetic ligands results in a ferromagnetic coupling between the two Mn^{II} ions. A($S = 3$) ground state was found for the dimer with four semiquinone radicals, which couple antiferromagnetically with the Mn^{II} ions.

A



B

Hendrickson et al.[80] described a green tetrameric complex $[Mn_4(3,5\text{-DBSQ})_8]$ (3,5-DBSQ = 3,5-di-*tert*-butyl-1,2-benzoquinone) with four Mn^{II} ions and semiquinone ligands, which are weakly coupled ($\mu_{eff} = 5.1\ \mu_B$ per Mn at 295 K).

4.2. Binuclear Mn^{III} Complexes

The discovery of a series of iron-containing metalloproteins which contain the binuclear structural unit μ-oxo-bis(μ-carboxylato)diiron(III), led to the synthesis of simple binuclear molecular complexes of this type.[18] This synthesis is amazingly simple, occurring by 'spontaneous self-assembly'.[4b, c] This suggests that the formation in solution of this structural unit from labile mononuclear metal cations, polydentate and bridging ligands is favored given the correct conditions of concentration, temperature and solvent. Once these conditions had been found, complexes of this type were prepared for most trivalent metal ions of the first row transition series, including manganese(III).[81–84] In Figure 14 all

$[(tacn)_2Mn_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$ **9**

$[L_2Mn_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$ **10**

$[L^1_2Mn_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]$ **11**

$[(bpy)_2Mn_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2(H_2O)_2]^{2\oplus}$ **12**

$[L^2_2Mn_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$ **13**

Fig. 14. The binuclear Mn^{III} complexes **9**–**13** with μ-oxo-bis(μ-acetato)dimanganese(III) core. For ligands see Scheme 2.

such complexes structurally characterized by X-ray diffraction are given. Complex **13** is the only one without a structural analysis.

As in the case of the Fe^{III} complexes of this type, it was quickly recognized that the analogous Mn^{III} complexes are excellent model complexes for the electronic characteristics of the Mn^{III} centers in the biomolecules discussed in Section 2.3:

1) The electronic spectrum in the visible is characteristic for a μ-oxo-bis(μ-carboxylato)dimanganese(III) unit. Almost independent of the nature of the remaining ligands two very intense bands between 400 and 600 nm ($\varepsilon > 600$ L mol^{-1} cm^{-1}) are observed (Fig. 15). These are not simple

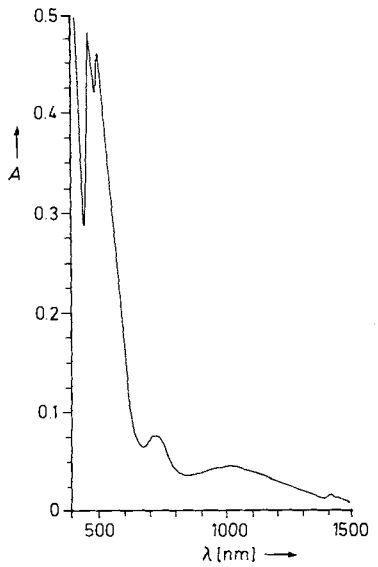


Fig. 15. Electronic spectrum of **10** in CH_3CN ([**10**] = 7.2×10^{-4} M, 1-cm cell) [81].

d–d transitions of octahedrally coordinated Mn^{III} ions and their nature is not yet fully understood. They could be due to the so called 'simultaneous pair excitation' (*Gray* et al.[91] and *Güdel* et al.[92]), in which it is suggested that two electrons per dimer (one for each Mn^{III} center) are excited simultaneously by one photon. This would mean that the observation of such absorptions in the active centers of the biomolecules described in Section 2.3 would prove their dimeric character. Interestingly, these bands are *not* observed in metalloenzymes with *mononuclear* centers. e.g. SODs.

2. Unlike the complexes with Fe^{III}–O–Fe^{III} units which exhibit strongly antiferromagnetically coupled Fe^{III} ions, the complexes **9**–**13** have Mn^{III} ions that are only very weakly coupled (ferromagnetic for **9**, **10** and **13**, antiferromagnetic in **12** and uncoupled in **11**; Table 2).

Table 2. Mn · · · Mn separation and spin exchange coupling constants in the binuclear Mn^{III} complexes **9**–**19** (Fig. 14, 17).

Complex	Mn · · · Mn [Å]	J [cm^{-1}]	Ref.
9	3.084	ferromagnetic	[81, 72]
10		+ 9	[72]
11	3.159	− 0.5	[82]
12	3.132	− 3.4	[83]
13	unknown	+ 1.72	[84a]
14	3.247	antiferromagnetic	[93]
15	2.869	− 19.1	[85]
16	2.931	− 19.6	[87]
17	3.533	not coupled	[89]
18	2.72	not reported	[86]
19	3.808	− 3.6	[90]

3. The ESR spectroscopic behavior of these complexes is still controversial. We found that **9**, **10** and **11** are ESR inactive in anhydrous solutions in the temperature range 4–290 K. *Nishida*[84b] reported a 16-line spectrum for **9** and **13** at 77 K. I think this is an artefact caused by H_2O catalyzed disproportionation of the Mn_2^{III} dimers to the $Mn^{II}Mn^{III}$ and $Mn^{III}Mn^{IV}$ dimers. The latter species show the usual 16-line spectrum. The disproportionation of **9**, **10** and **11** has been established.[71, 72]

4) The electrochemical behavior of **9**, **10**[71, 72, 81] and **11**[82] models the redox behavior of the catalase enzymes and PS II. In anhydrous solutions they can undergo reversible one-electron reduction and oxidations, giving binuclear $Mn^{II}Mn^{III}$, $Mn^{III}Mn^{IV}$ and Mn_2^{IV} complexes [Eq. (h)] without the structure rearranging.

$$Mn^{II}Mn^{III} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} Mn^{III}Mn^{III} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} Mn^{III}Mn^{IV} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} Mn^{IV}Mn^{IV} \quad \text{(h)}$$

The hydroxy bridged species **2** can likewise be electrochemically oxidized twice giving μ-OH bridged complexes of $Mn^{II}Mn^{III}$ and Mn_2^{III}, respectively [Eq. (i), Fig. 16].

$$Mn^{II}Mn^{II} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} Mn^{II}Mn^{III} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} Mn^{III}Mn^{III} \quad \text{(i)}$$

In aqueous acidic solution, **10**, can be protonated at the μ-oxo bridge giving a μ-hydroxy bridged species; both compounds are related by the pH dependent equilibrium illustrated in Equation (j)

$$Mn^{III}\text{–}O\text{–}Mn^{III} \overset{H^{\oplus}}{\rightleftharpoons} Mn^{III}\text{–}OH\text{–}Mn^{III} \quad \text{(j)}$$

Figure 16 illustrates that due to their respective redox potentials the protonated form of **10** can oxidize the unproto-

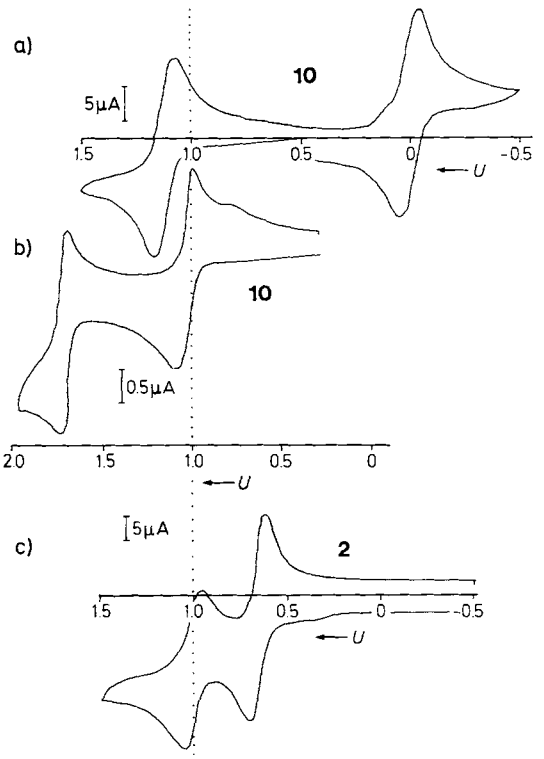

Fig. 16. Cyclic voltammogram of **10** · $(PF_6)_2$, a) in CH_3CN, b) in liquid SO_2 and c) of **2** (PF_6)·CH_3OH in CH_3CN [72].

nated form. Consequently, in aqueous acidic solution **10** disproportionates according to Equation (k).

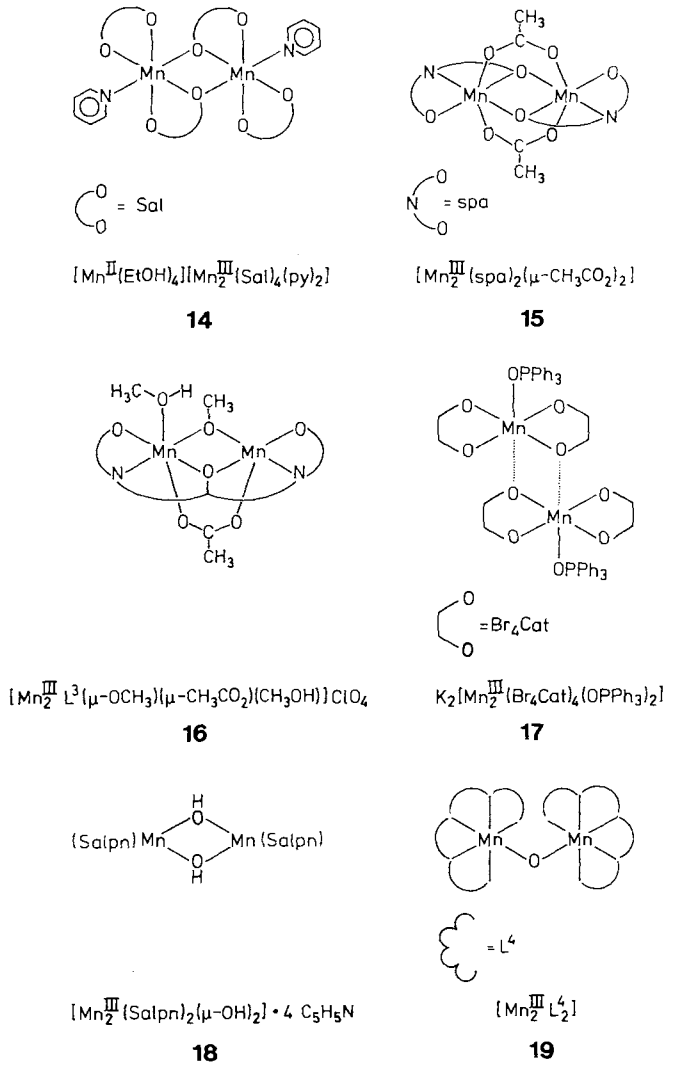
$$Mn^{III}(OH)Mn^{III} + Mn^{III}OMn^{III} \rightarrow Mn^{II}(OH)Mn^{III} + Mn^{III}OMn^{IV} \quad \text{(k)}$$

The reduced $Mn^{II}(OH)Mn^{III}$ form decomposes to mononuclear complexes in aqueous solution but the oxidized form Mn^{III}–O–Mn^{IV} can be isolated in crystalline form and displays a 16-line ESR spectrum at 70 K. Complex **44** in Section 4.5 has been characterized by X-ray diffraction.[71b]

This acid dependent disproportionation reaction was also found for the pseudocatalase of *Lactobacillus plantarum*.[20] This could be the cause for *Nishida*'s ESR spectrum of **11** and **13**.[84]

5. The Mn · · · Mn distances in the μ-oxo- and μ-hydroxo-bis(μ-carboxylato)dimanganese model complexes vary according to the oxidation state of the metal centers and are in the range of ca. 3.1–3.4 Å. They are therefore about the same as those distances found in *Thermus thermophilus* and PS II (second vector).

Some hydroxy, alkoxy and phenoxy bridged binuclear complexes of Mn^{III} have been synthesized and their structures determined.[85–93] Figure 17 again shows a representative cross-section, and Table 2 lists their magnetic properties. The spin coupling of the high spin Mn^{III} ions in these complexes is small. Comparing the Mn–O bond lengths in the μ-oxo bridged complexes to those of the μ-OH, μ-alkoxy and μ-phenoxy bridged complexes, it can be seen that the Mn–O_{oxo} bonds are always substantially shorter (ca. 1.80 Å as opposed to 1.95 Å).



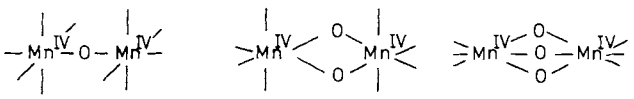


Fig. 17. The binuclear Mn^{III} complexes **14–19.** For ligands see Scheme 2.

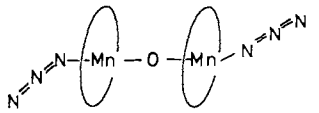
4.3. Binuclear Mn^{IV} Complexes



Binuclear complexes of manganese(IV) can contain one, two or three μ-oxo bridges; two octahedrally coordinated Mn^{IV} centers are connected in such a manner that the two octahedra are corner-, edge- or face-sharing as shown in structures **C, D** and **E**.

C **D** **E**

Typical examples are given in Figure 18 and Table 3. The magnetic properties of these complexes differ considerably from those of the hydroxy and alkoxy bridged complexes of Mn^{II} and the corresponding bridged compounds of Mn^{III}: the Mn^{IV} ions are strongly intramolecularly antiferromag-

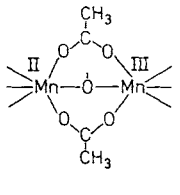
26	1.82	2.625	st. antifer.	[72]
27	1.82	2.296	− 390	[72]

[a] st. antifer. = strongly antiferromagnetic; n.r. = not reported.

netically coupled ($S = 0$ ground state). The face sharing tris(μ-oxo)dimanganese(IV) complex **27** has a coupling constant of $J = -390\ cm^{-1}$ ($H = -2JS_1S_2$; $S_1 = S_2$ 3/2). It has a magnetic moment of 0.8 μ_B per dimer at room temperature and an extremely short Mn · · · Mn distance of 2.296 Å.

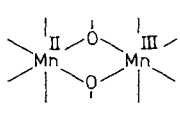


Octahedral Mn^{IV} complexes with d^3 electronic configuration have empty antibonding e_g^* orbitals, and therefore the Mn–N and Mn–O bond lengths are distinctly shorter than in the analogous Mn^{III} or Mn^{II} complexes. The Mn^{IV}–O_{oxo} bond lengths are about 1.74–1.82 Å, whereas the Mn^{III}–O_{oxo} bond lengths are 1.81–1.83 Å. The intramolecular Mn · · · Mn distances in compounds of type **C**, **D** and **E** are 3.54, 2.6, and 2.296 Å respectively. Compounds of type **D** therefore model the short Mn · · · Mn distance in PS II.

The edge-sharing compounds **21** and **23** with the di-μ-oxo-dimanganese core **D** and phenanthroline and bipyridyl ligands, respectively, have been thoroughly investigated. They can be electrochemically reversibly reduced to the corresponding $Mn^{III}Mn^{IV}$ species and to the Mn_2^{III} dimer.[99] This redox behavior has already been described for complexes containing the μ-oxo-bis(μ-carboxylato)dimanganese structural unit.[72] The corresponding binuclear Mn^{IV} complexes of this latter type are strong oxidizing agents and have still not been isolated in crystalline form. They are, however, estimated to have a Mn · · · Mn distance of 3.1–3.4 Å and thus can be viewed as model complexes for the longer Mn · · · Mn distance of 3.3 Å in PS II.[53]

None of the above compounds are ESR active at low temperature ($S = O$ ground state).

4.4. Mixed Valence Binuclear $Mn^{II}Mn^{III}$ Complexes



Mixed valence binuclear $Mn^{II}Mn^{III}$ complexes were synthesized and structurally characterized only in recent years (Fig. 19, Table 4). With a variety of binucleating ligands they

$[Mn_2(L\text{-}py)(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$ **28**

$[Mn_2(L\text{-}Im)(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$ **29**

$[Mn_2(bcmp)(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$ **30**

$[Mn_2L^5(\mu\text{-}Cl)Cl\ Br]$ **31**

$[Mn_2(biphen)_2(biphenH)(bpy)_2]$ **32**

$[Mn_2L^6(OH)(OH_2)]$ **33**

form stable products and are generated from binuclear Mn^{II} precursors by air oxidation.

Dismukes et al.[102] have obtained a $Mn^{II}Mn^{III}$ complex by air oxidation of the mononuclear tetraphenylporphyrinatomanganese(II) in chlorobenzene. This compound has either a peroxo- or oxo-bridge, but in solution it converts slowly into a μ-oxo-bridged $Mn^{III}Mn^{IV}$ complex. Both forms

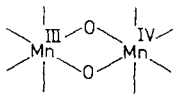
are ESR active, showing in each case 16 ^{55}Mn hyperfine signals at $g \approx 2.0$. The hyperfine coupling constants are different and hence the magnitude of these constants provides a method for determining the oxidation state in this case. *Hendrickson* et al.[101] have, however, previously pointed out that the knowledge of hyperfine constants is *alone* not enough to unequivocally determine oxidation states.

From the investigations of the complexes in Table 4 the following conclusions can be drawn:



1. The oxidation states of the manganese ions are localized. Therefore X-ray structural analysis can distinguish between the Mn^{II} and Mn^{III}, provided that there is no disorder.[104–109] A possible exception could be *Kida*'s complex **33**,[100] which exhibits an intervalence band at 1300 nm in its electron spectrum. In the absence of a structural analysis this complex has been tentatively assigned to Class II in *Robin* and *Day*'s[110] scheme of mixed valence complexes.

2. The spins of the Mn^{II} and Mn^{III} ions in complexes **28–30** with a μ-phenoxy-bis(μ-carboxylato)dimanganese(II/III) core are weakly antiferromagnetically coupled ($S = 1/2$, ground state). Due to dependence on the symmetry of the coordination geometry, the ESR spectra show complicated ^{55}Mn hyperfine splitting. The spectrum of **28** measured at 15 K shows 29 hyperfine signals at $g \approx 2.0$ and at higher temperature a broad signal at $g \approx 4$ arising from an excited state ($S = 3/2$).[105, 109] Compound **32** is the only $Mn^{II}Mn^{III}$ complex with ferromagnetic spin-spin coupling; it has a $S = 9/2$ ground state.[108] The ESR spectrum at 7.5 K shows accordingly a signal at $g = 12.0$, a signal with hyperfine structure at 5.1, and two weak signals at $g = 2.01$ and 1.47.

3. The μ-phenoxy-bis(μ-carboxylato)dimanganese(II/III) complexes undergo both reversible one electron reduction and oxidation forming the corresponding Mn_2^{II} and Mn_2^{III} dimers [Eq. (i)]. Unlike the μ-OH bridged complex **2**, no disproportionation occurs in aqueous solution, since the μ-phenoxy bridges are preserved.

4.5. Mixed Valence Binuclear $Mn^{III}Mn^{IV}$ Complexes

Three types of these complexes have been structurally characterized by X-ray diffraction (Fig. 20; Table 5): a) Compounds **34–41** with the di-μ-oxo-dimanganese(III/IV) core (edge-sharing octahedra), b) the μ-acetato-di-μ-oxo-dimanganese(III/IV) complexes **42** and **43**, c) Complex **44** containing the μ-oxo-bis(μ-acetato)dimanganese(III/IV) structural unit. In crystals which are not disordered the Mn^{III} and Mn^{IV} ions can be clearly distinguished (**42** and **44** are disordered). The valences are therefore localized. The Mn^{III} ions frequently show Jahn-Teller distortions (elongated or com-

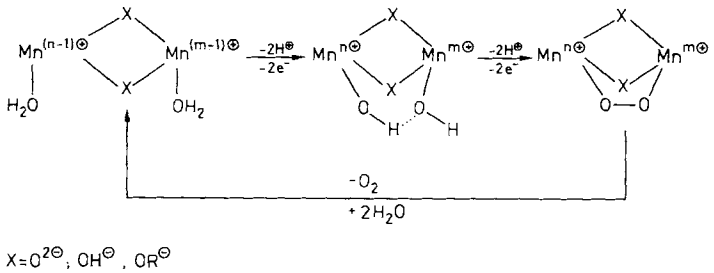
[a] Not differentiable due to disorder.

pressed octahedra), which is typical for the high spin d^4 electron configuration.



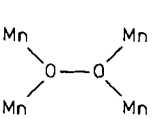
The spins of the Mn^{III} and Mn^{IV} ions in complexes of type a) and b) are intramolecularly strongly antiferromagnetically coupled ($S = 1/2$ ground state). Complex **44** shows comparatively weaker coupling (face-sharing octahedra).

Below ca. 70 K in frozen solutions complexes **34–44** all display the typical 16-line ESR spectrum with ^{55}Mn hyperfine structure at $g \approx 2.0$. This was also observed in the biomolecules of the catalase (Section 2.3.1) and the pseudocatalase (Section 2.3.2).

Complexes **34–41** are excellent models for the short Mn · · · Mn vector of 2.7 Å in PS II. They can all undergo reversible one electron oxidations and reductions giving Mn^{IV}_2 and Mn^{III}_2 dimers respectively. This has been discussed already for the complexes **9, 10** and **11** [Eq. (h)]. The redox potentials, not surprisingly, depend strongly on the nature of the ligands.

4.6. Water Oxidation by Binuclear Manganese Complexes

The manganese catalyzed oxidation of water to molecular oxygen and protons in PS II [Eq. (e)] presents a series of mechanistic problems. It seems plausible to accept that the process cannot follow from a single synchronous, concerted four-electron step. However, this poses several questions. Which intermediates are formed and how and when is the first covalent bond between the two oxygen atoms from the two H_2O molecules generated? Almost all models assume that the two H_2O molecules are coordinated to neighboring Mn atoms forming the active site of the precursor complex and that oxygen is formed stepwise by the formation of a peroxodimanganese complex, which then releases oxygen by intramolecular reduction of the manganese centers. Scheme 3 shows such a representation, which is based on the



$X = O^{2\ominus}$; $OH^{\ominus}$, $OR^{\ominus}$

Scheme 3. Model representation of the mechanism of water oxidation in PS II.

known coordination chemistry of peroxo, aqua, hydroxy and oxygen ligands. It is a simple model that only shows two Mn ions participating in the redox process.

It is surprising how little reliable experimental evidence is available for the ability of simple manganese complexes to oxidize water. Until recently, peroxo complexes of manganese were almost unknown.[129, 130] There have been many manganese(II) complexes reported that can reversibly bind O_2,[128, 131] but the products have not been fully characterized. Only two peroxo complexes of manganese have been fully structurally characterized. These are the mononuclear complex $[Mn^{III}(tpp)O_2]$ (tpp = tetraphenylporphyrinate)[129] with 'side-on' bound $O_2^{2\ominus}$ and the trinuclear complex $[Mn^{III}_3(dien)_3(\mu\text{-}CH_3CO_2)_2(\mu_3\text{-}O)(\mu\text{-}O_2)]I_3 \cdot H_2O \cdot 0.33\,CH_3OH$ (dien = diethylenetriamine) with a bridging $O_2^{2\ominus}$ ligand.[130] Recently, the coordination of an $O_2^{2\ominus}$ ligand to all *four* manganese ions in PS II has been suggested (see Scheme 4). *Lippard* et al. have characterized such a compound of iron(III) with a planar $\{Fe_4(\mu\text{-}O_2)\}$ group by X-ray diffraction.[127]

Scheme 4.

Sporadic reports have appeared of stoichiometric water oxidation and even of catalytic oxidation.[121–126] Oxidation of alcohols to aldehydes has also been reported.[119, 120, 129, 133] *McAuliffe* et al.[122–124] have found that a large number of probably binuclear manganese(III) com-

plexes with Schiff base type ligands evolve O_2 upon irradiation in aqueous solution in the presence of *p*-benzoquinone. *Sawyer* et al.[132] have described a series of such binuclear complexes, which in highly oxidized form can oxidize H_2O to O_2. Mononuclear dichloromanganese(IV) complexes with Schiff base ligands react with H_2O evolving O_2,[134] as do the oxidized mononuclear tris(picolinato)- or tris(acetonato)manganese(III) complexes.[135]

The mixed valence complexes **34** and **35** do not react with H_2O yielding O_2[125, 126] in homogeneous aqueous phase, not even on irradiation, but in heterogeneous phase in the presence of Ce^{IV} O_2 is evolved.[121] Complexes **38** and **39** in their oxidized Mn_2^{IV} forms should oxidize H_2O.[115] The above examples represent only the beginning of the development of functional models for the photosynthetic process.

4.7. Tetranuclear Manganese Complexes

The possibility that a tetranuclear cluster forms the active site in PS II, has in the last five years stimulated synthetic chemists to prepare and study the properties of complexes of this nuclearity. There has been much success in this area. The structurally characterized examples are shown in Figure 21. Important data of these complexes are listed in Table 6.

The first report of a crystallographically characterized tetranuclear manganese cluster was that of complex **45** in 1983. This relatively symmetric complex has an $[Mn_4^{IV}O_6]^{4\oplus}$ adamantane skeleton.[72, 136] Recently, *Armstrong* et al.[152] have shown that in acidic solution one of the oxo bridges can be protonated; they isolated and characterized **46** with a $\{Mn_4^{IV}O_5(OH)\}^{5\oplus}$ core. The magnetic properties of **45** and **46** are interesting: **45** shows weak ferromagnetic coupling of the four Mn^{IV} ions which changes on protonation to weak antiferromagnetic interaction in **46**.[137] In 1985, *McKee* et al. showed that a macrocyclic 'tetranucleating' ligand (L^{10}, Scheme 2) forms a Mn^{II} complex **47** with a cubane structure.[138a]

The synthesis of these simple molecular complexes showed at least that the intermediates suggested by *Brudvig* and *Crabtree* in their detailed mechanism (Fig. 9) could exist. However, there are a number of factors which disfavor this aesthetically pleasing suggestion. Namely, complexes **45** and **47** have no short Mn · · · Mn vector of ca. 2.7 Å (Table 6) – this has been unequivocally proven by the EXAFS spectrum of **45**, which is not like that of the PS II measurement.[52] Also **45** and **46** are clearly not mixed valence complexes. XANES measurements on PS II particles had suggested[51] that the oxidation states of the manganese centers in the S_1 and S_2 states resemble those of the model complexes with Mn^{III} and Mn^{IV} ions. Temperature dependent ESR measurements likewise suggest that they could be the mixed valence $Mn_3^{III}Mn^{IV}$ or $Mn^{III}Mn_3^{IV}$ clusters.[41] *Christou* suggested a $Mn_3^{III}Mn^{II}$ for the S_0 state. The actual oxidation states of the Mn ions in the S_0–S_4 states are still controversial, but the existence of a mixed valence form is not disputed. Better structural models should therefore feature two different Mn · · · Mn distances at 2.7 and 3.3 Å as well as different oxidation states of the manganese ions.

Christou et al.[140] were able in 1987 to fulfill both these criteria in a model complex. **49** represents an unsymmetric complex with a butterfly structure; it has two different nonbonding Mn · · · Mn distances of 2.848(5) and 3.299(3.384) Å, but all four manganese atoms are still in the same +III oxidation state. The same group subsequently synthesized **50**.[141] This complex comprises two Mn^{II} and two Mn^{III} ions and again two different Mn · · · Mn distances are observed, which are comparable to those in PS II. Complex **52**[143] has a similar structure, but the coordination sphere of all four metals ions consists exclusively of oxygen atoms. This was the conclusion drawn for PS II also from EXAFS measurements. In spite of this synthetic success it must be emphasized that the EXAFS spectrum of **49** does not concur particularly well with that of PS II.[52] Of course complexes **49**, **50** and **52** form the basis for the proposed reaction mechanism shown in Figure 10.

Christou has been able to continue his fascinating run of success by looking at the problem of chloride coordination in the PS II. Complexes **51**[144] and **53**[142] both have terminal Mn–Cl groups as well as a μ_3-chloro bridge to three manganese centers; the corresponding Mn–Cl distances are 2.2–2.3 Å and 2.63 Å. The EXAFS spectra of PS II had eluded to there being *no* chloride coordinated within 2.2 Å; either because there is only a small amount of $Cl^{\ominus}$ bound to the cluster or because the Mn–Cl distance is larger than 2.2 Å. A Mn–Cl distance of 2.63 Å would not be unequivocally identified because of the Mn · · · Mn bond length of 2.7 Å in the EXAFS spectrum. Complexes **51** and **53** have naturally served as models for *Dismukes*' structural proposal (Fig. 11). The oxidation level of **51** and **53** is described as $Mn^{IV}Mn_3^{III}$. Complex **53** has the rare ground state S = 9/2 and no low-lying excited states. The ESR spectra of **51** and **53** are very similar to that of the S_2 state of PS II, as a comparison of Figures 22 and 8 shows.

Both these complexes model best the known physical properties of the manganese cluster in PS II. They are still,

Table 6. Important data of the tetranuclear manganese complexes **45**–**54**.

however, not functional models and cannot oxidize H_2O to O_2 despite the high oxidation level of $Mn^{IV}Mn^{III}_3$.

Complex **48**[138b] is a good model for the suggestion that the manganese atoms in PS II form two neighboring dimeric pairs. The oxidation state, however, (four Mn^{II} ions) is too small and the Mn · · · Mn distances are too large.

4.8. Polynuclear Manganese Complexes

In the search for suitable synthetic methods for di- and tetranuclear manganese clusters with biological relevance, more and more complexes of higher nuclearity have been found. These molecules are of great interest to inorganic and theoretical chemists since the aggregation of paramagnetic centers leads to novel electronic and magnetic properties. Up to now, however, they have been of no biological significance, with the possible exception of the trinuclear complexes, and so in closing only a selection will be mentioned.

$Mn^{II}[Mn^{III}_4(\text{salicylhydroximate})_4(CH_3CO_2)_2(dmf)_5] \cdot 2\ dmf$
(dmf = dimethylformamide [145])
$[Mn^{III}_2Mn^{II}_4O_2(Me_3CCO_2H)(Me_3CCO_2)_{10}]$ [146]
$[Mn^{II}Mn^{III}_8(O_2CPh)_8(sal)_4(salH)_2(pyr)_4]$ (pyr = pyridine) [147]
$[Mn^{III}_4Mn^{IV}_6O_{14}\{N(CH_2CH_2NH_2)_3\}_6](CF_3SO_3)_8 \cdot 6\ CH_3CN$ **55**[148]
$[Mn_{12}O_{12}(H_2O)_4(CH_3CO_2)_{16}]$ [149]
$[Mn_{12}L^{12}_6(OH)_4(CH_3CO_2)_2]$ [150]
$[Mn_{12}O_{12}(O_2CPh)_{16}(H_2O)_4]$ **56**[151]

These complex molecules have all been characterized by X-ray diffraction (Figures 23 and 24 show two such structures, namely **55** and **56**, respectively).

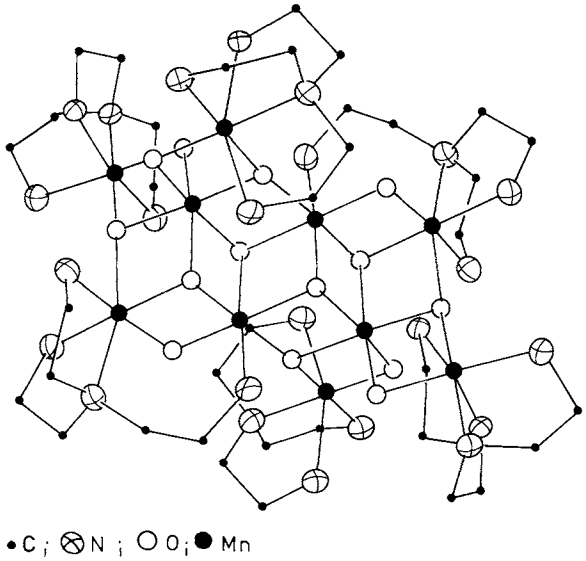

Fig. 23. The structure of the cation of **55** in the crystal [148]. It can be described as a layered inner Mn^{IV}_6 framework composed of edge-sharing MnO_6, MnO_5N and MnO_3N_3 octahedra (two of each). This layer is capped at the four corners by four $Mn^{III}O_2N_4$ octahedra (two under, two over). The cation is presumed to have antiferromagnetically coupled Mn centers.

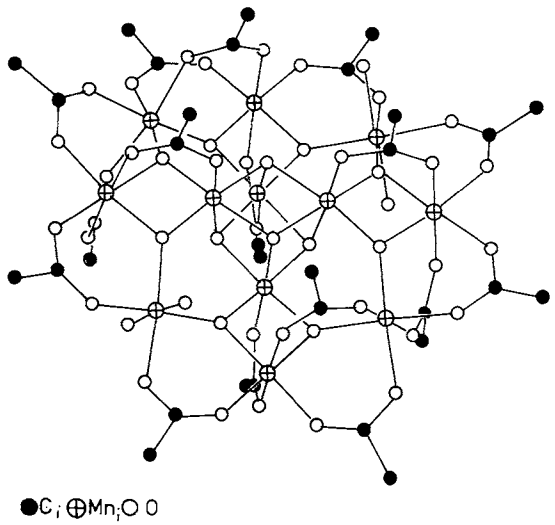

Fig. 24. The structure of **56** in the crystal [151]. The phenyl rings of the μ-benzoato bridges are not shown. Noteworthy is the central $\{Mn^{IV}_4O_4\}^{8\oplus}$ unit with a cubane core. The manganese centers are ferromagnetically coupled; the molecule has a S = 28/2 ground state (!), having eight Mn^{III} (d^4 h.s.) and four Mn^{IV} (d^3) centers.

5. Concluding Remarks

In this review, I have emphasized the modern interdisciplinary character between bio- and inorganic chemistry as exemplified by the research efforts of chemists from both camps on manganese-containing metalloproteins. The determination of the structure of their active sites and our understanding of the mechanism of their enzymatic functions is rapidly advancing by the fruitful interaction of physicists, biochemists and inorganic chemists. Structural and functional proposals from biochemistry can be scrutinized by inorganic chemists who can provide and test well characterized low molecular weight model compounds. Spectroscopic results on biomolecules are in general not readily interpreted without the availability of such compounds.

Over the last century the acquired knowledge of coordination chemistry relating to the structure, spectroscopic properties and reactivity of the essential transition metals has reached the stage where nearly all the biochemist's structural proposals can be reproduced on a simple molecular level. It

is therefore not presumptious to predict that the very complex problem of the oxygen evolution center in PS II will be better understood on a molecular basis within the next few years.

I would like to thank my co-workers for many enjoyable discussions and, of course, for their experimental prowess; their names are contained in the reference section. Frau U. Bossek deserves particular thanks for her 'golden touch' with which she so frequently crystallized tenacious materials. I thank Prof. J. Weiss and Dr. B. Nuber (Heidelberg) for friendly and invaluable cooperation over many years. I wish to thank Frau E. Padgett and Frau S. Altfeld for their help in preparing the manuscript. I am grateful to my colleagues W. H. Armstrong (Berkeley), S. P. Cramer (Brookhaven National Laboratories) and V. L. Pecarro (Ann Arbor) for providing preprints of their work prior to publication. I thank Prof. H. T. Witt (Berlin) and A. Trebst (Bochum) for their patient and comprehensive introduction into the complex world of photosynthesis. Thanks are also due to Prof. D. Sellmann (Erlangen) for critically reading the manuscript. Finally, generous financial support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

Cyclizations via Palladium-Catalyzed Allylic Alkylations

New Synthetic Methods (79)

By Barry M. Trost*

The history of ring systems in organic chemistry parallels their synthetic accessibility. Transition-metal-catalyzed cyclizations offer a new opportunity to create carbo- and heterocyclic compounds with great facility. Among these methods, allylic alkylations catalyzed by palladium have proven unusually productive because of the extraordinary chemo-, regio-, and diastereoselectivity and the continuing possibility for the development of enantioselectivity. The rules for ring closure differ from those for non-transition-metal-catalyzed reactions. A major benefit is the ability to generate medium (eight-, nine-, ten-, and eleven-membered) and large rings in preference to normal (five-, six- and seven-membered) rings. With the appropriate substrate, efficient macrocyclizations are possible under conditions of normal concentrations. A second major benefit derives from the complementary stereochemistry of the metal-catalyzed substitution (net retention of configuration) compared to non-metal-catalyzed reactions (inversion of configuration). Further, the requirement for the substrate to conform to the transition-metal template may impose a stereochemical preference in the intermediate that ultimately translates into the thermodynamically less stable organic product regardless of the stereochemistry of the starting material. While more work has focused on carbocyclic synthesis, the possibilities for heterocyclic synthesis are just beginning to be tapped. In addition to forming heterocycles by C–C bond formation, use of a heteroatom as a nucleophile has already proven effective for oxygen and nitrogen, with other nucleophiles awaiting investigation. New dimensions for cyclization via allylic alkylation arise by generating the requisite π-allylpalladium intermediates by methods other than palladium(0)-initiated allylic ionizations. In addition, metals other than palladium will clearly expand the possibilities, but as yet remain untapped.

1. Introduction

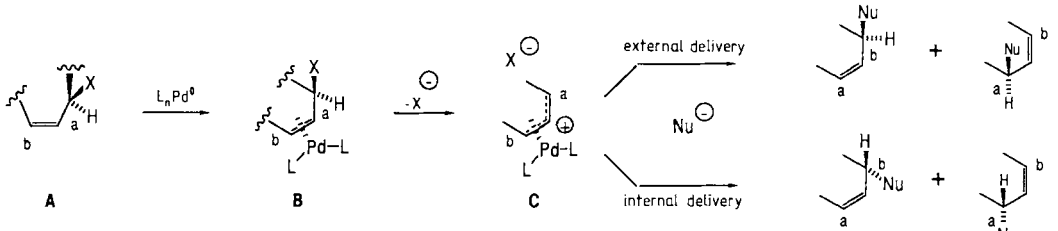
Ring systems have fascinated organic chemists from the very beginning of the science. From its early days, the normal rings, those of five, six, or seven members, have been a major part because of their common occurrence. The year 1985 marked the one hundredth anniversary of *Adolf von Baeyer*'s "theory of ring strain" describing the existence of three- and four-membered rings.[1] Medium- and large-ring chemistry developed somewhat later, with landmark contributions exemplified by *Willstätter*'s synthesis of eight-membered rings[2] and *Ružička*'s studies into the chemistry of muscone and civetone.[3,4]

A great deal of the emphasis on cyclic compounds emanated from their biological significance. The elucidation of the structure of steroids set off a wave of studies directed toward six-membered rings. The Robinson annelation represents an early milestone.[5] The culmination of steroid synthesis by polyolefin cyclization some fifty years later systematizes cation-induced cyclizations as a good strategy for ring formation if the proper initiator and terminator are found.[6]

The discovery and structure elucidation of prostaglandins in the 1960s unleashed a fierce attack on methods for five-membered ring synthesis.[7,8] A few innovations that emanated from these studies include free radical chemistry,[9] transition-metal-promoted carbene insertion,[10] [3 + 2] cycloadditions,[11] and intramolecular carbametalations.[12]

Appreciation for the importance of macrocycles possibly began with the isolation of the first macrolide antibiotic, pikromycin, in 1950.[13] Naturally occurring macrolides may be conveniently classified according to structural type.[14] Among the diverse members are the polyoxo (e.g., pikromycin,[15] erythromycin[16]), polyene (amphotericin B,[17] tetrin A[18]), spiroketal (avermectin,[19] milbemycin[20]), ionophoric (nonactin,[21] boromycin[22]), and lactam-containing (maytansine,[23] FK 506[24]) macrolides. Macrocyclic sesquiterpenes[25] (e.g., caryophyllenes, humulenes, bazzarenes, cyclogermacranes, and germacranes), diterpenes (e.g., jatrophanes,[26] taxanes,[27] fusicoccins[28]), sesterterpenes (e.g., ophiobolins[29,30]), and miscellaneous other macrocycles (e.g., cytochalasins, esperamycin[31]/calichemicin[32]) display a broad spectrum of activity ranging from insect pheromonal to antitumor.

The study of varied ring systems closely parallels their availability. Thus, the continuing evolution of cyclization methods plays a critical role in extending our understanding and in developing the utility of carbo- and heterocyclic rings. The ability of transition-metal catalysts to exercise control in bond-forming reactions under very mild conditions makes them excellent candidates to facilitate ring formation. Indeed, cyclooligomerization of unsaturated linkages such as the nickel-catalyzed oligomerization of dienes[33] and the cobalt-catalyzed cooligomerization of triple- and/or double-bonded molecules[34] are major developments. Defined cycloadditions, as illustrated by the palladium-catalyzed



[*] Prof. Barry M. Trost

Stanford, CA 94305 (USA)

[3 + 2],[11] [3 + 4],[35] and [3 + 6][36] cycloadditions, involving transfer of a trimethylenemethane unit, represent another important direction.

While such multi-bond-forming processes are attractive because of their efficiency in ring construction, the greater flexibility and diversity available from a cyclization in which only one bond is formed increases our need for improving this type of strategy. In this review, we consider the utilization of palladium-catalyzed allylic alkylations for cyclization.

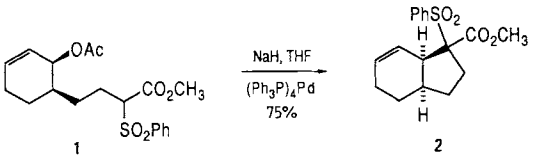
2. Reaction Features

Replacing functional groups that have high intrinsic reactivity, and can therefore lead to chemical instability and potential hazards, by relatively unreactive ones, which require activation to participate in chemical reactions, may increase selectivity as well as enhance ease of handling and safety. Palladium-catalyzed allylic alkylations allow compounds **A** with relatively unreactive leaving groups (Scheme 1), including, but not limited to, carboxylate (including carbonate), phenoxide, imino ether, sulfinate, phosphonate, ammonium, sulfone, and nitro groups, to be ionized with inversion of configuration to the salt **C** via the intermediacy of an olefin–PdL_2 complex (**B**).[37] Nucleophiles attack the cationic intermediate **C** either at Ca or Cb, independent of the original position of the leaving group. The substitution proceeds with inversion by direct attack at carbon (i.e., external delivery of nucleophile) to give overall *substitution with retention of configuration* with "soft nucleophiles" (i.e., stabilized carbon and most heteroatom nucleophiles). Alternatively, the substitution may proceed by initial attack at the metal followed by reductive elimination to product (internal delivery of nucleophile) to give overall *substitution with inversion of configuration* with "hard nucleophiles" (i.e., nonstabilized carbon and some heteroatom nucleophiles).

Scheme 1. Palladium-catalyzed allylic alkylation.

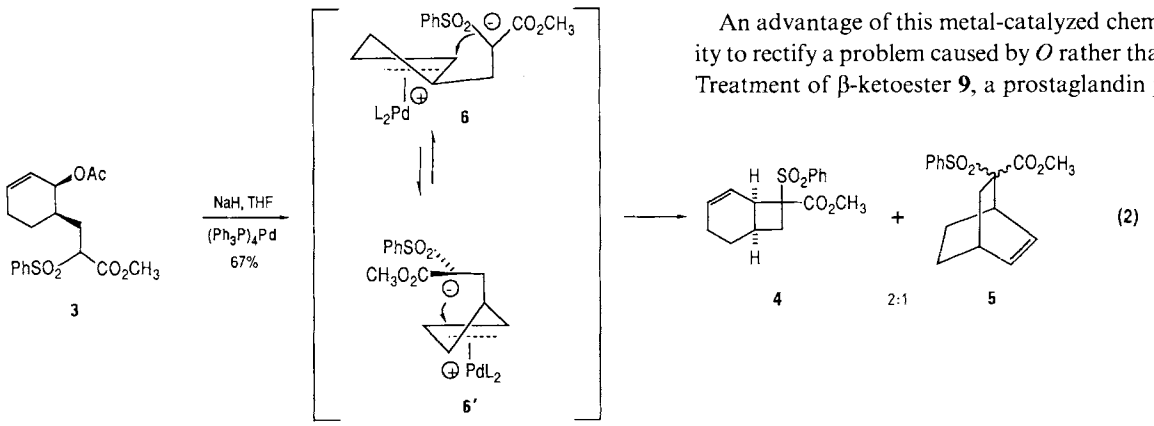
The regioselectivity depends primarily upon four factors: (1) charge distribution in the intermediate π-allylpalladium cation, which favors attack at the more substituted allyl terminus; (2) steric hindrance to approach of the nucleophile, which favors attack at the less substituted allyl terminus; (3) electronic effects of substituents of the allyl unit on the S_N2 transition state, which can favor either terminus depending upon the nature of the substituent; (4) the stability of the initial olefin–palladium(0) complex generated prior to dissociation of the product from the catalyst, which favors attack at the more substituted allyl terminus. For cyclization reactions, the ring size that derives from the regioselectivity will reflect all of the above factors, as well as the effect of the tether. The presence of many competing effects represents an opportunity to fine-tune the cyclization such that ring size can be chosen at will.

Such mechanistic diversity offers great opportunity to create cyclization methods. In addition, other strategies, such as Heck additions to allenes and dienes, permit entry into the π-allylpalladium manifold and ultimately may lead to cyclization methods.



Barry M. Trost (born in 1941 in Philadelphia) obtained a B.A. in 1962 from the University of Pennsylvania and a Ph.D. in 1965 from the Massachusetts Institute of Technology. In that same year, he joined the Department of Chemistry at the University of Wisconsin as Assistant Professor, becoming Professor in 1969, Helfaer Professor in 1976, and Vilas Research Professor in 1982. In 1987, he moved to his current position at Stanford University. His research interests revolve around the theme of selectivity. Developing new reactions and reagents that are chemo-, regio-, diastereo-, and enantioselective represent the challenge. Transition metal templates serving as the equivalent of the "chemists' enzymes," main group organometallic chemistry, small ring compounds, and sulfur chemistry provide new reactions and reagents which permit creation of novel synthetic strategies employed in the total synthesis of bioactive and novel molecules. In recognition of his many contributions, Barry Trost has received a number of awards, the latest being the Arthur C. Cope Scholar Award (1989). He is a Fellow of the American Association for the Advancement of Science (1977), a Fellow of the American Academy of Arts and Sciences (1982), and a member of the National Academy of Sciences (1980).

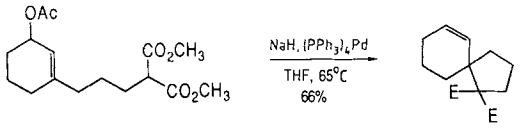
3. Cyclization Involving Carbon Nucleophiles



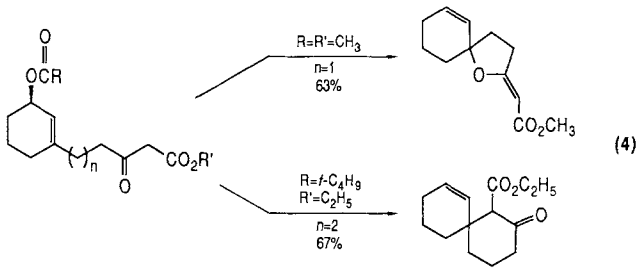
3.1. Carbocyclic Rings—Use of Soft Nucleophiles

The first example of a Pd^0-catalyzed cyclization of an allyl acetate was that of **1** [Eq. (1)]. Addition of sodium hydride

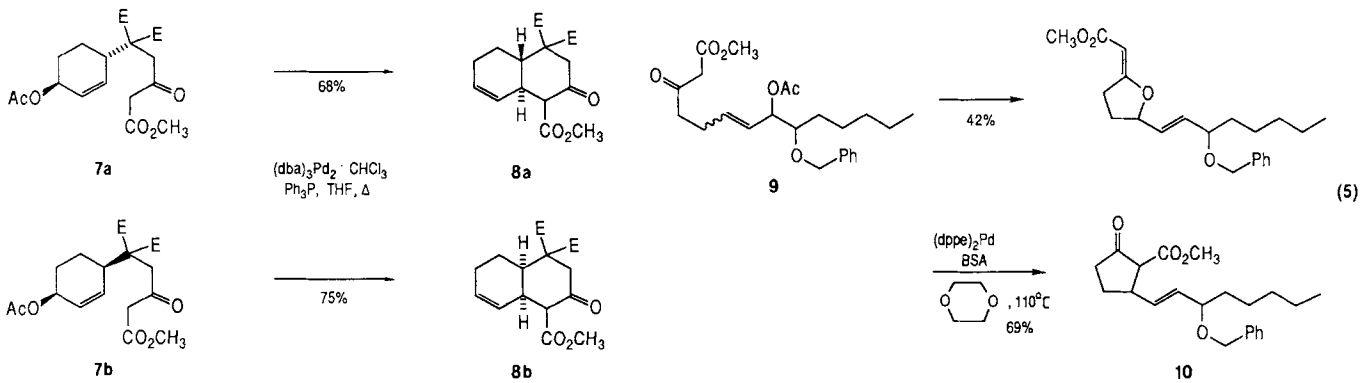
1 2 (1)



to generate the nucleophile in situ followed by 2 mol% of tetrakis(triphenylphosphane)palladium smoothly effects cyclization to form the five-membered ring product **2**. Subjecting the analogue of **1** bearing one less carbon in the side chain (**3**) to the identical conditions produces a 2:1 mixture of the four- and six-membered ring products **4** and **5**, respectively [Eq. (2)]. The predominance of the four-membered ring product may derive from the preference for the cyclization to proceed via complex **6**, in which the side chain occupies a pseudoequatorial position, rather than complex **6'**, where this chain is in a pseudoaxial orientation, in spite of the fact that an unfavorable ring size (i.e., a cyclobutane) is produced. From the outset, it became apparent that factors

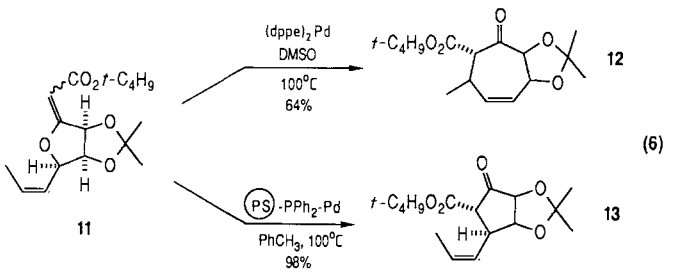


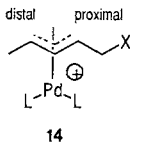
other than ring size may be most important in determining the regioselectivity of intramolecular nucleophilic attack at the two termini of a π-allylpalladium intermediate.



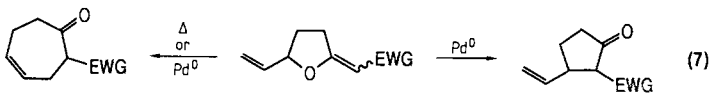
This displacement with net retention of configuration transforms the *trans* substrate **7a** into the *trans*-fused octalin **8a**, and the *cis* substrate **7b** into the *cis*-fused octalin **8b** (dba = dibenzylideneacetone).[39] Thus, this metal-catalyzed annulation complements conventional displacements which would have provided the reverse stereochemical result.

In addition to simple and fused rings, spiro rings form under these conditions [Eq. (3)].[40] Changing the nucleophile from malonate to a β-ketoester reveals the classic problem of *O* versus *C* alkylation, which mainly arises in the case of five-membered ring formation [Eq. (4); same conditions as (3)].

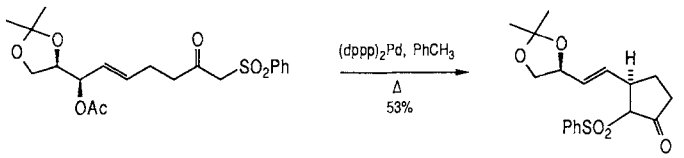




An advantage of this metal-catalyzed chemistry is its ability to rectify a problem caused by *O* rather than *C* alkylation. Treatment of β-ketoester **9**, a prostaglandin precursor, with $(PPh_3)_4Pd$ produces only the *O*-alkylated product [Eq. (5); same conditions as in (1)]. Switching to a sterically less demanding catalyst, $(dppe)_2Pd$ (dppe = 1,2-diphenylphosphinoethane), effects the equivalent of a [1,3] rearrangement to produce the desired cyclopentanone, **10** (BSA = *O*,*N*-bis(tri-

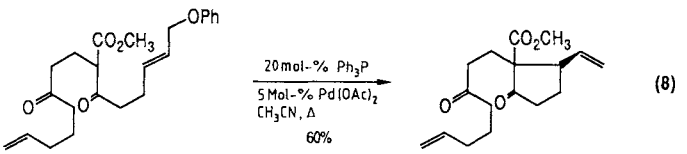


methylsilyl)acetamide).[41] Palladium-catalyzed rearrangement of allyl vinyl ethers is general and may complement their well-known thermal behavior.[42] Consider the allyl vinyl ether **11**. Use of $(dppe)_2Pd$ as catalyst led only to the seven-membered ring product [Eq. (6)]![43] This bias is observed because the inductive effect of an oxygen adjacent to an allyl system in the intermediate complex (**14**, X = OR)



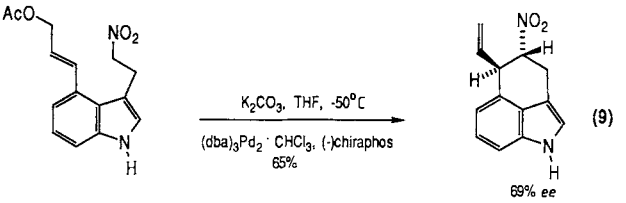
14

directs incoming nucleophiles distal to this substituent. On the other hand, increasing steric demands of the catalyst, as in the case of polymerically bound Pd^0, redirects the reaction to five-membered ring formation (**13**), since the preference for the palladium to coordinate to the less substituted allyl terminus is enhanced. As shown in Equation (7) (EWG = electron-withdrawing group), this translates into a novel reorganization of allyl vinyl ethers into either five- or seven-membered carbocycles. Full stereorelay occurs in forming both **12** and **13** with overall retention of configuration.

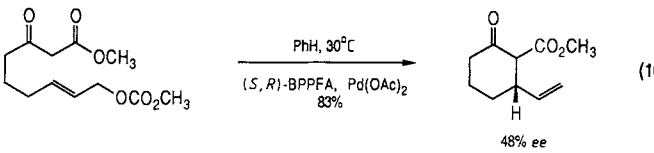


(7)

In contrast to β-ketoesters, a β-ketosulfone as the nucleophilic partner is less prone to undergo *O* compared to *C* alkylation. Excellent stereorelay accompanies this cyclopentanone synthesis (dppp = 1,3-bis(diphenylphosphino)-propane):[44]

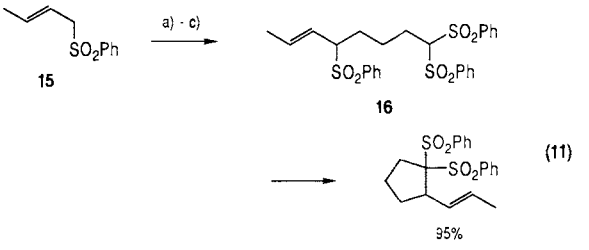


Palladium-catalyzed cyclization has formed the basis of a synthesis of the D ring of steroids in which phenoxide served as the leaving group [Eq. (8)].[45] This example illustrates a common practice in palladium-catalyzed reactions in which the catalytically active Pd^0 complex is generated in situ from a more convenient commercial Pd^{II} salt. While both palladium chloride and palladium acetate may be employed, the greater ease of reduction of the latter frequently makes it the salt of choice.



(8)

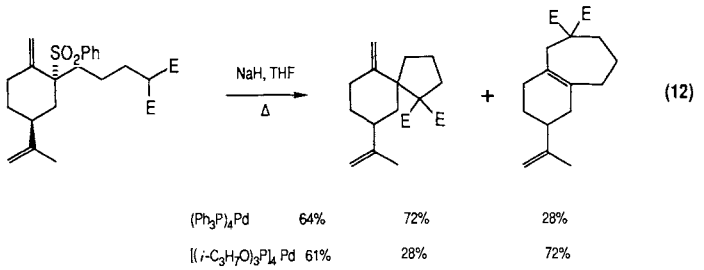
The potential for catalytic asymmetric induction constitutes a major feature of metal-catalyzed reactions. Extrapolation of the notion that chiral ligands on the metal may impart such enantioselectivity to allylic alkylations, however, is not simple. The bond-forming event occurs as far from the chiral environment as possible! Nevertheless, some modest successes have been noted in cyclizations [Eq. (9), chiraphos = 2,3-bis(diphenylphosphino)butane,[46] and (10), BPPFA = 1-[1,2-bis(diphenylphosphino)ferrocenyl]ethyldimethylamine[47]]. Equation (9) represents an asymmetric entry to the ergot alkaloids.



(9)

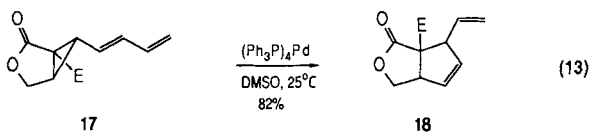
(10)

Variation of the leaving group can be important to the success of the cyclization. In some cases, use of a leaving group more reactive than acetate to allow milder conditions may be a necessity. An alternative concept considers versatility imparted by the leaving group. A sulfone stands out due to its ability to impart both nucleophilic and electrophilic properties to the adjacent carbon and has led us to describe organosulfones as chemical chameleons.[48] Equation (11) illustrates this feature.[49]



(11)

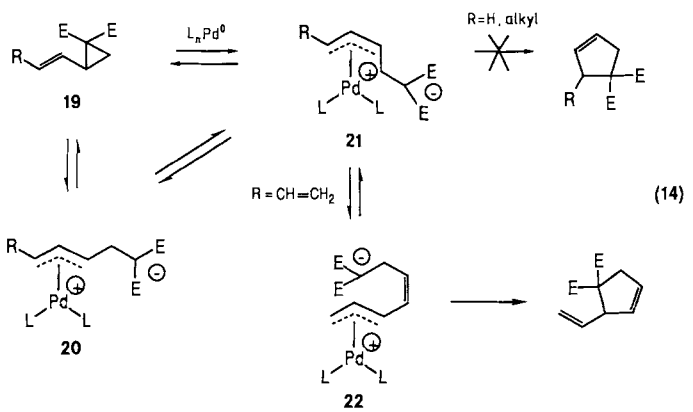
a) n-C_4H_9Li, Cl, b) NaI, c) K_2CO_3, $CH_2(SO_2Ph)_2$



Sulfone-stabilized carbanions prepared from **15** permit easy construction of the requisite cyclization substrate **16**. Selective cyclization to the cyclopentane derivative proceeds

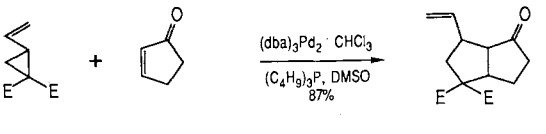
under standard conditions with a Pd^0 catalyst. Steric accessibility of the two termini can become important. Equation (12) reveals how a subtle change in the catalyst effects a

(12)



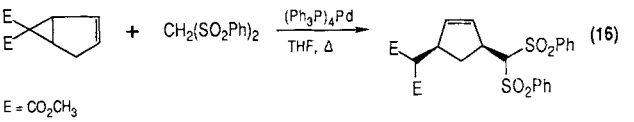
change from a charge-directed cyclization, which favors attack at the more substituted allyl terminus, to a sterically driven cyclization, which favors attack at the less substituted terminus.

(13)



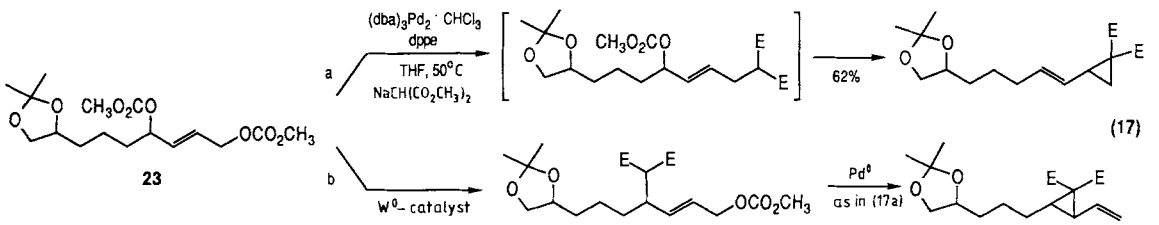
17 18

A most unusual leaving group is carbon in the form of an electron-deficient three-membered ring. The isomerization of the dienylcyclopropane **17** to the vinylcyclopentene **18** [Eq. (13)] illustrates the use of this leaving group.[50] This process also demonstrates one stereoelectronic aspect of this metal-catalyzed cyclization, since vinylcyclopropane analogues of **17** fail to give any discernible reaction. While a vinylcyclopropane such as **19** would be expected to generate the *syn* complex **20** preferentially, the *anti* complex **21** can form either directly or by well-documented isomerization processes from **20**. Cyclization of **21** requires a geometrically disfavored 5-*endo-trig* process.[51] On the other hand, the dienyl substrate **21** (R-vinyl) can isomerize to a new π-allylpalladium cation **22**, which can cyclize by a geometrically favorable 5-*exo-trig* process.

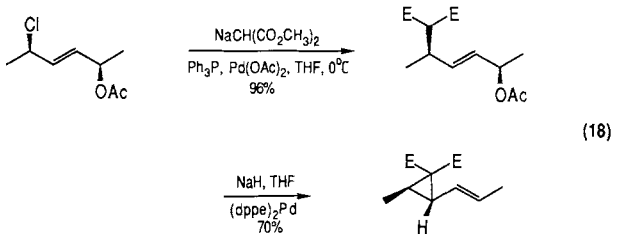


(14)

That **20** and/or **21** (R = H, alkyl) indeed form, but can only reclose to cyclopropane, has led to a novel annulation based upon the dual reactivity inherent in this zwitterion [Eq. (15)].[52] Simple diastereocontrolled alkylations are also possible [Eq. (16)].[53]

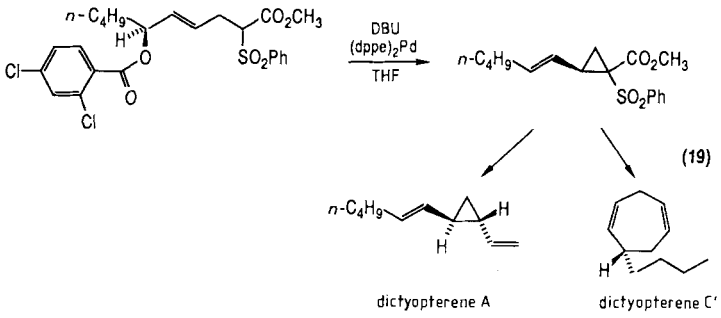


(15)



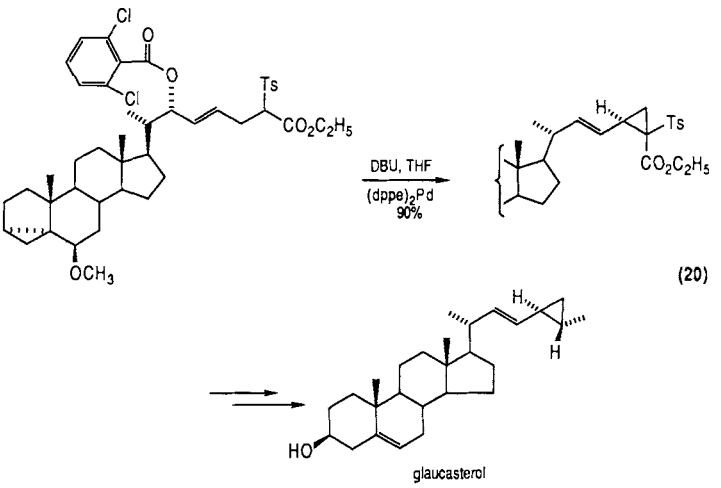
(16)

E = CO_2CH_3

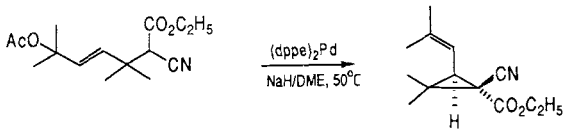


Cyclopropanes of the above type are themselves readily available by Pd-catalyzed allylic alkylations. A cyclopropanation process readily emerges as outlined in Equation (17), path a, where the bifunctional alkylating agent **23** demonstrates chemoselectivity for initial replacement of a primary leaving group in the presence of a secondary (or even tertiary) one.[54] Final Pd^0-catalyzed ring closure occurs simultaneously and produces the terminal cyclopropane. On the other hand, a regioisomeric cyclopropane may be obtained by initiating the sequence with a tungsten(0) catalyst, which allows chemoselective substitution of the secondary leaving group [Eq. (17), bath b]. Palladium(0) catalysis completes the sequence. Combining the stereochemical feature of Pd^0-catalyzed alkylations, retention of configuration, with this sequence generates a diastereocontrolled cyclopropanation [Eq. (18)].[55] To the extent that the absolute configuration of the leaving group can be controlled, the absolute configuration of the cyclopropane may also be controlled. The key step in a synthesis of dictyopterenes A and C′ employs just such a strategy [Eq. (19)].[56] Optimization of retention of stereochemistry required the use of the dichlorobenzoate leaving group. A similar strategy created the cyclopropyl steroid side chain of glaucasterol [Eq. (20)].[57] Use of achi-

(17)

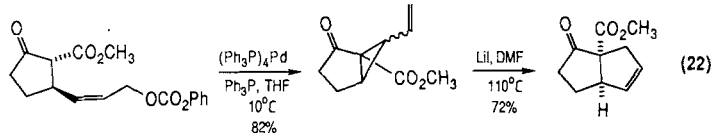


(18)



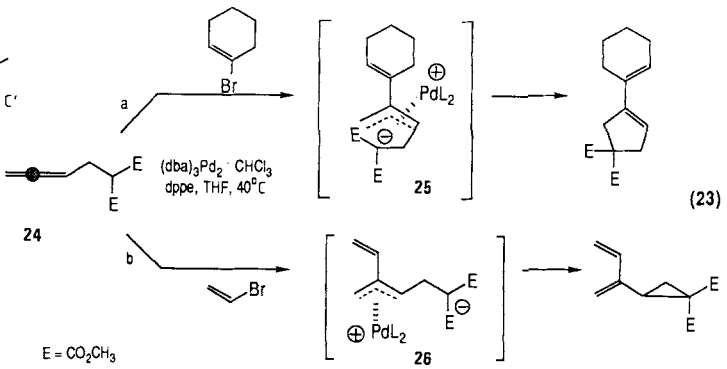
(19)

ral substrates and chiral palladium catalysts in this cyclopropanation has led to scalemic cyclopropanes, but of only modest enantiomeric excess.[58]



(20)

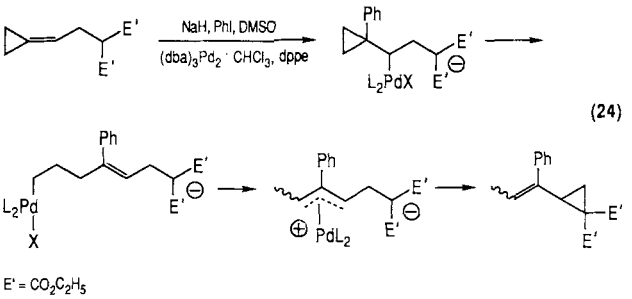
The stereochemistry at the nucleophilic carbon has been less explored, since this center is frequently nonstereogenic or its stereochemistry ultimately lost. In one cyclopropane-forming reaction [Eq. (21)], however, Pd-catalyzed cy-



(21)

cloalkylation directed the sterically small CN group exclusively to the more hindered face of the cyclopropane, a diastereoselectivity not observed in the non-metal-catalyzed reaction.[59] Combining Pd-catalyzed cyclopropanation with a vinylcyclopropane rearrangement can create a cyclopentene synthesis [Eq. (22)].[60]

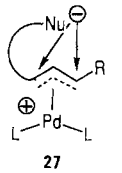
(22)



In all of the cases discussed so far, we created the reactive palladium electrophile by the addition of an allyl-X group to a Pd^0 complex. In principle, any reaction that creates a π-allylpalladium species can ultimately be followed by a reaction with a carbon nucleophile. The additions of C–Pd σ bonds to conjugated and nonconjugated dienes and to unsaturated cyclopropanes and cyclobutanes have been shown to produce stoichiometric π-allylpalladium complexes. Such addition to an appropriate allene **24** has led to a cyclization in which both a substituent C–C bond and a ring C–C bond have been formed in the same operation [Eq. (23)].[61] The

24

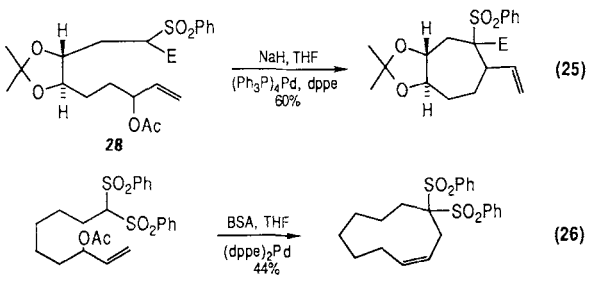
(23)



ring size depended upon the organohalide. A sterically bulky halide facilitates formation of the *anti* complex **25** as the reactive intermediate which, surprisingly, forms the cyclopentene, even though a 5-*endo-trig* cyclization is required. On the other hand, a less sterically demanding vinyl bromide leads, via the normally more stable *syn* complex **26** as the reactive intermediate, to the cyclopropane. An alkylidene cyclopropane participates in a similar sequence where the requisite reactive π-allylpalladium intermediate arises after a more complex set of reorganizations [Eq. (24)].[62]

(24)

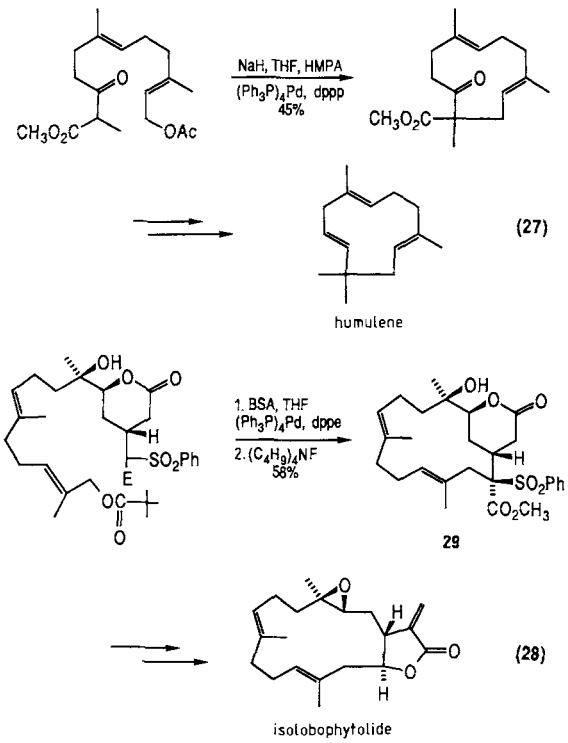
3.1.1. Medium- and Large-Ring Carbocyclizations



The regioselectivity of the Pd-catalyzed cyclizations determines the ring size. In the competition between three- and/or six- and eight-membered ring formation from the π-allylpalladium complex **27**, the smaller-sized ring usually predomi-

27

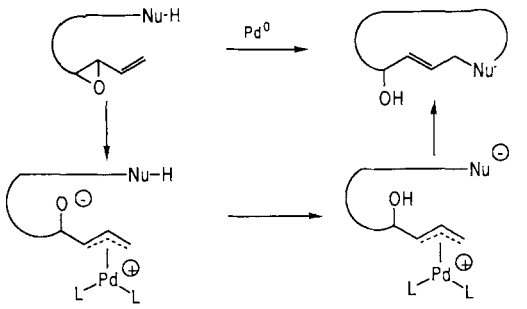
nates. In four-versus six-membered or five-versus seven-membered ring formation, both ring sizes appear accessible. Cyclization of the all-carbon system, in which seven- and nine-membered ring formation compete, shows how finely balanced this metal-catalyzed reaction is. Thus, cyclization of substrate **28** shows the usual propensity for seven-mem-



bered over nine-membered ring formation [Eq. (25)].[63] Increasing the steric hindrance of the nucleophile shifts the reaction to strongly favor nine-membered ring formation [Eq. (26)].[64] Heretofore, a plot of ring size versus yield almost always reached a minimum at nine members. The transition-metal template changes the rules to the point that the nine-membered ring is preferred over the more conventional seven-membered ring.

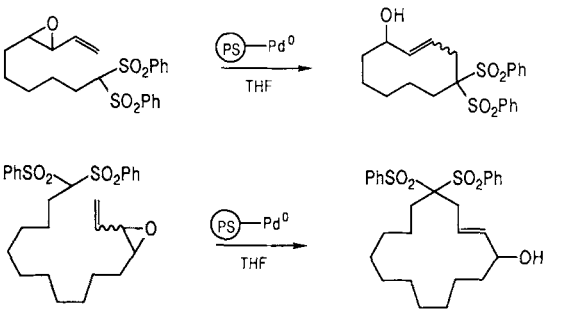
(25)

(26)



The surprising observation that nine-membered ring formation occurs easily leads to the expectation that larger rings should form even more easily—an expectation fully verified. Syntheses of the eleven-membered ring biosynthetic intermediate humulene [Eq. (27)][65] and the fourteen-membered ring cembranolide isolobophytolide [Eq. (28)][66] employ Pd^0-controlled cyclizations. The latter cyclization also exhibits high diastereoselectivity at the nucleophilic center since the macrocycle **29** was obtained as a single diastereomer.

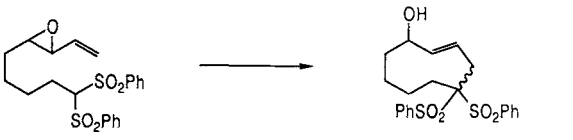
(27)



(28)

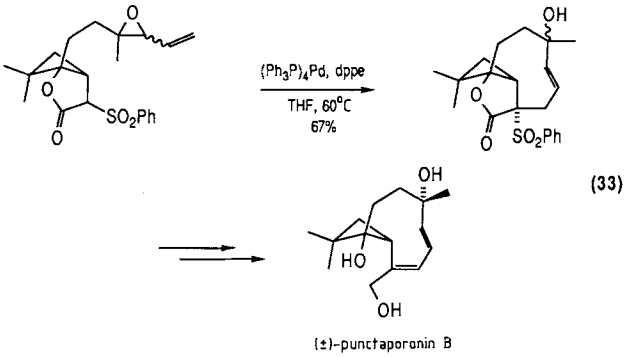
Changing the electrophilic partner in the cyclization to a vinyl epoxide has a dramatic effect on the efficacy of the macrocyclization. As illustrated in Equation (29), such cyclizations are now simple isomerizations. Such a reaction type is particularly well suited for effecting macrocyclizations at high concentration when the pseudodilution effect is exploited.[67] The reaction is compartmentalized into a storage zone, the solution of the substrate, and a reaction zone, an insoluble polymerically supported Pd^0 catalyst. The substrate, which lacks a nucleophile and a reactive electrophile in the absence of catalyst, must diffuse onto the polymer support *and* encounter an active site before it becomes reactive at all. The combined effect of having relatively few active sites and even fewer of them occupied helps ensure intramolecular reactions. The act of ionization creates the reactive electrophile in the form of a π-allylpalladium complex and a base [see Eq. (29)]. Unmasking the nucleophile re-

(29)



quires the pro-nucleophile to approach the base to permit proton transfer. The close proximity of the alkoxide to the π-allylpalladium cationic complex then translates into a close proximity of the nucleophile at its birth to the π-allyl unit. By operating in a nonpolar environment such as a polystyrene matrix, charge–charge attraction prevents diffusion of the nucleophile and electrophile away from each other. Simple charge neutralization then effects cyclization. In this way, ten- and fifteen-membered carbocyclic rings formed in 71% and 82% yields, respectively, at substrate concentrations of 0.1–0.5 M [Eqs. (30) and (31)].

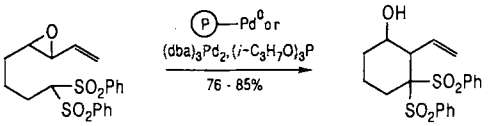
(30)



(31)

While extension to rings larger than fifteen-membered presented no problems, decreasing the ring size below ten did. Use of the pseudodilution technique provided the nine-membered ring product of Equation (32) in only low yield.

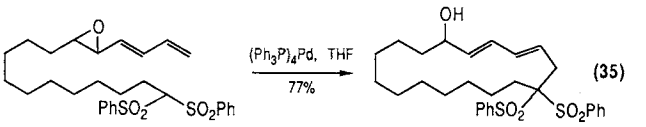
(32)



However, use of tetrakis(triisopropylphosphite)palladium at 0.01 M concentration provided the desired product in 73% yield.[68] A synthesis of the racemic form of the fungal metabolite punctaporonin B created its unusual ring system using this methodology [Eq. (33)].[69]

(±)-punctaporonin B

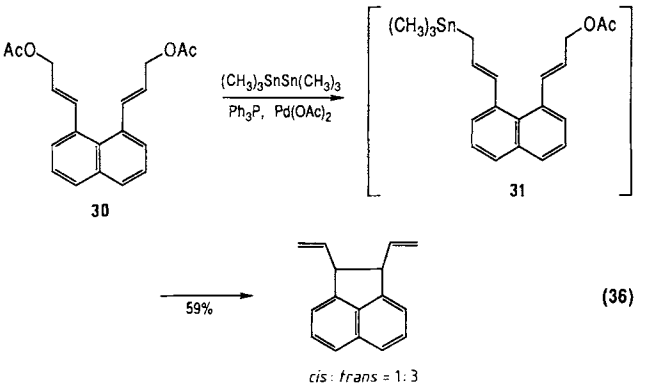
(33)



Formation of the medium- and large-sized rings in these examples derives from bond formation of the nucleophile to the less substituted terminus of the π-allylpalladium intermediate. The normal steric demands of the nucleophile are reinforced by the inductive effect of the adjacent alcohol in the intermediate complexes to direct the incoming nucleophile to the distal end of the π-allyl unit to itself. The limit of these

(34)

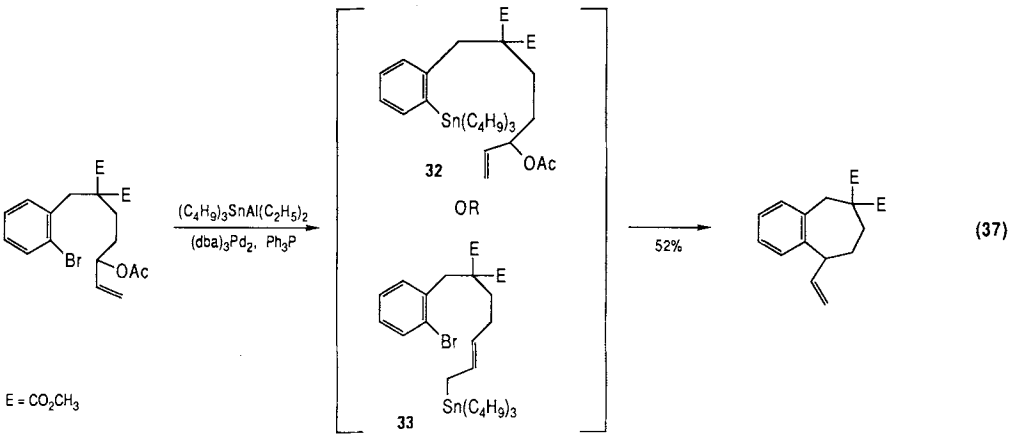
regiochemical control factors is reached in the analogue containing one less carbon where only the six-membered ring is observed when either polymeric heterogeneous or homogeneous catalysis is used [Eq. (34)].[68] However, this simple substrate may be an anomaly. Other work suggests that substrates with a modified tether may lead to preferential eight-membered ring formation.



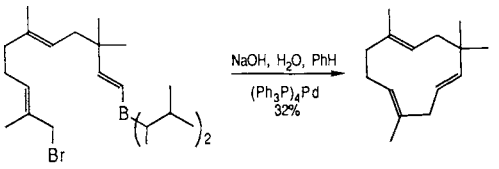
Extending the conjugation to a dienyl epoxide increased the number of possible regioisomeric products. Nevertheless, the combination of the inductive effect of the hydroxyl group and the steric preference for addition to the less hindered terminus of the allyl moiety led to only a single product [Eq. (35)].[70]

(35)

3.2. Use of Alternative Nucleophiles to Form Carbocyclic Rings



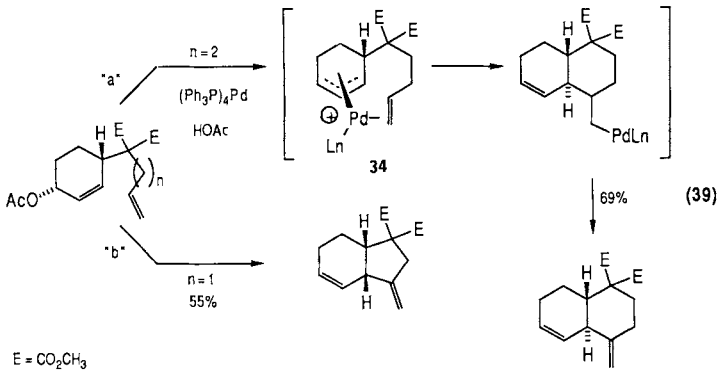
A major area yet to evolve is the employment of nucleophilic carbon partners other than stabilized carbanions. A reductive cyclization of bis(allyl acetates) such as **30** may involve an intramolecular coupling of allyl acetate **31** and an allylstannane formed in situ as shown in Equation (36).[71]



(36)

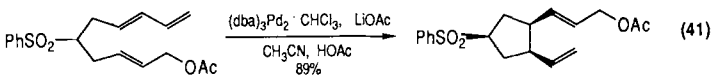
The related reductive cyclization illustrated in Equation (37) can also be envisioned to involve a Pd^0-catalyzed coupling of allyl acetate **32** and an organostannane formed in situ, although an alternative pathway via the allylstannane **33** appears more likely.[72] A clearer example of an intramolecular cross coupling via a π-allylpalladium complex involves organoboranes as the nucleophilic partner. These normally excellent nucleophilic partners in cross-coupling reactions provided only a modest yield of the eleven-membered ring product, humulene [Eq. (38)].[73]

A most interesting "nucleophile" for a π-allylpalladium complex is an olefin. Thus, Pd^0 effects cyclization of an allyl acetate onto a proximal double bond to generate five- and



(37)

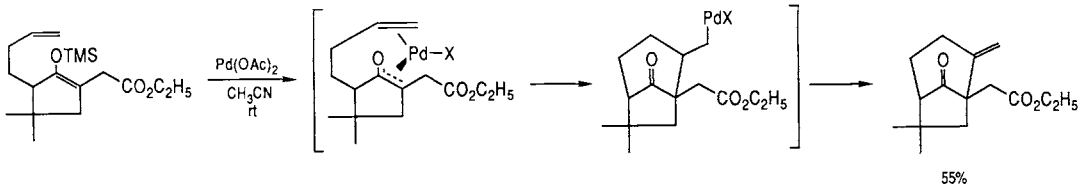
(38)



six-membered rings, the latter being illustrated in Equation (39).[74] In this reaction, coordination of the "nucleophile" to the metal (→ **34**) determines the ring sizes available and the stereochemistry of the ring closure by delivering the

(39)

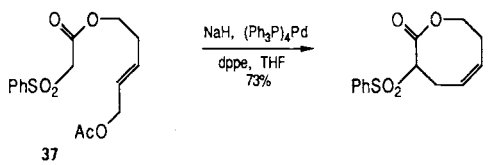
olefin *syn* to palladium. Since the ionization of the allyl acetate proceeds with inversion, this metallo-ene reaction proceeded with net *inversion*—the opposite stereochemical event from cyclizations with soft nucleophiles. When the tether was too short to coordinate in a *trans* fashion, as in the case of Equation (39), path b, only the *cis* ring-fused product formed, regardless of the stereochemistry of the starting material.[75] Equilibration of the starting material occurring faster than cyclization accounts for this observation.



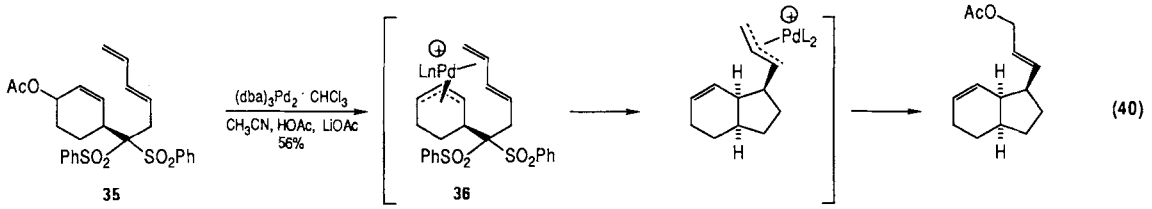
A most interesting example of cyclization via isomerization derived from the ability of the π-allylpalladium cation to add to dienes to generate a new π-allyl complex, which, in turn, may be captured by acetate to create a new allyl acetate which is simply isomeric to the starting material **35** [Eq. (40)].[76] While only the *Z* complex **36**, which derives from the *E* starting allyl acetate, can cyclize, rapid equilibration of the cyclization substrate permits the more accessible *Z* isomer to participate. Even in a conformationally non-biased system such as the acyclic substrate **37** [(Eq. (41)], only

(41)

a single diastereomeric product results under the standard Pd^0 cyclization conditions. The requirement for coordination between the π-allylpalladium cationic complex and the diene limits this cyclization to formation of five-membered rings.

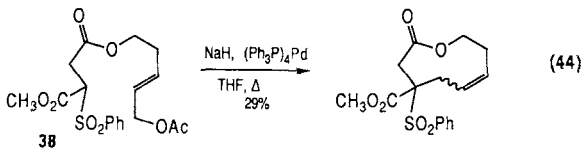


A Pd^{II}-promoted cyclization of enol silyl ethers onto olefins can be thought to involve an oxa-π-allylpalladium cationic intermediate in analogy to the reactions described above.[77–79] A synthesis of the antitimor sesquiterpene quadrone employed this novel cyclization [(Eq. (42)].[80] Evidence supporting an alternative mechanism involving nucleophilic attack on an olefin–palladium complex has been presented.[80]



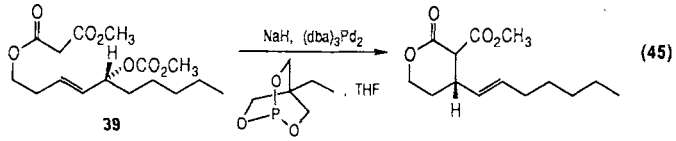
(42)

3.3. Heterocycles via C–C Bond Formation

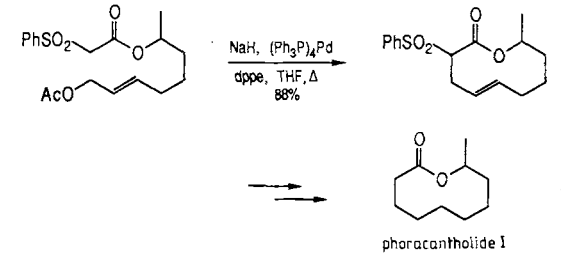


Introduction of heteroatoms into the tether connecting the cyclization termini can have a profound influence due to their conformational effects on the substrate and their coordinating ability for the metal. An early manifestation of this phenomenon was the cyclization of **37** [Eq. (43)] and **38**

(43)

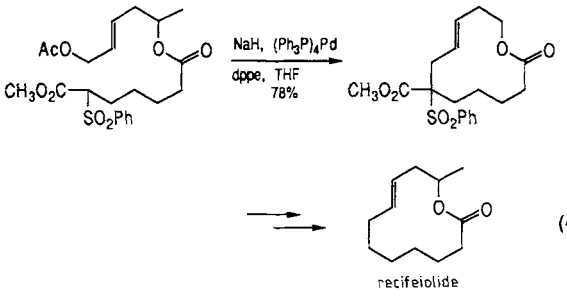


(40)

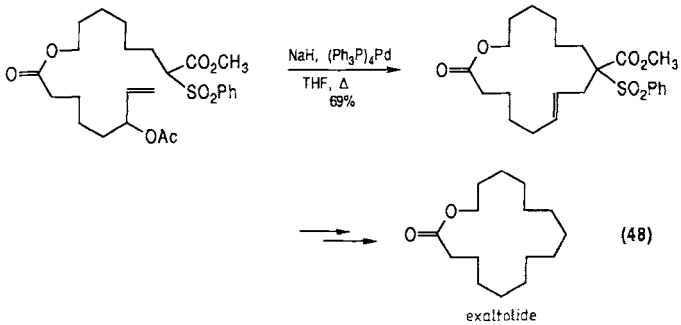


(44)

[Eq. (44)] to form the eight- and nine-membered rings preferentially or exclusively.[39, 64] The preference for eight-membered ring formation in Equation (43) in part derived from the preference for the nucleophile to attack the less substituted terminus of the allyl system. Equalizing the substitution pattern as in **39** returned the cyclization to six-membered ring formation [Eq. (45)].[81] This example also illustrates

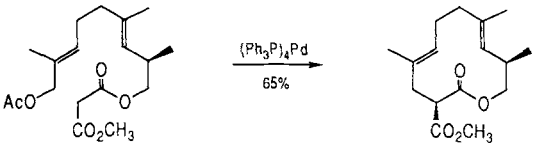


(45)

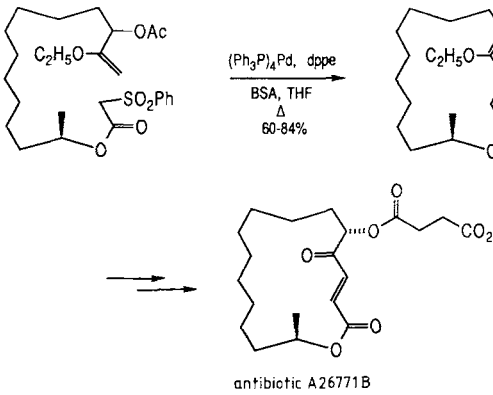


the high transfer of chirality possible in these metal-templated reactions, a feature that has previously been established in the more difficult bimolecular metal-mediated reactions.[82] The fact that the normally highly unfavorable medium-sized rings form so remarkably well implied that the larger macrolides would be readily accessible—a prediction amply fulfilled. Syntheses of the simple naturally occurring macrolides ranging from phoracantholide I [Eq. (46)] and J[39, 64] to recifeiolide [Eq. (47)][39, 83] to exaltolide [Eq. (48)][39, 84] illustrate formation of ten-, twelve-, and six-

(46)



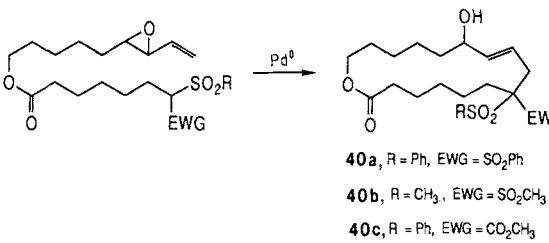
(47)



(48)

teen-membered macrolides. High diastereoselectivity with respect to the nucleophilic carbon has been observed. One example arose during the synthesis of a macrolide as an intermediate to polyether ionophores [Eq. (49)].[85]

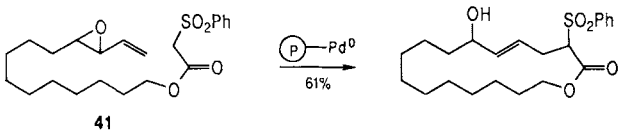
(49)



In a synthesis of antibiotic A26771B, this feature proved critical to transmit stereochemical information in creating the stereogenic center at C6 relative to that at C16 [Eq. (50)].[86] Thus, the sulfone served as a stereochemical

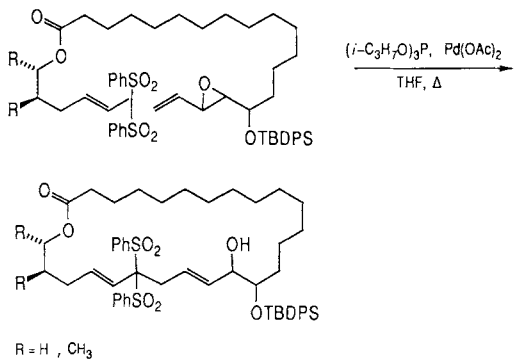
(50)

relay group. In both of these cases, whether the diastereoselectivity reflects kinetics or thermodynamics has not been resolved. The ability to perform the reactions with only BSA as the base, as was done for the synthesis of antibiotic A26771B [Eq. (50)], obviates problems caused by the hydroxide impurities that unavoidably accompany the hydride bases. Yields in all the other cases may be improved by this modification.



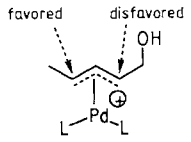
Using a vinyl epoxide permitted extension of the pseudodilution strategy of Equation (29) to macrolide formation.[87] Indeed, this variant has proved to be spectacularly successful. For example, the seventeen-membered ring macrolides **40a** and **40b** could be formed in 74–87% yields at 0.1–0.5 M concentrations [Eq. (51)]! The acidity of the hydrogen being transferred was critical. The kinetically less acidic sulfone ester substrate did not produce macrolide **40c**

(51)



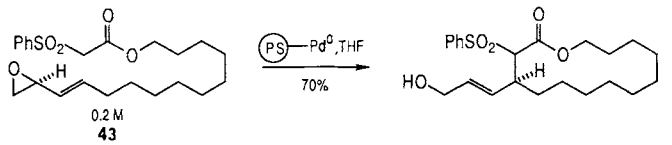
when the polymeric catalyst was used, but cyclized smoothly with the standard homogeneous Pd^0 catalyst. Restoration of a successful cyclization at high concentration with the poly-

meric Pd^0 catalyst by changing the pro-nucleophile from a methine to a methylene group as in **41** [Eq. (52)] supported the notion that the kinetic acidity of the proton being abstracted was an important feature of this high-concentration macrocyclization.



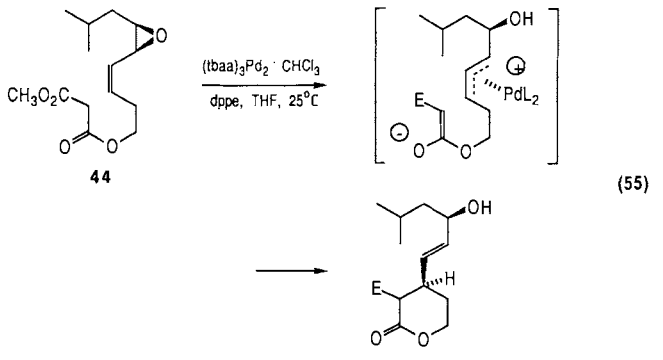
41 (52)

The choice of ligands may be important in this macrocyclization. In the homogeneously catalyzed version, the 26-membered ring model for a synthesis of the ring system of tetrin A could be formed in 92% yield by employing the better acceptor ligand triisopropylphosphite [Eq. (53)].[88]

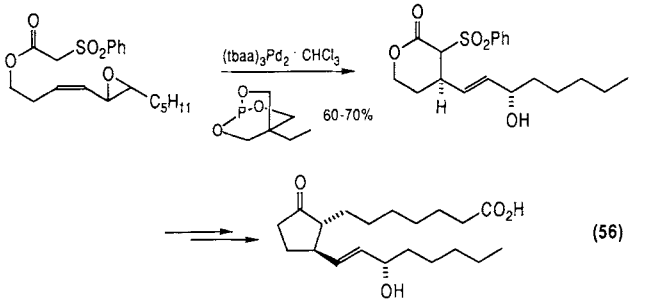


(53)

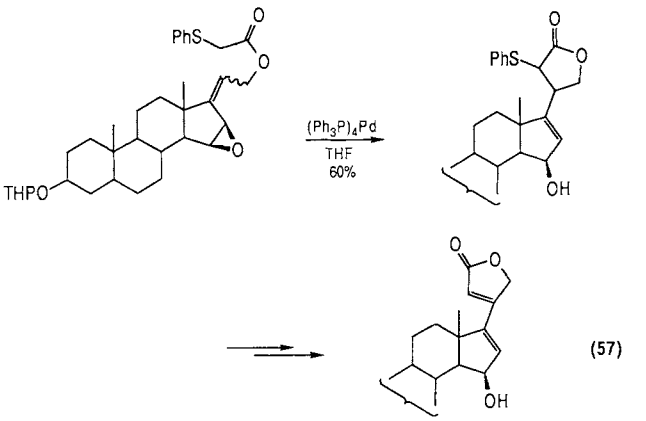
The adjacent electronegative hydroxyl group in the intermediate π-allylpalladium complex favored nucleophilic attack distal to itself as shown in **42**. This bias also dictated



42

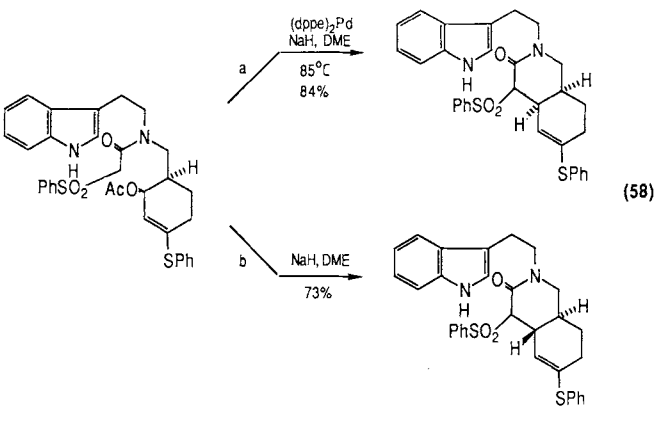


ring formation. Thus, cyclization of **43** [Eq. (54)][89] and **44** [Eq. (55)][90] generated the fourteen- and six-membered rings, respectively. In the latter case (tbaa = tris(benzylidene)acetylacetone), the transition-metal template faithfully transmitted the stereochemical information to the newly formed stereogenic center. This methodology has been employed to control the stereochemistry of C15 in prostaglandins [Eq. (56)][91] and to create the butenolide of cardenolides [Eq. (57)].[92]

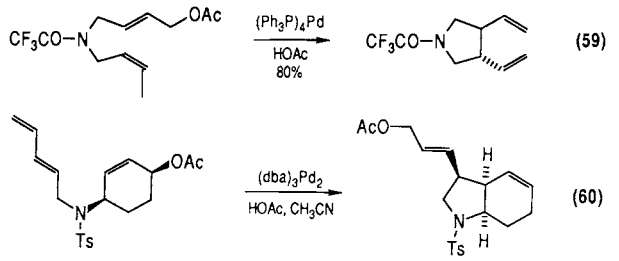


(54)

(55)



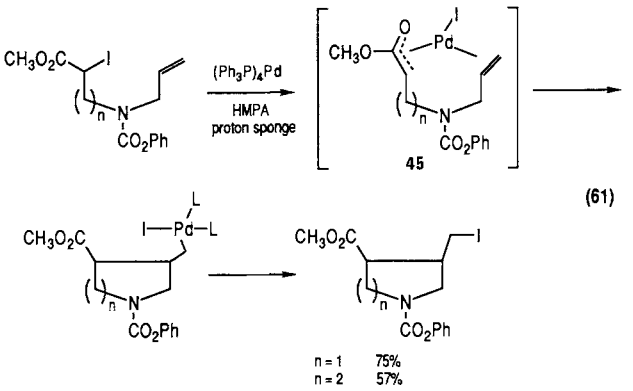
(56)



(57)

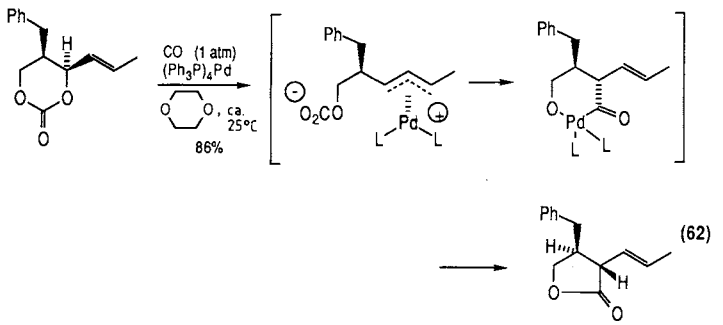
Replacing the ester linkage by an amide also led to successful heterocyclic synthesis directed to yohimbanes [Eq. (58)].[93] Comparing the Pd-catalyzed [Eq. (58), path a] and the noncatalyzed [Eq. (58), path b] reactions demonstrates the stereochemical complementarity available through metal-catalyzed reactions.

(58)



The metallo-ene reaction of π-allylpalladium intermediates derived from allyl acetates [Eq. (59)][94] and the cyclization via isomerization [Eq. (60)][95] have successfully generated nitrogen heterocycles. A version of the metallo-ene process with oxa-π-allylpalladium intermediates has been

(59)

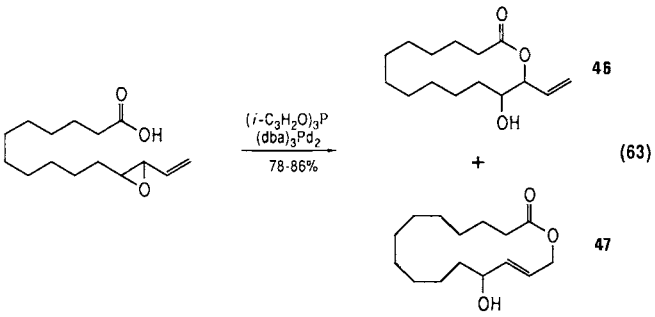


(60)

described.[96,97] The requisite intermediate **45** is formed by the oxidative addition of a Pd^0 complex to an α-iodoester. Olefin insertion followed by reductive elimination provided the pyrrolidine and piperidine products in a process which also can be described as a cyclization via isomerization (i.e., a cycloisomerization).

(61)

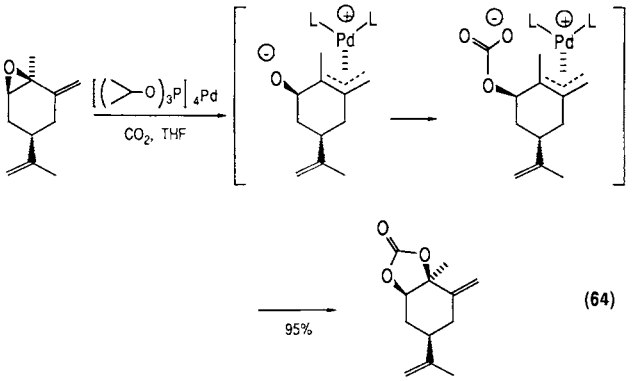
Intercepting the π-allylpalladium intermediate with carbon monoxide led to a novel lactone synthesis [Eq. (62)].[98] In this case, coordination of carbon monoxide to the palladium is followed by C–C bond formation with retention of configuration. Since the ionization step proceeded with inversion and the carbonylation step with retention, the overall process proceeded with inversion as depicted.



(62)

4. Cyclizations Involving Heteroatom Nucleophiles

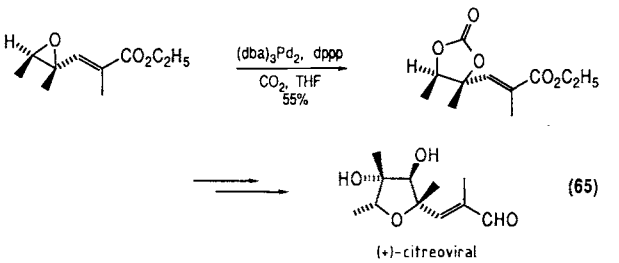
4.1. Oxygen Nucleophiles



Since π-allylpalladium cations are "soft" electrophiles, "soft" nucleophiles generally react best. Thus, stabilized oxygen nucleophiles react more readily than simple alkoxides. Carboxylates represent "soft" oxygen nucleophiles, but their products with π-allylpalladium complexes are allyl carboxylates, themselves substrates for palladium. If the substrate ionizes much more rapidly with Pd^0 than the allyl carboxylate, then such nucleophiles may be employed. Macrolactonizations initiated with vinyl epoxides occurred smoothly with carboxylate anions as the nucleophiles [Eq. (63)].[68] Kinetically, this oxygen nucleophile produced equal amounts of the two macrolides **46** and **47**. The fact that the

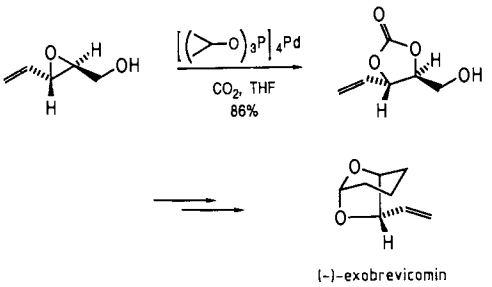
(63)

product is subject to ionization with the catalysts used for their formation permitted equilibration at reflux, whereby the larger macrolide **47** dominated to the extent of 9:1.



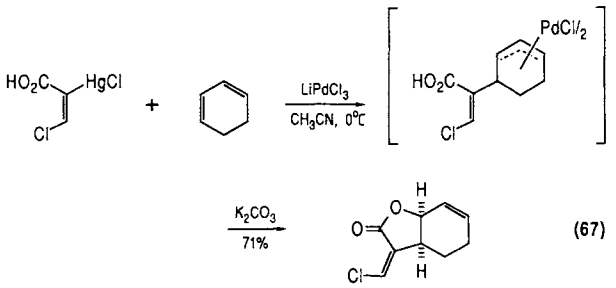
An unusual approach generates the carboxylate nucleophile in situ by capturing the oxygen leaving group in the Pd-catalyzed reactions of vinyl epoxides with carbon dioxide [Eq. (64)].[99] The tethering of the carboxylate nucleophile to

(64)



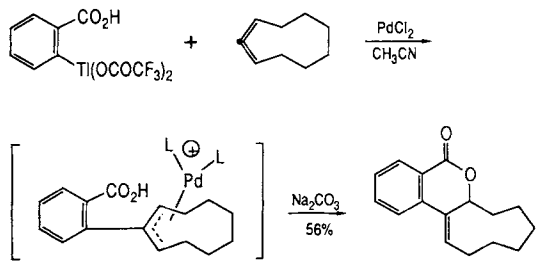
the oxygen leaving group changes the normal 1,4-addition of nucleophiles to vinyl epoxides under Pd catalysis to 1,2-addition. The ready availability of such epoxides in enantiomerically pure form makes this a practical asymmetric synthesis of vicinal diols that proved useful in a synthesis of (+)-citreoviral [Eq. (65)][100] and (−)-exo-brevicomin [Eq. (66)].[101]

Generating the π-allylpalladium complexes via routes not involving ionization of allylic leaving groups also permits



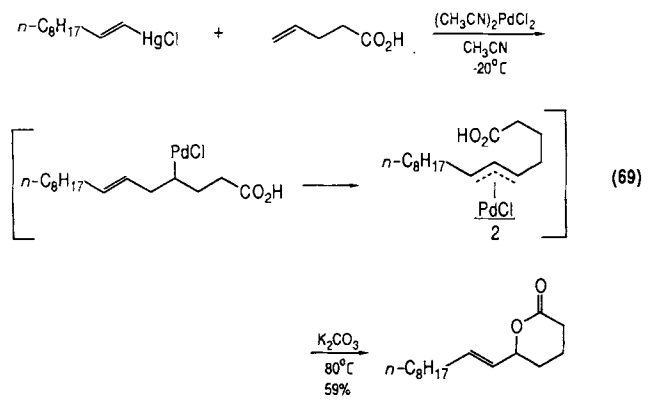
(65)

(+)-citreoviral

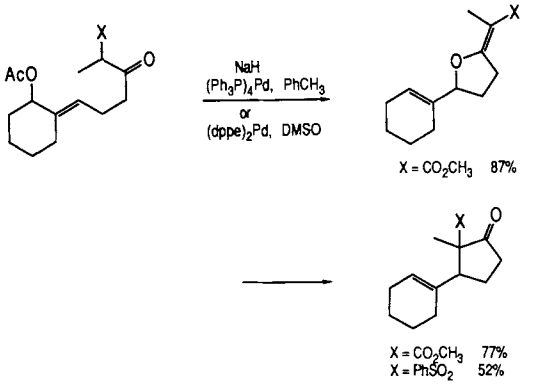


(66)

lactone formation using carboxylate nucleophiles. In situ formation of π-allylpalladium complexes by additions of σ-organopalladium intermediates, generated by transmetalations from organomercurial and organothallium compounds, to 1,3-dienes [Eq. (67)][102] and allenes [Eq. (68)][103] in the presence of stoichiometric amounts of

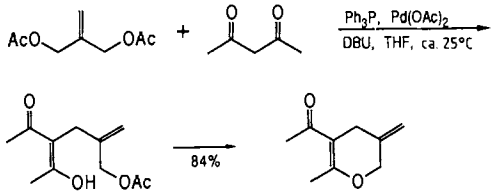


(67)



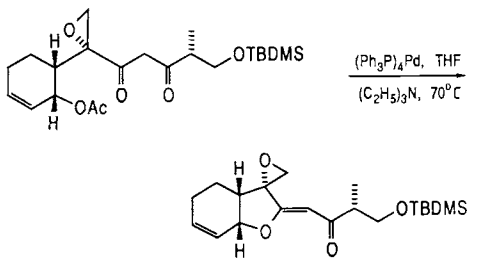
(68)

palladium produces good yields of lactones. Palladium-mediated additions of alkenyl organomercurials to unsaturated acids also produce lactones via carboxylate attack on a π-allylpalladium complex that forms after rearrangement of the kinetic adduct [Eq. (69)].[104]

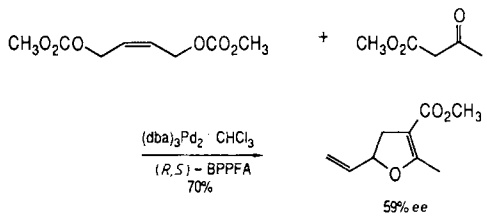


(69)

Enolates from β-ketoesters [Eq. (70)],[42,43] β-ketosulfones [Eq. (70)],[42,43] and 1,3-diketones [Eq. (71)][105] may

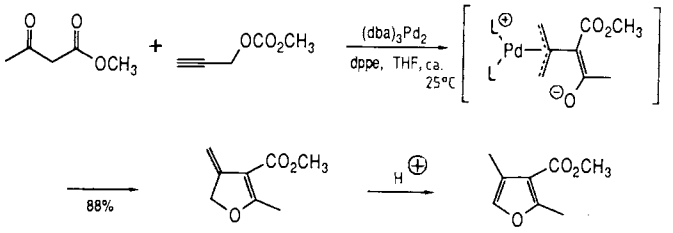


(70)



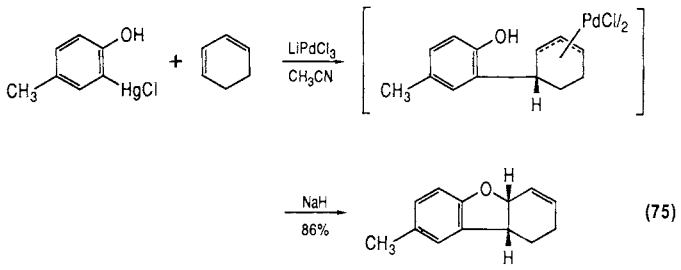
(71)

undergo preferential *O* rather than *C* alkylation. In the first two examples [Eq. (70)], prolonged treatment with the Pd^0 catalyst permuted the *O*-alkylated product to the *C*-alkylated one. The synthesis of the ring system of the aglucone of the antitumor agent phyllanthoside has been accomplished using this reaction [Eq. (72), TBDMS = *tert*-butyldimethylsilyl].[106] An asymmetric synthesis of dihydrofurans utilized a palladium catalyst bearing chiral ligands [Eq. (73)].[58] A



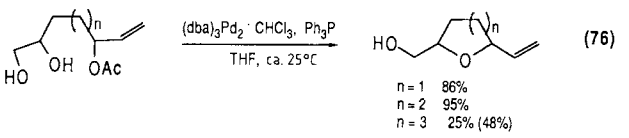
(72)

(73)



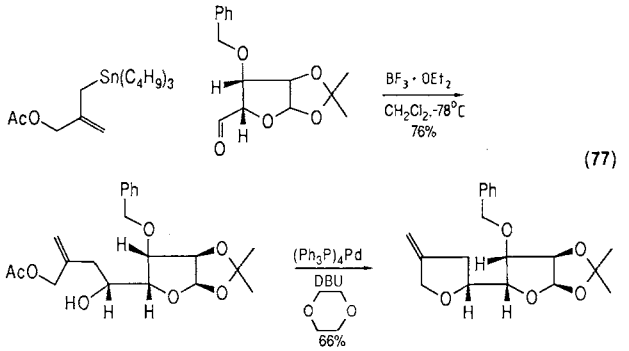
novel furan synthesis evolved from the Pd-catalyzed alkylation of β-ketoesters and 1,3-diketones with methyl propargyl carbonate.[107] The key cyclization of the oxygen nucleophile on the π-allylpalladium complex, which must have arisen by an unusual metal-promoted C–C bond formation and hydrogen shifts, involves a *5-endo-trig* attack [Eq. (74)]. Because of the geometrical constraints for such a process, the facility of this cyclization suggests that it might be viewed as an electrophilic reaction analogous to the ring closure of pentadienyl anions to cyclopentenyl anions.

Aryl oxides should also be good oxygen nucleophiles toward π-allylpalladium complexes. A synthesis of dihy-



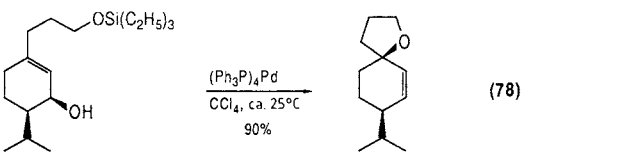
(74)

drobenzofurans involves just such a step, but utilizes stoichiometric amounts of palladium [Eq. (75)].[102] The *cis* stereochemistry of the product demands that the oxygen attack on the same face of the π-allyl unit bonded to palladium.

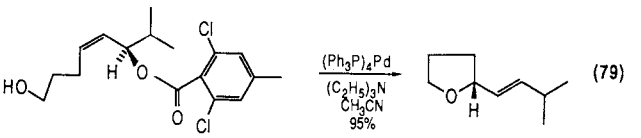


(75)

While simple alcohols are normally poor nucleophiles toward π-allylpalladium complexes in intermolecular reactions, they participate without complications in intramolecular reactions [Eq. (76)].[108] A diastereocontrolled 3-methylenetetrahydrofuran annulation employs this reaction for the ring-forming step [Eq. (77), DBU = 1,5-diazabicyclo[5.4.0]undec-5-ene].[109a]

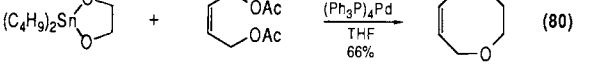


(76)



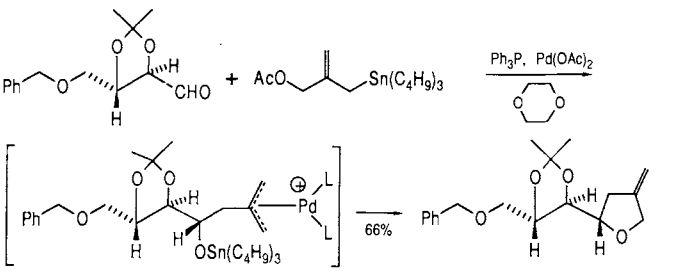
(77)

Silyl ethers have served as the nucleophiles but it is likely that desilylation to liberate a nucleophilic alkoxide occurred under the reaction conditions [Eq. (78)].[110] In addition, the



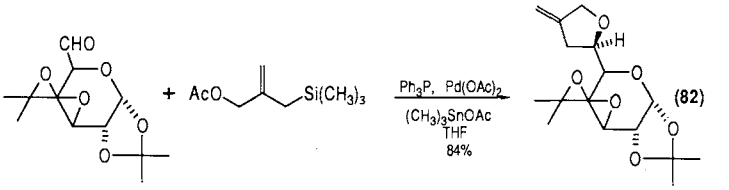
(78)

tetrakis(triphenylphosphane)palladium and carbon tetrachloride also serve to activate the allylic alcohol so that it can serve as a leaving group. The stereochemistry of the alkylation follows that associated with "soft" nucleophiles so that the leaving group departs and the nucleophile enters on the same face of the allylic unit [see Eq. (78)], in contrast to the result of Equation (75). The same stereochemistry was observed in an unconstrained acyclic substrate [Eq. (79)].[111]



(79)

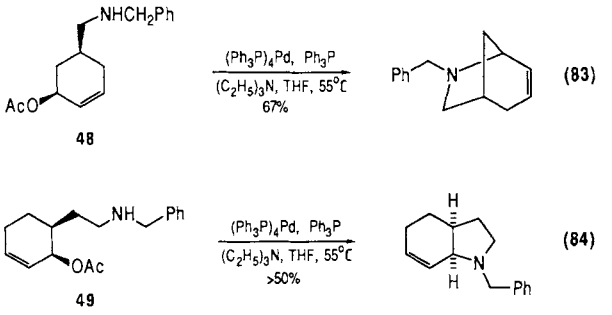
Stannyl ethers have been claimed to be excellent nucleophiles toward π-allylpalladium complexes. Indeed, medium-ring and macrocyclic polyethers form in excellent yields with such partners [Eq. (80)].[112] A [3 + 2] cycloaddition strategy to 3-methylenetetrahydrofurans takes advantage of this fact [Eq. (81)].[109b] The efficacy of the process allows a tin compound to be employed as a co-catalyst in effecting



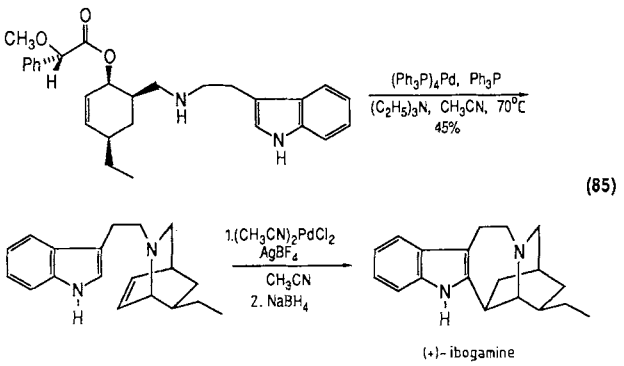
(80)

(81)

diastereocontrolled cycloadditions of aldehydes with 2-(trimethylsilylmethyl)allyl acetate [Eq. (82)].[113] The evolution of this cycloaddition strategy for the stereocontrolled synthesis of five-membered oxygen heterocycles provides additional functionality to permit further facile structural elaboration, thereby enhancing the power of this approach.

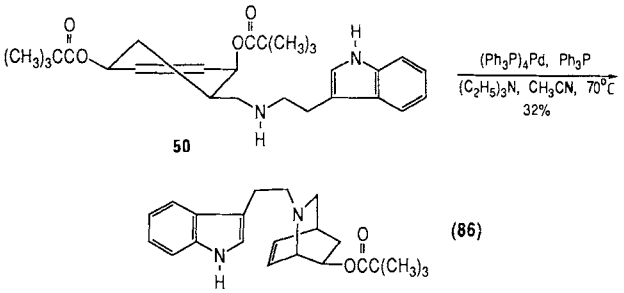


(82)

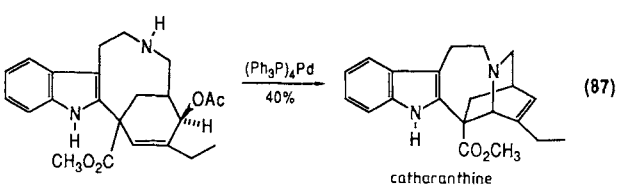


4.2. Nitrogen Nucleophiles

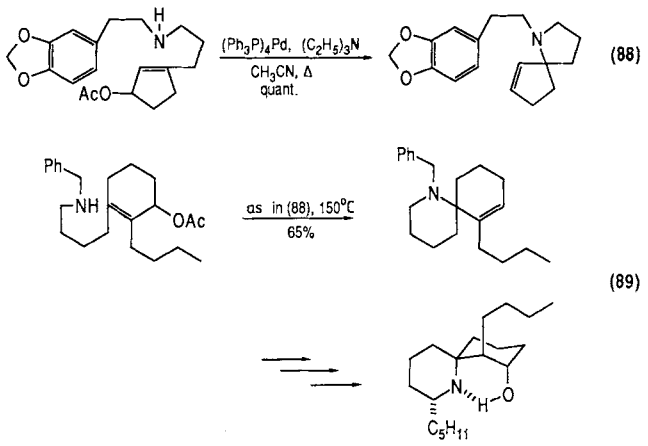
Amines are among the best nucleophiles for π-allylpalladium complexes. Their potency for intramolecular reactions was revealed by the simple construction of typical alkaloid skeletons represented by 6-azabicyclo[3.2.1]oct-3-ene [Eq. (83)] and 2,3,3a,4,5,7a-hexahydro-1*H*-indole [Eq.



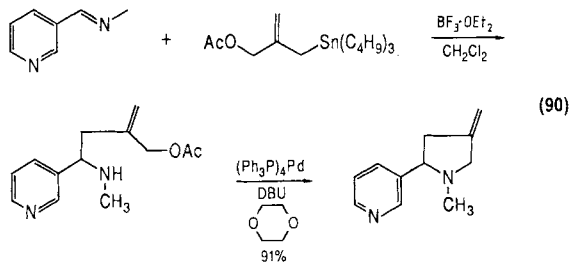
(84)].[114] The ease of availability of substrates possessing the NH and OAc functions *cis* to each other, as in substrates **48** and **49**, requires a cyclization method that permits substitu-



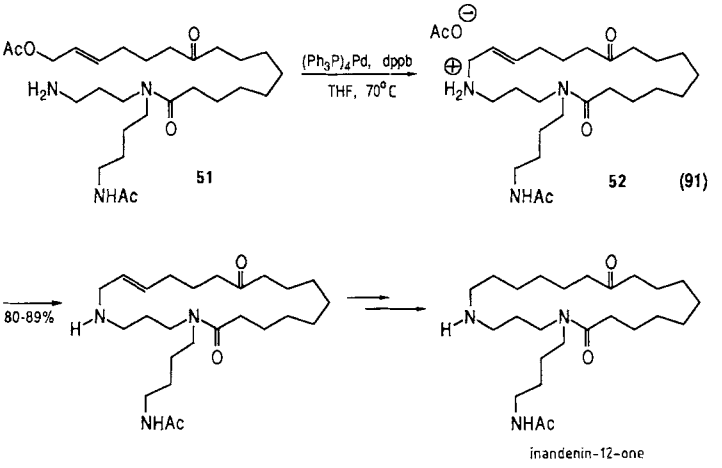
tion with *retention* of configuration, as effected by this palladium-based methodology. The Diels–Alder reaction leads to rapid construction of such substrates. An exceptionally facile synthesis of (+)-ibogamine, takes advantage of asymmetric induction in the Diels–Alder step [Eq. (85)].[115] Palladi-



um-catalyzed ionization of the ene dicarboxylate **50**, which is chemoselective due to the steric preference of the C3 pivaloyloxy group to be in the required axial orientation, extends this methodology to the biologically significant catharanthine system [Eq. (86)].[116] An alternative strategy to

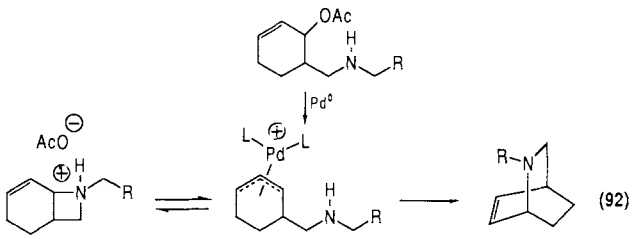


catharanthine employed the Pd-catalyzed cyclization as the final ring-forming step [Eq. (87)].[117]



Pyrrolidine- and piperidine-containing spiroheterocycles, a core ring system of some biologically important alkaloids represented by cephalotaxine and histrionicotoxin, may be readily formed by this metal-catalyzed chemistry, as shown in a model study for the former class [Eq. (88)][118] and a formal synthesis of an analogue of the latter class, perhydrohistrionicotoxin [Eq. (89)].[119, 120] A [3 + 2] cycloaddition

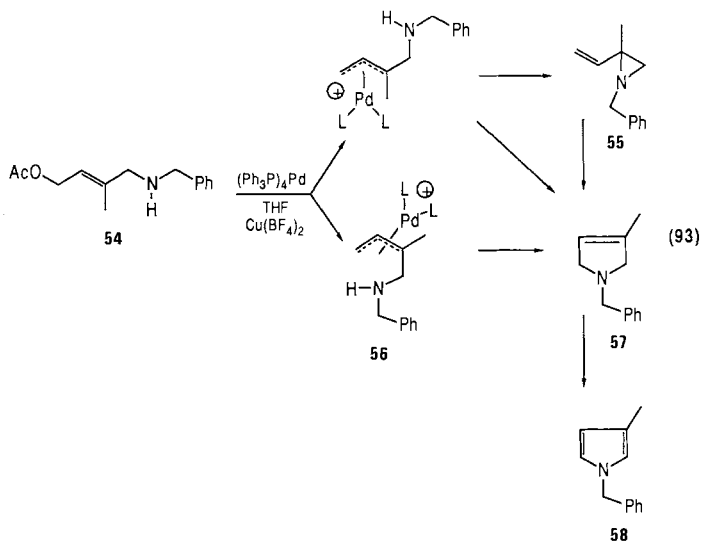
strategy to 3-methylenepyrrolidines embodies this cyclization as a key step.[108] Addition of the bifunctional conjunctive reagent 2-(tri-*n*-butylstannylmethyl)allyl acetate to imines creates the proper juxtaposition of nitrogen nucleophile and electrophile [Eq. (90)]. Exposure of the adduct to a Pd^0 catalyst completes the formation of the five-membered ring nicotine analogue.



The fact that cyclization employing nitrogen nucleophiles is an isomerization facilitates macroheterocyclization. The amino acetate **51** isomerizes to the 21-membered ring ammonium acetate **52** with excellent efficiency at modest dilutions

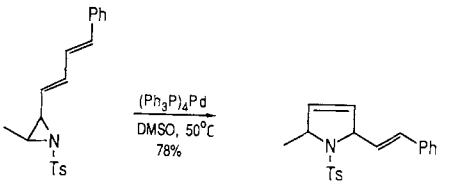
(0.02 M) using a catalyst generated from tetrakis-(triphenylphosphane)palladium and 1,4-bis(diphenylphosphino)butane (dppb) [Eq. (91)].[121] Neutralization, hydrogenation, and acetamide hydrolysis complete the synthesis of the spermidine alkaloid inandenin-12-one.

Thermodynamic considerations may explain the observed regioselectivity and thus the ring size for the examples reported so far, in contrast to the cyclizations involving carbon and oxygen nucleophiles. The preferential formation of the bicyclo[4.2.0]octyl ring system with a carbon nucleophile [Eq. (2)], but the bicyclo[2.2.2]octyl ring system with a nitrogen nucleophile [Eq. (85)], may be an illustration of this phenomenon. Kinetically, the intermediate π-allyl complex **53** may preferentially cyclize to the azetidine [Eq. (92)] in analo-



(92)

53

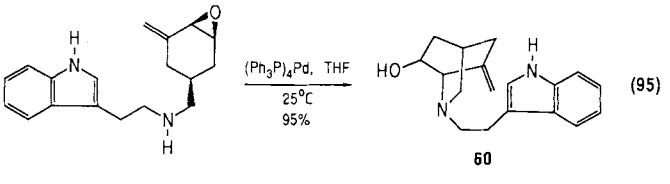


gy to the carbon case [Eq. (2)]. However, the ability of allylammonium salts to serve as substrates for Pd^0[122] permits reionization to **53**, which ultimately can collapse to the thermodynamically more stable isoquinuclidine. In support of such a suggestion, the isomerization of a *N*-tosyl-2-vinylazetidine to the six-membered ring has been reported.[123] Whereas, with carboxylate nucleophiles, both the kinetic and thermodynamic products could be obtained under cyclization conditions, only the thermodynamic product is observed with the amine nucleophiles.

A striking case is the cyclization of the amino-acetate **54**, which might have been expected to generate the vinylaziridine **55**. Instead, only the pyrrole **58**, which arises by oxidation of the initial cyclization product **57**, is obtained [Eq. (93)].[124] The attack of nitrogen on the face of the π-al-

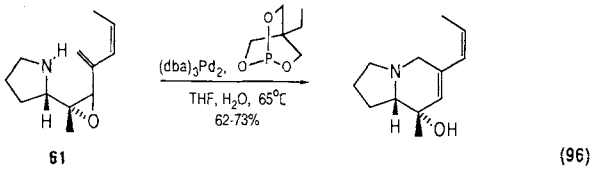
(93)

lyl unit opposite to the palladium to form the five-membered ring in intermediate **56** is geometrically difficult. The reported failure of *N*-tosyl-2-vinylaziridine to isomerize to the 2,4-dihydropyrrole in contrast to the smooth isomerization of the dienyl analogue **59** [Eq. (94)] may be attributed to the



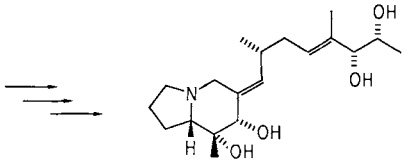
(94)

59



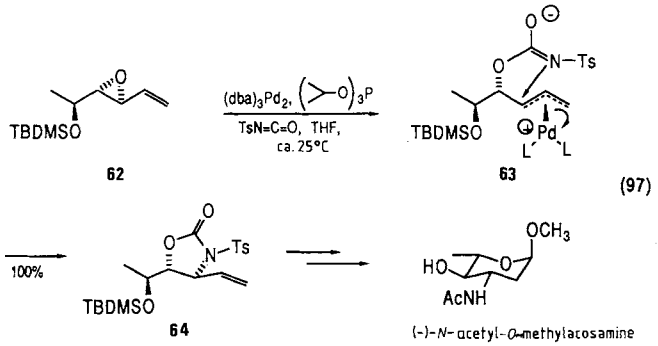
difference between a 5-*endo*- and a 5-*exo-trig* cyclization.[125] The success of the 5-*endo-trig* cyclization of **56** [Eq. (93)] may derive from a change in mechanism wherein the amine first coordinates to palladium, which then collapses by reductive elimination to give **57** (see below).

These issues become clouded when vinyl epoxides are used as electrophiles because of the propensity of the hydroxyl group adjoining the π-allyl unit to direct the regioselectivity distal to this substituent. Nevertheless, thermodynamic considerations appear to dominate. A synthesis of the enantiomerically pure isoquinuclidine **60**, a possible intermediate toward catharanthine, proceeded virtually quantitatively, even though the amine must attack proximal to the alcohol [Eq. (95)].[126] The successful cyclization of the vinyl epoxide **61** establishes the feasibility of the geometrically constrained



(95)

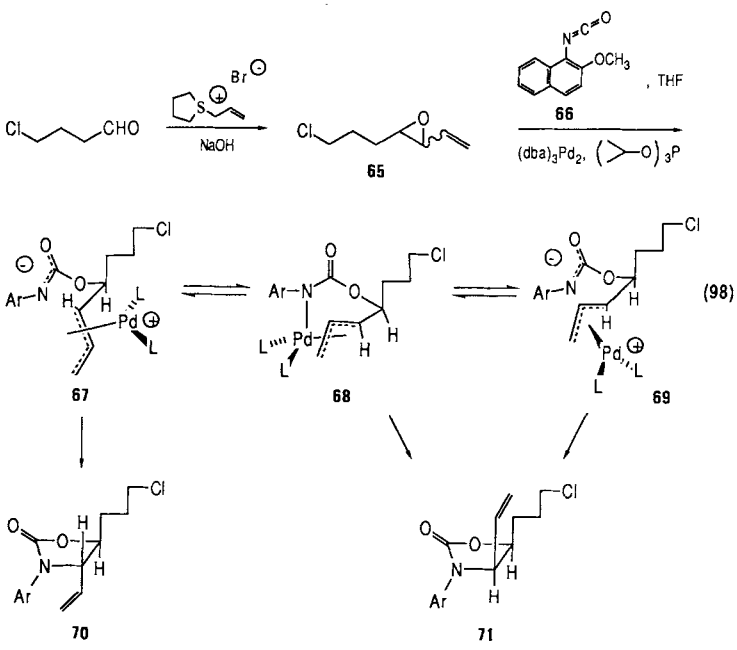
60



61

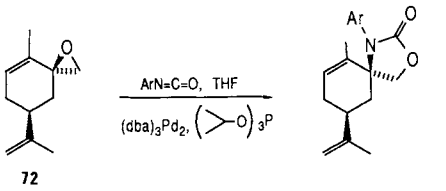
(96)

6-*endo-trig* cyclization.[127] Interestingly, addition of water enhances the rate of this reaction and minimizes side reactions. The effect of water may derive from its ability to solvate the epoxide oxygen, thereby enhancing its leaving group capabilities, as well as by its ability to stabilize the initial π-allylpalladium complex by protonating the forming alkoxide. For the case of vinyl epoxide substrates, the geometrical boundary for an *endo* type of cyclization lies between a five- and six-membered ring, since attempts to create a pyrrolizidine skeleton via a 5-*endo-trig* [cf. Eq. (93)] cyclization failed.[127]



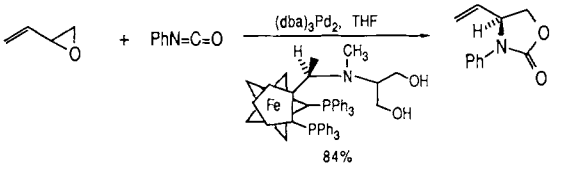
When vinyl epoxides are used, control of ring size may also be achieved by tethering the nucleophile to the epoxide oxygen in a fashion analogous to the formation of cyclic carbonates using vinyl epoxides and carbon dioxide [Eqs. (64)–(66)]. Isocyanates afford oxazolidin-2-ones, wherein ring formation occurs by nitrogen serving as a nucleophile exclusively vicinal to the oxygen, as shown in Equation (97).[128] The synthesis of the acosamine intermediate **64**

(97)



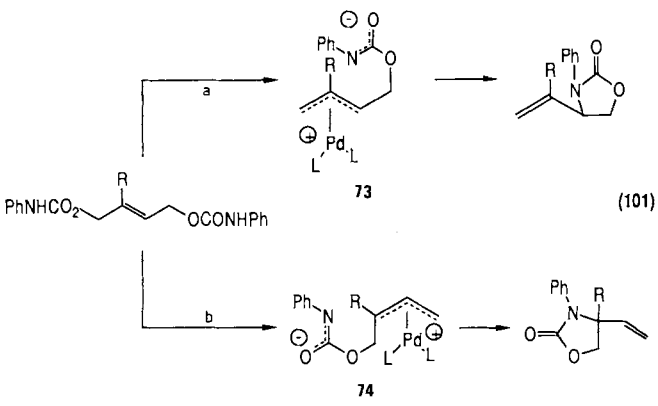
illustrates the normal stereochemical feature of substitution with net retention of configuration with *p*-toluenesulfonyl isocyanate.

Reaction of vinyl epoxides with aryl isocyanates led to a most unusual stereochemistry, which was optimized by using 2-methoxy-1-naphthyl isocyanate **66** [Eq. (98), Ar = 2-methoxy-1-naphthyl].[129] Exposing a 1:1 mixture of vinyl epoxide **65** to the isocyanate **66** under normal conditions produces a 10:1 ratio of the oxazolidin-2-one, favoring the thermodynamically less stable *Z* isomer **71**. Two explanations account for this result. In the first, kinetic generation of the normally preferred *syn* complex **67**, which generates the (*E*)-oxazolidin-2-one by the normal pathway of substitution, is followed preferentially by coordination of the nitrogen to palladium, as in **68**, and reductive elimination to give the *Z*



(98)

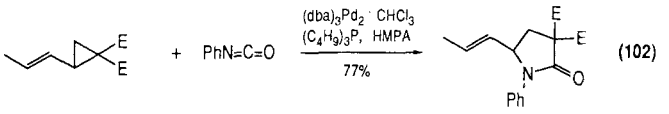
isomer. To test for this pathway, the vinyl epoxide **72** [Eq. (99)] was allowed to react with aryl isocyanates (Ar = aryl) under the usual catalytic conditions. The fact



(99)

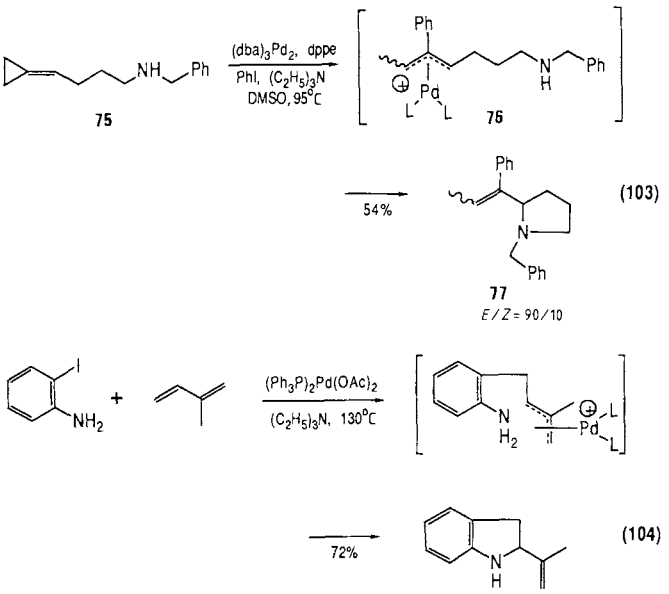
that only net retention of configuration was observed refutes the involvement of **68**.[130] An alternative explanation for the preferential formation of **71** in Equation (98) invokes rapid equilibration of the diastereomeric π-allylpalladium complexes **67** and **69**. Transition states derived from complex **69** are destabilized due to the eclipsing interaction between the vinyl and chloropropyl groups. On the other hand, the substantial interaction of the chloropropyl group with the template present in **67** may ultimately dominate. Thus, preferential formation of the *Z* isomer **71** may be an example in which the demands of the template to minimize nonbonded interactions require a product which, once released from the template, corresponds to the thermodynamically less stable one. Support for the rapid interconversion of the diastereomeric complexes **67** and **69** is provided by the observation that racemic butadiene monoepoxide reacts with phenyl isocyanate to generate the oxazolidin-2-one with 43% *ee* in the presence of enantiomerically pure ligands [Eq. (100)].[131]

(100)



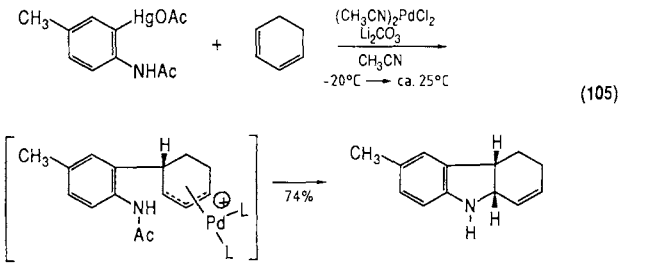
Oxazolidin-2-ones have also been formed by Pd-catalyzed cyclizations of the dicarbamates derived from 1,4-dihydroxy-2-alkenes [Eq. (101)]. Unsymmetrical substrates exhibit a remarkably high degree of chemoselectivity, favoring path a (R = *i*-C_3H_7, a:b, 96:4), which may derive from the

(101)

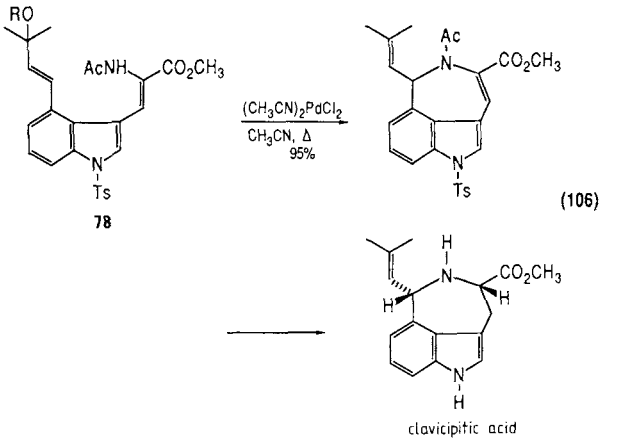


less destabilizing interactions between the organic moiety and the palladium template in intermediate **73** compared to complex **74**.[132] This same reaction with chiral ligands has led to an asymmetric induction as high as 73% *ee*.

Replacing the vinyl epoxide with a vinylcyclopropane known to undergo reversible palladium-initiated ionization in the reaction of isocyanates also successfully leads to interception of the zwitterionic intermediate [cf. Eqs. (14) and (15)] and heterocycle formation [Eq. (102)].[133] Generation

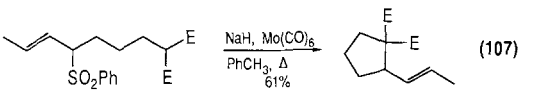


(102)

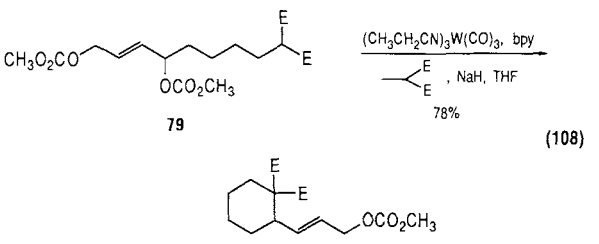


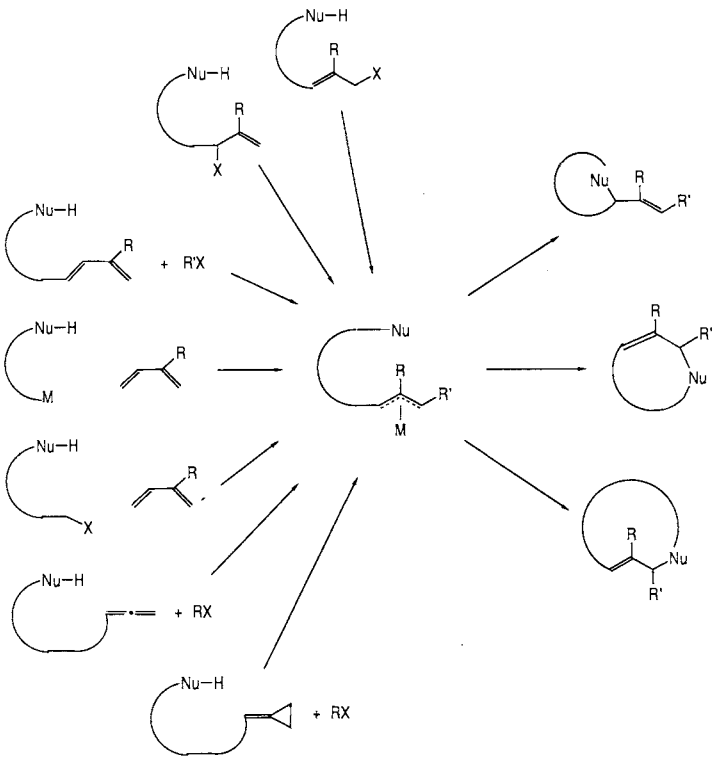
of π-allylpalladium complexes by methods other than allylic ionization in the vicinity of a nucleophilic nitrogen also can lead to nitrogen heterocycles. For example, arylation of the alkylidene cyclopropane **75** produces the pyrrolidine **77** via in situ formation of the palladium complex **76** [Eq. (103)].[62] Heck arylation of a diene with a bifunctional arylating agent leads directly to indolines [Eqs. (104)[134] and (105)[102]].

The *cis* stereochemistry in (105) arises by the amine attacking the face of the π-allyl unit proximal to the metal. It thus appears that the facial selectivity of amine nucleophiles mirrors that of oxygen. While attack may occur on the same face of the allyl unit to which the palladium is attached, the amine nucleophile generally prefers to attack the opposite side.



It should be noted that not all Pd-catalyzed allylic alkylations necessarily involve π-allylpalladium intermediates. An obvious candidate for cyclization via such intermediates arose in the synthesis of the ergot alkaloid clavicipitic acid. Nevertheless, any Pd^0 methodology with the substrate **78** (R = Ac or H) either failed or proceeded in very poor yields. On the other hand, **78** (R = H) cyclized nearly quantitatively using Pd^{II} complexes; the reaction apparently involves Pd-initiated amination of the olefin followed by elimination of the elements of palladium hydroxide.[135]





5. Conclusions

Metal-directed allylic alkylations offer a new control element for cyclizations. Chemo-, regio-, and diastereoselectivity can be totally altered. For example, the normal preference for six- and seven-membered rings can be overpowered by the metal, which may favor medium-sized (e.g., eight- and nine-membered) rings. Substitution may occur with net retention of configuration rather than inversion. Variation of the nucleophile has been very limited and clearly will expand beyond use of the stabilized carbanions or the oxygen and nitrogen nucleophiles discussed here. Other metals also catalyze allylic alkylations and will undoubtedly bring new opportunities for cyclization. Very preliminary signs establish the feasibility of this direction. A molybdenum catalyst effects the cycloalkylation of allylic sulfones [Eq. (107)].[49]

The dicarbonate **79** failed to cyclize with palladium, but smooth cyclization occurred when a tungsten catalyst was used [Eq. (108)].[136] Generating the π-allylpalladium inter-

Scheme 2. Summary of cyclizations via allylic alkylations.

mediate by methods other than allylic ionization offers great opportunities for totally new dimensions in cyclization. Scheme 2 summarizes the major routes known to date. The combinatorial possibilities assure many more will be discovered in the future. Further, the involvement of the π-allylmetal intermediate makes the metal and its attendant ligands the final arbiters in deciding the nature of the final cyclization product. One of the most important and exciting features of metal-catalyzed reactions is the development of chiral ligands for catalytic asymmetric induction—an area in which some strides have been made, but that mainly remains a prospect for the future.

I thank my many collaborators who have explored with me the utilization of abiological catalysis for synthetic selectivity. Their curiosity, intellectual and experimental skills, and enthusiasm made possible our contributions to this field. Our work has been primarily funded by the National Institutes of Health and the National Science Foundation. Merck, Sharp and Dohme Research Laboratories have provided important support for our programs. Fellowships from the Deutsche Forschungsgemeinschaft and the Alexander von Humboldt Foundation (FRG), NATO/SERC (UK), and the CNRS (France) have provided full or partial support for many of my postdoctoral associates from these countries.

The Beginnings of Organic Photochemistry

By Heinz D. Roth*

Although sunlight induced photochemistry must have occurred on the planet Earth for billions of years, the chemical changes caused by light have attracted systematic scientific scrutiny only relatively recently. How did scientists first conceive the idea that the interaction of materials with light could not only cause physical phenomena, but could also alter their chemical nature? When sunlight began to be employed as a heat source for distillation, the eventual discovery of photochemical reactions was assured. One can envision three types of changes that would have aroused the curiosity of laboratory chemists: color changes; the evolution of gas bubbles (oxygen in photosynthesis); and the precipitation of a photoproduct less soluble than its precursor. Less predictable was the observation that sunlight caused crystalline santonin to burst because it is converted into a product with a different crystal lattice. In the course of the eighteenth and nineteenth centuries a variety of photochemical reactions, some observed by chance, others uncovered in carefully planned studies, ultimately led to a major systematic investigation that established photochemistry as a viable branch of chemistry.

1. Introduction

Light induced reactions on this planet are significantly older than life itself. Sunlight induced photochemistry must have literally started as soon as the dust began to settle after the Earth's accretion phase.[1] The atmosphere of early Earth very likely was essentially free of oxygen. It may have contained chiefly a mixture of hydrocarbons and cyanocarbons, as found on Titan, the largest moon of Saturn.[2,3] In addition (or instead) it may have contained large quantities of water and carbon dioxide, as found on Mars and Venus, Earth's neighbor planets.[4] This atmosphere was exposed to radiation from a young Sun, whose spectrum very likely was quite different from the present solar spectrum, with UV fluxes one thousand times greater than the present values.[1]

Within the first one billion years plant life began to produce oxygen and to build up the atmosphere prevailing today.[5,6] At the same time it laid the foundation for seemingly inexhaustible energy resources and provided nourishment for higher forms of life. The photolysis of oxygen in the stratosphere generated the protective ozone layer, which would screen human and animal life from the high energy component of the solar spectrum.[7,8] When *homo sapiens* began to shed his hairy cover, the action of sunlight began to dimerize thymine units of human DNA and cause other changes, leading to skin cancer.[9] The human body, in turn, developed photoreactivation along with other repair processes.[9] All these photoreactions have been occurring for aeons without human intervention or, indeed, without being noticed.

How did scientists first conceive the idea that the interaction of materials with light could not only cause physical phenomena, viz. shadows, absorption, reflection, refraction, but could also alter their chemical nature? What kind of a change would be sufficiently noticeable to a chemist to whom chemical composition and appearance were the chief characteristics of a chemical substance and to whom the notion of "structure" was essentially unknown?

Numerous sunlight induced changes in the general appearance of materials or in their functionality were, indeed, noticed: the bleaching effect, exploited for the manufacture of fibers but detrimental to dyed fabrics; the preservation of oil paintings[10] and the "chalking" of exterior paint; deleterious effects on beer;[11] and the spoiling of gun cotton.[12] Aside from these matters of practical importance, three types of changes can be envisioned to arouse the curiosity of a laboratory chemist: color changes, either temporary (photochromism) or permanent; the development of gas bubbles in a liquid; and the precipitation of a photoproduct that is less soluble than its precursor.

It appears plausible that changes induced in a photochromic dye should have been the earliest photoreactions observed. Indeed, it has been claimed[13] that *Alexander the Great* exploited such an effect to coordinate the attack of his troops, which proved to be crucial for the outcome of his battles. The Macedonian troops supposedly carried rag bands around their wrists, which were impregnated with a photochromic dye. A color change caused by the exposure to sunlight thus could signal the time of attack. The device has been referred to as Alexander's Rag Time Band.[13] Alas, no scientific record of the underlying chemistry has been preserved; photochromism wasn't rediscovered until 1876.[14]

Attempts to utilize the energy of the sun are at least several thousand years old, although the fable of *Phaethon* appears to hint, that man is not meant to achieve this dream.[*] The burning mirror of *Archimedes* (Fig. 1) may well be the best known early device. More modest uses for laboratory experiments (or their outdoor equivalents) are documented as early as 1599 when *Conrad Gesner* described "The maner of

[*] *Phaethon*, the son of *Helios* and the nymph *Clymene*, tried to drive his father's golden chariot. However, unable to control the powerful steeds, he let the chariot plunge to earth, burning Mt. Oeta and drying the Libyan desert. The entire universe would have perished in the conflagration, had not *Zeus* killed *Phaethon* with a bolt of lightning.

Distilling in the Sunne" in his monograph on "The practise of the new and old phisicke".[15] Some fifty years later *John French* showed two setups "to rectify spirits" (Fig. 2), which included provisions for the collection and accumulation of solar radiation, based on the heat capacity of materials such as glass, marble, or cast iron.[16]

Fig. 3. A variety of distillation setups [17].

Less than fifty years later *Libavius* described several methods to focus sunlight on a designated area (Fig. 3). These methods employed mirrors or lenses and suggest an understanding of the principles of optics.[17] All uses suggested up to *Libavius'* time exploited the heat component of the sun's energy spectrum. Chemical changes were limited to combustion as a result of heating above the point of spontaneous ignition.

2. *Joseph Priestley*— Photochemistry in the Eighteenth Century

It was in a setup, similar to that of *Libavius*, that *Priestley* first encountered a comparably simple chemical conversion. In the course of his experiments on "different kinds of air" he used a twelve inch lens to focus sunlight on a sample of mercury in a closed vessel (Fig. 4).[18] He observed conversion of the mercury to a red solid with an increase in weight and a diminution of the volume of air. This pioneering experiment was correctly interpreted by *Lavoisier* as a combination of mercury with oxygen, i.e. as an oxidation.[18] Of course, this conversion is a thermal reaction.

Heinz D. Roth was born in Rheinhausen, in the Lower Rhine region of Germany, in 1936. After completing his formal education at the Universities of Karlsruhe and Köln he received a Dr. rer. nat. degree in Professor Emanuel Vogel's laboratory at the University of Köln with a dissertation on 1,6-methano[10]annulene. After two years as a postdoctoral fellow in W. von E. Doering's laboratory at Yale University he joined the Research Division of (AT&T) Bell Laboratories, Murray Hill, NJ. He has been interested in organic reaction mechanisms, particularly in the structure and reactivity of short-lived radical ions and carbenes; in electron donor-acceptor interactions and photoinduced electron transfer; and in the application of magnetic resonance techniques, especially chemically induced magnetic polarization. Since 1988 he has been Professor of Chemistry at Rutgers University, New Brunswick, NJ. In addition to his main scientific interests he pursues the historical development of the sciences as well as 16th–18th century european cartography.

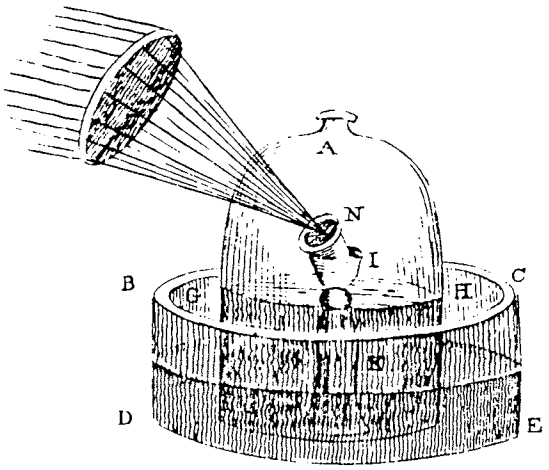

Fig. 4. Apparatus for carrying out calcinations credited to *Priestley* [18]. The metal is contained "in a porcelain cup N, placed upon the stand IK, under a jar A, in the bason BCDE, full of water; the water is made to rise up to GH by sucking out the air with a syphon, and the focus of a burning glass is made to fall upon the metal."

Fig. 5. *Joseph Priestley* (1733–1800), engraving by W. Hall – From a picture by *Gilbert Stewart*. C. Knight, London.

However, *Priestley* also was successful in observing at least two genuine photoreactions in two widely divergent fields: inorganic chemistry and photosynthesis. He exposed partially filled vials of "spirit of nitre" (nitric acid) to sunlight and observed that the liquid assumed a reddish color.[20] In follow-up experiments he ruled out a thermal reaction and established that the reddish product (nitrogen dioxide) was formed in the vapor phase and then dissolved in the liquid. "Being now satisfied that it was the action of *light* upon the *vapour* of spirit of nitre that gave it colour, I amused myself with throwing a strong light, by means of a lens, into the upper part of a phial, the lower part of which contained colourless spirit of nitre."[20]

After the initial observation these experiments were obviously well planned and executed. It must be considered the first laboratory photoreaction in the *gas* phase, although this assignment can be made only with all due apologies to its investigator. *Priestley* specifically rejected the term "gas", that had been suggested by the elder (*J. B.*) *van Helmont* (1577–1644), as unnecessary.[21a]

Priestley (Fig. 5) also deserves credit for first recognizing some facts regarding photosynthesis. In his own words, he "fully ascertained the influence of light in the production of dephlogisticated air (oxygen) in water by means of a *green substance*". When he had first observed the gas evolution, he had explained it as a light-induced reaction of water. However, in later experiments he noticed the presence of *green matter* and a colleague identified tiny plants under a microscope.[21b]

After learning of *Priestley*'s early experiments, *Jan Ingenhousz*, a Dutch physician, who practiced in England and Austria, carried out experiments of his own. He determined that the action of light on plants "improves" air and that *Priestley*'s "green matter" must be a plant.[22] *Nicholas Theodore de Saussure* (1767–1845) resolved the problem in 1804, when he grew plants in enclosed spaces that allowed him to monitor changes in the gas content quantitatively. He demonstrated that the influence of light causes plants to consume water and carbon dioxide and to generate oxygen.[23]

In concluding this brief overview of *Priestley*'s contributions to photochemistry, it is interesting to compare his views of the nature of light with those of his French contemporary *Lavoisier*. *Priestley* considered light a *"chemical principle"* and an *"important agent in the system of nature"*, although he conceded that its "effects ... are as yet but little known."[21b] *Lavoisier*, on the other hand, considered heat and light as agents capable of combining with chemical substances, causing them to expand.

About the more elusive of the two he wrote: "The combinations of light, and its mode of acting upon different bodies are still less known ... it appears to have great affinity with oxygen ..." *Lavoisier* deserves credit for the formulation of many chemical concepts, but the paucity of experimental facts was insufficient to reveal to him the nature of light. His most eloquent statement about light was of a philosophical nature: "By means of light, the benevolence of the Deity has filled the earth with organization, sensation, and intelligence. The fable of Prometheus might perhaps be considered as giving a hint of this philosophical truth even to the ancients."[24]

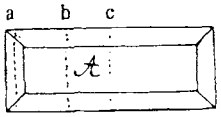
3. *J. W. Döbereiner* and the Light Induced Reduction of Metal Ions

An interesting laboratory experiment in photochemistry was carried out by *Döbereiner*. The August 1831 issue of *Pharmaceutisches Central Blatt* (later *Chemisches Zentralblatt*) contains an abstract, which is introduced as follows: "Prof. Döbereiner, dem die Chemie schon so viele interessante Tatsachen verdankt, theilt folgende bemerkenswerthe Beobachtungen über die chemische Wirkung des Lichts mit."[*] *Döbereiner* exposed an aqueous solution of oxalic acid and iron(III) oxide in a small glass bulb to sunlight. He observed that many tiny gas bubbles developed, which he

[*] "Professor *Döbereiner*, to whom chemistry already owes so many interesting facts, reports the following remarkable observation about the chemical effect of light."

identified as CO_2, and that a basic iron(II) oxide, humboldtite, precipitated.[25] With appropriate modifications this reaction has become the basis for ferrioxalate actinometry.[26, 27]

Döbereiner found similar reductions for salts of Pt, Ag, Ir, and ruled out the corresponding dark reactions by control experiments. However, he missed out on the first photoreaction of a ruthenium compound, because the element that has become the mainstay of so many photochemical studies was not discovered until 1844.



Johann Wolfgang Döbereiner (1780–1849) taught at Jena University and belonged to *J. W. von Goethe*'s circle of friends. He made important contributions in several areas: he developed a pneumatic gas lighter; he investigated oxidation reactions with "platinum black"; and he suggested (before *Faraday*) the use of simple galvanic cells for stoichiometric studies. His most important contribution to chemistry was his attempt to order the chemical elements into "triads". These considerations foreshadowed (and aided) *Mendeleev*'s and *Meyer*'s work on the periodic table. The photoreduction of metal salts in the presence of oxalate ion appears to have been *Döbereiner*'s only excursion into the field of photochemistry.

4. The Photochemistry of Santonin—*Trommsdorff, Sestini, Cannizzaro*

Perhaps the longest known photoreaction of an organic compound is that of santonin, an anthelmintic sesquiterpene lactone. It occurs in the leaves and flower buds of various species of *artemisia* and is the active ingredient of Levant wormseed which was widely used in medicine. It was first isolated in 1830 by *Kahler*[28] and by *Alms*.[29] As early as 1834, *Hermann Trommsdorff* reported the curious observation that exposure to sunlight causes santonin to turn yellow, and its crystals to burst.[30] Several years later, *Heldt* observed these changes under the microscope and was able to determine the directions of the ruptures (Fig. 6).[31] These experiments are the first dealing with solid state photochemistry.

Die Santoninkrystalle zerspringen zuerst nach Schnitten, welche normal auf die Längenaxe zugehen; die zugeschärften Endflächen werden gleichfalls durch Schnitte abgetrennt, welche die Längenaxe rechtwinklich schneiden. Die Schnittflächen sind keine Ebenen, sie haben sehr unregelmäfsige Begrenzungen.

Ist A die Oberansicht eines Krystalls, so zeigen die Linien a, b, c die Richtung der Spaltungsflächen an.

Die abgelösten Stücke zerfallen dann weiter in kleinere, an welchen eine regelmäfsige Form nicht mehr erkennbar ist.

Fig. 6. Rupture of santonin crystals upon irradiation, after *Heldt* [1]. "The santonin crystals are cleaved first along cuts normal to the long axis; the inclined crystal faces are also separated along cuts perpendicular to the long axis. The newly created surfaces are not planar but have quite irregular boundaries. If A is the top view of a crystal, the lines a, b, c, indicate the directions of cleavage. The separated pieces are then cleaved further into smaller fragments which no longer show any regular shape."

Trommsdorff came from a well established family of apothecaries; his father (*Johann Bartholomäus*) was an Editor of *Annalen der Pharmacie — Deutsche Apothekerzeitung*, which would become *Justus Liebigs Annalen der Chemie*. As an apothecary, *Trommsdorff* had ready access to santonin (or at least to Levant wormseed), and had the skill and the equipment to carry out diligent experiments.

Given this background it may not come as a surprise that *Trommsdorff* was interested in the wavelength dependence of the light induced change, and probed it with the help of a prism. He determined that "Das Santonin wird sowohl durch den unzerlegten, als durch den blauen und violetten Strahl gefärbt . . .;. . . der gelbe, grüne und rothe bringen nicht die mindeste Veränderung hervor".[30][*] This study must be considered the first to probe the wavelength dependence of an organic photoreaction, a remarkable feat over 150 years ago.

The attempts to characterize santonin and its yellow photoproduct led *Trommsdorff* to the view that these were "two isomeric modifications."[30] Similarly, *Heldt*, on the basis of elemental analyses, argued: "White and yellow santonin are identical in their composition, but different in their molecular construction."[31] The early workers, of course, did not understand the structures of santonin or its photoproduct.

About twenty years after *Heldt*'s publication an Italian chemist began an investigation of santonin, its structure, and its photochemistry.[32–36] *Fausto Alessandro Sestini* (Fig. 7)

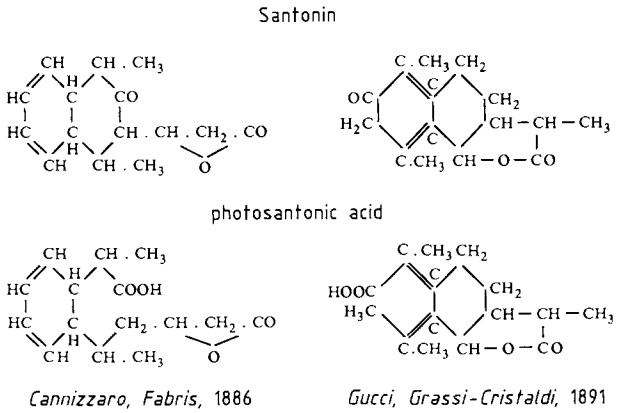
Fig. 7. *Fausto Sestini* (1839–1904), during his year in Pisa. He became director of the Institute of Agricultural Chemistry in 1876 and founded the Institute of Toxicology in 1892. In 1911 his grateful students unveiled a bust in his honor which still graces the hall of the Faculta Agraria. *Sestini* introduced *Cannizzaro* to photochemistry and through him, *Ciamician* and *Silber*.

was a teacher in Forli and served as president of the Udine Technical Institute. In 1872 he became director of the agricultural station in Rome and, concurrently, Inspector General for technical education in the Italian Department of Agriculture. In 1876, he accepted a position at the University of

[*] "Santonin is turned yellow not only by the undivided, but also by the blue and violet ray"... whereas..."the yellow, green and red one cause not even the slightest changes."

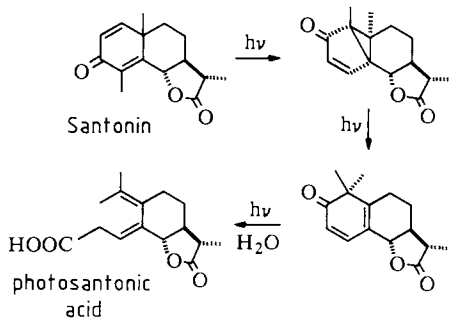
Pisa as professor and director of the Institute for Agricultural Chemistry; later he founded an Institute of Toxicology. He was a productive chemist and has many publications to his credit, the majority dealing with agricultural products.

Sestini irradiated santonin in 65% aqueous ethanol and obtained "photosantonin", which he later recognized as a diethyl ester that could be converted into a lactone/acid (photosantonic acid). The latter was prepared directly by irradiation of santonin in 80% acetic acid. These pioneering studies provided the decisive stimulus for Italian photochemistry. When *Sestini* came to Rome, his path crossed that of *Cannizzaro* and he roused his interest in the challenging problems posed by the structure of santonin and its photoproducts. They jointly published one paper,[33] and in the following years, pursued the problems independently.



Cannizzaro (Fig. 8) and his co-workers confirmed the formation of photosantonic acid and discovered a new photo-

Fig. 8. *Stanislao Cannizzaro* (1826–1910), known for the base induced "disproportionation" reaction of benzaldehyde named after him and for the elegant treatise on molecular theory which he presented at the 1860 Karlsruhe Congress, studied the structures of santonin and two of its photoproducts, photosantonic acid and isophotosantonic acid. In his laboratory *Giacomo Ciamician* first became acquainted with photochemical experiments.



product, which they called isophotosantonic acid.[37–40] These products were well characterized by their composition, crystal properties,[41] solubilities, optical rotations,[42] and by the properties of their salts.[35] Based on these data *Cannizzaro* recognized the relation of the santonin skeleton to naphthalene, but the correct position of the functional groups in this skeleton eluded him. We illustrate the difficulty of this assignment by the structures proposed by *Cannizzaro* and *Fabris*[40] in 1886 and by *Gucci* and *Grassi-Cristaldi*[44] in 1891 (Scheme 1).

Aside from the unusual stereochemistry of the lactone ring, the latter authors assigned a large segment of the structure correctly and only failed to recognize one five-carbon fragment. However, their proposal did not enjoy a better reception than any of the alternative formulations, which deviate more substantially from the correct structure. Organic chemistry simply had not matured to a level that would have allowed an unambiguous assignment. The structural

Scheme 1.

and stereochemical complexity of santonin and the intriguing nature of its photoreactions would continue to puzzle chemists: the structure of photosantonic acid was elucidated only in 1958[45,46] and the intermediates in its formation were not identified until 1963 (Scheme 2).[47,48]

Scheme 2.

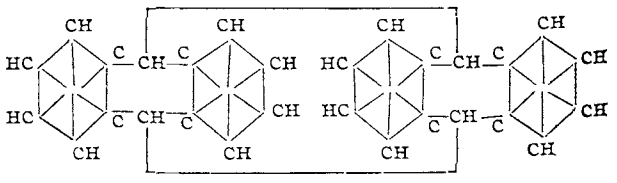
Throughout twenty years of investigating santonin and its photoproducts, *Cannizzaro* always gave *Sestini* credit for the discovery of photosantonic acid, and *Sestini* emphasized his priority.[34] *Sestini*'s importance in the history of photochemistry can hardly be overestimated: he deserves credit for having introduced *Cannizzaro* to light reactions and, through him, *Ciamician* and *Silber*.

5. Early Photodimers—Contributions by *Fritzsche* and *Liebermann*

Among the photoreactions, which first revealed themselves by the precipitation of less soluble products, dimerizations are the chief examples. The earliest laboratory photodimerization was that of anthracene, observed by *Fritzsche* in Petersburg in 1867.

Carl Julius Fritzsche (in the Russian literature *Yulii Fedorovich Fritzsche*, 1808–1871) was a student of *Mitscherlich*. After completing his studies he moved to Petersburg, where he worked for thirty-five years (1834–1869). He was concerned mainly with organic chemical problems, for example he was the first to recognize aniline as a degradation product of indigo. However, he also described the gray modification of tin (tin pest) and deserves credit for his early

work on donor-acceptor complexes. As early as 1857 he had observed and characterized 1:1 molecular complexes of picric acid with benzene, naphthalene, and anthracene.[49, 50] Remarkably, *Fritzsche* already understood these aromatics as a series of homologs:



$C_4H_4 + C_8H_2$, $C_4H_4 + 2\,C_8H_2$, and $C_4H_4 + 3\,C_8H_2$

The discrepancy with today's formulation is due to the fact that carbon was assumed to have an atomic weight of six.

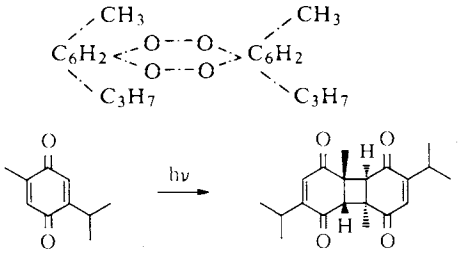
Fritzsche carried out detailed investigations of the components of coal tar. During these experiments, he noticed that some tar fractions lost their orange color upon exposure to sunlight. Although no specific reaction was associated with this "bleaching" effect, it is probably best understood as the formation of *endo* peroxides from polycyclic aromatic hydrocarbons. In connection with these experiments, *Fritzsche* noted that anthracene itself was light sensitive. "Gegen das Licht zeigt der Körper $C_{28}H_{10}$ ein sehr merkwürdiges Verhalten. Setzt man eine in der Kälte gesättigte Lösung desselben dem directen Sonnenlichte aus, so beginnt in derselben... die Ausscheidung von mikroskopischen Krystallen..."[*] Through appropriate control experiments, *Fritzsche* established that he was indeed dealing with a light induced reaction; he also noted that heating above the melting point regenerated anthracene.[51]

Fritzsche did not speculate in print about the chemical nature of the photoproduct, which he called the "para body". However, his colleague *Butlerov*, in an obituary address commemorating *Fritzsche*'s accomplishments, referred to the dimer as an "isomer", probably reflecting *Fritzsche*'s thoughts on the subject.[52] Apparently, this view was shared by a new generation of chemists,[53] and it prevailed for two more decades.

Twenty-five years after *Fritzsche*'s first report *Elbs* recognized the photoproduct as a dimer based on a molecular weight determination[54] by freezing point depression, a method that had been developed in the 1880's. Subsequently, *Linebarger*[55] as well as *Orndorff* and *Cameron*[56] proposed the actual structure (Scheme 3) which has been confirmed by an X-ray diffraction analysis.[57]

Scheme 3.

Another dimerization reaction was discovered in 1877 by *Liebermann* (Fig. 9) in Berlin. *Liebermann* was familiar with *Fritzsche*'s work and, like him, used exposure to sunlight to "bleach coal tar fractions", for example, in the isolation of chrysene.[58] Thus, the thought that light might cause chemical changes was not foreign to him. While working with

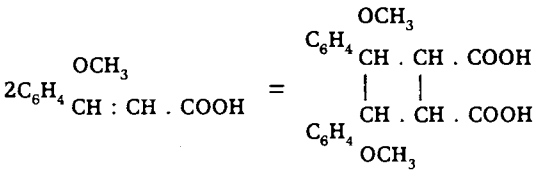


[*] "Towards light the body $C_{28}H_{10}$ shows a strange behavior. When a cold, saturated solution is exposed to sunlight, microscopic crystals begin to precipitate."

Fig. 9. *Carl Theodor Liebermann* (1842–1914), who elucidated the chemistry of many naphthalene and anthracene derivatives and had a major role in the first synthesis of alizarin as well as its industrial fabrication, carried out a greater variety of photochemical reactions than any other nineteenth century chemist.

thymoquinone, he observed that the yellow crystals under the influence of sunlight turned into a white porcelain-like mass. Through appropriate control experiments he established the conversion as a photoreaction, the first known organic [2 + 2]cycloaddition and a milestone in solid-state photochemistry.[59, 60] Of course, the elucidation of the exact structure was not achieved until much later.

Liebermann considered the compound a "polymer", a term which, at the time, would have included dimers or trimers. Concerning the structure of the photoproduct *Liebermann* noted that it was cleaved under reducing conditions. He concluded that the quinone molecules were linked through the oxygen atoms,[60] as shown below (Scheme 4). On the other hand, he had achieved the conversion of the "polymer" into a "polydioxime",[60] which suggests that the carbonyl groups are free to react and, therefore, cannot be involved in the bonding.



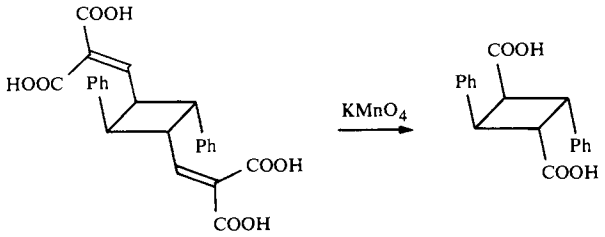
Scheme 4.

One year after *Liebermann*'s publication, *Breuer* and *Zincke* reported the isolation of a quinone, $C_{16}H_{10}O_2$, which upon exposure to sunlight gave two different "polymeric" materials.[61, 62] They did not understand the structure of the quinone, nor the nature of the photoproducts. However, they noted that one of the products readily regenerated the parent quinone upon heating, whereas the second product proved to be more stable. The quinone was later recognized as 2-phenylnaphthoquinone; the dimers likely

have cyclobutane structures.[63] A head-to-head dimer might be cleaved more readily than a head-to-tail one.

Liebermann also observed the photodimerization of styrene derivatives. In 1895, he referred to a photochemically generated "polycinnamate".[64] Also, he found that exposure of cinnamylidenemalonic acid to sunlight converted the yellow substance into a white crystalline product.[65] He suggested that this reaction was not "simply a stereoisomeric conversion" (*vide infra*) but he failed to recognize the product.

However, the credit for the first dimerization of a styrene derivative clearly belongs to *Bertram* and *Kürsten*, two industrial chemists in Leipzig.[66] Their work preceded that of *Liebermann* (though narrowly), is further reaching in its understanding, and more definitive in its conclusions. *Bertram* and *Kürsten* were working on the constituents of cassia oil when they noted that β-methylcoumaric acid slowly "polymerized" when exposed to diffuse daylight. Based upon the molecular weight they identified the product as a dimer and also recognized its structure: "this union is likely to occur by mutual saturation of the double bonds." They concluded: "Unter dem Einfluss des Lichts haben sich also zwei Moleküle der β-Methylcumarsäure zu einem Molekül der neuen Säure zusammengelagert. Diese Vereinigung wird wahrscheinlich unter Aufhebung der Doppelbindungen durch gegenseitige Sättigung stattgefunden haben, denn die polymere Säure wird nach dem Behandeln mit Brom, oder nach Einwirkung von Natriumamalgam zum grössten Theile unverändert wieder gewonnen" (Scheme 5).[*]



Scheme 5.

They extended their investigation to cinnamic acid and obtained an acid of melting point 274 °C, which they identified as α-truxillic acid.[66] It is remarkable that these chemists recognized the nature of the dimer, whereas *Liebermann* failed to recognize his "polycinnamate", in spite of his familiarity with truxinic and truxillic acids.

The photoproduct derived from cinnamylidenemalonic acid was recognized by *Rüber*, who reinvestigated this reaction with *Liebermann*'s encouragement.[67] He determined that the product had twice the molecular weight of the diolefin diacid. Permanganate oxidation of the product have rise to α-truxillic acid, establishing structure and stereochemistry (Scheme 6). *Rüber* also succeeded in converting cinnamic acid into (the same) α-truxillic acid[68] apparently unaware of the earlier work by *Bertram* and *Kürsten*. This earned him a reprimand by *Ciamician* and *Silber*,[69] who had begun an extensive study of photochemical reactions (see Section 11).

[*] "Under the influence of light, two molecules of β-methylcoumaric acid have associated. This union is likely to occur by mutual saturation of the double bonds; for the polymeric acid is recovered mostly unchanged after treatment with bromide or exposure to sodium amalgam."

Scheme 6.

Carl Theodor Liebermann[70, 71] spent his entire scientific career in Berlin at the Gewerbeakademie Charlottenburg, which later became the Technische Universität Berlin. In 1863 he was one of the first to join *Adolph Baeyer* as students; he received his doctorate in 1865. Together with *Carl Graebe* he elucidated the structure of alizarin, the active component of the natural dyestuff madder, and carried out the first successful synthesis of this dye with anthraquinone as starting material. This was a significant achievement as it was the first instance of a natural vegetable coloring matter having been produced artificially by a purely chemical method. Subsequently, in 1869, *Caro, Graebe,* and *Liebermann* patented a commercially promising procedure; their patent application (BP 1936) was received one day before that of *Perkin*'s (BP 1948).[72, 73]

In 1872, when *Baeyer* was offered the chemistry chair in Strassbourg, an event precipitated by the outcome of the Franco-Prussian War,[74] *Liebermann* succeeded him in Berlin, and he kept this position until his retirement in 1913 (Fig. 10). He was a founding member of the Deutsche Chemische Gesellschaft and held the office of president for two terms.

Fig. 10. The Geheime Regierungsrat *Liebermann*, in later years (after 1900), no longer actively pursued photochemical problems. However, he followed the work of *Ciamician* and *Silber* and exchanged with them unpublished results concerning the isomerization of oximes.

His scientific work is characterized by a wide range of interests. He developed the chemistry of anthracene and many derivatives, he discovered β-naphthylamine, and char-

acterized thiourethane and thiohydantoin and their derivatives. He was especially attracted to natural products occurring in plants, the coca alkaloids foremost among them. During this work he discovered the (*cis*-) stereoisomer of (*trans*-) cinnamic acid and also cinnamic acid crystals of two different crystal structures, without however recognizing them as such! *Liebermann* made several contributions to solution photochemistry, but his most important contributions were solid state photoreactions: the dimerization of quinones[59, 60] and styrene derivatives.[64, 65] He also evaluated the efficiency of several artificial light sources.[65]

6. Geometric Isomerization of Olefins—*W. H. Perkin* as a Photochemist

Geometric isomerization is one of the most general photoreactions of olefins. The credit for the first observation of this kind, in 1881, belongs to *Perkin* (Fig. 11). He was investigating 2-alkoxycinnamic acids obtained from coumarin and observed the conversion of several "α-acids" into their "β-isomers" upon exposure to sunlight.[75]

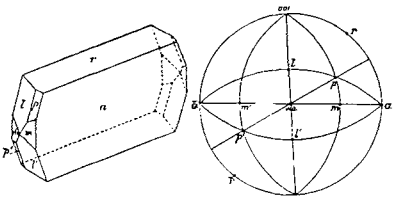


Fig. 11. *William Henry Perkin* (1838–1907), a pioneer of the synthetic dyestuff industry, was the first to observe a light-induced *cis-trans* isomerization.

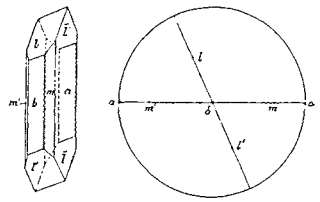
Perkin's paper is distinguished by the thorough characterization of these compounds; it contains melting points and boiling points, solubility data, specific gravity at two temperatures, magneto-optical rotation data, refractive indices, and a detailed crystallographic description (Scheme 7). This is the first reference to magneto-optical rotation, which *Perkin* soon developed into an important tool for assigning structures.[76, 77]



Perkin's paper is also of interest because he pronounced "the cause of isomerization of these bodies... unexplainable", and continued to discuss fumaric and maleic acid in "traditional" fashion (Scheme 8). Although he definitely was aware of *van't Hoff*'s 1874 paper, he apparently did not adopt the new concept of stereochemistry to his system.

Concerning the photochemical content, *Perkin* not only described the light-induced *cis-trans* isomerization, but he also studied the wavelength dependence of the photoreaction. In order "to see which rays of light caused the change", he used "variously colored solutions" as filters, of which he identified "sulphate of quinine" and "ammoniacal sulphate of copper". He concluded that "the alteration is due to the action of the violet and ultraviolet rays".[75]

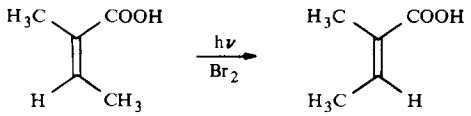
About ten years later *Liebermann* observed similar photoinduced *cis*-to-*trans* rearrangements for cinnamic and several other unsaturated acids.[78] In the course of these studies one of his coworkers tried "die für Isozimmtsäure so characteristische Umlagerung durch Jod in Schwefelkohlenstoff".[*] This led to greatly accelerated interconversions. A benzene solution of "allo"-cinnamic acid required five months of exposure to produce a 40% precipitation of cinnamic acid, whereas a solution containing iodine required only 12 days for 70% precipitation, a more than tenfold increase in rate. "Allo"-furfuracrylic acid reacted much faster, but the most rapid rearrangement was observed for "allo"-cinnamylideneacetic acid (δ-phenylpentadienoic acid), which required only one minute of exposure to produce a precipitate of the more stable isomer.[65] *Liebermann* considered the iodine assisted photoinduced isomerization a "general group reaction of the aromatic allo-acids" and suggested the most rapid conversion for a classroom demonstration.[65]

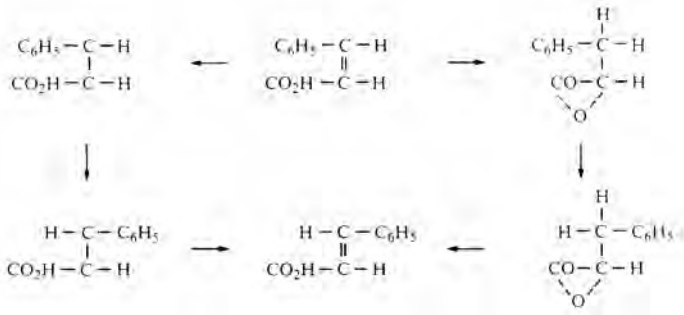


Liebermann's attempts to extend the iodine assisted photoisomerization to nonaromatic unsaturated acids did not meet with success.[65] However, *Wislicenus* (Fig. 12) achieved this interconversion. Irradiation in the presence of aqueous bromine converted isocrotonic into crotonic acid, angelic into tiglic acid (Scheme 9), and, most rapidly, maleic into fumaric acid.[79] Although *Wislicenus* is a minor contributor to the development of organic photochemistry, a few remarks about this scientist appear justifiable.

[*] "rearrangement with iodine in carbon disulfide... so characteristic for isocinnamic acid."

Fig. 12. *Johannes Wislicenus* (1835–1902), professor at Würzburg and Leipzig Universities, best known for his unsurpassed insight into stereochemical problems. His mechanism for the thermal (and light induced) isomerization of olefins is a classic of mechanistic chemistry.

Wislicenus is best known for his thorough understanding of structural and stereochemical problems. Even before the publications by *van't Hoff* and *LeBel* he had concluded: "Es muss nun unbedingt die Möglichkeit zugegeben werden, dass ... bei Körpern von *gleicher* Strukturformel ... doch noch Verschiedenheiten in gewissen Eigenschaften als Ergebnis von verschiedener *räumlicher* Anordnung der Atome ... auftreten können."[80][*]



Scheme 9.

In his involvement in photochemistry he showed the same clarity of thought and the skill that characterize his entire work. He recognized that the halogen assisted reactions do not lead to a complete conversion into the more stable isomer, but that the reverse reaction could also occur, resulting in equilibrium mixtures.[79]

Wislicenus also appears to have had a superb understanding of mechanistic problems. He perceived the mechanism of heat (or light) induced geometric isomerization as follows: "dass durch die zugeführte Energie eine solche Lockerung der doppelten Bindungen eintrete, dass die vorher doppelt gebundenen Kohlenstoffatome vorübergehend dreiwerthig werden, in Folge dessen erst eine Wanderung von Atomgruppen, dann die Drehung, und hierauf ein erneuter Zusammenschluss der Kohlenstoffatome stattfinde."[81][**] To the mechanistic chemist of the 1980's this description may lack some details, but on the whole it is quite acceptable (Scheme 10).

[*] "If molecules can be structurally identical, yet possess dissimilar properties, the difference can be explained only by a different arrangement of the atoms in space."

[**] "The added energy causes a weakening of the double bond, so that the formerly doubly bonded carbon atoms become temporarily trivalent. This leads to a migration of groups, then to rotation, and then to renewed bonding of the carbon atoms."

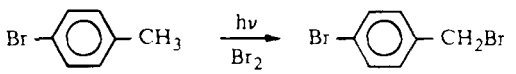
Wislicenus, 1887 — *Liebermann*, 1890

Scheme 10.

Liebermann, on the other hand, considered this mechanism too complicated. As an alternative he proposed[78] "dass die durch die gesteigerte Energie veranlasste Lockerung der doppelten Bindung dazu führt, dass sie mit Hilfe des Carboxyls thatsächlich gelöst wird, indem dessen Wasserstoff an das eine, dessen frei gewordene Sauerstoffaffinität aber an das andere der vorher doppelt gebundenen Kohlenstoffatome tritt." ... "das innere Anhydrid" ... gibt - ... "dann Gelegenheit für die Drehung des Kohlenstoffatoms in die bevorzugte Lage und für die darauf erfolgende Rückbildung der Zimmtsäure."[*] Quite obviously, this alternative mechanism is of little but historical merit (Scheme 10).

7. Photoinduced Halogenations

In connection with the halogen induced geometric isomerizations of olefins it is of interest to mention briefly the light induced halogenation of aromatic hydrocarbons. These reactions were investigated[82–85] between 1884 and 1888 by *Julian Schramm* in Lvov, the center of eastern Galica, which was then a province of Poland.



At the time it was recognized that the halogenation products of aromatic hydrocarbons varied with the reaction temperature: bromination of toluene yielded *o*- and *p*-bromotoluene in the cold, but benzyl bromide at elevated temperatures. *Schramm* systematically studied the light induced brominations of alkylbenzenes with normal and branched side chains. In the words of a contemporary reviewer "wirken ... Licht bezw. Finsterniss in derselben Richtung wie höhere bezw. niedere Temperatur."[**] *Schramm* found that direct sunlight or diffuse daylight caused side chain bromination even at low temperatures.[85]

Schramm apparently had a good knowledge of the chemical literature (which was a somewhat easier task in the 1880's than in the 1980's). He realized that *p*-bromobenzyl bromide had been isolated, though not recognized, as early as 1874 in the light induced bromination of toluene.[86] *Paul Jannasch*, in *Fittig*'s laboratory in Göttingen, tried to improve the poor yield of a dibromo derivative obtained from toluene. Ac-

[*] "... the increased energy causes the weakened double bond to be broken with the help of the carboxyl group, as its hydrogen adds to one and the freed oxygen affinity to the other carbon atom." ... "The resulting internal anhydride allows for rotation of the carbon atom into the preferred position and the regeneration of cinnamic acid."

[**] "... light and darkness work in the same way as elevated and low temperatures, respectively."

cordingly, he carried out the bromination "unter gleichzeitiger Einwirkung des directen Sonnenlichts bei Sommertemperatur."[*] In one of these experiments[86] he obtained crystals of m.p. 63 °C which *Schramm* recognized as *p*-bromobenzyl bromide (Scheme 11).

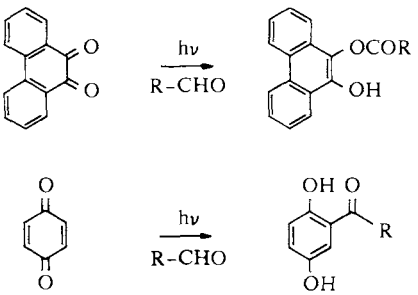
Scheme 11.

Schramm also foresaw the commercial potential of photohalogenations: "Hoffentlich wird die Methode geeignet auch zur fabrikmäßigen Darstellung der genannten Producte."[83][**] Eventually, this expectation became reality: photochlorinations have long been exploited commercially, although the reactions discovered by *Schramm* are not of industrial interest today.

8. *Heinrich Klinger*— the Photoreduction of Carbonyl Compounds

Aside from the dimerization of quinones, which is observed mainly in the solid state, photoreductions must be considered the principal light-induced reactions of quinones in solution. The credit for having observed and investigated the first reactions of this type belongs to *Heinrich Klinger*, who originated his work in *Kekule*'s institute in Bonn during an investigation of isobenzil, an assumed isomer of the long-known diketone. In an attempt to produce the supposed isomer from a solution of benzil in ether, he observed the slow precipitation of a crystalline material. However, this result was not always reproducible.[87, 88]

Among the pioneers of photochemistry, *Klinger* is the only one who relates the puzzled frustration of an experimental chemist dealing with an unknown variable and faced with seemingly irreproducible results. After "many time-consuming experiments" he finally noticed that "some of the tubes were exposed to direct sunlight in the morning hours".[88] He identified the crystals as a molecular complex of two moles of benzil with one mole of benzoin and concluded that "sunlight causes a partial reduction of benzil dissolved in wet ether".[88]



Having recognized the reducing action of sunlight on benzil, *Klinger* carried out analogous experiments with phenanthrenequinone with similar results (Scheme 12). He also began to investigate the role of the solvent and he reported the existence of preliminary results for benzoin, nitro compounds, several quinones, fuchsone, etc. *Klinger* first reported these results in preliminary form in *Sitzungsberichte der niederrheinischen Gesellschaft für Natur- und Heilkunde* in 1883 and 1885;[87] he formally published them in *Berichte* in 1886.[88] There is very little doubt that *Klinger* had priority over *Ciamician* (see Section 9), albeit by a narrow margin.

Scheme 12.

Two years later he reported an interesting extension of his work. When he replaced the ether by acetaldehyde "um dadurch die Arbeit des Sonnenlichts gleichsam zu erleichtern"...[*] he observed: "Die Wirkung des Lichts ist ... eine ganz eigenartige, synthetische, wie sie ... bisher nur in der lebenden Pflanze beobachtet wurde; ... als die beiden Substanzen sich zu einer Verbindung vereinigen, in welcher das Chinon als reducirt, der Aldehyd dagegen als oxydirt erscheint."[89][**] The product observed in this light-induced reaction, monoacetylphenanthrenehydroquinone, was indeed a new type of photoproduct.

Klinger extended the reaction to a series of aldehydes and ketones and also investigated alternative quinones. The reaction of benzoquinone with benzaldehyde proved to be particularly interesting.[90, 91] The product isolated in this reaction, 2-benzoylhydroquinone (or 2,5-dihydroxybenzophenone), established an interesting variation of the phenanthrenequinone derived product (Scheme 13). *Klinger* referred to these reactions as "Synthesen durch Sonnenlicht" (syntheses by sunlight); he must be considered the first to have exploited photochemical methods for synthetic purposes. He perceived these reactions as similar to the photosynthesis of the living plant.[90–92]

Scheme 13.

To probe this similarity further he investigated the wavelength dependence by using aqueous solutions of inorganic ions as filters, including cuprous ammonium sulfate and potassium dichromate solutions. He noted that the photochemical response of the quinones was most pronounced in the blue region, whereas green plants showed optimum response in the red region of the spectrum.[89]

Although the photoreactions discovered by *Klinger* give rise to products that appear to be widely different, it is clear that their formation is initiated by a common mechanism. The photoexcited quinone reacts with the various substrates by hydrogen abstraction, and the resulting radicals form the isolated products by recombination, disproportionation, or by free radical addition or abstraction.

Heinrich Konrad Klinger (1853–1945) studied in Leipzig and Bonn and received a doctorate in 1875 in Göttingen as

[*] "... at summer temperatures under simultaneous exposure to direct sunlight."

[**] "Hopefully, this method could prove suitable for the industrial preparation of these products."

[*] "... to facilitate the work of the sunlight."

[**] "The effect of light is a strange synthetic one ... with precedent only in the living plant ... as the two compounds are joined to form one, in which the quinone appears reduced but the acetaldehyde oxidized."

a student of *O. Wallach*. It is an interesting coincidence that *Klinger* received his doctorate (Fig. 13) in Göttingen in the same year in which *Jannasch*[86] published his light-induced experiments. We do not know whether *Klinger* knew of this work, whether he interacted with *Jannasch*, or even met him at all. He had carried out his thesis work in Bonn and received his degree in Göttingen only because his mentor had moved there.

Klinger returned to Bonn, where he rose to direct the pharmaceutical chemistry branch. In 1896 he accepted a call or, more correctly, followed a ministerial order to Königsberg (Fig. 14), where he served as director of the pharmaceutical laboratory and professor of chemistry. Following his retirement in 1922, he lived to the age of almost 92. He died on March 1, 1945 in East Prussia during the destructive climax of World War II.

9. *Ciamician* and *Silber*—an Early Episode

It was in *Cannizzaro*'s Istituto Chimico della Regia Universita in Rome that *Ciamician* and *Silber* were first introduced to photochemical reactions. It would have been hard to overlook an effort involving ... "one kilogram of santonin dissolved in 52 liters of acetic acid ... exposed to sunlight in several bottles".[40] Nevertheless, their interest was aroused only slowly. When they joined *Cannizzaro*'s group in 1881, they first focussed their attention on pyrrole chemistry. They produced a sizeable body of work, which earned *Ciamician* the Gold Medal of the Regia Accademia dei Lincei in 1887.

In the summer of 1885 *Ciamician* (Fig. 15) began some photochemical experiments[93, 94] and the following year *Silber* joined in the investigations.[95] *Ciamician* "insolated"

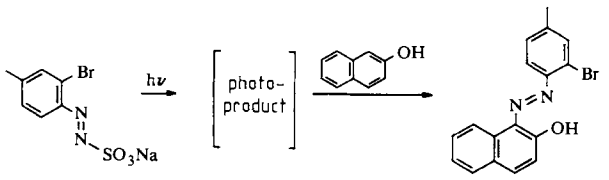
(exposed to sunlight) alcoholic solutions of benzoquinone. After five month's exposure he observed conversion into hydroquinone and acetaldehyde. The following year *Silber*

exposed an alcoholic solution of nitrobenzene. This reaction produced aniline and acetaldehyde, but the exceptionally skilled *Silber* also found evidence for the formation of 2-methylquinoline (quinaldine, Scheme 14).

Scheme 14.

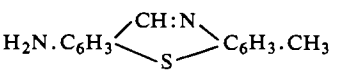
These were interesting and promising results, and the two investigators must have had every intention to follow up these early findings. However, their first engagement in photochemical research was not destined to be of extended duration. The limitation of their initial efforts had its roots in the custom of nineteenth century chemistry that allowed a researcher to "reserve" a field for continued investigation. Most respectable scientists honored such a claim (chemistry has indeed come a long way in the last one hundred years).



After reporting his first results in the *Rendi conti della Regia Accademia dei Lincei* on January 3, 1886,[93] *Ciamician* became aware of *Liebermann*'s 1885 publication.[60] He must have considered the potential overlap between *Liebermann*'s solid state photodimerization and his own photoreduction in solution and must have been satisfied that these two areas were sufficiently different. He rushed his work to publication in the *Gazzeta Chimica* "per acquistare il diritto di continuare le mie ricerche intraprese..."[*] even though he had not yet proven that the observed redox reaction was indeed a photoreaction ("That the conversion is indeed caused by light will be ensured by repeating the experiment in the dark").[94] However, before *Ciamician*'s *Gazzetta* paper was reviewed in *Berichte, Klinger*'s work on the reaction of phenanthrenequinone appeared, in which *Klinger* claimed this area of research for himself, including specifically the photoreduction of nitrobenzene.[88]

There is very little doubt that *Ciamician*'s experiments in Rome were carried out independent of *Klinger*'s studies in Bonn. The *Rendi conti* publication[93] appeared only a few months later than *Klinger*'s *Sitzungsbericht* of 1885.[87b] Nevertheless, *Ciamician* and *Silber* honored *Klinger*'s claim graciously. They sent a brief summary of their preliminary work to *Berichte;* it contained the previously missing control experiment for the benzoquinone photo-reduction and a brief account of the nitrobenzene reduction. They announced that, for the time being, they would not pursue the subject any further and concluded: "Wir sehen mit grossem Interesse den Resultaten der weiteren von Hrn. *Klinger* in Aussicht gestellten Untersuchungen entgegen."[95][**]

We do not know whether they took this action readily or whether they may have been persuaded by *Cannizzaro*, who had been elected to honorary membership in the Deutsche Chemische Gesellschaft in 1873. The fact remains that *Ciamician* and *Silber* did not publish another photochemical paper until fourteen years later. It also is obvious that *Ciamician* and *Silber*, having obeyed research etiquette themselves, expected similar consideration. Their major body of photochemical work in the early 1900's contains several quick rebuttals and some polemics, particularly against *Ciamician*'s compatriot *Paterno*.



10. Photochemistry of Diazo and Diazonium Compounds

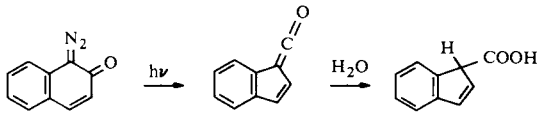
Because of their practical importance as photoresist materials and their significance as precursors for divalent-carbon species, it appears appropriate to discuss briefly the photoreactions of diazo compounds and of the somewhat related diazonium salts. This class of compounds became accessible through the pioneering studies of *Peter Griess* beginning in 1858.[96] Although it is not clear when their sensitivity to light was first noticed, attempts to utilize them for the purpose of imaging are documented as early as 1889. *Adolf Feer* noticed that irradiation of diazonium sulfonates, $R-N=N-SO_3Na$, in the presence of phenolates or arylamines led to the formation of azo dyes, presumably via the free diazonium ion. After a film containing these reagents was exposed, unreacted diazonium sulfonate could be removed by washing, leaving a colored negative (Scheme 15).[97]

Scheme 15.

Only a year later, *Green, Cross* and *Bevan* received a patent for a process generating a positive image based on the fact that irradiation converts the diazo compounds of "dehydrothiotoluidine" (primulin) into products incapable of coupling. After exposure, an image could be "developed" by converting the unreacted diazonium compound to an azo dye with an appropriate reagent (Scheme 16).[98]

Scheme 16.

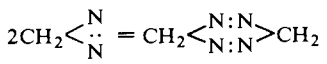
It is indicative of the progress of photochemistry that in 1890 *Green* and colleagues no longer considered mere light sensitivity noteworthy. They were concerned with the practical exploitation of this property: "Von den zahlreichen Verbindungen, welche lichtempfindlich sind, erfüllen nur wenige die Bedingungen zur Erzeugung eines photographischen Bildes..."[98][*] Other imaging systems were proposed by *Andresen*,[99] *Schön*,[100] and *Ruff* and *Stein*.[101]



Diazoketones have been known since 1881 when *Schiff* prepared diazocamphor,[102] and by the turn of the century several such compounds were known.[103, 104] However, commercial application in diazo-type manufacture became possible only after *Kögel* and *Neuenhaus* had introduced ap-

[*] "... to ensure the unencumbered continuation of my research."

[**] "We are looking forward with great interest to the results of the further experiments delineated by *Klinger*."



[*] "Among the many compounds that are light sensitive only a few meet the requirements for generating a photographic image..."

propriately substituted "naphthoquinone diazides" (1-diazonaphthalene-2(1*H*)-ones).[105] The nature of their photoproducts and the course of the reaction was elucidated by *Oscar Süs*,[106] who recognized that these materials undergo Wolff rearrangement with loss of nitrogen and ring contraction, generating a ketene. Reaction with adventitious water produces a carboxylic acid which can be removed by an alkaline wash (Scheme 17). The application of this photochemistry for positive photoresist materials has become a multimillion dollar industry.

Scheme 17.

Concerning other diazo compounds, despite their pronounced light sensitivity, their photoinduced decomposition was not discovered until early in the 20th century. Several diazo compounds were synthesized in the 1880's.[107–109] For example, ethyl diazoacetate was prepared by *Curtius* in 1883;[107] diazomethane was obtained by *von Pechmann* in 1894;[110] neither publication mentions any light-induced reactions.

Scheme 18.

The first reference to the irradiation of diazomethane appeared in 1901 when *Hantzsch* and *Lehmann* reported that the action of sunlight upon the diazo compound generates dihydrotetrazine (Scheme 18).[111] This interesting claim was corrected when *Curtius* et al. found only nitrogen, ethylene, and a very low yield of a greasy residue.[112] Although this paper must be considered an early report on poly(m)ethylene, it stimulated neither polymer nor carbene chemistry. We ascribe this fact to the lack of appreciation for the unique nature of divalent-carbon intermediates and to a failure to understand the relation between diazo compounds and carbenes.

11. Conclusion

At the end of the nineteenth century photochemistry was but a modest facet of the exciting and rapidly expanding science of chemistry. The principal contributors studied photochemical problems only as an aside to the work for which they were (and still are) best known. Only a limited number of reactions were known, and the sun was virtually the exclusive light source; its light was used unfocussed and unfiltered.

Only *Liebermann* experimented with alternative light sources, particularly with an arc lamp, a gas burner with a metal oxide mantle, and a magnesium flame; his results were far from promising.[65] *Trommsdorff* had evaluated the wavelength dependence of a photoreaction with the help of a prism;[30] *Perkin*[75] and *Klinger*[89] used filter solutions. *Perkin* also mentions an experiment in which "light was concentrated on..." a sample, an obvious reference to a focussing device.[75]

On the other hand, several of the general reaction types known today had been encountered. When *Liebermann* discovered the iodine mediated photoisomerization of olefins, he subjected a representative cross section of then known photoreactions to the newly found reaction conditions.[65] He surveyed three dimerizations and one rearrangement, but did not refer to abstraction or transfer reactions, such as those studied by *Klinger* and *Ciamician*; the fourth general reaction type, photocleavage, had yet to be discovered.

Organic photoreactions were being utilized for the purpose of imaging,[97–101] and *Klinger* et al.[89–91] and *Schramm*[85] had pointed out, respectively, the preparative and industrial prospects of photochemistry. All these facts suggest that the time was ripe for an outstanding scientist who would devote a major effort to organic photochemistry and establish it as a major scientific discipline.

With the advent of the twentieth century *Ciamician* (Fig. 16) and *Silber* began a systematic investigation of photochemical reactions. Their achievements far surpassed any

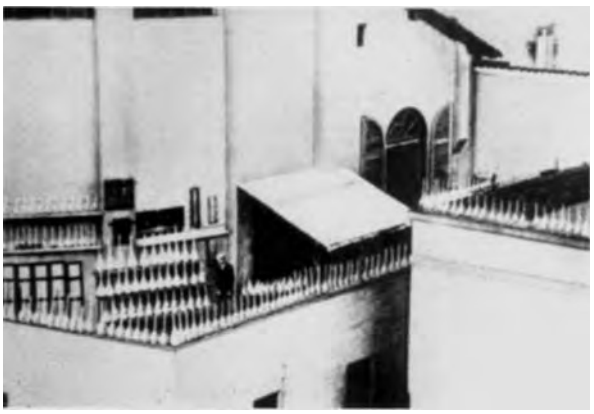


Fig. 16. *Ciamician* in his "laboratory", on the roof of the chemistry building in Bologna. The Dipartimento di Chimica "G. Ciamician" in the Via Selmi in Bologna is a fitting memorial to this pioneer of photochemistry.

previous effort and established photochemistry as a major branch of chemistry. In particular, they provided many examples of ketone photochemistry: in addition to photoreductions (vide supra) they discovered photopinacolization, intramolecular cycloadditions, and both α- and β-cleavage. These systems would later prove to be of great importance for the development of molecular photochemistry, as they revealed many fundamental principles, for example, the concepts of singlet and triplet as well as n,π* and π,π* states.

Ciamician and *Silber* reported their findings in two parallel series of thirty-seven publications entitled "Azione Chimiche della Luce" in *Gazzetta Chimica Italiana* and "Chemische Lichtwirkungen" in *Berichte der deutschen chemischen Gesellschaft*. These papers deal with an astonishing variety of systems and document unmatched skills in the separation of sometimes complex product mixtures, unprecedented understanding in the identification of the components, and unparalleled insight into the nature of photo-

chemical reactions. However, *Ciamician*'s crowning achievement was the truly astonishing lecture he delivered before the International Congress of Applied Chemistry in New York in 1912. Under the title "The Photochemistry of the Future" he summarized the status which photochemistry had attained in little more than a decade chiefly through his and *Silber*'s efforts and revealed his prediction of its future. He emphasized particularly the utilization of solar energy which he deemed second only to nuclear energy.[113] We note that *Ciamician* is not the first to have entertained the thought of solar energy conversion. *Swift* described *Gulliver*'s encounter with a Lagadoan academician "upon a project for extracting sunbeams out of cucumbers"[114] and *Goethe*'s Faust yearned for "Bäume, die sich ewig neu begrünen", a task, incidentally, which Mephisto thought achievable: "Ein solcher Auftrag schreckt mich nicht, mit solchen Schätzen kann ich dienen".[115] Of course, *Ciamician* was the first to put this dream on a rational basis. It is a testimony to *Ciamician*'s vision that more than three quarters of a century after his prophetic lecture the promise of harvesting solar energy has yet to be fulfilled.

The author is indebted to numerous colleagues for making available original literature and for stimulating discussions and helpful suggestions, especially Professor William Agosta, New York, Dr. E. A. Chandross, Murray Hill, NJ, Professor Arthur Greenberg, Newark, NJ, Professor Ned Heindel, Bethlehem, PA, Professors G. O. Schenck and K. Schaffner, Mülheim, and Ms. Thelma McCarthy, Philadelphia, PA. He also gratefully acknowledges the following for providing illustrations: Professor A. Greenberg for Figures 2 and 4; Professors F. Calderazzo, G. Lotti, and Mrs. M. G. Venditti for Figure 7; Professor W. Rettig, Berlin, for Figure 11; Dr. P. Schmidt, Archiv der Universität Bonn, for Figures 13 and 14; Professor N. D. Heindel for Figures 15 and 16. Figures 1, 3, 5, and 10 are reprinted from the collection of the author, and Figures 8, 9, 12 are reprinted courtesy of the E. F. Smith Memorial Collection, The Beckman Center for the History of Chemistry, University of Pennsylvania.

Single-Source III/V Precursors: A New Approach to Gallium Arsenide and Related Semiconductors

By Alan H. Cowley* and Richard A. Jones*

Until recently, the production of gallium arsenide, indium phosphide, and related compound semiconductors has fallen in the domain of the materials scientist and the electrical engineer. By clever use of classical chemistry, exemplified by the thermal reaction of Me_3Ga and AsH_3, it is possible to make semiconductors on a commercial scale. However, there are some drawbacks associated with the existing methodology, including the environmental and health hazards of handling pyrophoric and toxic starting materials as well as stoichiometry control problems and undesirable side reactions. Can the synthetic inorganic and organometallic chemist play a useful role in this important area by designing and developing new reagents for the production of semiconductor materials? We believe the answer is yes, and in this article we discuss a new approach to the preparation of GaAs and InP thin films based on single-source precursors. These compounds feature strong σ-bonding between the group III and V elements, together with substituents that are capable of facile thermal elimination. The III/V precursors are more stable toward air and moisture and considerably less toxic than either adducts or mixtures of group III and V compounds.

1. Introduction

Group III/V semiconductors[1] have received much attention due to their usefulness in high-speed digital circuits, microwave devices, and optoelectronics. Several techniques have been employed for the preparation of thin films of these materials, including organometallic chemical vapor deposition (OMCVD) and molecular beam epitaxy (MBE).[2] The OMCVD method is often preferred for larger scale processes and typically involves the reaction of a group III trialkyl such as Me_3Ga with a group V hydride such as AsH_3 or PH_3 at elevated temperatures (600–700 °C).[3] A carrier gas such as H_2, He, or N_2 is used to sweep the volatile species through the reaction chamber. The most studied reaction is that of Me_3Ga and AsH_3 to produce GaAs [Eq. (a)].

$$Me_3Ga + AsH_3 \rightarrow GaAs + 3\,CH_4 \qquad (a)$$

There are a number of important disadvantages to the conventional OMCVD method. Alkyls of the group III elements tend to be pyrophoric and group V hydrides such as AsH_3 are extremely toxic. Apart from the potential environmental, safety, and health hazards of handling these reagents, the conventional OMCVD methodology also suffers from several other drawbacks. The high reactivity of these compounds makes them difficult to purify and handle and, once purified, they tend to react with their storage containers, thereby introducing new contaminants.[4] Other problems include carbon incorporation[5] and the difficulty in maintaining the desired film stoichiometry when growing ternary and quaternary compounds. The production of nonvolatile species via reagent prereactions has also proved to be a difficulty in the growth of InP, although this problem seems to have been overcome recently by the use of higher purity reagents.[6] Finally, the high temperatures involved in some OMCVD processes can promote interdiffusion of layers and dopants which prevents sharp heterojunctions from being achieved.

Attempts to grow superior films by modifications of the conventional OMCVD process include low-pressure,[7] plasma-enhanced,[8] and rapid thermal OMCVD systems[9] as well as hybrid MBE-OMCVD systems.[10] Several groups of workers have investigated the use of alternative sources of both the group III and group V components. Group V sources that have been investigated include Me_3P, Et_3P, $tBuPH_2$,[11] $tBuAsH_2$,[12] and Et_2AsH.[13] Group III alkyls have generally been limited to trimethyl and triethyl derivatives.[14]

The use of group III adducts has also been explored, both as direct replacements of the group III alkyls and as high-purity sources of the latter.[15] Adducts such as $Me_3In \cdot PEt_3$, for example, are less air sensitive than their components and are correspondingly easier to handle and purify.[4] A further advantage of the use of adducts is that troublesome prereactions tend to be avoided.[6] However, the donor–acceptor bonds in the adducts are generally considered to be weaker than the other bonds present (such as Ga-C or As-H).[16] As a consequence, dissociation of the adduct can occur and, typically, an excess of PH_3 or AsH_3 is necessary for the production of satisfactory III/V films.

It occurred to us that some of the problems outlined above might be overcome by the use of single-source III/V precursors of the general type $(L_nMEL'_n)_x$ which feature the desired 1:1 stoichiometry of the group III (M) and group V (E) elements. Our strategy was to cause the M–E bonds to be as strong as, or stronger than, the other bonds in the cluster by employing two-center, two-electron (σ) bonds rather than the donor–acceptor linkages found in adducts. We also sought ligands, L and L′, which are capable of facile hydrocarbon elimination. This review describes the progress which has been made with this approach.

2. Synthesis of Precursors

Although this article is concerned with the heavier group III elements Ga and In, it is appropriate to mention that the trimer $[Me_2AlPMe_2]_3$ was prepared almost 50 years ago via the thermal reaction of Me_6Al_2 with Me_2PH.[17, 18] In the 1960s *Coates* et al.[19, 20] employed this alkane elimination method to prepare similar gallium and indium derivatives [Eq. (b); M = Ga, In; E = P, As; R = Me, Ph]. The aryl

$$Me_3M + R_2EH \longrightarrow \tfrac{1}{n}(Me_2MER_2)_n + CH_4 \qquad (b)$$

compounds (R = Ph) were reported to be dimeric (n = 2), while the corresponding alkyl compounds were polymeric glasses in the condensed phase, but trimeric in solution. The analogous reactions of Me_3M with primary phosphanes and arsanes afforded nonvolatile polymers.

Our initial approach to 1:1 precursor formation was to treat $GaCl_3$ with one equivalent of tBu_2ELi (E = P, As) and two equivalents of RLi (R = Me, *n*Bu) in toluene or THF solution at −78 °C [Eq. (c); salt elimination].[21] Subsequently, this method has been extended to the synthesis of the corresponding indium compounds.[22, 23]

1-4

A wide range of 1:1 precursors has now been prepared using both salt and alkane elimination methods (Table 1). As first noted by *Wells* et al.,[29] the alkane elimination method becomes very sluggish and therefore impractical when the steric bulk of the substituents increases. In such cases, silyl halide elimination methods can be very useful (Table 1). In

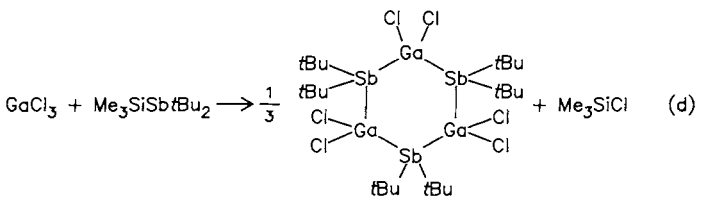
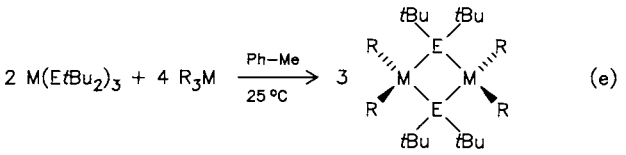
[a] A, alkane or arene elimination; B, salt elimination; C, silyl halide elimination; D, $M(EtBu_2)_3 + R_3M$.



Alan H. Cowley was born in Manchester, England, in 1934. His formal education was obtained at the University of Manchester, where he received the Doctor of Philosophy in 1958. He was a Postdoctoral Fellow at the University of Florida during the period 1958–1960, and from 1962 to 1988 he was professor at The University of Texas at Austin. In 1988 and 1989 he was the Sir Edward Frankland Professor of Inorganic Chemistry at Imperial College, London. Effective September 1, 1989, he has been appointed to the Robert A. Welch Chair of Chemistry at The University of Texas at Austin. Alan Cowley has received several awards, including the Royal Society of Chemistry Award for Main-Group Element Chemistry (1980), the Centenary Medal and Lectureship of the Royal Society of Chemistry (1986), and the American Chemical Society Southwest Regional Award (1986). He was elected a Fellow of the Royal Society in 1988 and serves on the editorial boards of many journals.

Richard A. Jones was born in Abingdon, England in 1954. His university education was at the Imperial College of Science and Technology, London, where he received the Doctor of Philosophy in 1978 (supervisor Professor Sir Geoffrey Wilkinson). He joined the University of Texas at Austin in 1980 and was appointed to Full Professor in 1988. He received the 1983 Meldola Medal and Prize (awarded by the Royal Society of Chemistry in concurrence with the Society of Maccabaeans). He has authored and co-authored over 110 publications in transition-metal and main-group organometallic and coordination chemistry.



our own work we have found that the silyl elimination is preferable to salt elimination for the synthesis of antimony-containing complexes [Eq. (d)].[35] An alternative and novel

(d)

7

method for the synthesis of alkylated derivatives involves comproportionation of the $M(EtBu_2)_3$ unit accompanied by alkyl group transfer from R_3M [Eq. (e)].[22] Interestingly,

(e)

1, 3, 5, 8

the reaction of $M(EtBu_2)_3$ with less than two equivalents of R_3M leads only to mixtures of $[R_2M(\mu\text{-}EtBu_2)]_2$ and unreacted $M(EtBu_2)_3$.

Thus far, only four compounds of 1:2 stoichiometry have been prepared using either salt or silyl halide elimination methods (Table 2). Compound **9** is noteworthy since it is the first antimonido derivative of In^{III}.[37] The anion of the salt $[V_2(\mu\text{-}Cl)_3(thf)_6][Ga(PtBu_2)_2Cl_2]$ also features a 1:2 stoichiometry. This compound results from the reaction of $Ga(PtBu_2)_3$ with VCl_3 in THF solution.[38]

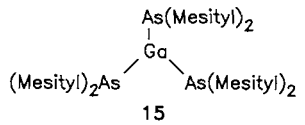
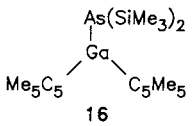
[a] A, alkane elimination; B, salt elimination; C, silyl halide elimination.



Complexes of 1:3 stoichiometry have been prepared either by salt elimination or silyl halide elimination methods (Table 2). Steric effects play a role of obvious importance because the reaction of Ph_2ELi with MCl_3 in 3:1 stoichiometry results only in intractable, apparently oligomeric, materials.[41] Interestingly, however, treatment of MCl_3 with Ph_2ELi in 1:4 stoichiometry affords the "ate" complexes **10**–**12**.[41] By contrast, it is not possible to make the corresponding "ate" complexes using the bulkier $EtBu_2$ ligands. As pointed out above, the complexes of 1:3 stoichiometry, $M(EtBu_2)_3$, are useful for synthesizing 1:1 complexes by treatment with R_3M. Such a method is also applicable to the synthesis of all six mixed metal dimers in the series $Me_2M(\mu\text{-}EtBu_2)_2M'Me_2$ (M, M' = Al, Ga, In; E = P, As) as well as heterodinuclear ethyl derivatives from Et_3Al.[42] The sole example of a 3:1 stoichiometry complex, **13**, was isolated from the reaction of $(Me_3Si)_3As$ with $GaBr_3$.[43] Finally, mention should be made of the novel complex **14** ($R = Me_3SiCH_2$), which was synthesized via the reaction of $PhAsH_2$ with $(Me_3SiCH_2)_3Ga$.[40]

3. Structural Studies



Three monomers (**13**, **15**, and **16**) have been investigated by X-ray crystallography. As expected on the basis of simple electron counting procedures, **15** and **16** exhibit approximately trigonal-planar and tetrahedral geometries at Ga and

13

15

16

As, respectively.[30, 34] Note, however, that in **15** the Ga atom is located 0.149 Å out of the As_3 plane; moreover, the geometries at the As centers depart considerably from the ideal as reflected by the wide range of Ga–As–C angles (93.1(1) to 122.1(1)°). The Ga–As bond length in **16** (2.433(4) Å) and the average Ga–As bond length in **15** (2.492(1) Å) are close to the sum of the covalent radii for Ga and As (2.46 Å).[44] In **16** the conformation is such that the As lone pair lies in the mirror plane defined by the Ga and the atoms bonded directly to it, thus obviating the possibility of As–Ga dative π-bonding. In **15** the dihedral angles between the As_3 plane and the As lone pair range from 52 to 86°, and the overall conformation corresponds to that of a staggered propeller blade arrangement. The arsenic-centered monomer **13** lies on a crystallographic C_3 axis and involves a pyramidal Ga_3As skeleton with a Ga–As–Ga bond angle of 94.4(1)° and a rather short Ga–As bond length of 2.401(4) Å.[43] The geometry at each gallium is distorted tetrahedral due to coordination of a molecule of THF.

Perusal of Table 1 reveals that compounds of empirical formula RR'MER"R'" with substituents of modest size are trimeric. Increasing the steric demands of the substituents results in dimer formation. Some compounds "on the borderline" such as **17** exhibit dimer/trimer equilibria.[31]

The available structural data for dimeric compounds are summarized in Table 3 and the structure of **3**, a typical example, is illustrated in Figure 1. Both the group III and the group V atoms adopt approximately tetrahedral geometries, consistent with a mixture of canonical forms **A** and **B**. With the exception of **22**, a weakly bonded dimer,[39] the central M_2E_2 ring is planar or nearly so. Indeed, in many of the structures the planarity of the M_2E_2 ring is imposed crystallographically. The puckered Ga_2As_2 ring of **22** resembles the Ga_2S_2 ring of the bulky thiolate complex $(i\text{PrSGaI}_2)_2$.[45] However, the fold angle along the Ga–Ga vector is considerably less in **22** than in the sulfur compound (13.6 vs. 36.7°).[39] In all the dimeric structures the endocyclic bond angle at E is larger than that at M and, typically, there are two sets of M–E bond lengths. The M ··· M and E ··· E distances are sufficiently long to preclude any cross-ring bonding interactions. The average endocyclic M–E bond lengths are somewhat longer than those found in the corresponding monomeric derivatives. This is attributable to changing the hydridization of Ga from sp^3 in the dimers to sp^2 in the monomers and/or to the possibility of dative E → M π-bonding in the latter. In a similar context, note that some of the compounds in Table 3 (e.g., **21** and **22**) feature exocyclic M–E bonds (Fig. 2) and that such bonds are always shorter than those within the M_2E_2 rings.

Table 3. Summary of structural data for the dimers $(RR'MER''R''')_2$. The average values of the bond lengths [Å] and bond angles [°] are given.

Steric effects are manifested in substantial changes in the exocyclic RMR' and R"ER'" angles. In fact, the M_2E_2 ring angles are remarkably constant. In cases where there is a choice between a bridging halide or a bridging R"R'"E moiety, the latter is always favored. The use of models indicates that this preference, together with the mutually *trans* disposition of the exocyclic R"R'"E groups, results from the minimization of steric repulsions.

It is apparent from Table 4 that several conformations of the six-membered M_3E_3 rings are close in energy. The case of

[a] Calculated from IR data. [b] Two crystallographically independent molecules. [c] Planar and puckered froms present in same asymmetric unit.

28 is particularly interesting because of the presence of two independent conformations in the same asymmetric unit (Fig. 3).[35] One molecule adopts an approximately planar conformation, the deviations from the least-squares In_3As_3

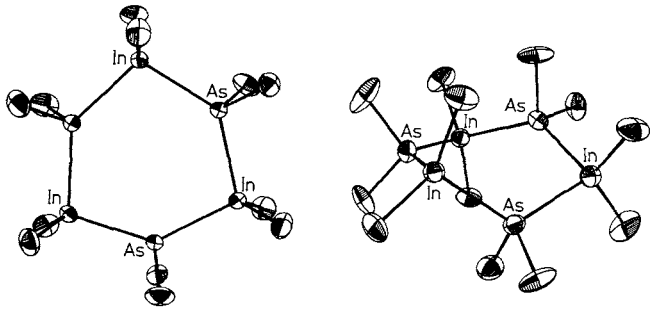

Fig. 3. Crystal structure of $[Me_2InAsMe_2]_3$. The planar conformer is shown on the left and the puckered conformer on the right.

plane ranging from 0.097(4) to −0.139(3) Å. The other molecule possesses a puckered six-membered ring. The three In atoms and one of the As atoms are virtually coplanar and the two remaining As atoms are located above and below this plane by 1.037(4) and 1.252(3) Å. Interestingly, the overall geometry of the puckered In_3As_3 core resembles those of some d-block phosphido derivatives such as $[Co\{\mu\text{-}P(C_6H_{11})_2\}(CO)_2]$.[46]

As expected on the basis of conformational flexibility, there is a wide variation in the endocyclic MEM and EME angles (Table 4). The average M–E bond lengths for the trimers are shorter than those of the corresponding dimers. In addition to the relief of steric strain in passing from the dimer to the trimer (i.e., bulky substituents lead to dimer formation), electronic effects also appear to be important. Comparing **27** and **7** (both trimers), we note that the Ga–Sb bond is longer in **27**. We attribute this to the greater electronegativity of Cl, which causes the Ga atomic radius to be smaller. Thus, the Cl and Me ligands are approximately the same size, yet the average Ga–Sb bond length in **27** is ca. 0.06 Å longer than that in **7**. Finally, we note that the In–As and In–Sb distances in Table 4 are the first such bond lengths other than those in InAs and InSb.[47]

Two further structural types have been investigated. The structures of the salts **10**–**12**[41] are of interest because GaP, GaAs, InP, and InAs all feature tetracoordinate structures of the zinc blende type.[47] The "ate" anions possess approximately tetrahedral geometries at the M and E centers (Fig. 4); however, the EME angles, for example, range from 97.3(1) to 116.0(1)°. Although the overall symmetry of these anions is C_1, in each case three of the four EPh_2 groups are related approximately by a C_3 axis. The relatively unsymmetrical structures of the $[M(EPh_2)_4]^{\ominus}$ ions contrast with those of the tetraamide and tetraphosphide transition-metal derivatives (D_{2d} skeletal symmetry).[48] The average M–E bond lengths of the group III/V anions are shorter than those of the neutral dimers (Table 3) but slightly longer than those found in GaP (2.360 Å),[47] GaAs (2.448 Å),[47] or InP (2.541 Å).[47] The structure of the "ate" complex $[V_2(\mu\text{-}Cl)_3(thf)_6][Ga(PtBu_2)_2Cl_2]$ has also been determined.[38]

The structure of the cluster **14** (R = Me_3SiCH_2) involves two nonplanar Ga_2As_3 rings.[40] These rings are linked by

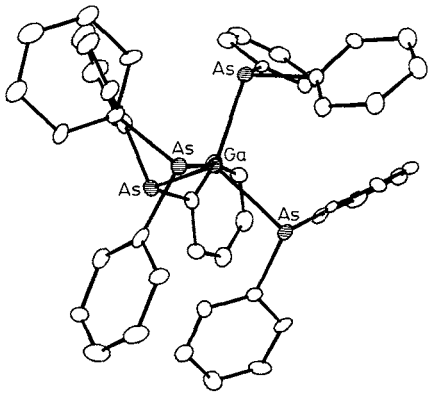

Fig. 4. View of the anion of **11** in the crystal.

two Ga–As bonds and bridged by a Ga–As unit. The average Ga–As bond length of 2.503 Å lies between the ranges found for monomeric and dimeric derivatives.

4. Spectroscopic Aspects

NMR studies have been particularly useful for discerning the structures of the III/V precursors in solution. For example, although X-ray crystallography indicates a *trans* solid-state structure for $[tBu_2GaP(H)C_5H_9]_2$ **18**, two resonances are apparent in the ^{31}P NMR spectrum at 25 °C.[26] Although specific assignments were not made, these signals were attributed to the presence of *cis* and *trans* isomers (Table 5). In the case of **21**, it was possible to assign these

12	− 30.2	[41]

[a] Both *cis* and *trans* isomers are present. See text.

isomers and to estimate a *trans* → *cis* barrier of 1.3 kcal mol^{-1} using $^{13}C\{^1H\}$ NMR spectral data and assuming no difference in NOE between the *cis* and *trans* Me_3Si peaks.[31] Compounds with bridging and terminal arsenido or antimonido groups such as **9**,[37] **21**,[31] **22**,[39] and **33**[29] tend to exhibit ^1H and $^{13}C\{^1H\}$ NMR spectral equivalence of these moieties at or above ambient temperature. Simulation of the dynamic NMR spectra of **33**, for example, provided a $\Delta G^{\neq}$ value of 17.0 kcal mol^{-1} for the exchange process.[29] As pointed out by *Wells* at al.,[31] three types of process could explain the spectral observations: dissociation into and subsequent recombination of monomers [Eq. (f)]; opening of

one bridge bond, followed by rotation and formation of a new bond [Eq. (g)]; associative processes involving, for example, pentacoordinate group III metals [Eq. (h)].

(f)

(g)

(h)

A priori it might be thought that the dissociative mechanism [Eq. (f)] is a prohibitively high-energy process. For the compounds $[(Me_3SiCH_2)_2MPPh_2]_n$ (M = Ga, In) and $[(Me_3CCH_2)_2InPPh_2]_n$, however, concentration-dependent $^{31}P\{^1H\}$ NMR peaks are detectable and have been attributed to the concomitant presence of monomers and dimers (Table 5).[27]

The ^{31}P NMR chemical shifts for the anions $[M(PPh_2)_4]^{\ominus}$ of **10** and **12** (Table 5) fall within the range anticipated for terminal phosphido groups behaving as one-electron donors[41] and are similar to that of Ph_2PLi ($\delta = -38.5$).

Compounds **31** and **32** are not suitable for X-ray diffraction study.[21,22] However, the ^{31}P NMR chemical shifts (Table 5) are in a region indicative of one-electron-donor phosphido groups. Such a conclusion is consistent with the X-ray crystal structure of **15**.[30] Interestingly, upon cooling from 25 to −95 °C, the ^{31}P NMR chemical shifts of **31** and **32** change to +39.90 and +63.68, respectively.[22] This temperature sensitivity could be due to solvent interaction ([D_8]toluene) or to rapid interconversion between one- and three-electron-donor phosphido moieties.

Given the variety of conformations for the six-membered rings, trimeric compounds of the type $(R_2MER'_2)_3$ are expected to be highly fluxional. Little NMR information is available at the present time; however, dynamic ^1H NMR data for **28** indicate that equivalent In–Me environments persist to −80 °C.[35] This observation implies either rapid interconversion of the planar and nonplanar forms or a preference for the planar conformation in solution (both forms are present in the crystal; cf. Table 4).

^{71}Ga NMR spectroscopy is potentially useful for complex characterization, but information is rather sparse at the present time. The ^{71}Ga NMR chemical shifts of $[Ga(EPh_2)_4]^{\ominus}$ in **10** and **11** have been measured.[41] The signals are quite broad ($w_{1/2} \approx 3500$ Hz), presumably as a consequence of the overall C_1 symmetry at Ga.

5. Thin Film Deposition and Characterization

Initial effort has focused on III/V precursors of the general formula $[Me_2MEtBu_2]_2$ (M = Ga, In; E = P, As).

OMCVD REACTOR SYSTEM

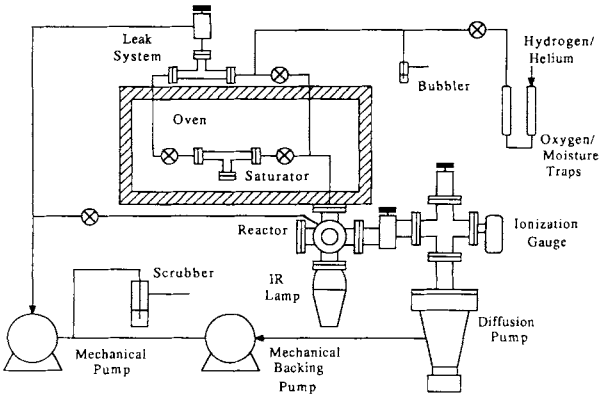

Fig. 5. Schematic drawing of a cold-wall OMCVD reactor.

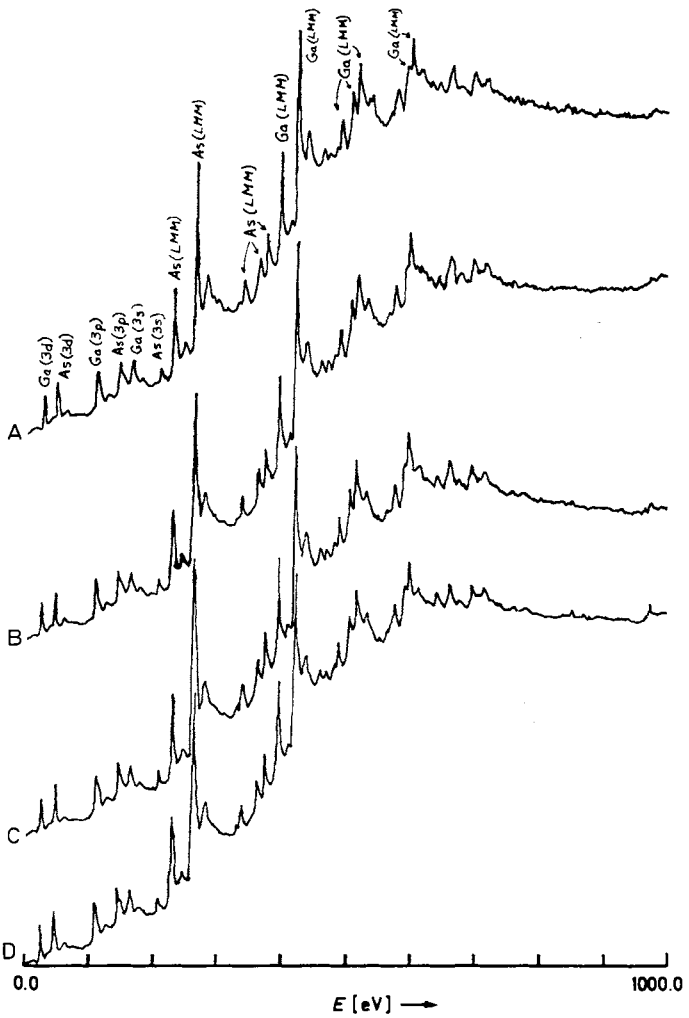
Thin films of GaAs and InP have been grown using an OMCVD cold-wall reactor (Fig. 5) which is capable of operating over the pressure range 760 to 10^{-6} torr and at temperatures up to 780 °C. Several substrates have been employed for the deposition studies:[49] quartz to identify the temperatures and pressures where the precursors decompose to produce smooth, mirrored films; Si(100) 3° off toward (011) to determine GaAs sputtering rates during X-ray photoelectron spectroscopic (XPS) studies; semi-insulating GaAs(100) and Si-doped GaAs(100) to explore whether epitaxial film growth could be achieved. The optimum conditions involved a saturator temperature of 130 °C, substrate temperatures of between 450 and 700 °C, and a total system pressure of 10^{-4} torr. Use of the foregoing conditions resulted in growth rates of 0.7 to 1.0 μm h^{-1}. Interestingly, either H_2 or He can be employed as the carrier gas, thereby implying that H_2 is not involved in the thermolysis process. Similar results were obtained using the analogous indium phosphide precursor.

The films have been investigated by an array of techniques: X-ray diffraction to establish crystallinity, XPS to determine chemical composition and gross carbon contamination, secondary ion mass spectrometry (SIMS) to identify impurities, scanning electron microscopy (SEM) to observe the morphological properties, and low-temperature photoluminescence (PL) to explore the band edge. The XPS of the GaAs films exhibit signals corresponding to Ga(3d), Ga(3p), Ga(3s), As(3p), and As(3s) ionizations which match those of a single-crystal substrate (Fig. 6). No carbon was detected in the XPS experiments and, moreover, the Ga:As atomic ratio was 1:1 within experimental error. These results contrast with the somewhat high carbon levels that were reported in an OMCVD study of $[Et_2GaPEt_2]_3$.[24]

Carbon impurity levels were tested with SIMS because XPS cannot detect less than 1000 ppm of carbon. We did not have calibration standards when the SIMS profiles were taken; however, SIMS studies of the 570 °C films showed that the films did not contain any more carbon than the electronic-grade GaAs substrates. Trace amounts of the metallic impurities Na, K, Al, Si, In, Ti, Cr, and Fe were also detected. The SIMS results are significant and demonstrate that, as expected, precursor ligand loss was complete and that carbon incorporation into the films did not occur. Most of the films have



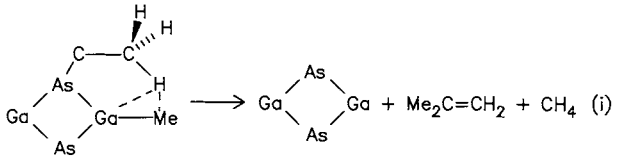


Fig. 6. X-ray photoelectron spectra of GaAs films. A: An electronic-grade sample. B: A sample grown at 700 °C with He carrier gas. C: A sample grown at 700 °C with H_2 carrier gas. D: A sample grown at 570 °C with H_2 carrier gas. E = electron binding energy.

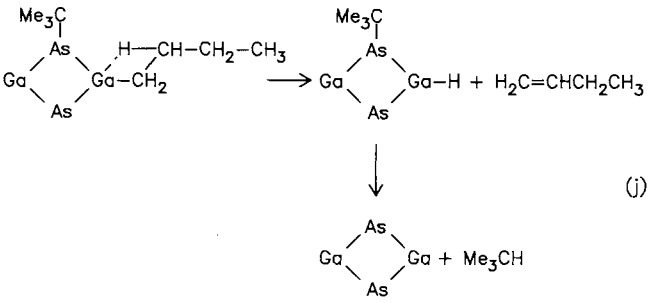
been found to be polycrystalline by X-ray diffraction; however, of key significance are low-temperature (2 K) PL measurements on films of GaAs, grown on semi-insulating GaAs(100) and Si-doped GaAs(100) at 570 °C. These materials exhibit PL signals, thus indicating that crystalline domains are present. Although the measurements indicate degeneratively n-doped material, they also show that very good Ga:As ratios and very low levels (ca. 1 ppm) of impurities have been achieved. So far, no attempts have been made to purify the precursor compounds rigorously in order to prepare films of ultra-high electrical quality. However, we believe that this will be ultimately possible.

6. Mechanistic Considerations



In designing the precursors, attention was paid not only to strong bonding within the skeleton but also to the necessity for substituents that are prone to facile hydrocarbon expulsion.

Substituents featuring β hydrogens such as *t*Bu, *n*Bu, *i*Pr, and Et appeared to provide the best option for facile thermal elimination of alkenes. Preliminary thermal decomposition studies of $[Me_2GaAstBu_2]_2$ **3** reveal that at 570 °C methane and isobutene are the principal hydrocarbons produced during film growth.[49] A plausible mechanism for the deposition of III/V films involves interaction of the group III metal with the C–H bond of a *t*Bu substituent, cleavage of an As–C bond to form isobutene, and the elimination of methane from Ga. This is shown for a *t*Bu and a Me substituent in Equation (i). Such a suggestion is consistent with the X-ray

crystal structure **3**.[21] Although the H atoms were not located in the X-ray experiment, placement of them in idealized positions results in a "close" Ga · · · H nonbonded distance of 2.62 Å.

Thermolysis of $[nBu_2GaAstBu_2]_2$ **4** at 250 °C results in a smooth expulsion of 1-butene and isobutane, together with smaller quantities of *n*-butane and isobutene. In this case, the primary mechanism may involve β-hydrogen transfer from an *n*Bu group giving 1-butene, followed by elimination of isobutane from a *t*BuAs moiety [Eq. (j)]. A competing path-

way, analogous to that proposed for **3**, would be responsible for the production of isobutene and *n*-butane.

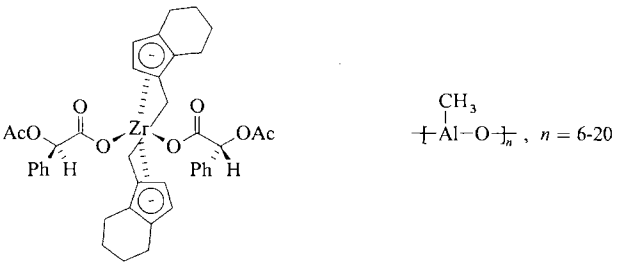
Finally, low-temperature production of GaAs has been achieved using solution techniques. Treatment of **16** with *t*BuOH in pentane at ambient temperature resulted in the elimination of pentamethylcyclopentadiene and $tBuOSiMe_3$ and formation of a reddish powder [Eq. (k)].[34] The powder

$$(Me_5C_5)_2GaAs(SiMe_3)_2 \xrightarrow[-\ Me_5C_5H\ -\ tBuOSiMe_3]{tBuOH} GaAs \qquad (k)$$

16

was shown to be GaAs plus some organic impurities by elemental analysis, scanning electron microprobe analysis, and X-ray powder diffraction. However, annealing this material at 500 °C for 48 h resulted in crystalline GaAs. *Wells* et al.[50] have also produced GaAs and InAs of 88–96% and 98% purity, respectively, via the solution reaction of $(Me_3Si)_3As$ with MCl_3 (M = Ga, In), followed by heating at higher temperatures. In our laboratories, we have found that the crystalline compound $[tBu_2GaAsH_2]_3$ **34** is thermally stable at ambient temperature in the solid state. However, in solution this compound undergoes a smooth decomposition at 25 °C to finely divided, amorphous gallium arsenide.[25]

7. Addendum (August 7, 1989)



A number of important developments have occurred since the submission of this manuscript. *Bradley* et al.[51] have investigated the deposition of InP from $[Me_2InPtBu_2]_2$ using the metal-organic molecular beam epitaxy (MOMBE) technique. These authors demonstrated that indium-rich growth occurs at all substrate temperatures studied and that stoichiometric growth is only possible at 480 °C with a simultaneous incident flux of dissociated phospane. In a related publication, *Bradley* et al.[52] described the preparation of $[Me_2InPtBu_2]_2$ and $[Me_2InPPh_2]_2$ through the reaction of Me_3In with tBu_2PH and Ph_2PH, respectively. The X-ray crystal structure analysis of $[Me_2InPtBu_2]_2$ was also reported. *Wallbridge* et al.[53] have prepared $[Et_2InPtBu_2]_2$ and $In(PtBu_2)_3$ by alkane and salt elimination methods, respectively. Both compounds were investigated by X-ray crystallography. Finally, *Barron* et al.[54] have prepared polycrystalline InP by treatment of $InCl_3$ with $(Me_3Si)_3P$. The intermediates in this reaction were investigated by X-ray photoelectron spectroscopy, elemental analysis, and X-ray powder diffraction.

The work in our laboratories was carried out by the following co-workers: B. Benac, R. Geerts, D. Giolando, P. Harris, D. Heaton, K. Kidd, M. Mardones, C. Nunn, J. Power, S. Schwab, D. Westmoreland. We are also grateful for our interaction with colleagues in the Department of Chemical Engineering at the University of Texas at Austin, Professor John Ekerdt and James Miller, who have conducted the OMCVD studies. We thank Professors Ben Streetman and Al Tasch of the Department of Electrical and Computer Engineering at the University of Texas at Austin for very helpful discussions. The work has been supported by the Robert A. Welch Foundation, the National Science Foundation, and the Texas Advanced Technology Research Program.

Asymmetric Oligomerization of Propene and 1-Butene with a Zirconocene/Alumoxane Catalyst

By *Walter Kaminsky,* Aurelia Ahlers,* and *Nico Möller-Lindenhof*

Dedicated to Professor Hansjörg Sinn on the occasion of his 60th birthday

Highly isotactic polymers have been prepared from propene and longer chain α-olefins with chiral transition-metal compounds such as (*R,S*)-[1,1'-ethylenebis(4,5,6,7-tetrahydro-1-indenyl)]zirconium dichloride and methylalumoxane as cocatalysts.[1–3] If, instead of the racemate, one of the two enantiomers of the transition-metal compound is used, the resulting polyolefins should exhibit practically no optical activity in solution.[4] By contrast, measurable optical rotations are expected for oligomers. Thus, *Pino* et al. were able to synthesize optically active alkanes by hydrooligomerization of propene with this catalyst system.[5, 6] Of greater preparative interest are the more reactive, optically active alkenes. However, hydrogenation cannot be used to control their molecular weights in the asymmetric oligomerization. Instead, similarly low degrees of oligomerization have to be achieved by a method that preserves the terminal double bond. This is possible by raising the catalyst concentration and simultaneously lowering the monomer concentration, thereby increasing the rate of chain termination relative to chain growth in the polymerization.

Use of (*S*)-[1,1'-ethylenebis(4,5,6,7-tetrahydro-1-indenyl)]-zirconium bis(*O*-acetyl-(*R*)-mandelate)[7] and methylalumoxane[8] (Scheme 1) thus allowed the preparation of optically active propene and 1-butene oligomers. The mandelate was employed because its activity is similar to that of the corresponding dichloride and may be obtained in purer form. In the first step, an olefin molecule undergoes insertion into a transition-metal methyl bond formed by methylation with methylalumoxane (Scheme 2). Subsequent insertions lead to chain growth. Chain termination takes place by β-hydrogen transfer to the transition-metal atom or to a complex-bound olefin, resulting in formation of the hydrido or alkyl transition-metal compound in addition to the oligomer. The former, in turn, allows new insertion steps to occur. Up to 100 molecules of propene or 1-butene undergo insertion per molecule of catalyst per hour.

Gas chromatography (Fig. 1) reveals the presence of dimers to heptamers of 1-butene. In the case of trimers and higher oligomers, the isomeric mixtures obtained consist mainly of configurational isomers. The dimer and trimer mixtures contain 88 and 78 wt%, respectively, of a main component. The tetramer fraction contains 72% of a 5:4 mixture of diastereomeric (*R,R*)/((*S,S*)- and (*R,S*)/(*S,R*)-2,4,6-triethyl-1-decenes (all four configurational isomers are presumably present since the catalyst does not function in a completely stereospecific fashion). Similarly, the main components of the pentamer fraction consist of the four possible enantiomer pairs of 2,4,6,8-tetraethyl-1-dodecene. Under comparable oligomerization conditions, propene preferentially affords pentamers and 1-butene yields trimers and tetramers (Table 1).

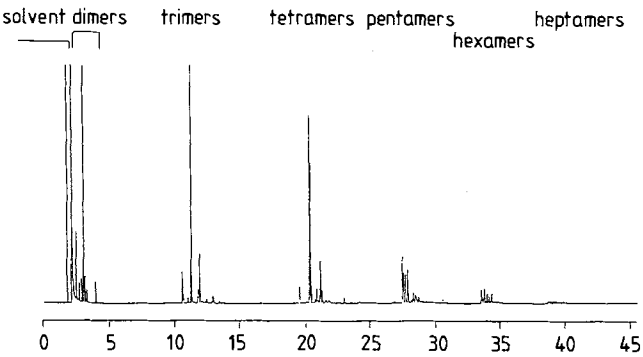

Fig. 1. Gas-chromatographic separation of the oligomerization products of 1-butene (50-m capillary column CP Sil 5 CB; 10 × 0.32 mm; d_f 0.12 μm; temperature 50–270 °C).

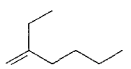
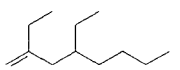
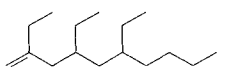
[**] This work was supported by the Volkswagen-Stiftung. We thank Prof. Dr. *H. H. Brintzinger* (Konstanz) for help in the synthesis of the optically active zirconocenes.

Table 1. Amount [wt%] of propene and 1-butene oligomers of differing degrees of oligomerization n [a].







n	2	3	4	5	6	7
Propene oligomers	2.4	8.9	11.5	12.2	11.3	9.4
Butene oligomers	9.5	17.9	17.5	14.3	10.2	5.3

[a] The remaining 44.3 and 25.3 wt%, respectively, consists of higher oligomers.

The ^{1}H NMR spectrum of the mixture of 1-butene oligomers (recorded in $CDCl_3$/TMS) displays two singlets at $\delta = 4.69$ and 4.74 in the olefinic region, which, in agreement with the calculated chemical shifts[9] and the results of ^{13}C NMR spectroscopy, are assigned to 2-alkyl-substituted 1-alkenes.

The first three oligomer fractions were separated by distillation and characterized by ^{13}C NMR spectroscopy, mass spectrometry, and polarimetry (Table 2).

Table 2. Molar optical rotations $[\Phi]_\lambda^T$ of alkenes prepared by asymmetric oligomerization of propene and 1-butene.

Oligomers	Structure of the main components	$[\Phi]_{589}^{25}$	$[\Phi]_{365}^{25}$	c [a] [mg mL^{-1}]
from propene				
$n = 2$		0.0	0.0	11.5
$n = 3$		+1.1	+3.7	10.9
$n = 4$		+4.7	+14.6	10.1
from 1-butene				
$n = 2$		0.0	0.0	56.2
$n = 3$		−0.7	−2.5	61.0
$n = 4$		−2.6	−9.4	58.1

[a] Concentration in the measuring cuvette ($l = 1$ dm); solvent, toluene.

The structures of the alkenes are those expected for 1,2-insertion of the monomers. Accordingly, the number of chiral centers is always smaller by two than the degree of oligomerization. In the case of 1-butene, *König* et al.[10] succeeded in carrying out gas-chromatographic separation of the enantiomers of the trimer mixture on a modified cyclodextrin phase. The enantiomeric excess *ee* for the first diastereoselective partial reaction in 1-butene oligomerization was thereby determined to be 27%. In analogy to the results obtained in the hydrooligomerization of propene,[5] this asymmetric reaction should preferentially afford the *R* enantiomer. The stereoselectivity of the second diastereoselective partial reaction is significantly higher, since the stereocenters of the growing oligomer enhance the stereodifferentiation.[5] The diastereomer ratio (1:1.25) of the triethyl-1-decenes determined by gas chromatography reveals that the second chiral center is formed in the *R* configuration with a stereoselectivity of 80%. In agreement with this, the molar optical rotation also increases by a factor of roughly 4 (see Table 2).

Figure 2 shows the ^{13}C NMR spectrum of the trimer fraction obtained from 1-butene. Comparison of the calculated[11, 12] and the measured chemical shifts of the carbon nuclei leads to the structure shown in Figure 2, which was

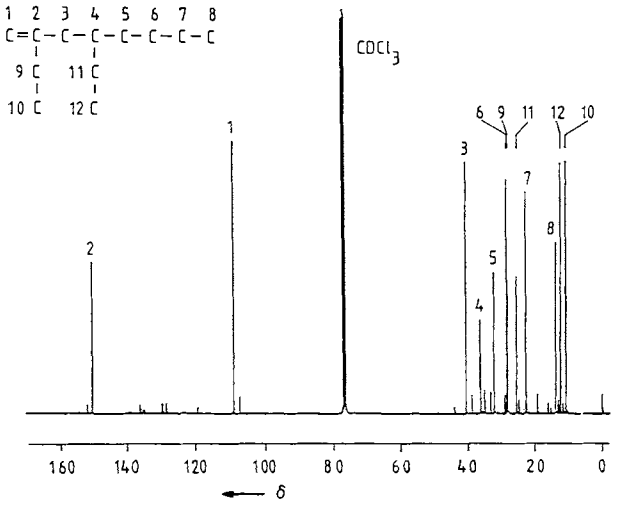


Fig. 2. 90.6-MHz ^{13}C NMR spectrum of the trimer fraction obtained in the oligomerization of 1-butene, recorded in $CDCl_3$ (main component: 2,4-diethyl-1-octene).

corroborated by mass-spectrometric data. In the mass spectrum of the trimer mixture after separation by gas chromatography (GC/MS), the molecular ion peak (m/z 168) is accompanied by peaks for $[C_nH_{2n-1}]^\oplus$ fragment ions, which are typical of alkenes, and by the peak for the product of McLafferty rearrangement (m/z 70), which is the main fragmentation product for many 2-alkyl-substituted 1-alkenes.[13]

We have thus shown that, with small amounts of optically active catalyst (10^{-4} M), it is possible to synthesize molar amounts of optically active alkenes from simple olefins. The oligomerization can be controlled so as to produce mainly dimers to pentamers. Such alkenes were previously accessible only by complicated, multistep syntheses. These oligomers may find application in the synthesis of pheromones and of chiral compounds with little functionality.

Experimental Procedure

All operations were carried out under argon. Toluene (155 mL), methylalumoxane (520 mg, 9.0×10^{-3} mol Al), and (*S*)-[1,1'-ethylenebis(4,5,6,7-tetrahydro-1-indenyl)]zirconium bis(*O*-acetyl-(*R*)-mandelate) (56.6 mg, 76×10^{-3} mol; $[\alpha]_{589}^{25} = -20.5$ ($c = 9.7$ mg mL^{-1} in toluene, $l = 1$ dm)) were placed in a 1-L glass autoclave and heated at 50 °C using a thermostat. 1-Butene (32.14 g, 0.57 mol) was then added over 16 h using a mass flow controller. Subsequently, the reaction mixture was stirred with 10% potassium hydroxide. The products were separated by fractional distillation. Yield 26.2 g (81%) of a colorless oil: $[\alpha]_{589}^{25} = -0.8$ ($c = 86.8$ mg mL^{-1} in toluene). Propene (20.4 g, 0.48 mol) was similarly added over 19 h. Yield 18.0 g (88%): $[\alpha]_{589}^{25} = +3.3$ ($c = 10.9$ mg mL^{-1} in toluene).

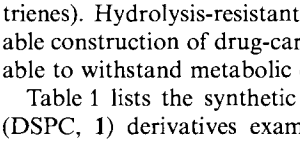
Chain-Substituted Lipids as Substrates for Phospholipase A_2**

By *Fredric M. Menger** and *M. G. Wood, Jr.*



Recent monolayer,[1] calorimetric,[2] mass spectrometric,[3] biochemical,[4, 5] ^{13}C NMR,[6] and transport[7] studies of new lipid systems required the synthesis of "lysophospholipid" intermediates via phospholipase-A_2-catalyzed hydrolyses [Eq. (a)]. In the course of our work, we found that the

(a)

phospholipase gave no isolable products with phospholipids bearing certain alkyl groups on the first half of their C_{18} chains. This observation inspired further investigation owing to the possibility that the chain-substituted lipids, like related short-chain lecithins,[8] inhibit normal phospholipase-A_2 activity. Developing such inhibitors is a major goal of current chemopharmacological research[9–13] because phospholipase A_2 catalyzes the release of arachidonic acid (a precursor for prostaglandins, thromboxanes, and leukotrienes). Hydrolysis-resistant phospholipids would also enable construction of drug-carrying liposomes that are better able to withstand metabolic degradation.

Table 1 lists the synthetic distearoylphosphatidylcholine (DSPC, **1**) derivatives examined with phospholipase A_2.

1

In a typical preparative run,[14] lipid (40 μmol in 3.3 mL of 1:9 methanol/ether) was mixed with crude snake venom (1 mg *Crotalus adamanteus*[15] in 30 μL of 5 mM $CaCl_2$). After 24 hours of magnetic stirring and TLC monitoring, the reactions were quenched with 5 mL of water, after which the water layer was separated, washed with ether, and lyophilized. Reaction yields were determined by one of two methods: (1) Integrated ^1H NMR signals of the α-methylene and choline methyl groups were compared. (2) Lysophosphatidylcholine was isolated by column chromatography (silica; 8:2 $CH_3OH/CHCl_3$ as eluant).

As seen in Table 1, a yield of 97% was obtained with the parent DSPC **1**. On the other hand, *n*-propyl and *n*-butyl branching at positions 4, 6, and 8 gave 0% yields regardless of whether both chains ("1,2") or only the second chain ("2") was substituted. An *n*-butyl at a more distal locus (C-12) did not result in 0% yield but instead reduced it to 34%. Methyl groups exerted little effect on the yield (85–100%) even when they were situated close to the hydrolytic site. Yields tumbled to 5–15% with ethyl groups on carbons 4, 6, and 8. In summary, phospholipid hydrolyses are impaired by alkyl substituents, particularly large ones, located in the first half of the chains.

Table 1. Yields and rates of phospholipase-A_2-catalyzed hydrolyses of **1** and its derivatives.

Substituent	Chain(s)	Location [a]	Yield [%] [b]	Relative initial rate $v_{i,rel}$ [c]

Phenyl	1,2	12	–	50

[a] Numbering system counts the carbonyl carbon of the fatty acid as C-1. Either both chains ("1,2") or only the second chain ("2") bears a substituent at the indicated location. [b] The percentages marked with an asterisk reflect the isolated yields after column chromatograpy. All other yields were determined in duplicate by ^1H NMR spectroscopy. [c] Rates were measured using 5.9 mM lipid substrate. Reaction conditions were different from those used to determine yields (see text). V_{max} (**1**) = 420 μmol mg^{-1} min^{-1}.

Initial rates of phospholipase-A_2-catalyzed hydrolyses (Table 1) were all measured under identical conditions: 6.0 mL of an aqueous mixture composed of 5.9 mM lipid, 20 mM Triton X-100, and 10 mM $CaCl_2$, bath-sonicated at 65 °C to produce a mixed-micellar system.[12, 16] Subsequent hydrolysis, initiated with 0.2 units of purified phospholipase from *Crotalus adamanteus* venom[17] (167 units per mg), was measured with a Radiometer pH-stat at 40.0 °C by titrating at pH = 8.0 under N_2 with 2 or 5 mM KOH.

Relative rates $v_{i,rel}$ in Table 1 parallel roughly the reaction yields (an exact correspondence not being expected since conditions for obtaining the two parameters were entirely different). The following conclusions can be drawn from the $v_{i,rel}$ data: (1) The $v_{i,rel}$ values increase steadily as the methyl groups are shifted away from the carbonyl group (e.g., $v_{i,rel}$ = 12, 23, 45, and 100 for bis-methylation of carbons 4, 6, 8, and 12). (2) Methyl groups on both chains produce about a twofold lower $v_{i,rel}$ than identically positioned methyl groups on chain-2 alone. Thus, substitution need not occur on the labile fatty acid to affect the rate. (3) Ethyl and *n*-propyl groups reduce $v_{i,rel}$ from 3- to 30-fold depending on the proximity to the hydrolytic site. Interestingly, a single *n*-propyl group on C-8 of chain-2 gave a 0% yield with an ether solvent system but only a threefold rate decrease with the lipid incorporated into aqueous micelles. (4) *n*-Butyl groups induce dramatic rate decreases: DSPC bearing two *n*-butyl groups on C-4 hydrolyzes more slowly than DSPC **1** by a factor of 390 (a value that could be only approximated owing to the extreme sluggishness of the former reaction). When the butyl groups were moved to C-12, the inhibition almost disappeared. As seen from Table 1, the effect of phenyl groups is similar to that of *n*-butyl groups.

Conventional enzyme kinetics revealed details about the *n*-butyl group inhibition. Thus, micellar **1** gave K_m and V_{max} values of 3.8 mM and 420 μmol mg^{-1} min^{-1} (in satisfactory agreement with related studies on egg phosphatidylcholine[18]). The 4,4'-dibutyl derivative was shown to behave as a competitive inhibitor with K_i = 2.0 mM (Fig. 1). *n*-Butylation of the fatty acid chains, therefore, does not impair binding to the active site but instead severely impedes subsequent hydrolysis.[19]

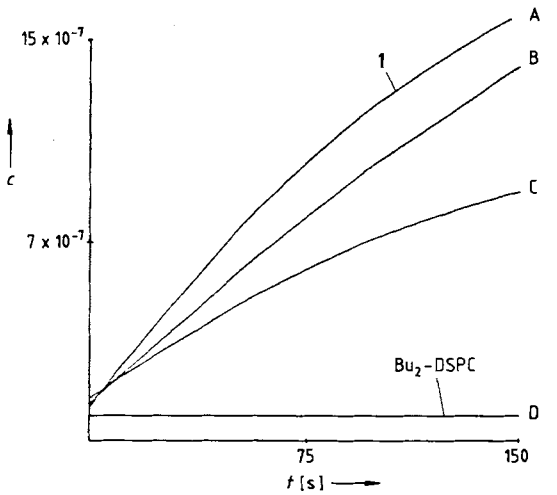

Fig. 1. Competitive inhibition of the hydrolysis of **1** by 4,4'-di-*n*-butyl-DSPC (pH-stat output; pH = 8.0, 40.0 °C). c = added equivalents of KOH. A: 0.84 mM DSPC **1**, no inhibitor. B: **1** + 1.0 mM inhibitor. C: **1** + 3.0 mM inhibitor. D: 5.9 mM 4,4'-di-*n*-butyl-DSPC alone.

On the basis of our results, chain modification of phospholipids would seem to constitute a promising method of altering lipid susceptibility to phospholipase A_2. The potential for thereby controlling prostaglandin levels, and for designing more stable drug delivery systems, should again be mentioned.[20]

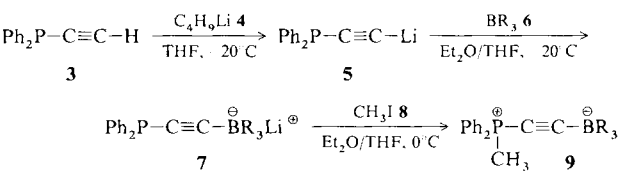
[19] We cannot exclude the possibility that alkylated phosphatidylcholine modifies the micellar system, although this appears unlikely since a large excess of neutral surfactant, Triton X-100, was employed.
[20] Protein kinase C activation and inhibition by our lipid derivatives [4, 5] must be taken into consideration here.

Phosphonioboratoacetylenes: C_2 Stabilized by Donor and Acceptor Molecules

By *Hans Jürgen Bestmann,* Harald Behl,* and *Matthias Bremer*



Dedicated to Professor Ernst Ruch on the occasion of his 70th birthday

Hexaphenylcarbodiphosphorane **1**[1] can be formally regarded as a "complex" consisting of two donor molecules and an electron-rich, excited carbon atom.[2] Such a purely hypothetical formulation raises the question whether the C_2 molecule[3] can be stabilized by complexation. In principle,

1 **2**

this should be possible by coordination of a donor molecule to one C atom and an acceptor molecule to the other C atom. For our investigations, we chose a phosphane as donor and a borane as acceptor. Compound **2** was used in ab initio calculations as the simplest example of this as yet unknown molecule with betaine structure. The following synthetic route led to the target molecules **9** (Scheme 1):

3 **5** **7** **9**

Scheme 1. Synthesis of **9**, **6–9**: **a**, R = Ph; **b**, R = CH_2Ph.

Ethynyldiphenylphosphane **3**[4] is transformed into the lithium acetylide **5** with butyllithium **4**. Compound **5**, in turn, reacts with triphenylboron **6a** or tribenzylboron **6b** to give the oily ate complexes **7**. Reaction of compounds **7** with methyl iodide **8** affords **9a** and **9b**, the first derivatives of **2**.[5] The overall yields of **9a** and **9b** are 64 and 53%, respectively. These very stable compounds can be recrystallized from acetonitrile: **9a**, m.p. 201 °C (dec.); **9b**, m.p. 157 °C (dec.).

The IR spectra of **9a** and **9b** display a typical C≡C valence vibrational band at 2085 cm^{-1}. The ^{13}C NMR chemical shifts[6] of C2 (**9a**, $\delta = 71.33$; **9b**, $\delta = 72.13$) and the P–C2 coupling constants (**9a**, $^1J_{PC} = 183.1$ Hz; **9b**, $^1J_{PC} = 184.6$ Hz) are similar to the values for the P-bound C atom in 1-alkynylphosphonium salts.[7] Owing to the coupling with the P atom in β position and the B atom in α position and to the short relaxation time of the latter, the signal for C1 is not observable. (Measurements at low temperatures are not possible because of the insolubility of **9**.) The ^{31}P NMR signals[6] of **9a** ($\delta = -3.63$ in D_5C_5N) and **9b** ($\delta = -5.76$) are near to the region expected for 1-alkynylphosphonium compounds.[7] The position of the ^{11}B NMR signal[6] in the same solvent (**9a**, $\delta = -11.13$; **9b**, $\delta = -14.94$) indicates the presence of a tetravalent boron atom.

The result of the X-ray structure analysis of **9a** is given in Figure 1.[8] The C1–C2 distance (121.6(5) pm) corresponds

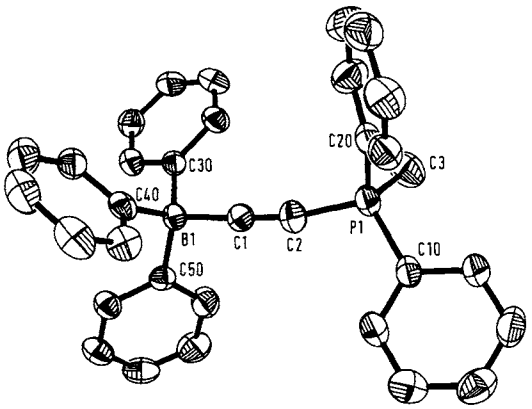

Fig. 1. Molecular structure of **9a** (ORTEP).

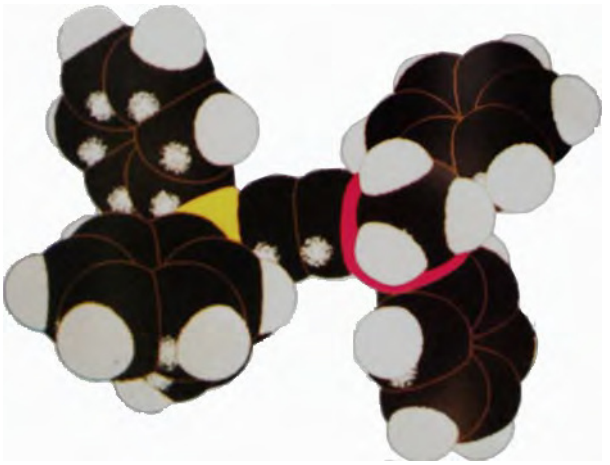
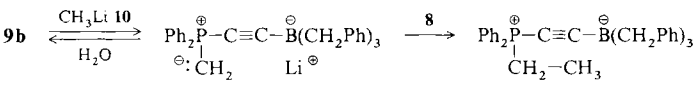
to a C–C triple bond. The B1–C1 distance is 159.3(5) pm and that between P1 and C2 169.9(4) pm. The molecule is not linear, the P1–C2–C1 angle being 168.9(4)°, the B1–C1–C2 angle 178.7(4)°, and the dihedral angle B1-C1-C2-P1 11.2°.

An ab initio calculation for **2** with the 3-21G basis set[9] gives bond lengths of 121.2, 159.4, and 169.4 pm for C1-C2, B1-C1, and P1-C2, respectively, in very good agreement with values found experimentally for **9a**. However, the calculation gives a linear molecule **2**. This could indicate that the bent structure of **9a** is due to a crystal packing effect.[10]

A space-filling model (Fig. 2) of **9a** shows that the C–C triple bond is very strongly shielded by the bulky groups on phosphorus (red) and boron (yellow). Indeed, **9a** and **9b** do not react, even over long periods of time, with 1,3 dipoles such as diazomethane, esters of diazoacetic acid, and phenyl azide.

As revealed in Figure 2, however, it should be easy to abstract a proton from the P-CH_3 group with methyllithium **10**. Compound **9b** thus yields phosphonium ylide **11**, which is also an ate complex (^{31}P NMR[6] (C_6D_6): $\delta = 6.76$); **11**





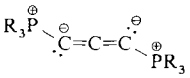


Fig. 2. Space-filling model of **9a** according to the X-ray data [8].

is transformed back into **9b** by treatment with water and reacts with methyl iodide **8** to give **12**, which, like **9**, has a betaine structure (m.p. 120 °C; NMR data[6] (D_5C_5N): ^{31}P, $\delta = 3.67$; ^{11}B, $\delta = -15.00$; ^{13}C, $\delta(C2) = 70.1$ ($^1J_{PC} = 182$ Hz); ^1H, $\delta = 1.12$ (dt, CH_3–CH_2, $^3J_{PH} = 21.61$, $^3J_{HH} = 7.3$ Hz), 2.86 (dq, CH_3–CH_2, $^2J_{PH} = 12.21$, $^3J_{HH} = 7.3$ Hz).

11 **12**

The successful synthesis of **9** raises the question whether the C_3 molecule might also be "stabilized". In analogy to the stabilization of a C atom in **1**, this should be possible by two donor molecules (**13**). Correspondingly, C_4 might be stabilized, as in C_2, by a donor and an acceptor molecule (**14**). We are currently investigating the synthesis of such systems.

$[VO(O_2CtBu)_3]$ and $[V_6O_6(\mu\text{-}O)_4(\mu\text{-}O_2CPh)_9]$: Structural Characterization of a Mononuclear V^V and a (2 + 4)-Nuclear $V^{IV}V^V_5$ Carboxylato Complex. Models for Vanadate-Dependent Peroxidases**

By *Dieter Rehder,* Wolfgang Priebsch,* and *Maren von Oeynhausen*

In recent years the bioinorganic chemistry of vanadium[1] has received increasing attention owing in part to the isolation of a vanadate(v)-dependent peroxidase from marine brown algae.[2] Haloperoxidases from knobbed wrack (*Ascophyllum nodosum*) catalyze the bromination and iodination of organic substrates with H_2O_2 and bromide or iodide, respectively. The ^{51}V NMR spectroscopic properties and the features in the XANES spectrum[3] led us to propose that the vanadium in these haloperoxidases is coordinated by six to eight ligand oxygen atoms, four to six of which belong to strained structural elements such as those formed by η^2 coordination of side-chain carboxylato groups of acidic amino acids in the protein matrix.

We have now synthesized and structurally characterized carboxylato complexes which might serve as models for the binding of vanadium in the active site of peroxidases. Simple carboxylato complexes of pentavalent vanadium, described earlier by *Preuss* et al.,[4] have still not been structurally characterized. By contrast, there exist several structurally established multinuclear acetato and benzoato complexes of vanadium with oxidation states of II, III, and IV in which the ligands serve a bridging function.[5]

The complexes $[VO(O_2CtBu)_3]$ **1**, $[VO(O_2CPh)_3]$ **2**, and $[V_6O_6(\mu\text{-}O)_4(\mu\text{-}O_2CPh)_9]$ **3**, obtained from $VOCl_3$ and the silver salts of pivalic or benzoic acid in inert solvents, form yellow (**1** and **2**) and deep red-brown (**3**) crystalline powders, which are quite stable when protected from moisture. The structures of **1** and **3**, the latter containing two molecules of CH_2Cl_2 in the unit cell ($Z = 4$), have been determined by X-ray analysis.

The mononuclear complex **1**[6] (Fig. 1) displays a pentagonal-bipyramidal structure, which is not unusual for V^V complexes of coordination number 7. All three pivalato ligands are coordinated in a bidentate fashion to vanadium, one of them being axial/equatorial with a relatively large distance of 220 pm between the vanadium atom and the axial carboxylate oxygen. The second axial ligand, in *trans* position, is a doubly bonded oxygen atom. The O–V–O12 angle is 162°; the vanadium atom is 30 pm outside the pentagonal plane. The structure of **1** found in the single crystal probably does not correspond to those of **1** and **2** in solution. The ^1H NMR and IR spectra of **1** reveal the presence of carboxylato ligands coordinated in mono- and bidentate fashion (hexacoordinated V).[4] In addition to the IR data of **1** and **2**[7] in solution, the ^{51}V NMR spectra [$\delta(^{51}V) = -597$, relative to $VOCl_3$] indicate that the chelate rings are easily opened and, on time average, contribute only partly to the overall structure.

Complex **3**,[8] shown in Figure 2, is a remarkable new type of multinuclear vanadium complex. This compound consists

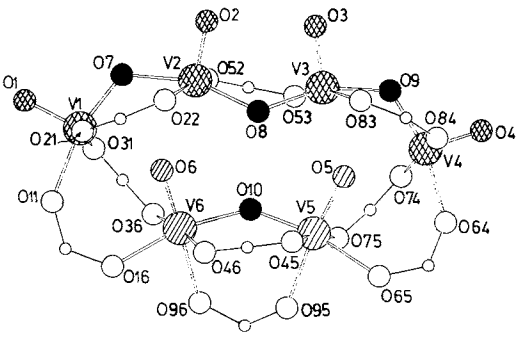

Fig. 2. Molecular structure of **3** (phenyl groups omitted). The vanadium atoms of the double bonded, terminal $O^{2\ominus}$ of the V_2 unit are hatched, those of the V_4 unit cross-hatched; $\mu\text{-}O^{2\ominus}$ shown as solid circles, carboxylate O as empty circles. The small, empty circles are the carbon atoms of the carboxylate groups. Broken lines indicate the two $\mu_3\text{-}O^{2\ominus}$. Selected bond lengths [pm] and angles [°]: V1–O1 157.3(9), V1–O7 171.0(8), V1–O11 199.8(9), V1–O21 198.9(9), V1–O31 196.4(8), V1 · · · O6 233.3(8), V2–O2 157.3(10), V2–O7 193.8(8), V2–O8 177.3(8), V2–O22 197.9(8), V2–O52 199.4(8), V2 · · · O6 243.0(8), V6–O6 161.5(8), V6–O10 185.7(7), V6–O16 199.9(8), V6–O46 200.1(7), V6–096 209.2(9), V1 · · · V2 319.5(3), V1 · · · V6 355.9(3); O1–V1–O7 102.3(4), O1–V1–O11 95.4(4), O1–V1–O21 98.8(4), O1–V1–031 99.2(4), O7–V1–O21 89.8(4), 07–V1–O31 96.1(4), O11–V1–O21 81.8(4), O11–V1–O31 86.6(4), O21–V1–O31 159.4(4), O2–V2–O7 99.7(4), O2–V2–O8 103.8(4), O7–V2–O52 80.8(3), O7–V2–O22 95.7(3), O7–V2–O2 99.7(4), O8–V2–O22 97.1(3), O8–V2–O52 89.3(3), O22–V2–O52 160.0(4), O6–V6–O10 96.4(4), O6–V6–O16 97.9(4), O6–V6–O46 94.0(3), O6–V6–O96 176.9(3), O10–V6–O36 94.0(3), O10–V6–O46 89.2(3).

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

of one binuclear and one tetranuclear fragment, which may be regarded as mixed anhydrides of benzoic acid with divanadic and linear tetravanadic acid, respectively, the anions of which, $H_2V_2O_7^{2\ominus}$ and $HV_4O_{13}^{5\ominus}$, are known.[9] As shown by the IR spectrum (Nujol mull), compound **3** no longer contains OH groups. The V_2 and V_4 moieties in **3** are linked through four benzoate units, while the bridges within the two fragments consist of benzoate and oxo groups. The six-membered vanadium ring thereby formed adopts a flat, twist-boat conformation (puckering parameter 87.8°). The vanadium centers V5 and V6 of the V_2 unit, joined through two carboxylate bridges, have octahedral configurations. The vanadium centers V1–V4 of the tetranuclear fragment are each surrounded by five ligands, the arrangement of which corresponds to a tetragonal pyramid distorted toward a trigonal bipyramid (Fig. 3). This distortion is particularly

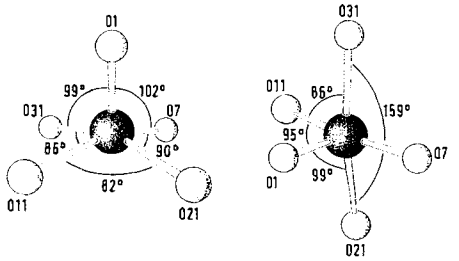

Fig. 3. Surrounding of V1 in complex **3** in the perspective of the tetragonal (left) and trigonal-bipyramidal (right) pyramids. The distance of the vanadium atom from the mean plane formed by O7, O11, O21, and O31 is 31 pm, the deviation from the trigonal plane through O1, O7, and O11 is 6.7 pm.

noticeable for the two peripheral vanadium atoms V1 and V4. This is of interest since trigonal-bipyramidal complexes of vanadium are rare.

The distances of the four vanadium centers of the V_4 unit to the vanadyl oxygen atoms O5 and O6 of the V_2 fragment (227–243 pm) lie within the range of vanadium–oxygen bonds, indicating the presence of strongly asymmetric μ_3-oxo bridges. Symmetrical μ_3-oxo bridges are commonly observed in other multinuclear vanadium complexes.[5, 10]

Of further interest is the presence of both V^{IV}[11] and V^V in **3**, as is observed in other vanadium clusters.[10] This is one more example of the frequently observed tendency of V^V to act as an oxidation agent toward organic substrates in solution.

Experimental Procedure

1: All operations were carried out under N_2 because of the high sensitivity of the compounds to moisture. A suspension of silver pivalate (6.1 g, 29.2 mmol) in 25 mL of highly purified, dry CH_2Cl_2 was slowly treated at −70 °C with a solution of $VOCl_3$ (0.84 g, 4.84 mmol) in 15 mL of CH_2Cl_2. After stirring for 60 min at this temperature, the solution was filtered to remove precipitated AgCl and the filtrate was evaporated under vacuum. The yellow, finely crystalline residue was dissolved in *n*-pentane and kept at −70 °C, resulting in the formation of suitable crystals within several hours. According to the spectroscopic data, **1** is identical with the tris(pivalato)oxovanadium(v) compound described earlier by *Preuss* et al.[4] Compound **2** was prepared similarly by reaction of $VOCl_3$ with silver benzoate at room temperature. Treatment of a solution of **2** in CH_2Cl_2 with *n*-pentane resulted, within ca. 1 week, in the crystallization of **2** along with the formation of very deep red crystals of **3** in small amounts. Compounds **1** and **2** dissolve in chlorinated solvents, the solutions turning red.

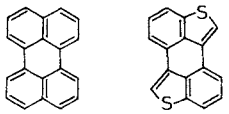
3,3′:4,4′-Bis(thieno[2,3-*b*]thiophene): A Novel Fused Heteroarene**



By *Yasuhiro Kono, Hisakazu Miyamoto, Yoshio Aso, Tetsuo Otsubo, Fumio Ogura,* Takanori Tanaka,* and *Masami Sawada*

The perylene–iodine complex was the first organic solid which exhibited high electrical conductivity.[1] In addition, perylene **1** formed radical-cation salts which qualified as low-dimensional organic metals.[2] The unusual properties of **1** are based on its relatively low ionization potential compared with other hydrocarbons.[3] Heteroaromatic compounds usually have lower ionization potentials than aromatic hydrocarbons. In addition, the incorporated heteroatom may induce higher polarization in the molecule and enhance intermolecular interactions. *Wudl* et al. reported an

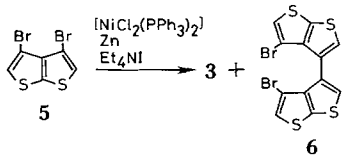
isoelectronic heterocyclic analogue of **1**, 3,4′:4,3′-bis(benzo[*b*]thiophene) **2**, which formed an iodine complex with very similar properties to those of the known perylene–iodine solid.[4]

1 **2**



Suitable electron-donor components for organic metals must satisfy the following requirements: high symmetry, high planarity, high polarizability, low ionization potential, and strong intermolecular interaction.[5] In this connection, 3,3′:4,4′-bis(thieno[2,3-*b*]thiophene) **3**, the perimeter of which consists only of thiophene rings, might be a superior electron-donor to **1** and **2**. The unique fused structure of **3** is also interesting. Here we report the synthesis, structure, and some properties of **3**.

The simplest approach to **3** seemed to be dimerization of thieno[2,3-*b*]thiophene **4** at the two β positions. Following

3 **4**

this strategy, we attempted a reductive coupling of 3,4-dibromothieno[2,3-*b*]thiophene **5**, prepared from **4** according to a known method.[6] The conventional treatment of **5** with a catalytic amount of bis(triphenylphosphane)nickel(II) chloride, excess active zinc, and tetraethylammonium iodide in refluxing benzene[7] gave only 4,4′-dibromo-3,3′-bis(thieno[2,3-*b*]thiophene) **6** (maximum yield 28%). However, increasing the quantity of the nickel reagent resulted in formation of the desired product **3**, whose yield was optimized up to 14%.[8]

5 **6**

Compound **3**, though its molecular model reveals severe strain, was very stable and crystallized in the form of pale brown needles from carbon disulfide. It sublimed around 270 °C at atmospheric pressure and did not melt up to 300 °C in a sealed tube. The simple ^{1}H and ^{13}C NMR spectra support its highly symmetrical structure (see Table 1). Compound **3** is not so colored as perylene **1**, but the UV/VIS absorption spectrum exhibits marked bathochromic and hyperchromic shifts as compared with that of thieno[2,3-*b*]thiophene **4**; this reflects the extended π conjugation of **3**.[9]

Table 1. Some spectral data of **3**.

^{13}C NMR (67.8 MHz, [D$_6$]DMSO): δ = 121.95, 125.15, 132.98, 150.17; ^{1}H-NMR (60 MHz, CS_2): δ = 7.23(s). IR (KBr): $\tilde{\nu}$ = 3100, 1421, 819, 740, 719, 693 cm^{-1}. MS (70 eV): *m/z* (intensity [%]), 276 (100, $M^{\oplus}$), 277(16), 278(19), 279(2.7), 280(1.5). UV/VIS (THF): $\lambda_{max}(\varepsilon)$ = 242 (46400), 254 (34200), 330 nm (22000).

The structure of **3** was confirmed by an X-ray crystallographic analysis (Fig. 1).[10] The molecule is planar and has a center of symmetry. The five-membered rings suffer from considerable strain in bond angles rather than in bond lengths as compared with the structures of thiophene[11] and thieno[3,2-*b*]thiophene.[12] In conformity with this view and in contrast to perylene,[13] the central six-membered ring is somewhat deformed and different from a regular hexagon.

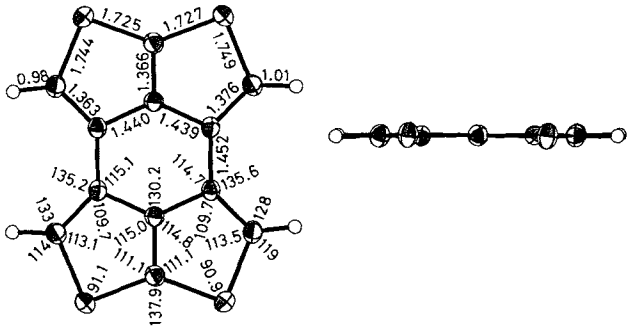


Fig. 1. Molecular structure of **3** viewed from above the plane (left) and from the side (right). The figure shows bond lengths [Å] and angles [°].

The cyclic voltammogram of **3** showed one reversible redox wave with a half-wave potential at 1.01 V versus a Ag/AgCl standard electrode.[14] This value is considerably lower than that (> 1.5 V) of **4** but equal to that (1.00 V) of **1**. Repetitive cycling soon changed the voltammogram to two redox waves at 0.74 and 1.10 V and resulted in a black polymeric deposit on the working electrode.[15] The same material was also formed by potentiostatic electropolymerization of **3** at 1.05 V in benzonitrile solution containing tetrabutylammonium perchlorate as supporting electrolyte. Since **3** has four reactive sites for polymerization, the polymer must have a complex network structure. The elemental analysis (C, 45.57; H, 1.05%) suggested that the polymer was doped with the counterion $ClO_4^{\ominus}$ (doping level 0.5). Its electrical conductivity measured on a compressed pellet at room temperature was 0.06 S cm^{-1}. Like **1** and **2**, compound **3** formed fine black crystals from chlorobenzene solution containing an equivalent amount of iodine. The complex had 1:1 stoichiometry of **3** to iodine and showed the relatively high electrical conductivity of 0.11 S cm^{-1}.

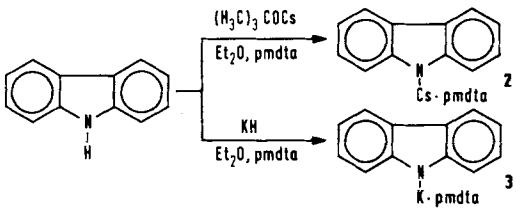
N-Cesiocarbazole · pmdta and *N*-Potassiocarbazole · pmdta (PMDTA = *N,N,N′,N″,N″*-Pentamethyldiethylenetriamine). Cation Size and Multihapto Bonding**



By *Karina Gregory, Matthias Bremer, Paul von Ragué Schleyer,* Peter A. A. Klusener* and *Lambert Brandsma*

We compare the solid state structures of *N*-cesiocarbazole · pmdta and *N*-potassiocarbazole · pmdta. To our knowledge,[1] these are the first single crystal diffraction analyses of a Cs-amide and of an aromatic K-amide. Compared to the rich literature on the structures of Li-amides,[2] relatively little information is available for derivatives of the heavier alkali metals.[3] Since we determined the X-ray structures of *N*-lithiocarbazole · 2 THF,[2a] and of *N*-sodiocarbazole · 2 HMPTA,[3b] we have chosen the cesium and the potassium salts as our next objectives. For *N*-lithiopyrrole (**1**, M = Li) simultaneous σ and π interactions have been predicted but are only partially achieved in the solid state structure of *N*-lithiocarbazole · 2 THF.[2a] However, multihapto bonding should become more important with increasing cation size. As the structures of the organic anion moieties are not expected to vary greatly, attention focusses on the differences in the location of the alkali metal cations and in their coordination.

1

N–Cesiocarbazole · pmdta (**2**) was prepared by treatment of a suspension of Cs-*tert*-butoxide in ether containing pmdta with a solution of carbazole in ether [Eq. (a)]. Storing for one week at -26 °C gave yellow crystals of X-ray quality. *N*–Potassiocarbozole · pmdta (**3**) was prepared in analogous manner using KH[4] as metalating agent [Eq. (b)].

The structures were solved by direct methods.[5] **2** exists as two different dimeric aggregates in the solid state. The atom numbering scheme, selected bond lengths and angles are shown in Figure 1 and 2. The asymmetric unit consists of three molecules of **2**, two of which form a dimer with C_1 symmetry. A crystallographic inversion center generates a second dimer with C_i symmetry. In each of the dimers, two chelated cesium cations bridge two organic anions differently, by making use of both σ and π interactions (π bond in this context describes the electrostatic interaction of the $Cs^{\oplus}$ cation with the π face of the carbazole system). The tridentate donor ligand PMDTA completes the $Cs^{\oplus}$ coordination sphere. In the dimer with C_i symmetry (Fig. 1), the cesium

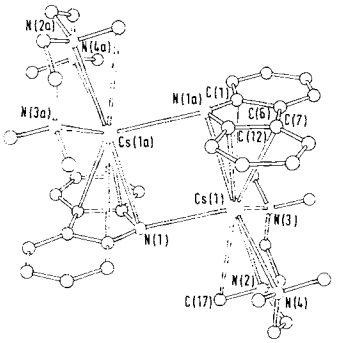


Fig. 1. Structure of the C_i-symmetric dimer of **2** in the crystal (drawn with the program XP-SHELXPLUS). Selected bond lengths [Å] and angles [°]: Cs(1)–N(1) 3.102(6), Cs(1)–N(1a) 3.335(5), Cs(1)–C(1) 3.399(6), Cs(1)–C(6) 3.511(6), Cs(1)–C(7) 3.450(5), Cs(1)–C(12) 3.343(5), Cs(1)–N(2) 3.178(5), Cs(1)–N(3) 3.200(5), Cs(1)–N(4) 3.179(7), Cs(1)–C(17) 3.473(7); Cs(1)–N(1)–Cs(1a) 91.9(2), N(1)–Cs(1)–N(1a) 88.1(2), N(1)–Cs(1)–N(2) 92.9(1).

cations are each σ bonded to one carbazole nitrogen and at the same time π bonded to the five membered ring of a second carbazole unit. The central unit, a planar $(M–N)_2$ four membered ring, also is observed in dimeric Li-amide structures.[2a–g] The Cs–C distances, indicated as close contacts in Figure 1, range from 3.3 to 3.5 Å, i.e. are shorter than the Cs–CH_3 distances (3.53 Å) found in the powder structure of methylcesium.[6] The Cs–N σ and π separations are 3.10 and 3.34 Å, respectively. The CH_3 groups on the

central pmdta N-atoms are bent twoards the σ bonded carbazole units, exhibiting additional metal–methyl carbon interactions at 3.47 Å. This shows again[1] that the presence of the methyl H's does not preclude short Cs–C contacts. The C_i dimer represents the ideal simultaneous combination of σ and π interactions initially predicted for *N*-lithiopyrrole (**1**, M = Li).[2a]

The dimer of **2** with C_1 symmetry (Fig. 2) has the same structural features as the C_i dimer but is distorted and exhibits significant differences. The distortion of the C_i dimer is shown by the 20.6° tilting of the carbazole units relative to one another. Hence, the central $(Cs–N)_2$ four-membered ring is non-planar. Only Cs(3) is located centrally above the five-membered ring of the carbazole anion, while Cs(2) has a reduced number of coordinative π interactions with the second anion. The Cs(2)–N(1′) and Cs(2)–(C12′) π distances (3.18 and 3.23 Å, respectively) are much shorter than in the C_i dimer. This Cs–N π distance is nearly the same as the Cs(2)–N(1″) σ separation (3.12 Å). An additional short distance of 3.43 Å between Cs(2) and the carbon atom C(17′) of the central pmdta-CH_3 group is present again. The inverted orientation of the pmdta ligand of Cs(3), compared with the C_i dimer, results in an increase of the Cs(3)–C(17″) distance (3.55 Å). Cs(3) exhibits π interactions shorter than 3.5 Å with all four carbon atoms of the central five membered ring of the carbazole unit.

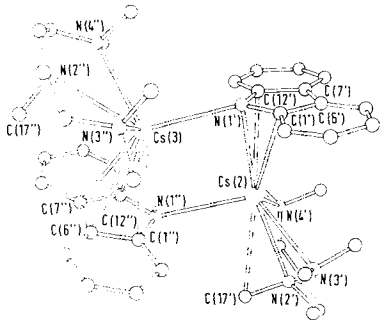

Fig. 2. Structure of the C_1-symmetric dimer of **2** in the crystal. Selected bond lengths [Å] and angles [°]: Cs(2)–N(1″) 3.116(5), Cs(2)–N(1′) 3.181(5), Cs(2)–C(1′) 3.441(5), Cs(2)–C(6′) 3.754(6), Cs(2)–C(7′) 3.625(6), Cs(2)–C(12′) 3.233(6), Cs(2)–N(2′) 3.177(5), Cs(2)–N(3′) 3.191(5), Cs(2)–N(4′) 3.149(4), Cs(2)–C(17′) 3.427(7), Cs(3)—N(1′) 3.096(5), Cs(3)–N(1″) 3.360(5), Cs(3)–C(1″) 3.396(6), Cs(3)–C(6″) 3.469(5), Cs(3)–C(7″) 3.433(6), Cs(3)–C(12″) 3.337(6), Cs(3)–N(2″) 3.198(4), Cs(3)–N(3″) 3.201(4), Cs(3)–N(4″) 3.152(5), Cs(3)–C(17″) 3.551(7); Cs(2)–N(1′)–Cs(3) 92.0(1), Cs(2)–N(1″)–Cs(3) 88.3(1), N(1′)–Cs(2)–N(1″) 90.4(1), N(1′)–Cs(3)–N(1″) 87.5(1), N(1″)–Cs(2)–N(2′) 101.3(1), N(1′)–Cs(3)–N(2″) 136.2(1).

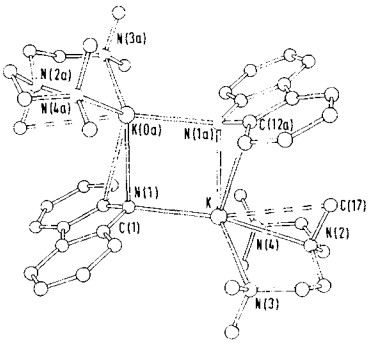
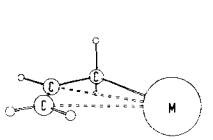
3, the potassium analogue of **2** crystallizes as a C_i dimer and is intermediate structurally between the lithium and the cesium derivatives (Fig. 3). **3** shows similarities with both the C_i and the C_1 dimer of **2**. However, due to the smaller coordination sphere of $K^{\oplus}$, the π bonded $K^{\oplus}$ cation (K–N(1a) 2.83 Å) shows only one short K–C(12a) π contact of 3.35 Å, whereas the σ bonded (K–N(1) 2.81 Å) is shifted towards the other side of the carbazole moiety resulting in one weak carbon σ separation of 3.47 Å. The orientation of the pmdta ligands attached to the cations is the same as in the C_1 dimer of **2** at Cs(3), and therefore reversed to that in the C_i dimer of **2**. Due to the increased bending of the ligands towards the π bonded carbazole moieties, the N(1)–K–N(2) bond angle is 162.8° and the K–C(17) separation 3.33 Å. The corresponding N(1)–M–N(2) angles in **2** are 92.9° at Cs(1), 101.3° at Cs(2) and 136.2° at Cs(3).

Ab initio calculations[7] on methylcesium/potassium and the classical, nonbridging *syn*-form of allylcesium/potassium





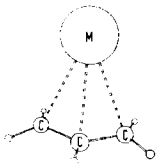


Fig. 3. Structure of the C_i-symmetric dimer of **3** in the crystal. Selected bond lengths [Å] and angles [°]: K–N(1) 2.812(3), K–N(1a) 2.827(4), K–C(12a) 3.348(4), K–C(1) 3.469(4), K–C(2) 3.521(5), K–N(2) 2.872(4), K–N(3) 2.989(4), K–N(4) 2.860(4), K–C(17) 3.327(5); K–N(1)–K(0a) 93.1(1), N(1)–K–N(1a) 86.9(1), N(1)–K–N(2) 162.8(1).

(with M in the carbon plane, **4**) gave Cs–C bond lengths of 3.073 and 3.066 Å (M = Cs) and K–C bond lengths of 2.754 and 2.750 Å (M = K), respectively. In the symmetrically bridged structure of allylcesium (**5**, M = Cs), the Cs–C distances are calculated to be somewhat longer: 3.218 Å from the Cs cation to the terminal carbon atoms and 3.210 Å to the central carbon. These values are in good agreement with the Cs–C distance of 3.29 Å in the graphite inclusion complex,[8] determined from layer spacings, and with our experimental findings for the Cs–C π separations, taking the expected effect of solvation of the cesium cations into account. Solvation in organo-lithium and -sodium compounds increases the carbon–metal distances by about 0.2 Å;[1] a similar lengthening for Cs derivatives is now indicated. The calculated bond lengths for the bridged structure of allylpotassium (**5**, M = K) are 2.888 and 2.857 Å and therefore in good agreement with the shortest K–C π separations found in the solid state structure of fluorenyl potassium · tmeda (3.04 to 3.35 Å).[9] The slightly longer K–C(12a) π bond in **3** (3.35 Å) must be due to the tridentate donor pmdta, that solvates the $K^{\oplus}$ cation more effectively than the bidentate donor tmeda in the fluorenyl compound.

4

5

The solid state structure of **2** results from the large coordination propensities of the cation. The cesium cation is stabilized via multihapto bonding with the anion, with the tridentate donor ligand, pmdta, and with the nitrogen of the second carbazole. Three of the four Cs-cations are formally nine-coordinated (taking only Cs–C separations less than 3.5 Å into account), the fourth $Cs^{\oplus}$ has only eight occupied coordination sites but with tighter interactions. The smaller coordination sphere of $K^{\oplus}$ seems to be satisfied by the pmdta ligand and the two carbazole nitrogen atoms. Only one additional K–C π contact is indicated. The corresponding dimeric solid state structures of the Li- and Na compounds[2a, 3b] differ significantly from that of *N*-cesio-carbazole. The smaller cations bridge the two anions by making use of σ and π interactions but only with the nitrogen atoms of the carbazole moieties and not with the π faces as in **2**. The smaller coordination spheres of $Li^{\oplus}$ and $Na^{\oplus}$, preclude the higher degree of multihapto bonding which is possible with

$Cs^{\oplus}$. The intermediate situation, with one M–C π contact, is presented by the potassium compound.

Experimental Procedure

Preparation of $(H_3C)_3COCs$: After opening a cold (0 °C) sealed ampule containing cesium (11.5 g, 86.5 mmol) under nitrogen, the metal was suspended in 300 ml of dried THF under argon atmosphere and warmed to 35 °C. *tert*-Butyl alcohol (5.5 g, 74 mmol) in 10 ml of THF was added in one portion under vigorous stirring. After 2 h all the alcohol had reacted, as evidenced by the formation of a light blue color. Evaporation of the solvent after filtering the reaction mixture and carefully removing unreacted metal gave $(H_3C)_3COCs$ as a white powder. The last traces of solvent were removed in vacuo at 40 °C. Yield: 13.8 g (91%).

2: $(H_3C)_3COCs$ (1.756 g, 8.5 mmol) was suspended in dried ether (20 ml) under argon atmosphere and first pmdta (3.0 ml, 14.0 mmol) and then 1.325 g of carbazole (7.9 mmol) dissolved in 20 ml of ether were added. The yellow-fluorescing reaction mixture was stored at −26 °C. After one week, yellow crystals had formed. Yield: 1.63 g (43.6%).

3: As described for **2**, using KH [4] (0.431 g, 8.5 mmol). Recrystallization gave green-yellow plates. Yield: 1.89 g (63.9%).

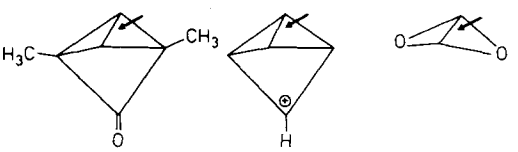
Very Short C–C Single Bonds and Their Origin. The Central Bond Length in Bitetrahedryl**

By *Paul von Ragué Schleyer** and *Matthias Bremer*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday



Single C–C bonds in saturated systems were once believed to be remarkably invariant in length. Compilations give 1.537(1) Å as the standard value taken from a large number of X-ray structures.[1] The C–C bond length in diamond is 1.54452 Å.[1c] However, an increasingly large number of significantly longer[2] or shorter[3–9] C–C bonds[1] are now being found, both experimentally[3–8] and calculationally.[9] The short 1.408 Å[3b] distance in **1** appears to be the experimental record in saturated systems, although the central C–C lengths are around 1.38 Å when two dicoordinate carbons are joined; e.g. in butadiyne, cyanoacetylene, and cyanogen (Table 1).

Table 1. Dicoordinate C–C bond lengths [Å].

Molecule	3-21G	6-31G*	Experimental

In the cation **2** corresponding to **1**, 6-31G* calculations indicate a comparable length of 1.372 Å for the central bond.[9b] Our ab initio examination of 2,4-dihetero-bicyclobutanes reveals an even greater shortening of the C–C central bond; the 6-31G* length is predicted to be only 1.338 Å in **3**.[9a] The accuracy of 6-31G* ab initio structures

is extensively documented; average errors in C–C bond lengths are less than 0.01 Å[10] (cf. Table 1 and Scheme 2). Errors with the smaller 3-21G basis set are only somewhat greater.[10]

When two tertiary or bulky alkyl groups are bound together, the central bond lengthens, often appreciably, due to

steric interactions and to angular distortions.[2] When, however, the alkyl moieties are "bent back" as in the cage and bridged ring systems, bicubyl **4**, bi(bicyclo[1.1.1]pentyl) **5**, bi(bicyclo[1.1.0]butyl) **6** and bitetrahedryl **7**, appreciable shortening of the central bond results.[4] This effect has been emphasized recently;[3-7] we now provide a more detailed explanation along with calculational data for a number of these compounds including the ultimate (but experimentally inaccessible) goal, bitetrahedryl, **7**. The central bond length

is 1.438 Å, when optimized with the 6-31G* basis set. This basis, which contains d-type polarization functions on carbon, gives creditable agreement with experiment for the central bond lengths of **4**–**6**. The comparison given below (Scheme 2) includes the optimized distances obtained with the smaller split valence 3-21G basis set and with the semiempirical MNDO[11] method. For comparison, the C–C length in ethane at the ab initio levels used here are 1.542 Å (3-21G) and 1.528 Å (6-31G*) (the experimental value is 1.531 Å).[10]

Both these ab initio basis sets reproduce the 3 kcal mol^{-1} experimental rotation barrier in ethane satisfactorily.[10] To probe the reasons for the C–C bond length changes, we carried out a series of 3-21G optimizations of both staggered (D_{3d}) and eclipsed (D_{3h}) ethane in which all H-C-C bond angles were fixed, but the bond lengths allowed to attain their minimum energy values. The results, shown in Figure 1 for both conformations, are remarkable. When the HCC angle is widened to 150° to simulate the situation in **7**, the C–C distance in both conformers decreases to about 1.38 Å, and the rotational barrier (Fig. 2) essentially vanishes. A decrease in the HCC angle has the opposite effect, the C–C bond length increases (Fig. 1) as does the rotation barrier (Fig. 2).

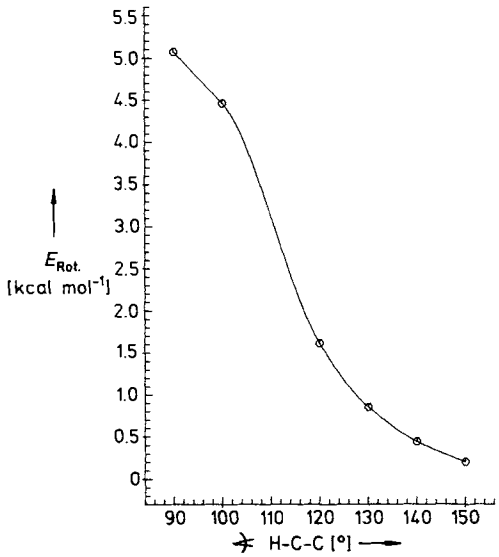

Fig. 2. The rational barrier E_{rot} for distorted ethane as a function of the H-C-C angle (3-21G).

Walsh diagrams[12] (plots of the valence orbital energies as a function of the HCC angle) provide insights. Figure 3 shows this for the D_{3d} form; the D_{3h} plot is similar. The largest change is noted for the a_{1g} orbital;[13] the energy becomes much lower at large HCC angles. This bonding sigma MO is comprised of carbon *p*-orbitals aligned with the

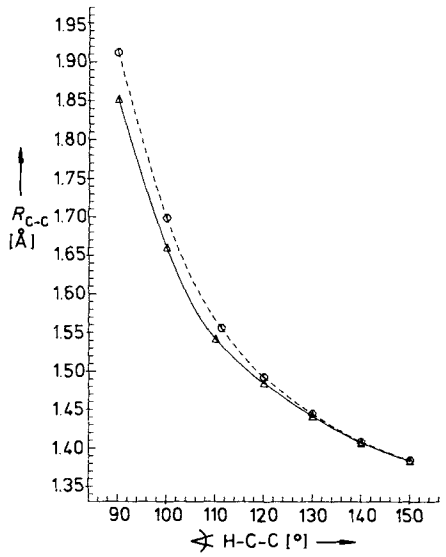

Fig. 1. The C–C bond length in distorted enthane (D_{3d}-symmetry, D_{3h} dashed) as a function of the H-C-C angle (3-21G).

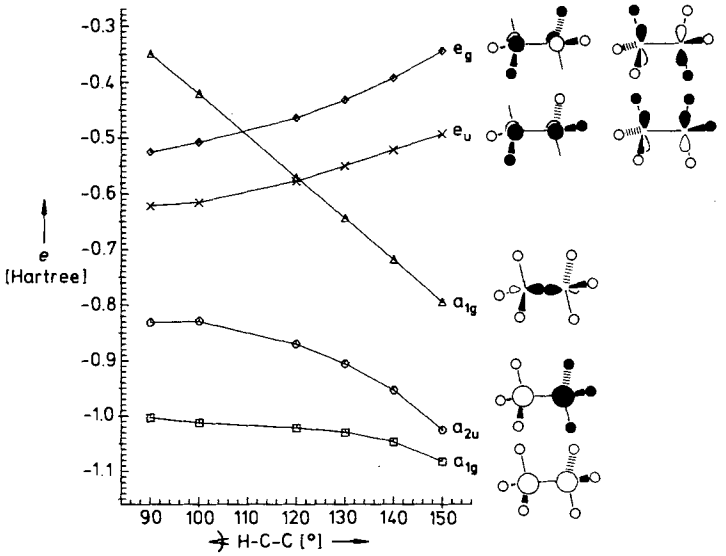

Fig. 3. Walsh diagram for distorted D_{3d}-ethane: the 3-21G orbital energies versus the HCC angle.

C–C bond. When the hydrogens are bent inward, they approach the nodes and their coefficients decrease. This means that CH bonding character is diminished. The opposite is true when the hydrogens are bent back. Not only additional CH but also enhanced CC bonding develops. The energy of the a_{2u} orbital is lower when the HCC angles are enlarged. This orbital is comprised largely of s components and has CC antibonding character. The latter is reduced on bending.

When the carbon *p*-orbitals are aligned perpendicular to the C–C bond, degenerate MO's of pseudo-π (e_u) and pseudo-π* (e_g) symmetry result. The energies of both sets of these orbitals increase at larger CCH angles since the CH bonding character is diminished. Of course, ethane distortion from the equilibrium geometry raises the overall energy, but the effects are distributed differently. A large CCH angle favors CC bonding, whereas this is decreased when this angle becomes smaller. The effects of these distortions on the CH bond energies are opposite.

Distortion also alters the hybridization. With an ethane HCC angle of 90°, the bonds to the hydrogens are nearly sp^2 hybridized, whereas very little s-character is present in the C–C bond. Conversely, a widened HCC angle increases the s-character along the C–C bond. This rehybridization effect, long familiar in cyclopropane, is more dramatic in tetrahedrane, as the external bonds have roughly sp character.[14] Hence, the central C(sp)–C(sp) bond in **7** can be compared with the central bond in 1,3-butadiyne (Table 1). Not just the hybridization in the latter, but also the conjugation and the lower coordination reduce the bond length to 1.38 Å (Table 1). Hence, the value calculated for **7** is somewhat larger.

As has been pointed out by *Ermer, Szeimies,* et al. it might be possible to prepare the hexa-*tert*-butyl derivative of **7**.[4b] They suggested that the X-ray central bond length of 1.440(2) Å in a bi-[1-tricyclo[3.1.0.0^{2,6}]hexyl] derivative might be taken as the upper limit for the C1–C1′ value in **7**. Our 6-31G* calculations agree. We predict the central bond in **7** to be 1.438 ± 0.01 Å in length. The 3-21G rotational barrier is 2.3 kcal mol^{-1}, considerably smaller than the ca. 10 kcal mol barriers for typical *tert*-butyl group rotations.[15]

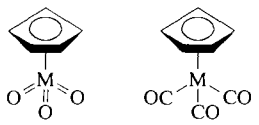
On the Stability of Trioxo(η^5-Cyclopentadienyl) Compounds of Manganese, Technetium, and Rhenium: An ab initio SCF Study**

By *Thomas Szyperski** and *Peter Schwerdtfeger**



Trioxo(η^5-pentamethylcyclopentadienyl)rhenium(VII),[1] Cp*ReO_3, first prepared in 1984, has meanwhile become very important as a key compound in the synthesis of oxoalkyl- and oxoarylrhenium species.[2] The homologous trioxomanganese and -technetium, as well as the monoxo- and dioxo compounds of the scandium and vanadium groups, respectively, have not yet been isolated. The results presented in this communication suggest that the analogous trioxo(η^5-pentamethylcyclopentadienyl)technetium(VII), Cp*TcO_3, should be stable, but not the manganese con-

[**] This work was supported by the Alexander-von-Humboldt-Stiftung and the Studienstiftung des Deutschen Volkes. We thank Prof. *Manfred L. Ziegler* (Heidelberg) for communicating his results concerning the trioxo technetium species, Prof. *W. A. Herrmann* (München), who gave the inspiration to perform this work, and *Michael Dolg* (Stuttgart) for providing the pseudopotential parameters.

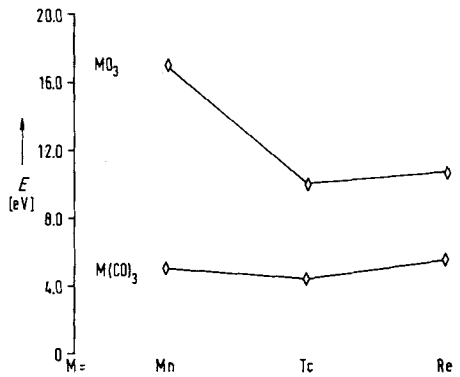
gener. We also find that the fragments MO_3 (M = Tc, Re) are isolobal to CH_3, which suggests that a large number of $RTcO_3$ and $RReO_3$ compounds (R = organic or inorganic ligand) could be synthesized.

In order to study the stability of such compounds we performed Hartree–Fock (HF) calculations for the $MO_3^{\oplus}$, MO_3 (M = Mn, Tc, Re), C_5H_5 (Cp), and $C_5(CH_3)_5$(Cp*) fragments and the $CpMO_3$ compounds **1**. The $CpM(CO)_3$ compounds **2** are well characterized;[4] hence, we also performed calculations for the $M(CO)_3^{\oplus}$ and $M(CO)_3$ fragments for comparison with the oxo compounds.

1 **2**

Energy-adjusted relativistic pseudopotentials (ARPP) for Mn, Tc, and Re with a low core definition were used.[5, 6] These were tested in calculations of $MO_4^{\ominus}$.[6] Furthermore, we performed all-electron HF calculations for the manganese oxo compounds $MnO_4^{\ominus}$, $MnO_3^{\oplus}$, and MnO_3, which yield the same results as those obtained from ARPP calculations. For example, for $MnO_4^{\ominus}$ we obtain r(Mn-O) = 155 pm with both methods. All calculations were performed with a modified version of GAUSSIAN86.[7] The geometries used for rhenium compounds are those obtained from X-ray analyses.[2, 4] For the unknown manganese and technetium species, the bond distances and angles were estimated from the geometries of the $MO_4^{\ominus}$,[8] $CpM(CO)_3$,[4] and Cp^*ReO_3[3] compounds. Sufficiently large basis sets with diffuse and polarization functions were used. For example, for the fragments we used a 6-311+G* basis set for O, a valence (10s/5p/5d)/[8s/2p/4d] basis set for the metal atoms, and for C_5H_5 a 31G basis set for H and a 6-31+G basis set for C. These were slightly reduced for the $CpMO_3$ compounds.[6]

The $CpML_3$ molecular orbital (MO) interactions are usually discussed using ionic fragments $ML_3^{\oplus}$ (L = CO, O, etc.) and $Cp^{\ominus}$ (see, for example, *Burdett* et al.[9] or *Lichtenberger* and *Fenske*[10]). The calculated vertical HF ionization energies of the neutral fragments $M(CO)_3$ and MO_3 are shown in Figure 1. Compared with the rather large $M(CO)_3$ and MO_3 ionization potentials, the electron affinity for Cp is small (0.47 eV at the HF level using a 6-31+G* basis set[6, 7]). This suggests a mainly covalent Cp–M bond in **1**. Hence, the Cp–M bond should be discussed using the neutral radicals $M(CO)_3$, MO_3, and Cp rather than the ionic fragments. We can support this from Mulliken population analyses obtained for **1**, where the net fragment charges are very small: for example, + 0.05 for ReO_3 in $CpReO_3$.



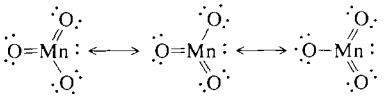


Fig. 1. Vertical ionization energies for the fragments MO_3 and $M(CO)_3$ (M = Mn, Tc, Re).

It is evident from Figure 1 that MnO_3 has an unexpectedly large ionization energy compared to all other fragments. Analyses of the molecular orbital schemes of the fragments $M(CO)_3$ (M = Mn, Tc, Re) and MO_3 (M = Tc, Re) indicate that the ground state in each case is of $^2A_1$ (C_{3v}) symmetry due to a singly occupied a_1 HOMO consisting mainly of metal s, p_z, and d_{z^2} orbitals (defining the C_3 and z axes coincident). Consistent with this result, we obtained for the $M(CO)_3^{\oplus}$ (M = Mn, Tc, Re) and $MO_3^{\oplus}$ (M = Tc, Re) ions an a_1 LUMO. For MnO_3 we obtained a $^2A_2$ ground state with a singly occupied a_2 HOMO consisting of oxygen orbitals orthogonal to the z direction, which can be simplified by the resonance structure **3**. Hence, the overlap between a_2 (MnO_3; C_{3v}) and a_2''(Cp; D_{5h}) is expected to be very small. We believe that the $a_1(MO_3)$–a_2''(Cp) interaction (M = Tc, Re) is fundamental for the stability of compounds **1**. This is not possible for MnO_3. To examine more closely this interaction, we performed HF calculations for compounds **1** (M = Mn, Tc, Re) in C_s symmetry and optimized the distance between the metal and the plane of the cyclopentadienyl ring.

3

The MO picture of the Re compound **1** is shown in Figure 2. The characters of only a few MOs are substantially different from those obtained for the fragments. As a result, the stability of the M–Cp bond is primarily described by the orbital interactions $3a_1(ReO_3) + a_2''$(Cp) (σ type) and $4e(ReO_3) + e_1''$(Cp) (π type). The $3e(ReO_3) + e''_2$(Cp) interaction is of δ type and consequently much smaller than the σ-type and the π-type linear combinations. *Lichtenberger* and *Fenske* have shown that for the $3a_1(Re(CO)_3^{\oplus}) + a_2''(Cp^{\ominus})$ interaction the overlap is small.[10] The $3a_1 + a_2''$ interaction leads to a stabilization of $\varepsilon_1 = 0.17$ Hartree for a_2'' (Cp), whereas e_1''(Cp) is stabilized only by $\varepsilon_2 = 0.05$ Hartree by the $4e + e_1''$ interaction. We therefore conclude that the linear combination $3a_1 + a_2''$ is the dominant contribution to the Cp–ReO_3 bond. This is not the case for the Cp–$Re(CO)_3$ bond, where the higher lying 5e orbitals also contribute. This is consistent with the significant bond lengthening encountered for the Re–C(Cp) bonds in the trioxo species (241 pm) when compared to the tricarbonyl species (228 pm).[3] The reason for the weak nature of the $4e + e_1''$ interaction in **1** is probably the unexpectedly high metal d character for the 4e LUMOs of ReO_3 (compared to those of $Re(CO)_3$, which are mainly of metal p character), resulting in a decreased overlap.

To obtain the relative stabilities of $CpMO_3$, we calculated the dissociation energies D_M for reaction (a) at the optimized

$$CpMO_3 \rightarrow Cp^{\cdot} + MO_3^{\cdot} \qquad \text{(a)}$$

M–Cp distance r_M: $D_{Re} = 35$ kJ mol^{-1}, $r_{Re} = 220$ pm (exp. Cp^*ReO_3 209 pm[3]); $D_{Tc} = 68$ kJ mol^{-1}, $r_{Tc} = 214$ pm (geometrical relaxation of the fragments was neglected[11]). From the Cp–MO_3 bond distance optimization, we calculat-

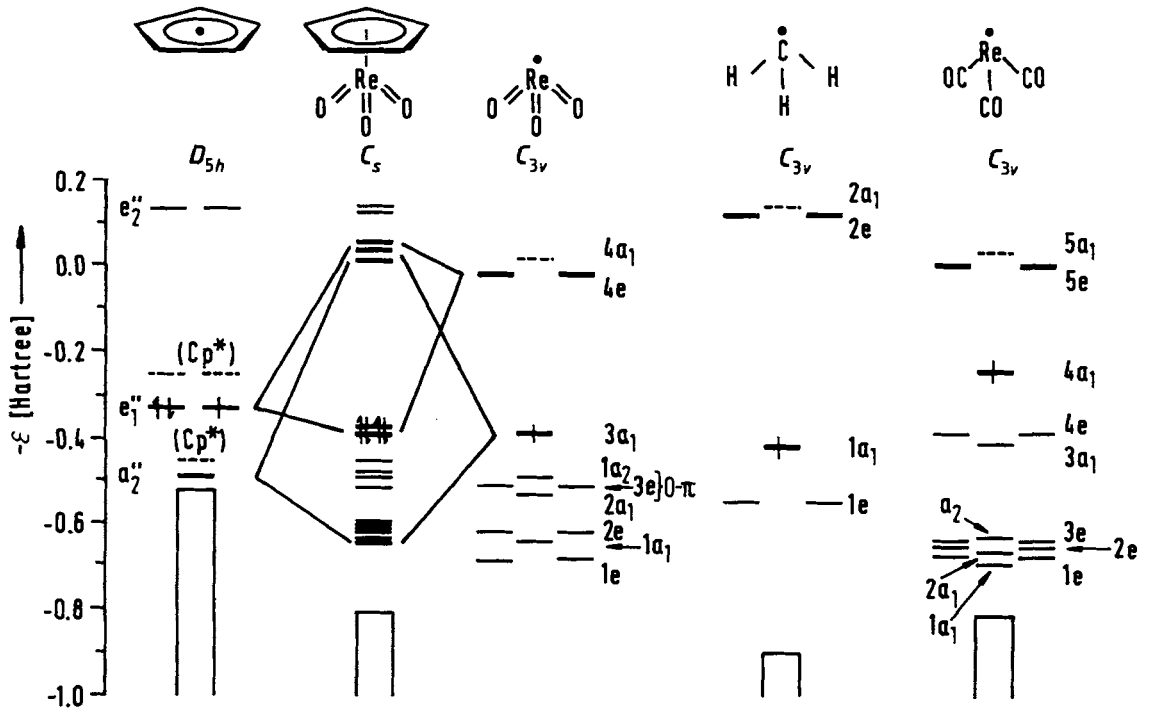

Fig. 2. Molecular orbital picture of $CpReO_3$ and the fragments Cp, Cp*, ReO_3, CH_3, and $Re(CO)_3$. Core orbitals are represented by boxes. High-lying core orbitals of Cp have been omitted from the $CpReO_3$ column for clarity. The electrons in the filled orbitals below the HOMO are not shown.

ed positive force constants for the Cp–MO_3 bond for M = Re (287.3 Nm^{-1}) and M = Tc (307.4 Nm^{-1}), whereas for M = Mn we found a Cp–MnO_3 repulsion ($\partial E/\partial r$ (for r = 200 pm) = − 1.3 kJ mol^{-1} pm^{-1}). Since the e_1'' and the a_2'' orbitals are raised in Cp* compared to Cp, the energy gaps of the interacting orbitals decrease (Fig. 2). Consequently, we expect increased thermodynamic stability for Cp*MO_3 (M = Tc, Re).

Our orbital sequence, where $e_1''(Cp) > 1a_2(ReO_3) > 3e(ReO_3) > 2a_1(ReO_3)$ (in the local symmetry of the fragments), agrees with the previously published[11] photoelectron spectrum of Cp*ReO_3. Furthermore, if we assume that the stabilization of e_1''(Cp*), due to the interaction with the $4e(ReO_3)$ LUMO, is equal to that calculated for $CpReO_3$, we get a Koopmans ionization potential of 8.1 eV (exp. 8.5 eV).[11] Very similar stabilization energies ($\varepsilon_1 = 0.16$, $\varepsilon_2 = 0.04$ Hartree) and MO picture are found for $CpTcO_3$.

Others have demonstrated that $Re(CO)_3$ (d^7-ML_3) is isolobal to $CH^{2\oplus}$ [9] and we propose that ReO_3 and TcO_3 are isolobal to $CH^{2\oplus}$ and CH_3, allowing comparisons of Cp*ReO_3 and Cp*$CH^{2\oplus}$ [13] in the first case and of the well-characterized compound CH_3ReO_3 [14] to CH_3CH_3 in the second case. Figure 2 shows that the number, symmetry properties, electron occupation, and approximate energies of the frontier orbitals of CH_3 and ReO_3 are indeed similiar. For example, compared to the a_1 HOMOs of $M(CO)_3$ (ε = 0.2 Hartree), the a_1 HOMOs of MO_3 (M = Tc, Re) are of much lower energy (0.37 Hartree for TcO_3 and 0.39 Hartree for ReO_3) and are therefore more comparible to the a_1 HOMO of CH_3 (ε = 0.43 Hartree) in C_{3v} symmetry. Additionally, the ReO_3 fragment has no high-lying metal d orbitals in contrast to $Re(CO)_3$. On the other hand, MnO_3 is not isolobal to CH_3. Consistent with this is the fact that CH_3MnO_3 is not known.

We conclude that Cp*TcO_3 (not currently known) should be a stable species if a suitable synthetic route can be developed.[15] Cp*MnO_3 is probably not stable for reasons discussed above. As a result of the isolobal analogy, we further suggest that the dinuclear species $(CO)_5M'$–$M''O_3$ (M' = Mn, Tc, Re; M'' = Tc, Re) are possibly stable.

[11] Reasonable dissociation energies are obtained only in CI or MP calculations including a geometry optimization, because generally HF calculations underestimate dissociation energies [12]. However, this is not practical, since a single-point HF calculation of $CpMnO_3$ using our basis set (276 primitive Gaussians contracted to 139 basis functions) yields 45 million two-electron integrals, requiring a total CPU time of about 3 hours on an IBM 3081. Nevertheless, we emphasize the striking difference between $CpMnO_3$ and $CpMO_3$ (M = Tc, Re) which, in our opinion cannot be compensated by correlation or geometrical relaxation.

[15] After submission of this paper we were informed by Prof. *Manfred L. Ziegler* that the oxidation of $Cp^*Tc(CO)_3$ with H_2O_2 leads to a polymer $[Cp^*Tc_2O_3]_n$. X-ray structure determination of this compound shows, in principle, Cp^*TcO_3 units, but the three oxygen atoms serve as bridging ligands to another Tc atom [16]. This observation does not change our proposed isolobal analogy and the stability behavior discussed above.

$P_{14}iPr_4$ – The First Hexacyclic Organophosphane **

By *Marianne Baudler*,* *Harald Jachow, Bernhard Lieser, Karl-Friedrich Tebbe,* and *Magda Fehér*

A large number of polycyclic phosphorus–hydrogen compounds P_nH_m ($m < n$) have been detected by mass spectrometry[1] and interest has meanwhile focused on their structural elucidation. However, the corresponding organo derivatives P_nR_m are better suited for investigation, since they are more readily soluble and crystallizable and they are easier to prepare. Accordingly, numerous bi- and tricyclic, as well as several tetra- and pentacyclic, organophosphanes have been synthesized and their structures elucidated.[1]

In 1975 *Fritz* et al.[2] reported the "inorganic" substituted tetradecaphosphane $P_{14}(SiMe_3)_4$, formed as a side product in the synthesis of $P_7(SiMe_3)_3$, but did not further characterize it structurally. The authors suggested that the compound contained the same nortricyclene-like structural element as $P_7(SiMe_3)_3$[3] and consisted of two P_7 units joined through one P atom of each unit. The corresponding $P_{14}(4)$ framework **1** was verified several years later by *von Schnering* et al.[4] by X-ray structure analysis of the polyphosphide $Na_4P_{14}(en)_6$ (en = ethylenediamine). By contrast, we found structure **2** for the tetradecaphosphide $Li_2H_2P_{14}(thf)_6$ by nuclear magnetic resonance spectroscopy.[5] The synthesis and structural investigation of a tetra*organo*tetradecaphosphane were therefore of considerable interest. We have now prepared tetraisopropyltetradecaphosphane **3**, a *hexacyclic* phosphane with an unexpected structure.

Compound **3** is formed to about 3 mol% upon thermolysis of the product mixture obtained from the reaction of dichloro(isopropyl)phosphane with white phosphorus and magnesium, which contains up to ca. 15 mol% of alkyl-rich polycyclophosphanes P_niPr_m ($n = 9-16$, $m = 6-9$). According to the mass spectrum of the thermolysis mixture, P_9iPr_3, P_9iPr_5, P_7iPr_5, $P_{11}iPr_5$, P_7iPr_3, and small amounts of P-richer isopropylcyclophosphanes are also present. Compound **3** can be enriched to about 40% by stepwise column-chromatographic separation of the thermolysis mixture and can be subsequently obtained in analytically pure form by crystallization from THF.

The tetradecaphosphane **3** forms yellow, needle-shaped, THF-containing crystals, which are stable under THF-containing inert atmosphere. They disssolve in THF and warm benzene, but not in cyclohexane or aliphatic hydrocarbons. At temperatures above 90 °C or under high vacuum, they lose THF and afford a yellow, insoluble solid (m.p. 121 °C, sealed tube). Compound **3** is sensitive toward oxidation, especially in solution. In the mass spectrum (field ionization), only the signal for the $M^{\oplus}$ ion (m/z 606) is observed.

The framework of **3** corresponds to neither **1** nor **2**, as shown by the $^{31}P\{^1H\}$ NMR spectrum (THF, 25 °C, 121.497 MHz), which displays a series of strongly overlapping multiplets between $\delta = +77$ and -25, but no signals in the high-field region typical of three-membered ring phosphorus compounds.[6] In agreement with these findings, a single-crystal structure analysis[7] identified **3** as 3,4,10,11-tetraisopropylhexacyclo[6.6.0.0^{2,6}.0^{5,14}.0^{7,12}.0^{9,13}]tetradecaphosphane (Fig. 1), present as an enantiomeric pair owing to its chirality.

Sequence Dependence of Template-Directed Syntheses of Hexadeoxynucleotide Derivatives with 3′–5′ Pyrophosphate Linkage**

By *Günter von Kiedrowski,* Britta Wlotzka,* and *Jörg Helbing*

Chemical models for self-replicating systems are of central interest in studies on chemical evolution.[1] Our demonstration of the autocatalytic synthesis of the self-complementary hexadeoxynucleotide **3a** from the two complementary trideoxynucleotides **1a** and **2a** in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) as activator provided the first evidence that self-replication is possible in enzyme-free minimal systems and can be studied using the methods of bioorganic chemistry.[2] The key observation was the involvement of the hexamer **3a** with a reaction order of 1/2 in the kinetics of its own synthesis.[2] This finding has meanwhile been corroborated with a second system consisting of oligonucleotide components.[3]

Here we report the first results of sequence-dependent nonenzymatic syntheses of oligodeoxynucleotides *in the presence of a self-complementary oligonucleotide as template.* The new 5′-methylthiomethyl (MTM) trideoxynucleotide 3′-phosphates[4] **1b–h** were used in these investigations. They react with the 5′-phosphorylated trimer **2b** in the presence of EDC, undergoing 3′–5′ pyrophosphate coupling to give the 5′-MTM hexadeoxynucleotides **3b–h**. The 5′–5′-coupled pyrophosphate **4**, formed by self-condensation of trimer **2b**, was also identified as a main product. The 3′–3′-coupled pyrophosphates, however, could only be detected in a few cases.

$^{3'}$pG-G-C$^{5'}$pp$^{5'}$C-G-Gp$^{3'}$

4

The reactions were carried out in 1-μL precision capillaries and followed by means of HPLC (Spherisorb 5 ODS II, 4 × 250 mm; A, 0.1 M ammonium acetate; B, acetonitrile/water 30:70 (v/v); 18–50% B within 16 min at a flow rate of 1 mL min^{-1}; detection at $\lambda = 254$ nm). Measurements of the initial rate of formation of hexamer **3f** in the presence of increasing concentrations of template **3a** showed, as observed in the system studied so far,[2] that the reaction follows the empirical rate equation (1)[5] (Fig. 1).

$$dc'/dt = a\sqrt{c} + b \qquad (1)$$

Accordingly, the synthesis of hexamer **3f** occurs via a template-dependent reaction channel, described in Figure 1 by the slope a, as well as via a template-independent channel, represented by the intercept b.

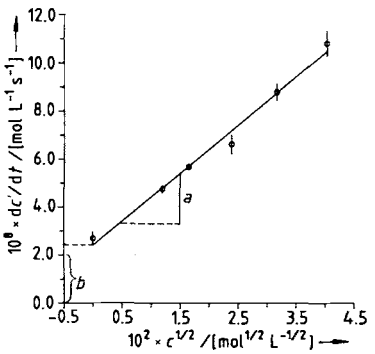

Fig. 1. Plot of the initial rate of formation of hexamer **3f** (dc'/dt) versus the square root of the initial concentration of template **3a** ($c^{1/2}$). The initial rates were determined from measurements of concentration versus time (maximum conversion 25%) by exponential regression, whereby each rate was calculated from the results of four experiments with a total of 16 HPLC runs. Initial concentrations and experimental conditions: 0.004 M **1f**, **2b**, $c = 0$–0.002 M, 0.2 M EDC, 0.1 M 2-morpholinoethanesulfonic acid (pH 6.15), 0.05 M $MgCl_2$, $T = 20$ °C, $t = 0$–12 h.

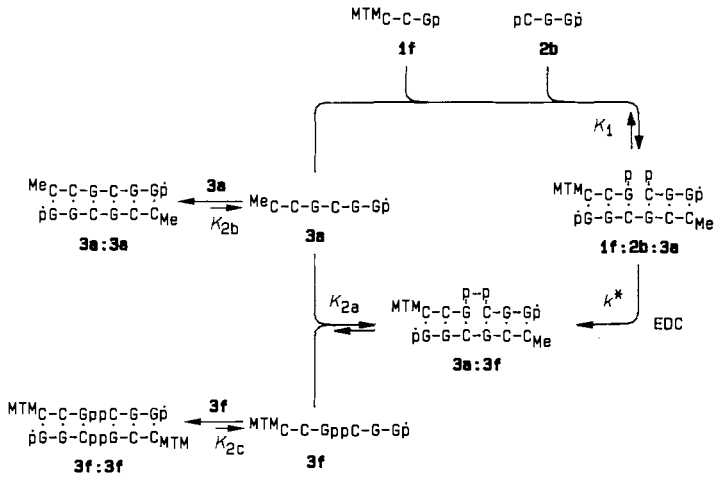

In contrast to previously studied reactions of **1a** with **2a** to give **3a**, the reaction product in this case, **3f**, differs from the template employed, **3a**, so that the constant a reflects catalysis instead of autocatalysis. Under the reaction conditions described in Ref. [2], the template-dependent synthesis of pyrophosphate **3f** is about 21 times faster than that of **3a**, whereas the rate of template-independent synthesis is only higher by a factor of 10.

According to Equation (1), catalyst **3a** participates in the rate equation for the synthesis of pyrophosphate **3f** with a reaction order of 1/2. This finding agrees with the theoretical expectation, assuming that the reaction proceeds according to the mechanism shown in Scheme 1 and three prerequisites are fulfilled:

1. The rate-determining step (k^*) is the carbodiimide-dependent formation of the 3′–5′ pyrophosphate bond within a complex formed from the template and the trimer components, **1f:2b:3a**. It is not important whether the activation by EDC takes place on the 3′-phosphate group of **1f** or

Tammannstrasse 2, D-3400 Göttingen (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

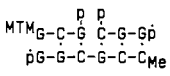
Scheme 1. Proposed mechanism for the template-dependent synthesis of **3f**.

the 5′-phosphate group of **2b** before or, instead, after formation of the complex. EDC-dependent pyrophosphate syntheses on a non-self-complementary template (completely complexed)[6] give an estimated half-life in the magnitude of 10^3 s for this step under the reaction conditions.

2. All single- and double-stranded oligonucleotides are in dynamic equilibrium, their concentrations being equilibrated at all times. Typical association rate constants of C/G-rich oligonucleotides give – largely temperature-independent – values of 10^6–10^7 $M^{-1}\,s^{-1}$;[7,8] the dissociation rate constants of the hexamer duplexes should be comparable to those of $(dC\text{-}G\text{-}C\text{-}G\text{-}C\text{-}G)_2$ and are presumably in the magnitude of $1\,s^{-1}$ at $T = 25\,^{\circ}C$.[8]
3. Under the reaction conditions, the majority of the template molecules are present in the form of complex **3a:3a** or **3a:3f**; a smaller number are present as complex **1f:2b:3a** and a very small number as the single-stranded species **3a**. Thermodynamic investigations on complexes with pyrophosphate-modified oligodeoxynucleotides[6] lead to the expectation that **3a:3a** should be about 1 kcal mol^{-1} more stable than **3a:3f**. Furthermore, these investigations[6] indicate that the stability of complex **1f:2b:3a** should be very similar to that of the complex consisting of **1a, 2a,** and **3a** proposed in Ref. [2]. On the other hand, a considerable difference in stability (at least 4 kcal mol^{-1}) should exist between **1f:2b:3a** and **3a:3a**. For $K_{2a} \approx K_{2b} \approx K_{2c} \gg K_1 \gg 1$, the proportionality relation (2) approximately holds for small conversions.

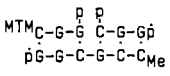
$$a \sim k^* K_1 K_{2b}^{1/2} \qquad (2)$$

Table 1 shows how *a* and *b* change when, instead of trinucleotide **1f**, which is fully complementary to the partial sequence C-G-G of template **3a**, trinucleotides that are not at all or only partially complementary are used. As expected, the rate of the template-dependent reaction (cf. *a*) is largest when the trinucleotide sequence optimally matches the template; mismatch sequences are incorporated 2 to 50 times more slowly under the reaction conditions. Less pronounced is the effect of the sequence on the template-independent reaction channel (cf. *b*); in this case, too, trinucleotide **1f** reacts fastest. Trinucleotides containing 3′-terminal deoxyguanosine residues react, on average, about 4 times faster than trinucleotides containing 3′-terminal deoxycytidine residues.



The 5′–5′-coupled pyrophosphate **4** is always formed more slowly in the presence of template **3a**, since its synthesis must

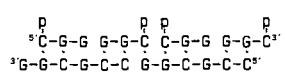
Table 1. Characteristic parameters of the template-dependent (*a*) and template-independent (*b*) syntheses of hexadeoxynucleotides **3b–h** in the presence of template **3a**; a_{rel} and b_{rel} are the values of *a* and *b* relative to **3f**. For initial concentrations and experimental conditions see Figure 1.



Hexamer	$10^8\,a/([M^{1/2}\,s^{-1}])$	a_{rel}	$10^9\,b/([M\,s^{-1}])$	b_{rel}
3b	15.0	0.07	2.4	0.09
3c	5.3	0.02	4.9	0.19
3d	6.4	0.03	6.2	0.25
3e	106	0.53	7.6	0.31
3f	198	1.00	24.6	1.00
3g	69.8	0.35	22.8	0.92
3h	12.8	0.06	11.5	0.46

compete with that of a 3′–5′-coupled product for activated precursors. In the absence of template **3a**, the sums of the reaction rates for the synthesis of the 3′–5′-coupled product **3** and the 5′–5′-coupled product **4** are comparable for **3b–3e,g,h** ($\Sigma = (2.18 \pm 0.16) \times 10^{-8}\,M^{-1}\,s^{-1}$), whereas the sum of rates obtained experimentally for **1f** ($\Sigma = 5.55 \times 10^{-8}\,M^{-1}\,s^{-1}$) deviates significantly.

The differences in *a* can be explained by the fact that the syntheses of hexamer pyrophosphates **3b–f** in the presence of hexamer **3a** are template-directed reactions, which proceed via complexes of the Watson–Crick type. According to Equation (2), the observable *a* is dependent on the kinetics of pyrophosphate coupling (k*) as well as on the difference in stability of the respective complex **1:2b:3a** and the template duplex **3a:3a** ($K_1 K_{2b}^{-1/2}$). The stability of the complexes **1:2b:3a** is determined by the number of C/G base pairs, the optimum value of which is only attained in complex **1f:2b:3a.** In all of the other complexes, destabilizing mismatch pairs are necessarily present, whereby G/G mismatch pairs generally cause less destabilization than C/C mismatch pairs.[7] Mismatch pairs in the vicinity of the reaction center should affect the kinetics of 3′–5′ pyrophosphate coupling more strongly than those further apart. Thus, trimer **1g**, whose complex **1g:2b:3a** contains one terminal G/G mismatch pair, reacts faster than the sequence-isomeric trimer **1h**, whose complex **1h:2b:3a** contains a G/G mismatch pair closer to the reaction center. Surprisingly, however, **1e**, the



1g:2b:3a

1h:2b:3a

analogous complex of which contains three mismatch pairs, exhibits reaction behavior similar to that of **1g**. A possible explanation would be the participation of a "concatenated" complex of type **5** in which a more removed G/G mismatch pair may be formulated such as that in **1g:2b:3a**.

5

Thermodynamic data of comparable oligonucleotides[9] indicate that the trimer pair formed from **1f** and **2b** can exist and participate in the reaction as a double-stranded complex under the reaction conditions. The reaction behavior of a double-stranded complex should differ from that of single-stranded complexes in activation and hydrolysis and in pyrophosphate synthesis. We suggest that this is the reason why

both the 3′–5′-coupled pyrophosphate **3f** and the 5′–5′-coupled **4** are rapidly formed in the template-independent reaction with **1f** (cf. *b*).

The results described here offer evidence that chemical self-replication is possible even in model systems in which oligonucleotides with 3′–5′ pyrophosphate bonds are synthesized. Oligonucleotides with pyrophosphate backbones are increasingly being discussed as possible prebiotic "information molecules"; their template properties in nonenzymatic oligomerizations have been described recently.[10] Further investigations into sequence dependence will presumably show to what extent the selection values of self-replicating molecules can be understood in terms of thermodynamically and kinetically controlled selectivities in the synthesis of alternative sequences. Such studies might afford insight into the question whether a self-constitution[11] of sequential information must be considered in the later phases of chemical evolution.

[4] The use of an MTM protecting group instead of the previously used methyl group has, in addition to logistical advantages in the synthesis of trimers, the effect that the kinetic measurements can be carried out more exactly by HPLC. Thus, **1f** reacts with the 5′-hydroxy trimer **2a** to give a hexamer, which differs from the template used, **3a**, only in the protecting group at the 5′ end, but which can be separated chromatographically from **3a**. This obviates the necessity of following the reaction by calculating differences between HPLC integrals.
[5] Equation (1) should be referred to as the "square root law", where c' is the concentration of the hexamer formed (here, **3f**), c the concentration of the added template (here, **3a**), a an empirical constant for the template-dependent synthesis of **3f**, and b the rate of the template-independent synthesis of **3f**. The constants a and b correspond to k_a and k_b in [2], K_a and K_b in [1], and α and β in [3].

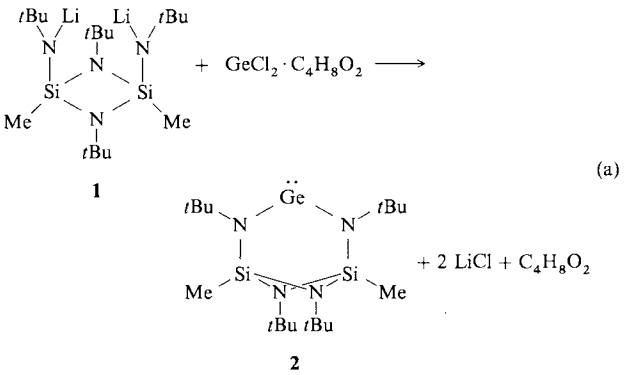
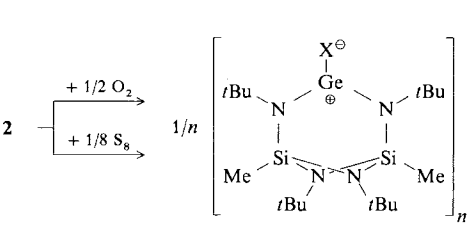
A Base-Stabilized Ge–S Double Bond



By *Michael Veith*,* *Sabine Becker*, and *Volker Huch*

Elements of higher periods (principle quantum number $n \geq 3$) apparently undergo multiple bonding with oxygen or sulfur when the d-orbitals can participate in the stabilization of the system or when resonance structures can be invoked in which the element in question carries a positive charge and the chalcogen atom a negative charge. This type of bonding is particularly common in the case of phosphorus where it is generally described in terms of the resonance structures **Ia** and **Ib**.[1] Recently, silicon-containing intermediates have also been characterized to which a structure analogous to that of the phosphorus compounds can be ascribed (Scheme 1).[2]



Scheme 1. X = O,S; El = Si, Ge; B = base.

We posed ourselves the question of just how far the "base-stabilization concept" can be extended to the homologous element germanium. All attempts to isolate compounds with "unprotected" Ge–O and Ge–S double bonds have previously failed, even with sterically demanding ligands on the germanium.[3–5] We wanted to achieve intramolecular addition of a base at germanium and therefore used polycyclic lithium silylamide **1** (Li bridges),[6] which apart from containing two amide nitrogen atoms also contains two amine nitrogen atoms capable of coordination.

(a)

1 reacts with the dioxane adduct of germanium(II) chloride to give the bis(amino)germanediyl **2** in high yields [Eq. (a)], which has been characterized by elemental analysis, molecular weight determination and ^{1}H NMR spectroscopy.[7] **2** can be easily converted with oxygen or sulfur into the oxidation products **3** and **4**, respectively [Eq. (b)].

(b)

3, X = O, n = 2
4, X = S, n = 1

The ^{1}H NMR spectra of **3** and **4** are identical at room temperature (in each case three resonance signals are observed for the *tert*-butyl groups,[7] indicating intramolecular chelation by one of the N-atoms of the N_2Si_2 group in solution, whereas the spectrum of **4**, in contrast to that of **3**, becomes simpler on increasing the temperature (coalescence of two *tert*-butyl signals). Apparently, in the case of **4** the

[*] Prof. Dr. M. Veith, Dipl.-Chem. S. Becker, Dr. V. Huch
Institut für Anorganische Chemie der Universität
D-6600 Saarbrücken 11 (FRG)

N–Ge donor bond then rapidly opens and closes on the NMR time scale (competition between the N-atoms in the N_2Si_2 ring). The compounds also differ greatly in their solubility: **3** precipitates as main product from the solution of **2** upon the introduction of oxygen, whereas **4** is readily soluble. X-Ray crystal structure analyses of **3** and **4** confirm that **3** is present as a dimer, whereas **4** is surprisingly, monomeric, i.e. contains a singly coordinated sulfur atom (in the crystalline state **4** still contains 1/2 molecule of benzene per formula unit).

The structures of the oxidation products **3** and **4** are shown alongside each other in Figure 1. The germanium

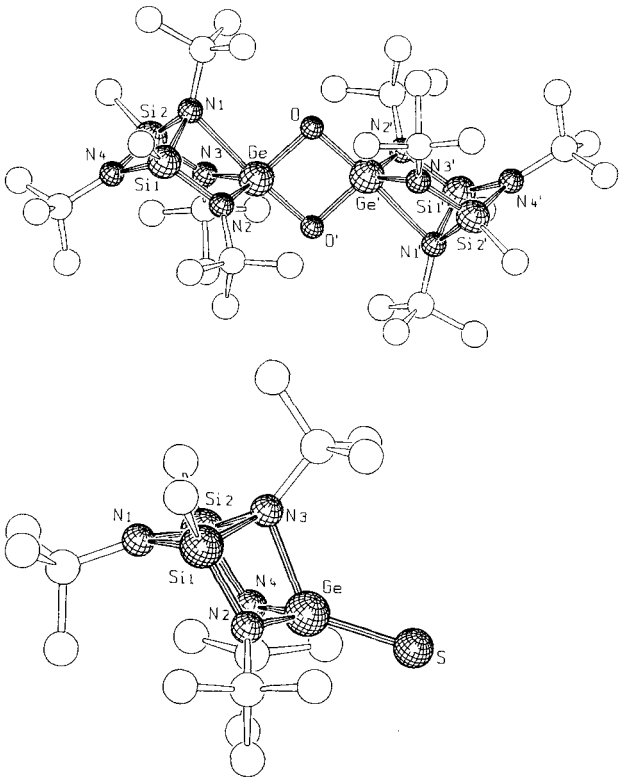


Fig. 1. The molecular structures of **3** (top) and **4** (bottom) (the carbon atoms are not labelled) [8]. Some important bond lengths [Å] and bond angles [°]: **3**: Ge–O 1.809(4), Ge–O′ 1.825(4), Ge–N1 2.370(5), Ge–N2 1.880(5), Ge–N3 1.887(5), Si–N 1.744(9) (mean); N1–Ge–O 90.5(2), N1–Ge–O′ 175.3(2), N2–Ge–O′ 108.1(2), N3–Ge–O′ 109.9(2), N2–Ge–O 119.9(2), N3–Ge–O 119.3(2), N2–Ge–N3 110.7(2), O–Ge–O′ 84.8(2), Ge–O–Ge′ 95.1(2). – **4**: Ge–S 2.063(3), Ge–N3 2.050(6), Ge–N2 1.882(6), Ge–N4 1.886(6), Si–N(1,2,4) 1.721(8) (mean), Si(1,2)–N3 1.831(5) (mean); N2–Ge–S 121.4(2), N4–Ge–S 123.0(2), N2–Ge–N4 110.6(3), S–Ge–N3 128.9(2), N2–Ge–N3 79.8(2), N4–Ge–N3 79.5(2).

atoms in **3** are coordinated almost trigonal-bipyramidally by two oxygen atoms and three nitrogen atoms, whereby the longer bonds are, as expected, the axial bonds in each case (to N1 and O′ and N1′ and O, respectively). The polycycle, with crystallographic point group $\bar{1}(C_i)$, contains two seconorcubane units (N_4Si_2Ge), which are coupled to each other via a Ge_2O_2 four-membered ring.

In **4** the germanium atom is only four coordinate. The coordination can be described as distorted tetrahedral, or better still as trigonal-planar (N2, S, N4) with an additional bond (Ge–N3), since the sum of the angles at the germanium atom for the bonds to N2,S and N4 deviates only 5° from the ideal value of 360°. Especially striking is the difference in length (0.17 Å) between the Ge–N3 bond and the other, shorter Ge–N bonds. The Ge–S distance of 2.063(3) Å is so far the shortest germanium–sulfur distance and is about 0.2 Å shorter than the value for a Ge–S single bond.[9] In the thiogermanate ion $Ge_4S_{10}^{4\ominus}$, which has an adamantane-like structure, the terminal Ge–S distances are 2.12(1) Å[10] and are thus 0.06 Å longer than in **4**. According to calculations on $H_2Ge=S$ the pπ–pπ Ge–S double bond should be 2.02 Å in length.

Accordingly, all structural data suggest that the bonding model **II** can also be applied to **4**. Compound **4** is therefore the first isolable compound with a base-stabilized double bond between sulfur and a tetravalent element of a higher period. Molecules with intramolecular base-stabilized Si–S and Ge–S bond, respectively, have recently been obtained via an entirely different route.[12] Of interest in the importance of the resonance structures **IIa** and **IIb** for the description of **4** is that a molecule isoelectronic to **4** with Ga and Cl instead of Ge and S exists[13] (see also the corresponding methylgallium derivative).[14]

Experimental

2: A solution of the dilithium compound **1** (385 mg, 1 mmol) in benzene was added dropwise within 30 min to a slurry of the dioxane adduct of germanium(II) chloride (232 mg, 1 mmol) in benzene (5 mL)[6]. After 12 hours the precipitate was filtered off, the solvent removed from the filtrate by distillation, and the resulting residue sublimed at 80 °C/10^{-3} torr; this furnished 363.3 mg (82%) of colorless, crystalline **2**.

3,4: A solution of 181.1 mg (0.41 mmol) of **2** in 2 mL of toluene was treated with a stream of oxygen diluted with nitrogen, or with 13.1 mg (0.41 mmol) of sulfur. **3** precipitated as a colorless powder, which was recrystallized from benzene; **4** could first be isolated after evaporation of the solution to dryness. Yields 112.9 mg (60%) **3**; 190.6 mg (98%) **4**.

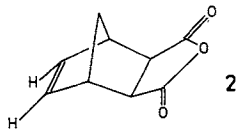
Double-Bond Geometry of Norbornene: Neutron Diffraction Measurement of a Derivative at 15 K



By *Otto Ermer,* Peter Bell,* and *Sax A. Mason*

Norbornene **1** is a prototypal strained olefin and as such a prominent model system of mechanistic organic chemistry. Numerous experimental and theoretical studies have shown that the reactivity of the double bond of **1** is characterized by a pronounced preference for *exo* attack. Inter alia, this has been rationalized in terms of the geometry of the double bond, which is not completely planar but bent in *endo* direction by the angle χ (*endo* pyramidalization, symmetric out-of-plane bending). The related changes in hybridization and steric factors favor *exo* attack.[1]

Despite the multitude of previous work,[1] the magnitude of the *endo* bending of the double bond of **1**, that is, the angle χ, is not reliably known. For example, from theoretical calculations applying quantum-chemical models or empirical force fields the following χ angles have been derived: 1.7° (MM2 force field),[1h] 4.2° (extended Hückel MO),[1i] 4.5° (CFF force field),[2a] 4.9° (ab initio, STO-3G).[1d,g] Furthermore, a number of X-ray analyses have been undertaken, which in most cases, however, involved unfavorable derivatives. Still worse, the light hydrogen atoms obviously can in principle not be located reliably by X-ray diffraction.

1

2

In order to place the extensive norbornene discussion on a sound basis, that is, to localize reliably the double-bond H atoms, we have performed a neutron diffraction measurement at 15 K on the simple derivative **2** (*exo-exo*-2,3-norborn-5-enedicarboxylic anhydride).[3] Norbornene itself is not suitable for such purposes: At room temperature the low-melting (m.p. 46 °C) and rather spherical hydrocarbon forms soft, deliquescent crystals of unknown structure. The present structural problem of norbornene is comparable to that of *trans*-cyclooctene, which involves a strongly nonplanar double bond and also plays the role of a prominent reference olefin. Some time ago, we reliably measured the double-bond geometry of *trans*-cyclooctene by means of neutron diffraction.[4]

Key results of the neutron diffraction measurement on the norbornene derivative **2** are collected in Figure 1.[5] Strictly

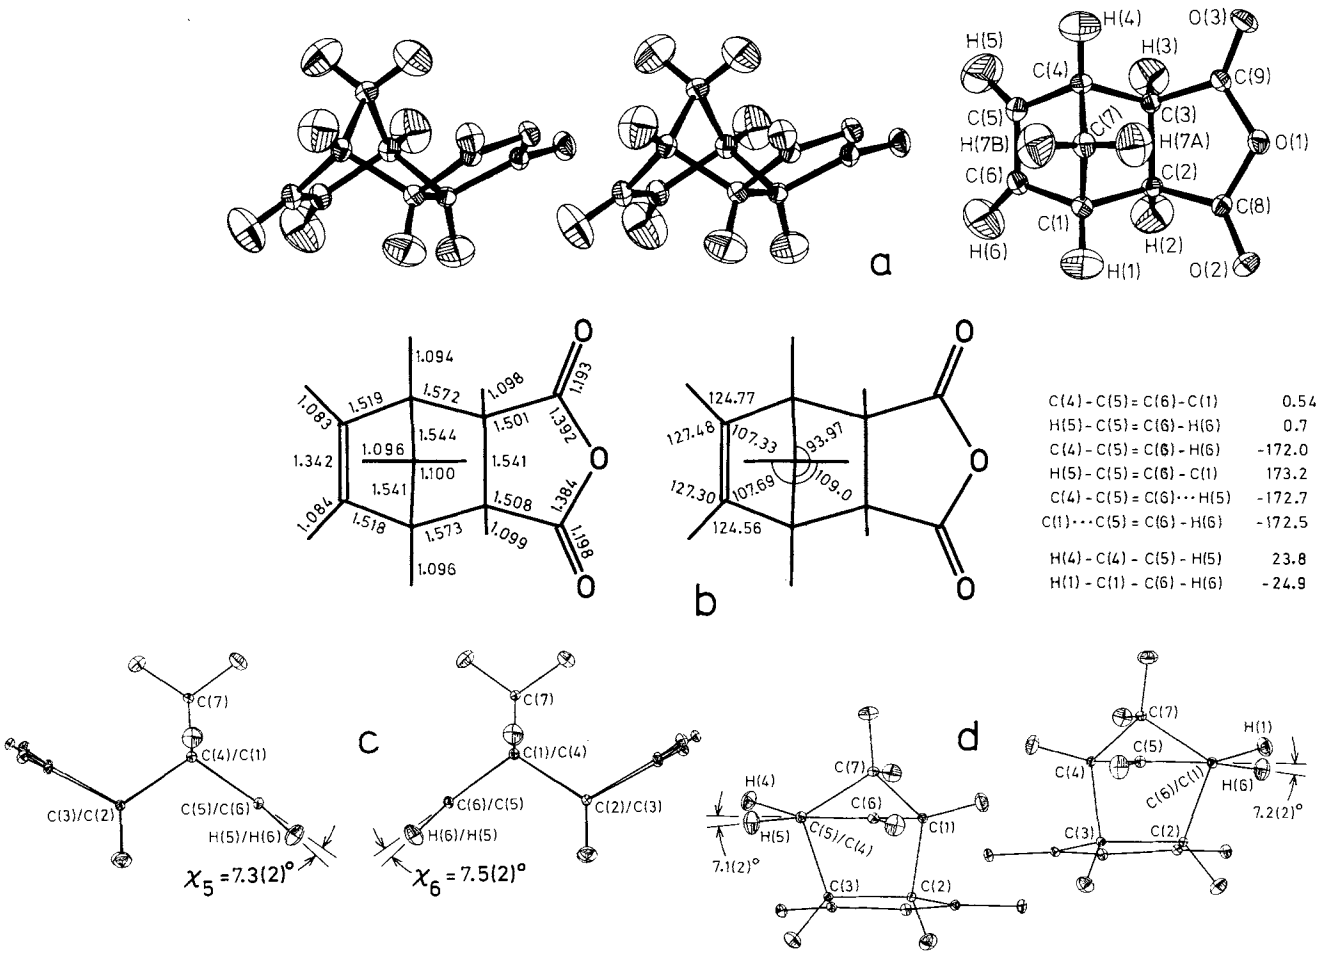

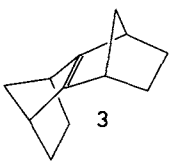

Fig. 1. Neutron diffraction results of **2**. a) Stereoview, atomic numbering, vibrational ellipsoids (90% probability). b) Bond lengths [Å], selected bond angles and torsion angles [°]; estimated standard deviations: CC,CO 0.001, CH 0.002–0.003 Å; CCC 0.06–0.07, HCC, HCH 0.2°; CCCC 0.09, HCCC 0.2, HCCH 0.3°. c) Projections down the CC double bond: illustration of the out-of-plane bending (pyramidalization) angles. d) Projections down the $C(sp^2)$–$C(sp^3)$ single bonds: influence of the double-bond bending on these partial conformations (ellipsoids 25%).

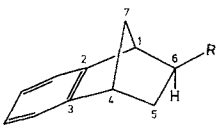
speaking, the molecules of **2** possess no symmetry in the crystal, yet are mirror-symmetric to a very good degree of approximation. The analytical description of the nonplanar double-bond deformations requires three independent geometry parameters,[4, 9] which in the present case are defined as follows: a) Twisting angle Φ_D = "torsion angle" between the p orbitals at C5 and C6 = arithmetic mean of the two double-bond torsion angles C4-C5-C6-C1 and H5-C5-C6-H6; b) out-of-plane bending (pyramidalization) angles χ_5 and χ_6 at C5 and C6 = deviation from planarity of the two dihedral angles C4-C5-C6/H5-C5-C6 and C1-C6-C5/H6-C6-C5.[10] The twisting angle Φ_D has the very small value 0.6(2)°, and the double bond is thus almost untwisted ($\Phi_D = 0°$ for exact mirror symmetry). The bending angles χ_5 and χ_6, which are at the focus of this work, amount to 7.3(2) and 7.5(2)°, respectively, and correspond to *endo* pyramidalization (Fig. 1c). In line with the approximate mirror symmetry, both bending angles are practically equal, and our neutron diffraction measurement thus affords a pyramidalization of $\chi = 1/2(\chi_5 + \chi_6) = 7.4(2)°$. This precise value turns out to be roughly twice as high as usually estimated for norbornene **1** (see above).

Like always in such cases, the question arises as to the influence of crystal packing and substituent effects on χ. In view of the absence of particularly short intermolecular contacts and the closely approximated molecular mirror symmetry, packing effects are likely to be negligible. Likewise, the rather remote anhydride moiety is expected to exert little influence on the double-bond bending; comparative quantum-chemical calculations on **1** and **2** could help settle this problem quantitatively.[2b]

Regarding other structural properties of **2**, the reader is referred to the collection of bond lengths and angles in Figure 1b. Mention is made only of the bond angle H-C7-H of 109.0(2)°, which is somewhat widened relative to the normal value of about 106–107°, since the angle C1-C7-C4 amounts to only 93.67(6)°.[11] The bond lengths C1-C2 and C3-C4 are somewhat lengthened, probably due to the anhydride group. Suffice it to say that other comparable carboxy derivatives of norbornane also show this feature, whereas we have found shortened C1–C2 bonds in ester derivatives of *exo*-2-norbornanol.



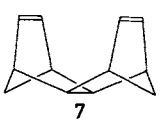
According to the simple empirical force-field models,[1h, 2a] the driving force for *endo* bending of the double bond of norbornene is to be sought in a decrease of torsional strain around both C(sp^2)–C(sp^3) single bonds, since the *endo* pyramidalizations lead to a more staggered orientation of the C(sp^2)–H bonds. The two projections of Figure 1d show quantitatively that the three torsion angles around C4-C5 and C1-C6, in which H5 and H6, respectively, participate, each assume more favorable (more staggered) values by 7.1 and 7.2° through the *endo* pyramidalizations. In the *syn*-sesquinorbornene **3**, two norbornene systems are fused

3

across the double bond such that on *endo* pyramidalization the torsional strain is lowered around four C(sp^2)–C(sp^3) single bonds as compared to two in **1**. In the light of the present norbornene results it is therefore gratifying to note that the out-of-plane bending angles χ of about 16–18° measured for a number of derivatives of **3**[12] are roughly two times larger than in norbornene. However, it is to be conceded that this very simple and more qualitative picture most likely does not convey the whole truth since the quantitative reproduction of the double-bond bendings in the force-field calculations is not satisfactory. For example, the amount of double-bond bending in **3** is probably also influenced by angle strain factors.[9a, 12e]

For benzonorbornene **4** considerably smaller pyramidalization (at C2 and C3) than in norbornene **1** may be anticipated, since the rotational barriers around C(sp^2)–C(sp^3) bonds at a benzene ring are substantially lower than around such bonds at an olefinic double bond. (Compare the sixfold rotational barrier of the methyl group in toluene of only 0.013 kcal mol^{-1}[13a] with the essentially threefold barrier in propene, which amounts to 1.98 kcal mol^{-1}.[13b]) Furthermore, pyramidalization (out-of-plane bending) at the benzene ring is energetically somewhat more costly relative to olefinic double bonds.[14] We have prepared the two crystalline benzonorbornene derivatives **5** and **6** and have sub-

4 R = H
5 R = COOH
6 R = COO-*p*-C_6H_4-NO_2



jected them to X-ray analysis.[15] The resulting average bendings χ (*endo* direction) at the C(sp^2)–C(sp^2) bond shared by the norbornene unit and the benzene ring are 2.7(3)° in **5** and 2.0(9)° in **6**. These rather similar *endo* pyramidalizations are thus indeed much smaller than observed in **2**.

Engl. 23* (1984) 55. b) In [2a] the X-ray analysis of a derivative of tetracyclo[6.2.1.$1^{3,6}$.$0^{2,7}$]dodeca-4,9-diene **7** is described, which consists of two norbornene units fused across a single bond and

7

which has two parallel double bonds in close proximity. A relatively large *endo* pyramidalization of $\chi = 8.1(2.1)°$ was found for one of the two double bonds and ascribed to particularly strong nonbonding repulsions between the double bonds due to orbital symmetry. However, comparison with the reliable neutron diffraction results on **2** now available indicates that this influence of orbital symmetry is smaller than previously [2a] believed. More definite conclusions would necessitate diffraction measurement also on the tetracyclododecadiene derivative.

[3] A relatively crude X-ray measurement was reported earlier for **2** (photographic intensity data, $R = 0.086$, hydrogen positions constructed on the basis of a planar double bond but not refined): G. Filippini, C. M. Gramaccioli, C. Rovere, M. Simonetta, *Acta Crystallogr. B28* (1972) 2869. In order to avoid unpleasant disturbances (e.g., disorder), we performed a renewed X-ray measurement on **2** (four-circle diffractometer) before embarking upon neutron diffraction and obtained a well-refinable "clean" structure free from any unusual features ($R = 0.038$). Altogether we prepared six simple norbornene derivatives and tested their suitability for neutron diffraction by means of complete X-ray analyses, until eventually the anhydride **2** was selected.

[4] O. Ermer, S. A. Mason, *Acta Crystallogr. B38* (1982) 2200.

[5] Thick orthorhombic plates of **2** [6] were grown from acetone solution; m.p. 142 °C. Space group $P2_12_12_1$, $Z = 4$, $a = 7.362(2)$, $b = 7.968(2)$, $c = 12.500(2)$ Å, temperature 15.0(1) K. Neutron intensities of altogether 2991 reflections were measured at this low temperature on the four-circle diffractometer D9 of the Institut Laue-Langevin, Grenoble (focusing Be monochromator, two-dimensional position-sensitive detector, $\lambda = 0.8429$ Å, $\theta_{max} = 51°$, crystal size ca. $3.7 \times 3.6 \times 1.3$ mm^3). After averaging, 2687 independent observed reflections with $I > 0$ remained, which were fed into the least-squares refinements. Absorption corrections were applied with a corresponding coefficient $\mu = 1.47$ cm^{-1} adopting an incoherent scattering cross-section of 35 barns for hydrogen. The final R value after anisotropic refinement of all atoms was 0.033 ($R_w = 0.032$, $\sum w(\Delta F)^2$ minimized, $w = 1/\sigma(F_0)^2$, extinction correction, nuclear scattering lengths taken from a recent compilation of *Sears* [7]). The refined atomic nuclear coordinates and anisotropic temperature factor coefficients are given in Table 1. A list of observed and calculated neutron structure amplitudes has been deposited [8].

Table 1. Fractional atomic nuclear coordinates ($\times 10^5$) and anisotropic temperature factor coefficients (Å$^2 \times 10^4$) of **2** at 15 K with estimated standard deviations in parentheses. Temperature factor expression of the form: $\exp[-2\pi^2(U11h^2a^{*2} + \ldots + 2U12hka^*b^* + \ldots)]$.

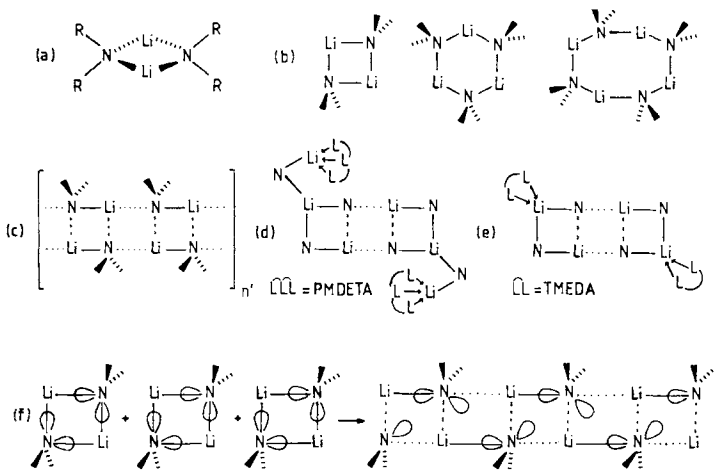
$[H_2\overline{C(CH_2)_5NLi}]_6$, the First Cyclized Lithium Amide Ladder: Synthesis and Structure of Hexamethyleneimidolithium **

By *Donald Barr, William Clegg, Susan M. Hodgson, Glenn R. Lamming, Robert E. Mulvey, Andrew J. Scott, Ronald Snaith,** and *Dominic S. Wright*

Lithium amides (amidolithiums), RR'NLi, are valuable reagents in both organometallic and organic syntheses.[1] As such, solutions of these reagents are usually either bought, or prepared in situ by lithiation of amines, then used forthwith in subsequent reactions.[2] More recently, however, a selection of these materials has been isolated and they have been examined in their own right; in particular, structures have been elucidated (in the crystal by X-ray diffraction,[3] and in solution by molecular mass measurements and NMR spectroscopy[4]), and attempts have been made to rationalize the occurrence of such structures.[5] Here we describe the synthesis, solid-state structure, and solution behavior of hexamethyleneimidolithium, **1**. Most importantly, in the crystal **1** is a hexamer (n = 6), and as such it is the first uncomplexed lithium amide structure with $n > 4$ and the first which is not a simple planar $(NLi)_n$ ring.[6] Despite such novel features, the structure of **1** is consistent with the prior rationalizations of amidolithium structures: although the hexamer could be viewed as arising from two vertically stacked trimeric rings, analysis of N–Li bond lengths within it reveals that it is in fact best seen as a ladder-type structure with sufficient N–Li rings (six) that the ladder can turn back on itself and cyclize.



$[H_2\overline{C(CH_2)_5NLi}]_6$ **1**

The building blocks for lithium amide structures appear to be planar $(NLi)_n$ rings (Scheme 1a, shown for n = 2). In the

absence of donors, such ring structures have been found (with n = 2–4,[6] Scheme 1 b) usually only when R,R′ groups

Scheme 1.

are particularly bulky. More typically, lithiation of amines RR′NH in non-donor solvents produces insoluble, seemingly polymeric materials. Such continuous association cannot, it has been argued[5] have taken place vertically by stacking of rings (as occurs for most other types of organolithium compounds[7]) since their R,R′ groups project above and below the ring plane (Scheme 1 a). Rather, it must presumably have taken place laterally, by joining $(NLi)_n$ ring edges and so giving "ladders" or "fences"[8] (Scheme 1 c). Some credence has been given to such a view by the recent isolation of oligomeric ladders: thus, although lithiation in toluene solvent of pyrrolidine **2**—chosen as its R,R′ groups are both small and tied—produces an insoluble, polymeric amide **3**, lithiations in the presence of pentamethyldiethylenetriamine (PMDETA) or tetramethylethylenediamine (TMEDA) result in donor-intercepted ladders, **4** and **5** respectively (cf. Scheme 1 d and e, resp.).[9] Interestingly,

$H_2\overline{C(CH_2)_3NH}$ **2** $[H_2\overline{C(CH_2)_3NLi}]_\infty$ **3**

$\{[H_2\overline{C(CH_2)_3NLi}]_3 \cdot PMDETA\}_2$ **4**

$\{[H_2\overline{C(CH_2)_3NLi}]_2 \cdot TMEDA\}_2$ **5**

lithiation of a higher homolog of **2**, hexamethyleneimine, in the absence of a donor produces the crystalline, arene-soluble lithium amide, **1** (see Experimental). The crystal structure[10] of **1** reveals a hexamer. This could be viewed (Fig. 1) as a cyclized ladder composed of six NLi rungs, or as a stack of two six-membered, trimeric $(NLi)_3$ rings (Fig. 2). In the context of these alternatives, it has been argued on the basis of MO optimizations of $(H_2NLi)_6$ structures [a stack of two rings, $[(H_2NLi)_3]_2$, being lower in energy than a ladder of six rungs, $(H_2NLi)_6$][11] that lithium amide rings should be able to associate vertically. In the case of **1** these alternatives can be resolved by inspection of the N–Li distances (Fig. 2): these fall clearly into two sets, (i) short, 1.99(1)–2.00(2) Å, (ii) long, 2.06(1)–2.12(2) Å. A short-medium-long pattern has been observed for a series of iminolithium hexamers,[12] each structure then being readily interpretable in terms of two stacked trimeric rings, with alternating short and medium length N–Li bonds within each ring and long bonds

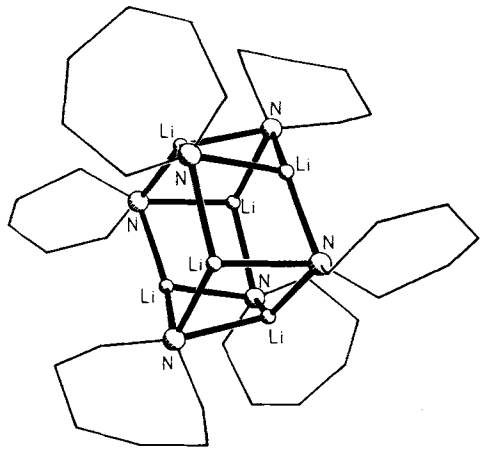

Fig. 1. Molecular structure of 1. The molecule has crystallographic inversion symmetry.

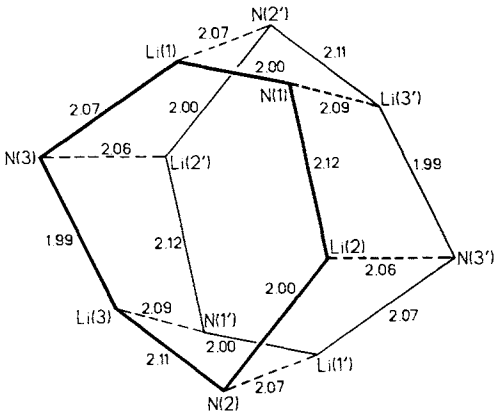

Fig. 2. Li–N bond lengths in 1 (standard deviation 0.01–0.02 Å). Hexamethylene units have been omitted for clarity.

between the rings. In the observed structure for **1**, however, the bonds between six-membered rings are not the longest; the pattern is rather one of alternating short and long bonds within the six-membered rings, which are held together by medium length bonds (though there is one instance of overlap of the medium and long distances). This implies that the structure of **1** is better viewed as a cyclized ladder (Fig. 1). As shown in Scheme 1 f, for $(RR'NLi)_2$ rings to come together laterally, one of the two lone-pair lobes on each amide $N^\ominus$ center must be redirected markedly, so to bond to two Li centers; the resulting ladder edges (N · · · Li) and rungs (N---Li) will thus be longer than the two-center edges (N-Li). A continuation of such ladder formation, and eventual cyclization, will thus produce short-long N-Li edges, with fairly constant (medium) length N–Li rungs; this is essentially the pattern observed for **1**.

In arene solutions it seems that **1** can form even higher aggregates than the hexamer found in the solid. Cryoscopic measurements on benzene solutions of **1** give association state values (n) of around 6 in relatively dilute solution, but these values increase markedly, to over 10, on concentration.[13] The ^{7}Li NMR spectra of $C_6D_5CD_3$ solutions of **1**[14] concur with the above. At ambient temperatures, a singlet is observed for each solution examined, though this broadens and moves to higher frequency (from $\delta \approx -1.1$ to $\delta \approx -0.8$) in more concentrated solutions. When the spectra are recorded at −90 °C, two signals ($\delta \approx -0.5$, -1.6) of approximately equal intensity are observed in dilute solutions; on progressive concentration, the higher frequency

singlet grows in intensity relative to the other singlet until, finally, it is the only signal observed. The implications of these cryoscopic and spectroscopic results are that there are (at least) two species present: presumably the hexamer (especially at lower concentrations; [δ (^{7}Li) ≈ -1.6] and an aggregate with n > 6 [δ (^{7}Li) ≈ -0.5].

Experimental Procedure

1: *n*BuLi (6.25 ml of a 1.60 M solution in hexane, 10 mmol) was added under N_2 to a chilled solution of hexamethyleneimine $H_2C(CH_2)_5NH$ (0.99 g, 10 mmol) in hexane/toluene (6 ml/4 ml). At room temperature, a white solid precipitated; this dissolved on warming to give a pale yellow solution. Cooling gave large colorless cube-shaped crystals which were filtered and characterized as **1**, [0.90 g, 86%, m.p. 112–115 °C; found C 68.4%, H 11.3%, Li 6.8%, N 13.4%. Calculated for $C_6H_{12}LiN$ = C 68.6%, H 11.4%, Li 6.7%, N 13.3%. ^{1}H NMR (C_6D_6, 80 MHz, 20 °C) δ = 1.71 (br s, 8H), 3.02 (br m, 4H)]. Single crystals suitable for X-ray crystallography were sealed under N_2 in Lindemann capillary tubes prior to data collection.

[6] Uncomplexed lithium amides (RR'NLi)$_n$ with (NLi)$_n$ ring structures are a) R = R' = Me_3Si, n = 2 (gas phase, by electron diffraction), T. Fjeldberg, P. B. Hitchcock, M. F. Lappert, A. J. Thorne, *J. Chem. Soc. Chem. Commun. 1984*, 822; b) R = R' = Me_3Si, n = 3 (crystal structure), R. D. Rogers, J. L. Atwood, R. Grüning, *J. Organomet. Chem. 157* (1978) 229; c) R = R' = $PhCH_2$, n = 3 (crystal structure), D. R. Armstrong, R. E. Mulvey, G. T. Walker, D. Barr, R. Snaith, W. Clegg, D. Reed, *J. Chem. Soc. Dalton Trans. 1988*, 617; d) RR'N = $Me_2C(CH_2)_3CMe_2N$, n = 4 (crystal structure), Ref. [2].

[7] The so-called "ring-stacking principle" is applicable to organolithium ring compounds whose R,R' groups are relatively coplanar with the (ELi)$_n$ rings (n = 2 or 3) e.g., in imidolithium compounds (RR'C = NLi)$_n$, E = N, in alkoxy- and enolatolithium compounds (ROLi)$_n$, and [R(H_2C=)COLi]$_n$ respectively, E = O, and in alkynyllithiums, (RC≡CLi)$_n$, E = C. Such relatively flat systems can thus associate vertically, giving clusters (e.g., two dimeric rings, to give a pseudocubane tetramer; two trimeric ones to give a hexamer). See a) D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, K. Wade, *J. Chem. Soc. Chem. Commun. 1986*, 295; b) D. R. Armstrong, D. Barr, R. Snaith, W. Clegg, R. E. Mulvey, K. Wade, D. Reed, *J. Chem. Soc., Dalton Trans. 1987*, 1071; c) D. Barr, R. Snaith, W. Clegg, R. E. Mulvey, K. Wade, *J. Chem. Soc. Dalton Trans. 1987*, 2141, and references cited therein.

[8] The term "fences" was first used in H. Kato, K. Hirao, K. Akagi, *Inorg. Chem. 20* (1981) 3659, to describe lateral associations of (LiH)$_2$ rings within a theoretical MO study of structural options for lithium hydride.

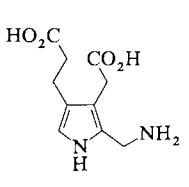
[9] D. R. Armstrong, D. Barr, W. Clegg, S. M. Hodgson, R. E. Mulvey, D. Reed, R. Snaith, D. S. Wright, *J. Am. Chem. Soc.*, in press. See also Ref. 5a].

[10] **1**: $C_{36}H_{72}Li_6N_6$, M_r = 630.7, triclinic, space group $P\bar{1}$, a = 9.966(4), b = 10.539(4), c = 11.692(5) Å, α = 116.01(2), β = 96.76(2), γ = 108.90(2)°, V = 914.2 Å^3, Z = 1, D_c = 1.053 g cm^{-3}, F(000) = 348, $Cu_{K\alpha}$ radiation, λ = 1.54184 Å, μ = 0.41 mm^{-1}. The structure was determined by direct methods and refined from 1522 unique observed reflections measured at room temperature with a Stoe-Siemens diffractometer ($2\theta_{max}$ 110°), with anisotropic thermal parameters, and with isotropic H atoms in calculated positions; R = 0.098, R_w = 0.098, S = 1.06 for 218 parameters. Further details of the crystal structure investigation can be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW (UK). Any request should be accompanied by the full literature citation for this communication.

[11] These calculations (K. Raghavachari, A.-M. Sapse, D. C. Jain, *Inorg. Chem. 26* (1987) 2585 showed, for $(LiNH_2)_6$ as two stacked trimeric rings, two "short" Li–N bonds (1.99 Å) and one "long" bond (2.06 Å) for each triply-bridging N atom. The fact that three sets of bond lengths are found for experimental imidolithium hexamers[12] was attributed to crystal packing effects. This attribution, and the validity of comparing theoretical amidolithium structures with experimental imidolithium ones, was challenged (W. Clegg, R. Snaith, K. Wade, *ibid. 27* (1988) 3861), drawing a response from the original authors (K. Raghavachari, A.-M. Sapse, D. C. Jain, *ibid. 27* (1988) 3862).

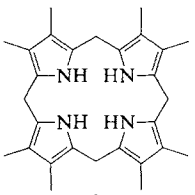
[12] The hexameric imidolithiums, (RR'C=NLi)$_6$, R = R' = *t*$BuMe_2N$, R = Ph, R' = *t*$BuMe_2N$, display average lengths of 1.98, 2.01, and 2.05 Å for their N–Li bonds. See Refs. [7a] and [7b].

[13] Cryoscopy was carried out on benzene solution of **1**. Relative molecular mass values found (molarity of solution, M, expressed in terms of the empirical formula of **1**, n = 1), and hence association states (n) were: 564 ± 23 n(0.055 M) = 5.37 ± 0.22; 895 ± 33 n(0.113 M) = 8.52 ± 0.32; 1061 ± 53 n(0.139 M) = 10.11 ± 0.51.



[14] Variable-temperature (25 °C, −90 °C) and variable-concentration (0.19 M, 0.25 M, 0.61 M solutions) ^{7}Li NMR spectra (139.96 MHz) were recorded for solutions of **1** in $C_6D_5CD_3$. At 25 °C each solution afforded a singlet: these were sharp (δ = −1.13, −1.24) in the relatively dilute solutions, much broader (δ = −0.80) in the concentrated one. At −90 °C, the 0.19 M and 0.25 M solutions each displayed two signals, though of differing relative integrals [δ = −0.50, −1.63 (ca. 1:1) and −0.49, −1.61 (ca. 2:1), respectively]; the 0.61 M solution spectrum consisted of just one, very broad resonance, at δ = −0.48.

Biomimetic Synthesis of an Inverted Porphyrinoid with Peripheral N Atoms**



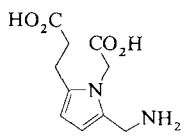
By *Karl-Heinz Schumacher* and *Burchard Franck**

Dedicated to Dr. Günther Ohloff on the occasion of his 65th birthday

A key step in the biosynthesis of all porphyrin natural products is the cyclocondensation of monopyrrole porphobilinogen **1** to give a colorless, nonconjugated porphyrinogen **2**.[2, 3] We have mimicked this biosynthetic reaction to

1

2



condense derivatives of **1** in vitro under acid catalysis to give novel, structurally modified porphyrinogens.[3, 4] These biomimetic[5] porphyrin syntheses excel other procedures in the low number of steps and the good overall yields.

Of particular interest is the question whether it is possible to prepare an inverted porphyrinogen **4a** by biomimetic condensation of a porphobilinogen isomer such as **3**. Here we

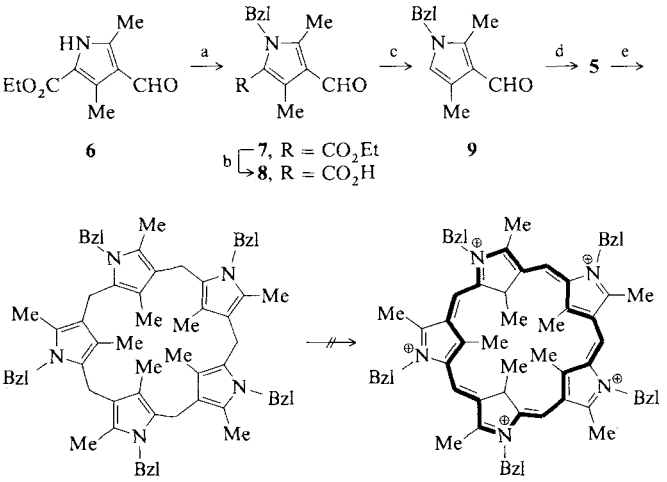
4a, n = 1
4b, n = 2

report the first biomimetic synthesis of a compound with the ring system of **4b**.

Inverted porphyrinogens, the nitrogen atoms of which are on the periphery of the molecule instead of in the interior, give rise to several questions which are important for understanding porphyrin systems:

1. Can inverted porphyrinogens be dehydrogenated to give the corresponding, possibly aromatic porphyrins?
2. Are cyclic tetrapyrroles preferentially formed in the biomimetic synthesis of inverted porphyrinogens as they are for natural porphyrinogens?
3. Does the comparison of inverted porphyrinogens with normal porphyrinogens offer evidence of transannular interactions between the N atoms of the latter?

The porphobilinogen isomer **3** and the structurally similar monopyrroles, which were initially considered as starting pyrroles for the biomimetic synthesis of an inverted porphyrinogen, proved unsuitable because of their tendency to undergo polymerization. Therefore, the better protected *N*-benzylpyrrole **5** was chosen for subsequent investigations.



5

Although this pyrrole was expected to undergo some cyclocondensation to give products in which the *C*-methyl groups are directed toward the center of the ring, earlier experience[4a] indicated that this reaction would not interfere with the cyclization.

The synthesis of monopyrrole **5** (Scheme 1) started from the known[6] pyrrole aldehyde **6**, accessible in two steps from acetylacetone and diethylhydroxyiminomalonate by Kleinspehn condensation[7] and formylation. *N*-Benzylation to give **7**, ester saponification to give **8**, and thermal decarboxylation afforded aldehyde **9** (m.p. 64 °C), which crystallizes as needles and serves as a stable synthetic precursor.

To perform the biomimetic condensation, **9** was reduced to the reactive hydroxymethylpyrrole **5** by treatment with $NaBH_4$. Compound **5** was then treated in situ at −50 °C under oxygen-free conditions with *p*-toluenesulfonic acid/glacial acetic acid. Subsequent warming to 20 °C afforded a 71% yield of an oxygen-sensitive solid, which was pure according to thin layer chromatography. Elemental analysis and mass spectrometry ($M^{\oplus}$, *m/z* 985, 40%) gave the empirical formula $C_{70}H_{75}N_5$ for the condensation product; structure **10** was derived from the fragment peaks in the EI mass spectrum and from the ^1H NMR data.[10]

Compound **10** is the first inverted porphyrinoid. It is especially interesting that, in this biomimetic condensation, the

Scheme 1. Synthesis of the inverted porphyrinoid **10** via *N*-benzyl-3-formyl-2,4-dimethylpyrrole **9**. Reaction conditions: a) BzlBr, NaH/DMF, 20 °C, 30 min; 96% **7** (m.p. 48 °C). b) 25% NaOH, 100 °C, 2 h; 86% **8** (m.p. 157–158 °C). c) Kugelrohr distillation 180 °C/0.2 mbar; 80% **9** (m.p. 64 °C). d) $NaBH_4$/MeOH, 20 °C, 15 min. e) *p*-TosOH/AcOH, −50 °C, 1 h; 71% **10** [10].

inversion of the pyrrole rings leads with high selectivity to a cyclic *penta*pyrrole instead of a tetrapyrrole. This has never been observed before in similar condensations with porphobilinogen **1**.[2] We propose the name *inverto-pentaphyrinogen* for the basic framework of **10**.[8]

Further noteworthy are the chemical reactivity and oxidation sensitivity of **10**. Whereas non-inverted porphyrinogens, like our new vinylogously enlarged porphyrinogens,[1,4d–f] are smoothly dehydrogenated by bromine and other oxidation agents to give stable, aromatic porphyrins, we failed, despite extensive attempts, to transform **10** under these conditions into a conjugated, possibly aromatic inverto-pentaphyrin such as **11**; instead, only decomposition products were obtained. A possible explanation might be that, although **11**, the hypothetical dehydrogenation product of **10**, can form an aromatic 22 π-electron perimeter, this results in a destabilizing accumulation of charge.[11]

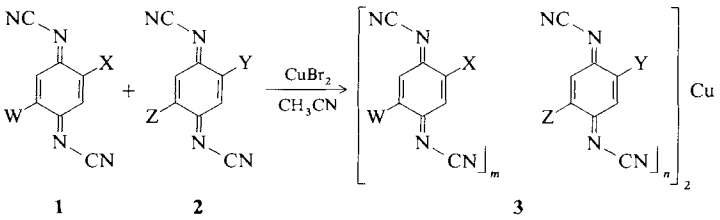
[8] This nomenclature proposal corresponds to the term "pentaphyrin", introduced by *Rexhausen* and *Gossauer* [9], for porphyrin-like cyclic pentapyrroles. Accordingly, the porphyrinogen analogues of cyclic pentapyrroles are called "pentaphyrinogens". Since **10** differs from these in the inversion of the five pyrrole rings, it is called an "inverto-pentaphyrinogen".
[9] H. Rexhausen, A. Gossauer, *J. Chem. Soc. Chem. Commun. 1983*, 275.
[10] The new compounds **7**–**10** were completely characterized by elemental analyses and spectroscopic data.
[11] Structure **11** may be regarded as the most likely tautomer of a dehydrogenation product of **10**. A smaller conjugated perimeter, which would enclose the inward directed methyl-substituted C atoms of all pyrrole rings, would contain 20 π electrons and thus be antiaromatic. Likewise, less charged structures, in which the outer CN double bonds not involved in the π-electron perimeter are hydrogenated, may presumably be excluded for the dehydrogenation product of **10**.

Binary Alloys of 2,5-Disubstituted DCNQI Radical Anion Salts of Copper and Their Electrical Conductivity**



By *Peter Erk, Hans-Jörg Gross, Siegfried Hünig,* Uwe Langohr, Hubert Meixner, Hans-Peter Werner, Jost Ullrich von Schütz,* and *Hans Christoph Wolf*

Dedicated to Professor Gottfried Märkl on the occasion of his 60th birthday

N,N'-Dicyanoquinodiimines (DCNQIs),[1] particularly in the form of their 2,5-substituted benzoquinone derivatives, have proven very useful as novel acceptors in charge transfer (CT) compounds[1c, 2] and especially in radical anion salts of the type [2,5-X,Y-DCNQI]$_2$M (M = monovalent metal ion).[3] Despite wide variation of the substituents X and Y (see below) and of M (Li, Na, K, Rb, Cu, Ag, Tl,[3c] NH_4[3c, 4a] all these salts crystallize in the same structure type:[3a, 3c, 4] by tetrahedral coordination of the metal ions these are strung out like a pearl necklace and surrounded by four stacks of DCNQI units.[3a, 3c, 4a] The retainment of the same structure type despite large variation of the substituents and counterions is unknown in the case of other conductive radical salts.

The copper salts [2,5-X,Y-DCNQI]$_2$Cu play a special role, for only they show a multidimensional[5, 6] and significantly increased metallic conductivity. As in many analogous cases,[7, 8] in the salts with X,Y = Me/Cl, Me/Br, Cl/Cl, Cl/Br, Br/Br a metal-semiconductor transformation takes place on cooling as a result of a Peierls distortion.[3c, 4c, 5] Contrastingly, when X,Y = Me,Me,[3a] Me,I[3b] and MeO, MeO[4c] the conductivity steadily increases up to < 3 K, whereby values of up to 5×10^5 S cm^{-1} are achieved.[3a] So far, however, neither the substituent-dependence[9] nor the unusual pressure-dependence[10] of the phase transitions are fully understood. It was therefore considered of interest to prepare alloys of the corresponding copper salts in which two differently substituted DCNQIs are incorporated in the stack, so as to study the influence of this disturbance on the electrical conductivity and other physical properties in a fundamentally similar crystal lattice.

For the synthesis of the necessary single crystals of binary alloys of the type [(2,5-W,X-DCNQI)$_m$(2,5-Y,Z-DCNQI)$_n$]$_2$Cu **3** we first resorted to the usual method of electrocrystallization.[3a] In this way (method A), **3a–c, 3g, 3i** and **3k** (Table 1) could be obtained. However, the much simpler method of immersing a polished copper wire into a solution of the DCNQIs in acetonitrile (method B)[11] also led to well crystallized alloys, as demonstrated by the examples **3d–f, 3h, 3j, 3l,** and **3m**. The ratio of the two components in the alloy frequently deviate thereby from that obtained by electrocrystallization, even though equimolar amounts of the two DCNQIs were employed in all cases.

1 **2** **3**

The ratios $\mathbf{1}_m/\mathbf{2}_n$ in the salts **3** were ascertained from the elemental analyses and are therefore subject to the corresponding errors. All alloys crystallize isotypically to the individual components (space group $I4_{1/a}$).[12] Which factors determine the composition is still unknown. The difference ΔE in the redox potentials of the components **1** and **2** (Table 1)[2c, 3c] can only play a subordinate role; e.g. for $\Delta E = +0.21$ V corresponding to an energy difference of 4.8 k calmol^{-1}, a ratio of easily reducible to difficulty reducible components of ca. 3000:1 would be expected if thermodynamic factors alone were to be responsible. Thin (10–30 μm), black, shiny crystalline needles of ca. 1–15 mm in length are obtained by methods A and B. Their structureless IR spectrum (KBr) in the region 4000–600 cm^{-1} immediately points to high electrical conductivity.[13] This is confirmed by powder conductivities[14] of ca. 0.1–0.2 S cm^{-1} and sin-

gle-crystal conductivities[15] of 100 to 500 S cm^{-1} which almost reach those of the components.[2b, 3, 4b, 4c]

That mixed crystals are actually present and not just mixtures with different elemental analyses is demonstrated by the following findings:

1) In several single crystals of **3k** both bromine as well as iodine could be detected.
2) The X-ray powder diagrams of **3i** show reflections which cannot be assigned to either of the two components.[12] Their large half-widths and the high noise-to-signal ratios point to a strong disorder, presumably as a result of random distribution of the components.
3) The temperature-dependence of the electrical conductivity, which is discussed in detail elsewhere,[16] deviates significantly from that of the component copper salts, whereby three different types with metallically conductive alloys can be distinguished: a) alloys which exhibit a sharp phase transition to the semiconductor between 180–120 K (**3g** and **3i**); b) alloys with a very broad phase transition to the semiconductor (**3a** and **3b**); c) alloys whose conductivity increases up to 4 K (**3c, 3f** and **3k–m**).

Remarkable is the case of **3k** (Fig. 1): although the component [2,5-Br,Me-DCNQI]$_2$Cu is characterized by a sharp

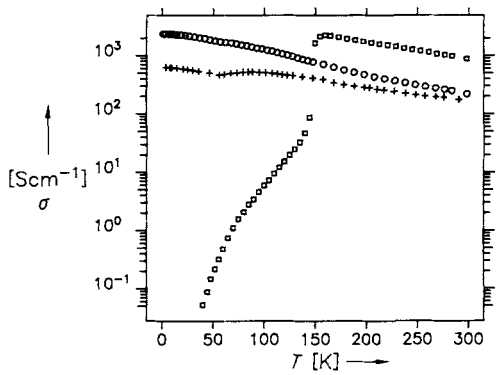

Fig. 1. Comparison of the temperature-dependent conductivities σ of [2,5-Br,Me-DCNQI]$_2$Cu (□□□) and [2,5-I,Me-DCNQI]$_2$Cu (○○○) with that of the alloy **3k** (+ + +) of both components.

phase transition to the semiconductor at 150 K,[4c, 5] the breakdown in conductivity in the mixed crystal is suppressed with [2,5-I,Me-DCNQI]$_2$Cu. The phase transition is still albeit only weakly in the temperature range 90–20 K. Upon further cooling it is apparently cancelled, so that the conductivity increases to 600 S cm^{-1} as the temperature approaches 4 K. Our studies are being extended to tertiary[16] and quaternary alloys of the same type, the first examples of which have already been synthesized.

Experimental Procedure

Method A: A mixture of 200–400 μmol each of **1** and **2** and 200–300 μmol of $CuBr_2$ in 60 mL of acetonitrile was electrolyzed galvanostatically in a three-compartment cell with Pt wire at 30–50 μA for 4–5 days at room temperature. The crystals that were filtered off were washed with acetonitrile and dried.

Method B: As described in Ref. [11] a freshly polished copper wire was immersed in a solution of 100 μmol each of **1** and **2** and 150 μmol of $CuBr_2$ in 25 mL of acetonitrile. After 3–4 days the crystals that separated (40–90%) were filtered off, washed with acetonitrile, and dried.

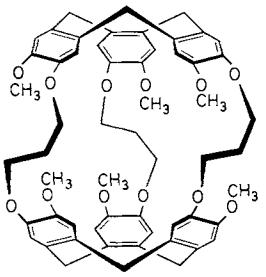
Structure and Properties of the Cryptophane-E/$CHCl_3$ Complex, a Stable van der Waals Molecule**



By *Josette Canceill, Michèle Cesario, André Collet,* Jean Guilhem, Liliane Lacombe, Bénédicte Lozach,* and *Claudine Pascard*

What are the driving forces leading to the formation of stable complexes between neutral host and guest molecules *in the absence of hydrophobic effects*? Examples of such complexes are the 1:1 complexes between cryptophane-E **1** and chloroform[1] or isobutane,[2] which form reversibly in 1,1,2,2-tetrachloroethane with association constants of over 10^2 M^{-1} at room temperature.[3] We report here some evidence that the above complexes may be viewed as "van der

Waals molecules", that is, structurally well-defined assemblies of two neutral species noncovalently bound to each other.[4] This conclusion stems from an X-ray structure determination of the **1** · $CHCl_3$ complex and from variable-temperature ^1H NMR studies of a series of complexes of **1** with neutral guest molecules of appropriate size.

1

The structure of the **1** · $CHCl_3$ complex in the crystalline state is depicted in Figure 1.[5] The host molecule is almost spherical (10 Å in diameter) and displays nearly noncrystallographic D_3 symmetry. The two cyclotriveratrylene caps are twisted with respect to each other by ca. 60° around the pseudo C_3 axis, and the benzene rings α, β, and γ of the upper cap are parallel to the rings β′, γ′, and α′, respectively, of the lower cap. The three $O(CH_2)_3O$ bridges have about the same conformation, with the pseudo C_2 axes of the D_3 group passing through the inner methylenes of the chains. One of the methoxy groups shows orientational disorder (three positions), whereas the others are roughly coplanar with the aromatic rings to which they are bound. In this conformation, they partially obstruct the windows giving access to the host cavity.

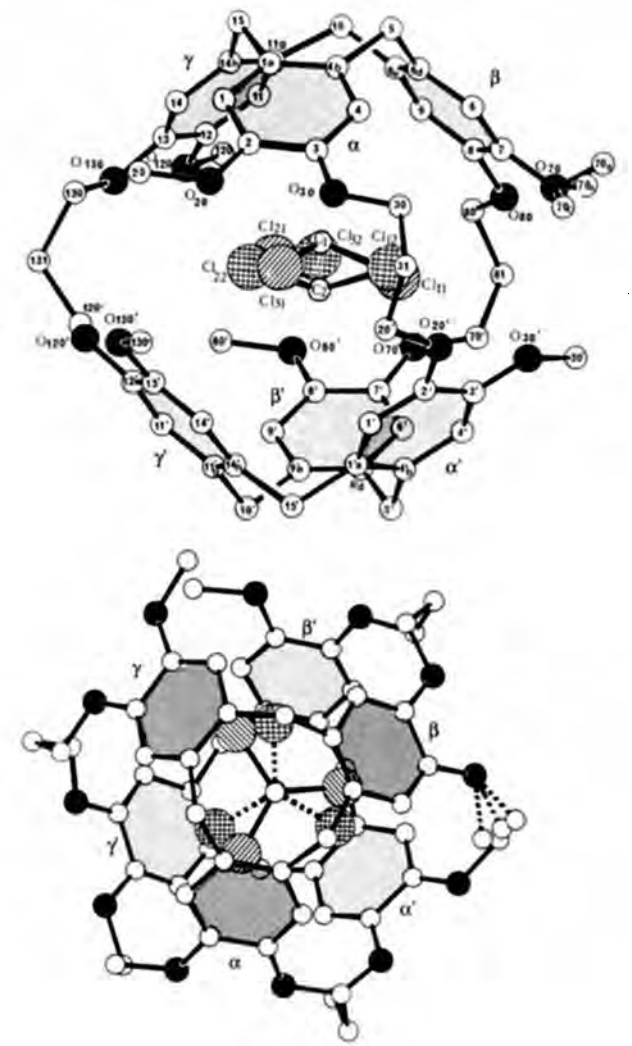

Fig. 1. Side view (top) and top view (bottom) of **1** · $CHCl_3$ in the crystal.

In the crystal, the encaged chloroform molecule exhibits two almost equivalent and equiprobable orientations, in which the chlorine atoms occupy the central equatorial plane of the host and the C–H bond points either up or down along the pseudo C_3 axis. The two positions are related by pseudo-symmetry around the C_2 axes of the host, and the two complexes are thus structurally similar. We cannot decide whether this situation is the consequence of a static disorder, where the host molecules are filled statistically with a chloroform molecule turned up or down, or of a dynamic disorder of the guest turning upside down (and possibly rotating around its C_3 axis) during the time needed for the X-ray data collection.

In ^1H NMR studies (Table 1) of complexes between **1** and various guests ranging in size from CH_3I (54.5 Å^3) to $(CH_3)_3CCl$ (93.9 Å^3) in 1,1,2,2-tetrachloro-1,2-dideuterioethane as solvent, we observed in all cases a slow exchange, on the NMR time scale, between the free and complexed guest molecules. The resonances of the latter were shifted upfield ($\Delta\delta$ = 2.9–4.5 ppm) with respect to those of the free species, as a result of the shielding effect of the six aromatic rings of the host. The $\Delta\delta$ values given in Table 1 suggest that the complexes of **1** with CHXYZ guests in solution have a structure similar to that of the chloroform complex in the crystal, with the H atom embedded in one of the cyclotriveratrylene caps ($\Delta\delta$ = 4.25–4.44 pm) and the X, Y, and Z groups in the equatorial plane ($\Delta\delta$ = 2.95 ppm for the methyl groups in isobutane).

In the $CCl_n(CH_3)_{4-n}$ complexes (n = 1–3), which are much weaker in strength than the CHXYZ complexes, the observed $\Delta\delta$ values presumably represent some averaging between axial and equatorial positions of the methyl groups. In the CCl_3CH_3 complex, the methyl $\Delta\delta$ value approaches that of an axial group, whereas in the $CCl(CH_3)_3$ complex it is close to that of isobutane, which indicates that the chlorine

atom is preferentially axial. In these two cases, the complex of higher symmetry (C_3) seems to be preferred. The fact that a single signal was observed for the methyl groups in all these complexes means that the substituents exchange their position rapidly on the NMR time scale.

In Figure 2, we have plotted the complexation free energy (ΔG_i) at 300 K as a function of the van der Waals volume

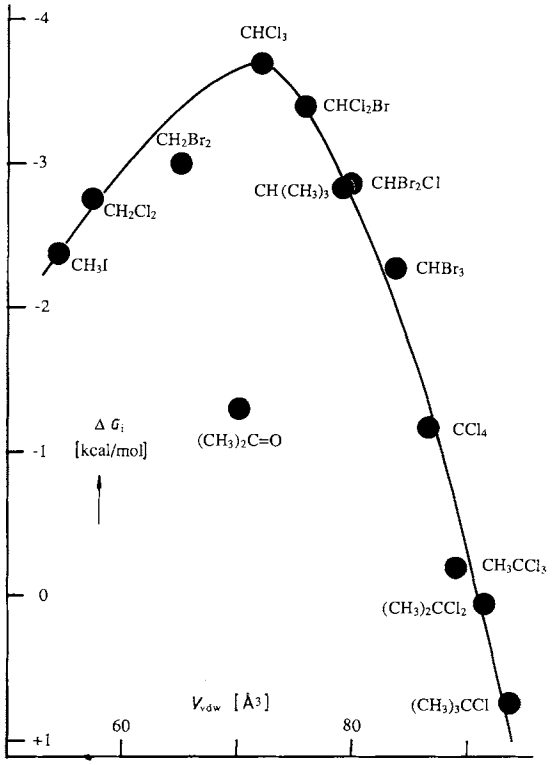

Fig. 2. Free energy of formation (ΔG_i) at 300 K of a series of complexes of **1** as a function of the size (V_{vdw}) of the guests.

(V_{vdw}) of the guest.[6] At this temperature, **1** displays a smooth and steep size recognition and, for instance, discriminates between $CHCl_3$ and $CHCl_2Br$ by 0.3 kcal mol^{-1}, an energy difference which is best appreciated by considering that the difference in volume of these two molecules is only 5%. However, **1** does not discriminate between isobutane and $CHBr_2Cl$, which have the same V_{vdw}. On the other hand, acetone is more weakly bound than chloroform although they have almost the same size. Host **1** therefore efficiently recognizes tetrahedral (sp^3) versus flat (sp^2) molecules. It is noteworthy that we did not observe any significant increase of the inclusion barrier ($\Delta G_i^{\neq}$ in Table 1) on going from the smallest (CH_3I) to the largest guest ($CHBr_3$) for which this value was measured. Therefore, the cross section of the windows does not control the selectivity, at least in this range of guest size.

From the temperature dependence of ΔG_i (over a range of at least 40 K) we obtained relatively precise[7] values of the enthalpy ΔH_i and entropy ΔS_i for guest inclusion (Table 1). These data indicate that the driving forces for complexation depend on the guest size. The complexation of $CHCl_3$ and of slightly larger substrates (at least up to isobutane) is enthalpy driven and entropy disfavored. In 1,1,2,2-tetrachloroethane, solvophobic forces[8] are probably too weak to account for the magnitude of ΔH_i for these guests (-3.8 to -6.0 kcal mol^{-1}), and the stability of these complexes should therefore be ascribed to attractive host–guest interactions, provided by dispersion forces. These interactions require a good fit between partners, which is apparently experimentally realized with CHXYZ substrates that are 70–80 Å^3 in size (a value ca. 20% smaller than that suggested by CPK models[9]). We may thus consider these complexes as examples of very stable van der Waals molecules.

By contrast, the complexation of smaller (CH_2Cl_2) or larger substrates (> $CHClBr_2$) by **1** is not enthalpy driven. These complexes therefore do not owe their stability to attractive host–guest interactions, but rather to the operation of external factors. These factors may include solvophobic effects, as well as more subtle thermodynamic contributions, such as specific heat and/or volume differences between the complexes and their separated components. Whether or not these complexes still belong to the category of van der Waals molecules is only a matter of definition.[4]

[4] As presently accepted, the term "van der Waals molecule" only applies to species of very short life time such as He · · · He or $C_6H_6 \cdot Cl_2$ assemblies, which have been the object of numerous theoretical and experimental investigations. Here we extend this definition to supermolecules, which, in solution, may have life times of the order of several seconds at 273 K; see: A. van der Avoid, P. E. S. Wormer, F. Mulder, R. M. Berns, *Top. Curr. Chem. 93* (1980) 3; P. Hobza, R. Zahradnik, *ibid.* (1980) 53.
[5] The crystal used for the X-ray data collection was grown from chloroform/95% ethanol. The asymmetric unit consists of one $\mathbf{1} \cdot CHCl_3$ supermolecule with additional $CHCl_3$ and H_2O molecules outside in nonstoichiometric ratios, corresponding to [($C_{57}H_{60}O_{12} \cdot CHCl_3$), 0.2 $CHCl_3$, 0.2 H_2O]. Monoclinic, space group $P2_1/n$, $a = 38.262(14)$, $b = 12.441(5)$, $c = 12.748(5)$, Å, $\beta = 95.78(6)°$, $V = 6037$ Å^3, $Z = 4$, $\varrho_{calcd} = 1.192$ g cm^3. A total of 8688 independent reflections were collected on an automatic four-circle diffractometer, using graphite monochromated $Cu_{K\alpha}$ radiation (1.5418 Å); 4380 reflections were used in structure solution and refinement [$(I > 3\sigma(I)$]. Lorentz and polarization corrections were applied but no absorption corrections. The structure was solved by Direct Methods [10] and the atomic coordinates and anisotropic thermal parameters for heavy atoms (except for solvent molecules and a disordered methyl group) were refined to $R = 13.3\%$ ($R_w = 11.9\%$) using a large-blocks least-squares refinement program [11]. Hydrogen atoms were introduced at their theoretical positions (C-H 1.08 Å) and assigned the equivalent isotropic thermal factors of the C atoms to which they are bound. The electronic density analysis of the inner part of the cavity showed the chloroform molecule in two equally occupied orientations. One of the six methyl groups showed rotational disorder over three positions, with occupancy factors 0.6, 0.2, and 0.2. Fourier-difference series revealed the presence of additional molecules in the lattice vacancies, namely chloroform molecules in two mutually exclusive positions (occupation factor = 0.09 and 0.11) and a water molecule (occupation factor = 0.20). The refinement of internal and external chloroform molecule coordinates was performed in rigid groups, using a theoretical model (C-Cl = 1.73 Å, Cl-C-Cl = 111°). The highest residue on the final electronic density map is 0.58 e. Å^3. Further details of the structure analysis are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (UK), on quoting the full literature citation.

Cryptophane Radical Cations as Components of Three-Dimensional Charge-Transfer Salts**

By *Anne Renault, Daniel Talham, Josette Canceill, Patrick Batail, André Collet,* and *Janine Lajzerowicz**

Most organic donors known to date are flat molecules such as tetrathiafulvalene (TTF), which, when associated with suitable electron acceptors, tend to form charge-transfer (CT) salts of low dimensionality.[1] The use of increasingly larger inorganic anions,[2] or of electron-rich molecules that cannot achieve a flat conformation (e.g., *para*-cyclophanes)[3] has been recently considered as a way to increase the dimensionality of these materials. We report here a series of *three-dimensional* charge-transfer complexes in which a large, essentially spherical (10 Å in diameter) cryptophane molecule is employed as the donor. A cryptophane[4] such as **1**[5] is made of two electron-rich cyclotriveratrylene units **2** held together rigidly by three short chains. We anticipated that oxidation of **1** would afford radical cation species which might be stabilized by delocalization over the entire molecule.

1

2

Indeed, we found that cryptophane-E **1** in acetonitrile solution showed two reversible oxidations (Fig. 1) at 0.69 V ($\mathbf{1}/\mathbf{1}^{\oplus}$) and 0.85 V ($\mathbf{1}^{\oplus}/\mathbf{1}^{2\oplus}$) versus $Ag/Ag^{\oplus}$.[6] We also observed another oxidation ($\mathbf{1}^{2\oplus}/\mathbf{1}^{3\oplus}$), approaching chemical reversibility, at 1.11 V. The behavior of **1** contrasts markedly with that of cyclotriveratrylene itself, which, under the same conditions, shows two nonreversible waves at 0.87 and 1.03 V; irreversibility in the latter case might be due to a conformational change (crown to saddle) occurring on oxidation and leading to reactive species, as in the case of the cyclotriveratrylene cation itself;[4] such a conformational change cannot take place in cryptophane **1**.

Well-faceted, blue-green hexagonal single crystals of a series of charge-transfer salts $[(\mathbf{1}^{\bullet\oplus})(X^{\ominus})(CHCl_3)]$ were grown

at a platinum wire anode by constant-current electrolysis (20.5 μA cm^{-2}) of a $CH_2Cl_2/CHCl_3$ (4:1) mixture containing **1** (10^{-3} M) and the tetrabutylammonium salts (10^{-1} M) of various $X^{\ominus}$ ions ($BF_4^{\ominus}$, $ClO_4^{\ominus}$, $PF_6^{\ominus}$, and $ReO_4^{\ominus}$) as supporting electrolytes. Their unit-cell parameters are similar (Table 1), which indicates that their structures are related.

Table 1. Single-crystal lattice parameters for charge-transfer complexes of $\mathbf{1}^{\bullet\oplus}$ with inorganic anions [a].

Anion	a [Å]	b [Å]	c [Å]	V [Å^3]
$PF_6^{\ominus}$	12.692(7)	12.692(6)	30.467(11)	4209
$ClO_4^{\ominus}$	12.595(7)	12.595(6)	29.783(11)	4104
$ReO_4^{\ominus}$	12.617(7)	12.617(6)	30.011(11)	4137
$BF_4^{\ominus}$	14.805(7)	14.805(7)	25.878(9)	4881

[a] Rhombohedral lattice with hexagonal cell parameters, $\alpha = \beta = 90°$, $\gamma = 120°$ for all complexes.

The stoichiometry of the salts has been determined by the crystal structure analysis[7] of $[(\mathbf{1}^{\bullet\oplus})(PF_6^{\ominus})(CHCl_3)]$ (Fig. 2). Indeed, this salt is a fully charge-transferred 1:1 complex, since the asymmetric unit consists of one oxidized cage $\mathbf{1}^{\bullet\oplus}$ and one $PF_6^{\ominus}$ ion and also contains a chloroform molecule

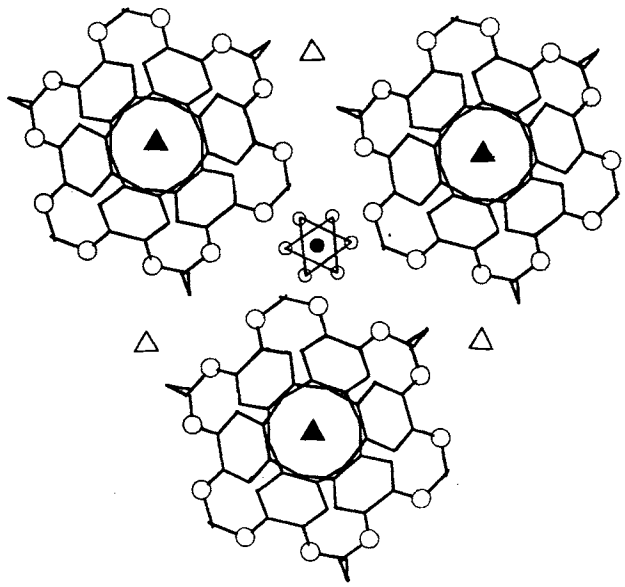

Fig. 2. Projection of the structure of $[(\mathbf{1}^{\bullet\oplus})(PF_6^{\ominus})(CHCl_3)]$ onto a plane perpendicular to the threefold axis; ▲ and △ centers of 1 at $z = 0$ and $z = 1/3$, respectively; ● center of $PF_6^{\ominus}$ at $z = 1/6$.

accommodated within the cryptophane cavity, as in the [**1** · $CHCl_3$] complex.[8] The packing is a face-centered cubic array of the large spherical cations, with the anions (roughly thirteen times smaller) located in all the octahedral sites (at the edge centers and body centers of the cubic unit cell).[9]

ESR spectra of single crystals of $[(\mathbf{1}^{\bullet\oplus})(PF_6^{\ominus})(CHCl_3)]$ at room temperature displayed a single line with $g = 2.0030$ and with a line width of ca. 1.8–2 gauss. This further demonstrates the existence of quasi-free, delocalized π electrons. Also, the paramagnetic signal was still present when the crystals were dissolved in dichloromethane, from which we conclude that $\mathbf{1}^{\bullet\oplus}$ is a stable species.

For some single crystals of $[(\mathbf{1}^{\bullet\oplus})(PF_6^{\ominus})(CHCl_3)]$ the temperature dependence of the spin susceptibility was measured directly using a squid susceptometer in the range of 4 to 300 K and found to follow a Curie–Weiss law with a weak antiferromagnetic coupling. The corrected magnetic moment is 1.7 μ_B, corresponding to one essentially noninteracting spin ($S = 1/2$) per molecule of **1**. The observed insulating character of the complex is thus a consequence of the purely ionic nature of the salt and indicates the lack of stabilization of any intermolecular mixed valence state in the solid, presumably because of the very poor overlap between the radical cations.

In conclusion, we would like to focus on the following ideas: (1) The above results suggest that **1** and presumably other cryptophanes easily form a radical cation on oxidation and hence represent a new family of organic donors. (2) These large, spherical molecules drive the crystal structure toward three-dimensional close-packed arrays, in contrast to flat donor molecules which often stack in unidimensional columns. (3) The cryptophane cavity can accommodate relatively large guest species[4] (here, a chloroform molecule); this feature may aid in the design of new materials. (4) Finally, we wish to point out that the second oxidation wave of **1** (not investigated thus far), which is also chemically reversible, generates a dication with a potential triplet ground state (D_3 symmetry).[10]

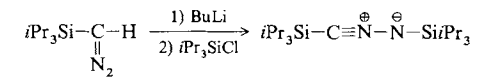
A Distillable *C*- and *N*-Silylated Nitrile Imine**

By *Florence Castan, Antoine Baceiredo,* and *Guy Bertrand**



Since the famous *Huisgen* reviews[1] in 1963, 1-3 dipolar cycloadditions have been the subject of a tremendous number of papers. In this area, much work has been dedicated to the study of nitrile imines.[2] However, it was only in 1988 that the first compound of this type, (**2**), was isolated.[3]

1 **2**

It was of interest to know if the method used for synthesizing **2** was generally applicable to the preparation of other stable nitrile imines with common substituents, which could be of use for the facile synthesis of a variety of heterocycles. Here we wish to report the synthesis and reactivity of a distillable *C*- and *N*-silylated nitrile imine.

Bulky substituents are necessary in order to kinetically stabilize highly reactive species. We therefore chose to study the action of the lithium salt of triisopropylsilyldiazomethane on the triisopropysilyl chloride. The reaction occurred between $-90°$ and $-100\,°C$, in dry THF, in the presence of a crown ether, affording the desired nitrile imine **4**.[4]

3 **4**

Interestingly, compound **4** is stable enough to be purified by distillation at 90–100 °C (0.15 torr) without noticeable decomposition (80% yield) as a pale yellow oil (λ_{max} = 272 nm). The strong and broad absorption in the IR spectrum at 2120 cm^{-1} was slightly shifted compared to that observed for *N*-silylated nitrile imines in a matrix[5] but its position excluded the diazirine and isodiazirine isomers as possible products. The non-equivalence of the silicon atoms, demonstrated in the ^{29}Si NMR spectrum, excluded the four other isomers, namely the diazo compounds carbodiimide, cyanamide and isocyanamide. The ^{13}C NMR signal for the quarternary carbon is shifted downfield compared to that in the starting diazo compound **3**. This was also observed for compound **2** (Table 1).

Table 1. ^{13}C,^{29}Si, and IR spectroscopic data for the compounds **1**–**4** and **8**. The ^{13}C and ^{29}Si NMR spectra were recorded at 75.469 and 59.628 MHz, respectively, in $CDCl_3$ (**1**–**3**) and in C_6D_6 (**4**, **8**); the IR spectra in pentane.

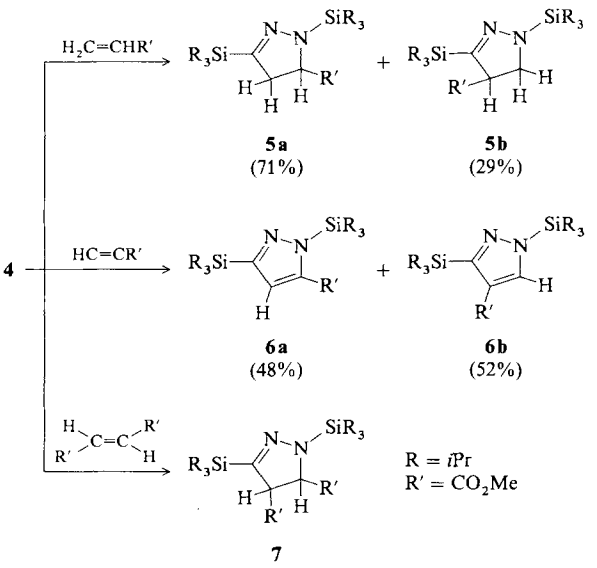
[**] This work was supported by the Pierre-Fabre-Medicaments Company. We thank *Dennis Bigg* for helpful discussions.

The influence of bulky substituents on the course of the reaction is quite obvious, and *Seyferth* et al.[6] have reported that the lithium salt of the tri*methyl*silyldiazomethane reacts with tri*methyl*silylchloride giving the bis(trimethylsilyl)diazomethane.

The silylated dipolar compound **4** reacts at room temperature, in the presence of a large excess of methyl acrylate, methyl propiolate and dimethyl fumarate, affording the expected adducts **5–7** in 20 to 30% isolated yield (Table 2).



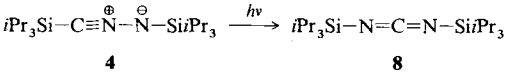


Table 2. ^{13}C and ^{29}Si NMR spectroscopic data for the adducts **5–7**. The ^{13}C NMR spectra were recorded at 50.323 MHz (**7**) and at 75.469 MHz (**5, 6**) in $CDCl_3$, the ^{29}Si NMR spectra at 39.761 MHz in $CDCl_3$.

Cpd.	^{13}C NMR δ(C=N)	δ(CCC)	δ(CCN)	^{29}Si NMR δ
5a	147.16	45.60	59.42	−1.02, 8.12
5b	142.66	56.63	45.60	−0.05, 7.40
6a	151.33	120.59	139.79	−0.92, 20.28
6b	154.11	121.42	140.17	1.70, 15.96
7	142.75	61.55	63.92	0.11, 9.39

The low yield of these reactions was probably due to some decomposition of the products on the silica gel since NMR analysis of the crude reaction mixtures indicated a nearly quantitative yield. The non-regioselectivity observed for non-symmetrical dipolarophiles has already been noted in the trapping reactions of unstable nitrile imines[7] and has been explained using molecular orbital theory.[8]

Depending on the nature of the substituents, nitrile imines thermally rearrange either by a 1,3 sigmatropic shift to form diazo compounds,[9] a 1,4 shift to form azines,[10] or cyclization.[9b, 11] Rearrangement to a carbodiimide has been detected only at very high temperature (> 500 °C) in the gas phase[10] or photochemically in a matrix along with the cleavage of the N–N bond.[12] No thermal rearrangements have been observed for **4** up to 250 °C in the gas phase, but irradiation of a pentane solution at 300 or 254 nm for 1 day quantitatively afforded bis(triisopropylsilyl)carbodiimide **8** (Table 1).

4 **8**

The facile cleavage of silicon-nitrogen and even silicon-carbon bonds makes this first bis(silylated)nitrile-imine **4** a synthetic equivalent of the parent compound (HCNNH) which should be a useful tool in organic synthesis. Moreover, these results demonstrate the wide applicability of the synthetic method used.

Hg_8 ("Mercubane") Clusters in $Rb_{15}Hg_{16}$

By *Hans-Jörg Deiseroth** and *Axel Strunck*

RbHg is so far the only compound among the alkali-metal amalgams of composition MHg (M = alkali metal) whose conditions of existence are unclear. On attempting to synthesize RbHg by a method that had proven successful in the case of several other amalgams[1] we have now unexpectedly, but reproducibly obtained gold-colored, shiny metallic single crystals of the composition $Rb_{15}Hg_{16}$ which are extremely

[*] Prof. Dr. H.-J. Deiseroth, Dr. A. Strunck
Fachbereich 8 – Anorganische Chemie der Universität-GH
Postfach 101240, D-5900 Siegen (FRG)

air-sensitive. The compound contains isolated, almost ideal cubic-shaped Hg_8 clusters ("mercubane") of a type that has hitherto never been detected in any other amalgam. Rectangular Hg_4 clusters, as have been found in the amalgams CsHg, KHg and Na_3Hg_2,[2-5] were also observed.

The tetragonal crystal structure of $Rb_{15}Hg_{16}$,[6,7] thus far only observed in this compound, is a defect variant of the CsCl type. Its structure and its lattice constants[7] can be interpreted in terms of an ensemble embodying $4 \times 4 \times 4 = 64$ CsCl unit cells (each $a \approx 410$ pm, $Rb_{64}Hg_{64}$). This large cubic cell is somewhat elongated in one direction, such that it corresponds to the real c-axis of the tetragonal unit cell of $Rb_{15}Hg_{16}$. The 64 Hg atoms of the idealized unit cell, arranged in cubic primitive geometry (d(Hg–Hg) = 410 pm) now "relax" to a real structure of a type that forms eight Hg_4 squares (32 Hg atoms) and four Hg_8 cubes (32 Hg atoms) with Hg–Hg distances of ca. 300 pm (Fig. 1).

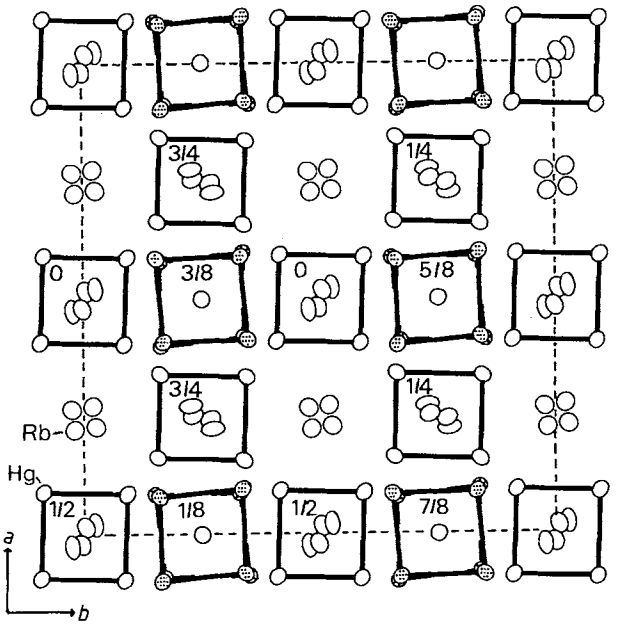

Fig. 1. Projection of the crystal structure of $Rb_{15}Hg_{16}$ along [001]; dotted Hg-atoms form Hg_8 cubes, undotted Hg_4 squares; the numbers indicate the approximate coordinate of the center of the respective square or cube in z. The Rb atoms are shown uncoupled.

The centers of the cubes occupied by rubidium atoms in the ideal structure are, as a result of the reduced Hg–Hg distance, no longer occupied in the real structure, so that the composition $Hb_{60}Hg_{64} = Rb_{15}Hg_{16} = RbHg_{1.067}$ approaches RbHg.

The distances within the mercury clusters ($d \approx 300$ pm) and between them ($d > 500$ pm) are significantly different in the compound described here. The shortest distances between the clusters (cube–cube, cube– square etc.) are 539.65 pm (Hg1–Hg4); the distances within the clusters are shown in Figure 2.

The preferred Hg–Hg–Hg angles of ca. 90°, not only in $Rb_{15}Hg_{16}$ but also in KHg, CsHg and Na_3Hg_2, are a clear indication of the presence of σ_p bonds (6p) between the Hg atoms. The bonding electrons necessary for this are provided by rubidium, which itself is present as $Rb^{\oplus}$ ion (shortest Rb–Rb distances in $Rb_{15}Hg_{16}$ 378.9 pm, in γ-Rb_2O 338 pm, in Rb metal 468 pm). This simplified picture of the chemical bond is also supported by the results of relativistic band structure calculations for NaHg, another CsCl variant.[8]

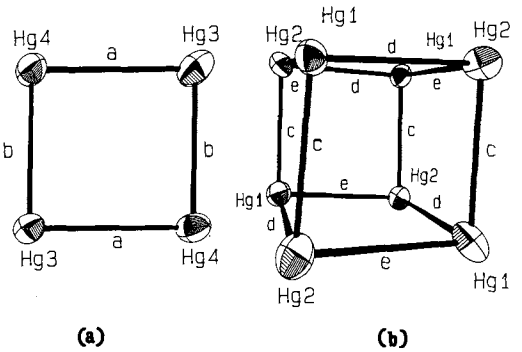

Fig. 2. Hg_4 square (a) and Hg_8 cube (b) in $Rb_{15}Hg_{16}$: distance [pm]: $a = 295.6(3)$, $b = 304.2(3)$, $c = 295.5(3)$, $d = 297.9(3)$, $e = 293.9(3)$; interatomic angles [°] at Hg1: 85.66(7), 86.38(7), 86.16(7); Hg2: 94.26(7), 93.44(8), 93.69(7); Hg3: 90.32(7); Hg4: 89.68(8).

According to these calculations the electronic states in the neighborhood of the Fermi edge are essentially dominated by Hg(6p) (small proportions of Na(3s) and Na(6s)).

The quasimolecular units Hg_8 and Hg_4 in the heavy alkali metal amalgams belong to a previously unknown class of mercury clusters. These differ from the already classical linear polycations $Hg_n^{2\oplus}$ in that σ_p bonds dominate in such clusters.[10] The chemical bonding in the polycations, on the other hand, has σ_s character. The latter is primarily realized by removal of electrons from antibonding 6s states, whereas in the former cases additional electrons (from the alkali metal) are transferred into the 6p states.

A critical interpretation of the phase diagrams determined from thermal analyses (see, e.g. Ref. [11]) would indicate the possibility of further previously unknown alkali-metal amalgams with mercury clusters in the range of composition around MHg (M = Na, K, Rb, Cs).

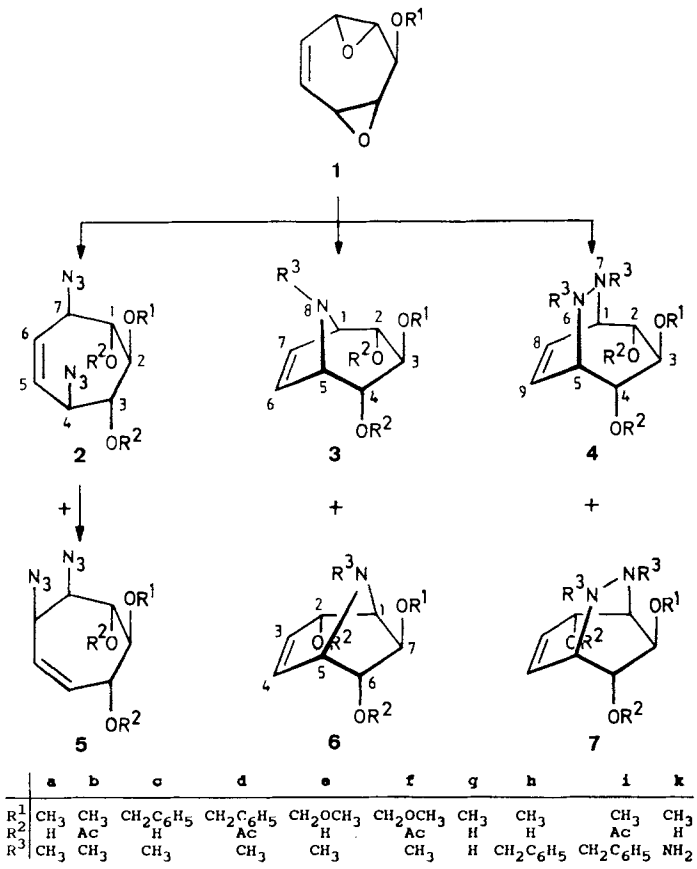
Unsaturated 1,4-*cis* and 1,4-*trans*-Diaminotetradeoxycycloheptites—Enantiomerically Pure, Polyfunctionalized Tropa Derivatives by Enzymatic Hydrolysis**



By *Manuela Falk-Heppner, Manfred Keller,* and *Horst Prinzbach**

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

For the total syntheses of non-natural aminoglycoside antibiotics of the astromicin, sannamycin and sporaricin type, we have developed efficient routes to diverse chemically modified aglycone building blocks (**C**[1]**D**,[2] **E**[3]) starting from epoxycyclohexene bromides **A** or *cis*-benzene trioxide **B**. Further modification of this class of bioactive substances involves the replacement of the diaminocyclohexite units by diaminocycloheptite units.[4] We report here the syntheses of sannamine- and sporamine-analogous unsaturated *cis*-/*trans*-1,4-diaminotetradeoxycycloheptites **F** and **G**, respectively, as well as the 1,4-*trans*-diamines **H**. Starting material is generally the *anti,cis*-diepoxycycloheptene alcohol **1** (R^1 = H) that has been prepared from tropone in another context.[5] The entry to racemic *cis*-1,4-diamino aglycones of the type **F** thus is reduced to the substitution of the two allylically activated epoxide C–O bonds by suitable *N*-nucleophiles. Subsequent epimerization by inter- or intramolecular S_N2 substitution at an N-bearing site should provide access to the *trans*-1,4-diamine series **G**.

From a comprehensive study of the behavior of **1a**, **1c** and **1e** towards mono- and bifunctional *N*-nucleophiles[4, 6] the findings collected in Scheme 1 are of relevance here: with NaN_3 in fourfold excess (methanol/water, $MgSO_4$, reflux, 10 h), the 1,4-diazide **2a** (isolated as **2b**, 70–75%) was formed selectively from **1a** (30 mmol);[7] depending on the reaction conditions the *cis*-1,2-diazide *rac*-**5a** (15–20% *rac*-**5b**) resulting from S_N2'-attack or Cope rearrangement is also formed. The opening of the second epoxide ring is much more rapid, so that different *N*-substituents cannot be selectively introduced in this way. Methylamine (2 equiv., 40% aqueous solution, 80 °C) adds almost quantitatively to give a ca. 3:1 mixture of the isomeric 8-aza-bicyclo[3.2.1]octene skeletons **3a/6a** (only one invertomer detected in each case at room temperature (^{1}H NMR)) without a primary adduct being detectable (even after acetylation to **3b/6b**); by addition of Lewis acids ($LiClO_4$, $MgSO_4$, $ZnSO_4$) this ratio can be improved to ca. 4:1. With benzylamine, **3h** and **6h** are formed in the ratio 2.3:1 (isolated as **3i/6i**, 67% and 29%, respectively). Hydrazine (water, reflux) behaves as a 1,1- and 1,2-dinucleophile towards **1a**: aside from ca. 50% of the desired 6,7-diazabicyclo[3.2.2]nonene **4g**, ca. 50% of 8-azabicyclo[3.2.1]octene **3k** is formed (more than 3% of **6k** or **7g** would have been detected). 1,2-Dimethylhydrazine reacts with **1a** to give exclusively **4a** (93%).[4]

Scheme 1.

The diols (diacetates) **2**, **3**, and **4** are *meso* compounds with favorable structural prerequisites for enzyme-catalyzed esterification (hydrolysis) (relatively rigid 1,3-diol arrangement).[8] The results of the hydrolysis of some diacetates **2–4** and of **8–10** carried out with porcine liver esterase (PLE, Boehringer) in water (where necessary, with addition of up to 10% methanol or acetone) are collected in Table 1: even at total conversion and with amounts of starting material of up to ca. 15 mmol—except in the case of **10**—both the yields of monoester as well as the *ee* values (determined ^{1}H NMR

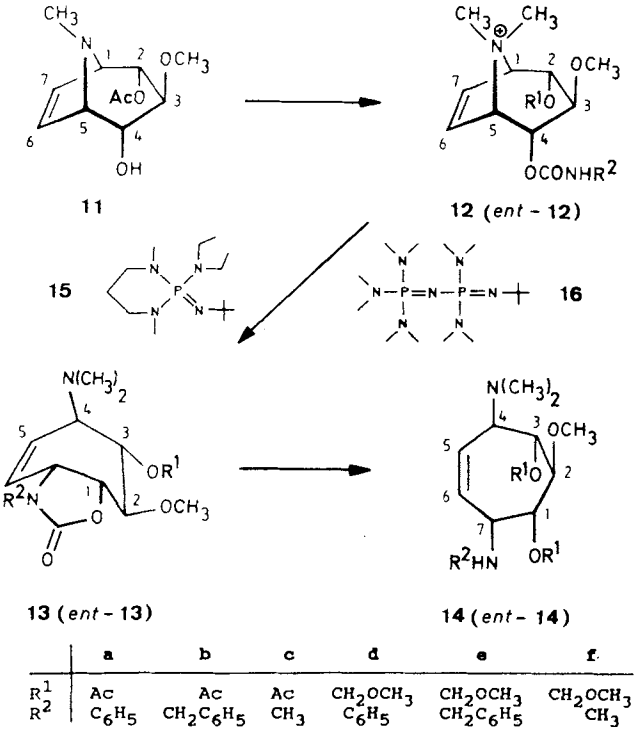
Kammerer* for help with the enzymatic work, and to Prof. Dr. *H. Fritz* and Dr. *D. Hunkler* and Dr. *J. Wörth* for the NMR and MS analyses, respectively.

Table 1. PLE hydrolysis of the *meso*-diacetates.



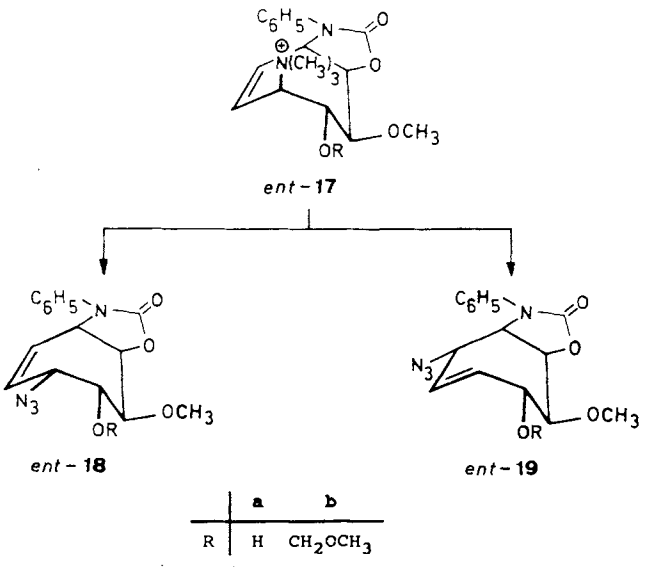
Diacetate	Amount of substance [mmol]	Monoacetate Yield [%]	*ee* [%]
2b	0.3	88	86
3b	15.0	100	>99
3d	0.3	100	>99
3f	0.5	86	>99
3i	0.4	97	>99
4b	0.5	89	>99
8	0.4	100	>99
9	0.4	73	89
10	0.3	no conversion	

spectroscopically with the (*R*)- and (*S*)-MTPA esters (MPTA = α-methoxy-α-trifluoromethylphenylacetic acid)[9] are very good to excellent. Accordingly, transesterification (racemization) is largely ruled out. It follows from the absolute configuration derived with the help of the Mosher model that the "frontal" acetate group in the illustrated formula (cf. **11**) is hydrolyzed[11] (uncertain in the case of **3i**).

8 **9** **10**

How the stereoisomeric compounds of the *trans*-diamino series can be prepared, starting from the enantiomerically pure monoacetates obtained from **3**, is illustrated by examples in Scheme 2: reaction of the monoacetate **11** (1–3 mmol) with phenyl, benzyl or methyl isocyanate in THF, if necessary in the presence of catalytic amounts of di-*n*-butyltin laurate,[12] affords the carbamates (> 95%), which can be quaternized to the ammonium salts **12a–12c** with methyl iodide (80 °C). From the vicinal J_{HH} couplings ($J_{1,2(4,5)} = 4.5$, $J_{2,3(3,4)} = 7.5$ Hz) a chair conformation of the six-membered ring with quasi-equatorial disposition of the three residues has been established for **12a–12c**. The cyclization **12** → **13** associated with the quasi-axial orientation of the carbamate residues involves complications, not unexpected because of the steric/stereoelectronic conditions. After a series of inadequately selective reactions with a variety of conventional bases (NaH, KH, lithium diisopropylamide(LDA), *t*BuOK etc.) the Schwesinger iminophosphorane bases **15** ($pK_a = 27.6$, CH_3CN) and **16** ($pK_a = 32.7$, CH_3CN)[13] eventually enabled a breakthrough: thus, with **15**, 92% of **13a** was formed from **12a** and, with the stronger base **16**, 76% of **13c** from the less acidic **12c**. After hydrolysis of the acetate residues, all functions in the resulting alcohols (**13a**, $R^1 = H$: $[\alpha]_D^{25} = -226$ ($c = 0.5$, $CHCl_3$)) are protected, except the OH group to be glycosidated. Hydrolysis of the urethanes ($Ba(OH)_2/CH_3OH/H_2O$, reflux) and subsequent acetylation quantitatively affords the unsaturated *trans*-diaminotetradeoxycycloheptite diacetates **14a–14c**. After protection of the 4-OH group in **11** (here as methoxymethyl (MOM) ether) and acetate hydrolysis, the enantiomeric series of compounds *ent*-**12d–12f** to *ent*-**14a–14c** are obtained analogously and with comparable results (*ent*-**13a**, $R^1 = H$: $[\alpha]_D^{25} = +229$ ($c = 0.1$, $CHCl_3$)). By control measurements with the camphanoic acid derivatives of **13a** and *ent*-**13d** consistently high *ee* values (> 99%) are ensured. Variations regarding *N*-substitution are possible in this way.

11 **12** (*ent*-**12**) **15** **16**



13 (*ent*-**13**) **14** (*ent*-**14**)

	a	b	c	d	e	f
R^1	Ac	Ac	Ac	CH_2OCH_3	CH_2OCH_3	CH_2OCH_3
R^2	C_6H_5	$CH_2C_6H_5$	CH_3	C_6H_5	$CH_2C_6H_5$	CH_3

Scheme 2.

Further perspectives of this project are indicated: an alternative entry to the *cis*-1,4-diamino series **F**—even with different *N*-residues—is possible via S_N2 substitution (1 mmol, dimethylformamide (DMF), 100 °C) of the allylic trimethylammonio group in the substrates *ent*-**17a,b** prepared from *ent*-**13d** ($J_{1,2} = J_{1,7} = 7.5$, $J_{2,3} = 9.5$, $J_{3,4} = 8.3$, $J_{4,5} = 5.6$, $J_{5,6} = 12.0$, $J_{5,7} = 2.3$, $J_{6,7} = 2.5$ Hz), whereby the size of the neighboring residue R significantly influences the outcome. With R = H (MOM), 70% (35%) *ent*-**18a(b)** ($J_{1,2} = J_{2,3} = 8.3$, $J_{3,4} = 4.2$ Hz) is isolated together with 21% (52%) *ent*-**19a(b)** ($J_{1,2} = 8.3$, $J_{2,3} = 9$, $J_{6,7} = 2.3$ Hz).

An efficient entry to diamines **H** based on the step **12** → **13** emerges, in that rearrangement of **12** into the less strained 8-azabicyclo[3.2.1]non-3-ene skeleton, which, depending upon the reaction conditions competes with the cyclization, can be steered selectively if not specifically with certain base systems and residues R. Thus, e.g., with *t*BuOK/*t*BuOH (25 °C), **20** ($[\alpha]_D^{25} = -62$ ($c = 0.08$, CH_3CN; $J_{1,2} = J_{4,5} =$

Sulfur Cyanide Pentafluoride SF_5CN **

By *Oliver Lösking* and *Helge Willner**

Since the discovery of SF_5Cl,[1] the chemistry of SF_5 has developed very rapidly—a chemistry which claims special interest by virtue of the bulky, kinetically stable SF_5 group and the highly charged sulfur atom. The reactive SF_5Br and the inert S_2F_{10}, as well as numerous SF_5–C-, SF_5–N- and SF_5–O-compounds, have already been intensively studied.[2–4] The detection of the simplest SF_5 compounds containing a formal sp-hybridized C atom or N atom, SF_5CN and SF_5NC respectively, however, has thus far never succeeded.

The synthesis of SF_5CN by fluorination of methyl thiocyanate was first reported as long ago as 1959,[5] but it later turned out that the boiling point and spectroscopic data unequivocally corresponded to the isomer $CF_3-N=SF_2$.[6] All other attempts to synthesize SF_5CN, such as by the reaction of $(FCN)_3$ with SF_4 in the presence of CsF,[7] by the photochemical reaction between S_2F_{10} and $(CN)_2$[8] and by the metathesis between $CsSF_5$ and BrCN[9] also failed to give the target compound. In all cases the reactions led to the formation of, inter alia, $CF_3-N=SF_2$. On the basis of this observation it was finally concluded that SF_5CN very readily isomerizes [Eq. (a)].[9]

Herein we report the first successful preparation of the surprisingly stable SF_5CN; the synthesis of sulfur pentafluoride isocyanide will be described in the following communication.[10]

For the synthesis of SF_5CN a solution of dirhodane in 1,1,2-trichloro-1,2,2-trifluoroethane was allowed to react with dilute fluorine ($F_2:N_2 = 1:10$) at $-20\,^{\circ}C$. The resulting product mixture was frozen out from the gas stream at $-183\,^{\circ}C$ and separated from co-condensed solvent in vacuo by fractional condensation at $-120\,^{\circ}C$. The pre-separated mixture consisting of ca. 10% SF_5CN, 3% SF_6, 30% SF_4, 40% SOF_2, 8% NSF_3, 4% $(FCN)_3$ and 5% CF_3NSF_2 was condensed into a 2 M KOH solution and shaken for a few minutes at room temperature. The mixture thus freed of SF_4, SOF_2 and $(FCN)_3$, could then be dried over $Mg(ClO_4)_2$ and completely separated by repeated fractional condensation in a vacuo into a series of cooled traps at $-127\,^{\circ}C$, $-140\,^{\circ}C$, and $-196\,^{\circ}C$. According to the IR, Raman, UV and ^{19}F NMR spectra, the middle fraction consisted of SF_5CN with less than 1% impurities (CF_3NSF_2, NSF_3). Based on reacted $(SCN)_2$ the yield was about 5%.

Sulfur cyanide pentafluoride is a stable colorless gas at room temperature (boiling point $-25\,^{\circ}C$, triple point $-107\,^{\circ}C$). In the temperature range -100 to $-30\,^{\circ}C$ its vapor pressure curve can be described by the equation

$$\log_{10}(p/1013) = -(A/T) + B$$

where A = 1244 K and B = 5.017 (p in mbar, T in K). Noteworthy is that SF_5CN does not isomerize spontaneously to CF_3NSF_2 as was hitherto presumed. The compound does not decompose even on pyrolysis in a corundum tube at 350 °C, ca. 10^{-4} mbar with a contact time of ca. 10^{-3} s. Under the same conditions 90% of S_2F_{10} decomposes to SF_4 and SF_6 and 50% of SF_5Br to SF_4 and BrF, as demonstrated in matrix isolation experiments.

The molecular weight determination according to *Regnault* gave a value of 154 ± 2 g mol^{-1}, which agrees with the calculated molecular weight of 153.1 g mol^{-1}.

The spectrum of the gaseous substance (Fig. 1) shows the characteristic CN stretching vibration at 2235 cm^{-1}; the corresponding band of the isocyanide is observed at 2080 cm^{-1}.[10] These values are comparable with those of CF_3CN ($\tilde{\nu}_{CN} = 2278$ cm^{-1}[11]) and CF_3NC ($\tilde{\nu}_{NC} = 2133$ cm^{-1}[12]), which are somewhat higher because of the strong coupling with the XC and XN stretching vibrations, respectively. The presence of a S-C-N subunit in the new compound can be demonstrated by comparison of the measured frequency shifts of the CN stretching vibration of ^{13}C- and ^{15}N-containing isotopomers with values from model calculations (Table 1; the measured frequency shifts derived from matrix isolated SF_5CN (Ar matrix, 14 K) with natural content of ^{13}C and ^{15}N). Analogous calculations were carried out on Me_3SiCN and Me_3SiNC.[13]

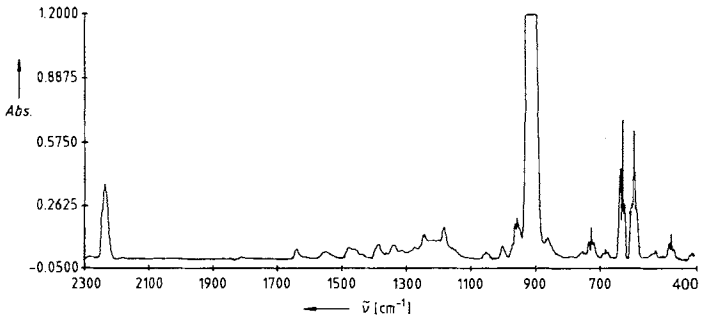

Fig. 1. IR spectra of SF_5CN in the gas phase. $p = 7$ mbar, optical path length 20 cm; Abs = absorption.

Table 1. Calculated isotopic shifts of the CN stretching vibration.

		$\tilde{\nu}$ [cm^{-1}]	Shifts $\Delta\tilde{\nu}$ [cm^{-1}] [a] ^{13}C	^{15}N
SF_5CN	$(SF_5)-C$	630	52 (51.1)	30 (29.5)
	$C\equiv N$	2235		
SF_5NC	$(SF_5)-N$	630	42.5	38
	$N\equiv C$	2235		

[a] Measured values in parenthesis.

The ^{19}F NMR spectrum (188.5 MHz, CD_2Cl_2, CCl_3F int.) of the new compound, measured at $-40\,^{\circ}C$, showed the typical AB_4 spin system of an SF_5 group with a total of nine lines for the axial fluorine atom (A) and two multiplets for the four equatorial fluorine atoms (B). The spectrum could be simulated with the parameters $\delta_A = -61.4$, $\delta_B = -80.1$; $J_{AB} = 163$, $J_{BB} = 0$ and $J_{BB'} = 2$ Hz – values which are typical for SF_5 compounds. On some lines the signals of the ^{34}S isotopomer are recognizable on the lower frequency side, thus confirming the presence of an SF_5 moiety. We are currently carrying out structure determinations by microwave spectroscopy and electron diffraction.

Sulfur-Pentafluoride Isocyanide, SF_5NC**

By *Joseph S. Thrasher** and *Krishnan V. Madappat*

Of the six possible chalcogen pentafluoride cyanates and isocyanates, four are now known ($SF_5N=C=O$, $SF_5O-C\equiv N$, $SeF_5O-C\equiv N$, and $TeF_5N=C=O$), with the latest addition being $SF_5O-C\equiv N$.[1] On the other hand, there is

Nielsen* for technical assistance, and Prof. *Helge Willner* for sharing his research results prior to publication.

not a single correct report of a chalcogen pentafluoride cyanide or isocyanide. There are, however, both incorrect as well as unsuccessful reports on one of these materials, namely SF_5CN.[2-7] Many other research groups have also had an interest in and have made attempts to prepare SF_5CN because of the commonly held belief that it would be a better electron capture agent than SF_6[8] as well as a useful precursor for synthetic chemistry. Recently, we succeeded in preparing the first chalcogen pentafluoride isocyanide SF_5NC,[9] while the C-bonded isomer SF_5CN has been described in the preceding paper.[10]

By utilizing the chemistry developed by *Lentz* for a high yield, high purity synthesis of CF_3NC,[11] we have been able to prepare SF_5NC (Scheme 1). However, the following differences are noteworthy: first, $SF_5N{=}CCl_2$, unlike $CF_3N{=}CCl_2$,[11] does not react with magnesium in tetrahydrofuran (THF);[12] second, the $<5\%$ yield of SF_5NC in no way compares with the 65–90% yield of CF_3NC.[11] We

$$SF_5N{=}CCl_2 + 3HF \longrightarrow SF_5NHCF_3 + 2HCl^{[13]}$$

$$SF_5NHCF_3 + BBr_3 \xrightarrow{-HBr} [SF_5N(CF_3)BBr_2 \xrightarrow{-BF_3} SF_5N{=}CBr_2^{[14]}$$

$$SF_5N{=}CBr_2 \xrightarrow[-MgBr_2]{Mg/THF} SF_5NC$$

Scheme 1.

have even tried a number of reactions of $SF_5N{=}CBr_2$ with lithium reagents such as *n*-C_4H_9Li, *sec*-C_4H_9Li, *t*-C_4H_9Li, C_6H_5Li, and CH_3Li, but in each case we have obtained no more than a 5% yield of the isocyanide. Only traces of SF_5NC were produced in reactions of $SF_5N{=}CCl_2$ with these lithium reagents.

The new isocyanide SF_5NC is a colorless gas which has been characterized by its IR, ^{19}F NMR, and mass spectra as well as by a vapor-density molecular weight determination (found 154 ± 4; calc. 153.1). In the gas phase SF_5NC was unexpectedly found to isomerize to the cyanide even at room temperature and reduced pressure (<50 torr). Partial isomerization of the sample was apparent within a few hours, while complete isomerization generally took about one week. In addition, both SF_5NC and SF_5CN were observed in the product mixtures of some reactions which were carried out at approximately $-45\,^{\circ}C$ instead of colder. Thus, the stability of SF_5NC towards isomerization strongly contrasts with that of CF_3NC. Although CF_3NC is known to undergo polymerization even at $-78\,^{\circ}C$ in either the condensed phase or at pressures greater than 150 torr,[11] temperatures of almost 500 °C are required for its isomerization to CF_3CN in the gas phase in vacuo.[15] Unfortunately, both the poor yield and the instability of SF_5NC have thus far prevented us from obtaining reliable data for a vapor pressure curve; however, one can conclude that SF_5NC has a lower boiling point than SF_5CN, as a $-135\,^{\circ}C$ slush bath will stop SF_5CN while SF_5NC passes through to a $-155\,^{\circ}C$ slush bath (10^{-4} torr vacuum). Similar relative volatilities are observed for CF_3NC and CF_3CN.

The appearance of the NC stretching frequency at 2080 cm^{-1} in the infrared spectrum of SF_5NC clearly indicates that the compound is an isocyanide and not a cyanide. It is interesting to compare this stretching frequency to that observed in CF_3NC (2133 cm^{-1}).[11] Although isocyanides in general display an inverse frequency behavior (i.e., more electron-withdrawing substituents lower $\tilde{\nu}_{CN}$),[16] this alone cannot explain the large variation of 53 cm^{-1} between the two compounds. Since the isocyanide stretch is a coupled vibration, most of the variation is due instead to both differences in mass between the sulfur and carbon based groups as well as differences in the respective strengths of the S–N and C–N bonds adjacent to the isocyanide link.[16] Further support for the identity of the product from Scheme 1 as an isocyanide is found by comparison with the CN (NC) stretching frequencies of other known sulfur(VI) cyanides or isocyanides: $CF_3SF_2(CN)_2Cl$, 2210 cm^{-1};[17] FSO_2CN, 2213 cm^{-1}; CF_3SO_2CN, 2195 cm^{-1};[18] and SF_5CN, 2235 cm^{-1}.[10] We have also calculated the normal-mode vibrational frequencies of SF_5NC, SF_5CN, CF_3NC, and CF_3CN by the AM1 method:[19] SF_5NC, 2239 cm^{-1} (calc./observed 1.08); SF_5CN, 2489 cm^{-1} (1.11); CF_3NC, 2338 cm^{-1} (1.10); CF_3CN, 2566 cm^{-1} (1.13). Even though computational methods consistently give calculated frequencies which are 10–15% larger than the experimental values,[20] these results lend further credence to the correct identification of our product as the isocyanide SF_5NC.

As expected from the diamagnetic anisotropy of the isocyanide function, the axial fluorine atom in SF_5NC resonates upfield (59.1 ppm) of the equatorial fluorine atoms (77.3 ppm, $J_{ab} = 158.8$ Hz) in the ^{19}F NMR spectrum (cf. Ref. [21]). The spectrum, which was measured on a dilute solution of the isocyanide in THF, remained unchanged for more than several months while storing the sample at room temperature. The mass spectrum of SF_5NC displays the molecular ion $M^{\oplus}$ at $m/z = 153$ (3%) as well as the expected fragmentation pattern [$m/z = 134$ ($SF_4NC^{\oplus}$, 19%), 127 ($SF_5^{\oplus}$, 100%), 108 ($SF_4^{\oplus}$, 10%), 89 ($SF_3^{\oplus}$, 53%), 70 ($SF_2^{\oplus}$, 9%), 51 ($SF^{\oplus}$, 3%)].

Starting from $TeF_5N{=}CCl_2$,[22] it should also be possible to prepare TeF_5NC by the route shown in Scheme 1. In fact, we have recently prepared $TeF_5N{=}CBr_2$,[23] but we anticipate even greater problems in our efforts to isolate the product (cf. Ref. [24]) as TeF_5-substituted materials generally have 25–40° higher boiling points than do their SF_5 analogues.[22]

Experimental Procedure

In a typical reaction $SF_5N{=}CBr_2$ (2.54 g, 8.12 mmol) was condensed at $-196\,^{\circ}C$ into a 250-mL reaction vessel containing CH_3Li (10.0 mmol) in 25 mL of dry diethyl ether/tetrahydrofuran. The reaction vessel was connected to a series of traps held at $-196\,^{\circ}C$, and the entire apparatus was filled with approximately 200 torr of dry nitrogen. The reaction mixture was then warmed to $-78\,^{\circ}C$ and stirred for 4 h before being allowed to warm slowly to room temperature. After pumping off the noncondensable gases, the volatile products were distilled through a series of traps at -135, -155, and $-196\,^{\circ}C$. Repeated distillation afforded 0.06 g of SF_5NC (5%) in the $-155\,^{\circ}C$ trap.

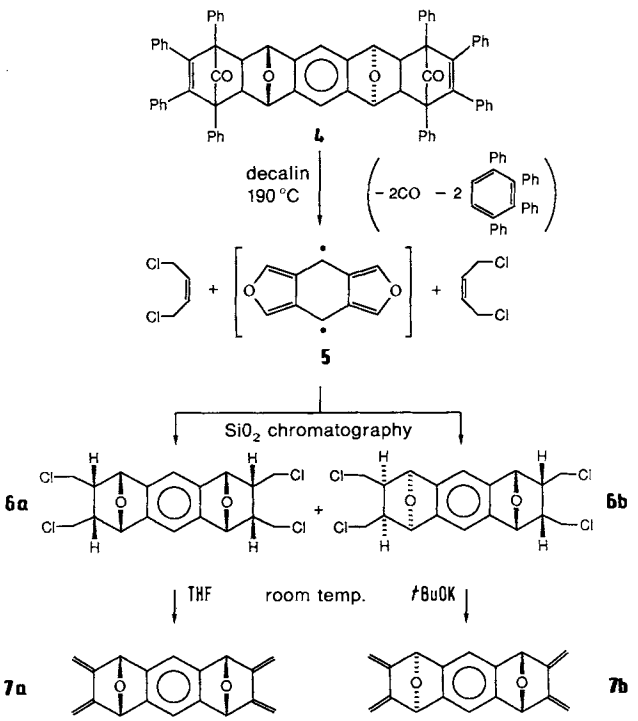
Stereoregular Oligomerization by Repetitive Diels–Alder Reactions**



By *Peter R. Ashton, Neil S. Isaacs, Franz H. Kohnke, John P. Mathias,* and *J. Fraser Stoddart**

In recent times, linear polyacenes and their derivatives[1] have become increasingly attractive synthetic goals because of their potential applications[2,3] in science and technology. In an attempt to circumvent solubility difficulties, oxygen atoms have been introduced either into exocyclic positions, as in the polyacenequinones,[4] or into bridging endocyclic positions, as in the epoxypolyacenes.[4] Although a number of synthetic strategies may be envisaged,[5] the repetitive Diels–Alder approach[1,4,6–8] has many attractions. However, in those cases where stereogenic centers are created during reactions between dienes and dienophiles, some stereochemical uncertainty associated with isomer production and consequent oligomer/polymer heterogeneity at a configurational level is often encountered. The realization[9,10] that the [12]cyclacene derivative **1**, with its 20 stereogenic centers,[11] can be synthesized[12] in at least 28% overall yield[13] in two steps from the bisdiene **2**[14] and the bisdienophile **3a**[15] shows that it is possible to program small molecules to express themselves through their mutual reactions in unique structural fashions without reagent control and to create thereby much larger molecules that are highly ordered.[16] Treble diastereoselectivity[9,16] is exercised repetitively in the four Diels–Alder reactions that allow the construction of **1** out of a pair of bisdienes **2** and a pair of bisdienophiles **3a**. The next question was whether this high degree of stereoelectronic control can be incorporated into

oligomerizations—and hence polymerizations—to yield acyclic products through repetitive Diels–Alder reactions. Here, we report firstly the high pressure diastereoselective synthesis[17] of the novel oligomers **8b** and **9** (Scheme 2), containing 11 and 19 laterally-fused six-membered rings, respectively, from the bisdiene **7a** (Scheme 1) and the bis-

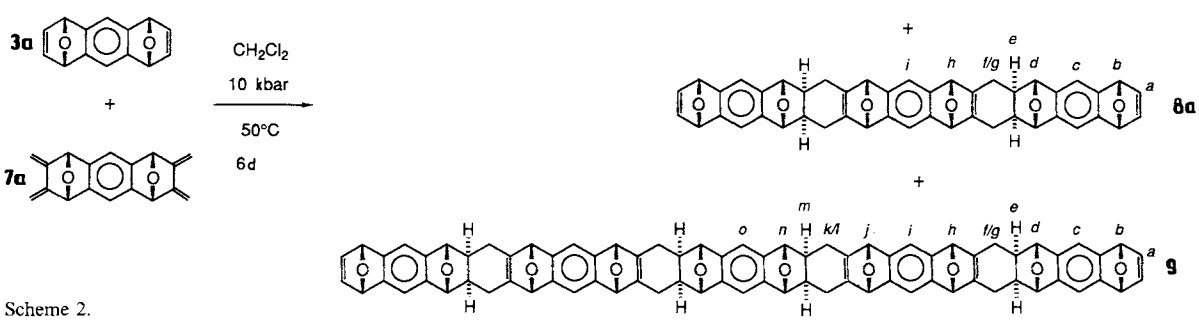
dienophile **3a** and secondly the facile double Diels–Alder reaction of **8b** with the bisdiene **2** to afford the [14]cyclacene derivative **10** (Scheme 3) without, rather surprisingly, having to resort to the use of high pressure to promote the final intramolecular polymacrocyclization.



Employing a literature procedure,[18] a mixture of the *syn*- and *anti*-tetrachlorides **6a** and **6b** were obtained (Scheme 1) by reaction of *cis*-1,4-dichlorobut-2-ene with the benzo[1,2-*c*:4,5-*c'*]difuran equivalent **5**, generated in situ by the thermolytic decomposition of the bisadduct **4**, formed between the *anti* isomer **3b** of 1,4:5,8-diepoxy-1,4,5,8-tetrahydroanthracene[20] and tetraphenylcyclone. The satisfying aspect of this synthetic approach is that **3b**, obtained during the preparation[12, 15] of the desired (Scheme 2) *syn*-isomer **3a**, is also utilized. As a result of the presumed planar nature of the intermediate **5**, the relative configurations of the endoxide (and carbonyl) bridges in **4** are of no consequence[18] in the synthesis of **6a** and **6b**, which have now been separated chromatographically and characterized fully by X-ray crystallography.[19, 20] Eliminations have then been performed stereospecifically[21] on the separate and pure isomers **6a** and **6b** to afford the bisdienes **7a** and **7b** with the *syn* and *anti* configurations, respectively. Reaction (Scheme 2) of two molar equivalents of the *syn*-bisdienophile **3a** with the *syn*-bisdiene **7a** under high pressure in dichloromethane solution yields the 2:1 and 3:2 adducts **8a** and **9**, with the all-*syn* configurations, as the major products[22]: these all-*syn* adducts are believed to be the result[23] of trebly diastereoselective Diels–Alder reactions, involving exclusively *endo* and *exo* approaches with respect to the diene and dienophile units, respectively. The all-*syn* 2:1 adduct **8a** is accompanied by trace amounts[23] of the *syn-anti* 2:1 adduct **8b**, implying the existence of a minor reaction pathway where the approach is *exo* with respect to both diene and dienophile units. On account of their remarkably high solubilities in most organic solvents, **8a, 8b,** and **9** have been separated with ease by silica gel chromatography and characterized structurally by fast atom bombardment mass spectrometry (FABMS), high field ^{13}C- and ^{1}H-NMR spectroscopies, and, in the case of **8a**, by its reaction (Scheme 3) with **2** in refluxing toluene, without having to use high pressure, to give the [14]cyclacene derivative **10**.[24]

In accordance with their C_{2v} symmetries, the all-*syn* adducts **8a** and **9** exhibit 12 and 20 resonances respectively in their high resolution broad-band decoupled ^{13}C-NMR spectra. By contrast, the 2:1 adduct **8b** with the *syn-anti* configuration displays 23 peaks, in harmony with its lower C_s symmetry. The ^{1}H-NMR chemical shift data summarized in

Scheme 3.

matrix fashion in Table 1 emphasizes the structural similarities and highlights the structural differences between **8a, 8b, 9, 10** – and **1**. The assignment of the *endo* configurations to all ring junction hydrogen atoms (*e* and *m*) is supported by the very small coupling constants[1, 14] they exhibit towards the vicinal hydrogen atoms (*d* and *n*, respectively) at the neighboring bridgehead positions. Most intriguing is the appearance, at appreciably lower frequencies (shifted by ca. 0.36, 0.16 and 0.07 ppm, respectively), of the signals for protons *a, b,* and *c* (Scheme 2) in **9** relative to those for the "same" protons in **8a** and **8b**. This suggests that the 3:2 adduct **9** with the all-*syn* configuration adopts a "Swiss roll-like" conformation, wherein the six-membered rings at the termini of the oligomeric chain are forced into close proximity. In this regard, it is interesting that all attempts to effect a cyclization of **8a** with the bisdiene **7a** and thus construct a [16]cyclacene derivative have failed so far. Yet, reaction of

[a] The spectra were recorded at ambient temperature on either a Bruker AM250 or WH400 spectrometer using Me_4Si as an internal standard. [b] In many cases, it is not possible to differentiate with certainty assignments of protons to signals with very similar δ values. [c] The δ values (recorded in boldface) for protons *a*, *b* and *c* are all shifted to higher field relative to those for the 'same' protons in **8a** and **8b**.

8a with the smaller bisdiene **2** in refluxing toluene produced **10** (Scheme 3) in the remarkably high isolated yield of 76%. In particular, the final intramolecular Diels–Alder cyclization must be stereoelectronically favored, i.e. the reaction is enthalpically and entropically favorable.

Stereoregular oligomerizations – and hence polymerizations – by repetitive Diels–Alder reactions using "intelligent" monomers can be performed[25] by choice to give either acyclic or cyclic products. The high yielding and diastereoselective preparations of compounds such as **1**, **8a**, **8b**, **9**, and **10** are obviously *directed by the structures of the substrates and/or the products.*[26] *There are inherently simple ways of making apparently complex unnatural products*[27] *from appropriate substrates without the need for reagent control or catalysis:* call it structure-directed synthesis?

Experimental Procedure

8a/8b/9: Reaction (10 kbar, 50–55 °C, 6 days) of **3a** (1.67 g, 7.97 mmol) with **7a** (1.04 g, 3.98 mmol) in CH_2Cl_2 (45 mL) afforded, after chromatography (SiO_2/$CHCl_3$-MeOH) and in order of elution, **8b** (40 mg, 1.5%) as a white solid [*m/z* (positive ion FABMS) 682 for $M^{\oplus}$ and 705 for $[M + Na]^{\oplus}$; ^{1}H-NMR (see Table 1); ^{13}C-NMR ($CDCl_3$): δ = 26.4, 26,5, 40.3, 40.4, 82.2, 82.3, 84.6, 84.7, 86.7, 86.8, 111.9, 112.2, 112.3, 143.1, 143.4, 143.7, 147.9, 148.0, 148.2, 148.2, 148.6, 148.9, 148.9], **8a** (696 mg, 25%) [m.p. > 140 °C (decomp.), *m/z* (positive ion FABMS) 682 for $M^{\oplus}$ and 705 for $[M + Na]^{\oplus}$; ^{1}H-NMR (see Table 1); ^{13}C-NMR ($CDCl_3$): δ = 26.5, 40.4, 82.3, 84.6, 86.7, 111.9, 112.3, 143.3, 143.5, 147.9, 148.3, 148.7] and **9** (48 mg, 2%) as a white solid [*m/z* (positive ion FABMS) 1154 for $M^{\oplus}$ and 1177 for $[M + Na]^{\oplus}$, *m/z* (negative ion FABMS) 1153 for $[M - H]^{\ominus}$, ^{1}H-NMR (see Table 1); ^{13}C-NMR ($CDCl_3$): δ = 26.7, 26.7, 38.1, 41.9, 82.1, 84.8, 84.8, 86.1, 88.4, 110.4, 111.9, 112.3, 143.2, 143.6, 145.3, 146.7, 147.6, 148.1, 148.5, 149.4].

10: **2** (13 mg, 0.09 mmol) and **8a** (55 mg, 0.08 mmol) were heated under reflux (17 h) in toluene (60 mL), affording, after chromatography (SiO_2, $CHCl_3$ MeOH), the [14]cyclacene derivative **10** (51 mg, 76%) as a white solid [*m/z* (positive ion FABMS) 829 for $[M + H]^{\oplus}$, ^{1}H-NMR (see Table 1); ^{13}C-NMR ($CDCl_3$): δ = 26.3, 27.3, 40.5, 42.8, 84.3, 85.3, 86.0, 86.4, 110.3, 112.2, 144.5, 144.7, 148.1, 148.4, 151.2].

[11] In addition to having 16 chiral centers, it should be noted that **1** contains 4 pseudochiral centers at C-6, C-12, C-19 and C-25. Thus, the systematic name for the compound, referred to trivially as kohnkene [9] should be

revised from the original designation (P. R. Ashton, N. S. Isaacs, F. H. Kohnke, A. M. Z. Slawin, C. M. Spencer, J. F. Stoddart, D. J. Williams, *Angew. Chem. 100* (1988) 981; *Angew. Chem. Int. Ed. Engl. 27* (1988) 966) to rel-(1*R*,4*S*,4a*S*,6*r*,7a*R*,8*R*,10*S*,10a*S*,12*r*,13a*R*,14*R*,17*S*,19*r*,20a*R*,21*R*,23*S*,23a*S*,25*r*,26a*R*)-1,4:6,25:8,23:10,21:12,19:14,17-hexaepoxy-1,4,4a,5,6,7,7a,8,10,10a,11,12,13,13a,14,17,17a,18,19,20,20a,21,23,23a,24,25,26,26a-octocosahydro-2,16:3,15-dimethanoundecacene.

[12] F. H. Kohnke, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, *Angew. Chem. 99* (1987) 941; *Angew. Chem. Int. Ed. Engl. 26* (1987) 892.

[13] This yield should be looked upon as only a *conversion* since, in the final high pressure step [12] the production of **1** is accompanied by substantial amounts of unreacted starting materials.

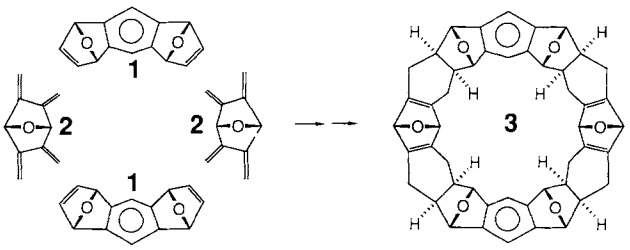
[22] The systematic names for **8a** and **9** are rel-(1*R*,4*S*,6*R*,6a*R*,8*S*,10*R*,11a*S*,12*S*,14*R*,17*S*,19*S*,19a*R*,21*S*,23*R*,24a*S*,25*S*)-1,4:6,25:8,23:10,21:12,19:14,17-hexaepoxy-1,4,6,6a,7,8,10,11,11a,12,14,17,19,19a,20,21,23,24a,25-eicosahydroundecacene and rel-(1*R*,4*S*,6*R*,6a*R*,8*S*,10*R*,11a*S*,12*S*,14*R*,14a*R*,16*S*,18*R*,19a*S*,20*S*,22*R*,25*S*,27*R*,27a*R*,29*S*,31*R*,32a*S*,33*S*,35*R*,35a*R*,37*S*,39*R*,40a*R*,41*S*)1,4:6,41:8,39:10,37:12,35:14,33:16,31:18,29:20,27:22,25-decaepoxy-1,4,6,6a,7,8,10,11,11a,12,14,14a,15,16,18,19,19a,20,22,25,27,27a,28,29,31,32,32a,33,35,35a,36,37,39,40,40a,41-hexatriacontahydrononadecacene, respectively. The systematic name for **8b** is identical to that of **8a** except for the replacement of the configurational descriptor by rel-(1*R*,4*S*,6*R*,6a*R*,8*S*,10*R*,11a*R*,12*R*,14*S*,17*R*,19*S*,19a*S*,21*S*,23*R*,24a*S*,25*S*).

[23] The 2:1 and 3:2 adducts contain, respectively, 16 and 28 chiral centers and can exist in 10 and 136 diastereoisomerically-different configurations, respectively. Analytical HPLC on a 5μ Hypersil Silica Gel Cartridge Column using 2% MeOH in CH_2Cl_2 as eluent revealed that the ratio of **8a**:**8b** in the crude high pressure reaction mixture is 16:1. We thank Mr. *I. Staton* for obtaining this result.

[24] The systematic name for **10** is rel-(1*R*,4*S*,4a*S*,6*r*,7a*R*,8*R*,10*S*,10a*S*,12*R*,14*S*,15a*R*,16*R*,19*S*,19a*S*,21*R*,23*S*,24a*R*,25*R*,27*S*,27a*S*,29*r*,30a*R*)-1,4:6,29:8,27:10,25:12,23:14,21:16,19-heptaepoxy-1,4,4a,5,6,7,7a,8,10,10a,11,12,14,15,15a,16,19,19a,20,21,23,24,24a,25,27,27a,28,29,30,30a-triacontahydro-2,18:3,17-dimethanotridecacene. Note, that in addition to 20 chiral centers, **10** contains 2 pseudochiral centers (at C-6 and C-29).

[25] "Small molecules evolve into bigger ones by eating smaller ones, although it is not always clear which is the eater and which the eaten. Little molecules eat by impact, and what emerges from their collisions is sometimes a bigger molecule"... "complex molecules emerge from simpler ones inhabiting planets; and so the specification could be simplified still further. That simplification can itself be simplified, for if you merely specify the elements, and perhaps some other things, sooner or later there will be elephants." Excerpts from P. W. Atkins: *The Creation*, Freeman, Oxford 1981, p. 3 and 4. For a recent thought-provoking analysis of the topologies of complex organic molecules in relation to periodic minimal surfaces, see Z. Blum, S. Lidin, *Acta Chem. Scand. B42* (1988) 332.



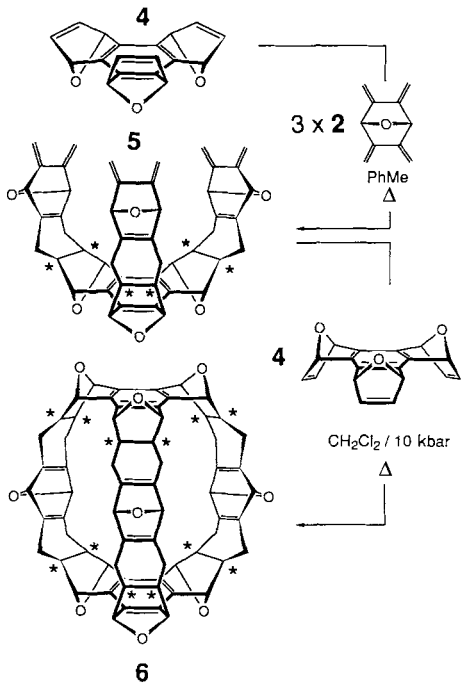
[26] Although the stereoselectivities of Diels–Alder reactions involving bicyclic dienes and bicyclic dienophiles has been discussed at length [in particular, by K. N. Houk (p. 1), L. A. Paquette (p. 41), R. Gleiter and M. C. Böhm (p. 105), and P. Vogel (p. 147) in W. H. Watson (Ed.): *Stereochemistry and Reactivity of Systems containing π-Electrons*, Verlag Chemie International, Deerfield Beech, FL (USA) 1983], it is not yet clear in th case of the present examples, what kind of controls – kinetic and/or thermodynamic – preside over the close (*endo* versus *exo*) and remote (*syn* versus *anti*) aspects of the trebly diastereoselective cycloadditions.

[27] The concept of structure-directed synthesis has already been addressed in the field of biomolecules and natural product synthesis. In analyzing the specific structural elements of vitamin B_{12}, Prof. Dr. *Albert Eschenmoser* [*Angew. Chem. 100* (1988) 5; *Angew. Chem. Int. Ed. Engl. 27* (1988) 5] has drawn attention to the fact that "these outwardly complex structural elements are found to 'self-assemble' with surprising ease under structurally appropriate preconditions; the amount of 'external instruction' required for their formation turns out to be surprisingly small in view of the complexity and specificity of these structural elements." See also G. Kansder, G. Bold, R. Lattmann, C. Lehmann, T. Früh, Y.-B. Xiang, K. Inomata, H.-P. Buser, J. Schreiber, E. Zass, A. Eschenmoser, *Helv. Chim. Acta 70* (1987) 1115. We should stress that, in extending the concept of structure-directed synthesis to the field of unnatural product synthesis, we wish to draw attention to the fact that the synthesis of complex new materials can be achieved without having to resort to the use of sophisticated reagents or exotic catalysts. It is the structures of the substrates and/or products that are important. A recently published series of communications concerning the synthesis of dodecahedrane derivatives from *Prinzbach* et al. elegantly demonstrates the point: G. Lutz, D. Hunkler, G. Rihs, H. Prinzbach, *Angew. Chem. 101* (1989) 307; *Angew. Chem. Int. Ed. Engl. 28* (1989) 298 and four communications following.

Trinacrene – a Product of Structure-Directed Synthesis**

By *Peter R. Ashton, Neil S. Isaacs, Franz H. Kohnke, Guglielmo Stagno D'Alcontres,* and *J. Fraser Stoddart**

The fact that the macropolycyclic belt-like compound kohnkene **3** can be prepared[1] stereoselectively by consecutive Diels–Alder reactions in two steps (Scheme 1) from the readily-available bisdienophile **1**[2] and bisdiene **2**[3] has led us to speculate[4] that cage compounds with barrel-like structures might be accessible starting from **2** and building blocks containing three or more rigid and suitably-disposed



Scheme 1. The general strategy employed in the synthesis of **3**.

dienophilic units. In this communication, we firstly, establish that this speculation has become reality and announce the successful completion[5] of the stereoselective synthesis (Scheme 2) of a cage compound *trinacrene* **6**[6] from the bisdiene **2** and the trisdienophile **4**[7] via the intermediacy of trisadduct **5**, and secondly, call attention to the prospect that the concept of *structure-directed synthesis*[8] provides a new and fundamental platform from which small but stereoelectronically-programmed, molecular building blocks[9] can be elaborated through the practice of a kind of precision molecular "LEGO", into large and ordered structural arrays of organic materials.[10]

[**] This work was supported by the Agricultural and Food, and the Science and Engineering Research Councils in the United Kingdom and by the University of Messina in Italy.

Scheme 2. The two step synthesis of **6**. The H atoms at the ring junctions indicated by asterisks all have the *endo* configuration.

Hexabromobenzene was treated with a 1:1 molar equivalent of *n*BuLi and an excess of furan at −78 °C in toluene-hexane, which was allowed to warm up to room temperature before being cooled to −78 °C in preparation for the addition of a further 2.2 molar equivalents of *n*BuLi. This reaction mixture, after it had been allowed to reach room temperature for the second time and had been extracted and chromatographed repeatedly, afforded[11] two configurationally-isomeric trisdienophiles in the molar ratio 1:3[12] (Scheme 3). The relative configurations of the minor and major isomers were established unambiguously[13] as **4** and **4a** respectively on the basis of their ^{1}H-NMR spectra which can be interpreted with a knowledge of their molecular sym-

Scheme 3. The preparation of the trisdienophile **4**.

metries, viz. C_{3v} for **4** and C_s for **4a**. In particular, the C_{3v} isomer **4** shows only two equal-intensity resonances centered on δ 5.72 and 6.78 in its ^{1}H-NMR spectrum ($CDCl_3$, 400 MHz).

Reaction of **4** with 3.3 molar equivalents of **2** in toluene under reflux afforded, after chromatography, a trisadduct **5** in 48% yield along with minor amounts of a bisadduct and a monoadduct.[14] Despite the fact that there are 16 diastereoisomeric trisadducts, only *one* has been isolated and characterized. ^{1}H-NMR spectroscopy is consistent with the C_{3v} symmetry and the *endo* configurations[15] for the methine hydrogen atoms at the junctions of the newly-formed cyclohexene rings, and after subjecting equimolar amounts of **5** and **4** in CH_2Cl_2 solution to an intermolecular, followed by two intramolecular, Diels–Alder reactions under very high pressure[16] only trinacrene **6** was isolated. The positive ion fast atom bombardment mass spectrum (FABMS) of **6** revealed an intense peak at m/z 991 for $[M + H]^{\oplus}$ with little fragmentation of the molecule. Five resonances are observed in the high field ^{1}H-NMR spectrum of **6** recorded in $CHCl_3$ at δ = 1.56–1.66, 2.35–2.45, 2.76–2.88, 4.92, 5.10 (cf. the equivalent resonances at δ = 1.58–1.74, 2.25–2.40, 2.57–2.76, 4.89, 5.08 in **3**) for the five sets of heterotopic protons in the molecule with D_{3h} symmetry.

From a preliminary examination of trinacrene **6** by computer molecular graphics, it is clear that its large rigid molecular cavity could play host to a variety of organic, organometallic, metalloorganic and inorganic guest species, both neutral and charged. As with kohnkene **3**, chemical modification[1] (e.g. deoxygenation, dehydration, hydrogenation, and dehydrogenation) of **6** should permit useful steric and electronic manipulation of the structure. The synthesis of trinacrene **6** with its 24 chiral centers and 6 pseudochiral centers in two steps from **2** and **4** establishes the principle of *structure-directed synthesis* in the realm of unnatural products.[17]

Experimental Procedure

4/4a: Hexabromobenzene (33 g, 59.8 mmol) and furan (90 mL) in toluene (1.8 L) was cooled down to −78 °C and 1.1 mol equiv. of BuLi (24 mL of a 2.5 M solution in 60 mL of hexane) was added with stirring under argon during 4 h. The reaction mixture was allowed to warm up to room temperature (16 h) before being cooled down again to −78 °C prior to the addition (8 h) of a further 2.2 mol equiv. of BuLi (48 mL of a 2.5 M solution in 120 mL of hexane). After allowing the reaction mixture to warm up to room temperature, a work-up procedure, involving addition of water (50 mL), washing the organic phase with water (3 × 100 mL), drying ($CaSO_4$), and concentration, yielded a crude product, which, after chromatography (SiO_2,CH_2Cl_2/$CHCl_3$), afforded two components, both of which crystallized on addition of acetone. The compound, which was eluted first from the column, was characterized as the *anti*-isomer **4a** [300 mg, 1.8%, m.p. > 250 °C, m/z (EIMS) 276 for M$^{\oplus}$. ^{1}H-NMR ($CDCl_3$): δ = 5.68 (m, 2H), 5.69 (m, 2H), 5.75 (m, 2H), 6.72 (m, 2H), 6.88 (m, 2H), 6.89 (m, 2H); ^{13}C-NMR ($CDCl_3$): δ = 79.9, 80.0, 80.1, 134.0, 134.3, 134.6, 140.8, 140.9, 141.1] and the second compound to be eluted from the column was characterized as the all-*syn* isomer **4** [100 mg, 0.6%, m.p. > 250 °C, m/z (EIMS) 276 for M$^{\oplus}$. ^{1}H-NMR ($CDCl_3$): δ = 5.73 (m, 6H), 6.78 (m, 6H).

5: The bisdiene **2** (105 mg, 0.73 mmol) and the trisdienophile **4** (61 mg, 0.22 mmol) were heated under reflux (16 h) in toluene (20 mL) affording after chromatography (SiO_2,CH_2Cl_2/EtOAc) the trisadduct **5** [76 mg, 48%, recrystallized from CH_2Cl_2, m.p. > 250 °C, m/z (positive ion FABMS) 715 for $[M + H]^{\oplus}$, ^{1}H-NMR ($CDCl_3$): δ = 1.68–1.81 (6H, m), 2.28–2.43 (6H, m), 2.60–2.73 (6H, m), 4.98 (6H, s), 4.99 (6H, bs), 5.10 (6H, bs).

6: Reaction (CH_2Cl_2, 10 kbar, 50 °C, 6 days) of **5** (36 mg, 0.05 mmol) and **4** (14 mg, 0.05 mmol) yielded, after chromatography (SiO_2,$CHCl_3$/MeOH) **6** [ca. 2 mg, recrystallized from MeOH, m.p. > 300 °C, m/z (positive ion FABMS) 991 for $[M + H]^{\oplus}$; ^{1}H-NMR ($CDCl_3$): δ = 1.58–1.66 (12H, m), 2.35–2.45 (12H, m), 2.76–2.88 (12H, m), 4.92 (12 H, s), 5.10 (6H, s).

[4] Conceptually, in structural terms, the progression from "divalent benzene", expressed as the bisdienophile **1** and used in the construction of molecular belts, to "trivalent benzene", present in the trisdienophile **4** and employed here in the assembly of a molecular cage by repetitive Diels–Alder reactions, is reminiscent of the emergence (B. Dietrich, J.-M. Lehn, J.-P. Sauvage, *Tetrahedron Lett. 1969*, 2885, 2889) of [2.2.2]cryptand from 18-crown-6 (C. J. Pedersen, *J. Am. Chem. Soc. 89* (1967) 7017) wherein two diagonally-related divalent oxygen atoms are replaced by trivalent nitrogen atoms joined together (in both cases) by $-CH_2CH_2OCH_2CH_2OCH_2CH_2-$ chains. Note that a naphthalene nucleus is potentially "tetravalent".

[5] F. H. Kohnke, G. Stagno d'Alcontres, J. F. Stoddart, *Abstr. 13th Int. Symp. Macrocyclic Chem.*, Hamburg, 4–8 September 1988, Gesellschaft Deutscher Chemiker, Frankfurt am Main 1988, p. 244.

[6] The trivial name *trinacrene* for **6** has been coined from the old name for Sicily, i.e. *Trinacria*, which according to legend refers to the three-pointed shape of the island. As if to emphasize this shape, the emblem of Trinacria became (A. Colocci, *La Trinacria Trichetria*, Catania, Italy 1908) the Trichetria, i.e. the head (of Medusa) with three legs.

Trinacrene **6**

Trichetria

[7] The trisdienophile has only been reported (M. B. Stringer, D. Wege, *Tetrahedron Lett. 21* (1980) 3831) as a mixture of the all-*syn* (**4**) and *anti* (**4a**) isomers after a low yielding stepwise synthesis starting from 3,6-dibromoanthranilic acid.

[8] The regioselective synthesis of a range of pyrrole derivatives has been accomplished (G. Ksander, G. Bold, R. Lattmann, C. Lehmán, T. Früh, Y.-B. Xiang, K. Inomata, H.-P. Buser, J. Schreiber, E. Zass, A. Eschenmoser, *Helv. Chim. Acta 70* (1987) 1115; A. Eschenmoser, *Angew. Chem. 100* (1988) 5; *Angew. Chem. Int. Ed. Engl. 27* (1988) 5) with remarkable ease in high conversions starting from substrates such as 2-amino-2-propenenitrile without the need for any reagent control. Thus, inherently simple syntheses exist for the production of apparently complex structures. Since the syntheses of **3** and **6** rely upon high diastereoselectivities in consecutive Diels–Alder reactions, which are dictated by the *structures* of the substrates and possibly the products, we have chosen (P. R. Ashton, N. S. Isaacs, F. H. Kohnke, J. P. Mathias, J. F. Stoddart, *Angew. Chem. 101* (1989) 1266; *Angew. Chem. Int. Ed. Engl. 28* (1989) 1258) to refer to this kind of *unnatural product synthesis* as being *structure-directed*.

[9] Although the bicyclic nature of **1**, **2** and **4** incorporating diene and dieneophilic units is a necessary component of their design, the bridging oxygen atoms can, in principle at least, be replaced by other atoms (e.g. S) and groups (i.e. CH_2 and NR) without necessarily sacrificing the desired diastereoselectivities in the [4 + 2] cycloadditions between the diene and dienophilic units.

[10] In principle, there is no reason to restrict the description *structure-directed synthesis* to organic compounds. The existence of clays and zeolites bears witness to the spontaneous ordering of inorganic substrates and no doubt there are also many potentially new organometallic materials where organic substrates have reacted with inorganic substrates in a highly ordered manner: see, for example, J.-M. Lehn, A. Rigault, J. Siegel, J. Harrowfield, B. Chevrier, D. Moras, *Proc. Natl. Acad. Sci. USA 84* (1987) 2565; J.-M. Lehn, A. Rigault, *Angew. Chem. 100* (1988) 1121; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1095.

[11] Although hexabromobenzene is formally a trisaryne equivalent, the trisadducts **4** and **4a** are *only* formed in the very low yields of 0.6 and 1.8% respectively when a stepwise addition (Scheme 3) of reagents is employed. When 1.1, followed by 2.2, molar equivalents of *n*BuLi are added, we assume that the reaction proceeds via a monoadduct and that a small quantity of a 1,3-bisaryne is generated, following lithiation of the *para*-oriented bromine atoms and subsequent elimination of lithium bromide. Interestingly, if only 2.2 molar equivalents of *n*BuLi are employed in one step then the major reaction product is 9,10-dibromo-1,4:5,8-diepoxy-1,4,5,8-tetrahydroanthracene – the *anti*-isomer has been characterized (A. M. Z. Slawin, D. J. Williams, unpublished results) by X-ray crystallography. The polylithiation of polyhaloarenes to produce bisaryne equivalents has been investigated extensively (H. Hart, G. C. Nwokogu, *Tetrahedron Lett. 24* (1983) 5721; G. C. Nwokogu, H. Hart, *Tetrahedron Lett. 24* (1983) 5725; H. Hart, C. Lai, G. C. Nwokogu, S. Shamouilian, A. Teuerstein, B. Zlotogorski, *J. Am. Chem. Soc. 102* (1980) 6649; H. Hart, C. Lai, G. C. Nwokogu, S. Shamouilian, *Tetrahedron 43* (1987) 5203). Currently, we are investigating the use of hexahalogenobenzenes containing several different halogens in the hope of exploiting the differences in their reactivities towards lithiation in the hope of achieving trisaryne generation with high regioselectivity. An efficient synthesis of the trisdieneophile **4** is an essential prerequisite to obtaining substantial quantities of trinacrene **6**.

[12] Note that, statistically, the *anti*-isomer **4a** is three times more likely to be formed than the all-*syn* isomer **4**.

[13] Cf. P. G. Gassman, I. Gennick, *J. Am. Chem. Soc. 102* (1980) 6864.

[14] It should be noted that cycloadditions involving the "first" diene unit in **4** usually occur much faster (> 100 times) than those involving the "second" diene unit (Y. Bessière, P. Vogel, *Helv. Chim. Acta 63* (1980) 232).

[15] The fact that the bridgehead methine protons in the hexahydrotriphenylene trisendoxide resonate as a singlet establishes the *endo* configuration for the methine hydrogen atoms at the ring junctions (C. Mahaim, P.-A. Carrupt, J.-P. Hagenbuch, A. Florey, P. Vogel, *Helv. Chim. Acta 63* (1980) 1149).

Efficient Ion Exchangers and Receptors for Organic and Organometallic Cations**

By *Stefan Eller, Peter Brandt, Abdul K. Brimah, Peter Schwarz, and R. Dieter Fischer**

It has long been known that polymeric metal cyanides may also be ion-exchangers.[1] Whereas all previous observations have largely concerned the exchange of $H^{\oplus}$ and alkali metal cations, the Sn^{IV}-organic coordination polymers $[A(Me_3Sn)_3M^{II}(CN)_6]_\infty \triangleq [AM^{II}(\mu\text{-}CN \cdot Me_3Sn \cdot NC)]_\infty$ (M = Fe[2] and Ru) now being investigated in detail by us enable the preferred exchange of organic and organometallic cations $A^{\oplus}$. The equations (1)–(3) depict some representative and, in all cases, *quantitative* ion-exchange reactions (Route A).

$$[A(Me_3Sn)_3M(CN)_6]_\infty \xrightarrow[H_2O]{Et_4NCl} [(Et_4N)(Me_3Sn)_3M(CN)_6]_\infty + A^{\oplus}_{aq} \quad (1)$$

1a, A = Li, M = Fe[3] — **4a**, M = Fe
2a, A = NH_4, M = Fe, — **4b**, M = Ru
3a, A = Me_3Sn, M = Fe[4]
3b, A = Me_3Sn, M = Ru

$$[A(Me_3Sn)_3Fe(CN)_6]_\infty \xrightarrow[H_2O]{Me_3SnCl} [(Me_3Sn)_4Fe(CN)_6]_\infty + A^{\oplus}_{aq} \quad (2)$$

1a, 2a, 5a — **3a**

$$[A(Me_3Sn)_3Fe(CN)_6]_\infty \xrightarrow[H_2O \text{ or } EtOH]{[Cp_2Co][ClO_4]} [(Cp_2Co)(Me_3Sn)_3Fe(CN)_6]_\infty + A^{\oplus}_{aq} \quad (3)$$

2a, 3a — **6a**

5a, A = Et_3NH, M = Fe(EtOH)

That these heterogeneous reactions proceed to completion after only a few hours at room temperature[5] is more likely due to the pronounced lipophilicity of the cavities of the polymeric host lattice that are well padded by CH_3 groups than to the occasionally largely differing hydration en-

thalpies of competing cations (e.g. of $Li^{\oplus}/Cs^{\oplus}$, cf. Table 1). However, only products of the general composition $[(R_4N)_x(Me_3Sn)_{4-x}M(CN)_6]_\infty$ ($0 < x < 1$) are formed from **3** with $R_4N^{\oplus} \neq Et_4N^{\oplus}$ and $A^{\oplus} = Me_3Sn^{\oplus}$ [Eq. (1)], whereas **1a**, **2a** and **3a** show absolutely no ion-exchange with $K^{\oplus}$- or $Cs^{\oplus}$-salts. Thus, the affinity to the polymeric host system varies approximately in the following order: $K^{\oplus}$, $Cs^{\oplus} < Li^{\oplus}$, $NH_4^{\oplus} < NR_4^{\oplus}$ ($R \neq Et$), $Me_3Sn^{\oplus} < Et_3NH^{\oplus} < Cp_2Co^{\oplus}$, $Et_4N^{\oplus}$ (cf. Table 1).

Table 1. Proportion x of encapsulated cation $A^{\oplus}$ from results of elemental analyses.

$A^{\oplus}$	Route A [a]	Route B [b]	Route C [c]
$Li^{\oplus}$	0	0	1.0
$Na^{\oplus}$	0	0	1.0
$Cs^{\oplus}$	0	0	< 0.25
$NH_4^{\oplus}$	0.5	0	1.0
$Me_4N^{\oplus}$	0.7	0.3 0.8	1.0 [d]
$Et_4N^{\oplus}$	1.0	1.0 1.0	1.0
$nPr_4N^{\oplus}$	0.9	0.7 0.9	0.4
$nBu_4N^{\oplus}$	0.5	0.5 0.5	0.2

[a] Starting compound: **1a**; product $[A_xLi_{1-x}(Me_3Sn)_3Fe(CN)_6]_\infty$; standard conditions: see [5]. [b] Cf. Eq. (4); product: $[A_x(Me_3Sn)_{4-x}Fe(CN)_6]_\infty$; left: $(Me_3SnCl)/(R_4NCl)$ 1:1; right: $(Me_3SnCl)/(R_4NCl)$ 1:2. [c] product: $[A_x(Me_3Sn)_3Fe^{II}_xFe^{III}_{1-x}(CN)_6]_\infty$. [d] Estimated on the basis of relative IR intensities (ν-CN).

The topochemically favored host-guest systems **4**, with R = Et, and **5a** can also be synthesized according to Equation 4, by simple precipitation from H_2O[6] (Route B) and, with M = Fe, as for the already described[2] host-guest system $[(Cp_2Fe)(Me_3Sn)_3Fe(CN)_6]_\infty$, via the tribochemical reaction (5) (Route C).

$$\left.\begin{array}{l} 3\,Me_3SnCl + Et_4NCl + K_4[M(CN)_6] \xrightarrow[-4\,KCl]{(H_2O)} \\ 3\,Me_3SnCl + [Et_4N]_4[M(CN)_6] \xrightarrow[-3\,Et_4NCl]{(H_2O)} \end{array}\right\} \textbf{4a, 4b} \downarrow \quad (4)$$

$$[(Me_3Sn)_3Fe^{III}(CN)_6]_\infty + Et_4NI \xrightarrow[-1/2\,I_2]{\text{grinding}} [(Et_4N)(Me_3Sn)_3Fe^{II}CN)_6]_\infty \quad (5)$$

7a → **4a**

The routes A–C lead to the same products (**4**), whose superimposable X-ray powder diagrams rule out a cubic "super Prussian blue"–like host lattice.[8] With $R_4N^{\oplus}$ ($R \neq Et$), precipitated products of the complex type $[(R_4N)_x(Me_3Sn)_{4-x}M(CN)_6]_\infty$ are again formed, also via Route B, whereas with $M^{\oplus} = Li^{\oplus}$–$Cs^{\oplus}$ and $NH_4^{\oplus}$ only the compounds **3** are formed (cf. Table 1). Route C [Eq. (5)], appropriately modified,[13] also serves for the synthesis of **1a**[3] and **2a**.[7] The tribochemical reaction of R_4NI ($R \neq H$, Me, Et) and MI ($M \neq Li$, Na) with **7a** no longer proceeds to completion (Table 1). The anionic host lattice present in the host-guest systems **1a**–**6a** forms a rare example of an efficient $Et_4N^{\oplus}$ receptor: whereas molecular anionic receptors generally only form very weak complexes with tetra*alkyl*ammonium ions,[9] the likewise polymeric $R_4N^{\oplus}$/zeolite cation intercalates[11] formed in the gel synthesis of zeolites[10] (after subsequent $Na^{\oplus}/R_4N^{\oplus}$ ion exchange) appear to be best comparable with **4**. The encapsulation of metallocene cations $Cp_2M^{\oplus}$ (M = Co, Fe; cf. **6a**) in zeolites by ion exchange was first described only recently.[12]

In contrast to the previously obtained coordination polymers of the general type $[(R_3Sn)_mM(CN)_n]_\infty \triangleq [M(\mu\text{-}CN \cdot R_3Sn \cdot NC)_{n/2}]_\infty$[14] where $m = n/2$, in the case of **3** $m = n/2 + 1$, so that in this instance not all four Me_3Sn groups can be incorporated in equivalent, trigonal-bipyramidally (tbp) configurated $Me_3Sn(NCM\cdots)_2$ bridges. The tempting (in view of the easy ion exchange [Eq. (1)–(3)]) assumption of one (per M atom) coordinatively extremely weakly anchored and therefore unusually mobile $Me_3Sn^{\oplus}$ ion in the lattice does not however manifest itself either in the vibrational spectra of **3**[15] or in the ^{119}Sn Mössbauer spectrum[16] of **3a**. On the other hand, the CP-MAS ^{119}Sn-NMR spectra[17] of **3a** and **3b** clearly show two widely separated ($\Delta\delta > 100$) signals.

Dioxane inhibits the spontaneous precipitation of **3** (Route B); the very slowly crystallizing novel host-guest system **8a** [Eq. (6)] now contains *all* Sn atoms in bridging tbp

$$4\,Me_3SnCl + K_4[Fe(CN)_6] \xrightarrow[-4\,KCl]{H_2O/C_4H_8O_2(1:2)} [(Me_3Sn)_4Fe(CN)_6 \cdot 2\,H_2O \cdot C_4H_8O_2]_\infty \quad (6)$$

8a

units.[18] The incorporation of the apparently more mobile $Me_3Sn^{\oplus}$ ions of **3a** into chain building blocks of the type

leads, compared to **3a**, to a drastic quenching of the $Me_3Sn^{\oplus}/Et_4N^{\oplus}$ ion exchange.[19]

The findings described here open up new possibilities for the systematic development of host-guest complexes with numerous organometallic and organic cations. Such solid state compounds with acentric space groups are especially interesting for the development of materials with high nonlinear second order effects (e.g. for frequency doubling).[20, 22]

[5] Synthesis of **4a** and **4b** (as examples for Route A): **3** (or **1a**) (0.5 mmol) was treated with a solution of 1.0 mmol of Et_4NCl in 20 mL of H_2O. After 30 minutes of stirring at room temperature and filtration the colorless solid remaining was washed three times with 10 mL of H_2O and dried for ca. 5 h (high vacuum, ca. 30 °C). Yields > 85% in each case. Elemental analysis calculated for **4a** ($C_{23}H_{47}N_7Sn_3Fe$): C 33.14, H 5.68, N 11.76, Fe 6.70, Sn 42.72%; found: C 33.11, H 5.56, N 11.67, Fe 6.60, Sn 42.54%.
[6] Synthesis of **4b** (example for Route B): A stirred solution of 0.30 g (0.70 mmol) of $K_4[Ru(CN)_6]$ and 0.36 g (2.10 mmol) of Et_4NCl in 20 mL of H_2O was treated with a solution of 0.42 g (2.10 mmol) of Me_3SnCl in 10 mL H_2O. The spontaneously separating colorless precipitate was filtered off, washed with H_2O and dried for several hours (high vacuum, room temperature). Yield: 0.56 g (0.64 mmol) = 92%. – Alternative: Addition of a solution of 84 mg (0.423 mmol) of Me_3SnCl in 10 mL of H_2O to a solution of 110 mg (0.141 mmol) of $[NEt_4]_4[Ru(CN)_6]$ in 10 mL of H_2O. Yield after work-up as in [5]: 10 mg (0.132 mmol) = 94%. Elemental analysis calculated for **4b** ($C_{23}H_{47}N_7Sn_3Ru$): C 31.43, H 5.39, N 11.16, Sn 40.52%; found: C 31.25, H 5.30, N 10.89, Sn 39.14. Alternative: C 31.36, H 5.35, N 11.07, Sn 39.30%. **4a** can be prepared analogously. Decomp. temp.: **4a**, 283 °C; **4b**, 322 °C.
[7] Synthesis of **4a** (example for Route C): orange $(Me_3Sn)_3Fe^{III}(CN)_6$ **7a** (500 mg, 0.7 mmol) was ground for 5 minutes together with 360 mg (1.40 mmol) of Et_4NI. After washing several times with methanol (in the synthesis of **1a** and **2a** with isopropyl alcohol) the product was dried for 1 h (high vacuum, room temperature).

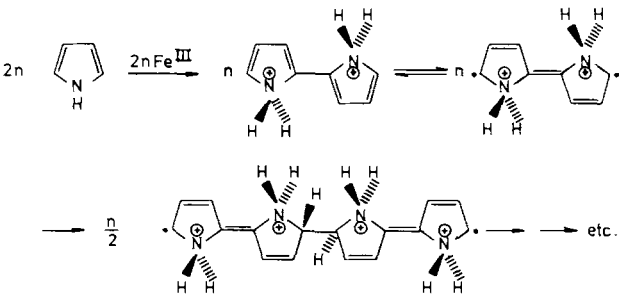
Spontaneous Oxidation and in-situ Polymerization of Pyrrole in Channels of the Three-Dimensional Coordination Polymer $[(Me_3Sn)_3Fe^{III}(CN)_6]_\infty$ **



By *Peter Brandt, R. Dieter Fischer,* Enrique Sanchez Martinez* and *Ricardo Diaz Calleja**

The zeolite-like coordination polymer $[Fe^{III}(\mu\text{-}CN\cdot Me_3Sn\cdot NC)_3]_\infty \triangleq [(Me_3Sn)_3Fe^{III}(CN)_6]_\infty$ **1** oxidizes ferrocene[1] as well as numerous metal and ammonium iodides under encapsulation of the respective remaining cation $A^\oplus$ ($Cp_2Fe^\oplus$, $1/nM^{n\oplus}$, $R_4N^\oplus$ etc.) in the spacious channels[1,2] of the negatively charged host lattice afforded after reduction of its Fe^{III} ions. The resulting cation-"intercalates" of the type $[(A_x(Me_3Sn)_3Fe^{II}_xFe^{III}_{1-x}(CN)_6]_\infty$ $(1 \geq x > 0)$ – type I – are not only of interest as novel ion-exchangers and chemical storage materials,[2] but also as potential cation conductors. We describe here primarily the novel cation-encapsulation compound **2** [Eq. (1)], whose guest ions $A^\oplus$ consist of oligomerized and/or polymerized[17a] pyrrole (Ppy) units, and might therefore also give rise to a more pronounced *electronic* conductivity than e.g. **1** and type I systems with $x < 1$.[3]

$$\underset{\textbf{1 (orange)}}{[(Me_3Sn)_3Fe^{III}(CN)_6]_\infty} \xrightarrow{\text{pyrrole}} \underset{\textbf{2 (black)}}{[(Ppy)(Me_3Sn)_3Fe^{II}(CN)_6]_x} \qquad (1)$$

Ppy ≙ $[1/n(C_4H_5N)_n]^\oplus$, n = average degree of oligomerization/polymerization

1 reacts spontaneously with freshly distilled pyrrole (and also pyridine[17b]) at room temperature,[4] but not with thiophene. The salts $K_3[Fe(CN)_6]$ and $[nBu_4N]_3[Fe(CN)_6]$, which do not form inclusion compounds, oxidize neither pyridine nor pyrrole. The strict absence of $Fe^{III}(CN)_6$ units, apparent from both the ν(CN) region of the IR spectrum[5] and the diamagnetism of **2**, supports, in accordance with the elemental analyses,[6] the assumption that each pyrrole molecule transfers one electron to a Fe^{III} ion[17c] of the host after entering a channel of **1**. While the diamagnetism would at least advocate for the pairwise dimerization of all $C_4H_5N^{\cdot\oplus}$ radical cations, the deep "color" and the comparatively good conductivity of **2** suggest spontaneous oligomerization or polymerization (Scheme 1).

Scheme 1. Conceivable initial steps of the oxidative polymerization of pyrrole in channels of **1**.

The electrical conductivity σ[7] of **2** exceeds that of freshly prepared and "aged" (irradiated[8]) **1** (i.e. of **1** and **1'**, respectively) as well as that of the type I reference systems **3**–**5**[9] (cf. Table 1) by at least three orders of magnitude (Table 2

Table 1. General properties of the samples **1**–**5**.

	Sample Composition	Color	Dec.-temp. [°C]	μ_{eff} [B.M.]
1	$[(Me_3Sn)_3Fe^{III}(CN)_6]_\infty$	orange	180	2.18
1'	[a]	blue-green	ca. 110	1.08 [b]
2	$[(C_4H_5N)(Me_3Sn)_3Fe^{II}(CN)_6]_\infty$	black	ca. 250	diamagn.
3	$[Cp_2Fe^{III}(Me_3Sn)_3Fe^{II}(CN)_6]_\infty$	deep blue	ca. 80	3.65 [1]
4	$[Li_{0.3}(Me_3Sn)_3Fe^{II}_{0.3}Fe^{III}_{0.7}(CN)_6]_\infty$	yellow	ca. 200	1.54
5	$[Fe^{II}_{0.1}(Me_3Sn)_3Fe^{II}_{0.2}Fe^{III}_{0.8}(CN)_6]_\infty$	green	ca. 200	2.43

[a] Sample **1'** has the same composition as **1**; structural details are still unknown. [b] Exhaustive ageing, bright blue sample.

Table 2. Arrhenius parameters and room temperature conductivity of samples **1–5**.

Sample	Preexponential factor σ_0 [S cm^{-1}]	Activation energy E_a [eV]	σ [S cm^{-1}]	T [K]
1	[a]		3.74×10^{-8}	290
1'	1.21×10^{-3}	0.86	7.42×10^{-11}	300
2	1.65×10^{-1}	0.39	7.02×10^{-5}	300
3	3.0×10^{-3}	0.96	2.60×10^{-11}	300
4	10^{-1}	0.98	4.94×10^{-10}	300
5	1.5×10^{-4}	0.50	8.51×10^{-9}	300

[a] $\ln\sigma$ is not proportional to T^{-1}.

and Fig. 1). The absolute value of σ, however, rules out the presence of pure "highly conducting" polypyrrole[10] in **2**. The H-content of **2** also turns out to be too high for polymeric Ppy chains with ideally conjugated double bonds throughout. Although the IR spectra of the Ppy units of **2** and of the cation intercalate "$Ppy_{0.34}FeOCl$" **6**[11] (prepared recently

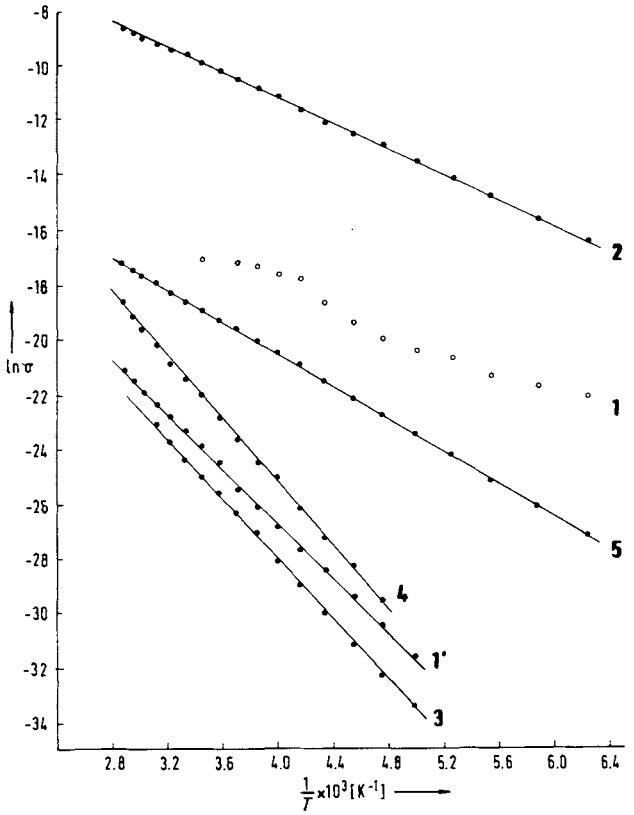

Fig. 1. Temperature dependence of ln σ of the samples **1–5** (see also Tables 1 and 2).

from pyrrole and $Fe^{III}OCl$) strongly resemble each other, the Ppy in the partially reduced FeOCl is likely to be more exhaustively oxidized than the Ppy in **2**. Thus the σ-value of **6**[11] exceeds that of **2** by a factor of 10^3. The significant deviations of the linear $\log\sigma$-vs-T^{-1} plot ($200\,K < T < 340\,K$) of **2** from the two almost parallel $\log\sigma$-vs-T^{-1} curve sections of **6** and host-free $(Ppy)(NO_3)_{0.27}$[11] make it very unlikely that the conductivity of **2** is dominated by only small amounts of non-encapsulated (i.e. externally chemisorbed) "highly conducting" Ppy.[12] It cannot be fully ruled out, however, that the enhanced semiconductivity of **2**[13] may at least in part be due to a particularly high mobility of the charge-compensating protons[14, 17b] which have only formally been attributed to N-atoms of the Ppy chain in Scheme 1.

In view of the approximate cross-section of ca. 6.8 Å of the parallel channels running through the starting compound **1**,[1] the oxidative in-situ oligomerization (or polymerization) of pyrrole in **1** should proceed without chain-branching (cross-linking) and charge transfer interactions between neighboring Ppy chains (formation of ideal "molecular wires"[15]). Some first results of similar experiments with zeolites as host systems of Ppy have most recently been reported.[16]

[3] The simultaneous presence of transition metal ions in different oxidation states (e.g. in the case of type I when $x < 1$) should likewise make electron hopping possible.

[4] Synthesis of **2**: 3 g (4.3 mmol) of **1** was placed on a frit under an atmosphere of N_2 and covered with a layer of 5 mL of freshly distilled pyrrole. The undissolved solid remaining on the frit first turned green and then black. After 30 min at ca. 20 °C the excess pyrrole was filtered off and the solid product washed with CH_2Cl_2 and dried in vacuo (30 °C). Elemental analysis, calculated for $C_{19}H_{32}N_7FeSn_3$: C 29.62, H 4.19, N 12.73, Fe 7.25, Sn 46.22%; found: C 29.53, H 4.22, N 12.48, Fe 7.29, Sn 44.03%.

[5] ν(CN)-absorptions (in cm^{-1}, IR): **2**: 2050 (s, br); **1**: 2141(vs), 2080(w).

[6] The analytical data (see [4]) lead to the significant ratios H(Ppy)/N(Ppy) 6.11, C(Ppy)/N(Ppy) 4.61, Sn/N(Ppy) 3.42; cf. the values quoted for "$Ppy(ClO_4)_{0.33}$" [10b]: H/N 3.37, C/N 3.94.

[7] Cylindrical pellets of **1** to **5** (diameter: 1 cm, height: 1–2 mm) were prepared under a pressure of 5×10^8 Pa. The resistances were measured in a non-commercial apparatus (evacuated corundum pot, gilted electrodes, resistance thermometer Pt-100, Eurotherm Single Loop Communication Controller 820, Hewlett-Packard Multimeter 4329A).

[8] Synthesis of **1'**: orange-yellow **1** was exposed under air, either for several months to daylight, or just a week to a UV lamp. The color changed to green and then to blue; concomitant decrease of μ_{eff}. IR, $\tilde{\nu}$[cm^{-1}]: ν-CN, 2142(vs), 2085(vs), δ-$Fe^{II}C$, 600(w), ν-SnC, 555(s), ν-$Fe^{II}C$, 412(m). Elemental analysis: As for **1**.

[9] Synthesis of **4** and **5** according to the procedure given in Ref. [2]; correct elemental analyses (C, H, N, Fe); for **3** see [1].

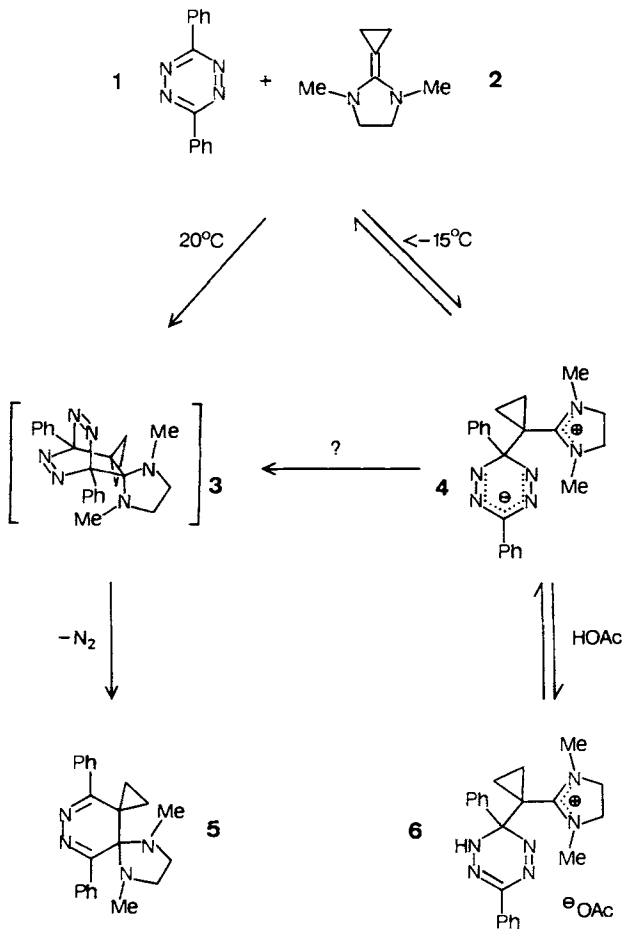
[16] a) Cf. [15b]; b) T. Bein, P. Enzel, *197th. ACS Nat. Meet. Dallas, Tx, 9.–14. April 1989*, Abstr. INOR 135; c) *Chem. Eng. News 67* (1989) No. 17.



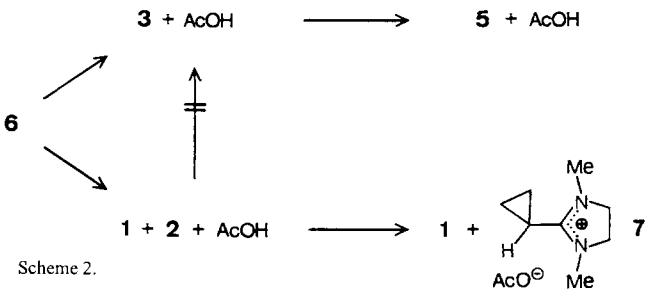
[17] Note added in proof: a) Quite unexpectedly, at least some of the Ppy encapsulated in **2** can be liberated by ion-exchange (according to Ref. [2]) without notable color change of the solid. b) The conductivity of the likewise diamagnetic, but brown reaction product of **1** with pyridine which could also contain "charge-compensating protons" is notably lower than 10^{-9} S cm^{-1}. c) In aqueous solution, a clean 1:1 (i.e. oxidant/pyrrole) oxidation of pyrrole has so far not been observed; see: S. P. Armes, *Synth. Met. 20* (1987) 365. d) First attempts to dope **2** with I_2 did not lead to a significant increase of σ.

Isolation of a Zwitterion in a Diels–Alder Reaction with Inverse Electron Demand**

By *Klaus-Peter Hartmann* and *Manfred Heuschmann**

Cycloadditions of electron-deficient tetrazines with electron-rich ketene acetals[1] have served as impressive model reactions for the chemist's understanding of Diels–Alder reactions with inverse electron demand.[2] It is generally assumed that the reaction products, functionalized pyridazines, are formed in a reaction cascade of cycloaddition, nitrogen extrusion, and elimination of alcohol, thiol or amine. Despite extensive and detailed investigations not much is known of the individual steps of the reaction. We report here on the first detectable two-step Diels–Alder reaction of a tetrazine with a ketene *N,N*-acetal.

From the high reactivity[3] of 2-cyclopropylidene-imidazolidine **2** in inverse Diels–Alder reactions it may be expected that it reacts with tetrazines even at very low temperatures and should thus enable the isolation of thermally labile intermediates. Indeed, the deep-red solution of the diphenyltetrazine **1** in [D_2]dichloromethane decolorized even at $-60\,^{\circ}C$ after addition of **2**. A yellow solid crystallized from the viscous solution; at temperatures above $10\,^{\circ}C$ this redissolved, and concomitant elimination of nitrogen resulted in the formation dihydropyridazine **5**. Small amounts of tetrazine **1** were also detectable (Scheme 1).



Scheme 1.

The ^1H NMR spectrum of the labile intermediate is fully consistent with the structure of the zwitterion **4**. The signals for the *N*-methyl and *N*-methylene groups[4] resemble those of the dihydroimidazolium iodide **8**[5] (cf. **7** in Scheme 2, $I^{\ominus}$ instead of $OAc^{\ominus}$) and lie markedly further downfield than in the final product **5**. On the other hand, the phenyl groups of **4** absorb further upfield than those of **5**, as might be expected for a dihydrotetrazine anion.[7] In toluene, **4** crystallized in 88% yield at $-15\,^{\circ}C$; upon warming the mixture to room temperature, we isolated **5** in 78% yield. The sparing solubility of **4** in unpolar, polar aprotic and protic solvents and its temperature sensitivity precluded an accurate spectroscopic characterization of the zwitterion.

As could be expected from the pK_A values of dihydrotetrazines,[7] acetic acid (or [D_4]acetic acid) protonates the zwitterion and leads to a salt that is readily soluble in [D]chloroform and [D_2]dichloromethane and whose ^1H and ^{13}C NMR spectra[8] confirm the structure **6**. The signals correlate well with the chemical shifts of 4,5-dihydroimidazolium ions[5] and 1,6-dihydrotetrazines.[7] The change in the spectrum as a function of the acid concentration as well as the reactivity is consistent with an equilibrium between **4** and **6**. Upon warming to room temperature, **6** also loses nitrogen but more slowly than **4**. The ^1H NMR spectrum of the resulting product was identical with that of isolated dihydropyridazine **5** in $CDCl_3/CD_3CO_2D$. In addition, we identified ca. 5–10% of the tetrazine **1**.

Two fundamentally different mechanisms can explain these observations. Either the zwitterion **4** is an intermediate of the Diels–Alder reaction and closes the ring in an intramolecular reaction to give the bicyclic adduct **3**, or **4** is formed in a reversible side reaction and splits again into the starting compounds **1** and **2**, which then form the same adduct **3** in a concerted cycloaddition. In both cases **3** then loses nitrogen in a rapid secondary [4 + 2]-cycloreversion. Zwitterions are often formed in side reactions upon reaction of tetrazines and triazines with ketene acetals,[9a,10] but all attempts to prove their participation in two-step cycloadditions have thus far failed.

Since the dihydropyridazine **5** is formed from the protonated zwitterion **6** even in the presence of an excess of acetic acid, a concerted cycloaddition, which requires a retrocleavage to the starting compounds **1** and **2**, can be ruled out: independent experiments show that the cyclopropylidene-imidazoline **2** reacts much more rapidly with acetic acid than with tetrazine **1** (Scheme 2). Both at $-30\,^{\circ}C$ as well as at

Scheme 2.

$20\,^{\circ}C$ only the dihydroimidazolium acetate **7** is formed when **2** is added dropwise to a mixture of tetrazine **1** and acetic acid (1:2) in $CDCl_3$. Even after prolonged heating of the mixture for several hours at $80\,^{\circ}C$ we could not detect any trace of the dihydropyridazine **5**. Consequently, in the conversion of **6** into **5**, which proceeds in ca. 90–95% yield, no free ketene aminal **2** can occur in the presence of acetic acid; hence, the Diels–Alder reaction proceeds in two steps.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

In cycloadditions of other ketene acetals, too rapid a retrocleavage of the zwitterions to the starting compounds prevents any decision regarding two-step or concerted mechanisms.[10] Retrocleavage of the zwitterion **4** into the starting compounds is observed only as an insignificant side reaction, which with other substitutions, however, can easily become the major reaction. The ca. 14 kcal mol^{-1} higher strain energy of methylenecyclopropane[11] compared to that of cyclopropane, which must be provided for the formation of the cyclopropylidene-imidazolidine **2** from the zwitterion **4**, specifically retards this retrocleavage and thus enables the detection of the two-step mechanism. On the other hand, to a first approximation, the cyclopropyl group has no effect on the difference in the activation energies of concerted and two-step cycloaddition. One may therefore conclude that Diels–Alder reactions of ketene acetals, at least of ketene *N,N*-acetals, with tetrazines generally proceed in two steps. This provides a new basis on which to discuss previously unexplainable phenomena, e.g. the special position of the ketene *N,N*-acetals with regard to regioselectivity and its solvent dependence.[9]

1-Phenalenol: Isolation and Disproportionation

By *Yoshikazu Sugihara, Hidetoshi Kawanaka,* and *Ichiro Murata**

1-Phenalenol **1** is of fundamental importance for phenalene chemistry.[1] This compound has been suggested as a probable intermediate generated in situ in the hydrolysis of the phenalenium ion **2**[2] and the hydride reduction of phenalenone **3**.[3] However, attempts to isolate and characterize **1** have so far failed, presumably owing to its marked propensity to disproportionate into phenalene **4** and phenalenone **3**.[1, 2, 3a, 3c] We wish to report for the first time the isolation of **1** through the controlled hydride reduction of **3** and the disproportionation reaction of **1**.

For the reduction of **3**, we used sodium borohydride in the presence of ceric chloride in methanol.[4] To a solution of **3** (100 mg) and ceric chloride hexahydrate (197 mg) in methanol (10 mL) was added sodium borohydride (90 mg) in small portions with ice cooling. Usual workup of the reaction mixture afforded equal amounts of **3** and **4** in a total isolated yield of 96%. When the reduction was conducted in a dilute methanol solution (80 mL) with a large excess of sodium borohydride (300 mg), however, a single new spot due to neither **3** nor **4** was detected on the thin layer chromatogram. After several attempts, a new product could be separated by the following procedures.[5] The solvent was evaporated in vacuo to give a colorless solid which was extracted into dichloromethane containing a small amount of triethylamine. The organic layer was poured into water through cotton placed on a funnel, separated, and concentrated. Recrystallization of the residue from hexane below 30 °C afforded colorless needles (m.p. 64.5–65.0 °C, 83% yield). The elemental analysis[6] and the spectral data of this compound (Table 1) are consistent with the structure of **1**, which, however, suffered a very small amount of disproportionation to **3** and **4** as detected by careful ^{1}H NMR inspection.[7]

Table 1. Spectral data of **1**.

400-MHz ^{1}H NMR ($CDCl_3$): δ = 7.74 (d, J = 8.25 Hz, H-7), 7.71 (dt, J = 7.25, 1.28 Hz, H-9), 7.66 (d, J = 8.24 Hz, H-6), 7.51 (dd, J = 8.25, 7.25 Hz, H-8), 7.35 (dd, J = 8.24, 6.96 Hz, H-5), 7.18 (d, J = 6.96 Hz, H-4), 6.74 (dd, J = 9.79, 1.10 Hz, H-3), 6.18 (dd, J = 9.79, 4.03 Hz, H-2), 5.52 (m, H-1), 2.19 (d, J = 9.16 Hz, OH)

100-MHz ^{13}C NMR ($CDCl_3$): δ = 135.6, 132.5, 129.2 (C-3a, C-6a, C-9a), 129.3 (C-2), 128.3 (C-3), 128.0 (C-6), 127.9 (C-9), 127.8 (C-7), 126.5 (C-8), 126.1 (C-9b), 126.0 (C-5), 124.7 (C-4), 66.0 (C-1)

EI-MS: *m/z* 182 ($M^{\oplus}$, 0.5%), 181 ($M^{\oplus}-H$, 3.0), 180 ($M^{\oplus}-H_2$, 100), 165 ($M^{\oplus}-OH$, 7.0), 152 ($M^{\oplus}-H_2-CO$, 15.6)

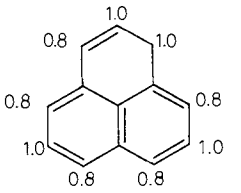
IR (CH_2Cl_2): $\tilde{\nu}$ = 3420 cm^{-1}

The disproportionation of **1** was studied by means of time-dependent ^{1}H NMR spectroscopy, labeling, and competition reactions. Compound **1** did not undergo disproportionation in deuteriochloroform. In [D_4]methanol distilled from potassium carbonate, however, **1** disproportionated slowly but cleanly into **3** and **4** with a half-life of 7 d. Since the

[*] Prof. Dr. I. Murata, Dr. Y. Sugihara, H. Kawanaka
Department of Chemistry, Faculty of Science
Osaka University, Toyonaka, Osaka 560 (Japan)

disproportionation reaction occurred in deuteriochloroform in the presence of a small amount of [D_1]acetic acid (**1**:[D_1]acetic acid = 30:1) with a half-life of ca. 30 min, protic substances are involved in the reaction. During the ^{1}H NMR measurement no signals ascribable to the reaction intermediate could be observed.

1-Deuteriophenalenol [D_1]**1** was prepared by reduction of **3** with sodium borodeuteride in [D_1]methanol followed by washing with water. When [D_1]**1** was subjected to reaction with a small amount of acetic acid in benzene, the clean disproportionation reaction was complete within 2 d. The products were separated into **3** and **4** by column chromatography with deactivated alumina (5% H_2O). ^{1}H NMR (500 MHz) spectroscopy revealed that no deuterium is incorporated into **3** whereas two deuterium atoms are present in **4** ([D_2]**4**). Since the vicinal coupling patterns of H-3, H-4, H-6, H-7, and H-9 of [D_2]**4** are the same as those of undeuterated **4**, the deuterium atoms are not located at the 2-, 5-, and 8-positions. As expected, the intensities of the ^{1}H NMR signals for H-2, H-5, and H-8 were found to be the same. From the integrated intensity of each proton with respect to that of the well-separated H-2 signal, it can be concluded that the two deuterium atoms are distributed at the 1-, 3-, 4-, 6-, 7-, and 9-positions of **4** with appreciable scrambling as shown in Figure 1. Because of the fast hydrogen migration characteristic of the phenalene skeleton,[1] the distribution of two deuteriums in [D_2]**4** could not be explained explicitly. Nevertheless, these findings mean that the deuterium introduced in [D_1]**1** is transferred directly from the 1-position of [D_1]**1** to another molecule of [D_1]**1** with the formation of [D_2]**4** together with **3** (Scheme 1).



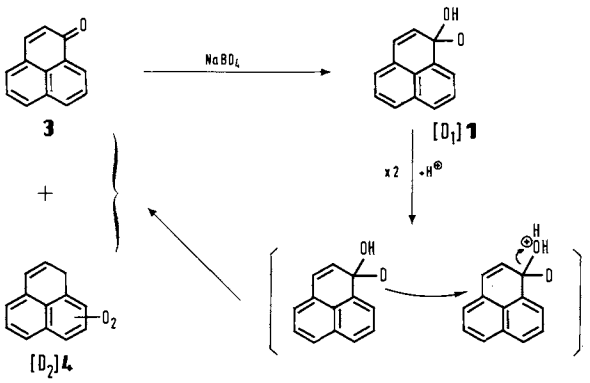


Fig. 1. Integrated intensities of the protons in [D_2] **4**.

Scheme 1. Conceivable mechanism for the disproportionation of **1**.

In the presence of carbonyl compounds (ca. 1 equivalent) such as benzophenone, 1-naphthaldehyde, and phenalanone, the disproportionation of **1** preferentially took place with a small amount of acetic acid in benzene. Alcohols, which should be produced by Meerwein–Pondorf–Verley reduction, were not found. Hydride is transferred more rapidly to phenalenium ion than to added ketone or aldehyde, since the cation has a lower reduction potential.[8]

Compound **1**, as has been inferred for a long time, undergoes very facile disproportionation in the presence of protic substances. The present work opens a possible route to the unknown cycloheptatrienol and cyclopropenol.

Synthesis and Structure of $[(C_5H_5)_2TiS_4AsCH_3]$—a New Reagent for the Synthesis of Sulfur-Rich Heterocycles**

By *Ralf Steudel,** *Birger Holz*, and *Joachim Pickardt*

Titanocenepentasulfide, Cp_2TiS_5 **1** (Cp = η^5-C_5H_5), has proved extremely valuable as a reagent for the synthesis of sulfur- and selenium-containing homo- and heterocycles since it reacts under mild conditions with numerous sulfur and selenium halides to give the corresponding ring compounds with elimination of Cp_2TiCl_2. Twelve compounds of the types S_n and Se_xS_y ($n = 6-20$; $x = 1-3$; $x + y = 6-8$) have been prepared in this way and obtained in pure form.[1] The symmetrical binuclear complexes $Cp_4Ti_2S_4$ and $Cp_4Ti_2S_6$ also react with SCl_2, S_2Cl_2, $SeBr_2$, and Se_2Cl_2 with elimination of Cp_2TiCl_2, a mononuclear titanocene complex being the main product[2] [see, e.g., Eq. (a)]. In an analogous way, we have now obtained the first arsenic-containing titanocene polysulfide complex [Eq. (b)].

$$[Cp_2Ti(\mu\text{-}S_2)_2TiCp_2] + SCl_2 \rightarrow \underset{\mathbf{1}}{Cp_2TiS_5} + Cp_2TiCl_2 \qquad (a)$$

$$[Cp_2Ti(\mu\text{-}S_2)_2TiCp_2] + CH_3AsCl_2 \xrightarrow[CCl_4]{20\,^\circ C} \underset{\mathbf{2}}{[Cp_2Ti(\mu\text{-}S_2)_2AsCH_3]} + Cp_2TiCl_2 \qquad (b)$$

Compound **2** was obtained in 20% yield as black-red crystals, which are air-stable at 20 °C.[3] Compound **2** is readily

[**] Sulfur Compounds, Part 128. This work was supported by the Deutsche Forschungsgemeinschaft and the Verband der Chemischen Industrie. Part 127: R. Steudel, G. Holdt, T. Göbel, *J. Chromatogr.* 475 (1989) 442.

soluble in CS_2, CH_2Cl_2, and $CHCl_3$, but less soluble in CCl_4. In the mass spectrum (17 eV, 100 °C), the signal for the molecular ion (m/z 396) is observed. In the ^1H NMR spectrum (80 MHz), recorded at 20 °C in $CDCl_3$, three singlets at $\delta = 6.35$ (Cp), 5.86 (Cp), and 0.43 (CH_3) are found.[3] Accordingly, the conformation of the metallacycle is rigid at 20 °C, as found for Cp_2TiS_5, the Cp NMR signals of which coalesce at 90 °C.[6] However, an equivalence of the Cp ligands requires not only ring inversion of the metallacycle but also simultaneous pyramidal inversion at the As atom. The two Cp proton signals in the NMR spectrum of **1** ($CDCl_3$, 80 MHz) are found at $\delta = 6.35$ and 6.09. The first value coincides exactly with that of a Cp signal in the spectrum of **2**. Therefore, this signal can be assigned to the protons of the Cp ligand furthest removed from the methyl group.

A single-crystal X-ray structure analysis[7] revealed that a chair-shaped TiS_4As ring is present in **2**, the methyl group on the arsenic atoms being in axial position (Fig. 1). The molecular structure of **2** strongly resembles that of **1**,[8] insofar as

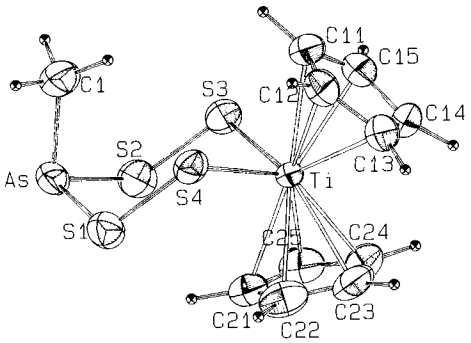

Fig. 1. Molecular structure of **2** in the crystal. Selected distances [pm] and angles [°]: C1-As 195, As-S1 226.4, As-S2 225.9, S1-S4 205.6, S2-S3 205.9, Ti-S4 241.9, Ti-S3 243.0; C1-As-S1 99.0, C1-As-S2 99.6, As-S1-S4 107.4, S1-S4-Ti 111.0, S4-Ti-S3 94.4, Ti-S3-S2 111.1, S3-S2-As 108.3, S2-As-S1 105.9.

angles and distances in the fragment Cp_2TiS_4 are nearly identical in both compounds. Thus, the average distance of the Cp carbon atoms from the titanium atom is 237.4 pm in **1** and 238.2 pm in **2** and the S–Ti–S angle is 94.6° in **1** and 94.4° in **2**. The two S–S distances in **2** (average 205.8 pm) are not only nearly identical to the corresponding distances in **1** (205.9 pm), but also to those in the likewise chair-shaped *cyclo*-hexasulfur (S_6: 206.8 pm[9]). The two As–S distances (226 pm) are somewhat longer than those in As_2S_3 (221 pm) and As_4S_4 (224 pm).[10] Although the molecules of **2** occupy general positions in the crystal, the TiS_4As ring displays nearly C_s symmetry. To a certain extent, this ring resembles that in $[Cp_2Ti(\mu\text{-}S_2)_2C(CH_3)_2]$.[5]

Compound **2** reacts rapidly and quantitatively with SCl_2 or S_2Cl_2 in CCl_4 at 20 °C to give initially Cp_2TiCl_2 and *cyclo*-arsasulfanes CH_3AsS_m, which can be separated and identified by reversed-phase (RP) HPLC and ^1H NMR spectroscopy [Eq. (c)].

$$Cp_2TiS_4AsCH_3 + S_xCl_2 \longrightarrow CH_3AsS_{4+x} + Cp_2TiCl_2 \quad (c)$$
$$x = 1,2$$

The two new compounds CH_3AsS_5 and CH_3AsS_6,[11] along with the known CH_3AsS_7,[12] form a homologous series of heterocyclic compounds, since their ^1H NMR shifts are very similar and their HPLC retention times, expressed as $\ln k'$, are linearly dependent on the ring size $m + 1$, as for sulfur homocycles (Table 1). Therefore, it is very likely that

Table 1. Retention times t_R of CH_3AsS_m and S_n under the same chromatographic conditions ($k' = (t_R - t_0)/t_0$; t_0 = dead time = 1.20 min [13]). The correlation coefficients of the linear regression were better than 0.995.

Ring size		6	7	8	9
CH_3AsS_m:	t_R (min):	2.71	3.19	3.67	–
S_n:	t_R (min):	3.17	3.72	4.80	6.38

$\ln k'_1 = 0.246\,(m+1) - 1.236$; $\ln k'_2 = 0.326\,n - 1.492$.

the structure of CH_3AsS_6 is similar to that of S_7.[15] In contrast to the synthesis of CH_3AsS_7, which is formed from CH_3AsCl_2 and Cp_2TiS_5 in CS_2 under reflux in a reaction whose mechanism is not yet understood, the synthesis according to Equation (c) affords *cyclo*-arsasulfanes of defined ring size.

CH_3AsS_6 undergoes decomposition upon exposure to sunlight in CCl_4 solution with formation of homologous CH_3AsS_m molecules and sulfur rings S_n. Both CH_3AsS_6 and CH_3AsS_7 react slowly with S_2Cl_2 at 20 °C in CCl_4 according to Equation (d).

$$CH_3AsS_m + S_2Cl_2 \longrightarrow CH_3AsCl_2 + S_{m+2} \quad (d)$$
$$m = 6,7$$

In this way it was possible to determine the ring size of the arsasulfanes, since the resulting sulfur rings S_{m+2} could easily be identified by their HPLC retention times (Table 1 and Ref. [14]). CH_3AsCl_2 was identified by ^1H NMR spectroscopy. Since reaction (d) partly takes place during reaction (c), the reaction products always contain, besides CH_3AsS_m, some S_8, especially when S_2Cl_2 is used in excess.[11]

[3] $Cp_4Ti_2S_4$ (1.2 g, 2.48 mmol) [4], suspended in 200 mL of CCl_4, was stirred for 10 min and treated with CH_3AsCl_2 (0.214 mL, 2.40 mmol). After ca. 15 h at 20 °C, the precipitate was separated by filtration from Cp_2TiCl_2 and excess starting material, the filtrate was evaporated to dryness, and the residue (0.6 g) was dissolved in CH_2Cl_2. The solution was fractionated by column chromatography on silica gel 40 F_{254} (95 g, column length 55 cm: eluant CH_2Cl_2) (side products: Cp_2TiS_5, S_8, and others). The fractions containing **2** (monitored by HPLC) were combined, evaporated to dryness in vacuo, dissolved in a small amount of CH_2Cl_2, and chromatographically fractionated again (eluent: CCl_4/diethyl ether 70/30 v/v). The fractions with **2** were evaporated and the product was recrystallized from 10 mL of hot CCl_4. Yield: 190 g **2** (0.48 mmol), m.p. 155 °C (dec.). The CH analysis agrees with that calculated. The mass spectrum shows the signal for the molecular ion ($M^{\oplus}$) at m/z 396 and signals for the fragment ions at m/z 332 ($M^{\oplus}$-S_2), 317 ($M^{\oplus}$-S_2CH_3), 276 ($As_2(CH_3)_2S_3$), 261 ($As_2CH_3S_3$), 242 (Cp_2TiS_2), 210 (Cp_2TiS),197 (As_2CH_3S), 178 (Cp_2Ti), and 154 ($AsCH_3S_2$). Nitrogenase Model Compounds: $[\mu\text{-}N_2H_2\{Fe(\text{“}N_HS_4\text{”})\}_2]$, the Prototype for the Coordination of Diazene to Iron Sulfur Centers and Its Stabilization through Strong N-H · · · S Hydrogen Bonds**

By *Dieter Sellmann,* Wolfgang Soglowek, Falk Knoch,* and *Matthias Moll*

Biological N_2 fixation is one of the fundamental synthetic processes of nature. It is catalyzed by nitrogenases, and the elucidation of the structure and function of these enzymes constitutes a major task in chemistry and biochemistry. The dominating metal in all nitrogenases is iron in a coordination sphere of sulfur. Most nitrogenases also include molybdenum and some of them vanadium.[1] Recently, however, a nitrogenase type was characterized which contains exclusively iron.[2] This casts doubt on the presumption prevalent for many years that the heterometal centers Mo or V ought to be the N_2 bonding site in Mo/Fe or V/Fe nitrogenases;[1] it rather demonstrates that the iron centers could very well be the N_2 bonding site in all nitrogenases. Hence, iron complexes with biologically occurring donors, e.g. thiolate, thioether or amine ligands, are of major importance as model compounds for nitrogenases, especially when they possess binding sites for N_2 and its reduction products. In this context, the coordination of diazene, HN=NH, is as equally important as that of molecular nitrogen. In the course of N_2 reduction, diazene should be regarded as the product of the first $2e^\ominus$ reduction step.[3]

$$N_2 + 2e^\ominus + 2H^\oplus \rightarrow N_2H_2$$

It is, however, extremely unstable in the free state ($\Delta H_f^{298} = 212$ kJ/mol[4]). Thus, the question arises by what means it is stabilized in nature at the metal centers of nitrogenase in order to avoid insurmountably high energy barriers in the course of N_2 reduction.

An answer is provided by the diazene complex **1**, which was prepared from a hydrazine complex.[5]

$$[Fe(N_2H_4)(\text{“}N_HS_4\text{”})] + O_2 \xrightarrow[DMF]{-60\,^\circ C} \underset{\mathbf{1}}{[\mu\text{-}N_2H_2\{Fe(\text{“}N_HS_4\text{”})\}_2]} + \text{other products}$$

$$\text{“}N_HS_4\text{”} - H_2 = o\text{-}HS-C_6H_4-S-CH_2CH_2-NH-CH_2CH_2-S-C_6H_4-SH(o)$$

1 is a prototype model compound for enzymatic N_2 fixation in several respects: 1) **1** is the first example for the coordination of diazene to iron. 2) Being ligated by $\text{“}N_HS_4\text{”}^{2\ominus}$, the iron center is exclusively coordinated by biologically occurring donor atoms. 3) The diazene is stabilized not only by coordination to iron and by considerable steric shielding but also by strong tricentric (forked) N−H · · · S hydrogen bridges. Therefore, **1** meets, for the first time, all the functional (coordination and stabilization of N_2H_2) *and* structural (Fe centers and donor atoms) requirements for such model complexes.

An X-ray structure analysis[6] revealed that **1** possesses a center of inversion at the midpoint of the N=N bond (Fig. 1). The *trans* N_2H_2 ligand bridges two iron atoms, each of which are pseudo-octahedrally coordinated by the additional amine nitrogen and four sulfur donor atoms.

The N_2H_2 protons were located by a difference Fourier synthesis. N_2H_2, Fe and S(thiolate) atoms form a plane (±3 pm). The N–N distance of 130.0(7) pm and the trigonal-

[**] Transition Metal Complexes with Sulfur Ligands, Part 48. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. – Part 47: D. Sellmann and I. Barth, *Inorg. Chim. Acta 164* (1989) 171. – $\text{“}N_HS_4\text{”}$-H_2 = 2,2'-bis(2-mercaptophenylthio)diethylamine).

ly planar N atoms characterize the N_2H_2 unit as a diazene ligand. The Fe–N(diazene) distance (186.7(4) pm) is significantly shorter than the Fe–N(amine) distance (203.7(4) pm). These results and the intense color of **1** (λ_{max} = 573.6 nm) indicate a 4c-6e$^{\ominus}$-π bond in the Fe $\doteq$ N $\doteq$ N $\doteq$ Fe core.[7] The steric shielding of the N_2H_2 ligand between the [Fe("N_HS_4")] fragments becomes particularly evident from the space-filling model of **1** (Fig. 2). The N_2H_2 entity is protected by the [Fe("N_HS_4")] fragments (Fig. 2a) as though by the shells of a bivalve; however, it is not totally encapsulated, as shown by the side view (Fig. 2b). In fact, **1** reacts rapidly with bases.[8]

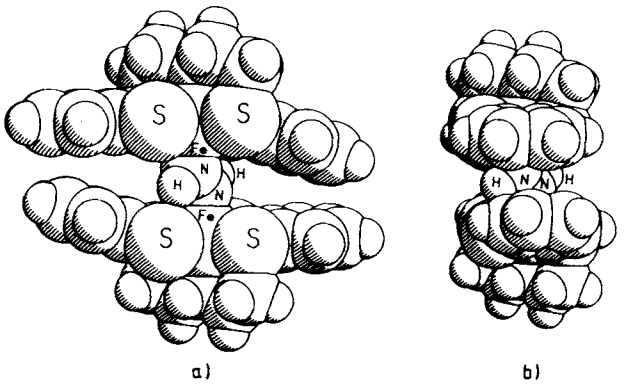

Fig. 2. Space-filling model of **1**; a) front view, b) side view.

The stabilization of the diazene ligand by N–H $\cdots$ S hydrogen bridges follows from the distances (Fig. 1). X–H $\cdots$ S bridges (X = O, N, S) are generally weak (ΔH_f^{298} (HSH $\cdots$ SH_2) = 7.7 kJ/mol).[9] In special cases, as, e.g., (amide)NH $\cdots$ S(cysteine) bridges in ferredoxines, however, they can exhibit substantially higher bonding energies up to 80 kJ/mole.[10]

As follows from the short distances (Fig. 1) the N–H $\cdots$ S bridges of **1** must have considerable strength. As far as we are aware, 220 pm is the shortest H $\cdots$ S distance ever reported; a length of 278 pm for the longer branch of the tricentric H bond is still distinctly less than the sum of the van der Waals radii of H and S (285–305 pm).[11] The important role of the H bridges follows also from the stereochemistry of **1**. The [Fe("N_HS_4")] fragment can form several isomers;[12] in **1**, only that isomer is found which allows the maximum number of N–H $\cdots$ S(thiolate) bridges. When account is taken of the ΔH_f(N—H $\cdots$ S) values calculated for ferredoxines, a total energy of at least 70 kJ/mol may be estimated for the H bridges in **1**. Thus, alone by forming H bridges $\Delta H_f(N_2H_2)$ could be reduced by ca. 30%. Consequently, in nitrogenases complexation and stabilization via 4c-π bond, steric hindrance and H bridges should favor the formation of a diazene in accord with Figure 3. The stabilization by H bridges is of major significance because such H bridges are not to be expected for a precursor N_2-complex and have never been observed in isolable N_2-complexes.

If in nitrogenase centers the same structural principles are realized as are found in **1**, these results show that the $N_2 \rightarrow N_2H_2$ conversion, the most difficult step of N_2 fixation, should be facilitated and possibly even become exoenergetic.

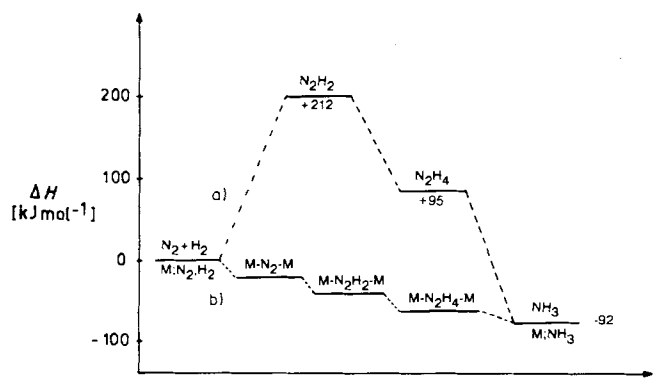

Fig. 3. Energy diagram for reactions between N_2 and H_2; a) in gas phase without metals, b) proposal for a reaction pathway via metal-stabilized intermediates.

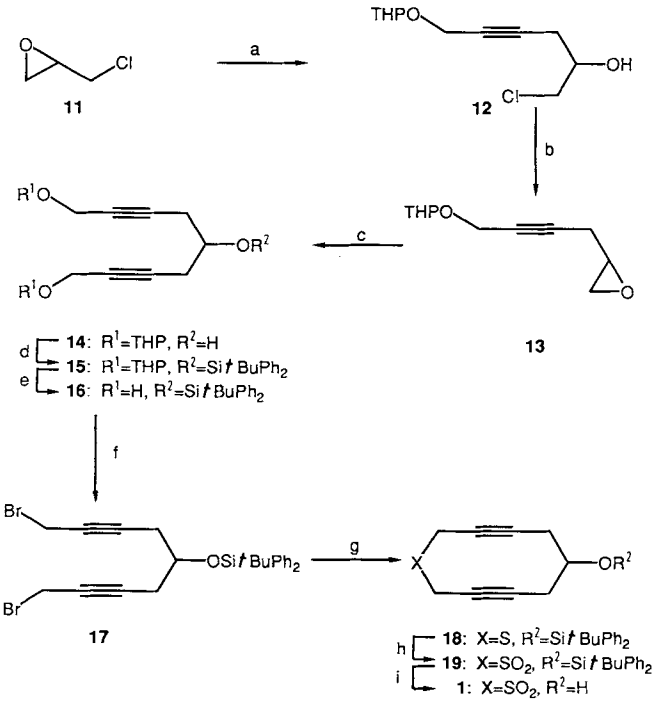
design.[2] In this communication we report the design, synthesis, and activity of a new class of DNA-cleaving compounds equipped with a propargylic or allenic sulfone moiety.[3]

Scheme 1. Hypothesis for DNA cleavage by bis(propargyl) sulfones via the Garrat–Braverman reaction sequence [4, 5]. For paths a and b, see text.



Scheme 1 depicts the mechanistic rationale that led to the design of the first active compounds in this series. Specifically, it was hypothesized that the Garratt[4]–Braverman[5] reaction sequence (Scheme 1) would proceed in aqueous solutions at pH > 7, transforming a bis(propargylic) sulfone **A** first to bis(allenic) sulfone **B** and subsequently to the diradical **C**[6] (path a), which might then initiate DNA strand scission.[7] Alternatively, nucleophilic attack (path b) by nitrogen nucleophiles from DNA on the conjugated allenic acceptor **B** could lead to structures such as **E**, which were then expected to undergo Maxam–Gilbert[8] type chemistry leading to clean DNA rupture as depicted in Scheme 1. To test this hypothesis, compounds **1**–**7** (Table 1) were designed

Table 1. Unsaturated sulfones **1**–**10** with DNA-cleaving properties.

and synthesized as potential DNA-cleaving agents. These compounds were chosen so as to allow subsequent attachment of a variety of appendages to probe the effect of molecular shape on the DNA interaction and to study reaction rates as a function of ring size.

The synthesis of the 10-membered ring bis(propargylic) sulfone **1** is shown in Scheme 2.[9] Thus, opening of epichlorohydrin **11** with the anion of propargyl tetrahydropyranyl ether in the presence of $BF_3 \cdot Et_2O$ resulted in the formation of compound **12**, which was converted into the epoxide **13** by base treatment. Reiteration of the epoxide opening as above then gave the diacetylene **14**, from which

compounds **15–17** were sequentially generated by standard methods. The reagent[10] derived from Na_2S and Al_2O_3 reacted smoothly with dibromide **17** in CH_2Cl_2/EtOH at 25 °C, producing the cyclic sulfide **18** in 55% yield. Finally, oxidation of **18** with *m*-chloroperbenzoic acid to the corresponding sulfone **19**, followed by disilylation, gave the requisite target **1**. The synthesis of the remaining compounds in Table 1 was performed by standard methods.

Compounds **1–7** (Tables 1 and 2) cleaved double-stranded DNA in alkaline solution. Thus, incubation of **1–7** (1000 μM) with supercoiled ΦX174 DNA (form I) aerobically at pH 8.5 and 37 °C produced DNA rupture, leading initially to form II and finally to form III DNA, as shown in Figure 1 (lanes 1–7). Of interest is the more extensive scission produced by the two 11-membered ring sulfones **2** and **6** and the acyclic bis(propargylic) sulfone **7** as compared to the 10-membered ring compound **1** and the higher ring sulfones **3–5** under the same conditions. As expected, the saturated analogue of sulfone **2** produced no DNA cleavage under similar conditions (Fig. 1, lane 11).

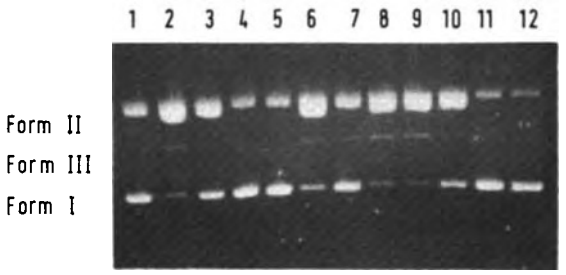

Fig. 1. ΦX174 form I DNA (50 μM per base pair) was incubated for 24 h with various compounds (1000 μM) in buffer(Tris-acetate, pH 8.5, 50 mM) and analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Lanes 1–11, compounds **1, 2, 3, 4, 5, 6, 7, 8, 9, 10**, and the saturated analogue of **2**, respectively; lane 12, DNA alone. For forms II and III, see text.

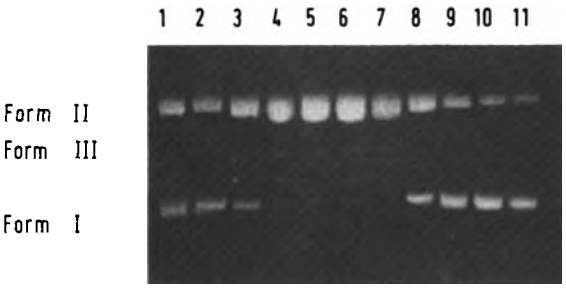
Further investigations demonstrated that a series of monopropargylic and monoallenic sulfones (e.g., **8–10**, Table 1) exhibited DNA-cleaving properties (Fig. 1, lanes 8–10) under similar conditions. DNA cleavage by the propargylic and even the allenic sulfones exhibited a striking pH dependence as shown in Figure 2 for the case of **2**. It is worth noting that the DNA-cleaving action of a 10-membered ring enediyne recently reported from these laboratories[3a] showed no such pH dependence. As Figure 2 shows, optimum cleavage occurred at around pH 8.5, whereas little cleavage was observed at pH < 7 or > 10. Although less, considerable rupture was also observed at pH 7 and pH 10 (Fig. 1).



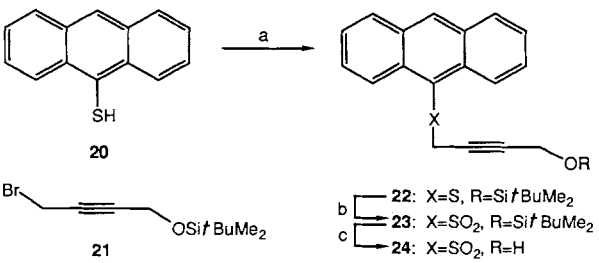


Fig. 2. ΦX174 form I DNA (50 μM per base pair) was incubated for 24 h with compound **2** (1000 μM) in various pH buffers (50 mM) and analyzed as described under Fig. 1. Lanes 1–10 correspond to pH 5.0, 6.0, 7.0, 7.4, 8.0, 8.5, 9.0, 9.5, 10.0, and 10.7, respectively; lane 11, DNA alone at pH 8.5. For forms II and III see text.

The expectation that DNA intercalators and other DNA binding moieties would enhance the potency of these compounds as DNA cleavers was born out in preliminary experiments. Thus, the anthryl sulfone **24** (Scheme 3, Table 2)[11] synthesized by standard chemistry from thiol **20**[11] and bromide **21**,[12] exhibited much higher potency as a DNA cleaving agent (at concentrations as low as 0.1 μM) than any of the compounds of Table 1. Figure 3 demonstrates the action of **24** and some of its relatives on supercoiled ΦX174 DNA. Noteworthy is the ca. 100-fold loss of activity in the sulfoxide derivative of **24** (Figure 3, lane 5) and the even further loss of activity in the corresponding sulfide (Fig. 3, lane 6).[13] Not surprisingly, the saturated analogue of **24** was devoid of any DNA-cleaving properties (Fig. 1, lane 4).

Scheme 3. Synthesis of **24**: Reagents and conditions. a) 1.1 equiv. NaH, 0.75 equiv. **21**, DMF, 0 → 25 °C, 0.5 h, 100%; b) 3.0 equiv. *m*-chloroperbenzoic acid, CH_2Cl_2, 0 → 25 °C, 4 h, 75%; c) 48% aqueous HF:CH_3CN (1:5), 0 → 25 °C, 0.25 h, 90%.

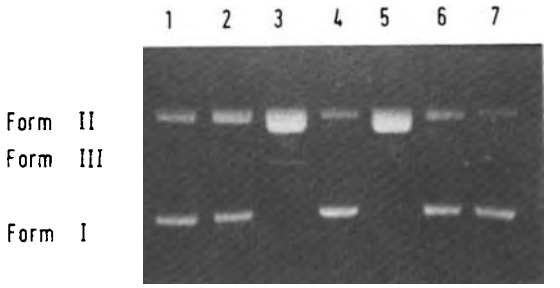

Fig. 3. ΦX174 form I DNA (50 μM per base pair) was incubated for 24 h with various compounds and at various concentrations in buffers (Tris-acetate, pH 8.5, 50 mM) and analyzed as described under Fig. 1. Lane 1, **24**, 0.1 μM; lane 2, **24**, 1 μM; lane 3, **24**, 10 μM; lane 4, saturated analogue of **24**, 1000 μM; lane 5, sulfoxide of **24**, 1000 μM; lane 6, sulfide of **24**, 1000 μM; lane 7, DNA alone. For forms II and III see text.

Studies currently in progress include gathering information on structure-activity relationships, experiments designed to elucidate the precise mode of action (e.g., nucleophilic versus radical addition, Scheme 1)[7] of these molecules and the design of sequence-specific DNA-cleaving systems and anticancer agents.

[13] This loss of potency in the series sulfone → sulfoxide → sulfide was observed in other systems such as compounds **2** and **7** (Table 1).

Dithia Dications from Cyclic and Acyclic Precursors by Gas-Phase Oxidation ("Charge Stripping") of 3e/2c-Radical Cations**

By *Thomas Drewello, Carlito B. Lebrilla, Klaus-Dieter Asmus,* and *Helmut Schwarz**

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

Two-center three-electron bonds (2c/3e) have attracted considerable interest in recent years.[1] They are formed in cationic, neutral and anionic radicals generated from heteroatom-containing compounds. The most extensively studied group of such species are the sulfur-centered radical cations. Detailed investigations have been carried out in the gas phase,[2] in liquids[3] and in solid matrixes.[4] Experimental results as well as theoretical calculations have unambiguously shown the formation of homo- and heteronuclear binding structures of the general types **1** and **2** (X,Y: fragments with sulfur, selenium, nitrogen, phosphorus, halogen, oxygen etc.).

1 $X \cdot\cdot X^{\oplus}$ $\quad$ $X \cdot\cdot Y^{\oplus}$ **2**

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Gesellschaft von Freunden der Technischen Universität Berlin. We thank *Dr. E. Anklam* for synthesizing some of the dithia compounds.

The 2c/3e bond (with a formal bond order of 0.5) is characterized by two electrons located in a σ-orbital and one electron in an antibonding σ*-orbital. The actual bond strength is essentially determined by the extent of orbital interaction between the heteroatoms (X,X or X,Y), i.e. by the overlap or in general by structural parameters and by the electronic nature of the substituents at the heteroatoms. For example, the experimentally determined S···S bond strength in $[(CH_3)_2S \cdot\cdot S(CH_3)_2]^{\oplus}$ is ca. 25 kcal/mol,[2b, 3j, 3l] in very good agreement with theoretical calculations.[1b, c, d]

An indication of the strength of the 2c/3e bond is given by the optical absorption spectrum. The maxima of the UV/VIS bonds are proportional (at least to a first approximation) to the difference between the σ and σ* energy levels and can thus be directly correlated with the extent of orbital interaction between X,Y in **1** and **2**.[1] Accordingly, any increase in bond strength shows up as a blue-shift in λ_{max}, while bond weakening in a 2c/3e system results in a corresponding red shift of the absorption band.[3e, k]

Considering that one of the electrons in a 2c/3e bond is antibonding in nature, it can be expected that the removal of this σ*-electron, e.g. via ionization, requires considerably less energy than the removal of a bonding electron from the σ-bond. Chemically, such a process constitutes an oxidation of **1** or **2** to the respective paramagnetic dications **3** and **4**.

$X^{\oplus}-X^{\oplus}$ **3** $\quad$ $X^{\oplus}-Y^{\oplus}$ **4**

This should be accompanied by a shortening of the X–X and X–Y bonds[5] which has experimentally verified very convincingly in a number of cases, particularly for nitrogen-centered systems.[4a, 6]

Dications could also be generated by the oxidation of quite a number of cyclic di- and polythia compounds in solution.[3c, d, 7] So far, however, it has not been possible to detect any dications from acyclic dithia compounds, not even as short-lived transients. This is considered to be mainly due to the fact that such 2c/3e radical cations are powerful oxidants. Therefore they generally act as electron acceptors rather than to suffer loss of an electron. But, even if formed, any such dications would probably undergo fast charge transfer reactions or solvent assisted deprotonation processes, particularly in polar solvents like water.

A much more suitable environment for the stabilization of sulfur-centered dications is expected to be the gas phase. This is indeed the case, as will be demonstrated in this paper, for a series of cyclic as well as acyclic dithia compounds. All of these substrates yield 2c/3e radical cations via intramolecular (transannular) stabilization after one-electron oxidation. The respective dications can then be generated if these 2c/3e species (**5–14** in Table 1) are subjected to a "charge stripping" experiment.[8] One of the interesting parameters such experiments reveal is the vertical ionization energy IE_v for the underlying general process $M^{\oplus} \rightarrow M^{2\oplus} + e^{\ominus}$.

The electron to be removed from the 2c/3e bond upon oxidation (i.e. from $M^{\oplus}$), on energetic grounds, is expected to be the antibonding σ*-electron. Considering that the energy of this σ*-electron depends on the σ/σ* separation a direct correlation should exist between IE_v and the extent of X,X (X,Y) orbital interaction. The experimental results on IE_v and λ_{max} as listed in Table 1 clearly substantiate this assumption.

Considering species **5–10** it is noted that an increasing sulfur-p-orbital interaction, as facilitated by increasingly favorable sterical structures, results in an increasing σ/σ* separation and a corresponding blue-shift in λ_{max}.[3e, m] As the

Table 1. Vertical ionization energies, IE_v, and λ_{max} values [a] of the dithia radical cations **5**–**14**.

Radical cations		IE_v [eV]	λ_{max} [nm]	ΔE (σ^*/σ) [eV]
	**5**	15.0 ± 0.3	650	1.91
	**6**	14.1 ± 0.4	600	2.07
	**7**	13.3 ± 0.2	525	2.36
	**8**	13.2 ± 0.2	470	2.64
	**9**	12.7 ± 0.3	450	2.76
	**10**	12.3 ± 0.3	440	2.82
	**11**	15.3 ± 0.3	[b]	–
	**12**	14.3 ± 0.4	650	1.91
	**13**	15.2 ± 0.2	≈ 650 [c]	≈ 1.9
	**14**	13.3 ± 0.2	610	2.30

[a] λ_{max} values taken from Ref. [3e, f, m]. [b] The lifetime of **11** in solution is too short for accurate measurement of λ_{max}; the latter presumably lies in the near IR. [c] A large error limit has to be allowed for λ_{max} of the radical cation **13** owing to its short lifetime and low yield.

σ^* energy rises to higher levels the measured IE_v values decrease continuously from 15.0 to 12.3 eV.

While **10** constitutes one extreme in our series, species **11** represents the other. In the latter, sulfur-p-orbitral interaction is practically prevented by the rigid and almost planar structure of the 1,3-dithiacyclopentane moiety. Accordingly, this system has a particularly low-lying σ^* level, if any, and correspondingly exhibits the highest IE_v value for the ionization of the primarily formed radical cation.

The observed correlation between the blue-shift in λ_{max} and the decrease in IE_v for species **11, 12** and **14** can also be explained in steric terms. Substitution of hydrogen by methyl at the C(2) position, particularly in the case of geminal dialkylation, changes the molecular geometry in favor of p-orbital interaction.[3m] This results in a strengthening of the 2c/3e bond, a rise of the σ^* level and a decrease in IE_v. The opposing, i.e. bond-weakening effect caused by electron induction from the methyl substituent cannot compete with this structural factor for C(2) substitution. It becomes apparent, however, in the case of methylation at C(4) (species **13**), which exerts no further structural changes on the 1,3-dithiacyclopentadiene moiety. Electron donation is now the only factor to affect the σ/σ^* splitting in **13** as compared to **12**. The resulting decrease in the strength of the 2c/3e bond is reflected in a comparatively higher IE_v.

It is interesting to note that this latter effect does not show up in the optical measurements, which are rather insensitive for the weak 2c/3e bonds absorbing at $\lambda_{max} \approx 600$ nm. (Here is a large error limit of ca. ± 30 nm due to broadness of the absorption band, low yields and low kinetic stability.) The expected differences between **12** and **13** are clearly reflected, however, in the respective IE_v values.

The remarkable correlation between the optical data and IE_v values obtained for the three-electron bonded radical cations renders "charge stripping" an excellent complementary method to pulse radiolysis, particularly for the investigation of weak 2c/3e bonds.

[8] All experiments were performed on a ZAB-HF-3F triple-sector mass spectrometer under the following conditions: the radical cations $m^{\oplus}$ were generated by 70 eV electron impact ionization of the corresponding neutral molecules and mass selected by means of B(1). Charge stripping was brought about by collision of an 8 keV beam of $m^{\oplus}$ with oxygen (pressure ca. 10^{-4} torr) in a collision chamber located between the magnetic (B) and electric sector E. Dications $M^{2\oplus}$ formed in the collision experiment are detected by scanning the electric sector voltage at ca. $E/2$, where E corresponds to the voltage necessary to transmit the primary ion beam $m^{\oplus}$. The ionization energy necessary for the oxidation of $m^{\oplus}$ is provided by the kinetic energy of $m^{\oplus}$ with the consequence that the "charge stripping" signal of the reaction $m^{\oplus} + O_2 \rightarrow m^{2\oplus} + O_2 + e^{\ominus}$ is not recorded at exactly $E/2$ but is shifted to a smaller value ($E/2 - \delta$). The energy deficit (Q_{min}) of the reaction, after calibration of the energy scale determined from the "onset" of the signals, in a first approximation corresponds to the vertical ionization energy IE_v of $m^{\oplus}$ (Ref. [9]). Oxidation of toluene radical cations was employed for the calibration of the energy scale (F. M. Dorman, J. D. Morrison, *J. Chem. Phys. 35* (1961) 575).—For further details, see: T. Drewello, *Dissertation D83*, Technische Universität Berlin 1989.

Multiple "Remote Functionalization" of Different Sites in Flexible Molecules by "Anchored" Bare Fe^{I} Ions**

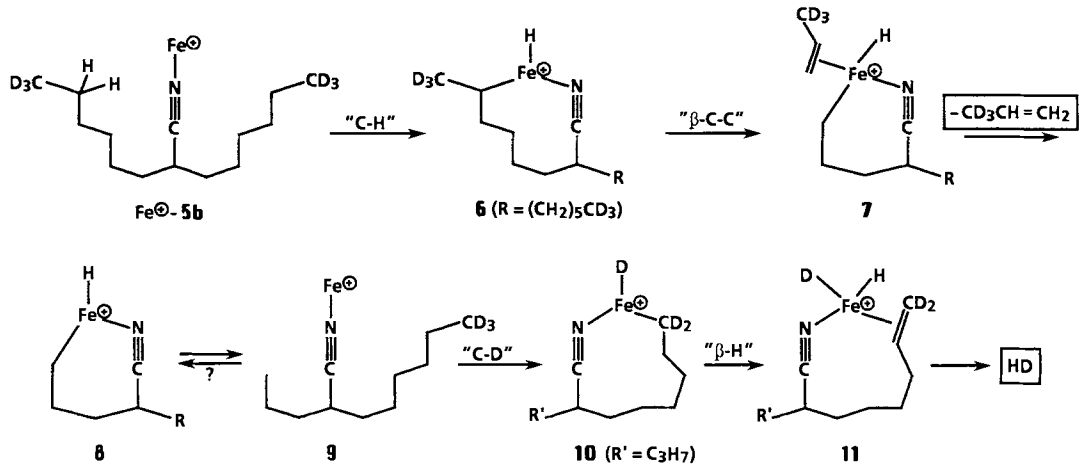
By *Gregor Czekay, Karsten Eller, Detlef Schröder,* and *Helmut Schwarz**

Dedicated to Dr. Günther Ohloff on the occasion of his 65th birthday

The direct functionalization of *remote* C–H or C–C bonds, i.e. several carbon atoms away from an activating group, represents a great challenge. While such processes are common to enzymes, which "anchor" a functional group and *geometrically* select a specific segment of the substrate, only a few cases are reported[1] for relatively rigid molecules where a similar principle seems to be operative. *Breslow*[1a,b] has coined the term "remote functionalization" for this method of coordination of a functional group followed by selective reactions at sites away from the complexed functionality.

We[2] and later others[3] have demonstrated that a similar principle holds true in the gas phase for quite a variety of *flexible* organic substrates including aliphatic nitriles,[2,3] isonitriles,[4] amines,[5] alcohols,[6] ketones,[7] alkynes[8] and allenes,[9] respectively. For example, the chemistry of the $Fe^{\oplus}$-complexes of unbranched nitriles e.g. **1** (Scheme 1) is unique, in that *selective C-H activation occurs only at positions remote from the CN group*. The results of detailed studies[2] are compatible with a mechanism in which the reaction commences with the formation of an "end-on" complex **1**. For nitriles containing four to seven carbon atoms, the "anchored" transition-metal ion, $Fe^{\oplus}$, activates exclusively the C–H bond of the terminal methyl group (R = H) by oxidative addition (**1** → **2**). The insertion is followed by competitive β-hydrogen transfer (**2** → **3**) or β-cleavage of the C–C bond (**2** → **4**) to generate intermediates from which eventually neutral ethylene and molecular hydrogen are eliminated. If the carbon chain is lengthened, activation of internal C–H bonds is also observed. While the previous studies[2–9] permitted a detailed insight into many mechanistic details, no examples are known for the operation of *multiple* "remote functionalizations" of different sites in flexible molecules. Here, for the first time, evidence will be presented for the existence of such a reaction, which is also without precedence in condensed phase chemistry.

Scheme 1.



The metastable ion (MI) mass spectrum of mass-selected $(CH_3(CH_2)_5)_2CHCN/Fe^{\oplus}$ (**5a**-$Fe^{\oplus}$)[10] contains in addition to signals corresponding to the loss of neutral H_2 (46%), C_2H_4 (30%), C_3H_6 (15%) and C_4H_8 (3%), two signals which can be ascribed to the production of C_2H_6 and C_3H_8 (3% each). While the genesis of molecular hydrogen and of the alkenes[11] can be accounted for in terms of the traditional concept,[2] there exist two pertinent questions related to the formation of C_2H_6 and C_3H_8: (i) Do the neutral compounds correspond to genuinely formed alkanes C_nH_{2n+2} or are the observed mass differences due to the combined production of $C_nH_{2n}H_2/H_2$? (ii) If the latter is true, are both species formed from the same alkyl chain, or do the neutral fragments originate from both alkyl chains, and what sequence prevails?

The experimental findings are unambiguously in favor of the second alternative. This is evidenced by a study of the $Fe^{\oplus}$-complex of $(CD_3(CH_2)_5)_2CHCN$ (**5b**). If ethane and propane would be generated from **5b** according to the established pathway,[2,12] complex **5b**-$Fe^{\oplus}$ should undergo losses of CD_3CH_3 (Δm = 33) and $CD_3CH_2CH_3$ (Δm = 47). These two mass differences are *not* observed; rather, one finds Δm = 33 and 48. Moreover, if one selects, in a tandem experiment,[13] the $[M-28]^{\oplus}$ and $[M-42]^{\oplus}$ species unimolecularly generated from **5a**-$Fe^{\oplus}$ and studies their MI mass spectra, the *only* product formed corresponds to the production of H_2. While the latter experiment leaves no doubt that actually no alkanes but rather alkenes and molecular hydrogen are formed,[14] the labeling experiment proves for the C_3 neutral (and, by analogy, the same is presumed for the C_2-neutral) that *both* alkyl chains are involved in the $Fe^{\oplus}$-mediated C—H and C–C bond activation processes. For the formation of $C_3H_4D_4$, i.e. sequential losses of $CD_3CH=CH_2$ and HD, a mechanism is depicted in Scheme 2.

While for the nitrile complex **5a**-$Fe^{\oplus}$ the double remote functionalization constitutes a relatively minor decomposition path, the situation is very different for the $Fe^{\oplus}$-complex of 5-nonanone (**12a**-$Fe^{\oplus}$). The MI mass spectrum of this complex consists of three signals which are due to the losses of H_2 (31%), C_2H_4 (17%) *and* C_2H_6 (52%). The study[15] of the isotopomers **12a–h** leaves no doubt that molecular hydrogen and ethylene are formed in a process analogous to Scheme 1 ("remote functionalization"). However, the "alkane" generated from **12a**-$Fe^{\oplus}$ does *not* correspond to authentic ethane; rather it is due to the combined eliminations of ethylene and molecular hydrogen which are formed from the two alkyl chains in an unambiguous manner involving the $\omega/(\omega-1)$ and $\omega'/(\omega'-1)$ positions. This is evidenced by the data given in Table 1.[16] In addition, tandem experiments with the $[M-C_2H_4]^{\oplus}$- and $[M-H_2]^{\oplus}$-species prove

Scheme 2.

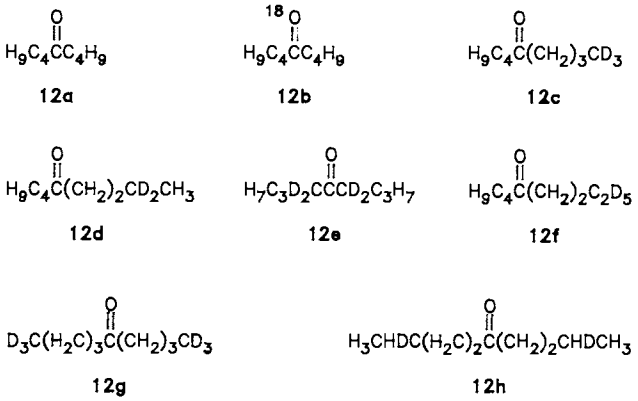

Table 1. Unimolecular elimination of molecular hydrogen, ethylene and "ethane" [a] from the $Fe^{\oplus}$-complexes of 5-nonanone isotopomers **12a–h**.

Δm [b]	12a	12b	12c	12d	12e	12f	12g	12h
2	31	25	26	18	23	15	–	15
3	–	–	12	6	–	–	18	6
4	–	–	–	–	–	3	–	–
28	17	20	10	16	17	20	–	–
29	–	–	–	–	–	–	–	23
30	52	55	7	8	60	–	27	–
31	–	–	23	27	–	–	–	40
32	–	–	22	25	–	34	–	16
33	–	–	–	–	–	–	55	–
34	–	–	–	–	–	28	–	–

[a] See text; "ethane" actually corresponds to the consecutive losses of ethylene and molecular hydrogen. [b] Δm corresponds to the mass differences with regard to the $Fe^{\oplus}$-complexes of **12a–h**; data are given in %, Σ fragment ions = 100%.

once more that the reaction follows the sequence **12a**-$Fe^{\oplus}$ → C_2H_4 → H_2 and not the reverse one.

To the best of our knowledge, the present results demonstrate for the first time beyond any doubt that an "anchored" transition-metal ion is capable of consecutively activating different sites of flexible molecules.

[10] The experimental set-up has been described in detail in earlier papers [2, 4–9]. Briefly, $Fe^{\oplus}$ is generated from $Fe(CO)_5$ by electron impact ionization (100 eV) and reacted with the organic substrate of interest in a chemical ionization source of a VG Instruments ZAB-HF-3F triple sector mass spectrometer. (For a description of the machine, see: a) T. Weiske, Dissertation D83, Technische Universität Berlin (1985); b) J. K. Terlouw, T. Weiske, H. Schwarz, J. L. Holmes, *Org. Mass. Spectrom. 21* (1986) 665). The organometallic complexes corresponding to RCN/$Fe^{\oplus}$ and ketone-$Fe^{\oplus}$, respectively, and having 8 keV kinetic energy, are mass-selected and focused with B(1)E (B stands for magnetic and E for electrostatic sector). Unimolecular reactions occurring in the field-free region between E and B(2) were recorded by scanning B(2). MS/MS/MS experiments, performed in order to prove the multi-step decomposition of **5a**-$Fe^{\oplus}$ and **12a**-$Fe^{\oplus}$, were conducted by mass-selecting **5a**-$Fe^{\oplus}$ and **12a**-$Fe^{\oplus}$ by means of B(1); the products due to metastable losses of H_2 or alkenes were "isolated" by using E; fragment ions originating from further dissociations of $[M-H_2]^{\oplus}$ or $[M-C_nH_{2n}]^{\oplus}$ were recorded by scanning B(2). The signal-to-noise ratio was improved by using signal averaging techniques employing the VG 11/250 data system.

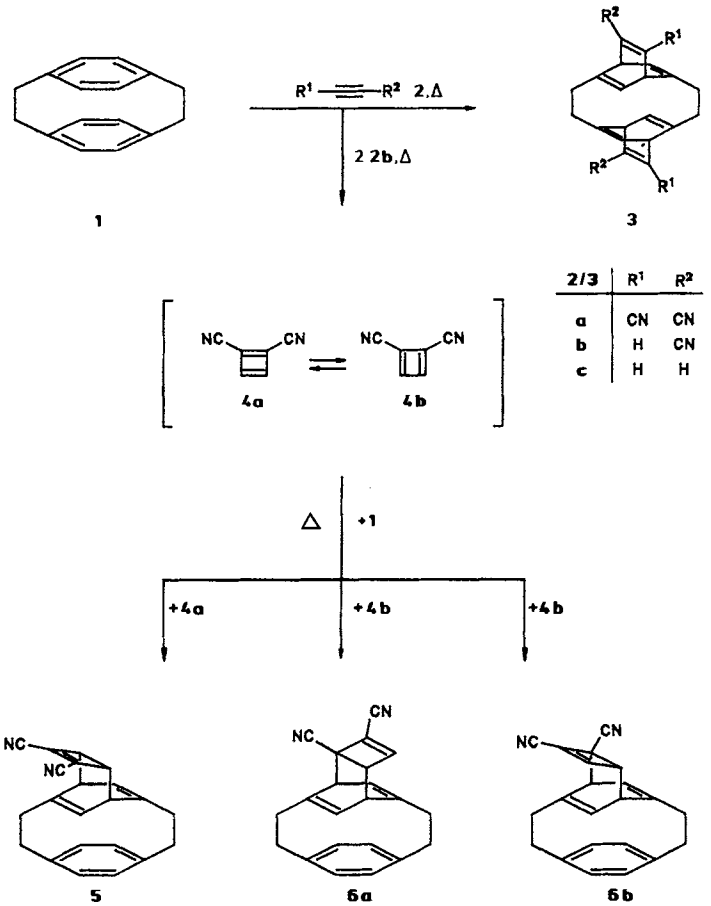
[11] A detailed discussion of the mechanisms by which these species are formed, is given in: G. Czekay, T. Drewello, K. Eller, W. Zummack, H. Schwarz, *Organometallics*, in press.

[12] For the transition metal ion mediated alkane formation in most cases reported it is, strictly speaking, not possible to distinguish between the two reaction sequences, i.e. 1) insertion of the metal ion in a C–C bond followed by β-hydrogen transfer, or 2) oxidative addition of a C–H bond followed by β-alkyl migration to the metal center. Both variants generate the same intermediate from which eventually reductive elimination of RH occurs.

[13] a) F. W. McLafferty (Ed.): *Tandem Mass Spectrometry*, Wiley Interscience, New York (1983); b) K. L. Busch, G. L. Glish, S. A. McLuckey: *Mass Spectrometry/Mass Spectrometry: Techniques and Applications of Tandem Mass Spectrometry*, VCH, Weinheim (1988).

[14] The reverse sequence, i.e. loss of H_2 followed by elimination of $RCH=CH_2$ (R = H, CH_3), does *not* contribute to the formation of "alkanes". This is evidenced by studying the mass-selected $[M-2]^{\oplus}$ species formed from **5a**-$Fe^{\oplus}$; no signals due to loss of $RCH=CH_2$ are present in this spectrum.

[15] D. Schröder, *Diploma Thesis*, Technische Universität Berlin (1989).



[16] A full discussion of these and other data, together with a detailed analysis of the kinetic isotope effects associated with the generation of molecular hydrogen, ethylene and "ethane", is given in [7, 15].

Does Cyanoacetylene Dimerize Thermally to 1,3-Cyclobutadiene-1,2-dicarbonitrile?**

By *Bernhard Witulski, Ludger Ernst, Peter G. Jones,* and *Henning Hopf**

Dedicated to Professor Virgil Boekelheide on the occasion of his 70th birthday

Strained aromatic compounds such as [2.2]paracyclophane **1** and its multiply bridged homologues undergo [2 + 4] cycloadditions under much milder reaction conditions than benzene and its methyl derivatives.[1] In 1967 *Ciganek*[2] found that **1** reacted with dicyanoacetylene **2a** in benzene at 130 °C to give a 1:2 cycloadduct, to which he assigned structure **3a**.[3] Since **3a** is a tetracarbonitrile derivative of a still unknown $C_{20}H_{20}$ hydrocarbon (**3c**, "double barrelene"), which might exhibit interesting rearrangement reactions (access to other $C_{20}H_{20}$ isomers such as dodecahedrane[4] or pagodane[5]?), we have reexamined the reaction of **1** with cyanoacetylenes. To minimize the number of further required steps (**3b** → **3c**), however, we used the mononitrile **2b** instead of **2a** (Scheme 1).

Scheme 1.

To our surprise, instead of compounds **3b** (isomeric mixture) analogous to *Ciganek*'s adduct, we obtained 2:1 adducts of a completely different type. [2.2]Paracyclophane **1** reacts with an excess of **2b** at 160 °C in benzene (sealed ampoule) within 22 h to give a complex mixture of products. Column chromatography (silica gel/dichloromethane) and recrystallization (chloroform/pentane) afforded a 47% recovery of starting material together with two main fractions in 6% and 21% yield, respectively. According to the ^{1}H NMR spectrum, the second fraction consists of two isomers in a ratio of 2.5:1. Further recrystallization (chloroform/pentane) allowed two of the three adducts to be obtained in analytically pure form. According to X-ray structure analysis and spectroscopic data, these adducts are compounds **5** (6%) and **6a** (15%). Because of limited space, only a summary of the crystallographic data (Fig. 1), together with the ^{1}H and ^{13}C NMR spectroscopic data (Table 1), is presented[6] for only one of the two compounds.

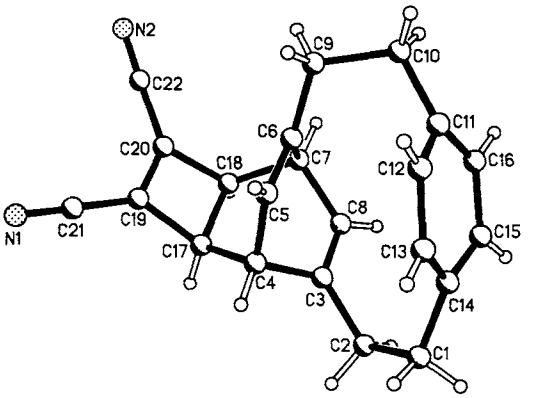


Fig. 1. Molecular structure of **5** (arbitrary atomic radii). Crystal data for **5**: $C_{22}H_{18}N_2$, $M_r = 310.4$, monoclinic, space group $P2_1$, $a = 779.2(3)$, $b = 760.3(3)$, $c = 1402.2(6)$ pm, $\beta = 96.13(3)°$, $V = 0.8259$ nm^3, $Z = 2$, $\varrho_{calcd} = 1.25$ Mg m^{-3}, $\lambda = 71.069$ pm ($Mo_{K\alpha}$), $\mu = 0.07$ mm^{-1}, $F(000) = 328$. Colorless plates, $0.8 \times 0.7 \times 0.15$ mm. Nicolet R3 diffractometer, $2\theta_{max} = 55°$, 3946 reflections, 3800 unique ($R_{int} = 0.009$), $3518 > 4\sigma(F)$. Orientation matrix refined on the basis of 50 reflections in the range $2\theta = 20$–$23°$. Structure solution by direct methods. Refinement to $R = 0.036$ for 216 parameters (hydrogen atoms positioned geometrically and refined using a riding model). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53941, the names of the authors, and the journal citation. The crystals of **6a** were of relatively poor quality (thin, weakly scattering plates with broad, irregular reflection profiles). Nonetheless, an X-ray structure analysis, which confirmed the connectivity of the molecule, could be carried out. In view of the low accuracy, only the crystal data are given: further details are available as described above. Crystal data for **6a**: orthorhombic, space group *Pbca*, $a = 1432.4(3)$, $b = 1235.4(5)$, $c = 1857.4(6)$ pm, $V = 3.287$ nm^3, $Z = 8$, $\varrho_{calcd} = 1.25$ Mg m^{-3}, $\mu(Mo_{K\alpha}) = 0.07$ mm^{-1}, $F(000) = 1312$. $R = 0.105$ for 1466 reflections.

The formation of cycloadducts **5** and **6** can be explained most simply by answering the title question in the affirmative. Thus, head-to-head coupling of two molecules of **2b** would form 1,3-cyclobutadiene-1,2-dicarbonitrile, which should exist as an equilibrium mixture of the valence tautomers **4a** and **4b**. In a subsequent step, these products would be trapped by **1** to give the [2 + 4] adducts (Scheme 1), which are derivatives of the Nenitzescu hydrocarbon. Whereas **6a, b** could also be formed by a Diels–Alder addition of **2b** to **1** followed by a [2 + 2] cycloaddition, there is no analogous route for the formation of **5**. Whatever reaction mechanism ultimately proves operative, it is clear that

[a] At 400.1 and 100.6 MHz, respectively, in $CDCl_3$/TMS. Atom numbering as in Fig. 1. The first δ(H) value for CH_2 groups refers to the proton *cis* to H-4 on the ring C1–C6, C9–C14–C1. [b] H,H coupling constants J(H-12,13) = J(H-15,16) = 7.8, J(H-12,16) = 1.9, J(H-13,15) = 1.8, J(H-4,5) = J(H-7,8) = 6.3, J(H-5,9c) = J(H-2t,8) = 1.5 Hz (c,t rel. to H-4); the remaining J(H,H) could not be assigned or are involved in higher order spin systems. The ^{13}C and ^{1}H NMR spectra of **5** and **6a** [8] were assigned using $^{1}H\{^{1}H\}$ NOE difference spectra, decoupling experiments, and two-dimensional techniques (H,H and C,H COSY and C,H COLOC) [9]. A notable feature of the ^{13}C data is that the shifts of the aromatic carbon atoms C-12 and C-15, which are found below the sp^2-hybridized atoms C5 and C-8, respectively, are similar to those in **1** (δ = 133.1), whereas C-13 and C-16, under the sp^3-hybridized bridgeheads C-4 and C-7, respectively, are shielded by about 4 ppm relative to C-12 and C-15. A correlation of the inter-ring C–C distances in **1** (309 pm) [10], **5** [1/2 ($r_{5,12}$ + $r_{8,15}$) = 303 pm, 1/2 ($r_{4,13}$ + $r_{7,16}$) = 361 pm] and in [3.3]paracyclophane **7** (330 pm) [11] with the chemical shifts of the corresponding arene carbon atoms in **1** (δ_C = 133.1), in **5** [1/2 (δ_{C-12} + δ_{C-15}) = 132.4, 1/2 (δ_{C-13} + δ_{C-16}) = 128.5], and in **7** (δ_C = 129.7) indicates that this phenomenon is probably due more to the larger nonbonding distances $r_{4,13}$ and $r_{7,16}$ in **5** than to the changed hybridization of C-4 and C-7. In the ^{13}C spectrum of **6a**, the same effect is observed as in the spectrum of **5**.

cyanoacetylene **2b** behaves as an equivalent of the cyclobutadienes **4** under these reaction conditions.[7]

[3] In the structure shown, **3a**, the two dicycanoethene bridges are parallel to each other. Besides this adduct, an isomer with mutually orthogonal (crossed) bridges is also conceivable. The preferred mode of addition was not originally determined [2], though the second alternative seems more probable, since *N*-phenylmaleimide reacts to give a crossed 2:1 product, as shown by X-ray structure analysis: K. Matsumoto, T. Okamoto, A. Sera, K. Itoh, K. Hameda, *Chem. Lett. 1987*, 805.
[4] Summary: L. Paquette in T. Lindberg (Ed.): *Strategies and Tactics in Organic Synthesis, Vol. 1*, Academic Press, Orlando 1984, p. 175ff.
[5] R. Pinkos, J.-P. Melder, H. Fritz, H. Prinzbach, *Angew. Chem. 101* (1989) 319; *Angew. Chem. Int. Ed. Engl. 28* (1989) 310, and previous publications as well as references cited therein.
[6] **5**, m.p. 163–64 °C; **6a**, m.p. 212 °C. The other spectroscopic data and elemental analyses are also in agreement with the structures suggested above for **5** and **6a**. Repetition of the experiment at lower temperatures (130 °C) afforded traces of adduct **5** and a mixture of **6a/b** in 4% yield together with 90% recovery of **1**. There is no indication that a 1:1 adduct is formed between **1** and **2b**.
[7] As by-products in the cycloadditions described here, varying amounts of 1,2,4- and 1,2,3-tricycanobenzene were also formed. These products can likewise be explained in terms of intermediates of type **4**. In the 1960's *Viehe* et al. observed that *tert*-butylfluoroacetylene underwent oligomerization in solution in an exothermic reaction to give trimers and tetramers: H. G. Viehe, R. Merenyi, J. F. M. Oth, J. R. Senders, P. Valange, *Angew. Chem. 76* (1964) 922; *Angew. Chem. Int. Ed. Engl. 3* (1964) 755. The trimers are Dewar benzene and benzvalene derivatives, which may have been formed via the corresponding cyclobutadienes. Although trapping experiments were carried out (cf. H. G. Viehe, *ibid. 77* (1965) 768 and *4* (1965) 746) they were unsuccessful (personal communication from Prof. *Viehe* on June 27, 1989). Cyanoacetylene **2b** belongs to the class of highly unsaturated compounds that have recently been detected in interstellar space: G. Winnewisser, *Top. Curr. Chem. 99* (1981) 39; molecules such as **4a/b** may also be stable under these extreme conditions.
[8] **6a**: ^{13}C NMR (100.6 MHz, $CDCl_3$, standard TMS)/^{1}H NMR (400.1 MHz, $CDCl_3$, standard TMS): δ_C/δ_H = 155.4/6.68, 51.7/2.84 (CH in four-membered ring); 111.1, 46.8 (C in four-membered ring); 118.8, 118.7 (CN); 132.5/6.91, 132.4/6.92, 128.5/6.89, 128.2/6.84 (CH_{ar}); 139.4, 139.0 (C_{ar}); 133.2/5.61, 127.5/5.15, 47.2/3.03, 44.8/2.81 (CH in cyclohexadiene ring); 139.9, 138.5 (C in cyclohexadiene ring); 34.4/2.67,2.33 and 34.1/2.46,1.99 (CH_2 bonded to C=C); 33.0/2.91,2.76 and 33.0/2.85,2.72 (CH_2 bonded to aryl). Isomer **6b** has not yet been obtained free of **6a**. The structural assignment given in the scheme is based above all on the similarity of the nuclear magnetic resonance spectra of the two adducts **6**. The distinct ^{1}H NMR signals of **6b** in the **6a/b** mixture show the same splitting pattern and similar shifts as the corresponding absorptions of **6a**. **6b**: ^{1}H NMR (400.1 MHz, $CDCl_3$, standard TMS): δ = 6.66 (=C*H* in the four-membered ring), 5.56, 5.06, 3.04 (three of the four C*H* units in the cyclohexadiene ring), 2.25, 2.16 (part of the CH_2 bonded to C=C).

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Chromatographic Enantioseparation—Methods and Applications. (Ellis Horwood Series in Analytical Chemistry). By *S. G. Allenmark*. Halsted Press, New York/Wiley, Chichester 1988. 224 pp., hard cover, £ 38.50.—ISBN 0-85312-988-6/0-470-21080-X.

Research on chiral chromatographic separations is at a peak at the present time, about 25 years after the feasibility of direct resolution of chiral phases by modern techniques was first demonstrated. The variety of systems now known to display stereoselectivity is considerable, and new developments are constantly emerging. However, the understanding of the mechanisms involved in chiral recognition lags behind practical achievements. Also, comparative studies of different procedures recommended for the solution of a certain problem are scarce.

Under these circumstances, it is not easy to summarize satisfactorily and comprehensively the state of the art. The author is to be commended on having attempted to do so, although, in the opinion of the reviewer, he has only succeeded in part.

The best chapters are those dealing with "Chiral Liquid Chromatography" and with "Analytical Applications in Academic Research and Industry"; they represent about half of the book. This is not surprising, as the direct experience of the author seems to have been mainly in these areas. Even so, some interesting recent contributions to chiral LC have not been included, and in the applications chapter there is no mention of geochemical, cosmochemical and archaeometric analyses, or the study of the configuration of bacterial cell wall constituents, and of racemization of proteins in living (including human) beings.

The summary treatment of chiral GC does not do justice to the importance of this mode of chromatography, nor does the section on resolution via diastereomers. Such interesting procedures as the precolumn derivatization of amino acids by *o*-phthaldialdehyde plus *N*-acetyl-L-cysteine (D. W. Aswad, *Anal. Biochem.*, 1984) and the resolution of olefins through Pt complexes coordinated to chiral ligands (M. Goldman et al., *J. Am. Chem. Soc.*, 1981) are disregarded.

Chiral TLC is not referred to, to say nothing of techniques related to chromatography, such as droplet counter-current chromatography and capillary electrophoresis, which have lately been shown to produce effective enantioseparations.

Some topics, such as the use of cyclodextrins as selectors, would already have to be largely rewritten one year after the appearance of the book. This is also true, to some extent, of the brief chapter on "Preparative Scale Enantioseparations".

The author has not discussed available spectroscopic evidence for some proposed chiral recognition models, nor the results of any relevant calculations of favored conformations of selectors likely to be involved in the recognition process. Such material might perhaps be outside the scope of a book which is essentially practically orientated. However, certain of the examples of models of chiral recognition that are shown would have been more instructive if accompanied by some additional critical comments. For instance, in Fig. 7.15 the nature, and indeed the necessity, of involving a $-CH\cdots O=C-$ hydrogen bond in the intermediate stereoselective complex should have been discussed; and for the model in Fig. 7.16, possible alternatives to the proposed C_5-C_5 hydrogen bonded association should have been given (C_7-C_5 association or intercalation between two selector molecules).

Though the text is, in general, lucid, there are instances in which the original papers have not been accurately quoted or are better formulated. All statements are, however, referenced and can be readily checked. The legends and annotations of the figures taken from the literature have not always been adapted to the new text, and the data listed in the tables are not always complete.

In spite of the above shortcomings, the monograph should be useful to many readers, particularly as it is at present the only book covering a relatively wide range of the subject. It will provide a good idea of the potential of the approach for researchers in academia, and analysts in industry dealing with optically active compounds. The copious bibliography (more than 600 references) will be of great value to the reader.

There are almost no printing errors in the text; the structure given in Fig. 3.3 is drawn incorrectly.

Theory and Methods of Calculation of Molecular Spectra. By *L. A. Gribov* and *W. J. Orville-Thomas*. Wiley, Chichester 1988. xxvii, 636 pp., hard cover, £ 85.00.—ISBN 0-471-91882-2

It is appropriate and welcome that the authors have written a comprehensive book on the theory of molecular spectra and methods of calculation at the present time. The attractive presentation of this book, the generality of its title, and its size (more than 600 pages) thus raise high expectations on the part of potential readers. However, there is a little disappointment on discovering that the book concentrates mainly on the traditional forms of spectroscopy (IR, Raman, and vibrational excitations caused during electronic transitions).

The book treats molecular vibrations with great thoroughness, and addresses some interesting aspects and problems. Thus, for example, the kinetic energy of vibrational motions—including internal rotations—is treated in detail and illustrated by numerous applications. The expression for the

kinetic energy, in the form appropriate for large amplitude vibrations, is simplified in stages by introducing the relevant approximations according to different problem situations. An appropriate amount of space in the book is devoted to normal coordinate analysis and the treatment of anharmonicities, including suggestions for numerical methods suitable for computer calculations, together with examples. The theory of band intensities in infrared and Raman spectra is treated in two separate chapters.

A topic which I found especially interesting was the "inverse spectral problem", which is referred to frequently in the book. This is the problem of using experimental spectra to derive information about the molecule and its physical parameters. The authors describe models which allow simulation of an experimental spectrum, with successive modifications of the model to improve the matching.

Several chapters are concerned with the theory of electronic states and methods for calculations thereon. These chapters have little relevance to the central theme of molecular vibrations, and do not seem to fit well into the book. They are too long to provide just a brief survey of this area, while at the same time being insufficiently detailed and consistent to give the reader a proper understanding. Many books dealing with this topic are already available.

Although the treatment of some of the topics is very thorough, the work is not suitable for use as a student textbook. Considerable parts of it can only be fully understood with the help of supplementary reading, and many of the papers cited are only available in Russian. It is noticeable that recent publications from authors in the Western world are rarely cited, and it is disconcerting to find that about 25% of the references are to the authors' own papers. Three particularly striking examples of this appear in Chapters 9, 12 and 15. Chapter 9, "The Potential Function of a Polyatomic Molecule and its Properties", contains references to work by authors from the West only up to 1971, despite the considerable more recent progress in this field (which is even covered in textbooks). Chapter 12, "Characteristic Vibrations of Polyatomic Molecules", begins with a reference to the authors' own work and contains only two citations. Chapter 15, on the important and much discussed topic of Raman intensities, contains only three references, two to the authors' own work and one to a 1954 paper by *W. Heitler*.

Although this book deals with many interesting and important problems, and is of the right length to provide an accurate but nevertheless easily readable account of the subject, I find that I have to express my disappointment with the result. The discussions and derivations are often lengthy but, despite this, not easy to understand. The literature coverage is infuriating, the nomenclature is rather unfortunate in some places (e.g. the well-known Wilson G- and F-matrices have been renamed), and certain modern concepts such as local modes and vibrations in short-lived electronic states are not discussed. The authors in their preface say that criticisms are welcomed. I hope that the comments offered here will be taken as constructive.

Catalytic Antibodies

By Peter G. Schultz*

The vast binding repertoire of the immune system has been exploited for the generation of tailor-made biological catalysts. A number of strategies have been developed to generate catalytic antibodies that carry out a wide range of reactions with exquisite specificities. The generation and characterization of these novel catalysts is not only providing new insights into the nature of biological recognition and catalysis, but may also lead to novel catalysts for applications in chemistry, biology, and medicine.

1. Introduction

The synthesis of catalysts with tailored specificities and catalytic properties is a challenging problem to both chemists and biologists alike. A key element in the design of enzymelike catalysts is the rational generation of receptors capable of discriminating ligands with high selectivity. To date, most efforts in this regard have focused on either the synthesis and functionalization of relatively small cavity-containing hosts or the alteration of the natural specificity of enzymes by chemical modification or oligonucleotide-directed mutagenesis.

With the advent of hybridoma technology[1] it has become possible to generate homogeneous, high-affinity antibody binding sites that selectively recognize a large number of structurally diverse ligands. Antibodies have been generated against large biopolymers such as nucleic acids, peptides, and polysaccharides, natural products such as steroids and prostaglandins, and small synthetic molecules such as phenylphosphonates and benzylamines. The immune system's ability to selectively generate antibodies against virtually any molecule of interest has resulted in the widespread use of antibodies (1) as therapeutic and imaging agents, (2) as diagnostic agents, and (3) as probes for isolating and unraveling the structures of complex biological molecules.[1b, 2]

Because antibodies can be generated against virtually any molecule of interest, the development of general strategies for introducing catalytic activity into antibody combining sites should lead to a new class of enzymelike catalysts *with tailored specificities*. Catalytic antibodies could have considerable value as biochemical or molecular-biological tools, as therapeutic agents, or in the synthesis of pharmaceuticals and novel materials. To date, two general approaches have been pursued for the generation of catalytic antibodies. The steric and electronic complementarity of an antibody to its corresponding hapten (the ligand against which the antibody is elicited) has been exploited to generate combining sites that (1) are complementary to the rate-determining transition state, (2) act to overcome the entropy requirements involved in orienting reaction partners, (3) contain an appropriately positioned catalytic amino-acid side chain, or (4) contain cofactor binding sites. Alternatively, catalytic groups can be introduced directly into the combining site of an antibody by chemical modification or by site-directed mutagenesis or genetic selection. The ability to generate antibody combining sites with specific catalytic groups and/or

[*] Prof. P. G. Schultz

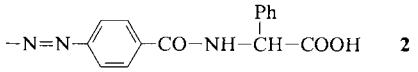
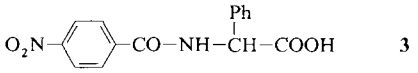
microenvironments should, in addition to affording selective catalysts, also help dissect the contribution of various factors involved in enzymatic catalysis, including transition-state stabilization, general acid–base catalysis, nucleophilic catalysis, ground-state strain, and proximity effects.



2. Antibody Generation, Structure, and Function

2.1. Antibody–Ligand Interaction



Much of our current knowledge of the nature of antibody–ligand interactions is based on measurements of the binding affinities of heterogeneous polyclonal antibodies to a series of haptens (substances which are not immunogenic until coupled to a carrier molecule) of defined structure.[3] The high specificity of antihapten antibodies can be illustrated by the following experimental examples. Polyclonal antibodies were elicited to the "*p,p'*-azophenylazobenzoate" group **1**

$$(p)\text{-}N{=}N\text{-}C_6H_4\text{-}N{=}N\text{-}C_6H_4\text{-}COO^{\ominus}\text{-}(p) \quad \mathbf{1}$$

conjugated to the carrier protein bovine serum albumin.[4] Relative average binding affinities of a series of hapten analogues to the anti-*p,p'*-azophenylazobenzoate antibodies were then determined by precipitation inhibition assays.[5] These antibodies effectively discriminated aryl rings substituted with sulfonate ($-SO_3^{\ominus}$), phosphonate ($-PO_3H^{\ominus}$), and arsonate ($-AsO_3H^{\ominus}$) groups as well as the neutral hydroxyl (-OH) group relative to the planar carboxylate monoanion. In addition, neither acetate nor cyclohexanecarboxylate inhibits the precipitation reaction, indicating antibody specificity for the flat aryl ring. *Karush* has demonstrated that polyclonal antibodies directed against the D isomer of **2** bind the L isomer of **3** with approximately 200-fold lower affinity than the D isomer.[4b]

2

3

Electrostatic interactions play an important role in ligand recognition by antibodies. Chemical modification experiments by *Pressman* and co-workers have revealed the presence of positively charged arginine and lysine residues in the combining sites of antibodies to the "*p*-azobenzoate" group, $(p)\text{-}N{=}N\text{-}C_6H_4\text{-}COO^{\ominus}$, and, conversely, the presence of carboxylate groups in antibodies specific to the *p*-trimethylammoniophenylazo ("*p*-azobenzenetrimethylammonium") group.[6] Hydrophobic and hydrogen-bonding interactions also play an important role in antibody–ligand recognition. For example, NMR experiments have shown that a tryptophan π-stacks with the aryl ring in the anti-2,4-dinitrophenyl (DNP) antibody MOPC 315.[7] X-ray crystallography has revealed that hydrogen-bonding interactions are important in the recognition of lysozyme by an antilysozyme antibody[8] and in the recognition of phosphorylcholine by the antibody McPC 603.[9]

Antibodies bind ligands ranging in size from about 6 to 34 Å with association constants in the range of 10^4 to 10^{14} M^{-1}.[3] The rate constants for the forward reaction of hapten with antibody are typically in the range of 1×10^7 to 1×10^8 $M^{-1}\,s^{-1}$,[10] whereas the rate k_{off} of the reverse reaction can vary considerably; for example, k_{off} is 1.1 s^{-1} for ε-DNP-lysine with anti-DNP antibody and 1300 s^{-1} for DNP-glycine with MOPC 315.[10]

2.2. Antibody Structure

Antibodies are large proteins (ca. 150 000 daltons for an IgG monomer) that consist of four polypeptide chains: two identical heavy chains of ca. 50 000 daltons and two identical light chains of ca. 25 000 daltons, cross-linked by disulfide bonds.[11] The light chains are divided into two domains, V_L (variable) and C_L (constant), while the heavy chains consist of V_H, C_{H1}, C_{H2}, and C_{H3} domains. Amino-acid sequencing has shown that light and heavy chains of the same antigenic class possess a constant amino-acid sequence in the C_L and C_H regions, while the V_L and V_H regions are unique and highly polymorphic for each immunoglobulin (Ig). The ligand combining site of immunoglobulins consists of six hypervariable regions, that is, regions of extensive amino-acid diversity, located in roughly the first 110 amino acids of

Peter G. Schultz received his Ph.D in 1983 under Prof. Peter Dervan (California Institute of Technology) and was an NIH postdoctoral fellow with Prof. Christopher Walsh (Massachusetts Institute of Technology) in 1984. He joined the faculty in the Department of Chemistry at the University of California, Berkeley, in 1985 and was promoted to Associate Professor in 1987 and Professor of Chemistry in 1989. His research program focuses on the study of the mechanisms of molecular recognition and catalysis and the applications of these studies to the design of highly selective catalysts for applications in chemistry, biology, and medicine. His research includes the generation and characterization of catalytic antibodies, the development and application of new mutagenesis methods for selectively introducing unnatural amino acids into proteins and the design of sequence-specific nucleases for large RNAs and DNAs. Peter G. Schultz has received a number of awards including the ACS Nobel Laureate Signature Award, the NSF Waterman Award, and the ACS Award in Pure Chemistry. He is an NSF Presidential Young Investigator, Searle Scholar, and Alfred P. Sloan Fellow. He is also a founding scientist of the Affymax Research Institute, a novel drug discovery effort.

the light (V_L) and heavy (V_H) polypeptide chains of the Ig[11] (Fig. 1). Combinatorial joining of the gene segments encoding the V_L and V_H genes and combinatorial association of different light and heavy chains generate a minimum of 10^8 different antibody molecules; mutations expand this baseline repertoire of receptors still further.[12] Cleavage of immunoglobulins with papain results in the formation of an F_{ab} fragment containing the light chain as well as the V_H and C_{H1} regions of the heavy chain (Fig. 1).

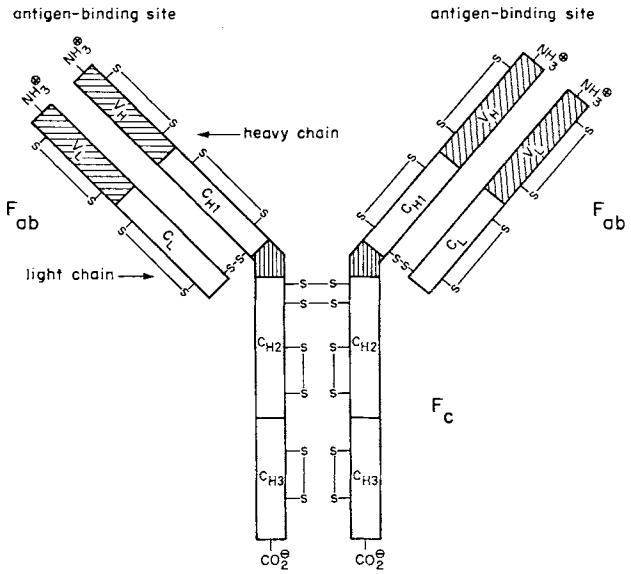


Fig. 1. The schematic structure of immunoglobulins (antibodies).

The structural basis for antibody binding affinity and specificity has been probed by X-ray crystallography, ESR and NMR studies of spin-labeled haptens, and affinity-labeling studies. High-resolution X-ray diffraction studies have led to three-dimensional structures for a number of antibody F_{ab} fragments, including those of the F_{ab} fragment of the myeloma protein McPC 603 with phosphorylcholine,[9] the F_{ab} fragment of human protein New with a vitamin K derivative,[13] the F_{ab} fragment of two immunoglobulins with lysozyme,[8] an F_{ab} fragment with the viral protein neuraminidase,[14] and the F_{ab} fragment Kol.[15]

2.3. Generation of Monoclonal Antibodies

Work on catalytic antibodies to date has focused entirely on the generation of monoclonal antibodies. A monoclonal antibody is a single molecule with defined affinity and specificity for a hapten.[1] A polyclonal antibody preparation, on the other hand, contains a variety of antibody molecules directed against the same antigen. These antibodies can differ in affinity and specificity, and the composition of the preparation may vary. Consequently, it is more straightforward (and meaningful) to characterize a monoclonal catalytic antibody rather than the average properties of a polyclonal mixture. Moreover, monoclonal antibodies can be generated *reproducibly* and on a gram scale.

The protocol for preparing monoclonal antibodies is outlined in Figure 2.[1] After an antigenic response to the desired immunogen is achieved, antibody-producing plasma cells

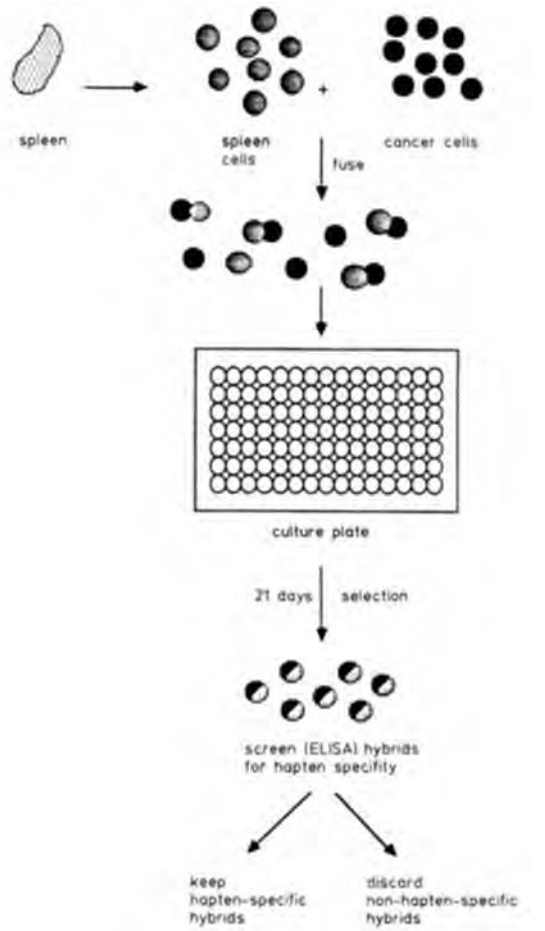

Fig. 2. The production of monoclonal antibodies.

from the spleen are fused (or hybridized) to an immortal myeloma cell line. This step insures that the antibody-producing cells can be cultured and caused to multiply indefinitely. The hybridomas are then cloned or separated into colonies of cells which produce a single antibody. The resulting cells are screened by an ELISA (enzyme-linked immunosorbent assay) for their ability to generate antibodies that bind selectively and with high affinity to the ligand of interest (Fig. 3).[16]

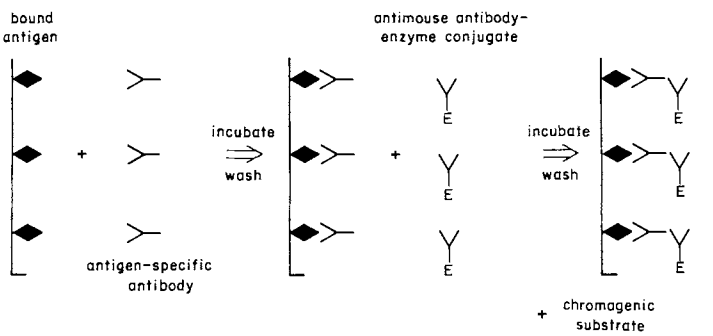

Fig. 3. Enzyme-linked immunosorbent assay (ELISA) for screening antibodies for selectivity and high affinity.

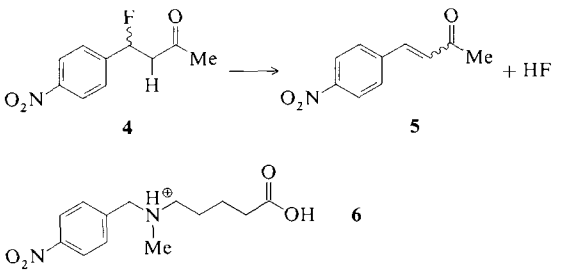
Since small haptens are not immunogenic unless coupled to a carrier molecule, all of the haptens described in this review were coupled to the carrier protein bovine serum albumin (BSA) and keyhole limpet hemocyanin (KLH). The length of the spacer arm between the hapten and carrier is in the range of 6 to 8 Å, which should preclude any steric interference with carrier side chains.[17] The haptens were typically coupled to BSA and KLH via *N*-(3-dimethylaminopropyl)-*N'*-ethylcarbodiimide or the *N*-hydroxysuccinimide ester at pH 5.5 in water.[17] Other coupling strategies have included disulfide exchange reactions, electrophilic aromatic substitution with diazonium salts, and reductive amination.[17] Hapten-to-carrier ratios typically ranged between 8 and 15 haptens per carrier.

Balb/c, Swiss Webster, or AJ1 mice were immunized with the KLH–hapten conjugate emulsified in complete Freund's adjuvant.[18] Fusions were carried out by standard methods with Sp2/0 myeloma cells as fusion partners.[19] Antibodies were screened by ELISA for cross-reactivity with the BSA–hapten conjugate, for inhibition of binding to the BSA–hapten conjugate by free hapten, and for lack of cross-reactivity with KLH. IgG's were purified from ascites fluid by protein A affinity chromatography[20] or Mono Q cation-exchange chromatography and judged to be homogeneous by 12% sodium dodecyl sulfate polyacrylamide gel electrophoresis.



The purity of monoclonal antibodies is tremendously important, especially when an enzyme is known to catalyze the reaction of interest. For example, if k_{cat} for a catalytic (IgG) antibody is $1\ min^{-1}$ and a natural enzyme has a k_{cat} of $3 \times 10^4\ min^{-1}$, contamination of the antibody with 6×10^{-5}% (mol/mol) of the natural enzyme would lead one to believe that the antibody is catalytic, when, in fact, contaminating enzyme is responsible for the rate-enhancement observed. Kinetic analysis, specificity, or inhibition data cannot always distinguish between catalysis by an antibody and catalysis by an enzyme impurity. Rigorous checks of specific activity must therefore be performed after each purification step, along with a comparison between different methods of purification and a comparison of whole antibody versus isolated Fab. For example, we have found it very difficult, even after considerable purification (including affinity chromatography), to remove glycosidase, adenosine deaminase, and ribonuclease impurities from what appears by gel electrophoresis to be homogeneous antibody.

3. Catalytic Antibodies

3.1. Generation of Antibody Combining Sites Containing Catalytic Amino-Acid Side Chains

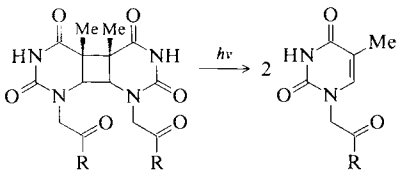
3.1.1. Hapten–Antibody Complementarity

A β-Elimination Reaction. One strategy for inducing catalytic residues, such as basic or acidic amino-acid side chains, in the combining site of an antibody involves generating antibodies to a hapten whose structure is complementary to that catalytic group. In fact, an important goal in the design of catalytic antibodies is the development of general rules relating hapten structure to the corresponding catalytic groups or microenvironment in the antibody combining site. One such example involves the use of electrostatic complementarity between a hapten and antibody to generate an amino-acid side chain that catalyzes the β-elimination reaction **4** → **5**.[21] This reaction, which involves C–H proton

abstraction, is a member of an important class of reactions including elimination and isomerization reactions and aldol and Claisen condensations. Proton abstraction in enzymes that catalyze these reactions is often performed by the carboxylate side chain of glutamic or aspartic acid. These residues typically display higher than normal pK_a values in the hydrophobic active sites of enzymes.[22]

Aspartate and glutamate residues have been generated in the combining sites of antibodies by taking advantage of charge complementarity between haptens and the corresponding antibodies.[6] Consequently, we reasoned that an antibody combining site could be generated that contains a carboxylate within bonding distance of an abstractable substrate proton by using the appropriate positively charged hapten. Importantly, the position of the charged group in the hapten should reflect that of the target C–H group in the substrate. Hapten **6** contains a positively charged ammonium ion replacing the α-CH_2 group of substrate **4**. The fact that the hapten and substrate share a common recognition element, the *p*-nitrophenyl group, should insure reasonable binding affinity of substrate to the antibodies. Moreover, replacement of hapten by substrate in the antibody combining site should lead to an increase in the pK_a of the catalytic carboxylate group since a stabilizing salt-bridge interaction is lost.

Of six antibodies generated against the KLH conjugate of **6**, four catalyzed the β-elimination reaction **4** → **5**. The IgG 43D4-3D3 obeyed the classical Michaelis–Menten expression [Eq. (1)] ($k_{cat} = 0.2\ min^{-1}$, $K_m = 182\ \mu M$ at 37 °C, pH 6.0), demonstrated substrate specificity, and was competitively inhibited by hapten ($K_i = 290\ nM$). Chemical



$$\mathrm{Ig} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{Ig{\cdot}S} \xrightarrow{k_{cat}} \mathrm{Ig} + \mathrm{P}$$

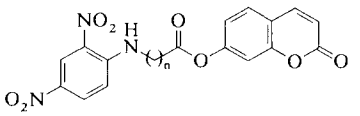
$$v = \frac{k_{cat}[E_T][S]}{K_m + [S]}, \quad K_m = \frac{k_{-1} + k_{cat}}{k_1} \qquad (1)$$

modification experiments with the carboxylate-specific reagent diazoacetamide, in the presence and absence of bound hapten, demonstrated that a glutamate or aspartate residue was responsible for catalysis. Determination of k_{cat} as a function of pH revealed that the carboxylate had a pK_a of 6.2 in the presence of bound substrate. The increased pK_a of the carboxylate side chain is consistent with loss of a salt-bridge interaction when hapten **6** is replaced by substrate in the

antibody combining site. The rate enhancement obtained by introduction of the carboxylate residue in the antibody combining site, compared to acetate free in solution, is 8.80×10^4 at pH 6.0. This value is similar to the rate acceleration of about 10^4 attributable to the bases Glu 43 in staphylococcal nuclease[23] and Asp 102 in trypsin.[24]

A [2 + 2] Cycloreversion Reaction. A second example in which hapten structure was used to induce a catalytic side chain in an antibody combining site involves the generation of antibodies which catalyze the light-dependent [2 + 2] cycloreversion reaction of thymine dimer **7a**.[25] Thymine dimers are the predominant DNA photolesion produced by UV light. Model studies have shown that photosensitizers such as indoles, quinones, or flavins can reversibly transfer an electron to or accept an electron from a thymine dimer, resulting in facile cleavage of the intermediate thymine-dimer radical.[26–28] These results suggest that an antibody combining site specific for a thymine dimer and containing an appropriately positioned sensitizer should act as a photorepair enzyme. It seemed reasonable to us that antibodies generated against the polarized π system of a pyrimidine dimer might contain a complementary tryptophan residue in the combining site, much as antibodies generated against positively charged haptens contain complementary aspartate and glutamate residues.[3] In order to test this strategy, antibodies were generated against *cis,syn* thymine dimer **7b**.

7a: R = OH
7b: R = $NHCH_2COOH$



Five out of six antibodies generated against the KLH conjugate of dimer **7b** catalyzed the photoreversion of dimer **7a** to the corresponding monomer when irradiated with 300-nm monochromatic light. The k_{cat} of the IgG 29E5 was 1.2 min^{-1} (under conditions of nonsaturating light), *close to the k_{cat} of 3.4 min^{-1} for thymine-dimer cleavage by the repair enzyme Escherichia coli DNA photolyase.*[29] The quantum yield of the photocleavage reaction, corrected for the number of tryptophans, was $\Phi \geq 0.75$, compared to the quantum yield of approximately 1.0 for DNA photolyase. The antibody did not catalyze the cleavage of the corresponding *N,N'*-dimethyl substrate, consistent with the high specificity of antibodies. The wavelength dependence of the photocleavage quantum yield as well as fluorescence quenching experiments demonstrated the involvement of a tryptophan in catalysis. Pulse radiolysis experiments have shown that dimethyl and tetramethyl thymine-dimer radical anions decay to the corresponding monomers with a frequency of 0.05.[30] Since the quantum yield of the antibody-sensitized reaction is significantly higher than 0.05, the antibody appears to partition the breakdown of the intermediate radical anion. Further experiments are being carried out to precisely define the mechanism of this antibody-catalyzed reaction.

In the two examples described above, a high percentage of the antibodies isolated were catalytic. This result may reflect the generality of using electrostatic and π-stacking interactions to elicit complementary combining-site residues. The generation of antibodies with rate accelerations on the order of 10^8 or greater will likely involve the simultaneous application of two or more strategies for introducing catalytic activity into antibodies. Clearly then, strategies, such as that described above, that yield a high percentage of catalytic antibodies relative to the total number of hapten-specific antibodies isolated are the most desirable and generalizable. One can imagine many other reactions which can be catalyzed by antibodies using this strategy (or this strategy in conjunction with those detailed in Section 3.1.2), including aldol reactions (a β-aminophosphonate hapten), ester/amide hydrolysis (an *N*-oxide hapten), and oxy-Cope rearrangements (an aminocyclohexane hapten). It should also be noted that monoclonal antibodies have been reported that fortuitously contain nucleophilic residues that react in a stoichiometric fashion with an activated ester analogue of the hapten.[31]

3.1.2. Site-Directed Mutagenesis

An alternative approach for the introduction of catalytic groups into an antibody combining site involves site-specific mutagenesis. This approach has also been applied to the antibody MOPC 315,[32] which binds substituted 2,4-dinitrophenyl ligands with association constants ranging from 10^3 to 10^7 M^{-1}.[33, 34] The combining site has been characterized by spectroscopic methods (UV, fluorometry, NMR), chemical modification, and amino-acid sequencing of the variable region. Moreover, earlier affinity-labeling studies with reagents of varying structures[35] defined a number of reactive amino-acid side chains in the vicinity of the combining site.

In the absence of an X-ray crystal structure of MOPC 315, *chemical modification experiments* were used to guide the mutagenesis. Despite the presence of 14 potentially reactive side chains in the hypervariable region (2 histidines, 2 lysines, 3 arginines, and 7 tyrosines), DNP-containing affinity labels alkylate primarily two residues, tyrosine 34L and lysine 52H.[35] Tyrosine 34L was chosen as the initial target for mutagenesis since it appeared that a histidine at residue 34 would be situated to catalyze the hydrolysis of esters **8a–c**. The role of tyrosine 34L in DNP binding has not been clearly established; affinity labeling of the tyrosine to form the 5-mercapto-2-oxopentyl ether prevents binding of ligands,[35] perhaps by sterically blocking the entrance to the site. Nitration of the tyrosine ring has no effect.[36] Phenylalanine was also substituted to assess the contribution of the tyrosine hydroxyl group to hapten binding.

8a: n = 2
8b: n = 4
8c: n = 5

In order to generate mutants of MOPC 315, we chose to express the variable region (F_v) of the antibody in *E. coli*. MOPC 315 IgA can be proteolyzed with pepsin to yield functional F_{ab} or F_v fragments.[37] The F_v fragment (26 kD) is a heterodimer consisting of two peptides, V_H (14 kD) and V_L

(12 kD) (cf. Fig. 1), and contains all the sequences necessary for folding of the binding domain and recognition of the DNP hapten. Reduced and separated V_H and V_L peptides of MOPC 315 and several other antibodies can be recombined to form a stable F_V (Fig. 4).[37] The single disulfide bond in

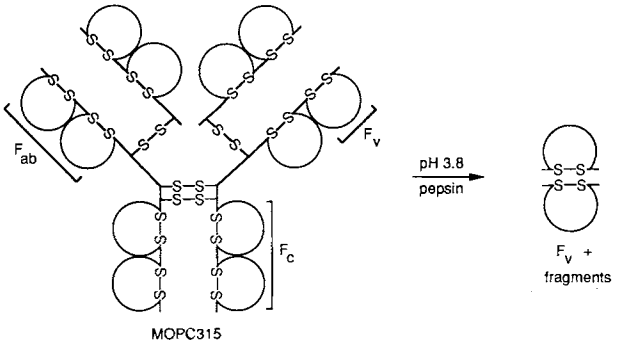


Fig. 4. The schematic structure of the antibody MOPC 315 and its cleavage by pepsin.

V_H or V_L can be efficiently formed by oxidation of the reduced forms prior to reconstitution.[37] The simplicity and efficiency of reconstitution makes the F_V fragment a desirable target for expression of an antibody combining site in *E. coli*. We have exploited this property to produce a hybrid F_V fragment, in which recombinant V_L produced in *E. coli* is reconstituted with V_H derived from MOPC 315 IgA. Functional F_V and F_{ab} fragments of other antibodies have been previously expressed in *E. coli*.[38] A gene encoding the 115 *N*-terminal amino acids of MOPC 315 light chain was chemically synthesized and expressed in *E. coli* as a fusion with the lambda cII gene.[39] The resulting hybrid protein was cleaved at one site with Factor Xa, the liberated V_L peptide was reconstituted with V_H, and the resulting F_V fragment was purified by gel filtration and affinity chromatography.

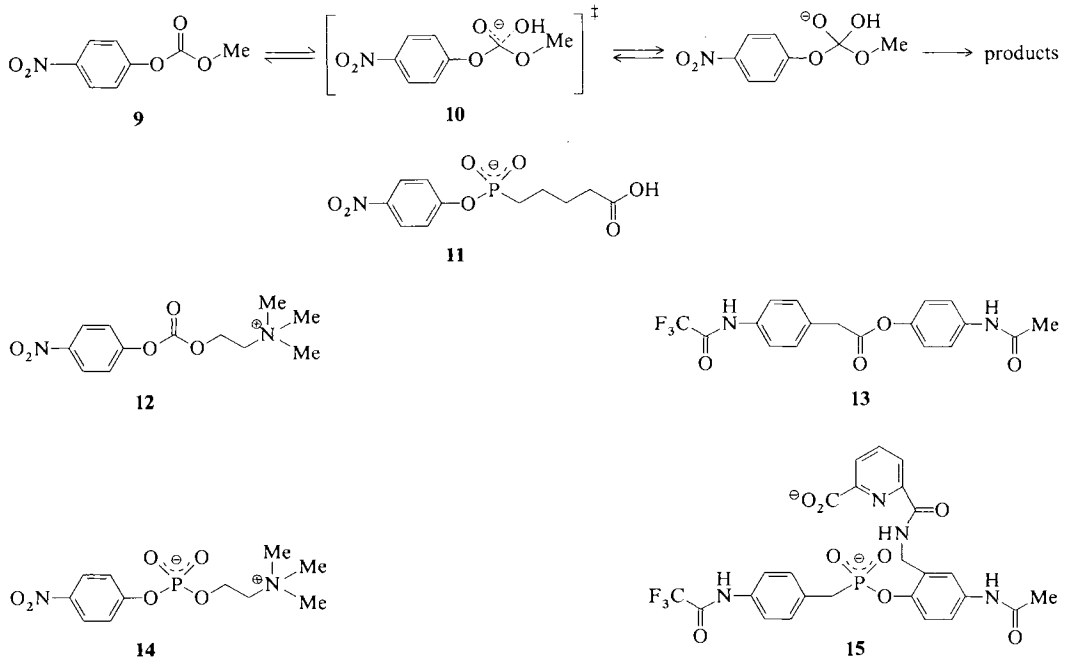
Wild-type F_V (F_V(315)) and the phenylalanine mutant (F_V(Y 34 F_L)) bound DNP-L-lysine with similar affinities at pH 6.8 ($K_D = 250 \pm 20$ nM), while the histidine mutant (F_V(Y 34 H_L)) bound DNP-lysine with sixfold lower affinity ($K_D = 1400 \pm 200$ nM). The histidine mutant F_V fragment accelerated hydrolysis ($k_{cat}/K_M/k_{4-MeIm}$) of ester **8b** $6.0 \pm 3.0 \times 10^5$ fold over the reaction with 4-methylimidazole at pH 6.8. The initial rate of ester cleavage is 50 times faster than that of wild-type F_V or the F_V(Y 34 F_L) mutant. In addition, the hydrolyses of the homologous esters **8a** and **8c** were not significantly accelerated, consistent with the postulated location of the His 34 side chain in the active site.

Site-directed mutagenesis should prove a powerful tool for augmenting the rate enhancements of catalytic antibodies generated via other strategies and for the stepwise evolution of catalytic activity in antibodies to produce efficient selective catalysts. In addition, genetic selection or screening might also be used to generate a catalytic residue in the combining site of an antibody already specific for the substrate (or transition-state analogue) of interest.

3.2. Generation of Antibodies Complementary to Transition-State Analogues

An antibody generated to a haptenic group resembling the transition-state configuration of a given reaction should lower the free energy of activation of the reaction by stabilizing the corresponding transition-state relative to reactants or products.[40] In fact, the active sites of many enzymes are complementary in structure and electronic distribution to rate-limiting transition states, as evidenced by studies of enzyme active sites[41] as well as enzyme inhibition by transition-state analogues.[42] Antibodies elicited to transition-state analogues have been demonstrated to catalyze a variety of reactions (see Sections 3.2.1 to 3.2.3), including carbonate, ester, and amide hydrolysis, the Claisen rearrangement of chorismic acid to prephenic acid, bimolecular amide bond formation, a six-membered ring lactonization reaction, and peptide bond formation.

3.2.1. *Carbonate, Ester, and Amide Hydrolysis*



The first examples of catalytic antibodies specific for transition-state (TS) analogues bound tetrahedral, negatively charged phosphate and phosphonate TS analogues for the hydrolysis of carbonates and esters.[43,44] A number of factors were considered in the design of this first generation of catalytic antibodies. Carbonates and esters undergo substantial structural and electronic changes on the reaction pathway from substrate to product, making possible differential binding and stabilization of the transition state. Moreover, the tetrahedral transition states for these hydrolytic reactions have been successfully mimicked with tetrahedral phosphonate, α,α-difluorocarbonyl, and hydroxymethylene groups. Hydrolytic reactions do not necessarily require catalytically active side chains (such as a nucleophilic serine); they can also take place by simple attack of a water molecule on the polarized carbonyl of the substrate in the binding site. Additional considerations included the desirability of common recognition elements in both substrate and transition state, as well as diminished affinity of the antibody for the reaction products.

Monoclonal antibodies specific for tetrahedral transition-state analogues **11**, **14**, and **15** were found to selectively catalyze the hydrolysis of the corresponding substrates **9** (transition state **10**), **12**, and **13**, respectively, with kinetics consistent with the Michaelis–Menten rate expression [Eq. (1)].[43,44] The antibody-catalyzed reactions were competitively inhibited by their corresponding transition-state analogues. In each case, the inhibition constant (K_i) is substantially lower than the corresponding K_m of the substrate, suggesting that transition-state stabilization plays a role in catalysis. A comparison of the rates of the antibody-catalyzed reactions [Eq. (2)] with the rates of hydroxide-dependent hydrolysis [Eq. (3)] afforded antibody rate accelerations in the range of 10^3 to 10^5.[43] These accelerations are in the

$$v_{Ig} = k_{Ig}[Ig \cdot S][OH] \quad (2)$$

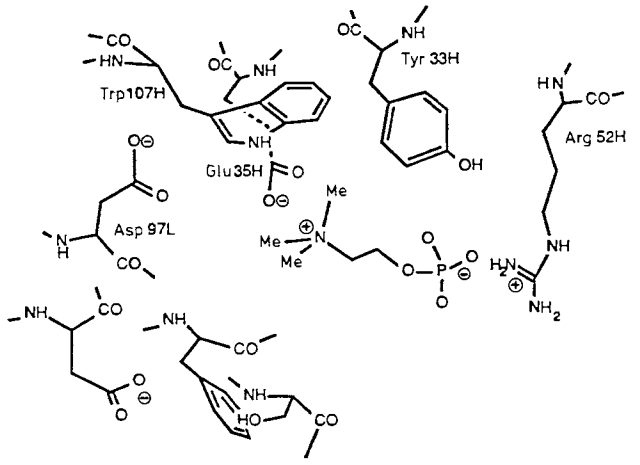
$$v_{OH} = k_{OH}[S][OH] \quad (3)$$

same range as those attributable both experimentally and theoretically to transition-state stabilization in hydrolytic enzymes. For example, a triple mutant of the enzyme subtilisin, in which each amino acid of the catalytic triad of His, Ser, and Asp is replaced by an alanine residue, hydrolyzes a *p*-nitroanilide peptide substrate 3000-fold more rapidly than the corresponding uncatalyzed reaction, which gives an esti-

9 10 11 12 13 14 15

mate of the extent of catalysis that can be achieved by stabilization of the transition state by binding determinants other than the catalytic triad.[45] In all cases the antibodies also displayed high substrate specificity.

The three-dimensional structure of the antibody McPC603, which is highly homologous to the catalytic phosphorylcholine-binding antibodies T15 and MOPC167, has been solved. The crystal structure makes possible direct identification of the combining-site residues responsible for catalysis (Fig. 5).[9] The hapten is bound in the cavity of



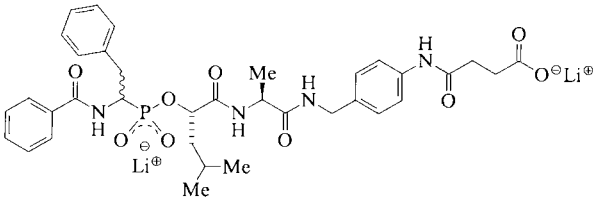


Fig. 5. Phosphorylcholine in the combining site of the antibody McPC603.

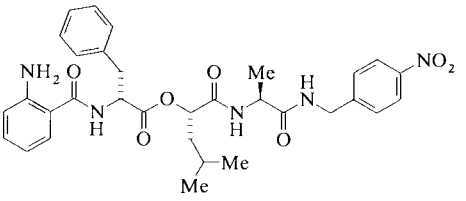
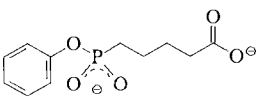


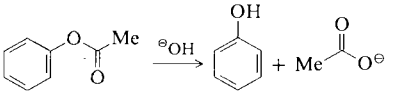
McPC603 with the choline group deep in the interior and the phosphate toward the exterior, in contact with aqueous solvent. The heavy-chain residues Tyr33H and Arg52H, which are invariant in all of the phosphorylcholine-binding Ig's sequenced to date,[46] bind the phosphate through hydrogen bonding and electrostatic interactions with the phosphoryl oxygen atoms. The combining site of McPC603 is both sterically and electronically complementary to the tetrahedral, negatively charged phosphate moiety of phosphorylcholine. Inasmuch as this tetrahedral phosphate mimics the transition state for the hydroxide-ion-catalyzed hydrolysis of carbonate **12**, the phosphorylcholine antibodies should be capable of polarizing the bound carbonyl group of **12** for attack of hydroxide ion in the rate-determining step. In light of the fact that the ground-state structure of **12** differs substantially from the transition-state configuration (cf. **10**), the differential binding affinity of the Ig to these two species should be reflected in a lowered free energy of activation for reaction. In fact, the transition-state analogue 4-nitrophenyl phosphorylcholine **14** is bound more tightly than the corresponding substrate by both MOPC167 and T15[46] (K_i = 5 μM, K_m = 208 μM for MOPC167). However, the differential binding of T15 and MOPC167 to carbonate **12** and the transition-state analogue **14** does not fully account for the magnitude of the rate accelerations. Therefore, although the crystallographic and binding data strongly suggest that T15 and MOPC167 selectively stabilize the transition-state configuration and thereby reduce the barrier to reaction, other factors are contributing to the rate acceleration. Site-directed mutagenesis is currently being used to characterize the catalytic roles of various amino acids in the active site of phosphorylcholine-specific antibodies. Biophysical studies and chemical modification experiments suggest that tyrosine and arginine also play a catalytic role in the antibodies specific for hapten **11**.[43] Again, these residues can act to stabilize the tetrahedral transition state. Histidine or tyrosine is thought to be involved in catalysis by antibodies specific for **15**.[44] It is not yet clear what catalytic role these residues play.

Antibodies have also been generated to phosphonate transition-state analogues that catalyze the stereospecific hydrolysis of unactivated alkyl esters under mild conditions.[43f]Antibodies were generated against hapten **16**, a tripeptide transition-state analogue for the hydrolysis of ester **17** under basic conditions. Note that the hapten also contains analogues of the fluorogenic groups at the amino

and carboxy termini of substrate **17**. These groups allow hydrolysis of the substrates to be monitored by observing the fluorescence increase which occurs when the fluorescent 2-aminobenzoyl group is separated from the quenching 4-nitrobenzylamide in the reaction.[47] This sensitive assay may allow direct screening of ELISA plates for catalytic activity, facilitating the production of catalytic antibodies.

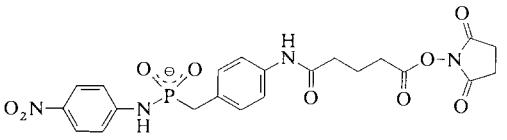


16

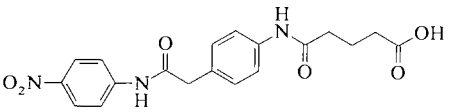


17

The antibody-catalyzed hydrolyses were 50- to 300-fold faster than reaction with hydroxide ion. With relatively large transition-state analogues such as tripeptides **16**, the tetrahedral phosphonate probably contributes proportionally less to the overall binding energy of the hapten to the antibody and, consequently, the rate acceleration observed is less than those of antibodies raised to smaller transition-state analogues. Interestingly, all 18 antibodies (out of 25) found to accelerate the hydrolysis of ester **17** were selective for the D-phenylalanine-containing diastereomer, although a mixture of diastereomers was used to generate the antibodies.[48] With three of the five IgG's, the ratio of the rate of hydrolysis of the L-phenylalanine-containing ester to that of the D-phenylalanine-containing ester was less than 0.5%. The antibodies also show a high degree of substrate specificity. Esters containing nitrophenylalanine, leucine, or tryptophan in place of phenylalanine are not hydrolyzed by any of the antibodies. Antibodies of this sort may prove useful in the chiral resolution of amino acids and alcohols.[49] *Benkovic* and co-workers have reported antibodies with lipase activity, *R* or *S* substrate specificity, and rate accelerations of 8×10^4 fold.[49]



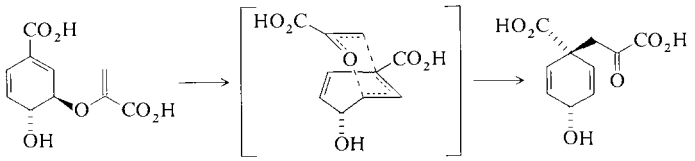
Antibodies can also carry out reactions on water-insoluble organic substrates. Antibodies specific for the phenylphosphonate transition-state analogue **18** were capable of catalyzing the hydrolysis of phenyl acetate in reverse micelles.[50] The k_{cat} and K_m values of the antibody solubilized in isooctane in reverse micelles were 3.74 min^{-1} and 650 μM, respectively [Wo value (water to detergent ratio) of 23], compared to the corresponding values of 18.8 min^{-1} and 157 μM in aqueous solution. The optimal value of Wo is significantly higher than that previously reported for enzymes, consistent with the increased molecular weight of IgG molecules. The ability of antibodies to function in reverse micelles should significantly expand the versatility of antibodies in catalysis and immunoassays.



18

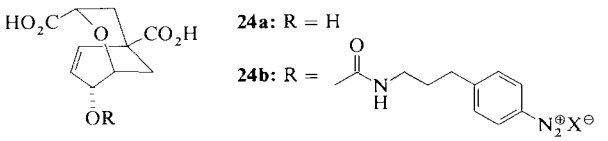
More recently, antibodies have been generated against the KLH conjugate of arylphosphonamidate **19**. One antibody was found to catalyze the hydrolysis of the nitroanilide **20**[51] with a k_{cat} of 0.08 min^{-1} and a K_m of 562 μM. The antibody-catalyzed reaction is characterized by high specificity and a rate enhancement of 2.5×10^5 relative to the uncatalyzed reaction. The difference in binding of the phosphonamidate transition-state analogue (K_i) and substrate (K_m) ($\Delta\Delta G^{\neq} = -2.2$ kcal mol^{-1}) does not account for the magnitude of the rate acceleration. Therefore, other factors such as acid or base catalysis or ground-state destabilization must be involved in catalysis. Generation of an antibody combining site with these additional catalytic interactions may have simply been the result of immunological diversity (one IgG out of 44 was found to be catalytic) or could be a consequence of hapten structure. The P-NH and P-O groups

19



20

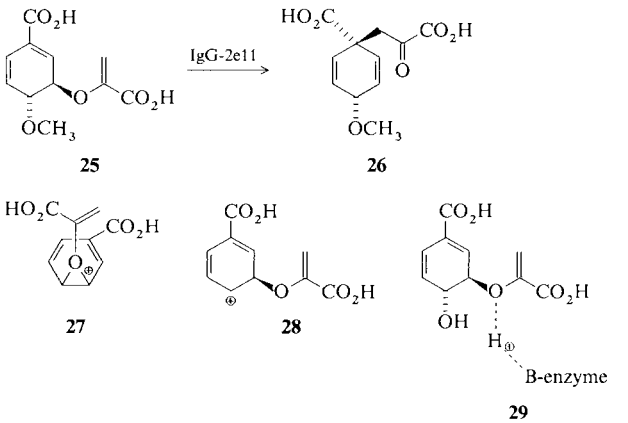
each have a lone pair that can act as a hydrogen-bond acceptor, whereas only the P-NH group can act as a hydrogen-bond donor. It is not clear, however, how this difference in hydrogen bonding pattern would affect the nature of the combining site. Mechanistic analysis of this antibody-catalyzed reaction should provide important insight into the generation of antibodies that catalyze the related, but considerably more energetically demanding hydrolysis of peptide bonds. One can also imagine transition-state analogues for the hydrolysis of glycosidic (nojirimycin derivatives) and phosphodiester (nucleoside vanadyl complexes) bonds.



3.2.2. A Claisen Rearrangement

It should also be possible to generate antibodies which increase reaction rates by reducing entropic barriers to reactions. The binding energy in this case acts to reduce translational and rotational motions for reaction by properly orienting the reactants in the antibody combining site. This approach should be applicable to intramolecular reactions such as macrocyclic lactonization reactions or intermolecular reactions such as peptide bond formation or Diels–Alder reactions.

We have used these ideas to guide us in the generation of antibodies that carry out the formal Claisen rearrangement of chorismic acid **21** to prephenic acid **23**.[52] This thermal 3,3-sigmatropic rearrangement occurs through an asymmetric chairlike transition state (**22**) in which the carbon–oxygen bond is substantially broken while carbon–carbon bond formation has not occurred to any appreciable extent.[53] The activation entropy and enthalpy of reaction have been determined to be -12.85 cal K^{-1} mol^{-1} and 20.7 kcal mol^{-1}, respectively.[53] The unimolecular rearrangement is catalyzed approximately 10^6-fold by the enzyme chorismate mutase at the branch point in the biosynthesis of aromatic amino acids in bacteria and plants.[54] Although the enzymatic reaction has also been demonstrated to proceed through a chairlike transition state, the mechanism by which chorismate mutase accelerates the rearrangement remains poorly understood.[55]

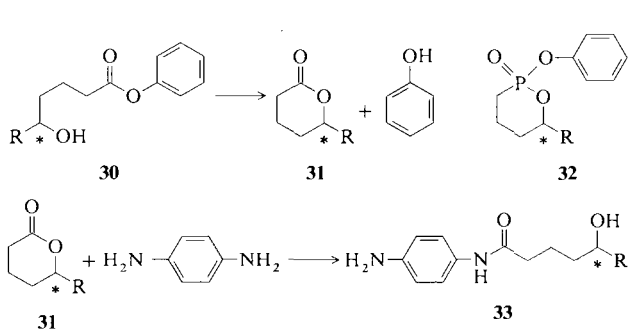


21 **22** **23**

24a: R = H

24b: R =

One might expect that an antibody combining site, complementary to the conformationally restricted transition-state configuration, but presumably lacking catalytic side chains, could accelerate the Claisen rearrangement of chorismic acid to prephenic acid. Monoclonal antibodies were elicited to the *endo* bicyclic transition-state analogue **24a**, the most potent known inhibitor of chorismate mutase with a K_i of 0.15 μM.[56] One of eight antibodies (IgG) generated to the KLH conjugate of **24b** was found to catalyze the Claisen rearrangement **21** → **23**, with initial rates consistent with the Michaelis–Menten rate expression [Eq. (1)] (k_{cat} = 2.7 min^{-1}, K_m = 260 μM at 10 °C). The rate of the antibody-catalyzed reaction can be directly compared with that of the uncatalyzed unimolecular thermal rearrangement, affording a value of k_{cat}/k_{uncat} of 1×10^4 at 10 °C and pH 7.0. This factor can be compared with the 3×10^6-fold acceleration by chorismate mutase from *E. coli* under the same conditions. Of the various mechanisms put forth for the enzymatic rearrangement, most can be ruled out for the antibody-catalyzed process. For example, the fact that the (±) methyl ether of chorismic acid, **25**, is converted into the (±) ether of prephenic acid, **26**, argues against mechanisms involving loss of the 4-hydroxyl group (such as formation of **27** or a C-4 cation such as **28**). Moreover, the observation of a D_2O solvent isotope effect of 1 on the antibody-catalyzed reaction excludes general acid or base catalysis (cf. **29**) in the rate-limiting step. One is left with the appealing mechanistic alternative that the antibody catalyzes the reaction by providing an environment complementary to the conformationally restricted transition state. Consistent with this



25 **26** **27** **28** **29**

notion, the $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the antibody-catalyzed reaction are 18.3 kcal mol^{-1} and -1.2 cal K^{-1} mol^{-1}, respectively.[57]

A second antibody, independently generated against an ester-linked analogue of **24a**, also catalyzed the rearrangement of chorismic acid to prephenic acid, but at a 100-fold lower rate.[58] In this case the ratio K_i/K_m corresponds roughly with the observed rate enhancement consistent with preferential binding of the transition-state analogue by the antibody. The stabilization was shown to be largely enthalpic in nature. In addition, catalysis was shown to be highly regioselective; only the (−) isomer of chorismic acid was a substrate for the antibody.[58]

3.2.3. *Transacylation Reactions*

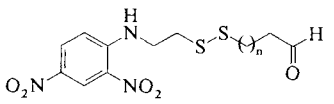
The constraints imposed by the antibody binding pocket should also accelerate an intramolecular cyclization by reducing rotational entropy.[59] *Benkovic* and co-workers have demonstrated that an antibody elicited to transition-state analogue **32**, which is representative of a six-membered ring lactonization reaction, acts as a catalyst for the cyclization of the substrate **30** to give lactone **31**.[60] The rate of the antibody-catalyzed reaction relative to that of the uncatalyzed reaction was 167. Again, the antibody-catalyzed reaction was competitively inhibited by the corresponding cyclic phosphonate. The antibody cyclization reaction was stereoselective, permitting isolation of the lactone **31** in an enantiomeric excess of 94%.[60] Antibodies specific for **32** also catalyzed the stereospecific formation of amide **33** from

30 **31** **32** **31** **33**

racemic lactone **31** and 1,4-diaminobenzene.[61] The antibody bound 1,4-diaminobenzene and lactone **31** with K_m values of 1.2 mM and 4.9 mM, respectively, and the transition-state analogue **32** with a K_i of 75 nM. The acceleration of

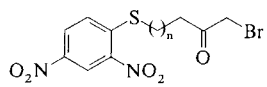
the antibody-catalyzed reaction relative to the uncatalyzed reaction was 16 M, which compares with a $K_m \cdot K_m/K_i$ value of 155 M. A second phosphonamidate-specific antibody was also shown to catalyze bimolecular amide bond formation with an effective molarity of 10.5 M (in this case the hapten did not incorporate the leaving group, an important element of the transition state).[62] These values are considerably below the value of 10^8 M, which is thought to represent an approximate upper limit for an antibody-catalyzed reaction compared to its bimolecular counterpart.[63] Nonetheless, the demonstration that an antibody can catalyze bimolecular reactions offers the possibility of antibody-catalyzed peptide bond formation, Diels–Alder reactions, macrolide synthesis, or transglycosylation reactions. Recently, an antibody has been generated that catalyzes peptide bond ligation.[74]

3.3. Introduction of Chemical Catalysts into Antibody Combining Sites



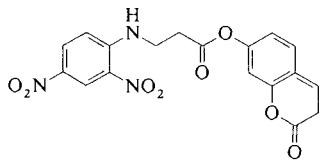
3.3.1. Semisynthetic Antibodies

One strategy whereby catalytic groups can be introduced into antibody combining sites involves the selective chemical modification of antibodies with natural or synthetic catalysts such as transition-metal complexes, cofactors, bases, or nucleophiles. *Kaiser* and co-workers demonstrated that enzymes can be selectively modified with cofactors to afford semisynthetic enzymes with new properties.[64] This approach has recently been extended to antibodies, making it possible to combine the exquisite binding specificity of the immune system with the efficient diverse catalysts available from synthetic chemistry.[65, 66]



The key to the generation of semisynthetic catalytic antibodies is the development of mild methods for selectively introducing derivatizable groups of unique reactivity into or near the combining site. These groups can then be modified in a second step to incorporate the chemical functionality (cofactor, metal–ligand complex, fluorophore, etc.) of interest. One such derivatizable group is a free thiol, which, by virtue of its high nucleophilicity and ease of oxidation, can be selectively modified via disulfide exchange or electrophilic reactions. Moreover, introduction of a nucleophilic thiol into an antibody combining site might directly afford a catalytic antibody. We have used cleavable affinity labels to selectively modify the antibody combining site of the IgA MOPC315 with a nucleophilic thiol.[65] Importantly, this method does not require knowledge of the three-dimensional structure of the antibody and should therefore be applicable to a large number of proteins of interest.

Cleavable affinity-labeling reagents were synthesized that contain the DNP group linked to an electrophilic aldehyde or α-bromoketone via cleavable disulfide or sulfide linkages (cf. **34** and **35**, respectively).



The distance between the DNP group and electrophilic moiety of the affinity labels was varied, since the position of a nucleophilic Lys, His, or Tyr side chain in the combining site was not precisely known. Covalent attachment of the label to the antibody, followed by cleavage of the cross-link and removal of the free ligand, resulted in site-specific incorporation of a free thiol into the antibody combining site (cf. **36a**, Fig. 6). Affinity labeling of the antibody with the aldehyde labeling reagent **34b** in the presence of $NaCNBH_3$ provides, after cleavage of the disulfide linkage, homogeneous antibody containing a free thiol attached to Lys 52H[65] (bromoketone **35b** selectively modified the antibody at Tyr 34L). The binding affinity of this modified antibody to *N*-DNP-glycine was similar to that of native MOPC315. The thiol itself is appropriately positioned to act as a nucleophile in the thiolysis of coumarin ester **8a**.[65] The semisynthetic

34a: n = 1
34b: n = 2

35a: n = 1
35b: n = 2
35c: n = 3

8a

antibody demonstrated saturation kinetics and was competitively inhibited by *N*-DNP-glycine with a K_i of 8 μM. The rate acceleration by the thiol-containing antibody relative to dithiothreitol was 6×10^4 for ester **8a**. This value is quite similar to that found in the antibody-catalyzed β-elimination reaction and suggests that proximity of a base or nucleophile to a complexed substrate can lower $\Delta G^{\neq}$ for reaction by up to 7.0 kcal mol^{-1}.

Importantly, the thiol also acted as a handle to introduce other synthetic chemical functionality into the antibody combining site.[65, 66] Imidazole was incorporated in greater than 90% yield by treatment of the pyridyl disulfide adduct of the antibody with 4-(mercaptomethyl)imidazole[66] (Fig. 6). The resulting semisynthetic antibody of type **36c** catalyzed the hydrolysis of coumarin ester substrate **8a** with

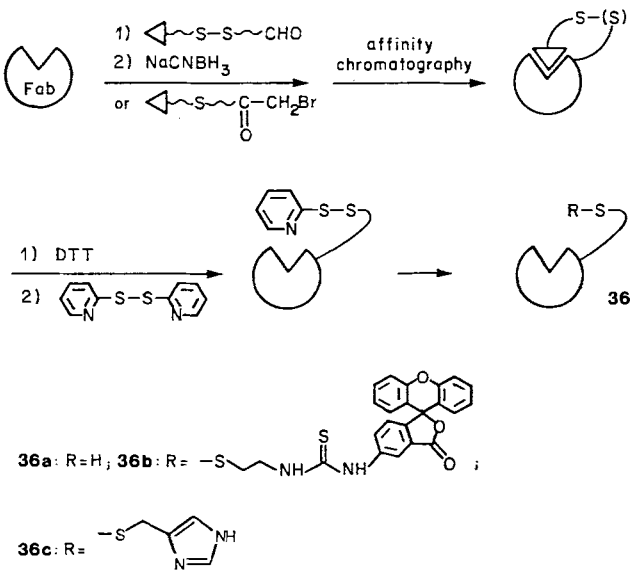


Fig. 6. The incorporation of synthetic catalysts in the combining site of antibodies. DTT = dithiothreitol.

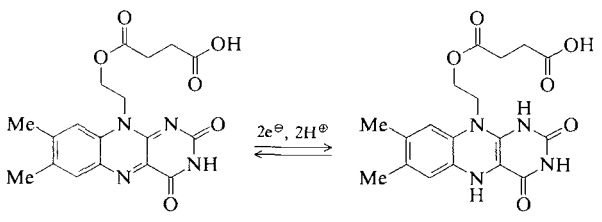
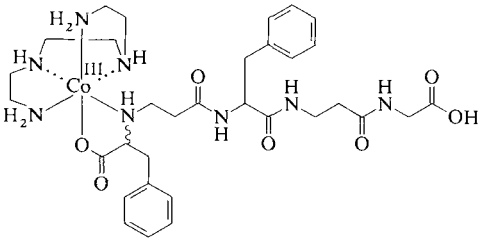


a rate 10^3 times faster than the rate of catalysis by 4-methylimidazole. Presumably, imidazole is acting as a general base or nucleophile in the hydrolysis of **8a**. The slower rate with this antibody is likely due to the increased flexibility of the imidazole side-chain linkage. The semisynthetic antibody showed specificity for the 3-(DNP-amino)proprionate ester **8a** versus the *N*-DNP-glycine or 4-(DNP-amino)butyrate ester.

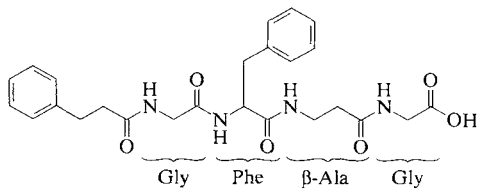
It is interesting to compare catalysis by $F_V(Y34H_L)$ (see Section 3.1.2) and by chemically modified MOPC315, containing imidazole linked to lysine 52 of the heavy chain through a flexible eight-bond tether.[8] $F_V(Y34H_L)$ hydrolyzes **8a** approximately 16 times more rapidly than the imidazole-modified F_{ab} fragment. This difference is likely due to the decreased number of degrees of freedom of the histidine-34 side chain imposed by the protein backbone and surrounding side chains. In addition, the imidazole may be better aligned for attack on the carbonyl or for activation of a water molecule.

The thiol-containing antibody could also be modified with a fluorophore.[65] Addition of the ligand *N*-DNP-glycine to the adduct **36b** resulted in a decrease in fluorescein fluorescence, providing a direct assay of ligand binding. The binding constant obtained from quenching of fluorescein fluorescence was identical within experimental error to that reported in the literature for unmodified MOPC315.[34] Semisynthetic antibodies of this sort may prove useful as sensors and in diagnostics. Derivatization of antibodies with other groups ($Zn^{2\oplus}$– or $Co^{3\oplus}$–ligand complexes, flavins, pyridoxamine, etc.) should enable us to generate semisynthetic antibodies with a variety of novel catalytic activities. Therapeutic agents can also be incorporated proximate to the antibody combining site via this strategy.

3.3.2. *Cofactor Binding Sites*



Another strategy whereby catalytic groups can be introduced into antibody combining sites involves generating, in addition to the substrate binding site, a cofactor (either natural or synthetic) binding site.[67] To this end, antibodies have been generated to flavin **37**. Because flavin **37** and the 1,5-dihydroflavin **38** have substantially different electronic



37 **38**

and conformational properties,[68] antibodies generated specifically to **37** preferentially bind **37** with 4×10^4 higher affinity than 1,5-dihydroflavin **38**. This differential stabilization of the oxidized and reduced forms of the cofactor by the antibody combining site makes the Ig·**38** complex a substantially stronger reducing agent than free **38** in solution; the reduction potential of **37** bound to antibody is −342 mV, representing a lowering of the reduction potential ($E_m = -206$ mV) by approximately 5 kcal mol^{-1}. Because the Ig·**38** complex is a stronger reducing agent than free **38**, the substrate Safranine T ($E_m = -289$ mV) could be rapidly reduced by Ig·**38**, but not by **38** itself. The antibody–flavin complex is able to mediate redox processes not thermodynamically accessible to free flavin. Incorporation of a substrate binding site into these antibodies may lead to catalytic antibodies which can carry out stereocontrolled chemical reductions.

An exciting recent result in the area of catalytic antibodies has been the generation of antibodies that bind a metal-complex cofactor and catalyze the specific hydrolysis of a Gly–Phe bond of peptide substrate **40** at neutral pH.[69] The

39

40

antibodies were produced by immunizing with hapten **39**, a Co^{III}–peptide complex containing the triethylenetriamine ("trien") ligand. These antibodies as a group are capable of binding trien complexes not only of Co^{III} but also of numerous other metals. The antibody–trien–metal complex selectively cleaved the Gly–Phe amide bond of peptide **40**. One antibody was studied in detail, and cleavage was observed for **40** with the trien complexes of Zn^{II}, Ga^{III}, Fe^{III}, In^{III}, Cu^{II}, Ni^{II}, Lu^{III}, Mg^{II}, or Mn^{II} as cofactors. A turnover number of 6×10^{-4} s^{-1} was measured. Interestingly, the amide bond hydrolyzed is one removed from the bond one might have expected to be cleaved based on model chemistry by *Buckingham* and others.[70] Nonetheless, this work is a starting point for the generation of sequence-specific peptidases, "restriction enzyme" equivalents for proteins.

The generation of antibody combining sites that bind natural and synthetic cofactors should prove a general powerful approach for the generation of new catalytic antibodies for hydrolytic and redox reactions. It should be noted that a number of years ago *Stollar* et al. attempted to generate antibodies with pyridoxamine binding sites that catalyze Schiff base formation and transamination.[71] Their lack of success may have been due to the fact that polyclonal antibodies were used.

4. Related Applications in Organic Chemistry

Antibodies may find a number of other applications in organic chemistry. For example, antibodies have recently

been used as templates to control the stereochemical outcome of photoaddition reactions.[72] Antibodies to cyclic peptides might be used to evaluate binding contributions of conformational restriction in drug design. Antibodies to a covalently linked electron donor and acceptor might be used as a scaffold to probe through-bond versus through-space effects on electron-transfer rates. And antibodies to azoalkanes might be used to probe environmental effects on radical reactions. Clearly, the ability to generate a tailored chemical microenvironment in the form of a monoclonal antibody should provide organic chemists with exciting new opportunities.

5. Conclusion

In the short period of time which has elapsed since the first reports of antibody catalysis in 1986,[43, 44] a considerable number of different reactions have been catalyzed using antibodies. The specificities of catalytic antibodies are high and rate enhancements approaching those of enzymes have been demonstrated. A number of general strategies have also evolved for generating catalytic antibodies. The development of antibodies with 10^8-fold or higher rate enhancements will require careful mechanistic analysis of those factors affecting antibody catalysis and the generation of antibodies which *combine several of these features*. This process will not only provide new insight into the nature of molecular recognition and catalysis, but may also afford tailor-made catalysts for applications in chemistry, biology, and medicine.

The author gratefully acknowledges the invaluable contributions of all co-workers named in the citations as well as support of this work by the Office of Naval Research, the National Science Foundation, the Department of Energy, and the National Institutes of Health.

Metal Complexes of Small Cycloalkynes and Arynes

By Martin A. Bennett* and Heinz P. Schwemlein*

Cyclooctyne is the smallest unsubstituted cycloalkyne that can be isolated in the free state and it is more reactive than acyclic alkynes towards transition metal complexes. Smaller cycloalkynes such as cycloheptyne, cyclohexyne, benzyne and cyclopentyne, which are transient molecules in the free state, can be stabilized by coordination either to mononuclear, electron-rich, transition metal-containing fragments, e.g. $[ZrCp_2(PMe_3)]$ and $M(PR_3)_2$ (M = Ni, Pt), or by formation of dinuclear or polynuclear metal complexes, e.g. $[Os_3H_2(CO)_9(C_6H_4)]$ and $[Pt_2(\mu\text{-}PPh_2)(\mu\text{-}C_5H_6)(PPh_3)_3]$. The alkynes can donate between two and four π-electrons to the metal centers, the higher number being favored for the early transition metals. The metal–cycloalkyne and metal–aryne bonds in the mononuclear complexes readily insert molecules containing C=O, C=C, C≡C and C≡N bonds, a feature that may be useful in organic synthesis. The highly unsaturated species 1,4-benzdiyne acts as a bridging ligand between two metal centers in $[\{Ni(Cy_2PCH_2CH_2PCy_2)\}_2(\mu\text{-}C_6H_2)]$.

1. Introduction

Although cyclooctyne **1** is the smallest unsubstituted carbocyclic alkyne that can be isolated in the free state, it is well established that its smaller homologues cycloheptyne **2**, cyclohexyne **3**, and cyclopentyne **4** exist as transient, highly reactive molecules which oligomerize readily in the absence of a suitable trapping agent. Undoubtedly the most extensively studied member of this class is benzyne (1,2-didehydrobenzene) **5**, whose fleeting existence was first established by the classic studies of *Wittig* and *Roberts* in the 1950's, and which can now be regarded as a standard organic reagent. Although the main evidence for the intermediacy of benzyne and small cycloalkynes came initially from trapping and kinetic studies, some of these species have been generated in matrices at low temperature or in the gas phase at low pressure and have been studied by appropriate spectroscopic techniques. Not surprisingly, the lifetime of the cycloalkynes becomes shorter with decreasing ring size, although it can be increased by methyl substitution adjacent to the triple bond. Thus, 3,3,7,7-tetramethylcycloheptyne can be isolated, although 3,3,6,6-tetramethylcyclohexyne cannot. In addition to cyclopentyne, other five-membered ring cycloalkynes that are believed to exist as short-lived intermediates are norbornyne (bicyclo[2.2.1]hept-2-yne) **6**, acenaphthyne **7**, and 2,2,5,5-tetramethyl-1-thiacyclopentyne **8**. However, there is no evidence for the independent existence of the smaller rings cyclobutyne and cyclopropyne. Authoritative reviews on the chemistry of benzyne and cycloalkynes are available.[1–11]

The first attempts to form transition metal complexes of benzyne were made by *Wittig* and *Bickelhaupt* in 1958.[12] They treated 1,2-dilithiobenzene with various transition metal salts but could only isolate biphenyl and polyphenyls. More recent work has shown that benzyne and cycloalkynes form complexes with both early and late transition elements, some of which are stable and can be isolated; others are reactive intermediates. The complexes, not surprisingly, show markedly different chemistry from that of the parent hydrocarbons, and some of them are promising reagents in synthetic organic chemistry. Before discussing these developments, it is useful for purposes of comparison to summarize current views on the bonding in the organic ligands themselves.

2. Structure and Properties of Benzyne and Cycloalkynes

Benzyne in its ground state can be represented as a resonance hybrid of the cycloalkyne structure **5a** and the cumulene structure **5b**, and has been subjected to theoretical calculations at various levels of sophistication.[13–20] Figure 1 shows bond lengths and angles obtained from an ab-initio

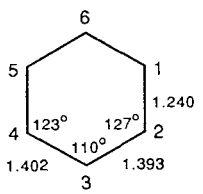

Fig. 1. Calculated bond lengths [Å] and angles [°] in benzyne. [19]

6-31G*-based calculation;[19] the former are corrected values based on the standard C=C and C≡C bond lengths of 1.334 Å and 1.203 Å respectively. The acetylenic bond length C1–C2 generally falls in the range 1.22–1.25 Å and is thus only slightly longer than a normal C≡C bond; there is some disagreement about the trend in the other C–C distances.

The microwave spectrum of benzyne in the gas phase can be simulated using the ab-initio geometry; the predicted and observed rotational constants agree to within 1%.[21] The IR spectrum of benzyne, measured in an argon matrix,[22] shows a C≡C stretching band at 2085 cm^{-1}, which is only slightly lower than the value of ca. 2200 cm^{-1} in acyclic alkynes. However, the C1–C2 bond length of 1.344 Å derived from a force-constant analysis of the IR spectrum[23a] is larger than those obtained from the most recent calculations.[23b]

Structural determinations and spectroscopic studies on isolable seven- and eight-membered cycloalkynes are summarized in Ref. [11], from which most of the following information is taken. In cyclooctyne **1**, the C≡C bond length of 1.23 Å found by electron diffraction is significantly greater than that found in cyclononyne (1.21 Å). The internal C≡C–C bond angle of 158.5° is close to the value of 159.3° determined by X-ray analysis of 1,5-cyclooctadiyne **9**. The

9

corresponding angles in cycloheptyne **2**, cyclohexyne **3**, and cyclopentyne **4** have been calculated as 150.4°/145°, 130.6° and 116.2°, respectively. The IR C≡C stretching frequencies of **1** (measured as a liquid) and **2** (measured in an argon matrix) are 2260/2206 cm^{-1} and 2121 cm^{-1} respectively. The corresponding value for free 3,3,7,7-tetramethylcycloheptyne (2190/2170 cm^{-1}) is higher than for cycloheptyne.

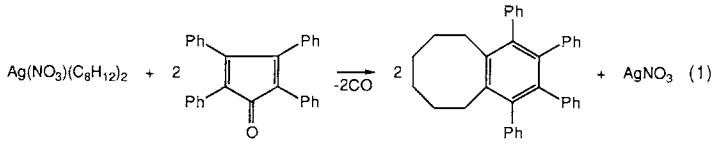
One consequence of *cis*-bending of an alkyne moiety is that the in-plane and out-of-plane π-orbitals are no longer degenerate. The splitting is not detectable by photoelectron spectroscopy in the case of eight-membered rings such as cyclooctyne and 1,5-cyclooctadiyne, but is measured as about 0.3 eV for the more strained seven-membered rings 3,3,7,7-tetramethylcycloheptyne and 3,3,6,6-tetramethylthiacycloheptyne.[25, 26] For cyclohexyne, the splitting is predicted to be ca. 1 eV.[26] Ab-initio calculations on cyclohexyne[27, 28] and cyclopentyne[29] confirm that these species in their ground states should be regarded as highly strained alkynes having diradical character, corresponding to partial breakage of the in-plane π-bond. The predicted values for the C≡C stretching frequencies in **3** are 2003 cm^{-1}[27] or 2169 cm^{-1}[28]; as expected, the predicted value for **4** is much lower (1828 cm^{-1}).[29] The last value can be compared with the frequency of 1930 cm^{-1} tentatively assigned to the C≡C stretching frequency of matrix-isolated acenaphthyne **7**.[30]

A second consequence of *cis*-bending of an alkyne, which is evident from ab-initio calculations of the frontier MO's, is a marked lowering of the LUMO; this is due to efficient mixing of the π*-orbital with a σ*-orbital lying only slightly higher in energy.[31] There is only a small effect on the HOMO. This feature accounts for the characteristic electrophilicity of benzyne and small cycloalkynes e.g. their ready reaction with alcohols, amines, thiols, water, and carbanions, because there is a strong interaction of the benzyne or cycloalkyne LUMO with the HOMO of the nucleophile. In contrast, the benzyne or cycloalkyne HOMO–electrophile LUMO interaction will be normal.

3. Metal Complexes of Small Cycloalkynes

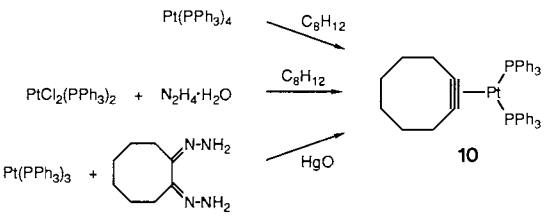
3.1. Cyclooctyne and Related Eight-Membered Rings

Even though it can be isolated, cyclooctyne (C_8H_{12}) is considerably more reactive than acyclic alkynes or larger cycloalkynes, as is shown, for example, by its reactions with



Martin Bennett was born in Harrow, near London, England on August 11, 1935. He graduated from Imperial College of Science, London in 1957 and obtained a Ph.D. from the same institution in 1960 for his work on olefin and carbonyl complexes of transition metals under the direction of Sir Geoffrey Wilkinson. After a postdoctoral year with Professor Arthur Adamson at the University of Southern California, he returned to London as a Turner and Newall Fellow to work with the late Sir Ronald Nyholm at University College London and was appointed to a lectureship there in 1963. In 1967 he moved to the newly formed Research School of Chemistry of the Institute of Advanced Studies at the Australian National University, Canberra, where he is now a Professorial Fellow. He has a long-standing interest in the activation of organic and inorganic molecules by transition metal compounds, especially those of the platinum metals. His work has appeared in about 170 publications. Since 1980 he has been a Fellow of the Australian Academy of Science. He received an award from the Royal Society of Chemistry (1981) as well as the H. G. Smith Medal (1977) and the G. J. Burrows Award (1987) of the Royal Australian Chemical Institute. With the support of the Alexander von Humboldt Foundation, he spent two six-month periods in the Federal Republic of Germany at the Max-Planck-Institut für Kohlenforschung in Mülheim/Ruhr in 1973 and at the Institut für Anorganische Chemie in Würzburg in 1981.

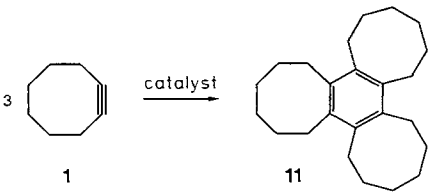
Heinz Schwemlein was born in Balingen, West Germany on June 20, 1955. He studied chemistry at the University of Konstanz (1975–1981), where he received his Diplom degree in 1981 and his Ph.D. in 1985 working with Professor H. H. Brintzinger on ansa metallocenes. He then joined the group of M. A. Bennett at the Research School of Chemistry, ANU, as a postdoctoral fellow. Since 1988 he has been working as a chemist at the analytical center of the Development Center Agro, Ciba-Geigy AG, Switzerland.



Diels–Alder reagents at room temperature. This enhanced reactivity is also evident in its transition metal chemistry. Thus, cyclooctyne metal complexes are more stable with respect to dissociation of the ligand than the complexes of acyclic alkynes. Cyclooctyne also undergoes cyclooligomerization in the presence of transition metal compounds far more readily than do acyclic alkynes.

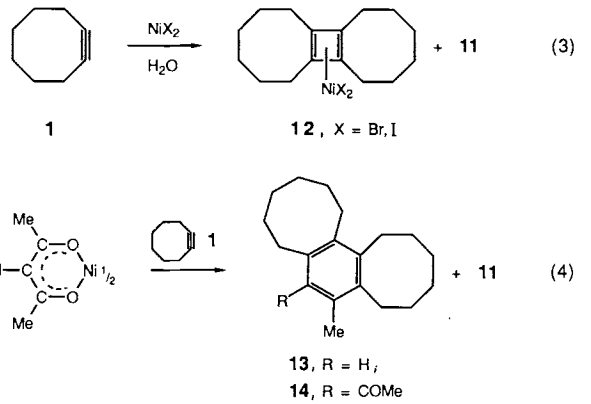
Whereas 4-octyne does not form stable complexes with the univalent coinage metals, cyclooctyne forms air-stable, solid complexes $[CuBr(C_8H_{12})_n]$ (n = 1,2),[32] $[AgNO_3(C_8H_{12})_2]$,[33] and $[AuBr(C_8H_{12})_2]$.[32] These compounds are labile in solution and react with tetracyclone to give the adduct derived from cyclooctyne [Eq. (1)].

(1)



The more stable platinum(0) complex **10** can be prepared in high yield by direct reaction of cyclooctyne at room temperature either with $Pt(PPh_3)_4$[34] or with ethanolic *cis*-$[PtCl_2(PPh_3)_2]$ in the presence of hydrazine hydrate.[32] **10** is formed in lower yield when cyclooctyne is generated in situ by mercuric oxide oxidation of 1,2-cyclooctanedionebis(hydrazone) in the presence of $Pt(PPh_3)_3$[35] (Scheme 1). The

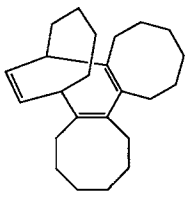
Scheme 1. Synthesis of cyclooctynebis(triphenylphosphane)platinum **10**.



triphenylphosphane ligands of **10** can be replaced by dppe [dppe = ethane-1,2-diylbis(diphenylphosphane)] to give $[Pt(dppe)(C_8H_{12})]$. However, attempts to prepare analogues of **10** by reaction of cyclooctyne with the two-coordinate complexes PtL_2 (L = tBuPh$_2$P, tBu$_2$PhP) were unsuccessful, presumably because of steric hindrance by the bulky phosphanes.[36] In contrast to 4-octyne and other acyclic alkynes, cyclooctyne is not readily displaced from its $Pt(PPh_3)_2$ complex, and **10** does not react with typical Diels–Alder reagents.

Although cyclooctyne is thermally fairly stable in the absence of catalysts, it undergoes cyclotrimerization to tris(hexamethylene)benzene **11** in the presence of many transition metal compounds, including $TiCl_4$,[37] nickel compounds NiX_2 (X = Br, I, CN),[38] nickel(II) acetylacetonate,[38] bis(acrylonitrile)nickel,[32] $Fe(CO)_5$,[39] and $Mo(CO)_6$[40] [Eq. (2)]. The $TiCl_4$-promoted reaction occurs

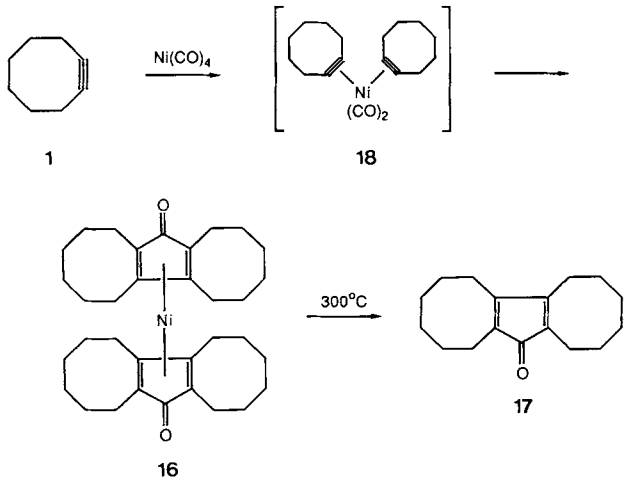
(2)



cleanly and rapidly at room temperature, while that with $Ni(CN)_2$ occurs in boiling THF. When the reaction between cyclooctyne and nickel(II) halides is carried out in the presence of small amounts of water, bis(hexamethylene)cyclobutadiene-nickel(II) complexes **12** are obtained in low yield, in addition to **11** [Eq. (3)].[38] Also, in the reaction of cyclooctyne with nickel(II) acetylacetonate, small amounts of the bis(hexamethylene)aromatic compounds **13** and **14** are formed [Eq. (4)].[38] These are presumably derived by a

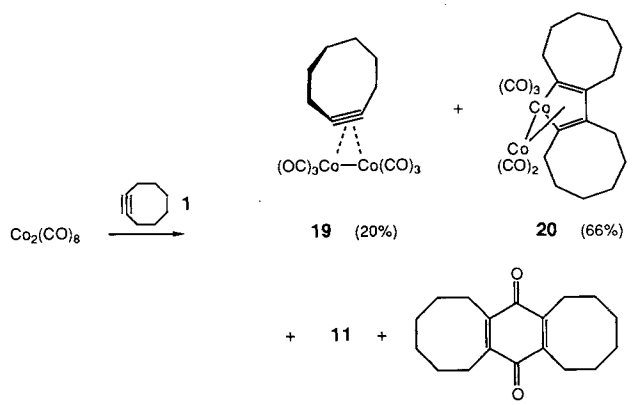
(3)
(4)

metal-promoted condensation of two cyclooctyne molecules with one of the β-diketonato ligands and subsequent loss of water or acetic acid, since cyclooctyne does not react with free acetylacetone. It is noteworthy that, although the cyclooligomerization of acyclic alkynes can be catalyzed by Ni^0 and Ni^{II} compounds, only strained cycloalkynes such as cyclooctyne can give isolable cyclobutadiene complexes by direct reaction with nickel(II) halides.



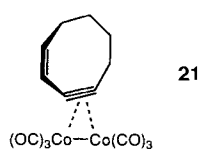
Reaction of $[Pt(PPh_3)_2(C_8H_{12})]$ **10** with cyclooctyne in a 1:1 mol ratio at 75 °C gives a non-aromatic cyclotrimer for which structure **15** has been suggested;[32] when the relative amount of cyclooctyne is increased, a mixture of **11** and **15** is formed. Since $[Pt(PPh_3)_2$(acenaphthylene)] catalyzes only the formation of **11** from cycloctyne, **10** is clearly the species responsible for the generation of **15**, but the topic deserves further investigation.

15



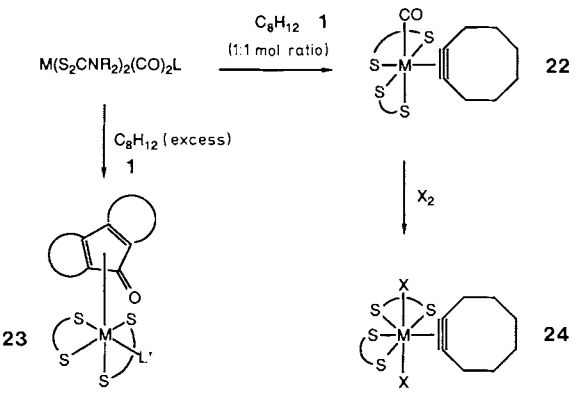
The reactions of cyclooctyne with metal carbonyl compounds are characterized by the ready oligomerization of the alkyne with CO. Thus, the final product from the reaction with $Ni(CO)_4$ in ether is the cyclopentadienone complex **16**, from which dodecahydrocyclopentadicycloocten-13-one (**17**) is liberated at 300 °C (Scheme 2).[38] There is evidence for an intermediate bis(cyclooctyne) complex **18**.

In the dark, both $Fe(CO)_5$ and $Mo(CO)_6$ slowly catalyze the formation of **11** from cyclooctyne. Under UV irradiation, $Fe(CO)_5$ and cyclooctyne form mainly the $Fe(CO)_3$ complex of **17** and dodecahydrobenzo[1,2:4,5]dicyclo-



Scheme 2. Formation of dodecahydrocyclopentadicycloocten-13-one **17**.

octene-7,14-dione.[39] Under similar conditions reaction of cyclooctyne with $Mo(CO)_6$ gives mainly **11** and dodecahydrobenzo[1,2:4,5]dicyclooctene-7,14-diol, together with smaller amounts of the quinone and a complex $[Mo(CO)(C_8H_{12})_3]$.[40] Cyclooctyne reacts with $Co_2(CO)_8$ in ether or pentane at room temperature to give the μ-alkyne complex **19** of the usual type, together with a complex of empirical formula $[Co_2(CO)_5(C_8H_{12})_2]$, which was shown by X-ray crystallography to be a cobaltacyclopentadiene **20** (Scheme 3).[41] Such complexes have not been observed hith-



Scheme 3. Reaction of octacarbonylcobalt with **1**.

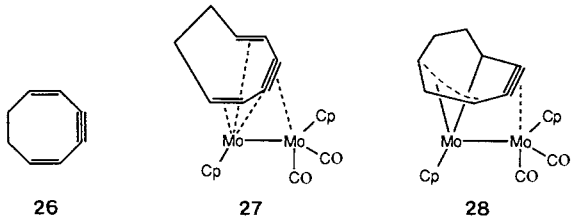
erto in the reactions of $Co_2(CO)_8$ with acyclic alkynes, though they may be precursors to the well-known "fly-over" complexes $[Co_2(CO)_4(alkyne)_3]$ that are formed under forcing conditions.[42] Both **19** and **20** separately catalyze cyclotrimerization of cyclooctyne to **11**. The formation of **20** and other oligomerization products can be largely suppressed by adding $Co_2(CO)_8$ to cyclooctyne in a 1:1 molar ratio, and **19** can then be isolated in 71% yield.[43] The $Co_2(CO)_6$ complex of the even more highly strained *cis*-cyclooct-1-en-3-yne **21** has been made similarly, but

attempts to liberate the alkyne from the complex by ceric ion oxidation led to polymerization, even at −40 °C.[43]

Cyclooctyne forms stable complexes with molybdenum and tungsten in oxidation states +2 and +4. Deep green dialkyldithiocarbamato complexes **22** are obtained upon reaction of cyclooctyne with $[M(S_2CNR_2)_2(CO)_2L]$ (M = Mo, L = PPh_3; M = W, L = CO) in a 1:1 mol ratio (Scheme 4).[44] The highly deshielded alkyne ^{13}C resonances and the

Scheme 4. Reactions of cyclooctyne-molybdenum and -tungsten complexes. L = CO, PPh_3; L' = CO, C_8H_{12}; $\widehat{S\,S}$ = Me_2NCS_2, Et_2NCS_2; X = Br, I; M = Mo, W.

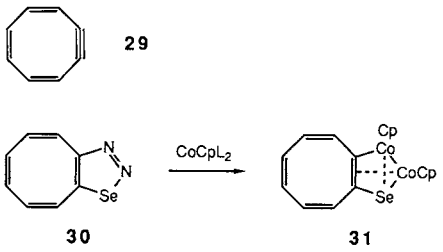
failure of the complexes to react with CO and tertiary phosphanes suggest that in **22** cyclooctyne donates four electrons from its orthogonal π-orbitals to the metal atom. In this respect, complexes **22** resemble the corresponding acyclic alkyne complexes. The latter, however, react only under forcing conditions with an excess of alkyne (CO being displaced) to give the bis(alkyne) complexes $[M(alkyne)_2(S_2CNR_2)_2]$. In contrast, complexes **22** react readily with an excess of cyclooctyne, with retention of CO, to give complexes **23** (Scheme 4).[45] Further, complexes **22** are readily oxidized by iodine or bromine to give the cyclooctyne complexes **24** of molybdenum(IV) or tungsten(IV),[44] the acyclic alkyne analogues of which are unknown. Likewise, the cyclooctyne molybdenum(IV) complexes $[MoO(S_2CNR_2)_2(C_8H_{12})]$ (R = Me, Et) do not readily lose their coordinated alkyne, in contrast to the behavior of the corresponding complexes of C_2H_2, PhC_2H and PhC_2Ph.



Cyclooctyne also forms divalent metal-tertiary phosphane complexes **25** [Eq. (5)], but attempted halogenation of these compounds led only to decomposition.

$$[MBr_2(CO)_n(PEt_3)_2] \xrightarrow{C_8H_{12},\ 1} [MBr_2(CO)(PEt_3)_2(C_8H_{12})] \quad (5)$$

M = Mo, n = 2; M = W, n = 3 — **25**

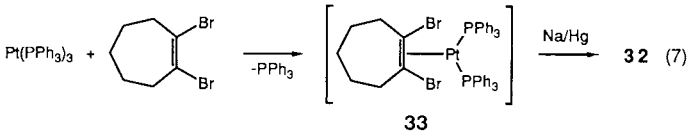


The unknown 1,5-cyclooctadien-3-yne **26** can be stabilized in the form of a purple dimolybdenum complex **27**, which is formed by heating $[\{Mo(Cp)(CO)_3\}_2]$ with cyclooctatetraene in *n*-octane.[46] The alkyne unit lies across a Mo–Mo bond, the two C=C bonds being coordinated to one of the molybdenum atoms. Clearly the formation of **27** requires hydrogen migration in the C_8H_8 ring, and such a process also occurs when **27** is dissolved in polar solvents. The product is the

thermodynamically stable isomer **28** in which the bridging alkyne unit is retained but there is now a η^1, η^3-interaction of the remaining C=C bonds with one of the molybdenum atoms.

26 **27** **28**

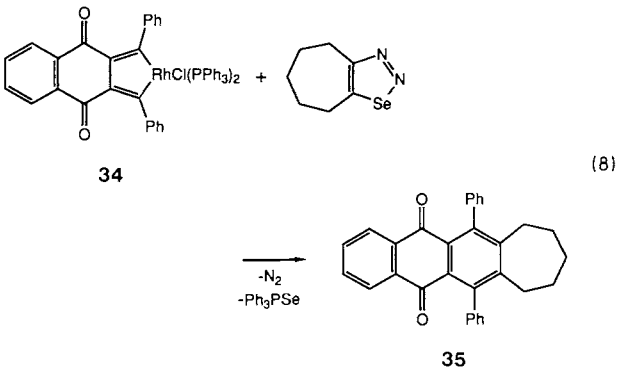
An attempt to stabilize the unknown 1,3,5-cyclooctatrien-7-yne (**29**) by metal complexation was unsuccessful. Treatment of the 1,2,3-selenadiazole **30** with $CoCpL_2$ (L = PPh_3, C_2H_4) gave a green-black complex **31** in which a C_8H_6Se fragment is attached to a Co_2Cp_2 unit [Eq. (6)].[47]



29

30 **31** (6)

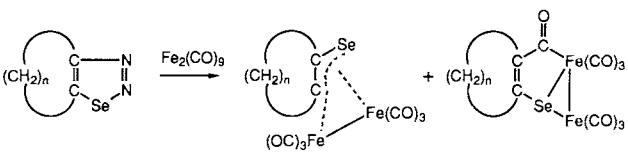
3.2. Cycloheptyne and Related Seven-Membered Rings



Although free cycloheptyne, C_7H_{10}, cannot be isolated, its platinum(0) complex **32** has been made in 20% yield by mercuric oxide oxidation of 1,2-cycloheptanedionebis(hydrazone) in the presence of $Pt(PPh_3)_3$, and in 80% yield by reaction of $Pt(PPh_3)_3$ or $Pt(PPh_3)_4$ with 1,2-dibromocycloheptene in the presence of 1% sodium amalgam (Scheme 5).[35,48] The first reaction undoubtedly involves trapping of transient cycloheptyne by $Pt(PPh_3)_3$. This may hold also for the second reaction, since cycloheptyne can be generated by alkali- or alkaline-earth metal reduction of 1,2-dibromocycloheptene. Recent work (Sections 3.3, 3.4), however, suggests that a more likely mechanism is reduction of a transient complex **33** [Eq. (7)]. Chelating phosphanes

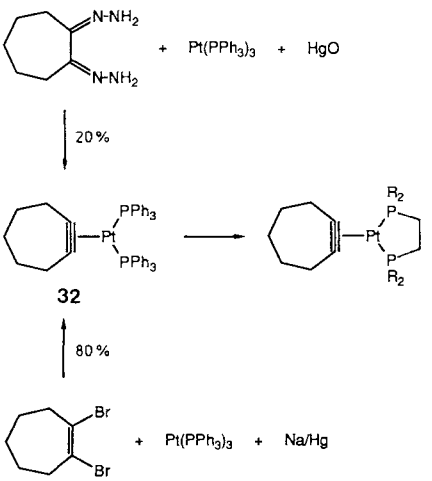
33 **32** (7)

$R_2PCH_2CH_2PR_2$ (R = Ph, Me) displace PPh_3 from **32** without removing the cycloalkyne (Scheme 5).



The palladium(0) analogue of **32** has been made from $Pd(PPh_3)_4$, 1,2-dibromocycloheptene, and 1% Na/Hg, but there have been no other reported attempts to form cycloheptyne metal complexes by generating the cycloalkyne in the presence of low-valent metal complexes. Clearly, a low-valent metal complex may not survive the drastic thermal or oxidizing conditions necessary to generate the cycloalkyne and, in addition, trapping by the complex must compete with oligomerization. Nevertheless, cycloheptyne, generated by the thermal decomposition of 4*H*-5,6,7,8-tetrahydro-1-selena-2,3-diazaazulene, does insert into the rhodium–carbon bonds of the metallacyclopentadiene **34** to give the anthraquinone **35** in 47% yield[49] [Eq. (8)]. The selenadiazoles

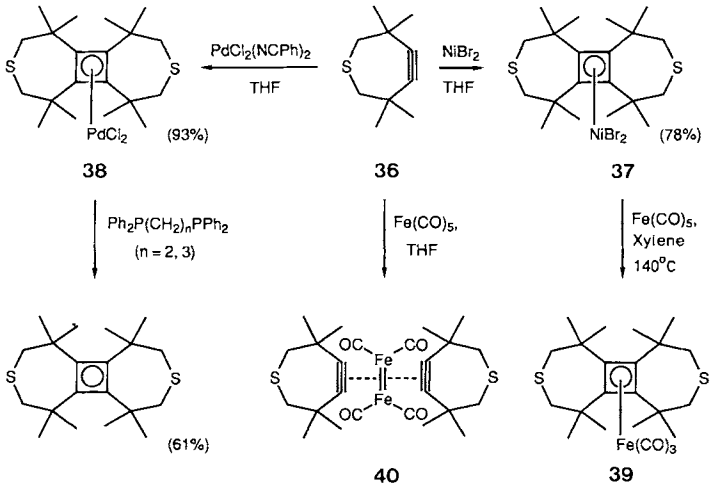
34 (8)



35

themselves react with metal-carbonyls to give stable complexes which still contain selenium (Scheme 6).[50]

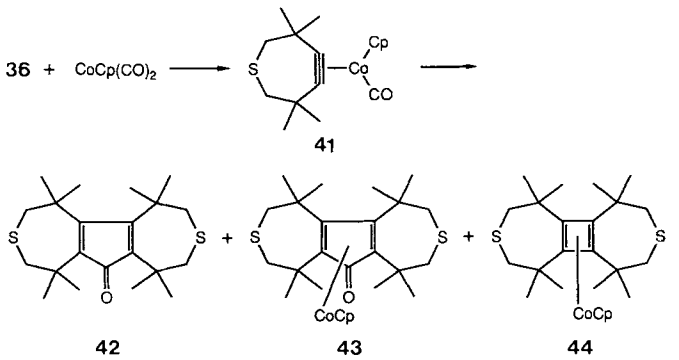
Scheme 6. Reaction of selenadiazoles with $Fe_2(CO)_9$.



The isolable strained cycloalkyne 3,3,6,6-tetramethylthiacyclohept-4-yne **36** dimerizes on reaction with anhydrous $NiBr_2$ or $[PdCl_2(NCPh)_2]$ to give deep violet and yellow crystals, respectively, of the corresponding monomeric cyclobutadiene metal dihalide complexes **37** and **38** in high yields[51,52] (Scheme 7). The cyclobutadiene can be transferred from Ni to Fe by heating with $Fe(CO)_5$[53] and can be displaced from **38** (but not from **37**) by heating with $Ph_2P(CH_2)_nPPh_2$ (n = 2,3). As expected, the free cyclobuta-

Scheme 5. Synthesis of cycloheptyne-platinum(0) complexes. R = Ph, Me.

diene has alternating long and short C–C bonds (1.600, 1.344 Å),[54] whereas the C–C bond lengths in **38**[55] and in the $Fe(CO)_3$ complex **39**[53] are almost equal at ca. 1.45–1.48 Å.

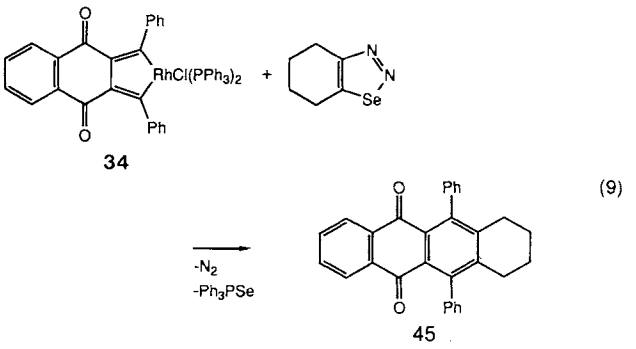


Direct reaction of $Fe(CO)_5$ with **36** gives complex **40**, in which two cycloalkyne units lie across an $Fe_4(CO)_4$ unit; the

Scheme 7. Reactions of 3,3,6,6-tetramethylthiacyclohept-4-yne **36** with transition metal compounds.

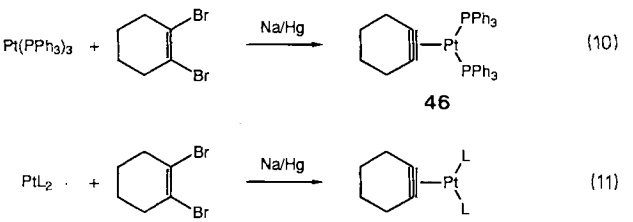
remarkably short Fe–Fe distance, 2.225(3) Å, indicates the presence of a double bond between the metal atoms.[56]

At low temperatures **36** reacts with $[CoCp(CO)_2]$ to give a mono-alkyne complex **41** almost quantitatively; on heating, a mixture of the cyclopentadienone **42**, its CoCp complex **43**, and the cyclobutadiene complex **44** is formed, presumably via **41** as intermediate (Scheme 8).[57]



Scheme 8. Reaction of 3,3,6,6-tetramethylthiocyclohept-4-yne **36** with the complex $CoCp(CO)_2$.

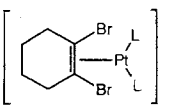
3.3. Cyclohexyne and Related Six-Membered Rings



Cyclohexyne is much shorter-lived than cycloheptyne and most attempts to form metal complexes by generating it in the presence of a low-valent metal complex have been unsuccessful. However, thermally generated cyclohexyne inserts into the Rh–C bonds of **34** to give the anthraquinone **45** in 38% yield [Eq. (9)].[49]

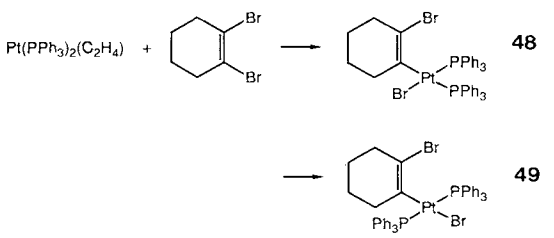
The cyclohexyne-platinum(0) complex **46** can be obtained as colorless, air-stable crystals in 70–90% yield by reaction of 1,2-dibromocyclohexene, 1% sodium amalgam, and

(9)



$Pt(PPh_3)_3$ [Eq. (10)].[35,48] The corresponding complexes $PtL_2(C_6H_8)$ (L = P-*t*Bu_2Ph, P-*t*$BuPh_2$) are formed similarly in ca. 30% yield by a similar reaction employing the two-coordinate complexes PtL_2 in place of $Pt(PPh_3)_3$ [Eq. (11)].[36] The cyclohexyne-palladium(0) complex $[Pd(PPh_3)_2(C_6H_8)]$ has been prepared similarly in 25% yield from $Pd(PPh_3)_4$.[35]

(10)

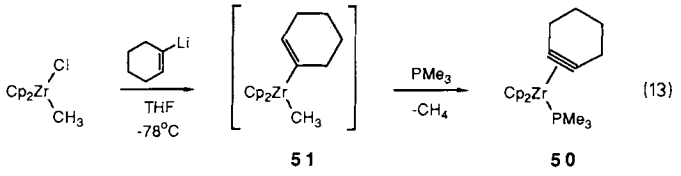


(11)

These reactions probably do not proceed via the free cycloalkyne but by rapid reduction of a transient 1,2-dibromocyclohexene complex **47** (see Section 3.4).

47

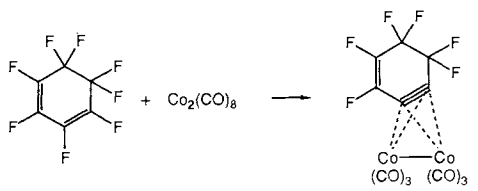
In the absence of sodium amalgam, 1,2-dibromocyclohexene reacts at room temperature with the ethylene complex $[Pt(PPh_3)_2(C_2H_4)]$ to give the *cis*-oxidative addition product **48** which isomerizes slowly to the *trans*-compound **49** [Eq. (12)]. Presumably **48** is formed via **47**, though the latter



(12)

has not been detected. Neither **48** nor **49** are reduced by 1% sodium amalgam to **46**.[58]

The phosphane ligands of **46** can be replaced without affecting the coordinated cyclohexyne by diphenylmethylphosphane and by various ditertiary bisphosphanes

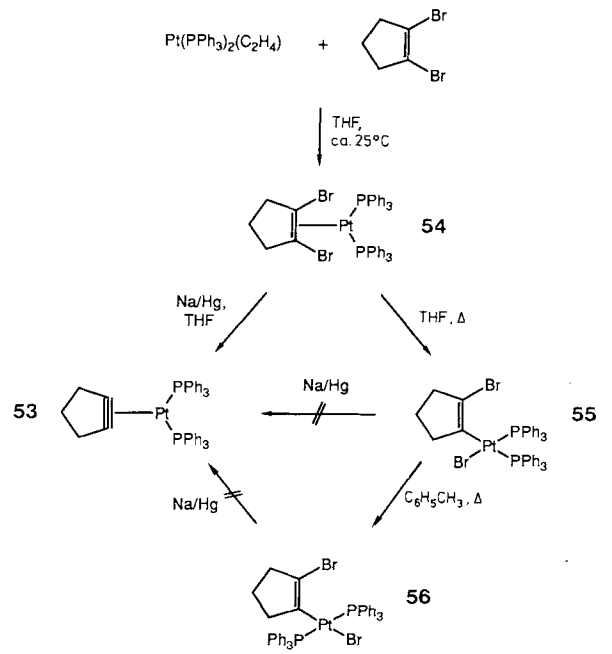


e.g. $Ph_2P(CH_2)_nPPh_2$ (n = 2,3,4), (*Z*)-$Ph_2PCH=CHPPh_2$, and $Me_2PCH_2CH_2PMe_2$.[35, 36, 59]

So far, only one other transition element, zirconium, has been reported to form a mononuclear cyclohexyne complex. Treatment of [ZrClMe(η-Cp)$_2$] with 1-cyclohexenyllithium at low temperature and subsequent addition of trimethylphosphane gives the cyclohexyne-zirconium complex **50** in 60% yield as an air- and moisture-sensitive solid.[60] The reaction proceeds by elimination of methane from the (1-cyclohexenyl)(methyl)zirconocene **51** to give a coordinatively unsaturated zirconocene cyclohexyne, [Zr(η-C_5H_5)$_2$(C_6H_8)], which is trapped by PMe_3 [Eq. (13)].

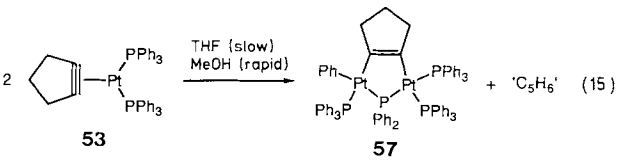
51 50 (13)

A remarkable example of stabilization of a small cycloalkyne by coordination is provided by the reaction of octafluoro-1,3-cyclohexadiene, C_6F_8, with $Co_2(CO)_8$ at 80 °C. The resulting dinuclear complex **52** (15% yield) contains hexafluorocyclohex-1-en-3-yne bound to two cobalt atoms by its triple bond, which is oriented at right-angles to the Co-Co axis in the usual way [Eq. (14)].[61]



52 (14)

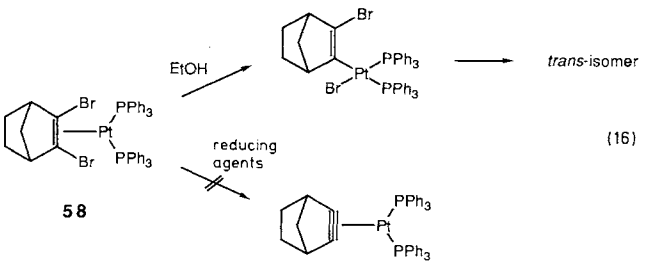
Other metal-carbonyl or organometallic precursors tested did not react similarly with C_6F_8 and no attempts to extend this interesting reaction have been reported.



3.4. Cyclopentyne and Related Five-Membered Rings

Early attempts to prepare cyclopentynebis(triphenylphosphane)platinum **53** similarly to the cyclohexyne analogue **46** by treating a mixture of 1,2-dibromocyclopentene and $Pt(PPh_3)_3$ with 1% sodium amalgam were unsuccessful.[35] Recently, however, **53** has been isolated as a colorless, very reactive solid as shown in Scheme 9.[58] Reaction of ethylene bis(triphenylphosphane)platinum with 1,2-dibromocyclopentene gives the olefin complex **54**, which isomerizes successively to the *cis*- and *trans*-oxidative addition products **55** and **56**, respectively. This process is slow at room temperature, so that **54** (in contrast to the corresponding 1,2-dibromocyclohexene complex **47**, cf. Section 3.3) can be isolated. Reduction of **54** with 1% sodium amalgam in THF at room temperature gives **53**, which has been fully characterized by ^1H, ^{13}C, and ^{31}P NMR spectroscopy (Section 3.5). This complex loses a C_5H_6 fragment (slowly in THF, rapidly in methanol at room temperature) and undergoes P–Ph bond

Scheme 9. Synthesis of cyclopentynebis(triphenylphosphane)platinum **53**.

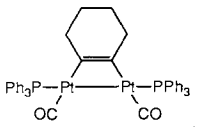


cleavage, presumably according to Equation (15), to give the dinuclear complex **57** containing bridging cyclopentyne (or cyclopentene-1,2-diyl) and PPh_2 groups, as shown by X-ray crystallography.[62]

53 57 (15)

Complexes **55** and **56** are not reduced to **54** by 1% sodium amalgam. Similar lack of reactivity is found in the six-membered ring series (Section 3.3), so that these oxidative addition products cannot be intermediates in the formation of the cycloalkyne complexes. The results in the five-membered ring series strongly suggest that the six- and seven-membered ring analogues of **54**, i.e. **47** and **33**, are intermediates in the formation of the corresponding cycloalkyne complexes **46** and **32**, though they have not been detected or isolated.

Attempts to stabilize norbornyne (**6**) by a similar method have been unsuccessful.[63] Reaction of 2,3-dibromobicyclo[2.2.1]hept-2-ene with $Pt(PPh_3)_3$ or [$Pt(PPh_3)_2(C_2H_4)$] gives the olefin complex **58**, which, like **53**, rearranges slowly to the *cis*- and, finally, the *trans*-oxidative addition products [Eq. (16)]. Unlike **53**, however, **58** is unaffected by sodium amalgam, naphthalenesodium, or *n*-butyllithium.

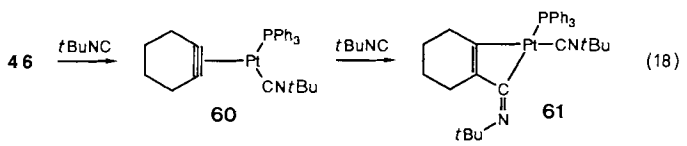


58 (16)

3.5. Reactivity of Cycloalkyne-Metal Complexes

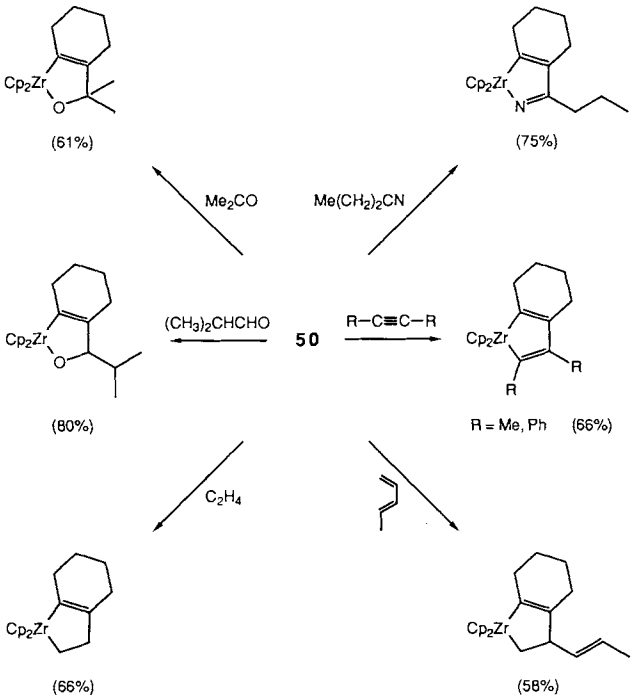
The preparative results show clearly that six- to eight-membered ring cycloalkynes, in general, are less easily displaced from their metal complexes than are the corresponding acyclic alkynes. Chelating ditertiary phosphanes replace only PPh_3 from the $Pt(PPh_3)_2$ complexes of cyclohexyne, cycloheptyne, and cyclooctyne (**46**, **32** and **10**, respectively).[35, 59] The only π-acceptor ligands that seem to be able to displace cyclohexyne completely from **46** are PF_3 and tetracyanoethylene (TCNE) [Eq. (17)], and the fate of the cyclohexyne has not been established.

$$Pt(PF_3)_2(PPh_3)_2 \xleftarrow{PF_3} \mathbf{46} \xrightarrow{TCNE} Pt(TCNE)(PPh_3)_2 \qquad (17)$$



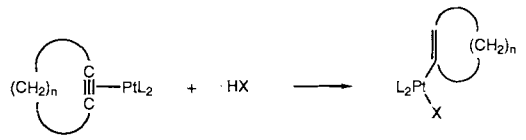
Interestingly, carbon monoxide is inert towards the cycloheptyne complex **32**, but it reacts with the cyclohexyne complex **46** to form the dinuclear μ-cyclohexyne- or cyclohexene-1,2-diyl-platinum(I) complex **59**, together with unidentified carbonyltriphenylphosphane platinum(0) complexes. Again,

59



the fate of the displaced cyclohexyne is unknown.[35] The reaction is reminiscent of the formation of the cyclopentene-1,2-diylcomplex **57** from cyclopentynebis(triphenylphosphane)platinum **53**. It suggests that mononuclear metal complexes of the smaller cycloalkynes are strained and, at least in the case of platinum, that the strain can be relieved by formation of a four-membered dimetallacycle containing two M–C σ-bonds.

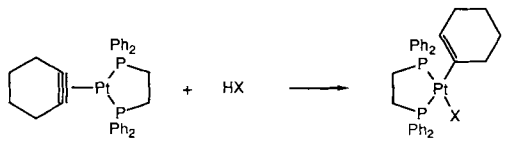
One consequence of this strain is that simple unsaturated molecules readily insert into the cycloalkyne-metal bond. Thus, **47** reacts with *tert*-butyl isocyanide at room temperature to give first the substitution product **60** and then the insertion product **61** [Eq. (18)]; **32** does not react similarly.[35]



(18)

The cyclohexyne-zirconium complex **50** undergoes insertion reactions of this type with many substrates, including alkenes, alkynes, aldehydes, ketones and nitriles, towards which the platinum complex **46** is inert (Scheme 10). Probably, in the first step, the trimethylphosphane ligand of **50** is displaced by the unsaturated molecule, and coupling then occurs. In some cases the same result can be achieved by generating $[Zr(\eta\text{-}Cp)_2(C_6H_8)]$ in situ at low temperature and treating it with the unsaturated compound.[60]

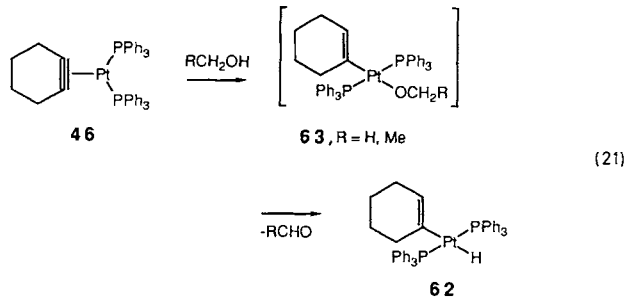
Scheme 10. Insertion reactions of $[ZrCp_2(PMe_3)(C_6H_8)]$ **50**.



The bis(triphenylphosphane)platinum(0) complexes of cyclohexyne (**46**) and cycloheptyne (**32**), and their ditertiary bisphosphane analogues, are readily protonated by strong acids HX (X = Cl, CO_2CF_3) to give η^1-cycloalkenylplatinum(II) complexes [Eq. (19)]. Excess of acid cleaves the Pt–C σ-bond to give PtX_2L_2.

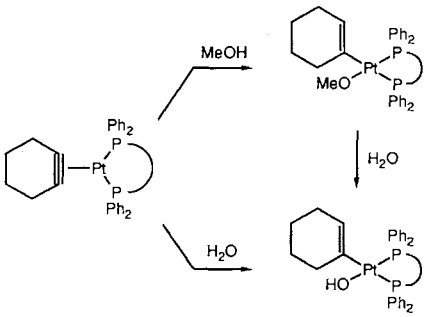
(19)

n = 4, 5



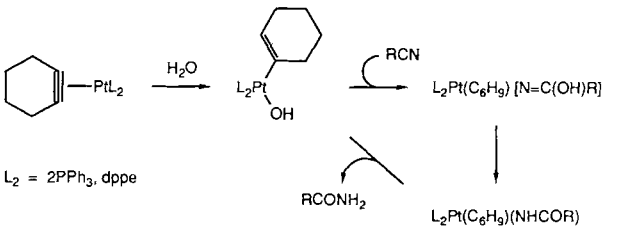
Similar reactions are well-known for acyclic alkyne-platinum(0) complexes. However, the cyclohexyne compounds are unique in this series in being protonated irreversibly even by weak acids. For example, $[Pt(dppe)(C_6H_8)]$ reacts with thiophenol, *p*-cresol, nitromethane, acetonitrile, phenylacetonitrile, carboxamides, and (in the presence of water) methyl ketones [Eq. (20)].[35, 59]

(20)



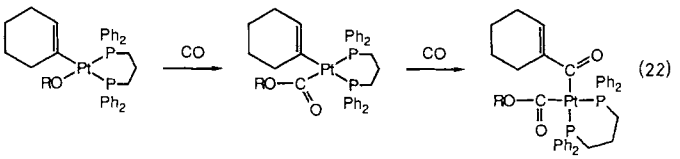
X = SPh, *p*-OC_6H_4Me, CH_2NO_2, CH_2CN, CH(Ph)CN

46 also reacts readily with methanol or ethanol under reflux to form the η^1-cyclohexenyl hydrido complex **62**. Initially **46** is probably protonated to give an alkoxide **63** which then undergoes β-hydride migration and elimination of aldehyde [Eq. (21)]. The corresponding complexes



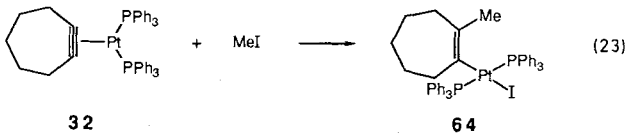
(21)

[Pt(P⌒P)(C$_6$H$_8$)] with ditertiary bisphosphane ligands (P⌒P) react with methanol to give isolable methoxoplatinum(II) species [Pt(OMe)(P⌒P)(C$_6$H$_9$)] that do not undergo β-elimination even on prolonged heating. They are readily hydrolyzed to monomeric hydroxo complexes [Pt(OH)(P⌒P)(C$_6$H$_9$)], which can also be obtained directly from [Pt(P⌒P)(C$_6$H$_8$)] and water (Scheme 11).[35, 48, 59]



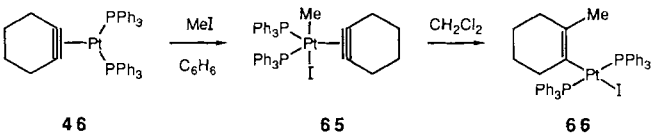
Scheme 11. Reactions of [Pt(P⌒P)(C$_6$H$_8$)] with water and methanol.

The ability of **46** and [Pt(C$_6$H$_8$)(dppe)] to catalyze the formation of carboxamides from nitriles and water undoubtedly depends on the initial formation of hydroxoplatinum(II) complexes (Scheme 12),[64] even though [Pt(OH)(C$_6$H$_9$)(PPh$_3$)$_2$] has never been isolated from the reaction of water with **46**.



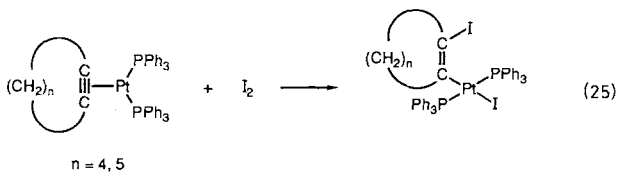
Scheme 12. Catalysis of the synthesis of carboxamides from water and cyanides by cyclohexyne-platinum(0) complexes.

The discovery of these hydroxy compounds has led to the preparation of many monomeric alkyl- or aryl-hydroxoplatinum(II) complexes whose chemistry is outside the scope of this review.[64] We note here that the η^1-cyclohexenylhydroxy- and methoxy-platinum(II) complexes readily insert CO to give the corresponding hydroxycarbonyl and methoxycarbonyl complexes. Further, when the ditertiary phosphane is Ph$_2$P(CH$_2$)$_3$PPh$_2$, insertion of CO into the Pt–C σ-bond also takes place to give acyl cyclohexenyl complexes [Eq. (22)].[65]



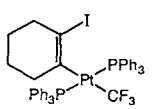
(22)

Electrophiles such as methyl iodide and iodine also add to cycloalkyne-PtL$_2$ complexes.[66] Thus, methyl iodide reacts with **32** to give the 2-methylcycloheptenyl complex **64** as the main product [Eq. (23)] together with a small amount of *trans*-[PtIMe(PPh$_3$)$_2$]. The latter is the only organoplatinum compound obtained from [Pt(PPh$_3$)$_2$(PhC$_2$Ph)] and methyl iodide.



(23)

The first step in this "insertion" reaction is probably oxidative addition of methyl iodide to the metal atom. In the case of the reaction of methyl iodide with the cyclohexyne complex **46** in benzene, the oxidative addition product **65** can be isolated; it rearranges to the 2-methylcyclohex-1-enyl complex **66** in dichloromethane [Eq. (24)].



(24)

Iodine reacts similarly with **33** and **47** to give mainly the *trans*-2-iodocycloalk-1-enyl complexes [Eq. (25)], whereas [Pt(C$_6$H$_8$)(dppe)] and [Pt(C$_7$H$_{10}$)(dppe)] give mainly PtI$_2$(dppe).

(25)

Trifluoromethyl iodide acts as a source of positive iodine in its reaction with **46**: the product is the 2-iodocyclohex-1-enyl complex **67**.[66]

67

3.6. Structure, Spectroscopic Properties and Bonding of Some Cycloalkyne-Metal Complexes

Important parameters obtained from X-ray structural analyses of cycloalkyne-metal complexes are summarized in Table 1. The basic geometry and structural parameters relating to the MC_2 unit of the cycloalkyne-$Pt(PPh_3)_2$ complexes **10**, **32** and **46**[48, 67–69] are very similar to those of the complex $[Pt(PPh_3)_2(Ph-C\equiv C-Me)]$ **68**.[70] All four complexes have an almost planar coordination geometry. The C≡C distances in all four complexes (1.28–1.30 Å) do not differ significantly and are longer than a normal C≡C bond. The bend-back angle of the substituents at the alkyne carbon atom is very similar (34–41°) for **10**, **32** and **68**, but the smaller ring in **46** causes an increase to 53°. Similarly large bend-back angles are observed in **50**[60] and **52**.[61] The C–C–C bond angles in the six-membered rings of **46** and **50**, and in the eight-membered ring of **10**, are close to the expected tetrahedral value; this probably indicates release of strain when the cycloalkyne is bound to the metal atom. Surprisingly, however, some of the ring C–C–C bond angles in the cycloheptyne complex **32** are considerably distorted and some of the C–C distances are substantially shorter than normal C–C single bonds.

Table 1. Selected structural parameters for the alkyne metal complexes $[Pt(PPh_3)_2(C_8H_{12})]$ **10**, $[Pt(PPh_3)_2(C_7H_{10})]$ **32**, $[Pt(PPh_3)_2(C_6H_8)]$ **46**, $[Pt(PPh_3)_2(PhC_2Me)]$ **68**, $[ZrCp_2(PMe_3)(C_6H_8)]$ **50** and $[Co_2(CO)_6(C_6F_6)]$ **52**.

[a] Average value.

The bonding in mononuclear alkyne-metal complexes can be described similarly to that in alkene-metal complexes.[71, 72] Forward donation from the filled alkyne $\pi_{\parallel}$ orbital into a vacant metal orbital is supplemented by back donation from a filled metal π^* orbital to an empty π^* orbital of the alkyne. In contrast to alkenes, an additional pair of electrons is available from the orthogonal $\pi_{\perp}$ orbital, so that alkynes can donate up to four electrons, especially to earlier transition elements, which have suitable vacant d-orbitals.[73] Infrared C≡C stretching frequencies[72] and the ^{13}C chemical shifts of the alkyne carbon atoms (δ_c)[74] are useful qualitative indicators of the nature of alkyne–metal bonding. The shift $\Delta\tilde{\nu}$(C≡C) relative to $\tilde{\nu}$(C≡C) of the free alkyne gives a rough estimate of the extent to which the C≡C bond is modified by coordination.[72] For cyclooctyne complexes (Table 2), the $\Delta\tilde{\nu}$(C≡C) values range from ca. 150–600 cm^{-1}, being lowest for the labile complexes of Cu^I, Ag^I and Au^I. The chemical shifts of the alkyne carbon atoms correlate qualitatively with the number of π-electrons donated by the alkyne to the metal, ranging from $\delta = 100-140$ for two-electron donors to $\delta = 200-240$ for four-electron donors.[74] The cyclooctyne complexes of molybdenum and tungsten provide a good illustration of the trend. Thus, in the complexes **22** (R = Me, Et) and **25**, cyclooctyne should donate four π-electrons if the metal atoms are to reach the 18 electron configuration, and this is borne out by the ^{13}C chemical shifts (Table 2). In contrast, cyclooctyne behaves as a two π-electron donor in the complexes **23**. In the oxomolybdenum(IV) complexes $[MoO(S_2CNR_2)_2(C_8H_{12})]$, cyclooctyne has to compete with the strongly π-donor oxo-ligand for the vacant metal d_{xy}-orbital, and the ^{13}C chemical shift suggests that cyclooctyne donates about three π-electrons in this compound.[44]

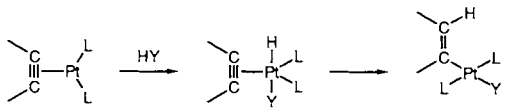
[a] Not located. [b] M = Mo. [c] M = W.

The complex $[Mo(CO)(C_8H_{12})_3]$[40] seems to be exceptional. For the 18-electron configuration to be achieved, each alkyne should donate on average 3⅓ electrons to the metal, but the reported ^{13}C chemical shifts (δ = 95.0, 106.8) are more typical of a two-electron donor and are very different from those of the hex-3-yne complex $[W(CO)(EtC_2Et)_3]$ (δ = 170.8, 191.1).[74]



The $Pt(PPh_3)_2$ complexes of acyclic alkynes show $\tilde{\nu}$(C≡C) frequencies of ca. 1800 cm^{-1} and their C≡C ^{13}C NMR signals lie in the range $\delta = 100-120$, so they can be classified as 16-electron platinum(0) complexes **A** in which the alkyne is a two-electron donor. Alternatively, the alkyne can be considered to bind to the metal atom by two σ-bonds giving a dicarbanion of platinum(II) or a platinacyclopropene **B**. It can be shown that the two formulations are equivalent when

the metal-alkyne interaction is very strong.[71, 75] The bending-back from linearity of the alkyne substituents on coordination (ca. 40°) is believed to be a consequence of back-bonding and gives an indication of the extent to which the alkyne is perturbed on coordination.[75, 76] In the case of

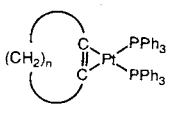
small cycloalkynes, the substituents suffer less distortion relative to the free ligand on coordination to $Pt(PPh_3)_2$ (ca. 12° for cyclohexyne, cycloheptyne and cyclooctyne, based on the C–C≡C angles for the free ligands given in Section 2.1). This must be an important factor that contributes to the great stability of the complexes.

The bend-back angle from linearity of 53° in cyclohexyne complexes probably indicates exceptionally strong metal–ligand back-bonding. For **46** this probably is due to good overlap of the low-lying LUMO of cyclohexyne (Section 2) with the HOMO of $Pt(PPh_3)_2$ (mainly $d_{x^2-y^2}$ in character), while the σ-bond is formed by overlap of the energetically higher HOMO of cyclohexyne with the LUMO of $Pt(PPh_3)_2$ comprising $6p_y$, $6p_z$ and 6s orbitals. It is not yet clear why the cyclohexyne-platinum(0) complexes should be so reactive towards weak acids. For acyclic alkyne complexes, protonation with HCl or CF_3CO_2H probably occurs first at the metal atom to give a hydridoplatinum(II) species **69**; the hydride then migrates to the coordinated alkyne [Eq. (26)].[77] Back-bonding to the alkyne in the corresponding hydrido intermediate [Eq. (26)] may be strong enough to

(26)

69

allow attachment of strongly electron-donating anions derived from weak acids.



The chemical shifts of the alkyne C atoms and the coupling constants $^1J_{PtC}$ are greater in $[Pt(PPh_3)_2(cycloalkyne)]$ than in $[Pt(PPh_3)_2(MeC_2Me)]$, and both increase with decreasing ring size (Table 3). The trend in $^1J_{PtC}$ is consistent

Table 3. Comparison of IR and NMR data for the C≡C units of the cyclic and acyclic alkyne complexes $[Pt(PPh_3)_2(C_7H_{10})]$ **32**, $[Pt(PPh_3)_2(C_6H_8)]$ **46**, $[Pt(PPh_3)_2(C_5H_6)]$ **53**, $[Pt(PPh_3)_2(MeC_2Me)]$, $[Pd(PPh_3)_2(C_7H_{10})]$ and $[Pd(PPh_3)_2(C_6H_8)]$.

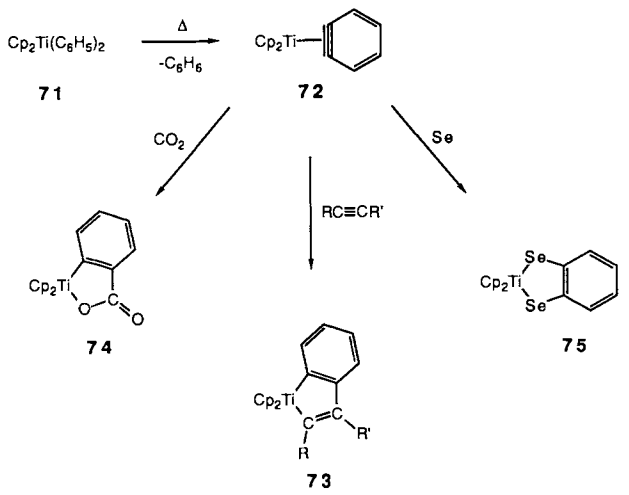
with increasing Pt 6s-character in the σ-bonding orbital used in the alkyne–metal bond, i.e. the metallacyclopropene structure **70** becomes increasingly important for the smaller rings. This correlates with the increasing diradical character of the smaller rings in the free state (Section 2).

70

Despite the constancy of the C≡C distances in **10**, **32** and **46**, there is a steady decline in $\tilde{\nu}$(C≡C) along the series from ca. 1800 cm^{-1} to ca. 1700 cm^{-1}, and there is a further drop to ca. 1630 cm^{-1} for **53**. This trend correlates well with increasing metallacyclopropene character, though it may arise from different degrees of coupling of the C≡C stretch with other ring vibrations. The values of $\Delta\tilde{\nu}$(C≡C) generally decrease for the smaller cycloalkynes and are less than those for acyclic alkynes, reflecting the fact that the former are less perturbed on coordination than the latter.

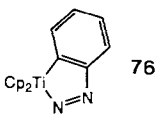
4. Mononuclear Metal Complexes of Benzyne

Many benzyne complexes are dinuclear or polynuclear, the C_6H_4 unit being attached to two metal atoms by two σ-bonds or by σ- and π-bonds to three or four metal atoms. For mononuclear benzyne complexes, as for other alkyne complexes, two limiting modes of coordination, **C** and **D**, can be considered.



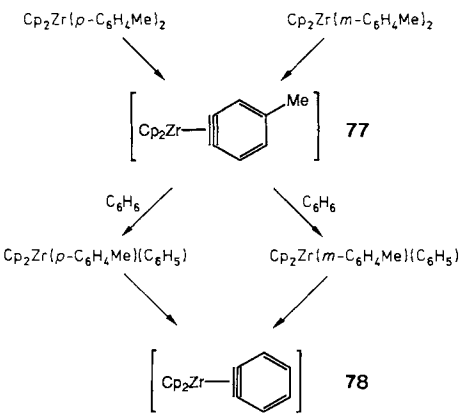
C **D**

Some authors refer to the σ-bonded compounds (whether mononuclear or polynuclear) as *o*-phenylene derivatives (**C**) and to the π-bonded mononuclear compounds as benzyne complexes (**D**). At least for mononuclear compounds, the representations are equivalent when the metal-ligand interaction is strong, and it is difficult to distinguish between the terms benzyne and o-phenylene in this context.



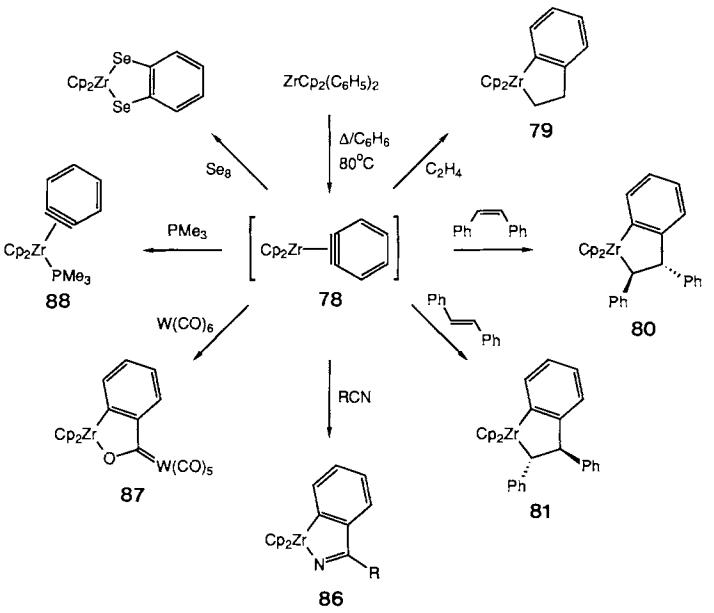
4.1. Complexes of Early Transition Metals (Ti, Zr, Nb, Ta, Mo, W, Re) and Actinoid Elements (U, Th)

A benzyne-chromium complex is one of the suggested intermediates in the hydrolytic σ- to π-rearrangement of $[Cr(C_6H_5)_3(thf)_3]$ to $[Cr(C_6H_6)_2]^{\oplus}$ (the classic Hein reaction)[79] and, in general, benzyne complexes are strongly implicated as reactive intermediates in the thermal decomposition of perphenyl derivatives of the early transition elements, and of uranium and thorium; they can sometimes be isolated from such reactions. When $[TiCp_2(C_6H_5)_2]$ **71** is heated in the solid state or in hydrocarbon solvents, the main organic product is benzene. Almost no biphenyl is formed, so free phenyl radicals are not involved. The benzene is formed mainly by elimination of one phenyl group with a hydrogen atom from the *ortho*-position of the other phenyl group, although there is a minor pathway in which a hydrogen atom is abstracted from one of the Cp rings.[80–82] Similar processes occur on heating titanium complexes with substituted aryl groups, and the presumed intermediates e.g. **72** can be trapped by reaction with alkynes,[83–85] CO_2[86] or selenium[87] to give the expected titanacycles **73**–**75** (Scheme 13). **72** is probably also formed when $TiCl_2Cp_2$ is treated with *o*-bromofluorobenzene and magnesium, for in the presence of diphenylacetylene the titanacycle **73** (R = R′ = Ph) can be isolated in 15% yield.[88]



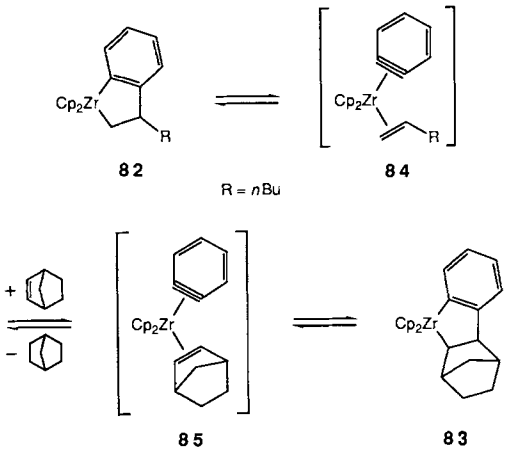
Scheme 13. Generation and trapping of $[TiCp_2(C_6H_4)]$ **72**.

When **71** or its *m*- or *p*-tolyl analogues are heated in benzene or ether at 80–130 °C under nitrogen (100 atm) and the solution is subsequently hydrolyzed, small amounts of aniline (or the appropriate toluidine) are formed in addition to the main product, ammonia. Aniline is also formed from $TiCl_2Cp_2$, *o*-bromofluorobenzene and magnesium under N_2 (100 atm). These results are thought to indicate that **72** reacts with N_2 to give the insertion compound **76**. The aromatic amines are not formed in the corresponding zirconium systems.[89]



76

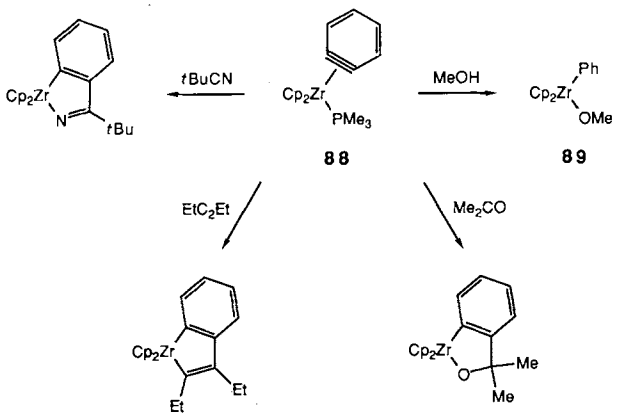
On heating in aromatic solvents, zirconium complexes $ZrCp_2(Aryl)_2$ undergo successive replacements of their aryl groups by aryl groups from the solvent (Scheme 14).[90] This behavior is suggestive of a 16-electron, coordinatively unsaturated aryne-metal intermediate (e.g. **77**). The trapping reactions of aryne-zirconocene complexes formed in this way with multiply bonded molecules have been studied more



Scheme 14. Aryl group exchange in $[ZrCp_2(Aryl)_2]$.

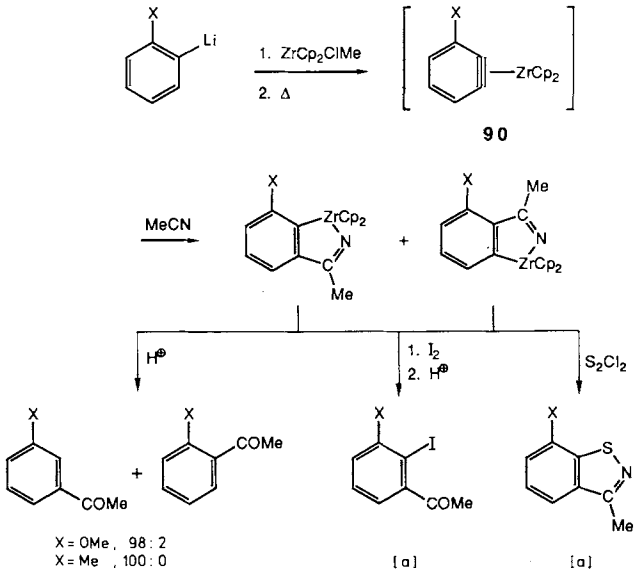
intensively than those of the titanium system, possibly because Cp ligands are not cleaved so easily from the heavier element, so there is less net decomposition.[90b] Typical reactions of $[ZrCp_2(C_6H_4)]$ **78** are summarized in Scheme 15.

Scheme 15. Reactions of $[ZrCp_2(C_6H_4)]$ **78**.



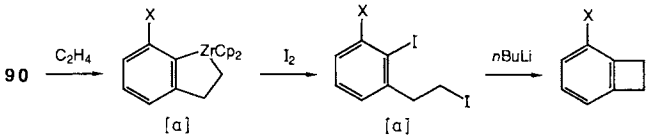
Ethylene inserts to give the zirconaindan **79**[91] and the substituted derivatives **80** and **81** are formed stereospecifically from *cis*- and *trans*-stilbene respectively.[92] The zirconaindan **82** formed from **78** and 1-hexene undergoes olefin exchange on heating with norbornene to give a new zirconaindan **83** (Scheme 16), suggesting that **82** and **83** are in equilibrium with their respective zirconocene benzyne olefin complexes **84** and **85**.[91]

Scheme 16. Olefin exchange in zirconaindan complexes.



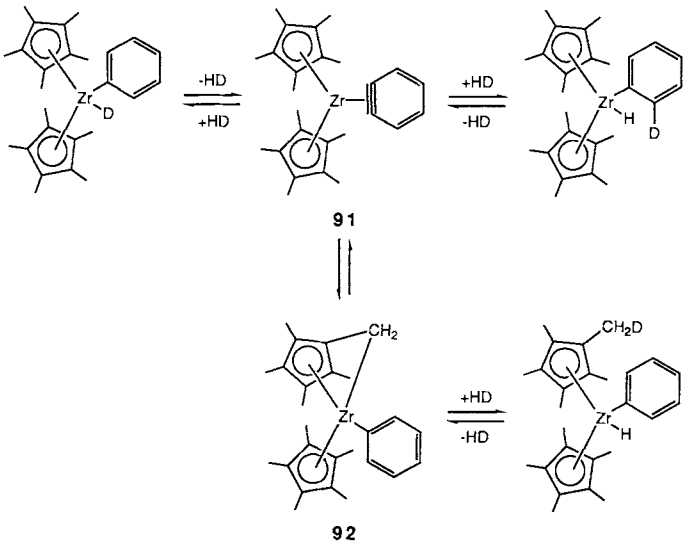
78 also reacts with cyanides to give dimeric azazirconacyclopentenes **86** which can be hydrolyzed to ketones.[93] The marked oxophilicity of the Cp_2Zr unit is demonstrated by the reaction of **78** with $W(CO)_6$ to give the zirconaoxycarbene complex **87**.[94] **78** can be trapped almost quantitatively in the form of its stable trimethylphosphane adduct **88** which

contains η^2-benzyne, as shown by X-ray crystallography.[95] The trimethylphosphane is readily displaced by other ligands in solution, so **88** represents a convenient alternative source of **78**. High-yield insertion reactions of **88** with *tert*-butyl cyanide, 3-hexyne and acetone have been carried out; methanolysis of **88** gives the stable methoxy-complex **89** (Scheme 17).



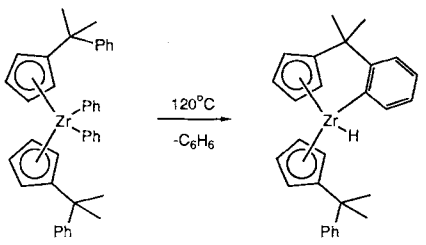
Scheme 17. Reactions of $[ZrCp_2(PMe_3)(C_6H_4)]$ **88**.

A more general route to aryne-zirconocene complexes is to treat the chloro(methyl) complex $[ZrCp_2Cl(Me)]$ with an aryllithium.[96] The resulting complex $[ZrCp_2(Aryl)(Me)]$ loses methane on heating and the transient aryne complex **90** can be trapped with cyanides or ethylene (Scheme 18). This



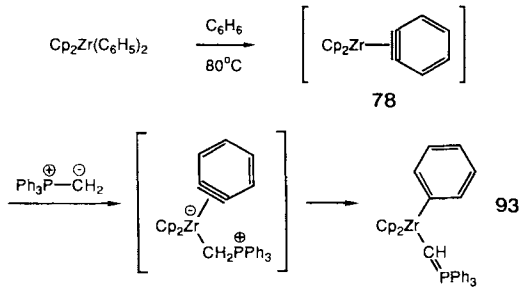
Scheme 18. Synthesis and reactions of $[ZrCp_2(aryne)]$ **90**. [a] Only isomer observed for X = OMe, Me.

procedure can be used to produce 3-substituted benzyne complexes which would otherwise be inaccessible; zirconocene complexes containing two *o*-substituted aryl ligands cannot be prepared, probably because of steric crowding. The zirconacycles can be converted, without being isolated, into organic products such as aromatic ketones and *o*-iodophenylketones, isothiazoles (Scheme 18) and dihydrocyclobutabenzenes (Scheme 19). Steric hindrance by the substituents X to the approach of the trapping agent is probably responsible for the high regiospecificity observed in the reaction of cyanides with 3-substituted benzyne zirconocenes.



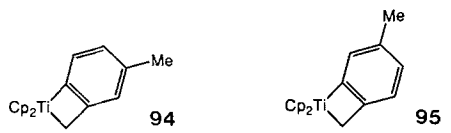
Scheme 19. Synthesis of dihydrocyclobutabenzenes from aryne-zirconocene complexes **90**. [a] Mixture of regioisomers.

Phenyl derivatives of bis(pentamethylcyclopentadienyl)-zirconium,[97,98] -uranium[98] and -thorium[99] also undergo phenyl group exchange with aromatic solvents, and the intermediate benzyne complexes can be trapped with ethylene or diphenylacetylene. A solution of $[ZrCp_2^*D(Ph)]$ in C_6D_6 incorporates deuterium in both the *ortho*- positions of the phenyl ring and in the Cp* methyl groups at room temperature; these processes probably proceed via the benzyne complex **91** (Scheme 20). When either $ZrCp_2^*Ph_2$



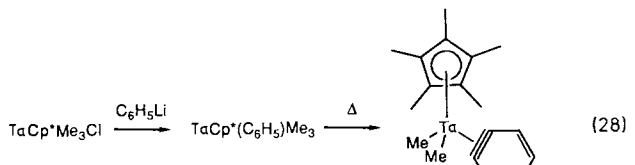
Scheme 20. H/D exchange in $[ZrCp_2^*D(Ph)]$.

or $[ZrCp_2^*H(Ph)]$ is heated in benzene, the cyclometalated complex **92** is formed by hydrogen transfer from a Cp* methyl group to the coordinated benzyne.[97,98] Similar processes occur on heating the substituted Cp complexes $[Zr(\eta^5\text{-}C_5H_4CMe_2Ph)_2Ph_2]$ and $[Zr(\eta^5\text{-}C_5H_4CMe_3)_2Ph_2]$; in the first case, a phenyl C–H bond of the CMe_2Ph substituent is cleaved preferentially [Eq. (27)].[100]



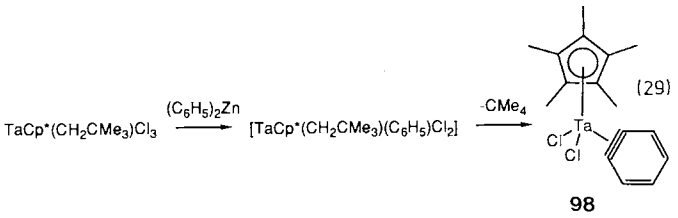
(27)

When $Ph_3P{=}CH_2$ reacts with $ZrCp_2(C_6H_4)$ **78** a hydrogen atom is transferred from the ylide to coordinated benzyne to give the phenylzirconium(IV) complex **93**, probably via an intermediate zirconium(II) complex (Scheme 21).



Scheme 21. Reaction of $[ZrCp_2(C_6H_4)]$ **78** with methylenetriphenylphosphorane.

Similarly, the 4-methylbenzyne complex **77** reacts with $Ph_3P{=}CH_2$ to form a mixture of 3- and 4-tolyl derivatives in the ratio 2:3.[101] The titanium analogue of **77** behaves similarly, but in this case there is a competing reaction in which PPh_3 is eliminated and CH_2 inserts into the titanium–aryne bond to give isomeric titanacyclobutanes **94** and **95**.[102]



The elimination of benzene from two adjacent σ-phenyl groups, or of an alkane from adjacent σ-phenyl and σ-alkyl groups, has been used to prepare benzyne complexes of niobium, tantalum, molybdenum, tungsten and rhenium, but the chemistry of most of these compounds has received little attention. Treatment of $[TaCp^*Me_3Cl]$ with phenyllithium (1:1 mol ratio) gives $[TaCp^*(C_6H_5)Me_3]$ which, on heating in chlorobenzene at 120°, loses methane to give the pale yellow, fairly air-stable benzynetantalum(III)- complex **96** [Eq. (28)].[103] This was the first mononuclear benzyne com-

(28)

plex to be characterized structurally.[103, 104] The niobium analogue **97** can be made similarly. Both **97** and **98** undergo insertion with ethylene to form the expected benzometallacyclopentene complexes. The dichlorotantalum compound **98** can be made directly by the action of diphenylzinc on $[TaCp^*(CH_2CMe_3)Cl_3]$ [Eq. (29)], the presumed intermediate neopentyl-phenyl complex being undetected.[103]

(29)

Treatment of $TaCp^*_2Cl_2$ with phenyllithium (1:2 mol ratio) gives directly the hydrido(benzyne) tantalum(III) complex $[TaCp^*_2H(C_6H_4)]$, which is shown by variable temperature NMR spectroscopy to be in equilibrium with the σ-phenyl complex $[TaCp^*_2(C_6H_5)]$. At 50 °C the free energy of activation for the β-hydride migration is 70.6 kJ mol^{-1}.[105]

Sarry et al.[106–111] have shown that pentahalides of tantalum, niobium, tungsten and molybdenum react with an excess of phenyllithium (or aryllithium) in ether to form a remarkable series of complexes of general formula $[Li(Et_2O)]_n[M(C_6H_4)_2(C_6H_5)_4]$ in which two benzyne units are coordinated to each transition metal atom. The compounds described to date are given in Table 4, together with

Table 4. Anionic bis(aryne) complexes isolated from reactions of early transition metal pentahalides with aryllithium reagents.

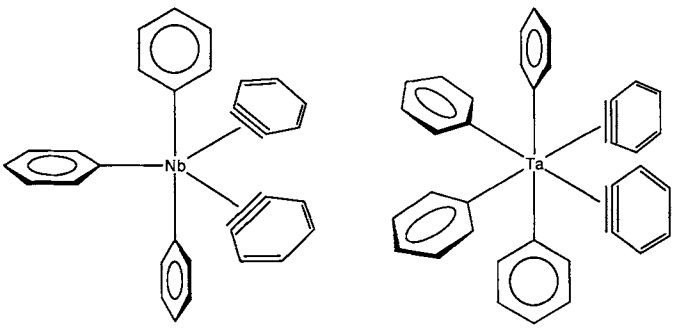
the formal oxidation states and electron configurations of the metal atoms; these have been calculated on the assumption that benzyne acts either as a neutral donor or as a dianionic ligand. The products isolated from these reactions are very sensitive to slight changes in experimental conditions and to the reagents used. In the cases of tantalum and niobium, different compounds in which the oxidation states of the metal atoms differ by one can be obtained from similar reaction mixtures. The compounds themselves are generally very sensitive to heat, air and moisture and they tend to lose ether, so the proportions of ether in **99**–**104** are approximate.

In early work, the compounds of W, Ta and Nb were formulated[106–108] as hexaphenylmetalates

$[Li(Et_2O)]_n[M(C_6H_5)_6]$ by analogy with the known chromium(III) complex. Compounds of this type are undoubtedly precursors to the bis(benzyne) complexes and can be isolated in some cases. For example, $MoCl_5$ reacts with phenyllithium (1:10 mol ratio) to give the bis(benzyne) complex **102**, whereas under the same conditions *p*-tolyllithium gives the hexa(*p*-tolyl)molybdate complex $[Li(Et_2O)]_3[Mo(C_6H_4Me)_6]$. In contrast, WBr_5 reacts with *p*-tolyllithium to give the bis(4-methylbenzyne) complex **104**.[111] The strongly basic aryllithium evidently abstracts *ortho*-protons from the aryl groups, but the exact conditions and mechanism have not been elucidated.

Recently, the crystal structures have been determined of complexes with the empirical formulas **105** and **106**, which have been isolated in low yield from the reactions of $NbCl_5$ and $TaCl_5$, respectively, with phenyllithium in THF.[112] The niobium atom in **105** has an approximately trigonal bipyramidal coordination sphere comprising two η^2-benzyne ligands and a σ-phenyl group in equatorial positions and two σ-phenyl groups in axial positions. The tantalum atom in **106** is coordinated in approximately octahedral fashion by mutually *cis*-η^2-benzyne ligands and four σ-phenyl groups (Fig. 2). Alternatively, if C_6H_4 is regarded as a dianionic



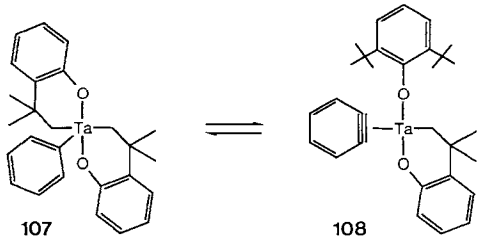


Fig. 2. Primary coordination spheres of the anions of complexes **105** and **106**.

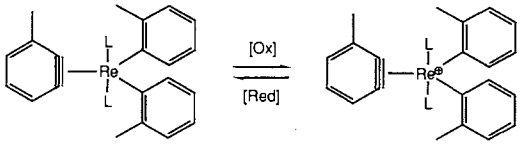
ligand, the coordination geometries of **105** and **106** could be described as approximately pentagonal bipyramidal (seven-coordinate) and square antiprismatic (eight-coordinate), respectively. Both anions contain a complicated secondary coordination sphere in which there are extensive interactions between solvated lithium ions and carbon atoms of the benzyne and phenyl rings. These interactions are important for stabilizing the structures.



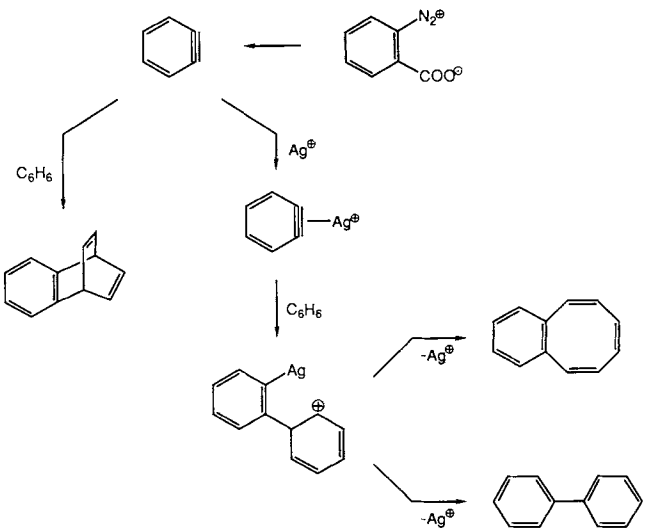
There is one other example of a benzyne-tantalum complex as an intermediate which is not stabilized by the presence of Cp, Cp* or PMe_3 ligands. At 120 °C the phenyl-substituted metallaspiro complex **107** is in equilibrium with the benzyne complex **108**, a hydrogen atom being transferred

107 108 (30)

reversibly from the phenyl group to the Ta–CH_2 group of the metallacycle [Eq. (30)].[113, 114]

Treatment of tetra-*o*-tolylrhenium with two equivalents of PMe_3 or PMe_2Ph(L) at −40 °C causes rapid elimination of toluene and formation of dark red 3-methylbenzyne complexes **109**, which are paramagnetic (one unpaired electron) and very stable to air and heat [Eq. (31)].[115] They readily undergo reversible oxidation to the diamagnetic cations **110**,

109 110 (31)

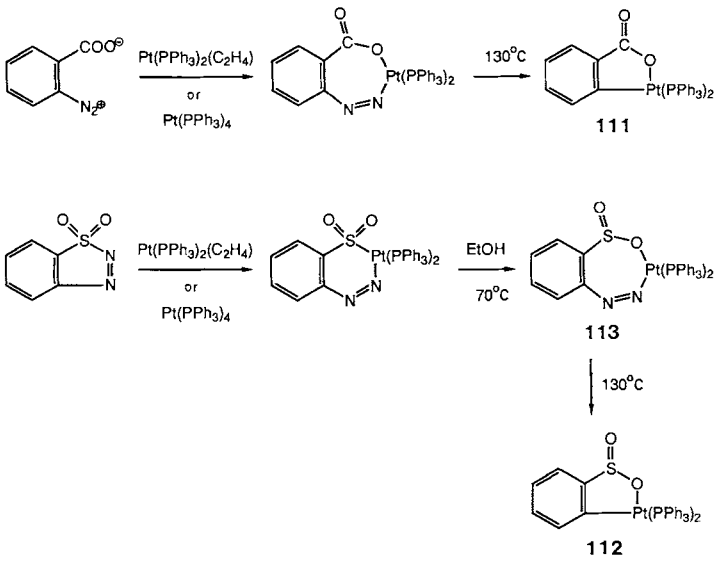


[Ox] = $[FeCp_2]^{\oplus}$, I_2, $Co_2(CO)_8$, $Ag[CF_3SO_3]$, CF_3SO_3H;

[Red] = $Li[Et_3BH]$, Me_3SiCH_2MgCl

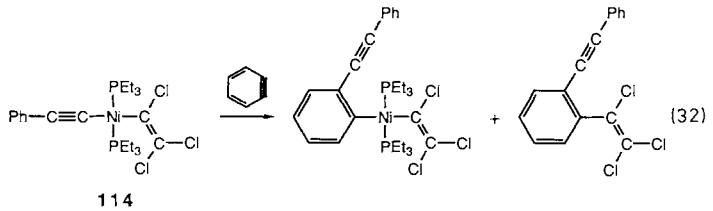
which can be isolated as $PF_6^{\ominus}$, $CF_3SO_3^{\ominus}$, $BPh_4^{\ominus}$, and $I_5^{\ominus}$ salts. The X-ray structure analyses of **109** (L = PMe_2Ph) and **110** (L = PMe_3; $I_5^{\ominus}$ salt) show that both species are approximately trigonal-bipyramidal, if the C_6H_4 unit is assumed to occupy one coordination site; the tertiary phosphane ligands are in axial positions. Both **109** and **110** are remarkably inert towards a variety of substrates, including CO, H_2, olefins, acetylenes, acetonitrile, and acetone.

4.2. Complexes of Late Transition Metals (Ag, Ni, Pt)



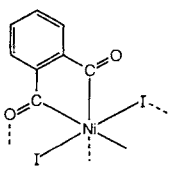
The first indication of complex formation between benzyne and a d^{10} metal atom was the observation that the cycloaddition of benzyne to benzene is strongly influenced by the presence of traces of silver ion. The normal 1,4-cycloaddition to give benzobarrelene is suppressed and the main products become benzocyclooctene and biphenyl. *Friedman*[116] proposed that a silver-benzyne complex is formed which is more electrophilic than benzyne itself (Scheme 22).

Scheme 22. Influence of $Ag^{\oplus}$ on the cycloaddition of benzyne to benzene.



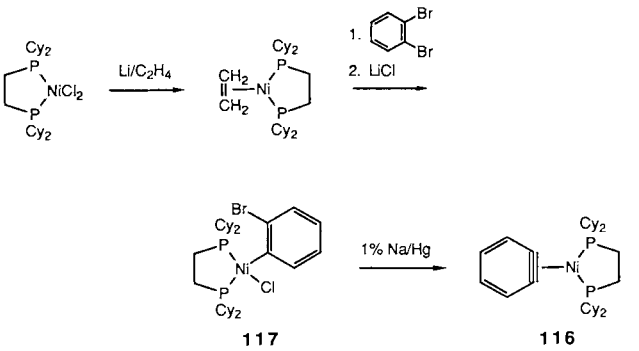
Similar effects are observed in other cycloadditions of benzyne.[117]

An early attempt to prepare $[Pt(PPh_3)_2(C_6H_4)]$ by treating 1,2-dilithiobenzene with *cis*-$[PtCl_2(PPh_3)_2]$ failed.[118] Efforts to trap benzyne, generated from suitable precursors, by zerovalent platinum complexes have also been unsuccessful. Thus, thermal decomposition of 2-diazoniobenzoate or benzo-1,2,3-thiadiazole *S*,*S*-dioxide in the presence of $[Pt(PPh_3)_2(C_2H_4)]$ or $Pt(PPh_3)_4$ gives the metallacyclic platinum(II) complexes **111** and **112**, respectively, as the final products (Scheme 23).[34, 119, 120] These will not eliminate



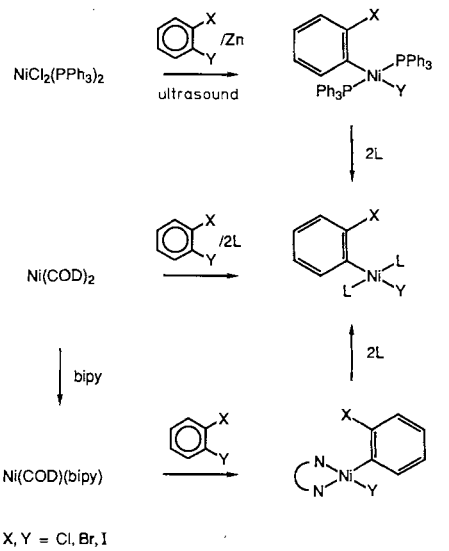
Scheme 23. Reaction of benzyne precursors with Pt^0 complexes.

CO_2 or SO_2 to give $[Pt(PPh_3)_2(C_6H_4)]$, although UV irradiation of **113**, a precursor to **112**, does generate free benzyne which can be trapped with furan or tetracyclone.[34, 120] Free benzyne also inserts into the acetylide-metal bond of the nickel(II) complex **114** [Eq. (32)].[121]



Although $Ni(CO)_4$ was claimed to react with *o*-diiodobenzene to give a benzyne complex, this was subsequently shown to be a polymeric nickel(IV) complex **115** containing a tridentate benzene-1,2-dicarbonyl group.[122]

115

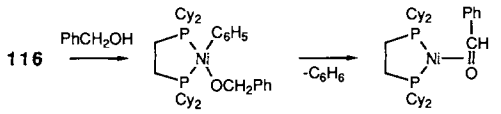


The first mononuclear benzyne-nickel(0) complex **116** was obtained as a yellow, crystalline solid by reduction of the (2-bromophenyl)chloronickel(II) complex **117** with 1% sodium amalgam (Scheme 24), and its structure was confirmed

Scheme 24. Preparation of $[Ni(Cy_2PCH_2CH_2PCy_2)(C_6H_4)]$ **116**.

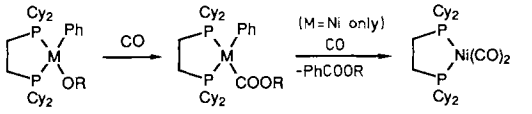
by X-ray crystallography.[123] The complexes $NiL_2(C_6H_4)$ (L = PCy_3, $PiPr_3$; Cy = cyclohexyl) have been obtained in a similar way,[124] although the PEt_3 complex has been assigned a dimeric μ-*o*-phenylene structure (cf. Section 6).[125] Reduction of **117**, Ph instead of Cy, with various alkali-metal reducing agents, gave only $Ni(dppe)_2$ instead of the expected benzyne complex.[124]

Unfortunately, **116** or its analogues cannot be made similarly to the zirconium compound **78** by heating diphenyl- or methyl(phenyl)-nickel(II) complexes, because the σ-bonded carbon ligands on nickel(II) generally undergo reductive elimination rather than hydrogen abstraction.[126] It is therefore necessary to have convenient high-yield syntheses of the (2-halogenphenyl)nickel(II) halide precursors, and these are summarized in Scheme 25.[124]



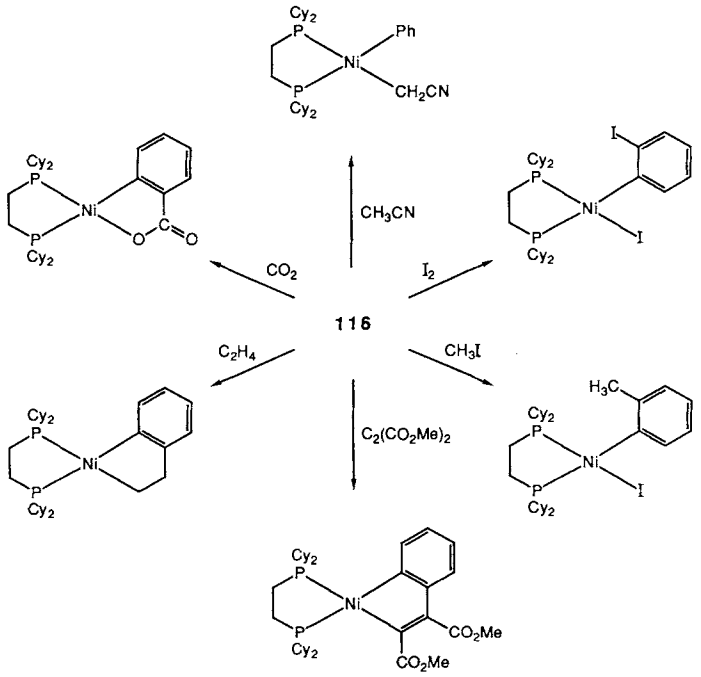
Scheme 25. Preparation of (2-halogenphenyl)nickel(II) halides. COD = cyclooctadiene, bipy = bipyridine.

Mononuclear benzyne-platinum(0) complexes $PtL_2(C_6H_4)$ (2L = $2PEt_3$, $2PCy_3$, $2PiPr_3$, $Cy_2PCH_2CH_2PCy_2$) have been prepared similarly to their thermally less stable nickel analogues, 43% sodium amalgam being the best reducing



agent.[124] Attempts to prepare $ML_2(C_6H_4)$ (M = Ni, Pt; L = PMe_3, PPh_3) by the reduction method have not been successful. However, the triisopropylphosphane ligands in $[M(PiPr_3)_2(C_6H_4)]$ can be substituted, partially or completely, by less bulky tertiary phosphanes, reaction being more rapid and complete in the case of nickel. Compounds that have either been isolated or identified by NMR spectroscopy include $[M(PMe_3)_2(C_6H_4)]$ (M = Ni, Pt) and $[Pt(PiPr_3)L(C_6H_4)]$ (L = PMe_3, PEt_3, PPh_3, PMe_2Ph, $PMePh_2$).[124]

The benzyne-nickel and -platinum complexes are even more sensitive to water, alcohols, and other protonic solvents than the cyclohexyne complex **46**. The nickel complex **116** reacts rapidly with primary and secondary alcohols to give alkoxides; these are unstable at room temperature and eliminate benzene with formation of a nickel(0) complex of the corresponding aldehyde or ketone [e.g. Eq. (33)].



(33)

The Pt^{II} methoxide $[Pt(OMe)(C_6H_5)(Cy_2PCH_2CH_2PCy_2)]$ is thermally stable but is rapidly hydrolyzed by traces of water to the corresponding hydroxide. The M–O bonds in these alkoxides of nickel(II) and platinum(II) readily insert CO, but only in the case of platinum can the insertion product be isolated; in the case of nickel, both σ-bonded groups undergo reductive elimination [Eq. (34)].[124]

(34)

The benzyne–nickel bond in **116** is attacked by other electrophiles such as iodine and methyl iodide and undergoes insertions with CO_2, ethylene, and dimethyl acetylenedicarboxylate to give metallacycles (Scheme 26).[123] Whereas acetonitrile inserts into the benzyne-zirconocene complex **78**,[93] it is deprotonated by **116**.[124] Also in contrast with **78**, **116** does not undergo insertion with diphenylacetylene; instead, the benzyne is displaced to give $[Ni(Cy_2PCH_2CH_2PCy_2)(PhC_2Ph)]$.[123]

Scheme 26. Reactions $[Ni(Cy_2PCH_2CH_2PCy_2)(C_6H_4)]$ **116**.

4.3. Structure, Spectroscopic Properties and Bonding of Benzyne Complexes

Table 5 compares the benzyne C–C bond lengths determined by X-ray crystallography in various complexes with those in free benzyne as obtained by an ab-initio calculation.[119] In all cases the "acetylenic" bond (C1–C2) is lengthened on coordination; the remaining C–C bonds are of about the same length as, or slightly shorter than, those in free benzyne.

Table 5. Comparison of C–C bond lengths in metal benzyne complexes with those in free benzyne [a].

	C_6H_4 [b]	**116**	**88**	**96**	**105**	**106**	**109**	**110**
C1-C2	1.240	1.332(6)	1.364(8)	1.364(5)	1.419(7)	1.384(8)	1.34(1)	1.39(2)
					1.410(7)	1.402(8)		
C2-C3	1.393	1.386(6)	1.389(8)	1.410(5)				
C3-C4	1.402	1.383(7)	1.383(9)	1.362(2)				
C4-C5	1.421	1.390(8)	1.380(9)	1.403(6)	1.388(8)–	1.380(9)–	1.37(1) –	1.36(2)–
C5-C6	1.402	1.383(7)	1.377(9)	1.375(6)	1.416(7) [c]	1.404(9) [c]	1.43(1)	1.44(2)
C6-C1	1.393	1.389(6)	1.406(8)	1.408(6)				

[a] Carbon atoms numbered as in Fig. 1. [b] Values from Ref [19]. [c] C4-C5 is the shortest bond.

In **116**, benzyne is considered to be a two-electron donor, similar to alkynes in the 16e ML_2(alkyne) (M = Ni, Pt) complexes. The C1–C2 bond length of 1.332 Å is greater than the value of 1.29 Å typical of most ML_2(alkyne) complexes, but the lengthening on coordination relative to the free ligand (Δr = 0.08–0.09 Å) is about the same. Correspondingly, the $\tilde{\nu}$(C≡C) value of ca. 1580 cm^{-1} in $ML_2(C_6H_4)$ (M = Ni, Pt) complexes is less than the value of ca. 1700 cm^{-1} found in ML_2(alkyne) complexes, but the decrease relative to the free ligand is of the same order ($\Delta\tilde{\nu}$ = 400–500 cm^{-1}) in both series.

Electron-counting suggests that benzyne should behave as a 2e donor in **88**, since the zirconium atom then achieves its 18e configuration, but the C1–C2 distance (1.364 Å) is significantly greater than in **116**. The other benzyne C–C distances in **88** and **116** are almost equal, suggesting that the delocalized benzometallacyclopropene structure **118** is a reasonable representation in these cases.

118 **119**

If benzyne is regarded as a 2e donor, the tantalum atom in **96** has only 14 valence electrons and is thus highly electron-deficient. The C1–C2 distance in **96** is similar to that in

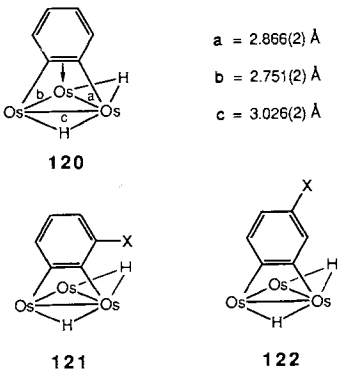
88, but the remaining C–C distances in the six-membered ring of **96** show a small but distinct long-short alternation. Also, the benzyne ligand in **96** is oriented perpendicular to the plane of the Cp* ring, whereas in the ethylene complex $[TaCp^*Me_2(C_2H_4)]$ the olefin is parallel to this plane. These observations have led to the suggestion that both sets of orthogonal benzyne π-orbitals are involved in bonding to the metal.[103, 104] Thus, benzyne in **96** may donate up to four π-electrons and the bonding could be represented simplistically as in **119**.

The benzyne ^{13}C chemical shifts provide some support for this idea. The δ values for C1 and C2 in **116** and **96** are 145.2 and 230.5 respectively, the latter being in the region expected for alkynes acting as four π-electron donors (Section 3.6). The former value is somewhat higher than expected for a typical two π-electron donor alkyne, but the difference can probably be attributed to the small ring which increases the contribution from the metallacyclopropene structure **118** (Table 3). The chemical shifts of the nonequivalent C1 and C2 atoms of **88** (δ = 154.1, 174.3) are intermediate between those of **116** and **96**.

The NMR spectra of **88, 110** and **116** indicate that in these complexes the benzyne ligand is rigid on the NMR time scale, whereas the benzyne ligand in **96** is apparently rotating rapidly about the metal–ring axis ($\Delta G^{\neq} \leq 37.8$ kJ mol^{-1}). At first sight this seems incompatible with the idea that benzyne donates more than two π-electrons, but the fluxional process may be associated with a pseudorotation of the formally pseudotetragonal pyramidal structure of **96**.

A feature of the structures of **105,106, 109** and **110** is that the M–C(aryne) bonds are shorter by 0.07–0.14 Å, and presumably stronger, than the σ–M–C(aryl) bonds. The C1–C2 distances in the anions of **105** and **106** [1.414(8) Å (av.) and 1.393(8) Å respectively] are slightly larger than in **96** and **88**; the same trend is apparent in the remaining benzyne C–C bond lengths, which also are reported to show some evidence for bond alternation. The general bond lengthening has been attributed[112] to the good σ-donor and poor π-acceptor properties of the σ-phenyl co-ligands and to the extensive interactions of the anions with lithium ions.

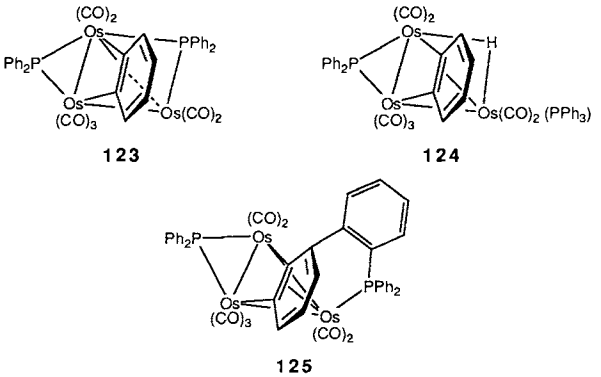
5. Metal Cluster Complexes of Benzyne and Small Cycloalkynes



By far the largest number of known benzyne complexes are those based on the trinuclear osmium carbonyl framework.[127] These compounds can be generated by cleavage of aromatic carbon-element (commonly C–H) bonds in simple aromatic compounds. Most interest has concentrated on the structures adopted and on their fluxional behavior; little attention has been paid to their chemistry.

The parent compound $[Os_3H_2(CO)_9(\mu_3\text{–}C_6H_4)]$ **120** (Scheme 27) is obtained as yellow crystals in ca. 30% yield by heating benzene with $Os_3(CO)_{12}$ at 194 °C[128] or, more conveniently, with $[Os_3(CO)_{10}(MeCN)_2]$ under reflux.[129] Other methods of preparation are the thermal decarbonylation of $[Os_3H(\mu_2\text{-}COPh)(CO)_{10}]$[130] or $[Os_3H(OCH_2Ph)(CO)_{10}]$[131] which are obtained by heating $Os_3(CO)_{12}$ with benzaldehyde and benzyl alcohol, respectively, and the photoinduced isomerization of the face-capping benzene complex $[Os_3(CO)_9(\mu_3\text{–}\eta^1\text{:}\eta^2\text{:}\eta^1\text{–}C_6H_6)]$.[132]

X-ray analysis of **120** shows that the C_6H_4 unit lies over a triangle of bonded Os atoms, the dihedral angle between the two planes being 64° or 69° (two independent molecules).[129] The benzyne donates four electrons to the Os_3 triangle, being bound by σ-bonds to two metal atoms and by a π-bond to the third. The cluster has 48 valence electrons and each Os atom has the 18e configuration, assuming three Os–Os bonds to be present.



The ring C–C distances do not vary significantly from the mean [1.43(7) Å]. The hydride ligands in **120** are equivalent on the NMR time scale at room temperature, probably because of rapid rotation or flipping of the C_6H_4 unit and rapid reversible hydride migration between the metal triangle and the C_6H_4 ring.[133]

Analogues of complex **120** have been made from $[Os_3(CO)_{10}(MeCN)_2]$ and mono- and di-substituted arenes. The complexes derived from toluene and chlorobenzene exist in solution as mixtures of positional isomers **121** and **122** (Scheme 27).[129]

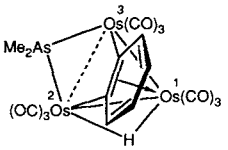
Scheme 27. Structures of the trinuclear osmium complexes **120**–**122**. X = CH_3, Cl; CO ligands omitted for clarity.

When $Os_3(CO)_{12}$ is treated with arylphosphanes or arylarsanes in high-boiling solvents or, more conveniently, when the ligand substitution products of $Os_3(CO)_{12}$ are first isolated and then thermolyzed, P–C (or As–C) and C–H bonds are cleaved to give a range of products, including μ_3-benzyne complexes. These are isolated, usually in poor yield, after chromatographic separation. Thus, from the reaction of $Os_3(CO)_{12}$ with PPh_3 in refluxing xylene, or from thermolysis of $[Os_3(CO)_{10}(PPh_3)_2]$, the μ_3-benzyne compounds **123, 124** and **125** have been isolated and structurally character-

ized.[134–136] The X-ray structure of the ruthenium analogue of **123**, obtained from $[Ru_3(CO)_9(PPh_3)_3]$ in refluxing decalin or mesitylene[137] has also been determined.[138]

Complex **125** apparently arises by "insertion" of coordinated C_6H_4 into a cyclometalated triphenylphosphane.

Complexes derived similarly from PMe_2Ph or $AsMe_2Ph$ and $Os_3(CO)_{12}$ include **126, 127** (E = P, As) **128** and **129**. In **126**, which is analogous to **123**, variable temperature NMR



$Os_3(CO)_7(EMe_2)_2(C_6H_4)$ **126**

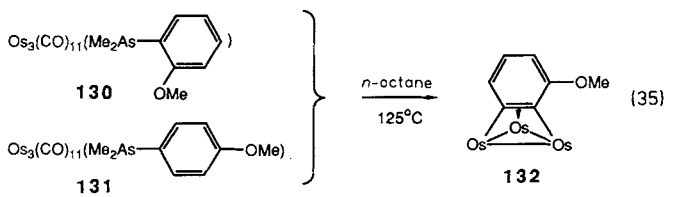
$Os_3H(CO)_9(EMe_2)(C_6H_4)$ **127**

$Os_3H(CO)_8(PMe_2Ph)(PMe_2)(C_6H_4)$ **128**

$Os_3H(CO)_8(PMe_2)(Me_2PC_6H_4C_6H_3)$ **129**

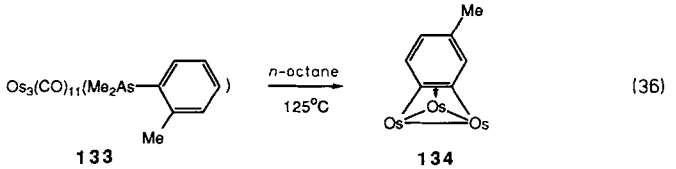
studies suggest that the C_6H_4 ligand executes two independent 60° rotational processes about the Os_3 triangle.[127, 139, 140] Complexes **127** and **128** each contain one more two-electron donor ligand than the otherwise similar compound **124**; likewise **129** differs from **125** only by the presence of an additional CO group. To account for this, it was initially suggested[139] that in **127** C_6H_4 donates only two electrons to the cluster. However, the X-ray structure of **127** (E = As) shows that, in contrast to **124**, the triangle of metal atoms contains only two Os–Os bonds.[140] The four-electron donor C_6H_4 unit is π-bonded to Os 1 and σ-bonded to the two non-bonded Os atoms [Os 2, Os 3], which are bridged by $AsMe_2$.

127



Os 1 - Os 2 2.95Å

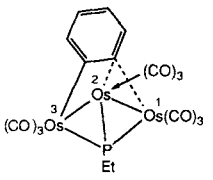
Os 1 - Os 3 2.84Å



Os 2 - Os 3 3.93Å

∠ Os 2 - Os 1 - Os 3 85.5°

The ^1H and ^{13}C (CO) NMR spectra of **127** between −60 °C and +27 °C have been interpreted in terms of hydride migration from one Os–Os bond to the other accompanied by angular reorganization of the CO groups.[140] As in **120**, the hydride ligand also migrates reversibly between the metal atoms and the six-membered ring. Thus, both **130** and **131** in *n*-octane at 125 °C give the *same* 3-methoxybenzyne complex **132** [Eq. (35)], and the *o*-tolyldimethylarsane complex **133** gives only the 4-methylbenzyne complex **134** instead of the expected 3-isomer [Eq. (36)].[141]

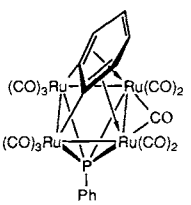


130 **131** **132** (35)

133 **134** (36)

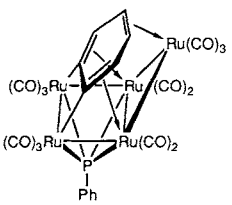
A complex similar to **127** containing SMe in place of $AsMe_2$ has been prepared in low yield from the reaction of $Os_3(CO)_{12}$ with methyl phenyl sulfide. Variable temperature NMR studies show that, in addition to hydride migration between the Os–Os bonds, there is a higher energy process involving inversion at sulfur.[142]

Other modes of interaction of benzyne with metal clusters have been found. In the yellow complex **135**, which is formed in high yield on heating $[Os_3(CO)_{11}(PPh_2Et)]$ in nonane, one benzyne carbon atom is σ-bonded to one osmium atom while the other carbon atom bridges the other two osmium atoms.[143] The PEt group bridges all three osmium atoms but, as in **127**, there are only two Os–Os bonds, so that C_6H_4 again contributes four electrons to the cluster. An interesting feature of **135** is the distance between the benzyne carbon atoms of 1.53(5) Å, typical of a single bond. The complexes are highly fluxional, probably owing to a rocking motion of the six-membered ring such that the two benzyne carbon atoms become equivalent.



135

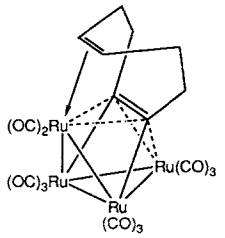
Os 1 - Os 2 2.789(2)Å



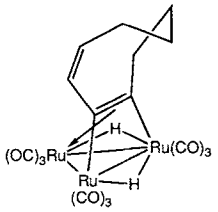
Os 2 - Os 3 2.929(2)Å

∠ Os 1 - Os 2 - Os 3 89.1°

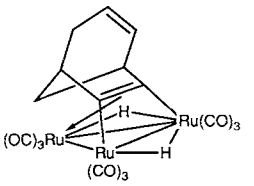
When $[Ru_3(CO)_{11}(PPh_3)]$ is heated in toluene, the complexes $[Ru_3(CO)_7(\mu\text{-}PPh_2)_2(C_6H_4)]$, **136**, and **137** are formed.[144] In **136** benzyne bridges four ruthenium atoms in a square plane and donates six electrons to them. The same structural unit is found in **137**, but an additional $Ru(CO)_3$ group replaces one bridging carbonyl group and is attached to the remaining double bond of C_6H_4, so that benzyne now acts as an eight-electron donor. This mode of coordination provides a model for the activation of two *ortho*–C–H bonds of benzene at a step site on a (111) metal surface.[132, 144]



136



137



Cycloolefins undergo dehydrogenation similarly to benzene on reaction with carbonyls of ruthenium and osmium. The complexes $[Os_3H_2(CO)_9(\text{cycloalkyne})]$ obtained from $Os_3(CO)_{12}$ and cyclopentene[128] or cyclooctene[145, 146] are structurally similar to the benzyne complex **120**. They show two hydride resonances at low temperatures but these coalesce above room temperature owing to hydride migration between the Os–Os bonds and rotation of the organic ligand. Reaction of indene with $Os_3(CO)_{12}$ leads to the indyne complex $[Os_3H_2(CO)_9(C_9H_6)]$ whose hydride ligands are derived from the five-membered ring.[147] Cyclopentadiene similarly gives ca. 2% yield of $[Os_3H_2(CO)_9(C_5H_4)]$, which is believed to contain cyclopent-1-en-3-yne.[148] Reaction of either 1,5- or 1,3-cyclooctadiene with $[Ru_4H_4(CO)_{12}]$ or $[Ru_4H_2(CO)_{13}]$ gives a mixture of products in low yield, including

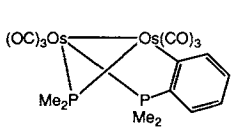
140

the black C_8H_{10}-complex **138**.[145] This contains cyclooct-1-en-5-yne bound to four metal atoms in a butterfly arrangement, as shown by X-ray crystallography.[149] 1,3-Cyclooctadiene and 2,6-bicyclo[3.2.1]octadiene undergo dehydrogenation on reaction with $Ru_3(CO)_{12}$ to give the complexes **139** and **140**, respectively.[145, 150]



6. Dinuclear μ_2-Benzyne (μ-*o*-Phenylene) Complexes

In compounds of this class the C_6H_4 group is bound by two σ-bonds to two metal atoms. No systematic synthetic methods have been developed, although in principle the compounds could serve as precursors both to mononuclear η^2-benzyne complexes and to higher nuclearity clusters containing bridging C_6H_4 groups.

When $[Os_3(CO)_{10}(AsMe_2Ph)_2]$ is heated, small amounts of the dinuclear μ_2-C_6H_4 complexes **141** and **142** are formed in addition to the trinuclear μ_3-C_6H_4 species **126** and **127**; **142** is also produced on heating $[Os_3(CO)_{11}(AsMe_2Ph)]$.[139] Unlike the trinuclear complexes, **141** and **142** show temperature-invariant NMR spectra. Analogous dinuclear complexes are not formed in the corresponding PMe_2Ph system; treatment of $[Os_3(CO)_7(PMe_2)_2(C_6H_4)]$ **126** with CO in refluxing nonane induces coupling of the C_6H_4 ligand with one of the PMe_2 groups to give the dinuclear complex **143**.

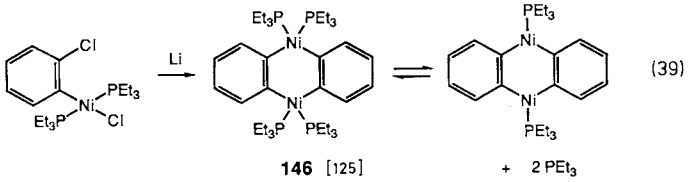
143

Other μ-*o*-phenylene complexes (**144**–**149**) have been obtained by various routes and in varying yields as summarized in Equations (37)–(40) and Schemes 28 and 29.[125, 151–156] Complex **144** is formed in poor yield upon irradiation of



144 (6.3%) [151]

[$IrCp(CO)_2$] in benzene via an unstable intermediate hydrido(phenyl) complex [$IrCp(C_6H_5)(CO)$].[151] The palladium(II) complexes **147** and **148** are formed, respectively, by double oxidative addition of *o*-diiodobenzene to a dipalladium(0) complex [Eq. (40), dpm = dipivaloylmethane][153] and by cyclometalation (Scheme 28).[154] Complex **149** (Scheme 29) is apparently formed by direct trapping of

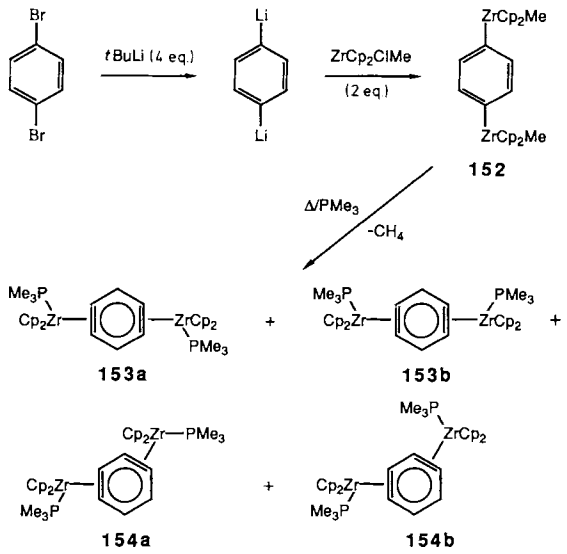
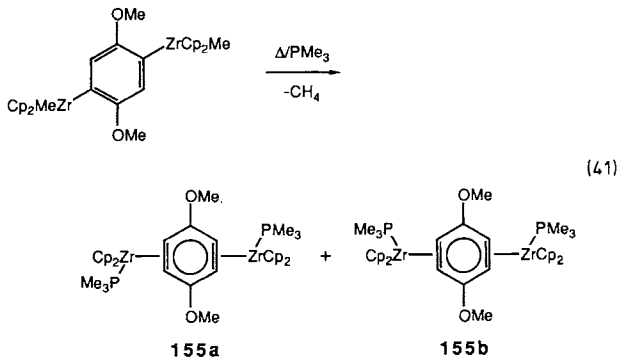
tetrafluorobenzyne, generated by decomposition of C_6F_5MgBr in dioxane, with $Fe_3(CO)_{12}$.[155, 156] A similar reaction using $Co_2(CO)_8$ in place of $Fe_3(CO)_{12}$ gives a tetranuclear species $[Co_4(CO)_{10}(C_6F_4)]$, but using $Pt(PPh_3)_4$ does not give $[Pt(PPh_3)_2(C_6F_4)]$.[155]

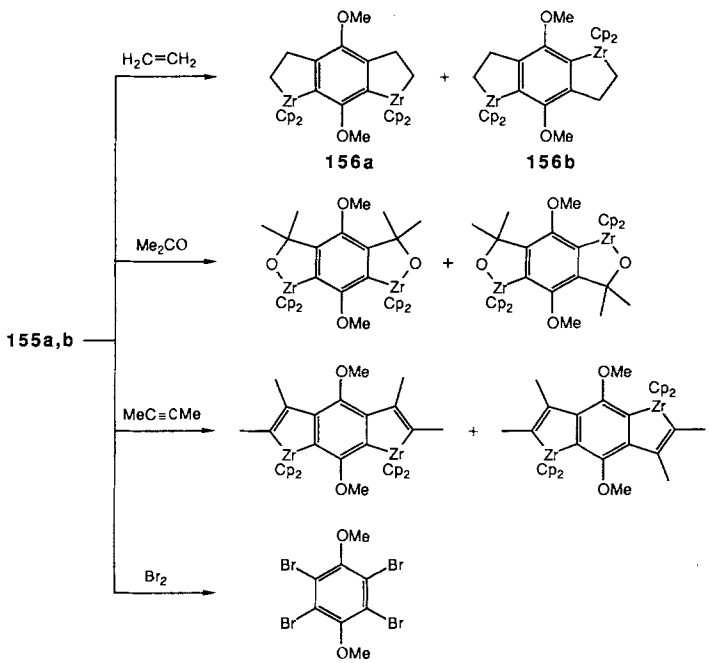


7. Metal Complexes of Tetradehydrobenzene and Dimethoxytetradehydrobenzene

Recent work has shown that the more highly unsaturated analogues of benzyne, 1,4-benzdiyne (1,2,4,5-tetradehydrobenzene) **150** and 1,3-benzdiyne (1,2,3,4-tetradehydrobenzene) **151** can be stabilized as dinuclear metal complexes. The free molecules have never been observed, and theoretical calculations suggest that their ring-opening to give HC≡C–C≡C–C≡CH will be more favorable than the corresponding process for benzyne to give HC≡CH and HC≡C–C≡CH.[20] However, 1,2,4,5- and 1,2,3,4-tetrabromoarenes behave as useful benzdiyne synthons, because on treatment with two equivalents of an organolithium reagent in the presence of a suitable diene, the Diels–Alder bis-adducts are formed.[157]

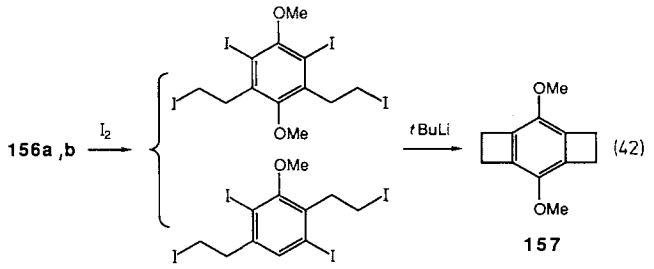


The zirconocene complexes of **150** and **151** have been prepared by an extension of the procedure used to synthesize the benzyne complex **88** (Scheme 30).[158] Treatment of 1,4-dilithiobenzene with two equivalents of $[ZrCp_2ClMe]$ gives the *p*-phenylenezirconium complex **152** which, on heating, eliminates CH_4 to give a mixture of two pairs of isomers. One pair (**153a, 153b**) contains 1,4-benzdiyne bound to two $ZrCp_2(PMe_3)$ units, the other (**154a, 154b**) contains 1,3-benzdiyne, also bound to two $[ZrCp_2(PMe_3)]$ units. The isomers in each pair differ in having *anti*- or *syn*-arrangements of the PMe_3 ligands.

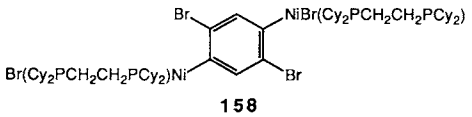


Upon heating with trimethylphosphane, the 1,4-dimethoxy-substituted analogue of **152** gives a pair of isomers **155a** and **155b** containing 1,4-dimethoxy-2,5-benzdiyne [Eq. (41)]. The *anti*-isomer **155a** crystallizes from the reaction mixture and its structure has been confirmed by

Scheme 30. Synthesis of the benzdiyne-zirconocene complexes **153a, b** and **154a, b**.

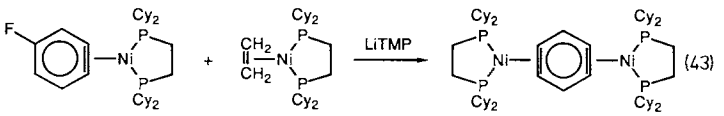


X-ray crystallography.[158] It undergoes insertions with unsaturated organic molecules e.g. acetone, 2-butyne and ethylene to give bis(metallacycles) (Scheme 31). The com-



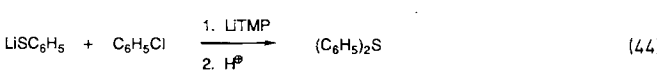
Scheme 31. Reactions of the benzdiyne-biszirconocene complexes **155a, b**.

pounds derived in this way from ethylene (**156a, 156b**) give, on successive treatment with iodine and *tert*-butyllithium, the tetrahydrodicyclobutabenzene **157** [Eq. (42)].



(42)

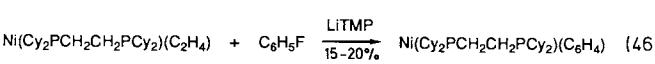
For reasons discussed in Section 4.2, a different approach is necessary to make a dinickel(0) complex of 1,4-benzdiyne. In principle, alkali metal reduction of the dinickel(II) complex **158** could be expected to give the 1,4-benzdiyne dinickel(0) complex **159**, but all attempts to make **158** or its analogues by double oxidative addition of 1,2,4,5-tetrabromobenzene to nickel(0) precursors have failed. However, treatment of the 4-fluorobenzyne nickel(0) complex **160** with a large excess of lithium tetramethylpiperidide (LiTMP) in the presence of $[Ni(Cy_2PCH_2CH_2PCy_2)(C_2H_4)]$ gives **159** as a yellow solid in ca. 60–70% yield [Eq. (43)].[159]



158

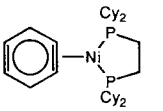
(43)

160 **159**



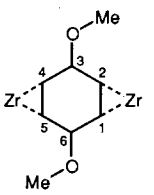
The success of this synthesis is based on the following observations: If chlorobenzene is treated with a powerful, poorly nucleophilic base such as LiTMP, the resulting benzyne can be trapped either by added nucleophiles such as C_6H_5SLi [Eq. (44)][160] or as a Diels–Alder adduct by e.g. 1,3-diphenylisobenzofuran [Eq. (45)].[161] If the nickel(0) complex $[Ni(Cy_2PCH_2CH_2PCy_2)(C_2H_4)]$ is used as trapping reagent in this type of reaction, the benzyne-nickel(0) complex **116** can be detected spectroscopically [Eq. (46)], but the

(44)



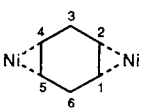
(45)

(46)



116

yields are poor (15–20%), and there are other unidentified products. We assume that in the first step of Equation (44) the *mononuclear* benzdiyne complex **161** is formed by the reaction of LiTMP with **160** and that **161** is intercepted by the ethylene nickel(0) complex to give **159**. The surprisingly high yield of **159** suggests that **161** may be longer-lived than benzyne.



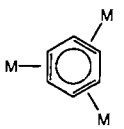
161

The structural analyses of **155a** and **159** show the same features, the coordination geometries being similar to those of the corresponding benzyne complexes **88** and **116**. In both cases the metal atoms are displaced slightly from the plane of the aromatic ring [0.17 Å (**155a**), 0.08 Å (**159**)]. The "acetylenic" C1–C2 bond length in **155a** is slightly greater than in **159** (Fig. 3); the same trend is evident on comparison of **88** and **116**.

Bond lengths [Å]		Bond angles [°]	
C1 - C2	1.345(11)	∠ C1 - C2 - C3	121.1(6)
C2 - C3	1.398(11)	∠ C2 - C3 - C4	118.8(7)
C3 - C4	1.401(10)	∠ C6 - C1 - C2	120.1(6)

C1 - C2	1.313(12)	∠ C1 - C2 - C3	124.1(9)
C2 - C3	1.402(13)	∠ C2 - C3 - C4	112.2(8)
C3 - C4	1.417(13)	∠ C6 - C1 - C2	123.6(9)

Fig. 3. Comparison of the bond lengths [Å] and angles [°] of the 1,2,4,5-tetradehydrobenzene (1,4-benzdiyne) ligands in **155a** and **159**.



8. Summary and Outlook

Methods have been developed for the synthesis of thermally stable but highly reactive mononuclear complexes of small cycloalkynes and arynes. These compounds are formed mainly with low-valent, early transition elements, e.g. Zr, Nb, Ta, Mo, W, and with low-valent, late (d^{10}) transition elements (Ni, Pt). Unsaturated molecules readily insert into the benzyne–metal bonds of e.g. $[ZrCp_2(PMe_3)(C_6H_4)]$ and $[Ni(Cy_2PCH_2CH_2PCy_2)(C_6H_4)]$ to form new metallacycles that may be useful in organic synthesis. The aryne zirconium compounds show particular promise in this respect because they can be prepared from aromatic monohalides, whereas the nickel compounds require less easily accessible *o*-dihaloarenes. Few mononuclear benzyne or small cycloalkyne complexes of the mid-transition elements are known, and new synthetic methods may be needed for these compounds.[162–165] One possibility is to transfer an aryne or cycloalkyne unit from zirconium or nickel to another metal center. This could give new mononuclear aryne or cycloalkyne complexes or, if transfer is incomplete, it could

give interesting heterobinuclear or heteropolynuclear bridging aryne or cycloalkyne complexes.

A potentially valuable reaction is the generation of coordinated arynes or cycloalkynes directly from arenes or cycloolefins by hydrogen transfer to a metal system. So far this has been achieved in moderate yield only with $Os_3(CO)_{12}$ or its derivatives. Undoubtedly the modest yields, the expense of the metal, and the reversibility of the hydrogen transfer have limited synthetic applications.

In principle, there seems to be no reason why the methods developed so far should not be applicable to the synthesis of a range of metal-stabilized heteroarynes and polynuclear arynes. The isolation of the first complexes of 1,4-benzdiyne also suggests that even more highly unsaturated cyclic molecules could be similarly stabilized, and an obvious synthetic target is 1,3,5-benztriyne (C_6) coordinated to three metal atoms (**162**).[166]

162

One of the authors (M.A.B.) wishes to thank the Institute of Molecular Science, Okazaki, Japan for the award of a three-month Visiting Professorship which enabled much of this review to be written, and Professor Hidemasa Takaya (now at the University of Kyoto) and his group for their kindness and hospitality.

[23] a) J. W. Laing, R. S. Berry, *J. Am. Chem. Soc. 98* (1976) 660. b) Recent calculations on benzyne [20, 23c, d] suggest that the bond length C1–C2 is in fact 1.25–1.26 Å and that the C–C stretching frequency of this bond is only 1965–2010 cm^{-1}; a band at 1860 cm^{-1} in the gas phase photodetachment spectrum has been assigned to the same mode [23e]. The more recent work suggests that the band at 2085 cm^{-1} in the IR spectrum of matrix-isolated benzyne, which has been confirmed experimentally by several groups, [23f] is due to some other species. The question is obviously wide open; c) I. Hillier, M. A. Vincent, M. F. Guest, W. von Niessen, *Chem. Phys. Lett. 134* (1987) 403; d) A. C. Scheiner, H. F. Schaefer III, B. Liu, *J. Am. Chem. [162] The first example of such a complex has been synthesized and characterized by X-ray crystallography [163]. Treatment of *cis*-[RuClMeL$_4$] (L = PMe$_3$) with C_6H_5MgBr gives *cis*-[Ru(C_6H_5)MeL$_4$], which, on heating in benzene at 110 °C, eliminates methane to give the η^2-benzyne ruthenium(0) complex [RuL$_4$(η^2-C_6H_3)] **161a**. The coordinated C-C bond length in **161a** is 1.355(3) Å. Compound **161a** resembles the d^{10} metal-benzyne complexes in its high basicity, but it also undergoes C-H and C-C activation reactions, e.g. with acetophenone it forms the cyclometalated species, $L_4\dot{R}u$-*o*-$C_6H_4\bar{C}(=\bar{C}H_2)\ddot{O}$ **161b**, presumably by elimination of C_6H_6 from an intermediate phenyl(*O*-enolate) [L_4Ru(C_6H_5){OC(CH_2)Ph}]. Remarkably, **161b** is also formed from **161a** and acetone, a reaction in which the C-C bond of acetone is cleaved and methane is eliminated.
The ion [FeC_6H_4]$^{\oplus}$ has been generated in the gas phase by reaction of $Fe^{\oplus}$ with chlorobenzene [164] and its reactions with alkanes have been studied by FT-mass spectrometry [165].

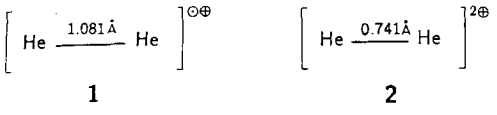
Organic Dications: Gas Phase Experiments and Theory in Concert

By Koop Lammertsma,* Paul von Ragué Schleyer,* and Helmut Schwarz*



Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

Knowledge of structure and bonding are integral parts in the understanding of the chemistry of neutral, radicaloid and positively or negatively charged species. The interplay of molecular bonding and the inherent electrostatic repulsion in doubly-charged molecules expands our insight in the versatility of bonding in electron deficient molecules. Small organic dications are now routinely detected in the gas phase by a variety of mass spectrometric techniques. Ab initio molecular orbital theory has advanced to the stage of accurately predicting potential energy surfaces. This review highlights the symbiotic relationship between gas-phase ion and computational studies and gives a rationale for the salient bonding features in doubly-charged organic cations.

1. Introduction

Whereas polycharged species were first recorded over half a century ago,[1] only the recent developments in mass spectrometric techniques now permit organic dications to be observed routinely in the gas phase. Simultaneously, computational studies have provided an understanding of the structures and energies of these doubly charged species. Both these sources of information complement the already extensive data on the larger dications that are observable in solution.[2] This review combines the information available from the theoretical and experimental gas phase studies on the newly emerging classes of organic dications. The two approaches are complementary: mass spectrometric studies reveal the existence of small dications, whereas ab initio MO calculation (on species in isolation) provide structural details—comparisons of observed and calculated energies provide a calibration of the agreement between experiment and theory. Previous reviews focused on more specific aspects of dications.[3]

As illustrated by the recent detection of $He_2^{2\oplus}$,[4] virtually any dication can be generated in the gas phase. The smallest two-electron diatomic dication, $He_2^{2\oplus}$ has a surprisingly large 33.2 kcal/mol barrier to dissociation despite the 200 kcal/mol exothermicity.[5] This kinetic stability also is emphasized by the very short He–He bond of 0.741 Å, even 0.037 Å shorter than the H–H bond in the hydrogen molecule. The He–He distance contracts upon successive removal of electrons from the neutral He-dimer to $He_2^{\odot\oplus}$, **1**, and then to the dication **2**. The observation of $He_2^{2\oplus}$ highlights what *Pauling*[6a] already envisioned in the 1930s, as substantiated later by *Dunitz* and *Ha*,[6b] that bonding interactions can counteract strong electrostatic charge-charge repulsions sufficiently to result in kinetically stable species (Fig. 1). Consequently, the number of observable dications is virtually unlimited. Hence, we will not discuss each dication exhaustively, but will emphasize common trends. We do not consider di- and polycations based on diatomics, noble gas and other clusters, organometallics, and polycyclic aromatics, and we limit ourselves mainly to ab initio calculations, as the available semiempirical methods have not been calibrated for such species.

1 **2**

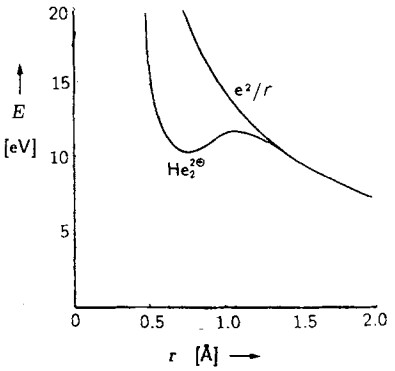


Fig. 1. The potential energy surface of $He_2^{2\oplus}$ and the Coulomb repulsion curve. [6a]

The ground states of organic dications, that have been detected in the gas phase, are revealed by theory to have remarkable properties. We discuss briefly the different mass spectrometic techniques and the theoretical methods that are commonly used. Throughout we concentrate on the formalisms of double oxidations, diprotonations, and charge-transfer complexes as bases for understanding the chemistry of gas phase dications. These can result from ionizations of monocations. Although we focus on gaseous species, implications for the dications observable under stable ion solution

conditions are drawn. We first document and analyze the very small dications. Then we consider the effects of substituents. A "building block" approach is used to highlight the common structural rules for organic dications.

2. Methods

The two gas phase techniques commonly employed to detect small dications are *c*harge-*s*tripping (CS) and *d*oubly *c*harged *i*on (DCI) mass spectrometry. These methods differ fundamentally in their approach, and are complemented by the charge-separation technique. This provides energetic information on metastable (decomposing) dications. Other mass spectrometric techniques (e.g., photoionization, *p*hoto*i*on-*p*hoto*i*on *c*oincidence (PIPICO), and *i*on *k*inetic *e*nergy *s*pectra (IKES)) which give or can be applied to dications are less important.

2.1. Charge-Stripping Mass Spectrometry [3d, 7, 8, 9]

This technique uses a double-focusing mass spectrometer, preferentially of reversed geometry (BE configuration). Most studies have been conducted on a VG Micromass ZAB-2F. The singly charged positive ions $M^{\oplus}$, which can be generated with a variety of ionization methods (typically *e*lectron *i*mpact, EI) or ion molecule reactions (when no suitable neutral precursors are available as for example $CH_5^{\oplus}$, $H_3O^{\oplus}$, etc.)) are mass selected by means of a magnetic field (*B*) before interacting with a target gas G (e.g., nitrogen, helium, or oxygen) in the collision cell located in the second field-free region. As the charge-stripping process [Eq. (1)] takes place in an isolated system, the energy necessary to drive the reaction is provided by the translational energy of $M^{\oplus}$ (typically several keV).

$$M^{\oplus} + G \rightarrow M^{2\oplus} + G + e^{\ominus} \quad (1)$$

Koop Lammertsma was born in Makkum, the Netherlands, in 1949. He received his M.Sc. in 1974 from the University of Groningen and his Ph.D. in organic chemistry in 1979 from the University of Amsterdam (with H. Cerfontain). After postdoctoral work with Professors F. Sondheimer, P. von R. Schleyer, and G. A. Olah, he joined the University of Alabama at Birmingham in 1983. His present research interests include the study of structures and reactivities of carbocations, electron deficient systems, strained hydrocarbons, small clusters, and lately the chemistry of phosphinidenes.

Paul von Ragué Schleyer was born in 1930 in Cleveland, Ohio, USA and was educated at Princeton University (B.A. 1951) and at Harvard University (M.A. 1956, Ph.D. 1957). He joined the Chemistry Department of Princeton University becoming Full Professor in 1965 and Eugene Higgins Professor of Chemistry in 1969. In 1976 Schleyer accepted his present position in Erlangen, West Germany. Among his many honors are the degree Honoris Causa bestowed by the Université de Lyon, France, in 1971, the Adolf von Baeyer Prize of the German Chemical Society (1986), the James Flack Norris Award in Physical Organic Chemistry of the American Chemical Society (1987), and the C.K. Ingold Medal and Lectureship of the Royal Society of Chemistry, London (1988). Schleyer is a Fellow or member of numerous scientific organizations. Seven books dealing with carbonium ions, the norbornyl cation, and ab initio molecular orbital theory, and over five hundred research publications are to his credit. His research contributions include the discovery of simple ways of synthesizing adamantane and other cage molecules by rearrangement, elucidation of solvolysis mechanisms, reactive intermediates, and a broad range of physical organic, organo-metallic, inorganic and theoretical topics. The discovery of basically new molecular structures by computer, particularly those involving lithium, is one of his major achievements.

Helmut Schwarz, born in Nickenich, Eifel, West Germany, worked for four years as a technician in chemical industry before beginning his studies at the Technical University in Berlin in 1966. In 1972 he was awarded a Ph.D. while working with F. Bohlmann and habilitated two years later. Post doctoral work with J. Seibl (Zurich), K. Biemann (MIT), and D. H. Williams (Cambridge, UK) led him to work in mass spectrometry. Since 1983 he has occupied a chair in Organic Chemistry at the Technical University in Berlin. He is co-editor of the International Journal of Mass Spectrometry and Ion Processes. He has been a guest Professor at the universities of Cambridge, Lausanne, Jerusalem and Haifa. His work on the gas phase chemistry and physics of ions has led to 400 scientific papers and has been recognized by the award of a "Dozentenstipendium" by the Fonds der Chemischen Industrie and the Otto-Klung Prize for Chemistry. In November he will receive the Otto-Baeyer Prize of Bayer AG, Leverkusen.

Charge-stripping peaks are obtained by scanning the electric sector voltage (E) around $E/2$, where E represents the electric voltage required to transmit stable $M^{\oplus}$ ions. The resulting spectra are known as $E/2$ spectra. The displacement of the peak from $E/2$ reflects the translational energy loss in the charge-stripping process and corresponds in a first approximation to the (presumably) vertical ionization energy of the monocation $M^{\oplus}$ if both $M^{\oplus}$ and $M^{2\oplus}$ are in their electronic ground states [eq. 2 and 3] and the collisions are

$$E_{obs} = (E - Q_{min})/2 \quad (2)$$

$$Q_{min} = IE(M^{\oplus} \rightarrow M^{2\oplus}) \quad (3)$$

inelastic. The minimum translational energy loss (Q_{min}) is measured from the high-energy side of this charge-stripping peak by extrapolation to the base line (Fig. 2).[7] While it

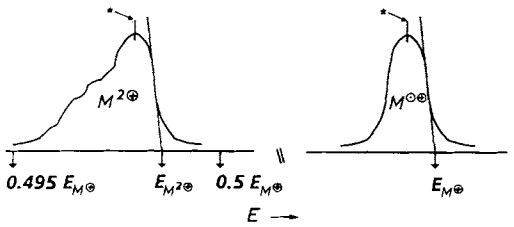

Fig. 2. Illustration of the method used to determine Q_{min} from a charge-stripping spectrum.

has been recognized that the cross-section for process (1) is affected by the nature of the collision gas, the ionization energies (IE) are considered to be independent of the collision gas used and can be compared with theoretically calculated vertical IE_v and adiabatic IE_a. Interference from singly charged ions can occur in cases in which a $M^{\oplus}$ dissociates to $(M/2)^{\oplus}$. Moreover, an experimental complication results from isotopic species due to naturally occurring isotopes. For example, high resolution mass spectrometry is required to distinguish between the $^{12}CH^{\oplus}$ and $^{13}C^{\oplus}$ cations and to make sure which "m/z 13" species is probed in the C.S. experiment (see below). The two different calibration methods that are in use for the determination of Q_{min} complicate comparisons with theoretical values. *Schwarz, Stahl,* and coworkers[3e] advocate a multiplicative calibration, whereas *Ast* and *Beynon*[3d, 7] employ an additive correction factor,

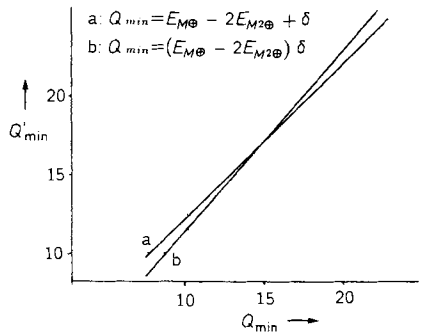

Fig. 3. Illustration of the additive a) and multiplicative b) calibration methods for determining Q_{min} values. Method (a) is used by the *Beynon/Ast* groups and method (b) by the *Stahl/Schwarz* groups. Both methods often use the value of 15.7 eV of toluene as standard for calibration.

both using toluene as calibrant with $Q_{min} = 15.7\,eV$[10] for $C_7H_8^{\odot\oplus} \rightarrow C_7H_8^{2\oplus}$. The values obtained in this manner become significantly different when the measured Q_{min} values are much larger (or much lower) than that of toluene as summarized in Figure 3. The results only are comparable when the measured Q_{min} value is similar in magnitude to that of the reference compound.

Charge-stripping mass spectrometry is a two step process in which the dications are generated in the second step through ionization of monocations that are thermally relaxed (lifetime $> 10^{-5}$ s). As a consequence, dications (like $CH_4^{2\oplus}$) can be detected that are not observable from direct double (vertical) ionization methods (EI) which may generate species above the dissociation threshold (Fig. 4).[11]

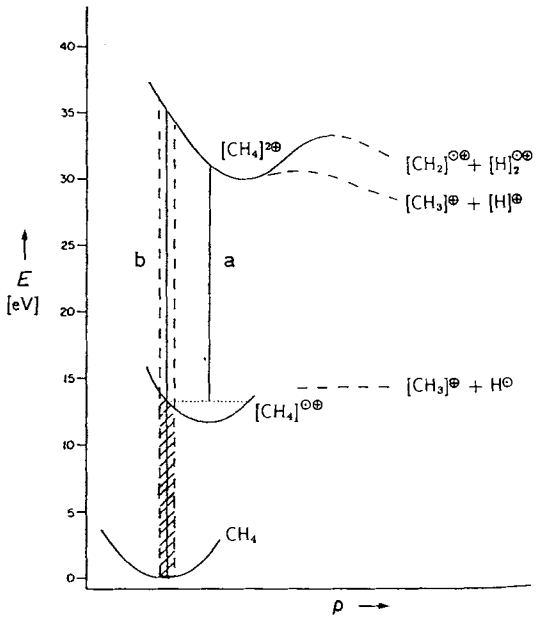

Fig. 4. Calculated MINDO/3 hypersurface for CH_4, $CH_4^{\odot\oplus}$, and $CH_4^{2\oplus}$. [11] The vertical lines represent the Franck-Condon transitions. The charge-stripping from $CH_4^{\odot\oplus}$ to $CH_4^{2\oplus}$ is indicated by a. Electron impact ionization of CH_4, shown by b gives an excited $CH_4^{2\odot}$ that lies above the dissociation asymptote.

2.2. Doubly-Charged Ion Mass Spectrometry[3d, 9b, 12, 13]

With this technique doubly charged ions, generated in the ion source, are fully accelerated into the first field-free region where the dications $M^{2\oplus}$ undergo single electron transfer with a target gas G [Eq. (4)].

$$M^{2\oplus} + G \rightarrow M^{\oplus} + G^{\oplus} \quad (4)$$

In this collision the momentum of the charged species is maintained. Thus, the resulting monocation product $M^{\oplus}$ has essentially the same velocity as the fast dication reactant $M^{2\oplus}$. The fast singly charged ions are transmitted through an electric sector operated at twice the normal voltage ($2E$) and subsequently through the magnetic sector for momentum analysis. The electric sector, set at $2E$, acts as a kinetic filter and discriminates against fast singly charged ions $M^{\oplus}$, formed by electron impact, and unreacted dications. A variant of this technique employs a reversed geometry instrument where the charge exchange reaction [Eq. (4)] occurs in

the second field-free region to momentum-analyzed ions. Similarly, the electric sector is set at twice the normal value required to transmit ions. The results are known as $2E$ spectra. A typical example is shown in Figure 5. *Beynon* has

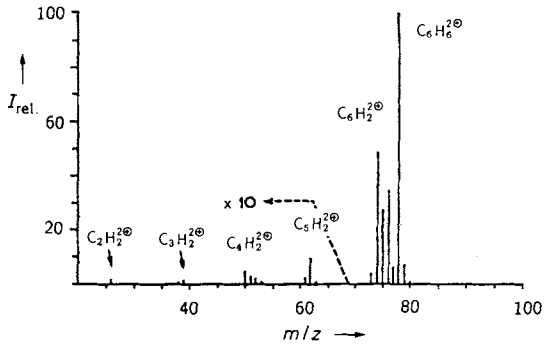

Fig. 5. Doubly-charged ion mass spectrum of benzene. [13b]

advocated the use of charge exchange for higher resolution of charge-stripping peaks in a multi-sector mass spectrometer.[14]

2.3. Charge Separation Mass Spectrometry[3d, 13a, 15]

Unimolecular fragmentations of dications [Eq. (5)] may occur in the second field-free region between the magnet and the electrostatic sector. Such processes ("Coulomb explosions"[*]) can be recorded by scanning the voltage across the sector from E to $2E$. The charge-separation peaks are typically steep sided and severely dished (Fig. 6). The width of a dished metastable peak is determined by the spread of total translational energy release E_T (in eV) of the ions. The release of this kinetic energy has been related to the release of Coulombic repulsion between two point charges in the fragmenting dication, separated by the intercharge distance R. Although the calculated value of R [Eq. (6)] is fictitious because of charge delocalization, it is inter alia used to discriminate between linear and cyclic dication structures. It must also be recognized that the determined kinetic energy release E_T refers to the transition state for the Coulomb explosion and may not necessarily be related to a ground state species.

Fig. 6. Unimolecular Mass-Selected-Ion-Kinetic-Energy (MIKE) spectrum of $C_4H_2^{2\oplus}$ ions. Peaks are due to charge-separation reactions: a–a from reaction $C_4H_2^{2\oplus} \rightarrow C_3H_2^{\odot\oplus} + C^{\odot\oplus}$ and b–b from reaction $C_4H_2^{2\oplus} \rightarrow C_3H^{\oplus} + CH^{\oplus}$.

[*] The "Coulomb explosion" in mass spectrometry should not be confused with the physical phenomena that one observes when high speed charged particles (with kinetic energy on the order of MeV) are accelerated through a thin solid film, at which process all the electrons are stripped from the nucleus. The resulting aggregate of positive ions (lifetime $<10^{-14}$ s) explodes due to the enormous Coulomb repulsion. All the velocity components of all the emerging fragment ions are measured precisely with a detector. From this on obtains a "picture" of $M^{\oplus}$ before the charge stripping. The most impressive example is that of $C_2H_3^{\oplus}$; it can be shown that the vinyl cation $H_2C=\overset{\oplus}{C}H$ has the non-classical bridged structure $HC(H^{\oplus})=CH$ instead of the open structure. For reviews see Z. Vagar, R. Naaman, E. P. Kanter in J. P. Maier (Ed.): *Ion and Cluster Ion Spectroscopy and Structure*, Elsevier, Amsterdam 1989, p. 1–26; *Science (Washington) 244* (1989) 426.

$$M^{2\oplus} \rightarrow M_1^{\oplus} + M_2^{\oplus} \quad (5)$$

$$R \text{ (in Å)} = 14.40/E_T \text{ (in eV)} \quad (6)$$

2.4. Computational Methods

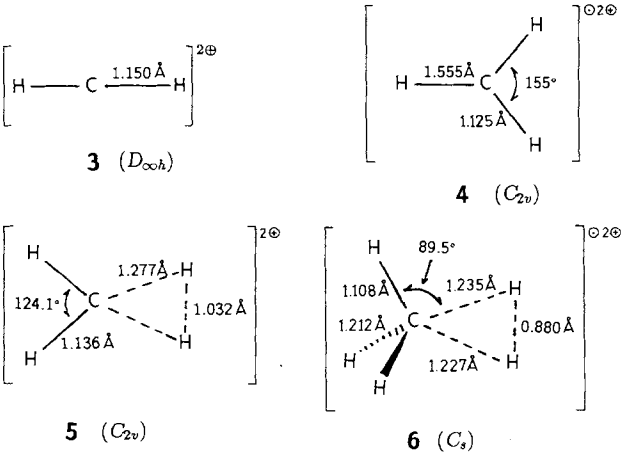
Most but not all of the ab initio calculations referred to in this review have been carried out with the GAUSSIAN series of programs, developed by *Pople* et al.[16] The strategy for ab initio calculations[16] and the available basis sets[16, 17] are well documented. However, a short synopsis may be useful. For electron deficient species, the minimal STO-3G basis set is inadequate. Typically, most studies start with a split-valence basis set like 3-21G at the Restricted (for singlets) or Unrestricted (for triplets) Hartree-Fock (HF) level of theory. The more flexible 6-31G* basis set includes valence d-functions to provide for polarization of the "heavy" (non-hydrogen) elements. The 6-31G** basis set also includes p-functions to describe H-polarization. The most complete basis set we refer to is 6-311G**, which has single zeta core, triple zeta valence, and polarization functions on all atoms.

Of the various ways to include the effect of electron correlation in energy evaluations, we refer mainly to the use of Møller-Plesset (MP) perturbation theory. The most common level is MP2, this refers to the second order treatment which occasionally is included in geometry optimizations. However, only single point calculations are feasible with MP4(SDTQ); this full fourth order treatment includes contributions from single, double, triple, and quadruple substitutions. Such calculations are denoted MP4(SDTQ)/6-311G**//HF/6-31G*, where "//" means "at the geometry of."

Generally, geometries are fully optimized at the (Un)Restricted Hartree-Fock level under specified symmetry constraints. Throughout the text we refer to HF/6-31G* optimized geometries unless indicated otherwise. A geometry is fully characterized as an equilibrium structure (or minimum) if the Hessian (force constant) matrix of its stationary point (identified by a gradient of zero) has only positive eigenvalues; such a structure has only real harmonic frequencies. A transition structure is characterized by one imaginary frequency, whose normal mode indicates the reaction coordinate.

3. Observed and Calculated Gaseous Dications

In order to appreciate the structural features that are common to gaseous dications, we focus on small carbodications.



Virtually all are known. Both the larger carbodications and the heterodications display similar structural trends.

3.1. One Heavy Atom Dications, $XH_n^{2\oplus}$

Described in the following and listed in Table 1 are the observed and calculated dication hydrides containing the heavy elements C, Si, N, P, O, and S.

3.1.1. C_1-Dications

Charge-stripping of methane[7, 8, 18] produces the $CH_4^{2\oplus}$ **5**, $CH_3^{\odot 2\oplus}$ **4**, $CH_2^{2\oplus}$ **3**, and $C^{2\oplus}$ dications, but not $CH^{\odot 2\oplus}$. In contrast to the charge-stripping (and PIPICO)[19] experiments, the $2E$ spectrum[11] of methane does not show a trace of its $CH_4^{2\oplus}$ dication. Figure 4 presents a rationale for this observation (see also section 2.1.). Ionization of the methonium ion $CH_5^{\oplus}$ leads to $CH_5^{\odot 2\oplus}$ **6**.[20] The experimental and

theoretical ionization energies (Q_{min}) of the corresponding monocations are given in Table 1, in which the barriers for deprotonation and thermodynamic stabilities of the dications are also tabulated. The reported data for $CH^{\odot 2\oplus}$, a controversial species (see below), also are given.

The experimental and theoretical adiabatic ionization energies listed in Table 1 appear to be in good agreement. Differences can be attributed to the occurrence of excited monocations which give lower experimental values. The discrepancies in most experimental ionization energies result from different calibration methods (see comment in section 2.1.).

The odd-electron species $CH^{\odot 2\oplus}$ is the smallest and most controversial diatomic carbodication. Initial studies by *Beynon* et al. claimed its observation by charge-transfer using N_2 as collision gas.[7, 18] However, the first theoretical study showed the $CH^{\odot 2\oplus}$ energy potential to be repulsive.[21] *Mathur* et al.[22] have subsequently supported the experimental finding. *Wetmore* et al.'s theoretical study[23] using multireference CI-DZP calculations gave a kinetic stability for $CH^{\odot 2\oplus}$ of 0.01 eV. However, *Koch* et al. (using O_2, which is known to have the highest cross-section for charge stripping) have found no experimental evidence for $CH^{\odot 2\oplus}$ nor did they find a minimum on the potential energy surface of the three lowest $^2\Sigma^{\oplus}$ states of $CH^{\odot 2\oplus}$ using CISD (five electrons correlated) on the large 6s6p3d1f/4s3p1d Slater-type basis set.[24] They conclude that there is no metastable $CH^{\odot 2\oplus}$ radical dication and attribute the earlier erroneous

Table 1. Theoretical (IE_a) and experimental (Q_{min}) ionization energies of $XH_n^{\oplus}$ (n = 1–6) cations and the kinetic and thermodynamic stabilities (in kcal/mol) toward deprotonation of the corresponding dications $XH_n^{2\oplus}$.

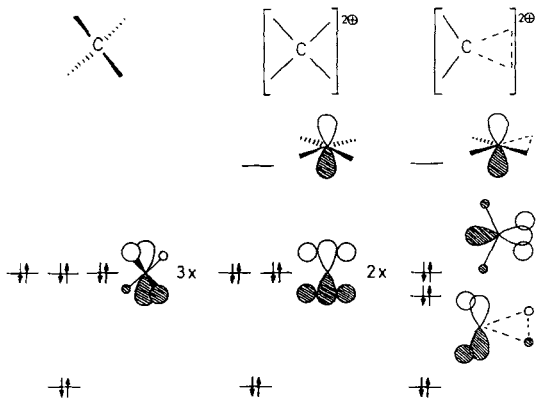
conclusion to experimental artifacts possibly led by incomplete separation of the isotopic $^{13}C^{\oplus}$ and $^{12}CH^{\oplus}$ species in the earlier experiments.

Oxidation of the methyl cation leads to $CH_3^{\odot 2\oplus}$ **4** with a C_{2v} geometry, that can be viewed as a complex between $CH_2^{2\oplus}$ and a hydrogen atom.[21] Charge-stripping of $CH_5^{\oplus}$, the parent "non-classical" ion, gives the methonium radical dication $CH_5^{\odot 2\oplus}$ with a similar C_s geometry.[20]

Because of the two-electron difference, dications display structural trends that differ from their neutral precursors. This is already evident in the parent C_1-dications. For example, the methylene dication, $CH_2^{2\oplus}$ **3**, is linear ($D_{\infty h}$) with a divalent, dicoordinate sp-hybridized carbon atom[21] similar to the isoelectronic BeH_2, whereas singlet methylene, $:CH_2$ (C_{2v}), contains a sp^2-carbon. The methane dication, $CH_4^{2\oplus}$ **5**, has a planar C_{2v} symmetry with a planar, trivalent, tetracoordinated "sp^2-hybridized" carbon and an empty p-orbital orthogonal to the plane of the molecule,[25] while neutral methane (T_d) is sp^3-hybridized. A molecular orbital diagram (Fig. 7) shows that removal of two electrons from the triply degenerate methane HOMO results in a planar dication structure due to the Jahn–Teller effect. Because there are only six valence electrons available to bond four hydrogens to carbon, the best bonding arrangement results with two regular CH bonds and one 3 center 2 electron (3c–2e) CHH bond. Consequently, the methane dication can be viewed as a $CH_2^{2\oplus}$–H_2 complex where the hydrogen molecule interacts in an "side-on" fashion with one of the vacant p-orbitals of the methylene dication.[25] Earlier studies at lower theoretical levels indicated a square planar D_{4h} structure for $CH_4^{2\oplus}$[21, 26].



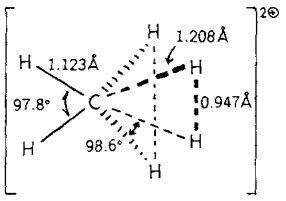


Fig. 7. MO diagram of methane and the planar D_{4h} and C_{2v} dications.

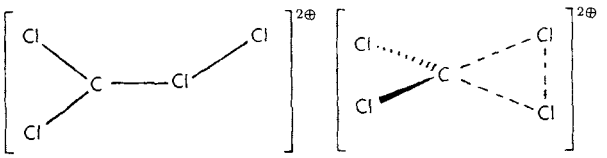
Both $CH_2^{2\oplus}$ and $CH_4^{2\oplus}$ units can be used as building blocks in the structural analysis of larger dications, as the ylid dications and the cation-substituted methonium ions, (see section 3.3.6). The methane dication, the simplest example of anti-van't Hoff stereochemistry, already represents a $CH_2^{2\oplus}$-H_2 complex. Diprotonated methane $CH_6^{2\oplus}$ **7** contains

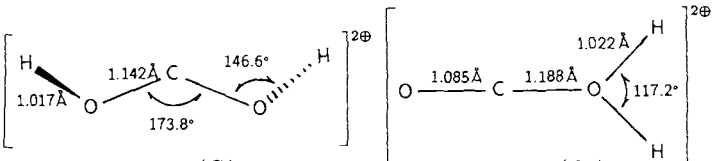


7 (C_s)

a tetravalent, hexacoordinate sp^3-hybridized carbon atom with two elongated 3c–2e ligands and can be pictured as a $CH_2^{2\oplus}$ dication complexed with two hydrogen molecules.[27] $CH_6^{2\oplus}$ has not been observed experimentally. As $CH_4^{2\oplus}$ and $CH_6^{2\oplus}$ illustrate, there is no simple monocation analogy with regard to "classical" and "non-classical" carbodications.

3.1.2. Halogenated C_1-Dications

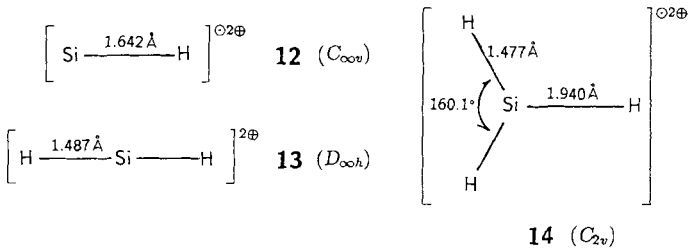
Oxidation of carbon tetrachloride to its dication, accomplished by electron impact (EI) ionization, has been shown by *m*ass-selected *i*on *k*inetic *e*nergy spectrometry (MIKE).[28a] In sharp contrast to the methane dication which prefers a planar $CH_2^{2\oplus}$–H_2 complex conformation, planar $CCl_4^{2\oplus}$ does not correspond to a stationary point. The planar "end-on" complex between $CCl_2^{2\oplus}$ and Cl_2 **8** is 39 kcal/mol more stable than $CCl_4^{2\oplus}$ **9** which represents a transition structure (C_{2v}).[29] At HF/4-31G the ylid dication $Cl_2CClCl^{2\oplus}$ **8** is the global $CCl_4^{2\oplus}$ minimum, but appears to be very unstable thermodynamically (> 100 kcal/mol)



8 (C_s) **9** (C_{2v})

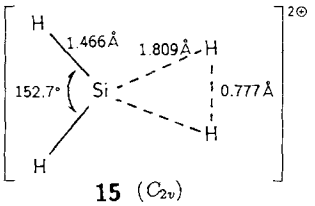
toward all fragmentations.[29] Interestingly, $CCl_4^{2\oplus}$ can not be generated by charge-stripping from the $CCl_4^{\odot\oplus}$ radical cation (distorted C_{2v}) nor from the $Cl_2CClCl^{\odot\oplus}$ distonic radical cation that is generated by the decarbonylation of $CCl_3COCl^{\oplus}$.[28] However, a double charge transfer experiment gave a double ionization energy for CCl_4 of 29.3 eV.[30]

The $CCl_3^{\odot 2\oplus}$ and $CCl_2^{2\oplus}$ dications have been observed in several EI studies.[31] Their appearance energies (AE) have been determined to be 30.4 and 31.8 eV, respectively.[31a] The coincidence method has been applied to the $CCl_4^{2\oplus}$ and $CF_4^{2\oplus}$ dications.[32] The latter shows three dissociations, e.g. the fragmentation to $CF_3^{\oplus} + F^{\oplus}$ releases 5.0 eV of kinetic energy. Similarly, the $CH_3I^{2\oplus}$ dication releases 5.1 eV kinetic energy during the dissociation into $CH_3^{\oplus} + I^{\oplus}$.



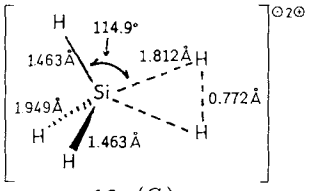
A variety of halogenated $CX^{\odot 2\oplus}$ and $CX_2^{2\oplus}$ dications (X = F, Cl, Br, and I) has been observed by charge-stripping.[33] The bond lengths in these $D_{\infty h}$ ground states are remarkably short,[34] but relatively long in the transition structures for dissociation.[35] The C–F bond of 1.146 Å (MP2/6-31G*) in $CF^{\odot 2\oplus}$ is extremely short.[34] Similarly, the C–F bond of 1.166 Å in $CF_2^{2\oplus}$ is 0.149 Å shorter than in neutral CF_2. Also the C–O bonds in the dihydroxycarbene dication $C(OH)_2^{2\oplus}$ are relatively short (1.142 Å).[36] Comparison with *neutral* $C(OH)_2$ is appropriate. This structure **10** has a near linear OCO geometry and is 11 kcal/mol (MP4/6-311G**) more stable than the H_2O–CO dication complex **11**. No experimental data on $CH_2O_2^{2\oplus}$ have been reported.

10 (C_2) **11** (C_{2v})



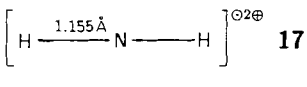
3.1.3. Heterodications

Charge-stripping experiments have afforded the silicodications $SiH^{\odot 2\oplus}$ **12**, $SiH_2^{2\oplus}$ **13** and $SiH_3^{\odot 2\oplus}$ **14**.[33, 37] In sharp contrast to $CH^{\odot 2\oplus}$, the $SiH^{\odot 2\oplus}$ radical dication has a remarkable kinetic stability toward deprotonation of

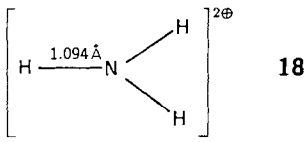


12 ($C_{\infty v}$) **13** ($D_{\infty h}$) **14** (C_{2v})

1.06 eV as calculated by MRDCI (multireference CI) and CASSCF (*c*omplete *a*ctive *s*pace SCF).[37c] As a result of the lower electronegativity and higher polarizability of silicon, the calculated (thermodynamic) deprotonation energies of the silicon dications are markedly less exothermic than that of the corresponding carbodications.[37a] The $SiH_4^{2\oplus}$ **15** and $SiH_5^{\odot 2\oplus}$ **16** dications are kinetically stable, but have not been

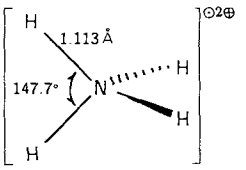


15 (C_{2v})



16 (C_1)

observed in the gas phase due to lack of suitable precursor ions. Both dications can be viewed as hydrogen complexes of $SiH_2^{2\oplus}$ and of $SiH_3^{2\oplus}$, respectively,[37a] having sets of short two electron and of long 3c–2e Si–H bonds.



Of the $NH_n^{2\oplus}$ series, only the $NH_2^{\odot 2\oplus}$ **17** and $NH_3^{2\oplus}$ **18** dications are accessible by charge-transfer mass spectrometry.[8, 38] $NH^{2\oplus}$ has a repulsive potential energy surface.[38, 39] The ammonium dication, $NH_4^{\odot 2\oplus}$ **19**, is kinetically stable, but vertical ionization leads to an energy state above the threshold for deprotonation.[38, 39] In contrast to the $NH_n^{2\oplus}$ dications, no experimental data are available for $PH_n^{2\oplus}$. A theoretical study shows that all these phosphodications (n = 1–4, (**20**–**23**)) are kinetically stable, with a deprotonation barrier for $PH^{2\oplus}$ as high as 64.5 kcal/mol.[38a] Also the $NH_5^{2\oplus}$ (C_{4v}) and $PH_5^{2\oplus}$ (C_s) are calculated to be kinetically stable species.[39b]

it has eluded gas phase detection due to the lack of a suitable precursor, but was inferred from H/D exchange in the protonation of $H_3O^{\oplus}$ in super acid media.[40b] The diatomic $OH^{\odot 2\oplus}$ has a repulsive potential energy surface.[38a, 40a] Similarly, evidence has been presented for the existence of $SH_4^{2\oplus}$ **30** under stable-ion solution conditions[41] and $SH_n^{2\oplus}$ (n = 1–3, (**27**–**29**)) in charge-stripping experiments.[8] All sulfodications have high barriers for deprotonation.[38a, 41]

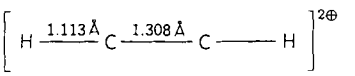
3.2. Two Heavy Atom Dications

This section is mainly limited to carbon based dications. Few other two heavy atom systems have been studied.

3.2.1. C_2-Dications

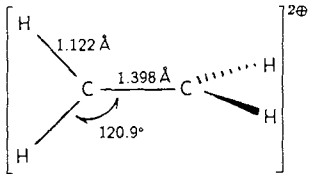


The $C_2H_n^{2\oplus}$ dications with n = 1–6 have been observed in the gas phase by charge-stripping from ethane and ethyl halides.[7, 18] The second ionization energies Q_{min} ($M^{\oplus} \rightarrow M^{2\oplus}$) are given in Table 2.

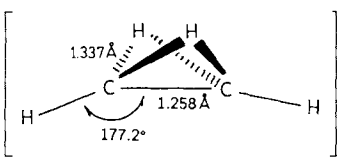
Table 2. Experimental (Q_{min}) ionization energies of C_2-cations and theoretical stabilities (in kcal/mol) of the corresponding dications.

Monocations	Q_{min} [eV] [a]		Dications	Deprotonation Barrier	Deprotonation Stability
$C_2H^{\oplus}$	20.4	21.6	$C_2H^{2\oplus}$		
$C_2H_2^{\odot\oplus}$	20.5	20.8	$C_2H_2^{2\oplus}$	65	−9.8 [b]
$C_2H_3^{\oplus}$	20.1	21.3	$C_2H_3^{\odot 2\oplus}$		
$C_2H_4^{\odot\oplus}$	17.8	20.0	$C_2H_4^{2\oplus}$	69	−16 [c]
$C_2H_5^{\oplus}$	19.1	20.2	$C_2H_5^{\odot 2\oplus}$		
$C_2H_6^{\odot\oplus}$	19.4	18.4	$C_2H_6^{2\oplus}$	57	−105 [d]
$C_2H_7^{\oplus}$	20.5	–	$C_2H_8^{2\oplus}$	–	−100 [e]

[a] First column: 5 keV accelerating voltage, N_2 as collision gas. *Beynon*'s calibration. [7, 18, 45, and 49] Second column: 8 KeV, O_2, *Stahl*'s calibration, unpublished data by *D. Stahl* and [47]. [b] Ref. [42]. [c] Ref. [43]. [d] Ref. [48], the barrier for demethylation is 32 kcal/mol (MP4/6-311G**). [e] Ref. [27b].



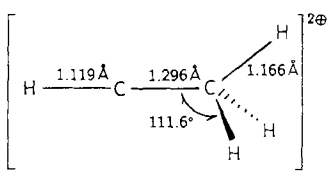
The acetylene dication $C_2H_2^{2\oplus}$ **31** is linear with a triplet electronic configuration and can be viewed as dioxidized acetylene, with oxidation occurring from its degenerate π-or-



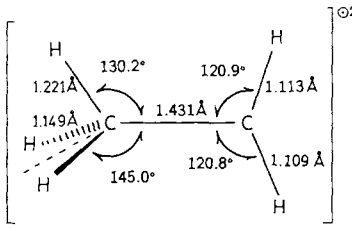
31 ($D_{\infty h}$)

bitals.[42] The short C–C bond length of 1.308 Å (HF/6-31G*) in the $C_2H_2^{2\oplus}$ dication is only 0.123 Å longer than that in neutral acetylene. The dication has a higher barrier of 62 kcal/mol deprotonation, which is only 9.8 kcal/mol exothermic.

The ethylene dication $C_2H_4^{2\oplus}$ (**32**, D_{2d}) also has a relatively short C–C single bond, 1.398 Å (MP2/6-31G*).[43] In the planar form this bond lengthens to 1.587 Å and the energy increases by 28 kcal/mol. The short C–C bond results from significant hyperconjugation of each monocation center with its neighboring CH_2 group i.e., *cross-hyperconjugation*.[3a] This effect is maximized in the doubly-H-bridged structure **33**, which can be viewed as diprotonated acetylene; the C–C bond length is 1.258 Å. However, this non-classical species is 12 kcal/mol (MP4/6-311G**) less stable than the classical D_{2d} isomer.[43c,d] The hyperconjugative stabilization in the ethylidene dication CH_3–$CH^{2\oplus}$ (**34**, C_{3v}) also results in a short C–C single bond distance, 1.297 Å,[43c,d] although this species is 22 kcal/mol higher in energy.

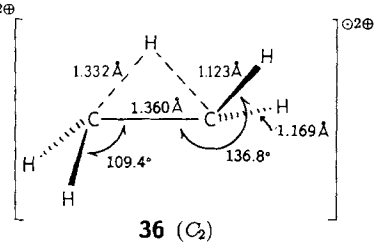


32 (D_{2d})



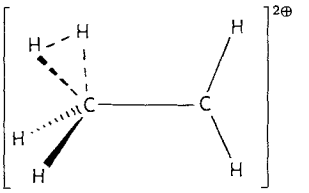
33 (C_{2v})

∠HCCH=104.3°

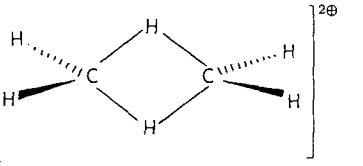


34 (C_{3v})

The ethyl dication $C_2H_5^{\odot 2\oplus}$ **35** has an open (classical) structure with a C–C bond length of 1.431 Å (MP2/6-31G*), this is 6.5 kcal/mol more stable than the hydrogen-bridged (nonclassical) transition structure **36**.[44] The calculated[44] second adiabatic ionization energy of 19.7 eV is in reasonable agreement with the experimental[7,45] values of 19.1 and 20.2 eV.

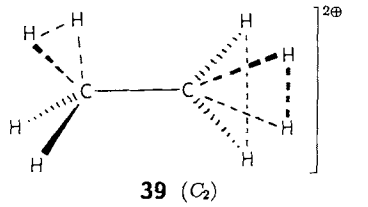


35 (C_s)



36 (C_2)

The ethane dication $C_2H_6^{2\oplus}$ has been the subject of several theoretical studies.[27b,46] Charge stripping of the ethane cation radical with O_2 (but not N_2)[7,45] as collision gas resulted in the detection of a minute amount of $C_2H_6^{2\oplus}$.[47] Although it has been argued that the observed species is $^{13}CCH_5^{\odot 2\oplus}$,[45b] the detection of both these dications has now been achieved.[48] Two $C_2H_6^{2\oplus}$ minima have been identified by theory.[27b,46,48] The $C_2H_6^{2\oplus}$ dication was observed in a collision-induced MIKE spectrum of $C_2H_6^{\odot\oplus}$; an IE of 19.4 eV was reported.[49] The most stable $C_2H_6^{2\oplus}$ structure is a carbenium-carbonium dication **37**, which can be viewed as a hydrogen molecule complex of the ethylene (D_{2d}) dication **32**.[27b] This isomer is 12 kcal/mol (MP4/6-311G**) more stable than the "diborane" form **38**. The energetically preferred pathway for dissociation of the ethane dication $C_2H_6^{2\oplus}$ is homolytic cleavage into the two methyl cations ($\Delta\Delta H_f^\circ$ = 32 kcal/mol). It is likely that the process involves the diborane structure.[48] The deprotonation barrier for this dication is much higher, 52 kcal/mol.



37 (C_s)

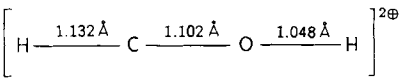
38 (D_{2h})

The $C_2H_7^{\odot 2\oplus}$ radical dication has been observed in a collision-induced MIKE spectrum of $C_2H_7^{\oplus}$. An ionization energy of 20.5 eV is reported.[49] No theoretical data are available on $C_2H_7^{\odot 2\oplus}$.

Diprotonated ethane, $C_2H_8^{2\oplus}$ **39**, has only been studied theoretically.[27b] Its structure resembles a di-hydrogen complex of the ethylene dication ($C_2H_4^{2\oplus}$, D_{2d}, **32**). The likely dissociation route is the formation of $CH_5^{\oplus}$ + $CH_3^{\oplus}$.

39 (C_2)

3.2.2. *Halogenated C_2-Dications*

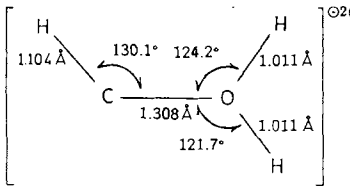


Several fluoro substituted ethylene dications $C_2H_nF_{4-n}$ (n = 0–3) have been observed and have been studied by theory.[50] The measured second ionization energies (Q_{min})[50c] are for some systems in reasonable agreement with the theoretical values[50a] (given in parentheses); 18.7 (19.1) eV for $H_2CCHF^{\odot\oplus}$, 18.7 (19.0) eV for $H_2CCF_2^{\odot\oplus}$, 20.4 (18.4) eV for $HFCCF_2^{\odot\oplus}$, and 19.0 (18.2) eV for $F_2CCF_2^{\odot\oplus}$. In contrast with the ethylene dication, $C_2F_4^{2\oplus}$ prefers the planar D_{2h} structure over the D_{2d} form by 2.3 kcal/mol.[50a,b] Its long C–C and short C–F bond lengths

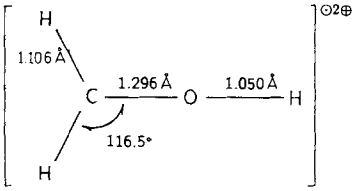
of 1.587 and 1.199 Å, respectively, result from effective interactions between the fluorine lone pairs and the cationic centers.

3.2.3. Substituted Methylene Dications, $HCX^{2\oplus}$

The methyl derivative of the doubly charged methylene carbene, the ethylidene dication $HCCH_3^{2\oplus}$ **34**[43] was discussed above.



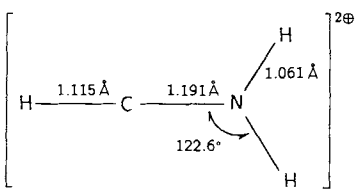
The hydroxymethylene dication $H–C–OH^{2\oplus}$ **40**, but not the isomeric formaldehyde dication $H_2CO^{2\oplus}$, has been ob-



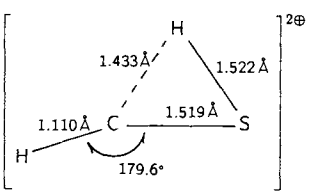
40 ($C_{\infty h}$)

served in the gas phase.[51] The calculated ionization energies[52] of 18.9 (IE_v, vertical) and 17.2 (IE_a, adiabatic) eV are in reasonable agreement with the experimental Q_{min} value of 17.7 eV.[51] Theory confirms dication **40** to be the global minimum with a 20 kcal/mol barrier for deprotonation to $H–CO^{\oplus}$.[52] The intercharge distance R for this process is 4.0 Å as estimated from $E_T = 3.6$ eV.[51] We note that the calculated H,H-separation in the corresponding transition structure is 4.104 Å at MP2/6-31G*.[52]

Although the oxoniomethylene radical dication $H–C–OH_2^{\odot 2\oplus}$ **41** is 22.7 kcal/mol (MP2/6-31G**) more stable than the hydroxymethyl radical dication $H_2C–OH^{\odot 2\oplus}$ **42**,



41 (C_s)

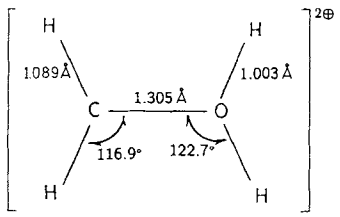


42 (C_{2v})

they are separated by a barrier of 24 kcal/mol. This prevents rapid interconversion.[53a] In fact, only the higher energy isomer is observed in the charge stripping of $H_2C–OH^{\oplus}$. The experimental Q_{min} of 22.5 eV, is in good agreement with the theoretical ionization energy, $IE_v = 22.2$ eV.[53a]

The most stable $H_3CN^{2\oplus}$ species, the aminomethylene dication $H–C–NH_2^{2\oplus}$ **43**, resides in a deep potential well. The barrier for deprotonation is 42 kcal/mol (MP4/6-311G**).[53b] Its estimated ionization energies are IE_v = 18.7 eV und IE_a = 17.3 eV, but due to the lack of a suitable precursor no experimental data are available. The halogenated carbene dications $H–C–F^{2\oplus}$ (C–F = 1.138 Å, IE_v =

43 (C_{2v})



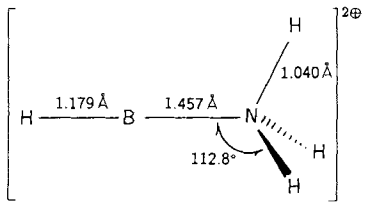
44 (C_s)

21.0 eV), $HC–Cl^{2\oplus}$ (C–Cl = 1.459 Å, IE_v = 17.8 eV), and the H-bridged $CH_2S^{2\oplus}$ **44** are predicted by theory (MP3/6-31G**) to be experimentally observable.[43d]

3.2.4. Ylid Dications, $H_2C–XH^{2\oplus}$

Structures of the type $H_2C–XH^{2\oplus}$ (X = halogen, OH, SH, NH_2) can be viewed as dioxidized ylids. Formal removal of the free electron pair of the ylid carbon strengthens the bond between the carbon and the heteroatom. While the interaction between methylene and XH in the neutral ylid is at best weak,[54] the dication strongly prefers a tight structure.

The $CH_4O^{2\oplus}$ ylid dication results from charge-stripping of $H_2COH_2^{\odot\oplus}$,[55] and also from the methanol radical cation $CH_3OH^{\odot\oplus}$, if oxygen is used as collision gas.[55c] The $CH_3OH^{2\oplus}$ dication is purely repulsive.[55c] The theoretical vertical ionization energy for $H_2COH_2^{\odot\oplus}$, 16.6 eV, is in good agreement with the experimental Q_{min} value of 16.5 eV.[55c] A short C–O bond length of 1.314 Å (MP2/6-31G*) is calculated for this planar methyleneoxonium dication **45**,[56] which

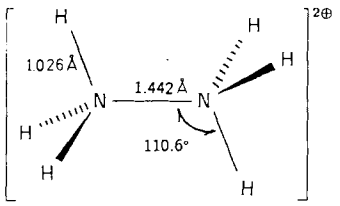


45 (C_{2v})

is isoelectronic with ethylene. In contrast, the C–O distance in the hydrated methylene ylid (C_s) is 1.805 Å (MP2/6-31G*).[54c]

Vertical ionization energies (Q_{min}) have also been obtained by charge-stripping experiments[55c] and theory[56] for related ylids. They are, (with the theoretical values in parentheses): 19.8 (15.7) eV for $H_2CSH_2^{\odot\oplus}$, 18.9 (16.2) eV for $H_2CNH_3^{\odot\oplus}$, 17.9 (18.8) eV for $H_2CFH^{\odot\oplus}$, 17.5 (17.2) for $H_2CClH^{\odot\oplus}$, 17.6 eV for $H_2CBrH^{\odot\oplus}$, and 16.3 eV for $H_2ClH^{\odot\oplus}$. The discrepancies between the theoretical and experimental data for the sulfonium and ammonium ylids are significant and are as yet unexplained. Theoretical studies show that these ylid dications have high barriers for both deprotonation and homolytic cleavage to $CH_2^{\odot\oplus} + XH^{\odot\oplus}$. The HF/6-31G* calculated C–X bond distances are 1.420 Å for $H_2C–NH_3^{2\oplus}$, 1.738 Å for $H_2C–SH_2^{2\oplus}$, 1.348 Å $H_2C–FH^{2\oplus}$, and 1.673 Å for $H_2C–ClH^{2\oplus}$.[56] The bond lengths in all these dications are shorter than in the neutral ylids. The calculated phosphonium ylid dication (C–P = 1.879 Å)[56] has not yet been observed experimentally.

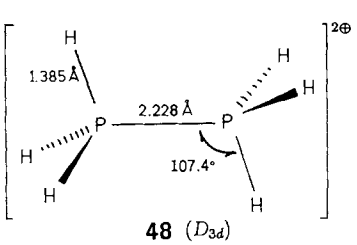
3.2.5. Heterodications



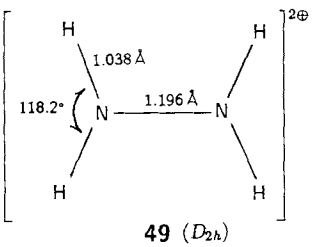
Aminoborane is isoelectronic with ethylene. Charge-stripping shows the formation of a $BNH_4^{2\oplus}$ dication from the radical cation precursor. The observed Q_{min} value of 15.2 eV is in reasonable agreement with the IE_v value of 15.8 eV (MP4/6-311G**) calculated for the ammonia borene $H_3NBH^{2\oplus}$ **46**; the 0.6 eV energy difference results since oxi-

46 (C_{3v})

dation occurs from the excited aminoborene $HB{-}NH_3^{\odot\oplus}$.[57] The structural preference for $H_3N{-}BH^{2\oplus}$ (isoelectronic with the high-energy ethylene dication isomer $H_3C{-}CH^{2\oplus}$ **34**), over the aminoborane dication $H_2N{-}BH_2^{2\oplus}$ (cf. $H_2C{-}CH_2^{2\oplus}$) is attributed to the strong donor–acceptor interaction (see section 3.3.6) between the $BH^{2\oplus}$ and NH_3 fragments.



The hydrazinium dication **47** has been subject to a variety of spectrometric studies. An X-ray structure on the $N_2H_6F_2$



47 (D_{3d})

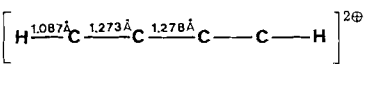
salt is available.[58] The calculated short N–N bond of 1.442 Å (HF/6-31G*)[56] is in agreement with the geometry in the crystal. Theory predicts that the dication should not be accessible by charge-stripping, because vertical ionization of the $H_3NNH_3^{\odot\oplus}$ radical cation with its long N–N bond of 2.164 Å would lead to dissociation.[59] Even though protonation of $N_2H_5^{\oplus}$ is exothermic, this is not possible in the gas phase, due to the barrier resulting from electrostatic repulsion. Dissociation of the dication **47** into two $NH_3^{\odot\oplus}$ radical cations (33 kcal/mol) has a 41 kcal/mol barrier (MP4/6-311G**).[60] The staggered form of $P_2H_6^{2\oplus}$ **48** also is calculated to reside in a deep potential well. In contrast, $H_2OOH_2^{2\oplus}$, $H_2SSH_2^{2\oplus}$, $HFFH^{2\oplus}$, and $HClClH^{2\oplus}$ have small dissociation barriers.[60]

The hydrazine dication $H_2NNH_2^{2\oplus}$ **49** is isoelectronic with ethylene and has a planar D_{2h} structure with a N–N bond

48 (D_{3d})

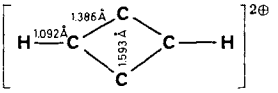
49 (D_{2h})

only 1.196 Å in length (HF/6-31G*). The calculated IE_v of 16.2 eV agrees well with the observed Q_{min} value of 15.8 eV for the gas phase oxidation of ionized hydrazine.[61]



3.3. The Building Block Approach

The dications discussed so far reveal structural features applicable to larger systems. To elaborate this theme, we now discuss classes of larger gaseous dications. Because the $C_nH_2^{2\oplus}$, $C_nH_4^{2\oplus}$, and $C_nH_6^{2\oplus}$ carbodications are ubiquitous in doubly charged ion mass spectra,[3d,62] we will employ these species to illustrate common features and building blocks that can be used more generally to describe dication structures.

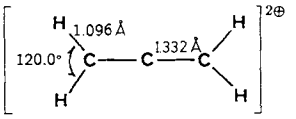


3.3.1. The $C_nH_2^{2\oplus}$ Carbodications

Doubly-charged species with n = 2–9, have been the subject of several studies.[63–66] Expectantly, linear acetylene-like structures $H{-}C_n{-}H^{2\oplus}$ are found for all, but $C_4H_2^{2\oplus}$ is an exception (see below).[64] The different fragmentation patterns observed[64] in the charge-separation reactions of $C_nH_2^{2\oplus}$ ions with even and with odd numbers of carbon atoms qualitatively confirm the theoretical prediction that these doubly-charged ions prefer, respectively, singlet and triplet states. The deprotonation of $C_nH_2^{2\oplus}$ with n = even has been ascribed to formation of excited dications; the ground state deprotonations for all $C_nH_2^{2\oplus}$ dications (n > 2) are endothermic.[65]

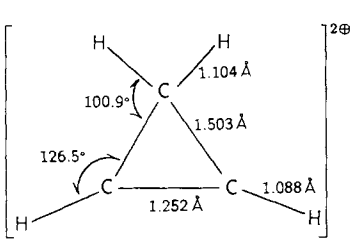
$C_4H_2^{2\oplus}$ and Inverted Tricoordinate Carbons: Two charge-separation reactions are observed for $C_4H_2^{2\oplus}$ i.e., to give $C_3H^{\oplus} + CH^{\oplus}$ and to give $C_3H_2^{\odot\oplus} + C^{\odot\oplus}$.[64] Formation of the latter fragments is considered to result from a cyclic form. The two processes have different translational energies E_T, corresponding to a difference in intercharge distance R of 0.4 Å.[64] A theoretical study[67] on $C_4H_2^{2\oplus}$ shows the linear triplet **50** to be only 13.3 kcal/mol (MP3/6-31G*) more stable than its rhombic D_{2h} isomer **51**. The energies of the two observed $C_4H_2^{2\oplus}$ fragmentations are in agreement with experiment. Dissociation of $CH^{\oplus}$ from the linear structure is endothermic by 36.7 kcal/mol, while loss of $C^{\odot\oplus}$ from the rhombic isomer "costs" 14.7 kcal/mol.[67]

50 ($D_{\infty h}$)



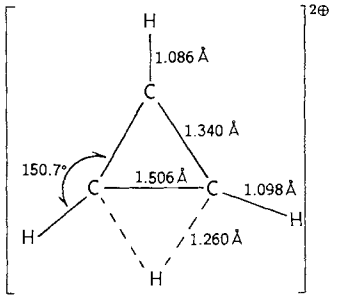
51 (D_{2h})

Rhombic $C_4H_2^{2\oplus}$ **51** can be viewed as diprotonated rhombic C_4 and is of considerable interest because of its two inverted tricoordinate carbons.[68] Its stability arises from π-electron aromatic delocalization. This balances the high ring-strain which is augmented by the "non-bonding" σ-orbital between the two bridgehead carbons. The transannular and ring C–C bond distances, 1.593 and 1.386 Å (HF/6-31G*), respectively, are remarkably short for a doubly charged cyclic species.[67,68]



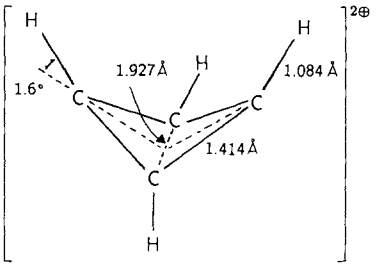
3.3.2. The $C_nH_4^{2\oplus}$ Carbodications

These dications, present in high abundance in the 2*E* spectra of a variety of hydrocarbons,[62,69] also have been studied theoretically several times.

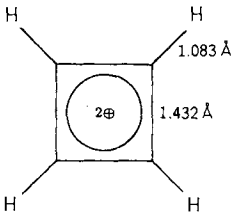


The methane $CH_4^{2\oplus}$ and ethylene $C_2H_4^{2\oplus}$ dications already have been discussed above. A kinetic energy release E_T of 4.44 eV for the $C_3H_4^{2\oplus}$ dication has been determined for the charge separation involving loss of a proton.[70] Since this translates into an intercharge distance of 3.24 Å (significantly less than the $R = 4.29$ Å (from $E_T = 3.36$ eV) measured in the same study for $C_3H_2^{2\oplus}$), a cyclic $C_3H_4^{2\oplus}$ structure has been suggested.[70] Collisional activation (CA) and charge-stripping of three $C_3H_4^{\odot\oplus}$ isomers (allene, propyne, cyclopropene) suggest the existence of isomeric dications.[71] A study using the coincidence method also suggests the presence of two isomers.[72] $C_3H_4^{2\oplus}$ dications have also been observed in $2E$ spectra; an appearance potential of 30.2 eV is reported in an EI study.[73] In strongly acidic media H/D exchange has been observed for donor-stabilized cyclopropenium ions, and has been suggested to occur through C-protonation.[74] Our recent ab initio study[75] on the parent $C_3H_4^{2\oplus}$ indicates the existence of a protonated cyclopropenium ion to be unlikely. Instead, the linear allene dication **52** with a planar (D_{2h}) structure is found to be the global minimum. This lies in a deep potential well with a deprotonation barrier of 83 kcal/mol and barriers of ca 15 kcal/mol (all MP4/6-31G*) for both hydrogen and carbon scrambling **53**, **54**.

52 (D_{2h})

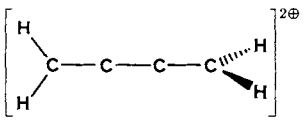


53 (C_{2v})



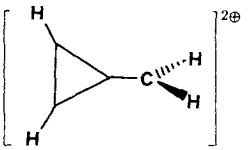
54 (C_{2v})

The cyclic $C_4H_4^{2\oplus}$ isomer has attracted interest since it is the smallest Hückel aromatic dication. *Olah* et al. succeeded in generating a variety of long-lived substituted cyclobutadiene dications substituted with F, CH_3, and/or phenyl groups in superacid media, but the parent $C_4H_4^{2\oplus}$ was not observed.[76] Calculations on this $C_4H_4^{2\oplus}$ dication show the puckered (D_{2d}) isomer **55** to be the global minimum.[77, 78] The energy difference between the puckered **55** and planar **56** forms is 9.6 kcal/mol (MP4/6-31G*).[78] Also the tetramethyl substituted dication prefers a puckered structure according to ab initio data.[77c, 78] Using the IGLO method[79] and the HF/6-31G* geometry the calculated ^{13}C NMR chemical shifts are remarkably similar to those observed experimentally ($\delta = 18.8$ and 209.7 ppm).[78] Hence, the long-lived tetramethylcyclobutadiene dication has a puckered conformation.[78]



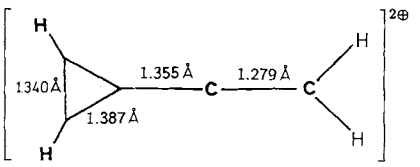
55 (D_{2d})

∠CXC=137.4°

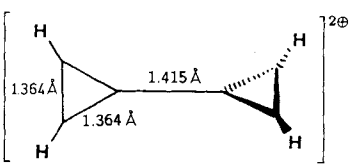


56 (D_{4h})

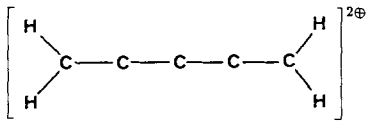
$C_4H_4^{2\oplus}$ has been observed in gas phase studies from a variety of precursors including aromatic substrates.[62a] Charge-stripping experiments give a Q_{min} value of 16.5 eV;[7] no theoretical second IE is available. The $2E$ spectrum of *n*-butane gives an appearance potential of 32.6 eV for $C_4H_4^{2\oplus}$.[69] Although no structural analyses were conducted, the $C_4H_4^{2\oplus}$ dication was assumed to have a cumulene-like structure.[3d] However, an ab initio study shows linear D_{2d} structure **57** to be 19.7 kcal/mol (estimated MP2/6-31G*) less stable than the puckered cyclobutadiene dication **55** and to have a rotational barrier of 19.1 kcal/mol (same level).[77a] In contrast, the methylenecyclopropene dication **58**, which also benefits from aromatic delocalization, is only 9.1 kcal/mol (same level) less stable than the global $C_4H_4^{2\oplus}$ minimum.



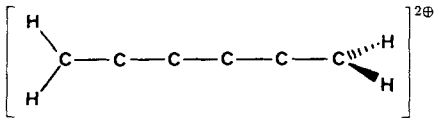
57 (D_{2d})



58 (C_{2v})



The preference for 2π-electron aromatic species is also evident from a theoretical study on the $C_5H_4^{2\oplus}$ and $C_6H_4^{2\oplus}$ dications, which indicate the vinylidenecyclopropenium **59** and trifulvalene **60** structures to be the global minima, respectively.[80] Derivatives of the trifulvalene dication have been characterized in solution.[81] The cumulene dications are higher energy isomers i.e., only 9.4 kcal/mol (MP2/6-31G*) for $C_5H_4^{2\oplus}$ **61** but 16.1 kcal/mol (HF/6-31G*) for $C_6H_4^{2\oplus}$ **62**.[80] Common methyl substituted acetylenic structures, CH_3–$C_{(n-1)}$-$H^{2\oplus}$, have been suggested for the $C_nH_4^{2\oplus}$



59 (C_{2v})

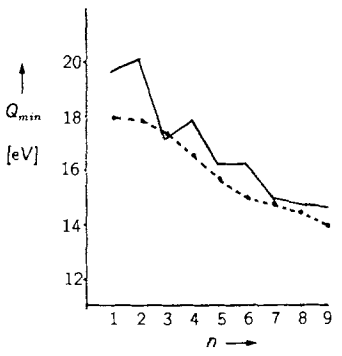
60 (D_{2d})

61 (D_{2h})

62 (D_{2d})

dications observed in the gas phase.[3d] This is very unlikely for $C_5H_4^{2\oplus}$ and $C_6H_4^{2\oplus}$ as these dications are high energy isomers i.e., $\Delta E = 55.6$ and 77.2 kcal/mol, respectively.[80] Charge-stripping gives a Q_{min} value of 15.6 eV for $C_5H_4^{2\oplus}$ and 15.0 eV for $C_6H_4^{2\oplus}$.[7] Both dications are common in the $2E$ spectra of a series of *n*-alkanes,[69] olefins,[62b] and aromatics.[62a]

It appears that no common structure represents all $C_nH_4^{2\oplus}$ dication global minima. Plots of Q_{min} (from charge-stripping) vs carbon number show a smooth curve for $C_nH_4^{2\oplus}$, but a jagged line (lowest values for n = odd) for the $C_nH_2^{2\oplus}$ dications, with linear acetylenic-like structures (Fig. 8).[7] Additional detailed experimental data are needed to confirm the theoretical analyses. Interestingly, the $C_nH_4^{2\oplus}$ dications have the lowest Q_{min} values among the $C_nH_m^{2\oplus}$ (n = 1–9, m = 0–8) dications.[7]



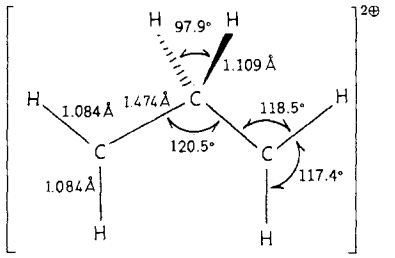


Fig. 8. Dependence of Q_{min} on the number of carbon atoms C_n for carbodications containing two (——) and four (– – –) hydrogens. [7]

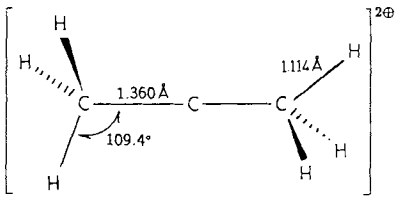
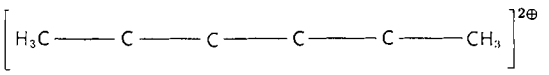


3.3.3. The $C_nH_6^{2\oplus}$ Carbodications

Many mass spectrometric observations of $C_nH_6^{2\oplus}$ dications from a variety of precursor molecules have been reported.[3d, 62, 69, 82] The $C_2H_6^{2\oplus}$ dication was discussed above. The following Q_{min} values (in eV) have been determined,[7a] using N_2 as collision gas in charge-stripping experiments: $C_3H_6^{\odot 2\oplus}$, 18.2; $C_5H_6^{\odot 2\oplus}$, 16.0; $C_6H_6^{2\oplus}$, 16.4; $C_7H_6^{\odot 2\oplus}$, 14.7; $C_8H_6^{2\oplus}$, 15.4; $C_9H_6^{\odot 2\oplus}$, 14.6. Appearance potentials obtained from $2E$ spectra depend on the precursor substrate.[62] Because the $C_nH_6^{2\oplus}$ dications loose $CH_3^{\oplus}$ readily with large intercharge distances, a common linear H_3C–$C_{(n-2)}$-$CH_3^{2\oplus}$ structure has been proposed.[3d] The corresponding kinetic energy releases (with *R* values in parentheses), $C_6H_6^{2\oplus}$ 2.6 (5.5 Å) and $C_8H_6^{2\oplus}$ 2.0 eV (7.3 Å), probably refer to the decomposition of high energy isomers.[3d] $C_8H_6^{2\oplus}$ also fragments into $C_5H_3^{\oplus} + C_3H_3^{\oplus}$ with an E_T of 3.0 eV, giving an *R* value of 4.8 Å.[13a] Theoretical studies do not support a common $C_nH_6^{2\oplus}$ dication structure.

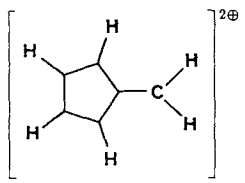
Our recent ab initio study[83] of $C_3H_6^{2\oplus}$ isomers indicated the global minimum to be the central-protonated allyl cation **63** with the two charges formally on the terminal carbons. The CCC angle of 120.5° and the relatively short C–C bond distances, 1.474 Å (HF/6-31G*), resemble those of the allyl cation. These geometrical parameters reveal the importance of *bishyperconjugation*, i.e., the combined hyperconjugative effect on the same C–H bond(s) by two adjacent cation centers. The propylidene dication **64**, where the central carbon formally (but only formally) bears both charges, has virtual-

63 (C_{2v})



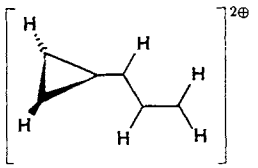
64 (D_{3d})

ly the same energy (MP4/6-31G* + ZPE). Its very short C–C bond lengths of 1.360 Å can be compared with those of the ethylene (**32**, 1.289 Å) and of the ethylidene dication (**34**, 1.398 Å) and are attributed to *cross-hyperconjugation*, i.e., hyperconjugation occurring in two orthogonal planes. The preferred fragmentations into $CH_3^{\oplus} + C_2H_3^{\oplus}$ and into $H_3^{\oplus} + C_3H_3^{\oplus}$ are both exothermic by ca. 60 kcal/mol (MP3/6-31G*), but are assumed to have sizable barriers.

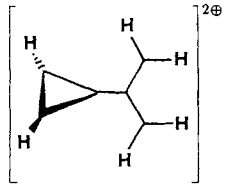


The calculated IE_a of 15.9 eV for the "protonated" allyl cation **63** from the cyclopropane radical dication differs significantly from the measured[7] Q_{min} value of 18.2 eV for $C_3H_6^{2\oplus}$. This discrepancy, once again, may reflect an experimental vertical ionization to an excited dication. The suggested cyclic structure, based on $R = 2.36$ Å for the deprotonation of $C_3H_6^{2\oplus}$ ($E_T = 6.1$ eV),[70] also does not agree with the theoretical predictions. Clearly, more detailed mass spectrometric studies are needed for experimental characterization of the gaseous $C_3H_6^{2\oplus}$ dications.

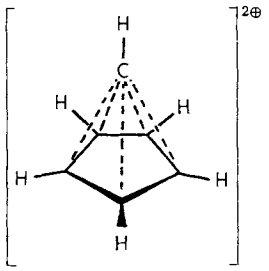
The $C_6H_6^{2\oplus}$ Ions: The best known species in this family is the hexamethyl derivative $C_6(CH_3)_6^{2\oplus}$ synthesized by *Hogeveen* and *Kwant*.[84] A pyramidal geometry with a hexacoordinate apical carbon was assigned to this dication based on synthetic routes, spectrometric methods, trapping experiments, and theoretical calculations.[84] The nature of the bonding in this symmetrical pentagonal pyramid has been extensively discussed.[85, 86] In contrast, less information is available for the parent gaseous $C_6H_6^{2\oplus}$ dication.[7, 62, 82] Mass spectrometric studies initially focused on the fragmen-



tation yielding $C_5H_3^{\oplus} + CH_3^{\oplus}$. The dimethylacetylenic structure for $CH_3CCCCCH_3^{2\oplus}$ was assigned based on the calculated $R = 5.5$ Å ($E_T = 2.6$ eV).[3d] However, our ab initio study[85a] showed this (triplet) isomer **65** to be 45.1 kcal/mol (3-21G) higher in energy than the global minimum, the fulvene dication **66**. The latter is stabilized over the two allylcyclopropenium ion isomers **67**, **68** by only 5–6 kcal/mol. Calculations at higher theoretical levels are needed to determine the energy difference between the fulvene **66** and the non-classical "Hogeveen" dication **69**, (29 kcal/mol at HF/3-21G). Due to its degenerate π HOMO, dioxidation

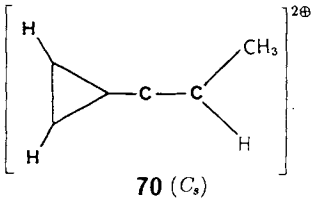


65 (D_{3d})

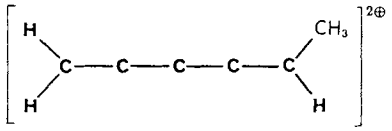


66 (C_{2v})

67 (C_s)



68 (C_{2v})

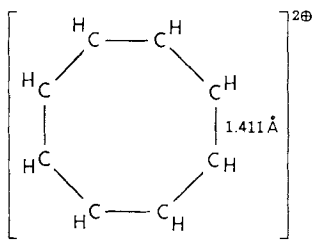


69 (C_{5v})

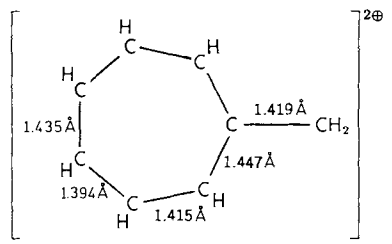
from benzene results in a D_{6h} triplet $C_6H_6^{2\oplus}$ dication, which is estimated to be 17.5 kcal/mol less stable than the fulvene dication (3-21G with triplet correction). The singlet benzene dication, which is virtually of the same energy as the triplet form, is subject to Jahn–Teller distortion. An elongated cyclic double-allyl D_{2h} geometry is calculated at HF/3-21G to have C–C bond distances of 1.418 (4×) and 1.525 Å (2×).[85a] MINDO/3 favors a C_{2h} chair conformation for this species.[86a] A surface-induced collision study suggests that the $C_6H_6^{2\oplus}$ ions generated from benzene by electron impact have the same cyclic structure as singly ionized benzene.[82a]

In order to interpret the observed dissociation of metastable $C_6H_6^{2\oplus}$ into $CH_3^{\oplus} + C_5H_3^{\oplus}$, several methyl group containing structures were calculated.[85a] Two possible candidates, the methyl substituted ethynylcyclopropenium **70** and the C_5-cumulene **71** dications, lose $CH_3^{\oplus}$ exothermically by 47 and 25 kcal/mol (HF/3-21G), respectively. Assuming that the fragmentation requires only a modest activation energy, then the energy of the former process (47 kcal/mol) is in reasonable agreement with the experimental translational energy release of ca. 60 kcal/mol (2.6 eV). However, we note that (U)HF/3-21G, MINDO/3, and MNDO give very large differences in calculated relative $C_6H_6^{2\oplus}$ energies. The fact that different structures are deduced from experiments in solution and in the gas phase while still others are indicated by MO theory (3-21G and MINDO/3) indicates the need for more detailed investigations.

70 (C_s)



71 (C_s)



3.3.4. The $C_nH_8^{2\oplus}$ Ions

Little information is available on these dications other than that the $C_6H_8^{2\oplus}$, $C_7H_8^{2\oplus}$, $C_8H_8^{2\oplus}$, $C_{10}H_8^{2\oplus}$, and $C_{12}H_8^{2\oplus}$ dications are ubiquitous in the 2E spectra of n-alkanes and aromatic hydrocarbons.[62, 69, 82]

MINDO/3 calculations on a series of (bi)cyclic and cage structures gave as most stable $C_8H_8^{2\oplus}$ isomer the cyclooctatetraene dication.[87] Di- and tetra-substituted methyl and phenyl derivatives of this isomer have been observed under stable-ion solution conditions.[88] The isomeric octamethyldihydro-pentalene and bis(tetramethylhomocyclopropenyl) dications have also been observed.[88] It has not been possible to observe the parent cyclooctatetraene dication **72** in solution. Ab initio calculations at the STO-3G level found this species to be 25 kcal/mol less stable than the planar heptafulvene dication **73**.[89] The 2E spectra of a variety of hydrocarbons show the presence of $C_8H_8^{2\oplus}$.[90] Collisional activation spectra of the ions results in dissociation into $C_5H_3^{\oplus} + C_3H_5^{\oplus}$ ($E_T = 2.4$ eV), $C_6H_5^{\oplus} + C_2H_3^{\oplus}$ ($E_T = 3.3$ eV), and $C_7H_5^{\oplus} + CH_3^{\oplus}$ ($E_T = 3.2$ eV). It was suggested that all $C_8H_8^{2\oplus}$ dications have cyclic structures.[91]

72 (D_{8h})

73 (C_{2v})

3.3.5. The anti-van't Hoff Rule

According to the stereochemical rules determined by *van't Hoff* in 1875,[92] cumulenes with an even number of double bonds and an odd number of carbons, (e.g., methane, allene and pentatetraene), prefer perpendicular (D_{2d}) arrangements (methane of T_d symmetry), while cumulenes with an odd number of double bonds and an even number of carbons, (e.g., ethylene und butatriene), prefer planar (D_{2h}) struc-

tures. Removal of two electrons to give a cumulene dication reverses the van't Hoff stereochemistry: perpendicular neutral species become planar dications and vice versa.[80] The same applies to structures where a terminal cumulene carbon is replaced by an allyl or a cyclopropenium cation group. Figure 9 shows representative examples of planar and perpendicular dications.

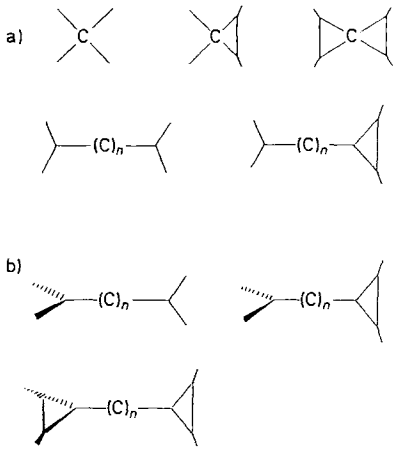


Fig. 9. Anti van't Hoff dication structures. a) Planar dications, n = odd. b) Dications with allene type arrangement of the substituents, n = 0, even.

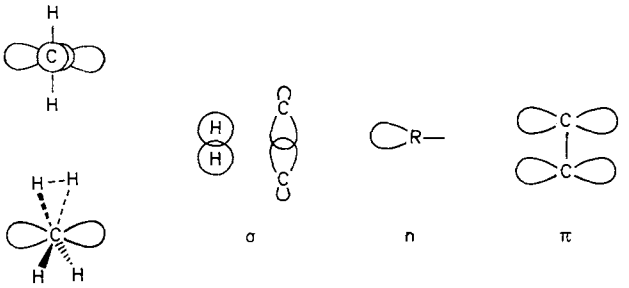
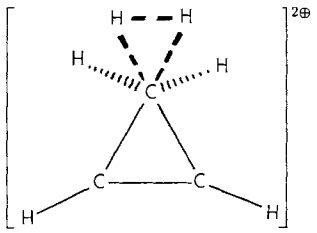
3.3.6. The $CH_2^{2\oplus}$ and $CH_4^{2\oplus}$ Building Blocks

Saturated hydrocarbons and their derivatives have C-chains that are terminated by methyl groups. This is precluded in cationic systems when a charge is located at a terminal position. Maintaining single C–C or C–X bonds, the terminus can either be a $CH_2^{\oplus}$ group formally derived from hydride abstraction from CH_3, or $CH_4^{\oplus}$, formally a protonated methyl group. Hence, many dications can be considered to be comprised of a $CH_2^{2\oplus}$ or $CH_4^{2\oplus}$ dication joined to a neutral molecule. Using such a building block approach, donor-acceptor complexes can be formed and used didactically to explain bonding patterns in doubly charged species.[3a–c, e, f, 43, 48, 53, 93, 94] The acceptor molecule is either the linear $CH_2^{2\oplus}$ or the planar $CH_4^{2\oplus}$, both having an empty p-orbital perpendicular to the axis/plane of the molecule. The two-electron donor interactions with σ-, π-, and n-donor molecules X can be deduced from Figure 10.

Also note that CH_2–$X^{2\oplus}$ and CH_4–$X^{2\oplus}$ dications differ by only one H_2-molecule. Thus, the substituted methonium dication CH_4–$X^{2\oplus}$ represents a hydrogenated ylid dication CH_2–$X^{2\oplus}$ (Fig. 10).[93] The CH_4–$X^{2\oplus}$ dication is a methonium ion $CH_5^{\oplus}$ with one H-ligand replaced for a cation substituent $X^{\oplus}$. The 3c–2e bonding in pentacoordinate tetravalent $CH_5^{\oplus}$ arises via a 40 kcal/mol favorable interaction between $CH_3^{\oplus}$ and H_2. CH_4–$X^{2\oplus}$ should be analogous.[93]





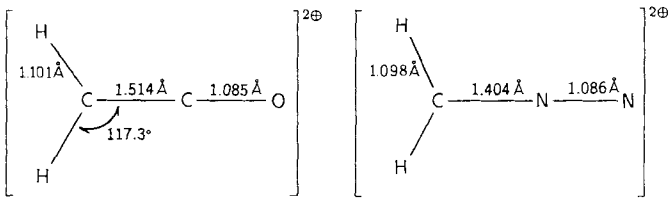


Fig. 10. Donor–acceptor interactions for carbodications. The carbocations $CH_2^{2\oplus}$ and $CH_4^{2\oplus}$ (left) interact with the σ-, n-, and π-two electron donors (right).

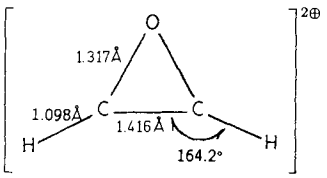
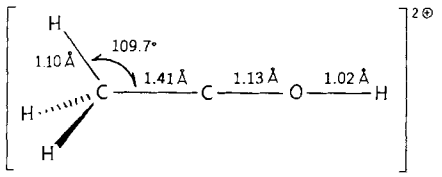
The ethane dication discussed above illustrates these arguments nicely. First, we build the familiar D_{2d} ethylene dication **32** from the interaction of neutral $:CH_2$ and the $CH_2^{2\oplus}$ dication **3**. One of the resulting $CH_2^{\oplus}$ termini can then be hydrogenated to give the carbonium-carbenium CH_4–$CH_2^{2\oplus}$ dication **37**. The same species results conceptually both from "complexation" of neutral $:CH_2$ with the planar methane dication **5** and from replacement of a hydrogen in $CH_5^{\oplus}$ by a $CH_2^{\oplus}$-ligand. Other illustrations are the ylid dications above discussed, which can be considered to be complexes between $CH_2^{2\oplus}$ and a neutral n-donor molecule, like FH, ClH, OH_2, SH_2, and NH_3.[94] Other unfamiliar and sometimes high energy structures can be understood on the same basis. For example, interaction with π donors, $CH_2^{2\oplus}$ with ethylene and $CH_4^{2\oplus}$ with acetylene, give three-membered ring $C_3H_6^{2\oplus}$ transition structures **53**, **74**.[83] Similarly, interaction of atomic C with $CH_4^{2\oplus}$ gives CH_4–$C^{2\oplus}$, which is an exotic high energy isomer of the ethylene dication.[43c]



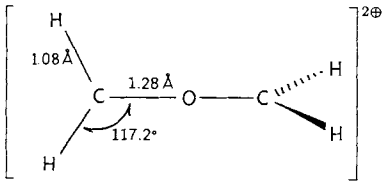
74 (C_{2v})

The CH_n-$XY^{2\oplus}$ (n = 2,4) Dications: The ketene **75** and diazomethane **76** dications also illustrate this approach when viewed as complexes of the $CH_2^{2\oplus}$ dication and carbon

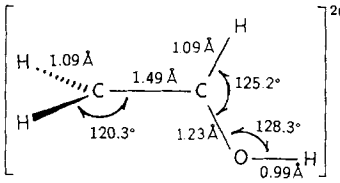


75 (C_{2v}) **76** (C_{2v})

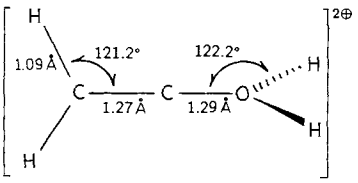
monoxide and nitrogen, respectively.[93] The dioxygen complex is similar, and there is perfect agreement between the Q_{min} value determined for $C_2H_2O^{2\oplus}$ and the calculated IE_v (MP2/6-31G*). Both are 18.6 eV.[95] The ketene dication **75** is the global $C_2H_2O^{2\oplus}$ minimum. The isomeric oxirene dication **77**, 27 kcal/mol (MP2/6-31G*) less stable, lacks experimental confirmation since no suitable gas phase precursors are available.[95] In contrast, the isomeric hydroxyacetylene dication, which is 59 kcal/mol (same level) less stable, has been observed.[96] The same is true for the isoelectronic aminoacetylene dication, $HCCNH_2^{2\oplus}$. The reported Q_{min} value of 17.9 eV is in good agreement with theory.[97]



77 (C_{2v})

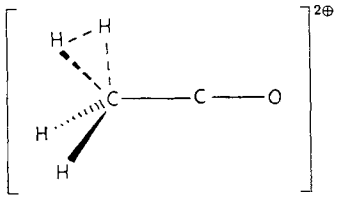


The $C_2H_4O^{2\oplus}$ dications have been studied by charge-stripping mass spectrometry and ab initio theory.[98] Because of the isoelectronic relationship between $C_2H_4O^{2\oplus}$ and the $C_3H_6^{2\oplus}$ dications, similarities are expected and confirmed. The global $C_2H_4O^{2\oplus}$ minimum is the hydroxy substituted ethylidene dication CH_3–C–$OH^{2\oplus}$ **78**. This is 14.7 kcal/mol (MP2/6-31G*//HF/4-31G) more stable than the ring-opened ethylene oxide dication **79**, which can be



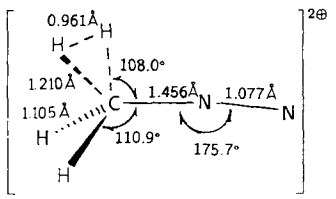
78 (C_{3v})

79 (D_{2d})



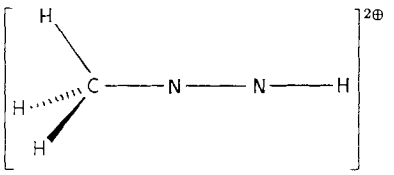
80 (C_s)

81 (C_{2v})

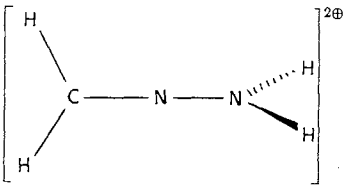


viewed as the complex between $CH_2^{2\oplus}$ and formaldehyde.[98] This stability order differs from that for the $C_3H_6^{2\oplus}$ carbodications, which shows the related dication isomers to be of virtually equal stability at MP4/6-31G*//HF/6-31G*; note that the propylidene dication is bent whereas the H_2C–O–$CH_2^{2\oplus}$ structure **79** has a linear D_{2d} geometry.[83] Other stable $C_2H_4O^{2\oplus}$ isomers are dioxidized vinyl alcohol **80** and the H_2C–C–$OH_2^{2\oplus}$ structure **81**, which is reminiscent of allene.[83] Charge-stripping experiments[98] on $CH_2OCH_2^{\odot\oplus}$ and $CH_2CHOH^{\odot\oplus}$ gave Q_{min} values of 16.3 (15.6) and 17.1 (17.2) eV, respectively, in good agreement with the theoretical IE_v values that are given in parentheses.[83] Charge-stripping from $CH_3COH^{\odot\oplus}$ gave a too low abundance for determination of the Q_{min} value. Derivatives of $C_2H_4O^{2\oplus}$ are discussed in section 3.4.2.

A different $C_2H_4O^{2\oplus}$ structural type results when $CH_4^{2\oplus}$ and CO are used as building blocks.[93] The resulting species can be viewed as a hydrogenated ketene dication **82**. However, this CH_4–$CO^{2\oplus}$ isomer is 24.6 kcal/mol (HF/6-31G*) less stable than CH_3–C–$OH^{2\oplus}$ **78**. Nevertheless, the relatively modest energy difference between the O- and C-protonated forms of the acetyl cation may render experimental verification under stable ion-solution conditions feasible. The trends discussed for these O-containing dications are also reflected in the $C_2OH_3^{\odot 2\oplus}$ radical dications.[99] Thus, the charge stripping from the 1-hydroxyvinyl cation gives a Q_{min} of 18.7 eV, but the 29 kcal/mol (MP2/6-31G*) less stable acetyl radical dication could not be generated from the corresponding cation.[99b, c]



82 (C_s)



$C_2H_4O^{2\oplus}$ and the diazomethane dication are similar, but the latter has not yet been studied by charge-stripping mass spectrometry. The dioxidized diazomethane dication $CH_2N_2^{2\oplus}$ **76** can be considered as a complex of $CH_2^{2\oplus}$ **3** and dinitrogen. Formal complexation of the $CH_4^{2\oplus}$ dication **5** with nitrogen results in CH_4–$N_2^{2\oplus}$ **83**, which can be viewed as hydrogenated CH_2–$N_2^{2\oplus}$ dication as well as di-*C*-protonated diazomethane.[93] Although **83** is 12 kcal/mol (HF/3-21G) more stable than the *N*-protonated methyl diazonium ion (**84**, a transition structure), it is 49.5 kcal/mol (HF/6-31G*) less stable than the di-*N*-protonated isomer $H_2C{=}N{=}NH_2^{2\oplus}$ **85**.[93] This is in agreement with a stable ion-solution study.[100]

83 (C_s)

84 (C_{3v})

85 (C_{2v})

3.4. Special Types of Dications

The structures of many observed and calculated simple dications can be understood on the basis of their electronic properties. Dication structures typically are very different

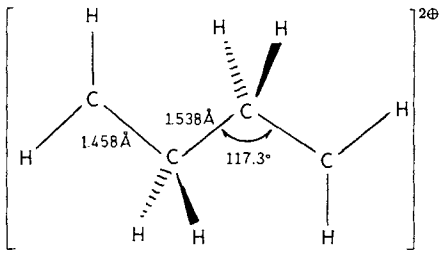
from those of their neutral homologues. We now consider the next question. Can dications be as versatile as the many intriguing monocations that have fascinated chemists for decades? Highlights of recent carbodication chemistry are discussed in the remainder of this review.

3.4.1. Classical versus Non-Classical Carbodications

Part of the richness of carbocation chemistry arises from the ability of the electron deficient center to gain stabilization through hypercoordination. This non-classical behavior results in more efficient charge distribution throughout the molecule. Thus, all primary and most secondary and many tertiary cations tend to form non-classical ions, or ions with significant non-classical character.[101] This characteristic also applies to carbodications, but is more restricted due to the Coulombic repulsion of charges. Hence, in a non-classical dication the two formally charged centers compete to a greater extent for charge delocalization than is the case in a classical structure. However, charge-charge repulsion may be countered with effective π-delocalization as in e.g., the Hogeveen **69** and dehydroadamantanediyl dications **104** (see section 3.4.3.). Of the many possible examples, the ethylene and ethane dications can be used to illustrate σ-delocalized systems.

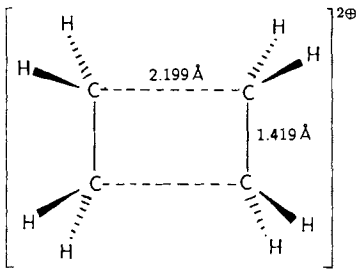
The classical D_{2d} ethylene dication **32**, with its two neighboring cation centers oriented in an orthogonal fashion, is 12 kcal/mol (MP4/6-311G**) more stable than the non-classical bis-hydrido bridged structure **33**.[43c] This is due to the less effective charge distribution in the latter diprotonated acetylene structure. That charge-charge repulsion is the dominant factor is also indicated by the isoelectronic B_2H_4, where the di-H-bridged structure is only 1.5 kcal/mol (MP2/6-31G**) less stable than the D_{2d} isomer.[102] In contrast, both the singly charged ethyl and vinyl cations prefer H-bridged structures.[103]

Similarly, the open ethane CH_4–$CH_2^{2\oplus}$ dication structure (**37**, C_s), is 7 kcal/mol (MP4/6-31G**) more stable than the doubly bridged diborane-like isomer **38**.[48] Most of the positive charge resides on the hydrogens, and in **37**, these are as far apart as possible. Consequently, protonation of a C–H bond of the ethyl cation is preferred over that of a C–C bond.



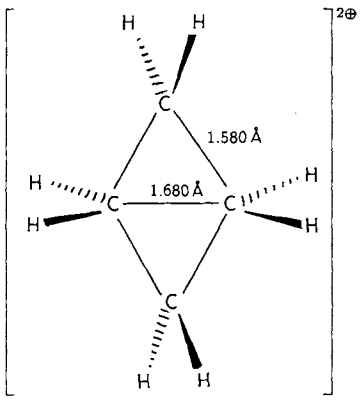
3.4.2. Proximity of Cation Centers

It is of interest to examine in more detail the structural and energetic effect of one cation center on the other. Again, we recall some of the already discussed dications. In the D_{2d} ethylene dication **32**, the charged centers are located next to each other; the resulting *crosshyperconjugation* yields a formal C–C single bond that is 0.14 Å shorter than that of a regular aliphatic hydrocarbon. Several ethylene dications with aryl substituents have been observed under stable ion-solution conditions. An X-ray study[104a] of the dichloroiodate salt of the tetra-*t*-anisylethylene dication reveals a 41° twist around the 1.43 Å short central C–C bond (compare 1.432 Å for $C_2H_4^{2\oplus}$, HF/6-31G*). Also crystals (no X-ray) have been obtained for a related species in which two neighboring tetrakis(dimethylamino)-allyl cation units are connected via their central carbons.[104b]



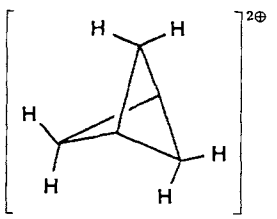
Separating the charges with one CH_2-unit as in the protonated allyl cation (**63**, $C_3H_6^{2\oplus}$) still yields short C–C bonds now because of *bishyperconjugation* i.e., the combined hyperconjugative effects on the central CH_2-group. Attempts to prepare a 1,1,3,3-tetramethyl derivative under stable ion-solution conditions failed because of deprotonation and disproportionation reactions.[105] However, experimental and theoretical studies on diprotonated 1,6-methano[10]annulene confirm the bishyperconjugative effect.[106] This species contains the cyclopropyl-1,1-diallenyl dication fragment in a frozen conformation that shows significant C–C bond lengthening in the cyclopropane ring (1.602 Å, HF/6-31G*) enabling conjugation between the two allylic units. Isoelectronic replacement of the central CH_2-group in $C_3H_6^{2\oplus}$ for oxygen results in a larger number of experimentally characterized dications of the type R_2C–O–$CR_2^{2\oplus}$ (R = NH_2, $N(CH_3)_2$, $C_5H_{10}N$, C_6H_5) and R–O–$R^{2\oplus}$ (R = cyclopropenylium, tropenylium, pyridinium, etc.); X-ray structures are known for some of the dication ether triflates R–O–$R^{2\oplus}$.[107] The determined C–O–C angles are for R = 1,2-bis(dimethylamino)-3-cyclopropenyliumyl 116.7°,[107a] for R = bis(dimethylamino)carbinyl 122.4°,[107b] for R = tropenyliumyl 125.3°,[107f] and for R = 1,3-dimethyl-2-imidazoliniumyl 120.3°.[107e] These experimental angles are very similar to the calculated angle of 120.5° (HF/6-31G*) for the corresponding $C_3H_6^{2\oplus}$ isomer.[83] The calculated energy differences between the bent and linear R–O–$R^{2\oplus}$ forms is small; MINDO/3 gives a 3.3 kcal/mol preference for a linear bistropenyliumyl ether dication in contrast to the X-ray crystal structure.[107g] The parent ether dication H_2C–O–$CH_2^{2\oplus}$ prefers a linear D_{2d} structure.[98]

Under stable ion-solution conditions several acyclic aryl substituted and the tetramethyl ($R_2C^{\oplus}$–CH_2CH_2–$CR_2^{\oplus}$) dications have been generated. The CH_2–CH_2-unit separates the cation centers.[105] The vicinal 1,2-(diphenylcarbinyl)-cyclopropane has also been generated in solution.[105] Recent theoretical studies on a series of $C_4H_8^{2\oplus}$ dications (**86, 87, 88**)[108a] show the parent 1,4-butanediyl dication **86**, C_i to be the global energy minimum. This structure, like the corresponding $C_3H_6^{2\oplus}$ dication, also shows significant hyperconjugation of both cation centers with their neighboring CH_2-groups. This is evident from the C–C–C angles of 117.3°, the C–$C^{\oplus}$ bond lengths of 1.454 Å, and the C–C bond length of 1.539 Å (HF/6-31G*).

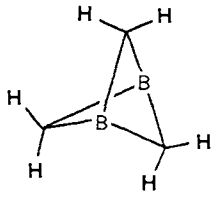


Several cyclic and polycyclic aliphatic carbodications have been probed by experiment and theory for the through-space proximity of the two cation centers. The [1.1.1]-, [2.2.2]-, and [3.3.3]propellanes enable the study of such dications, where the charged centers are connected through C_1, C_2, and C_3 bridges, respectively. The highly strained [1.1.1]propellane has been extensively studied. Since theoretical studies give a central C–C separation ranging from 1.543 Å (HF) to 1.592 Å (MP2 (Full)/6-31G*)[109a–c] and show the HOMO to be of "non-bonding" σ-character,[109d] removal of its two electrons (dioxidation) should not have a major structural impact other than that resulting from charge-charge repulsion. Although this $C_5H_6^{2\oplus}$ dication **89** has not yet been studied neither by theory nor by charge-stripping techniques, the isoelectronic diborabicyclo[1.1.1]pentane $C_3H_6B_2$ **90** has been calculated to have a B–B separation of only 1.61 Å (HF/4-31G), a length equal to the C–B bonds.[109d] Alternative to the dioxidation diprotonation would yield the bicyclo[1.1.1]pentane dication $C_5H_8^{2\oplus}$ which

86 (C_i)

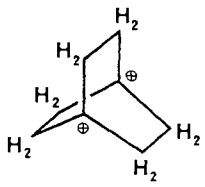


87 (D_{2h})

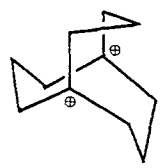


88 (D_{2h})

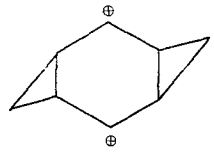
is calculated to have a short C1–C3 distance (1.452 Å, 6-31G*) in D_{3h} symmetry. The corresponding nonbonded distance is 1.869 Å (6-31G*) in bicyclo[1.1.1]pentane. However, an ab initio study of this $C_5H_8^{2\oplus}$ species[108b] shows not to be a minimum on the potential energy surface.



89

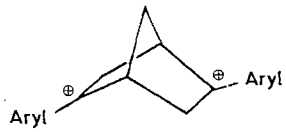


90



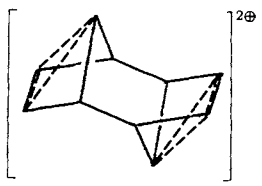
Despite the favorable electronic structure of the 1,4-bicyclo[2.2.2]octanediyl dication $C_8H_{12}^{2\oplus}$ **91**, as first indicated by MINDO/3, claims of its experimental observation under stable ion-solution conditions could not be confirmed.[110] The calculated distance between the bridgehead cation centers is 1.990 Å (MINDO/3),[110b] 2.147 Å (3-21G), and 2.118 Å (6-31G*),[110c] while a value of 1.512–1.57 Å (HF and TCSCF/6-31G*) is reported for neutral [2.2.2]propellane.[109a–c] Furthermore, IGLO chemical shift calculations on **91**[110c] rule out the possibility that this species was observed experimentally. In contrast, a "stable" species is observed when the charged centers are connected through propylene bridges as in the 1,5-bicyclo[3.3.3]-undecanediyl (manxyl) dication $C_{11}H_{18}^{2\oplus}$ **92**.[111] This is not the case when the three bridges are *vic*-substituted cyclopropanes,[112a] even though MINDO/3 calculations predicted such dications to be stabilized up to 12 kcal/mol, relative to **91**.[112b] However, dications are observed under stable ion-solution conditions when the cation centers are bridged by only two cyclopropane rings as in substituted 2,6-antitricyclo[5.1.0.$0^{3,5}$]-octanediyl dications **93**.[113] Even 1,4-diaryl-1,4-cyclohexanediyl dications **94** have been studied by NMR spectroscopy.[114] In the observed 2,5-diaryl-2,5-norbornanediyl dication **95** the charged centers are separated by two C_2-units.[114]

91

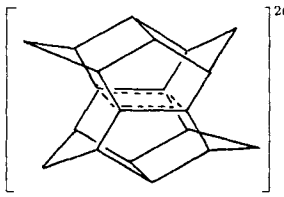


92

93

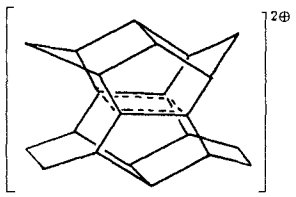


94



95

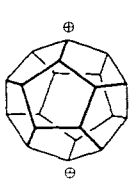
A Sandwiched Bishomoaromatic Dication: The anti-tricyclo[4.2.1.$1^{2,5}$]deca-3,7-diene-9,10-diyl dication $C_{10}H_{10}^{2\oplus}$ **96** has been generated under stable ion-solution conditions and studied by NMR spectroscopy.[115] This dication represents a sandwiched bishomoaromatic system. The two monocations, each delocalized in a bishomoaromatic 3c-2e interaction, are linked together by two C_2-units. The NMR data suggest that the two cation systems are essentially independent of one another. Neither theoretical nor gas phase studies have been reported on this or related dications.



96

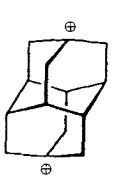
$C_4H_8^{2\oplus}$ and the Pagodane Dication. Oxidation of [1.1.1.1]pagodane[116] under stable ion-solution conditions generates a dication **97** that has been characterized by NMR spectroscopy and quenching experiments.[117] Charge-stripping mass spectrometry has shown the formation of dications from [1.1.1.1]-**97** and [2.2.1.1]pagodane **98**, $C_{20}H_{20}^{2\oplus}$ and $C_{22}H_{24}^{2\oplus}$, respectively.[118] Unfortunately, the corresponding Q_{min} values of 13.4 (± 0.7) and 13.2 (± 1.0) eV have large uncertainties such that in this case charge-stripping does not

97



98

discriminate between structurally closely related hydrocarbon radical cation isomers.[118] MNDO and ab initio calculations (STO-3G and 3-21G) suggest that the pagodane cage structure contains a substituted rectangular D_{2h} cyclobutane dication. Rather than being of σ-aromatic nature,[117, 118] the 2.21 Å (3-21G) separation[108a] (2.58 Å MNDO) for **97** suggests the interaction of the two olefin radical cation moieties to be weak.

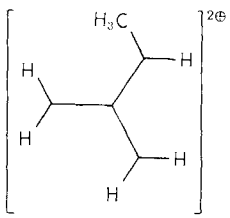


A recent theoretical study on several parent $(CH_2)_4^{2\oplus}$ structures shows the open C_i *trans*-tetramethylene dication **86** (minimum, see above) to be 22.4 kcal/mol (MP2/6-31G*) more stable than the rectangular D_{2h} cyclobutane **87**.[108a] The C–C bonds in the latter structure are 1.419 and 2.199 Å (HF/6-31G*). There is only 2.3 kcal/mol energy difference between this cyclic isomer and the less stable (classical) open C_{2v} *cis*-tetramethylene dication, which has C–C bond lengths of 1.477 (2×) and 1.632 Å; however, both structures have 3 imaginary frequencies (HF/3-21G) indicating that they are neither minima nor transition structures! An interesting D_{2h} cyclobutane dication **88** is calculated with four C–C peripheral bonds of 1.580 Å and a transannular C–C bond of 1.680 Å (HF/6-31G*). This species is a candidate for the transition structure (15.1 kcal/mol, MP2/6-31G**) for dyotropic rearrangement of the open **86** tetramethylene dication,[108a] but it has two imaginary frequencies at MP2/6-31G*.

The 1,16-Dodecahedryl Dication, $C_{20}H_{18}^{2\oplus}$. The pentagonal dodecahedrane[119] has the highest symmetry I_h of all organic molecules. Ionization with subsequent protonation of chlorododecahedrane[120] under stable ion-solution condition affords the apical/apical 1,16-dodecahedryl dication **99**.[121] NMR analysis shows the positive charges to be localized at opposite sides of the hydrocarbon cage. This conclusion is supported by MNDO calculations.[121] No charge-stripping experiments have been performed on the $C_{20}H_{18}^{2\oplus}$ dication.

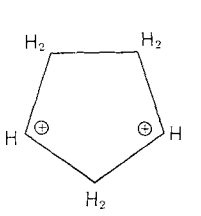
The 4,9-dication of diadamantane $C_{14}H_{20}^{2\oplus}$ **100**,[122] generated in solution from the corresponding dichloro precursor, also has its charged centers located at opposite bridgehead positions.[84] The diminished C–C hyperconjugation as compared to monocations was attributed to charge–charge repulsion. Neither gas phase nor theoretical studies have been performed on this dication. We conclude that charge–charge repulsion is important in these saturated hydrocarbon cages, especially when stabilization mechanisms to disperse or delocalize charge over the carbon framework are lacking.

99



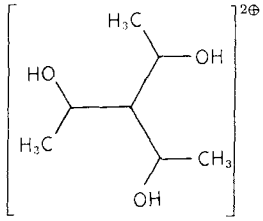
100

3.4.3. Aromatic Dications



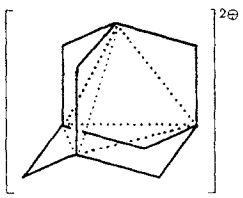
Many dioxidized or diprotonated aromatic compounds and (4n + 2) Hückel annulene aromatic dications, studied under stable ion conditions in solution, have been reviewed elsewhere.[2] Here, we consider less common two-electron aromatic dications.

We have discussed two-σ electron systems, i.e., the [1.1.1.1]-pagodane dication, and σ-π delocalized systems already. The latter bishyperconjugated dications can also be viewed as mixed σ,π Y-aromatic species. Aromatic π systems, satisfying the (4n + 2) rule, can be classified into three topological groups, i.e., ring systems, systems with a node, and three-dimensional (or cage) systems. The cyclobutadienyl dication, a member of the first class, has already been discussed in detail.



The planar trimethylene methane dication $C_4H_6^{2\oplus}$ is the parent molecule for Y-aromaticity.[123] Although of considerable theoretical interest, this dication has eluded experimental gas phase verification. MNDO calculations indicated that doubly charged Y-conjugated systems may even be more stable than their cyclic aromatic counterparts.[124] Recent calculations on the $C_5H_8^{2\oplus}$ potential energy surface[108b] show the methyl-trimethylene methane dication **101** to be the global minimum, 0.9 kcal/mol (HF/6-31G*) more stable than the cyclopentanediyl dication **102**. Whereas attempts to generate methyl and phenyl substituted trimethylene methane dications proved unsuccessful, a trimethyl-trihydroxy derivative **103** has been observed under stable ion-solution conditions.[125]

101



102

103

The Didehydroadamantanediyl Dication, $C_{10}H_{12}^{2\oplus}$: The long sought after 1,3-dehydro-5,7-adamantanediyl dication **104**[122] was synthesized recently by ionization of the difluorodehydroadamantane precursor.[126] This species is a prime

104

example of three-dimensional aromaticity. The four p-orbitals of the adamantane bridgehead carbons all point inwards and overlap appreciably. Occupancy of this bonding orbital with two interstitial electrons is favorable. Theoretical calculations preceded the experimental realization and predicted a tetrahedral aromatic unit in the hydrocarbon cage.[126] The calculated C–C interbridge distances of this tetrahedron are 2.052 Å (HF/6-31G*). The dication structure with its 1.504 Å C–C bonds and flattened bridgeheads is more condensed than adamantane itself. The dication contains a $C_4^{2\oplus}$ tetrahedron with each of its six edges bridged by an aliphatic CH_2-unit. No gas phase data related to this species are available.

4. Conclusion

The detection and the characterization of small organic dications have flourished in the last decade. There is a symbionic relationship between gas phase experiments and ab initio molecular orbital studies. Generally good agreement is found between measured and calculated ionization energies of monocations from which dications are formed. The combined experimental and theoretical approach has provided detailed understanding of small dications. The salient features that confer kinetic (and even thermodynamic) stability to dications are now recognized. As a consequence, the structural changes, often quite large, in going from neutral molecules to di-charged cations can now be understood. The small gaseous dications are often related to the substituted and the thermodynamically more stable dications that are observable in solution. With the advance of new mass spectrometric techniques and computational methods (e.g. IGLO) it is inevitable that the relationship between gas phase, solution, and theoretical studies is even further strengthened. Clearly, the chemistry of multiply charged cations has a bright future.

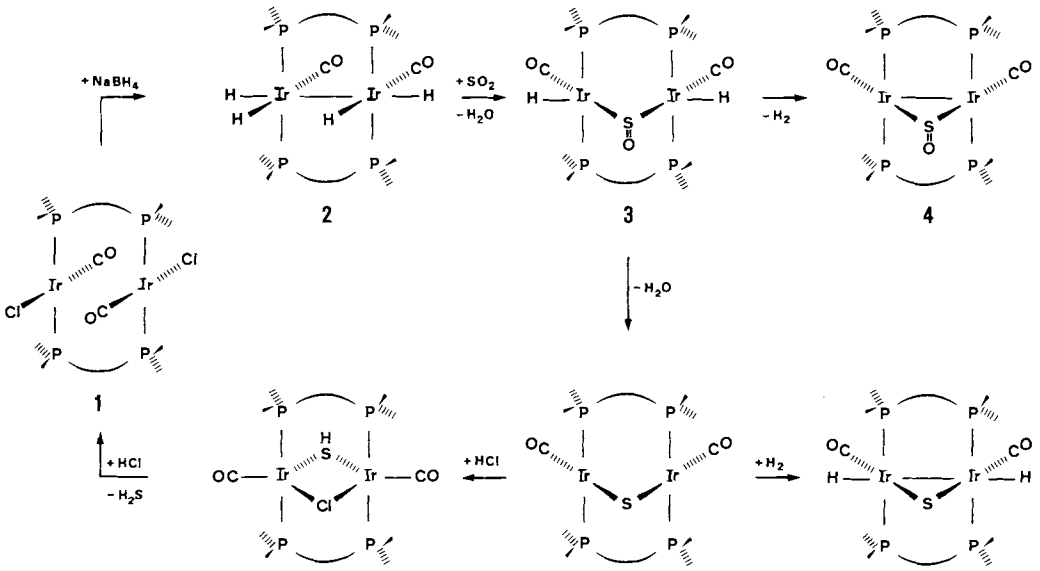
Metal-Induced Reduction of Sulfur Dioxide to Sulfur Monoxide and Sulfur**

By *Armin Neher* and *Ingo-Peter Lorenz**



Sulfur dioxide is an important and versatile reagent in the chemistry of transition-metal complexes. Free SO_2 can be added to or inserted into complexes: coordinated SO_2 can undergo elimination, substitution, addition, oxidation, and reduction reactions. A focus of interest is the reduction of SO_2, particularly the development of model systems for the reductive removal of SO_2 from flue gas and, in bioinorganic chemistry, for the active center of sulfite reductase. Transition-metal-mediated reductions of SO_2 have so far afforded disulfido,[1] thiosulfato,[2] and dithionito complexes[3]—the latter via the metallosulfinic acids.

In our investigations of sulfur monoxide as a complex ligand, we succeeded in deoxygenating free SO_2 to complex-bound sulfur monoxide and sulfur. To reduce SO_2, we used the tetrahydrido complex $[Ir(CO)(dppm)H_2]_2$ **2** (dppm = $Ph_2PCH_2PPh_2$), which is more easily obtained from the dichloro complex **1**[4] and $NaBH_4$ in refluxing ethanol than according to the literature procedure.[5]

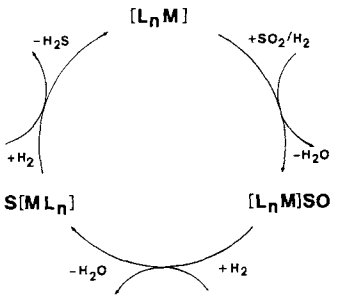
When SO_2 is bubbled through a solution of **2** in toluene, the very unstable μ-SO complex **3**, containing two hydrido ligands, is initially formed. Complex **3** gives two decomposition products upon chromatographic workup on silica gel: loss of H_2 or H_2O leads to the μ-SO complex **4** or the μ-S complex **5**. Bubbling SO_2 for at least 30 min through a solution of **2** in toluene results in a red solution containing mainly **5** along with a small amount of **4**. The μ-S complex **5** was identified by analytical and spectroscopic comparison with an authentic sample, accessible by reaction of **1** with sodium sulfide.[6] Analogous reactions in CH_2Cl_2 or THF afforded smaller yields of **5**.

To carry out the reaction catalytically, we attempted to reduce **5** further in the hope of liberating the μ_2-sulfur as H_2S. However, we failed to obtain the expected hydrido complex **2** either by simply bubbling H_2 through solutions of **5** (cf. Ref. [7]) or by treating **5** with H_2 in an autoclave (80 bar, 60 °C). Instead, we obtained the known[6] isomeric mixture of **6** with an iridium:hydride ratio of 1:1; this product is also obtained by controlled reduction of **5** with $NaBH_4$ in ethanol (Scheme 1).

As a further possibility for liberating H_2S from **5**, we investigated the stepwise protonation of the μ_2-sulfur ligand. Admission of HCl gas to a solution of **5** in THF results in formation, after only a few minutes, of the mixed bridged complex **7**. Only after 5 d of stirring is the SH bridge gone.

Scheme 1.

The product thereby obtained is the purple starting material **1**. Thus, the cycle shown in Scheme 1 is complete. These stoichiometric reactions indicate that **1** might be used catalytically in the reduction of SO_2 (cf. Scheme 2). If reduction



1	+	3 H_2	⟶	**2**	+	2 HCl
2	+	SO_2	⟶	**5**	+	2 H_2O
5	+	2 HCl	⟶	**1**	+	H_2S
3 H_2	+	SO_2	⟶	2 H_2O	+	H_2S

Scheme 2.

of **1** to **2** is possible with H_2 instead of $NaBH_4$, a catalytic reaction as shown in Scheme 3 would be conceivable. We are currently investigating this possibility.

Scheme 3.

Complexes **1–7** were characterized by IR and $^{31}P\{^1H\}$ NMR spectroscopy and by FAB mass spectrometry (Table 1). The CO complexes **1** and **7**, which have *trans* configurations, show only one ν(CO) absorption band in the IR

Table 1. Important spectroscopic data for complexes **1–7**.

Compd	IR $\tilde{\nu}$ [cm^{-1}] [a] ν(CO)/ν(SO)	$^{31}P\{^1H\}$ NMR [b] δ	FAB MS *m/z*	Color

spectrum: by contrast, the two ν(CO) absorptions of complexes **2–6** indicate a *cis* arrangement of the CO ligands. The relatively high wavenumber of the ν(SO) bands of the two SO complexes **3** and **4** indicates a four-electron donor function of the SO bridging ligand, which hinders polarization of the $S^{\delta\oplus}=O^{\delta\ominus}$ bond and increases the SO bond order. Accordingly, **3** and **4** are 18-electron compounds. The very similar ^1H NMR spectra of these complexes provide little information; those of the hydrido complexes **2, 3** and **6** display multiplets at −10 to −12 ppm. Resolution of the signals and isomer assignment, as in Ref. [7], has not yet been accomplished. As the $^{31}P\{^1H\}$ NMR spectra show, the hydrido species **3** and **6** consist of mixtures of isomers (only one isomer of each species is shown in Scheme 1; cf. Ref. [7]). Thus, depending on the coordination of the hydride ligands, both singlet and multiplet signals are observed for the phosphorus atoms of the dppm ligand, whereas the other, symmetrically bridged complexes **2, 4, 5** and **7** each show only singlets. On the other hand, similar compounds of rhodium exhibit complicated splitting patterns.[8] The FAB mass spectrum of each compound, except for the hydrido complexes **2, 3,** and **6**, always contains the molecular ion peak.

The reaction of **2** with SO_2 confirms that a direct transition-metal-promoted reduction of sulfur dioxide via sulfur monoxide to sulfur is possible. The four hydrogen atoms required for the reduction are present at the reaction center and the individual intermediates can be identified. As the results for the palladium[9] and rhodium[8] systems have already shown, the relatively stable A-frame complexes play an important role in these reactions. At the same time, this work offers an alternative synthesis of SO complexes.[10]

Experimental Procedure

2: A suspension of **1** (200 mg, 0.156 mmol) and $NaBH_4$ (48 mg, 1.25 mmol) in 15 mL of ethanol was refluxed for 15 min, the color changing from purple to orange. After cooling, the reaction mixture was filtered and the product was washed with ethanol and dried under vacuum. Yield: 134 mg (71%).

3: A weak stream of SO_2 was bubbled for 3 min through a solution of **2** (92 mg, 0.076 mmol) in 15 mL of toluene. The yellow precipitate of **3** thereby formed was completely precipitated by addition of *n*-hexane, filtered, and dried under vacuum. Yield: 76 mg (78%).

4, 5: a) Chromatography of **3** on silica gel with THF as eluant afforded two red fractions containing **4** and **5**. Yield: 29 mg (38%) **4** and 33 mg (44%) **5** (R_f = 0.65 (**4**), 0.79 (**5**)). b) SO_2 was bubbled for 30 min through a solution of **2** (85 mg, 0.07 mmol) in 15 mL of toluene; concentration of the reaction solution to about 2 mL and chromatography on silica gel afforded **5** as the first red fraction. Yield: 70 mg (80%).

6: Hydrogenation reactions: a) H_2 was bubbled for 30 min through a solution of **5** in CH_2Cl_2. b) 3 h under H_2 in an autoclave at 60 °C and 80 bar. c) A solution of **5** (30 mg, 0.024 mmol) and $NaBH_4$ (38 mg, 0.173 mmol) in 5 mL of ethanol was stirred for 2 h. In each case, an isomeric mixture of **6** was obtained.

7: After HCl was bubbled for 10 min through a solution of **5** (60 mg, 0.048 mmol) in 10 mL of THF, a marked color change from red to yellow occurred. Addition of 20 mL of *n*-hexane resulted in the precipitation of **7** as a gray powder, which was filtered, washed and dried under vacuum. Yield: 58 mg (95%). When HCl was bubbled through the yellow solution of **7** for 30 min, the solution gradually turned red; after 5 d of stirring, 30 mg (50%) of **1** was obtained.

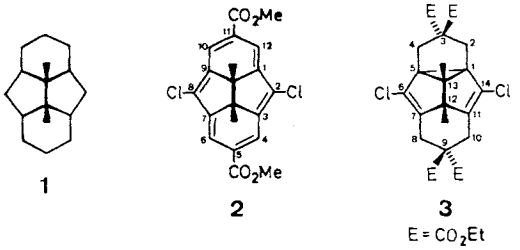
From the Bicyclo[3.3.0]octane Framework to Multiply Bridged [12]Annulenes and Semibullvalenes**



By *Harald Kohnz, Bernhard Düll,* and *Klaus Müllen**

The previously unknown tetracycle **1** (12,13-*cis*-dimethyltetracyclo[9.2.1.0^{5,13}.0^{7,12}]tetradecane) is the basic framework of attractive target compounds. Generation of cyclic π conjugation would lead to an ethanediylidene-[12]annulene and suitable transformation of the central bicyclo[3.3.0]octane unit would lead to a long-sought doubly

[*] Prof. Dr. K. Müllen, Dr. H. Kohnz, Dipl.-Chem. B. Düll

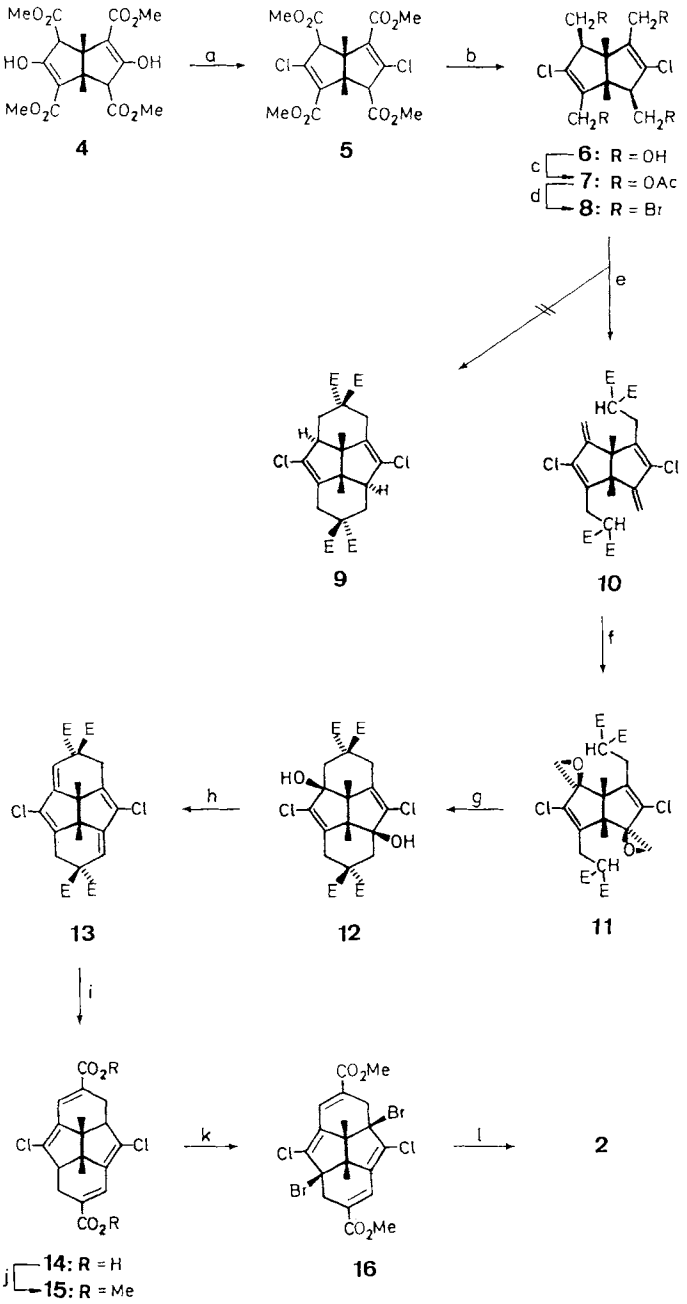
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

bridged semibullvalene. We report here on compounds **2** and **3**, the first examples of the two title compounds. Annulene **2** can serve as a conformationally rigid 12π analogue of cyclooctatetraene for studying electron-transfer processes, and the strained semibullvalene **3** is of interest for investigating extremely rapid Cope rearrangements.

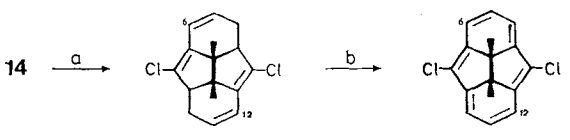
1 **2** **3**
E = CO_2Et



The readily accessible tetraester **4**[1] is a convenient starting material for the synthesis of **2** and **3**, since it already contains 14 of the 16 required C atoms (of **1**) in the topologically correct arrangement.[2] The synthetic strategy (Scheme 1) envisioned the coupling of two malonate moieties with a tetrafunctional electrophile derived from **4**. In order to preserve the double bonds of the "bis-enol" **4** and to establish their *anti* arrangement, dichloride **5** was generated by treatment of **4** with phosphorus pentachloride and re-formation of the allyl ester functions, which were also attacked. Tetrol **6**, formed by reduction of **5**, was transformed into the tetrafunctional bromide **8** via the tetraacetate intermediate **7**.

Direct incorporation of a malonate ester (with formation of **9**) is not possible for steric reasons. Treatment of **8** with potassium diethyl malonate leads instead to **10**. Therefore, a new electrophile (**11**) with "inverted" configuration at C-4 and C-8 was generated by regioselective and *exo*-stereoselective epoxidation of the exocyclic double bonds of **10** with *m*-chloroperbenzoic acid in diethyl ether. After deprotonation with potassium *tert*-butoxide, double ring closure occurs to give diol **12**. The routes leading to annulene **2** and semibullvalene **3** (Scheme 3) branch at this point.

Diol **12** cannot be isolated without decomposition. However, the tetrahydro[12]annulene **13**, formed by acidic dehydration, is stable. Saponification and decarboxylation of the malonate ester moieties afford dicarboxylic acid **14** under mild conditions. Compound **14** is converted into its dimethyl ester **15** by treatment with diazomethane in ether. Dibromide **16** is formed by selective Wohl–Ziegler bromination and can be dehydrobrominated with potassium acetate in acetonitrile to give **2**.



The presence of (alkoxycarbonyl and chloro) substituents in **2** is important, since, on the one hand, they contribute to stabilization of the $4n\pi$ annulene and, on the other hand, they allow coupling of several annulene units and therefore oligomerization of redox-active $4n\pi$ systems.[3] Compound **14** can be decarboxylated to **17**, which, in turn, may be transformed into the [12]annulene **18** by bromination/dehydrobromination (Scheme 2).

The [12]annulene **2** [^{1}H NMR (200 MHz, [D$_8$]THF: δ = 2.51 (CH_3), 3.69 (OCH_3), 5.95 (H-4,6,10,12)][4] forms green-black crystals (m.p. 140–142 °C), which dissolve in organic solvents to afford orange-brown solutions. Comparison of the ^{1}H NMR chemical shifts of annulenes **2** and **18** [^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.58 (CH_3), 5.1–5.5 (m, CH)] with those of the model compounds **15** and **17**, which are not cyclically conjugated, reveals significant shielding of

the ring protons of **2** and **18** [**2/15**, $\Delta\delta_H$ (H-6) = 1.40; **18/17**, $\Delta\delta_H$ (H-6) = 1.02) as well as deshielding of the methyl protons (**2/15**: $\Delta\delta_H$ = 1.43; **18/17**, $\Delta\delta_H$ = 1.53). These findings can only be explained in terms of the paratropism of the cyclic $4n\pi$ system.[5, 6]

Reaction of the crude diol **12** with phosphorus tribromide leads instantaneously to a semibullvalene precursor, the *exo, exo* dibromide **19**. Reductive dehalogenation of **19** with magnesium, in a reaction monitored by NMR spectroscopy,[7] generates **3**.[8] A chemical structural proof for **3** is provided by its reaction with bromine, which results in reformation of **19**[3, 9] (Scheme 3).

The attractivity of semibullvalene is due to its particularly strained divinylcyclopropane structure, which allows a degenerate Cope rearrangement to occur with extremely low activation energy. Attempts to further accelerate the Cope rearrangement have involved substitution[10–13] and the introduction of nitrogen atoms,[14, 15] but the extreme case of a "bishomoaromatic" ground state has not yet been attained. Simple bridging of the semibullvalene framework, as in **20a**,[16] leads to nonequivalence of the valence isomers **20a/20b**. In the first doubly bridged semibullvalene **3**, the Cope rearrangement of which is again degenerate, the two bridges should increase the strain in the ground state more than in the transition state, thus further lowering the activation barrier of the Cope rearrangement.[17] In a ^{13}C NMR

20a **20b**

X = e.g., CH_2, $(CH_2)_2$, $(CH_2)_3$, O, S, NR, CH_2–O–CH_2, CH_2–S–CH_2

measurement [50 MHz, dimethyl ether:[D$_8$]THF (5:1)], the averaged signal for the terminal centers C-1,5,7,11 of the allyl systems in **3** revealed no significant line broadening even at −160 °C. Therefore, the Cope rearrangement is rapid on the NMR time scale even at this temperature. From the Eyring relationship, an upper limit of ca. 15 kJ mol^{-1}[18] for the free energy of activation $\Delta G^{\ddagger}_{93}$ can be estimated for **3**; this value is considerably less than the value for semibullvalene $\Delta G^{\ddagger}_{93}$ = 23 kJ mol^{-1}).[19, 20]

[18] A shift difference of 4500 Hz was assumed for the signals of C-1 and C-7 in the slow exchange domain. This value corresponds to the shift difference for C-2 and C-4 of unsubstituted semibullvalene. A value of −180 °C was chosen for the coalescence temperature T_c. Based on experience with other semibullvalenes [19] with respect to the temperature range in which dynamic processes result in line-shape changes, however, T_c is presumably considerably lower.

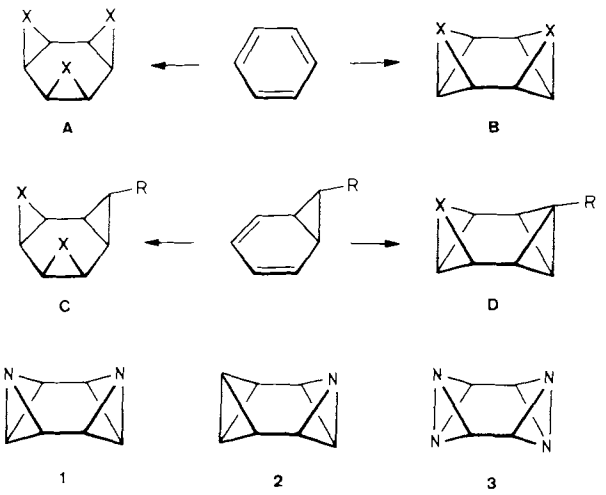
[20] The fastest degenerate Cope rearrangement ($\Delta G^{\ddagger}_{115}$ = 13.0 kJ mol^{-1}) was observed for 1,5-dimethylsemibullvalene-2,6-dicarbonitrile.



Azaoctabisvalenes**

By *Björn Trupp, Hans Fritz,* and *Horst Prinzbach**

Our syntheses of the preparatively challenging and theoretically intriguing carbo- and heterocyclic all-*cis*-tris-σ-homobenzenes **A** and **C** are based ultimately on benzene[1] and substituted cycloheptatrienes,[2] respectively. The readily accessible intermediates involved in these syntheses provided the main impulse for our work on the highly strained octabisvalenes **B** and **D**.[3] Here we describe the synthesis of diazaoctabisvalene (**B**, X = N) and azaoctabisvalenecarbonitrile (**D**, X = N, R = CN). Like the framework of the still unknown tetraaza analogue **3**,[4] the heterocyclic frameworks **1** and **2**, with their azabicyclobutane subunits,[5] should have a strain energy on the order of that

(E_{st} = 154 kcal mol^{-1} [3]) calculated for the recently reported $(CH)_8$ parent framework **B** (X = CH).[6]

A key intermediate in the synthesis of *cis*-trioxide **A** (X = O) is the *anti-cis*-dibromoepoxycyclohexene **4**.[1] Its facile conversion to the *muco*-diazido- and *muco*-diamino-dideoxyinositols **5a** and **6a**, respectively, has been described.[7, 8] The use of suitably functionalized derivatives reduces the preparation of **1** to the intramolecular substitution of the four OR leaving groups *trans*-vicinal to the *N* functions (**4** → **5** (**6**) → **7** → **8** → **10** → **1**). A potential complication was the competing cyclization of monoaziridine **7** ⇄ **7′** to 1,4-bis(aziridine) **9**.

Also uncertain was whether **1**, with its highly reactive C4(8)–N bonds and acidic C4(8) hydrogens, would withstand the conditions required for the final bond formation, which, according to calculations, involves a significant increase in strain. After unsatisfactory results with the diamino tetraesters **6b, c**, we focused our efforts on the diazido tetramesylate **5b**.[9] Compound **5b** was first treated with $LiAlH_4$ under the conditions used for the preparation of *cis*-tris(imine) **A** (X = NH) (THF, 10 → 25 °C, 2 h).[10] In agreement with the explanation given there for the selective course of the reaction, we were unable to obtain satisfactory results, despite wide variation of the reaction conditions. By contrast, treatment of **5b** with triphenylphosphane/acetonitrile[11] afforded the unstable bis(aziridine) **8a** in 65–70% yield (20-mmole scale) as a crystalline solid; the intermediate monoaziridine **7** was not isolated. Repeated, careful monitoring of the reaction (TLC, ^{1}H NMR) revealed no evidence of bis(aziridine) **9a**. This competing reaction, which adversely affects the synthesis of the analogous carbocyclic compounds,[12] is presumably suppressed by the enormous repulsion of the nitrogen lone pairs oriented in an *endo, endo* fashion in the boatlike transition state leading to **9a**. According to the ^{1}H NMR spectrum (cf. Table 1) **8a** (**b, c**) has C_s symmetry at room temperature; this reflects the equilibration between the equivalent 5e,6a and 5a,6e half-chair conformations.

Owing to the relatively weak acidity of the aziridine *N* protons, which engage in hydrogen bonding, very strong bases are required for the two deprotonation steps leading from **8a** to **1**. Therefore, a potentially competing reaction was β-elimination to give **11**. The best result so far has been achieved by treating **8a** (2–3 mmol) with 2.2 equivalents of *n*BuLi/THF (−78 → + 25 °C). The unstable, ambiphilic, volatile $C_6H_6N_2$ pentacycle **1** (*Z*-3,7-diazapentacyclo[5.1.0.0^{2,4}.0^{3,5}.0^{6,8}]octane) was easily isolated as a pure crystalline solid in 45–55% yield by ether extraction of the solid residue (containing **1** as the only monomeric component according to TLC and ^{1}H NMR). Attempts to obtain the tetracyclic intermediate **10** by use of ca. 1 equivalent of base provided, in addition to starting material (ca. 18%) and traces of **1**, mainly polymeric material along with ca. 3% of the 1,4-dihydro-1,4-diazocine **12**[13] derived from the *cis*-diaza bis-σ-homobenzene **11**; according to the ^{1}H NMR data, **12** is planar-diatropic. The mono-N-"anion" derived from **8a** is presumably stabilized by an internal hydrogen bond, only the bis-N-"anion" cyclizing via **10** to **1**. Control experiments showed that, under the conditions used here, **1** is slowly metalated at C-4(8) and thereby slowly lost as polymer. Crystalline **1** exhibits high thermal stability; it sublimes upon heating above ca. 95 °C and melts (on a preheated hot plate) at ca. 136 °C with decomposition. In the ^{1}H and ^{13}C NMR spectra (Fig. 1), the two signals are shifted downfield relative to those of the C_8H_8 framework;[6] the ^{13}C,H coupling constants differ only slightly, whereas the H,H coupling constants (determined for **1** by spectral simulation) and ^{13}C, ^{13}C coupling constants differ significantly. The ^{15}N shift, mea-

Table 1. Physical data for selected compounds.

(1α,2α,4α,5α,6α,7α)-3,8-Benzoyl-3,8-diazatricyclo[5.1.0.0^{2,4}]octane-5,6-diyl bismethanesulfonate **8c**: m.p. 182–183 °C ($CHCl_3$/ether); ^{1}H NMR ($CDCl_3$): δ = 8.04 (m, 4*o*-H), 7.60 (m, 2*p*-H), 7.46 (m, 4*m*-H), 5.37 (m, 5-,6-H), 3.41 (m, 1-,2-H), 3.25 (s, 2 CH_3), 3.23 (br.m, 4-,7-H)

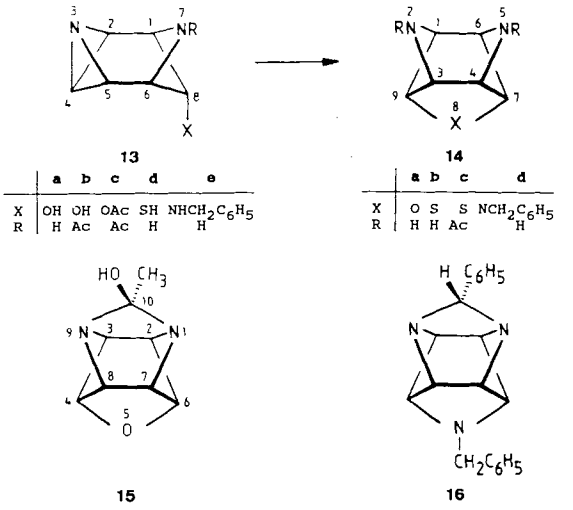
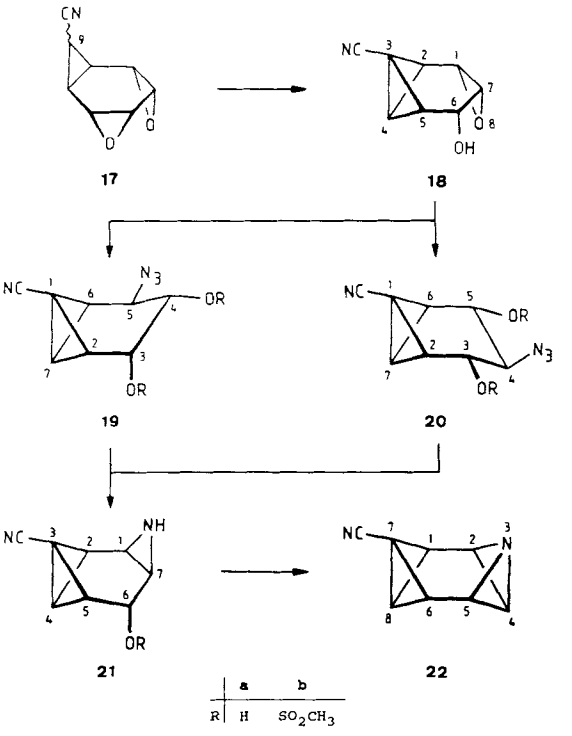
8-Benzyl-2,8-diazatetracyclo[4.3.0.0^{3,9}.0^{4,7}]nonane-5-*endo*-carbonitrile **26**: m.p. 82 °C (ether); ^{1}H NMR ($CDCl_3$): δ = 7.2–7.4 (m, 5H), 4.67 (m, 7-H), 4.48 (m, 9-H), 3.80 (m, 1-,3-H), 3.34 (s, CH_2), 2.91 (s, 5-H), 2.78 (m, 4-,6-H), 1.99 (br.s, N-H; $J_{1,6} \approx 3.5$, $J_{1,9} \approx 2.5$, $J_{4,5} \approx 2.5$, $J_{7,9} \approx 2.5$ Hz; ^{13}C NMR ($CDCl_3$): δ = 137.4, 128.8, 128.6, 127.6 (6C), 122.2 (CN), 77.5 (C-9), 75.0 (C-7), 61.4 (C-1,-3), 52.3 (CH_2), 43.1 (C-4,-6), 22.2 (C-5); MS (EI, 70 eV): *m/z* 237 ($M^{\oplus}$, 2%), 91 ($C_7H_7^{\oplus}$, 100%), etc.

sured for the first time for an azabicyclobutane, deviates considerably from that of aziridine.[14]

Compound **1** behaves like azabicyclobutanes[5] and octabisvalenes[3, 6] toward nucleophiles (1-mmole scale): $ZnSO_4$-catalyzed addition of water leads, via the nonobservable

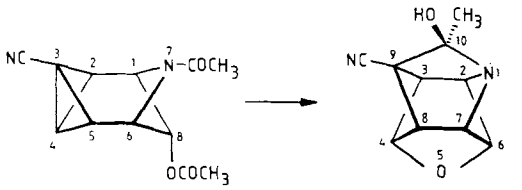


1

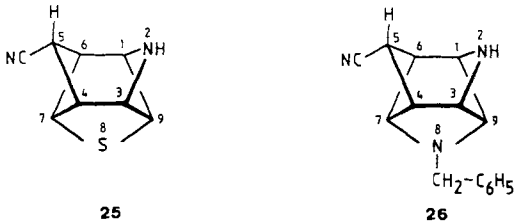


22

Fig. 1. Selected spectral data for **1** and **22** (in [D_6]benzene and, in parentheses, $CDCl_3$). **1**: $J_{1,2}$ = 4.65, $J_{1,6}$ = 4.41, $J_{1,8}$ = 1.40 Hz; $J_{C1,H}$ = 168, $J_{C4,H}$ = 209, $J_{C1,C8}$ = 29.2, $J_{N,4H} \approx 8$ Hz. MS (EI, 70 eV): *m/z* 106 ($M^{\oplus}$, 3%), 52 (100%), etc. **22**: $J_{1,2} \approx 4$, $J_{1,8} \approx 3$, $J_{2,4} \approx 1.5$ Hz; $J_{C1,H}$ = 164, $J_{C2,H}$ = 170, $J_{C4,H}$ = 209, $J_{C8,H}$ = 212 Hz. MS (EI, 70 eV): *m/z* 130 ($M^{\oplus}$, 21%), 129 ($M^{\oplus}-1$, 100%), etc.



13a, to oxadiazatetracycle **14a** (which, in water, is complexed with $Zn^{2\oplus}$ according to ^{1}H NMR). Similarly, reaction with the nucleophiles Na_2S (*t*BuOH/50 °C/1 d) and benzylamine/BF_3 (*t*BuOH/50 °C/1 d) selectively leads, via **13d/e**, to the analogous thiadiaza- and triazatetracycles **14b(c)** (ca. 90%) and **14d** (ca. 85%), respectively. The piperazine boat in tetracycles **14** is ideally suited for transannular *N,N* bridging. Thus, **13c**, prepared by treatment of **1** with acetic anhydride, reacts with weak bases (NH_3, Na_2CO_3) to afford a nearly quantitative yield of oxadiazapentacycle **15**; triazapentacycle **16** is likewise obtained from **14d** and benzaldehyde.



A mixture of epimeric *trans*-dioxatris-σ-homobenzenecarbonitriles **17**,[2] which has proved useful for syntheses in the **C** series,[1] is a readily accessible starting material for monoazaoctabisvalenes **2**. Compound **17** is sufficiently acidic at C-9 to be deprotonated without affecting the epoxide functions and to be regioselectively cyclized (three-membered ring formation) to **18** (0.15 M scale, 1 equiv. lithium-bis(trimethylsilyl)amide/THF, 0–20 °C, 50–60%; m.p. 135–136 °C, $J_{1,2} \approx 3.5$, $J_{1,7} \approx 4$, $J_{2,4} \approx 3.5$, $J_{2,5} \approx 3.5$, $J_{4,5} \approx 3.5$ Hz). In the reaction of **18** (50 mmol) with sodium azide/$MgSO_4$ (5 equiv., H_2O, 40 °C, ca. 5 d) – substitution at C-4 does not compete – the product (90–95% overall yield) consisted of a mixture of azidodiols **19a** (78%) und **20a** (7%) along with three (characterized) diazides arising therefrom (in toto 5–10%): the main components could be sepa-

rated without material loss by flash chromatography. The bismesylates **19b/20b**, prepared under standard conditions in 85–90% yield, can be converted into the tetracyclic aziridine **21b** (70–85%) under the conditions used for **5b** (10 mmol, triphenylphosphane/THF). Cyclization of **21b** to **22** proceeds under the optimized conditions found for **1** (5 mmol, 1.05 equiv. *n*BuLi/THF, $-78 \rightarrow +20\,^{\circ}C$) without any competition by the base-induced reactions typical of bicyclobutanecarbonitriles[15] and azabicyclobutanes. Trituration of the crude product with ether affords a practically quantitative yield of crystalline **22** (*Z*-3-azapentacyclo-[5.1.0.0^{2,4}.0^{3,5}.0^{6,8}]octane-7-carbonitrile), which remains unchanged up to its melting point (128 °C). The NMR data (Fig. 1) are characteristic for cyanocyclobutane and azabicyclobutane moieties.

23 **24**

25 **26**

Saponification of **23**, obtained by treatment of **22** with acetic anhydride, leads "directly" to oxaazapentacycle **24**: reaction of **22** with Na_2S (CH_2Cl_2/*t*BuOH, reflux) and with benzylamine/BF_3 (CH_2Cl_2/*t*BuOH, 50 °C) gives heterocycles **25** and **26**, respectively (55–60%, not optimized).

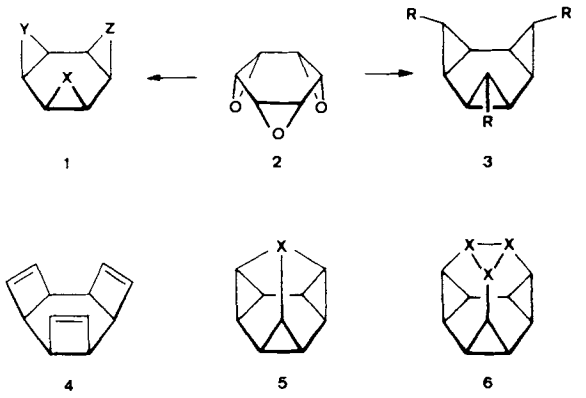
Stabilized *cis*-Tris-σ-homobenzenes: Syntheses, [σ2 + σ2 + σ2] Cycloreversions**



By *Wolf-Dieter Braschwitz, Thomas Otten, Christoph Rücker,* Hans Fritz,* and *Horst Prinzbach**

Extensive variation of the X, Y, and Z positions of the carbo- and heterocyclic *cis*-tris-σ-homobenzenes **1** is of interest from both mechanistic and preparative points of view.[1] Such carbocyclic frameworks have so far been rare[2, 3]—in part because of their inherent steric properties and their pronounced tendency to undergo [σ2 + σ2 + σ2] cycloreversion (estimated/calculated E_a value for the still unknown C_9H_{12} framework **3** (R = H), 24–28/37 kcal mol^{-1}[4–6]). Triple oxirane → aziridine and oxirane → thiirane transformations, starting from the readily accessible *cis*-benzene trioxide **2**, provided us with an efficient approach to compounds **1**, X,Y,Z = NR or S.[1] However, the analogous construction of carbocyclic frameworks (**2** → **3**) by triple oxirane → cyclopropane transformation met with severe complications.[3] Here we describe an efficient synthesis, based on **2**, of 3,6,9-tris-acceptor-substituted *cis*-tris-σ-homobenzenes **3**. This special kind of substitution should provide kinetic stability and facilitate the transformation of **3** to the ring-expanded compound **4** and, still more important, to bridged structures of the diademane type **5** (X = CH)[4, 5] and the semiregular Archimedian polyhedron **6** (X = CH, "truncated tetrahedron"[7]).[8]

The synthetic pathway shown in Scheme 1 is based on the following findings and assumptions: (1) The starting material, *scyllo*-tripropargyltriol **7b** (see Table 1), was obtained in 60–65% yield by triple epoxide opening of trioxide **2** with the reagent [(*i*Pr)$_3$SiC≡CCH$_2$(2-thienyl)Cu(CN)Li$_2$][9] to give **7a** followed by desilylation.[3, 10] (2) Tritosylate **7c** (all-equatorial) preferentially gave elimination products upon treatment with bases.[3, 11] However, elimination reactions should be suppressed by restricting the CH_2R^1/OR^2 sub-

Scheme 1.

stituents to axial positions such as in **8** and **9**. (3) In **9** and **11**, R = CO_2Alkyl, the α-methylene groups should be metalated faster than the cyclopropane rings; cyclization of **9** to **10** and **11** and of **11** to **13** should therefore be favored over cyclization to **14** and **15**, respectively.[12] (4) The isopropyl ester groups in **8d** hinder self-condensation.[13]

Table 1. Physical data for selected compounds.

(1α,2β,3α,4β,5α,6β)-2,4,6-Tris(prop-2-ynyl)cyclohexane-1,3,5-triol **7b**: m.p. 172 °C (EtOH/petroleum ether); ^{1}H NMR ($CDCl_3$): δ = 3.93 (br.d, 3 OH), 3.54 (m, 1-,3-,5-H), 2.64 (t, 6H), 2.02 (t, 3H), 1.50 (m, 2-,4-,6-H); $J_{1,2}$ = 10.5, $J_{2,CH2}$ = 3.5, $J_{CH,CH2}$ = 3, $J_{1,OH}$ = 5 Hz; ^{13}C NMR ($CDCl_3$): δ = 81.4 (3 C), 71.0 (3 CH), 69.0 (C-1,-3,-5), 48.8 (C-2,-4,-6), 17.1 (3 CH_2)

DL-[(1α,2α,4α,5α,6β,7α,8α)-6-Isopropoxycarbonylmethyl-3,8-bis(isopropoxycarbonyl)tricyclo[5.1.0.0^{2,4}]oct-5-yl] dimethyl phosphate **11a**: m.p. 123 °C (ethyl acetate); ^{1}H NMR ($CDCl_3$): δ = 5.05 (sept., 2H), 4.9 (sept., 1H), 3.77 (OCH_3), 3.74 (OCH_3), 3.61 (m, 5-H), 2.74 (dd, 9-H), 2.48 (m, 6-H), 2.22 (dd, 9-H), 2.05 (1-,2-H), 1.80 (m, 7-H), 1.59 (m, 4-H), 1.38 (m, 3-H), 1.22 (s, CH_3), 1.2 (m, 8-H); $J_{4,5}$ = 3.5, $J_{5,6}$ = 9, $J_{6,7}$ = 4.5, $J_{6,9}$ = 3.5, $J_{6,9'}$ = 10, $J_{9,9'}$ = 15 Hz, $J_{P,5}$ = 12, $J_{P,6}$ = 0, $J_{P,OMe}$ = 11 Hz; ^{13}C NMR ($CDCl_3$): δ = 171.8 (CO), 171.4 (CO), 171.3 (CO), 76.5 (C-5), 68.3 (CH), 68.3 (CH), 68.0 (CH), 54.5 (OCH_3), 54.3 (OCH_3), 36.4 (C-9), 34.3 (C-6), 27.4 (C-7), 24.5 (C-3), 23.3 (C-4), 21.8 (2 CH_3), 21.7 (2 CH_3), 20.1 (C-1), 19.1 (C-2), 18.8 (C-8); $J_{P,5}$ = 6, $J_{P,6}$ = 9, $J_{P,OCH3}$ = 6 Hz.

Triisopropyl (1α,2α,3α,4α,5α,6α,7α,8α,9α)-tetracyclo[6.1.0.0^{2,4}.0^{5,7}]nonane-3,6,9-tricarboxylate **3a** (see also Fig. 1): m.p. 132 °C (cyclohexane): ^{1}H NMR ($CDCl_3$): δ = 4.99 (3 C*H*Me_2), 1.83 (6H), 1.25 (6 CH_3), 0.52 (3H); ^{13}C NMR ($CDCl_3$): δ = 172.8 (3 CO), 66.4 (3 CH), 21.8 (6 CH_3), 21.6 (3 C), 15.5 (6 C).

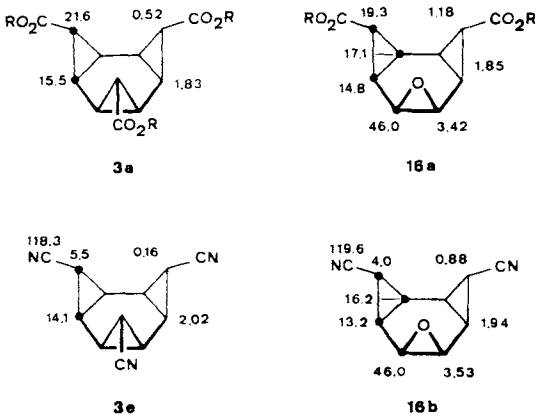
Triisopropyl *cis,cis,cis*-cyclonona-2,5,8-triene-1,4,7-tricarboxylate **17a**: ^{1}H NMR ($CDCl_3$): δ = 5.54 (6H), 5.02 (3 CHMe_2), 4.61 (3H), 1.23 (6 CH_3); ^{13}C NMR (C_6D_6): δ = 171.4 (CO), 126.6 (6 C), 68.5 (3 CH), 43.6 (3 C), 21.5 (6 CH_3)

Treatment of triol **7b** (20 mmol) with $POCl_3$/pyridine (80 °C) affords the crystalline adamantoid phosphate **8a** (m.p. 207 °C; $J_{1,2}$ = 3, $J_{2,CH2}$ = 10, $J_{P,1}$ = 19 Hz) in at least 60% yield (along with oligomers). Oxidative cleavage of the three alkyne functions of **8a** to give triacid **8b** was best accomplished with RuO_2/$NaIO_4$ in CH_3CN/CCl_4/H_2O (2:2:3).[14] The yield, after esterification of **8b** with diazomethane to give **8c**, was over 90%. Triple transesterification of **8c** to triisopropyl ester **8d** (m.p. 210 °C) proceeded smoothly with Ti[OCH(CH_3)$_2$]$_4$[15] (3.5 equiv., 80 °C, 4 h, 94%). In reactions of **8c** or **8d** (5-mmole scale) with various bases, including lithiumdiisopropylamide (LDA), NaH, and *n*BuLi, the combination **8d**/LDA(THF) gave the best results: (1) At −70 °C, **8d** does not react with base (1.1 equiv.; no H/D exchange); warming the reaction mixture to room temperature, followed by hydrolysis and esterification with diazomethane, gave a crude product, which, according to TLC and ^{1}H NMR monitoring, consisted of unreacted **8d** and the monocyclic compound **9a** (50%; 1:1 mixture of diastereomeric phosphates). The ^{1}H NMR analysis of **9a** ($J_{1,2} \approx 0$, $J_{2,3} \approx 3$, $J_{3,4} \approx J_{4,5} \leq 1$, $J_{5,6} = J_{6,1} = 9$, $J_{6,7} = J_{7,1} = 4.5$ Hz, etc.) revealed a half-chair conformation with the 7-ester group in α position, quasi-*trans*-diaxial CH_2R/phosphate moieties, and a chairlike phosphate ring. (2)

Reaction of **8d** with an excess of base (5(10) equiv. LDA, $-50 \rightarrow +20\,^{\circ}C$), followed by the same workup (CH_2N_2), gave a 7:3 mixture (TLC, ^1H NMR) of the bicyclopropa compound **11a** (m.p. 123 °C) and the C_s isomer **10a** (oil) in ca. 75% yield; the two products could be separated by chromatography (silica gel, cyclohexane/ethyl acetate 7:3). Compound **3a** was not detected, in agreement with the low nucleofugality of the phosphate dianion substituent in **11** ($-OPO_3^{2\ominus}$). 3,6,9-Triisopropyl ester **3a** was obtained in 85% yield by treatment of trialkyl phosphate **11a** with 3.0 equivalents of LDA ($-30 \rightarrow +20\,^{\circ}C$, THF, 30 min); **3a** was then converted, via triacid **3b**, into trimethyl ester **3c**. Compounds **3a,c** isomerize (**17a,c**) upon melting (130–132 °C).

Synthesis of the 3,6,9-trinitrile **3e**, which was of special interest for preparative purposes, was first attempted via triamide **3d**. This approach was unsuccessful, however, owing to the kinetic lability of the intermediates. Trinitrile **7g** was easily obtained from triamide **7f**. Despite wide variation of the reaction conditions, however, the phosphate ester **8f** could not be satisfactorily prepared from **7g** (< 10%; the same is true for **7d** → **8c**). A route to **3e**, which was surprisingly efficient in view of the complexity of the reactions involved, emerged from the rather vague notion, based on the regioselectivity observed in the preparation of **7a** from **2**,[3, 16] that it should be possible to ensure conformations with leaving groups in axial positions in the "triscarbanion"[16] of **7h**, as well as in the intermediates (with deprotonated three-membered rings), by lithium cluster formation (**12/13**[17]). Indeed, after treatment of **7h** (1 mmol, THF, $-78 \rightarrow +20\,^{\circ}C$) with at least 5 equivalents of lithium-diisopropylamide and complete conversion, **3e** emerged as the only monomeric component along with polymers (TLC, ^1H NMR) and could be easily isolated (filtration through silica gel) as a crystalline solid in 35% yield (m.p. 239 °C (dec.)). Diverse control experiments support a reaction path starting from the **7h** "triscarbanion"; for example, use of only 1 equivalent of base led neither to **3e** nor to intermediate or competition products (cf. **10, 11, 14, 15**).

Informative with respect to the spectroscopic and kinetic data of *cis*-tris-σ-homobenzenes **3a,c,e** is the comparison with the analogously substituted oxa compounds **16a,b**.[18] ^1H and ^{13}C NMR data (Fig. 1) confirm the presence of pla-



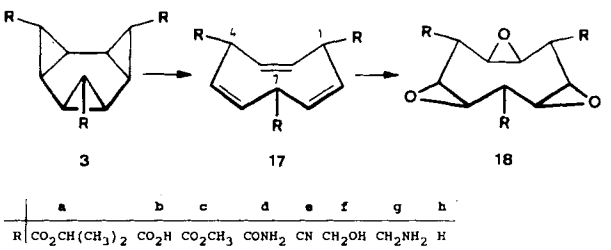


Fig. 1. Selected NMR data ($CDCl_3$) for *cis*-tris-σ-homobenzenes **3a,e** and **16a,b**.

nar, C_{3v}-symmetric structures. Compounds **3a** ($\Delta G^{\neq}$ (C_6D_6, 142 °C) = 28.5 kcal mol^{-1}) and **3e** ($\Delta G^{\neq}$ ($CDCl_3$), 142 °C) = 29.0 kcal mol^{-1}) are thermally more labile than **16a,b** ($\Delta G^{\neq}$ (benzene, 140 °C) = 32.1 and 32.4 kcal mol^{-1}, respectively), in agreement with the "additive" contribution of the respective three-membered ring components to the activation barrier for these [σ2 + σ2 + σ2] cycloreversions.[1] According to NMR analysis, the *cis,cis,cis*-cyclononatriene derivatives **17a,c,e**, which are stable under the thermolysis conditions, prefer a C_{3v} crown conformation with outward directed R groups. Triester **17a** is oxidized stereospecifically to the *exo,exo,exo*-trioxide **18a** (98%) by treatment with

benzoylperoxycarbamic acid in excess (benzene, 80 °C).[19] Attempted reduction of **3a,e** to **3f,g** (precursor to **4**) with $LiAlH_4$ ($-50 \rightarrow$ ca. 0 °C) only led to the corresponding π isomers **17f,g** (80–85%).[4, 5]

Trihomobenzenes **3a–c,e** are now available in gram quantities for preparative use.[8]

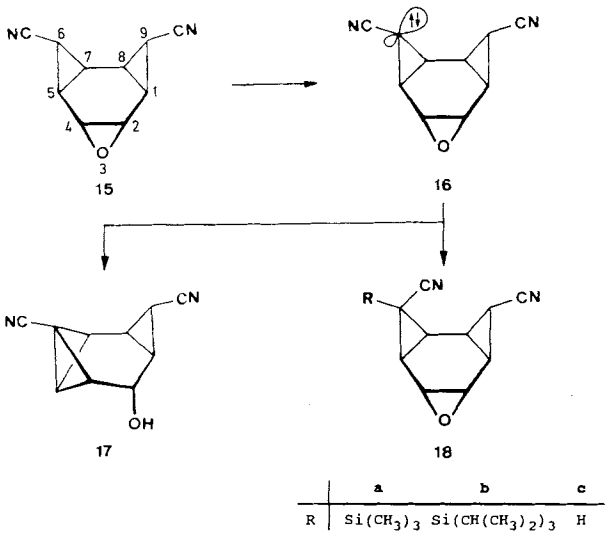
Bridged *cis*-Tris-σ-homobenzenes: Heterodiademanes**

By *Dirk-Rainer Handreck, Dieter Hunkler,* and *Horst Prinzbach**



Attempts to prepare the highly interesting triply bridged *cis*-tris-σ-homobenzenes (cf. **5** and **6**)[1,2]—as carbocycles or with N atoms in diverse positions—have been of limited success so far. The $(CH)_{10}$ framework **1** ("diademane"[3] ("mitrane")[4]) and a C_{11} "homologue"[3] are known; however, the photochemical [π2 + σ2] step **4** → **1** is not efficient. Moreover, our efforts to obtain the triaza analogues **2** by bridging *cis*-trisimine **5** were unsuccessful.[5,6] Here we describe an approach to heterodiademanes of type **3** ("heterohexadehydroadamantanes"), which is based on bridge formation in *cis*-bis-σ-homobenzenes **6** and features some variability.

The following preliminary findings[9] were crucial for planning the reaction sequence[7] presented in Scheme 1: (1) The *cis*-bis-σ-homobenzene diester **7b**[10] and the dinitrile **7c**[11]—obtainable from cyclooctatetraene in decigram quantities by a meanwhile improved procedure[12]—are considerably more stable (**7c** → **8c**, $t_{1/2}$ (38 °C) ca. 520 min)[11,12] than the parent compound **7a** (**7a** → **8a**, $t_{1/2}$ (− 22 °C) ca. 38 min).[13] (2) Compounds **7b,c** are deprotonated practically instantaneously at C-3[8] with lithiumdiisopropylamide (LDA)/THF (1.0–1.2 equiv.) at −78 °C. Of the resulting, rapidly inverting "carbanions"[14] **9b,c/10b,c**, only that of the dinitrile can be trapped, with D_2O preferentially as the *endo* product **11c**, with bulky trimethylsilyl chloride (2 equiv. added to the reaction solution) nearly quantitatively as the *exo* product **12c**. (3) "Dianions" **13b,c**, generated with an excess of base (2–5 equiv.), cannot be detected, presumably owing to their expected, very rapid cycloreversion to the 10π aromatic dianions **14b,c**. (4) Monoanion **16**, generated from **15**[11] with LDA/THF at −78 °C, undergoes regioselective substitution at C-4 above − 60 °C to give **17** (C2–C6 bond formation does not compete). After inversion, **16** reacts rapidly at −78 °C with trimethylsilyl chloride to give **18a**.[15] (5) In contrast to **7c**, the silylated derivative **12c** is oxidized by trifluoroperacetic

acid in an *exo*-specific fashion to give the *trans*-oxa tris-σ-homobenzene **18a** (see Table 1).

Compound **18a** (3–5 mmol) reacts with 1.1 equivalents of LDA at −78 °C (THF) rapidly and completely (**19a**); the three components identified after addition of pH 7 buffer (TLC, ^1H NMR) and isolated in pure form by chromatography are the desilylated, epimeric (reusable) dinitriles **15** and **18c** (no **24a**) and the pentacyclic, crystalline imine **20a**, obtained as an *E*/*Z* pair (3:1) (up to 35%; optimization in favor of **20a** has not yet been carried out). The sterically bulky triisopropylsilyl group in **18b** does not significantly control the product ratio (ca. 35% **20** (R = triisopropyl, 8:1

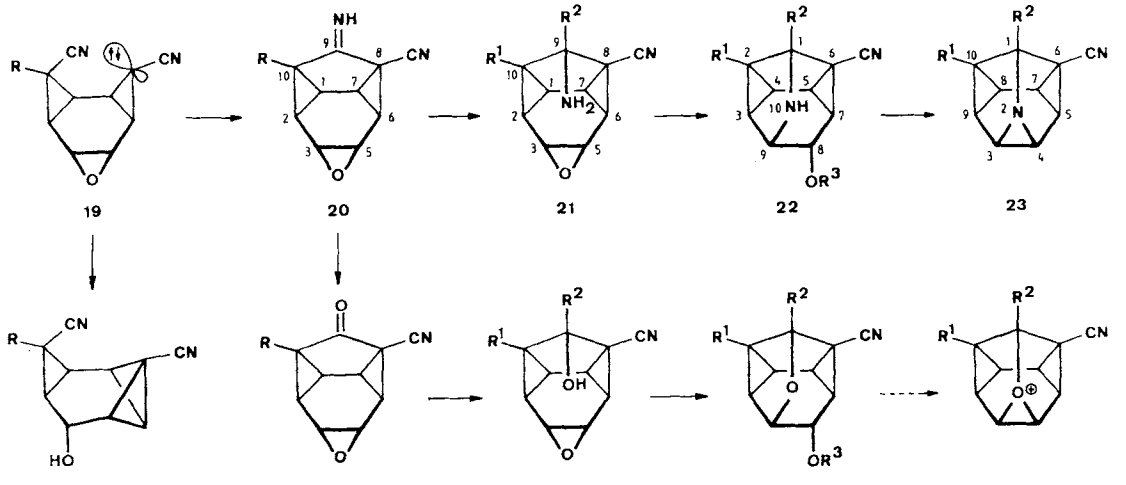
Table 1. Physical data for selected compounds.

DL-(1α,2β,4β,5α,6β,7α,8α,9α)-6-Trimethylsilyl-3-oxatetracyclo[6.1.0.0^{2,4}.0^{5,7}]-nonane-6,9-dicarbonitrile **18a**: m.p. 129–130 °C (ether); IR (KBr): $\tilde{\nu}$ = 2240 (CN), 2205 (CN) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 3.48 (m, 4-H*), 3.39 (m, 2-H*), 3.00 (dd, 9-H), 2.09 (m, 8-H), 1.97 (dd, 1-H), 1.6 (m, 5-,7-H), 0.19 (s, 3 CH_3); $J_{1,2}$ = 4.5, $J_{1,8}$ = 8.5, $J_{1,9}$ = 4.5, $J_{2,4}$ = 3.9, $J_{4,5}$ = 4.5, $J_{8,9}$ = 4.8 Hz.

DL-(1α,2α,3β,5β,6α,7α)-9-Imino-4-oxapentacyclo[5.3.0.0^{2,10}.0^{3,5}.0^{6,8}]decane-8-carbonitrile **20b**: m.p. 134–150 °C (ether); IR (KBr): $\tilde{\nu}$ = 3234 (=N–H), 2230 (CN), 1630 (C=N) cm^{-1}; ^{1}H NMR ($CDCl_3$): δ = 9.94 (br.s, NH), 3.66 (m, 3-,5-H), 2.91 (ddd, 7-H), 2.43 (ddd, 6-H), 2.3 (m, 1-,10-H), 1.90 (ddd, 2-H); $J_{1,2}$ = 9.0, $J_{1,6}$ = 1.0, $J_{1,7}$ = 5.6, $J_{2,3}$ = 3.0, $J_{2,7}$ = 1.0, $J_{2,10}$ = 8.5, $J_{3,5}$ = 4.0, $J_{5,6}$ = 3.0, $J_{6,7}$ = 8.5 Hz.

DL-8-Hydroxy-1-*methoxy*-2-trimethylsilyl-10-azapentacyclo[4.4.0.0^{2,4}.0^{3,9}.0^{5,7}]-decane-6-carbonitrile **22a**: m.p. 129–131 °C (ether); IR (KBr): $\tilde{\nu}$ = 3274 (NH), 3212 (OH), 2214 (CN) cm^{-1}; ^{1}H NMR ($CDCl_3$): δ = 4.11 (dd, 8-H), 3.65 (ddd, 9-H), 3.55 (s, OCH_3), 2.56 (dd, 5-H), ≈2.1 (br.s, NH, OH), 1.87 (ddd, 7-H), 1.69 (dd, 4-H), 1.54 (dd, 3-H), 0.0 (s, 3 CH_3); $J_{3,4}$ = 7.0, $J_{3,9}$ = 6.5, $J_{4,5}$ = 5.0, $J_{5,7}$ = 8.5, $J_{7,8}$ = 4.5, $J_{7,9}$ = 1.5, $J_{8,9}$ = 4.5 Hz.



DL-(1α,2α,3β,5β,6α,7α)-9-Oxo-4-oxapentacyclo[5.3.0.0^{2,10}.0^{3,5}.0^{6,8}]decane-8-carbonitrile **25b**: m.p. 188–189 °C (methanol); IR (KBr): $\tilde{\nu}$ = 2225 (CN), 1730 (C=O). ^{1}H NMR ($CDCl_3/C_6D_6$, 250 MHz): δ = 2.91 (ddd, 3-H), 2.73 (ddd, 5-H), 2.00 (ddd, 7-H), 1.62 (dd, 6-H), 1.60 (dd, 10-H), 1.37 (dddd, 1-H), 1.03 (ddd, 2-H); $J_{1,2}$ = 9.0, $J_{1,3}$ = 1.0, $J_{1,7}$ = 6.0, $J_{1,10}$ = 6.6, $J_{2,3}$ = 3.0, $J_{2,7}$ = 0.7, $J_{2,10}$ = 9.0, $J_{3,5}$ = 4.8, $J_{5,6}$ = 3.1, $J_{5,7}$ = 0.7, $J_{6,7}$ = 8.7 Hz.

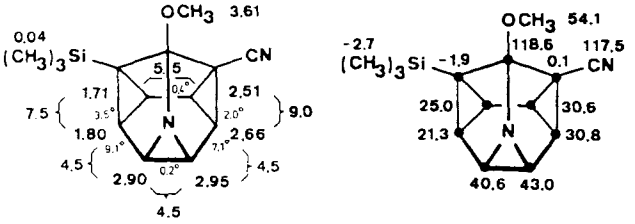
DL-(7α,8α)-8-Hydroxy-10-oxapentacyclo[4.4.0.0^{2,4}.0^{3,9}.0^{5,7}]decane-6-carbonitrile **27c**: oil; IR (neat/NaCl): $\tilde{\nu}$ = 2212 (CN) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 4.96 (d, 1-H), 4.46 (ddd, 9-H), 4.19 (dd, 8-H), 3.08 (ddd, 2-H), 2.63 (dd, 5-H), ≈2.2 (br.s, OH), 2.04 (dddd, 4-H), 1.95 (ddd, 7-H), 1.88 (ddd, 3-H); $J_{1,2}$ = 4.0, $J_{2,3}$ = 8.7, $J_{2,4}$ = 8.7, $J_{3,4}$ = 7.5, $J_{3,9}$ = 5.4, $J_{4,5}$ = 5.3, $J_{4,9}$ = 1.0, $J_{5,7}$ = 8.7, $J_{7,8}$ = 4.7, $J_{7,9}$ = 1.0, $J_{8,9}$ = 4.5 Hz.

mixture)). The importance of the Si moiety in the transannular C–C bond formation to give **20** is manifested by the fact that **20b** could not be obtained from **15** (which instead afforded a nearly quantitative yield of **18c**). Slow chromatographic workup of **20a** (silica gel) or careful hydrolysis results in formation of ketone **25a** with practically no material loss. Removal of the Si "auxiliary groups" in **20a** (→ **20b**) and **25a** (→ **25b**) was accomplished with tetra-*n*-butylammonium fluoride · 3 H_2O, whereby partial hydrolysis of **20b** to **25b** has to be accepted: the use of dry reagents leads to a mixture of the epimeric dinitriles **15** and **18c** from **20a**. The desired *exo* attack on the C=N bond in **20a**, that is, the introduction of an *endo* NH_2 group in **21a**, should be sterically favored according to models.

Indeed, the addition of methanol to **20a** in methanol/ammonium acetate (20 °C) is highly selective; however, the product, isolated in ca. 90% yield and crystallized from ether, is not the amino epoxide **21a**, but rather the alcohol **22a**[16] arising from regioselective substitution at C-3. Proton catalysis should in fact favor this epoxide opening over that at C-5. The NH and OR^3 groups in **22** have the quasi-axial orientation (**22b**: $J_{8,9}$ = 4.5 Hz) needed for the subsequent cyclization. After (as yet unselective) esterification of **22a** to **22b** (ca. 15%, along with *N*-mono- and *O,N*-disulfonates), treatment with triethylamine at room temperature effects rapid and exclusive substitution to give azadiademane **23a** (1-methoxy-10-trimethylsilyl-2-azahexacyclo[4.4.0.0^{2,4}.0^{3,9}.0^{5,7}.0^{8,10}]decane-6-carbonitrile). Attempts to synthesize only doubly (singly) substituted **23b** (**c**) by reaction of **20a** (**b**) with "mild" hydride sources such as $LiBH_3CN$, $NaBH_3CN$,[17] and $KBH(OiPr)_3$[18] (to avoid attack at the CN and epoxide groups) have not afforded satisfactory results so far. Thus, **20a** was unreactive toward $KBH(OiPr)_3$, whereas **20b** underwent opening to **18c**, a notorious behavior of the imide anion. Selective reduction of the ketone function in **25b** is best accomplished with $KBH(OiPr)_3$/THF (1 equiv., 0 → 20 °C). The reproducible yield of epoxy alcohol **26c**, together with varying amounts of **27c** depending on the workup,[16] is 85%. The isomerization **26c** → **27c** occurs rapidly and cleanly on silica gel. The intermediacy of oxoniadiademanes **28a, b** in the solvolysis of ester sulfonates **27b, d** has not yet been elucidated.

The ^{1}H and ^{13}C NMR data for **23a** (Fig. 1), especially the H/H coupling constants between the three-membered rings, are of the magnitude known for "mixed" *C,N-cis*-tris-σ-homobenzene frameworks.[19] Distortions of the six-membered ring are revealed by the calculated H/H interplanar angles. Also noteworthy is the fragmentation pattern upon electron impact (EI, 70 eV: *m/z* 257 ($M^{\oplus}$ – 1, 0.8%), 154 ($M^{\oplus}$ – $Si(CH_3)_3$, – OCH_3, 100%), 128 ($M^{\oplus}$ – $Si(CH_3)_3$, – OCH_3, – CN, 14%)). Compound **23a** behaves differently from hydrocarbon **1** upon thermolysis: In 10^{-2} M

Scheme 1.



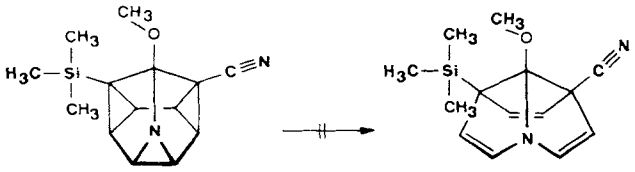


Fig. 1. ^{1}H and ^{13}C NMR shifts ($CDCl_3$), H,H coupling constants and calculated interplanar angles of **23a**.

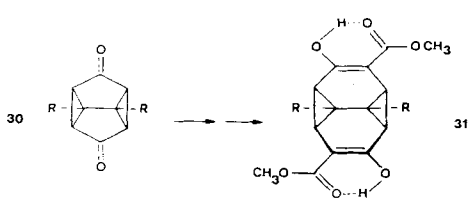
degassed $CDCl_3$ solution, **23a** does not undergo any change upon heating to 150 °C for several hours; ^{1}H NMR monitoring of the rapid decomposition occurring above 180 °C revealed polymer, but no azatriquinacene **29**. This consider-



ably higher kinetic stability of **23a** as compared with **1** (E_a = 32.3 ± 0.7 kcal mol^{-1} [3]) mirrors primarily the influence of the cyano group and the steric compression accompanying the [σ2 + σ2 + σ2] cycloreversion **23a** → **29**.

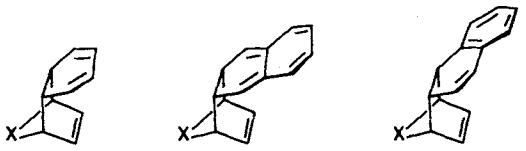
Diels–Alder Adducts on the *b* Side of Naphthalene: Rapid Cycloreversion of *o*-Quinodimethanes**

By *Wolfram Grimme,* Peter Höner, Heinz Theo Kämmerling, Robert Waldraff,* and *Jakob Wirz**



Cycloreversions are a fascinating type of reaction both mechanistically and preparatively, since their rates can be varied over 18 orders of magnitude by structural changes and since their first-order kinetics allow them to be carried out both in the gas phase and in glass matrices.

The cycloreversion of benzene–arene adducts is accompanied by a considerable increase in resonance energy. For adducts of type **1b, c,** *one* isolated or fused benzene ring is formed in each of the cleavage products. We have found that the free energies of activation $\Delta G^{\neq}$ for six of these adducts, derived from kinetic data, depend linearly[1] on the gain in resonance energy ΔE calculated according to the method of *Dewar* and *de Llano*.[2] The fastest cycloreversion in this series occurs for *o,p*-dibenzene **1b**, which forms two isolated benzene rings. Also conceivable, however, are Diels–Alder adducts of arenes that, upon cleavage, regain the *entire* resonance energy of a fused-ring aromatic system: for example,

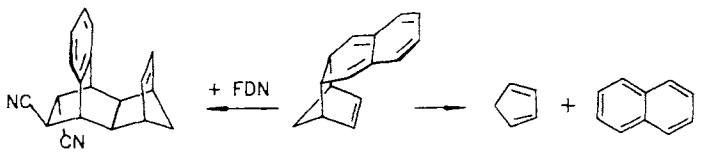
compounds of type **2**, the synthesis of which formally involves the *b* side of naphthalene as the dienophile. According to the linear dependence of ΔG^{+} on ΔE, cycloreversion of these adducts should proceed much faster than that of the isomeric adducts **3**, involving the *a* side of naphthalene, and even faster than that of the benzene adducts **1**.

1 **2** **3**



a: X = CH_2; **b**: X =  ; **c**: X =

To synthesize adducts **2**, we chose the benzobicyclo[2.2.0]hexene unit as precursor for their *o*-quinodimethane structural element. This strategy made tetracycle **6**, prepared via **4**[3] and **5**, the immediate precursor of adduct **2a** with cyclopentadiene (CpH). We obtained **6** by electrolytic bisdecarboxylation of the initially formed cycloadduct **5** followed by dehydrogenation with dichlorodicyanobenzoquinone (DDQ).

4 **5** **6**

The benzobicyclo[2.2.0]hexene unit in **6** opens at 80 °C, affording the naphthalene–CpH adduct **2a**, which, in a very rapid and quantitative subsequent reaction, undergoes cleavage to its components. In the presence of excess fumarodinitrile (FDN) in refluxing benzene 0.04 M, however, **2a** is trapped almost completely as Diels–Alder adduct **7**. When the concentration of FDN is decreased to 0.005 M, addition to the *o*-quinodimethane moiety of **2a** competes with retro-Diels–Alder reaction of **2a**, leading to formation of a 1:1 mixture of **7** and the FDN adduct with CpH.

7 **2a**

After a control experiment had shown that **6** could also be opened by photolysis at $\lambda = 254$ nm, we attempted to use flash photolysis to determine the rate of cycloreversion of **2a**. However, we found that the cycloreversion did not follow first-order kinetics in degassed hexane and, moreover, was influenced by the intensity of the light used ($\lambda = 400$ nm, $t_{1/2}$ on the order of minutes). The rate constants of cycloreversion were therefore determined indirectly by addition of FDN. For the kinetic measurements, a solution of **6** (0.001 M) and FDN (0.005 M) in hexane was exposed in a quartz photolysis cell to flashes of light generated by capacitor discharge. From the observed first-order rate constants ($k = k_2$[FDN] = 1.12 and 1.25 s^{-1} at 29.9 °C: 0.71, 0.61, and 0.69 s^{-1} at 20.1 °C; 0.47 and 0.40 at 11.8 °C), we calculated the Arrhenius parameters for the cycloaddition of FDN to **2a**: $E_a = (9.54 \pm 0.80)$ kcal mol^{-1} and $A = (1.74 \pm 1.02) \times 10^9$ M^{-1} s^{-1}. The rate constant of addition k was calculated to be (11 ± 5) s^{-1} for the above competition between the cycloreversion of **2a** and its addition to FDN. (80 °C, [FDN] = 0.005 M). That of cycloreversion is of the same magnitude. Table 1 contains important physical data for the new compounds.

Table 1. Selected physical data for compounds **2b**, **3a**, **4**, **6–9**, **13**, and **14**. ^{1}H NMR spectra recorded at 90 MHz (**7**, **14**) or 300 MHz (**13**) in $CDCl_3$ or CCl_4 (**3a**, **6**), TMS as standard.

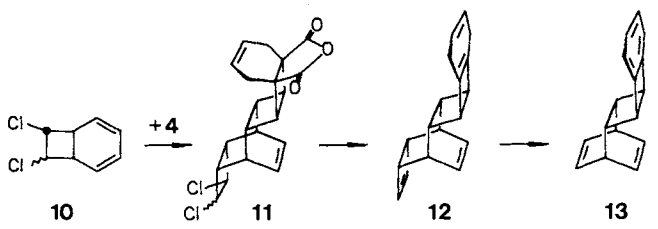
[a] EPA is a 5:5:1 mixture of Et_2O, $Me_2CHCH_2CH_3$, and EtOH.



The synthesis of the CpH adduct **3a**, isomeric to **2a**, started from the CpH adduct of indenone, **8**,[4] which was allowed to react with dibromomethane and base to give the ring-expanded ketone **9**.[5] After reduction with sodium borohydride and esterification with methanesulfonyl chloride, reaction with alumina (activity I) in ether at room temperature gave **3a**. The cycloreversion of **3a** in *n*-decane was monitored continuously between 80 and 92 °C in a thermostated quartz cell at $\lambda = 311$ nm; the reaction is first order with the kinetic parameters $E_a = (25.77 \pm 0.72)$ kcal mol^{-1} and $A = (1.03 \pm 1.04) \times 10^{12}$ s^{-1}. The rate constant k at 80 °C is 1.0×10^{-4} s^{-1}; thus, **2a** undergoes cycloreversion 10^5 times faster than the isomer **3a** and 2×10^3 times faster than the benzene adduct **1a**[2]!

To obtain Diels–Alder adducts with even higher rates of cycloreversion, we synthesized the adduct of benzene with the *b* side of naphthalene in an analogous way; the precursor was the tetracycle **13**. By cycloaddition of anhydride **4** to a stereoisomeric mixture of 8,9-dichlorobicyclo[4.2.0]octadiene **10**, we obtained adducts **11**; two further double bonds were introduced by electrolytic bisdecarboxylation and dechlorination with sodium in ammonia. Treatment of the resulting hexacyclic compound **12** with DDQ led to aromatization. Finally, photolysis of the *o*-chloranil adduct removed the cyclobutene ring to give **13**.

The benzobicyclo[2.2.0]hexene moiety in **13** also opens at 80 °C, affording the naphthalene–benzene adduct **2b**, which immediately undergoes cycloreversion to its components. Compound **2b** could no longer be trapped with fumarodinitrile, but only with the more reactive *N*-phenylmaleimide (NPMA). In the presence of an excess of this dienophile in benzene (1.18 M), **2b** afforded, after 48 h at 80 °C, cycloadduct **14** in addition to naphthalene in a ratio of 1:4.4. The

rate constant for the trapping reaction can be estimated under two assumptions: (1) The *o*-quinodimethane units in **2a** and **2b** add FDN at the same rate; (2) At 80 °C, NPMA and FDN differ in reactivity toward the *o*-quinodimethane unit by a factor of 22, the value determined by *Sauer* et al.[6] for CpH. Under these two assumptions, the rate constant for the trapping reaction giving **14** is $5 \times 10^4\ s^{-1}$ and that for the cycloreversion $2 \times 10^5\ s^{-1}$.

The benzobicyclo[2.2.0]hexene moiety in **13** can also be opened by photolysis at $\lambda = 254$ nm. At room temperature, only naphthalene and benzene are obtained. At 77 K in an EPA glass, however, **2b** is thermally stable and can be identified by UV spectroscopy.[7] Since **2b** undergoes further cleavage photochemically, its concentration remains small; the photocleavage is completed by irradiation at $\lambda =$ 436 nm. Laser flash photolysis (248 nm) of **13** in air-saturated hexane solution (0.0013 M, 24 °C) allows the cycloreversion of the **2b** formed to be followed by UV spectroscopy. Analysis of the transient recorded at 430 nm gives a first-order rate constant k of $(6 \pm 0.5) \times 10^3\ s^{-1}$. This value is in agreement with that found by competition experiments at 80 °C; the free energy of activation for cycloreversion of **2b** obtained from both values is $\Delta G^{\neq} = 12.2$ kcal mol^{-1}. This value, which makes **2b** the least stable alicyclic Diels–Alder adduct, and the calculated gain in resonance energy, $\Delta E = 50.5$ kcal mol^{-1}, agree with the linear relation established earlier.

The free energies of activation $\Delta G^{\neq}$ for the [2 + 4] cycloreversions of compounds **1–3** are listed in Table 2. As observed

Table 2. Free energies of activation, $\Delta G^{\neq}$, and calculated gain in resonance energy, ΔE [2], for the [4 + 2] cycloreversion of arene adducts.

	2b	**1b**	**1c**	**2a**	**1a**	**3a**
$\Delta G^{\neq}$ [a]	12.2	15.7	20.8	19.1	24.4 [9]	27.1
ΔE [b]	50.5	40.0	30.5	30.5	20.0	10.5

a) At 80 °C, in kcal mol^{-1}. b) In kcal mol^{-1}.

for the arene–arene adducts, a linear relation between the free energy of activation and the gain in resonance energy is found again for the arene–CpH adducts **1a**, **2a**, and **3a**, in agreement with the hypothesis of a synchronous process.

Tetraphosphacyclobutadiene as Complex Ligand**

By *Otto J. Scherer,* Jürgen Vondung,* and *Gotthelf Wolmershäuser*

Of the *cyclo*-P_x compounds[1] isoelectronic to the carbocyclic $(CH)_x$ π systems, x = 3–6, *cyclo*-P_4 has not yet been reported. Structures **C** and **D** may be postulated for the phosphorus analogues of cyclobutadiene **A**[2] and its dianion **B**.[3]

C_4H_4 **A** $C_4H_4^{2\ominus}$ **B** P_4 **C** $P_4^{2\ominus}$ **D**

The P_x complexes **2–4** have now been prepared photochemically under very mild conditions starting from $[Cp^*Nb(CO)_4]$ **1** and white phosphorus.

$$[Cp^*Nb(CO)_4] \xrightarrow[n\text{-}C_6H_{14},\ ca.\ 20\,^\circ C]{P_4,\ h\nu} [Cp^*(CO)_2Nb(\eta^4\text{-}P_4)] + [\{Cp^*(CO)Nb\}_2(P_4)] + [\{Cp^*Nb\}_2(P_6)]$$

1 **2** **3** **4a**

$Cp^* = \eta^5\text{-}C_5Me_5$

Complex **2** forms yellow crystals, **3** pink microcrystals, and **4a** dark red needles, which are readily soluble in dichloromethane, moderately soluble in benzene, and sparingly soluble in pentane (in each case, **3** is less soluble than **2** and **4a**). All of the compounds can be handled for a short time in the air; **2** and **3** are appreciably more air sensitive in solution than **4**.

The $^{31}P\{^1H\}$ NMR spectrum of **2**[4] at room temperature displays a broad singlet, which, at 223 K, splits into the well-resolved signals of an AMX_2 spin system.[4] This finding reveals hindered rotation of the *cyclo*-P_4 ligand. The $^{31}P\{^1H\}$ NMR, ^1H NMR, and IR spectra as well as the mass spectrum of **3**[4] indicate the presence of *trans*-$[\{Cp^*(CO)Nb(\mu,\eta^2\text{-}P_2)\}_2]$, which formally requires a Nb–Nb double bond to attain an electron count of 18 valence electrons per Nb atom.

The crystal structure analysis of **2**[5a] (Fig. 1) shows that the molecule exhibits nearly C_s symmetry. The four P atoms

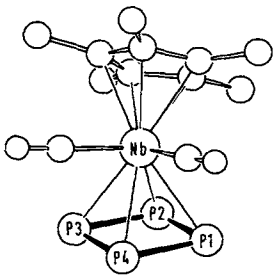

Fig. 1. Molecular structure of **2**. Selected distances [Å] and angles [°]: P1-Nb 2.639(1), P2-Nb 2.607(1), P3-Nb 2.631(1), P4-Nb 2.634(1), P1-P2 2.136(2), P2-P3 2.141(2), P3-P4 2.181(2), P4-P1 2.178(2), Nb-Cp*(center) 2.084, Nb-P_4(center) 2.139; P1-P2-P3 92.6(1), P2-P3-P4 88.4(1), P3-P4-P1 90.4(1), P4-P1-P2 88.6(1), Cp*(center)-Nb-P_4(center) 142.0.

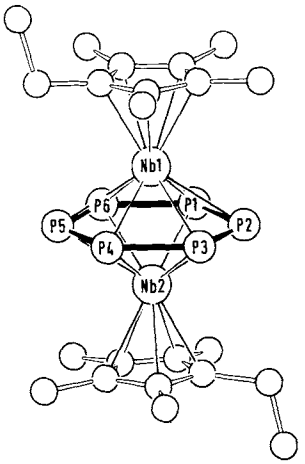
are coplanar and form a slightly distorted (kite-shaped) square (P3-P4 = 2.181(2), P4-P1 = 2.178(2), P1-P2 = 2.136(2), P2-P3 = 2.141(2) Å); the P2–Nb bond (2.607(1) Å) is slightly shorter than the other three P–Nb bonds (average 2.635 Å).

These findings can be explained in terms of an allyl-like, distorted *cyclo*-$P_4^{2\ominus}$ ligand **D** (d^2-Nb) or a *cyclo*-P_4 ligand **C** (d^4-Nb), whose slight distortion is possibly due to the different ligands on the Nb atom. Compared with **2**, complex **5**[6] displays a more pronounced lack of symmetry in the metal–

$[(Me_3P)_2ClRh(P_2C_2tBu_2)]$ **5**

heterocyclobutadiene distances, at least for the C atoms. The flattening of the *cyclo*-$P_4^{2\ominus}$ ligand in **2** would be in agreement with the geometry calculated for $Li^{\oplus}C_4H_4^{2\ominus}$.[3] The Wade–Mingos electron counting rules[7] give seven electron pairs for the slightly distorted square pyramid P_4Nb of **2**, in accordance with a *nido* structure.

A crystal of **4a** suitable for X-ray structure analysis has not yet been obtained; however, X-ray data are available for the triple-decker complex $[\{Cp'Nb\}_2(P_6)]$ **4b** (dark red crystals, Cp′ = $\eta^5\text{-}C_5Me_4Et$; for NMR data, see Ref. [4]), the "decks" of which are planar and mutually parallel.[8] A noteworthy structural feature of the 26-valence-electron complex **4b**[5b] (Fig. 2) is the *cyclo*-P_6 middle deck, which can be



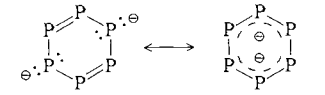


Fig. 2. Molecular structure of **4b**. Selected distances [Å] and angles [°]: Nb1-Nb2 2.791(2), Nb1-P1 2.581(5), Nb1-P2 2.573(6), Nb1-P3 2.619(5), Nb1-P4 2.581(5), Nb1-P5 2.574(5), Nb1-P6 2.630(5), Nb2-P1 2.585(5), Nb2-P2 2.567(6), Nb2-P3 2.620(5), Nb2-P4 2.579(5), Nb2-P5 2.578(6), Nb2-P6 2.628(5), P1-P2 2.241(10), P2-P3 2.181(9), P3-P4 2.149(9), P4-P5 2.243(9), P5-P6 2.157(9), P6-P1 2.140(9), Nb1(2)-Cp′(center) 2.080(2.072), Nb1(2)-P_6-(center) 1.395(1.396); P1-P2-P3 120.6(3), P2-P3-P4 118.3(3), P3-P4-P5 120.5(3), P4-P5-P6 121.0(3), P5-P6-P1 118.8(3), P6-P1-P2 120.7(3), Nb1-P-Nb2 64.1(1)–65.8(1) (average 65.1), Cp′(center)-Nb1(2)-Nb2(1) 179.4 (178.5), P_6(center)-Nb1(2)-Cp′(center) 179.4(178.1), Nb1-P_6(center)-Nb2 179.1. The figure shows one of the two rotationally disordered conformers.

regarded formally as consisting of two allyl-like $P_3^{\ominus}$ units joined to form the *cyclo*-$P_6^{2\ominus}$ ligand. There are two long (P1-P2 = 2.241(10), P4-P5 = 2.243(9) Å) and four short

E  **F**

(2.140(9)–2.181(9), average 2.157 Å) P–P distances. In agreement with this, the Nb1(2)–P3 distances (2.619(5) and 2.620(5) Å) and the Nb1(2)–P6 distances (2.630(5) and 2.628(5) Å) are significantly longer than the remaining eight Nb–P distances (2.567(6)–2.585(5) Å, average 2.577 Å). Thus, **4b** may be formulated as $[Cp'Nb(\mu,\eta^3,\eta^3\text{-}P_6)NbCp']$. Such a distortion has also been discussed for the 26-valence-electron triple-decker complex $[\{CpV\}_2(C_6H_6)]$ containing C_6H_6 as a 2 × 3-electron ligand.[9] The differences in the P–P bonds (two short, four long) found for **6**[10] may be inter-

$[Cp'V(\mu,\eta^6\text{-}P_6)VCp']$ **6**

preted in terms of a preference for the resonance structure **E**. LCAO-MO calculations[11] for the series *cyclo*-$P_6^{n\ominus}$ (n = 0, 2, 4, 6) indicate that *cyclo*-$P_6^{2\ominus}$ (idealized symmetry 6/mmm) is most stable.

The synthesis of **2** and **4** establishes a further bridge between the molecular and solid-state chemistry of polyphosphides.[12]

Experimental Procedure

A solution of **1** (400 mg, 1.18 mmol) [13] and P_4 (150 mg, 1.21 mmol) in 250 mL of hexane was irradiated at room temperature for 7 min with UV light (150-W high-pressure mercury lamp, Quarzlampen GmbH, Hanau, FRG). After removal of the solvent under oil-pump vacuum, the residue was chromatographed at ca. −50 °C on silanized silica gel (Merck, particle size 63–200 μm, column 100 × 3 cm). Unreacted **1** (50 mg, 12%) was eluted with petroleum ether as a red-orange fraction. The following yellow fraction contained **2** along with small amounts of **4a** (crude yield 69 mg, containing ca. 5% **4a**); the products were separated by recrystallization (twice) from CH_2Cl_2/hexane (1:1). Yields: 12 mg (3% based on reacted **1**) of **2** as yellow crystals and 1 mg (0.15%) of **4a** as dark red needles [8]. Toluene as eluant afforded a pink fraction, which, at the end, overlapped with a green fraction. A second chromatographic separation (basic Al_2O_3, activity II, column 25 × 3 cm, watercooled) with petroleum ether/toluene (10:1) gave a pink fraction (crude yield: 25 mg, 4%). Recrystallization from CH_2Cl_2/hexane (2:1) afforded pink **3**. Toluene eluted traces of a green fraction, the exact composition of which is still unknown. Partial decomposition with formation of a brown residue occurred during both chromatographic separations.

Aurophilicity as Concerted Effect: Relativistic MO Calculations on Carbon-Centered Gold Clusters**

By *Notker Rösch,** *Andreas Görling, Donald E. Ellis,* and *Hubert Schmidbaur**

A strong attractive interaction has been observed between gold atoms with d^{10} configuration and + 1 oxidation state in numerous polynuclear gold compounds.[1–6] It is manifested in molecular conformations with relatively close Au · · · Au contacts (2.9–3.0 Å)[1,2] or discrete Au–Au bonds,[3,4] whose strength has been estimated from spectroscopic data to be 6–8 kcal mol^{-1}.[3] Noteworthy is the tendency of polyaurated organogold compounds to bond further gold(I) units, $[LAu]^{\oplus}$ (L = R_3P), to a carbon center.[1,2] The term aurophilicity has been coined for this phenomenon.[5] Particularly striking examples of this interaction are provided by the recently synthesized carbon-centered gold-cluster cations $[\{(C_6H_5)_3PAu\}_nC]^{(n-4)\oplus}$ (n = 5,6).[5,6] The X-ray structure analyses of these compounds revealed an only slightly distorted highly symmetric arrangement of the gold atoms (trigonal-bipyramidal for n = 5,[6] octahedral for n = 6[5]) around a central carbon atom. Accordingly, these clusters offered an ideal starting point for a more detailed theoretical study of aurophilic interactions,[7] the results of which are presented here. Although this investigation focused on the analysis of the electronic structure of the carbon-centered gold cluster $[\{(C_6H_5)_3PAu\}_6C]^{2\oplus}$, our goal was to arrive at general conclusions on the bonding in polyauriomethanes.

The MO structure of the quasi-octahedral cluster is best derived through fragment analysis, proceeding from the uncomplexed cluster $[Au_6]^{2\oplus}$ via the carbon-centered cluster $[Au_6C]^{2\oplus}$ to the complete cluster $[(LAu)_6C]^{2\oplus}$. Any discussion of the electronic structure of a "centered" metal cluster has to take into consideration the interplay of tangential bonds within the metal polyhedron and of radial bonds to both the central atom and the outer ligands,[7,8] since this influences the hybridization of the metal atoms. Furthermore, it is important to bear in mind that the 6s orbitals of gold are lowered in energy owing to the relativistic increase in mass;[9,10] sp hybridization with 6p orbitals is thereby made more difficult, whereas sd hybridization with 5d orbitals is facilitated. In the following MO analysis, all three features of the bonding in gold clusters are treated together theoretically for the first time. Starting from the reference configuration d^{10}, for which a (weakly) repulsive interaction between gold(I) atom pairs is assumed,[8,11] we used the *extent of disruption of the closed 5d valence shells* as a criterion for the strength of a possible aurophilic interaction. This approach considers only one, though important, aspect of the Au–Au interaction; the bonding picture so obtained must therefore be augmented by an analysis of orbital interactions[7] (see Fig. 1 and the accompanying text).

The calculations for the systems $[Au_6]^{2\oplus}$, $[Au_6C]^{2\oplus}$, and $[(LAu)_6C]^{2\oplus}$, as well as for $[Au_5]^{\oplus}$ and $[Au_5C]^{\oplus}$, were performed using the discrete variational (DV) Xα method,[12] a

self-consistent LCAO–MO method within the framework of density functional theory;[13] both nonrelativistic and relativistic versions of the computer program are available, the latter based on four-component Dirac spinors. Symmetry-adapted molecular orbitals were constructed from atomic orbitals, numerically determined for the atomic configurations present in the cluster by a self-consistent Mulliken population analysis.[12] The DV Xα method takes into consideration all electrons, but only the valence electrons were included in the self-consistent process. To simplify the calculations still further, we selected a model with SH_2 instead of Ph_3P ligands, so that the assumed symmetry of the resulting cluster was appreciably higher (point group T_h). However, because of its nonbonding orbital perpendicular to the molecular plane and the associated interaction, SH_2 is not a fully adequate model for Ph_3P.[14] An idealized octahedral structure was assumed in these calculations (d(Au-Au) = 3.005,[5] d(Au-C) = 2.125, d(Au-S) = 2.270, d(S-H) = 1.345 Å, $\sphericalangle$ (H-S-H) = 90°).

We found that the use of a relativistic MO method is essential for a *complete* theoretical description of the aurophilic interactions. This is shown in Table 2 by the Mulliken populations of the gold and carbon valence orbitals and the resulting atomic charges. In *all* systems studied, the relativistic treatment yields the expected increase (by about 0.2) in the Au 6s population, the Au 5d population decreasing by nearly the same amount. Compared with the inert d^{10} configuration, the deficit in the Au 5d population of the Au_6 cluster calculated relativistically is practically twice as large as the deficit calculated nonrelativistically. The tendency toward Au–Au interaction should correspondingly increase, in accordance with the criterion given above ("disruption of the closed 5d valence shell"). (Even nonrelativistic calculations on the cluster $[Au_6]^{\oplus}$, with a 5d population of 9.80, revealed a deficit of 0.20, so that the Au 5d orbitals can make a definite, though small, contribution to the Au–Au bond.) The radial bonds of the gold cluster (to the central carbon atom as well as to the outer ligands) lead to a further reduction in the Au 5d population, thereby improving the possibility of an aurophilic interaction. The central carbon atom is of crucial importance for the stability of the complete cluster (see below), though its direct contribution to further disruption of the Au 5d shell of (relativistically described) gold(I) units, $[LAu]^{\oplus}$, is likely to be small.

Table 1. Mulliken valence orbital populations and resulting atomic charges Q [|e|] from nonrelativistic (nr) and relativistic (r) DV Xα MO calculations for the clusters $[Au_6]^{2\oplus}$, $[Au_6C]^{2\oplus}$, and $[(LAu)_6C]^{2\oplus}$ (L = SH_2) as well as for the clusters $[Au_5]^{\oplus}$ and $[Au_5C]^{\oplus}$ [a].

	r	0.85	0.18	9.52	+0.45	1.41	3.85	−1.26

[a] Because of the largely systematic agreement between the results obtained for the pentanuclear and the corresponding hexanuclear clusters, we did not carry out the relatively involved calculation on the cluster $[(LAu)_5C]^{\oplus}$. [b] Q(L) = −0.04 (nr); +0.04(r). [c] Values determined for the axial and equatorial Au atoms.

Comparison of the results presented above with those obtained for the systems $[Au_5]^{\oplus}$ and $[Au_5C]^{\oplus}$ shows that it should be possible to extend this analysis to other gold clusters. There is clear agreement of the charge distribution with those of the corresponding octahedral systems, especially for the population of the Au 5d orbitals and for the changes found upon relativistic treatment. Noteworthy, however, is the higher Au 6s population for the Au_5 clusters and the fact that the charge on the central carbon atom is reduced in nearly direct proportion to the number of ligands.

We have thus shown that the use of a relativistic MO method yields the correct contributions of the Au 6s orbitals to the disruption of the d^{10} configuration. In the following discussion, we present a qualitative orbital interaction analysis of the systems $[Au_6]^{2\oplus}$, $[Au_6C]^{2\oplus}$, and $[(LAu)_6C]^{2\oplus}$ based on nonrelativistic calculations, since they offer the advantage of symmetry classification according to the normal point groups. This analysis obviates the interpretation of the much more complex relativistic orbitals and thus the necessity of using double groups with their lower number of irreducible representations. A further complication encountered in relativistic calculations is caused by appreciable spin–orbit interaction in gold atoms, which can be neglected in a qualitative discussion of the bonding. In the following, only orbitals of symmetry a_{1g} and t_{1u} (point group O_h) are analyzed, since the valence orbitals of the central carbon atom only encompass these irreducible representations (Fig. 1). A population analysis of the corresponding orbitals of the cluster $[(LAu)_6C]^{2\oplus}$ is given in Table 2.

In previous discussions[5, 6, 8] of the electronic structure of Au_6 clusters, the closed d^{10} shells were neglected and only

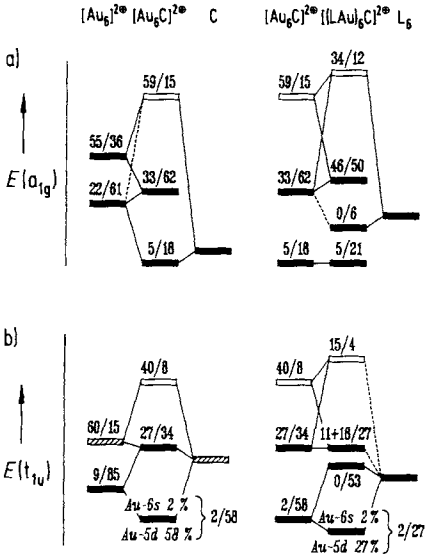

Fig. 1. Schematic interaction diagram of orbitals with the irreducible representations a_{1g} (a) and t_{1u} (b) – or 1_g and t_u in T_h – for the systems $[Au_6]^{2\oplus}$-C and $[Au_6C]^{2\oplus}$-L_6, derived by self-consistent DV Xα calculations. For clarity, only orbitals containing dominant contributions from the carbon atom or from the ligands L (=SH_2) are represented (the latter limited to the σ interaction with the Au_6 cluster). Furthermore, the diagram focuses on the 6s–5d hybridization of the gold atoms: the numbers on the energy levels give the gold 6s and gold 5d populations [%] (in this order). The populations for the Au-6p, C, and L orbitals are omitted (they are listed in Table 2). Unoccupied orbitals are drawn as empty bars; the two hatched bars represent energy levels partially filled with two electrons each. In the bar labeled 11 + 18/27, the orbitals $3't_{1u}$ and $3t_{1u}$ are summarized from Table 2; the 5d orbital population in the $3't_{1u}$ orbital is not given since these orbitals are largely of π character with respect to Au–L bonding. For the selection of the orbitals of symmetry type t_u, see text [7].

Table 2. Energies and Mulliken populations [%] for those molecular orbitals of the cluster $[(LAu)_6C]^{2\oplus}$ ($L = SH_2$) that make essential contributions to the radial bonds (nonrelativistic calculations). See also Figure 1.

Energy [eV]	Symmetry [a]	Au 6s	Au 6p	Au 5d	C 2s	C 2p	L
−19.36	$2a_g$ ($1a_{1g}$)	5	0	21	70	–	4
−16.44	$3t_u$ ($1t_{1u}$)	2	1	27	–	7	63
−15.62	$3a_g$ ($2a_{1g}$)	0	3	6	9	–	82
−14.29	$4t_u$ ($2t_{1u}$)	0	−1	53	–	27	21
−12.20	$4a_g$ ($3a_{1g}$)	46	0	50	0	–	4
−12.07	$7t_u$ ($3't_{1u}$) [b]	11	1	72	–	2	14
−9.23 [c]	$9t_u$ ($3t_{1u}$) [b]	18	12	27	–	28	15
−4.77	$6a_g$ ($4a_{1g}$)	34	0	12	12	–	42
−3.75	$11t_u$ ($4t_{1u}$)	15	4	4	–	16	61

[a] Numbering based on all valence orbitals of the cluster, irreducible representations of the point group T_h; the corresponding representations for idealized octahedral symmetry are given in parentheses with only those orbitals included that contribute to Au–C and Au–L bonding. [b] Interaction distributed over two orbitals. [c] HOMO.

the six (6sp) hybrid orbitals considered. The direct interaction between Au 5d orbitals is relatively weak, but cannot be neglected. The following values for the Au 5d overlap integrals S can be derived from the DV Xα orbitals:[7] $S(\sigma) = 0.039$, $S(\pi) = 0.026$, $S(\delta) = 0.002$. These values are about twice as large as those assumed in earlier calculations.[8] In the octahedron, the σ(sp) hybrid orbitals span orbitals of symmetry types a_{1g}, t_{1u}, and e_g (in order of increasing energy). The highest occupied orbital (HOMO) of $[Au_6]^{2\oplus}$, the $2t_{1u}$ σ(sp) level, contains two electrons. However, the $2a_{1g}$ σ(sp) orbital shows a significant Au 5d population (36%, cf. Fig. 1) and lies energetically within the "band" of the 5d level. Correspondingly, the $1a_{1g}$ level, formally ascribed to the Au 5d cluster orbitals, displays 39% sp character. In the relativistic calculation, this energetically *lowest-lying* valence orbital of the cluster ($1a_{1g}$) has to be identified as the Au σ(sp) level (6s, 57%; 6p, 21%; 5d, 22%), whereas the $2a_{1g}$ orbital is formally ascribed to the Au 5d cluster orbitals.[10] The interaction with the central carbon atom leads to the expected charge transfer Au → C. Formally, the $2a_{1g}$ and $2t_{1u}$ levels of the cluster $[Au_6]^{2\oplus}$ are emptied in favor of the $2t_{1u}$ HOMO of the carbon-centered cluster $[Au_6C]^{2\oplus}$. However, the HOMO is localized to a considerable extent on the gold atoms (6s, 27%; 5d, 34%). In the complete cluster, $[(LAu)_6C]^{2\oplus}$, the character of the HOMO changes only slightly. Nonetheless, since the reduction of the Au_6–ligand interaction to a minimum number of involved energy levels for the symmetry type t_u (point group T_h) is incomplete, the choice of the orbitals is not unambiguous[7] (cf. Fig. 1 and Table 2).

For the orbitals formally ascribed to the Au 5d manifold, the radial (essentially σ-like) interactions of the Au_6 cluster both with the central carbon atom and with the outer six ligands L lead to changes that can be interpreted in terms of a classical perturbational approach[15] (cf. Fig. 1). Examples are the orbitals $1a_{1g}$ of $[Au_6]^{2\oplus}$ and $2a_{1g}$ of $[Au_6C]^{2\oplus}$; although they are largely nonbonding with respect to the Au–Au interaction, energetically higher-lying orbitals of the respective starting cluster can "mix" into them through the interaction partner C or L.[11] Since these higher-lying orbitals display a stronger Au 6s character and a correspondingly weaker Au 5d population, this mixing disrupts the "closed" Au 5d shell and establishes the orbital-dependent prerequisite for aurophilic interaction. The effect of the outer ligands exceeds that of the central carbon atom, as revealed by the charge balance (Table 1) and the character of the individual orbitals (Fig. 1 and Table 2).

Synthesis and Pharmacological Properties of a Novel Cardioactive Steroid**

By *Ulrich Werner, Uwe Möller, Petra Wagner, Peter Welzel,* Christa Zylka, Siegfried Mechmann, Hermann Pusch,* and *Helfried Günther Glitsch**

The $Na^{\oplus}$ pump of animal cells generates and maintains the $Na^{\oplus}$ and $K^{\oplus}$ gradients across the cell membrane. These ion gradients are essential for the electrical excitability of the plasma membrane. In addition, the $Na^{\oplus}$ gradient serves as an energy source for the transmembrane transport of specific substances: for example, sugar and amino-acid import and $Ca^{2\oplus}$ transport out of the cell.[1]

Cardioactive glycosides inhibit the $Na^{\oplus}$ pump, thereby raising the intracellular $Na^{\oplus}$ concentration. The resulting decrease in the $Na^{\oplus}$ gradient across the sarcolemma reduces the energy available for transport of $Ca^{2\oplus}$ out of the cell by

$Na^{\oplus}/Ca^{2\oplus}$ exchange. This ultimately leads to the (medicinally used) positive inotropic effect of these substances.[2]

The molecular basis of the $Na^{\oplus}$ pump is a $Mg^{2\oplus}$-dependent $Na^{\oplus}$-and $K^{\oplus}$-activated ATPase in the plasma membrane. This ATPase consists of a large catalytic α subunit and a smaller β subunit whose function is still unknown. The complete amino-acid sequence of the α subunit was recently determined.[1] The protein chain presumably spans the plasma membrane eight times. At least four of the extracellular regions are assumed to be involved in binding the steroid moiety of the cardiac glycosides; however, the precise site of binding and the mode(s) of binding have not yet been determined.[1] To localize the lactone binding site of the ATPase by affinity labeling,[3] we have attempted to develop a general route to cardioactive steroids containing a (latently) reactive group in the lactone ring. The target compounds were the previously unknown bufenolides of type **11**, which differ from the classical bufadienolides—for example, bufalin **12**—in the absence of a double bond between C-22 and C-23.

The unsaturated aldehyde **2**,[4] accessible in five steps from deoxycholic acid **1**, underwent $Eu(fod)_3$-catalyzed[6] reaction with *Seebach*'s ketene acetal **3a**[5] to give the [4 + 2] cycloadduct **7a** in 96% yield. Similarly, **7b** was obtained from **2** and **3b**.[5] According to ^1H NMR analysis, **7b** was a 3:1 mixture of two diastereomers. $Cu^{2\oplus}$-catalyzed hydrolysis transformed **7a** and **7b** into the enol lactones **10a**[7] and **10b**,[8] respectively. Product **10b** was also a 3:1 diastereomeric mixture. NMR analysis[9] revealed that in the main component the 23-methyl group occupies an axial position; however, the configuration at C-23 could not be determined, even by means of circular dichroism ($\lambda_{max}(\Delta\varepsilon) = 286$ (+ 0.88), 234 (+ 5.6), 202 nm (− 0.5).

To introduce the 14β-OH group, we used a procedure recently developed by us.[10] The method consists of four steps: (1) photochemical rearrangement of a 12-oxo-14α-steroid to an unsaturated secoaldehyde (here: **7** → **4**); (2) reduction of the secoaldehyde (**4** → **5**); (3) mesylation (**5** → **6**); (4) ring closure under solvolysis conditions (**6** → **8**). The orthoester group in **7** has the advantage that there is no interfering overlap between its UV absorptions[11] and the n → π* band of the keto group at 300 nm.[12] On the other hand, the aldehyde group in secoaldehydes such as **4** also absorbs at 300 nm and undergoes an H-transfer reaction in the excited state.[13] The photochemical rearrangement **7** → **4** was therefore carried out in the presence of a selective reducing agent that immediately reduces the newly formed aldehyde **4** to **5** without attacking the keto group in **7**. Lithium tri-*tert*-butoxyhydridoaluminate was well-suited for this purpose, and **5** was obtained in 59% yield (based on **7**). Mesylation (**5** → **6**) and subsequent solvolysis then led to **8** (49%). Finally, the protecting groups were removed: first, the 3-OH group was deprotected (**8** → **9**),[14] then the enol lactone (**9** → **11a**). Cleavage of the thioacetal function in **9** could not be accomplished by a number of commonly used procedures;[15] only the conditions given in Scheme 1 led to a good yield of **11a** (93%). Careful NMR analysis showed that the side chain of **11a** (in $CDCl_3$ solution) adopts a conformation in which the torsional angle (17-H)C-17–C-20(C-21) is ca. 30° (NOE effects between CH_3-18 ⤳ 21-H and 17-H ⤳ 21-H.

The positive inotropic effect of 22,23-dihydrobufalin **11a** was investigated with guinea-pig papillary muscles and the inhibition of the $Na^{\oplus}$ pump with Purkinje fibers of sheep heart by electrophysiological methods. Some details of the contraction measurements are found in the caption to Figure 1. The example in Figure 1 shows that **11a** has a markedly positive inotropic effect on guinea-pig heart. The effect is

dose dependent and reversible. After a control period, the muscle is bathed in a solution containing 10^{-6} mol L^{-1} of **11a**. The contractile force increases and, after a few minutes, reaches a new steady state. When **11a** is washed out, the contractile force returns to the control value. A smaller concentration of **11a** effects a smaller positive inotropic effect, which is also reversible (see Fig. 1). Figure 2 shows the dose–response curve for 22,23-dihydrobufalin **11a**, as well as for **12**, which, for comparison, was studied on the same muscle. The ordinate gives the contractile force of the muscle relative

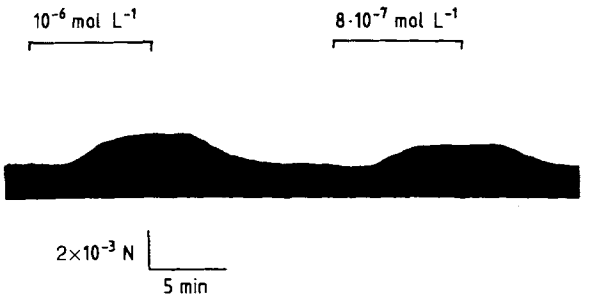

Fig. 1. Positive inotropic effect of **11a** (two concentrations) on a guinea-pig papillary muscle. The bracketed regions represent times during which the muscle was bathed in solution containing **11a** (bathing fluid, Tyrode solution containing 2.7×10^{-3} mol L^{-1} KCl and 1.8×10^{-3} mol L^{-1} $CaCl_2$; pH 7.4, 35 °C). The contractions were induced by square-wave electrical pulses (stimulus potential, twice the threshold potential; pulse duration 4 ms; frequency, 1.2 Hz) and recorded with a mechano-electrical transducer (Endevco, model 8107-20) on a recorder (Schwarzer Physiopolygraph Varioscript; units in Newton).

to that during the preceding control period; the abscissa gives the logarithmic concentrations of **11a** and **12**. The linear parts of the curves reveal that **11a** is less active than **12** by a factor of 10. Spontaneous activity of **12** (toxic effect) is observed at a concentration of 5×10^{-6} mol L^{-1}, whereas **11a** shows no toxic effect at a concentration of 4×10^{-6} mol L^{-1}. Increasing the extracellular $K^{\oplus}$ concentration leads to a rightward shift of the two dose–response curves (not shown). Similar results were obtained with two other papillary muscles.

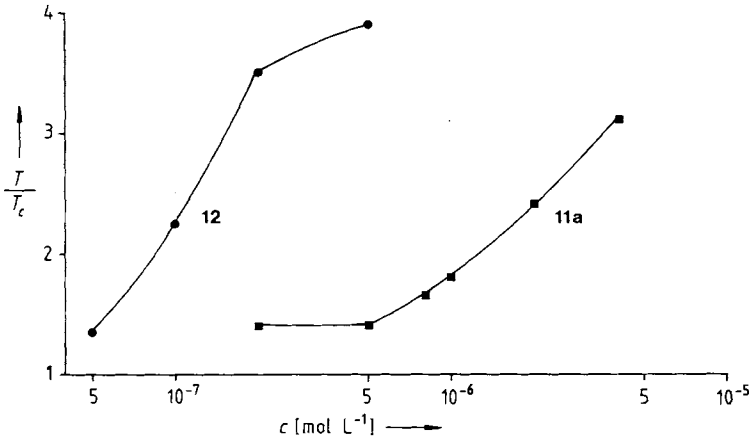

Fig. 2. Dose–response curves of the positive inotropic effect of steroids **11a** (■) and **12** (●) on a guinea-pig papillary muscle. Ordinate: contractile force (T) relative to the contractile force of muscle during the preceding control period (T_c). Abscissa: concentrations (logarithmic). Note that the numbers 5 on the abscissa stand for 5×10^{-8}, 5×10^{-7}, and 5×10^{-6}.

Compound **11a** also inhibits the $Na^{\oplus}$ pump current of sheep Purkinje fibers (measured as described previously[16]) in a dose-dependent fashion: At **11a** concentrations of 5×10^{-8}, 1×10^{-7}, and 5×10^{-7} mol L^{-1}, the transient outward (pump) current decreased by 27.5, 38.6, and 62%, respectively. Apparently, **11a** is active on sheep Purkinje fibers at lower concentrations than those required for guinea-pig papillary muscle, in agreement with similar results obtained for three cardiac glycosides.[17]

The results described here show that 22,23-dihydrobufalin **11a** exhibits the characteristic pharmacological properties of cardioactive steroids: it displays positive inotropic activity and inhibits active $Na^{\oplus}/K^{\oplus}$ transport. We plan to extend these investigations to compounds of type **11** whose R group is suitable for affinity labeling of the ATPase.

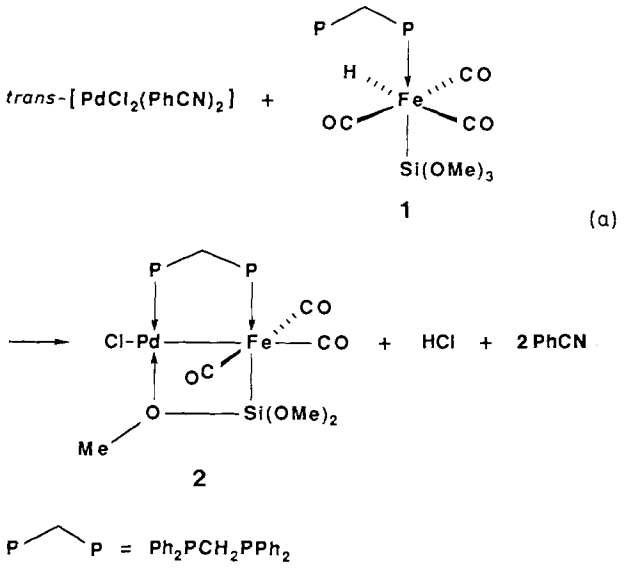
Complexes with an η^2-μ_2-SiO Bridge. Structure of the Bimetallic Complex $[Fe(CO)_3\{\mu\text{-}Si(OMe)_2\overline{OMe}\}(\mu\text{-dppm})PdCl]$-(*Fe-Pd*)**

By *Pierre Braunstein,* Michael Knorr, Antonio Tiripicchio,* and *Marisa Tiripicchio Camellini*



Interest in the synthesis and study of molecular clusters having iron–palladium bonds largely stems from their still relatively small number[1] and their successful use as precursors of SiO_2-supported heterogeneous catalysts, in particular

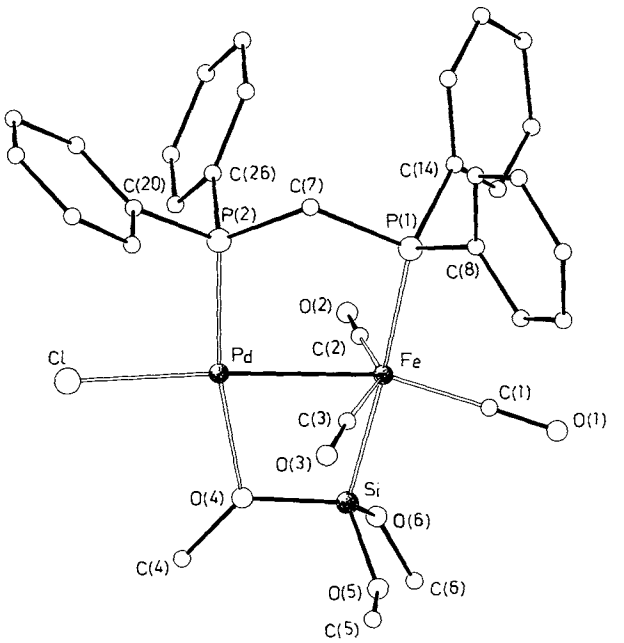
for highly selective reductive carbonylation reactions.[2] Moreover, there is a renewed interest in the chemistry of silicon-containing transition-metal compounds.[3] In attempts to combine these two facets, we have sought to prepare Pd–Fe–Si systems and report here the first complexes in which a siloxy ligand acts as an η^2-μ_2-SiO bridge between two metal centers, thus forming novel $\overrightarrow{MM'SiO}$ four-membered ring structures.

Reaction of the *mer* hydrido complex **1**[4] with $[PdCl_2(PhCN)_2]$ in toluene was expected to afford a bimetallic complex resulting from HCl elimination and dppm-assisted metal–metal bond formation [Eq. (a)] (dppm = bis(diphenylphosphino)methane). In addition, the structure of the

product **2**, fully elucidated by X-ray diffraction methods, shows an unprecedented η^2-μ_2-siloxy bridging ligand (Fig. 1).



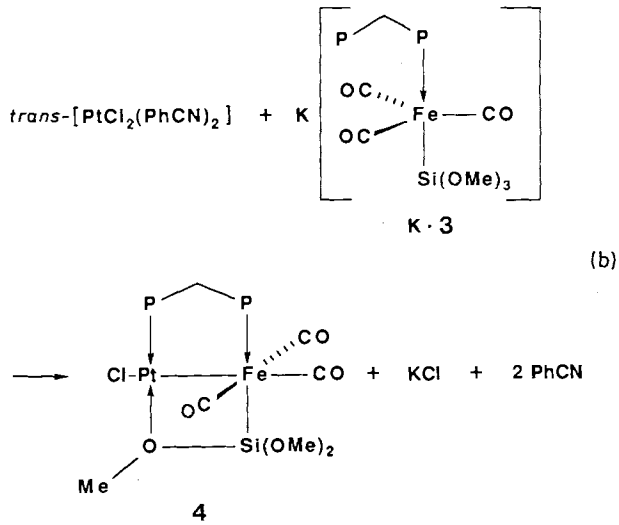


Fig. 1. Perspective view of the molecular structure of **2**. Selected bond lengths [Å] and angles [°]: Fe-Pd 2.582(1), Fe-P(1) 2.241(2), Fe-Si 2.275(2), Fe-C(1) 1.758(5), Fe-C(2) 1.776(7), Fe-C(3) 1.782(6), Pd-P(2) 2.185(1), Pd-Cl 2.303(2), Pd-O(4) 2.100(4), Si-O(4) 1.659(4), Si-O(5) 1.630(6), Si-O(6) 1.627(5); Pd-Fe-P(1) 100.4(1), Pd-Fe-C(1) 162.1(2), Pd-Fe-C(2) 77.8(2), Pd-Fe-C(3) 71.5(2), Pd-Fe-Si 76.2(2), Cl-Pd-P(2) 94.0(1), P(2)-Pd-Fe 90.6(1), O(4)-Pd-Fe 79.7(1), Cl-Pd-O(4) 95.3(1), Pd-O(4)-Si 103.2(2), O(4)-Si-Fe 100.8(2).

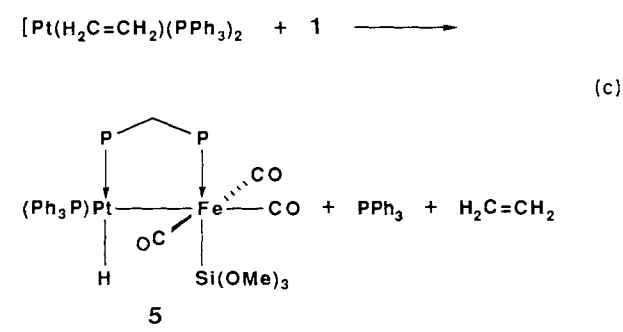
The Fe atom in **2** has an octahedral environment which retains the *trans*-P–Fe–Si arrangement found in the precursor. The square-planar geometry about the Pd atom is achieved by oxygen coordination of one of the Si-OMe groups (the O(4) atom deviates by 0.114(5) Å from the mean plane passing through the Pd, Fe, P(2), Cl, and O(4) atoms). The PdFeSiO(4) four-membered ring is almost planar (the Pd–Fe–Si–O(4) torsion angle is 1.5(2)°) and nearly coplanar with the P(1)FeP(2)Pd moiety, the dihedral angle between the two mean planes being 3.8(1)°).



Reaction of the trigonal-bipyramidal anion **3** with $[PdCl_2(PhCN)_2]$, $[PdCl_2(PPh_3)_2]$, or $[PdCl_2(dppm)]$ also leads to **2**. In the latter case, it is noteworthy that no bis-dppm complex was formed.[5] The entropically favored intramolecular η^2-μ_2-SiO bridge formation wins over intermolecular nucleophilic displacement by a donor ligand such as CO (acetone, 20 min) or PPh_3 at room temperature. The Fe–Pt complex **4**, analogous to **2**, was prepared according to Equation (b).

In solution, Pd–O dissociation readily occurs in **2**, as shown by the presence of only one signal for all nine OMe protons in the ^1H NMR spectrum. The Pt–O bond in **4** is less labile and two signals are observed for the methoxy protons in a 2:1 ratio, the latter resonance showing coupling with phosphorus ($^4J_{PH}$ = 2.5 Hz).

The oxidative addition reaction of the Fe–H bond of **1** to Pt^0, shown in Equation (c), affords the hydrido bimetallic complex **5**, in which there is no evidence for a Pt–O interaction. Spectroscopic data support the structure drawn.

The new η^2-μ_2-SiO bonding mode presented here opens the possibility of using the "hemilabile" behavior of the $Si(OR)_3$ ligand in solution for the stabilization of unsaturated, catalytically active polynuclear systems. It also provides

a new structural model for the bonding of small metal clusters or aggregates onto silica, a dominant theme in heterogeneous catalysis.[2a, 2b, 6] The additional bonus in dealing with heterometallic systems is further exemplified here by their ability to display selective metal–ligand interactions.

Experimental Procedure

Satisfactory elemental analyses were obtained for all new compounds. ^{1}H NMR signals of phenyl protons not given. **2**: Method A: A mixture of $[PdCl_2(PhCN)_2]$ (384 mg, 1 mmol) and **1** (646 mg, 1 mmol) in 40 mL of toluene was stirred at -20 °C for 1 h. The solution became dark red at room temperature. After solvent evaporation to ca. 10 mL under reduced pressure, **2** precipitated as a red-orange powder. Addition of ca. 40 mL of hexane completed the precipitation. Filtration and recrystallization from CH_2Cl_2/hexane gave 378 mg (48%) of **2** as red crystals. IR (nujol) $\tilde{\nu}$(CO)[cm^{-1}]: 1985 m, 1925 s, 1905 s. FT IR (polyethylene): $\tilde{\nu}$(PdCl)[cm^{-1}] = 270. ^{1}H NMR (200 MHz, [D$_6$]acetone, TMS, 20 °C): δ = 3.74 (s, 9H, OMe), 4.36 (t, 2H, CH$_2$, ^2J(PH) = 11 Hz). ^{31}P{^{1}H} NMR (81.02 MHz, C_6D_6/CH_2Cl_2, 20 °C): AX spin system: δ_A = 34.9 (d, P(Pd), J(PP) = 55 Hz); δ_X = 48.0 (d, P(Fe)).

2: Method B: A solution of K·**3** (685 mg, 1 mmol) in 20 mL of THF was added dropwise at -40 °C to a suspension of $[PdCl_2(PPh_3)_2]$ (701 mg, 1 mmol) in 25 mL of THF. Upon slowly warming to room temperature, the solution turned dark red. After 10 h agitation, the solution was filtered (to remove KCl) and concentrated to ca. 5 mL under reduced pressure. Complete precipitation of **2** was achieved by addition of hexane. PPh_3 was eliminated by extraction with Et_2O/hexane. Yield: 510 mg (65%).

4: A solution of K·**3** (685 mg, 1 mmol), prepared by the reaction of **1** with KH in THF (for the PPh_3 analogue, see Ref. [7]), in 20 mL of THF was added dropwise (1 h) at room temperature to a suspension of $[PtCl_2(PhCN)_2]$ (472 mg, 1 mmol) in 30 mL of THF. After stirring for 12 h, the dark red solution was filtered (to remove KCl) and concentrated to ca. 10 mL under reduced pressure. Addition of 40 mL of hexane induced precipitation of **4** as a yellow-brown powder. Subsequent recrystallizations from CH_2Cl_2/pentane afforded yellow microcrystals of **4**. Yield: 210 mg (24%). IR(THF) $\tilde{\nu}$(CO) [cm^{-1}] = 1995 m, 1935 s, 1910 m, sh. ^{1}H NMR (200 MHz, [D$_6$]acetone, TMS, 20 °C): δ = 3.74 (s, 6H, Si(OMe)$_2$), 3.80 (d, 3H, Pt-OMe, ^4J(PH) = 2.5 Hz), 4.04 (t with ^{195}Pt satellites, 2H, CH$_2$, ^2J(PH) = 11, ^3J(PtH) = 66 Hz). ^{1}H NMR (200 MHz, C_6D_6, TMS, 20 °C): δ = 3.25 (t, 2H, CH$_2$, ^2J(PH) = 11 Hz), 3.74 (s, 6H, Si(OMe)$_2$), 3.90 (d, 3H, Pt-OMe, ^4J(PH) = 2.5 Hz). ^{31}P{^{1}H} NMR (81.02 MHz, [D$_6$]acetone, 20 °C): δ = 7.7 (d with ^{195}Pt satellites, P(Pt), J(PP) = 47 Hz, ^1J(PPt) = 4756 Hz), 52.9 (d, P(Fe)).

5: A solution of $[Pt(C_2H_4)(PPh_3)_2]$ (751 mg, 1 mmol) in 20 mL of toluene was allowed to react at room temperature with successive fractions of **1** (total 646 mg, 1 mmol). Each time, gas evolution was noted. At the end of the reaction (ca. 0.5 h, IR monitoring), the yellow solution was concentrated to ca. 5 mL, 20 mL of hexane was added, and the colorless precipitate of **5** was washed with Et_2O/hexane to remove free PPh_3. Yield: 905 mg (82%). Compound **5** may be recrystallized from CH_2Cl_2/hexane IR(KBr): $\tilde{\nu}$(PtH)[cm^{-1}] = 2149 w. IR(CH_2Cl_2): $\tilde{\nu}$(CO)[cm^{-1}] = 1965 m, 1900 s, 1870 s. ^{1}H NMR (200 MHz, CD_2Cl_2, TMS, 20 °C): δ = -4.51 (dt with ^{195}Pt satellites, 1H, PtH, ^2J(P$_{trans}$H) = 197.6, ^2J(PH) = 13.9 ^1J(PtH) = 686 Hz), 3.56 (s, 9H, OMe), ca. 3.5 (2H, CH$_2$, overlapping with OMe signal). ^{31}P{^{1}H} NMR (81.02 MHz, C_6D_6/toluene, 20 °C): ABX spin system: δ = 29.4 (d with ^{195}Pt satellites, P(Pt), J[PP(Fe)] = 130, ^1J(PtP) = 2074 Hz), 32.0 (t with ^{195}Pt satellites, PPh_3, ^3J(PP) = 10, ^1J(PtP) = 3478 Hz), 72.2 (dd with ^{195}Pt satellites P(Fe), J(pp) = 130.10, ^2J(PtP) = 88 Hz).

Crystal structure determination of **2**: monoclinic, $C2/c$, Z = 8, a = 24.644(8), b = 15.839(5), c = 17.795(5) Å, β = 112.95(2)°; V = 6396(4) Å^3; M_r = 787.32; ϱ_{calcd} = 1.635 g cm^{-3}; F(000) = 3184, μ(Mo$_{K\alpha}$) = 12.69 cm^{-1}. Siemens AED diffractometer, $\theta/2\theta$ scan technique and Nb-filtered Mo$_{K\alpha}$ radiation (λ = 0.71073 Å), $3 < \theta < 25°$, 6075 unique reflections, 3722 observed with $I > 2\sigma(I)$. The structure was solved by Patterson and Fourier methods and refined by the full-matrix least-squares method with anisotropic thermal parameters for all non-hydrogen atoms. The SHELX system of computer programs was used (G. M. Sheldrick, *Program for Crystal Structure Determination*, Cambridge 1976). Some hydrogen atoms were clearly located and refined isotropically, the others were placed at their geometrically calculated positions and introduced in the final structure-factor calculation with fixed isotropic thermal parameters. R = 0.0285, R_w = 0.0354. Further details of the crystal structure analysis may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-54012, the names of the authors, and the journal citation.

Two Novel Polyoxomolybdates Containing the $(MoNO)^{3\oplus}$ Unit: $[Mo_5Na(NO)O_{13}(OCH_3)_4]^{2\ominus}$ and $[Mo_6(NO)O_{18}]^{3\ominus}$ **

By *Pierre Gouzerh,* Yves Jeannin, Anna Proust,* and *Francis Robert*

The chemistry of polyoxometalates is under active investigation because of their use for imaging in metal oxide surface chemistry. A few organopolyoxomolybdate derivatives structurally related to $[Mo_6O_{19}]^{2\ominus}$ [1] with a terminal oxo group replaced by a nitrogen-ligated group such as a diazenido, hydrazido, imido, or nitrido ligand have been recently reported.[2] A number of dinuclear,[3] tetranuclear,[4] and octanuclear[5] diazenidomolybdenum species are also known. Despite the obvious analogy between $RN_2^{\oplus}$ and $NO^{\oplus}$ [6] and extensive studies of the reaction of hydroxylamine with oxomolybdenum compounds,[7, 8] nitrosyl derivatives of polyoxomolybdates were hitherto unknown. The reductive nitrosylation of oxomolybdenum complexes was found to produce either mononuclear[7] or polynuclear[8] molybdenum(II) complexes containing the $(MoNO)^{3\oplus}$ unit. Here we report the first polynuclear species containing both $(Mo^{II}NO)^{3\oplus}$ and $(Mo^{VI}O)^{4\oplus}$ units.

$(NBu_4)_2[Mo_4O_{12}\{NC{-}CH{=}CH{-}C(NH_2)NO\}_2]$ **1**

$(NBu_4)_2[Mo_5Na(NO)O_{13}(OCH_3)_4]\cdot 4CH_3OH$ **2**

Treatment of complex **1** [9] with hydroxylamine in refluxing methanol and cooling the solution led to the formation of violet crystals, which were identified as complex **2** by chemical analysis and X-ray structure determination.[10] The crystals readily lose solvent. Their structure (cf. Fig. 1) derives from the Lindqvist structure. One MoO group is missing and is replaced by a sodium cation interacting with four terminal oxygen atoms of the polyanion and one methanol molecule. The linear $(MoNO)^{3\oplus}$ group is opposite to sodium, and four methoxo ligands asymmetrically bridge Mo^{II} to its four Mo^{VI} neighbors. Formal molybdenum oxida-

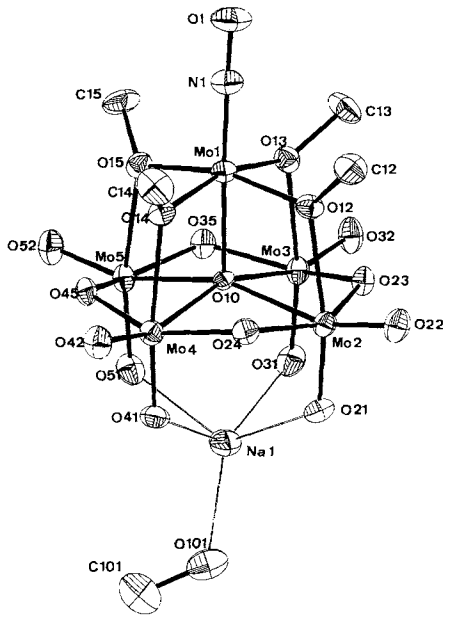

Fig. 1. Molecular structure of **2** Selected bond distances [Å] and angles [°]: Mo1-N1 1.75(1), N1-O1 1.22(1), Mo1-O10 2.122(5), Mo2-O10 2.343(5), Mo3-O10 2.363(5), Mo4-O10 2.319(5), Mo5-O10 2.348(5), Na-O10 3.191(7); Mo1-N1-O1 178(1). Asymmetrical OCH_3 bridges with averaged distances: Mo1-O(12-15) 1.995(6), Mo(2-5)-O 2.279(7); Mo1-O-Mo 106.8(3). Na-O(21-24) 2.379(9) (averaged).

tion states may be inferred from the polyanion charge; this polymolybdate contains localized Mo^{II} and Mo^{VI} atoms.

When **2** is dissolved in dichloromethane or acetonitrile, it spontaneously transforms into another polymolybdate, **3**. The X-ray study[10] revealed another Lindqvist structure type and confirmed the formula obtained by chemical analysis. The unit cell contains two independent $[Mo_6(NO)O_{18}]^{3\ominus}$ anions located on inversion centers. The disorder of both anions influences the observed interatomic distances. Since this disorder might also result from a statistical distribution of $[Mo_6(NO)_2O_{17}]^{4\ominus}$ and $[Mo_6O_{19}]^{2\ominus}$, an electrochemical

$(NBu_4)_3[Mo_6(NO)O_{18}]$ **3**

study was undertaken; cyclic voltammetry in CH_2Cl_2 on a Pt electrode in the range -1.0 to $+1.0$ V vs. SCE reveals only one quasi-reversible one-electron oxidation process at $+0.87$ V; pure $[Mo_6O_{19}]^{2\ominus}$ shows a reversible reduction process at -0.29 V. Therefore, the occurrence of $[Mo_6O_{19}]^{2\ominus}$ is ruled out and the species is a mononitrosylhexamolybdate derived from $[Mo_6O_{19}]^{2\ominus}$ by replacing one MoO group by one $(MoNO)^{3\oplus}$ group. Compound **3** is another member of the family $[Mo_6O_{18}L]^{n\ominus}$.[2]

Compounds **2** and **3** are the first examples of polyoxomolybdates containing an $(MoNO)^{3\oplus}$ unit. Moreover, **2** is the first example of a lacunar Lindqvist structure.

Experimental Procedure

2: In a typical experiment, **1** [9] (32 g, 25 mmol) in 20 mL of methanol was mixed with 80 mL of 1 M NH_2OH in methanol (the hydroxylamine was prepared from $NH_2OH \cdot HCl$, which was poured into a methanolic solution of sodium methoxide; NaCl was then removed by filtration). The suspension was refluxed for 3 h. After standing ca. 12 h at room temperature, the solution afforded 5 g of violet crystals (yield: 18%).

3: Compound **2** (5 g, 3.7 mmol) was dissolved in hot acetonitrile (30 mL) and the solution was refluxed for 5 h. Cooling the solution gave 2.3 g of brown crystals (yield: 38%). IR(KBr): $\tilde{\nu}$(NO): **2**, 1630; **3**, 1575 cm^{-1}.

$HoAl_3Cl_{12}$ in Crystalline Form**

By *Dietmar Hake* and *Werner Urland**

The chemical transport of metal halides is only possible through the formation of gas-phase complexes with, for example, $AlCl_3$, $GaCl_3$, or $FeCl_3$.[1] Thus, the relatively nonvolatile trichlorides of the lanthanoids ($LnCl_3$) can be transported with $AlCl_3$;[2,3] spectroscopic studies reveal the formation of gaseous complexes of empirical formulas $LnAl_3Cl_{12}$ and $LnAl_4Cl_{15}$,[4] in which the lanthanoid ion, depending on its size, is probably nona- or hexacoordinated.[5] Here we report, for the first time, the synthesis and crystal structure of $HoAl_3Cl_{12}$.

$HoAl_3Cl_{12}$ was synthesized by reaction of commercially available holmium oxide with aluminum trichloride followed by chemical transport;[6] the analytical composition was determined by ICP analysis and argentometric titration with potentiometric indication.[7] The salmon-colored compound is sensitive to moisture and decomposes within a few minutes upon exposure to air.

[**] This work was supported by the Fonds der Chemischen Industrie.

The result of the X-ray structure analysis[8] is shown in Figure 1. The structure type presented here is, to our knowledge, the first in which a cation is surrounded by chlorine

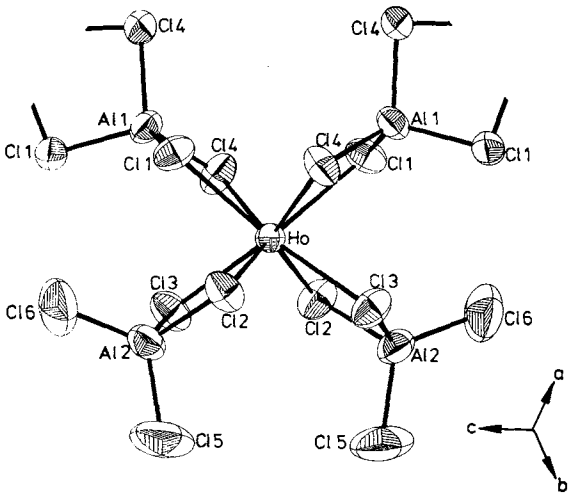

Fig. 1. ORTEP view of $HoAl_3Cl_{12}$ with the coordination polyhedron for $Ho^{3\oplus}$. Selected bond lengths [pm]: Ho-Cl1 281.7(2), Ho-Cl2 273.4(2), Ho-Cl3 270.8(2), Ho-Cl4 287.7(2), Al1-Cl1 212.4(2), Al1-Cl4 213.6(3), Al2-Cl2 218.9(3), Al2-Cl3 220.0(3), Al2-Cl5 206.9(3), Al2-Cl6 206.7(4), Ho-Al1 368.2(1), Ho-Al2 366.8(2).

atoms in such a way as to form a square antiprism. Usually, a trigonal bicapped prism is formed for octacoordinated lanthanoid trichlorides.[9, 10] The square antiprism found here is edge-linked with four $AlCl_4$ tetrahedra, two of which are linked to the next $HoCl_8$ polyhedron. This linkage leads to a screw-shaped chain along [001]. The Ho–Cl distances within the antiprism vary from 270.8 to 287.7 pm. The antiprism is slightly distorted; this is especially revealed in the slightly bent faces, which, ideally, are square planar (Fig. 1). The terminal Al–Cl distances (206.7 and 206.9 pm) are significantly shorter than the Al–Cl bridging distances, in agreement with the results of a crystal structure analysis of $PdAl_2Cl_8$.[11]

The synthesis and X-ray structure analysis of $HoAl_3Cl_{12}$ and of analogous compounds is of particular interest in connection with the determination of thermodynamic data for a better understanding of chemical transport and with respect to the role of these substances in high-pressure discharge lamps.[12]

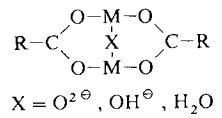
Synthesis, Structure and Magnetic Properties of a Dinuclear Manganese(II) Complex with One μ-Aqua and Two μ-Carboxylato Bridges **



By *Andrea Caneschi, Fabrizio Ferraro, Dante Gatteschi,* Maria Chiara Melandri, Paul Rey,* and *Roberta Sessoli*

Polynuclear manganese complexes are currently of great interest owing to their relevance to many important naturally occurring processes. In particular, a cluster of four manganese ions is known to be involved in the photosynthetic water-oxidizing complex,[1] and two manganese ions per protein subunit are present in the pseudo-catalase from *Lactobacillus plantarum*.[2]

During our efforts to synthesize magnetic materials by using manganese(II) and stable organic radicals comprising two equivalent NO groups,[3] we isolated the dinuclear complex **1**, L = 2-ethyl-4,4,5,5-tetramethyl-3-oxo-4,5-dihydro-

$[Mn_2(F_5C_2COO)_4(H_2O)_3L_2]$ **1**

1*H*-imadazolyl-1-oxyl (see Table 1).[4] Complex **1** contains one μ-H_2O and two μ-carboxylato bridges with a structure of the $Mn_2(\mu\text{-}H_2O)(\mu\text{-}O_2CR)_2$ core analogous to that observed in hemerythrin,[5] the marine invertebrate oxygen transport protein, and in various metal complexes.[6]

Scheme 1. Framework of complexes **1**–**7** (Table 1).

Complex **1** is the first such manganese compound in which X is water (see Scheme 1), although similar structures are known for ruthenium, cobalt, and nickel compounds[7] (an iron analogue does not exist). This provides the opportunity to compare the efficiency of the three X groups in transmitting exchange interactions between the two d^5 ions.

The X-ray analysis[8] of compound **1** reveals that the two nonbridging carboxylates are monodentate and bind to the two metal ions (Fig. 1). The distances of the noncoordinated

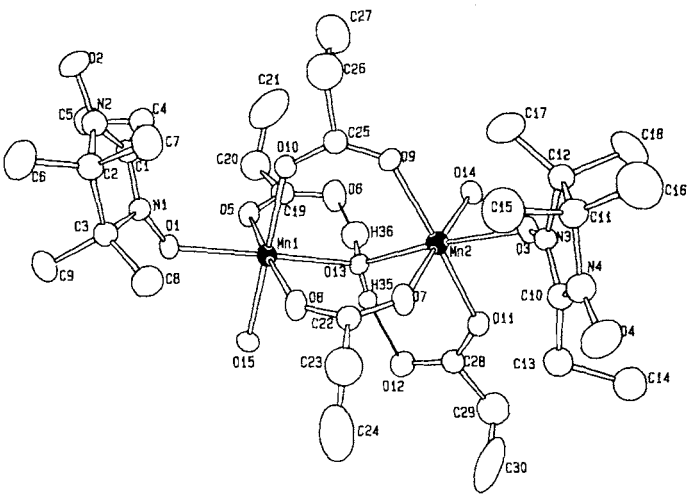

Fig. 1. Molecular structure (ORTEP) of complex **1** . The fluorine atoms are omitted for the sake of clarity. Selected bond distances [Å] and angles [°]: Mn1-Mn2 3.739(2); Mn1-O1 2.164(6); Mn1-O5 2.210(6), Mn1-O8 2.146(7), Mn1-O10 2.114(8), Mn1-O13 2.228(7), Mn1-O15 2.137(9), Mn2-O3 2.158(6), Mn2-O7 2.099(8), Mn2-O9 2.141(7), Mn2-O11 2.226(7), Mn2-O13 2.214(7), Mn2-O14 2.166(9), O1-N1 1.309(10), O3-N3 1.326(9), O6-H36 1.33(8), O12-H35 1.75(7), O13-H35 0.87(7), O13-H36 1.29(9); Mn1-O13-Mn2 114.6(3), Mn1-O1-N1 127.1(5), Mn2-O3-N3 128.3(5), H35-O13-H36 106(7). The hydrogen bonds O6-H36 and O12-H35 are drawn as solid lines.

oxygen atoms to the oxygen of the μ-H_2O bridge (O6-O13 2.55, O12-O13 2.56 Å) clearly indicate the presence of hydrogen bond interactions, which certainly contribute to stabilizing the dinuclear structure. A similar geometry around the bridging water molecule was found in a Ru^{II} dimer with one μ-H_2O and two μ-carboxylato bridges.[7b] Each radical L is bound through one of its oxygen atoms to a manganese ion, whose octahedral coordination environment is completed by one water molecule. The lengths of the N–O bonds confirm that the radical nature of the ligand is preserved. The two radicals are magnetically well separated from each other; the shortest distance between noncoordinated NO groups is about 5 Å.

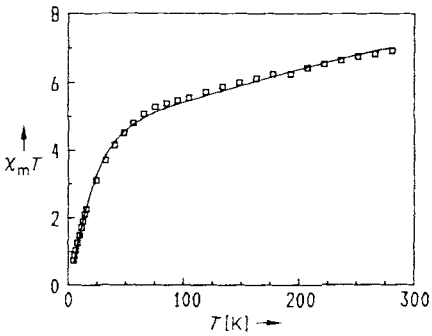
The temperature dependence of the magnetic susceptibility is shown in Figure 2 in the form $\chi_m T$ versus T. The product $\chi_m T$ decreases slowly in the range 300–100 K, but decreases dramatically at lower temperatures. This finding suggests that the four spins are antiferromagnetically coupled with a large and a small coupling constant. This prediction is confirmed by a quantitative calculation for a cluster of four spins, coupled as shown in Scheme 2.

NO′(ligand)—$\overset{J'}{}$Mn—$\overset{J}{}$Mn—$\overset{J'}{}$NO′(ligand)

Scheme 2.

The best-fit curve ($R = 4.6 \times 10^{-4}$) is shown in Figure 2; the corresponding parameters are $J' = 113(1)\ cm^{-1}$, $J = 3.3(0.2)\ cm^{-1}$, and $g = 2.02$. We use the spin Hamiltonian in the form $\boldsymbol{H} = J\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$. The value of J' is slightly smaller than those reported for other manganese(II) complexes with similar NO·-containing ligands,[9] presumably due to the longer Mn–O distance in **1**.

The coupling constant J, which reflects the manganese–manganese interaction, is determined in principle by the three bridges between the two metal ions. However, it is



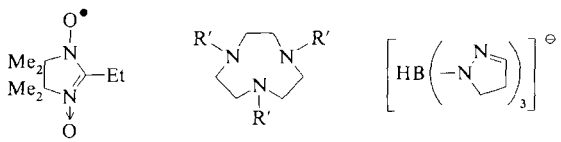


Fig. 2. Temperature dependence of the magnetic susceptibility of **1** in the form $\chi_m T$ vs. T. □: experimental value. The solid line represents the best-fit calculated values. Ordinate: $\chi_m T$ in [$cm^3\ mol^{-1}\ K$].

Table 1. Magnetic coupling constants J (see Scheme 2) in dinuclear $M_2(RCOO)_2X$ moieties of the complexes **1**–**7** (see Scheme 1). M = Mn^{II}, Fe^{III}; X = $O^{2\ominus}$, $OH^{\ominus}$, H_2O.

L L′: R′ = Me; L″: R′ = H L‴

Complex	J [cm^{-1}]	Ref.
1 $[Mn_2F_3C_2COO)_4(H_2O)_3L_2]$	3.3	
2 $[Mn_2(CH_3COO)_2(OH)L'_2](ClO_4)$	18	[10]
3 $[Fe_2(CH_3COO)_2(OH)L''_2]^{\oplus}$	34	[11]
4 $[Fe_2(CH_3COO)_2OL'_2](PF_6)_2$	190, 238	[12, 6]
5 $[Fe_2(CH_3COO)_2OL'_2](ClO_4) \cdot H_2O$	238	[6]
6 $[Fe_2(CH_3COO)_2L''_2]I_2 \cdot 0.5\,NaI \cdot 3\,H_2O$	168	[12, 13]
7 $[Fe_2(CH_3COO)_2OL''_2]$	242	[14]

generally assumed[6] that the carboxylates are rather ineffective in transmitting the exchange interaction, and that the X group (see Scheme 1) governs the coupling. Accordingly, the differences in the magnetic coupling in complexes with X = $O^{2\ominus}$, $OH^{\ominus}$, and H_2O must be ascribed entirely to the X group. The values of the coupling constants J for some $M_2(RCOO)_2X$ clusters are given in Table 1. A direct comparison cannot be performed because no μ-oxo manganese(II) species has been reported. However, since the μ-hydroxo manganese(II) and iron(III) species have comparable J values, it is apparent that on going from $O^{2\ominus}$ to $OH^{\ominus}$ to H_2O, J decreases by roughly one order of magnitude at each step. The decrease of J in the series $O^{2\ominus} > OH^{\ominus} > H_2O$ is perfectly in line with the decrease in bonding interaction between ligand and metal on decreasing the charge on the ligand. This result confirms the possibility that azidodeoxyhemerythrin, which has a paramagnetic ground state, has indeed a μ-aqua bridge.[6, 15, 16]

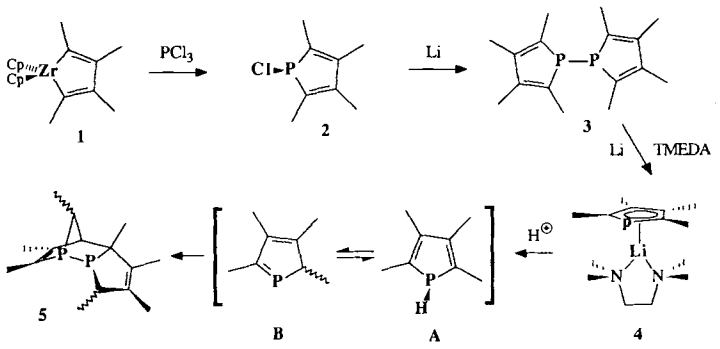
Synthesis and Crystal Structure of a Phospholyl Anion**



By *Trevor Douglas* and *Klaus H. Theopold**

The study of phospholes is an active research area of heterocyclic chemistry.[1] However, the available synthetic routes to these five-membered rings can be of very low yield and generally produce derivatives with aryl or alkyl groups on phosphorus. Here we report simple procedures for the synthesis of a chlorophosphole and a phospholyl anion in high yields as well as the first crystal structure determination of a phospholyl anion.

Fagan et al. have recently reported the synthesis of several main-group heterocycles by transfer of the organic ligand of the easily prepared zirconacyclopentadienes to various main-group electrophiles.[2] We have now found that reaction of $Cp_2ZrC_4Me_4$ **1** with PCl_3 yields the permethylated chlorophosphole **2** (Scheme 1). Compound **2** is a volatile yellow oil, which was isolated in 85% yield by sublimation at 0 °C.[3] It slowly decomposes at room temperature but can be stored at − 20 °C for months without any signs of decomposition.

Scheme 1.

The common synthetic route to phospholyl anions involves the reductive cleavage of 1-phenylphospholes and is stricken with the concomitant generation of phenyllithium, which may interfere in subsequent reactions of the phospholyl anion.[1] Several strategies (involving selective removal of the phenyllithium) have been devised to overcome this problem.[4] However, reduction of the chlorophosphole **2** with excess lithium (in THF at room temperature, excess tetramethylethylenediamine (TMEDA) added) cleanly yielded the lithium salt of the phospholyl anion, $Li(tmeda)PC_4Me_4$ **4**, which was isolated as colorless needles in 80% yield by recrystallization from ether.[5] The crystal structure of **4** is shown in Figure 1.[6]

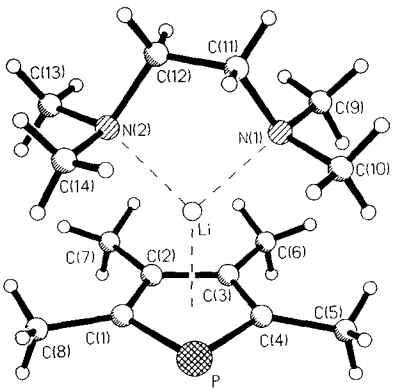

Fig. 1. The molecular structure of $Li(tmeda)PC_4Me_4$. Selected bond distances [Å] and angles [°]: P-C(1) 1.750(5), P-C(4) 1.752(4), C(1)-C(2) 1.396(5), C(2)-C(3) 1.424(7), C(3)-C(4) 1.396(7), P-Li 2.531(7), C(1)-Li 2.373(8), C(2)-Li 2.373(8), C(3)-Li 2.398(8), C(4)-Li 2.425(8), N(1)-Li 2.136(9), N(2)-Li 2.127(8); C(1)-P-C(4) 90.5(2), P-C(1)-C(2) 112.2(4), C(1)-C(2)-C(3) 112.6(4), C(2)-C(3)-C(4) 112.2(4), C(3)-C(4)-P 112.4(4), N(1)-Li-N(2) 85.2(3).

The crystal features a monomeric molecule with η^5 coordination of the heterocycle to lithium. The coordination sphere of the alkali metal is completed by a chelating TMEDA ligand. Carbon atoms C(11) and C(12) of the diamine exhibit large thermal ellipsoids, probably indicating disorder, but the configuration shown in Figure 1 is the predominant one. The carbon–carbon bond distances within the heterocycle [C(1)-C(2) 1.396, C(2)-C(3) 1.424, C(3)-C(4) 1.396 Å] are very similar, indicating a high degree of delocalization. Similarly, the phosphorus–carbon bonds [P-C(1) 1.750, P-C(4) 1.752 Å] are significantly shorter than P–C single bonds (ca. 1.83 Å), consistent with partial double-bond character. These structural features are direct evidence for the highly aromatic nature of the phospholyl anion, in accord with theoretical studies.[7] Calculations have also suggested considerable negative charge density on the phosphorus, and a comparison of the lithium–phosphorus distance of 2.531 Å and the lithium–carbon distances (average 2.39 Å) with the respective sums of the covalent radii (Li-P

2.29, Li-C 2.00 Å) indeed suggests that the lithium is displaced toward the phosphorus atom. A comparison with the structurally characterized transition-metal derivative $(PC_4Me_4)_2ZrCl_2$ revealed no significant differences between the bond distances or angles of the heterocyclic anion in the two structures.[8]

When the reduction of **2** was carried out in the absence of TMEDA (in THF), donor-free $LiPC_4Me_4$ was isolated as a white solid.[9] In addition, **2** could be reduced with potassium; in the presence of 1.0 equivalent of 18-crown-6, the salt $K(18\text{-crown-6})PC_4Me_4$ was isolated as colorless crystals in 89% yield.[10] Monitoring of the lithium reduction of **2** in [D$_8$]THF by ^{1}H or ^{31}P NMR allowed the detection of an intermediate, which could be isolated and identified as the 1,1′-biphospholyl **3**.[11] This dimer was presumably formed by a fast reaction of phospholyl anion with remaining chlorophosphole starting material. No NMR resonances of $LiPC_4Me_4$ were observed until all of the chlorophosphole had been consumed. In a separate experiment $LiPC_4Me_4$ was allowed to react with **2**. Even at −78 °C this reaction was too fast to be followed by NMR and yielded **3** cleanly.

Protonation of the phospholyl anion (with NH_4BF_4 or HBF_4) yielded a new compound which exhibited a fairly complex ^{1}H NMR spectrum. The spectroscopic data of this material are consistent with a dimer (**5** in Scheme 1)[12] formed by a Diels–Alder reaction of the 2*H*-phosphole **B**, which is in equilibrium with the 1*H*-phosphole **A**. This transformation is well precedented.[13]

Zirconacyclopentadienes similar to **1** are easily prepared with a wide variety of ring substituents.[14] The transformations reported here thus represent a convenient synthetic entry to phosphole chemistry. The isolation of pure phospholyl anions in particular should facilitate the use of these nucleophiles in further reactions. We are currently employing **4** in the synthesis of various organometallic derivatives and we are also investigating the extension of this chemistry to other group 15 elements.

Experimental Procedure

NMR: Bruker WM 300 spectrometer (300 MHz for ^{1}H, 75.47 for ^{13}C, and 121.49 for ^{31}P). Shifts are reported relative to TMS for ^{1}H and ^{13}C and relative to an external PCl_3 reference ($\delta = 219$) for ^{31}P. MS: Kratos MS 890. IR: Mattson Alpha Centauri FT-IR. X-ray: Nicolet R3$_m$/V. M.p. uncorrected.

2: Cp_2ZrCl_2 (13.5 g, 46.2 mmol) was reduced using 46.2 mL of a 2.0 M solution of *n*-butyllithium (92.4 mmol) at −78 °C in THF. After addition of 2-butyne (5.0 g, 92.4 mmol), the reaction mixture was allowed to warm to room temperature and then stirred for 16 h. The mixture was filtered, the solvent evaporated, and the zirconium metallacycle **1** crystallized from pentane at − 30 °C (93.8% yield). Compound **1** (3.2 g, 9.7 mmol) was dissolved in pentane, and PCl_3 (1.3 g, 9.7 mmol) was added. An immediate color change from deep red to yellow was observed. Following filtration of the reaction mixture and evaporation of the solvent, the residue was sublimed at 0 °C and the chlorophosphole **2** was collected as an air-sensitive yellow oil (85% yield).

4: Excess lithium dispersion was added to a THF solution of **2** (300 mg, 0.17 mmol), containing an excess of TMEDA. After stirring for 1 h, the reaction mixture was filtered and the solvent was evaporated. The phospholyl anion was recrystallized from ether at − 30 °C and isolated as colorless crystals (80% yield).

Comments on the Molecular Structure and Bonding in $[W_4Cl(O)(O\mathit{i}Pr)_9]$ and $[W_4(O)(O\mathit{i}Pr)_{10}]$. Analogies with Tetranuclear Carbonyl Clusters

By *Malcolm H. Chisholm,* Kirsten Folting, Charles E. Hammond, John C. Huffman,* and *James D. Martin*

The cluster **1** was discovered as a minor product formed in the preparation of $[W_4(H)_2(O\mathit{i}Pr)_{14}]$ from the reactants $[W_2(O\mathit{t}Bu)_6]$, $NaO\mathit{i}Pr/\mathit{i}PrOH$, and $Me_2NH_2^{\oplus}Cl^{\ominus}$.[1] Com-

[**] This work was supported by the Department of Energy, Office of Basic Sciences, Chemistry Division.

pound **1** is very soluble in hexane and is readily obtained as orange crystals from Et_2O. This allows it to be isolated in analytically pure form and easily separated from $[W_4(H)_2(O\mathit{i}Pr)_{14}]$ and $[W_4(O\mathit{i}Pr)_{12}]$, which are present in the reaction mixture. The reaction pathway leading to **1** is not known.

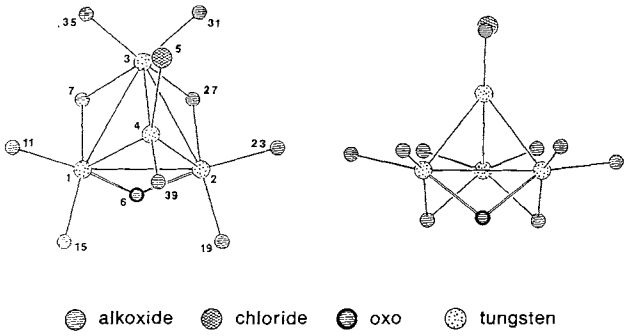
$[W_4Cl(O)(O\mathit{i}Pr)_9]$ $[W_4(O)(O\mathit{i}Pr)_{10}]$
1 **2**

The cluster **2** is observed as a minor product in the thermal decomposition of $[W_4(O\mathit{i}Pr)_{12}]$ in hydrocarbon solvents and is also formed upon addition of H_2O (0.5 equiv.) to solutions of $[W_2(O\mathit{t}Bu)_6]$ in hexane/*i*PrOH. Compound **2** forms analytically pure, dark red-brown crystals from Et_2O and reacts with $Me_2NH_2^{\oplus}Cl^{\ominus}$ (1 equiv.) to generate **1**.

The ^1H NMR spectra of **1** and **2** suggest that they are structurally related, having five types of O*i*Pr ligands. In **2** these form five pairs with one having nondiastereotopic methyl groups, whereas in **1** they are in the integral ratio 2:2:2:2:1 with the methyl groups of the unique isopropyl ligand being nondiastereotopic. Evidently both molecules have one plane of symmetry.

The molecular structure of **1**, deduced from an X-ray study,[2] is shown in Figure 1. A WCl(O*i*Pr) unit caps a W_3 triangle that is supported by two bridging O*i*Pr ligands and one bridging oxo group. The geometry about each tungsten atom in the basal plane corresponds to a square plane formed by two terminal O*i*Pr ligands and two oxygen atoms from either two bridging alkoxide ligands or one bridging alkoxide and one oxo ligand. Of particular note are the short W–W distances of ca. 2.50 Å from the tungsten atoms of the W_3 unit to the capping WCl(O*i*Pr) unit and the longer W–W distances in the basal plane (2.85–2.96 Å). In a localized valence bond (V.B.) description, these are suggestive of a significant contribution of resonance form **B** relative to the fully delocalized form **A** for a 12-electron M_4 unit.

The ^1H NMR spectrum of **1** is entirely consistent with the structure observed in the solid state and the structure of **2** can most reasonably be formulated as being related to that of **1** by the formal replacement of Cl by O*i*Pr. In solution, however, there must be facile rotation of the $W(O\mathit{i}Pr)_2$ unit of **2** above the W_3 fragment.



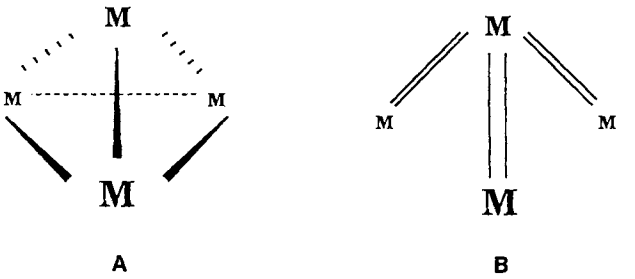


Fig. 1. Two views of the central $W_4Cl(O)_{10}$ skeleton of $[W_4Cl(O)(O\mathit{i}Pr)_9]$. Pertinent distances [Å] and angles [°]: W1-W2 2.847(2), W1-W3 2.958(2), W1-W4 2.484(1); W2-W3 2.965(2), W2-W4 2.470(1), W3-W4 2.547(1), W4-Cl5 2.462(4), W-O (terminal) 1.88(2) (averaged), W-O (oxo) 1.92(1), W-O (μ-OR) 2.01–2.07; Cl5-W4-O39 85.8(4).

The bonding in **1** is best understood from a fragment molecular orbital analysis.[3] We consider the cluster to be formed from the fragments WCl(OR) and $W_3(O)(OR)_8$ and have investigated the bonding by using the method of *Fenske* and *Hall*[4] for the model compound $[W_4Cl(O)(OH)_9]$. An OH bond distance of 0.96 Å was used; otherwise, bond distances and bond angles for the model compound were taken from the solid-state molecular structure of **1** and idealized to C_s symmetry. The important interactions are shown in Figure 2.

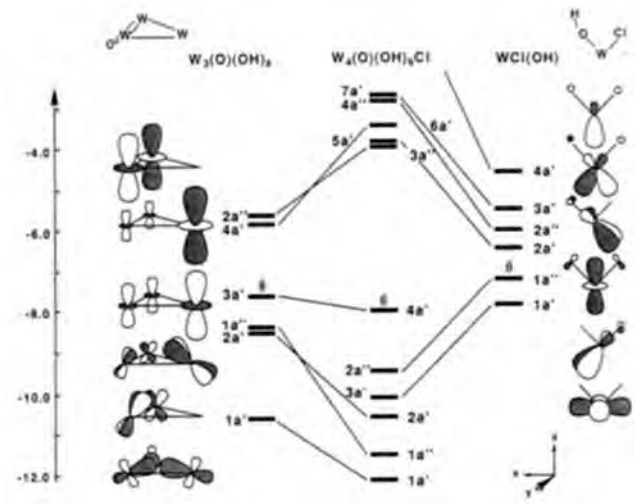

Fig. 2. Frontier orbital interactions showing the formation of $[WCl(O)(OH)_9]$ from the fragments WCl(OH) and $W_3(\mu\text{-}O)(\mu\text{-}OH)_2(OH)_6$. Ordinate: E[eV].

The molecular orbitals of the $W_3(O)(OH)_8$ fragment are similar to those seen in the $W_3(OR)_9$ fragment[5] of $[W_3(OR)_9(\mu_3\text{-}CMe)]$,[6] though the presence of the bridging oxo group results in a reduction of symmetry from C_{3v} to C_s and a loss of one electron from the M_3 cluster fragment. The orbitals of the WCl(OH) fragment are reminiscent of those expected for an ML_2 fragment except for the notable mixing of the 1a″ and 2a″ orbitals so as to minimize the π antibonding between the tungsten d_π and oxygen p_π electrons.

On combining the fragments, the filled 1a′ and 1a″ orbitals of WCl(OH) find their match with unoccupied 4a′ and 2a″ nonbonding orbitals of the tritungsten fragment. Similarly, the 1a′, 2a′, and 1a″ W–W bonding orbitals and the 3a′ occupied nonbonding orbital of the W_3 fragment, made up of the in-phase combinations of tungsten z^2 orbitals, interact strongly with the respective 2a′, 2a″, 3a′, and 4a′ unoccupied orbitals of the ML_2 cap. Placing electrons into M_3 nonbonding (or weakly antibonding) orbitals and withdrawing electrons from the M_3 bonding orbitals causes the Mulliken atomic charges to be −0.631 for the capping tungsten atom and 1.407, 1.407, and 1.343 for the tungsten atoms in the

basal plane. This results in a severe weakening of the M–M bonding in the basal plane and leads to M–M multiple bonding to the capping tungsten atom.[7] The importance of the V.B. description depicted by resonance structure **B**, relative to that of **A**, is apparent. A slightly weaker interaction would be obtained were the WCl(O) fragment rotated by 180° such that the Cl was directed toward the bridging oxo group owing to an increased population of the W–O π^* orbitals.

We have previously discussed[5] the relationships between d^3-$W(OR)_3$ and d^9-$Co(CO)_3$ and their respective clusters of formula $M_3X_9(\mu_3\text{–}Y)$ (M = W, X = OR, Y = CR[6] or P[8]). Aspects of the bonding in **1** are reminiscent of the hypothetical cluster **3** discussed by *Hoffmann*,[9] where the

$[O_3(CO)_9(\mu_3\text{-}PtL_2)]^{2\ominus}$ **3** $[Os_3Pt(H)_2(CO)_{10}(PR_3)]$ **4**

hydrides of **4**[10] are treated as protons. We suggest here that the $Os_3(CO)_9^{2\ominus}$ fragment is related to the $Co_3(CO)_9$ fragment in a similar fashion as $W_3(O)(OR)_8$ is to $W_3(OR)_9$. Furthermore, we suggest an internal isolobal analogy relates the yz and z^2 orbitals of the d^4-WCl(OH) fragment to the xz and sp hybrid orbitals of the d^{10}-PtL_2 fragment. From this simple analysis, we conclude that the orientation of the respective ML_2 fragments to the M_3 plane should be rotated by 90° for the early and late cluster elements, W versus Os, as indeed is observed by X-ray crystallography. Nonetheless, the orthogonal sets of orbitals in both ML_2 and M_3X_9 fragments allow facile rotation of the capping ML_2 groups, as seen here from the ^{1}H NMR spectrum of **2** in [D_8]toluene at 22 °C.

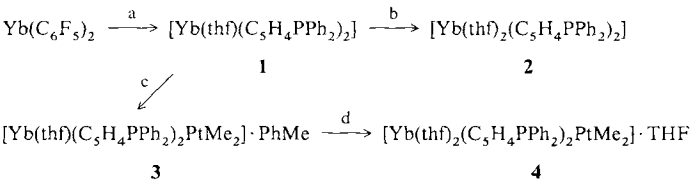
Complexation of a Novel Organoytterbium(II) Ligand with Dimethylplatinum(II): Crystal Structure of the Resulting Heterobimetallic Complex **



By *Glen B. Deacon,* Andreas Dietrich, Craig M. Forsyth,* and *Herbert Schumann**

Dedicated to Professor Friedo Huber on the occasion of his 60th birthday

Heterobimetallic complexes (see, e.g. Ref. [1]) have attracted attention because of the possibility of unusual catalytic activity, including redox catalysis due to cooperative reactivity involving both metal centers. We now report a new organoytterbium(II) ligand **1**, as well as the preparation and crystal structure of a derived heterobimetallic complex **4** with Yb^{II} and Pt^{II} centers. The present example is novel among organolanthanoid d-block-element bimetallic complexes[2–4] in having the lanthanoid in the donor rather than the acceptor part of the molecule.

Metalation of diphenylphosphinocyclopentadiene[5] with bis(pentafluorophenyl)ytterbium[6] gives the phosphinoytterbocene **1** as a green air-sensitive solid[7] (Scheme 1). Dissolution of **1** in THF gives a wine-red solution from which orange-red **2** is isolated. The distinctive identities of **1** and **2** are evident from solid-state visible spectra.[7] The chemical shift of the single ^{31}P NMR resonance of **1** in THF[7] is indicative[1] of equivalent uncoordinated phosphane groups. This result, together with the similarity of the visible spectra of **1** in THF and solid **2**, suggests no P → Yb coordination in the latter, but such bonding cannot be ruled out for solid **1**. Thus, **2** probably has pseudo-tetrahedral eight coordination for ytterbium as observed in **4** (see below).

Reaction of a suspension of **1** in toluene with $PtMe_2$(cod) (cod = *cis,cis*-cycloocta-1,5-diene) results in displacement of cyclooctadiene and formation of the air-sensitive heterobimetallic complex **3**[8] (Scheme 1). Coordination of the

Scheme 1. Reagents and conditions: a) 2 $C_5H_5PPh_2$, THF/OEt_2, 20 °C, 40 h, evaporation to dryness, then 80 °C, vacuum for 2 h, followed by toluene, 20 °C, 24 h; b) THF, 20 °C, 10 min; c) $PtMe_2$(cod), toluene, 20 °C, 22 h; d) slow cooling of a saturated solution in hot THF.

phosphane groups is evident from the single ^{31}P NMR resonance[8], which shows the expected[1] downfield shift from that of the free ligand **1**, and from the P–Pt coupling,[8] which is similar in magnitude to that (1856 Hz) of *cis*-$PtMe_2(PEt_3)_2$.[9] Crystallization of **3** from THF yielded single crystals of **4** (Scheme 1). An X-ray crystal structure

determination[10] revealed that the bis(diphenylphosphino)ytterbocene acts as a chelating phosphane ligand to platinum (Fig. 1). Ytterbium has pseudo-tetrahedral eight coordination (two staggered cyclopentadienyl ligands and two tetrahydrofuran oxygens), while platinum has approximately square-planar stereochemistry. The Pt···Yb distance (5.01 Å) precludes any interaction. There is a marked similarity between the ytterbium geometry of **4** and that of $[Yb(thf)_2(C_5H_4SiMe_3)_2]$[12] and between the platinum stereochemistry in **4** and that for other *cis*-$PtMe_2P_2$ complexes.[13] Thus, coordination of the organoytterbium ligand **1** to the dimethylplatinum(II) complex to give **4** does not cause major disruption of the parent structures.

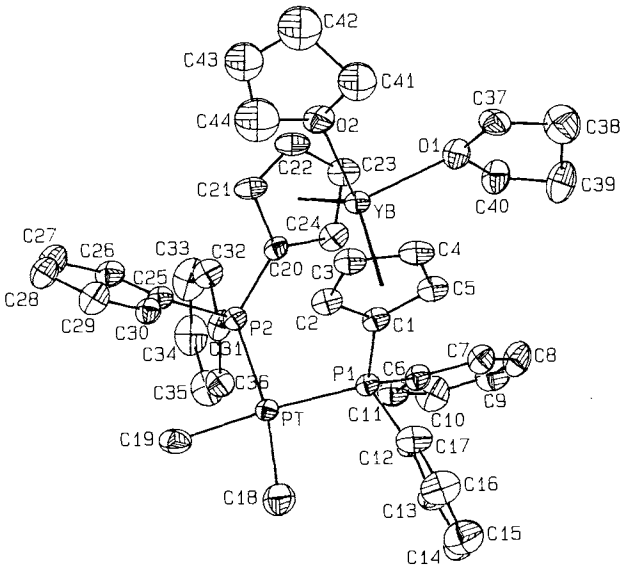

Fig. 1. Crystal structure of **4** (H atoms and THF of solvation omitted for clarity). Selected bond distances [Å] and angles [°] (CT1 and CT2 denote the centroids of cyclopentadienyl rings C1-C5 and C20-C24, respectively): Yb-CT1 2.422(8), Yb-CT2 2.434(9), mean Yb-C (C1-C5, C20-C24) 2.71, Yb-O1 2.428(8), Yb-O2 2.379(6), Pt-P1 2.288(3), Pt-P2 2.290(3), Pt-C18 2.10(1), Pt-C19 2.12(1); CT1-Yb-CT2 133.6(3), O1-Yb-O2 93.7(3), CT1-Yb-O1 104.3(3), CT1-Yb-O2 106.5(3), CT2-Yb-O1 106.2(4), CT2-Yb-O2 105.5(4), C18-Pt-C19 82.2(5), P1-Pt-P2 99.4(1), C18-Pt-P1 92.1(4), C19-Pt-P1 174.2(4), C18-Pt-P2 168.5(4), C19-Pt-P2 86.3(4).

Mechanism of the Hetero-Diels–Alder Reaction of Oxadienes and Alkenes: Calculation of the Acrolein/Ethene System**

By *Lutz F. Tietze,* Jens Fennen,* and *Ernst Anders**

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

The Diels–Alder reaction is still—more than 60 years after its discovery—of special preparative value, since it not only offers an approach to carbocyclic compounds, but also to a variety of heterocycles. Furthermore, it is often characterized by high selectivity. The theoretical discussion of this reaction has focused above all on whether it proceeds by a synchronous, a concerted two-stage, or a two-step mechanism involving diradicals or zwitterions as intermediates.[1] Since the temporal sequence of bond breaking and bond formation is difficult to determine experimentally, quantum-chemical calculations have been used to analyze the mechanism of the Diels–Alder reaction.[2] The ab initio calculations carried out for the butadiene/ethene system [Eq. (a)] by

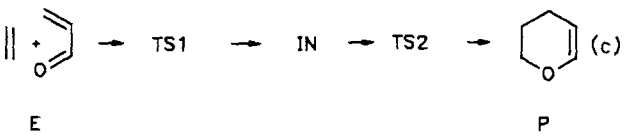
[**] Inter- and Intramolecular Hetero-Diels–Alder Reactions, Part 27. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. *P. von R. Schleyer*, Dr. *T. Clark* (Universität Erlangen-Nürnberg), and Prof. Dr. *M. C. Zerner* (University of Florida, Gainsville, USA) for helpful discussions. Part 26: M. Buback, W. Tost, T. Hübsch, E. Voß, L. F. Tietze, *Chem. Ber. 122* (1989) 1179–1186.

Houk et al.,[2b] *Ortega* et al.,[2c] *Bernardi* et al.,[2d] and *Gajewski* et al.[2e] gave a symmetrical transition state, whereas *Dewar* et al.,[2f] using the semiempirical AM1/CI method (half electron approximation), found an unsymmetrical diradicaloid intermediate. Calculations for Diels–Alder reactions of heterodienes such as acrolein have been performed only once, without considering the problem of diradicaloid intermediates.[3]



In our studies of intramolecular Diels–Alder reactions[4] of heterodienes such as **1**, readily accessible in situ by condensation of an aldehyde with a 1,3-dioxo compound, we were able to show that cycloaddition to give **2** [Eq. (b)] very

(b)

1 **2**

likely proceeds in a concerted fashion without the intermediacy of diradicaloids.[5] Moreover, we obtained the first experimental proof that this type of reaction proceeds via an unsymmetrical transition state.[6] Here we present the results of a theoretical study, using the AM1 method, of the intramolecular cycloaddition of acrolein and ethene [Eq. (c)],

E P

the parent reaction of (b), and we compare the results with those obtained for the butadiene/ethene system [Eq. (a)]. Our goal was to develop a theoretical framework for understanding the stereoselectivity of the reaction. The most important results of the calculations for reaction (c) are summarized in Table 1.

The assessment of the radicaloid character of intermediates requires quantum-chemical methods capable of treating open-shell systems. In carrying out these calculations, we found it advantageous to determine approximately the geometries of the transition states TS or intermediates IN by using an MMX force field[7a] and to use the results as starting points for the restricted Hartree–Fock (RHF) optimization of the geometries with initially fixed C–C and C–O bond lengths. This approach saves CPU time and proved to be widely applicable.

The enthalpies of formation ΔH_f of starting materials E and products P were calculated by using the AMPAC[7b] or VAMP program package.[7c] All structures were completely optimized without symmetry restrictions. After the RHF optimization of the geometry, the RHF transition state TS was completely calculated (NS01A routine[7d] of the VAMP program package). Its structure then served as the starting geometry for calculating the two unrestricted Hartree–Fock (UHF) transition states TS1 and TS2. The determination of the configuration interaction (CI) transition states TS1 and TS2 is generally straightforward when the UHF transition states are known and the NS01A routine is used. The NS01A geometries were refined[7e] and then characterized by a FORCE calculation.[7f] NS01A and SADDLE routines[7g] were generally found to give nearly identical results. For relatively long partial bonds (starting at ca. 240 pm) and only insignificantly differing heats of formation, NS01A afforded somewhat deviating structural parameters. This may be explained by the overall very flat potential energy surfaces close to the first transition state TS1.

For the two reactions (a) and (c), both the UHF and the CI approximation revealed the existence of an intermediate IN and thus indicated a two-step mechanism. However, the energy profiles of reactions (a) and (c) are fundamentally different both qualitatively and quantitatively (Fig. 1, left and right, respectively).

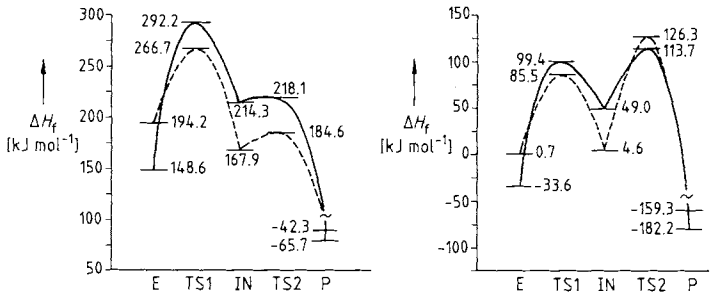


Fig. 1. Reaction profile for cycloaddition calculated with the semiempirical methods AM1/UHF (– – –) and AM1/CI (—). Left: Reaction (a) [2f]. Right: Reaction (c).

Table 1. Characteristic data for the hetero-Diels–Alder systems acrolein/ethene; AM1 results for reaction (c).

Method	Species	ΔH_f [kJ mol^{-1}]	r(C-C) [pm]	r(C-O) [pm]	S^2	Coefficients of the configurations [a] a^1b^1	a^2	b^2
RHF	TS [b]	126.3	198.7	200.8	–	–	–	–
UHF	E	0.7	–	–	–	–	–	–
	TS1	85.5	194.7	354.5	0.836	–	–	–
	IN	4.6	152.2	364.2	1.050	–	–	–
	TS2	126.3	198.7	200.8	0.000	–	–	–
	P	−159.3	148.2	137.7	0.000	–	–	–
CI	E	−33.6	–	–	–	–	–	–
	TS1	99.4	184.0	265.8	–	0.055 [c]	0.953	−0.298
	IN	49.0	151.7	358.3	–	0.319 [c]	−0.686	0.654
	TS2	113.7	198.6	200.9	–	0.041 [c]	0.989	−0.142
	P	−182.2	148.1	137.1	–	0.014	0.985	−0.172

[a] a indicates the HOMO, b the LUMO. [b] Dipole moment, 2.104 D; charge separation; arcolein/ethene, −0.13/+0.13. For comparison, butadiene/ethene [2f]: 0.560 D, −0.00/+0.00. [c] For comparison, a^1b^1 values for butadiene/ethene [2f]: TS1, 0.055; IN, 0.872; TS2, −0.241.

Thus, the second transition state in (c) is higher in energy than the first and therefore rate-determining. In reaction (a), the first—nonradicaloid—transition state initially appears to be rate-determining owing to its higher energy. The ΔH_f value of the second transition state must be corrected, however, because of its radicaloid character (see below);[2g] the resulting increased importance of TS2 in reaction (a) makes it impossible to determine which transition state is rate-determining.

The ΔH_f values calculated by the two open-shell approximations (UHF and CI) differ by only ca. 13 kJ mol^{-1} for both TS1 and TS2 in reaction (c); this value is much smaller than that calculated for cycloaddition (a) (Fig. 1, left, $\Delta\Delta H_f$(TS1) = 25.5, $\Delta\Delta H_f$(TS2) = 33.5 kJ mol^{-1}; the higher value in each case was obtained from the CI calculation[2g]). The C–C bonds being formed in the two transition states

TS 1 and TS 2 of reaction (c) are more similar in length (184.0 and 198.6 pm, respectively) than those of reaction (a) (193 and 153.2 pm, respectively). The C–O bond being formed in TS 1 of (c) is only 265.8 pm, a very short value compared with that of the second C–C bond in TS 1 of (a) (498.9 pm). Comparison of the TS 2 bond lengths in cycloadditions (c) and (a) shows that the rate-determining transition state TS 2 of (c) (r(C-C) = 198.6 pm, r(C-O) = 200.9 pm) is surprisingly "symmetric" (TS 2 of (a): r(C-C) = 153.2 and 290.3 pm).

The involvement of radicaloids in reaction (c) is usually expressed by the coefficient contributions to the singlet CI eigenfunction, composed of the configurations a^1b^1, a^2, and b^2 (Table 1), though there are a number of other criteria for determining the extent of mixing of singly excited states;[8] the a^1b^1 coefficient is particularly suitable. The rate-determining transition state TS 2 ($a^1b^1 = 0.041$) in (c), in contrast to TS 2 of (a) ($a^1b^1 = -0.241$), displays almost no radicaloid character, but does exhibit a certain degree of polarity, as revealed by comparison of the dipole moments of the RHF transition states (footnote [b] in Table 1). An only slightly higher a^1b^1 contribution (0.055) is obtained for transition state TS 1 of (c), whereas the radicaloid character of intermediate IN is pronounced ($a^1b^1 = 0.319$). Since the stability of these species is overestimated by the use of such calculation methods, however, it is necessary to correct the calculated heats of formation to a more positive value.[2f] Although the amount of this correction is somewhat uncertain,[2b, 2f] even an increase of only a few kJ mol^{-1} in the heat of formation of IN in (c) decreases its importance as a sufficiently long-lived and therefore significant intermediate for the reaction.[9] Our experimental finding that the configuration of the dienophilic moiety of **1** is retained in the intramolecular hetero-Diels–Alder reaction (b) may thus be explained on the basis of this AM 1 study.

The essential difference between reactions (a) and (c) lies in the finding that the total course of the hetero-Diels–Alder reaction (c) is governed by the structural and energetic properties of transition state TS 2. Of particular importance is the fact that, in contrast to reaction (a), all methods employed here (RHF, UHF, CI) gave very similar results for TS 2 of (c). Therefore, the much less time-consuming RHF method may be used for calculating the hetero-Diels–Alder reaction of oxadienes. Thus, it should also be possible to describe—at least roughly—more complex transition-state structures containing substituents of practical relevance with the RHF method.

Generation and Ionization Pattern of the Iso(valence)electronic Compounds $ClP(=O)_2$ and $ClP(=S)_2$**

By *Manfred Meisel,* Hans Bock,* Bahman Solouki,* and *Matthias Kremer*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

According to the "classical" Walsh rules[1] tetraatomic chalcogen-element halides $Hal_2E{=}X$ and $HalE(=X)_2$ with 24 valence electrons are planar, and in the case of the main group elements E they form a link between the likewise planar iso(valence)electronic molecules F_3B and SO_3. In spite of their fundamental importance as π/σ bond models, only the (diamagnetic) neutral compounds $Hal_2C{=}O$ (Hal = F,Cl,Br),[2] $Hal_2C{=}S$ (Hal = F,Cl),[2] $F_2C{=}Se$[2] and $HalN(=O)_2$ (Hal = F,Cl)[2] have thus far been characterized by their ionization patterns, since unsaturated derivatives such as $F_2Si{=}O$[3a] tend to oligomerize and can frequently only be generated and investigated in noble gas matrices at low temperatures. The same applies for $ClP(=O)_2$, which previously had to be either cold-trapped from rather non-selective gas reactions[3b] or generated from $ClP{=}O$ by photolyzing[3c] ozone in a joint matrix[3d] (Scheme 1).

[**] Gas-Phase Reactions, Part 76. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by the Land Hessen. Part 75: H. Bock, M. Bankmann, *Angew. Chem. 101* (1989) 950; *Angew. Chem. Int. Ed. Engl. 28* (1989) 911.

In contrast, pyridinium betaines which are readily accessible from pyridine and P_4O_{10} or P_4S_{10} and $Cl_3P{=}O$ or $Cl_3P{=}S$ provide an easy access to dioxophosphorus(v) chloride $ClP(=O)_2$ and the previously unknown $ClP(=S)_2$ (Scheme 2).

Scheme 2.

According to the PE spectra (Fig. 1), evaporation under a pressure of about 10 Pa already leads to the dissociation into the respective betaine components. The energies of the radical cation states of $ClP(=O)_2$ and $ClP(=S)_2$ can be "extracted" from the recorded ionization band patterns of the dissociation mixtures by digital subtraction of the computer-stored spectrum of pyridine (Fig. 1: hatched); they can then be assigned by Koopmans' correlation with MNDO eigenvalues, supported by characteristic band shapes and by comparison of the iso(valence)electronic molecules (Fig. 1).

The unexpectedly readily accessible "textbook" compounds, $ClP(=O)_2$ and $ClP(=S)_2$, not only extend the scope of preparative phosphorus chemistry but, at the same time, constitute a "missing link" in the discussion of planar tetraatomic molecules with 24 valence electrons. This will be discussed in greater detail for a series of such compounds based on their structures,[6] their π-radical cation states (see Fig. 1 and Ref. [7]), and their total- and π-charge densities calculated by the semiempirical MNDO method,[8] starting from the self-consistent Koopmans' assignment of the $ClPO_2^{\cdot\oplus}$ and $Cl_2PS_2^{\cdot\oplus}$ states (Fig. 2).

Obviously (Fig. 2), the structures of the planar 24 valence electron molecules Hal_3E, Hal_2EX, $HalEX_2$ and EX_3 are largely comparable; regarding the different EX bond lengths, reference is made to the various covalent radii, r_E and r_X.[6a] All of them possess six π electrons, so that in the case of D_{3h} symmetry the $M^{\cdot\oplus}$ states $1e'' < 1a_2''$ are to be expected, and on removal of the threefold axis in C_{2v} the sequence $1a_2 < 2b_1 < 1b_1$ (Fig. 2; exception $Cl_2C{=}S$ with $2b_1 < 1a_2$ (···) as a result of the readily ionizable π_{CS} group). A correlation according to dominant $M^{\cdot\oplus}$ contributions immediately demonstrates the influence of the effective nuclear charges: $\pi(1b_1)$ decreases from −14.7 to −18.1 eV (!) upon exchanging S → O and P → N; at the same time the $M^{\cdot\oplus}(1a_2)$ states, which might be used as "π-standard" because of their nodal plane through the bond Cl–E, unequivocally allow to read off $\alpha_S^\pi = 9.8$ eV or $\alpha_O^\pi \approx 12$ eV as respective parameters. Various interactions are superposed, which, for example, for the molecules $ClE(=X)_2$ can be discussed in terms of second order perturbations[9] $\beta^2_{Cl/PX2}/\Delta\alpha_{Cl/PX2}$ and are reflected in different $M^{\cdot\oplus}$ charge distributions: thus, the accompanying MNDO calculations for $ClP(=S)_2$ in its $\pi(2b_1)$ and $\pi(1b_1)$ states assign about 50% each Cl and PS_2 contributions, whereas for $ClP(=O)_2$ in $\pi(2b_1)$ 85% and—vice versa—in $\pi(1b_1)$ 88% PO_2 are obtained ($ClN(=O)_2$: $\pi(2b_1)$ 95% Cl and $\pi(1b_1)$ 94% NO_2). The charge distributions calculated by MNDO (Fig. 2) are also consistent with the π ionization patterns. In all cases except for the thio derivatives the positively charged center E is surrounded in a star-like fashion by negatively charged centers (Fig. 2; Q_μ^{MNDO}), whose "π back-bonds"—beginning with Cl_3B which in contrast to $(H_3B)_2$ is monomeric—lead to considerable π-electron densities (Fig. 2: $q_{\mu\pi}^{MNDO}$) at the centers E. Based on the general comparability of the tetraatomic molecules with 24 valence electrons, the following trend in polarization in accord with the effective nuclear charges and total electron densities becomes particularly evident:

$$\overleftarrow{B{-}Cl} > \overrightarrow{C{-}S} \quad \text{or} \quad \overrightarrow{P{-}S} < \overrightarrow{P{-}O} < \overrightarrow{N{-}O} \ll \overrightarrow{S{-}O}$$

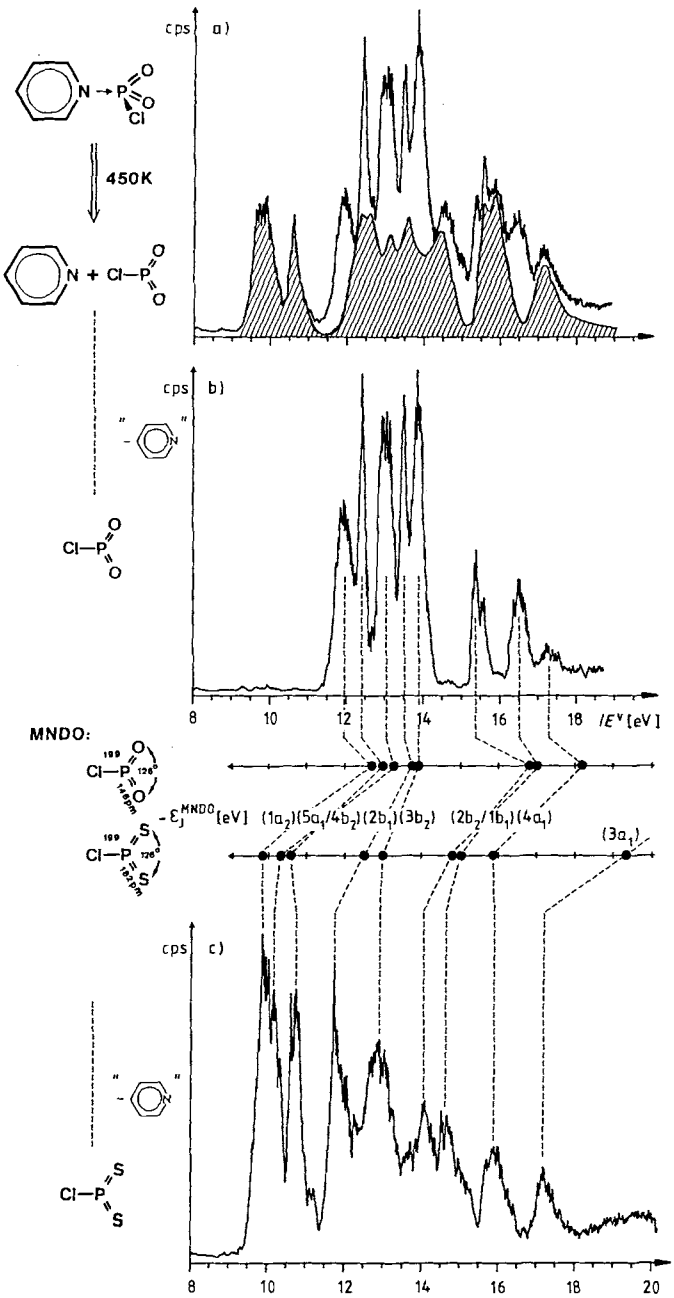

Fig. 1. He(I) PE spectra of the mixture formed upon dissociation of the betaines I at 450 K [5] in pyridine and $ClP(=O)_2$ (a) and of dioxophosphorus(v) chloride (b) and dithiophosphorus(v) chloride (c), extracted by digital subtraction of the computer-stored pyridine band pattern (hatched) [5] together with their Koopmans' assignment on the basis of MNDO eigenvalues.

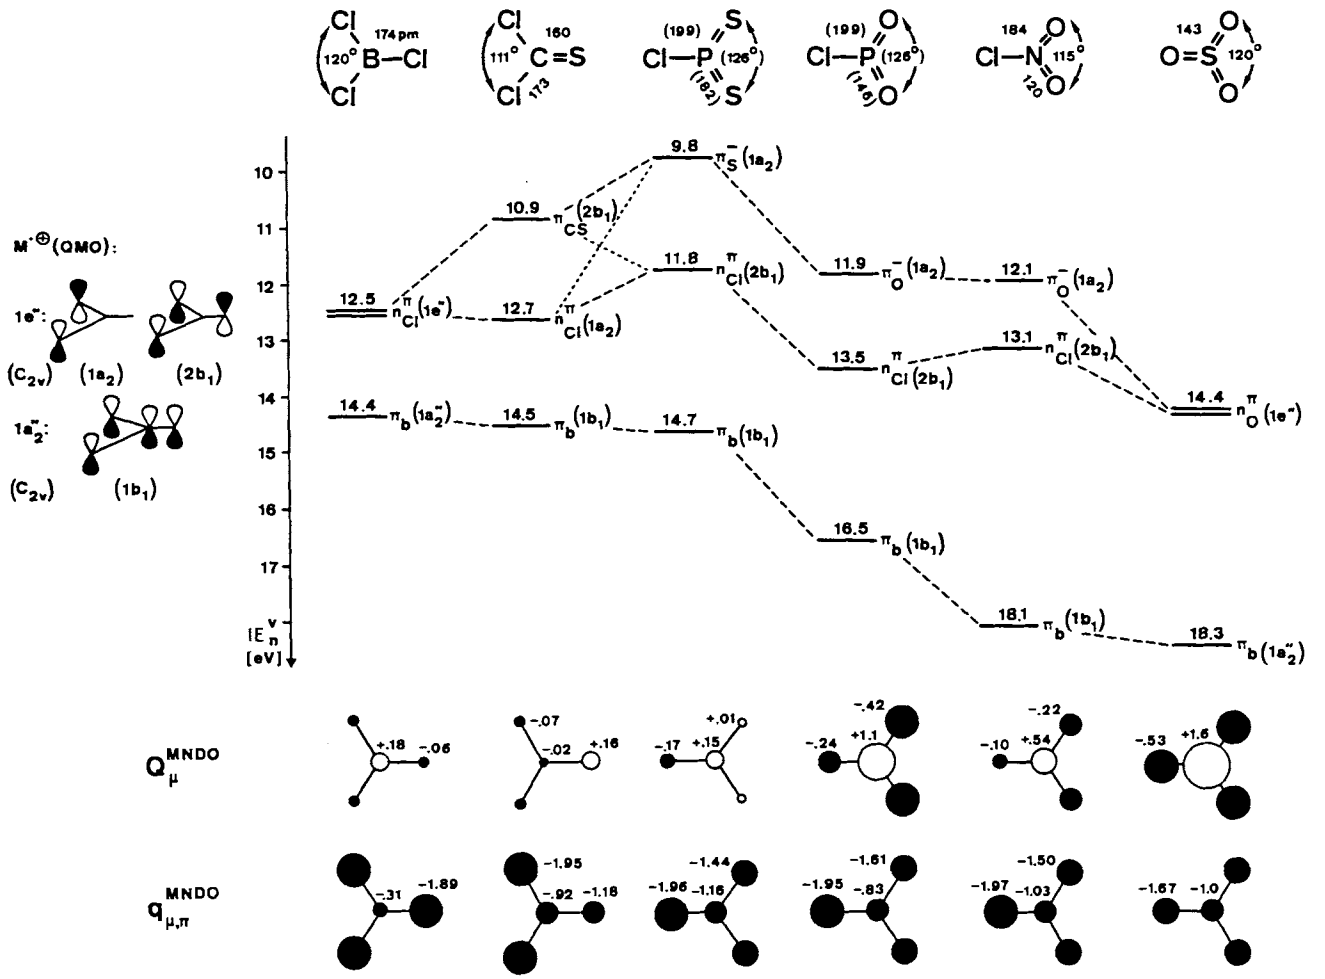

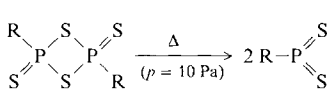

Fig. 2. Structures [6] of Cl_3B, $Cl_2C{=}S$, $ClP(=S)_2$, $ClP(=O)_2$, $ClN(=O)_2$ and SO_3, their vertical π-ionization energies [7] with $M^{+\bullet}$-state characterization by dominant contributions and (in brackets) the respective irreducible representations as well as total- and π-charge densities from geometry-optimized MNDO calculations [8] (cf. text).

Thus, the extreme π-back bonding in SO_3, for whose S center MNDO calculations yield the total charge +1.6 (!) (Fig. 2: Q_μ^{MNDO}) and which formally provides three of the six π electrons, partially replenishes the substantial electron deficit in the σ skeleton.

The preceding discussion of the PES data, supported by the calculated charge distributions, also enlightens various aspects regarding the still unknown reactivity of $ClP(=O)_2$ and $ClP(=S)_2$. For illustration, the suitability of $RP(=S)_2$ derivatives as novel complex ligands is pointed out, which can be expected because of the low first ionization energy (Fig. 1) and the electron distribution (Fig. 2). The reactive methyl and ethyl derivatives are easily synthesized by heating the preparatively accessible dimers in vacuum.[10]

R = CH_3, C_2H_5

With these molecules as well as $ClP(=S)_2$, the class of phosphorus(v) compounds $Y{-}P(=X)_2$ with three-coordinate phosphorus is further extended. The first prototype of this class, $(R_3Si)_2N{-}P(=NSiR_3)_2$,[11a] which is kinetically stabilized by steric encapsulation, has in the meantime been succeeded by numerous Y,X-substituted derivatives[11b] including the supermesityl compound $tBu_3C_6H_2P(=S)_2$[11c] and the trithiometaphosphate $[(H_5C_6)_4As]^{\oplus}[PS_3]^{\ominus}$.[11d]

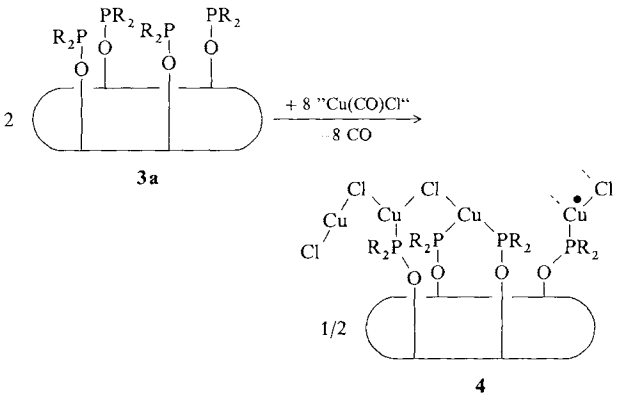
Aggregation of Metal Ions with Functionalized Calixarenes: Synthesis and Structure of an Octanuclear Copper(I) Chloride Complex**

By *Carlo Floriani,* Denis Jacoby, Angiola Chiesi-Villa,* and *Carlo Guastini*



A number of peculiarities, such as the simultaneous presence of a hydrophobic and a hydrophilic site, a receptor cavity, and the possible functionalization of donor atoms, make calixarenes[1] a very attractive class of molecules for binding metal ions[2] in the form of aggregates. In such metal derivatives both the cavity and the metal ions may act synergetically for the fixation and activation of certain substrates. Accordingly, we converted *p-tert*-butyl-calix[4]arene **1a**[3] and *p-tert*-butyl-calix[8]arene **1b**[3] using the 3-*tert*-butyl-2-chloro-1,3,2-oxazaphospholidine and the chlorodiphenylphosphane, into the corresponding multidentate phosphorus ligands[4] **2a,b** and **3a,b**, respectively. (Scheme 1).

Scheme 1.

Compounds **2a,b** and **3a,b** can be isolated in pure, crystalline form in very good yields (see Experimental Procedure). Crystals suitable for X-ray analysis are often difficult to obtain due to the tendency of the crystals to decompose by loss of solvent molecules. A further significant problem existing in calixarene chemistry is the possibility of various conformations. However, a "frozen" conformation can be obtained by adding bulky groups to the oxygen atoms.[1] In this work, cone conformation for calixarenes is supported by both NMR spectroscopy and X-ray structural analysis for **2a** and **4**, a metal derivative of **3a**.

We used $[Cu(CO)Cl]_n$[5] as a source of copper(I) which has a high affinity for phosphorus-containing ligands. The reaction of **3a** with $[Cu(CO)Cl]_n$ gave a polymetal species containing one copper ion per phosphorus atom. Only half of the symmetric dimer is shown in Scheme 2.

Scheme 2. The dot marks the center of symmetry.

This result was proven by analytical data (see Experimental Procedure) and is exemplified by the structure of **4**[6] (Fig. 1). Complex **4** is a centrosymmetric molecule, in which the eight phosphorus donor atoms derived from two *p-tert*-butyl-calix[4]arenes define a binding surface for six copper atoms. The mode of aggregation of such a polymetallic unit depends on a) the coordination requirements of the metal, b) the proximity of the phosphorus within the calixarene geometry, and c) the binding mode of the chloride ligand. The four copper atoms of the half-molecule are arranged in an irregular metal chain determined by the factors cited above. Since the reaction was carried out with a specific

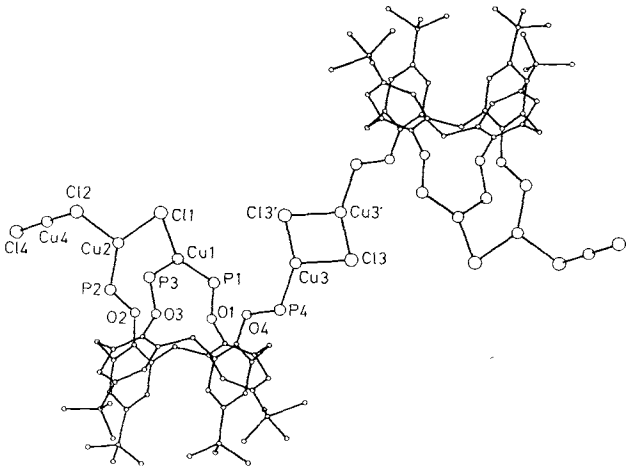

Fig. 1. Structure of complex **4** in the crystal. The oxazaphospholidine rings and the related structural parameters have been omitted for clarity. Bond lengths [Å] and angles [°]: Cu1-Cl1 2.251(5), Cu1-P1 2.210(4), Cu1-P3 2.233(6), Cu2-Cl1 2.275(5), Cu2-Cl2 2.295(5), Cu2-P2 2.167(5), Cu3-Cl3 2.217(6), Cu3-Cl3' 2.253(6), Cu3-P4 2.137(6), Cu4-Cl2 2.120(8), Cu4-Cl4 2.077(8), P1-O1 1.621(11), P2-O2 1.638(10), P3-O3 1.605(10), P4-O4 1.671(10); P1-Cu1-P3 129.5(2), Cl1-Cu1-P3 114.7(2), Cl1-Cu1-P1 114.6(2), Cl2-Cu2-P2 120.0(2), Cl1-Cu2-P2 136.7(2), Cl1-Cu2-Cl2 103.2(2), Cl3-Cu3-P4 148.0(3), Cl3'-Cu3-P4 111.2(2), Cl3-Cu3-Cl3' 99.3(2), Cl2-Cu4-Cl4 178.8(3). Prime indicates a transformation of x, $-y$, $1-z$.

stoichiometry and in the absence of any other good ligand for copper(I), the metal centers maintain low coordination numbers. The main structural features of complex **4** can be summarized as follows: 1) the conformation of half a molecule corresponds to the cone conformation of calix[4]arenes, the oxygen atoms almost forming a plane on one side of the molecule. They are arranged to form an irregular ellipse having the principal axes O1···O3 and O2···O4 equal to 3.536(13) and 5.994(12) Å, respectively, the other O···O distances ranging from 3.255(11) to 3.897(11) Å; 2) the P1, P2, P3 atoms are at the vertices of an approximate isosceles triangle (nearly parallel to the O1, O2, O3, O4 plane) with the two shorter edges P1···P3 [4.019(6) Å] and P2···P3 [4.115(7) Å] respectively chelating and bridging the Cu1 and Cu2 copper atoms. P1···P2 equals 4.457(6) Å, while the P···P distances involving P4 (displaced by 1.864(6) Å from the P1, P2, P3 plane) range from 5.504(7) to 8.995(6) Å; 3) the aggregation mode appears to be the result of a compromise between the flexibility of the ligand and the coordination needs of copper. The bridging capability of chlorine is relevant not only in causing dimerization but also in satisfying the coordination geometry of adjacent copper atoms which show a great adaptability, adopting digonal (Cu4), and trigonal (Cu1, Cu2, Cu3) coordination, and binding chlorine atoms at very different distances (see Fig. 1); 4) the Cu···Cu separations being the result of geometric constraints imposed by the ligand, varying from 2.930(3) [Cu1···Cu2] and 2.960(4) [Cu3···Cu3'] to 3.342(4) Å [Cu2···Cu4].

Experimental Procedure

2a, b and **3a, b**: The detailed procedure is given for **2a**, all the other compounds being synthesized by the same method. Yields are between 70 and 85% based on recrystallized products. Analytical and spectroscopic data agree with the proposed formulas. Spectroscopic and analytical measurements were carried out on crystals rigorously dried in vacuo. A hexane solution (77.5 mL) of *n*BuLi (1.6 M, 0.125 mol) was added at room temperature to a THF suspension (300 mL) of **1a** (20.0 g, 0.031 mol). An orange solution, containing some insoluble white solid formed, and then $ClPPh_2$ (22.8 mL, 0.125 mol) was added, keeping the suspension at 0 °C. The resulting light-brown solution was heated at 60 °C for 2 h. The solvent was evaporated and the residue dissolved in toluene (300 mL). LiCl was removed by filtration, and 75% of the toluene was evaporated. The slow addition of CH_3CN gave a light-yellow crystalline solid (31.0 g, 72%) which could be recrystallized from a toluene–acetonitrile mixture as white crystals and dried in vacuo (m.p. 225–227 °C). ^1H NMR (200 MHz, CD_2Cl_2): $\delta = 1.03$ (s, 9H, *t*Bu), 2.14 (d, 1H, $J_{HH} = 13.3$ Hz, CH_2), 4.00 (d, 1H, $J_{HH} = 13.3$ Hz, CH_2), 6.58 (s, 2H, C_6H_2), 7.07–7.44 (m, 10H, C_6H_5).

4: A THF suspension (300 mL) of CuCl (0.74 g, 7.70 mmol) reacted with carbon monoxide gave a suspension of the white microcrystalline "CuCOCl".[5] The ligand **3a** (2.28 g, 1.86 mmol) was then added as a solid at room temperature and rapid evolution of carbon monoxide was observed. The suspension was heated for 1 h at 50 °C, and a little insoluble solid was removed by filtration. The solvent was evaporated to a third of its original volume, causing a microcrystalline white solid to form (2.60 g, 86%). Crystals suitable for X-ray analysis were obtained from the mother liquor. The two solids are identical. Analysis was performed on crystals whose solvent of crystallization had been removed in vacuo. The amount of solvent determined by G.C. and ^1H NMR was ca. 2.5 THF molecules per calix[4]arene unit. Solvent molecules are only weakly bound. ^1H NMR (200 MHz, CD_2Cl_2): $\delta = 0.57$–1.81 (series of singlets, 18H, *t*Bu), 3.12–4.10 (series of multiplets, 6H, CH_2), 6.64–7.17 (m, 2H, C_6H_2). This ^1H NMR spectrum can be compared with that of the free ligand. $\delta = 0.966$–1.303 (singlets, 18H, *t*Bu), 2.97–5.31 (multiplets, 6H, CH_2), 6.64–6.94 (multiplets, 2H, C_6H_2).

[6] Structure of **4**: $C_{136}H_{208}Cl_8Cu_8N_8O_{16}P_8 \cdot 5C_4H_8O$, $M_r = 3611.5$, triclinic, space group $P\bar{1}$, $a = 18.175(2)$, $b = 22.033(2)$, $c = 15.523(1)$ Å, $\alpha = 106.19(1)$, $\beta = 112.29(1)$, $\gamma = 89.66(1)°$, $V = 5488.62(10)$ Å^3, $Z = 1$, $\varrho_{calcd} = 1.093$ g cm^{-3}, $\lambda(Cu_{K\alpha}) = 1.54178$ Å, $\mu(Cu_{K\alpha}) = 26.87$ cm^{-1}; crystal dimensions $0.30 \times 0.46 \times 0.55$ mm^3. The structure was solved by the heavy atom method (Patterson and Fourier synthesis) and refined by full-matrix least-squares. For 6285 unique observed structure amplitudes [$I > 2\sigma(I)$, corrected for absorption] collected at room temperature on a Siemens AED diffractometer in the range $6 < 2\theta < 120°$, the R value is 0.089. Five independent residues in regions far from the complex molecule, corresponding to five "partial" THF molecules were found from successive difference Fourier syntheses and isotropically refined trying different site occupation factors. The best fit was found for s.o.f's corresponding to a dimer/THF molar ratio of 1/5. The hydrogen atoms were ignored. Rigid body constraints were applied to the benzene rings and THF molecules. All calculations were carried out using SHELX 76. Further details of the crystal structure investigation are available from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England) on quoting the full journal citation.

$[Ir_2(\mu\text{-}CH_2)(CO)_4(Me_2PCH_2PMe_2)_2][CF_3SO_3]_2$, an Unprecedented Electrophilic Methylene Complex; $H^{\ominus}$ Addition to Prepare a Bridging Methyl Complex **

By *Mark K. Reinking, Phillip E. Fanwick,* and *Clifford P. Kubiak**

The first stable CH_2-bridged transition metal complex was prepared by *Herrmann* et al. in 1975.[1] Since then, numerous μ-alkylidene complexes have been reported.[2] "Herrmann

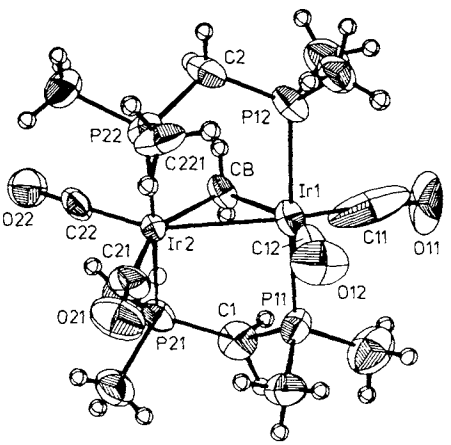
1

($J_{PH} = 8.5$ Hz) is assigned to the μ-CH_2 protons. Two dmpm methylene multiplets ($\delta = 3.25, 2.99$) and two methyl signals ($\delta = 2.12, 2.10$) are indicative of a *trans,trans* dmpm bridged structure.[4] The structure of **1** was confirmed by X-ray crystallography (Fig. 1).[5a, c] The μ-CH_2 group symmetrically bridges the two Ir atoms and exhibits metrical parameters (Ir1-CB 2.11(1) Å, Ir2-CB 2.10(1) Å; Ir1-CB-Ir2 81.5(5)°) essentially identical to those of the only other structurally characterized $Ir_2(\mu\text{-}CH_2)$ complex.[6]



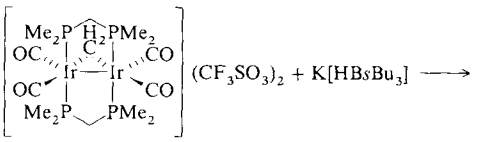


Fig. 1. Structure of $[Ir_2(\mu\text{-}CH_2)(CO)_4(dmpm)_2]^{2\oplus}$ in the crystal (ORTEP). Selected distances [Å] and angles [°]: Ir1-Ir2 2.7534(9), Ir1-CB 2.11(1), Ir2-CB 2.10(1), Ir-P(ave) 2.360(5); Ir1-CB-Ir2 81.5(5), Ir1-Ir2-CB 49.4(4), Ir2-Ir1-CB 49.1(4), P11-Ir1-P12 174.2(2), P21-Ir2-P22 175.3(1), CB-Ir1-C11 106.9(8), CB-Ir1-C12 149.2(7), CB-Ir2-C21 151.5(7), CB-Ir2-C22 100.4(7).

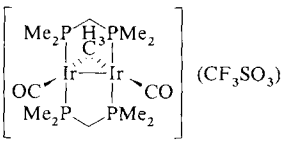
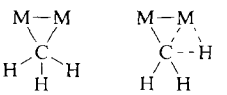


Bridging methylene ligands are generally considered to possess significant formal negative charge.[2, 7] Indeed, most Herrmann carbene complexes react readily with electrophiles.[1, 2] Remarkably, complex **1** is *completely unreactive* toward aqueous 1 M CF_3SO_3H. Similarly, reaction of **1** with Br_2 and I_2 does not result in formation of dihalomethanes.

However, the μ-CH_2 group of complex **1** is reactive toward nucleophiles. Addition of tri-*sec*-butyl borohydride (K-selectride, 1 equiv.) to a THF solution of **1** produces the methyl complex **2** [Eq. (b)].

1

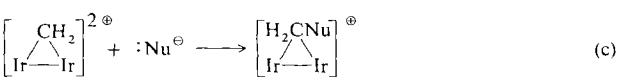


(b)

2

The IR spectrum of **2** exhibits two $\tilde{\nu}$(CO) bands at 1948(s) and 1915(s) cm^{-1} and a single dmpm $\tilde{\nu}$(P-C) band.[8] **2** has further been characterized by ^1H, 2D-NOESY ^1H, and $^{31}P\{^1H\}$ NMR studies, as well as by X-ray crystallography.[5b, c] The ^1H NMR spectrum of **2** shows a quintet at $\delta = 3.34$ ($J_{PH} = 4.7$ Hz), a multiplet at $\delta = 2.84$ and a singlet at $\delta = 1.85$. The quintet is assigned to the μ-CH_3 fragment.

Shapley et al. have employed equilibrium isotope effects to distinguish between symmetrical (**I**) and "agostic" (**II**) C···H···M interactions.[9]



I **II**

The partially deuterated complex $[Ir_2(\mu\text{-}CD_2H)(CO)_2(dmpm)_2][CF_3SO_3]$ $[D_2]$-**2** was prepared from $[D_2]$-**1** and K[HB*s*Bu$_3$]. The ^1H NMR spectrum of complex $[D_2]$-**2** at 25 °C however did not show a discernible difference in the μ-CHD_2 chemical shift compared to **2**. These data suggest that the μ-CH_3 group of **2** symmetrically bridges the metal centers in solution and that there are no significant C···H···Ir interactions at 25 °C (see [10]).

The structure of **2** is that of a symmetrically methyl-bridged "A-frame" complex (Fig. 2). A noteworthy feature of the structure is the overall "boat" conformation of the $Ir_2(PCH_2P)_2$ ring and close μ-$CH_3 \cdots CH_2(PMe_2)_2$ interactions (C31···C2, 3.24(4) Å, C31···C1, 3.11(4) Å). We have investigated the possibility of a μ-$CH_3 \leftrightarrow CH_2(PMe_2)_2$ exchange by 2D-NOESY ^1H NMR spectroscopy and find that if exchange does occur, the exchange rate constant, k_{ex}, is $< 1\ s^{-1}$. The extreme thermal sensitivity of **2** in various solvents at temperatures above −78 °C has so far frustrated our attempts to study the chemistry of **2** in more detail.

Complex **1** adds other nucleophiles to the μ-CH_2 group. For example, addition of NaOPh to a solution of **1** produces the cation $[Ir_2(CH_2OPh)(CO)_4(dmpm)_2]^{\oplus}$.[11]

The unprecedented reactivity of **1** toward nucleophiles is most likely due to a combination of factors which have not

(c)

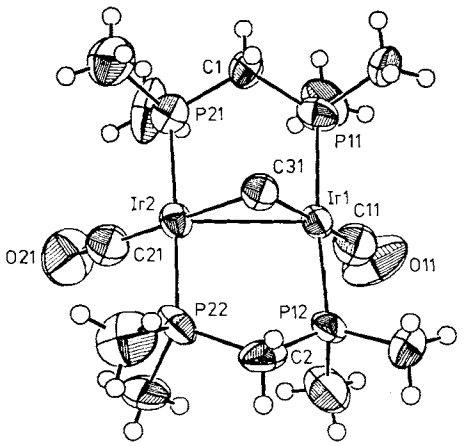


Fig. 2. Structure of $[Ir_2(\mu\text{-}CH_3)(CO)_2dmpm)_2]^{\oplus}$ in the crystal (ORTEP). Selected distances [Å] and angles [°]: Ir1-Ir2 2.885(1), Ir1-C31 2.19(2), Ir2-C31 2.17(2), Ir-P(ave) 2.328(8), Ir-C(ave) 1.95(4); Ir1-C31-Ir2 82.8(8), Ir2-Ir1-C31 48.3(6), Ir1-Ir2-C31 48.8(6), P11-Ir1-P12 171.0(3), P21-Ir2-P22 171.7(3), C11-Ir1-C31 173(1), C21-Ir2-C31 178(1).

been encountered previously. The dicationic nature of the complex effectively limits the metal electron density available for donation to the vacant p-orbital of the methylene fragment.[12] The presence of four carbonyl ligands diminishes the electron density on the μ-CH_2 group further.

Experimental Procedure

1 was prepared from $[Ir_2(CO)_4(dmpm)_2]$ (0.14 g, 0.18 mmol) in CH_2Cl_2 by reaction with 2 equivalents of $CF_3SO_3SiMe_3$ (0.073 mL) for 12 h. Yield: 0.14 g (70%). Me_3SiCl was identified as the only coproduct. $CF_3SO_3SiMe_3$ alone does not react with CH_2Cl_2.[13] ^1H NMR (CD_3CN): $\delta = 5.05$ (quint., 2H), 3.25 (m, 2H), 2.99 (m, 2H), 2.12 (s, 12H), 2.10 (s, 12H). $^{31}P\{^1H\}$ NMR (CD_3CN): $\delta = -45.8$(s), IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2071 (s, CO), 2033 (s, CO), 945 (s, PC). The corresponding μ-CD_2 complex was prepared from CD_2Cl_2 in place of CH_2Cl_2. ^1H NMR (CD_3CN): $\delta = 3.16$ (m, 4H), 2.08 (s, 24H). $^{31}P\{^1H\}$ NMR (CD_3CN): $\delta = -45.8$(s). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2065 (s, CO), 2033 (s, CO).

2 was prepared by addition of K-Selectride (0.07 mL of 1.0 M of tri-*sec*-butylborohydride in THF) to **1** (0.072 g, 0.066 mmol) in THF at -78 °C. The solution was immediately placed under vacuum and after 0.5 h the solution was allowed to slowly warm to room temperature under vacuum. Pure **2** was carefully removed and recrystallized from THF/hexane. Yields of this reaction were not consistent and varied from 0 to 80%. Numerous other attempts to synthesize **2** were made. The use of other $H^{\ominus}$ sources (catecholborane, sodium trimethoxyborohydride), different reaction and recrystallization solvents (C_6F_6, C_6H_6, CH_3CN, Et_2O), and higher reaction temperatures were not successful. ^1H NMR (CD_3CN): $\delta = 3.34$ (quint., 3H), 2.84 (m, 4H), 1.85 (s, 24H). $^{31}P\{^1H\}$ NMR (CD_3CN): $\delta = -37.2$(s). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1948 (s, CO), 1915 (sh, CO), 945 (s, PC).

trienedial under McMurry conditions.[2] After complete separation from **2** (colorless liquid) the cyclic hydrocarbon **1** crystallizes as colorless needles with a melting point of 35.5 °C.[3] **1** is of special interest as a tetrahomo-8π-system, when all four π-bonds are so arranged that maximum interaction is guaranteed. This arrangement is realized with the crown conformation[4] **1a**, which according to force-field calculations (MM2)[5] is predicted to be about 17.6 kJ mol^{-1} less in energy than the chair conformation **1b** (Fig. 1). The

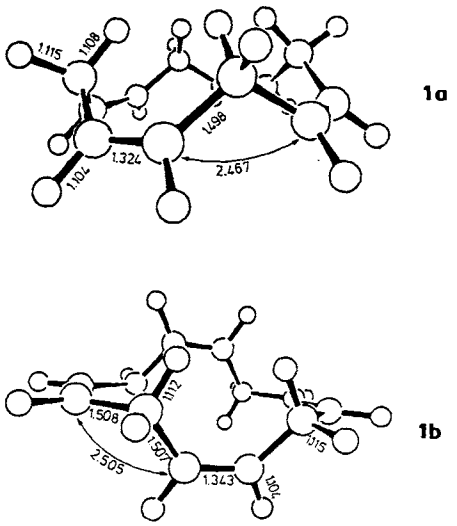

Fig. 1. MM2-optimized crown conformation **1a** and chair conformation **1b**; distances in Å. Calculated enthalpies of formation ΔH_f (strain energies SE) in kJ mol^{-1}: **1a**, 235.0(53.5); **1b**, 252.6(71.1).

X-ray structure analysis of **1** at 120 K[6] confirms the conformation **1a** in the solid state (Fig. 2), whereby eight independent molecules crystallize in the space group *Pbca*, and, within the limits of error, have C_{4v} symmetry. The C=C bond lengths (mean 1.324 Å) correspond approximately to those in the planar 1,4-cyclohexadiene **3** (1.318 Å),[7] whereas the single bonds (mean 1.503 Å) are somewhat longer then in **3** (1.486 Å). The distance between the CH_2-bridged sp^2 centers is on average 2.48 Å. As a result of the interactions between neighboring hydrogen atoms that are directed towards the center of the ring and whose separation, with a mean distance of 2.01 Å, is clearly shorter than the sum of the van der Waals radii of 2.4 Å (the C–H distances were expanded from the observed hydrogen positions to the standard value of 1.09 Å), all the C–C–C bond angles are widened (mean value: C(sp^2) 127.4°, C(sp^3) 111.2°). The intramolecular hydrogen distances agree astonishingly well with those obtained by ab-initio calculations on **1a** (HF–SCF, dz basis),[8] just as do the bond lengths and angles (maximum deviation 0.007 Å and 0.8°, resp.) as well as the torsion angles (experimental averages C–C–C=C 117.3, C–C=C–C 1.9°, calculated 116.5 and 0°, resp.).

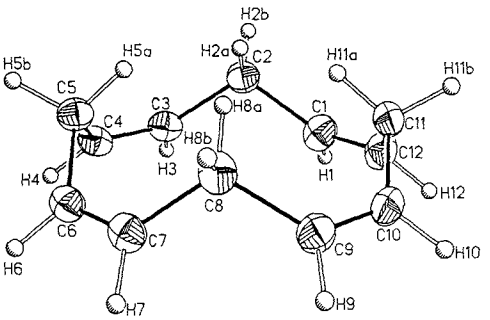

Fig. 2. Structure of **1** in the crystal (not systematically numbered) [6]. Distances [Å] and angles [°], standard deviation in parenthesis: C1-C12 1.323(2), C3-C4 1.326(2), C6-C7 1.325(2), C9-C10 1.321(2), C1-C2 1.506(2), C2-C3 1.503(2), C4-C5 1.501(2), C5-C6 1.507(2), C7-C8 1.506(2), C8-C9 1.503(2), C10-C11 1.505(2), C11-C12 1.495(2); C2-C1-C12 127.1(1), C2-C3-C4 127.5(1), C5-C6-C7 127.2(1), C8-C9-C10 126.8(1), C3-C4-C5 127.3(1), C6-C7-C8 127.7(1), C9-C10-C11 127.5(1), C1-C12-C11 127.5(1), C1-C2-C3 111.7(1), C4-C5-C6 110.3(1), C7-C8-C9 112.0(1), C10-C11-C12 110.8(1); C1···C3 2.489(1), C4···C6 2.469(1), C7···C9 2.495(1), C10···C12 2.470(1).

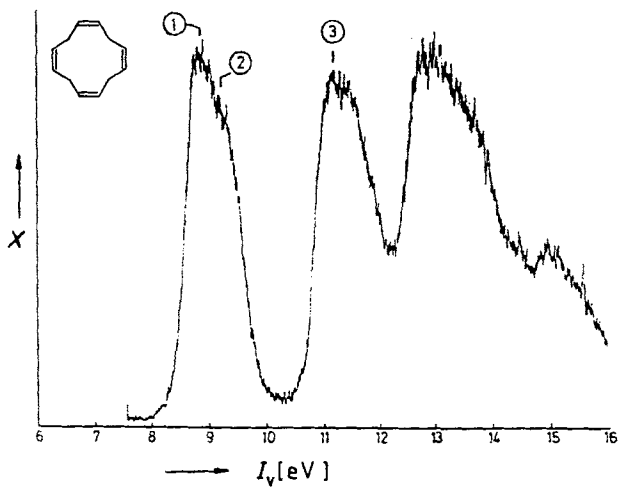

Fig. 3. PE spectrum of **1** [14]. x = count rate.

Table 1. Comparison of measured vertical ionization energies I_{vj} [eV] and calculated orbital energies ε_j [eV] of **1**.

	I_{vj}	Assignment	$-\varepsilon_j$ (HF–SCF)	$-\varepsilon_j$ (MINDO/3)
		$5b_1$	9.27	9.09
①	8.9	11e	9.43	9.29
②	9.3	$5a_1$	9.85	9.46
		$6b_2$	12.57	10.79
③	11.2	$3a_2$	12.84	10.89
		10e	12.99	10.90

The lower homologue all-*cis*-1,4,7-cyclononatriene **4**[9] is likewise present in the crown conformation, and its PE spectrum indicates a homoconjugative interaction of the three double bonds.[10] According to the concept of *Winstein* et al.[11] **4** is a trishomobenzene; however, the results of more recent investigations are inconsistent with a homoaromatic stabilization of the ground state.[12] Homoantiaromatic interactions have been observed in the monohomo-8π-system of 3*H*-cyclonona[*def*]biphenylene.[13] Therefore, it was to be expected that **1a** should be destabilized and thus **1b** be energetically more favorable. In order to establish incidental electronic interactions in **1**, the He(I) photoelectron spectrum[14] of this compound was recorded (cf. Fig. 3 and Table 1). It shows a broad band at 8.9 eV with a shoulder at 9.3 eV.

On the basis of semiempirical (MINDO/3)[15] and ab-initio calculations (HF–SCF, dz basis)[8] on **1a**, we assign to the first peak (①, ②) four ionizations from the π-MOs $5b_1$, $11e$, and $5a_1$. The small half-width of this peak contradicts a homoconjugative interaction. A similar bandwidth is found for **2** (I_{v1} = 9.1 eV). The results of a population analysis[16] for **1a**, SEN (C1···C3) = 0.06, likewise show that a significant homoconjugation is missing.

Our investigations show that **1**, in contrast to cyclooctatetraene, prefers a conformation in which all double bonds are coplanar. We attribute this to the absence of a homoantiaromatic destabilization.

Experimental Procedure

A mixture of 15.76 g (102.5 mmol) of $TiCl_3$ and 18.7 g of Zn/Cu couple in 1000 mL of dimethoxyethane (DME) was heated under reflux for 3 h in an inert atmosphere (Ar). A solution of 2.0 g (10.2 mmol) of *all,cis*-dodeca-3,6,9-trienedial[11] in 800 mL of DME was then added dropwise for 40 h and the mixture kept under reflux for a further 5 h before cooling and filtering over Florisil. The filtrate was evaporated to 50 mL using a 20-cm Vigreux column, treated with 250 mL of water, and extracted several times with pentane. The combined organic phases were washed with water, dried over Na_2SO_4, and concentrated to ca. 5 mL with a column. After chromatography on silica gel/pentane (2: R_f = 0.38; 1: R_f = 0.2) and removal of solvent by distillation, the enriched fractions of **1** and **2** were further purified by preparative gas chromatography,[17] at 115 °C (injector 200 °C). 150 mg (9.0%) of **2** (retention time 35 min) and 38 mg (2.3%) of **1** (retention time 45 min) were obtained. Colorless needles with a melting point of 35.5 °C (uncorrected) were obtained by careful sublimation of **1** at room temperature/50 torr.

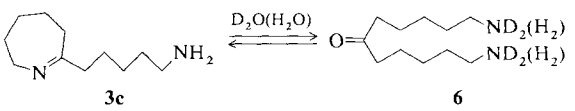
The First Tricyclic Diaziridines—a Simple Synthetic Route**



By *Sergej N. Denisenko, Eva Pasch,* and *Gerd Kaupp**

Diaziridines are of special interest with regard to the synthesis of anticancer drugs[1] and psychopharmaceuticals.[2] Numerous bicyclic representatives have been described,[3] but tricyclic condensed diaziridines were hitherto unknown. We report here on simple syntheses of **4a** and **4b** and on their ring-opening reactions leading to bicyclic protonated azomethine imines.

a: n = 1, **b:** n = 2, **c:** n = 3

When the lactams **1** are heated in the presence of LiOH, NaOH or CaO under strictly controlled reaction conditions, a complex reaction involving elimination of CO_2 takes place, leading to formation of the spiroaminals/iminoamines **2/3** in moderate to good yields which can be purified by distillation.[4–6] This provides an attractive preparative entry to **2/3**, because the starting materials are inexpensive. By-products are olefins and tar, and, in the case of **2b**, 2-methylpiperidine.[7] According to the NMR spectra (Table 1) in $CDCl_3$ and D_2O the plausible equilibria **2/3** lie either completely on the right-hand side (**3a, c**) or completely on the left-hand side (**2b**). Only **3c** is hydrolyzed to the diaminoketone (82% **6** at 25 °C in D_2O)—presumably due to ring strain effects. In the case of the isomeric pairs **2a/3a** and **2b/3b**, semiempirical AM1 calculations[8] give comparable energy values for the geometrically most favorably optimized conformations, so that prediction of this surprising behavior was not possible. Also hydrolysis equilibria can rarely be predicted reliably as yet.

Reaction of **3a** and **2b** with *tert*-butyl hypochlorite, or more conveniently sodium hypochlorite, leads respectively

to the diaziridines **4a** and **4b**. In contrast, no corresponding derivative **4c** could hitherto be obtained from **3c** because of a high tendency to polymerization and hydrolysis. After distillation, however, labile **7** could be isolated in 10% yield.

7

The highly strained tricyclic derivatives **4a, b** can be distilled without decomposition. Their structure is unequivocally established by the number and position of the signals in the ^1H and ^{13}C NMR spectra. On steric grounds, which are confirmed by AM1 calculations (with geometry optimization), they must be present in the *trans*-configuration (Fig. 1). Nevertheless, their stability is remarkable in view of the abnormal calculated bond angles at the quaternary carbon ($\sphericalangle$ CC_qC, CC_qN, NC_qN for **4a**: 121.5, 111.7, 57.3°; for **4b**: 112.5, 121.8, 57.3°). The bond angles calculated for *trans*-tetramethyldiaziridine (109.8, 123.1, 57.5°) are taken as normal.

The much greater strain in **4a** also manifests itself in large differences in the δ values of the quaternary carbon atoms

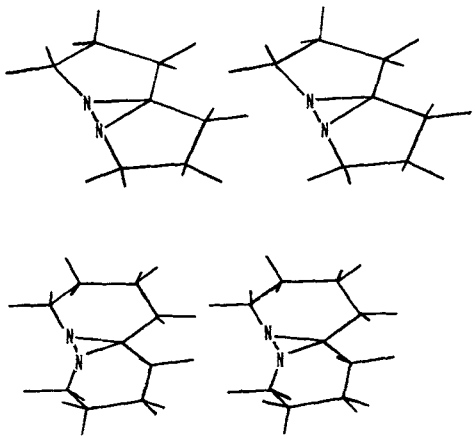

Fig. 1. Stereoplots of the optimized AM1 geometries of **4a** (top) and **4b** (bottom) (lowest energy symmetric conformation).

($\Delta\delta = 20$!) (see Table 1). The strain, however, is not released even by a conceivable ring opening to the isomeric azomethine imines (**5a/b**-CF_3COOH) upon distillation. In contrast, such ring openings very readily take place upon protonation.[9] Thus, the trifluoroacetates **5a** and **5b** of the azomethine imines are formed immediately upon dissolution in [D]trifluoroacetic acid. These are remarkably stable; even upon prolonged heating with concentrated HCl the protonated azomethine imines are not hydrolyzed to the expected ketohydrazines.[10]

The compounds **4a, b** should be very suitable for theoretical studies because of the restricted molecular mobilities, which are reflected in the spectroscopic data when the ring size is varied. Further physical measurements and quantum chemical calculations would be desirable.[11] For practical applications, nucleophilic substitutions at the quaternary C atom and cycloadditions with the tricyclic diaziridines appear attractive.

Experimental Procedure

2b: A mixture of **1b** (10 g, 100 mmol) and $LiOH \cdot H_2O$ (2.1 g, 50 mmol) was heated to 200 °C in order to distil off the water. Thereafter the crude product was driven over by heating to 320 °C. The crude mixtures from two batches were fractionated on a heatable rotary band column; yield 7.2 g (36%) **2b**.

3a [5] and **3c** [6] were prepared according to procedures given in the literature. Yields after rotary band column distillation: 88% and 55%, respectively.

4a: A mixture of **3a** (5.2 g, 41 mmol) and NaOH (3.0 g, 75 mmol) in water (70 mL) was treated with 30 mL of a 15% NaOCl solution at 5 °C. After 10 h stirring at 20 °C, 10 g of NaOH was added and the mixture extracted with CH_2Cl_2 and distilled at 14 torr over a Vigreux column; yield 3.8 g (74%) of **4a**. Compounds **4b** and **2b** were obtained analogously and purified by distillation. Yield 66%. Both diaziridines evolve iodine from aqueous HI. Reaction of **2b** with *t*BuOCl and NEt_3 in diethyl ether afforded 32% **4b**, while reaction of **3c** with *t*BuOCl and Na_2CO_3 in dichloromethane furnished 10% **7**.

Solvolyses of **4a** and **4b**: 100 mg of the respective diaziridine was dissolved with cooling in 1 mL of CF_3COOD and the ^1H NMR spectra were measured immediately. After evaporation of the solutions to dryness the ^1H and ^{13}C NMR spectra were measured in $CDCl_3$ and the UV spectra in CH_3OH. The same UV spectra were obtained after 1 h and ca. 2 min, when dilute solutions of **4a** and **4b** in CH_3OH were treated with one drop of 2N H_2SO_4 (1 mm cell).

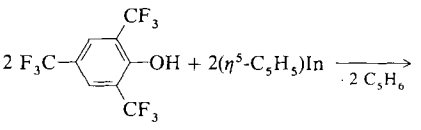
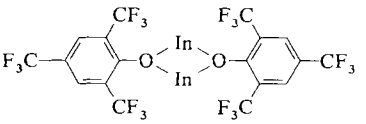
Indium 2,4,6-Tris(trifluoromethyl)phenoxide—a Dimer with the Coordination Number Two at the Indium Atoms**



By *Mario Scholz, Mathias Noltemeyer,* and *Herbert W. Roesky**

Dedicated to Professor Kurt Issleib on the occasion of his 70th birthday



Compounds containing low-coordinate boron have been the subject of numerous investigations just recently.[1] However, in the case of aluminum the number of structurally characterized compounds is not large, even with three-coordinate Al centers.[2]

We describe here the first synthesis of an indium(I) compound with two-coordinate indium atoms. 2,4,6-tris(trifluoromethyl)phenoxide appeared suitable as ligand to stabilize indium(I), for it is sterically demanding and has electron-attracting properties. 2,4,6-tris(trifluoromethyl)phenol **1**, prepared from bis(trimethylsilyl)peroxide and 2,4,6-tris(trifluoromethyl)phenyllithium,[3] reacts with cyclopentadienylindium[4] in *n*-hexane to give indium 2,4,6-tris(trifluoromethyl)phenoxide **2**. The title compound is formed in good yield (67%) as a white solid which is unstable towards air and water. In the FI-mass spectrum the molecular peak (*m/z* 824) is observed with low relative intensity (4%).

Single crystals suitable for an X-ray structure analysis[5] were obtained from *n*-hexane. Owing to the random arrangement of the CF_3 groups, the molecule has no crystallographic symmetry; the two phenyl groups, however, lie almost in one plane (2.9° deviation) and very nearly at right angles (within ± 2.5 pm) to the planar four-membered In_2O_2 ring.

1

2

The number of structurally investigated indium(I) compounds is small. Notable examples are $(\eta^5\text{-}C_5Me_5)In$[6] and the arene complexes investigated by *Schmidbaur* et al.,[7] which, however, are hexameric or polymeric in the solid state.

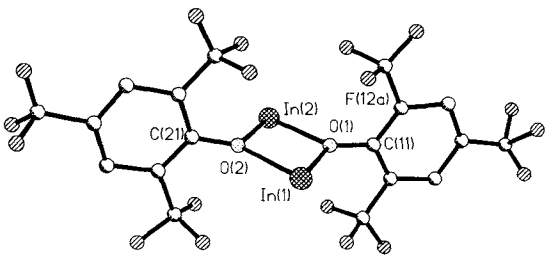


Fig. 1. Crystal structure of the dimer **2**.

The average In–O distance in **2** is 232.0 pm; this value can best be compared with that in complex **3** (217.1 pm).[8]

$[L_2In_2(MeCO_2)_4(\mu\text{-}O)] \cdot 2\ NaClO_4$ **3**, L = 1,4,7-triazacyclononane

At the same time, however, it must be taken into account that the indium atoms in **3** have the formal oxidation state + 3 and are octahedrally coordinated. The covalent radii of In (144 pm) and O (66 pm) would give an In–O distance of only 210 pm.[7]

Thus, the 2,4,6-tris(trifluoromethyl)phenoxide ligand appears to be preferentially suitable for the stabilization of metals with lower coordination numbers.[3]

Experimental Procedure

2: A solution of **1** (2.5 g, 8.3 mmol) in *n*-hexane (30 mL) was added dropwise to a suspension of $(\eta^5\text{-}C_5H_5)In$ (1.5 g, 8.3 mmol) in 30 mL of *n*-hexane at room temperature. The resulting colorless, slightly cloudy solution was allowed to stand for 12 h and then was filtered through a thin layer of celite. The filtrate was evaporated down to half its original volume and, upon cooling to 4 °C, **2** crystallized as a colorless solid. Yield: 2.3 g (67%) **2**. ^1H NMR (80 MHz, C_6D_6, TMS ext.): δ = 7.8 (s, Aryl-H). $^{19}F\{^1H\}$ NMR (75.39 MHz, C_6D_6, $CFCl_3$ ext.): δ = − 60.5 (s, *o*-CF_3), − 61.9 (s, *p*-CF_3). MS (70 eV): *m/z* 824 ($M^{\oplus}$, 4%). IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 1630 m, 1580 w, 1310 w, 1290 m, 1260 m, 1200 m, 1150 m, 1120 m, 915 m, 840 m, 790 m.

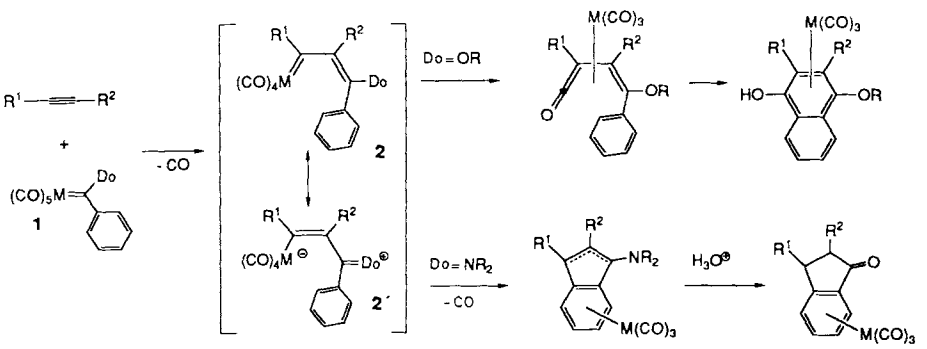
Activated Aminocarbene Complexes of the Fischer Type: Synthesis, Structure, and Annelation Reactions**

By *Karl Heinz Dötz,* Douglas Grotjahn*, and *Klaus Harms*

The annelation of Fischer type alkoxycarbene complexes[1] **1** (M = Cr, Do = OR) with alkynes leads to 4-alkoxyphenols[2] and is also of interest in natural product synthesis[3] because of its regioselectivity and the mild reaction conditions. The corresponding aminocarbene complexes (**1**: Do = NR_2) require higher temperatures (90–125 °C) and are annelated exclusively *without* incorporation of a CO ligand.[4] Apparently the better donor nitrogen strengthens the metal–CO bond and thus slows down the incorporation of the alkyne **1** or hinders a CO insertion in **2**/**2'**. We have now tried to weaken the marked donor character of the nitrogen-carbene substituent by its acylation and hoped at the same time that the amide function favored a decarbonylation of **1** (Do = NC(=O)R) with formation of a tetracarbonyl-chelate carbene complex. Chelate carbene complexes have already proven to be excellent starting materials for carbene annelation.[5]



After preliminary experiments with carboxylic acid chlorides, which immediately led via the expected *mono-N*-acyl species **4** to the *bis*acylation product,[6] we found that di-*tert*-butyl dicarbonate $(t\text{BuOCO})_2\text{O}$ is a selective monoacylating agent, which, in the presence of 4-dimethyl-aminopyridine (DMAP), is suitable for both amino- and *N*-alkylamino-carbene complexes (Table 1). Under the reaction conditions, predominantly the tetracarbonyl-chelate compounds **5** are formed directly via the pentacarbonyl(acylaminocarbene) complexes **4**, which can be detected during the reaction by IR spectroscopy and thin-layer chromatography. The decarbonylation is slower in the case of *alkyl*aminocarbene complexes than in the case of the *aryl* homologues; thus, in a CO-saturated solution **4f** is obtained as major product from **3e** together with only small amounts of the corresponding complex **5**. When less than 2 equivalents of di-*tert*-butyl dicarbonate and 0.1 equivalents of DMAP are used, the reaction does not go to completion. Only *N*-unsubstituted aminocarbene complexes (**3a**) react smoothly with Ac_2O/NEt_3/DMAP.

Table 1. Acylation of aminocarbene complexes. Conditions: 2.0 equivalents $(t\text{BuOCO})_2\text{O}$, 0.1 equivalents DMAP, Et_2O, 25 °C, 8–16 h.

	R	R^1	R^2	Product	Yield [%]
3a	*p*-Tolyl	H	*t*BuO	**5a**	83
3a	*p*-Tolyl	H	CH_3	**5b**	60 [a]
3b	*p*-Tolyl	Benzyl	*t*BuO	**5c**	76 [b]
3c	Phenyl	CH_3	*t*BuO	**5d**	57 [c]
3d	1-Cyclohexenyl	Benzyl	*t*BuO	**5e**	76 [b]
3e	CH_3	H	*t*BuO	**4f**	80 [d]

[a] In the presence of $(CH_3CO)_2O$ (1.49 equiv.) and NEt_3 (1.46 equiv.) instead of $(t\text{BuOCO})_2\text{O}$. [b] Total yield including aminolysis, based on the corresponding methoxycarbene complex. [c] Only 1.3 equiv. of $(t\text{BuOCO})_2\text{O}$ was used. [d] Under 1 bar CO.

The chelate complexes **5** form brown needle-like crystals that are briefly stable in air. The X-ray structure analysis[7] of **5a** (Fig. 1) shows a planar five-membered chelate ring with a short chromium–carbene bond (1.985(4) Å) and a

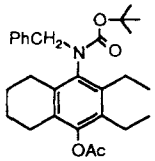
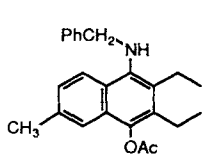
relatively long chromium–oxygen distance (2.144(3) Å).[8] In the ^{13}C NMR spectra the signals for the carbene carbon ($\delta = 311-330$) are shifted markedly downfield compared to that in aminocarbene complexes ($\delta \approx 280$) (for comparison: alkoxycarbene complexes $\delta = 330-350$). Above 0 °C, a rapid exchange on the NMR time scale is observed for the four CO ligands. This may indicate the formation of a fluctional coordinatively unsaturated tetracarbonyl-carbene fragment[9] and thus an easy opening of the chelate ring.



From the NMR spectroscopic and structural characteristics the arylcarbene chelate complexes appear to be suitable as starting materials for an aminocarbene annelation. Thus **5a, c, e** react with alkynes to give the aminoindenes **6, 7** and/or with insertion of CO to give the aminophenol derivatives **8–10**, whereby the non-alkylated complex **5a** affords primarily the five-membered ring compound **6**, whereas the benzyl complex **5c** furnishes mainly the six-membered ring compounds **8, 9**. As has been demonstrated by IR spectroscopy, $Cr(CO)_3$-coordinated annelation products are formed initially, which, however, are partly demetalated under the reaction conditions. Complete demetalation was



6: R = H

effected with Fe^{III} after in-situ acetylation of the aminonaphthols. The ready cleavage of the $Cr(CO)_3$ fragment is not unexpected, at least in the case of the benzyl-substituted annelation products **8–10**: herein the benzyl hydrogen atoms in the ^1H NMR spectrum are diastereotopic, indicating a sterically determined tilting of the amino substituents from the aminophenol plane, which in turn favors a demetalation. Terminal alkynes are incorporated with the regioselectivity known from the alkoxycarbene annelation: during the formation of five- and six-membered ring products the carbene carbon is preferentially added at the sterically less shielded alkyne carbon atom. By activation with the readily recleavable *tert*-butyloxycarbonyl (Boc) protecting group,[11] also aminocarbene complexes undergo selective annelation reactions under mild reaction conditions and open up – for example by an intramolecular variant – a new route to the synthesis of azapolyheterocycles.

Experimental Procedure

Example of an acylation: A solution of pentacarbonyl methoxy (4-methylphenyl)carbene chromium (1.20 g, 3.68 mmol) in 4 mL of ether was treated dropwise with 0.412 mL (3.77 mmol) of benzylamine. Upon completion of addition the solution boiled and, within 5 min, was decolorized. After 30 min the solution was concentrated in high vacuum and the viscous liquid residue was dissolved in a solution of 1.64 g (7.51 mmol) of $(tBuO_2C)_2O$ in 10 mL of ether. After addition of 45 mg (0.37 mmol) of DMAP the mixture was stirred at RT for 16 h. Subsequent workup by column chromatography on silica gel (– 20 °C, ether/petroleum ether 1/4 to 1/2) afforded **5c** as fine brown needles (1.33 g, 76%). – IR (KBr): $\tilde{\nu}$ = 2014, 1951, 1893, 1863 [$Cr(CO)_4$], 1660 cm^{-1} (NC=O); ^{13}C NMR (– 40 °C, CD_3COCD_3, 100.6 MHz): δ = 326.0 (Cr=C), 235.5, 230.6, 216.0 [1:1:2, $Cr(CO)_4$], 161.0 (NC=O), 145.5, 139.2, 137.1, 129.5, 129.4, 128.2, 126.7, 123.0, 89.5 ($OC(CH_3)_3$), 53.4 (NCH_2Ph), 27.3 [$OC(CH_3)$], 21.0 (CH_3 aryl); EI-MS: *m/z* 473 ($M^{\oplus}$, 1.65%).

Example of a carbene annelation: A degassed solution (triple sequence of freezing, evacuating and thawing, – 196 °C to RT, "freeze-pump-thaw") of 0.189 g (0.408 mmol) of **5e** and 0.093 mL (0.82 mmol) of 3-hexyne in 1.6 mL of toluene in a screw-capped vessel was heated to 55 °C for 4 h. The solution was then treated at RT with Et_3N (0.114 mL, 0.82 mmol), Ac_2O (0.069 mL, 0.73 mmol) and DMAP (4.8 mg, 0.020 mmol). After 3.5 h the mixture was oxidized with 0.6 g (2.2 mmol) of $FeCl_3 \cdot 1.5$ DMF.[12] After 20 min, filtration of the mixture with ether/petroleum ether (1/1) over silica gel and subsequent radial chromatography on silica gel with ether/petroleum ether (1/3) afforded 0.123 g (67%) of **10** as a viscous oil. Its NMR data showed the presence of two rotamers in the ratio 3:1. – Main rotamer: ^1H NMR (C_6D_6, 300 MHz): δ = 7.25–7.3 and 7.0–7.2 (m, 5H), 4.71 and 4.61 (each d, *J* = 13.9 Hz, each 1H, NCH_2Ph), 2.0–2.8 (m, 8H, CH_2 aryl), 1.85 (s, 3H, OAc), 1.35 [s, 9H, $C(CH_3)_3$], 1.3–1.6 (m, 4H), 1.15 and 1.07 (each t, *J* = 7.5 Hz, each 3H, 2 CH_2CH_3); secondary rotamer: distinct signals at δ = 4.47 and 4.44 (each d, *J* = 14.5 Hz, each 1H, NCH_2Ph), 1.85 (s, 3H, OAc), 1.54 [s, 9H, $C(CH_3)_3$]; IR (NaCl, CH_2Cl_2): $\tilde{\nu}$ = 1759 (OAc), 1696 cm^{-1} (NC=O); EI-MS: *m/z* 451 ($M^{\oplus}$, 6%).

Spectroscopic characterization of a five-membered ring annelation product: **6**: IR (NaCl, CH_2Cl_2): $\tilde{\nu}$ = 1699 cm^{-1} (NC=O); ^1H NMR (C_6D_6, 300 MHz): δ = 7.08 (d, *J* = 7.6 Hz, 1H), 7.05 (s, 1H), 7.00 (d, *J* = 7.5 Hz, 1H), 5.6 (br. s, 1H, NH), 3.26 (dd, *J* = 4.2, 5.4 Hz, 1H, CHN), 2.52 (dq, *J* = 7.5, 15 Hz, 1H), 2.25 (s, 3H, CH_3 aryl), 2.0–2.2 (m, 1H), 1.85 (ddq, *J* = 4.2, 7.4, 14.7 Hz, 1H), 1.64 (ddq, *J* = 5.4, 7.4, 14.7 Hz, 1H), 1.42 [s, 9H, $C(CH_3)_3$], 1.01 (t, *J* = 7.5 Hz, 3H), 0.54 (t, *J* = 7.4 Hz, 3H); ^{13}C NMR and multiplicity test (C_6D_6, 75.5 MHz): δ = 153 (br, NC=O), 145.2 (C), 141.7 (C), 140.9 (C), 134.0 (C), 127.3 (CH), 123.8 (CH), 118.3 (CH), 79.5 [$OC(CH_3)_3$], 48.2 (CH,CN), 28.4 [$C(CH_3)_3$], 22.8 (CH_2), 21.6 (CH_3 aryl), 19.9 (CH_2), 13.6 (CH_3), 8.5 (CH_3); MS: *m/z* 301.2059 ($M^{\oplus}$, 26%, calculated for $C_{19}H_{27}NO_2$: 301.2076).

Chlorocarbon Activation: Catalytic Carbonylation of Dichloromethane and Chlorobenzene**

By *Marc Huser, Marie-Thérèse Youinou,* and *John A. Osborn**

Chlorocarbons are of interest as intermediates but suffer from their relatively inert character (C–Cl bond energy ≈ 80 kcal mol^{-1}), and consequently catalytic functionalization of halocarbons has almost exclusively involved the use of the more reactive but expensive bromo- and iodo-compounds.

Dichloromethane is known to be activated by strong nucleophiles[1] or by oxidative addition (thermal[2] and photochemical[3]). Our initial objective was the monoactivation of CH_2Cl_2 using a mononuclear complex, allowing access in a catalytic process to chloromethyl organic products (e.g. $ClCH_2COOR$). Two conditions appeared necessary for monoactivation: a) an extremely electron-rich metal center and b) sufficiently sterically bulky ligands to impede further attack on the M–CH_2Cl unit. It was eventually found that Pd^0 complexes with strongly donating, but voluminous phosphanes, e.g. PCy_3 and $PiPr_3$, have the required properties. The complex **1a** reacts rapidly with CH_2Cl_2 at 25 °C, yielding after recrystallization the colorless chloromethyl complex **2a.**

$[Pd(PCy_3)_2(dba)]$ **1a**
dba = dibenzylideneacetone, Cy = cyclohexyl
trans-$[Pd(PCy_3)_2(CH_2Cl)Cl]$ **2a**
trans-$[Pd(PCy_3)_2(CH_2Br)Br]$ **2b**

Its ^1H NMR spectrum shows a triplet at $\delta = 3.92$ (2H, $^3J_{HP} = 8$ Hz) for the Pd–CH_2Cl resonance, as well as the cyclohexyl resonances. In the analogous bromomethyl complex **2b** prepared similarly from CH_2Br_2, the ^1H resonance of Pd–CH_2Br is shifted to $\delta = 3.70$. The $^{31}P\{^1H\}$ NMR (80 MHz, CD_2Cl_2) shows the expected singlet resonance at $\delta = 24.0$ (**2a**) and $\delta = 23.5$ (**2b**). Notably in the infrared spectra, the absorption at 650 cm^{-1} (assigned to νC–Cl) in **2a** is replaced by an absorption at 585 cm^{-1} (νC–Br). Similar observations have been made using $PiPr_3$ as ligand, but in contrast complexes with less basic ligands (e.g. $P(CH_2Ph)_3$, PPh_3 and PPh_2Cy) do not react with CH_2Cl_2.

When **2a** is treated with CO (30 bar) in C_6D_6 at 25 °C, the NMR spectra (^1H and ^{31}P) show the formation of the complex **3** and diketene **4**; the ^1H NMR signals appearing at $\delta = 4.56$ (1H), 3.92 (1H) and 2.88 (2H) are characteristic for diketene. Two feasible mechanisms (**A, B**) for this reaction are shown in Figure 1, both of which have analogues in the literature.[5, 6] We note that stable Pt^{II} ketene complexes (of type **5**) have recently been synthesized.[6c]

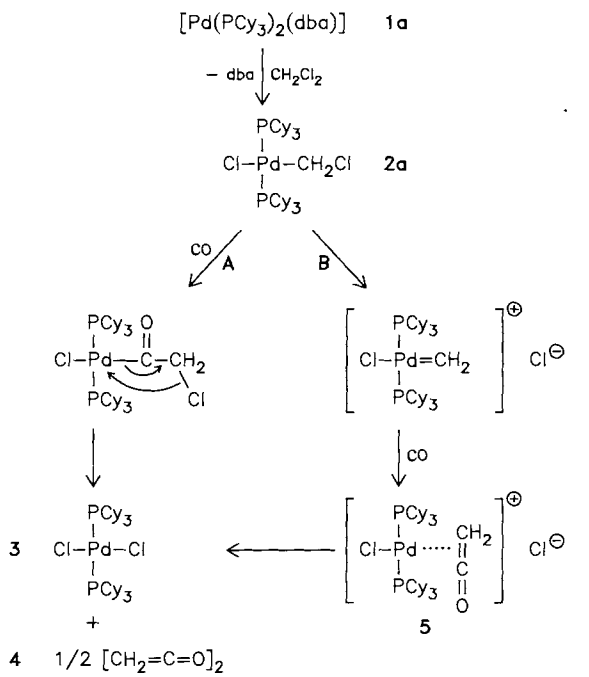

Fig. 1. Possible mechanisms **A** and **B** for the formation of ketene by carbonylation of **2a**.

Chlorobenzene activation by Ni,[7] Pd[8] or Pt[8c, 9] complexes has been reported, but a catalytic functionalization has so far not been observed. We have now found that solutions of the complexes **1** in chlorobenzene turn from orange to yellow at 60 °C and white crystalline phenyl complexes **6** can be isolated in good yields. Unexpectedly, under the same conditions neither the Pd^0 complexes with basic but more bulky phosphane ligands ($PtBu_3$, $PtBu_2Ph$) nor those of lower basicity but similar steric volume (PPh_2Cy, $P(m\text{-tol})_3$)

yield phenyl complexes of type **6**. Further, **6a**, can be rapidly carbonylated (25 °C, 30 bar CO) to yield **7a**; the reaction is reversible at 60 °C under argon.

$[Pd(PR_3)_2(dba)]$ **1**, $PR_3 = PCy_3$ (**1a**), PCy_2Ph, $P(CH_2Ph)_3$, $PiPr_3$
trans-$[Pd(PR_3)_2(C_6H_5)Cl]$ **6**, $PR_3 = PCy_3$ (**6a**)
trans-$[Pd(PR_3)_2(COC_6H_5)Cl]$ **7**, $PR_3 = PCy_3$ (**7a**)

The substituted chlorobenzenes, p-RC_6H_5Cl ($R = OCH_3$, NO_2, COOEt) also react to form complexes analogous to **7a**, the rate of reaction decreasing in the order $R = NO_2 > COOEt \gg H > OCH_3$. The X-ray structure analysis of the adduct, **6a**,[10] confirms the *trans* arrangement of the phenyl- and chloro-ligands (Fig. 2).

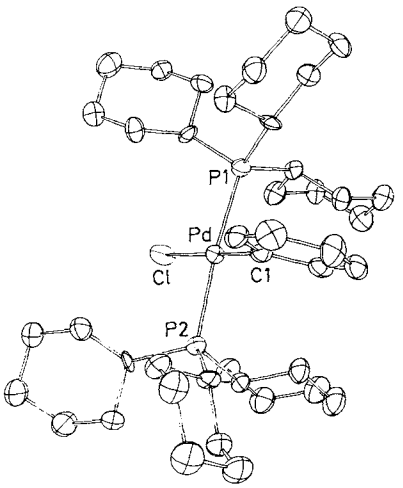

Fig. 2. Structure (ORTEP) of complex **6a**. Principal bond distances [Å]: Pd-P1 2.343(1), Pd-P2 2.347(1), Pd-Cl 2.403(1), Pd-C1 2.004(6); selected bond angles [°]: P1-Pd-P2 173.98(5), C1-Pd-Cl 177.5(2), Cl-Pd-P1 90.07(5), Cl-Pd-P2 90.05(5), C1-Pd-P1 90.4(1), C1-Pd-P2 89.8(1).

Under suitable conditions, the activation and functionalization of these chlorocarbons can be carried out catalytically with **1a**. Thus, the carbonylation of CH_2Cl_2 to ketene (or its derivatives) is possible if the complex **3** formed from **1a** can be reduced to regenerate the active species $Pd(PCy_3)_2$. This has been carried out using H_2 and a base B to trap the HCl formed as $BH^{\oplus}Cl^{\ominus}$. However, B must be a) a poor nucleophile (e.g. sterically hindered) to minimize chloride displacement in **2a** and quaternization of CH_2Cl_2, but b) more basic than PCy_3 to prevent protonation of the phosphane. Excess PCy_3 is used to maintain $Pd(PCy_3)_2$ as the predominant species of Pd^0 even under CO pressure. To illustrate the catalytic formation of ketene, NCy_2H was used as base so as to trap ketene by its reaction with the N–H function to form CH_3CONCy_2, which is stable under the reaction conditions and readily quantified. Hence, using **1a**/PCy_3 (1:3), CH_2Cl_2 (25 equiv.) and NCy_2H (50 equiv.) in toluene at 180 °C under CO/H_2 (30 bar, 1/1) a 40% yield of CH_3CONCy_2 and CH_3NCy_2 (1/1) is formed over 2.5 hours. Using $NEtiPr_2$ as base under the same conditions, both $CH_3CONiPr_2$ and $CH_3CONEtiPr$ were produced at a turnover rate of 5 (mol Pd)$^{-1}$ h^{-1}.

With chlorobenzene, two catalytic reactions were studied: alkoxycarbonylation and hydrocarbonylation with **1** or **6** as catalyst. The equations (a) and (b) show examples.

$$C_6H_5Cl + CO + ROH + B \rightarrow C_6H_5COOR + BH^{\oplus}Cl^{\ominus} \quad (a)$$

$$C_6H_5Cl + CO + H_2 + B \rightarrow C_6H_5CHO + BH^{\oplus}Cl^{\ominus}. \quad (b)$$

B = base

Typical conditions for these reactions are presented in the Experimental Section, but we note:

1) Significant catalytic activity is found only with phosphanes which are *both strongly basic* ($pK_a > 6.5$[11]) and with *well defined steric volume*, i.e. the cone angle θ[12] must exceed ca. 160° but be less than 180°. Hence in alkoxycarbonylation [Eq. (a)], only PCy_3 (pK_a 9.7, $\theta = 179°$) and $PiPr_3$ (pK_a 8.7, $\theta = 160°$) gave active catalysts, complexes involving smaller (PEt_3, pK_a 8.7, $\theta = 130°$), larger ($PtBu_3$, pK_a 10.3, $\theta = 182°$) or less basic phosphanes ($P(CH_2Ph)_3$, pK_a 6.0, $\theta = 165°$; PPh_3, pK_a 2.9, $\theta = 145°$) being totally inactive. Using methanol, both C_6H_5COOMe and C_6H_5COOEt were observed, the latter resulting from metathetical alkyl exchange with the base NEt_3. No double carbonylation products were detected.[13] In hydrocarbonylation [Eq. (b)], the use of PCy_3 and $PiPr_3$ again gave the highest activity, other phosphanes studied giving either inactive (PPh_3, $P(m\text{-tol})_3$, PPh_2Bu, $P(CH_2Ph)_3$) or poorly active (PEt_3, $PnBu_3$, $PtBu_3$) catalyst systems. The only products detected were C_6H_5CHO (ca. 90%) and C_6H_6 (ca. 10%).

2) On addition of *excess phosphane* to the catalyst system a) the Pd catalyst is more stable to decomposition and b) the rate of catalysis increases until a certain phosphane concentration is reached. Further addition of phosphane beyond this optimum value causes a decrease in the reaction rate. Thus, on using **6a** as catalyst, addition of 3 equiv. of PCy_3 increased the rate of hydrocarbonylation fourfold. However, if a further 5 equiv. of PCy_3 are added, the rate now observed is only twice that found initially. The optimum concentration of phosphane depends on the conditions used and, in general, increases with increasing CO pressure.

3) The *nature* and *concentration* of the *base* B are both important. The base must have a pK_a higher than that of the phosphane used if the phosphane is not to serve as proton acceptor. Further, the rate of hydrocarbonylation increases with increasing concentration of base used. Hence on doubling the base concentration under standard conditions, the catalytic rate increases from 1.9 to 3.4 (mol Pd)$^{-1}$ h^{-1}, the selectivity for C_6H_5CHO remaining constant.

The observation that a maximum rate occurs for a certain phosphane concentration can be related to two opposing effects. Firstly, an increase in phosphane concentration will increase the concentration of the C–Cl activating species, $Pd(PR_3)_2$, with a concomitant decrease in inactive carbonyl-containing species. A rate increase is thus expected but will only occur if the phosphane is sufficiently bulky to prevent further formation of less reactive $Pd(PR_3)_n$ (n = 3,4) species. Secondly, the rate limiting step in such reactions is the base-assisted alcoholysis[13] or hydrogenolysis of **7** which is inhibited by phosphane, addition of which will thereby cause a decrease in rate.

In conclusion, although the catalytic reactions of bromo- and iodo-aromatics are well known,[13] the analogous chloro-derivatives have resisted functionalization except when coactivated by coordination to a tricarbonylchromium moiety.[14] The molecular Pd complexes reported here show a well defined window of reactivity imposed by the electronic and steric properties of the phosphane ligands. Further, despite our preconceptions, the C–Cl activation of CH_2Cl_2 and C_6H_5Cl is not rate limiting in the catalytic process and, unexpectedly, is comparatively facile.

Experimental Procedure:

Synthesis of **2a**: 186 mg (0.2 mmol) of **1a** were dissolved in CH_2Cl_2 (10 mL). After 15 min, the red solution had turned yellow. The solvent was removed, and the recovered solid washed with 2×10 mL Et_2O and recrystallized from 1:1 $(CH_3)_2CO/Et_2O$ to yield colorless microcrystals. Yield 95 mg (65%). ^1H NMR (200 MHz, C_6D_6): $\delta = 3.92$ (t, $^3J(P-H) = 8$ Hz, 2H, Pd-CH_2Cl), 1.20–2.66 (m, 66H, C_6H_{11}P); $^{31}P\{^1H\}$ NMR (80 MHz, C_6D_6): $\delta = 24.0$(s); IR (nujol) $\tilde{\nu}$[cm^{-1}] = 650 (C–Cl); MS: $m/z = 715$ ($M^{\oplus} - Cl$), 701 ($M^{\oplus} - CH_2Cl$).

Synthesis of **6a**: 1.3 g (1.44 mmol) **1a** were dissolved in C_6H_5Cl (100 mL) and the solution heated at 60 °C for 2 h and filtered to remove traces of metallic Pd. After evaporation of the filtrate, the resultant colorless solid was washed with ether (50 mL) to extract free dba. Yield 850 mg (76%). Crystals suitable for an X-ray structure determination were obtained from toluene solutions. ^1H NMR (200 MHz, C_6D_6): $\delta = 7.74$ (d, 2H, H *ortho*), 7.13 (t, 2H, H *meta*), 7.00 (t, 1H, H *para*), 1.2–2.35 (m, 66H, C_6H_{11}, P); $^{31}P\{^1H\}$ NMR (80 MHz, C_6D_6): $\delta = 22.9$(s). Satisfactory microanalyses (C,H,P,Cl) were obtained. Similar procedures were used for other phosphane complexes **6**, and substituted chlorobenzenes.

Carbonylation of **2a**: a solution of 400 mg **2a** in C_6D_6 (10 mL) was stirred at room temperature under CO (30 bar). Sample were analyzed periodically by ^1H and $^{31}P\{^1H\}$ NMR. The reaction was complete after 48 h, giving **3** and diketene **4** quantitatively.

Catalytic experiments were carried out in a 125 mL autoclave (Hastelloy HB2): A typical experiment used: Pd complex (1 mmol), PCy_3 (total 5 mmol), CO (15 bar), C_6H_5Cl (50 mmol), NEt_3 (55 mmol), in toluene (total volume 30 mL), 180 °C. In reaction a) CH_3OH (50 mmol) was added; in reaction b) H_2 (15 bar) was used. The Pd catalysts originally used were **1** or **6** with 3 equiv. of PR_3 in addition, but their generation in situ under the appropriate conditions by use of $Pd(CH_3COO)_2$ with 5 equiv. of phosphane was found to give similar behavior. Products from a) were C_6H_5COOR where $R = CH_3$ or C_2H_5 with turnover rates of ca. 1.2 (mol Pd)$^{-1}$ h^{-1}. Products from b) were C_6H_5CHO and C_6H_6 (selectivity ca. 9:1) with a turnover rate of 1.9 (mol Pd)$^{-1}$ h^{-1}. Using no excess PCy_3, a rate of 0.5 (mol Pd)$^{-1}$ h^{-1} was observed. Using 110 mmol NEt_3, the rate of 3.4 (mol Pd)$^{-1}$ h^{-1} was measured.

Pronounced Anion Dependence of Valence Detrapping Temperature in Mixed-Valence 1′,1‴-Disubstituted Biferrocenium Salts**

By *Robert J. Webb, Arnold L. Rheingold, Steven J. Geib, Donna L. Staley,* and *David N. Hendrickson**

The study of intramolecular electron-transfer events in mixed-valence metal complexes[1] in the solid state has given fundamental information about environmental effects on rates of electron transfer. The lowest-energy electronic states are vibronic[2] and as a result mixed-valence complexes are very sensitive to their environments. The sensitivity to solvate molecules (S) has been demonstrated for mixed-valence μ-oxo-centered $[Fe_3O(O_2CCH_3)_6(py)_3] \cdot S$ complexes.[3] However, little is known of what effect a change in counterion has on the rate of intramolecular electron transfer in binuclear or trinuclear mixed-valence complexes. In this paper we report dramatic changes in the temperature of valence detrapping which occur for the mixed-valence 1′,1‴-diiodobiferrocenium and related cations as the anion is changed (see **1**).

1

X = I, Br, Cl, $CH_2C_6H_5$
Y = I_3, SbF_6, PF_6

Detailed physical data have been presented[4] for the $I_3^{\ominus}$ and Br–I–Br$^{\ominus}$ salts of various 1′,1‴-disubstituted biferrocenium cations. The $I_3^{\ominus}$ salts of the 1′,1‴-dibromo- and 1′,1‴-diiodobiferrocenium cations are valence detrapped (one

doublet) on the ^{57}Fe Mössbauer time scale at 4.2 K. This has been attributed[4d,f,g,i] to rapid tunneling ($> 10^9\ s^{-1}$ at 4.2 K) between the two vibronic states of the cation which are at equal energy as a result of the site symmetry of the cation in the crystal. On the other hand, the analogous 1′,1‴-dichlorobiferrocenium salt is valence trapped to 340 K, a fact attributed[4d] to an asymmetric positioning of the anion relative to the nearest cation. In this case one of the two vibronic states for the cation is at lower energy and the cation is valence trapped in this one state.

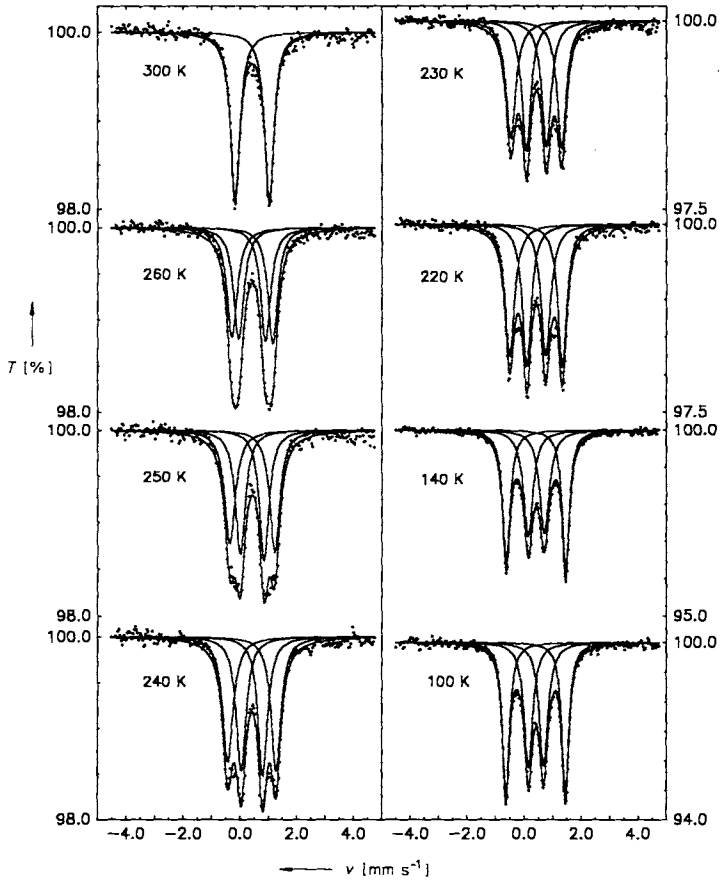

Fig. 1. Variable-temperature ^{57}Fe Mössbauer spectrum of a polycrystalline sample of 1′,1‴-diiodobiferrocenium hexafluoroantimonate. The solid lines result from least-squares fits of the data to Lorentzian lineshapes. T = transmission; v = rate.

It was surprising to find that changing from $I_3^\ominus$ to $PF_6^\ominus$ for the 1′,1‴-diiodobiferrocenium counteranion leads to a change from valence detrapped (one doublet) at 4.2 K to valence trapped at 350 K (two doublets) on the Mössbauer time scale. Furthermore, it was found that the $SbF_6^\ominus$ salt of this same cation begins to convert from trapped to detrapped at ca. 230 K and is completely converted by ca. 300 K (Fig. 1). It must be emphasized that the mixed-valence cation in all of these salts does have a potential-energy barrier for electron transfer, as evidenced by IR data where the ⊥ C–H bending mode is oxidation-state dependent.[5] The $I_3^\ominus$ salt has Fe^{II} and Fe^{III} bands at 820 and 845 cm^{-1}, respectively; the corresponding bands are found at 814 and 853 cm^{-1} for the $SbF_6^\ominus$ salt. A large IR band associated with the $PF_6^\ominus$ anion obscures this region, but it is clear from the Mössbauer data that this salt has a barrier. The cations in the $PF_6^\ominus$ and $SbF_6^\ominus$ salts are indicated to be electronically quite similar from their 7 K powder EPR signals: $g_{||} = 3.306$ and $g_\perp = 1.886$ for the $PF_6^\ominus$ salt and $g_{||} = 3.362$ and $g_\perp = 1.817$ for the $SbF_6^\ominus$ salt. These signals are characteristic of species which are trapped on the EPR time scale. 1′,1‴-Diiodobiferrocenium triiodide exhibits at 4.2 K quite a different powder EPR signal ($g_x = 1.97$, $g_y = 2.01$, and $g_z = 2.75$) which indicates it is also valence detrapped at 4.2 K on the EPR time scale.[4] The X-ray structure[4d] of the $I_3^\ominus$ salt shows that the cation does have the trans conformation found for the other compounds and the cation is relatively isolated from other cations.

Pronounced anion sensitivity of the valence-detrapping temperature has been observed for several other 1′,1‴-disubstituted biferrocenium compounds, yet there is no systematic response as the anion is changed from $I_3^\ominus$ to $PF_6^\ominus$ to $SbF_6^\ominus$. For example, the $I_3^\ominus$ salt of 1′,1‴-dibromobiferrocenium cation is detrapped at 4.2 K as with isostructural 1′,1‴-diiodobiferrocenium triiodide. However, in the case of the 1′,1‴-dibromobiferrocenium cation it is the $SbF_6^\ominus$ salt which remains trapped up to 345 K, whereas, the $PF_6^\ominus$ salt is detrapped down to at least 100 K.

For all twelve 1′,1‴-disubstituted biferrocenium compounds for which there is an X-ray structure[5–7] the mixed-valence cation assumes a *trans* conformation where the central ligand is essentially planar and remains so independent of temperature. Such is the case for 1′,1‴-dibenzylbiferrocenium $PF_6^\ominus$ and 1′,1‴-dibenzylbiferrocenium $SbF_6^\ominus$ salts of which we determined the 299 K X-ray structures.[8] These two compounds crystallize in sheets of 1′,1‴-dibenzylbiferrocenium cations separated by the anions. Figure 2 illustrates the packing in the $PF_6^\ominus$ salt. The mixed-valence cation has a center of inversion and the $PF_6^\ominus$ ion is disordered in two orientationally related positions. The inversional symmetry of the cation at 299 K is consistent with the observation that the cation becomes detrapped at ca. 165 K on the Mössbauer time scale. The two iron ions of the cation in the $SbF_6^\ominus$ salt are crystallographically inequivalent at 299 K. The Fe-ring ligand distances [Fe1-ring = 1.697(8) Å, Fe2-ring = 1.644(5) Å], as well as the Fe-Sb distances to the nearest $SbF_6^\ominus$ ion [Fe1-Sb = 5.649(8) Å, and Fe2-Sb = 6.166(9) Å] indicate Fe^{III} and Fe^{II} metallocene moieties for Fe1 and Fe2, respectively. Despite this asymmetry the $SbF_6^\ominus$ salt does de-

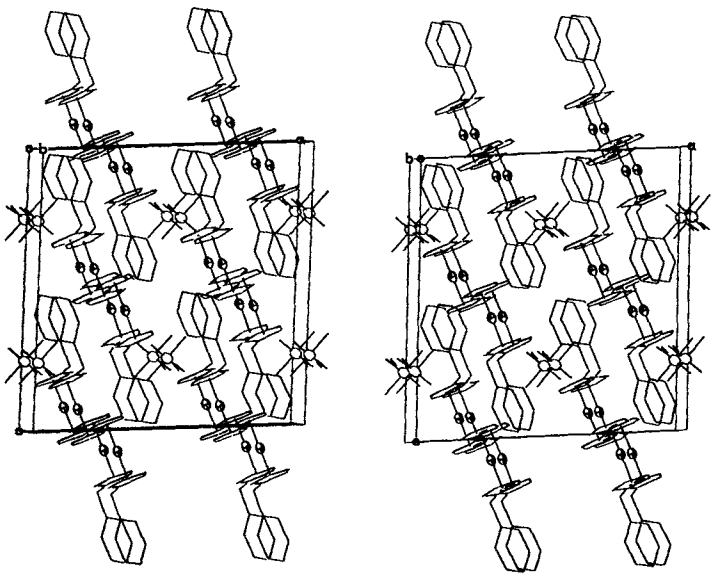

Fig. 2. Stereoview of the packing in $C2/c$ symmetry 1′,1‴-dibenzylbiferrocenium hexafluorophosphate. The viewing direction is approximately parallel to the b-axis.

trap in the vicinity of 200 K; however, in contrast to the $PF_6^\ominus$ salt the Mössbauer spectrum at high temperatures is a superposition of two valence-detrapped signals. The $SbF_6^\ominus$ complex is the first documented case of a binuclear mixed-valence complex with two crystallographically different metal ions which becomes detrapped as the temperature is increased. The two vibronic states for the cation are at different energies, but the difference in energy must be small enough to permit extremely fast thermally activated tunneling on the Mössbauer time scale. It appears that it is the coulombic interaction between the cation and its neighboring anions which dictate the rate of oscillation of the mixed-valence cation between its two vibronic states (i.e., electron-transfer rate).

It is the crystalline environment about a mixed-valence cation which is the most important factor controlling the rate of intramolecular electron transfer in complexes which have a potential energy barrier. It is not too surprising that the rate of electron transfer in chemical and biological systems can be sensitively controlled by subtle environmental conditions.[9] Understanding how the specificity of electron flow is controlled in biological electron transport chains is important.[10]

Novel Nickel Clusters with Se and Cp′ as Ligands: $[Ni_4Se_2(CO)BrCp'_3]$, $[Ni_6Se_4Cp'_5]$, $[Ni_{15}Se_{10}(CO)_3Cp'_8]$, and $[Ni_{15}Se_{10}(CO)Cl_2Cp'_8]$ **

By *Dieter Fenske** and *Achim Hollnagel*

Complexes of transition metal halides containing allyl-, cyclopentadienyl- or phosphane-ligands react with silyl derivatives of the elements P, As, S, Se, and Te to give metal-rich cluster complexes.[1,2] Our investigations, so far, show that the structures of the compounds formed are influenced by the solvent and the ligand bound to the transition metal atom. For example, upon reaction of $[NiCl_2(PPh_3)_2]$ with $Se(SiMe_3)_2$ mixtures of clusters are obtained containing 2,4,6,8,9,12,15 and 34 nickel atoms. In contrast, upon reaction of [NiCp(PPh$_3$)Cl] (Cp = cyclopentadienyl) with the same selenium reagent only tetranuclear complexes such as $[Ni_4Se_2Cp_4]$ **1** and $[Ni_4Se_2Cp_4(PPh_3)_2]$ are formed.[3]

If the complex [NiCp′(CO)Br][4] presumably formed in the reaction of $[NiCp'(CO)]_2$ (Cp′ = methylcyclopentadienyl) with Br_2 is allowed to react with $Se(SiMe_3)_2$ in diethyl ether, CO is evolved, and a finely crystalline black precipitate of **2**, **3** and **4** separates. After filtration of the reaction mixture black crystals of **2**, **3** and **4** can be isolated from the filtrate after several days standing. If the reaction is carried out in the presence of solid $NiCl_2$, **5** is also formed. Compounds **2**–**5** are only sparingly soluble in THF, acetone and dichloromethane, but cannot be recrystallized from these solvents without decomposition.

$[Ni_4Se_2(CO)BrCp'_3]$ **2** $[Ni_6Se_4Cp'_5]$ **3**

$[Ni_{15}Se_{10}(CO)_3Cp'_8]$ **4** $[Ni_{15}Se_{10}(CO)Cl_2Cp'_8]$ **5**

The IR spectra of **2**–**5** are almost identical, with the exception of the bands observable for the CO stretching vibrations in **2**, **4** and **5** [**2**: $\tilde{\nu} = 2004$ cm^{-1}; **4**: 1992, 1975(sh); **5** = 2001 (in KBr). The ^{1}H NMR spectra of the diamagnetic compounds **2**, **4** and **5** show characteristic signals for the Cp′ ligands.

To elucidate the molecular structures we carried out X-ray structure analyses on **2**–**5**.[5] Accordingly, **2** (Fig. 1) is a

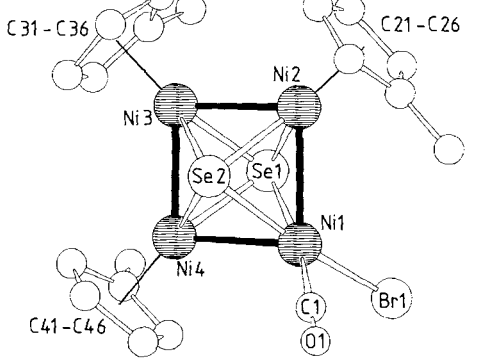

Fig. 1. Structure of **2** in the crystal. Important bond lengths [pm] and angles [°]: Ni1-Ni2 263.1(2), Ni1-Ni4 259.7(2), Ni2-Ni3 255.1(2), Ni3-Ni4 252.8(2), μ_4-Se-Ni 235.0–239.1(2), Ni1-Br1 237.2(2), Se1···Se2 301.3(2), Ni1-C1 192.4(1.7), Ni-C(Cp′) 210.5–216.1(1.2); Ni-Ni-Ni 87.6–91.4(1), Ni-Se-Ni 64.9–67.6 and 100.4–101.3(1), Se2-Ni1-Br1 171.8(1), Se1-Ni1-Br1 94.0(1), Se1-Ni1-C1 171.3(4), Se2-Ni1-C1 96.6(4), C1-Ni1-Br1 91.3(4).

[**] Cp′ = $C_5H_4CH_3$. – This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

square planar Ni_4 cluster in which Ni2, Ni3 and Ni4 are each bound to a η^5-Cp′ ring and Ni1 is coordinated by one $Br^{\ominus}$ ligand and one CO ligand. The Ni_4 square is additionally bridged by two μ_4-Se ligands. If one assumes that $Se^{2\ominus}$-, $Cp'^{\ominus}$- and $Br^{\ominus}$-ligands are present then Ni has the formal oxidation number + 2.

In contrast to the 68e-cluster $[Ni_4Se_2Cp_4]$ **1** (Ni–Ni 257–258 pm), the 66e-cluster **2** (Ni–Ni 252.8–263.1 pm) contains only two electrons more than one would expect according to the 18-electron rule. Complex **2** must be considered as a reactive intermediate for the synthesis of larger clusters. If, for example, **2** is allowed to react with [NiCp′(CO)Br] and $Se(SiMe_3)_2$ in THF the hexanuclear cluster **3** (Fig. 2) is formed by reaction at Ni1.

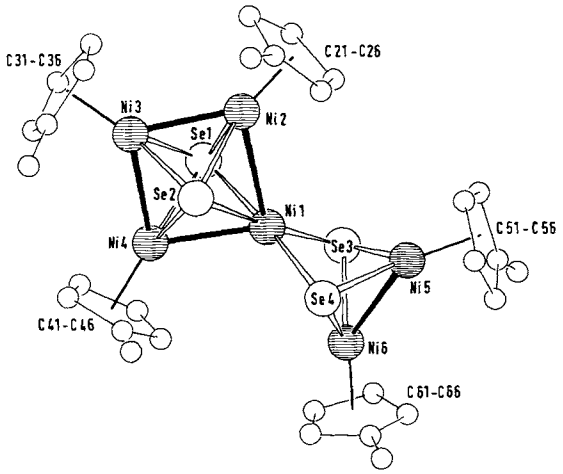

Fig. 2. Structure of **3** in the crystal. Important bond lengths [pm] (error ± 0.3 pm) and angles [°] (error ± 0.1°): Ni1-Ni2 262.9, Ni2-Ni3 251.4, Ni3-Ni4 250.2, Ni1-Ni4 261.3, Ni1-Ni5 319.4, Ni1-Ni6 319.3, Ni5-Ni6 253.1, Se1-Ni-(1–4) 236.8–238.2, Se2–Ni(1–4) 234.1–238.0, Se3–Ni(1,5,6) 227.1–230.7, Se4-Ni(1,5,6) 229.4–232.2, Se1 ··· Se2 304.6, Se3 ··· Se4 302.0; Ni-Ni-Ni (Ni_4-ring 88.1–93.1, Ni-μ_4-Se-Ni 63.6–67.3 bzw. 99.2–100.2, Ni-μ_3-Se-Ni 66.5–88.5.

Complex **3** also contains a planar Ni_4-ring, which is bridged by two μ_4-Se ligands. This Ni_4-ring is joined by two μ_3-Se ligands (Se3, Se4) to a Ni_2-dumbbell. With the exception of Ni1, which is planar coordinated by four Se atoms, all Ni atoms are bound to an η^5-Cp′ ligand; the Ni-μ_3-Se bonds (227.1–232.3 pm) are significantly shorter than the Ni-μ_4-Se bonds (234.1–238.2 pm). The Ni–Ni distances in the four-membered ring of **3** are comparable with those in **2**. In the same way, the distance Ni5–Ni6 (253.1 pm) can also be compared with the Ni–Ni bonding that has been found in other Ni clusters.[1, 6, 9, 11] If one assumes that five Ni–Ni single bonds are present in **3** the paramagnetic 101e-cluster contains three electrons more than would be expected according to the 18-electron rule.

In **2** and **3** the distance between the μ_4-Se and μ_3-Se ligands (301.3–304.6 pm) lies significantly below the van-der-Waals distance that has been found in Se_n and $Se_8^{2\oplus}$ [7] – possibly there is a weak interaction between the Se ligands, as has already been discussed for the μ_4-E ligands in $[Co_4(CO)_{10}(\mu_4\text{-}E)_2]$ (E = S, Te).[8]

The molecular structures of **4** and **5** (Fig. 3) are practically identical: In **4**, three Ni atoms (Ni10, Ni13, Ni15) are bound to CO ligands, and in **5**, two of these ligands (C1-O1 and C2-O2) are replaced by Cl1 and Cl2. The structures of **4** and **5** depicted in Figure 3 show that a previously unknown cluster condensation principle exists. Accordingly, **4** consists of

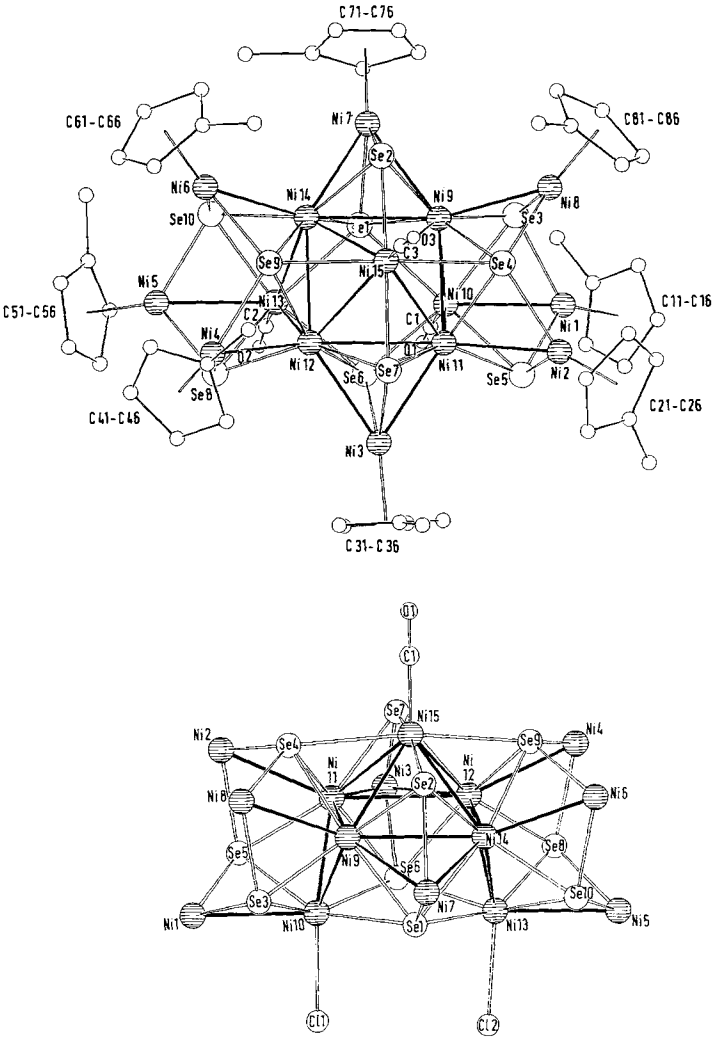

Fig. 3. Top: Structure of **4** in the crystal. Important bond lengths [pm] and angles [°] in **4** (error ± 0.2 pm and ± 0.1°, resp.): Ni1-Ni10 259.6, Ni2-Ni11 259.6, Ni3-Ni 261.3–265.9, Ni4-Ni12 252.3, Ni5-Ni13 259.0, Ni6-Ni14 257.2, Ni7-Ni 265.9–268.3, Ni8-Ni9 254.5, Ni9-Ni11 282.0, Ni11-Ni12 294.8, Ni12-Ni14 283.0, Ni9-Ni14 291.1, Ni15-Ni 271.8–273.5, Ni9-Ni10 259.5, Ni10-Ni11 259.0, Ni12-Ni13 258.5, Ni13-Ni14 259.0, μ_4-Se-Ni 228.3–248.6; μ_5-Se-Ni 232.7–258.2, Ni-C(carbonyl) 180–184(1), C-O: 108–113(2); ✳ □ (Ni9, Ni11, Ni12, Ni14) 89.2–91.0, Ni-Ni15-Ni 62.3–64.7, △ (Ni7, Ni9, Ni14) 56.6–66.0, △(Ni12, Ni13, Ni14) 56.9–66.3, △(Ni3, Ni11, Ni12) 55.3–66.3, Ni-(μ_4-Se)-Ni on Se2 and Se7 67.8–76.7 and 125.5–126.4, on Se3, Se5, Se8 and Se10 64.9–68.5 and 107.0–119.2, Ni-(μ_5-Se)-Ni on Se1 and Se6 63.5–95.9 and 117.0–126.7, resp., on Se4 and Se9 63.5–106.8 and 120.7–125.3, resp. Bottom: Structure of **5** in the crystal (without Cp′ groups). The bond lengths and angles in **5** differ by ±4 pm and ±2° maximally from those in **4**.

a central square Ni_5-pyramid (Ni9, Ni11, Ni12, Ni14, Ni15), in which the Ni–Ni distances in the Ni_4 base [**4**: 282–294.8; **5**: 278.9–289.9 pm] are distinctly longer than the distances to the pyrimid apex Ni15 [**4**: 271.8–273.5; **5**: 270.3–273.9 pm]. Eight further Ni atoms are bound to the Ni_5 cluster (Ni2–4, Ni6–8, Ni10, Ni13), whose distances from each another are 252.3–268.3. The cluster is completed by the atoms Ni1 and Ni5 bound to Ni10 and Ni13, respectively (Ni–Ni 259.0–261.5 pm). Eight η^5-Cp′ groups are bound to the peripheral Ni atoms 1–8 of **4** and **5**, and all faces of the Ni_{15} polyhedron are capped by Se ligands, which either function as μ_4-Se-ligands (Se2, Se3, Se5, Se7, Se8, Se10) or as μ_5-Se-ligands (Se1, Se4, Se6, Se9). The Ni–Se distances in **4** and **5** compare with the values which we have already found in other cluster complexes (Ni-μ_4-Se: 227.7–248.6, Ni-μ_5-Se: 233.1–257.8 pm).[9] The unusual μ_5-coordination of Se

atoms as in **4** and **5** was first observed quite recently in the complex ion $[Co_8Se_8(PPh_3)_6]^{\oplus}$.[10]

One could alternatively consider the structure of the Ni_{15} cluster consisting of four Ni_3 triangles (Ni1, Ni2, Ni8; Ni9, Ni10, Ni11; Ni12, Ni13, Ni14; and Ni4, Ni5, Ni6). The Ni–Ni distances in the outer rings (Ni1, Ni2, Ni8 and Ni4, Ni5, Ni6) are very long (368–378 pm), and in the inner rings (Ni9, Ni10, Ni11, Ni12, Ni13, Ni14) they are 258.5–283.0 pm, i.e. in the range for Ni–Ni bonds. The cluster core is completed by the atoms Ni3, Ni7 and Ni15.

If it is assumed that $Se^{2\ominus}$ and $Cp'^{\ominus}$ ligands are present in **4**, and $Se^{2\ominus}$, $Cp'^{\ominus}$ and $Cl^{\ominus}$ ligands in **5**, then the Ni_{15} clusters in **4** and **5** have the formal charges + 28 and + 30, respectively. Moreover, assuming that the Ni–Ni bonds depicted in Figure 3 are single bonds, it is surprising to note that the valence-electron concentration (226e) in **4** (236e) and **5** (234e) predicted according to the 18-electron rule is relatively well fulfilled. The 18-electron rule is rigidly fulfilled in the case of **5**, even if the long Ni–Ni distances in the central Ni_4 ring (282–294 pm) are interpreted as non-bonding contacts.

Also other authors have already reported on the synthesis of multinuclear nickel complexes with Cp ligands. Examples of such compounds are $[Ni_6Cp_6]^{n\oplus}$ (n = 0, + 1), $[Ni_5Cp_4S_4]$ and $[Ni_3Cp_3S_2]$.[11] Investigations currently under way, however, clearly demonstrate that a direct variation of the Cp ligands can lead to metal-rich cluster compounds with novel structures.

Experimental Procedure

A solution of $[NiCp'(CO)]_2$ (2.2 g, 6.63 mmol) in 35 mL of diethyl ether was treated with 0.34 mL (6.60 mmol) of Br_2 at − 80 °C. After 30 min, a solution of 1.41 mL (6.60 mmol) of $Se(SiMe_3)$ in 10 mL of diethyl ether was added dropwise. Evolution of CO was observed, and at the same time a black crystalline precipitate separated out which consisted of a mixture of **2**, **3** and **4**. After 24 h the residue was filtered off and the filtrate was allowed to stand for several days. A mixture of **2** (black needles), **3** (black hexagons) and **4** (black rhombuses) crystallized from the filtrate. When the reaction described above was carried out in the presence of 0.2 g of solid $NiCl_2$, **5** (black columns) was also formed. Yields: 30% **2**, 20% **3**, 20% **4**, and 30% **5**.

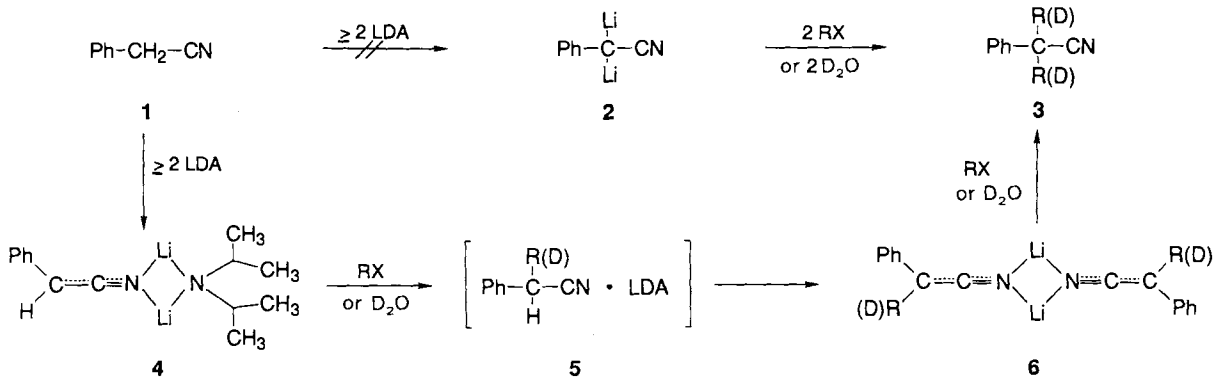
X-Ray Structure Analysis of α-Lithiophenylacetonitrile·Lithium Diisopropylamide·2 Tetramethylethylenediamine— a "Quasi-Dianion Complex"**



By *Wolfgang Zarges, Michael Marsch, Klaus Harms,* and *Gernot Boche**

The reaction of phenylacetonitrile **1** (or other CH-acidic compounds with acceptor substituents) with 2 mol equivalents of a base such as lithium bis(trimethylsilyl)amide, *n*-butyllithium or lithium diisopropylamide (LDA) misled one to the assumption that "dianions" of the type **2** were formed, since the subsequent alkylation with 2 mol equivalents of RX or the deuteriation with 2 mol equivalents of D_2O afforded dialkylated and dideuteriated products **3**, respectively, in ca. 80% yield.[1]

The complex $(CH_3)_3SiCCNLi_2$ recently characterized by us as a true geminal dianion by an X-ray structure analysis actually reacts with methyl iodide to give 2-methyl-2-trimethylsilylpropiononitrile in 86% yield.[2] However, *Meth-Cohn, Wakefield* et al. recently showed, on the basis of ^{13}C NMR investigations, that in the case of phenylacetonitrile under the aforementioned conditions, monoanions are formed which should be present, with a molecule of base, in the form of "quasi-dianion complexes (QUADACs)" having the structure **4**.[5] If this is the case, then the subsequent reaction of **4** is as follows: 1. RX or D_2O(!) reacts selectively with the PhCHCNLi moiety of **4**, whereby **5** is formed;[6] 2. **5** must be present as the LDA-adduct, since only a reprotonation within an adduct to give the anion **6** can compete with the intermolecular reaction of LDA with RX or D_2O(!).[7] In the subsequent alkylation (deuteriation) of **6**, **3** is formed. The assumption that PhCR(D)CNLi should be present as dimer **6**,[5] was confirmed by the solid state structure of $(PhCHCNLi \cdot TMEDA)_2 \cdot C_6H_6$ **7** (Scheme 1, structure without cocrystallizing C_6H_6).[8] In the following we demonstrate, on the basis of the solid state structure of **4** · 2 TMEDA,[9] that also the assumption of QUADACs was correct. Figure 1 shows the complexation via a Li–N–Li–N four-membered ring of the kind also found in the dimer **7**

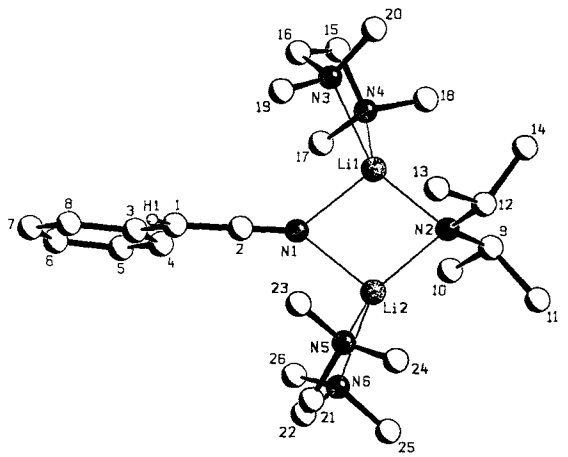
(and in other α-lithionitriles[2b]). The bond lengths Li1–N2 and Li2–N2 in the four-membered ring of **4** · 2 TMEDA (203.5(8) and 203.5(9) pm, respectively) compare very closely with those in the four-membered ring of **7** (mean value: 204(3) pm); the distances Li1–N1 (207.5(9) pm) and Li2–N1 (210.9(8) pm) are slightly longer. Since also the bond lengths in the PhCHCN moiety of **4** · 2 TMEDA and **7** are largely comparable, e.g. d(C1-C2) = 138.3(8) compared with 137.8(8) pm and d(C2-N1) = 117.3(7) compared with 117.9(8) pm, the PhCHCN anions in **4** · 2 TMEDA and **7** are similarly structured and bound to lithium. In contrast, the bonds from the TMEDA molecules to lithium differ completely in the two compounds. Thus, the mean value of the Li–N(TMEDA) distances in **7** (205(4) pm) is normal, and the TMEDA molecules are located at practically equal distances from both PhCHCN anions. In **4** · 2 TMEDA, on the other hand, the Li–N(TMEDA) distances are considerably longer [220(1), 220.6(9), 232.0(9) and 234.7(8) ppm[17]]. The TMEDA molecules are concomitantly bent away from the iPr$_2$N moiety towards the PhCHN moiety. The N1–Li1–N3 and N2–Li1–N3 angles (100.1(3)° and 135.2(4)°, respectively) demonstrate this very nicely. The sterically demanding isopropyl groups are undoubtedly responsible for the long Li–N(TMEDA) distances, and also for the bending away of the TMEDA molecules.[18, 19]



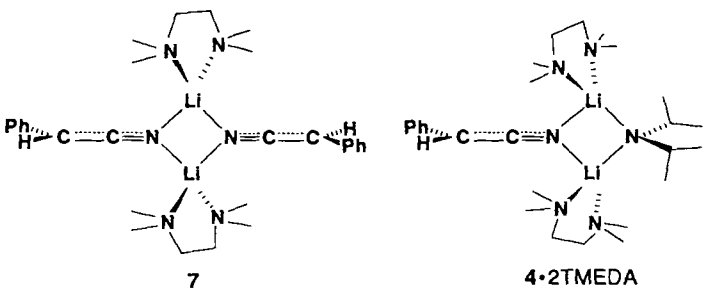


Fig. 1. Asymmetric unit of the structure of **4** · 2 TMEDA in the crystal [10]. Important bond lengths [pm] and angles [°]: Li1-N1 207.5(9), Li1-N2 203.5(8), Li1-N3 234.7(8), Li1-N4 220.6(9), Li2-N1 210.9(8), Li2-N2 203.5(9), Li2-N5 220(1), Li2-N6 232.0(9), C1-C3 143.2(8), C1-C2 138.3(8), C2-N1 117.3(7); C1-C2-N1 179.5(7), N1-Li1-N2 99.2(3), Li1-N2-Li2 82.7(3), N2-Li2-N1 98.1(4), Li2-N1-Li1 80.0(3), N1-Li1-N3 100.1(3), N2-Li1-N3 135.2(4) N1-Li1-N4 111.3(3), N2-Li1-N4 126.8(4), N1-Li2-N5 107.0(4), N2-Li2-N5 128.4(4), N1-Li2-N6 100.2(3), N2-Li2-N6 137.6(4).

4 · 2 TMEDA represents the first adduct of the QUADAC type to be structurally characterized.[20] Preliminary reactions with electrophiles confirm the reaction sequence outlined at the outset. Further details of the reaction, from which it follows that adducts such as **4** · 2 TMEDA have quite other properties than the two anions from which they form, will be reported later.

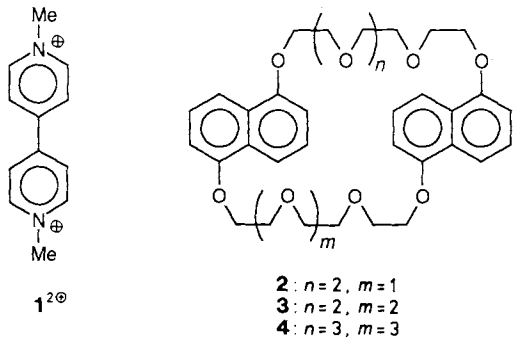
[16] Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-320008, the names of the authors, and the journal citation.

[17] The Li–N (TMEDA) distances in **4** · 2 TMEDA [232.0(9) and 234.7(9) pm] are the longest hitherto known. In three of the 97 Li-TMEDA compounds on the Cambridge Data Files, distances of between 230 and 231 pm were found: a) D. Seebach, R. Amstutz, T. Laube, W. B. Schweizer, J. D. Dunitz, *J. Am. Chem. Soc. 107* (1985) 5403; b) P. von R. Schleyer, R. Hacker, H. Dietrich, W. Mahdi, *J. Chem. Soc. Chem. Commun. 1985*, 622; c) W. Bauer, G. Müller, R. Pi, P. von R. Schleyer, *Angew. Chem. 98* (1986) 1130; *Angew. Chem. Int. Ed. Engl. 25* (1986) 1103.

[18] The long Li–N(TMEDA) distances were also attributed to "local overcrowding" in Ref. [17a].

[19] The space-filling of the isopropyl groups in the dimer $[(LDA)_2(THF)_2]$, in which the isopropylamide anions are likewise coupled via a Li–N–Li–N four-membered ring, leads to only *one* more THF molecule being bound to the only three-coordinate Li(P. G. Williard, cited as [81] in [7b]); a comparable situation is found in $[\{(Me_3Si)_2NLi\}_2 \cdot 2\,OEt_2]$ [M. F. Lappert, M. J. Slade, A. Singh, J. L. Atwood, R. D. Rodgers, R. Shakir, *J. Am. Chem. Soc. 105* (1983) 302].



[20] A mixed complex of the lithium enolate of 5-(*tert*-butyldimethylsiloxy)-3,3-dimethylpentan-2-one and LDA has been described: P. G. Williard, M. J. Hintze, *J. Am. Chem. Soc. 109* (1987) 5539.

A Polymolecular Donor–Acceptor Stack Made of Paraquat and a 1,5-Dihydroxynaphthalene-Derived Crown Ether **

By *Jean-Yves Ortholand, Alexandra M. Z. Slawin, Neil Spencer, J. Fraser Stoddart,** and *David J. Williams*

Our interest[1] in the rôle of dispersive forces in determining the complexing abilities and supramolecular structures of macrocyclic receptors containing π-electron rich aromatic units with π-electron deficient substrates (e.g. Paraquat $\mathbf{1}^{2\oplus}$) has led us to investigate the effect of varying both the macrocyclic ring size and the nature of the π-donor. Since a major contributing factor in complex formation is undoubtedly the presence and constitutional disposition of the aryl oxygen atoms associated with the π-donor, we have examined[2] the effect of replacing benzo with naphtho units in the macrocyclic polyether cyclophanes.

We have already established[2] that macrocycles, such as **2** and **3**, containing two 1,5-dihydroxynaphthalene residues will form 1:1 inclusion complexes with Paraquat $\mathbf{1}^{2\oplus}$. Furthermore, solution studies[3] on **4** also provide evidence for

$\mathbf{1}^{2\oplus}$

2: $n = 2$, $m = 1$
3: $n = 2$, $m = 2$
4: $n = 3$, $m = 3$

the formation of a 1:1 inclusion complex with $\mathbf{1}^{2\oplus}$. However, a single crystal X-ray investigation[4] has revealed not a 1:1 inclusion complex but – for the first time – a 2:1 stoichiometry[5] with the formation of a continuously stacked π-donor/π-acceptor structure with Paraquat dications alternately included within and sandwiched between adjacent macrocycles (Fig. 1). As in the case of the adduct $[\mathbf{3} \cdot \mathbf{1}]^{2\oplus}$, in the solid

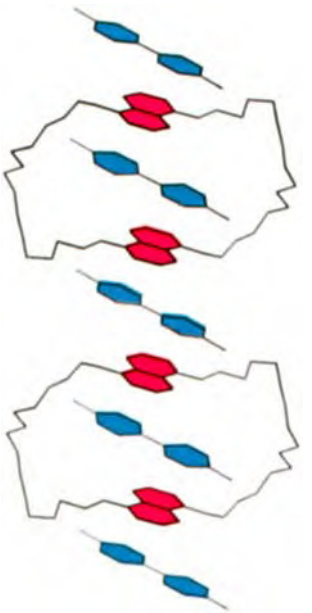


Fig. 1. Structure of $[\mathbf{4} \cdot 2\,(\mathbf{1})]_n^{4n\oplus}$ in the crystal (Paraquat = blue, 1/5 dinaphtho unit = red). Crystal data for $[\mathbf{4} \cdot 2\,(\mathbf{1})][PF_6]_4$. Me_2CO: triclinic, $a = 11.160(5)$, $b = 13.187(7)$, $c = 15.466(9)$ Å, $\alpha = 97.33(4)$, $\beta = 105.47(4)$, $\gamma = 107.86(4)^{\circ}$, $V = 2033$ Å^3, space group $P\bar{1}$, $Z = 1$ (the molecule is disposed about a center of symmetry), $\varrho = 1.41$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 19$ cm^{-1}. 3603 independent observed reflections with $[|F_0| > 3\sigma(|F_0|), 2\theta \leq 116^{\circ}]$, $R = 0.110$, $R_w = 0.120$.

state structure of $[\mathbf{4} \cdot 2\,(\mathbf{1})]^{4\oplus}$, a Paraquat dication[6] is positioned (Fig. 2) about a crystallographic center of symmetry and sandwiched within the macrocycle between the parallelly-aligned naphtho residues and oriented so as to maximize overlap between the two π-electron rich naphtho units and each pyridinium ring of the π-electron deficient dication. The second Paraquat dication[6] is also positioned (Fig. 1) about a crystallographic center of symmetry between parallel lattice-translated complexes and nearly perfectly co-aligned with its included counterparts. In contrast with $[\mathbf{3} \cdot \mathbf{1}]^{2\oplus}$, the interplanar separation between the naphtho units in the $[\mathbf{4} \cdot \mathbf{1}]^{2\oplus}$ complex[2] is reduced significantly from 7.1 to 6.8 Å with a consequent reduction in the receptor-substrate separation. The same interplanar separation is present between adjacent complexes and the intercalated Paraquat dications. Clearly, this continuous alternating arrangement

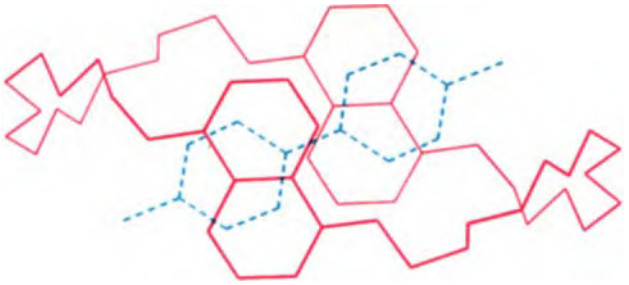

Fig. 2. Side-on view (normal to the mean plane of the Paraquat dication) of the skeletal representation of the $[\mathbf{4}\cdot\mathbf{1}]^{2\oplus}$ complex (Paraquat = blue, **4** = red).

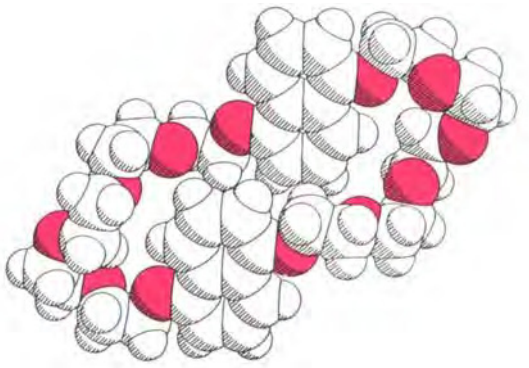
of π-donors and π-acceptors in the solid state merits further investigation, particularly in regard to potential conductivity properties.[7]

Since an important feature in the design of a molecular receptor targeted towards a specific substrate is the presence or absence of a pre-organized[8] receptor geometry, we have also investigated the solid state structure[4] (Fig. 3) of **4**[9].



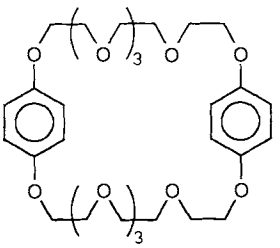


Fig. 3. Space-filling representation of the solid state structure of **4** (O = red). Crystal data for **4** · 7X where X corresponds to unidentified solvent fragments of scattering approximately equal to C atoms: monoclinic, $a = 8.750(3)$, $b = 15.056(4)$, $c = 16.270(5)$ Å, $\beta = 90.51(3)°$, $V = 2143$ Å^3, space group $P2_1/a$, $Z = 2$ (the molecule is disposed about a center of symmetry), $\varrho = 1.25$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 7$ cm^{-1}. 2031 independent observed reflections with $[|F_o| > 3\sigma(|F_o|), 2\theta \leq 100°]$, $R = 0.095$, $R_w = 0.098$.

This shows that this free macrocycle has a gross conformation highly reminiscent[10] of the crown ether **5**, which contains polyether chains of the same length. **4** is also self-filling and, unlike **2**,[2] does not display any intramolecular naph-

5

tho-naphtho stabilizing interactions. However, investigation of the crystal packing shows that the intermolecular face-to-face[11] and edge-to-face[12] interactions[13] are present.

Experimental Procedure

4: Partial benzylation [K_2CO_3 (1 mol equiv.)/DMF/rt/18 h] of 1,5-dihydroxynaphthalene with $PhCH_2Br$ (1 mol equiv.) afforded the monobenzylether (m.p. 136–138 °C) in 21% yield after chromatography (SiO_2:$CHCl_3$). Reaction [NaH(0.5 mol equiv.)/DMF/70 °C/12 h] of this naphthol with $Ts(OCH_2CH_2)_5OTs$ (0.5 mol equiv.) gave 1,14-bis-(5′-benzyloxynaphthoxy)-3,6,9,12-tetraoxatetradecane (70%, m.p. 90–92 °C) after chromatography [SiO_2:CH_2Cl_2/Et_2O (98:2)]. Deprotection (H_2/Pd on C, MeOH/$CHCl_3$), followed by reaction [NaH (3 mol equiv.)/THF/66 °C/96 h] of the derived dinaphthol with $Ts(OCH_2CH_2)_5OTs$ (1 mol equiv.) afforded **4** (39%, m.p. 89–91 °C) after chromatography [SiO_2:$CHCl_3$/Et_2O/MeOH (68.5:30:1.5)]. EI-MS: *m/z* 724; ^{1}H NMR (CD_3COCD_3): $\delta = 3.61$ (s, 8H), 3.63 (m, 8H), 3.69 (m, 8H), 3.89 (m, 8H), 4.12 (m, 8H), 6.75 (dd, 4H), 7.29 (t, 4H), 7.79 (dd, 4H); ^{13}C NMR (CD_3COCD_3): $\delta = 68.9, 70.4, 71.5, 71.5, 71.7, 106.6, 115.1, 126.0, 127.7, 155.3$.

[3] By employing the charge-transfer band as a quantitative spectroscopic probe ($\lambda_{max} = 416$ nm) at 25 °C, and subjecting the data to a modified (R. Foster, D. L. Hammick, A. A. Wardley, *J. Chem. Soc. 1953*, 3817; R. Foster: *Organic Charge-Transfer Complexes*, Academic Press, London 1969, p. 125) Benesi–Hildebrand treatment (H. A. Benesi, J. H. Hildebrand, *J. Am. Chem. Soc. 71* (1949) 2703) using experimental procedures recommended (W. B. Person, *J. Am. Chem. Soc. 87* (1965) 167; D. A. Deranleau, *ibid. 91* (1969) 4044) for weak complex formation (substrate concentration range, 1.0–9.1 mM), 1:1 stoichiometry was established in MeCN solution for the interaction between **4** and Paraquat $\mathbf{1}^{2\oplus}$. The value of 317 ± 5 M^{-1} obtained for K_a corresponds to $\Delta G^0 = -3.41$ kcal mol^{-1}. The receptor concentration was held constant at 1.8 mM and the substrate concentration was varied accordingly to ensure that UV/VIS absorption data were obtained in those regions of the "saturation curve" where errors are minimal. The data were corrected for a very weak absorption ($\varepsilon_{\lambda(max)} = 4.3$) in the 460–500 nm range. The inclusion nature of the 1:1 complex was confirmed by FAB-MS and ^{1}H NMR spectroscopy. **4** (5 mg, 6.9×10^{-3} mmol) was dissolved in $CHCl_3$ (< 1 mL) and **1** $[PF_6]_2$ (3.3 mg, 6.9×10^{-3} mmol) in Me_2CO (< 3 mL) was added. The red crystalline sample, obtained on evaporation of the solvent, was examined on a Kratos MS80RF mass spectrometer using argon. From a 3-nitrobenzylalcohol matrix, the crystals afforded a strong $[\mathbf{1}\cdot\mathbf{4}\cdot PF_6]^{\oplus}$ ion at *m/z* 1055 as a result of loss of one $[PF_6]^{\ominus}$ counterion from the 1:1 complex. The crystalline 1:1 complex was redissolved in CD_3COCD_3 for ^{1}H NMR spectroscopic studies. Relative to spectra recorded for free **4** and free Paraquat $\mathbf{1}^{2\oplus}$, chemical shift changes ($\Delta\delta$) of up to −0.29 were observed for the naphtho protons (H-3/H-7) in the receptor with $\Delta\delta$ values of −0.30 and −0.55 for the protons α and β to nitrogen in Paraquat $\mathbf{1}^{2\oplus}$.
[4] Nicolet R3m diffractometer, ω-scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structures were solved by direct methods and refined anisotropically. Further details of crystal structure investigations can be obtained from the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation of this communication.
[5] When the CD_3COCD_3 solution of $[\mathbf{1}\cdot\mathbf{4}][2PF_6]$, employed (Experimental Procedure) in the NMR spectroscopic studies, was subjected to vapor diffusion with iPr_2O, deep red colored single crystals, with a stoichiometry for **1**-$[PF_6]_2$:**4** of 2:1 and suitable for X-ray crystallography, were obtained.
[6] In contrast to the situation in previously characterized Paraquat inclusion complexes with macrocyclic polyethers, where stabilizing [C-H · · · O] receptor substrate interactions have been evident (see [1]), here (Fig. 1 and 2) there is a distinct absence of any such interactions. The shortest contact between any of the polyether oxygen atoms and the carbon atoms α to the nitrogen atoms in the Paraquat dications is a long 3.51 Å.
[7] Currently, experiments to obtain crystals of a size [at least 0.5 mm along the (110) direction] adequate for conductivity measurements are in progress.

A [2]Catenane Made to Order**

By *Peter R. Ashton, Timothy T. Goodnow, Angel E. Kaifer, Mark V. Reddington, Alexandra M. Z. Slawin, Neil Spencer, J. Fraser Stoddart,* Cristina Vicent,* and *David J. Williams*

Our discovery[1] of the ability of bisparaphenylene-34-crown-10 to form (Fig. 1) a 1:1 inclusion complex **1** with the paraquat dication ($PQT^{2\oplus}$) in both solution and the solid state by virtue of electron donor-acceptor interactions led[2, 3] to the successful realization that the donor-acceptor rôles of receptor and substrate could be reversed, giving rise to the 1:1 supramolecular complex **2** of cyclobis(paraquat-*p*-phenylene) with 1,4-dimethoxybenzene. The observation,[4] that a continuous alternating electron donor-acceptor stack is formed in crystals containing 1,5-dinaphtho-44-crown-12 and $PQT^{2\oplus}$ in a molar ratio of 1:2, suggested to us the possibility (Fig. 1) of combining the features of **1** and **2** to create the novel [2]catenane **3**. This communication reports 1) the highly efficient one-step template-directed synthesis (Scheme 1) of **3** from the bis(pyridinium) salt **4** · $2PF_6$, 1,4-bis(bromomethyl)benzene **5**,[5] and bisparaphenylene-34-crown-10 **6**,[1] 2) the crystal structure of **3** as its tetrakis(hexafluorophosphate) and MeCN adduct, 3) its dynamic ^1H NMR spectroscopic behavior, and 4) its intriguing electrochemical properties in solution.

When **4** · $2PF_6$ was stirred in acetonitrile at room temperature with 1.0 molar equivalent of **5**[5] and a 2.5 molar excess of **6**,[1] copious amounts of a red precipitate emerged from a highly colored solution. The 70% yield (see Experimental Procedure) takes no account of any product which remains in solution, i.e. a highly efficient reaction has ensued. Following the isolation of the crude product and its conversion into the tetrakis-(hexafluorophosphate), positive-ion FAB-MS revealed peaks at *m/z* 1491 and 1347 corresponding to loss of one and two $PF_6^{\ominus}$ counterions respectively from **3** · $4PF_6$. The complete lack of fragmentation ions thereafter down to *m/z* 810 for the loss of two $PF_6^{\ominus}$ counterions from the parent cyclobis(paraquat-*p*-phenylene) tetrakishexafluorophosphate substantiated the view that a [2]catenane had indeed been formed.[6] This deduction was confirmed by obtaining good quality single crystals, which were subjected to X-ray crystallographic analysis.[7, 8] This has exposed (Fig. 2 and 3) the elegantly ordered structural arrangement with the tetracationic cyclobis(paraquat-*p*-phenylene) intimately interlocked with the bisparaphenylene-34-crown-10. As anticipated, the dominant noncovalent bonding interactions are the electrostatic and dispersive forces associated with the mutual sandwiching of 1) a hydroquinol unit between parallelly-aligned bipyridinium moieties and of 2) a bipyridinium moiety between parallelly-aligned hydroquinol units. An important structural feature (Fig. 4) is the existence of an identical orientation within the tetracation of one of the hydroquinol units in **6** to that observed[3] in **2** for 1,4-dimethoxybenzene. In contrast to **1**, however, where the

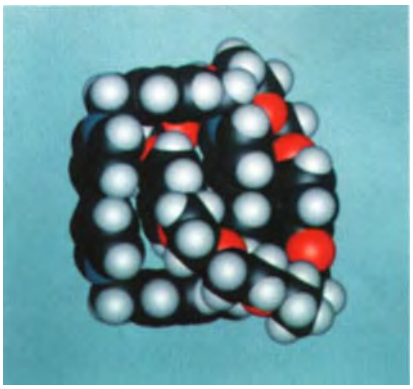

Fig. 2. Computer generated space-filling representation of the [2]catenane **3**.

macrocyclic polyether possesses[1] crystallographic C_i symmetry with its consequent alignment of the hydroquinol units, in **3**, they are no longer so oriented, probably as a result of their different stereoelectronic environments "in-

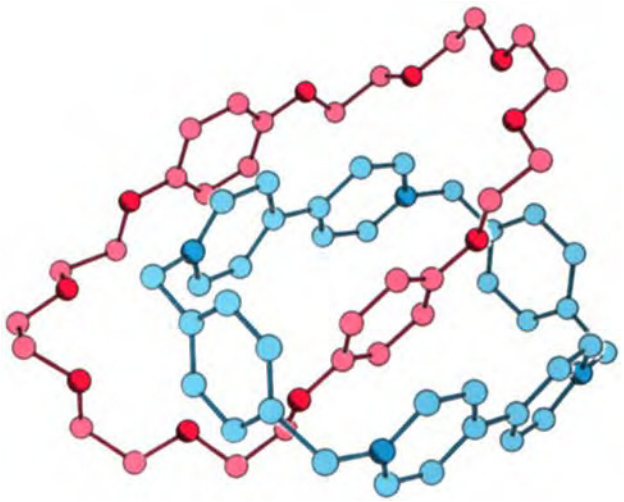

Fig. 3. Structure of **3** in the crystal with the donor and acceptor macrocycles shaded red and blue respectively. O atoms are dark red and N atoms are dark blue.

side" and "alongside" the tetracation. The effective interplanar separations between the two hydroquinol units and their associated bipyridinium moieties are, in all cases, ca. 3.5 Å. As observed previously,[3] there is a small twist angle of ca. 6° between the pyridinium rings within each bipyridinium moiety. Furthermore, the weak electrostatic edge-to-face

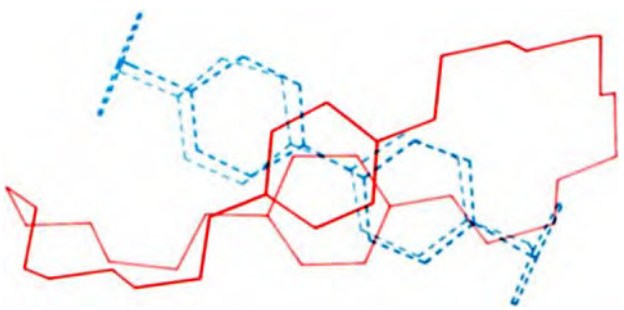

Fig. 4. Skeletal representation of **3** viewed normal to the plane of the hydroquinol ring lying within the tetracationic cavity. The donor is red and the acceptor is blue.

interactions, noted[3] in **2** between the orthogonally-aligned *para*-phenylene units in the tetracation and an included 1,4-dimethoxybenzene molecule, are also present in **3**.

Investigation of the packing[9] of the anions, tetracations, and solvent (MeCN) molecules uncovered the existence of continuously-stacked catenane entities aligned along the crystallographic *b* direction (Fig. 5). This alternating pattern

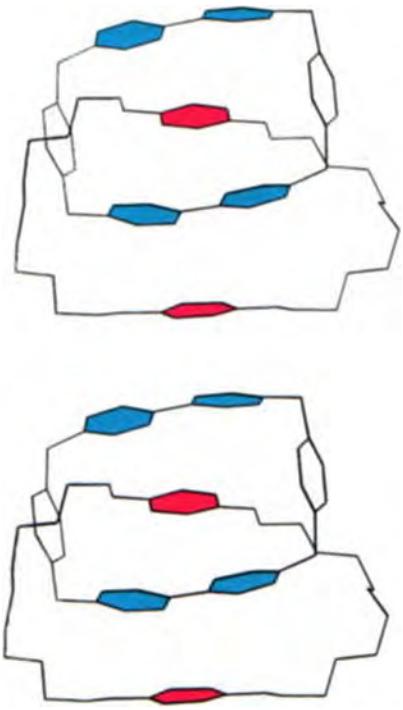

Fig. 5. Part of the continuous sequence of [2]catenanes **3** in the crystal. Donors are red and acceptors are blue.

of overlapping π-electron rich and deficient components is directly analogous to the solid state structure[4] of 1,5-dinaphtho-44-crown-12 incorporating two paraquat dications, one included within the macrocycle and the other sandwiched between adjacent 1:1 complexes. The approximate interplanar separation between overlapping π-electron rich and deficient components in adjacently stacked catenane entities is ca. 3.5 Å. Not only does the obvious possibility exist for investigating the conductivity in a suitably grown single crystal, but this polymolecular array provides a prototype for the design of a new generation of highly ordered electron donor-acceptor polymer chains.

Most importantly, the ordered arrangement of the [2]catenane **3** in the solid state is retained in solution. Dynamic ^{1}H NMR spectroscopy of $\mathbf{3}\cdot 4PF_6$ reveals (Fig. 6) the occurrence of temperature dependent processes operating both below (in CD_3COCD_3) and above (in CD_3CN or CD_3SOCD_3) room temperature. At + 25 °C, two equal intensity singlets are observed in CD_3CN at $\delta = 3.45$ and 6.16, which may be assigned respectively to the protons on the hydroquinol ring located "inside" the cavity of the tetracation and those on the hydroquinol ring associated with the face "alongside" one of the bipyridinium units of the tetracation (Fig. 7). The coalescence temperature (T_c) of + 81 °C observed at 250 MHz can be employed,[10] along with the limiting chemical shift difference ($\Delta\nu$) of 678 Hz between the singlets for the slowly exchanging protons, to obtain a $\Delta G_c^{\neq}$ value of 14.0 kcal mol^{-1} from the first order rate constant (k_c) of 1500 s^{-1} for the site exchange process. The free ener-

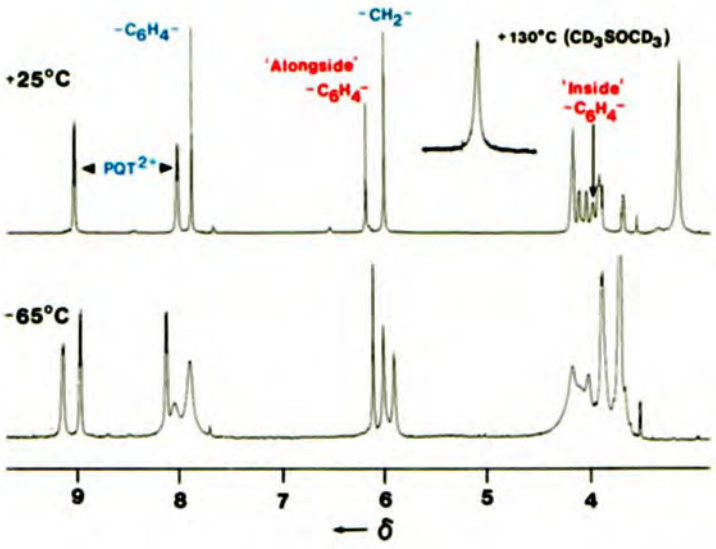

Fig. 6. The ^{1}H NMR spectra of $3 \cdot 4PF_6$ recorded in CD_3COCD_3 at -65 °C and at $+25$ °C. The signal for the phenylene protons in the bis(phenylene)-34-crown-10 portion of **3** is also shown recorded in CD_3SOCD_3 at $+130$ °C.

gy of activation ($\Delta G_c^{\ddagger}$) is for the degenerate supramolecular process (I) involving passage of the bisparaphenylene-34-crown-10 macrocycle through the center of the tetracation, leading to exchange of the hydroquinol rings (A and B) between "inside" and "alongside" environments. The other degenerate supramolecular process (II), which involves the exchange of the bipyridinium rings (A and B) of the tetracation between "inside" and "alongside" environments with respect to bisparaphenylene-34-crown-10, requires one hydroquinol ring in the macrocycle to sweep round the external periphery of the tetracation by pirouetting about the O–C_6H_4–O axis of the other hydroquinol ring. A $\Delta G_c^{\ddagger}$ value of 12.2 kcal mol^{-1} was obtained for this process from the temperature dependence of the signal for the benzylic methylene protons of the tetracation in the ^{1}H NMR spectrum of **3** in CD_3COCD_3, which resonates as a singlet at $+25$ °C but separates[11] out into two equal intensity singlets at -65 °C

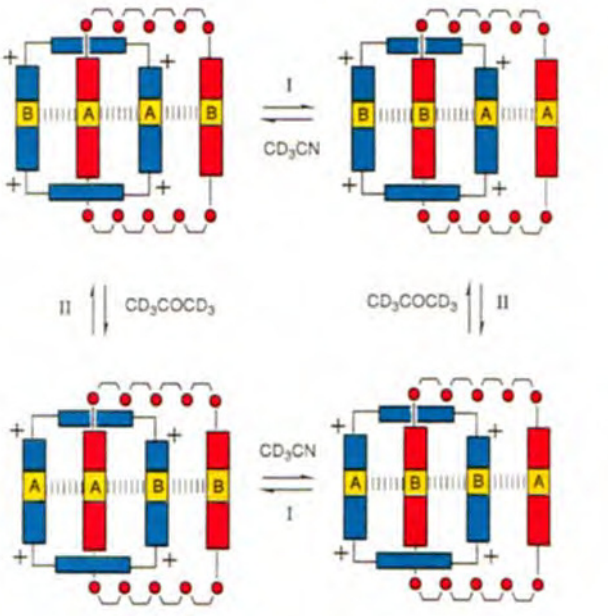

Fig. 7. A diagrammatic scheme showing the degenerate rearrangements (processes I and II) involving aromatic rings labelled A and B between "inside" and "alongside" positions for both donor (red) and acceptor (blue) macrocycles.

with $\Delta\nu = 46$ Hz giving[10] $k_c = 102\ s^{-1}$ at $T_c = -23$ °C. The ordering of the tetracationic [2]catenane **3** in solution suggests strongly that its remarkably efficient production[12] is templated (Scheme 1) during its formation from the dicationic starting material **4** via, presumably,[13] a complexed tricationic intermediate. Moreover, the non-covalent bonding responsible for this templating action "lives on" in **3**, distinguishing this [2]catenane from any of its predecessors.

Cyclic voltammetry of free cyclobis(paraquat-*p*-phenylene) in 0.1 M nBu$_4$PF$_6$/MeCN reveals two redox couples (Fig. 8a). The first monoelectronic reduction ($PQT^{2\oplus}/PQT^{\oplus}$) of both paraquat moieties appears as a single reduction process ($E^{0\prime} = -0.279$ V) and so does the second redox process ($PQT^{\oplus}/PQT$, $E^{0\prime} = -0.703$ V). This is the expected behavior for a molecule having two identical and independent paraquat units that undergo electron transfer at similar potentials.[5] In contrast with this, $3 \cdot 4PF_6$ shows three well resolved redox couples (Fig. 8b). The $PQT^{2\oplus}/PQT^{\oplus}$ process

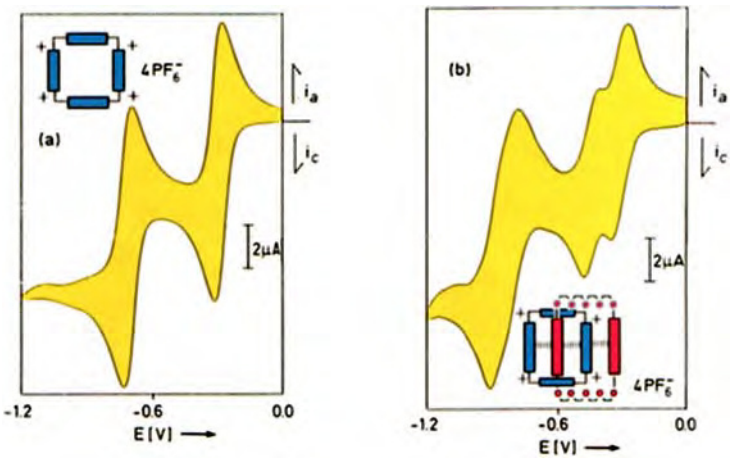

Fig. 8. Cyclic voltammetry at 25 °C of 0.5 mM solutions of a) free cyclobis-(paraquat-*p*-phenylene) and b) $3 \cdot 4PF_6$ in 0.1 M nBu$_4$NPF$_6$/MeCN. Scan rate: 20 mV s^{-1}. Donors are red and acceptors are blue.

is split into two distinct couples having $E^{0\prime}$ values of -0.307 and -0.438 V, respectively. The ensuing reduction of the paraquat units appears as a single redox process at $E^{0\prime} = -0.841$ V although the shape of the waves suggests two close but unresolved redox steps. The splitting of the first reduction process may result from the topological differences between the "inside" and "alongside" paraquat units in the catenane. The "inside" paraquat is more strongly stabilized by the interactions with the two adjacent hydroquinol units than the "alongside" paraquat which interacts with only one of these. Thus, the "alongside" $PQT^{2\oplus}$ is reduced more easily than the "inside" $PQT^{2\oplus}$ (see Fig. 9). In the next reduction step, the differences between the two paraquat units are not so marked because the strength of their interaction with the hydroquinol groups is probably diminished by the decreased acceptor character of the $PQT^{\oplus}$ units. An alternative interpretation of the splitting of the $PQT^{2\oplus}/PQT^{\oplus}$ redox process can be offered if one assumes that the electronic communication between the two paraquat units is greatly enhanced in the catenane by the intervening hydroquinol moiety. One-electron reduction of the catenane would then yield a cation radical having the spin density delocalized through the two paraquat units and, perhaps, the hydroquinol group. This possibility is currently under investigation using EPR spectroscopy. In any instance, the electro-

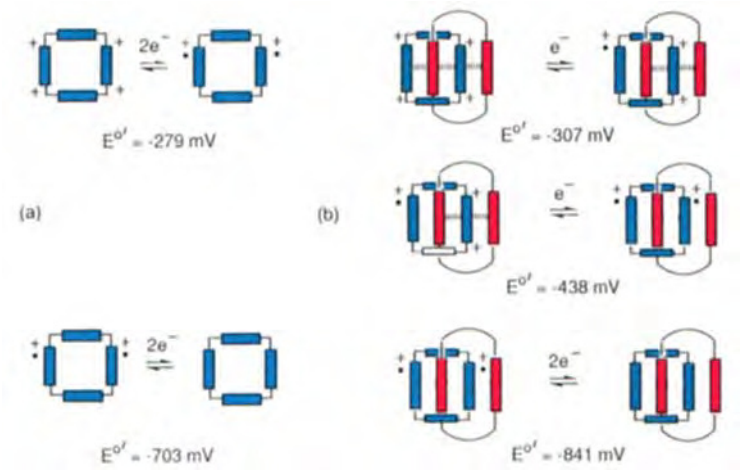

Fig. 9. A diagrammatic scheme comparing the redox processes of $3 \cdot 4PF_6$ and free cyclobis(paraquat-*p*-phenylene). Donors are red and acceptors are blue.

chemical properties of $3 \cdot 4PF_6$ are very intriguing since they suggest that either an electrochemical gradient between the two paraquat units exists in the catenane or that both reducible subunits are electronically coupled in a highly efficient manner.

The preparation of the [2]catenane **3**, involving repetitive nucleophilic substitution reactions, is another example[15] of a synthesis of an unnatural product[16] which is *structure-directed*.[17] The exploitation of this principle looks set to create many new molecular ensembles.

Experimental Procedure

$3 \cdot 4PF_6$: $4 \cdot 2PF_6$ (140 mg, 0.2 mmol) was dissolved in dry MeCN (5 mL) and then added to a solution of **6** (280 mg, 0.52 mmol) in dry MeCN (5 mL) under N_2 with stirring. A deep yellow color was formed immediately and **5** (56 mg, 0.2 mmol), dissolved in dry MeCN (5 mL), was added. After 4 h, the reaction mixture had become deep red and overnight a red precipitate formed. After stirring at room temperature for 48 h, the precipitate was filtered off, washed with $CHCl_3$ to remove excess of **6**, dissolved in H_2O, and filtered to remove a small amount of insoluble material. An aqueous solution of NH_4PF_6 was added until no further precipitation occurred. The precipitate was filtered off, washed (H_2O), and dried. Recrystallization from $MeCN/H_2O$ gave $3 \cdot 4PF_6$ (230 mg, 70%) as a pink solid, m.p. > 280 °C. Single crystals, suitable for X-ray crystallography, were grown by vapor diffusion of iPr_2O into a solution of $3 \cdot 4PF_6$ in MeCN.

[6] The first fragmentation of the bisparaphenylene-34-crown-10 ring in **3**, which will lead to its mechanical disconnection with the intact tetracationic macrocycle by an unthreading process, is expected to give subsequent fragmentations that are characteristic of the component rings. This distinctive behavior has been observed in the mass spectra of other catenanes: see, for example, W. Vetter, E. Logemann, G. Schill, *Org. Mass Spectrom. 12* (1977) 351; C. O. Dietrich-Buchecker, J.-P. Sauvage, J. M. Kern, *J. Am. Chem. Soc. 106* (1984) 3043.
[7] Crystal data for $3 \cdot 4PF_6 \cdot 5MeCN$: triclinic, $a = 13.847(6)$, $b = 13.998(4)$, $c = 26.584(15)$ Å, $\alpha = 84.36(4)$, $\beta = 80.91(4)$, $\gamma = 60.79(3)°$, $V = 4440$ Å^3, space group $P\bar{1}$, $Z = 2$, $\varrho = 1.38$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 17$ cm^{-1}, 5188 independent observed reflections with [$|F_o| > 3\sigma(|F_o|)$, $2\theta \leq 100°$], refined to a current $R = 0.141$, $R_w = 0.136$.
[8] Nicolet R3m diffractometer, ω-scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structure was solved by direct methods and refined anisotropically. Further details of the crystal structure investigation can be obtained from the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation of this communication.
[9] There is extensive solvtion of the crystals by acetonitrile molecules, there being 3 at full weight, 2 at three-quarters, and 1 at half weight per $3 \cdot 4PF_6$. The counterions and these solvent molecules are intercalated between layers of catenanes.
[10] Values for k_c were obtained (I. O. Sutherland, *Annu. Rep. NMR Spectrosc. 4* (1971) 71) using the approximate expression, $k_c = \pi(\Delta\nu)/(2)^{1/2}$, and the Eyring equation was then used to calculate $\Delta G_c^{\ddagger}$ values at T_c.
[11] The signals for the protons α to the nitrogen atoms on the bipyridinium rings also separated (Fig. 6) out into equal intensity signals in the ^1H NMR spectrum of **3** recorded in CD_3COCD_3 at −65 °C.
[12] For a historical perspective and a discussion of the early research carried out on catenanes, see G. Schill: *Catenanes, Rotaxanes and Knots*, Academic Press, New York 1971. More recently, an excellent review by *C. O. Dietrich-Buchecker* and *J. P. Sauvage* (*Chem. Rev. 87* (1987) 795) has surveyed the different routes to catenanes, which had been devised and exploited up to 1986. Previously, macrocyclic polyethers have been incorporated into catenanes by statistical threading (G. Agam, D. Graiver, A. Zilkha, *J. Am. Chem. Soc. 98* (1976) 5206) and by using transition metals as covalent templates (C. O. Dietrich-Buchecker, J. P. Sauvage, *Tetrahedron Lett. 24* (1983) 5095; C. O. Dietrich-Buchecker, J. P. Sauvage, J. M. Kern, *J. Am. Chem. Soc. 106* (1984) 3043; J. P. Sauvage, *Nouv. J. Chim. 9* (1985) 299; *D. K. Mitchell, J. P. Sauvage, Angew. Chem. 100* (1988) 985; *Angew. Chem. Int. Ed. Engl. 27* (1988) 930). The most recent communication from the Strasbourg group relates to a synthetic molecular trefoil knot (C. O. Dietrich-Buchecker, J. P. Sauvage, *Angew. Chem. 101* (1989) 192; *Angew. Chem. Int. Ed. Engl. 28* (1989) 189.
[13] Experiments to assess the nature and the strength of the binding of the bisparaphenylene-34-crown-10 with the tricationic compound, obtained by reaction of the bis(pyridinium) salt $4 \cdot 2PF_6$ with *para*-methylbenzyl bromide, are in progress.
[14] Electrochemical experiments were performed with a Princeton Applied Research Model 175 universal programmer, a Model 173 potentiostat, and a Model 179 digital coulometer equipped with positive feedback circuitry for IR compensation. Voltammograms were recorded on a Soltec VP-6423S X-Y recorder. A glassy carbon disk electrode (0.080 cm^2), Pt flag, and sodium chloride saturated calomel (SSCE) were used as the working, auxiliary, and reference electrodes, respectively. All solutions for the voltammetric experiments were deoxygenated by sparging with nitrogen gas; a nitrogen atmosphere was maintained above the solution during the experiments.
[15] In a structure-directed synthesis, no reagent or catalyst is required (P. Ellwood, J. P. Mathias, J. F. Stoddart, F. H. Kohnke, *Bull. Soc. Chim. Belg. 97* (1988) 669).

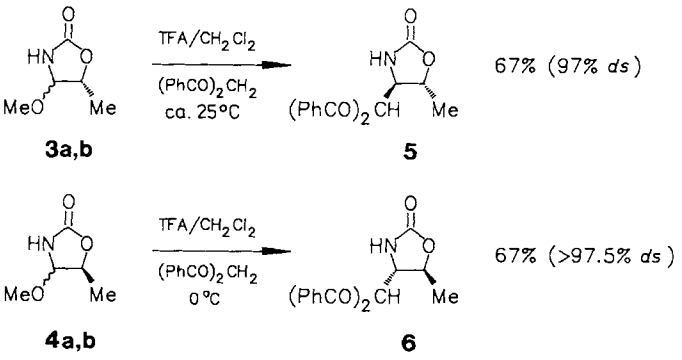
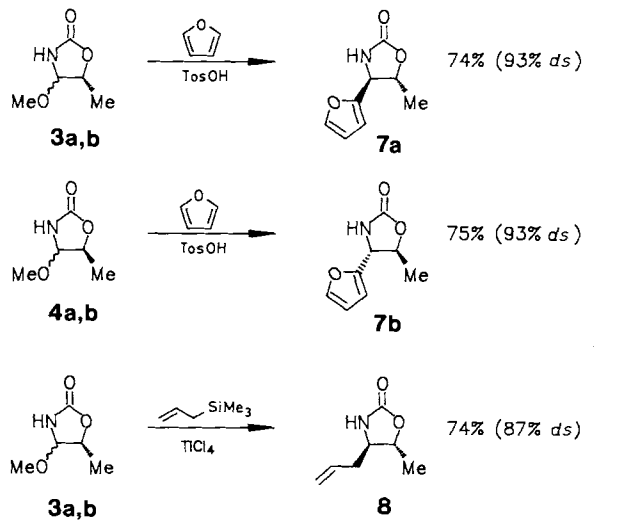
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, BASF AG, and DEGUSSA AG (donation of chemicals). We thank Prof. Dr. *E. Breitmaier* (Bonn) for carrying out NMR shift and NOE experiments. Communicated in part in lectures delivered at the 20th European Peptide Symposium (Tübingen, September 4–9, 1988) and the 7th EUCHEM Conference on Electrochemistry (Assisi, April 17–22, 1989).



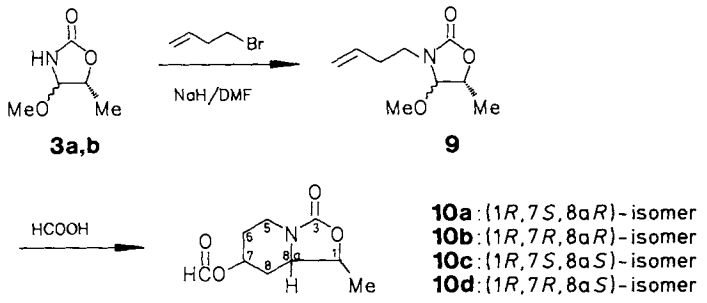
lonic acid half ester by a methoxy group (non-Kolbe reaction) is readily carried out and leads to interesting synthetic building blocks.[1-6] Remarkable, however, is that the anodic methoxylation usually proceeds with a diastereoselectivity of maximally only 2:1.[3,4] Replacement of the methoxy group by nucleophiles shows the highest diastereoselectivity when the C atom in the α-position to the methoxy group is part of a cyclic system, as for example in a (4*R*)-4-hydroxy-2-methoxypyrrolidine derivative.[4] In some cases, however, even the chelate effect, brought about by $TiCl_4$, leads to practicable diastereoselectivities.[5] The anodic decarboxylation of cyclic systems such as (2*R*,4*S*)-2-(*tert*-butyl)oxazolidine-4-carboxylic acid with introduction of an acetoxy group already proceeds with good diastereoselectivity in the electrochemical step.[5a,6]

We have now found that anodic decarboxylation of the (4*S*,5*R*)-, (4*S*,5*S*)-, and (4*R*,5*S*)-5-methyl-2-oxooxazolidine-4-carboxylic acids **1** and **2a, b** as starting substances in methanol affords the (4*R*,5*R*)- and (4*S*,5*S*)-4-methoxy-5-methyloxazolidin-2-ones **3a** and **4a** respectively with 77% *ds* in each case.



1 and **2a, b** are readily obtainable in 75% yield by cyclization of L-threonine, L-allothreonine and D-threonine, respectively, with methyl chloroformate. The electrolyses of the carboxylic acids (divided cell, methanol) in the presence of sodium acetate proceed almost quantitatively (95% isolated yields of **3a, b** and **4a, b**, respectively). Even in undivided cells using graphite electrodes and the same electrolyte the diastereomeric mixture **3a, b** is obtained in 89% yield after consumption of 3 Faraday mol^{-1}. The diastereomeric mixture can be separated by column-chromatography (silica gel, ether). Thus, starting from L-threonine or D-threonine **3a** and **4a**, respectively, have been obtained enantiomerically pure (**4a**: $[\alpha]_D^{20} = -140.7°$, $c = 1.025$, $CHCl_3$; **3a**: $[\alpha]_D^{20} = +144.1°$, $c = 1.025$, $CHCl_3$). In each case, however, the diastereomeric mixture itself can be used for further reactions.

Thus, **3** and **4** are readily accessible precursors for α- and β-chiral β-aminoalcohols and their derivatives. According to the findings of *Ben-Ishai* et al.,[7] *Shono* and *Irie* et al.,[8] *Speckamp* et al.,[9] and our own,[10] the methoxy groups in **3** and **4** can be replaced by nucleophiles, either under the conditions of proton catalysis or catalysis by Lewis acids. The reactions involve intermediary formation of *N*-acyliminium ions. Reaction of the diastereomeric mixtures **3a, b** or **4a, b** with dibenzoylmethane in trifluoroacetic acid affords the *trans*-derivatives **5** ($[\alpha]_D^{20} = -24.9°$, $CHCl_2$, $c = 0.5$) and **6** ($[\alpha]_D^{20} = +26.1°$, CH_2Cl_2, $c = 0.5$), respectively, as pure enantiomers with 97% and >97.5% *ds*.



Reaction of furan with **3a, b** in the presence of 10 mol-% *p*-toluenesulfonic acid at room temperature furnishes the (4*S*,5*R*)-*trans*-isomer **7a** ($[\alpha]_D^{20} = +40.2$, $CHCl_3$, $c = 1.025$, after diastereomeric separation) with 93% *ds* whereas **4a, b** affords the (4*R*,5*S*)-*trans*-isomer **7b** ($[\alpha]_D^{20} = -41.6°$, $CHCl_3$, $c = 1.025$, after diastereomeric separation) with the same diastereoselectivity. The diastereomers were separated by flash chromatography on silica gel, and their enantiomeric purity was determined by NMR spectroscopy with chiral shift reagents. The oxazolidine-2-one ring in **7** can easily be opened with NaOH (1.25 M in EtOH:H_2O 70:30) to give the corresponding amino alcohol.

Reaction of allyltrimethylsilane with **3a, b** in the presence of $TiCl_4$ (CH_2Cl_2, 0 °C; $TiCl_4$:**3a, b**:allyltrimethylsilane = 1.2:1:1.2) affords the (4*R*,5*R*)-*trans*-isomer **8** with 87% *ds*. *Kano* et al.[11] have reported analogous reactions with *N*-alkylated 4-alkoxyoxazolidin-2-ones as being completely diastereoselective.

N-alkylation of **3a, b** with homoallyl bromide affords **9**, which in accordance with the findings of *Speckamp* et al.[9] and *King* et al.[12] can be cyclized with formic acid. **10** is formed in 65% yield as a mixture of four diastereomers in the ratio **a:b:c:d** = 8.5:2:3:1. By flash chromatography on silica gel (eluent: diethyl ether), the enantiomerically

pure (1*R*,7*S*,8a*R*)-1-methyl-3-oxo-1,5,6,7,8,8a-hexahydro-oxazolo-[3,4-*a*]-pyrid-7-yl formate **10a** ($[\alpha]_D^{20} = -8.59°$, CH_2Cl_2, $c = 0.8$; 1.7% contamination by the other diastereomers) can be isolated in 36% yield. In **10a** the six-membered ring is coupled *trans* to the methyl group, and the formate residue is oriented equatorially, whereas the formate residue in **10b** assumes the axial position. **10c** and **10d** are

the *cis*-coupled diastereomers with equatorial and axial arrangement of the formate residue. The ratio of *trans*- to *cis*-coupling is 2.6:1 and is thus substantially higher than in comparable cyclizations with diastereomeric ratios of 1:1[13] and 1.5:1.[14] The diastereoselectivity of the ring closure via *N*-acyliminium ions can be drastically increased if the double bond is terminally substituted.[13, 14]

The configurations of the products were determined by ^1H NMR spectroscopy and NOE measurements. All the compounds were characterized by IR, NMR, and mass spectra and elemental analyses. The replacement of the methoxy group by other nucleophiles and the preparation of interesting amino alcohols are currently the subject of intensive investigation.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Advances in Boron and the Boranes. (Series: Molecular Structure and Energetics). Series editors: *J. F. Liebman* and *A. Greenberg;* volume editors: *J. F. Liebman, A. Greenberg* and *R. E. Williams*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. xx, 547 pp., hard cover, DM 195.00. – ISBN 3-527-26624-0/0-89573-272-6

Whereas most of the nine volumes published so far in this series have titles ("Physical Measurement", "Studies of Organic Molecules", "Structure and Reactivity", etc.) that are as general and non-specific as the series title, this volume treats a more clearly defined subject area, that of molecular compounds of boron. It excludes the important area of solid compounds of boron, and thus does not deal with the oxide, nitride and carbide ceramic phases nor with the metal oxoborates and metal borides. The hundred or so full-time molecular boron chemists throughout the world look to *Alfred Stock* as their spiritual ancestor. The scientific legacy which he left was continued mainly in the USA, where a center of boron chemistry was built up during the 1930s around *Schlesinger* at Chicago University. One of the most important representatives of this group is *Anton B. Burg*. To celebrate his eightieth birthday the Loker Hydrocarbon Institute arranged a symposium in Los Angeles on 14 March 1985. Because of this location most of the boron chemists who took part were American. The symposium proceedings resulted in this volume, in which only one chapter of the 22 contributions is of non-American origin. The articles are largely concerned with boron cluster chemistry and therefore with electron-deficient compounds formed by "non-classical" multicenter bonding.

The first chapter contains the text of *Burg*'s birthday lecture. Although *Burg* has still continued to publish important papers even after his eightieth birthday (the one-time cham-

pion high-jump athlete having kept himself young), this chapter is mainly one of historical reminiscence. As well as having unrivalled knowledge and experience, he is as original in his writing, embellished with verse, as he has always been in his personal style. As, for example, when in his younger days he would make a standing leap over other researchers seated in the departmental library, a useful form of exercise for a high-jumper but a startling experience for the others; or later when, as a professor at UCLA, he cycled along the Californian highways wearing a gas mask, a symbol not so much of public protest but more of the constructive and pragmatic attitude which experimental chemistry teaches us.

It is therefore not surprising that quite a number of the chapters that follow have a historical theme running through them, and seek to show general relationships. *R. E. Williams*, the organizer of this symposium and one who has played a prominent part in the systematization of boron cluster chemistry, in a joint paper with *G. K. S. Prakash, L. D. Field* and no less than *G. A. Olah*, reports that there is a proportional relationship between the NMR chemical shifts of boron and carbon nuclei at equivalent positions in two isoelectronic cluster molecules; conversely, one can infer isoelectronic analogies in cases where such a proportionality is observed. For example, this method has shown that the carbocation $C_3H_7^{\oplus}$ formed by protonation of cyclopropane in a superacid is isoelectronic with the familiar anion $B_3H_8^{\ominus}$. If one now regards protonated nortricyclanes, such as the norbornyl cation whose structure was at one time hotly disputed, as derivatives of the basic $C_3H_7^{\oplus}$ structure, the earlier discussions are at last seen in a systematic light: evidently we have here a non-classical cation, rather than a case of valence tautomerism between two enantiomeric classical cations, and this is now just as obvious as, for example, the rejection of a valence tautomerism between two cyclohexatriene molecules as a model for the structure of benzene. Using the same proportionality rule the cation $Me_2CBH_4^{\oplus}$ can be shown to be isoelectronic with 1,1-dimethylborane, and $MeC_2BH_7^{\oplus}$ with the anion $MeB_3H_7^{\ominus}$, which amounts to a proof that anomalous CHB bridges are formed as a result of the action of $Me_2CH^{\oplus}$ on BH_3.

R. N. Grimes appropriately points out that synthetic boron cluster chemistry (in contrast to the analytical chemistry of these compounds) is now at a stage of development similar to that of organic chemistry during last century (the "hunter and gatherer" stage, as one might say). Nevertheless, *Grimes* himself makes notable contributions towards passing beyond this stage, e.g. in achieving structure doubling by the oxidative fusion of two halves of a cluster, or η-bonding of the metal atom of a metallacarbaborane to aromatic compounds such as C_6H_6, $C_7H_7^{\oplus}$, $C_8H_8^{2\ominus}$ or paracyclophane. Another contribution which deals mainly with syntheses is that by *S. G. Shore*, who is more at home with the pure boron hydrides than virtually anyone else. In collaboration with *J. R. Wermer* he reports here, amongst other topics, on efficient syntheses of higher hydrides of boron and boron hydride anions from pentaborane(9), and on an anion $B_{10}H_{14}I^{\ominus}$ with an unusual structure. The Czech authors *B. Stibr, J. Plesek* and *S. Hermanek* report results on the preparation of nona-, deca- and undecaboranes and -borates containing C, N, S or Se as heteroatoms, and in some cases also Fe, Co, Ni or Pt. In the area of boron clusters with three to six atoms, *G. Kodama* has prepared some further electron-rich *hypho* species by the addition of Lewis bases, while *J. A. Morrison* gives a useful account of the chemistry of the boron subhalides, which are extremely electron-deficient ("electron-hyperdeficient"), the main ones being B_4Cl_4, B_8Cl_8 and B_9Cl_9, and reports several new reactions. *N. S. Hosmane* and *J. A. Maguire* give a detailed enumeration of all those carbaboranes which contain, in addition to carbon, skeletal heteroatoms of heavy elements belonging to Main Groups 3 or 4. Concluding this section, *L. J. Todd, A. Arafat, J. Baer* and *J. C. Huffman* report on the area of the thiaboranes and the scarcely developed azaboranes.

Anyone wishing to remedy the present lack of a unified systematization of synthetic methods cannot avoid becoming involved in elucidating reaction mechanisms. *D. F. Gaines*, in collaboration with *D. E. Coons* and *J. E. Heppert*, has incorporated a ^{10}B atom into 2-methylpentaborane(9) and has shown by NMR spectroscopy that a base-induced rearrangement of the B_5 skeleton occurs. *T. B. Fehlner* has used a molecular beam mass spectrometer to investigate the mechanisms of the reactions between the unstable basic borane unit BH_3 and various organic molecules, as well as the structure and reactivity of the BH_3 unit in the cluster molecule $[HFe_3(CO)_9(BH_3)]$. *T. Onak* devotes his paper to the mechanism of the isomerization of mono- and dihalogen derivatives of *closo*-dicarbaheptaborane. *L. Sneddon* and *E. W. Corcoran* have investigated the catalytic effect of $PdBr_2$ in the alkenylation of cluster molecules, and that of $PtBr_2$ in the formation of BB linkages. Conversely, *M. F. Hawthorne*, the doyen of metallacarbaborane chemistry, has used a rhodadicarbadodecaborane as a catalyst for the shifting or hydrogenation of double bonds in alkenes.

R. A. Beaudet summarizes the epoch-making history of the structure of diborane. The prejudice in favor of an ethane-type structure persisted until the middle of this century, despite the intuitively correct suggestion by *Dilthey* in 1921 and *Burg*'s pointers in the late 1930s. Eventually, however, the belief in the predominance of two-electron two-center bonding had to be modified, and the model extended to include non-classical multicenter bonding, both on the basis of incontrovertible experimental data (first from infrared spectroscopy and electron diffraction, and later from X-ray diffraction), and on theoretical grounds. It took the chemical community at large longer to accept multicenter σ-bonding than it had taken to accept multicenter π-bonding, perhaps because the familiar canonical forms that were in use in the fifties and sixties for describing conjugated π-electron systems led the theoretically inexperienced to believe that fixed two-electron two-center bonds were present. *Beaudet* also gives a detailed review of the known structures of neutral boron hydrides and carbaboranes, and lists some structural problems that remain to be solved. In the appendix he collects together in the form of a table the atomic coordinates for 31 crystalline compounds.

S. H. Bauer, the doyen of electron diffraction and *Burg*'s colleague for more than half a century, gives an excellent review of the preparation and the thermodynamic and spectroscopic properties of highly reactive boron-containing molecules, and of the kinetics of some of their elementary reactions with small molecules and with oxygen and nitrogen atoms. *J. F. Liebman, J. S. Chickos* and *J. Simons* have developed simple rules for predicting thermodynamic parameters, especially enthalpies of vaporization, and applied them to boron compounds of all kinds. Only the future can tell us whether or not the "plemeioelectronic relationship" of a substance will gain acceptance as a useful concept. In collaboration with *Z. S. Hermann, L. Pauling* applies his latest statistical theory of non-synchronized resonance in covalent compounds to elemental boron (unfortunately, though, to the so-called "tetragonal boron", which does not exist in its pure form) and to the simpler boron hydrides.

One of the papers on topics other than boron clusters is that by *D. S. Matteson* on the asymmetric synthesis of alco-

hols of the types R–CHMe–OH and R–CHMe–CHMe–OH using the pinandiolatoboryl group as an auxiliary group. *K. Niedenzu* describes the preparation and properties of 76 "pyrazaboles", i.e. the six-membered ring cyclo-dimers of the unstable (1-pyrazolyl)borane. *A. R. Siedle* begins by reviewing the well-known Brønsted acidity of certain of the hydrogen atoms in boron hydrides, then discusses bis(fluorosulfonyl)methane and bis(fluorosulfonyl)amine as strong protonic acids. *B. F. Spielvogel* summarizes the numerous chemotherapeutic properties of amino-acid homologs of the $L-BH_2-COOR$ and $L-BH_2-CONEt_2$ types ($L = NH_xMe_{3-x}$), but these have been found unsuitable for use in neutron capture therapy.

Several monographs on the molecular chemistry of boron, and in particular on boron cluster chemistry, are now available, such as the 1982 monograph by *R. N. Grimes* on "Metal interactions with Boron Clusters", published in the "Modern Inorganic Chemistry" series. The rapid progress in the field is also reviewed every three years in reports dealing with the main papers presented at the IUPAC conferences on boron chemistry. The present volume should be regarded as something intermediate between a monograph and a progress report. The emphasis laid on chemical history or on reviewing particular topics or on presenting new results in a given field varies from chapter to chapter. The careful preparation by the publishers and good typographical presentation make this book a must for all boron chemists, and it can be recommended to everyone working in the field of cluster compounds, and also to those who are only concerned with the field as a fringe interest, or who are interested in the recent history of chemistry. Every library which aims to be well equipped in the area of inorganic molecular chemistry should buy this book.

Chaos und Ordnung: Die komplexe Struktur des Lebendigen. By *F. Cramer*. Deutsche Verlagsanstalt, Stuttgart 1988. 320 pp., hard cover, DM 48.00. – ISBN 3-421-02753-6

It is a privilege to review this exceptional book, which gives a unique account of the problems we face at the end of this century in the vast domain extending from science to philosophy. The book contains nine chapters dealing mainly, but not solely, with biological problems. Each chapter is preceded by a dialogue, whose hero in most cases is *Georg Christoph Lichtenberg*, and ends with a poem; a quite unusual structure indeed, which reflects the wide range of interests and artistic tastes of Professor *Cramer*.

As is the case in great works of art, this book refers to multiple levels of reality. The world around us is full of aspects which seem contradictory: the regularity of planetary motion, the long-range unpredictability of the weather, the static structure of crystals, the dynamic and self-organizing properties of living systems. Nevertheless, we have to find a way of incorporating these various aspects into a coherent view of nature. For all who are interested in trying to obtain such an overall picture, Professor *Cramer*'s book will be an excellent guide, Obviously, we are far from a final, all-encompassing answer. However, great strides have been made and we may today propose solutions to these apparent contradictions which only a few years ago would have been impossible even to formulate.

This book is first and foremost an excellent introduction to the main problems of modern molecular biology. The author's constant concern is to put these problems into the context of the progress that has recently been achieved in the theory of nonlinear systems far from equilibrium. In recent years the ideas of order and disorder have gone through a radical revision. For a long time, equilibrium structures such as crystals were considered as ideal ordered systems, while hydrodynamic flow and chemical reactions were associated with ideas of randomness and disorder. This is no longer so today. We now know that nonequilibrium can be the source of order. Self-organization is no longer outside the scope of science.

Classical dynamics was associated with time-reversible and deterministic behavior, as is indeed the case for planetary motion. But we now know that this description applies only to a restricted class of dynamic systems. The fascinating properties of unstable dynamic systems which may lead to chaos, to the generation of information, are now studied from the perspectives of an ever-increasing number of disciplines which include physics, chemistry and biology, as well as economics and social sciences. *Cramer*'s presentation is clear and accurate, and will assist the interested reader in finding his way through the labyrinth of these new concepts developed in recent years.

Professor *Friedrich Cramer* is well known for his own original contributions to molecular biology; but characteristically, he uses his insights in this field as a starting point for trying to develop an overall picture of the great questions which have always fascinated men: the position of *Homo sapiens* in relation to other living things, the position of life in relation to matter, and that of matter in our evolving universe.

It is unavoidable that some of Professor *Cramer*'s conclusions will not be shared by everybody. For example, on pages 250–252, he states that the famous "Big Bang" gives us a kind of cosmic horizon, that the question of what time and space would be before the Big Bang is meaningless. Nevertheless, many physicists try to give a physical meaning to the Big Bang, and therefore also to the state of the universe preceding its present structure. This, I think, is unavoidable. Science does not deal with unique events; we have to categorize the Big Bang within some class of grand-scale cosmic phenomena. There is, of course, a wide variety of opinions ranging from *Hawking*'s introduction of a cosmic wave function to models which I favor, in which the Big Bang corresponds to an entropy-producing instability whereby the gravitational field is transformed into matter.

The dialogues placed at the start of each chapter relate its content to the global history of ideas. It is remarkable to read that *Goethe* (page 76) writes of "bewegliche Ordnung" – a kind of dynamic nonequilibrium state. It is also interesting that *Goethe* emphasized that "creation" is still going on. This seems to clash with the ideas of *Newton* as presented on page 219, where *Cramer* appears to state that *Darwin* would be the father of the evolutionary picture of nature. This is, however, not in agreement with historical evidence. What we call the Newtonian or mechanistic concept of nature was not *Newton*'s personal view. He believed in a world which would decay if God did not intervene to repair the damage. Indeed, this is the main theme of controversy between *Newton* and *Leibnitz* as documented by the correspondence between *Leibnitz*, who favored a static view of the universe, and *Clarke*, writing for *Newton*.

"Chaos und Ordnung" is the work of a man who rejects a fragmented view of the universe, who refuses to be a prisoner of preconceived doctrines. There is a feeling of excitement, a

feeling that we are living at a unique moment in the history of science. The world appears to us at the same time as more strange, but also more connected and more harmonious, than to any of the generations which have preceded us. I can only hope that *Cramer*'s book will inspire many readers and will receive the international acclaim it fully deserves.

Ab Initio Calculation of the Structures and Properties of Molecules. By *C. E. Dykstra*. Elsevier, Amsterdam 1988. x, 275 pp., hard cover, HFl 210.00. – ISBN 0-444-43013-X

The development of useful approximate methods and the enormous progress made in computer technology have enabled quantum chemical ab initio methods to become an equal partner alongside experimental methods in determining structures and properties of molecules in the gas phase. However, it is difficult for the non-specialist to assess the credibility and reliability of results obtained from a particular calculation, despite the fact that the subtle factors which determine the accuracy that can be achieved for a given problem are generally well understood in quantum chemistry. The author of this book has set himself the commendable objectives of equipping the non-specialist with the knowledge needed to make such a judgement, and providing him with a survey of the capabilities of modern ab initio methods. This has confronted him with the difficult task of conveying in a condensed form the required knowledge of the methods and the terminology used. *Dykstra* tackles this in a descriptive manner with the authority of an experienced quantum chemist (Chapter 3, 40 pp.). Whether or not this presentation is informative even for the non-specialist will be tested by the verdict of this reader.

In Chapter 1 (10 pp.) the nature of the task of theoretically determining molecular structures is illustrated by five examples from astrophysics. After an explanation of the fundamental concept of the potential surface (and that of the property surface) as applied in the Born-Oppenheimer approximation, Chapter 4 (21 pp.) gives a systematic account of ab initio structures. Chapters 6 to 8 deal in turn with molecular vibrations (18 pp.), electrical properties (44 pp.) and magnetic properties (22 pp.). The 390 literature references, which extend up to the beginning of 1988, are arranged alphabetically in the form of a bibliography, and it is pleasing that they also include the titles of the papers cited. An author index and a subject index are also included, although regrettably the latter does not include details of which molecules are covered in the text.

The compilation and discussion of results is not comprehensive. It deals almost exclusively with molecules and molecular complexes which contain two or three atoms of elements of Period 2 together with some hydrogen atoms (only two pages are devoted to heavy elements). The author, who naturally draws mainly on results in his own field of research, has consciously applied this restriction. Nevertheless, it is difficult to understand why there are no references to earlier books on the same subject, such as those of *Hehre, Radom, Schleyer* and *Pople* (1986)[*], *Mulliken* and *Ermler* (1981), and *Carsky* and *Urban* (1980), nor to relevant review articles. The author's special area of interest also accounts for the relatively large amount of space given to the rather formal description of the role of analytical derivations in quantum chemistry (Chapter 5, 26 pp.), and to the "Polymatrix Approach for SCF and Local Space SCF" (11 pages in Chapter 9).

The book is well written, and its production and presentation are such that it is pleasing to read. The number of printing errors is within acceptable limits, and they only alter the meaning in a few cases, e.g. on page 118 where "quartic" has become "quadratic". All quantum chemists will welcome the compilation of important results which this volume contains. On the other hand, the non-specialist will need to supplement his reading with other monographs, review articles and original papers in order to get a full and balanced view of the capabilities of ab initio methods and the results that it has given up to now, especially as quantum chemists themselves have still not reached agreement on the usefulness of some of the approximate methods (e.g. those for taking account of electron correlation in structure determination).

ADVANCED MATERIALS

The European Ceramic Society (ECerS)

Editorial Essay

By Rudi Metselaar*

The European Ceramic Society was founded in 1987 as a federation of the ceramic societies of eleven European countries: Belgium, France, Federal Republic of Germany, Italy, The Netherlands, Norway, Portugal, Spain, Sweden, the United Kingdom, and Yugoslavia. Important goals of the Society are to improve mutual communication between ceramists within European countries, to maintain a calendar of meetings and to coordinate international meetings. Until now conferences were organized independently in different countries, sometimes leading to unfortunate timetable clashes. Now, meetings are planned by the ECerS, not only within Europe, but also on a global scale. Examples of topical meetings are the Conference on Ceramic Powder Processing Science organized in an alternating manner in Europe and the USA, and the Symposium on Ceramic Materials and Components for Engines organized in a similar way in Europe and Japan.

The need for a larger meeting covering the whole field of ceramics was also recognized. In June this year we organized the 1st Conference and Exhibition of the ECerS, in Maastricht, The Netherlands. It was the aim of this conference to bring together scientists, engineers and technicians with an interest in all fields of ceramics and this first conference was certainly a great success. A total number of 1400 participants and over 450 technical papers are clear evidence of the enthusiasm, and the interest from outside Europe was also great, 38 countries being represented. The papers presented covered basic science, engineering ceramics, bioceramics, electronic ceramics, and silicate ceramics and an exhibition of scientific equipment, raw materials and products was organized to run simultaneously. Special attention has been paid in order to make the Society and its activities attractive to young people. For example, student poster contests have been organized for those having just finished their masters or Ph.D. degrees. It was decided to continue this series of conferences in 1991 under the direction of the new president of the Society, *Hans Hausner* (Berlin) in the Federal Republic of Germany and in 1993 in Spain. From then on the conference will probably be organized annually, although the presidency of the Society will continue to change hands (and country) every two years.

During the meeting in Maastricht another important achievement was announced. As a result of discussions between the ceramic societies of Europe, Australia, USA, China, Canada, Japan, South Africa, USSR and South America it was decided to establish a world federation under the name International Ceramic Federation. I will be the first president of the Federation, and Dr. *McLaren* of the American Ceramic Society will occupy the post of Secretary. The role that the Society played in the establishment of the ICF is clear evidence of the influence and strength of the European Ceramic Society. Another important development is the founding of the Society's new journal. The first issue of the *Journal of the European Ceramic Society* which is set up as a scientific journal with high standards appeared in June this year. Indeed, there has been a great need for such a journal in Europe, as until now, the results of European research in ceramic science and engineering have been scattered over many different journals. From now on it will be possible to present the European research effort in a coherent way. In view of the rapid developments in technical ceramics and the correspondingly strong competition, we consider this an important achievement. Readers of *Advanced Materials* may wonder if it is useful to start a discipline-oriented society at a time when everywhere else more general materials societies are being founded. The answer, in my opinion, is partly given above. Both the speed of the scientific and technological developments and the competitive nature of the materials industry produce the need for dedicated journals and specialist meetings.

[*] Prof. Dr. R. Metselaar
Centre for Technical Ceramics, Eindhoven University of Technology
P.O. Box 513, 5600 MB Eindhoven (The Netherlands)

Rudi Metselaar (born 1936) studied chemistry at the University of Amsterdam, The Netherlands, obtaining a Ph.D. in molecular spectroscopy of solids at the same university. From 1967–1977 he worked as a research scientist on magnetic materials at Philips Research Laboratories in Eindhoven. Since 1977 he has been professor of physical chemistry at the Eindhoven University of Technology and has been scientific director of the Centre for Technical Ceramics at the university since it was founded. He has just finished a two year term as the first president of the European Ceramic Society and is now chairman of the International Ceramic Federation.

The future of ceramics in Europe requires a joint (international) effort. This does not mean that the ceramists want to stay in an isolated position and are not interested in developments in other fields of materials science. On the contrary, in some areas there is so much overlap of interests that a cooperation with for instance, metallurgists or polymer chemists is certainly necessary and fruitful. For ceramists this is not new, since ceramics has always been an interdisciplinary science practised by chemists, physicists and metallurgists and now, as a result, the European Society is always open for discussions with other societies or for bilateral meetings.

In this respect cooperation in education should be encouraged in order that European materials science and technology will in the future hold a strong position in the world of advanced materials. The ECerS is ready to contribute and participate.

Liquid Crystalline Elastomers

By Rudolf Zentel*

Crosslinkable Polymers
Chiral Phases
Piezo Electric Effects
Mechanical Orientability
Rubber-Like Elasticity

Today, material science is directed towards the development of multifunctional and oriented structures. One example of such supramolecular systems are liquid crystalline (LC) elastomers which combine the properties of LC phases (the combination of order and mobility) with rubber elasticity, one of the most typical polymer properties. Their most outstanding characteristic is their mechanical orientability; strains as small as 20% are enough to obtain a perfectly oriented LC monodomain. This orientability, if LC elastomers with chiral phases are used, leads, for example, to elastomers with chiral smectic C* phases which are likely to show piezo-electric behavior.

1. Introduction

LC Phases combine the long range order of crystals with the mobility of liquids. Their formation from molecules with anisotropic forms, the so called "mesogenic" groups, has long been known for low molar mass compounds and structure-property relationships are well established.[1,2] These LC Phases are thermodynamically stable phases that exist in a temperature range between the crystalline phase and the isotropic melt. For rod-like mesogenic groups, these phases can be subdivided into the nematic phase, for which the long range order is only caused by the – more or less – parallel orientation of the mesogenic groups, and into different smectic phases, in which the molecules are additionally arranged in layers. Different orientations of the mesogenic groups with respect to the layers, which can be perpendicular or tilted, are the basis for a further discrimination between smectic A and smectic C phases (Fig. 1). The transitions among the different phases can be detected by, for example, differential scanning calorimetry (DSC) which measures the latent heat associated with the phase transitions. The most prominent property of these phases is their orientability in electric and magnetic fields.

LC Polymers[3–5] combine the self organization of the mesogenic groups into the ordered structure of LC phases with some typical polymer properties, such as the freezing of the disorder of the polymer chain at the glass transition temperature. Thus, in most cases, the LC phases also freeze glassy on cooling. In addition, an induced orientation can be frozen-in. LC Polymers can be prepared by incorporating the anisotropic mesogenic groups into polymeric systems. Three different ways (Fig. 2) to do this will be discussed, the first two of which are most commonly used. First, the mesogenic groups can be linked to the polymer chain as side groups, to produce LC side group polymers. Second, they

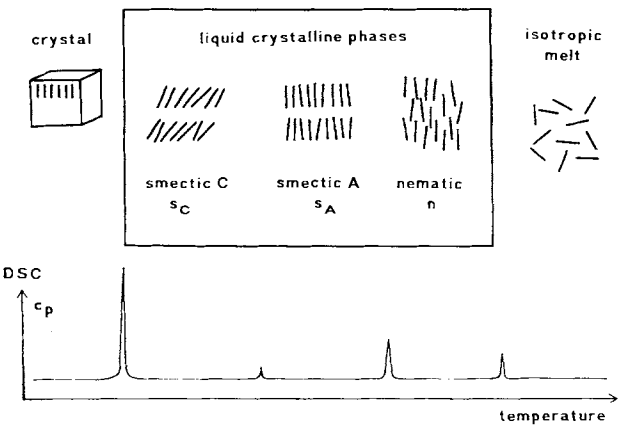

Fig. 1. Schematic representation of different LC phases that exist at temperatures between the crystalline and the isotropic phase. The transitions between these phases show up as peaks in Differential Scanning Calorimetry (DSC) mesurements (C_p vs. temperature).

[*] Priv. Doz. Dr. R. Zentel
Institut für Organische Chemie
Universität Mainz, J.-J. Becher-Weg 18–20
D-6500 Mainz (FRG)

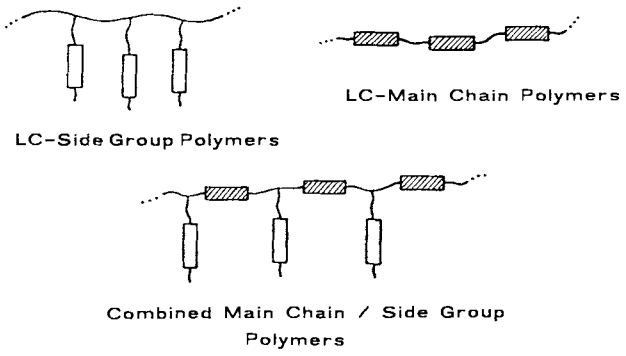

Fig. 2. Different types of LC polymers [5].

can be incorporated into the polymer chain, to obtain LC main chain polymers. Third, both structural principles can be combined, to prepare combined main chain/side group polymers ("combined" LC polymers).[5]

LC Elastomers (Fig. 3) combine the properties already discussed, with rubber elasticity. In these systems a macroscopic deformation of the crosslinked sample (above the glass transition temperature) leads to a corresponding equilibrium deformation of the polymer chains. Different degrees of orientation of the polymer chains can be achieved by stretching the macroscopic sample to different degrees. Afterwards an orientation of the mesogenic groups, which results due to interactions of polymer chains and mesogenic groups, can be determined under equilibrium conditions. In uncrosslinked LC polymers however, non equilibrium orientations resulting from flow above the glass transition temperature have to be frozen-in below T_g. Therefore LC elastomers seem to be ideal systems in which to investigate the interaction of the orientation of the polymer chains (induced by mechanical fields) and that of the mesogenic groups (induced by electric fields). As polymer networks, which are not liquid crystalline, cannot be swollen with mesogenic groups in the LC phase due to incompatibility,[6] the mesogenic groups must be linked covalently to the polymer chains (Fig. 4) to prevent a demixing.

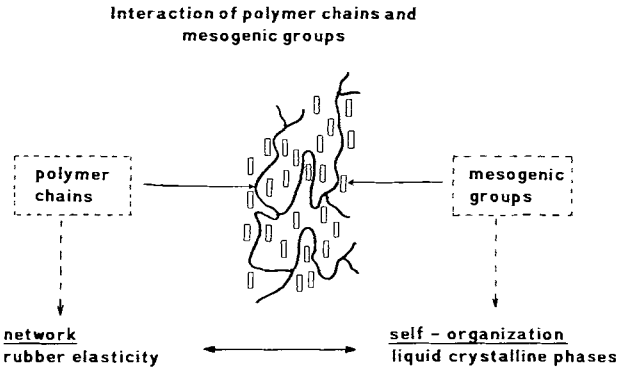

Fig. 3. Schematic representation of a crosslinked LC elastomer. The linkage between polymer chains and mesogenic groups is not yet specified.

In the following, ways to prepare differently structured LC elastomers (see Section 2.1.), as well as their properties, will be discussed. This will be done for achiral LC elastomers (see Section 2.2.) which have been studied most intensively, and then for the new elastomers with chiral LC phases (see Section 2.3.) which are interesting because of their optical and electrical properties.

2. Liquid Crystalline Elastomers

2.1. Structural Variation of Achiral Elastomers

Densely crosslinked thermosets with a liquid crystalline structure that remains unchanged up to the decomposition temperature of the polymer have been known for some time.[7, 8] Slightly crosslinked LC polymers, however, which show reversible phase transitions on heating and cooling and which show elastic properties, are relatively new. The first to be prepared were based on crosslinked side-group polymers (Fig. 4) with a polysiloxane backbone.[9–12] This work has been summarized by *Finkelmann* et al.[13] Shortly afterwards the work on LC elastomers was extended to crosslinked side group polymers with polyacrylate and polymethacrylate backbones[14–18] and also to slightly crosslinked main chain polymers and "combined" polymers (Fig. 4).[14, 19, 20] A comparative investigation of LC elastomers of these different structures is interesting because the behavior of the two "subsystems" (network of the polymer chains – mesogenic groups) in each case should be different. Thus the coupling between the orientation of polymer chains and mesogenic groups should differ significantly for the different types (Fig. 4). For crosslinked side group polymers the orientation

Rudolf Zentel (born 1953) studied chemistry at the University of Mainz, FRG, obtaining his Diploma in 1980 and his Ph.D. in 1983 after working with Professors G. Strobl and H. Ringsdorf. After this, he spent one year as a post-doctoral fellow at the University of Freiburg with Professor H.-J. Cantow, and then returned to Mainz in 1984 to start work on "Liquid Crystalline Elastomers". In April 1989 he finished his Habilitation and obtained the "Venia Legendi" in Organic Chemistry. Since July 1989 he has been at the IBM Almaden Research Center in San Jose (USA) as a Visiting Scientist working on materials for optical data storage. He has published 27 papers on various topics in polymer chemistry.

of the mesogenic groups is relatively free with respect to the polymer chain, since they are decoupled by a flexible spacer. In crosslinked main chain polymers, however, the mesogenic groups are directly incorporated into the polymer chains. Crosslinked "combined" polymers may behave in an intermediate manner because one half of the mesogenic groups are incorporated into the polymer chains, while the other half are linked to the polymer backbone as side groups via a flexible spacer. Both types of mesogens must, however, interact cooperatively to form an LC phase (both types of mesogens orient parallel to each other (Fig. 4)).[19]
